Double Asymmetric Synthesis and a New Strategy for Stereochemical Control in Organic Synthesis

By Satoru Masamune*, William Choy, John S. Petersen, and Lawrence R. Sita

Dedicated to Professor Raymond U. Lemieux on the occasion of his 65th birthday

This account examines double asymmetric induction from theoretical and practical viewpoints. In the context of four major organic reactions—the aldol, Diels-Alder, catalytic hydrogenation, and epoxidation—it is shown that a double asymmetric induction can be analyzed in terms of the single asymmetric reactions of each of the two chiral reactants. A rule which qualitatively relates the results of these single asymmetric reactions with the outcome of the double asymmetric reaction is proposed. A powerful new strategy based on this rule for the predictable creation of new chiral centers is discussed and the use of this strategy for the synthesis of sugars and macrolides is presented.

1. Introduction

Organic chemists are well acquainted with the notion of (single) asymmetric synthesis, which, as originally defined by *Marckwald*[1], is the process of forming an optically active compound through the reaction of an *achiral* substrate with a *(homo)chiral* reagent[2][**]. It should be stressed at the outset that this process should be distinguished, in an important way, from *double* asymmetric synthesis, which concerns the interaction of *two homochiral* reactants, a substrate and a reagent[3,4][**]. The stereochemical analysis of this *double asymmetric synthesis* will lead to a new hypothesis from which one can design a strategy that is potentially capable of constructing any new *chiral* center or centers on a *chiral* substrate in a *predictable and controlled* manner[**]. Thus, the objective of double asymmetric synthesis is not simply to prepare optically active compounds but to achieve a high diastereoselection as well. Obviously, this process is critically important and frequently encountered in natural products synthesis. As will be elaborated upon below, this strategy demands the development of homochiral reagents that must meet a new set of criteria. Such reagents have been prepared recently to effect four major organic reactions with excellent stereochemical control: the aldol reaction, the Diels-Alder reaction, catalytic hydrogenation, and epoxidation. This account will describe this newly introduced synthetic strategy and then illustrate the use of these reagents in the total synthesis of several natural products of medium complexity which serves to demonstrate the degree of stereochemical control that has now been achieved.

[**] "Homochiral" is synonymous with "enantiomerically pure", a term conventionally used. For the accurate definition of several other terms pertinent to stereochemistry, see reference [2].—The substrate, as opposed to reagent, is defined herein as a reactant whose main structural unit is maintained throughout a sequence of reactions leading to the formation of a target molecule.—"Control" is used throughout this Account in the sense that a new center or centers of *either* chirality can be created with excellent stereoselection.

2. Stereochemical Analysis of Double Asymmetric Induction

2.1. Diastereofacial Selectivity

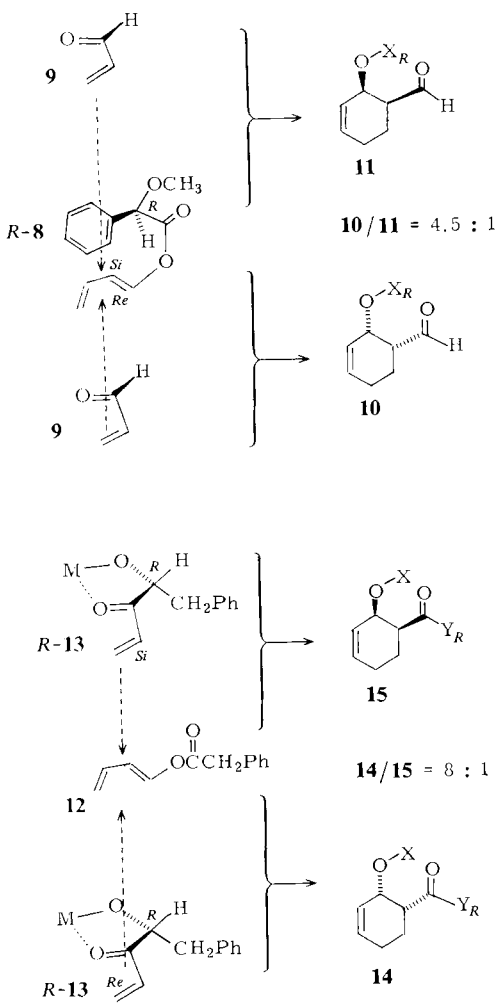
Consider first a general case where a *chiral substrate* **1** having an sp^2 carbon (e.g., a ketone) reacts with an *achiral reagent* to give products **A** and **B** (Scheme 1). Since **1** is chiral, one of the two diastereomeric transition states (*Si*-attack or *Re*-attack) will be lower in energy than the other. This results in one product being produced to a greater extent, and thus the product ratio **A/B** is not unity. This ratio will be referred to throughout this Account as the diastereofacial selectivity (D.S.) of **1**, and this definition is applied to any chiral substrate or reagent[5]. For instance, reduction of norcamphor **2** with lithium aluminum hydride provides a mixture of *endo*- and *exo*-norborneols (**3** and **4**), the D.S. of **2** being 8.1 : 1 in favor of the *endo* isomer[6]. This example, although very simple, illustrates a well-established principle that has guided synthetic organic chemists in (cleverly) *designing the structure of a substrate* in order to incorporate proper stereochemistry in the reaction product. *Note that the chirality of the substrate dictates the stereochemical outcome of the reaction forming the new chiral center,* and that the reagent plays a minor role in this sense. A variety of complex natural products possessing many chiral centers have almost invariably been synthesized in this way[**].

A/**B**(diastereofacial selectivity of **1**) ≠ 1

Scheme 1[*].

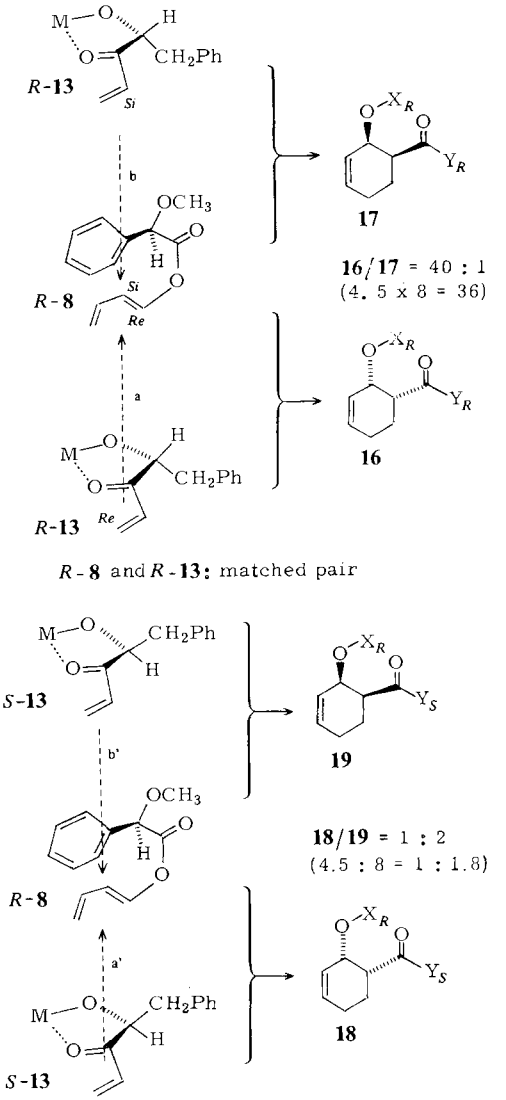
In contrast to the cyclic system exemplified above by **2**, a high diastereofacial selectivity is normally more difficult to attain with acyclic systems. For instance, hydride reduction of 3-methyl-2-pentanone **5** will, in all likelihood, proceed non-stereoselectively. The acyclic ketone **5** is conformationally flexible and the differences in both the steric and stereoelectronic effects exerted by the methyl and ethyl groups attached to the C3 carbon of **5** are insignificant. Thus, the two products, **6** and **7**, will be formed in nearly equal quantities. One is led to ask: Are there new means available for achieving high stereoselection in this last case, and further, can we even reverse the "normal" stereochemical course of the reduction of **2** (to secure **4** rather than **3**) without recourse to a classical, perhaps costly structural modification of the substrate?[***] These are fundamental problems and indeed we addressed ourselves to them when our macrolide project was launched a few years ago.

2.2. Interaction of Two Chiral Reactants and the Concept of Matched and Mismatched Pairs



The interaction of two chiral reactants is evaluated in terms of the diastereofacial selectivities of two chiral reactants, and the following two sets of model experiments, the Diels-Alder reaction[7] and the aldol reaction[8] appear to best serve as illustrations. Thus, the pericyclic reaction of *Trost*'s chiral diene *R*-**8**[9] with achiral acrolein **9** in the presence of $BF_3 \cdot OEt_2$ provides a 4.5 : 1 mixture of diastereoisomers **10** and **11** (Scheme 2). This diastereofacial selectivity (D.S.) of *R*-**8** can be rationalized on the basis of the proposed transition state conformation in which the phenyl group of **8** covers one face of the butadiene π-system, i.e., the *Si* face of the diene moiety is more "shielded" to the attack of **9** than the *Re* face (see Section 5). In a similar manner butadienyl phenylacetate **12**, an achiral diene chosen as a model for **8**, is predicted to approach the chiral dienophile *R*-**13** from the latter's *Re* face inasmuch as the coordination of the catalyst $BF_3 \cdot OEt_2$ with the α-hydroxyketone moiety of *R*-**13** brings about a five-membered chelate. The two faces of the chelate ring are differentiated by the (small) hydrogen and (large) benzyl groups attached to the chiral center of *R*-**13**. Indeed, the D.S. of *R*-**13** is 8 : 1, favoring the formation of **14** over **15**[7].

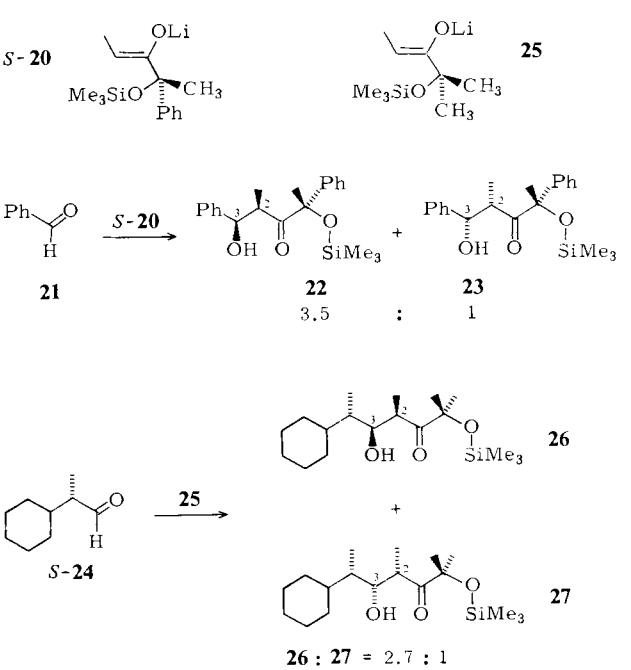
Now that the D.S.'s of the diene *R*-**8** and the dienophile *R*-**13** have been determined, one can evaluate the interaction of the two chiral reactants (Scheme 3). Compare the interaction between the *Re*-face of *R*-**8** and the *Re*-face of *R*-**13** (arrow a) with that between the *Si*-face of *R*-**8** and the *Si*-face of *R*-**13** (arrow b) which should lead to the formation of the products **16** and **17**, respectively. Since the two phenyl groups of *R*-**8** and *R*-**13** both impede the formation of **17** as shown in Scheme 3, the D.S.'s of both reactants are acting in concert. The ratio of **16** and **17** is 40 : 1 (larger than the D.S. of either reactant) and this combination of *R*-**8** and *R*-**13** is referred to as a "matched pair." In contrast, the reaction of *R*-**8** and *S*-**13** brings about a different stereochemical outcome. (Note that the chirality of the dienophile is now reversed from *R* to *S*.) In



[*] R^1 is chiral. Assuming that the Cahn-Ingold-Prelog priority of R^1 is higher than that of R, the *Si* and *Re* faces of **1** are those shown in Scheme 1.

[**] This statement is valid for virtually all the syntheses of racemic compounds recorded in the literature.

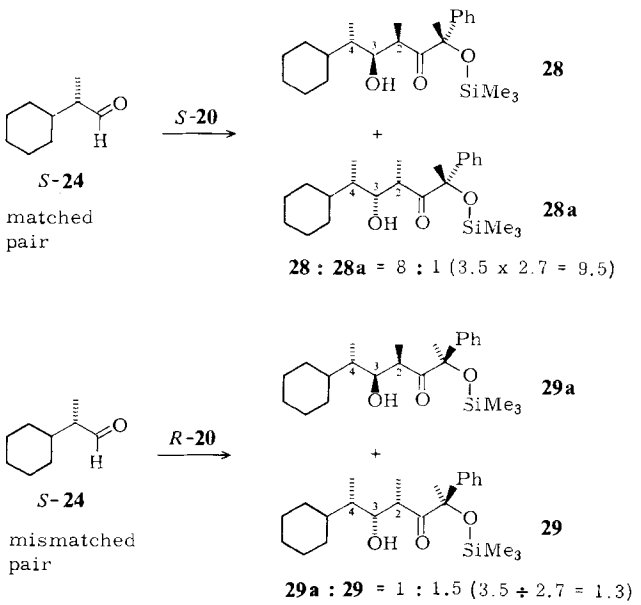
[***] The "art" of organic synthesis exhibited in many multi-step syntheses (much more complicated than the problem of **2**) is attributed, at least in part, to the skills of synthetic chemists in solving these stereochemical problems in this conventional, indirect manner. Readers will find it interesting to devise a pathway leading to **4** stereoselectively and to evaluate it in light of the discussions that will unfold in this Account.



Scheme 2.

Scheme 3.

each of the two face interactions discussed above, designated as paths a′ and b′ in Scheme 3, there intervenes one phenyl group, either that of *R*-**8** or *S*-**13**, between the two reacting π-systems. Therefore, the two diastereofacial selectivities of *R*-**8** and *S*-**13** are counteracting each other. Thus, *R*-**8** and *S*-**13** are called a "mismatched pair," and the expected products **18** and **19** result in a 1 : 2 ratio, a ratio smaller than either of the two D.S.'s[*].

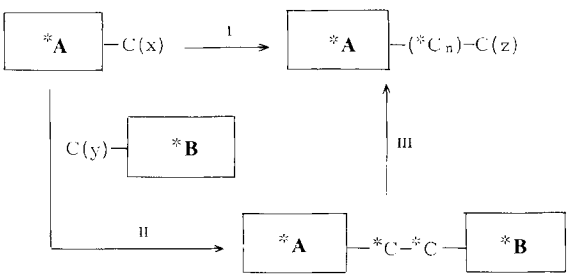


A set of aldol reactions also demonstrates a similar trend (Scheme 4)[8]. The chiral lithium enolate *S*-**20** reacts with (achiral) benzaldehyde **21** to provide the diastereomeric aldol products **22** and **23** in a 3.5 : 1 ratio which represents the D.S. of **20**. The two substituents at the C2 and C3 positions are *syn*-related[8] in both **22** and **23** but their absolute configurations are different; both β in **22** and both α in **23**. As will be elaborated on in Section 4, the absolute configurations are directly related to the face selection exercised by the chiral reagent *S*-**20**. Likewise, using the achiral lithium enolate **25**[10] the D.S. of the aldehyde *S*-**24** is determined to be 2.7 : 1, the ratio of the two products **26** and **27**.

Scheme 4.

[*] In general, this ratio is predicted to be smaller than the larger of the two D.S.'s.

Inspection of the absolute configurations of the C3 hydroxyl groups in **22** and **26** (Scheme 4), both of which are the predominant products of the above two reactions, immediately suggests that *S*-**20** and *S*-**24** constitute a matched pair (Scheme 5). In fact, the reaction of this pair leads to the enhancement of stereoselection (8 : 1), providing the major product **28** which incorporates the C3 hydroxy group in a β configuration and with an *anti*-relationship to the 4-methyl group. The corresponding mismatched pair of *S*-**24** and *R*-**20** reacts with inferior stereoselection (1 : 1.5) as predicted. A slight excess of **29** over its diastereoisomer **29a** is noteworthy in that the larger D.S. of *R*-**20** (reagent) compared with that of *S*-**24** (substrate) determines the stereochemical outcome of this reaction.

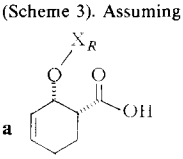


Scheme 5.

With the above results in hand, one cannot resist hypothesizing the multiplicativity of two diastereofacial selectivities in double asymmetric synthesis. The *degree of asymmetric induction is approximated to be (a × b) for a matched pair and (a ÷ b) for a mismatched pair* where a and b are the D.S.'s of a substrate and a reagent, respectively[*]. Fully admitting that several fortuitous events have brought about the above sets of product ratios that support the hypothesis, it is clear even at this preliminary stage that the multiplicativity will be valid only in a qualitative sense. Organic reactions are far too complex to be treated in the simplistic manner presented above, and many secondary interactions which occur in the regions remote from the reaction site are entirely ignored. Moreover, the diastereofacial selectivity is not a fixed number but has a range depending on the choice of an achiral model. A more critical analysis of the reaction course will be presented in Section 9, after having examined many examples of double asymmetric induction in Sections 4—7. For the time being, however, let us accept the validity of this multiplicativity of diastereofacial selectivities and see how it can be utilized for organic synthesis in terms of stereocontrol[3][**].

[*] The values of D.S.'s are selected in such a way as to be greater than 1. Obviously the two terms, a × b and a ÷ b, concern the relative directionality of the two diastereofacial selectivities.

3. A New Strategy for Stereochemical Control



In natural products synthesis we frequently encounter the need to build a new chiral center or centers on a chiral substrate. Process I in Scheme 6 formulates this transformation: chiral substrate *A–C(x) is converted into

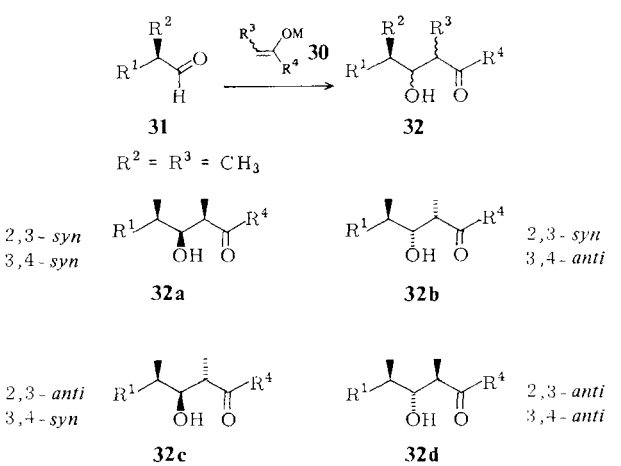
Scheme 6. Strategy for generation of new chiral centers on a chiral substrate. **A** and **B** must be homochiral. *A–C(x): chiral substrate; *B–C(y): chiral reagent; I: desired transformation; II: double asymmetric induction; III: removal of the chiral auxiliary.

A–(C_n)–C(z), where both C(x) and C(z) denote appropriate functional groups for the chemical operation. In order to achieve this task a chiral reagent *B–C(y) is allowed to react with *A–C(x) to provide a mixture of stereoisomers expressed by *A–*C–*C–*B (Process II). The reagent *B–C(y) is chosen so that a high stereoselection (at *C) is achieved in this process. Having served its purpose, the chiral auxiliary *B is removed in such a fashion so as to leave a functional group C(z) for further transformation (Process III). During this process the stereochemical integrity of the new chiral centers must be preserved. From the analysis detailed in the preceding section, it follows that: (1) When the desired *A–*C–*C–*B is the major product in the matched pair reaction, the resulting stereoselection should be higher than the diastereofacial selectivity of *A–C(x) (being augmented by that of the reagent), and (2) if the desired product *A–*C–*C–*B happens to be the minor product of the above reaction, then the reagent of

[**] Readers can easily recognize that this hypothesis of multiplicativity of D.S.'s is valid only for a pair of *homochiral* reactants, but not valid with racemates. Consider, for instance, that *R*-**8** (2 equiv.) reacts with a racemate consisting of *R*-**13** (1 equiv.) and *S*-**13** (1 equiv.) in the above Diels-Alder reaction (Scheme 3). Assuming that *R*-**8** couples with both

R-**13** and *S*-**13** at the same rate (no kinetic resolution), a simple calculation predicts that after removal of the chiral auxiliaries Y_R and Y_S (in **16**—**19**) with $NaIO_4$, the resulting product consists of **a** and **b** in a 1.9 : 1 ratio. Compare this ratio with those (40 : 1 and 1 : 2) obtained in the matched and mismatched reactions shown in Scheme 3. When equimolar *rac*-**8** and *rac*-**13** are used in the same reaction, then a mixture of *rac*-**a** and *rac*-**b** (X_R's in both **a** and **b** are X_R and X_S) in the same ratio will result.

the opposite chirality should be used. This latter case represents a mismatched pair reaction, and the diastereofacial selectivity of the reagent must be large enough to outweigh that of *A–C(x) in order to create the desired *C–*C stereochemistry with high selection. Such reagents of either chirality (at *B) can be, and have been, prepared. The same arguments are also applicable to highly enantioselective catalysts[*] which make the direct transformation of Scheme 6 (Process I) possible.



A short time ago, the preparation of a reagent or catalyst with a 20:1 stereoselection [90.4% diastereomeric excess (*de*) or enantiomeric excess (*ee*)] for the reaction with achiral substrates was regarded as a worthy accomplishment. *Chiral* acyclic systems which we *normally* encounter in synthesis exhibit a small diastereofacial selectivity ranging from 1 to 5. Therefore, in order to achieve the same degree of stereoselection (20:1) in the mismatched pair reaction with a *chiral* acyclic substrate possessing a 5:1 D.S., the above analysis of double asymmetric induction demands that to a first approximation the reagent be capable of a D.S. of at least 100:1. With such reagents a >100:1 stereoselection is expected for a matched pair while even a mismatched pair brings about a minimal isomeric ratio of 1:20, roughly the limit of stereoselection which is of practical significance in organic syntheses. Both the D.S. of the substrate and the extent of stereoselection desired in the double asymmetric synthesis determine the D.S. demanded of the reagent. Readers are urged to appreciate the greater demand placed on reagents in double asymmetric reactions.

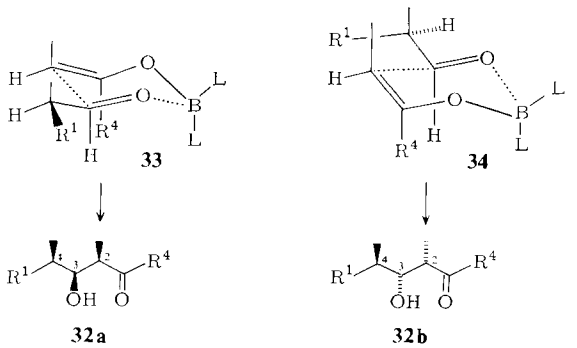
As elaborated upon above, the stereochemistry of organic reactions may be controlled by the chirality of reagents (and substrates) rather than substrates alone as it has been in most cases to date, and as a result a stereoselection of one order of magnitude higher than that previously attained may accrue through this double asymmetric methodology. As frequently happens in science, the first unequivocal demonstrations (to our best knowledge) of such *stereochemical control* (in the sense defined in Section 1) were documented in 1980 by more than one group engaged in widely diverse branches of chemistry, the aldol reaction[8] and catalytic hydrogenation[11][**]. Let us see how successfully this new strategy has since been applied in the stereocontrol of major organic reactions to achieve 20:1 or better stereoselection, the standard that is set for this Account[***].

4. Aldol Reaction

This venerable reaction formulated in Scheme 7 involves an enolate (**30**) and an aldehyde (**31**) which react to form a new carbon-carbon bond. Recent intense and extensive studies on the reaction have covered a wide variety of reaction conditions and structural modifications[3, 12], and have disclosed that only a few sets of reaction parameters bring about the high stereoselection that meets the standards set above (Section 3). In this regard, the use of chiral boron enolate reagents is notably successful and is discussed below.

In general, the aldol reaction creates two new chiral centers producing four possible stereoisomers **32a–d**, as exemplified for the reaction of a chiral aldehyde (R^2 = Me in **31**) and the enolate (R^3 = Me in **30**) derived from an ethyl ketone (Scheme 7). Two elements of control are necessary to achieve a high stereoselectivity for this process. Assume that the boron-mediated aldol reaction proceeds via the chair-type cyclic transition state (Zimmerman-Traxler model)[13] such as **33** shown for a *Z*-enolate attacking an aldehyde from the *Re* face of the latter (Scheme 8). Then, under kinetic control, there are four possible reaction courses: (1) *Z*-Enolate attacking the *Re*-face of the aldehyde **31** (**33** → **32a**), (2) *Z* attacking *Si* (**34** → **32b**), (3) *E* attacking *Re* (not shown) and (4) *E* attacking *Si* (not shown), thereby forming the isomers **32a–d**[14, 15]. From this analysis, tabulated in Scheme 8, it can be seen that (a) the enolate geometry should be translated into control of the 2,3-stereochemistry of the products (**32**), and (b) the direction of the enolate approach should determine the absolute configuration of the 3-hydroxy group of **32**, thereby providing control of the relative stereochemistry at the 3,4-positions. Two sets of experiments involving *achiral Z*- and *E*-boron enolates with *achiral* aldehydes provide the corresponding racemic 2,3-*syn*- and 2,3-*anti*-aldol products, respectively[16][**]. Thus, these results lend strong support to the proposed model and further justify the pursuit of 3,4-stereochemical control which, obviously from the discussions of the preceding Section, concerns the diastereofacial selectivities of both reactants. The following examples best illustrate this crucial issue.

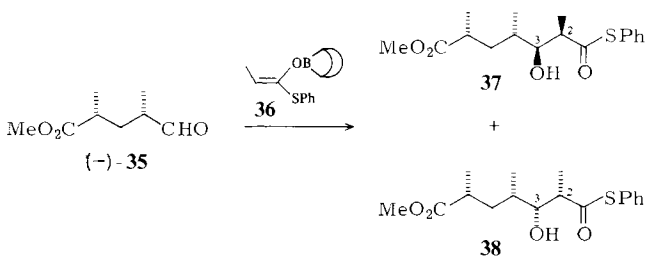
Scheme 7 [*].



[*] The reaction of an achiral substrate with a chiral catalyst or stoichiometric addend provides the corresponding enantiomers rather than diastereoisomers in unequal quantities. However, since the reaction proceeds through diastereomeric transition states, the term diastereofacial selectivity is also retained for the chiral catalyst and addend.

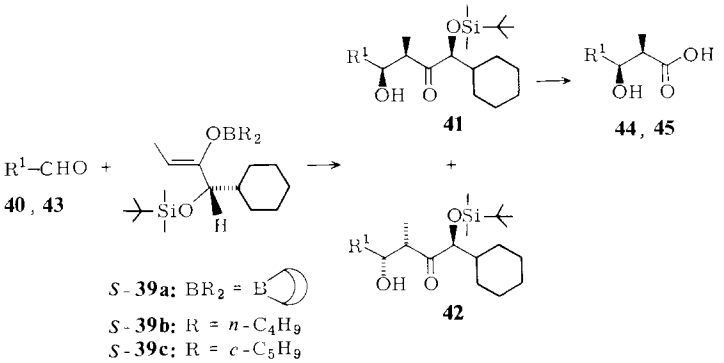
[**] For the decade preceding these demonstrations, several examples of double asymmetric induction without control appeared sporadically. These will be summarized in Section 9.

[***] We advise that those who are not interested in numerous examples of double asymmetric reactions proceed from here to Section 8.



[*] The "*syn,anti*" nomenclature proposed in references [8] and [14] appears to have now been accepted for general use, as it has been used in recent representative review articles (references [12c] and [15]).

[**] For instance, reaction of isobutyraldehyde with the enolate derived from ethyl cyclohexyl ketone (R^1 = Me, R^4 = cyclohexyl in **33** and **34** in Scheme 8) provides **32a** and **32b**, a 1:1 mixture of which is a racemic aldol.



Scheme 8. Routes to **32a—d**.
Re-attack:
Z-**30** + **31** ⟶ **33** ⟶ **32a**, 2,3-*syn*, 3,4-*syn*
E-**30** + **31** ⟶ **32c**, 2,3-*anti*, 3,4-*syn*
Si attack:
Z-**30** + **31** ⟶ **34** ⟶ **32b**, 2,3-*syn*, 3,4-*anti*
E-**30** + **31** ⟶ **32d**, 2,3-*anti*, 3,4-*anti*

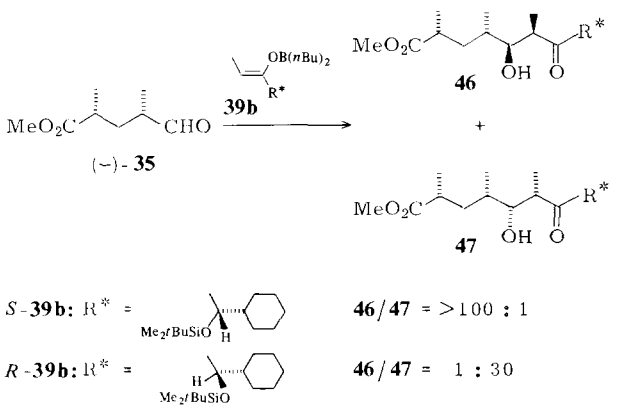
As shown in Scheme 9 the reaction of (−)-dimethylglutaric hemialdehyde **35** with an *achiral* *Z*(*O*)-enolate[*], e.g. **36**, provides an approximately 3:2 mixture of **37** and **38** which correspond to **A** and **B** in Scheme 1. Note that (1) the two substituents at the 2,3-position of the products are *syn*-oriented in both **37** and **38** but are opposite in terms of the absolute configuration and (2) the 3:2 ratio is the diastereofacial selectivity for aldehyde **35**. This ratio represents roughly the degree of diastereoselection that one can attain in the aldol reaction of **35** without recourse to double asymmetric induction.

Scheme 9. **36** is a 9-borabicyclo[3.3.1]non-9-yl derivative.

Now the task is to develop chiral enolate reagents which have high diastereofacial selectivities (≥100:1) in single asymmetric reactions. Of the many chiral *Z*(*O*)-enolates that have been prepared and examined, those (**39**) shown in Scheme 10, prepared from optically pure (*S*)- or (*R*)-mandelic acid, meet the criteria set for the chiral reagents[17]. Thus, *achiral* aldehyde **40** undergoes aldol reaction with *S*-**39c**, the most stereoselective (but least reactive) boron enolate of the three (**39a**—**39c**), to provide a 100:1 mixture of diastereoisomers **41** and **42**. With isobutyraldehyde **43**, an α-branched aldehyde, the selectivity of the reaction is very high (>100:1 of **41** to **42**; Table 1) even with the least selective (but most reactive) boron enolate *S*-**39a**. Successive treatment of a mixture of **41** and **42** with hydrogen fluoride (or fluoride anion) followed by sodium metaperiodate provides the corresponding 2,3-*syn*-3-hydroxy-2-methylcarboxylic acids (**44** and **45**) with an enantiomeric excess higher than 98%. This removal of the chiral auxiliary corresponds to Process III of Scheme 6. Thus, the diastereofacial selectivity of **39** exceeds 100:1 with the proper selection of a ligand attached to the boron atom.

Scheme 10. *S*-**39a** is a 9-borabicyclo[3.3.1]non-9-yl derivative.

Table 1. Reaction of aldehydes with boron enolates **39** (see Scheme 10).

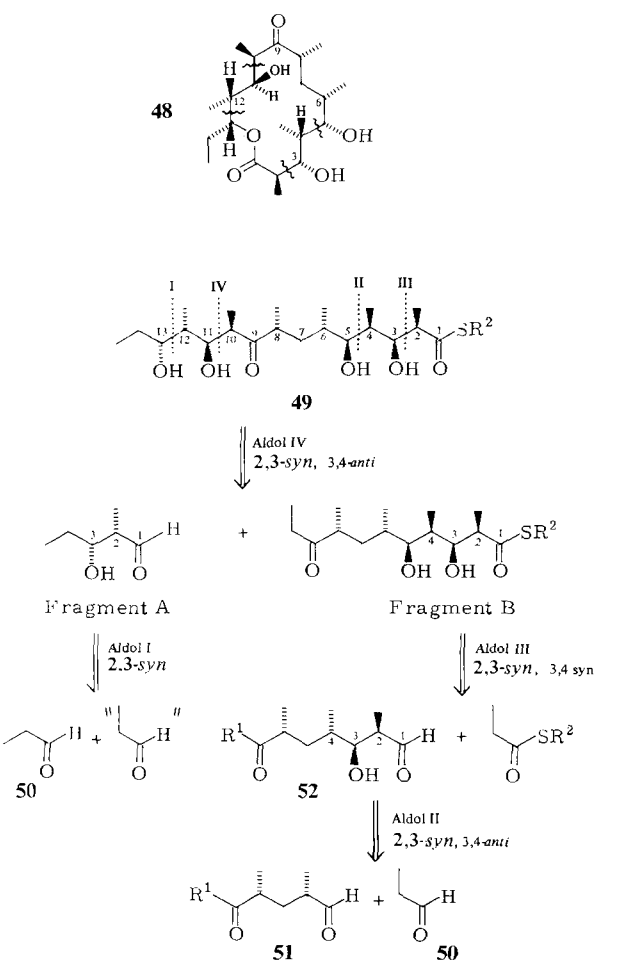


Aldehyde	R^1	Boron enolate	**41**:**42**	Acid [a]
40	$PhCH_2OCH_2CH_2$	*S*-**39a**	16:1	**44**
		S-**39b**	28:1	
		S-**39c**	100:1	
43	$(CH_3)_2CH$	*S*-**39a**	>100:1	**45**
		S-**39b**	>100:1	
		S-**39c**	no reaction	

[a] Main product.

One can now examine the interaction of the *chiral* aldehyde (−)-**35** with the *chiral* enolate *S*-**39b**[18]. This aldol reaction provides two diastereoisomers **46** and **47** in a ratio of >100:1 (Scheme 11). A change in the chirality of the enolate reagent brings about a reversal of the result: The combination of (−)-**35** and *R*-**39b** leads to the formation of **46** and **47** in a ratio of 1:30 favoring the latter (**47**). The significance of these two reactions is threefold: (1) Both ratios are far superior to the ratio of 3:2 obtained with an achiral enolate, (2) the chirality of R* in **39b** is directly correlated to the stereochemistry at the 3,4-positions of the reaction products, and thus either the 2,3-*syn*-3,4-*anti* or 2,3-*syn*-3,4-*syn* system can be constructed in a preselected manner, and (3) the multiplicativity of the two diastereofacial selectivities (3:2 and 100:1) is *roughly* realized; the two reactions, (−)-**35** + *S*-**39** and (−)-**35** + *R*-**39**, representing matched and mismatched pairs, respectively. The stereochemical course of the aldol reaction is now fully under control and the power of double asymmetric induction is clearly demonstrated.

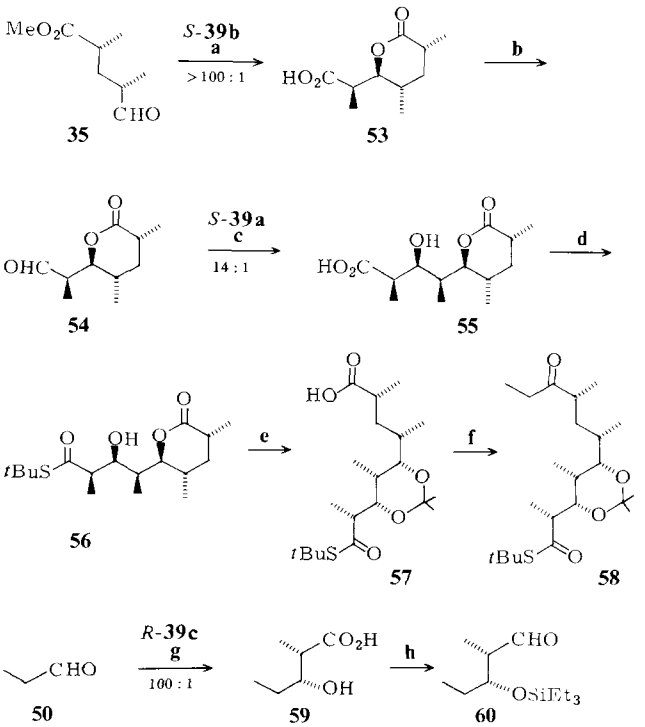
It is appropriate to insert here a brief account of our recent synthesis of the macrolide 6-deoxyerythronolide B **48**[19]. It was during the course of this synthesis that the new strategy emerged as a means of solving the stereochemical problems associated with the target molecule. The achievement was the first successful demonstration of double asymmetric synthesis applied to the construction of molecules of this stereochemical complexity. The macrol-



[*] Here, *Z*(*O*) signifies that the element oxygen has arbitrarily been given the highest priority (see reference [14]).

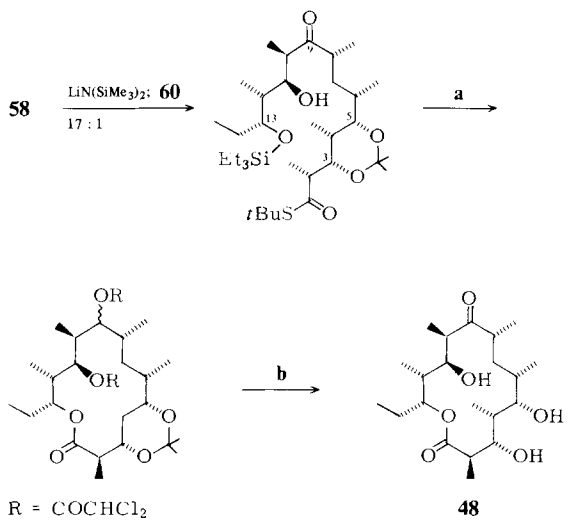
Scheme 11. (−)-**35** + *S*-**39b**: matched pair; (−)-**35** + *R*-**39b**: mismatched pair.

ide **48** is the lactone derived from the 13-hydroxypentadecanoic acid **49** which consists of seven propionate building blocks[*] (Scheme 12).



Splitting this seco-acid **49**, drawn in zigzag fashion, into fragments A and B immediately suggests the order of the aldol reactions to be used in the synthesis. Aldol reaction I (involving propanal **50** and its enolate equivalent) produces fragment A, while aldol reactions II (**50** and **51**) and III (**52** and an equivalent of **50**) complete a synthesis of fragment B. Finally, both fragments are combined via aldol reaction IV. Note that aldol reactions I, II, and III all concern the creation of 2,3-*syn* stereochemistry, a task that can be readily achieved with the *Z*-enolates **39a**—**c**.

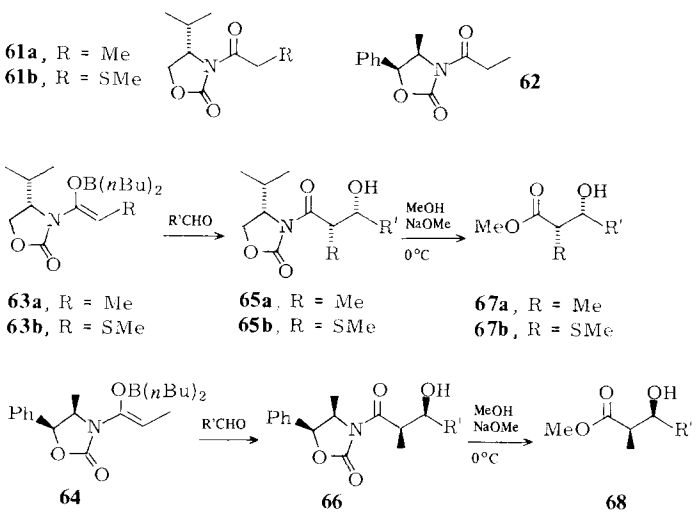
Scheme 12. Retrosynthetic analysis of 6-deoxyerythronolide B **48**.



[*] More accurately, these are one propionyl CoA and six methylmalonyl CoA's.

The first step of the seco-acid synthesis has already been discussed (Scheme 11). The reaction of (−)-**35** with *S*-**39b** provides the desired product with > 100 : 1 stereoselection and the resulting aldol product **46**, after removal of the chiral auxiliary (HF and then $NaIO_4$: Process III of Scheme 6), is converted into the Prelog-Djerassi lactonic acid **53** in optically pure form (> 98% *ee*) (Scheme 13). Addition of the C1—C2 fragment (see **49**) to the aldehyde **54** derived from acid **53** uses the *S*-chiral reagent **39a** (aldol reaction III, Scheme 12). Thus, reaction of **54** provides the desired aldol product (14 : 1 stereoselection) which, upon standard treatment, is transformed to the carboxylic acid **55** and then to its thiol ester **56**. After modification of the functional groups of **56** through a series of routine reactions the resulting carboxylic acid **57** is further converted to the corresponding ethyl ketone **58**, which is an equivalent of fragment B. The enantioselective synthesis (selectivity > 100 : 1) of the hydroxy acid **59** corresponding to fragment A is readily achieved using propanal (**50**) and *R*-chiral reagent **39c** (aldol reaction I). A sequence of standard operations converts **59** into aldehyde **60**. Thus, eight chiral centers out of the ten embedded in the target molecule **48** have been created with remarkable efficiency and stereo-

Scheme 13. Synthesis of **58** and **60** (equivalents of fragments B and A, respectively, *in* Scheme 12). **a**: 1) nBu_4NF, 2) $NaIO_4$, 85% yield; **b**: 1) $(COCl)_2$, 2) H_2, 5% $Pd/BaSO_4$, $(Me_2N)_2C{=}S$, 95% yield; **c**: 1) HF, 2) $NaIO_4$, 71% yield; **d**: $ClCO_2Et$, $TlStBu$; **e**: 1) KOH, 2) $tBuPh_2SiCl$, 3) $CH_2{=}C(OMe)Me$, trifluoroacetic acid, 4) nBu_4NF, 46% yield from **55**; **f**: 1) $(COCl)_2$, 2) $LiCuEt_2$, 84% yield; **g**: 1) HF, 2) $NaIO_4$, 85% yield from **50**; **h**: 1) CH_2N_2, 2) Et_3SiCl, 3) diisobutylaluminum hydride, 4) $CrO_3(py)_2$, 75% yield.—The stereoselection is shown under the arrows.

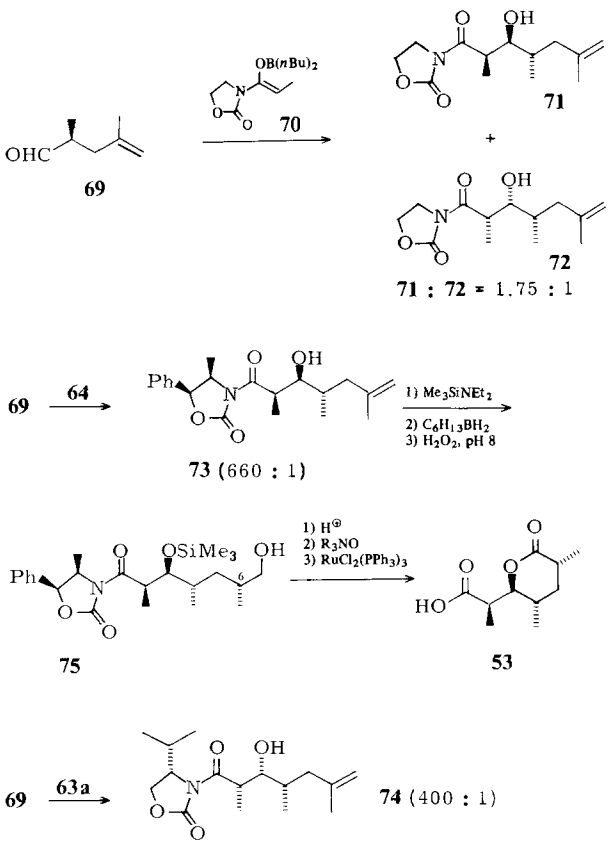


selection (Scheme 13). At this stage the overall yield is 30% and overall stereoselectivity is approximately 90%. The remaining tasks consist of the final aldol coupling (aldol reaction IV in Scheme 12) of fragment A with B and the macro-lactonization of the resulting derivative of the seco-acid **49**, both of which have been successfully executed, as outlined in Scheme 14.

Scheme 14. Synthesis of a derivative of the seco-acid **49** and ring closure to 6-deoxyerythronolide B **48**. The yield in the first step is 88%. **a**: 1) $NaBH_4$, 2) $(Cl_2CHCO)_2O$, 3) AcOH, 4) $CuOSO_2CF_3$; $Et(iPr)_2N$, 34% yield; **b**: 1) KOH, 2) pyridinium chlorochromate, NaOAc, 3) trifluoroacetic acid (quantitative).—The stereoselection is given under the first arrow.

The macro-lactonization has already been adequately reviewed[20], and the stereochemical control in the aldol reaction IV is methodologically different from that which has been discussed above[21][*]. Therefore, both transformations in the final stages of the 6-deoxyerythronolide B synthesis are omitted from the discussion in this Section.

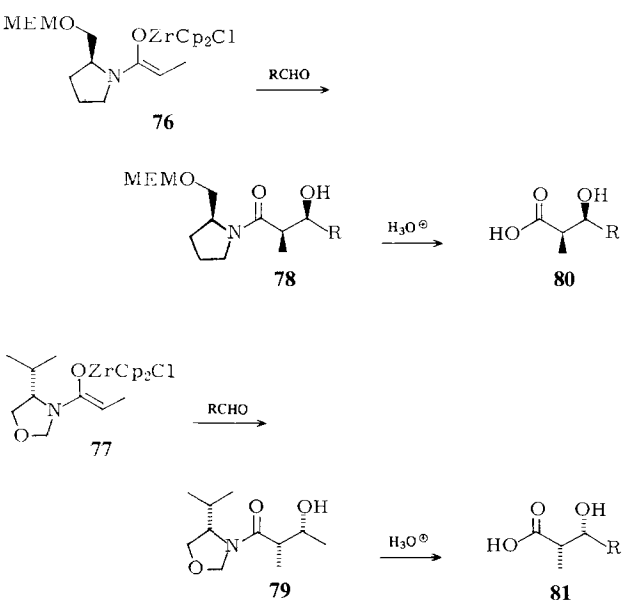
Chiral enolate reagents that exhibit a $>100:1$ diastereofacial selectivity in the aldol reaction are rare at present, and documented examples of double asymmetric induction using such reagents are even more scarce. In this connection, the boron enolate chemistry developed in *Evans'* laboratories along a line similar to that outlined above deserves special mention (Scheme 15). Thus, a pair of chiral *N*-acyl-2-oxazolidinones **61a** and **62** (derived from (*S*)-valine and (1*R*,2*S*)-norephedrine, respectively) are converted under the standard conditions ($nBu_2BOSO_2CF_3$ and iPr_2NEt) into the corresponding *Z*-boron enolates (**63a** and **64**) each of which is allowed to react with a set of achiral aldehydes[22]. The 2,3-*syn* diastereoisomers **65a** and **66** are virtually the sole products of these reactions with **63a** and **64**, respectively, showing that both the enolate formation and the aldol reaction proceed with (near) perfect stereoselection (ca. 500 : 1). Treatment of **65a** and **66** with sodium methoxide (molar ratio 1 : 1) in methanol provides the corresponding 2,3-*syn*-3-hydroxy-2-methylcarboxylates **67a** and **68** of >99% optical purity, and these products **67a** and **68** are opposite in chirality. Similarly the boron enolate **63b** derived from **61b** (R = SMe) reacts with aldehydes to provide the products **65b**. The diastereofacial selectivity of the enolate **63b** ranges from 9 : 1 to 50 : 1 in these cases.



Scheme 15.

A typical demonstration of double asymmetric induction analogous to that shown in Scheme 11 is now available for the pair of reagents **64** and **63a**[23]. The chiral aldehyde selected is **69** which has a diastereofacial selectivity of 1.75 : 1, as determined by the ratio of two aldol products **71** and **72** obtained from the reaction of **69** with the achiral boron enolate **70**, structurally similar to **64** and **63a**. The reaction of **69** with **64** and **63a** provides exclusively **73** and **74** (with stereoselections of 660 : 1 and 400 : 1), respectively. Thus the chirality of the reagents, but not of the substrate, clearly dictates the stereochemical course of the reactions. The concept of matched and mismatched pairs can also be recognized in this example. The product **73** is further converted through a sequence of reactions: (1) trimethylsilylation, (2) hydroboration with thexylborane (*single* asymmetric induction with 5.7 : 1 in favor of the diastereoisomer **75**, see C6) followed by oxidative workup, (3) acid hydrolysis to remove the trimethylsilyl group of **75**, (4) ruthenium-catalyzed oxidation of the primary hydroxy group, and finally (5) hydrolytic removal of the chiral auxiliary. The resulting product is the (+)-Prelog-Djerassi lactonic acid **53** discussed earlier in Scheme 13. More elaborate incorporation of double asymmetric induction in the synthesis of several complex natural products is underway in *Evans'* laboratories[24] and will be formally documented in the near future.

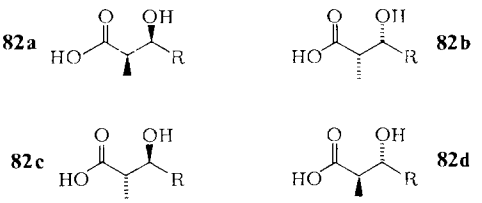
Other qualified chiral reagents include the zirconium enolates **76** and **77**, which are obtainable from the corresponding lithium enolates via metal exchange with Cp_2ZrCl_2[25].



Reactions of both **76** and **77** with representative achiral aldehydes (Scheme 17) proceed with excellent 2,3-*syn*/*anti*

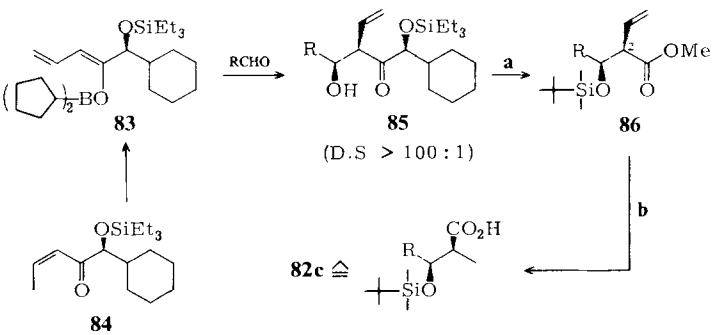
[*] Aldol reaction IV, which is also a double asymmetric reaction, is distinguished from aldol reactions I—III in that it (IV) involves the coupling of two structurally *prefixed* components. Another important aspect of this reaction is that the coordination of $Li^{\oplus}$ with the β-ethereal oxygen atom of the aldehyde **60** is mainly responsible for the attainment of a 17 : 1 stereoselectivity (reference [21]). This chelation effect will be discussed in Sections 8 and 9.

Scheme 16.



selection (96—98%) and also with a diastereofacial selection ranging from 50:1 to 200:1. Therefore, both **76** and **77** should, and indeed do exert their power in controlling the stereochemistry of aldol reactions with a chiral aldehyde as well. The recorded example uses 3-benzyloxy-2-methylpropanal and the results conform to the concept of matched and mismatched pairs. Removal of the chiral auxiliaries from **78** and **79** to obtain the corresponding carboxylic acids **80** and **81** (Process III of Scheme 6) requires

Scheme 17. MEM = methoxyethoxymethyl, Cp = cyclopentadienyl.

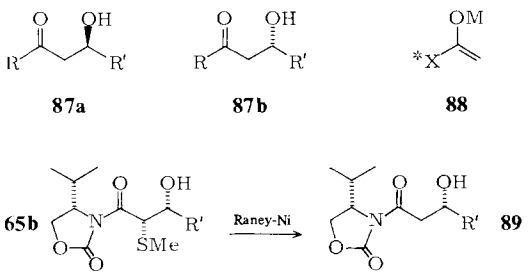


acid-treatment (5% HCl, 10 equiv. $H^{\oplus}$, 100°C, 2 h) which may cause some problems with acid-sensitive aldol products that might be encountered in the synthesis of complex natural products.

The foregoing discussions have been confined to the preparation of 2,3-*syn*-substituted units **82a** and **82b**, using a chiral *Z*-enolate. Because many attempts at devising *qualified* chiral *E*-enolates have met thus far with only partial success, the 2,3-*anti* units **82c** and **82d** (Scheme 18)

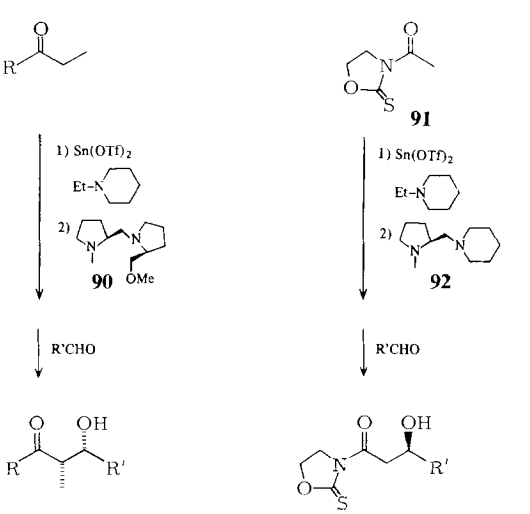
Scheme 18.

cannot be constructed through the *direct* aldol methodology at present. An indirect and somewhat circuitous approach (which provides a temporary solution to this problem) is outlined in Scheme 19[14,26]. The dicyclopentylboron *Z*-enolate **83** prepared from *Z*-enone **84** adds to an aldehyde in the expected manner (diastereoselection >100:1) to provide **85** which is converted into **86** in the



Scheme 19. Synthesis of an **82c**-equivalent. **a**: 1) HF, 2) $NaIO_4$, 3) CH_2N_2, 4) tBuMe$_2$SiOSO$_2$CF$_3$; **b**: 1) diisobutylaluminum hydride, 2) *p*-toluenesulfonyl chloride, 3) NaI, 4) $NaBH_3CN$, 5) O_3.

usual manner. This ester has two different functional groups, an olefin and an ester, both of which can be modified in a straightforward manner to reach **82c**. It is apparent that the right-hand end of the main chain and the 2-substituents of **86** are interchanged in **82c**. Thus, using one of the "tricks" synthetic organic chemists have often employed, a chiral *Z*-enolate eventually leads to the formation of 2,3-*anti* aldol products.

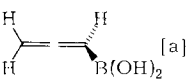


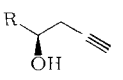
In the biosynthesis of important polyketide natural products another important structural unit (**87a**, **b**) emerges from the incorporation of an acetate building block (rather than a propionate as in the cases of **82a—d**). For several reasons now becoming clearer, all of the chiral enolates **88** (*X = chiral auxiliary) prepared in a manner analogous to that for **39**, **61**, and **76** exhibit an insignificant diastereofacial selectivity. Hence, the enolates **88** are at present incapable of constructing either **87a** or **87b** with high stereoselection. (However, see ref. [108]) A device to

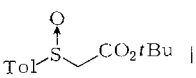
surmount this problem utilizes the aldol product **65b** obtainable in sufficient homogeneity as discussed earlier (Scheme 15). Desulfurization with Raney nickel proceeds to provide, "in good yield," **89** from which the chiral auxiliary can be removed (Scheme 20)[22][*]. Thus, the indirect methods for the construction of **82c, d** and **87a, b** discussed above are viable for the aldol reaction with a variety of chiral aldehydes (double asymmetric inductions).

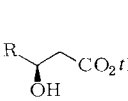
Scheme 20.

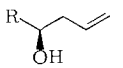
Our criteria set for the chiral enolate reagent are that it exhibits >95% *syn/anti* selection and a ≥100:1 diastereofacial selectivity. The tin(II)-mediated aldol reaction (developed in *Mukaiyama*'s laboratories), although not meeting both criteria, deserves due attention in that the asymmetric induction is brought about not by a chiral auxiliary attached to the enolate, but importantly by a chiral ligand[27]. Thus, each of several representative achiral ethyl ketones is converted with tin(II) bis(trifluoromethanesulfonate) and *N*-ethylpiperidine into its tin enolate, which, after the addition of the diamine **90** derived from (*S*)-prolinol, is allowed to react with a set of achiral aldehydes (Scheme 21). The *syn/anti* selection and the diastereofacial selectivity for the *syn* products range between 3:1 and 20:1 and between 3:1 and 9:1, respectively. The same reaction using 3-acetylthioazolidine-2-thione (**91**) as the enolate precursor and the diamine **92** as the chiral ligand provides a mixture of two enantiomers, the ratio of which ranges from 4.7:1 to 19:1, the diastereofacial selectivity of

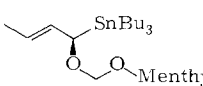


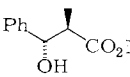












Scheme 21. Tf = CF_3SO_2O.

[*] For comments on this removal, see p. 56 of reference [3a].

the reaction species carrying the diamine. Further improvement of these stereoselectivities is eagerly awaited as the advantage of this aldol reaction which does not require removal of a chiral auxiliary is clear.

In closing this Section, several chiral reagents or catalysts are tabulated which are equivalent to the enolate reagents discussed above in the sense that all these achieve the same task of constructing the 3-hydroxycarbonyl system formulated in **82a–d** and **87a, b**. None of these "equivalents" has been tested in terms of double asymmetric induction, but their diastereofacial selectivities are excellent (Table 2)[28–31]. These reactions are reserved for a future review. They are complementary with the aldol methodology in that the latter is still inefficient in effecting the "acetate" addition. In Section 7 we will address an entirely different approach to the solution of this "3-hydroxycarbonyl" problem.

Table 2. Reactions of some chiral reagents or catalysts with aldehydes. Tol = *p*-tolyl, Ipc = 3-pinanyl ("isopinocampheyl").

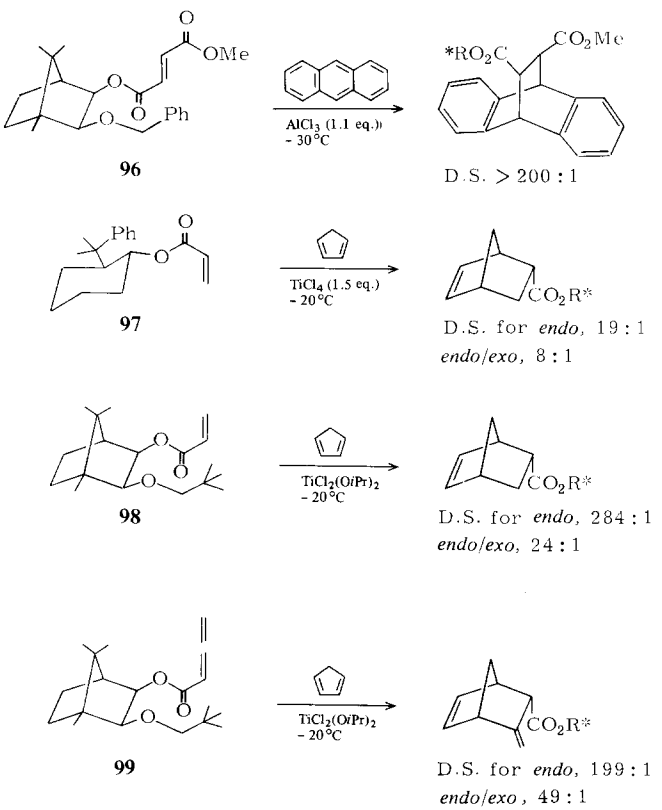
5. Diels-Alder Reaction

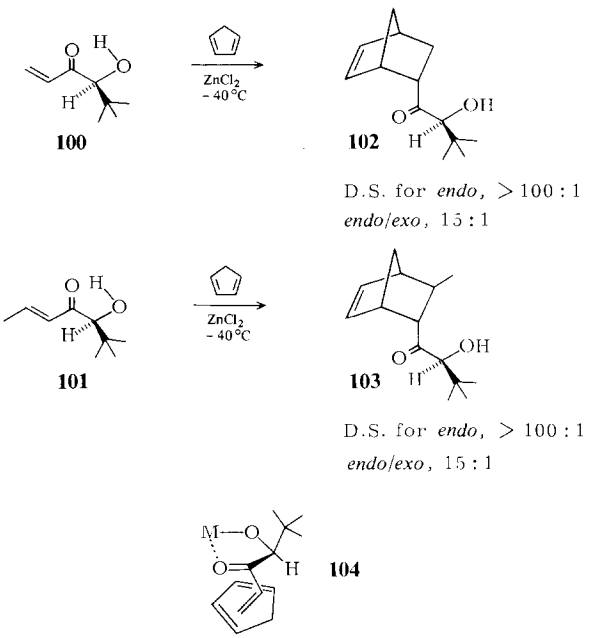
The Diels-Alder reaction effects one of the most efficient organic transformations in that it can create as many as four chiral centers as exemplified in Scheme 22. The pericyclic reaction of two chiral components, diene **93** and dienophile **94** can hypothetically produce $2^4 = 16$ stereoisomers, isomeric at the C2, C3, C4, and C5 atoms in **95**. The attainment of the potential stereoselection requires the advantageous (and simultaneous) exercise of, at least, four elements which govern the stereochemical course of the reaction. These elements are well known: *cis*-addition, *endo*-addition, and diastereofacial selectivities of both the chiral ene and diene[*]. With regard to the last factors, diastereoselectivities have received renewed interest in recent years. Since many chiral reactants recorded prior to early 1982 are adequately surveyed in several review articles[32],



[*] The last factor (the diastereofacial selectivity of the chiral diene) is closely related with the orientation of **93** to **94** in the transition state (regiochemistry of **93**).

this section is mainly concerned with the most recent development of chiral dienophiles, which may be divided into two categories, the Type I and Type II reagents. In the Type II reagents a chiral auxiliary (R*) is attached one atom closer to the three-carbon enone unit than in the Type I[*].

Scheme 22.

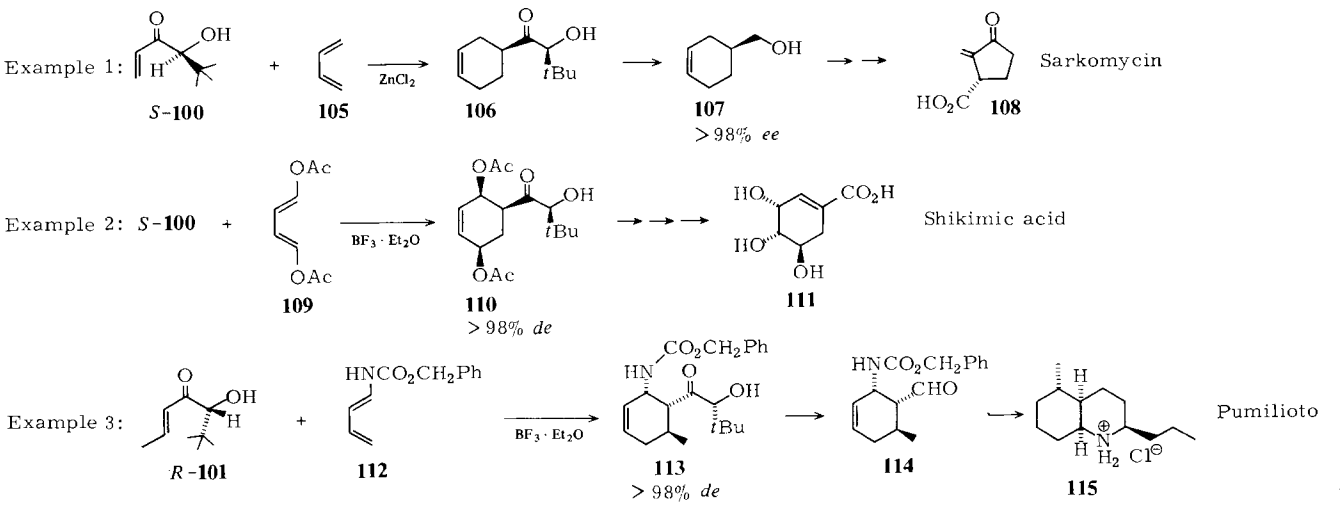


Of the many Type I chiral dienophiles some recent additions, **96**—**99**, clearly stand out as compared with the dienophiles reported earlier. As exemplified in Scheme 23[33-36], **96**—**99** undergo Diels-Alder reactions in the presence of a Lewis acid catalyst with a diastereoselection exceeding 100 : 1. The Type II dienophiles are newcomers to the asymmetric Diels-Alder reaction and were devised with the hope that the chiral group (R*) may act as a highly effective chiral inducer because it is placed so closely to the reaction site. Since the reagents **100** and **101** have been investigated far more thoroughly than the others in terms of diastereofacial selectivity and double asymmetric induction[37], the following discussions mainly concern these dienophiles.

Scheme 23.

[*] After completion of this Account, a further review of asymmetric Diels-Alder reactions appeared in the literature [104].

Coupling of **100** with cyclopentadiene in the presence of $ZnCl_2$ at $-40\,^{\circ}C$ is complete within 1 h and provides almost exclusively one *endo*-adduct (**102**) (diastereoselection for the two *endo*-products, > 100 : 1; *endo/exo*, 15 : 1) (Scheme 24)[*]. Likewise, the reaction of **101**, a homolog of



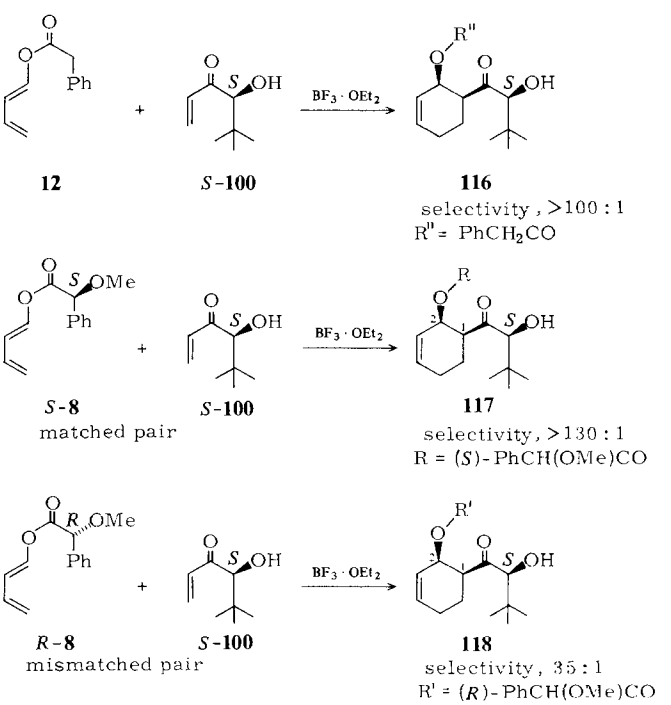
Scheme 24.

100, with cyclopentadiene under identical conditions proceeds smoothly with equally high stereoselection (D.S. for *endo* adducts, > 100 : 1). The results of these and other related experiments disclose at least two important features of the Diels-Alder reaction. First, coordination of the Lewis acid catalyst with the α-hydroxyketone moiety of the dienophile **100** leads to the formation of a rigid five-membered chelate, thus making the two diastereotopic faces of the enone system highly distinguishable (see **104**). Second, from the established absolute configurations of **100** and **101** (and also **102** and **103**), one concludes that within the chelated framework of **104** the Diels-Alder reaction proceeds, at least in these particular instances, with the enone fragment in its cisoid (synplanar) conformation (as opposed to the transoid conformation often postulated earlier for chiral esters of Type I)[**].

A variety of dienes react with **100** and **101**[37]. In the three examples shown in Scheme 25 the cycloaddition reaction provides a single adduct to the detection limits of ^{1}H-NMR spectroscopy (270 MHz). Oxidative removal of the chiral auxiliary group from the adduct (cf. a similar

[*] General problems associated with the *endo/exo* ratio have not been fully resolved. This important issue, however, is excluded from discussion.

[**] These experiments show how the investigation of an asymmetric synthesis can provide rich information about the transition state of a reaction.

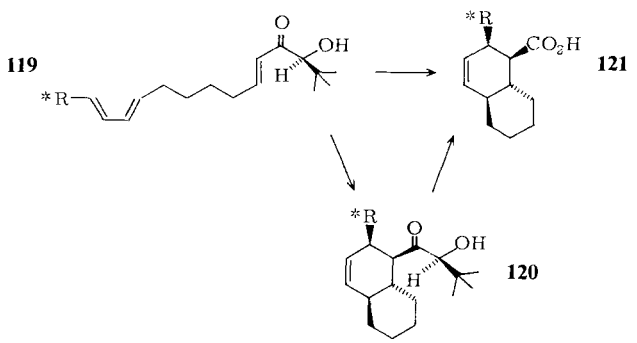


Scheme 25.

transformation of the aldol products discussed in Section 4) leads to a homochiral product (at minimum 98% *ee* or *de*) which serves as an intermediate for the synthesis of a natural product. *Example 1:* Reaction of *S*-**100** with excess butadiene (**105**) in the presence of $ZnCl_2$ gives rise to **106** which is in turn transformed via three steps to alcohol **107** (98% *ee*). Conversion of the enantiomer of **107** into natural sarkomycin **108** has already been documented[38]. *Example 2:* 1,3-Butadienylene diacetate (**109**) and *S*-**100** are coupled with the aid of $BF_3 \cdot OEt_2$ as catalyst. Product **110**, which is the exclusive stereoisomer of this cycloaddition, is then subjected to a series of six transformations analogous to those used earlier to provide optically pure shikimic acid (**111**)[39]. *Example 3:* A mixture of *R*-**101** and $BF_3 \cdot OEt_2$ is allowed to react with excess diene **112** to provide an adduct **113** with >100:1 diastereoselection, which is in turn converted in two steps to aldehyde **114**. Conversion of **114** to the hydrochloride of (+)-pumiliotoxin **115** follows the published procedure[40].

The above examples of single asymmetric induction clearly demonstrate that the chiral dienophilic reagents **100** and **101** are highly diastereoselective (>100:1), and satisfy the prerequisites for successful double asymmetric induction which is the issue central to this Account. In order to examine the validity of the matching and mismatching concept as applied to the Diels-Alder reaction, a set of experiments has been carried out using butadienyl phenylacetate **12** as an achiral diene and (*S*)- and (*R*)-*O*-methyl mandelates (*S*-**8** and *R*-**8**) as chiral dienes. Diene **8** has a moderate diastereoselectivity of 4.5:1 as described earlier in Section 2[*].

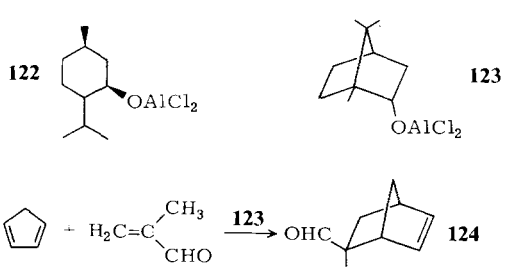
The first experiment involving *S*-**100** and **12** (Scheme 26) reconfirms the high diastereofacial selectivity of *S*-**100** as applied to **12**, which is close in structure to chiral diene **8**. As expected, **116** is the major product of the reaction which proceeds with >100:1 stereoselection in the presence of the catalyst $BF_3 \cdot OEt_2$. In the next two experiments, two chiral reactants are coupled under identical conditions. The reaction of diene *S*-**8** with dienophile *S*-**100** provides a >130:1 mixture of **117** and its diastereoisomer, while the ratio of adduct **118** and its stereoisomer



Scheme 26.

obtained from diene *R*-**8** and *S*-**100** is 35:1. Note that in the latter two cycloadditions the absolute configurations of the two major products **117** and **118** are the same at the C1 and C2 centers and are directly correlated with the chirality of **100** (but not with that of **8**). Thus the stereochemistry of these reactions is controlled through the selection of *R*- or *S*-**100**. As demonstrated in the aldol reaction (Sec-

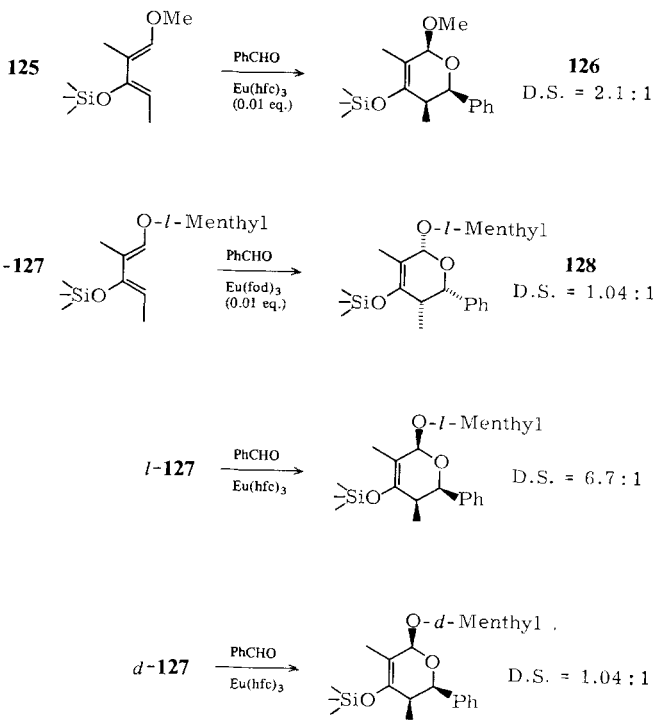
[*] The corresponding hexahydromandelic acid derivative, cyclohexyl replacing phenyl in **8**, is as diastereoselective as **8** with the same directionality (reference [41]). Therefore, these results cast some doubt upon the validity of the proposed "π-stacking" as the origin of diastereoselectivity (see reference [9]).



tion 4), this outcome reflects the large diastereofacial selectivity of **100** as compared with that of **8**. The different ratios (130 : 1 and 35 : 1) observed in the above reactions obviously correspond to matched and mismatched pairs, respectively. Thus, both **100** and **101** have been proven to be capable of creating new chiral centers in a predictable manner[*].

Intramolecular versions of the asymmetric Diels-Alder reaction abound in the recent literature and have achieved notable success in many natural product syntheses[32b,42]. The majority of these examples, if not all, use single asymmetric induction in the process of creating new chiral centers and also do not exactly follow Scheme 6 outlined in Section 3. The chirality-inducing moiety is not used as an auxiliary but is incorporated in a substrate as in the case of the aldol reaction discussed in Scheme 14 (also see Section 9). Therefore, the stereochemistry of these Diels-Alder reactions is not "controlled" in the sense used in this account. Those which should be "controlled" are formulated in Scheme 27 and several examples of double asymmetric induction that fall in this category (**119** to **121** via **120**) are currently under investigation[43].

Scheme 27.



Only a few chiral Lewis acid catalysts such as **122** and **123** have been used in the Diels-Alder reaction[44]. The D.S.'s of these catalysts as determined by the cycloaddition of cyclopentadiene with methyl acrylate and acrolein are low (1 : 1 to 1.7 : 1) but they become rather significant in the reaction with methacrolein (6 : 1) (Scheme 28). Note that the major product **124** is formed via *exo*-addition. The rational design of effective chiral catalysts is indeed difficult because knowledge concerning the exact orientation of the catalysts in the transition state is lacking. In this

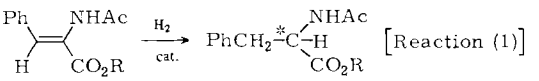
Scheme 28.

[*] The application of this double asymmetric synthesis to complicated cases (e.g., natural product syntheses) can be visualized if two major fragments are assembled via a Diels-Alder reaction.

connection, *Danishefsky*'s recent studies on the Lewis-acid catalyzed cycloaddition of benzaldehyde to dienes are of special interest[45], although this reaction involves a hetero-dienophile rather than the homo-dienophile, to which the discussions have been confined thus far.

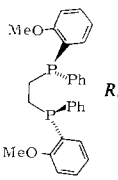
Scheme 29. *l*- and *d*-Menthyl denote the substituents derived from (−)- and (+)-menthol, respectively.

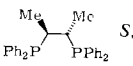
Like common Lewis acids, the lanthanide NMR shift reagents, present even in trace amounts, catalyze the formal cycloaddition of benzaldehyde with several dienes. The chiral version of the reagents, $Eu(hfc)_3$, exhibits a small but non-negligible D.S. of 2.1 : 1 as exemplified by the reaction of **125** with benzaldehyde leading to **126** (Scheme 29)[46]. The D.S. of the chiral diene *l*-**127** as determined with (achiral) $Eu(fod)_3$ is very small (1.04 : 1) (see **128**). Since the facial selections of $Eu(hfc)_3$ and *l*-**127** (if these small numbers are taken seriously) are opposite, the combinations of *l*-**127** + $Eu(hfc)_3$ and *d*-**127** + $Eu(hfc)_3$ should constitute mismatched and matched pairs, respectively. The experiments that have been carried out show that in the former mismatched combination the selectivity (6.7 : 1) exceeds even that of $Eu(hfc)_3$, while the chirality of the catalyst has no influence on the stereoselectivity of the latter matched pair reaction. A similar trend prevails with three other dienes similar to **127**. Thus, this set of reactions represents an apparent anomaly to the postulated multiplicativity of two diastereofacial selectivities. There have been recorded in the literature other (albeit few) such anomalies which occur when the degree of diastereofacial selectivity to be dealt with is small, as will be seen in Section 6. It would be desirable to use other dienes with a larger D.S. to evaluate the validity of the matched and mismatched concept in this set of experiments. As pointed out in Section 3, our analysis is of first order, ignoring many

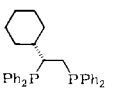


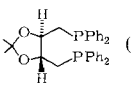
elements of a complex organic reaction which perturb the multiplicativity. This perturbation can become relatively significant in the case where both reactants have small diastereofacial selectivities (see Section 9).

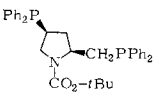
6. Homogeneous Catalytic Hydrogenation

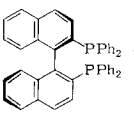












During the mid-1960's, three significant events took place making possible the development of homogeneous catalytic hydrogenation, namely: (1) *Wilkinson* et al. discovered chlorotris(triphenylphosphane)rhodium $[RhCl(PPh_3)_3]$, which exhibited remarkable properties as a soluble hydrogenation catalyst for unhindered olefins[47]. (2) Optically active phosphanes were prepared by two groups led by *Horner* et al. and *Mislow* et al.[48]. (3) *Horner* et al. and *Knowles* et al. independently demonstrated that the replacement of the triphenylphosphane in *Wilkinson*'s catalyst by chiral methyl(phenyl)propylphosphane effected a modest but definite asymmetric induction in catalytic hydrogenation of substituted styrenes[49]. Not surprisingly, therefore, the following decade witnessed a surge of efforts directed towards the preparation of more stereoselective chiral catalysts. Thus, while the range of substrates is limited, notably high optical yields, approaching 100% enantiomeric excess (*ee*), are now attainable in the hydrogenation of *N*-acetylaminocinnamic acid derivatives, such as **129**, to yield the corresponding amino acid derivatives (**130**) [reaction (1)]. The catalyst may be prepared in situ by adding 2 equivalents of chiral ligand (per mole of rhodium) to $[Rh(olefin)_2Cl]_2$ or a preformed complex of the type $[Rh(bis\text{-}ligand)(diene)]^{\oplus}BF_4^{\ominus}$ may be used. Table 3[50–55] lists some representative chiral catalysts (**131** — **136**) that exhibit high stereoselection. The dependence of the rates and stereoselectivities of catalytic hydrogenation on the electronic and structural variations of the catalysts and substrates have been investigated empirically, and elaborate mechanistic studies have been carried out notably by *Halpern* et al.[56] and by *Brown* et al.[57]. Since numerous comprehensive reviews have recently appeared[58], only the salient features of homogeneous hydrogenation will be outlined before the utility of this reaction for double asymmetric induction is discussed.

The seemingly simple net transformation of hydrogenation takes a complex stereochemical course (Scheme 30)[56]. Thus the prochiral olefin **129b** (R = Me in **129**) and the catalyst **132** form a rapidly equilibrating pair of diastereomeric complexes, **137a** (minor) and **137b** (major). The rate of complex formation and equilibration is much faster than that of the overall hydrogenation process. In the next stage oxidative addition of hydrogen to the minor complex **137a** proceeds *much more rapidly* than the addition to the main isomer **137b**, with the outcome that the former complex **137a** is responsible for the formation of the major hydrogenation product **130**. The resulting dihydride **138** rearranges to the organorhodium complex **139** in which hydrogen is transferred to the β-carbon and the metal bonds to the α-position. Reductive elimination to give *R*-**130b** and to regenerate the catalyst **132** completes the catalytic cycle. The stereochemical control occurs at either step **137a** → **138** or **138** → **139**.

Table 3. Hydrogenation with chiral rhodium catalysts and the enantiomeric excess of **130a** (R = H) in reaction (1). The catalysts **131–133** form five-membered rings, the catalysts **134–136** form seven-membered chelates.

[a] Olefin ligands are omitted.

With highly stereoselective catalysts at hand (see Table 3) the effect of these catalysts on chiral substrates can be examined, and numerous examples of double asymmetric induction have been recorded since 1980. The major contributors have been *Kagan* et al.[59] and *Ojima* et al.[60]. Unfortunately, some data pertinent to the diastereofacial selectivities of both substrate and catalyst used in many of these examples are not available. Therefore only a few *full* sets of experiments for double asymmetric induction can be discussed. One such set is shown in Scheme 31.

Upon hydrogenation with the achiral rhodium catalyst **140**, the dehydrodipeptide **141** provides a 1.9 : 1 mixture of two diastereomers in favor of the *S,S*-combination (**142**). The diastereofacial selectivity of the diop catalyst **134** can be calculated to be 11 : 1 from Table 3, using **129a** as a substrate. The stereoselectivities observed for the pairs **141**/(+)-**134** and **141**/(−)-**134**, 16 : 1 and 1 : 4.5[60] (or 19 : 1 and 1 : 4[59]), respectively, are in excellent (but obviously fortuitous) agreement with those (21 : 1 and 1 : 5.8) predicted from the postulated multiplicativity of D.S.'s. In Ta-

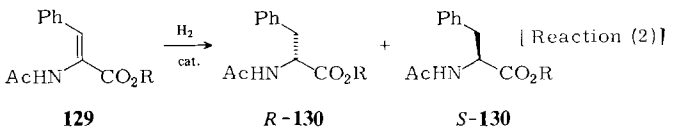
Scheme 30. R = CH_3, S' = Solvent, $\widehat{P*P}$ = Chiraphos.

Scheme 31.

ble 4 the entries 1–4 summarize these results. When the bppm catalyst **135** with a D.S. of 21 : 1 (from Table 3) is used for the same reaction (entries 5 and 6), the product ratios **142/143** obtained with (+)-**135** (matched) and (−)-**135** (mismatched) are remarkable: 161 : 1 and 1 : 25, ratios that are definitely higher than one would expect from the multiplicativity. This may be due, at least in part, to the injudicious choice of achiral models for the determination of the D.S.'s of **141** and **135**[*]. For instance, the protected dehydrophenylalanylglycine **144** would appear to be a better model substance to evaluate the above set of experiments. As repeatedly stated earlier, the multiplicativity should be appreciated in a qualitative sense rather than a quantitative sense. In particular, caution must be taken in the case where small D.S.'s are dealt with. In entries 7 and 8 of Table 4, the [Rh(dioxop)]$^{\oplus}$ catalyst **145** has a small D.S. of 1.2 : 1[61], smaller than that of the substrate **141** (1.9 : 1), yet in the mismatched reaction (entry 8) the stereochemistry of the product formed slightly in excess is correlated with the directionality of the D.S. of the catalyst **145** (rather than **141**) and the ratio in the matched case, 13 : 1, is much higher than predicted.

Table 4 [a]. Catalytic hydrogenation of the dehydrodipeptide *S*-**141** to *S,S*-**142** and *R,S*-**143** (see Scheme 31).

Entry	Substrate	Catalyst	Ligand	**142** : **143** matched	**142** : **143** mismatched	Ref.
1	*S*-**141**	(+)-**134**	(+)-diop	16 : 1		[60]
2		(−)-**134**	(−)-diop		1 : 4.5	[60]
3		(+)-**134**	(+)-diop	19 : 1		[59]
4		(−)-**134**	(−)-diop		1 : 4	[59]
5		(+)-**135**	(+)-bppm	161 : 1		[60]
6		(−)-**135**	(−)-bppm		1 : 25	[60]
7		**145**	*R,R*-dioxop	13 : 1		[61]
8	*R*-**141**	**145**	*R,R*-dioxop		1 : 1.5 [b]	[61]



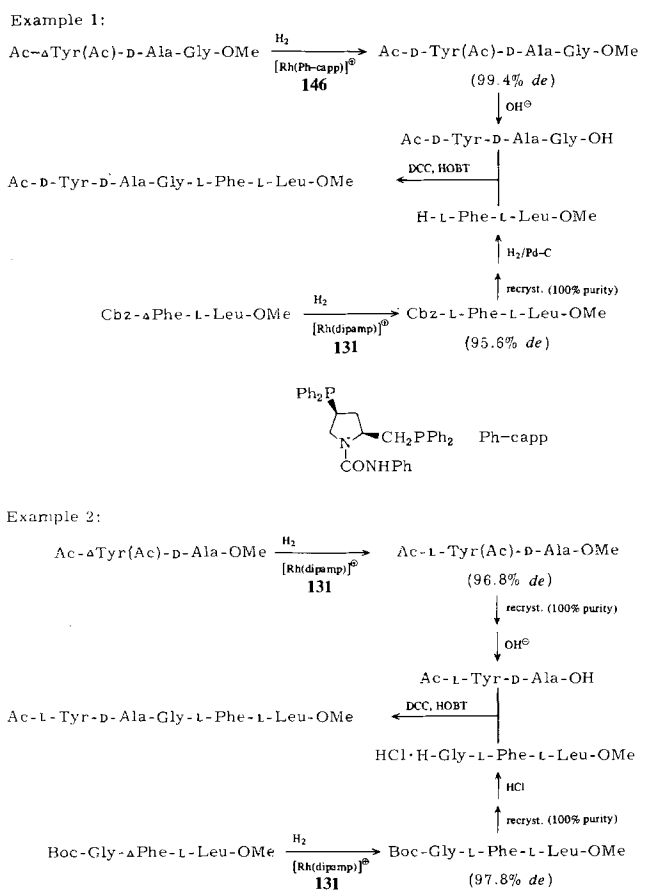
[a] The D.S. of the substrate **141** is 1.9 : 1 (**140**). The D.S.'s of the catalysts **134**, **135**, and **145** are 11 : 1 (**129**), 21 : 1 (**129**), and 1.2 : 1 (**144**). The numbers in parentheses are the compound numbers of models used to determine these values. [b] Ratio *R,R* : *S,R*.

There have been recorded many other examples of double asymmetric hydrogenation in which the chirality of the catalyst is the dominating factor for the stereochemical course of this process. Most of these examples are adequately reviewed in several articles[60,62] which interested readers should consult. What has escaped attention are *Glaser*'s earlier studies on double asymmetric induction[63]. In order to clarify the chronological development of this field and also to further illustrate how the arbitrariness in the model selection for D.S. effects the postulated multiplicativity, his work is summarized below.

Of several achiral acetyldehydrocinnamates examined, the isopropyl ester **129c**[63b] appears to be the most appropriate model for determining the D.S. of the chiral diop catalyst as **129c** is structurally similar to the chiral menthyl **129d** and bornyl **129e** esters (Table 5). Thus, the D.S. of (−)-**134** is taken as 7.3 : 1 (entry 1). The determination of the D.S.'s for **129d** and **129e** is somewhat problematic. As shown in entry 2, **129d** shows two different values with the

[*] *Ojima* invokes the concept of "induced fit", a term that should be used in the same sense as that used in enzyme chemistry (see reference [60]).

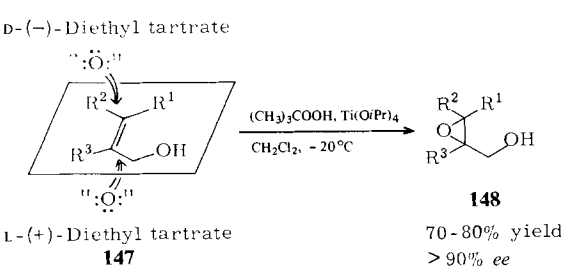
Table 5. Hydrogenation with chiral rhodium catalysts according to reaction (2) (cf. Table 3).



129 *R*-**130** *S*-**130**

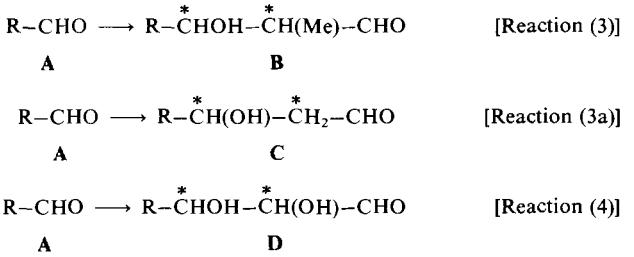
Entry	R	Catalyst	*R*-130 : *S*-130
1	**129c** *i*Pr	$[Rh((-)\text{-diop})]^{\oplus}$	(−)-**134** 7.3 : 1
2	**129d** (−)-Menthyl	$[Rh(Ph_2P(CH_2)_3PPh_2)]^{\ominus}$	**140a** 1 : 1.1
	129d (−)-Menthyl	$[Rh(Ph_2P(CH_2)_4PPh_2)]^{\ominus}$	**140b** 1.3 : 1
3	**129d** (−)-Menthyl	$[Rh((-)\text{-diop})]^{\oplus}$	(−)-**134** 3.2 : 1
	129d (−)-Menthyl	$[Rh((+)\text{-diop})]^{\oplus}$	(+)-**134** 1 : 7.6
4	**129e** (−)-Bornyl	$[Rh(Ph_2P(CH_2)_3PPh_2)]^{\ominus}$	**140a** 1 : 1.1
	129e (−)-Bornyl	$[Rh(Ph_2P(CH_2)_4PPh_2)]^{\ominus}$	**140b** 1.2 : 1
5	**129e** (−)-Bornyl	$[Rh((-)\text{-diop})]^{\oplus}$	(−)-**134** 4.6 : 1
	129e (−)-Bornyl	$[Rh((+)\text{-diop})]^{\oplus}$	(+)-**134** 1 : 3.0

achiral catalysts $[Rh(Ph_2P(CH_2)_nPPh_2)]^{\ominus}$ **140** (**a**: n = 3; **b**: n = 4), namely 1 to 1.1 and 1.3 to 1, respectively. Thus, the directionality of asymmetric induction is *opposite* in these two cases of hydrogenation using the achiral catalysts. Inspection of entry 3 shows that the D.S. of the catalyst outweighs that of the substrate, and the two pairs, **129d**/(+)-**134** and **129d**/(−)-**134** appear to correspond to the matched and mismatched pairs, respectively. Therefore the lower D.S. (1 : 1.1) of **129d** obtained by the use of **140a** fits with the data. The dilemma created by this selection emerges in the case of the bornyl ester **129e** (see entries 4 and 5). Now **129e**/(−)-**134** (entry 5) appears to be a matched pair and the D.S. (1.3 : 1) of **129e** secured through **140b** fits the result better. Obviously the "numbers" entertained above are too small to be of practical significance, and as in the case of the hetero-Diels-Alder reactions (discussed towards the end of Section 5), readers should not "play" numbers in the analysis of double asymmetric induction.



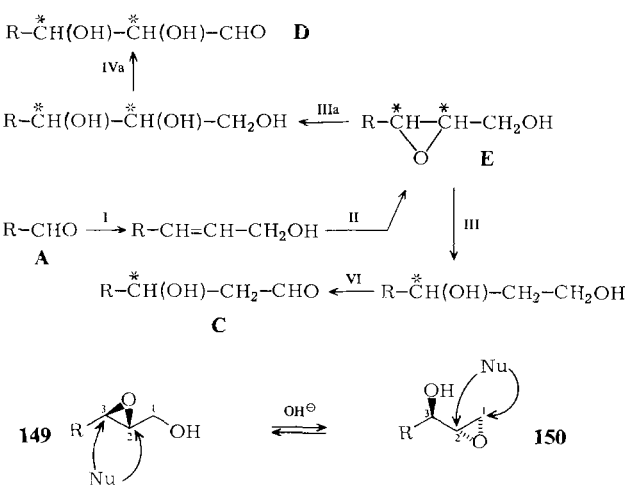
Before this Section is concluded an impressive recent application should be described. The asymmetric hydrogenation of dehydrodipeptides described above has been extended to cover dehydrotripeptides and dehydrotetrapeptides as substrates[64]. The degree of success in attaining high diastereoselectivities is equally superb and in fact all these efforts have now culminated in the synthesis of two leucine-enkephalin analogues (Scheme 32)[65]. Other useful applications of this hydrogenation technology including the regio- and stereoselective incorporation of deuterium and tritium into peptides are evident and have been recorded[64].

Scheme 32. The conventional descriptors D and L are used instead of *R* and *S*. DCC = dicyclohexylcarbodiimide; HOBT = hydroxybenzotriazole; CBz = Benzyloxycarbonyl; Boc = *tert*-butyloxycarbonyl.—Δ before the symbol of an amino acid means dehydro.



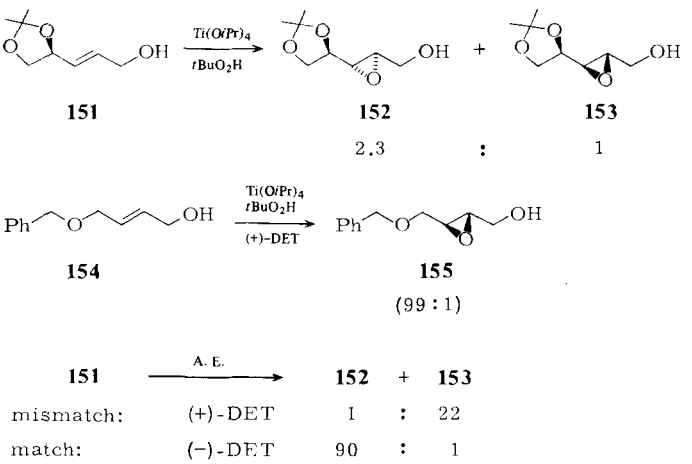
7. Epoxidation of Allylic Alcohols with the Katsuki-Sharpless Reagent

The celebrated Katsuki-Sharpless reagent consists of titanium(IV) tetraisopropoxide, *tert*-butyl hydroperoxide, and (+)- or (−)-diethyl tartrate (Scheme 33)[66]. With (−)-diethyl tartrate the oxidant approaches the allylic alcohol from the topside of the plane shown in **147**, whereas the bottom side is open for the (+)-diethyl tartrate reagent, giving rise to the corresponding optically active epoxy alcohols **148**. This asymmetric epoxidation in all likelihood proceeds through a chiral reagent-substrate complex which exhibits a high face-selection, approaching 100 : 1, as demonstrated in many reactions with achiral allylic alcohols[67]. This important reactive intermediate has been an object of intense study in *Sharpless*' laboratories, and the mechanistic course of this entire process will be documented in definitive terms in the near future[68]. The reagent, when announced in 1980, immediately caught our attention and we have been involved in a joint project with Professor *Sharpless*' group in order to investigate some aspects of the reaction. Thus, the writing of Section 7 reflects this background.



Scheme 33. Epoxidation of an allyl alcohol with the Katsuki-Sharpless reagent. The unnatural D-(−)-diethyl tartrate attacks "from above", the natural L-(+)-enantiomer "from below".

As already described in Section 4 concerning the aldol reaction, the excellent stereoselective addition of a propionate unit to an aldehyde **A** can be used to prepare any of the stereochemically possible 3-hydroxy-2-methylaldehydes **B** [reaction (3) Scheme 34], whereas the aldol reaction for transforming **A** into **C**, formally the addition of an acetate unit [reaction (3a)] proceeds with marginally useful stereoselection. For the latter transformation, a route involving epoxidation and reductive ring opening was considered promising. All that was needed for this transformation was an epoxidizing reagent with high diastereofacial selectivity, a property that seemed to be ideally satisfied by the Katsuki-Sharpless reagent. It soon became apparent that this intentionally general route, with some modification, would bring about another important transformation, **A** to **D** [reaction sequence (4)], thus creating two consecutive chiral hydroxymethylene (−*CHOH−) centers in one sequence.

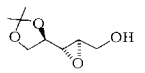


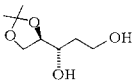
Scheme 34.

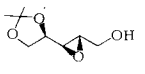
Reaction sequences (3a) and (4) are formulated as follows (Scheme 35): The first step I consists of the construction of an *E*- or *Z*-allylic alcohol (or a precursor) via a Wittig reaction. In the next step II the asymmetric epoxidation plays a key role. Together, these two steps could provide the necessary elements of stereochemical control. For the overall conversion of **A** into **C** and **A** into **D**, the subsequent steps, III and IIIa, involve little known transformations of the epoxy alcohol **E**. For example, **149** can be rearranged to the isomeric alcohol **150** with base (Payne rearrangement)[69]. Thus, all of the C1, C2, and C3 positions of **E** can be sites for appropriate nucleophilic attack as shown in **149** and **150**.

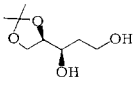
Scheme 35. Step II is an asymmetric epoxidation with the Katsuki-Sharpless reagent [Ti(O*i*Pr)$_4$, *t*BuO$_2$H, and (+)- or (−)-diethyl tartrate].

Our prime concern was then the question of whether the multiplicativity of D.S.'s in double asymmetric induction would also be applicable to the asymmetric epoxidation as we had observed for the aldol reaction (Section 4). To answer this question the epoxidation of allylic alcohol **151** derived from D-glyceraldehyde was studied (Scheme 36). Treatment of **151** with titanium(IV) tetraisopropoxide and *tert*-butyl hydroperoxide (Katsuki-Sharpless reagent *without* (+)- or (−)-diethyl tartrate) provides a 2.3 : 1 mixture of epoxy alcohols **152** and **153**. This ratio (2.3 : 1) which represents the D.S. of **151** is much smaller than that of the chiral epoxidizing agent, as reconfirmed with the asymmetric epoxidation of the allyl alcohol **154**, which provides **155** with 99 : 1 stereoselection. All the conditions necessary to achieve the stereochemical control of epoxidation in a double asymmetric reaction appear to have been met. The asymmetric epoxidation of **151** with (+)- or (−)-diethyl tartrate proceeds smoothly to provide epoxy alcohols **152** and **153** in ratios of 1 : 22 and 90 : 1, respectively. As predicted and verified by these results, **151** with the (+)-ester and **151** with the (−)-ester constitute mismatched and matched pairs, respectively.

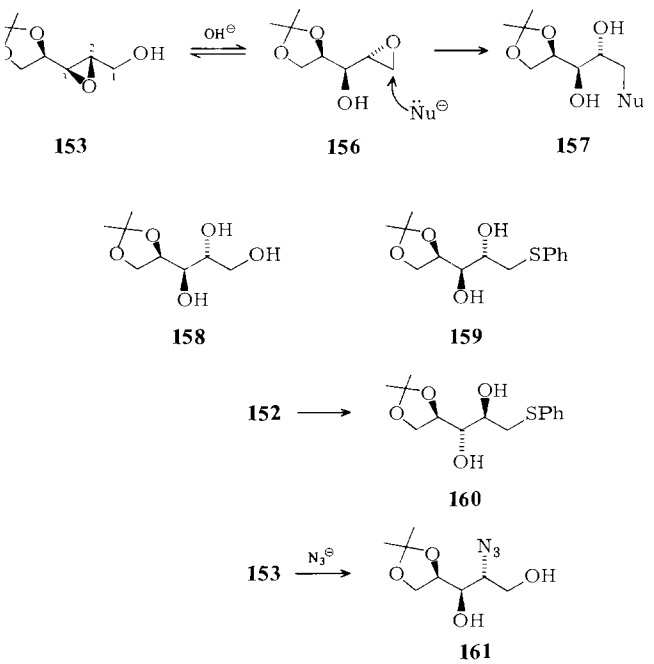








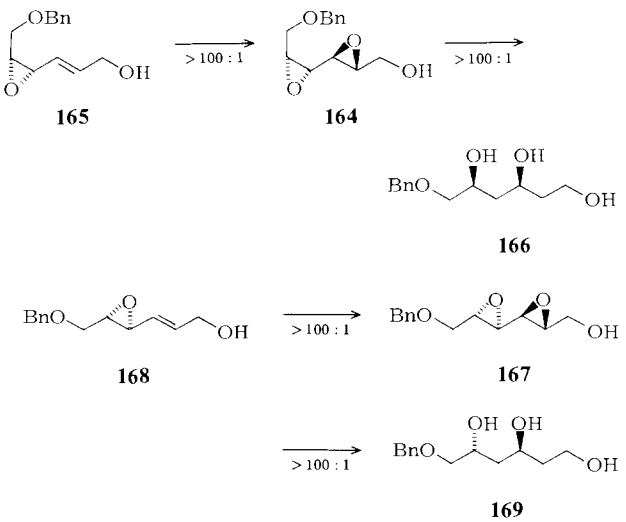
Scheme 36. DET = diethyl tartrate. A.E. = asymmetric epoxidation.



A brief comment may be appropriate at this point on the ring opening of epoxy alcohols which have been proven to be extremely versatile synthetic intermediates. Of many transformations now fully documented in several review articles[67], the following reactions are rather illustrative. The C1 position of compound **153** (Scheme 37), for instance, is by far the most reactive electrophilic site for a range of nucleophiles under basic conditions. Thus, the attack at C1 of **156** leads to **157**, as exemplified by the predominant formation of **158** (with hydroxide) and **159** (with benzene thiolate as nucleophile)[70]. In a similar manner **152** gives **160**. Thus, equilibration of 2,3- and 1,2-epoxy alcohols (i.e., **149** and **150**) has been exploited to draw out a subtle mode of reactivity. Under proper conditions it is also possible to direct nucleophiles selectively to either C2 or C3. For example, reaction of **153** with the azide ion provides compound **161** as the major product[67b]. A most interesting example is reduction at C2 with metal hydrides, in particular sodium bis(methoxy-

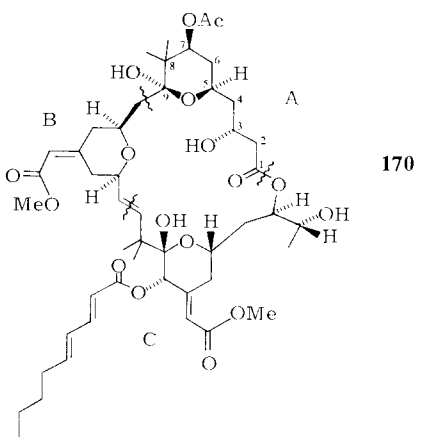
ethoxy)aluminum hydride (Red-Al®). The regiospecificity of this reduction plays a major role in developing the reaction sequence (3a) which can achieve the stereospecific addition of an acetate unit to aldehydes (see Section 4). Table

Table 6. Two examples of the reduction of epoxides with $Na[Al(CH_3OCH_2CH_2O)_2H_2]$ (Red-Al) at 0 °C.



Epoxy alcohol	1,3-diol : 1,2-diol	Yield [%]	Major product
152 	> 100 : 1	78	**162** 
153 	> 100 : 1	82	**163** 

6 lists two examples of many in which Red-Al reduction of epoxy alcohols proceeds smoothly under normal conditions to provide a single product, a 1,3-diol[71]. The regioselectivity is uniformly high and in many cases no traces of the corresponding 1,2-diols are found.



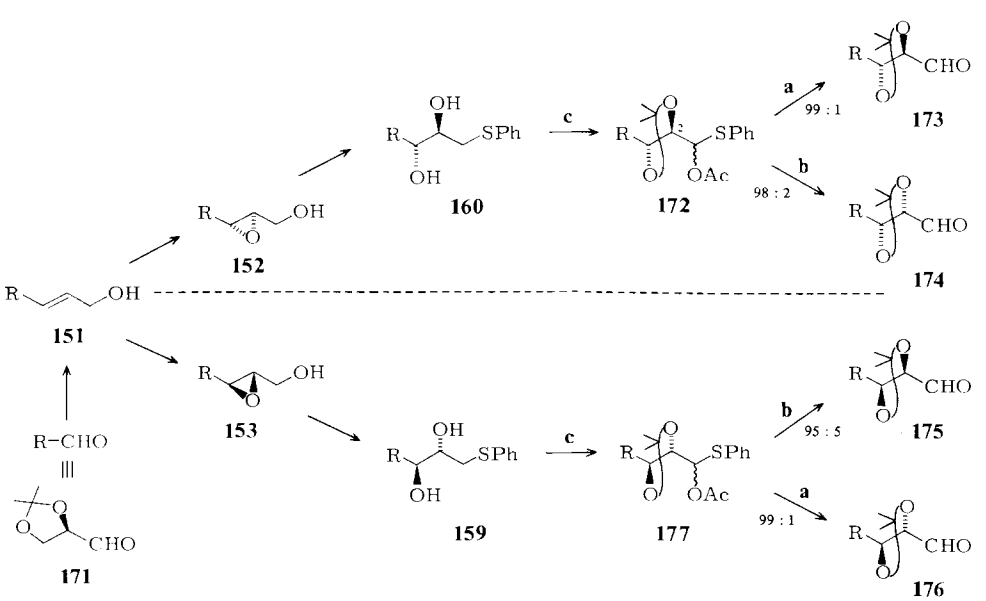
Scheme 37. **153** is allowed to react with azide in 2-methoxyethanol/water under reflux.

A more impressive demonstration of this selectivity includes the reduction of 2,3 : 4,5-diepoxy alcohols with the same reductant. Compound **164** (prepared from **165** by asymmetric epoxidation) undergoes clean double ring-opening to provide only one product, 1,3,5-triol **166** with the indicated stereochemistry (Scheme 38). Similarly, Red-Al reduction of **167** (obtained from **168**) provides **169** exclusively. These findings, in particular the simultaneous creation of two new hydroxylated chiral centers of 1,3-relationship, are important and have been utilized in the construction of the C1–C9 fragment of bryostatin 1 (**170**)[72].

Scheme 38. Bn = benzyl.

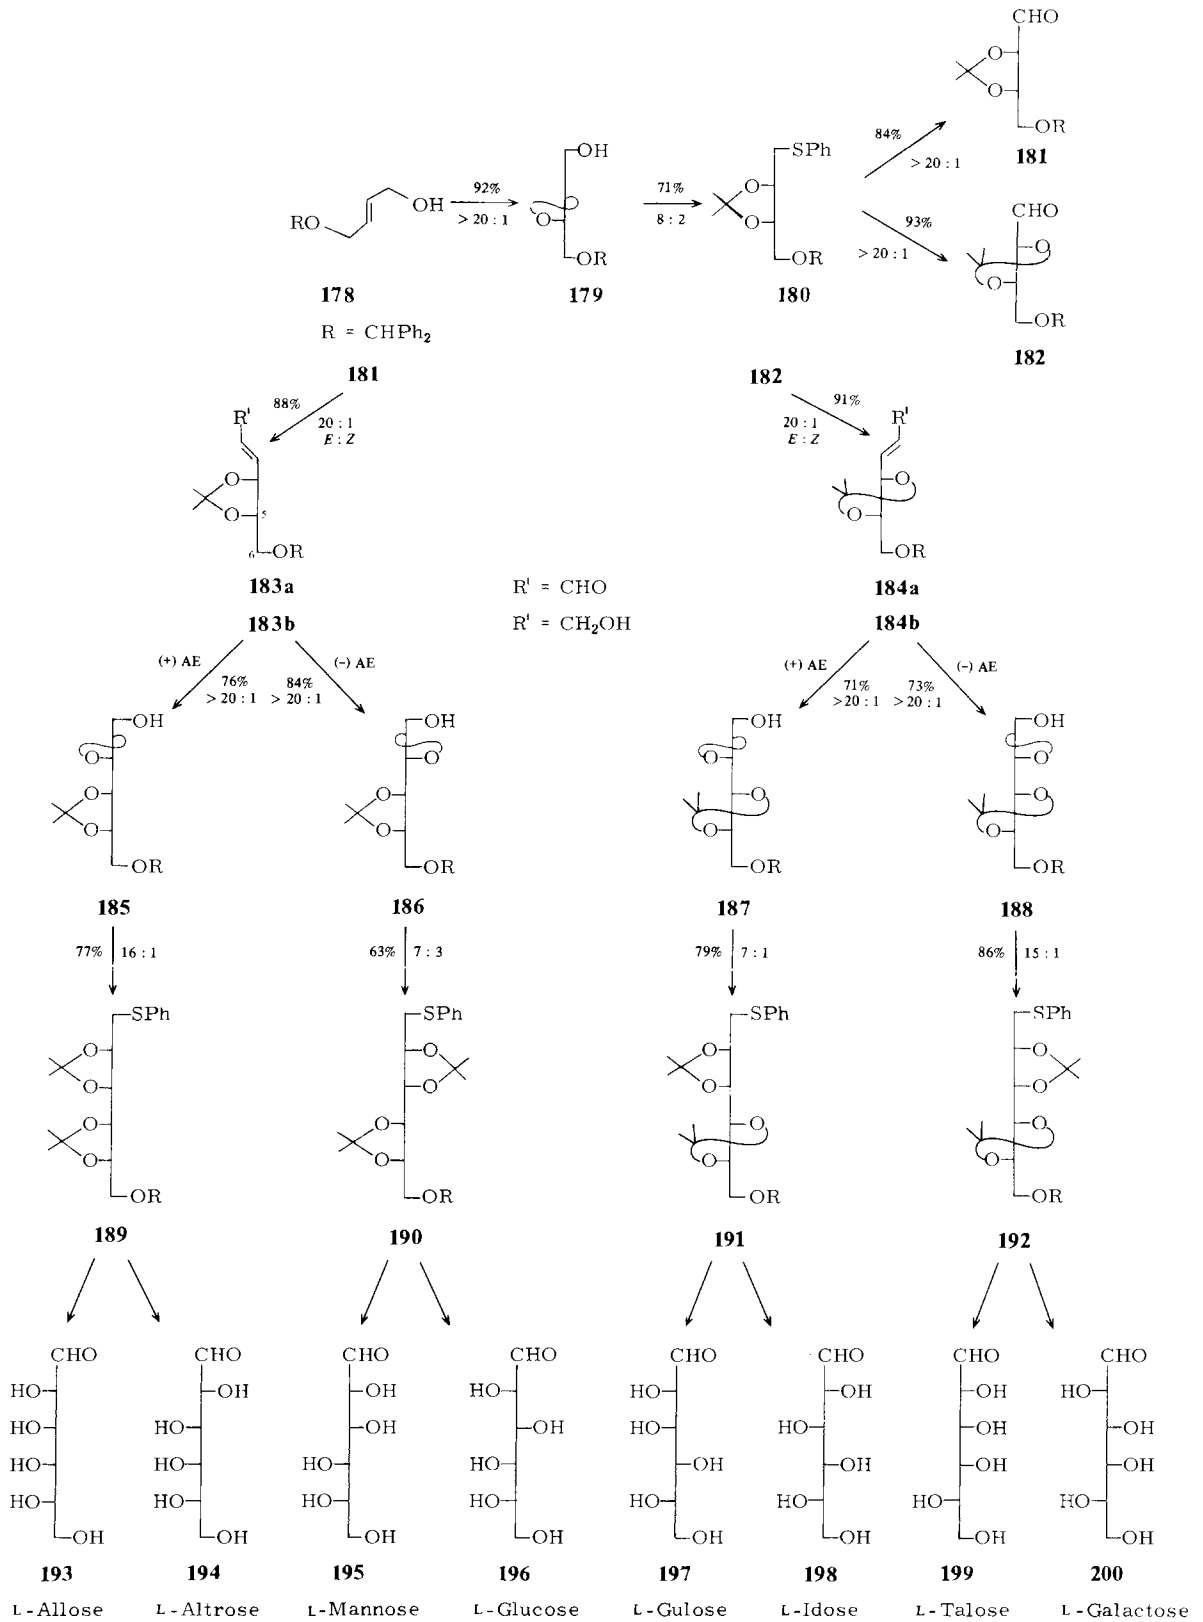
Reaction sequence (4) (see Scheme 34) is aimed at the stereoselective, systematic synthesis of monosaccharides and their analogues. An efficient, practical execution of this bishomologation has been developed by *Kishi* et al.[73] and by us[74] for the synthesis of the pentoses. Scheme 39 outlines our version. Thus, the epoxy alcohol **152** undergoes ring opening to provide **160**, which is converted to the acetonide **172** through kinetically controlled acetonation followed by oxidation and acetylation. Reaction of **172** with diisobutylaluminum hydride provides, virtually without epimerization, a product **173** which has been proven to have the ribose configuration. Compound **172** can also be converted to the C2 epimer of **173**. Thus, treatment of **172** with potassium carbonate in methanol causes hydrolysis of the acetoxythioacetal group and epimerization at the C2 center to give a mixture of **174** and **173** in a 98 : 2 ratio. Compound **174** has the arabinose configuration. The acetonides (**175** and **176**) of xylose and lyxose are prepared from **177** in exactly the same manner. In this way a highly efficient route from the single intermediate **151**[*] to either the *erythro-* or *threo*-2,3-dihydroxyalde-

[*] Epoxidation of the corresponding *Z*-allylic alcohol with either (+)- or (−)-diethyl tartrate is too slow to be practical (reference [70]). Thus, readers notice that one element of control, the olefin geometry, which was originally planned, could not be fully employed and the two pentoses **174** and **175** are obtained via the epimerization reaction.



hydes has been established. It is obvious that the success of this scheme depends heavily upon both the high double asymmetric induction realized by the titanium-catalyzed epoxidation with (+)- or (−)-tartrates and the conventional, but highly critical epimerization technique. These constitute two elements of control, the conditions necessary and sufficient for the stereoselective creation of any two new chiral centers. Note that through this sequence a single chiral aldehyde has been converted into the four stereochemically possible bishomologated aldehydes, each of which is ready for a second two-carbon extension. Indeed, the synthesis of all the possible hexoses via a double application of the sequence has been completed as shown in Scheme 40[75]. The top row of the scheme represents the first cycle of the hexose synthesis, which begins with a single building block, 4-benzhydryloxy-(*E*)-2-buten-1-ol **178**, readily prepared from (*Z*)-2-butene-1,4-diol. Step I of the extension cycle is therefore eliminated in this initial case. Conversion of **178** into **181** and **182** completes the first cycle, and the conversion of **181** and **182** into **193**—**200** constitutes the entire set of the second cycle. The yield and selectivity are described for each step. All steps in this scheme except for the conversions **179** → **180** and **186** → **190** proceed with remarkable regio- and stereoselection. Since the mirror image of every compound can be prepared by simple exchange of the chiral ligand (tartrate ester) in the asymmetric epoxidation, the formal synthesis of the D-hexoses has also been achieved. This achievement adequately proves that the concept of matching and mismatching is valid for asymmetric epoxidation as well.

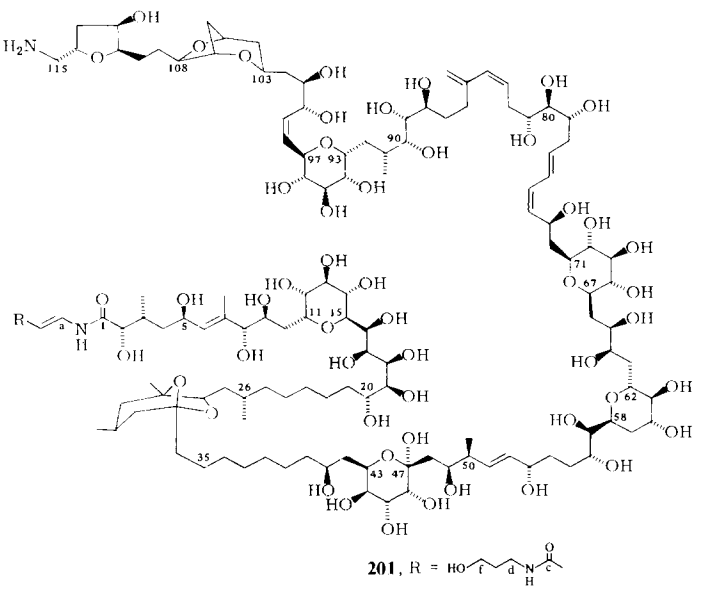
Finally, mention should be made of recent monumental achievements by *Kishi* et al. which have led them to propose the entire stereochemistry of palytoxin **201**[76]. This marine product, having 64 asymmetric centers, was degraded into numerous fragments through the elaborate work of *Hirata* et al.[77] and *Moore* et al.[78]. Altogether these fragments incorporate all of the chiral carbon atoms embedded in the carbon framework of **201** and the connectivity among them has been established. *Kishi* et al. have synthesized each of these fragments using reactions which are supposed to proceed with predictable stereochemical outcomes whenever the creation of a new chiral center or centers is involved. *Kishi* has developed reaction sequences conceptually similar to those in Scheme 39 as mentioned above and repeatedly used them in this work. It is evident that his work could not have been accomplished without recourse to such a strategy. Thus, the approximate multiplicativity of D.S. is taken implicitly as an *established rule which is apparently valid in all asymmetric epoxidations of E-allylic alcohols they have examined.*



8. Merits of the New Synthetic Strategy as Applied to Natural Products Synthesis

Numerous reactions documented in the preceding Sections have established the multiplicativity of diastereofacial selectivities as a valid rule within defined limitations. At least four major organic transformations[79][*] can be executed with high diastereoselection using chiral reagents or catalysts. This Section will emphasize two distinct features of natural product synthesis based on the new synthetic strategy: 1) The target molecules are necessarily synthesized in optically pure form since any substrates to be used in double asymmetric synthesis are homochiral, and—*much more importantly*—2) the process of retrosynthetic analysis for many stereochemically complex molecules and the execution of the synthetic plan are substantially simplified. In some cases retrosynthesis becomes straightforward and provides a relatively short and efficient synthetic scheme (see the example of 6-deoxyerythronolide B **48** in Section 4). Even for those natural products such as bryostatin 1 **170** and palytoxin **201**, which are much more

[*] Single asymmetric alkylation has already been reviewed adequately by *Evans* [79b], *Meyers* et al. [79c], and *Enders* [79d]. Since examples of double asymmetric alkylation are scarce, this subject is not presented in this article.

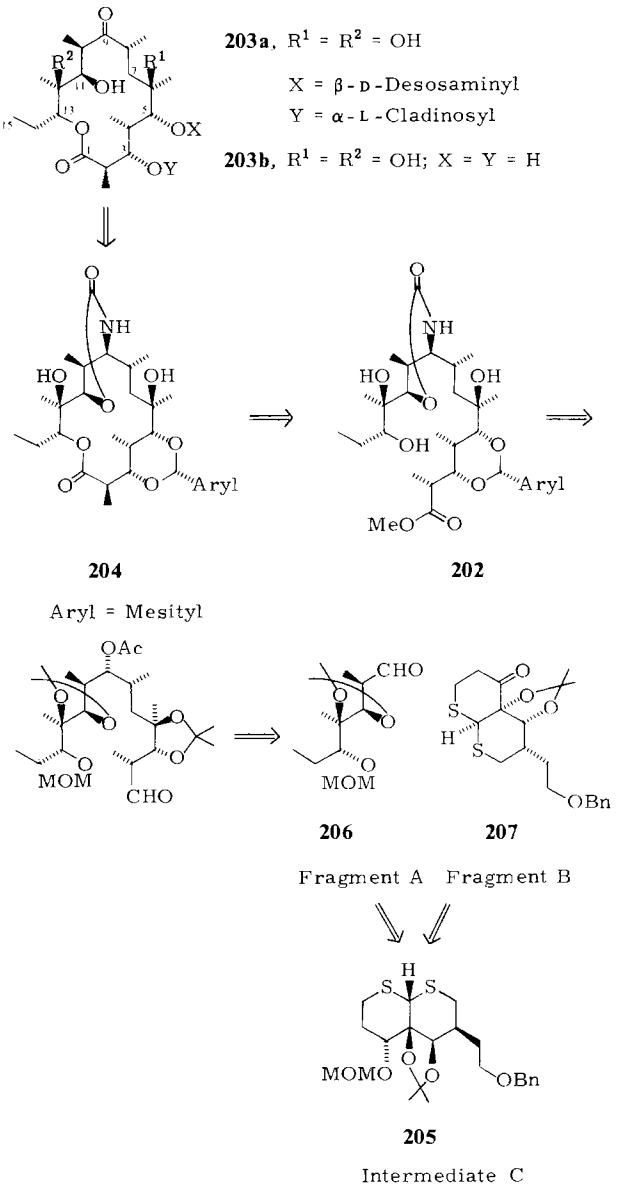


Scheme 39. **a**: diisobutylaluminum hydride; **b**: K_2CO_3, MeOH; **c**: 2-methoxypropene, *m*-chloroperbenzoic acid, Ac_2O.

Scheme 40. (+)AE and (−)AE signify asymmetric epoxidation in the presence of (+)- and (−)-diethyl tartrate, respectively.

complicated than the celebrated erythromycins[80][*], workable schemes can now be drawn with *relative* ease. Natural products, in particular those of polyketide origin, very

[*] The late Professor *Woodward* made the following often quoted remark in 1956; "Erythromycin, with all our advantages, looks at present quite hopelessly complex, particularly in view of its plethora of asymmetric centers. ..." [80].



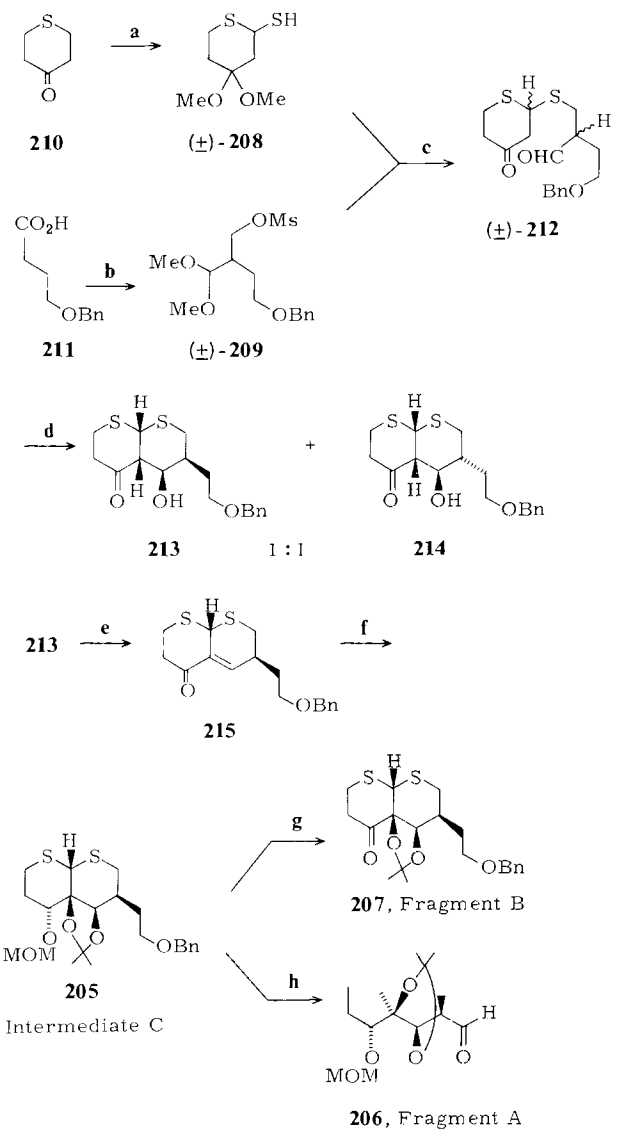
201, R = HO(f)(d)N(H)(c)=O

often consist of a limited number of basic units. Therefore, judicious reiteration of several reaction sequences as discussed in Sections 4—7 leads to a final target molecule.

We will now critically evaluate the new strategy which uses homochiral reagents for stereochemical control (reagent-control) in comparison with the traditional strategy which uses chiral substrates for the same purpose (substrate-control). This evaluation will be made using several recent examples of macrolide synthesis in which both strategies have been applied to the synthesis of the same or closely-related macrolide antibiotics[3c].

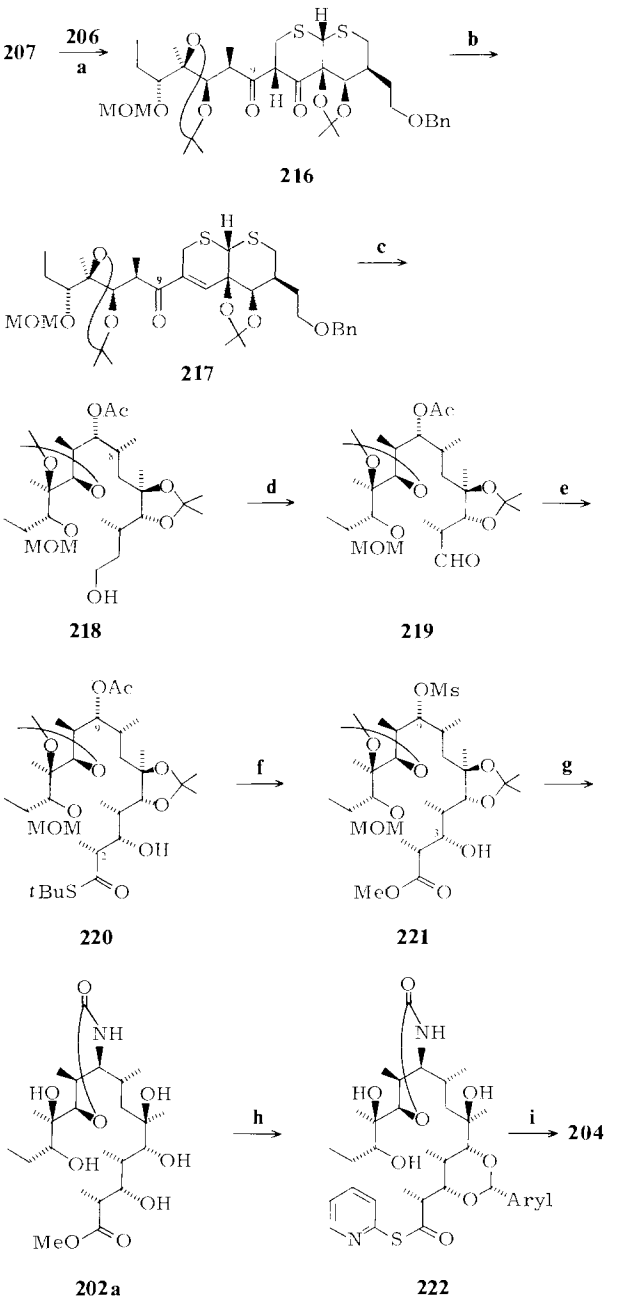
One of the three major synthetic challenges posed by this class of antibiotics is the construction of the seco-acid esters (e.g., **202**) having a "hopelessly complex"[80] array of chiral centers. This challenge has been met by several groups[3c]. For instance, *Woodward* et al. recorded in mid-1981 the synthesis of the antibiotic erythromycin A **203a** which had been brilliantly executed in the traditional Woodward style (substrate-control)[81]. As has already been described, acyclic substances normally have synthetically insignificant diastereofacial selectivities (Section 3). Without recourse to powerful chiral reagents, the required stereochemical control must take full advantage of cyclic systems which can be designed in such a way as to have a large D.S. Once substituents are introduced on a cyclic system with clearly defined *cis* or *trans* relationships, ring cleavage transfers this stereochemistry to the resulting acyclic system. This "cyclic approach" in general demands ingenious design and unique solutions to each new stereochemical problem, and indeed *Woodward*'s group spent many years for the construction of the erythronolide framework by adopting this approach. A brief summary of their accomplishment to the stage of the synthesis of an erythronolide A[*] derivative (**204**) is given below in order to illustrate merits of each of the traditional and new approaches, although this description may digress somewhat from the main theme of this Account.

[*] Erythronolide A **203b** is the aglycone of erythromycin A.



Scheme 41.

Woodward's synthesis recognized "hidden symmetry"[20a] in the aglycone **203b** (cf. the stereochemistry of the fragment C4—C6 with that of C10—C12) and thus uses the common intermediate C **205** for the construction of the two segments, A **206** and B **207**, of the aglycone (Scheme 41). The majority of the erythronolide stereochemistry is built on the rigid dithiadecalin ring system and then the sulfur atoms are extruded.

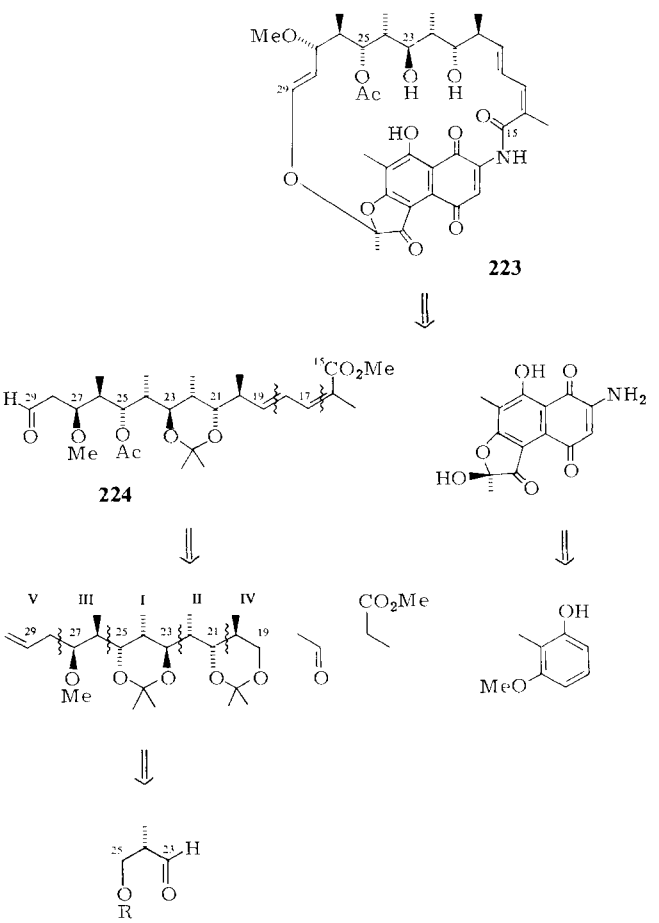


The synthesis of the common intermediate C **205** is described in Scheme 42. Racemic compounds **208** and **209** are prepared from **210** and **211**, respectively, through a sequence of routine transformations. Coupling of **208** and **209** leads to **212**, which is a mixture of two diastereomers, each diastereomer being a racemic mixture. Intramolecular aldol reaction of **212** catalyzed by D-proline leads to a 1 : 1 mixture of diastereomers **213** and **214**, each diastereomer being enriched in the enantiomer drawn by 36% ee. Ketone **213** is separated from the diastereomer **214** and is dehydrated to give enone **215**, which is resolved by recrystallization. Thus, optically pure **215** is obtained in 10—12%

yield from racemic starting materials **208** and **209**. Reduction of the keto functionality of **215**, protection of the resulting hydroxyl group, osmylation, and finally acetonide formation convert **215** into **205** (Intermediate C). Note that the stereochemistry of this osmylation is fully governed by the rigid conformation of the dithiadecalin system.

Scheme 42. Synthesis of the intermediate product C **205** and of the Fragments A **206** and B **207**. **a**: 1) $(CH_2OH)_2$, $H^{\oplus}$, 2) *N*-chlorosuccinimide, 3) thiourea, 4) NaOH, 5) HCl, 6) $(MeO)_3CH$, toluenesulfonic acid, MeOH, 65% yield; **b**: 1) esterification, 2) $LiN(iPr)_2$; HCO_2Me, 3) $(MeO)_3CH$, H_2SO_4, MeOH, 4) $LiAlH_4$, 5) methanesulfonyl chloride, pyridine, 60% yield; **c**: 1) NaH, 2) AcOH; **d**: catalyst D-proline; **e**: 1) methanesulfonyl chloride, pyridine, 2) Al_2O_3, 3) recrystallization; yield of optically pure (+)-**215** 10 to 12% from (±)-**208** and (±)-**209**; **f**: 1) $NaBH_4$, 2) $MeOCH_2I$, KH, 3) OsO_4, 4) $Me_2C(OMe)_2$, toluenesulfonic acid, 74% yield; **g**: 1) trifluoroacetic acid, 2) $(CF_3CO)_2O$, dimethyl sulfoxide, $Et(iPr)_2N$, 85% yield; **h**: 1) H_2, Raney nickel W-2, 2) o-$O_2NC_6H_4SeCN$, PBu_3, 3) H_2O_2, 4) O_3; Me_2S, $NaHCO_3$, 80% yield.—Ms = mesyl, MOM = $-CH_2OMe$.

Intermediate C **205** is converted into both Fragment A **206** and Fragment B **207**. Hydrolysis of the methoxymethyl group of **205** followed by oxidation gives **207**. Reductive desulfurization and debenzylation of **205** give an alcohol which is converted into the aldehyde **206** (Fragment A) via the corresponding selenide, selenoxide, and olefin.



Scheme 43. Synthesis of the erythronolide A derivative **204**; **a**: 1) mesityllithium, 2) $(CF_3CO)_2O$, dimethyl sulfoxide, $Et(iPr)_2N$, 76% yield; **b**: 1) KH, 2) AcCl, 3) $NaBH_4$, 4) methanesulfonyl chloride, 5) 4-dimethylaminopyridine, pyridine, MeOH; **c**: 1) $PhCH_2SLi$, 2) $LiAlH_4$, 3) Ac_2O, 4) H_2, Raney nickel W-2; **d**: 1) o-$O_2NC_6H_4SeCN$, PBu_3, 2) H_2O_2, 3) O_3; Me_2S, 50% yield from **216**; **e**: 1) EtCOS*t*Bu, $LiN(iPr)_2$, 2) *t*BuLi, tetramethylethylenediamine, 3) AcOH, 77% yield, 11 : 1 at C2; **f**: 1) Na_2CO_3, MeOH, 2) $(PhOCH_2CO)_2O$, 4-dimethylaminopyridine, pyridine, 3) methanesulfonyl chloride, pyridine, 4) LiOH, H_2O_2; 75% yield; **g**: 1) LiN_3, 2) H_2, PtO_2, 3) p-$O_2NC_6H_4OCOCl$, 4) $NH_2OH \cdot HCl$, KH_2PO_4, 5) Et_3N; 53% yield; **h**: 1) mesitylaldehyde dimethyl acetal, trifluoroacetic acid, 85% yield, 2) EtSLi, hexamethylphosphoric triamide, 3) 2-pyridyl-S-COCl, Et_3N; **i**: toluene, reflux, 70% yield.—Aryl = mesityl.

The coupling of Fragments A **206** and B **207** and cyclization of an erythronolide seco-acid derivative (**202a**) is outlined in Scheme 43. Aldol reaction between the lithium enolate of **207** and aldehyde **206** followed by oxidation gives **216**, which is converted into enone **217** via the C9

enol acetate. Conjugate addition of phenylmethanethiolate to **217** gives a single ketone product which, after hydride reduction, protection of the hydroxy group, and hydrogenation with Raney nickel, provides **218**. The stereochemistry at the C8 position in **218** arises from kinetically controlled protonation on the convex face of the dithiadecalin ring system in the conjugate addition. The following hydride reduction of the C9 keto functionality proceeds through chelation with the C11 ethereal oxygen to yield a single hydroxy group. Through the same sequence of reactions used earlier (i.e., **205** to **206**) **218** is converted into the aldehyde with one less carbon **219**. Aldol reaction of **219** with the lithium enolate derived from *tert*-butyl thiopropionate followed by kinetically controlled protonation of the presumed trianion[*] of the aldol product gives the thiol ester with the desired C2 stereochemistry shown in **220**[82][**].

With all the chiral centers of erythronolide A in place, modification of the protecting groups present in **220** was necessary for efficient macrocyclization[***]. After considerable investigation, the following selection was found to be satisfactory. Thiol ester **220** is converted to ester **221** through a sequence of reactions: 1) hydrolysis of the C9 acetate with concomitant conversion of the thiol ester into the corresponding methyl ester; 2) selective acylation at the C3 hydroxyl group; 3) mesylation of the C9 hydroxy group; and finally 4) deprotection at the C3 hydroxy group. Displacement of the mesylate in **221** with lithium azide followed by reduction gives the inverted C9 amino group that is converted into the carbamate. The subsequent removal of the acetonide groups with concomitant cleavage of the methoxymethyl protecting group and then cyclization lead to the formation of the cyclic carbamate **202a**. Selective acetal protection of the C3, C5 dihydroxy group and conversion to an activated ester (**222**) sets the stage for macrocyclization, which proceeds in very high yield to provide **204** (see Scheme 41). A series of deprotections and glycosidations converts **204** into erythromycin A. This final conversion alone, though not discussed here, is a remarkable achievement.

Readers have now seen the elaborate design and experimentation that the cyclic, "substrate-controlled" approach demands in order to properly introduce the ten chiral centers[****] onto the long-chain seco-acid **222**. This monumental achievement represents an ultimate demonstration of organic chemists' imagination, but at the same time demonstrates the limitations of this popular traditional approach. Imagine an analog of erythronolide A that had several more chiral centers somewhere in the ring system or that was stereoisomeric at several chiral centers. The synthesis of this hypothetical molecule would very likely constitute an entirely new project which would be just as demanding as that described above. It is the recognition of these limitations that spurred the conceptual development of the new synthetic strategy based on double asymmetric induction. 6-Deoxyerythronolide B **48**, whose synthesis was recorded in early 1981[19], has the same number (10) of chiral centers as that of erythronolide A, but is missing the hydroxy groups at the C6 and C12 positions that exist in the latter. Therefore, it is not entirely justified to compare the synthesis of 6-deoxyerythronolide B with that of erythronolide A[83][*]. However, a striking difference is noted when reexamining our retrosynthetic analysis of **48** and its synthesis (Schemes 12, 13, and 14). The two major fragments A and B are basically constructed through one and two aldol reactions, respectively, using the enolate reagent **39** with the chirality of the reagent being appropriate for each reaction. Assembly of the two fragments, again via the aldol methodology followed by macro-lactonization, completes the synthesis. The comparative evaluation of the two syntheses of **48** and **204** in terms of the overall selectivity, the overall yield, and the number of steps involved in the synthesis is tabulated in Table 7. The power of the new

Scheme 44. Retrosynthetic analysis of rifamycin S **223**. Chain extension by two carbon atoms in each step takes place in the sequence I→V.

[*] The three protons located at C2–H, C3–OH, and C9–$OCOCH_3$ are probably removed under these conditions.

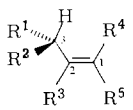
[**] The dianion derived from a β-hydroxy ester exists in a cyclic conformation. Kinetic protonation from the least hindered face of this ring would probably have brought about the desired C2 stereochemistry (see reference [82]).

[***] The efficiency of macrolactonization depends highly on the seco-acid conformation (reference [20a]). The many erythronolide seco-acid derivatives examined in this work serve as an excellent demonstration of this effect.

[****] The 9-amino group in **202** or **222** is oxidized to the keto-group at a later stage of the synthesis.

[*] Readers will find it interesting to design a scheme leading to erythronolide A using methods outlined in Sections 4–7 and some additional information now available in the literature. (For instance, see reference [83] for the construction of a tertiary hydroxy group.) Several concise and likely workable schemes can be drawn.

Table 7. Comparison of some total syntheses of natural products [a].

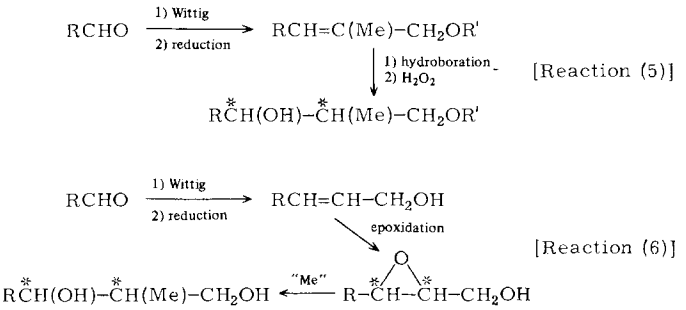


Target Molecule	Approach (control)	Number of new chiral centers created	Overall Stereo-selectivity [%]	Overall yield [%]	Number of steps	Starting Material	Ref.
48, 6-Deoxyerythronolide B	acyclic (reagent)	8	85	5.7	23	**35**	[19]
204, Erythronolide A derivative	cyclic (substrate)	10	46	0.3	49	**210**	[81]
(±)-**236**, Ansa chain of rifamycin S	acyclic (substrate)	7	50	0.2	49	(±)-**226**	[84]
236	acyclic (reagent)	7	75	2.1	46	(−)-**226**	[85]
236	acyclic [b]	8	78	13.8	24	**40**	[87]

[a] For a convergent synthesis, the values are those of the longest reaction sequence connecting the indicated starting material and final product and are calculated from the schemes shown in this Account. When both yield and selectivity are stated for a series of transformations in the schemes, that yield represents the combined yield of the desired and undesired products. Yields presented here do not account for recycling. [b] The control is not clearly defined.

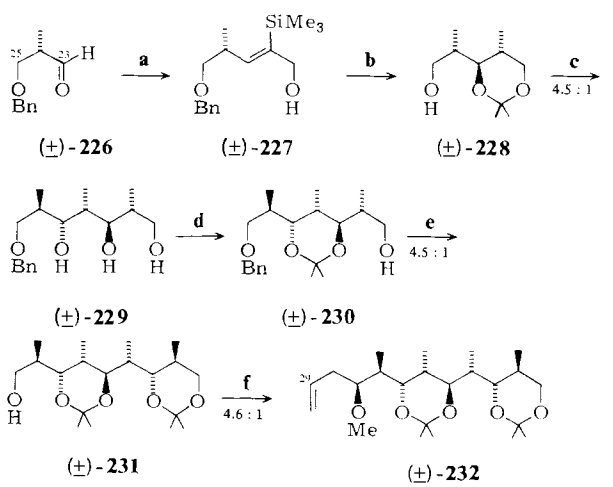
strategy is clear: retro-synthesis is straightforward, the resulting schemes are efficient, and the stereochemical outcome of each reaction is capable of creating virtually any stereoisomer (also see the hexose synthesis in Section 7).

In the preceding discussions, the *cyclic, substrate-control* approach has been compared with the *acyclic, reagent-control* approach. This latter approach can also be compared with the *acyclic, substrate-control* approach which is illustrated below by the first synthesis of rifamycin S **223**[84], one of *Kishi*'s many landmark synthetic achievements. This antibiotic is a representative ansamycin, characterized by a distinct structural feature: A long aliphatic "ansa" (Latin for handle) chain **224** that is joined to an aromatic nucleus (such as a benzene or naphthalene derivative) at two non-adjacent positions to form a macrolactam. Our discussions in this section are limited to the construction of the ansa chain which is rich in chirality (Scheme 44).



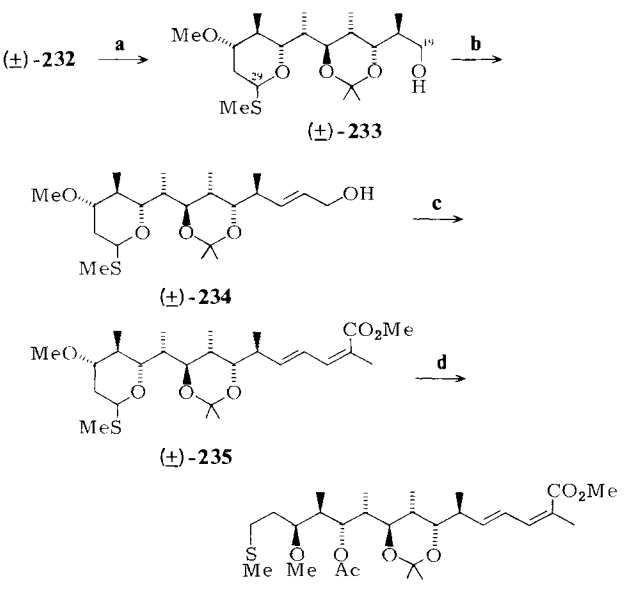
The acyclic, substrate-control approach must necessarily utilize the properties of some acyclic systems which exhibit a significant D.S., a feature that is rarely seen in these systems as repeatedly mentioned above. Thus, *Kishi* recognized that a certain type of *Z*-olefin (R^1, R^2, $R^4 \neq H$) **225** prefers to take the unique conformation in which the C1,

225



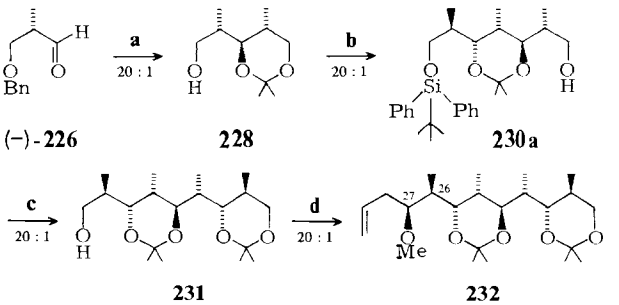
C2, C3, and H3 are (nearly) coplanar due to allylic strains as shown. This conformation in all likelihood is retained in the transition states of many reactions, and thus the two sides (faces) of the plane are differentiated. In this way, hydroboration in reaction sequence (5) (Wittig followed by hydroboration) and epoxidation in reaction sequence (6) (Wittig, epoxidation, and epoxide opening by a methyl anion or vinyl anion equivalent) can be executed with moderate diastereoselection (Scheme 45).

Both sequences, similar to those discussed in Section 7, constitute two basic methods for the two-carbon extension to be utilized in the synthesis of **224**. (±)-3-Benzyloxy-2-methylpropionaldehyde **226** is the starting material and the two-carbon extension methods are repetitiously applied in the order indicated in Scheme 44.



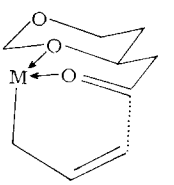
Scheme 45.

The aldehyde (±)-**226** constitutes the C23–C25 fragment (rifamycin numbering) in the synthesis of the racemic antibiotic (Scheme 46). Conversion of **226** into a silylacetylene ($Me_3SiC{\equiv}C-$) followed by hydroalumination and iodination give a vinyl iodide that is transformed into the allylic alcohol **227** (cf. **225**). Epoxidation of **227** proceeds



Scheme 46. Synthesis of the precursor (±)-**232** for *rac.* rifamycin S (±)-**223**. **a**: 1) CBr_4, PPh_3, 2) *n*BuLi; Me_3SiCl, 3) diisobutylaluminum hydride; I_2; 4) *n*BuLi, $ClCO_2Me$, 5) diisobutylaluminum hydride, 45% yield; **b**: 1) *m*-chloroperbenzoic acid, 2) nBu_4NF, 3) $LiCuMe_2$, 4) Me_2CO, camphorsulfonic acid, 5) Li, liq.NH_3, 70% yield; **c**: dimethyl sulfoxide, $(COCl)_2$; Et_3N, 2) $Ph_3P{=}C(Me)CO_2Et$, 3) $LiAlH_4$, 4) $PhCH_2Br$, KH, 5) HCl, 6) B_2H_6, H_2O_2, NaOH, 36% yield; **d**: 1) *t*BuCOCl, pyridine, 2) Me_2CO, camphorsulfonic acid, 3) $LiAlH_4$, 90% yield; **e**: steps 1)—3) as in **c**, 4) HCl, 5) B_2H_6, H_2O_2, NaOH, 6) $Me_2C(OMe)_2$, camphorsulfonic acid, 7) Li, liq.NH_3, 34% yield; **f**: 1) dimethyl sulfoxide, $(COCl)_2$; Et_3N, 2) diallylzinc, 3) MeI, KH, 66% yield.—The stereoselection is given under the arrows.

stereoselectively to yield a single epoxide which, after a series of reactions (desilylation, cuprate opening, protection of the diol, and liberation of the C25 hydroxy group) [corresponding to Sequence (6)] affords **228**. A Wittig reaction on the aldehyde derived from **228**, followed by reduction, leads to the formation of an allylic alcohol that, after protection of the hydroxy group and removal of the acetonide group, undergoes stereoselective hydroboration to provide **229** (4.5 : 1 selection). Repetition of nearly the same sequence converts **230** to **231** which, after oxidation to the corresponding aldehyde, is allowed to react with diallylzinc to provide **232** (4.6 : 1 selection), a key intermediate that contains all eight chiral centers present in the ansa chain. Further transformation of **232** to the full ansa chain involves the addition of the *E,Z*-diene moiety which is another challenging task. However, since this transformation does not involve the creation of any new chiral centers, the sequence of reactions leading to the ansa chain derivative **236** through **234** and **235** is simply summarized in Scheme 47. The compound **236** is properly functionalized for coupling with the aromatic portion of rifamycin. Several difficult problems involved in this coupling have been solved in an elegant manner to complete the synthesis of the antibiotic.



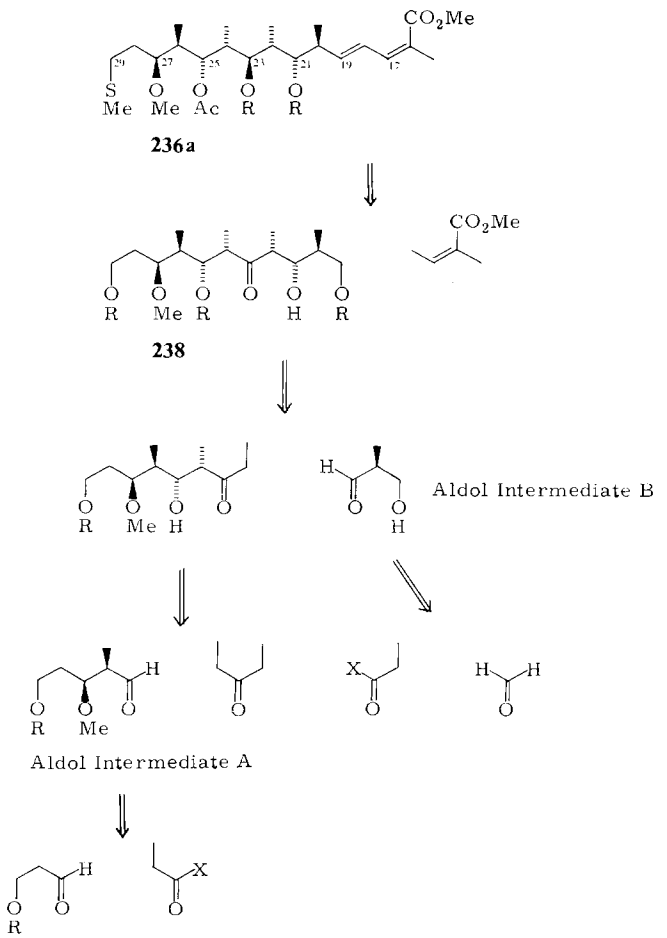
Scheme 47. Synthesis of the precursor (±)-**236** for *rac.* rifamycin S(±)-**223**. **a**: 1) HCl, 2) *t*BuCOCl, pyridine, 3) OsO_4, KIO_4, 4) MeSH, $BF_3 \cdot Et_2O$, 5) $Me_2C(OMe)_2$, camphorsulfonic acid, 6) $LiAlH_4$, 56% yield; **b**: 1) pyridinium dichromate, 2) $Ph_3P{=}CHCO_2Et$, 3) diisobutylaluminum hydride; **c**: 1) pyridinium dichromate, 2) $(MeO)_2P(O)CH(Me)CN$, KO*t*Bu, 3) diisobutylaluminum hydride, 4) NaCN, MnO_2, MeOH, 45% yield from (±)-**223**; **d**: 1) $HgCl_2$, $CaCO_3$, 2) $NaBH_4$, 3) *t*$BuPh_2SiCl$, 4) Ac_2O, pyridine, 5) *n*Bu_4NF, 6) methanesulfonyl chloride, Et_3N, 7) MeSNa, 69% yield.—The stereoselection is given under the arrows.

This synthesis of the racemic ansa chain can be compared with an enantioselective version which *Kishi* et al. documented a year later[85][*]. This version (acyclic, reagent-control approach) incorporated the concept of double

Scheme 48. NH_3, 57% yield; **b**: 1) dimethyl sulfoxide, $(COCl)_2$; Et_3N, steps 2)—5) as in **a**, steps 1)—4), 6) *t*$BuPh_2SiCl$, 7) AcOH, 8) *t*BuCOCl, pyridine, 9) $Me_2C(OMe)_2$, camphorsulfonic acid, 10) $LiAlH_4$, 63% yield; **c**: steps 1)—5) as in **b**, but with (−)-diethyl tartrate, 6) $Me_2C(OMe)_2$ camphorsulfonic acid, 7) *n*Bu_4NF, 68% yield; **d**: 1) dimethyl sulfoxide, $(COCl)_2$; Et_3N, 2) $CH_2{=}CHCH_2I$, $SnCl_2$, 3) MeI, KH, 65% yield.—The stereoselection is given under the arrows.

asymmetric induction earlier demonstrated in the synthesis of 6-deoxyerythronolide B. The entire scheme shows significant improvements in terms of overall stereoselectivity owing mainly to the incorporation of Katsuki-Sharpless asymmetric epoxidation (Section 7) in the synthetic routes. Thus, the synthesis which begins with enantiomerically pure aldehyde **226**[86][*] uses this asymmetric epoxidation three times (Scheme 48). The construction of tri-substituted *Z*-olefins of the type **225** to effect substrate-controlled reactions is no longer necessary (see above). Reaction of (−)-**226** with a stabilized Wittig (Horner-Wadsworth-Emmons) reagent, followed by reduction gives an allylic alcohol, which is subjected to asymmetric epoxidation and regioselective cuprate opening of the resulting epoxide to establish the desired stereochemistry. Standard protecting group manipulations lead to **228**. The overall stereoselectivity of this entire process is 20 : 1. The ensuing steps, conversions of both **228** to **230a** and **230a** to **231** are, in essence, repetition of the above sequence. The last chiral center to be created is at C27. Addition of allyltin to the aldehyde derived from **231** proceeds with high stereoselection to provide the chiral aliphatic segment **232**. In order to explain this stereoselection, the *trans*-decalin-type transition state **237** was proposed. At this stage, the synthetic route takes the same path as the synthesis in the racemic series (Scheme 47).

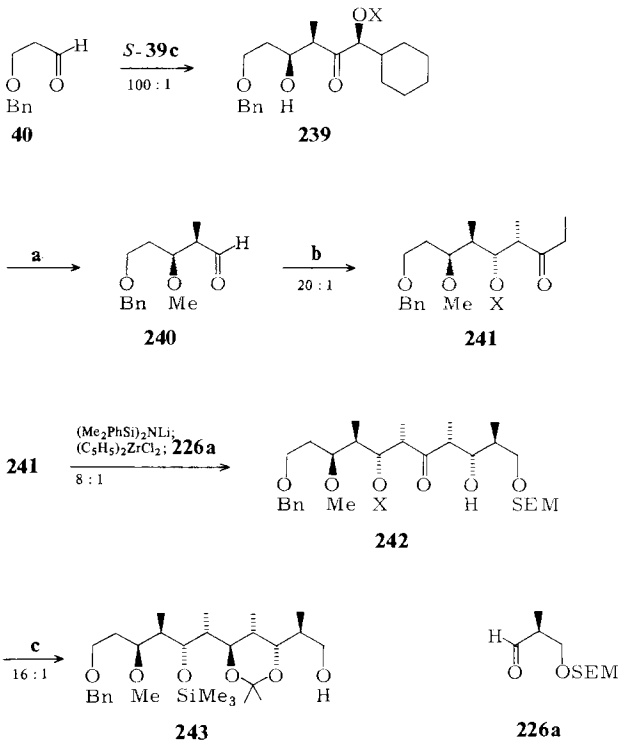
237



The merits of the acyclic, reagent-controlled approach (exemplified by *Kishi*'s enantioselective synthesis of **236**) as compared with the acyclic, substrate-controlled approach (see *Kishi*'s first synthesis of (±)-**236**) are clear. Interestingly, the reaction sequences for the two-carbon extension can be replaced by a single aldol reaction which

[*] Another enantioselective version has also been documented [85] by *Kishi* but will not be discussed here fore the sake of brevity.

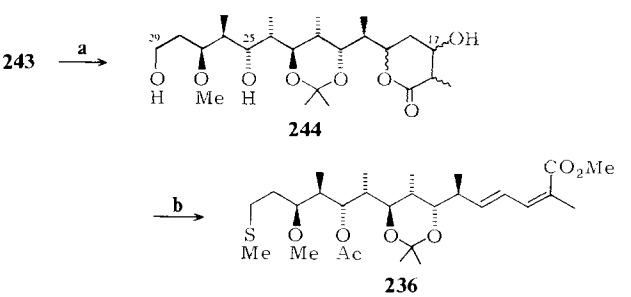
[*] Prepared in six steps from (*S*)-3-hydroxy-3-methylpropionic acid; see reference [86].



achieves the overall transformations even more efficiently. The aldol reaction (Section 4) establishes two chiral centers in one step, and this approach has also been applied to the synthesis of the ansa chain **236** (cf. Scheme 51)[87].

Our retrosynthetic analysis demonstrates that seven chiral centers out of the eight present in the chain **236a** can be constructed through a convergent series of four asymmetric cross-aldol reactions (Scheme 49). The two aldol intermediates A and B were prepared earlier in connection with the development of the chiral boron reagents shown in Scheme 11. The remaining chiral center, C23, is created by stereoselective reduction of the corresponding ketone **238**. Finally, the construction of the *E,Z*-dienoate moiety [C15–C19] leads to **236a**. Scheme 50 shows the synthesis.

Scheme 49. Retrosynthetic analysis of **236a**.

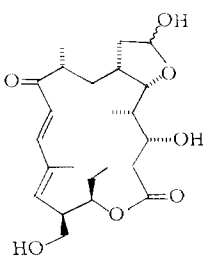


Reaction of the aldehyde **40** with the boron-enolate reagent *S*-**39c** almost exclusively provides the aldol product **239** which is converted to aldehyde **240** through removal of the chiral auxiliary, protection, and adjustment of oxidation state (Section 4)[17]. Aldehyde **240** is allowed to react with the *Z*-enolate of 3-pentanone, selectively generated with lithium 1,1,3,3-tetra-methyl-1,3-diphenyldisilazide[21], and the resulting product is silylated to provide **241**. Note that the cation used in this aldol reaction is lithium and that the methoxy group at the β-position of **240** plays an important role in this stereochemical outcome.

Scheme 50. Synthesis of **243**, a precursor of **236**. The first step proceeds in 75% yield, the fourth step in 70% yield. **a**: 1) HF, CH_3CN, 2) $NaIO_4$, 3) CH_2N_2, HBF_4, 4) $LiAlH_4$, 5) pyridinium chlorochromate, 75% yield; **b**: 1) Et_2CO, $(Me_2PhSi)_2NLi$, 2) *t*$BuMe_2SiOSO_2CF_3$, 90% yield; **c**: 1) diisobutylaluminum hydride, 2) $Me_2C(OMe)_2$, H_2SO_4, 3) *n*Bu_4NF, 4) Me_3SiCl, aqueous work-up, 85% yield.—X = *t*$BuMe_2Si$, SEM = $CH_2OCH_2CH_2SiMe_3$.—The stereoselection is given under the arrows.

The coupling of **241** and **226a** is achieved through a zirconium-mediated aldol reaction (Section 4) with the *Z*-enolate of **241** to provide the ketone **242** which, after stereoselective reduction and subsequent protecting group manipulations, is converted to the alcohol **243**. The addition of the [C15–C19] *Z,E*-dienoate moiety to **243** has been carried out efficiently to yield through **244** the same ansa chain derivative **236** as that used in *Kishi*'s synthesis (Scheme 51). A detailed discussion of this last transformation is deleted for the reason mentioned above.

Readers may wonder if the above aldol-based synthesis of **236** is "reagent-controlled". Not exactly. Two aldol reactions (**40** → **239** and formaldehyde → **226a**) use the chiral reagents solely for single asymmetric induction, and the



Scheme 51. Conversion of **243** into **236**. 1) $CrO_3(py)_2$, 2) benzyl-2-methylacetoacetate, 2) $LiN(iPr)_2$, 3) $NaBH_4$, 4) H_2, Pd/C, 5) toluene, reflux, 85% yield; b: 1) $(CF_3CO)_2O$, Et_3N, 2) hydrolysis, 3) toluenesulfonyl chloride, pyridine, 4) MeSNa, 5) CH_2N_2, 6) Ac_2O, pyridine, 68% yield.—The stereoselection is given under the arrows.

other two (**240** → **241** and **241** → **242**) take advantage of metal-chelation in order to obtain the desired stereoisomers. Even the last reaction (**241** → **242**), although it is a double asymmetric reaction, is not stereochemically *controlled* in the sense defined earlier. However, we have included the aldol-based synthesis in this Section, because, like the two examples described earlier (**58** + **60** and the aldehyde derived from **231** + diallyltin), the formation of a metal-chelated ring intermediate leads to the highly selective synthesis of a diastereoisomer whose stereochemistry can be predicted. This metal chelation methodology which effectively enhances the D.S. of a reactant to the extent of a synthetically acceptable level has received renewed interest in recent years and its importance justifies its inclusion above.

Having discussed several total syntheses, it is worth tabulating 1) the overall stereoselectivity, 2) the overall yield, and 3) the number of steps associated with each of the syntheses. Since the last two criteria are subject to the arbitrary choice of starting material, the starting materials used to calculate these figures are listed in Table 7. It is evident that the reagent-controlled syntheses are clearly more advantageous than those which are substrate-controlled in virtually all the criteria used to evaluate the efficiency of the multi-step synthesis.

There have been recorded only a few natural product syntheses in which the majority of the chiral centers are constructed through reagent-controlled reactions. The synthesis of 6-deoxyerythronolide B **48** served as a prototype and has been followed by those of tylonolide **245** (aglycone of the antibiotic tylosin[5, 88]) and the pentoses and

245

hexoses[*]. The other three examples are the synthesis of enkephalin S (Section 6) by *Ojima* et al. and the syntheses of the pentoses and rifamycin S by *Kishi*. Now that the distinct advantages of this approach are delineated, the new strategy will receive more attention from synthetic organic chemists.

Finally, mention should be made of the availability of homochiral substrates used in double asymmetric reactions as starting materials or synthetic intermediates[**]. Such substances are prepared from appropriate achiral compounds through either single asymmetric synthesis (as shown above on a number of occasions) or conversion of abundantly available homochiral natural products such as glucose, malic acid, tartaric acid, and several terpenes. Conversion of a natural product into another compound of a vastly different structural type has been used quite often in the past, as exemplified notably and perhaps most elegantly by the transformation of (+)- and (−)-camphor into fragments of vitamin B_{12}[89]. Many examples in the field of macrolide synthesis also demonstrate the rather efficient conversion of these natural products into small fragments which have several chiral centers. Readers should consult recent reviews for this development[3c, 90]. It is our belief that the adoption of the new strategy coupled with the judicious selection of a homochiral substrate will become a standard method for designing the synthesis of many natural products of polyketide origin.

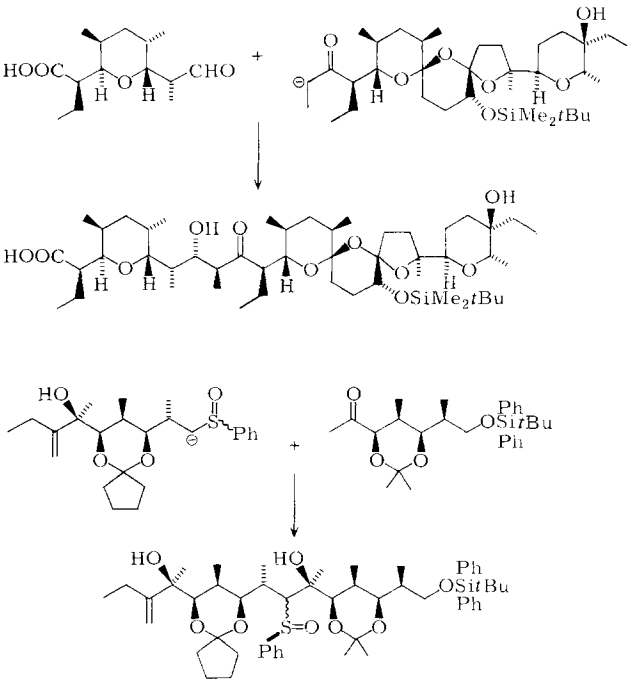
9. Concluding Remarks

The term "synthèses asymétriques par double induction" was first used by *Horeau, Kagan* and *Vigneron* in 1968[4a]. Since then the experimental outcome of this process has been recorded sporadically, e.g., *Glaser*'s experiments in catalytic hydrogenation (1976, Section 6), *Ojima*'s hydrosilylation[91] and *Aratani*'s cyclopropanation[92] (1977), *Heathcock*'s aldol reaction[93] and *Noyori*'s aluminum hydride reduction[94] (1979), and *Hoffmann*'s carbonyl addition of crotylboronic acid esters (1980)[95]. All these have conceptually contributed to the first demonstrations of "reagent-controlled" organic reactions that appeared in 1980[8, 11]. In Sections 1—3, several new terms have been coined which may be used to explain some processes closely related to double asymmetric induction. For example, kinetic resolution can be understood on the basis of a rate difference between "matched" and "mismatched" reactions. The discussion of this important process, however, is deliberately excluded from this Account to simplify the presentation of this new strategy.

What changes may organic synthesis undergo? It is evident from Section 3 that the validity of multiplicativity of two diastereofacial selectivities is not limited to either the acyclic systems used to illustrate the rule, or the four major organic reactions discussed in Sections 4—7. Thus, additional highly diastereoselective reagents and catalysts are expected to emerge. Catalytic processes are obviously more advantageous than those using chiral reagents and therefore stronger emphasis will probably be placed on the design of chiral catalysts. These anticipated developments are reserved for a future review. With appropriate chiral reagents and catalysts at hand, the synthetic design of many natural (and unnatural) products will become straightforward, and as a result some of the aesthetic elements of traditional organic synthesis, as exemplified by the synthesis of erythronolide A in Section 7, may well be lost. *Woodward*'s 1956 remark, "There is excitement, adventure, and challenge, and there can be great art, in organic synthesis"[80], will still pertain to the many synthetic problems not amenable to iterative solutions. However, the power of the new strategy has already made possible what appeared to be almost impossible even a few years ago. In this sense a new era which is characterized by the evolu-

[*] Our synthesis of the ansa chain of rifamycin S **223** is excluded from this listing.

[**] Somewhat ironically, many syntheses in racemic form now turn out to be more difficult to design and execute with equal efficiency than the corresponding enantioselective syntheses. See also the footnote on p. 4.

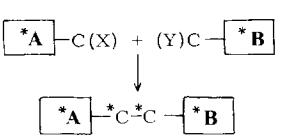


tion from substrate-controlled to reagent-controlled organic synthesis is definitely emerging[*].

In order to further understand the interaction of two chiral reactants, some comments are in order on two aspects of diastereofacial selectivities: 1) their multiplicativity and 2) their extent and directionality. The multiplicativity is dependent on the validity of the assumption that the single and double asymmetric reactions used as a set to evaluate the rule proceed through very similar transition states. Using energy terms, this statement may be illustrated more conveniently. Thus, $\Delta\Delta G_1^{\ddagger}$ and $\Delta\Delta G_2^{\ddagger}$, which correspond to the D.S.'s of two reactants, represent the energy difference in the two diastereomeric transition states of the reaction used to determined the D.S. of each reactant in a specific reaction. Expressing the stereoselectivity observed in the double asymmetric reaction by $\Delta G^{\ddagger}$, the D.S. multiplicativity rule is now shown by the following equations for the matched and mismatched pair reactions.

$$\Delta G^{\ddagger}(\text{matched}) = \Delta\Delta G_1^{\ddagger} + \Delta\Delta G_2^{\ddagger} + \Delta G_{12}^{\ddagger}$$
$$\Delta G^{\ddagger}(\text{mismatched}) = \Delta\Delta G_1^{\ddagger} - \Delta\Delta G_2^{\ddagger} + \Delta G'^{\ddagger}_{12}$$

Both $\Delta G_{12}^{\ddagger}$ and $\Delta G'^{\ddagger}_{12}$ are perturbation terms closely related, in most cases, to the (normally small) conformational change brought in the transition state of the double asymmetric reaction relative to the transition states of the model single asymmetric reactions (for the D.S. measurements). The magnitude of these terms is difficult to estimate a priori and constitutes a limitation of the rule. Many examples in this Account show that they are small as compared with $\Delta\Delta G_1^{\ddagger}$ and $\Delta\Delta G_2^{\ddagger}$, provided that the selection of achiral model compounds is appropriate.



The extent and directionality of the D.S. of an acyclic compound is, by definition, the same as the Cram : *anti*-Cram ratio often used in the recent literature. Which stereoisomer results as the predominant product from the reaction of an acyclic compound with an achiral reagent (the directionality of the D.S.) is supposedly predictable on the basis of *Cram*'s *acyclic* model[96] or its later version, *Felkin*'s model[97]. Unfortunately, many predictions have proven to be incorrect. Readers may note that the aldol reactions of **24**, **35**, and **69** all provide the respective *anti*-Cram products predominantly[**]. Moreover, the Cram : *anti*-Cram ratio (or its reciprocal) normally does not exceed 5 : 1 (or 1 : 5) (Section 3), a stereoselectivity that does not quite satisfy today's standards and should either be enhanced or effectively overridden. In contrast to the *acyclic* model, *Cram*'s *cyclic* metal-chelate model[98] is extremely useful for predicting the stereochemical outcome of many reactions. The proper design of either reactant or both reactants brings about a rigidly chelated framework which creates two highly distinguishable diastereotopic faces, resulting in a stereoselectivity of the reaction being as high as 100 : 1 in some cases[99]. Thus, the metal-chelation methodology effectively enhances the normally small D.S. of an acyclic reactant with predictable directionality. Examples quoted in this account are: the two aldol reactions **57** + **60** in Scheme 14, and **241** + **226a** in Scheme 50. Two notable others chosen from many examples in the literature are shown in Scheme 52[100,101].

Scheme 52. *Kishi*'s narasin synthesis [100] proceeds with exclusive stereoselection; in *Stork*'s erythronolide A seco-acid synthesis the selectivity is 5 : 1.

These four examples are deliberately selected because they illustrate an important synthetic process: Two prefixed homochiral segments [*A–C(X), *B–C(Y)] are joined together with the concurrent creation of a new chiral center or centers (Scheme 53). This process must be clearly distinguished from the major theme of this review formulated in Scheme 6. Note that neither *A–C(X) nor *B–C(Y) serves as a chiral reagent. Therefore, these successful connections have not been executed *with control* in the sense defined in the account. Therefore at the time of retrosynthesis one must be confident that the assembly of two segments of this type, which normally appears in the late stages of the synthesis, will proceed in the desired manner. Can we control this stereochemistry? The answer is no; at least not at present. A *general* solution to this extremely challenging, fundamental problem appears to demand a third chiral component in the form of a catalyst.

In concluding this lengthy Account we would like to express briefly our personal feelings about the entire problem of asymmetric synthesis. When we agonized over the

Scheme 53. Neither A nor B is a reagent.

[*] By "evolution" the authors do not imply a "revolution" in which the traditional order is destroyed. There is much that the new supplements and complements the old.

[**] In formulating his rule, *Cram* often used phenyl-substituted substrates. This substituent exerts a strong electronic effect which can override other effects. Therefore, the rule does not necessarily apply to aliphatic substrates.

stereochemical complexity of 6-deoxyerythronolide B, our thoughts turned to enzymatic processes just as they had when we secured the hint of using a thiol ester to effect macrolactonization of the methynolide seco-acid[102]. How does an enzyme create chiral centers? Since a substrate binds tightly to an enzyme which is rich in chirality, only one face of the reacting prochiral group of the substrate is effectively exposed to external attack. We have succeeded in creating a small chiral environment near the reaction site which mimics the active site of the enzyme. Although lacking the catalytic nature of an enzyme or its substrate-specificity, our reagent holds one decisive advantage over the enzyme in that both matched and mismatched reactions can be utilized to our benefit. An enzyme is generally limited to the matched pair reaction. Once again we have learned from Nature only to wonder what we might be taught next[*].

With great pleasure we thank many collaborators whose names appear in the references. They have contributed experimentally as well as conceptually to the development of the new strategy presented in this Account. It is also a memorable and gratifying experience for us to have collaborated with Professor Sharpless in the exploitation of his reagent which has culminated in the synthesis of the hexoses. This Account has evolved from the senior author's preliminary documentations[3a–c], one of which is coauthored by Peter McCarthy. His careful and concise review on the ever-growing field of macrolide synthesis has greatly aided us in completing Section 8. We would like to acknowledge the helpful criticisms of various Sections provided by Rick Danheiser, Samuel Danishefsky, Iwao Ojima, Bill Roush, and Barry Sharpless. Many of the improvements are a direct result of their efforts but errors remain ours. We would also emphasize that Professor Kagan has brought our attention to the early work on double asymmetric syntheses. The work and this writing have been supported by grants from the National Institutes of Health and National Science Foundation (USA) as well as from the Kao Corporation (Japan). J.S.P. is a National Cancer Institute Trainee (NCI-5-T-32-CA-09112) of the Public Health Service, USA.

[*] After the final version of this review was completed, several additional publications pertinent to what has been expounded here have appeared in the literature. For instance, see [103]–[108].

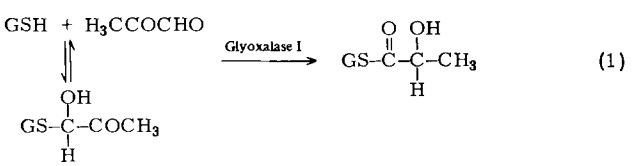
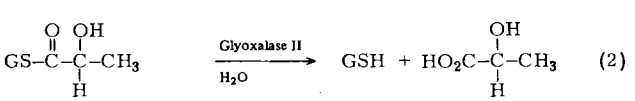
Chemical Basis of the Action of Glyoxalase I, an Anticancer Target Enzyme

By Kenneth T. Douglas* and Seiji Shinkai



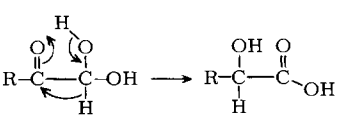
Although glyoxalase I was discovered in 1913 the physiological role of this ubiquitous enzyme is still far from clear. It catalyzes the reaction of α-ketoaldehydes and glutathione to produce *S*-D-lactoylglutathione, from which D-lactate and glutathione are produced by glyoxalase II. Argument raged for many decades about the nature of the natural substrate. Was it methylglyoxal? Was methylglyoxal ever formed metabolically or was it purely artifactual? Some of these questions have been resolved in that a number of metabolic processes which produce α-ketoaldehydes have now been recognized. Equally unsuccessful have been attempts to ascribe a physiological role to glyoxalase. This is clearly an important question since glyoxalase I occurs in cells at all levels of evolution. Time and time again glyoxalase I has been claimed to be linked to cancer, and a number of research groups worldwide are using it as a model for designing potential anticancer drugs. In this review article the mechanism of action of the enzyme is discussed, knowledge of which enables stronger inhibitors to be synthesized. Until roughly ten years ago when powerful NMR techniques were used to study it for the first time, it was assumed that the key step in the mechanism was a hydride ion transfer. Today, the mechanism is envisaged as a proton transfer.

1. Introduction



It has long been known that α-keto aldehydes are strongly carcinostatic[1]; however, their direct use as anticancer drugs is prevented by their rapid conversion in vivo into the corresponding inactive[1] α-hydroxy acids by the glyoxalase enzyme system. The glyoxalase system was discovered[2] in 1913 and consists of two enzymes and their cofactor, glutathione (GSH). Glyoxalase I (lactoylglutathione lyase, EC 4.4.1.5) converts the monohemithioacetal formed from GSH and methylglyoxal or other α-oxoaldehydes into *S*-lactoylglutathione[3] as shown in equation (1). This thioester is then hydrolyzed by glyoxalase II (hydroxyacylglutathione hydrolase, EC 3.1.2.6), as shown in equation (2), to produce lactic acid and free glutathione [Eq. (2)].

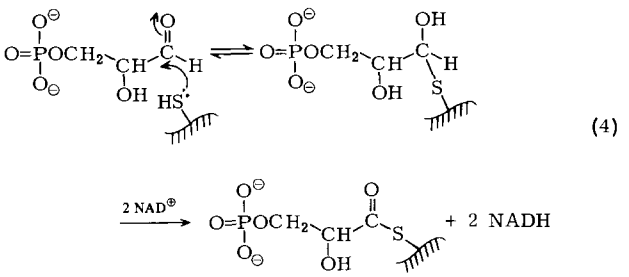
Glutathione (GSH)



(1)

(2)

Walsh[4] has suggested that direct oxidation of the aldehyde would require removal of two electrons from an already strongly electrophilic site. Prior formation of the glutathione monohemithioacetal allows ready removal of two electrons from a nonelectrophilic center and gives a thioester product, with a high group transfer potential. Undoubtedly, this aids in the hydrolase step catalyzed by glyoxalase II. However, another mechanism which leads directly from the hydrated form of the aldehyde (the vastly predominant species) to lactic acid is also feasible [eq. (3)].



(3)

Presumably, the use of two enzymes and a glutathione coenzyme, with a free thioester intermediate, offers better metabolic and control advantages. The sequence may be sensitive to GSH cellular flux, and to relative rates of synthesis and breakdown of the enzymes, etc. The *S*-lactoylglutathione intermediate itself may possess important biological properties as reported by *Gillespie*[7].

Although it has been known for so long, many features of the glyoxalase reaction are unclear. What is its physiological role? What is its detailed mechanism of action? The nature of the substrate for glyoxalase I is a complex question. The substrate could either be the hemithioacetal of GSH and CH_3COCHO (formed nonenzymically) or free GSH and CH_3COCHO which react in a random or ordered way with the enzyme. The importance of glyoxalase I can be seen as two-fold. 1) It is of interest as a current anticancer target enzyme—a considerable body of data appears to support the view that its inhibitors are frequently cytotoxic and several have in vivo antitumour activity. 2) The enzyme is also of interest from a mechanistic stand-

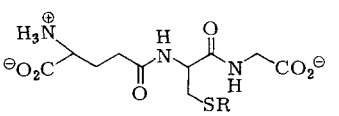
point. A similar sequence of reactions occurs in the reaction of glyceraldehyde 3-phosphate dehydrogenase[5]. The Cys-149 residue of the enzyme forms a hemithioacetal with glyceraldehyde 3-phosphate, which is then oxidized (using $NAD^{\oplus}$) to an enzyme-bound thioester [eq. (4)].

(4)

The redox process is intramolecular for glyoxalase I (1,2 hydrogen shift) and intermolecular for glyceraldehyde 3-phosphate dehydrogenase (hydride transfer to $NAD^{\oplus}$). Glutathione-dependent formaldehyde dehydrogenase[6] similarly converts formaldehyde into a high energy glutathione thioester of formic acid via an intermolecular ($NAD^{\oplus}$-dependent) redox reaction of the glutathione hemithioacetal [eq. (5)].

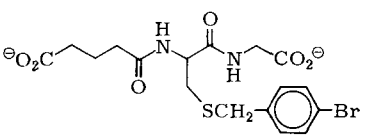
(5)

2. Biological Basis



2.1. Hypotheses on Why Glyoxalase I Inhibition Should Be Anticancer Active

Although a number of proposals concerning the natural role of glyoxalase I have been made, little has been firmly established. It has been suggested that it plays a role in the enhancement of anti-(immunoglobulin E)-induced histamine release[7a], in microtubule assembly[7b], in protection against intestinal bacteria[8], in a postulated metabolic cycle for the degradation of glycine and threonine (since methylglyoxal is the deamination product of aminoacetone)[9], and is possibly involved in the heme biosynthetic pathway[10]. These will not be discussed further here.



The possibility that glyoxalase I inhibitors might have anticancer activity appears to have been suggested at about the same time by *Vince* and *Wadd*[11] and by *Szent-Györgi*[12]. *Vince* and *Wadd* argued[11] that because glyoxalase I rapidly converts[13-15] the cytotoxic methylglyoxal into nontoxic lactate in the presence of GSH, which is known[16] to be necessary for cell division, inhibitors of glyoxalase I might be used to concentrate methylglyoxal in tumor cells and thus inhibit cellular growth. *Szent-Györgyi* argued[12] that normal cellular growth requires a careful balance between a growth-retarding force (methylglyoxal) and a growth-promoting force (glyoxalase I). Thus, inhibitors of glyoxalase I might be expected on this rather simple basis to be anticancer agents. It is now clear that the situation is much more complicated than either of these suggestions.

2.2. Some Examples of Glyoxalase I Inhibitors with Cytotoxic or Anticancer Activity

Early approaches to anticancer compounds involved the preparation and screening of analogues of glyoxalase I substrates. Thus, a large number of *S*-substituted glutathiones **1** have been synthesized and found to be strong inhibitors of glyoxalase I[11, 17, 18, 19]. Many of these were cytotoxic to L1210 leukaemia and KB cells in tissue culture[20]. In addition, several *S*- and *N*-substituted cysteinylglycines have been evaluated as glyoxalase inhibitors[21]. However, their rapid metabolism rendered them (including **1**) inactive in vivo[21, 22]. One compound which is resistant to γ-glutamyl cleavage by γ-glutamyl transpeptidase is **2**: this appears to have promising biological properties.

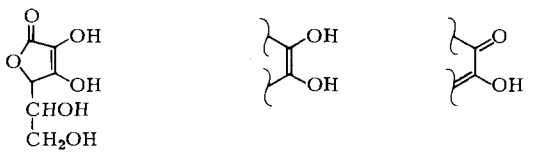
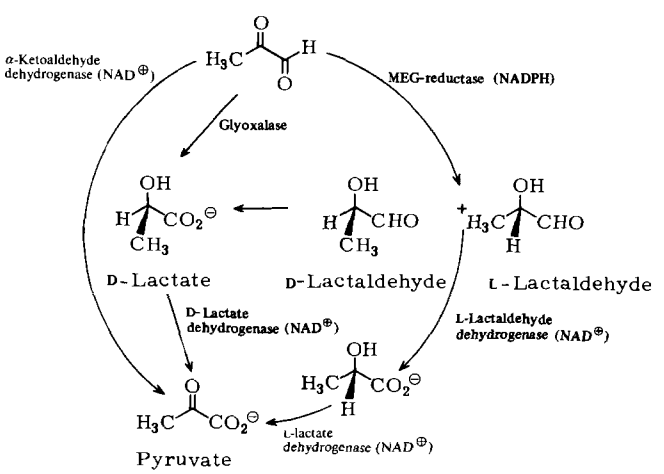
2



Whilst *S*-(*p*-bromobenzyl)glutathione is a strong glyoxalase I inhibitor (especially of the human erythrocyte enzyme), it is not clear whether its antitumour activities and those of analogous compounds result from this effect. For example, glutathione derivatives inhibit ribonucleotide reductase (Scheme I), an enzyme which catalyzes the reduction of the furanose moiety of ribonucleotides to deoxyribonucleotides, in a complex manner[23, 24]; a process which can be the rate-determining step in DNA replication in many systems. Consequently, inhibition of this vital process can be seen as a prime target for potential anticancer activity and much research has been invested in this area. One of the dithiol donor proteins, glutaredoxin, is recycled via a pathway involving glutathione, and it was surprising to find that glutathione derivatives blocked on sulfur or nitrogen inhibited the donor activity of glutaredoxin or of *E.*

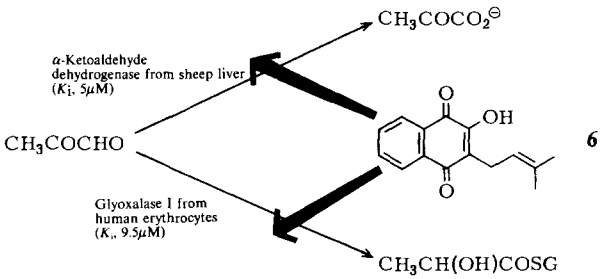
Scheme 1. Mechanism for the conversion of ribonucleotides into deoxyribonucleotides catalyzed by the enzyme system ribonucleotide reductase.



coli ribonucleotide reductase[23]. Even more striking inhibitory effects have been observed with analogues of oxidized glutathione and ribonucleotide reductase from *E. coli*[24].

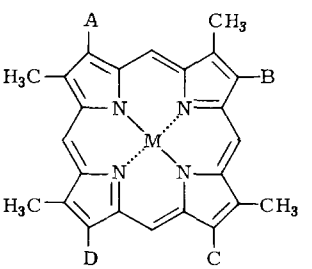
Reductones (e.g. ascorbic acid **3**) suppress the growth of Sarcoma 180 and are also effective glyoxalase inhibitors, suggested to be because of their structural similarity to methylglyoxal[25]. However, the inhibition of glyoxalase I by **3** and other compounds containing the enediol **4** or *paene*-enediol structure **5**[*] has been rationalized[26] on the basis of their similarity to part of the putative transition state structure for glyoxalase I reactions of this enzyme. Such compounds are powerful chelating agents and some or all of their inhibition of glyoxalase I, a Zn-containing metalloenzyme, may result from this[27].

3 **4** **5**



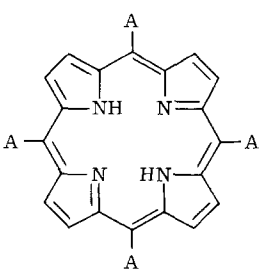
Methylglyoxal is detoxified by a number of other routes, which are summarized in Scheme 2. The direct (NAD-dependent) reduction to pyruvate by α-ketoaldehyde dehydrogenase occurs in mammalian cells[27], including some tumor cells, and in bacteria. The NADPH-branch, via lactaldehyde, has been reported in bacteria[28]. For effective build-up of the concentration of cellular α-ketoaldehyde in mammalian systems, at least both the glyoxalase I and α-ketoaldehyde dehydrogenase detoxification routes must be blocked, a point first emphasized by *Vince* and *Daluge*[20].

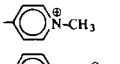
Scheme 2. α-Ketoaldehyde catabolism.



Lapachol **6** and some derivatives are effective against several tumor types. We have recently shown that lapachol not only strongly inhibits human erythrocyte glyoxalase I, but also sheep liver α-ketoaldehyde dehydrogenase[29].

Lapachol is involved in other places in metabolism[29]. As a hydroxyquinone it decouples oxidative phosphorylation, presumably in an analogous manner to 2,4-dinitrophenol. It also inhibits succinate dehydrogenase and 3-α-hydroxysteroid-mediated transhydrogenase. Recently, it has been suggested that its primary antineoplastic activity may involve inhibition of L-dihydroorotate dehydrogenase in pyrimidine biosynthesis.





6

The cytotoxic action of methylglyoxal is potentiated by co-application of an *S*-blocked glutathione as glyoxalase I inhibitor[20]. Further, *Yamamoto*[30,31] has reported that the binding of phytochlorin sodium (a porphyrin) to cancer cells in vitro upon irradiation with visible light is enhanced by methylglyoxal. Methylglyoxal also lowers the tumor-forming ability by almost threefold[30,31]. In view of the synergism between α-ketoaldehyde and porphyrin in cancer cell division, *Yamamoto* suggested involvement of the glyoxalase system in mitosis. We have found that glyoxalase I purified from a number of species (see Fig. 1) is

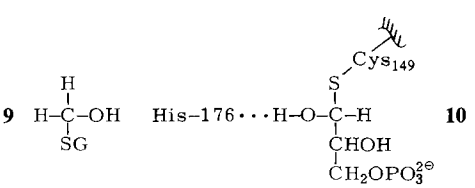
strongly inhibited by a range of porphyrins[32,33], supporting *Yamamoto*'s proposal. The inhibition is stronger at lower pH, and since cancer cells, especially after glucose treatment, have lower pH values than normal tissues[34], inhibition of glyoxalase I by porphyrins may be stronger than in normal cells and contribute to the selective uptake of some porphyrins by cancer cells[32].

Umezawa et al. have found a potent, competitive inhibitor[35] ($K_i = 4.6 \times 10^{-6}$ M) of glyoxalase I in the culture broth[35] of a mushroom. This compound **7** inhibits the growth of Yoshida sarcoma cells but has no in vivo effect, presumably because of the ready cleavage[36] of the ester bond. Recently, **7** has been found to inhibit a number of other enzymes[37]. Another glyoxalase I inhibitor isolated

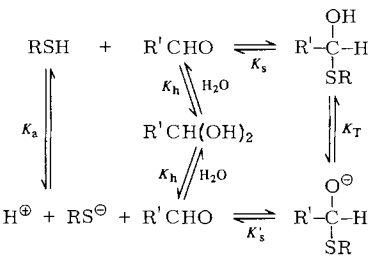
7



8a **8b**

from actinomycetes[38,39] is the crotonate ester **8a** which reacts rapidly with glutathione to give **8b**, thus inhibiting glyoxalase I. **8** showed no significant antibacterial activity, but did inhibit Yoshida rat sarcoma cells in tissue culture. Growth of both ascitic and solid forms of Ehrlich carcinoma in mice was suppressed by daily intraperitoneal injection of **8**, which also prolonged the survival period in mouse leukaemia L1210[38,39].

3. Chemical Basis of the Action of Glyoxalase I



3.1. The Thiol-Aldehyde Reaction

The reaction between thiols and aldehydes has been known for a hundred years[40]. This reaction provides the substrates for glyoxalase I [eq. (1)], and for formaldehyde dehydrogenase (**9**)[41,42] together with intermediates in the glyceraldehyde 3-phosphate dehydrogenase reaction sequence (**10**)[43]. The tight-binding inhibition of some thiol

9 **10**

proteases by aldehydes also involves this reaction. The behavior is complicated by a) hydrates of the aldehyde[44], b) ionization of the thiol[44,48], and c) ionization of the OH group of the monohemithioacetal[41,48]. Equation (6) shows a minimal reaction scheme[44] (K_s = true association constant of RSH and the aldehyde; K_a = acid dissociation constant of the thiol). Since values of pK_T (for the dissociation

(6)

constant of the OH group of the hemithiolacetal) for the aldehyde used were greater than 12, the observed equilibrium constant (K^{obs}) for hemithioacetal formation is given by equation (7).

$$K^{obs} = K_s/(1 + K_a/H^{\oplus})(1 + K_h) \quad (7)$$

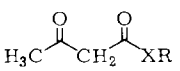
Using this relationship the effects on K_s of structural variations in the aldehyde were determined[44] for both glutathione and 4-nitrothiophenol. Steric effects in aldehydes would be expected to be more significant with the bulky glutathione than with water, but both hydration and hemithioacetal equilibria responded in a similar way to steric changes ($\log K_s$ correlated well with $\log K_h$). Aldehydes with ionic substituents (e.g. glyceraldehyde 3-phosphate) fitted the correlation, indicating that ionic interactions between GSH and the aldehyde do not contribute to the hemithioacetal stability[44].

Within experimental error, K_s appears to be independent of thiol, and the sensitivity to σ^* for aliphatic aldehydes also appears to be thiol independent[44]. For the aldehydes (including methylglyoxal) the hemithioacetal adduct with glutathione was found to be 4.3 (± 0.2) kcal mol^{-1} more stable than the corresponding hydrate[44].

The pK_a of the hemithioacetal (pK_T) is rather insensitive to the thiol pK_a [eq. (8)] for acetaldehyde[44,47].

$$pK_T = 0.16\ pK_a + 11.1 \quad (8)$$

A number of experimental equilibrium constants (K^{obs}) for hemithioacetal formation from various α-ketoaldehydes and *N*-substituted glutathiones are collected in Table 1. At the pH (ca. 6.60) usually used for glyoxalase I enzymatic studies K^{obs} needs little if any correction for the effect of pH on thiol ionization[44,48], but such corrections may be necessary at higher pH. It can be seen from Table 1 that even for GSH the equilibrium is displaced to the hemithioacetal side. Indeed, the hemithioacetals of some α-ketoaldehydes have been isolated[49,50].



For acetaldehyde the equilibrium constant (K) is independent of the pK_a of the thiol[45,46]. However, values of K (determined from the saturation kinetics observed in the amine-catalyzed rearrangement of the hemithioacetal to thioester) for phenylglyoxal appear to have a small, but real dependence on thiol basicity. A plot of K^{obs} (from [48]) against pK_a of the thiol is linear with a slope -0.3 over ca. three thiol pK_a units. This is similar to the sensitivity of bridging methylene pK_a in acetoacetates **11**[51] to the pK_a

Table 1. Equilibrium constants (K^{obs}) at 25 °C for thiohemiacetal formation from an aldehyde (RCHO) and glutathione; K^{obs} is defined as [thiohemiacetal]/[RCHO][GSH].

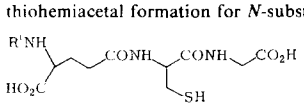
11, X = O,S

Table 2 summarizes the equilibrium constants (K^{obs}) for the reaction of α-ketoaldehydes with glutathione substituted at nitrogen. *N*-Acetylation appears to affect the K^{obs} value for methylglyoxal slightly, phenylglyoxal scarcely, and *p*-chlorophenylglyoxal not at all. For phenylglyoxals the data clearly exclude any significant contribution from Schiff base formation between the glutathione amino group and the aldehyde or keto group (**12** or **13**).



12

13

The equilibrium between glutathione and methylglyoxal is such that in the cell, where the level of GSH is quite high (often 10^{-3} M or greater[52]) and that of methylglyoxal is very low[53], nearly all the methylglyoxal is bound, leaving very little free electrophilic aldehyde. This favorable equilibrium must contribute significantly to the detoxification of this highly cytotoxic aldehyde, as it purchases time for the glyoxalase system to encounter the α-ketoaldehyde and act on it. In contrast to the (relative to GSH) low flux of the glyoxalase enzymes, the higher cellular level of GHS means that encounter of the α-ketoaldehyde with it is considerably more likely.

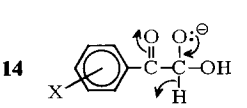
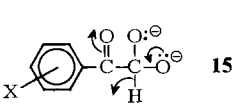
[a] From [17] and [67]. [b] From [67]. [c] K. T. Douglas, C. D'Silva, unpublished (pH 6.60, 25 °C).

The apparent first-order rate constants for the reaction of GSH with a series of α-ketoaldehydes (25 °C, formate buffer, pH 3.0, [GSH]/[α-ketoaldehyde] ≈ 12) were found[54] to be essentially independent of the structure of the α-ketoaldehyde (including methylglyoxal and nine arylglyoxals). This behavior parallels the absence of substituent effects on the equilibrium constants for this system. Substituents also have little effect on the stretching frequency of the aldehyde carbonyl group (1727 cm^{-1}), whereas the keto group is markedly sensitive. The rate constants reported represent the approach to hemithioacetal equilibrium and also reflect the hydration equilibria[54].



3.2. Model Systems for the Mechanistic Study of the Hemithioacetal-Thioester Rearrangement

The rearrangement of hemithioacetals derived from α-ketoaldehydes to the corresponding α-hydroxythioesters catalyzed by glyoxalase I occurs in the absence of enzyme in a number of model systems. In this section we review the chemistry of this rearrangement and apparent analogues (e.g. the Cannizzaro reaction) in model systems.

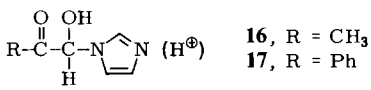


A number of systems have been considered as models for the glyoxalase I reaction. These include Franzen-type catalysts based on 2-(dialkylamino)ethanethiols[55–60], base-catalyzed rearrangement of hemithioacetals of simple thiols either with[61] or without[48,58,60] metal ion catalysis, as well as $OH^{\ominus}$-catalyzed rearrangements of arylglyoxals to mandelates[62] (intramolecular Cannizzaro reactions[62–65]) and analogues[66].

3.2.1. Models for the Study of Hydride Ion Transfer—Cannizzaro Type

It is fairly well established that the hydroxide ion catalyzed disproportionation of phenylglyoxal in aqueous media to give the mandelate ion involves internal hydride transfer[62,65] in the hydrate anion **14** and dianion **15**[*].

14



15

For substituted phenylglyoxals the Hammett ρ-value is +2.0, indicating that the transition state is strongly stabilized by electron withdrawal from the α-keto group[65]. The reaction correlates well with the ketonic C=O stretching frequencies of both hydrated and free aldehyde forms[65].

[*] A free radical route for the benzaldehyde Cannizzaro reaction has recently been proposed: S.-K. Chung, *J. Chem. Soc. Chem. Commun. 1982*, 480.

3.2.2. General Base Catalysis

In the presence of the bases imidazole and $HPO_4^{2\ominus}$, the glutathione-derived hemithioacetals of methyl- and phenylglyoxal rearrange to the corresponding *S*-lactoyl- and *S*-mandeloylglutathiones, respectively[58,61]. Imidazole forms an adduct **17** with the α-ketoaldehyde, which probably does not rearrange to mandeloylimidazole[58]. The

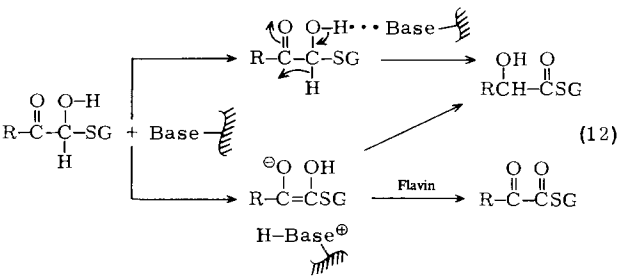
16, R = CH_3
17, R = Ph

rearrangement was suggested to be general base catalyzed, since supported by more detailed kinetic studies[48], and, when run in D_2O it resulted in the incorporation of solvent deuterons at C-2 of the α-hydroxy acid product[58]. In contrast, under Cannizzaro conditions (strong base in D_2O) methylglyoxal is converted into lactate with no significant deuterium incorporation at C-2, i.e. hydride transfer occurred in the absence of thiol at high pH, but under milder, general base conditions (pH 7) proton transfer occurs in the presence of glutathione[58]. For the general base catalyzed reaction there was a kinetic solvent isotope effect (k_H/k_D) of 3.3 ± 0.5 for CH_3COCHO and 2.3 ± 0.2 for PhCOCHO, comparing the CDO derivatives in each case: the values are considerably less than those for $OH^{\ominus}$-catalyzed Cannizzaro reactions (typically 3.8 and 5.0[67]). The authors[58] suggested that glutathione has the role of a covalent catalyst whose sulfur atom acidifies the α-CH group and that there is a basic active-site amino acid residue in glyoxalase I for this purpose. The metal ion, if important, serves only to chelate the substrate to the active site[58].

The data of *Okuyama* et al.[48] show that the solvent isotope effects reported above are complex, having been obtained at a fixed concentration of thiol[58]. For the hemithioacetals from phenylglyoxal and β-mercaptoethanol or glutathione the rate of rearrangement to thioester shows hyperbolic dependence on thiol concentration, reflecting both the rearrangement and the thiol-aldehyde equilibrium. For the rearrangement the solvent isotope effect $k_{H_2O}/k_{D_2O} \approx 1.0$, whereas for the thiol-aldehyde equilibrium it is 0.38, although primary isotope effects were not reported[48]. The studies by *Hall* et al.[58] do not appear to allow for the solvent isotope effect on the aldehyde-thiol equilibrium, which should be felt in the kinetics of thioester formation (it was not stated whether primary isotope experiments with PhCOCDO were conducted in H_2O or D_2O). The kinetics follow equation (9)[48], in which K_h is the formation constant of the hemithioacetal and k_{max} the maximal rate constant at high thiol concentrations, ascribed by *Okuyama* et al.[48] to the rearrangement reaction.

$$k_{obs} = \frac{k_{max} \cdot K_h [RSH]}{(1 + K_h [RSH])} \tag{9}$$

At low thiol concentrations $K_h[RSH] \ll 1$, and we obtain equation (10).



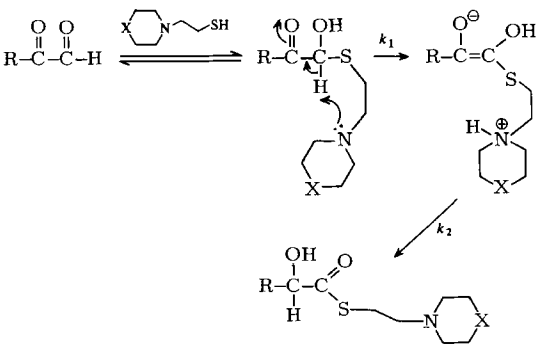
$$k_{obs} = k_{max} \cdot K_h [RSH] \tag{10}$$

Hence the primary isotope effect $k_{obs(H/D)}$ (e.g. comparing PhCOCHO in H_2O with PhCOCDO in D_2O) is given by equation (11)

$$k_{obs(H/D)} = k_{max(H/D)} \cdot K_{h(H/D)} \tag{11}$$

For phenylglyoxal a value of 6.1 for $k_{max(H/D)}$ is obtained for the rearrangement using a value of 2.3 for $k_{obs(H/D)}$ (assuming that the primary isotope effect will not be greatly affected by the solvent change) and using a value[48] of 0.38 for $K_{h(H/D)}$ (assuming that the change from PhCOCHO to PhCOCDO will not affect the value of K_h as much as the change from H_2O to D_2O). This k_{max} value is in line with extensive hydrogen transfer in the transition state but does not distinguish between hydride and proton transfer. However, the products is formed (in D_2O from PhCOCHO) with deuterium incorporated at the α-position (PhCD(OD)COSR) consistent with a proton transfer pathway as suggested by *Hall* et al.[58].

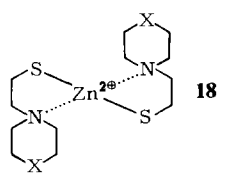
It is known that flavins are able to trap transient enediols oxidatively, while they do not serve as efficient hydride acceptors[59]. This implies that, if the reaction proceeds via an enediol intermediate, added flavin should inhibit the rearrangement and effect oxidation. In the presence of tetra-*O*-acetyl-3-methylriboflavin the rearrangement of hemithioacetals to α-hydroxythioesters was almost totally inhibited and the products were α-keto acids[59]. In accord with the results of *Hall* et al.[58], this finding supports the idea that the rearrangement occurs via an enediol intermediate [eq. (12)].



(12)

Kinetic studies established that the oxidation by the flavin was zero order with respect to flavin and first order with respect to thiols and glyoxals. Thus the reaction sequence consists of the rate-limiting deprotonation of the hemithioacetal to form the enediol intermediate, followed by its rapid oxidation by the flavin. The k_H/k_D values of 5—12 for C_6H_5COCHO/C_6H_5COCDO are apparently consistent with this proposal[59].

3.2.3. Intramolecular Catalysis



Franzen showed early on that β-amino-substituted thiols are effective intramolecular catalysts[55-57]. The Franzen catalysts (2-dialkylaminoethanethiols) have been reinvestigated kinetically and the reaction proceeds via a hemithioacetal initially formed between the catalyst and phenylglyoxal[60]. This hemithioacetal then rearranges in a general base catalyzed process to afford the product thioesters.

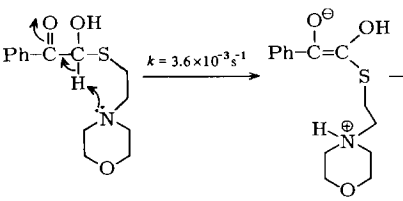
It was proposed that for X = O the rate-determining step was an intramolecular deprotonation (k_1) to form the enediolate. For X = CH_2, the rate-determining step at pH < 8 was deprotonation to form the enediolate, but at pH > 8 it was suggested that the rate-determining step was reprotonation of the enediol at C-2 (k_2) to give the thioester. Compared to intermolecular catalysis of the hemithioacetal rearrangement by amino groups[48], the intramolecular process shows low effective molarities (30 M (X = O) and 90 M (X = CH_2)). Low effective molarities are common for intramolecular general base processes[68], in line with this view.

3.2.4. Metal Ion Effects

In an early paper, *Hall* and *Poet* reported a highly effective catalysis by divalent metal ions of the rearrangement of hemithioacetals to thioesters in non-aqueous systems[61] which was not effective in aqueous media[58]. The absence of metal ion catalysis in aqueous media has been confirmed and proposed[60] to arise from inhibition of hemithioacetal formation since the 2-(dialkylamino)ethanethiol sequesters the metal ion as complex **18**.

18

On the basis of these results, the authors proposed[60] that the active site of glyoxalase is sufficiently nonpolar to be subject to metal ion catalysis and is highly protected against water molecules. While it is certainly the case that the active site of glyoxalase contains a large hydrophobic pocket[11,17,19-22,29,32,33] in the region of the "enediol" site (the S-site[69]), it has been reported that the metal ion in the active site of Mn^{II}-glyoxalase I binds two water molecules. Indeed, a mechanism has been proposed which incorporates both of these water molecules[70]. It is likely that the prevention of effective hemithioacetal formation in vivo or in the presence of the enzyme system by complexation of metal ions by glutathione presents fewer problems than in model systems. The metal ion active site of glyoxalase stereoselectively binds one of the diastereomeric hemithioacetals in preference to free GSH[95]. In the cell the lever of free GSH is likely to vastly exceed the levels of divalent metal ions freely available in the cell.



3.2.5. Conclusions from Model Systems

Whereas the intramolecular Cannizzaro reaction of arylglyoxals in sodium hydroxide is a hydride transfer, the analogous rearrangement of the hemithioacetals from α-ketoaldehydes to α-hydroxythioesters occurs via a proton transfer involving an enediolate intermediate as well as carbanion species. The rate-determining step may be deprotonation of hemithioacetal to the enediolate ion or reprotonation of the enediol at C-2 to afford an α-hydroxythioester, depending on the nature of the 2-(dialkylamino)ethanethiol catalyst. Metal ion catalysis is only significant in nonaqueous media.

The thiol presumably stabilizes the carbanion formed upon deprotonation of the hemithioacetal at C-1 (cf. mandeloylimidazole **17**, e.g., does not rearrange[58]). This deprotonation is assisted by the neighboring RCO-group.

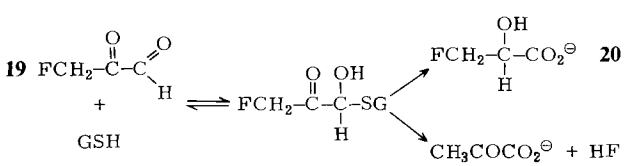
3.3. Rate of Glyoxalase I Reaction

The v_{max} values for glyoxalase I are relatively independent of the nature of the α-ketoaldehyde, but do depend on the species from which the enzyme was isolated. For methylglyoxal and glyoxalase I isolated from rat liver, k_3 (the turnover number) has been reported[71] to be 2×10^3 sec^{-1} and about 1×10^3 sec^{-1} for the enzyme from human erythrocyte[72]. In a model system[60] in which the hemithioacetal of phenylglyoxal and *N*-(2-mercaptoethyl)morpholine rearranged as shown in equation (13) to the corresponding thioester of mandelic acid the rate constant was 3.6×10^{-3} sec^{-1}.

(13)

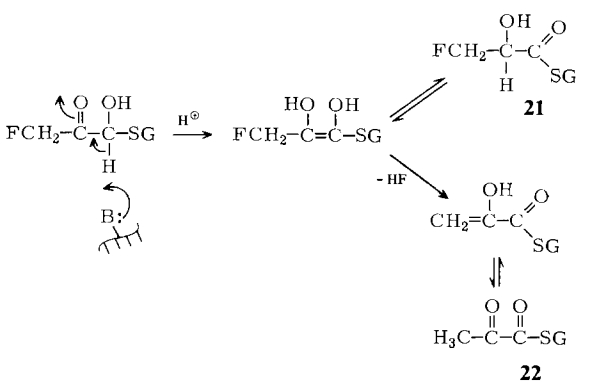
Even if rate-determining steps differ, in the unimolecular step the enzyme reaction is at least 10^6-fold faster than in the model system. The comparison is useful only if, as appears likely, both enzyme and model reactions follow the enediol route. If bimolecular rate constants of the glyoxalase I reaction (k_{cat}/K_m for glyoxalase[71] $= 4 \times 10^6$ M^{-1} sec^{-1}) and the *N*-methylmorpholine-catalyzed rearrangement[48] of the hemithioacetal from phenylglyoxal and 2-mercaptoethanol to thiomandelate ester ($k_B = 4.5 \times 10^{-4}$ M^{-1} sec^{-1}) are compared, the rate advantage of glyoxalase I is of the order of 10^{10}—a powerful catalysis.

4. Mechanism of the Enzyme Reaction

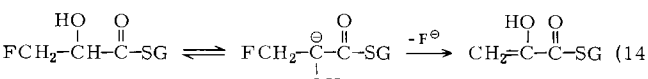


4.1. Proton Exchange

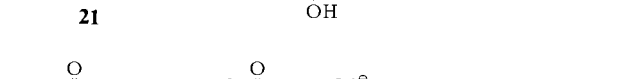
Assuming that the hemithioacetal is the substrate for the enzyme, a mechanism involving either a hydride transfer or proton transfer (enediol) can be envisaged. These two



possibilities are usually distinguished in classical organic chemistry by a straightforward isotopic tracer experiment. The hydride route is indicated by absence of incorporation of a hydrogen isotope from labeled solvent into the product. Exchange into the product from labeled solvent is consistent with a proton transfer (the enediol) mechanism. For enzymes the situation is complicated by the problem of "buried bases"; these bases lie in the interior of the enzyme and can be totally protected against free proton exchange with the solvent either by the presence of tightly bound substrate or by the conformation of the protein itself. An added complication arises for substrates which are weakly acidic, e.g. CH acids. The rates of exchange of some of these substrates at neutrality can be quite slow. Consequently, lack of proton exchange for enzymic catalysis is not strong evidence for a hydride transfer.

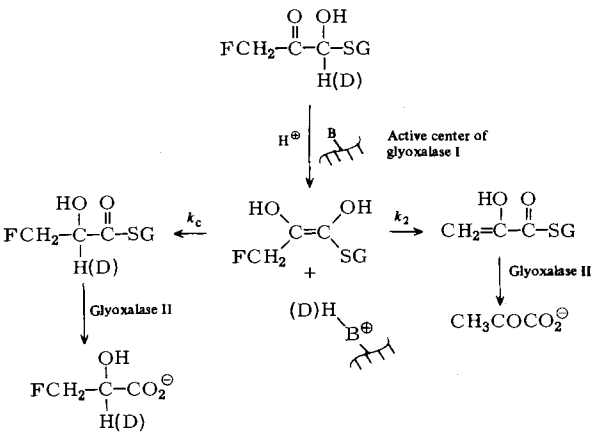


For glyoxalase I the hydride mechanism has been preferred until quite recently because of some early experiments which showed little, if any, deuterium (3% maximum)[55] or tritium incorporation (4%)[73] into the lactic acid product. However, at higher temperatures some recent NMR results have detected deuterium incorporation (ca. 15% at 25°C and ca. 22% at 35°C) into the lactate upon addition of glyoxalase II, which cleaved the initially-formed *S*-lactoylglutathione[74]: neither lactic acid nor *S*-lactoylglutathione incorporated deuterium under these conditions. In support of this, *Rose*[73] has reported no deuterium incorporation from solvent for *S*-lactoylglutathione. However, it has recently been reported that very high concentrations of glyoxalase I (human erythrocyte) catalyze H/D exchange at the C–H group in *S*-lactoylglutathione[78]. H/D Exchange for yeast glyoxalase I using phenylglyoxal/D_2O or [1-D]-phenylglyoxal/H_2O has also been reported[74]. If the glyoxalase I reaction does indeed proceed with isotopic incorporation, especially at higher temperatures[75], a shielded enzymic base and proton transfer mechanism may be indicated[*]. In the glyoxalase I catalyzed formation of fluorolactate from fluoromethylglyoxal (both [1-H] and [1-D]) practically no H/D exchange was observed[77].

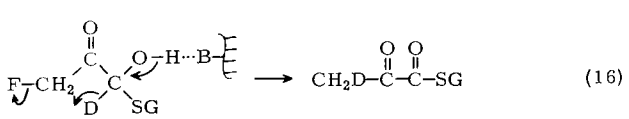


Kozarich et al.[78] have used fluoromethylglyoxal **19** as a substrate for yeast glyoxalase I and reported that, in addition to the normal enzymatic product (after glyoxalase II-catalyzed conversion to fluorolactate), pyruvate is also formed via elimination of HF.

This was explained[78] by postulating that a part of the enzymically-produced enediolate is reprotonated normally at C-2 and another part is converted by elimination of fluoride ion into the enol form of *S*-pyruvoylglutathione[78]. The same amounts of fluoride ion and pyruvate were produced, consistent with this hypothesis. More difficult to explain is the observation that thioester formation (followed at 240 nm) is complete long before $F^{\ominus}$ elimination. Whilst formation of **21** could be independent of $F^{\ominus}$ elimination, formation of **22**, also a thioester, should parallel it (or perhaps occur more slowly if the keto-enol transformation is slow). Moreover, the authors[78] point out in a footnote that the *S*-pyruvoylglutathione might arise fortuitously by an enzyme-catalyzed elimination of HF from **21** (which, need not have formed via an enediol). The reported reversibility[72] of the glyoxalase I reaction and the exchange of the lactate hydrogen atoms[76] (which should be easier for the fluorolactate **20**) in *S*-lactoylglutathione with glyoxalase I is consistent with this view. As pointed out[78], this "fortuitous" base effect in glyoxalase could also explain the low levels of hydrogen isotope incorporation. It is possible[77] that *S*-(fluorolactoyl)glutathione **21** undergoes nonenzymic β-elimination [eq. (14)]. The α-hydrogen of thioesters is markedly acidic and eliminations for such esters are known, although these usually involve thiol elimination[79–82] [eq. (15)].



In an elegant analysis, *Chari* and *Kozarich*[77] suggested that it was conceivable that the enzymic reaction was a hydride transfer followed by an active-site dependent process. This "fortuitous" base could effect the proton exchange of *S*-lactoylglutathione with solvent or the elimination of fluoride ion from *S*-(fluorolactoyl)glutathione. In either case, they argued, the competing process would be release of product from the enzyme. They defined a partition ratio as the ratio of fluoride ion released from fluoromethylglyoxal/GSH by glyoxalase I and glyoxalase II (i.e. total fluoride releasable)[77]. They then studied the effect of deuterium substitution at C-1 of fluoromethylglyoxal and found that when [1-D]-fluoromethylglyoxal was used instead of the [1-H]-compound, the amount of fluoride ion released (i.e. the partition ratio) significantly increased for glyoxalase I from a number of species. *Chari*

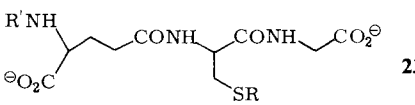


[*] As pointed out by *W. P. Jencks*, exchange at higher but not at lower temperatures is also in accord with an inherently slowly exchanging base, i.e. not specially "protected" from the environment. See: W. P. Jencks: *Catalysis in Chemistry and Enzymology*, McGraw-Hill, London 1969.

and *Kozarich* proposed that this could only be explained in terms of the enediol mechanism, as outlined in Scheme 3[77].

Scheme 3.

Any primary isotope effect in the formation of the enediol will not affect its subsequent partitioning to *S*-(fluorolactoyl)glutathione and *S*-pyruvoylglutathione. Solvent exchange of the active-site base is slow and the rate constant for fluoride elimination k_e should be largely the same irrespective of whether deuterium or hydrogen is present on the active-site base. However, the normal substrate conversion to *S*-(fluorolactoyl)glutathione k_c requires reprotonation by the active-site base at C-2, which is subject to a primary isotope effect. Thus, at the partitioning stage of reaction with this substrate analogue the presence of a deuterium will decrease the rate of formation of normal product relative to the protio-substrate whilst the fluoride elimination step should not be much affected by the H/D substitution. The net result would be a relative increase in the amount of fluoride eliminated for the deuterio substrate. The hydride transfer mechanism[77] predicts the opposite effect. However, if as in equation (16) one writes the fluoride elimination as a hydride (or deuteride) transfer, both normal substrate conversion (hydride transfer to C-2) and fluoride elimination (hydride transfer to C-3) are subject to (different) primary (H/D) isotope effects, making diagnostic use of the "partition" effect difficult. In this mechanism, however, deuterium labeling of the substrate would afford a deuterium labeled methyl group in the pyruvate formed, assuming that pyruvoylglutathione and pyruvate did not undergo H/D exchange at C-3 under the reaction conditions.



