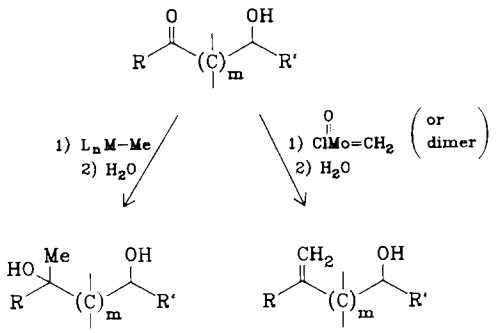
Strongly Preferential Alkylation and Carbonyl Olefination of α- and β-Hydroxycarbonyl Compounds by Organo-Transition Metal Reagents in Competition Experiments with the Corresponding Deoxy Compounds**

By *Thomas Kauffmann,* Thomas Möller, Heidi Rennefeld, Siegfried Welke,* and *Raphael Wieschollek*

The functional groups of organic compounds usually have lone electron pairs or π-electron pairs and thus are almost always potential ligands for metals with empty d-orbitals. Therefore, it is not surprising that alkyl transition-metal complexes, which have proved to be very selective towards single electrophilic functional groups,[2] can also react in a highly selective fashion with arrangements of functional groups ("multigroup selectivity").



The high diastereoselectivity in the alkylation of alkoxy- and some hydroxycarbonyl compounds with alkyltitanium and alkylzirconium compounds indicates chelate control;[1,3,4] i.e., the reagents are bound to the oxygen of the alkoxy or hydroxy group during the alkylation process. We presumed, therefore, that ketones and aldehydes that contain an oxygen-donor group in the vicinity of the carbonyl group would be attacked more quickly by alkyl transition-metal compounds than those lacking such a donor group.

Since the metal-carbon bond in alkylchromium and alkyltitanium compounds is surprisingly resistant towards hydroxy groups,[1] we examined by means of competition experiments whether α- and β-hydroxycarbonyl ketones are easily alkylated by such reagents. Corresponding experiments were carried out with the carbonyl olefination

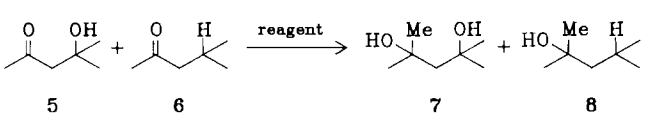
[**] Transition-metal-activated organic compounds, Part 18. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 17: [1].

reagent $ClMo(O)=CH_2$, which is especially resistant towards hydroxy groups.[5] We found, as expected, chemoselective methylation and carbonylolefination according to Scheme 1 (the reaction is usually carried out at $-60°C$ and the reaction mixture is warmed over the course of ca. 12 h to room temperature).

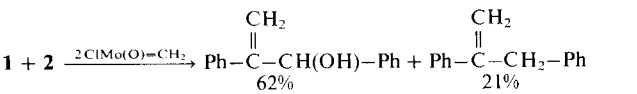
Scheme 1. m = 0, 1.



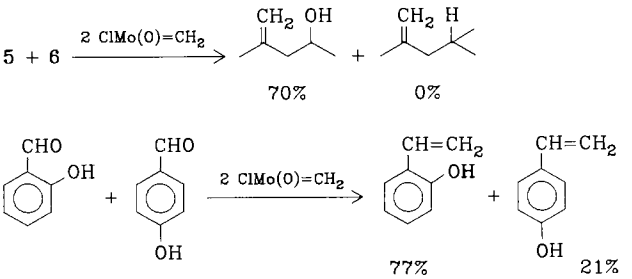
The fixation of the metal atom to the hydroxy group supposedly plays an essential role in these reactions. However, the activating effect, the $-I$ effect, of the hydroxy group of **1** and the deactivation of **2** via enolate formation have to also be taken into consideration.

Scheme 2. For yields see Table 1 [6].

Table 1. Competition experiments according to Scheme 2.



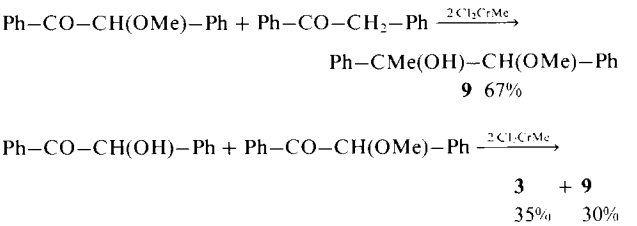
Reagent	Mole ratio substrate : reagent	Yield [%] 3	4	Recovery [%] 1	2
Cl_2Cr–Me	1 : 1 : 1	40	0	52	96
Cl_2Cr–Me	1 : 1 : 2	52	0	36	99
$(iPrO)_3Ti$–Me	1 : 1 : 2	56	0	—	89
IMg–Me	1 : 1 : 1	15	20	67	75
IMg–Me	1 : 1 : 2	38	29	58	61
Li–Me	1 : 1 : 2	23	41		



Scheme 3. For yields see Table 2 [6].

Table 2. Competition experiments according to Scheme 3.

Reagent	Mole ratio substrate : reagent	Yield [%] 7	8	Recovery [%] 5	6
Cl_2Cr–Me	1 : 1 : 1	31	1	41	84
Cl_2Cr–Me	1 : 1 : 2	50	1	29	80
$(iPrO)_3Ti$–Me	1 : 1 : 2	42	1	—	80
IMg–Me	1 : 1 : 1	13	22	65	70



Scheme 4 [6].

Scheme 5 [6].

That methoxy groups also facilitate the attack on a neighboring carbonyl group is shown by a result of *Reetz*[7] as well as the first experiment depicted in Scheme 6, in which **4** is not formed at all. The second experiment depicted in Scheme 6 shows that the chromium reagent only weakly prefers the hydroxy over the corresponding methoxy compound.

Scheme 6 [6].

Since the *erythro* isomer of **3** is formed practically exclusively in the separate reaction of benzoin **1** with two equivalents of $(iPrO)_3Ti$–Me,[4] the diol **3** obtained in our competition experiments with $(iPrO)_3Ti$–Me and Cl_2Cr–Me is most probably also the *erythro* isomer. This has not yet been possible to show since no NMR data is given in the literature for *erythro*-**3**. Whether **9** also is present as only one diastereomer, as may be assumed, is also not yet certain.

The chemoselective reactions according to Scheme 1 (*nucleophilically* active ligands) are a direct analogy of the chemoselective oxidations of allyl- and homoallyl alcohols by *Sharpless* et al.[8] (*electrophilically* active ligand in the form of a peroxide group). Thus a general reaction principale is illustrated here.