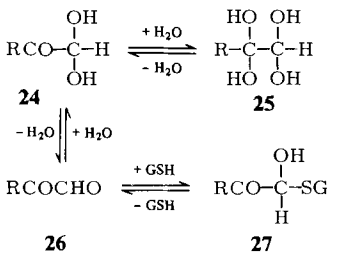
(16)

The trapping of the enediolate species in the nonenzymic rearrangement of hemithioacetals to α-hydroxythioesters by flavins has now been applied successfully[83] to the glyoxalase I catalyzed reaction. Since flavins do not function as hydride ion traps, an intermediate enediolate species is the most likely explanation. It has not yet been established whether the enediolate trapped is intercepted while still bound to the enzyme or reacts in the free form.

4.2. Role of the Metal Ion in the Active Center and Enzyme Flexibility

Early work suggested that glyoxalase I was a $Mg^{2\oplus}$-dependent enzyme[84], but it has now been established[85,86] that both yeast and mammalian enzymes are Zn-metalloenzymes. Yeast glyoxalase I is not amenable to metal ion replacement, in contrast to the mammalian enzyme[84–90]. Recently, zinc has been shown to be at the active site and it has been replaced by $Mn^{2\oplus}$ and $Co^{2\oplus}$ for spectroscopic studies[70,76,91]. High-resolution NMR studies of the $Mn^{2\oplus}$-enzyme with the bound product *S*-lactoylglutathione and the competitive inhibitor *S*-acetonylglutathione have indicated that in these complexes the oxygen atoms of the lactoyl and acetonyl groups are not in the first coordination sphere of the metal[76]. However, the structure of an enzyme/product or enzyme/inhibitor complex need not closely resemble the structures of either the enzyme/substrate complex or of any complexes involving high energy intermediates (e.g. enediols). There is considerable evidence for conformational flexibility in glyoxalase I. For example, fluorescence studies indicated a conformational change of the native enzyme on binding the strong competitive inhibitor *S*-(*p*-bromobenzyl)glutathione[89], and the EPR spectrum of the Co^{II}-enzyme is slightly perturbed on binding this inhibitor[91]. We have detected the perturbation on inhibitor binding of a tyrosine residue on yeast glyoxalase I by difference CD spectra[92] although there are no major peptide backbone changes in this process. Chemical evidence for flexibility in the glutathione-based peptide inhibitor backbone and/or glyoxalase I itself has been obtained[69] using a series of *N,S*-substituted glutathiones **23**.

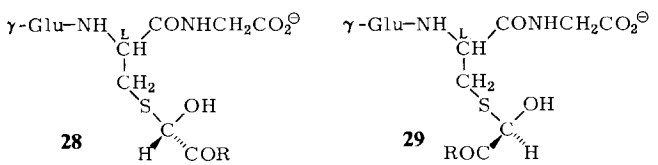
23



All of these derivatives proved to be competitive inhibitors but the degree of weakening of K_i for various *N*-acylations (e.g. on proceeding from $-NH_3^{\oplus}$ via $-COCH_3$ to $-COPh$) depended markedly on the substituent at the sulfur atom (comparing $SCH_2-C_6H_4-Br(p)$ and $SCH_2-C_6H_4-CF_3(m)$). Further indications of protein flexibility have been obtained from comparisons of steady-state and equilibrium binding parameters[93,94]. In addition, K_i values for *S*-(*m*-trifluoromethylbenzyl)glutathione[66] and *S*-(*p*-bromobenzyl)glutathione[33] are pH-independent for yeast glyoxalase I. In view of the significant effects[67] of pH on v_{max}/K_m and on K_m, such insensitivities of K_i values are surprising and possibly indicate that the enzyme can exist in more than one conformation. According to NMR studies, the bound conformations of *S*-lactoyl- and *S*-acetonylglutathione also differ[76].

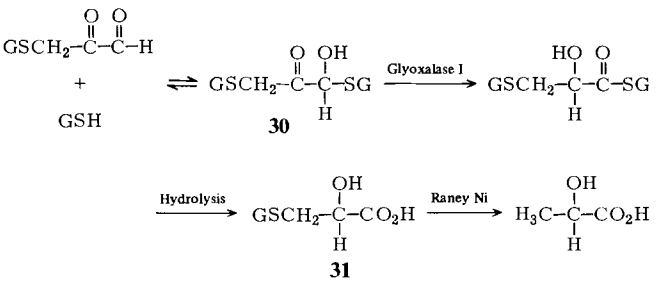
Because of this possible conformational flexibility the role of the metal ion in glyoxalase I should be considered in more detail. Is the metal ion directly bonded to substrate oxygens at the S-site or do these oxygen atoms lie in the second coordination sphere of the zinc? It is reasonably well established[89–91] that the metal ion lies in the active site, quite close to the S-site. It is unlikely to be coordi-

nated to the N-terminal site of the glutathione substrate in view of NMR studies (which also exclude the Glu α-CO_2 site). The rather small effect of *N*-acetylation of inhibitors and substrates on the K_i value also suggests this[67,69]



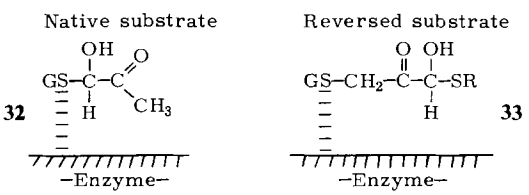
4.3. Stereochemical Aspects

It has already been pointed out that the nature of the glyoxalase I substrate is not yet fully clear. α-Ketoaldehydes exist largely as their hydrates (**24**, **25**) and not as the free aldehyde (**26**). Thus, equation (17) is a more realistic representation than equation (1). For phenylglyoxal, only

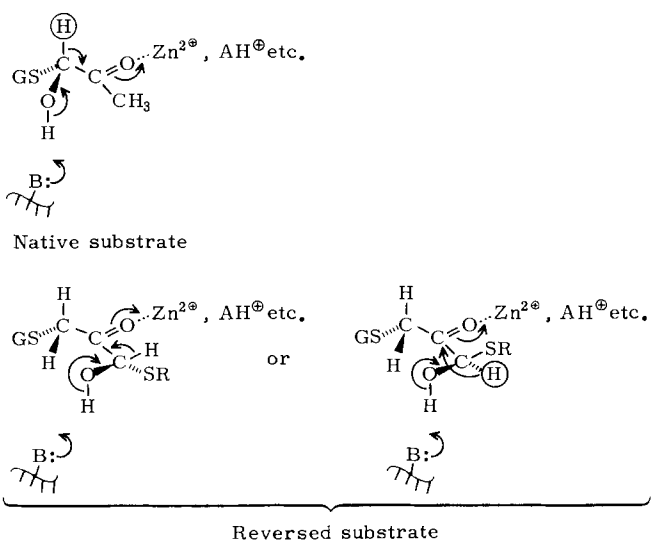


(17)

the monohydrate **24** was detectable by ^{1}H- and ^{13}C-NMR spectroscopy[95]. Three basic mechanisms have previously been proposed for glyoxalase I. In the two-substrate mechanism[18] the substrates are the free aldehyde form of the α-ketoaldehyde and GSH. For the one-substrate mechanism the substrate is the hemithioacetal[19]. The third possibility is a hybrid route, i.e. a branching, alternative one- and two-substrate mechanism in which the one-substrate is the hemithioacetal and the first of the two-substrates is GSH, with the α-ketoaldehyde the second[96]. The hemithioacetal from GSH and phenylglyoxal exists in two diastereomeric forms (see **28**, **29**, R = Ph) which can be detected by high resolution ^{1}H-NMR spectroscopy[95]. Addition of glyoxalase I at pD 4.4 led to selective disappearance of the signals from one of the diastereotopic methine protons (lower field signal). This directly establishes the asymmetric binding of the hemithioacetal as the origin of the stereospecificity of the glyoxalase I reaction, leading to formation of (*S*)-D-mandeloylglutathione[97] and (*S*)-D-lactoylglutathione[98]. If the enzyme mechanism involves a *cis*-enediolic intermediate or transition-state, the base of the enzyme's active site removes the proton from the (*S*)-configuration **28**. For a *trans*-enediol the (*R*)-configuration **29** would be the substrate involved. For a hydride transfer, assignment would not be possible.



An interesting stereochemical trick has been performed with glyoxalase I[99]. The normal product from methylglyoxal[48] or phenylglyoxal[97] is the D-isomer of *S*-lactoylglutathione or *S*-mandeloylglutathione. The hemithioacetal formed between GSH and (glutathiomethyl)glyoxal, **30**,

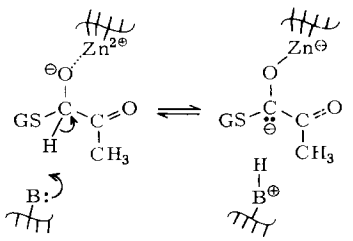


is also a substrate for yeast glyoxalase I and forms a thioester which is hydrolyzed to the 3-(glutathione)lactic acid **31**. Its stereochemistry was determined by Raney nickel desulfurization (relative amounts of D- and L-lactic acid determined by D- and L-lactate dehydrogenases).

Compound **30** gave predominantly D-lactate as might be expected. However, the hemithioacetals of **30** with ethanethiol and β-mercaptoethanol were also substrates, and this procedure (with mild base cleavage of thioesters) affords predominantly (≈4:1) the L-lactic acid - the opposite stereochemical result. Clearly, for the ethanethiol and β-mercaptoethanol binding of the hemithioacetal occurs in the opposite sense to that of the normal substrate, in each case binding specificity being determined by the glutathione moiety (see **32** and **33**)[99].

Although the authors rationalized their results in terms of the enediol mechanism[99], they can equally be explained by a hydride transfer route (Scheme 4).

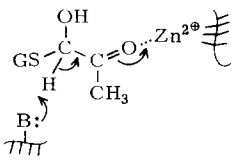
Scheme 4. $AH^{\oplus}$ = acid.



Immobilized forms of glyoxalase I and II have been used to synthesize optically active α-hydroxy acids from α-ketoaldehydes in high enantiomeric excesses[100].

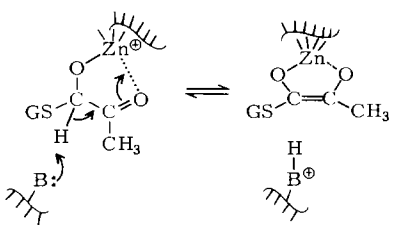
4.4. Possible Mechanisms for the Glyoxalase I Reaction

The balance of evidence favors a proton-transfer pathway with an enediolate intermediate, and the discussion will be based on this. Two extreme types of mechanism must be considered: a) The substrate is bound directly to the active-site of the metal ion ($Zn^{2\oplus}$). b) The substrate is in the second coordination sphere.



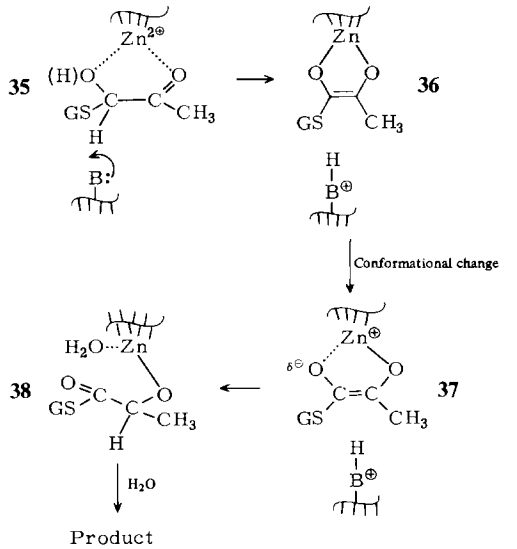
4.4.1. Substrate in the First Coordination Sphere of $Zn^{2\oplus}$

$Zn^{2\oplus}$ can bind to the substrate either via the oxygen atom at C-1 or that at C-2. In the first case the carbanion (and the transition-state) formed by deprotonation at C-1 is stabilized [eq. (18)].



(18)

In the second case ionization of an enediolate intermediate is markedly supported by polarization of the ground state and by stabilization of the transition state (see **34**).

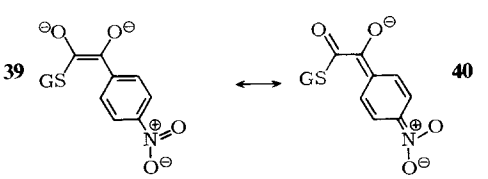


34

Finally, chelate binding via both oxygen atoms is possible. As is evident from equation (19) this would combine the C–H bond activation and transition-state stabilization.

(19)

Enediols form stable metal complexes, and at first sight such a reaction seems attractive. However, formation of a symmetrical $Zn^{2\oplus}$-enediolate of this type raises problems: If, as seems most reasonable, $Zn^{2\oplus}$ binding with the substrate is arranged to facilitate deprotonation and formation of enediol by chelation, then the converse process, reprotonation at C-2 to give product must be impaired by such a chelate. If a chelated enediol transition state were to form there would have to be a minor configurational change at the active-site to distort the chelate geometry (to favor reprotonation at C-2) and to realign the protonated base. Scheme 5 shows a reasonable minimal scheme for such a mechanism.

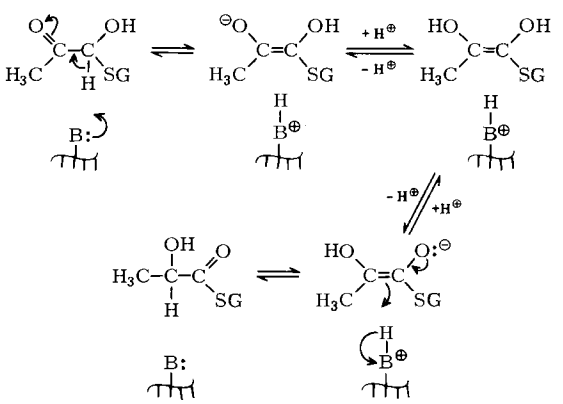


Scheme 5.

In this scheme, substrate binds with (**35**) $Zn^{2\oplus}$ facilitating proton transfer from C-1 to the buried active-site base B either by binding to C-1–O (protonated or deprotonated) and/or to C-2=O. Proton transfer leads to the almost symmetrical Zn-enediol chelate **36** (probably deprotonated at both oxygens as metal ions lower –OH pK_a values significantly). There may be considerable strain in such an enediol-$Zn^{2\oplus}$ chelate in view of the size of $Zn^{2\oplus}$ and this may aid the next step which is a conformational change to allow selective binding of Zn to the oxygen of C-2 aiding reprotonation by $-BH^{\oplus}$, which has been reoriented for attack at C-2, **37**. B might be a carboxylate ion which can transfer the proton that it sequesters from C-1 to C-2 by a simple rotation, as is known for triosephosphate isomerase[102]. The mechanism formulated in Scheme 5 requires a *cis*-enediol, for which there is no direct evidence[24–26] (but see Appendix).

In principle the first two mechanisms are possible for a *trans*-enediol bound only via one oxygen atom. The problems of a symmetrically chelated enediol-$Zn^{2\oplus}$ complex favoring deprotonation but inhibiting reprotonation are clearly not present for the *trans*-enediol mechanism, since no chelate is formed.

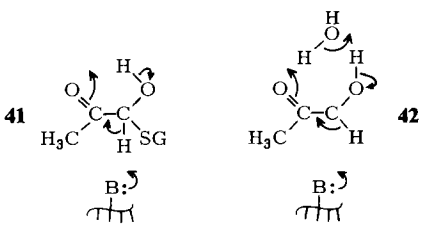
A mechanism involving partial or completely rate-determining deprotonation at C-1 to form the enediol intermediate is consistent with the observed[67] kinetic primary deuterium isotope effect at C-1 ($k_{cat}^{H}/k_{cat}^{D}=3.2$). However, it is difficult to reconcile such a mechanism with the absence of substituent effects reported[54] for substituted phenylglyoxals (k_{cat} varies approximately only 4-fold for ten of these compounds, including methylglyoxal). The enediol intermediate and, from the Hammond postulate, the transition state leading to it, should be stabilized by electron-withdrawing groups—especially if ionized at C-1—because of the conjugation in **39/40**. Furthermore, if such an interaction were to occur one would expect a correlation between the reaction rates and the Hammett σ^--constants.



It is possible, however, that the enediolate is stabilized by the metal atom and that this "swamps" such resonance effects, or that there is rate-determining deprotonation of C-1–H. Reprotonation of the enediol at C-2 would also be expected to exhibit marked substituent effects, since the resonance interaction would be lost on protonation. The absence of substituent effects is consistent with the hydride mechanism[67], or with a rate-determining conformational change of the enzyme (e.g. on substrate binding, in the switch in site of enediol-metal polarization or on rate-determining product desorption), or rate-determining deprotonation at C-1–H.

4.4.2. *Substrate in Second Coordination Sphere of* $Zn^{2\oplus}$

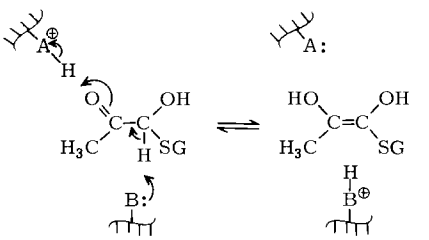
In the previous section we discussed the range of mechanistic options available to glyoxalase I if the metal ion is directly coordinated to the ketoaldehyde oxygen atoms of the substrate. Recent NMR evidence indicates that these oxygen atoms lie in the second coordination sphere of the metal ion in the enzyme-product[76] and enzyme-*S*-acetonylglutathione complexes[103]. We shall now discuss the possible mechanisms available.



Reactions Involving a Single Base

A single base probably deprotonates C-1 which has been activated by the adjacent sulfur atom and possibly by $Zn^{2\oplus}$ polarization (Scheme 6).

Scheme 6.

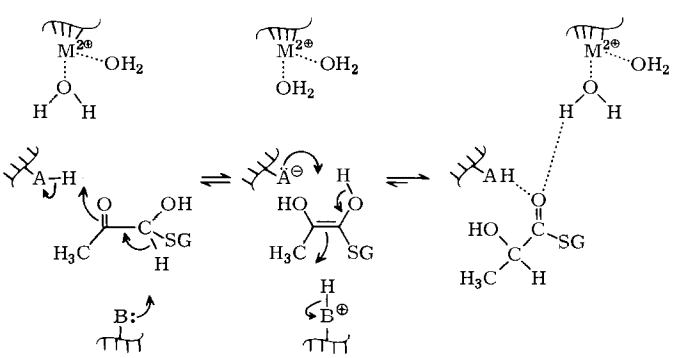


For the overall reaction a series of proton transfers is necessary. These may be avoided in the case of a *cis*-enediol either by direct "intramolecular" proton transfer (**41**) or by a water-mediated analogue (**42**).

The base B can either be an amino acid side-chain or $[Zn(OH)]^{\oplus}$. In the water-mediated proton transfer the H_2O molecule may be Zn-bound, but this would require that the Zn simultaneously act as a source of hydroxide ion (base) and promote proton donation by water.

Reactions Involving One Acid and One Base

The cooperative action of an active-site acid and base is possible for either a *cis*- or *trans*-enediol intermediate (Scheme 7) (the Zn-bound water molecule is a special case of $AH^{\oplus}$).



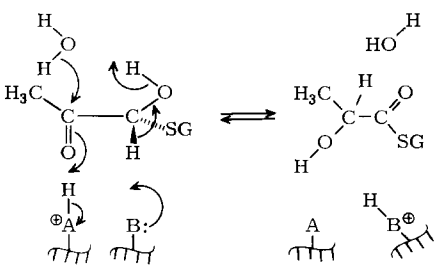
Scheme 7.

Deprotonation at C-1 would then rely on the acidity of the OH group; the minor conformational change necessary to relocate B for protonation at C-2 might also relocate A for deprotonation of C_1–OH. If $AH^{\oplus}$ in Scheme 7 were $[Zn(H_2O)]^{2\ominus}$, it could serve not only as an acid-base catalyst in the Brønsted sense by activating proton transfers but also as a Lewis acid by polarizing the substrate for the initial C–H cleavage.

Mechanisms of this type, in which the substrate is located in the second coordination sphere of the metal ion, i.e. with an intervening water molecule or hydroxide ion, have been proposed for a number of metalloenzymes[104].

One mechanism suggested by *Sellin* et al.[76] is shown in Scheme 8. In addition to the proton shift from C-1 to C-2

Scheme 8.



there is also a proton transfer to the keto site of the hemithioacetal substrate, which is converted into an –OH group during catalysis. The authors suggested[76] that although a metal-bound water molecule could polarize the carbonyl site, protolysis of the bound water could not supply the proton transferred to the oxygen of the substrate keto group as proton dissociation from $Co^{2\oplus}$, $Zn^{2\oplus}$, $Mn^{2\oplus}$ and $Mg^{2\oplus}$ (based on pK_a values) is orders of magnitude slower than is v_{max} for glyoxalase I[76]. However, proton transfer from an enzyme-bound acid to an essentially contiguous *enzyme-bound* base within the confines of an active site is effectively an intramolecular reaction and will

be limited not by diffusion rates or other bimolecular features, but will be a unimolecular rate constant. The upper limit on unimolecular rate constants is ca. 10^{-13} sec^{-1}, determined by the vibration frequency of the molecular bonds. Clearly, intramolecular proton transfers between neighboring electronegative atoms could be very rapid indeed relative to v_{max} for the enzyme reaction, and the AH species in Scheme 8 may yet be a metal-bound water molecule buried under the substrate. The authors also suggested that AH may be the OH group of the substrate[76] (cf. **41**).

An alternative second sphere mechanism has also been proposed by *Sellin* et al.[70]. This pathway involves participation of two ligand water molecules on the metal ion and incorporates a conformational change associated with product formation. Fluorescence studies suggest that the hemithioacetal substrate, glutathione itself, or the competitive inhibitor *S*-(*p*-bromobenzyl)glutathione, but *not* the product *S*-D-lactoylglutathione induces a conformational change on binding to the enzyme. Using circular dichroism, we have detected a minor configurational change in a tyrosine residue on binding *S*-(*p*-bromobenzyl)glutathione to yeast glyoxalase I[105].

Concerted Proton Transfer

In principle, there would be no need for an enediol intermediate if the proton transfer were concerted, as shown in Scheme 9. However, such a mechanism is not consistent with the lack of hydrogen exchange with solvent, nor with the flavin reduction studies in which a carbanion was trapped.

Scheme 9.

5. Summary and Prognosis

It is now clearly established that the substrate of glyoxalase I is the α-ketoaldehyde-derived hemithioacetal of glutathione, which is converted into *S*-D-lactoylglutathione by a proton transfer mechanism and not via a hydride ion route. There is a good body of evidence now implicating an enediolate intermediate. Armed with such knowledge, the avenue is clear for the design of novel tailor-made inhibitors. The inhibition of glyoxalase I by cytotoxins appears promising, at least in tissue culture. Antiglyoxalase I activity in a compound is, at the very least, a useful prescreening step in the search for elusive biological activity.

A number of questions remain. Does antiglyoxalase I activity cause the cytotoxic activity of some of these compounds, either as the sole or as a contributing factor? Can very powerful and specific inhibitors be designed to help such studies? In line with this question are some basic remaining problems about the mechanism of action of glyoxalase I. Is the enediol a *cis*- or *trans*-compound? Which diastereomer is the substrate? Does catalysis require one, two, or indeed any of the water ligands detected by NMR spectroscopy at the active-site metal? How is the conformational flexibility of the enzyme related to mechanism? Does the dimeric nature of mammalian glyoxalase I, in contrast to monomeric structure of the yeast enzyme, hold any functional significance? The application of powerful modern techniques (e.g. NMR) has already shed considerable light on aspects of the interaction of products with the enzyme and on the nature of the metal site. It is to be hoped that the rapid progress in recent years in this field continues apace.

6. Appendix

After completion of the manuscript a number of aspects of the glyoxalase I mechanism have been clarified. The conformations of four derivatives of glutathione bound at the active site have been computed from NMR data. The tripeptide inhibitors were found to be bound in an extended Y-shape, reminiscent of the structure of GSH determined by theoretical calculation and by X-ray diffraction. The distances between the active-site and the metal substrate- and product-complexes are different; an ionic inhibitor *S*-(methoxycarbonyl)glutathione was bound in the third coordination sphere, in contrast to the second coordination sphere occupancy of other bound inhibitors[106]. In addition, there has been a report of nonstereospecific substrate conversion by glyoxalase I[107], which implies that the enzyme can convert one of the substrate diastereomers into the other, yielding the *cis*-enediol intermediate, and this intermediate has now been detected by NMR spectroscopy[108]. Theoretical calculations have been carried out on the structure of the transition state mimics of glyoxalase I such as maltol[109]. Finally, EXAFS studies have revealed some of the ligands around the Zn atom of the active site[110].

[105] A. P. Seddon, Ph. D. Thesis, University of Essex 1982. We have also discovered in preliminary studies that yeast glyoxalase I is sensitive to the nitration of tyrosine by tetranitromethane. The rate of loss of enzyme activity on nitration depends on an ionization ($pK^{app} \approx 7.5$); this deactivation is efficiently protected against by the competitive inhibitor, *sp*-bromobenzylglutathione. This probably indicates that the tyrosine (detected by the peak at $\lambda \approx 400$ nm after nitration and G-25 gel filtration) lies in a crucial segment of the enzyme, probably the active site (S. Carrington, K. T. Douglas and D. I. Gohel, unpublished).

A Simple Notation System for Transition-Metal Clusters**

By *Tien-Yau Luh**, *Henry N. C. Wong*, and *Brian F. G. Johnson*

The description of the spatial distribution of metals and ligands in metal clusters is a nontrivial problem[1]. Here, we wish to propose a relatively simple system of notation which hopefully will facilitate a more useful method of describing clusters.

There are ample examples in the literature demonstrating that the ligands in clusters occupy positions that define the vertices of regular and semiregular polyhedra[2,3]. One of us has used Föppl notation[4] to illustrate the structure and fluxional behavior of carbonyl ligands in various clusters[2,3]. This approach considers a metal polyhedron[5] sitting inside a ligand polyhedron envelope. We felt that this concept can be used to represent cluster structures pictorially, and formulate the following rules:

Rule 1. The structures of metal and ligand polyhedra are described by appropriately modified Föppl notation (Table 1) written in sequence in square brackets with a hyphen between the brackets. The notation therefore has the general form $[m_1:\ldots m_p:\ldots:m_n]$-$[l_1:\ldots:l_i:\ldots:l_z]$.

Table 1. Modified Föppl notation [2—4].

n	designates a planar polygon with n vertices.
(n)	designates a planar polygon with n vertices which is in an anti-prismatic configuration to a previously assigned n-vertex polygon [a].
n′	designates a polygon of n vertices which is not strictly planar [b].

[a] Cf. rule 4 and Figure 1. [b] n′ must be even. An n′ polygon can therefore also be described as two anti-prismatic n′/2 polygons. For example, the chairform of a hexagon, which consists of two anti-prismatic triangles, is named 6′ rather than 3 : (3).

Rule 2. All metal polyhedra are numbered along the principal rotation axis.

Rule 3. A metal polyhedron is considered as a basic set. The orientation of the planes defined by the polygons in the ligand polyhedron is related to this basic set.

Rule 4. If the polyhedron is viewed along its principle rotation axis, two eclipsed lines, or one polygon[6] having at least one edge parallel to a line, or two polygons[6] having at least one pair of eclipsed edges are considered to be prismatic. Otherwise, they are denoted as anti-prismatic (see Table 1). Graphical representations of various arrangements are shown in Figure 1.

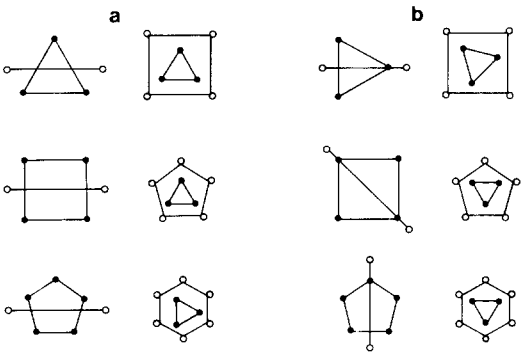

Fig. 1. Graphical representations of some a) prismatic and b) anti-prismatic arrangements.

Rule 5. The plane of the polygon (or the line) defined by the first number l_i greater than or equal to 2 in the modified Föppl notation of the ligand polyhedron should be parallel to the plane of the polygon (or the line) defined by the first number m_l greater than or equal to 2 of the metal polyhedron. Hence, the polygon m_l defines the orientation of the polygon l_i, which, in turn, defines the orientation of the rest of the polygons in the ligand polyhedron.

Examples of the application of these rules are given in Table 2. The notations for mononuclear metal complexes are straightforward (Nos. 1—3). The notation [1 : 1] rather than [2] is used to define the metal polyhedron in binuclear

Table 2. Notations for some metal clusters.

No.	Formula	Notation	Ref.
1	$Ni(CO)_4$	[1]-[1 : 3]	[7]
2	$Fe(CO)_5$	[1]-[1 : 3 : 1]	[8]
3	$Mo(CO)_6$	[1]-[1 : 4 : 1]	[9]
4	$Co_2(CO)_8$	[1 : 1]-[3 : 2 : 3]	[10]
5	$Fe_2(CO)_9$	[1 : 1]-[3 : (3) : 3]	[11]
6	$Mn_2(CO)_{10}$	[1 : 1]-[1 : 4 : (4) : 1]	[12]
7	$Mn_3(CO)_{14}^{\ominus}$	[1 : 1 : 1]-[1 : 4 : (4) : 4 : 1]	[13]
8	$Fe_3(CO)_{12}$ **2**	[3]-[(2) : 2 : (4) : 2 : (2)]	[33]
9	$Os_3(CO)_{12}$	[3]-[3 : 6 : 3]	[14]
10	$Re_3Cl_{12}^{3\ominus}$	[3]-[3 : (6) : 3]	[15]
11	$Ni_3(CO)_6^{2\ominus}$	[3]-[(6′)]	[16]
12	$Co_4(CO)_{12}$ **1**	[1 : 3]-[(3) : 6′ : 3]	[32]
13	$Ir_4(CO)_{12}$	[1 : 3]-[(3) : (6) : 3]	[17]
14	$Fe_4(CO)_{13}^{2\ominus}$	[1 : 3]-[(3) : 3 : 6 : 1]	[18]
15	$H_4Ru_4(CO)_{12}$	[1 : 3]-[(3) : (6) : 3]	[19]
16	$Re_4(CO)_{16}$	[4]-[4 : 8 : 4]	[20]
17	$HFe_4(CO)_{13}^{\ominus}$	[2 : (2)]-[4 : 1 : (4′) : 4]	[21]
18	$Ni_5(CO)_{12}^{2\ominus}$	[1 : 3 : 1]-[(3) : 6 : (3)]	[22]
19	$Fe_5C(CO)_{15}$	[1 : 4]-[3 : 8 : 4]	[23]
20	$Os_5(CO)_{16}$	[1 : 3 : 1]-[(3) : 3 : 4 : 3 : (3)]	[24]
21	$Mo_5Cl_{13}^{\ominus}$	[1 : 4]-[1 : (4) : (8′)]	[25]
22	$Ni_6(CO)_{12}$	[3 : 3]-[(6′) : (6′)]	[16]
23	$Pt_6(CO)_{12}$	[3 : 3]-[(6) : (6)]	[26]
24	$Co_6(CO)_{14}^{4\ominus}$	[1 : 4 : 1]-[1 : (4) : 4 : (4) : 1]	[27]
25	$Rh_6(CO)_{16}$	[1 : 4 : 1]-[2 : (2) : 4 : 4 : 2 : (2)]	[28]
26	$Os_6(CO)_{18}^{2\ominus}$	[1 : 4 : 1]-[3 : 6′ : (6′) : 3]	[29]
27	$[(Nb_6Cl_{12})Cl_6]^{2\ominus}$	[1 : 4 : 1]-[1 : 4 : (8) : 4 : 1]	[30]

metal complexes (Rule 2). Similarly, [1 : 1 : 1] is employed to represent a linear arrangement of three metal atoms.

The CO ligands in either $Co_4(CO)_{12}$ **1** (Table 2, No. 12)[32] or $Fe_3(CO)_{12}$ **2** (No. 8)[33] form an eicosahedron (Fig. 2). The notation for the metal polyhedron in **1** is [1 : 3] rather than [3 : 1]; $m_l = 3$. The ligand polyhedron can be

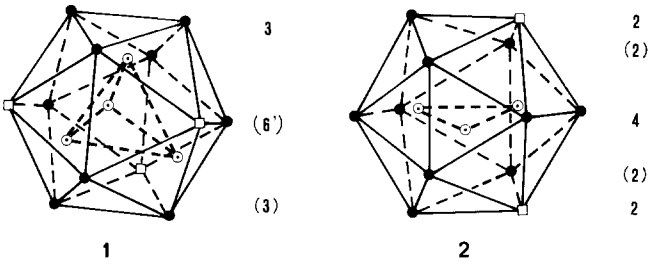

Fig. 2. Structures of $Co_4(CO)_{12}$ **1** and $Fe_3(CO)_{12}$ **2**. ⊙: Metal atom, ○: terminal CO ligand, □: bridging CO ligand.

represented by [3 : (6') : (3)], where $l_i = 3$ and the triangle defined by the last number (3) is anti-prismatic relative to that defined by l_i. Furthermore, the two triangles defined by m_l and by l_i are also anti-prismatic. It follows that the notation for **1** should be [1 : 3]-[(3) : 6' : 3]. It should be noted that the 6'-polygon in the ligand envelope is also anti-prismatic with respect to the 3-polygon, or triangle, in the metal polyhedron. In other words, three of the six vertices of the ligand 6'-polygon are anti-prismatic to the three vertices of the metal 3-polygon. Three CO ligands therefore function as bridging ligands. On the other hand, the ligand eicosahedron in **2** can be represented by [2 : (2) : 4 : (2) : 2], and l_i is anti-prismatic to the triangle defined by the three metal atoms. Hence, the notation for **2** should be [3]-[(2) : 2 : (4) : 2 : (2)].

At the present stage, interstitial atoms or groups and bridging hydrides are not included in our notation, since they do not, in general, affect the geometry of clusters (cf. Nos. 15, 17, 19 in Table 2)[31]; however, they can be treated as substituents[34].

To specify the structure of a metal cluster, we propose combining its formula and notation. For example, **2** can be written as $Fe_3(CO)_{12}$:[3]-[(2) : 2 : (4) : 2 : (2)] or triiron[3]-dodecacarbonyl[(2) : 2 : (4) : 2 : (2)].

In summary, using our notation cluster structures can easily be drawn and the nature of the ligands unequivocally assigned. We are currently extending this system to describe the structure of other heteronuclear and heteroligand clusters as well as nontransition-metal clusters such as boranes.

[5] The metallic part of a cluster may consist of one or more metal atoms. In what follows, for simplicity, the term "metal polyhedron" will designate not only polyhedra in the geometrical sense, but also isolated atom or groups of two or three atoms which, in this sense, are not polyhedra.
[6] Polygons need not necessarily be regular. They can also be puckered, and in this case the projection on the plane perpendicular to the principal rotation axis will be considered.

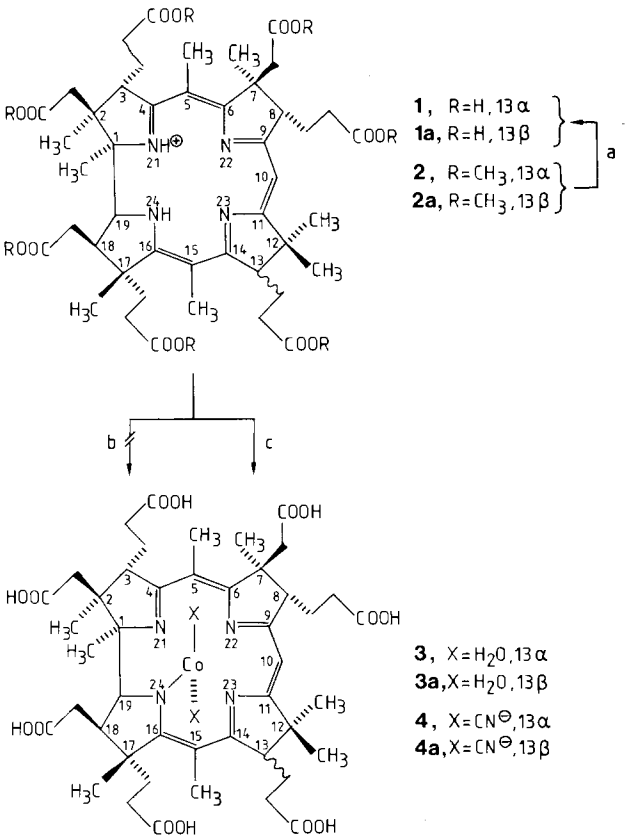
Hydrogenobyrinic Acid and Vitamin B_{12}**



By *Trutz E. Podschun* and *Gerhard Müller**

The final step in the biosynthesis of the vitamin B_{12}-precursor cobyrinic acid **3** could be the insertion of cobalt into the cobalt-free analogue, the so-called hydrogenobyrinic acid **1**. Compound **1** has hitherto never been detected, neither in studies on the biosynthesis of **3** nor in photosynthesizing bacteria, which form cobalt-free corrinoids[1a]. In order to check whether **1** is a precursor of **3**, we have converted the hydrogenobyrinic acid amides described by *Koppenhagen* et al.[1] into the free acids **1** and then allowed these to react with enzyme preparations which catalyze a cobalt insertion and enable the de-novo synthesis of **3**.

A mixture of mono-, di-, and triamides of **1** was prepared, as described in ref. [1b], using *Rhodopseudomonas sphaeroides* (yield: ca. 200 μg/L culture medium). Methanolysis of the amide mixture led to formation of a 3 : 2 mixture of the 13α- and 13β-hydrogenobyrinic acid heptamethyl esters **2** and **2a**, respectively, together with some byproducts. 1 μmol of the mixture of hydrogenobyrinic acid amides was allowed to react with 26.5 μmol $BF_3 \cdot 2MeOH$ in 11 mL MeOH for 48 h at 55 °C in the absence of light and oxygen. After addition of $CHCl_3$ the mixture was neutralized with $NaHCO_3$ and washed with

Scheme 1. [a]: 1 μmol **2** or **2a** in 2 mL 2M piperidine (degassed), 4 h, room temperature, in the dark. [b]: Enzyme + $^{57}Co(NO_3)_3$, pH 7, 32°C, 16 h [5]. [c]: 1 μmol **1** or **1a** + 1.5 μmol $Co(NO_3)_2$ in 2 mL NH_4OH, pH 11, 20 min boiling-water bath under argon, finally room temperature, pH 7 (HCN + CH_3COOH), electrophoresis pH 8.6 and 2.7.

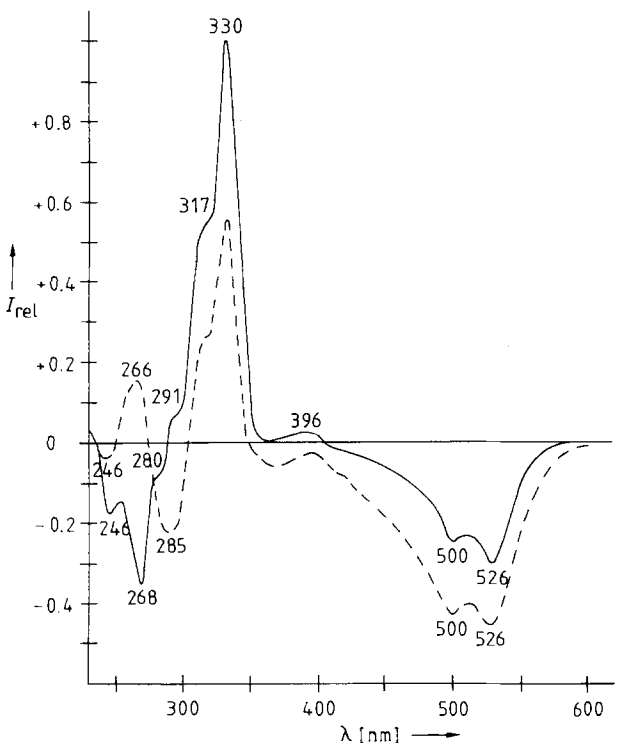

Fig. 1. CD spectra of 13α-hydrogenobyrinic acid heptamethyl ester **2** (——) and 13β-hydrogenobyrinic acid heptamethyl ester **2a** (------). Solvent: $CHCl_3$.

H_2O. The $CHCl_3$ phase was then dried over Na_2SO_4, concentrated by evaporation, and chromatographed on Merck silica gel 60 (CH_2Cl_2/MeOH (9:1, v/v)). The epimeric mixture **2**/**2a** ($R_F = 0.7$; yield 56%) occurring as main zone afforded **2** ($R_F = 0.55$) and **2a** ($R_F = 0.64$) on rechromatographic separation (toluene/*i*PrOH/MeOH (5:3:2, v/v/v)). The spectra and analytical values[2] of **2** and **2a** (UV/VIS, fluorescence, FD-MS and ^{1}H-NMR, and, after hydrolysis, electrophoresis) were characteristic for **2** and **2a** and showed no significant differences. According to the CD spectra (Fig. 1) **2** is the 13α isomer[3]. The CD spectra after chemical insertion of cobalt into **1** and **1a** (see Scheme 1, c) were decisive for verification of the correctness of the assignment, for they did indeed correspond to those of the heptamethyl esters of **4** and **4a**[1b,4].

Does **1** play a significant role in the biosynthesis of vitamin B_{12}? To answer this question, we checked with $^{57}Co^{2+}$ whether tetrapyrrole-free cell extracts from *Propionibacterium shermanii*[5] catalyze the insertion of cobalt into **1** (and **1a**) (Table 1, Experiments 1—4). Incubations, and isolation of **4** (transformation product of **3**) and its quantitative determination by reversed isotope dilution were carried out as described in ref. [5].

Table 1. Formation of **3** with enzyme preparations from *P. shermanii* [5], $^{57}Co^{2+}$, and substrates [a].

Experiment	1	2	3	4
		Cobyrinic acid **3** [nmol]		
a	42	17	17	80 [b]
b	—	5 [c]	7 [d]	32 [b, d]
c	—	10 [e]	14 [f]	57 [b, f]
d	5.8 [g]	—	—	—

[a] In each case the same enzyme preparation per series of experiments (a—d), (25 g moist bacteria/experiment); substrates: 3.3 μmol $^{57}Co(NO_3)_2$, specific radioactivity: 104 Bq/nmol and [b] 15 μmol 5-aminolevulinate and 37 μmol *S*-adenosyl-L-methionine, [c] 0.6 μmol **1**, [d] 0.4 μmol **1**, [e] 0.6 μmol **1a**, [f] 0.4 μmol **1a**, and [g] 1.3 μmol **1** + **1a**.

From Table 1 it follows that the formation of **3** from precursors still present in the enzyme preparations (Experiments 1a—3a) is markedly inhibited if **1** (2b and 3b), **1a** (2c and 3c), or **1**/**1a** (1d) is added. This effect is the strongest in the case of **1**, but is also manifested in the case of added species which additionally contain precursors of **3** (4b and 4c compared to 4a).

From theses findings it follows that **1** does not play any significant role in the biosynthesis of vitamin B_{12} by *P. shermanii*. The question of when the cobalt ion is inserted during the formation of vitamin B_{12} remains open.

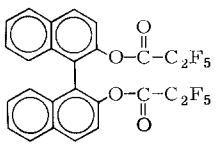
Direct Enantiomer Resolution of Hydroxy and Carbonyl Compounds by Gas Chromatography on Chirasil-Val**

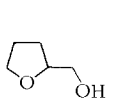
By *Bernhard Koppenhoefer**, *Hans Allmendinger*, and *Graeme Nicholson*



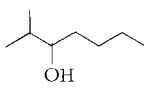
New methods for the chemical and biotechnological synthesis of chiral active substances[1] have led to extraordinarily high enantiomeric excesses (*ee*), which can be accurately determined only by sensitive, direct methods. Gas chromatography on chiral stationary phases[2] such as Chirasil-Val[3] is the method of choice, providing the substances are sufficiently volatile and have favorable chromatographic properties (retention time, separation factor α, peak shape).

Polar compounds are, as a rule, derivatized in order to shorten the time of analysis and avoid peak tailing. Recourse to acylation of hydroxy compounds[4] leads to small separation factors, since the donor functions for hydrogen bonding with the stationary phase are eliminated. A complete separation on Chirasil-Val is only observed if at least two ester carbonyl groups are present; aromatic π-systems additionally promote the separation. Arylethanediols, which are formed in high enantiomeric yields (*ee* = 99.4%) by reduction with bakers' yeast[5], and the atropisomeric chiral reagent[1e] 2,2'-dihydroxy-1,1'-binaphthyl are chromatographed as diperfluoropropionates **1** and **2**, respectively[6]. (The respective separation factor α, the column temperature, and the more strongly retained enantiomers are given in brackets under the formulas; in some cases, however, the order of elution of the enantiomers has not been determined.) Cyclic carbonates obtained from diols and phosgene have only one carbonyl group and are separable only under carefully optimized conditions[7].

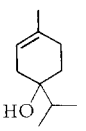
The derivatization of hydroxy groups with nitrogen-containing reagents also has disadvantages: Admittedly, the separation factors are increased by N–H donor functions, but the volatility is considerably reduced. Furthermore, the conversion into urethanes[8] includes the danger of side reactions and racemization (e.g. in the case of mandelic acid), often accompanied by an unsatisfactory conversion.



1a, X = H (1.043, 80 °C, *R*)
1b, X = F (1.050, 80 °C, *R*)
1c, X = Cl (1.050, 80 °C, *R*)
1d, X = Br (1.050, 80 °C, *R*)

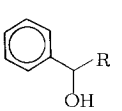


2 (1.038, 180 °C, *R*)

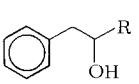


By using suitably deactivated glass capillaries (e.g. with diphenyltetramethyldisilazane), the functionalization of the hydroxy groups can be dispensed with in a number of classes of compounds, since the peak tailing caused by absorption on the column wall is largely suppressed. Thus, enantiomeric alcohols[9] can now be resolved on amide phases without recourse to derivatization. This method is applicable to primary (**3**), secondary (**4**), and tertiary (**5**) alcohols. The surprising resolution of **4** demonstrates that *one strong attractive interaction* (e.g. hydrogen bridges of the type O–H···O=C) can lead to a satisfactory discrimination of the enantiomers, since **4** contains neither a hetero atom like **3** nor a π system like **5**.

3 (1.129, 50 °C)



4 (1.036, 50 °C)



5 (1.067, 80 °C)

From these findings, we can derive a model of the separation mechanism. In the thin-film capillary (film thickness ca. 0.1 μm) there are about 10^2 superjacent chiral polymer chains (selectors of the order of magnitude of 1 nm). Hence, there is a stationary liquid phase which *completely* surrounds the substrate. By rapid reversible inclusion of the enantiomeric selectands from the gas phase in the chiral cavities of the condensed phase (which are already present or are formed by a change in conformation), the entropy is reduced at the expense of the (more favorable) enthalpy[6]. Moreover, since the changing shape of the cavities is averaged over all orientations of the selectands accomodated within them, usually only small differences in free energies of interaction of the enantiomers result ($-\Delta\Delta G_{333} = 0.1$ J/mol for **4**). The mobility, however, is already sufficiently restricted by *one* hydrogen bridge, for even on rotation about this axis the enantiomers of **4** always differ regarding the sum of the various van der Waals interactions (attractive and repulsive) with the boundaries of the virtual chiral cavities. In combination with the high efficiency of the capillary columns employed (10^5 theoretical plates), even such an unspecific mechanism enables the clean separation of a large variety of enantiomeric pairs on the same stationary phase. For instance, 1-menthen-4-ol **5** was detected in the pheromone bouquet of bark beetles[10].

6a, R = Me (1.034, 50 °C, *R*)
6b, R = Et (1.040, 50 °C, *R*)
6c, R = *i*Pr (1.051, 50 °C, *R*)
6d, R = *t*Bu (1.074, 50 °C, *R*)

7a, R = Et (1.034, 50 °C, *R*)
7b, R = *i*Pr (1.061, 70 °C, *S*)
7c, R = *t*Bu (1.130, 70 °C, *S*)

The enantiomers of the phenyl-substituted alcohols **6** and **7** have been obtained by asymmetric synthesis[1e] from the corresponding ketones. In addition, we have been able to assign the absolute configuration by reduction with bakers' yeast. In **6**, the preference given by the stationary phase for the *R*-enantiomers increases with the size of the alkyl groups (see also Fig. 1). The homologous benzyl derivatives **7** show an analogous trend (in both series, the L-configurated alcohol is eluted later[11]). The average relative retention time of **7c** is only 0.09 at 110 °C, referred to the corresponding isopropylurethane[12].

Also in the case of the mesityl derivative **8** (hindered rotation), the separation factor α is astonishingly high. The corresponding naphthyl and anthryl derivatives behave similarly to **6a**. Even dihydroxy compounds, e.g. the phe-

group, e.g. pantolactone **11** or mevalonolactone **12a**. Compounds **12a** and **12b** are key building blocks in the biosynthesis of juvenile hormones in insects. The fluoro-compound **12c** (see Fig. 1) has been employed as suicide substrate for the inhibition of hormone production in parasites (e.g. the tobacco horn worm *Manduca sexta*)[13]; this is an interesting alternative to biological pest control with pheromones.

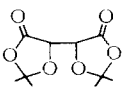
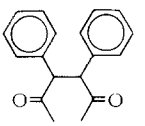
Consequently, open-chain hydroxy acids require only a simple racemization-free[14] esterification of the carboxy group. Similarly, as in the case of the 2-hydroxy acids[14], 3-pentanol proves to be the most suitable alcohol component in the case of 3-hydroxy acids with regard to separation factor, volatility, and polarity of the derivatives. The separation factors α increase with the size of the main chain. In contrast to the 2-hydroxy acid esters, however, the L-enantiomer of the 3-hydroxy esters (e.g. *S*-**13a** or *R*-**13b**) usually undergoes the stronger interaction with L-Chirasil-Val. Tropanoic acid, a 3-hydroxy acid with an asymmetry center on C-2 (cf. **14**), is the chiral component of the alkaloids atropine and hyoscyamine.



Polyfunctional hydroxycarboxylic acids such as *threo*-2,3-dihydroxybutanoic acid or 2-hydroxyglutaric acid lactone are separated as 3-pentyl esters **15** and **16**, respectively; the preparatively useful enantiomers of tartaric acid are best separated by way of the bisacetonide **17**. As was demonstrated some years ago[6], even diketones can be completely resolved into the enantiomers without resorting to derivatization. On the basis of theoretical considerations, the 3,4-diphenyl-2,5-hexanedione **18** with C2 symmetry has been chosen as example.



15 (1.133, 80 °C, 2*S*, 3*R*)

16 (1.039, 80 °C, *S*)

17 (1.040, 80 °C, 2*S*, 3*S*)

18 (1.031, 130 °C)

Thus, the scope of application of peptide phases partially overlaps that of complexation gas chromatography[9], which is still indispensable in the case of less polar compounds, e.g. pheromones with a spiroketal structure[15]. On the other hand, the thermally stable polymeric phase Chirasil-Val has also proven useful for many polar, less volatile compounds.

[11] The CIP nomenclature is less helpful for describing the uniform elution behavior of the alcohols **6** and **7**; due to the priority sequence ethyl < benzyl < isopropyl, the descriptor of the absolute configuration is interchanged within the homologous series. The D/L nomenclature is more consistent in describing the fact that the substituents phenyl (benzyl), alkyl, and H are always arranged in a clockwise manner in the more strongly retained enantiomer when viewed from the direction of the OH group (referred to L-Chirasil-Val).

Photooxidation of Chloroform: Isolation and Characterization of Trichloromethyl Hydroperoxide

By *Siegmar Gäb* and *Walter V. Turner*

A series of thorough studies since the beginning of this century has shown that a peroxide is formed in the photooxidation of chloroform. Formulated as Cl_3COOH **1**, this peroxide is stable enough to build up over several months at room temperature; nevertheless, until now all attempts to isolate it by distilling out the chloroform have failed[1].

We have found that stripping photooxidized chloroform on a rotary evaporator at 0°C yields a peroxidic oil[2], which on the basis of its physical and chemical properties is identified as trichloromethyl hydroperoxide **1** [^{13}C-NMR ($CDCl_3$, 20 MHz): $\delta = 116.4$; ^{1}H-NMR ($CDCl_3$, 80 MHz): $\delta = 9.9$, broad; IR (CCl_4): strong bands at $\nu = 3500$, 1370, 1025, 900 cm^{-1}]. Iodometric titration of the oil in glacial acetic acid showed a peroxide content of ca. 90% of that calculated for **1**. Cryoscopy in benzene gave a slightly too high molecular weight (calc., 151.3; found, 160).

On reaction with N_2O_5 and $NaHCO_3$ in $CHCl_3$ at −25°C, **1** is converted in high yield into **2** [^{13}C-NMR ($CDCl_3$): $\delta = 116.1$; IR (CCl_4): strong bands at $\nu = 1750$, 1300 cm^{-1}[3]]. The ^{13}C-NMR signals of **1** and **2** lie close together, but can be distinguished in a mixture of the two compounds.

Treatment of **1** with acetyl chloride leads to the perester **3**[4] [^{13}C-NMR ($CDCl_3$): $\delta = 164.9$, 114.6, 16.8; ^{1}H-NMR ($CDCl_3$): $\delta = 2.21$; IR (CCl_4): strong bands at $\nu = 1818$, 1160, 1025 cm^{-1}]. The colorless product **3** melts above 6°C and can be chromatographed on silica gel with hexane/chloroform (2:1). The elemental analyses were correct. The molecular weight was determined as 191 by cryoscopy and 185 by iodometric titration (calc. 193.4). Perester **3** can readily be prepared in gram quantities without isolating **1**, by exposing a solution of acetyl chloride in alcohol-free chloroform under oxygen to either direct or diffuse sunlight[5].

Hydroperoxide **1** is more stable than CH_3CCl_2OOH[6]; a considerable portion survives even several hours' refluxing in $CHCl_3$. IR measurements showed that **1** slowly decomposes in CCl_4 at ca. 35°C to yield CO_2 (an additional absorption at 2345 cm^{-1}) and $COCl_2$ (additional absorptions at 1815 and 850 cm^{-1}); under these conditions **2** forms $COCl_2$. In a sealed tube under O_2, **3** was found by ^{1}H-NMR to have a half-life of ca. 10 h at 60°C. Several perchlorinated dialkyl peroxides have also recently been shown to be more stable than expected[7]; there may be important implications here for the photochemical degradation of organochlorine compounds in the atmosphere.

Caution! *Although small quantities of* **3** *have been distilled in a miniature sublimator, the compound exploded on one occasion when an attempt was made to remove a few droplets from the cold finger with a capillary pipette.*

[2] Commercial analytical grade $CHCl_3$ was shaken with H_2SO_4, then H_2O, dried over Na_2SO_4, and distilled. Portions of 100 mL were stirred under O_2 in 1 L Pyrex flasks and exposed to diffuse daylight until iodometric titration in glacial acetic acid revealed a peroxide content of ca. 0.1 mmol/mL (at least a week). Portions of 20 mL of the photooxidized solution were stripped at 0°C and 15 torr to **1**, a viscous oil. In this concentrated state, **1** is far less stable above 0°C than in dilute solution.

[3] These absorptions correspond to those of **2** in the gas phase, where its formation in the chlorine-sensitized oxidation of $CHCl_3$ in the presence of NO_2 was studied by IR spectroscopy. H. Niki, P. D. Maker, C. M. Savage, L. P. Breitenbach, *Chem. Phys. Letters* 61 (1979) 100; R. Simonaitis, J. Heicklen, *ibid.* 62 (1979) 473; O. Morel, R. Simonaitis, J. Heicklen, *ibid.* 73 (1980) 38.

[4] Perester **3** is also obtained by reaction of acetyl chloride with the product (presumably **1**) from ozonolysis of either trichloro- or tetrachloroethylene in the presence of HCl.

[5] Over several weeks the concentration of **3** in a solution of $CHCl_3$ and acetyl chloride (1:1) rises to more than 0.2 mmol/mL. After removal of the solvent, the oily residue was chromatographed.

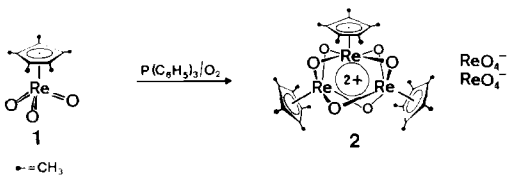
Reductive Trimerization of the Trioxo Half-Sandwich Complex $[(\eta^5\text{-}C_5Me_5)ReO_3]$ with Deoxygenation: The Electron-Deficient Cluster Ion $[(\eta^5\text{-}C_5Me_5)_3Re_3(\mu\text{-}O)_6]^{2+}$ **

By *Wolfgang A. Herrmann**, *Ricardo Serrano*, *Manfred L. Ziegler*, *Heike Pfisterer*, and *Bernd Nuber*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday



The readily accessible, unusually stable Re^{VII} complex $[(\eta^5\text{-}C_5Me_5)ReO_3]$ **1**[1] is functionalized by Lewis acids and Lewis bases with partial deoxygenation and reduction of the transition metal[2–4]. A particularly useful reaction from a synthetic point of view proved to be the reductive coupling of **1** by means of PPh_3 to give the binuclear Re^V derivative $[(\eta^5\text{-}C_5Me_5)_2Re_2O_4]$, whose synthesis, however, could only be achieved under rigorous exclusion of air[2,3]. We have now found that on reaction of **1** with PPh_3 in the presence of atmospheric oxygen, a further type of reaction surprisingly takes place, leading via intermediates to an unusual electron-deficient cluster compound.

Treatment of a solution of **1** in *aerated* tetrahydrofuran (THF) with an excess of PPh_3 rapidly leads to a gradual deepening in color of the solution from yellow to brown

[**] Multiple bonds between main group elements and transition metals, Part 14. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Degussa AG, Herbert Quandt-Stiftung der VARTA AG, and the Spanish Ministry of Education (Fellowship grant for *R. S.*, 1982–84).—Part 13: W. A. Herrmann, J. Rohrmann, H. Nöth, C. K. Nanila, I. Bernal, M. Draux, *J. Organomet. Chem.*, in press.

until, after ca. 20 min, bluish green crystals of the novel complex compound **2** precipitate which are completely air-stable. That **2** must be a salt follows from the equivalent conductivity, $\Lambda = 134\ cm^2\ \Omega^{-1}\ mol^{-1}$ (dilute nitromethane solution, 25 °C), which value is characteristic of completely dissociated 2:1 electrolytes. The complex, which is isolable in 70–90% yield, is diamagnetic and shows only *one* sharp methyl signal at $\delta = 2.22$ in the ^{1}H-NMR spectrum (270 MHz, $CDCl_3$, 25 °C); and even in the ^{13}C-NMR spectrum, only the simple set of signals of chemically equivalent C_5Me_5 ligands is observed ($\delta(C_5Me_5) = 118.75$, $\delta(CH_3) = 11.18$). Since a total analysis gave an empirical formula $C_{30}H_{45}O_{14}Re_5$ and the signal pattern of correct intensity for the trinuclear cluster species $[(C_5Me_5)_3Re_3O_6]$ reproducibly occurred in the FD mass spectrum ($M/z = 1056$, ^{185}Re), it was suspected that this compound consists of a dication which is associated with two perrhenate anions. This presumption was further strengthened by an X-ray structure analysis of a single crystal having the composition $[(C_5Me_5)_3Re_5O_{14}]\cdot 1/2\,CH_2Cl_2$ (obtained from dichloromethane/THF).

The trinuclear dication of **2** consists of three chemically equivalent $[(\eta^5\text{-}C_5Me_5)ReO_2]$ structural groups coupled via angular symmetrical oxo bridges in such a way that an empty "trigonales Trigonprisma" of C_3 symmetry is formed (Fig. 1). The six bridge ligands occupy the corners of a trigonal prism whose faces form two equilateral triangles and three almost square rectangles. There are no bonding interactions between the oxo ligands ($d(O\ldots O) = 263$ pm, mean value). Each rhenium atom is symmetrically arranged above each rectangle which, taking into consideration the pentamethylcyclopentadienyl ligands oriented almost parallel to the threefold axis of the molecule, lies at the center of an only slightly distorted square-pyramidal coordination polyhedra. In each case, four oxygen atoms with angles summing up to 320.1° form the basal ligand set. The angles at the oxo-bridges average 89.3°, and the bond lengths of 193–197 pm between the rhenium and the oxygen atoms fall within the typical range for such structural units[2–5].

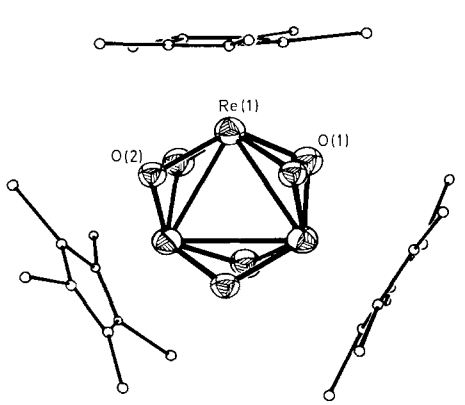

Fig. 1. Structure of the C_3-symmetrical cluster ion $[(\eta^5\text{-}C_5Me_5)_3Re_3(\mu\text{-}O)_6]^{2+}$ in the complex **2** (from THF/CH_2Cl_2); cubic, space group $T^4\text{-}P2_13$; $a = b = c = 1613(1)$ pm, $V = 4197 \times 10^6$ pm^3; $R_{iso} = 0.050$, $R_w = 0.035$. Selected bond lengths [pm] and angles [°]: Re–Re 274.7(2), Re–O(1) 197(2), Re–O(1′) 195(2), Re–O(2) 197(2), Re–O(2′) 195(2), Re–C(C_5Me_5) 219–237, C–C 124–148 (C_5 rings); O(1)–Re–O(1′) 89(1), O(1)–Re(1)–O(2) 73(1), O(1)–Re(1)–O(2′) 132(2), O(1′)–Re(1)–O(2) 133.0(2), O(1′)–Re(1)–O(2′) 72.1(10), O(2)–Re(1)–O(2′) 88.3(13), Re–O–Re 89.3 (mean value).—The two perrhenate counterions and the solvent molecule are not involved in bonding interactions, either between themselves or with the cation.—Further details of the crystal structure investigation are available upon request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51024, the names of the authors, and the journal citation.

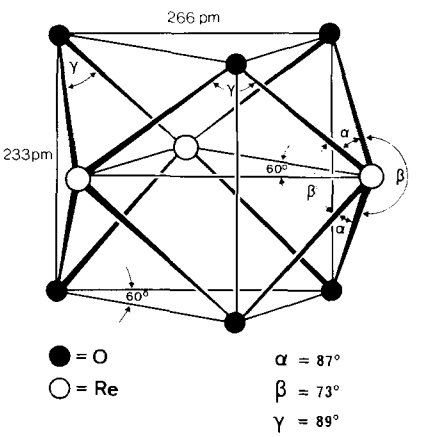

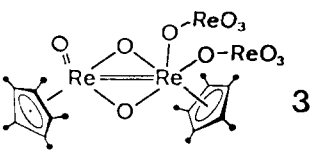

Fig. 2. The Re_3O_6 geometry in the cluster ion of **2** consists of a trigonal prismatic coordination polyhedron of six oxygen atoms, whose three rectangular faces are each bridged symmetrically by a rhenium atom ("trigonales Trigonprisma"). The ReORe triangular faces form an interplanar angle of 123° with the Re_3 framework; the interplanar angle of the ReORe and ReO′Re planes is 114°.

With regard to their inconclusively interpretable bond order, the metal-metal distances (274.7(2) pm) compare with the length of double bonds or of shortened single bonds[3]. Since the complex cation $[(\eta^5\text{-}C_5Me_5)_3Re_3(\mu\text{-}O)_6]^{2+}$ of **2**, with only 46 valence electrons, is an electron-deficient species, four bonding electrons are left over after taking into account the nine ligands for the Re_3 cluster structure, thus giving a formal bond order of 2/3. Whether there is any bonding interaction at all between the metal atoms, despite the relatively short metal-metal distances, must be checked by an MO calculation[6]. The metal atoms of the cluster ion have a formal oxidation state of $+5\frac{2}{3}$.

Despite the facile formation of **2**, the reaction mechanism is still unclear. On the basis of control experiments, it can be concluded that the complex **3**, formed from **1**, PPh_3 and a little oxygen[2], does not react with excess **1**.

3

The electronically unsaturated cluster ion of **2** is not only the first example of a square-planar complex of the type $LReO_4$, it also represents a novel M_3O_6 skeletal geometry in organometallic chemistry.

Synthesis of 3′-*C*-Methyl-2′-deoxyribonucleoside with Methylmagnesium Iodide**

By *A. Grouiller, H. Essadiq, H. Pacheco, S. Juntunen,* and *J. Chattopadhyaya**

Branched-chain sugar nucleosides have previously been prepared by reaction of Grignard reagents with pentofuranosuloses and hexopyranosuloses followed by coupling with a suitable base[1].

We report here a more convenient route to a new branched-chain sugar nucleoside **5** via a one-step preparation of 2′-deoxy-3′-*C*-methyl-5′-*O*-trityluridine **2** by Grignard reaction of 2′-*O*-tosyl-5′-*O*-trityluridine **1** with methylmagnesium iodide (Scheme 1).

Scheme 1. Procedure for **2**: To a stirred solution of **1** [5] (1 g, 1.56 mmol) in anhydrous tetrahydrofuran (50 mL) was gradually added a freshly prepared solution of MeMgI (15 equiv.) in diethyl ether at 0 °C under N_2. The mixture was then stirred for 90 min at 25 °C and subsequently heated to 65 °C for 30 min. After cooling, 10% aqueous NH_4Cl (18 mL) was added. The organic layer was separated, dried, and concentrated to give a syrup, which was chromatographed on a short silica gel column with 2% ethanol/chloroform mixture to afford **2** (280 mg, 37%).—The reaction of **1** with 7 equivalents of MeMgI gave essentially **3** [6].

The synthesis of 3′-branched-chain 2′-deoxysugar nucleosides of this type is important in view of the biological properties of the corresponding ribofuranosyl derivatives[2]. The availability of these compounds would enable the synthesis of corresponding DNA analogues which should assist in our understanding of the conformational role of the 2′-deoxysugar residue in protein-DNA interactions. To our knowledge, there are only two reports of such branched, deoxysugar nucleosides: *Acton* et al.[3] have reported the preparation of α- and β-2′,3′-dideoxy-3′-(hydroxymethyl)thioguanosine starting from a modified sugar and *Ueda* et al. have described a multistep synthesis of 2′,3′-dideoxy-3′-(hydroxymethyl)uridine starting from 1-(3-amino-2,3-dideoxy-β-D-glucopyranosyl)uracil[4].

The structure of **2** was determined by spectroscopy[7]. **2** was assigned the *erythro*-configuration by comparison with similar reactions of carbohydrates[1a–c, 8] and also from the downfield shift ($\delta = 0.3$) of 4′-H in **4** (m.p. = 183 °C), obtained by acetylation of the tertiary hydroxyl group in **2**[1c]. According to *Kawana* et al.[9] Grignard reaction of methyl-5-*O*-benzyl-2-*O*-tosyl-β-D-ribofuranoside led to a mixture of the *threo*- and *erythro*-isomers of the 2′-deoxy-3′-*C*-methyl derivatives in 57 and 20% yields, respectively, in contrast to our present example with the ribonucleoside **1** where we isolated exclusively the *erythro*- isomer **2**. Such stereoselective control is desirable for the preparation of DNA analogues. This result may be rationalized as arising from steric hindrance of the α-side of the 3′-carbonyl carbon atom by the 5′-*O*-trityl group, facilitating stereoselective nucleophilic attack from the β-side and giving **2**. Previously we observed[10] a similar "steric blocking" in the regioselective preparation of a 2′-*O*-methylribonucleoside.

Finally, compound **2** was detritylated to obtain **5**[11] (Scheme 2). We presume that under these acidic conditions a complex such as **6** is formed which releases anhydrous HBr that in turn acts as a detritylating agent.

Scheme 2. Preparation of **5** by detritylation of **2** with $ZnBr_2$ and anthranilic acid (molar ratio 1 : 1.6 : 4) in anhydrous nitromethane (24 mL/mmol), 3 h, yield 54%.

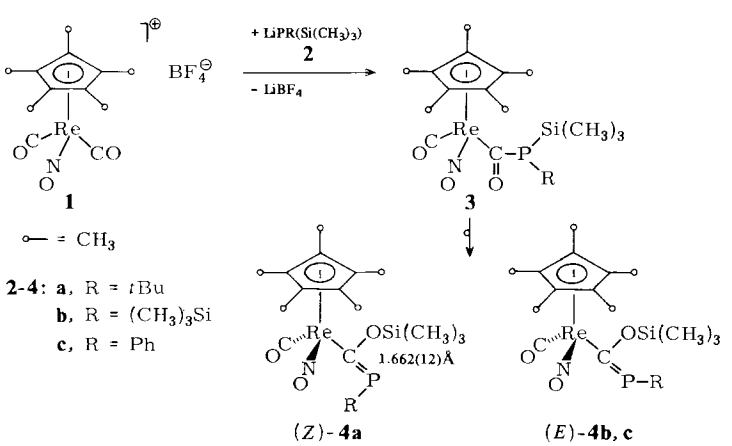
Phosphaalkenylrhenium Complexes—a Novel Class of Substances with P=C Bonding**



By *Lothar Weber** and *Klaus Reizig*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

Compounds containing phosphorus-carbon multiple bonds are very interesting, both from the theoretical as well as the preparative point of view[1-6]. The synthesis of the P=C unit is generally accomplished by reaction of organically bound carbonyl groups with polysilylated phosphanes. However, the preparation of carbon-phosphorus multibonded systems from carbonyl ligands which are coordinated to transition metals has so far not been reported in the literature.

We report here on the first reaction sequence of this kind, which leads to a novel class of compounds, the phosphaalkenyl complexes **4**.

The silylated lithium phosphides **2a—c** react with an ethereal suspension of the complex cation **1** at −78 °C to give an orange-yellow solution which turns reddish brown on warming to room temperature. The phosphaalkenylrhenium complexes **4a—c** are isolated from this reaction solution as dark-red crystalline solids[7]. The initial step of the reaction could be the nucleophilic addition of the phosphide to a CO ligand of **1**. In the phosphinocarbonyl complexes formed in the reaction, a 1,3-Si(CH$_3$)$_3$-shift with formation of **4** takes place at elevated temperatures.

Institut für Anorganische Chemie der Universität
Universitätsstr. 5—7, D-4300 Essen 1 (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and Degussa AG.

The reaction of **1** with **2a** can be monitored by ^{31}P-NMR spectroscopy. A singlet at δ = 43.2 (−60 °C) is assigned to **3a**[8]. Above −40 °C, this signal diminishes in intensity and at −10 °C can no longer be detected. In place of it, a new signal is recorded at δ = 240.1. At 20 °C, in the course of several hours a further singlet appears at δ = 272.8, while that at δ = 240.1 disappears.

The complex **4a** isolated shows a ^{31}P-NMR signal at δ = 271.7 in C_6D_6. The Re(CO)(NO) group is recognizable by strong bands at 1970 (ν(CO)) and 1685 cm^{-1} (ν(NO)) in the IR spectrum (n-hexane). A medium-strong band at 1050 cm^{-1} (Nujol) is assigned to the ν(SiOC) vibration. Aside from the downfield shift in the ^{31}P-NMR spectrum, the vapor pressure osmometric M_r determinations as well as the $M^{\oplus}$ ion in the mass spectrum also verify the monomeric structure of the complex. The configuration at the P=C bond was ascertained by analysis of the ^{13}C-NMR spectra. Besides the doublet for the carbon atom of the P=C moiety (δ = 241.9; ^1J(PC) = 80.7 Hz), a singlet is observed at δ = 211.0 for the CO ligand. The signal of the (CH$_3$)$_3$Si group is recorded as a doublet (δ = 1.87, ^4J(PC) = 8.4 Hz). Assuming that this PC coupling is transferred by the free electron pair on the phosphorus atom[9], **4a** has *Z*-configuration. This is confirmed by the X-ray structure analysis[10].

We presume, therefore, that the ^{31}P-NMR signal at δ = 240.1 is due to the *E*-isomer initially formed from **3a**, which slowly rearranges into the isolated *Z*-isomer. On the basis of similar findings we assign **4b** and **4c** the *E*-configuration[7].

The complexes **4a—c** are the first phosphorus analogues of the η^1-alkenyltransition-metal class of complexes of the type $L_nM-C(R^1)=CR^2R^3$[11]. Disregarding the posphavinylidene complex $(C_5H_5)(CO)_2Mo=P=C(Si(CH_3)_3)_2$[12], all the previously known phosphaalkene transition-metal compounds[13-16] contain the intact $R^1P=CR^2R^3$ structure unit.

Crystal Structures of Potassium Ozonide and Rubidium Ozonide**

By *Wolfgang Schnick* and *Martin Jansen**

In the case of main group elements, bond systems with uneven numbers of electrons are an exception to the rule; on the other hand, a host of such systems appears to exist in the case of triatomic units with 19 valence electrons. This may be a coincidence. But there are also indications of such systems being especially stable: for example, the markedly low tendency for chlorine dioxide to dimerize. As further supporting evidence of this concept, one could mention the tendency of N_2F_4 to dissociate into NF_2 radicals, or the exceptionally long S–S bond in the dithionite ion (239 pm, bond order noticeably less than one), indicating a tendency for decomposition into two SO_2^- moieties. The group of 19-electron systems also includes the ozonide ion O_3^-. However, despite intensive studies over the past twenty years and more[1], the existence of this anion has still not been unequivocally settled. In particular, there has been lack of reliable data on its geometry: thus, the data on experimentally determined O–O bond lengths vary between 119 and 142 pm, with the O–O–O angle being quoted as 100°[1a]. Theoretically, values of between 128 and 135 pm are predicted for the bond lengths and between 108 and 120° for the bond angle. We have now determined the dimensions of the ozonide ion by X-ray structure analyses on single crystals of KO_3 and RbO_3.

Of the possible strategies available for the preparation of alkali-metal ozonides[1c], it was found from detailed preliminary investigations that the reaction of solid potassium or rubidium hyperoxide with O_2/O_3 mixtures was the most suitable. The hyperoxides of potassium and rubidium, obtained by oxidation of the alkali metals with O_2[2], were ozonized for 1 h in a fluidized bed reactor (capacity ca. 100 mL) with O_2/O_3 mixtures (6 vol.-% ozone). About 0.02 mol of hyperoxide was converted per run. Optimal reaction temperatures are 5°C and 20°C for KO_3 and RbO_3, respectively. The reaction can be monitored by the change in color of the reaction mixture from yellow to intense red.

For the growth of single crystals the ozonides were extracted at –40°C with liquid ammonia, while unreacted hyperoxide remained undissolved. The solvent was then removed under argon with cooling; the alkali-metal ozonides precipitated as transparent deep-red crystals. The single crystals for the X-ray structure analysis were prepared under an inert gas at 10°C.

The X-ray structure analyses[3] confirm the predicted composition of the alkali-metal ozonides. Isolated angular O_3^- ions are present whose dimensions in RbO_3 (O–O(averaged) 134.1(15) pm, bond angle 114.6(13)°) and KO_3 (135.7(5) pm, bond angle 113.4(8)°) agree within the standard deviations[3]. Thus, packing effects seem to have no significant impact on the geometry of the anion. With respect to the bond lengths and angles previously determined on the basis of inadequate data[1c] (RbO_3: 142(9) pm, 101(5)°, KO_3: 119 pm, 100°), there are considerable discrepancies.

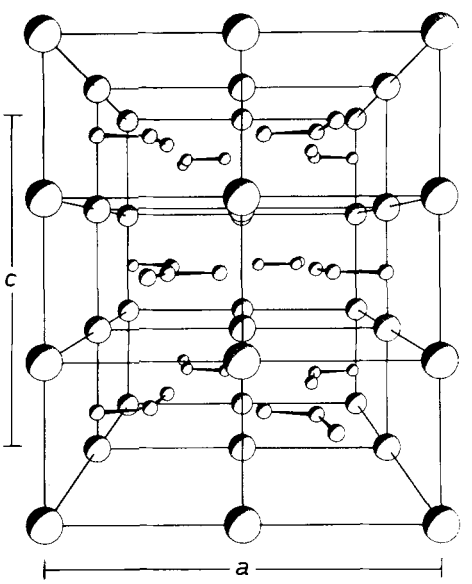

Fig. 1. Perspective diagram of the crystal structure of KO_3, viewed along [100]; large circles denote potassium, small circles oxygen.

The O–O bonds are longer than in ozone (127.8 pm)[4]. Since the additional electron occupies an antibonding molecular orbital, this tendency is consistent with expectation. The bond angle is reduced slightly from 116.8° to 114.0°. The distance between the two terminal oxygen atoms increases significantly from 218 to 226 pm.

With considerable simplification the packing of K^+ or Rb^+ and O_3^- to a three-dimensional crystal array can be rationalized as the CsCl-type structure (Fig. 1). The shortest contacts between oxygen and alkali-metal ions are, in the case of KO_3 exclusively and in the case of RbO_3 predominantly, those at the terminal O-atoms of the anion. This structural feature enables qualitative conclusions to be drawn about the polarity of the ozonide ion. Common to both ozonides is a marked deviation (86 pm (KO_3), 58 pm (RbO_3)) of the anion from the center of the polyhedron that is formed by the eight alkali-metal ions. There is still

no satisfactory explanation for the complete order of the ozonide anions at room temperature, which is in contrast with the comparable $RbNO_2$[5]. Intermolecular interactions between the ozonide ions (dimerization) can be ruled out on the grounds of the large intermolecular distances[3]. Also still inexplicable are the marked differences in the stability of the compounds with 19-electron systems (NF_2, SO_2^-, O_3^-, S_3^-, ClO_2) towards dimerization. Whichever of the conceivable criteria is analyzed for an explanation (repulsion of non-bonding electron pairs, differences in electronegativity[6], charge of the monomer, state of aggregation) there are inconsistencies.

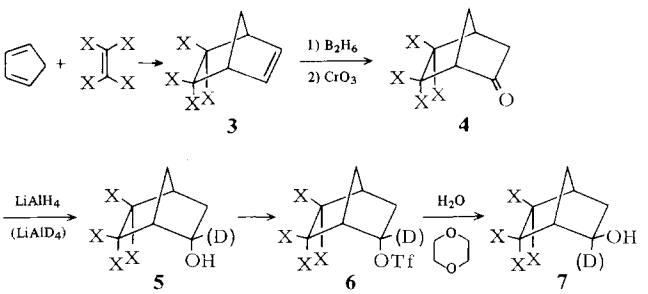
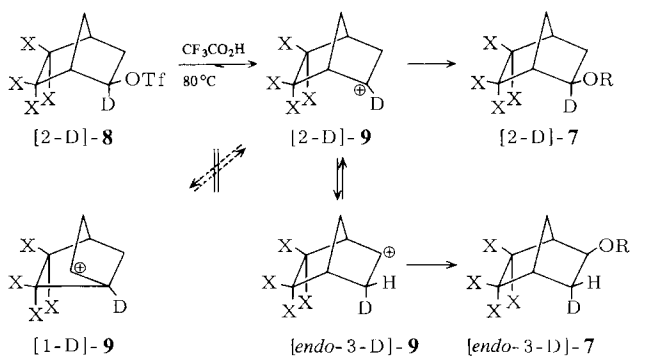
Destabilized 2-Norbornyl Cations



By *Wolfgang Kirmse**, *Uwe Mrotzeck*, and *Rainer Siegfried*

A conspicuous property of the 2-norbornyl cation **1** (≡ **1′**) is the equivalence of C-1 and C-2 in its spectra and reactions[1], as expressed by the σ-delocalized ("nonclassical") structure **2**. If an acceptor substituent is present at C-6, Wagner-Meerwein rearrangement and attack by the solvent appear to compete with each other; norbornyl cations of this type are considered to be unsymmetrically

1 **2** **1′**



bridged[2]. The presence of four fluorine atoms or four trifluormethyl groups[3] at C-5 and C-6 should intensify the electron deficiency and at the same time maintain the symmetry of the parent system. We have found that the Wagner-Meerwein rearrangement is completely forestalled by such a substitution pattern—largely with retention of the *exo*-selectivity.

3 **4** **5** **6** **7**

Scheme 1. **a**, X = F; **b**, X = CF_3. Tf = trifluoromethylsulfonate.

The reactions of the substituted norbornenes **3**[4] sketched in Scheme 1 proceeded in good yields. Solvolysis of the *endo*-trifluoromethylsulfonate(triflate) **6** in dioxane-water afforded predominantly the *exo*-alcohols **7** (Table 1) without scrambling of a 2D-label. The *exo*-triflate **8a**

[2-D]-**8** [2-D]-**9** [2-D]-**7** [1-D]-**9** [*endo*-3-D]-**9** [*endo*-3-D]-**7**

Scheme 2. **a**, X = F; **b**, X = CF_3.

(Scheme 2) reacts only three- to four-times more rapidly than the *endo*-triflate **6a** and 20-times slower than 7-norbornyl triflate (ca. 10^{11}-times slower than *exo*-2-norbornyl triflate). The strongly solvent-dependent product ratio 7 : 5 (Table 1) suggests a competition between an S_N2 and an S_N1 reaction; the S_N1 reaction dominates only in trifluoroacetic acid. In contrast, in dioxane-water the *exo*-triflate **8b** underwent practically only elimination to give the alkene **3b**; in formic acid and trifluoroacetic acid **8b** reacted with high *exo*-selectivity (S_N1) (Table 1). In trifluoroacetic acid or formic acid the labeled triflates [2-D]-**6** and [2-D]-**8** led to a scrambling of D in **7** (Table 2). As indicated by the

Table 2. Deuterium scrambling in **7** upon solvolysis of [2-D]-**6** and [2-D]-**8**.

Educt	Conditions	*endo*-2-D	*endo*-3-D
endo-Series			
[2-D]-**6a**	CF_3CO_2H, CF_3CO_2Na, 80°C	95	5
[2-D]-**6b**	HCO_2H, HCO_2Na, 100°C	85	15
exo-Series			
[2-D]-**8a**	CF_3CO_2H, CF_3CO_2Na, 80°C	61	39
[2-D]-**8b**	CF_3CO_2H, CF_3CO_2Na, 80°C	84	16
[2-D]-**8b**	HCO_2H, HCO_2Na, 100°C	78	22

chemical shift in the ^{2}H-NMR spectrum and the coupling in the ^{1}H-NMR spectrum[5], the rearrangement product bore deuterium at the *endo* 3-position, but not at the bridgehead (C-1). A Wagner-Meerwein rearrangement had therefore not occurred, but rather an *exo,exo*-3,2-H shift. Scrambling of D in the solvolysis of [2-D]-**6a** is less than in [2-D]-**8a**, which indicates a higher S_N2 contribution in the reaction of **6a**; the difference is less pronounced for **6b**/**8b**. 3,2-H shifts are also known in 2-norbornyl cations; however, here they have the highest activation energy of all rearrangements and are insignificant under solvolysis conditions[6]. As indicated by the behavior of the cations **9**, the bridged structure **2** is more destabilized by F or CF_3 substituents than the open form **1**. The absence of Wagner-Meerwein rearrangement unequivocally characterizes **9a**, **b** as open ("classical") cations. The *exo*-selectivity of the 3,2-H shift cannot be accounted for here by σ-delocalization, but must have its origins elsewhere. The steric effects of the *endo*-substituents[1,6], torsional effects along the C1–C2 bonds[7], and deformation of the p-orbital at C-2 ("nonequivalent orbital extension")[8] have all been discussed in this connection.

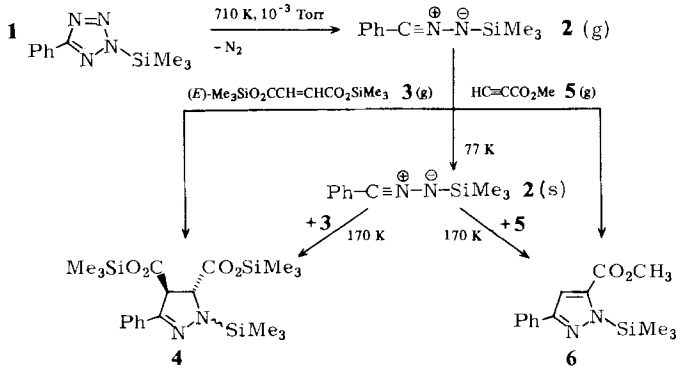
Nitrile Imines: Thermal Generation, Direct Observation, and Subsequent Trapping**

By *Curt Wentrup**, *Stephan Fischer*, *André Maquestiau*, and *Robert Flammang*

Nitrile imines are important intermediates for 1,3-dipolar cycloadditions in solution[1]. Diphenyl- and *N*-phenylnitrile imine have been observed by IR and UV spectroscopy following low-temperature irradiation of matrix-isolated precursors[2]. Also trapping with protic solvents and use of an intramolecular cycloaddition reaction have been described[2c]. However, no direct observation of a thermally generated nitrile imine has been reported, there is no evidence for the existence of discrete nitrile imines in the gas phase, and the crucial link between the gas-phase or matrix-isolated species and the solution-phase intermediates, trappable in intermolecular 1,3-dipolar cycloaddition reactions and presumed to be nitrile imines, has not been established. We now wish to report evidence for each of these points.



In order to observe a nitrile imine in thermal reactions, gas-phase generation with short contact times and subsequent low-temperature isolation are appropriate. However, nitrile imines with *N*-aryl groups undergo rapid cyclization to indazoles in the gas phase, thereby precluding direct observation[3]. Furthermore, *N*-methyl and related nitrile imines isomerize in the gas phase to azines and carbodiimides[4]. A nonisomerizing *N*-substituent is therefore required, and *N*-silyl substituents proved to be the best in this respect.

Flash vacuum pyrolysis of *C*-phenyl-2-trimethylsilyltetrazole **1**[5] at 710 K/10^{-3} torr gave gaseous *C*-phenyl-*N*-trimethylsilylnitrile imine **2**, which was led directly into the ion source of a mass spectrometer situated ca. 1 cm from the exit of the pyrolysis tube, or trapped on a KBr window at 77 K as the neat solid for IR spectroscopy. For UV spectroscopy the nitrile imine was co-condensed with isopentane on a quartz window at 77 K.

The molecular ion from **1** disappeared as a result of the pyrolysis, leaving an intense signal of the molecular ion of **2** (*m/z* 190). The collisionally induced dissociation (CID) mass spectrum of the latter ion was significantly different

[a] 70-eV electron ionization mass spectrum (Varian MAT 311A instrument). Ion abundancies in percent of the base peak. [b] CID mass spectrum of *m/z* 190 from the electron ionization mass spectrum, obtained on a triple sector (*E/B/E*) modified MS 902 instrument at an accelerating potential of 8 kV using air as the collision gas at a pressure of ca. 5×10^{-5} torr. [c] Obtained by pyrolysis of **1** at 700 K.

When the pyrolysis gas was mixed with bis(trimethylsilyl)fumarate **3** or methyl propiolate **5** vapor at the exit of the pyrolysis tube, the adducts **4**[6] and **6**[7] were isolated in 90—100% and 70—80% yield, respectively.

The solid nitrile imine **2** (s) exhibited strong IR absorptions at 2955, 2230 cm^{-1} (asymmetrical stretch), 1375 and 1355 (symmetrical stretch), 1245, 1098, 835, 750, and 680 cm^{-1}. The UV spectrum in an isopentane matrix showed a maximum at 303 nm. The nitrile imine was stable indefinitely at 77 K, but disappeared irreversibly on warming to 170—180 K.

Proof of the identity of the isolated nitrile imine **2** (s) was obtained by co-condensing the compound at 77 K with the trapping agent **5**. The IR spectrum of the nitrile imine was still observable at 77 K, but on warming to 170 K the spectrum was replaced by that of the 1,3-dipolar cycloaddition product **6**. In particular, bands due to **2** at 2230, 1375, 1355, and 1098 cm^{-1} disappeared synchronously with the development of new bands from **6** at 1140, 1073, and 635 cm^{-1}. After warming to room temperature the adduct **6** was isolated in essentially quantitative yield and its identity with the previously isolated material from the gas-phase reaction established. Similar results were obtained using **3** as the trapping agent.

Other *N*-silylated nitrile imines have been generated, observed, and trapped in analogous reactions, e.g. *N*-dimethylsilyl-*C*-phenylnitrile imine (2230 ($C\equiv\overset{\oplus}{N}-\overset{\ominus}{N}$), 2117 (Si–H) cm^{-1}); *C*-phenyl-*N*-triphenylsilylnitrile imine (2242 cm^{-1}; $\lambda_{max} = 310$ nm); *N*-methyldiphenylsilyl-*C*-phenylnitrile imine (2242 cm^{-1}); *N*-trimethylsilyl-*C*-methylnitrile imine (2259 cm^{-1}).

These results unambiguously demonstrate the existence of discrete nitrile imines, indefinitely at 77 K[2], and at least for several ms in the gas phase, and thus open the possibility of securing precise structural information and ionization potentials, the latter of which are of paramount importance for the determination of HOMO energies for use in theoretical treatment of 1,3-dipolar reactivity.

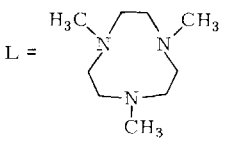
Preparation, Magnetism, and Crystal Structures of the Tautomers [LCu(μ_2-OH)$_2$CuL](ClO$_4$)$_2$ (Blue) and [LCu(μ_2-OH$_2$)(μ_2-O)CuL](ClO$_4$)$_2$ (Green): μ-Aqua-μ-oxo vs. Di-μ-hydroxo Linkage



By *Phalguni Chaudhuri**, *Dirk Ventur*, *Karl Wieghardt*, *Eva-M. Peters*, *Karl Peters*, and *Arndt Simon*

Binuclear, di-μ-hydroxo-bridged complexes of almost all the transition metals have been prepared and their structures and chemistry thoroughly investigated. Antiferromagnetic and ferromagnetic intramolecular interactions of the unpaired electrons of the metal centers are the objects of numerous studies, in which particularly the relationships between structure and magnetism are being studied[1]. For compounds of copper(II) of this type *Hodgson*

and *Hatfield* et al. have discovered a correlation between the spin interaction parameter $2J$ and the Cu–O–Cu bond angle ϕ[2]. Unsymmetrical tautomeric bridging through an oxo and an aqua ligand was previously not known.

We obtained *blue* single crystals of **1**[4] from aqueous reaction solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ and the cyclic amine *N,N',N''*-trimethyl-1,4,7-triazacyclononane[3]. Interestingly, after addition of an aqueous solution of $NaClO_4$ to methanolic solutions of $CuCl_2 \cdot 2H_2O$ (but *not* of $Cu(ClO_4)_2 \cdot 6H_2O$) and the amine, we obtained *green* crystals of **2**, which are identical in composition with those of **1**[4]. Aqueous solutions of **2** are *blue*, and **1** can be crystallized from them. The UV spectra of **1** and **2** in the solid state are slightly different: **1**: $\lambda_{max} = 620$, 950 nm; **2**: 630, 1070 nm. Aqueous solutions of **1** and **2** are blue and their UV spectra are identical: $\lambda_{max} = 636$ nm ($\varepsilon = 138$ L mol^{-1} cm^{-1}), ≈ 1000 (70).

X-ray structure analysis of **1** reveals[5] that the blue crystal consists of $[LCu(\mu\text{-}OH)_2CuL]^{2\oplus}$ ions of C_i symmetry and of isolated $ClO_4^{\ominus}$ ions (Fig. 1). The positions of the H atoms of the OH groups were clearly recognizable as maxima in the difference Fourier synthesis.

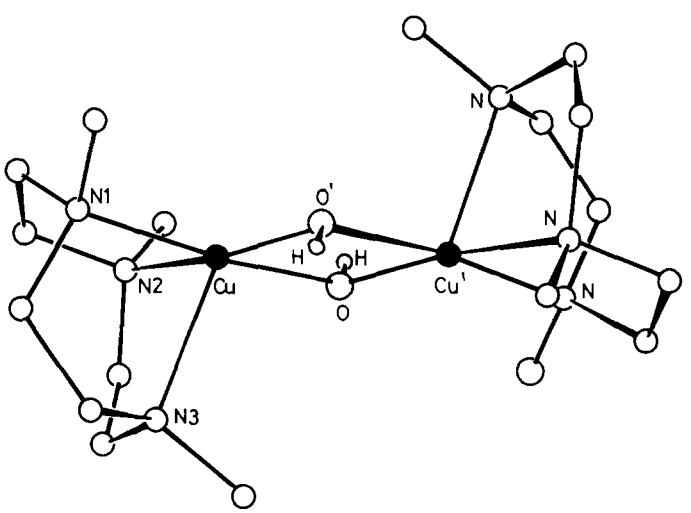

Fig. 1. Structure of the dimeric cation in the crystal of **1**. Selected distances [pm] and angles [°] (values for **2** in parentheses): Cu–O 193.9(4) (222.0(5)), Cu–O' 193.6(4) (219.9(5)), Cu–N1 208.3(4) (207.3(7)), Cu–N2 206.0(5) (206.4(7)), Cu–N3 223.8(4) (222.1(7)), Cu–Cu' 297.1(1) (303.2(1)); Cu–O–Cu' 100.1(2) (88.6(2)), O–Cu–O' 79.9(2) (91.4(2)), N1–Cu–O' 97.0(2) (91.1(2)), N1–Cu–N2 85.7(2) (86.3(3)), N2–Cu–O 96.6(2) (90.8(2)), O–Cu–N3 102.6(2) (107.8(2)), N2–Cu–N3 83.6(2) (84.0(3)).

Surprisingly, **2** crystallizes in the same space group as **1** and has very similar lattice constants[5]. According to a structure analysis, the packing of binuclear dications and $ClO_4^{\ominus}$ ions in **2** is almost identical to that in **1**. However, in **2** the O atoms of the bridges between the Cu^{II} centers are disordered (described with marked anisotropic temperature factors) and the H atoms on the O atoms could not be localized. The results of differential thermal analysis indicate that in the solid state **1** and **2** are not interconvertible. Significant differences between **1** and **2** are revealed by their IR spectra in the regions 3700—3000 and 1800—1600 cm^{-1}. **1** displays a sharp ν(OH) vibration at 3600 cm^{-1}, which is consistent with the absence of H bonds and of water of crystallization. In contrast, **2** exhibits a very broad ν(OH) band at 3400 and a ν(H–O–H) deformation mode at 1630 cm^{-1}; both of these are absent in the spectrum of **1**.

Since **2** also crystallizes free of water of crystallization, we suggest that this finding arises from the presence of an unsymmetrical μ-aqua-μ-oxo bridge between the two Cu^{II} centers. This type of bridging has not been described previously; pure μ-aqua bridging between transition metals is also rare[9]. In the crystal, the cation of **2** is statistically disordered, and no H bonds from the aqua bridge to $ClO_4^{\ominus}$ are formed.

1 and **2** are tautomeric complexes; in aqueous solution the equilibrium lies completely to the side of **1**.

The magnetic susceptibilities of **1** and **2**[6] differ markedly. The expression for the temperature-dependent susceptibility was derived from the general, isotropic spin Hamiltonian operator $H = -2J \cdot S_1 \cdot S_2$ for $S_1 = S_2 = 1/2$[7].

$$\chi_M = 2Ng^2\beta^2/3kT \cdot [1 + 1/3\exp(-J/kT)]^{-1}$$

ESR studies of **1** indicated a $\langle g \rangle$ value of 2.13[8]; the same value was assumed for **2**. By means of a fitting procedure using least-squares analysis, J values of -45 and $+37$ cm^{-1} were estimated for **1** and **2**, respectively. **1** is therefore antiferromagnetic (singlet ground state), whereas **2** is ferromagnetic (triplet ground state). The $2J$ value calculated for **1** fits the $2J/\Phi$-correlation well[2].

Quantitative HPLC Analysis and Thermodynamics of Sulfur Melts**

By *Ralf Steudel**, *Reinhard Strauss*, and *Lothar Koch*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

Because of its unique thermal behavior, liquid sulfur has been the subject of numerous physicochemical and theoretical investigations. As a rule, it is assumed that, below the polymerization temperature (159°C), the melt essentially consists of S_8 molecules. However, we have already previously shown by means of vibrational spectra[1] that rings other than S_8 (mainly S_7, S_6, and S_n with $n > 8$) are present at all temperatures in liquid sulfur, and that these—in comparison with S_8—are considerably more reactive species and strongly influence the properties of the melt[2].

The separation of sulfur homocycles by means of high-pressure liquid chromatography (HPLC)[3] now enables a much more accurate quantitative analysis. Using this technique, we have now found that, after establishment of the equilibrium

$$n/8\,S_8 \rightleftharpoons S_n \quad (n \neq 8) \qquad (1)$$

at constant temperature (23 samples, 13 temperatures) and then quenched in liquid nitrogen, accurately weighed at 20 °C (4.1–7.2 g), and immediately extracted quantitatively with ca. 200 mL CS_2[4]. After filtration and dilution to a prescribed volume, the solution was analyzed quantitatively by HPLC. The insoluble residue (polymeric sulfur, S_μ) was washed with CS_2, dried, and weighed.

In the chromatograms[5], the areas A of 18 S_n ring-molecules ($n = 6$–23) could be measured by electronic integration. For the calibration, at least ten solutions of different concentration c of each of the pure compounds were measured in the case of S_6, S_7, S_8, S_{10}, S_{12}, and S_{20}. The calibration curve was linear ($c = aA$) with a correlation coefficient better than 0.9999 over the range 5–500 μg S/mL CS_2. Since the slope a is proportional to the number of S atoms in the molecule (except in the case of S_7), the calibrations could be calculated for the remaining molecules.

Representative analytical values at 13 different temperatures are listed in Table 1. As expected[6], the concentrations of the S_n rings ($n \neq 8$) pass through a maximum at 159°C: besides 3% S_μ, only 83.4% S_8 is present. The missing "rest" of the 100% assay is ascribed to soluble S_n molecules ($n > 23$) and analytical errors (maximally 3%). Molecules with $n < 6$ were not detectable.

After S_8 and S_7, the most frequently occurring molecules in the melt are S_6, S_9, and S_{12}. The relevant reaction enthalpies $\Delta H(1)$ of Equation (1) can be calculated from the temperature-dependence of the concentrations of the molecules listed in Table 1. From the linear regressions in the temperature range 116–159°C the values shown in Table 2 are obtained.

Assuming an equally strong intermolecular interaction (per atom) for all molecules in the melt (zero enthalpy of mixing), the mean bond energies (m.B.E.) in the sulfur rings shown in Figure 1 can be calculated from the $\Delta H(1)$

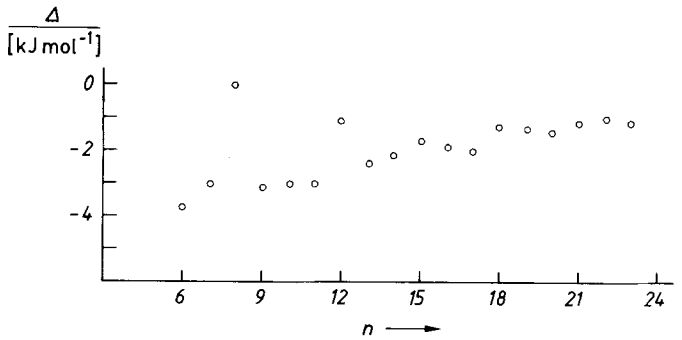

Fig. 1. Difference Δ between the mean bond energies (m.B.E.) of the ring molecules S_n ($n = 6$—23) dissolved in liquid S_8 and the m.B.E. of S_8:

$$\Delta = \text{m.B.E.}\ (S_n) - \text{m.B.E.}\ (S_8) = -\Delta H(1)/n$$

According to [7], m.B.E. (S_8) = 226.6 kJ mol^{-1} (atomization energy of gaseous S_8 at 25°C).

values and the bond energy of S_8. It emerges that S_{12} is the next most stable molecule after S_8, while the smallest ring (S_6) detectable in the melt has the smallest mean bond energy. Thus, for the first time, accurate thermodynamic data for sulfur molecules with more than 8 atoms are now known.

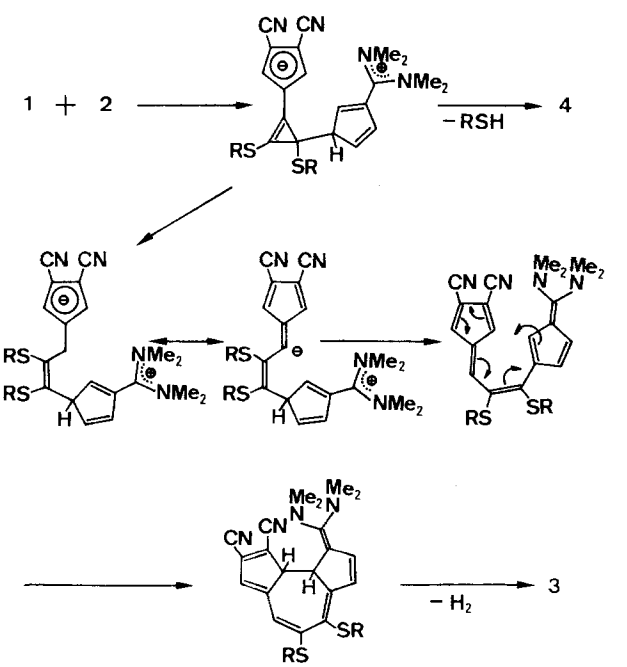
A Novel Transformation of a Calicene to an Azulenofulvene

By *Zen-ichi Yoshida**, *Mitsuhiro Shibata*, *Eiji Ogino*, and *Toyonari Sugimoto*



Calicenes (cyclopropenylidenecyclopentadiene) exhibit interesting reaction behavior, as expected from their novel structural features. For example, methyl-1-(dipropylcyclopropenylidene)-3-indenecarboxylate[1], 9-(dimethylcyclopropenylidene)fluorene and 5-(dimethylcyclopropenylidene)-1,2,3,4-tetraphenylcyclopentadiene[2] are converted into naphthalene derivatives by reaction with dimethyl acetylenedicarboxylate. In contrast, we have now found a novel skeletal conversion of 4-[bis(*tert*-butylthio)cyclopropenylidene]-1(5),2-cyclopentadiene-1,2-dicarbonitrile **1**[3] into the azulene derivative **3** upon reaction with 6,6-bis(dimethylamino)fulvene **2**.

Treatment of tetramethylammonium 1,2-dicyanocyclopentadienide[4] with tris(*tert*-butylthio)cyclopropenylium perchlorate[5] in dichloromethane gave **1** in 97% yield[3]. When **1** was allowed to react with **2** in refluxing tetrahydrofuran, 5,6-bis(*tert*-butylthio)-9-[bis(dimethylamino)methylene]-1,2-cyclopent[*e*]azulenedicarbonitrile **3** (dark blue crystals, m.p. = 250—251°C, 11% yield) and the substitution product **4** (yellow crystals; m.p. = 130—132°C, 52% yield) were obtained (Scheme 1). Both compounds possess novel π-electronic structures.

Scheme 1.

The structure of **4** was easily determined from the ^{1}H-NMR spectroscopic data. The IR spectrum of **3** shows no absorption attributable to the cyclopropene stretching vibration around 1800 cm^{-1}, suggesting cleavage of the three-membered ring. Also, in the ^{1}H-NMR spectrum, two protons on the fulvene moiety and one proton on the di-

Yoshida, Kyoto 606 (Japan)

cyanocyclopentadienyl moiety appear as two doublets and a singlet, respectively. These results, together with the mass and ^{13}C-NMR spectroscopic data[6], suggest that **3** is an azulenofulvene derivative[7] with two *tert*-butylthio groups and two cyano groups.

A formation scheme involving 1) attack by the 2-position of **2** at the 5-position of **1**, 2) opening of the three-membered ring, 3) proton transfer, 4) disrotatory 10π-electrocyclic reaction, and finally 5) dehydrogenating aromatization is shown in Scheme 2[8].

Probing the Structure and Crystallinity of a Lithium Silicate Glass by ^{29}Si Magic-Angle-Spinning NMR Spectroscopy

By *C. N. R. Rao*, John M. Thomas*, Jacek Klinowski, U. Selvaraj, K. J. Rao, G. Robert Millward,* and *Subramaniam Ramdas*

It is now well established that high-resolution magic-angle-spinning NMR spectroscopy (MASNMR) can monitor the nature of short-range order in both non-crystalline and crystalline solids[1,2]. ^{29}Si-MASNMR studies of silicates have shown that the ^{29}Si chemical shift is related to the Si–O–Si angles and to interatomic distances[3]. In glasses, where a wide range of such structural parameters are simultaneously present, lineshapes provide information about the nature of the distribution functions[4]. We have found that useful information on the distribution of Si–O–Si angles may be obtained from ^{29}Si-MASNMR spectra of glasses in which the crystallinity varies from zero to 100%, as gauged by electron microscopy.

We have chosen lithium disilicate glass, thermally treated to yield a range of materials extending between the two extremes of 100% crystallinity and 100% non-crystallinity. Lithium disilicate, $Li_2O \cdot 2\,SiO_2$, is a particularly suitable material for such a study since its crystal structure is known[5], and no change of composition is observed on devitrification. Crystalline lithium disilicate consists of a double-chain arrangement of apex-shared SiO_4^{4-} tetrahedra in such a way that each Si atom has three equivalent silicon neighbors. Partly crystalline $Li_2O \cdot 2\,SiO_2$ contains minute microcrystals immersed in an amorphous matrix, apparent even in scanning electron micrographs, and is readily detectable by electron diffraction.

In recording the ^{29}Si-NMR spectra, we noted that the spin-lattice relaxation times T_1 of the nucleus were very different in the microcrystalline and non-crystalline regions; in the former case this was of the order of seconds while in the latter of the order of hours. This large difference in relaxation times makes it possible to distinguish between the two regions and measure the relative amounts of material in each. Whereas the spectrum of the crystalline part of the mixture can be obtained relatively easily, a spectrum comprising signals of both the amorphous and crystalline regions can be measured only if short pulses and long pulse delays are used, and we used 30° pulses separated by 90 min delays.

Even those samples which, by microscopy, appeared largely (80%) non-crystalline, contained traces of microcrystallinity, and hence the resulting spectrum (Fig. 1a) contains the characteristic, though somewhat broader signal at $\delta = -92$ from tetramethylsilane (TMS) superimposed upon a much broader background resonance, the chemical shift of which ranges from $\delta = -70$ to -120 and which is attributable to non-crystalline regions of the sample.

The total range of ^{29}Si-NMR chemical shifts in silicates lies between $\delta = -60$ and -120. This is split up into five intervals[2] corresponding to Si atoms in monosilicates, i.e. to isolated SiO_4^{4-} groups (denoted by Q^0), disilicates and

chain end groups (Q^1), middle groups in chains (Q^2), chain branching sites (Q^3), and fully crosslinked framework sites (Q^4). Within each structural category the ^{29}Si chemical shift is correlated with the Si–O–Si bond angles and the interatomic distances. We conclude that, in agreement with the established structure, the sharp resonance at $\delta = -92$ is attributable to Q^3 groupings (chain branching sites), and the chemical shift corresponds to an Si–O–Si angle of ca. 135°. The single sharp resonance at $\delta = -61$ (x) is due to Q^0 (monosilicate) present as binder in the ZrO_2 magic-angle spinner.

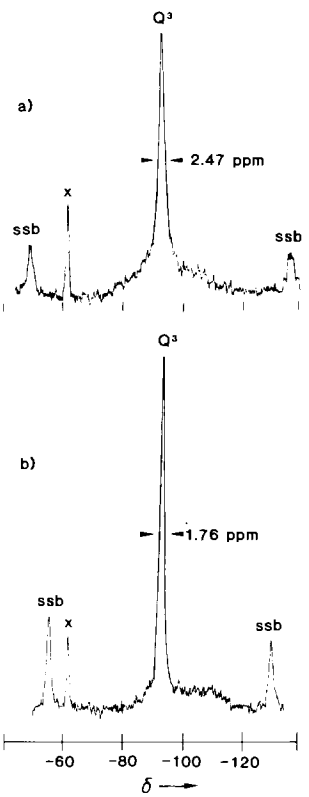

Fig. 1. ^{29}Si-MASNMR spectra (59.60 MHz, Bruker CXP-300). a) Partially crystallized lithium disilicate glass; b) almost completely crystalline $Li_2O \cdot 2SiO_2$. Samples spun at ca. 3.5 kHz in Andrew-Beams spinners made of Delrin. δ-values given in ppm relative to TMS branching sites.

There are also distinct spinning sidebands (ssb) equidistant from the main signal, which are due to chemical shift anisotropy. Their presence supports our assignment of the main signal as arising from Q^3 units; Q^4 (fully cross-linked framework sites) units resonate at a higher field and involve much smaller chemical shift anisotropy. Spinning sidebands from Q^4 sites in framework silicates are much less distinct than in the present Q^3 case. Finally, no Q^2 signals (corresponding to the termination of the double chain) are visible in the spectra, indicating that their concentration is low.

The range of resonances ($\delta = -70$ to -120) for the noncrystalline regions can be interpreted in several ways: 1) Q^1, Q^2 and Q^3 groups are present, 2) the Si–O–Si angles range from ca. 120 to 180° in the Q^3 groupings, and 3) the interatomic distances vary. Of these possibilities, a combination of 2) and 3) is the most likely explanation. The fact that the spectrum of the largely crystalline sample (electron diffraction studies) also contains a broad background resonance signifies the presence of some crystallographically disordered material. When the composition of a lithium silicate glass $Li_2O \cdot x\,SiO_2$ is varied by increasing x, a broad NMR signal is observed whose chemical shift approaches that of Q^4 units.

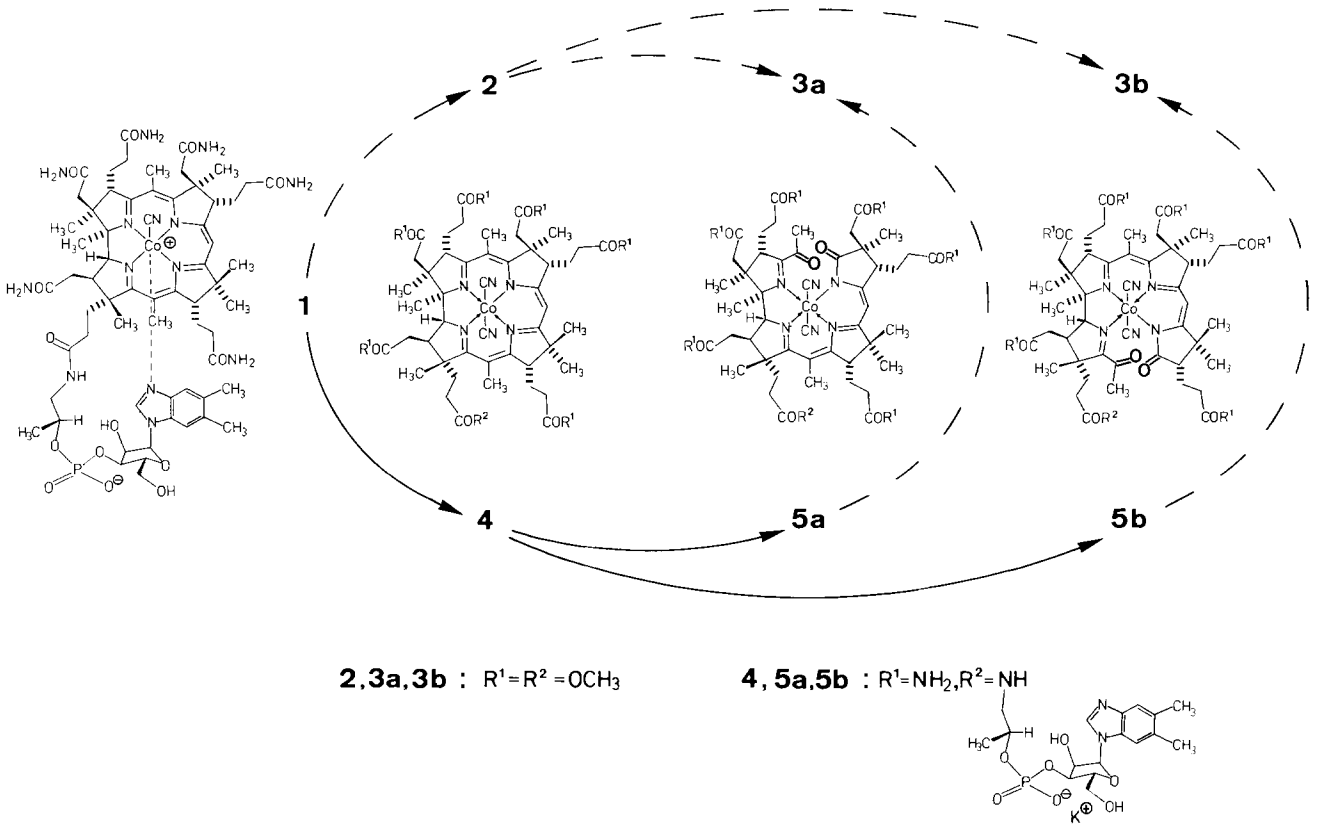
Photooxygenolysis of Vitamin B_{12}**



By *Bernhard Kräutler** and *René Stepánek*

Studies of the action of singlet oxygen ($^1O_2$) on vitamin B_{12} **1** are still outstanding, but should be of interest because of the medical[1], biological[1,2], and preparative[2,3] role of $^1O_2$. We recently found that heptamethyl-dicyano-Co^{III}-cobyrinate **2** ("cobester"[4]), the nucleotide-free methanolysis product of vitamin B_{12}, undergoes selective photooxygenolysis to afford the dioxosecocobyrinates **3a** and **3b**[5]. This degradation reaction with $^1O_2$[5] opened an efficient route to **3a** and **3b**, the former of which *Inhoffen* et al.[6] had already prepared via partial ozonolysis of heptamethyl-dicyano-Co^{III}-10-bromocobyrinate. We now report on the photooxygenolytic cleavage of the corrin macrocycle of vitamin B_{12} (see Scheme 1).

Upon irradiation with visible light, vitamin B_{12}, dissolved in oxygen-saturated CD_3OD, exhibited considerable inertness, even in the presence of the $^1O_2$-sensitizer methylene blue (MB). Only after addition of KCN (1 mol per mol **1**) to a solution of **1** (λ_{max} is shifted from 548 to 584 nm, corresponding to the conversion **1** → potassium dicyanocobalamin **4**) and of MB in CD_3OD did the photolysis lead to degradation of the corrin within a few hours[7]. In CH_3OH, but otherwise under the same conditions, the photolysis proceeded approximately 7 times more slowly[8]. Irradiation[9] of an oxygen-saturated solution of **1**, KCN, and MB (molar ratio 1 : 1 : 0.005) in CD_3OD at ca. −70 °C with a 150-W tungsten lamp led after 45 min to ca. 50% degradation of the educt and to formation of products which absorb at shorter wavelengths (λ_{max} ca. 490 nm). Work-up of the reaction mixture and HPLC separation[9] allowed recovery of 31% of **1** and afforded potassium dicyano-5′,6′-dimethylbenzimidazolyl-5,6-dioxo-5,6-secocobamide **5a** (10%) and its regioisomer **5b** (24%). The structures of the noncrystalline photooxygenolysis products **5a** and **5b** result from comparison of their UV/VIS, CD, IR,

Scheme 1. **1**→**2** methanolysis [4]; **2**→**3a**+**3b**: photooxygenolysis [5]; **1**→**4**: see text; **4**→**5a**+**5b**: photooxygenolysis [9]; **5a**→**3a** and **5b**→**3b**: methanolysis [10].

^{1}H-, and ^{13}C-NMR, as well as of their FAB-MS spectra with those of **3a**[5,6] and of **3b**[5] (see Table 1). Moreover, upon acid-catalyzed methanolysis[10] **5a** is converted into **3a** and **5b** into **3b**. The characteristic regioselectivity and the ratio of **5a** : **5b** ≈ 0.4 : 1 can be interpreted as the outcome of electrophilic attack of $^1O_2$[8] that occurs to a similar extent at the *meso*-positions C-5 and C-15 of the corrin ligand (in comparison: photooxygenation of **2** afforded **3a** : **3b** ≈ 2 : 1[5]).

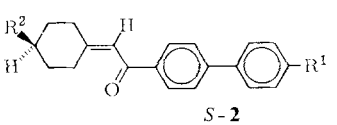
Axial Chirality can lead to Chiral Smectic and Cholesteric Liquid Crystals**

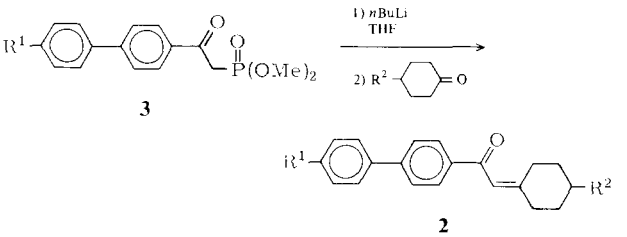


By *Guy Solladié** and *Richard G. Zimmermann*

Although the fact that optically active compounds can form mainly cholesteric liquid crystals has been known for some time[1], the chirality has always been introduced by way of one or more asymmetric centers, generally located in a terminal chain. In contrast, there are no reports of any attempts to synthesize optically active liquid crystal materials having molecular asymmetry[2], although such molecules could be of interest as dopants for nematic displays.

S-**1**

R′ = CO−R″



S-**2**

Here we report our results on the synthesis of optically active compounds with axial chirality. The axial chirality arises from the presence of the chiral cyclohexylidene ethanone unit **1** (R′ = CO−R″); the plane defined by C4, R, and H is perpendicular to the plane of the double bond substituents. Compounds **2** with suitable substituents R^1 and R^2 were shown to be chiral smectic or cholesteric liquid crystals (in some cases at room temperature).

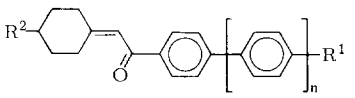
2h	*n*-C_5H_{11}	O−CO−*p*-C_6H_4−CN	c 128 i (110 n)
2i	*n*-C_5H_{11}	O−CO−*p*-C_6H_4−Cl	c 125 i (97 n 77 s_A)

[a] c = crystalline, i = isotropic, n = nematic, s, s_1, s_2 = unidentified phases, s_A = smectic A, a = unidentified anisotropic phase.

As shown in Table 1, most of these compounds exhibit monotropic mesophases which are generally smectic. Compounds **2e** and **2f** are notable because they do not crystallize but occur as smectic mesophases at room temperature and below. **2a** is the only compound which does not exhibit mesomorphic properties, probably because it has no pentyl chain (R^1) at the "aromatic end". In contrast, **2b**, which has no substituents R^2 at the "cyclohexyl end", has a monotropic mesophase.



The optically active, substituted cyclohexylidene ethanones *R*-**2** and *S*-**2** were obtained by stereoselective acylation[3] of the sulfoxides *R*-**4**, followed by stereospecific elimination of the sulfoxide[4] (Scheme 2, Table 2).

From the results listed in Table 2 it can be concluded that the presence of a biphenyl moiety is necessary for formation of liquid crystals (compounds **6a** and **6b** are iso-

Scheme 2. *p*-Tol = *p*-Tolyl.

[a] In parentheses: conc. in acetone. [b] See Table 1, footnote [a]; ch = cholesteric.

tropic). Most of the compounds in Table 2 exhibit smectic phases. However, **2k** and **2n** also display a cholesteric phase, while **2l** shows only cholesteric properties. **2l** is also the first example of a cholesteric liquid crystal having axial chirality.

Although these substituted cyclohexylidene ethanones showed low light stability, which prevents their practical application, this study has demonstrated that molecules having axial chirality and in this case a 90° dihedral angle between the two parts of the molecule, can exhibit liquid crystalline properties.

Short Synthesis of Cerebrosides**

By *Richard R. Schmidt** and *Rudolf Kläger*

Cerebrosides are major constituents of the membranes of brain cells. They are the simplest glycosphingolipids and serve as model substances for more complex lipids of this kind. Furthermore, they are credited with important properties as receptors for hormones, interferons, and toxins[1]. Herein we describe a short synthesis of natural D-*erythro*-configurated D-glucosylcerebroside[2].

We prepared D,L-C_{18}-sphingosine **1**-D,L using a method developed by us for the two-step synthesis of *erythro*-sphingosine[3]. In analogy to previously described methods[4], on reaction of **1** with palmitoyl chloride we obtained the D,L-ceramide **2**-D,L[5] (77%) and, on subsequent tritylation, the 1-*O*-tritylated compound **3**-D,L (60%). 3-*O*-Benzoylation with benzoyl chloride/pyridine (to **4**-D,L, 92%) and detritylation with $BF_3 \cdot OEt_2$ then afforded the 1-*O*-unprotected ceramide **5**-D,L (69%)[4,6].

Scheme 1. In the case of **1**-D,L, **2**-D,L, **3**-D,L, **4**-D,L, and **5**-D,L only the D-isomers are depicted. For catalysts for the reaction of **5**-D,L see text. Bz = benzoyl, Trt = trityl.

The best method for the glycosylation of **5**-D,L proved to be that developed by us, namely the trichloroacetimidate method[7], which, without optimization, afforded better yields than the cerebroside synthesis according to the Koenigs-Knorr method or the Helferich-Weis method[1,4,8]. Thus, with *O*-(2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl) trichloroacetimidate in dichloromethane at room temperature, using $BF_3 \cdot OEt_2$ or trimethylsilyl trifluoromethanesulfonate as catalyst, the diastereomeric D-glucocerebrosides **6**-D,D[6] and **6**-D,L[6] were obtained in 50—70% yield. Despite only small differences in elution behavior[9], the separation of the diastereomers could be realized by column chromatography. On treatment of **6**-DD and **6**-DL with so-

dium methoxide/methanol, the *O*-unprotected cerebrosides **7**-D,D[6] and **7**-D,L[6] were formed quantitatively; both compounds are of interest for biological investigations[2].

For verification of the structure and for the direct synthesis of the natural cerebroside **7**-DD the racemate **3**-D,L was acylated at the 3-hydroxy group with L-*O*-acetylmandelic acid chloride in the presence of pyridine. The diastereomers thus obtained were separated chromatographically and converted into the enantiomeric ceramides **3**-D and **3**-L (total yield 70%) by treatment with sodium methoxide/methanol. These compounds afforded, as described above, the well-known ceramides **5**-D and **5**-L, respectively, which could be identified by comparison of their rotations[10]. Moreover, the natural isomer **5**-D was converted, via compound **6**-DD, into the cerebroside **7**-DD.

Synthesis and Structure of $[(C_5H_5)_3M_3(CO)_6(\mu_3\text{-As})]$ (M = Mo, W), Transition-Metal-Stabilized Arsanetriyl Compounds**

By *Klaus Blechschmitt, Heike Pfisterer, Thomas Zahn,* and *Manfred L. Ziegler**

Reaction of the molybdenum complex **1** with As_4S_4 in toluene leads to formation of the compound **2** and the species **3a** and **4** containing Mo_2As_2 and $MoAs_3$ clusters, respectively[1]. The Mo_2As_2 moiety has also been detected in the cyclopentadienyl complex **3b**, R = H, by X-ray crystallography[2]. Hence, in the homologous series As_nMo_{4-n} (n = 0—4), the only member missing is $AsMo_3$. Compounds containing μ_3-As bridging atoms in transition-metal clusters have hitherto only been found in the iron- and cobalt-complexes **5**[3] and **6**[4], respectively. In these complexes the arsenic atom is in a trigonal-pyramidal environment[5].

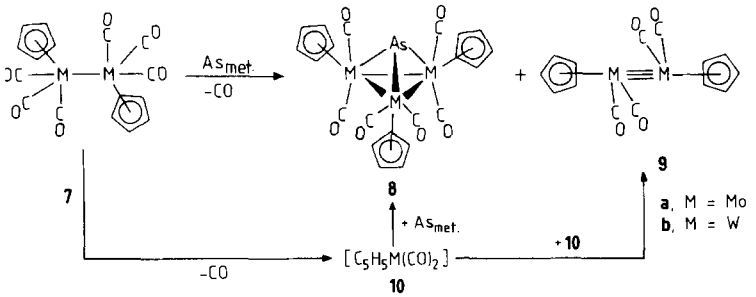
$$[(C_5Me_5)_2Mo_2(CO)_4] \xrightarrow[\text{toluene}]{As_4S_4} [(C_5Me_5)_2Mo_2(\mu\text{-}As_2S)(\mu\text{-}S_2)] +$$

1 **2**

$$[(C_5R_5)_2Mo_2(CO)_4(\mu\text{-}As_2)] + [(C_5Me_5)Mo(CO)_2As_3]$$

3a R = Me **4**

$$[\{Fe(CO)_3\}_3(\mu_3\text{-}As)(\mu_3\text{-}As)] \quad [\{Co(CO)_3\}_3(\mu_3\text{-}As)]$$



5 **6**

We have now been able to prepare the clusters **8a**, **b** from the binuclear complexes **7a**, **b** and metallic arsenic in a surprisingly simple reaction[6], and to unequivocally characterize them by elemental analysis, spectroscopic data[7], and, in the case of **8a**, by an X-ray structure analysis[8]. The simplicity of the method of preparation of these clusters containing Mo_3As and W_3As units is surprising, in particular since the arsanetriyl derivatives **5** and **6** are only accessible via the AsX_3 compounds (**5**: X = F, **6**: X = Cl, Br, I). On heating **7a**, **b** and As under reflux in *p*-xylene, **8a** and **8b** are formed in 65% and 40% yield, respectively (referred to **7a**, **b**), together with **9a**, **b** (≈15%). It can therefore be concluded that homolytic dissociation of **7** and elimination of CO leads to intermediate formation of **10a**, **b**, which then react further with arsenic to give the compounds **8** or dimerize to the species **9**[9].

According to the X-ray structure analysis, **8a** has a tetrahedrane structure (trigonal pyramidal). Since the absorption pattern in the ν_{CO} region of the IR spectrum of **8a** is identical with that of **8b**, it can be assumed that **8b** has an analogous structure. The Mo—As—Mo bond angles have a

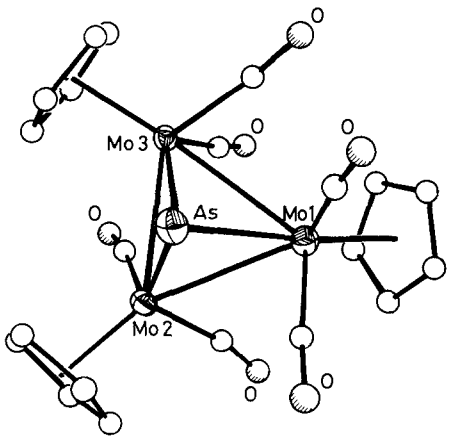
mean value of 75.87°, and are therefore distinctly larger than in As_4 and in **5** (67.87°)[3]. The Mo–As bonds have a mean length of 253.4 pm and are thus shorter than in **4** (266.1 pm) and in **3b** (262.0 pm).



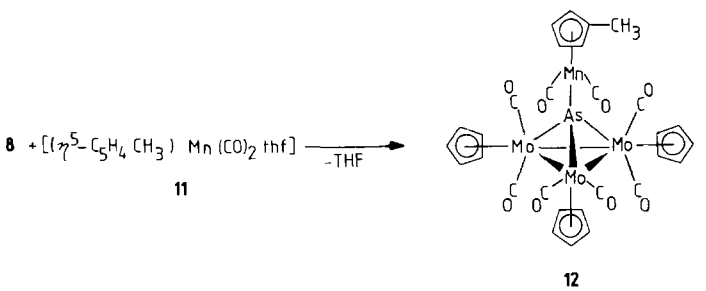


Fig. 1. Structure of **8a** in the crystal.

In compounds **8**, arsenic utilizes only three of its five valence electrons; therefore, electrophilic reactions at the arsenic atoms are to be expected. Accordingly, **8a** reacts with the substitution-labile THF-complex **11** (THF = tetrahydrofuran) with formation of the cluster **12**[10].

[6] A solution of **7a** (1.5 g, 3.3 mmol) in *p*-xylene (50 mL) was treated with 2.6 g (34.6 mmol) metallic arsenic and the mixture stirred under reflux in a nitrogen atmosphere for 12 h. The green reaction solution was filtered, concentrated to 10 mL, and transferred onto a column (silica gel 0.05–0.2, length 40 cm, diameter 2 cm). A red zone (unreacted **7a**) and then a brown zone (**9a**) were eluted from the column with hexane/toluene (2:1). On subsequent elution with toluene/ether a green solution of **8a** was obtained, which, after removal of solvent and recrystallization from toluene/ether (1:1) at −18°C, furnished analytically pure, dark-green crystals (65% yield referred to **7a**). **8b** could be prepared analogously (yield 40% referred to **7b**). In the analogous reaction of $[(C_5H_5)_2Cr_2(CO)_6]$ with metallic arsenic, no identifiable products were formed.

c-TiS_2, a New Modification of Titanium Disulfide with Cubic Structure

By *Robert Schöllhorn** and *Andreas Payer*

Hexagonal titanium disulfide belongs to the group of transition-metal chalcogenides with layer structure and has been extensively studied with respect to correlations between structural anisotropy, physical properties, and chemical reactivity[1]. Moreover, the compound has found technical application as an electrode material for high energy-density secondary batteries[2]. We report here on the formation and basic properties of a new metastable modification of this compound with cubic structure.

Ternary thermal phases $A_xM_yX_z$ (A = alkali metal, Cu, Ag, Tl; M = transition metal; X = nonmetal) having appropriate structural and electronic properties and an ionic constituent A selectively mobile in the lattice at low temperatures can undergo topotactic redox reactions via electron/ion transfer to yield new binary phases M_yX_z[3]. The reactions described below are based on this mechanistic concept.

[+] New address:
Institut für Anorganische und Analytische Chemie
der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12

The starting compound chosen was the copper thiospinel $CuTi_2S_4$ (cubic lattice parameter $a = 999.8$ pm), prepared at 1100 K from the elements[4]. We found that the $Cu^{\oplus}$ ions are mobile at ambient temperature and that the electronic properties of the system are consistent with the following redox reaction:

$$CuTi_2S_4 \rightleftharpoons Cu_xTi_2S_4 + (1-x)Cu^{\oplus} + (1-x)e^{\ominus}$$

The oxidation can be performed chemically in aqueous suspension with strong oxidants, e.g. $FeCl_3$; however, it was not possible to avoid contamination of the products by titanium hydroxide oxide formed at the surface of the crystallites under these conditions. Pure phases were obtained electrochemically on anodic galvanostatic or potentiostatic oxidation of pressed polycrystalline $CuTi_2S_4$ working electrodes in aprotic $Cu^{\oplus}$ electrolytes. The oxidation products belong to a nonstoichiometric series $Cu_xTi_2S_4$ and exhibit an almost linear correlation between the change in copper content x and the lattice parameter a (Fig. 1). The chemical diffusion coefficients $\tilde{D}$ for copper ions measured by the electrochemical potential step technique lie in the range 10^{-11} to 10^{-12} cm^2 s^{-1} at 300 K.

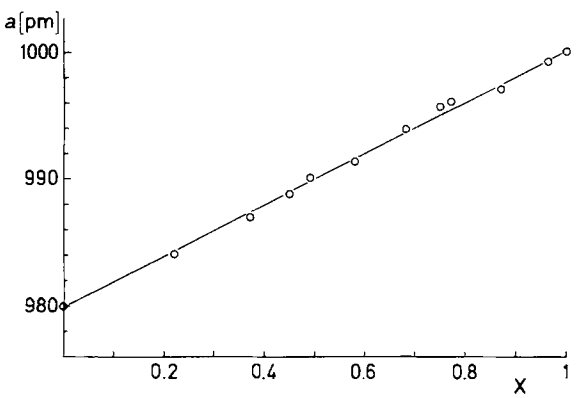

Fig. 1. Variation of the cubic lattice parameter a with the copper level x in $Cu_xTi_2S_4$ phases prepared by anodic oxidation of the thiospinel $CuTi_2S_4$ in $Cu^{\oplus}$ electrolytes at 300 K.

The phase range observed corresponds to $1 \geq x \geq 0$, and the pure cubic binary phase Ti_2S_4 or c-TiS_2 can thus be obtained. Analytical studies confirm this composition and the quantitative removal of copper. The lattice parameter is $a = 980.1$ pm, and the space group is Fm3m (Fd3m). The structure can be derived from a sodium chloride lattice in which half of the octahedral cation positions are vacant, i.e. $\square_{1/2}Ti_{1/2}S$. So far no single crystals of appropriate quality could be prepared, but the intensity calculation from the X-ray powder data ($R = 0.09$) confirms the structural model, which is also supported by the reversibility of the above reaction. The AB_2 structural type to which cubic titanium disulfide belongs has been observed so far only for a modification of MnO_2, prepared similarly via a ternary phase[5].

At temperatures above ca. 700 K, c-TiS_2 undergoes a phase transition to hexagonal TiS_2 with the lattice parameters $a = 339.2$, $c = 569.1$ pm. Both the change in symmetry and the decrease in unit cell volume (3%) suggest that c-TiS_2 is a metastable phase. Differential thermal analysis (DTA) studies indicate a rather small exothermic effect with a sluggish transformation over a large temperature range; this is most probably due to the kinetics of $Ti^{4\oplus}$ diffusion.

The thiospinel $CuTi_2S_4$ can formally be described as $Cu^{\oplus}[Ti^{3\oplus}Ti^{4\oplus}(S^{2\ominus})_4]$ and is a metal in terms of its electronic structure and transport properties[6]. Since c-TiS_2 is a d^0-system, it is expected to exhibit semiconductor properties. The data for polycrystalline samples show, however, that the electronic conductivity between 80—295 K is almost constant with a relatively high value of 60 Ω^{-1} cm^{-1}. Conclusions on the electronic nature of c-TiS_2 cannot therefore be derived from the present data; we draw attention to hexagonal TiS_2, which exhibits metallic properties, although the origin of the carriers is still under discussion[7].

At ambient temperature c-TiS_2 behaves as a framework host lattice for the intercalation of small atomic guest ions ($H^{\oplus}$, $Li^{\oplus}$, $Cu^{\oplus}$) via electron/ion transfer. Cathodic reduction of c-TiS_2 in $Cu^{\oplus}$ electrolytes, the reverse of the above reaction, affords the spinel $CuTi_2S_4$ with lattice parameters identical to those of the thermal phase. A maximum charge transfer of $3e^{\ominus}$/c-TiS_2 is observed upon electrochemical intercalation of lithium from a $LiClO_4$/propylene carbonate electrolyte. The partial molar free energy of reaction for the uptake of one equivalent of lithium ($Li + Ti_2S_4 \rightarrow LiTi_2S_4$) estimated from the potential/charge transfer is $\Delta G_R = -205$ kJ mol^{-1}. This is comparable to that for the formation of the corresponding phase $Li_{0.5}TiS_2$ from hexagonal TiS_2. Cubic titanium disulfide is thus of interest with respect to its use as an electrode material for secondary batteries; compared to layered hexagonal TiS_2 it offers the advantage that solvent co-intercalation on extended cycling is precluded by the framework structure.

A considerable number of other copper transition-metal chalcogenides CuM_2X_4 with the spinel structure have been described in the literature[8], and further studies are required to establish whether additional metastable binary compounds with the c-TiS_2 structure (e.g. cubic ZrS_2, VS_2, $CrSe_2$) can be obtained by this type of reaction. We also expect that the corresponding lithium chalcogenospinels will exhibit similar reactivity.

Novel Aspects of the Coordination Chemistry of Phosphane**

By *E. A. V. Ebsworth** and *R. Mayo*

Phosphane, PH_3, is not generally regarded as a good ligand. It is a poor σ-donor, and the absence of electronega-

[*] Prof. E. A. V. Ebsworth, R. Mayo
Chemistry Department, University of Edinburgh
West Mains Road, Edinburgh EH9 3JJ (Scotland)

[**] We are grateful to the Science and Engineering Research Council for a studentship to *R. M.*, and to Johnson Matthey for lending us chemicals.

tive ligands appears likely to make it a weak π-acceptor. Most of the known PH_3-complexes of transition metals are of the elements of the chromium triad[1]. Phosphane does not add oxidatively to $PtClH(PEt_3)_2$; instead, it displaces chloride ion at low temperatures[2], forming the cationic complex $[PtH(PEt_3)_2(P'H_3)]^{\oplus}$, which loses PH_3 and gives the starting material when warmed. We have recently discovered a richer coordination-chemistry of phosphane, involving both donor-acceptor complex formation and oxidative addition, in reactions with Ir^I substrates.

Phosphane adds oxidatively to *trans*-$[Ir(CO)X(PEt_3)_2]$ (X = Br or Cl) in toluene, forming a PH_2-complex of Ir^{III} with H *trans* to X.

$$[Ir(CO)X(PEt_3)_2] + PH_3 \longrightarrow [Ir(CO)XH(PEt_3)_2(P_c'H_2)]$$
1, X = Cl; **2**, X = Br

We have isolated **2** and the arsenic analogues of **1** and **2** (**1a** and **2a**, respectively) and characterized them by NMR spectroscopy (Table 1), their reactions, and the crystal

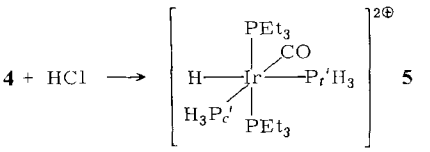
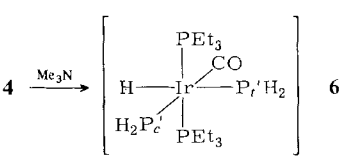
structures of **1a** and of the $RuCl_2$(*p*-cymene) complex of **2**[3]. The reaction between $[Ir(CO)X(PEt_3)_2]$ and PH_3 in dichloromethane takes a different course. At 180 K the ^{31}P-{^{1}H} spectrum shows that the reaction is rapid, and the first product is a bis-PH_3 complex of pentacoordinated Ir.



$$[Ir(CO)X(PEt_3)_2] + 2\,PH_3 \longrightarrow [Ir(CO)(PEt_3)_2(P'H_3)_2]^{\oplus}\ \mathbf{3}$$

This product is formed even in equimolar solutions, leaving excess of the Ir^I starting-material. **3** was characterized by NMR spectroscopy. The ^{31}P-{^{1}H} spectrum shows the presence of two equivalent PEt_3-groups and two equivalent $P'H_3$-groups; the presence of three hydrogen atoms bound to P′ is established from the proton non-decoupled spectrum, when a complex pattern is observed arising from the magnetic nonequivalence of the $P'H_3$-groups. Analysis of the second-order P′*H*-NMR spectrum gives $^2J(P'P') = 80.3$ Hz, a value much too large for a complex of hexacoordinated Ir^{III}, but appropriate for pentacoordinated Ir^I[4]. The same product is obtained when X = Cl and X = Br, showing that there is no halogen bound to Ir in **3**, and no noncondensible gas is evolved. **3** is unstable at temperatures above 230 K and undergoes internal oxidative addition to give an Ir^{III} complex cation **4** containing a $P'H_2$ and a $P'H_3$ ligand; the PH_3-phosphorus atom has $^2J(P'IrH) = 140.7$ Hz and is therefore *trans* to the H atom.



Cation **4** has been isolated as the chloride and characterized by its NMR spectra (which are particularly characteristic) and by its reactions with electron pair acceptors.

The ^{31}P- and ^{1}H-NMR spectra show clearly that there is no fast exchange of protons between $P_c'H_2$ and $P_t'H_3$; $^1J(P'H)$ is retained for both groups up to 273 K, and the two P′ resonances remain sharp and widely separated. **4** reacts with an excess of HCl to give the bis-(PH_3) dication **5**:

This reaction is reversible, and in the presence of an equimolar proportion of HCl the equilibrium shifts markedly with temperature. At 180 K ca. 90% of the iridium is present as the dication **5**; resonances in the ^{31}P-{^{1}H} spectrum arising from both **4** and **5** are sharp, and proton coupling can be observed in all P′ resonances. As the temperature is raised, the relative intensities of the resonances from **4** increase, and all the P′ resonances broaden and shift. Peaks arising from $P_c'H_2$ of **4** and $P_c'H_3$ of **5** move towards each other, as do those from $P_t'H_3$ of **4** and $P_t'H_3$ of **5**. When proton coupling is restored, $^1J(P'H)$ can be observed in the resonances from $P_t'H_3$ of **4** and $P_t'H_3$ of **5**, but not in the resonances from $P_c'H_2$ of **4** and $P_c'H_3$ of **5**. This shows that the broadening is due to proton exchange between $P_c'H_2$ of **4** and $P_c'H_3$ of **5**; there is no fast exchange of protons involving $P_t'H_3$ of **4** or $P_t'H_3$ of **5**. Exchange of P′ cannot be involved, since $^2J(PP')$ is retained for both **4** and **5** in the mixture. Free PH_3 cannot be involved either, since some is present in solution and its resonance remains sharp. As the temperature is raised still further, the resonances from $P_c'H_2$ of **4** and $P_c'H_3$ of **5** coalesce; with increasing temperature the coalesced peak then moves towards the position of the resonance from $P_c'H_2$ of **4**, showing that the position of equilibrium shifts to the left as the temperature rises, possibly because of the change in solubility of HCl with temperature. Above ca. 260 K, the complexes decompose, giving $[Ir(CO)ClH(PEt_3)_2(P'H_3)]^{\oplus}$ with H *trans* to the $P'H_3$ group.

We have also deprotonated **4** with Me_3N, and characterized the complex **6** formed, which contains two PH_2 ligands, from its NMR spectra and chemical reactions.

The ease with which Cl or Br is expelled from $[Ir(CO)X(PEt_3)_2]$ (X = Cl, Br) to form the bis-PH_3 cation of pentacoordinated Ir^I is surprising, as is also the marked dependance of the basicity of the coordinated PH_2-group upon the ligand *trans* to it. A coordinated PH_3-group is normally acidic; the absence of proton exchange between $P'H_2$ and $P'H_3$ in **4** is unexpected and clearly reflects a re-

duction in electron-donor properties of $P'H_2$ *trans* to CO as opposed to $P'H_2$ *trans* to H.

$[CuCo(CO)_4]_n$—Crystal Structure of a Polymer with a One-Dimensional, Infinite Copper-Cobalt Bonding System**

By *Peter Klüfers**

$CuCo(CO)_4$ crystallizes dimorphically. The tetrameric molecules **1b** with a Cu_4Co_4 eight-membered ring are the building blocks of one modification which forms orange-red crystals[1]. These are frequently accompanied by strongly distorted yellow platelets or needles of the same composition, which, according to an X-ray structure analysis, consist of the polymeric modification **1a**.

The existence of an infinite metal atom chain in a carbonylheterometal, established here for the first time by a single crystal investigation, has frequently been the subject of controversy for compounds of the type $MFe(CO)_4$ (M = Zn, Cd, Hg). Based on the results of the structure analysis on $[CdFe(CO)_4]_4[(CH_3)_2CO]_2$, oligomeric building units are assumed for this class of compounds[3].

The Cu–Co chains in **1a** are constructed from a slightly bent backbone of copper atoms, in which every two Cu atoms are bridged by a $Co(CO)_4$ group to form Cu–Co bonds. This results in a [010] wavy zig-zag chain of metal atoms along [001] (Figs. 1 and 2). The center of gravity of each of the pairs of copper atoms lies approximately on a twofold axis of a $Co(CO)_4$-tetrahedron. The edge of the tetrahedron which is directed towards the Cu_2-fragment is markedly lengthened (Table 1, Fig. 2).

Apart from an almost linear environment of the Cu atoms in **1a**, the geometry of the $Cu_{2/2}Co(CO)_4$ building blocks is almost the same as in **1b**; furthermore, both modifications have approximately the same spatial requirements (Table 1).

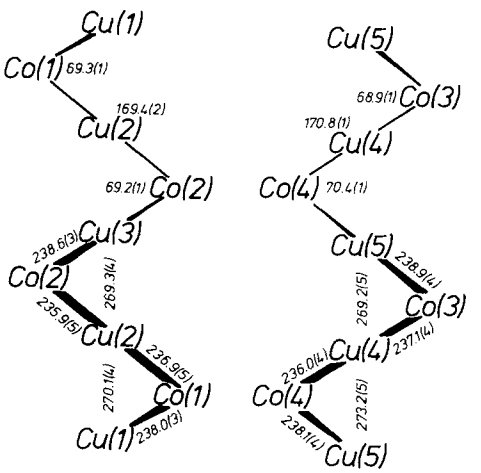

Fig. 1. Distances [pm] (below) and angles [°] (above) in the two symmetrically independent metal atom chains in **1a**. Projection along [010]. Left: chain at $y \approx 0$; Cu1 and Cu3 in the centrosymmetric position. Right: $y \approx 1/4$, all atoms in the general position. Cu–Cu–Cu angle at Cu2 147.6(1), Cu4 145.7(1), Cu5 176.1(1).

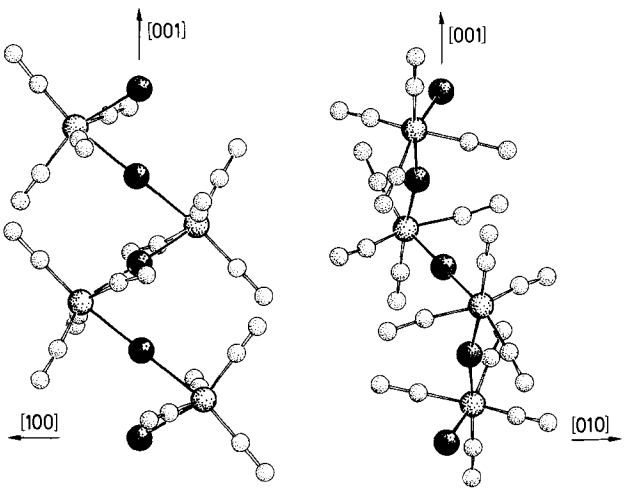

Fig. 2. Structure of the carbonylmetal chain at $y \approx 0$ in the crystal. The geometry of the chain at $y \approx 1/4$ is only slightly different. Left: Projection along [010] as in Figure 1—zig-zag chain along [001]. Right: chain rotated counterclockwise—waves of the zig-zag chain in [010].

Table 1. Mean atomic distances [pm] and bond angles [°] in **1a** and **1b**; V/Z = volume of a $CuCo(CO)_4$ moiety [10^6 pm^3].

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen. I thank Professor *H.-U. Schuster* for discussions.

The mechanical properties of **1a** are dominated by the orientation of the metal atom chains: the strongly distorted crystals—the needles are often bent—do not cleave perpendicular to [001], but rather separate into fibers. The appearance of the lemon-yellow, water-clear crystals gives no indication of charge delocalization along the metal atom chains. Here, the usefulness of the simplifying concept which regards carbonylmetalate (1−) ions as large, nucleophilic pseudohalide ions becomes apparent[4].

After $[AgCo(CO)_4]_4$[5] (isotypic with WOF_4[6a]), **1a** is a further example of a structural relationship between carbonylmetal compounds and fluorides: polymeric structures with similar geometry have been described for $MoOF_4$ **2**[6b] ($a_{1a}=c_2$, $b_{1a}=b_2$, $c_{1a}=2a_2$).

Synthesis and Structure of a Thallium Complex with an Anionic Sandwich Complex Ligand**

By *Klaus Stumpf, Hans Pritzkow,* and *Walter Siebert**

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

In the solid state, cyclopentadienylthallium is ionic and occurs as a zig-zag chain, but in solution and in the gas phase is a mononuclear molecular unit[1]. SCF-MO calculations[2] support the proposed predominantly covalent Tl–C bond[3]. From the isolobal analogy between $C_5H_5^\ominus$ and the heterocycle side of the sandwich complex ion $\mathbf{1}^\ominus$, a thallium compound [**1**·Tl] is expected, whose structure should, however, differ from that of $[Tl(C_5H_5)]$. We report here the first sandwich complex with an apical thallium atom **2**, which can also be described as a hepta-atomic *closo*-structure.

Reaction of the neutral complex (η^5-cyclopentadienyl)(η^5-1,3,4,5-tetramethyl-2,3-dihydro-1*H*-1,3-diborolyl)-cobalt [**1**·H][4] with $[Tl(C_5H_5)]$ in refluxing tetrahydrofuran (THF) affords orange-brown, crystalline **2** in 61% yield[5]. In solution the complex, which is readily soluble in nonpolar solvents, is rapidly decomposed by air, but in the solid

$\mathbf{1}^\ominus$ R = CH_3 **2**

state is stable for some time. Upon sublimation **2** partially decomposes to form $[Tl(C_5H_5)]$. In the mass spectrum (EI) the $M^\oplus$ ion appears in low relative intensity (m/z 448; 13%), and $(M-Tl)^\oplus$ forms the base peak. The ^{1}H-NMR spectrum[5], like that of $[Tl(C_5H_5)]$[6], exhibits no ^{205}Tl-^1H coupling. In the ^{11}B-NMR spectrum (C_6D_6, $\delta=20.4$) the boron atoms are strongly shielded, as in triple-decker sandwich complexes[7].

The X-ray structure analysis[8] indicates that in the crystal **2** occurs as discrete molecules and differs from the polymeric zig-zag chain structure of $[Tl(C_5H_5)]$. The distances between thallium and the atoms of neighboring molecules (>3.6 Å) preclude further interactions. The molecule lies on a mirror plane through Co, Tl, C2, and C6, and the distances of the metal atoms to the plane through the almost planar rings (deviations $\le\pm0.02$ Å) are (C_5H_5)–Co 1.67 Å, (C_2B_2C)–Co 1.60 Å, and (C_2B_2C)–Tl 2.47 Å [(C_2B_2C): heterocycle]. The geometry of the $[(C_5H_5)Co(C_2B_2C)]$ moiety hardly differs from that of the triple-decker sandwich complexes $[(C_5H_5)Co(C_2B_2C)M(C_5H_5)]$ (M = Fe, Ni)[7] (Figs. 1 and 2).

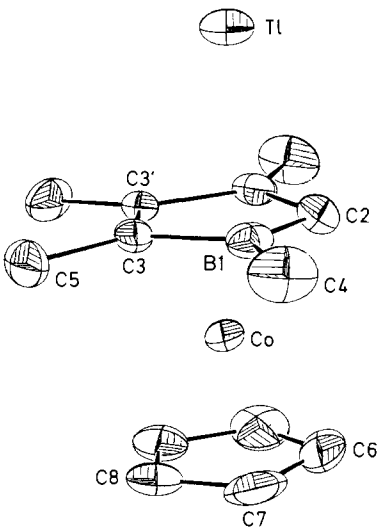

Fig. 1. Structure of **2** in the crystal. Selected bond lengths [Å]: Tl–B1 2.771(8), Tl–C2 2.700(11), Tl–C3 2.892(6), Co–B1 2.101(8), Co–C2 2.035(9), Co–C3 2.034(7), B1–C2 1.527(10), B1–C3 1.574(10), C3–C3' 1.450(13).

The thallium atom does not lie exactly over the centroid of the C_2B_2C ring, but is displaced by 0.24 Å in the direction of C2, the site of highest charge density in $\mathbf{1}^\ominus$. Thallium assumes a similar position over the C_2B_3-opening in the complex $[(C_6H_5)_3P{-}CH_3]^\oplus[3,1,2\text{-}TlC_2B_9H_{11}]^\ominus$[9] (Tl–($C_2B_3$) 2.39 Å; Tl shifted towards B8 by 0.34 Å). The

borinato derivatives $[Tl(C_5H_5BR)]$ ($R=CH_3$, C_6H_5) have similar properties to $[Tl(C_5H_5)]$. One therefore expects that they should have similar structures[10]. Compared to the 6e-ligands $C_5H_5^{\ominus}$ and $C_5H_5BR^{\ominus}$, the heterocyclic anion in **1** exhibits stronger acceptor functions which in the solid state prevent dissociation into ions.

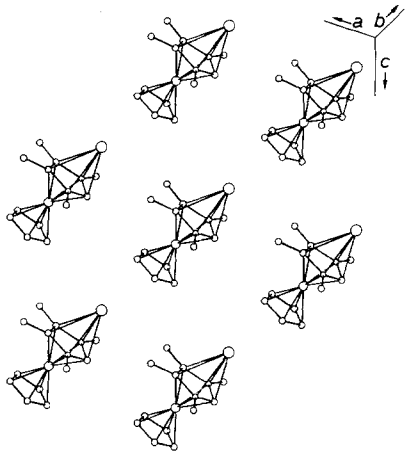

Fig. 2. Section of the crystal structure.

We view **2** as a cluster with the 16 skeletal electrons necessary for the stabilization of the hepta-atomic *closo*-structure[11] being provided by the framework atoms carbon ($3\times 3e$), boron ($2\times 2e$), cobalt (2e), and thallium (1e).

$(C_6H_5Sb)_6\cdot$(1,4-Dioxane), the First Cyclohexastibane**

By *Hans Joachim Breunig**, *Karl Häberle*, *Martin Dräger*, and *Tevfik Severengiz*

Monocyclic organostibanes $(RSb)_n$ have previously been prepared as three-, four-, and five-membered ring compounds with bulky organic substituents $R=t$-C_4H_9, $(Me_3Si)_2CH$[1]. In contrast, various attempts to synthesize a phenylstibane $(C_6H_5Sb)_n$ have led to formation of high-polymer black solids[2,3]. Only one yellow crystalline compound whose properties are consistent with those of a cyclostibane has been reported. The proposed structure, $(C_6H_5Sb)_6\cdot C_6H_6$, could, however, only be substantiated by elemental analysis[4].

We now report the synthesis and X-ray structure analysis of hexaphenylcyclohexastibane·(1,4-dioxane) **1**, which crystallizes directly as yellow needles when the reaction solution produced by mixing $C_6H_5Sb(SiMe_3)_2$ and 1,4-dioxane is slowly oxidized in air[5]. As easily detectable by its ^{1}H-NMR signal at $\delta=0.1$, hexamethyldisiloxane also readily forms in the reaction mixture, and hence the overall reaction can be described by the following equation

$$6\,C_6H_5Sb(SiMe_3)_2 + 3\,O_2 + 1,4\text{-}C_4H_8O_2 \longrightarrow (C_6H_5Sb)_6\cdot(1,4\text{-}C_4H_8O_2) + 6\,(Me_3Si)_2O$$
1

The novel cyclostibane has several unusual properties. As indicated by its synthesis in the solid state, the compound is remarkably inert towards O_2. In contrast, solutions of **1**, which is slightly soluble in $CHCl_3$ and toluene, react very rapidly with air to afford colorless solids. Conversion into a black-brown solid—presumably the polymeric "phenylantimony"—occurs upon warming and subsequent cooling of solutions of **1** in toluene. Both for this reason and because of the low solubility of **1** at room temperature, the size of the ring could not be determined by M_r-determinations in solution. EI mass spectroscopy[6] was also unable to provide identifying evidence, since the significant signals that appear at oven temperatures of ca. 200 °C and above originate from fragment ions such as $(C_6H_5Sb)_4^{\oplus}$ and $(C_6H_5Sb)_3^{\oplus}$ and from rearrangement products such as $(C_6H_5)_5Sb_3^{\oplus}$. Signals from dioxane occur at 100 °C. In the FD mass spectrum only oxidation products could be observed. Above 200 cm^{-1} the IR spectrum of **1** exhibits absorptions typical of C_6H_5Sb moieties and dioxane. Signals from dioxane can also be detected in the ^{1}H-NMR spectrum ($CDCl_3$), where their position is not influenced by the $(C_6H_5Sb)_6$ ring. In solution, therefore, a strong interaction is not expected. Broad multiplet signals from the phenyl protons appear in the region expected.

In order to obtain unequivocal evidence for the molecular structure and to clarify the role played by the dioxane in stabilizing the $(C_6H_5Sb)_6$ ring against oxidation and chain formation, a crystal structure analysis of **1**[7] was performed. This indicates the presence of isolated centrosymmetric $(C_6H_5Sb)_6$ molecules (Fig. 1) in which the Sb_6 rings adopt a chair conformation and the phenyl groups are equato-

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

rial (overall symmetry, approximately D_{3d}). The Sb_6-chair is considerably steeper than in the analogous $[(C_6H_5)_2Sn]_6$[8] and the Sb–Sb distances (284 pm) are in accord with those in distibanes (283–287 pm[9]). No specific interactions occur between the dioxane molecules and Sb atoms; in the crystal, dioxane is present with van der Waals contacts to the phenyl groups and a mutual 8:8-coordination between $(C_6H_5Sb)_6$ and dioxane.

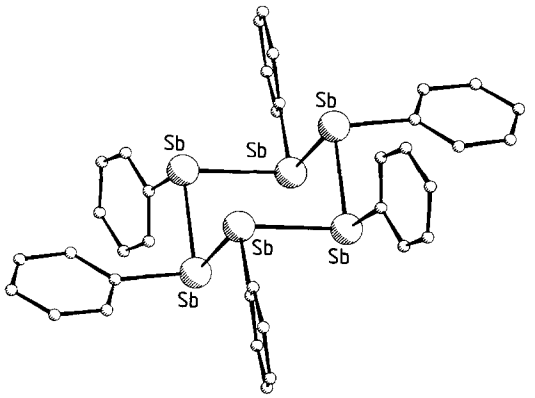

Fig. 1. Structure of the centrosymmetric $(C_6H_5Sb)_6$ molecule in crystals of **1**. Distances: Sb–Sb 283.6–283.9(1), Sb–C 216–217(1) pm. Bond angles: Sb–Sb–Sb 86.8–93.6(1), Sb–Sb–C 92.8–99.7(3)°. Torsion angles: SbSb–SbSb 86.4–93.2(1), SbSb–C_6H_5 166.9–179.7(3)° [7].

At first sight, the mode of formation of **1** is surprising since Sb–Sb bonds are usually reductively coupled. Similar behavior has recently been observed for $(Me_3Sn)_3Sb$, which is oxidized in air to $(Me_3Sn)_2O$ and $(Me_3Sn)_2Sb–Sb(SnMe_3)_2$[10].

If the oxidation of $C_6H_5Sb(SiMe_3)_2$ is conducted in benzene instead of dioxane, orange-yellow crystals of composition $(C_6H_5Sb)_6 \cdot C_6H_6$ **2** are formed, the structure of which has also been corroborated by full elemental analysis[11].

C_6H_5Sb moieties and crystal benzene can also be detected in **2** by IR and ^{1}H-NMR spectroscopy: In its properties **2** is similar to the "phenylantimony" described by *Issleib* and *Balszuweit*[4]. We therefore presume that they are one and the same compound.

[5] Procedure: $C_6H_5Sb(SiMe_3)_2$ (200 mg) is dissolved in 1,4-dioxane filled to half the depth of a glass tube (length 180 mm, diam. 5 mm). The tube is sealed with a plug so that it is not quite airtight and stored for 7 d at room temperature. The reaction solution initially becomes colored, and after a few days needles form in the tube; these are first outwardly black-brown and then become yellow. These crystals of **1** are filtered off, washed with dioxane, and dried in vacuo. Yield 20 mg (16%), correct elemental analysis.

[6] MS (30 eV, 230°C) relative to ^{121}Sb, observed isotopic pattern corresponds to the calculated: *m/z* (relative intensity) 792 (1, $(C_6H_5)_4Sb_4^{\oplus}$), 748 (2, $(C_6H_5)_5Sb_3^{\oplus}$), 715 (2, $(C_6H_5)_3Sb_4^{\oplus}$), 594 (10, $(C_6H_5)_3Sb_3^{\oplus}$), 550 (10, $(C_6H_5)_4Sb_4^{\oplus}$), 484 (8, $Sb_4^{\oplus}$), 319 (1, $C_6H_5Sb_2^{\oplus}$), 275 (30), 198 (60), 154 (100). 30 eV, 100°C: 88 (70, $C_4H_8O_2^{\oplus}$), 58 (80), 28 (100).

[7] Crystal structure analysis of **1**: $P2_1/c$, $a = 576.2(1)$, $b = 2189.9(4)$, $c = 1661.3(2)$ pm, $\beta = 99.45(2)°$, $V = 2068 \times 10^6$ pm^3, $Z = 2$, $\rho_{calc} = 2.06$, $\rho_{exp} = 2.04$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 39.0$ cm^{-1}. CAD4-diffractometer: 5120 reflections, 2795 of which with $I > 2\sigma(I)$, 207 variables, $R = 0.042$, $R_w = 0.058$, no H atoms. In part, dioxane disordered: two different positions for the O. Further details of the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51148, the names of the authors, and the journal citation.

[11] Procedure: $C_6H_5Sb(SiMe_3)_2$ (500 mg) is allowed to react with air as described above. After 10 d the crystals formed are filtered off, washed with C_6H_6, and dried in vacuo. Yield of **2**: 60 mg (20%). Correct C, H, Sb elemental analysis.

A Novel Rearrangement in $(R_2S\cdot\cdot SR_2)^{\oplus}$-Radical Cations with a 3e-Bond

By *Roland Goslich, Joachim Weiss, Hermann J. Möckel, Jörg Mönig,* and *Klaus-Dieter Asmus**

Dedicated to Professor Dietrich Schulte-Frohlinde on the occasion of his 60th birthday

Radical cations derived from aliphatic sulfides $R_2S^{\odot\oplus}$ show a marked tendency to stabilize themselves by reacting with a second sulfide molecule R_2S[1,2] via the equilibrium

$$R_2S^{\odot\oplus} + R_2S \rightleftharpoons (R_2S\cdot\cdot SR_2)^{\oplus}$$

The "dimeric" radical cation thus formed is characterized by a 3e-bond (two σ-electrons and one σ*-electron)[3]. Pulse radiolytic[1–5] and ESR-spectroscopic studies[6,7] have provided some information about the reactivity of these radical cations and some radicals derived from them. The development of sensitive methods for determination of organic sulfur compounds[8,9] has now enabled us to undertake qualitative and quantitative product analysis. In the course of investigations on the radical-induced oxidative degradation of some aliphatic sulfides, we have discovered a remarkable rearrangement, which we report here.

The 1e-oxidation of aliphatic sulfides in aqueous solution was carried out using $^{\odot}OH$ radicals, generated by γ-irradiation of N_2O-saturated aqueous solutions. End products were identified and determined by capillary GC-MS.

The main products of the oxidation of dimethyl sulfide (Me_2S) are found to be 1,2-bis(methylthio)ethane (1,2-BMTE) and diethyl disulfide (EtSSEt). The yields are independent of pH between pH 3 and pH 10, but exhibit a marked inverse dependence on the Me_2S concentration (Fig. 1). 1,2-BMTE is the main product at low Me_2S concentrations and its yield decreases with increasing Me_2S concentration. The yield of EtSSEt, however, increases drastically only at concentrations above 0.01 mol dm^{-3} Me_2S. The formation of 1,2-BMTE is attributed to the reaction

$$2\,\overset{\odot}{C}H_2SCH_3 \longrightarrow CH_3SCH_2CH_2SCH_3$$

i.e. combination of two radicals formed from deprotonation of molecular radical cations. Addition of phosphate

[*] Prof. Dr. K.-D. Asmus, Dipl.-Chem. R. Goslich,
Dr. J. Weiss, Dr. H. J. Möckel, Dr. J. Mönig

Postfach 39 01 28, D-1000 Berlin 39

ions to the system doubles the yield of 1,2-BMTE, since deprotonation of the radical cation is favored at the expense of competing reactions. Oxygen (2.8×10^{-4} mol dm^{-3}, corresponding to air saturation), which scavenges $^{\ominus}CH_2SCH_3$ in a fast reaction, completely suppresses formation of 1,2-BMTE.

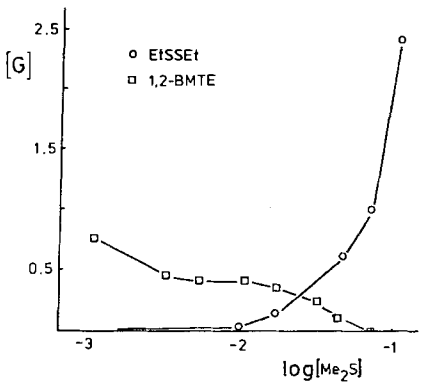

Fig. 1. Yields of 1,2-BMTE and EtSSEt vs. Me_2S concentration in N_2O-saturated solutions at pH 7. (Yields [G] = molecules formed per 100 eV absorbed radiation energy, highest EtSSEt yield corresponds to ca. 40% of the $(Me_2S.\cdot.SMe_2)^{\oplus}$ yield).

Doubtless more interesting than the formation of 1,2-BMTE is that of EtSSEt. Since the latter compound is only observed at high Me_2S concentrations, the participation of a second Me_2S molecule is indicated. Remarkably, the yield of EtSSEt is not affected by the presence of oxygen (2.8×10^{-4} mol dm^{-3}). Free $EtS^{\odot}$ radicals cannot therefore be responsible for formation of EtSSEt, since oxygen reacts rapidly with $EtS^{\odot}$[10]. The inverse behavior of 1,2-BMTE and EtSSEt yields at increasing Me_2S concentration clearly shows that new reactions occur when $(Me_2S.\cdot.SMe_2)^{\oplus}$ is increasingly stabilized at higher Me_2S concentrations. These new reactions compete with deprotonation of the molecular radical cation, $R_2S^{\oplus\odot}$, which is in equilibrium with $(Me_2S.\cdot.SMe_2)^{\oplus}$. The formation of EtSSEt is therefore not only fundamentally connected with the existence of $(Me_2S.\cdot.SMe_2)^{\ominus}$, but derives from the 3e-system itself. Mechanistically this can only be explained by a rearrangement, i.e. migration of a methyl group across the sulfur bridge in every contributing Me_2S molecule. The yield of EtSSEt in 0.1 mol dm^{-3} Me_2S solutions corresponds to ca. 40% of that of $(Me_2S.\cdot.SMe_2)^{\oplus}$.

For formation of the rearrangement product we suggest the following mechanism: The first step involves deprotonation of the 3e-species **1** at a C-atom in the α-position to one of the sulfur atoms, the rest of the stabilized electronic structure being preserved. The first rearrangement step occurs in carbanion **2**. The neutral radical **3** also possesses a 3e-bond and is expected to exist in the equilibrium

$$\mathbf{3} \rightleftharpoons Me_2S + {}^{\odot}SCH_2CH_3$$

in analogy to all σ^2/σ^* bonded systems. Dimerization of $^{\odot}SCH_2CH_3$ radicals could represent a route to EtSSEt. However, this overlooks the fact that EtSSEt is formed even in the presence of oxygen. The formation of EtSSEt can therefore only be understood in terms of a fast, second rearrangement within the 3e-species **3**, which is likely to be unreactive towards oxygen[10]. The simplest mechanism involves either homolytic fission of a C–H bond or electron transfer associated with deprotonation [reaction (c)]. Rearrangement to afford EtSSEt can be expected to occur from **4**, particularly from its equivalent ionic form **4a**.

Isotope-effect experiments corroborate the proposed mechanism. Both for reaction (a), and particularly for reaction (c), a marked difference between H- and D-substituted compounds should be observed. In fact, in the oxidation of $(CD_3)_2S$ even at a concentration of 0.16 mol dm^{-3} no diethyl disulfide is found. Instead, however, a large yield of sulfoxide is observed. Formation of sulfoxide therefore seems to be an important process competing with the rearrangement.

Comparable results were also obtained for the oxidation of other sulfides. Thus, the rearrangement product di-*sec*-butyl disulfide is formed from diethyl sulfide, Et_2S, via the 3e-bonded radical cation $(Et_2S.\cdot.SEt_2)^{\oplus}$.

The present results unequivocally identify radical cations with 3e-bonds between two sulfur atoms as the source of a rearrangement. The two steps of this rearrangement are reminiscent of the well-known Wittig and Stevens rearrangements.

The Chemistry of the Metal-Carbon Bond. Vol. 1: The Structure, Preparation, Thermochemistry and Characterization of Organometallic Compounds. Edited by *F. R. Hartley* and *S. Patai*. John Wiley, Chichester 1982. xii, 1071 pp., bound, £ 125.00.

According to the editors' foreword this book is the first volume of a series covering the highly topical field of the chemistry of organometallic compounds and should (again according to the foreword) be of particular interest to organic chemists. Whether it achieves this aim is, however, questionable. The subtitle itself is confusing; even though *without* index there are 969 pages available *nothing* is said about the preparation and almost nothing is said about the structure of the organometallic compounds of the main group elements; in other words not a word about Grignard reagents, nothing about organolithium compounds (apart from the structure of CH_3Li and the enthalpies of formation of C_2H_5Li and n-C_4H_9Li), nothing about organoaluminum, organozinc, organocadmium, organomercury compounds (apart from some thermodynamic data) and all that for the princely sum of £ 125 (!!). It is stated in the foreword that the editors had other ideas concerning the arrangement of this and the succeeding volumes, but that is not consolation to the reader. What a pity—particularly when one considers the contents of some of the chapters (there is a total of 22).

Chapter 1 of the book *(A. D. Redhouse)* deals in very concentrated form with the structures of organometallic compounds (more precisely organotransition metal compounds) but unfortunately omits any reference to their bonding relationships. Anyone wishing to know *why* a compound like $C_6(CH_3)_6RuC_8H_8$ possesses the structure given on p. 26 has to wait for the following volumes and hope to find an answer there. Have the editors not heard of "Structure *and* Bonding"? Chapter 2 *(G. Pilcher* and *H. A. Skinner)* covering thermodynamic aspects is significantly more informative. Here one learns where details concerning enthalpies of formation and bonding energies are to be found and where the difficulties lie in such investigations. The next 4 chapters—Synthesis of ylide-metal complexes *(L. Weber)*, Carbenemetal complexes *(H. Fischer)*, Carbyne-metal complexes *(U. Schubert)* and Alkyl and aryl transition metal complexes *(R. J. Puddephatt)* are similarly competently produced. Here it can be seen that the authors are themselves active in their respective fields and understand their metiers. This also applies to Chapter 12 (Synthesis of organolanthanide and organoactinide complexes by *W. J. Evans*) and 13 (Metal atoms in organometallic synthesis by *M. J. McGlinchey*), in which, pleasingly—as the interested reader would expect—also the most recent literature (1980 and 1981) is taken into account. This ought to be automatic—at least in a book that the editors wish to present as a standard work.

Chapters 7 and 9—11 on the synthesis of η^3-allyl complexes *(P. Powell)* and complexes with η^4, η^5, η^6, η^7 and η^8 coordinated ligands *(G. Marr* and *B. W. Rockett)* are somewhat less up-to-date than those mentioned above and only provide a limited view of the "state of the art"; they lack references later than 1979 and the sovereignty of choice, which is featured in Chapters 12 and 13 for example. Chapters 14—19 (by *T. R. Crompton* 180 pp.) are largely superfluous. Anyone wishing to know how to determine $Pb(C_2H_5)_4$ in gasoline, how to ascertain the carboxyhemoglobin content of blood and how to measure small quantities of H_2Se in air (where is the metal carbon bond?) will probably inform himself from the standard analytical literature. One seeks in vain, here, for any connection with the reality of the practical preparative organometallic chemist, who characterizes his compounds by elementary analysis (which he does not usually perform himself) and by spectroscopy.

These spectroscopic methods are discussed in Chapters 20 (IR and Raman by *M. J. Taylor*), 21 (NMR by *J. A. Davies*) and 22 (MS by *T. R. Spalding*). The treatment of the application of NMR spectroscopy deserves unstinting praise; it its exceedingly informative and takes account of both theoretical and practical problems. There is no doubt that an engaged author was at work here, who did not shy at the effort of including the latest publications (from 1981 and 1982) in an appendix. This is missing in the chapter concerned with mass spectroscopy, in which the treatment of such currently important areas as field ionization and field desorption techniques is crammed into half a page.

Finally the question—who is going to buy it? And above all—who can pay for it? Are the editors of such series and the publishers not aware of the situation in the universities today (not only in the Federal Republic of Germany)? In view of just this situation, should one not consider more critically and scrupulously how best to serve the reader—and here this means the organometallic (and organic) chemist—at his place of work? The present work does not exhibit signs of such considerations and that has to be laid, above all, at the door of the editors. It is scarcely possible to recommend purchase under present conditions.

der Universität Würzburg

Organic Chemistry in Colour. By *P. F. Gordon* and *P. Gregory*. Springer-Verlag, Berlin 1983, xi, 322 pp., bound, DM 178.00.

Dyestuffs chemistry is applied organic chemistry. Since it is mainly practised in the laboratories and finishing shops of the dyestuff manufacturers, this review, written by employees of one of these companies (ICI), deserves particular attention.

The book, which is almost exclusively devoted to textile dyes, begins in Chapter 1 with a retrospect, which covers the period before *Perkin* through the structural assignment of the natural dyestuffs up to the most recent areas of dyestuff application.

Two sections of Chapter 2 with cleverly chosen and generalizable examples of the synthesis of dyestuffs and intermediates will meet with approval. Probably these sections would have been enriched if Chapters 3 to 5 had followed this pattern and emphasized market and environmentally oriented synthesis strategies more markedly. The normal classification method, whereby textile dyes are divided into a maximum of seven main structural classes, has been effectively adopted. A second classification principle and its influence on the C.I. (Color Index) dyestuff names, which are frequently quoted in this work, ought to have been explained in more detail in view of the heterogeneous readership. However, to devote a section to classification principles is not very helpful if the care has not been taken which is necessary for the coordination of individual struc-

tural features or even if both principles are combined. The headings to 2.2.3 and 2.4.3 (vat dyestuffs) and most of subsection 2.2.9 (miscellaneous) in particular can be criticized on these grounds.

Phenylogue polymethine dyestuffs, alongside the cyanines the most important class with delocalized charge, are grouped under the heading arylcarbenium. Inconsistently, however, it is left to the reader to place the charge sign in the correct place in the formulas or to search (in vain) for a carbenium center. May be because of the (apparent) dilemma with mono and pentamethinecyanines, the authors exclusively employ inapplicable resonance formulas with the charge on one of the heteroatoms, which cannot be said to be acceptable nowadays for anything other than to illustrate a symmetry-hostile nomenclature (Chemical Abstracts, cyanines).

The main concern of the authors is obviously the interaction between structure, chemical and physical properties, on the one hand, and marked value, on the other, which may to some extent justify the size of Chapters 3—5. Chapter 3, azo dyes, is introduced by a short section concerning the structure of the basic chromogen. The section on tautomerism emphasizes the relationship between substitution, equilibrium position and extinction. A further section is concerned with metal complexes including some aspects of complex isomerism. The section on constitution and color gives the same weight to a review as to the results of MO treatment. Chapter 4, anthraquinone dyes, is similarly constructed, while the remaining structural classes are treated somewhat more briefly in Chapter 5.

The discussion of textile fibers is reduced to a minimum and included in Chapter 6. The section on application and wet fastness is very clearly laid out with a classification according to bonding principles; there is no mention of a competing concept which views the binding of direct dyestuffs to cellulose in terms of the demonstrable—to be sure only in solution and on films—aggregate formation. Light fastness is also discussed in detail; key words are test methods, photochemical principles, attempts to clarify the bleaching mechanisms, catalytic processes, photochemical fiber damage. Short sections concerning fastness to sublimation, solvolysis in the dyeing vat, fastness to bleaching, solvatochromism, photochromism and metamerism round off the chapter. Extensive reference lists are included at the end of each chapter and (concerning MO theory, colorimetrics and the often neglected facet of color perception) in the appendix.

This book is primarily intended for readers practising the subject. Students of chemistry and possibly of textiles will find a wealth of useful information, which will not replace lectures on dyestuffs but can usefully complement them. A book that deliberately sets its accent differently and (the criticisms mentioned above excepted) a book that can be recommended.

Synthesis of Cyclosporine and Analogues: Structural Requirements for Immunosuppressive Activity**

By Roland Maurice Wenger*

Cyclosporine is a new immunosuppressive drug which was first marketed in 1983 under the trade name Sandimmune®. This compound, an innovation in selective immune modulation, was isolated from a fungal culture and characterized as a cyclic undecapeptide containing a novel amino acid together with several *N*-methylated amino acids. The new amino acid (4*R*)-4-[(*E*)-2-butenyl]-4,*N*-dimethyl-L-threonine (MeBmt) was the only unknown amino acid of cyclosporine and there had previously been no means for its isolation. For this reason and because it seemed possible that MeBmt could play a significant role in determining the pharmacological activity of cyclosporine, its synthesis in enantiomerically pure form was undertaken. The next step was the development of a total synthesis of cyclosporine, which appeared attractive, not only for its intrinsic worth, but also as an important tool for investigating the relationships between structure and immunosuppressive activity. Essential for the immunosuppression are the amino acids MeBmt, Abu, Sar, and MeVal in the positions 1, 2, 3 and 11, but probably also still larger parts of the molecule. Such information could be valuable for finding new chemical leads or drugs with a new activity profile.

1. Introduction

1.1. Pharmacological Activity and Clinical Application of Cyclosporine

As reported by *Borel* et al.[2–6], cyclosporine is a selective immunosuppressive drug with antifungal and antiinflammatory properties. It has been shown to strongly suppress the production of haemagglutinating antibodies against sheep erythrocytes in mice and to be effective in inhibiting both humoral and cell-mediated immune responses. Its effect is reversible, and for T-lymphocytes specific; the hemopoietic tissues in immunosuppressed animals are not affected. More recently *Bueding* et al.[7] demonstrated an antischistosomal activity and *Thommen-Scott*[8] an antimalarial effect of cyclosporine, both antiparasitic activities being independent of immunosuppression.

The first transplantations in humans with the aid of cyclosporine were reported in 1978 by *Calne* et al.[9] for kidney and by *Powles* et al.[10] for bone marrow. Today, cyclosporine is used successfully to prevent graft rejection following bone-marrow and organ transplantations. Other possible applications, such as in the treatment of autoimmune and other diseases, are currently under investigation.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1985 0570-0833/85/0202-0077 $ 02.50/0

1.2. Production of Cyclosporine

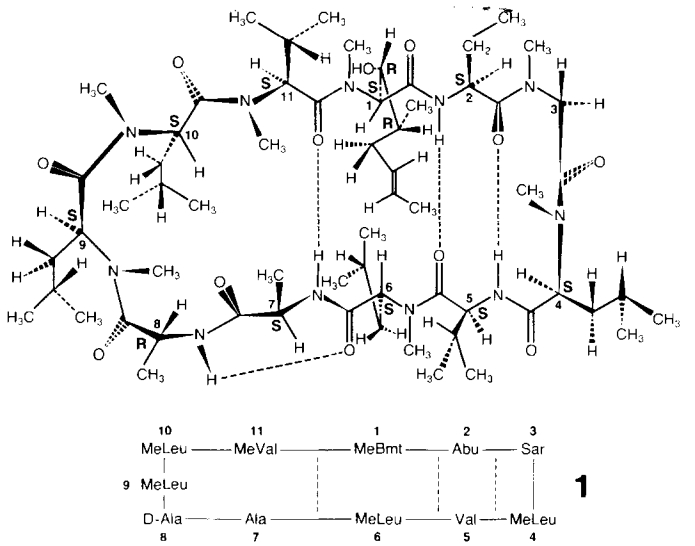
Cyclosporine[*], originally named "cyclosporin A" by *Rüegger* et al.[13], was shown by *Dreyfuss* et al.[14][**] to be produced by fungi of the genus *Tolypocladium* in submerged cultures. In normal fermentation broths it is the main component of a group of cyclic peptides, each comprising 11 amino acids. These naturally occurring cyclosporine analogues have been partly reported by *Traber* et al.[17–19]. They usually differ in their chemical structure only at one amino acid and their biosynthesis can be directed by externally supplying the corresponding precursor. For example, *Kobel* et al.[20] reported the more selective production of (norvaline^2)cyclosporine by adding L-norvaline to the fermentation broths. Addition of D,L-α-aminobutyric acid almost completely suppresses the formation of undesired cyclosporine analogues and leads to a higher percentage of cyclosporine in the crude product.

1.3. Elucidation of the Structure of Cyclosporine

The structure of cyclosporine **1** (Fig. 1) was determined by chemical degradation[13] together with an X-ray crystallographic analysis of the iodo derivative **1a**.

1a

As described by *Petcher* et al.[21], this analysis not only established the sequence of the native peptide, but also gave an insight into its shape. Later, *Loosli* et al.[22] were able to confirm the structural and conformational assignments by an X-ray crystallographic analysis and by two-dimensional nuclear magnetic resonance (NMR) studies of cyclosporine itself. Cyclosporine (Fig. 1) is a neutral, hydrophobic, cyclic peptide composed of eleven amino acid residues, all having the L-configuration of the natural amino acids, except for the D-alanine (D-Ala) in position 8 and the non-chiral sarcosine (*N*-methylglycine) in position 3. Seven amino acids—in positions 1, 3, 4, 6, 9, 10 and 11—are *N*-methylated. Ten of the eleven ring members are derivatives of known aliphatic amino acids: they are α-aminobutyric acid (Abu) in position 2, sarcosine (Sar) in position 3, *N*-methylleucine (MeLeu) in positions 4, 6, 9 and 10, valine (Val) in position 5, alanine (Ala) in position 7, D-alanine (D-Ala) in position 8, and *N*-methylvaline (MeVal) in position 11. These amino acids were readily characterized following acid hydrolysis of cyclosporine. One amino acid, namely that in position 1, was hitherto unknown. Being composed of 9 carbon atoms this amino acid was reported on under the name "C-9 amino acid"[13]. It was found to have the composition (2*S*,3*R*,4*R*,6*E*)-3-hydroxy-4-methyl-2-(methylamino)-6-octenoic acid, and, in accord with amino acid nomenclature, is now designated as (4*R*)-4-[(*E*)-2-butenyl]-4,*N*-dimethyl-L-threonine and abbreviated MeBmt. Thus, the novel amino acid has the polar features of an *N*-methyl-L-threonine which is substituted at the end of the carbon chain by butenyl and methyl groups. This amino acid was hitherto not known in the free form, since only artifacts and derivatives were obtained from degradation experiments on cyclosporine[13]. Hydrolysis of cyclosporine followed by ion-exchange chromatography afforded a cyclic derivative **1b** of the MeBmt amino acid as the only isolable MeBmt-derivative, while acidic treatment of cyclosporine **1** in the absence of water effects an *N*,*O*-acyl migration of the methylvalyl moiety and furnishes isocyclosporine **1c**. A modified Edman degradation of isocyclosporine **1c** using methyl isothiocyanate produced an anhydrothiohydantoin-derivative **1d** as the only isolable MeBmt derivative and thus established MeBmt as the first amino acid in the peptide sequence. The complete sequence was established by repetitive Edman degradation.



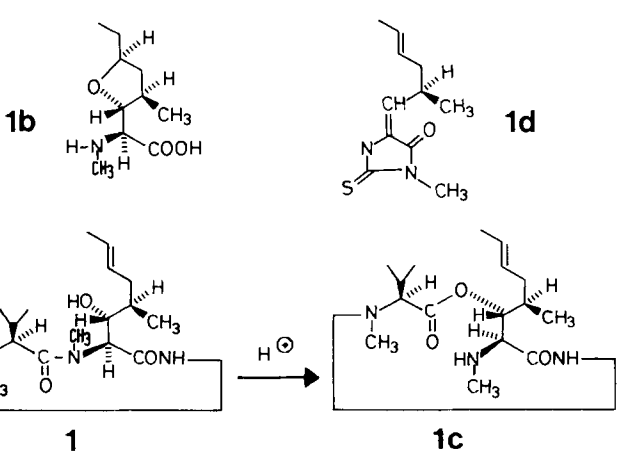


Fig. 1. Structure of cyclosporine **1** (schematic). MeBmt = (4*R*)-4-[(*E*)-2-butenyl]-4,*N*-dimethyl-L-threonine (see text).

[*] For practical reasons, it was previously proposed to define "cyclosporin" as the cyclic undecapeptide with the structure of "cyclosporin A" [11, 12]. Now that the USAN name "cyclosporine" has been accepted in the USA, this name will be adopted for the basic structure. Meanwhile the following names have been accepted in other countries: England, cyclosporin (BAN name); France, ciclosporine; Switzerland and others ciclosporin (INN name, WHO).

[**] The cyclosporine-producing organism which was initially identified as *Trichoderma polysporum* [14] is now classified under the genus *Tolypocladium* established by *Gams* [15] and is called *Tolypocladium inflatum* Gams [16].

From the X-ray structure and NMR data it follows that cyclosporine assumes a rather rigid conformation, both in the crystalline state and in solution (Fig. 2). A large portion

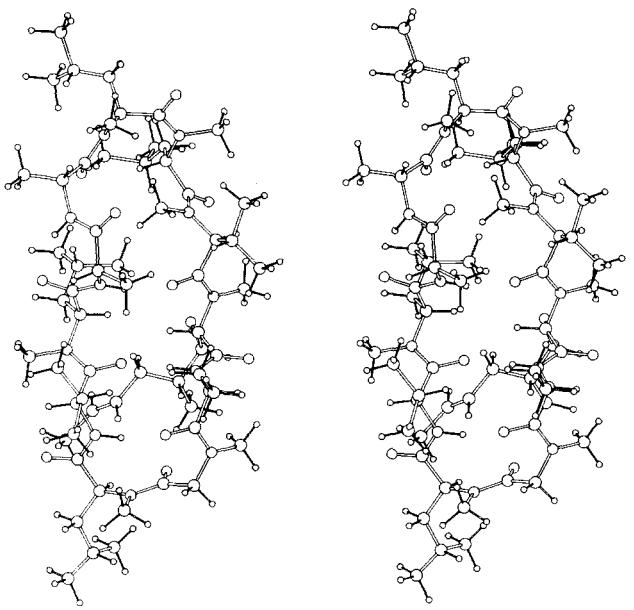

Fig. 2. Conformation of cyclosporine **1** in the crystal (stereograph).

of the backbone (residues 1—6) adopts an antiparallel β-pleated sheet conformation which contains three transannular H-bonds and is markedly twisted. The sarcosine in position 3 and *N*-methylleucine in position 4 participate in a type II′ β-turn[23-25]. This means that, in the orientations chosen in Figures 1 and 2, the CO group of Abu-2 and the *N*-CH_3 group of MeLeu-4 are up and the CO group of Sar-3 and NH group of Val-5 are down. The *pro-S* proton of the methylene group of Sar-3 is axial, and the side chain of MeLeu-4 equatorial. The remaining residues 7—11 form an open loop. This loop contains the only *cis*-amide linkage in the molecule between the two adjacent *N*-methylleucine residues 9 and 10. The remaining H-bond is of a γ-type and serves to hold the backbone in a folded L shape.

As a consequence of this rather rigid conformation of the cyclosporine skeleton, six amino acids have their side chains directed quasi-perpendicular to the plane of the peptide ring: In Abu-2, Val-5, Ala-7 and MeVal-11 they are pointing upwards, in MeBmt-1 and MeLeu-6 they are pointing downwards. The side chains of the remaining five amino acids lie more or less in the plane of the peptide ring.

1.4. Biosynthesis of Cyclosporine

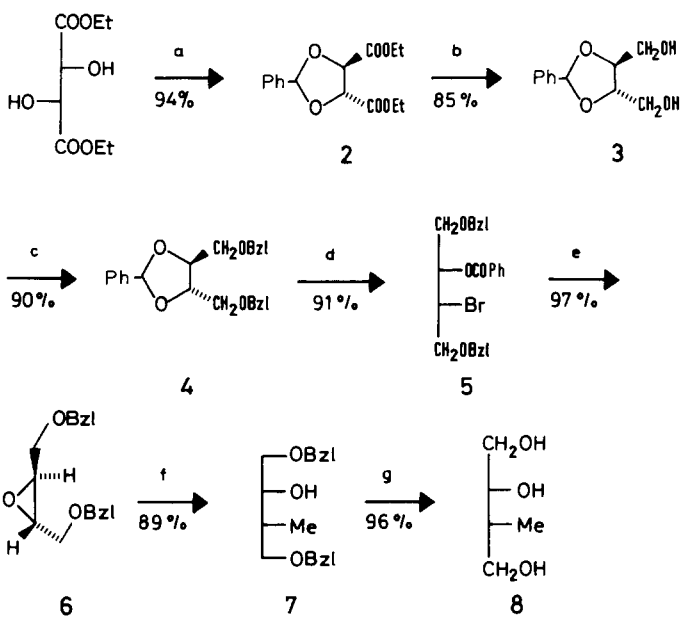
In the initial biosynthetic studies of *Kobel* et al.[26], ^{3}H- and ^{13}C-labeled precursors were fed to the culture and the position of incorporation of the label in cyclosporine was determined by NMR spectroscopy. It was demonstrated that the *N*-methyl groups of the molecule and the methyl group in the γ-position of the unsaturated amino acid MeBmt are introduced as intact methyl groups from methionine and that the remaining carbons of the MeBmt moiety are derived from the head-to-tail condensation of four acetate units. The ^{13}C-NMR spectrum of the enriched cyclosporine derived from [1-^{13}C]acetate showed four enhanced signals corresponding to the carbon atoms 1, 3, 5 and 7 of the MeBmt unit and no ^{13}C incorporation into any other amino acid.

In enniatin, an analogous example of non-ribosomal cyclic peptide synthesis by fungi, *Zocher* and *Kleinkauf*[27] demonstrated that a multifunctional enzyme carries out the *N*-methylation of the constituent amino acids following an activation step when the acids are bound to the enzyme as thioesters. Supporting evidence for a similar mechanism in cyclosporine biosynthesis was provided by the observation of *Zocher* et al.[28] that [^{14}C]sarcosine was not incorporated and that the radioactivity from [Me-^{14}C]methionine incorporated into each *N*-methylated amino acid was directly proportional to the number of the corresponding amino acid residues in cyclosporine, thus indicating that *N*-methylation of the amino acids occurred simultaneously.

From the results of *Kobel* et al.[26] the site of biosynthesis of the Bmt unit remains unclear. However, the results obtained by the *Kleinkauf* group[28] with short-term feeding experiments using labeled acetate and methionine, in which probably only incorporation of label in the *N*-methyl group occurred, suggest that the amino acid Bmt is not biosynthesized on the enzyme matrix but at some other site before incorporation into cyclosporine.

2. Enantioselective Synthesis of the Amino Acid MeBmt from (*R*,*R*)-Tartaric Acid[*]

In the amino acid (4*R*)-4-[(*E*)-2-butenyl]-4,*N*-dimethyl-L-threonine (MeBmt) the MeNH- and OH-groups are in a *threo*-configuration and the OH- and CH_3-groups in an *erythro*-configuration; the double bond has the *trans*-(or *E*-)configuration. The systematic name (see Ref.[30]) for MeBmt is (2*S*,3*R*,4*R*,6*E*)-3-hydroxy-4-methyl-2-(methylamino)-6-octenoic acid.

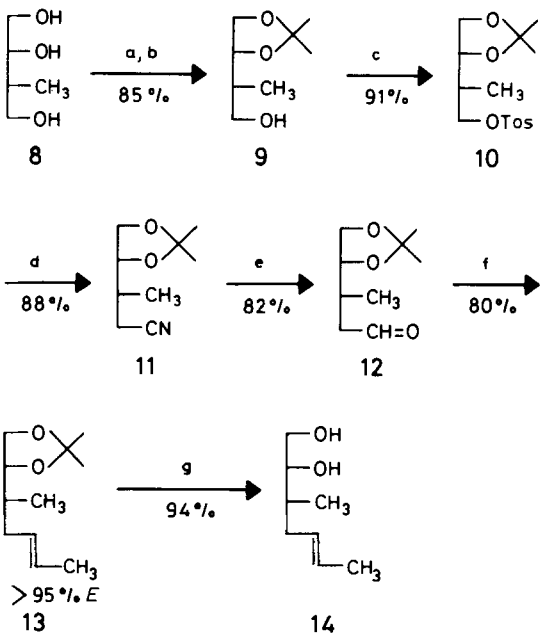


(*R*,*R*)-(+)-Tartaric acid was used as the basic chiral building block—for the use of tartaric acid as a practical source of chiral building blocks for syntheses, see the recently published review by *Seebach* and *Hungerbühler*[31]. It was modified in three major operations to introduce the features of the target amino acid. In the first operation, summarized in Scheme 1, one OH-group of the (*R*,*R*)-(+)-tartaric acid molecule was incorporated with the correct configuration, and the other OH-group was replaced by a CH_3-group accompanied by inversion of configuration. This provided the asymmetric centers C3 and C4 of the amino acid MeBmt. The second operation consisted of introducing the (*E*)-butenyl moiety (Scheme 2) after having elongated the carbon chain by formation of an aldehyde which was the starting material for a Wittig reaction under Schlosser and Christmann conditions[32]. The third operation consisted of oxidizing the diol **14** to the hydroxy aldehyde **19** (Scheme 3) and of introducing the MeNH- and the COOH-groups via a cyclic intermediate permitting ste-

[*] For details of the synthesis of MeBmt see reference [29].

reochemical control during the formation of the asymmetric center at C2 (Scheme 4).

2.1. Synthesis of (2*R*,3*R*)-3-Methyl-1,2,4-butanetriol 8; Formation of the Asymmetric Centers C3 and C4

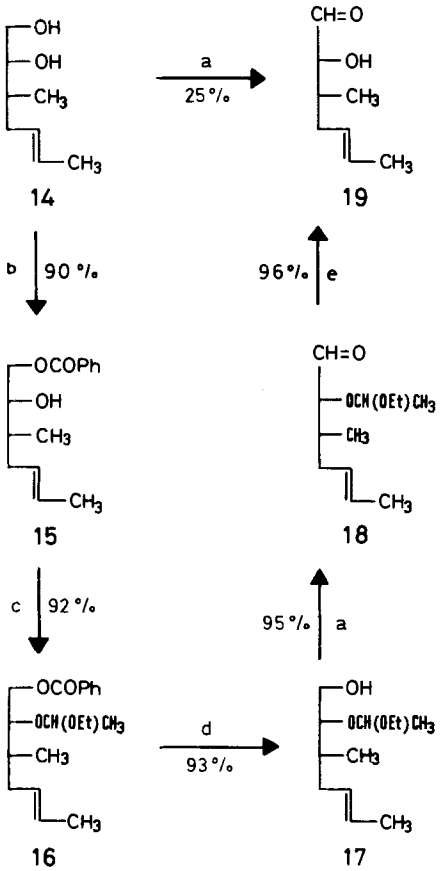


As shown in Scheme 1, the OH-groups of (*R*,*R*)-diethyl tartrate are first converted with benzaldehyde into the acetal **2**. Reduction with $LiAlH_4$ to give the diol **3** and subsequent benzylation then furnishes the dioxolane **4**. For the replacement of one of the OH-groups of tartaric acid by a CH_3-group with inversion of configuration, the epoxide **6** is first prepared from **4** according to the procedure described by *Seeley* and *McElwee*[33]; because of the symmetry of **4** it is immaterial on which of the two secondary C-atoms the displacement occurs. Thus, treatment of **4** with *N*-bromosuccinimide yields the bromo ester **5**, which upon alkaline hydrolysis is directly converted into the optically active and therefore *trans*-disubstituted oxirane **6**. Methylation of the epoxide (C_2-symmetry) using the method of *Johnson* et al.[34] affords the single product **7**. Hydrogenolysis of the benzyl-protecting groups leads to formation of the triol **8** in an overall yield of 56% from diethyl tartrate (seven steps).

Scheme 1. Synthesis of **8**. a: $PhCHO/HC(OEt)_3/TosOH \cdot H_2O$. b: $LiAlH_4$/tetrahydrofuran (THF). c: BzlBr/toluene/KOH. d: *N*-bromosuccinimide (NBS)/CCl_4. e: KOH/EtOH. f: 2 MeLi (CuI)/Et_2O, −15 °C. g: Pd/H_2.— Bzl = benzyl.

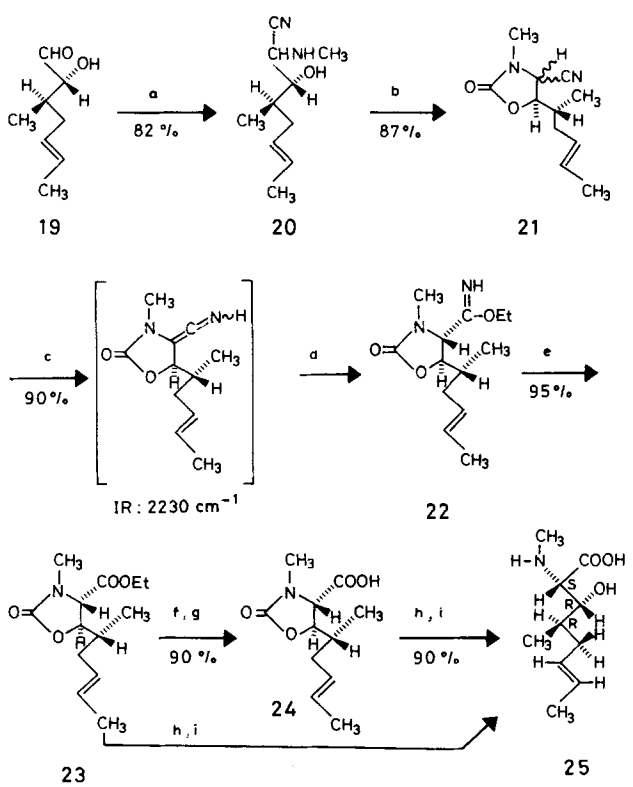
2.2. Synthesis of (2*R*,3*R*,5*E*)-3-Methyl-5-heptene-1,2-diol 14; Chain Elongation with Introduction of the *trans*-Double Bond

The two vicinal OH-groups of the triol **8** are, as shown in Scheme 2, selectively protected by preparation of the ketal **9**. The formation of 10—15% of the isomeric 1,3-dioxane besides the desired dioxolane **9** could not be avoided. The dioxolane **9** is converted into the tosylate **10**. Subsequent carbon chain elongation with potassium cyanide furnishes the nitrile **11**, which is converted into the aldehyde **12**. The aldehyde is then subjected to a *Wittig* reaction to give **13**[32]. After removal of the isopropylidene-protecting group the diol **14** is obtained in 42% overall yield from the triol **8** (six steps).



Scheme 2. Synthesis of **14**. a: $Me_2C(OMe)_2/TosOH \cdot H_2O/C_6H_6$, 2 h reflux. b: $Me_2CO/TosOH \cdot H_2O$, 15 h reflux. c: TosCl/pyridine, 35 °C, 4 h. d: KCN/dimethyl sulfoxide (DMSO), 20 °C, 3 d. e: Diisobutylaluminum hydride/hexane, −75 °C, 2 h. f: $Ph_3EtPBr/BuLi$, Schlosser-conditions [32]. g: 1.1 equiv. 1 N HCl/(THF/H_2O 4:1), 20 °C, 2 d.

2.3. Synthesis of (2*R*,3*R*,5*E*)-2-Hydroxy-3-methyl-5-heptenal 19; Oxidation of 14 to 19



The oxidation of the diol **14** (Scheme 3) can be effected by the Pfitzner-Moffatt method[35] in one step, but only in low yield (25%). To obtain the hydroxyaldehyde **19** in high yield, it is necessary to protect the secondary OH-group of **14**. This is done by monobenzoylation (→ **15**), followed by protection of the secondary OH-group as the ethoxyethyl derivative **16**, and alkaline hydrolysis of the benzoate to give the primary alcohol **17**. Using the Pfitzner-Moffatt method, **17** can now be oxidized to the aldehyde **18** in 95% yield. Removal of the ethoxyethyl-protecting group furnishes the hydroxyaldehyde **19** in a total yield of 70% (five steps).

2.4. Synthesis of (2*S*,3*R*,4*R*,6*E*)-3-Hydroxy-4-methyl-2-(methylamino)-6-octenoic acid (MeBmt) 25; Introduction of the Methylamino-Group and the Carboxy-Group

Scheme 4 outlines the last steps of the MeBmt synthesis. Reaction of freshly prepared hydroxyaldehyde **19** with potassium cyanide and methylammonium chloride affords the cyanohydrin **20** as a mixture of diastereomers. The mixture **20** is converted into the 2-oxazolidinone **21** (6:1/*cis*:*trans* relative to the ring). **21** can be converted in high yield into the imidate **22** by treatment with potassium car-

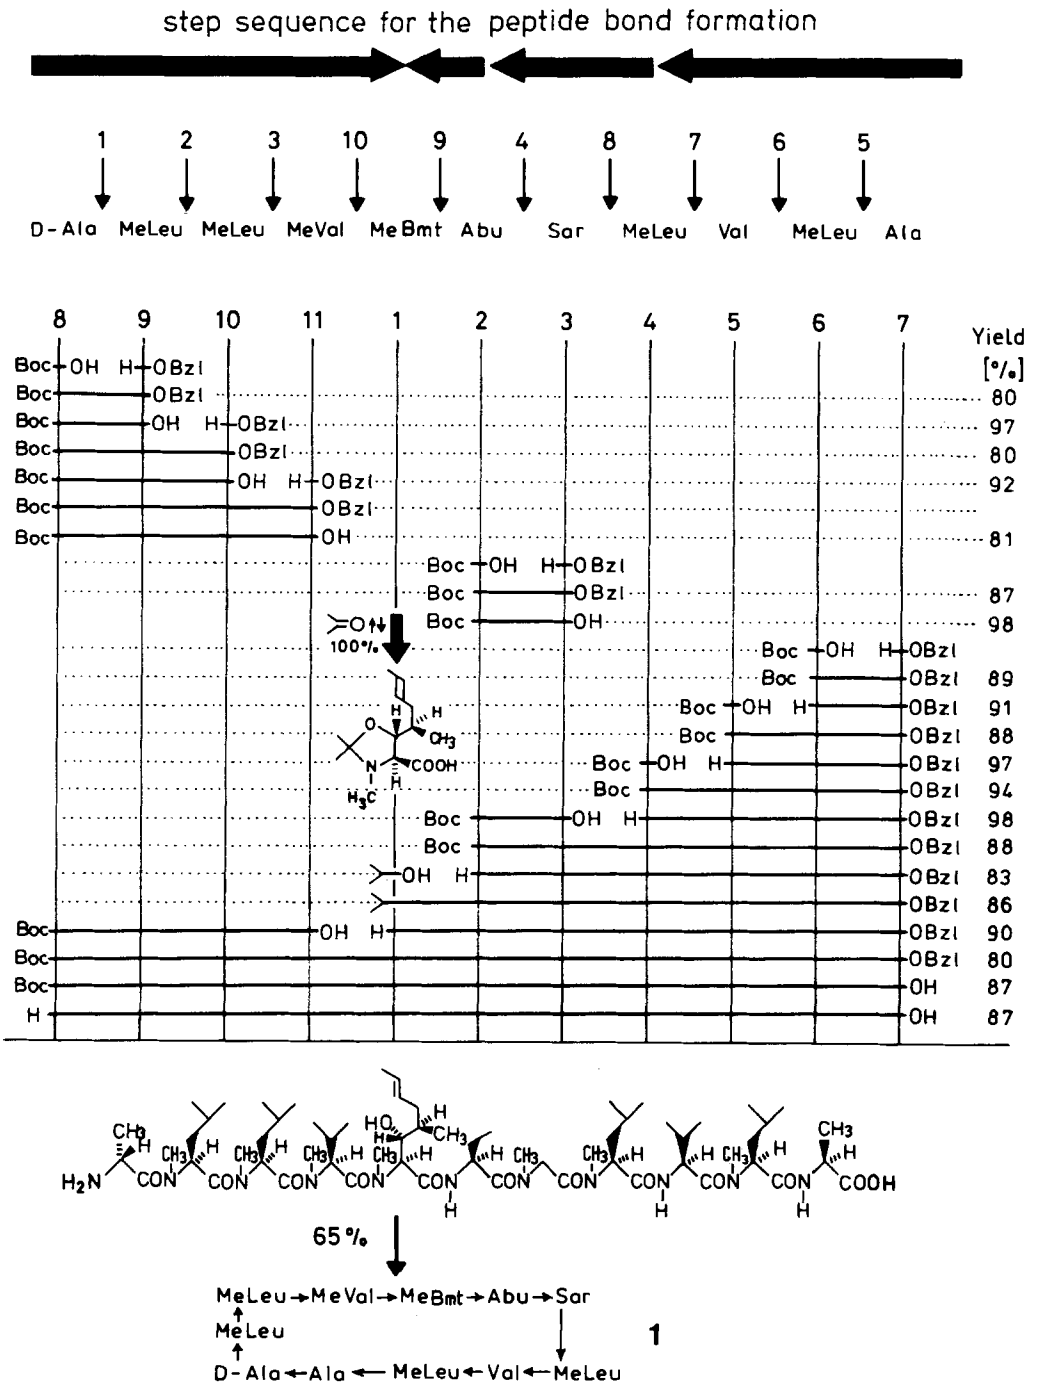
Scheme 3. Synthesis of **19**. a: Dicyclohexylcarbodiimide (DCCI)/DMSO/C_6H_6/pyridine/trifluoroacetic acid (TFA), 20°C, 2 h. b: PhCOCl/pyridine, 20°C, 1 h. c: CH_2=CHOEt/TFA, 20°C, 1—3 d. d: 10 N KOH/EtOH, 20°C. e: 1 N HCl/THF, 20°C, 2 h.

Scheme 4. Synthesis of MeBmt **25**. a: KCN/$MeNH_2$·HCl/MeOH/H_2O, 20°C, 2 h. b: 1,1'-Carbonyldiimidazole/CH_2Cl_2, 20°C, 16 h. c: K_2CO_3/EtOH, 20°C, 6 h. d: EtOH. e: 1 equiv. 1 N HCl/EtOH, 20°C, 1.5 h. f: 0.1 N KOH/dioxane, 20°C, 1 h. g: HCl (pH 2). h: 2 N KOH/H_2O, 80°C, 3 h. i: HCl (pH 5).

bonate in ethanol. The intermediate iminomethylene derivative (IR band at 2230 cm^{-1} in ethanol) reacts stereospecifically to give the thermodynamically more stable *trans*-imidate **22**. Hydrolysis of **22** furnishes the enantiomerically pure *N*-methylamino acid derivative **23** with the *O*- and *N*-functional groups in the desired *threo*-configuration. Both protecting groups of **23** can be removed in one step, or stepwise via **24**. The desired *N*-methylamino acid **25** crystallizes from the reaction mixture following acidification to pH 5 with 1 N HCl. The yield of **25** is 48% after six steps from the aldehyde **19** or 7.8% after 24 steps from (*R,R*)-diethyl tartrate. This corresponds to an average yield of 90% per step.

The stereospecific synthesis described here allowed the characterization of the new amino acid MeBmt **25** for the first time, and thus opened the way for a total synthesis of cyclosporine.

3. Total Synthesis of Cyclosporine[*]



3.1. Strategy Used for the Synthesis of Cyclosporine

For the synthesis of cyclosporine **1** (Fig. 1), the peptide bond between the L-alanine in position 7 and the D-alanine in position 8 was chosen for the cyclization step. There were two main reasons for choosing this strategy: 1. The intramolecular hydrogen bonds between the amide groups of this linear peptide could operate so as to stabilize the open chain in folded conformations approximating the cyclic structure of cyclosporine and thus assist cyclization. 2. The bond formation between *N*-methylated amino acids is more difficult than between non-methylated amino acids (for further details see [36, 37]); therefore, bond formation between the only consecutive pair of non-methylated amino acids in cyclosporine appeared the logical choice for the cyclization step.

For the synthesis of the undecapeptide, a fragment-condensation technique introducing the amino acid MeBmt at the end of the synthesis was used. In this way, the number of steps after the introduction of this amino acid was minimized. Scheme 5 shows the step sequence used for joining the (protected) peptide fragments.The carboxy groups were generally activated using a variation of the mixed pivalic anhydride method reported by *Zaoral*[38] and adapted by us for *N*-methylamino acid derivatives[36]. This strategy allowed slow anhydride formation in chloroform at −20°C with pivaloyl chloride in the presence of 2 equivalents of a tertiary base such as *N*-methylmorpholine before adding the amino acid or peptide esters to be coupled in the form of their free bases. The free bases were obtained by removal of the Boc-protecting groups with trifluoroacetic acid at −20°C and subsequent neutralization with $NaHCO_3$; the benzyloxy-protecting groups of the peptide intermediates were removed hydrogenolytically with palladium/carbon in ethanol.

The tetrapeptide Boc-D-Ala-MeLeu-MeLeu-MeVal-OBzl was synthesized from the left to the right by forming

[*] For details of the synthesis of cyclosporine see references [12, 36].

Scheme 5. Synthesis of cyclosporine **1**. Bold arrows: strategy for the synthesis of the peptides. For details see text. Boc = *tert*-butoxycarbonyl, Bzl = benzyl, >—OH = isopropylidene-protected MeBmt.

bonds 1, 2 and 3 (Scheme 5). Bond 4 was formed on synthesis of the dipeptide Boc-Abu-Sar-OBzl. The tetrapeptide Boc-MeLeu-Val-MeLeu-Ala-OBzl was synthesized from the right to the left by forming bonds 5, 6 and 7 in that order. Subsequent coupling (bond 8) with the previously synthesized dipeptide then furnished the hexapeptide Boc-Abu-Sar-MeLeu-Val-MeLeu-Ala-OBzl. During incorporation of the amino acid MeBmt, the hydroxy- and *N*-methylamino functions were protected in the form of a dimethyloxazolidine derivative. This isopropylidene-protecting group was readily introduced by refluxing the amino acid in acetone and has the advantage of avoiding epimerization of the amino acid MeBmt during peptide-bond formation. This means that the oxazolidine ring retains the thermodynamically more stable *trans*-configuration of substituents during carboxy activation and peptide formation. On preparation, but before activation, the protected MeBmt amino acid was stabilized by addition of *N*-methylmorpholine (1 equiv.). To prepare the protected heptapeptide from the protected MeBmt amino acid and the hexapeptide, the dicyclohexylcarbodiimide (DCCI) coupling method was used in presence of *N*-hydroxybenzotriazole[39]. After removal of the isopropylidene-protecting group (1 equiv. of 1 N HCl/MeOH), the final amide linkage 10 was made by coupling Boc-D-Ala-MeLeu-MeLeu-MeVal-OH with the heptapeptide in presence of *N*-me-

thylmorpholine in CH_2Cl_2 at room temperature using the reagent (1*H*-1,2,3-benzotriazol-1-yloxy)tris(dimethylamino)-phosphonium hexafluorophosphate ($BtOP(NMe_2)_3^{\oplus}PF_6^{\ominus}$) developed by *Castro* et al.[40]. After hydrolysis of the ester group (NaOH at 0°C) and removal of the Boc group (CF_3COOH at −20°C), the unprotected undecapeptide was cyclized at room temperature to cyclosporine **1** (0.0002 M CH_2Cl_2, 1 equiv. $BtOP(NMe)_3^{\oplus}PF_6^{\ominus}$[40], *N*-methylmorpholine). The yield of crystalline cyclosporine was 62%. By using the mixed phosphonic anhydride method described by *Wissmann* and *Kleiner*[41] or the pentafluorophenol-DCCI complex of *Kovacs*[42] to effect cyclization of the unprotected undecapeptide, the yield of cyclosporine could be increased to 65%. Using the fragment-condensation technique described here it is now possible to synthesize cyclosporine very efficiently in 27.5% yield with respect to the amino acid MeBmt. Thus, 1.6 g of cyclosporine can be produced starting from 1 g of the amino acid MeBmt. This synthesis of cyclosporine also opens the way for the preparation of analogs with which the many unanswered problems concerning the structure-activity relationships of this drug can be investigated.

4. Cyclosporine Analogues

4.1. Choice of Variations

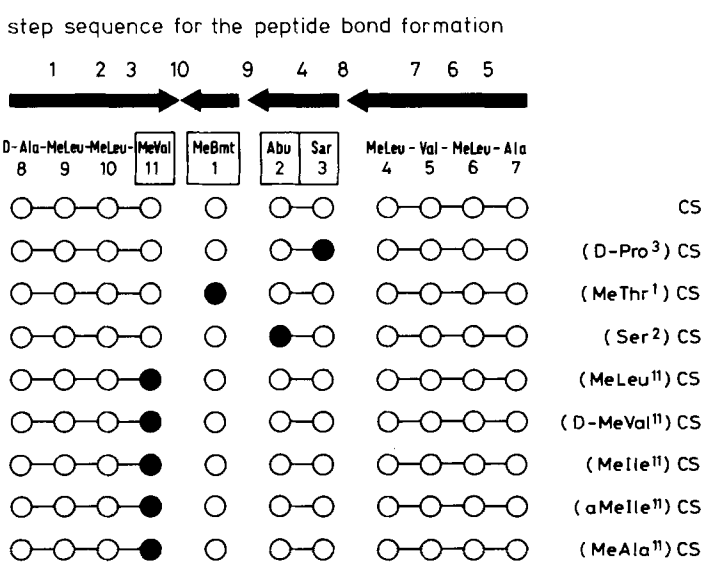
Some naturally occurring modifications of the cyclosporine peptide structure have been described by *Rüegger* et al.[13] and *Traber* et al.[17–19] and their contribution to our understanding of structure-activity relationships will be described below (see Section 5). In principle, the new synthetic approach enables any amino acid of the peptide chain of cyclosporine to be modified and thus allows successive examination of specific aspects of the structure-activity relationships. The first aspect to be studied was the importance of the near environment of the MeBmt amino acid in position 1 of cyclosporine; for this purpose variations at positions 1, 2, 3 and 11 were undertaken. Seven such variations will be described here together with the synthesis of (*N*-methyl-D-valine[11])cyclosporine, a naturally occurring isomer of cyclosporine.

In order to study the importance of the unusual side chain of MeBmt in position 1 of cyclosporine, this amino acid was replaced by *N*-methylthreonine (MeThr); thereby, the polar features of MeBmt are retained, but not the pronounced lipophilic character of the side chain.

(Threonine[2])cyclosporine [(Thr[2])CS], a naturally occurring isomer of cyclosporine, is a potent immunosuppressant. However, in contrast to other natural analogues with variations of the amino acid in position 2, (Thr[2])CS contains a hydroxy group. To examine whether or not this hydroxy group is involved in some special receptor interaction, a modified cyclosporine with a serine in position 2 (replacing Abu in cyclosporine and threonine in (Thr[2])CS) was prepared.

The X-ray structure analysis of cyclosporine indicates that the sarcosine in position 3 participates in a type II′ β-turn (see Section 1.3). Replacement of sarcosine by D-proline would be expected to stabilize this structural feature and make it more rigid. The proline ring would be expected to take an equatorial position relative to the peptide ring and should not alter the conformation of the peptide backbone relative to that of cyclosporine.

To relieve steric crowding and to allow more flexibility at position 11, of the peptide ring, MeVal was replaced by MeLeu, i.e. by an amino acid having one additional methylene group on its carbon chain.



The replacement of MeVal by MeIle (*N*-methyl-L-isoleucine) or aMeIle (*N*-methyl-L-alloisoleucine), two amino acids containing a *sec*-butyl instead of an isopropyl side chain, afforded models resembling more closely the natural cyclosporine. In the case of MeIle a hydrogen atom of the *pro-S* methyl of MeVal is replaced by a methyl group, while in aMeIle a hydrogen atom of the *pro-R* methyl of MeVal is replaced by a methyl group.

A further variation was the introduction in position 11 of a less hindered and smaller amino acid, namely MeAla (*N*-methylalanine), instead of MeVal, thus replacing the two methyl groups of MeVal by two hydrogen atoms.

The above modifications of cyclosporine would also be expected to provide information on the sensitivity of the biological activity of cyclosporine toward minor changes at each position and to indicate whether or not these amino acids are likely to be involved in interactions with the receptor.

4.2. Synthesis of Cyclosporine Analogues

Following the same strategy as used for the synthesis of cyclosporine (Scheme 5), the new peptide fragments were synthesized as shown in Scheme 6. The new peptide fragments were built up in the direction shown by the arrows using the step sequence indicated; the black circles show the positions of the modified amino acids. The undecapeptides with a free amino group and a free carboxy group were cyclized with $(PrPO_2)_3$[41] in the presence of 4-dimethylaminopyridine in CH_2Cl_2.

Scheme 6. Concept for the synthesis of cyclosporine analogues (see also Scheme 5). Black circles: modified amino acids. CS = cyclosporine.

4.3. Determination of the Structure of the Cyclosporine Analogues

The structural assignments for these cyclosporine analogues (Scheme 6) have been supported by NMR data. All analogues excepting (D-MeVal[11])cyclosporine, whose complicated NMR-spectrum indicates at least 7 peptide ring conformations, have NMR-spectra similar to that of natural cyclosporine, with essentially only one conformation in $CDCl_3$. Hence, it could be predicted that the new cyclosporine analogues have a conformation similar to that of cyclosporine. In the case of (MeLeu[11])cyclosporine, the structure predicted on the basis of its synthesis and physical data has been confirmed by an X-ray crystallographic analysis. This also showed that the backbone of (MeLeu[11])cyclosporine has practically the same conformation as cyclosporine itself in the solid state. The geometric arrangement of the β-carbons of *N*-methylvaline and *N*-methylleucine in position 11 are identical.

5. Biological Activity and Structure-Activity Relationships of Cyclosporine Analogues

The relative potencies of some synthetic and naturally occurring analogues of cyclosporine are shown in Table 1. The compounds were characterized using pharmacologic models previously used for testing cyclosporine[2-6]. The suppression of *the humoral immune response* was determined by measuring the antibody-forming cells in the spleens of mice immunized against sheep erythrocytes (Jerne plaque forming test). The suppression of *the cell-mediated immune response* was quantified in an immune reaction of a delayed-type hypersensitivity (DTH) by measuring the suppression of the oxazolone-induced skin reaction in mice. The *suppressive index* in vitro could be determined by quantifying the suppression of the proliferative response of lymphoid cells which are activated by mitogens or alloantigens.

From the results presented in Table 1 it is evident that the side chain of amino acid 1 (MeBmt) is important for biological activity. Removal of the nonpolar part of the side chain, as in (MeThr[1])cyclosporine, dramatically reduces the immunosuppressive activity; this is also the case on modification of the hydroxy group, as seen in *O*-acetyl- and deoxy-cyclosporine. Even the double bond makes a contribution to the biological activity: dihydro compounds are generally less potent immunosuppressants. MeBmt alone, however, has no immunosuppressive activity.

Amino acid 2 (Abu) permits some variation with alkyl chains of 2–3 carbons, resulting in good activity. Although (Thr[2])cyclosporine is a potent immunosuppressant, (Ser[2])cyclosporine is significantly less active. This would suggest that hydrophobic interactions are more important for the interaction of the aliphatic chain of amino acid 2 with the receptor.

Although (D-Pro[3])cyclosporine and (MeLeu[11])cyclosporine should have almost the same conformation as cyclosporine itself (similar NMR spectra of both analogues and similar structure of cyclosporine and (MeLeu[11]) in the solid state) they are negative variants, suggesting that in this case the steric bulk of the peptide side chains, in position 3 and 11 respectively, probably prevents efficient binding of these derivatives to the cyclosporine receptor. The loss of activity observed with (D-MeVal[11])cyclosporine, a derivative in which the conformation of the peptide ring at this position is certainly different (NMR) from that of cyclosporine, also confirms that the carbon chain of amino acid 11 is important for biological activity.

Minor variations of the structure of amino acid 11 can reduce the immunosuppressive activity of cyclosporine analogues. According to X-ray structure analyses on cyclosporine the *pro-R* methyl group of *N*-methylvaline would appear to be closer to the *N*-methyl group of MeBmt than the *pro-S* methyl group and is somewhat more sensitive to variation. The lower activity of the MeAla analogue could be due to the failure to fill a critical hydrophobic cavity on the receptor or to reduce conformational rigidity of the molecule.

Table 1. Immunosuppressive activity of some cyclosporine analogues and derivatives. Irrespective of its source, the cyclosporine (CS) has strong immunosuppressive activity (***); H-MeBmt-OH has no activity (*).

CS contains	Position	Analogue/Derivative contains	Source [a]	Activity [b]

[a] n = natural, ss = semisynthetic, s = synthetic. [b] *** = strong immunosuppressive activity in pharmacological models previously used to test cyclosporine [2-6]; ** = average activity; * = little or no activity.

6. Conclusion

Some structure-activity relationships (SAR) for cyclosporine are now emerging from the study of specifically modified derivatives. However, in order to obtain a more exact picture of SAR for cyclosporine, and then to synthesize derivatives with an improved activity profile, much remains to be done.

It is nevertheless already clear that the unusual MeBmt chain is intimately involved in the biological actions of the cyclosporine molecule but that it alone is not sufficient for immunosuppressive activity. The biological activity is associated with a larger portion of the cyclosporine structure and the results presented above (Section 5) indicate that this probably includes amino acids 1, 2, 3 and 11.

The synthesis of further derivatives should help answer many of the remaining questions concerning the structure-activity relationships of this drug.

Basic Principles of Protease-Catalyzed Peptide Bond Formation

By Hans-Dieter Jakubke*, Peter Kuhl, and Andreas Könnecke

The stereospecific formation of peptide bonds under mild conditions and without side reactions is still a formidable task in peptide synthesis. One approach that springs to mind, namely the use of the naturally occurring catalyst involved in the biosynthesis of proteins, the ribosomal peptidyl transferase, cannot be realized in practice. The fact, however, that the natural cleavage of proteins is carried out by other enzymes, namely the proteases, together with the reversibility of these cleavage reactions in principle, has led to an interesting synthetic concept. Proteases normally catalyze the enzymatic degradation of proteins and peptides by hydrolytic cleavage of the peptide bond in an exergonic reaction. The use of physicochemical principles in order to influence the equilibrium, the concentration of products, and the kinetic parameters of the reaction results in the successful application of the catalytic properties of proteases to peptide synthesis. The purpose of this review is to describe and summarize the methods used in such approaches and to attempt a systematic categorization. The principles are applied to the synthesis of such practically relevant products as aspartame and human insulin.

1. Introduction

Peptide synthesis has made a significant contribution over the last 30 years to progress in peptide research[1-3]. Besides the total synthesis of native active peptides and their analogues, which play an important role in the elucidation of structure-activity relationships, the semisynthesis of proteins[4] as well as the chemical modification of peptides and proteins, in order to modulate physiological or pharmacological effects, have been the focus of attention.

Ideally, the formation of the peptide bond should proceed fast and without racemization or other side reactions and, using equimolar amounts of carboxy and amino components, should result in quantitative yields. This goal, however, is not reached by any of the more than 130 variations of chemical peptide bond formation. Even the use of pro-

ven synthetic concepts in combination with well-tested coupling methods, which in model systems do not result in any racemization, does not guarantee the absolute avoidance of racemization when applied to the condensation of peptide segments. Accordingly, in order to improve peptide synthesis, the avoidance of undesired side reactions plays an important role. Based on such considerations, the use of appropriate enzymes to form the peptide bond springs to mind, since most enzymatic reactions are highly stereospecific. Unfortunately, one cannot use the ribosomal peptidyl transferase to such an end, since it can only act as an integral component of the ribosome in coordination with further factors that are involved in elongation of the peptide chain[5].

Based on considerations concerning chemical equilibria, *van't Hoff* already discussed in 1898 the possibility of using proteases, which normally catalyze the hydrolysis of peptide bonds, to catalyze their formation[6]. About 40 years later *Bergmann* and *Fraenkel-Conrat* presented experimental proof that the reversibility of protease-catalyzed reactions can be used to form peptide bonds[7,8]. *Bergmann* and his students, in particular *Fruton,* came to the right conclusions about enzymatic peptide synthesis, based on results on the hydrolytic action of proteases as well as their substrate specificity and stereospecificity. Enzymatic peptide synthesis, however, lost its importance with the elucidation of the central principles of protein synthesis in vivo. Apart from subsequent basic research, it was only unambiguously shown in the mid-seventies that proteases could be used successfully as biocatalysts in the synthesis of peptides on a preparative scale. The use of biocatalysts in peptide synthesis lies within the general trend to employ enzymes for organic synthesis[9], and the numerous reviews dealing with this subject[10-19] reflect the wide interest in protease-catalyzed peptide synthesis over the last 10 years.

It is in principle possible to influence the enzymatic formation of peptide bonds either thermodynamically or kinetically. Based on energetic considerations, significant differences emerge. Taking the basic principles of peptide bond formation using proteases as catalysts into account, an attempt will be made to illustrate systematically the present possibilities and limitations of this novel synthetic approach.

2. Thermodynamically Controlled Peptide Synthesis

The thermodynamically controlled formation of peptide bonds represents the direct reversal of the catalytic cleavage of peptides by proteases[10-13]. Since, however, concentrations are used in the description below instead of activities, this is not an exact thermodynamic treatment. In contrast to the hydrolysis, the synthesis of a peptide bond is an endergonic process, i.e. proceeds with loss of entropy and is energetically so unfavorable that the equilibrium constant K_{syn} for the coupling of two unprotected amino acids is $<10^{-5}$. Since the ionic forms of the two substrates are unreactive, for the thermodynamic approach two equilibria have to be taken into account:

$$R{-}COO^{\ominus} + H_3\overset{\oplus}{N}{-}R' \overset{K_{ion}}{\rightleftharpoons} R{-}COOH + H_2N{-}R' \overset{K_{inv}}{\rightleftharpoons} R{-}CO{-}NH{-}R' + H_2O$$

Preceding the "inversion equilibrium" K_{inv} between the uncharged substrates and the product is an "ionization equilibrium" K_{ion}. Taking the concentration of water into the equilibrium constant, the total process is given by

$$K_{syn} = K_{ion} \cdot K_{inv} = [R{-}CO{-}NH{-}R'] \cdot ([R{-}COO^{\ominus}] \cdot [H_3\overset{\oplus}{N}{-}R'])^{-1}$$

For any given pair of substrates and known pH, K_{ion} and K_{inv} are fixed. Therefore, the peptide concentration for the inversion equilibrium is dependent on the concentrations of the uncharged substrates that are formed in the preceding ionization equilibrium. These concentrations in turn are determined by their pK values. pK values of *N*- and *C*-protected amino acids as well as those for longer segments are substantially different from those of free amino acids; therefore, sufficiently high concentrations of uncharged substrates are present in the ionization equilibrium to give measurable concentrations of peptide in the inversion equilibrium.

The only function of the protease is to accelerate the attainment of the equilibrium for formation of the peptide. Its effectiveness is greater the more specific the protease is for the substrates. Therefore, reaction conditions should be chosen that ensure a high catalytic activity of the protease. The pH optimum of the synthesis lies—apart from pepsin-catalyzed couplings—in the pH range between the pK of the α-carboxyl group and that of the amino group of the substrates, i.e. normally between pH 6 and 7. The time necessary to finally attain the inversion equilibrium is determined by the concentration and the catalytic activity of the protease as well as the affinity of the protease for the substrates; this can be several minutes up to several days.

Thermodynamically controlled peptide synthesis can be employed for all proteases in conjunction with carboxy components unprotected at the *C*-terminus. However, if nonspecific proteases are used to condense segments, undesired peptide cleavages may occur. Even for highly specific proteases, such side reactions can take place if the sequence of one segment contains any amino acids that correspond to the substrate specificity of the protease.

There are two principal ways by which one can further influence thermodynamically controlled peptide formation:

- —increasing K_{ion} by alteration of the pK values of the substrates, and
- —increasing the concentration of the peptide product via manipulations based on the law of mass action.

Both possibilities can be achieved in quite different ways; in practice, however, one generally prefers to influence the equilibria in favor of synthesis by a combination of both factors. For didactic reasons the different possibilities of control are discussed separately below.

2.1. Increase in K_{ion}

For a given set of reaction conditions there are two ways to decrease the difference in pK values between amino and

carboxy components in order to increase K_{ion}. This leads, in turn, to an increase in $K_{syn} = K_{ion} \cdot K_{inv}$.

2.1.1. Use of Water-Miscible Organic Solvents[20]

Water-miscible organic solvents decrease the acidity of the α-carboxy group of the carboxy component, whereas they only marginally influence the pK value of the amino group of the nucleophile. For example, the pK value of acetylglycine (Ac-Gly) in water is 3.60, while in 80% (v/v) dimethylsulfoxide it is 6.93; the pK values of Gly-NH_2, 8.20 and 8.10, respectively, remain almost constant. Since pK_{app} values measured in organic solvents have no great relevance, pK values determined under the same conditions should bear greater significance. In water ΔpK for acetylglycine/Gly-NH_2 is 4.60, while in 80% (v/v) DMSO it is only 1.11. A variety of other cosolvents can be used to change the pK value by one to two units, resulting in a significant increase in K_{syn}. For the coupling of 1 mM Z-Trp with 100 mM Gly-NH_2 at pH 6.7 using chymotrypsin, K_{syn} is 0.45 M^{-1} in water, 2.12 M^{-1} in 60% (v/v) glycerol and 38 M^{-1} in 85% (v/v) 1,4-butanediol.

This approach, however, is problematic insofar as the catalytic activity of proteases decreases with increasing concentration of the cosolvent; thus, the time required to reach the inversion equilibrium increases. Using 50% (v/v) ethanol, dimethylformamide (DMF), DMSO, dioxane, acetone, or acetonitrile results in inactivation of chymotrypsin, and no synthesis occurs. Only polyalcohols, which act as enzyme stabilizers, may be used at higher concentrations without inactivation of the enzyme[21], but even in these cases one finds a negative effect on the catalytic activity[22-25]. It was shown that no significant alteration of the substrate specificity occurs[20].

2.1.2. Use of Biphasic Systems

In systems consisting of an aqueous phase and a nonmiscible phase (nonpolar organic solvent), pK values are influenced in such a way that K_{ion} increases[23]. Depending on the volume ratio α of organic and aqueous phase and the partition coefficient P, an increase in the pK values of the carboxy components and a decrease in the pK values of the amino components by $\lg(1+\alpha \cdot P)$ is observed.

Since the enzyme is localized in the aqueous phase, the activity can be influenced only by the saturation concentration of the organic solvent in water, and the enzyme is therefore inhibited far less than by solvents miscible with water[24,25]. This advantage, however, is counteracted by the prolonged time required to reach equilibrium, and additional partition equilibria are most likely the rate-determining steps. Solubility of the substrates in the nonpolar organic phase limits the general use of biphasic systems for the enzymatic peptide synthesis.

2.2. Influence on Product Formation Based on the Law of Mass Action

The first positive experimental results for the potential use of a reversal of protease-catalyzed peptide hydrolysis were based on the limited solubility of the products, which thus are removed from the inversion equilibrium and accumulate[11]. The product can also be removed from the equilibrium by extraction or specific complexation.

2.2.1. Formation of Insoluble Products

If sufficiently high concentrations of substrates are employed, such that in the equilibrium K_{inv} it is possible to have a peptide concentration that lies above the maximal saturation concentration, precipitation occurs and thus the product of the synthesis accumulates. This can be explained using the law of mass action (see also [23]). If two substrates A and B of equal concentration react to form a product C, the equilibrium $A + B \rightleftharpoons C$ exists in solution, the equilibrium constant of which is given by Equation (1).

$$K = [C]([A] \cdot [B])^{-1} = [C] \cdot [A]^{-2} \tag{1}$$

If part of the product C forms a precipitate, Equation (2) holds.

$$K_{app} = ([C]_l + [C]_s) \cdot [A]^{-2} \tag{2}$$

where $[C]_l$ is the maximal concentration of the product in solution and $[C]_s$ the concentration of the insoluble product with respect to the total volume.

Using the starting concentration $[A]_0$, the mass balance results in Equation (3)

$$[A]_0 - [A] = [C]_l + [C]_s \tag{3}$$

with [A] as the equilibrium concentration of the substrate A in solution. Insertion of Equation (3) into Equation (2) results in

$$K_{app} = ([A]_0 - [A]) \cdot [A]^{-2} \tag{4}$$

Substitution of $[A] = \left(\frac{[C]_l}{K}\right)^{1/2}$ from Equation (1) with $[C] = [C]_l$ into the above equation gives, after rearrangement, Equation (5).

$$K_{app} = \frac{K}{[C]_l}[A]_0 - \left(\frac{K}{[C]_l}\right)^{1/2} \tag{5}$$

Thus, the apparent equilibrium constant for a reaction in which some of the product precipitates due to its limited solubility in the system is greater the higher the starting concentration of substrates and the lower the solubility of the product in this system.

Using one component in excess may result in almost quantitative reaction of the other substrate. This method is very popular in practice since the condition of low solubility of the product compared to that of the substrates frequently holds.

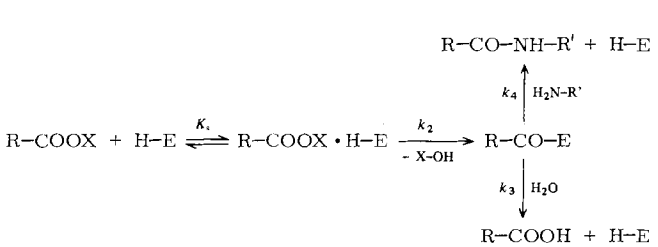
2.2.2. Extraction of Products

In biphasic systems the product is removed from the equilibrium if, due to a favorable position of the partition

equilibrium, it is extracted and thus accumulates in a nonpolar phase that is not miscible with water. *Martinek* et al.[23] derived the following equation for a reaction A + B ⇌ C + D [Eq. (6)].

$$K_{\text{biphas}} = K_{\text{aq}} \frac{(1+\alpha P_{\text{C}})\cdot(1+\alpha P_{\text{D}})}{(1+\alpha P_{\text{A}})\cdot(1+\alpha P_{\text{B}})} \qquad (6)$$

where $\alpha = V_{\text{org}}/V_{\text{aq}}$ and P is the partition coefficient. They showed that $K_{\text{biphas}}(\alpha)$ shows a maximum for a defined ratio of partition coefficients. This means that the effective equilibrium constant may be smaller or larger than that in either of the two phases alone.



In most cases, however, the product is only marginally soluble in the organic phase; it precipitates and is thus removed from the equilibrium[24-28]. This can also be achieved by the use of particular solvent combinations which allow the adjustment of the saturation concentration of one substrate, so that the product with the longer peptide chain is less soluble in that particular system[24].

2.2.3. *Specific Complexation of the Product*

If compounds are available that can form specific complexes with the product, the latter can be removed from the equilibrium by adding such a complex-forming material and the complex can be accumulated[29] (see also Section 4.7).

3. Kinetically Controlled Syntheses

Investigation of the catalytic mechanism of serine and cysteine proteases using chymotrypsin and papain as examples revealed that, in the presence of nucleophiles, acyl-enzyme intermediates R–CO–E are deacylated competitively by water and the nucleophile H_2N-R'[30-32]. If the nucleophile is an amino acid or peptide derivative, then a new peptide bond is formed during the aminolytic deacylation (Scheme 1). If $k_2 \gg k_3 + k_4$ and $k_4[H_2N-R'] > k_3[H_2O] = k_3'$, then a kinetically controlled accumulation of the peptide product occurs, with a concentration greater than the thermodynamic equilibrium concentration. Especially suitable carboxy components for this type of enzymatically catalyzed peptide synthesis are acylamino acid alkyl esters if they match the substrate specificity of the particular protease, since in general they fulfill the condition $k_2 \gg k_3 + k_4$. Furthermore, k_2 of the ester substrate is substantially greater than k_2 of the peptide formed[33-35], which results in a maximum for product formation (Fig. 1) before the slower hydrolysis of the product starts to become important.

Scheme 1. Peptide synthesis catalyzed by serine and cysteine proteases (H–E) with R–COOX as the acyl donor (carboxy component) and H_2N-R' as *C*-protected amino acid or peptide (amino component); X = alkyl.

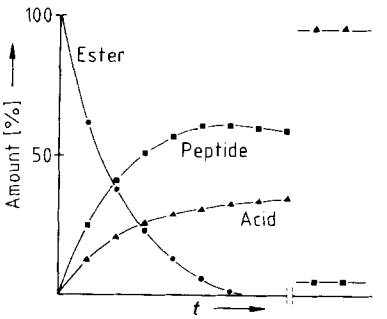


Fig. 1. Characteristic reaction pathway of a kinetically controlled peptide synthesis using an *N*-protected amino acid ester or peptide alkyl ester as acyl donor.

The area in which kinetically controlled synthesis can be used in practice is limited to serine and cysteine proteases with preferably acylamino acid esters as the carboxy component. The reactions are characterized by short reaction times and low enzyme requirements. In contrast to the thermodynamically controlled equilibration, here the ester substrate only occurs once as the acyl-enzyme intermediate, which is the decisive step for the ratio of peptide formation to hydrolytical cleavage.

3.1. Nucleophile Specificity of Proteases

Substrate binding sites in the active centers of proteases exhibit differentiated specificity towards nucleophiles such as amino acid and peptide derivatives. This influences primarily k_4 and thus the success of kinetically controlled peptide synthesis[13,32,36-41]. An acyl-enzyme breaks down via hydrolysis and aminolysis with reaction velocities v_3 and v_4, respectively. From Scheme 1, Equation (7) is obtained.

$$\frac{v_3}{v_4} = \frac{\dfrac{\text{d[R–COOH]}}{\text{d}t}}{\dfrac{\text{d[R–CO–NH–R']}}{\text{d}t}} = \frac{k_3'[\text{R–CO–E}]}{k_4[H_2NR'][\text{R–CO–E}]} \qquad (7)$$

This simplifies to Equation (8)

$$\frac{\text{d[R–COOH]}}{\text{d[R–CO–NH–R']}} = \frac{k_3'}{k_4[H_2N-R']} = \frac{p}{[H_2N-R']} \qquad (8)$$

with $p = k_3'/k_4'$. The partition constant p corresponds to the necessary concentration of nucleophile for d[R–COOH] = d[R–CO–NH–R'][40]; i.e., partition of the acyl-enzyme into peptide and acylamino acid occurs to 50% each. Table 1 contains some partition constants. These values indicate the possible use of p as an efficiency parameter for various nucleophiles. They also show that p is not a universal constant, since it is influenced by the acyl part of the acyl-enzyme. Nevertheless, it is possible to deduce the order of magnitude of the concentration of nucleophile required for a particular peptide synthesis directly from the value of p. Equation (8) is strictly valid only

Table 1. Partition constants p of some acylchymotrypsins [a].

Nucleophile	p [mol·L^{-1}·10^{-3}] Ac-Phe-CT [b]	Ac-Tyr-CT [c]	Mal-Phe-CT [40]
Gly-NH_2	90.0	104.7	95.0
Ala-NH_2	22.7	23.0	35.5
Val-NH_2		21.4	73.3
Leu-NH_2		19.3	20.2
Arg-NH_2			0.15

[a] CT = chymotrypsin; Mal = maleyl-(3-carboxyacryloyl-). [b] δ-CT; calculated according to [32]. [c] α-CT; calculated according to [39].

for the case where one finds a linear relationship between the concentration of nucleophile and the partition in the range of interest. This is true in the majority of cases investigated. However, deviations from linearity have been found[39]. The mathematical treatment of these cases is rather complicated since p becomes a function of the concentration of nucleophile.

3.2. Influence of the Reaction Medium

Since only the non-protonated form of the nucleophile reacts in the aminolytical deacylation of the acyl-enzyme, it is necessary to take the effective concentration of nucleophile instead of the total concentration into account. This can be calculated from the pK value of the nucleophile and the pH of the medium. Since pK values of α-amino groups of amino acid and peptide derivatives lie around 8, it is advisable to carry out kinetically controlled peptide synthesis at pH ≥ 8. The partition constant p is also dependent on pH. For the proteases trypsin and chymotrypsin p is reduced in alkaline medium, which results in increased synthesis[37]. Organic solvents and ionic substances as well as the reaction temperature can influence the partition constant p.

4. Selected Examples

Compared to the well-established chemical coupling reactions, a synthetic strategy based on proteases as catalysts is naturally still in its infancy. The majority of studies with respect to the usefulness of proteolytic enzymes for the formation of peptide bonds were initially model studies. In general, therefore, the methodological aspects were more important than any practical applications and substrates were chosen in such a way as to correspond to the specificity of the proteases employed. Recently, however, examples of the syntheses of biologically active peptides using coupling steps exclusively or partially catalyzed by proteases have increased. The area of semisynthesis of proteins has seen considerable progress based on the use of proteases[4,42].

The following selected examples illustrate the strategy and tactics as well as the present possibilities for the use of proteolytic enzymes in the synthesis of biologically active peptides and proteins.

4.1. Aspartame

The precursor (Z-Asp-Phe-OMe) for the peptide sweetener aspartame (Asp-Phe-OMe) is obtained by a thermolysin-catalyzed coupling of Z-Asp with Phe-OMe in a thermodynamically controlled reaction. An insoluble salt is formed with the enantiomer of the amino component, Z-Asp-Phe-OMe · Phe-OMe, which results in an almost quantitative shift of the equilibrium towards the product[43]. In this reaction the strategy of minimal protection is fortuitously complemented by the salt formation. Enzymatic synthesis is thus superior to chemical methods since the latter require the use of β-protected aspartate derivatives.

4.2. Leucine-Enkephalin

The kinetically controlled synthesis of Leu-enkephalin, Tyr-Gly-Gly-Phe-Leu, was achieved by stepwise elongation of the C-terminal end of the peptide via catalysis with the serine exoprotease carboxypeptidase Y (CPD-Y)[44]. Amino acid amides were used as nucleophiles since free amino acids produce only low yields and amino acid esters give rise to side reactions which are difficult to control[45]. Thus, the seemingly complicated route of selectively removing the C-terminal amide group with CPD-Y followed by esterification of the peptide had to be resorted to before it was possible to use the peptide in the next coupling step as the substrate. The protecting group for the α-amino function was Bz-Arg, which can easily be removed by tryptic cleavage[17,46].

4.3. Dynorphin(1-8)

Dynorphin(1-8), Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile, a Leu-enkephalin that is extended at the C-terminal end, was synthesized by a combination of thermodynamically and kinetically controlled couplings with papain, chymotrypsin, and trypsin as biocatalysts[47]. To this end, four dipeptides were synthesized enzymatically and subsequently condensed to yield two tetrapeptide segments. Coupling of the two tetrapeptides Boc-Tyr(Bzl)-Gly-Gly-Phe-OEt and Leu-Arg-Arg-Ile-NH-NH-C_6H_5 with chymotrypsin results in a partially protected octapeptide, which after deblocking yields the biologically active dynorphin(1-8) (Fig. 2). The protecting group for the carboxy function is in general phenylhydrazide, which can be introduced via papain catalysis into Boc-amino acids[48] and can easily be removed by oxidation or can be converted into an ester[49].

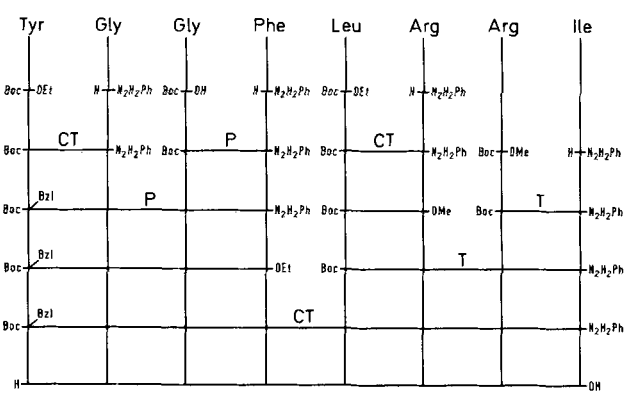

Fig. 2. Synthesis of dynorphin(1-8) catalyzed by proteases [47]; CT = chymotrypsin, P = papain; T = trypsin; Bzl = benzyl, Boc = tertbutoxycarbonyl.

This example demonstrates two major advantages of enzymatic peptide synthesis: condensation of segments containing a variety of amino acids can be achieved without the risk of racemization and it is not necessary to protect the guanidino group of arginine.

4.4. Bz[Gly^{21}(Acm)Cys^{31}] EGF(21—31)NHEt

The advantages of the combined use of chemical and enzymatic methods are illustrated by the synthesis of segments of the mouse epidermal growth factor (EGF)[50]. All couplings catalyzed by proteases were carried out under kinetic control (Fig. 3) since this ensures a short reaction time, even when low concentrations of enzyme are used. Enzyme-labile protecting groups were Bz-Arg and Bz-Phe[17,46], which were also used to regulate the hydrophobicity and hydrophilicity of the partial sequences.

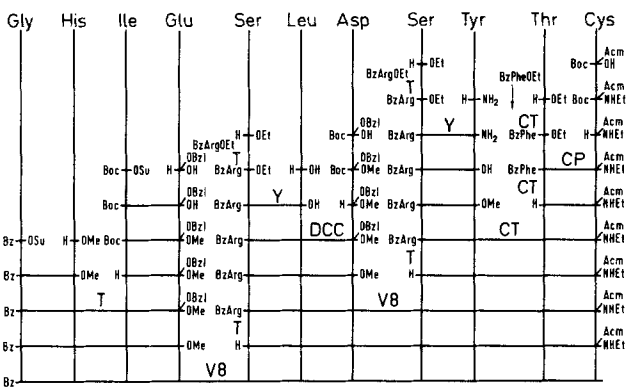

Fig. 3. Synthesis of Bz [Gly^{21}(Acm)Cys^{31}] EGF(21—31)NHEt [50]; CP = chymopapain, V8 = *Staphylococcus aureus* protease V8, Y = carboxypeptidase Y, DCC = dicyclohexylcarbodiimide; Bz = benzoyl, Su = succinimido, Acm = acetamidomethyl.

4.5. Eledoisin (6-11)-Hexapeptide

This hexapeptide was obtained by kinetically controlled couplings using papain and chymotrypsin in the biphasic system CCl_4/buffer[51] (Fig. 4). The biphasic system was employed not primarily to influence the equilibrium, but to insure a high catalytic activity of the protease dissolved in the buffer as well as excellent solubility of the substrates in the organic phase. Thus, the total reaction volume could be kept small, ensuring yields that are higher than can be achieved using water-miscible cosolvents[52].

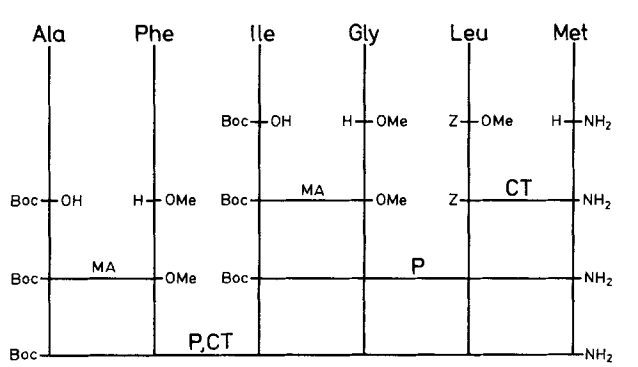

Fig. 4. Synthesis of eledoisin (6-11)-hexapeptide [51]; MA = mixed anhydride method; Z = benzyloxycarbonyl.

The *C*-terminal dipeptide could also be obtained by a thermolysin-catalyzed reaction in which the equilibrium of the thermodynamically controlled condensation was shifted in the direction of products by extraction of the product Z-Leu-Met-NH_2 into the organic phase.

4.6. Human Insulin

Using thermodynamically controlled reactions it is possible in a variety of ways to obtain semisynthetic human insulin and analogues from porcine insulin, which is available from natural sources (Fig. 5). The control of the thermodynamic equilibrium is always achieved by high concentrations of the appropriate nucleophilic amino component and frequently also by a large volume of water-miscible organic cosolvents. The simplest way to obtain the human insulin ester is in a one-step reaction involving an enzyme-catalyzed exchange of the *C*-terminal alanine-B30 of porcine insulin for a threonine ester[53-57]. Using the above reaction conditions prevents almost completely the possible cleavage of the Arg^{B22}-Gly^{B23} bond by trypsin. Such methods are now used commercially for the production of human insulin.

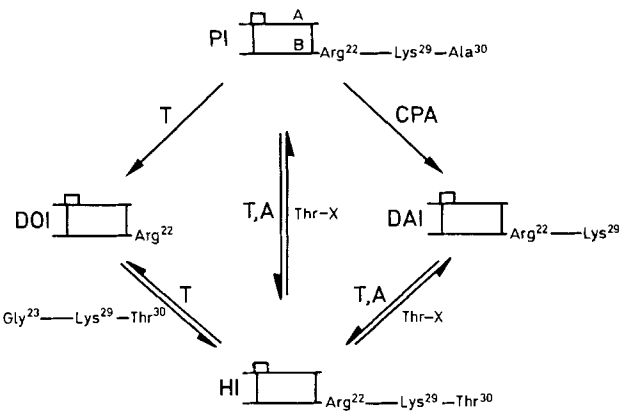

Fig. 5. Semisynthetic conversion of porcine insulin into human insulin; PI = porcine insulin, HI = human insulin; DAI = des-Ala^{30}-insulin, DOI = deoctapeptide$^{B23\text{-}B30}$-insulin, A = *Achromobacter* protease, CPA = carboxypeptidase A.

One can also use des-Ala^{B30}-[54,58,59] or deoctapeptide$^{B23\text{-}B30}$-insulin[21,60] as substrates which can be coupled to synthetic peptides and thus provide an easy approach to the synthesis of insulin analogues[61]. Apart from trypsin, a lysine-specific *Achromobacter* protease[54,58,59] and CPD-Y[55] have been used. The advantages of the enzymatic semisynthesis over chemical methods are obvious for the above mentioned examples since nearly all problems connected with blocking or deblocking are avoided using proteases.

4.7. Ribonuclease S-Peptide(1-15)

One example for the specific complexation of the peptide formed, which is thus removed from the synthesis equilibrium, is the coupling of the synthetic ribonuclease S-peptide segments 1—10 and 11—15 catalyzed by clostripain. The resulting peptide 1—15 is complexed by native ribonuclease(21-24) S-protein[29].

5. Use of Immobilized Proteases

For future applications of the enzymatic peptide synthesis, the use of immobilized proteases will probably be of technological and economical importance. Basic studies on the applicability of immobilized proteases have been carried out under kinetic as well as thermodynamic control using covalently bound chymotrypsin, trypsin, thermolysin, and papain[62–64]. It was shown that the immobilized biocatalysts have almost the same efficiency as the native enzymes. Contrary to earlier results[64], it could also be shown that immobilized papain is ideally suited for kinetically controlled synthesis at high pH values[37].

The effort involved in immobilizing an enzyme is compensated for by the possibility of its repeated use. Depending on the stability of the immobilized protease, this is guaranteed if short reaction times are employed, which is a characteristic of kinetically controlled reactions. In model experiments the possibility of repeated use under different reaction conditions could be demonstrated[37,62–64]. A further notable advantage of immobilized enzymes is the fact that the products are not contaminated with proteolytically active or denatured enzymes. Furthermore, the possibility of a continuous flow application may become a reality.

Of practical importance so far is the synthesis of the aspartame precursor using ionically bound thermolysin in a mixture of greater than 99% (v/v) ethyl acetate; this, however, requires rather long reaction times[65].

The thermodynamically controlled coupling of des-Ala^{B30}-insulin with Thr-O*t*Bu in the presence of high concentrations of water-miscible organic solvents is also effectively catalyzed by covalently bound *Achromobacter* protease[66] or trypsin[67].

6. Criteria for Synthesis Planning

In contrast to the synthesis of di- and tripeptides, it is necessary for the assembly of longer chains of peptide sequences to carry out an exact synthetic plan, the specific method of coupling being at first of little importance. The strategy of a peptide synthesis normally means the order in which the particular amino acid residues are coupled, namely either via stepwise addition from the *C*- or the *N*-terminal end or via condensations of presynthesized segments (segment condensation). A stepwise chemical synthesis starting from the *N*-terminal end, analogous to the ribosomal protein biosynthesis, is prohibited due to the permanent risk of racemization. Apart from the severe solubility problems in the synthesis of polypeptides with complete side-chain protection, it is mainly the risk of racemization that leads to the enormous variety of synthetic strategies for the chemical synthesis of peptides.

Although enzyme-catalyzed coupling reactions take place stereospecifically (free of racemization) and require only minimal side-chain protection, thereby solving the aforementioned problems, the substrate specificity is a limitation, which prevents this method from being universally applicable. A protease is much more limited in its area of use compared to chemical coupling methods, which are only influenced at most by the steric factors of the components to be coupled. This disadvantage, however, is compensated for completely by other advantages. These include not only the aforementioned factors (the stereospecific course of the reaction and the dispensing with the protection of side chains of trifunctional amino acids) but also mild and ecologically advantageous reaction conditions. If the potential of proteolytic enzymes that are to be used principally for the formation of peptide bonds is examined, it is seen that exopeptidases should find preferential application to the stepwise synthesis of short peptides and segments, while condensations to larger blocks should best be carried out by catalysis using endopeptidases of the required specificity. Exopeptidases have the great advantage that, in starting a stepwise synthesis either from the *C*-terminal end (aminopeptidases) or from the *N*-terminal end (carboxypeptidases), the internal peptide bonds within the growing chain can no longer be proteolytically cleaved by the enzyme employed as the biocatalyst. For preparative purposes aminopeptidases seem less well suited, since both substrate and product contain free α-amino functions which complicate the isolation of the product. Furthermore, since the substrate specificity is not strongly determined, there is a possibility of undesired coupling reactions. Carboxypeptidases exhibit superior properties as biocatalysts for stepwise coupling reactions, especially the serine protease carboxypeptidase Y (see also Section 4.2). Since, however, even the application of CPD-Y shows some preparative limitations, it is advantageous to have endopeptidases available for the synthesis of short peptides, especially since such enzymes can even be used for the synthesis of dipeptides if appropriate combinations of protecting groups are employed. Furthermore, one can use endopeptidases with broader specificity for stepwise synthesis as was shown for oligopeptide synthesis catalyzed by papain[68].

Problem-free coupling of segments require endopeptidases with high substrate specificity and the absence of the specific amino acids in the segments, except for the position where the peptide bond is to be formed. Apart from the lysine-specific *Achromobacter* protease, trypsin catalyzes the formation of a peptide bond after lysine and arginine residues. Thus, coupling of segments can only be carried out under the conditions described above for carboxy components that carry one of the mentioned basic amino acids in the *C*-terminal position. This restriction necessarily leads to the conclusion that one may employ less-specific proteases to catalyze coupling of segments. In order to avoid undesirable chain cleavage, manipulations that favor the synthesis have to be carried out, as described in Sections 2 and 3. From the literature, examples are known for the synthesis of biologically active oligopeptides using exclusively protease-catalyzed coupling steps (see also Sections 4.2 and 4.3). However, without intending to play down this ambitious synthetic concept, it seems unlikely that in the near future chemical coupling methods will be generally replaced by the enzymatic approach. Instead, the enzyme-catalyzed couplings will contribute significantly to the methods available to the peptide chemist.

In a given synthesis project it must first be determined if, for the separation into segments, favorable combinations

of amino acids can be found that permit protease-catalyzed coupling of segments. The synthesis of the segments should preferably be carried out in combination with proven chemical coupling reactions. Therefore, simple chemical coupling reactions without the risk of racemization are preferred by all means over enzymatic reactions, especially for segments containing a large number of amino acids that do not need further protecting groups. On the other hand, for segments with predominantly trifunctional amino acid residues where semipermanent side chain protection is not desired, enzyme-catalyzed reactions using proteases of the appropriate substrate specificity are preferable. In this way, segments are obtained with sufficient solubility to be used in protease-catalyzed block couplings.

For the use of serine and cysteine proteases a further point needs to be decided; namely, should the carboxy component be used as the acylamino acid or should a derivative (e.g. alkyl ester) that would favor acylation be used. Although the kinetically controlled reaction with little enzyme requirement and short reaction time should be preferable, the decision in each case will be determined by the overriding total synthetic concept. An unfavorable nucleophile specificity may be better taken care of in a thermodynamically controlled reaction with the appropriate manipulations of conditions than in a kinetically controlled coupling, where requirements are less flexible.

For the synthesis of biologically active peptides or segments with predominantly hydrophobic amino acid residues it is frequently necessary to overcome the poor solubility of the reactants through the introduction of solubilizing protecting groups[69]. The introduction of such solubilizing residues into the classical N^{α}- and C^{α}-protecting groups cannot be regarded as the solution to this problem; for enzyme-catalyzed peptide synthesis totally different protecting groups are required. Even polyethylene glycol esters, which have proved useful for chemical synthesis in aqueous solution[70], are less useful as carboxy components, whereas amino components blocked in this way can be reacted without any problems[71]. In general, protecting groups that can be removed under mild conditions are required, as is possible, for example, in the ease of Bz-Arg or Bz-Phe as α-amino protecting groups which can easily be cleaved off by trypsin or chymotrypsin[17,46,72]. Solubilizing ester groups attached to the carboxy component increase the solubility of the respective reactant in kinetically controlled reactions. After the coupling, however, this solubilizing effect is naturally lost. It is possibly preferable to use non-ionic solubilizing ester groups rather than charged residues.

The improvement of the solubility of reactants and products is of immediate importance for a continuous flow synthesis using immobilized proteases. Their application seems justified if the effort required for the immobilization is compensated for by the repeated use of the biocatalyst.

Finally, the question arises whether the use of proteases as catalysts can be of advantage for peptide bond formation via a polymer-based route. Simple model studies using a polymer-bound amino component show that polyethylene glycol is well suited as a soluble polymer[71]. Silica gel as the insoluble polymer matrix seems less promising since the fixed nucleophile is limited in its mobility and because of the possibility of steric hindrance between the enzyme and the polymer[73]. By the use of appropriate spacers as well as polymers with a high loading capacity for nucleophiles, these limitations should be successfully surmountable.

7. Summary and Prospects

Based on the classical studies of the reversibility of reactions catalyzed by proteases, it has been possible in the last ten years to show convincingly that proteolytic enzymes can in principle be used as biocatalysts. Thus, they can be employed in peptide bond formation on a preparative scale and are of practical use in the biotechnological synthesis of biologically active peptides and proteins. The stereospecificity of proteases guarantees the formation of stereochemically uniform products and requires only minimal semipermanent protection of side-chain functions in trifunctional amino acid residues. However, due to the substrate specificity, the universal applicability of proteases is limited. Therefore, it is of great importance to select proteases with modified substrate specificity based on strategic and tactical considerations with respect to the various product sequences. The advantages of both the thermodynamically and the kinetically controlled reactions have to be optimally exploited. Environmentally acceptable reaction conditions, which are characteristic of biotechnological processes, together with the potential for continuous flow application using immobilized proteases, should be an important stimulus to develop and perfect the methodology of enzyme-catalyzed peptide synthesis in order to improve and augment the armamentarium of the synthetic peptide chemist.

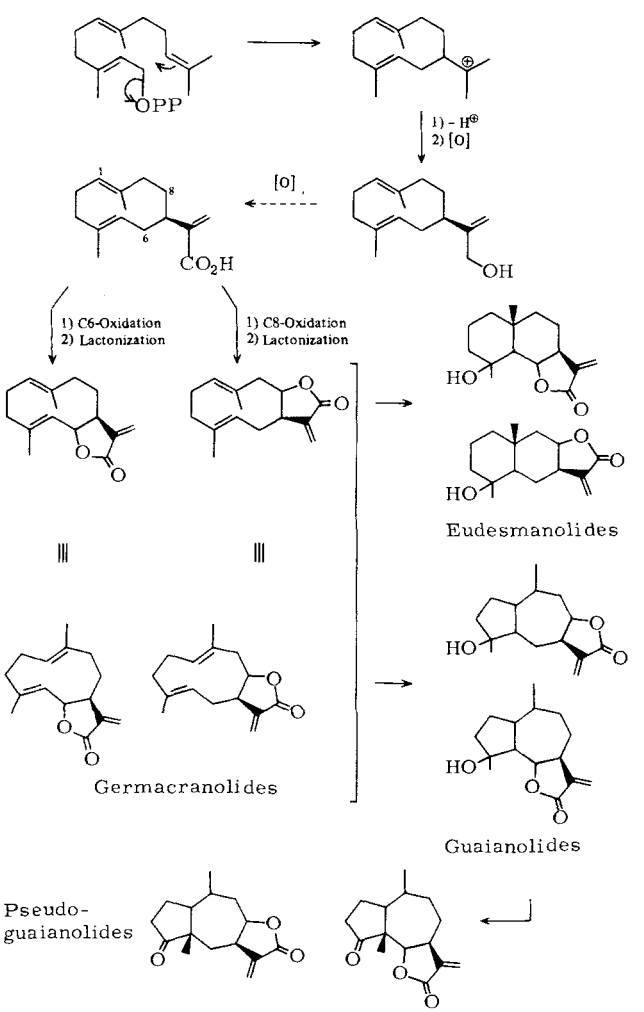
Synthesis and Biological Activity of α-Methylene-γ-butyrolactones

By H. M. R. Hoffmann* and Jürgen Rabe

Dedicated to Dr. Wilhelm A. Schuler on the occasion of his 70th birthday

α-Methylene-γ-butyrolactones [dihydro-3-methylene-2(3*H*)furanones] constitute an important group of natural products and possess wide-ranging biological activities. Progress in the synthesis of the heterocycle and the classification of the synthetic methods are not only of practical interest, but also fundamentally important as a current example for the construction of an unusual 1,4-functionality distance and an α-substituted acrylic ester moiety which is susceptible to nucleophilic attack.



1. Introduction

The α-methylene-γ-butyrolactone ring is an integral building block of many natural products, especially the sesquiterpene lactones, which exhibit interesting biological properties. In a book[1a] published in 1973, ca. 200 representatives of this class of compounds together with their ^{1}H-NMR spectra and other physical data were listed; 6 years later there were already ca. 900[1b]. Since then the number of these compounds has risen further: a Chemical Abstracts Online Search with projection shows that at present at least 2000—3000 α-methylene-γ-butyrolactones, mainly of the sesquiterpene type, are known. Since the current number of structurally elucidated natural products has been estimated to be only between 25000 and 30000[2], α-methylenelactones represent (with approx. 10%) a major class of known natural products. α-Methylene-γ-butyrolactones have been dealt with in a series of articles[4a–d], which quickly appeared following the first review by *Grieco*[3] in 1975. After a description of the biological activities it is our purpose to present the various conceptions for the synthesis of the heterocycle and to describe recently developed syntheses.

2. Biosynthesis

The biosynthesis of the sesquiterpenoid α-methylene-γ-butyrolactones is fairly simple[1,5]. The compounds are derived from *trans,trans*-farnesyl pyrophosphate, which first cyclizes to give the strained cyclodecadiene skeleton of germacradiene (or germacra*triene*) and then reacts further intramolecularly to form a perhydroazulene system (e.g., guaiane and pseudoguaiane) or a decalin system (e.g., eudesmane). The sequence of oxidation steps is less well understood. In accord with Scheme 1, the lactone moiety, which is indicated by the suffix "olide", is *cis*- or *trans*-fused to a six-, seven-, or ten-membered ring. Further rearrangements and oxidative modifications give rise to the structural diversity of these compounds.

Many plants which belong to the large, species-rich family of the *Compositae*[1c] (composites) contain sesquiterpene lactones as characteristic constituents. These compounds are colorless, lipophilic, often bitter-tasting, and are mainly present in the leaf tissue, where they can constitute up to 5% of the dry weight. The closer two species are related to each other, the smaller is the difference between the distribution of these terpenes. In addition to morphology, i.e., the comparison of external plant form, chemotaxonomy, in which secondary plant metabolites are identified and compared, has established itself as a method for the botanical classification of plants and for the clarifica-

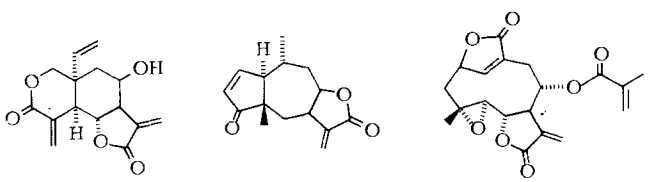
tion of evolutionary problems (sesquiterpene lactones as chemotaxonomic markers)[1a,c].

3. Important Biological Activities

α-Methylene sesquiterpene lactones show cytotoxic, antitumoral, and bactericidal properties. Other representatives cause an allergenic contact dermatitis or affect plants by inhibition of growth. There are already several studies on the relationship between biological activity and structure[6-10]. As has been shown, α-methylene-γ-butyrolactones must be looked upon as alkylating agents which are biologically active because they undergo a Michael reaction with biological nucleophiles such as L-cysteine or thiol-containing enzymes (Enz-SH).

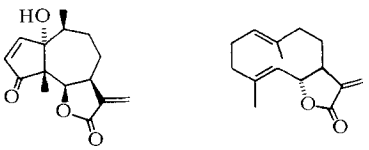


It is probable that these lactones inhibit the incorporation of selected amino acids into proteins, i.e., they inhibit the metabolism at the cellular level, but do not alkylate DNA[8,11-15].

Presumably, the residual molecule and its lipophilicity also determine the specificity and the site of the activity.

3.1. Antitumoral and Cytotoxic Activity

A large number of active sesquiterpene lactones, including vernolepin[18a], aromaticin[11], and elephantopin[18b], have been isolated from plant extracts which show tumor-inhibiting activity[16,17] (Scheme 2).

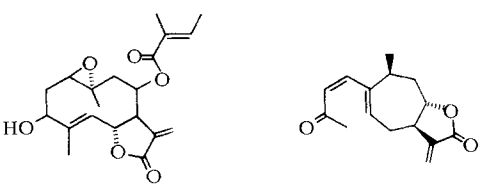


Scheme 2. From left to right: vernolepin, aromaticin, elephantopin.

It has been shown that almost all known cytotoxic sesquiterpene lactones possess an α,β-unsaturated lactone structure, and that the conjugated double bond must be exocyclic. A cyclopentenone or an additional α-methylene lactone moiety enhances the cytotoxic activity; hydroxy groups can also cause an enhancement. The high cytotoxicity of the sesquiterpene lactones is probably due to the inhibition of DNA synthesis and/or transcription[15]. However, protein synthesis, also, is partially impaired[13,14]. It should be mentioned, however, that at present there is no sesquiterpene cytostatic which is used clinically, apparently because of the relatively high toxicity of the compounds. Attempts to increase the activity by chemical modification have, so far, been unsuccessful.

3.2. Allergenic Activity

Many people suffer from an allergic contact dermatitis (ACD) which is caused by contact with plants or their chemical constituents[19]. Sesquiterpene lactones, which are sometimes present in the pollen, can cause this allergic contact dermatitis—even when carried by the wind. The presence of an α-methylene butyrolactone moiety is a sufficient requirement for the allergenic activity. For example, parthenin, present in *Parthenium hysterophoros,* is a primary allergen of this wide-spread and unusually aggressive pioneer plant. The allergy thus caused represents a serious dermatological problem in India and her neighboring countries[20].

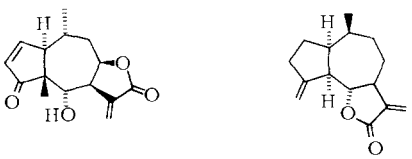


Scheme 3. Left: Parthenin; right: costunolide.

Perfume oils extracted from the costus root *(Saussurea lappa)*[21] or from the laurel *(Laurus nobilis)*[22], cultivated since antiquity, can also cause a dermatitis due to the germacranolide costunolide present in both mixtures. In order to obtain a perfume free from allergen, one passes the raw oil through a column containing a nucleophile on a solid support, e.g. β-aminoethyl-polystyrene. Thus, the allergen is bound to the nucleophile[19b]. Finally, even simple acrylic esters, such as those used in the printing trade and in other industries, can cause occupational dermatitis[19d]. With respect to the pathogenesis of ACD, it is assumed that the α-methylene lactone becomes bonded to a skin protein via a Michael reaction, thus forming an antigen which causes the sensitization of the lymphocytes[20b]. In view of the widespread occurrence of ACD, further research efforts can be expected in this area.

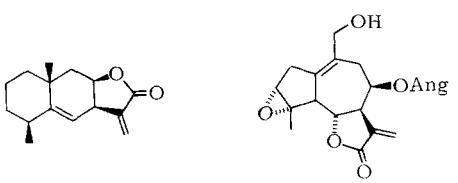
3.3. Phytotoxic and Antimicrobial Activities

In addition to the cytotoxic and allergenic activities described, phytotoxic activities are shown by a number of sesquiterpene lactones[6,7]. Thus, heliangin, a germacranolide of the tuberous sunflower *(Helianthus tuberosus L.,* also called topinambur or Jerusalem artichoke), and vernolepin, from *Vernonia hymenolepsis,* cause plant growth inhibition[6,23]. Xanthatin is also used in the regulation of plant growth[5] (Scheme 4).



Scheme 4. Left: heliangin; right: xanthatin.

According to *Hager*[24a-c], α-methylene sesquiterpene lactones can attack an SH-group of the auxin-receptor complex; upon binding of the growth hormone auxin to its protein receptor the SH-group is set free. As a result of this

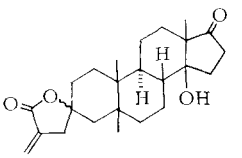


sulfur bond, the lactone effects the irreversible inhibition of plant growth. The α-methylene lactones present in the common sunflower *(Helianthus annuus L.)* appear to be *stress metabolites*, i.e. they are formed, e.g., during attack by pests, during periods of dryness or overexposure to sunlight and heat, and probably act mainly as chemical defenses against pests, especially microorganisms[24c]. This fascinating plant, originating in the USA and Mexico, is mainly cultivated at present in the USSR and in Eastern Europe. It is, after the soybean, the second most important oil-producing plant in the world (annual world production in 1982 more than 16 million metric tons of sunflower seeds)[24d].

Other α-methylene-γ-butyrolactones show bactericidal, fungicidal, and anthelminthic activities[25]. Helenalin[26a] and eremanthin[26b] are shown here as representatives of such compounds (Scheme 5).

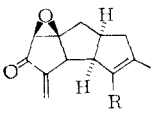
Scheme 5. Left: helenalin; right: eremanthin.

Recently, *Picman* et al. were able to show that sesquiterpene lactones such as parthenin and alantolactone, which are present in the sunflower, also play a role in the defense of plants against insects[27a–c] and even against herbivorous mammals[27d]. Similarly, euponin, which has been isolated from the leaves of *Eupatorium japonicum*, inhibits the development of the fruit fly *(Drosophila melanogaster)* at the egg stage and thus protects the plant from insect attack[27e] (Scheme 6).



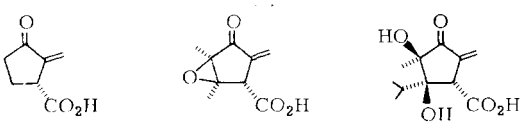
Scheme 6. Left: alantolactone; right: euponin.

Not only highly functionalized, complex sesquiterpene lactones but also simple representatives have been studied for their biological activity. Several years ago, two compounds with fungicidal properties were isolated from tulip bulbs and identified[28]. Tulipalin A is the simplest α-methylene-γ-butyrolactone possible (Chemical Abstracts Name: dihydro-3-methylene-2(3*H*)furanone). The 4-hydroxy derivative, i.e., tulipalin B, is present in nature as the (*S*)-enantiomer (Scheme 7). It appears certain that α-methylene-γ-butyrolactones, due to their high and selective antibiotic activities, afford important protection to plants. In the course of evolution, this fact, together with the outstanding adaptive and reproductive capabilities of the *Compositae*, has contributed to a selective advantage in the survival of this plant family and also to its broad distribution over all continents with the exception of Antarctica.

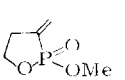


Scheme 7. Left: tulipalin A; right: tulipalin B.

In the future, the study of analogues[16] will become increasingly important. The steroidal spiro-α-methylene lactones[29], which are not found in nature, possess tumor-inhibiting activity (see also [10,66b]).



Thus, α-methylene-γ-butyrolactones can serve as a model in the search for biological activity. The structurally related five-membered-ring α-methylene ketones pleurotellol and pleurotellic acid have been found in fungi and show antibiotic activity[30] (Scheme 8).

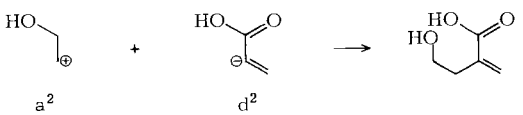


Scheme 8. R = CH_2OH: pleurotellol; R = CO_2H: pleurotellinic acid.

Comparatively simple representatives of this type are the cyclopentanoid antitumor agents called pentenomycins and methylenomycins, e.g., sarkomycin, methylenomycin A, and xanthocidin[31] (Scheme 9).

Scheme 9. From left to right: sarkomycin, methylenomycin A, xanthocidin.

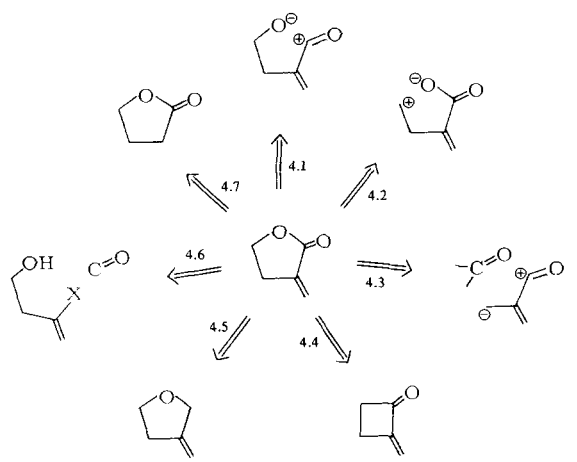
In view of the similarity of the ester group to the $P(O)(OR)_2$ group as π-acceptor (compare also the Horner-Wittig reaction), a corresponding modification of the lactone is of interest. As *Benezra* et al.[32] were able to demonstrate, the biological activity changes: cyclic phosphonates (Scheme 10) show no allergenic activity and only a very low cytotoxicity.



Scheme 10. 2-Methoxy-3-methylen-2-oxo-1,2λ⁵-oxaphospholane.

Because of their broad range of biological activities and their interesting structural features, α-methylene-γ-butyrolactones present a scientific challenge which is reflected in an increasing number of investigations and syntheses of these heterocycles.

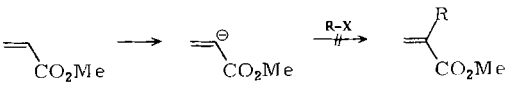
4. Syntheses of α-Methylene-γ-butyrolactones



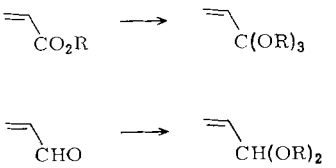
Two main problems dominate the synthesis of these lactones:

1. The construction of the unusual 1,4-functionality distance in the acrylic precursor of the heterocycle. This fundamental synthetic problem, which also appears in the synthesis of simpler five-membered heterocycles such as the furans, pyrroles, and thiophenes as well as their saturated derivatives, can be solved, among other methods, by "umpolung"[33], e.g., the combination a^2+d^2, where the d^2 component is frequently an enolate and the a^2 component an epoxide (umpolung). The combination a^1+d^3 is also feasible: in an efficient synthesis the d^3 building block (umpolung) is also an $a^1d^3d^{3'}$ component (cf. Section 4.3).

2. The construction of the nucleophile-sensitive α-acrylic ester moiety.

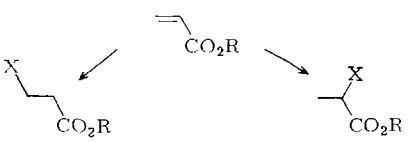


The presence of additional oxygen-containing functionality and the stereochemistry of the residual carbocyclic portion of the molecule increase the appeal of the naturally-occurring sesquiterpene lactones as a synthetic goal. However, the total syntheses of these complex compounds and the elegant work already carried out have recently been described comprehensively in a book by *Heathcock* et al.[34] and will remain largely neglected here. Instead, we will concentrate on the methods of synthesis of the simple, key five-membered-ring. Insofar as meaningful, we will use the retrosynthetic approach both for the classification and the mechanistic interpretation of the large number of synthetic methods. Thus, the organization of the article is predetermined (cf. Scheme 11).



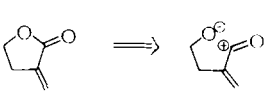
Scheme 11.

If the molecule is dissected as outlined in Sections 4.1—4.4, the educt can be regarded as a functionalized acrylic ester.



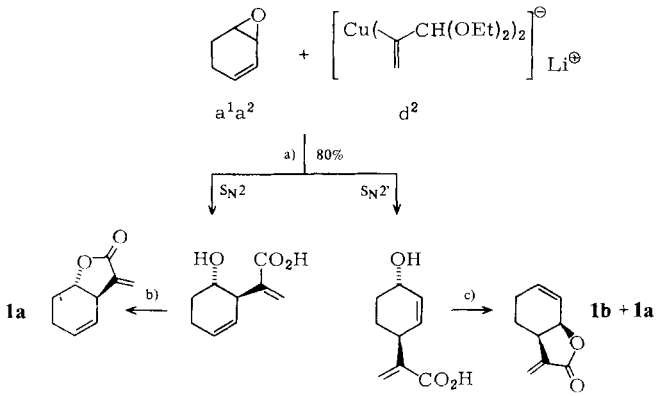
The direct α-functionalization of acrylic compounds via the α-anion is only of limited use due to the pronounced tendency of acrylic esters to polymerize under basic conditions[35]. For this reason, the detour via masked acrylic esters is often chosen, since these are generally easier to functionalize.

The problem of polymerization of α-acrylic esters can be circumvented in different ways. On the one hand, the reactivity of the carbonyl group can be masked by conversion of the ester group or the aldehyde group into an ortho ester or an acetal, respectively.



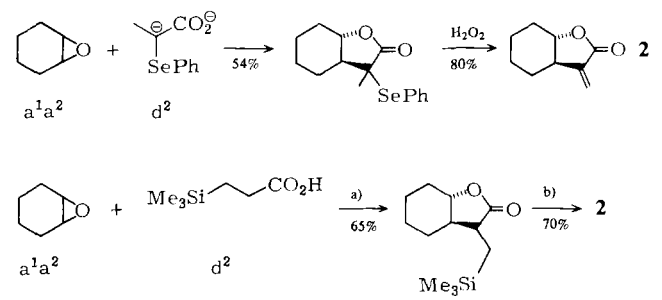
On the other hand, it is possible to mask the CC double bond, e.g., by adding groups in the α- and β-positions that are capable of undergoing elimination (Scheme 12). Masking is also possible by reversible cycloaddition (see Section 4.8).

Scheme 12. X = groups capable of elimination.



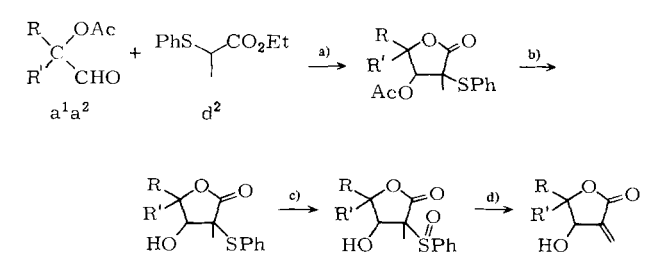
4.1. Cyclization of 4-Hydroxy-2-methylenebutanoic Acids

Dissection:



This dissection reduces the synthesis to the preparation of a homoallyl alcohol, the methylene group of which must also be part of an acrylic acid or a masked acrylic acid.

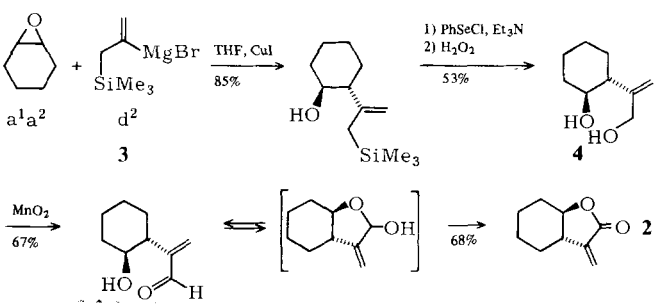
Marino et al.[36a,b] used the diethyl acetal of acrolein as acrylic acid equivalent and allowed it to react as the cuprate (d^2 building block) with epoxides (a^1a^2 building block) (Scheme 13). The two isomeric alcohols formed contain the desired 1,4-functionality distance or vinylogous 1,4-distance and can be cyclized to *trans*- and *cis*-fused α-methylene lactones **1a** and **1b**, respectively, following oxidation to their respective acids. As a d^2 component for the reaction with epoxides, dimethyl sodiomalonate has been used, also; subsequent decarboxylative methylenation (cf. Section 4.7) gives the α-methylene lactone[36c].



Scheme 13. (a) 1) Tetrahydrofuran (THF)/ −40 °C, 2) $Ag_2O/OH^{\ominus}$. (b) Dicyclohexylcarbodiimide (DCC), $CHCl_3$; 5-*exo-trig*. (c) TosOH (Tos = tosyl), C_6H_6; 5-*exo-trig*.

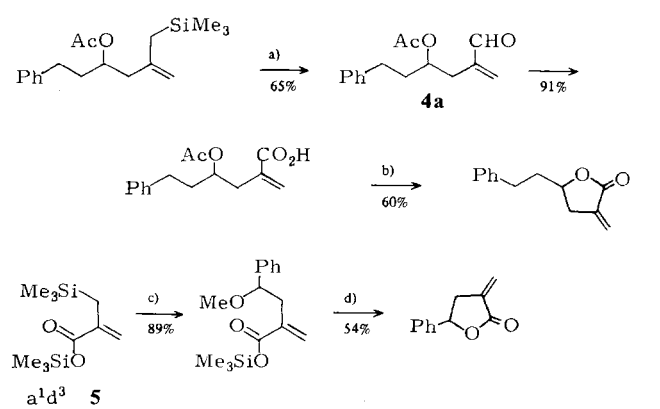
After masking of the double bond, acrylic compounds can also be functionalized. This can be accomplished by introducing a phenylseleno group via the dianion of 2-phenylselenopropionic acid according to *Petragnani* and *Ferraz*[37] or of a trimethylsilyl group according to *Fleming* et al.[38a] (Scheme 14). After cyclization, both groups can be eliminated with regeneration of the double bond. However, in the case of the silicon compound a bromination is necessary; the selenide, which only needs to be oxidized to the selenoxide, is especially useful, because intramolecular elimination is spontaneous. In both reactions the *trans*-lactone **2** is formed.

Scheme 14. (a) 1) 2 Lithium diisopropylamide (LDA), 0 °C, then reflux, 2) TosOH, toluene, reflux. (b) LDA, THF, −78 °C, 2) Br_2, CCl_4, −78 °C, 3) $(PhCH_2)Me_3N^{\oplus}F^{\ominus}$, THF.



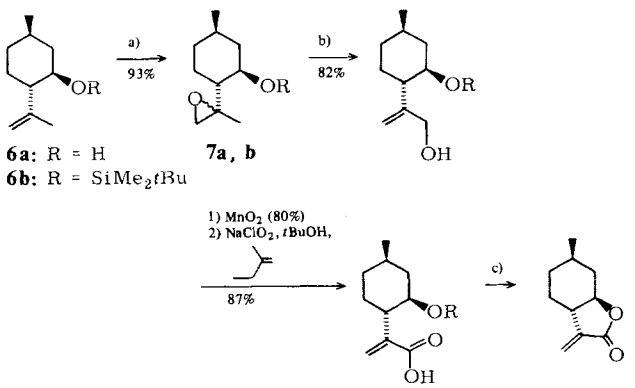
Benezra et al.[38a] used an α-phenylthiopropionic ester as a d^2 acrylic acid in the synthesis of β-hydroxy-α-methylenelactones (Scheme 15). Similarly to the selenide group, the sulfide group can be removed after oxidation to the sulfoxide. However, unlike the selenoxide, the sulfoxide requires heating for elimination to occur.

Scheme 15. (a) LDA, −78 °C (acyl-shift). (b) 1) $Ba(OH)_2$, 2) $H^{\oplus}$. (c) [O]. (d) Δ, toluene.



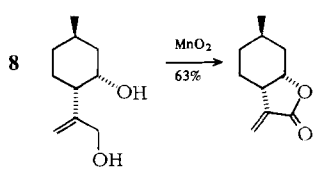
Homologues of α-phenylselenopropionic esters can generally be used in the synthesis of α-alkylidene-γ-butyrolactones also[39].

The allylsilane **3** was employed by *Itoh* et al.[40] as a masked d^2 acrylic acid and was allowed to react with an epoxide (a^2a^1) to give the functionalized homoallylic alcohol (Scheme 16). Reaction with PhSeCl and subsequently with H_2O_2 (desilylating oxidation via the allyl selenide and oxidative rearrangement) gave the allyl alcohol **4**, which was oxidized with MnO_2 to give selectively the α,β-unsaturated aldehyde. As also occurs in other examples (see below), the second hydroxyl function is not attacked by MnO_2; the aldehyde cyclizes to give the lactol, which is further oxidized in situ to the lactone. The starting material for the Grignard reagent **3** is 2-bromo-3-(trimethylsilyl)propene **21**, which was also used by *Trost* et al.[85], although in a different way, in the synthesis of α-methylene lactones (see Section 4.6).



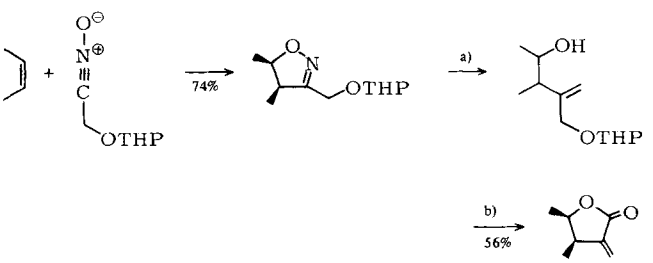
Scheme 16.

Functionalized allylsilanes appear as intermediates in the syntheses described by *Fujita* et al.[41] and *Sakurai* et al.[142a] also. The key step in *Fujita*'s (Scheme 17) work is a desilylating oxidation of an allylsilane to give an α,β-unsaturated aldehyde. This was achieved in a novel way, using iodosylbenzene, which was activated by coordination with a Lewis acid. In contrast to the oxidation of an allylsilane with *m*-chloroperbenzoic acid, which proceeds with allyl inversion (intermediate formation of the epoxide), the formation of **4** and **4a** proceeds with allyl retention. In the case of oxidation giving **4** and **4a**, an S_E2' attack on the electron-rich allylsilane is followed by an intramolecular 3,2-shift. *Sakurai* et al.[42a] allowed the trimethylsilyl ester **5** to react with an acetal and obtained by dealkylation the α-methylene-γ-butyrolactone (Scheme 17).



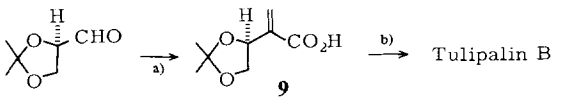
Scheme 17. (a) C_6H_5IO, $BF_3 \cdot Et_2O$. (b) DCC, pyridine. (c) $PhCH(OMe)_2$, $BF_3 \cdot Et_2O$. (d) 1) Me_3SiI, 2) MeOH.

The combined homoallylic alcohol-allylic alcohol such as **4**, formed in the reaction sequence of *Itoh*[40] (Scheme 16), is an intermediate in many other synthetic routes since the selective oxidation with MnO_2 yields a cyclizable compound and therefore offers convenient access to the desired lactones. Thus, in the work of *Pinnick* et al.[42b] (Scheme 18) the protected isopulegol **6b** is converted into the epoxide **7b**, which in the presence of the strong base $LiNEt_2$ undergoes a regioselective E2 reaction to give the allylic alcohol. The further oxidation of the α,β-unsaturated aldehyde, formed by reaction of the alcohol with MnO_2, to give the α,β-unsaturated carboxylic acid is not trivial, nor is the oxidation of other allylic alcohols to their carboxylic acids. Recently, inexpensive $NaClO_2$ has been recommended for this oxidation, also in the presence of sensitive functional groups.

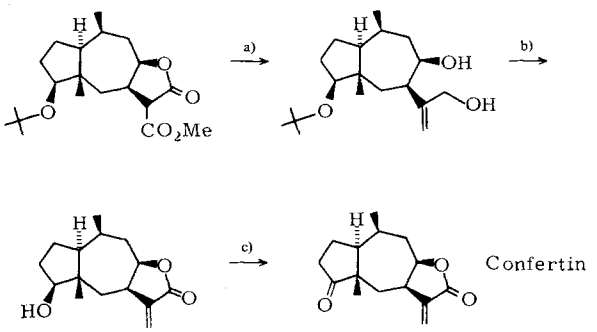


Scheme 18. (a) *m*-Chloroperoxybenzoic acid (CPBA). (b) $LiNEt_2$, −78°C→RT. (c) 1) Desilylation, 2) DCC, pyridine (77%); or 1) Me_3SiI, $CHCl_3$, Δ, 2) Distillation.

With MnO_2, the epimeric diol **8** is directly converted via the cyclic hemiacetal into *cis-p*-menthenolide[42b]. Thus, cyclization to the *cis*-fused lactone proceeds more easily than to the *trans*-fused isomer.



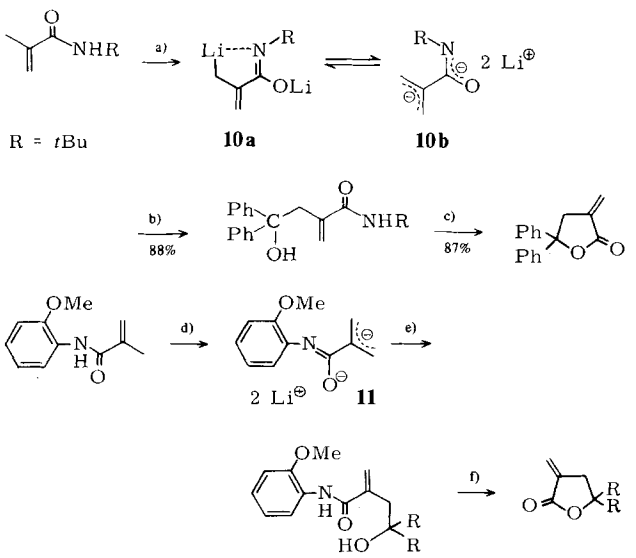
In the route described by *Kozikowski* et al.[43a] (Scheme 19) an isoxazoline, formed by cycloaddition, is reductively opened and the *exo*-methylene double bond is then formed by a Wittig reaction. Again, cleavage of the tetrahydropyranyl (THP) ether and oxidation with MnO_2 affords the α-methylene lactone.



Scheme 19. (a) 1) H_2, Raney nickel, 2) $H_2C{=}PPh_3$. (b) 1) TosOH, MeOH (OTHP→OH), 2) MnO_2, CH_2Cl_2.

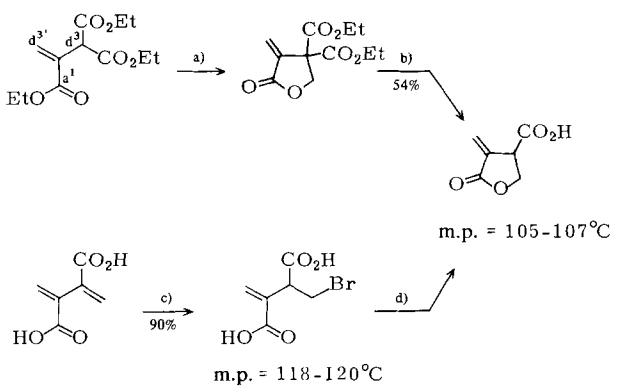
2,3-*O*-Isopropylideneglyceraldehyde—a chiral building block which has been used a great deal recently and has perhaps also become something like a vogue compound[43b]—was homologized in several steps to **9** and then cyclized to tulipalin B using acid catalysis[43c] (Scheme 20).

Scheme 20. (a) 5 steps. (b) 1 NHCl.



Another possibility for obtaining the desired "crossed" allylic-homoallylic alcohol was demonstrated by *Marshall* et al.[44] in the synthesis of confertin (Scheme 21). The enolate of a modified malonic ester, formed on using KH, is reduced by $LiAlH_4$ to the dialcohol stage. Oxidation with MnO_2 affords the α-methylene lactone, although in unreported yield. This method was already described in 1965 and is still used today[45,46].

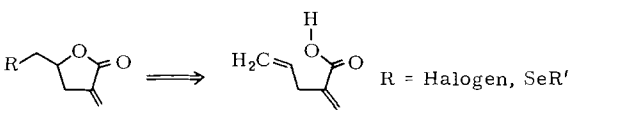
Scheme 21. (a) 1) KH, 2) $LiAlH_4$. (b) 1) MnO_2, C_6H_6, 2) CF_3CO_2H, 3) *i*PrOH, NaOH. (c) CrO_3, pyridine, CH_2Cl_2 (Collins oxidation).



N-substituted methacrylamides can be used as synthetic equivalents of the hypothetical $a^1d^3d^{3'}$ methacrylic acid since they are more easily deprotonated and alkylated than acrylic esters. This method, developed in 1980, was used by three different research groups in the synthesis of α-substituted acrylamides[47] and of α-methylene lactones[48,49a] (Scheme 22). These syntheses proceed via the dianions **10b** and **11**, which polymerize less easily, probably because the amide nitrogen chelates a lithium ion and the reactivity of the carbonyl group is simultaneously reduced by electron delocalization. Trapping with ketones yields the cyclizable homoallylic alcohols (cf. also Section 4.3, i.e. the umpolung of (*Z*)-2-bromomethyl-2-alkenoic esters to give $a^1d^3d^{3'}$ components).

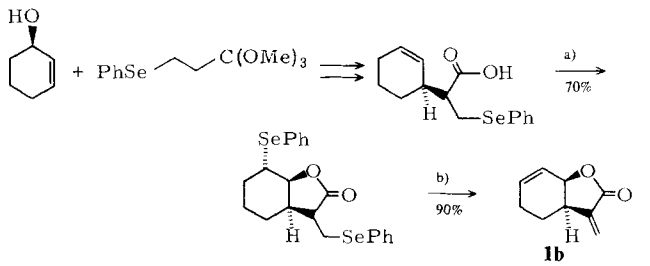
An interesting $a^1d^3d^{3'}$ building block is the readily accessible, doubly activated triethyl 2-propene-1,1,2-tricarboxylate, as shown recently by *Dowd* et al.[49b]. For this compound even catalytic amounts of potassium bicarbonate suffice for deprotonation and for bringing about the nucleophilic addition to formaldehyde. After decarboxylation of the crude lactone diester with hydrochloric acid, the crystalline β-carboxylic acid of α-methylene-γ-butyrolactone is obtained in 54% overall yield. Alternatively, butadiene-2,3-dicarboxylic acid has been converted smoothly into bromomethyl-itaconic acid, which in turn cyclizes

Scheme 22. (a) 2 BuLi/*N,N,N',N'*-tetramethylenediamine (TMEDA)/THF, −70→−20°C, 1 h. (b) Ph_2CO. (c) Xylene, reflux, 3 d. (d) KO*t*Bu/BuLi. (e) 1) R_2CO, 2) H_2O. (f) 10% HCl.



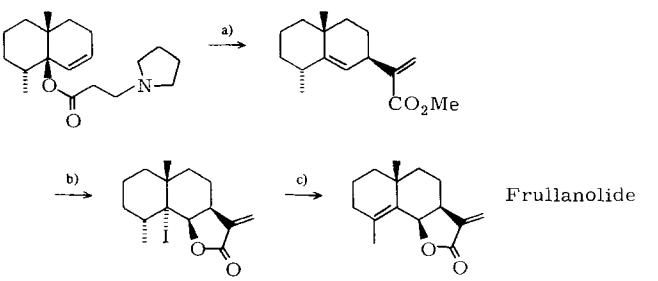
spontaneously to the same lactone in neutral or basic conditions[49b] (Scheme 23).

Scheme 23. a) 35% CH_2O, catalytic amounts $KHCO_3$, 65°C, 25 min. b) 20% HCl. c) HBr/AcOH (1 mol). d) neutral or basic solvent.



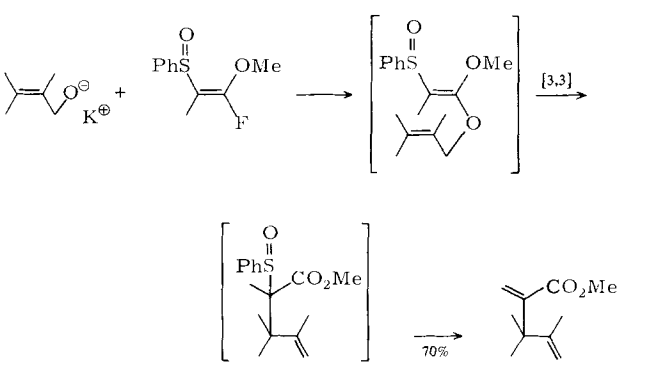
4.2. Cyclization of 2-Methylene-4-pentenoic Acids

Dissection:



Raucher et al.[50] used the Claisen ortho ester rearrangement, which leads directly to the desired arrangement of carboxyl group and terminal CC double bond, i.e., to the γ,δ-unsaturated carboxylic acid or 4-pentenoic acid; cyclization was accomplished via seleno-lactonization. Oxidation of the selenium group and spontaneous elimination gave the α-methylene group and—thanks to the second phenylselenide group—another double bond (Scheme 24).

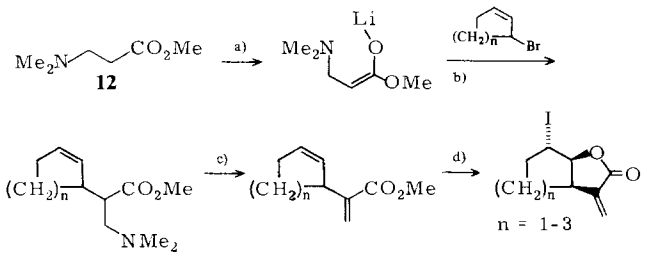
By analogy with the synthesis described by *Raucher* et al.[50], *Still* et al.[51] had previously started from an allylic alcohol and used a Claisen triethylsilylketene acetal rearrangement, i.e., the Ireland variant, for the synthesis of a functionalized acrylic ester, which was converted into the desired frullanolide in two steps in 30% total yield (Scheme 25).



Scheme 24. (a) PhSeX. (b) 30% H_2O_2, THF. The two parallel arrows mean: 1) heating in mesitylene (160°C, 24 h) in the presence of trimethylacetic acid (0.1 equiv.); 2) demethylation with LiI in 2,6-dimethylpyridine, reflux, 2 h.

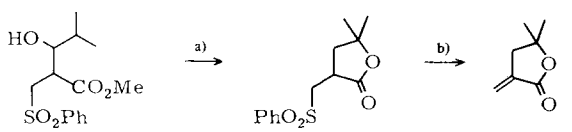
Scheme 25. (a) 1) LDA/THF, 2) Et_3SiCl, 3) Δ, 4) $(MeO)_2SO_2$, MeOH, K_2CO_3. (b) Iodolactonization; 5-*exo*-*trig*. (c) 1,8-Diazabicyclo[5.4.0]undec-7-ene (DBU).

Mechanistically related is the one-pot reaction recently described by *Vatele*[52] for the synthesis of α-methylene-γ,δ-unsaturated esters. An allylic alcohol is again used as starting material, which is transformed in three steps into a cyclizable 2-methylene-4-pentenoic acid (Scheme 26):



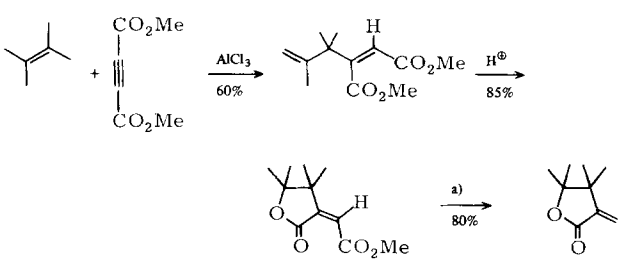
1. nucleophilic substitution at the activated vinylic carbon atom,
2. Claisen ester enolate rearrangement, and
3. sulfoxide elimination to introduce the double bond.

Scheme 26.



Helquist and *Yu*[53a] used methyl 3-(*N,N*-dimethylamino)propionate **12**, which is readily available via Michael addition of dimethylamine to acrylic ester, as d^2 acrylic building block. As in the case of the methacrylamides already described (Section 4.1), metalation of the ester is fa-

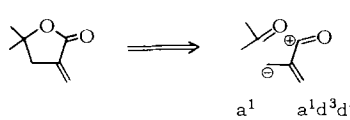
cilitated by complexation with nitrogen[53]. Reaction of the anion with allyl bromides gives the desired γ,δ-unsaturated ester, which, following elimination of the amino group, is subjected to iodolactonization.



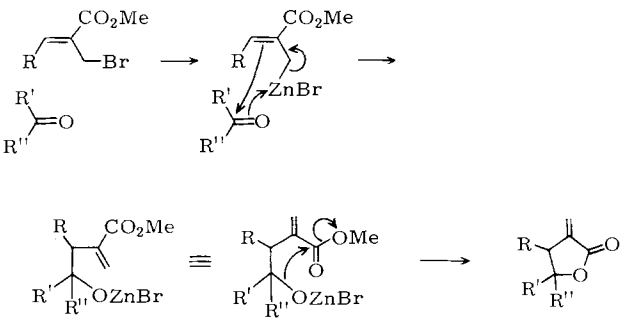
Scheme 27. (a) LDA, THF, −78°C. (b) THF, hexamethylphosphoric triamide (HMPT), −78°C→25°C. (c) 1) MeI, CH_3OH, 2) 1,5-Diazabicyclo[4.3.0]non-5-ene (DBN), C_6H_6. (d) 1) KOH, CH_3OH, H_2O, 2) HCl, H_2O, 3) KI, I_2, $NaHCO_3$.

The methods of *Shono* et al.[54] (Scheme 28) and *McCulloch* et al.[55] are mechanistically interesting but not generally applicable because of their drastic reaction conditions. *Shono* et al.[54] applied a method for lactone formation described by *Dobrev* and *Ivanov*[56] to the synthesis of α-methylene lactones.

Scheme 28. (a) Conc. H_2SO_4. (b) Na_2CO_3, dimethylformamide (DMF).



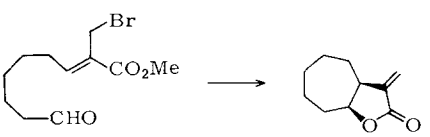
The synthesis of *McCulloch* et al.[55] (Scheme 29) begins with an $AlCl_3$-catalyzed ene reaction[57] of the strongly enophilic dimethyl acetylenedicarboxylate. After acid-catalyzed lactonization, the ester function is removed by reductive treatment with copper in quinoline. Since the reduction is only successful for highly substituted five-membered rings, the range of application of the reaction is limited.



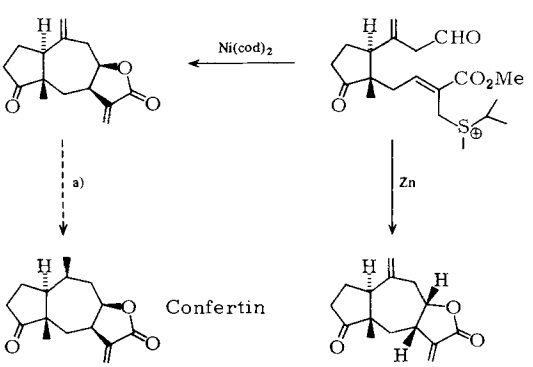
Scheme 29. (a) Cu, quinoline.

4.3. Metal-Promoted Reaction of Aldehydes and Ketones with $a^1a^3a^{3'}$ Components

Dissection:

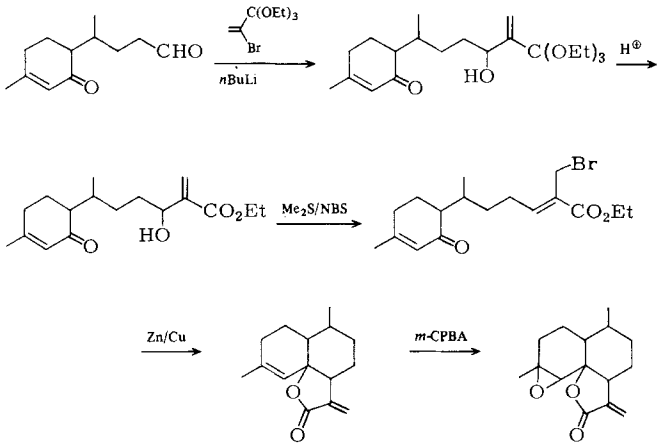


In this method (Scheme 30), developed by *Dreiding* et al.[58,59] and *U. Schmidt* et al.[60], a (*Z*)-2-bromomethyl-2-alkenoic ester ($a^1a^3a^{3'}$ building block) is treated with zinc to give an $a^1d^3d^{3'}$ intermediate with umpolung. The combination with the a^1 aldehyde takes place with allylic shift and yields an intermediate alkoxide, which cyclizes spontaneously to the α-methylene lactone. The Dreiding-Schmidt reaction, which is also incorrectly called a Reformatsky synthesis (in which d^2 enolate esters, but not d^3 components are used), has been very useful in the synthesis of monocyclic and spiro-α-methylenelactones[61].



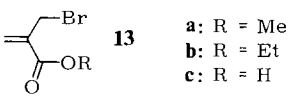
Scheme 30.

The intramolecularization of the reaction affords bicyclic α-methylenebutyrolactones from acyclic compounds in one pot[62] (Scheme 31).



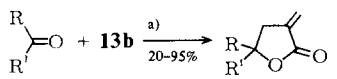
Scheme 31.

In this fashion, *Semmelhack* et al.[63] successfully synthesized (±)-confertin in 1978 (Scheme 32). They obtained the confertin isomer with the unnatural configuration by zinc-promoted cyclization, whereas nickel-promoted cyclization yielded the natural isomer. The selective hydrogenation of this precursor to confertin was unsuccessful; however, it was accomplished by a detour.



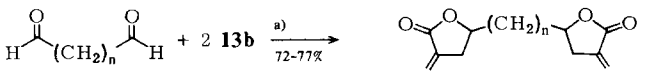
Scheme 32. (a) Low yield. cod = cyclooctadiene.

Dreiding et al.[64] synthesized compounds of the arteannuin type (Scheme 33).



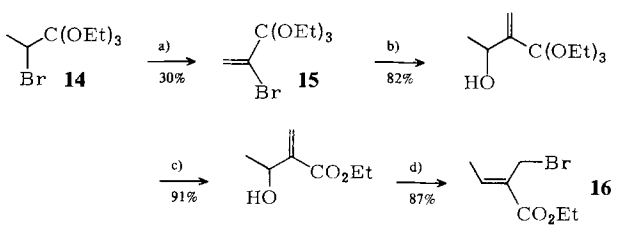
Scheme 33. NBS = *N*-bromosuccinimide.

Perhaps the most important building blocks in the synthesis of γ-monosubstituted and γ,γ-disubstituted α-methylene-γ-butyrolactones are the 2-(bromomethyl)acrylic ester **13a** and the ethyl ester **13b.**



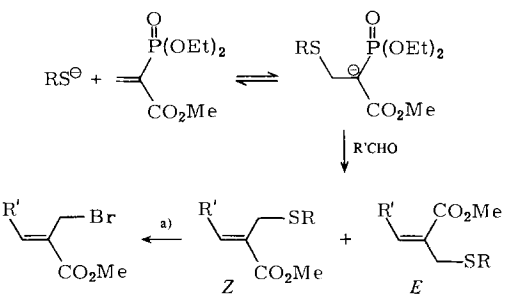
Recently, the synthesis of **13a** in three steps (50% yield) and that of **13b** in two steps (30% yield) have been described[65a]. 2-(Bromomethyl)acrylic acid **13c** is also available commercially[65b]. Starting from **13b**, *Benezra* et al.[10] reported the synthesis of more than thirty lactones, some of which are structurally quite complex (Scheme 34).

Scheme 34. (a) 1) Zn/THF, 2) dil. HCl.



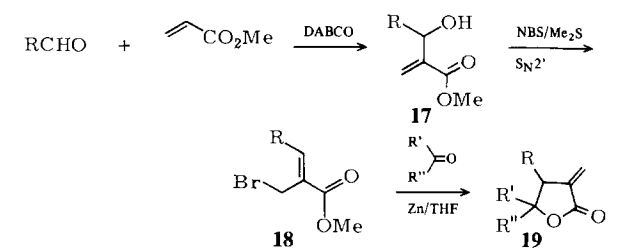
Heindel et al.[66a], *Lee* et al.[66b], and *Cassady* et al.[67a] (Scheme 35) proceeded similarly; *Cassady* et al. also obtained bislactones[67a], i.e., double haptens, from dialdehydes by using the corresponding one-pot reaction[67c].

Scheme 35. (a) 1) Zn/THF, 2) dil. H_2SO_4, 0°C.



A synthetic difficulty in the metal-promoted cyclization to give bicyclic α-methylene lactones has been in the synthesis of the functionalized methacrylic acid as starting material.

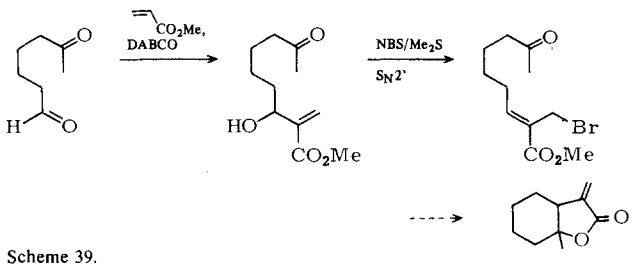
Starting from the ortho ester **14**, *Dreiding* et al.[68a] synthesized the ortho ester **15** of 2-bromoacrylic acid in several steps. **15** was metalated with *n*-butyllithium to give the corresponding lithium compound, i.e., a d^2-acrylic ester. After trapping of the lithium compound with aldehydes, the hydroxy ester was rearranged to the substituted allyl bromides **16** (Scheme 36).



Scheme 36. (a) 1) KO*t*Bu, 2) Br_2, CuO, 3) KOH, EtOH. (b) 1) BuLi, 2) CH_3CHO. (c) H_2SO_4. (d) NBS/Me_2S.

The synthesis of the allylic sulfur compound used by *Semmelhack* et al.[68b] as $a^1a^3a^{3'}$ precursor, also requires several steps and is not (*Z*)-selective. The last step, the conversion of the allylic sulfide into the bromide, is not very simple either (Scheme 37).

Scheme 37. (a) 1) [O], 2) $(MeO)_3P$, 3) PBr_3 (overall yield 20—25%); or 1) $MeOSO_2F$, 2) LiBr (overall yield 93%).

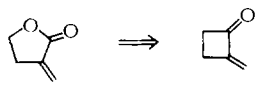


In connection with the synthesis of a wide range of allyl alcohols and their precursors, which are further functionalized on the central carbon atom[69], we have prepared the necessary $a^1a^3a^{3'}$ coupling reagents (the allylic bromides **18**) in excellent yields by DABCO (diazobicyclo[2.2.2]octane)-catalyzed coupling of acrylic esters and aldehydes to **17** and subsequent bromination accompanied by allylic rearrangement[70–72] (Scheme 38).

Scheme 38.

The reaction of 2-(hydroxyalkyl)acrylates **17** with *N*-bromosuccinimide/dimethyl sulfoxide yields regioselectively (S_N2' reaction) and stereoselectively (*Z*)-2-(bromomethyl)-2-alkenoic esters **18** irrespective of the group R[70–72]. Metal-induced coupling of **18** with carbonyl compounds allows ready access to β-substituted α-methylene lactones (compare **19**). Another advantage of this approach is that parent acrylic ester can be α-functionalized without loss of material, much additional functionality being tolerated. Esoteric acrylic acid building blocks and organometallic conditions are unnecessary. The selective coupling of a ketoaldehyde, e.g., 6-oxoheptanal, with an

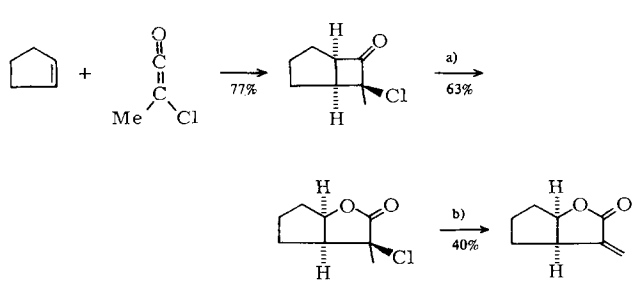
acrylic ester in the presence of DABCO is also possible; the less reactive ketone group need not be masked, e.g. by ketalization. After bromination with NBS/Me_2S, which entails clean allylic rearrangement, a cyclizable molecule is obtained[73] (Scheme 39).



Scheme 39.

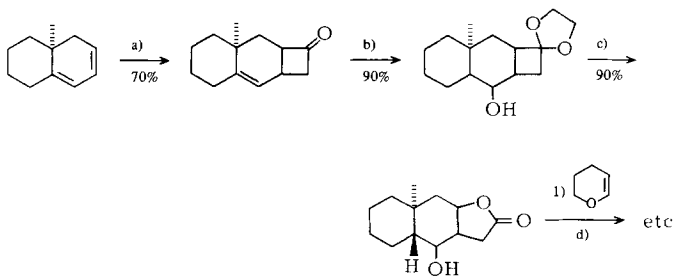
In addition to these compounds, other a^1d^3 components—as already described in Section 4.1—have been used in the cyclization: the allylsilane **5** and the dianions **10** and **11**. The allylic bromoester method offers the advantages of a simple synthesis, a high degree of convergence, mild reaction conditions, and compatibility with other functionality. At least for many of the structurally more simple α-methylene-γ-butyrolactones, this is the method of choice.

4.4. Insertion of the Oxygen via Baeyer-Villiger Oxidation of 2-Methylenecyclobutanones



Dissection:

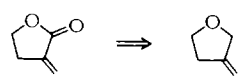
There are only a few examples of the synthesis of α-methylene lactones via the Baeyer-Villiger oxidation.



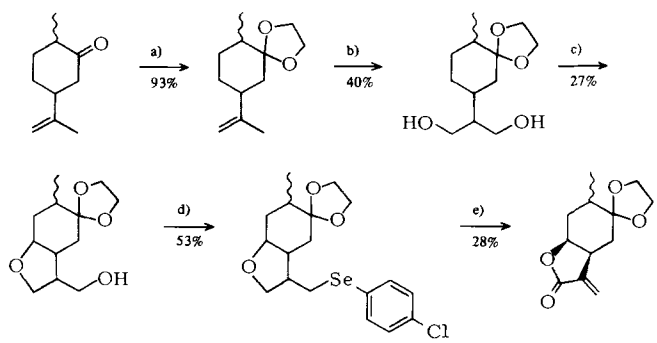
The syntheses of *Hassner* et al.[74] and *Roberts* et al.[75] will be presented here. As shown in Scheme 40, this approach begins with a [2+2]-cycloaddition of chloro- and bromoketenes to reactive double bonds to form a functionalized cyclobutanone. Baeyer-Villiger oxidation with exclusive migration of the bridgehead carbon atom and subsequent elimination of hydrogen halide yields the desired lactone.

In following the fate of the three carbon atoms of the chloroketene one may see that these are incorporated into the product as the desired acrylic moiety. In the example given here, the total yield of α-methylene lactone—starting from the haloketene precursor—is 20%. It remains to be seen whether this route can be developed preparatively. A limitation of the cycloaddition route is that only *cis*-fused lactones result (cf. also Section 4.8).

Scheme 40. (a) H_2O_2, CH_3CO_2H. (b) Diazabicyclo[2.2.2]octane (DABCO), NaI, dimethyl sulfoxide (DMSO).



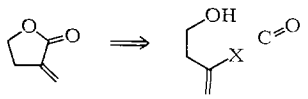
Grieco et al.[76] also used a Baeyer-Villiger oxidation to construct a γ-lactone and subsequently incorporated the α-methylene group by reaction of the enolate with formaldehyde (see Section 4.7) (Scheme 41).



Scheme 41. (a) 1) $Cl_2CHCOCl$, 2) Zn/CH_3CO_2H. (b) 1) Ketal formation, 2) BH_3/THF, $NaOH/H_2O_2$. (c) 1) 10% HCl, 2) HOAc/30% H_2O_2. (d) α-Methylenation.

4.5. Introduction of the Carbonyl Oxygen by Oxidation of 3-Methylenetetrahydrofurans

Dissection:



This very simple method, which could also be of biosynthetic interest, has only been described recently. Starting from dihydrocarvone, *Brocksom* and *Ferreira*[77] synthesized monoterpenoid α-methylene-γ-butyrolactones (Scheme 42). After an interesting oxidative cyclization using lead tetraacetate to give the furan derivative (compare also the Barton reaction), the *exo*-methylene group is formed by selenoxide elimination. Finally, the carbonyl oxygen is introduced, in analogy to the method of *Dauben* et al.[78], by Collins oxidation with $CrO_3 \cdot 2$ pyridine. It remains to be seen whether other oxidizing agents will bring about an improvement in yield.

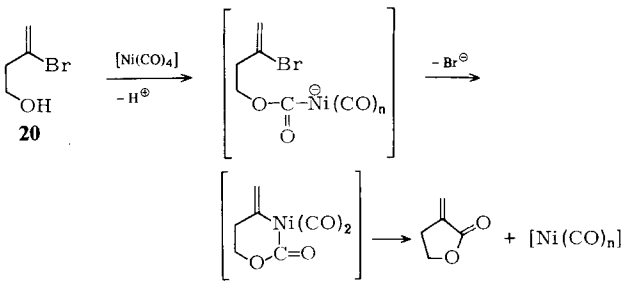
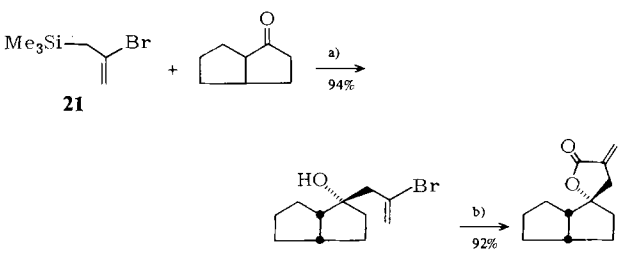
4.6. Insertion of a Carbonyl Group into Functionalized Homoallylic Alcohols



Dissection:

This synthesis can be realized using reactions taken from the organic chemist's "box of magic tricks", namely by

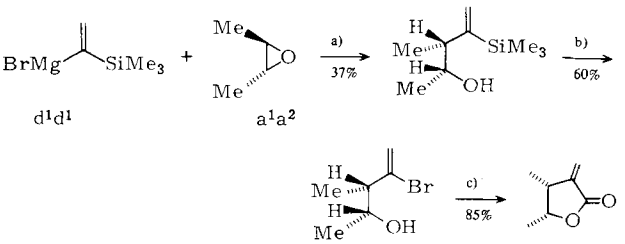


a) transition-metal-catalyzed carbonylation of a vinylically substituted homoallylic alcohol and
b) use of the Shapiro reaction.

a) In recent years the intramolecular version of the transition-metal-catalyzed carbonylation described by *Corey* and *Hegedus*[79] has been used increasingly for the synthesis of α-methylene lactones. Zero-valent transition metal compounds, usually of nickel or palladium, function as catalysts and reagents. Scheme 43 shows the proposed mechanism[80,81] of the nickel-induced reaction, in which 3-bromohomoallylic alcohols **20** have been employed as starting compounds. Recently, *Ban* et al. have also used the more reactive 3-iodohomoallylic alcohols[86b].

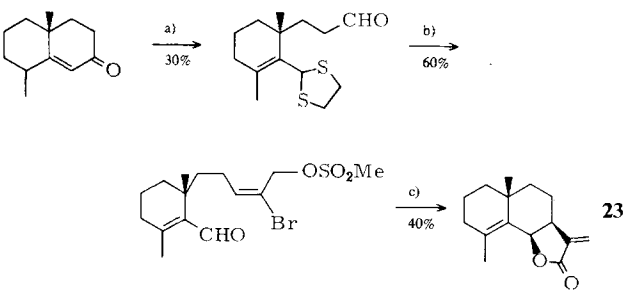
Scheme 43.

Representative of other syntheses[82–84] are those of *Trost* et al.[85] and *Stille* et al.[86], described here. *Trost* et al.[85] joined a functionalized allylsilane to a carbonyl compound to obtain the functionalized homoallylic alcohol which is necessary for the insertion of the carbonyl group. The tricyclic spiro-α-methylenelactone is formed stereoselectively and in high yield (Scheme 44).

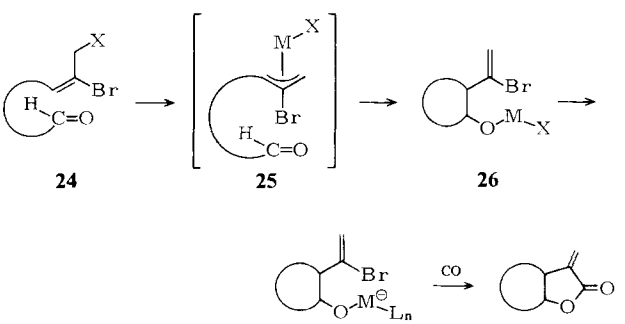


Scheme 44. (a) $TiCl_4$, CH_2Cl_2, −70→0°C. (b) 1.5 $[(Ph_3P)_2Ni(CO)_2]$, Et_3N, THF, reflux.

The Grignard reagent **3** prepared from 2-bromo-3-(trimethylsilyl)propene **21** can also be combined with epoxides to establish the desired 1,4-distance of functional groups[40] (cf. Section 4.1) and added to α,β-unsaturated enones in Michael fashion using CuI catalysis, cyclopentane precursors being formed[85]. The possibility of storing the carbanion reactivity of 2-bromo-3-(trimethylsilyl)propene while selectively activating the allylsilane (with $TiCl_4$), and subsequently metalating the bromide (with magnesium) makes **21** a valuable equivalent for the hypothetical dianion **22** (cf. also the conversion of **3** into **4**).



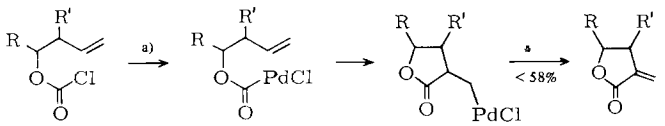
Stille et al.[86a] reacted a vinylic Grignard compound (a d^1d^1 ethylene building block) with epoxides (a^1a^2 components) and thus obtained the desired homoallylic alcohol. Electrophilic substitution of the trimethylsilyl group by bromine yielded the 3-bromohomoallyl alcohol required for the carbonylating cyclization[86a] (Scheme 45).



Scheme 45. (a) 1) CuI, THF, Et_2O, 2) $H^{\oplus}$. (b) 1) Br_2/CH_2Cl_2 −78°C, 2) NaOMe/MeOH. (c) 1) CO, $[Pd(PPh_3)_4]$, 2) CH_3CN, K_2CO_3.

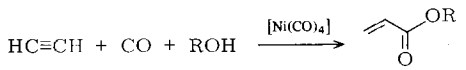
Carbonylnickel plays an interesting double role in the synthesis of (±)-frullanolide (*Semmelhack* et al.[87], Scheme 46).

Scheme 46. (a) 4 steps. (b) 2 steps. (c) $[Ni(CO)_4]$, C_6H_6, 65°C.



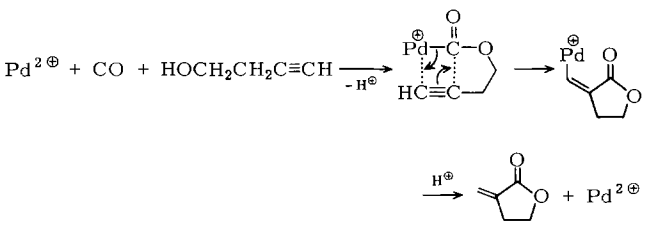
The allylic system in **24** can first be activated as π-allylnickel complex **25** (M = Ni)[88] and cyclized with the aldehyde function to give **26** (potentially a *cis/trans* mixture). In the next step, tetracarbonylnickel functions as carbonylating reagent to form the α-methylene lactone (Scheme 47).

Scheme 47.



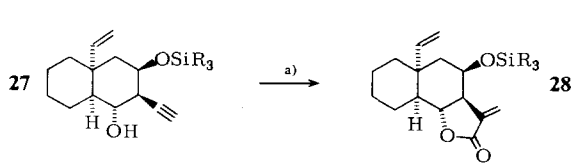
Experimentally, a very high selectivity is observed for the formation of a *cis*-fused lactone as well as for the *syn*-orientation of the lactone with respect to the angular methyl group (cf. **23**). The reason for these stereochemical results is not yet clear.

A variant of the transition-metal-catalyzed cyclization was recently presented by a French research group[92]. In this reaction, CO is not inserted and cyclized using Pd^0 catalysis. Instead, the homoallyl alcohol is esterified with phosgene as C_1 building block to give the chloroformate, which is then cyclized to give the α-methylene lactone (Scheme 48).



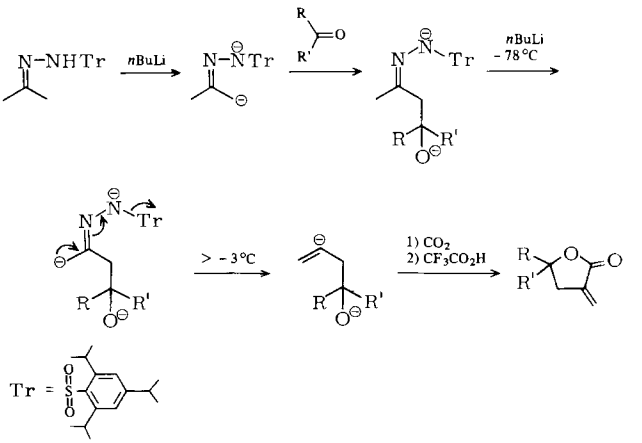
Scheme 48. (a) $[Pd(PPh_3)_4]$, Na_2CO_3.

A fundamental result of Reppe chemistry is the synthesis of acrylic esters by nickel-catalyzed carbonylation of acetylene[89] (Scheme 49).



Scheme 49.

As *Norton* et al. were able to show, this reaction can also be intramolecularized by treating a homopropargyl alcohol with CO in the presence of catalytic $PdCl_2/SnCl_2$ and a tertiary phosphane[90] (Scheme 50).

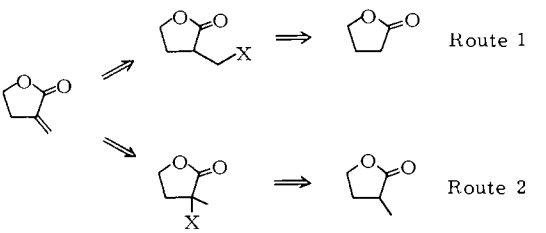


Scheme 50.

The reaction proceeds under comparatively mild conditions. In a model experiment for establishing the functionality in the BC ring, *Heathcock* et al.[91] converted the *trans*-homopropargyl alcohol **27** into the *trans*-fused lactone **28** (Scheme 51). Although the yield is low (21%), the α-methylene lactone is formed directly in this way, and the normally chosen α-methylenation of a γ-lactone precursor (cf. Section 4.7) is not necessary.

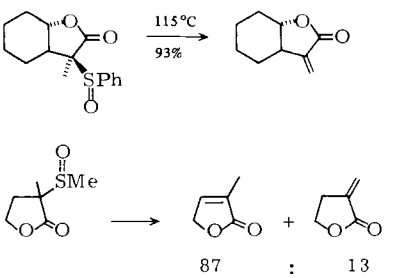
Scheme 51. (a) $PdCl_2$, CO, thiourea.

b) A further variant is the insertion of CO, according to *Barrett* et al., via the Shapiro reaction, in which CO_2 functions as CO building block[93] (Scheme 52).



Scheme 52.

The dianion from the activated hydrazone of acetone is allowed to react with ketones. As usual, elimination of nitrogen yields a vinyl anion (cf. also **22**), which after trapping by carbon dioxide (carboxylation instead of carbonylation) is cyclized to the α-methylene lactone. This reaction sequence requires strongly basic conditions, which are not always tolerated by highly functionalized molecules.

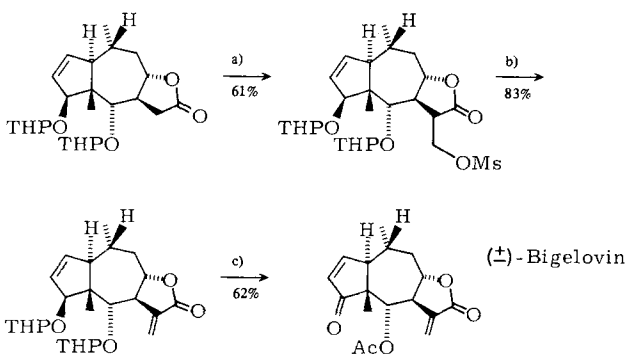


4.7. α-Methylenation of 2-Oxotetrahydrofurans

Dissection:

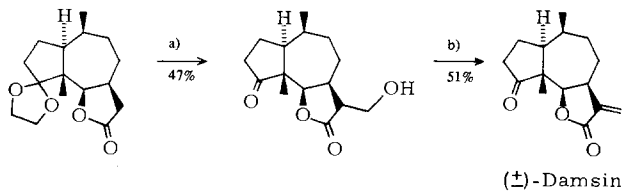
The later incorporation of the α-methylene group into a preformed lactone has been used for many years in the synthesis of α-methylene lactones. Since the various methods have also been reviewed, only variations and new methods will be mentioned here.

For the incorporation of the α-methylene moiety, a functionalized C_1 building block is usually introduced and the double bond is formed by subsequent elimination (Route 1). However, the introduction of a leaving group α to the carbonyl group, when the methyl group is already present, is also known (Route 2). In this case, elimination results in the exocyclic double bond, although the endocyclic double bond can also be formed[94–96] (Scheme 53).



Scheme 53.

In order to avoid the formation of the endocyclic double bond, one introduces the leaving group advantageously β to the carbonyl group (Route 1).

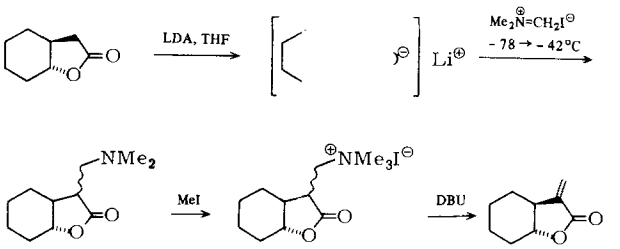


Two methods are used most frequently at present:

1. The lactone is converted into the enolate and subsequently trapped with formaldehyde to give the hydroxymethyl derivative. Alternatively, the anion is trapped with formic esters and reduced to give the hydroxymethyl derivative. After conversion of the hydroxy group into a tosylate or mesylate group, elimination is easily carried out with a base.

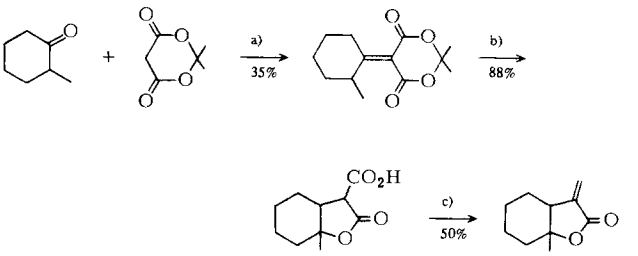
   As almost arbitrary examples the synthesis of (±)-bigelovin by *Grieco* et al.[97] (Scheme 54) and of (±)-damsin by *Vanderwalle* et al.[98] and *Kretchmer* et al.[99] (Scheme 55) are shown here.

Scheme 54. (a) 1) LDA, 2) CH_2O, 3) MsCl (Ms = methanesulfonyl), pyridine. (b) DBU. (c) 1) Hydrolysis, 2) MnO_2, 3) Ac_2O, dimethylaminopyridine (DMAP).



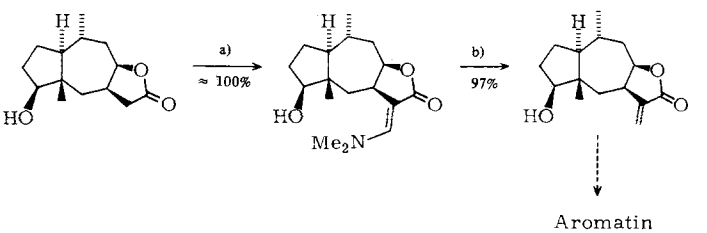
Scheme 55. (a) 1) NaH, HCO_2Et, 2) $NaBH_4$, MeOH, 3) HCl, MeOH. (b) 1) TosCl, 2) Δ, pyridine.

Other sesquiterpene lactones which have been obtained via α-methylenation are, e.g., (±)-ambrosin, (±)-psilostachyin C[100a], as well as (±)-eriolanin and (±)-eriolangin[100b]. This methodology, which was developed by *Grieco* et al.[101c], has also been applied to other representatives of the guaianolides (which have been investigated much less than the pseudoguaianolides), including, inter alia, (±)-compressanolide and (±)-estafiatin (*Vanderwalle* et al.[101a,b]).



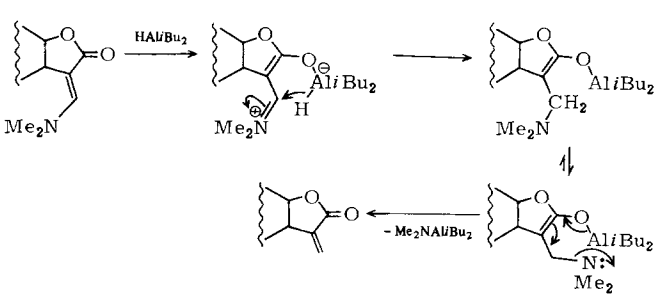
2. Another valuable method for introducing the α-methylene group uses the $-\overset{\oplus}{N}R_3$ group as leaving group. This can be introduced by trapping of the enolate of the lactone with dimethyl(methylene)ammonium salts. After quaternization of the nitrogen, elimination affords the double bond[102-105] (Scheme 56).

The synthesis of (±)-eriolanin by *Schlessinger* et al.[106a] and that of vernolepin by *Isobe* et al.[106b] were carried out similarly. The incorporation of the α-methylene group by reductive amination of an α-carboxy lactone with CH_2O/



Scheme 56.

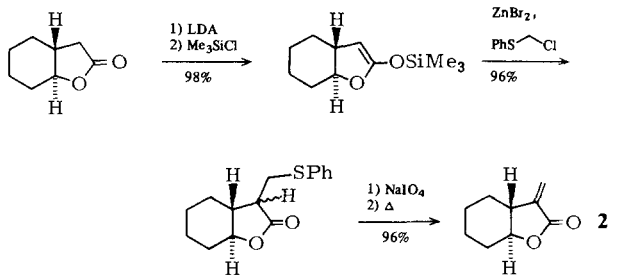
$HNEt_2$ has been known for ten years[107a] and was used again recently in the synthesis of bicyclic α-methylene lactones via Meldrum's acid[107b] (Scheme 57).



Scheme 57. (a) $TiCl_4$, THF, pyridine. (b) H_2SO_4. (c) 1) $H_2CO/HNEt_2$, 2) NaOAc/HOAc.

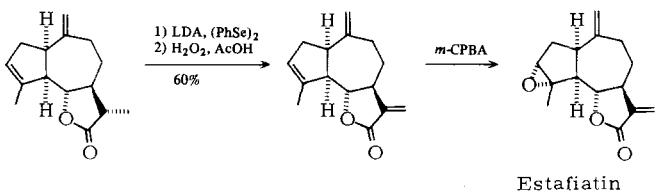
A disadvantage of many of the methods described until now is the use of strong bases for generating the lactone enolate. In this respect the introduction of the Bredereck reagent[108] by *Ziegler* et al.[109] has brought about an improvement (Scheme 58).

Scheme 58. (a) $(Me_2N)_2CHOMe$, Δ. (b) 1) $HAliBu_2$, THF, hexane, −78→25°C, 2) aq. NH_4Cl.



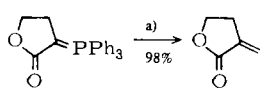
Using this reagent, one prepares the vinylogous carbamate in the first step. This is reduced to the α-methylene lactone selectively and in remarkably high yield with $HAli\text{-}Bu_2$ (Scheme 58). The use of strong bases, which are otherwise necessary for generating the lactone enolate, is thus avoided. The reaction mechanism formulated by us

Scheme 59.



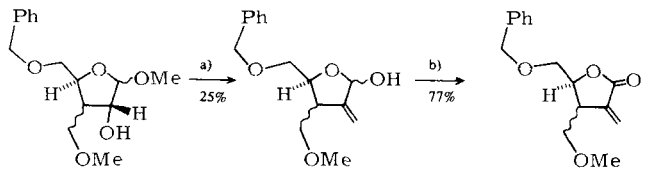
(Scheme 59) suggests that the specific deuteration of the methylene position[109a] should be feasible by reduction of the vinylogous carbamate with diisobutylaluminum deuteride ($DAliBu_2$).

Sulfur and especially selenium may also serve as leaving groups. The following synthesis, in which sulfur is incorporated exocyclically in the β-position (Route 1) was described by *Paterson* and *Fleming*[110a]. The sulfur, following its oxidation to the sulfoxide, is removed as usual in a pericyclic reaction by heating (Scheme 60).



Scheme 60.

The incorporation of the phenylseleno group via electrophilic diphenyl diselenide and its elimination to give the double bond were steps in the synthesis of estafiatin[110b,c] (Scheme 61).

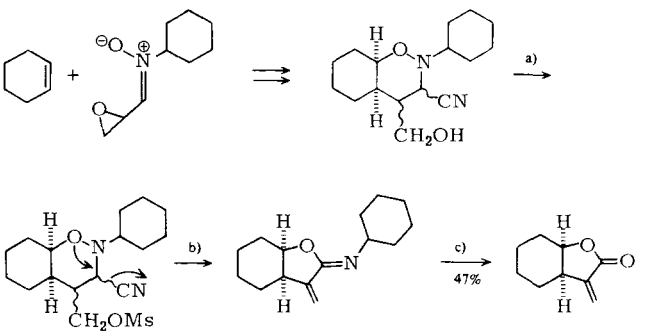


Scheme 61.

It has been known for several years that α-methylene lactones can be synthesized via a Wittig reaction[111,112], but this reaction has only been employed in specific cases (Scheme 62).

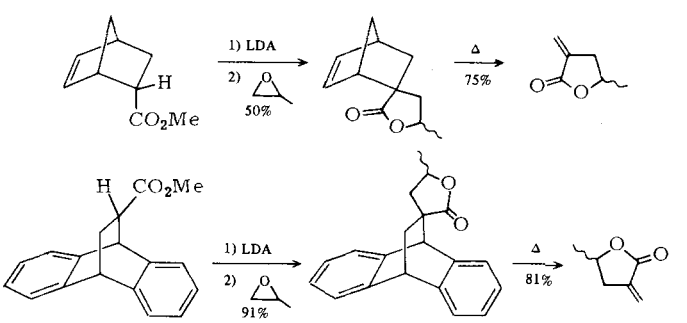
Scheme 62. a) Paraformaldehyde.

Fraser-Reid et al.[113] and *Nair* et al.[114a] have shown that chiral α-methylene lactones can be obtained from the chiral pool using a Wittig reaction (Scheme 63).



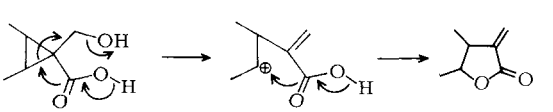
Scheme 63. a) 1) Pyridiniumchlorochromate (PCC), CH_2Cl_2, 2) $Ph_3P{=}CH_2$, 3) 1,2-Dimethoxyethane (DME)/H_2O. b) Ag_2CO_3-celite.

4.8. Other Methods



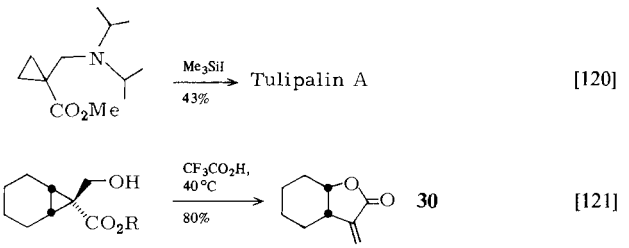
Synthetic methods which have not been considered in Scheme 2 will be dealt with in this section. These involve pericyclic reactions and rearrangements:

a) The cycloaddition of nitrones to olefins (Diels-Alder reaction with inverse electron demand) described by *Eschenmoser* et al.[115] was further studied by *Riediker* and *Graf*[116]. As already mentioned (see Section 4.4), the cycloaddition route is limited in its applicability insofar as only *cis*-fused lactone rings can be prepared (Scheme 64).



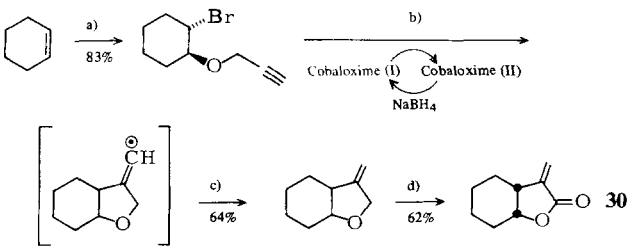
Scheme 64. a) MsCl/pyridine. b) KO*t*Bu/*t*BuOH. c) 0.25 N H_2SO_4, CCl_4.

b) The Diels-Alder reaction can be used for the protection of the CC double bond of acrylic ester as cycloadduct. After the deprotonation with lithium diisopropylamide (LDA), the S_N2 reaction with propylene oxide gives the desired 1,4-functionality distance and then the spirolactone is formed. In the final step, the protecting group is cleaved off by cycloreversion[117,118] (Scheme 65).



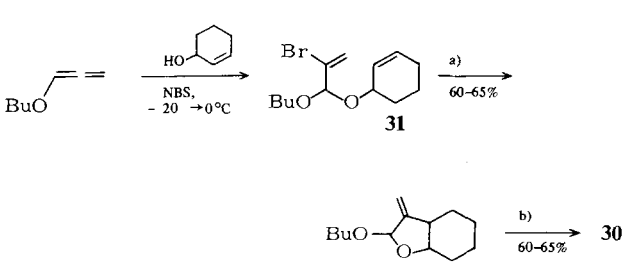
Scheme 65.

c) A third route to synthesize α-methylene lactones is the cyclopropane rearrangement developed by *Hudrlik* et al.[119]. All the atoms of the product are already present in the cyclopropane educt **29**. The cyclopropylmethyl-homoallyl rearrangement is facilitated by S_N1-like conditions (Scheme 66). In the case of the formation of the bicyclic lactone **30** the two rings are *cis*-fused (Scheme 67).



Scheme 66.

Recent examples have been described by *Hiyama* et al.[120] and *Hudrlik* et al.[121]. The remarkably sensitive tulipalin A is formed in 43% yield under almost neutral, anhydrous conditions[120].



Scheme 67.

d) The formation of CC bonds can also be brought about by carbon radicals, and this approach has become a popular field of research in recent years. Carbon-centered radicals react with electron-rich and electron-deficient π-systems under neutral conditions. Thus, compounds with numerous further potential reaction centers are employable without the need for protecting groups. One example is the cyclization of a propargyl ether to a secondary carbon radical. This radical is formed by single electron transfer (SET) from catalytic amounts of cobaloxime(I), which is cyclically regenerated from cobaloxime(II)[123]. The last step, i.e. the oxidation of the 3-methylenetetrahydrofuran to the lactone, is still preparatively difficult (Scheme 68).

Scheme 68. (a) $HC{\equiv}C{-}CH_2OH$, NBS, $-30°C \rightarrow RT$. (b) $e^{\ominus}(-Br^{\ominus})$. (c) Solvent-H. (d) CrO_3, pyridine, CH_2Cl_2.

One other route starts from functionalized bisallyl ether **31**, which, once again, is prepared with NBS and an excess of allyl alcohol at low temperature, probably via an ionic intermediate. The generation of the vinyl radical from **31** takes place under normal conditions. Although **31** carries different types of labile hydrogen atoms (allylic and one acetal hydrogen), the cyclization proceeds in respectable yield (60—65%). Jones oxidation furnishes the desired lactone **30**[124] (Scheme 69).

Scheme 69. (a) Bu_3SnH, 2,2'-azobis(isobutyronitrile) (AIBN), C_6H_6. (b) Jones oxidation.

Besides 2-cyclohexenol, other allylic alcohols can be used for the reaction with the allenyl ether.

The various radical reactions illustrate that new synthetic methods must go through the trials of practical application and total synthesis. Conversely, it is clear that such an important class of heterocycles as the α-methylene-γ-butyrolactones mobilizes the whole arsenal of synthetic methods which are at our disposal.

5. Outlook

Kupchan's discovery in 1970 of the cytotoxic activity of the sesquiterpene lactones was the green light for a rapid development, which is continuing today and proceeding in various directions. The isolation and identification of many additional representatives, especially by *Bohlmann* et al.[125], the total syntheses, and the discovery of a broad spectrum of biological activities followed. At the same time the lactones functioned as a lead in the search for analogues and attention was focussed also on completely different constituents of the *Compositae*, as well as on their pharmaceutical and economic uses. Of the many new and ingenious methods that have been published on the preparation of the α-methylene-γ-butyrolactone moiety, a large number are of academic interest only. The most commonly used methods include:

1. oxidative cyclization of crossed allylic-homoallylic alcohols (Section 4.1),
2. halogeno-lactonization and seleno-lactonization of 2-methylene-4-pentenoic acids (Section 4.2),
3. metal-promoted cyclization of $a^1a^3a^{3'}$ components with carbonyl compounds (Section 4.3),
4. transition-metal-catalyzed carbonylation of 3-bromo- and 3-iodohomoallylic alcohols (Section 4.6);
5. α-methylenation of preformed γ-butyrolactones (Section 4.7).

The investigations carried out in this sector have enriched heterocyclic chemistry, terpene synthesis, and, at the same time, contributed to the development of new synthetic methods.

The future offers a wide choice for interdisciplinary efforts regarding the use of α-methylene-γ-butyrolactones in the fields of organic chemistry, biology, immunology, medicine, and pharmacology.

We thank Carola Grundke, Andreas Köver, Winnfried Hasel, and Wolfgang Poly for experimental assistance and Dr. Engelbert Zass, ETH Zürich, for his help in researching the literature. Thanks are due to Ulrike Büttel for drawing the chemical formulas. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Phenyl Silaisocyanide: The First Organosilicon Compound with a Formal Si≡N Triple Bond**

By *Hans Bock** and *Ralph Dammel*

Dedicated to Professor Gerhard Fritz on the occasion of his 65th birthday

The assumption that main-group elements of the higher (eight-membered) periods exhibit only limited ability to form $p_\pi p_\pi$-multiple bonds, the so-called "double bond rule", has been disproven more and more in the years since 1979 also for organosilicon compounds. It has been possible both to detect spectroscopically short-lived parent molecules such as silatoluene[1a], silabenzene[1b], or silaethene[1c] as well as to isolate derivatives with Si=C[1d] or Si=Si[1e] double bonds which are stabilized kinetically by bulky substituents. The matrix photolysis of azidosilane H_3SiN_3 to H–NSi had already been reported 20 years ago[2a], and, recently, calculations on the still unknown system RSi≡SiR↔R_2Si=Si have been published[3]. Here we present PE-spectroscopic evidence for phenyl silaisocyanide H_5C_6–N≡Si **3**, an organosilicon compound with a presumably linear[4] C–N≡Si group and terminal silicon of coordination number 1.

The starting material for the pyrolysis is triazido(phenyl)silane **2**, prepared from trichloro(phenyl)silane **1** by $AlCl_3$-catalyzed azide exchange with azidotrimethylsilane[5].

"Controlled explosion" of **2** in a flow system at low pressure requires temperatures in excess of 700 °C (!). As with other azides[6a–c] the pyrolysis can be carried out safely with small amounts of sample using PE-spectroscopic real-time gas analysis[6d, 7]. By inspection of the ionization patterns recorded as a function of temperature, the N_2 extrusion conditions can be optimized and—in the case of preponderantly homogeneous reaction channels—the resulting N_2 elimination products directly identified[6] (Fig. 1).

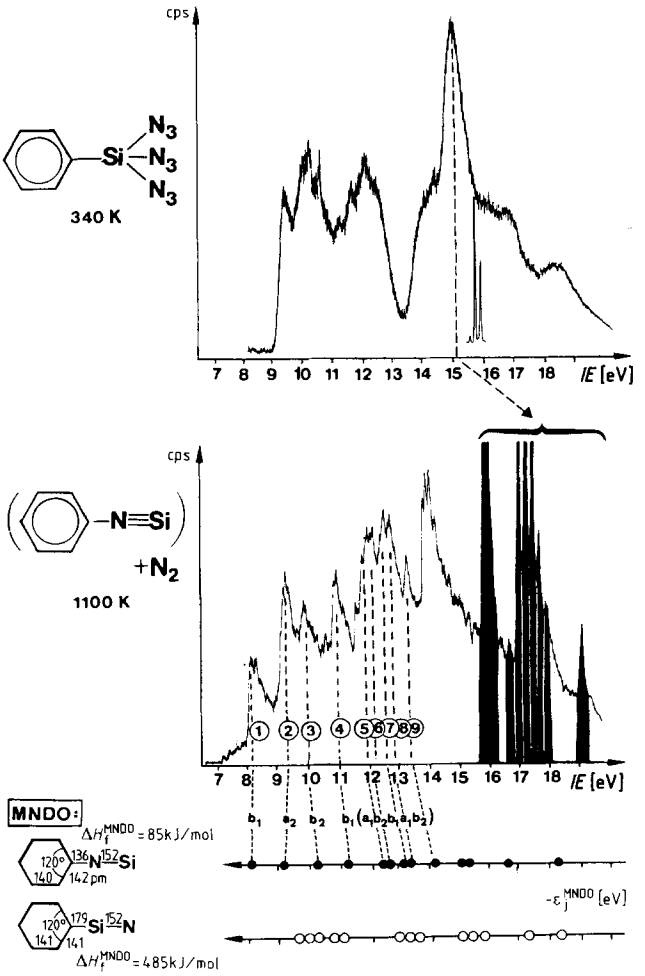

Fig. 1. He(I)-PE spectra of **2** at 340 K (top) and its pyrolysis product at 1100 K (middle) [7] (N_2 bands in black). The assignment of the 1100 K spectrum to one of the isomers H_5C_6–N≡Si **3** and H_5C_6–Si≡N via Koopmans correlation, $IE_n^v = -\varepsilon_j^{MNDO}$, is based on the eigenvalues obtained from geometry-optimized MNDO calculations (see text).

The PE spectra (Fig. 1) demonstrate that the triazidosilane **2** is completely decomposed[7] at 1100 K: its strong azide band between 15 eV and 16 eV has been replaced by intense N_2 bands (Fig. 1, black). In the low energy region between 8 eV and 14 eV the pyrolysis mixture exhibits an ionization pattern consisting of nine well-separated bands[7], assigned to phenylsilaisocyanide **3** with the following arguments:

- MNDO calculations with complete geometry optimization ($E_{total}^{MNDO} = -1140.13$ eV) reproduce the experimental ionization pattern (Fig. 1) via Koopmans theorem $IE_n^v = -\varepsilon_j^{MNDO}$.
- The assignment of the four lowest radical cation states of $H_5C_6NSi^{\odot\oplus}$ can be rationalized by means of MNDO orbital plots with a "molecules in molecule" (MIM) perturbation model (Fig. 2). Coupling of the subunits $H_5C_6(H)$ with $IE_{1,2}^v = 9.25$ eV and (H)NSi with $\varepsilon_1^{SCF} \approx 10.2$ eV[2b] to form H_5C_6–NSi leads to the π-interaction $\pi_s \pm \pi_{NSi}$ between the levels of equal (b_1) symmetry with comparable splittings $\Delta E \approx \pm 1$ eV (contri-

[**] Gas-Phase Reactions, Part 48. Part of the Dissertation by *R. Dammel*. The results were presented at the VIIth Int. Symp. Organosilicon Chem. in Kyoto/Japan, September 1984. This work was supported by the Deutsche Forschungsgemeinschaft, the Land Hessen, and the Fonds der Chemischen Industrie.—Part 47: M. Binnewies, B. Solouki, H. Bock, R. Becherer, R. Ahlrichs, *Angew. Chem. 96* (1984) 704; *Angew. Chem. Int. Ed. Engl. 23* (1984) 731.

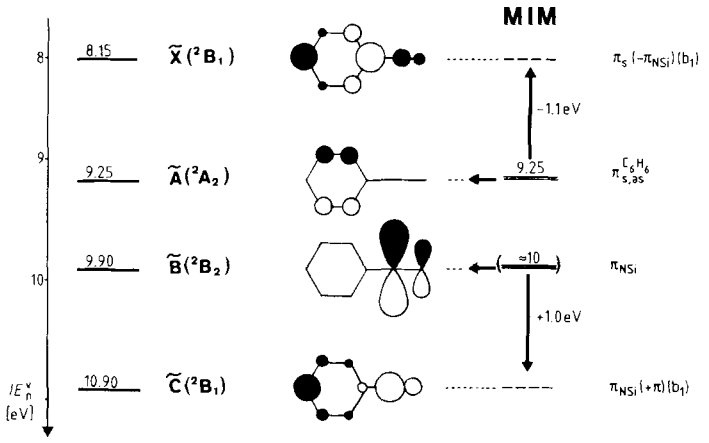

Fig. 2. MIM perturbation model for the first four radical cation states of phenyl silaisocyanide (cf. text).

butions $-\pi_{NSi}$ and $+\pi_s$ both ca. 20%). As expected, the second ionization energy of **3** is equal to the first ionization energy of benzene; the substituent $-N\equiv Si$ acts as a π-electron donor[8].

- The PE spectrum of the pyrolysis product of **2**, which is characteristic of a benzene derivative with an electron donor substituent, cannot be assigned to the isomeric silacyanide $H_5C_6-Si\equiv N$, for which an MNDO calculation of the same quality ($E^{MNDO}_{total} = -1135.98$ eV) predicts only two ionization humps of strongly overlapping bands between 9.5 and 11 eV and around 13 eV (Fig. 1, below).
- According to the MNDO heats of formation, $H_5C_6-Si\equiv N$ is predicted to be 400 kJ/mol less stable than $H_5C_6-N\equiv Si$ **3**. This is confirmed by highly correlated calculations on the parent molecules HNSi and HSiN[2b,c].
- Geometry-optimized MNDO calculations, the results of which are corroborated by Koopmans correlation and the perturbation model (Fig. 1, 2), yield other verifiable molecular parameters for the pyrolysis product $H_5C_6-N\equiv Si$ **3**: thus, the bond length d^{MNDO}_{N-Si} of ca. 152 pm is consistent with the HNSi bond distance $d_{N-Si} = 154$ pm determined spectroscopically[2a] or obtained from CI calculations[2b,c]. A comparison with known SiN single and triple bond lengths ($d_{Si-N} \sim 175$ pm, $d_{Si\equiv N} = 157$ pm[2c]) suggests triple bond contributions also for the $-N\equiv Si$ group in phenyl silaisocyanide which according to the calculations should be linear.

The pyrolysis of triazido(phenyl)silane **2**, which is driven by the energetically favorable extrusion of 4 N_2 molecules, according to the PE spectroscopic and quantum chemical arguments presented, enforces the formation of a polar $N\equiv Si$ triple bond. The optimum conditions determined here for the decomposition of **2** should facilitate corroboration of the interesting result by other physical measurements and by chemical trapping reactions[9].

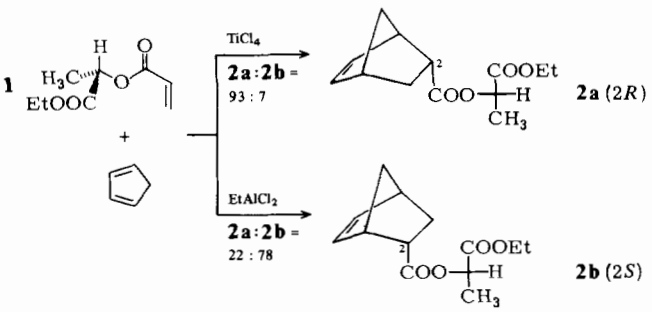
Soc. 105* (1983) 7681; c) for other azides $X-N_3$ with $X = CR_3$, SiR_3, CF_nH_{3-n}, CN, NR_2 cf. Dissertation R. Dammel, Universität Frankfurt am Main 1984; d) for the principles and applications of PES real-time gas analysis cf. H. Bock, B. Solouki, *Angew. Chem. 93* (1981) 425; *Angew. Chem. Int. Ed. Engl. 20* (1981) 427.

[7] The short path pyrolysis apparatus has been described in detail in *Chem. Ber. 115* (1982) 3747. The thermal decomposition of **3** 1100 K was carried out five times and yielded the following ionization regions for the respective bands: ① 8.14—8.19, ② 9.24—9.29, ③ 9.86—10.06, ④ 10.83—10.97, ⑤, ⑥ 11.76—12.0, ⑦, ⑧ 12.5—12.7, ⑨ 13.09—13.2 eV.

[8] The PE spectrum of pure phenyl isocyanide (V. Y. Young, K. L. Cheng, *J. Electron Spectr. Rel. Phen. 9* (1976) 317) was recorded again for purposes of comparison and was assigned by geometry-optimized MNDO-calculations in the region up to 13 eV as follows: 9.43 eV ($3b_1$), 10.01 eV ($1a_2$), 10.96 (sharp needle of high intensity: n_C, $13a_1$), 11.92 eV (b_2), 12.34 eV ($2b_1$). A perturbation treatment analogous to that shown in Figure 2 is not possible: since the effective nuclear charge at the nitrogen center is not compensated for by the isocyanide carbon atom, the $-N\equiv C$ group acts as a strong (−I)-substituent.

[9] Matrix isolation studies of the photolysis of $C_6H_5Si(N_3)_3$ **2** are currently being carried out by G. Gross, J. Michl, R. West (Salt Lake City, UT and Madison, WI, USA, resp.) (personal communication R. West); the pyrolysis products at the optimized temperature $T > 980$ K (Fig. 1) are being investigated by H. P. Reisenauer and G. Maier (Giessen).

Concerning the Mechanism of the Asymmetric Diels-Alder Reaction: First Crystal Structure Analysis of a Lewis Acid Complex of a Chiral Dienophile**



By *Thomas Poll, Joachim O. Metter,* and *Günter Helmchen**

The Lewis acid catalyzed addition of dienes to chiral acrylic acid esters is a promising method for the enantioselective preparation of numerous important building

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results were presented in a lecture at the 5th Int. Conf. Org. Synth. in Freiburg (*G. H.*) on August 28, 1984. We thank Dr. *E. Keller*, Freiburg, for supplying us with the program SCHAKAL.

blocks[1]. We recently found that very high levels of stereoselectivity can be achieved[3] even with extremely cheap acrylates of alkyl lactates such as **1**[2]. In contrast to other dienophiles, **1** reacts with cyclopentadiene[4] to give differently configurated adducts depending on the Lewis acid employed ("stereodichotomy"): with $TiCl_4$, formation of **2a** is favored; but with $EtAlCl_2$[5] formation of the diastereomer **2b** is preferred (Scheme 1)[6].

Scheme 1. Stereodichotomy in the Lewis acid-catalyzed Diels-Alder reaction (−63 °C; top arrow: 0.7 equiv. $TiCl_4$, CH_2Cl_2/*n*-hexane (1 : 1), bottom arrow: 2.5 equiv. $EtAlCl_2$, CH_2Cl_2).

The varying influence of the Lewis acids is also manifested in the dependence of diastereoselectivity (*ds*)[7] on the molar ratio Lewis acid : **1** (Fig. 1). With $TiCl_4$ an optimum is found at ca. 1 : 1, with $EtAlCl_2$ a continuous increase over the whole range of measurement. As has already been pointed out[3], these results suggest assumption of a **1**-$TiCl_4$ chelate complex as reacting species for the region of optimum selectivity of the $TiCl_4$-catalyzed reaction. However, on the basis of known model concepts on the asymmetric Diels-Alder reaction (modified Walborsky model[8]) no structure could be proposed which would explain the preference for adduct **2a**.

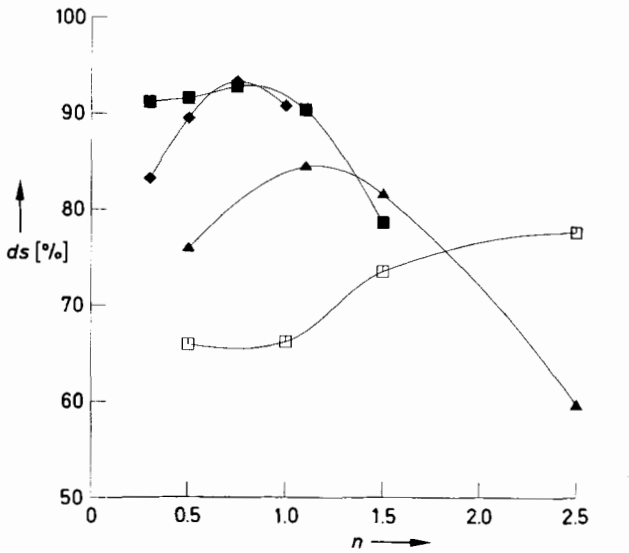

Fig. 1. Dependence of the diastereoselectivity *ds* [7] of the Lewis acid-catalyzed Diels-Alder reaction of **1** with cyclopentadiene (cf. Scheme 1) on the ratio *n*, Lewis acid: **1** (*T* = −63 °C). ■ $TiCl_4$, CH_2Cl_2; ◆ $TiCl_4$, CH_2Cl_2/*n*-hexane; ▲ $TiCl_4$, toluene; □ $EtAlCl_2$, CH_2Cl_2.

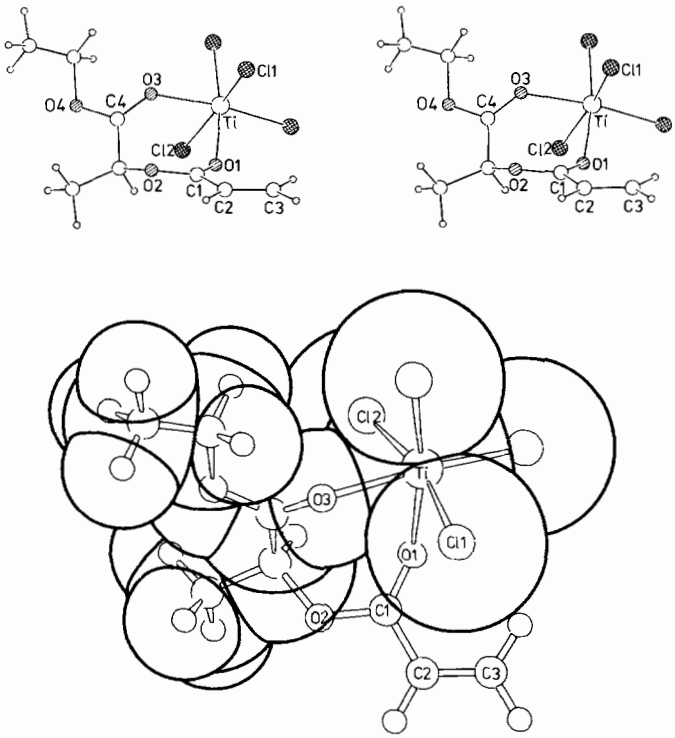
We have now been able to obtain crystals of a **1**-$TiCl_4$ complex and to determine its structure[9]. The complex **3** (Fig. 2, Scheme 2) shows several remarkable features. The enoate group[10] is not antiplanar, as had to be expected (vide infra), but synplanar. Furthermore, in the case of titanium compounds, a seven-membered ring chelate structure has, to our knowledge, not been reported hitherto. The geometry of the ring is such that the Ti atom lies far outside of the two planes delineated by the ester groups. Hence, these are partially π-coordinated.



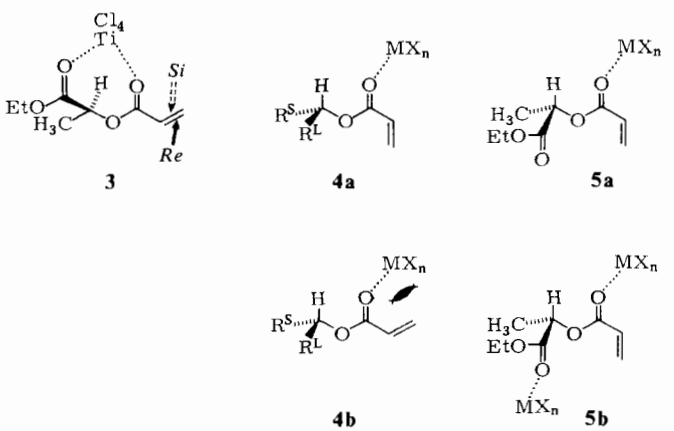


Fig. 2. Structure of **3** in the crystal [9]. Top: Stereograph. Selected bond lengths [Å], bond angles [°], and torsion angles [°]: C3–C2 1.311(7), C2–C1 1.456(7), C1–O2 1.316(5), C1–O1 1.243(5), O1–Ti 2.109(3), Ti–O3 2.136(3), Ti–Cl (averaged) 2.26, O3–C4 1.215(6), C4–O4 1.294(6), C3–C2–C1 120.55(45), C2–C1–O1 123.14(41), C2–C1–O2 114.18(39), C1–O1–Ti 134.14(30), O1–Ti–O3 81.36(12), Ti–O3–C4 132.00(32), C2–C2–C1–O1 8.9, O2–C1–O1–Ti 63.6, O4–C4–O3–Ti −132.2.—Bottom: Projection (SCHAKAL) onto the plane C1,C2,C3. The position of the hydrogen atoms was determined by force field calculations (MM2, N. L. Allinger, *J. Am. Chem. Soc. 99* (1977) 8127). Space filling model: Van-der-Waals radius according to L. Pauling, The Nature of the Chemical Bond, 3rd edit. Cornell University Press, Ithaca, 1960; small circles: 20% of the van-der-Waals radius.

If **3** is the species reacting in solution then the high diastereoselectivity of the upper reaction in Scheme 1 is explained by a shielding of the *Re* face of the ene part of the enoate group by one of the chlorine atoms (Fig. 2: Cl-1).

Scheme 2. Fundamental types of Lewis acid complexes of chiral acrylates. MX_n: Lewis acid; R^L, R^S: apolar groups of large (L) and small (S) steric bulk; for all cases the enoate group is considered to lie in the plane of the paper.

Remarkably, the enoate group lies in a concave[8] environment relative to the Lewis acid (Fig. 2); the substituents at the chirality center make *no* significant contribution to the diastereoface-differentiation.

How does this interpretation fit into the general picture? For complexes of "classical" chiral acrylates (prototype: menthyl acrylate) with only *one* center capable of coordination (carbonyl-O), reactive conformers **4a** with antiplanar enoate conformation are postulated on the basis of the configuration of their addition products[1,8]. Consistent with this postulation is the structure of a 2:1-methyl cinnamate-$SnCl_4$ complex in the crystal[11a]. This structure, as well as two additional structures of achiral ester complexes[11], further suggest that σ-coordination, with the position of the Lewis acid as given in **4**, is preferred for nonchelate complexes. The synplanar conformation of the enoate group in the complex **4b** could consequently be destabilized due to repulsive interactions[12]. Other than in the case of **3**, the σ-coordinated Lewis acid does not contribute to the diastereodifferentiation.

Complexes of the type **4** might also play a role for the reactions of the lactate **1**. We assume that **3** is in equilibrium with complexes **5** ($MX_n = TiCl_4$). For these, preferred *Re*-attack of the diene (to give **2b**) is to be expected. Since the formation of **5b** is favored by high concentration of $TiCl_4$, the stereoselectivity of the addition reaction is lowered if the ratio $TiCl_4$: **1** is > 1 (Fig. 1). Assumption of alternatives **3** and **5** also explains the stereodichotomic effect: with $TiCl_4$, predominantly the chelate complex **3** reacting to give **2a** is formed, whereas with tetracoordinating Lewis acids such as $EtAlCl_2$ or BF_3 the complexes **5** predominate, from which **2b** is then formed selectively.

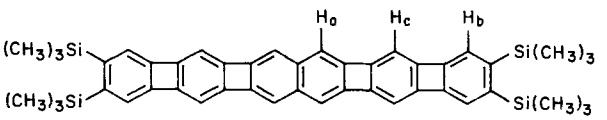
Synthesis of the First Linear (*o*-Phenyleno)naphthalenes; a New Class of Benzenoid Aromatics**

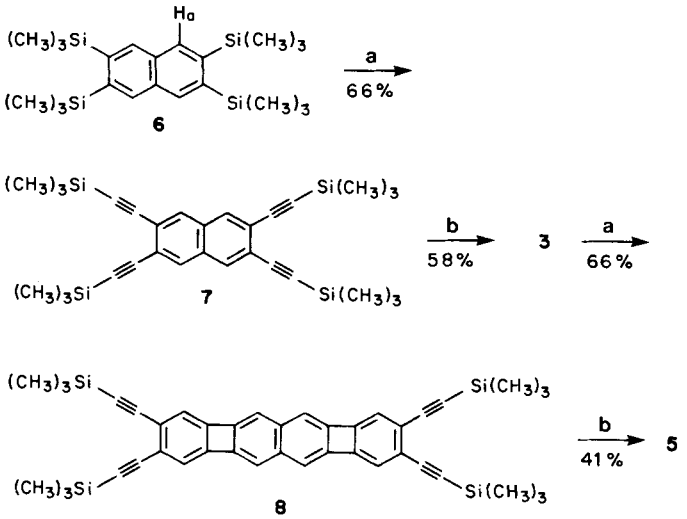
By *Harold E. Helson, K. Peter C. Vollhardt**, and *Zhen-Yu Yang*



We have recently outlined a synthetic strategy which allows the iterative construction of the multiphenylene framework, an arrangement in which the aromatic benzene ring is juxtaposed to the cyclobutadiene moiety by alternating linear fusion[1]. This work led to the synthesis and investigation of the properties of the first members of the series, the terphenylenes **1** and **2**. Here we report the preparation of the (*o*-phenyleno)naphthalenes **3**, **4**, and **5**, of interest per se as novel benzenoid hydrocarbons, but also as key elements in our efforts to develop this methodology for the synthesis of potentially conducting organic materials[2]. While all systems contain a [4n+2] π-periphery, only **3** and **4** can avoid cyclobutadienoid[3] circuits[4], and might therefore show unusual naphthalene-type stability.

1, R = $Si(CH_3)_3$; **2**, R = H

3, R = $Si(CH_3)_3$; **4**, R = H



5

Our synthetic approach is shown in Scheme 1 and begins with 2,3,6,7-tetrakis(trimethylsilyl)naphthalene **6**, prepared in one step from acyclic materials by cobalt catalysis[5]. Iodination, palladium-catalyzed ethynylation, desilylation, and cyclization with bis(trimethylsilyl)acetylene then proceed, as described previously[1a], to give **3**, and eventually **5**. Protodesilylation of **3** with trifluoroacetic acid afforded **4**[6], conditions under which **5** decomposed. The power of the methodology becomes apparent when one realizes that *all* of the component rings, involving eleven of the bonds in **3** and **4**, and seventeen (!) in **5**, are constructed by cobalt-catalyzed steps.

The physical properties of the key compounds are shown in Table 1. Even though **3** and **5** have an aromatic

[**] This work was supported by the National Institutes of Health (CA 20713). *H. E. H.* was an undergraduate research participant (1982—1983) and *K. P. C. V.* a Camille and Henry Dreyfus Teacher-Scholar (1978—1983).

Scheme 1. **a**: 1) ICl, 2) trimethylsilylacetylene, $[PdCl_2(PPh_3)_2]$, CuI, Et_3N, piperidine; **b**: 1) CH_3OH, potassium hydroxide, 2) bis(trimethylsilylacetylene), $[(C_5H_5)Co(CO)_2]$.

π-electron count, the cumulative effect of the paratropism exerted by the increasing number of cyclobutadienoid rings along the series becomes apparent. The ^{1}H-NMR assignments, particularly of **5**, are tentative and based on analogies[1], the work of *Figeys* et al.[7], and knowledge of the deshielding effect of the trimethylsilyl group on *o*-hydrogen atoms[1,5]. Moreover, in **4**, where the assignments are unambiguous, the naphthalene absorption occurs at $\delta = 6.73$ (s), with the remaining signals occurring as an AA'BB' multiplet centered at 6.88 and 6.80. Thus, remarkably, the central naphthalene moiety experiences an extraordinary shielding, which must be due to not only the paratropic influence of the four-membered rings but also bond-fixation, and hence a reduced diamagnetic ring current in this portion of the molecule. In fact, the systems appear to prefer to behave as "phenylenophenylenes" rather than as "benzocyclobutanaphthalenes". For example, the key signals in the ^{13}C-NMR spectrum of **3** [$\delta(CDCl_3) = 149.4$, 149.1, 148.4, 136.3, 123.8, 117.3, 2.14] strongly resemble those of 2,3-bis(trimethylsilyl)biphenylene[1a] [$\delta(CDCl_3) = 152.5$, 150.5, 147.7, 128.1, 122.7, 117.6, 2.14]. The electronic spectra along the series exhibit a fairly constant bathochromic shift increment of 70 nm on cyclobutabenzoannelation, as seen earlier[1]. Interestingly, the UV spectrum of **3** is very similar to that of **1**. Finally, preliminary cyclic voltammetry data reveal that the phenylenes readily accept electrons. While the relatively stable **3** exhibits reversible one- and two-electron reduction waves, the heat-, air-, and acid- ($CDCl_3$, silica gel) sensitive **5** decomposes under these conditions. Nevertheless, the data suggest that the stoichiometric multiple redox chemistry of these systems should be interesting.

Table 1. Physical properties of **6**, **3**, and **5**.

	Appearance M.p. [°C]	^{1}H-NMR ($CDCl_3$), δ H_a	H_b	H_c	CH_3	UV (hexane) $\lambda_{max.}$ [nm], $\varepsilon \times 10^{-4}$	$E_{1/2}$ [V] [a]
6	colorless crystals, 288	8.06			0.44	244 (12.3)	−2.81
3	yellow crystals, 314 (dec.)	6.69	7.06		0.29	287 (3.0), 302 (6.9), 315 (13.6), 390 (0.65), 408 (1.6), 432 (2.6)	−2.23, −2.62
5	red powder, >360 (dec.)	6.42	6.77	6.32	0.30	321 sh, 331 (4.3), 360 (3.5), 472 (1.7), 490 sh, 504 (2.7)	(−1.41, −1.75, −1.98, −2.17)

[a] Pt electrode vs. $Ag/Ag^{\oplus}$, THF, 0.1 M $Bu_4N^{\oplus}PF_6^{\ominus}$.

In this vein, we have reduced **3** to its brown dianion by exposure to sodium in tetrahydrofuran (THF), the reaction proceeding via the green (presumed) radical anion intermediate. At −80 °C the ^{1}H-NMR spectrum reveals three singlets at $\delta = 6.70$, 6.37, and 0.17. Exposure of this sample to air led to re-formation of **3** [$\delta([D_8]THF) = 7.15$, 6.79, 0.36]. That the reduced species was indeed a di- and not a higher anion was shown by the ^{13}C-NMR spectrum [$\delta([D_8]THF) = 131.6$, 124.0, 123.7, 121.0, 114.0, 106.0, 3.5] in which the cumulative up-field shift was only compatible with a doubly negatively charged molecule. As observed in the reduction of **1**[1b], the strong shielding of the ^{1}H-NMR absorptions in $\mathbf{3}^{2\ominus}$, expected to occur since a $(4n+2)$ π- is converted into a $(4n)\pi$-system and a neutral compound into a dianion, does not materialize. Again, it is tempting to assume that the system has the capability of assuming an electronic structure which maximizes aromatic at the expense of antiaromatic ring currents[8]. This hypothesis might be testable in the reduction of **5**, which could furnish both the di- and the tetraanion.

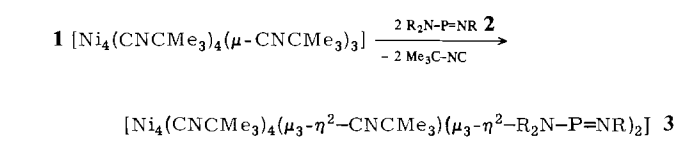
Amino(imino)phosphanes as Face-Bridging Complex Ligands

By *Otto J. Scherer**, *Richard Walter*, and *William S. Sheldrick*



Amino(imino)phosphanes $>N-P=N-$ are versatile complex ligands[1]: Besides the preferred terminal *P*-coordination (**A**)[1], examples of μ-*P*- (**B**)[2a] and *N,P*-coordination (**C**) have also been described[2b].

We have now prepared the Ni_4-cluster **3**, in which three triangular faces are bridged by two μ_3-η^2-$R_2N-P=NR$ ligands and one μ_3-η^2-$C\equiv N-CMe_3$ ligand as in **D** and **E**, respectively, by reaction of the isocyanide cluster $[Ni_4(CNCMe_3)_7]$ **1**[3a] with $R_2N-P=NR$ **2**, $R = SiMe_3$ (Fig. 1).

Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

3 forms dark-red crystals[4] which are readily soluble in benzene, toluene, pentane, dichloromethane, and diethyl ether, but only sparingly soluble in acetonitrile. The ^{1}H-NMR spectrum[5] of the chiral Ni_4-cluster 3 shows five

Me_3C signals and four Me_3Si signals. Temperature-dependent measurements (−60 to +60 °C) show a change in the signal pattern only below 0 °C, since the rotation about the R_2N–P bonds is frozen-in. In the $^{31}P\{^1H\}$-NMR spectrum, an unusually large upfield shift is observed for the two doublets of the P atoms (different environment, Fig. 1).

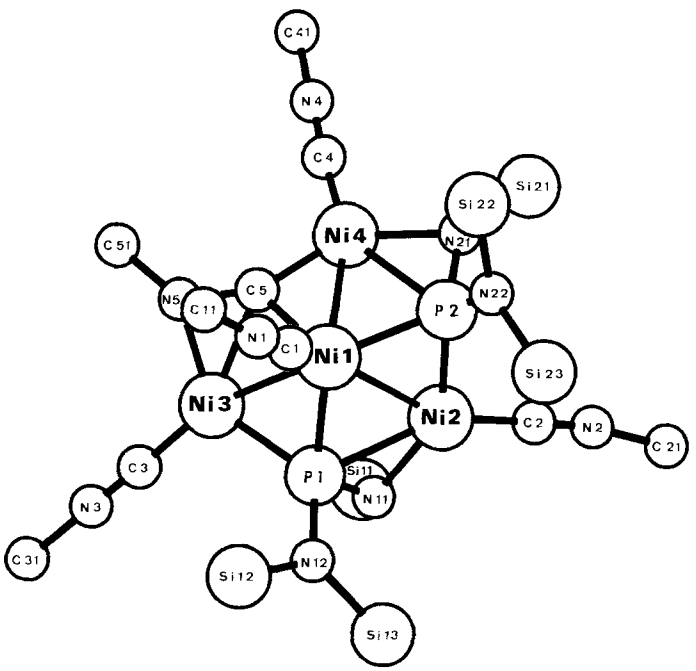

Fig. 1. Structure of 3 in the crystal (methyl groups have been omitted for the sake of clarity). Selected bond lengths [Å] and angles [°] (see also text): Ni1–Ni2 2.493(2), Ni1–Ni3 2.451(2), Ni1–Ni4 2.422(2), Ni2···Ni3 3.887(2), Ni2···Ni4 3.494(2), Ni3···Ni4 3.667(2), Ni1–C5 1.913(8), Ni4–C5 1.788(11), Ni3–C5 2.112(11), Ni3–N5 1.880(9), Ni1–P1 2.195(4), Ni3–P1 2.143(3), Ni2–P1 2.372(3), Ni2–N11 1.959(8), P1–N11 1.610(10), P1–N12 1.732(8), Ni1–P2 2.176(3), Ni2–P2 2.143(4), Ni4–P2 2.409(3), Ni4–N21 1.949(8), P2–N21 1.596(8), P2–N22 1.709(9), mean value of the terminal C≡N bonds 1.156, C5-plane Ni1,Ni3,Ni4 0.63, P1-plane Ni1,Ni2,Ni3 1.08, P2-plane Ni1,Ni2,Ni4 1.45; Ni3–C5–N5 61.4(6), Ni3–N5–C5 80.6(6), Ni2–P1–N11 55.0(3), Ni2–N11–P1 82.7(4), N11–P1–N12 104.3(4), Ni4–P2–N21 53.7(3), Ni4–N21–P2 85.0(4), N21–P2–N22 107.7(4); dihedral angle: N12–P1–N11–Si11 127.9, N22–P2–N21–Si21 77.7, Ni3–C5–N5–C51 154.2.

The crystal structure analysis[6] (Fig. 1) shows that 3, like the educt 1[3a], consists of a compressed trigonal pyramid (distance of Ni1 from the Ni2,Ni3,Ni4 plane = 1.22 Å), whose base (Ni2,Ni3,Ni4) exhibits marked differences in the Ni···Ni distances (3.494(2)—3.887(2) Å). The distances of the basal Ni atoms from the apical Ni1 atom, with a mean value of 2.455 Å are distinctly greater than those found in 1 (mean value 2.338 Å)[3a]. The difference between the distance Ni1–C1 (1.851(13) Å = longest bond) and the mean value (1.770 Å) of the Ni–C distances between the basal Ni atoms and their terminal Me_3C–NC ligands in 3 is, with a value of 0.081 Å, only slight; in 1, with a value of 0.34 Å, this is otherwise[3a]. The structurally most interesting aspect is the μ_3-η^2-coordination of the C≡N- and –P=N-ligand moieties (Fig. 1 and **D** and **E**). Me_3C–NC as four-electron donor (**E**) extends the recently found type of coordination in $[Fe_3(CO)_9(\mu_3\text{-}\eta^2\text{-}CNCMe_3)]$[7], in which Me_3C–NC functions as six-electron donor (2σ and 4π electrons), by a novel variant of face bridging. Characteristic of this type of structure are the C5–N5 distance (1.316(13) Å) and C5–N5–C51 angle (131.5(9)°) and the ν(CN) at 1595 (s) cm^{-1} (ν(CN) (pentane) of the terminal ligands = 2090 (s), 2060 (vs), 2015 (sh) cm^{-1}). Distinction between a face- or edge-bridging for the three bridging isocyanide ligands in 1 could not be made, because of disorder in the crystal[3a]; in later publications[3b,c], only the edge-bridging comes under discussion.

The coordination type **D** of a trivalent phosphazene found in 3 for the first time (cf. the recently verified μ_3-η^2-bridge of a phosphaalkene ligand generated on a Fe_3 cluster[8]), shows, in contrast to **B** and **C**, the following peculiarities: The P=N-bond is on average longer (1.603 Å) than in the educt 2 (1.545(2) Å)[9]. In the case of the coordination types **B** (Pt_3 cluster with two μ-R_2N–P=NR ligands and a μ-$CNCMe_3$ ligand)[2a] and **C** ($[Re_2(CO)_6(\mu\text{-}Br)_2(\mu\text{-}RR'N\text{–}P\text{=}NR')]$, R = $SiMe_3$, R′ = CMe_3)[2b] the P=N bond is, at a maximum, 0.02 Å longer. The $^{31}P\{^1H\}$-NMR signals[5] of 3 are shifted by ca. 155 ppm upfield compared to those of added 2 (δ = 327); in the case of coordination type **B**[2a] they are shifted only ca. 30—40 ppm, in **C**[2b] only ca. 24 ppm.

With the synthesis of 3[10], a further example has been found for the displacement of bridging isocyanide ligands by trivalent phosphazenes. It is clearly emerging that ligands of the type >N–P=N– exhibit a coordination behavior very similar to that of isocyanide ligands[11].

[Mn(S$_2$C$_6$H$_3$Me)$_2$]$^{n-}$: Mononuclear Manganese Complexes with Square-Planar (n = 1) and Distorted Tetrahedral (n = 2) Sulfur Coordination**

By *Gerald Henkel**, *Klaus Greiwe*, and *Bernt Krebs*

Transition metal ions are essential components of important enzymes, and, as such, participate in many biological processes. In addition to the widely disseminated elements iron, copper and molybdenum, even manganese centers have been observed in proteins, but in several cases the nature of such centers has not been completely clarified[1]. Because of the overall significance of metal centers in proteins containing sulfur atoms as coordination sites we have extended our investigations of sulfur-containing transition metal complexes to the elements of the manganese group.

We report here on the synthesis, properties, and structural principles of the mononuclear anions [Mn(tdt)$_2$]$^{2-}$ **1** and [Mn(tdt)$_2$]$^-$ **2** (tdt^{2-} = toluene-3,4-dithiolate), complex anions which can be isolated as the crystalline salts [Ph$_4$P]$_2$[Mn(tdt)$_2$]·2 MeOH **3** and [Ph$_4$P]$_2$[Mn(tdt)$_2$]-[Mn(tdt)$_2$MeOH]·3 MeOH **4**, respectively. According to the structure analysis the crystals of **4** contain not only anions **2** but also mononuclear [Mn(tdt)$_2$MeOH]$^-$ ions **5** with fivefold coordinated Mn[2].

Reaction of $MnCl_2 \cdot 4H_2O$ with Na_2tdt in MeOH in the molar ratio $\leq$ 1 : 2 leads in the absence of oxygen to the formation of a yellowish-brown solution, from which brown columnar-shaped crystals of **3** precipitate out on addition of Ph$_4$PBr. If the solution is brought into contact with atmospheric oxygen prior to the addition of the precipitating reagent, the color immediately turns dark brown. Black crystals of **4** can be precipitated from the oxidized reaction mixture with Ph$_4$PBr. The formation of a mononuclear tris-chelate complex [Mn(tdt)$_3$]$^{2-}$[3] was not observed.

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

The effective magnetic moment determined for **4** is 5.2 μ_B per manganese at room temperature. While this value suggests the presence of trivalent metal centers in **2** and **5** with d^4 high-spin configuration, **3** shows the typical high-spin behavior for monomeric thiolate-substituted manganese complexes with tetrahedrally arranged sulfur atoms and d^5 configuration[4b,5]. In the UV spectrum of **4**[6] the band at 900 nm could be assigned to a d-d excitation characteristic for Mn^{III} complexes[7]. The transition Mn$^{III} \rightarrow$ Mn^{II} is observed in the cyclovoltammogram[8] of **4** at -1.09 V (dimethylformamide (DMF) solution) or at -0.82 V (CH_2Cl_2 solution). The potential difference between the oxidation peak and the reduction peak shows a distinct dependence on the solvent (0.610 V for DMF, 0.270 V for CH_2Cl_2). According to results of polarographic investigations a one-electron transfer probably takes place here. Further waves, in which corresponding oxidation and reduction currents are of about the same magnitude, do not occur. On the basis of magnetic and electrochemical investigations the assignment of discrete oxidation states for manganese in **1** (+2) as well as in **2** (+3) and in **5** (+3) would seem justified.

The ^{1}H-NMR spectrum of **4** shows signals shifted upfield (referred to TMS) for the aromatic protons. Thus, resonances are observed at δ = 4.6, 9.3 and 20.8 in [D$_6$]Me$_2$SO, while the signals of the methyl protons appear downfield at δ = -15.7. Further isotropically shifted signals were not observed, so that only solvated [Mn(tdt)$_2$]$^-$ ions should be present in solution.

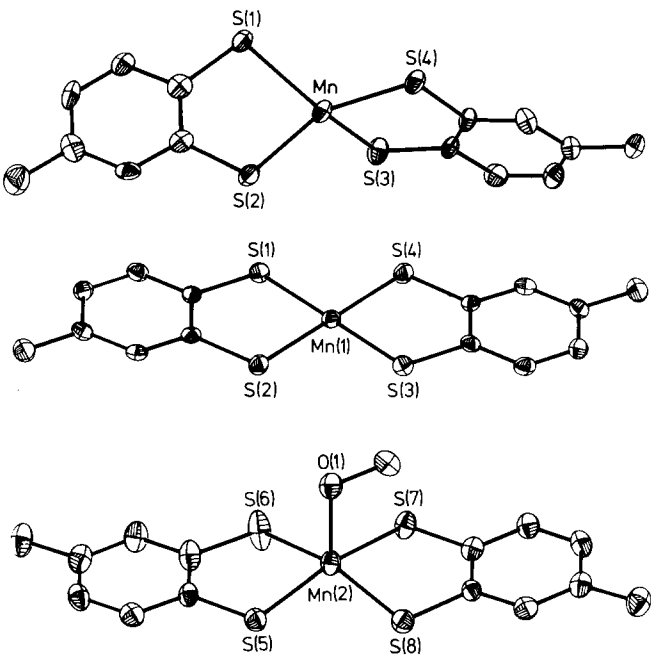

Fig. 1. Top: Structure of **1** in the crystal of **3**. Mn–S bond lengths (σ = 0.002 Å): 2.395, 2.414, 2.425, 2.434 Å; S–Mn–S valence angles (σ = 0.07°): 88.59, 89.15, 117.13, 117.41, 123.06, 124.59°. Center: Structure of **2** in the crystal of **4**. Mn–S bond lengths (σ = 0.001 Å): 2.280, 2.281, 2.282, 2.283 Å; S–Mn–S valence angles (σ = 0.04°): 89.77, 89.81, 90.18, 90.23, 179.86, 180.00°. Bottom: Structure of **5** in the crystal of **4**. Mn–S bond lengths (σ = 0.001 Å): 2.306 (2×), 2.312, 2.314; Mn–O 2.224(2) Å; S–Mn–S valence angles (σ = 0.04°): 88.16, 88.76, 88.99, 89.45, 161.17, 165.78°; S–Mn–O valence angles (σ = 0.06°): 95.48, 98.17, 98.74, 100.65°. All structures with vibration ellipsoids (50% probability, without H-atoms, -130°C). Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51174, the names of the authors, and the journal citation.

The structures of **1** and **2** are shown in Figure 1 (top and center, respectively). Since the planes of the tdt^{2-} ligands in **1** are oriented almost perpendicular to each other (89.0°) a strongly distorted tetrahedral sulfur coordination is present. The short S···S distances within the bidentate chelate ligands (mean value 3.384 Å) lead to two very small (mean value 88.87°) and four larger S–Mn–S valence angles which are much wider than the ideal tetrahedral angle and which can join together as two pairs of 117.27 and 123.83° (mean values). The Mn–S distances in **1** vary between 2.395(2) (Mn–S(3)) and 2.434(2) Å (Mn–S(1)). In comparison to the likewise tetrahedral mononuclear thiolate complexes $[Mn(SPh)_4]^{2-}$[4] and $[Mn(SCH_2CH_2S)_2]^{2-}$[5], a shortening of the mean Mn–S distance by about 0.025 and 0.015 Å, respectively, is observed.

The oxidation of the dianion **1** to the monoanion **2** forces the transition from the distorted tetrahedral to the square-planar sulfur coordination. In contrast to the identically composed Fe^{III} complex[9] and to the analogous Mn^{III} complex with ethanethiolate (edt^{2-}) ligands[5, 10] in which monomeric $[Fe(tdt)_2]^-$ and $[Mn(edt)_2]^-$ moieties are associated pairwise via metal-sulfur bridges, the shortest metal-metal distances in **4** are greater than 9.7 Å and thus even indirect interactions between the metal centers can be excluded.

The Mn–S bonds in **2** ranging from 2.280(1) (Mn(1)–S(1)) to 2.283(1) Å (Mn(1)–S(2)) are of almost exactly the same length and, because of the higher oxidation state of manganese are on average 0.14 Å shorter than the corresponding bonds in **1**. The additional coordination of a neutral methanol molecule extends the ligand sphere of manganese and leads to the formation of anions **5**, which occur along with **2** in crystals of **4**. Figure 1 (bottom) shows a projection of **5** in crystals of **4**. The resulting coordination polyhedron in **5** is a square pyramid whose apex is occupied by the O-atom of the MeOH molecule (Mn–O: 2.224(2) Å), while the S-atoms define the basal plane. The extended coordination in **5** leads, in comparison to the case of **2**, with square-planar metal environment, to somewhat longer Mn–S distances (mean value: 2.310 Å).

Ag_2O_3, a Novel Binary Silver Oxide**

By *Burkhard Standke* and *Martin Jansen**

In the group of coinage metals copper, silver, gold there are many instances where the homology principle is not satisfied. Thus, in aqueous solution the species Cu^{2+}, Ag^+ and Au^{3+} dominate, without, for example, the oxidation state +2 being realized in the case of silver and gold in this medium. In principle, according to the present state of our knowledge the circumstances are similar in the solid-state chemistry of these elements. Here there are inexplicable discrepancies, even when only one element is considered: a whole series of well-defined *ternary* fluorides, such as $CaAgF_4$ or $KAgF_4$, of bi- and trivalent silver are well-known[1], but still no corresponding oxides[2]. It is surprising, therefore, that there is more than ample evidence for the existence of *binary* oxides or peroxides with silver in a higher valency state[3] which, without exception, call for a final confirmation. During attempts to characterize these phases in more detail, which, as constituents of the anodes in zinc/silver oxide primary cells, are also of practical importance, we have been able to isolate well-defined single crystals of Ag_2O_3 for the first time by anodic oxidation in aqueous solution.

The electrolysis was carried out at 0°C in a platinum dish (as cathode) with an approximately 12 cm-long spirally wound 0.3 mm-diameter platinum wire anode. To avoid short-circuiting between the silver depositing on the cathode and the oxide forming on the anode a watch glass was placed under the anode so as to collect the precipitating product and, at the same time, protect it against reduction at the cathode. The nature of the oxidation product depends strongly on the anion of the silver salt employed: for example, $Ag_7O_8NO_3$ is formed from $AgNO_3$ solutions, whereas in the case of anions such as PF_6^-, which apparently can no longer be accomodated in the $Ag_7O_8^+$ framework, the novel compound Ag_2O_3 is formed. Suitable electrolytes are neutral, 0.1 N aqueous solutions of $AgClO_4$, $AgBF_4$ or $AgPF_6$. The anodic current density should be ca. 8 mA/cm^2. Since the pH is not regulated, the electrolysis must be terminated after 2 h; otherwise dissolution of the product takes place.

The black, shiny metallic Ag_2O_3 crystals (maximum dimensions $0.4 \times 0.6 \times 1.0$ mm^3) thus obtained, mostly consist of intergrown single crystals and slowly lose oxygen at room temperature and atmospheric pressure, but can be stored for some time at −20°C. Ag_2O_3 is rapidly decomposed by strong acids. According to the X-ray structure analysis[5], silver is coordinated by an almost square-planar array of oxygen atoms (Fig. 1), with the Ag projecting

[**] This work was supported by the Fonds der Chemischen Industrie.

about 9 pm from the best plane defined by them. The AgO_4 groups are linked via common O-atoms to give a three-dimensional network structure. From the empirical formula it essentially follows that O1 and O2 thus perform different topological functions: O1 with the coordination number (C.N.) 3 and O2 with C.N. 2 referred to silver. The slight deviations of the AgO_4 polyhedron (cf. Fig. 1) from the ideal D_{4h} point symmetry are chiefly due to the different coordinative demands on the oxygen atoms. Consistent with this, the Ag–O2 distance is the shortest, with a value of 197.6 pm. The average Ag–O distance of 202 pm is conspicuously close to the corresponding value in the isotypic Au_2O_3 (201 pm)[6]. The differences in the bond lengths within the AgO_4 group are qualitatively in agreement with those in Au_2O_3. However, the *trans*-effect discussed in the case of Au_2O_3 is not noticeable in Ag_2O_3.

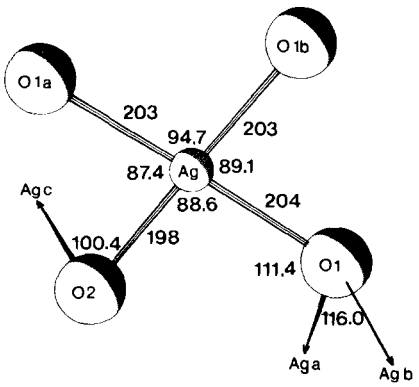

Fig. 1. Projection of the AgO_4 moiety on the best plane defined by oxygen with bond lengths [pm] and angles [°]. Symmetry-equivalent atoms are indicated in small Roman letters. The Ag–O1–Agb angle is 108.7°. The shortest Ag–Ag distance is 304 pm. Maximum standard deviations: 3 pm (bond lengths) and 0.8° (bond angles).

The existence of Ag_2O_3 strikingly contrasts with the previously mentioned lack of ternary oxides containing higher valency silver and emphatically underscores our opinion that in principle no obstacles, for instance in the chemical nature of silver, stand in the way of formation of such oxides.

Nonacarbonylbis(μ_3-fluoromethylidyne)triiron: Formation of a Biscarbyne Cluster from Carbonyliron and Tribromofluoromethane

By *Dieter Lentz**, *Irene Brüdgam*, and *Hans Hartl*

Bismethylidyne complexes, in particular those of cobalt and of rhodium, have been the subject of intensive investigations in recent years[1], not least because of their importance in acetylene cleavage, acetylene metathesis, and the Fischer-Tropsch process. $[(\mu_3\text{-CF})\{Co(CO)_3\}_3]$, its derivatives[2], and the hetero-clusters obtainable therefrom by metal exchange[3], were hitherto the only fluoromethylidyne complexes known. According to the 18-electron rule or the Wade rules[4] a further CF ligand can be incorporated in the analogous Fe-cluster, which should lead to a trigonal-bipyramidal iron-carbon cluster. In contrast to numerous compounds containing the $Co_3(CR)_2$ system $[Fe_3(CO)_9(\mu_3\text{-}CCH_3)(\mu_3\text{-}COCH_3)]$ was the only known compound containing an $Fe_3(CR)_2$ moiety[5].

Reaction of $Fe(CO)_5$ or $Fe_2(CO)_9$ with $CFBr_3$ leads to formation of **1** (yield 2–3%) as the major component of the reaction products that are soluble in hexane.

$$Fe_2(CO)_9 \text{ or } Fe(CO)_5 \xrightarrow[60-80\,^\circ C]{CFBr_3/n\text{-heptane}} [Fe_3(CO)_9(\mu_3\text{-}CF)_2]\ \mathbf{1}$$

The trace amounts of byproducts soluble in hexane can be readily separated by preparative thin-layer chromatography (silica gel, Merck 0.5 mm, hexane). According to its spectroscopic data[6] **1** is a bis(fluoromethylidyne) complex. The presence of the isomeric difluoroacetylene complex could be ruled out, in particular by the extreme downfield shift of the ^{13}C-NMR resonance of the carbyne carbon atom ($\delta = 365.8$, $^1J_{CF} = 452$ Hz). The very large ^{19}F-^{13}C coupling constant is indicative of a strong s-part in the CF bond. The resonance of the CF-group lies at $\delta = 69.5$ in a region unusual for CF-compounds and clearly demonstrates the influence of the metal array on the CF-bond.

According to the X-ray structure analysis[7] the two CF-ligands and the three iron atoms form a trigonal bipyramid with the CF-ligands in the axial positions (Fig. 1). Three of the carbonyl ligands are in the Fe_3-plane. The remaining

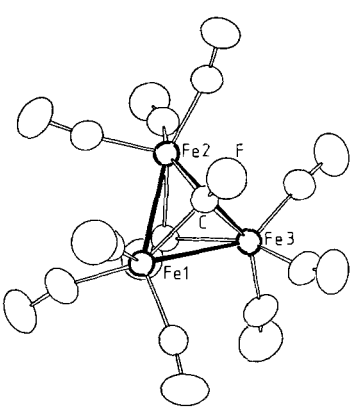

Fig. 1. Molecular structure of **1**. Important bond lengths [pm] and angles [°]: Fe–Fe 253.6–254.4(2). Fe–CF 189.4–194.9(4), C–F 135.4(4), Fe–C (in the Fe_3 plane) 178–179(2), Fe–C (above and below the Fe_3 plane) 182.5–187.9(4), Fe···C 295–301(2), C–O 104–116(2); Fe–CF–Fe 82.6–84.0(2), C–Fe–C 93.0–99.7(3), Fe–C–O 165.0–174.0(10).

CO-ligands are located in pairs above and below the Fe_3-plane, which forms a mirror plane of the molecule. The symmetry of the molecule is approximately 3/m (C_{3h}). The nine CO-ligands are terminal; carbonyl bridges do not occur. Each iron atom is coordinated by a distorted square-pyramidal array of three CO- and two CF-ligands. Further CO-ligands, which, because of their large Fe···C distances can no longer be regarded as bound, extend these arrays to distorted octahedra (Fig. 1). The three $Fe(CO)_4(CF)_2$ octahedra are coupled via common faces (inverse $Cs_{11}O_3$-structure[8]) to give the trinuclear cluster **1** with a common CF–CF edge.

The Fe-cluster occupies two different point positions, each of population parameter 1/2 and linked via a mirror plane (Fig. 2). The CO/CF molecular framework in both arrangements is almost identical; only the positions of the three carbonyl C-atoms in the Fe_3-plane are so different (distance between C-atom pairs: 52–64(2) pm) that they can be refined as split atom sites. The two arrangements are interconvertable by a slight cooperative shift of the Fe atoms within the octahedron. A disorder of the Fe-triangle by rotation, as was predicted for $Fe_3(CO)_{12}$ on the basis of solid-state ^{13}C-NMR spectra[9] would also appear possible in this case. However, the small anisotropy of the temperature factors of the Fe atoms and the Mössbauer spectrum[10] make a dynamic disorder below 300 K improbable in this case. Whether the observed disorder is a random disorder or concerns domain twins is still unclear. $[Fe_3(CO)_9As_2]$[11] and $[Fe_3(CO)_{12}]$[12] have analogous structural features in the solid state: the Fe_3-triangles are arranged statistically in two different positions without changing the ligand sphere.

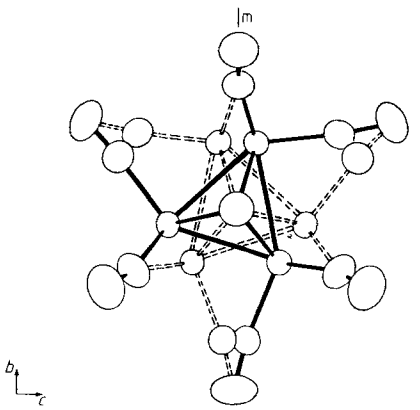

Fig. 2. Disordered structure of **1**; projection on plane bc. The two partial structures (dashed and full lines) are interconvertible through the mirror plane in $z = 1/4$.

In the ^{13}C-NMR spectrum[6], the carbonyl carbon atoms give rise to only one triplet, thus indicating that they are equivalent on the NMR time scale. This is consistent with a non-rigid structure in solution. Also according to IR data[6] there are no carbonyl bridges present in solution. Because of the sparing solubility of the compound it was impossible to carry out low-temperature ^{13}C-NMR measurements for the elucidation of the exchange process.

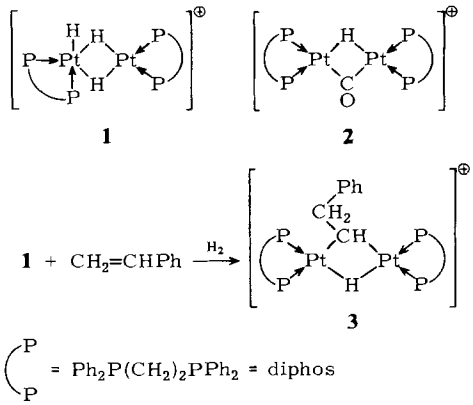
Synthesis and structure of $[Pt_2(\mu\text{-}H)(\mu\text{-}CHCH_2Ph)(diphos)_2][BF_4]$**



By *Giovanni Minghetti**, *Alberto Albinati*, *Anna Laura Bandini*, and *Guido Banditelli*

Several binuclear platinum hydrides $[Pt_2H_3(L{-}L)_2]$, where L–L is a chelating bisphosphane, have previously been described[1]. Complex **1** was shown by X-ray analysis to contain one terminal and two bridging hydride ligands: the $Pt(\mu\text{-}H)_2Pt$ fragment was found by neutron diffraction to be markedly unsymmetrical[2]. The hydrides $[Pt_2H_3(L{-}L)_2]^{\oplus}$ react with two-electron ligands such as CO or CNR to give diplatinum(I) derivatives: in **2**, both the hydrogen atom and the carbonyl group are in bridging positions[3].

Here we report the reaction of complex **1** with styrene in the presence of hydrogen to give the binuclear species **3**, which, to our knowledge[4], is the first compound containing one hydride and one alkylidene ligand bridging two platinum atoms:

1 **2**

3

P = $Ph_2P(CH_2)_2PPh_2$ = diphos

Complex **3** (pale yellow crystals) is stable in the solid state and in $CHCl_3$ solution. **3** has been characterized by NMR spectroscopy (^1H, ^{13}C, ^{31}P, ^{195}Pt)[5] and X-ray structure determination.

The chemical shift of the bridging C atom is in the range expected for a μ-alkylidene (or μ-carbene) group[6]: the C atom of bridging alkylidyne (or μ-carbyne) groups is reported to absorb at much lower field[4, 7]. The NMR spectra are in agreement with the existence of a binuclear species where each bisphosphane ligand (diphos) is chelated to a Pt atom and the two (diphos)Pt fragments are linked by a hydride and an alkylidene group.

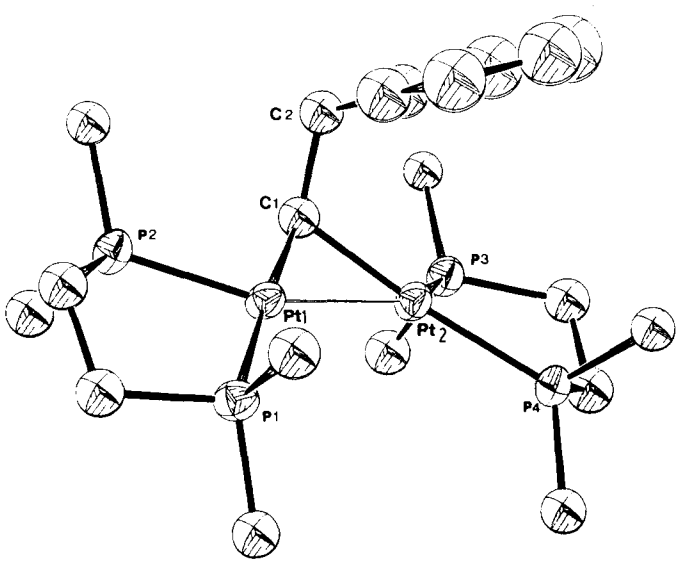

Fig. 1. ORTEP view of the structure of cation **3** in the crystal of $\{Pt_2(\mu\text{-}H)(\mu\text{-}CHCH_2Ph)(diphos)_2\}[BF_4]$. Bridging hydride not located; only one C atom of each *P*-phenyl group is shown. Selected bond lengths [Å] and angles [°]: Pt1–Pt2 2.735(1), Pt1–C1 2.02(2), Pt2–C1 2.07(2), Pt1–P1 2.316(4), Pt1–P2 2.277(4), Pt2–P3 2.217(4), Pt2–P4 2.286(4), C1–C2 1.52(2); Pt1–C1–Pt2 84.1(6), P1–Pt1–C1 172.8(2), P4–Pt2–C1 176.5(2), P1–Pt1–P2 84.5(1), P3–Pt2–P4 87.2(1).

Figure 1 shows the structure of **3** in the crystal[8]. The coordination of each platinum atom can be described as distorted square-planar, with the two coordination planes defined by Pt and P atoms making an angle of 23.9°. The Pt1–Pt2 distance (2.735(1) Å) is comparable with that found in other binuclear complexes having two bridging groups[9] (e.g. complex **1**: 2.728(1)[1]; complex **2**: 2.716(1) Å[3]) and is consistent with a bonding metal-metal interaction.

The μ-alkylidene ligand is symmetrically bonded to the two metal centers (average Pt–C 2.04(3) Å); the angle Pt1–C1–Pt2 (84.1(6)°) is almost equal to that found in complex **2** (84.6(2)°[3]). The bridging hydride ligand could not be located with certainty; however, its presence was inferred from the ^1H-NMR spectrum. It is noteworthy that the Pt–P distances *trans* to the hydride bridge (2.277(4) and 2.217(6) Å for Pt1–P2 and Pt2–P3, respectively) are significantly different. Thus, it is likely that the position of the H atom is unsymmetrical even in this case.

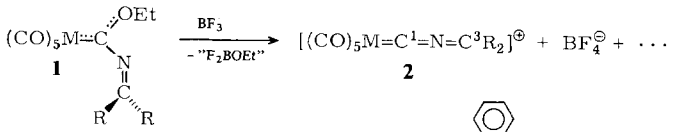
Cationic 2-Azaallenylidene Complexes, Novel Compounds with Unusual Photochemical Properties**



By *Helmut Fischer**, *Friedrich Seitz*, *Jürgen Riede*, and *Jürgen Vogel*

Complexes in which the ligand-metal fragment is a component of a cumulated π-electron system have recently attracted increasing interest[1], since the properties of metal-carbon double bonds change considerably on incorporation in a cumulated multiple-bond system. This is readily

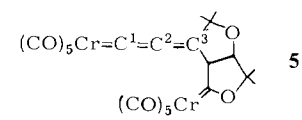
[**] Metallaheterocumulenes, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft.

demonstrated by comparing carbene complexes[2] with vinylidene and allenylidene complexes[1]. We report here on novel complexes which formally derive from allenylidene complexes by replacement of the central C-atom by $N^{\oplus}$.



1 → $\xrightarrow[-\text{"}F_2BOEt\text{"}]{BF_3}$ $[(CO)_5M{=}C^1{=}N{=}C^3R_2]^{\oplus}$ + $BF_4^{\ominus}$ + ... **2**

a, M = Cr, CR_2 = CPh_2; **b**, M = Cr, CR_2 =  ; **c**, M = W, CR_2 = CPh_2

The pentacarbonyl[diorganomethyleneamino(ethoxy)-carbene] complexes **1a**—**1c**[3,4] already react with BF_3 in dichloromethane/pentane between −100 and −60 °C with cleavage of the ethoxy group[5] to give deep-blue diamagnetic cations **2a**—**c** which can be isolated as $BF_4^{\ominus}$ salts ([**2a**—**2c**]BF_4); these salts are insoluble in pentane but readily soluble in CH_2Cl_2. The IR spectra of the cations **2a**—**2c** each show—in addition to the three bands expected to appear in the ν(CO)-region for pentacarbonylmetal fragments—an absorption (between 1880 and 1926 cm^{-1}) which can be assigned to the asymmetric stretching vibration of the 2-azaallenylidene ligand[6]. The ^{13}C-NMR spectrum[6] of **2a** shows a signal at $\delta = 200.4$ for the metal-bonded C-atom and a signal at $\delta = 166.5$ for the other cumulene C-atom. These values are comparable with those of the corresponding signals in the allenylidene complex **3** [$\delta(C^1) = 226.6$, $\delta(C^3) = 155.6$, [D$_8$]tetrahydrofuran (THF)][7] and in the isocyanide complex **4** [$\delta(C^1) = 200.0$, [D$_8$]THF][8]. In complete contrast, the signal of the carbyne carbon atom of the cationic complex $[(CO)_5Cr{\equiv}C{-}NPh_2]SbCl_6$ appears at $\delta = 273.7$[9]. The change in the central metal atom on going from **2a** to **2c** leads to a diamagnetic shift of the signal for the metal-bound C-atom (**2c**: $\delta(C^1) = 182.3$), while the resonance of the terminal cumulene C-atom remains virtually unchanged ($\delta(C^3) = 166.1$).

$[(CO)_5Cr{=}C^1{=}C^2{=}C^3(Ph)NMe_2]$ **3** $[(CO)_5Cr{=}C^1{=}N{-}C^3{\equiv}N]$ **4**

An X-ray structure analysis was carried out on **2b** (Fig. 1)[10]. The Cr—C^6 distance (189.9(6) pm) is almost the same as that found in the corresponding allenylidene complex **5** (191.3(7) pm)[11] and in the isocyanide complex **4** (Cr—C^1 188.3(3) pm)[8]. The Cr—C (carbyne) bond in $[(CO)_5Cr{\equiv}C{-}NEt_2]BF_4$, on the other hand is considerably shorter (179.7(9) pm)[12]. The two NC distances in **2b** (C6—N 118.2(8) and N—C61 134.5(8) pm) show a large deviation in length (C^1—N in **4**: 116.7(5) pm). Different bond lengths in the cumulene ligand are, however, also a structural feature of allenylidene complexes (e.g. in **5**: C^1—C^2 126(1), C^2—C^3 135.9(9) pm). The same holds for the small but significant deviation of the cumulene system from a linear arrangement (**2a**: C6—N—C61 170.9(6); **5**: C^1—C^2—C^3 174.3(7)°). The formation of two orthogonal π-systems is only slightly affected by the observed puckering. **2a**—**2c** are therefore best described in terms of the resonance structure **A** with participation of structure **B** (isocyanide complex with a carbenium center in the α-position to the isocyanide group). For resonance structure **C** a reversed sequence of the C—N distances would be expected.

5

$[(CO)_5M{=}C{=}\overset{\oplus}{N}{=}CR_2]$ ⟷ $[(CO)_5\overset{\ominus}{M}{-}C{\equiv}\overset{\oplus}{N}{-}\overset{\oplus}{C}R_2]$ ⟷ $[(CO)_5\overset{\oplus}{M}{\equiv}C{-}\ddot{N}{=}CR_2$

A **B** **C**

In their UV/VIS spectra **2a**—**2c** each show four absorption bands, two of which, respectively, strongly overlap. The two lower energy bands ($S_1 \leftarrow S_0$, $S_2 \leftarrow S_0$) can, according to an HMO calculation carried out on **2b**, be assigned to CT-transitions from metal d-orbitals into the LUMO of the complex mainly localized in the ligand. In the case of the higher energy transitions ($S_3 \leftarrow S_0$...) there are more possibilities to be taken into consideration (M→π^*(CO)-, intraligand-, d-d-transitions).

The photochemical behavior of **2a** and **2b** is unusual. On irradiation in the long-wavelength group of bands[13] the ligands fragment with cleavage of CR_2; the dimer $R_2C{=}CR_2$ can be isolated in ca. 30% yield. The second fragmentation product $[(CO)_5M{-}CN]^{\oplus}$ is unstable under the reaction conditions and reacts to give compounds which no longer absorb in the ν(CO)-region. No indications of a rupture of the M—C^1 bond could be found. On the other hand, if irradiation is carried out only with light of wavelength 300 nm $< \lambda <$ 500 nm (region of the two short-wave absorptions) no photoreaction can be observed under otherwise the same conditions, even on prolonged irradiation. Surprisingly, no relaxation from the higher excited states to the first excited state takes place. On irradiation in the short-wavelength group of bands, however, fluorescence occurs (maximum emission: **2a**: $\lambda = 480$ nm, **2b**: 425 nm, **2c**: 460 nm). The singlet character of the excited states follows from the high extinction coefficients in the absorption spectrum, which do not get smaller on going from the tungsten to the chromium complex (**2c**→**2a**: decreasing spin-orbit coupling), and from the short fluorescence lifetime of **2b** (11 ns). However, because of the low fluorescence quantum yields ($< 10^{-3}$) it can be assumed that triplet states participate in the relaxation of the

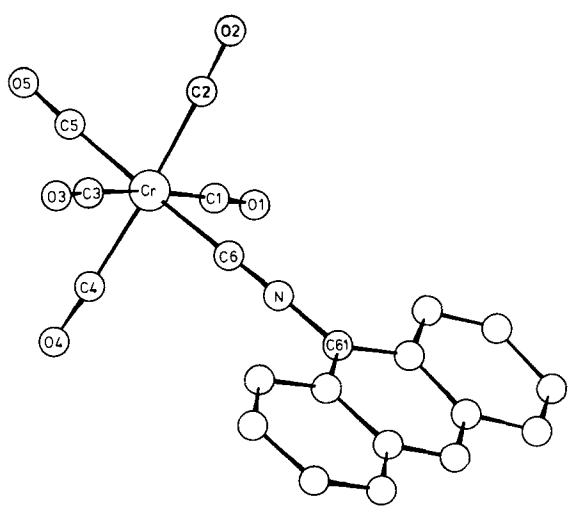


Fig. 1. Structure of the cation **2b** in the crystal. Important bond lengths [pm] and angles [°]: Cr—C6 189.9(6), C6—N 118.2(8), N—C61 134.5(8), Cr—CO(*cis*) 191.2 (mean), Cr—CO(*trans*) 191.8(7); Cr—C6—N 179.0(6), C6—N—C61 170.9(6).

higher excited states. The complexes **2a**—**2c** thus belong to the few compounds in which fluorescence from higher excited states is observed[14].

1,3,4-Thiazaphospholes**

By *Alfred Schmidpeter**, *Konstantin Karaghiosoff*, *Cornelia Cleve*, and *Dietmar Schomburg*

During the past 15 years a series of heterophospholes have been synthesized which substantiate that twofold coordinated phosphorus(III) can form a five-membered ring arene equally as well as the classical heterocyclic members nitrogen and sulfur. However, only in exceptional cases can the synthesis of the phospha systems follow the routes leading to analogous aza systems. Thus, the customary synthetic route to 1,3,4-thiadiazoles such as **8a**[1] cannot be extended to that of 1,3,4-thiazaphospholes **5**, if only because of the lack of precursors. Their synthesis can, however, be accomplished by incorporating phosphorus as last member into the ring by condensation. Compounds **5** represent the first examples of a system containing S, N, and P as members of one and the same ring (all in twofold coordination), thus enabling an intramolecular comparison.

The synthesis of the 1,3,4-thiazaphospholes starts from thiocarboxamides or *N,N*-disubstituted thioureas (examples investigated: **1**, R = Ph, NMe_2), whose NCS chain is extended in the first step at the sulfur by alkylation with a benzyl bromide or ethyl bromoacetate **2**. Condensation of the resulting salt **3** with PCl_3 then closes the chain to give the ring **5**.

Scheme 1. **5a**—**f** and **8a**: R, R′, yield [%]: **a**: Ph, Ph, 20; **b**: Ph, C_6H_4Me-4, 55; **c**: Ph, $C_6H_4NO_2$-4, 65; **d**: Ph, CO_2Et, 98; **e**: NMe_2, Ph, 62; **f**: NMe_2, C_6H_4CN-4, 71.

The triethylamine used in the condensation reaction should not be added prematurely. Otherwise, migration of the alkyl moiety from S to N takes place, leading to formation of the *N*-(dichlorophosphino)thioamides **6**. If, on the other hand, it is added in the presence of PCl_3 the thiazaphospholes **5** are formed (in various yields) (Table 1)[2]. In those cases where the yields are low it is found that the alkylthio-chlorophosphanes $PCl_{3-n}(S-CH_2-R')_n$, n = 1 (**7**), 2, 3, are formed as products of a secondary reaction. To explain their formation, we assume that the condensation starts at the amide group, initially leading to the (here not detectable) 1,3,2,4-diazadiphosphetidines **4**[3]. If there is sufficient CH_2-activation (R′ = CO_2Et) this intermediate reacts exclusively in a second condensation step with formation of **5**. Failing this, the 1,3-shift of the alkylthio group from carbon to phosphorus competes, resulting in elimination of nitrile. If R′ = H, only this reaction is ob-

[**] Four- and Five-Membered Phosphorus Heterocycles, Part 65. Presented in part at the International Conference on Phosphorus Chemistry, September 1983, Nice; cf. *Phosphorus Sulfur 18* (1983) 456. This work was supported by the Fonds der Chemischen Industrie.—Part 64: A. Schmidpeter, A. Willhalm, *Angew. Chem. 96* (1984) 901; *Angew. Chem. Int. Ed. Engl. 23* (1984) 903.

served; that is, heterocycles **5** with R′ = H are not accessible in this way.

Table 1. Data of the 1,3,4-thiazaphospholes **5**.

	Color	M.p. [°C]	δ^{31}P	δ^{13}C($^{1,2}J$(PC) [Hz]) C-2	C-5
5a	colorless	85–87	250.0	176.6 (19.6)	182.1 (74.0)
5b	yellow	75–76	256.9	176.5 (19.4)	182.7 (74.0)
5c	red	210–212	270.0		
5d	pale yellow	43–45	300.0	181.6 (21.2)	167.7 (75.8)
5e	yellow	54–56	248.7	175.0 (18.8)	170.2 (64.1)
5f	yellow	103–104	262.2	176.2 (19.1)	167.1 (65.2)

Thiazaphospholes **5**, like other azaphospholes, are stable towards oxidation, but sensitive to hydrolysis. They absorb at longer wavelengths than the correspondingly substituted thiadiazoles **8**[4] do. Since synthetic routes to non-aromatic P^{III}- and P^{V}-compounds containing a 1,3,4-thiazaphosphole skeleton are also still missing, reactions which enable conversion of **5** into such compounds are of preparative importance.

With reference to the introductory remark, the question arises as to what kind of structural changes accompany the homologous replacement of N by P in a five-membered arene. Compounds **5a** and **8a**, whose structure has already been determined by X-ray crystallography[5], offered themselves for comparison.

The X-ray structure analysis of **5a**[6] shows that it crystallizes isomorphically with **8a**, thus indicating very similar molecular structures (Fig. 1). In **8a** the molecular axis through the S atom is coincident with a crystallographic C_2 axis. Despite its lack of symmetry, the thiazaphosphole molecule **5a** also lies along this axis. The crystallographic symmetry arises through a statistical disorder, in the sense of a rotation of the molecule about this axis, i.e. an interchange of P and N. By cautious refinement it is possible to separate the two disordered atoms P and N (distance 38.5 pm), but their bonding parameters are subjected to large standard deviations (Fig. 1). Nevertheless, it becomes evident that all bonds of the planar (maximal deviation from the plane 3 pm) five-membered ring have an increased bond order. Since the NC bond is longer and the CS bond shorter than in **8a** (Fig. 1), resonance seems to equalize bonds in the thiazaphospholes **5** even better so than in the thiadiazole **8**. However, the poor quality of the comparison material makes a check on a further pair of examples necessary.

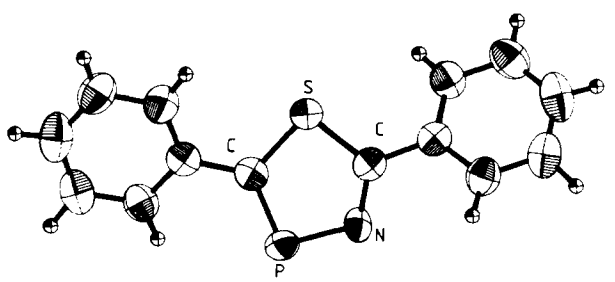

Fig. 1. Structure of **5a** in the crystal. Comparison with **8a** [4] (bond lengths [pm] and angles [°]):

[2] A solution of **3** (5 g) and an equimolar amount of PCl_3 in acetonitrile (100 mL) was stirred vigorously at 0°C. To it was added dropwise a fourfold molar amount of triethylamine within 0.5 h. During addition of the last quarter of the triethylamine the solution turned yellow to orange-yellow. The triethylammonium halide precipitate was filtered off, washed with a little acetonitrile, and the filtrate evaporated to dryness. The residue was digested with 100 mL ether and the etheral solution filtered. After removal of the ether there remained analytically pure **5**. **5c** was insoluble in acetonitrile; it was separated together with the triethylammonium halides, from which it was extracted with a large volume of benzene.

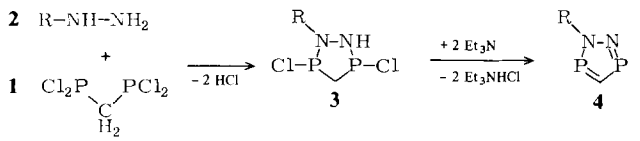
1,2,3,5-Diazadiphospholes — The First 1,3-Diphospha-1,3-diene System**

By *Alfred Schmidpeter**, *Christian Leyh*, and *Konstantin Karaghiosoff*

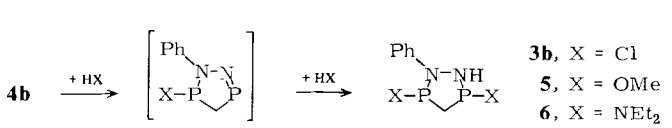


The incorporation of phosphorus(III) in a 6π system favors the twofold rather than threefold coordination of phosphorus and enables the preparation of stable cyclic phosphaalkenes −P=CH− and iminophosphanes −P=N−[1], whereas comparably substituted acyclic compounds are unstable. Is this stabilization also adequate

[*] Prof. Dr. A. Schmidpeter, Dipl.-Chem. C. Leyh, Dipl.-Chem. K. Karaghiosoff
Institut für Anorganische Chemie der Universität
Meiserstrasse 1, D-8000 München 2 (FRG)

[**] Four and Five-Membered Phosphorus Heterocycles, Part 66. This work was supported by the Fonds der Chemischen Industrie.—Part 65: A. Schmidpeter, K. Karaghiosoff, C. Cleve, D. Schomburg, *Angew. Chem. 97* (1985) 125; *Angew. Chem. Int. Ed. Engl. 24* (1985) 123.

enough to hold two phosphorus atoms in one ring with twofold coordination and thus, in particular, to permit the isolation of a cyclic 1,3-diphospha-1,3-diene system? Attempts to synthesize an acyclic 1,3-diphospha-1,3-diene have so far failed[3,4].



The condensation of bis(dichlorophosphino)methane **1**[5] with primary hydrazines **2** seemed a simple and direct route to a five-membered ring with conjugated phosphaethene and iminophosphane unit $-P{=}CH-P{=}N-$. Indeed, **1** reacts with phenylhydrazine (in excess or with pyridine as auxiliary base) to give the isolable but unstable 1,2,3,5-diazaphospholane **3b**. With triethylamine as auxiliary base, the reaction proceeds further with loss of more HCl to give the desired 1-phenyl-1,2,3,5-diazadiphosphole **4b**[6], which can be purified by distillation. However, due to the formation of insoluble byproducts, its yield is low[7].

a, R = Me; **b**, R = Ph

4b is a colorless liquid. On heating, it remains unchanged up to 80 °C, and then solidifies within a few seconds; correspondingly, an insoluble and unmeltable precipitate separates at 80 °C from a solution of **4b** in toluene. While azaphospholes typically are insensitive towards oxidation[8], **4b** is extraordinarily sensitive towards O_2: when oxygen is admitted, **4b** gets warm, becomes orange-colored and turns within 2 h into a viscous, then gelatinous, and finally hard brown insoluble mass, which does not melt up to 300 °C. According to a chemical analysis the product is formed by the take-up of two (or three) atoms of oxygen per molecule of **4b**. α-Diones such as diacetyl or 1,2-naphthoquinone do not react with **4b** even at 50 °C. **4b** cannot be methylated with MeI or with $[Me_3O]BF_4$.

The conjugative stabilization of the twofold coordination of the two phosphorus atoms in **4b** is apparent in that additions always take place at both double bonds, i.e. that the adduct of the first step no longer stabilized by resonance adds more readily than the starting compound. Thus, **4b** takes up HCl in the molar ratio 1 : 2 with reformation of **3b**; if less HCl is offered, a part of **4b** remains unchanged. In the same way, with methanol and diethylamine the diazaphospholanes **5** and **6**, respectively, are formed (Table 1). In each case only one (on the basis of the ^{1}H-NMR (CH_2)-splitting pattern most likely the *trans*) isomer is observed.

Corresponding to the preparation of **4b**, reaction of **1** with methylhydrazine afforded (via **3a**) the 1-methyl-1,2,3,5-diazadiphosphole **4a**, but it could not be purified by distillation. The reactions of **1** with **2**, R = 4-$NO_2C_6H_4$ or Ph_2PO, remained unsuccessful. Noteworthy in the NMR spectra of **4** (Table 1) are the downfield shifts of the phosphorus resonance, characteristic for 1,2-azaphospholes, and the unusual downfield position of the 4-H signal.

Table 1. NMR data of **4**, **3**, **5**, and **6**; if not otherwise stated, in $CDCl_3$ (J [Hz]).

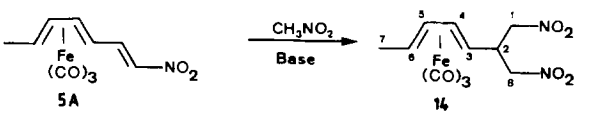
Reactions of Tricarbonyl(sorbaldehyde)iron with Carbanions: A Repeatable Organometallic Reaction with $Fe(CO)_3$-Migration**

By *Andreas Hafner, Wolfgang von Philipsborn,* and *Albrecht Salzer**



Dedicated to Professor Karl Schlögl on the occasion of his 60th birthday

Unsaturated aldehydes of the crotonaldehyde or sorbaldehyde type are only of limited suitability for the synthesis of linear polyenes by aldol condensation[1]. Since the terminal methyl group exhibits the same reactivity as the α-methylene group of unsaturated aldehydes, self-condensation to give polymeric products always occurs as main reaction. Moreover, some C–H acidic methylene groups undergo extensive Michael addition at the double bonds without any noticeable Knoevenagel condensation taking place[2]. We have now found that in the case of sorbaldehyde these side reactions can be completely suppressed by coordination to an $Fe(CO)_3$ group and that a large number of functionalized polyolefins are accessible in good yields as $Fe(CO)_3$-complexes. The complexation of the olefinic π-system and its extremely weaker conjugation with the reactive functional group can be recognized, inter alia, by way of the $^{13}C,^{13}C$-coupling constants. [Sorbaldehyde-$Fe(CO)_3$] **1** and [1,3-pentadiene-$Fe(CO)_3$] exhibit very similar sets of $^1J_{CC}$ values that are typical for compensated bond orders in an η^4-1,3-diene system ($J_{CC}=44.5+1.5$ Hz)[4]. The same holds for the complexed ketones and esters[5].

Some reactions of the 1,3-diene complex **1** with C–H acidic compounds require only catalytic amounts of base[6a] and afford the corresponding triolefin complexes **2A**–**7A** (Table 1) in yields of between 75 and 95% with complete diastereoselectivity regarding the newly formed double bond. The importance of compounds of the type **4A** in enantioselective syntheses has already been pointed out by *Monpert* et al.[7] and *Franck-Neumann* et al.[8].

Only the reaction of **1** with acetaldehyde proceeds primarily with self-condensation of the aliphatic aldehyde and with little formation of **8**, an indication that the reactivity of the aldehyde carbon in **1** is reduced by the diene-$Fe(CO)_3$ unit. A double addition was observed on carrying out the reaction in pure nitromethane, with the Michael addition of the second nucleophile taking place exclusively at the unprotected double bond of **5A**[9a].

Surprisingly, the reaction with strongly basic nucleophiles follows a somewhat different course. The reaction of **1** with acetone in $KOH/CH_3OH/H_2O$ yields only the expected product **9A**. On using KOH/CH_3OH, only the isomeric **9B** can be isolated[6a]. Also the reactions of $LiCH_2CN$ and $LiCH_2CO_2C_2H_5$ with **1** at −78°C lead, on breaking off the reaction after 15 min, initially to condensation products of the type **A** (as *cis/trans* mixture) together with unreacted **1**. On prolonged reaction, however,

no product **A** is isolated, but **10B** and **11B** in 80—90% yield. At least two molar equivalents of nucleophile are required for this reaction[6b]. The formation of **9B** — **11B** with migration of the $Fe(CO)_3$ group at low temperatures (according to quenching experiments partially at −78 °C, completely at room temperature) is apparently base-catalyzed and essentially kinetically controlled. **9A** — **11A** cannot be rearranged to the isomeric complexes in the same base system, so that the migration must take place via an intermediate formed in the reaction. The migration does not take place, however, if the carbanion carries a further substituent R^2. Thus, the reaction of **1** with ethyl propionate leads to **12A** (85%).

Metal shifts of this type were, to our knowledge, previously without example. Thermal 1,3-migrations of an $Fe(CO)_3$ group in acyclic triolefin complexes normally require activation energies of >130 KJ/mol[10]. We found that on prolonged heating of **11B** in boiling toluene, **11A** is partly formed as a *cis/trans* mixture. According to investigations by *Goldsmith* et al.[11], the composition of this product mixture probably corresponds to that of the isomers at thermodynamic equilibrium. Complexes of type **B** are more stable when R^1 is an electron-attracting moiety[10].

Compounds of type **B** can be employed for an unusual repeatable reaction: Thus, **10B** can, after reduction to the aldehyde **8B** (90%)[6a], be subjected to a further condensation/migration sequence leading to the nitrile **13** in 85% yield. The $Fe(CO)_3$ group, which once again experiences a 1,3-shift, here also effects a uniform reaction course.

The free polyolefins are obtainable in approximately 90—95% yield by oxidative decomplexation (1.5 equivalents $Ce(NH_4)_2(NO_3)_6$, acetonitrile, 0 °C, reaction time <1 h). If $FeCl_3$ is used instead of $Ce(NH_4)_2(NO_3)_6$ under the same reaction conditions the yields are 85%[12].

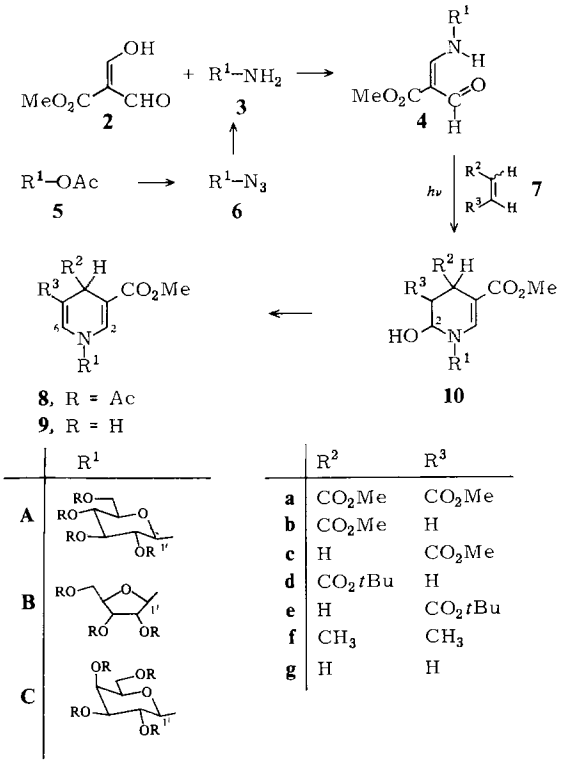
Synthesis of 1,4-Dihydropyridine Nucleosides by Photochemical Cycloaddition**

By *Lutz F. Tietze** and *Andreas Bergmann*

1,4-Dihydropyridine nucleotide coenzymes such as NADH **1a** and NADPH **1b** count among some of the biologically most important compounds[1]. Consequently numerous NADH and NADPH analogues have been prepared and examined regarding their physiological and chemical activities. However, the synthetic methods available hitherto are far from being satisfactory in that they are generally unselective, permit only slight variation of the substituents, and the yields are, at best, only moderate[2].



1a, R = H
1b, R = $HPO_3^{\ominus}$

Herein we describe a novel method which leads directly and in almost quantitative yields to 1,4-dihydropyridine nucleosides **8**. The particular advantage of this new method lies in the possibility of widely varying the substituents on the dihydropyridine nucleus and in the simple introduction of labeling at the ring[3]. A mixture of an *N*-glycosyl enaminecarbaldehyde **4** and an alkene **7** (ratio 1 : 100) in dichloromethane or acetonitrile is irradiated at −20 to −40 °C in a ring reactor (Duran) with a 500 W mercury high-pressure lamp[4]. After 1—5 h the 2-hydroxytetrahydropyridines **10** are obtained in almost quantitative

yield and, without isolation, are converted by heating in toluene (1—3 h, 110°C) in the presence of molecular sieves (4 Å) into the 1,4-dihydropyridine nucleosides **8**, also in almost quantitative yield (Table 1). A chromatographic purification of the products, in which decomposition can occur due to the high reactivity of 1,4-dihydropyridines, is seldom necessary. When the prochiral alkenes **7b**—**7f** are employed, diastereomeric mixtures of **8** are obtained (Table 1). On using the unsymmetric alkenes **7b** and **7d**, small amounts of the regioisomeric cycloadducts **8Ac** (7%) and **8Ae** (8%) are isolated in addition to the 1,4-dihydropyridines **8Ab** and **8Ad**.

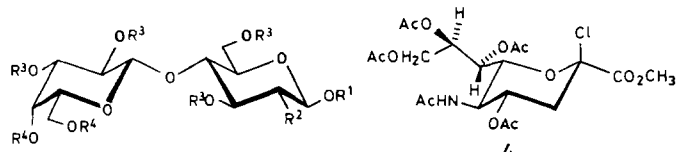
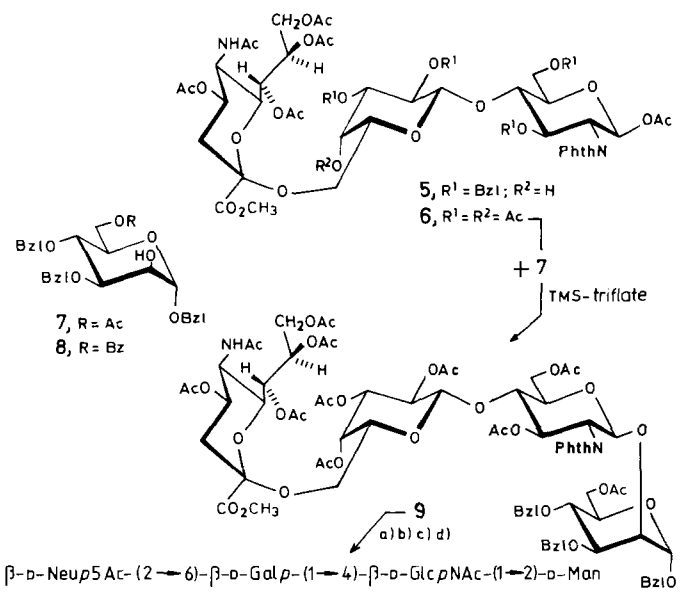
Preparation of an *N*-Acetylneuraminic Acid-Containing Trisaccharide and Its Use in Oligosaccharide Syntheses**



By *Hans Paulsen** and *Holger Tietz*

N-Acetylneuraminic acid is terminally bound to many glycoproteins and glycolipids[2]. The coupling of *N*-acetylneuraminic acid to larger oligosaccharides, however, is difficult. It was therefore of interest to search for an oligosaccharide building block already containing *N*-acetylneuraminic acid and capable of coupling. We have now been able to prepare a trisaccharide building block capable of coupling from *N*-acetylneuraminic acid and lactosamine.



The allylglycoside **1** (Scheme 1), which is capable of functionalization on C-1 and which can be prepared by reaction of the corresponding *O*-acetylated α-1-nitrate[3,4] with sodium allylate[5], was chosen as starting material for the reaction. Benzylidenation and subsequent benzylation of **1** (standard methods) afforded **2** (73%). After reduction of the azido group with H_2S and conversion of the resulting amino group into a phthalimido group[6], the allyl group is removed with $PdCl_2$ and replaced by an acetyl residue (61%). Selective deblocking (80% AcOH, 1 h, 80°C) of the benzylidene group gives the desired glycosyl acceptor **3** (67%), which, under the conditions tested by us, reacts with the chloride of the *N*-acetylneuraminic acid **4**. In the presence of $Hg(CN)_2/HgBr_2$ (CH_2Cl_2), **3** reacts with **4** to give the anomeric mixture of the trisaccharides **5** and

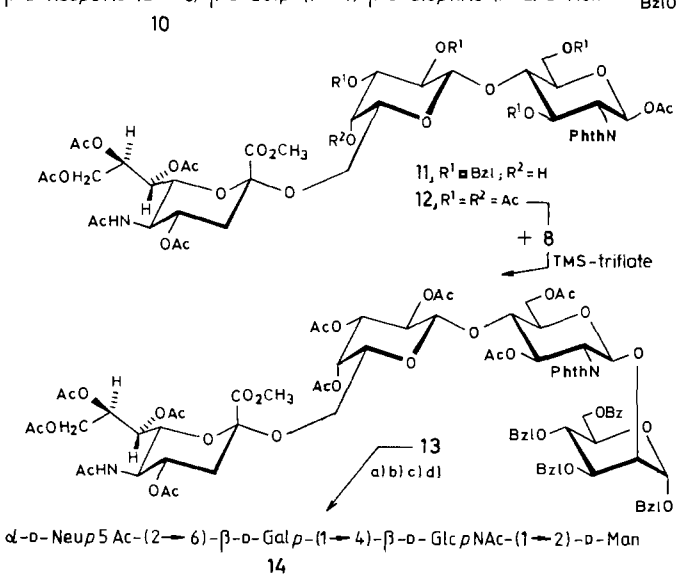
[**] Oligosaccharide Building Blocks, Part 62.—Part 61: [1].



11 in yields of over 60%. Subsequent chromatographic separation furnishes **5** in 37% yield and **11** in 25% yield (assignment by ^{1}H-NMR spectroscopy[6]). Both compounds are capable of coupling and are suitable for a glycoside synthesis.

Scheme 1. a) CH_3OH, 1N NaOH (50:6, v/v), 3 h, 20°C. b) C_2H_5OH, $NH_2-NH_2 \cdot H_2O$ (15:1), 3.5 h, 80°C. c) CH_3OH, Ac_2O (10:3), 20 h, 20°C. d) CH_3OH, H_2O (1:3), Pd–C, 6 h, 30 bar.—Bzl = benzyl, Phth = phthaloyl, Ac = acetyl, Bz = benzoyl, TMS-triflate = trimethylsilyl trifluoromethanesulfonate.

For stabilization of **5** the benzyl groups are replaced by acetyl groups by hydrogenolysis and acetylation (**5**→**6**, 88%). Despite the complexity of the molecule in the case of **6**, a glycosidation by the trimethylsilyl trifluoromethanesulfonate (triflate) method[5] was possible, with the β-*O*-acetyl group on C-1 functioning as leaving group (neighboring group participation). A prerequisite for this reaction is that the glycosyl donor and glycosyl acceptor do not contain any acid-labile groups. Consequently, the 6-*O*-acetate of mannose **7** is resorted to as glycosyl acceptor since 6-*O*-benzyl derivatives are sensitive towards acids. The tetrasaccharide **9** [$[\alpha]_D^{20} = -18.3$ ($c = 3.6$, $CHCl_3$); 400-MHz ^{1}H-NMR (C_6D_6, TMS): $\delta = 5.46$ (1′-H), 4.91 (1-H), 4.43 (1″-H), 2.58 (3‴-H_e), 1.74 (3‴-H_a)] is obtained in 76% yield on reaction of **6** with **7** in the presence of trimethylsilyl triflate and 4 Å molecular sieve (CH_2Cl_2).

For the deblocking of **9**, the *O*-acetyl groups are cleaved and the methyl ester is hydrolyzed in one step with aqueous 1N NaOH; this leads to partial opening of the phthalimido group. On subsequent treatment with hydrazine the phthalimido group is completely removed; the product is purified on Sephadex LH-20 and *N*-acetylated with acetic anhydride in methanol. Finally, the benzyl groups are cleaved hydrogenolytically in methanol. The overall yield of this four-step conversion from **9** to the deblocked tetrasaccharide **10** is 48% [$[\alpha]_D^{20} = -25.2$ ($c = 0.8$, H_2O); 400-MHz ^{1}H-NMR (D_2O, referred to HDO, $\delta = 4.75$): $\delta = 5.20$ (1-H), 4.61 (1′-H), 4.47 (1″-H), 2.40 (3‴-H_e), 2.06 (2 NAc), 1.65 (3‴-H_a)].

The α-product **11** is likewise converted into the acetate **12** and used as a glycosyl donor under similar conditions. The benzoate **8** is used as glycosyl acceptor since the product then obtained is better to purify. Surprisingly, the acetate **12** is less reactive than **6**; consequently, more trimethylsilyl triflate and longer reaction times are required. The tetrasaccharide **13** is formed in 47% yield [$[\alpha]_D^{20} = -16.3$ ($c = 1.6$, $CHCl_3$); 400-MHz ^{1}H-NMR (C_6D_6, TMS): $\delta = 5.56$ (1′-H), 5.05 (1-H), 4.66 (1″-H), 2.64 (3‴-H_e), 2.00 (3‴-H_a)].

13 can be deblocked in the same was as **9**. The α-glycosidically coupled tetrasaccharide **14** is obtained in 48% yield [$[\alpha]_D^{20} = -21.0$ ($c = 1.0$, H_2O); 400-MHz ^{1}H-NMR (D_2O, HDO): $\delta = 5.20$ (1-H), 4.62 (1′-H), 4.44 (1″-H), 2.67 (3‴-H_e), 2.05, 2.02 (2 NAc), 1.72 (3‴-H_a)]. These values agree with the data of the oligosaccharide obtained via another route[7] and with those of the natural products which contain this sequence[8].

Both examples demonstrate that glycoside coupling with the trisaccharides **6** and **12** is possible and that the trimethylsilyl triflate method can also be used even with this complex molecule. The method has the advantage that the *N*-acetylneuraminic acid-containing building block can be coupled to any saccharide.

"Dimers" of Aldosterone**

By *Klaus Lichtwald** and *Michael Przybylski*

The aldehyde function in position 18 was the determining factor in changing the name electrocrotin to aldosterone **1**[1]. As an adrenocortical steroid, **1** exerts a regulatory influence on the metabolism of electrolytes and water (electrolyte balance). Although a general mechanism has indeed been formulated for steroid activity at the cellular level[2], much further effort is required for the resolution of events at the molecular level. Structural investigations have shown that the pattern of substitution in rings C and D of the steroids is of great importance for the mineralocorticoid activity[3].

Depending on its molecular environment, **1** exists as an isomeric mixture or as a pure tautomer[4]; thus, according to *Kirk* et al., mainly the tautomers analogous to **1a** and **1b** are present in the case of 3α,5β-tetrahydroaldosterone in chloroform[5]. The ^{13}C-NMR spectrum of aldosterone in chloroform shows a signal distribution that is not compatible with formula **1**. Consistent with this finding, a thin-layer chromatographic analysis revealed the presence of a mixture of at least six substances. The R_f values indicated that the starting material **1**, aldosterone acetal **2**, and aldosterone-γ-lactone **3**[6,7] were components of the mixture. Their separation by HPLC and their retention times lent further support to this finding. The eluate of the most intense spot (UV) in the thin-layer chromatogram yielded two components **4a** and **4b** on HPLC separation.

The chromatographic behavior of the substances on silica gel [R_f(**1**) < R_f(**4a,b**) < R_f(**2**)] was exactly the converse of that observed on reversed phase (C-18) HPLC separation [R_t(**1**) < R_t(**2**) < R_t(**4a**) < R_t(**4b**)]. This finding suggested an increase in molecular weight with higher lipophilicity of **4a**, **b** compared to **2**. Consistent with this inference, mass spectroscopic investigations (Fast Atom Bombardment (FAB) and Field Desorption (FD)) revealed protonated molecular ions ($MH^{\oplus}$; *m/z* 685) of high intensity in the case of **4a** (Fig. 1). The molecular weight (MW) of 684 corresponds to an aldosterone dimer minus two molecules of water. This was further supported by the observation that FAB mass spectra were obtained with high sensitivity in a solvent/tetraethylene glycol (TEG) matrix, but not in the highly polar matrix glycerine[8]. The FAB mass spectra of **4b** likewise gave a MW of 684, indicative of an isomer which showed similar fragmentation pattern. The proposed structure of **4** is based on the assumption of an oxygen-bridging of C-20 with C-21. Besides the conceivable coupling of both C-20 positions with each other and both C-21 positions with each other, in each case via an oxygen atom, possible variations at the four chiral centers have also not been taken into consideration. An X-ray structure analysis should provide more information in this respect.

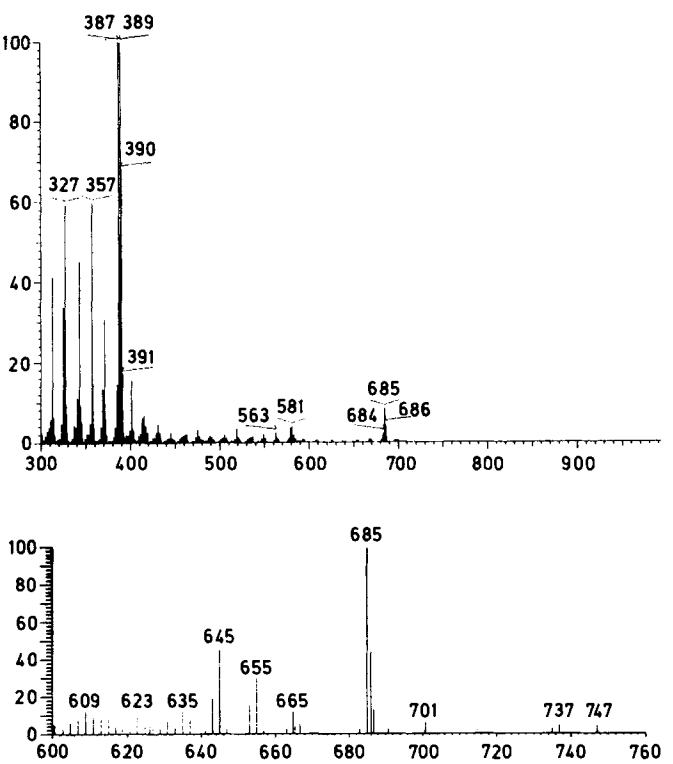

Fig. 1. Mass spectra of the aldosterone derivative **4a** obtained by a) FAB-MS (CH_2Cl_2/TEG matrix) and b) FD-MS (CH_2Cl_2 solution).

It may be assumed that the formation of the "dimers" **4a**, **b** is proton-catalyzed; support for this hypothesis is provided by the additional formation of the substances **2** and **3** which have been reported to be formed under acidic conditions[9]. The existence of such aldosterone derivatives

might be taken into account on considering molecular events during the reaction of aldosterone—assuming their formation is also possible under physiological conditions. In this respect, the finding that the physiological site of aldosterone action in the kidney is close by the site of proton release could be of importance.

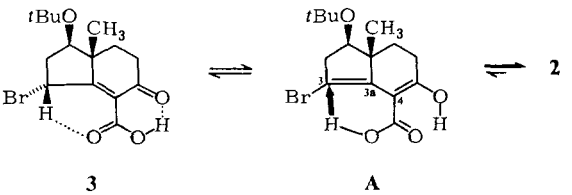
Stereospecific Synthesis of 3-Substituted Hexahydroindane Derivatives

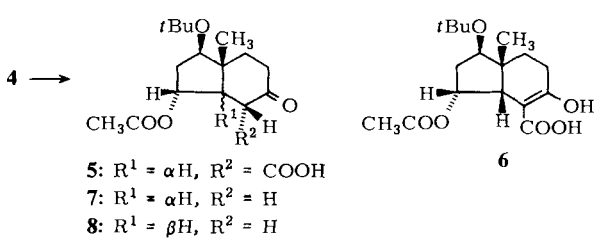


By *Hans-Eckart Radunz** and *Günter Schneider*

The aim of our investigations was to insert an oxygen function stereospecifically into the 3-position of the readily accessible carboxylic acid **1**[1]. Compounds of this type are suitable synthons for rigidified postaglandin analogues. Halogenation of **1** with *N*-bromosuccinimide (NBS) affords the readily crystallizable bromide **2** in 68% yield.

The isomeric bromide **3** can be isolated in amounts less than 10% by rapid chromatography of the mother liquor on silica gel (A60, E. Merck). The relative stereochemistry of the two allyl bromides could be elucidated by ^{1}H-NMR spectroscopy[2]. The observed product pattern was surprising in view of the fact that a high stereoselectivity could not be expected in the NBS bromination, which proceeds via a radical mechanism[3]. In the absence of a radical initiator (e.g. benzoyl peroxide or UV light), no bromination takes place.

It was assumed that **3** is transformed into the bromide **2** via the dienol A (Scheme 1). This assumption is supported by the following findings: (a) in methanol, **3** is slowly transformed into **2**, and (b) an epimeric transformation is not observed with the methyl ester of **3**[4].



Scheme 1.

The signal of the 7αβ-methyl group of the allyl bromide **2** appears at unusually low field ($\delta = 1.51$)[5]. This marked shielding effect can only be explained in terms of a strong 1,3-interaction between bromine atom and methyl group. This interpretation is supported by the ^{1}H-NMR spectrum of the isomeric allyl bromide **3**, in which the methyl signal once again appears in the "normal" position[1] at $\delta = 1.16$ because of the absence of the shielding effect. However, a shielding of the proton on C^1 is observed.

In the following reaction step, **2** is allowed to react with silver acetate in glacial acetic acid; **4** is obtained in 56% yield. Since this reaction ought to proceed by an S_N2 mechanism a product showing the methyl signal in the "normal" position[1] is to be expected; $\delta = 1.16$ is observed.

Subsequent catalytic hydrogenation of **4** should lead to the *trans*-hexahydroindane framework. *Hajos* and other authors[1,6] reported that the hydrogenation of 5-oxo-5,6,7,7a-tetrahydroindanes, which are substituted at C-4 (cf. **1**), affords *trans*-hexahydroindanones. However, if **4** is hydrogenated in ethyl acetate with Pd–C (5%) at room temperature under normal pressure until 1 mol H_2 (per

mol **4**) has been taken up, four new compounds (**5**–**8**) are formed which are chromatographically separable (silica gel, diisopropyl ether). Their structures were elucidated on the basis of spectral data[7]. That **6**, in contrast to **5**, is present in the enolized form is supported not only by the fine structure of the ^{1}H-NMR signal of C^{3a}–H, but also by the fact that only **6** shows an Fe^{3+}-reaction. It follows from the NMR data that the hydrogenation of **4** does not exclusively afford *trans*-compounds (**5** and **7**) but also *cis*-isomers (**6** and **8**) (*trans/cis* ratio ≈ 4 : 1). The primary products **5** and **6** are readily decarboxylated[8], so that only the compounds **7** and **8** can still be detected after hydrogenation, separation of the catalyst, and heating of the filtrate for 1 hour on a water-bath.

We obtained products with *trans*- and with *cis*-hexahydroindane frameworks on hydrogenation of **4**, whereas *Hajos* and *Parrish*[1] did not observe the formation of prod-

[*] Dr. H.-E. Radunz, G. Schneider
E. Merck, Pharmaforschung, Oberleitung Pharmazeutische Chemie
Frankfurter Strasse 250, D-6100 Darmstadt (FRG)

ucts with *cis*-hexahydroindane framework in the hydrogenation of **1**. This was explained in terms of hydrogenation of the 3,3a-double bond of the intermediary dienol and not of the 3a,4-double bond (see Scheme 1, analogue **A**). If this were true the formation of a dienol would lead to a planarization of the symmetry center at C-3. Thus, on addition of hydrogen the C^3-epimer of **5** should be formed. However, this inversion is not observed.

The acetate **7** obtainable from **1** is a molecule which exhibits the same relative stereochemistry at the centers **3**, **3a**, and **7a** as observed in the naturally occurring prostaglandins.

Experimental

2: A solution of **1** (11.1 g, 4.1 mmol) and NBS (10 g, 5.6 mmol) in CCl_4 (300 mL) was heated to boiling for 2.5 h. After cooling, succinimide was filtered off, the filtrate evaporated down in a vacuum, and the residue taken up in a little ether. 9.7 g of **2** (68%) crystallized out within about 12 h on cooling the filtrate in a refrigerator at ca. 0°C. Colorless crystals, m.p. 154°C; IR: 1750, 1640, 1605 cm^{-1} (CO); ^{1}H-NMR: $\delta = 1.18$ (s, 9H, *t*Bu), 1.52 (s, 3H, 7a-CH_3), 3.58 (dd, 1H, $J_{1,2} = 10.1$, $J_{1,2'} = 7.6$ Hz, C^1–H), 5.87 (dd, 1H, $J_{3,2} = 8.9$, $J_{3,2'} = 7.4$ Hz, C^3–H).

3: The isomeric bromide **3** can also be isolated (in smaller amounts than 10%) from the mother liquor on silica gel with ether. Colorless crystals, m.p. 132°C (ether/petroleum ether; IR: 1745, 1640 cm^{-1} (CO); ^{1}H-NMR: $\delta = 1.16$ (s, 1H, 7a-CH_3), 1.24 (s, 9H, *t*Bu), 4.28 (dd, 1H, $J_{1,2} = 10.0$, $J_{1,2'} = 6.3$ Hz, C^1–H), 6.04 (dd, 1H, $J_{3,2} = 5.0$, $J_{3,2'} = 1.2$ Hz, C^3–H).

4: A solution of **2** (3.4 g, 1 mmol) and silver acetate (2 g, 1.2 mmol) in glacial acetic acid (100 mL) was heated to boiling for 3.5 h. After cooling, silver bromide was filtered off, the solvent removed in a vacuum, and the residue crystallized from ether/petroleum ether (1:1); yield 1.8 g (56%). Colorless crystals, m.p. 131–132°C; IR: 3300–2400 (br.), 1750, 1710, 1690 cm^{-1} (CO); ^{1}H-NMR: $\delta = 1.19$ (s, 9H, *t*Bu), 1.21 (s, 1H, 7a-CH_3), 2.03 (s, 3H, acetate), 3.90 (dd, 1H, $J_{1,2} = 11.5$, $J_{1,2'} = 6.5$ Hz, C^1–H), 6.24 (dd, 1H, $J_{3,2} = 8.5$, $J_{3,2'} = 2$ Hz, C^3–H).

Synthesis of $[(C_5Me_5)_2Mo_2XS_3Co(CO)_2]$ Clusters (X = P, As) and Structural Characterization of a μ_2,η^2-AsS Ligand

By *Henri Brunner, Heike Kauermann, Ulrich Klement, Joachim Wachter*, Thomas Zahn,* and *Manfred L. Ziegler*

Spectroscopic investigation of the complexes **1** and **2**, which were synthesized from $[C_5Me_5(CO)_2Mo]_2$ and As_4S_4 or P_4S_3, revealed the possible presence of an unusual μ,η^2-XSX-structural unit[1]. Since it has so far proven impossible to confirm the presence of such a unit by single-crystal X-ray structural analyses, we attempted the preparation of clusters via a secondary reaction with $Co_2(CO)_8$ in the hope that their mode of synthesis might throw some light on the structure of **1** and **2**.

However, according to elemental analyses and mass spectra, the diamagnetic clusters **3** and **4**[2] formed on reaction of **1** and **2** respectively with $Co_2(CO)_8$ surprisingly contained one X-atom less than expected. An X-ray structure analysis carried out on **3** showed the presence of

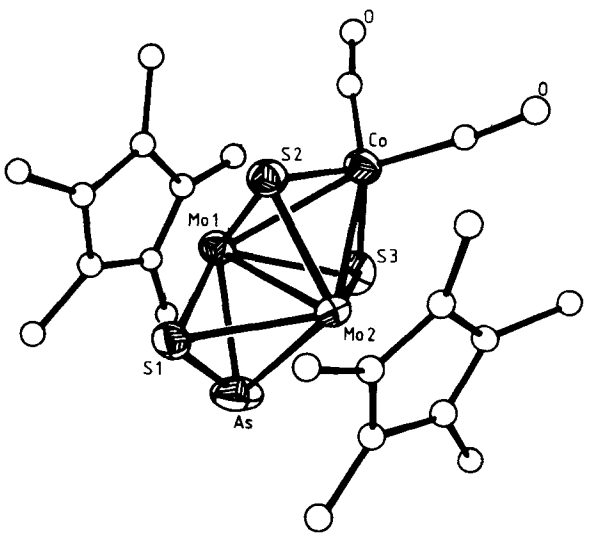

Fig. 1. Molecular structure of **3** in the crystal (ORTEP diagram). Selected bond lengths [Å] and angles [°]: Mo1–Mo2 2.610(1), Mo1–Co 2.722(2), Mo1–As 2.533(2), Mo1–S1 2.517(2), Mo1–S2 2.406(3), Mo1–S3 2.416(4), Mo2–Co 2.725(2), Co–S2 2.178(3), Co–S3 2.165(4), As–S1 2.237(3); Mo2–Mo1–Co 61.4(0), Mo2–Mo1–As 58.7(0), Mo2–Mo1–S1 58.6(1), Mo2–Mo1–S2 57.3(1), Mo1–Co–S2 57.5(1). The As and S1 positions are each 50% statistically occupied by arsenic and sulfur.

an Mo_2Co-triangle bridged by two μ_3-sulfur ligands and a new structural unit, an η^2-AsS ligand as bridge between two Mo atoms. The AsS-ligand, the two S-bridges and the Co-atom lie in a plane bisecting the molecule. The carbonyl groups are located in the plane of the three-membered ring of metal atoms (Fig. 1). Hence, **3** constitutes the first example of a molecule containing complex-stabilized arsenic monosulfide, which, in the free state, is unstable. With the proviso that there is a 50% statistical distribution of arsenic and sulfur at the As and S1 sites, the As–S1 distance in **3** can be said to be 2.237(3) Å, a value which corresponds to the average length of the As–S single bond in α-As_4S_4[4]. We conclude, therefore, that the new ligand has a bond order of 1 and functions as a 5e-donor. Furthermore, if we consider the μ_3-S atoms as 4e-donors and the remaining ligands as 5e-donors (C_5Me_5-moieties) and 2e-donors (CO groups), then each metal atom acquires noble-gas configuration by formation of M–M single bonds. The experimentally determined metal-metal distances lend support to this conclusion.

Remarkably, the $Co(CO)_2$-fragment is incorporated exclusively in the η^2-S_2-group of **1** and **2**, even though there are several sites open to attack in the ligand sphere of the starting complex. The S_2-bridge over the Mo atoms is thereby enlarged to an SCoS unit, while elimination of X from the XSX-bridge leads to formation of the bridging XS-ligand. This apparent lability of an Mo–X bond is confirmed by the sensitivity of **1** towards oxidation: Only the previously reported arsenic-free complexes $[(C_5Me_5)_2Mo_2O_2S_2]$ and $[(C_5Me_5)_2Mo_2OS_3]$ can be isolated from toluene solutions of **1** in presence of air.

Novel MoFeS Clusters from $[(C_5Me_5)_2Mo_2S_4]$ and $Fe(CO)_5$ or $Fe_2(CO)_9$

By *Henri Brunner, Norbert Janietz, Joachim Wachter*, Thomas Zahn,* and *Manfred L. Ziegler*

Thio-transition-metal clusters containing various metal atoms serve as model compounds, both in the catalysis of industrially important desulfurization reactions as well as in the deciphering of bioinorganic reactions. Of particular importance is the coupling of Mo and Fe with sulfur to give "heterocubanes", among which, compounds with a $Mo_2Fe_2S_4$ core are still very poorly represented in the literature. The first such cluster to be prepared and spectroscopically characterized was $[(C_5Me_5)_2Mo_2Fe_2(NO)_2S_4]$[1]. But "mixed" trinuclear clusters with a trigonal pyramidal $M_2M'S_2$ core and a μ_2,η^2-di-(main group element) ligand are also still relatively rare[2].

The three new diamagnetic MoFeS clusters **2**–**4** are formed on reaction of the complex **1** with $Fe_2(CO)_9$ in tetrahydrofuran (THF) (molar ratio 1:1.3). **2** and **4** are also formed in the photochemical reaction of **1** with $Fe(CO)_5$ (in the molar ratio 1:2) in THF[3a]. The composition of each product has been confirmed by elemental analysis and mass spectra. The ^{1}H-NMR and IR spectra[3b] are consistent with the results of the X-ray structure analysis.

Characteristic of the structures of **2** and **3**[4] (Figs. 1 and 2) is a trigonal-bipyramidal Mo_2FeS_2 core; the $Mo_2Fe(CO)_2$ moiety is perpendicular to the plane of the sulfur ligands. As 48e-clusters, **2** and **3** each contain three metal-metal single bonds, consistent with the observed

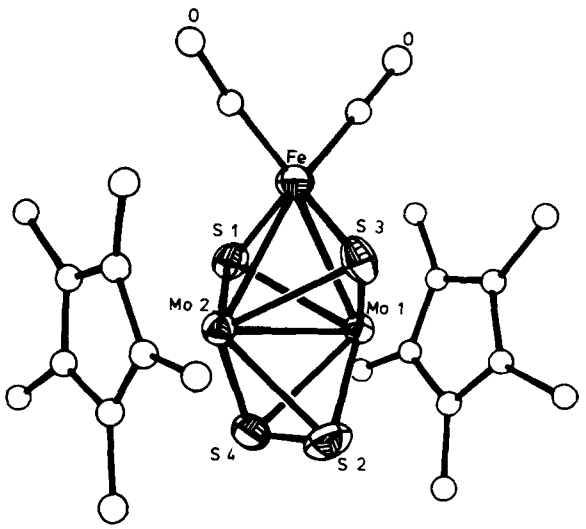

Fig. 1. Molecular structure of **2** (ORTEP diagram). Selected bond lengths [Å] and angles [°]: Mo1–Mo2 2.592(0), Mo1–Fe 2.778(1), Mo1–S1 2.432(1), Mo1–S2 2.437(1), Mo1–S3 2.436(1), Mo1–S4 2.440(1), Mo2–Fe 2.776(1), Fe–S1 2.153(1), S2–S4 2.071(1); Mo2–Mo1–Fe 62.1(0), Fe–Mo1–S1 48.3(0), S1–Mo1–S4 76.5(0), S2–Mo1–S4 50.3(0), S1–Mo1–S3 89.1(0), Mo1–Fe–S1 57.4(0).

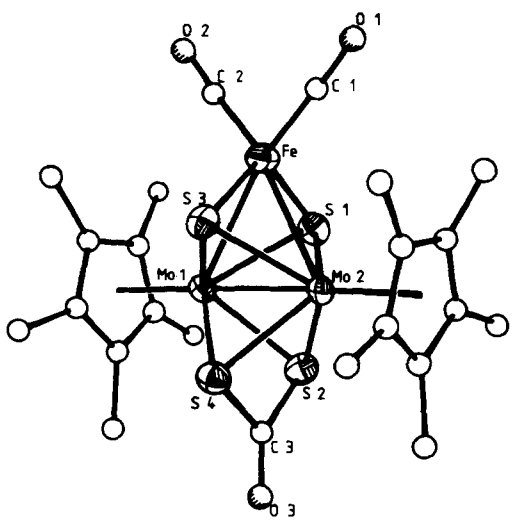

Fig. 2. Molecular structure of **3** (ORTEP diagram). Most important bond lengths [Å] and angles [°]: Mo1–Mo2 2.574(0), Mo1–Fe 2.830(1), Mo1–S1 2.467(1), Mo1–S2 2.470(1), Mo1–S3 2.448(1), Mo1–S4 2.467(1), Mo2–Fe 2.819(1), Fe–S1 2.130(1), S2–C3 1.800(4), S4–C3 1.817(4), C3–O3 1.196(5); Mo2–Mo1–Fe 62.7(0), Mo2–Mo1–S1 58.1(0), S1–Mo1–S2 69.8(0), S1–Mo1–S3 87.1(0), S2–Mo1–S4 68.2(0), Mo1–S4–C3 89.2(1), S2–C3–O3 130.7(3).

M–M distances. Thus, in both cases the relatively short Mo–Mo distance is ascribable to a "bracketing effect" of the bridge ligands. **2** can be regarded as an $Fe(CO)_2$-adduct of **1**[5], whereas **3** unexpectedly contains a dithiocarbonato-ligand as structural element bridging the two Mo atoms.

The X-ray structure analysis of **4**[4] confirms the presence of a $Mo_2Fe_2S_4$-cubane with relatively small differences (up to 0.09 Å) between the Mo–S and Fe–S bond lengths. In **2** and **3**, however, these differences are up to 0.44 Å. There are five metal-metal bonds of equal length (on average 2.803 Å) as opposed to one Fe–Fe distance of 3.334 Å (Fig. 3). A qualitative confirmation of this finding is obtained from the distribution of the 62 valence electrons over the cluster. A similar situation is found in the

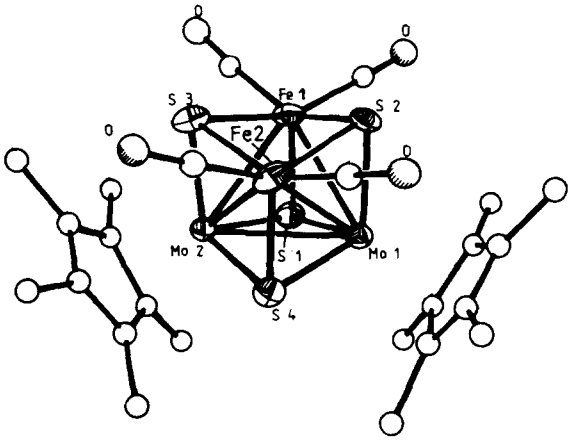

Fig. 3. Molecular structure of **4** (ORTEP diagram). Selected bond lengths [Å] and angles [°]: Mo1–Mo2 2.761(1), Mo1–Fe1 2.832(4), Mo1–Fe2 2.792(3), Mo1–S1 2.357(2), Mo1–S2 2.333(2), Mo1–S4 2.320(2), Mo2–Fe1 2.813(3), Mo2–Fe2 2.815(4), Mo2–S1 2.342(2), Mo2–S3 2.282(2), Mo2–S4 2.303(2), Fe1–S1 2.214(3), Fe1–S2 2.271(5), Fe1–S3 2.330(4), Fe1···Fe2 3.334; Mo2–Mo1–Fe1 60.4(1), Mo2–Mo1–Fe2 60.9(1), Fe1–Mo1–Fe2 72.7(1).

complex **5**, which is isoelectronic with **4** and is accessible from **6** and $Ni(CO)_4$[6]. However, in contrast to **1**, **5** is only able to incorporate $Fe(CO)_5$ or $Fe_2(CO)_9$ in a 66e-cluster **7** with planar metal framework[7]. The 62e-complex **8** obtainable from **1** and $Mo(CO)_6$ in boiling toluene should, on the other hand, be isostructural with **4**.

$[(C_5H_5)_2Mo_2Ni_2(CO)_2S_4]$	$[(MeC_5H_4)_2Mo_2(SH)_2S_2]$
5	**6**
$[(MeC_5H_4)_2Mo_2Fe_2(CO)_6S_4]$	$[(C_5Me_5)_2Mo_4(CO)_6S_4]$
7	**8**
$[(MeC_5H_4)_2V_2S_4]$	$Hg[Fe(NO)(CO)_3]_2$
9	**10**

The clusters **2**–**4** are formed in different ways: **2** and **3** can be synthesized by stepwise substitution of CO in the carbonyliron complexes by the two μ-S bridges in **1**, whereas transformation of the η^2-S_2-ligand into two μ_3-S-bridges requires a redox reaction with participation of the carbonyliron compounds. This reaction behavior essentially conforms with that of the vanadium complex **9**, which gives a similar reaction sequence with the iron complex **10**, resulting in a 58e-cluster with a $V_2Fe_2S_4$ core[2b]. However, the extraordinarily mild carbonyl transfer from $Fe_2(CO)_9$ to the η^2-S_2-ligand warrants further investigation.

Diamminebis(1,5-cyclooctadiene)(μ-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-N^7,N^{16})dirhodiumbis(hexafluorophosphate): An Example of Simultaneous First and Second Sphere Coordination**

By *Howard M. Colquhoun, Simon M. Doughty, Alexandra M. Z. Slawin, J. Fraser Stoddart**, and *David J. Williams*

Previously, we have observed several examples[1] of second sphere coordination[2] of transition-metal complexes by crown ethers. Although numerous cases of first sphere coordination of transition metals to macrocyclic polyether ligands containing nitrogen atoms have been described[3], we now report a remarkable example of simultaneous first and second sphere coordination of rhodium by 1,4,10,13-tetraoxa-7,16-diazacyclooctadecane **1**[4].

cyclo-[(O−CH_2CH_2)$_2$NH−CH_2CH_2]$_2$ **1**
[Rh(cod)$(NH_3)_2$][PF_6] **2**
[{Rh(cod)$(NH_3)_2$}$_2$ · **1**][PF_6]$_2$ **3**

The fortuitous discovery[5] of [{Rh(cod)$(NH_3)_2$}$_2$ · **1**][PF_6]$_2$ (cod = 1,5-cyclooctadiene) **3** followed an unsuccessful attempt to isolate a crystalline adduct between [Rh(cod)$(NH_3)_2$][PF_6] **2**[6] and **1**. Elemental analysis[5] indicated the formation of a 2:1 covalent complex with loss of 2 NH_3[7]. X-Ray analysis[8] not only confirmed the constitution of the complex **3** but also revealed several interesting conformational features (Fig. 1). The complex contains a

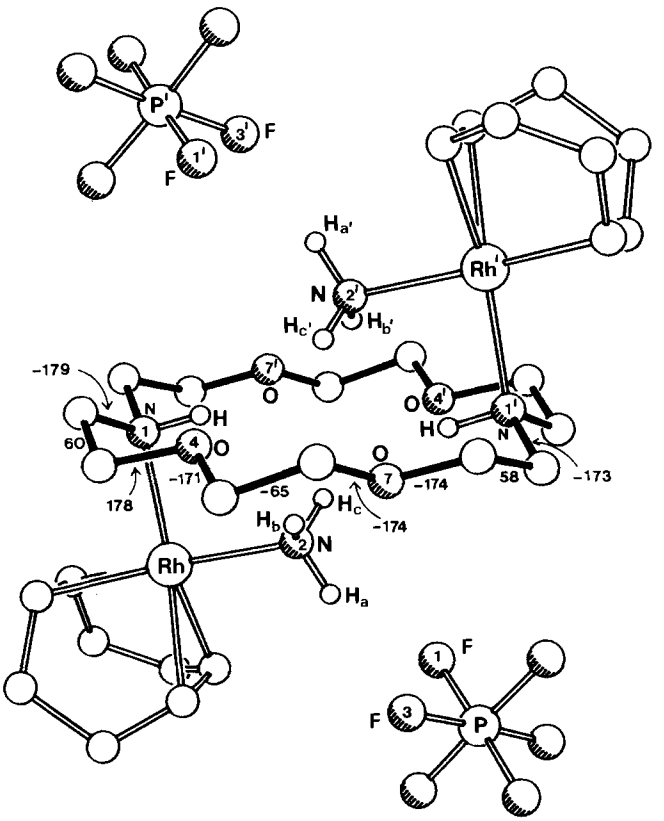

Fig. 1. Structure of **3** in the crystal. **3** is monoclinic, $a = 11.445(3)$, $b = 11.329(3)$, $c = 15.192(5)$ Å, $\beta = 90.45(2)°$, $V = 1970$ Å^3, space group $P2_1/n$, $Z = 2$, $\rho = 1.71$ g cm^{-3}, $\mu Cu_{K\alpha} = 86$ cm^{-1}, 2213 independent reflections with $[|F_o| > 3\sigma(|F_o|), \theta \leq 55°]$, $R = 0.101$. Torsional angles [°] associated with the 18-membered ring are shown beside the relevant bonds. Selected bond lengths [Å]: Rh−N(1) 2.17(1); Rh−N(2) 2.14(1). Selected bond angles [°]: Rh−N(1)−C(2) 117(1); Rh−N(1)−C(9') 116(1); C(2)−N(1)−C(9') 111(1). Intramolecular contact distances from N(2) to O(4), O(4'), O(7), O(7'), F(1), F(3): 3.22, 3.50, 3.45, 3.45, 3.22, 3.13 Å. Distance of N(2) from the mean plane of the ring heteroatoms: 1.92 Å. N(2)···N(2') distance: 3.97 Å. The PF_6^- ions have two orientations of estimated occupancies 0.65 and 0.35. Only the orientation of the major occupancy is illustrated.

crystallographic center of symmetry at the center of the 18-membered ring[9]. Despite the torsional freedom around the N(1)−Rh bonds, the ammine ligands [N(2)] are oriented directly over the faces of the macrocycle. There is also an appreciable flattening of the expected tetrahedral geometry at N(1), which is confined to the Rh−N−C angles (117 and 116°), enabling a closer approach of the ammine ligands to the faces of the macrocycle. However, the resulting N(2)···O distances are still rather long with only N(2)···O(4) (3.22 Å) lying within what would conventionally be considered a hydrogen bonding distance. In this instance, the contact is to an oxygen atom [O(4)] on the opposite face of the macrocycle, i.e., a nesting arrangement[10] analogous to that observed in [$(Ph_3PMe)_2$ · [18]crown-6][PF_6]$_2$[11]. The associated H_b···O(4) distance and N(2)−H_b···O(4) angle are 2.41 Å and 142°, respectively. The other H···O distances are 2.60 Å for H_b···O(7) and 2.59 Å for H_c···O(4'). The associated N(2)···O distances are given in the Figure caption[12].

[**] This work was supported by the Science and Engineering Research Council in the United Kingdom.

To our knowledge, this is the first example[13] of a crown ether containing nitrogen atoms acting as both a first and second sphere ligand towards a transition metal. Clearly, an extensive range of such complexes should exist[14]. This report could herald the preparation of a wide range of novel compounds, including polymers, in which transition-metal complexes and aza-crown ethers are covalently bonded.

BOOK REVIEWS

The Analysis of Gases by Chromatography. By *C. J. Cowper* and *A. J. DeRose*. Pergamon Press, Oxford 1983. xii, 147 pp., bound, DM 114.00.

P. G. Jeffery writes in the foreword that he hopes that this book will be received with the same enthusiasm that greeted his contribution "Gas Analysis by Gas Chromatography" more than ten years ago. This book by *Cowper* and *DeRose*, which is published as Volume 7 of the "Pergamon Series in Analytical Chemistry" and which really ought to be entitled "The Analysis of Gases by *Gas* Chromatography" is long overdue; since the publication of the 2nd edition of *P. G. Jeffery* and *P. J. Kipping's* book in 1972, this field of application of gas chromatography has undergone immense development, which is documented in countless publications. However, a comprehensive review of this particular area has been lacking for a long time, apart from a company brochure entitled "Fundamentals of Gas Analysis by Gas Chromatography" by *B. Thompson*.

The present volume has certainly succeeded in largely closing this gap. A short introduction devoted to the problems and peculiarities of gaseous samples as compared with those of liquids is followed by an account of the apparatus required for such analyses. Alongside the equipment for regulating and controlling the flows of carrier gas and auxiliary gases and for sample introduction the main emphasis is on the detectors used in gas analysis. The focal point of this book lies in the three chapters that follow, in which there is a 43 page-long detailed discussion of the normal separating materials, the choice of carrier gas in connection with the detector of choice for a particular problem, the possibilities of multi-column operation and specific operating methods. Arrangements for two and three column operation with valve switching and "valveless" according to *Deans*, the techniques of fore and back flushing, heart cutting, and other techniques are discussed with the aid of a large number of operating strategies.

A chapter devoted to examples of applications follows, in which suggestions for the separation of the components of air, of noble gases, of natural gas, of refinery, synthesis and fuel gases are illustrated with numerous chromatograms. Neither is stimulation lacking concerning the separation of gaseous sulfur, nitrogen and halogen-containing compounds, nor the separation of isotopes and the seldom analyzed gaseous compounds of boron, silicon, germanium, phosphorus and arsenic. In all this, account is taken of the circumscribed size of the book and, in the main, the reader is referred back to the literature.

Chapter 7 is devoted to the analysis of liquified gases and to gases dissolved in liquids. Emphasis is laid on the devices used for sampling, handling and dosing. Head-

space analysis is deliberately omitted and the reader is referred to the book by *Hachenberg* and *Schmidt*. The authors devote the last two chapters to the quantification and evaluation of chromatograms and to the preparation of standard gas mixtures. For the latter they limit themselves to a brief review of the various methods and techniques for the preparation of mixtures of gases and their critical assessment.

The book includes an extensive reference list in order of authors' names (172 references), which includes publications up to 1981. Additionally an appendix includes publications from the years 1981 and 1982 (19 references).

A point worthy of criticism is the plethora of units quoted. With Anglo-American nonchalance and uninfluenced by IUPAC recommendations or even SI regulations, pascals, pounds per square inch, atmospheres and metric and imperial units of length are quoted alongside each other. This will, however, not present any difficulty to the analyst who practises gas chromatography every day.

This book is written for the man at the bench. It is easy to read, comprehensibly laid out, and easy to understand even for the reader whose native language is not English. There are almost no printing errors. Within its compass of 140 pages the book contains a wealth of information, which will be of great use to the reader who is acquainted with the basic principles and practice of gas chromatography in helping him in his choice of apparatus and in the analysis of complex mixtures of gases.

Atomabsorptionsspektrometrie. By *B. Welz*. 3rd completely revised edition. Verlag Chemie, Weinheim 1983. xiii, 527 pp., bound, DM 128.00.

Almost every new edition of a scientific or technical book is offered to the reader as being "completely revised". During the period of eight years between the publication of the second edition[*] and the present third edition atomic absorption spectroscopy has undergone a great deal of development. The basic principles of AAS remain unaltered, but general knowledge has been greatly augmented through the large increase in the application of this analytical technique. A really "new" book must combine the old basic knowledge with the new developments, additional fields of application, and also a critical description of the method. *Welz* has attempted this in the new edition and seems to have succeeded well. The wealth of material has almost doubled the size of the book; the number of figures has been enlarged from 73 to 140, the number of tables has only been slightly increased from 46 to 51. The real extent of the enlargement of knowledge, however, is best seen in the additional 1103 references; the total is now 2491. The increase demonstrable in these numbers is sufficient alone to justify the publisher's claim of "complete revision" of this book.

The additional figures are particularly welcome, both in the sections covering the basic principles and in those dealing with interferences. The clarity is significantly improved in both cases. The beginner receives an easier entry into the basics of the subject. Those who are already familiar with the problems of AAS can estimate the real extent of interferences much better with the aid of the diagrams.

The methodic layout of the volume is very similar to that of the previous edition. The chapters are naturally somewhat longer, but neatly tailored to accommodate the newer methods. A short introduction is followed by a brief, but adequate, description of the radiation sources in use nowadays (e.g. HCL, EDL). The chapter on atomization techniques includes the flame technique, the graphite furnace technique, the hydride and cold vapor techniques. The author deals both with the basic theory and with the current design of apparatus for each method. The historical outline of the techniques and further reference to specific techniques convey not only topical hints but a general picture to the reader with a greater interest in AAS. Concisely constructed chapters on optics and detection and output give an insight into spectrometer structure. Since most users of AAS do not wish to rebuild their instruments a short treatment here is appropriate. A great deal of space is devoted to interferences in AAS. They are described in a separate chapter, but also in the detailed section "Techniques of atomic absorption spectroscopy". This indication of the many possibilities of interference can be of great help to the practitioner in avoiding systematic errors in his determinations. A great deal of space in this context is devoted to the hydride and cold vapor techniques, where even today the interferences often constitute unresolved problems. The third edition too contains the indispensable descriptions of the individual elements. For each element the description of the standard conditions is followed by allusion to the various sources of interference. Although only a minority of possible interferences can be covered in such a section, it will certainly be of help in avoiding a multiplicity of the more usual errors.

No matter what its length the chapter devoted to specific applications is, considering its aims, of necessity too short. This deficit is made up for here by the large number of references to specific applications in the original literature.

"Welz" is the only German-language book dealing with atomic absorption spectroscopy. The 3rd edition can be understood both as a textbook and as a laboratory handbook. It can provide both the interested laboratory technician and the experienced practitioner of AAS with a profusion of practical advice and a deeper understanding of the method.

Transition Metal Carbene Complexes. With contributions by *K. H. Dötz, H. Fischer, P. Hofmann, F. R. Kreissl, U. Schubert*, and *K. Weiss*. Verlag Chemie, Weinheim 1983. xiii, 264 pp., bound, DM 120.00.

This book is dedicated to Professor *E. O. Fischer* and is written by some of his more recent senior co-workers in honor of his 65th birthday (November 10, 1983). The theme of the book relates to an area discovered by the dedicatee in 1964, and has been a principal preoccupation of his group in the intervening years. Hence, the appropriateness of the topic and the selection of the contributors is to be commended.

The book is attractively produced. Details of its chapter headings are as follows. 1. The Synthesis of Carbene Complexes *(H. Fischer)*, 66 pages, 476 refs.; 2. Spectroscopic Properties of Transition Metal Carbene Complexes *(H. Fischer* and *F. R. Kreissl)*, $1\frac{1}{2}$ pages, 12 refs.; 3. Solid State

[*] Cf. *Angew. Chem. Int. Ed. Engl. 15* (1976) 447.

Structures of Carbene Complexes *(U. Schubert)*, 37 pages, 159 refs.; 4. Electronic Structures of Transition Metal Carbene Complexes *(P. Hofmann)*, 35 pages, 55 refs.; 5. Metal Complexes from Carbene Complexes: Selected Reactions *(F. R. Kreissl)*, 37 pages, 174 refs.; 6. Carbene Complexes in Organic Synthesis *(K. H. Dötz)*, 34 pages, 88 refs.; 7. Carbene Complexes as Intermediates in Catalytic Reactions *(K. Weiss)*, 18 pages, 75 refs.; 8. Mechanistic Aspects of Carbene Complex Reactions *(H. Fischer)*, 16 pages, 76 refs. It is somewhat unexpected that there should be no subject index.

In the Preface, the authors indicate that their aim is to identify principles rather than to attempt to provide a comprehensive coverage of the field. No doubt it is right that they should concentrate their attention on what are now known generally as Fischer-type carbenemetal complexes, that is to say, they devote the majority of their detailed attention to complexes of the type $[M(CO)_5(CRR')]$, in which M = Cr or W, R is an alkyl or aryl group, and R′ is a π-electron-donor group such as methoxy or amino. In most chapters there is no indication of the literature cut-off date; but Professor Schubert, who incidentally does provide a comprehensive table of data on structures (150 in all), states that his bibliography coverage ends with September 1982.

The authors are, of course, experts in their fields. Therefore, it is not unexpected that they write with authority. Two chapters seem less good than might have been anticipated. To cover spectroscopy in $1\frac{1}{2}$ pages and in so doing ignore a topic such as the rotational barrier around the metal-carbon bond is surprising; and, moreover to have references, which with two exceptions (1974, 1977) terminate in 1972 is also curious. The section dealing with carbene complexes as catalytic intermediates could quite well have been omitted, in the light of the rather low level at which the discussioni is pitched, and the existence of superior reviews of this topic.

This book is clearly to be welcomed, particularly as a useful summary of some of the major achievements in this field of the Munich group. It will be of considerable value to other workers elsewhere; although they might well have preferred a more comprehensive coverage, with perhaps a somewhat different balance.

E. O. Fischer's achievements in organometallic chemistry are, of course, outstanding. This book gives readers an opportunity to reflect how, in only one of his major areas, a vast amount of current chemistry can be directly traced back to his initiatives. Furthermore his skill as a teacher has obviously been transmitted to many of his coworkers.

Monoclonal Antibodies: Their Chemistry, Functions, and Possible Uses

By Friedrich Robert Seiler*, Peter Gronski, Roland Kurrle, Gerhard Lüben, Hans-Peter Harthus, Wolfgang Ax, Klaus Bosslet, and Hans-Gerhard Schwick

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday

In December of last year the Nobel Prize for Medicine or Physiology was awarded to the natural scientists *N. K. Jerne, C. Milstein,* and *G. Köhler.* These three immunologists have contributed fundamentally to our understanding of antibody synthesis by the individual immune cell. They confirmed the rule, established in the sixties, that *only one antibody comes from each type of immune cell,* thus giving it the status of a dogma. *Jerne* worked out the basic understanding of the great variety of antibodies, and his Jerne-Plaque-Test (1963) has enabled us to describe and analyze a single antibody-producing immune cell in vitro. Thus, the study of immune cell interaction and the cooperation of lymphocyte subpopulations, which leads to the formation of antibodies, received decisive impulses and important methodological prerequisites. In 1975 *Köhler* and *Milstein* succeeded in permanently stabilizing, i.e., *immortalizing,* the antibody production of an already immunologically specifically primed mortal immune cell by means of cell fusion *(hybridization)* with an immortal, cancerous immune cell (myeloma cell). The hybrid cell and the hybrid cell clone grown from it in cell culture produced a homogeneous antibody, having the desired constant binding specificity, in a practically unlimited fashion and independently of an animal organism, a *monoclonal antibody.* This scientific breakthrough was the beginning of a tremendously stimulating new biotechnological development, which very quickly spread to laboratories in diverse fields and which today enables us to take up, and in part even solve, scientific, technical, and medical problems that would otherwise not have been analyzable at present.

1. Introduction

Emil von Behring was the first (1890) to discover antibodies as the carriers of immunity in the serum of an organism immune against a toxic agent[1]. He was awarded the first Nobel Prize for Medicine in 1901 for his therapeutic success with immune serum won from previously specifically vaccinated animals. Not until long after his discovery, however, between 1950 and 1970—when protein structure chemistry and immune chemistry had been inspired by many new analytical and preparative methods, the use of immunodiagnosis with antibodies had become established, and immunological research had been challenged by new medical problems, for instance graft rejection—could the structure of the antibody molecules be explained and a better understanding of the extent of their functions be obtained.

In 1972 *G. M. Edelmann*[2] and *R. R. Porter*[3] were awarded the Nobel Prize for their contributions to explaining the structure of antibodies. The analysis of pathologically occurring myeloma proteins also proved useful in their work. These turned out to be monoclonal antibody molecules, partial molecules, or fragments thereof produced in an uncontrolled way by a degenerate immune cell clone and appearing in unusually high concentrations in the serum or the urine of patients. For the immunologists, however, the *myeloma cells*, the malignant cells producing these proteins pathologically, were important aids in achieving their aim of developing *immortalized immune cell hybrids* and producing *monoclonal antibodies* in vitro. Thus the honor afforded last year to the work of *N. K. Jerne*[4] and of *C. Milstein* and *G. Köhler*[5] with the Nobel Prize logically follows upon nearly one hundred years of development in the field of antibodies.

This review of monoclonal antibodies does not intend to cover the immense and still growing flood of publications in this new field. Its intention, rather, is to stress the particular properties of *monoclonal* antibodies and to compare them to *heteroclonal* and *polyclonal* antibodies in order to illustrate how monoclonal antibodies can provide us with a new and deeper understanding of the great variety of antibodies and their functions. We intend to show how a monoclonal antibody can emerge from an antibody family, which previously was only generally understood as a group with structures and properties that varied within certain limits, and how it thus suddenly acquires its own determination, significance, and use. Above all, attention will be directed towards the new technical and medical uses known at present or envisioned for the future.

2. Antibody Formation

2.1. Antibody Formation in vivo

When foreign substances or infectious pathogens invade the body of a vertebrate or when organs are transplanted from a donor to a recipient, the body defends itself, by means of its immune apparatus, with protective reactions, which normally lead to the elimination of the foreign substances from the body. The white blood corpuscles, the immune cells, are the vehicles of the immune system. These are, on the one hand, phagocytosing cells, such as *granulocytes* and *macrophages*, and, on the other, lymphocytes, which can be divided into two groups—*T-lymphocytes* (thymus-determined) and *B-lymphocytes* (bone-marrow-derived). In the course of an immune response, resting B-lymphocytes finally form, after several stages of development, mostly under the influence of T-lymphocytes and their hormone-like immune factors, differentiated *plasma cells*, whose only function is antibody synthesis. Antibodies are protein molecules and belong to the large group of immunoglobulins (see Section 3). They are capable of binding with partial structures (determinants) on the surface of foreign substances, the *antigens*, in a highly specific manner, and thus of initiating the expulsion of the antigens from the body[6, 7].

Antibodies are coded by the V-genes (variable part; see Section 3) and by the C-genes (constant part) of DNA. Both gene groups are situated on *one* chromosome, but separated by an intron which plays no part in synthesis. For their biosynthesis, the complete DNA section, together with the intron, is first transcribed into RNA. The intron is then cut out and the shortened RNA strand appears as mRNA. This mRNA codes for the sequence of an amino acid chain of the antibody molecule, which is synthesized at the ribosome. After the linking of usually two heavy and two light chains by disulfide bonds and the glycosylation of the heavy chains, the completed antibody molecule is secreted out of the plasma cell.

One important functional characteristic of an antibody molecule is its specificity for only *one* determinant on *one* antigen. This also means that an immunologically determined maturated B-cell as its succeeding antibody producer, the plasma cell, only produces one antibody type of one specificity, a *monoclonal antibody* as it were. However, in response to an antigen stimulus the organism always produces an antibody family with related specificity and reaction patterns, namely, *heteroclonal antibodies*. In this way it is more able to protect itself and is safeguarded in a number of ways. The family includes antibodies against different determinants on one antigen as well as those which differ in form and strength of binding. Thus it is almost impossible to isolate a monoclonal antibody from a heteroclonal serum, since these antibody molecules with their related specificities are, as a rule, too alike in their protein chemical properties. It is likewise not possible to isolate a plasma cell and cultivate a clone from it in order to produce monoclonal antibodies, since these cells cannot survive in a culture medium.

2.2. Antibody Formation in vitro

It was the pioneering work of *G. Köhler* and *C. Milstein*[5] that first made the in-vitro synthesis of a monoclonal antibody with the desired specificity and in almost any amount possible. They obtained B-lymphocytes from the spleen of mice specifically immunized against sheep erythrocytes, a cellular antigen, and then brought them into close contact with a mouse myeloma cell line (X63-Ag8) along with a fusion-promoting agent (Sendai virus; polyethylene glycol 4000; dimethylsulfoxide), thus achieving cell fusion *(hybridization)*. The fusion mixture was cultivated in a selective culture medium (HAT medium, containing hypoxanthine, aminopterine, and thymidine), in which only *hybridoma cells* are able to grow[8, 9].

Although the myeloma tumor cell is immortal and grows in a culture medium, it does not have the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) and cannot survive in a HAT medium. Only those cells can multiply in a HAT medium which contain the enzyme HGPRT, which enables exogenously supplied hypoxanthine to be used for the salvage pathway of purine nucleotide synthesis. Aminopterine, an antagonist of folic acid reductase, blocks the main synthesis pathway for thymidine. Hybridoma cells are HGPRT+ and also contain the enzyme thymidine kinase (they are TK^+); thus, they can make use of exogenously supplied hypoxanthine and thymidine. This is also of significance for myeloma cell line

variants, selected on account of a thymidine kinase defect[8, 10].

The hybrid cells are not all useful producers of monoclonal antibodies at first, since they contain chromosomes of both parental lines and can, in principle, produce two types of both heavy and light antibody chains. A monoclonal antibody, however, only consists of one type of heavy and light chain, which should only be coded by spleen cell chromosomes, for antibody specificity is selected via the specificity of the fused spleen cells. Hybrid cells lose chromosomes during the first cell divisions; the number of chromosomes is reduced from about 112 (40 from the B-lymphoblasts and 72 from the myeloma cell) to a more stable number of about 70 to 80. Thus, the proteins that are coded on the lost chromosomes cannot be synthesized. A purging process therefore takes place at this stage of cloning. The useful clones must then be especially carefully selected, so that the desired hybridomas and monoclonal antibodies are obtained. Finally, after the elimination and destruction of all undesired cells and unusable hybrid cells, the selected and stabilized clones are continuously multiplied in tissue culture or in the peritoneum of the mouse (higher antibody yield). In order to maintain the stock, parts are frozen in liquid nitrogen; they can thus be stored for a practically unlimited period of time and reintroduced into the cell culture at will.

3. Antibodies: Basic Structure and Function

The understanding of the structure of antibody molecules, from the primary structure up to an exact three-dimensional structure[11–13], afforded insights into their biosynthesis and genetic determination and made possible a further understanding of their biological significance and function.

All antibody molecules are built up according to the same scheme and have four structural features in common (Fig. 1)[14, 15]:

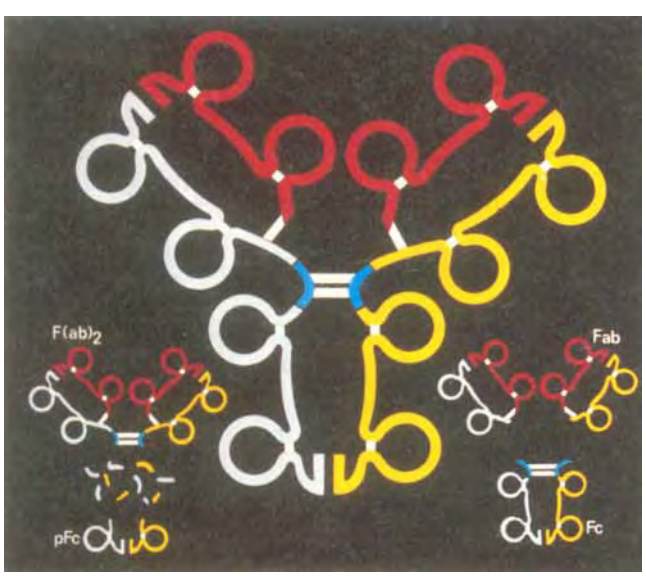

Fig. 1. Model of an immunoglobulin G molecule. Red: light chains (L-chains); light blue and yellow: heavy chains (H-chains); dark blue: hinge (hinge region); white: disulfide bonds. Bottom left: the results of cleavage with pepsin [F(ab')$_2$ and pFc]. Bottom right: the results of cleavage with plasmin or papain [Fab and Fc]. For further details see text.

- Antibodies are symmetrical and consist, in the case of immunoglobulin G (IgG), of two heavy (H) chains (50 kDa) of equal length and of two light (L) chains (25 kDa) of equal length. The L-chains flank the H-chains from their amino end onwards; L- and H-chains are joined by a number of different chemical bonds. Thus they constitute two antigen-binding moieties of the molecule, the Fab parts *(fragment antigen binding)*. The two still free halves of the H-chains link together and form the stem of the molecule (Fc moiety; *fragment crystallizable*). The overall structure therefore has the T- or better known Y-form (Fig. 1).
- The basic structural component of both the H- and the L-chains is a polypeptide chain folded in about the same way in each unit (pleated sheet structure) and with ca. 110 amino acids and a molecular weight of about 12 kDa. L-chains are always composed of two such basic components *(domains)*, the H-chains of IgG and IgM of four and five domains, respectively. The domains are connected over short, mobile polypeptide pieces *(switch region)*, which contain the functionally important hinge *(hinge region)* of the antibody molecule in the area where the H-chains are linked by disulfide bonds. This region allows great mobility of the Fab arms during interaction with the antigen and is particularly exposed to attack by proteases. Thus the enzymes plasmin and papain and certain leukocyte proteases cleave the IgG molecule into an Fc and two Fab fragments (Fig. 1, bottom right). Pepsin and certain tissue cathepsins cleave IgG into pFc and still bivalently binding F(ab')$_2$ fragments (Fig. 1, bottom left).
- In each of the first *N*-terminal domains of the H- and L-chains there are variable sequences (V-domains), whereas all the other domains of a particular immunoglobulin class have largely constant amino-acid sequences (C-domains). The C-domains thus ensure the structural and functional uniformity of an Ig class, whereas the V-domains, with their three or four hypervariable regions, are responsible for the diverse specificity for the binding of all possible antigens. In order to bind an antigen the V-domains of H- and L-chains are joined together to act, as it were, as a hand of the antibody molecule which seizes the antigen and holds on to it.
- The disulfide bonds are an essential and stabilizing structural feature. Each domain contains an interchain bond in the vicinity of the pleated sheet. The L-chains are linked to the H-chains, and the H-chains to one another in the hinge region, via interchain disulfide bonds. The number of bridges between the H-chains varies within the subclasses. Carbohydrates are found in the C_H2 domain; they prevent an intensive protein-protein interaction in this domain area.

3.1. Human Immunoglobulins

Despite the great uniformity in the structures of the immunoglobulins, there are also clear differences, as can be seen from the arrangement of human immunoglobulins in Fig. 2: in the number of H-chain domains, the number and position of the disulfide bonds, and in the assembly of the

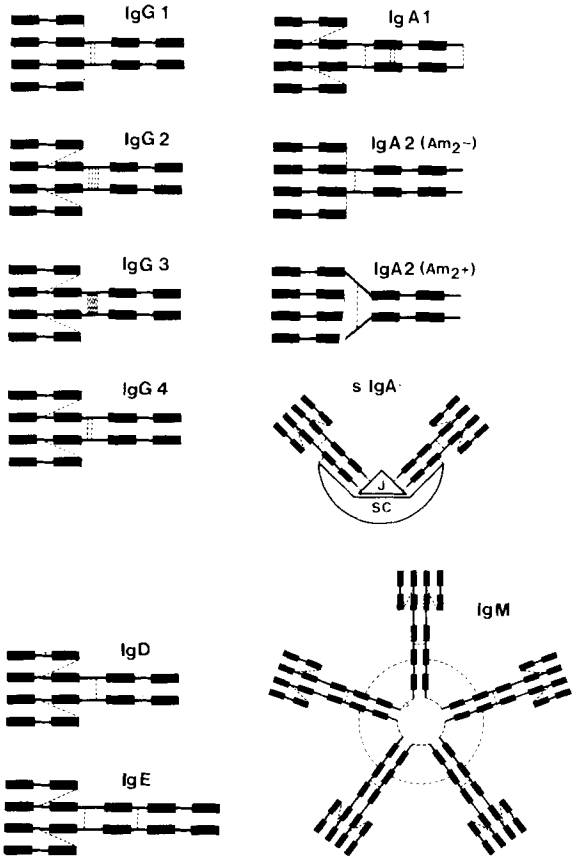

Fig. 2. Model structures of the classes of human immunoglobulins and the subclasses of IgG and IgA. The chains are composed of linearly arranged components of the same type, the domains (▬); these are linked by switch peptides (—) and disulfide bonds (----). J: J-chain; SC: secretory components. For further information see text.

basic molecules, for instance as dimers (IgA) or pentamers (IgM). The immunoglobulin classes are defined as IgG, IgA, IgM, IgD, and IgE according to their differently constructed H-chains and therefore their different overall structures. The H-chains are named according to their corresponding Greek letters (γ-, α-, μ-, δ-, and ε-chains). There are only two variations for the L-chains of all immunoglobulin classes and subclasses (e.g., IgG1 to IgG4), kappa and lambda chains (κ and λ).

The five immunologically and biochemically easily distinguishable classes of antibody molecules appear in an organism in greatly varying quantities and fulfill different functions. Apart from their different molecular weights, their different half-lives, etc., the following immunological features of the individual Ig classes should be stressed: IgE is the main mediator of allergies, IgD is probably an important receptor on lymphoid cells in the early phase of differentiation, IgM is a natural antibody in the first phase of immune resistance, the so-called primary reaction, with special significance for the lysis of bacteria, IgA is the main carrier of immune resistance in secretions and on mucous membranes and is conspicuously active against viruses, and secretory IgA is the most important antibody in colostrum. There are several structural variants of IgA which also have functional significance. The dimer of IgA, bound by a *J*-chain and equipped with a *secretory piece*, constitutes the acid-resistant form of IgA. IgG, which exhibits almost all the functional characteristics of antibodies, fulfills, moreover, the task of passive immune protection in the fetus, since it is the only immunoglobulin that is able to pass the placental barrier. IgG constitutes about 75 to 80% of the immunoglobulins in an organism: approximately 180 g blood with 80 g cell-free plasma contains about 1.3 g immunoglobulins; of this, about 1 g is IgG.

Besides structural variants of IgA, there are also four subclasses of IgG, which differ mainly in the number and position of their disulfide bonds. No noteworthy distinguishing functional characteristics are at present known to us. IgG1 constitutes about 60% and IgG2 about 30% of total IgG, whereas the share of IgG3 and IgG4 is only about 5% each.

3.2. Mouse Immunoglobulins

Due to difficulties in the production of human monoclonal antibodies (see Section 5.4.4), the major role is still played by mouse antibodies. A summary of mouse IgG subclasses that occur as monoclonal antibodies is given in Figure 3 (IgM is not included). It can be assumed that the knowledge of human antibodies can, in principle, be applied to those of the mouse on account of their structural similarity; however, there are large differences in their secondary functions, which are governed by the Fc fragment of the antibody, as is also the case within the human Ig classes. The reactivity of the Fc fragment with human receptor structures plays an important role in the in-vivo human use of mouse immunoglobulins.

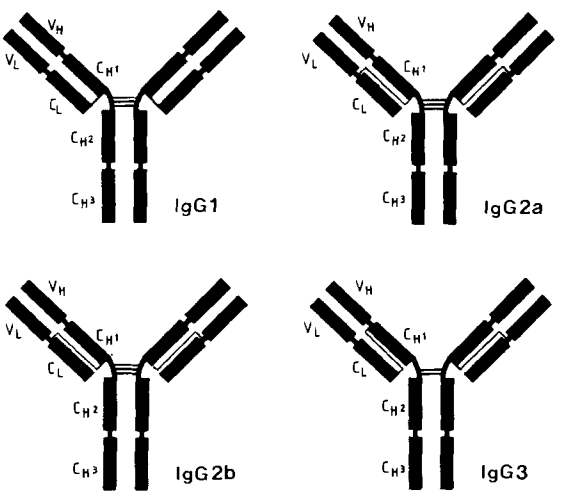

Fig. 3. Model structures of mouse IgG subclasses. Compare also with Figure 2.

Fc-mediated Antibody Effects

Formerly, antibodies were thought of predominantly in connection with specific resistance towards and control of infectious pathogens and poisons. Nowadays subsequent reactions, which are predominantly Fc-mediated, must also be considered. These reactions have controlling and regulatory functions (Table 1). Moreover, antibodies are not only humorally active, but also mediate between cellular and humoral immunity via Fc-dependent mechanisms.

Table 1. Fc-mediated reactions and functional features of IgG that are generally induced upon antigen-antibody interaction.

Bindung to Fc receptors in an organism
Regulation of IgG synthesis: positive/negative feedback
Complement activation via C1q (classical)
Phagocytosis (if via Fc receptors)
Platelet activation and aggregation
Antibody-dependent cellular cytotoxicity (ADCC)
Biological half-life of the antibody (mediated by carbohydrate of the C_H2 domain)
Placental transfer (passive immunity of the fetus)

The induction of Fc activity requires first either the binding of the antibody to the corresponding antigen, which normally leads to cross-linking or polymerization of the antibody-antigen complex, or an antigen-independent, artificial, in-vitro aggregation, which can normally take place during the routine process for the isolation of IgG from serum. In any case, the Fc fragments of several immunoglobulin molecules must come together in order to initiate the subsequent reactions.

The Fc stem binds to the Fc receptor, which can be found in very different parts of the body. Its best known location is on the surface membranes of various cells. Certain lymphocyte populations, for example, granulocytes, macrophages, thrombocytes, and mast cells, have been well investigated.

The Fc receptor, and thus the Fc part of the antibody, plays an important role in the regulation of antibody formation. A negative feedback effect on IgG synthesis has been shown.

One of the important secondary functions resulting from antibody binding to the antigen is the activation of the complement system. This is a plasma protein system consisting of now well-characterized single components (ten to twenty, depending on the point of view); included are proenzymes and enzymes, activators, and inhibitors, which, after the activation of the starter components (C1 or C3) and in the course of the cascade-like reaction, play a number of important biological and physiological roles. These can be either of a humoral nature (especially via the anaphylatoxins C3a and C5a) or of a cellular nature (reviews in [6, 7]). The most important is usually the lytic destruction of the relevant cells, cellular organisms, or bacteria.

The activation of the complement system takes place either via the *classical pathway*, in which C1 is activated and C1q must first bind to the Fc portions (e.g., of immune complexes), or via the *alternative pathway* ("properdin pathway"), which begins with the cleavage of C3 into C3b and C3a, is not Fc-dependent, and can also be regarded as a cell-bound mechanism in connection with macrophages[16, 17]. Thus the classical pathway joins the alternative one via its own specific starter reaction sequence (C1→C4→C2). C3 can also be cleaved, and thus the alternative pathway activated, by enzymes such as plasmin, thrombin, and tissue and bacterial proteases, as well as by various other substances.

A simplified and still very temporary summary of some Fc functions of mouse IgG subclasses is given in Table 2. Only very little information from comparable studies is available on the reaction of mouse IgG with human cells that carry Fc receptors; therefore, this information should be considered as being only schematic. Fc functions have been selected which are important for the technical and medical uses discussed below.

Table 2. Fc-dependent functions of mouse immunoglobulin subclasses.

Subclasses	Complement-dependent Cytolysis (Rabbit C)	Staphylococcus Protein A Binding	Staphylococcus Protein A Elution at pH	Fc Receptor (human)
IgG 1	−	+	6.0	+/−
IgG 2a	++	++	4.5–5.0	+
IgG 2b	++/+++	+++	3.0–3.5	+/−
IgG 3	+	++	4.0–4.5	+

4. Purification and Fragmentation

4.1. The Isolation of Monoclonal Antibodies

The hybrid cells that produce monoclonal antibodies are either grown in special culture media, containing essential amino acids, vitamins, and salts as well as the serum protein albumin or fetal calf serum, or they are grown in the peritoneal cavity of mice. Whereas antibody concentrations of usually 1–20 μg/mL can be achieved in cell culture supernatants, the results achievable in the serous fluid of the peritoneal cavity (ascites fluid) are up to 1000 times better. Since very large volumes must be handled for antibody isolation from cell culture supernatants, the second method of in-vivo cultivation is sometimes preferred, despite difficult separation problems, on account of the much greater production capacity. For the production in the ascites fluid the monoclonal antibodies have to be isolated from a protein mixture having a composition similar to that of serum (Fig. 4). To this end, methods are successfully applied which have proved of value in the purification of polyclonal antibodies[18].

Due to the fact, however, that established procedures have been optimized for polyclonal immunoglobulin mix-

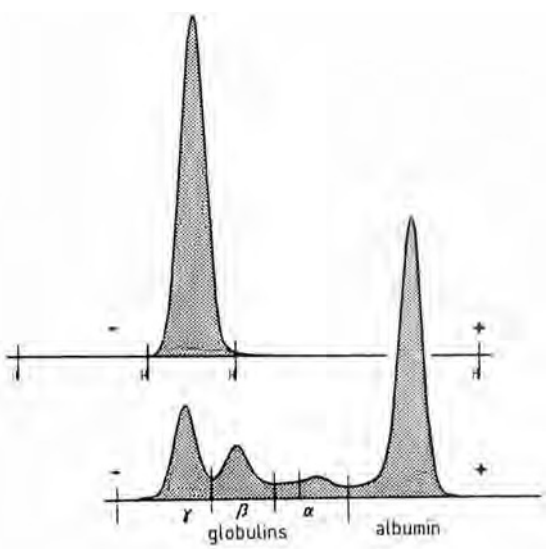

Fig. 4. Microzone electrophoresis of mouse ascites fluid (lower profile) and the IgG fraction isolated from it (upper profile).

tures, particular problems may arise with monoclonal antibodies when the product of one clone has protein chemical properties considerably different from the average properties of a heteroclonal mixture. In order to isolate a monoclonal antibody it is therefore advisable to select methods and conditions of separation on the basis of its particular properties and to adjust them accordingly[19]. Gel filtration, based on molecule size as the separation principle, is frequently a more suitable purification procedure than anion exchange chromatography, which uses the quite variable charge of the antibody molecule for purification. Fractional precipitation with the aid of a neutral salt, such as ammonium sulfate, or the use of carrier-bound staphylococcus protein A in the case of monoclonal antibodies of the class IgG, has similarly proved to be useful. The IgG subclasses often show such a great affinity for protein A that separation from other proteins in the ascites fluid can take place in an elegant one-step procedure (see also Table 2)[20-22].

Since the ascites fluid has a protein composition similar to that of serum, and thus also contains polyclonal immunoglobulins of the "producing" mouse, further problems can arise. The specific activity of the monoclonal antibody fraction in a clone of only moderate productivity is decreased by the non-separable polyclonal immunoglobulins. These products are less suitable for the production of so-called *immunotoxins* (see Section 5.4.2).

4.2. The Enzymatic Fragmentation

In the production of certain antibody fragments using proteases such as pepsin, plasmin, or papain, the subclass to which they belong (Fig. 1) plays an important role. Thus, in general, the classical method, according to which $F(ab')_2$ fragments are produced by pepsin fermentation of human polyclonal IgG with a natural subclass composition[23], is also successful with mouse antibodies of the subclass IgG2.

An $F(ab')_2$ preparation can be produced from the subclass IgG1 with previously activated papain in a thiol-free reaction medium after optimization of the amount of enzyme and the fermentation period, parameters which can differ from one antibody to another[19]. The absence of SH-agents (cysteine, mercaptoethanol, dithiothreitol, etc.), which are usually used to activate papain, is recommended on account of the otherwise possible heterogeneity of the reaction products after the partial cleavage of the three disulfide bonds that link the heavy chains. Monovalent Fab' fragments can now be easily produced from $F(ab')_2$ preparations by reductive cleavage of the hinge-region disulfide bonds. A combination of anion exchange and gel permeation chromatography normally makes possible a satisfactory separation of reaction mixtures containing IgG, $F(ab')_2$, Fab', Fc, and papain.

What has been said above about the isolation and enzymatic cleavage of monoclonal antibodies shows quite clearly that there is no standard procedure which can be used under all circumstances, but that individual methods have to be used which are adjusted to the given protein chemical properties of the relevant monoclonal immunoglobulins.

5. Uses of Monoclonal Antibodies

5.1. Use in Biochemistry and Biotechnology

Monoclonal antibodies are available for a large number of different purposes in research. Apart from their direct medical uses (Section 5.4) such as, for example, the production of antibody-drug conjugates (e.g., immunotoxins; Section 5.4.2), the analytical possibilities in all scientific fields, which we can only deal with in part (Sections 5.2 and 5.3), have been greatly increased.

In affinity chromatography, monoclonal antibodies bound to a solid phase continue to be a suitable aid in isolating certain antigens from a heterogeneous mixture. The isolation of interferon or other immune factors can be taken as an example here[24]. Monoclonal antibodies are also used for this purpose in gene technology. Thus, it is possible, with their aid, to isolate DNA fragments via gene banks cloned in E. coli or λ-phages. These code seemingly interesting epitopes (antigenic determinants) of viral coat proteins[25].

The combination of monoclonal antibodies of differing specificities often permits the differentiation and classification of antigens, owing to their characteristic reaction patterns. Here, too, one must mention the possibility of characterizing diverse cell subpopulations (see Section 5.3)[26,27].

Changes in conformation are often discussed in protein chemistry as the triggering principle for certain reaction sequences. An example of this is the activation of the first complement component, the C1 complex, in the classical pathway. This activation process can be triggered off by interaction of the C1q subcomponent with antigen-antibody complexes. The subcomponents undergo a change in conformation, in the course of which an epitope is exposed, which has only recently been detected with the aid of monoclonal antibodies[28].

Not only changes in conformation but also enzymatic cleavage are a necessary precondition for many cascade-like reaction processes (complement activation, blood coagulation, etc.). During such processes a reactive partner without enzymatic activity *(zymogen)* is normally cleaved by a specific protease, which is located one step ahead of it in the activation cascade. Via this process, the zymogen becomes an enzyme which is able to continue the reaction sequence. The process is shown schematically in Fig. 5: the zymogen is a typical protein with a number of different antigenic determinants (A, B, C, and D), which can be indi-

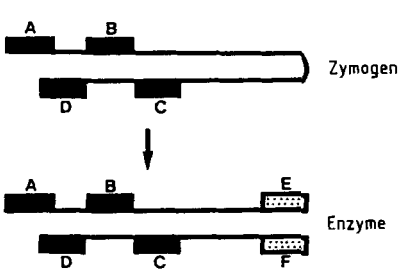

Fig. 5. Above: Schematic representation of a polypeptide chain with four different epitopes (A, B, C, and D). Below: Enzymatic cleavage of the chain causes the appearance of two new antigenic determinants (E and F).

vidually well detected and identified with the relevant monoclonal antibodies. After enzyme cleavage and the changes in structure involved, new epitopes (E and F) arise, against which monoclonal antibodies can be produced. With their aid the new enzyme can then be selectively and specifically detected. With polyclonal antibodies, this would often not have been possible, or only with considerable difficulty.

Antibodies can, as normally bivalent molecules, form precipitating immune complexes with antigens having sufficient size and a sufficient number of antigenic determinants. The influence of molecular parameters, such as concentration, affinity, or the heterogeneity of the antibody populations involved in precipitation, which have somewhat different specificities, can only be investigated to a certain extent with heteroclonal antibody mixtures. In this case, definable reaction conditions and monoclonal antibodies and combinations of them can also help in dealing with unanswered questions.

Monoclonal antibodies will also make possible the study of antibody structure and variety, of the variability of the antigen-binding sites, as well as of special areas of the molecule (e.g., the Fc part) to which various effector functions are linked. Thus relationships between structure and function, as well as genetic determination and individual-specific significance, can be better investigated.

These examples are only intended to give an impression of the many possible uses of monoclonal antibodies and thus to show what a valuable instrument has been made available to natural scientists of all disciplines.

5.2. General Diagnostic Uses

5.2.1. The Advantages of Monoclonal Antibodies in Immunoassay Systems

Polyclonal antisera are characterized by their heterogeneity. The use of highly purified antigens for immunization, the special selection of animals, and immune adsorption techniques have already allowed the development of sensitive test systems of high specificity and reproducibility. However, the problems relating to these antisera remain: serum batches obtained from different animals or groups of animals, or from one animal at different times, have different antibody contents and do not usually show an identical reaction pattern. Moreover, the small share of specific antibodies (ca. 1—15%) is often a disadvantage.

On account of their great specificity, identity, and unlimited availability, monoclonal antibodies are nowadays an obvious choice as diagnostic reagents. They have numerous advantages, especially in immunoassay systems. The most frequently employed test systems are competitive binding assays (RIA, EIA; Fig. 6a) and the "Sandwich" assays (IRMA, ELISA; Fig. 6b). Whereas labeled antigen is used in the competitive tests, labeled antibodies are used in the Sandwich test systems. So far both systems have a number of important disadvantages. The competitive assays require pure antigen, which has to be labeled without altering its immune reactivity; the reference curve is not linear; and the reaction cannot take place in the presence of an excess of reagent.

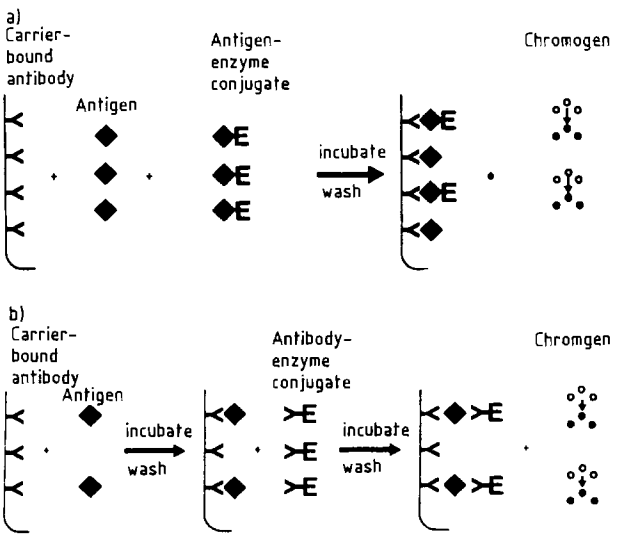

Fig. 6. a) The principle of the competitive immunoassay: RIA = radioimmunoassay; EIA = enzyme immunoassay. The antigen labeled with enzyme E and the unlabeled antigen react competitively with the carrier-bound antibody, so that the unknown amount of antigen can be determined if, for comparison, a reaction with pure antigen of known concentration is carried out. An excess of reagent is to be avoided. b) The principle of the Sandwich immunoassay: IRMA = immunoradiometric assay; ELISA = enzyme-linked immunosorbent assay. The antigen to be determined is bound by the carrier-bound antibody and quantitatively determined by an enzyme-labeled second antibody. These test systems require large amounts of purified (highly specific) antibody and can take place with an excess of reagent.

The Sandwich assays require large amounts of antibodies purified by affinity chromatography. Since a mixture of antibodies with different affinity constants is present, the standard calibration curve is linear only within narrow test limits. One advantage over the competitive tests is the possibility of using solid phase and labeled antibodies in excess, which allows a higher reaction rate in the test. IRMA and ELISA are thus test systems that can make full use of the advantages of monoclonal antibodies; namely, specificity, identity, and unlimited availability.

In the Sandwich assay (Fig. 6b) the solid phase (microtiter plates, tubes, beads) is coated with monoclonal antibodies. In the first stage of the reaction, the antigen reacts with the antibodies bound to the solid phase. In the second incubation step, an isotope-labeled or enzyme-labeled monoclonal antibody reacts with the antigen-antibody complex on the solid phase. The samples are evaluated in a γ-scintillation counter, or a substrate solution is added to the samples and the enzyme activity determined. The antigen concentration is determined by means of a reference curve.

The advantages of monoclonal antibodies can be summarized as follows:

- Uniform affinity constants and homogeneity of material usually make shorter incubation times possible.
- Very high standardization of reagents allows a better reproducibility.
- The solid phase is optimally used, due to the homogeneous affinity of monoclonal antibodies. False determinations (high-dose hook effects), which can arise with large amounts of antigen in test samples are, in part, avoided.

- When two monoclonal antibodies have been found which recognize two epitopes of an antigen and cooperate in a Sandwich assay, *one* incubation step is sufficient, since the antibodies bound to the solid phase and the labeled antibodies do not compete for the binding sites.
- The calibration curves are linear over a large measuring range so that the number of standardization points can be reduced.
- The sensitivity and the measuring range of the test systems can be varied using monoclonal antibodies with different affinity constants[29].

5.2.2. *Examples of Uses*

Drug Monitoring

The first immunoassay for a drug was described for digoxin, a heart glycoside, approximately 15 years ago. Nowadays it is possible to demonstrate the presence of substances in nanomolar ranges, and the active form of a drug can be distinguished from closely related metabolites. There are already numerous publications describing the use of monoclonal antibodies for *drug monitoring*. Digoxin was again the first examined, since it is an uncharged and chemically well-defined hapten. *Margolis* et al. and *Mudgett* et al.[30,31] obtained highly affine monoclonal antibodies, which, unlike conventional digoxin-specific antisera, made the differentiation of molecules possible.

Kato et al.[32] have produced monoclonal antibodies against the antitumor drug methotrexate (MTX). Competitive binding RIAs showed that the specificity patterns of monoclonal and conventional antibodies for MTX and structural analogues were similar, although the monoclonal antibodies cross-reacted less strongly with folic acid and other derivatives. *Hoebeke* et al.[33] were able to produce highly affine monoclonal antibodies against β-adrenergic ligands and tricyclic antidepressive drugs (alprenolol, nortriptyline). Apart from the use of these antibodies for the study of receptor-ligand structure relationships, the antibodies could also be used for a quantitative determination of these substances in biological fluids.

Tumor Marker Diagnosis

Monoclonal antibodies are particularly suited for the diagnosis of tumors and for the demonstration of the presence of tumor-associated antigens (Section 5.3). Numerous monoclonal antibodies have been produced against the presently existing markers, such as the carcinoembryonic antigen (CEA), α-fetoprotein (AFP), chorionic gonadotropin (human chorionic gonadotropin, HCG), β_2-microglobulin (β_2M), ferritin, and the acid prostate phosphatase, and there are good indications that a higher specificity and sensitivity can be achieved with monoclonal antibodies in tumor diagnosis and monitoring (see also Section 5.4.1)[34–36].

Further, new antigens will most likely be brought to light with monoclonal antibodies (see also Sections 5.3.3, 5.3.4, and 5.4). *Koprowski* et al. described a monoclonal antibody that reacts specifically with a surface antigen on colorectal tumor cells[37]. This antigen was later described as "carbohydrate antigen" CA 19-9. Using an inhibition RIA, the authors were able to show that increased levels of CA 19-9 only appear in the sera of patients with tumors in the colorectal area, in the stomach, and in the pancreas. Thus CA 19-9 could be a useful tumor marker. This is also the case for CA 125, another carbohydrate antigen. *Bast* et al. have described a monoclonal antibody against this antigen, which is found on most non-mucous, epithelial ovarial carcinomas[38].

Polypeptide Hormones

The specific detection of polypeptide hormones is a further important area of use. The pituitary hormones thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH), as well as HCG, are complex molecules with a large number of antigenic determinants. These glycoproteins have the same α-subunits and differ only in parts of their β-subunits. Due to the problems of producing specific antisera against them, it has so far been very difficult to develop good immunodiagnostic test systems.

Nowadays there are monoclonal antibodies with specificity for the α- or β-subunit[39] and for conformation epitopes[40], which only react with the intact molecule. By combining these three types of antibodies, test systems can be developed in which either only the intact molecule or only the free subunit is specifically detected.

Earlier investigations with monoclonal antibodies led to the expectation of some disadvantages in precipitation and agglutination. However, in recent years monoclonal antibodies have also been described which are very much able to precipitate and agglutinate[41]. *Rahamim* et al. obtained a monoclonal antibody against the β-subunit of HCG, which agglutinates HCG-coated erythrocytes. Due to the sensitivity, specificity, and affinity, this monoclonal antibody is very well suited for detecting HCG in biological fluids. Further interesting monoclonal antibodies have also been developed against L-thyroxin, *T4*, and L-triiodothyronine, *T3*[42]. They have an improved specificity and are more quickly bound.

Microbiological Diagnosis

Monoclonal antibodies have become important for the differential diagnosis of viral, bacterial, and parasitic infectious diseases, since the pathogen can be thereby specifically detected. New diagnostic possibilities have, in some cases, been found. *Wiktor* et al.[43], for instance, were able to reliably recognize animals infected with rabies by means of brain cell smears. The diagnosis of sexually transmitted diseases, such as *herpes, Chlamydia trachomatis, Neisseria gonorrhoeae,* has also been made easier[44]. Not so very long ago a direct demonstration of chlamydia infections was not possible. With monoclonal antibodies and using the immunofluorescence technique, urethral and cervical smears produce characteristic reaction patterns for chlamydia infections even after only 30 min. These results have been confirmed by *Ruijs* et al.[45], who compared the rapid detection of *C. trachomatis* in urethral smears and urine sediments using monoclonal antibodies with conventional culture methods.

As *Nowinski* et al.[44] also showed using immunofluorescence studies with monoclonal antibodies specific to herpes simplex virus (HSV) I and II, the classification of HSV into two subgroups produced complete correlation with the results of the restriction endonuclease analysis of viral DNA. *Franze*[46] also successfully showed a differentiation of HSV I and II in an ELISA test.

Sometimes the specificity of monoclonal antibodies is too high for a viral or bacterial infection, especially when, with a large number of strains, no common antigenic determinant is present. In such cases a mixture of monoclonal antibodies can often be used successfully for immunodiagnosis. *Nowinski* et al., for example, used a mixture of three monoclonal antibodies for their studies of *Neisseria gonorrhoeae*[44]. This mixture identified 99.6% of the tested samples without cross-reaction with 17 other Neisseria-related species.

Monoclonal antibodies continue to be used in IgM antibody tests: the determination of virus-specific IgM antibodies is often more advantageous for demonstrating fresh virus infections than the measurement of the IgG antibody titer increase (see Section 3.1). The antibodies are used as antihuman-IgM catcher antibodies on the solid phase[47].

Using highly affine monoclonal antibodies, *Wands* et al.[48] improved the determination of hepatitis-B surface antigen (HBsAg) in human sera. *Richman* et al.[49] were able to demonstrate influenza viruses in cell cultures which had been infected with clinical samples from sick patients. With monoclonal antibodies, it should be possible to demonstrate antigen variations on influenza virus molecules; this would be of very great epidemiological interest.

5.2.3. Heterobispecific Antibodies

Heterobispecific antibodies (hybrid antibodies) are characterized by two binding sites, issuing from two different immunoglobulins. These two binding sites can be directed against different epitopes of an antigen, or they can demonstrate similar specificity with different H-chains, due to their being composed of different subclasses. Hybrid antibodies can have very great advantages in immune tests, immunohistochemistry, and immunotherapy.

Until recently hybrid antibodies could only be produced using chemical methods. Disulfide bonds were selectively cleaved by means of careful reduction, and the dissociated half molecules of two different immunoglobulins were then carefully oxidatively coupled.

A new and elegant method was made possible by the hybridoma technique. When cells of two hybridoma clones are fused, the hybrid hybridomas thus created are capable of producing hybrid antibody molecules, the synthesized immunoglobulin chains being determined by the genes of the two fusion partners[5,50]. One use of these techniques for a special immunohistochemical method was described by *Milstein* and *Cuello*[51], who were able to produce a bispecific, antisomatostatin antiperoxidase antibody.

Hybrid antibodies could be used in many ways. For example, they make possible a one-step immunoassay in which the bispecific antibody binds the antigen on the one hand and the indicator molecule (peroxidase, phosphatase) on the other. Heterobispecific antibodies could also have special advantages as immunotoxins (Sections 5.4.2), and antigen-bound toxins could be transported to the target of the second antibody binding site[52]. Further examples for the production of hybrid antibodies by cell fusion were described by *Martinis* et al.[52].

5.2.4. Perspective

By means of the special selection of two or three monoclonal antibodies, which react with closely located antigenic determinants, the absolute epitope specificity of monoclonal antibodies can open up completely new possibilities for immunoanalysis; for instance, on the basis of fluorescence excitation through energy transfer[54]. Two monoclonal antibodies recognizing neighboring epitopes are conjugated with two indicator molecules, rhodamine and fluorescein being used for fluorescence quenching. The use of two enzymes is also conceivable, whereby the first enzyme must produce the substrate for the second.

5.3. Cell Diagnosis

There is no doubt that cell diagnosis is at present undergoing profound changes due to the use of monoclonal antibodies. Access has been gained to biological structures whose presence could only be detected with great difficulty, or not at all, using the classical biochemical and immunological methods. Fig. 7 shows schematically that, for example, it is possible, on the one hand, to discover new structures expressed on the surface of the cell membrane, to demonstrate their presence in a highly specific way, and to characterize them biochemically and, on the other hand, with the relevant number of different antibodies, to inspect and describe anew the surface of a cell. Thus structures can be described which are only expressed in connection with cell activation, cell growth, or cell differentiation. With immune cells, it will soon be possible to characterize and, where necessary, to re-catogorize all the cell populations and subpopulations between the original stem cell in the bone marrow and the final functionally determined immune cells (see Sections 5.3.1 and 5.3.2). With this extremely effective instrument for differentiation of the cell populations of the immune system, we hope to be able to obtain information from which valuable conclusions about the immune reactions may be drawn[55].

Similarly, attempts are now being made to find and characterize specific growth, differentiation, and activation markers on tumor cells, to comprehend their structure and function, and thus perhaps to gain new insights into the formation and spread of tumors and of regulatory and possible counterregulatory mechanisms (see Sections 5.3.3 and 5.3.4).

5.3.1. Methods and Areas of Use

Antibodies bind to surface determinants on cells and in tissues. In order to detect the antibodies, they can be directly labeled, or they can be indirectly labeled by fluorescent dyes or enzyme-labeled second antibody (immunohis-

tochemistry; see Fig. 6–9). Complement-activating monoclonal antibodies are also suitable for complement-mediated cytolytic assays, which play a part as a micromethod in histocompatibility testing (Fig. 7).

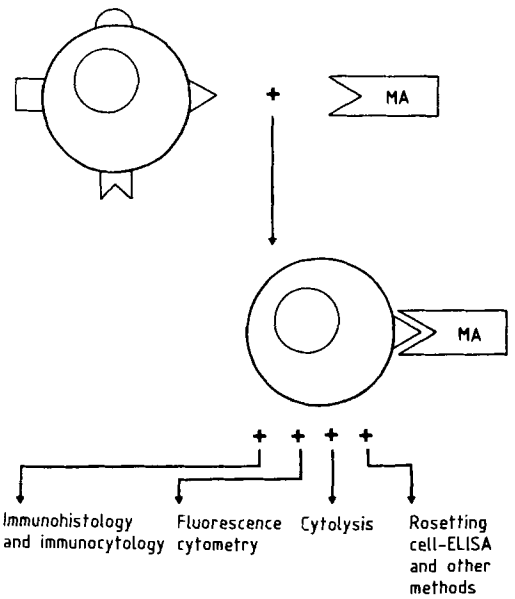

Fig. 7. Schematic representation of methods of testing monoclonal antibodies against cell-bound antigens: a cell, which, in this example, schematically expresses four different antigens on the cell surface, of which (for instance) only one antigen is cell population specific, is recognized by a specific monoclonal antibody (MA) and bound, and can thus be quantified: the antigen as a cell surface determinant thus allows the determination of the number of cells bearing the antigen. The MA is either directly labeled *(direct method)*, or an unlabeled second antibody, in this case an *anti-MA*, binds additionally to the already bound MA *(indirect method)*. Since the MA is usually a mouse IgG, the second antibody is, e.g., a rabbit-anti-mouse IgG. Rosetting means a ring-like adhesion of several erythrocytes around one leukocyte.

For the direct detection of cellular antigens via immunofluorescence, fluorescein- or rhodamine-labeled monoclonal antibodies are used. In indirect immunofluorescence this is achieved by means of labeled second antibodies, which, in the case of monoclonal antibodies, are usually anti-mouse immunoglobulins. Evaluation takes place by counting under a microscope, or, nowadays, with increasing automation, by flow cytofluorimetric analysis.

In immunohistology and immunocytology, monoclonal antibodies are applied to cryostatic sections, cytocentrifuge and smear preparations, and paraffin sections. It is remarkable that all known monoclonal antibodies are suitable for use on cryostatic sections, a number can be used in cytocentrifuge and smear preparations, but only a few are suitable for use on formalin-fixed, paraffin-embedded sections. Rosetting, cell-ELISA, and cell-RIA are very time-consuming and elaborate methods, which cannot yet be recommended as routine procedures (Fig. 7).

Monoclonal antibodies allow the observation of structures in living cells and, at the same time, the recognition of their function in the immune system. This had not been possible before with other methods. With monoclonal antibodies, human lymphoid and myeloid cell populations can also be identified in lymphatic tissues and, after infiltration, in diseased organ regions. For pathology and histology this therefore means a simplified evaluation of histological sections, since judgment no longer has to be made on the basis of morphology and staining alone.

Numerous systemic diseases result from faulty regulation of the immune system or accompany disturbances in cellular immunity. These include primary immune deficiency, acquired immune defects, e.g., "aquired immune deficiency syndrome" (AIDS), autoimmune diseases, leukemias, lymphomas, and infectious diseases. Dysfunctions in the immune system are usually linked to changes in the different lymphocyte populations. Both the activation of the lymphocytes as well as their effector functions can be impaired to the same extent.

The phenotype characterization of thymocytes, bone marrow cells, and peripheral lymphocytes with monoclonal antibodies makes a better definition of these complex disorders now possible for patients with primary immune deficiencies. In immune deficiency and autoimmunities the relationship of T-helper cells (T4) to T-suppressor cells (T8) is often disturbed. In AIDS, for instance, the population of T-helper cells is greatly diminished and, in the case of autoaggressive diseases, often that of the T-suppressor cells.

The diagnostic significance of monoclonal antibodies therefore lies in the field of cell characterization. Cells that had been difficult or impossible to recognize and categorize morphologically can now be found and defined. With T-lymphocyte markers (Table 3), it has become possible to follow the maturation process of T-lymphocytes from the bone marrow to the peripheral blood and to categorize exactly the stages of differentiation. In analogy, it would be very nice to observe the differentiation and growth of tumor cells and other cellular differentiation systems. B-cell markers will gain in significance for hematologists, since a large number of malignant lymphatic disorders in human beings derive from the unregulated proliferation of B-lymphocytes at various stages of development. Cell-surface membrane-bound immunoglobulin has always been, and still is, considered as a marker for mature B-lymphocytes. Early developmental stages of B-lymphocytes in the bone marrow, in which surface immunoglobulin is not yet expressed, can nowadays be identified using monoclonal antibodies. Apart from the B-lymphocytes circulating in the blood, those in the peripheral lymphatic organs, especially in their germinal centers, can be detected. As a result, further differentiation antigens, of especial importance for lymphoma research, have become recognizable (Fig. 8).

Due to hybridoma technology, a completely new picture has emerged, especially for the characterization of myelomonocytic cells. Today, we have at our disposal a large number of monoclonal antibodies against myeloid differentiation antigens. Here, a rough distinction can be made between antibody groups: antibodies that react with granulocytes *and* monocytes, those that react *only* with granulocytes, and those that react *only* with monocytes (see also Table 3).

With monoclonal antibodies, thrombocyte antigens can also be used today in the characterization of immature blasts. Thus it has become possible to identify immature and atypical thrombocyte precursors, which until now could only be recognized using an electron microscope, if at all.

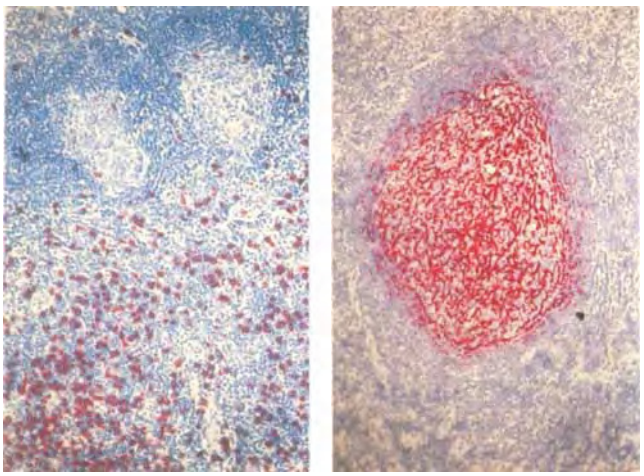

Fig. 8. Alkaline-phosphatase anti-alkaline-phosphatase reaction (APAAP) with a monoclonal anti-alkaline-phosphatase antibody and an unconjugated rabbit-anti-mouse immunoglobulin bridge antibody (red-blue Fast-Red/Haemalaun method). Cryostatic section of a human tonsil: left: T-8-positive suppressor T-lymphocytes in the interfollicular area; right: dendritic reticulum cells in the germinal center of a follicle (enlargement ca. 250 times; preparation: Institute of Pathology, University of Kiel, FRG).

5.3.2. *Lymphocytes and Immunology*

The activation of the immune system as a response to confrontation with a natural immunogen is an extremely complex reaction. Even under in-vitro conditions an effective stimulation of the cellular components of the immune system is only possible when all the parameters necessary for the cascade-like sequence of an immune reaction are considered. On the one hand, the cellular interactions both on the induction and differentiation level and in the effector phase are dependent on the structures coded in the major histocompatibility complex and are thus genetically controlled. On the other hand, essential signals for differentiation of immune reactive cells are only transmitted by various immune mediators[56, 57].

Both the knowledge of the genetic control of cellular immune reactions and the demonstration of the immune factors involved in an immune reaction have enabled some basic immune mechanisms to be explained. A large number of elaborate experimental systems have made possible a definition of the experimental cell populations involved as well as a description of their functions. By the use of the conventional methods of leukocyte differentiation, however, it was normally not possible to attribute functions to individual cells on the basis of cell morphology. Thus the description of lymphocyte populations was limited for T-cells to functional systems (induction of DNA synthesis by the mitogens phytohemagglutinin (PHA) and Conconavalin A, and by antibody-mediated cellular cytotoxicity (ADCC), natural killer cells (NK), and cytotoxic T-lymphocytes (CTL)) or to phenotypical markers. The determination of the extent of B-lymphocyte differentiation was analogously based on the interaction with various activators (e.g., lipopolysaccharide (LPS), pokeweed mitogen (PWM), *Staphylococcus aureus*, Convan I (SAC)) and the demonstration of cytoplasmatic or cell-surface-bound immunoglobulin. However, not until the relevant monoclonal antibodies were available was it possible to clarify the relationship between a phenotype of a lymphocyte and its function[58-60]. In the meantime it has often been shown that the antigen recognized by the monoclonal antibody is not only a marker structure for the relevant function of the cell, but that it itself is involved in the cell function (e.g., as a receptor)[61-64].

In order that monoclonal antibodies, which can be used to differentiate human leukocytes, may be internationally compared, the *First International Workshop for Human Leukocyte Differentiation Antigens* in Paris in 1982 undertook to assign monoclonal antibodies to characteristic differentiation antigens[65]. The subsequent congress in Boston in 1984 continued the work of characterizing the various stages of differentiation with monoclonal antibodies, and produced newly formulated *differentiation clusters* (Table 3).

The specificity of an antileukocyte antibody, and thus its belonging to defined *clusters*, only considers in part the de-

Table 3. Monoclonal antibodies for classification of human leukocytes [a, b].

Cluster of Differentiation (CD)	Cell Type and Antigen	Characterized Cell Population	Selected antibodies with cluster-defined specificity
CD 1	Thy, p45-12 [c]	cortical thymocytes	T6; M241; SK9/Leu 6
CD 2	T, p50	E-rosette-forming T-lymphocytes	T11; 9.6; S2/Leu 56
CD 3	T, p19-29	mature T-lymphocytes	T3, BW 264/56 (BMA 030); SK7/Leu 4
CD 4	T, p55	T-cell subpopulation; predominantly T-helper lymphocytes	T4; BW 264/123 (BMA 041); MT321 (BMA 040)

[a] Modified according to [65]; partially supplemented: results of the 2nd Int. Workshop and Conference on Human Leukocyte Differentiation Antigens, Boston 1984. [b] Abbreviations: Thy = thymocytes; T = T-lymphocytes; nT-nB = nonT-nonB cells; M = monocytes, macrophages; G = granulocytes; NK = natural killer cells, p = protein. Abbreviations in the last column represent the original, individual nomenclature of laboratories, institutes, or firms, which is still in use and to be found in the literature. All the clones listed were selected and catalogued by the workshop committee. [c] Molecular weight in kDa.

mands made upon monoclonal antibodies for therapeutic purposes (see Section 5.4.3).

Monoclonal antibodies that bind to the T3 complex have been described as activating T-lymphocytes[66] if they are also able to bind to the Fc receptors of *monocytes*[67-69]. However, we were able to isolate four monoclonal antibodies against the T3 complex, of which only the antibodies BW 264/56 (CD3b) and BW 242/55 (CD3a) are capable of activating human T-cells, whereas BW 239/347 (CD3b) and BW 242/412 are not able to do so (Table 4). The specificity of these antibodies was determined with isolated cell populations, using double labeling and comodulation experiments and by means of competitive binding tests. T-cell activation leads to modulation of the T3 complex, induction of DNA synthesis, release of immune mediators such as interleukin-2 and γ-interferon, and to IgM synthesis in vitro (Table 4). All test systems showed that only the binding of anti-T3 antibodies of the isotypes IgG2a and IgG3 led to a T-cell activation, whereas the corresponding antibodies of the isotype IgG2b were not able to induce a T-cell activation[70].

Table 4. The activation of T-lymphocytes by monoclonal CD3 antibodies [a].

Antibody [b]	Isotype	Mitogenicity		Induction of IgM Synthesis		Modulation of the T3-Antigen	
		R	NR	R	NR	R	NR
Leu 4	IgG 1	+	−	+	−	+	−
BW 264/56	IgG 2a	+	+	+	+	+	+
OKT3	IgG 2a	+	+	+	+	+	+
BW 239/347	IgG 2b	−	−	−	−	−	−
BW 242/412	IgG 2b	−	−	−	−	−	−
BW 242/55	IgG 3	+	+	+	+	+	+

[a] Peripheral blood lymphocytes of healthy blood donors are classified as reactive (R) or non-reactive (NR) according to their reactivity with CD3 antibodies (anti-T3) of subclass IgG 1 [146]. [b] BW: Behring-Werke; Leu4: Becton Dickinson; OKT3: Ortho.

Thus, during the therapeutic use of monoclonal mouse antibodies, Fc-mediated immune reactions also have to be considered. When using monoclonal antibodies of the cluster type CD3, which activate T-cells, these reactions must at least be taken into consideration if the monoclonal antibodies are to be used for immune suppression (e.g., in organ and bone marrow transplantation) (see Section 5.4.3).

5.3.3. Leukemias and Lymphomas

Comparative phenotype characterization of normal and malignant cells of the hemotopoietic system with the aid of monoclonal antibodies is a decisive step forward in the search for the cellular origin of lymphatic diseases and their classification and thus also signifies a step forward for prognosis and therapy. Malignant lymphatic diseases are due to an uncontrolled expansion of a neoplastic lymphatic cell clone which has remained at a certain stage during its maturation process. The cells of such a clone express the surface markers of the corresponding normal cell type, and can therefore be easily identified with monoclonal antibodies. Only rarely do additional markers of foreign cell lines appear.

Acute lymphatic leukemias (ALL) are divided, according to the differentiation state of the cell types involved, into five main groups: 1. undifferentiated ALL, 2. common ALL (cALL), 3. pre-B-ALL, 4. B-ALL, and 5. T-ALL. 60–70% of all cases of ALL can be attributed to *Common ALL*. Using monoclonal antibodies (the best known presently seems to be VIL-Al), a differentiation antigen with a molecular weight of about 100 kDa has been demonstrated on the membrane of the blasts of this form of leukemia. This was first called the *Common Acute Lymphatic Leukemia Antigen* (CALLA) in 1975 (Table 3). This is not leukemia specific, but a normal differentiation antigen which can also be found on normal bone marrow lymphocytes.

No CALLA is expressed in undifferentiated ALL; the cells of pre-B-cell leukemia are characterized by the demonstration of intracytoplasmatic immunoglobulin chains (μ-chains). Acute leukemias of the B-cell type are rare (1—5%). B-lymphocyte antigens, the same as those found on mature B-cells, are found on the blasts along with additional cell-surface membrane-bound immunoglobulin, mostly of the IgM isotype.

With about 20%, T-ALL is the second largest group of acute lymphatic leukemias. By the use of monoclonal antibodies, typical markers of T-cell differentiation can be found on the blasts of this form of leukemia, such as the T-11 antigen, the E-receptor, or in the case of the corticothymocytic form, the normal cortical thymocyte marker, T6. In addition, the markers T9 (transferrin receptor) and T10 (hemopoietic precursor cell) can be demonstrated.

Chronic lymphocytic leukemias (CLL) result from the malignant proliferation of B-lymphocytes that have been held up in their further development. Only 5% of all CLL cases derive from the peripheral T-cell compartment; they bear the markers T3, T10, and either T4 or T8.

The so-called Non-Hodgkin Lymphomas can be divided according to their surface makers into a heterogeneous group of lymphoblastic lymphomas, which express thymus antigens, or, for example in the Burkitt lymphoma, they clearly belong to the B-cell type with cell surface IgM and an Epstein-Barr-Virus-specific membrane antigen. T-lymphomas of the skin and the Sezary syndrome are due to the malignant proliferation of helper T-lymphocytes (T4).

Myeloid leukemias are judged according to morphological criteria. An intensive search is still going on for monoclonal antibodies able to recognize immature myeloblasts. At present it is still necessary to work with a combination of antibodies, e.g., the antibodies VIM C6 and VIM 2, with which all myeloid leukemias can be detected. The antibodies VIM C6 and VIM D2 can already be used today to differentiate between the monocytic and granulocytic forms of leukemia (see Table 3).

5.3.4. Immune Histochemistry and Solid Tumors

The histological diagnosis of tumors from solid tissues is largely dependent on the pathologist's interpretation of tissue sections. Discrepancies arise between various observers, when using conventional histomorphological methods

for classification, if only little biopsy material is available. However, in routine examinations, too, especially in the case of lung carcinomas of different histology, questionable interpretations are possible[71]; in such cases, markers enabling a differentiation between adenocarcinomas of the lung and mesotheliomas could be of great help[72].

Reagents for classifying metastases, which derive from undiscovered primary carcinomas, sarcomas, or melanomas of different origins, would make the choice of an adequate patient-specific therapy easier[73]. A precondition for the development of such reagents is the selective distribution of antigens or antigenic determinants (epitopes) on those tissue types to be differentiated. Monoclonal antibodies are ideal reagents for the immune histochemical demonstration of marker epitopes if they react with structures that are very strongly expressed on certain tumor types but not at all, or only to a small extent, on others.

The indirect immunoperoxidase method[74] and the avidin-biotin peroxidase method[75] are the most frequently employed techniques for judging the tissue distribution of epitopes that are defined by monoclonal antibodies. Especially when working with formalin-fixed tissue sections, these techniques have resulted in a very precise histochemical staining reaction in a well-preserved tissue structure. The distribution of the dye enables the determination of qualitative differences in reactivity within defined compartments of the tissue sections, e.g., in tumor cell regions, stroma components, or non-malignant structures.

The method allows the fine specificity of monoclonal antibodies to be tested on all available human tissues, since undesired reactivities are revealed. Extensive specificity analyses have so far only been carried out with a small number of monoclonal antibodies that recognize formalin-resistant epitopes[76–80]. With such antibodies, indirect immunoperoxidase tests on formalin-fixed, paraffin-embedded tissues, can be carried out. One example is shown in Figure 9, in which the monoclonal antibody BMA 130b (Behring Diagnostics) reacts with a pancreas carcinoma (brown staining in the region of the tumor cells), but not at all with the tissue of a chronic pancreatitis. Monoclonal antibodies that recognize formalin-sensitive epitopes cannot be tested in the same way, since fresh or frozen human tissue is only available to a limited extent[81–83].

The majority of the presently existing monoclonal antibodies, raised and selected using cell lines, bind to formalin-sensitive epitopes, which means that fine specificity analysis can hardly be carried out on many human tissues[84–87]. These antibodies are especially suited for finding out the physiological functions of cell surface antigens; e.g., the receptors for growth factors, for hormones, and for attachment factors[88–90]. Similarly, antigen distribution on cell surface membranes or the heterogeneity of cell populations can be examined[91–93].

Together with macrophages and killer cells, monoclonal antibodies of different isotypes, which recognize glycoproteins or glycolipid molecules on tumor cell surface membranes are able to lyse target cells to very different extents[94,95]. Monoclonal antibodies coupled with isotopes, toxins, cytostatic drugs, or immunogenic molecules, will probably play an important role in the in-vivo demonstration and therapy of tumor illnesses (see Section 5.4.1 and 5.4.2).

5.4. Medical Uses

5.4.1. Tumor Localization: Radioimmunoscintigraphy of Tumors

For several decades attempts have been made, more or less unsuccessfully, to incorporate scintigraphical methods into the in-vivo diagnosis of malignant tumors. Gamma-emitting substances are administered to the patient intravenously, in the hope that these will be transported in the blood stream to the tumor, will accumulate there, and will be detectable with a radiation detector. Elaborate techniques, using so-called gamma-cameras, are available for this radiation detection.

Pressman first had the idea of using the specificity of antibodies for in-vivo accumulation of radioactivity in the relevant tumors. He found that the antibody molecule can be labeled with radioactive iodine without losing its binding capacity[96] and that, after "radio-iodine labeling" and in-vivo application, the antibodies directed against individual organs accumulated in the relevant organs, for instance, in the kidneys[97]. The way seemed open for the evaluation of this principle for tumor detection. An obsta-

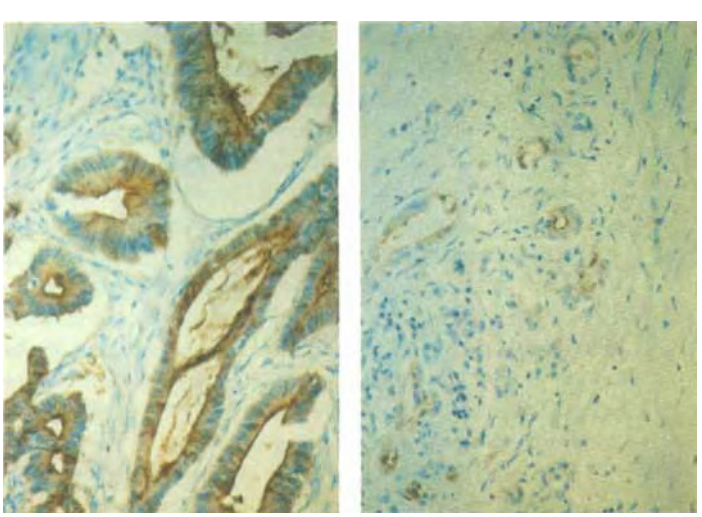

Fig. 9. Left: Indirect immune peroxidase staining of formalin-fixed, paraffin-embedded tissue sections from a pancreatic carcinoma. The brown staining shows the reaction with the tumor cell areas. Right: No reaction with the tissue from a chronic pancreatitis. Slight counter staining with hematoxilin (enlargement ca. 250 times).

cle was raised, however, by the then insurmountable problem of nonspecific binding of antibodies to tissue not belonging to the tumor. Moreover, accumulation was mainly due not to the tumor antigens but to fibrin, which had been increasingly deposited in the tumor region owing to the inflammatory processes taking place there. This observation gave rise to the idea of using specific antifibrin antibodies[98], which, however, did not provide the hoped for breakthrough in tumor imaging.

It was clear, even then, that one of the most important conditions for successful immunoscintigraphy is the purity of the antibody used. Until then, however, only hyperimmune sera had been available, whose immunoglobulin fraction always contained, at most, 1% of the specific antibody, even after separation from the other serum proteins.

An important step forward was made with the use of antibodies against a series of so-called tumor-associated antigens. These proteins are frequently produced in large quantities by certain types of tumors and released into the blood, where they can be detected by means of sensitive diagnostic methods[119]. They can be isolated from blood serum or tumor tissue and then used in affinity chromatography for the purification of the relevant antibodies from xenogenic immune sera.

Table 5. Heteroclonal antibodies (purified by affinity chromatography) already used in clinical studies for radioimmunodetection of solid human tumors.

Antigen	Site of Tumor	Number of Cases (positive/total)	Ref.
Carcinoembryonal antigen (CEA)	Colon	1/2	[99]
	Breast	3/23	
	Medullar thyroid gland	0/5	
	Colon, rectum; also lung, larynx, medullar thyroid gland	28/31	[100]
	Colon, rectum, pancreas various other organs	22/53	[101]
	Colon, rectum	35/41	[102]
	Ovary	21/24	
	Lung	12/17	
	Pancreas	4/8	
	Breast	9/14	
	Uterus	28/31	
	Stomach	5/6	
	Various other organs	25/39	
	Colon, rectum (primary)	10/12	[103]
	Colon, rectum (metastases)	49/53	
	Colon, rectum (primary)	4/5	[104]
	Colon, rectum (metastases)	8/11	
Human chorionogonadotropin (HCG)	Lung, pelvis, abdomen (Chorion Carcinoma)	9/14	[105]
	Brain, lung, abdomen (Teratoma)	3/7	
α-Fetoprotein (AFP)	Testes (Teratoma)	8/12	[106]

The most important systematic investigations of this kind (antigens, tumors, findings) are shown in Table 5. This summary clearly shows that not all the research groups obtained results as convincing as those of *Goldenberg*[102, 103]. One objection to the carcinoembryonic antigen (CEA), which is mentioned most frequently here, is that it cross-reacts with a number of similar proteins which are widespread in the organism, so that the condition of tumor specificity is only unsatisfactorily fulfilled.

Monoclonal antibodies should play the decisive role in solving the specificity problem; moreover, their many qualitative advantages may allow the standardization and use of radioimmunodetection on a wide scale. Unfortunately, the tumor antigens known to date can, at best, be called tumor-associated, since they can also be found in smaller quantities in normal tissue.

Table 6. Monoclonal antibodies already used in clinical studies for radioimmunodetection of solid human tumors.

Antibody	Antigen	Tumor Type	Number of Cases (positives/total)	Ref.
17-1A	Colon carcinoma cell line	Colon carcinoma	3/9	[107]
			31/59	[108]
			22/38	[109]
19-9	Monosialoganglioside	Colon carcinoma	10/13	[107]

Anti-p97	p97 (cell membrane antigen of melanoma)	Melanoma	22/25	[112]
MAb VII 23	Carcinoembryonal antigen	Colon carcinoma	14/28	[113]
MAb 35, $[F(ab')_2]$	Carcinoembryonal antigen	Colon carcinoma	18/24	[114]
HMFG1 HMFG2	Membrane of milk fat globules	Ovarial carcinoma	11/12	[115]
		Colon carcinoma	4/6	
		Ovarial carcinoma	35/40	[116]

Table 6 shows that, under clinical conditions, it has so far been possible to use only a few monoclonal antibodies on a limited number of tumor types (with varying degrees of success). Far more experience has been gathered, however, with animal models, using, in most cases, xenogenic tumor transplants on athymic nude mice[117]. This test regimen is considered an important preclinical test system, even though, for several reasons, it makes the in-vivo behavior of antibodies often appear in a more favorable light than is the case in human beings.

Antibody binding in the transplanted tumor (xenograft) is judged using either external scintigraphy with the gamma-camera or by calculation of the localization indices (L. I.)[118], as the examples in Fig. 10 and 11 show[79]. Figure 10 shows the time-dependent accumulation of radioactivity in the tumor and the simultaneous decrease in the central region of the mouse quite clearly. Fig. 11 shows increased L. I. values and thus specific antibody accumulation in the tumor alone. This procedure utilizes the double labeling method first described by *Pressman* et al.[120] for the in-vivo determination of tumor-imaging antibodies.

There is no clear answer to the question as to how large a tumor has to be before it can be discovered with the aid

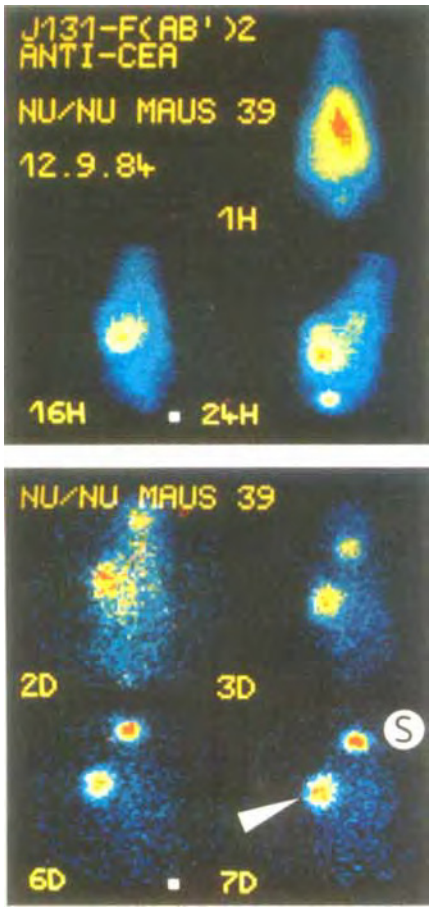

Fig. 10. Radioimmunoscintigram of a nude mouse with a colon-carcinoma xenograft on the left side (white arrow); monoclonal antibody BW 431 ($F(ab')_2$ fragment of a monoclonal antibody against carcinoembryonal antigen) radioactively labeled with ^{131}I; gamma-camera pictures after 1 h, 24 h, 2 d, 3 d, 6 d, and 7 d. The thyroid gland of the animal (S) was not blocked, thus radioactivity could also accumulate there. (Pictures by *A. Schwarz* et al., Hoechst AG.)

of radioimmunoscintigraphy, owing to the numerous influencing parameters. Even for monoclonal antibodies, the sensitivity limit in human beings, under favorable conditions, is a minimum diameter of about 1 cm, or a minimum

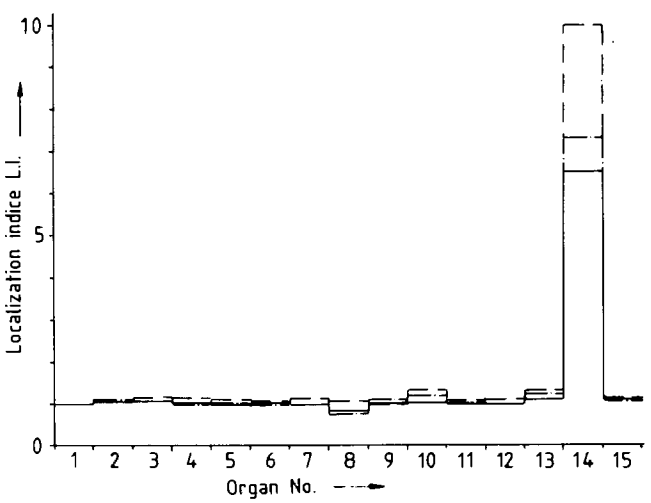

Fig. 11. Accumulation of the monoclonal antibody BW 431 in a colon-carcinoma-bearing nude mouse after 3 d (three animals: ––, -·-, and —). L.I. > 1 means specific accumulation of the monoclonal antibody. Organs: blood (1), bladder (2), heart (3), intestine (4), kidneys (5, 6), liver (7), spleen (8), lung (9), thyroid gland (10), head (11), muscles (12), stomach (13), tumor (14), the rest of the body (15).

mass of 0.1 g[121]. In animal models, however, tumor diameters of 1 mm have been reported[122].

The results of scintigraphy are strongly dependent on the relationship of radioactive absorption in the tumor to that in the surrounding tissue. Substraction procedures, in which other chemical substances are used to label the blood pool (e.g., ^{99m}Tc-human serum albumin) or to represent the nonspecific absorption in the reticulo-endothelial system (e.g., ^{99m}Tc-colloidal sulphur), often lead to false-positive results[99]. If this principle is to be used at all, a nonspecific antibody preparation should be employed as a control and be labeled with a radioisotope of the same chemical element according to the same method[120]. The consideration that Fc-mediated binding to Fc receptors of the cellular immune system could be partly responsible for nonspecificity led to the use of the antibody fragments $F(ab')_2$ and Fab instead of the complete molecule. These have the advantage that they are much quicker than the complete molecule to leave the circulation, penetrate into the tissue, and be excreted via the kidneys; the background activity in the blood dies down more quickly (clearance) and the tumor therefore emerges more rapidly from the background. It seems at present unclear which of the two fragments should be given preference. On account of its quick and direct clearance, Fab seems to be responsible for an increased background radiation in the region of the kidneys[123]; however, reports have appeared on disturbing radioactivity accumulation in the kidneys and bladder with $F(ab')_2$, which is also metabolized more rapidly than complete IgG. The relative position of the tumor, of course, determines whether these effects impair tumor imaging. Nevertheless, tomographic visualization techniques can provide more clarity in this respect than simple scintigraphy.

In order to obtain optimal scintigrams, as many labeled antibody molecules as possible must reach the tumor and bind to the tumor cells. Therefore, vascularization of tumor tissue and antigen density on the cells are of great importance for the extent of antibody binding. Whereas it is hardly possible to influence vascularization, it is possible, in the case of an insufficient antigen density on the cell surface, to use several antibody types directed against different epitopes instead of one antibody. This procedure is also advantageous, since the antigen structure of tumor cell membranes not only varies from one patient to another, but also in one and the same patient depending on localization and clonal differentiation[109]. There is little scope for increasing the accumulation of radioactivity in the target tissue by means of a higher degree of antibody labeling. Higher labeling means a greater risk of damage to the antibody and a greater tendency to nonspecific binding and accelerated excretion due to metabolism. Here, often on account of their uniform structure, monoclonal antibodies are at a greater risk than heteroclonal ones.

Without going into the details concerning scintigraphy at this point, suffice it to say that the presently used gamma-cameras are not optimal for the most frequently employed radionuclide, ^{131}I (γ: 0.36 MeV, $t_{1/2}=8.0$ d). ^{123}I, with a gamma-emission of mainly 1.60 MeV, seems better suited; however, its short half-life often creates delivery problems. Short half-lives are still generally of interest, due to the lower level of radiation for the patient. However,

with radioimmunoscintigraphy, the fact that useful tumor/background relationships are generally only available after a period of two days must be taken into consideration, unless, as described above, Fab or $F(ab')_2$ fragments are used. For this reason there is little use for ^{99m}Tc (γ: 0.14 MeV, $t_{1/2}=6.1$ h), which was almost always used in classical organ imaging. More success can thus be expected with complex-forming radionuclides, such as ^{111}In (γ: 0.17, 0.25 MeV, $t_{1/2}=2.8$ d) or ^{67}Ga (γ: 0.09, 0.18, 0.30, 0.39 MeV, $t_{1/2}=3.3$ d), even though they have to be bound via a chelating agent, such as diethylenetriaminepentaacetic acid (DTPA), to the antibody molecule. It has already been shown how useful ^{111}In, in particular, is for the radioimmunoscintigraphy of tumors[100], although this radionuclide can often lead to problems of nonspecific accumulation in the liver, spleen, and kidneys.

In the course of the few years in which monoclonal antibodies have been available, they have proved their suitability for radioimmunodetection and have shown themselves to be at least as good as other competing detection methods, including X-ray computer tomography. In the near future we can expect important, if not spectacular breakthroughs, due to the finding of new antibody specificities, the testing of available antibodies with regard to their specificity and avidity (stronger antigen-antibody binding), the continuing standardization of antibody fragments, and the improvements in the adjustment of measuring techniques to the radiation properties of the radionuclides. This development will be followed by the first therapeutic applications with radioactively labeled antibodies (radioimmunotherapy), as is already being done in a few centers[124]. Moreover, localization experiments provide useful indications for the later use of immunotoxins or immunocytostatic drugs (see next section).

5.4.2. *Immunotoxins: Preparative Problems and Possible Uses*

The terms immunotoxins and, in certain cases, antibody-drug conjugates refer to cytotoxic agents[125–128] which, via a specific antibody binding site, are intended to reach specifically their target cell, for example, a tumor cell. There the toxic agent should interfere in the cell metabolism and cause its death.

Various problems, several of which are dealt with in part below, have to be solved during the preparation of such conjugates. First, a high-affinity antibody of the required specificity, in its pure and native form, has to be isolated (Table 7). Monoclonal immunoglobulins, mainly from the mouse at present, are an obvious choice. A later in-vivo use in human beings can therefore lead to problems of antigenicity.

Table 7. Immunotoxins: problems connected with the antibody.

Problem	possible solution
Specificity/affinity	monoclonal antibodies
Purity/nativity	special fractionation
Antigenicity	human monoclonal antibodies
Pharmacokinetics Enzymatic cleavage Chemical modifications	selection of suitable class or subclass

The question also arises as to which immunoglobulin class or subclass is especially suitable; for this choice also determines which biological and Fc-mediated activities the antibody will be able to perform (see Section 3.2) and which chemical modifications can be used. The problems arising in the use of enzyme cleavage for the production of certain antibody fragments and in their isolation have been discussed in Section 4.2.

In the selection of toxic compounds, a choice can be made between different working principles (Table 8). Various toxins, cytostatic drugs, or radionuclides are available. The toxins, such as ricin, abrin, or diphtheria toxin, are proteins that can inhibit protein synthesis. In these toxins two functionally differing molecular moieties can be distinguished: one containing the toxic activity (A-chain or A-fragment) and one on which the binding site for cell surface receptors is found (B-chain or B-fragment). In order, therefore, to avoid undesired interaction with cells other than those of the target tissue (target cells), either the B-chain (B-fragment) has to be removed from the complete molecule prior to binding the A-chain to the antibody or antibody fragment, or the relevant binding site for carbohydrates on the B-chain has to be inactivated or blocked. In general, toxin-antibody conjugates are quite useful for the case of low antigen density on the target cell since even a few toxin molecules can cause cell death.

Table 8. Immunotoxins: problems related to the toxic component.

Problem	possible solution
Selection of adequate toxic principle (toxin, cytostatic, radionuclide, etc.)	estimation of antigen density on the target cell surface
Undesired interactions	modification of toxic components
Low amount of toxic agent at the target site	carrier molecule

On the other hand, low molecular weight cytostatic drugs, such as adriamycin, which belongs to the group of anthracyclines, daunomycin, and methotrexate, can be used; these are compounds which can inhibit cell division. These cytostatic agents can, in principle, be directly linked to an antibody molecule. Since relatively large amounts are required, in comparison to toxins, to destroy a cell, a large number of toxic molecules are bound to the antibody; in general, however, this lowers the specific binding activity of immunoglobulin[127]. For this reason the use of carrier molecules is often considered; *one* carrier molecule is loaded with cytostatic drugs and then linked to *one* antibody molecule.

The problems confronting the biochemist (Table 9) when he couples the antibody (i.e., specific binding principle or the targeting unit) with the toxin (the toxic principle) to form a conjugate are summarized in Table 9. The linking strategy has to be selected in such a way that the activities of the two components are as little impaired as possible. The linking method and the spacer must be so chosen that stable conjugates are formed reproducibly and in good yield. These conjugates normally then have to be sep-

arated from excess starting components in a purification step. Otherwise there is a danger that the free antibody molecules not linked with a cytotoxic agent will compete in the later reaction and thus decrease the effectiveness of the conjugates. Moreover, in order for the toxic principle to be effective, it is especially important that the bond between antibody and toxin can be cleaved in the phagosome after endocytosis has taken place[129-131].

Table 9. Immunotoxins: problems associated with the synthesis of conjugates of antibodies with the toxic agent.

Problem	possible solution
Activity/stability Reproducible production Yield In-vivo cleavage of the conjugate bonds	selection of suitable coupling methods
Formation of homopolymers	heterobifunctional reagents
Pluridirectional bindings (statistical)	selection of specific binding sites
Antigenicity/solubility	selection of suitable coupling *principle*

Special problems arise, if, as in the case of toxin-antibody linkage, two proteins are to be linked (Fig. 12). Due to the more or less statistical distribution of the groups that are often used for linkage reactions (ε-amino group of lysine, carboxyl group of glutamic or aspartic acid), and their differing levels of reactivity, conjugate formation takes place at various sites on the molecule, including those located in the vicinity of the antibody binding site. This can result in inactivation of this site.

Heterobifunctional linkage reagents are preferred in all cases, since they help to prevent the formation of homopolymers, that is to say antibody-antibody and toxin-toxin conjugates. The level of substitution obtained is merely an average value. Thus there are both more and less substituted fragments, of which the more highly substituted have a better chance of taking part in the reaction. In many cases the specific antibody reactivity is lower for higher levels of substitution. This example also shows quite clearly that surplus unreacted groups may remain in the conjugates and thus create additional problems for the subsequent application.

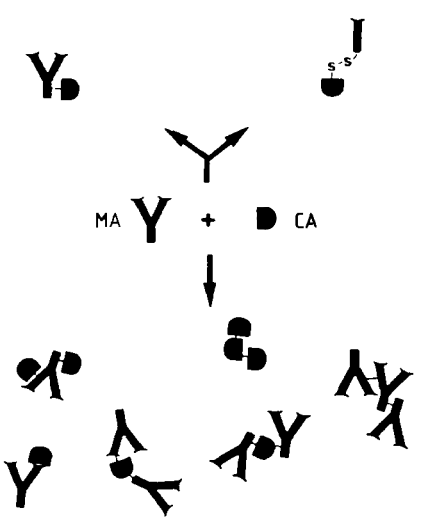

Fig. 12. Problems that can arise in the coupling of monoclonal antibodies (MA) to cytotoxic agents (CA) are shown in the lower half of the picture: Homopolymers can form or the antibody binding site can be blocked. Sought are conjugates via groups [e.g., the carbohydrate moiety in the Fc area (top left) or the SH groups of former inter-H-chain disulfide bonds in the Fab' fragment (top right)] that do not cause any impairment of the antibody binding site.

Thus the ideal methods of conjugate formation would be those using groups that, on account of their position in the molecule, do not result in impairment of the antibody binding site. The carbohydrate moiety, mainly found in the Fc domain of the molecule, or the SH groups of the former inter-H-chain disulfide bonds present mainly in the Fab' fragment fulfill these requirements. In this way SH groups can be converted into activated disulfide bonds with various reagents. These are then able to form the desired conjugate with the SH group of a ricin A-chain.

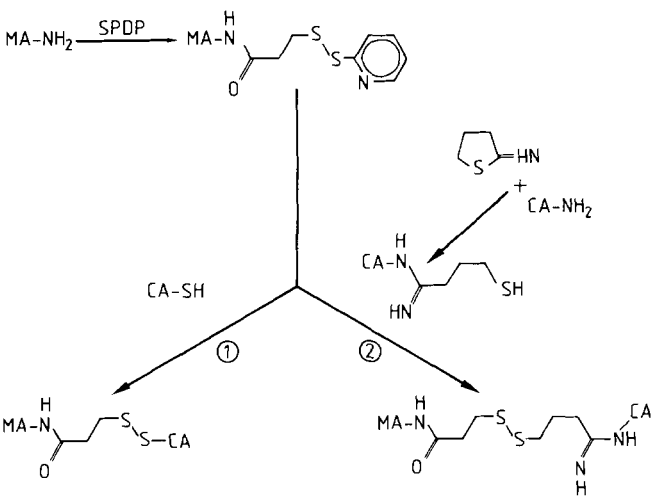

Fig. 13. Synthesis of conjugates from monoclonal antibodies (MA) and cytotoxic agents (CA): activated disulfide bonds can be introduced into monoclonal antibodies with the heterobifunctional reagent *N*-succinimidyl-3-(2-pyridyldithio)propionate (*SPDP*). The reaction leading to the desired coupling product takes place via SH groups that are either already present in the cytotoxic agent (reaction pathway ①) or have to be introduced (e.g., with iminothiolane; reaction pathway ②).

However, many methods cannot be employed on account of either the high losses during production of the Fab' fragments or the poor yields during the linking reaction. The possibility remains of introducing activated disulfide bonds via the amino groups of uncleaved immunoglobulin with the aid of special reagents (SPDP, etc.). These can then be similarly used for the synthesis of conjugates (Fig. 13). Thus, from a pragmatic point of view, compromises must always be sought.

Fig. 14 shows the dose-dependent effect of a ricin-antibody conjugate in an in-vitro cell system, in which protein synthesis was measured quantitatively via ^{14}C-leucine incorporation. Since the complete toxin molecule and not the ricin A-chain was coupled to the monoclonal antibody in this experiment, the nonspecific binding site on the B-chain for the ubiquitously appearing carbohydrate cell surface structures with terminal galactose had to be blocked by the addition of lactose (0.1 mol/L). The reactive immunotoxin has an effect comparable to that of free ricin,

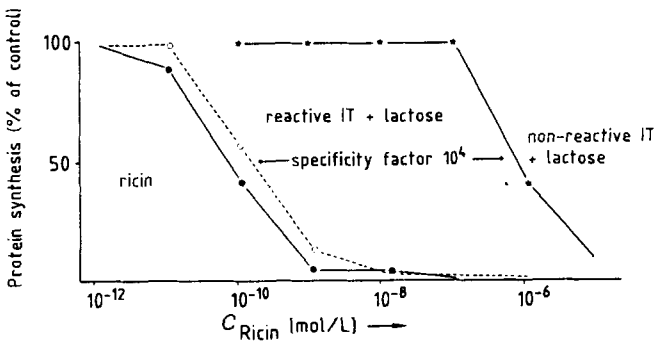

Fig. 14. The dose-dependent effect on protein synthesis in an in-vitro cell system of ricin-antibody conjugates. The immunotoxins (IT) were tested in the presence of 0.1 mol/L lactose in order to suppress nonspecific cell binding by ricin B-chain (for further information see text).

whereas an analogous conjugate with a non-reactive monoclonal antibody is less toxic by about four orders of magnitude *(specificity factor)*.

It is clear that, due to the lack of detailed knowledge, an empirical approach is still required in each individual case. The problems are still graver for the in-vivo use of antibody-linked cytotoxic agents. As is shown schematically in Fig. 15, it is expected that, in this case, the conjugate reacts first with a membrane-bound antigen on the target cell[132]. The correct antibody specificity on the one hand and the antigen stability on the other guarantee that the antigen-antibody complex forming on the cell surface is not only cleaved, but also taken into the cell via endocytosis. The cytotoxic principle will be subsequently released in the phagosome in order to inhibit finally protein synthesis or DNA replication. In tumor therapy this blockage must be able to inactivate and destroy more than 99.99% of the target cells in order to be effective[133, 134]. Variability in the target antigen, such as in primary tumors and metastases, reduces the effectiveness. Mechanisms that enable the nonspecific absorption of agents into non-target cells can lead to undesired side effects with all their negative consequences. The use of the relatively small monovalent antibody fragments with their shorter half-lives, even in the conjugate, will most likely be advantageous.

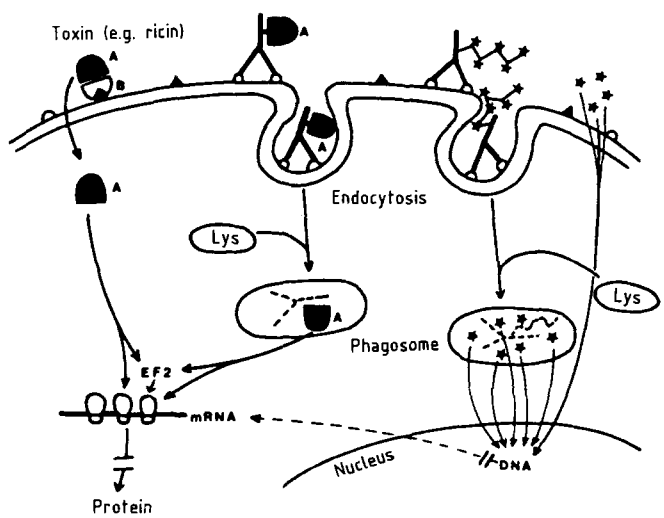

Fig. 15. Schematic representation of actual in-vivo mechanisms of immunotoxins and cytotoxic agents (for further information see text). ▲ = Receptor, ▭ = cell antigen, ✱ = cytostatic agent, EF = elongation factor, Lys = lysosome.

5.4.3. *Transplantation*

During the therapeutic use of mouse monoclonal antibodies, Fc-mediated immune reactions must be considered (see Sections 3.2 and 5.3.2). These also have to be considered when using CD3 monoclonal antibodies with T-cell-activating properties if such monoclonal antibodies are used for immune suppression (organ transplantation and bone marrow transplantation). At present clinical experience is available for only one type of T-cell-activating antibody (OKT3) with CD3 specificity. This antibody was principally used for treating kidney transplant patients, both prophylactically and, during acute rejection crises, therapeutically[135-137]. In allogenic bone-marrow transplantation, OKT3 was used to prevent "graft versus host" (GvH) reactions, both in vitro for the elimination of immune reactive T-cells and in vivo for the treatment of acute GvH reactions[138, 139]. Whereas an overwhelmingly positive therapeutic effect could be achieved with OKT3 for organ transplantation and allogenic bone-marrow transplantation in leukemia pateints, an in-vitro/in-vivo treatment with OKT3 in severe combined immune deficiencies (SCID) was not able to prevent GvH reactions[140].

Monoclonal antibodies with other specificities than that of CD3 have also been used in both organ transplantation and allogenic bone-marrow transplantation. The individual considerations and experiments underlying the choice of each monoclonal antibody cannot be discussed in detail here; however, some general examples will be given. Campath 1, a monoclonal rat antibody of the IgM class with wide reactivity on mononuclear cells, has been used in allogenic bone-marrow transplantation; it was chosen on account of its ability to effectively lyse target cells with the aid of human complement[141]. Mixtures of several antibodies are often preferred to avoid *escape* mechanisms and for a more exact definition of target cell populations. In this case either cell elimination takes place via complement-mediated cytolysis or the antibodies act directly as immunotoxins[142, 143].

For organ transplantation, the immune reactive T-lymphocyte, the target cell, is hit with an anti-T12-antibody, as was the case for OKT3[144]. A different target cell population is the basis of therapy with CBL1. This antibody could be capable of eliminating the B-lymphoblast clones activated during a transplant rejection reaction[145].

5.4.4. *Human Hybridomas*

Compared with conventional antisera, monoclonal antibodies of mouse origin have the decisive advantage of monospecificity. When judging their therapeutic value, however, the complete immunoglobulin molecule has to be taken into account since numerous Fc-mediated immune mechanisms are involved in complex immune reactions (see Section 3.2). Due to the polymorphism of human Fc receptors, mouse immunoglobulins of the subclass Ig1 or IgG2b cannot be processed analogously to human immu-

noglobulins, or only to a limited extent[67, 146]. Thus Fc-mediated immune reactions, such as antibody-dependent cellular cytotoxicity (ADCC), cannot take place as effectively as they can with rabbit or human antibodies. Moreover, mouse immunoglobulins are antigens for the human immune system, so that anti-mouse-Ig antibodies may be induced after the administration of mouse monoclonal antibodies. Such anti-mouse-Ig antibodies, at high titers, can impair therapy. This sort of difficulty is not to be expected when using human monoclonal antibodies[147].

In principle, human monoclonal antibodies can be produced by three basic methods:

- Epstein-Barr-Virus (EBV) transformation of B-lymphocytes[148-150],
- cell fusion, in analogy to the mouse system, and
- via heterohybrids, mouse-human (mouse myeloma cell line).

For the production of human antigen-specific monoclonal antibodies, the availability of appropriately stimulated human lymphocytes has often been a limiting factor. Whereas the mouse immune system can be activated, as a rule, by in-vivo immunization—only for extremely small amounts of antigen was in-vitro immunization occasionally preferable—the stimulation of human B-cells must be carried out in vitro for the majority of antigens. Not until improvements were made in culture conditions, for example, the use of serum-free Iscove's medium, and the T-cell help for stimulation of B-cells was optimized, was a more effective in-vitro induction of the human Ig synthesis possible for certain selected antigens.

The increasing understanding of the activation mechanisms in lymphocyte stimulation and the biochemical characterization of the factors involved have now also made it possible to interfere specifically in the differentiation and proliferation of B-lymphocytes[56, 151, 152]. If antigen-specific precursor cells can be expanded selectively with the aid of mediators produced by gene technology (B-cell growth factor (BCGF), B-cell differentiation factor (BCDF), interleukin-2, γ-interferon), the preconditions would be created for specifically producing human antibodies in high yields. The immortalization of B-lymphocytes (transformation or fusion) would then play a subordinate role.

Since *Olsson* and *Kaplan* described the first human monoclonal antibodies[153], many different approaches have been used for the isolation of activated B-lymphocytes. At first, monoclonal antibodies could mainly be isolated against antigens with which blood donors had been naturally or artificially immunized. Now, however, human monoclonal antibodies with specificity against tumors can be produced via the fusion of lymphocytes from tumor-draining lymph nodes. Table 10 is a summary of selected human monoclonal antibodies with different specificities.

It is noteworthy that xeno-hybrids based on human-mouse fusions can be produced in relatively good yields[159, 161, 164, 165]. The in-vivo use of human-mouse monoclonal antibodies has, to date, been limited to case studies of tumor patients[167]; however, new horizons, especially for tumor therapy, appear with the isolation of further human monoclonal antibodies having different specificities.

Table 10. Specificity of human monoclonal antibodies.

Binding specificity for	Ref.
Tetanus Toxoid [a]	[159, 160]
Diphtheria Toxoid [a]	[159]
Sheep erythrocytes	[156]
Thyrotropin Receptor	[158]
Hemophilus influencae B.	[159]
Keyhole Limpet Hemocyanin	[161]
Influenza virus	[154]
Pneumococcus	[155]
Human monoclonal antibody with reactivity against human tumors (colon, lung, breast, glioma, melanoma, and others)	[157, 162—166]

[a] A toxoid is a toxin that has retained its antigenicity but lost its toxic effect due to inactivation.

Human monoclonal antibodies would be very desirable for the production of hyperimmune sera, specifically against bacterial and viral pathogens for which suitable and well-tolerated vaccines are not available or difficult to produce.

5.4.5. *The Problems of Using Monoclonal Antibodies in Humans*

The in-vivo application of monoclonal antibodies, whether they are coupled to cytotoxically effective agents or not, gives rise to problems which, above all, have to be taken into account by the various health organizations when they authorize the use of such preparations. Up to now monoclonal antibodies have only been used to a limited extent for therapy on human beings, so that no general summary of tolerance and side-effects is available[168]. It is understandable that, for this new drug, all possible safety precautions are considered. Of course, depending on the purpose of the application (anti-tumor therapy, immune modulation, immune suppression, passive immunization, diagnosis, etc.), the possible damages must be weighed against the benefits. Experience gained over the course of time will certainly help to identify the criteria with real practical significance.

High demands are therefore made on the cells used for fusion (myeloma lines, B-lymphocytes), as well as on the cloned hybridoma line which produces the relevant monoclonal antibody, with regard to their being free from bacteria, viruses (especially lymphocytic choriomeningitis (LCM) and respiratory-enteric-orphan (REO) viruses type 3), and mycoplasmas.

The method of purification for monoclonal antibodies should guarantee, in a reproducible manner, the removal of viruses and undesired macromolecules, including DNA. Sterility, the absence of pyrogens, stability of the final product, and its biochemical (subclass, electrophoretic mobility, aggregate content, etc.) and functional (specific activity, titer information, etc.) characterization must also be guaranteed. Likewise, the safe use of the product for human beings must be assured by general and specific pharmacological and toxicological animal tests. All the investigations summarized in part here must, of course, be sufficiently documented.

6. Summary and Outlook

The success of immunological research over the past one hundred years lies in the establishment of antibody therapy, the discovery of many infectious pathogens, and the provision of numerous vaccines, as well as in the development of immunodiagnosis. Above all, in the last twenty years, immunology has studied the immune system more closely and thus enabled us to seize upon new forms of therapy.

Access to monoclonal antibodies has set a new milestone in the history of immunology: the discovery that they could be produced in vitro by means of immortalized hybrid cell clones has now become a matter of general interest, not only in the field of immunology but in many fields of science, technology, and medicine.

The particular advantages of monoclonal antibodies could be first and most easily shown for immunodiagnosis. The discussion concerning their superiority over conventional, heteroclonal antibody preparations, however, is still underway. There is no question about the advantages of monoclonal antibodies for the differentiation and the fine analysis of cell surface structures, e.g., for immune cells, parasites, bacteria, and viruses. The histological differentiation of tissue structures, too, is expected to make interesting progress.

However, as already shown in pilot studies, the new medical uses could become of greater importance. First signs of success have been recorded in the localization of tumors in a living organism using radioactively labeled monoclonal antibodies. The search, however, for suitable antibodies is still very costly and difficult. The aim is to discover specific or tumor-associated antigens for many types of tumor and to characterize them, showing at the same time that such substances cannot be found in normal tissue, or only in negligibly small concentrations. The next goal is tumor therapy, either directly with monoclonal antibodies or with antibody conjugates (with radionuclides in suitable doses, with tumor cytostatic drugs, or with toxins). Very encouraging initial successes have been achieved with a few sorts of tumors, but we shall have to await the results of further clinical trials.

In addition to the immune mediators now accessible by gene technology, monoclonal antibodies are receiving more attention with regard to immunoregulatory forms of therapy. The value of this type of treatment has been shown by the first clinical studies in organ and bone-marrow transplantation. Much hope has also been placed in antibodies that may enable us to treat the undesired immune reactions in autoimmune disorders by possibly inactivating or eliminating immune cells with immunologically wrongly primed recognition structures.

To what extent conventional immunosubstitution with homologous human antibody preparations can be replaced by specific monoclonal antibodies depends on the progress made in the field of human hybridomas. These systems do not work as well as the mouse systems. Further improvements are necessary, and, above all, methods of in-vitro immunization must be developed to specifically stimulate still unprimed B-lymphocytes with any desired antigen. In principle, this is possible, but still not to the required extent or in any direction.

Intensive research with and into monoclonal antibodies is being carried out worldwide, so that the many still unsolved problems will presumably be quickly solved and improved methods will most likely be developed. Interesting developments can also be expected from the use of the methods of gene technology in the production of antibodies or the occasionally more advantageous antibody fragments.

Unfortunately, this revolutionizing hybridoma technology is confronted with rather conventional production methods: modern cell culture methods are relatively underdeveloped and thus normally still very expensive. If one considers that ca. 100000 L of cell culture would have to be prepared to produce 1 kg of monoclonal antibody, an amount certainly necessary for an established therapy, then limits become apparent. However, there are also efforts here to produce the same quantity of antibody with only 1000 to 10000 L of cell culture. This unfavorable situation also exists for the production of recombinant protein from mammalian cell cultures. The demands of two modern biotechnologies will surely accelerate the urgently needed breakthrough in cell culture technology.

We would like to thank Mrs. Waltraud Noll for her extraordinary understanding and great patience during the typing of the manuscript.

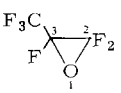
Hexafluoropropene Oxide— A Key Compound in Organofluorine Chemistry



By Hans Millauer, Werner Schwertfeger, and Günter Siegemund*

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday

Of the important C_3-compounds in organofluorine chemistry, namely hexafluoropropene, hexafluoroacetone and hexafluoropropene oxide, the latter is chemically the most versatile compound. Hexafluoropropene oxide provides another example of the frequently observed change in reactivity when hydrocarbon compounds are converted into their perfluorinated derivatives. The overwhelming majority of the known reactions of hexafluoropropene oxide are initiated through attack by a nucleophile. The conversion of hexafluoropropene oxide into hexafluoroacetone in the presence of Lewis acids is the basis of further development of the chemistry of this synthetic chemical. Hexafluoropropene oxide is also regarded as a convenient source of difluorocarbene. In industrial chemistry it now plays a significant part in the manufacture of high-grade organofluorine products.

1. Introduction

In 1959 E.I. du Pont de Nemours & Co. filed a patent application on fluorocarbon epoxides as a new class of perfluorinated compounds, whose industrial importance for the manufacture of highly upgraded perfluorinated polymers was clear from the outset. In the 25 years since then the most important member of this new class of compounds has proved to be hexafluoropropene oxide (HFPO, 2,2,3-trifluoro-3-trifluoromethyloxirane).

HFPO

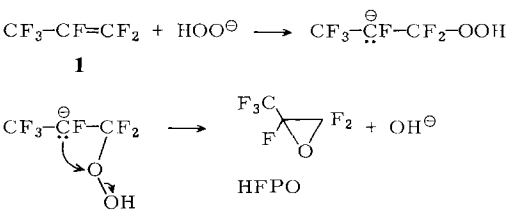
Various methods of synthesis and a multitude of reactions justify a survey of the extensive chemistry of HFPO. Reviews already published are either somewhat old[1,2] or are not readily accessible[3].

2. General Properties of HFPO

HFPO is a colorless, nonflammable gas with a slight odor and a boiling point of −27.4 °C/1013 mbar. Even when liquified under pressure HFPO is stable at room temperature in the dry state and in the absence of Lewis acids or bases. Spontaneous polymerization has not been observed. Marked thermal decomposition occurs only at a temperature of 150 °C or above[2].

The interatomic distances and bond angles of HFPO have been determined[4]; unlike the analogous hydrocarbon compound, propylene oxide, the perfluorinated compound has a shorter C–O distance and a lengthened C–CF_3 bond.

The ^{19}F-NMR spectrum has been described[5]. In the IR spectrum HFPO exhibits a strong band between 1480 and 1620 cm^{-1} with a maximum at 1550 cm^{-1}, which characterizes perfluorinated epoxides and in a number of instances can be employed for quantitative determination.

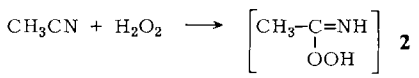


HFPO is a relatively non-toxic compound. In the test for acute inhalation toxicity a 4-hour LC 50 of 3700 ppm was recorded[6]. In the Ames test, HFPO displayed no mutagenic activity[7].

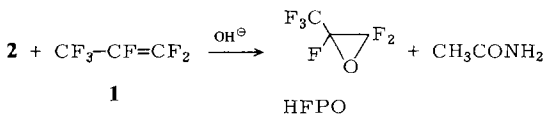
3. Preparation and Purification of HFPO

All known methods for the synthesis of HFPO are based on the reaction of hexafluoropropene **1** (HFP) — a commercially available fluoroolefin — with an oxygen donor. Depending on the type of oxidizing agent, epoxidation can be regarded as a nucleophilic, electrophilic or radical reaction.

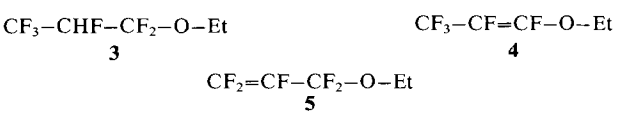
3.1. Nucleophilic Syntheses



HFPO was first prepared, in about 35% yield, by reacting hexafluoropropene **1** with 30% hydrogen peroxide in aqueous-methanolic potassium hydroxide solution at −40 °C[8]. It is assumed that the hydroperoxide anion, which is a stronger nucleophile than the hydroxide anion, attaches itself preferably to the electron-deficient double bond. The resultant carbanion stabilizes with elimination of a hydroxide ion and ring-closure to the epoxide[2].



The reaction can also be carried out in other water-miscible organic solvents or in aqueous solution in the presence of sodium perfluorooctanoate[8]. Higher yields (54%) and a reduced consumption of feedstock are achieved by

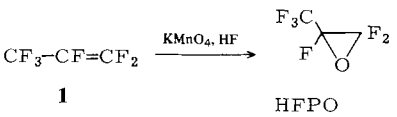


[*] Dr. G. Siegemund, Dr. H. Millauer, Dr. W. Schwertfeger
Hoechst Aktiengesellschaft, Hauptlaboratorium
Postfach 80 03 20, D-6230 Frankfurt am Main 80 (FRG)

slowly adding the potassium hydroxide solution to the reaction mixture[9]. Similarly, high yields (about 52%) are said to have been achieved by adding the reactants simultaneously and continuously to the reaction vessel[10]. Another continuous method employs an aqueous hydrogen peroxide solution at pH 7.5—8 in the presence of acetonitrile[11]. Oxygen is transferred by the intermediate acetoperoxyimidic acid **2** or by its anion. Stoichiometric quantities of acetamide are formed as a by-product.

Sokolov et al.[12] investigated the structure of the by-products formed in the reaction of **1** with alkaline, aqueous-ethanolic hydrogen peroxide solution. With a molar ratio of H_2O_2 : HFP greater than 4 : 1, the main products obtained are HFPO and trifluoroacetate, whereas with a molar ratio less than 1 : 1 the ethers **3**, **4** and **5** are formed.

HFPO is also produced by the action of hypohalites, especially sodium hypochlorite, on **1**. The reaction is carried out at pH 9—11 and 15—20°C in the presence of water-miscible aprotic solvents, e.g. acetonitrile or diglyme[13, 14].



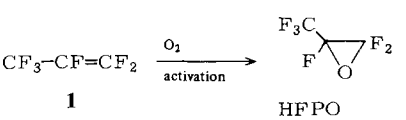
Other methods employ a two-phase system, consisting of an aqueous hypohalite solution and a water-immiscible organic solvent. The reaction in this case proceeds only in the presence of a phase transfer catalyst or a lipophilic alkali metal-ion chelating compound[15, 16]. Aliphatic and aromatic hydrocarbons, chlorinated hydrocarbons, and chlorofluoroalkanes, e.g. 1,1,2-trichloro-1,2,2-trifluoroethane, are suitable for the organic phase. Catalysts mainly mentioned are quaternary ammonium salts, whilst macrocyclic ethers are mentioned as complexing agents. Anionic and nonionic surface-active compounds, too, are described as activators[17]. The HFP conversions and the yields are generally higher in the hypohalite method than in the peroxide method.

One variant of the hypohalite method is the electrolysis of a two-phase mixture consisting of aqueous alkali chloride solution and organic solvent in an undivided cell in the presence of HFP and one of the above-mentioned catalysts or lipophilic complexing agents[18]. In this case the hypochlorite is produced and reacted continuously in the cell.

HFPO is produced, along with a considerable quantity of 1,2-dichlorohexafluoropropane, in the reaction of **1** with chlorine in the presence of aqueous bases at room temperature in the absence of light[19].

3.2. Electrophilic Syntheses

The epoxidation of hexafluoropropene **1** under electrophilic conditions has so far been observed in only a few instances. *Belen'kij* et al.[20] obtained HFPO in 30% yield on reaction of **1** with potassium permanganate in anhydrous hydrogen fluoride at −70°C.



When chromium trioxide is used in fluorosulfuric acid, the yield is about 55%[21].

The anodic epoxidation of **1** can also be regarded as an electrophilic reaction. Suitable electrolytes are HFP-saturated, aqueous, aliphatic carboxylic acids or nitriles, and suitable conductive salts are nitrates, perchlorates or tetrafluoroborates. Platinum is a suitable universal anode material; in acetic acid/nitric acid electrolytes, a lead dioxide anode can also be used[22, 23]. The reaction is carried out in a tubular flow cell. The material yield is 92%, while the current yield is 55%[24, 25].

3.3. Radical Syntheses

3.3.1. Syntheses with Molecular Oxygen

Methods for the production of HFPO with molecular oxygen have been thoroughly investigated. In these reactions either thermal activation, the use of energy-rich radiation, or the addition of radical-forming agents is generally necessary; a combination of various methods has occasionally been used.

The main by-products formed are carbonyl difluoride, trifluoroacetyl fluoride and hexafluoroacetone. Depending on the reaction conditions, the different methods are carried out in the liquid phase or in the gas phase.

The syntheses in the liquid phase are usually carried out under pressure in an autoclave with oxygen being added to the HFP. The reaction temperatures are generally 100—200°C; the yields reach 76% with a conversion of 70%. Frequently, the liquid phase is diluted with a solvent (e.g. fluorocarbons or chlorofluoroalkanes)[26, 27]. By adding 5—500 ppm benzene or diphenyl ether the undesired rearrangement of HFPO to hexafluoroacetone is suppressed[28]. By using a reactor lined with Teflon® (du Pont), *Kartsov* et al.[29] achieved double the yields they obtained in a stainless steel reactor. According to a Japanese patent[30] very high yields (90% selectivity with 100% conversion) are said to be achieved by adding oxygen in small portions in the absence of other substances. Organic per-

oxides, too, such as benzoyl peroxide or *tert*-butyl perbenzoate[31], or oxygen difluoride[32] have been used as activators for oxygen.

The photoinitiated reaction of **1** with oxygen in the gas phase was investigated by *Heicklen* and *Johnston*[33]. Substantial quantities of COF_2 and CF_3COF were detected in addition to HFPO as reaction products at room temperature and with the use of UV light. Under similar conditions *Sianesi*[34] found only 1% HFPO in addition to 15% COF_2, 37% CF_3–COF and 47% higher-molecular compounds of the type **6**

$CF_3O(CF_2O)_n$–COF $CF_3O(CF_2O)_n$–CF_2–COF (n = 0–15)
6a **6b**

HFPO has also been obtained by the action of X-rays on an HFP/O_2 mixture rendered inert in the gas phase[35]. Several methods for the epoxidation of **1** with oxygen in the gas phase over solid catalysts at temperatures of 100–350 °C have been described in the patent literature. Catalysts claimed are either pretreated silicic acid[36,37], carriers consisting of silicic acid[38] or silicic acid/aluminum oxide mixtures[39] doped with copper compounds, zeoliths doped with transition metals[40], or catalysts prepared from barium compounds[41]. With conversions between 10% and 40%, selectivities between 30% and 80% are mentioned for the gas phase methods.

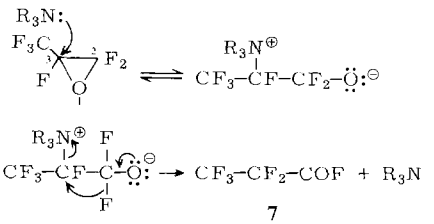
3.3.2. Syntheses with Other Oxidizing Agents

Organic hydroperoxides in the presence of catalysts are also suitable as oxygen donors in the epoxidation of hexafluoropropene **1**. With *tert*-butyl hydroperoxide and hexacarbonylmolybdenum as catalyst, the reaction proceeds in 1,1,2-trichloro-1,2,2-trifluoroethane at 70 °C with 39% conversion and a selectivity of 88%[42].

Ruff and *Merritt*[5] obtained HFPO together with other products on reacting oxygen difluoride with **1** in the gas phase under UV radiation at 35 °C. The same reaction has also been carried out with silver difluoride as catalyst[43,44].

3.4. Purification Methods

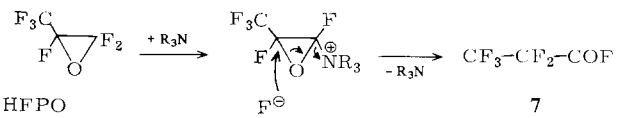
In most reactions for the preparation of HFPO, partial conversion of **1** is accepted as sufficient. Special methods are required for the separation of unreacted **1**, which boils at −29.4 °C. On the laboratory scale the HFPO/**1** mixture is allowed to react with bromine; in this reaction, **1** forms 1,2-dibromohexafluoropropane, which can be readily separated by distillation.



For industrial purposes extractive distillation is employed as the purification method[45–49]. The extractants used include dichloromethane, 1,2-dichloroethane, 1,2-dimethoxyethane, diisopropyl ether and toluene (for the solubility of HFPO and **1** in various organic solvents see [50]).

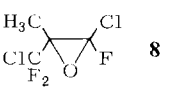
Very pure HFPO with <0.1 ppm HF, <1 ppm H_2O, <0.2% acid fluoride and <0.01% hexafluoroacetone is obtained by passing HFPO successively over potassium hydroxide and calcium hydride[51].

4. Reactions with Nucleophiles



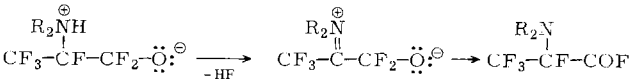
HFPO is highly sensitive to nucleophilic reagents. It reacts with strong nucleophiles even below room temperature. The attack usually takes place at C-3 and only rarely at C-2. The following mechanisms have been suggested for the reactions of HFPO with secondary or tertiary amines, which result in perfluoropropionic acid derivatives:

Sianesi et al.[52] and *Knunyants* et al.[53] assume that the attack by tertiary amines takes place at C-3,



7

whereas *Bekker* et al. postulate an attack by the amine at C-2 and substantiate this mechanism by reference to analogous reactions at the epoxide **8**[54].

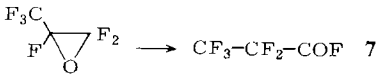


HFPO

8

Evidence for attack at C-2 is also provided by the fact that secondary amines likewise give perfluoropropionic acid derivatives. Attack at C-3 would, however, lead to a betaine **9**, which should react further with elimination of HF.

9



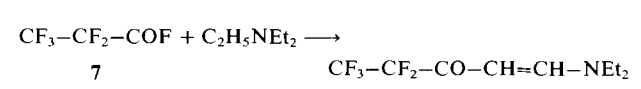
The explanation given in the literature[54] for the extraordinary behavior of secondary and tertiary amines with HFPO (NH_3 and primary amines usually react at C-3; see Section 4.7 and 4.8) is the increasing steric hindrance of the amines, which no longer permits "normal" attack but causes substitution of a fluoride ion at C-2 as an initial step.

4.1. Isomerization of HFPO to Perfluoropropionic Acid Fluoride

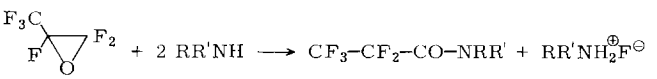
One of the most frequently observed reactions of HFPO with nucleophiles is the exothermic isomerization to perfluoropropionic acid fluoride **7**.

The following nucleophiles have been used for this reaction: tertiary amines (particularly triethylamine)[52,53,55–63]; secondary amines[52,53]; primary amines[64]; enamines[65];

Me_3SiOMe, $Me_2Si(OEt)_2$[66]; halide ions (particularly fluoride ions)[67-71].



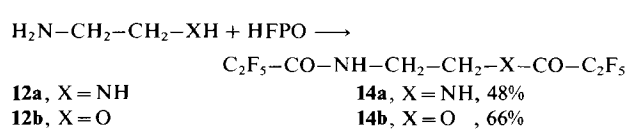
HFPO



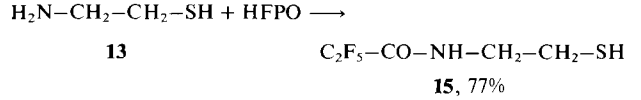
If the isomerization is carried out in the presence of tertiary amines the resultant **7** is usually not isolated but allowed to react further in situ. Thus, on allowing **7** to react with alcohols[52,58,63], thiols[58,61,63], ammonia[52], primary amines[58,60,61] and 1,2-bifunctional ethanes ($X-CH_2-CH_2-Y$; X, Y = OH, SH)[62] the corresponding derivatives of pentafluoropropionic acid are obtained (see also Section 4.8).

The reaction mixture consisting of **7** and NEt_3 is also used as a fluorinating agent in the preparation of carboxylic acid fluorides from the free carboxylic acids[57,59].

However, triethylamine itself also reacts with **7**; this yields the unsaturated ketone **10**[55,56].

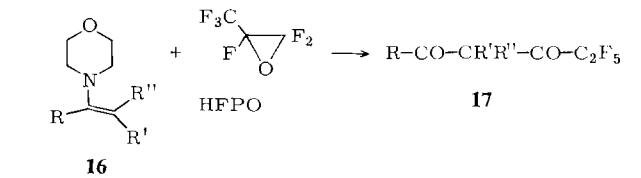


The reaction of HFPO with secondary amines yields pentafluoropropionic acid amides **11**[52,53].

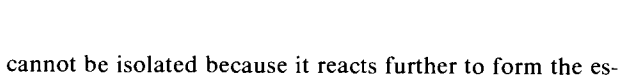


HFPO

Assuming the mechanism suggested by *Bekker* et al.[54], it is however unlikely that **7** occurs as an intermediate product in this reaction.

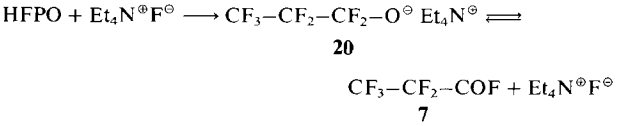


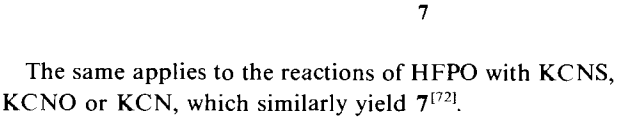
Whereas most primary amines react with HFPO by attacking the C-3 atom (see Section 4.7 and 4.8), the perfluoropropionic acid derivatives **14** and **15** are produced when the amines **12** and **13** are reacted under comparable conditions[64].



The reaction of *N*-(1-alkenyl)morpholines **16** with HFPO proceeds via **7** to give the diketones **17** in yields of up to 80%[65].

Even in the reaction of HFPO with the silanes **18** and **19** in the presence of activated carbon the initially formed **7** cannot be isolated because it reacts further to form the ester[66].

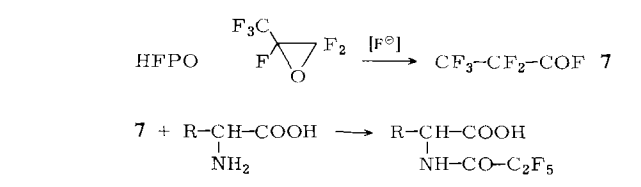


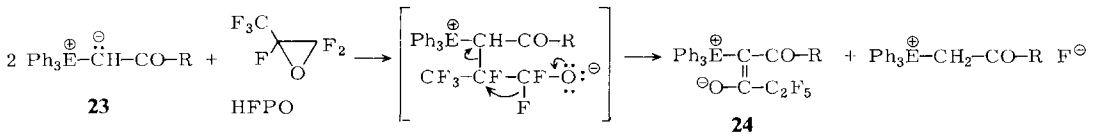


The fluoride-ion catalyzed rearrangement of HFPO to **7** is carried out both in the presence[67-70,72] and in the absence[71] of solvents. Thus, for example, by passing HFPO over KF/activated carbon the yield of perfluoropropionic acid fluoride **7** is >90%[71]. When solvents are used, the yield of **7** has been found to be highly dependent on the solvent[69].

It is not always necessary to employ fluoride ions for the isomerization; they are often formed in situ in a previous reaction.

The action of $Et_4N^{\oplus}Cl^{\ominus}$ on HFPO in dichloromethane yields, for example, the propoxide **20**, which is in equilibrium with **7** and $Et_4N^{\oplus}F^{\ominus}$[67]. It is suggested that the chloride ion from $Et_4N^{\oplus}Cl^{\ominus}$ attacks HFPO nucleophilically and is bound irreversibly. The fluoride ion thus liberated then catalyzes the isomerization to **7**.



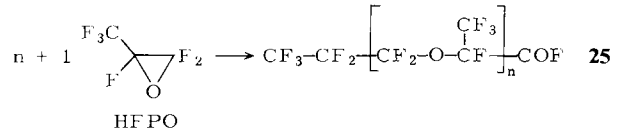


The same applies to the reactions of HFPO with KCNS, KCNO or KCN, which similarly yield **7**[72].

On the other hand, when HFPO is reacted with trimethylchlorosilane, the resultant fluoride ion is captured as trimethylfluorosilane, and so the formation of **7** is prevented[66].

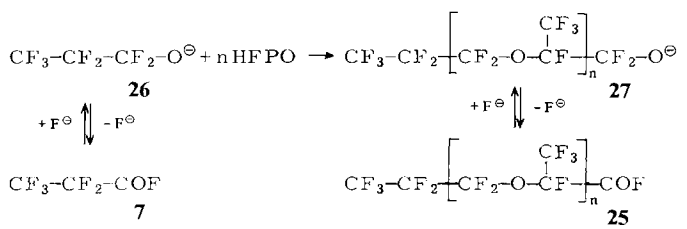
Even in the reaction of amino acids **21** with HFPO, which leads to the acylated derivatives **22**, *Ishikawa* et al. assume catalysis by intermediary fluoride ions[70].

a, E = As, R = OMe; **b**, E = As, R = Ph; **c**, E = P, R = OMe; **d**, E = P, R = Ph



7 is quoted as an intermediate in the reaction of triphenylarsoranes **23a**, **b** or triphenylphosphoranes **23c**, **d** with HFPO to form the fluorinated ylides **24a**—**d**[74].

In this reaction the carbanion attacks at the C-3 of HFPO nucleophilically and initiates isomerization to **7**, which then reacts with **23** to form **24**.



Recent investigations[75] have not been able to confirm the previously described thermal isomerization of HFPO to **7**[8].

4.2. Oligomerization of HFPO

HFPO can be converted by anionic polymerization into oligomers having the general formula **25**, where n can have values between 1 and > 100.

The initial oligomerization step is the isomerization of HFPO to perfluoropropionic acid fluoride **7** described in Section 4.1. The perfluoropropoxide ion **26**, which is in equilibrium with **7**, attacks one molecule of HFPO, giving rise to the alkoxide **27** (n = 1); this then continues to react in the same way (n > 1) or forms the acid fluoride **25** (n = 1) after elimination of one fluoride ion.

The degree of oligomerization depends on the catalyst system, the reaction conditions, and the purity of the HFPO. Acid fluoride mixtures are always produced whose molecular weight distribution can be kept within narrow limits only by using special measures. Numerous investigations have been carried out concerning the mechanism and kinetics of oligomerization and the influence of the catalyst system[69, 76–84].

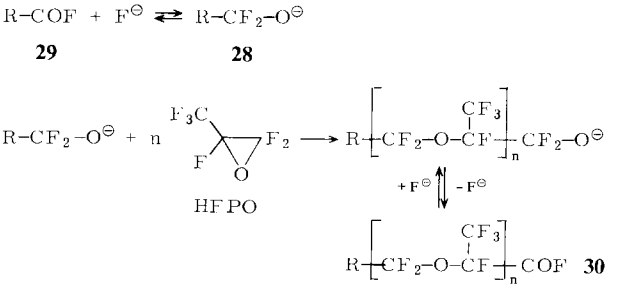
Table 1 contains a list of catalyst systems and the degrees of oligomerization obtained. Many of the reactions given in Table 1 were carried out with an HFPO/HFP mixture[87–89, 91, 93, 96, 97] (for further catalyst systems for the oligomerization of HFPO see [90]).

Table 1. Degree of oligomerization of HFPO to **25** with different catalyst systems (see text).

Catalyst	n in **25** (Yield)	Ref.
Activated carbon	wide product range	[85]
CsF/tetraglyme	> 33 (≥ 85%)	[86, 87]
$AgNO_3$/acetonitrile, propionitrile	1 (86%), 2 (3%)	[88]
Activated carbon	mainly higher-oligomer material	[89]
Ph—NMe_2/tetrahydrofuran	1 (88%)	[90]
$(Me_2N)_3PF_2$/diglyme	1 (23%), 2 (34%), > 2 (10%)	[91]
$(Me_2N)_3PF_2$/diglyme	1 (12%), 2 (30%), 3 (17%)	[91]
Trialkylsulfonium salt/solvent	1–3	[92]
Tris(dialkylamino)sulfonium salt/solvent	1–3	[92]
Tris(dialkylamino)sulfonium salt · Me_3SiF/solvent	1–3	[92]
$(Me_2N)_2CF_2$/diglyme	1 (to 7%), 2 (to 59%), 3 (to 45%)	[93]
$(Me_2N)_2CO$/diglyme, tetraglyme	1 (to 77%), 2 (to 50%), 3 (to 40%), 4 (to 44%)	[93, 94]
$(Me_2N)_2CS$/diglyme	1 (13%), 2 (40%), 3 (22%)	[93]
KF/polyethylene glycol/glyme	1 (49%), 2 (17%)	[95]
CuCl/acetonitrile/acrylonitrile	1 (to ≈ 82%)	[96]
CuCl/$CuCl_2$/acetonitrile/acrylonitrile	1 (82.7%), 2 (3.8%), ≥ 3 (11.2%)	[97]
KF/diglyme	1 (53%)	[98]
CsF/diglyme/ $CF_3(CF_2)_2O$—$CF(CF_3)$—COF	1 (83%)	[99]
CsF/diglyme	1 (52%)	[99]
KF/[18]crown-6/diglyme	1 (41%), 2 (18%)	[100]

The dependence of the degree of oligomerization on the nature of the solvent was the subject of an investigation[69], in which cesium fluoride was reacted in various solvents with HFPO at 30 °C and 10^5 Pa and the concentration of the alkoxide ions **27** present was determined (see Table 2).

Table 2. Degree of oligomerization of HFPO to **25** in different solvents (see text). n and yields were determined for the alkoxide ions **27**.



Solvent	Rel. yield [%]					
	n = 0	n = 1	n = 2	n = 3	n = 4	n = 5
Tetrahydrofuran	100					
Acetonitrile	88	9	3			
Glyme	71	20	9			
Diglyme	32	31	25	10	2	
Tetraglyme	16	17	21	20	16	10

The influence of the halide ion on the oligomerization of HFPO follows from Table 3.

Oligomeric material can also be obtained by irradiating HFPO using a Van de Graaff generator[101].

Table 3. Degree of oligomerization of HFPO to **25** in presence of different halides of potassium. Other components of the catalysts: CH_3CN as solvent; reaction conditions: autoclave, 6 h, 22°C.

KX X=	Yield [%] n=1	n=2	n=3	n=4	n=5
F	6.4	27.0	40.4	23.0	2.7
Cl	26.4	42.1	24.4	5.3	
Br	45.5	41.0	7.3	0.2	
I	75.1	16.9	0.2		

4.3. Reactions of HFPO with Fluorinated Alkoxides

4.3.1. Primary Fluorinated Alkoxides

Primary fluorinated alkoxides **28**, which are accessible by addition of a fluoride ion to a carboxylic acid fluoride **29**[102], can attack HFPO nucleophilically to form the addition products **30**.

The oligomerization of HFPO described in Section 4.2 is a special example of this reaction and differs from it only in that formation of a perfluoropropoxide ion **26** from HFPO occurs initially. It is therefore not surprising that the oligomerization of HFPO always occurs as a side reaction.

Suitable starting compounds are acid fluorides **29** with very different structures. The yield of addition products **30**

Table 4. Reactions of acid fluorides **29** with HFPO to give (partially oligomeric) addition products **30**.

29 R	Molar ratio **29** : HFPO	Catalyst	n in **30** (Yield)	Ref.
F		Activated carbon	1 (33%)	[103]

[a] Calculated on HFPO used. [b] Hexafluoropropene/HFPO mixture used. [c] Calculated on reacted acid fluoride **29**. [d] 3,3,4,4-Tetrafluoro-1,2-oxathietane *S,S*-dioxide is used, which isomerizes under the reaction conditions to form $FSO_2–CF_2–COF$.

that can be achieved depends, inter alia, on the radical R of the acid fluoride **29** and, thus, on the stability of the fluoroalkoxide **28**[102]. It has been possible, however, using special catalyst systems that favor the formation of **28** and suppress the reaction of HFPO leading to **7** or **25**, to obtain satisfactory yields of **30** even with fairly unreactive acid fluorides.

Table 4 contains a list of acid fluorides and catalyst systems used and the yields achieved.

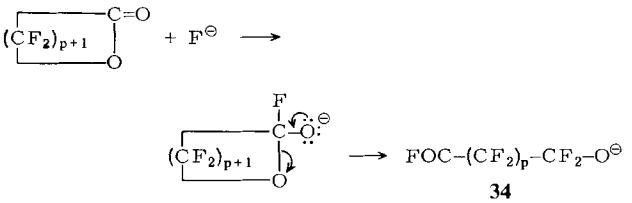
The chain lengths of the HFPO addition products **30** are mainly dependent on the molar ratio of the acid fluoride **29** to HFPO used. Usually, the aim is to produce addition products **30** with n = 1-3.

When dicarboxylic acid difluorides **31** are used, the product distribution is further influenced by the possibility of addition of HFPO on one or both functional groups[128]. It has of course been possible to prepare the monoaddition products **32** (m + n = 1) in high yield (R_f is a completely

fluorinated group). Table 5 lists the results of some HFPO additions to **31** (for longer-chain compounds see, for example, [129]).

Perfluorodicarboxylic acid difluorides **31** are also frequently used for the synthesis of high-molecular perfluoropolyethers[51,76,80,132,133]. This "bifunctional oligomerization" of HFPO is discussed in detail in [76].

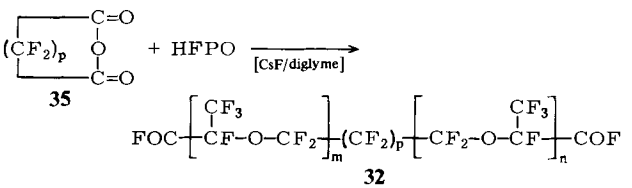
Table 5. Reactions of perfluorodicarboxylic acid difluorides **31** or perfluorolactones **33** with HFPO to give addition products **32**.



31 R_f	Molar ratio **31** : HFPO	Cat. [a]	m + n in **32** (Yield)	Ref.
–	1 : 2.37	A	1 + 1 (12.3%)	[103]
–		B	1 + 1 (40.3%)	[127]
CF_2	1 : 1.15	C	0 + 1 (85.9%)	[130]
$(CF_2)_2$	1 : 1	C	0 + 1 (80%)	[131]
$(CF_2)_3$	1 : 2.42	C	1 + 1 (80%)	[103]
$(CF_2)_3$	1 : 1.15	C	0 + 1 (75%)	[131]
$(CF_2)_4$	1 : 1.11	C	0 + 1 (79.9%)	[130]
$(CF_2)_4$		C	m + n = 2-6	[128]
$CF(CF_3)$	1 : 1.44	B	0 + 1 (71.4%) 1 + 1 (8.7%)	[132]
33 R_f	Molar ratio **33** : HFPO	Cat. [a]	m + n in **32** (Yield)	Ref.
CF_2	1 : 1	D	0 + 1 (81%)	[134]
$(CF_2)_2$	1 : 1.11	D	0 + 1 (87.8%)	[134]
$(CF_2)_2$	1 : 2.36	D	1 + 1 (82%)	[134]
$(CF_2)_3$	1 : 1.09	D	0 + 1 (85%)	[134]

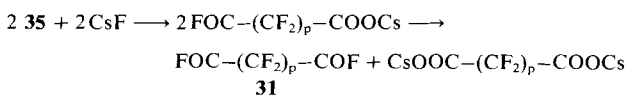
[a] A = activated carbon, B = CsF/tetraglyme, C = CsF/diglyme, D = CsF/glyme.

Other starting materials for this type of reaction of HFPO are perfluorinated lactones **33**[134].



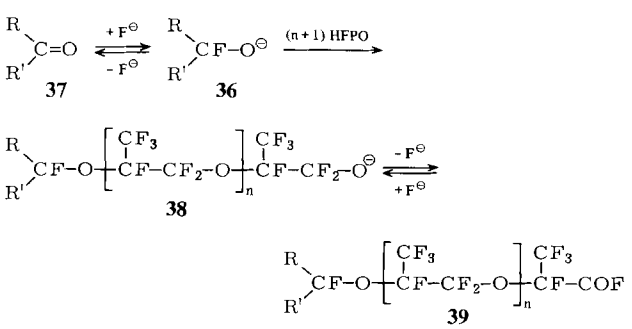
The same products **32** are formed that are also isolated when the unbranched perfluorodicarboxylic acid difluorides **31** (isomeric with **33**) are used as starting compounds (Table 5).

The reaction is presumably initiated by the addition of a fluoride ion to the carbonyl group of the lactone **33** with ring-opening. The alkoxide **34** obtained then reacts with HFPO to form **32** ($R_f = (CF_2)_p$).



It is worth noting that no ring-opening takes place in the reaction of the lactone 3,5,5,6-tetrafluoro-3,6-bis(trifluoromethyl)-1,4-dioxan-2-one **102** with HFPO in the presence of fluoride ions (see Section 5).

The reaction of perfluorinated anhydrides **35** with HFPO similarly yields the addition products **32** ($R_f = (CF_2)_p$), though at the same time a substantial quantity of HFPO oligomers **25** is produced[135].



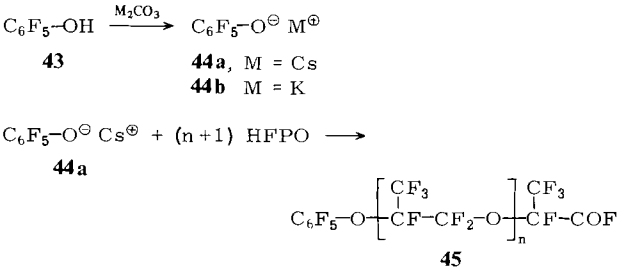
The reaction probably proceeds via the acid difluoride **31** ($R_f = (CF_2)_p$), which is formed by dismutation after ring-opening of **35**.

4.3.2. *Secondary Fluorinated Alkoxides*

Secondary fluorinated alkoxides **36**, which are obtained by the addition of a fluoride ion to a fluorinated ketone **37**[102], also attack HFPO at C-3 nucleophilically. The pri-

mary alkoxides **38** (n = 0) are obtained, which either yield the acid fluorides **39** (n = 0) after elimination of a fluoride ion or give the acid fluorides **39** (n ≥ 1) after reaction with further HFPO via the alkoxides **38** (n ≥ 1).

Fluorinated ketones **37** generally give better yields of addition products than do acid fluorides **29**. Furthermore, fewer byproducts (HFPO oligomers **25**) occur. Here, too, it is true that the formation of HFPO oligomers **25** can be largely suppressed by employing a suitable catalyst system if less reactive ketones are used[136]. Some examples are shown in Table 6.



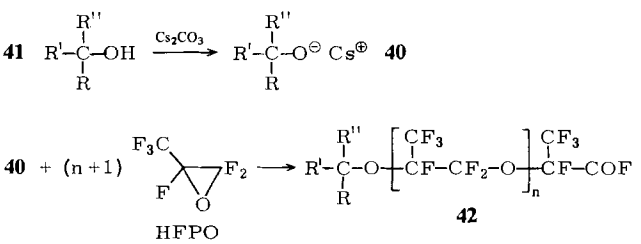


Table 6. Reactions of fluorinated ketones **37** with HFPO to give acid fluorides **39**.

37 R	37 R'	Molar ratio 37 : HFPO	Catalyst	n in **39** (Yield)	Ref.

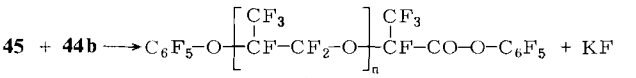
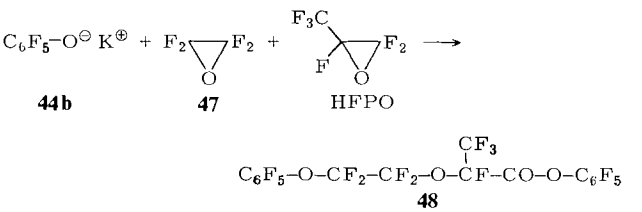
[a] Hexafluoropropene/HFPO mixture used. [b] Referred to HFPO used.

4.3.3. Tertiary Fluorinated Alcohols and Pentafluorophenolate

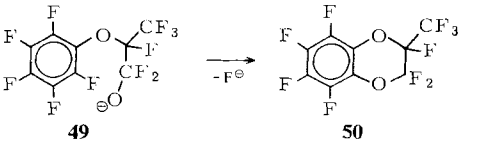


Only a few examples of the reaction of tertiary alkoxides **40** with HFPO have so far been reported[79,140]. The starting compounds **40** are prepared by reacting fluorinated tertiary alcohols **41** with cesium carbonate and, unlike the primary and secondary alkoxides **28** and **36**, are stable in the pure form.



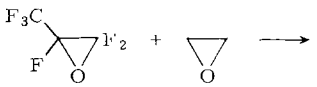
The reaction of the alkoxides **40** with HFPO normally yields higher oligomeric compounds **42**. When 1.14 mol cesium *tert*-perfluoroamylate is reacted with one mole HFPO, about 20% monoaddition product is isolated[140].

Pentafluorophenol **43** can also be converted with alkali carbonate into the phenolate **44**. The result of the reaction of **44** with HFPO is, however, greatly dependent on the cation. When the cesium ion is used (→ **44a**), the expected addition products **45** are formed[141,142]. **45**, n = 1, and **45**, n = 2, are formed together in 90% yield; the product ratio is 55 : 45.

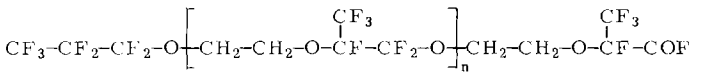


Skoblikova et al.[143] confirm these findings and also state that, when potassium pentafluorophenolate **44b** is used, the esters **46** are obtained instead of the acid fluorides **45**. They are produced by further reaction of the acid fluorides **45** with **44b**.

Experimental data are however available only for the reaction of **44b** with tetrafluoroethylene oxide **47** and HFPO, in which the ester **48** is one of the products isolated.



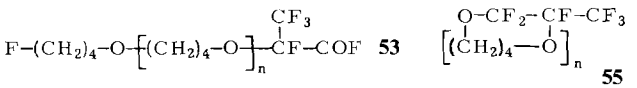
If the reaction of **44a** with HFPO is carried out in the presence of catalytic amounts of cesium carbonate, the alkoxide **49** cyclizes to benzodioxane **50** (yield up to 10%)[144].



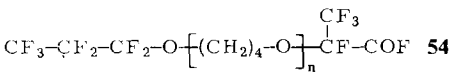
4.4. Reactions of HFPO with Ethers

4.4.1. Non-Fluorinated Ethers

HFPO can react with ethylene oxide **51** in the absence of catalysts to form products having the structure **52**[145].



HFPO **51**

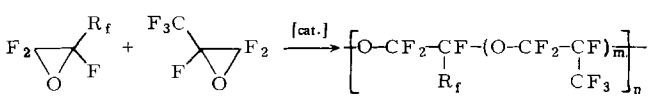


52 ($n \geqslant 0$)

Tetrahydrofuran (THF) also reacts with HFPO. At 0–40°C the products **53**–**55** are formed[146] (for the mechanism and kinetics of this reaction see[146, 147]).

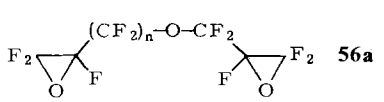
53 **55**

54



The reaction of HFPO with pure THF proceeds substantially more slowly than the oligomerization of HFPO in the presence of cesium fluoride. THF can therefore be used as a solvent in the preparation of HFPO oligomers **25**[69].

The reaction of HFPO with dimethoxyethane at −25 to +25°C also yields a mixture of substances, from which the following compounds have been characterized[146].

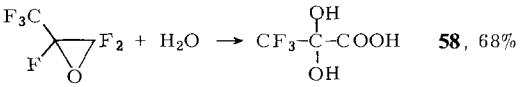


HFPO + $CH_3-O-CH_2-CH_2-O-CH_3$ ⟶
CH_3F + $CH_3-O-CH_2-CH_2-F$ + $CH_3-O-CF(CF_3)-COF$
+ $CH_3-O-CH_2-CH_2-O-CF(CF_3)-COF$
+ $CH_3-O-CH_2-CH_2-O-CF(CF_3)-CF_2-O-CH_3$
+ $CH_3-O-CH_2-CH_2-O-CF_2-CF(CF_3)-O-CH_3$
+ $CF_3-CF_2-CF_2-O-CH_3$

4.4.2. Fluorinated Ethers

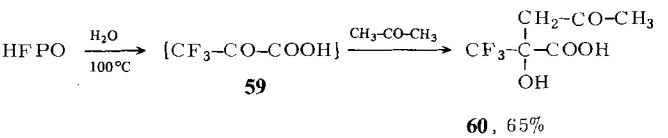
HFPO can be copolymerized with other fluorinated epoxides **56** and **56a**. Polyethers having the general structure **57** are thereby produced. A fluorinated alkoxide is normally used as catalyst.

56 HFPO **57**



56a

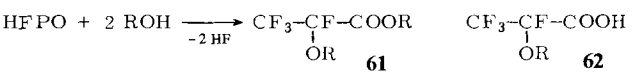
The following epoxides have been used: **56**, $R_f=(CF_2)_n-CF=CF_2$, n = 0 to ≈10[148]; $R_f=(CF_2)_2X$, X = Cl, Br, C_3F_7[149]; $R_f=CF_2-O-X$, $X=(CF_2)_2SO_2F$[150], $(CF_2)_4COF$[150], $(CF_2)_2CN$[150, 151], $(CF_2)_3-O-C_6F_5$[150], $CF_2-CF(CF_3)-O-(CF_2)_2-CN$[150], C_6F_5[150]; **56a**, n = 3 or 6[151].



4.5. Reactions of HFPO with Water, Alcohols, and Thiols

HFPO reacts with water in dioxane as solvent (room temperature, glass ampule) to form the hydrate **58** of trifluoropyruvic acid[152].

HFPO **58**, 68%



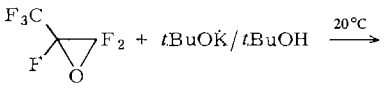
By raising the temperature and using SiO_2 the yield can be increased to 80% (reaction in steel vessel, solvent: ether)[152]. If hydrolysis is carried out in the presence of acetone, the trifluoropyruvic acid **59** produced as an intermediate reacts further to give the acid **60**[152].

59

60, 65%

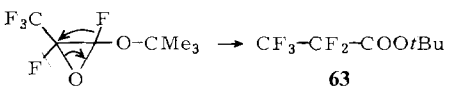
When primary or secondary alcohols are used instead of water, solvolysis of HFPO is not as complete and the 2-alkoxytetrafluoropropionic acid esters **61** are obtained. The same reaction with the addition of alkali yields the 2-alkoxytetrafluoropropionic acids **62**.

61 **62**



One special case is the reaction of HFPO with methanol/potassium hydroxide solution and hydrogen peroxide, which leads to trifluoroacetic acid[153]. Table 7 lists the results of the reaction of HFPO with alcohols.

Table 7. Reactions of alcohols with HFPO to give esters **61** or acids **62**.



ROH/MOH	Yield [%] **61**	**62**	Ref.

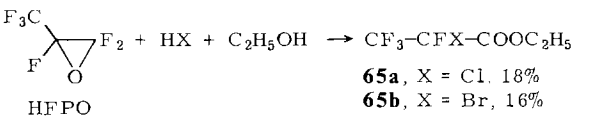
[a] With 22% conversion.

HFPO is not affected in *tert*-butyl alcohol even in the presence of fluoride ions. On the other hand, a solution of potassium *tert*-butoxide in *tert*-butyl alcohol reacts with HFPO even at 20°C. The *tert*-butyl perfluoropropionate **63** is isolated in 91% yield[158]. The formation of the "abnormal" product would seem to be due to the steric hindrance of the alkoxide.

HFPO



63

Ethanethiol reacts with HFPO to form the thio ester **64**[52, 154].

HFPO + 2 EtSH ⟶ CF_3–CF(SEt)–COSEt **64**, 40%

4.6. Reactions of HFPO with Hydrogen Halides and Sodium Iodide

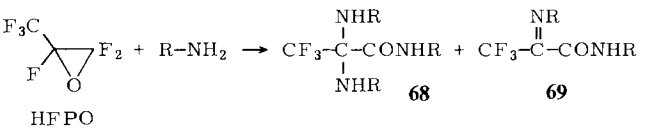
The reaction of HFPO with solutions of HCl or HBr in ethanol was first described as long ago as 1966. The halide attacks the epoxide at C-3 to give the 2-chloro- and 2-bromotetrafluoropropionic acid ethyl esters **65a** and **65b**, respectively[52, 154].

HFPO

65a, X = Cl, 18%
65b, X = Br, 16%

A substantially higher yield is quoted in the literature[53] for 2-bromotetrafluoropropionic acid **66**.

HFPO + HBr(H_2O) ⟶ CF_3–CFBr–COOH
66, 74%



The reaction of HFPO with sodium iodide in acetone proceeds spontaneously and, after treatment with ammonia, yields the ammonium salt **67** of 2,3,3,3-tetrafluoropropionic acid[159].

HFPO $\xrightarrow[-F^{\ominus}]{+I^{\ominus}}$ CF_3–CFI–COF $\xrightarrow[-I_2]{+I^{\ominus}}$ $[CF_3–CF–COF]^{\ominus}$
$\xrightarrow{CH_3–CO–CH_3}$ CF_3–CHF–COF $\xrightarrow[2)\ NH_3]{1)\ H_2O}$ CF_3–CHF–$COONH_4$
67

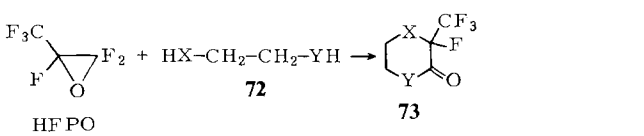
See Section 6.2 for details of the reaction of HFPO with anhydrous hydrogen fluoride.

4.7. Reactions of HFPO with Ammonia, Primary Amines, and Dimethylaminotrimethylsilane

Unlike secondary and tertiary amines, which yield perfluoropropionic acid derivatives when reacted with HFPO, ammonia and most primary amines attack the HFPO at C-3. Depending on the group R, compounds having the structure **68** and/or **69** are obtained[52].

HFPO **68** **69**

R	**68**, yield [%]	**69**, yield [%]
H	41 (10.5 [152])	–
Et	–	50
Ph	70	–
o-Cl–C_6H_4	25	5
m-Cl–C_6H_4	64	–
p-Cl–C_6H_4	70	–
o-MeC_6H_4	–	52
p-MeC_6H_4	69	–



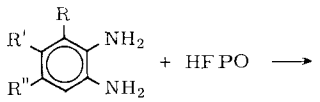
In these reactions small quantities of perfluoropropionic acid derivatives occur as by-products[64]. See Section 4.1 for details of reactions of primary amines in which the perfluoropropionic acid derivative is the main product.

Trimethyl(dimethylamino)silane **70** is so far the only highly substituted amine that reacts with HFPO without forming perfluoropropionic acid fluoride **7** or its derivatives. Instead the substituted propionic acid amide **71** is formed[66].

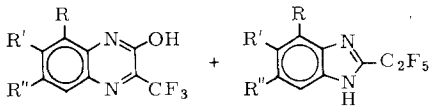
HFPO + 2 Me_3SiNMe_2 ⟶
70
CF_3–CF(NMe_2)–$CONMe_2$ + 2 Me_3SiF
71

4.8. Reactions of HFPO with Bifunctional Alcohols, Thiols, and Aromatic Amines

Some bifunctional nucleophiles react with HFPO to form heterocyclic compounds. A frequent side reaction is isomerization of HFPO to perfluoropropionic acid fluoride **7**, which reacts to form derivatives (e.g. **74**, **81**, **82**) (see Section 4.1). Thus, the 1,2-bifunctional ethanes **72** react with HFPO to yield heterocyclic compounds having the structure **73**[64].



HFPO **72** **73**



+ C_2F_5–CO–X–CH_2–CH_2–Y–H

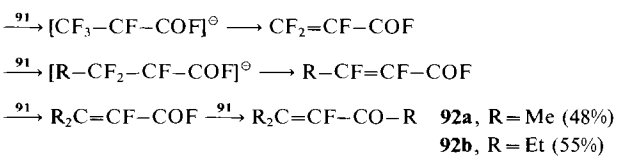
90, R = Me 82%
Et 85%
*i*Pr 77%

4.9. Reactions of HFPO with Organometallic Compounds

4.9.1. Grignard Reagents

Equimolar quantities of Grignard reagents **91** and HFPO give the 2-halogenotetrafluoropropionic acid esters **65** in yields of up to 65% if work-up is carried out in an aliphatic alcohol[159].



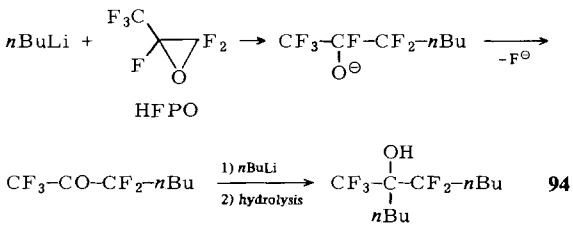
HFPO **91** **65**

This, however, applies only to Grignard reagents **91** with X = Cl or Br; no defined product could be obtained when methylmagnesium iodide was used.

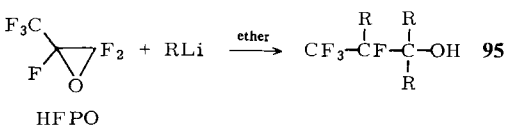
The reactions of **91** with HFPO in the molar ratio 1 : 1 do not yield compounds that indicate the incorporation of an alkyl group in the HFPO molecule. Perfluoropropionic acid derivatives are likewise not detectable.

Excess Grignard reagent **91** causes secondary reactions that give the unsaturated ketones **92**[159].

92a, R = Me (48%)
92b, R = Et (55%)



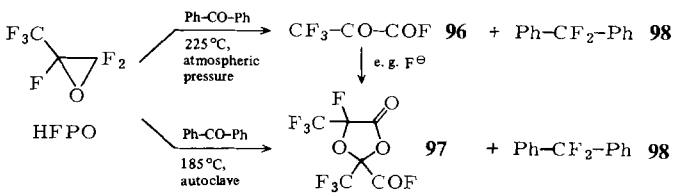
The reaction of trifluorovinylmagnesium bromide **93** with HFPO in a molar ratio of 4 : 1 yields only very high-boiling material, whose formation via the ketone **92c** (R : $CF=CF_2$) can be explained by further reaction with **93**[159].



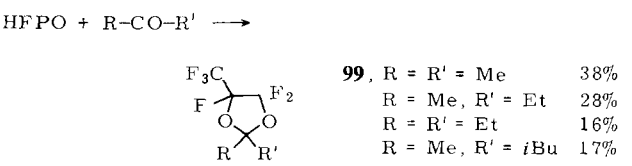
93 **92c**

4.9.2. Alkyllithium Compounds

The reaction of HFPO with butyllithium in hexane is another example of the attack by a nucleophile at C-2 of HFPO. The tertiary alcohol **94** is obtained[161].

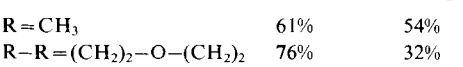


By way of contrast, in the presence of ether the nucleophile attacks primarily at C-3, and the tertiary alcohol **95**, R = *n*Bu, is produced in 55% yield. Other alkyllithium compounds have also been used for this reaction[161] (R = Me, Et, *n*Pr, *n*-C_5H_{11}; yields 92, 52, 45, 44%).

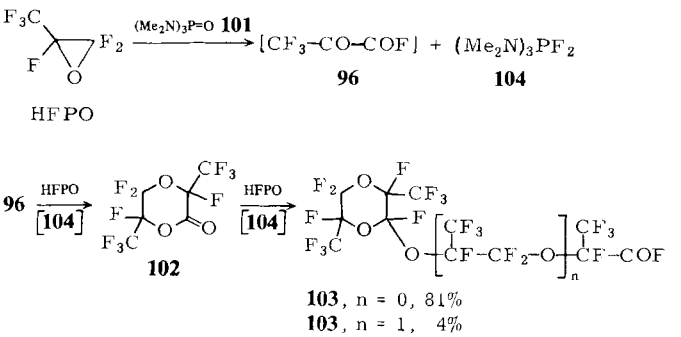


Attempts to react HFPO with pentafluorophenyllithium, trifluorovinyllithium or trifluoropropynyllithium failed to produce any defined products[161].

5. Perfluoropyruvic Acid Fluoride and Derivatives

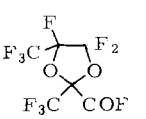


The reaction of HFPO with carbonyl compounds such as benzophenone (or benzaldehyde) at temperatures of about 200°C yields monomeric **96** or dimeric perfluoropyruvic acid fluoride **97**[162], depending on the reaction conditions; difluorodiphenylmethane **98** is formed as a by-product[163].



Unlike the reaction just described, the reaction of HFPO and aliphatic ketones at temperatures of 20–60°C gives moderate yields of 1,3-dioxolanes **99**[164].

Reaction of HFPO with dimethylformamide[165,166] or other *N*-formylated secondary amines[166] leads to formation of **97**, even below room temperature. Partially fluorinated tertiary amines **100** are thereby produced in equimolar quantity to the reacted HFPO.

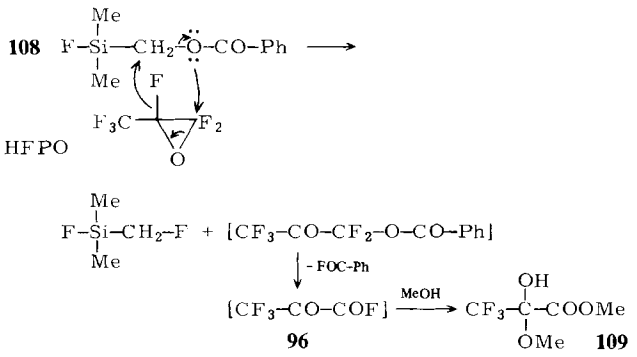


Perfluoropyruvic acid fluoride **96** occurs as an intermediate product in the reaction of HFPO with hexamethylphosphoric acid triamide **101**. It reacts with further HFPO to give the dioxanes **102** and **103**[167]. The difluorophosphorane **104** produced from **101** acts as a catalyst in the further reaction of **96** with HFPO (for the further use of **104**, see Tables 1, 4, and 6).

The reaction of HFPO with a mixture of dimethylformamide and **104** or **101**, similarly gives the products **102** and **103**, whereby the dimethylformamide is required solely as a reagent for the production of **96**, whereas the **104** produced from **101** or introduced direct is used as a catalyst for the formation of **102** and **103**[168].

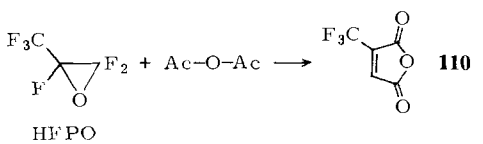
The reaction of **96** with HFPO to give dioxane **102** (73% yield) using cesium fluoride in diglyme as the catalyst has also been described[162]. Heating the reaction mixture to 140°C leads to formation of the dioxolane **105**.

105, 70%



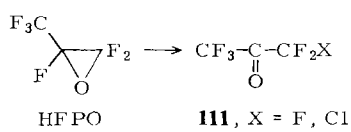
HFPO also reacts with tetramethylurea **106** to give **96** and its derivatives[93].

Evidently, the oligomerization of HFPO under the influence of the **107** produced proceeds substantially faster than the reaction with **106**, because mainly the simple oligomers **25** are isolated[93].



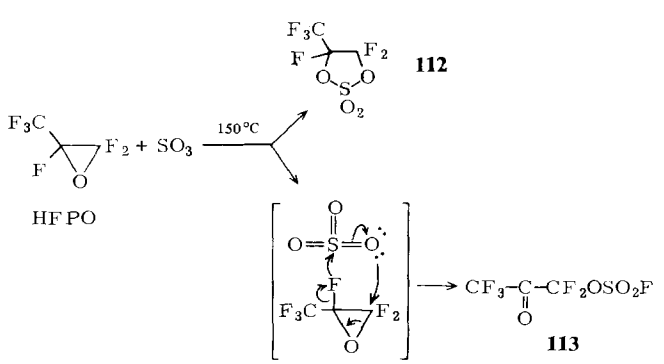
Perfluoropyruvic acid fluoride **96** is present as an intermediate product in two more reactions of HFPO.

The reaction of HFPO with the silane **108** is likewise formulated in terms of intermediary perfluoropyruvic acid **96**. Work-up with methanol furnishes the trifluoropyruvic acid derivative **109**[169].



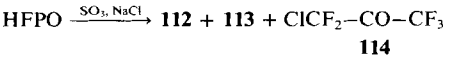
The unexpected formation of α-trifluoromethylmaleic anhydride **110** from HFPO and acetic anhydride also evidently proceeds via **96**. The proposed mechanism was verified by reaction of **96** (used as dimer **97**) with acetic anhydride[163].

6. Reactions of HFPO with Electrophiles



6.1. General

The numerous reactions of HFPO with nucleophiles underline its electrophilic properties. As is to be expected, reactions of HFPO with electrophiles are rarely observed, especially as they require even higher temperatures. The oxirane ring is changed into a keto function; in contrast to the reactions with nucleophiles, the oxygen atom remains bound to C-3 of HFPO.

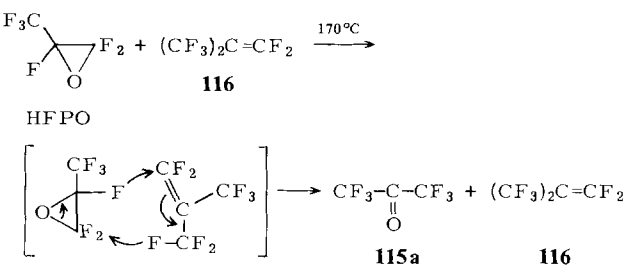


There are as yet no agreed ideas on the mechanism of formation of the keto derivatives **111** from HFPO and the various other reactants with their differing degrees of electrophilicity.

On reaction of SO_3 with HFPO at 150°C[170] the addition of SO_3 at the oxirane ring to give 1,2-perfluoropropylene sulfate **112** competes with the fluorophilic attack of SO_3 at the fluorine atom on C-3 of HFPO to form 2-oxoperfluoropropyl fluorosulfate **113**.

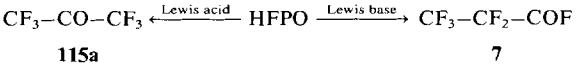
Since **112** cannot be isomerized to **113** either thermally or in the presence of KF, SO_3 or NEt_3, two independent synthesis routes are assumed[170]. **113** is similarly formed when HFPO is heated with FSO_3H to 200–220°C, and is the sole product formed even at room temperature when chromium(III) oxide is added[21].

If NaCl is added to the reaction mixture of HFPO and SO_3, formation of chloropentafluoroacetone **114** occurs in addition to **112** and **113**[170].



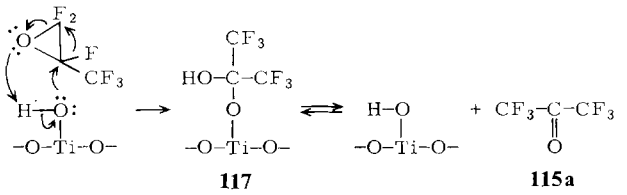
114 is also found as the main product in the thermal reaction of HFPO with $CaCl_2$[171] and with SO_2Cl_2[170], whereas predominantly hexafluoroacetone **115a** can be isolated alongside **114** when $SbCl_5$ is used[170]. This difference in behavior can be explained by the firm bonding of fluorine in calcium or sulfonyl fluorides.

6.2. Isomerization of HFPO to Hexafluoroacetone



The rearrangement of HFPO in the presence of catalysts, which facilitate the migration of the F atom from C-3 to C-2 of HFPO, is an important route to the reactive hexafluoroacetone **115a**.

The highly electrophilic octafluoroisobutene **116** acts in this way. When it is heated with HFPO to 170°C, it brings about isomerization to **115a** in 77% yield and can be recovered as such[170].

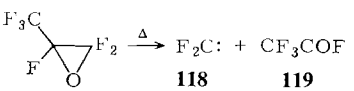


Isomerization of HFPO to **115a** in the presence of SbF_5 must be formulated similarly but can be made to yield **115a** almost exclusively with quantitative conversion of HFPO[172, 173].

Metal oxides, too, can be employed for rearrangement reactions of HFPO, especially in the vapor phase[174]. Depending on their characteristics as Lewis acids or Lewis bases, either **115a** or **7** or mixtures of both are then obtained.

Metal oxides, such as TiO_2, γ-Al_2O_3 or Cr_2O_3, which have OH groups at their large surface after calcination at 400–500°C max., selectively catalyze the rearrangement of HFPO to **115a**. IR spectroscopic investigations of TiO_2,

which was treated with HFPO[175] or with **115a**[176], showed that both isomers are not absorbed physically at the surface but react chemically with OH groups at the surface to give the same structural element **117**. When the temperature is raised, only **115a** is liberated from the surface[175].



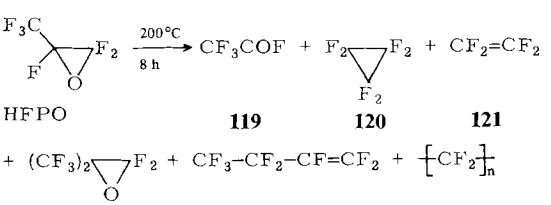
117 **115a**

The activity and selectivity of γ-Al_2O_3 and Cr_2O_3 are said to be improved if they are pretreated with HF or NH_4F[177-180], treated with HFPO[181], or assisted by promoters such as perfluoroketones or perfluoroalkyl fluoroformates[182]. Similarly, the use of mixed oxides, e.g. of SiO_2/Al_2O_3[177], Cr_2O_3/Al_2O_3 and Cr_2O_3/TiO_2[179,180], is described for HFPO conversions up to 100% and selectivities for **115a** up to 97% at 110–130°C.

Differing results have been obtained in the isomerization of HFPO to **115a** in the liquid phase. Whereas $AlCl_3$ in liquid SO_2 at room temperature rearranges 79% of the HFPO to **115a** and some **7**[174], conversion in hydrogen fluoride at 100°C under autogenous pressure proceeds at a conversion rate of 99% and a selectivity of 99%[183]. **115a** then appears as an adduct with HF, which can be used directly for addition and condensation reactions with phenols and methylarenes.

7. HFPO as a Source of Difluorocarbene

When heated to temperatures above 150°C, HFPO decomposes exclusively into difluorocarbene **118** and trifluoroacetyl fluoride **119** with a half-life of about 6 h at 165°C[184].



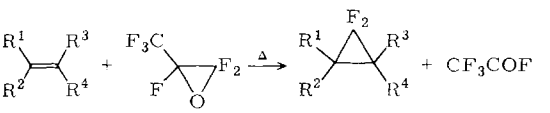
118 **119**

HFPO

In the absence of suitable reactants hexafluorocyclopropane **120** and **119** are the main products at 200°C. The byproducts occurring in the reaction of **118** with itself or with HFPO are tetrafluoroethylene **121**, octafluoroisobutene oxide **139a**, perfluoro-1-butene and polytetrafluoroethylene[185].

Of the starting materials that eliminate difluorocarbene **118** purely thermally, HFPO offers several advantages.

HFPO **119** **120** **121**



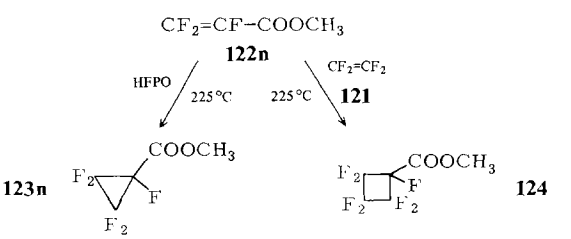
139a

Thus, it decomposes at lower temperatures (170–220°C) than **120** and **121** and yet is much more easily accessible than the fluoro(trifluoromethyl)phosphoranes $(CF_3)_{5-x}PF_x$ (x = 1–4), which eliminate **118** at even lower temperatures. HFPO can be ranked alongside sodium chlorodifluoroacetate in terms of use as a donor of **118**, being suitable chiefly for reactions with low-boiling substances.

7.1. Thermal Reactions of HFPO with Alkenes

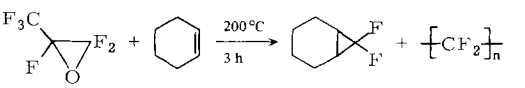
7.1.1. Fluorocyclopropanes

HFPO does not react with olefinic double bonds below the elimination temperature of **118**. By way of contrast, mixtures of HFPO with alkenes **122** react above 170°C to give cyclopropanes **123**, in which **118** once again occurs as a ring component.



122 HFPO **123** **119**

Almost exclusively **119** occurs as byproduct, which generally does not react with **122** and can be easily removed from the reaction product because of its low boiling point. Table 8 lists some cyclopropanes **123** accessible by this route which are derived from non-halogenated as well as partially- to perhalogenated olefins.

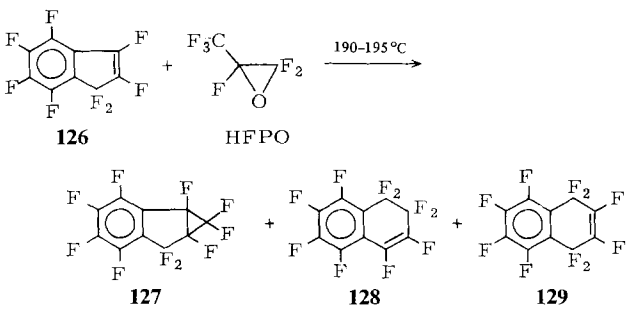


Sargeant succeeded in showing that **118** produced from HFPO adds stereospecifically, e.g., to *trans*-**122d** to give *trans*-**123d**[185]. The *cis*-isomer of **122d** behaves analogously. The pure isomers **123d** are converted into the equilibrium mixture (*cis*:*trans* = 33:67) only on prolonged heating to 200°C.

An interesting observation is that, at 225°C, HFPO reacts with **122n** to form **123n**[199], while **121** does not liberate any difluorocarbene **118** but undergoes cycloaddition with **122n** to give methyl heptafluorocyclobutanecarboxylate **124**.

123n **124**

118 adds to cyclohexene to give difluoronorcarane **125** in only moderate yield[200]; it also reacts with itself to give polytetrafluoroethylene.



HFPO **125**, 35%

Table 8. Reactions of alkenes **122** with HFPO to give fluorocyclopropanes **123**.

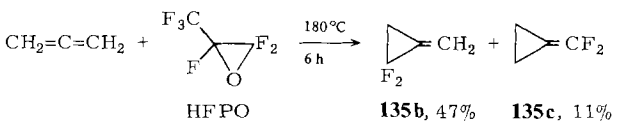
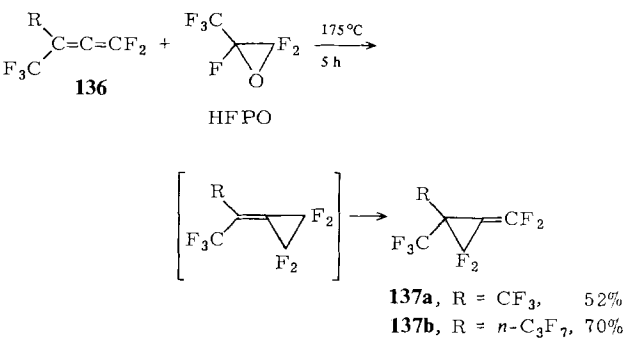
The cycloaddition product **127** obtained on reaction of **118** with perfluoroindene **126** partially rearranges at 190—195°C into the dihydronaphthalenes **128** and **129**, which are the main products at 230°C[202].



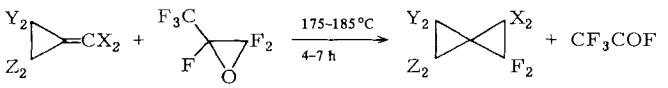
7.1.2. Fluorocyclopropene and Difluoromethylenecyclopropanes

If difluorocarbene **118** is eliminated from HFPO in the presence of alkynes or allenes, both 1:1 and 2:1 addition products are obtained. On being heated with HFPO to 185°C hexafluorobutyne **130** adds **118** to give 3,3-difluoro-1,2-bis(trifluoromethyl)cyclopropene **131**[203].



Moreover, an isomeric mixture of 2:1 adducts of **118** and **130** (perfluoro-1,3-dimethylbicyclo[1.1.0]butane **132**, perfluoro-1,3-dimethylcyclobutene **133**, and perfluoro-2,3-dimethylbutadiene **134**) is isolated.

An exocyclic double bond is preserved in the reaction of allenes with HFPO at 175—180°C. The reaction conditions are mild enough, e.g., for allene to be converted predominantly into 1,1-difluoro-2-methylenecyclopropane **135b** with only very little being converted into the isomer 1-(difluoromethylene)cyclopropane **135c**[204], which is formed from **135b** by thermal rearrangement.

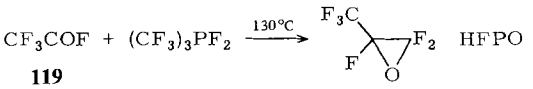


In the case of substituted perfluoroallenes **136**, on the other hand, the primary products are rearranged completely into the perfluoromethylenecyclopropanes **137** even at 175°C[205].

7.1.3. Fluorinated Spiropentanes

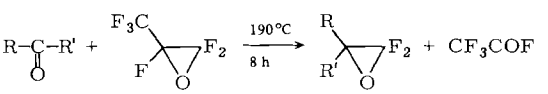
Also methylenecyclopropanes **135** add difluorocarbene **118** to the exocyclic double bond under the conditions of HFPO decomposition and are converted into fluorinated spiropentanes **138**. By this route it was possible to synthesize difluoro- (**138a**), tetrafluoro- (**138b**, **c**), hexafluoro- (**138d**) and perfluorospiropentanes (**138e**)[198]. The starting compounds **135b**, **c** are accessible as a separable mixture (see Section 7.1.2). **135d** and **135e** can be prepared from **123k**[179] or **123i**[194], which in turn are products derived

from alkenes and HFPO, by dehalogenation with zinc/dioxane[198].



135 HFPO **138** **119**

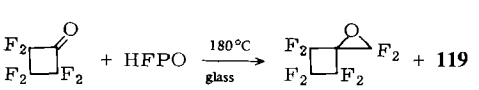
	X	Y	Z	Yield [%]
a	H	H	H	34
b	H	H	F	–
c	F	H	H	–
d	F	F	H	63
e	F	F	F	36



7.2. Reactions of HFPO with C=O, C=S, and C=N Double Bonds

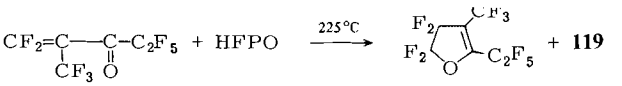
The thermal decomposition of HFPO to difluorocarbene **118** and **119** is reversible; **119** reacts with **118**, which was generated at 130°C from $(CF_3)_3PF_2$, to give HFPO[184].

119



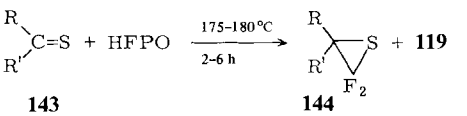
HFPO can also be employed for the synthesis of other perfluoroepoxides **139**, which remain stable at the temperatures for liberation of **118** from HFPO. Examples are the reactions of HFPO with perfluoroketones **115** at 190°C[200,206]. No data regarding yields are available, except in the case of **139a** (50%).

115 HFPO **139** **119**



a, R = R' = CF_3; **b**, R = R' = C_2F_5; **c**, R = iC_3F_7, R' = CF_3; **d**, R = R' = CF_2Cl; **e**, R = CCl_3, R' = CF_3

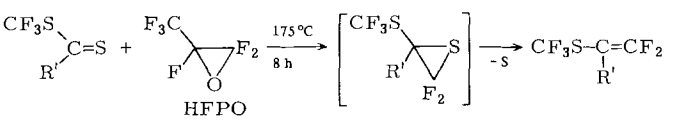
Perfluorospiroepoxide **140**, which is highly stable to heat and radiation, can be obtained in yields of over 90% by reaction of HFPO with perfluorocyclobutanone at 180°C; however, at 220°C and in the presence of steel it is converted into a number of secondary products[207].



140

If difluorocarbene **118** is generated from HFPO in the presence of perfluoroethyl-(1-methylvinyl)ketone **141** at 225°C, perfluoro-2,3-dihydrofuran **142** is formed with the incorporation of keto function and conjugated C=C double bond[208].

141 **142**

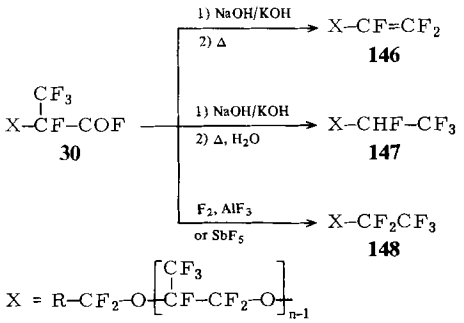


Co-pyrolysis of thiocarbonyl compounds **143** with HFPO at 175–180°C leads to formation of fluorinated thiiranes **144**, which are obtained in yields of up to 56% under strictly controlled reaction conditions[209–211].

143 **144**

	R	R'	Yield [%]
a	F	F	50
b	CF_3	F	42.5
c	Cl	F	20–30
d	CF_3	CF_3	56

For the preparation of **144a** this is the best laboratory method known so far. Less successful, on the other hand, was the attempt to produce CF_3–S-substituted thiiranes by reaction of thiocarbonyl compounds **143e–g** with HFPO; after splitting off of the sulfur, only the ethylenes **145e–g** could be identified[212].



HFPO

143e, R' = CF_3S **145e**, 47.5%
143f, R' = Cl **145f**, 40.6%
143g, R' = F **145g** –

Pentafluoro-2-aza-1-propene, $CF_3–N=CF_2$, remains unchanged when it is heated with HFPO to 200°C[213]. CF_3COF **119** and $CF_2=CF_2$ were obtained as pyrolysis products of HFPO.

8. Uses

Some of the intermediate products of HFPO described above have now gained importance in industrial applications, particularly the perfluorinated 2-alkoxypropionic acid fluorides **30**, which have very different uses, depending on the type of modification of the skeletal unit $-CF(CF_3)COF$ derived from one molecule of HFPO. Industrially important derivatives of **30** are comonomers **146** with the trifluorovinyloxy group, which are accessible by dry pyrolysis of the alkali metal salts prepared from **30**. Thermal treatment in the presence of moisture leads, in contrast, to the products **147** with the tetrafluoroethoxy radical as a stable end group. The perfluoroethyl ethers **148** are formed on reaction of **30** with fluorinating agents[214].

8.1. Comonomers for the Modification of Polytetrafluoroethylene (PTFE)

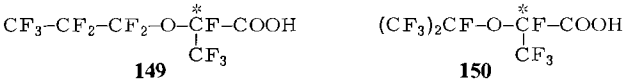
Copolymers of tetrafluoroethylene **121** and vinyl ethers **146** extend the uses of fluoropolymers considerably, without reducing the unusual thermal stability and chemical inertness of PTFE.

Perfluoropropylvinyl ether **146**, $R=C_2F_5$, $n=1$, lowers the melt viscosity of the copolymer with **121** sufficiently to make injection molding and extrusion possible. Under the trademarks Teflon® PFA (du Pont) or Hostaflon® TFA (Hoechst AG) it is used for linings in pipes, valves, and pumps, and for wire and cable insulation[215,216]. Perfluoromethylvinyl ether **146**, $R=F$, $n=1$, copolymerizes readily with **121**, eliminates the crystallinity of PTFE when added in amounts of over 30 mol%, and gives a perfluorinated elastomer (Kalrez®, du Pont)[217]. This material is thermally stable up to 285 °C and has minimal gas permeability and no cold flow. It is suitable for the production of O rings, moldings, membranes, and hoses that are resistant to chemically aggressive media[218].

The copolymers of **121** and **146**, $R=FSO_2CF_2$, $n=2$ and $R=CH_3OOC-(CF_2)_2$, $n=1$-2, contain ion-exchange groups on a perfluorinated carbon skeleton. The main use for these products at present is in membrane technology for alkali chloride electrolysis (Nafion®, du Pont; Flemion®, Asahi Glass)[219,220].

8.2. Perfluorinated Polyethers

Oligomeric HFPO **25**, $n=8$-100, after treatment with fluorinating agents (elemental fluorine, AlF_3, SbF_5), furnishes chemically and thermally stable liquids of differing consistencies with unusual electrical and acoustic properties. The inert liquids of type **148** ($R=C_2F_5$) are used, inter alia, in the chemical industry, in nuclear engineering, in air liquefaction plants, etc.[221] (example: Krytox®, du Pont).



8.3. Oxygen-Dissolving Perfluorinated Inert Liquids

The physiological harmlessness and the comparatively high adsorption power of perfluorinated compounds of the type **147** for gases such as oxygen, nitrogen, and carbon dioxide have focused attention on their use as plasma volume expanders in medicine[222,223].

Such compounds are being tested for use in the perfusion of isolated organs and as oxygen carriers in extracorporeal fluid oxygenators (heart-lung machines)[224].

8.4. Auxiliary Reagents in Synthesis and Analytical Chemistry

Both the dimeric HFPO (**25**, $n=1$) and the product of the nucleophilically catalyzed reaction of hexafluoroacetone with HFPO (**39**, $n=0$, $R=R'=CF_3$) contain a chiral center. *Ishikawa* et al. have used the basic acids **149** and **150**, after separating them into the enantiomers, as chemi-

cally and optically stable chiral *N*-acylating agents for converting α-amino acids into their diastereomers, which can be separated by means of gas chromatography[138,225].

8.5. HFPO as Starting Product for Hexafluoroacetone

The isomerization of HFPO to hexafluoroacetone **115a** described in Section 6.2. opens up a new industrial route to this ketone which prevents the formation of the highly toxic chloropentafluoroacetone **114**. **115a** undergoes a series of novel reactions[227,228], besides the classical reactions of fluorinated ketones[226].

8.6. Outlook

Further derivatives of HFPO such as some partially fluorinated cyclopropanes **123**, which are being tested as inhalation anesthetics[187-190,192,193], are on the advent of being used commercially. Even products already in use are finding new applications. The versatility of HFPO is a challenge to the chemist to find new reactions and to devise new processes for converting HFPO into industrial products. The incentive will be all the greater, the more we succeed in incorporating all the special properties of HFPO into products with unusual stability characteristics.

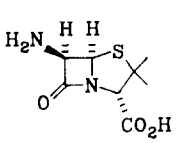
Recent Developments in the Field of β-Lactam Antibiotics

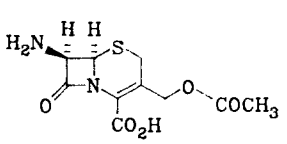
By Walter Dürckheimer*, Jürgen Blumbach, Rudolf Lattrell, and Karl Heinz Scheunemann

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday



The era of β-lactam antibiotics, which represent the most important class of drugs against infectious diseases caused by bacteria, began more than fifty years ago with the discovery of penicillin G. Further improvements by isolation and structure elucidation of new natural compounds, and systematic chemical modification of these, is a striking example of to what extent chemistry can contribute to the progress of drug therapy. The complex relationship between structure and activity requires, even today, a largely empirical approach. The minimum structural unit for antibiotic activity had to be revised several times over decades. Both the activated β-lactam ring with an acidic group and the nature and spatial arrangement of the other substituents and rings decisively affect the potency, antibacterial spectrum, pharmacokinetics, and toxicity. Totally synthetic mono- and bicyclic compounds from the series of monobactams, penems, carbapenems, 1-oxacephems, and 1-carbacephems are increasingly joining the classic groups obtained by semisynthesis from 6-aminopenicillanic acid and 7-aminocephalosporanic acid.

1. Introduction



This review attempts to summarize the chemistry and biological activity of the β-lactam antibiotics that have gained significance in clinical practice in the last ten years or are now being clinically tested. Structures that could point the way for future developments are also presented. Drug combinations and prodrug forms are largely not dealt with, although, in therapy, a certain amount of progress can undoubtedly also be achieved with these. There are a number of detailed monographs and reviews on the extremely extensive field of β-lactam antibiotics, dealing with the chemistry, antibacterial activity, biosynthesis, microbiology, and mechanism of action[1–26].

The development in the field of antibiotics is characterized by the fact that, despite the discovery and structure elucidation of thousands of new antibiotics, only relatively few basic structures are to be found among the clinically important antibiotics. Penicillin G has passed on the dominant role it had from the very beginning to the group of structurally related β-lactams, which today constitute about 60% of the antibiotic market and are distinguished by high antibacterial activity, good tolerance, and therapeutic safety.

The further development of β-lactam antibiotics was considerably assisted by the easy technical accessibility of the penicillin and cephalosporin parent compounds, namely, 6-aminopenicillanic acid (6-APA) and 7-aminocephalosporanic acid (7-ACA). A large number of semisynthetic derivatives were isolated and tested. The proportion of successful compounds setting new standards in clinics was relatively low. The main reason for this lies in the complex mechanism of action. The relationships between structure and biological activity are difficult to quantify and do not permit rational design. A great deal of progress originates from chance observations or knowledge which nature hands on to us during the elucidation of the structures of new antibiotics. And so it happened that an acylation product of 7-ACA produced purely by accident was the impetus for the synthesis of the highly active group of aminothiazole cephalosporins. Intensive work on carbapenems and monocyclic β-lactams began in the mid-seventies with the isolation of thienamycins and monolactams from bacteria.

6-APA

7-ACA

The biologically active principle of all β-lactam antibiotics is the β-lactam ring, the reactivity and selectivity of which towards biological substrates can be decisively influenced by substituents or fused rings[21]. The antibacterial properties are based on the ability to selectively inhibit enzymes essential for the synthesis of the stabilizing framework of the bacterial cell wall, the peptidoglycan; this inhibition is accompanied by cleavage of the β-lactam ring.

In recent years, better understanding of the mechanism of action of β-lactam-binding enzymes—described as PBPs (penicillin-binding proteins)—has been achieved. These are transpeptidases which are generally bound to membranes[22]. Some species of *Streptomyces* secrete water-soluble D-alanyl-D-alanine peptidases during growth. Several authors have used such enzymes as models of membrane-bound systems and have investigated binding kinetics with β-lactam antibiotics and β-lactamase inhibitors. From these kinetic data, it can be deduced that, in the first step, β-lactams are reversibly bound to the target enzymes. The

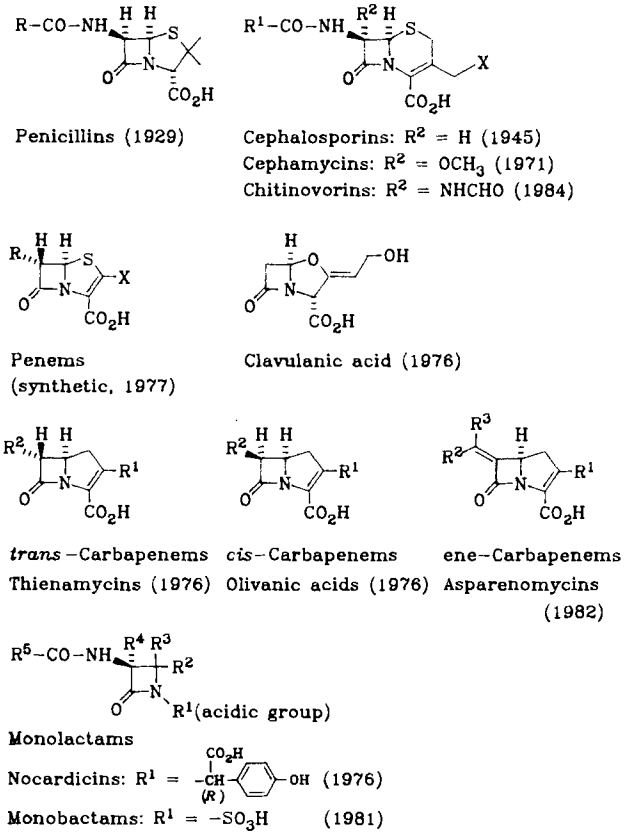

Fig. 1. Basic structures of important categories of β-lactam antibiotics (year of discovery of first compound of this type in brackets).

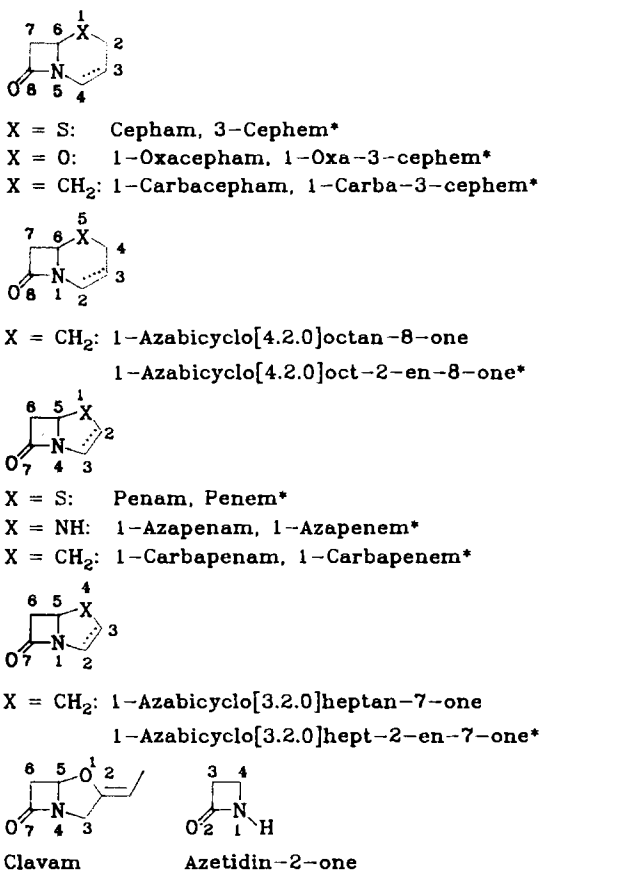

Fig. 2. Nomenclature and numbering of β-lactam skeletons. Names that are followed by a star apply to the compounds with the indicated double bond in the six- or five-membered ring.

following irreversible acylation step is dependent on the nature of the substituents on the β-lactam, which, by dint of additional binding sites on the enzyme, can have a considerable inductive effect. Recently, the three-dimensional structure of a DD-carboxypeptidase/transpeptidase from *Streptococcus R.* 61 was successfully elucidated to a resolution of 2.8 Å, and the specific binding site for β-lactam antibiotics was located[23].

In microorganisms, the interactions with the β-lactam antibiotics are complex and vary from species to species. In Gram-negative bacteria a multilayer cell-wall structure often prevents the active substances from penetrating into the cell. To complicate matters, specific enzymes (the β-lactamases) cleave the β-lactam antibiotics before the target enzymes are reached[17,24,25]. To be antibacterially active, β-lactams have to have the following basic properties:

- good permeation through the outer layers of the cell wall
- high stability against deactivating enzymes, in particular β-lactamases
- a high affinity for the target enzymes (PBPs) essential for bacterial cell-wall biosynthesis.

The combination of these properties, which can nowadays be individually evaluated by special experimental arrangements, determines the antibacterial effectiveness. The minimal inhibitory concentration (MIC) and the minimal bactericidal concentration (MBC) are criteria for assessing the potency. These parameters are determined in vitro.

The pharmacokinetics and toxicity of the antibiotics are of crucial importance for their effectiveness in man[26].

The clinicopharmacological parameters for assessing compounds and ascertaining the optimal regimen are the mode of administration (enteral or parenteral), the distribution up to the site of infection, serum and tissue levels, serum binding, the serum elimination half-life, biotransformation (metabolism), excretion, and the nature and frequency of adverse effects.

The basic structures of important β-lactam antibiotics are presented in Fig. 1. Fig. 2 shows the nomenclature and numbering. The abbreviated chemical names for the β-lactam framework, which are listed on the figure, are often used as an alternative to systematic nomenclature.

2. Penicillins and Cephalosporins

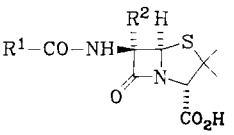
2.1. Structure and Activity

In the last decade, β-lactam research made considerable progress. The antibacterial activity was substantially improved and the activity spectrum appreciably extended in such a way that pathogens which were resistant to the older antibiotics are inhibited by the new compounds. Moreover, the pharmacokinetic properties were improved and the adverse reactions reduced. The development was mainly concentrated on semisynthetic penicillins and cephalosporins. Tens of thousands of semisynthetic derivatives were produced, mainly by reacylation of the amino

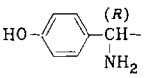
group in 6-APA and 7-ACA and, for the cephalosporins, additionally by nucleophilic substitution of the 3′-acetoxy group. Exceptional importance for antibacterial activity is attributed to the 6β- or 7β-acylamido side chain[*], the nature and spatial orientation of the substituents being contributory factors. Aromatically and heteroaromatically substituted acetic acid residues with polar substituents, e.g., hydroxy, carboxy, sulfo, and ureido, proved to be particularly advantageous. In cephalosporins, the substituents in the 3-position are extensively variable and affect antibacterial activity, metabolism, pharmacokinetics, and toxicity.

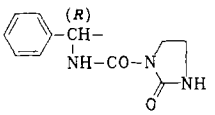
Various reviews have been published on the classification and biological activity of parenterally and orally administered penicillins and cephalosporins[1-3], which cover the field up to 1981. Since then, new developments in penicillins have been limited. For parenteral cephalosporins and for the nonclassic β-lactams, dynamic progress has taken place.

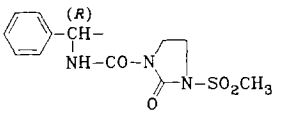
2.1.1. Penicillins

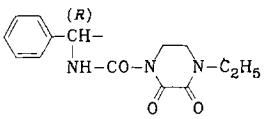


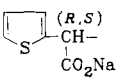
Structural variation of the first broad-spectrum antibiotic ampicillin **1**, which continues to be the most important standard orally administered compound, was a successful step forward in the penicillin field. *p*-Hydroxylation of the phenyl side chain to give amoxicillin **2** brought improvements with regard to absorption and a more rapid bactericidal effect (see Table 1). Ampicillin and amoxicillin are ineffective against β-lactamase-producing microorganisms. Combination with β-lactamase inhibitors[18], such as clavulanic acid **8** and sulbactam **9**, was consequently successful; although such inhibitors themselves show only slight antibiotic activity, they improve the effectiveness of these antibiotics by inhibiting β-lactam-cleaving enzymes.

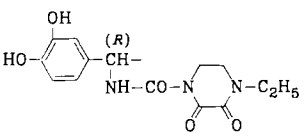




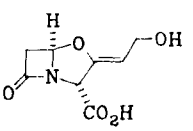








The acylation products of ampicillin and amoxicillin considerably extended the antibacterial spectrum to cover a great number of bacterial genera, provided that these are not pronounced β-lactamase-producing organisms. From Bayer research came the parenterally administered ureidopenicillins azlocillin **3** and mezlocillin **4**, which cover Gram-positive cocci, Enterobacteriaceae, *Bacteroides, Hemophilus,* and, especially, *Pseudomonas*. Piperacillin **5** (Toyama/Pfizer) is comparable in activity to azlocillin against *Pseudomonas*. Its antibacterial spectrum is extensive and includes that of mezlocillin which is mainly effective against Enterobacteriaceae and *Klebsiella*.



To solve the problem of penicillin resistance with Gram-negative organisms that form numerous β-lactamases, there are new approaches in which a methoxy group is inserted into the 6-position of the ring skeleton, characteristic of cephamycins (cf. Fig. 1). Temocillin **6** (6-methoxyticarcillin) is effective against β-lactamase-forming Enterobacteriaceae, but is ineffective against Gram-positive bacteria and *Pseudomonas*.

An extensive study of 6α-substituted penicillins was carried out at Beecham. The most potent compound in this series, BRL 36650 **7**[27], has a 6α-formylamino group. It is stable against plasmid-coded and chromosomally coded β-lactamases and, in its antibacterial spectrum, is comparable to the third-generation cephalosporins. 7-(Formylamino)cephalosporins were isolated recently as natural fermentation products of *Flavobacterium* species by Squibb[28a] and Shionogi and named chitinovorins by the latter group[28b,c].

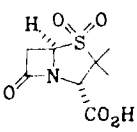


Table 1. Penicillins. The year of discovery is given below the generic name.

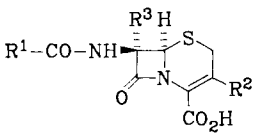
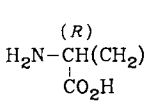
No.	R^1	R^2	Generic name and/or scientific code
1		H	Ampicillin (1962)
2		H	Amoxicillin (1971)
3		H	Azlocillin (1974)
4		H	Mezlocillin (1974)
5		H	Piperacillin (1977)
6		OCH_3	Temocillin (1982)
7		NHCHO	BRL 36650 (1984)

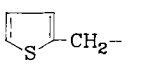
8, Clavulanic acid

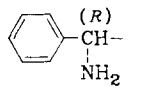
9, Sulbactam (CP 45 899)

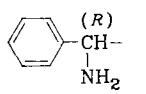


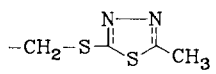
2.1.2. Cephalosporins

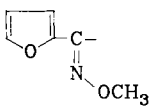


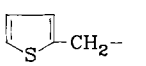












The development of cephalosporins began in 1945 with the isolation of cephalosporin C **10** from a *Cephalosporium acremonium* strain by *G. Brotzu* and with the structure elu-

[*] β and α indicate the spatial orientation of the substituents ("upwards" and "downwards", respectively) in penicillins and cephalosporins when the skeletons are drawn as they are here (N below, S upper right).

cidation by *Newton* and *Abraham* (1961). Cephalosporin C required substantial improvements in the antibacterial spectrum; one could make use of the vast experience of penicillin chemistry. An essential structural variant was discovered in the cephamycins (1971)—these are 7α-methoxycephalosporins with exceptional stability against β-lactamases. The most valuable property of the first semisynthetic cephalosporin, cephalothin **11**, was its high level of activity against penicillin-resistant staphylococci. Further development led to orally effective compounds (Table 2), e.g., cephalexin **12** or cefaclor **13**. However, the activity of these first-generation products against Gram-negative problem bacteria, such as *Proteus, Klebsiella, Shigella, Serratia, Bacteroides, Hemophilus,* and *Pseudomonas,* was insufficient. The main reasons were aggressive β-lactamases in these bacteria and inadequate penetration to the target enzymes. The second generation includes a number of parenterally effective cephalosporins which, on account of extensive stability toward β-lactamases, are also effective against Gram-negative bacteria. Cefazolin **14**, cefuroxime **15**, and cefoxitin **16**, for example, which nowadays play a major role in clinical practice, belong to this generation.

Table 2. First- and second-generation cephalosporins. The year of discovery is given below the generic name.

No.	R^1	R^2	R^3	Generic name
10		$-CH_2-O-COCH_3$	H	Cephalosporin C (1945)
11		$-CH_2-O-COCH_3$	H	Cephalothin (1962)
12		$-CH_3$	H	Cephalexin (1967)
13		$-Cl$	H	Cefaclor (1974)
14			H	Cefazolin (1970)
15		$-CH_2-O-CONH_2$	H	Cefuroxime (1975)
16		$-CH_2-O-CONH_2$	OCH_3	Cefoxitin (1972)

2.1.3. Aminothiazole cephalosporins: Cefotaxime

The most recent generation of cephalosporins, which gained admission to clinical practice a few years ago, will be considered in more detail here. The first example was cefotaxime **17**. This antibiotic was discovered in 1975 by *R. Heymès* et al.[29] in the course of a research program carried out jointly by Hoechst and Roussel-Uclaf. After numerous carboxylic acids had already been coupled with 7-ACA, it was very surprising that its acylation with the easily accessible 2-aminothiazol-4-ylacetic acid should afford a highly active key compound. This compound had to be further modified, since its β-lactamase stability was not entirely satisfactory. The introduction of a *syn* methoxyimino group onto C-2 of the 7-side chain was the decisive step in overcoming this obstacle. The *syn* configuration is essential.

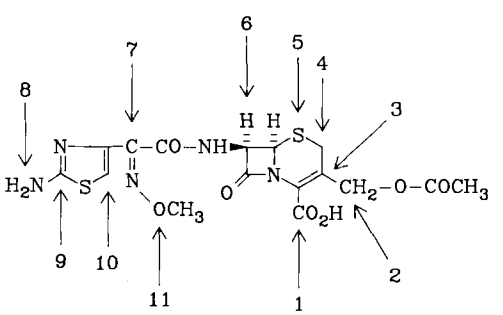
It should be mentioned that Takeda (Japan) has independently synthesized the *anti*-methoxyimino isomer of cefotaxime and the corresponding amino compound obtained from this by reduction. Both compounds have only minimal antibiotic activity. With cefotaxime, a decisive improvement in the intensity of action and in the spectrum of parenterally administered cephalosporins was achieved. Whereas its activity against Gram-positive bacteria is comparable to that of the older cephalosporins (Table 2), an improvement by a factor of 10—100 is achieved with many Gram-negative bacteria. *Serratia,* indole-positive *Proteus,* and many multiply resistant strains of *E. coli, Proteus, Klebsiella,* and Enterobacteriaceae are covered. Cefotaxime was the first cephalosporin with clinically relevant activity against bacteria of the genus *Pseudomonas*[30].

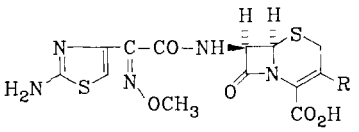
2.1.4. Successors to cefotaxime

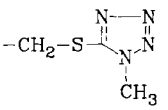
The astoundingly good antibiotic properties of cefotaxime triggered an avalanche of research on further modification of this molecule. All chemically modifiable positions in the cefotaxime molecule were manifoldly varied (Fig. 3). The 2-aminothiazol-4-ylacetyl side chain was also successfully combined with other β-lactam parent compounds, for example, with the 1-carba and 1-oxacephem skeleton[12,32] and with monolactam sulfonic acids (cf. Section 6).

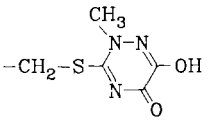
Of the thousands of derivatives, a number of successor compounds have been chosen, some of which are already on the market or in clinical trial. Tables 3 and 4 contain the most important current aminothiazole cephalosporins.

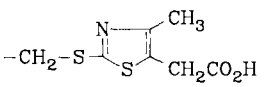
Modifications in the 3-position and in the oxime: The compounds **18**—**25** in Table 3 differ from cefotaxime **17** in the 3-position; in **25** the oxime group is also modified.

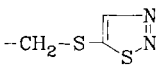


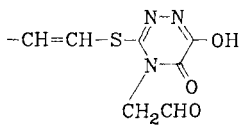


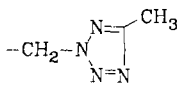












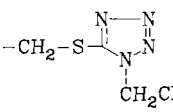


Fig. 3. Structural variation of cefotaxime **17**. The numbered arrows indicate the positions of modification.

Table 3. Aminothiazole cephalosporins.

No.	R	Generic name and/or scientific code	Ref.
17	$-CH_2-O-COCH_3$	Cefotaxime (HR 756)	[29, 30, 31, 41, 76, 78, 79, 80, 81]

24		T 2525	[39]
25[a]		Cefotiam (SCE 963)	[40]

[a] Contains $-CH_2-$ instead of $-C(=N-OCH_3)-$.

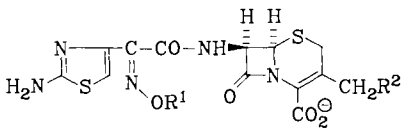
The 1-methyltetrazol-5-ylthiomethyl group of cefmenoxime **18** is also found in other cephalosporins—for instance, in cefoperazone **35**, cefotetan **40**, or latamoxef (Scheme 3)—since it has a particularly favorable effect on the antibacterial activity. Recent studies have shown that 1-methyltetrazole-5-thiol, which appears in small amounts as a metabolite of these cephalosporins in man, can trigger alcohol intolerance (Antabuse effect) and blood coagulation disorders. The latter can largely be avoided by administering vitamin K.

The 3′-substituents bound via sulfur do not substantially alter the antibacterial spectrum compared to that of cefotaxime, but affect the pharmacokinetics, β-lactamase stability, and metabolism. In man, about 20% of cefotaxime is cleaved enzymatically to desacetylcefotaxime **17**, $R = CH_2OH$[41]. Ceftriaxone **20**[35] and cefodizime **21**[36], which have an additional acidic function, are characterized by high protein binding and a long serum elimination time (8 and 3 h, respectively).

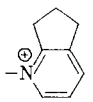
The polar aminothiazole cephalosporins are summarized in Table 4. The favorable influence of a 3′-pyridinium group in cephalosporins on the antibacterial activity is already known from the older compounds cephaloridine **32**[49] and cefsulodin **33**[50]. The latter compound is very polar as a result of the additional sulfo group, penetrates easily through the cell wall of *Pseudomonas*, and has extremely good inhibitory values particularly against this bacterial genus, but is almost inactive against Gram-positive organisms. In aminothiazole cephalosporins, the introduction of a pyridinium residue led initially to the development of ceftazidime **26**[43], which also has very good inhibitory values against *Pseudomonas* and many other Gram-negative bacteria. Compared with cefotaxime, a distinct decrease in activity against staphylococci and other Gram-positive organisms is evident.

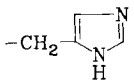
The combination of a neutral methoxyimino group with a 3′-cyclopentenopyridinium residue resulted in cefpirome **27**, which has a very extensive antimicrobial spectrum and inhibits the growth of isolates of *Pseudomonas*, Enterobacteriaceae, *Staphylococcus*, and enterococci at very low concentrations. Cefpirome is extremely stable against hydrolysis by plasmid-coded and chromosomally coded β-lactamases[44]. The successor compounds **28**[45], **29**[46], **30**[47], and **31**[48] have similar antibacterial spectra. The introduction of a pyridinium function into the 7-side chain, e.g., **34**[51], however, does not increase the antibacterial activity observed in the 3′-pyridinium compounds.

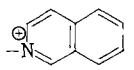
The effect of substitution in the oxime residue was extensively examined in the series cefotaxime **17**[29,31], ceftizoxime **19**[42], and cefpirome **27**[44c,d]. Compounds with lower alkyl groups are favorable. The introduction of acidic groups increases the activity against *Pseudomonas*. Cefotiam **25**, a compound without an oxime group, has diminished β-lactamase stability[40].

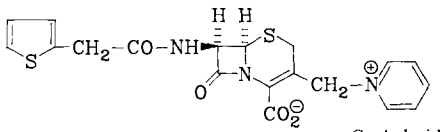


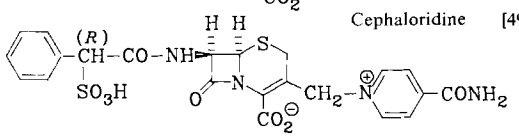
The effect of substitution in the pyridinium residue in the cefpirome series[44c,d,47b] was also examined in detail. Residues with annulated rings (cyclopentenopyridines, cyclohexenopyridines, quinolines, isoquinolines, thienopyridines, and furopyridines) exhibit high activity.

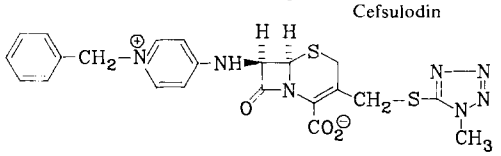












Oxidation of the cephem ring sulfur: Cefotaxime was oxidized to give the (*S*)- and (*R*)-sulfoxide and the sulfone of cefotaxime[52]. The (*S*)-sulfoxide (HR 109) is more active than the (*R*)-sulfoxide and is characterized by high β-lactamase stability and good penetrating ability in the case of Gram-negative bacteria; however, the activity against *Staphylococcus* and *Pseudomonas* is limited.

Modification of the 4-carboxy group: This polar group is essential for antibiotic activity. Only esters that are cleaved spontaneously or enzymatically in vivo are of interest as prodrug forms on account of their altered pharmacokinetics[53].

Modification in 7-position: The introduction of a 7α-methoxy group (cf. cephamycins, Fig. 1) often improves the β-lactamase stability and the activity against anaerobic bacteria. In the cefotaxime[31] and cefpirome series[54], the minimal inhibitory concentration (MIC) changes for the worse on introduction of this group.

Table 4. "Polar" aminothiazole cephalosporins.

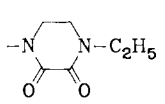
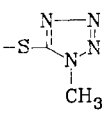
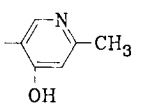
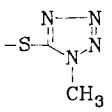
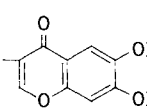
32			Cephaloridine	[49]
33			Cefsulodin	[50]
34			L 640876	[51]

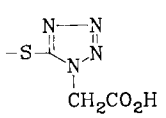


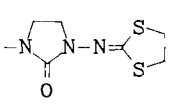


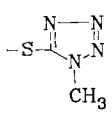


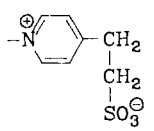












Modification of the aminothiazole ring: The amino group on the thiazole is essential. Derivatization or removal decreases the activity. Replacement of the hydrogen at C-5 of the thiazole ring with chlorine or bromine leads, in the cefotaxime[31] and cefpirome series[44d], to potent compounds which, however, bring no advantages over cefotaxime and cefpirome. By replacement of the 2-amino-1,3-thiazole residue with other amino heterocycles, e.g., 5-amino-1,2,4-thiadiazole, compounds with comparably good activity are obtained[55]. The antibacterial activity of 5-amino-1,3,4-thiadiazoles[56], 2-aminopyridines[57], 4-amino-1,3-pyrimidines[58], 5-amino-1,2,4-triazoles[59], and 2-amino-1,3-oxazoles[60,61] is distinctly lower.

2.1.5. *N*-Acylated Phenylglycine Cephalosporins

Cefoperazone **35** (Table 5) is a parenterally administered cephalosporin derivative showing structural relationship to piperacillin **5**, a ureido penicillin. **35** is a broad-spectrum cephalosporin with high activity against *Pseudomonas*. Its stability against TEM β-lactamases produced by *E. coli* is lower than that of the third-generation cephalosporins[62]. With cefpiramide **36**, E-702 **37**, KIT-180 **38**, and cefpimizole **39**, the excellent activity against *Pseudomonas*, caused by high affinity for PBP-3, is impressive. A pronounced inoculum effect, i.e., a deterioration in the MIC when there is a very high bacterial count in the culture medium, is observed with these compounds.

2.1.6. *Cephamycins*

The discovery of cephamycins opened up new possibilities of structural variation in the cephalosporin series[67]. These are 7α-methoxycephalosporins which are produced by *Streptomyces*. Similarly to cephalosporins, they can be varied semisynthetically. The 7α-methoxy group can be introduced stereoselectively into cephalosporins by several methods[67a] and imparts to these molecules excellent sta-

bility against β-lactamases. Cefoxitin **16** (Table 2) was the first cephamycin to achieve success in clinical practice, especially in the case of mixed infections with β-lactamase-forming anaerobes (e.g., *Bacteroides fragilis*). Table 6 shows more recent semisynthetic cephamycins which have a 3-[(1-methyltetrazolyl)thiomethyl] substituent. Cefotetan **40**, which has a tautomerizing 7β-acyl side chain, is less active against Gram-positive bacteria, but is more active against Gram-negative problem bacteria (e.g., Enterobacteriaceae, *Serratia, Proteus*) than cefoxitin and has a long half-life (3.3 hours in man). Cefbuperazone **41** is excreted to about 10% via the bile and, thus, is suitable for treating infections of the bile duct. Its activity against problem bacteria is comparable to that of **40**, while its effectiveness against anaerobes (e.g., *Bacteroides*), like that of all 7α-methoxycephalosporins, is very good. Compared with cefoxitin, cefminox **42** has advantages similar to those of **40** and **41**.

2.1.7. *Enterally Absorbed Cephalosporins*

The orally active cephalosporins in clinical practice, e.g., cephalexin **12** and cefaclor **13**, belong to the first generation with low β-lactamase stability. The aminothiazole cephalosporin FK 027 **43**, which contains a 3-vinyl group and has been known since 1981, is a new structural type. The compound is only moderately active against Gram-positive bacteria but, against Gram-negative organisms, comes close to the third-generation cephalosporins[71] (Table 7).

The method for improving enteral absorption, namely, esterification of the 4-carboxy group—e.g., by means of the pivaloyloxymethyl group in pivampicillin and the phthalidyl group in talampicillin (prodrug concept[53])—which was successful in penicillin chemistry, brought little success in the case of cephalosporins. Cefuroxime-Axetil

Table 7. Enterally absorbed cephalosporins.

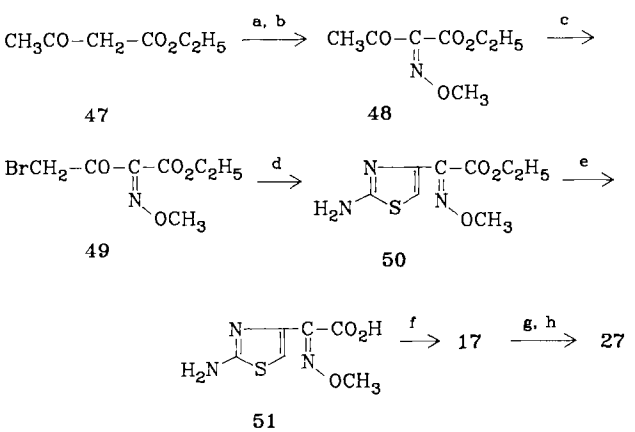
46				KY 109	[74]



45 is in clinical trial. Enteral absorption is about 35%. Adverse gastrointestinal side effects have been reported in elderly patients[73b]. Human studies of the esters T-2588 **44** (pivaloyloxymethyl ester of **24**)[72] and KY 109 **46**[74] have begun.

2.2. Syntheses

On account of the high sensitivity of the β-lactam bond to acids and bases, all synthetic procedures in the β-lactam antibiotic series require agents that are selectively activating, protecting groups that can be split off gently, and reaction temperatures that are as low as possible. The following steps typify the semisynthesis of a cephalosporin antibiotic:

1. Chemical cleavage of cephalosporin C to 7-ACA[75]
2. Displacement of the 3′-acetoxy residue in 7-ACA with S- or N-nucleophiles
3. Synthesis of the 7-side-chain acid and, where necessary, protection of functional groups
4. Coupling of the side-chain acids to the 7-aminocephem skeleton and, if need be, removal of protecting groups
5. Preparation of stable, physiologically well-tolerated salts

The nucleophilic exchange of the 3′-acetoxy residue (step 2) can also be performed on cephems already bearing the appropriate 7-acyl side chain (step 4). Some cephem structures are not easily accessible from 7-ACA. In such cases, a longer synthetic route is necessary. For example, the 3-unsubstituted 7-amino-3-cephem skeleton is built up starting from penicillin via 3-methylenecephams (cf. Section 2.2.4). Scheme 1 shows the preparation of cefotaxime **17** and cefpirome **27** as an illustration of acylation and nucleophilic displacement.

Scheme 1. 2.2.1. *Acylation of the 7-Amino Group*

Table 8 contains a selection of activation reactions suitable for 2-(2-aminothiazol-4-yl)-2-(methoxyimino)acetic acids and many other acids. Methods that do not require protection of the 2-amino group in the thiazole ring, for example, condensation with thioesters or HOBT esters, are advantageous. Halogenated pyridinium salts[82] and tetramethylchloroformamidinium chloride[83] are also used for activation. With very polar components, the coupling is carried out advantageously in aprotic polar solvents, such as DMF, possibly with the addition of water[43b].

Table 8. Methods for activating 2-(2-aminothiazolyl)-2-(methoxyimino)acetic acids (cf. **51**) and protecting groups for the 2-amino group [a].

Protecting group	Activation method	Product	Ref.
Chloroacetyl	Acid chloride: PCl_5	**17** and 3′-derivatives	[76]
Trityl	Acid chloride: PCl_5	**26**	[43b]
Trityl	Anhydride: DCCD	**17**	[29]

—	Vilsmeier: $COCl_2$/DMAA	**17**	[78]
Trityl	Mixed anhydride: tosylchloride	**17**	[79]
—	Active ester: HOBT	**17**	[80]
—	Thioesters: benzothiazole-2-thiol, other thiols	**17**	[81]

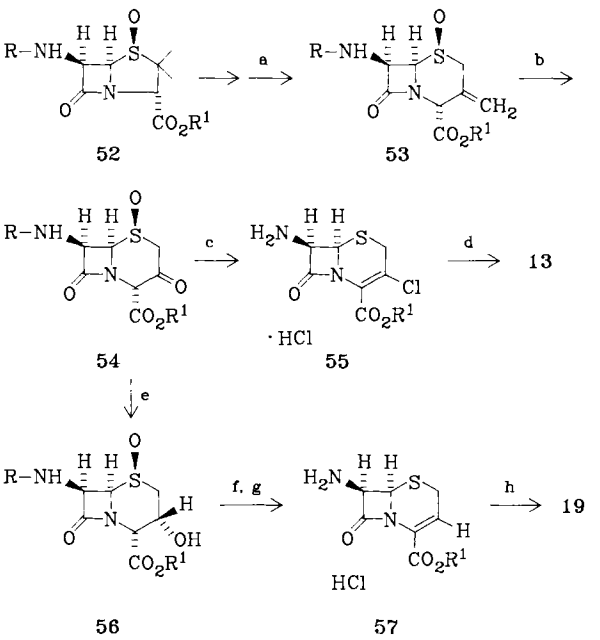
[a] Abbreviations: DCCD: dicyclohexylcarbodiimide; DMAA: *N,N*-dimethylacetamide; DMF: *N,N*-dimethylformamide; BSA: *N,O*-bis(trimethylsilyl)acetamide; HOBT: 1-hydroxy-1*H*-benzotriazole. [b] Active reagent: $(CH_3)_2\overset{\oplus}{N}=CHCl\ Cl^{\ominus}$.

To protect the carboxy function in 7-ACA derivatives, the *tert*-butyl, diphenylmethyl, and p-nitrophenyl esters are often used. Silylation of the carboxy and amino groups with chlorotrimethylsilane, bis(trimethylsilyl)acetamide, or specific silylating agents, e.g., *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide, increases the solubility in solvents of low polarity and frequently raises the reaction velocity and the yield.

2.2.2. *Substitution in the 3′-Position*

In cephalosporin derivatives, displacement of the 3′-acetoxy group by S- and N-nucleophiles is mostly carried out in aqueous solution (pH about 6) between 40 and 90 °C[84]. Similarly, the 3′-acetylacetoxy[76] and 3′-carbamoyloxy groups can be displaced[85]. In reactions with weak nucleophiles, simultaneous hydrolysis of the β-lactam ring reduces the yield[86]. Pyridine bases substitute better in the presence of a high molar excess of potassium iodide or potassium thiocyanate[49] (synthesis of **32**). The catalytic mechanism of these salts has not yet been clarified. A 3′-substitution in anhydrous solvents, e.g., acetonitrile, is achieved with the addition of acids or Lewis acids[84,86a,87]. A resonance-stabilized carbonium ion is proposed as polar intermediate[86a].

Halogen atoms in the 3′-position are excellent leaving groups. Synthesis via 3-methylenecephams requires considerable effort[88]. Direct halogenation of the 3-methyl group in 3-cephems leads to 2-cephems, unless the more devious route via the sulfoxides is chosen[89]. Conversion



of the 3-hydroxymethyl group, resulting from enzymatic hydrolysis of the acetoxymethyl group, to a methyl halide group ($CH_2OH \rightarrow CH_2Cl \rightarrow CH_2I$) is also unsatisfactory (cf., for example, the synthesis of **31**)[48]. The preparation of 3-iodomethylcephems from appropriate 3′-acetates with iodotrimethylsilane brought decisive progress. By the use of the ester cleavage procedure developed originally by *Olah*[90] et al., 3-iodomethylcephems are formed which react, either in situ or after isolation, with diverse S- and N-nucleophiles[91]. Examples are the synthesis of the 3′-isoquinolinium derivative **30** from a silylated cefotaxime precursor[47a] and the synthesis of cefpirome **27**, in which an excess of pyridine base is important (Scheme 1, reaction h)[92]. The introduction of a 3′-carbamoyloxy group into cephalosporins has proved to be favorable for their effectiveness, since this group is not cleaved by esterases in the organism. Reaction of 3-hydroxymethylcephems with reactive isocyanates turned out to be a suitable synthetic route[43b,93].

2.2.3. *Synthesis of 3-Vinylcephalosporins*

3-Vinylcephems are obtained by several methods. Functionalization of the 3-methyl or 3-hydroxymethyl group by oxidation to an aldehyde and Wittig-Horner olefination[94] or condensation with *tert*-butoxybis(dimethylamino)methane is the method most frequently used (synthesis of ceftiolen **23**: $CH_3 \rightarrow CH{=}CHN(CH_3)_2 \rightarrow \rightarrow$ **23**)[38]. A 3-chloromethylcephem derivative is the starting material for **43**[71].

2.2.4. *Synthesis of 3-Chlorocephems and of 3-Unsubstituted Cephems*

3-Methylenecepham sulfoxides of the type **53** are easily obtained by the Kukolja rearrangement of penicillin sulfoxides **52**[95a]. The compounds **53** are key intermediates in the preparation of the clinically important 3-chlorocephalosporins and 3-unsubstituted cephalosporins of the cefaclor **13**[95] and ceftizoxime **19** type[96]. Scheme 2 shows a preferred reaction sequence. The 3-oxocepham **54**, obtained by ozonolysis of 3-methylenecepham-S-oxide **53**, reacts with $(PhO)_3PCl_2$ to give 3-chlorocephem **55**. Reduction of the 3-oxo group and dehydration yields the cephem skeleton without 3-substituents.

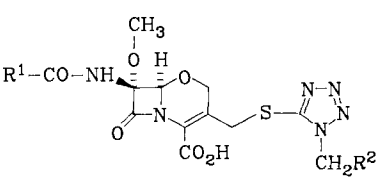
3. 1-Oxacephalosporins



3.1. Structure and Activity

After semisynthetic cephalosporins had been obtained by replacement of peripheral residues and successfully launched in therapy, several teams began to vary the cephalosporin skeleton itself. Of the numerous variations, the 1-oxacephalosporins have the most interesting antibiotic properties. Racemic 1-oxacephalothin[97] was the first active compound of this series and was followed by D,L-1-oxacephamandole[98], which was twice as active as cephamandole. A four- to eightfold increase in activity was observed with the optically active 1-oxacephalothin, which was synthesized starting from penicillin[99]. Encouraged by these findings, Japanese firms, in particular, investigated the effect of various side chains on the biological activity of 1-oxa-3-cephem-4-carboxylic acid[100].

Replacement of sulfur by oxygen in the cephalosporin skeleton increases the skeleton's tension and intensifies the pyramidal character of the β-lactam nitrogen and, consequently, the reactivity of the lactam bond. The hydrophilicity of the entire molecule is increased, serum binding is reduced, and penetration of the cell wall of Gram-negative bacteria facilitated. The diminished β-lactamase stability of 1-oxacephems can be overcome by introduction of a 7α-methoxy group and an oxime or carboxy function in the C-2 of the 7-acetamido side chain[100,101].

The first broad-spectrum 1-oxacephalosporin, which belongs to the third generation of cephalosporins, is latamoxef, produced by Shionogi.

Structure-activity studies[100,101] revealed that the 2-carboxy group of the 7-side chain broadens the activity spectrum and, together with the 7α-methoxy group, leads to excellent β-lactamase stability, which also extends to the group of anaerobes *(Bacteroides fragilis)*. The *p*-hydroxy group increases the blood levels and prolongs the serum

Latamoxef (6059-S):

R^1 = HO–(*R,S*)–CH(–CO_2H)–,

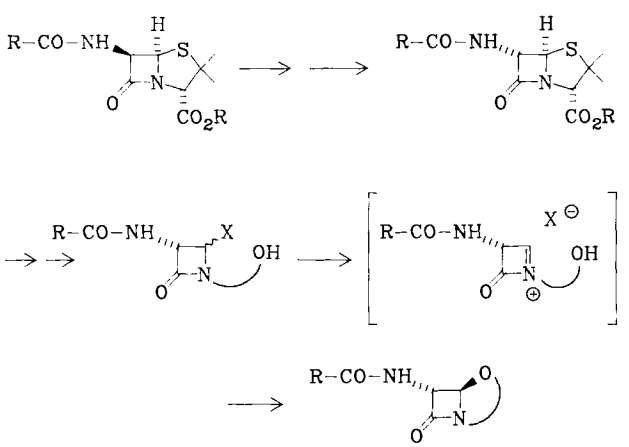
R^2 = H

6315-S: $R^1 = F_2CH{-}S{-}CH_2{-}$, $R^2 = CH_2OH$

elimination half-life. The 3′-(methyltetrazolylthio) substituent increases the antibiotic effectiveness toward Gram-negative bacteria and impedes metabolism. (For a detailed review on microbiology, pharmacology, and adverse reactions see [16].) A new 1-oxacephalosporin is the compound 6315-S, which no longer shows activity against *Pseudomonas* but, instead, exhibits improved activity against *Staphylococcus*[102].

3.2. Synthesis

The configuration of active 1-oxacephalosporins is identical to that of natural cephalosporins. Stereoselective syntheses were elaborated by several teams[103, 104]. The principle of such a synthesis is shown in Fig. 4. The most frequent chiral starting material is 6-APA which, initially, is degraded to a monolactam. After oxidation to an *S*-oxide and C-6 epimerization, the thiazolidine ring is opened; a reactive leaving group X is inserted in the 4-position and, upon later closure to an oxazine ring, is replaced by an oxygen nucleophile. In order to obtain the desired (*R*)-configuration at C-6 (such as, e.g., in latamoxef), the adjacent chiral center at C-7, which directs the incoming substituent into the *trans* position, has to be epimerized.



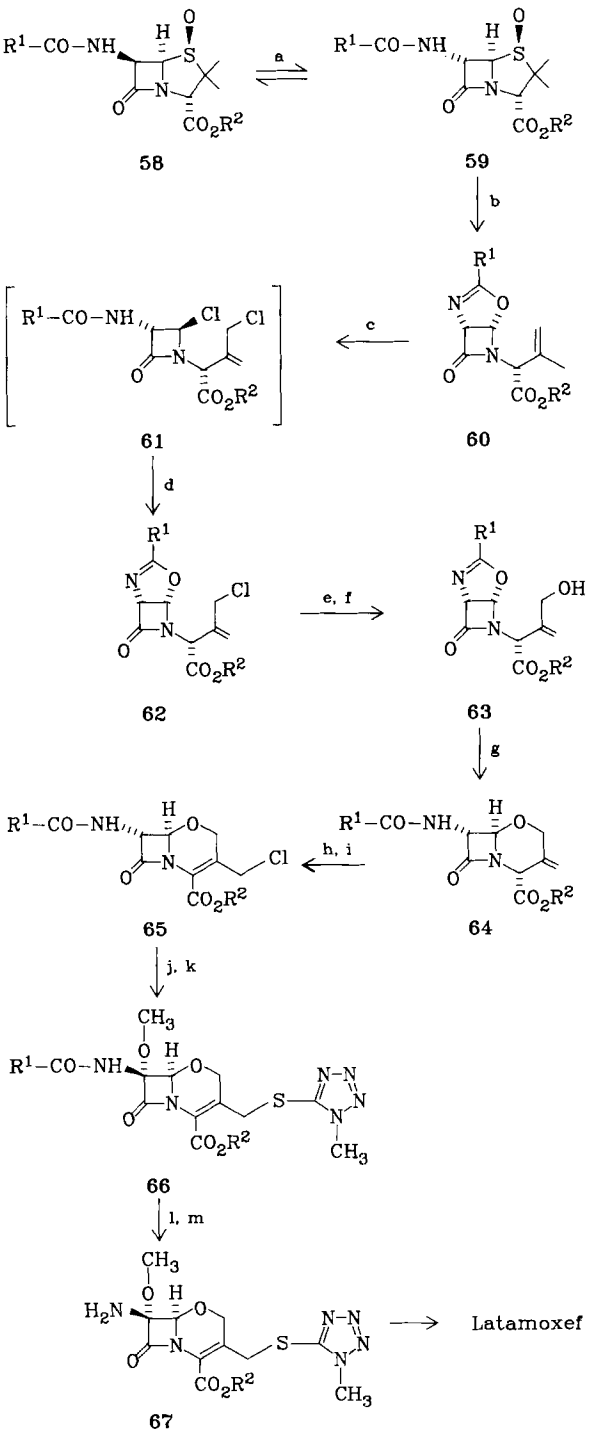


Fig. 4. Synthetic principle for 1-oxacephems.

Scheme 3 illustrates a rational synthesis of latamoxef[105], which utilizes all C atoms of 6-APA and is extremely variable with regard to side-chain substitution.

Starting from 6-APA, the sulfoxide **58**, which can easily be epimerized at C-6 with bases to give **59**, is obtained in high yield. Opening of the thiazolidine ring by heating with triphenylphosphane results in the bicyclic compounds **60**. This reaction can be applied to a wide range of *N*-acyl derivatives and esters (for the reaction mechanism see [106]). A similar ring opening of penicillin-S-oxides with normal configuration at C-6 has been described by *Cooper* et al.[107] and *Hatfield* et al.[108] (see Fig. 5).

Although direct allylic oxidation of **60** to **63** was intensively investigated, the indirect route via allylic chlorination with molecular chlorine or with SO_2Cl_2 to give **62**, which proceeds via an ene mechanism, proved to be superior for large-scale synthesis.

Scheme 3. Synthesis of latamoxef (6059-S). R^1=Ph, R^2=$CHPh_2$. a) base; b) 80 °C, PPh_3; c) Cl_2; d) $NaHCO_3$; e) NaI; f) dimethylsulfoxide (DMSO)/H_2O/Cu_2O; g) $BF_3 \cdot Et_2O$; h) Cl_2, hν; i) piperidine; j) ClO*t*Bu, $LiOCH_3$; k) sodium 1-methyltetrazole-5-thiolate; l) PCl_5, pyridine; m) CH_3OH.

Direct chlorine/hydroxy exchange is difficult due to the low reactivity of the allylic chloride **62**. It is better to substitute initially iodide for chloride and to introduce the allylic OH group with Cu_2O in DMSO-H_2O. It is assumed that DMSO forms an active alkylsulfonium intermediate with the allylic iodide. Cu_2O both activates the iodide and traps the resulting hydrogen iodide.

Allylic alcohol **63** is stereospecifically cyclized to (6*R*)-3-methylene-1-oxacepham **64** by proton or Lewis acid ca-

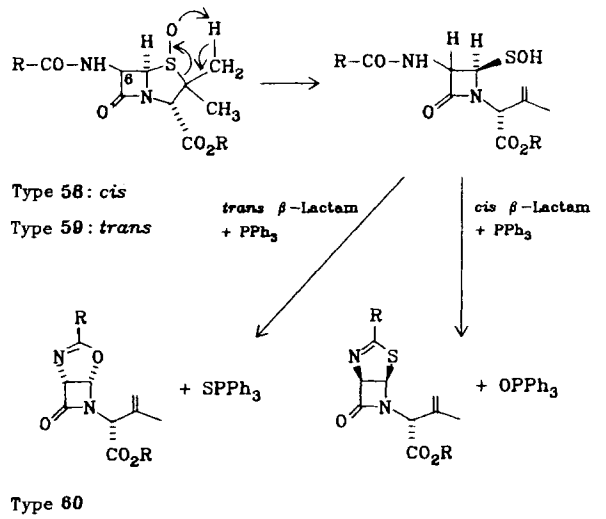

Fig. 5. Ring opening of penicillin-*S*-oxides with natural (*cis*) and unnatural (*trans*) configuration at C-6. With PPh_3, 2-thia- and (1*S*, 5*R*)-2-oxa-4,7-diazabicyclo[3.2.0]hept-3-en-6-one, respectively, are formed.

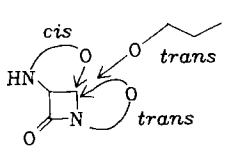
talysis. Intermediate **64** allows extensive variation at the 3-methylene group. Ozonolysis leads to the series of 3-substituted oxacephems[109]. Light-induced addition of chlorine to **64** and elimination of HCl to give **65** permits the construction of a chloromethyl side chain which can react with a large number of nucleophiles. By methoxylation of **65** at C-7, the acylamino group is again brought into the desired β-position; the product is subsequently converted, without isolation, into **66**.

Removal of the acyl group to give **67**, reacylation, and deprotection are effected by the usual methods. Unlike cephalosporins[110], the 7β-amino-7α-methoxyoxacephems **67** do not epimerize in acidic medium. Here, the configuration of the amino group is stabilized by a strong hydrogen bond to the ring oxygen[111].

The stereochemistry at C-6 and C-7 can also be controlled in a way different from that in Scheme 3 and Figure 5. If an oxygen nucleophile is passed on intramolecularly from the 3-amido side chain of the azetidinone by ring closure at C-4, only the *cis* arrangement of the two substituents is possible for steric reasons (Fig. 6). This strategy was applied by, among others, Fujisawa[112] (Scheme 4). The azetidinone **68**, accessible by cleavage of 6-aminopenicillanic acid benzyl ester, is acylated to **69** with protected glycolic acid. The methylthio group can be cleaved off with elemental chlorine to yield a 4α-chloroazetidinone which, without purification, cyclizes with silver salt catalysis to oxazoline **70**. In two successive steps—acylation at the dihydrooxazole nitrogen to give **71** and acid hydrolysis of the oxazolidine—the intermediate **73** is obtained. The reaction sequence can also be reversed (**70** → **72** → **73**).



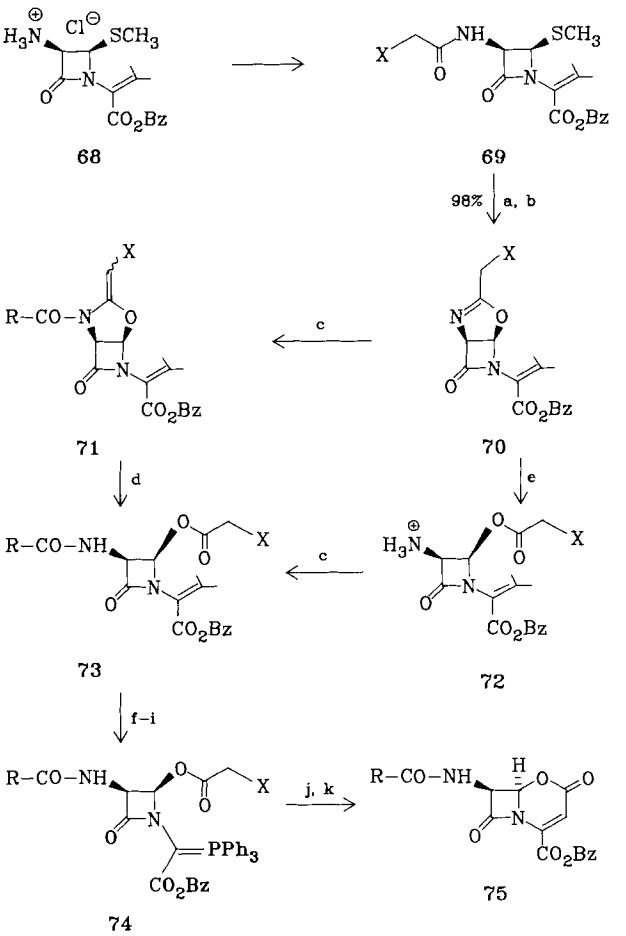


Fig. 6. Stereochemistry of the reactions of unsubstituted azetidiones.

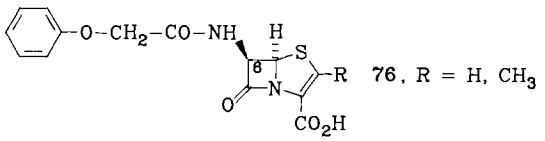


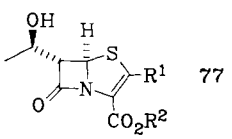
Scheme 4. Synthesis of the oxacephem skeleton. Bz=benzyl, X=$Cl_3C-CH_2-O-CO-O$, R=$Ph-O-CH_2$. a) Cl_2; b) $AgBF_4/Ag_2O$; c) $Ph-O-CH_2-COCl$; d) camphorsulfonic acid/H_2O; e) *p*-TosOH·H_2O; f) O_3; g) $Zn/EtCO_2H$; h) $SOCl_2$/pyridine; i) PPh_3; j) Zn/CH_3CO_2H; k) DMSO/Ac_2O.

The oxazine ring is built up by an intramolecular Wittig reaction which was elaborated for the first time by *Woodward* et al. for the total synthesis of cephalosporins[113] and, since then, has been used extensively in the total synthesis of other β-lactam skeletons. Ozonolysis of **73**, zinc/propionic acid reduction of the resulting oxalic acid monoamide, chlorination with thionyl chloride, and reaction with triphenylphosphane leads to the phosphorus ylid **74** in an overall yield of 42%. The trichloroethoxycarbonyloxy protecting group in **74** is cleaved off with zinc/glacial acetic acid, and the hydroxy ketone is oxidized by the *Moffat* method to the aldehyde which cyclizes spontaneously to give the oxacephem **75**.

4. Penems

In 1975, the synthesis of the new β-lactam skeleton **76**, which had hitherto not been found in nature, was announced by a team at the Woodward Research Institute in Basel and later published in detail[114, 115].

This type of compound, which is called a 'penem', can be regarded as a hybrid between penicillins and cephalosporins. It proved to be antibiotically active, but too unstable chemically and therefore unsuitable for practical use.



76, R = H, CH_3

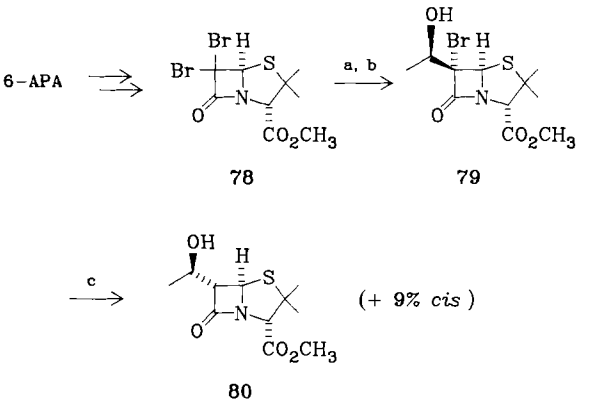
Unexpectedly, it was soon discovered that the chemically more easily accessible and more stable 6-unsubstituted penems are also antibiotically active. In order to improve antibacterial activity and β-lactamase stability, various teams introduced new substituents into the 2- and 6-positions. In particular, the 6-(*R*)-hydroxyethyl group in the thienamycin-like 5,6-*trans* configuration has proved to be optimal so far. Consequently, penems of the type **77** were extensively varied at C-2 by many firms, including Merck Sharp & Dohme[117], Sankyo[118], and Hoechst[119], since this position also decisively affects the biological activity and bioavailability[*].

Meanwhile, 6-hydroxyethylpenems of the type **77** (Table 9) have been brought into clinical development by Schering/Plough and Farmitalia/Carlo Erba. The orally administered SCH 29482 **77a** had to be replaced by the parenterally administered SCH 34343 **77b**, since **77a** is degraded by endogenous enzymes, e.g., dehydropeptidase I, releasing small amounts of ethanethiol. FCE 22101 **77c** is parenterally active and is therefore being clinically tested as the orally administered prodrug ester FCE **77d** (22553).

Table 9. Penems **77** in clinical trial.

77

No.	R^1	R^2	Scientific code name	Ref.
77a	S–Et	Na	SCH 29482	[120]
77b	$S-CH_2CH_2-O-CONH_2$	Na	SCH 34343	[121]
77c	$CH_2-O-CONH_2$	Na	FCE 22101	[122]
77d	$CH_2-O-CONH_2$	$CH_2-O-COtBu$	FCE 22553	[122]



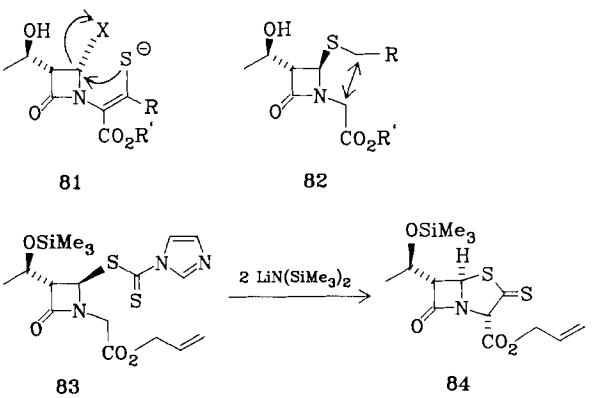
The 6-hydroxyethylpenems are broad-spectrum antibiotics with very good in-vitro activity against Gram-positive and Gram-negative bacteria. They also excellently inhibit anaerobes. However, they are not sufficiently active against *Pseudomonas*.

6-Hydroxyethylpenems are highly stable against plasmid-coded (e.g., TEM) and chromosomally coded (e.g., Kl) β-lactamases. These properties plus the possibility of finding enterally absorbable, highly active antibiotics by appropriate choice of the 2-substituent and/or the ester group make penems a class of very potent antibiotics.

A selection of interesting reactions elaborated in connection with the total synthesis of penems will be discussed in the following.

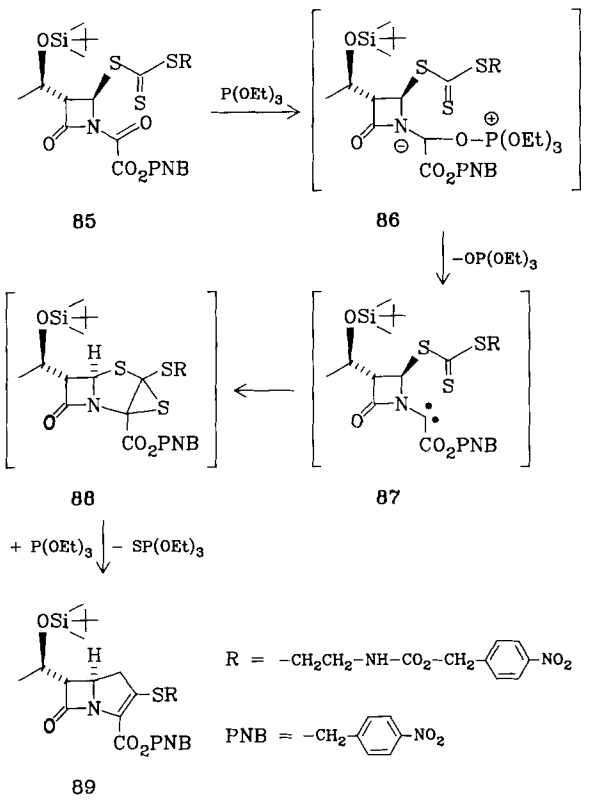
[*] For a summary of the chemistry and bacteriology of the penems see [116].

6-Aminopenicillanic acid (6-APA) is used in the majority of syntheses as an inexpensive chiral starting material into which the hydroxyethyl side chain can be introduced in a stereocontrolled way. As an example, the procedure of *Laenza* et al.[117] is described in detail (Scheme 5).



78 **79** **80**

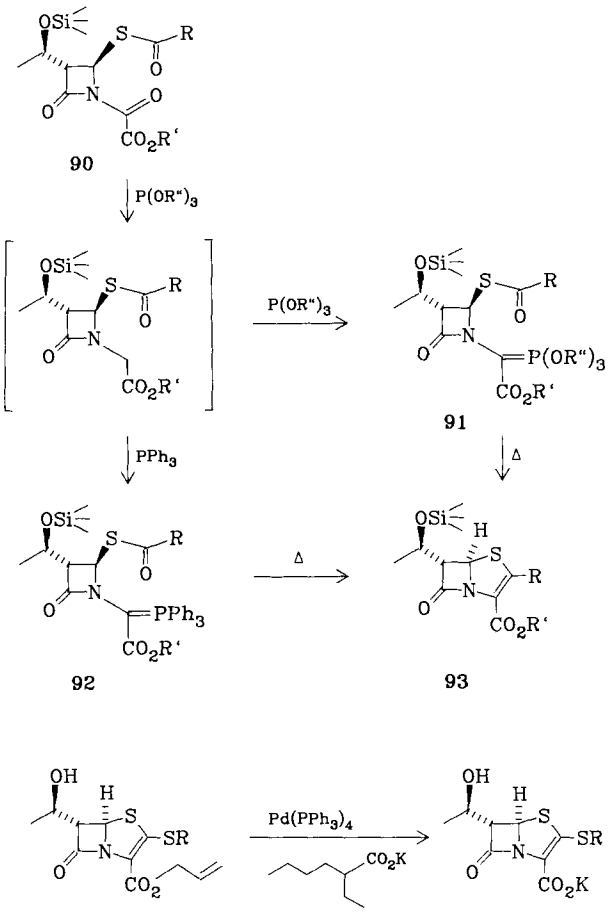
Scheme 5. Synthesis of 6-hydroxyethylpenams. a) CH_3MgBr; b) CH_3CHO; c) Zn, pH 6–7.



6,6-Dibromopenicillanic acid methyl ester **78**, easily obtained from 6-APA, reacts with methylmagnesium bromide to give an α-bromoenolate, which is reacted with excess acetaldehyde to give a mixture of stereoisomeric bromohydrins. The desired isomer **79** can be isolated in 66% yield. Mild reduction with zinc removes the bromine atom and simultaneously results in inversion at C-6. In the mixture, *trans*-hydroxyethylpenam **80** is formed along with ca. 9% of the *cis*-hydroxyethylpenam **80**. In general, it is further degraded to a hydroxyethylazetidinone onto which the thiazoline ring of the penem is annelated stepwise. Two strategies have been successful:

a) Ring closure by nucleophilic attack of the sulfur at C-4 of azetidinone **81**[118, 119, 123]. Defined configuration at C-4 is a prerequisite for stereocontrolled ring closure[119, 123].
b) Cyclization with formation of the double bond between C-2 and C-3 (see **82**). Besides the Wittig olefination already used by *Woodward* et al. in the first penem syntheses[117, 120a, 122, 124], two new procedures have been introduced recently: anion cyclization[117, 125] (**83** → **84**[125])

81 **82** **83** **84**



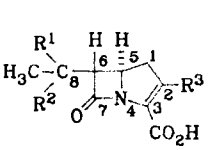
and, in particular, reductive cyclization of oxalic acid monoamides **85** with trialkylphosphites[126, 127]. The carbene **87**, which adds onto the C=S bond of the trithiocarbonate, is formed as intermediate. The thiiran **88** is desulfurized with a second equivalent of trialkylphosphite. Formation of a phosphorane is possible as a secondary reaction of the carbene with excess phosphite. Consequently, the desulfurization is carried out under high-dilution conditions and with gradual addition of the phosphite. If no sufficiently reactive C=X bond is available, this reaction becomes predominant[127].

85 86 87 88 89

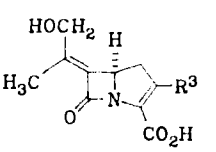
The Farmitalia group[128, 129] found that the carbene formed intermediately can also trap other phosphorus(III) compounds. It is thus possible to prepare, e.g., the triphenylphosphoranes **92** in a single-step reaction, these being otherwise only accessible in several steps via the usual Woodward method. The phosphoranes **91** and **92** cyclize on heating to the penems **93**.

In looking for a stable carboxy protecting group, which can be cleaved off under the mild neutral conditions required by sensitive systems such as β-lactams, *Jeffrey* and *McCombie*[130] found that allylic esters, carbonates, and carbamates are cleaved smoothly and in high yields with catalytic amounts of $Pd(PPh_3)_4$. In the presence of alkali-metal salts of long-chain fatty acids, the alkali-metal salts of the deprotected carboxylic acids precipitate. The allyl protecting group has meanwhile also been successfully employed by other groups[125, 131].

90 91 92 93



5. Carbapenems



5.1. Structure and Activity

Since the discovery of thienamycin, an antibiotically highly active fermentation product of *Streptomyces cattleya*[132, 133], the number of thienamycin derivatives and of other closely related carbapenems of natural origin has risen to over thirty. These include epithienamycins, olivanic acids[134], carpetimycins[135], asparenomycins[136], pluracidomycins[137], and carbapenems of the PS group[138].

Table 10 gives a general outline of the structural differences between the groups. In general, the residue R^3 is cys-

Table 10. General outline of the carbapenems.

Asparenomycins

Type	R^1	R^2	H5/H6	C-6	C-8
Thienamycins	OH	H	*trans*	*S*	*R*
Olivanic acids	OH	H	*cis*	*R*	*S*
Pluracidomycins	$OSO_3^{\ominus}$	H	*cis*	*R*	*S*
Carpetimycins	OH	CH_3	*cis*	*R*	—
PS group	H	H or CH_3	*trans*	*R*	—

teamine or a derivative thereof. Hence, the amino group of this residue can be acylated, the sulfur can be present as sulfoxide, and the ethylene bridge can be dehydrogenated. In pluracidomycins, residues such as $-SO_3^-$, $-SOCH_2CO_2^-$, or $-SO-CH(OH)_2$ are bound to C-2. The hydroxy group of the C-6 side chain can be sulfonated. The isolation of the parent carbapenem has recently been reported[139]. Little is known about the biosynthesis of carbapenems. Glutamic acid seems to be a structural element. A summary of biosynthetic transformations within the carbapenem groups is given in [140].

The majority of carbapenems are highly active broad-spectrum antibiotics. Detailed investigation of the effect of the substitution pattern and stereochemistry in thienamycins and olivanic acids shows that high antibiotic activity is linked to the combination of *8S* and *cis* configuration or of *8R* and *trans* configuration at the β-lactam[141]. Stability against TEM β-lactamases is found both for the *trans* compounds and for sulfate esters of the (*8S*) *cis* compounds. TEM β-lactamases are only inhibited by (*8S*) compounds, whereby sulfonation at the 8-hydroxy group considerably further increases the inhibition. Table 11 gives a qualitative survey of these relationships.

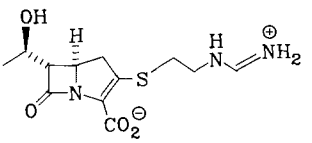


Table 11. Selected properties of carbapenems (for formulas see Table 10; $R^2 = H$).

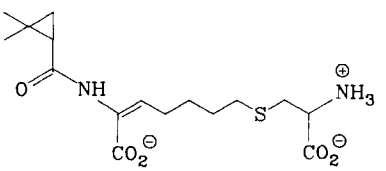
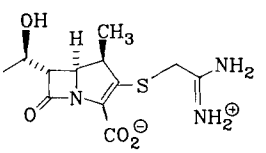
Type	R^1	C-8	H5/H6	Antibiotic activity	Resistance against TEM β-lactamases	Inhibition of TEM β-lactamases
Thienamycins	OH	*R*	*trans*	+++	+	0
8-*epi*-Thienamycins	OH	*S*	*trans*	+	+	+
Olivanic acids	OH	*S*	*cis*	++	0	+
Pluracidomycins	$OSO_3^\ominus$	*S*	*cis*	++	+	++

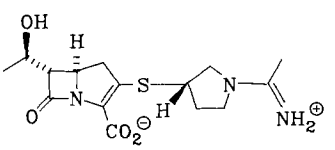


The carbapenems are highly reactive compounds on account of their strained ring system. They are sufficiently chemically stable only in a limited pH range around neutrality. This, plus the fact that it has so far not been possible to increase fermentation yields by strain optimization, has made their isolation in large quantities from culture filtrates difficult.

Consequently, the focus was soon placed, especially at Merck Sharp & Dohme, on a totally synthetic approach, particularly to thienamycin **106**. In the meantime, carbapenem total syntheses and formal total syntheses devoted to special stereochemical aspects have been introduced by a great number of teams (for a summary see [142, 143]). Thienamycin **106** is a highly active broad-spectrum antibiotic which is effective both against Gram-positive and Gram-negative bacteria and against *Pseudomonas* and *Bacteroides*, including β-lactamase-forming strains[144]. At high concentrations, it is unstable in aqueous solution: the amino group of the cysteaminyl portion cleaves the β-lactam ring intermolecularly.



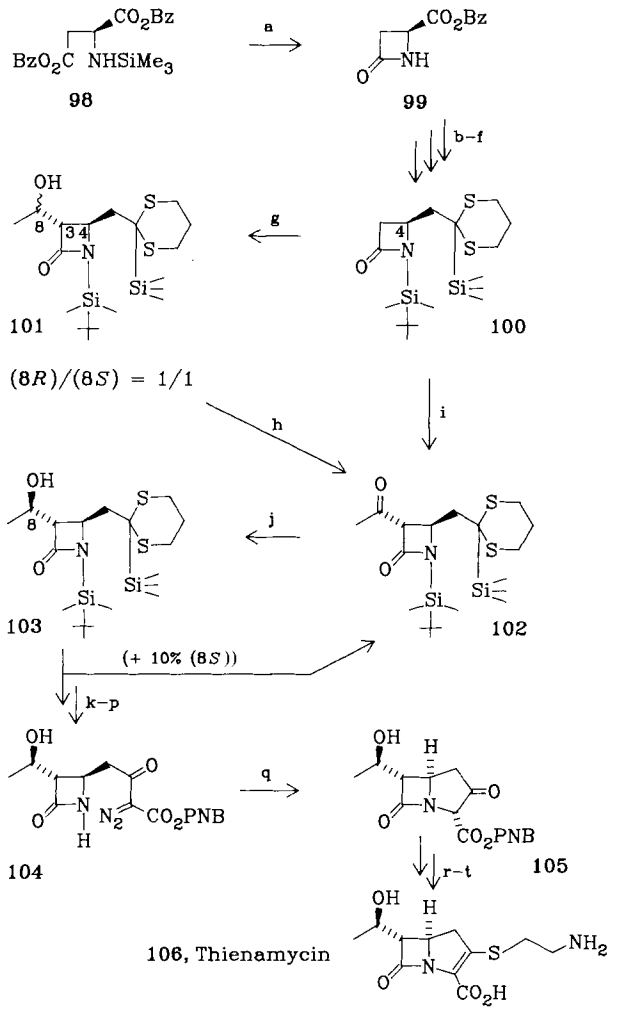
Formimidoylthienamycin (imipenem, MK-0787) **94** is a derivative combining improved chemical stability and extensive antibiotic activity[145–148]. This antibiotic, in which great hopes were placed in clinical practice, is inactivated in vivo, however, by dehydropeptidase I and has therefore unfavorable pharmacokinetics[149]. A combination of **94** and cilastatin **95**, a competitive inhibitor of this enzyme, which suppresses the metabolism of imipenem in the kidneys and prevents nephrotoxicity, is at present being clinically tested[150].



94, Imipenem

95, Cilastatin

96, L-646 591

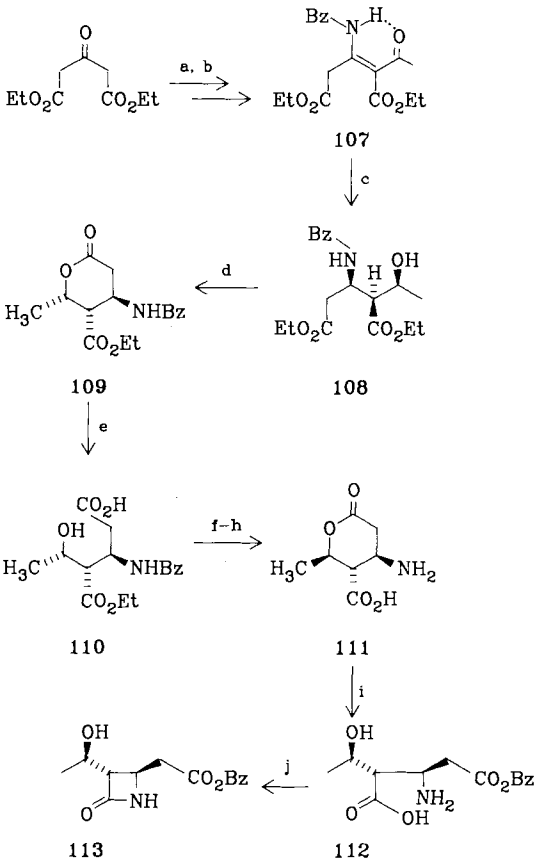


97

Compound L-646 591 **96** is a further development of imipenem **94**. The additional β-methyl group stabilizes the molecule toward dehydropeptidase. The side-chain amidino group, linked via carbon, affects the antibacterial activity in a similarly favorable way to that of the amidino group linked via nitrogen in **94**[151].

RS-533 **97**, developed by Sankyo in Japan, is also a highly active synthetic carbapenem[152].

5.2. Syntheses

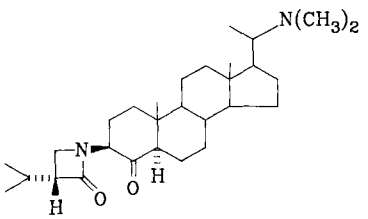


Scheme 6 shows a total synthesis of (+)-thienamycin **106**[153], which uses L-aspartic acid as chiral educt and builds up the carbapenem skeleton in a stereocontrolled way. The β-lactam ring closure with *tert*-butylmagnesium chloride at an early stage is one of the special features. By way of a five-step sequence, the C-4 side chain of the azetidinone is subsequently homologized by one C-atom to give the silyldithiane **100**, which is a carboxylic acid analogue. The total yield starting from L-aspartic acid amounts to 40%.

Scheme 6. Synthesis of (+)-thienamycin **106**. a) *t*BuMgCl, Et_2O; 2 N HCl, NH_4Cl; b) $NaBH_4$, MeOH; c) CH_3SO_2Cl, NEt_3; d) NaI, acetone; e) *t*$BuMe_2SiCl$, NEt_3, DMF; f) 2-trimethylsilyl-1,3-dithian-2-yllithium; g) $LiN(iPr)_2$, tetrahydrofuran (THF), CH_3CHO; h) $LiN(iPr)_2$, THF, 2 acetylimidazole (AcIm), THF; i) DMSO/trifluoroacetic anhydride, NEt_3; j) K-selectride, KI, Et_2O; k) $HgCl_2$, HgO, CH_3OH/H_2O; l) H_2O_2, MeOH; m) Im_2CO, THF; n) $(PNBO_2C-CH_2CO_2^{\ominus})_2Mg^{2\oplus}$; o) HCl/MeOH; p) HO_2C-*p*-$C_6H_4-SO_2N_3$, NEt_3, CH_3CN; q) 0.001 $Rh(OAc)_2$, toluene 80 °C; r) $ClPO(OPh)_2$, 4-dimethylaminopyridine (DMAP), iPr_2NEt, CH_3CN; s) $HS(CH_2)_2NHCO_2PNB$, iPr_2NEt; t) H_2, Pd/C (10%).

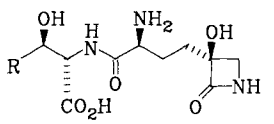
Diphenylphosphoryl chloride is superior to other activating reagents for the subsequent introduction of the cysteaminyl side chain. The (+)-thienamycin **106** thus prepared proved to be identical to the natural product.

Merck Sharp & Dohme have also published a technically feasible (±)-thienamycin synthesis[154, 155] which eliminates one of the apparent weak points in Scheme 6, namely, the expensive homologization of **99** (Scheme 7).



Scheme 7. The initial steps in a synthesis of (±)-thienamycin. a) $BzNH_2$, molecular sieves; b) ketene; c) $NaCNBH_3$, HOAc; d) HCl, CH_2Cl_2; e) 1.0 $NaHCO_3/H_2O$; f) 1.3 PPh_3, 1.3 diethylazodicarboxylate, THF; g) conc. HCl, reflux; h) $H_2/Pd(OH)_2/C$ (20%); i) $PhCH_2OH$, 70°C; j) NEt_3, DCCD, $PhCH_2OH$, 55°C.

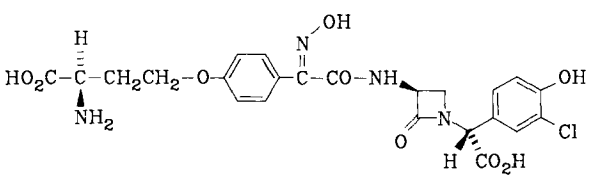
The aldol condensation with acetaldehyde, by which the hydroxyethyl group in **100** is introduced, is stereoselective with regard to C-3 of the azetidinone: equal proportions of (8*R*)- and (8*S*)-isomers **101** are formed. The chirality of the side chain is removed by Moffat oxidation to 3-acetylazetidinone **102**, which can also be obtained in higher yield directly from **100** by acetylation. Subsequent reduction of the keto group with K-selectride is stereoselective. The unwanted (8*S*)-diastereomer forms only to 10% and can be recyclized. After cleavage of the dithiane **103**, the resulting carboxylic acid is elongated using a modified Masamune method and converted by diazo transfer into the carbene precursor **104**. **104** cyclizes quantitatively, under mild conditions in the presence of catalytic amounts of rhodium(II) acetate, to give 2-oxocarbapenam **105**. During the entire reaction sequence from **103** to **105**, the hydroxy group does not need to be protected.



Starting from diethyl acetonedicarboxylate, the enamine **107**, in which a strong hydrogen bond forces the acetyl group into the *cis* position relative to the benzylamino group, is prepared. By stereoselective reduction with $NaCNBH_3$, the racemic diester **108**, which contains all atoms of the carbapenem skeleton except for two carbon atoms and in which all substituents except for the OH group have the desired relative configuration, is obtained. By way of the sequence **109** → **111**, the hydroxyethyl group can be epimerized via an intramolecular Mitsunobu reaction. The lactone **111** is opened to give the benzyl ester **112** by solvolysis in benzyl alcohol and converted into the azetidinone **113** with dicyclohexylcarbodiimide. Here, the reaction sequence joins up with the total synthesis of thienamycin in Scheme 6 (**113** corresponds to **103**).

6. Monocyclic β-Lactam Antibiotics

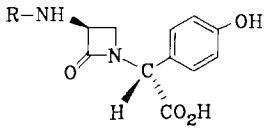
Monocyclic β-lactam antibiotics were first described in the mid-seventies. In fact, other monocyclic β-lactams of natural origin had already been found previously, such as pachystermine A **114**[156]—an alkaloid isolated from *Pachysandra terminalis* species—or tabtoxine **115a**[157] and its lower homologue [Ser²]tabtoxine **115b**[158]—a β-lactam



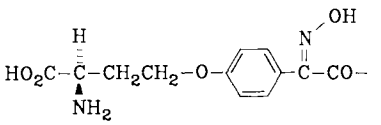
114, Pachystermine A

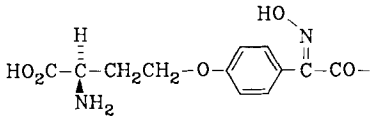
115a: R = CH_3, Tabtoxine
115b: R = H, [Ser²]Tabtoxine

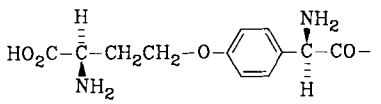
produced on tobacco plants by the phytopathogenic bacterial species *Pseudomonas tabaci*, which causes chlorosis of the green leaves. The first stereospecific total synthesis of tabtoxine was described in 1983[159]. These β-lactams were at first treated as curiosities on the fringe of natural products chemistry, since no therapeutic significance was attributed to them. Only the development of highly sophisticated screening methods for new antibiotic structures[160], e.g., the use of extremely sensitive test strains of bacteria, made the discovery of a new class of monocyclic β-lactam antibiotics possible.

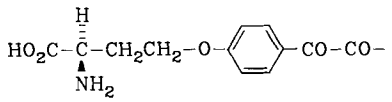


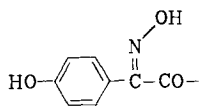
118, Chlorocardicin

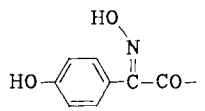


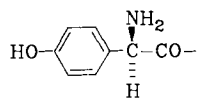












6.1. Nocardicins

Structural elucidation of nocardicin A **116a** and B **116b**[161, 162], the first two antibiotics isolated from the actinomycetes species *Nocardia uniformis subsp. tsuyamanensis* ATCC 21806, revealed their structural relationship to cephalosporins and penicillins: The configuration of the amide-carrying C-3 carbon of the β-lactam is identical, and an oxime function, which is only seldom observed in nature, is present. The nocardicins C-G **116c—g** could be isolated from *Nocardia uniformis*[163]. They are all derivatives of 3-aminonocardicinic acid (3-ANA) **117**, which is obtained by chemical[164] or enzymatic[165] deacylation of norcardicin (Table 12). Chlorocardicin **118** was recently isolated from the fermentation broth of a *Streptomyces* species[185]. Nocardicins have no therapeutic importance. Only nocardicin A shows moderate activity against some

Table 12. Nocardicins.

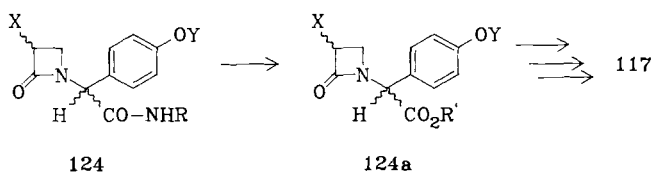
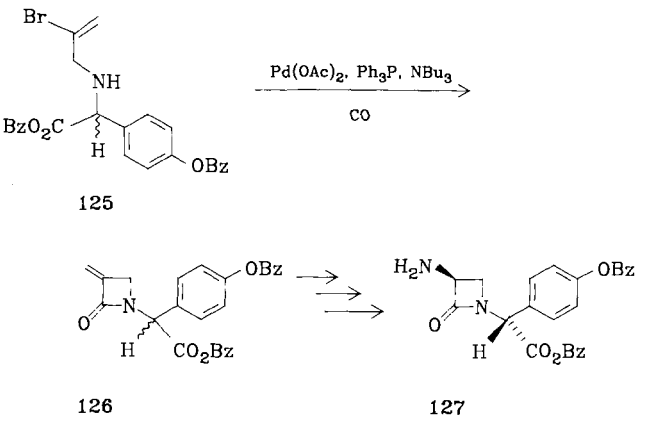
Gram-negative species and against *Pseudomonas*. As with other β-lactam antibiotics, the antibiotic effect of nocardicin is based on the inhibition of murein-synthesizing enzymes.

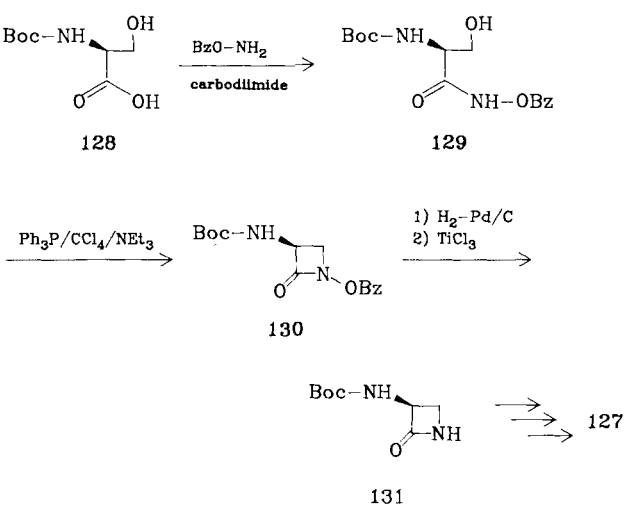


6.1.1. Total Syntheses of Nocardicin

Kamiya et al. built up the β-lactam ring from an acid chloride and a Schiff base by the classic method according to *Sheehan* and *Ryan*[166]. Since C-4 of the β-lactam remains unsubstituted, an easily removable group must be a constituent of the Schiff base. This problem was solved by the use of the methylthio compound **119**, synthesized from D-(4-hydroxyphenyl)glycine via several steps[167]. Desulfurization of the β-lactam **121** with Raney nickel leads to the 4-unsubstituted nocardicin precursor **122**. This intermediate is formed directly by release of the unstable formaldehyde imine **123** from its stable trimer (accessible from D-(4-hydroxyphenyl)glycine) using Lewis acid catalysis and reaction of **123** with acid chloride **120**[168]. *Curran* et al. pursued a similar strategy[169].

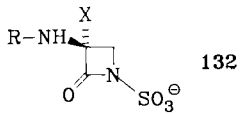


The azetidinone synthesis by a four-component condensation reaction according to *Ugi*[170] was elaborated independently by two teams. The problem of converting the

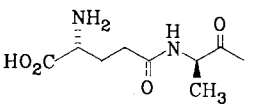


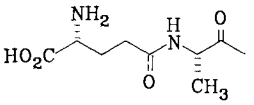
amides **124** resulting from this reaction into easily saponifiable esters **124a** was solved in different ways. Whereas *Isenring* and *Hofheinz*[171] converted the amide **124**, R = diphenylmethyl, thermally into the ester **124a**, R′ = diphenylmethyl, via the *N*-nitroso derivative, *Hatanaka* et al.[172] successfully achieved selective amide cleavage of **124**, R = *tert*-butyl, using imidoyl chloride with PCl_5 and subsequent methanolysis to give ester **124a**, R′ = CH_3.

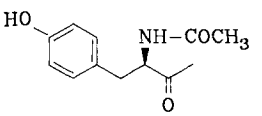
Ban et al.[173] used the Pd-catalyzed carbonylation of α-bromoallylamine **125** to build up the β-lactam skeleton **126**, the 3-methylene group of which is converted into the 3-amino group of dibenzyl 3-ANA **127**. **125** is obtained from DL-(4-hydroxyphenyl)glycine. A further nonstereoselective 3-ANA synthesis was published by *Wassermann* et

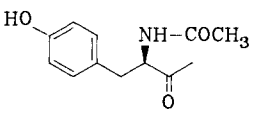


al. in 1979[174]. An important stereoselective cyclization to β-lactams was introduced by *Mattingly* and *Miller*[182,186]. *N*-Boc-L-serine **128** is converted with *O*-benzylhydroxylamine in the presence of a carbodiimide into the hydroxamic acid **129**. Due to the high acidity of the hydroxamic acid, cyclization to **130** with triphenylphosphane-CCl_4-triethylamine proceeds smoothly and in good yields, without racemization, elimination, and formation of by-products. Debenzylation by hydrogenolysis and reduction of the *N*-hydroxy-β-lactam with titanium trichloride affords **131** which, after amide alkylation and partial removal of the protecting groups, yields **127**, an intermediate of nocardicin synthesis.









6.2. Monobactams

The most important group of monocyclic β-lactam antibiotics was discovered a few years ago. In 1981, teams from Takeda[175] and Squibb[176], independently of each other, described this new class of natural products. As characteristic feature, sulfazecins or monobactams—the latter name has meanwhile become widely accepted for the entire class—have a 4-unsubstituted β-lactam ring, a 3-acylamido group, and the function $>N-SO_3H$, which rarely occurs in nature. In some compounds, the acyl group consists of a di-, tri-, or oligopeptide; however, the

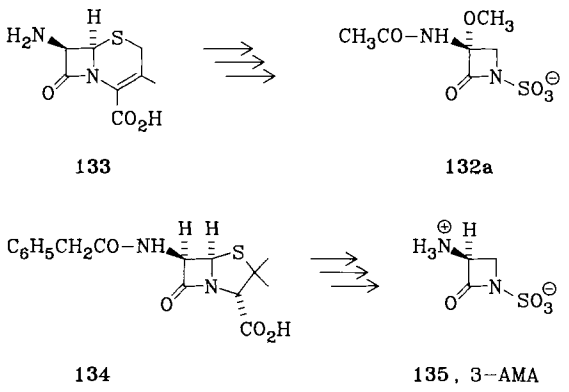


Table 13. Monobactams

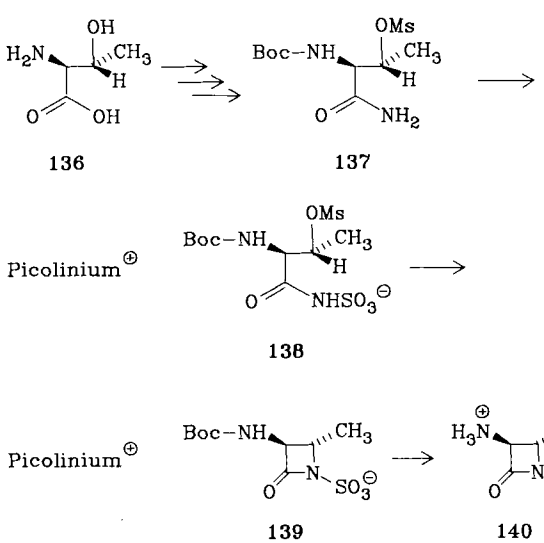
132

No.	Generic name and/or scientific code	R	X
132a	SQ 26180	CH_3CO	OCH_3
132b	SQ 26445 Sulfazecin		OCH_3
132c	Isosulfazecin		OCH_3
132d	SQ 26700		H
132e	SQ 26875		OCH_3

monoacetylated compound has also been found. Natural monobactams mainly occur as 3-methoxy derivatives. The nonmethoxylated monobactams probably constitute an intermediate stage of biosynthesis. The first natural monobactams (Table 13) were detected by extensive screening programs with the aid of β-lactam-ultrasensitive bacterial test strains of *Bacillus lichenoformis*[175], *Pseudomonas aeruginosa PsC*^{ss}, and *Escherichia coli PG8*. In contrast to penicillins, cephalosporins, and nocardicins, monobactams are metabolic products of bacteria. **132b** was isolated from a number of different strains of *Gluconobacter sp., Pseudomonas sp., Agrobacterium radiobacter, Flexibacter sp.*, and *Chromobacterium violaceum*[177]. Due to its 3-methoxy group, it has high β-lactamase stability. Similar to nocardicins, natural monobactams only exhibit minimal antibiotic activity against Gram-negative bacteria and *Pseudomonas* and are hardly active against Gram-positive pathogens. The skeleton and the 3-acylamido side chain were varied in order to improve antibiotic activity. For this purpose, the parent compound, 3-aminomonobactamic acid (3-AMA) **135**, had to be synthesized. Its formation via deacylation of material obtained from fermentation broths was not practicable, since the fermentation product is a mixture of several monobactams which are difficult to separate and in which the methoxylated products, whose antibiotic activity is lower, predominate. Conversion of 7-aminodesacetoxycephalosporanic acid **133** into 3-acetyl-3-amino-3-methoxymonobactamic acid **132a**[178] and of penicillin G **134** into 3-aminomonobactamic acid **135**[179,180] proved the identity of the configuration of the 3-amino group of **135** with that of the 7-NH_2 of cephalosporins and

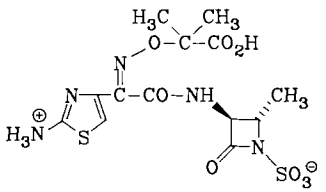


133 **132a**

134 **135**, 3-AMA

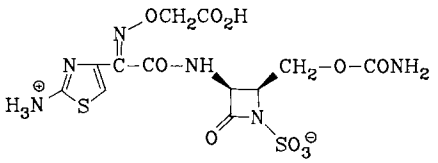
the 6-NH_2 of penicillins. 4-Substituted monobactams, however, are not accessible in this way. The only alternative is their total synthesis.

A stereospecific total synthesis of (*S*)-3-aminomonobactamic acids, which also permits preparation of 4-alkylated β-lactams, was published by Squibb[181]. An appropriate educt with two asymmetric centers is threonine **136**. It is essential to avoid racemization of either of these two centers in the following steps: after conversion of threonine into its amide and blocking of the α-amino group, the hydroxy group is converted by mesylation into a potential leaving group. Sulfonation of the amide nitrogen with the picoline-SO_3 complex acidifies the amide hydrogen atom sufficiently for intramolecular cyclization in the presence of potassium bicarbonate as base to take place. By removal of the protecting groups, (3*S*,4*S*)-*trans*-3-amino-4-methylmonobactamic acid **140** is obtained in ca. 50% yield (based on threonine); **140** is a suitable starting material for the synthesis of active monobactams.



136 **137**

Picolinium$^{\oplus}$ **138**

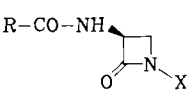


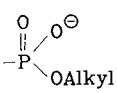
Picolinium$^{\oplus}$ **139** **140**

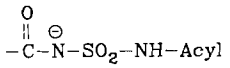
Structural variations of the 3-acylamido residue led to aztreonam (SQ 26776) **141**[183], a parenterally administered antibiotic with high activity against Gram-negative bacteria and *Pseudomonas*, comparable to that of third-generation cephalosporins, but only minimal activity against Gram-positive bacteria. **141** is highly stable against plas-

mid-coded and chromosomally coded β-lactamases, owing to the 3-acylamido side chain and to the 4-methyl group. Like most β-lactam antibiotics, aztreonam is distinguished by low toxicity and good tolerance.

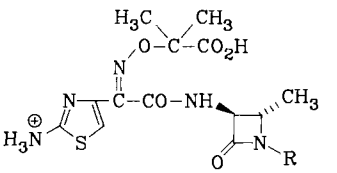
141, Aztreonam



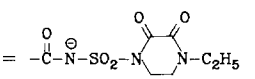




142, Carumonam



Meanwhile, another parenterally effective monobactam—carumonam (AMA 1080; Ro 17-2301) **142**, developed jointly by Takeda and Hoffmann-La Roche—has reached the clinical development stage. In its antimicrobial and pharmacological properties, it is comparable to aztreonam. Several syntheses, including a stereorational synthesis starting from L-ascorbic acid[184b], have so far been published[184a].



Monocyclic β-lactams with other electron-withdrawing acidic substituents at the β-lactam nitrogen were obtained by total synthesis and tested for antibiotic activity (Table 14). Depending on the 3-acylamido substituent, they exhibit moderate to good antibacterial activity[187]. SQ 82228 **143** and SQ 27327 **144**, for example, are comparable to aztreonam. Variation of the 4-substituent was extensively studied. Although higher homologues of methyl increase the stability of the monobactams against β-lactamases, their antibacterial activity diminishes[187, 191]. Of the functionalized 4-methylmonobactams, the 4-fluoromethyl compound **145** has received particular attention. **145**, independently synthesized by three teams[192–194], showed high antibacterial activity, comparable to that of aztreonam, against a number of Gram-negative species.

146a, SQ 82 531, R = $CH_2CO_2C(CH_3)_3$
146b, SQ 82 291, R = Na

A prodrug form of a monocyclic β-lactam has recently been reported[195]. After oral administration of SQ 82531 **146a** to animals, high blood levels of the parent compound **146b** were observed.

7. Conclusion and Outlook

This general survey has endeavored to describe the status of β-lactam antibiotics from the viewpoint of medicinal chemistry. The physicochemical and biological properties of this class of drugs have been scrutinized like no other, yet considerable research efforts are still being made to achieve further progress. The principle of drug optimization by modification has been outstandingly successful and is an example of the contribution that the synthetic chemistry of natural products can make to the treatment of infections. The new β-lactam antibiotics that have recently entered the market or are in clinical trial have exceptional antibacterial spectra and appreciably widen and improve therapeutic possibilities in severe and life-threatening infections. Progress of this kind is not always fully appreciated, since the treatment of infectious diseases is almost

taken for granted by the layman. Also, it is asking too much of many doctors to expect them to select the optimal drug for a specific infection.

The ideal antibiotic has undoubtedly not yet been found. The difficulties in advancing towards this goal lie in the considerable diversity of bacteria and in their defence strategy which has been optimized over billions of years. This strategy is an expression of the enormous variability of the living cell under selection pressure. The gradually increasing development of resistance in bacteria follows the principle of move and countermove, as in a game of chess. It is based on many different molecular mechanisms, of which the induction of β-lactamases, reduced ability to penetrate the bacterial cell wall, and lower affinity for the target enzymes of the bacteria under antibiotic treatment are of particular importance. The shift in the spectrum of pathogenic organisms is a further factor complicating the advance of antibiotic therapy. In particular, Gram-negative organisms and opportunists, for example, *Pseudomonas, Serratia,* and *Proteus* species, are nowadays triggering serious infections much more frequently than was formerly the case. The problem of chronic infections has not yet been solved.

New β-lactam antibiotics with improved properties demand much more sophisticated chemistry. In particular, the synthesis of new "nonclassic" compounds from the series of penems and carbapenems confronts the research chemist with the problem of transferring reactions that require specific conditions to large scale synthesis. For the future, it is important, by the combination of enzymatic and easy-to-perform stereoselective reactions, to elaborate short economical synthesis routes producing high yields[196]. The antibiotic market has become more price-sensitive and an upper price limit cannot be exceeded. Genetic engineering will help to develop better isolation procedures for natural antibiotics. By interfering with the microorganisms' DNA, it should be possible to develop species that give higher yields in fermentation or even enable the production of new antibiotics.

The quest for more potent antibiotics will have to remain a permanent task of chemotherapeutic research, if we want to maintain the high standard in the treatment of infectious diseases. The new drugs will have to be selected and evaluated with regard to efficacy, tolerance, and necessity according to very strict criteria before they can be used in clinical practice.

Cationic Thionitrosyl and Nitrosyl Complexes**

By *Gabriele Hartmann* and *Rüdiger Mews**

Compared to the seemingly countless number of nitrosyl complexes that have been reported in the literature, the number of hitherto unequivocally characterized organometallic thionitrosyl complexes is pathetically small[1,2]. The main reason for this is the lack of a general method of synthesis[2]. Herein, it is shown that the thionitrosyl cation[4], like the nitrosyl cation[3], could also provide a general entry to such complexes when used as reaction partner in the form of the stable hexafluoroarsenate or hexafluoroantimonate.

The complex cation of the salt **1**[5] reacts with NS^+- and NO^+-salts with formation of the thionitrosyl- and nitrosyl-complex dications of the salts **2** and **3**, respectively.

$$\underset{\mathbf{1}}{[CpFe(CO)_2SO_2]^+AsF_6^-} + NS^+AsF_6^- \xrightarrow{-SO_2} \underset{\mathbf{2}}{[CpFe(CO)_2NS]^{2+}(AsF_6^-)_2} \quad (1)$$

$$\mathbf{1} + NO^+AsF_6^- \xrightarrow{-SO_2} \underset{\mathbf{3}}{[CpFe(CO)_2NO]^{2+}(AsF_6^-)_2} \quad (2)$$

$$\underset{\mathbf{4}}{[Re(CO)_5SO_2]^+AsF_6^-} + NS^+AsF_6^- \xrightarrow{-SO_2} \underset{\mathbf{5}}{[Re(CO)_5NS]^{2+}(AsF_6^-)_2} \quad (3)$$

$$\mathbf{4} + NO^+AsF_6^- \not\rightarrow [Re(CO)_5NO]^{2+}(AsF_6^-)_2 \quad (4)$$

In an analogous way, **4**[6] reacts with $NS^+AsF_6^-$ to give **5**, but does not react with $NO^+AsF_6^-$.

The reactions (1)—(3) proceed quantitatively. At first sight, the reaction of cations with cations to give dications seems absurd; but, if one reflects on the bonding in SO_2-complexes such as **1** or **4**[5–8], such a reaction is perfectly logical. The main contributer to formation of the metal-sulfur bond is the π-back bonding from the metal to the ligand. Since SO_2 is only a weak π-acceptor, stronger π-acids—such as, e.g., NS^+ or NO^+—should replace this ligand. **4** does not react with $NO^+AsF_6^-$ [Eq. (4)], thus indicating that the σ-donor ability of the ligands (that of NS^+ is greater than that of NO^+) is of importance for such reactions.

NO^+ can also replace CO in complexes[3,9,10].

$$\underset{\mathbf{6}}{[CpMn(CO)_3]} + NO^+AsF_6^- \xrightarrow[-CO]{SO_2} \underset{\mathbf{7}}{[CpMn(CO)_2NO]^+AsF_6^-} \quad (5)$$

$$\mathbf{6} + NS^+AsF_6^- \xrightarrow[-CO]{SO_2/-60^\circ C} \underset{\mathbf{8}}{[CpMn(CO)_2NS]^+AsF_6^-} \quad (6)$$

In liquid SO_2, the exchange proceeds according to Eq. (5) in high yields at room temperature, while **8** is formed almost quantitatively even at −60 °C. However, since **8** readily eliminates CO it was not possible to isolate the compound in analytically pure form[11]. Due to a lack of

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

sufficient data, no unequivocal statements could hitherto be made about the ligand properties of NS^+ compared to those of NO^+[2]. It was concluded from a comparison of the IR spectra of $[CpCr(CO)_2NO]$[9, 12] and $[CpCr(CO)_2NS]$[13] (see Table 1) that the NS^+-ligand is the better π-acceptor. The same conclusion was drawn from the PE spectra and theoretical investigations[14]; yet it was also shown that NS^+ is the better σ-donor[14]. On changing the d^6-central atom M in the series of complexes $[CpM(CO)_2NX]^{n+}$ (X = O, S) from chromium(0) through manganese(I) to iron(II), the π-donor ability of the central atom dramatically decreases; ν(CO) and ν(NX) shift to higher wave numbers. The IR spectra of **2** and **3** show the highest ν(NS) and ν(NO) frequencies thus far found for organometallic compounds. In the nitrosyl complex cations of **3** and **7** the frequencies of the stretching vibrations lie distinctly higher than in the corresponding thionitrosyl complex cations **2** and **8**, respectively, an indication of the greater π-acidity of NO^+.

Table 1. Selected IR data of the complexes $[CpM(CO)_2NX]^{n+}(AsF_6^-)_n$ (Nujol or Kel-F mull) [cm^{-1}].

$[CpM(CO)_2NX]^{n+}$		X = O			X = S	
		ν(NO)	ν(CO)		ν(NS)	ν(CO)
Chromium(0) [9, 12]		1706	2020/1946		1165	2023/1963 [13]
Manganese(I)	**7**	1878 sh/ 1838 vs	2114/2075	**8**	1284	(2108/2070)
Iron(II)	**3**	1982	2198/2183	**2**	1388	2178/2165

A comparison of the IR data (Table 1) confirms the hypothesis that the acceptor ability of NS^+ compared to that of NO^+ depends on the charge density in the complex[15].

Experimental:

Exactly equimolar amounts (1–2 mmol) of the transition-metal complexes **1**, **4** or **6**, and of the NO^+ or NS^+ salts were weighed separately into a two-limbed flask in a dry box. After attachment of the flask to a vacuum apparatus, SO_2 (15 mL) was condensed onto both substances simulataneously at −196°C and the resulting solutions combined at −60°C. After warming to room temperature, the mixture was stirred for 12 h (in the case of **5**: 3 d) and the solvent removed. **2**, **3**, **5**, and **7** remained in almost quantitative yield as analytical pure residues[16]. **8** is synthesized at −60°C and the solvent is removed in vacuo at −40°C[17].

SO_2 seems to be especially suitable for reactions with nitrosyl and thionitrosyl salts, whereas the solvents CH_3CN[6] and CH_2Cl_2[13] mentioned in the literature can easily lead to exchange and decomposition reactions.

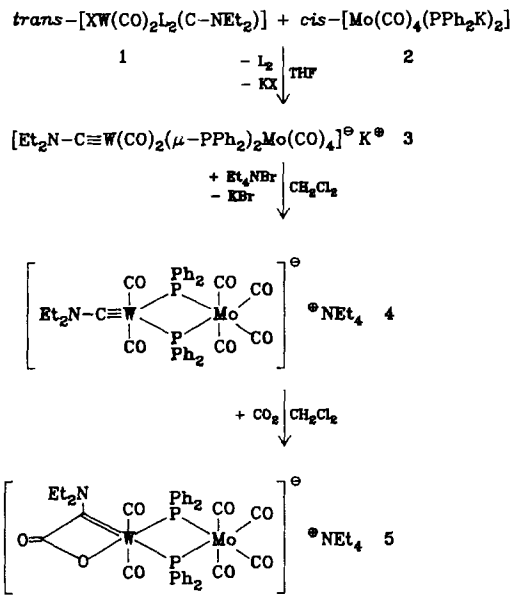
[16] The elemental analyses of compounds **2**, **3**, **5**, and **7** are consistent with the calculated values. **2**: wine-red solid, sparingly soluble in SO_2, decomp. 172°C; IR (Nujol/Kel-F mull): 3130 m, 2178/2165 vs, 2118 sh, 2080 m, 2020 m, 1429 s, 1420 s, 1388 vs, 1362 sh, 1338 sh, 1252/1250 w, 1118 s, 1019 w, 1010 w, 880 s, 700 vs, 604 sh, 570 sh, 545 vs, 528 vs, 453 w, 438 w, 390 vs, 366 w, 320 w cm^{-1}. **3**: yellow-green solid, decomp. 137°C; IR (Nujol/Kel-F mull): 3128 s, 2198 vs, 2183 vs, 2140 sh, 2120 vw, 1982 vs, 1978 sh, 1963 sh, 1429 m, 1418 m, 1110 w, 884 m, 699 vs, 598 s, 568 s, 552 sh, 475 vw, 420 sh, 390 vs cm^{-1}. **5**: light-red solid, sparingly soluble in SO_2, decomp. 136°C; IR (Nujol mull): 2220 vs, 2200 w, 2178 sh, 2160 vs, 2068 m, 2038 sh, 1370 vs, 700 vs, 542 m, 522 m, 488 w, 392 vs, 318 vw cm^{-1}. **7**: light-green solid, decomp. 136°C; IR (Nujol/Kel-F mull): 2114 vs, 2075 vs, 1878 sh, 1838 vs, 1430 w, 1420 w, 1120 vw, 1022 vw, 869 m, 700 vs, 680 sh, 658 m, 628 s, 530 w, 395 vs cm^{-1}.
[17] **8**: light-brown solid; IR (Nujol/Kel-F mull): 3120 w, 2108 vs, 2070 vs, 1430 w, 1284 vs, 865 w, 700 vs, 672 w, 588 w, 568 w, 555 sh, 390 vs cm^{-1}. The elemental analysis of **8** always shows C < 7 and an N:S ratio of 1:1. On prolonged storage in solution at higher temperatures, **8** loses CO quantitatively with formation of a solid which is insoluble in SO_2.

Synthesis of $[Et_2N{-}C{\equiv}W(CO)_2(\mu\text{-}PPh_2)_2Mo(CO)_4]^{\ominus}$, the First Anionic Carbynemetal Complex; Addition of CO_2 to the W≡C Bond**

By *Ernst Otto Fischer**, *Alexander C. Filippou*, *Helmut G. Alt*, and *Ulf Thewalt*



Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

We were able to demonstrate that neutral and cationic carbyne(carbonyl)metal complexes are obtainable on allowing carbene complexes to react with boron trihalides at low temperature[1, 2]. In complete contrast, however, all attempts to isolate anionic carbyne complexes have hitherto failed. Thus, for example, on reaction of stable, substituted carbyne complexes of the type $[Br(CO)_2L_2WCR]$ (L_2 = phen, bpy; R = C_6H_5, CH_3) with KCN, replacement of CO by $CN^{\ominus}$ with formation of an anionic carbyne complex does not take place. Instead, as we have recently discovered, insertion of CO into the W≡C bond takes place with formation of an anionic ketene complex[3]. This finding automatically raises the question whether this insertion

[**] Transition-metal carbyne complexes, Part 78. — Part 77: E. O. Fischer, J. Schneider, D. Neugebauer, *Angew. Chem. 96* (1984) 814; *Angew. Chem. Int. Ed. Engl. 23* (1984) 820.

reaction might be forestalled on appropriately varying the R moiety attached to the carbyne ligand (NEt_2 instead of C_6H_5 or CH_3).

Scheme 1. **1a**, X = Br, L_2 = bpy; **1b**, X = Br, L_2 = phen; **1c**, X = I, L_2 = bpy; **1d**, X = I, L_2 = phen.

In analogy to the synthesis of other substituted carbyne complexes[4] *trans*-$[XW(CO)_4(CNEt_2)]$ (X = Br, I)[5] was allowed to react with 2,2'-bipyridyl (bpy) or 1,10-phenanthroline (phen) in CH_2Cl_2 to give the carbyne complexes **1**. Reactions of complexes **1** with the Mo-compound **2** always lead to the same diamagnetic anionic complex **3**, which can be precipitated with Et_4NBr as counterion and, after careful purification, isolated as yellow, microcrystalline **4** in analytically pure form (total analysis). The complex **4** reacts with CO_2 in CH_2Cl_2 to give the red adduct **5**, which can be isolated from CH_2Cl_2 as dark red crystals $5 \cdot 1.5\,CH_2Cl_2$, the structure of which has been determined by X-ray diffraction analysis (Fig. 1)[6].

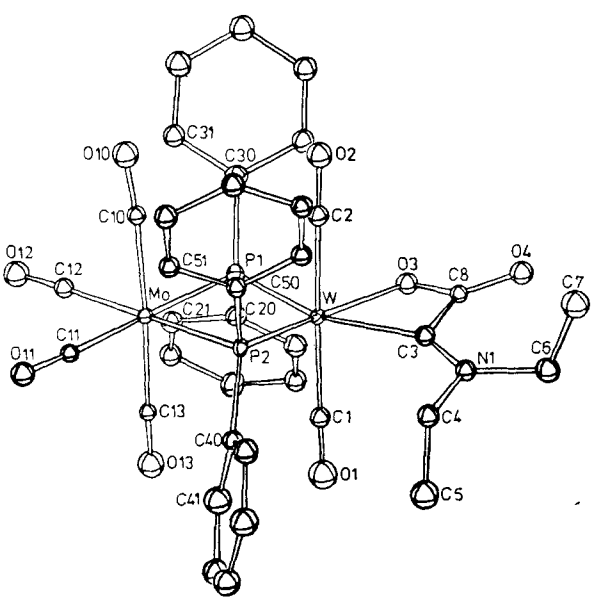

Fig. 1. Structure of the anion of **5** in the crystal [6].

A comparison of the IR, ^{1}H-NMR, ^{31}P-NMR, and ^{13}C-NMR spectra of compounds **4** and **5**, as well as the reactivity, lend support to the proposed structure of **4**. The IR spectra of **4** and **5** (Table 1) are very similar between 4000 and 300 cm^{-1}; it may be concluded, therefore, that the two compounds contain identical structural units. The spectrum of **5** contains an intense band at 1645 cm^{-1} due to the CO_2-unit of oxatungstacyclobutenone, a band which is missing in the spectrum of **4**.

Table 1. ^{1}H-, ^{13}C-, and ^{31}P-NMR data and selected IR data (carbonyl bands) of **4** and **5** in DMF.

	4	**5**
^{1}H-NMR [δ values] [a]	1.48 (t, 6H, CH_3; $^3J_{HH}$ = 6.7); 3.51 (q, 4H, CH_2; $^3J_{HH}$ = 6.7); 7.19, 7.27, 7.87, 7.96 (m, 20H, Ph)	1.29 (t, 6H, CH_3; $^3J_{HH}$ = 7.1); 3.41 (q, 4H, CH_2; $^3J_{HH}$ = 7.1); 7.27, 7.33, 7.67, 8.24 (m, 20H, Ph)

^{31}P-NMR [δ values] [g]	+ 161.7 ($^1J_{WP}$ = 341.8)	+ 160.0 ($^1J_{WP}$ = 349.1, $^2J_{PP}$ = 4.9); + 160.8 ($^1J_{WP}$ = 222.2, $^2J_{PP}$ = 4.9)
IR [cm^{-1}]	2000 (s), 1908 (st), 1881 (m), 1834 (m)	2010 (s), 1918 (st), 1900 (m), 1877 (m), 1841 (m)

[a] 90 MHz in [D_7]-dimethylformamide (DMF), −20°C, δ values referred to DMF (δ = 2.74, 2.90, 8.04), coupling constants in Hz. [b] 90 MHz in [D_7]DMF, −20°C, δ values referred to DMF (δ = 30.1, 35.3, 162.7), coupling constants in Hz. [c] *cis* with respect to the two μ-PPh_2 bridges. [d] *cis* with respect to one μ-PPh_2 bridge, *trans* with respect to the other. [e] *J* not determinable. [f] The second coupling is not observed. [g] 90 MHz in [D_7]DMF, −20°C, δ values referred to 85% H_3PO_4 solution (ext.). Coupling constants in Hz.

The ^{1}H-NMR spectra of **4** and **5** (Table 1) show, along with the signals for the aromatic protons, the triplet and quartet expected for the diethylamino group on the carbyne carbon atom and on the carbene carbon atom, respectively. The ^{31}P-NMR spectrum of **4** shows only one signal for the two P-atoms, whereas the spectrum of **5** shows two signals; this is due to the different environment of these atoms (Table 1). In the ^{13}C-NMR spectrum of **4**, the signal of the carbyne C-atom (δ = 290.8) appears as a triplet, due to coupling with two homotopic P-atoms. The signal of the carbene C-atom of **5** (δ = 242.9), on the other hand, is split into a double doublet due to coupling with two diastereotopic P-atoms. The carbonyl ligands bound to the W-atom in **4** and **5** give rise, in each case, to only one signal, i.e., they are magnetically equivalent (Table 1).

The reaction of **4** with CO_2, leading to formation of **5**, not only affords further evidence in support of the proposed structure of **4**, it also opens up a route to new metallacycles. All these findings are indicative of **4** being the first anionic carbynemetal complex; anionic alkylidynemetal complexes, on the other hand, have been known for some time[8, 9].

Experimental:

All operations were carried out under argon using anhydrous and oxygen-free solvents.

1c: A solution of $[IW(CO)_4(CNEt_2)]$ (7.71 g, 15.2 mmol) in CH_2Cl_2 (100 mL) was treated at −40°C with 2.8 g (17.9 mmol) 2,2'-bipyridyl and the mixture

stirred at room temperature for 120 h. The color of the solution changed from orange to red and finally to violet, whereupon **1c** partially precipitated out. The mixture was then evaporated down and treated with Et_2O to complete precipitation of **1c**. Subsequent filtration and washing of the crude precipitate twice with Et_2O furnished 8.53 g (92%) of **1c** as permanganate-colored microcrystals.

4: The violet suspension of **1c** (1.17 g, 1.93 mmol) in THF (30 mL) was treated slowly at $-50\,^{\circ}C$ with a deep-orange solution of **2**. [Preparation of a solution of **2**: A solution of *cis*-$Mo(CO)_4(PPh_2H)_2$ [7] (1.97 g, 3.39 mmol) in THF (15 mL) is added to a suspension of KH (0.5 g, 12.5 mmol) in THF (15 mL) at room temperature; after 1 h, any excess KH is removed by filtration]. The reaction mixture was stirred for 2 h at room temperature; **1c** dissolved (brownish-yellow solution) and KI precipitated out. After filtration, the solvent was removed from the filtrate and the resulting brown residue was washed with 75 mL CH_2Cl_2 and dried in a high vacuum. The residue was then taken up in 20 mL CH_2Cl_2, treated with a solution of 2.03 g (9.66 mmol) Et_4NBr in 80 mL CH_2Cl_2, and filtered to remove insoluble KBr. After removal of solvent from the filtrate, dissolution of the residue in 100 mL THF, and removal of insoluble Et_4NX (X = Cl, Br, I) by further filtration, the final filtrate was evaporated down and treated with Et_2O to precipitate **4**; yield: 0.96 g (48%), yellow, finely crystalline powder.

5: A stream of dry CO_2 was passed into a solution of **4** (0.5 g, 0.48 mmol) in CH_2Cl_2 (50 mL) at $-10\,^{\circ}C$ until the brownish yellow solution turned dark red. After removal of the solvent, the residue was recrystallized from CH_2Cl_2; yield: 0.48 g (83%), red crystals which slowly lost their CH_2Cl_2 of crystallization at room temperature.

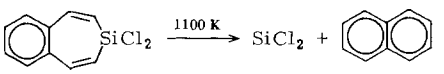
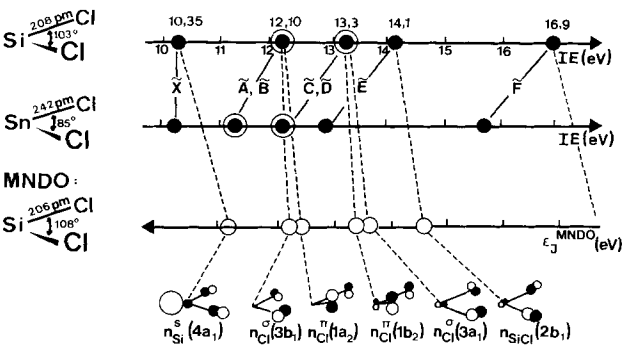
$SiCl_2$: Photoelectron Spectroscopic Optimization of Various Syntheses**



By *Hans Bock**, *Bahman Solouki*, and *Günther Maier*

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday

Dihalogensilanediyls (dihalogensilylenes) SiX_2[***], which, as coordinatively unsaturated species, can be inserted into many bonds between nonmetals[1], are available via several routes[1,2]: by high-temperature reaction of silicon halides with silicon[1,2a,b] and by thermolysis[1,2c] or photolysis[1] of appropriate organic precursors. We report here on the photoelectron (PE) spectrum of $SiCl_2$, obtained by reaction of hexachlorodisilane with silicon [reaction (a)], and on the optimization of reactions (b) and (c) by PE-spectroscopic on-line gas analysis[3].



$$Cl_3Si{-}SiCl_3 \xrightarrow{1450\ K/Si_\infty} 3\ SiCl_2 \qquad (a)$$

$$Cl_3C{-}SiCl_3 \xrightarrow{>1250\ K/Si_\infty} SiCl_4 \xrightarrow{1450\ K/Si_\infty} SiCl_2 \qquad (b)$$

(c)

The PE spectrum of $SiCl_2$, which is necessary as a standard and was unknown up to now, is recorded during the selective reaction (a); between 9 and 17 eV, it exhibits an ionization pattern consisting of three single and two double bands (cf. Fig. 1).

Scheme 1.

An unequivocal assignment is achieved by comparison of the radical cation states $\tilde{X}$ to $\tilde{F}$ with those of the iso(valence)electronic $SnCl_2$[4] (Scheme 1), taking into consideration the opposing influences of decreased effective nuclear charge and reduced bond angle. The assignment is in agreement with the results of a geometrically optimized MNDO calculation, which satisfactorily reproduces the gas-phase structure of $SiCl_2$[2a] (Scheme 1). According to MNDO and ab initio SCF calculations[5], the Si center of $SiCl_2$ carries an appreciable positive charge, which accounts for the insertion reactions[1] in bonds between nonmetals.

The reaction of trichloro(trichloromethyl)silane with silicon powder [reaction (b)][3] is a further example for a PE-spectroscopically optimized high-temperature reaction (Fig. 1).

The following changes in the PE spectra[3], continuously recorded at short intervals, were observed with rising oven temperature: Above 1000 K, $Cl_3Si{-}CCl_3$ begins to decompose, and at 1250 K the known PE spectrum of pure $SiCl_4$ is observed (Fig. 1, middle). Transient chlorinated hydrocarbons can not be detected; possibly, either SiC is formed

[**] Gas-phase reactions. Part 49. This work was supported by the Land Hessen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie.—Part 48: H. Bock, R. Dammel, *Angew. Chem. 97* (1985) 128; *Angew. Chem. Int. Ed. Engl. 24* (1985) 111.

[***] According to IUPAC rule D-6.12, silylenes are also called silanediyls.

on the Si surface or $(CCl_2)_\infty$ on cooler parts of the wall. At 1450 K, $SiCl_4$ reacts with Si—which can also be confirmed by direct reaction—almost completely to yield $SiCl_2$; according to the PE spectrum, only traces of unreacted $SiCl_4$ and of HCl are present, with the latter probably being formed by surface hydrolysis (Fig. 1, bottom).

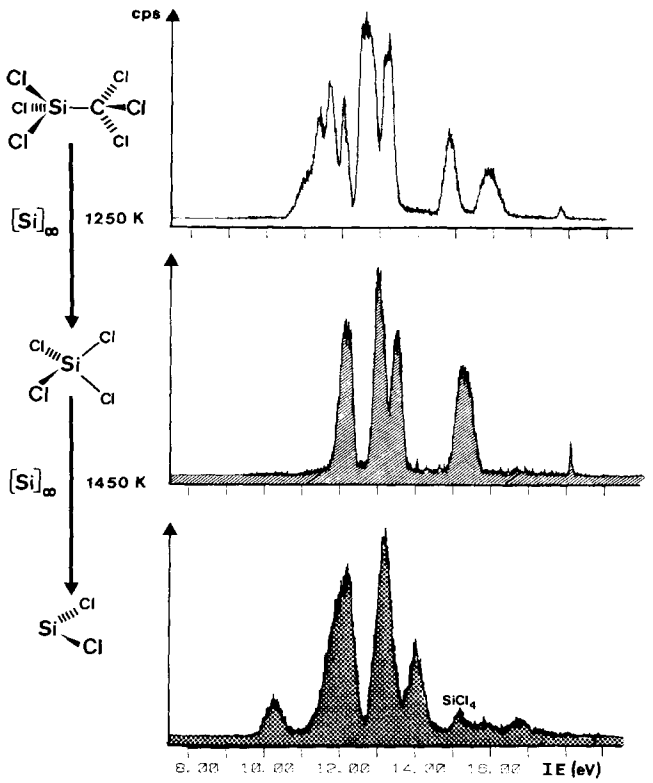

Fig. 1. He(I) PE spectra of $Cl_3Si-CCl_3$ (300 K, top) and of the products of its reaction with elemental silicon at 1250 and 1450 K (hatched: $SiCl_4$, dotted: $SiCl_2$, middle and bottom, respectively).

As a further route for the generation of $SiCl_2$, we investigated the thermolysis of 3,3-dichloro-3*H*-3-benzosilepin [reaction (c)], which eliminates naphthalene upon heating at 500°C; however, neither $SiCl_2$ nor secondary products have been reported[2c]. The PE-spectroscopically optimized thermal decomposition shows that at 1120 K the prominent bands of the benzosilepin have largely disappeared; the newly appearing bands in the low-energy region at 8.15, 8.90, and 10.0 eV (Fig. 2: ------▸) are assigned to naphthalene (Fig. 2; middle, hatched). If the PE spectrum of naphthalene is digitally subtracted from the PE spectrum of the product mixture, then the unequivocally identifiable band pattern of $SiCl_2$ emerges from the considerable background (compare Fig. 1 and Fig. 2 bottom).

These examples of synthetic routes to $SiCl_2$, which, with respect to the reaction temperatures [reactions (a) and (b)] as well as the required resolution [reaction (c)], are close to the present limits of measurement, demonstrate the advantages of digital recording of PE spectra in short time intervals as well as of their subtraction, termed "spectra stripping"[6]. It should also be possible to detect other silanediyls by PE spectroscopy, and to optimize their synthesis analogously.

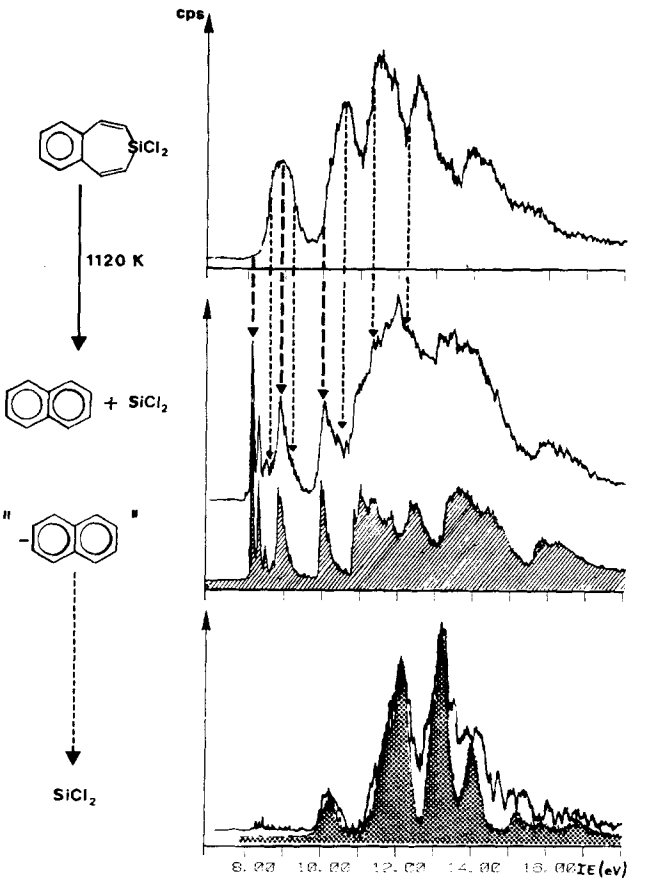

Fig. 2. He(I) PE spectra of 3,3-dichloro-3*H*-3-benzosilepin at 350 K (top) and of the product mixture after thermolysis at 1120 K (middle, new bands ------▸; disappearing bands – – →). Digital subtraction of the naphthalene PE spectrum (hatched) yields the ionization pattern of $SiCl_2$ (dotted, below).

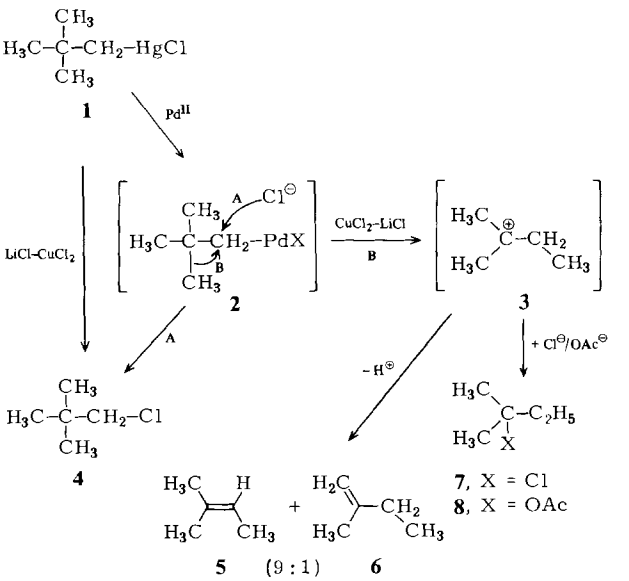
Methyl Migration and Transannular 1,5-Hydride Shift on Oxidative Cleavage of C–Pd Bonds with $CuCl_2$**

By *Andreas Heumann** and *Jan-E. Bäckvall**

The oxidative cleavage of the carbon-palladium bond is an important reaction step in many Pd-catalyzed reactions[1]. The oxidizing agent—frequently $CuCl_2$ or $Pb(OAc)_4$[2]—weakens the C–Pd bond, so that the palladium residue becomes a good leaving group[3]. The organic end product is then formed, e.g., by a nucleophilic substitution (Scheme 1, Path A).

In the Wacker reaction—the oxidation of ethylene to acetaldehyde—cleavage at the C–Pd bond is accompanied by a hydride shift[4]. Several comparable rearrangement reactions (Scheme 1, Path B) have been observed in recent years: a Wagner-Meerwein rearrangement on the norbornane skeleton[5], ring expansion reactions[6], and a ring opening reaction[7]. In such cases, oxidative cleavage of the C–Pd bond is almost always the last step in catalytic multiple-step reactions of Pd^{II} salts with various olefins.



Scheme 1

The easy accessibility of palladium σ-complexes from stable organomercury compounds via a stereospecific metal-exchange reaction

$$\text{Alkyl–Hg–Cl} + PdX_2 \rightarrow \text{Alkyl–Pd–X} + HgXCl$$

makes possible the study of specific palladated compounds. Recently, *Bäckvall* and *Nordberg*[8] reported the selective synthesis and oxidative cleavage of β-phenylethylpalladium complexes and their rearrangement in the presence of $CuCl_2$–LiCl via phenonium ions.

We have now found that, upon oxidation of complexes having the composition $R–CH_2$-metal under similar conditions, a methyl migration as well as a hydride shift over five carbon atoms can take place. In such cases, the rearrangement reactions[9] are favored by a low concentration of chloride (little or no LiCl), whereas a direct substitution at the Pd-substituted carbon atom takes place preferentially at higher concentrations of LiCl. The neopentylmercury chloride **1** proved to be a suitable model for the study of the reactivity of C–Pd bonds[10]. **1**, which can be prepared via standard reactions (Grignard reaction, mercuration with $HgCl_2$), reacts only very slowly upon direct oxidation ($CuCl_2$–LiCl–HOAc), being directly substituted to give exclusively **4** (Scheme 2). The addition of catalytic amounts of $Pd(OAc)_2$ results in a completely different spectrum of products (Scheme 2), via the in situ formation of palladium σ-complex **2**. In addition to neopentylchloride **4** (direct substitution, Path A), the methylbutenes **5** and **6**, as well as the chloride and the acetate **7** and **8**, respectively, are found (Path B).

Scheme 2

The effect of LiCl on the $CuCl_2$ oxidation of **2** is apparent from Table 1. In the Pd-catalyzed reactions, the proportion of rearranged products predominates. This can be attributed to the intermediate formation of the cation **3**. The proportion of unrearranged neopentyl chloride **4** (reaction with S_N2 character) increases with increasing amount of LiCl. For the rearranged compounds **7** and **8**, the acetoxy compound **8** is present in slightly larger proportion for low concentrations of chloride. A similar trend was already observed in the catalytic oxidation of ethylene in acetic acid[11, 12].

Table 1. $Pd(OAc)_2$-catalyzed reaction of neopentylmercury chloride **1** in the presence of $CuCl_2$–LiCl–HOAc [a].

Concentration [mol/L]		Products [b, c]		
$CuCl_2$	LiCl	**4**	**7**	**8**
1	0.5	1	3	2
1	2.5	5	2	1

[a] 5 mL solvent: 90% HOAc; 0.5 mol/L **1**, 0.02 mol/L $Pd(OAc)_2$, 45–50°C, 42 h. [b] GC analysis (SE-30). The compounds **4**, **7**, and **8** were extracted from the reaction solution with pentane and partially separated by Kugelrohr distillation. The products were characterized by 200 MHz ^{1}H-NMR spectroscopy. [c] 2-Methyl-2-butene **5** and 2-methyl-1-butene **6** could be identified by ^{1}H-NMR spectroscopy (ratio 9:1). Their proportion of the product mixture could not, however, be determined.

If R in $R–CH_2$-metal is an alicyclic group, such as, e.g., cyclohexyl in **9**, a β-elimination and several rearrangement processes (alkyl migration, hydride shift) are possible in addition to the direct substitution. As is apparent from Scheme 3 and Table 2, a dependence of the product composition on the LiCl concentration is also observed for the reaction of **9** with $PdCl_2$–$CuCl_2$–LiCl. Surprisingly, practically no elimination products are formed; these should

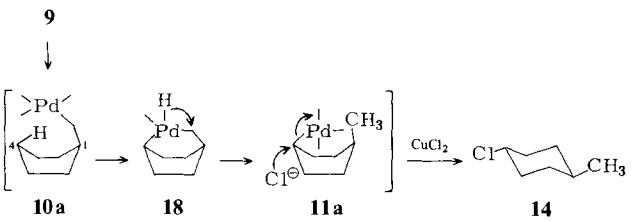
indeed be favored owing to the neighboring presence of a tertiary hydrogen and a metal atom. Chlorocycloheptane, the product of an alkyl migration[6], could not be observed either.

Table 2. $PdCl_2$-catalyzed reaction of cyclohexylmethylmercury chloride **9** with $CuCl_2$–LiCl–HOAc [a].

LiCl concentration [mol/L]	Products [b] 12	15	16	17	14	Not identified
1.66	44	5	3	5	8	35
0.66	11	Traces	2	12	28	47
0.33	4	—	3	13	41	39
—	1	—	—	5	74	20



[a] 3 mL solvent: 90% HOAc; 0.33 mol/L **9**, 0.66 mol/L $CuCl_2$, 0.013 mol/L $PdCl_2$, 45–48 °C, 70 h. [b] GC analysis: glass capillary column (25 m) CW-20M, temperature program 80–120 °C with 4 °C/min, 1 bar H_2. We thank Dr. *G. Mallet*, Faculté de St.-Jérôme, Marseille, for help with the GC analyses. Yields of isolated products: 50–60%(based on $C_7H_{13}Cl$). The reaction products were identified by comparison of their ^{1}H-NMR spectra with those of authentic compounds (synthesized via chlorination of the respective alcohols with PPh_3/CCl_4) [13]. A large number of side products were not identified.

Scheme 3.

1-Chloro-4-methylcyclohexane **14** (74%), which is almost exclusively formed in the absence of LiCl, can be formed via two routes: It could arise via a series of elimination-addition reactions (of Pd–H) and subsequent chlorination, as suggested by *Henry*[14] for the case of palladation reactions on deuterated cyclohexene. However, the absence of elimination products as well as the high regio- and stereoselectivity of the reaction are hardly in accord with such a reaction mechanism. In contrast, a transannular 1,5-hydrogen migration, via a palladabicyclooctane, such as **18**, leads to **11a** (Scheme 4). The *trans* configuration in **14** is then the result of the normal[15] course of the catalyzed $CuCl_2$ oxidation of the C–Pd bond (configuration inversion, **11a** → **14**).

Although the 1,2-isomer **16** (*trans*) and the 1,3-isomer **17** (*cis*) are also formed, **14** is the main product of the rearrangement and thus the attack on the "*para*"-C^4–H group is the most favorable reaction. The C–H abstraction proceeds, accordingly, via a cyclic seven-membered transition state and differs from the long known radical C–H activation, the Hofmann-Löffler-Freytag reaction[16] (six-membered transition state).

Scheme 4.

The C–H activation in alkanes of transition-metal compounds has been intensively investigated for the last few years[17]. It seems of interest, therefore, to determine to what extent the reaction discussed here is extendable to *n*-alkanes. Preliminary experiments show that, in the oxidation of n-$C_8H_{17}HgCl$ with $PdCl_2$–$CuCl_2$–HOAc, mainly products of a 1,2-hydride shift are formed ($C_6H_{13}CHX-CH_3$, X = Cl, OAc). Whether the Pd–Cu-catalyzed functionalization of C–H bonds can be extended to more complex systems (e.g., steroids) remain to be investigated.

Dicarbonyl-η^5-cyclopentadienyl(1-cyclopropenyl)iron Complexes—A New Class of σ-Cyclopropenyl Complexes**

By *Rudolf Gompper* and *Ekkehard Bartmann**

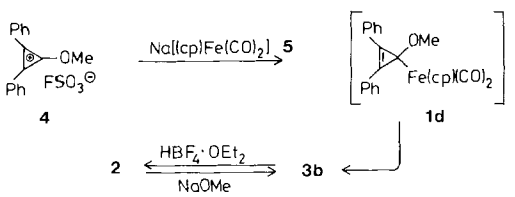
Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Many types of coordination and reactions at transition-metal centers can be realized with the cyclopropenylium system[1]. Whereas π-complexes of cyclopropenyl ligands (with symmetrical as well as unsymmetrical coordination)[2] are today an extensive class of compounds, σ-cyclopropenyl complexes (which are often suspected as intermediates in the formation of π-complexes) have thus far not been generally accessible[3]. After the synthesis of σ-cyclopropenyl derivatives **1** of dicarbonylcyclopentadienyliron in which the metal is bonded to the methylene C atom of the cyclopropene[4], we now also report the preparation of complexes in which the metal is bonded to the double bond of the three-membered ring.

The complexes **3** are simply obtained by reaction of the salt **2**[4a,5] with nucleophiles ($Nu^{\ominus}$); they are yellow, crystalline substances which are stable under exclusion of light and air[6].

1 **a**: $R^1 = R^2 = Ph$
b: $R^1 = Ph$, $R^2 = H$
c: $R^1 = t\text{Bu}$, $R^2 = Me$
$cp = C_5H_5$

2



3 **a**: $R^3 = H$: 44%
b: $R^3 = OMe$: 54%
c: $R^3 = CN$: 70%

The direction of nucleophilic attack on **2** observed here is not uncommon. Other cyclopropenylium complexes, as well as donor-substituted cyclopropenylium salts in general[7] (the metal, too, is practically a donor), are attacked by nucleophiles not at the C atom that bears the donor but at one of the other two C atoms of the three-membered ring. In these cases, a ring opening, however, usually occurs as a following reaction.

The positions of the carbonyl bands in the IR spectrum and the singlets of the cyclopentadienyl protons in the ^{1}H-NMR spectrum confirm that compounds **3** and not isomeric complexes of the type **1** were actually obtained. They are not in agreement with the corresponding signals of the known compounds **1a**, **b**, and **c**[4], but do fall in the region in which dicarbonylcyclopentadienyl groups that are bonded to vinyl or phenyl groups or to other sp^2 centers absorb[8,9].

The intense IR bands between 1700 and 1800 cm^{-1} confirm the presence of cyclopropene derivatives and not products with opened rings.

The formation of **3b** is reversible; **2** can be recovered by addition of etheral tetrafluoroboric acid. **3b** is also an intermediate in the earlier described synthesis of **2** from methoxydiphenylcyclopropenylium fluorosulfate **4** and sodium dicarbonylcyclopentadienylferrate **5**[4a,5]. In this reaction, a complex with the structure **1d** must initially be formed; however, **1d** is not stable, and rearranges immediately, via migration of the methoxy group, to **3b**.

In the reactions described here, pronounced differences are shown in the tendency of formation of complexes **1** and **3**. In general, the complexes **3** are also appreciably more stable than the earlier isolated compounds of type **1**; especially notable is the difference between **3a**[6] and its isomer **1b**, which quickly decomposes even at room temperature. This emphasizes once again the fact that 2-cyclopropenyl metal complexes such as **1** can be viewed as derivatives of the antiaromatic cyclopropenide ions.

Cofacial Dimer of a Diiminosuccinonitrile Complex Containing a Co^{II}–Co^{II} Bond and its Reduction to the Monomeric Co^{I} Complex**

By *Shie-Ming Peng**, *Der-Shin Liaw*, *Yu Wang*, and *Arndt Simon**

As a result of work on metal complexes with delocalized ground states, we report on two novel crystal structures of semidiiminosuccinonitrile (s-disn) complexes of cobalt (Scheme 1).

Scheme 1.

The blue binuclear complex $[Co^{II}(s\text{-}disn)_2]_2$ **1** was synthesized by the reaction of diaminomaleonitrile and $Co(OAc)_2$ in dimethylformamide (DMF), followed by oxidation. Suitable single crystals were grown by slow diffusion of air into the solution for one month. The structure of **1** consists of discrete DMF-solvated dimeric complexes, **1**·$(dmf)_3$ (Fig. 1). The complex **1** has a number of unusual features. First, it contains a short Co^{II}–Co^{II} bond (2.633(3) Å), which is shorter than those in $[Co_2^{II}(CN)_{10}]^{6\ominus}$ (2.794 Å)[2] and $[Co_2^{II}(CNCH_3)_{10}]^{4\oplus}$ (2.734 Å)[3]. The Co atoms are displaced 0.19 Å from the plane formed by the four N atoms toward one another. Both findings indicate a reasonably strong Co–Co σ-bond. Secondly, the two diiminosuccinonitrile ligands are arranged in an eclipsed fashion and are separated by only 2.9 Å. Thirdly, the ligands have more localized double bond character than those in similar complexes, such as $[Ni^{II}(s\text{-}disn)_2]$[4], $[Co^{III}(CN)(s\text{-}disn)_2]$[1] **2**, and $[Co^{I}(s\text{-}disn)_2]^{\ominus}$ **3**. In order to account for all these structural features, it is proposed that, in addition to the Co^{II}–Co^{II} σ-bond, a δ-type bond[5] exists between the two parallel s-disn ligands. These two types of bonds are synergic. The s-disn ligand in **1** has C_{2v} symmetry. Of the five π-electrons, four are in bonding orbitals (b_1, a_2) and one is in an antibonding orbital (b_1). The facial approach of two such monomeric units leads to a splitting of all the π-orbital pairs. Splitting of the antibonding states (b_1^*) and occupation of the lower set would lead to a net stabilization and the formation of one weak δ-type bond between the s-disn ligands. The proposed bonding scheme removes much of the antibonding character from the π* state and results in a more localized double bond arrangement of the s-disn ligands in this complex.

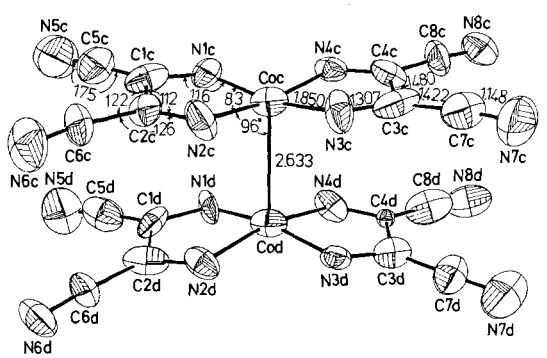

Fig. 1. ORTEP drawing of the crystal structure of **1**. $P\bar{1}$, $a = 13.328(4)$, $b = 27.999(26)$, $c = 9.488(13)$ Å, $\alpha = 85.91(10)$, $\beta = 98.66(8)$, $\gamma = 90.16(6)°$. $Z = 4$. 3527 reflections with $F > 3\sigma(F)$, 833 parameters, $R = 0.082$, $R_w = 0.077$. The crystals easily crack and have poor quality. The bond distances and angles are the average values of 16 chemically equivalent bond parameters. Estimated standard deviations; 0.02–0.04 Å and 1–2°, respectively [8].

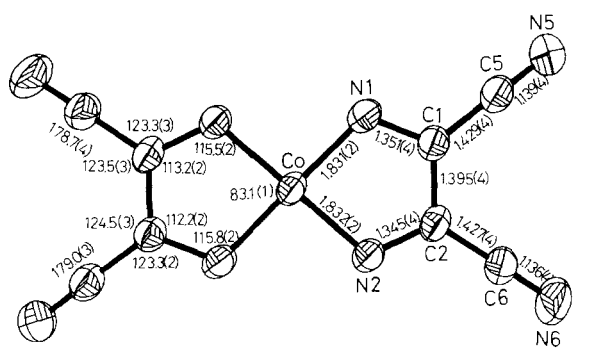

Fig. 2. ORTEP drawing of the anion **3** with 50 percent probability. C2/c, $a = 22.731(4)$, $b = 11.384(2)$, $c = 11.549(3)$ Å, $\beta = 93.23(2)°$. $Z = 4$. 3188 reflections with $I > 2\sigma(I)$, 193 parameters, $R = 0.039$, $R_w = 0.046$.

The reduction of **1** by hydrazine gives the monomeric complex anion $[Co^{I}(s\text{-}disn)_2]^{\ominus}$ **3**, which can be precipitated with the large cation $AsPh_4^{\oplus}$. Suitable single crystals can be grown from the salt **3**·$AsPh_4$. The structure of **3** is shown in Figure 2. The reduction of **1** results in a rupture of the Co–Co bond with formation of the square planar $[Co^{I}(s\text{-}disn)_2]^{\ominus}$ ion. The Co–N bond length, (1.831(2) Å) is short and comparable with that in $[Co^{I}(C_{10}H_{17}N_8)(CO)_6]$ (1.873 Å)[6] and with the M–N distances in complexes with delocalized ground states[1,4,7]. The C–C and C–N distances of the five-membered chelate rings in **3**, $[Co(CN)(s\text{-}disn)_2]$[1], $[Ni(s\text{-}disn)_2]$[4], and $[Pt(s\text{-}disn)_2]$[7] reveal the pronounced electron delocalization in the s-disn ligands of these complexes.

The anion **3** can be converted with CH_3I into the methylcobalt complex **4**, which can also be obtained directly from the dimer **1** by reaction with CH_3NHNH_2/O_2.

E→*Z*-Photoisomerization of a Diphosphene on Carbonylmetal Complexes (M = Cr, Mo, W)**

By *Masaaki Yoshifuji**, *Takashi Hashida*, *Naoki Inamoto*, *Ken Hirotsu**, *Teruhisa Horiuchi*, *Taiichi Higuchi*, *Keiji Ito*, and *Shigeru Nagase**

Recently, diphosphene-transition metal chemistry has developed very rapidly and extensively. We have been successful in the preparation and characterization of carbonylchromium(0), carbonylmolybdenum(0), and carbonyltungsten(0) complexes **2a**–**c** of *E*-mesityl-2,4,6-tri-*tert*-butylphenyldiphosphene **1** (THF = tetrahydrofuran). Transition-metal complexes involving formal P–P double bonds in the (*Z*)-configuration have been reported only very recently[1]. We now wish to report the first photoisomerization of (*E*)-diphosphenes on the pentacarbonylmetal complexes **2**.

In a typical experiment, **2a** (13.7 mg, 0.022 mmol) was dissolved in hexane (5.0 mL) and irradiated with a 100-W medium pressure Hg-lamp at 0°C for 15 min to give the (*Z*) isomer **3a** almost quantitatively. **3a** was purified by chromatography on silica gel at room temperature and recrystallization from pentane[2]. Similarly, upon irradiation, the molybdenum complex **2b** and the tungsten complex **2c** gave **3b** and **3c**, respectively. According to the ^{31}P-NMR spectra, the reaction rate decreases in the series Cr ≫ Mo > W. The FD-MS results were the same before and after irradiation[2].

Neither **2a** nor **1**, R = 2,4,6-tri-*tert*-butylphenyl[3] instead of mesityl, was isomerized on refluxing in $CDCl_3$ for several hours, whereas an *E*/*Z* equilibrium mixture has been formed upon laser irradiation of **1** at low temperature[4].

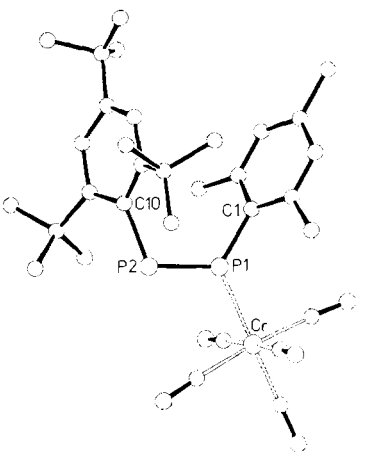

Fig. 1. Structure of **3a** in the crystal. $P2_1/c$, $a = 18.234(1)$, $b = 9.760(1)$, $c = 20.971(1)$ Å, $\beta = 114.72(1)°$, $Z = 4$. $Mo_{K\alpha}$-radiation, $\lambda = 0.7107$ Å, $R = 0.072$ for 2709 reflections with $I > 3\sigma(I)$. Important bond distances and bond angles, and the dihedral angle: P1–P2 2.039(3), P1–Cr 2.354(2) Å; Cr–P1–P2 116.3(1), Cr–P1–C1 124.9(3), P2–P1–C1 118.7(3), P1–P2–C10 109.6(3)°; *C1–P1–P2–C10 12.1(5)°. Further details of the crystal structure investigation* can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD 51177, the names of the authors, and the journal citation.

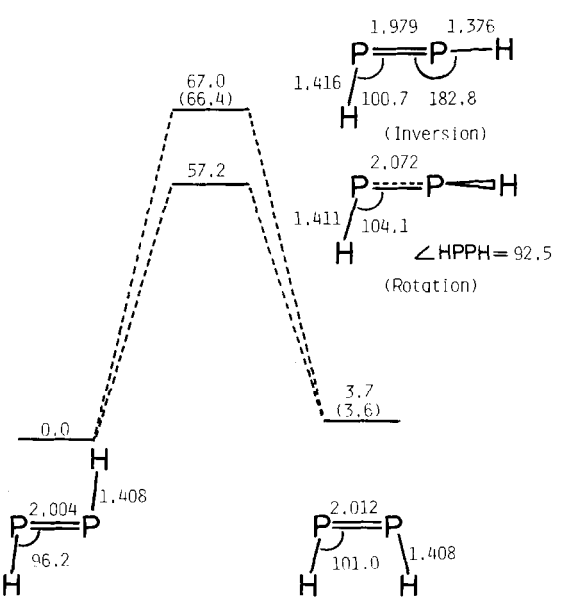

Fig. 2. Energies (kcal/mol) and geometries (Å, degrees) for the isomerization of HP=PH at the MP3/6-31G**//6-31G** level and the CI(S+D+Q)/6-31G**//6-31G** level (in parentheses). The rotational transition state is located by the use of complex molecular orbitals. See also the calculations of geometries optimized at the 3-21G level; T.-K. Ha, M. T. Nguyen, P. Ruelle, *Chem. Phys. 87* (1984) 23.

[**] This work was supported in part by the Ministry of Education, Science and Culture of Japan and the Kurata Foundation. We thank the crystallographic Research Center, Institute for Protein Research, Osaka University, for computer calculations. All ab initio calculations were carried out at the Computer Center of the Institute for Molecular Science, Japan, using IMSPAC (WF10-9) and Gaussian 80 (WF10-25) programs.

The structure of **3a** was determined by X-ray structure analysis (Fig. 1). **3a** is the first example of a (*Z*)-diphosphene as a ligand of a mononuclear carbonylmetal complex. It should be noted that P1, P2, Cr, and Cl are coplanar, whereas the dihedral angle C1–P1–P2–C10 is 12.1°. The bond distance P1–Cr (2.354 Å) is shorter than that for pentacarbonyl(triphenylphosphane)chromium (2.422 Å)[5].

In the absence of these transition metals, the energy barrier for the isomerization of diphosphene (HP=PH) is considerable, the rotational transition state being preferred to the inversion transition state (Fig. 2). On complexation, however, the rotational barrier could be lowered both sterically and electronically.

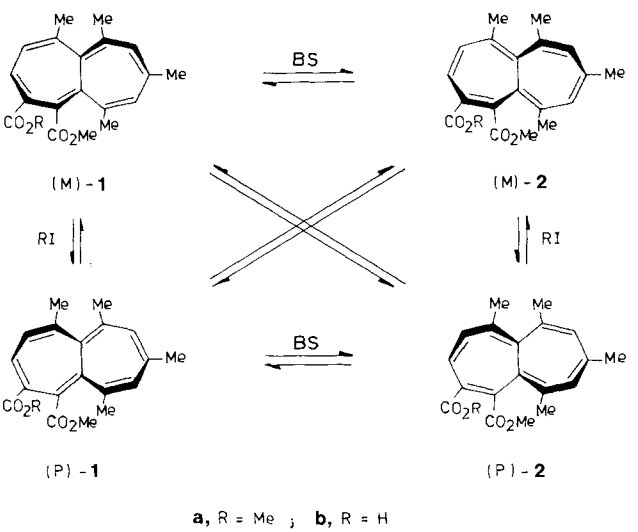
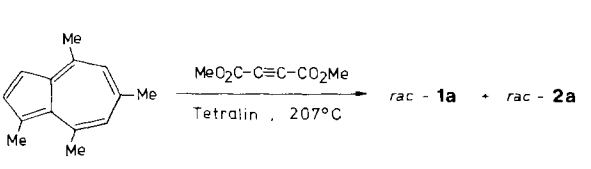
Synthesis and Dynamic Properties of Chiral Heptalenes**

By *Klaus Hafner**, *Günter L. Knaup*, *Hans Jörg Lindner*, and *Hans-Christian Flöter*



Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Mono- and bicyclic non-benzenoid systems with a 4n perimeter possess localized double bonds in the ground state. Their antiaromatic structures[1] with delocalized double bonds are transition states on the potential surfaces that connect the localized bond systens with one another. The results of experimental investigations on the 4nπ-electron systems tetra-*tert*-butylcyclobutadiene[2a], 1,3,5-tri-*tert*-butylpentalene[2b], cyclooctatetraene[2c], and heptalene[2d] are in agreement with this.



In contrast to cyclobutadiene and pentalene, their higher homologues cyclooctatetraene and heptalene are characterized by a nonplanar structure. X-ray structure analysis[3] of heptalene derivatives confirms a C_2 geometry for the bicyclic system with the two annelated seven-membered rings in boat conformations. For heptalenes, according to *Oth* et al.[4], four axially chiral isodynamic structures should be in equilibrium with one another via two dynamic processes [bond shift (BS) and ring inversion (RI)]. A study of both processes should provide information on their transition states and, therefore, also on the antiaromaticity of the delocalized heptalene system.

For the π-bond shift in heptalenes, *Vogel* et al.[2d, 5] determined an activation energy of 3.5 kcal·mol^{-1} by ^{13}C-NMR spectroscopy; for its 1,6-dialdehyde and dimethyl 1,6-dicarboxylate, a free energy of activation of 9.9 and 14 kcal·mol^{-1}, respectively. *Klärner*[6] found $\Delta G^{\ddagger}_{3°C} = 21.7$ and 21.0 kcal mol^{-1} for the isomerization of the bond-shift isomers of dimethyl 6,8,10-trimethyl-1,2-heptalenedicarboxylate[7], which can be separated by low-temperature chromatography. The kinetic parameters for the ring inversion of the heptalene system have not yet been determined.

We have succeeded for the first time in isolating in pure form all four possible isomers, (M)-**1**, (P)-**1**, (M)-**2**, and (P)-**2**, of a substituted heptalene, dimethyl 5,6,8,10-tetramethyl-1,2-heptalenedicarboxylate[8], and in investigating the kinetics of both dynamic processes for this heptalene derivative.

In analogy to the reaction[7] of azulene with dimethyl acetylenedicarboxylate, the reaction of 1,4,6,8-tetramethylazulene **3** with dimethyl acetylenedicarboxylate in boiling tetralin affords both isomers of *rac*-heptalene **1a** (yellow crystals, m.p. = 130°C) and **2a** (orange crystals, m.p. = 89–91°C) in 38 and 4% yield, respectively; the two compounds could be separated by chromatography on alumina at room temperature[9].

rac-**1a** and *rac*-**2a** differ characteristically in their electron and NMR spectra (Table 1). The position of the double bonds is determined from the ^{1}H-NMR spectra and the

Table 1. Spectroscopic data for racemic heptalenes **1** and **2**.

rac-**1a**: 300-MHz ^{1}H-NMR ($CDCl_3$): $\delta = 1.74$ (s, 3H, 6-Me), 1.96 (d, $J = 1.2$ Hz, 3H, 10-Me), 2.00 (dd, $J = 1.4$, 1.0 Hz, 3H, 5-Me), 2.04 (d, $J = 1.2$ Hz, 3H, 8-Me), 3.69, 3.70 (2s, each 3H, $2CO_2Me$), 6.01 (quint., $J = 1.1$ Hz, 1H, 9-H), 6.14 (s, 1H, 7-H), 6.27 (dq, $J = 6.9$, 1.4 Hz, 1H, 4-H), 7.53 (dq, $J = 6.9$, 1.0 Hz, 1H, 3-H); UV (*n*-hexane): $\lambda_{max}(\lg\varepsilon) = 211$ (4.38), 264 (4.21), 322 sh (3.46) nm.

rac-**1b**: 300-MHz ^{1}H-NMR ($CDCl_3$): $\delta = 1.73$ (s, 3H, 6-Me), 1.95 (d, $J = 1.1$ Hz, 3H, 10-Me), 2.00 (br. s, 3H, 5-Me), 2.03 (d, $J = 1.2$ Hz, 3H, 8-Me), 3.67 (s, 3H, 1-CO_2Me), 6.01 (s, 1H, 9-H), 6.14 (s, 1H, 7-H), 6.28 (dq, $J = 5.9$, 1.4 Hz, 1H, 4-H), 7.61 (dq, $J = 5.9$, 1.1 Hz, 1H, 3-H), 11.10 (s, 1H, 2-CO_2H); UV (dioxane): $\lambda_{max}(\lg\varepsilon) = 265$ (4.20), 318 sh (3.50), 369 sh (2.92) nm.

rac-**2a**: 300-MHz ^{1}H-NMR ($CDCl_3$): $\delta = 1.68$ (s, 3H, 10-Me), 1.77 (s, 3H, 5-Me), 1.99 (d, $J = 1.2$ Hz, 3H, 8-Me), 2.02 (d, $J = 1.3$ Hz, 3H, 6-Me), 3.71, 3.82 (2s, 3H each, $2CO_2$ Me), 6.01 (s, 1H, 9-H), 6.10 (s, 1H, 7-H), 6.55 (d, $J = 11.8$ Hz, 1H, 3-H), 6.59 (d, $J = 11.8$ Hz, 1H, 4-H); UV (*n*-hexane): $\lambda_{max}(\lg\varepsilon) = 210$ (4.34), 230 sh (4.21), 270 (4.31), 308 sh (3.54), 378 (2.74) nm.

rac-**2b**: 300-MHz ^{1}H-NMR ($CDCl_3$): $\delta = 1.72$ (s, 3H, 10-Me), 1.77 (s, 3H, 5-Me), 1.99 (d, $J = 1.0$ Hz, 3H, 8-Me), 2.03 (d, $J = 1.2$ Hz, 3H, 6-Me), 3.73 (s, 3H, 1-CO_2Me), 6.01 (s, 1H, 9-H), 6.10 (s, 1H, 7-H), 6.57 (d, $J = 11.8$ Hz, 1H, 3-H), 6.70 (d, $J = 11.8$ Hz, 1H, 4-H), 11.00 (s, 1H, 2-CO_2H). UV (dioxane): $\lambda_{max}(\lg\varepsilon) = 231$ sh (4.21), 271 (4.30), 309 sh (3.56), 381 (2.75) nm.

The saponification of *rac*-**1a** and *rac*-**2a** with CH_3OH/KOH affords the *rac*-acids **1b** (yellow crystals, m.p. = 150–155 °C (decomp.)) and **2b** (yellow crystals, m.p. 156–157 °C (decomp.)), respectively, which could be reconverted quantitatively into *rac*-diester **1a** and **2a**, respectively, with diazomethane. The resolution of **1b** is achieved by fractional crystallization of the cinchonine and (+)-α-phenylethylamine salts followed by liberation of the acids with 2 N sulfuric acid; that of **2b** in a corresponding way with (+)- and (−)-ephedrine[11].

The enantiomeric purity of the heptalenes so obtained, (+)- and (−)-**1b**, and (+)- and (−)-**2b**, is greater than 98%, as shown on the basis of the signals of the methoxy group in the ^{1}H-NMR spectra of the ephedrine salts. The enantiomerically pure acids, (+)- and (−)-**1b**, and (+)- and (−)-**2b**, and the enantiomerically pure esters obtained from these with diazomethane, (+)- and (−)-**1a** and (+)- and (−)-**2a**, have the high specific optical rotations typical for molecules with chiral chromophores (Table 2).

Table 2. Specific optical rotations of the heptalenes (+)-**1** and (+)-**2** (in $CHCl_3$) [12].

	$[\alpha]_{546}^{20}$	$[\alpha]_{578}^{20}$
(+)-**1a**	+1930 ($c = 1.028$)	+1460 ($c = 1.028$)
(+)-**1b**	+2550 ($c = 1.004$)	+1910 ($c = 1.004$)
(+)-**2a**	+1860 ($c = 0.921$)	+1310 ($c = 0.921$)
(+)-**2b**	+2140 ($c = 0.514$)	+1430 ($c = 1.029$)

The kinetic parameters for the bond shift, starting from *rac*-**2a**, were determined by ^{1}H-NMR spectroscopy in [D_{14}]-diglyme at temperatures between 50 and 80 °C. The rate constants for the reverse reactions were calculated from the equilibrium constants, which were determined in the temperature range of 50 to 170 °C, since the equilibrium ratio *rac*-**1a** : *rac*-**2a** is about 10 : 1 and therefore the measurements starting from *rac*-**1a** afford only very inaccurate data (Table 3).

Table 3. Kinetic parameters for the bond shift (BS) and ring inversion (RI) of the heptalenes **1a** and **2a** [13].

	$\Delta H^{\neq}_{25\,^\circ C}$ [kcal·mol^{-1}]	$\Delta S^{\neq}_{25\,^\circ C}$ [cal·mol^{-1}·K^{-1}]
BS **2a** → **1a**	22.8 ± 0.6	−11.1 ± 2.0
BS **1a** → **2a**	25.7 ± 0.6	− 7.8 ± 1.7
RI (−)-[**1a** ⇌ **2a**] → *rac*-[**1a** ⇌ **2a**]	28.3 ± 0.4	−11.6 ± 0.9

The rates of racemization were determined on the basis of the decrease in optical rotation of solutions of optically active heptalenes **1a** and **2a** in diglyme at 130 to 150 °C. Since the same rate constants are obtained starting from **1a** and **2a**, the bond shift may occur in a preceding equilibrium.

The kinetic data for the dynamic processes of the heptalenes **1a** and **2a** are not in accord with a planar transition state for the bond shift. For the bond shift, which proceeds with retention of configuration, a helical chiral transition state with a delocalized π-electron system must be assumed. In the case of planar transition states, like those assumed by *Paquette*[14] for the analogous processes of substituted cyclooctatetraenes, the energy barrier for the bond shift should be higher than that for ring inversion by the amount of energy required for the delocalization of the anti-aromatic π-electron system.

According to π-SCF force-field calculations[15] for the dynamics of both processes of 1,5,6,10-tetramethylheptalene, which are in agreement with experimental results, the bond shift should proceed via a helical, delocalized transition state ($\Delta H^{\neq}$: 30 kcal·mol^{-1}); the ring inversion, on the other hand, should occur via an only partly planar and localized transition state ($\Delta H^{\neq}$: ca. 31 kcal·mol^{-1}). In contrast to this, the corresponding processes with planar transition states require activation enthalpies of more than 50 kcal·mol^{-1}.

The Homothiopyrylium Ion; Generation and Characterization

By *Kagetoshi Yamamoto, Shoko Yamazaki,* and *Ichiro Murata**

Recently we succeeded in identifying several homothiopyrylium ions generated by protonation of 2,7-di-*tert*-butylthiepines[1] and 1-benzothiepine[2]. We describe now the parent homothiopyrylium ion **7**. Since the use of the protonation sequence to generate **7** requires the hitherto unknown unsubstituted thiepine, which is expected to be an extremely unstable compound[3], we have considered the ionization route for the preparation of **7** and synthesized the precursor 4,5-dihydrothiepin-4-ol **6** using a double Pummerer reaction.

1, X = S
2, X = SO
3, X = S
4, X = SO
5, R = Pnb
6, R = H

Pnb = O_2N–C$_6$H$_4$–CO–

Oxidation of *p*-nitrobenzoyl-protected hexahydro-4-thiepinol **1** (prepared from hexahydro-4-thiepinol[5]) with sodium periodate in aqueous methanol afforded the sulfoxide **2**[4] quantitatively. Interestingly, **2**, on treatment with acetic anhydride, afforded the protected tetrahydro-4-thiepinol **3** as the sole isolable product[4]. The structure of **3** was determined by ^{1}H-NMR (Table 1). After oxidation of **3** with sodium periodate in aqueous methanol or *m*-chloroperbenzoic acid in dichloromethane to the sulfoxide **4**[4], the second double bond was introduced by a modified Pummerer reaction[6]. When **4** was treated with diisopropylethylamine in dichloromethane followed by addition of freshly distilled trimethylsilyl iodide under nitrogen, protected 4,5-dihydro-4-thiepinol **5** was obtained. Finally, the alcohol **6** was smoothly liberated from **5** by hydrolysis with KOH in aqueous *tert*-butyl alcohol.

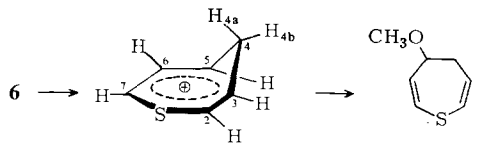
Table 1. Some physical data for the new compounds. In order to facilitate comparison, the atoms in **3** and **6** are numbered as in **7**.

1, colorless crystals, m.p. = 85.0–85.5°C

3, m.p. = 79.5–80.5°C, 37% yield based on **1**. ^{1}H-NMR (100 MHz, $CDCl_3$): $\delta = 5.36$ (dddd, $J = 9.0$, 7.5, 4.5, 3.0 Hz, H-5); 6.05 (ddd, $J = 9.5$, 7.5, 6.0 Hz, H-3); 6.42 (d, $J = 9.5$ Hz, H-2); 8.26 (AA′BB′, 4 Aryl-H); 2.14–2.56 (m, 2H-6); 2.60–3.14 (m, 2H-4, 2H-7)

5, yellow crystals, m.p. = 107–108°C, 56% yield based on **3**.

6, colorless crystals, m.p. = 42–43°C (hexane/ether). ^{1}H-NMR (360 MHz, $CDCl_3$): $\delta = 2.20$ (bs, OH); 2.66 (dddd, $J(4a,4b) = 13.6$, $J(4a,5) = 8.7$, $J(4a,3) = 6.2$, $J(4a,6) = 1.3$ Hz, H-4a); 2.73 (dddd, $J(4a,4b) = 13.6$, $J(4b,3) = 7.8$, $J(4b,5) = 3.0$, $J(4b,2) = 1.4$ Hz, H-4b); 4.43 (dddd, $J(5,4a) = 8.7$, $J(5,6) = 3.2$, $J(5,4b) = 3.0$, $J(5,7) = 1.5$ Hz, H-5); 5.98 (ddd, $J(7,6) = 11.2$, $J(7,2) = 1.6$, $J(7,5) = 1.5$ Hz, H-7); 6.01 (ddd, $J(3,2) = 9.6$, $J(3,4b) = 7.8$, $J(3,4a) = 6.2$ Hz, H-3); 6.05 (ddd, $J(6,7) = 11.2$, $J(6,5) = 3.2$, $J(6,4a) = 1.3$ Hz, H-6); 6.24 (ddd, $J(2,3) = 9.6$, $J(2,7) = 1.6$, $J(2,4b) = 1.4$ Hz, H-2). IR (KBr): ν(OH) = 3175 cm^{-1}. MS (70 eV): M^+, m/z 128 (100%)



7, ^{1}H-NMR (100 MHz, $CD_2Cl_2 + SO_2 + HFSO_3$, −80°C, standard Me_4Si with $\delta_{CHDCl_2}(Me_4Si) = 5.30$): $\delta = 7.99$ (d, $J(2,3) = 7.5$ Hz, H-2); 6.32 (dt, $J(2,3) = J(3,4a) = J(3,4b) = 7.5$ Hz, H-3); 1.16 (m, H-4a); 4.44 (m, H-4b); 7.15 (dt, $J(5,6) = J(5,4a) = J(5,4b) = 7.9$ Hz, H-5); 7.99 (m, H-6); 10.04 (d, $J(7,6) = 6.1$ Hz, H-7). ^{13}C-NMR (22.5 MHz, $CD_2Cl_2 + SO_2 + HFSO_3$, −70°C, standard Me_4Si with $\delta_{CH_2Cl_2}(Me_4Si) = 53.8$): $\delta = 131.2$ (C-2 or C-6); 133.4 (C-2 or C-6); 129.7 (C-3); 33.76 (C-4); 150.5 (C-5); 178.9 (C-7)

The hydroxy group of **6** can be cleaved off as follows: 10 mg **6** in 0.2 mL CD_2Cl_2 was mixed with 0.2 mL SO_2, containing three drops of fluorosulfuric acid, in an NMR

Department of Chemistry, Faculty of Science
Osaka University, Toyonaka, Osaka 560 (Japan)

tube under nitrogen at −78 °C. This afforded a yellow solution containing a single cationic species, which, as shown by the ^{1}H-NMR spectrum (−80 °C), is the homothiopyrylium ion **7** (Table 1).

The ^{1}H-NMR spectrum of **6** contains two signals assigned to methylene protons at $\delta = 2.66$ and 2.73. In going from **6** to **7**, one signal shifts upfield ($\delta = 1.16$) and the

7 **8**

other downfield ($\delta = 4.44$); the chemical shift difference of these signals in **7** ($\Delta\delta = 3.28$ ppm) is even greater than that observed in the 2,7-di-*tert*-butylthiopyrylium ion[1]. This large value of $\Delta\delta$ is mainly caused by the homoaromatic ring current (H-4a lies above this ring whereas H-4b is situated in the deshielding zone)[7].

Delocalization of positive charge is indicated by the proton chemical shifts in **7**. The average chemical shift of the protons (except for H-4a,b) is $\delta = 7.9$ whereas that of the olefinic protons in **6** is $\delta = 6.07$. Although no valence bond structures of **7** can be written in which the positive charge is localized on either C_6 or C_2, the signals (coincidentally equivalent) of the protons attached to these carbons appear considerably downfield at $\delta = 7.99$. This demonstrates that C_2 and C_3, as well as C_5 and C_7, comprise part of a delocalized six-membered ring cation. The vicinal coupling constants are also informative. Thus, $J_{2,3}$, $J_{5,6}$, and $J_{6,7}$ in **7** are in the range of 6.1—7.9 Hz. In **6**, these are $J_{2,3} = 9.6$ and $J_{6,7} = 11.2$ Hz. This indicates again that the C-atoms at 2, 3, 5, 6, and 7 are part of a six-membered ring.

Retention of the seven-membered ring skeleton during the formation of **7** is confirmed by the fact that quenching of the solution of **7** with a mixture of methanol and $NaHCO_3$ at −78 °C gives 4-methoxy-4,5-dihydrothiepine **8** (colorless oil)[4].

Pentamethyldiethylenetriamine(phenyl)lithium, a Monomeric Organolithium Compound**

By *Uwe Schümann, Jürgen Kopf*, and *Erwin Weiss**

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Organolithium compounds normally occur as oligomers, with a preferred degree of association of 2, 4 or 6[1]. They rarely exist in a monomeric form, as, e.g., in the compounds **1**[2] or **2**[3] in which association is hindered by sterically bulky organic moieties. However, donor ligands can also decisively influence the structure, as is strikingly demonstrated, for example, by phenylethynyllithium. In this instance the species **3**[4] and **4**[5] have been characterized, where the complexing diamine molecules differ only in their chain length.

$[Ph_3CLi(tmeda)]$ — $[(Fluorenyl)Li\{N(C_2H_4)_3CH\}_2]$

1, tmeda = $Me_2N(CH_2)_2NMe_2$ — 2

$[PhC{\equiv}CLi(tmpda)]_2$ — $[(PhC{\equiv}CLi)_4(tmhda)_2]$

3 — 4

$Me_2N(CH_2)_nNMe_2$: tmpda: n = 3, tmhda: n = 6

Also remarkable in this respect is phenyllithium. In the crystalline state it exists in the dimeric form **5**[6]; when dissolved in ether it is dimeric[7] or tetrameric[8], and in the crystalline state with ether of crystallization it is present as the tetramer **6**[9]. A common feature of many structures of this kind is the fourfold coordination of lithium. On using the tridentate ligand pentamethyldiethylenetriamine (PMDTA) only one coordination site remains free for the binding of the organic moiety. Consequently, oligomerization is suppressed. A number of examples of this type have already been reported in the literature, e.g. **7**[10].

$[PhLi(tmeda)]_2$ — $[PhLi(OEt_2)]_4$

5 — 6

$[Li\{CH(SiMe_3)_2\}(pmdta)]$ — [PhLi(pmdta)]

7, pmdta = $[(CH_3)_2NCH_2CH_2]_2NCH_3$ — 8

An attempt to prepare a monomeric phenyllithium in an analogous way met with success. Addition of PMDTA to a suspension of phenyllithium in hexane/pentane mixtures led to formation of [PhLi(pmdta)] **8** (Fig. 1).

The Li atom is located only 2 pm above the plane of the benzene ring with the Li−C(1)−C(2) and Li−C(1)−C(6) angles being almost identical. It is thus strongly monohapto-bonded to an sp^2-hybridized C atom (bond length 213.5 pm). The Li−C distances in **5** and **6** of ca. 221 and 230 pm, respectively, are noticeably longer. This elongation is characteristic for bridge ligands.

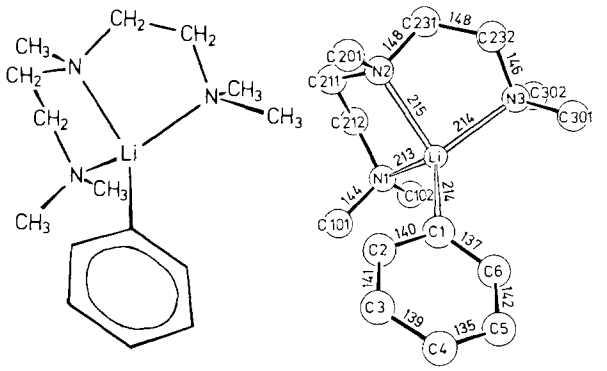

Fig. 1. Structure of **8** in the crystal. Left: line drawing; right: ORTEP diagram with bond lengths [pm]; $P2_1/n$, $a = 859.6(4)$, $b = 1583.2(10)$, $c = 1322.4(9)$ pm, $\beta = 92.72(5)°$, $\rho_{calc} = 0.9509$ g cm^{-3}, $Z = 4$; $Mo_{K\alpha}$ radiation, solution of structure by direct methods (SHELX), refinement to $R = 0.072$ (unweighted) with 746 reflections [$|F| > 4\sigma(F)$], measured to $\theta = 20°$, anisotropic temperature factors, H not determined, refined isotropically with calculated H positions. Important bond lengths ([pm], mean values): Li–C 213.5(16), C–C(phenyl) 138.9, Li–N 214.0(15); angles [°]: N1–Li–N2 87.1(6), N2–Li–N3 87.2(6), N1–Li–N3 115.4(7). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51118, the names of the authors, and the full citation of the journal.

The benzene ring is approximately planar; but the hexagon is distinctly distorted (angle at C1 113.1 instead of 120°, while those at C2 and C6 on the other hand, with values of 123.9 and 125.1°, are significantly enlarged). These deformations are likewise characteristic for metal-bound phenyl groups, e.g. in **5**, **6**, or $[Ph_2Mg(tmeda)]$[11].

Phenyllithium is so far the only organolithium system in which three different structures are formed, depending upon the nature of the ligands.

Experimental:

All operations were carried out under an inert gas using dry solvents. Freshly distilled PMDTA (0.83 g, 1 mL, 4.79 mmol), previously dried over potassium, was added dropwise with stirring to a suspension of PhLi (0.5 g, 5.95 mmol), prepared from *n*BuLi and iodobenzene, in 25 mL of a hexane/pentane mixture (1:1). The suspension first became clear then very cloudy again. The mixture was allowed to stand for a while. The supernate was then filtered off, and, after cooling to −30°C, furnished 0.25 g (20%) of **8**. An elemental analysis of the product was fully consistent with that expected for **8**. Crystals suitable for an X-ray structure analysis were obtained on slowly cooling a saturated solution of the product to 8°C followed by drying at 20°C in a stream of argon. The crystals are extremely sensitive and tend to deliquesce after their isolation if excess PMDTA is present.

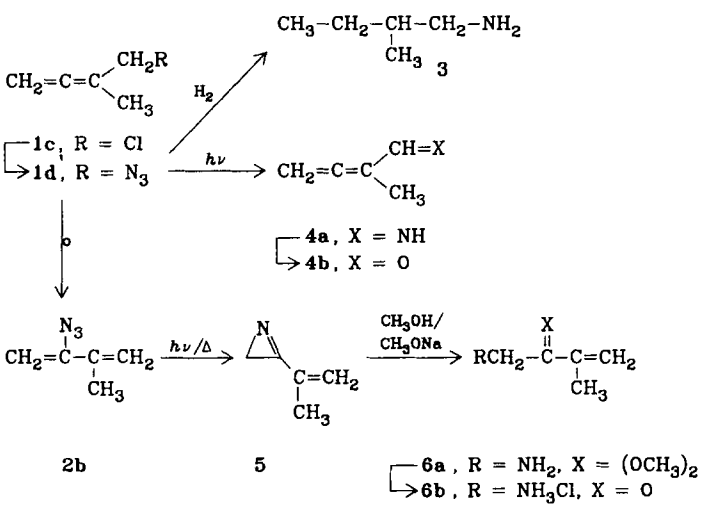
Synthesis and Reactions of 4-Azido-3-methyl-1,2-butadiene**



By *Klaus Banert**

Vinyl azides have recently attracted renewed interest, largely because of their manifold reactions[1]. The most common method of synthesis[2]—addition of haloazide to an alkene with subsequent elimination of hydrogen halide—gives only partially satisfactory results in the case of 1,3-butadienes[3,4]. Recently, a synthesis of 2-azido-1,3-butadiene **2a** from 4-bromo-1,2-butadiene **1a** involving an allyl rearrangement has been reported[5]. The postulated intermediate **1b** could not be isolated.

1a, R = Br **2a**

Independently thereof, our own investigations have shown that 4-chloro-3-methyl-1,2-butadiene **1c**[6] reacts with sodium azide in aqueous ethanolic solution quantitatively to give 2-azido-3-methyl-1,3-butadiene **2b** (Table 1)[7]. If, however, the reaction is prematurely terminated and work-up carried out rapidly and carefully, not only **2b** and unreacted **1c** but also the intermediate 4-azido-3-methyl-1,2-butadiene **1d** can be isolated (Table 1). Considerably more efficient is the preparation of **1d**[8] from tributylhexadecylphosphonium azide[9] and **1c**. Apparently the halides **1a** and **1c** do not react in an S_N2'-like fashion, but with direct substitution and subsequent rapid allyl rearrangement. The quantitative rearrangement **1d** → **2b** was monitored by ^{1}H-NMR analysis in chloroform between 20 and 60°C. The activation parameters of the 1st order reaction are: $\lg A = 10.54$, $E_a = 85.9$ kJ/mol, $\Delta H^{\neq}_{298} = 83.5$ kJ/mol, $\Delta S^{\neq}_{298} = -51.5$ J mol^{-1} K^{-1}. The reaction rate increases only slightly with increasing solvent polarity; relative reactivities at 41°C: [D$_{12}$]cyclohexane 1.00, $CDCl_3$ 2.73, 70 wt-% [D$_6$]acetone/D_2O 4.59. Similarly as in the rearrangement of simple allyl azides[10], the large negative

[**] Reactions of Unsaturated Alkyl Azides, Part 1.

activation entropy and the minimal influence of solvent rule out an ionic mechanism. The reaction **1d** → **2b** could proceed via bicyclic triazolines[10] or be interpreted as a hetero-Cope rearrangement[11].

Table 1. Some physical data of the new compounds **1d**, **2b**, **4a**, **5**, **6a**, and **6b**.

1d: IR (CCl_4): ν = 2990, 2930, 2860, 2100, 1955, 1580, 1430, 1370, 1330, 1300, 1265, 1230, 985, 955, 910, 880, 855 cm^{-1}; ^{1}H-NMR (C_6D_6): δ = 1.43 (t, J = 3.2 Hz, 3H), 3.17 (t, br, 2H), 4.51 (tq, J = 2.3, 3.2 Hz, 2H); ^{13}C-NMR (C_6D_6): δ = 16.1 (q), 54.3 (t), 75.7 (t), 94.7 (s), 207.3 (s); GC-MS (70 eV): m/z 109 ($M^{\oplus}$, 0.4%), 81 ($M^{\oplus} - N_2$, 69), 66 ($M^{\oplus} - HN_3$, 6), 54 (6), 53 (13), 51 (6), 42 (12), 41 (100), 40 (13), 39 (42)

2b: IR (CCl_4): ν = 2990, 2960, 2940, 2180, 2120, 2080, 1580, 1460, 1440, 1390, 1330, 1300, 1265, 1140, 915, 845 cm^{-1}; ^{1}H-NMR (80 MHz, C_6D_6): δ = 1.59 (ddd, J = 1.45, 0.75, 0.25 Hz, 3H), 4.53 (dddq, J = 2.33, 1.69, 0.68, 0.25 Hz, *Z*-1-H), 4.71 (ddd, J = 2.33, 0.73, 0.71 Hz, *E*-1-H), 4.84 (dddq, J = 1.70, 1.69, 0.73, 1.45 Hz, *E*-4-H), 5.49 (dddq, J = 1.70, 0.71, 0.68, 0.75 Hz, *Z*-4-H); ^{13}C-NMR (100 MHz, C_6D_6): δ = 19.7 (q), 98.3 (t), 115.2 (t), 137.2 (s), 146.0 (s); GC-MS (70 eV): m/z 81 ($M^{\oplus} - N_2$, 73%), 66 ($M^{\oplus} - HN_3$, 7), 54 (7), 53 (16), 51 (7), 42 (12), 41 (100), 40 (20), 39 (53), 38 (7)

4a: ^{1}H-NMR ($CDCl_3$): δ = 1.92 (t, J = 2.9 Hz, ca. 3H), 5.03 (m, 2H), 8.02 (s, br, 1H)

5: IR (CCl_4): ν = 3100, 3050, 2980, 2960, 2920, 2900, 1730 (C=N), 1620, 1460, 1440, 1380, 1340, 1195, 990, 930, 630 cm^{-1}; ^{1}H-NMR (C_6D_6): δ = 1.43 (s, 2H), 1.81 (dd, J = 1.0 + 1.6 Hz, 3H), 5.36 (m, 2H); ^{13}C-NMR ($CDCl_3$): δ = 16.9 (q, J = 126 Hz), 20.6 (t, 180 Hz), 128.6 (t, 160 Hz), 132.2 (s), 166.9 (s); GC-MS (70 eV): m/z 81 ($M^{\oplus}$, 100%), 55 (17), 41 (95)

6a: IR (CCl_4): ν = 3400 br, 3100, 2960, 2840, 1450, 1185, 1135, 1090, 1055, 970, 920 cm^{-1}; ^{1}H-NMR ($CDCl_3$): δ = 1.20 (br, position concentration-dependent, ca. 2H, 1.70 (m, 3H), 2.75 (s, 2H), 3.17 (s, 6H), 5.19 (m, 1H), 5.30 (m, 1H); ^{13}C-NMR ($CDCl_3$): δ = 18.7 (q), 42.3 (t), 48.6 (q), 103.7 (s), 117.3 (t), 141.3 (s)

6b: White crystals, Fp = 142 °C (methanol/ethyl acetate); IR (KBr): ν = 3420 br, 2980 br, 1670, 1465, 1385, 1365, 1300, 1120, 1090, 1015, 985, 975, 920, 895 cm^{-1}; ^{1}H-NMR (D_2O): δ = 1.84 (dd, J = 1.5 + 0.9 Hz, 3H), 4.35 (s, 2H), 6.08 (m, 2H); ^{13}C-NMR (dioxane/D_2O 1:9): δ = 17.0, 45.2, 130.0, 142.0, 196.0

1d represents the first example of a compound in which an allene system and an azide group are connected via one carbon atom. The structure is confirmed, not only by the spectroscopic data (Table 1), but also by the hydrogenation to **3**. Photolysis of **1d** affords the imine **4a**, hydrolysis of which leads to the aldehyde **4b**[12, 13].

Thermolysis or photolysis of **2b** yields the azirine **5**[14]. This can be cleaved to give the amino acetal **6a** which makes the oxoammonium salt **6b** accessible[15]. The hydrogenation of the CC double bond to give 3-methyl-2-oxobutylammonium chloride[16] supports the constitution of **6b**. If the isolation of intermediates during the reaction sequence **1c** → **1d** → **2b** → **5** → **6a** → **6b** is dispensed with, the yields increase considerably[17].

The reactions **1d** → **4a** and **1d** → **2b** show that **1d** is a typical azide with allyl structure. In contrast, the useful azirine precursor **2b** can be regarded as an "internal"[1] vinyl azide.

[7] **2b**: A solution of **1c** (3.9 g, 38 mmol) and sodium azide (5.0 g, 77 mmol) in ethanol (10 mL) and water (15 mL) was vigorously stirred at room temperature for 6 d in the absence of light. It was then poured into ice-water and extracted with ether (3×); the ethereal solution was then washed with water (3×), dried over $MgSO_4$, and the ether removed by distillation, leaving **2b** (4.1 g, 99%). Subsequent gas-chromatographic separation (PGC) furnished **2b** as a colorless light-sensitive liquid.
[8] **1d**: 0.22 g (2.1 mmol) **1c** was added dropwise at ca. 30 °C to a supercooled melt of tributylhexadecylphosphonium azide. After 25 min stirring at room temperature the mixture was cooled to −196 °C and recondensed. A mixture of **1d** + **2b** (82:18, 215 mg, 92%) was obtained as a colorless liquid; after PGC, the purity of **1d** was 97%.

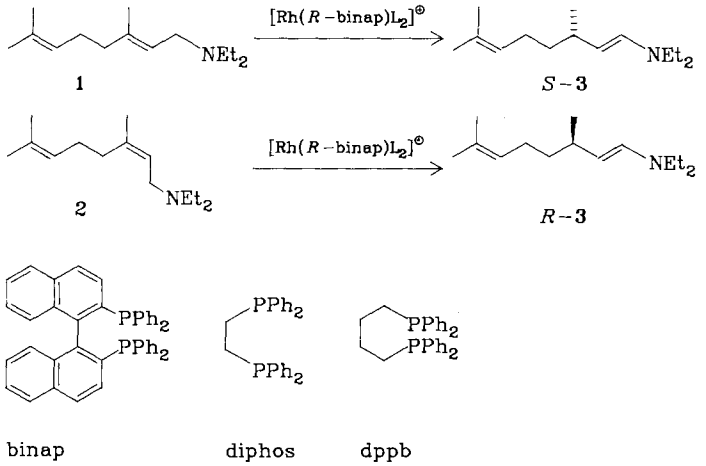
[17] When concentrated etheral solutions of **2b** (from **1c** → **2b**) are diluted with chloroform and photolyzed, **5** can be obtained in 83% yield (referred to **1c**). The direct photolysis of **2b** (16 h) in CH_3OH/CH_3ONa (ca. 2%) affords, after aqueous work-up, **6a** (96% yield) and, on treatment with dilute hydrochloric acid, **6b** (73% yield).

Bis[(*R*)-(+)-binap]rhodium(I) Perchlorate, a Highly Efficient Catalyst for the Asymmetric Isomerization of Allylamines



By *Kazuhide Tani**, *Tsuneaki Yamagata*, *Yoshitaka Tatsuno*, *Yuriko Yamagata*, *Ken-ichi Tomita*, *Susumu Akutagawa*, *Hidenori Kumobayashi*, and *Sei Otsuka**

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Cationic Rh(I) complexes [Rh(bisphosphane)L_2]$^{\oplus}$ (L_2 = diene or two solvent molecules) catalyze the isomerization of allylamines to the corresponding (*E*)-enamines[1]. With optically pure (*R*)-binap as the bisphosphane ligand, we obtained extremely high optical yields (>99% *ee*) of the enamines *S*-**3** and *R*-**3**, derived from citronellal. Serendipitously we found that the bis(binap) complex **4** also proved to be an excellent catalyst for the asymmetric isomerization.

Consistent with the lack of catalytic activity of the bis(bisphosphane) complex **5**[1c], an addition in situ of an equimolar amount of binap to the catalyst [Rh(binap)(diene)]$^{\oplus}$ caused strong retardation of the reaction below 40 °C. Unexpectedly, however, the catalytic reaction

proceeded above 80°C at a reasonable rate. We were able to confirm this catalytic activity with the isolated complex *R*-**4**.

$[Rh(binap)_2]ClO_4$ **4** $[Rh(diphos)_2]ClO_4$ **5**

$[Rh(cppb)_2]X$

6a, $X = ClO_4$; **6b**, $X = BF_4$

[Rh(*R*-binap)(norbornadiene)]ClO_4 **7**

The bis(binap) complex *R*-**4** is easily prepared in ca. 70% yield from [Rh(*R*-binap)(cod)]ClO_4 (cod = 1,5-cyclooctadiene) and an equimolar amount of *R*-binap in acetone at room temperature; *R*-**4** forms fairly air-stable, deep red crystals (m.p. = 206°C, decomp.)[2]. Table 1 shows examples for the catalytic activity of *R*-**4** and *S*-**4**. Surprisingly, the same stereoisomer **3** was obtained with mono- and bis(binap) complexes having the same chirality. Furthermore, the stereochemical correlation[1c] between the substrate geometry (*E* or *Z*), the ligand chirality (*R* or *S*), and the product configuration (*R* or *S*) was also the same. Since, in addition, the bis(binap) complex **4** can be used repeatedly without significant loss of catalytic activity, it can be regarded as a better catalyst than the mono(binap) complexes.

Table 1. Representative examples for the isomerization of **1** and **2** [a] to **3** with *R*-**4** and *S*-**4** as catalyst in THF. The selectivity for **3** was higher than 98%.

Substrate	Cat.	*T* [°C]	*t* [h]	[Substrate]/[Rh]	Yield [%]	**3** Conf.	*ee* [%] [b]
2	*R*-**4**	40	23	176	13	*R*	96
1	*S*-**4**	60	2	800	55	*R*	99
1	*S*-**4**	100	15	8000	≈100	*R*	98

[a] Purity of **1**: 99.7%; of **2**: 97.5%. [b] Determined on the basis of the maximum optical rotation of *R*-**3**: $[\alpha]_D^{21} = -77.6$ (*n*-hexane) [1c].

The catalytic activity of several cationic mono- and bis(bisphosphane)rhodium(I) complexes for the isomerization of **2** is compared in Table 2. The bis(diphos) complex **5** is totally inactive (up to 120°C). The bis(dppb) complex **6a** is catalytically active at temperatures as high as 120°C.

The high catalytic activity of **4** may be ascribed to the dissociation of one of the binap ligands, yielding the mono(binap) complex. This inference is supported by the strong compression of the phenyl substituents as revealed by the X-ray structure analysis (Fig. 1)[3]. In the unit cell two crystallographically different types of cation exist; one possesses C_2 symmetry and the other a very similar D_2 symmetry. In the C_2 cation, the Rh is almost rectangular planar coordinated. The angle between planes P1–Rh1–P2 and P1′–Rh1–P2′ is 6.2(2)°. The bis(dppb) complex **6a** has a tetragonal coordination geometry, which is distorted toward tetrahedral, and also possesses two seven-membered chelate rings[4]; the significant tetrahedral distortion was ascribed to the steric crowding. In the bis(binap) complex *R*-**4**, the steric crowding appears to be relieved mainly by elongation of the Rh–P distances (2.368(6)–2.388(6) Å), which are the longest in the known bisphosphane Rh(I) complexes (examples: 2.305(1)–2.321(1) Å in **7**[5]; 2.289(6)–2.313(6) Å in **5**[6]; 2.304(2)–2.361(2) Å in **6b**[4]). The acuter bite angles in the cation of C_2 symmetry (86.3(2)°) and in the cation of D_2 symmetry (86.9(2)°) compared to that in **7** (91.82(5)°) reflect the longer Rh–P distances.

Table 2. Isomerization of **2** with mono- and bis(bisphosphane)rhodium(I)-complex catalysts. A [D_8]tetrahydrofuran solution containing 1.0 mol/L **2** and 0.005 mol/L catalyst was heated in an NMR tube. Yield and selectivity for **3** (>96%) were determined by ^{1}H-NMR spectroscopy at 27°C.

Catalyst	*T* [°C]	*t* [h]	Yield [%]
[Rh(diphos)(cod)]ClO_4	40	23	17
[Rh(dppb)(cod)]ClO_4	90	4	78
[Rh(*R*-binap)(cod)]ClO_4	90	4	~100
$[Rh(diphos)_2]ClO_4$ **5**	90	4	0
	120	18	0
$[Rh(dppb)_2]ClO_4$ **6a**	90	4	0
	120	18	72
$[Rh(R\text{-binap})_2]ClO_4$ *R*-**4**	90	4	95
	120	18	~100

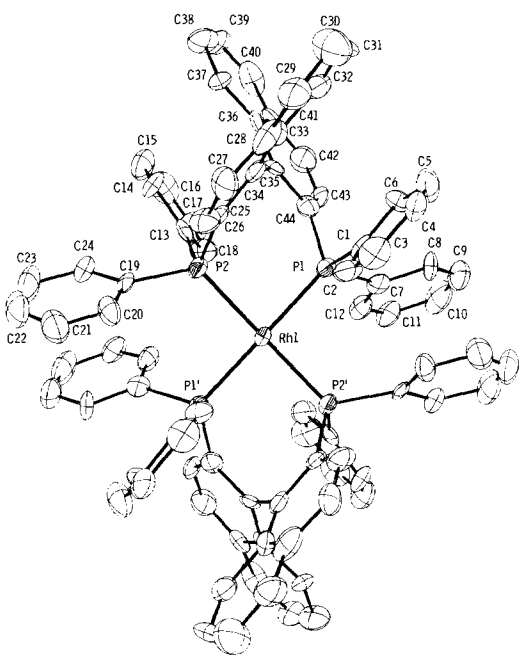

Fig. 1. ORTEP drawing of a cation (C_2 symmetry) of the complex *R*-**4** in the crystal (from CH_2Cl_2–Et_2O). Most important distances [Å] and angles [°]: Rh1–P1 = 2.368(6), Rh1–P2 = 2.388(6), P1–Rh1–P2 = 86.3(2), P2–Rh1–P2′ = 174.0(2), P1–Rh1–P2′ = 93.8(2), P1–Rh1–P1′ = 178.7(2), Rh1–P1–C1 = 114.5(6), Rh1–P1–C7 = 113.7(6), Rh1–P1–C44 = 120.8(6), Rh1–P2–C13 = 116.7(6), Rh1–P2–C19 = 121.2(6), Rh1–P2–C25 = 110.2(6). The angle between the least-squares planes through the two naphthyl rings in a binap ligand is 71.0(3)°. Vibration ellipsoids: 50% probability level.

Isotopic labeling studies on the mono(binap) complex-catalyzed isomerization of allylamines indicated an exclusive 1,3-hydrogen migration[1b], suggesting a mechanism involving a π-allylhydridorhodium(III) intermediate. The identical correlation between the stereochemistries of the product and the chirality of the ligand for mono- and bis(binap)Rh(I) complex-catalyzed isomerizations suggests involvement of very similar π-allyl intermediates. This requires the dissociation of one of the binap ligands in **4**. In the process, however, the conformation of the chelate ring is retained; *R*-binap has a λ-skew configuration[5]. In the exchange between the free and the coordinated binap, the conformation of the chelate ring does not change because the C_2 symmetry is retained tenaciously.

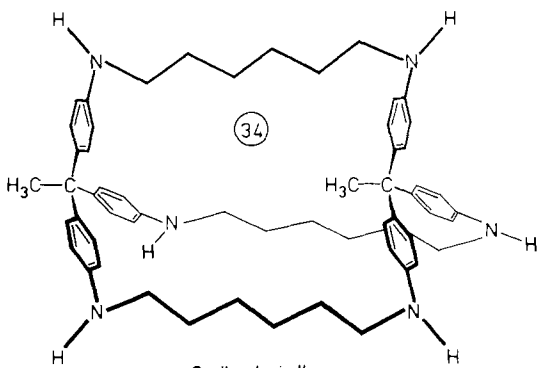
"In-out"-Isomeric Large Cavities and Their Differing Guest Selectivity**



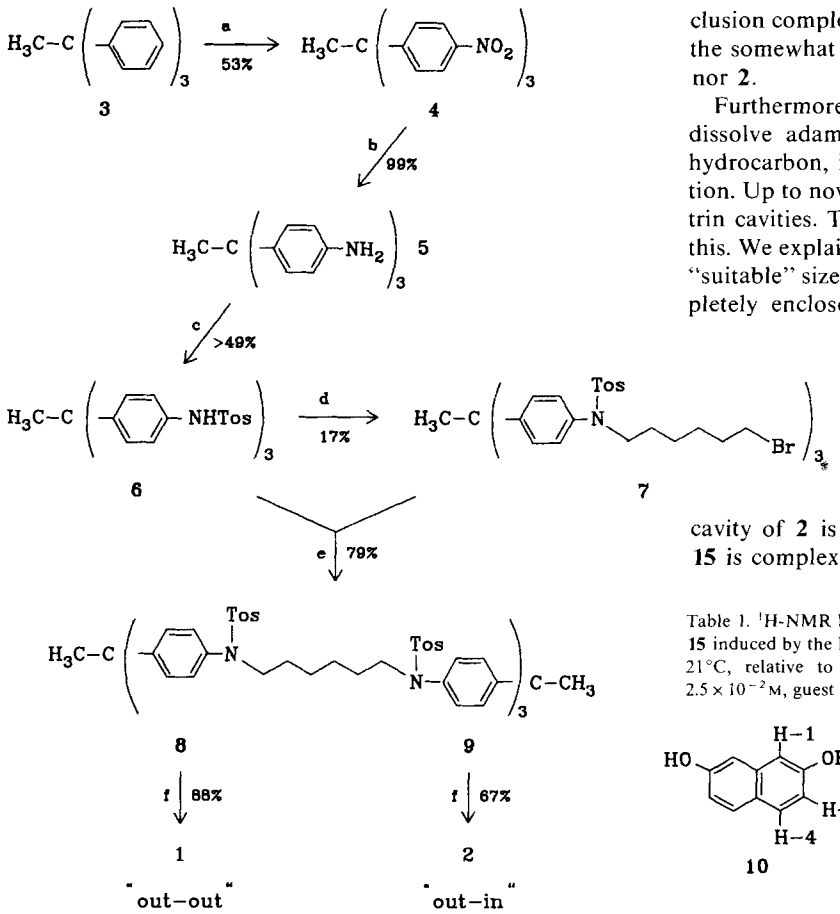
By *Joachim Franke* and *Fritz Vögtle**

Macro*bi*cyclic large cavities (number of ring members about 30) enclosed on several sides have been hardly known up to now[1]. The enclosure of guest molecules on "all sides" should increase the stability and selectivity of the complex due to the better screening of the hydrophobic niches.

We report here the synthesis and properties of two new spherical host compounds **1** and **2** of the speleand type[2], which, despite the same chemical constitution and therefore similar chemical properties, differ in the form and size of their cavities. The water solubility is achieved by protonation of the six amine nitrogens.

1, "out-out"

2, "out-in"



The triphenylethanes[3] **1** and **2**, linked by three chains, were obtained together starting from **3** via **4**—**9** (Scheme 1)[4].

Despite the fact that a loss in yield must be reckoned with during the chain-extension step **6**→**7** due to intramolecular ring closure, the decisive macro-cyclization of **6** with **7** to give **8** and **9** was achieved in the unexpectedly high total yield of 79%! By chromatography of the crude product, the two isomeric macrobicyclic compounds, whose structure we interpret as "out-out" (**8**) and "out-in" (**9**) isomers, could be obtained in a ratio of 1 : 1. The detosylation of **8** and **9** to give **1** and **2**, respectively, was achieved with HBr/phenol in different yields: 88% and 67%, respectively. The assigned structures[4] given for **8** and **9**, and for **1** and **2**, are supported by the ^{1}H- and ^{13}C-NMR spectra, as well as the differing complexation properties.

Table 1 gives some results for the complexation of potential guests with the isomeric host compounds **1** and **2** in deuterated aqueous solution. The corresponding chemical shifts in the ^{1}H-NMR spectrum (δ values) of protons of se-

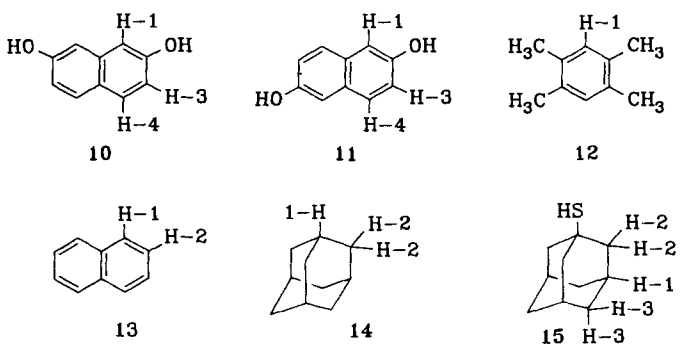
Scheme 1. Synthesis of the host compounds **1** and **2**. a) HNO_3, b) H_2/Pt; c) TosCl; d) $Br(CH_2)_6Br$; e) K_2CO_3, dimethylformamide (DMF), the yield given refers to **8** + **9**. Separation of **8** and **9** by chromatography on SiO_2; gradient elution with dichloromethane/petroleum ether 40–60°C/ethyl acetate 1:1:0.2 to 1:1:2; f) HBr, phenol.

lected guest compounds and their changes upon complexation ($\Delta\delta$ values) are also given.



The $\Delta\delta$ values are composed of anisotropy effects between host and guest molecules as well as effects of the positive charges of the ammonium centers. The different shifts of the protons of a single guest molecule we attribute to its spatial orientation with respect to the anisotropy and charge centers of the host.

With **1**, we observe complete H/D exchange for the protons labeled H-1 of guests **10** and **11** within 24 h[6]. Neither **2** nor the comparison compound **16**[7] allow this exchange.

Complexes of synthetic host compounds with arenes lacking functional groups have been seldom up to now[1,5,7,8]. Surprisingly, both hosts **1** and **2** also form inclusion complexes with naphthalene **13** as guest. However, the somewhat larger durene **12** is complexed by neither **1** nor **2**.

Furthermore, with **1**, it was possible for the first time to dissolve adamantane **14**, a non-functionalized aliphatic hydrocarbon, in aqueous medium by selective complexation. Up to now, this has only been possible with cyclodextrin cavities. The isomeric host **2** is not capable of doing this. We explain this marked difference in selectivity by the "suitable" size and form of the cavity of **1**, which can completely enclose the spherically shaped adamantane; the cavity of **2** is too small. Accordingly, 1-adamantanethiol **15** is complexed only by **1** and not by **2**.

Table 1. ^{1}H-NMR high-field shifts of protons of the guest compounds **10**–**15** induced by the host compounds **1** and **2** (400 MHz, D_2O/DCl, pD = 1.2, 21°C, relative to δ = 4.8 for HDO as standard; concentrations: host 2.5×10^{-2} M, guest 1.25×10^{-2} M.

Guest	Guest proton	δ	Guest + **1** $\Delta\delta$ [ppm]	Guest + **2** $\Delta\delta$ [ppm]
10	H-1	7.03	−0.73	−0.5
	H-3	6.93	−0.43	−0.4
	H-4	7.69	−0.69	ca. −0.5 [a]
11	H-1	7.13	−0.4	−0.5
	H-3	7.06	−0.4	−0.43
	H-4	7.61	ca. −0.5 [a]	ca. −0.5 [a]
12	H-1	6.8	—	—
[b]	CH_3	2.13	—	—
13	H-1	7.82	−0.5	−0.5
[b]	H-2	7.45	−0.5	−0.5
14	H-1	1.9	−0.6	—
[b]	H-2	1.8	−0.5	—
15	H-1	2.05	−0.3	—
[b]	H-2	2.12	to	—
	H-3	1.72	−0.5 [c]	—

[a] The chemical shift could not be exactly determined since the signals overlap with those of the host. [b] The complexes were prepared by solid/liquid extraction in D_2O/DCl:CD_3OD (4:1) (cf. [5]). [c] The guest signals could not be exactly assigned.

The fluorescence spectroscopy measurements[9] gave a value of pK = 4.0 for the complex formation of **2** with 8-anilino-1-naphthalenesulfonic acid (ANS) as guest; this value is similar to that for the **16**·ANS complex (pK = 3.8[7]). In this case, too, the **1**·ANS complex (pK = 4.6) is noticably more stable.

Thus, it is shown for the first time that it is possible to obtain two isomeric, structurally very similar host com-

pounds (**1** and **2**), whose differing selectivity can only be attributed to the size of the cavity. Specific deuterations/tritiations appear to be possible in practice with these tailor-made host cavities; moreover, it should be possible to extract organic compounds selectively from a lipophilic phase into the aqueous phase[8].

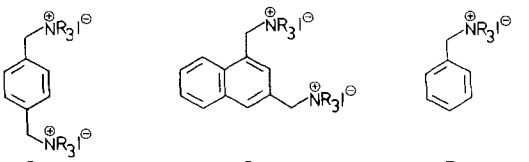
Large Carbocyclic Cavities for the Selective Inclusion of Organic Guest Molecules in Aqueous Solution**

By *Fritz Vögtle**, *Thomas Merz*, and *Herbert Wirtz*

The inclusion of guest molecules in aqueous solution has, up to now, only been achieved with certainty for heterocyclic host compounds[1,2]. Large carbon rings would have the advantage of being chemically more stable and, via reactions of the side chains, more variable. We report for the first time a water-soluble, *carbo*macrocyclic host compound **2** with a 30-membered cavity.



1: R=C_2H_5
2: R=H

4: R=C_2H_5

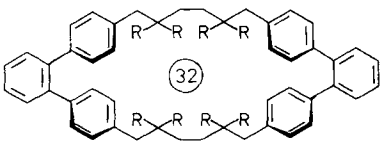
Reaction of the diphenylmethane derivative **3** with the disodium salt of the 2,2′-ethylenebis(malonic)tetraester **4** under high-dilution conditions affords the desired "dimeric" octaester **1** (m.p. = 190°C) in 1.8% yield[3,4]. Alkaline hydrolysis leads to the macrocyclic octacarboxylic acid **2** (m.p. >320°C), which, as desired, is soluble as the anion[1,2] in alkaline water.

Upon addition of guest compounds—which spatially fit the cavity—such as 1,4-xylylenebis(trimethylammonium)diiodide **5** to solutions of **2** in D_2O/NaOD, all the protons of the guest molecule experience characteristic, strong high-field shifts[5] (cf. Table 1).

5 **6** R=CH_3 **7**

Table 1. ^{1}H-NMR high-field shifts of protons of the guest compounds **5**–**7** due to the host compound **2** (400 MHz, D_2O/NaOD, pD = 14, 21°C; standard defined as HDO at δ = 4.8; concentrations: host 5×10^{-2} M, guest 2.5×10^{-2} M).

Guest	δ(Aryl-H)	$\delta(CH_2)$	$\delta(N-CH_3)$
5	7.75	4.6	3.16
6	7.95	4.93, 4.71	3.2
7	7.55	4.66	3.06
	$\Delta\delta$(Aryl-H)	$\Delta\delta(CH_2)$	$\Delta\delta(N-CH_3)$
5 + **2**	−0.5	−0.6	−0.3
6 + **2**	−0.13	−0.1	−0.25
7 + **2**	−0.16	−0.2	−0.18



The inclusion of organic guest molecules, in this case, quaternary ammonium compounds, in the cavity of the new type of host **2** is thus demonstrated. In contrast to all receptor model substances so far described for which the inclusion of the guest in the host cavity is certain, **2** contains no donor centers in the ring skeleton; hydrogen-bond bridges between host and guest are largely ruled out. The shift of *all* protons of the guest **5** indicates the enclosure of all parts of **5** by the host compound on a time average. That the host **2** forms different inclusion complexes is shown qualitatively by the finding that the high-field shifts are very different, depending on the guest molecule. Whereas the naphthalene derivative **6**, apparently due to its large spatial demands, is not enclosed like **5**, the quaternary monoammonium salt **7** apparently fits somewhat better; however, the shifts are not so pronounced as those of **5**. In contrast, naphthalene could not be transferred into the aqueous phase with **2**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Fluorescence spectroscopy measurements give a value of $pK = 2.35$ in water for the complex formation of **2** with 8-anilino-1-naphthalenesulfonic acid (ANS). This is higher than the value for the β-cyclodextrin·ANS complex in neutral aqueous solution.

The ease with which the new host system **2** can be structurally varied is shown by the successful synthesis in an analogous way of the 32-membered host compounds **8** and **9**, derived from *o*-terphenyl, as well as of the 16-membered "monomers" **10** and **11**, respectively[6].

8: R=CO_2Et
9: R=CO_2H

10: R=CO_2Et
11: R=CO_2H

Carbomacrocycles as host compounds have the advantage that their large ring cannot be hydrolytically cleaved. This is especially important if functional groups other than the carboxy group are attached to the large ring in order to effect host reactions that are analogous to enzymatic reactions[1,7]. Accordingly, compounds of the types **1** and **8** can be derivatized under harsh conditions, e.g., to give *uncharged*, but nonetheless water-soluble, host compounds with oligoamide, urea, or barbiturate side chains. Oligocarboxylic acids of the types **2** and **9** are, moreover, also (acid) complex formers for *cations*. If the carboxy groups point inward, a smaller cavity is formed, which is more suitable for metal cations.

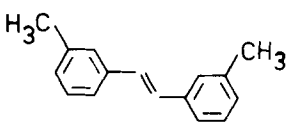
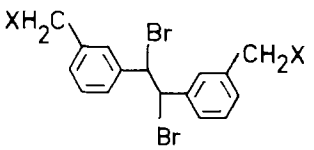
A Three-Blade Propeller Compound with Seven Bracketed Benzene Rings**

By *Wolfram Kissener* and *Fritz Vögtle**

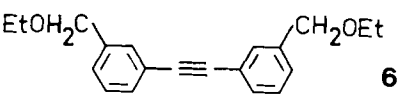
In contrast to heptahelicene[2], which has a twofold symmetry axis, a three-blade propeller symmetry[3] is predicted for the hydrocarbon $C_{48}H_{36}$ **1**, derived from hexaphenylbenzene. This requires that the outer benzene rings be arranged in a stepwise displaced fashion, in analogy to the isolated "propeller blade" **2**[4], alternately above and below the plane of the central benzene ring[5].



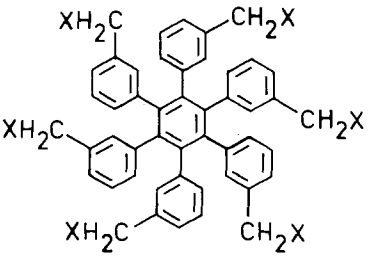
1 (all-*anti*)



2 (*anti*)



The synthesis of the helically chiral hydrocarbon **1**[6], for which, based on the results for **2**[4], high optical rotation could be expected, has now been achieved by us starting from stilbene **3** via the intermediates **4**—**8**[7]. The cyclization of the hexakis(bromomethyl) compound **8** with phenyllithium could only be achieved at unusually high temperatures (boiling tetrahydrofuran).



3

4: X = H
5: X = Br

6

7: X = OEt
8: X = Br

[**] New helical molecules, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We also thank Dipl.-Chem. *A. Aigner* and *K.-H. Duchêne* for their cooperation.—Part 10: [1].

Via this reaction, we surprisingly directly obtained not only **1** but, in addition, two isomers, which we assign[8] to the unexpectedly stable *syn,syn,anti-* and *syn,anti,anti*-conformations **9** and **10**[7] (Fig. 1) on the basis of their ^{1}H-NMR spectra and their thermal rearrangement to give **1**.

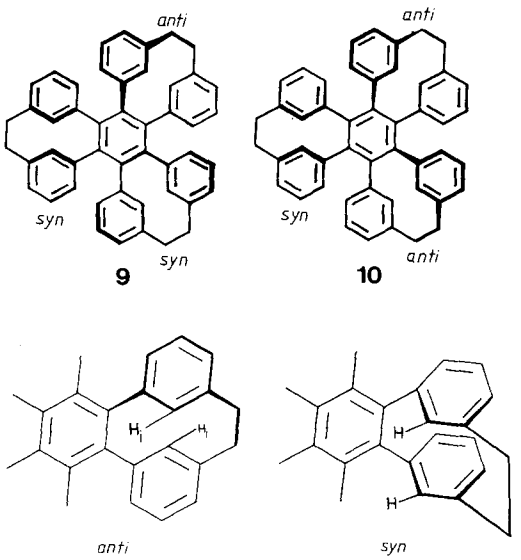

Fig. 1. *anti-* and *syn*-Arrangements (selected) in **1**, **9**, and **10**.

Upon heating of the products of the phenyllithium cyclization to 350 °C, a *syn*→*anti* rearrangement takes place, which is at first apparent by change in the crystal structure under the hot-stage microscope, but also in the completely changed ^{1}H-NMR spectrum (Fig. 2). Whereas the *syn* conformers **9** and **10** exhibit arene signals at $\delta = 5.15$, 5.22, and 5.45 as well as CH_2 signals centered at $\delta = 2.1$ and 3.2, the ^{1}H-NMR spectrum of **1** proves its structure on the basis of the strong high-field shifts of the inner protons [$\delta(H_i) = 5.4$]. The inner protons of the comparison compound **2** absorb at the same field strength ($\delta = 5.44$).

Racemic **1** (all-*anti*) is almost colorless; above 380 °C, it turns brown[9]. A base-line separation of the racemic mixture of **1** was achieved by HPLC on (+)-poly(triphenylmethylmethacrylate) [(+)-PTrMA][10]. As expected, the optical rotations are high: $M^{22}_{436} = +5235$[9].

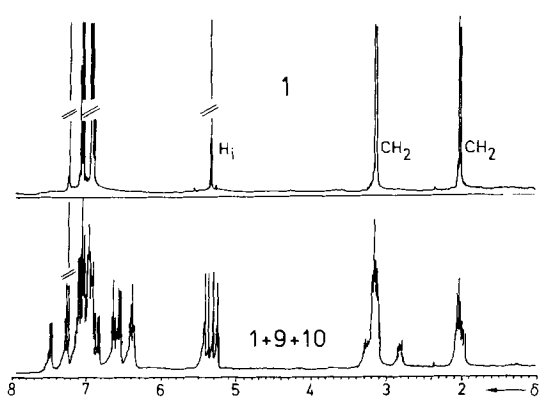

Fig. 2. ^{1}H-NMR spectra of the synthetically obtained mixture of **9**, **10**, and **1** (below) and of pure **1** (above): 400 MHz, in $CDCl_3$.

As expected, the optical stability of the new molecular propeller **1**, which is important for practical applications[11], is considerable; it is even higher than that of the helicenes. **1** even sustains heating at 310 °C for several minutes—conditions that lead to the racemization of the helicenes as well as of **2**. This is plausible since the inversion of a phenylene group in the *anti*-position is coupled with that of each of the other five, in contrast to the independent ring inversion in **2**.

By analogous synthetic strategy, other helices, with high optical rotation and stability, might be accessible[12]. The dehydrogenation product of **1**, a diphenanthroovalene, is also of interest due to its polycyclic aromatic structure.

[**] Cyclic Diazastannylenes, Part 21. This work was supported by the Fonds der Chemischen Industrie.—Part 20: M. Veith, W. Frank, *Angew. Chem. 96* (1984) 163; *Angew. Chem. Int. Ed. Engl. 23* (1984) 158.

with resort to bond theory and structural and chemical aspects for evidence of the existence or non-existence of such an activity. In the case of molecular compounds of divalent elements of the fourth main group (especially of Ge^{II} and Sn^{II}), primarily the existence of transition-metal complexes of the type X_nM-ElY_2[2] or $[X_nM-ElY_3]^{\ominus}$[2] (El = Ge, Sn) has been taken as supporting evidence for these elements being able to function as bases by virtue of the lone pair of electrons; however, the particular electronic structure of the transition metal was ignored (back-bonding etc., cf. also carbene complexes[3]). Even though a whole series of acid-base adducts such as $(Cp)_2Sn \cdot AlX_3$[2] (Cp = cyclopentadienyl, X = halogen) and $X_2Sn \cdot BF_3$[2] have been reported, neither the exact structures are known, nor is the formulation of the compounds as adducts confirmed. According to most recent structure investigations even the species $(\eta^5\text{-}C_5H_5)_2Sn-BF_3$ designated as adduct must be described as $[(BF_4)^{\ominus}\{(\mu\text{-}\eta^5\text{-}C_5H_5)_2Sn(\mu\text{-}\eta^5\text{-}C_5H_5)\}^{\oplus} \cdot thf]_n$[4]. By reaction of the cubane-like compounds $(GeNtBu)_4$[5] and $(SnNtBu)_4$[5] with aluminum trichloride we have now succeeded in preparing adducts which contain Ge–Al and Sn–Al bonds, respectively. By varying the molar ratio of the reaction partners, we have tried to prepare the adducts $(t\text{BuNEl})_4 \cdot (AlCl_3)_x$ with x = 1–4; however, on crystallization only those adducts with x = 2 could be isolated.

$$(t\text{BuNEl})_4 + Al_2Cl_6 \xrightarrow[\text{toluene}]{\Delta} (t\text{Bu}-\text{NEl})_4 \cdot 2\,AlCl_3$$
1, El = Ge; **2**, El = Sn

The ^{1}H-NMR spectra of the reaction solutions surprisingly contain (see molecular structure in Fig. 1) only one singlet, whose chemical shift depends upon the ratio of the reaction partners (when x = 2, **1**: $\delta = 1.30$ (s); **2**: $\delta = 1.32$ (s), 60 MHz, 28 °C, toluene)[6]. This finding could be explained in terms of the presence of various adducts and a rapid exchange of the $AlCl_3$ groups in solution. An X-ray structure analysis on single crystals of **2** confirmed the adduct structure. **1** and **2** are relatively unstable; they decompose into the starting components, slowly in solution and rapidly under reduced pressure (in the mass spectrometer).

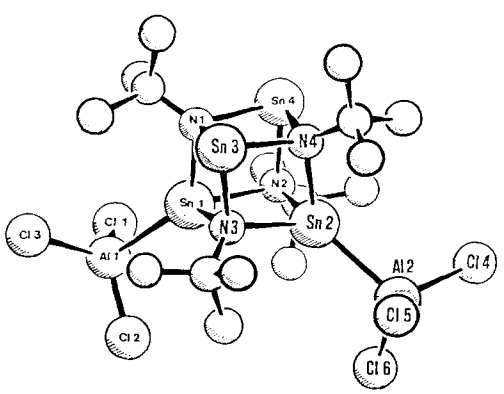

Fig. 1. Structure of **2** in the crystal. The unnamed atoms are carbon atoms; the hydrogen atoms of the methyl groups are not shown. The Sn_4N_4 skeleton is retained on adduct formation, the point symmetry of **2** is almost C_{2v} (mm2). Cell dimensions: $a = 1032.5(5)$, $b = 2311.2(9)$, $c = 1981.4(8)$ pm, $\beta = 124.3(1)°$. Space group: $P2_1/c$; $Z = 4$. Four-circle diffractometer, $R = 0.074$ with a reflection-parameter ratio of 14.07 : 1. Some selected (averaged) bond lengths: Sn–Al 278(1), Al–Cl 212.4(8), Sn–N 219(2), N–C 150(1) pm. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51183, the names of the authors, and the full citation of the journal.

The structure analysis of **2** (Fig. 1) proves for the first time that low-valency elements such as Sn^{II} can function as donors in Lewis acid-base adducts. The Sn–Al bond length corresponds exactly to that expected from the atomic radii[7]; the aluminum atoms coordinate in a distorted tetrahedral fashion, with the Cl–Al–Cl angle of 113.9° (mean) lying in the range typical for $AlCl_3$ adducts[8]. On comparing the structure of **2** with the structure of the uncoordinated $(SnNtBu)_4$[9] the following differences emerge: a) the distance between the fourfold coordinated tin atoms in **2** is reduced (Sn1 ··· Sn2 = 323.6(2) pm, in $(SnNtBu)_4$: 333 pm[9]), while the other intramolecular distances all remain, within the standard deviations, the same. b) As a direct consequence of this closing-up, the N–Sn–N angles in the four membered ring N2–Sn1–N3–Sn2 (84° in **2** compared to 80° in $(SnNtBu)_4$) are widened and the Sn–N–Sn angles compressed. A very superficial interpretation of this effect could lead to the conclusion that the distance between the respective tin atoms becomes smaller by withdrawal of the electron density of the lone electron pairs. The adducts **1** and **2** support the hypothesis that the $(t\text{BuNEl})_4$ molecules (El = Ge, Sn) may better be described as cage molecules with oriented bonding[9]. But it is still unclear why only the adducts with two $AlCl_3$ moieties crystallize and not also those with another Al : Sn ratio.

Experimental:

Newly sublimed aluminum trichloride (0.152 g, 1.14 mmol) was treated with a solution of $(t\text{BuNGe})_4$[5] or $(t\text{BuNSn})_4$[5] (0.58 mmol) in toluene (30 mL) in the strict absence of moisture. On heating the mixture to boiling the $AlCl_3$ dissolved. The resulting solution was concentrated by evaporation and allowed to stand. After a few hours, rhombus-shaped crystals separated out. Yields: **1**, 0.36 g (75.6%); **2**, 0.38 g (65%). The crystals gave correct elemental analyses.

Mechanism of Purpurogallin Formation: An Adduct from 3-Hydroxy-*o*-benzoquinone and 4,5-Dimethyl-*o*-benzoquinone

By *Walter Dürckheimer** and *Erich F. Paulus*

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday

Purpurogallin **1**, found in nature as a glycoside, is formed upon oxidation of pyrogallol in water. The mechanism of this reaction is still largely speculative. *Salfeld*[1] and *Horner* et al.[2] postulated an intermediate **3** formed

[*] Dr. W. Dürckheimer, Dr. E. F. Paulus
Hoechst Aktiengesellschaft, Pharma-Synthese
Postfach 800320, D-6230 Frankfurt am Main 80 (FRG)

1 2 3

4 5 6

from two molecules of 3-hydroxy-*o*-benzoquinone **2**; however, **3** has not yet been isolated. Previous studies[3] showed that pyrogallol forms 3-hydroxy-*o*-benzoquinone **2** upon oxidation with a variety of oxidizing agents in water; **2** quickly reacts in situ with itself or with an *o*-quinone, containing at least one unsubstituted double bond, to form dihydroxybenzotropolones of the purpurogallin type[2].

We have now been able to synthesize the adduct **4** from **2** and 4,5-dimethyl-*o*-benzoquinone **5**. **4** exhibits extensive structural analogy to the postulated intermediate **3** and therefore supports the previous conceptions regarding the mechanism of formation of purpurogallin[4]. The structure of **4** was determined on the basis of its spectra[5] and by an X-ray crystal structure analysis (Fig. 1). The relatively small standard deviation of the bond lengths reflects a high quality X-ray structure analysis and allows one to conclude that the bond C07–C08 (1.568(2) Å) is especially labile and that its cleavage could lead to further reactions.

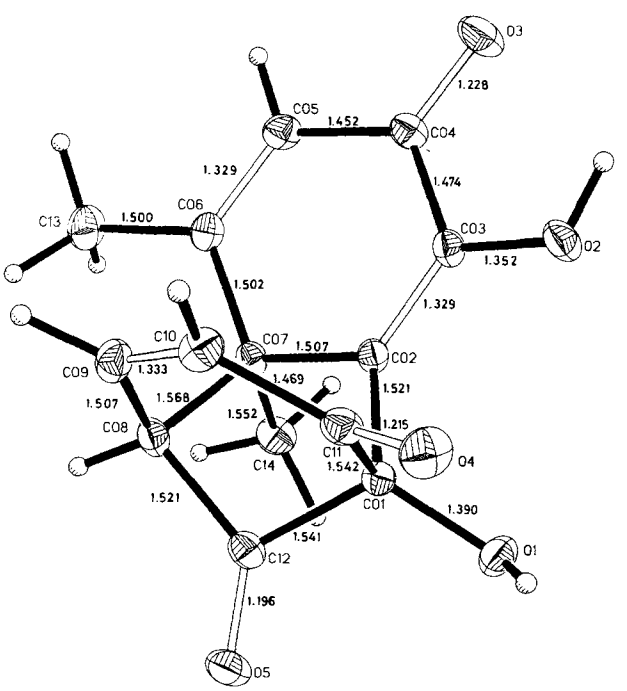

Fig. 1. Crystal structure of **4** with thermal vibration ellipsoids [6]. Bond lengths in Å.

It is assumed that the formation of this unusual carbonyl-bridged seven-membered ring system takes place in several steps. First, pyrogallol is dehydrogenated by **5** to give the highly reactive **2**, which is a vinylogous carboxylic acid. **5** and **2** have similar redox potentials in water. In the next step, the anion of **2** reacts with **5** in a Michael-type addition to give intermediate **6**, which cyclizes via nucleophilic attack of the carbanion on the central carbonyl group of the 1,2,3-tricarbonyl system. This carbonyl group is the most electrophilic due to the inductive effect of the neighboring carbonyl groups.

Procedure:

1,3-Dihydroxy-6,7-dimethyltricyclo[6.3.1.$0^{2,7}$]dodeca-2,5,9-triene-4,11,12-trione **4**: 2.7 g (0.02 mol) **5** is suspended in 20 mL anhydrous dioxane and a solution of 1.3 g (0.01 mol) pyrogallol in 10 mL dioxane is slowly added dropwise while shaking. **5** quickly dissolves, and, after the solution has stood for a short time at room temperature, 2.4 g (92%) **4** precipitates as pale yellow crystals. These are suctioned off and washed with a small amount of dioxane. Recrystallization from ethyl acetate gives 2.1 g (81%) **4**, with a point of decomposition of 165 °C. With iron(III) chloride, **4** gives a strong enol reaction. A colorless diacetate, which has a point of decomposition of 214–216 °C, is formed with acetic anhydride.

Cleavage of Tris(cyclopentadienyl)lanthanide Complexes with Alkyllithium Compounds—a New Route to Alkylbis(cyclopentadienyl)lanthanides**

By *Herbert Schumann** and *Gerald Jeske*

Alkylbis(cyclopentadienyl)lanthanide complexes are accessible by reaction of bis(cyclopentadienyl)lanthanide

[**] Organometallic compounds of the lanthanides, Part 26. This work was supported by the Fonds der Chemischen Industrie and by special funds of the TU Berlin.—Part 25: I. Albrecht, E. Hahn, J. Pickardt, H. Schumann, *Inorg. Chim. Acta*, in press.

halides with Grignard reagents or alkyllithium[1]. However, this method is limited to the synthesis of such compounds containing the lanthanides samarium to lutetium. It has not yet been possible to prepare bis(cyclopentadienyl)lanthanide halides of lanthanum, cerium, and praseodymium[2,3]. Proton acids, such as 1-alkyne[4], hydrogen cyanide[5], or formic acid[2], react with tris(cyclopentadienyl)neodymium to form the bis(cyclopentadienyl)neodymium derivatives $[(C_5H_5)_2NdX]$ ($X = C{\equiv}CR$, CN, O_2CH); these do not afford the possibility, however, of synthesizing bis(cyclopentadienyl)neodymium hydride, which has promise as a hydrogenation catalyst[6].

We have now found that, even below room temperature, tris(cyclopentadienyl)lanthanides react with *sec*-butyl- and *tert*-butyllithium to form butylbis(cyclopentadienyl)lanthanide complexes **1** and **2** along with cyclopentadienyllithium[7]. **1a** and **1b** already decompose at $-30\,^{\circ}C$ and $0\,^{\circ}C$, respectively, to form butene and, respectively, bis(cyclopentadienyl)neodymium hydride and bis(cyclopentadienyl)lutetium hydride, **3a** and **3b**[8].

$$[(C_5H_5)_3Ln(thf)] + LiR \xrightarrow[-78\,^{\circ}C]{THF} [(C_5H_5)_2Ln{-}R(thf)] + LiC_5H_5$$

1a, Ln = Nd, R = *sec*-C_4H_9
1b, Ln = Lu, R = *sec*-C_4H_9
2a, Ln = Nd, R = *tert*-C_4H_9
2b, Ln = Lu, R = *tert*-C_4H_9

$$2\,\mathbf{1a,1b} \xrightarrow{THF} [(C_5H_5)_2LnH(thf)]_2 + 2\,C_4H_8$$

3a, Ln = Nd,
3b, Ln = Lu

THF: tetrahydrofuran

2a and **2b** react with hydrogen in toluene at room temperature, resulting in cleavage of *iso*-butane and formation of **3a** and **3b**, respectively, the latter of which is also obtainable via other routes[9,10]. **3a**[11], which precipitates in 82% yield in the form of blue needles, is a superb hydrogenation catalyst for alkynes[6].

$$2\,\mathbf{2a,2b} \xrightarrow[1\,atm.]{H_2} \mathbf{3a,3b} + 2\,iso\text{-}C_4H_{10}$$

Tris(cyclopentadienyl)neodymium does not react with $LiCH_3$, Li–*n*-C_4H_9[12], $LiCH_2SiMe_3$, and $LiCH(SiMe_3)_2$ to form alkylbis(cyclopentadienyl)neodymium complexes. Tris(cyclopentadienyl)praseodymium reacts with *n*-butyllithium in THF to form $[(C_5H_5)_3Pr{-}C_4H_9]^-$[13]; the replacement of the second cyclopentadienyl ligand by excess *tert*-butyllithium has not yet been achieved.

Symmetrical and Unsymmetrical Triphosphenium Ions**

By *Alfred Schmidpeter**, *Siegfried Lochschmidt*, and *William S. Sheldrick*

The isoelectronic molecules and ions $(Ph_3P)_2E^{(n-4)+}$ can be regarded as triphenylphosphane complexes of the nonmetals E, main group n, and are known for E = C, N, O. In the case of E = P, such an ion with an element of the third period is now also accessible.

Neither triphenylphosphane nor aluminum chloride react alone with phosphorus trichloride; together, however, they effect the reductive break-up of PCl_3 with formation of a chlorophosphonium and a triphosphenium ion[1] [eq. (1)].

$$PCl_3 + 3\,Ph_3P + 2\,AlCl_3 \longrightarrow [Ph_3P{-}P{-}PPh_3^+]AlCl_4^- + Ph_3PCl^+AlCl_4^- \quad (1)$$

1

1,1,1,3,3,3-Hexaphenyltriphosphenium tetrachloroaluminate **1**[2] (Table 1) crystallizes with half a molecule of CH_2Cl_2. Its X-ray structure analysis[3] shows two independent, yet not significantly different cations (Fig. 1). The average PP distance lies between that of a PP single bond and a PP double bond (220–225 and 200–205 pm, respectively); the PPP angle is, nevertheless, small[4]. A PNP

On redissolving in CH_2Cl_2, **1** decomposes, whereby Ph_3P is liberated and more $Ph_3PCl^+AlCl_4^-$ is formed. The amorphous orange-yellow precipitate that separates is a phosphorus subchloride in which chlorine is partially replaced by triphenylphosphonio moieties; the replaced Cl^- reacts with $AlCl_3$ to give $AlCl_4^-$. In the decomposition reaction, the redox reaction between PCl_3 and Ph_3P which started in equation (1) thus continues further. This is initiated by the chloride ions that become available from the dissociation of $AlCl_4^-$, which increases with dilution. The decomposition can consequently be suppressed by the addition of $AlCl_3$ (about 0.3 mol/mol **1** for a 0.5 M solution of **1**).

In the presence of 1.5 mol $AlCl_3$/mol **1**, reaction of **1** with HCl or *tert*-butyl chloride proceeds according to Eq. (2) to give the hexaphenyltriphosphanediium salt **2** (Table 1). The ^{31}P-NMR spectrum of **2** is characterized by a high PH coupling constant ($J_{PH} = 235$ Hz), otherwise observed for diacyl- or bis(perfluorophenyl)phosphanes

$$\mathbf{1} + HCl + AlCl_3 \longrightarrow \underset{\mathbf{2}}{[Ph_3P{-}PH{-}PPh_3^{2+}](AlCl_4^-)_2} \quad (2)$$

With other alkyl chlorides RCl, **1** reacts under the same conditions to give the 2-alkylhexaphenyltriphosphanediium salts **2**, R instead of H[5].

Consistent with **1** being regarded as a phosphane complex, its PPh_3 moieties can be stepwise replaced by more basic phosphanes L according to Eq. (3) (Table 1).

$$\mathbf{1} \xrightarrow[-Ph_3P]{+L} \underset{\mathbf{3}}{[L{-}P{-}PPh_3^+]AlCl_4^-} \xrightarrow[-Ph_3P]{+L} \underset{\mathbf{4}}{[L{-}P{-}L^+]AlCl_4^-} \quad (3)$$

The salts of the unsymmetrical triphosphenium ions **3** are also formed on reaction of the salts with the symmetrical ions **1** and **4** [Eq. (4)]. The equilibria (4) usually lie distinctly on the side of **3** ($K > 100$). Exceptions are found with phosphanes that exhibit only slightly higher basicity towards P^+ than does triphenylphosphane: $MePh_2P$, $K = 93$; Et_2NPh_2P, $K = 59$; $PhNHPh_2P$, $K = 1.8$.

$$\mathbf{1} + \mathbf{4} \rightleftharpoons 2\,\mathbf{3} \quad (4)$$

The PP coupling constants of the unsymmetrical ions in **3** correspond on the average quite well with the mean of J_{PP} in **1** and **4** (with the same L), but may (as in the case of **3k**) deviate rather strongly from it (Table 1).

Sulfur Monoxide as 4-Electron Bridge-Ligand in the Complex $[\{(\eta^5\text{-}C_5H_5)(CO)_2Mn\}_2SO]$**

By *Ingo-Peter Lorenz*, Johannes Messelhäuser, Wolfgang Hiller,* and *Klaus Haug*

In the free state, sulfur monoxide is extremely unstable; its stabilization by complexation was first described by *G. Schmid* et al. and *M. Höfler* et al.[1]. We have now succeeded in synthesizing the first SO-complex **3** with symmetrical SO-bridge and sp^2-hybridized sulfur (3c4e system).

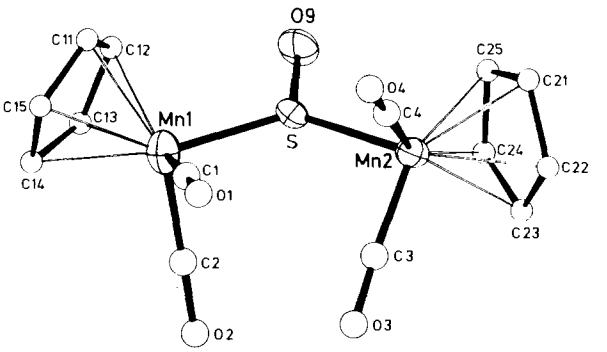
Sulfur monoxide is generated in solution in the presence of the substitution-labile solvent complex **1a** by thermolysis of thiirane *S*-oxide **2** at room temperature[2] and is trapped by complexation in **3** (ca. 10%), a black-violet, crystalline solid that is sensitive to light and air in solution; more productive is the irradiation of the carbonylcyclopentadienylmanganese complex **1b** and **2** in petroleum ether (ca. 30%)[3].

$$2\ [(\eta^5\text{-}C_5H_5)(CO)_2MnL] + \underset{O}{\overset{}{S}} \xrightarrow[-2\ L]{\text{room temperature or } h\nu} [\{(\eta^5\text{-}C_5H_5)(CO)_2Mn\}_2SO] + C_2H_4$$

1a, L = thf; **1b**, L = CO; **2**; **3**

The mechanism of formation of **3** is still unclear. We postulate initial adduct formation of **2** with **1** to give an unstable intermediate, which is converted via C_2H_4- and L-elimination and addition of the Lewis acid **1**-L into **3**. The composition and structure of the complex was confirmed by elemental analysis, ^{1}H-NMR, IR, UV, and mass spectra, and by an X-ray structure analysis. The FD mass spectrum shows the molecular ion at $m/z = 400$. The IR spectrum (KBr) shows, in addition to the C_5H_5- and CO-bands (ν(CO) = 2010 s, 1995 m-s, 1948 vs, 1923 vs, 1908 w, cm^{-1}; (pentane): 2027 s, 2019 w, 1965 m, 1947 vs, cm^{-1}), three further absorptions at 1037 m, 475 w-m and 454 w, cm^{-1}, which are assigned to the S=O- and SMn_2-stretching vibrations, respectively. The ^{1}H-NMR spectrum shows only one singlet at $\delta = 4.77$ for the ring protons, even at -40 °C ($CDCl_3$). The deep violet color of **3** is attributed to the very intense band at 18450 cm^{-1} in the UV/VIS spectrum ($^1A_1$-$^1B_2$ transition in the 4π-SMn_2 skeleton, C_{2v}).

According to a single-crystal X-ray structure analysis[4], the complex **3** contains the SO-ligand as a 4-electron donor oriented in a symmetrical bridge position (Fig. 1). The S-atom is bound to the two Mn atoms via two short bonds (Mn1–S 212.6(2), Mn2–S 212.1(2); the S–O9 distance of 150.4(4) pm is negligibly longer than in the free molecule. The bond angles M1–S–Mn2, Mn1–S–O9, and Mn2–S–O9 are 130.78(7), 114.4(2), and 114.8(2)°, respectively, thus the four atoms of the central SOMn skeleton lie exactly in a plane. The Mn1–Mn2 distance of 386.2(1) pm rules out any bond interaction[5]. The CO ligands are rotated pairwise through an angle of 34.8° with respect to each other.



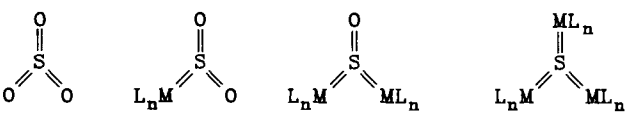


Fig. 1. Crystal structure of **3**. Selected bond lengths [pm] and angles [°]: S–O9 150.4(4), Mn1–S 212.6(2), Mn2–S 212.1(2), Mn1–C1 176.3(7), Mn1–C2 178.6(7), C1–O1 116.3(7), C2–O2 115.2(7); Mn1–S–Mn2 130.78(7), Mn1–S–O9 114.4(2), Mn2–S–O9 114.8(2), S–Mn1–C1 94.9(2), S–Mn1–C2 93.1(2), Mn1–C1–O1 177.5(6), Mn1–C2–O2 179.0(6). The two independent molecules of **3** show, within the limits of error, the same geometry.

It follows from the trigonal-planar arrangement and Mn=S double bonding of **3** that it is not to be regarded as an organometallic derivative of sulfoxides, but, because of the isolobal relationship $O \rightarrow \overline{O} \leftarrow (\eta^5\text{-}C_5H_5)(CO)_2Mn$, as a derivative of sulfur trioxide **I**. Since a trigonal-planar sulfur environment is also present in the complex **II**[6] an isotypic series of the known compounds **I**—**IV** can be formulated.

$L_nM = (\eta^5\text{-}C_5H_5)(CO)_2Mn$

Höfler et al.[1b] have described the oxidation of the sulfido complex $[\{(\eta^5\text{-}C_5H_5)(CO)_2Mn\}_2S]$ with atmospheric oxygen to give **3**. Aside from color and molar mass, our findings are not reconcilable with those already published[1b]; rather, it would seem that **3** can form two structural isomers, depending on the synthetic route used; that is, two structures which differ in the electron-donor ability of their SO bridge (3c2e system).

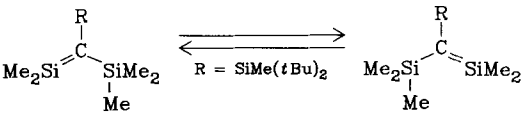
Isolation and Structure of a Stable Molecule Containing a Silicon-Carbon Double Bond**

By *Nils Wiberg**, *Gerhard Wagner*, and *Gerhard Müller**



The stable, tetrahydrofuran (THF)-containing silaethene **1** is obtained in crystalline form in THF[1a]. By the same reaction sequence, the THF-free **2** is formed in diethyl ether in ca. 60% yield. It could not, however, be isolated

from the reaction mixture in crystalline form[1b]. Its existence was demonstrated by characteristic trapping experiments[1b, 1c] as well as by the formation of **1** upon addition of THF to **2**:

$$\mathbf{2} + \text{THF} \rightleftharpoons \mathbf{1}$$

We have now succeeded in converting **1** into crystalline **2** by removing THF from **1** by azeotropic distillation with benzene (see Experimental Procedure). The silaethene **2** ($M^{\oplus}$: m/z 300) forms colorless prisms which are stable at room temperature but decompose above 65°C over the course of several days. The ^{1}H-NMR spectrum (90 MHz, $C_6D_5CD_3$, 30°C: $\delta=0.55$ (very broad, Me_2Si, Me_3Si, MeSi), 1.26 (sharp, tBu_2Si)) indicates a rapid methyl exchange, which was also observed for the silaethene $Me_2Si{=}C(SiMe_3)_2$[1c, 2].

The X-ray structure analysis (Fig. 1)[3] shows an essentially planar $C_2Si{=}CSi_2$ skeleton for **2** (the sums of the valence angles at Si1 and C1 each 360.0°[4]). The torsional distortion along the Si=C bond amounts to only 1.6° (Fig. 2). The deviations of the valence angles at the unsaturated centers Si1 and C1 from standard sp^2 values may be easily explained by the steric strain exerted by the $SiMe_3$ and especially the $SiMe(tBu)_2$ groups at C1.

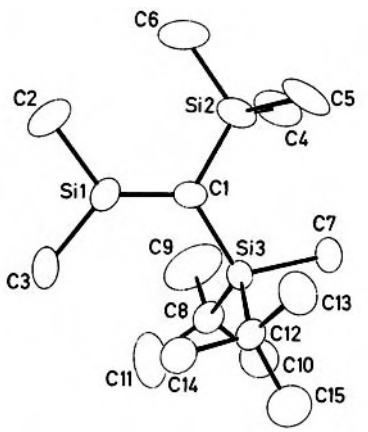


Fig. 1. Structure of **2** in the crystal (ORTEP, thermal ellipsoids 50%). Important distances [Å] and angles [°]: Si1–C1 1.702(5), Si1–C2 1.851(5), Si1–C3 1.842(5), C1–Si2 1.865(5), C1–Si3 1.890(5), C1–Si1–C2 127.0(3), C1–Si1–C3 129.0(2), C2–Si1–C3 104.0(3), Si1–C1–Si2 119.5(3), Si1–C1–Si3 122.8(3), Si2–C1–Si3 117.7(2).

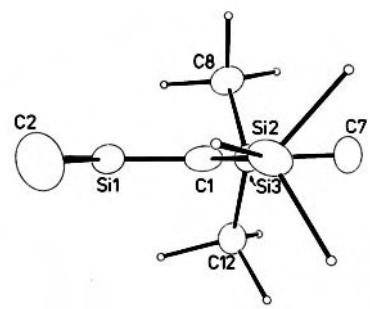

Fig. 2. View of **2** perpendicular to the plane of the double bond (methyl groups at Si2, C8, C12 with arbitrary radii). Angle of planes Si1C1C2C3–C1Si1Si2Si3 = 1.6°.

[**] Part 9, Unsaturated Silicon Compounds; Part 60, Compounds of Silicon. For Part 8 (Part 59) see [1c].

The length of the Si=C bond, the subject of considerable controversy[5a], is 1.702(5) Å in **2**. Thus, it fits astonishingly well into the range of 1.69–1.71 Å predicted theoretically by ab initio calculations[5]. Compared to a typical Si–C bond (1.87 Å), the observed Si=C distance is shortened by ca. 0.17 Å (shortening C–C→C=C: 0.19 Å). It is drastically shorter than the Si=C bond in the silaenol ether $(Me_3Si)_2Si{=}C(OSiMe_3)$(1-adamantyl) (1.764(3) Å[6]), which is twisted by 14.6°. The reason for the bond length and torsional distortion of this Si=C bond is thought to be the bulkiness of the substituents as well as the high electronegativity of the $OSiMe_3$ group[5,6]. Since the silaethene **2** contains less bulky and not particularly electronegative substituents, the observed Si=C bond length in **2** should be representative for silaethenes $R_2Si{=}CR_2$ with moderately bulky substituents R = H, alkyl, silyl. The previously found Si=C bond length of 1.747(5) Å in the THF adduct **1**[1a] had already indicated that the Si=C distance in unsaturated systems like **2** should be shorter than in the aforementioned silaenol ether. The observed double bond geometry of the silaethenes shows close resemblances to that of ethenes. This implies a similar bonding situation in both systems.

Experimental Procedure:

The benzene from a solution of 1.5 mmol of crystalline **1** (prepared according to [1a]) in 25 mL of anhydrous benzene contained in a flask A was distilled in high vacuum into a flask B which had been cooled to −78°C and contained 10 mmol of pure LiBu as a THF scavenger. By cooling A to −78°C and warming B to room temperature, the benzene was distilled back into A. After repeating this process 40 times, 1 mL of anhydrous pentane was distilled onto the benzene-free residue in A. The pentane solution thus obtained was cooled to −90°C for 2–3 d (formation of seed crystals) and subsequently to −78°C. The pentane was decanted off and the crystals were dried in vacuo.

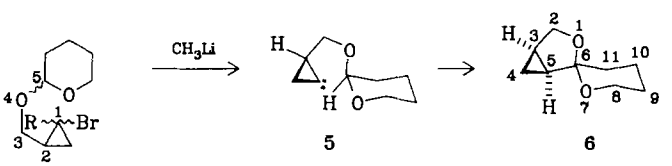
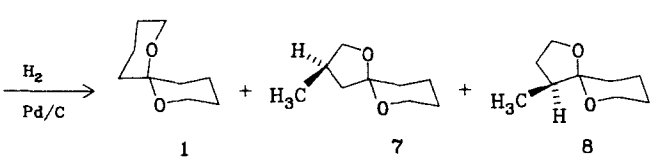
Spiroacetal Formation by Carbene (Carbenoid) Insertion Reaction: Synthesis of the Major Constituent of the Sex Attractant of the Olive Fly *(Dacus oleae)***



By *Udo H. Brinker*, Ali Haghani,* and *Klaus Gomann*

The spiroacetal unit is a frequently occurring structural element in antibiotics and insect pheromones[2]. Herein we present a novel strategy for the synthesis of spiroacetals[3], the key step of which is an intramolecular C–H insertion reaction of a cyclopropylidene (cyclopropylidenoid) (**A** → **B**). Subsequent selective opening of the three-membered ring in **B** should enable the synthesis of methylated spiroacetals and(or) spiroacetals with expanded rings.



To test this synthetic concept we chose 1,7-dioxaspiro-[5.5]undecane **1**, the prototype of some spiroacetals isolated from natural products. **1** is the major constituent of the sex attractant of the female olive fly *Dacus oleae* (Gmelin); the biological activity of the racemate has been confirmed by field experiments[4].

[**] Carbene Rearrangements, Part 18. This work was supported by the Fonds der Chemischen Industrie. We thank Dr. *W. Dietrich*, Priv.-Doz. Dr. *H. Duddeck*, and Dr. *M. Kaiser* for recording the 2D-^{1}H-NMR (NOESY and COSY) spectra of **6** and Dr. *D. Müller* for the GC-MS determinations.—Part 17: [1].

Addition of allyl alcohol to 3,4-dihydro-2*H*-pyran **2** in the presence of traces of hydrochloric acid[5] affords the acetal **3** (yield: 85%). Dibromocarbene, generated by phase-transfer catalysis, adds to the double bond of **3**[6] with formation of two diastereomers **4a** (ratio ca. 1:1, yield: 64%). Reaction of **4a** with methyllithium in ether at $-75\,^{\circ}C$ leads to formation of the tricyclic spiroacetal **6**[6] as main product (20%, not yet optimized), along with the bromocyclopropane compounds **4c** (ca. 15%)[6,7] and the methylated diastereomers **4d** (ca. 5%).

The tricycle **6** is the product of an intramolecular insertion of the cyclopropylidene(oid) into the tertiary C–H bond of **5**. Dreiding models show that this "activated"[8] C–H bond, flanked by two oxygen atoms, is located in a favorable position for the insertion. Insertions into C–H bonds adjacent to a heteroatom (O[9], N, S) with formation of a five-membered ring are well-known[8]. Compounds resulting from insertion into secondary C–H bonds in the α-position to the oxygen atoms are, according to the mass spectrum of the crude mixture (coupled GC-MS), not formed. Accordingly, **6** is the only product formed on reaction of the carbene(oid) **5**[10]. The exclusive formation of **6**, in which the cyclopropane ring and the oxygen atom of the six-membered ring are located on the same side of the molecule[10], could be due to the fact that no steric interaction of the geminal three-membered ring protons on C-4 with the protons on C-11 takes place in the transition state of the insertion reaction. This stereoselectivity could also be favored by an intramolecular complexation in **4b**. After coordination of the lithium by the oxygen atoms in **4b** and subsequent LiBr cleavage, the resulting carbene(oid) **5** can insert into the tertiary C–H bond.

No allene could be detected by IR and ^{1}H-NMR spectroscopic examination of the crude mixture formed in the reaction of **4a**. The two oxygen atoms in **5** would therefore also appear to prevent a competing cyclopropylidene-allene rearrangement at $-75\,^{\circ}C$[9b,11]. On the other hand, reaction of **4a** at room temperature leads to formation of an allene as well as **6**. **4c** and **4d** could be formed by protonation and methylation of **4b**, respectively[7]. The hydrogenation[12] of **6** (10% Pd on activated charcoal, CH_3OH, 5 bar, 25 °C) affords 3- and 4-methyl-1,6-dioxaspiro[4.5]decane **7** and **8**, respectively (1.5:1) and the natural product **1**[5,13] in an overall yield of 80% (**7** + **8** : **1** = 1.75 : 1).

[6] The structures of the new compounds are confirmed by IR, MS, and ^{1}H-NMR spectra; **6**: ^{13}C-NMR (100.6 MHz, $CDCl_3$): δ = 6.3 (t, C-4), 14.6 (d, C-5), 20.3 (t, C-10), 25.4 (t, C-9), 25.5 (d, C-3), 31.0 (t, C-11), 61.6 (t, C-8), 68.0 (t, C-2), 105.0 (s, C-6). **4a**, **6**, and **7** + **8** gave correct elemental analyses.
[7] The relatively large amount (ca. 15%) of **4c** could be explained as follows: The bromocyclopropane compounds **4c** can be formed from *both* diastereomeric dibromocarbene adducts **4a**. Two diastereomeric carbenoids are generated in the reaction of diastereomers **4a** with methyllithium. Of these, only **5** appears to undergo the insertion reaction, since the spiroacetal diastereomeric to **6** was not detected[10]. Since this as well as other reactions apparently do not take place in the case of the other diastereomeric carbenoid, **4b** can, e.g., be protonated almost exclusively to **4c** in the aqueous work-up procedure.

[10] Formation of the spiroacetal diastereomeric to **6**, in which the cyclopropane ring and oxygen atom O-7 are on opposite sides of the molecule, is not observed. This isomer would result from the reaction of the other diastereomer **4a** with methyllithium. The differentiation of these compounds and the structure assignment to the structure **6** is based on the NOESY experiment. The proton on C-4 *endo* to O-1 shows only cross peaks with the protons of the three-membered ring and with the proton H-2 located on the same side of the molecule. On the other hand, a much more distinct nuclear Overhauser effect should be observed for the H-4_{endo}–H-11 interaction in the case of the other isomer, since the distance between these protons is considerably shorter than that between H-4_{endo} and H-2.

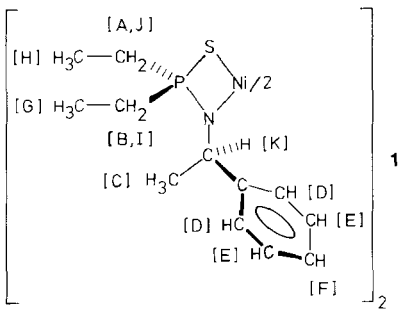
The First Application of 2D-NMR to the Spectral Analysis of a Paramagnetic Complex. Example: Bis[*R*-(+)-*P*,*P*-diethylthiophosphinic acid-*N*-α-methylbenzylamido]nickel(II)



By *Wilfried Peters*, *Manfred Fuchs*, *Hermann Sicius*, and *Wilhelm Kuchen**

Paramagnetic transition-metal complexes with short electron spin lattice relaxation times ($< 10^{-11}$ s) can be well characterized by NMR spectroscopy[1]. The assignment of the resonances to individual structural elements, however, is frequently problematic, since as a result of line broadening a fine structure of the signals is usually lacking[2]. Using the nickel complex bis[*R*-(+)-*P*,*P*-diethylthiophosphinic acid-*N*-α-methylbenzylamido]nickel(II) **1** as example, we wish to demonstrate that such problems of assignment can be elegantly solved with the aid of the 2D-NMR technique[3].

1 is obtained according to

$$2\ R\text{-}(+)\text{-}Et_2P(S)NCH(Me)Ph^-Li^+ + NiCl_2 \longrightarrow 2\,LiCl + \mathbf{1}$$

1

in the form of dark green crystals[4]. The complex, extremely sensitive to hydrolysis, is monomeric in benzene. It is paramagnetic (3.11 B.M., 291 K) and shows the following absorptions in the UV/VIS spectrum (toluene): $\tilde{\nu}(\varepsilon)=6200$ (40), 12270 (40), 17450 (145) cm^{-1} (L mol^{-1} cm^{-1}). **1** therefore contains the pseudotetrahedral chromophore NiN_2S_2[5]. As a result of the paramagnetism the phosphorus resonance in **1** ($\delta=414$, 293 K) shows an extremely strong downfield shift compared to that of the free ligand ($\delta=73$) and that of the analogous diamagnetic zinc complex ($\delta=81$).

The bis-chelate complex **1** has three chirality centers (2C, Ni); hence during its synthesis a mixture of the diastereomers (+, Δ, +) and (+, Λ, +) should be formed. However, only the number of resonances corresponding to one form is observed in the NMR spectra (^{31}P, ^1H), a finding which can be ascribed to rapid Δ-Λ isomerization[6]. As a result of the chirality, both the two ethyl groups on the phosphorus as well as the two methylene protons of each ethyl group behave diastereotopically.

In the 200-MHz ^1H-NMR spectrum of a 0.1 M solution of **1** in [D_6]benzene, eleven characteristic resonances (A—K) are observed (Table 1). They cover the unusually wide range from $\delta=+263.1$ to -9.5.

Table 1. 200-MHz ^1H-NMR data of **1**, $c=0.1$ M in [D_6]benzene, 293 K. Internal standard: benzene.

Resonance	$\delta(^1H)$	Rel. int.	Resonance	$\delta(^1H)$	Rel. int.
A	28.6	1	G	3.6	3
B	24.2	1	H	0.0	3
C	20.5	3	I	−9.0	1
D	19.1	2	J	−9.5	1
E	11.4	2	K	263.1	1
F	6.7	1			

Since the scalar couplings $^nJ_{HH}$ and $^nJ_{PH}$ (n=2—4) are not resolved, conventional methods of NMR spectroscopy cannot be resorted to for the structure interpretation. The coupling relationships not evident in the 1D-NMR experiment, however, are elegantly rendered visible by $^1H,^1H$-correlation spectroscopy (COSY[7]).

The signals A, J, H and B, I, G of the ^1H-homoscalar correlated 2D-NMR spectrum at 200 MHz[8] (Fig. 1) can be assigned by direct inspection to the CH_3—CH_2 groups. A precise stereochemical interpretation of the $\delta(^1H)$ values (Table 1), however, is not possible with the present state of the art, i.e. the notations A and J just as B and I of the resonances of one CH_2 group can be exchanged, as also A, J, H and B, I, G.

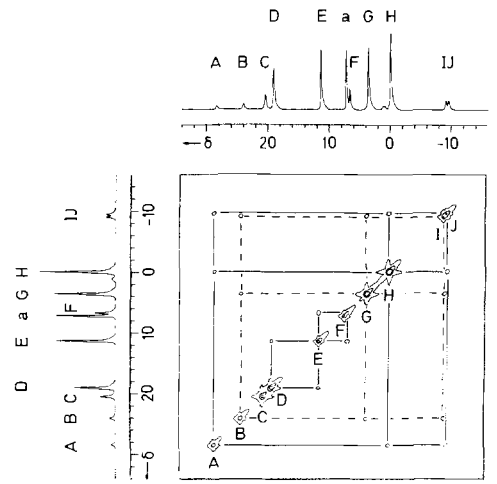

Fig. 1. Homoscalar correlated 2D-^1H-NMR spectrum (COSY 90) of a 0.1 M solution of **1** in [D_6]benzene at 293 K [8]. Size of matrix 512 × 2048, spectral width in F_1 and F_2 10000 Hz, measuring frequency 200.13 MHz, measuring time ca. 16 min, Bruker AM200 spectrometer. The resonance signals of **1** are denoted by capital letters. a: Benzene.

The observed nonequivalence of the methylene protons A, J and B, I with values of $\Delta\delta=38.1$ and 33.2 respectively, is unusually large. Corresponding values of diamagnetic compounds are lower by a factor of about 100[9]. On the basis of their intensities and their coupling behavior, the resonances D, E, F can be unequivocally assigned to the phenyl group: F to the proton in the *para*-position, E to the *meta*- and D to the *ortho*-protons. Resonance C does not couple with any of the other resonances in Figure 1. Therefore, and because of its relative intensity (3 protons) C is assigned to the methyl group on the chiral C-atom. The resonance shifted strongly downfield at $\delta=263.1$ is assigned to the hydrogen atom K, which of all protons is closest to the paramagnetic center.

The signal-structure assignment described here is, to our knowledge, the first example of a successful 2D-NMR correlation of a paramagnetic complex. The 2D-technique also proved to be an efficient method for the interpretation of the structure of the corresponding Ni^{II}-complexes with the achiral ligands $Et_2P(S)NR^-$ (R = Ph, *cyclo*-hex, *t*Bu)[10]. It thus extends the arsenal of suitable methods for the investigation of the structures of paramagnetic coordination compounds. The extremely short relaxation times compared to those of diamagnetic compounds turn out to be exceptionally favorable with regard to the time of measurement[11].

[7] COSY = Correlated Spectroscopy: impulse sequence $[D_1 - \pi/2(x) - t_1 - \pi/2(x) - t_2]$. D_1 is the time required for establishment of equilibrium magnetization. t_1 is variable and is determined by number of data and spectral width, while t_2 is the recording time of the normal 1D-NMR spectrum. The data matrix had 512 (t_1) × 2048 (t_2) points. The FID signals were multiplied in both directions by a gaussian function. After the Fourier transformation the resolution in the F_1 and F_2 direction was 9.8 Hz at a spectral width of 10000 Hz in each case.

[8] Resonance K cannot be taken into account in the 2D-NMR experiment since an extension of the range of measurement from 10000 to 60000 Hz leads to too great a loss of digital resolution.

[10] W. Peters, M. Fuchs, W. Kuchen, unpublished.

[11] In the case of the paramagnetic complexes investigated by us D_1 (see COSY impulse sequence) can be set to times $\leq 10^{-3}$ without any loss of information. The measurement of corresponding diamagnetic compounds, on the other hand, requires D_1 times between 1 and 5 s.

BOOK REVIEWS

Modern Synthetic Methods 1983. Vol. 3: Transition Metals in Organic Synthesis. Edited by *R. Scheffold.* Salle + Sauerländer, Frankfurt (for the Federal Republic of Germany, Austria, Switzerland); Wiley, Chichester (for other countries) 1983. 440 pp., paperback, DM 48.00.

The Seminars on Modern Synthetic Methods held in Interlaken are aimed at providing an easy access to important and rapidly developing areas of synthetic organic chemistry. The 1983 Seminar was dedicated to the explosively growing contribution of transition metal chemistry to organic synthesis. The present book restores the remarkably successful conference in a preservable form.

The volume comprises five chapters. The introductory chapter written by *J. K. Stille* (60 pages, 115 references) deals generally with the "Principles of Transition Metal Chemistry", which include the basic structure and bonding in organometallic compounds and fundamental reactions such as oxidative addition, reductive elimination, insertion, nucleophilic addition to coordinated ligands, transmetalation, etc., with emphasis of the relevant mechanisms. The final section describes some representative homogeneous catalytic processes which are achievable by combination of the above simple reactions, typical examples being the Wacker process, Monsanto acetic acid synthesis, transition metal-catalyzed C–C coupling reactions, rhodium-catalyzed olefin hydrogenation, decarbonylation and hydroformylation promoted by rhodium complexes, oxo reactions, and nickel-catalyzed olefin hydrocyanation.

The second chapter by *L. S. Hegedus* is concerned with "Group VIII Transition Metals in Organic Synthesis" (78 pages, 127 references). This is an excellent collection of the classic works in this area and introduces the largely stoichiometric use of nickel, iron, and palladium complexes. This chapter is subdivided, according to the structures of the metal complexes involved, into reactions of carbonylmetal compounds, alkyl complexes, olefin complexes, and π-allyl complexes. Here, particular emphasis is placed on the demonstration of the usefulness of these complexes in natural product synthesis.

The following three chapters deal successively with some specific elements and metal complexes of increasing synthetic importance. *J. F. Normant* et al. present a progress report on "Organocopper and Organomanganese Reagents". Part I of this chapter (33 pages, 63 references) deals mainly with the authors organocopper-mediated stereospecific synthesis of conjugated dienes and enynes. The existing methods for the diene synthesis are also introduced. Part 2 (44 pages, 216 references) is concerned with organomanganese chemistry and outlines the preparation of organomanganese reagents, their reactions with carbonyl and various C=X type functionalities, and application to ketone synthesis. A review entitled "Titanium and Zirconium Derivatives in Organic Synthesis" is then given by *D. Seebach, B. Weidmann,* and *L. Widler* (137 pages, 218 references). These group 4 elements play a significant role as components of the catalysts used in a variety of industrial processes such as Ziegler-Natta polymerization, metathesis, and nitrogen fixation, etc.; however, the present article is restricted to the non-catalytic use of these derivatives. The systematic description is quite impressive. In the laboratory the use of these complexes stems largely from their marked selectivities rather than novel reactivity. The authors deal with the availability and preparation of the reagents and starting materials, with C–C bond-forming processes, and with functionalizations and functional group interconversions. Potential applications in various enantioselective and diastereoselective reactions are also demonstrated. The final chapter (86 pages, 285 references) is devoted to the particularly noteworthy work by *R. Scheffold, G. Rytz,* and *L. Walder* on "Vitamin B_{12} and Related Co-Complexes as Catalysts in Organic Synthesis". It is seen that the cobalt complexes including vitamin B_{12}, though finding few applications in the past, are attracting increasing attention as useful synthetic reagents or catalysts. After a brief introduction, the authors describe cobalt complexes possessing unique structures, and outline their synthesis, properties, and reactions, and application in organic synthesis. The fascinating account on vitamin B_{12}-related chemistry will amuse the readers.

Each article ends with ample literature citations up to 1981 or 1982. This book is characterized by the amount of space alotted to selected experimental procedures, which is extremely helpful to laboratory practitioners.

Organotransition-metal chemistry is now recognized as a major synthetic tool in industrial processes and in the laboratory. To present such an expansively developing area

in a single volume is not an easy task, and, consequently, it has not been the aim of this book to provide a comprehensive coverage of this wide area of chemistry. Rather a valiant efforts has been made at giving an insight into current developments in this field by suitable selection of the authors and subjects, and this concept has, in my opinion, proven successful. This book made a good impression on me; it can be recommended to all advanced students and all experienced chemists in industry and university who are involved in experimental organic chemistry.

Ryoji Noyori [NB 638 IE]
Department of Chemistry, Nagoya University (Japan)

Theoriewandel in der Wissenschaftsgeschichte. Chemie im 18. Jahrhundert. By *E. Ströker*. Vittorio Klostermann, Frankfurt am Main 1982. viii, 324 pp., hardback, DM 78.—, paperback, DM 48.—.

In recent years there have been numerous contacts between the history of science and the theory of science that have proven to be fruitful for both parties: history provides theories on the research methods and the logic of knowledge in the natural sciences with a medium for confirmation and differentiation, the modern theory of science provides historical analyses with categories and perspectives that can shed new light even on well-known sources. Along with other scholars, some of whom were active already in the eighteenth and nineteenth centuries, *Thomas Kuhn* in particular has called attention to the idea of progress in the natural sciences and the conditions that determine such progress. The dynamics of the natural sciences have increasingly come to be seen no longer only in terms of a gain in knowledge; instead, there is a growing awareness of the limitations and the losses involved here. The presuppositions for the development of natural science are ever more often viewed in connection with institutional changes and social history. Forms of such interaction with their varying accentuations according to the time and the specific field involved will prove to become an even more important theme for future studies, whereby the central question will be less concerned with the external than the immanent connections between internal and external dimensions.

The issues provide the background for *Elisabeth Ströker*'s stimulating and important study. In a concrete combination of theory and history, seventeenth and eighteenth century chemistry is presented in view of both the original sources and the scholarly discussion up to the present. This study is prefaced by a consideration of the possible and the already established connections between the theory of the history of science. This book contributes to an expansion in our knowledge both with regard to specific points as well as more general areas. One-sided deductions and approaches relying on explanations from a single cause are refuted. *Ströker* correctly indicates the danger of projecting later views into the past, for instance *Stahl*'s achievements into the phlogiston theory. The primary emphasis is consistently placed on professional and institutional backgrounds as well as on the scientists' intellectual orientations, furthermore, on the scientific mileau and its effect upon the development of a theory. *Ströker* shows that it is not at all possible—or, at least, that it is only in a relative sense possible—to speak of schools and paradigms in eighteenth century chemistry; the idea of traditions turns out to be much more accurate. The development of practical and technical fields possesses a dynamics of its own and can by no means be made primarily dependent upon the controversies regarding phlogiston chemistry. Future investigations will have to clarify the relationship between technology and the natural sciences further. In addition to these direct interconnections, there must have also been social and intellectual conditions which affected technology and the natural sciences.

This study discusses the reception and transformation of the phlogiston theory in detail and the genesis of pneumatic chemistry. The all-too-common exclusive orientation of historical presentations on oxygen is shown to be one-sided. Empirical observations led to modifications, changing theoretical and philosophical opinions also had their consequences. One might add that the phlogiston chemists' interest in the phenomenon of attraction demonstrates that this position in chemistry has a significance for the future which has been ignored by the "progressive" adherents of the oxidation theory. Professor *Ströker* points out new sources and, above all, illustrates new aspects of matters with which we are already familiar. She emphasizes connections which have been neglected in the usual histories of chemistry. *Kuhn*'s model is confronted with historical developments and structures that indicate the need for this model to be relativized and made more precise; the idea of rational argumentation and the augmentation of our knowledge as essential factors in progress is qualified and the concept of a scientific community is rendered questionable as well. *Ströker* advocates neither a univocal preference nor a univocal condemnation of any particular widespead dynamic approach. To the historian of science, this will appear as an advantage; for the theorist of science this means that he will have to continue his search for models that are further differentiated and better integrated.

Ambident Anions. By *O. A. Reutov, I. P. Beletskaya,* and *A. L. Kurts*. Plenum Publishing Corporation, New York 1983. xiii, 338 pp, bound, $ 59.50.

An introduction to the problems of the reactivity of ambident anions is followed by the most important chapter in this book, 127 pages on enolates and phenolates. The remaining five chapters on nitrites, anions of nitro compounds, cyanides, anions of heterocyclics and on other ambident anions are considerably shorter.

The Russian text was translated into English by *J. P. Michael* and was then photoprinted directly from the manuscript. This process has given rise to defects, which make the book difficult to read. On the one hand, the typeface is wearisomely uniform; on the other hand, the numerous and important tables are poorly arranged and explained. This is a very great pity in a book containing the systematic presentation of extensive experimental series. Many tables do not indicate the total yields of the alkylization and acylization reactions and it is only by addition to 100% that it is possible to guess whether the yields reported refer to the relative or absolute amount of C- or O-product. The book is made more difficult to read by the fact that only a few typed formulas are provided; the very few obvious typing errors constitute a positive feature.

The book contains almost a thousand references, chiefly

of results of the reaction of ambident anions with electrophiles. Attempts to interpret and classify the data are primarily made according to the HSAB principle of *Pearson*; the more up-to-date concepts of frontier orbital and charge interaction are largely ignored. There is a lengthy discussion of the influence of the solvent on the structure and reactivity of the salts.

All in all the book is an extensive summary of experimental results from West *and* East. The references close with 17 citations from 1977 and two from 1978. The index (25 pages) is very good and comprehensive.

Hans-Ulrich Wagner [NB 650 IE]

der Universität München (FRG)

Moleküle und Molekülanhäufungen. Eine Einführung in die physikalische Chemie. By *H.-D. Försterling* and *H. Kuhn*. Springer-Verlag, Berlin 1983. xvi, 369 pp., bound, DM 49.00.

This book provides an introduction to physical chemistry that differs in concept from most other introductions. Instead of the usual arrangement based on the practical requirements of traditional university courses, the present book is arranged so that in logical order quantum theory and statistical thermodynamics are presented before classical thermodynamics and the macroscopic description of chemical systems.

Consequently, the first part of the book opens after a short review of the experimental evidence for the quantum structure of matter with a brief and very clear introduction of the basic concepts of the quantum theory. These concepts are then extended to atoms and more complex molecules. This part which provides the basic knowledge for an understanding of the theory of chemical bonding is written so that a good and well-prepared chemistry student can master the material after the first typical undergraduate courses in physics and mathematics. It is certainly desirable to provide chemistry students as early as possible with the basic guides to the nature of chemical bonding, since both the organic and inorganic undergraduate courses make successful use of simple qualitative theoretical models for explaining structure and reactivity of molecules.

The second part of the book goes beyond the properties of individual atoms and molecules. After a clear and detailed discussion of the intermolecular forces, the kinetic theory of gases and the Boltzmann distribution law the concepts of energy, heat, work and entropy are introduced. This provides the basis for the final section which is concerned with the energetics and kinetics of chemical reactions. The book ends with a special section which considers the limitations of the concepts of physical chemistry and also discusses the evolution problem of life from the point of view of physical chemical processes.

This book which is replete with excellent explanatory diagrams and tables is highly recommended, both for its clarity and its readability. It should be of interest not only for chemistry students as a supplementary physical chemistry textbook, but also for research workers in chemistry who would like to renew their knowledge of the basic principles of physical chemistry from a different point of view.

Environmental Carcinogens: Polycyclic Aromatic Hydrocarbons. By *G. Grimmer*. CRC Press, Boca Raton, FL, USA 1983. 261 pp, bound, $ 81.50.

This book has been written by a total of 13 authors, led by *G. Grimmer* who is an internationally acknowledged authority on the analysis of polycyclic aromatic hydrocarbons (PAH), and covers, in eight chapters, the present state of knowledge concerning PAHs as environmental carcinogens. It largely consists of an updated English translation of "Luftqualitätskriterien für ausgewählte polyzyklische aromatische Kohlenwasserstoffe" (Umweltbundesamt, Berlin 1979).

Following a foreword by *H. von Lersner* and a short introduction by *D. Schmähl* the first chapter (*G. Grimmer* and *J. Misfeld* provides an overview of the strategy for the identification of PAHs as environmental carcinogens. The second chapter, from the pen of the editor alone, consists of, alongside a detailed introduction to the nomenclature, an explanation of the mechanistic aspects of the formation of PAHs during incomplete combustion processes and gives insight into the complicated area of PAH analysis. The following techniques are discussed: 1. extraction of PAHs from environmental samples such as fats, oils, foodstuffs, soot and water, 2. enrichment techniques such as liquid-liquid distribution and chromatography on solid phases, and 3. separation processes, in particular qualitative and quantitative determination by GC, TLC and HPLC. The third chapter *(G. Grimmer)* is devoted to the occurrence of PAHs in the environment. After a detailed presentation of the PAH profile as a function of the production processes (household fires, powered vehicles, cigarette smoke) the reader is provided with detailed, synoptical information concerning the contamination of air, soil, crude oil, sewage sludge and smoked foodstuffs by PAHs. After describing their uptake and distribution (*F. Pott* and *G. Oberdörster*) the fourth chapter covers their metabolism (*G. Grimmer* and *J. Jacob*). Not only the most important classes of metabolites such as phenols, arene oxides, catechols, dihydrodiols and dihydrodiol epoxides—which are thought today to be the actual carcinogens—but also the xenobiotic metabolizing enzymes (monoxygenases, epoxide hydrolases, glutathione transferases, sulfotransferases and UDP-glucuronosyltransferases) are discussed. The fifth and longest chapter (*D. Schmähl* et al.) deals with test systems for investigating the biological activity of PAHs. The short-term tests (Ames test, cell transformation tests and sebaceous gland atrophy test) which have some bearing on the carcinogenic activity of PAHs as well as the long-term tests in animal models (classified in terms of type of application) are discussed in a well arranged review. This is followed by the sixth chapter *(J. Misfeld)* in which in general introduction to the problems of epidemological investigations is followed by a critical review of studies devoted to the topic "lung cancer and air pollution" with particular reference to PAHs. The seventh chapter *(D. Schmähl)* contains a detailed discussion of the question of the transfer of experimental results from short and long-term tests to man. The last chapter *(S. Dobbertin)* contains a "quintessence" of all that has gone before from the standpoint of the discussion of emission limits for PAHs.

The index greatly facilitates the search for information in this interdisciplinary area. Each chapter is equipped with a list of references. However the literature is only covered in detail up to 1979 with the occasional reference from 1980/81. If a second edition is contemplated not only is the correction of several printing errors recommended—e.g. in Chapter 8 the atmospheric concentrations of ben-

zo[a]pyrene are quoted in ng/cm^3 instead of ng/m^3—but also the correction of the figure on p. 149 and the reference to Fig. 47 on p. 138. There is no doubt that this book fills a gap and will be a regular source of reference both for the toxicologist as well as for the scientist who is concerned with polycyclic aromatic hydrocarbons. The large quantities of information concerning various aspects of toxicology presented in this excellently compiled book justify the above average price.

High-Resolution X-ray Crystallography— An Experimental Method for the Description of Chemical Bonds

By Klaus Angermund, Karl Heinz Claus, Richard Goddard, and Carl Krüger*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

By increasing the accuracy of an X-ray analysis, results are obtained which allow one to go beyond the location of hydrogen atoms and say something about the distribution of electrons in molecules. Using several examples from organic and organometallic chemistry, the methods, problems, and results of this approach are described.

1. Introduction

The spatial arrangement of the electron density in molecules provides a direct route to an understanding of the chemical bond. In the past few years, therefore, there have been numerous theoretical[2] and experimental[3] studies that have endeavored to determine the changes in electron density that result from redistribution of the valence electrons during formation of chemical bonds.[1] Since the standard diffraction techniques used for X-ray structure determination depend on the interaction of X-rays with the electrons of atoms in a crystal lattice,[4] the diffraction patterns obtained are directly related to the distribution of electrons in the crystal and thus to the electron density distribution in the molecules.

This article describes how the electron density distribution in molecules can be observed by increasing the resolution[5] of the X-ray structure determination.[6–9] Using examples from organic and organometallic chemistry, the feasibility and limitations of this relatively new analytical method will be discussed, with particular attention being given to a critical evaluation of such analyses.

2. Methodological Aspects of High-Resolution X-ray Structure Determination

The total electron density obtained in a carefully performed X-ray structure determination is rather difficult to interpret because it is dominated by the core electrons, as is shown for a substituted anthracene[10] in Figure 1. The total electron density nevertheless contains complete information about the nature of the bonding in the molecule. In order to present this information in a more useful and visible form the concept of electron deformation density (EDD) has been introduced.[11] The EDD represents the change in the electron density that results from the deformation of the spherical charge distribution around free atoms when chemical bonds are formed. Since it is the electrons in the valence shells that are mainly redistributed during the deformation, it is they that contribute most to the EDD. The spherically symmetrical electron density distribution for a free atom can be accurately calculated by theoretical methods, and is subsequently used to calculate the scattering factors used in the standard X-ray structure determination.[12] The sum of all the electron densities of the spherical atoms placed at bonding distances from one another is known as the promolecule density,[13] and the molecule so formed the promolecule.

Figure 2 shows the promolecule density distribution in 9-*tert*-butylanthracene. The difference between the experi-

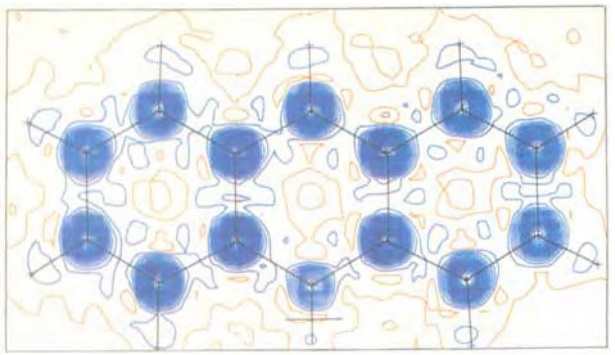

Fig. 1. Total electron density in 9-*tert*-butylanthracene **1**. In this figure as in all the following, blue lines indicate positive EDD and red negative EDD. The zero contour is yellow.

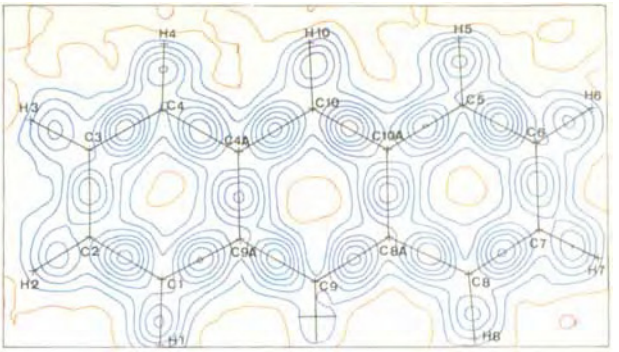

Fig. 3. Deformation density in **1**. Contour lines at 0.1 e/Å^3.

mentally determined or theoretically calculated total electron density, which describes the equilibrium state, and the promolecule density, which corresponds to a hypothetical distribution of electrons, is the EDD. A positive deformation density at a position in a molecule means that there is an increase in electron density over and above the sum of the electron densities of the free, spherically symmetrical atoms. Conversely, a negative deformation density represents a reduction in the corresponding electron density.

Figure 3 shows the deformation density in 9-*tert*-butylanthracene. A positive EDD is found between all bonded atoms. The results of numerous experimental and theoretical studies on a variety of compounds have shown that, depending on the type of atom and bond, not only positive but also negative deformation densities can be observed between atoms bonded to one another.

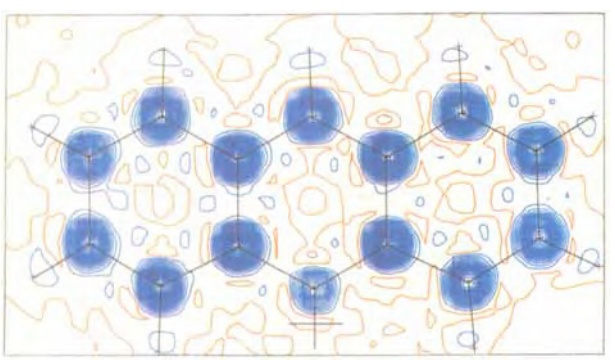

Fig. 2. Promolecule density in **1**.

The fact that a positive EDD is not observed between some types of atoms,[14] particularly those of electronegative elements, does not necessarily imply that there is no bond between these atoms, but rather reflects the difference in the valence configuration between the bonded and the free atom. This can be qualitatively explained by a simple model. When elements such as carbon, nitrogen, oxygen, or fluorine come together and form bonds, their valence configurations change. In the ensuing process electron density can be thought of as being transferred from atomic orbitals to hybrid orbitals situated further away from the atomic nucleus. Table 1 gives the approximate electronic configurations of several elements in their free and orientated (bonded) states. The configurations of the orientated atoms will depend on the type of bonding, and those given in Table 1 serve only as examples.

For the electronegative elements (N, O, F), the transition from spherically symmetric free atoms to bonded atoms also results in the formation of lone pairs. These processes are reflected in the EDD. The EDD in the bonding and lone pair regions can be derived by subtracting the population of a p-orbital in the free atom from that of the corresponding orbital in the orientated atom (see Table 1). According to Table 1, the C–C bond has a positive deformation density, whereas the EDD decreases continuously for N–N, O–O, and F–F. A comparison of the results from such a model with the experimentally determined or theoretically calculated EDD shows that in general it is possible not only to obtain the correct sign of the EDD but also a rough estimate of its value. Conversely, starting from the

Table 1. Simple method for estimating the EDD in the bonding and lone pair regions of molecules containing main group elements. The electron configuration of the orientated atoms were taken from the following molecules or groups: C, ethane; N, hydrazine; O, hydrogen peroxide; F, molecular fluorine; P, PN; S, CS.

Element	Electronic configuration		Difference (B–A) in		Ref.
	Free atom (A)	Orientated atom (B) in molecule	Bond region	Lone pair region	
C	$1s^2 2s^2 p_x^{2/3} p_y^{2/3} p_z^{2/3}$	$1s^2 2(sp^3)^1 (sp^3)^1 (sp^3)^1 (sp^3)^1$	+1/3	–	[15, 1b]
N	$1s^2 2s^2 p_x^1 p_y^1 p_z^1$	$1s^2 2(sp^3)^1 (sp^3)^1 (sp^3)^1 (sp^3)^2$	0	+1	[16]
O	$1s^2 2s^2 p_x^{4/3} p_y^{4/3} p_z^{4/3}$	$1s^2 2(sp^3)^1 (sp^3)^1 (sp^3)^2 (sp^3)^2$	−1/3	+2/3	[17, 14a]
F	$1s^2 2s^2 p_x^{5/3} p_y^{5/3} p_z^{5/3}$	$1s^2 2s^2 p_x^1 p_y^2 p_z^2$	−2/3	+1/3	[18]
P	$1s^2 2s^2 p^6 3s^2 p_x^1 p_y^1 p_z^1$	$1s^2 2s^2 p^6 3s^2 p_x^1 p_y^1 p_z^1$	0	0	[19]
S	$1s^2 2s^2 p^6 3s^2 p_x^{4/3} p_y^{4/3} p_z^{4/3}$	$1s^2 2s^2 p^6 3s^2 p_x^1 p_y^1 p_z^2$	−1/3	+2/3	[19]

EDD it is possible to obtain information about the electronic configuration of the constituent atoms.

In heteronuclear bonds (e.g., C–F) the more electronegative element contributes most to the total electron density and thus appears to determine the EDD. This explains, for example, why bonds involving nitrogen atoms have only slightly positive deformation densities while those involving fluorine have negative values.

Calculated deformation densities for species containing elements from the third row of the periodic table (e.g., PN or CS)[19] show that their bonds have smaller electron deformation densities than the corresponding bonds between lighter elements of the same group. These EDDs can be understood in terms of the small amount of hybridization of the heavier elements in the bonded state.[20]

Further predictions or interpretation of the spatial arrangement of the EDD, particularly in polar bonds and in the region close to transition metals, require consideration of additional effects, such as electronegativity and orbital symmetry. Accordingly, comparison of the magnitude of the EDD in bonds between different elements is not possible and the conclusions drawn from such comparisons may be wrong. It is just as meaningless to compare the EDD of a C–F bond with that of a C–C bond as it is to compare their bond lengths. However, if these aspects are taken into consideration, then a detailed analysis of the experimentally determined EDD provides a good description of the nature of the bonding in a molecule in a low-energy state in the crystal lattice; on the other hand, an interpretation of the theoretically calculated EDD affords a description of the nature of the bonding in the free molecule.

3. Experimental Aspects of High-Resolution X-ray Structure Determination

During the course of every X-ray structure determination, a structural model, consisting of spherically symmetrical non-interacting atoms, is optimized so as to give the best fit between the observed diffracted intensities and the intensities calculated for the model. The total electron density is then calculated by assigning phases, determined from the model, to the measured structure amplitudes. The difference between the observed electron density and the electron density for the model obtained in this way is known as the residual electron density. In favorable circumstances, its spatial distribution allows one to draw conclusions about the electron density distribution in the molecules.[21]

The atomic positions obtained during the refinement process are, however, influenced by the bonding electrons. This effect is particularly pronounced for light atoms, and is clearly illustrated by a comparison of the average C–H bond distances obtained from X-ray diffraction (0.95 Å) with those determined by neutron diffraction (1.08 Å). A more exact determination of the positions of atoms is possible using one of two experimental techniques. In the first method, the exact positions of the atoms are determined by neutron diffraction. This method requires considerable experimental effort and much larger crystals than are needed for the X-ray analysis. Since an additional X-ray structure determination is necessary in order to obtain information about the electron density distribution, problems arise from the difficulty of assimilating the two sets of results, which are necessarily obtained under slightly different experimental conditions. In the second method, the atomic positions are determined using only the X-ray diffraction data by taking advantage of the difference in the scattering ability of the core and valence electrons. A disadvantage of this method is that, in contrast to the neutron diffraction experiment, the determination of the positions of the lighter atoms is more inaccurate than that of the heavy atoms. The first technique[22] has come to be known as the X–N method;[23–27] the second technique is referred to as the X–X method.[28] At the present time the EDD determination of compounds that crystallize in acentric space groups is only possible with extreme difficulty, regardless of which method is used.[29]

The object of a high-resolution study is therefore not to obtain as small a residual electron density distribution as possible but rather to locate accurately all the atoms and to optimize all experimental parameters. Thus, the normal criteria for the estimation of the accuracy of an X-ray structure determination, such as the standard deviations of the atomic and geometrical parameters, are not sufficient for judging the accuracy of an EDD determination; instead, a comparison with theoretical calculations or with structure determinations of chemically similar compounds is necessary.

The experimental and computational effort required for a high-resolution study to allow such a comparison is much greater than that for a standard X-ray structure determination. Symmetry equivalent reflections need to be measured under different experimental conditions in order to eliminate instrumental errors and detect possible double reflections. Since thermal motion of the atoms can lead to a smearing of the observable features in the EDD, as low a measuring temperature as possible is necessary. A temperature of 100 K,[30,31] obtained by cooling the sample with a stream of cold nitrogen gas, has proved to be suitable for the experiments described here. It is essential that this temperature be maintained within a small range (± 0.5 K) over several weeks and that the crystal be kept free of ice.[31] In favorable cases, an effect similar to that of lowering the temperature is achieved when the molecules are held firmly in the crystal lattice by strong intermolecular interactions, such as hydrogen bonds. In such cases, quite acceptable deformation densities have been obtained even at room temperature.[32] A further restriction is that the crystal must be of excellent quality, and its morphology good. In order to correct for absorption effects it is necessary not only to index all the enclosing faces but also to measure them. If it proves necessary to study the substance in a capillary under an inert gas, then an additional correction for the absorption by the glass is essential.[33] Recommendations for experimental precautions have been made by the "Committee on Criteria for Publication of Charge Density Studies."[34] From the above, it is clear that the determination of deformation densities cannot be considered a routine procedure at present.

4. Determination of Deformation Density

4.1. EDDs of Organic Compounds

Several of the experimental difficulties in EDD determinations (see Section 3) are considerably reduced when heavy elements are absent. Organic compounds are thus particularly suited for studying developments in the method, and it was for this reason that the Oxalic Acid Project was initiated.[35] Subsequently, we undertook a comparative study[10] of 9-*tert*-butylanthracene **1**[36] and its valence isomer, 9-*tert*-butyl-9,10[Dewar]anthracene **2**.[37] X-ray structure determinations under standard conditions had shown that there was no molecular disorder in the crystals and that the hydrogen atoms could be unequivocally located. Both these factors are among the most important criteria for determining the crystal quality. If these conditions are not fulfilled, then a satisfactory EDD determination is rendered considerably more difficult.

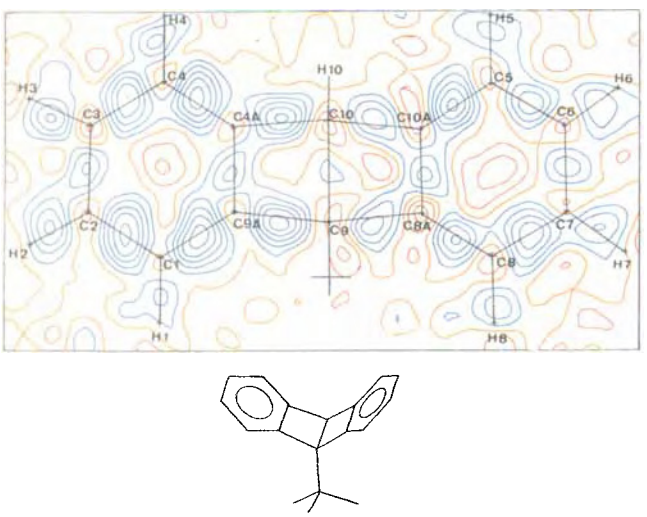

Fig. 4. Deformation density in **2**. Contour lines at 0.1 e/Å^3.

Figure 4 shows the deformation density of **2** in a similar orientation to the EDD of **1** (Fig. 3, Section 2). In **1** there is, as expected, a build up of electron density between all bonded atoms, and the EDD maxima lie on axes drawn between the atomic nuclei. A quantitative analysis (Fig. 5) shows that the observed EDD is directly proportional to bond parameters obtained by semiempirical methods, such as the bond order (calculated by HMO techniques for the idealized unsubstituted anthracene)[38] and the overlap

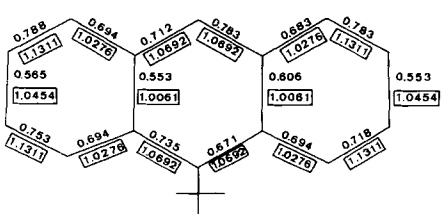

Fig. 5. Comparison of the experimentally determined EDD in the C–C bonds (e/Å^3) with overlap populations (boxes) calculated for idealized **1** by extended Hückel methods.

population (calculated by extended Hückel methods for the idealized 9-*tert*-butylanthracene).[39] Deviations from exact proportionality are only observed in the central ring of the anthracene framework. This is not planar, as was assumed in the calculations, but has a fold angle of 166.2°. The distortion can be attributed to steric interaction resulting from the large substituent at the 9-position.

In contrast to **1**, bent bonds are observed in the entire central bicyclic system of the corresponding Dewar isomer **2**. Electron density maxima are not found along the lines joining the atomic nuclei of bonded atoms, but are shifted about 0.2 Å outward.[21,40] In addition, the locations of the peak maxima in bonds involving the carbon atom at the 9-position are significantly displaced in the direction of the bridging group. This mirrors the effect that is observed in bonds between atoms with different electronegativities. The Dewar bond (C9–C10 1.623(2) Å) is also strongly bent, as can be seen in sections through the bond (Fig. 6). The bond length and the EDD suggest that this is the weakest bond in the molecule. Moreover, as can be seen in Figure 6 left, there is an additional interaction between the Dewar bond and the bonds at C9–C11 and C10–H10. The dihedral angle between the two four-membered rings along the C9–C10 bond is 113°.

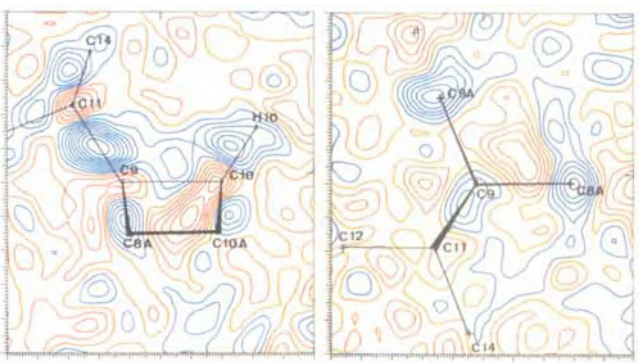

Fig. 6. Left: longitudinal section through the Dewar bond C9–C10 in **2**. Contour lines at 0.05 e/Å^3. The atoms C9, C10, C11, and H10 lie in the plane of the paper. Right: cross section through the Dewar bond. The plane cuts the C9–C10 bond at its midpoint. Contour lines at 0.05 e/Å^3.

The deformation densities given in Fig. 6 can be reproduced by ab initio calculations[41] on the model compound 1-methyl-1,4[Dewar]benzene. The corresponding sections are given in Figure 7. Very accurate ab initio calculations are necessary in order to reproduce the experimentally observed EDD. Comparison of various calculations[42] have shown that it is essential to use a large set of basis functions of at least double-ζ quality. At the present, therefore, ab initio calculations are possible for only a relatively restricted range of compounds.[2]

Nevertheless, it has been found very worthwhile to compare experimental with theoretical results to determine the effects of intermolecular interactions on the EDD of molecules in a crystal lattice since these are not usually taken into account in the ab initio calculations. The analysis of 1,2,3-triazine **3**[43,44] serves to illustrate the influence of intermolecular interactions in the crystal lattice on the EDD of the molecule. Figure 8 shows the experimentally deter-

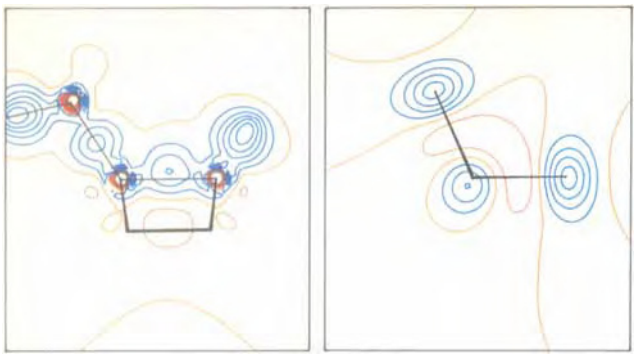

Fig. 7. Left: longitudinal section through the Dewar bond in 1-methyl-1,4[Dewar]benzene. The orientation corresponds to that in Figure 6 left. Ab initio SCF calculation with a double-ζ basis set. Contour lines at 0.1 e/Å^3. Right: cross section through the Dewar bond in 1-methyl-1,4[Dewar]benzene. The orientation corresponds to that in Figure 6 right. Ab initio SCF calculation with a double-ζ basis set. Contour lines at 0.1 e/Å^3.

mined and the theoretically calculated[45] deformation density of triazine. The theoretical deformation densities, shown in Figure 8 middle and right, have a mirror plane of symmetry passing through C2 and N2. This symmetry is also reflected in the observed bond distances (Fig. 9). According to crystallographic criteria, however, the environment of the molecule in the crystal lattice is asymmetric; this is also clearly seen in the experimentally determined deformation density (Fig. 8 left). It is immediately apparent that, in contrast to Figure 8 right, the EDDs in the C1–H1 and C3–H3 bonds differ, and the lone-pair electrons at N1 and N3 have different EDDs and spatial distributions.

An analysis of the packing of the molecules in the crystal shows that, as in 1,3,5-triazine,[46] the molecules stack in parallel layers containing triazine molecules bonded to one another by relatively long C–H···N hydrogen bonds. These layers are held together by both C–H···N hydrogen bonds and π-π bonding interactions[47] (Fig. 10). The atoms involved in these intermolecular interactions are those whose deformation density shows the greatest deviations from the theoretical density calculated for the free molecule.

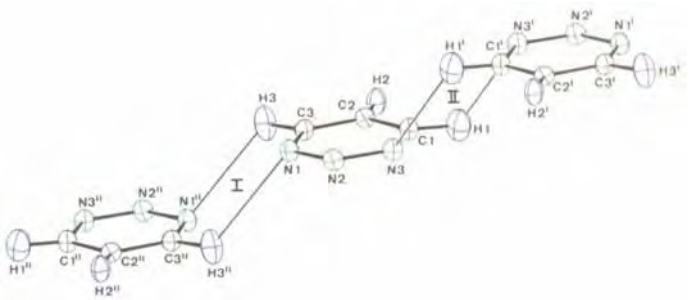

Fig. 10. Interaction between individual layers in crystalline **3**. **I** and **II** indicate the two crystallographically independent but chemically equivalent C–H···N hydrogen bonds. Each layer is represented by one triazine molecule.

Figure 11 shows the deformation density in the intermolecular regions where these interactions occur. The lone-pair electrons of N1 and N3 are clearly directed towards H3″ and H1′ on neighboring molecules. The observation of these weak interactions lies at the present experimental

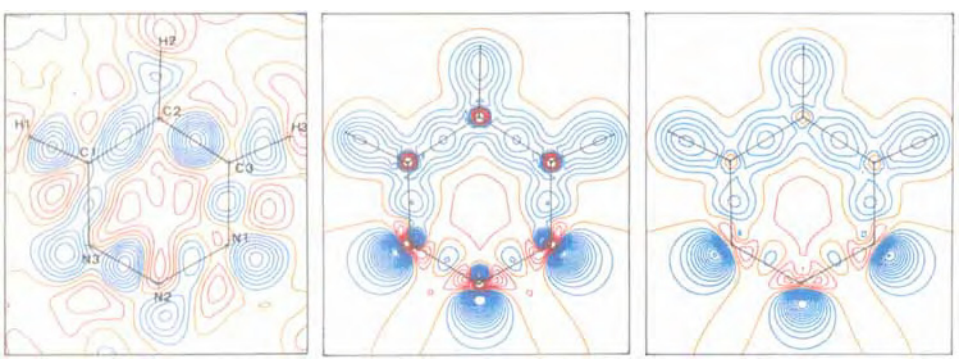

Fig. 8. EDD in **3** (mean plane through the N and C atoms). Contour lines at 0.1 e/Å^3. Left: experimentally determined EDD. Middle: theoretical static EDD (no thermal motion). limit of the technique. In this case, it is possible to estimate the experimental error. The two intermolecular interactions occur in regions that are crystallographically independent but chemically equivalent (Fig. 11). Since it is unlikely that experimental inaccuracies will manifest themselves in a similar manner in different regions of the unit cell, the agreement between the two deformation densities gives a measure of their accuracy.

The two-dimensional sections are rather unsuitable for the study and display of what are in general three-dimensional intermolecular interactions and of their effect on the

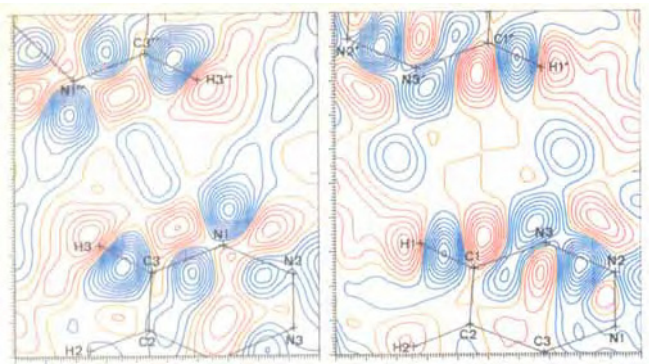

Fig. 11. The intermolecular EDD in crystalline **3** corresponding to Figure 10. Left: **I**: plane through N1, H3, N1'', H3''. Right: **II**: plane through N3, H1, N3', H1'.

intramolecular EDD. The influence of packing effects on the intramolecular EDD can be particularly well represented by a three-dimensional representation[48] (Fig. 12 left and middle), especially since the novel technique used here enables several EDD distributions to be shown simultaneously (Fig. 12 right). As shown in Fig. 12 right, the differences in the EDD in the lone pair regions are particularly large where the hydrogen bonds are formed.

The effect observed here is in disagreement with theoretical calculations on other systems, which predict the probability of observing intermolecular interactions to be quite small.[2a,49,50] Further experiments are, however, necessary in order to clarify this situation. In studies on organometallic compounds, we have already obtained evidence of the influence of packing effects on the EDD of the molecules in a crystal lattice. It was found that in substituted metal carbonyl complexes, the lone pairs on the oxygen atoms of the carbonyl groups are polarized in the direction of the neighboring molecules.[51] The differences between experiment and theory indicate that particular attention needs to be paid to intermolecular interactions when interpreting the results of a high-resolution study, even in those cases where such interactions cannot be inferred from the results of a normal X-ray structure determination.

4.2. EDDs of Organometallic Compounds

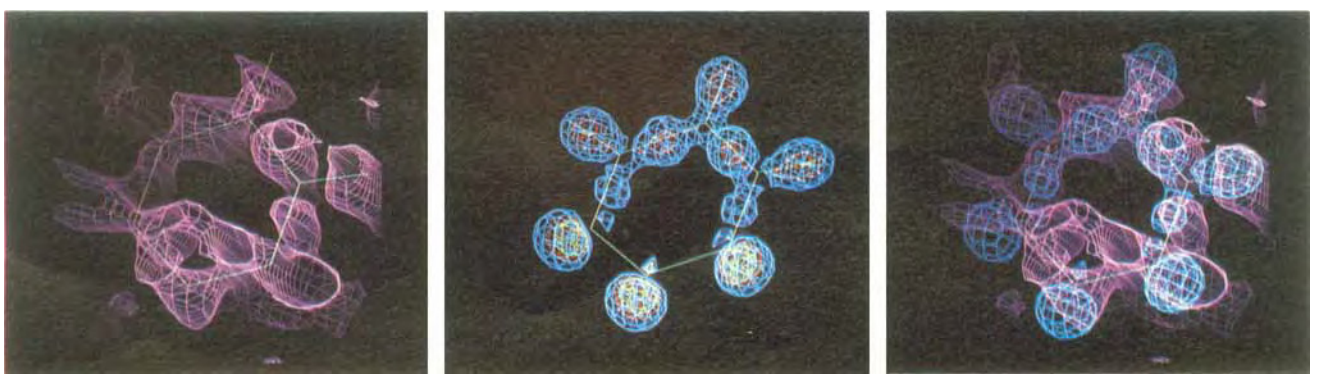
In the study of organometallic compounds, numerous additional experimental problems arise. When a heavy atom is present, the lighter atoms make only a small contribution to the total scattering of the molecule. This is one of the reasons for the increased difficulty in locating the light atoms using the X–X method. In addition, as the size of the heavy atom increases, physical effects such as absorption, anomalous dispersion, and thermal diffuse scattering of the X-rays become more important, and the measured intensities must be corrected for these. Insufficiently corrected data give poor EDD distributions with little or no information content.

In order to reduce errors to an absolute minimum, we restricted our studies at first to organometallic compounds containing metals from the fourth period (3d elements). Based on experience gained during studies on the organic compounds described above, and on oxalic acid **4** (Oxalic Acid Project)[35] an optimization of the necessary corrections was made for μ-octatetraenylbis[(η^5-cyclopentadienyl)chromium] **5**. In this study, data sets from four crystals of different sizes, grown from different solvents, were used. From the analyses, we obtained four EDD distributions, which differed only slightly in their absolute values (the number of contour lines) but which were otherwise equivalent.[55] It was shown that, in spite of the different corrections in each case, the spatial distribution of the EDD in organometallic compounds could be sufficiently well determined to allow interpretation.

The technique of measuring several crystals used here requires considerably more experimental and computational effort than is needed for organic molecules. We therefore developed a strategy that allowed us to estimate the accuracy of a single measurement. For molecules containing many electrons, a comparison of the results with those from ab initio calculations, as was the case with the organic compounds described in Section 4.1, is not always possible because of the considerable computation involved for such molecules. The following three criteria have, however, proved useful for estimating the accuracy of a single EDD determination:

1) Different transition metals with similar electronic configurations should show similar EDD distributions.

2) This should also be valid for chemically similar molecular fragments in different organometallic compounds, thus introducing the concept of the internal standard. A necessary condition is that the EDD distribution of the fragment be known from a previous study. The validity of



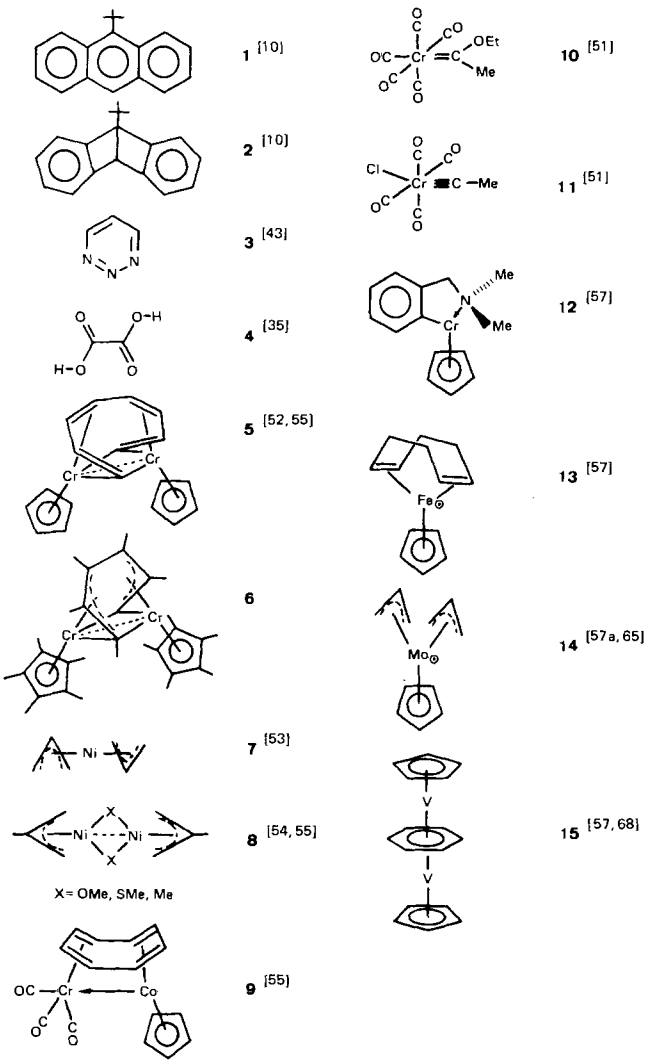


Fig. 12. Spatial representation of the electron deformation density in **3**. Contour surfaces at 0.2 e/Å^3. Left: experimentally determined EDD. Middle: theoretical EDD, calculated as for Figure 8 middle. Right: superposition of experimentally determined and theoretically calculated EDDs.

this assumption may be tested by comparing the EDDs obtained for the molecular fragment from different studies.

3) The EDDs of chemically equivalent but crystallographically independent parts of a molecule may also be compared. In such a case, the presence of a non-crystallographic symmetry allows an estimation of the experimental errors, even when comparable molecular fragments from other studies are not available (cf. intermolecular EDD in 1,2,3-triazine, Section 4.1).

These criteria are considered when we select a compound for study.

Besides EDD determinations on mononuclear organometallic complexes (e.g., **7**), several binuclear organometallic complexes (e.g., **8** and **9**) were studied in order to shed some light on the EDD distribution in metal-metal bonds. The compounds **5**[55] and **6**[56] also belong to this series. In the binuclear complex **5** there are four EDD maxima arranged in a plane about each of the symmetry-independent chromium atoms, 0.7–0.8 Å from the metals. Approximately perpendicular to the maxima and at about the same distance from the metal are two minima, one on each side of the plane. Each metal is thus surrounded by an approximate octahedron of lobes with the minima lying almost along the Cr–Cr axis (Fig. 13).

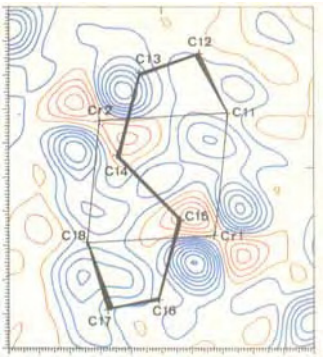

Fig. 13. Experimentally determined EDD in the plane of the metal-metal bond in **5**. Cr1, Cr2, C11, and C18 lie in the plane. Contour lines at 0.1 e/Å^3.

In complex **6** we found a planar arrangement of four EDD minima around each symmetry-equivalent chromium atom and two maxima perpendicular to these (Fig. 14), exactly opposite to that observed in compound **5**. The fact that the EDD distributions in the two chemically equivalent but crystallographically independent halves of **5** are similar (Fig. 13) and that the EDD distribution in the cyclopentadienyl ring in **6** is comparable to that observed in **5** and other compounds, supports the existence of EDD minima along the Cr–Cr axis. Further interpretation, particularly with regard to the bonding, requires additional experimental and theoretical studies on chemically similar compounds.

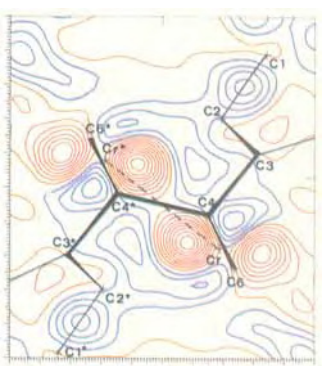

Fig. 14. Experimentally determined EDD in the plane of the metal-metal bond in **6**. Cr, Cr*, C2, and C2* lie in the plane. Contour lines at 0.1 e/Å^3.

We have also studied transition-metal complexes in which the metals are present in unusual electronic configurations (e.g., **8** and **9**) or in which an exact description of the nature of the bonding in novel ligands is required (e.g., **10** and **11**).

Compound **12**,[58] which was studied because of its unusual chemistry, belongs to the first group. In this case, an ab initio study is available for comparison.[59] The molecular structure is shown in Figure 15, which also gives several interatomic distances. The EDD distribution in a plane passing through the metallacycle is shown in Figure 16. The experimental and theoretical methods give essentially the same results. The agreement can be improved when thermal motion is taken into account in the theoretical cal-

culations (Fig. 16 right). Both the experimental and theoretical EDD distributions show an octahedral arrangement of maxima around the chromium atom, which lie 0.5–0.8 Å from the metal. The Cr atom is bonded to the ligand via a $Cr-C_{sp^2}$ bond and the aromatic π system appears to be delocalized over the chromium atom and the nitrogen

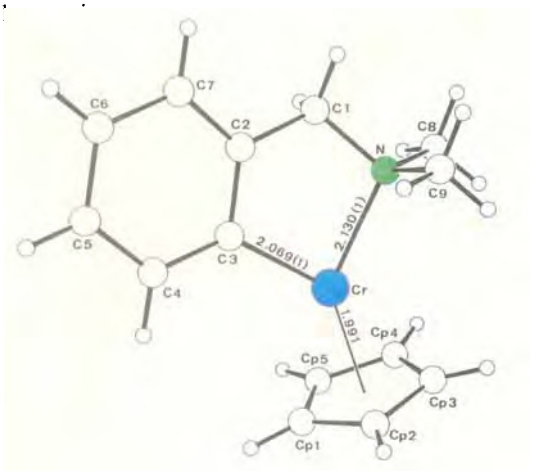

Fig. 15. Crystal structure of **12** (distances [Å]).

Application of several additional techniques allows further information to be obtained from the measured diffraction data. A direct integration of the electron density about the chromium atom[60] gave its charge as +0.3, and refinement of the valence shell populations[61] (Cr: $3d^4 4s^2$, N: $2s^2 2p^3$, and O: $2s^2 2p^4$) for a fixed total charge of zero on the molecule gave +0.43(3). These results are in accord with the theoretical calculations. Figure 17 shows a section of the EDD through two bonds in the aromatic system of the six-membered ring. Elongation of the electron deformation density of the C–C bonds in a direction perpendicular to the plane of the arene is clearly visible and is due to the π system. Although this is the first example where this has been observed in an organometallic compound, such distorted EDD distributions are already known from corresponding studies of organic compounds.[1a,62]

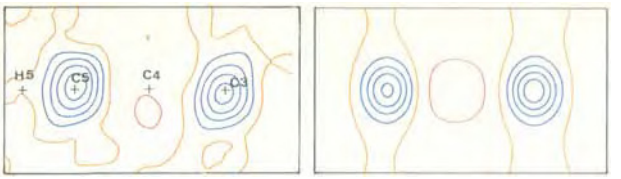

Fig. 17. Section through the benzene ring in **12**. Plane cuts the bonds C5–C6 and C2–C3 at their midpoints. Contour lines at 0.1 e/Å³. Left: experimentally determined EDD. Right: theoretical static EDD, calculated as for Figure 8 middle.

The effectiveness of the technique for clarifying the nature of the bonding in organometallic compounds will be illustrated with three further examples. It will thereby become clear that the high-resolution technique allows more than the usual interpretation of bond distances and angles.

In the two isoelectronic, paramagnetic 17e complexes 1,4-cyclooctadienyl-η^5-cyclopentadienyliron **13**[63] (Fig. 18) and bis(η^3-allyl)-η^5-cyclopentadienylmolybdenum **14**[64]

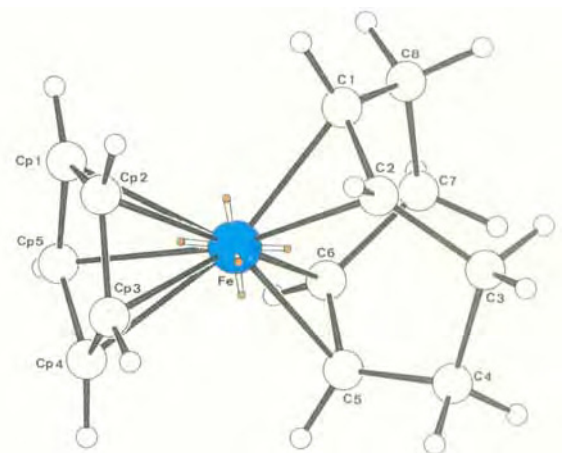

Fig. 18. Molecular structure of **13**, showing the EDD maxima around the iron atom.

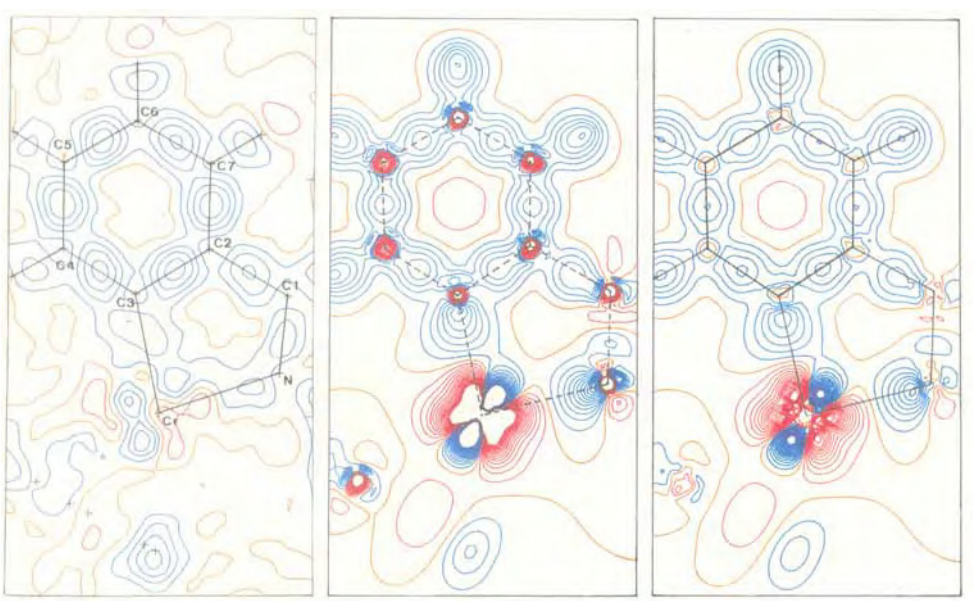

Fig. 16. EDD in the plane of the metallacycle in **12**. Contour lines at 0.1 e/Å³. Left: experimentally determined EDD. Middle: theoretical static EDD, calculated as for Figure 8 middle. Right: theoretical dynamic EDD, calculated as for Figure 8 right.

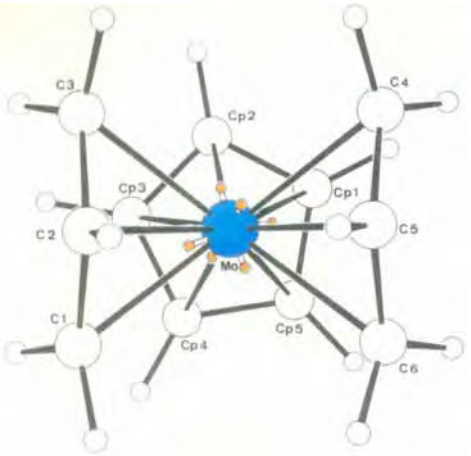

Fig. 19. Molecular structure of **14** (isoelectronic with **13**), showing the EDD maxima around the molybdenum atom.

(Fig. 19), there is also an octahedral distribution of EDD maxima around each metal atom (see Fig. 20 and 21). In both compounds one maximum is directed towards the cyclopentadienyl ring, and another, on the opposite side of the metal, is directed between the ligands. Whereas in **13** there is no interaction of this lobe with the ligands, in **14** there is a steric interaction with the *meso* hydrogen atom on the allyl group, which results in a distortion of the octahedral distribution of the EDD around the metal. As a consequence of the retention of linearity of EDD maxima on opposite sides of the metal, an asymmetry in the cyclopentadienyl ring is induced, which manifests itself in different bond lengths in the five-membered ring. The C–C bonds nearest to the EDD maximum have a higher EDD and are shorter than the other C–C bonds in the ring. The sterically determined asymmetric distortion of the EDD on the transition metal thus provides a possible explanation for the observed differences in the C–C bond distances, which have not yet been satisfactorily explained.

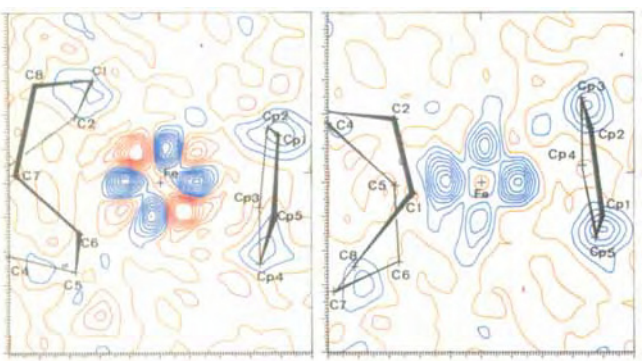

Fig. 20. Sections through the EDD maxima around the iron atom in **13**. Contour lines at 0.1 e/Å^3. Left: plane through the iron atom and the olefinic double bonds of the cyclooctadiene ligand. Right: plane perpendicular to that on the left.

Fig. 21. Section through the EDD maxima around the molybdenum atom in **14**.

The spatial arrangement of the four remaining equatorial EDD maxima in the two complexes is such that when viewed from the direction of the five-membered ring one peak eclipses one of the metal-carbon bonds to the cyclopentadienyl ligand, while the remaining three are directed between the ligands. The X-ray structure determination of the lithium adduct of **13**[66] (Fig. 22) shows that the least sterically hindered maximum is the preferred site of electrophilic attack; the position of lithium corresponds exactly to that of this EDD maximum. Thus it appears possible to determine positions of chemical attack in molecules by studying their electron deformation densities.

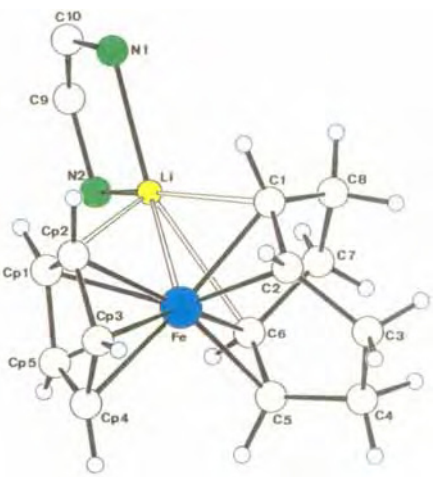

Fig. 22. Molecular structure of the 18e lithium adduct of **13**.

The stereochemical influence of the EDD distribution around transition metals provides a possible explanation for the nature of the bonding in the novel triple-decker complex **15**[66] (Fig. 23). The compound has 26 electrons in the valence shell and therefore does not obey the stability rules for triple-decker complexes put forward by *R. Hoffmann* et al.[69] According to these rules, triple-decker complexes with 30 and 34 valence electrons should be particularly stable. Closer inspection of the EDD in **15** (Fig. 24), whose structure is characterized by a center of symmetry in the central benzene ring, provides a possible explanation for the nature of the bonding in this type of compound.

As in complexes **13** and **14**, the metal atom in **15** is surrounded by an octahedral distribution of EDD maxima. The geometry of the central part of the molecule (V–V* distance 3.400(1) Å; V–C(benzene) average distance 2.236(5) Å) is such that two EDD maxima come close to one another across the center of the benzene ring. The observed distortion of the octahedra around the vanadium atoms can be explained in terms of repulsion of the two

adjacent EDD maxima since they approach one another to within 2.10 Å. The consequences of such a rearrangement of the lobes around the metal on the total bonding system are extensive. The central benzene ring can no longer be considered as a 6-electron ligand, but rather must be viewed as two 3-electron ligands due to the induced asymmetry. The result is particularly noticeable in the EDD in

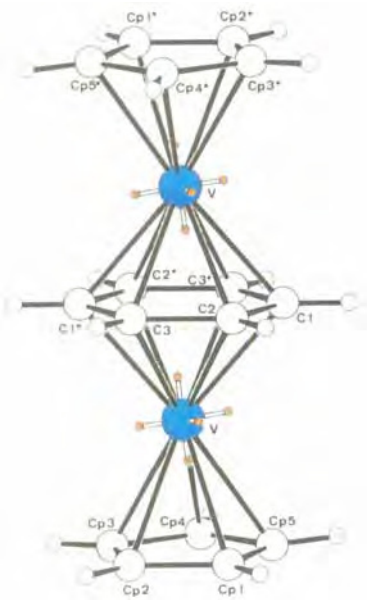

Fig. 23. Molecular structure of the triple-decker complex **15**, showing the EDD maxima around the vanadium atoms.

the plane of the six-membered ring (Fig. 24 right). A change in the bond lengths corresponding to such a distortion can only be observed in the bonds V–C1 (2.227(1) Å) and V*–C1 (2.243(1) Å). As in **13** and **14**, the reorientation of the octahedral EDD distribution in **15** results in an induced asymmetry in the cyclopentadienyl rings. Such an induced asymmetry in the bonding of the five-membered ring could possibly be the reason why the commonly observed disorder of the cyclopentadienyl ligands in sandwich complexes is not observed in this compound. The nature of the bonding in the triple-decker complex **15** can be simply explained, therefore, in terms of a separation of the π-system of the benzene ring into two three-electron units, with the assumption of 13e vanadium atoms.

5. Conclusion

The examples from organic and organometallic chemistry described here show that the experimental determination of the electron deformation density in molecules provides the chemist with a laborious, but none the less powerful technique for studying chemical compounds. This technique, together with the study of reaction paths[71] by the statistical evaluation of structural data from databases,[70] are two of the recent developments in the field of structure determination which are likely to lead to further interesting discoveries.

Many of the results described in this article result from a successful collaboration with numerous colleagues who have provided us with suitable samples. We extend our thanks to them. We are particularly indebted to the director of our institute, Prof. Dr. G. Wilke, for the continuous and generous support of our work. We also thank the Deutsche Forschungsgemeinschaft and the Max-Planck-Gesellschaft for financial support and grants.

[41] The EDD distributions were calculated by ab initio LCAO-SCF methods using the ATMOL program (*V. R. Saunders*, 1976) with idealized molecular geometries based on distances and angles taken from the X-ray analysis. The Gaussian basis sets were (10, 7, 5) for Cr, (6, 4) for C and N, and (4) for H. These basis sets were contracted to a minimal basis set for inner shells and to a double-ζ basis set for the valence orbitals. Atomic wave functions were calculated for the experimental ground state, and the electron density was spherically averaged by equally distributing the available electrons among the equivalent orbitals of the valence shell.

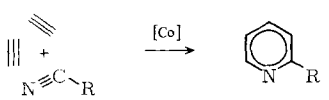
Organocobalt Compounds in the Synthesis of Pyridines—An Example of Structure-Effectivity Relationships in Homogeneous Catalysis**



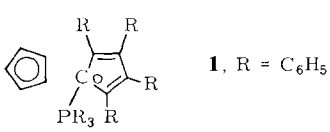
By Helmut Bönnemann*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The cocyclization of alkynes with cyano compounds using organocobalt catalysts of the type [YCoL] has evolved into a versatile and technically useful method for synthesizing pyridine and its derivatives. An important advance came with the realization that the organo group Y remains attached to the cobalt throughout the catalytic cycle. This opened up the possibility of optimizing the catalyst by varying the controlling ligand Y.

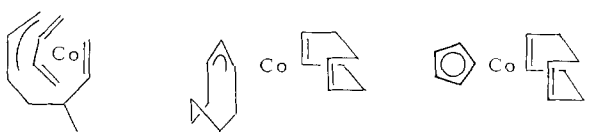
1. Introduction

Pyridine and its derivatives are technically important fine-chemicals. Their isolation from coal tar is decreasing, whereas their manufacture by synthetic methods has increased rapidly since 1950: in 1958, ca. 3700 t of pyridine and its derivatives were produced in the USA; by 1978, the yearly production had reached 14000 t, and, in 1980, it was already in excess of 16000 t. In the coming years the annual growth is expected to be 4%.[1] Aside from the parent compound most importance attaches to 2-methyl-, 2-ethyl-, 2-vinyl- and 2-amino-pyridine, all of which can be prepared selectively and in one step from acetylene and the appropriate cyano compound using soluble organocobalt catalysts [Eq. (1)].



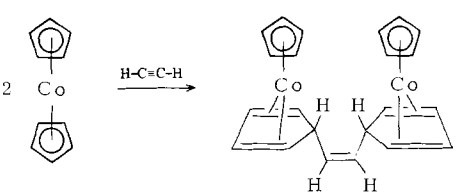
(1)

R = H, CH_3, $HC{=}CH_2$, NH_2



[Co] = soluble cobalt catalyst

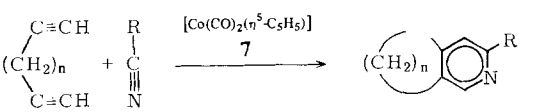
As long ago as 1876, *Sir William Ramsay*[2] obtained small amounts of pyridine on passing acetylene and hydrogen cyanide through a red-hot tube. In 1973, *Yamazaki* and *Wakatsuki*[3] first reported the homogeneous catalytic cycloaddition of alkynes and nitriles using the phosphane-stabilized cobalt(III) complex **1**.



1, R = C_6H_5

At the same time we[4] observed the catalyzed cocyclization [Eq. (1)] on cobalt catalysts prepared in situ, as well as on easily accessible organocobalt-diolefin complexes of the type **2**, **3**, and **4**.

2 **3** **4**



The Japanese authors later turned to cobaltocene **5**,[5,6] since the phosphane complex **1** proved to be unsuitable for practical purposes. *Hardt* (Lonza AG) developed various procedures for preparing pyridine derivatives with **5** as the catalyst.[7] An elegant model reaction by *Yamazaki* and *Wakatsuki*[5] showed that cobaltocene can be regarded as the precursor for the actual catalyst complex **6**: prior to the catalysis, **5** is converted by alkyne into an η^5-diene complex [Eq. (2)].

5 **6**

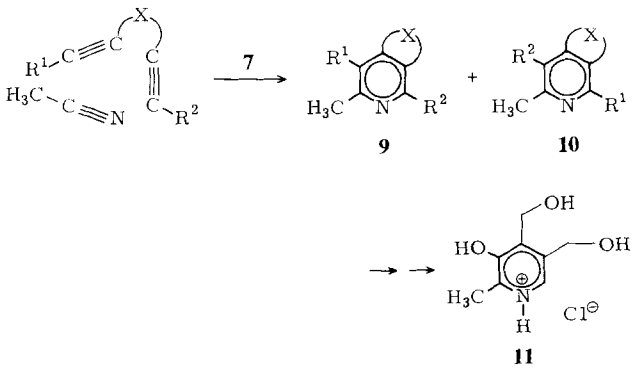
(2)

Vollhardt et al.[8,9] incorporated α,ω-diynes and nitriles in cobalt-mediated [2+2+2]-cycloadditions [Eq. (3)].

n = 3,4,5; R = alkyl, aryl, etc.

8

(3)



Using this variant of the cobalt-catalyzed cycloaddition, *Schleich* et al.[10] opened up a new route to pyridoxine (Vitamin B_6) as hydrochloride **11** (Scheme 1).

In our experience, substituents in the alkyne and in the cyano component can be widely varied, so that we have been able to develop the basic reaction [Eq. (1)] into a general synthetic method for preparing mono- to penta-substituted derivatives (for preparative results see [11,12]).

We concentrated on the development of highly reactive organocobalt(I) complexes of the type [YCoL], in particular for the homogeneous catalytic synthesis of 2-alkylpyr-

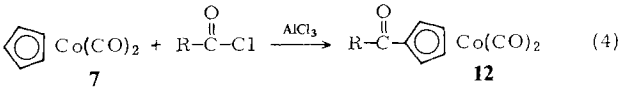
Scheme 1. Synthesis of substituted pyridines. X = O; $R^1 = R^2 = (CH_3)_3Si$; $R^1 = C_2H_5OCO$, $R^2 = (CH_3)_3Si$: ratio **9** : **10** = 16 : 1. Pyridoxine hydrochloride **11** is obtainable by secondary reactions.

idines and 2-vinylpyridine according to equation (1). Since the actual catalytic cycle occurs at a core-complex of the type [YCo], it is possible to change the properties of the catalyst by varying the organyl ligand Y.[13, 14] As shown in Scheme 2, a large number of catalyst complexes having a wide variety of Y and neutral ligands have been synthesized. The catalytic properties of these complexes were tested under standardized conditions. At first, the role of the neutral ligand was thoroughly investigated; in the subsequent catalyst-screening, the catalytic turnover number (TON) of the "controlling ligand" Y was determined.

Scheme 2. Synthesis of substituted pyridines with complexes of type [YCoL]. Y is the controlling ligand, L is the neutral ligand.

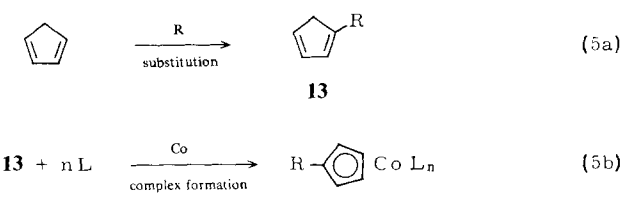


The final step involves optimization of the reaction conditions for the synthesis of 2-alkyl- and 2-vinylpyridine.

2. Synthesis of Complexes of the Type [YCoL]

In order to obtain as broad an insight as possible into the control function of the group Y attached to cobalt, we prepared cobalt complexes having mono- and multiply-substituted η^5-cyclopentadienyl, η^5-indenyl groups as well as boron-containing cyclopentadienyl and η-cyclooctenyl groups. Ethylene, various diolefins, aromatic hydrocarbons, carbon monoxide, and phosphorus-containing compounds served as the neutral ligands.

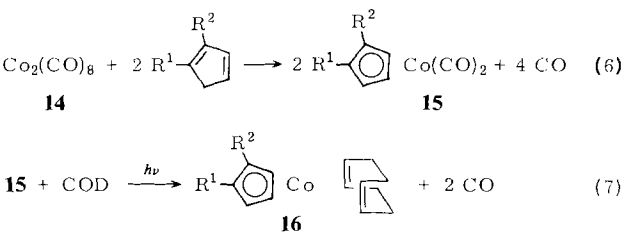
2.1. Y = η^5-Cyclopentadienyl Derivative



In contrast to ferrocene and similar compounds,[15] in the case of (η^5-cyclopentadienyl)Co^I half-sandwhich complexes only a few examples of ring substitution reactions are known. Thus, the acetyl- and benzoyl-derivatives **12**[16] are obtained on Friedel-Crafts acylation of the complex **7** [Eq. (4)].

(4)

R = CH_3, C_6H_5



For a general entry to (R–C_5H_4)Co complexes, it is first necessary to prepare appropriately substituted cyclopentadiene derivatives **13** and then in a second reaction step to complex these and the neutral ligand to cobalt [Eq. (5a), (5b)].

(5a)

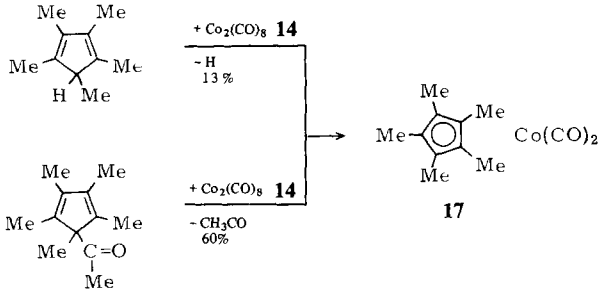
(5b)

A classic method for the complexation step (5b) involves the reaction of $Co_2(CO)_8$ **14** with monomeric cyclopentadiene derivatives, which leads to the corresponding dicarbonyl complex **15** in 70–90% yield[17, 18] [Eq. (6)].

(6)

(7)

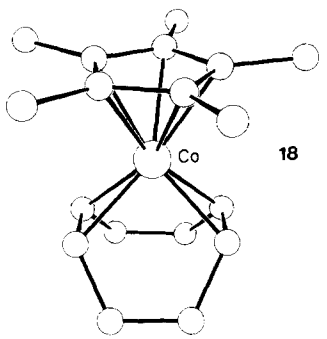
COD = 1,5-cyclooctadiene



R^1 = H; R^2 = H, CH_3, $(CH_3)_3Si$, C_6H_5

$R^1 = R^2 = (CH_3)_3Si$

The carbonyl groups can be cleaved either thermally or photochemically at room temperature. In the presence of 1,5-cyclooctadiene (COD), diolefin complexes **16** (type **4**) are obtained in high yields [Eq. (7)].



The two-step carbonyl method [Eq. (6), (7), and (8)] proved to be a very versatile catalyst synthesis on a laboratory scale.[19] The complex **17** can be prepared from either 1,2,3,4,5-pentamethylcyclopentadiene[18, 20] or methyl 1,2,3,4,5-pentamethylcyclopentadienyl ketone[21] according to equation (6). The subsequent transformation of **17** into the diolefin complex **18** is achieved in high yield by irradiation in the presence of COD[22] [Eq. (8)].

In order to stabilize the thermally unstable cyclopentadiene derivatives **13** as salts and then to react these to give the corresponding cobalt complexes under mild conditions, we adopted the approach developed by *Rausch* et

(8)

17 + COD $\xrightarrow[78\%]{h\nu}$ [(Me$_5$C$_5$)Co(cod)] **18**

18

al.[23] **14** reacts with an equimolar amount of iodine at 25 °C in tetrahydrofuran (THF) to give the intermediate **19**, which is allowed to react further with cyclopentadienide salts to yield derivatives of type **15** [Eq. (9)].

$$Co_2(CO)_8 + I_2 \xrightarrow{THF,\ 25\,^\circ C} 2\ "ICo(CO)_n" + (8-2n)CO$$

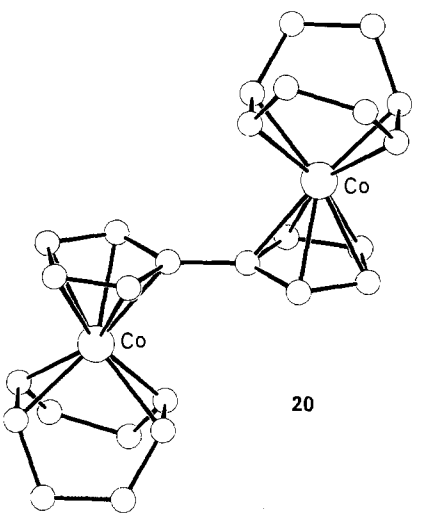
[a] Decomposition on irradiation. [b] Fulvalene derivative, cf. **20**. [c] (C$_6$H$_5$)$_4$C$_5$H instead of RC$_5$H$_4$. [d] "Monocarbonyl dimer" bridged via P, having the formula [(Ph$_2$PC$_5$H$_4$)Co(CO)]$_2$. [e] Not investigated.

The carbonyl complexes **15** were converted into the corresponding COD-complexes as shown in equation (7). The [YCoL] complexes which were prepared using the Rausch method are listed in Table 1.



We obtained the binuclear cyclooctadiene(fulvalenediyl)cobalt complex **20** in high yield and avoiding carbonyl intermediates by protolytic substitution of **2** with dihydrofulvalene [Eq. (10)].

(10)

2

[(cod)Co(C$_5$H$_4$–C$_5$H$_4$)Co(cod)] **20**

20

Using an analogous method to that developed by *Rausch* via "ICo(CO)$_n$" **19**, we devised a new synthetic route to [YCo(cod)] complexes. This approach is based on the reaction of halotris(triorganophosphane)cobalt(I) complexes with cyclopentadienide salts and subsequent displacement of both triorganylphosphane ligands with COD[19] [Eq. (11)].

$$[XCo(PR_3)_3] + LiY \longrightarrow [YCo(PR_3)_2] + LiX + PR_3$$

$$[YCo(PR_3)_2] + COD \xrightarrow{50\text{–}100\,^\circ C} YCo\text{(}C_8H_{12}\text{)} + 2\ PR_3 \quad (11)$$

R = OC_3H_7, C_6H_5; X = Cl, Br

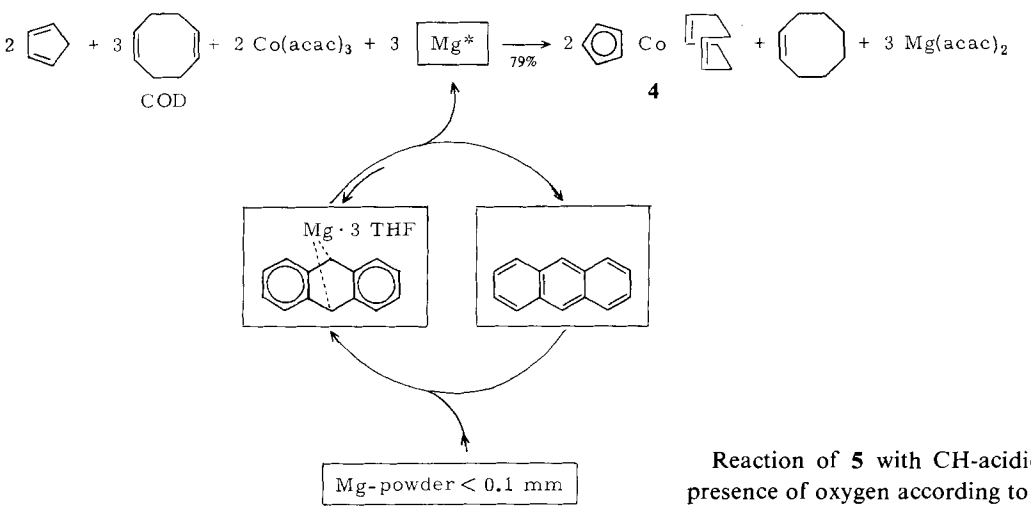
Y = 

In our search for a one-step synthesis of diolefin-complexes we developed the approach shown in Scheme 3.

In this direct reduction salts of di- and trivalent cobalt are allowed to react with various reducing agents in the presence of the substituted cyclopentadiene RC$_5$H$_5$ and the neutral ligand L to give half-sandwich complexes. Thus, Co(acac)$_3$ reacts in the presence of cyclopentadiene and COD with Al(C$_2$H$_5$)$_3$ to give **4** in 77% yield.[28] Elementary magnesium is better suited as the reducing agent in a technical direct synthesis of the catalyst complex according to Scheme 3. The magnesium is both economical

$$CoX_n + m\,Red \longrightarrow [Co] + Red_mX_n$$

Cobalt salt — Reducing agent — "Naked" cobalt



$$[Co] + RC_5H_5 + L \longrightarrow [(\eta^5\text{-}RC_5H_4)CoL]$$

Catalyst complex

L = diolefin, e.g. COD, norbornadiene, RC_5H_5, cyclohexadiene
X = Cl, Br, I, OC_2H_5, acac
n, m = 2, 3
Red = $Al(C_2H_5)_3$, $Al(C_4H_9)_3$, Na, K, Mg, Ca

Scheme 3. Synthesis of catalyst complexes with "naked" cobalt.

and easy to handle. The effectiveness of the reductant is however dependant on its active surface area: if magnesium is employed in Scheme 3 without any special precautions, then the catalyst complex is obtained in only ca. 10% yield due to only partial reduction of the cobalt salt. A substantial improvement was achieved when it was found that the addition of 3–6 mol-% of anthracene to the magnesium powder acts as a phase transfer catalyst to dissolve the magnesium. This "organic soluble" magnesium (Mg*) is quasi-atomic and is therefore able to totally reduce transition metal salts[29] (Scheme 4).

Scheme 4. Preparation of anthracene-activated magnesium (Mg*).

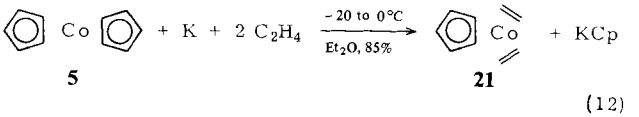


Table 2. Direct synthesis of $[(\eta^5\text{-}RC_5H_4)Co(\eta^4\text{-diolefin})]$ complexes using anthracene-activated magnesium (in analogy to Scheme 4). Numerical values: mmol.

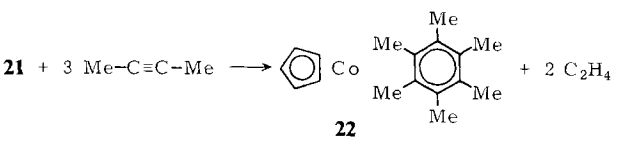
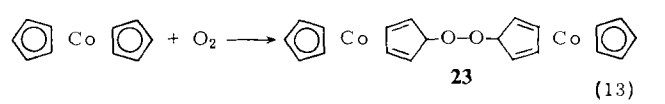
Me_3Ge	cod	5	15	0.3	5.5	11	30	[19]



[a] Starting from 1-methyl-1,3-cyclopentadiene.

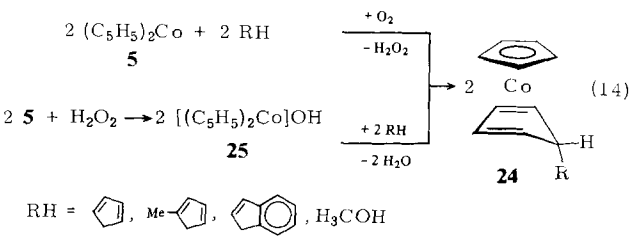
The resulting "naked cobalt" is stabilized by complexation with olefins. The direct reduction of cobalt salts with anthracene-activated magnesium in THF in the presence of cyclopentadiene or its derivatives and diolefin neutral ligands, in particular COD, represents the currently most economical route to $[(\eta^5\text{-}RC_5H_4)Co(\eta^4\text{-diolefin})]$ complexes (Table 2).



Two routes to give $[(\eta^5\text{-}C_5H_5)CoL]$ systems by varying the neutral ligand L involve transformations of cobaltocene **5**. The displacement of one cyclopentadienyl moiety from **5** with potassium in the presence of ethylene, as described by *Jonas* et al., smoothly yields the bis(ethylene)complex **21**, which reacts with 2-butyne to give the 20-electron system **22**[32] [Eq. (12)].

(12)

Reaction of **5** with CH-acidic organic reagents in the presence of oxygen according to the method developed by *Kojima* and *Hagihara* et al.[33] leads to $[(\eta^5\text{-}C_5H_5)Co]$-complexes which contain substituted η^4-cyclopentadiene groups as stabilizing neutral ligands [Eq. (13)].



(13)

RH = H_5C_6–C≡CH, H_3C–CO–CH_3, H_3C–CN, H_3C–CH_2–CN, $HCCl_3$
(56%, 70%, 87%, 51%, 97%)

The reaction proceeds via the peroxy bridged complex **23**. In the presence of CH-acidic compounds, the peroxy bridge is cleaved with liberation of H_2O_2 and formation of the η^4-R–C_5H_4 complex **24**. With the intention of convert-

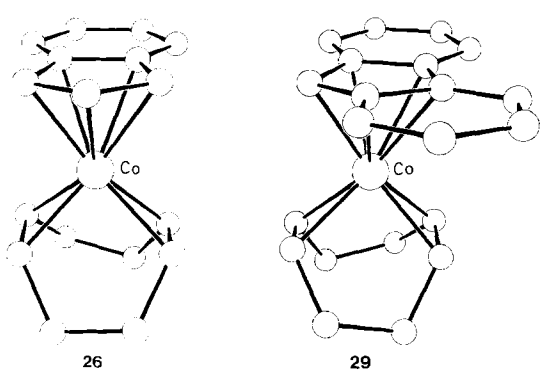
ing cobaltocene **5** into active catalyst complexes of type **24** using simple reagents, we extended the experiments of the Japanese authors[33] to reactions of **5** with cyclopentadiene, methylcyclopentadiene, indene, and methanol in the presence of oxygen [Eq. (14)]. In this way the transformation of an η^5-cyclopentadienyl group into an η^4-cyclopentadiene system having *exo*-substituents was achieved in all cases (yields 30–60%).[19,34]

(14)

The same result was obtained by reaction of **5** with H_2O in the presence of CH-acidic compounds.[19] The intermediate cobaltocenium hydroxide **25** is as basic as the alkali-metal hydroxides[35] and abstracts the proton from the acidic reagent RH to give water. The anion $R^{\ominus}$ undergoes nucleophilic addition to the cobaltocenium ion, and the formation of **24** is accompanied by a change in color from yellow to red.

2.2. Y = Annelated η^5-Cyclopentadienyl Derivative

The η^5-indenyl complex **26** (Fig. 1) was first prepared (in 50% yield) by *Samson* by protolytic substitution of **2** with indene (cf. [36]). The reduction of $Co(acac)_3$ with anthracene-activated magnesium in the presence of indene and COD in an analogous manner to Scheme 4 affords **26** in good yield.[37,38]



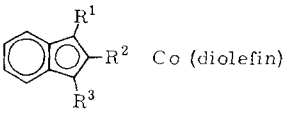


Fig. 1. Structure of η^4-cyclooctadiene(η^5-indenyl)cobalt **26** [38] and η^4-cyclooctadiene(η^5-fluorenyl)cobalt **29** [40] in the crystal.

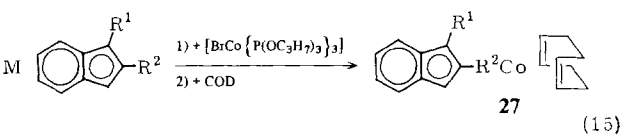

Analogues of **26** having substituted indenyl groups are readily prepared from indene derivatives, diolefins and cobalt salts by direct reduction with anthracene-activated magnesium (cf. Table 3).

Limitations to the direct synthesis are encounted when certain groups on the indene (e.g. amino- and halo-substituents) react with the activated magnesium. In these cases the indirect approach involving reaction of indenide salts with halotris(phosphite)cobalt(I) complexes and subsequent exchange of the phosphite with COD[24] must be resorted to [Eq. (15)].

Table 3. Synthesis of [(η^5-R^1,R^2,$R^3C_9H_4$)Co(η^4-diolefin)] complexes using anthracene-activated magnesium (in analogy to Scheme 4). C_9H_7 = indenyl. The complexes with 1-monosubstituted indenyl moiety were prepared from 1-substituted indene. Exception: $R^1 = C_6H_5$ from 3-phenylindene. Numerical values: mmol.

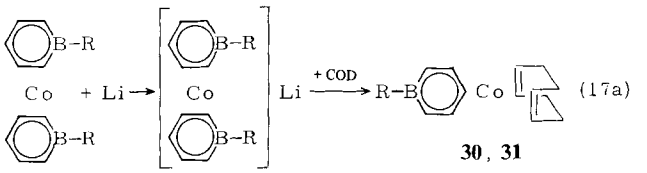
The η^5-fluorenyl complex **29** is obtained in almost quantitative yield on reaction of the bis(phosphite) complex[39] **28** with excess COD at 100 °C [Eq. (16)]. The bonding in **29** has been confirmed by X-ray structure analysis[40] (Fig. 1).

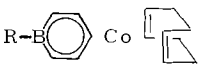


(16)

2.3. Y = Boron-Containing Ligand

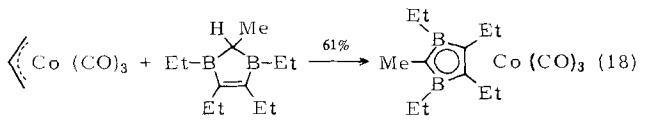
η^6-Borininato ligands were first used as Cp-analogous 6π-electron ligands for cobalt by *Herberich* et al. in 1972[41]. Using bis(η^6-borininato)cobalt as starting material, the diamagnetic COD-complexes **30** and **31** were prepared according to equation (17a).

In an alternative approach we prepared **30** in ca. 40% yield from 1-phenyl-1,4-dihydroborabenzene,[42] COD and $Co(acac)_3$ by direct reduction with soluble Mg*[13] [Eq. (17b)].



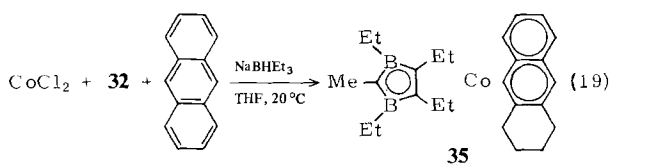
Siebert et al.[43] have described the preparation of numerous transition metal complexes having η^5-dihydro-1,3-diborolyl ligands. The preparation of the complex **33** was

(17a)



(17b)

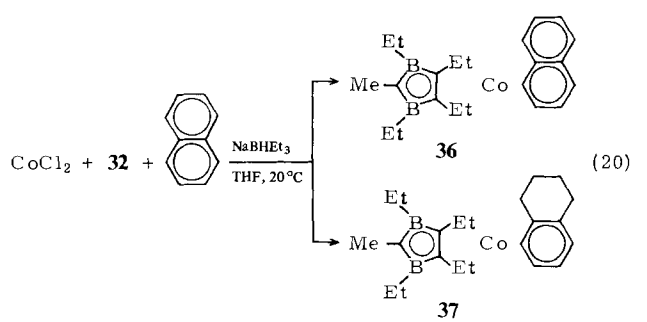
30, R = C_6H_5; **31**, R = C_2H_5



achieved by *Siebert* and *Bochmann* by reaction of the dihydrodiborole[44] **32** with $Co_2(CO)_8$ **14**.[45] Better yields were obtained by protolytic substitution of **34** with **32**[46] [Eq. (18)].

(18)

34 **32** **33**

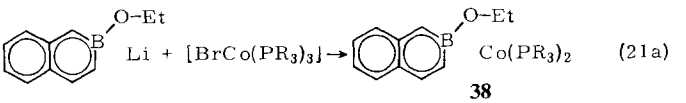


We obtained the crystalline, red, carbonyl-free complex **35** by reduction of $CoCl_2$ with $NaBH(C_2H_5)_3$ in the presence of the ligand **32** and anthracene[47] [Eq. (19)].

(19)

35

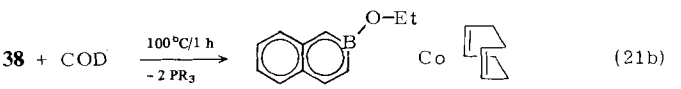
The structure of **35** was deduced from the ^{13}C-NMR data. An analogous reaction using naphthalene as the stabilizing ligand gave a mixture of **36** and **37** in the ratio 20:80[47] [Eq. (20)]. **36** and **37** are deep-red crystalline compounds; their structures could be unequivocally determined by ^{13}C-NMR spectroscopy. If the indene system is



(20)

36

37



extended by introduction of a boranediyl group, then formally "boranaphthalenes" result.[48] In collaboration with *Paetzold* and *Finke*[49] we were able to bind such a system to cobalt by the routes shown in equation (21a) and (21b).

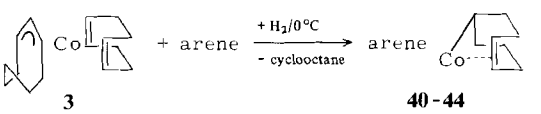
Reaction according to equation (21a) furnishes the phosphite-stabilized complex **38**. This intermediate is converted into the diolefin complex **39** [Eq. (21b)], which, after chromatography, separated as dark red crystals. **39** was completely characterized by its NMR and mass spectra.

(21a)

38

(21b)

R = OC_3H_7 **39**



2.4. Y = η^3-Cyclooctenyl

Besides the CpCo-analogous complexes discussed above, one can also use η^3-allyl-Co^I complexes in the pyridine synthesis [Eq. (1)]. In this case, the catalysis cycle occurs at an η^3-allylcobalt core-complex with 12 outer electrons[12-14] (Fig. 2).

Fig. 2. η^3-Allylcobalt core-complex.

We were able to prepare the long known[50] catalyst complex **3** in 70% yield from $Co(acac)_3$ and COD by direct reduction with $Al(C_2H_5)_3$.[14] A convenient synthesis of **3** based on cobaltocene has recently been developed by *Jonas* et al.[51] When **3** is allowed to react with hydrogen in the presence of arenes, the allylic C_8-ring is eliminated as cyclooctane and one obtains a new class of crystalline [Co(η^6-arene)(η^1,η^2-cyclooctenyl)] complexes such as **40**–**44** [Eq. (22)][52].

(22)

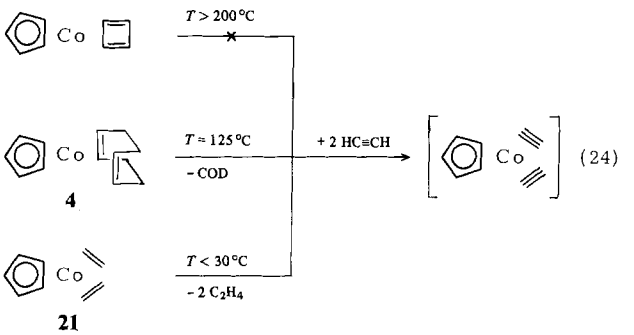
3 **40-44**

	Arene	Yield [%]
40	Benzene	62
41	Mesitylene	41
42	Hexamethylbenzene	12
43	Aniline	76
44	Anisole	69

Using ^{13}C-NMR spectroscopy it can be shown that the eight-membered ring in the new 18-electron complexes **40**–**44** is not bonded to cobalt as an allyl-system, but as an η^1,η^2-system.

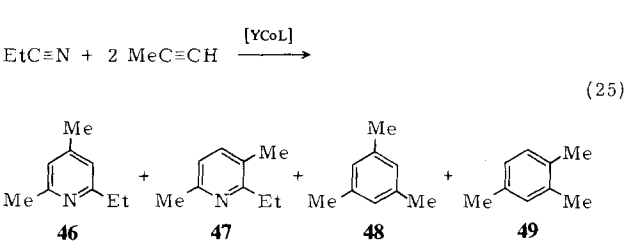
3. The Role of the Neutral Ligand L

As shown in Scheme 2, the initial step in the cobalt-catalyzed pyridine synthesis is the displacement of the neutral ligand L from [YCoL]-complexes by alkyne/nitrile. From complex-chemical[53] and kinetic[54,55] findings it is evident



that the coordination sites of the core-complexes [YCo] are occupied by two alkyne molecules to give **45**.

(23)



45

As can be deduced from equation (23), L merely functions as a "place-reserver" which stabilizes the catalytic central unit [YCo] as isolable complexes. The liberation of the propagating species **45** depends on the complexing ability of the neutral ligand. The nature of L is therefore of prime importance for the "starting behavior" of the various [YCoL]-complexes in the pyridine synthesis [Eq. (24)].

(24)

Ethylene is already displaced from the cobalt of **21** at room temperature in the presence of the substrates,[32d] whereas cyclobutadiene and its derivatives cannot be displaced from the central metal, either thermally or photochemically.[9] The chelating COD-ligand is a compromise between the weakly stabilizing neutral ligand and the "blocking" systems, since, as evidenced by GC, it can be displaced in a temperature range of practical importance (110—130 °C). The major influence of the various ligands on the initial step of the catalysis [Eq. (23)], and, therefore, on the "starting behavior" of the various [YCoL]-complexes in the catalyzed pyridine synthesis, was investigated using a test reaction [Eq. (25)]. In this study certain con-

(25)

centration ratios were adopted and a continuous flow apparatus (Fig. 3)[14, 54, 55] was used[19] (catalyst: 4.3 mmol/L; propyne: 262 g/L = 6.6 mol/L; propiononitrile: 213 g/L = 3.9 mol/L; toluene: 345 g/L).

The temperature of the reactor was slowly increased from 25 to a maximum of 180 °C and the propyne conversions on the various catalysts were determined on-line. The temperature range in which the first propyne-conversion could be measured indicated the "start" of the catalysis.

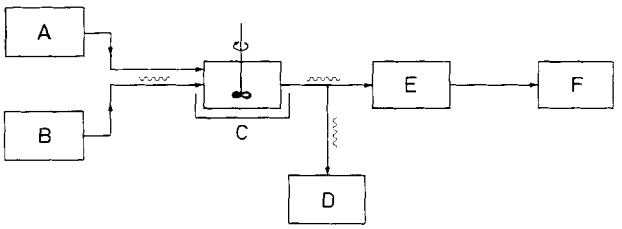


Fig. 3. Continuous flow apparatus for the optimization of homogeneous catalytic processes. A: catalyst solution, B: starting compounds, C: thermostated reactor, D: trap, E: gas-chromatograph, F: data evaluation.

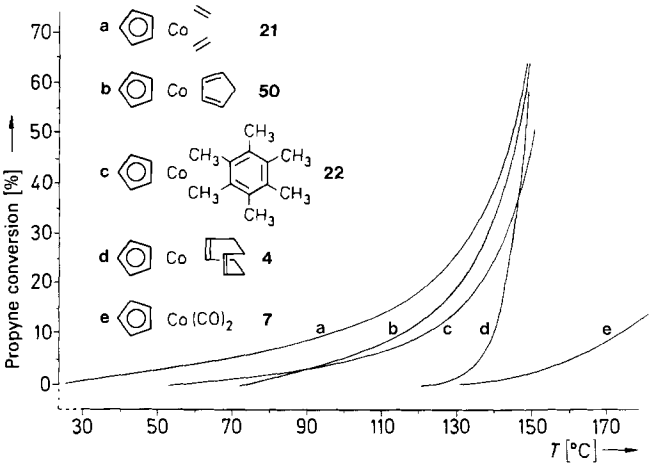
Thereafter, the temperature-dependence of the propyne-conversion was monitored and the temperatures at which each [YCoL]-system continually gave 65% propyne conversion in the test reaction [Eq. (25)] were determined. Figure 4 shows five such conversion/temperature curves.



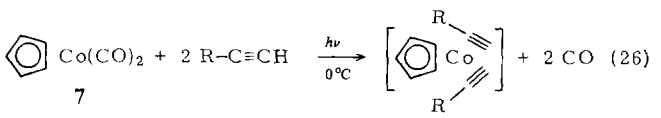


Fig. 4. Propyne conversion and reaction temperature for various [η^5-C_5H_5)CoL]-complexes as catalysts.

As can be seen in Figure 4, the "start behavior" of the individual (C_5H_5)Co compounds is clearly dependent on the complexing ability of the neutral ligands: the ethylene complex **21** already liberates the propagating (C_5H_5)Co-species at room temperature (curve a); the hexamethylbenzene complex **22** causes the first propyne-conversion at 50—60 °C (curve c); the η^4-cyclopentadiene- and COD-complexes **50** and **4**, respectively, first cause propyne-conversion at 75—85 °C and 120—125 °C, respectively (curves b and d). The conversion/temperature curves a—d of the (C_5H_5)Co-catalysts **21**, **50**, **22**, and **4** have the same characteristics: the influence of the neutral ligand on the liberation of the "active species" **45** [Eq. (23)] is noticeable in the temperature range in which 0—25% propyne-conversion takes place. Even the bis(ethylene)-complex **21** only achieves 25% propyne-conversion at ca. 120 °C. Above 120 °C the conversion/temperature curves a—d become more similar. In this temperature range the neutral ligands have been almost completely displaced, so that the propyne-conversion, which is now independent of the neutral ligand, depends on the catalytic activity of the (C_5H_5)Co-unit. At 150 °C, the catalyst complexes **21**, **50**, **22**, and **4** continually convert 65% of the propyne pumped in. With the dicarbonyl complex **7**, the catalytic propyne conver-

sion only starts above 130°C, and even at 150°C only 5% conversion occurs. It can be seen from the conversion/temperature curve e that thermal cleavage of the carbonyl ligands is incomplete even at 150°C. If the carbonyl groups are displaced photolytically[56] from the $(C_5H_5)Co$-unit as shown in equation (26), then the catalytically active species can be generated even below 0°C. The temperature/conversion behavior of **7** then closely corresponds to curve a.

If low reaction temperatures have to be used in the pyridine-synthesis because of thermally labile starting compounds, then the bis(ethylene)-complex **21** or the photolytic elimination of the carbonyl groups in the dicarbonyl complex **7** should be chosen. The reaction rates, however, are slow at room temperature, so that long reaction times or high catalyst concentrations are required. Using the test reaction (25) the individual [YCoL]-complexes can be characterized by the following parameters:

1) *Starting temperature*
(temperature-interval in which the first propyne-conversion is detected)
2) *Reaction temperature*
(required for 65% propyne conversion)
3) *Regioselectivity*
(molar ratio **46** to **47** or **48** to **49**)

Table 4 summarizes the results obtained for some [YCoL]-complexes.[19]

Table 4. Data for [YCoL] complexes in the test reaction (25). Apparatus, see Figure 3; for conditions see text.

[a] Reaction temperature for 65% propyne conversion.

Depending on the stabilizing effect of the ligand L in the $[(C_5H_5)Co(diolefin)]$ series the "starting temperature" varies between 30 and 125°C. In the η^4-cyclopentadienyl ligands, substituents with +I effect promote the displacement of ligand, whereas substituents with −I effect hinder the displacement, so that the "starting temperature" is increased. Inspection of Table 4 also shows that all $[(C_5H_5)Co(diolefin)]$-complexes convert 65% of the propyne in the continuous flow system under comparable conditions. After complete displacement of the neutral ligands, all the $(C_5H_5)Co$ systems have the same catalytic activity. Changes in the Y-ligands do however have a major influence on the "starting temperature" and the reaction temperature required for 65% conversion. This is evident on comparing the COD complexes **4**, **51**, and **26**.

The regioselectivity, which, within experimental error, is the same for all the $(C_5H_5)Co$-catalysts, changes immediately when the Y-ligand is varied.

In Figure 4 it can be seen that replacement of olefinic ligands L by stronger complexing carbonyl groups hinders the liberation of the propagating species **45**. The blocking of the $(C_5H_5)Co$-moiety by strongly coordinating ligands even at 150°C is reflected by the propyne conversions listed in Table 5.

Table 5. Starting temperature and propyne-conversion at 150°C using $[(C_5H_5)CoL]$-systems.

Catalyst	Starting temperature [°C]	Propyne conversion [%]
$[(C_5H_5)Co(cod)]$ **4**	120–125	65
$[(C_5H_5)Co(CO)_2]$ **7**	130–140	5
$[(C_5H_5)Co(PPh_3)_2]$ [53]	80– 85	16
$[(C_5H_5)Co(C_5H_5)]$ **5**	105–115	20

A change of the Y-ligand at the cobalt while keeping the same neutral ligand has a major effect on the "starting behavior" and the activity in the pyridine synthesis (cf. Fig. 5).

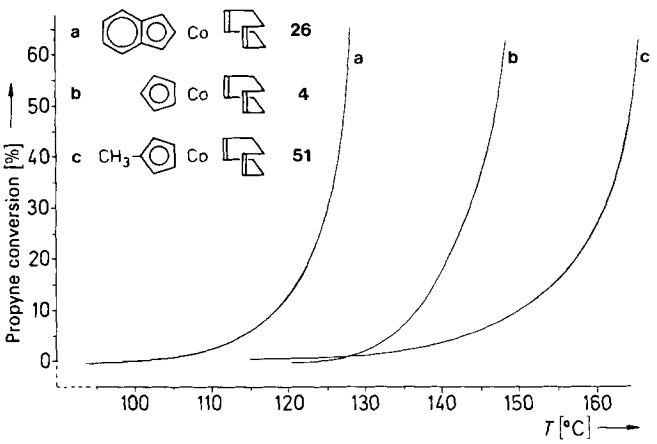

Fig. 5. Propyne conversion and reaction temperature for various [YCo(cod)]-complexes as catalysts.

Replacement of an η^5-cyclopentadienyl by an η^5-indenyl group as Y-ligand at the cobalt lowers the "starting temperature" by 25°C. This indicates that Y has an influence on the dissociation of L according to equation (23). A comparison of the conversion/temperature curves in Figure 5 shows that, after dissociation of the neutral ligand from [YCo(cod)], separate curves a–c result at higher temperatures. Whereas a uniformly effective YCo-system is generated after dissociation of the neutral ligands L from the $[(C_5H_5)CoL]$-complexes (as seen from the trend toward

congruence of the curves at 150°C and 65% conversion in Fig. 4), the results given in Figure 5 for various [YCo(cod)]-complexes show that the Y-ligand has a major influence on the "starting behavior" and on the activity of the catalyst. As can be seen in Table 4, the selectivity of the cobalt catalyst is also effected by Y. Comparison of the results obtained with methylcyclopentadiene as the neutral ligand L and as ligand Y clearly illustrates the roles played by these types of ligands. The result obtained with [(η^5-C_5H_5)Co(η^4-MeC_5H_4)] is no different from that obtained with other [(η^5-C_5H_5)CoL]-systems (Table 4) as far as the reaction temperature for 65% propyne conversion and the product distribution is concerned. If, however, the methyl group is introduced into the cyclopentadienyl part of the catalyst, which remains attached to the metal as the Y-ligand in the whole catalysis cycle, and therefore effects its reactivity, then the substituent effect is reflected in the activity and selectivity of the catalyst.

The role of the neutral ligand in [YCoL]-systems consists therefore in stabilizing the propagating central unit [YCo] by complexation and in effecting the "starting behavior" by liberating the active species at various temperatures. If the species **45** has been formed [Eq. (23)], the liberated neutral ligand has no further influence on the activity and selectivity in the catalytic cycle. In order to develop a catalyst which is reactive and selective one must therefore vary the ligand Y.

4. The Controlling Function of the Ligand Y

4.1. Catalyst-Screening Using Test Reaction (25)

In order to compare various [YCo]-systems, we investigated a series of [YCo(cod)]-complexes in the test reaction (25) under identical conditions in the continuous flow apparatus (Fig. 3).[24] Differences in the product distributions are due to the influence of Y, as all experiments were carried out under stationary conditions and hence kinetic effects or influence of the neutral ligand can be ruled out. The reaction temperature T required for 65% propyne conversion in the continuous system is a measure of the activity of the [YCo]-moiety. The lower the required temperature, the more reactive is the particular [YCo]-system. The molar ratio of pyridine- to benzene-derivatives gives the chemoselectivity and the ratio of the pyridine isomers **46** to **47** characterizes the regioselectivity.[13,14] Table 6 summarizes the results obtained.

Inspection of Table 6 reveals that the three above-mentioned parameters are strongly controlled by the ligand Y.

Table 6. Reaction temperature T (for 65% propyne conversion), chemo- and regioselectivity, and ^{59}Co-NMR shift of [YCo(cod)] catalysts in dependence of Y. For conditions see Eq. (25); ΔT and δ_{rel}, see text. $\delta(^{59}Co)$ of $K_3Co(CN)_6 = 0$.

The influence of Y on the charge distribution at the cobalt is easily determined from the ^{59}Co-NMR chemical shifts[14,59] (Fig. 6). If one relates the ^{59}Co-NMR-shifts in

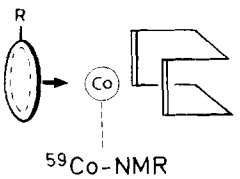

Fig. 6. Determination of ligand effect by ^{59}Co-NMR spectroscopy.

the series of η^5-cyclopentadienyl and η^5-indenyl complexes with the values of the unsubstituted parent compounds ($\delta_{rel}(^{59}Co)=0$), then a correlation between the relative chemical shifts and the electronic character of the ring substituent is found: alkyl groups which act as electron donors cause a larger deshielding of the metal center, whereas phenyl or acetyl groups decrease the deshielding. The influence of the substituents is clearly additive, so that $\delta_{rel}(^{59}Co)$ for $Y=Me_5C_5$ is five times higher than that found for $Y=MeC_5H_4$. In the case of Y = cyclopentadienyl or indenyl one can refer to them as "catalyst families" in which the electronic character of the parent systems can be widely varied by introducing further ring substituents (fine-control). This fine-control of the catalyst properties by additional substituents is mainly due to electronic effects. Thus, for example, in the η^5-C_5H_5 series an additional acetyl group on the ring induces an increase in the catalyst activity in comparison to a 1-hydroxyethyl group, which has nearly the same steric requirements. In the (η^5-cyclopentadienyl)Co-series, the pentamethyl system shows the lowest activity in the test reaction (25), whereas the highest activity at 65% propyne conversion is found for the benzoyl-substituted system (factor 1000 times more reactive than the pentamethyl system). Mesomeric substituent effects influence the activity more than inductive effects, so that replacement of a methyl- by a chloro-substituent only has minor influence on the activity. The regioselectivity is in general inversely proportional to the catalyst activity. Exceptions are found when $Y=1,2\text{-}(Me_3Si)_2C_5H_3$ and Ph_4C_5H. In these cases, both high regioselectivity and activity are found. This is probably due to the accumulation of sterically demanding substituents. Changing from (η^5-cyclopentadienyl)Co to (η^5-indenyl)Co catalysts lowers the reaction temperature required for the same propyne conversion by 20°C. This indicates that the latter complexes are four times more reactive. Additive substituent effects in the ^{59}Co-NMR spectra are also found in these "catalyst families", as can be seen by comparing the δ_{rel}-values for the mono- and dimethyl substituted derivatives. The fine-control of the activity and selectivity by additional indenyl ring substituents is as found in the η^5-cyclopentadienyl series. The results obtained with Y = fluorenyl and η^3-cyclooctenyl in the test reaction (25) listed in Table 6 cannot be directly compared with the other results as only 15% propyne conversion was achieved and an increase in reaction temperature resulted in catalyst decomposition. The substitution of an η^5-cyclopentadienyl by an η^3-cyclooctenyl group attached to cobalt causes a change in the chemoselectivity so that mainly benzene derivatives are formed.[13] With η^6-borininato groups as the controlling ligand Y attached to cobalt highly reactive catalysts with excellent chemo- and regioselectivity are obtained. A comparative study of [YCo(cod)] systems in a continuous flow system therefore allows a differentiation of molecular catalyst properties.

4.2. Correlation of the Control with ^{59}Co-NMR Data[14,24]

If one compares the change in the catalyst properties caused by ring substituents in the cyclopentadienyl- and indenylcobalt series with the relative chemical shifts $\delta_{rel}(^{59}Co)$ given in Table 6, then parallel trends become evident, especially between the activity and the signal position in the ^{59}Co-NMR spectrum. Furthermore, the increase in activity found on going from Y = cyclopentadienyl to Y = indenyl is reflected in a downfield shift. Y = η^6-borininato lies between the two "families" as far as activity and ^{59}Co-NMR shift are concerned. A relationship between the regioselectivity and the relative chemical shift $\delta_{rel}(^{59}Co)$ is also found: the more negative the $\delta_{rel}(^{59}Co)$ value the greater the control of ligand Y in favor of the symmetrically substituted pyridine derivatives **46**. If one plots the $\delta_{rel}(^{59}Co)$ values against the reaction temperature T which is needed for 65% propyne conversion in the continuous flow system for the [(C_5H_5)Co(cod)] family, then an almost linear correlation is found for the 15 members of this "catalyst family" (Fig. 7).

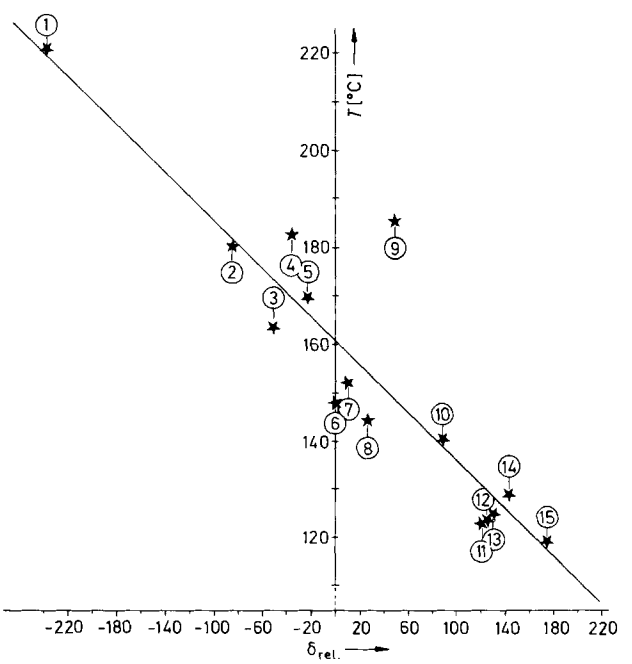

Fig. 7. Catalytic activity of [YCo(cod)]-complexes (Y = cyclopentadienyl derivative) as function of the ^{59}Co-NMR shift (reaction temperatures T in the test reaction (25) under standard conditions; ①—⑮ see Table 6).

Substituted [YCo(cod)]-systems (Y = cyclopentadienyl derivative) which have ^{59}Co resonances which are shifted to higher field ($\delta_{rel}(^{59}Co)$ is negative) are less active than [(C_5H_5)Co(cod)], whereas derivatives having downfield shifts ($\delta_{rel}(^{59}Co)$ is positive) show enhanced activity. The

linear relationship between the reaction temperature T and $\delta_{rel}(^{59}Co)$ in this catalyst family can also be expressed by the regressional equation (27).

$$T\,[°C] = 160.6 - 0.25 \cdot \delta_{rel}(^{59}Co) \quad (27)$$

significance level 95%, Fisher test;
correlation coefficient $r = 0.91$

[YCo(cod)]-complexes (Y = cyclopentadienyl derivative) with large positive $\delta_{rel}(^{59}Co)$ values are therefore particularly active. A similar quasi-linear correlation between regioselectivity and ^{59}Co-NMR shift is found in this series. The pentamethyl derivative preferentially forms the symmetrically substituted isomer **46**, whereas the benzoyl-substituted catalyst produces most of the asymmetric isomer **47**. Both catalysts are found at the extremities of the $\delta_{rel}(^{59}Co)$ shift scale. The linear relationship found between regioselectivity and ^{59}Co-NMR shift in this series can also be described by regressional equations (28a) and (28b).

$$\mathbf{46}\ [\%] = 64.93 - 0.05 \cdot \delta_{rel}(^{59}Co) \quad (28a)$$

$$\mathbf{47}\ [\%] = 35.07 + 0.05 \cdot \delta_{rel}(^{59}Co) \quad (28b)$$

significance level 95%, Fisher test;
correlation coefficient $r = 0.95$

This correlation is shown graphically in Figure 8.

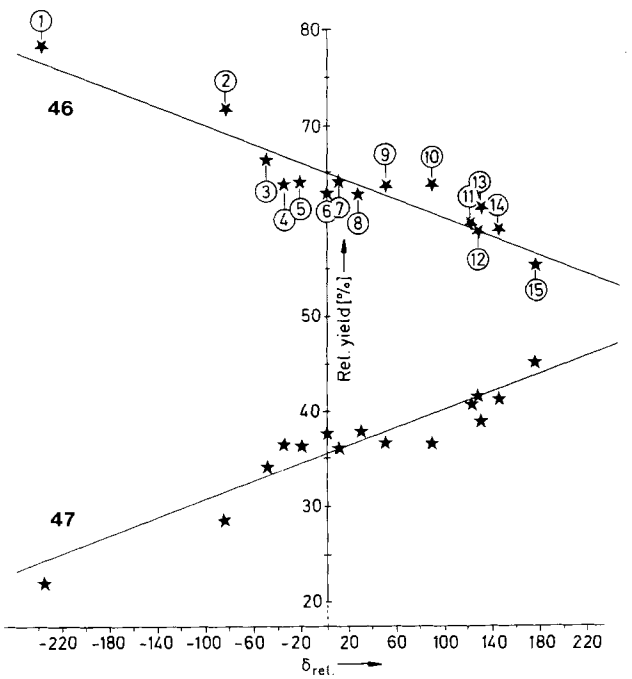

Fig. 8. Regioselectivity of [YCo(cod)]-complexes (Y = cyclopentadienyl derivative) as a function of the ^{59}Co-NMR shift (relative yield of **46** and **47** in the test reaction (25) under standard conditions; ①—⑮, see Table 6).

A direct relationship between catalytic properties and ^{59}Co-NMR shifts also appears to exist in other [YCo(cod)] catalyst families. In the indenylcobalt series we have ^{59}Co-NMR data for the parent compound and five derivatives thereof. As shown in Figure 9, a linear relationship between catalyst activity and $\delta_{rel}(^{59}Co)$ is also found in this case [cf. regression equation (29)].

$$T\,[°C] = 131.6 - 0.17 \cdot \delta_{rel}(^{59}Co) \quad (29)$$

significance level 95%, Fisher test;
correlation coefficient $r = 0.98$

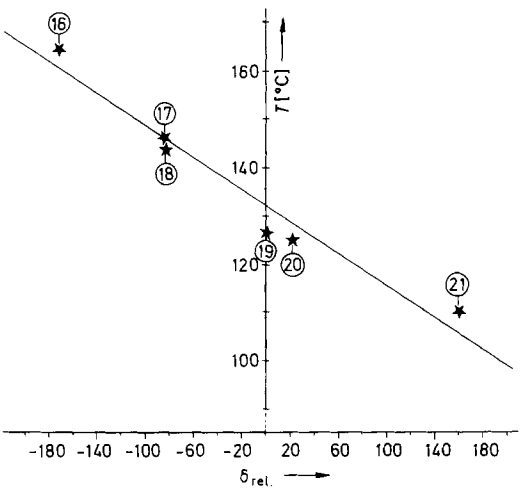

Fig. 9. Catalytic activity of [YCo(cod)]-complexes (Y = indenyl derivative) as a function of the ^{59}Co-NMR shift (reaction temperatures T in the test reaction (25) under standard conditions; ⑯—㉑, see Table 6).

An increasing shielding of the cobalt-cores by alkyl substituents is found in the η^5-cyclopentadienyl or η^5-indenyl systems. Increased electron density at the cobalt core therefore causes a reduction in the catalytic activity. In contrast, electron-withdrawing substituents lower the electron density at the cobalt core, resulting in deshielding and higher catalytic activity.

The empirically found correlations [Eq. (27)—(29)] have hitherto proven valid for the cyclopentadienylcobalt- and indenylcobalt-core complexes. We consider the ^{59}Co-NMR, and transition metal-NMR spectroscopy in general to be a very promising method for efficient catalyst screening because of the wide chemical shift scale and the sensitivity towards substituent effects.

4.3. Relationship between Crystal Structure and the Catalytic Activity

For purposes of comparison, several X-ray structure determinations were carried out in the η^5-cyclopentadienyl and η^5-indenyl series[40]. Some results are shown in Figure 10.

The X-ray structure data shows[40] that the average C—C-distance in the η^5-cyclopentadienyl rings and the average C=C-distance in the complexed COD remain constant. The distance between the Co atom and the center of the cyclopentadienyl ring or between the Co atom and the center of the C=C bond in COD do not vary to any relevant extent. The compounds investigated can, however, be classified into two groups according to the position of the substituents on the η^5-system relative to the arrangement of the C=C bond of the cyclooctadiene (Table 7). In the case of structure type I the substituent on the cyclopentadienyl ring crosses a double bond of the complexed COD, i.e. relative to the cobalt atom it is therefore *transoid* to the second double bond of the complexed COD. In the struc-

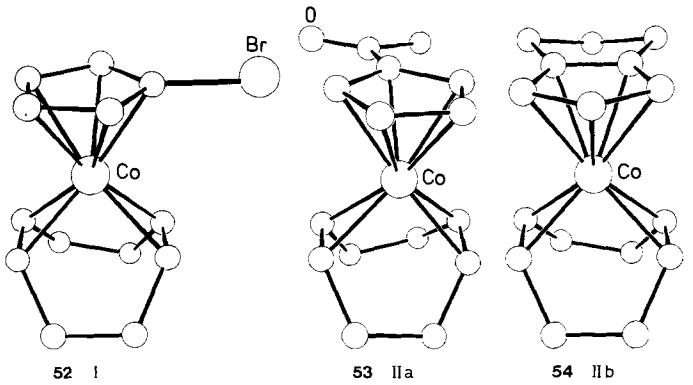

Fig. 10. Structure types of [YCo(cod)] complexes, Y = cyclopentadienyl derivative (see Table 7).

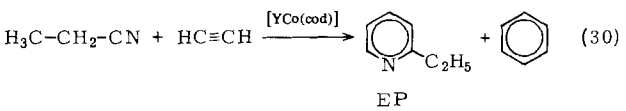
ture type IIa the bond of the substituent on the cyclopentadienyl ring is approximately *parallel* to both double bonds of the complexed COD. Structure type IIb also has a parallel orientation, but contains sterically very demanding substituents. If one correlates the structures with the ^{59}Co-NMR findings, then it becomes evident that substituents

Table 7. Structure types of [YCo(cod)] complexes (cf. Fig. 10).

		
Type I Y	Type IIa Y	Type IIb Y
$Cl-C_5H_4$ $Br-C_5H_4$ **52** $(CH_3)_5C_5$ **18** [a] **20**	$(C_6H_5)_4C_5H$ $(CH_3)_3Si-C_5H_4$ $CH_3CO-C_5H_4$ **53** C_9H_7 **26**	$(C_6H_5)_3C-C_5H_4$ Bicyclo[3.3.0]octadienyl **54**



[a] [YCo(cod)] = [(cod)$CoC_5H_4-C_5H_4$Co(cod)].

with strong donor ability (δ_{rel}(^{59}Co) is negative) belong to structure type I. Complexes of this type have a *lower* activity in the catalysis than the unsubstituted ligand Y. Cyclopentadienyl or indenyl derivatives which have a positive δ_{rel}(^{59}Co) value all belong to the structure group IIa. Compounds in this group have electron-withdrawing substituents and are more active than the parent compounds in the catalysis. Sterically demanding donor substituents force a parallel orientation of substituent and COD double bond (structure type IIb). Apart from these exceptions (type IIb), obviously induced by steric effects, correlations are found between structure type I or IIa, sign of the relative ^{59}Co-NMR shifts, and catalytic activity. The linear relationship between ^{59}Co-NMR shift and catalytic activity of the cyclopentadienyl- and indenylcobalt catalysts indicates that a relationship between electron distribution at the cobalt and the activity of various complexes in the catalysis is to be expected. In order to shed light on this, high resolution X-ray structure analyses are currently being carried out involving determination of deformation density by the X–X- and X–N-methods[60] on the complexes **4**, **53**, and **54**.

5. Application: Maximization of the Catalytic Turnover Number TON

5.1. 2-Ethylpyridine

With the intention of achieving maximal catalytic turnover numbers (TON_{Py}) for the industrially interesting synthesis of 2-ethylpyridine [Eq. (30)] we systematically investigated ca. 60 [YCoL]-complexes in a batch reactor.[19]

EP

The catalytic screening in the continuous flow system (see Table 6) enables a characterization of the catalyst properties. For preparative purposes, the alkyne concentration and temperature also have to be optimized for the various catalysts. Since two acetylene molecules are coordinated to the cobalt in the rate determining step,[53,54] the catalytic conversion has to be performed with a high stationary alkyne concentration.

The concentration of acetylene in organic solvents increases overproportionately with increasing pressure.[61] This is particularly the case when nitriles are used as solvents between 5 and 25 bar (Fig. 11).

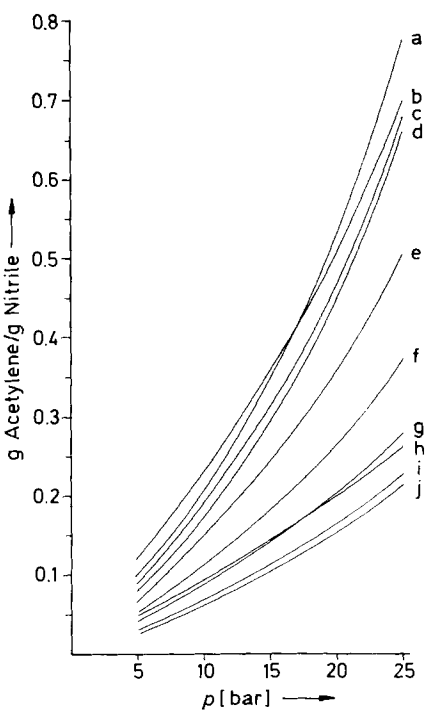


Fig. 11. Solubility of acetylene in nitriles and related compounds at 25 °C as a function of pressure. a: acetonitrile; b: isobutyronitrile; c: propiononitrile; d: acrylonitrile; e: butyl cyanide; f: methyl thiocyanate; g: benzonitrile; h: decyl cyanide; i: undecyl cyanide; j: benzyl cyanide.

The series of optimization experiments was carried out in a batch reactor[62] without inert gas using acetylene pressures of up to 60 bar. The safety precautions mentioned in "Technical Rules Acetylene"[63] were adhered to. The maximal TON values for the 2-ethylpyridine synthesis [Eq.

(30)] for some of the [YCo]-catalysts are given in Table 8. The values vary between 50 and 7000 product forming steps per cobalt, i.e. by a factor of 140. As expected from the catalyst screening involving variation of Y (Table 6), maximal TON values are obtained with such [YCo]-systems having electron-withdrawing groups on the ligand Y. Conversely, alkyl substituents lower the TON values drastically. In a reaction time of 2 h nitrile conversions between 2 and 42% are achieved. Catalysts which achieve propyne conversions in excess of 20% can be regarded as preparatively useful. The 2-ethylpyridine yield (based on nitrile conversion) varies between 15 and maximally 98%. Best chemoselectivity is found for the 1,2-bis(trimethylsilyl)cyclopentadienylcobalt catalyst, which gives ca. 11 moles of 2-ethylpyridine derivatives per mole of benzene. In the series $Y = Me_3E-C_5H_4$ (E = C, Si, Ge) the TON-maximum is found when E = Si. In the series Y = halocyclopentadienyl the best TON was found for the chloro substituent. The η^5-chlorocyclopentadienyl ligand proved to be noticeably more effective in the batch reactor than would be expected from its position in the "activity scale" (Table 6). This result again demonstrates that an optimization of the reaction parameters is vital prior to practical use of the catalysts.

[a] In 150 mL propiononitrile. [b] Acetylene reservoir at 20 °C in 150 mL propiononitrile. [c] Reaction temperature range. [d] Based on 2 h reaction time.

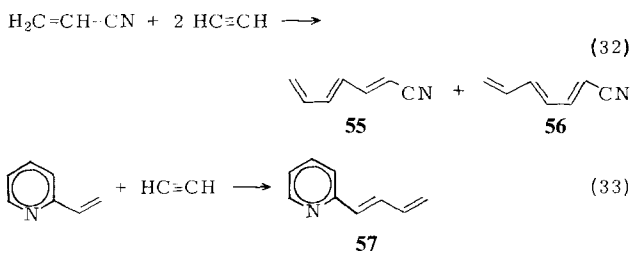
Comparison of the TON values of the [YCoL] complexes having various neutral ligands, verifies that strongly complexing ligands such as triphenylphosphane or CO hinder the liberation of the propagating species. The maximal TON values for these complexes, which are stabilized by more easily displaced ligands, are all of the same order of magnitude.

The maximum amount of acetylene which can be first introduced at room temperature, so that the maximum safety limit of 60 bar is not exceeded at the reaction temperature, is of importance for the preparative success of the cobalt-catalyzed 2-alkylpyridine synthesis [Eq. (30)]. Highly reactive catalysts quickly use up the acetylene reservoir, so that the pressure stabilizes after reaching a maximum between 40 and 60 bar and rapidly sinks at the end of the reaction. When using [YCo]-systems of low reactivity only small amounts of acetylene in the reservoir are used, so as not to exceed the safety limit of 60 bar. The temperature control is also of importance in the 2-alkylpyridine synthesis. A temperature control is used to slowly increase the temperature until the catalysis sets in and the strongly exothermic reaction is then moderated by water cooling. The thermal stabilities of the individual [YCo]-systems vary widely; the trimethylsilylcyclopentadienylcobalt system remains equally active at 200 °C, whereas the indenylcobalt system already decomposes at 140 °C under the catalysis conditions. In order to make full preparative use of the activity, especially for the highly reactive [YCo]-systems, the amount of acetylene and the temperature control have to be carefully optimized. Minor deviations from the optimal combination of the parameters can lead to TON value fluctuations of 1000 for one and the same catalyst.

5.2. 2-Vinylpyridine

The 2-vinylpyridine synthesis [Eq. (31)] must be carried out below 130–140 °C, since acrylonitrile and 2-vinylpyridine undergo thermal polymerization.[64] When using [YCo]-systems which only catalyze this reaction above 130 °C, the reaction must be carried out in dilute benzene or toluene solutions so that the TON values do not exceed ca. 500.

$$H_2C{=}CH{-}CN + 2\ HC{\equiv}CH \xrightarrow{[YCo(cod)]} \underset{VP}{\text{(N, CH=CH}_2\text{)}} + \bigcirc \quad (31)$$



Only very active catalysts can be used for achieving the conversion (31) in pure acrylonitrile. We investigated all the catalysts that were active below 125 °C according to the "activity scale" (Table 6) in a batch reactor for achieving reaction (31). A solution of the catalyst in pure acrylonitrile was saturated with acetylene at ca. 20 bar and then heated to 130 °C. The TON values found in this way after two hours' reaction time are summarized in Table 9.

Table 9. Synthesis of 2-vinylpyridine (VP) on [YCo(cod)] and related complexes according to Eq. (31) in the temperature range up to 130 °C.

(1-Ethoxy-3,4-benzoborininato)Co(cod) **39**	46	3.0	31.8	7.4	265

[a] In 150 mL acrylonitrile. [b] Acetylene reservoir at 20 °C in 150 mL acrylonitrile. [c] Based on 2 h reaction time.

The best results to date were obtained with the η^6-phenylborininato complex **30**. The outstanding position of this catalyst is apparently due to the fact that the catalytic vinylation reactions (32) and (33) are largely suppressed by it. All other catalyst systems named in Table 9 cause the reactions of acrylonitrile and 2-vinylpyridine to give appreciable amounts of **55** and **56** or **57**. These activated olefins can compete with acetylene for cobalt coordination sites and they therefore act as catalyst poisons.

Since indenylcobalt-core complexes are generally more reactive than the cyclopentadienylcobalt systems in the pyridine synthesis, it is to be expected that the introduction of boron into the indenyl system might have a similar positive effect on the catalytic activity in the 2-vinylpyridine synthesis, as was previously found on going from the cyclopentadienyl- to the η^5-borininato ligand.[13] The use of the complex **39** with Y = 3,4-benzoborininato[49], however, only gave relatively low TON values in the 2-vinylpyridine synthesis [Eq. (31)]. Similar results were also found with the 1,3-dihydroborolyl complex **33**. It is possible that the introduction of the boron is compensated by an activity-reducing secondary effect of the alkyl substituents or ethoxy group. This question will first be answered on carrying out the vinylpyridine synthesis [Eq. (31)] using boron-containing control ligands Y having activating substituents.

The author and his co-workers wish to thank the director of the Max-Planck-Institut für Kohlenforschung, Professor Dr. G. Wilke, for his continued support of this research. We are grateful to the analytical departments of the institute for their expert help: Dr. R. Benn, Dr. R. Mynott (NMR-spectroscopy); Dr. D. Henneberg (mass-spectroscopy); Prof. Dr. C. Krüger, Dipl.-Chem. K. Angermund (X-ray structure analyses); Priv.-Doz. Dr. G. Schomburg (chromatography) and Dr. K. Seevogel (IR-spectroscopy).

Catalytic Synthesis of Organolithium and Organomagnesium Compounds and of Lithium and Magnesium Hydrides—Applications in Organic Synthesis and Hydrogen Storage**

By Borislav Bogdanović*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

A recent development in homogeneous catalysis is the discovery of catalysts that are active for the lithiation of 1-alkenes to alkenyllithium compounds and lithium hydride as well as for the hydrogenation of lithium and magnesium under mild conditions. The catalytically prepared magnesium hydride is highly reactive and adds to 1-alkenes to give diorganomagnesium compounds and can also be used in the preparation of, for example, silane and "active" magnesium. The use of metal hydrides in hydrogen storage is discussed: hydrogenation/dehydrogenation experiments show that the catalytically prepared magnesium hydride (which can be doped with a second metal) can be used as a high-temperature hydrogen storage material.

1. Introduction

For decades organolithium and organomagnesium compounds (mainly in the form of Grignard reagents) have been among the most frequently used organometallic reagents for organic synthesis.[1] They are usually prepared by reaction of metallic lithium or magnesium with organic halides.[1–3]

In the following article it is shown that dialkylmagnesium compounds can be prepared catalytically in a manner analogous to the synthesis of trialkylaluminum compounds.[4] An important role in the catalytic activation of lithium is probably played by "poly-lithium complexes" which are formed from lithium and 1,6,6aλ⁴-trithiapentalenes (Section 2), while the catalytic hydrogenation of magnesium involves the activation of the metal through the re-

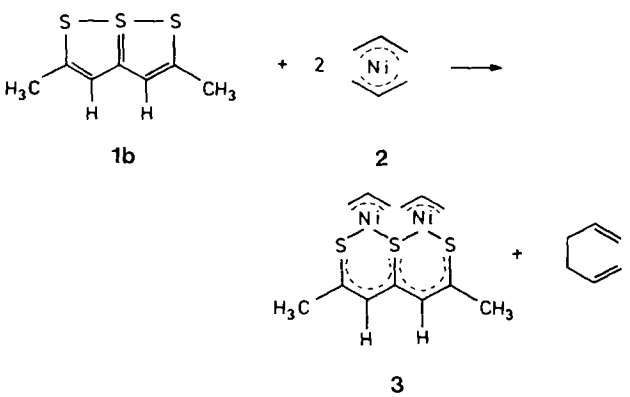
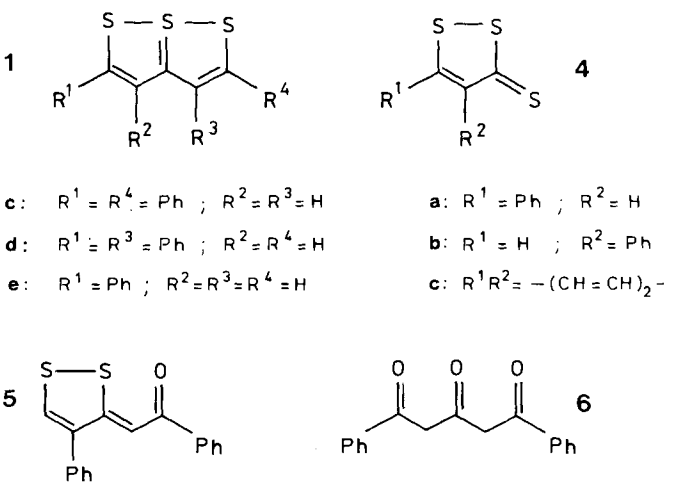
The author thanks these coworkers for their dedicated and enthusiastic assistance.



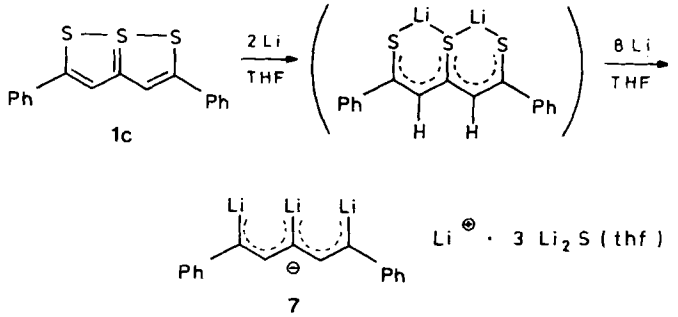
versible formation of "magnesium-anthracene" (Section 4). In both cases the formation of the catalytically active species involves a second metal—in general, a transition metal.

2. Poly-Lithium Complexes from Lithium and Phenyl-Substituted 1,6,6aλ⁴-Trithiapentalenes or Related Compounds[5,6]

The investigation of the reaction of the 1,6,6aλ⁴-trithiapentalenes **1a**[7-9] with lithium originated in the observation that **1b** reacts with bis(η³-allyl)nickel **2** to give the



binuclear nickel complex **3**[10] in what can formally be regarded as a redox process.



Since the reduction of the trithiapentalenes either with potassium or electrochemically has been reported to proceed only as far as the radical anion,[11,12] we decided to investigate whether they could be reduced to the dianion with excess alkali metal.[13] It was discovered that the phenyl-substituted trithiapentalenes **1c**—**1e** react in tetrahydrofuran (THF) or 2-methyltetrahydrofuran (MeTHF) not with two but with nine or ten mol Li per mol compound to give highly reactive, soluble "poly-lithium" complexes. Similar behavior was observed for 3*H*-1,2-dithiol-3-thiones **4a**—**c** (6—7 Li/compound), 2-(4-phenyl-3*H*-1,2-dithiol-3-ylidene)acetophenone **5** (≈10 Li/compound), and 1,5-diphenyl-1,3,5-pentanetrione **6** (≈8 Li/compound).[5]

The poly-lithium complex **1c**Li_{10}(thf) was suggested to have the constitution **7** on the basis of its reactions with water, methyl iodide, pentacene, and hydrogen.

Thus, the reaction of **1c** with lithium in THF or MeTHF is accompanied by the cleavage of all the C—S and S—S bonds present and their replacement by C—Li and S—Li bonds, whereby the resulting lithium sulfide is complexed to the organolithium compound.[14] The reaction of **1d**,**e**, **4a**—**c**, **5**, and **6** with lithium in THF or MeTHF probably proceeds in an analogous manner. This assumption is supported by the ^{7}Li- and ^{1}H-NMR spectra of the poly-lithium complex formed by treating **1d** with lithium.[5] More detailed information on the structure of these poly-lithium species is not available since all attempts to obtain satisfactory crystals failed. In connection with this work, it did, however, prove possible to obtain the crystal structure of the THF-TMEDA (*N*,*N*,*N*′,*N*′-tetramethylethylenediamine) adduct of benzophenonedilithium.[15]

3. Catalytic Reactions Using Trithiapentalene-MX_n-Lithium and Related Systems

3.1. The Catalytic Lithiation of 1-Alkenes[16,17]

The uncatalyzed reaction of 1-alkenes with lithium leads to 1-alkynyllithium compounds and lithium hydride; (*E*)-1-lithio-1-alkene was identified as a side product.[18]

$$RCH{=}CH_2 + 4\,Li \longrightarrow RC{\equiv}CLi + 3\,LiH$$

R = *n*-alkyl

The reaction of ethylene with lithium in dimethoxymethane or THF in the presence of biphenyl or naphthalene results in a low yield of vinyllithium, 1,4-dilithiobutane, and α,ω-dilithioalkanes.[19] Acidic hydrocarbons, 1-alkynes,[20] triphenylmethane,[21] and cyclopentadiene[22] can be directly metalated with lithium.

THF solutions of the "poly-lithium complexes" (Section 2) have only weak activity for the lithiation of 1-alkenes. The addition of metal halides MX_n leads to an increase in the catalytic activity and also allows the selectivity of the

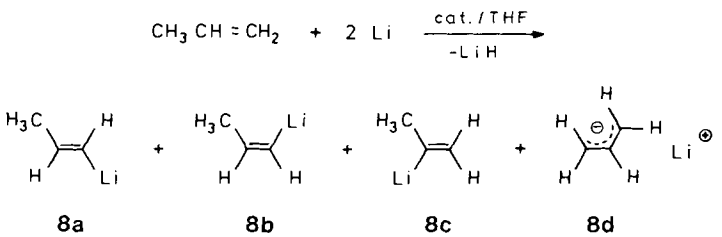
lithiation to be influenced. Particularly active is the combination of **1c** or **1d** with $ZnCl_2$, $FeCl_3$, or $CuCl_2$ and lithium.[23]

The lithiation of ethylene with **1c**/2$ZnCl_2$/Li as catalyst leads to the formation of vinyllithium in 70—75% yield and is accompanied by the formation of lithium hydride and traces of α,ω-dilithioalkanes.

$$H_2C{=}CH_2 + 2\,Li \xrightarrow[0\,^\circ C,\ 1\,bar]{cat./THF} H_2C{=}CHLi + LiH$$

The vinyllithium can be separated from the precipitated lithium hydride and isolated in crystalline form as $C_2H_3Li \cdot thf$[16] or in a solvent-free form.[24]

The effect of the MX_n components on the activity and selectivity of the **1c**/2MX_n/Li catalysts was investigated in the case of the lithiation of propene. The products of this reaction are lithium hydride and the four isomers **8a**—**d**, the relative amounts of which were determined by silylation with chlorotrimethylsilane followed by gas chromatographic (GC) analysis of the resulting organosilanes (Table 1).



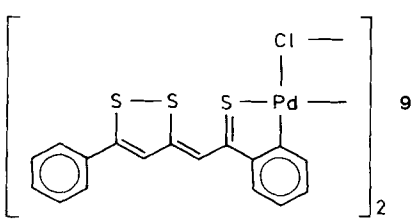


Table 1. The influence of metal salts on the activity and selectivity of catalysts for the lithiation of propene. Catalyst: 1% **1c**; [**1c**] = 0.04 mol/L.

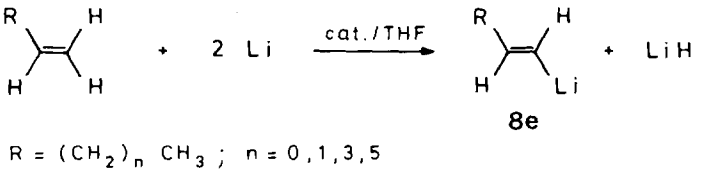
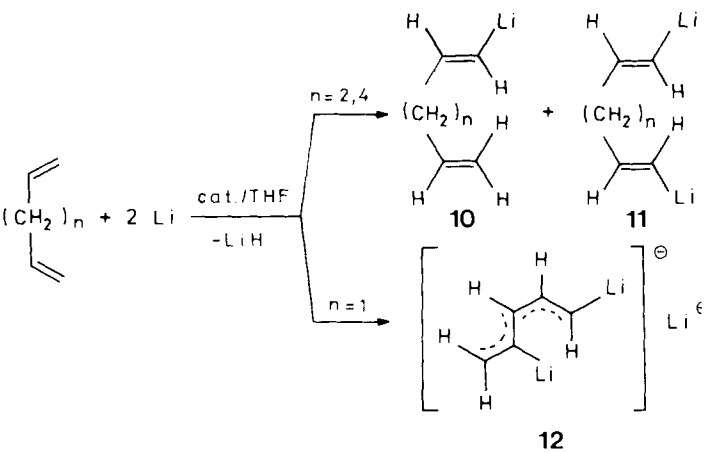


MX_n	mmol C_3H_6 / mmol cat·h	Total yield of C_3H_5Li [%] [a]	Isomer distribution [%] [b]			
			8a	**8b**	**8c**	**8d**
$ZnCl_2$	7–8	75–83	85–90	0.5–1	2–6	8–9
$CdCl_2$	5	47	90	1	2	7
$HgCl_2$	2	40	94	0.7	—	5
$FeCl_3$	5	56	83	2–3	7	7
$CuCl_2$	5	59	68	1	9	22
$PtCl_2$	3	75	37	1	2	60
[c]	1.6	41	13	0.3	1	85

[a] Relative to the initial concentration of Li. [b] GC analysis of the silylated product. [c] Catalyst: **9**.

When **1c**/2$ZnCl_2$/Li is used as catalyst, **8a** is formed with 85—90% selectivity. **8a** could be isolated by recrystallization or in a solvent-free form having 98—99% isomeric purity.[16,24] The amount of allyl lithiation is dependent on the nature of the MX_n component and increases in the order $FeCl_3$, $CuCl_2$, $PtCl_2$. The highest selectivity for **8d** (85%) was obtained using complex **9** which was prepared from **1c** and $PdCl_2$.[25]

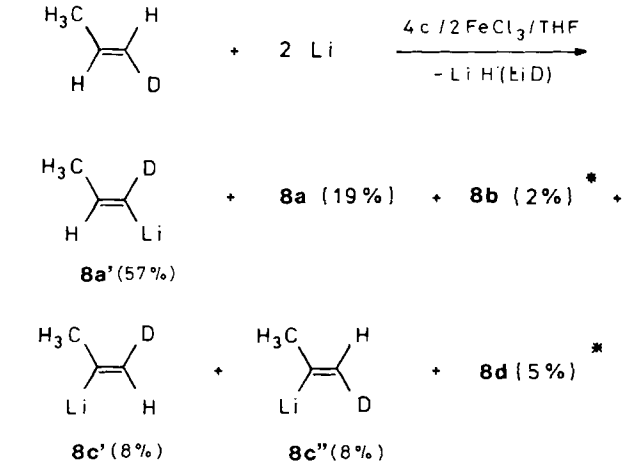


Higher 1-alkenes can be lithiated with 90—97% selectivity to (*E*)-1-lithio-1-alkenes **8e** with the **1c**/2$ZnCl_2$/Li catalyst.

R = $(CH_2)_n CH_3$; n = 0, 1, 3, 5

The lithiation of 1,5-hexadiene or 1,7-octadiene in the presence of **4c**/2$CuCl_2$/Li[23] gave a mixture of (*E*)-1-lithio-α,ω-alkadiene **10** and (*E*,*E*)-α,ω-dilithio-α,ω-alkadiene **11**, whereas reaction of 1,4-pentadiene with the same catalyst afforded the crystalline trilithium compound **12**.[26]

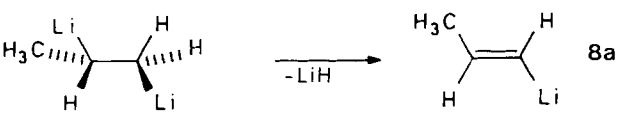
The mechanism of the catalytic lithiation (Scheme 1)[19a] presumably involves the stepwise addition (e.g., via **13**) of two lithium atoms to the C=C bond to give the 1,2-dilithioalkane **14**[27] followed by β-elimination of lithium hydride. Depending on the stereochemical course of the β-elimination from **14**, four isomers can form; e.g., **8a**—**d**, the products obtained from the lithiation of propene.



$$RCH{=}CH_2 \xrightarrow{Li} \underset{\mathbf{13}}{RCHCH_2Li} \xrightarrow{Li}$$

$$\underset{\mathbf{14}}{RCHLiCH_2Li} \xrightarrow[-LiH]{R=CH_3} \mathbf{8a-d}$$

Scheme 1.



This mechanism is supported by the *E*/*Z*-isomerization observed during the catalytic lithiation of (*E*)-1-deutero-1-propene, which resulted in the isomerization products (*E*)-1-deutero-1-lithio-1-propene **8a**′ and (*Z*)-1-deutero-2-lithio-1-propene **8c**′.[26]

Rotation about the C—C bond is possible in both **14** and its precursors (e.g., **13**). The high *E*-stereoselectivity observed for the catalytic lithiation of propene and other 1-alkenes (the *E*/*Z* ratio of 1-lithio-1-alkenes is 98/2—99/1 or higher) is possibly a result of steric restriction during the

[*] Degree and position of deuteration not determined

β-elimination from **14**. For example, β-elimination following the *syn*-addition of two Li atoms to the C=C bond can be expected to proceed preferentially by a *syn*-mechanism when the large CH_3 (or alkyl) group and Li occupy anticlinal positions.

It is still not fully understood how the MX_n component in the catalyst controls the direction of lithiation of propene to give **8a** or **8d**.

3.2. Catalytic Hydrogenation of Lithium

In 1968 it was reported that sodium can be catalytically hydrogenated under mild conditions using a catalyst prepared from titanium tetraisopropoxide, naphthalene, and sodium.[28] Bis(η^5-cyclopentadienyl)titanium dichloride in THF is also an active catalyst for this reaction.[29]

Lithium can be hydrogenated under mild conditions using trithiapentalene/MX_n/lithium and related systems as catalysts.[6,30] The preferred catalyst consists of a combination of **1c** or **4c** with $FeCl_3$ and lithium in THF and is capable of hydrogenating lithium almost quantitatively at 0° and 1 bar H_2 (Fig. 1). The lithium hydride precipitates from solution in a finely divided, highly reactive form.

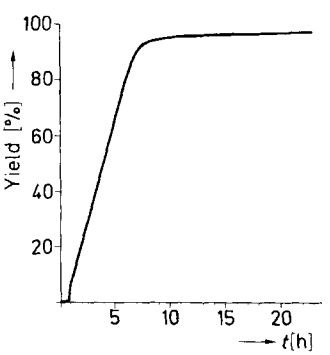


Fig. 1. The hydrogenation of lithium at 0°C; Catalyst: 2 mol-% **4c**, 4 mol-% $FeCl_3$, [**4c**] = 0.041 mol/L: Hydrogen up-take followed with an automatic gas-burette [31].

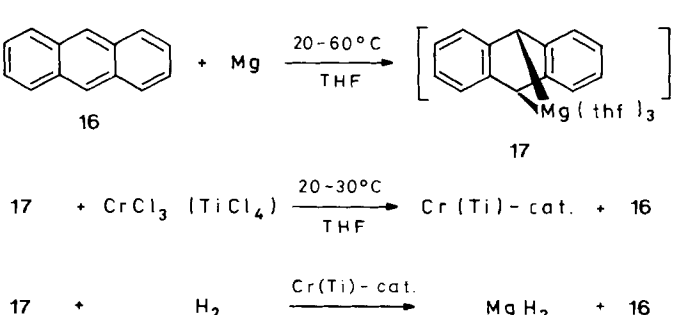
4. Catalytic Synthesis of Magnesium Hydride[32]

Drastic conditions and long reaction times are needed to prepare magnesium hydride from the elements.[33] Because of the potential significance of the hydrides of magnesium, its alloys, and its intermetallic compounds as reversible hydrogen storage systems,[34] many attempts have been made to increase the rate of hydrogenation by adding a further metal (see Section 8). At the start of our investigations, little was known about the use of homogeneous transition-metal catalysts in this reaction.[35]

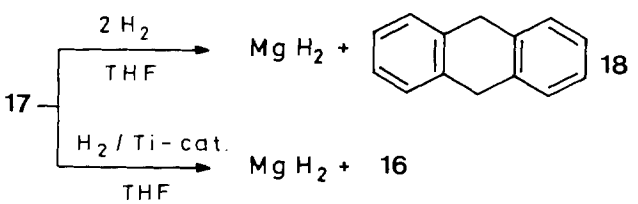


In analogy to the catalytic hydrogenation of lithium (Section 3.2), we initially investigated combinations of trithiapentalene with transition-metal halides as catalysts for the hydrogenation of magnesium. A catalytic reaction was observed upon addition of anthracene to activate the magnesium. According to *Ramsden*,[3] anthracene reacts with magnesium in THF to give insoluble "magnesium-anthracene". The reaction of magnesium and anthracene (or magnesium-anthracene) with, in particular, the halides of chromium, titanium, or iron in THF produces a hydrogenation catalyst that is active under mild conditions. The reaction proceeds slowly at room temperature and normal pressure and faster at 60–65 °C under pressure.[32]

$$Mg + H_2\,(1-80\ \text{bar}) \xrightarrow[20-65\,^\circ C]{\text{Mg-anthracene/MX}_n\text{/THF}} \underset{\mathbf{15}}{MgH_2}$$

$MX_n = CrCl_3$, $TiCl_4$, $FeCl_2$

Magnesium hydride **15** can be routinely prepared by this method and the reaction has been carried out on up to a 15-kg scale. Recent improvements in the catalyst have enabled the time required to be reduced from 12–16 h[32a] to 1–2 h.[36]

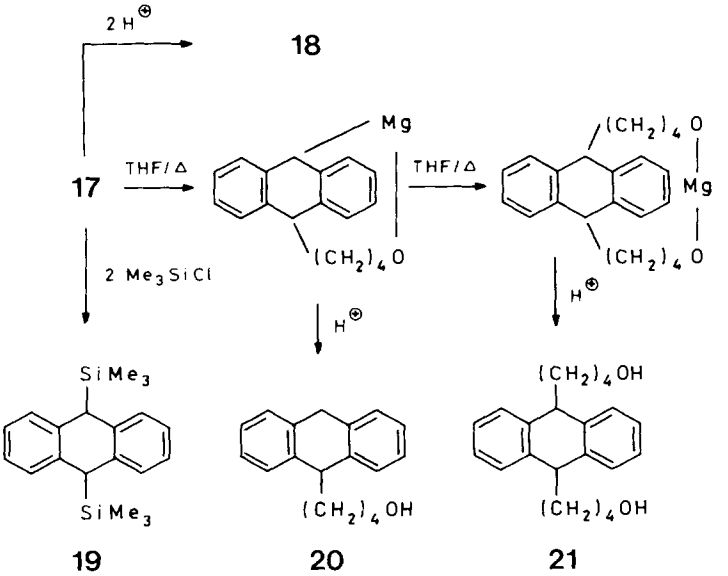


The following reactions have been shown to be involved in the hydrogenation reaction using the Mg-anthracene/$CrCl_3$ or Mg-anthracene/$TiCl_4$ catalyst:[32a] 1) Magnesium reacts with anthracene **16** in THF to give magnesium-anthracene **17**,[37] which is present in a temperature-dependent equilibrium with magnesium and **16**;[37] 2) The catalytically active transition-metal complex is formed by reaction of **17** with $CrCl_3$ or $TiCl_4$ in THF with release of anthracene **16**;[36] 3) **17** is hydrogenated to magnesium hydride in

Scheme 2.

the presence of the soluble chromium or titanium catalyst, **16** being liberated (only traces of 9,10-dihydroanthracene are detected). The first and third equations in Scheme 2 form a catalytic cycle, with **17** as reactive intermediate.

Insight into the role of the transition metal and of **17** in the catalytic hydrogenation of magnesium is afforded by a comparison of the hydrogenation of **17** in the presence and in the absence of a catalytic amount of $TiCl_4$. Hydrogenation of a suspension of **17** in THF at 58°C with hydrogen at 75 bar results in the slow (35 h) absorption of 2 mol H_2/mol **17** with the formation of magnesium hydride and 9,10-dihydroanthracene **18**. If, however, the hydrogenation is carried out under the same conditions in the presence of 1/50 mol $TiCl_4$ per mol **17**, the only reaction observed is the hydrogenation of magnesium at a tenfold faster rate with liberation of anthracene **16**.



The titanium catalyst is responsible for the formation of MgH_2 and **16** in the hydrogenation of **17**, while the reaction of **16** with magnesium maintains a stationary concentration of **17**.[38] Kinetic measurements show that the rate of formation of **17** in THF at 60°C is proportional to both the anthracene concentration and the Mg surface area.[37] In agreement with this, an increase in the anthracene concentration at 60°C leads to an increase in the rate of hydrogenation of the magnesium.[38]

In view of the importance of **17** for the catalytic hydrogenation of magnesium and for the synthesis of transition-metal complexes using anthracene-activated magnesium as a reducing agent,[39] the compound has been characterized both chemically and by NMR spectroscopy; moreover, the kinetics of its formation have been studied.[37] The ^1H- and ^{13}C-NMR spectra indicate that the magnesium atom in **17** is bonded to carbon atoms 9 and 10 of the anthracene ring. The Mg–C bond can be described as being covalent with a strongly polar character—the hybridization of the C-atoms lying between sp^2 and sp^3.

17 reacts in two ways. It behaves as a diorganomagnesium compound, i.e., as a nucleophile, upon protonolysis[37] and upon hydrogenolysis in the absence of a catalyst, both of which lead to **18**,[38] as well as in the reactions with chlorotrimethylsilane[36] and THF (at 120°C under pressure),[37] which lead to the 9,10-dihydroanthrylene derivatives **19**–**21**.

In contrast, the Mg–C bonds in **17** formally undergo homolytic cleavage in the dissociation reaction to give **16** and magnesium[37] as well as in the catalytic hydrogenation[38] and in reactions in which anthracene-activated magnesium is used as a reducing agent.[39] In these cases, **17** acts as a source of "soluble, atomic magnesium". The anthracene (**16**) that is liberated during reactions of this type can react with further magnesium to give **17** and thus

acts as a phase-transfer catalyst[39,40] to activate large quantities of magnesium.

5. Reactions of Catalytically Prepared Magnesium Hydride

The reactivity of magnesium hydride depends largely upon the method of preparation and upon the nature of any impurities present. Whereas samples prepared from the elements at high temperature and pressure are stable in air and only react slowly with water,[41] the product formed by pyrolysis of diethylmagnesium burns in air and reacts violently with water.[41a,42] The hydrogenation of magnesium in the presence of excess butadiene in THF leads to a reactive magnesium hydride powder having a large specific surface area (100 m^2/g).[43] The magnesium hydride prepared by *Ashby* et al.[44] from diorganomagnesium compounds or Grignard reagents and $LiAlH_4$[45] (or from $MgBr_2$ and NaH)[46] is particularly reactive. This "active" magnesium hydride has been used to prepare magnesium hydride halides,[47] alkoxides,[48] amides,[49] alkyls, and aryls[50] and has also been added to alkenes and alkynes[51] (see Section 5.1) and used to reduce organic compounds.[44]

In contrast to the magnesium hydride prepared from the elements,[33,41] the catalytically prepared sample **15**[32,36] is particularly reactive and is of potential interest as a hydrogen storage material and for the following applications:

- Separation of H_2 from gas mixtures
- Reducing and drying agent
- Preparation of soluble magnesium halide hydrides, of active magnesium, and of elements and their hydrides
- Cleavage of allyl ethers
- Carrier for heterogeneous catalysts
- Addition to 1-alkenes to give diorganomagnesium compounds (hydromagnesation)

Of these the reaction with alkenes (Section 5.1) and the use in hydrogen storage (Section 8) have been investigated in some detail.

For synthetic purposes **15** can be used either as a suspension in THF or as a solid, the highest activity being provided by a freshly prepared suspension. Only the solid is of interest for hydrogen storage. Both solid and suspension are pyrophoric and react violently with water; they should therefore be handled with care. Depending upon the catalyst and the hydrogenation and isolation conditions, the solid contains varying amounts of impurities: THF (1—5%), **16** (0.02—0.1%), **18** (0.02—0.2%),[*] **20** and **21** (together 0.1—0.3%),[*] *n*-butanol (0.3—0.8%),[*][37] $MgCl_2$ (5%), and Cr or Ti (0.1—0.7%). The specific surface area is 70—130 m^2/g. Electron microscopy (Fig. 2) and X-ray diffraction show the solid to consist of agglomerates (0.5 μm) of microcrystals (0.05 μm).[52] The high specific surface area makes **15** a suitable carrier for catalysts.[53]

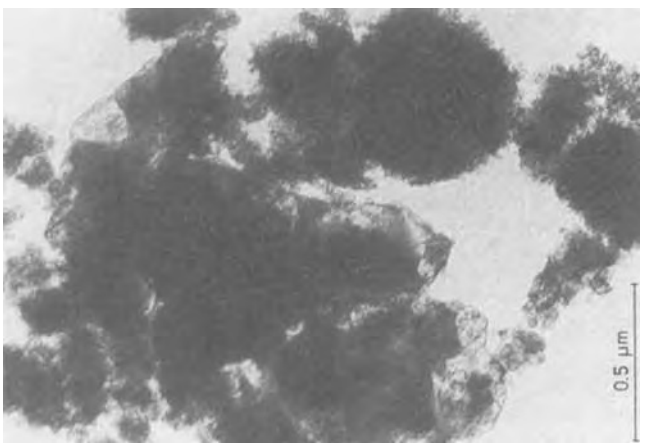


Fig. 2. An electron micrograph of catalytically prepared MgH_2 **15**.

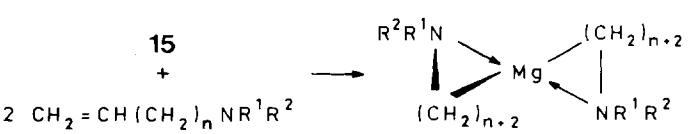
5.1. Catalytic Addition to 1-Alkenes ("Hydromagnesation" of Alkenes)[54]

Although the addition of the hydrides of aluminum,[55] boron,[56] silicon,[57] tin,[58] and zirconium[59] to alkenes and alkynes (hydrometalation) has been intensively studied during the last 25—30 years, little attention had been given prior to our studies to the addition of well-characterized magnesium hydrides to C=C bonds. The uncatalyzed reaction between magnesium hydride, prepared by various methods, and ethylene or other olefins affords a low yield of dialkylmagnesium compounds.[60] Recently, the Cp_2TiCl_2-catalyzed addition of "active" magnesium hydride to 1-alkenes and alkynes has been reported.[51] More attention has been given to the "indirect", titanium-[61] or nickel-catalyzed,[62] addition to alkenes and alkynes of "active" magnesium hydride prepared from Grignard reagents having β-hydrogen atoms.

Dialkylmagnesium compounds have attained industrial importance in the preparation of highly active Ziegler catalysts.[63] At present they are prepared according to the Grignard method via the Schlenck equilibrium[64] or by alkylation of magnesium chloride with organolithium compounds.[64c,65]

Attempts to add **15** to 1-alkenes led to the discovery that the **17**/$TiCl_4$ and to a lesser extent **17**/$CrCl_3$ catalysts, which are used for the hydrogenation of magnesium (see Section 4), also catalyze the addition reaction. The synthesis of diethyl-, dipropyl-, or dibutylmagnesium can, for example, be carried out by preparing **15** in the presence of the **17**/$TiCl_4$ catalyst and then treating it in situ with ethylene, propene, or 1-butene.[66] For instance, ethylene is converted quantitatively into the dialkylmagnesium compound within 2.5 h at 75 °C, and, after 3 h at 80—100 °C, 1-butene has reacted to 85—90%.[67]

$$Mg + H_2 \xrightarrow[THF]{17/TiCl_4} \mathbf{15} \xrightarrow[THF]{2\,CH_2=CHR} Mg(CH_2CH_2R)_2$$
$$R = H,\ CH_3,\ C_2H_5$$

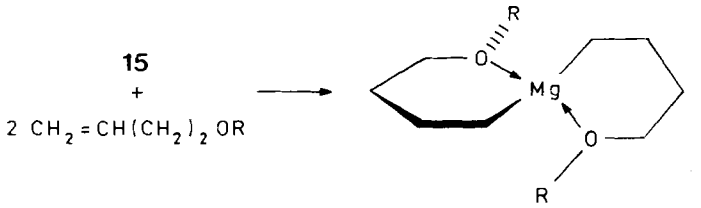


More active catalysts for the addition of **15** to 1-alkenes are obtained by the reaction of **15** with zirconium tetrahalides. In general, **15**, prepared using a Cr catalyst, is combined with the Zr catalyst and then reacted with the 1-alkene to give the dialkylmagnesium compound.

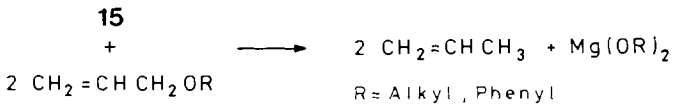
$$Mg + H_2 \xrightarrow[THF]{17/CrCl_3(TiCl_4)} \mathbf{15} \xrightarrow[THF]{ZrCl_4/2\,CH_2=CHR} Mg(CH_2CH_2R)_2$$
$$R = H,\ alkyl$$

The dialkylmagnesium compounds, prepared in THF, can be used directly for synthetic purposes; alternatively, the complexed THF can be removed in a vacuum at elevated temperatures to give, after extraction or crystallization, a hydrocarbon solution or a solid free of catalyst and practically free of THF.[54,67] The preparation of dialkylmagnesium compounds from magnesium hydride and 1-alkenes has several advantages over the usual procedures:[64,65] only about half as much magnesium is needed, only traces of magnesium-containing side products are formed, and, instead of primary alkyl halides, 1-alkenes can be used as starting materials. The reaction of the dialkylmagnesium compounds with electrophiles indicates that the catalytic addition of the hydride to the 1-alkene occurs in a highly regiospecific manner with up to 99.7% $M \rightarrow C_1$ addition. Practically no reaction is observed between MgH_2 and 1,1- or 1,2-dialkylalkenes.

15 can also be added catalytically (Zr-catalyzed) to tertiary allyl- and homoallylamines to give the monomeric compounds **22** and **23**, respectively, which can be distilled in vacuum.



The catalyzed addition of MgH_2 to homoallyl ethers occurs to give the analogous compounds **24**,[68,69] whereas the reaction with allyl ethers leads instead to reductive cleavage of the allyl-O bond.[68,70]



R^1, R^2 = Alkyl **22**: n = 1 **23**: n = 2

[*] After hydrolysis.

The catalyzed addition of **15** to isoprene and styrene has been discussed elsewhere.[71]

24: R = Alkyl

5.2. Reaction with Functionalized Organic Compounds

Relatively little attention has been given to the reaction of **15** with organic compounds having functional groups. Aliphatic and aromatic esters, aldehydes, and ketones afford only low yields of the alcohols upon reduction with **15** since the main reaction is condensation. The reductive cleavage of allyl ethers with **15** has been mentioned above (Section 5.1). *n*-Butyl chloride is reduced to *n*-butane by **15** in boiling THF, whereas magnesium chloride hydride (see Section 6) is the product of the reaction with allyl chloride.

5.3. Synthesis of Hydrides

15 reacts with chlorosilanes and organo-chlorosilanes in THF at room temperature (or slightly above) to give silanes in high yield. This reaction has been used, among others, to prepare SiH_4 (which is used in the synthesis of highly pure silicon)[72–74] in a one-pot synthesis from Mg, H_2, and $SiCl_4$.[75] (Methods for preparing SiH_4 are summarized in [74,76,77]).

The reaction of **15** with alkali-metal alkoxides in ether results in the formation of alkali-metal hydrides and soluble alkali-metal alkoxomagnesates.[78,79] *Nöth*[80] has shown that **15** reacts in THF at room temperature with diborane to give crystalline $Mg(BH_4)_2 \cdot 3\,thf$.

$$\mathbf{15} + n\,MOR \longrightarrow M_{n-2}Mg(OR)_n + 2\,MH$$
$$M = Li, Na, K;\ n = 3-5;\ R = Et, t\text{Bu}, cyclo\text{-}C_6H_{11}$$

6. Magnesium Chloride Hydride

Magnesium chloride hydride **25** is formed in low yield in the reaction of **15** with magnesium chloride in THF.[47] The yield is quantitative if the magnesium is hydrogenated with the **17**/$CrCl_3$ catalyst at 0°C in a saturated solution of $MgCl_2$ in THF (see Section 4).[32b,81] **25** (yield ca. 80%) is also obtained via the reaction of **15** with allyl chloride in THF[68] and is of interest as a soluble reducing agent and in Mg–H addition (hydromagnesation) reactions.

$$Mg + MgCl_2 + H_2 \xrightarrow{cat./THF} \underset{\mathbf{25}}{2\,HMgCl}$$

$$\mathbf{15} + CH_2{=}CHCH_2Cl \longrightarrow \mathbf{25} + CH_2{=}CHCH_3$$

7. Active Magnesium from Catalytically Prepared Magnesium Hydride

Activated forms of magnesium are used in chemical synthesis, particularly for Grignard reactions,[19] as reducing agents,[82] and in the preparation of magnesium-butadiene[83] and related compounds. With activated magnesium, the reactions are frequently more efficient and in some cases new reactions[84] are observed. According to *Rieke*, an active form of magnesium can be prepared by reducing a magnesium halide with an alkali metal (particularly potassium in THF or 1,2-dimethoxyethane),[85,86] if necessary with addition of naphthalene as an electron-transfer reagent.[87,88] Vaporization of magnesium leads to a finely divided form[89] which has also been used in synthesis.[90]

A highly reactive, pyrophoric form of magnesium, Mg*, which can be used in synthesis, can be prepared by dehydrogenation of **15** at 250°C at reduced pressure or above 300°C at normal pressure. This material has a specific surface area of 20–28 m^2/g.

$$\mathbf{15} \rightleftharpoons Mg^* + H_2$$

This method of preparation differs from those discussed above in that no solvent is present and the Mg* is not contaminated by alkali metal or alkali-metal halides.[91] The high reactivity of Mg* towards hydrogen is discussed in Section 8.3.

8. MgH_2/Mg as a Hydrogen Storage System

By way of introduction, the use of hydrogen as an energy source and the problems associated with its storage will first be reviewed.

8.1. Hydrogen as an Energy Source and Hydrogen Storage

Hydrogen is in many respects an ideal secondary energy source and its potential to solve present and future energy problems is the subject of widespread investigation and discussion.[92] Its advantages include the highest energy content per unit weight of all chemical fuels,[93] its versatile applications as a source of energy, and its simple, economical transportation as a gas through pipelines.[94]

The main advantage of hydrogen over coal, oil, or natural gas, taking into consideration air pollution and the threat of climatic changes in the next millenium as a result of a possible increase in the CO_2 content of the atmosphere (the "green house" effect),[97] is its combustion to water.[96]

A number of problems stand in the way of the development of a hydrogen economy, and an increase in the use of hydrogen as a source of energy is expected only towards the end of this century.[95] These problems are associated with both the production of hydrogen using primary energy sources (e.g., the sun or nuclear power) and the introduction of hydrogen as an energy source for industry, transportation, or the home, including the problem of hydrogen storage. The use of hydrogen in many of these areas (particularly transportation) rests upon the availability

of a simple, economic, and safe way to store large quantities of hydrogen in a small volume and with an acceptable weight.

In principle, hydrogen can be stored either in the elemental form, as a gas or a liquid, or in a chemical form. As a chemical form of hydrogen storage, metal hydrides are receiving the most attention.[98] NH_3 is used industrially to store hydrogen[99] and the use of methylcyclohexane has been considered.[100]

8.2. Metal Hydrides as Reversible Hydrogen Storage Systems

The reaction of hydrogen with metals, metal alloys, and intermetallic compounds frequently results in the formation of metal hydrides. Since these reactions are exothermic and reversible, the metal hydrides can release hydrogen if heated.

$$M + n/2\,H_2 \rightleftharpoons MH_n + \text{heat}$$

M = metal, metal alloy, intermetallic compound

In principle, the sequence can be repeated as often as desired and forms the basis for the use of the metal hydride/metal system in both hydrogen storage and heat storage.

Important criteria for the choice of the metal hydride are a high hydrogen content per unit weight and volume, a temperature-dependent hydrogen dissociation pressure, and a satisfactory rate of reaction, as well as the repeatability of the dehydrogenation/hydrogenation process and the effect of impurities in the hydrogen. Moreover, economic factors (raw material and production costs) play a crucial role. Table 2 summarizes data for some metal hydride/metal/H_2 storage systems. The so-called low-temperature storage systems (LaNi- or FeTi-H_2) contain relatively small amounts of hydrogen per unit weight but this is liberated at 20°C. On the other hand, the high-temperature systems (Mg_2Ni- and Mg-H_2) liberate hydrogen only at temperatures above 250°C. The hydrogen density in all these hydrides is higher than that in liquid hydrogen.

Table 2. Characteristics of various metal/metal hydride systems.

	Wt.-% H_2	Decomposition temperature [°C] (P_s = 1 bar)	Energy density [MJ/kg]
TiFe/TiFeH	1.00	− 6	1.2
$TiCr_2$/$TiCr_2H$	1.20	− 20	1.4
TiCo/TiCoH	1.30	130	1.4
$LaNi_5$/$LaNi_5H_6$	1.37	20	1.5
Mg_2Al_3/$Mg_2Al_3H_4$	3.00	230	3.6
Mg_2Ni/Mg_2NiH_4	3.16	250	3.8
Mg/MgH_2	7.66	284	9.0

Magnesium hydride has the highest hydrogen content (7.6%), and hence the highest energy density per unit weight (9 MJ/kg), of all the metal hydrides studied; moreover, magnesium is relatively cheap. Magnesium would therefore seem to be an optimal hydrogen storage material. So far, however, the unfavorable kinetic behavior of the MgH_2/Mg system,[33d-h, 101] as well as the high dissociation temperature, have made its use unattractive. The doping or alloying of magnesium with a second metal (Al,[102] In,[33e] Ce,[103] La,[103c] Fe,[104] and other metals[105]) or the formation of intermetallic compounds (Mg_2Ni,[34b, 102, 103a, 106] Mg_2Cu,[33g, 34a] $LaNi_5$[105a]) results in an improvement in the rate of dehydrogenation/hydrogenation, but a relatively high proportion of the second metal is needed (e.g., 10 wt.-% Ni)[103a, 106] and the storage capacity is less than that of magnesium hydride.[103a]

8.3. Catalytically Prepared Magnesium Hydride as a Hydrogen Storage Material[107]

We have used two methods to investigate the properties of various MgH_2 samples for hydrogen storage: the sample is either taken through one or more dehydrogenation/hydrogenation cycles under normal pressure or it is subjected to a series of cycles under slightly elevated (maximum 15 bar) pressures.

The normal pressure experiments are carried out in the specially constructed thermovolumetric apparatus shown in Fig. 3.[31] The oven with the MgH_2 sample (0.5—1.0 g) in the sample container is heated above the decomposition temperature of MgH_2 at normal pressure (284°C), e.g. to 330°C, and the liberation of hydrogen is followed using an automatic gas-burette. At the same time, the temperature of the sample is recorded. After complete dehydrogenation, the oven temperature is lowered to a value below 284°C (e.g., 230°C) and the absorption of hydrogen by the magnesium is followed in the same way. This procedure can be used to measure empirically the hydrogen content of MgH_2 (or of other metal hydrides) and to study the rate of release and up-take of hydrogen at normal pressure.[31]

The behavior of the various samples of MgH_2 (Fig. 4) depends upon their origin and treatment. The MgH_2 prepared at high temperature[33i] (Fig. 4a) liberates 3.5 wt.-%

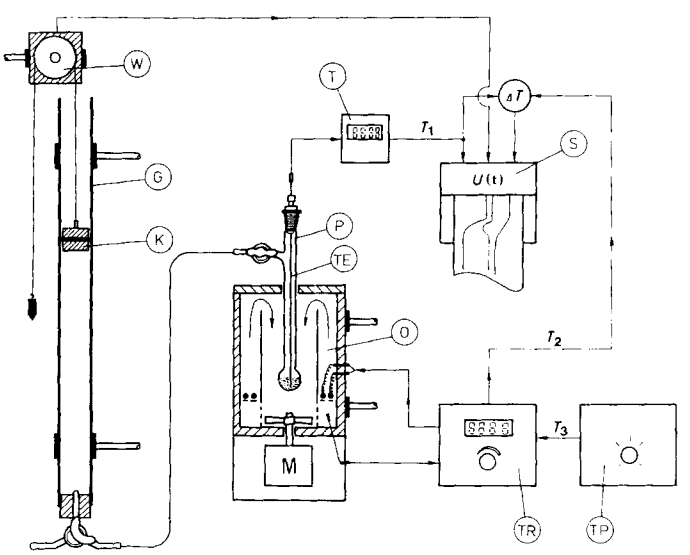


Fig. 3. Thermolysis apparatus used to investigate hydrogen storage materials at normal pressure. hydrogen over 6 h at 382 °C; the rehydrogenation at 230 °C leads to the reabsorption of only a small fraction of the hydrogen released. The dehydrogenation of a sample prepared from magnesium alloyed with 10% Ni (Fig. 4b) takes place rapidly at 330 °C with the release of 6.3 wt.-% hydrogen. However, here again only a partial rehydrogenation is observed at 230 °C and normal pressure. A more satisfactory result is obtained for the rehydrogenation of **15** (Fig. 4c) under the same conditions, and still further improvement in the properties can be obtained by doping **15** with traces (0.5—2%) of a second metal using a specially developed procedure (Fig. 4d).[108] Three dehydrogenation/hydrogenation cycles at normal pressure using doped **15** are shown in Fig. 5. To our knowledge, the conditions used are the mildest for the charging of a magnesium-based H_2 storage material.

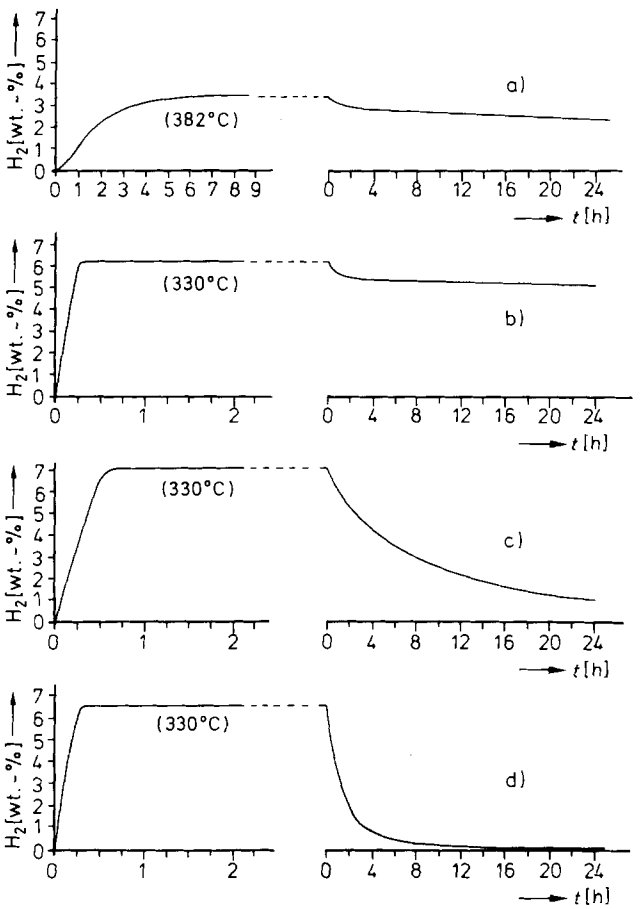

Fig. 4. Storage properties of various MgH_2 samples at normal pressure. a) technical MgH_2; b) hydrogenated $Mg_{90}Ni_{10}$ alloy; c) **15**; d) doped **15**. Left: dehydrogenation at 1 bar, temperature in parentheses; right: rehydrogenation at 1 bar, 230 °C.

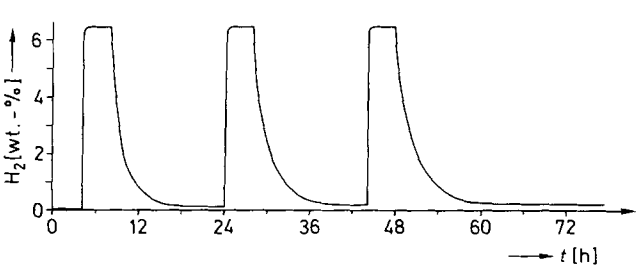

Fig. 5. Three hydrogenation/dehydrogenation cycles carried out on doped **15**.

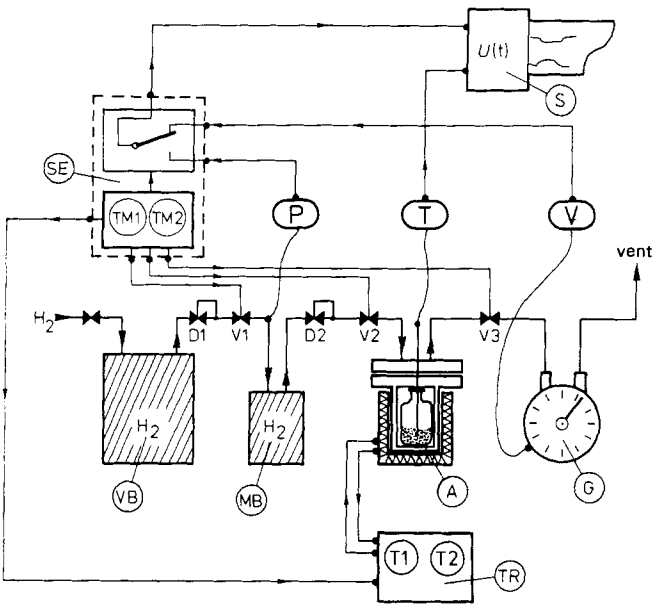

Fig. 6. An automatic apparatus for investigating MgH_2 samples under pressure (schematic drawing). A, autoclave with heater; D_1, D_2, pressure reduction valves; G, gasometer; MB, H_2 cylinder; P, pressure transducer; S, two-channel recorder; SE, electronic control unit; T, digital thermometer; T_1, T_2 temperature sensor for hydrogenation and dehydrogenation; TM1, TM2, timer for hydrogenation and dehydrogenation; TR, temperature control unit; V, gas volume transducer; V_1, V_2, V_3, electronically controlled valves; VB, H_2 source.

The series of cycles at elevated pressures are carried out in a fully automated apparatus (Fig. 6). Samples of **15** or **15** doped with a second metal, **15'**,[108] (or other magnesium hydride or metal hydride samples) are subjected typically to 30—50 dehydrogenation/hydrogenation cycles during which the hydrogenation pressure, temperature, and duration as well as the dehydrogenation temperature and duration can be varied. After 30—50 or more cycles, the kinetics and the storage capacity of the MgH_2/Mg systems **15** and **15'** are unaltered, within the experimental error, even though hydrogen having only 99.9% purity (i.e., not ultra-pure H_2) was used for these experiments. The rates of hydrogenation of **15** and **15'**, however, are very different (Fig. 7). The largest difference is observed for the

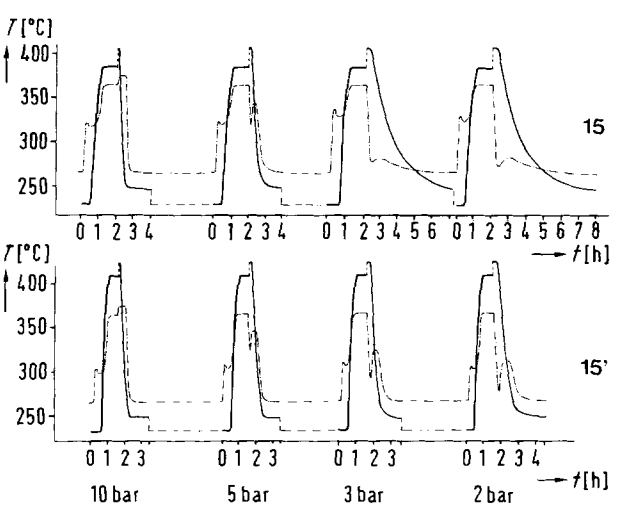

Fig. 7. Comparison of the storage properties of **15** and **15'** at various pressures. ——: H_2 absorption and desorption (arbitrary units); – – – –: temperature curve.

low pressure (2—3 atm of H_2) experiments: the effective hydrogenation time for **15** is three times longer. At higher pressures the difference in rate between the doped and undoped samples becomes less since, as the rate of hydrogenation increases, heat transfer becomes the rate-determining factor.

The results indicate that both **15** and **15′**, which have the highest (7%) known hydrogen storage capacity, might well have potential in hydrogen storage, whereby the mild hydrogenation conditions and the high rate of absorption and desorption of H_2 observed for **15′** could be of practical advantage.

To test the use of **15** as a hydrogen storage material, a number of hydride storage tubes were filled with cylindrical pellets of **15** (Fig. 8). The use of **15** in pellet form increases the hydrogen density per unit volume[109] while at the same time improving the heat conductance and decreasing the pyrophoric nature of the powder.[110] The storage capacity and kinetic behavior of the pellet form of **15** in a 60—70 cycle run at elevated pressure was shown to be similar to that of the powder.

Fig. 8. Pelleted, air-stable Mg/MgH_2 storage material with hydride storage tube (Zentrale Forschung der Daimler-Benz AG).

The applications of this magnesium-based hydrogen storage system range from hydrogen, and therefore energy, storage[98] to hydrogen transport,[111] heat storage,[112] and hydrogen separation and purification.[113]

Our investigations have shown that certain active forms of magnesium, which can be obtained, e.g., by dehydrogenation of **15** or **15′**, can be used to separate and purify hydrogen.[114] These even react with hydrogen at 200—230 °C and a partial pressure of 20—30 mbar and are inert towards methane or its homologues. Thus, hydrogen can be removed, in a one-step process, from mixtures of hydrogen and such gases and can subsequently be recovered by dehydrogenation of the resulting magnesium hydride. Only traces (1—2%) of hydrogen remain in the treated gas. It is of interest that the rate of absorption of hydrogen is hardly affected by traces (up to ca. 1 mol-%) of CO, CO_2, NH_3, or water vapor (saturated at 10 atm). These gases either react irreversibly with the active magnesium (or MgH_2) or are converted into other products (CO is reduced to CH_4). In this way, impurities can be removed from the gas; however, this is accompanied by a decrease in the hydrogen storage capacity. In contrast, the hydrogenation of the $LaNi_5$- or FeTi-H_2 storage systems is markedly inhibited by traces of CO, O_2, or H_2O in the hydrogen.[115] The following features characterize the use of **15** and **15′** in hydrogen storage:

- The initial catalytic hydrogenation of the magnesium can be carried out under mild, energetically favorable conditions.
- The kinetic characteristics can be improved by doping with traces of a second metal.
- **15** and **15′** do not have to be activated,[33h, 105a, 116] i.e., full activity (optimal kinetics and maximal absorption) is reached immediately without the need for a number of preliminary absorption-desorption cycles.
- The "active" magnesium derived from **15** or **15′** takes up hydrogen at a pressure lower than that observed for any previous magnesium-based storage system.
- The rate of hydrogenation is only slightly affected by the presence of impurities in technical hydrogen.

9. Summary and Outlook

The catalytically prepared magnesium hydride has made it possible to combine the high hydrogen-storage capacity of magnesium with a satisfactory rate of up-take and release of hydrogen (even at 1 bar), without having to resort to alloys. The use of soluble organometallic catalysts allows the initial hydrogenation to be carried out under mild conditions and gives a product that has favorable properties for chemical and practical purposes. It is to be hoped that such mild methods will be applied not only to the hydrogenation and activation of magnesium and the alkali metals but also to other areas involving the chemical conversion of metals.

The author, on behalf of his coworkers, would like to thank Professor G. Wilke, the Director of the Max-Planck-Institut für Kohlenforschung, for the generous support of this research. Thanks are also due to the heads of the instrumental-analytical departments and their coworkers: Dr. R. Benn (NMR spectroscopy), Dr. D. Henneberg (mass spectroscopy), Prof. Dr. C. Krüger (X-ray structural analysis), and Priv.-Doz. G. Schomburg (chromatography).

Oxidation of Organometallic Compounds

By Jack Halpern*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Stable organometallic compounds, notably of the later transition metals (groups VI—VIII), usually are characterized by closed shell electron configurations (typically 18-electron valence shells) which are destabilized by electron addition or removal. One-electron oxidation of such compounds results in the formation of unstable radical ions, whose characteristic reactivity patterns include susceptibility to nucleophilic attack, disproportionation, and metal-carbon bond dissociation. Two-electron oxidation may result in dissociation or oxidation of the organic ligand. In this review studies on the chemical and electrochemical oxidations of metal carbonyls, metal-olefin complexes, and alkyl transition-metal compounds are described. The studies encompass the following themes: (1) The kinetics and thermodynamics of the initial redox steps; (2) The characterization and reactivity patterns of the resulting oxidation products; (3) The synthetic and catalytic applications of organometallic redox processes.

1. Introduction

Whereas electron-transfer and simple redox reactions of inorganic coordination compounds have been extensively studied, and many features of their kinetics and mechanisms are well understood,[1] our knowledge and understanding of the corresponding redox chemistry of organometallic compounds is much less advanced. Indeed, only within the past decade have such redox processes received significant attention and study.

With a few notable exceptions (for example, $[V(CO)_6]$[2] and $[Fe(C_5H_5)_2]^{\oplus}$)[3] stable organometallic compounds, especially of the later transition metals (groups VI to VIII), correspond to closed shell electron configurations (often 18-, sometimes 16-, electron valence shells) which are destabilized by electron addition or removal, generating unstable products that undergo further reactions. Equations (1)—(3) illustrate this distinction (R = alkyl or aryl; Hdmg = dimethylglyoximato(1−); L = H_2O, py, etc.).

$$\underset{18e}{[Fe(CN)_6]^{4\ominus}} \xrightarrow{-e^{\ominus}} \underset{17e}{[Fe(CN)_6]^{3\ominus}} \quad \text{(stable)} \qquad (1)$$

$$\underset{18e}{[Cr(CO)_6]} \xrightarrow{-e^{\ominus}} \underset{17e}{[Cr(CO)_6]^{\oplus}} \quad \text{(unstable)} \qquad (2)$$

$$\underset{18e}{[R{-}Co(Hdmg)_2L]} \xrightarrow{-e^{\ominus}} \underset{17e}{[R{-}Co(Hdmg)_2L]^{\ominus}} \quad \text{(unstable)} \qquad (3)$$

This review is concerned particularly with the chemical and electrochemical oxidation reactions of organo-transition metal compounds, including those containing carbonyl, olefin, and alkyl ligands. The themes to be considered include: (1) the kinetics and mechanisms of the initial redox processes, (2) the characterization of the initial (often unstable and short-lived) organometallic oxidation products and the study of their chemical reactivities, and (3) the roles of oxidation of organometallic compounds in catalytic oxidation and other catalytic processes.

Only insofar as they impinge upon these themes will attention be directed to certain related topics, notably chemical and electrochemical *reductions* of organometallic compounds,[4,5] oxidative-addition and reductive-elimination reactions,[6,7] and redox reactions of non-transition metal organometallic compounds,[8,9] Attention is directed in the cited references to other reviews of some relevant aspects of these topics.

2. Oxidation of Metal Carbonyls

Our interest in this theme had its origin in our early studies on the oxidation of CO in aqueous solution by metal ions such as Hg^{II} and Ag^{I} [Eq. (4) and (5)].[10,11]

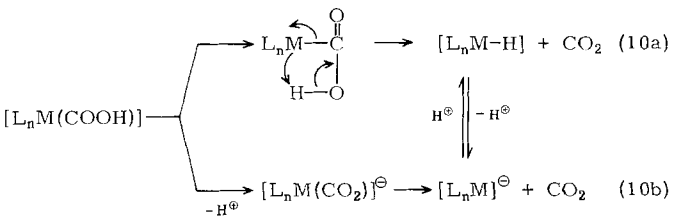
$$CO + 2\,Hg^{2\oplus} + H_2O \longrightarrow CO_2 + Hg_2^{2\oplus} + 2\,H^{\oplus} \qquad (4)$$

$$CO + 2[Ag(NH_3)_2]^{\oplus} + 2\,H_2O \longrightarrow CO_3^{2\ominus} + 2\,Ag + 4\,NH_4^{\oplus} \qquad (5)$$

These and subsequently identified oxidations of CO by other metal ions, such as Rh^{III}, Ni^{II}, and Cu^{II}, have been interpreted as proceeding through mechanisms involving hydroxycarbonyl (or metallacarboxylic acid) complexes such as **1** [Eq. (6) and (7)].[12]

$$Hg^{2\ominus} + CO + H_2O \xrightarrow{\text{rate-determining}} [Hg{-}\underset{\underset{\mathbf{1}}{\|}}{\overset{O}{C}}OH]^{\oplus} + H^{\oplus} \xrightarrow{\text{fast}} Hg^0 + CO_2 + 2\,H^{\oplus} \qquad (6)$$

$$Hg^0 + Hg^{2\oplus} \xrightarrow{\text{fast}} Hg_2^{2\ominus} \qquad (7)$$



[*] Prof. Dr. J. Halpern
Department of Chemistry, The University of Chicago
Chicago, IL 60637 (USA)

Pathways analogous to that depicted above for the oxidation of free CO extend also to the oxidation of coordinated CO. Thus, certain metal carbonyl complexes are decomposed by reaction with H_2O (or $OH^{\ominus}$) with the formation of CO_2 (or $CO_3^{2\ominus}$) and a reduced metal carbonyl or a metal hydride [Eq. (8) and (9)].[13,14]

$$[Fe^0(CO)_5] \xrightarrow{OH^{\ominus}} [Fe^0(CO)_4(COOH)]^{\ominus} \xrightarrow{2\,OH^{\ominus}} [Fe^{-II}(CO)_4]^{2\ominus} + H_2O + HCO_3^{\ominus}$$
$$\Updownarrow$$
$$[HFe^0(CO)_4]^{\ominus} + OH^{\ominus} \qquad (8)$$

$$trans\text{-}[Pt^{II}Cl(PEt_3)_2(CO)]^{\oplus} \xrightarrow[-H^{\oplus}]{H_2O} trans\text{-}[Pt^{II}Cl(PEt_3)_2(COOH)] \longrightarrow trans\text{-}[HPt^{II}Cl(PEt_3)_2] + CO_2 \qquad (9)$$

Only recently have several examples of stable hydroxycarbonyl complexes, including *trans*-$[PtCl(PEt_3)_2(COOH)]$, actually been intercepted and characterized.[15-18] Such complexes tend to be unstable and to decompose upon warming or upon reaction with water, with loss of CO_2 to form the corresponding hydrides. An unresolved mechanistic question is whether such decomposition, especially in the presence of water, involves the direct transfer of hydrogen to the metal (β-elimination of CO_2) according to Eq. (10a) or deprotonation to yield an intermediate CO_2 complex (or metallacarboxylate) according to Eq. (10b). Both processes are inherently plausible and it is possible that both occur in appropriate circumstances.

It is likely that the $[Hg(COOH)]^{\oplus}$ intermediate **1** in reaction (6) is formed by external nucleophilic attack of water on the transient mercury(II)-carbonyl complex **2** [Eq. (11)], analogous to the mercury(II)-olefin complexes (or mercurinium ions) **3** that have been postulated as intermediates in the closely related olefin oxymercuration reactions [Eq. (12)].[19]

$$Hg^{2\oplus} + CO \rightleftharpoons \underset{\mathbf{2}}{[Hg(CO)]^{2\oplus}} \xrightarrow{H_2O} [Hg(COOH)]^{\oplus} + H^{\oplus} \qquad (11)$$

$$Hg^{2\oplus} + CH_2{=}CH_2 \rightleftharpoons \underset{\mathbf{3}}{[Hg(CH_2{=}CH_2)]^{2\oplus}} \xrightarrow{H_2O}$$
$$[Hg(CH_2CH_2OH)]^{\oplus} + H^{\oplus} \qquad (12)$$

To the extent that such prior coordination of CO is an important component of the CO oxidation pathway, the scope of such oxidations would appear to be constrained by the limited tendency of CO to coordinate to metal ions in high oxidation states (for example, potential oxidants such as Co^{III}). It appeared to us that a possible approach to get around this limitation and thereby to extend the scope for possible metal-ion oxidations of CO (and related unsaturated molecules) would be to start with a stable metal-carbonyl complex in a low (i.e., non-oxidizing) oxidation state and to oxidize the pre-formed complex to a higher oxidation state of the metal ion which would not normally coordinate CO.

This approach was applied successfully to effect the oxidation of CO in the mixed ligand Co^I complex $[Co^I(CN)_2(PEt_3)_2(CO)]^{\ominus}$ (abbreviated $[L_nCo^I(CO)]^{\ominus}$), using $[Fe(CN)_6]^{3\ominus}$ (abbreviated $X^{3\ominus}$) as oxidant.[20] $[L_nCo^I(CO)]^{\ominus}$ was found to undergo two successive one-electron oxidations in aqueous solution to form the CN-bridged binuclear Co^{III} complex $[(NC)_5Fe^{II}(CN)Co^{III}(CN)_2(PEt_3)_2(CO)]^{3\ominus}$ (abbreviated $[XL_nCo^{III}(CO)]^{3\ominus}$). The fate of the latter is determined by the pH of the solution [Eq. (13)]; the paths (13a), (13b), and (13c) predominate in the pH ranges <4.5, 4.5—11.5, and >11.5, respectively. The rate constants $k_{(13b)}$ and $k_{(13c)}$ at 25° are 1.0×10^{-3} and $3.4\ s^{-1}$, respectively.

$$[L_nCo^I(CO)]^{\ominus} \underset{X^{4\ominus}}{\overset{X^{3\ominus}}{\rightleftharpoons}} [L_nCo^{II}(CO)] \xrightarrow{X^{3\ominus}}$$

$$[XL_nCo^{III}(CO)]^{3\ominus} \xrightarrow{H_2O} [XL_nCo^{III}(H_2O)]^{3\ominus} + CO \qquad (13a)$$
$$OH^{\ominus}\Updownarrow$$
$$[XL_nCo^{III}(COOH)]^{4\ominus} \xrightarrow{k_{(13b)}} [XL_nCo^{I}]^{5\ominus} + CO_2 + H^{\oplus} \qquad (13b)$$
$$OH^{\ominus}\Updownarrow H_2O$$
$$[XL_nCo^{I}(CO_2)]^{5\ominus} \xrightarrow{k_{(13c)}} [XL_nCo^{I}]^{5\ominus} + CO_2 \qquad (13c)$$

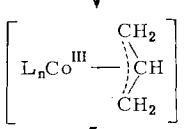
In the presence of excess $[Fe(CN)_6]^{3\ominus}$ the L_nCo^I produced in reaction (13b) or (13c) is irreversibly oxidized to a Co^{III} complex [Eq. (14)], resulting in the overall stoichiometry of Eq. (15). Under these conditions the effective reducing power of the coordinated CO, as well as of the Co^I ion, is utilized to supply electrons for the reduction of $[Fe(CN)_6]^{3\ominus}$ so that $[L_nCo^I(CO)]^{\ominus}$ acts as a 4-electron reductant.

$$[XL_nCo^I]^{5\ominus} + 2X^{3\ominus} + H_2O \longrightarrow [XL_nCo^{III}(H_2O)]^{3\ominus} + 2X^{4\ominus} \qquad (14)$$

$$[L_nCo^I(CO)]^{\ominus} + 4X^{3\ominus} + 2OH^{\ominus} \longrightarrow$$
$$[XL_nCo^{III}(H_2O)]^{3\ominus} + 3X^{4\ominus} + CO_2 \qquad (15)$$
$$CO_2 + 2OH^{\ominus} \rightleftharpoons CO_3^{2\ominus} + H_2O$$

The apparent reversibility of the sequence of steps corresponding to Eq. (16), and the relatively slow decomposition of the intermediate CO_2 complex, $[XL_nCo^I(CO_2)]^{5\ominus}$ ($k_{(13c)}=3.4\ s^{-1}$), identifies a pathway for the reduction of coordinated CO_2 to CO (i.e., by Co^I). Since CO_2 has been demonstrated to coordinate to other Co^I complexes,[21] this suggests a possible approach to the homogeneous catalytic reduction of CO_2, an objective of considerable current interest. The recently reported catalytic reduction of CO_2 to CO at carbon electrodes modified with cobalt phthalocyanine probably involves related chemistry.[22]

$$[XL_nCo^{III}(CO)]^{3\ominus} \overset{OH^\ominus}{\rightleftharpoons} [XL_nCo^{III}(COOH)]^{4\ominus} \overset{OH^\ominus}{\underset{H_2O}{\rightleftharpoons}} [XL_nCo^I(CO_2)]^{5\ominus} \quad (16)$$



Because of the effectiveness of CO_2 as a leaving group, redox pathways such as (17) may result in the formation of "coordinatively unsaturated" species, e.g., $[XL_nCo^I]^{5\ominus}$ (or $[L_nCo^I]^\ominus$, which presumably is formed readily from $[XL_nCo^I]^{5\ominus}$ by loss of $X^{4\ominus}$), with high affinities for a variety of ligands, notably those (e.g., olefins) that are effective in stabilizing low oxidation states. This opens up the possibility of synthetic approaches involving the "oxidative substitution" of CO by other ligands to generate complexes that are not readily synthesized by other methods, such as **4** and **5** [Eq. (17)–(19)].[20]

$$[L_nCo^I(CO)]^\ominus \xrightarrow[-X^{4\ominus}\ -H_2O]{2\,X^{3\ominus}\ 2\,OH^\ominus} [XL_nCo^I(CO_2)]^{5\ominus} \xrightarrow[-X^{4\ominus}]{-CO_2} [L_nCo^I]^\ominus \quad (17)$$

$$[L_nCo^I]^\ominus \xrightarrow{CH_2=CHCN} [L_nCo^I(CH_2{=}CHCN)]^\ominus \quad (18)$$

4

$$[L_nCo^I]^\ominus \xrightarrow{CH_2=CHCH_2OH} [L_nCo^I(CH_2{=}CHCH_2OH)]^\ominus \xrightarrow{-OH^\ominus} \quad (19)$$

5

When the oxidation of $[L_nCo^I(CO)]^\ominus$ according to Eq. (13b) and (13c) is conducted in the presence of an excess of CO, the coordinatively unsaturated $[L_nCo^I]^\ominus$ intermediate is readily trapped by CO to reconstitute the initial $[L_nCo^I(CO)]^\ominus$ complex. This results in the establishment of a catalytic cycle for the oxidation of CO [Eq. (20)]. When the oxidant is $[Fe(CN)_6]^{3\ominus}$ the overall catalytic reaction corresponds to Eq. (21).[20]

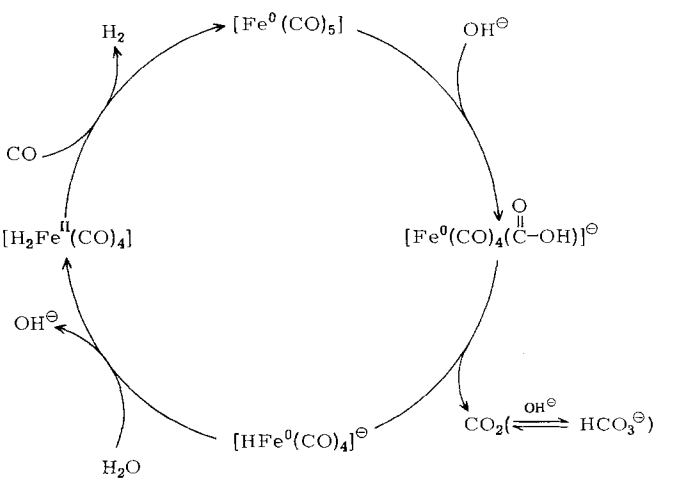
$$\begin{array}{ccc} [Co^I(CO)] & \xrightarrow{-2\,e^\ominus} & [Co^{III}(CO)] \\ \uparrow{\scriptstyle [CO]} & & \downarrow{\scriptstyle 2\,OH^\ominus\ (-H_2O)} \\ [Co^I] & \xleftarrow{-CO_2} & [Co^I(CO_2)] \end{array} \quad (20)$$

$$CO + 2\,OH^\ominus + 2\,[Fe(CN)_6]^{3\ominus} \xrightarrow{[L_nCo^I(CO)]^\ominus} CO_2 + 2\,[Fe(CN)_6]^{4\ominus} + H_2O \quad (21)$$

Catalysis of the oxidation of CO also has been observed in the case of certain other metal-ion oxidants (e.g., Cu^{II} and Rh^{III}) whose reduction products (Cu^I and Rh^I) form stable CO complexes.[12] In such cases reduction may be autocatalytic as in the reduction of $RhCl_3$ by CO [Eq. (22)] where both uncatalyzed and autocatalytic pathways are observed [Eq. (23) and (24)], corresponding to the rate laws $k'[Rh^{III}][CO]$ and $k''[Rh^{III}][Rh^I(CO)_2]$, respectively.

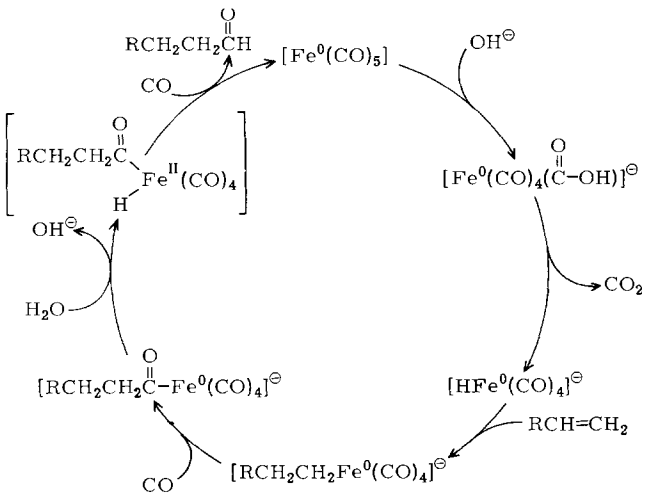
$$[Rh^{III}] + 3\ CO + H_2O \longrightarrow [Rh^I(CO)_2] + CO_2 + 2\ H^\oplus \quad (22)$$

$$[Rh^{III}] \xrightarrow{CO} [Rh^{III}(CO)] \xrightarrow[-H^\oplus]{H_2O} [Rh{-}\overset{O}{\overset{\|}{C}}OH] \xrightarrow[-H^\oplus]{-CO_2} [Rh^I] \xrightarrow{2\,CO} [Rh^I(CO)_2] \quad (23)$$



$$[Rh^{III}] + [Rh^I(CO)_2] \longrightarrow [Rh^I] + [Rh^{III}(CO)_2] \xrightarrow{H_2O,\ -H^\oplus} [Rh^{III}(CO)(COOH)] \xrightarrow{CO} [Rh^I(CO)] + CO_2 + H^\oplus \quad (24)$$

Other catalytic applications of the metal-carbonyl chemistry described above include catalysis of the water-gas shift reaction [Eq. (25)][12,23–25] and the use of combinations of CO and H_2O as a source of hydrogen or of electrons to effect hydrogenation, hydroformylation [Eq. (26)], or reduction [Eq. (27)].[23,26,27] Mechanistic schemes for reactions (25) and (26) are depicted in Schemes 1 and 2, respectively.



$$CO + H_2O \xrightarrow{[Fe(CO)_5]} H_2 + CO_2\ (\overset{OH^\ominus}{\rightleftharpoons} HCO_3^\ominus) \quad (25)$$

$$RCH{=}CH_2 + 2CO + H_2O \xrightarrow{[Fe(CO)_5]} RCH_2CH_2\overset{O}{\overset{\|}{C}}H + CO_2 \quad (26)$$

$$RNO_2 + 3CO + H_2O \xrightarrow{[Fe(CO)_5]} RNH_2 + 3CO_2 \quad (27)$$

Scheme 1. Mechanism of the $Fe(CO)_5$-catalyzed water-gas shift reaction [Eq. (25)].

Scheme 2. Mechanism of the $Fe(CO)_5$-catalyzed hydroformylation of alkenes [Eq. (26)].

The susceptibility of coordinated CO to nucleophilic attack by water and the instability of the resulting hydroxycarbonyl complexes usually precludes the direct detection and characterization of oxidized metal-carbonyl complexes in aqueous solution. In less nucleophilic solvents such as acetonitrile, oxidation may simply result in the liberation of coordinated CO and other ligands [Eq. (28) and (29), C_4H_6 = butadiene].[28]

$$[Fe(CO)_5] \xrightarrow{-e^{\ominus}} [Fe(CO)_5]^{\oplus}\ (?) \xrightarrow{-e^{\ominus}} Fe^{II} + 5CO \qquad (28)$$

$$[Fe(CO)_3(C_4H_6)] \xrightarrow{Fe^{III}\ or\ Ce^{IV}} Fe^{II} + 3CO + C_4H_6 \qquad (29)$$

In some cases the lifetimes of the oxidized species are sufficiently long that the electrochemical oxidations of metal carbonyls or mixed ligand carbonyl complexes to the corresponding 17-electron radical cations yield reversible cyclic voltammograms as in the example of Eq. (30) and the corresponding oxidations of $[Cr(CO)_5(PPh_3)]$,[29] $[CpMn(CO)(PPh_3)_2]$,[30] $[Fe(CO)_3(PR_3)_2]$,[31] $[Cr(CO)_5I]^{\ominus}$,[32] $[Ta(CO)_2(dmpe)_2Cl]^{\oplus}$,[33] $[CpCo(PPh_3)_2]$,[34] and $[Cr(CO)_6]$[35] (Cp = cyclopentadienyl; dmpe = bis(1,2-dimethylphosphino)ethane). Several such species have been characterized by electron absorption and EPR spectroscopy and at least one, $[Cr(CO)_4(PPh_3)_2]^{\oplus}$, has recently been isolated as a stable salt.[36] One decomposition pathway of such 17-electron radical cations in solution is through disproportionation [Eq. (31)].[37]

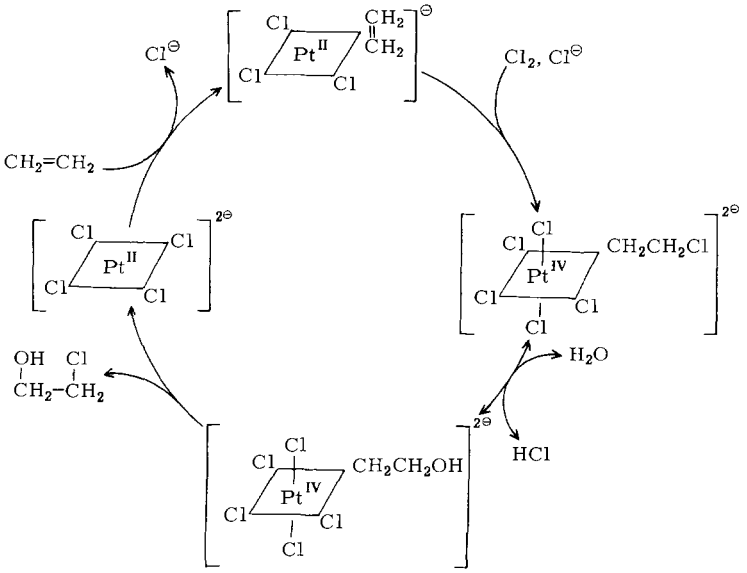
$$[Cr(CO)_6] \underset{e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} [Cr(CO)_6]^{\oplus} \qquad (30)$$

$$2[Cr(CO)_6]^{\oplus} \longrightarrow [Cr(CO)_6] + [Cr(CO)_6]^{2\oplus}\ (\longrightarrow Cr^{II} + 6CO) \qquad (31)$$
unstable

3. Oxidation of Metal-Olefin Complexes

Metal ions such as Pd^{II}[38,39] and Tl^{III}[40,41] are useful oxidants for olefins, particularly in view of the distinctive selectivities which they characteristically exhibit. Mechanistic pathways for such reactions have been postulated which involve both π- and σ-bonded organometallic intermediates, an example being the widely accepted mechanism of the Wacker reaction [Eq. (32)].

$$[PdCl_4]^{2\ominus} \xrightarrow[-Cl^{\ominus}]{CH_2=CH_2} [PdCl_3(CH_2=CH_2)]^{\ominus} \xrightarrow[-H^{\oplus}]{H_2O}$$



$$[PdCl_3(CH_2CH_2OH)]^{2\ominus} \longrightarrow Pd^0 + CH_3CHO + H^{\oplus} + 3Cl^{\ominus} \qquad (32)$$

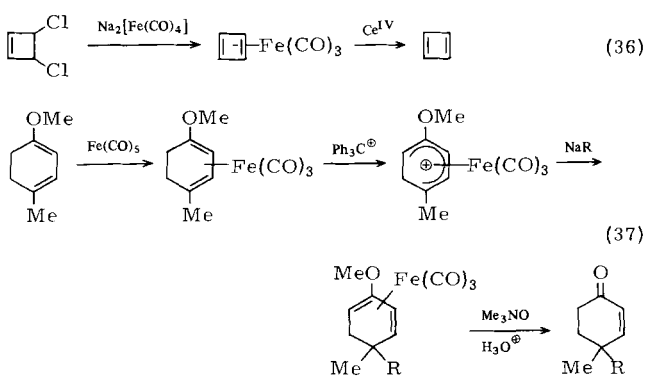
The evidence upon which this mechanism rests is not entirely conclusive, particularly with respect to the intermediacy of the σ-bonded organometallic species $[PdCl_3(CH_2CH_2OH)]^{2\ominus}$ for which there is only indirect evidence[38,39] (although analogous $[Tl{\geqslant}C-C{\leqslant}OH]^{2\ominus}$ intermediates have been identified in the oxidations of certain olefins by Tl^{III}).[40a] To the extent that initial π-coordination of the olefins to the metal ion is an important component of the oxidation pathway, such oxidations (like the corresponding oxidations of CO discussed above)[20] would appear to be constrained by the limited tendencies of olefins to coordinate to metal ions in high oxidation states. Accordingly, one strategy for extending the scope of metal-ion oxidations (paralleling that described above for CO oxidation) would be to start with a stable olefin complex of a metal ion in a low oxidation state and to oxidize the pre-formed complex to a higher oxidation state with an external oxidant.

An illustration of the successful application of this approach is provided by the oxidation of Zeise's anion, $[Pt^{II}Cl_3(CH_2=CH_2)]^{\ominus}$, in aqueous HCl solution by Cl_2.[42] The addition of a stoichiometric amount of Cl_2 results in the oxidation of the coordinated ethylene to chlorohydrin [Eq. (33)]. Excess Cl_2 further oxidizes $[Pt^{II}Cl_4]^{2\ominus}$ to $[Pt^{IV}Cl_6]^{2\ominus}$.

$$[Pt^{II}Cl_3(CH_2=CH_2)]^{\ominus} + Cl_2 + H_2O \longrightarrow \qquad (33)$$
$$[PtCl_4]^{2\ominus} + \overset{Cl}{\overset{|}{CH_2}}-\overset{OH}{\overset{|}{CH_2}} + H^{\oplus}$$

A detailed study of this reaction has revealed that it proceeds according to the stepwise mechanism in Scheme 3.[42] The first step of this sequence apparently involves the rapid oxidative addition of Cl_2 to $[Pt^{II}Cl_3(CH_2=CH_2)]^{\ominus}$ to form $[Pt^{IV}Cl_5(CH_2=CH_2)]^{\ominus}$, followed by nucleophilic attack of $Cl^{\ominus}$ on the coordinated ethylene to form the σ-bonded complex $[Pt^{IV}Cl_5(CH_2CH_2Cl)]^{2\ominus}$. In the second step, a reversible solvolytic nucleophilic displacement of the chloride, apparently reflecting the activating influence of the β-Pt substituent, yields the β-hydroxy σ-complex $[Pt^{IV}Cl_5(CH_2CH_2OH)]^{2\ominus}$, the analogue of the postulated $[Pd^{II}Cl_3(CH_2CH_2OH)]^{2\ominus}$ intermediate in the Wacker reaction [Eq. (32)]. In the third step, reductive elimination of chlorohydrin takes place. The latter step exhibits a first-order kinetic dependence on the $Cl^{\ominus}$ concentration, suggesting that it actually proceeds via nucleophilic displacement at the Pt-bonded carbon atom by an external $Cl^{\ominus}$ ion [Eq. (34) and (35)]. This is consistent with our earlier suggestion that the mechanism of the reverse reaction, i.e., of "oxidative addition" of organic halides to low-valent d^8 metals such as iridium(I), also involves such a nucleophilic displacement.[5,43]

Scheme 3. Mechanism of the $[PtCl_4]^{2\ominus}$-catalyzed oxidation of ethylene by Cl_2 [42].



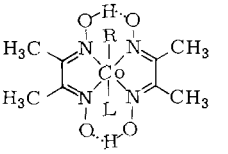
$$[Pt^{IV}Cl_5(CH_2CH_2OH)]^{2\ominus} + Cl^{\ominus} \longrightarrow [Pt^{II}Cl_5]^{3\ominus} + ClCH_2CH_2OH \quad (34)$$

$$[Pt^{II}Cl_5]^{3\ominus} \longrightarrow [Pt^{II}Cl_4]^{2\ominus} + Cl^{\ominus} \quad (35)$$

The known reaction of C_2H_4 with $[Pt^{II}Cl_4]^{2\ominus}$ to regenerate $[Pt^{II}Cl_3(CH_2{=}CH_2)]^{\ominus}$ completes a catalytic cycle for the highly selective oxidation of C_2H_4 to $ClCH_2CH_2OH$ (Scheme 3). All the intermediate species and the component steps of this catalytic cycle have been directly observed and characterized. This general approach would appear to be capable of extention to encompass the catalysis of the oxidation of olefins and related substrates by other metal complexes with potentially distinctive selectivities.

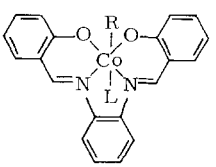
Few oxidation reactions of other metal-olefin complexes have been examined in any detail. Commonly, oxidation of metal-olefin complexes, and especially of mixed olefin-carbonyl complexes, results in liberation of the coordinated olefin (see, e.g., Eq. (29), C_4H_6 = butadiene).[28]

In recent years, "metal assisted syntheses", involving the construction or elaboration of organic molecules that are coordinated to metals (e.g., to fragments such as $Fe(CO)_3$ and $Cr(CO)_3$), have achieved increasing importance in synthetic organic methodology.[28,44] The application of this approach typically results in the production of the target organic molecule as a coordinated ligand. Oxidation of the



(36)

(37)



resulting complex has proved to be a useful method of liberating the organic product [Eq. (36)[28] and (37)[44]].

4. Oxidation of Cobalt Alkyl Complexes

The most extensive studies on the chemical and electrochemical oxidations of alkyl transition-metal compounds have been performed on organobis(dimethylglyoximato(1−))organocobalt(III) complexes $[RCo(Hdmg)_2L]$ (abbreviated [CoR]), **6**, where L is an axial ligand such as water or pyridine, and on related organocobalt complexes such as **7**, which have Schiff base compounds as ligands.[45-53,5] Such organocobalt compounds also have been studied extensively in other contexts because of their relevance as coenzyme B_{12} models.[54-56]

6, L = H_2O

7, L = py

[CoR] compounds (R = alkyl or benzyl) have been found to undergo reversible chemical and electrochemical one-electron oxidations in aqueous solution to generate the corresponding 17-electron radical cations, $[RCo(Hdmg)_2(H_2O)]^{\oplus}$ (abbreviated $[CoR]^{\oplus}$, Eq. (38)).[47,50]

$$[CoR] \rightleftharpoons [CoR]^{\oplus} \quad (38)$$

The $[CoR]^{\oplus}$ ions, which could also be generated by chemical oxidation with $[IrCl_6]^{2\ominus}$ [Eq. (39)], are unstable at room temperature and are decomposed by nucleophilic attack of water to form Co^{II} and ROH [Eq. (40)].[47,50] In accord with this scheme, the rate law of the overall reaction [Eq. (41)] was found to conform to Eq. (42).

$$[CoR] + [IrCl_6]^{2\ominus} \underset{k_{-39}}{\overset{k_{39}}{\rightleftharpoons}} [CoR]^{\oplus} + [IrCl_6]^{3\ominus} \quad (39)$$

$$[CoR]^{\oplus} + H_2O \xrightarrow{k_{40}} [Co^{II}] + ROH + H^{\oplus} \quad (40)$$

$$[CoR] + [IrCl_6]^{2\ominus} + H_2O \longrightarrow [Co^{II}] + ROH + [IrCl_6]^{3\ominus} + H^{\oplus} \quad (41)$$

$$\frac{-d[CoR]}{dt} = \frac{k_{39}k_{40}[CoR][IrCl_6^{2\ominus}]}{k_{-39}[IrCl_6^{3\ominus}] + k_{40}} \quad (42)$$

Values of $E_{1/2}$ for the electrochemical oxidations (determined by cyclic voltammetry) and of the kinetic parameters, determined from the kinetic measurements, are summarized in Table 1.[50] As expected, the trend of $E_{1/2}$ values is in the direction of increasing ease of oxidation with increasing electron donor power of R. At the same time the trend of lifetimes ($1/k_{40}$) of the $[CoR]^{\oplus}$ ions, i.e., CH_3, $C_2H_5 > i\text{-}C_3H_7$ and $p\text{-}NO_2C_6H_4CH_2 > C_6H_5CH_2 \gg p\text{-}CH_3OC_6H_4CH_2$, is consistent with a decomposition mode involving nucleophilic attack on R.

At −78 °C (in aqueous methanol or methylene chloride) the $[CoR]^{\oplus}$ ions (generated by oxidation with Ce^{IV} or

Table 1. Thermodynamic and kinetic parameters for the oxidation of **6** [50].

[a] Relative to the saturated calomel electrode. [b] $K_{39}=k_{39}/k_{-39}$.

PbO_2) were found to be stable for many hours and could be characterized by EPR.[47-49] The results convincingly support the formulation of these ions as cobalt(IV) complexes, i.e., as $[Co^{IV}R^{\ominus}]^{\oplus}$ rather than $[Co^{III}R^{\odot}]^{\oplus}$. Warming such solutions (CH_3OH/H_2O, 4:1) of $[CoR]^{\oplus}$, $R=C_6H_5CH_2$, to ca. -20°C resulted in decomposition according to Eq. (40). On the other hand, when $R=C_2H_5$, decomposition followed a different course, the products and kinetics of which are consistent with Eq. (43) and (44).[50]

$$2[CoR]^{\odot} \underset{k_{-43}}{\overset{k_{43}}{\rightleftharpoons}} [CoR] + [CoR]^{2\oplus} \quad (43)$$

$$[CoR]^{2\oplus} \xrightarrow{k_{44}} [Co^{III}] + \text{olefin} \quad (44)$$

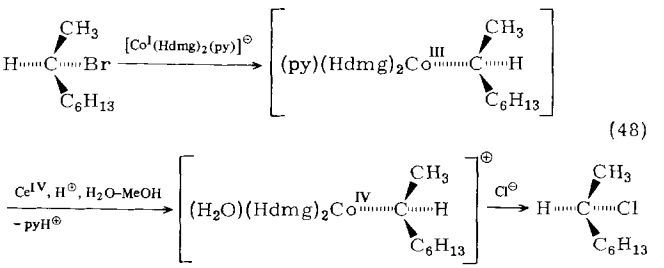
The reversible disproportionation of $[CoR]^{\oplus}$ [Eq. (43)] finds parallels in the corresponding reactions of other organometallic radical cations, e.g., $[Cr(CO)_6]^{\oplus}$ [Eq. (31)].[37] Failure to detect the disproportionative pathway in the case of the benzyl and *sec*-alkyl cobalt complexes presumably reflects the much higher reactivities of these complexes toward nucleophilically induced decomposition [Eq. (40)] as revealed by the values of k_{40} in Table 1.

Examination of the data in Table 1 reveals an unusual pattern of relationships between the rate constant (k_{39}) and equilibrium constant ($K_{39}=k_{39}/k_{-39}$) for reaction (39). For the series of *p*-substituted benzylcobalt complexes examined, the rate constant k_{39} exhibits a significantly larger dependence on the variation of R than the corresponding equilibrium constant K_{39}. These data give rise to a Marcus plot of $\log k_{39}$ vs $\log K_{39}$ with an anomalously large slope of ca. 2–3 instead of the slope of ca. 0.5 expected for a simple outer-sphere electron-transfer reaction (and found, for example, in the related oxidations of PbR_4 compounds by $[IrCl_6]^{2\ominus}$).[8] The results suggest that reaction (39) may actually be a stepwise process of the type depicted by Eq. (45) in which the second step presumably involves a structural rearrangement as well as an internal electron transfer. In such a case the measured rate constant and equilibrium constant would not refer to the same process. The testing of this suggestion calls for measurements on a faster time scale than can be achieved by the electrochemical and chemical oxidation procedures employed in these studies, e.g., pulse radiolysis.

$$[Co^{III}R^{\odot}]^{\oplus} \underset{\text{slow } (k_{45})}{\xrightarrow{-e^{\ominus}}} [Co^{III}R^{\odot}]^{\oplus} \xrightarrow[\text{fast}]{} [Co^{IV}R^{\ominus}]^{\oplus} \quad (45)$$

In related studies on the electrochemical oxidations of a variety of $[RCo(Hdmg)_2L]$ and [RCo(Schiff base)] complexes in acetonitrile solutions, the initially produced $[Co^{IV}R]$ radical cations were found to exhibit several different reactivity patterns, depending on the ligands used and on whether nucleophiles such as pyridine were added.[53] In addition to nucleophilic displacement of $R^{\odot}$ (either by pyridine [Eq. (46)], or by an oxygen atom of the Schiff base ligand) homolytic dissociation of the Co–R bond with formation of alkyl radicals was observed in some cases [Eq. (47)].

$$[Co^{IV}R]^{\oplus} + py \longrightarrow [Co^{II}] + Rpy^{\oplus} \quad (46)$$



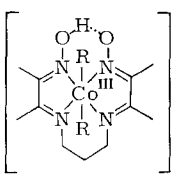
$$[Co^{IV}R]^{\oplus} \longrightarrow [Co^{III}] + R^{\odot} \quad (47)$$

Much of the research on the redox chemistry of organocobalt compounds such as $[RCo(Hdmg)_2(H_2O)]$ has been motivated, at least in part, by the relevance of such compounds as coenzyme B_{12} (5′-deoxyadenosylcobalamin) models. However, at this stage there is no evidence, and little reason to suspect, that oxidation or reduction of coenzyme B_{12} is involved in the cobalt-carbon bond dissociation step which triggers the coenzyme B_{12}-promoted rearrangement and in which the coenzyme's distinctive biochemical role is manifested.[54-56]

5. Implications for Halogen Cleavage of Metal-Alkyl Bonds

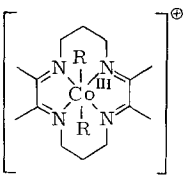
In contrast to the familiar halogen cleavage reactions of organomercurials, which typically proceed with retention of configuration at the metal-bonded α-carbon atom, and which have been interpreted as front-side electrophilic displacement processes,[57] halogen cleavage of alkyl transition-metal complexes, e.g., $[RCo(Hdmg)_2(H_2O)]$ and $[RFe(\eta^5\text{-}C_5H_5)(CO)_2]$, commonly proceeds with inversion of configuration.[58,59] The latter reactions have been alternatively interpreted as proceeding through (1) direct backside electrophilic attack at the α-carbon atom,[58] or (2) one-electron oxidation of the metal alkyl followed by nucleophilic attack of halide ion on the resulting radical cation.[46,59]

The demonstration that stable $[RCo(Hdmg)_2(H_2O)]^{\oplus}$ radical cations could be generated in solution by oxidation of $[RCo(Hdmg)_2(H_2O)]$ permitted a direct test of interpretation (2) to be made. Employing the sequence of steps depicted by Eq. (48), it was demonstrated that $Cl^{\ominus}$ does indeed react directly with $[RCo(Hdmg)_2(H_2O)]^{\oplus}$, displacing $R^{\oplus}$ with virtually quantitative inversion of configuration of the α-carbon atom. Accordingly, such a process does ap-



(48)

pear to be a viable step in halogen cleavage reactions of metal-carbon bonds that occur with inversion of configuration.[52]



6. Oxidation of Dialkyl Transition-Metal Compounds. Oxidatively Induced Reductive Elimination

Diverse reactivity patterns have been observed in studies on the oxidation of dialkyl transition-metal compounds.

One-electron oxidation of *trans*-[Me_2Co^{III}(dpnH)] **8**[*] or *trans*-[Me_2Co^{III}(tim)] **9**[*] in acetonitrile to the corresponding Co^{IV} complexes was found to be irreversible (by cyclic voltammetry) and generally to result in homolysis of one of the Co–C bonds, yielding a stable monoalkyl Co^{III} compound and a free $CH_3^{\oplus}$ radical whose fate (dimerization, H abstraction, or oxidation by excess oxidant) depends on the reaction conditions [Eq. (49)].[60]

[R_2Co(dpnH)] **8**

[R_2Co(tim)] **9**

$$[Me_2Co^{III}(chelate)]^{n\oplus} \xrightarrow{-e^{\ominus}} [Me_2Co^{IV}(chelate)]^{(n+1)\oplus} \longrightarrow [MeCo^{III}(chelate)]^{(n+1)\oplus} + Me^{\odot} \quad (49)$$

Oxidation of *cis*-[$R_2Pt^{II}(PR'_3)_2$] ($R = CH_3$, C_2H_5; $PR'_3 = PMe_2Ph$, PPh_3) complexes by $[IrCl_6]^{2\ominus}$ in acetonitrile afforded two types of products, depending on the nature of R and PR'_3 ($X = Cl^{\ominus}$, CH_3CN, etc.). *cis*-[$Me_2Pt(PMe_2Ph)_2$] reacted predominantly according to Eq. (50a), whereas *cis*-[$Et_2Pt(PPh_3)_2$] reacted predominantly according to Eq. (50b). For *cis*-[$Me_2Pt(PPh_3)_2$], competition between the two pathways was observed.[61a]

$$[R_2Pt^{II}(PR'_3)] \xrightarrow{2\,[IrCl_6]^{2\ominus}} [R_2Pt^{IV}(PR'_3)_2X_2] \quad (50a)$$

$$[R_2Pt^{II}(PR'_3)] \xrightarrow{2\,[IrCl_6]^{2\ominus}} [RPt^{II}(PR'_3)_2X] + RCl \quad (50b)$$

Oxidation of *cis*-[R_2Fe^{II}(bpy)$_2$] ($R = Me$, Et, *n*Pr, etc.) revealed still other reactivity patterns [Eq. (51)].[61b]

$$cis\text{-}[R_2Fe^{II}(bpy)_2] \underset{e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} \underset{\mathbf{10}}{[R_2Fe^{III}(bpy)_2]^{\oplus}} \xrightarrow{-e^{\ominus}} \underset{\mathbf{11}}{[R_2Fe^{IV}(bpy)_2]^{2\oplus}}$$
$$\downarrow \qquad\qquad \downarrow$$
$$[Fe^{I}] + 2\,R^{\odot}(\longrightarrow R_2 \text{ etc.}) \qquad [Fe^{II}] + R_2 \quad (51)$$

The one-electron oxidation product, **10**, whose formation was electrochemically reversible, was sufficiently stable to be isolated and characterized by EPR. The decomposition products (C_4H_{10}, C_2H_6, and C_2H_4 when $R = C_2H_5$) were interpreted as arising from cage reactions of a pair of $R^{\odot}$ radicals. On the other hand, the two-electron oxidation product, **11**, whose formation is irreversible, apparently undergoes a *concerted* reductive elimination to yield R_2 directly.[62]

Other reported examples of oxidatively induced reductive elimination include that depicted by Eq. (52) (R = alkyl or aryl, L = PEt_3).[62]

$$[(Aryl)(R)Ni^{II}L_2] \xrightarrow{-e^{\ominus}} [(Aryl)(R)Ni^{III}L_2] \longrightarrow Aryl\text{–}R + [Ni^{I}L_2] \quad (52)$$

Reductive elimination from a Ni^{III} intermediate according to Eq. (53)–(55) has been invoked to interpret the cross-coupling reactions of aryl halides (ArylX) with arylnickel complexes ($ArylNiXL_2$, L = PEt_3 and similar ligands) to yield biaryls [Eq. (56)].[63]

$$[Ni^{I}XL_2] + ArylX \longrightarrow [ArylNi^{III}X_2L_2] \quad (53)$$

$$[ArylNi^{III}X_2L_2] + [ArylNi^{II}XL_2] \longrightarrow [Aryl_2Ni^{III}XL_2] + [Ni^{II}X_2L_2] \quad (54)$$

$$[Aryl_2Ni^{III}XL_2] \longrightarrow Aryl_2 + [Ni^{I}XL_2] \quad (55)$$

$$[ArylNi^{II}XL_2] + ArylX \longrightarrow [Ni^{II}X_2L_2] + Aryl_2 \quad (56)$$

7. Oxidation of Non-Transition Metal Alkyls

Extensive studies also have been conducted on chemical and electrochemical oxidations of non-transition metal alkyl compounds such as R_4Pb, R_4Sn, and R_2Hg.[8] The course of the oxidation of Me_4Pb in acetic acid is typical of that found for such systems [Eq. (57)–(60)].

$$[Me_4Pb] + [IrCl_6]^{2\ominus} \xrightarrow{\text{rate-determining}} [Me_4Pb]^{\ominus} + [IrCl_6]^{3\ominus} \quad (57)$$

$$[Me_4Pb]^{\oplus} \xrightarrow{\text{fast}} Me^{\odot} + [Me_3Pb]^{\oplus} \left(\xrightarrow{HOAc} [Me_3PbOAc] + H^{\oplus}\right) \quad (58)$$

$$Me^{\odot} + [IrCl_6]^{2\ominus} \longrightarrow MeCl + [IrCl_5]^{2\ominus} \quad (59)$$

$$[Me_4Pb] + 2[IrCl_6]^{2\ominus} \xrightarrow{HOAc} [Me_3PbOAc] + MeCl + [IrCl_6]^{3\ominus} + [IrCl_5]^{2\ominus} \quad (60)$$

Differences between this behavior and that found for related oxidations of alkyl transition-metal compounds include the following: 1) Step (57) appears to be essentially irreversible and the postulated $[R_4Pb]^{\oplus}$ (or $[R_2Hg]^{\oplus}$) radical cations are too short-lived to be detected kinetically, electrochemically, or spectroscopically. 2) In contrast to the oxidized organo-transition metal complexes, for which alternative decomposition modes, including nucleophilic attack, disproportionation, or reductive elimination, usually are observed, $[R_4Pb]^{\oplus}$ and $[R_2Hg]^{\oplus}$ decompose exclusively by metal-carbon bond homolysis. The origin of these differences may be that the highest occupied molecular orbital (HOMO) from which the electron is removed in the oxidation of [R_4Pb] presumably is a metal-carbon σ-bonding orbital, whereas in the case of most transition metal complexes, such as $[R_nCo^{III}]$ or $[R_nFe^{II}]$, it is a nonbonding d-orbital.[64]

[*] dpnH = 2,3,9,10-tetramethyl-1,4,8,11-tetraaza-1,3,8,10-undecatetraen-11-ol-1-olate; tim = 2,3,9,10-tetramethyl-1,4,8,11-tetraaza-1,3,8,10-cyclotetradecatetraene.

Finally it should be noted that not all processes in which oxidation of an organometallic compound apparently occurs actually proceed through such a step. Thus oxidative cleavage of the Cr–C bond in $[PhCH_2Cr^{III}(H_2O)_5]^{2\oplus}$ by oxidants such as $Fe^{3\oplus}$, $Cu^{2\oplus}$, O_2, and H_2O_2 in aqueous solution exhibits first-order kinetics that are independent of the nature or concentration of the oxidant [Eq. (61)].[65]

$$[PhCH_2Cr^{III}(H_2O)_5]^{2\oplus} \xrightarrow{\text{rate-determining}} PhCH_2^{\oplus} + Cr^{2\oplus}aq \quad (61)$$
$$PhCH_2^{\oplus} \xrightarrow{\text{oxidation fast}} PhCH_2OH$$
$$Cr^{2\oplus}aq \xrightarrow{\text{oxidation fast}} Cr^{3\oplus}aq$$

8. Oxidatively Induced CO Insertion

There is extensive evidence that one-electron oxidation of transition metal complexes containing both alkyl and CO ligands promotes migratory insertion of CO into the metal-alkyl bond [Eq. (62)]. Specific examples encompassing this phenomenon are shown in Eq. (63) and (64).[66–68]

$$\left[L_nM\begin{matrix}CO\\R\end{matrix}\right] \xrightarrow{-e^{\ominus}} \left[L_nM\begin{matrix}CO\\R\end{matrix}\right]^{\oplus} \longrightarrow \left[L_nM{-}\overset{O}{\overset{\|}{C}}{-}R\right]^{\oplus} \quad (62)$$

$$[R{-}Fe(CO)_2(\eta^5{-}C_5H_5)] \xrightarrow[CuCl_2]{R'OH,\ CO} R\overset{O}{\overset{\|}{C}}OR' \quad (63)$$

$$[R{-}Mo(CO)_3(\eta^5{-}C_5H_5)] \xrightarrow[Ce^{IV}]{MeOH} R\overset{O}{\overset{\|}{C}}OCH_3 \quad (64)$$

It has been shown that such CO insertion reactions proceed with *retention* of configuration at the α-carbon atom.[66] Oxidatively induced migratory insertion of CO has been utilized in synthetic applications such as β-lactam synthesis [Eq. (65), $Cp=\eta^5$-C_5H_5].[69]

$$\left[Cp(CO)_2Fe\begin{matrix}R\\NHCH_2Ph\end{matrix}\right] \xrightarrow{-e^{\ominus}} \left[Cp(CO)_2Fe\begin{matrix}R\\NHCH_2Ph\end{matrix}\right]^{\oplus} \quad (65)$$
$$\longrightarrow \left[Cp(CO)Fe\begin{matrix}\overset{O}{\overset{\|}{C}}\\NH\ R\\CH_2Ph\end{matrix}\right]^{\oplus} \longrightarrow \begin{matrix}R\\N\\PhCH_2\end{matrix}\!\!\overset{O}{\overset{\|}{C}}$$

9. Redox-Catalyzed Reactions of Organometallic Compounds

The distinctive reactivity patterns of oxidized organometallic compounds may be incorporated into catalytic cycles which proceed through electron-transfer-propagated chain mechanisms.

An example of such catalysis is provided by the substitution reactions of metal carbonyls such as *cis*-$[L_2W(CO)_4]$ (L = MeCN or py), whose rates are enhanced by chemical or electrochemical oxidation according to the mechanism of Eq. (66)–(69), for which the chain length has been estimated to be ca. 20.[70]

$$\text{Initiation:} \quad [L_2W(CO)_4] \xrightarrow{-e^{\ominus}} [L_2W(CO)_4]^{\oplus} \quad (66)$$

$$\text{Propagation:} \quad \begin{cases} [L_2W(CO)_4]^{\oplus} + PPh_3 \longrightarrow [LW(CO)_4(PPh_3)]^{\oplus} + L & (67) \\ [LW(CO)_4(PPh_3)]^{\oplus} + [L_2W(CO)_4] \longrightarrow & \\ \qquad [LW(CO)_4(PPh_3)] + [L_2W(CO)_4]^{\oplus} & (68) \end{cases}$$

$$\text{Net reaction:} \quad [L_2W(CO)_4] + PPh_3 \longrightarrow [LW(CO)_4(PPh_3)] + L \quad (69)$$

Analogous mechanisms [Eq. (70)–(72)] have been invoked to account for the oxidatively induced migratory insertion reaction of $[(\eta^5\text{-}C_5H_5)(PPh_3)(CO)Fe(CH_3)]$ (abbreviated [Fp–CH_3]) [Eq. (73)].[71]

$$\text{Initiation:} \quad [Fp{-}CH_3] \xrightarrow{-e^{\ominus}} [Fp{-}CH_3]^{\oplus} \quad (70)$$

$$\text{Propagation:} \quad \begin{cases} [Fp{-}CH_3]^{\oplus} + CO \longrightarrow [Fp{-}\overset{O}{\overset{\|}{C}}{-}CH_3]^{\oplus} & (71) \\ [Fp{-}\overset{O}{\overset{\|}{C}}{-}CH_3]^{\oplus} + [Fp{-}CH_3] \longrightarrow & \\ \qquad [Fp{-}\overset{O}{\overset{\|}{C}}{-}CH_3] + [Fp{-}CH_3]^{\oplus} & (72) \end{cases}$$

$$\text{Net reaction:} \quad [Fp{-}CH_3] + CO \longrightarrow [Fp{-}\overset{O}{\overset{\|}{C}}{-}CH_3] \quad (73)$$

These processes parallel other examples of "electron-transfer catalysis", the principle of which has been recognized for some time also in other contexts.[72–74]

10. Concluding Remarks

The study of the oxidation reactions of organometallic compounds constitutes a relatively new field of research which has developed almost entirely within the past decade. The results yielded by the limited studies conducted thus far already reveal a rich and versatile array of chemistry associated with the primary redox processes themselves, with the distinctive electronic structures and reactivity patterns of the species produced by oxidation of stable organometallic compounds, and with the synthetic and catalytic applications of oxidatively induced organometallic reactions. At the same time many problems, both of understanding and of application, remain to be addressed. Research activity in this field continues at a high level and with great promise for the realization of important new discoveries and insights.

Support of our research in this field by the National Science Foundation is gratefully acknowledged.

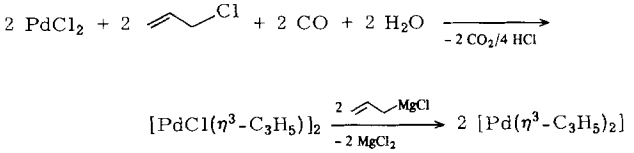
η^3-Allylpalladium Compounds**

By Peter W. Jolly*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The use of transition-metal complexes as homogeneous catalysts for the production of organic chemicals is of considerable industrial significance. Although palladium complexes have not attained the same importance as, for example, those of rhodium or cobalt, palladium is nonetheless one of the most versatile metals for synthetic organic purposes. An understanding of the role played by the metal in these reactions is essential for their optimal utilization. This necessarily entails a detailed study of the chemistry of the palladium-carbon bond. In this article we concentrate on η^3-allylpalladium complexes, which are frequently involved as intermediates in the Pd-catalyzed transformations of dienes. The study of their behavior gives a deeper insight into the individual steps of a catalytic cycle.

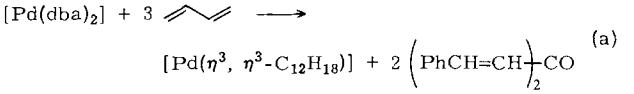
1. Introduction



The η^3-allyl complexes of palladium have played an important role in the development of organotransition metal chemistry. $[PdCl(\eta^3\text{-}C_3H_5)]_2$, which was reported in 1959, was the first complex for which the presence of a symmetrically bonded η^3-allyl group was postulated[1] and confirmed in solution[7] and in the crystal.[8] In addition, the fluxional behavior of the allyl group in this molecule in the presence of donor ligands, which was noted soon after its isolation,[9] was to have a significant and lasting influence on the development of the NMR spectroscopy[10] of organotransition metal complexes.

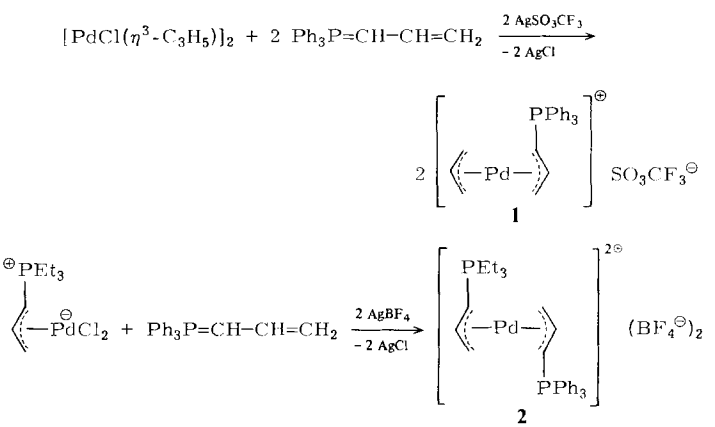
The synthesis of homoleptic η^3-allyl metal complexes such as $[Pd(\eta^3\text{-}C_3H_5)_2]$ by *G. Wilke* et al. introduced a new dimension as did the recognition that such complexes are a convenient source of the metal component in homogeneous catalysts and are involved, as intermediates, in a variety of transition-metal-catalyzed transformations of organic molecules.[11, 12] In this article we discuss some recent developments in η^3-allylpalladium chemistry.

2. Bis(η^3-allyl)palladium Complexes



2.1. Preparation

The first bis(η^3-allyl)palladium complex, $[Pd(\eta^3\text{-}C_3H_5)_2]$, reported in 1963, was prepared by reacting $PdCl_2$ with allylmagnesium chloride.[11-15] Subsequently, complexes containing η^3-1-MeC_3H_4, η^3-2-MeC_3H_4, η^3-1,1-$Me_2C_3H_3$, and η^3-1,3-$Me_2C_3H_3$ groups have been synthesized and there seems to be no reason why this list should not be extended. Highest yields (ca. 80%) are obtained by carrying out the reaction in two stages: the dichloride is first converted into $[PdCl(\eta^3\text{-}C_3H_5)]_2$[16] and this is then reacted with the Grignard reagent in ether at $-50°$ (Scheme 1).[17, 18] $[Pd(\eta^3\text{-}C_3H_5)_2]$ and $[Pd(\eta^3\text{-}2\text{-}MeC_3H_4)_2]$ are conveniently isolated from the reaction mixture by high-vacuum sublimation at 0° or by extraction and recrystallization from pentane.



Scheme 1.

Recently, we have succeeded in preparing bis(η^3,η^3-dodecatrienediyl)palladium by reacting bis(dibenzylideneacetone)palladium(0) $[Pd(dba)_2]$ with butadiene [Reaction (a)].[19]

(a)

A series of ionic η^3-allyl(ylide)palladium complexes, e.g., **1** and **2**, have been prepared by reacting the appropriate organopalladium chloride with an allylidene phosphorane in the presence of a silver salt (Scheme 2).[20]

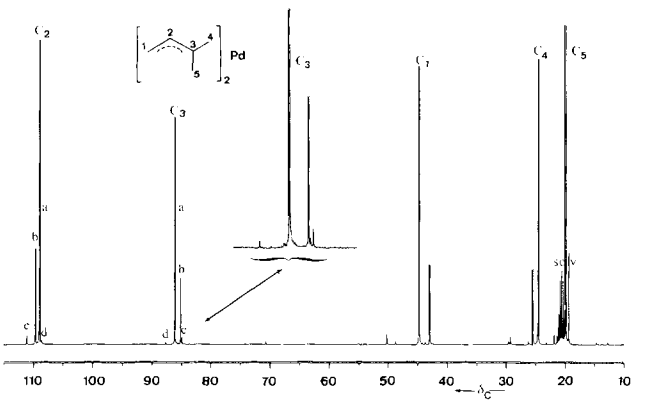
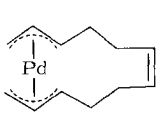
2.2. Structure and Bonding

The NMR spectra of the bis(η^3-allyl)palladium complexes[13-15,21-23] indicate that, as in the case of the corresponding complexes of nickel and platinum, isomers are present in solution. Although, surprisingly, no crystal structure determination of a palladium complex has been reported, the four complexes of nickel that have been studied, viz., [Ni(η^3-cyclooctenyl)$_2$], [Ni(η^3-2-MeC$_3$H$_4$)$_2$], [Ni(η^3-pinenyl)$_2$], and [Ni(η^3-C$_3$H$_5$)$_2$],[15,24-26] as well as [Pt(η^3-2-MeC$_3$H$_4$)$_2$][27] all contain η^3-allyl groups that are mutually *trans* (see **3**). It is generally assumed, although direct evidence is still lacking, that in the other isomer the η^3-allyl groups adopt a *cis* configuration, as in **4**. It should be noted that a neutron diffraction study of [Ni(η^3-C$_3$H$_5$)$_2$] has shown that the hydrogen atoms do not lie in the plane formed by the carbon atoms; the *syn*- and *meso*-hydrogen atoms are bent towards the metal by 8.9(4)° and 15.8(1)°, respectively, while the *anti*-hydrogen atoms are bent 29.4(7)° away from the metal. The direction and magnitude of this distortion is reproduced in an ab initio SCF calculation.[26]

The NMR spectra of [Pd(η^3-C$_3$H$_5$)$_2$] indicate that the two isomers are in equilibrium with each other; whether interconversion involves the intermediate formation of an η^1-allyl species or direct rotation about the η^3-allyl-metal axis has not been decided.[14,21,22] It has even been suggested that both mechanisms may be operating simultaneously.

Additional isomers are possible for complexes containing unsymmetrically substituted η^3-allyl groups. For example, the NMR-spectra of [Pd(η^3-1,1-Me$_2$C$_3$H$_3$)$_2$] indicate the presence of the four possible isomers **5**—**8** (Fig. 1). In the case of [Pd(η^3-1-MeC$_3$H$_4$)$_2$] additional isomers, e.g., **9** and **10**, are possible, depending upon the *syn*- or *anti*-arrangement of the methyl groups. In addition to the four main isomers, which have been shown to contain methyl groups in *syn* positions, two additional isomers are present in low (<5%) concentration.[15] The ionic η^3-allyl(ylide) complexes **1** and **2** also exist in solution as a mixture of isomers.[20]





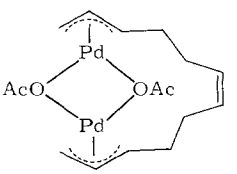


Fig. 1. The ^{13}C{^{1}H}-NMR spectrum of [Pd(η^3-1,1-Me$_2$C$_3$H$_3$)$_2$] (**5**—**8**) in [D$_8$]toluene at −30°C; a:b:c:d = 73:22:4:1.

The NMR spectra of [Pd(η^3,η^3-C$_{12}$H$_{18}$)] **11** at −30°C indicate a symmetrical arrangement of the dodecatrienediyl chain around the metal atom with *syn*-η^3-allyl groups and an uncomplexed *cis* double bond. It has still to be decided whether the η^3-allyl groups are mutually *cis* or *trans*. A similar arrangement is found in [Pd$_2$(OAc)$_2$(η^3,η^3-C$_{12}$H$_{18}$)] **12**, which can be prepared by reacting [PdOAc(η^3-C$_3$H$_5$)]$_2$ with butadiene.[19,28] **11** and **12** should be compared with the related complexes of nickel, [Ni(η^3,η^3-C$_{12}$H$_{18}$)],[15] ruthenium, [RuCl$_2$(η^3,η^3-C$_{12}$H$_{18}$)],[29] and molybdenum and tungsten, [M(CO)$_2$(η^3,η^3-C$_{12}$H$_{18}$)] (M = Mo, W),[30] all of which contain a metal-complexed *trans*-alkene but differ in the *anti* (Ni) or *syn* (Ru, Mo, W) substitution of the η^3-allyl groups. Below −80°C, the six signals observed in the ^{13}C-NMR spectrum of **11** split, suggesting either that at these temperatures the C$_{12}$-chain adopts an unsymmetrical arrangement or, more probably, that two symmetrical isomers exist whose interconversion is only slow enough below −80°C to be detected by NMR spectroscopy.[19]

The IR[13,31-33] and the Raman[15,32-35] spectra of [Pd(η^3-2-RC$_3$H$_4$)$_2$] (R = H, Me) have been studied extensively, and the low-frequency (50—800 cm^{-1}) absorptions have been recorded by inelastic neutron scattering.[36] The Raman spectra are particularly informative and the observation of only three Raman-active metal-ligand vibrations in [Pd(η^3-C$_3$H$_5$)$_2$] supports a centrosymmetric arrangement.

The He(I) photoelectron spectra of [Pd(η^3-C$_3$H$_5$)$_2$] and [Pd(η^3-2-MeC$_3$H$_4$)$_2$] have been recorded and the results

compared with those for the corresponding complexes of nickel and platinum.[37] The assignments of the bands to a particular molecular orbital should, however, be viewed with caution since the model used assumes that the carbon and hydrogen atoms of the allyl ligands are coplanar, which, at least for $[Ni(\eta^3\text{-}C_3H_5)_2]$, has been shown not to be the case (see above),[26] and a reassignment of the energy levels will be necessary.

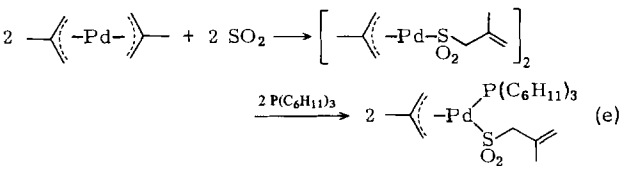
2.3. Reactions

Reactions of the bis(η^3-allyl)palladium complexes with donor ligands, which lead to formation of η^1-allylpalladium compounds, are discussed in Sections 3 and 4. Reaction of bis(η^3-allyl)palladium complexes with excess tertiary phosphanes leads to coupling of the allyl groups and formation of $[PdL_n]$ species.[14]

$[Pd(\eta^3\text{-}C_3H_5)_2]$ is a yellow, unpleasant smelling compound that decomposes at 50 °C liberating mainly propene.[13] Reaction with H_2 occurs instantaneously at room temperature to give propene and palladium metal,[13] which is active for the catalytic hydrogenation of olefins,[38] as is the catalyst prepared by reacting bis(η^3-allyl)palladium with the surface hydroxy groups of a variety of supports, such as La_2O_3.[39]

$$2\ [Pd(\eta^3\text{-}C_3H_5)_2] + 2\ Et_2NH \longrightarrow [PdNEt_2(\eta^3\text{-}C_3H_5)]_2 + 2\ C_3H_6 \quad (b)$$

Controlled protonolysis of bis(η^3-allyl)palladium with HCl,[13] H_2S,[40,41] or Et_2NH [Reaction (b)][42] results in cleavage of one η^3-allyl group. The reaction with H_2S proceeds in a stepwise manner to give ultimately η^3-allylpalladium-sulfur clusters [Reaction (c)] which may also be formed by reacting bis(η^3-allyl)palladium with trithiopentalene derivatives or S_8. Reaction of bis(η^3-allyl)palladium with $[Ni(SH)(\eta^3\text{-}C_3H_5)]_2$ leads to mixed metal clusters [Reaction (d)].



$$2\ [Pd(\eta^3\text{-}C_3H_5)_2] + 2\ H_2S \xrightarrow[-2\,C_3H_6]{} [Pd(SH)(\eta^3\text{-}C_3H_5)]_2 \quad (c)$$

$$\xrightarrow[-2\,C_3H_6]{2\,[Pd(\eta^3\text{-}C_3H_5)_2]} \frac{2}{n}\,[(\eta^3\text{-}C_3H_5)Pd\text{-}S\text{-}Pd(\eta^3\text{-}C_3H_5)]_n$$

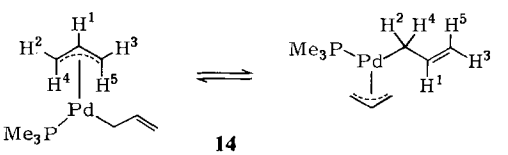
$$2\ [Pd(\eta^3\text{-}C_3H_5)_2] + [Ni(SH)(\eta^3\text{-}C_3H_5)]_2 \xrightarrow[-2\,C_3H_6]{} \frac{2}{n}\,[(\eta^3\text{-}C_3H_5)Pd\text{-}S\text{-}Ni(\eta^3\text{-}C_3H_5)]_n \quad (d)$$

Whereas bis(η^3-allyl)palladium is inert towards CO_2 under mild conditions,[43,44] it reacts with SO_2 at −78 °C:[43,45] reaction with bis(η^3-2-methallyl)palladium gives a dimer [Reaction (e)] in which the arrangement of the bridging atoms is not yet known. A ^{1}H-NMR study indicates that two isomers are present in solution. These are interconvertible and differ presumably in the arrangement of the sulfur-bonded and η^3-bonded methallyl groups. The dimer is cleaved upon treatment with tricyclohexylphosphane.

The reaction of SO_2 with $[Pd(\eta^3\text{-}C_3H_5)_2]$ is temperature dependent: at −78 °C a dimer, presumably related to that discussed above, is formed, whereas at −40 °C a monomer

(e)

$[PdSO_2C_3H_5(\eta^3\text{-}C_3H_5)]$ **13** of unknown structure results. The S–O stretching frequencies at 1020 and 1130 cm^{-1} in the infrared spectrum would seem to rule out a structure containing an η^1-bonded SO_2 molecule such as **13a**, while the presence of an uncomplexed double bond (IR band at 1625 cm^{-1}) makes **13b** unlikely. **13** reacts with tricyclohexylphosphane to give $[PdSO_2C_3H_5\{P(C_6H_{11})_3\}(\eta^3\text{-}C_3H_5)]$.



13a **13b**

The formation of $[PdCl(\eta^3\text{-}C_3H_5)]_2$ in the reaction of $PdCl_2$ with $[Pd(\eta^3\text{-}C_3H_5)_2]$ was one of the first examples of the intermetallic transfer of an organic ligand.[13]

3. Bis(η^1,η^3-allyl)palladium Complexes

3.1. Preparation and Structure

Although it has been known for many years that bis(η^3-allyl)palladium forms adducts with P-donor ligands,[13] it is only recently that their nature has been established. Reaction of the palladium complex with monodentate donor ligands results in the conversion of one η^3-allyl group into the η^1-allyl form; for example, with trimethylphosphane, **14** is formed.

14

The rearrangement of **14** is reflected in the temperature dependence of the ^{1}H-NMR spectra (Fig. 2): at −109 °C the rearrangement is too slow to be observed (on the NMR time scale); on raising the temperature the allyl groups exchange—without dissociation of the phosphane. The coalescence temperature for the exchange is ca. −50 °C which corresponds to a free energy of activation for the process of 9.6 ± 1.5 kcal/mol.[46,47] The η^1,η^3-arrangement of the allyl groups has been confirmed by X-ray crystallography for a related platinum complex (Fig. 3).[18]

$[Pd(\eta^3\text{-allyl})(\eta^5\text{-}C_5H_5)]$ reacts with donor ligands to form an adduct that also exists in two isomeric forms; these interconvert rapidly at room temperature [Equilibrium (f)]. An NMR study indicates that at low temperatures the isomer with the η^1-cyclopentadienyl group predominates. An X-ray diffraction study has established this structure in the crystal for the complex where L = P*i*Pr$_3$ and R = *t*Bu[48].

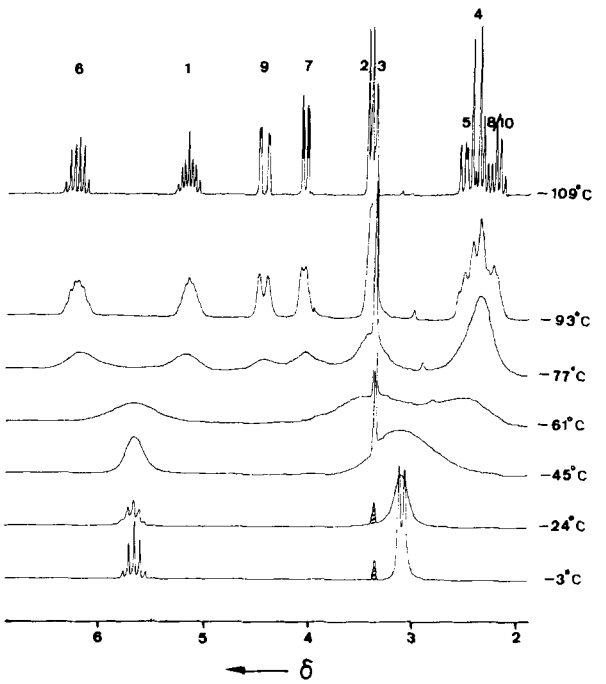


Fig. 2. The ^{1}H-NMR spectra of $[Pd(PMe_3)(\eta^1,\eta^3\text{-}C_3H_5)_2]$ **14** at different temperatures [46]. The numbers 1 — 10 above the peaks refer to the ten protons of the two allyl groups.

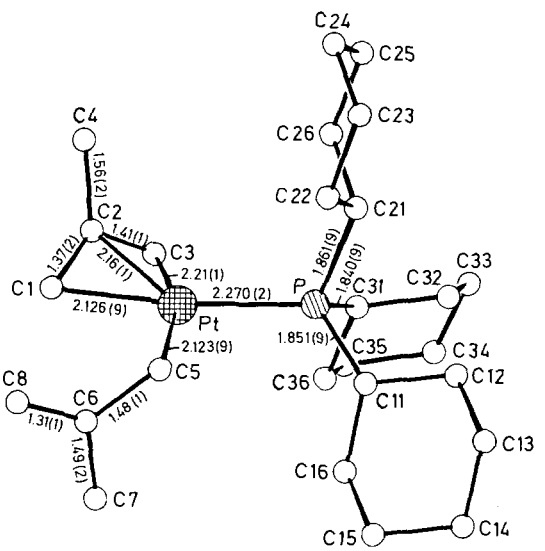

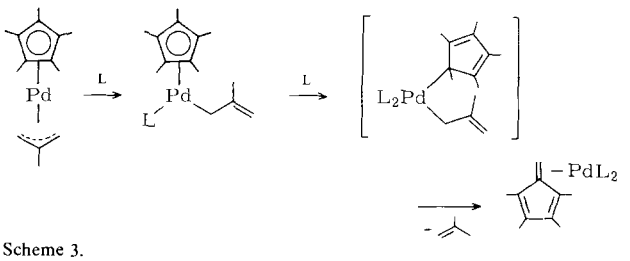

Fig. 3. The crystal structure of $[Pt\{P(C_6H_{11})_3\}(\eta^1,\eta^3\text{-}2\text{-}MeC_3H_4)_2]$ [18].

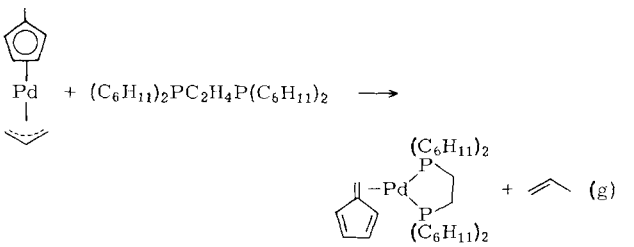
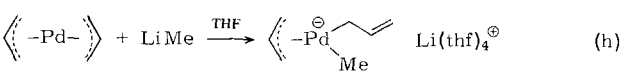
The rearrangement (f) forms the basis of a palladium-induced fulvene synthesis starting from substituted cyclo-



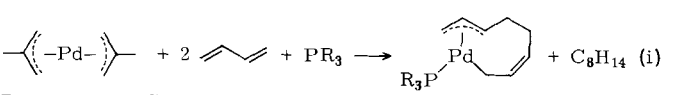
(f)

pentadienyl derivatives (Scheme 3). The final step in this reaction is a β-hydrogen transfer from the η^1-C_5Me_5 moiety to the η^1-allyl group.

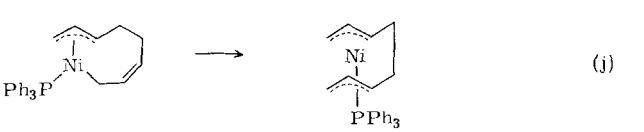


Scheme 3.

This reaction seems to be general and has, for example, been used to convert a methylcyclopentadienylpalladium complex into a fulvene complex [Reaction (g)].[49]



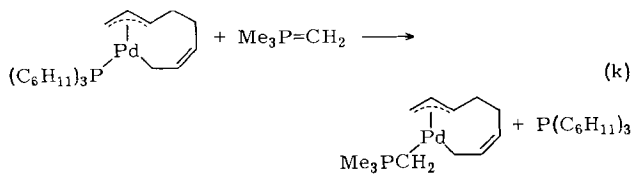
The conversion of an η^3-allyl group into the η^1-allyl form upon reaction with donor ligands is not limited to tertiary phosphanes but is also observed on treating bis(η^3-allyl)palladium with carbanions: ionic ate-complexes result. Such compounds have been isolated from reactions with methyl-, vinyl-, and phenyllithium [Reaction (h)].[50] Similar complexes involving nickel or platinum have been isolated; in the case of $[NiMe(\eta^1,\eta^3\text{-}C_3H_5)_2]^{\ominus}$, it was shown by NMR spectroscopy that η^1-η^3-allyl exchange occurs.



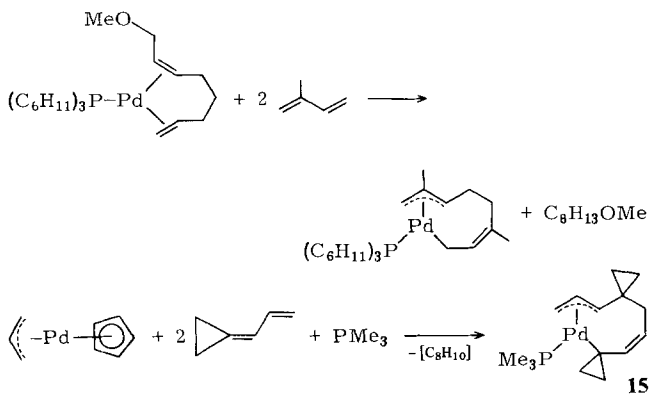
(h)

An important class of bis(η^1,η^3-allyl)palladium complexes—the η^1,η^3-octadienediyl complexes—may be prepared by reacting bis(η^3-allyl)palladium with butadiene in the presence of a donor ligand [Reaction (i)].[18,19,51]

R = Me, *i*Pr, C_6H_{11}, NMe_2, Ph



Interestingly, the complex stabilized by PPh_3 shows no tendency up to its decomposition point (> -25 °C) to rearrange in the manner established for the corresponding nickel complex [Reaction (j)]:[52]



(j)

Reaction (i) has been shown to proceed in a stepwise manner via $[Pd(PR_3)(\eta^1,\eta^3\text{-allyl})_2]$ and $[Pd(PR_3)(\mu\text{-}\eta^3\text{-al-}$

lyl)]$_2$ species. The η^1,η^3-octadienediyl complexes can also be prepared by reacting butadiene with [Pd(dba)$_2$], [Pd(η^3-C_3H_5)(η^5-C_5H_5)], or $PdCl_2$/Mg(anthracene)[53] in the presence of a phosphane or by reaction with bis(alkene)(phosphane)palladium complexes. In addition, a trimethylmethylenephosphorane-complex has been prepared by ligand exchange [Reaction (k)].[54]

Reaction (i) is not limited to butadiene; isoprene, 3-methylene-1-heptene, and allylidenecyclopropane react similarly[19,55] (Scheme 4).

Scheme 4.

The structure of the η^1,η^3-octadienediyl complexes has been verified by spectroscopic methods. The $^{13}C\{^1H\}$-NMR spectrum of [Pd(PMe$_3$)(η^1,η^3-C_8H_{12})] is shown in Figure 4 and should be compared with that of the analogous nickel complex.[52]

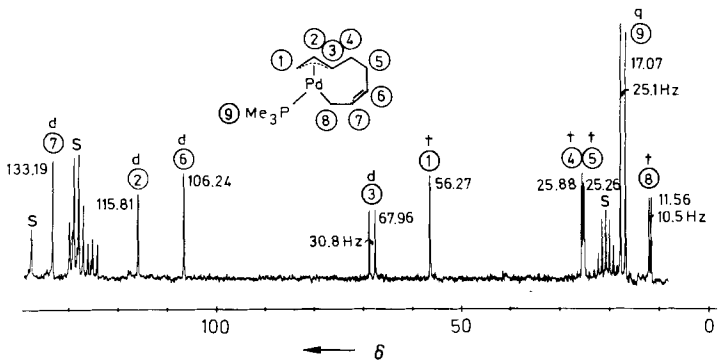


Fig. 4. The 25.2-MHz $^{13}C\{^1H\}$-NMR spectrum of [Pd(PMe$_3$)(η^1,η^3-C_8H_{12})] in [D$_8$]toluene at −30 °C [18].

Diagnostic for the structure is the high-field shift of the Pd-bonded carbon atom C-8 and its coupling to phosphorus ($J_{P,C\text{-}8}$ = 10.5 Hz), along with the large *trans* coupling between the terminal C-atoms of the η^3-allyl group and phosphorus ($J_{P,C\text{-}3}$ = 30.8 Hz) and the small *cis* coupling ($J_{P,C\text{-}1}$ = 1.4 Hz). The *syn*-substitution of the η^3-allyl group and the *cis*-configuration of the uncomplexed double bond follow from a detailed analysis of the 400-MHz ^{1}H-NMR spectrum. The X-ray structure determination indicates that the configuration in the crystal is the same as that in solution (Fig. 5). Disorder prevented a more exact determination of the bond distances; these are, comparable, however, with those found for the related nickel complex [Ni{P(C_6H_{11})$_3$}(η^1,η^3-2,6-$Me_2C_8H_{10}$)].[56] A similar disorder is found in the corresponding platinum complex which is,

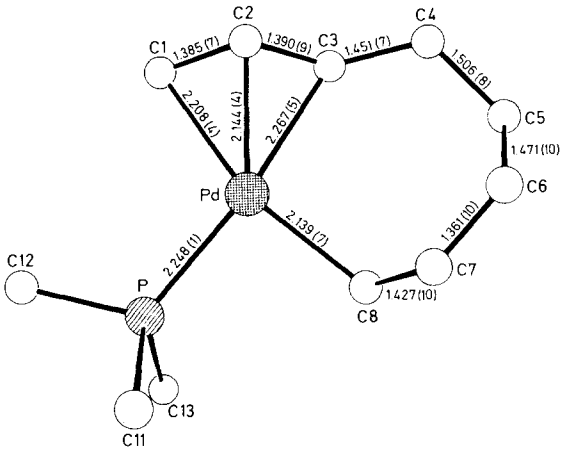

Fig. 5. The crystal structure of [Pd(PMe$_3$)(η^1,η^3-C_8H_{12})] [18].

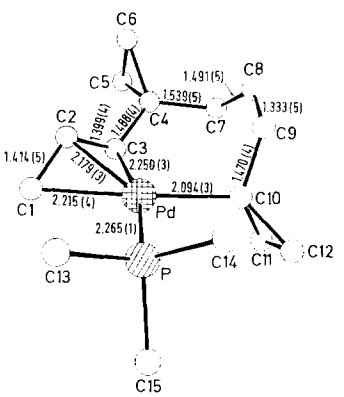
moreover, isomorphous with the palladium complex discussed here.[57] More precise structural parameters have been obtained for the complex **15** derived from allylidenecyclopropane (Fig. 6).



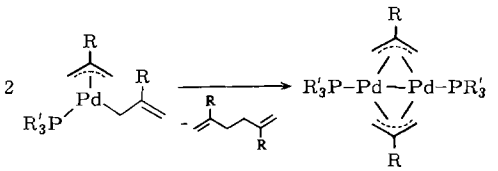


Fig. 6. The crystal structure of **15** [55].

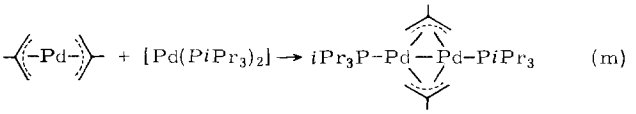
Of the four possible products of the reaction of two isoprene molecules at palladium (cf. Reaction (i)) only two are formed, viz., [PdL(η^1,η^3-2,6-$Me_2C_8H_{10}$)] and [PdL(η^1,η^3-2,7-$Me_2C_8H_{10}$)]. These result from head-tail and tail-tail coupling of the two diene molecules; it has been shown that the 2,6-disubstituted isomer is the product of a kinetically controlled reaction; the 2,7-isomer is thermodynamically more stable.[19]

3.2. Reactions



The [Pd(PR$_3$)(η^1,η^3-allyl)$_2$] complexes react further in solution at room temperature to give binuclear complexes

having bridging η^3-allyl groups [Reaction (l)].[18, 19, 58] Complexes of this type had previously been prepared by reacting bis(η^3-allyl)palladium with $[Pd(PR_3)_2]$ complexes [Reaction (m)].[59]

(1)

R = H; R' = Me, C_6H_{11}, Ph;
R = Me; R' = iPr_3, NMe_2, OC_6H_4Ph

(m)

The X-ray structure determination has confirmed the structure of the triphenylphosphane-substituted derivative (Fig. 7). The allyl groups are not symmetrically bonded to the metal atoms, suggesting a partial localization of the electrons within the organic ligands.

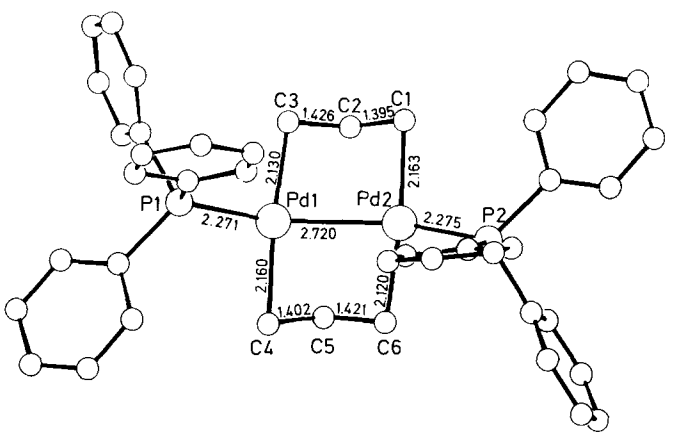


Fig. 7. The crystal structure of $[Pd(PPh_3)(\eta^3\text{-}C_3H_5)]_2$ [58].

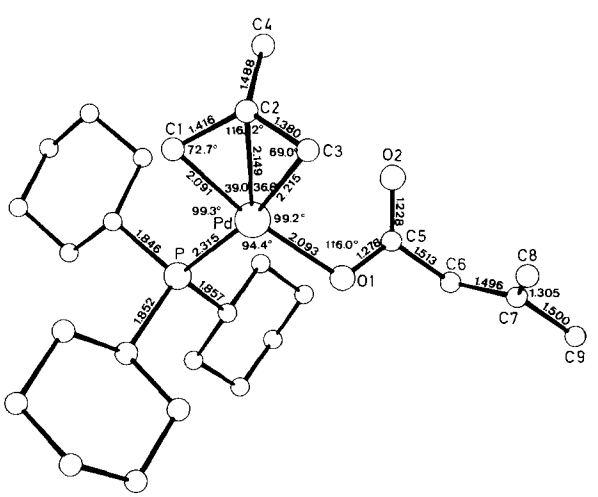
The bis(η^1,η^3-allyl)(phosphane)palladium complexes react with CO_2, SCO, and SO_2 with insertion into the Pd–C bond (Scheme 5).[43, 60] The structure of **16** has been confirmed by X-ray structure determination (Fig. 8).



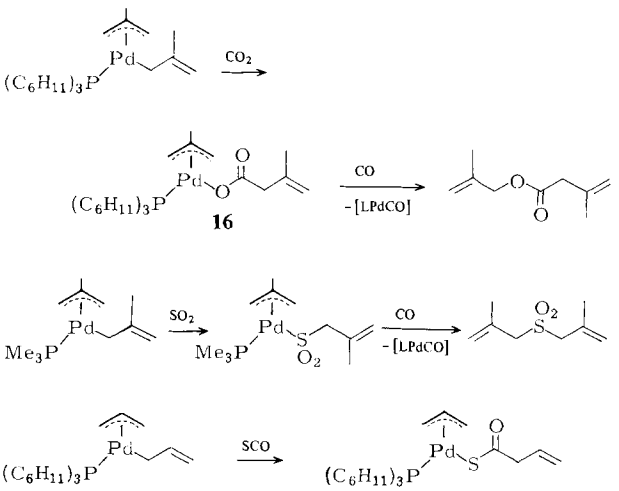


Fig. 8. The crystal structure of **16** [18].

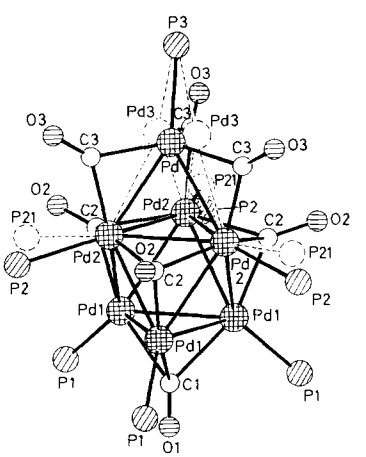
The η^3-allyl group in this molecule is asymmetric and is bonded unsymmetrically to the metal atom: the Pd–C bond *trans* to the phosphane is elongated and the allylic C–C bond shortened. For the complex shown in Scheme 5, the direction of insertion of SCO has also been confirmed by X-ray structure determination, although a satisfactory refinement of the data was hindered by disorder in the η^3-allyl group.[61]

Scheme 5.

Reaction of the η^3-allylpalladium carboxylate and S-sulfinate complexes with CO results in reductive coupling and elimination of an ester or sulfone (Scheme 5).[43, 60] On the other hand, the reaction of $[Pd(PMe_3)(\eta^1,\eta^3\text{-}C_8H_{12})]$ or $[Pd\{(C_6H_{11})_3\}(\eta^1,\eta^3\text{-}Me_2C_8H_{10})]$ with CO does not lead to reductive coupling and elimination of vinylcyclohexene or dimethylvinylcyclohexene (as observed for the analogous nickel compounds).[52] Instead, cleavage of the C_8-chain occurs with elimination of butadiene or isoprene.[18, 19] In the case of the trimethylphosphane-substituted complex this has been shown to be accompanied by the formation of a novel cluster compound $[Pd(PMe_3)(CO)]_7$. An X-ray structure determination (Fig. 9) has established that this compound is one of the few examples of a seven-metal-atom cluster in which the atoms are arranged in a face-capped octahedron. A phosphane molecule is bonded terminally to each palladium atom, whereas the CO molecules are both edge- and face-bridging.



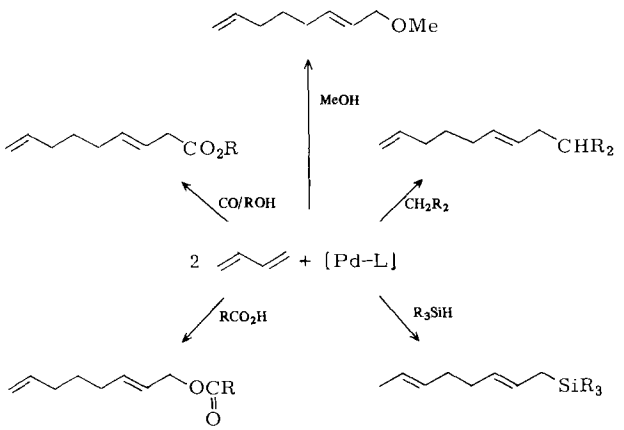


Fig. 9. The crystal structure of $[Pd(PMe_3)(CO)]_7$ [62].

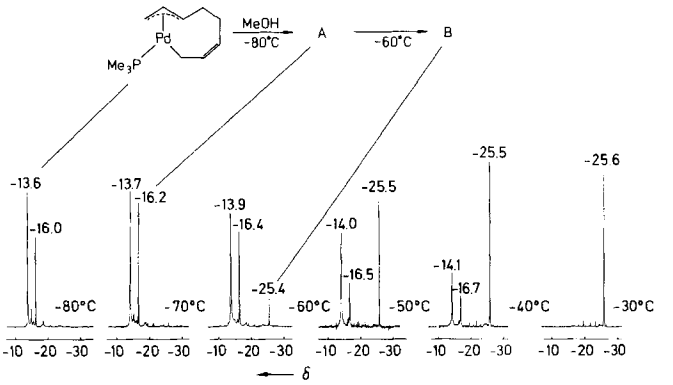
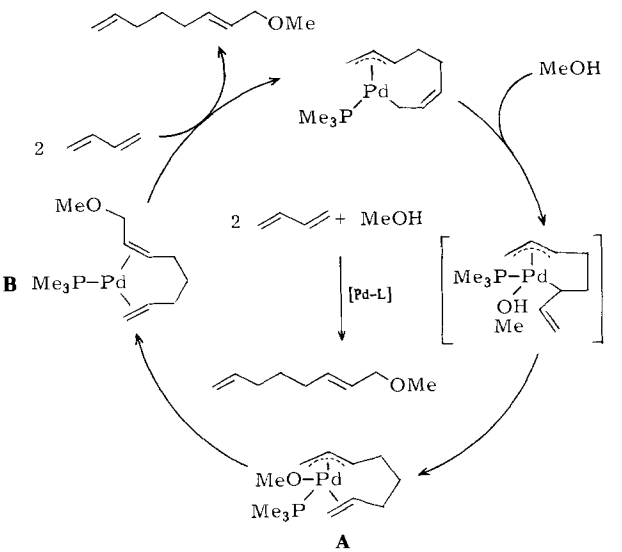
The significance of the [PdL(η^1,η^3-C_8H_{12})] complexes lies in their role as intermediates in palladium-catalyzed butadiene telomerization reactions, some of which are of considerable importance in organic synthesis (see Scheme 6).

Scheme 6 [63].

The relevance of the η^1,η^3-octadienediylpalladium species to these reactions is best illustrated by two examples: the reaction of [Pd(PMe_3)(η^1,η^3-C_8H_{12})] with methanol[18,51] and of [Pd{$P(C_6H_{11})_3$}(η^1,η^3-C_8H_{12})] with ethyl acetoacetate.[54] The ^{31}P-NMR spectra of the mixture obtained from the reaction of [Pd(PMe_3)(η^1,η^3-C_8H_{12})] with methanol at various temperatures is shown in Figure 10. The starting material [$\delta(^{31}P) \approx -13.6$] is converted via intermediate **A** [$\delta \approx -16.0$] into the product **B** [$\delta \approx -25.6$]; **A** and **B** have been identified as an η^2,η^3-octadienylpalladium complex and an η^2,η^2-1-methoxy-2,7-octadienepalladium complex, respectively. A plausible mechanism for the telomerization reaction is shown in Scheme 7. The reaction of **B** with butadiene with regeneration of the original η^1,η^3-octadienediylpalladium complex and displacement of methoxyoctadiene has been confirmed in a separate reaction.





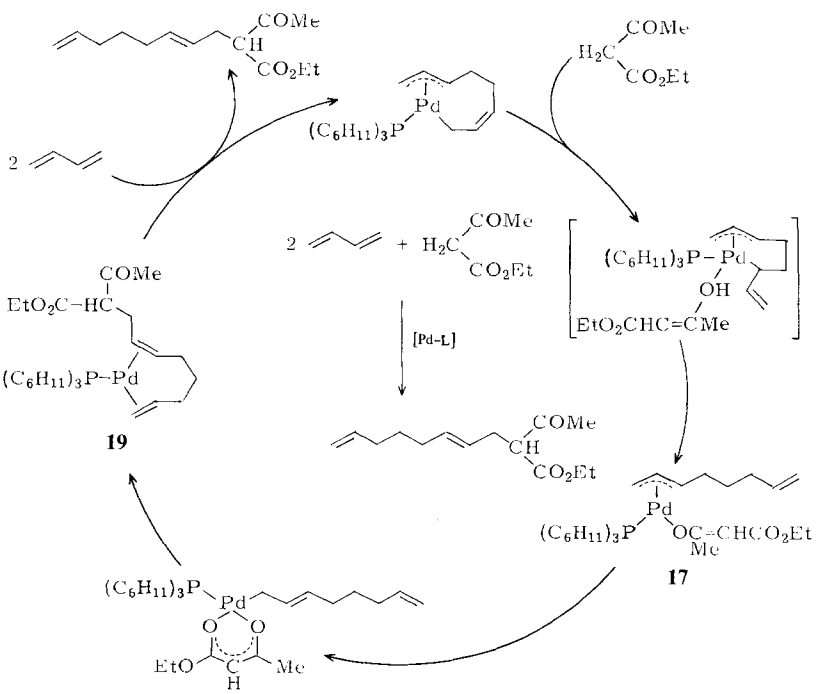


Fig. 10. ^{31}P-NMR spectra of the reaction mixture obtained from [Pd(PMe_3)(η^1,η^3-C_8H_{12})] and MeOH at different temperatures [18].

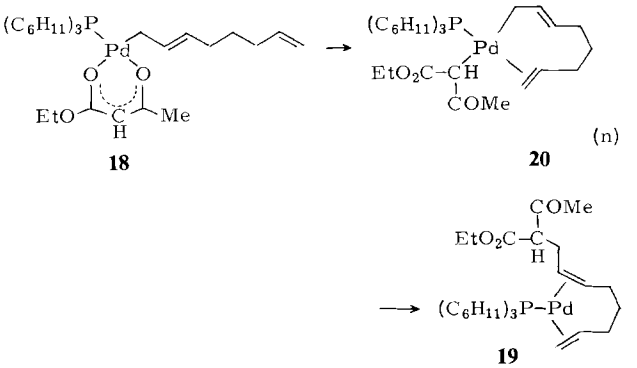
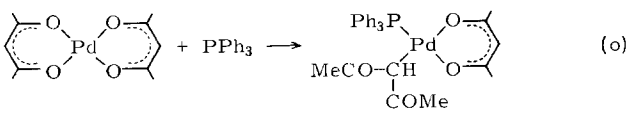
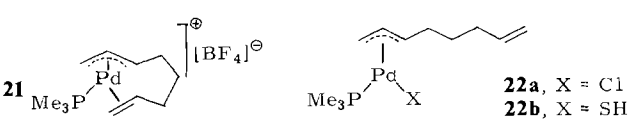


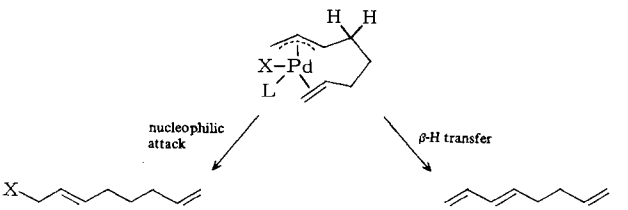


Scheme 7.

Scheme 8.

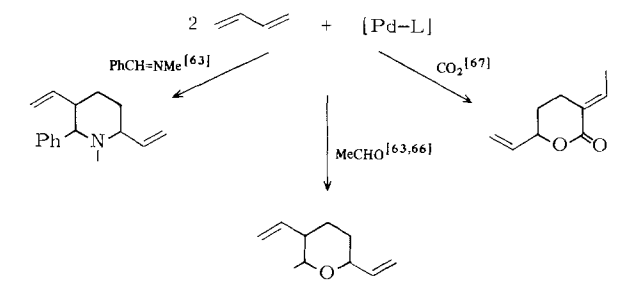


The reaction between $[Pd\{P(C_6H_{11})_3\}(\eta^1,\eta^3\text{-}C_8H_{12})]$ and ethyl acetoacetate, forming 2,7-octadienyl acetate, is more complicated. By a combination of chemical analysis and NMR spectroscopy, three intermediates, **17**, **18**, and **19**, could be identified; these support the catalytic cycle shown in Scheme 8. Apparently, the ethyl acetoacetate reacts through the enol form to give initially **17**. The rearrangement of **18** to **19** presumably proceeds via the intermediate formation of **20** in which a second Pd–C bond is formed; the rearrangement is instigated by complexation of the terminal double bond in **18** to the metal [Reaction (n)]. This rearrangement has precedence in that of palladium acetylacetonate in the presence of donor ligands [Reaction (o)].[64]



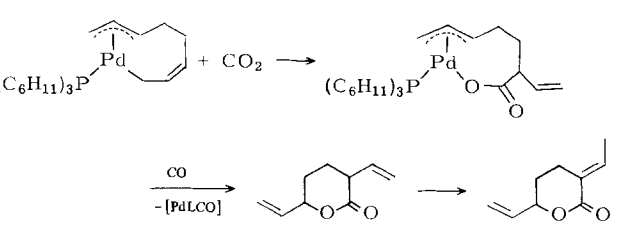
A number of questions concerning these reactions remain to be answered. In both cases it is suggested that the original η^1,η^3-octadienediyl chain rearranges, under the influence of the reactant, to give a vinyl-substituted isomer. This rearrangement explains directly the observed exclusive deuteration of C-6 on reaction with MeOD (or CH_3CO_2D in the analogous reaction with acetic acid). However, alternative explanations, e.g., direct attack on the uncomplexed *cis* double bond in the η^1,η^3-octadienediyl species, are possible. In addition, it has still to be decided whether **A** in Scheme 7 is better described by a covalent or by an ionic structure: the NMR data for **A** and for $[Pd(PMe_3)(\eta^1,\eta^3\text{-}C_8H_{13})]^{\oplus}[BF_4]^{\ominus}$ **21**, which has been shown by conductivity measurements to be ionic, are very similar.

Intermediates similar to those shown in Schemes 7 and 8 have also been isolated from the reactions of $[Pd(PR_3)(\eta^1,\eta^3\text{-}C_8H_{12})]$ complexes with Me_2CHOH, $H_2C(CO_2Et)_2$, $H_2C(CN)_2$, $H_2C(CN)CO_2Me$, $MeCO_2H$, and $PhCH(OH)CO_2H$. HBF_4 reacts to give **21a**, whereas HCl and H_2S give the non-ionic η^3-allyl complexes **21b** and **21c**, respectively.[54]



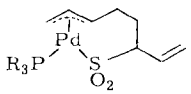
The η^2,η^3-octadienylpalladium species is a key "switch" intermediate: nucleophilic attack leads to the formation of a telomer, whereas β-hydrogen transfer leads to liberation of a linear dimer (Scheme 9). The addition of tertiary amines—which are known to promote the telomerization of,

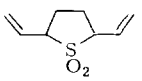
Scheme 9.



for example, acetic acid with butadiene[65]—presumably provides additional donor molecules, which displace the olefinic moiety in the octadienyl ligand from the metal atom and promote the rearrangement of the η^3-allyl group to the η^1-allyl form and its reductive coupling with acetate. Secondary or primary amines, in contrast, compete with the acetic acid in complexing with the metal, resulting in the formation of octadienylamines.

The η^1,η^3-octadienediylpalladium species are probably involved in the Pd-catalyzed cyclooligomerization of butadiene with heteroolefins (Scheme 10). Here, too, stoi-





Scheme 10.

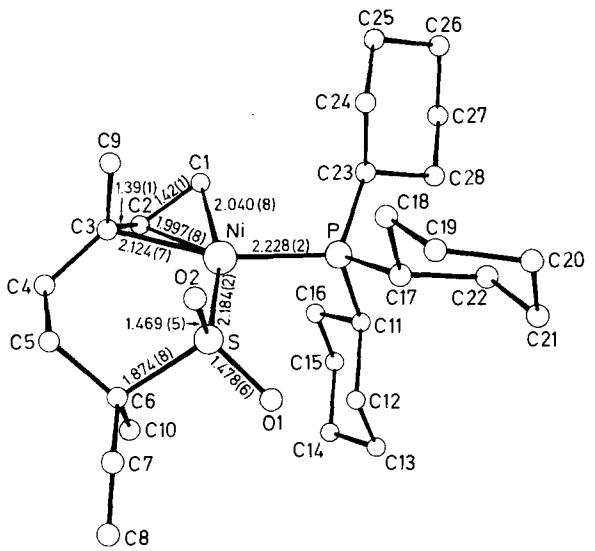
chiometric reactions throw some light on the course of reaction. For example, it has been shown that these organopalladium complexes react with CO_2 via insertion into the Pd–C bond. Reaction of the intermediate η^3-allylpalladium carboxylate with CO results in reductive coupling and displacement of a γ-lactone, which was shown to undergo facile thermal isomerization at room temperature to the lactone formed in the catalytic reaction (Scheme 11).[19,43]

Scheme 11.

Phenyl isocyanate reacts similarly.[18] SO_2 also inserts into the Pd–C bond of the η^1,η^3-octadienediylpalladium complexes to give the palladium-S-sulfinate complex **22**.[43] This complex might well be involved in the cooligomerization of SO_2 with butadiene to give 2,5-divinylsulfolane **23**. This reaction is catalyzed, albeit inefficiently, by a triphenylphosphane-modified palladium catalyst.[68]

22  **23** 

Complexes analogous to **22** have also been isolated from reactions involving nickel. For the reaction between $[Ni\{P(C_6H_{11})_3\}(\eta^1,\eta^3\text{-}3,6\text{-}Me_2C_8H_{10})]$ and SO_2, the crystal structure of the product has been established by X-ray crystallography (Fig. 11).



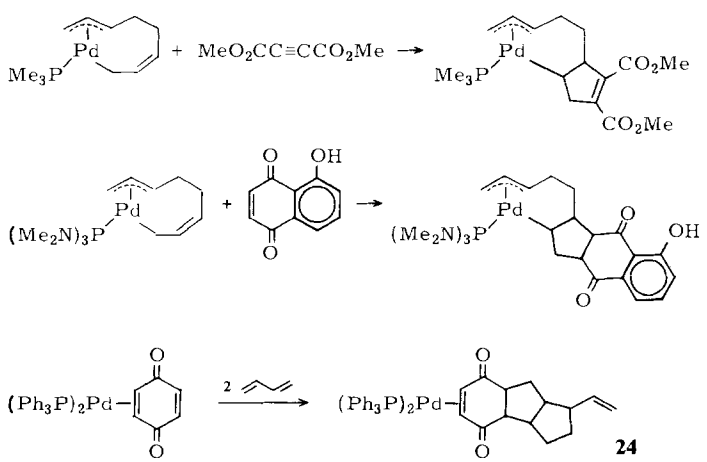


Fig. 11. The crystal structure of the product of the reaction of SO_2 with $[Ni\{P(C_6H_{11})_3\}(\eta^1,\eta^3\text{-}3,6\text{-}Me_2C_8H_{10})]$ [43, 61].

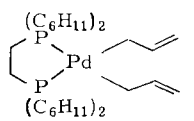
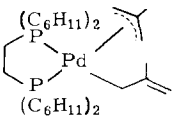
The reaction of the η^1,η^3-octadienediylpalladium complexes with unsaturated organic molecules takes a different course: electron-deficient alkynes and olefins undergo 1,3-addition to the η^1-allyl fragment (Scheme 12).[54] These

Scheme 12.





reactions are reminiscent of that between bis(triphenylphosphane)(η^2-*p*-benzoquinone)palladium and butadiene from which, the palladium complex **24** has been isolated.[69]

The reactivity of systems derived from substituted dienes should be similar to that of the η^1,η^3-octadienediylpalladium complexes. Preliminary investigations of the $[Pd(PR_3)(\eta^1,\eta^3\text{-}Me_2C_8H_{10})]$ complexes derived from isoprene have confirmed this for reactions with methanol, acetic acid, and mandelic acid.[19]

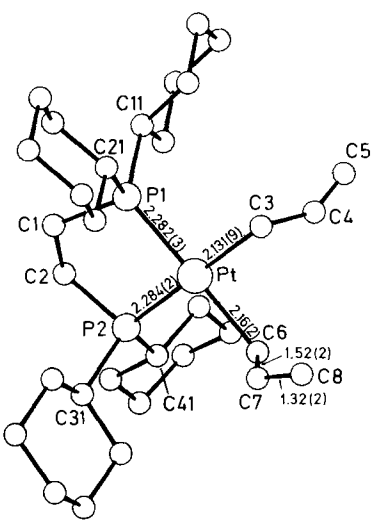
4. Bis(η^1-allyl)palladium Complexes

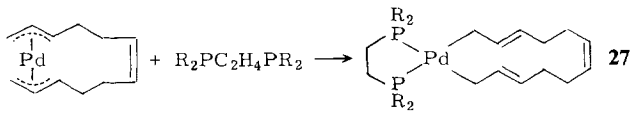
4.1. Preparation and Structure

Treatment of bis(η^3-allyl)palladium with two equivalents of a donor ligand could convert both η^3-allyl groups into the η^1-arrangement; indeed, this is observed in some cases upon reaction with chelating bidentate phosphanes. The course of the reaction is dependent upon the nature of both the phosphane and the allyl group: whereas bis(dicyclohexylphosphino)ethane reacts with $[Pd(\eta^3\text{-}C_3H_5)_2]$ as expected to give **25**, it reacts with $[Pd(\eta^3\text{-}2\text{-}MeC_3H_4)_2]$ to give the η^1,η^3-compound **26** in which the allyl groups undergo intramolecular exchange.[18, 19, 70]

25   **26**

25 is unstable at room temperature (hexadiene is eliminated to give $[(L_2Pd)_2C_6H_{10}]$). The analogous platinum compound, however, is stable, and the η^1-arrangement of the allyl groups has been confirmed by X-ray structure determination (Fig. 12).





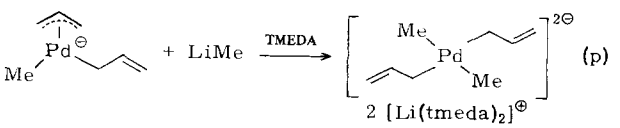


Fig. 12. The crystal structure of $[Pt\{(C_6H_{11})_2PCH_2CH_2P(C_6H_{11})_2\}(\eta^1\text{-}C_3H_5)_2]$ [61, 70].

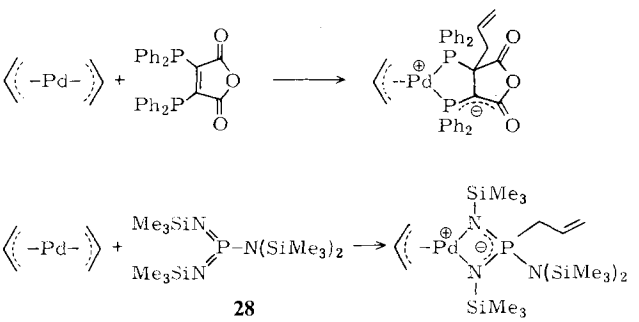
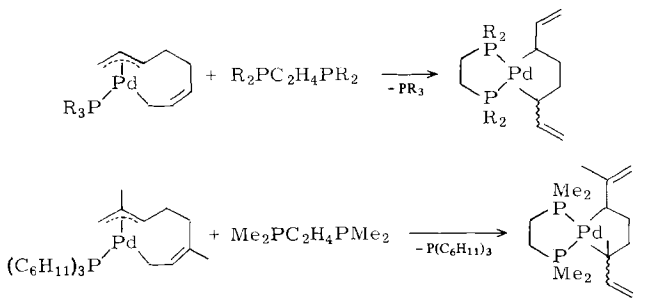
$[Pd(\eta^3,\eta^3,C_{12}H_{18})]$ reacts similarly on treatment with a variety of dialkyl-substituted bidentate phosphanes: the 13-membered palladium ring system **27** is formed—presumably a record for metallacycle size.



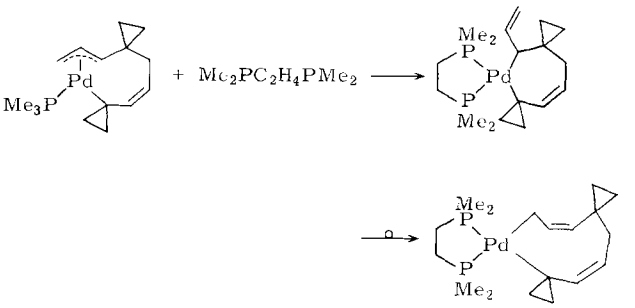
27

Although the reactions of the $[Pd(PR_3)(\eta^1,\eta^3\text{-allyl})_2]$ complexes with a second monodentate ligand have still to be investigated carefully, the anionic bis(η^1,η^3-allyl)(methyl)palladium complex has been shown to react with a second equivalent of methyllithium to form a tetraorganopalladate [Reaction (p)].[50] The reaction was carried out in the presence of tetramethylethylenediamine (TMEDA).



(p)

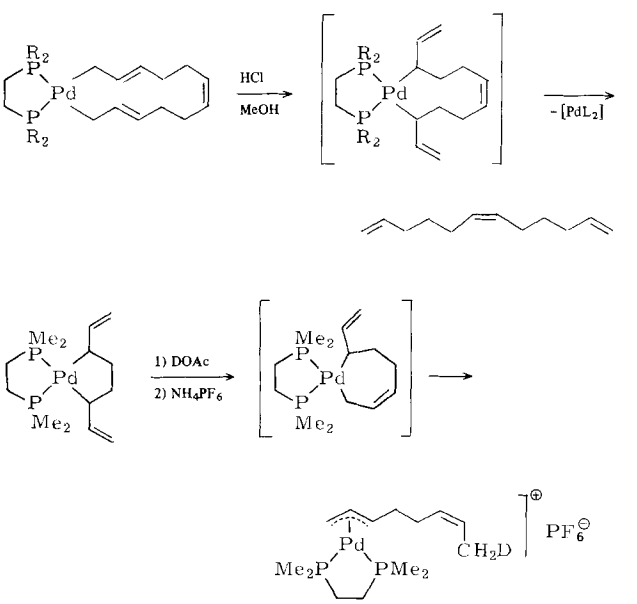
A few, rather exotic, bidentate ligands react anomalously with bis(η^3-allyl)palladium: bis(diphenylphosphino)maleic anhydride reacts with transfer of an allyl group from the metal to the ligand to give a zwitterion;[71] similar behavior is also observed in the reaction with the amino[bis(imino)]ylide **28**[72] (Scheme 13). In both cases the structure of the product has been confirmed by X-ray structure determination.



Scheme 13.

Treatment of the $[Pd(PR_3)(\eta^1,\eta^3\text{-}C_8H_{12})]$ complexes with chelating phosphanes frequently leads to ligand exchange and formation of a bis(η^1-allyl)palladium system. For example, 1,4-divinylpalladacyclopentane derivatives may be prepared in this way as a mixture of *cis* and *trans* isomers. A similar reaction is observed with the dimethyl-substituted octadienediyl derivatives[19] (Scheme 14).

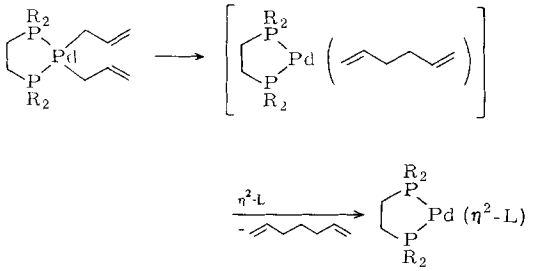
Scheme 14. R = Me, *i*Pr, C_6H_{11}; R' = Me, Ph, NMe_2.



The cyclopropane-substituted analogue reacts somewhat differently (Scheme 15): initially a palladacycloheptene derivative is formed which then rearranges to a palladacyclononadiene species whose structure has been verified by X-ray crystallography.[55]

Scheme 15.

4.2. Reactions

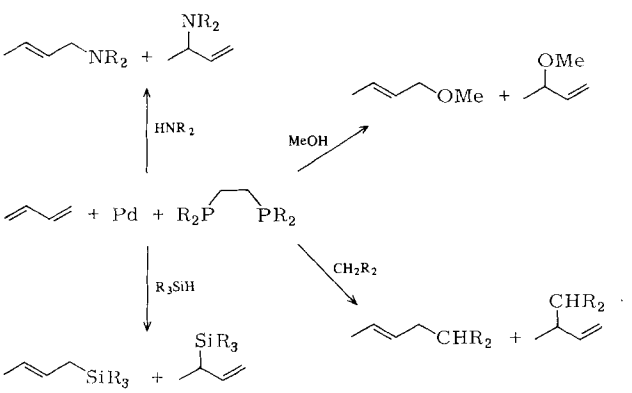


The $[PdL_2(\eta^1\text{-allyl})_2]$ complexes behave as typical dialkylpalladium systems. For example, the Pd–C bond can be cleaved by acids, and reactions with donor ligands lead to reductive coupling of the allyl groups or (where possible) to β-hydrogen transfer. Two non-trivial examples are the treatment of the palladacyclotridecatriene with methanolic HCl, from which *cis*-1,6-11-dodecatriene is liberated, and the reaction of a palladacyclopentane derivative with deuteroacetic acid, which results in deuteration of a terminal C-atom (Scheme 16).[19] The first reaction is of interest

Scheme 16. R = Me, *i*Pr, C_6H_{11}.

because it establishes the presence of a *cis*-double bond in the reacting metallacycle. Whether these reactions proceed via the palladacyclononene and palladacycloheptene derivatives shown in Scheme 16 is not known; direct attack of the acid on the double bond is possible.

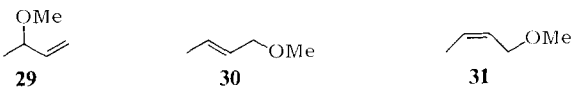
Ligand-induced or spontaneous reductive coupling of the allyl groups is observed for the simple $[PdL_2(\eta^1\text{-allyl})_2]$ species. There is some evidence that the resulting diene, which is initially complexed to the metal, can be displaced, providing a convenient access to a variety of $[L_2Pd]$ complexes of unsaturated organic molecules (Scheme 17).[18,70]



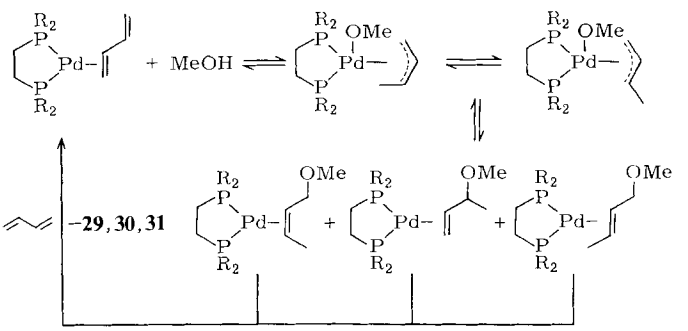
Scheme 17. R = *i*Pr, *t*Bu, C_6H_{11}.

The behavior of the palladacycles (Scheme 16) with excess donor ligand is anomalous: the palladacyclotridecatriene reacts with β-hydrogen transfer (presumably via the same nine-membered-ring intermediate) to give a mixture of dodecatetraene isomers; the palladacyclopentane derivative reacts with ring cleavage and liberation of butadiene.[19]

5. η^3-Allylpalladium Complexes with Bidentate Ligands[70]



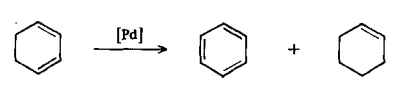
η^3-Allylpalladium complexes with bidentate ligands are presumably involved as intermediates in the numerous 1:1-telomerization reactions of butadiene with nucleophiles. Such reactions are catalyzed by palladium in the presence of chelating bidentate phosphanes or an excess of a monodentate phosphane (Scheme 18).[63]



Scheme 18.

The stoichiometric reaction of the $[PdL_2(\eta^2\text{-}C_4H_6)]$ complexes (prepared as shown in Scheme 17) with nucleophiles has provided insight into the mechanism of the reactions shown in Scheme 18. The reaction with methanol will be described in detail; similar results have been obtained with acetic acid and amines.

The reaction between butadiene and methanol is catalyzed by $[Pd\{(C_6H_{11})_2PCH_2CH_2P(C_6H_{11})_2\}(\eta^2\text{-}C_4H_6)]$; after 3 h at 100°C, practically the only product is a mixture of the three methoxybutene isomers **29**, **30**, and **31** in an approximate ratio of 7:4:1 and with a butadiene conversion of 40%. If the bis(diphenylphosphino)ethane-stabilized complex is used as the catalyst, the main product is the 2:1 telomer methoxyoctadiene.



An NMR spectroscopic investigation of the stoichiometric reaction between the η^2-butadienepalladium complex and methanol in tetrahydrofuran established that a multistep reaction occurs: initially at −80°C an *anti*-η^3-1-methallylpalladium complex is formed which, after rearrangement to the *syn*-isomer, reacts further at ca. −30°C by reductive coupling to give the expected η^2-methoxybutenepalladium complexes (Scheme 19).

Scheme 19. R = C_6H_{11}.

The reversibility of all these steps could be demonstrated in separate reactions with the individual methoxybutene isomers. Treatment of the complexes with butadiene leads to displacement of the olefins.

An attempt to carry out a similar reaction with the analogous η^2-1,3-cyclohexadienepalladium complex failed—instead, disproportionation to benzene and cyclohexene was observed. Catalysis of this disproportionation by elemental palladium was first reported in 1933.[73] In the early

1970s, a number of homogeneous transition-metal catalysts[74] were investigated. The addition of methanol to $[Pd\{(C_6H_{11})PCH_2CH_2P(C_6H_{11})_2\}(\eta^2\text{-}1,3\text{-}C_6H_8)]$ produces a catalyst which, although less active than elemental palladium, is much more stable. The reaction presumably proceeds through the intermediate formation of η^3-cyclohexylpalladium species in a manner analogous to that proposed for the Rh-catalyzed reaction.[75]

6. Outlook

The main objective of this article has been to demonstrate how a study of the chemistry of model complexes can provide information relevant to the individual steps of a catalytic process. Although we have limited ourselves here to reactions involving η^3-allylpalladium complexes and dienes, a similar approach can be applied to other systems and other metals. For example, a study of the chemistry of alkylpalladium complexes can give insight into the mechanism of the palladium-catalyzed transformations of alkenes. Investigations of this kind only partly elucidate the catalysis. A well-founded mechanism must incorporate kinetic data, which, however, is notoriously lacking in organometallic chemistry.

Much of the progress that has been made is not based so much upon new principles—the basic reactions involved in homogeneous catalysis were clearly identified more than two decades ago—but rather on the increasing sophistication of the spectroscopic tools available. It requires no particular enlightenment to predict that this development will continue. In particular, the routine use of variable temperature NMR spectroscopy will continue to be a cornerstone of these studies, whereby it is to be anticipated that, above and beyond the continued use of the established nuclei (^{1}H, ^{13}C, ^{31}P, etc.), the routine measurement of the metal-atom chemical shift will introduce a new dimension. Unfortunately, ^{105}Pd (natural abundance 22%) has a spin of 5/2 and the absorptions are broad, so that the data will not be as useful as those of other metals (e.g., Pt and Rh). However, the increased facility with which these measurements can be carried out has the inherent danger that many important processes in which paramagnetic species are involved will be neglected.

Although emphasis has been placed in this article on catalytic reactions, it should at least be mentioned that many synthetically valuable reactions, e.g., the coupling of palladium-bonded organic groups and the nucleophilic attack on complexed alkenes, are of a stoichiometric nature.[63, 76] Attempts are being made to carry out these reactions catalytically. Their success, however, will clearly depend on a detailed understanding of the chemistry of the organopalladium complexes involved.

I would like to thank Professor G. Wilke for his continuous support of this work without which it would not have been possible. It is a pleasure to acknowledge the stimulating cooperation of Professor C. Krüger, Dr. R. Goddard, Dr. Y.-H. Tsay, and their coworkers, who were responsible for the X-ray diffraction studies, and of Dr. R. Benn, Miss B. Gabor, Dr. R. Mynott, Dr. A. Rufińska, and Mr. G. Schroth, who were responsible for the NMR investigations. I am also indebted to Mr. A. Döhring and Mrs. S. Holle for their dedicated and skillful technical assistance.

Reactive Organometallic Compounds Obtained from Metallocenes and Related Compounds and Their Synthetic Applications**

By Klaus Jonas*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Progress in the synthesis of organometallic compounds via the partial or total degradation of metallocenes and related compounds under mild reaction conditions is reviewed. These degradation reactions permit highly reactive organo-transition metal complexes to be prepared which can in turn be used in a wide range of synthetic reactions. Examples include catalytic reactions such as the cobalt-catalyzed hydrogenation of benzene and the manganese-catalyzed cyclotrimerization of butadiene as well as stoichiometric syntheses of mono- and polynuclear transition metal complexes, some of which have novel structural features.

1. Introduction

As reported in a number of previous publications, metallocenes, alkali metals, and olefins can be used to prepare transition metal-olefin- or alkali metal-transition metal-olefin complexes.[1] More recently, developments arising from this synthetic approach have been having an impact on other areas of organometallic chemistry. The present paper reviews these and other current developments in this field.

The review is divided into two main parts. The first part deals primarily with those reaction schemes that have been studied in the Institute in Mülheim by which metallocenes and related compounds with pentacyclic ligands can be

degraded, while the second part demonstrates that these degradation reactions can provide access to highly reactive organometallic compounds which have wide synthetic applications.

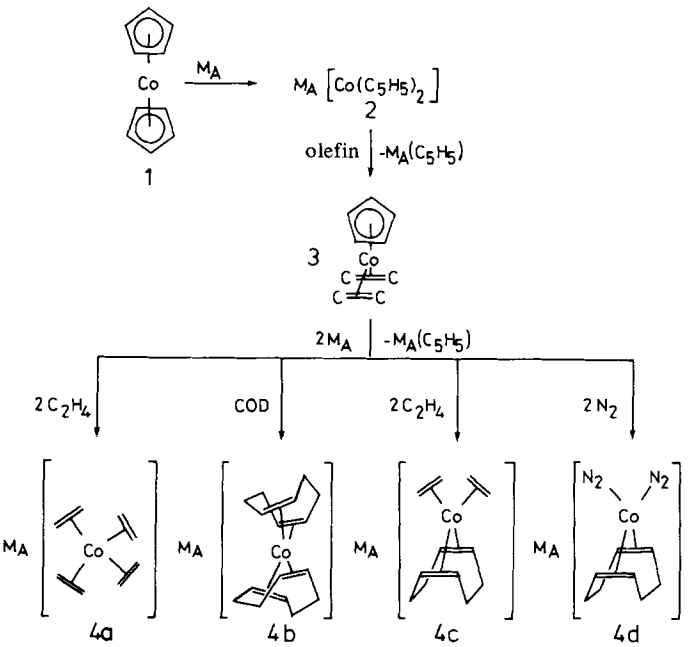
2. Synthesis of Reactive Organometallic Compounds by Partial or Total Degradation of Metallocenes and Related Compounds

This section describes reactions by which metallocenes and related compounds can be converted into reactive organometallic compounds, i.e. complexes of transition metals having readily accessible coordination sites. These reactions have in common that the cleavage of the transition metal five-membered ring ligand bonds takes place under especially mild reaction conditions. We have investigated the two following types of reaction[2] by which this can be achieved easily and which can be used for synthetic purposes:

A: Removal of the five-membered ring ligands by reaction with an alkali metal and olefin and/or another complexing agent (removal of one or both rings)

B: Exchange of the five-membered ring ligands by metathetical reactions with organometallic compounds or hydrides of the main group elements, especially of the alkali metals, either in the presence or absence of complexing agents (exchange of one or both rings)

In addition, reactions of type A and B can be combined in a synthesis, whereby one ring is removed from the transition metal by method A and the other by method B. Two-stage degradation reactions of this kind will be referred to as type C reactions in this publication.



C: A and B combined (removal of both rings)

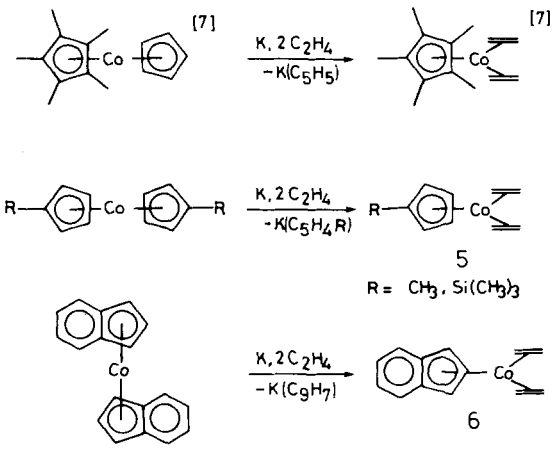
2.1. Degradation of Metallocenes and Related Compounds by Reaction with Alkali Metal and Olefin and/or Another Complexing Agent

2.1.1. Reactive Olefin Complexes of Cobalt and Iron

In 1973 we reported the synthesis and properties of tris(ethylene)nickel.[3] This compound, the first metal-olefin complex made up only of ethylene and a metal atom, is a beautiful example of "naked nickel".[4] Its discovery presented a challenge—could metal complexes with a similarly large number of ethylene ligands be prepared with transition metals further left in the periodic table? Today, such highly reactive ethylene complexes are also known for cobalt and iron,[1,2] thanks to the efficiency of the metallocene degradation of type A. Scheme 1 outlines the preparation of cobalt-ethylene and other cobalt-olefin complexes from cobaltocene **1**.

The first step in the reductive degradation of cobaltocene is the formation of 1 : 1 adducts between cobaltocene and an alkali metal atom M_A (M_A = Li, K) (see **2** in Scheme 1). The final products are cyclopentadienyl-free alkali metal cobaltates(−1) **4**, which contain readily replaceable olefin ligands, e.g. four coordinated ethylene molecules (**4a**). Further intermediates in the degradation are the half-sandwich complexes of type **3**, of which the most reactive is again the ethylene complex (**3a**). In practice, **3a** and **4a** are prepared by stirring cobaltocene **1** with the alkali metal in a reaction vessel connected to a gas bottle filled with ethylene. When diethyl ether is used as the solvent only one cyclopentadienyl ligand is removed, whereas when the reaction is carried out in THF both ring ligands are removed [Eq. (1) and (2)].[5]

Scheme 1. The preparation of cobalt-ethylene and other cobalt-olefin complexes from cobaltocene **1**. For clarity, the n-donor ligands tetrahydrofuran (THF), tetramethylethylenediamine (TMEDA) or diethyl ether (Et_2O) bonded to the alkali metal atoms M_A have been omitted from this and all other reaction schemes and equations in this publication.—Olefin = ethylene, butadiene, cyclohexadiene, cyclooctadiene etc.



$$(C_5H_5)_2Co + K + 2C_2H_4 \xrightarrow[-K(C_5H_5)]{Et_2O} (C_5H_5)Co(C_2H_4)_2 \qquad (1)$$
1 **3a**

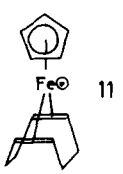
$$(C_5H_5)_2Co + 3M_A + 4C_2H_4 \xrightarrow[-2M_A(C_5H_5)]{THF} M_A[Co(C_2H_4)_4] \qquad (2)$$
1 **4a**

All these degradation reactions, including those where alkali metals are used in the presence of other complexing agents (see Scheme 1), proceed practically without side reactions and almost quantitatively (i.e., for **3** and **4** the yield is over 90%) and the alkali metal cyclopentadienides can be separated from the cobalt complexes **3** and **4** without difficulty.[*]

[*] This point is important enough to warrant further detail. For example, the $K(C_5H_5)$ formed according to Scheme 1 and Equation (2) is rather insoluble in THF at −78 °C compared to the potassium cobaltates **4a** and **4b**. Furthermore, it is precipitated in a form ideal for separation by filtration. Solid **4a** or **4b** is formed on evaporation of the THF-filtrate. The last traces of $K(C_5H_5)$ can be removed from the products by washing with diethyl ether, since the potassium cyclopentadienide is much more soluble in ether than in THF at 20 °C, while for the cobalt complexes exactly the reverse is true.

In order to develop a general method for the synthesis of cobalt(I)-ethylene complexes with substituted cyclopentadienyl ligands, the principle of reductive degradation of metallocenes has recently been extended to cobaltocene derivatives (Scheme 2). A particularly interesting variant of the $(C_5H_5)Co(C_2H_4)_2$ synthesis [Eq. (1)] is the preparation of the new indenylcobalt compound **6**.[6] This complex is unstable above 0°C and its reactivity can be expected to exceed that of the parent compound **3a**, which is stable at room temperature. This would be consistent with the known differences in reactivity of different half-sandwich complexes with carbonyl ligands.[8]

Scheme 2. Cobalt(I)-ethylene complexes prepared by reductive abstraction of five-membered ring ligands.



The potential of the reductive degradation of metallocenes is further illustrated by the fact that not only cobaltocene **1** and nickelocene **23** (electron-rich metallocenes)[1,9] can be degraded, but also that such a stable 18e compound as ferrocene **7** is a suitable starting material for the preparation of reactive iron-olefin complexes [Eqs. (3) to (5)]. Ferrocene reacts with lithium and ethylene to yield the iron-ethylene complexes **8**[10a] and **10**,[10b] while the corresponding reaction with 1,5-cyclooctadiene (COD) instead of ethylene produces **9**.[10a]

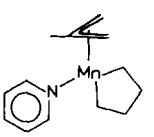
$$\underset{\mathbf{7}}{(C_5H_5)_2Fe} \xrightarrow[-Li(C_5H_5)]{2\,Li,\ 2\,C_2H_4} \underset{\mathbf{8}}{Li[(C_5H_5)Fe(C_2H_4)_2]} \qquad (3)$$

$$\underset{\mathbf{7}}{(C_5H_5)_2Fe} \xrightarrow[-Li(C_5H_5)]{2\,Li,\ COD} \underset{\mathbf{9}}{Li[(C_5H_5)Fe(cod)]} \qquad (4)$$

$$\underset{\mathbf{7}}{(C_5H_5)_2Fe} \xrightarrow[-2\,Li(C_5H_5)]{4\,Li,\ 4\,C_2H_4} \underset{\mathbf{10}}{Li_2[Fe(C_2H_4)_4]} \qquad (5)$$

Compound **9** can be delithiated with trityl chloride[10a] to produce **11** (Scheme 3). This mononuclear iron(I)-olefin complex, which has one unpaired electron, has been studied in detail by X-ray crystallography (for details, see the review by *Krüger* et al.).[11]

11



Scheme 3. Cyclooctadiene(cyclopentadienyl)iron(I) **11**—an iron-olefin complex with one unpaired electron.

2.1.2. The Reaction of Manganese(II) Cyclopentadienide with Alkali Metals and Olefins and Subsequent Reactions

When manganese(II) cyclopentadienide **12** is stirred with potassium at low temperatures (−60 to −20°C) in diethyl ether or THF, the surface of the potassium rapidly becomes coated with metallic manganese. The same is observed in the presence of ethylene or other olefins. Thus, compound **12**, which tends to dissociate into ions,[12] cannot be used in this way for organometallic syntheses. It is also unable to function as an alkali metal carrier, apparently because the $[(C_5H_5)_2Mn]^{\ominus}$ anion is unstable. For the metallocenes of Ni,[13] Co,[13–15] Cr and V,[13] the reversible one-electron reduction to the anion has been demonstrated by cyclic voltammetry, while $(C_5H_5)_2Co$ **1** (Scheme 1), $(C_5H_5)_2V$ **14** and $(C_5Me_5)V(C_5H_5)$ **15** (Section 2.1.3) and $(C_5Me_5)_2Mn$[17] form 1:1 adducts with alkali metals.

$Mn(C_5H_5)_2$ **12**

In order to prevent the deposition of manganese, the reactions have been carried out in the presence of conventional alkali metal carriers instead of the alkali metal alone.[18] This recent modification has proved to be most significant. Thus, the reaction of **12** in THF with naphthalenepotassium $[K(C_{10}H_8):Mn=3:1]$ and ethylene at −60°C to −40°C yields $K(C_5H_5)$, which is sparingly soluble in THF, in the amount calculated $[K(C_5H_5):Mn=2:1]$, together with a filtrate containing potassium and manganese in the ratio 1:1. On addition of methallyl chloride and then pyridine to the filtrate, the new metallacyclic mononuclear complex **13** can be isolated (Scheme 4).

13

Scheme 4. Proposed structure for η^3-methallyl(pyridine)manganacyclopentane **13**.

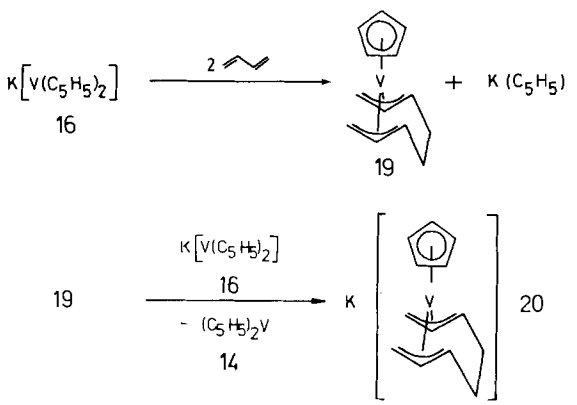
If iodine is added to the above filtrate instead of methallyl chloride ($K:Mn:I_2=1:1:1$) followed by $Li(C_5H_5)$ or $Li(C_5Me_5)$, novel binuclear complexes are isolated in which each manganese atom bears a five-membered ring ligand. Again, as found for **13**, these compounds are not manganese-ethylene complexes but contain manganese atoms coordinated to $(CH_2)_4$ ligands that have been formed from two ethylene molecules.

2.1.3. Olefin and Allyl Complexes of Vanadium from Vanadocene

When vanadocene **14** or pentamethylvanadocene **15** (Section 3.3.2) is reduced with potassium in THF at

-78 °C, a deep red solution is formed from which **16** or **17**, respectively, can be precipitated by addition of Et_2O or pentane [Eq. (6) and (7)].

$$\underset{\mathbf{14}}{(C_5H_5)_2V} + K \xrightarrow[-78\,^\circ C]{THF} \underset{\mathbf{16}}{K[(C_5H_5)_2V]} \quad (6)$$



$$\underset{\mathbf{15}}{(C_5Me_5)V(C_5H_5)} + K \xrightarrow[-78\,^\circ C]{THF} \underset{\mathbf{17}}{K[(C_5Me_5)V(C_5H_5)]} \quad (7)$$

These new compounds **16**[19] and **17** are further examples of isolable alkali metal-reduced metallocenes or metallocene derivatives—other examples are **2** and $Na[(C_5Me_5)_2Mn]$.[17] Both these complexes **16** and **17** are, like the cobalt compounds **2**, particularly suitable for the synthesis of half-sandwich complexes.

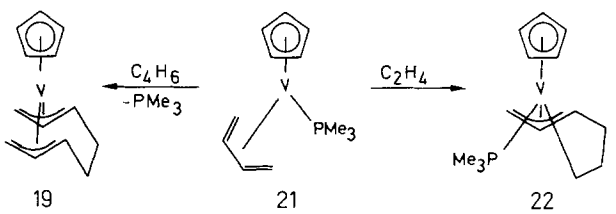
Carbon monoxide reacts with **16** and **17** at -78 to 20 °C. These carbonylations lead to the formation of $K(C_5H_5)$ and $[(C_5H_5)V(CO)_4]$[20] or **18**, respectively.

$$\mathbf{16} + 4CO \xrightarrow[-K(C_5H_5)]{-78\,^\circ C \ldots 20\,^\circ C} (C_5H_5)V(CO)_4 \quad (8)$$

$$\mathbf{17} + 4CO \xrightarrow[-K(C_5H_5)]{-78\,^\circ C \ldots 20\,^\circ C} \underset{\mathbf{18}}{(C_5Me_5)V(CO)_4} \quad (9)$$

Scheme 5. The formation of **20** from **16** and butadiene.

When **16** is treated with butadiene in THF at -78 to 20 °C, the potassium vanadate **20** can be isolated.[19] The formation of **20** probably occurs as shown in Scheme 5. The intermediate potassium-free vanadium(III) complex **19** is formed by reaction of **16** with butadiene and is subsequently reduced to **20** by a second molecule of **16**. Thus, **16** has a double function since it not only provides the $(C_5H_5)V$ units [Eq. (10)] but also acts as a source of potassium [Eq. (11)].



$$\underset{\mathbf{16}}{K[(C_5H_5)_2V]} \longrightarrow [(C_5H_5)V] + K(C_5H_5) \quad (10)$$

$$\underset{\mathbf{16}}{K[(C_5H_5)_2V]} \longrightarrow \underset{\mathbf{14}}{(C_5H_5)_2V} + K \quad (11)$$

The reaction of complex **16** with butadiene must be distinguished from that of **16** with a mixture of butadiene and trimethylphosphane. In this case **16** acts only as a source of $(C_5H_5)V$ units [Eq. (10)] and the product is the olefin-vanadium complex **21**, which contains no alkali metal [Eq. (12)]. [Compare this with Eq. (25) in Section 3.3.2.]

$$\underset{\mathbf{16}}{K[(C_5H_5)_2V]} + C_4H_6 + PMe_3 \xrightarrow[-78\ldots20\,^\circ C]{THF} \underset{\mathbf{21}}{(C_5H_5)V(C_4H_6)PMe_3} + K[C_5H_5] \quad (12)$$

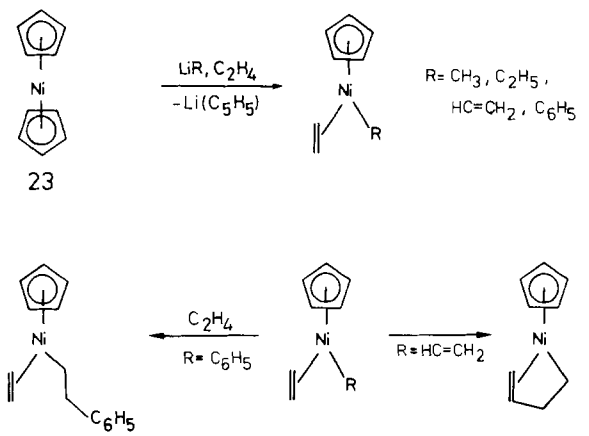
The reactions of **21** with butadiene or ethylene are particularly interesting because C–C coupling[21] of the olefin ligands occurs (Scheme 6). With butadiene, **19** and free trimethylphosphane are formed, but with ethylene the V–P bond is retained and **22** is produced. The structures of **21** and **22** were determined by X-ray crystallography.[22]

Scheme 6. Allylvanadium(III) complexes **19** and **22** prepared by reaction of the olefin-vanadium(I) complex **21** with olefins.

2.2. Degradation of Metallocenes and Related Compounds by Metathetical Reactions

For a long time, metathetical reactions of metallocenes with organometallic compounds of the main group metals were used remarkably little for synthetic purposes. In 1961 *Muetterties* et al., reported that nickelocene reacts with allylmagnesium chloride to afford the allylnickel complex $[(\eta^3\text{-}C_3H_5)Ni(C_5H_5)]$ [Eq. (13)].[23] Ten years later, two Russian groups reported the reactions of nickelocene and vanadocene with benzylmagnesium chloride or phenyllithium,[24,25] while in 1972 *Switzer* and *Rettig* described the successive exchange of C_5H_5 ligands on nickel, chromium and manganese by C_5D_5 groups [Eq. (14)].[26] Finally, in 1978 it was shown by *Seidel* and *Scholz* that a lithium vanadate(II) can be obtained from vanadocene **14** and mesityllithium [Eq. (15)].[27]

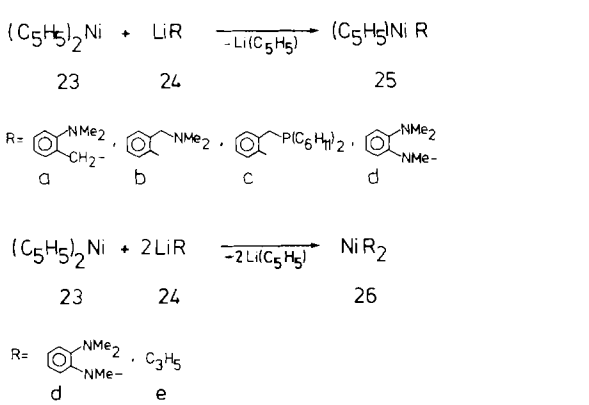
$$\underset{\mathbf{23}}{(C_5H_5)_2Ni} \xrightarrow[-C_4H_5MgCl]{C_4H_5MgCl} [(\eta^3\text{-}C_3H_5)Ni(C_5H_5)] \quad (13)$$



$$(C_5H_5)_2M \xrightarrow[-Li(C_5H_5)]{Li(C_5D_5)} [(C_5D_5)M(C_5H_5)] \xrightarrow[-Li(C_5H_5)]{Li(C_5D_5)} (C_5D_5)_2M \quad (14)$$
$M = Ni, Mn, Cr$

$$\underset{\mathbf{14}}{(C_5H_5)_2V} \xrightarrow[-Li(C_5H_5)]{2\,Li(C_9H_{11})} Li[(C_5H_5)V(C_9H_{11})_2] \quad (15)$$

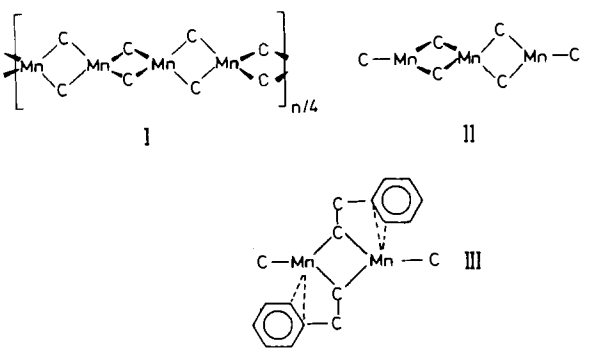
2.2.1. Half-Sandwich Complexes and other Mononuclear Complexes of Nickel(II) from Nickelocene



The are two major driving forces for the reactions of nickelocene with organometallic compounds of the main group metals which produce half-sandwich complexes. Firstly, the C_5H_5 ligand is the more strongly stabilized an-

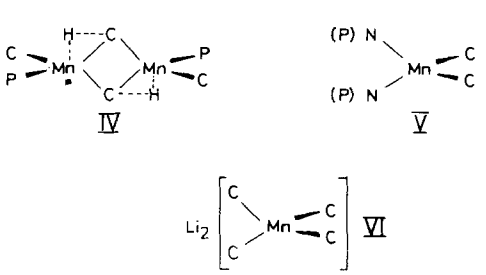
ion and so binds preferentially with the more electropositive main group metal.[28] Secondly, one of the reactants is a sandwich compound with an electron-rich 20e system, while on the product side a nickel(II) compound is formed which always obeys the inert gas rule [see Eq. (13)]. *Lehmkuhl* et al., have used both factors to advantage in a wide range of syntheses of nickel complexes.[29] They have also used this principle to prepare nickel complexes which are model compounds for intermediates in metal-catalyzed conversions of olefins. Scheme 7 depicts the insertion of ethylene into the Ni–C σ-bonds of two nickel complexes that were prepared from **23**, an organolithium compound, and ethylene.[30]

Scheme 7. Insertion of ethylene into Ni–C σ-bonds.



Recently, it was reported that the exchange of one of the Cp groups in nickelocene **23** can even be achieved by reaction with anhydrous lithium iodide. However, this reaction proceeds only when strong nucleophiles such as R_3P are added.[31] Finally, it should be mentioned that the reactions of nickelocene with the various organolithium compounds **24a–c** or the lithium amide **24d** lead to the formation of the new half-sandwich complexes **25a–d**.[6] Additionally, both C_5H_5 rings can be removed by treating **23** either with **24d** or with **24e** in the molar ratio 1:2 (Scheme 8).[6,30c]

Scheme 8. Exchange of one or both Cp moieties in nickelocene **23**.



2.2.2. *Organomanganese(II) Compounds from Manganese(II) Cyclopentadienide*

The first dialkylmanganese compounds whose structures were determined by X-ray crystallography are $[Mn(CH_2SiMe_3)_2]_n$ and $[Mn(CH_2CMe_2Ph)_2]_2$, prepared in 1976 by *Wilkinson* et al. from $MnCl_2$ and the corresponding Grignard reagent or dialkylmagnesium.[32] In the polymeric compound, the organic groups are found exclusively in bridging positions, so that manganese is four-coordinate and has a tetrahedral environment (**I** in Scheme 9), while in the binuclear complex two of the neophyl groups act as bridging ligands and two are bound terminally. Nevertheless, the metal atoms are apparently four-coordinate because each manganese atom interacts with the phenyl group from one of the bridging ligands as shown in **III** of Scheme 9. On the other hand, while the central manganese atom in the trinuclear mesitylmanganese(II) complex $[Mn(C_6H_2Me_3)_2]_3$ reported by *Floriani* et al., in 1983[33] is four-coordinate, there can be no doubt that the two outer manganese atoms are three-coordinate (see **II** in Scheme 9).

Scheme 9. The greatly simplified structures of some homoleptic alkyl(aryl)manganese(II) complexes. **I** to **III**, see text.

Homoleptic alkyl(aryl)manganese(II) complexes are electron-deficient compounds. They add tertiary amines[32] or phosphanes[34,35] and react with organolithium compounds to form ate-complexes.[32] For example, the $[Mn(CH_2SiMe_3)_2]_n$ polymer discussed above reacts with PMe_3 to form the centrosymmetric binuclear complex $[Mn(CH_2SiMe_3)_2PMe_3]_2$. The geometry at manganese is a distorted tetrahedron, with each manganese atom coordinated to a PMe_3 ligand, a terminal Me_3SiCH_2 group, and two bridging Me_3SiCH_2 groups. The bridges are bound unsymmetrically: in each bridging methylene group one of the hydrogen atoms exhibits bonding interaction with the nearer manganese atom (**IV** in Scheme 10). Polymeric $[Mn(CH_2SiMe_3)_2]_n$ reacts with TMEDA to produce the mononuclear complex $[(tmeda)Mn(CH_2SiMe_3)_2]$ (type **V** in Scheme 10),[32] and with $Me_2P(CH_2)_2PMe_2$ to yield

Scheme 10. Greatly simplified structures of a manganate(II) complex (**VI**) and of alkylmanganese(II) compounds (**IV**, **V**) with phosphanes or amines as co-ligands. **IV** to **VI**, see text.

$[\{Me_2P(CH_2)_2PMe_2\}Mn(CH_2SiMe_3)_2]$ (also type **V**),[35] while treatment with $LiCH_2SiMe_3$ gives the ate-complex $Li_2[Mn(CH_2SiMe_3)_4]$ (**VI** in Scheme 10).[32] In all three high-spin d^5-complexes, manganese is tetrahedrally coordinated.

Before the following syntheses had been carried out, no alkyl- or arylmanganese(II) complexes with C_5H_5 ligands were known. Furthermore, no manganese(II) complexes had been reported in which the manganese is bound to different σ-bonded organyl groups.

The C_5H_5 ligands in manganese(II) cyclopentadienide **12** can be replaced by phenyl groups in a two-stage reaction with phenyllithium. The tetramethylethylenediamine, which is used in these reactions [Eq. (16) and (17)] as a complexing diamine, has a double function in both steps.[18] After **12** has reacted with LiC_6H_5 (molar ratio 1:1) in THF and the solution then evaporated to dryness, addition of a TMEDA/diethyl ether mixture at room temperature causes the TMEDA-stabilized manganese complex **27** to be precipitated. The product is very pure because $Li(C_5H_5)$ is highly soluble in Et_2O/TMEDA. The solubility relationships are equally favorable when **28** is prepared from **27**. While **28** probably has a geometry of type **V** in Scheme 10, the structures of **27** and $(C_6H_{11})_3PMn(C_6H_5)_2$[36] are unknown.

$$(C_5H_5)_2Mn + LiC_6H_5 \xrightarrow[-Li(C_5H_5)]{\text{1. THF, 2. } Et_2O/TMEDA} [(C_5H_5)Mn(C_6H_5)(tmeda)] \quad (16)$$
12 **27**

$$\mathbf{27} + LiC_6H_5 \xrightarrow[-Li(C_5H_5)]{\text{1. THF, 2. } Et_2O/TMEDA} [(C_6H_5)_2Mn(tmeda)] \quad (17)$$
28

When **24b** or **24a** is used instead of phenyllithium on replacement of the C_5H_5 rings, then either the new binuclear complexes **29** and **30** [Eq. (18)] or the known complexes **31** and **32**[37] [Eq. (19)] are formed, depending upon the stoichiometries employed. Like **29** and **30**, **32** is binuclear but **31** is mononuclear (cryoscopic determination).

$$2(C_5H_5)_2Mn \xrightarrow[-2Li(C_5H_5)]{2\ \mathbf{24b},\ THF} [(C_5H_5)Mn(C_6H_4CH_2NMe_2)]_2$$
12 **29**

$$2(C_5H_5)_2Mn \xrightarrow[-2Li(C_5H_5)]{2\ \mathbf{24a},\ THF} [(C_5H_5)Mn(CH_2C_6H_4NMe_2)]_2 \quad (18)$$
12 **30**

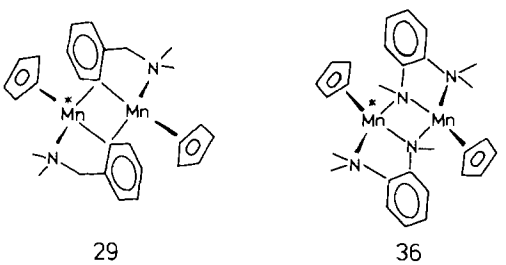
$$2(C_5H_5)_2Mn \xrightarrow[-4Li(C_5H_5)]{4\ \mathbf{24b},\ THF} 2[Mn(C_6H_4CH_2NMe_2)_2]$$
12 **31**

$$2(C_5H_5)_2Mn \xrightarrow[-4Li(C_5H_5)]{4\ \mathbf{24a},\ THF} [Mn(CH_2C_6H_4NMe_2)_2]_2 \quad (19)$$
12 **32**

It should be emphasized that the new complexes **29** and **30** can also be prepared by redistribution reactions (scrambling) on heating $(C_5H_5)_2Mn$ with **31** or **32** in toluene until a clear solution is formed. When the solution is cooled, highly pure **29** or **30** crystallizes out [e.g., Eq. (20)].

$$(C_5H_5)_2Mn + Mn(C_6H_4CH_2NMe_2)_2 \xrightarrow[\text{toluene}]{100\,^\circ C}$$
12 **31**

$$[(C_5H_5)Mn(C_6H_4CH_2NMe_2)]_2 \quad (20)$$
29



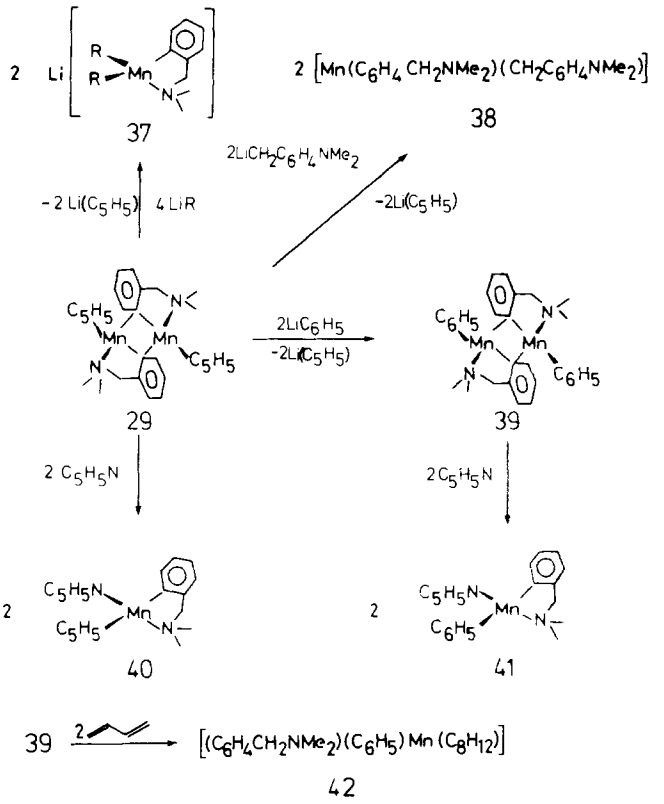
The new complexes **35**, which according to cryoscopic measurements in benzene are mononuclear, and the binuclear complex **36** can be prepared by the same method [Eqs. (21) and (22)]. The starting materials **33** and **34** were prepared in analogy to Equation (19) from **12** and $LiC_6H_4CH_2PR_2$ [$R = C_6H_{11}$ (**24c**), C_6H_5] or from **12** and **24d** (molar ratio 1:2), respectively.[18]

$$(C_5H_5)_2Mn + Mn(C_6H_4CH_2PR_2)_2 \xrightarrow[\text{toluene}]{40-70\,^\circ C}$$
12 **33**

$$2[(C_5H_5)Mn(C_6H_4CH_2PR_2)] \quad (21)$$
35

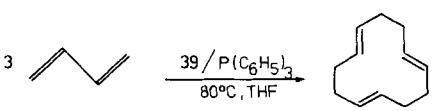
$$(C_5H_5)_2Mn + Mn(NMeC_6H_4NMe_2)_2 \xrightarrow[\text{toluene}]{60\,^\circ C}$$
12 **34**

$$[(C_5H_5)Mn(NMeC_6H_4NMe_2)]_2 \quad (22)$$
36



29 36

Scheme 11. The structures of crystalline **29** and **36** according to X-ray crystallography [22].

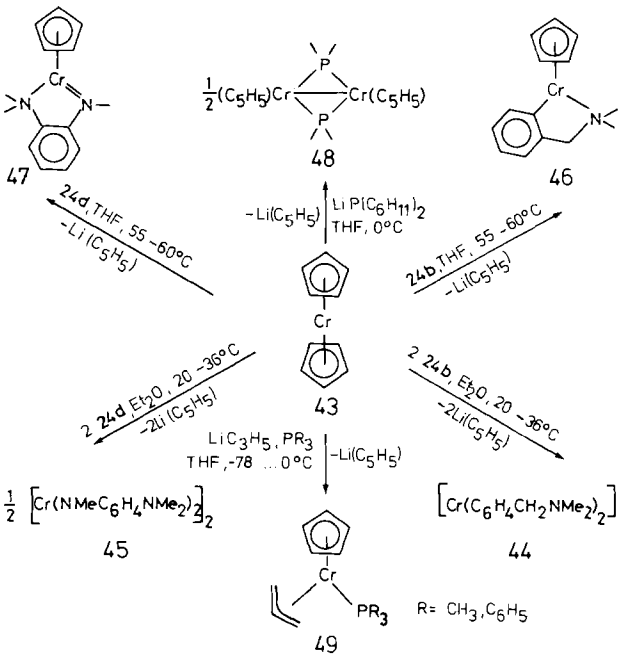


The manganese atoms have a pseudo-tetrahedral geometry in both the centrosymmetric binuclear complexes **29** and **36** (Scheme 11). The four coordination sites on manganese in **29** are taken up by a C_5H_5 ring, two bridging carbon atoms in unsymmetrical bridges, and a nitrogen atom; in **36**, each manganese atom is surrounded by a C_5H_5 ligand, two four-coordinate bridging nitrogen atoms in unsymmetrical bridges, and a terminal N-atom. The Mn–Mn distances in **29** and **36** lie between 2.428(6) and 2.632(7) Å and between 2.440(3) and 2.579(3) Å, respectively. They are thus considerably longer than the manganese-carbon distances for the centrally bound C_5H_5 ring in the dark brown modification of $Mn(C_5H_5)_2$ **12** (2.40–2.43 Å).[38]

Compound **29** reacts with LiR (R = CH_3, C_6H_5) (molar ratio 1:4) to afford the ate-complexes **37** and with $LiCH_2C_6H_4NMe_2$ **24a** or LiC_6H_5 (molar ratio 1:2) to yield **38** or the binuclear complex **39**, respectively.[18] Both the binuclear complexes **29** and **39** can be converted into mononuclear complexes (i.e. **40** and **41**, respectively) by treatment with pyridine. Much more interesting, however, is the reaction of the binuclear complex **39** with butadiene

Scheme 12. Some reactions of **29** and **39**.

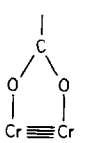
at 0°C, which produces **42** (Scheme 12). This red compound is, like **39** itself, an excellent catalyst for the cyclotrimerization of butadiene (Scheme 13).



Scheme 13. The highly selective manganese-catalyzed cyclotrimerization of butadiene to *ttt*-cyclododecatriene.

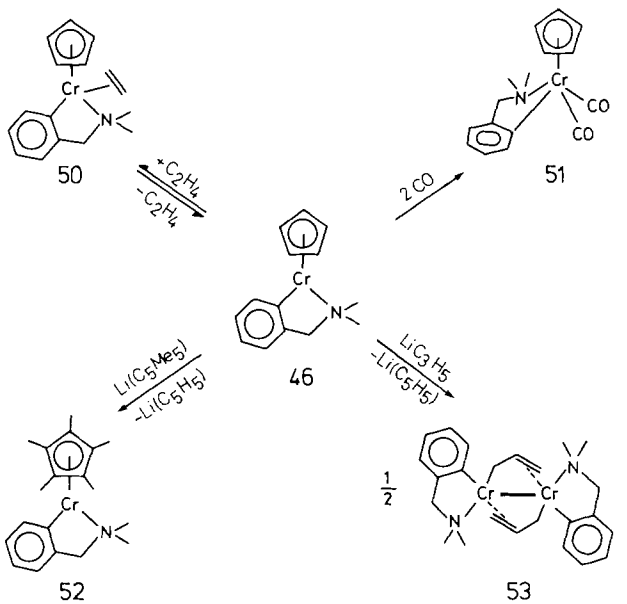
A turnover number of ca. 5000 C_4H_6/Mn was achieved in 2.5 h at 80°C in the presence of **39** and $(C_6H_5)_3P$ in the molar ratio 1:1. The product was a mixture containing over 95% *ttt*-cyclododecatriene (yield 85%). Manganese catalysts based on $Mn(acac)_3/AlR_3$[39] or Mn/Et_2AlCl[40] are much less active and much less selective.

2.2.3. *Half-Sandwich Complexes and other Chromium(II) Complexes from Chromocene*



Cyclopentadienyl exchange reactions which proceed with retention of the oxidation state of the transition metal can also be carried out using chromocene **43**. Once again, particular organo-alkali metal compounds have proved to be suitable reagents,[41,42] but lithium amides or phosphides can also be used.[41] However, if the most effective use of the degradation in synthesis is to be achieved, the reaction conditions must be observed exactly in order to avoid the formation of a mixture of products. Whether only one C_5H_5-ligand or both ligands are exchanged or indeed whether both processes take place side by side is dependent not only upon the reactants involved and their stoichiometric ratio to chromocene, but also to a great extent upon the solvent and temperature (Scheme 14).

Scheme 14. Half-sandwich and other new chromium(II) complexes prepared from chromocene **43** [41]. According to X-ray crystallographic studies [22], the chromium atoms in both **46** and **47** are pseudo-trigonal planar.

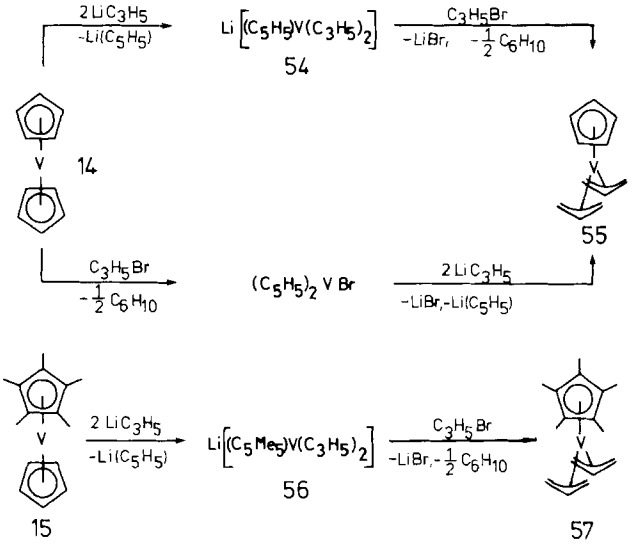


While both cyclopentadienyl groups are replaced by $Me_2NCH_2C_6H_4$ or $Me_2NC_6H_4NMe$ groups in ether at room temperature with the formation of only **44**[37] or **45**, respectively, the synthesis of the new half-sandwich complexes **46** and **47** requires more drastic reaction conditions (see Scheme 14) (yields 70—80%). Only a small quantity of **46** is formed in THF at temperatures below 0°C. Surprisingly, the major product under these conditions is the chromium(III) complex $Cr(C_6H_4CH_2NMe_2)_3$. This compound was first prepared by *Manzer*[43] from $CrCl_3$ and **24b** and it is also one of the products formed in the reaction of dichromium tetraacetate with **24b**.[44]

Quite remarkably, both the d^4 chromium complexes **46** and **47** are mononuclear. They are thus quite distinct from the numerous dimeric chromium(II) complexes, some of which have extremely short Cr—Cr distances.[45] *Cotton* has suggested that all these compounds have Cr—Cr quadruple bonds. The vast majority of these complexes have ligands (e.g., HCO_2, RCO_2, MeC_6H_3OMe) which bridge the chromium atoms to form dimetalla-five-membered rings (Scheme 15).

Scheme 15. Example of a three-membered bridging ligand in a binuclear chromium(II) complex.

The ligands forming the bridges in these systems nearly[*] always consist of three atoms, whereas bridges formed by the chelating groups *o*-$Me_2NCH_2C_6H_4$ and *o*-$Me_2NC_6H_4NMe$ are made up of four atoms. This difference is certainly important but it does not suffice to explain why **46** and **47** are mononuclear. Indeed, both the d^5 manganese complexes **29** and **36** (Scheme 11), which have the same set of ligands as the d^4 chromium complexes **46** and **47**, and some of the copper complexes characterized by *Noltes* and *van Koten*[47] show that the groups $Me_2NCH_2C_6H_4$ and $Me_2NC_6H_4NMe$ are perfectly capable of acting as bridging ligands. Furthermore, two binuclear complexes are known, $[V_2\{C_6H_3(OMe)_2\}_4(thf)_2]$[48] and $[Cr_2(CH_2SiMe_3)_4(PMe_3)_2]$,[49] which have metal-metal multiple bonds and have been shown by X-ray crystallography to contain in addition three-center bonds joining the metal atoms in M–C–M units.



Scheme 16. Some reactions of **46**.

The new 14e complex **46** reacts with ethylene to afford the deep-green ethylene complex **50**, in which the olefin is only weakly bound. The diamagnetic 18e complex **51** is considerably more stable. NMR and IR spectra indicate that this complex contains a chiral chromium atom. The cyclopentadienyl ligand is exchanged when **46** is treated with $Li(C_5Me_5)$ or allyllithium. Like **46**, **52** is mononuclear, but **53** is a diamagnetic binuclear complex[41] (Scheme 16). The latter compound, the structure of which has clear similarities to that of tetraallyldichromium $[(\eta^3\text{-}C_3H_5)Cr(\mu\text{-}C_3H_5)]_2$,[50] is characterized by a very short Cr–Cr distance (1.973(1) Å) and unsymmetrical allyl bridges—the C-C bond lengths within these allyl groups are different and the distances between the terminal carbon atoms and the chromium atoms are unequal.[22]

[*] Dimetalla-six-membered rings together with dimetalla-five-membered rings are observed in $[M_2(O_2CCH_3)_2(o\text{-}NMe_2C_6H_4CH_2)_2]$, M = Cr, Mo [46].

2.2.4. *Allylvanadium Complexes from Vanadocene and Pentamethylvanadocene*

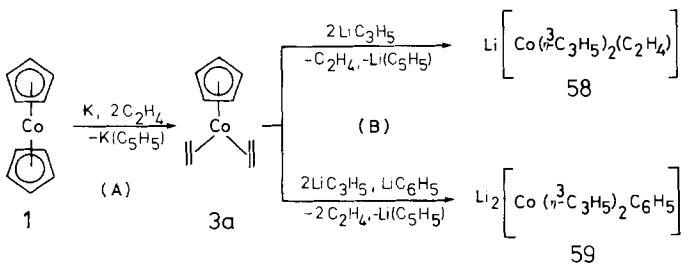
When we attempted the preparation of **54** and **55** in 1980, derivatives of these compounds were already known, i.e. the compounds **19** and **20** that were discussed in Section 2.1.3. Scheme 17 shows how simple it is to synthesize the parent compounds **54** and **55** starting with vanadocene **14**.[19]

Scheme 17. "One-pot" syntheses of allylvanadium(III) complexes.

Allyllithium **24e**, which is best prepared in pure form on a large scale by the treatment of C_3H_5MgCl with lithium metal,[51] reacts with vanadocene with C_5H_5/C_3H_5 exchange and addition at vanadium to form the ate-complex **54**. Treatment with allyl bromide leads to delithiation of the ate-complex and formation of the bis(allyl)cyclopentadienylvanadium **55**. Alternatively, if it is preferred to oxidize the vanadium in the first step by reacting **14** with allyl bromide, then $(C_5H_5)_2VBr$[52] is obtained as intermediate. Exchange of the bromine and one of the cyclopentadienyl rings by allyl groups leads, as before, to the formation of **55**. Both these degradation reactions and the third sequence of reactions given in Scheme 17, by which bis(allyl)pentamethylcyclopentadienylvanadium **57** was first prepared,[53] can be carried out as "one-pot" syntheses.

In 1984, *Teuben* et al.[54] reported the preparation of **55** by classical halide-organyl exchange [Eqs. (23) and (24)].

$$[VX_3(thf)_3] \xrightarrow[-3THF]{2PR_3} VX_3(PR_3)_2 \xrightarrow[-MX]{M(C_5H_5)} [(C_5H_5)VX_2(PR_3)_2] \quad (23)$$

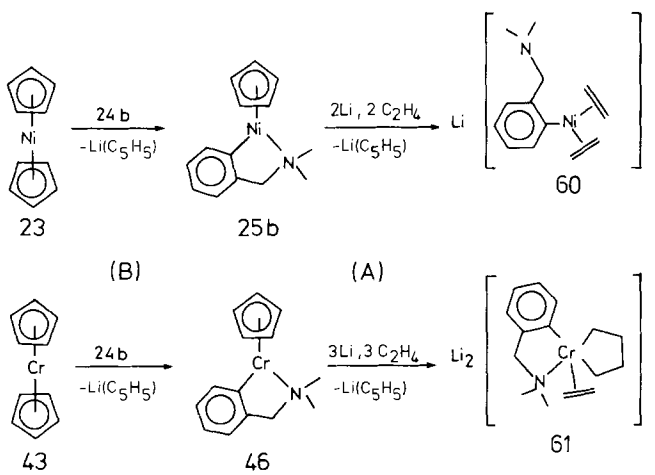


$$[(C_5H_5)VX_2(PR_3)_2] \xrightarrow[-2MgX_2,\ -2PR_3]{2C_3H_5MgX} \underset{\mathbf{55}}{[(C_5H_5)V(C_3H_5)_2]} \quad (24)$$

R = CH_3, C_5H_5

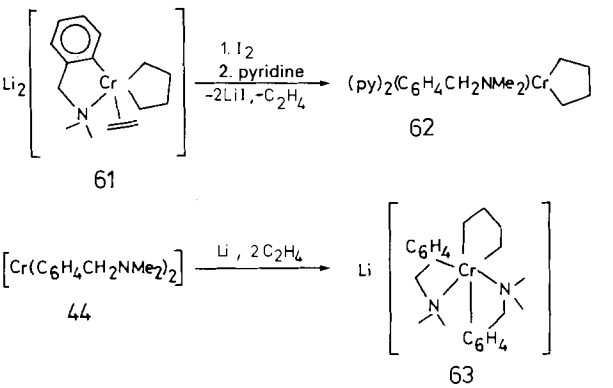
By comparison, this method has the disadvantage that intermediates of the type $[(C_5H_5)VX_2(PR_3)_2]$ must first be synthesized. These are stabilized by trialkylphosphane ligands, which are then liberated later in the synthesis. Furthermore, this procedure proved unsuitable for preparing **57**.

2.3. Metallocene Degradation by Combination of Metathetical Reactions and Reactions with Alkali Metals and Olefins



The removal of a C_5H_5 ring by method A can be combined with a metathetical reaction (type B) in the order A, B or B, A. Examples of type C reaction sequences A, B are the syntheses of the new lithium cobaltates(I) **58** and **59** (Scheme 18).[55]

Scheme 18. Syntheses of lithium cobaltates(I) from cobaltocene **1**, with cyclopentadienylbis(ethylene)cobalt **3a** as the intermediate.



In the first step (type A reaction) the removal of the C_5H_5 ligand is accompanied by reduction of the metal from cobalt(II) (d^7) in the 19e complex **1** to cobalt(I) (d^8) in **3a**. However, in the subsequent reaction step (type B) the exchange of the cyclopentadienyl ligand, the displacement of the ethylene, and the formation of the ate-complex all proceed with retention of the formal oxidation number in both cases. The anions of the ate-complexes **58** and **59** are isoelectronic with tris(allyl)cobalt.[56]

Two degradation reactions with the order B, A having $(C_5H_5)_2Ni$ **23** and $(C_5H_5)_2Cr$ **43** as starting materials are compared in Scheme 19. In these reaction sequences, not only are the educts isostructural and have identical ligand sets—the same holds true of the intermediates as well. Nevertheless, they react with identical reactants (i.e., lithium and ethylene) to give different types of product (**60** and **61**).

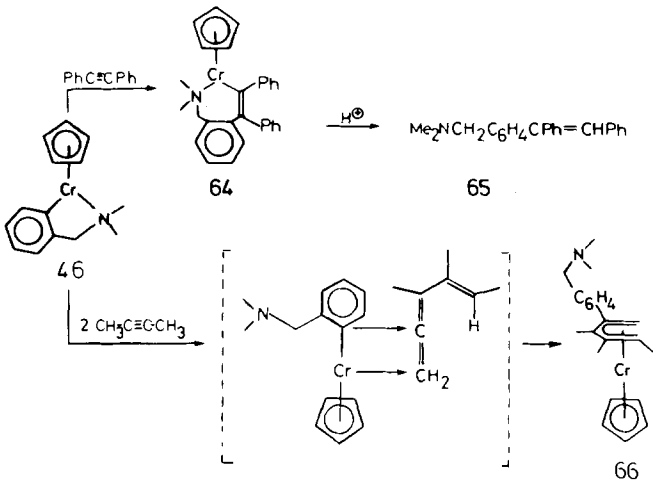
Scheme 19. Synthesis of **60** and **61**.

The ethylene nickel complex **60**[6] is salt-like; such complexes have been described in detail elsewhere.[1] On the other hand, both the chromium complex **61**, which has been characterized by X-ray crystallography,[22] and its mode of formation are new.[41] Two ethylene molecules have coupled with the chromium atom to form a chromacyclopentane ring; the third molecule of ethylene taken up by the chromium is π-bonded. A striking feature of the structure is the close bonding contact of the lithium atoms with the metallacycle and the π-bonded ethylene.

Scheme 20. Synthesis of **62** and **63**.

It is possible to delithiate **61** with iodine; the lithium-free metallacyclic complex can be stabilized with pyridine **62** (Scheme 20). Finally, a third example of a chromium complex in which a metallacyclic $Cr(CH_2)_4$ unit has been formed by the coupling[*] of ethylene molecules with chromium is the new chromium(III) complex **63**.[41,22]

The reactions in Schemes 19 and 20 and the first results with organomanganese compounds described in Section 2.1.2 show that those systems where metallacyclopentane rings are formed by the coupling of simple olefins (ethylene) can be anticipated to involve transition metals predominantly to the left of Group VIII in the periodic table. Equally relevant to this classification are the preparations of the metallacyclic complexes of Ta,[58,59] Zr,[21c,60] and Hf[21e] which were reported somewhat earlier by *Schrock, Bercaw,* and *Erker.*

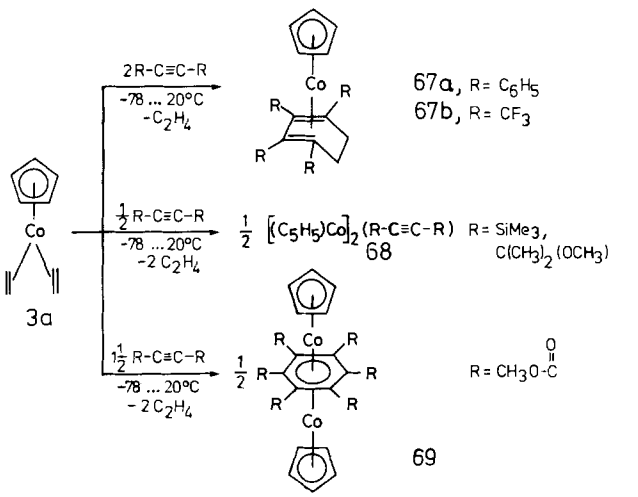


3. Syntheses Using Reactive Organometallic Compounds Prepared from Metallocenes

3.1. Reactions of Sandwich and Half-Sandwich Complexes with Alkynes under Mild Conditions

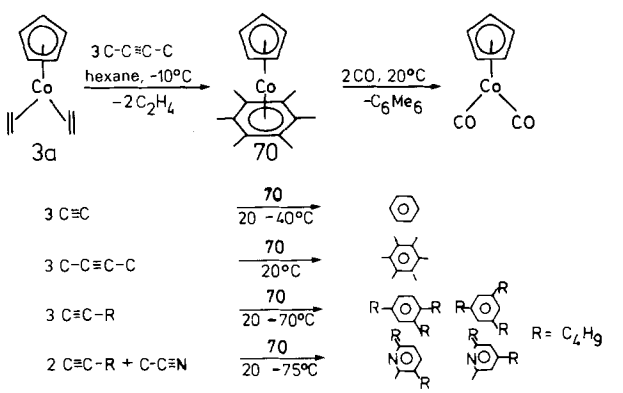
The reactions of metal complexes with alkynes or nitriles continue to be studied intensively. Complementary aspects of this field of research are stoichiometric synthesis, which has produced an extraordinarily wide range of different types of organometallic complexes,[61] and catalysis with metal complexes, by which organic compounds are obtained directly.[62-64] When the metal-containing component is a carbonyl or phosphane complex, it is frequently necessary to employ higher temperatures or photolysis to initiate the reaction. This can be a shortcoming

[*] Two other chromacyclopentane complexes that have been known for some time were prepared from chromium halides and 1,4-dilithiobutane [57].



when the organic substrates are sensitive. Some thermal reactions of alkynes with carbonyl-free metal complexes which proceed at room temperature or lower are collected in Schemes 21, 22, and 23.

Scheme 21. Reactions of **46** with alkynes.



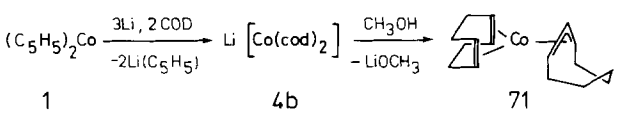
The mononuclear complex **46** obtained from chromocene **43** and **24b** reacts with diphenylacetylene to afford a chromium half-sandwich complex which probably has the structure **64**. In any case, the product of the protolysis of **64** is the styrene derivative **65**. **46** reacts with 2-butyne in excess to form the chromium(II) complex **66**. According to X-ray crystallography,[22] this compound has a sandwich-like arrangement of the cyclopentadienyl ring, chromium atom, and a pentadienyl ligand which lies practically parallel to the C_5H_5-ring in a manner reminiscent of chromocene. The nitrogen atom is no longer bonded to the chromium. The formation of **66** can be interpreted as a chromium-induced coupling of two butyne molecules to give the allene derivative 3,4-dimethyl-1,2,4-hexatriene (cf. the ene-reaction[65]), which inserts via the allene unit into the Cr–C σ-bond.[41]

Cyclopentadienylbis(ethylene)cobalt **3a**, which has also been finding increasing application in other groups as a starting material for synthesizing organocobalt compounds,[66–69] reacts with alkynes to form cobalt complexes whose modes of formation and structures can be very different from one another.

Scheme 22. Reaction of **3a** with alkynes.

For example, alkynes such as diphenylacetylene or hexafluorbutyne react with **3a** even below room temperature to produce the cobalt-complexed cyclohexadiene derivatives **67a**, **b**.[6] This should be contrasted with the synthesis of **67a** from the metallacyclic cobalt-phosphane complex $[(C_5H_5)CoC_4Ph_4(PPh_3)]$, when an ethylene pressure of 45 bar and a temperature of 150 °C are necessary.[71] From the reaction of **3a** with bis(trimethylsilyl)acetylene or with 2,5-dimethoxy-2,5-dimethyl-3-hexyne we obtained binuclear cobalt complexes **68** with alkyne bridges while **3a** and dimethyl acetylenedicarboxylate afford the cobalt complex **69**, the spectroscopic data of which are consistent with a triple-decker sandwich structure (34e complex).[6] A most interesting finding, especially in connection with the mechanism of the cobalt-catalyzed cyclization of alkynes, is the observation that **3a** reacts with 2-butyne at −10 °C to afford the arene complex **70** (Scheme 23).[5] In **70**, as in the isoelectronic cation of $[(C_6Me_6)_2Co]PF_6$,[71] the cobalt atom has two electrons more than required for a krypton electron configuration.

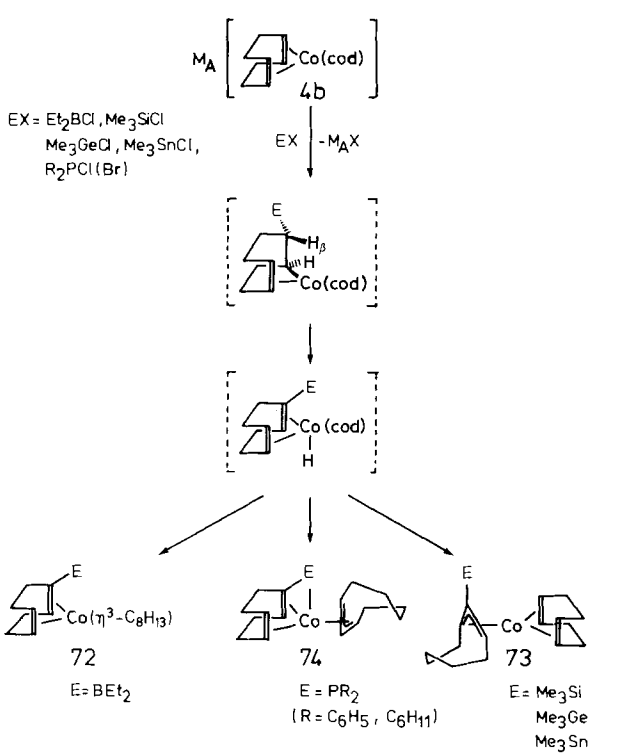
Scheme 23. Synthesis of the 20e sandwich complex **70** and the cobalt-catalyzed cyclization of alkynes and cocyclization of 1-hexyne and acetonitrile.



The fact that **70** is a 20e sandwich complex accounts for the ease with which the arene can be displaced by, for example, CO. It also explains why this paramagnetic cobalt complex, which can be recrystallized from boiling hexane, is (together with **3a**) the most reactive known complex containing the $(C_5H_5)Co$ unit capable of the cobalt-catalyzed cyclization of alkynes and cocyclization of alkynes and nitriles. When a mixture of 1-hexyne and THF or 1-hexyne and acetonitrile is treated with a catalytic amount of **70** at room temperature, no heating is required. Within a short time the mixtures reach boiling by themselves: the products are benzene and pyridine derivatives, respectively (for more details of the cobalt-catalyzed pyridine synthesis, see [72]).

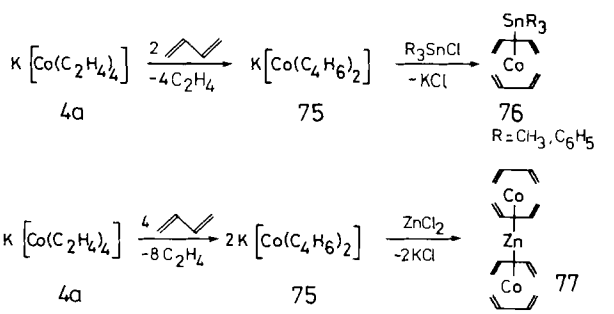
3.2. Syntheses with Alkali Metal-Olefin Cobaltates(−I)

Another group of versatile reagents are the alkali metal cobaltates **4**, which are prepared from cobaltocene, alkali metal and olefin according to reaction Scheme 1 and



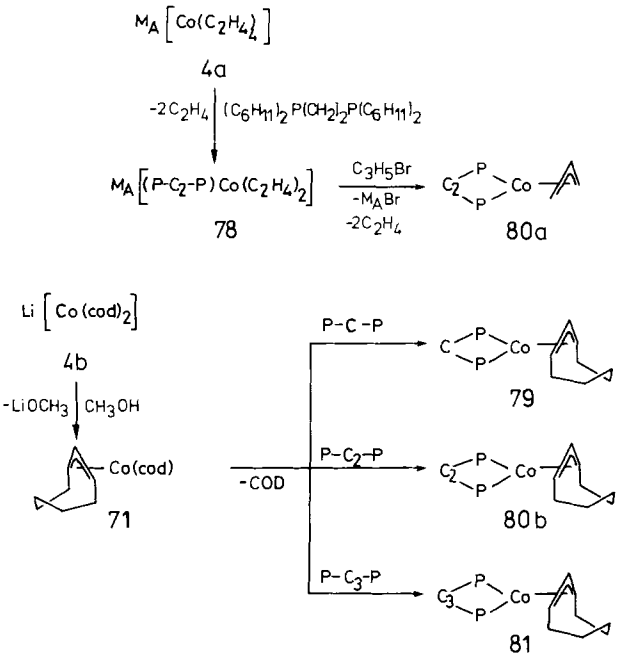
Equation (2). The anions in these reagents have a high nucleophilicity and, in contrast to the anions of $M_A[Co(CO)_4]$[73] and $M_A[Co\{P(OR)_3\}_4]$,[74] contain olefin ligands which are easily displaced from the cobalt atoms.

The reaction of **4b** with protonic acids such as methanol can be used to prepare highly pure **71**. This compound has also been prepared by the reduction of cobalt(II) chloride with sodium metal in THF/pyridine/COD[75] or from cobalt acetylacetonate and COD either electrochemically[76] or by reduction with R_2AlH[77] or $(C_2H_5)_3Al$[63]. When comparing this new synthetic route with those previously used, it must be remembered that a prerequisite for the synthesis of **71** according to Scheme 24 is the preparation of $Li[Co(cod)_2]$ **4b**, for which, in turn, cobaltocene is required. However, the preparation of cobaltocene, like that of other metallocenes, is not particularly difficult and the yield of highly pure **71** for both steps together is over 90%. Furthermore, it is not necessary to isolate **4b** for the subsequent reaction with methanol.



Scheme 24. Two stage synthesis of highly pure (η^4-1,5-cyclooctadiene)(η^3-cyclooctenyl)cobalt **71** starting with cobaltocene **1**.

Other electrophiles such as Et_2BCl, Me_3SiCl, Me_3GeCl, or Me_3SnCl react with **4b** to form the new cobalt complexes **72** and **73**. In these 16e complexes, the residue containing the main group element is bonded to one of the eight-membered ring ligands. In both the 18e complexes **74**, which are formed in the reaction of R_2PX compounds with **4b**, the R_2P groups are also bonded to cobalt[6]. All these reactions are probably initiated by *exo*-attack[78] of the organohalide compound of the main group element upon the complexed cyclooctadiene (Scheme 25), since only then can a β-H elimination take place to give a complexed double bond which bears the appropriate substituent. Whether the complex formed has the structure **72**, **73** or **74** is then only a question of the eight-membered ring to which the hydrogen atom of the cobalt hydride is transferred. In all cases, isomerization of the 1,4-enyl ligands leads to the formation of η^3-allyl units.



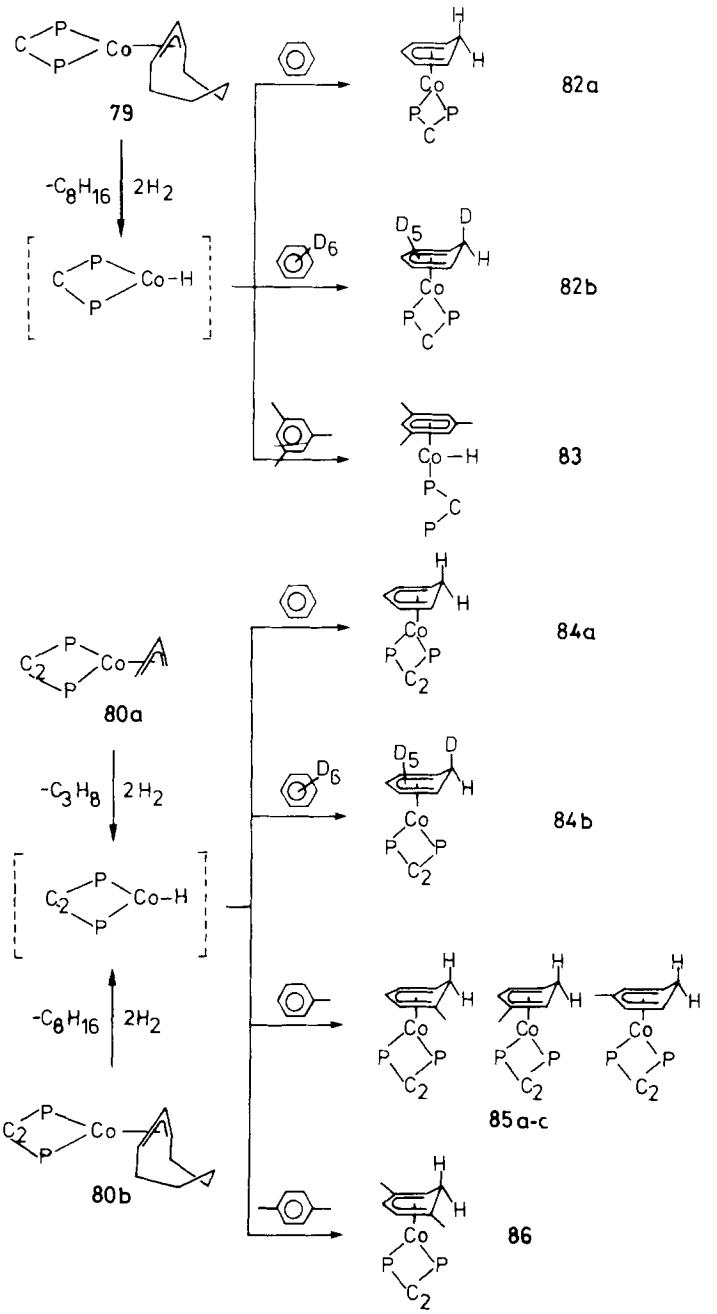
Scheme 25. *Exo*-attack of organohalides of the main group elements upon complexed cyclooctadiene. The products **72**—**74** have been examined in detail by ^{13}C-NMR spectroscopy [79]; **74** ($R=C_6H_5$) has also been studied by X-ray crystallography [22].

At the same time, the reactions of R_3SnCl or $ZnCl_2$ with alkali metal-olefin cobaltates containing complexed butadiene instead of cyclooctadiene show that electrophiles can attack the central cobalt atom directly (Scheme 26).[1,80] In the ^{13}C-NMR spectrum of the binuclear complex **76** (R = Me), spin-spin coupling between the terminal carbon nuclei of the η^4-butadiene ligands and ^{119}Sn is observed [$J(^{119}Sn\text{-}^{13}C) = 33$ Hz], indicating that an Sn—Co bond has been formed. Another highly symmetrical compound is the trinuclear complex **77**, in which four equivalent butadiene ligands are coordinated to the two cobalt atoms.[81] The corresponding trinuclear carbonyl complex $[Zn\{Co(CO)_4\}_2]$ was first reported as long ago as 1942.[82]

Scheme 26. Alkali metal-olefin cobaltates as cobalt nucleophiles.

Trityl chloride undergoes oxidative addition with $K[Co(cod)_2]$ at the cobalt(−1) ($d^{10} \rightarrow d^8$) to yield cyclooctadiene(trityl)cobalt.[6] The reactions of phosphane-stabilized olefin cobaltates with benzyl bromide or allyl halides are of the same type.[83] Suitable phosphorus ligands are bisphosphanes with bulky cyclohexyl groups on phosphorus.[1,2,83] Using this approach, which has previously proved useful for nickel,[84] it was possible to obtain (bisphosphane)cobalt(I) complexes which are coordinatively unsaturated. Scheme 27 shows how **80a**, which is dark blue, was synthesized.[2,83] Further examples of compounds of this type are the dark green complex **79**[85] and the dark blue complexes **80b**[2,83] and **81**.[85] It should be noted that the reaction of **71** with $CH_2[P(C_6H_{11})_2]_2$ to form the 16-electron complex **79**, containing a four-membered ring of cobalt, carbon, and two phosphorus atoms, proceeds much more slowly than the corresponding reactions with $(CH_2)_n[P(C_6H_{11})_2]_2$ (n = 2, 3) leading to **80b** and **81**.

Scheme 27. Synthesis of coordinatively unsaturated allylcobalt(I) complexes with bisphosphane ligands having bulky cyclohexyl groups on phosphorus.



3.3. New Developments in the Organometallic Chemistry of Arenes

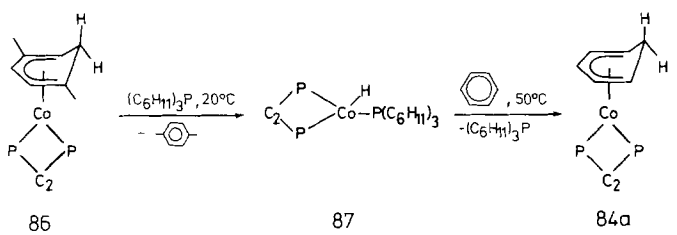
3.3.1. Hydrocobaltation and the Cobalt-Catalyzed Hydrogenation of Aromatic Hydrocarbons

A number of transition metal complexes are known which can act as homogeneous catalysts for the hydrogenation of aromatic hydrocarbons.[2,86-89] The cobalt-catalyzed arene hydrogenation with 18e catalyst precursors of the type $[(\eta^3\text{-}C_3H_5)Co\{P(OR)_3\}_3]$ has received most attention.[86] For several years it was assumed that the cobalt-bound allyl ligand in the precursor is retained in these systems under hydrogenation conditions and that this ligand stabilizes the catalytically active species so that it can retain its activity. However, in 1981 *Muetterties* et al.[90] reported that the allyl ligand is removed *before* the arene hydrogenation begins.

The new 16e cobalt complex **81** (Scheme 27) can also be used as a catalyst precursor for the homogeneous catalytic hydrogenation of arenes. However, **81** and compounds **79** and **80**[2] have a much greater significance as key compounds in a system that gives a detailed insight into the reaction course of metal-catalyzed arene hydrogenation.

When **79** or **80** is treated with H_2 (1 bar) in THF or hexane, the organic ligands are liberated even at -30 to 20°C as propane or cyclooctane, respectively. In addition, hydridocobalt complexes are formed, e.g. $[(C_6H_{11})_2P(CH_2)_2P(C_6H_{11})_2CoH_2]_3$,[2] which according to their cryoscopically determined molecular weights are polynuclear. How these products differ from the cobalt complexes obtained when solutions of **79** or **80** dissolved in aromatic hydrocarbon solvents are treated with H_2 at room temperature! Mononuclear cobalt complexes with η^5-cyclohexadienyl ligands (**82**, **84**—**86**) can be isolated in high yields. In mesitylene the novel hydridocobalt complex **83**

Scheme 28. Hydrocobaltation of benzene and alkylbenzenes with bisphosphanehydridocobalt species.

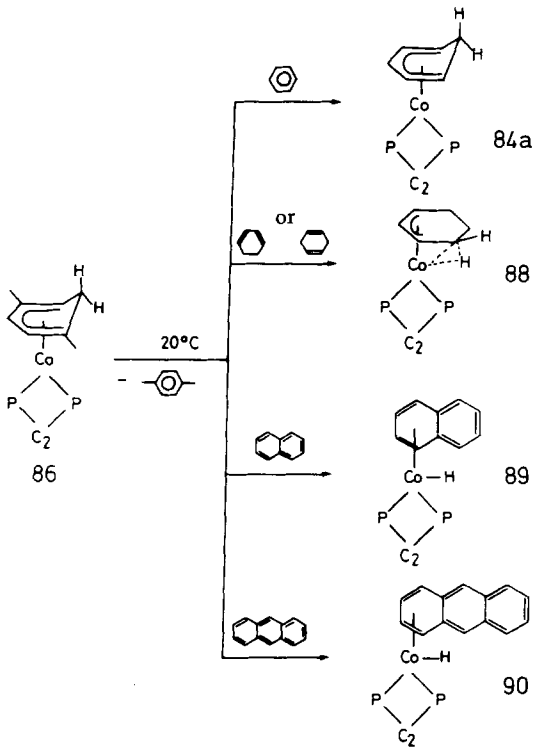


$[\nu(Co-H)$: 1890 $cm^{-1}]$ is produced. This compound has a η^6-coordinated arene ligand and is formed with the breaking of a Co—P bond and opening of the CoP_2C ring. According to IR spectroscopy, the hydrocobaltation of benzene and perdeuteriobenzene to form the cyclohexadienylcobalt complexes **82** and **84** proceeds via *cis*-addition of the bisphosphanehydridocobalt moiety to the aromatic ring, i.e. the hydrogen atom introduced by the cobalt goes into the *endo*-position. The compounds **82a** and **84a** show IR bands at 2760 and 2735 cm^{-1}, respectively, which in position and intensity are characteristic of metal complexes with η^5-cyclohexadienyl ligands $[\nu(C-H_{exo})$[91]]; these bands are missing in the IR spectra of **82b** and **84b**, which have absorbances at 2015 cm^{-1} and 2010 cm^{-1}, re-

spectively [ν(C–D_{exo})]. The hydrocobaltation of toluene leads to a mixture of the three positional isomers **85a–c**. The formation of the possible fourth isomer with the methyl group on the sp^3-carbon is not observed. Consistent with this, the hydrocobaltation of *p*-xylene results in just the one product, i.e. **86**.

The hydrocobaltation reactions summarized in Scheme 28 open up a new route to transition metal complexes with η^5-cyclohexadienyl ligands. They should be distinguished from the well established procedures for converting arene-metal cations into cyclohexadienyl complexes by reaction with hydrides of the main group metals.[92] In such reactions the arene has become activated towards nucleophilic attack by virtue of its coordination and the hydrogen from the hydride enters an *exo*-position on the ring.

The cyclohexadienylcobalt complexes **82** and **84–86** formed from bisphosphanehydridocobalt moieties and aromatic hydrocarbons are chemically rather labile compounds. This is particularly true of the product of hydrocobaltation of *p*-xylene **86**. The "retro"-hydrocobaltation occurs very easily, liberating the arene. While the arene regains its full aromaticity, the bisphosphanehydridocobalt fragment stabilizes itself by hydrocobaltation of another molecule or in some other way.



Using hydrocobaltated *p*-xylene **86** and tricyclohexylphosphane we obtained the dark blue 16e hydridocobalt complex **87** [ν(Co–H): 1763 cm^{-1}], which on reaction with benzene gave **84a** (Scheme 29).

Scheme 29. Hydrocobaltation of benzene by the stable hydridocobalt compound **87**.

This last reaction is a textbook example of an arene hydrometalation—both the product (**84a**) of the arene hydrometalation and the reacting metal hydride (**87**) on the educt side are stable enough to be isolated.

Compound **86** is labile and reacts with benzene at room temperature to form **84a**. With 1,3- or 1,4-cyclohexadiene, **86** produces the cyclohexenylcobalt complex **88**, which, in contrast to the corresponding cyclooctenyl compounds **79** (dark green), **80b**, and **81** (dark blue), is yellow. This suggests that the bonding relationship between cobalt and the eight-membered ring ligands differs from that between cobalt and the six-membered ring ligand. This was verified by NMR studies[79] and X-ray analysis[22] (see Fig. 2), which show that **88** is a fluxional molecule with an agostic[93] hydrogen atom. Finally, a further variant is found in compounds with a cobalt-bound terminal hydrogen atom as present in the hydridocobalt complexes **89** [ν(Co–H): 1910 cm^{-1}] and **90** [ν(Co–H): 1920 cm^{-1}], in which the arene is bound to the cobalt in a diene-like fashion (η^4) as in (C_5H_5)Co(anthracene)[5] (Scheme 30).

Scheme 30. Hydrocobaltated *p*-xylene **86** as a source of coordinatively unsaturated bisphosphanemonohydridocobalt fragments.

The structure of the (η^5-C_6H_7)Co unit in the 18e complex **84a** (Fig. 1) corresponds closely with those of other cyclohexadienyl transition metal complexes.[94] The carbon atoms C1, C2, C3, C5 and C6 are coplanar and bonded to cobalt. The angle between the plane of these carbon atoms and the plane C3, C4, C5 is 41°. The cyclohexenyl compound **88** (Fig. 2), which has two hydrogen atoms more than **84a**, must also be classified as an 18e complex, since in this and structurally related complexes (e.g. of Mn[95] and Fe[96]) a metal-H–C three-center bond is observed. Four coordination sites on the five-coordinate cobalt are occupied by the bisphosphane and the allyl group of the six-membered ring ligand, the fifth site is taken up by a

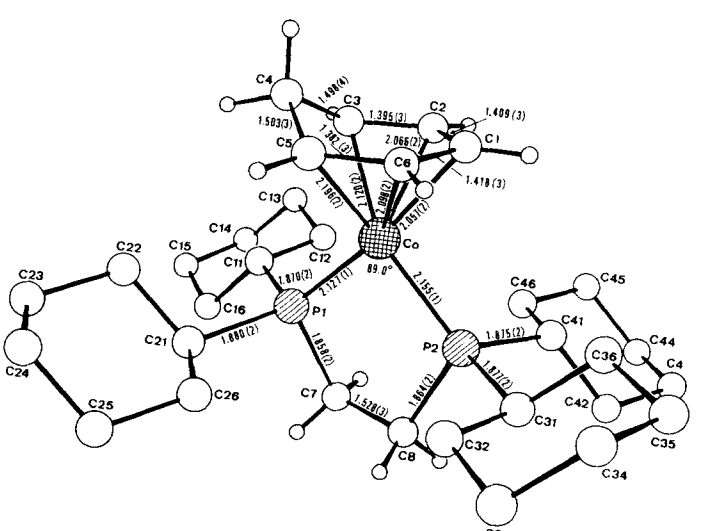


Fig. 1. Crystal structure of cyclohexadienyl[*P*,*P*'-ethylenebis(dicyclohexylphosphane)]cobalt **84a** formed by hydrocobaltation of benzene.

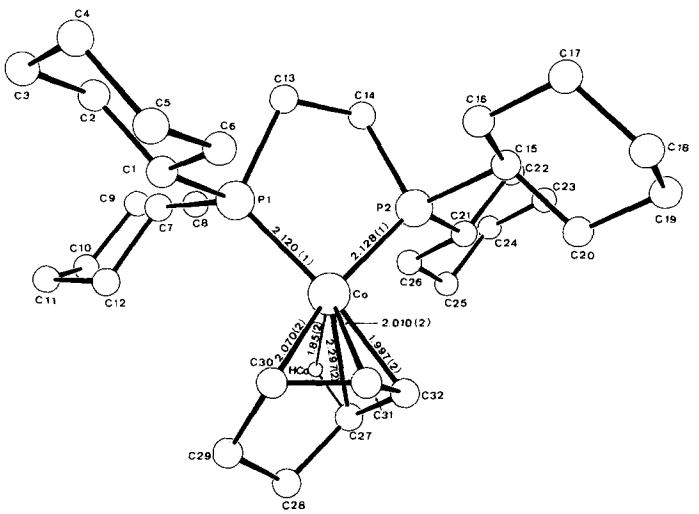
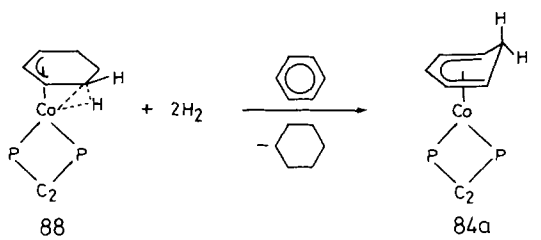
C–H_{endo} bond adjacent to the allyl unit. Characteristic of the $(C_6H_9)Co$ unit is a relatively large bond distance between Co and C27 (2.297(2) Å).





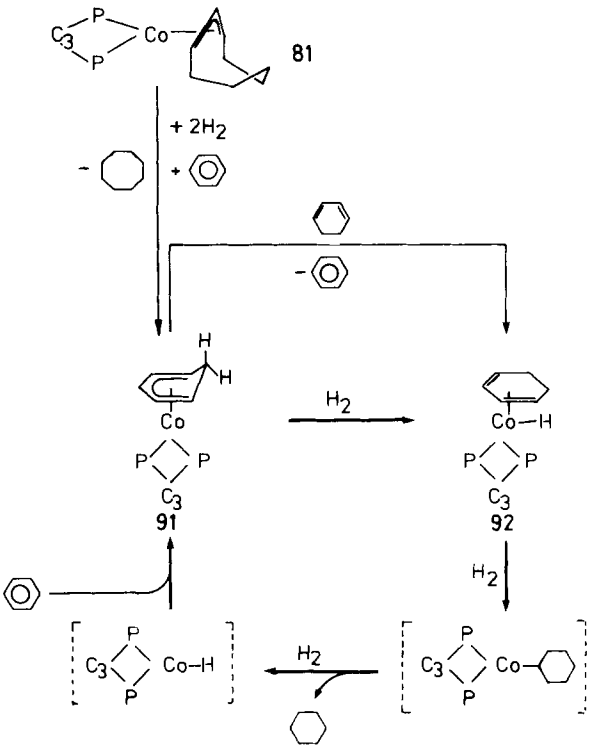


Fig. 2. Crystal structure of cyclohexenyl[*P,P'*-ethylenebis(dicyclohexylphosphane)]cobalt **88** formed by hydrocobaltation of cyclohexadiene.

In this cyclohexenylcobalt(I) complex **88** the cobalt and the two phosphorus atoms form part of a five-membered ring. Like the allylcobalt complexes **79** and **80** (Scheme 28), **88** reacts rapidly with hydrogen at room temperature. As to be expected, this reaction proceeds stoichiometrically in benzene solution to yield cyclohexane and **84a** (Scheme 31).

Scheme 31. Hydrogenolysis of **88** in benzene.

We were surprised, however, to discover that in benzene solution the hydrogenolysis of the cyclooctenylcobalt complex **81**, in which cobalt and the two phosphorus atoms are present in a less rigid six-membered ring (CoP_2C_3), by no means stops at the stage of the hydrocobaltated benzene. In this particular case, the benzene undergoes a cobalt-catalyzed hydrogenation to cyclohexane (Scheme 32). Thus, the cobalt complex **81** is a catalyst precursor for the hydrogenation of benzene. In addition, benzene solutions of **91** [ν(C–H_{exo}): 2760 cm^{-1}] or **92** [ν(Co–H): 1875 cm^{-1}], which are both sparingly soluble in aromatic solvents, can also take up hydrogen (1 bar) over a long period (30–40 h) at room temperature (e.g. 3.6×10^{-3} M solutions of **81** take up 216 H_2/Co in 6 h; this corresponds to 0.6 $H_2/(Co \cdot min^{-1})$.

Scheme 32. Cobalt-catalyzed benzene hydrogenation on $(CH_2)_3\{P(C_6H_{11})_2\}_2CoH$ fragments.

3.3.2. *Novel Types of Binuclear Complexes of Cobalt, Iron, and Vanadium with Benzene or Alkylbenzenes as Bridging Ligands*

Thirty years after the discovery of bis(benzene)chromium[97], mononuclear sandwich and half-sandwich complexes with arenes have become well established classes of compounds.[98] On the other hand, coordination compounds in which arenes are bonded to *two* metal centers and which have all six ring carbon atoms coordinated were not known until recently. In the past couple of years, no less than four different types of binuclear complex of this kind have been prepared in an astonishingly simple way in the Institute in Mülheim [Eqs. (25)–(28)]. Prerequisites for this were the educts **16**, **55**, and **11**, readily prepared from vanadocene and ferrocene, respectively, and the extraordinarily labile cobalt complex **86**, obtained by the hydrocobaltation of *p*-xylene.

$$2\,K[(C_5H_5)_2V] + \text{1,3-cyclohexadiene} \xrightarrow[-2\,K(C_5H_5)]{-78\ldots20\,^\circ C} [\{(C_5H_5)VH\}_2(\mu,\eta^4\!:\eta^4\text{-}C_6H_6)] \quad (25)$$

16 **93**

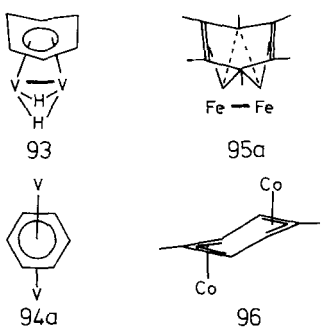
$$2[(C_5H_5)V(C_3H_5)_2] + \text{1,3-cyclohexadiene} \xrightarrow{100\,^\circ C} [\{(C_5H_5)V\}_2(\mu,\eta^6\text{-}C_6H_6)] + \cdots \quad (26)$$

55 **94a**

$$2[(C_5H_5)Fe(cod)] + 3\,R{-}C{\equiv}C{-}R \xrightarrow[-2\,COD]{20\,^\circ C} [\{(C_5H_5)Fe\}_2(\mu,\eta^4{:}\eta^4\text{-}C_6R_6)] \quad (27)$$

11

95a, $R = CH_3$



95b, $R = C_2H_5$

$$2[(CH_2)_2\{P(C_6H_{11})_2\}_2Co\{\eta^5\text{-}C_6H_5(CH_3)_2\}] \xrightarrow[-C_6H_4(CH_3)_2,\,-2H]{20\,^\circ C,\ hexane} [\{(CH_2)_2[P(C_6H_{11})_2]_2Co\}_2\{\mu,\eta^3{:}\eta^3\text{-}C_6H_4(CH_3)_2\}] \quad (28)$$

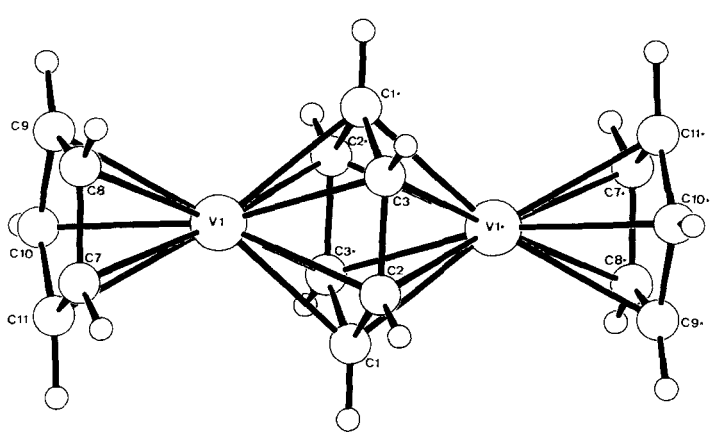
86

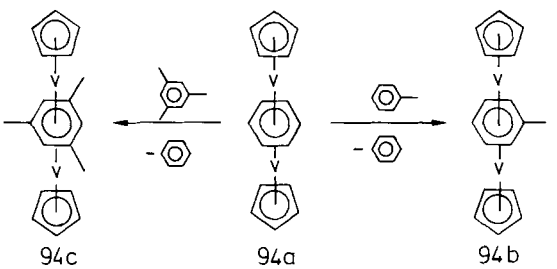
96

The structures of complexes **93**, **94a**, **95a**, and **96** were determined by X-ray crystallography.[99-101] In solution, **93**, **95a** and **95b** are fluxional. The most important structural features of these binuclear complexes are summarized in Scheme 33, while the full crystal structure of **94a** is illustrated in Figure 3.

Scheme 33. Binuclear transition metal-arene complexes in which benzene or alkylbenzenes act as bridging ligands and all six ring carbon atoms are coordinated to metal atoms.

Thus, the two metal atoms can be bound to one side of an arene ligand (synfacial) as in **93** and **95** or on opposite sides of the arene (antifacial) as in **94a** and **96**. Only in the binuclear vanadium complex **94a** (see Fig. 3), the first triple-decker sandwich complex with benzene as the "middle deck", does the benzene remain completely planar and retain equal C–C bond lengths in the coordinated state at room temperature. In all other binuclear complexes the arene ligands are either no longer planar (**93**) or are both non-planar and have different C–C bond lengths (**95**, **96**).





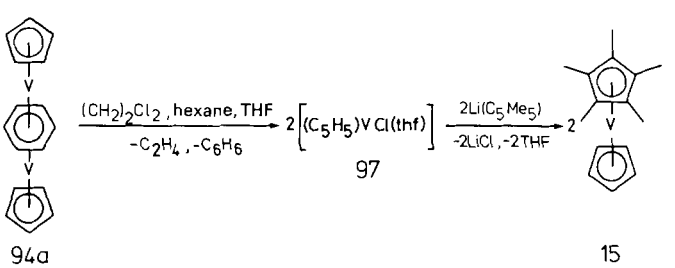


Fig. 3. Molecular structure of μ-benzenedicyclopentadienyldivanadium **94a**, the first triple-decker sandwich complex having complexed benzene as the "middle deck".

Remarkably, the coordinated benzene in **94a** can be displaced from the vanadium atoms by alkylbenzenes at 110 °C and this proceeds with retention of the triple-decker sandwich structure. For example, when **94a**, which is only sparingly soluble, is heated in toluene or mesitylene it goes into solution slowly. The new, much more soluble triple-decker sandwich complexes **94b** and **94c** are produced in which coordinated toluene or mesitylene now form the novel bridging group. An X-ray structure determination has also been carried out for **94c**[100] (Scheme 34).

Scheme 34. Replacement of complexed benzene in **94a** by toluene or mesitylene at 110 °C.

The triple-decker sandwich structure is lost when **94a** reacts with organic halides or iodine.[100] For example, when **94a** is treated with allyl chloride in THF, the vanadium(III) complex $[(C_5H_5)V(C_3H_5)Cl]$ is obtained, while treatment of **94a** with dichloroethane furnishes the vanadium(II) complex **97**. The reaction of **97** with lithium pentamethylcyclopentadienide forms pentamethylvanadocene **15** in high yield (Scheme 35), which in turn was used in the synthesis of **17** and **18** (Section 2.1.3) and of **56** and **57** (Section 2.2.4). In addition, **15** has proved to be a valuable starting material for a number of other syntheses.[102]

Scheme 35. Degradation of the triple-decker sandwich structure of **94a** and synthesis of **15**.

4. Conclusion

The use of cyclopentadienyl groups as ligands to stabilize transition metal atoms is one of the cornerstones of synthetic organo-transition metal chemistry. This situation has changed little in the three decades that have elapsed since the discovery of the metallocenes in the early 1950's. Indeed, the current literature shows a trend towards the use of alkylated five-membered ring ligands, frequently with the aim of forming even more stable systems.

In contrast, the properties of the C_5H_5 group as a mesomerically stabilized anionic leaving group have been neglected, and the consequent preparative applications have remained virtually unknown.

The degradation reactions based on this principle which have been described in this review are productive synthetic methods for preparing both coordinatively unsaturated transition metal complexes and those with labile ligands. These highly reactive compounds, many of which have not yet been prepared by other routes, are themselves suitable starting materials for a wide range of syntheses. We expect that numerous further examples will be discovered in the future. It also remains to be established whether this synthetic approach can also be successfully extended to cyclopentadienyl and related complexes of the f-elements.

We gratefully acknowledge the generous support of the Director of the Max-Planck-Institut für Kohlenforschung, Prof. Dr. G. Wilke, in this work. We also thank Prof. Dr. C. Krüger, Dr. R. Benn, Dr. R. Mynott, Dr. K. Seevogel, Dr. D. Henneberg and Dr. G. Schomburg and their co-workers for the analytical studies and for numerous discussions. The author thanks the Karl-Winnacker-Stiftung for a stipendium.

Formation of Organoaluminum Compounds in the Mixture $AlCl_3$–$TiCl_4$–Al–C_2H_4

By *Heinz Martin*,* *Helmut Bretinger*, and *Fritz Fürbach*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

In the thirty-year history of the Ziegler catalysts, there has been no lack of efforts to attack, circumvent, or infringe the patent rights of *Karl Ziegler*. An earlier publication of *Max Fischer*,[2]

$$Al + AlCl_3 + TiCl_4 \xrightarrow[\text{heptane}]{C_2H_4} \text{polyethylene} + ? \quad (1)$$

in combination with work of *Hall* and *Nash*,[3,4]

$$Al + AlCl_3 \xrightarrow{C_2H_4} EtAlCl_2 + Et_2AlCl \quad (2)$$

played an important role in connection with a series of legal controversies in the USA, most recently against Dart,[1] which have meanwhile been resolved. These dealt with the question of whether, under the conditions of this ethylene polymerization [Eq. (1)], ethylaluminum sesquichloride forms from Al and $AlCl_3$ with ethylene according to Equation (2), and, via reaction with $TiCl_4$ to form a Ziegler catalyst,[5] could be made responsible for the formation of a solid, high-molecular-weight polyethylene. If this could be shown, then the catalyst patented by *Ziegler* for the polymerization of olefins would, in the opinion of the defendant, not be new and therefore not be patentable.

There has been mostly speculation on this question:[6–11] at least in situ, ethylaluminum chlorides, as well as $AlEt_3$,

[*] Dr. H. Martin, H. Bretinger, F. Fürbach
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

ought to have been formed. This conclusion could not be reached experimentally[9] since, in the reporting of analytical data, those for Al were absent, or since distillative separation of the ethylaluminum compounds supposedly formed, either from one another or from hydrocarbons in the C_{10}–C_{12} range, could not have led to the reported success under the given conditions: the vapor pressure curves of the possible Al compounds differ from each other and from those of the hydrocarbons to such a small extent that the separation of pure components would not have been thus possible.[12–14] Under the conditions of the Max Fischer patent, it is not possible to detect organoaluminum compounds in the product.

If an organoaluminum compound is formed at all as intermediate, it could only be a small amount of an Al compound with a Cl/Al ratio $\geqq 2$ mixed with a relatively large excess of $AlCl_3$, and not Et_2AlCl. This conclusion is arrived at by calculation alone, based on the mole ratio of Al powder and $AlCl_3$ used—especially in view of the results of *Hall* and *Nash*.

$$370\,\text{mmol Al} + 225\,\text{mmol AlCl}_3 \xrightarrow{C_2H_4} 225\,\text{mmol}\,(\text{EtAlCl}_2 + \text{Et}_2\text{AlCl}) + 145\,\text{mmol Al}^{[3,4]} \quad (3)$$

$$37\,\text{mmol Al} + 225\,\text{mmol AlCl}_3 \xrightarrow[\text{heptane}]{C_2H_4} 111\,\text{mmol EtAlCl}_2 + 151\,\text{mmol AlCl}_3^{[2]} \quad (4)$$

By the use of the catalytic mixture described by *Fischer*, solid polyethylenes were isolated as solid products mixed with excess oil having Friedel-Crafts character. The solid products are structurally highly branched and have melting points between 100 and 120 °C.

Without the addition of $TiCl_4$ under otherwise identical, or even milder, conditions, a dichloroaluminum compound forms in the heptane solution (detected by volumetric analysis). The ^{27}Al-NMR spectrum of the solution (104 MHz, [D$_8$]toluene) indicates a corresponding concentration of a hydrocarbon-containing dichloroaluminum compound ($\delta = +39.2$, $+5.8$; $EtAlCl_2$ $\delta = +35$, $+2.3$; $AlCl_3$ $\delta = 0$). The formation of Et_2AlCl ($\delta = +70$) is ruled out with certainty according to the analytical results. The large excess of unreacted $AlCl_3$ in the reaction mixture supports these findings, since, with $AlCl_3$, even traces of Et_2AlCl would comproportionate immediately to $EtAlCl_2$ under the conditions of the Max Fischer patent according to the present state of knowledge.[15]

$$\text{Et}_2\text{AlCl} + \text{AlCl}_3 \longrightarrow 2\,\text{EtAlCl}_2 \quad (5)$$

Thus, the answer to the question asked at the beginning—whether Et_2AlCl could form from Al and $AlCl_3$ under conditions such as those described by *Fischer*[2]—is an unequivocal no.

The further investigation of the reaction mixture after reaction under comparably mild conditions (100–110 °C, 1 bar ethylene) led, however, to a surprising result. Upon treatment of both the separated undissolved part and the soluble part of the reaction mixture with D_2O, [D$_2$]ethane is found in the deuterolysis gas, namely, [1,2-D$_2$]ethane from the undissolved and [1,1-D$_2$]ethane from the dissolved part. The proportion of [D$_2$]ethane corresponds to ca. 26–30% of the maximal amount of $EtAlCl_2$ expected on the basis of Equation (4). Its origin can easily be explained by the formation of intermediates.

$$\gtrless\text{Al–CH}_2\text{CH}_2\text{–Al}\lessgtr + 2\,\text{D}_2\text{O} \longrightarrow 2\gtrless\text{AlOD} + \text{CH}_2\text{D–CH}_2\text{D} \quad (6)$$

$$\gtrless\text{Al–CH(CH}_3\text{)–Al}\lessgtr + 2\,\text{D}_2\text{O} \longrightarrow 2\gtrless\text{AlOD} + \text{CD}_2\text{H–CH}_3 \quad (7)$$

In the same way, we have prepared 1,2-ethanediyl bis(dichloroaluminum) **1** and the corresponding 1,1-ethanediyl compound **2**.[16]

$$2\,\text{Al} + 4\,\text{AlCl}_3 + 3\,\text{C}_2\text{H}_4 \longrightarrow \underset{\mathbf{1}}{3\,\text{Cl}_2\text{Al–C}_2\text{H}_4\text{–AlCl}_2} \quad (8)$$

The reactivity of the compounds **1** and **2**, which were hitherto unknown, towards $TiCl_4$ was compared with that of $EtAlCl_2$ (Table 1).

Table 1. Reduction of $TiCl_4$ at room temperature in heptane (10 mmol $TiCl_4$ + 10 mmol Al compound in 50 mL heptane).

Aluminum compound	t [min]	Ti$^{[11]}$ [%]
$Cl_2Al–C_2H_4–AlCl_2$ **1**	30	31.5
	60	34.5
$(Cl_2Al)_2CH–CH_3$ **2**	5	96
	15	100
$EtAlCl_2$	15	22.5
	60	42

Thus **2** exhibits comparatively exceptional reactivity. Although, under ethylene pressure at 150 °C, the external conditions as given in [2], the aluminum compound is no longer stable—it eliminates $EtAlCl_2$—it can be assumed that, in the presence of $TiCl_4$, it reacts immediately, without the formation of $EtAlCl_2$.

In the polymerization of ethylene at normal pressure using a catalyst prepared from **2** and $TiCl_4$, without addition of $AlCl_3$, a solid, high-molecular-weight, practically linear polyethylene is formed.

Even organoaluminum compounds containing more chlorine and appreciably fewer ethyl groups than Et_2AlCl are therefore suitable as cocatalysts, together with $TiCl_4$, for the conversion of ethylene into solid polymers. The structures of these polyethylenes, however, differ unequivocally from those that can be observed according to [12]. Such catalysts could not, therefore, result in the reactions described by *Fischer*.

Not only the examination of the stoichiometric ratios of catalyst components chosen by *Fischer*, but also of the mechanism of the reaction of Al and $AlCl_3$, indicates that the catalyst described by *Fischer* is of a different kind from that described by *Ziegler*.

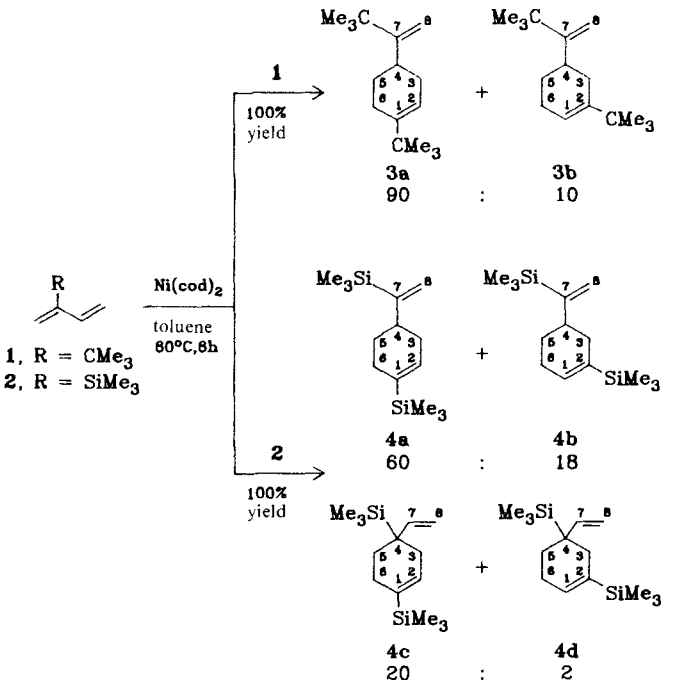
[16] 16 g Al powder, suspended in 500 mL *n*-heptane, was treated for 4 d with C_2H_4 (1 bar) after addition of 30 g $AlCl_3$ with stirring at 100°C. The mixture was filtered and the filtrate freed of solvent (maximum 50°C, 10^{-3} mbar). The oily residue (17.75 g) was treated with pentane. A colorless powder precipitated out (24.14% Al, 63.32% Cl, 12.32% ethane; deuterolysis: 95% [1,1-D_2]ethane, 5% [D_1]ethane). The structure of **2** shown here is in accord with the ^{1}H-NMR spectrum (230 K) ($\delta(C-H) = -1.20$, $\delta(CH_3) = 0.92$) as well as with the ^{13}C-NMR spectrum (210 K) ($\delta(C-H = 1.95$ (d), $\delta(CH_3) = 5.71$ (q)). The solid residue from the filtered reaction mixture contains undissolved **1** in addition to excess Al powder.

Nickel-Catalyzed Cyclodimerization of 2-*tert*-Butyl- and 2-Trimethylsilyl-1,3-butadiene**



By *Tamas Bartik, Paul Heimbach,* Thomas Himmler,* and *Richard Mynott*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The oligomerization of 1,3-butadiene, first carried out by *H. W. B. Reed* on Reppe catalysts ($L_2Ni(CO)_2$),[1] only became a widely applicable synthetic method with the introduction of carbonyl-free Ni^0 catalysts by *G. Wilke* et al.[2] Butadiene is cyclotrimerized on "naked" nickel; in the presence of P ligands (phosphanes or phosphites), cyclodimerization takes place to give divinylcyclobutane, 4-vinylcyclohexene, and (*Z,Z*)-1,5-cyclooctadiene.[3] In order to use the Ni^0-catalyzed oligomerizations and co-oligomerizations better, the controlling factors, e.g., the conformation of the diene or the relative donor-acceptor behavior of the substituents (structural and electronic variables, "molecular order effectors")[4] must be understood. We show here how the substituents CMe_3 and $SiMe_3$ in the 2-position of 1,3-butadiene affect reactivity and selectivity in the Ni-catalyzed cyclodimerization.

Whereas the 2-alkyl-substituted 1,3-dienes that have been studied to date oligomerize more slowly than butadiene,[5] 2-*tert*-butyl- and 2-trimethylsilyl-1,3-butadiene, **1** and **2**, respectively, surprisingly react appreciably faster. Under conditions[6] that result in 30—40% cyclotrimerization of butadiene on the ligand-free nickel catalyst, the reaction of the dienes **1** and **2** is quantitative. In the case of both dienes, cyclodimerization occurs and only substituted vinylcyclohexenes are formed (Scheme 1).

The isomeric pairs **3a/3b** as well as **4a/4b** and **4c/4d** each differ only in the respective substitution of the double bond in the ring. It was not possible to assign the structures unequivocally from simple ^{1}H- and ^{13}C-NMR spectra. This was only achieved with the 2D-INADEQUATE technique, in which the $^1J(^{13}C\text{-}^{13}C)$ couplings are used to generate a carbon-carbon connectivity map[7] (see Table 1).

Scheme 1.

Table 1. ^{13}C-NMR data for **3a**, **3b**, and **4a**—**4d**. The signal assignments for **3a**, **3b** [12], **4a**, and **4c** were made unequivocally on the basis of the 2D-INADEQUATE ^{13}C-NMR spectra. δ-Values recorded relative to $CDCl_3$ and recalculated relative to TMS [$\delta(CDCl_3) = 77.0$] [a]. For numbering of the C atoms see Scheme 1.

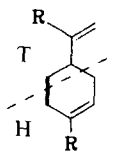
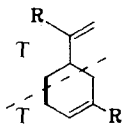
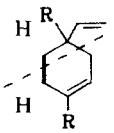
$C(CH_3)_3$	36.9/	36.9/				
	35.2	35.2				

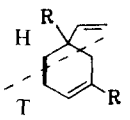
[a] The ^{13}C-NMR spectra were recorded in 10-mm tubes in $CDCl_3$ at 75.5 MHz on a Bruker WM-300 NMR spectrometer. Typical measurement conditions for the 2D-INADEQUATE spectra: data matrix $2K \times 256(t_2,t_1)$, 128 scans per t_2 increment; spectral width 11.9 kHz, τ-increment 5 ms (corresponding to average coupling $^1J_{CC} = 50$ Hz); cycle time 4.1 s.

The effect of the diene substituents (CMe_3, $SiMe_3$, and also CH_3[8]) on the relative proportions of head (H) and tail (T) coupling in the "diene" and "ene" parts for the reaction giving Diels-Alder products is shown in Table 2. The proportion of "symmetrically" coupled products (HH + TT) increases in the series $CMe_3 < SiMe_3 < CH_3$.









The rate of the Ni-catalyzed oligomerization is strongly affected by the addition of triphenylphosphane: the reaction of butadiene is accelerated, that of **1** and **2** inhibited (Fig. 1).

Using discontinuous inverse titration,[9] we were able to show that the Ni-catalyzed cyclodimerization of diene **2** to Diels-Alder products was practically fully suppressed upon addition of triphenylphosphane in the range $-1 < \lg[L]_0/[Ni]_0 < 0$, whereas, for the diene **1**, for ligand concentrations in the range $-1 < \lg[L]_0/[Ni]_0 < +1$, **3b** replaces **3a** as the main product in a very strongly inhibited

HT + TH [d]		90		62		40

[a] Proportion of the dimers in which the ene was incorporated as head or tail. [b] Proportion of the dimers in which the head or tail of the diene was coupled with the terminal C atom of the ene components. [c] Sum of the HH- and TT-coupled dimers. [d] Sum of the HT- and TH-coupled dimers.

reaction (yield $< 15\%$ for $\lg[L]_0/[Ni]_0 > +0.5$). Nevertheless, this very retarded reaction is also clearly catalytic, since the diene **1** thermally dimerizes to only 0.2% under these reaction conditions in the absence of catalyst. For diene **2**, the slower uncatalyzed Diels-Alder reaction (yield ca. 20%), in which the isomers **4a**—**4d** are formed, is observed after "turning off" the catalysis by addition of triphenylphosphane ($\lg[L]_0/[Ni]_0 > 0$); comparison of the thermal with the catalytic dimerization shows that, catalytically, three isomers are formed: **4a** and **4b** in appreciably larger proportion than in the thermal dimerization, and **4c** in only slightly increased proportion. The isomer **4d**, on the other hand, is only formed thermally.

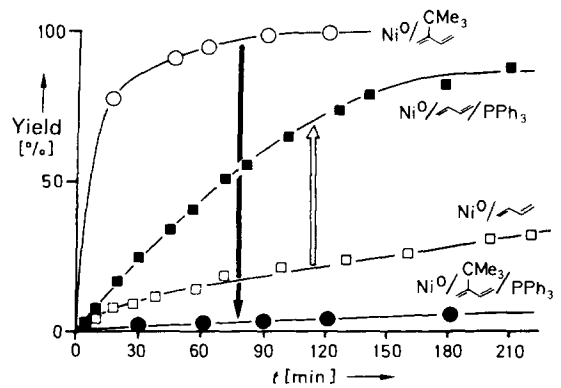

Fig. 1. Opposite effect of the addition of triphenylphosphane on the reaction rate (yield curves) in the Ni-catalyzed oligomerization of butadiene (activation) and 2-*tert*-butyl-1,3-butadiene **1** (inhibition); L : Ni = 10 : 1.

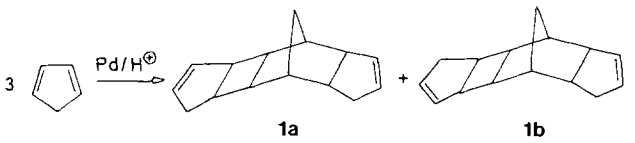
[12] Since the differences between the ^{13}C chemical shifts of **3a** and **3b** are unexpectedly small, we recorded the 2D-INADEQUATE spectrum of **3b** as a control. Especially noticeable are the similarities of the shifts of C-3 and C-6, respectively, in **3a** and **3b**. The signals of **4b** and **4d** were assigned by comparison with the other compounds.

Novel Trimerization of Cyclopentadiene with a Homogeneous, Bifunctional Palladium-Acid Catalyst System**

By *Arno Behr* and *Wilhelm Keim**

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Although bifunctional catalysts have found wide application in heterogeneous catalysis,[1] there are still only very few corresponding examples of their use in homogeneous catalysis.[2] Herein, we describe the synthesis of two hitherto unknown cyclopentadiene trimers using a novel, bifunctional, mixed catalyst comprising a palladium complex and a carboxylic acid ("$Pd/H^{\oplus}$").



This preparative result indicates that bifunctional catalytic systems can also play an important part in homogeneous catalysis with transition-metals.

In the trimerization of cyclopentadiene two isomers are formed that can be preparatively separated[3] and fully

[*] Prof. Dr. W. Keim, Dr. A. Behr
Institut für Technische Chemie und Petrolchemie
der Technischen Hochschule
Worringer Weg 1, D-5100 Aachen (FRG)

[**] We thank *F. Näf* and *R. Decorzant*, Firmenich SA (Geneva), for their help with the analytical-spectroscopic work.

characterized spectroscopically. On the basis of the 360-MHz H-NMR and 90-MHz ^{13}C-NMR spectra[4] and the result of decoupling experiments the trimers were assigned to the structures **1a** and **1b**. In both isomers the cyclopentene ring bound to the norbornane system is oriented in the *endo* position.

The 1:1 mixture of the pentacyclo[7.5.0.1^{2,8}.0^{3,7}.0^{10,14}]-pentadeca-4,12- **1a** and -4,11-diene **1b** forms white fibrous crystals (m.p. 49°C, b.p. 75°C/0.01 torr). No absorption maxima are observed in the UV spectrum above 200 nm; the IR spectrum[5] shows the typical C=C stretching band at 1608 cm^{-1} for the cyclopentene ring, while the stretching band of the norbornene ring at ca. 1570 cm^{-1} characteristic for Diels-Alder trimers is missing. The mass spectrum[6] is also consistent with the proposed structures.

In the catalytic hydrogenation of **1a** and **1b**, 2 moles of hydrogen are taken up per mole, in each case with formation of the same pentacyclopentadecane.

In the synthesis of **1a,b** palladium bis(acetylacetonate) Pd(acac)$_2$ or palladium bis(dibenzylideneacetone) Pd(dba)$_2$ is favored as palladium component of the catalyst. Both phosphanes (PEt_3, $PiPr_3$, PPh_3) as well as phosphites (triisopropyl phosphite, tris(*o*-tolyl) phosphite) are suitable as phosphorus ligands. As third component a carboxylic acid is required whose pK_a value lies between 3 and 5. This carboxylic acid must be present in at least the same molar amount as the starting cyclopentadiene; catalytic amounts of carboxylic acid are not sufficient for the formation of the trimers **1a**, **b**. The carboxylic acids employed were, e.g., acetic acid, monochloroacetic acid, benzoic acid, and pivalic acid. Too strongly acidic acids, e.g. trichloroacetic acid, lead to the formation of polycyclopentadiene. Remarkably, the catalyst system presented here is capable of almost completely suppressing formation of the Diels-Alder byproduct, dicyclopentadiene, even at reaction temperatures of 100 to 130°C.

The mechanism of the reaction is so far unclear. The reaction strongly depends on the solvent used, thus pointing to an ionic mechanism. A simple thermal [2+2]-cycloaddition can be ruled out, since comparative experiments without the bifunctional catalyst led only to the known Diels-Alder products. Also, when either the palladium complex or the acid alone is used as catalyst no trimer **1a**, **b** is formed.

Experimental:

In a typical reaction 0.65 mmol Pd(acac)$_2$ and 1.95 mmol PPh_3 were dissolved in 25 mL acetonitrile and treated with 9.9 g (0.15 mol) cyclopentadiene and 18 g (0.3 mol) acetic acid. Yield after 4 h at 100°C and subsequent work-up 7 g (70%) **1a**, **b**.

A New Method for Determining Enantiomeric Excess, where the Sample Serves as its Own Reference**

By *Maurice L. Pasquier* and *Werner Marty**

The determination of the enantiomeric excess (*ee*) of a new, chiral substance is usually based on diastereomeric interactions between molecules of this substance and molecules of a different substance of known *ee*.[1,2] However, measurable diastereomeric interactions between *enantiomers* (i.e., molecules having the *same* constitution) in a sample are sufficient for determining the *ee*,[2–6] even in the *absence of an enantiomerically pure standard*. Procedures for determining the *ee* based on this principle appear attractive, but have not to our knowledge been developed so far. We discuss here one possible way of determining the *ee* by the use of this principle, which may be applied to a wide variety of compounds.

When a mixture of enantiomeric molecules C(abcd) (containing, e.g., only one stereogenic atom) in an unknown ratio $[R]_0/[S]_0$ is reacted with a bifunctional, achiral reagent F, diastereomers are expected, viz., an achiral *meso* species **m** and an *enantiomeric pair* of chiral species **e**. The species **m** and **e** may be distinguishable, e.g., by NMR spectroscopy,[7] and from the ratio r = [**m**]/[**e**], $[R]_0/[S]_0$ can be worked out in principle.[4] However, r may be affected appreciably by *diastereoselectivity* in the formation of **m** and **e**. This diastereoselectivity may be kinetic or thermodynamic in origin; the experimental distinction between these two contributions is laborious.[5]

If **m** and **e** are formed *reversibly*, then only thermodynamic diastereoselectivity is possible, and its extent is easily determined by analysis of the diastereomer ratio arising in the reaction of *racemic* C(abcd) with F. The thermodynamic diastereoselectivity is defined by $d = ([\mathbf{m}]/[\mathbf{e}])_{racemate}$.

The condition of reversibility is met if F is a kinetically *labile metal ion* M^{n+}[8] or a metal complex with at least two labile ligands. Metal ions can serve as templates to hold coordinating substrates at a close distance and, at the same time, as transmitters for electronic effects, as required for diastereomeric interaction. If r is to be determined by NMR, then the use of diamagnetic metal ions is indicated.[9]

[*] Prof. Dr. W. Marty, Dr. M. L. Pasquier
Institut de chimie, Université de Neuchâtel
Av. de Bellevaux 51, CH-2000 Neuchâtel (Switzerland)

[**] This work was supported by the Swiss National Foundation for Scientific Research and the Ciba-Geigy Jubiläumsstiftung.

Complex formation may not be quantitative, or an *excess* of C(abcd) may be desirable to transform any $M[C(abcd)]^{m+}$ into $M[C(abcd)]_2^{g+}$. The *relative* amount of free substrate is defined by the ratio

$$h = [C(abcd)]_{free}/([\mathbf{m}]+[\mathbf{e}])$$

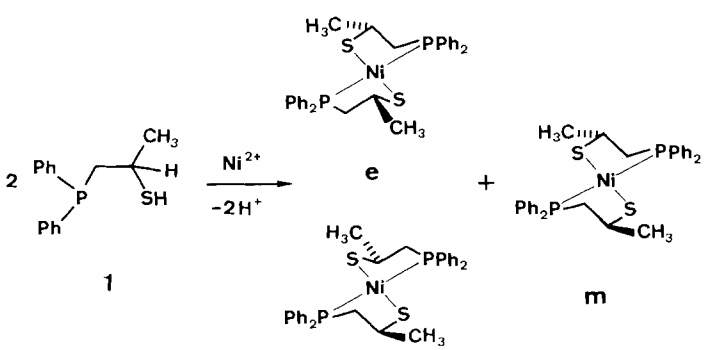
and may be determined, e.g., spectroscopically. It should be noted that the ratio of enantiomers in the excess substrate ($[R]/[S]$) may differ from that in the total substrate ($[R]_0/[S]_0$). This holds for any non-racemic mixture (where $r \neq d$) if $d \neq 1$.

For a system containing M^{n+}, C(abcd), $M[C(abcd)]^{m+}$, and $M[C(abcd)]_2^{g+}$ at equilibrium, the following equation is obtained, in which the experimental parameters r, d, and h are used:

$$\frac{[R]_0}{[S]_0} = \frac{\alpha^3(hr+h+2r+1)+\alpha^2(2r+1)+\alpha(1+hr+h)+1}{\alpha^3+\alpha^2(h+hr+1)+\alpha(2r+1)+2r+1+hr+h} \quad (1)$$

where α is the enantiomer ratio in the excess substrate;

$$\alpha = [R]/[S] = (r+\sqrt{r^2-d^2})/d.$$



From equation (1), the *ee* is obtained using the familiar expression (2).

$$ee[\%] = [([R]_0/[S]_0-1)/([R]_0/[S]_0+1)] \times 100 \quad (2)$$

If $h \approx 0$, Equation (1) takes a simpler form and *ee* is given by Equation (3).

$$ee[\%] \approx \sqrt{r^2-d^2}/(r+1) \times 100 \quad (3)$$

This procedure may, in principle, be applied to any bidentate or unidentate coordinating molecule by proper choice of a metal ion or of a complex containing additional, non-labile ligands.[10] The procedure is very sensitive at high enantiomeric purities, and is rewarded by economy of enantiomerically highly enriched derivatizing reagents, shift reagents, or solvents. The metal complexes are best prepared in situ, and in completely homogeneous solution, in order to avoid fractionation of diastereomers.

In one example of application, the *ee* of 1-diphenylphosphino-2-propanethiol **1**[11] was determined. Both racemic and enantiomerically enriched **1** were treated in situ with a less than stoichiometric amount of $Ni(NO_3)_2 \cdot 6H_2O$ in CH_2Cl_2/MeOH (10:1) to form **m** and **e** diastereomers of *trans*-$Ni(\mathbf{1})_2$.[12] The ^{31}P-NMR spectra showed singlets at (a) $\delta = 52.65$ and (b) $\delta = 53.55$ (CH_2Cl_2/MeOH (10:1), relative to ext. H_3PO_4 in CD_2Cl_2) with intensity ratios of $d = (a)/(b) = 2.0$[13] and $r = 27$ for the racemate and the enantiomerically enriched sample, respectively. The excess of free ligand gave a singlet at $\delta = -18.92$, the intensity of which gave $h = 0.12$. From these data, $ee = 96.0\%$.[14] This result was confirmed by ^{1}H-NMR spectroscopy ($CDCl_3$, int. TMS, CH_3: $\delta = 1.41$ in **m** and 1.31 in **e**, $J_{HH} = 6.3$ Hz; *o*-phenyl H: 8.12 in **m** and 8.00 in **e**).[15] Equilibrium was shown to be attained by mixing known amounts of enantiomerically enriched (known *ee*) and racemic **1**; calculated and experimental r values agreed shortly after mixing.

[1] The present discussion focuses on techniques that do not involve the resolution of enantiomers, e.g., by chromatography or isotope dilution. For a recent review on these two methods, see: J. D. Morrison: *Asymmetric Synthesis, Vol. 1*, Academic Press, New York 1983.

[2] A. Jacques, H. Collot, S. H. Wilen: *Enantiomers, Racemates and Resolutions*, Wiley-Interscience, New York 1981.

[3] Cf. [2], chap. 7.5.2., p. 410. These authors consider this possibility as an exception.

[4] J. P. Vigneron, M. Dhaenens, A. Horeau, *Tetrahedron 29* (1973) 1055.

[5] J. Leitich, *Tetrahedron Lett. 1978*, 3589.

[6] J. Reuben, *J. Am. Chem. Soc. 102* (1980) 2232.

[7] In some instances, the substrate molecules can *self-associate* (e.g., through hydrogen bonding in apolar solvents) to form diastereomeric aggregates with *anisochronous NMR signals:* (a) T. Williams, R. G. Pitcher, P. Bommer, J. Gutzwiller, M. Uskoković, *J. Am. Chem. Soc. 91* (1969) 1871; (b) M. I. Kabachnik, T. A. Mastryukova, E. I. Fedin, M. S. Vaisberg, L. L. Morozov, P. V. Petrovskii, A. E. Shipov, *Russ. Chem. Rev. 47* (1978) 821; (c) M. J. P. Harger, *J. Chem. Soc. Perkin 2 1977*, 188.

[8] If the diastereomers are to be analyzed by NMR, then the equilibration should be sufficiently slow such as to avoid exchange broadening of the lines. This may be ensured by proper choice of M^{n+}.

[9] However, lanthanide ions may serve as achiral shift reagents, increasing in some cases the chemical shift difference between the diastereomers [6].

[10] Proper choice of solvent may frequently prevent formation of significant amounts of undesired isomers with different coordination geometry, e.g., a *cis* or a *trans* square planar complex. Occasionally, the formation of such geometric isomers cannot be prevented, and then Equation (1) has to be modified, allowing for different diastereoselectivities of the individual geometric forms.

[11] a) Compound **1** (both racemic and enantiomerically enriched) was prepared in analogy to [11b] and [11c] from (±)-methylthiiran (Fluka) and (*R*)-methylthiiran, respectively. The products were foul-smelling, air-sensitive oils (b.p. 115–120°C, 0.02 torr; 87% yield); b) J. Chatt, J. R. Dilworth, J. A. Schmutz, J. A. Zubieta, *J. Chem. Soc. Dalton Trans. 1979*, 1595; c) T. Tsunetsugu, J. Furukawa, T. Fueno, *J. Polym. Sci. Part A1 9* (1971) 3529.

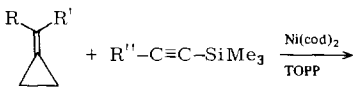
[12] E. Pfeiffer, M. L. Pasquier, W. Marty, *Helv. Chim. Acta 67* (1984) 654.

[13] For thermodynamically controlled reactions, this value corresponds to the absence of diastereoselectivity (no deviation from the statistical ratio of species concentrations).

[14] The peak areas of well-separated signals were determined with ±1% precision. If the accuracy of peak ratios is estimated as ±2% (W. H. Pirkle, S. D. Beare, *J. Am. Chem. Soc. 91* (1969) 5150; W. H. Pirkle, P. L. Rinaldi, *J. Org. Chem. 42* (1977) 3217), a value of 96.0±0.1% is obtained for the *ee* of the present example.

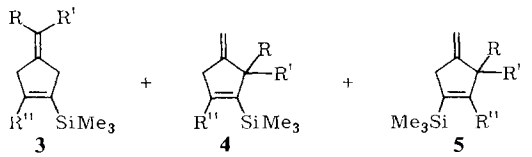
[15] The integrals of the ^{31}P-NMR signals were measured with due care, and interference from relaxation and nuclear Overhauser effects was eliminated.

4-Methylene-1-cyclopentenes from Methylenecyclopropanes and Alkynyltrimethylsilanes



By *Paul Binger,* Qui-Hao Lü,* and *Petra Wedemann*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday



[3+2]-Cycloadditions have found increasing use in recent years for the direct entry to cyclopentanes.[1] Espe-

cially suitable as a source for the C_3-unit required in such reactions are the methylenecyclopropanes **1**, which are also readily accessible in large amounts.[2] Thus, for example, 2,3- and 3,4-disubstituted methylenecyclopentanes can be obtained regioselectively from **1** and electron-deficient olefins, depending on the Ni^0- or Pd^0-catalysts used.[3,4].

Using triorganyl phosphite-containing Ni^0-catalysts, we have now also been able to carry out such additions of **1** to alkynes to give 4-methylene-1-cyclopentenes **3**—**5**; alkynylsilanes such as **2** (Table 1) are particularly suitable for these codimerizations.

Table 1. Ni(cod)$_2$/tris(*o*-phenylphenyl)phosphite (TOPP)-catalyzed addition of **1** to **2** [a].

[a] 1 mmol Ni(cod)$_2$, 1 mmol TOPP, 50 mmol **1**, 50 mmol **2**; 5—8 h, 80°C; the experiment with **1a** was carried out in a V4A steel autoclave, the experiments with **1b**—**1e** in a glass tube. [b] Calculated w.r.t. alkyne (consumed). In addition, non-distillable oligomers having unknown composition are formed. [c] All compounds were characterized by elemental analysis and ^{1}H-NMR, ^{13}C-NMR, and mass spectra. [d] Two isomers.

Corresponding reactions can also be carried out with 1-alkynes or dialkylacetylenes; so far, however, side reactions such as oligomerization in the case of 1-alkynes and cotrimerization and cotetramerization in the case of dialkylacetylenes could not be avoided. In contrast, alkynes with electron-attracting moieties, such as propiolates or acetylenedicarboxylates, cyclotrimerize so rapidly that an addition to **1** no longer occurs.

The cycloadditions of **1** to **2** outlined here show some remarkable differences compared to analogous reactions of **1** with alkenes on the same or similar Ni^0 catalysts. Thus, all the methylenecyclopropanes so far employed codimerize with alkynylsilanes with opening of the distal three-membered ring bond, irrespective of the number or type of substituents in the two reactants. In the cycloadditions of **1a** with electron-deficient olefins, on the other hand, it depends on the substituents in the olefin as to whether the σ-bond adjacent to the C=C bond or the distal σ-bond of **1a** is opened[3b]; in contrast, the methylenecyclopropanes **1b**—**1e** with substituents on the C=C double bond always react with opening of the distal three-membered ring bond.[5]

The tendency for the formation of methylenecyclopentanes in which the groups R and R' are bound to the five-membered ring at the α-position to the methylene group is distinctly higher in the cycloadditions described here than in the corresponding reactions with olefins. With **1d**, for example, over 90% **4d** and **5d** is obtained; an exception is found only on codimerization with the methoxycarbonylalkynyltrimethylsilane (Table 1, Entry 14). In contrast, the methyl groups largely remain bonded to the methylene group in the Ni^0-catalyzed cycloadditions of **1** with electron-deficient olefins.[5] The phenyl-substituted compound **1e** behaves differently. In the cycloadditions of **1e** with electron-deficient olefins the phenyl groups remain attached to the methylene group,[5] whereas with alkynes, **3e** and **4e**/**5e** are generally formed in about equal amounts. Here too, an exception is the methoxycarbonylalkyne derivative, which affords only the methylenecyclopentene of type **3e**.

The regioselectivity of the addition is generally low. Consequently, additions with **1b**—**1e** lead to two isomers, **4** and **5**. The regioselectivity can, however, be influenced by changes in the electronic properties of the substituents on the alkyne (cf. Table 1, e.g. Entries 6, 9 and 14 or 4 and 12). The trimethylsilyl group can be regarded as a weakly negative substituent, obviously because of the interaction with the π-electrons of the triple- and double-bond.[7]

No detailed information can, as yet, be given about the mechanism of these cycloadditions. In particular, the structure of the organonickel intermediates (formulated, e.g., as "η^4-trimethylenemethane"-nickel complex or polar "η^3-trimethylenemethane" complex, as in the case of palladium[6]) is still unknown.

cis-Triaza-tris-σ-homobenzene as Tridentate Ligand $[La(C_6H_9N_3)_4 \cdot CH_3CN \cdot (ClO_4)_3]$: LaN_{12} Complex with Icosahedral Coordination**

By *Reinhard Schwesinger, Klaus Piontek, Walter Littke,* and *Horst Prinzbach**

Originally, the readiness of the *cis*-trihetero-tris-σ-homobenzenes **1**–**3** to complex metal ions was studied merely from the analytical or preparative viewpoint.[1] But severe limits are set on such applications because the interactions in solution are usually very weak. The complexes gained importance, however, through the fact that unusual coordination behavior ought to be realizable with the potentially tridentate ligands, because of their special geometric and electronic properties.[2,3] For example, in [Ca $\mathbf{1}_3 \cdot H_2O \cdot (ClO_4)_2$],[3] [Sr $\mathbf{1}_4 \cdot (ClO_4)_2$], and [Ba $\mathbf{1}_4 \cdot (ClO_4)_2$][4] **1** does in fact function as a tridentate ligand, whereby unusually high coordination numbers of 10 and 12 are realizable (CaO_{10}: tetracapped trigonal prism; SrO_{12}, BaO_{12}: icosahedron).

As with **1**, numerous, generally microcrystalline compounds of the cation composition $M\mathbf{2}_2$ ($M = Li^+$, Na^+, Ca^{2+}, Sr^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Co^{3+}), $M\mathbf{2}_3$ ($M = Ba^{2+}$, Sc^{3+}, Y^{3+}), and $M\mathbf{2}_4$ ($M = La^{3+}$, Lu^{3+}) (elemental analysis) were also isolated with **2**.[4,5] In the case of $[Co\mathbf{2}_2 \cdot H_2O \cdot (NO_3)_3]$ an X-ray structure analysis confirmed that **2** was present as tridentate ligand.[4] Single crystals of the higher coordinated compounds could only be obtained in the case of $La\mathbf{2}_4^{3+}$. In acetonitrile, leaflet-shaped prisms of **4** were formed, which, unlike the microcrystalline, colorless material, are pale yellow. Presumably, they decompose slightly during the course of (several weeks) crystallization (**2** is sensitive towards O_2 and CO_2[1]). This might also be responsible for the rather large deviations in some of the data obtained from the X-ray structure analysis (Fig. 1, 2)[6] (particularly regarding the C–C bond lengths).

$[La(C_6H_9N_3)_4 \cdot CH_3CN \cdot (ClO_4)_3]$ **4**

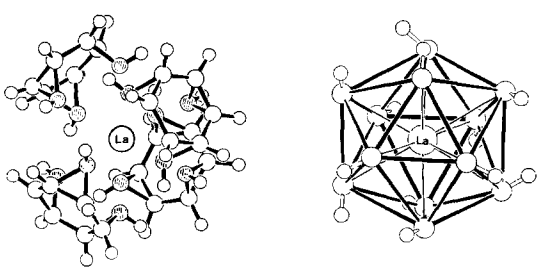

Fig. 1. Left: Structure of **4** in the crystal (N: hatched); right: LaN_{12} coordination polyhedron.

The central La^{3+} ion is complexed by four tridentate ligands **2**, the imino hydrogen atoms are oriented outwards, CH_3CN and counterions do not participate in the coordination. The coordination sphere corresponds to a slightly distorted icosahedron.[6] The mean N–N distance in **4** is smaller than that in the free H-bridged trisimine **2**; the interplanar angles in **4** are of the order of magnitude of the smallest in **2**; the C_6 rings in **4** are almost planar—consistent with the absence of the H-bridges and as a normal[4] consequence of complexation. The average H–N–La angle is 117°, which enables the imino hydrogen atoms to approach to within 2.7 Å of the adjacent N-atom of a neighboring molecule. Interactions between the imino protons and the perchlorate ions and CH_3CN molecules lead to a closest packing of the molecules.

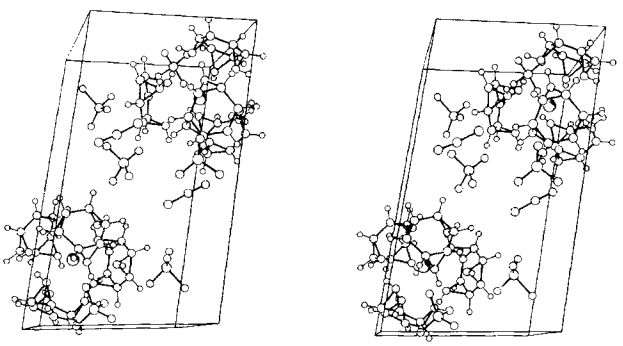

Fig. 2. Stereograph of the packing in the unit cell of **4**.

The MN_{12} coordination realized here is unusual;[7] in the case of $[Pr(Napy)_6 \cdot (ClO_4)_3]$[8] with the bidentate 1,8-naphthyridine (Napy) ligands, the deviations of the PrN_{12} polyhedron from the ideal geometry of the icosahedron are much greater. The stability of the 1:4 complex of **2** with $La(ClO_4)_3$ is due to a high lattice energy: In CD_3OD, no 1:4 complex is detectable (^{1}H-NMR); **2** ($\delta = 2.37$) forms the following complexes with $La(n\text{-}C_4F_9SO_3)_3$ **5** (depending on the stoichiometry, either as a single substance or as a mixture): $\mathbf{5} \cdot \mathbf{2}_3$ ($\delta = 2.73$, br. s, cf. the CaO_{10}-complex of **1**[3]); $\mathbf{5} \cdot \mathbf{2}_2$ ($\delta = 2.86$, br. s), $\mathbf{5} \cdot \mathbf{2}$ ($\delta = 2.91$, br. s) as well as a species of the (apparent) composition $\mathbf{5}_3 \cdot \mathbf{2}_2$ ($\delta = 2.95$, br. s). On addition of D_2O, lanthanum compounds precipitate out.

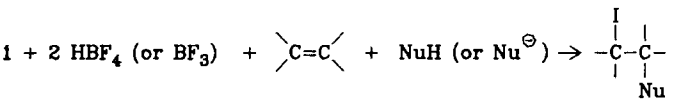
$I(py)_2BF_4$, a New Reagent in Organic Synthesis: General Method for the 1,2-Iodofunctionalization of Olefins**

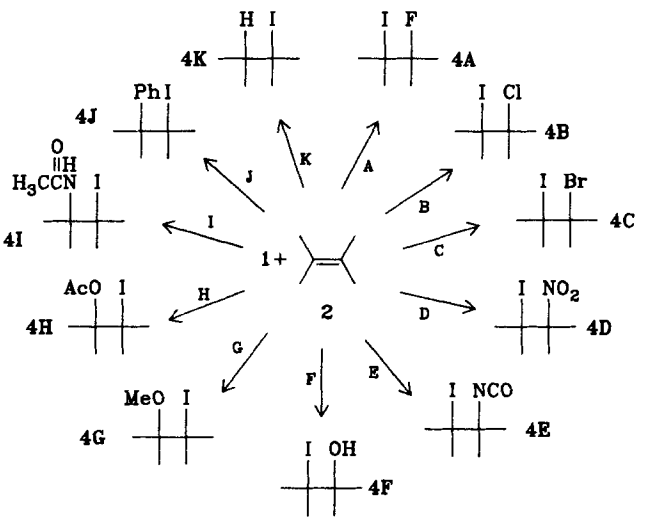
By *Jose Barluenga,* Jose M. González, Pedro J. Campos,* and *Gregorio Asensio*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday



The functionalization of olefins is an important process in organic synthesis. A common strategy is the use of iodine and a silver salt as reaction promoter to allow the iodofunctionalization by subsequent addition of a nucleophile. However, only strong nucleophiles or reagents giving stable I–Nu compounds can be added in this way to olefins.[1] A different approach, suggested by *Diner* and *Lown*,[2] is the use of bis(pyridine)iodine(I) nitrate. The scope of this method is, however, severely limited by the presence in the reaction medium of pyridine and the nitrate anion, which can act as nucleophiles.

In the course of our study on the mercury(II) oxide–tetrafluoroboric acid system as promotor in the iodination of arenes,[3] we found that this system, supported on silica gel, reacts with pyridine in the presence of iodine to afford a stable white solid, **1**.[4]



$$HgO \cdot HBF_4 \cdot \text{silica gel} + I_2 \xrightarrow[CH_2Cl_2]{\text{pyridine}} \underset{\mathbf{1}}{I(py)_2BF_4}$$

When compound **1** is allowed to react with olefins in the presence of a nucleophile and, if necessary, the stoichiometric amount of tetrafluoroboric acid or boron trifluoride to neutralize the pyridine, the corresponding 1,2-iodofunctionalized compounds **4** are obtained.

The low nucleophilicity of the $BF_4^{\ominus}$ anion allows a wide variety of charged as well as uncharged nucleophiles **3** to be added to the olefin **2**. Only in the absence of **3** does 1,2-iodofluorination take place.

The versatility of the bis(pyridine)iodine(I) tetrafluoroborate in the iodofunctionalization of olefins is illustrated in Scheme 1. Ethylene **2a**, cyclohexene **2b**,[5] and styrene **2c**[6] have been used as olefins; examples are given in Table 1. The products **4** showed elemental analyses and ^{1}H-NMR, ^{13}C-NMR, and IR spectra in good agreement with the proposed structures.

Scheme 1.

[**] This work was supported in part by the Comision Asesora de Investigacion Cientifica y Técnica (CAICYT).

Among the merits of the method it should be noted that a great variety of iodofunctionalized compounds are easily available from a single reagent, **1**, which is readily prepared from common chemicals. In this way, for instance,

the formal addition of H–I, Ph–I, and F–I to olefins is possible. The resulting 1,2-iodofunctionalized compounds can be converted into other synthetically useful compounds by transformation of the iodo functionality. The yields of compounds **4** and the reaction conditions have not yet been optimized.

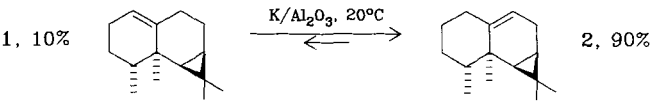
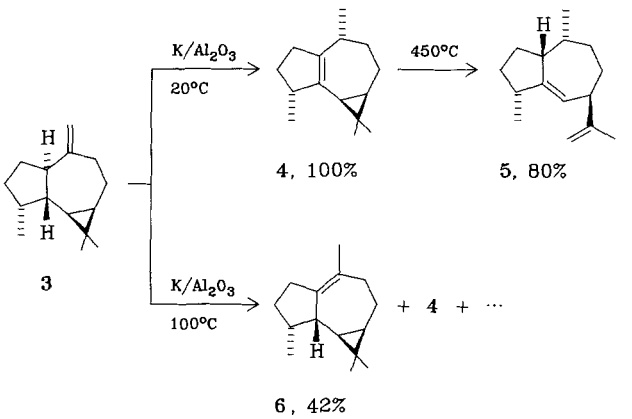
Catalytic Transformations of Sesquiterpene Hydrocarbons on Alkali Metal/Aluminum Oxide



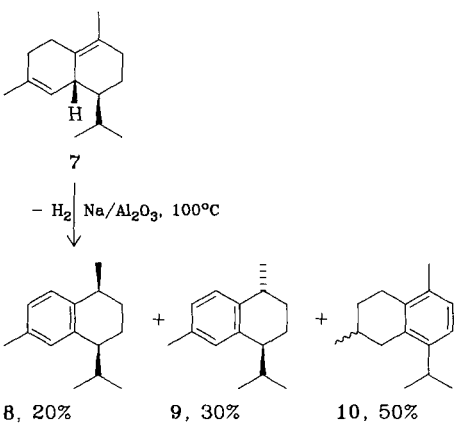
By *Roland Rienäcker** and *Jürgen Graefe*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

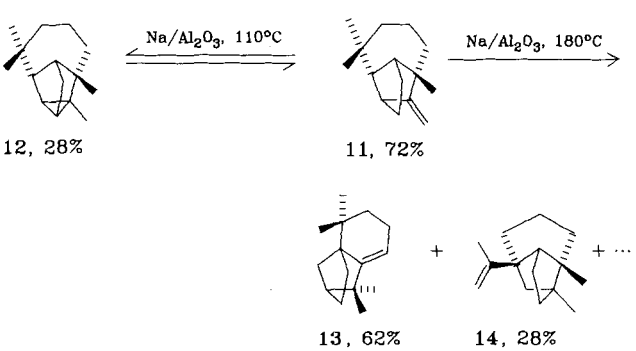


Of the variety of media used for the base-catalyzed isomerization of olefins,[1] alkali metal/aluminum oxide catalysts are especially noteworthy; according to our studies, they are able to effect new, selective transformations of cyclic sesquiterpene hydrocarbons. C=C bond shifts, dehydrogenations, and skeletal rearrangements can take place, depending on the structure of the substrate, the type of catalyst, and the reaction conditions. In some cases, compounds that were unknown up to now are formed.

Of the numerous sesquiterpene hydrocarbons studied by us, (+)-calarene **1**, (+)-aromadendrene **3**, (+)-δ-cadinene **7**, and (+)-longifolene **11** are presented here as examples of the possibilities of such catalytic transformations.



For instance, in the presence of K/Al_2O_3, **1** undergoes an extensive isomerization already at 20 °C to (–)-aristolene **2**, which is thus easily accessible for the first time.



The hydrocarbon (–)-**4**, unreported up to now, is obtained quantitatively from **3** with K/Al_2O_3 at room temperature; **4** can be transformed thermally to (+)-γ-gurjunene **5**.[5] When the isomerization of **3** with K/Al_2O_3 is carried out at 100 °C, 42% (+)-ledene **6** is obtained along with **4** and other isomers.

Upon treatment of **7** with Na/Al_2O_3, the isomerization is followed by a dehydrogenation with formation of (+)-*cis*-calamenene **8**, (–)-*trans*-calamenene **9**, and the hydrocarbon (+)-**10**.

When **11** is heated with Na/Al_2O_3, an equilibrium is established below 140 °C with (+)-longicyclene **12**. At higher temperatures, a skeletal rearrangement to (–)-isolongifolene **13**,[2] (–)-alloisolongifolene **14**,[3,4] and other

hydrocarbons takes place. Thus, e.g., a mixture containing 62% **13** and 28% **14** is obtained from **11** at 180°C.

The products were obtained in a purity of over 99% by vacuum fractional distillation on 1m-Spaltrohr® columns and identified on the basis of ^{1}H-NMR, ^{13}C-NMR, and mass spectroscopy, as well as on the basis of the physical data given in Table 1.

Table 1. Physical data of **1**—**14**.

[a] Specific rotation $[\alpha]_D^{20}$. [b] Calculated for optically pure **13**. [c] Neat.

Experimental Procedure

All work was carried out under argon with oxygen- and water-free solvents and with substrates that had been distilled from $NaAlEt_4$.

In order to prepare the catalysts, basic Al_2O_3 (Alumina Woelm® B-Super I) is dried in vacuum (1 torr) at 200°C and then vigorously stirred with 2 to 10 wt.-% sodium or potassium until the mixture cools. Uniformly colored, free-flowing powders are obtained which are not pyrophoric, but which, on exposure to air or water, immediately discolor and lose their activity. Na/Al_2O_3 is bright to dark grey, K/Al_2O_3 is bright to deep blue; the color intensity markedly increases with increasing alkali-metal content.

For isomerization or dehydrogenation, 5 to 10 wt.-% catalyst is added to the sesquiterpene hydrocarbons and the suspension is vigorously stirred for several hours under the conditions given. The course of the reaction is followed to completion by gas chromatography. Subsequently, the reaction products are distilled from the catalyst in an oil-pump vacuum.

Alternatively, in the conversion of **3** to **4**, 200 mL *n*-hexane and 400 g K/Al_2O_3 (10% K) are added per mole of **3**; at the end of the reaction, the catalyst is filtered off and the residue washed twice with *n*-hexane.

Torsional Isomerism in Metallocenes: Hindered Cp-Rotation in (*s-cis*-η-Butadiene)-bis(η-*tert*-butylcyclopentadienyl)zirconium**

By *Gerhard Erker,** Thomas Mühlenbernd, Reinhard Benn, Anna Rufińska, Yi-Hung Tsay,* and *Carl Krüger*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The cyclopentadienyl(Cp)-metal torsional barrier in metallocenes is often very small. The activation energy for rotation about the Cp—M bond, e.g. in ferrocene, has been determined reliably by various methods to be 0.9 to 1.8 ± 0.3 kcal/mol.[1] Consequently, rotation about the Cp(centroid)-metal vector in (η-cyclopentadienyl)transition-metal complexes has been regarded as unhindered in solution. This assumption, however, does not generally hold in the case of metallocenes when bulky substituents are present on the Cp ligands.[2] Substituted bent metallocenes are finding increasing application in organometallic chemistry.[3] We present here to the best of our knowledge the first evidence for hindered Cp-M rotation in solution in such molecules together with the estimated activation energy for this process.

At high temperature, the NMR spectra of (*s-cis*-η-butadiene)bis(η-*tert*-butylcyclopentadienyl)zirconium **1**[4] appear consistent with the molecule having C_{2v} molecular symmetry. Lineshape analysis of the low-temperature ^{1}H- and ^{13}C-NMR spectra reveals that this apparent simplicity of the high-temperature spectra results from two separate dynamic processes. In the 100.6-MHz ^{13}C-NMR spectrum of **1** at 188 K all the diene- and Cp-carbon atoms are nonequivalent (cf. Fig. 1, Spectrum A). On raising the temperature, pairwise coalescence of signals is observed (Spectrum B). We interpret this as resulting from equilibration of two enantiomeric Cp-rotational isomers **1** ⇄ **1′** (for a schematic representation, cf. Fig. 1). All these coalescences are consistent with a Gibbs activation energy of $\Delta G^{\neq}(233\,K) = 9.8 \pm 0.2$ kcal/mol. On increasing the temperature further, only two signals are observed for the Cp-methine carbon atoms (Spectrum C). In addition to the equilibration of the *tert*-butyl signals, the ^{1}H-NMR spectrum indicates that the terminal diene protons undergo exchange. This second dynamic process is a typical ring inversion in a metallacyclic σ^2,π skeleton (**1′** ⇄ **1″**),[5] for which a barrier $\Delta G^{\neq}(265\,K) = 13.5 \pm 0.2$ kcal/mol was estimated from the coalescences of signals in the NMR spectra. The transformation from apparent C_{2v}- via C_s-molecular symmetry to a chiral complex geometry can also be monitored in the temperature dependence of the 400-MHz ^{1}H-NMR spectra of **1**.[6]

The X-ray structure analysis of **1** shows a molecular geometry in the solid state that exhibits the characteristics of the most stable conformation found in solution at low temperature. The (*s-cis*-η^4-butadiene)zirconium moiety in **1** has a pronounced σ-character. The Zr—C1/C4 bond lengths are short. The substantially greater Zr—C2/C3 distances indicate π-interaction of the metal with the internal

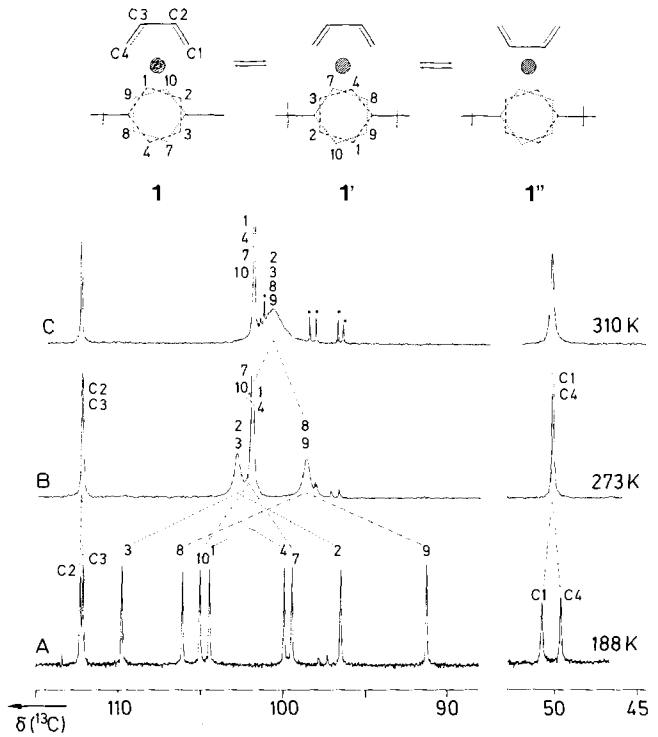

Fig. 1. Sections from the $^{13}C\{^1H\}$-NMR spectra (100.6 MHz, [D$_8$]toluene) of **1** at 188 K, 273 K, and 310 K. The signals marked with an asterisk do not belong to **1**.

diene positions.[7] Like the observed C–C bond length sequence (long/short/long) of the butadiene ligand, this is typical for diene-metallocene complexes of the group 4 transition metals.[5a,b] The most remarkable feature of the molecular structure of **1** is the arrangement of the substituted Cp-ligands; they are arranged in a staggered conformation, the *tert*-butyl substituents are located in the lateral sectors of the bent metallocene unit (Fig. 2). The C5–Cp5 and C9–Cp6 vectors are oriented at an angle of ca. 11° to the Cp planes pointing away from the metal. This, together with the small bending angle of the metallocene unit ($\theta = 122.5°$) compared to that in other Cp_2Zr complexes,[8] is probably due to steric interactions of the *tert*-butyl groups with the diene ligand.

It can be assumed that the preferred conformation of bis(*tert*-butylcyclopentadienyl)zirconium chloride **2**[9] has *trans* Cp substituents analogous to **1**. However, we found

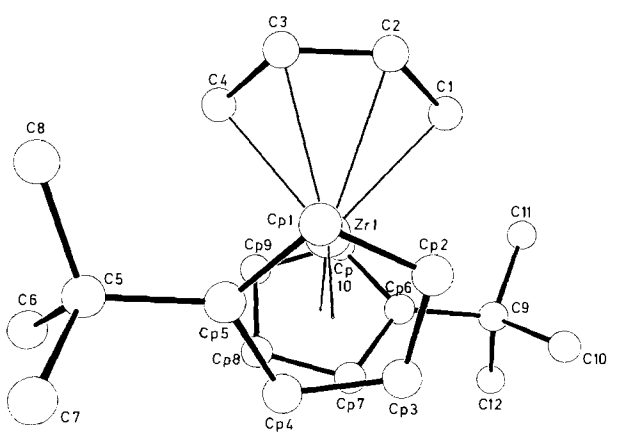

Fig. 2. Molecular structure of **1** in the crystal.

no indication of line broadening in the ^{13}C-NMR spectra of **2** down to −100°C that could be due to this rotamer (C_2 symmetry) freezing out in solution.[10] Therefore, the magnitude of the barrier to Cp-rotation in **1** appears to be determined by interaction between the diene ligand and the Cp substituents.

Ethynebis(triphenylphosphane)nickel(0)

By *Klaus R. Pörschke,* Yi-Hung Tsay,* and *Carl Krüger*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

According to *Reppe* and *Schweckendiek*,[1] a contact catalyst developed from $(Ph_3P)_2Ni(CO)_2$ **1** and ethyne at 100–120°C catalyzes the cyclooligomerization of ethyne at 60–70°C/15 atm to give a benzene/styrene mixture (7 : 1); it is assumed that ethynenickel complexes are involved in the catalytic cycle. Starting from $(Ph_3P)_2Ni(C_2H_4)$ **2**, *Wilke* and *Herrmann*[2] have obtained alkyne complexes $(Ph_3P)_2Ni(C_2R_2)$ with disubstituted acetylenes but not the ethyne complex. **2** does not react with ethyne in the cold; above −10°C, polyacetylene is formed.[2a] We have now succeeded in preparing via a modified reaction path the first ethyne complex of nickel(0)[3] **3** that is stable at room temperature.

When yellow **4**[4] is allowed to react with ethyne in ether at −78/−60°C, partial replacement of ethene occurs and a red-brown solution of the dinuclear complex **5**[5] is formed. This reacts at −30°C with further ethyne and a stoichiometric amount of triphenylphosphane to give **3**.

3 (yield 80%) crystallizes as yellow needles[6] which are stable towards air at room temperature (m.p. ca. 160°C, decomp.). In solution (tetrahydrofuran, toluene, CH_3CN) it slowly decomposes at 0°C with the formation of a brown flocculent precipitate ("niprene"). Reaction of **3** with $P(OPh)_3$ leads to liberation of ethyne; reaction with CO affords **1**. The CO-free complexes **2** and **3** catalyze the trimerization of ethyne without pretreatment ("Kontaktentwicklung"[11]) at 40°C/10 atm ethyne to give almost pure benzene (2% styrene). Like **3**, the complexes $(Ph_3P)_2Ni(C_2(H)CH_3)$ **6** (80%, yellow cubes) and $(Ph_3P)_2Ni(C_2(H)Ph)$ **7** (85%, fine rods) can be prepared in analytically pure form.

The ethyne ligand in **3** was characterized by an intense IR band ($\nu_{C\equiv C}$ = 1630 cm^{-1}) and by its ^{1}H- and ^{13}C-resonances (δ_H = 6.41 (m); δ_C = 122.1 (m)).[7] The coupling between the acetylenic H- and C-atoms is for **3** (J_{CH} = 212 Hz) less reduced compared to free ethyne (J_{CH} = 249 Hz) than for the corresponding trialkylphosphane complexes (J_{CH} = 201 Hz[3]). The ^{31}P-resonance of **3** (δ = 39.0) is shifted downfield considerably compared to that of **1** (δ_P = 32.6) and **2** (δ_P = 33.3; free PPh_3: δ_P = −5.5).

The X-ray structure analysis of **3**[8] revealed a structure comparable to the ethylene complex **2**[9] with trigonal-planar coordinated nickel atom (Fig. 1). The Ni–C bonds of **3** (1.873(3) and 1.882(3) Å) both lie below the P,P,Ni plane (angle to plane about 5.2°); the ethyne H-atoms even lie below the Ni,C,C plane and are turned away from the central atom (H–C–C 148(±2)°; H–C–C–H torsion angle 1°). The C–C distance of 1.239(4) Å in the ethyne ligand[10] is relatively short and lies between that in ethynecopper (1.19 Å[11]) and ethynemolybdenum or ethynetungsten complexes (1.29 Å[12, 13]). The propeller-shaped triphenylphosphane groups (Ni–P 2.153(1) and 2.166(1) Å) are oriented so as to minimize their steric hindrance.

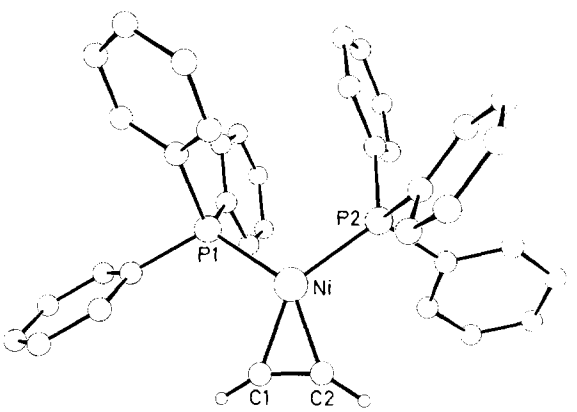

Fig. 1. Molecular structure of **3** in the crystal.

[5] K. R. Pörschke, unpublished. **5** is isolable in the form of yellow, temperature-sensitive needles. These and other bridged ethynenickel complexes will be reported on in more detail in a later publication.

[6] Procedure for **3** (with exclusion of oxygen and water): Ethyne (ca. 150 mL) was allowed to diffuse, without stirring, into a clear yellow solution of **4** [4] (1.88 g, 5.0 mmol) in ether (50 mL) at −60°C. The resulting reddish-brown solution was then treated with a solution of Ph_3P (1.31 g, 5.0 mmol) in ether (30 mL). On raising the temperature to −30°C, yellow crystals began to form. These were separated from the mother-liquor, washed twice with cold ether, and dried in an oil-pump vacuum. Yield of **3** 2.44 g (80%) (correct elemental analyses). (We thank *Petra Feldmann* for assistance with the preparative work.)

Simple Synthesis of Stable Iminoboranes**

By *Martin Haase* and *Uwe Klingebiel**

Tris(trimethylsilyl)methyllithium **1** and tris(trimethylsilyl)silyllithium **2** react with fluoro(trimethylsilylamino)silanes to give thermally stable silicon compounds of the type **3** and **4**, respectively.[1,2] Reaction of **1** and **2** with fluoro(trimethylsilylamino)phosphanes furnished the phos-

phaethenes **5** and stable silylated fluorophoshanes **6**, respectively.[2] The reaction of **2** with $(Me_3Si)_3C-PCl_2$, on the other hand, led to formation of the diphosphene **7**[3] via cleavage of $(Me_3Si)_3SiCl$.

We have now examined the reaction of **1** and **2** with difluorobis(trimethylsilyl)aminoborane. In tetrahydrofuran (THF), cleavage of LiF takes place in an exothermic reaction with formation of the substitution products **8** and **9**, respectively.[4] Compound **8** [$\delta(^{19}F) = 52$] steadily loses Me_3SiF on attempted distillation above ca. 60°C and could not be obtained in pure form; from **8**, the iminoborane **10** is obtained.[5] Compound **9** is stable up to 400°C and only thereafter loses Me_3SiF, with formation of the iminoborane **11**.[6]

Trimethylsilylimino[tris(trimethylsilyl)methyl]borane **10** and trimethylsilylimino[tris(trimethylsilyl)silyl]borane **11** are thermally unexpectedly stable iminoboranes;[7] e.g., no decomposition is observed up to 300°C during gas-chromatographic analysis. To our knowledge **10** and **11** are the first iminoboranes that can be stored for months at room temperature. Chemically, **10** and **11** are remarkably inert; e.g., **10** does not react with $AlCl_3$, $SiCl_4$, benzaldehyde, or methacrolein.

The structures of the substitution product **9** and of the iminoboranes **10** and **11** were elucidated by their NMR, IR, and mass spectra and by C,H elemental analyses. In the ^{29}Si-NMR spectrum of **10**, a coupling – $^1J_{SiN} = 15$ Hz – is observed, thus indicating the polar character of the iminoboranes.

Experimental:

A solution of **1** or **2** (0.05 mol) in THF (100 mL) was treated at room temperature with a solution of $F_2BN(SiMe_3)_2$ (0.05 mol) in THF (50 mL). In each case, the mixture was then heated under reflux for 1 h and the solution separated from LiF by filtration. **9** was recovered in pure form by distillation. **8** steadily loses Me_3SiF with formation of **10** on distillation at 60°C/0.01 torr. For recovery of **11** from **9** by cleavage of Me_3SiF, **9** was passed through a 30-cm furnace heated at 400°C at 6 torr. **10** and **11** were purified by distillation.

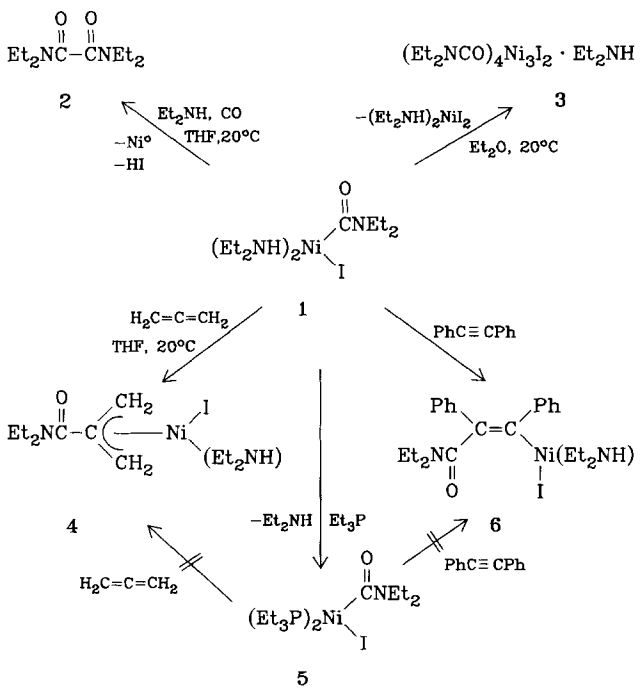
The First Isolated Carbonylation-Active σ-Carbamoylnickel Complex

By *Heinz Hoberg** and *F. Javier Fañanás*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday



Recently, we introduced a novel method for CC bond formation between CO and unsaturated substrates; it occurs under basic conditions, e.g., in the presence of secondary amines, with nickel(II) halides.[1] As intermediates, we postulated σ-carbamoylnickel complexes,[2] which, however, it has not yet been possible to isolate.

We have now succeeded in preparing the first reactive compound of this class of substances, the σ-carbamoylnickel iodide **1**. The compound, stable as a solid, is suitable for a variety of CC bond formations.

1

When a suspension of $(Et_2NH)_2NiI_2$ in Et_2NH/tetrahydrofuran (THF)/Et_2O (2/1/1) is treated with *one* mole equivalent CO (1 bar) at 20°C, the nickel salt dissolves, accompanied by a color change from green to dark red, and the ammonium salt Et_2NH_2I precipitates out almost quantitatively. The analytically pure σ-complex **1** can be isolated in 92% yield from the filtrate. The brown, microcrystalline solid **1** [m.p. = 82°C (decomp.)] exhibits characteristic bands in the IR spectrum (KBr) at 1480 [ν(C=O)] and 3120 cm^{-1} [ν(N−H)]. The mass spectrum contains peaks only for the ion fragments *m/z* 73 (Et_2NH) and 200 ($Et_2NCO-CONEt_2$, **2**); **2** is presumably formed by coupling of two Et_2NCO moieties. The carbamoyl complex **1** is diamagnetic, indicating a square-planar coordination in the *trans* configuration.

[*] Mof. Dr. H. Hoberg, Dr. F. J. Fañanás
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr 1 (FRG)

The complex **1** is unstable in solution (Et_2O) in the absence of Et_2NH and already disproportionates at 20°C into $(Et_2NH)NiI_2$ and the carbamoylnickel cluster **3**,[3] which is inactive for CC bond formation. The superb carbonylating activity of **1** is evident upon treatment with additional CO (1 bar) and Et_2NH in THF. Already at 20°C, the oxalic acid derivative **2**[1a,2a] is formed in 82% yield via intramolecular CC bond formation in a bis(carbamoyl)nickel complex which has not yet been isolated.

The ability of the Ni−C σ-bond in **1** to undergo addition to multiple bond systems is also very pronounced already at 20°C. Thus, upon addition of allene to a solution of **1** in THF, the η^3-allyl complex **4** [95%, m.p. = 82°C (decomp.); IR (KBr): ν = 1635 (C=O), 3130 cm^{-1} (N−H)] is formed via insertion. **4** can be protonated to give *N,N*-diethylmethacrylamide (67%) and, after addition of Et_2NH and CO (1 bar), yields the aminoamide $Et_2NCO-C(=CH_2)-CH_2NEt_2$ (69%), which is also obtained by the direct reaction of NiI_2 with allene, Et_2NH, and more than two mole equivalents of CO.[4]

1 reacts with diphenylacetylene via 1,2-addition to form the ocher-colored vinyl complex **6** [75%; m.p. = 102°C (decomp.); IR (KBr): ν = 1560 (C=O), 3160 cm^{-1} (N−H)]. **6** affords *cis-N,N*-diethyl-2-phenylcinnamamide (62%) upon protonolysis and the *N,N,N',N'*-tetraethyldiphenylmaleamide (68%)[5] after addition of Et_2NH with CO (1 bar, 20°C).

1 reacts quickly with a monodentate phosphane, such as Et_3P, via ligand exchange to form the inactive carbamoylnickel complex **5** (96%).[3]

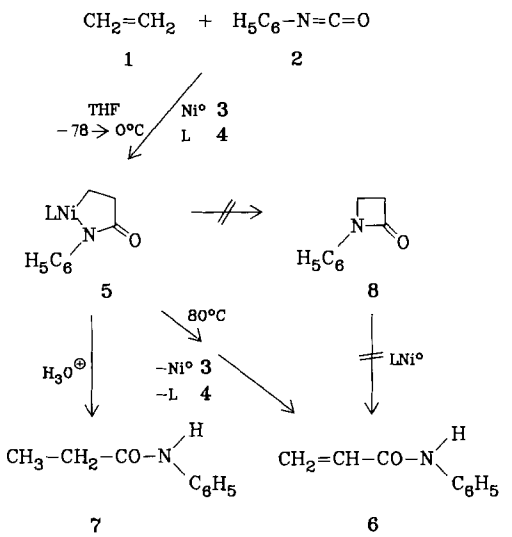
CC Bond Formation of Alkenes with Isocyanates on Ni^0 Complexes—a New Synthesis of Acrylamides

By *Heinz Hoberg,** *Klaus Sümmermann*, and *Armin Milchereit*



Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Acrylic acid derivatives are prepared by Ni-catalyzed reaction of ethyne with carbon monoxide and water, alcohols, or amines.[1] Reactive alkenes, such as enamines, can also react with isocyanates, the double bond being retained.[2] We report here the synthesis of acrylanilide from ethene and phenyl isocyanate on Ni(0) complexes.

Isocyanates react with multiple bond systems such as C≡C,[3] C=C,[4] C=N,[5] and C=O[6] on nickel(0) com-

plexes via 1 : 1-coupling to give five-membered nickelacycles, which are intermediates in catalytic cycles.[7] The reaction of ethene **1** with phenyl isocyanate **2** on Ni^0 complexes **3**,[8] in the presence of basic, sterically demanding monodentate ligands, such as (*cyclo*-$C_6H_{11})_3P$ **4**, leads to CC bond formation. When **2**, **3**, and **4** (mole ratio 5 : 1 : 1) are mixed in tetrahydrofuran (THF) at −78 °C in an autoclave in the presence of **1** (1 bar) and warmed to 0 °C over 20 h, then subsequently heated to 80 °C for 2 h, the acrylanilide **6** can be isolated in 90% yield (based on **3**) after hydrolytic workup.

The acrylanilide **6** is released already upon heating, and not only upon hydrolysis, thereby providing the basis for a catalytic reaction. The IR spectrum of the heated reaction solution already shows the typical bands of **6**, and, after removal of the volatile components, sublimation of the viscous reaction product at 60 °C and 10^{-6} bar also affords **6** (45%). **6** is presumably formed via an azanickelacyclopentanone, **5**,[9] which can be precipitated in 92% yield by the addition of *n*-pentane to the cold (−10 °C) reaction solution before it is heated to 80 °C.[10] As expected, the hydrolysis of **5** gives propionanilide **7** (83%).

We propose, therefore, the following reaction pathway for the formation of **6**: first, at low temperature, **1** couples with **2** on LNi^0 to form **5**. Upon heating, β-H cleavage and reductive elimination occur to give **6**. A route via the β-lactam **8** (**5**→**8**→**6**) can be ruled out, since independently synthesized **8** does not isomerize to **6** in the presence of LNi^0.

The formal addition of a vinylic C–H bond of ethene to the CN double bond of the isocyanate is the first metal-induced synthesis of an acrylic acid derivative from a non-activated alkene and an isocyanate.

Dimerization of a C_2B_3-*closo*-Carbaborane(5) to the C_4B_6-Adamantane and its 2z/3z Valence Isomerization to the C_4B_6-*nido*-Carbaborane(10)**

By *Roland Köster,* Günter Seidel,* and *Bernd Wrackmeyer*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Recently, we reported that pentaethyl-1,5-dicarba-*closo*-pentaborane(5) is dimerized in tetrahydrofuran (THF) by potassium metal and iodine to give decaethyltetracarbadecaborane(10).[1] Under the same conditions, we have now obtained **2**,[4a,5] which is also a crystalline dimer (MS),[3] from 2,3,4-triethyl-1,5-dimethyl-1,5-dicarba-*closo*-pentaborane(5) **1**;[2] **2**, however, undergoes autooxidation at room temperature. In the ^{11}B-NMR spectrum, **2** shows only one signal ($\delta = +65$) and is therefore not a C_4B_6-carbaborane,[1] but rather an organoborane with a C_4B_6-adamantane skeleton.[6,7] The X-ray structure analysis[8] confirms this and shows that, within the standard deviations, essentially all interatomic distances and bond angles of the C_4B_6 skeleton of **2** are in accord with those of the skeleton of the known $H_4C_4B_6(CH_3)_6$-adamantane.[9] Only the CC distances in the C_4B_6 skeleton of **2** are markedly longer by ≈0.07 Å.

With metallic potassium, a different type of product is slowly formed from **1** than from pentaethyl-C_2B_3-carbaborane(5). Upon treatment of **1** with potassium in a mole ratio of 1 : 1, the signal ($\delta = +13.5$)[6] of **1** vanishes completely in the ^{11}B-NMR spectrum of the diamagnetic solution. In addition to the resonances of small amounts of dicarba-*nido*-pentaborate(2−) 1^{2-}[1] ($\delta = -10, -24, -37$), an intense, broad signal ($\delta = +6.5$, $h_{1/2} \approx 900$ Hz) is observed. The oxidation of the equimolar K-**1** solution with iodine at 20 °C occurs rapidly with formation of **2**;[4a] **1** reacts with cesium in THF markedly faster than with potassium. Up to two moles of cesium are consumed per

[**] Boron compounds, Part 65. – Part 64: [1].

mole of **1**. **2** is obtained from the equimolar Cs-**1** solution with iodine; however, **1** is recovered from the 2Cs-**1** solution with iodine. The degree of metalation of **1** thus plays an important part in the C_2B_3 dimerization. **2** consumes potassium up to a mole ratio $\approx 1:2$ in THF at 0°C. Pure **2** can be recovered from the yellow-brown solution ($\delta^{11}B = +5.1$, $h_{1/2} \approx 1600$ Hz) with iodine at 0°C. From **1**, we have thus far only obtained a peralkylated C_4B_6-adamantane.[4b]

When **2** is heated in solution (e.g., mesitylene) or as a solid to ≈160°C, the isomer **3**[4c] with a C_4B_6-carbaborane structure[1] is obtained rapidly and quantitatively. The organoborane/carbaborane isomerization can be followed well by ^{11}B-NMR spectroscopy (cf. Fig. 1). **2**[10] thus differs clearly from the thermally highly stable $H_4C_4B_6(CH_3)_6$-adamantane.[7]

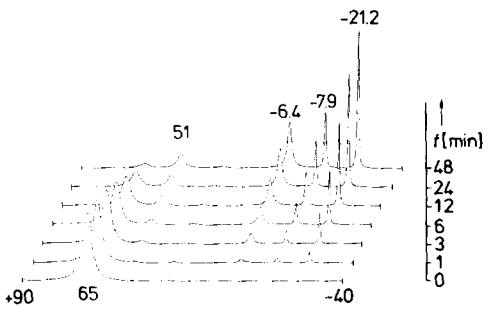

Fig. 1. ^{11}B-NMR spectra (96.3 MHz, [D_8]toluene, 25°C) [12] of the irreversible 2z/3z valence isomerization of **2** to **3**; recorded, in each case, after heating at ≈80°C.

The new carbaborane **3** has a dynamic structure. For the three ^{11}B-NMR high-field resonances of **3**,[11] an average signal ($\delta = -7.6$) is found above 100°C, while the ^{11}B-NMR signal at higher frequency ($\delta = +51$) becomes very broad.

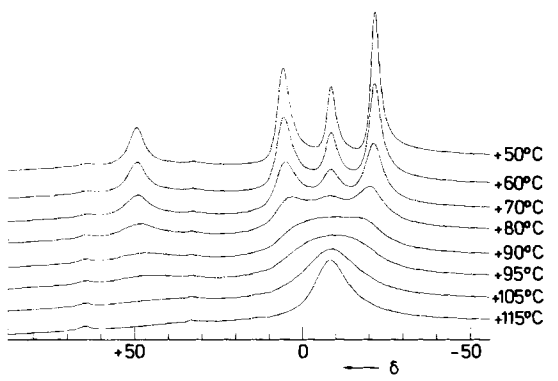

Fig. 2. Temperature-dependent ^{11}B-NMR spectra (64.21 MHz) of **3** in [D_8]toluene between 50 and 115°C.

The ^{13}C-NMR signals of the $CH_3(C)$ and $CH_3(CH_2B)$ groups are also broadened already at ≈20°C.[11] On the basis of the ^{11}B- and ^{13}C-NMR data, we suggest the same *nido*-C_4B_6 structure[13] for **3** as for the decaethyl derivative.[1]

In the dimerization of an equimolar mixture of 2,3,4-triethyl-1,5-dimethyl- and pentaethyl-1,5-dicarba-*closo*-pentaborane(5) using the potassium/iodine procedure, three C_4B_6-carbaboranes are obtained, which are separable by gas chromatography:[14] MS:[3] **3** (M^+, 348); $(H_3C)_2(H_5C_2)_2C_4B_6(C_2H_5)_6$ (376); $(H_5C_2)_4C_4B_6(C_2H_5)_6$ (404).[1] In the gas chromatographic separation,[14] owing to thermal equilibrium of the four skeletal C atoms, only one "mixed" dimer appears. An alkyl-methanetriyl exchange on the boron atoms can be ruled out by the results of the mixed dimerization.

3, like the decaethyl derivative,[1] is stable to ≈300°C. In contrast to **2**, **3** does not react at ≈20°C with oxygen. **3** is decomposed at ≈80°C by ethanol to ethyl-ethoxy boranes ($\delta^{11}B = 53.7, 31.1$). At 20°C in THF, **3** reacts with potassium metal; with cesium, it reacts markedly faster ($\delta^{11}B = -15.2$, $h_{1/2} \approx 100$ Hz). With iodine, **3** is quantitatively recovered from the yellowish brown solutions.

The formation of **3** from **2** is the first 2z/3z valence isomerization of an organoborane with $CN_B = 3$ to a carbaborane with $CN_B \geq 4$ to be followed by NMR spectroscopy (cf. Fig. 1). Apparently, the tendency to form carbaboranes depends, even for different alkyl substituents on the boron atoms, on the C substituents of the C_4B_6 skeleton. Thus, experimental evidence[15] is now available for the first time for the competition between classical and nonclassical structures in carbon-rich carbaboranes of the type $C_4B_nR_{n+4}$.

Crystal and Solution Structures of $[t\mathrm{Bu_2C{=}NLi\cdot O{=}P(NMe_2)_3}]_n$**

By *Donald Barr, William Clegg, Robert E. Mulvey, David Reed,* and *Ronald Snaith**

All previously known lithium methyleneamides have been clusters with the μ_3-amido ligands usually found over Li_3 triangular faces. Several lithium methyleneamides, such as **1a**, **1b**[1a], and **1c**,[1b] have solid-state hexameric structures (n = 6) based on slightly folded chair-shaped Li_6 rings with μ_3-N=CRR′ ligands over the six smaller of the eight triangular Li_3 faces. In contrast to these crystalline, soluble materials, lithium diarylmethyleneamides such as $(Ph_2C{=}NLi)_n$ are polymeric powders, though complexing agents can convert them into oligomers, e.g., the pseudo-cubane tetramer **2**[2a] and the pentanuclear lithiate **3**[2b]. **2**, like **1**, contains exclusively μ_3-N–Li linkages, though the latter additionally has amido ligands spanning Li_2 edges. Such μ_2-N–Li bonding is found in the compounds $[RR'NLi(donor)]_n$, n = 4, 3, 2, which always exist as $(NLi)_n$ rings, rather than as clusters. Examples are the tetramer **4**[3], the trimer **5**[4], and the dimer **6**[4].

[**] This work was supported by the U. K. Science and Engineering Research Council (*D. B., R. E. M., D. R., R. S.*) and by the Fonds der Chemischen Industrie (*W. C.* at the University of Göttingen, FRG).

The 1:1 complex **7** was obtained by reaction of HMPA with a solution of **1a** (see Experimental Procedure). Subsequent X-ray diffraction studies showed that complexation had in fact converted the hexameric cluster **1a** into the dimeric (n = 2) ring **7** (Fig. 1); **7** thus represents the first example of a lithium methyleneamide ring species in which the ligand exclusively engages in μ_2-bridging between two lithium atoms, as in **4**, **5**, and **6**.

The core of the solid-state structure of **7** is a strictly planar Li_2N_2 ring, the $C_2C{=}N$ plane being inclined at 58.6° to this ring. The Li–N bond lengths in **7** (1.923 and 1.948 Å)

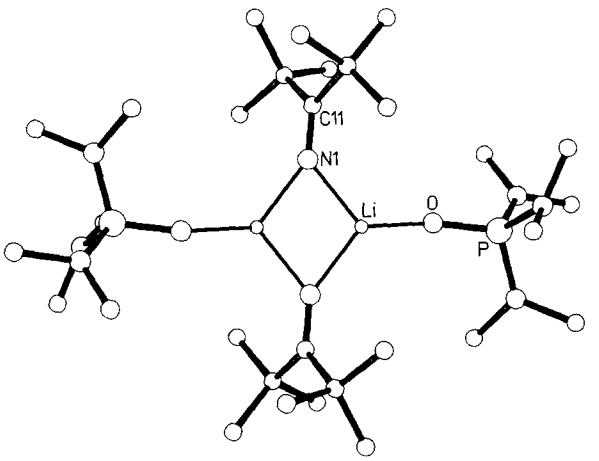

Fig. 1. Molecular crystal structure of **7**, n = 2. P$\bar{1}$, $a = 9.505(1)$, $b = 11.128(2)$, $c = 12.015(3)$ Å, $\alpha = 115.95(1)$, $\beta = 101.91(1)$, $\gamma = 98.22(2)°$, $Z = 1$, $R = 0.070$ for 2719 reflections with $F > 4\sigma(F)$. Further details on the crystal structure analysis can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD 51234, the names of the authors, and the journal citation.

are the shortest yet found in any organonitrogen-lithium ring compound, and can be compared with those in **6** (mean 2.007 Å)[4]. The ring angle at Li in **7** (104.6°) is slightly expanded compared to that in **6** (102.7°) and this, together with the shorter Li–N bonds, brings the lithium atoms much closer (Li···Li 2.368 Å in **7**, 2.505 Å in **6**); indeed the Li···Li distance in **7** is remarkably similar to the shortest ones found in the Li_3 triangles of **1** (2.395 Å).

Cryoscopic measurements at −108°C in tetrahydrofuran (THF) of (3,6-diethoxy-1-lithio-2,5-dimethyldihydropyrazine·1.5 thf)$_n$ which, like **7**, exists in the solid state as a dimeric $(NLi)_2$ ring[5], gave a value of n = 1.15, indicating a 5:1 ratio of monomer to dimer. Earlier isopiestic studies of the compound $[LiN(SiMe_3)_2]_3$[6] supported the existence of a monomer/dimer mixture in diethyl ether, whereas ^{7}Li-NMR spectra in THF at −40°C showed just one Li resonance at low concentration (assigned to the monomer); at higher concentrations, a second (dimer) resonance appeared[7]. Subsequently, a solid dimeric complex, $[(Me_3Si)_2NLi\cdot OEt_2]_2$, has been isolated from ether solution[3,8].

Molecular weight measurements show that in a dilute benzene solution (*ca.* 0.02 M) **7** has an average degree of aggregation of n = 1.12, indicating a roughly 6:1 preponderance of monomer over dimer, but that on concentration (to *ca.* 0.04 M), n increases to 1.33 (a 2:1 ratio).

In the high-field ^{7}Li-NMR spectra at room temperature (Fig. 2a), on dilution, the lower field resonance substantially grows (from 1:2.85 (n = 1.59) to 1:1.35 (n = 1.40)),

implying that it is due to Li nuclei within monomeric **7**. The corresponding ^{1}H-NMR spectra (Fig. 2b) support this conclusion: the two distinct *t*Bu group resonances have near-identical relative integration values to those of lithium (changing from 1 : 3.03 (n = 1.60) to 1 : 1.36 (n = 1.40) on dilution), though now the *t*Bu proton signals of the monomer are those at higher field. Therefore, on dilution, the $(NLi)_2$ ring, which is also present in the solid state, is cleaved. Amido-ligand exchange between the monomeric and dimeric species, if it occurs at all, is slow on the NMR time-scale.

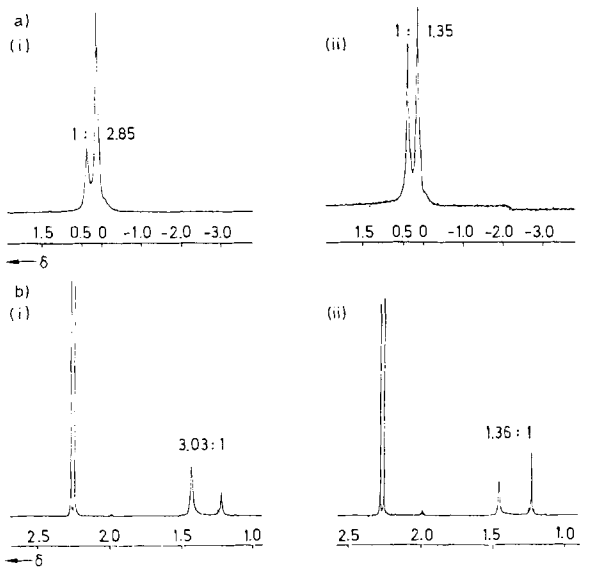

Fig. 2. High-field NMR spectra of **7** in [D_8]toluene at 33°C: a) ^{7}Li, 139.96 MHz; b) ^{1}H, 360 MHz; (i) relatively concentrated solution; (ii) dilute solution.

Experimental Procedure

Reaction of *t*BuCN (0.83 g, 10 mmol) in hexane (5 mL) with a chilled solution of *t*BuLi (5.0 mL of a 2.0 M solution in pentane, 10 mmol), gave a pale yellow solution of **1a**, n = 2. Addition of an equivalent of HMPA (1.79 g, 10 mmol) caused a deepening of the color, and cooling at −10°C afforded highly air-sensitive yellow crystals of **7**, m.p. = 128–130°C, yield 82%.

Activation Energy of the Racemization of Optically Active Tricarbonyl(tropone)iron Complexes**

By *Akio Tajiri,* Noboru Morita, Toyonobu Asao,* and *Masahiro Hatano*

The possible existence of tricarbonyl(tropone)iron **1**[1] in two enantiomeric forms, which was first noted by *Weiss* and *Hübel*,[2] prompted *Goldschmidt* et al.[3] to enrich a given isomer by selective destruction of the other with circularly polarized light. The recent interest shown in thermal rearrangements of polyene-transition-metal complexes motivated *Eisenstadt*[5] and *Hunt*[1c] to determine, by ^{1}H-NMR measurements, the activation energy of the 1,3 iron shift[4] which would racemize the complex **1**.

Herein we report on the resolution of **1** and 2,3-benzotropone(tricarbonyl)iron **2**[6] by high-performance liquid chromatography (HPLC) and on the determination of the kinetic parameters of the racemization by circular dichroism (CD) measurements on the optically active compounds **1** and **2** in solution.

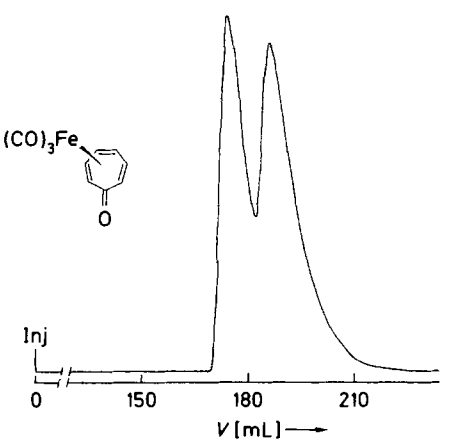

Fig. 1. Resolution of (±)-**1** at room temperature. Eluent: hexane/2-propanol (97 : 3); flow rate: 3 mL/min; column packing: CHIRALPAK OT(+); internal diameter of column 1.67 cm. *V* = elution volume.

Racemic complex **1** was resolved into the enantiomers at room temperature on a column packed with DAICEL CHIRALPAK OT(+), using hexane/2-propanol (97 : 3) as eluent (Fig. 1). Absorption and CD spectra of the first frac-

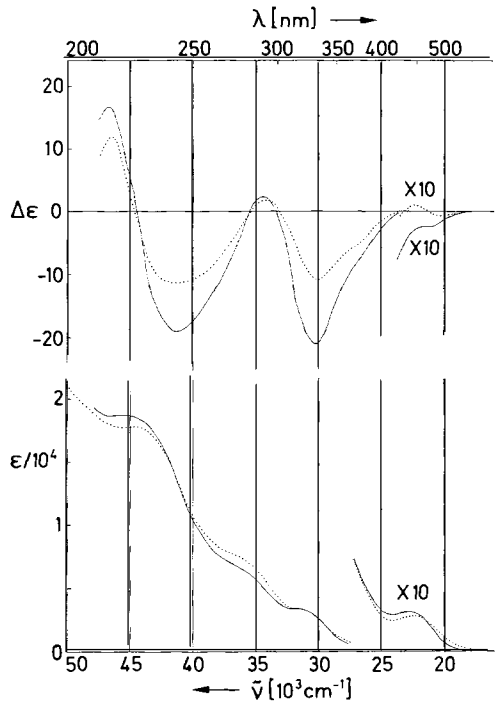

Fig. 2. Absorption (bottom) and CD (top) spectra of (−)-**1** in isooctane (—) and acetonitrile (·····) at room temperature.

tion, which is levorotatory, are illustrated in Figure 2.[7] $\Delta\varepsilon$ is 20—30, and, thus, only one tenth of the value found for biaryls[8] and helicenes.[9] The CD measurement in polar solvents indicates that the lowest wave number absorption shoulder, which occurs only in complexes, comprises two electronic transitions, one of which may be a charge-transfer (CT) transition.[10] A strong negative CD band at 30500 cm^{-1} could, in view of its position and its intensity, arise from a $\pi^* \leftarrow \pi$ transition of the distorted tropone ligand.

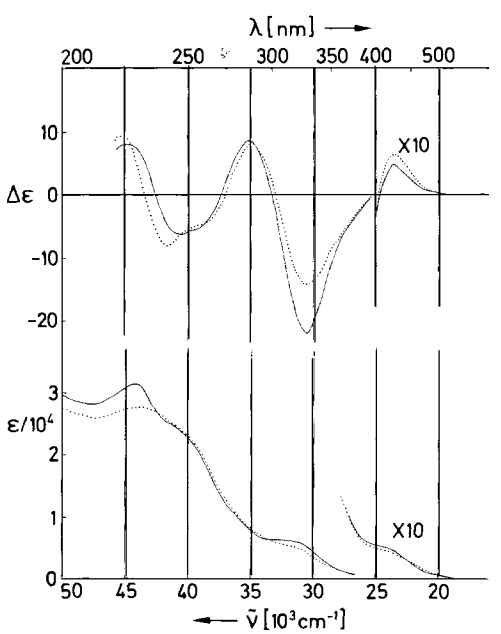

Fig. 3. Absorption (bottom) and CD (top) spectra of (−)-**2** in hexane (—) and acetonitrile (·····) at room temperature.

Absorption and CD spectra of the first fraction of **2**, which is likewise levorotatory, are shown in Figure 3. The spectra of (−)-**1** and (−)-**2** are similar in their profile. The second fraction in the resolution of both **1** and **2** is dextrorotatory and gives a mirror image of the CD spectrum of the first fraction.

The pure fractions racemize slowly within a week when stored in the dark at room temperature. Using the isooctane solution of (−)-**1**, the racemization in the temperature range 25—65 °C was monitored CD-spectroscopically by way of the band at $\tilde{\nu}_{max} = 30500\ cm^{-1}$. On plotting $\log K$ against $1/T$, a linear relationship is obtained, thus indicating that the racemization is a first order reaction. The activation energy for this process was found to be 25.8 kcal/mol^{-1} (108 kJ mol^{-1}). Experimental thermodynamic parameters at 65 °C are $\Delta G^{\neq} = 25.5$ kcal mol^{-1} (107 kJ mol^{-1}), $\Delta H^{\neq} = 25.1$ kcal mol^{-1} (105 kJ mol^{-1}), $\Delta S^{\neq} = -1.2$ kcal mol^{-1} (-5.0 J mol^{-1}) and $k = 2.7 \times 10^{-4}$ s^{-1}. Thus, the observed free energy of racemization is in agreement with the lower limit, 25 kcal mol^{-1} estimated by *Karel* et al.[4]

From a consideration analogous to that for the exchange process in tricarbonyl(cycloheptatriene)iron, a likely mechanism for the racemization of **1** involves a 1,3 iron shift by way of an η^2-intermediate. The activation energy of the racemization of **1** is substantially higher and the rate constant considerably smaller than in the isomerization of tricarbonyl(cycloheptatriene)iron and its derivatives; this is attributed to the strong interaction of the $2e_u$-MOs of $(CO)_3Fe$ with the HOMO of tropone.

Isooctane solutions of **2**, in which racemization is possible only through an intermolecular exchange process, exhibit no CD spectral change under the conditions of the racemization of **1**.[11]

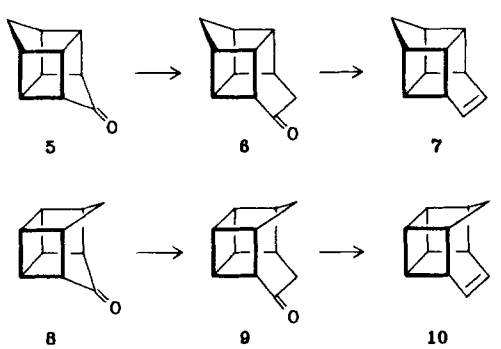
[11] Both (−)-**1** and (−)-**2** in solution exhibit distinctly different absorption spectra from that of **1** and **2** on prolonged heating (1 h) at temperatures over 50 °C, when decomposition seems to set in.

Intramolecular [4+2]-Cycloreversion of the Two Symmetrical Homobasketenes

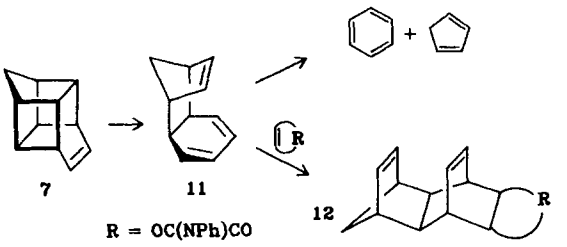
By *Wolfram Grimme,* Wolfgang Mauer,* and *Christian Sarter*



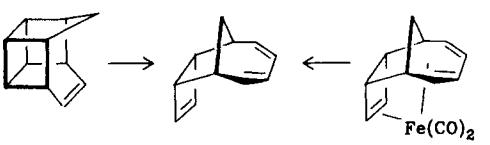
Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The reverse of the Diels-Alder reaction proceeds exothermally only in those cases when the fragments gain in aromatic resonance or when strain energy in the reactant is relieved. The latter-mentioned driving force is responsible for the intramolecular [4+2]-cycloreversion of basketene **1**[1] to give the *syn*-tricyclo[4.4.0.0^{2,5}]deca-3,7,9-triene **2** and of the asymmetric homobasketene **3**[2] to give the *syn*-tricyclo[5.4.0.0^{2,6}]undeca-3,8,10-triene **4**; both cage-openings are followed by further rearrangements.

1 **2** **3** **4**



The same mode of stabilization is open to the highly strained homobasketenes **7** (Table 1) and **10**; since we are interested in the relationship between structure and reactivity in cycloreversions, we have investigated the thermal behavior of the two cage compounds. The homobasketenes were obtained, using a standard method, from the bishomocubanones **5**[3] and **8**,[4] respectively, in which the symmetry of the target compounds is already present: Ring expansion with diazomethane in methanol/ether in the presence of lithium bromide affords the homologous ketones **6**[5] and **9**[6], respectively, which are converted with lithium diisopropylamide and diethyl chlorophosphate in tetrahydrofuran into the enol phosphates. Reduction of the enol esters with lithium in liquid ammonia/tetrahydrofuran/*tert*-butyl alcohol furnishes the homobasketenes **7** and **10**.[6]



5 **6** **7**

8 **9** **10**

The C_{2v}-homobasketene **7** decomposes to benzene and cyclopentadiene already at 80°C. This cleavage results from two consecutive [4+2]-cycloreversions, the first of which converts the homobasketene into the *endo*-tricyclo[6.2.1.0^{2,7}]undeca-3,5,9-triene **11**. This tricycle has already been obtained via an alternative route; its cleavage at 40°C to give benzene and cyclopentadiene is known.[7] The intermediate **11** can be trapped as the cycloadduct **12** (Table 1) if a mixture of **7** and *N*-phenylmaleimide (molar ratio 1:5) in dichloroethane is heated to boiling for 7.5 h; small amounts of the cycloadduct of cyclopentadiene are formed at the same time.

The C_s-homobasketene **10** undergoes cycloreversion at 150°C to give the tricyclo[4.4.1.0^{2,5}]undeca-3,7,9-triene **13**. The structure of **13** was established by independent synthesis from the dicarbonyliron complex **14**,[8] which is formed by photoaddition of cycloheptatriene to tricarbonyl(cyclobutadiene)iron. Oxidation with cerium ammonium nitrate in aqueous acetone leads to liberation of the organic ligand **13** from **14** (Table 1).

10 **13** **14**

Table 1. Some physical data of the compounds **7**, **12**, and **13**. The ^{1}H-NMR spectra were recorded at 90 MHz in $CDCl_3$ (that of **7** at 0°C in $CFCl_3$).

7, ^{1}H-NMR: δ=6.06 (AA'XX' half-spectrum, 2H), 3.32 (AA'XX' half-spectrum, 2H), 2.9 (m, 2H), 2.0 (m, 4H), 1.16 (t, 2H, CH_2); MS: *m/z* 141 (M^+), 78 ($C_6H_6^+$, 36%), 66 ($C_5H_6^+$, 100%)

12, m.p. 217–219°C (decomp.); ^{1}H-NMR: δ=7.5–7.0 (m, 5H), 5.64 (dd, 2H), 5.47 (t, 2H), 3.17 (m, 2H), 2.98 (t, 2H), 2.78 (m, 2H), 2.41 (m, 2H), 1.32 (AB, J=8 Hz, 2H, CH_2)

13, m.p. 86°C; ^{1}H-NMR: δ=6.10 (s, 2H), 5.7 (m, 4H), 3.45 (d, J=8 Hz, 2H), 2.6 (m, 3H), 2.23 (AB half-spectrum, J=11 Hz, 1H, CH_2); UV (hexane): λ_{max}=252 (ε=3800) sh, 257 (4200), 268 (3900), 279 (2100); MS: *m/z* 144 (M^+), 129 ($M^+ - CH_3$, 100%), 91 ($C_7H_7^+$, 36%)

In order to determine the kinetic parameters for the cleavage of **7** in dodecane solution between 81 and 85°C, the increasing extinction at 264 nm (cyclopentadiene absorption) was monitored until a constant value was observed. The kinetics of the isomerization of **10** were determined in heptane solution between 150 and 164°C by the ampule technique, the reactant/product ratio being measured by gas chromatography.

The activation parameters for the intramolecular [4+2]-cycloreversion of basketene **1** and its three homologues **3**, **7**, and **10** are listed in Table 2. Also listed is the strain re-

Table 2. Activation parameters and strain release for the intramolecular [4+2]-cycloreversion of basketene and its homologues.

Cpd.	log$A$ [a]	E_a [a] [kcal/mol]	ΔG^+(130°C) [kcal/mol] [a]	ΔE_{st} [kcal/mol]
1	13.2 [1]	29.7 [1]	29.8 [b]	113−(30+26+5)=52
3	12.8±0.5 [2]	35.3±1.0 [2]	35.6±0.1	74−(26+5+6) =37
7	12.0±0.6	25.9±0.4	28.2±0.1 [b]	81−(20+5) =56
10	12.5±0.7	33.2±1.2	34.0±0.2	87−(30+16) =41

[a] The error limits are the standard deviation from the linearly adjusted Arrhenius equation. [b] Because of twofold degeneracy of the reaction, $RT\ln 2$ was added.

Greinstrasse 4, D-5000 Köln 41 (FRG)

lease that occurs on opening of the cage compounds. Force field calculations are already available for the strain energy of the saturated educts;[9] the additional strain energy due to the double bond is almost the same in all four compounds and has been neglected. The strain in the products is made up additively from the contributions of the individual rings.[10]

There is a linear relationship [Eq. (1)] between the loss in strain energy ΔE_{st} and the free enthalpy of activation ΔG^{+} at 130°C; the correlation coefficient is 0.9999, at a confidence level of more than 99.5%.

$$\Delta G^{+} = 49.9 - 0.39\Delta E_{st} \qquad (1)$$

Equation (1) indicates that in the transition state for the opening of each of the structurally related cage compounds 39% of the strain release has occurred and that this alone determines the stability of the compounds. The extrapolation of Equation (1) to a [4+2]-cycloreversion without any loss of strain, which is not realizable in cage compounds, leads to $\Delta G^{+} = 50 \pm 0.6$ kcal/mol. For the cycloreversion of cyclohexene to ethene and butadiene, which proceeds without loss of strain, a free enthalpy of activation of 57 ± 1 kcal/mol at 130°C is obtained from the activation parameters;[11] the agreement is satisfactory, considering the extent of extrapolation.

A New Class of Tantalum(v) Dithiolate Complexes: Synthesis and Characterization of $[Ta(\eta^5\text{-}C_5Me_4R)(SCH{=}CHS)_2]$ (R = Me, Et) and $[Ta(\eta^5\text{-}C_5Me_5)(SCH_2CH_2S)_2]$

By *Kazuyuki Tatsumi, Junko Takeda, Yoitsu Sekiguchi, Masaki Kohsaka,* and *Akira Nakamura**

There is obvious fundamental and practical interest in understanding the chemistry of transition metal thiolate complexes because of their biological and catalytic implications.[1] In contrast to the ubiquitous *S*-coordinated chelate complexes of group 6, 7, and 8 transition metals, such complexes of group 5 metals, particularly of Nb and Ta, are scarce.[2-4] Herein we report the preparation[5a] and characterization[5b-d] of $[Ta(\eta^5\text{-}C_5Me_4R)(SCH{=}CHS)_2]$ **1a**, R = CH_3 and **1b**, R = C_2H_5 and $[Ta(\eta^5\text{-}C_5Me_5)(SCH_2CH_2S)_2]$ **2**.

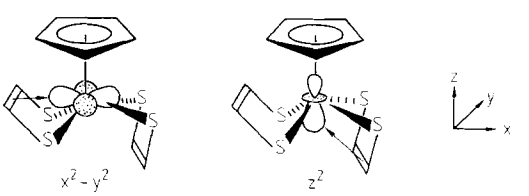
The ^{1}H-NMR spectrum of **1a** measured at 36°C shows a broad singlet at $\delta = 7.5$ for the SCH=CHS. At temperatures above 40°C, the broad peak begins to sharpen, while at low temperature (−50°C) it appears as two sharp singlets ($\delta = 7.14$, 7.84) of equal intensity. The spectral changes were found to be reversible and independent of concentration. On the other hand, the singlet of η^5-C_5Me_5 at $\delta = 2.25$ remained unchanged in the temperature range studied. These observations indicate the presence of two identical conformers in equilibrium, each of which contains orientationally nonequivalent dithiolate ligands.

Given the stoichiometry, $Ta(\eta^5\text{-}C_5Me_5)(SCH{=}CHS)_2$, the spectral data described above are consistent with the structure (I) in which two SCH=CHS ligands are folded around the SS axis, one with the open side pointing toward the η^5-C_5Me_5 group and the other with the opposite orientation. The conformation appears to be fluxional, and the mutual interconversion (I)⇄(I') occurs at a detectable rate ($\Delta G^{\ddagger}_{50°C} = 14.9$ kcal/mol, $\Delta H^{\ddagger}_{50°C} = 14.7$ kcal/mol, $\Delta S = -0.6$ cal mol^{-1} K^{-1}, $T_c = 34$°C),[6] probably by an inversion process of the five-membered TaS_2C_2 chelate rings. A similar temperature dependence of the SCH=CHS proton resonance was observed for **1b**, where the activation parameters were practically the same as those of **1a**. Nonplanarity of the TaS_2C_2 ring is not surprising, but is common to SCH=CHS complexes with d^0 transition metals, a typical example of which is the well-established structure of $[Ti(\eta^5\text{-}C_5H_5)_2(SCH{=}CHS)]$.[7] The folding in the Ti complex was attributed to the bonding interaction occurring between a vacant Ti d orbital and the occupied C=C π orbital of SCH=CHS.[8]

The interesting structure (I) can be explained with the aid of molecular orbital considerations. **1a** and **1b** contain four basal Ta–S σ bonds, forming a so-called four-legged piano stool skeleton. The d^0 "piano stool" molecule carries two low-lying vacant d orbitals[9, 10] (x^2-y^2 and z^2), which act as potential acceptors of electrons from the C=C π-donor orbital of SCH=CHS (Fig. 1); stabilization of **1** is maximal when both d orbitals are fully utilized in such a way that one C=C π orbital interacts with x^2-y^2 at the lateral side and the other π orbital with z^2 at the bottom. Conformation (I) fulfills this requirement.



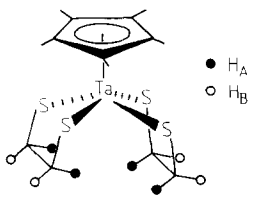


Fig. 1. Stabilization of the structure of **1a** and **1b**.

Lack of the additional donor interactions in **2** may be relevant to the experimental fact that **2** is much less stable than **1a** and **1b** under aerated conditions and/or in donor solvents, e.g., THF. The ^{1}H-NMR spectrum of **2** exhibits a symmetric A_2B_2 pattern for the SCH_2CH_2S protons, consisting of two multiplets at $\delta = 4.02$ and 4.64, and a singlet at 2.12 for the η^5-C_5Me_5 protons. This data is consistent with the structure (II). The spectrum is temperature independent between -70 °C and $+70$ °C, indicating that conformers arising from the possible ring puckering of the ethane portion are in labile equilibrium.

(II)

Noteworthy here is a contrast between fragmentation patterns observed in the EI mass spectra of **1a** (or **1b**) and **2**. In addition to the parent ion isotopic cluster, the mass spectrum for **2** exhibits two sets of peaks in close to theoretical isotopic abundances, which we assign as signals derived from $[Ta(\eta^5\text{-}C_5Me_5)(SCH_2CH_2S)(S_2)]^{\oplus}$ and $[Ta(\eta^5\text{-}C_5Me_5)(S_2)_2]^{\oplus}$. These ions are probably formed by a loss of one or two ethylene moieties from the parent ion. Fragmentation of **1a** (or **1b**), on the other hand, gave $[Ta(\eta^5\text{-}C_5Me_4R)(SCH{=}CHS)(SC_2H)]^{\oplus}$ and $[Ta(\eta^5\text{-}C_5Me_4R)(S_2)(SC_2H)]^{\oplus}$, R = Me or Et. The first step of fragmentation involves liberation of "SH" instead of C_2H_2. Although the mechanism of these fragmentations still needs to be elucidated, the unexpected behavior of **1a** and **1b** is compatible with the presence of bonding interactions between Ta and the olefinic carbons.

[4] Formation of $[V(\eta^5\text{-}C_5H_4Me)(S_2C_2R_2)_2]$, $R = CO_2CH_3$, CF_3, has briefly been reported on: C. M. Bolinger, T. B. Rauchfuss, A. L. Rheingold, *Organometallics 1* (1982) 1551.

[5] a) *Procedure:* A THF solution of $[Ta(\eta^5\text{-}C_5Me_5)Cl_4]$ was added slowly to a vigorously stirred suspension of two equivalents of $Na_2S_2C_2H_2$ in THF at -10 °C; an immediate color change from orange to dark green was observed. Rapid removal of THF followed by extraction with ether afforded a yellowish green powder. Recrystallization of the crude product from benzene and *n*-hexane afforded **1a** in 28% yield as analytically pure deep-green crystals [5b]. **1b** was synthesized in an analogous way from $[Ta(\eta^5\text{-}C_5Me_4Et)Cl_4]$ and $Na_2S_2C_2H_2$ [5b]. Treatment of $[Ta(\eta^5\text{-}C_5Me_5)Cl_4]$ with two equivalents of $Na_2S_2C_2H_4$ in CH_2Cl_2 at room temperature yielded **2** (23%) as a carmine-red crystalline powder [5c]. While **1a** and **1b** are relatively air-stable as solids, **2** is sensitive to air. All operations were carried out under an argon atmosphere, using degassed solvents.—**1a**, **1b**, and **2** gave satisfactory elemental analyses.—b) **1a**: m.p. 186—187 °C; ^{1}H-NMR (100 MHz, $CDCl_3$, room temperature) $\delta = 2.25$ (s, 15H, CH_3), $\delta = 7.5$ (br. s, 4H, SCH=CHS); MS (EI, 75 eV) *m/z* (rel. intensity) 499 (2), 498 (14), 497 (16), 496 (100, $C_{14}H_{19}S_4Ta$), 465 (2), 464 (3), 463 (40, $C_{14}H_{18}S_3Ta$), 439 (4), 438 (9), 437 (36, $C_{12}H_{16}S_3Ta$).—c) **1b**: m.p. 137—139 °C; ^{1}H-NMR ($CDCl_3$, room temperature) $\delta = 1.07$ (t, $J = 7$ Hz, 3H, CH_2CH_3), $\delta = 2.24$ (s, 12H, CH_3), $\delta = 2.56$ (q, 2H, CH_2CH_3), $\delta = 7.5$ (br. s, 4H, SCH=CHS); MS (EI, 75 eV) *m/z* (rel. intensity) 513 (4), 512 (20), 510 (100, $C_{15}H_{21}S_4Ta$), 479 (5), 478 (6), 477 (32, $C_{15}H_{26}S_3Ta$), 453 (6), 452 (8), 451 (34, $C_{13}H_{18}S_3Ta$).—d) **2**: m.p. 135—137 °C; ^{1}H-NMR (C_6D_6 or $C_6D_5CD_3$, room temperature) $\delta = 2.12$ (s, 15H, CH_3), $\delta = 4.02$, 4.64 (m, $J_{gem} = -11.5$ Hz, $J_{vic}(cis) = 3.5$ Hz, $J_{vic}(trans) = 7.4$ Hz, 8H, SCH_2CH_2S); MS (EI, 75 eV) *m/z* (rel. intensity) 503 (0.4), 502 (1.7), 501 (1.5), 500 (7.8, $C_{14}H_{23}S_4Ta$), 475 (3), 474 (17), 473 (15), 472 (88, $C_{12}H_{19}S_4Ta$), 447 (3), 446 (20), 445 (15), 444 (100, $C_{10}H_{15}S_4Ta$).

Complete Signal Assignment of the ^{13}C-NMR Spectra and Structure Determination of Corrinoids by 2D-INADEQUATE and 2D ^{13}C,^{1}H-NMR Chemical Shift Correlation Using ^nJ(C,H)

By *Reinhard Benn** and *Richard Mynott*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The structural analysis of corrinoids[1,2] has relied upon X-ray crystallography, chemical synthesis, and reaction studies and upon spectroscopic investigations. However, although the ^{1}H- and ^{13}C-NMR spectra of corrinoids are potentially very informative, the presence of several similar structural subunits makes it difficult to assign all the resonances unambiguously. As a result, a large variety of substances for comparison and the use of a number of special NMR techniques have usually been required.[3] We report here the application of 2D-NMR techniques to such compounds and show that 2D-INADEQUATE[4] or 2D ^{13}C,^{1}H-NMR[4] chemical shift correlation diagrams using ^nJ(C,H) are most powerful methods for making the assignments quickly and reliably and for determining the structure of corrins.

Heptamethyl cobyrinate **1**,[5] in which the cobalt has the formal oxidation state +1, is very soluble in benzene; it was therefore possible to obtain a 2D-INADEQUATE ^{13}C-NMR spectrum of a saturated solution at 100.6 MHz. Although the resonances of the 52 nonequivalent carbon atoms in **1** are found over a range of more than 17 kHz and the ^1J(C,C) coupling constants lie between 30 and 80 Hz,[6] all the carbon signals, with the exception of those from the methoxy groups, could be identified and assigned, starting with the trivial assignment of C1, C10, and C19 (Fig. 1).

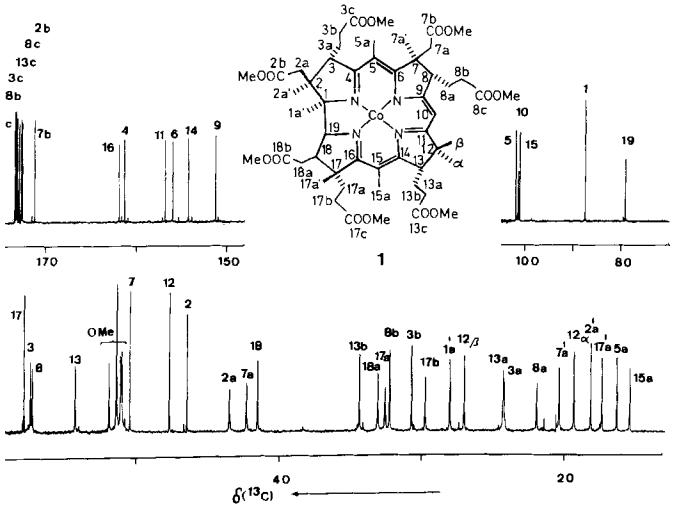

Fig. 1. Structure and ^{13}C-{^1H}-NMR spectrum of **1** recorded at 100.6 MHz (ca. 40 wt.-% in [D_6]benzene, sample volume ca. 3 mL).

Using the ^{13}C satellites of the olefinic carbon atoms 16, 4, 11, 6, 14, and 9 (Fig. 2), the resonances of their nearest neighbors were identified (i.e., 15 and 17; 3 and 5; 10 and 12; 5 and 7; 13 and 15; and 8 and 10, respectively).

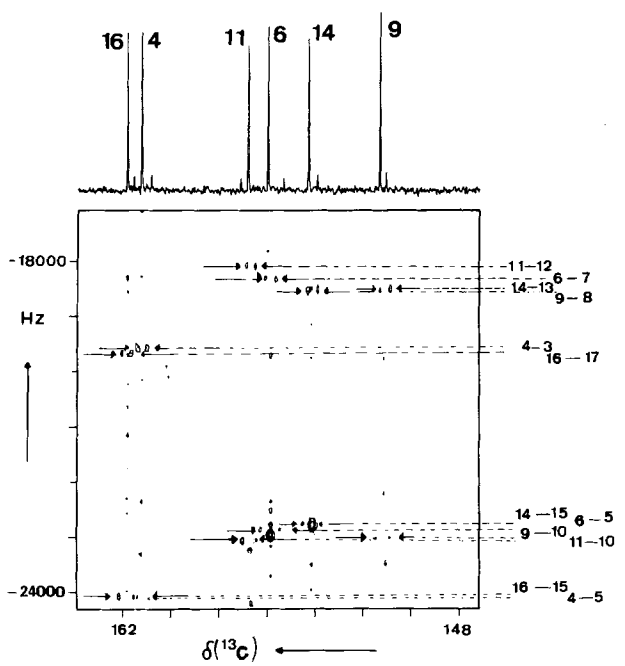

Fig. 2. Expansion of part of the low-field region of the 100.6-MHz ^{13}C-{^1H}-NMR spectrum of **1** (top) and of the 100.6-MHz 2D-INADEQUATE spectrum of the same sample (data matrix 4 K × 256, optimized for $^1J(C,C) = 54$ Hz, relaxation delay 1 s, 768 scans per increment, total measurement time 60 h) (bottom).

The ^{13}C satellites of these signals then revealed the connectivities of the skeletal carbon atoms 1—19. This in turn allowed the signals of all the other carbon atoms to be assigned, with the exception of the methoxy carbons. The latter, however, could be assigned from the 2D ^{13}C,^1H-NMR correlation diagram using the $^3J(C,H)$ coupling constants to identify the signals of the carbonyl carbon atoms to which the methoxy groups are bound (see Fig. 3).

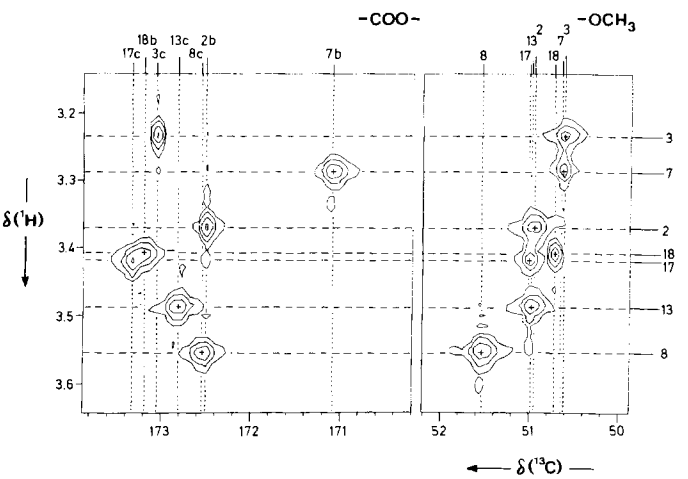

Fig. 3. Expansion of part of the 75.5-MHz ^{13}C,^1H-NMR chemical shift correlated spectrum of **1** ($\delta(^{13}C)$ along the x axis, $\delta(^1H)$ along the y axis, data matrix 4 K × 512, optimized for $^nJ(C,H) = 12$ Hz) showing the cross peaks of the carbonyl and O—CH_3 groups which stem from coupling to identical methoxy protons.

The proton signals of the remaining eight methyl groups are all singlets. The carbon atoms two and three bonds removed from these protons can also be identified via the $^nJ(C,H)$ couplings, since the signal assignment and the location of a given carbon in the skeleton can be derived by examining the cross peaks arising from the coupling with different protons. The assignments (Table 1) using the two techniques, which did not require prior assignment of the proton NMR spectrum, were made independently and are consistent with one another.

These results show that it is possible to determine the structure of corrinoids and to assign all the ^{13}C-NMR signals by 2D-NMR techniques. While the 2D-INADEQUATE method is more direct and does not require additional information, it needs more material in solution and a longer measurement time. The analysis can also be carried out using the 2D ^{13}C,^1H-NMR chemical shift correlation technique. The more methyl signals in the proton spectrum that are present as sharp singlets, the more effective the method. The cross peaks then undergo little modu-

Table 1. ^{13}C-NMR chemical shifts of **1** ([D_6]benzene, relative to internal TMS, 310 K). The numbering of the carbon atoms is given in Fig. 1.

lation due to $^1H,^1H$ coupling and the loss of magnetization occurring during the longer intervals in the pulse sequence for small $^nJ(C,H)$ couplings is not critical, even when the standard pulse sequence is employed.[7]

There are large differences between the chemical shifts of **1** and those of the corresponding dicyano Co(III) corrin **2**.[8] The same is found when the corrin skeleton is modified—even the signals of carbon atoms well removed from the site of alteration can be shifted considerably.[9] In some cases this can be interpreted as being due in part to changes in the conformation of the skeleton. It thus follows that conventional methods of assignment, such as comparison with related systems (as, for example, so successfully applied to steroids) are not only much more time consuming but can in addition lead to errors in interpretation.

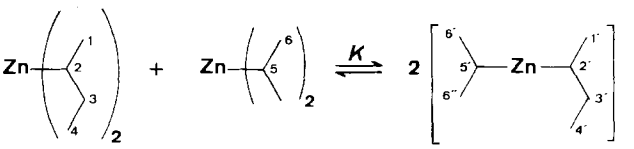
[7] H. Kessler, C. Griesinger, J. Lautz, *Angew. Chem. 96* (1984) 434; *Angew. Chem. Int. Ed. Engl. 23* (1984) 444, have reported a modified pulse sequence for 2D $^{13}C,^1H$-correlated spectra using long-range couplings. The INADEQUATE pulse sequence can be employed when more concentrated samples are available. Since this pulse sequence is a priori shorter, the losses due to relaxation in the case of **1** were not significant.
[8] The assignment of the ^{13}C resonances of **2**, obtained from the 2D $^{13}C,^1H$-NMR chemical shift correlation using $^nJ(C,H)$ without assignment of the ^1H-NMR spectrum, is consistent with that given in [3]. The resonances of C1, C8, C10, and C19 in **2** are shifted by 5.0, 3.1, 10.3, and 4.5 ppm, respectively, relative to those of **1**. The signals of C4, C6, C9, C11, C14, and C16 are shifted by -10 to -20 ppm relative to those of **1**.
[9] Hexamethyl 7-decarboxymethyl-7,8-didehydrocobyrinate **3** can be prepared from **1** by thermolysis (compare with the thermolysis of **2**, L. Ernst, G. Holze, H. H. Inhoffen, *Liebigs Ann. Chem. 1981*, 198). In the ^{13}C-NMR spectrum of **3**, even the signals of C18, C19, and C1, which are well removed from the site of the elimination, are shifted by 2.0, 3.4, and 4.3 ppm, respectively, relative to those of **1**.

^{13}C-NMR Spectroscopy of Mixed Dialkylzinc Compounds with Prochiral Alkyl Residues



By *Richard Mynott,* Barbara Gabor, Herbert Lehmkuhl,* and *Ingo Döring*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The existence of mixed diorganozinc compounds of the type R^1R^2Zn is disputed. According to *Job* and *Reich*,[1] they readily undergo exchange to form the symmetrical compounds R^1_2Zn and R^2_2Zn. Other authors[2–5] have reported that mixed diorganozinc compounds are isolable species which form the symmetrical components only after standing for some time or on warming.[2] Recent mass spectroscopic and calorimetric investigations show that mixed diorganozinc compounds are present in equilibrium with the symmetrical compounds.[6]

$$2\,R^1R^2Zn \overset{K}{\rightleftharpoons} R^1_2Zn + R^2_2Zn$$

We have now been able to prove the existence of mixed diorganozinc compounds directly by ^{13}C-NMR spectroscopy.

1 **2** **3**

In the course of ^{13}C-NMR investigations on dialkylzinc compounds with chiral alkyl groups, we observed splitting of the ^{13}C signals that appeared to be due to the presence of diastereoisomers. In bis(*sec*-butyl)zinc **1**,[7] the *sec*-butyl residue contains a chiral carbon atom; therefore, two sets of signals are to be expected, corresponding to the diastereoisomers in which these carbon atoms have the same (*RR,SS*) or different (*RS,SR*) configurations. This splitting is observed for each carbon resonance in the ^{13}C-NMR spectrum of **1** at -30°C (Fig. 1a).

In order to establish the formation of mixed species that contain two structurally different alkyl groups rather than groups that differ only in configuration, bis(isopropyl)zinc **2** was selected as the second component. There is just one methyl resonance observed in the ^{13}C-NMR spectrum of pure **2**[7] in [D_8]tetrahydrofuran (THF) (Fig. 1b) because the methyl groups are enantiotopic. The methyl carbons should (with the possible exception of restricted rotation at very low temperatures) give different signals *only* if the isopropyl group is part of a chiral compound.

The ^{13}C-NMR spectrum (-30°C) of a 1:1 mixture of **1** and **2** prepared at room temperature in [D_8]THF is shown in Figure 1c. In addition to the signals of **1** and **2**, resonances of a third component are observed which are assigned to the mixed compound **3**. Particularly significant is the nonequivalence of the methyl carbons C6′ and C6″ (numbering given in the formula) of the isopropyl group ($\delta = 23.50$ and 23.44, respectively).[8] This proves conclusively that the isopropylzinc moiety is bound to a chiral residue. The signal intensities indicate that **1**, **2**, and **3** are present in the ratio 0.27:0.40:0.33, so that the equilibrium constant K for the formation of **3** is 1.0 within experimental error.

The 25.2-MHz ^{13}C-NMR spectra of pure **1** in [D_8]THF and in [D_8]toluene were recorded between -80°C and $+35$°C. Although the splittings of the signals become smaller at higher temperature, the signals from C2, C3, and C4 of the diastereoisomers could still be resolved even at $+35$°C in [D_8]THF.

It was not possible to carry out a lineshape analysis of the exchange-modified resonances to obtain the thermodynamic parameters because the separations of the respective signal pairs are strongly temperature dependent. Neverthe-

less, the observation of a splitting of just 0.8 Hz for C3 at 35°C places an upper limit on the exchange rate ($k < 4$ s^{-1})[9] at this temperature. In [D$_8$]toluene, the signal splittings were smaller ($\Delta\delta < 0.06$). They also become smaller at higher temperature and were not resolved above 20°C.

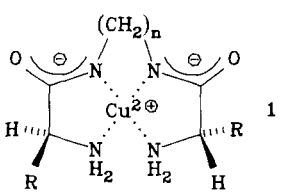
[8] ^{13}C-NMR spectra: Varian XL 100 15A or Bruker WP 80 FT (25.2 and 20.1 MHz, respectively). δ (20.1 MHz, [D$_8$]THF, −30°C) relative to int. TMS: **1**: δ = 31.68, 31.62 (C3); 26.54, 26.43 (C2); 20.12, 20.10 (C1); 17.40, 17.30 (C4).—**2**: δ = 23.79 (C6); 15.38 (C5).—**3**: δ = 31.87 (C3'), 26.08 (C2'), 23.50, 23.44 (C6', C6"); 20.47 (C1'); 17.43 (C4'); 15.62 (C5').
[9] The exchange process for the diastereoisomers in pure **1** is not a simple two-site exchange since not all transfer reactions lead to a change of environment for a given alkyl group. For example, exchange of alkyl groups between two molecules with *RR* configurations will not result in a change in environment for any alkyl group, while that between *RR* and *RS* molecules will change that of only two of the alkyl groups. Overall, the rate of exchange of alkyl groups in cases where the environment is changed (e.g., *RR* to *RS*, or vice versa) is exactly half the total rate of alkyl exchange. Since the two signals for C3 are resolved ($\Delta\nu = 0.8$ Hz), the apparent rate of exchange must be less than that at coalescence ($k = 2.22\,\Delta\nu$), so that the real exchange rate must be less than 4 s^{-1}. The activation energy for alkyl exchange is therefore greater than 72 KJ/mol.

Chiral Copper(II) Complexes for the Enantioselective Resolution of DL-Dansyl-Amino Acids by HPLC**



By *Rosangela Marchelli,* Arnaldo Dossena, Giuseppe Casnati, Francesco Dallavalle,* and *Shulamith Weinstein*

Separation of free or derivatized DL-amino acids by HPLC has mainly been achieved by using either chiral complexing stationary phases[1] or chiral metal complexes as additives to the mobile phase.[2] In both cases, the enantiomeric separation has been generally interpreted as being due to ligand exchange.

We report here the preliminary results obtained from a systematic study aimed at increasing the understanding of the molecular mechanism of chiral recognition. The present ligands were specifically designed to study the correlation of the structure and the stability of their copper(II) complexes with the ability of the complexes to separate DL-dansyl-amino acids, as well as to provide an insight into the nature of the interactions involved in the chiral recognition.

The main feature of the new ligands AA-NN-2 and AA-NN-3 is that two L-amino acid amides are joined via the amide nitrogen atoms by ethylene and trimethylene bridges, respectively, and endowed with varying degrees of lipophilicity and bulkiness according to the nature of the amino acid side chain (AA = alanine, valine, phenylalanine). They are easily synthesized as hydrochlorides in high yields (>90%) by condensation of the hydroxysuccinimidic esters of L-Z-amino acids (Z = benzyloxycarbonyl) with 1,2-ethane- and 1,3-propanediamine, respectively, followed by deprotection via hydrogenolysis and treatment with HCl in MeOH.

In agreement with the reported behavior of similar ligands,[3] AA-NN-3 forms only *one* complex with copper(II), $CuLH_{-2}$ **1**, in the pH range 7–8, whereas AA-NN-2 forms *two* Cu(II) complexes, $(Cu_2L_2H_{-2})^{2+}$ and $CuLH_{-2}$. However, since the best enantiomeric separation was obtained between pH 7.5 and 8, where the species $CuLH_{-2}$ is predominant, we assume that the latter is the species involved in the separation.

1. A typical separation of a racemic mixture containing a number of amino acids is shown in Fig. 1.

Table 1. Separation factors α of DL-dansyl-amino acids [a].

DL-dansyl-amino acid	L = Phe-NN-2 α	L = Phe-NN-3 α
glutamic acid	2.20	1.23
aspartic acid	2.48	1.36
serine	2.00	1.29
threonine	1.50	1.11
α-aminobutyric acid	1.23	1.00
valine	1.16	1.00
methionine	1.27	1.00
phenylalanine	1.47	1.10
tryptophan	2.01	1.20

[a] Column: 24 × 0.46 cm, C_8, 10 μm; eluent: H_2O: CH_3CN (67:27), $Cu(OAc)_2$ 2 mM, L 2 mM, NaOAc 0.3 M; pH = 7.5; flow rate 1.3 mL/min; room temperature; $\alpha = R_L/R_D$, where R_L and R_D are the adjusted retention times of the L and D enantiomers.

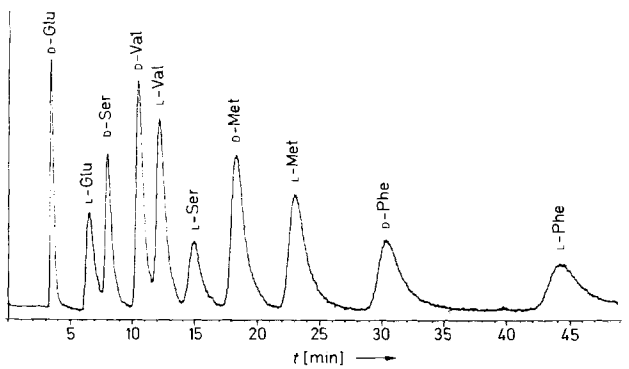

Fig. 1. HPLC separation of a DL-dansyl-amino acid mixture. Conditions as in Table 1; flow rate 1.2 mL/min.

In general, copper(II) complexes of ligands AA-NN-2 give better results than those of AA-NN-3. Phe-NN-2 and Val-NN-2 give comparatively good separations for most amino acids, whereas Ala-NN-2 gives no or poor resolution. The separation factors are pH-dependent; they increase as the pH is raised from pH 6.3 to pH 7.5—8, so that deprotonation of the dansyl-substituted amino group is also effective in the recognition process. For a given ligand, the order of elution of the enantiomers is constant: D-amino acids always elute before L-amino acids. As expected, the aromatic amino acids phenylalanine and tryptophan interact most strongly with the copper(II) complex and the column and therefore give higher retention times. However, enantiomer discrimination is more effective for the polar amino acids aspartic acid, glutamic acid, and serine, which give the best separation factors α.

CPK models of the $CuLH_{-2}$ complexes reveal structures with little conformational freedom. The AA-NN-2 ligands do not completely surround the copper ion, which is therefore more accessible to the amino acids to be separated; in contrast, the AA-NN-3 ligands circularly enclose the copper ion. It is to be noted that enantiomer discrimination is more effective with the weaker complex **1** ($\log\beta = -6.04(3)$ for L = Phe-NN-2) than with the stronger complex ($\log\beta = -2.73(2)$ for Phe-NN-3), which is presumably less able to interact further with the amino acid.

Moreover, the copper(II) complex **1** must be located at the interface between the mobile phase and the "organic" reversed phase; it must be at least partially embedded in the organic phase, thus exhibiting a specific diastereofacial selectivity.

In this context, it is difficult to assume that chiral discrimination takes place via ligand exchange between the tetradentate complex adsorbed on the organic phase and the enantiomer. It is more likely that the incoming dansyl-amino acid interacts initially (through the carboxylate) with the apical position of the copper complex, which is accessible to coordination, and eventually forms hydrogen bonds with the terminal NH_2 of the ligand or displaces it from the equatorial position. Although we do not have sufficient grounds on which to substantiate either mechanism, we think that the present model may allow further developments in this important area of research.

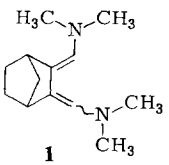
On the Role of Radical Ion Pairs in [4 + 2] Cycloadditions**

By *Mechthild Dern, Hans-Gert Korth, Gebhard Kopp,* and *Reiner Sustmann**

Dedicated to Professor Dietrich Schulte-Frohlinde on the occasion of his 60th birthday



The mechanism of the Diels-Alder reaction has been extensively investigated.[1] Depending on the pattern of substitution and the reaction conditions, the reaction can take place in a concerted fashion or in two steps via biradicals[1] or zwitterions;[2] most reactions can be interpreted as being concerted in the sense of the Woodward-Hoffmann rules. Several years ago it was postulated on the basis of theoretical studies that radical ions, formed by electron transfer from the electron-rich to the electron-poor reaction partner, could also be intermediates in the cycloaddition.[3] The observation of transient charge-transfer (CT) bands in a series of [4 + 2] cycloadditions appeared to support this argument since, in addition, a relationship between the wavelength of the CT absorption and the rate of reaction was observed.[4] The light-induced electron transfer by means of picosecond laser excitation of CT bands was recently studied. The results, however, provided no confirmation for the involvement of radical ion pairs as intermediates in the [4 + 2] cycloaddition.[5]

In order to induce an electron transfer between diene and dienophile in a normal Diels-Alder reaction, model compounds with a high-lying HOMO in the diene and a low-lying LUMO in the dienophile must be chosen. For this reason, the dienes **1** and **2** were synthesized.[6] **1** is

formed by the reaction of *trans*-2,3-norbornanedicarbaldehyde with tetrakis(dimethylamino)titanium[7] in 61% yield as a liquid mixture of isomers with a ratio of *trans/cis* : *trans/trans* = 3.3 : 1; **2** is formed exclusively in the *trans/cis* form in a yield of 88% via elimination of methanol twice from the bisdimethylacetal of *trans*-2,3-norbornanedicarbaldehyde in the presence of phosphoric acid and pyridine.

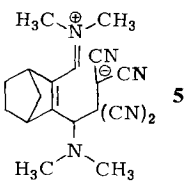
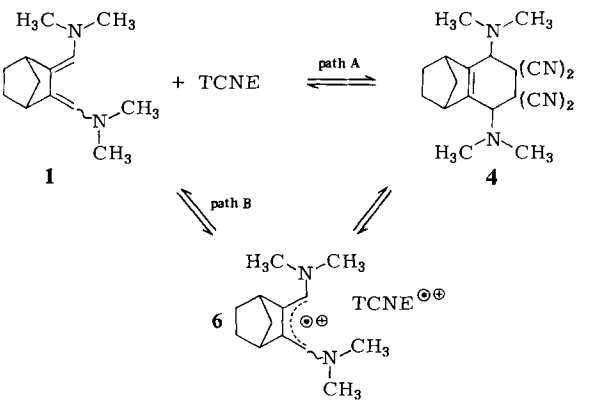
2



3

The reaction of **2** with tetracyanoethylene (TCNE) leads at room temperature in the absence of solvent to **3** (80%, colorless crystals, m.p. = 158—161 °C).[6] However, when the isomeric mixture of **1** is treated in tetrahydrofuran (THF) at room temperature with TCNE in ca. 1 M concentrations in a ratio of 1 : 1, a deep colored solution immediately forms, from which a finely crystalline, colorless precipitate begins to deposit after 5 min. After completion of the precipitation by addition of cyclohexane, a 1 : 1 adduct (correct elemental analysis) is obtained in quantitative yield; it melts with decomposition at 72 °C, turns brown in air as it slowly decomposes, and is light sensitive.

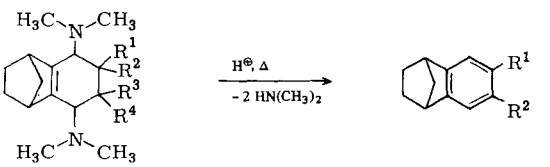
4



5

The IR spectrum of the adduct in Nujol exhibits a very weak band ($\nu_{C\equiv N}$ vibration) at 2236 cm^{-1},[8] which is characteristic for cycloadducts of **1** and cyanoolefins (Table 1) and therefore supports the structure **4** for the solid. The possible alternative structure, zwitterion **5**, should exhibit $\nu_{C\equiv N}$ bands at 2110—2120 and 2170—2180 cm^{-1}.[9,10] In a KBr pellet (prepared under nitrogen), the adduct shows a completely different IR spectrum: a broad, intense $\nu_{C\equiv N}$ absorption is observed at 2199 ± 5 cm^{-1} (two unresolved bands), which is typical for $\nu_{C\equiv N}$ vibrations of the TCNE radical anion;[11] this result is interpreted as indicating dissociation of **4** to the radical ion pair **6** in KBr (Scheme 1). The ESR spectrum of the crystalline compound contains a poorly resolved multiplet at $g = 2.00281 \pm 0.00001$, the main line of which (corresponding to the *g*-value of $TCNE^{\odot\ominus}$[11]) can be saturated, leaving a broad multiplet. By comparison with a standard (diphenylpicrylhydrazyl, DPPH), the amount of the radical ion pair **6** in the solid cycloadduct was shown to be ca. 0.001%. Dissolved in THF, **4** exhibits the intense ESR spectrum of $TCNE^{\odot\ominus}$ and, at higher gain, a highly resolved multiline spectrum, which is assigned to the radical cation of **1**; this spectrum, in contrast to that of $TCNE^{\odot\ominus}$, disappears after a relatively short time (1—2 h). This spectrum is also observed when **1** is oxidized with $AgBF_4$ in CH_2Cl_2.[12] The concentration of the radical ion pair in THF is ca. 0.001%, as it is in the solid. When a sample of the solid adduct is heated under argon to 60—70 °C in an ESR spectrometer, an increase in the intensity of the ESR signal (factor of 100) is observed: i.e., thermal dissociation to radical ions occurs. When the adduct is dissolved in polar acetonitrile, the amount of $TCNE^{\odot\ominus}$ increases by a factor of 2000. The increased dissociation is, however, also accompanied by a faster reaction to give non-radical secondary products.

Dilute solutions of **4** or of the reaction partner **1** and TCNE are not stable. An accurate UV/VIS investigation is extremely difficult since fresh solutions change their color several times within a short period of time. However, $TCNE^{\odot\ominus}$ bands could be identified unambiguously.[11]



Owing to the half-wave redox potentials of the diene[13] and of the dienophile TCNE (Table 1), a quantitative electron transfer is expected upon mixing of the partners. ESR spectra, taken immediately after mixing, support this expectation. The adduct **4** crystallizes out of a concentrated solution of **1** and TCNE; **4** reacts further irreversibly in solution via the radical ions to give subsequent products.

1 **4** **6**

Scheme 1.

These observations are accounted for by Scheme 1. Although the direct formation of **4** from **1** and TCNE (path A) cannot be excluded, the results appear to better support the path via the radical ion pair (path B).

Sealing and Opening Porous Monolayer Vesicle Membranes

By *Jürgen-Hinrich Fuhrhop,* Ulrich Liman,* and *Hans Hermann David*

We have recently reported on the pore-forming monensin pyromellitate **1**, which makes a monolayer vesicle membrane of **2a** permeable to lithium ions; as little as ten molecules of **1** suffice for generation of a lithium pore in a vesicle of about 10^5 molecules of **2a**.[1] Herein, we report on the further development of the porous vesicle to give a sealed vessel of molecular dimensions (diameter ca. 1000 Å, wall thickness ca. 25 Å), which can be opened by acidification. Analogous systems are so far known only for protein-containing cell membranes[2] and polymeric vesicular and capsular membranes with intercalates of monomeric disulfides[3] or with grafted polyelectrolytes.[4]

A prerequisite for sealing the negatively charged pores made from **1** with the positively charged bolaamphiphiles[5] **3a** and **3b** was the use of an *uncharged* membrane composed of **2b**. Salt-filled vesicles of the diol **2b** with pores of **1** were prepared by ultrasonication of 1.0 mmol **2b** and 10^{-2} mmol (≙ 1.0 mol-%) **1** in 10 mL of a 0.03 M LiCl solution. After gel-filtration over Sephacryl with 0.03 M NaCl solution the vesicle solutions did not contain any more lithium ions (Table 1). The porous vesicles of **2b** with 1.0 mol-% **1** are stable for long periods,[6] while vesicle solutions without **1** rapidly become turbid. $Li^{\oplus}$-permeable membranes of **2b** are formed only at relatively high concentrations (≥ 1.0 mol-%) on pore formers **1**; in the case of the membrane of negatively charged **2a**, concentrations of **1** a hundred times smaller suffice for generation of pores. We attribute both these findings to the de-aggregating action of the negative charges of **1** which only comes into effect in an uncharged but not in a negatively charged membrane.

Table 1. $Li^{\oplus}$ concentration of [a] gel filtered vesicles [b] with pore former **1**.

[1] [mol-%]	[$Li^{\oplus}$] [ppb] Vesicle of **2a**	[$Li^{\oplus}$] [ppb] Vesicle of **2b**
0	29	28
0.001	28	—
0.01	0	—
0.1	0	25
1.0	0	0
100	0	0

[a] Determined by atomic emission spectroscopy [1]. [b] 1 mL of the vesicle dispersion (1.0×10^{-3} mol in 3×10^{-2} M LiCl) was passed through a Sephacryl-S 1000 column (1 × 20 cm, 0.03 M NaCl). The 4—6 mL fraction contained the vesicle.

When 10^{-1} mmol (≙ 10 mol-%) of the bolaamphiphiles **3a** or **3b** were added during the sonication, the $Li^{\oplus}$ ions enclosed in the vesicle were not removed by gel filtration at pH 7 or 12.5. The pore was "sealed". However, when the vesicle sealed with **3b** was filtered at pH 3 over a Sephacryl gel, no more $Li^{\oplus}$ was detectable. When the solution was acidified for only a few seconds (pH 3), neutralized, and then chromatographed, the $Li^{\oplus}$ was likewise completely diffused out of the vesicle. Analogous experiments with bis(tetraalkylammonium) "stoppers" **3a** did not lead in any instance to a liberation of $Li^{\oplus}$ ions from the vesicle cavity (Table 2). **3a** is thus a "stopper" that cannot be removed again.

Takustrasse 3, D-1000 Berlin 33

Table 2. $Li^{\oplus}$ concentration [a] of gel filtered [b] vesicles of different composition [c].

pH	[$Li^{\oplus}$] [ppb] 1.0 mol-% **1**	[$Li^{\oplus}$] [ppb] 10 mol-% **3b**	[Li] [ppb] 10 mol-% **3b** 1.0 mol-% **1**	[$Li^{\oplus}$] [ppb] 10 mol-% **3a** 1.0 mol-% **1**
3	0 [d, f]	44 [d]	0 [d]	26 [d]
7	0 [f]	30	26	24
12.5	0 [e, f]	—	20 [e]	22 [e]

[a] Determined by atomic emission spectroscopy [1]. [b] 1 mL of vesicle dispersion (1.0×10^{-3} mol in 3×10^{-2} M LiCl) was passed through a Sephacryl-S 1000 column (1 × 20 cm, 0.03 M NaCl). The 4—6 mL fraction contained the vesicle. [c] The components were sonicated together and the vesicle dispersion immediately transferred to the Sephacryl column. [d] 0.058 M NaCl and 0.002 M HCl instead of 0.03 M NaCl. [e] 0.03 M NaOH instead of NaCl. [f] Fluorescent pyranine could be enclosed in the porous vesicle.

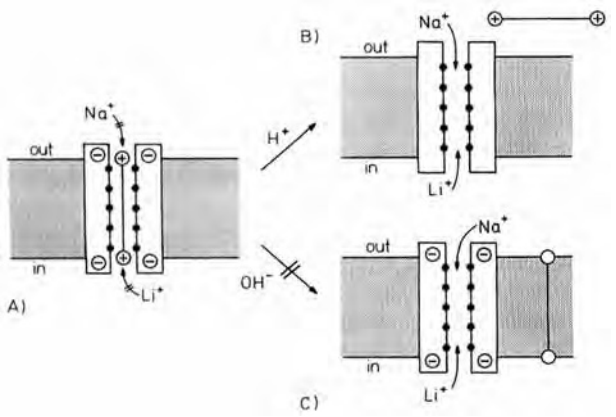

Fig. 1. A) The bolaamphiphiles **3a** and **3b** seal the negative pores of **1**. B) On acidification at pH 3 the carboxylate groups in **1** are neutralized, and the water-soluble stopper **3b** leaves the pore. C) On neutralization of the ammonium head-groups of **3b**, (reversible) diffusion of the amine from the pore into the hydrophobic membrane was expected; this does not occur.

We conclude from the above observations that the cases A and B of the model in Figure 1 can be realized with the diamine **3b**; opening of the sealed pore does not function in alkali (model C). To our knowledge the pore of **1** and the "stoppers" **3a** ("irreversible") and **3b** (partially "reversible") represent the first system in which a controllable formation and destruction of domains of foreign molecules closes or opens a lipid membrane for flow of ions.

[6] The slightly clouded vesicle solution of **2b** (10^{-3} M) became clear on sonication in the presence of **1** (10^{-5} M). The solution remained unchanged after three days. After a few weeks the vesicle precipitated, but could be quantitatively redissolved by ultrasonication.

A New, Facile Route to 2-Azaallenium Salts—Bis(2-adamantylidene)ammonium Hexachloroantimonate**

By *Ernst-Ulrich Würthwein,* Rainer Kupfer, Peter H. M. Budzelaar, Cornelia Strobel,* and *Horst P. Beck*

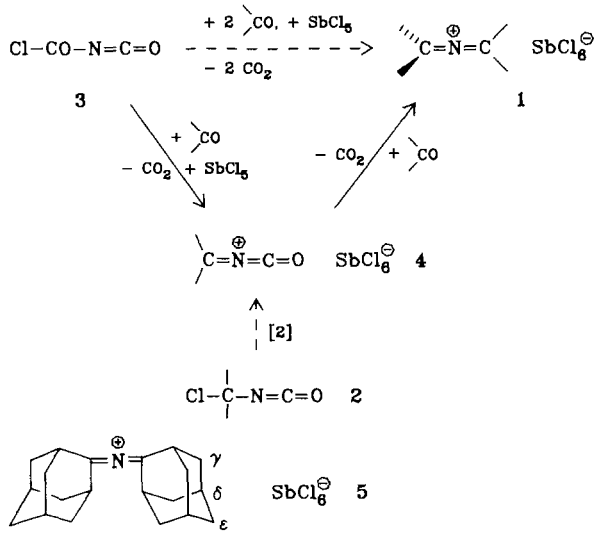
2-Azaallenium salts **1**, like ammonium, alkylideneammonium, and nitrilium salts, constitute a class of compounds with (formally) positively charged "octet" nitrogen atoms.

Ammonium salts	Alkylidene-ammonium salts	Nitrilium salts	2-Azaallenium salts
			1

The salts **1**, which are now accessible by several synthetic methods,[1,2] have been proposed as intermediates in S_N1 reactions.[3] Their gas-phase chemistry has been studied theoretically[4] and experimentally[5] and the structure of a derivative has been determined by X-ray analysis.[6]

We report here a simple, one-step synthesis of the salts **1**, starting from non-enolizable aldehydes and ketones.

Jochims et al.[2,6] use substituted chloromethyl isocyanates **2**, accessible from imines and phosgene,[7] as starting materials in their synthesis. The compounds **2** react with carbonyl compounds and Lewis acids to give 2-azaallenium salts **1**, analogously to the procedure reported by *Staudinger* et al.[8] for aryl isocyanates.



In our method we use this isocyanate reaction *twice* by reacting the commercially available chlorocarbonyl isocyanate **3** with two mole equivalents of the carbonyl compound in the presence of antimony pentachloride as Lewis acid. We thus obtain the salts **1** without the synthesis of imines, which are often very sensitive, and without use of phosgene. Chlorocarbonyl isocyanate **3** functions here as a reagent for the "$=\overset{\oplus}{N}=$" synthon, since only the nitrogen atom of **3** is present in the product **1**. Our ^{13}C-NMR experiments suggest that **3** is complexed and activated by $SbCl_5$, but not dissociated to the $O{=}C{=}\overset{\oplus}{N}{=}C{=}O$ ion, which has not yet been observed (see also [9]). As in the experiments of *Jochims* et al.,[2,6] 1-Oxa-3-azabutatrienium salts **4** are likely intermediates in this reaction.

In the absence of Lewis acids, **3** reacts with carbonyl compounds to give α-chloroalkyl isocyanatocarbonates.[10]

The aromatic carbonyl compounds benzaldehyde and benzophenone react smoothly to give the corresponding salts **1** in 59 and 75% yield, respectively (see also [11]). The reaction with pivaldehyde or di-*tert*-butyl ketone does not yield the expected salts **1**, possibly because of the chlorinating properties of antimony pentachloride. Adamanta-

none, however, leads to the hitherto unknown bis(2-adamantylidene)ammonium hexachloroantimonate **5** in 28% yield;[11] the cation of **5**, the first alicyclic 2-azaallenium salt, is isoelectronic with bis(adamantylidene)methane, first synthesized by *Wynberg* et al.[12]

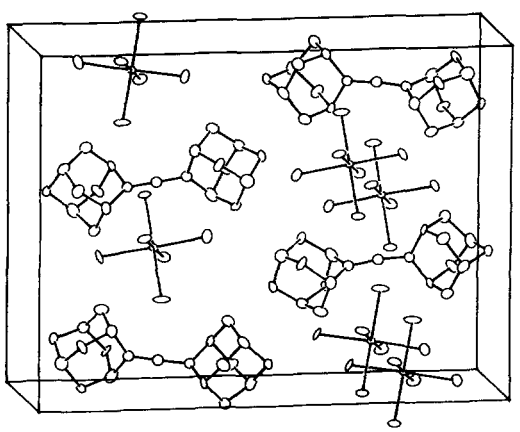

Fig. 1. ORTEP diagram of a unit cell of bis(2-adamantylidene)ammonium hexachloroantimonate **5**. View on (001). Vibration ellipsoids with 10% probability. The crystals are disordered, mainly with respect to rotations around the C=N=C axis of the cation.

The crystal structure of **5** was determined by X-ray analysis.[13] As with other highly symmetric molecules, the crystals of **5** are significantly disordered ($R = 0.092$)[14] (see Fig. 1). The theoretically predicted structural flexibility of this class of compounds[4] is indicated by the large temperature factors of the C=N=C bridging atoms (in Fig. 1 isotropic). The measured C=N bond lengths (130, 135±9 pm) and the C–N–C bond angle (167±10°) are too crude for a detailed conformational analysis, but the orthogonality of the skeleton of **5** is easily recognized in Figure 1. Surprisingly, the crystal packing strongly resembles the CaC_2 structure; a slight tilting of the dumb-bell shaped cations of **5** in the *c*-direction causes the observed hyperstructure (*c* is doubled in comparison to the CaC_2 structure). In other words, the structure of **5** may be regarded as being built up from layers of the cations of **5** parallel to 012 with the $SbCl_6$ anions in a separate layer above the gaps of the cation layer. A low-temperature X-ray structure determination of **5** is in preparation.

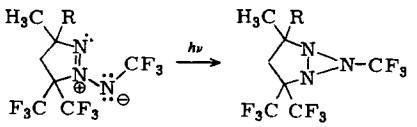
Stable Triaziridines**

By *Gerd Kaupp*,* *Oswald Dengler*, *Klaus Burger*,* and *Silvia Rottegger*



Many years of intense efforts to synthesize nitrogen homocycles afforded, apart from aromatic pentazoles,[1] only recently triaziridines, which, however, proved to be unstable at room temperature.[2] Triaziridines have also been postulated as intermediates in the photoisomerization of azimines.[3]

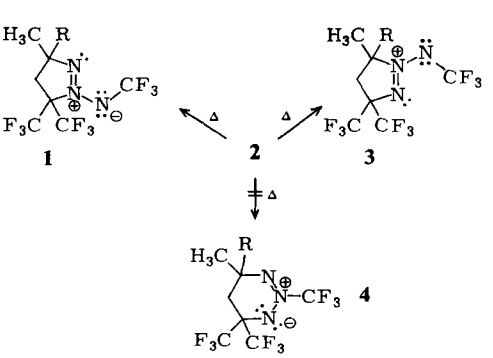
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We report now[4] the synthesis of triaziridines that are stable to at least 80°C by irradiation of suitably substituted azimines. In this process, both the steric stabilizing effect of *tert*-alkyl groups[5] and, in particular, the electronic stabilizing effect of perfluoroalkyl groups[6] are exploited.

The educts **1**[3] are readily available from trifluoromethyl-substituted azomethine imines[7] and trifluoronitrosomethane via dipole metathesis.[8] When the azimines **1** are irradiated with light of wavelength $\lambda = 253.7$ nm at room temperature, the triaziridines **2** are formed in very good yields; they can be purified by fractional distillation.[9]



1 **2**

a, R = CH_3; **b**, R = $C(CH_3)=CH_2$; **c**, R = C_6H_5

The structure assignment of **2** is based on the spectroscopic data. The characteristic IR absorption of the azimine function in the region 1495–1500 cm^{-1}[3] and the UV absorptions of **1** at $\lambda_{max} = 257$ nm are gone. The NMR spectra of **2a** (only one isomer) show the magnetic nonequivalence of the methyl groups and of the trifluoromethyl groups bonded to the five-membered ring [^1H NMR (200 MHz; $CDCl_3$): $\delta = 1.48$ (s, br.; CH_3), 1.52 (s; CH_3); ^{13}C NMR (50.24 MHz; $CDCl_3$): $\delta = 26.2$ (q, $J_{CF} = 3.3$ Hz; CH_3), 26.8 (s, CH_3); ^{19}F NMR (56.43 MHz; $CDCl_3$, trifluoroacetic acid as external standard): $\delta = 8.0$ (q, $J = 10.5$ Hz; CCF_3); 10.5 (q, $J = 10.5$ Hz; CCF_3); 5.7 (s; NCF_3)]. Since the five-membered ring is still intact (CH_2: $\delta = 2.22$; AB degenerated to a singlet), this result can only be accounted for by a ring closure of the azimine group. An NN double inversion[10] cannot be observed in the range of stability of **2**. Accordingly, for **2b** and **2c** (R ≠ CH_3), diastereomeric mixtures (two isomers each) are obtained;[9] these can be separated by capillary gas chromatography and identified by mass spectrometry.

Since triaziridines,[2,3] like other three-membered heterocycles, are valence tautomers of open-chain 1,3-dipoles,[11] the thermolysis of **2** above 100°C also confirms the structure. It results in the cleavage of either one of the nearly equivalent peripheral N–N bonds to give **1** and **3**,[9] as expected, in a ratio of ca. 1:1 (**3a**–**c** also give **2** upon photolysis, as shown by UV analysis); a ring enlargement to give the six-membered-ring azimine **4** could not be detected by ^{19}F-NMR spectroscopy. At 113.2°C in *n*-dodecane, the rate constants for formation of the azimine (UV-kinetics) from **2a**–**c** are $k_1 = 3.34 \times 10^{-4}$, 2.55×10^{-4}, and 2.42×10^{-4} s^{-1}, respectively. The Arrhenius parameters for the formation of **1a** + **3a** from **2a** were determined to be $E^a = 125$ kJ/mol and $\log A = 13$. In contrast, the tricyclic triaziridine ($E^a = 100$ kJ/mol) described in [2] already decomposes at room temperature.

1 **2** **3** **4**

The stability of the triaziridines **2** makes possible extensive physical investigations on this theoretically interesting ring system (see also [11]).

Experimental Procedure

1 [3] (1.0 g) is irradiated in anhydrous *n*-pentane (50 mL) for 2 h at room temperature under argon with a low-pressure mercury lamp (Hanau TNN 15). After evaporation of the solvent in vacuum and reflux (ca. 1 h; bath at 60°C), **2** is distilled (air bath heated with a heat gun) at 0.1 to 0.001 torr, condensed onto a cold finger at −30°C, and collected in a condenser cooled with liquid nitrogen; it is thus separated from a small amount of residue (45; 60; 55 mg). Analytically and spectroscopically pure **2a** (80%), **2b** (79%), and **2c** (85%) (not optimized) are obtained [9].

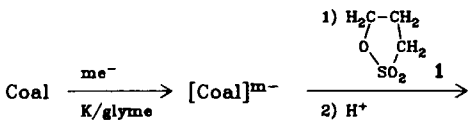
[11] Three-membered rings that contain at least one heteroatom with a lone electron pair can in principal open photochemically and thermally to give 1,3-dipoles. With triaziridine **2a**, we achieved the first photochemical ring opening to the 1,3-dipoles **1a** and **3a** by gas-phase photolysis ($\lambda = 184.9$ nm).

Reductive Alkylation of Bituminous Coal: Coal-Propanesulfonic Acids Having Remarkable Solubilities

By *Matthias W. Haenel*,* *Udo-Burckhard Richter*, and *Heribert Hiller*



Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

To study the chemistry of bituminous coal, soluble derivatives are needed which largely retain the original coal structure. In certain cases, remarkable solubilities in pyridine are found for coal derivatives that have been obtained by reducing bituminous coal with the "blue solutions" formed by potassium in oligomeric polyethylene glycol dimethyl ethers and quenching the "coal anions" so generated with dimethyl sulfate or alkyl halides.[1] New products

[*] Priv.-Doz. Dr. M. W. Haenel, Ing.-Grad. U.-B. Richter, H. Hiller

Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

having interesting solubilities were expected by the use of the γ-sultone of 3-hydroxypropanesulfonic acid **1** in the reductive alkylation of bituminous coal, since nucleophiles, including organometallic carbanion species, open the sultone ring, forming 3-substituted propanesulfonic acids.[2]

Accordingly, the reductive alkylation of a medium volatile bituminous coal from the Ruhr coalfield (Table 1) by treatment of the finely ground coal with potassium in a mixture (6:1) of dimethoxyethane and "octaglyme"[1] at −25°C and subsequent addition of **1** yielded coal-propanesulfonic acids **2**.

Coal−$(CH_2-CH_2-CH_2-SO_3R)_n$ **2**, R = H;
3, R = CH_3 ; **4**, R = NR_4^+

Elemental analyses and acidimetric determinations of the acid groups (Table 1) indicate that the average composition changes—neglecting the heteroatoms—from $C_{100}H_{63}$ in the starting coal to $C_{100}H_{76}(CH_2-CH_2-CH_2-SO_3H)_5$ in **2**. Hence, in addition to the alkylation with **1**, the coal was hydrogenated, having taken up ca. 13 hydrogen atoms per 100 carbon atoms via Birch-Hückel reduction of polycyclic arenes and/or reductive cleavages of ether bonds and benzylic C−C bonds.[3] ^{13}C-NMR spectra indicate that mainly the aliphatic (benzylic) C atoms of the "coal-anions" were alkylated in the analogous reductive methylation with [^{13}C]methyl iodide.[1b] Therefore, the majority of the propanesulfonic acid groups in **2** should be bonded in the same manner to C atoms of the coal skeleton.

2 and the sodium salts of **2** are up to 89% soluble in water; therefore, taking into consideration the mineral matter (4.1% ash, Table 1), only ca. 7% of the coal remains undissolved. This surprising water solubility apparently has to be attributed to the solvation of dissociated ions since the acids **2** are precipitated by concentrated hydrochloric acid and their methyl esters **3** (Table 1, prepared from **2** and trimethyl orthoformate[4]) are water-insoluble. Quaternary organic ammonium salts such as Hyamine 10-X[5] precipitate **4** (Table 1) from the black aqueous solutions of the sodium salts of **2** so completely that the supernatant solution above the black precipitate becomes water-clear. The ammonium salts **4** are soluble in polar organic solvents such as pyridine, methanol, and ethanol, indicating that undissociated ion pairs are probably present.[6] The salts of **2**, which, depending on the cation, can dissolve in water as well as in organic solvents, are therefore attractive coal-derivatives for further chemical and spectroscopic studies.

Table 1. Composition (expressed as normalized atomic ratios) and solubilities of the starting coal and of the coal derivatives **2**, **3**, and **4** [Westerholt mine, seam "Robert", 23.6% volatile matter, 4.1% ash, 0.7% water, 89.4% C, 4.7% H, 1.8% N, 3.8% O, 1.9% S]. **a**, **b**: representative examples.

	C	H	N	O [a]	S	H^+/100C [b, c]	n/100C [c]	Solubility [e]

3a	100	110.0	0.4	21.5	5.2		≈5	< 5% (p)
4a [d]	100	130.5	2.8	13.0	2.4		≈5	>90% (pme)
4b	100	128.8	2.6	13.3	2.3		≈5	

[a] Determined directly. [b] Determined acidimetrically. [c] Relative to 100C of the starting coal. [d] R_4N^+ = cation of Hyamine 10-X. [e] In pyridine (p), water (w), methanol (m), ethanol (e).

The solubility of the ammonium salts **4** in pyridine was utilized to obtain information on the molecular weights by carrying out preparative gel permeation chromatography (column: diameter 5.3, length 125 cm; volume 2750 cm^3, Sephadex LH 60, pyridine, 60°C) and subsequently determining the molecular weights of the individual GPC fractions by means of vapor-phase osmometry (pyridine, 60°C).[7] The satisfactory linear correlation found between the measured molar masses M_{ni} and the elution volumes EV_i (Fig. 1) demonstrates that the separation was mainly due to size exclusion chromatography and that interfering polar adsorption was essentially avoided.[7] From the molecular weight distribution between 800 and 15000 g mol^{-1}, which was plotted versus the weight percents m_i (Fig. 2), a calculated number average molecular weight of $\overline{M}_n$ = 2670 g mol^{-1} is obtained. Within the limits of experimental error, this corresponds to the value $\overline{M}_n$ = 3005 g mol^{-1} determined directly for the total product **4**.

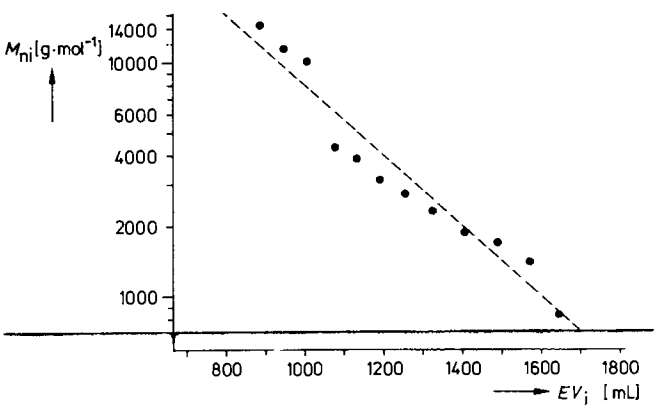

Fig. 1. Measured molecular weights M_{ni} of the GPC fractions of **4** versus the elution volumes EV_i (Sephadex LH 60, pyridine, 60°C).

If the mass fractions of the propanesulfonic acid groups and the quaternary ammonium cations in **4** are taken into consideration, molecular weights between 400 and 7000 g mol^{-1} are obtained for the bituminous coal investigated here.[8] However, it is not possible to deduce from these values the molecular sizes in the original coal since the de-

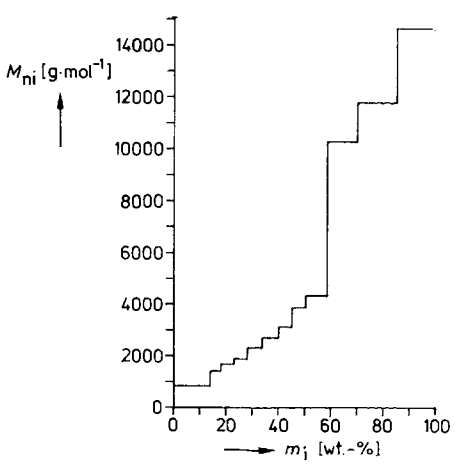

Fig. 2. Molecular weight distribution of **4** (M_{ni} versus weight percents m_i).

gradation that occurs through cleavage of ether and C–C bonds[3] in the potassium reduction cannot be quantified. We are therefore attempting to attach alkanesulfonic acid groups to the coal skeleton via non-reductive reactions.

Experimental procedure

Finely ground coal (10 g, average particle diameter 60 μm) was stirred at −25 °C for 24 h in a "blue solution", which had been prepared by adding potassium (10 g, 256 mmol) in small pieces to 300 mL of dimethoxyethane and 50 mL of polyethylene glycol dimethyl ether ("octaglyme").[1] After unreacted potassium (ca. 3.4 g) had been removed **1** (31.2 g, 256 mmol), dissolved in 20 mL of dimethoxyethane, was added within 10 min and the mixture was then stirred for 24 h at −25 °C. After the solvent had been distilled off, the residue was extracted with ether in a Soxhlet apparatus for 3 d and dried. All water-soluble reagents were removed by suspending the material in 200 mL of hydrochloric acid (50% v/v) and centrifuging in order to isolate the product; this process was carried out six times. The residue, after washing once more on a glass filter with acetone and drying (3 d at 10^{-3} torr and 25 °C), yielded 13.1 g dark **2**.[9]

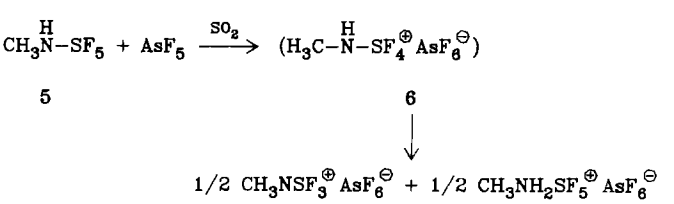
1a, M = P; **1b**, M = As

The *S*-alkyl salts **2**[3,4] could only be detected in solution at low temperatures (−100 to −40 °C) by NMR spectroscopy. At higher temperatures, they rapidly decompose.



For the amino derivatives **4**, which are analogous to **2**, the corresponding decomposition is not possible; moreover, dialkylamino groups should stabilize the cationic center. Thus, **3**[7] reacts with AsF_5 in liquid SO_2 at room temperature to give quantitatively the exceptionally stable salt **4**.[8] The salt **6**, which is expected from **5**[9] and contains a monoalkylamino group, is not stable and decomposes into **7**[10] and **8**.[11] In the amino sulfurpentafluorides **5** and **3**, the nitrogen is still basic,[12] as shown by the formation of **8** and **9**,[13] respectively.

The adduct $F_5S(CH_3)_2NAsF_5$ may be considered as a structural alternative to the salt **4**. The ^{19}F-NMR spectrum (Fig. 1) provided the unequivocal proof for the formation of **4**; at low temperatures, it shows the expected 14 lines of the A_2B_2 splitting pattern. The septet of each resonance is

$(CH_3)_2NSF_4^{\oplus}AsF_6^{\ominus}$—Synthesis and Stability of a Simple Pentacoordinated Sulfur(VI) Cation**

By *Thomas Meier* and *Rüdiger Mews**

Whereas pentacoordinated phosphoranes are well studied,[1,2] little information is available on the isoelectronic pentacoordinated sulfur(VI) cations,[3–6] which have also been called "persulfuranonium"[3,4] or "persulfonium"[5,6] ions. Up to now, only the salts **1a**, **b**, containing such an ion, have been described.[5,6] The chelating ligand is thought to be decisive for their stability.[4]

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

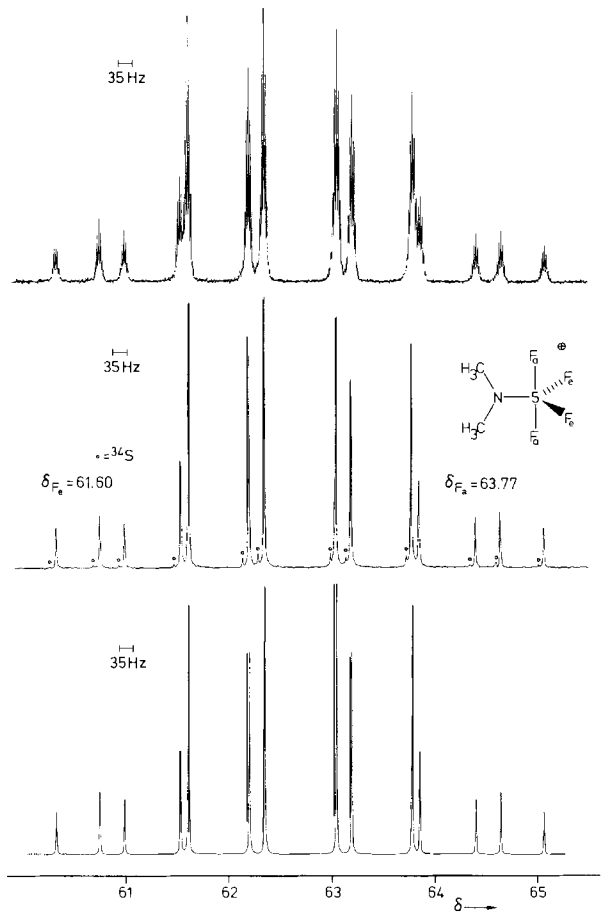

Fig. 1. Top: ^{19}F-NMR spectrum of the cation in **4** (Bruker AM 250, -55°C, 30 percent in SO_2); middle: same as above but proton-decoupled; bottom: calculated spectrum.

caused by interaction with the six protons of the dimethylamino group. The NMR data (Table 1) show that the cation in **4** exhibits trigonal bipyramidal coordination at the central sulfur. The dimethylamino group should occupy one of the equatorial positions[16] as in the isoelectronic phosphorane $(CH_3)_2NPF_4$.[1, 2, 14, 15]

Table 1. ^{19}F- and ^{1}H-NMR data for $(CH_3)_2NSF_4^{\oplus}$ (-55°C, 30 percent in $SO_2/CDCl_3/CFCl_3$; $\delta(^1H)$ relative to TMS) and $(CH_3)_2NPF_4$ (-90°C, toluene, $CFCl_3$ (^{19}F): room temperature, pure substance, TMS (^{1}H)) [14].

	$\delta(F_a)$	$\delta(F_e)$	$^2J(F_aF_e)$ [Hz]	$\delta(CH_3)$	$^4J(HF)$ [Hz]
$(CH_3)_2NSF_4^{\oplus}$	63.77	61.60	220.6	3.76	4.0
$(CH_3)_2NPF_4$	-59.0	-75.9	72	2.85	2.05

In contrast to **4**, only one signal is found in **2** for the different fluorine atoms of the cation.[3, 4] For the isoelectronic alkyltetrafluorophosphoranes RPF_4, the intramolecular motion can only be slowed down enough to observe the separate signals for F_a and F_e in the ^{19}F-NMR spectrum when R is the extremely bulky 2,4,6-(tBu)$_3$C$_6$H$_2$ group.[17] The NMR data presented in Table 1 show that the spectra of the isoelectronic species $(CH_3)_2NSF_4^{\oplus}$ and $(CH_3)_2NPF_4$ show a similar trend with regard to both the relative chemical shifts and the coupling constants. The assignment of the high-field signals to F_e in **4** was made in analogy to the phosphorane system.[18, 19] In contrast to $(CH_3)_2NPF_4$, no clean septet for the fluorine signal of **4** is found even at room temperature. The activation barrier for the pseudorotation in the cation is appreciably higher (≈ 55 kJ/mol at an estimated coalescence temperature of 35°C) than in the isoelectronic neutral compound (36.8 kJ/mol at -85°C).[15] The low-temperature spectra (-40°C) of **4** show no evidence of hindered rotation around the S–N bond. The splitting pattern of the ^{13}C-NMR signal (62.89 MHz, TMS: $\delta = 50.6$, $^3J(CF_a) \approx 7$ Hz, $^3J(CF_e) \approx -1.7$ Hz)[20] can be interpreted as the A part of an AX_2Y_2 spin system; the spectral type $AXX'Y_2$ would be expected for hindered rotation.

Coupling of 3-Diazo-3*H*-pyrazoles with 2-Alkoxy-1,6-methano[10]annulenes and Oxidative Cyclization to Pyrazolotriazines**

By *Richard Neidlein,* Uwe Jäschke, Alfred Gieren,* Gabriela Weber,* and *Thomas Hübner*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Coupling reactions of aryldiazonium salts with 2-alkoxy-1,6-methano[10]annulenes[1] usually lead via cleavage of ether to formation of "quinonehydrazones", i.e. 5-(arylhydrazono)-1,6-methano-1(10),3,6,8-cyclodecatetraen-2-ones.[2] Coupling of the 3-diazo-3*H*-pyrazoles **1a**, **b** and of the 3-diazo-3*H*-indazole **1c**[3] with 2-alkoxy-1,6-methano[10]annulenes **2a**–**c**[4,5] enables the synthesis of the pure azo dyes **3** in good yields under mild, neutral[6] conditions (Table 1).

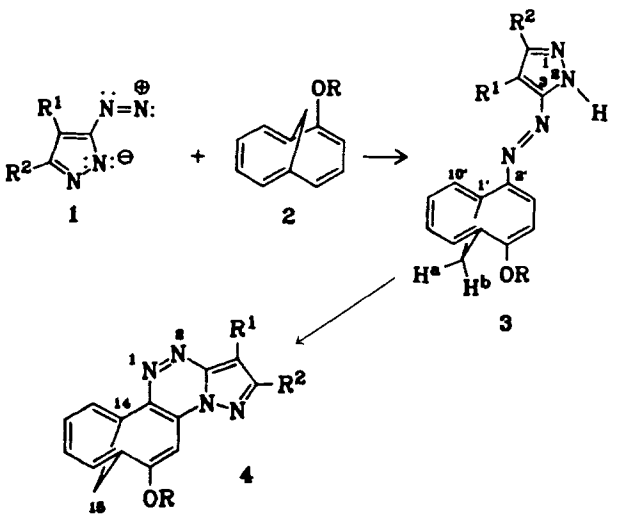

Table 1. Azo dyes **3** and pyrazolotriazines **4** that have been synthesized.

1	R^1	R^2	2	R	3,4	3		4

Cyclization of the *E*-configurated azo dyes **3** to triazine derivatives **4** (Table 1) was accomplished by irradiation of **3** in dioxane with a high-pressure Hg immersion lamp in the presence of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ). This oxidative ring-closure of **3** is, as expected, only possible in the case of the *Z*-isomer.[7]

4ab was characterized by X-ray structure analysis[8] (Fig. 1). In the perimeter of the 1,6-methano[10]annulene, only slight differences in the bond lengths occur in the unsubstituted seven-membered ring, whereas a stronger alternation between formal single and double bonds is recognizable in the substituted seven-membered ring. Both seven-membered rings are boat-shaped. The annelated pyrazolo[5,1-*c*][1,2,4]triazine system is almost planar; the largest deviation from the best plane is 0.05 Å. The bond lengths in this bicyclic 10π-electron system are, as expected, between those of single and double bonds.

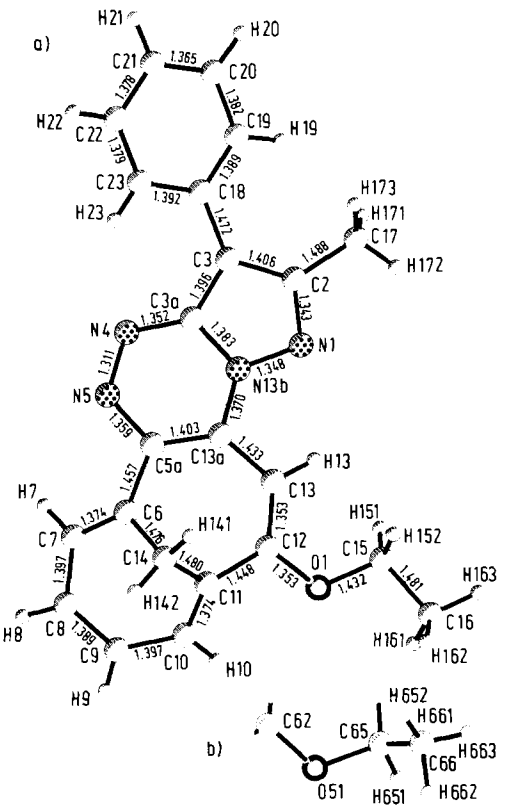

Fig. 1. a) Structure of **4ab** in the crystal, with bond lengths averaged over both molecules of the asymmetric unit. The standard deviations of the bond lengths without averaging are $0.001 \leq \sigma \leq 0.003$ Å. b) Deviating conformation at the O–C bond of the ethoxy moiety.

The crystal lattice contains two symmetry-independent molecules which differ from each other only in certain parts. Significantly different torsion angles occur with the ethoxy substituent: In one of the molecules the methyl group and the annulene ring are almost antiperiplanar (Fig. 1a, torsion angle C12–O1–C15–C16: 167.6°), in the other synclinal (Fig. 1b, C62–O51–C65–C66: 84.0°). In addition, the C6–C14–C11 angle differs by 3.4(1)°. The smaller angle is accompanied by a decrease in the distance between the bridge atoms C6, C11 from 2.21 to 2.14 Å and a decrease in the, albeit already small, difference in the bond lengths in the unsubstituted triene fragment ($\Delta(\max) = 0.02$ compared to 0.04 Å).

Experimental:

3: A solution of **2** (5 mmol) in CH_2Cl_2 (10 mL) was added dropwise to a stirred solution of **1** (5 mmol) in CH_2Cl_2 (250 mL) at 20°C. The solution immediately turned red in color. After two hours' stirring, the solvent was removed by distillation and the remaining black-red oil was purified by column chromatography (silica gel, 30 cm, ∅ 3 cm, eluent CH_2Cl_2/ether = 4/1). Recrystallization from ether/petroleum ether (1/10) furnished red or orange-red crystals.—**3ab**, ^{13}C-NMR (62.89 MHz, $CDCl_3$, δ values): C_6H_5: 132.4 (s), 126.8–130.1 (5d); CH_3: 13.3 (q); C_2H_5: 14.8 (q), 66.3 (t); 162.3 (s, C-5'), 151.3 (s, C-3), 146.9 (s, C-5), 148.8 (s, C-2'), 134.4 (d, C-3'), 125.8–131.5 (4d,

Cationic Allylruthenium Complexes via Interchange of Allyl Moieties**

By *Faouzi Bouachir, Bruno Chaudret, Denis Neibecker,* and *Igor Tkatchenko**

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Cationic allylnickel, allylpalladium, and allylplatinum complexes are reported to be active catalysts for the oligomerization,[1] telomerization,[2] and isomerization[3] of unsaturated substrates. Moreover, cationic allylmetal species have been suggested as intermediates in these processes.[3,4] In order to examine the scope and limitations of the use of such complexes, we extended to ruthenium the general synthetic procedure described for nickel and palladium consisting of the oxidative addition of allyloxyphosphonium salts **1** to zerovalent metal centers.[5] We now report a new type of reaction leading to η^3-allyl interchange on a metal center and preliminary results on the chemistry of and catalysis with cationic allylruthenium complexes.

2a, L_3 = 1,3,5-C_8H_{10}, Y = PF_6
2b, L_3 = C_6H_6, Y = PF_6
2c, L = CO, Y = BF_4
2d, L = CO, Y = PF_6
2e, L = $P(OMe)_3$, Y = PF_6

The reaction of **1a** and **1b** with [Ru(η^4-C_8H_{12})(η^6-C_8H_{10})] surprisingly leads to the quantitative evolution of propene and 2-methylpropene, respectively. The cationic complex **2a** is obtained in 78% yield.[6] Similarly, **2b** is obtained in 88% yield starting from [Ru(η^4-C_8H_{12})(η^6-C_6H_6)]. Structures **2a** and **2b** were assigned on the basis of ^{1}H- and ^{13}C-NMR spectra (Table 1).

Table 1. NMR data for the complexes **2a**, **2b**, and **2e**.

2a: ^{1}H-NMR (250 MHz, $(CD_3)_2CO$): δ = 0.22 (m, 1H), 1.80 (m, 1H), 2.15 (m, 1H), 2.50 (m, 4H), 2.80 (m, 1H), 3.25 (m, 1H), 3.47 (m, 1H), 5.02 (m, 1H), 5.95 (m, 1H), 6.21 (m, 2H), 6.41 (m, 2H), 6.45 (m, 2H); ^{13}C-NMR (62.9 MHz, $(CD_3)_2CO$): δ = 19.4 (C4), 27.0 ($-CH_2-$), 27.5 ($-CH_2-$), 34.9 (C8), 36.4 (C7), 40.2 (C3), 44.4 (C5), 79.0 (C1), 87.7 (C6), 94.4 (C2), 95.0 (–CH–), 96.0 (–CH–), 97.0 (–CH–), 99.3 (–CH–), 100.6 (–CH–).

2b: ^{1}H-NMR (250 MHz, $(CD_3)_2CO$): δ = 1.75 (m, 1H), 2.12 (m, 1H), 2.48–2.60 (m, 2H), 2.81 (m, 1H), 3.17 (m, 1H), 3.57 (m, 1H), 4.22 (t, J(HH) = 7.3 Hz, 1H), 4.51 (m, 1H), 5.12 (dd, J(HH) = 6.9, 7.9 Hz, 1H), 5.61 (m, 1H), 6.47 (s, 6H); ^{13}C-NMR (62.9 MHz, $(CD_3)_2CO$): δ = 19.2 (C4), 27.9 (C8), 29 (C3 [7]), 33.4 (C5), 35.9 (C7), 72.7 (C1), 79.8 (C6), 84.6 (C2), 92.3 (C-benzene).

2e: ^{1}H-NMR (250 MHz, $(CD_3)_2CO$): δ = 1.10 (t, J(HH) = 7 Hz, 1H), 1.82 (br. m, 1H), 2.80 (br. m, 2H), 3.00 (br. m, 1H), 3.90 (br. m, 9H), 4.40 (br. m, 9H), 4.55 (br. m, 1H), 4.80 (br. m, 1H), 5.00 (br. m, 1H), 5.45 (br. m, 1H), 5.80 (br. m, 1H), 7.45 (m, 1H).

According to the ^{13}C-NMR spectra, **2a** and **2b** are not symmetric; five $^{13}CH_2$-, and eleven ^{13}CH-signals are present in the spectrum of **2a**, and three $^{13}CH_2$- and six ^{13}CH-signals in that of **2b**.[7] In fact, the ^{13}C-NMR spectrum of **2b** is very different from that of **3**, which has been recently obtained by *Bailey* et al. from the reaction of $[Ru(H_2O)_6][p\text{-}MeC_6H_4SO_3]_2$ with 1,3-cyclooctadiene.[8] On the other hand, it is very similar to that reported by *Singleton* et al. for the η^5-C_8H_{11} complex **4**, which has been characterized by a single-crystal X-ray diffraction study.[9] Moreover, the data agree well with those reported for the corresponding tricarbonyl complex **2c**.[10] No evidence for an equilibrium of the type $[(\eta^3\text{-allyl})Ru]^{\oplus} \rightleftarrows [(\eta^4\text{-diene})RuH]^{\oplus}$, which has been recently demonstrated,[11] is detected in the ^{1}H-NMR spectra of **2a** and **2b**. **2a** reacts with CO and $P(OMe)_3$ to

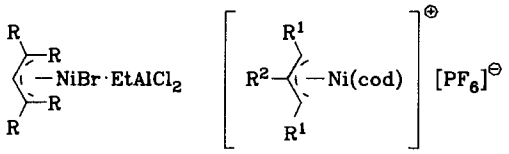
[**] Cationic allylmetal complexes, Part 11. This work was supported by the CNRS. – Part 10: [1f].

give **2c** and **2d**, respectively. The "masked hydride" character of **2a** and **2b** is evidenced by the formation of

$[RuH(dppe)_2(CH_3CN)]^{\oplus}[PF_6]^{\ominus}$ **5**



upon treatment of **2a** and **2b** with two equivalents of bis(diphenylphosphino)ethane (dppe) in acetonitrile.[12] In these reactions, two equivalents of 1,3,5-cyclooctatriene (1,3,5-cot) are evolved from **2a** and one equivalent of both 1,3,5-cot and benzene from **2b** according to gas chromatographic analysis.

Complex **2a** is a catalyst precursor for the dimerization of ethylene (turn-over number (TON) = 160; 1-butene : *cis*-2-butene : *trans*-2-butene = 18 : 30 : 51), the ring-opening polymerization of norbornene to a mixture of *cis*- and *trans*-polynorbornenes (TON = 480 in refluxing ethanol; TON = 350 in dichloromethane at room temperature), and the polymerization of butadiene to mainly *trans*-1,4-polybutadiene (TON = 150). **2a** is also a catalyst precursor for the isomerization and hydrogenation of alkenes. The isomerization only occurs under hydrogen and is *faster* than hydrogenation: from 1-hexene 1% hexane and 10% 2-hexenes are produced (TON = 40) after 3 h under 1 bar H_2, and 29.5% hexane and 70.5% 2-hexenes are obtained (TON = 870) after 20 h under 20 bar H_2. Noteworthy is the fact that mixtures of **2a** and dppe or **2a** and **5** are practically inactive for isomerization and hydrogenation.

The mechanism of formation of **2a** and **2b** deserves some comments. Although both compounds are also obtained by hydride abstraction of one allylic proton of 1,5-cyclooctadiene with $[Ph_3C]^{\oplus}[PF_6]^{\ominus}$, the reactivity pattern observed for the reaction of **1** with Ni^0 and Pd^0 species[5] led us to suggest another mechanism: the oxidative addition of **1** to an initially formed 16-electron species is followed by the activation of one allylic hydrogen of the coordinated 1,5-cyclooctadiene by the *electrophilic* ruthenium center, leading to a hydridoruthenium(IV) cation.[12] Reductive elimination of the hydrido and allyl ligands[13, 14] results in the evolution of propene or 2-methylpropene and the formation of **2a** or **2b**. Therefore, these complexes formally result from an interchange of allyl ligands [Reaction (a)].

$$[M(\eta^3\text{-allyl})^1(\eta^2\text{-alkene})^2]^{\oplus} \rightleftharpoons [M(\eta^2\text{-alkene})^1(\eta^3\text{-allyl})^2]^{\ominus} \qquad (a)$$

This reaction has little precedent in the case of ruthenium.[15] However, this behavior could be typical for cationic allylmetal complexes; e.g., the transformation of **6** and **7** reported by *Bogdanovic*[1b] and *Pardy* and *Tkatchenko*,[1c] respectively, could be interpreted in a similar way.
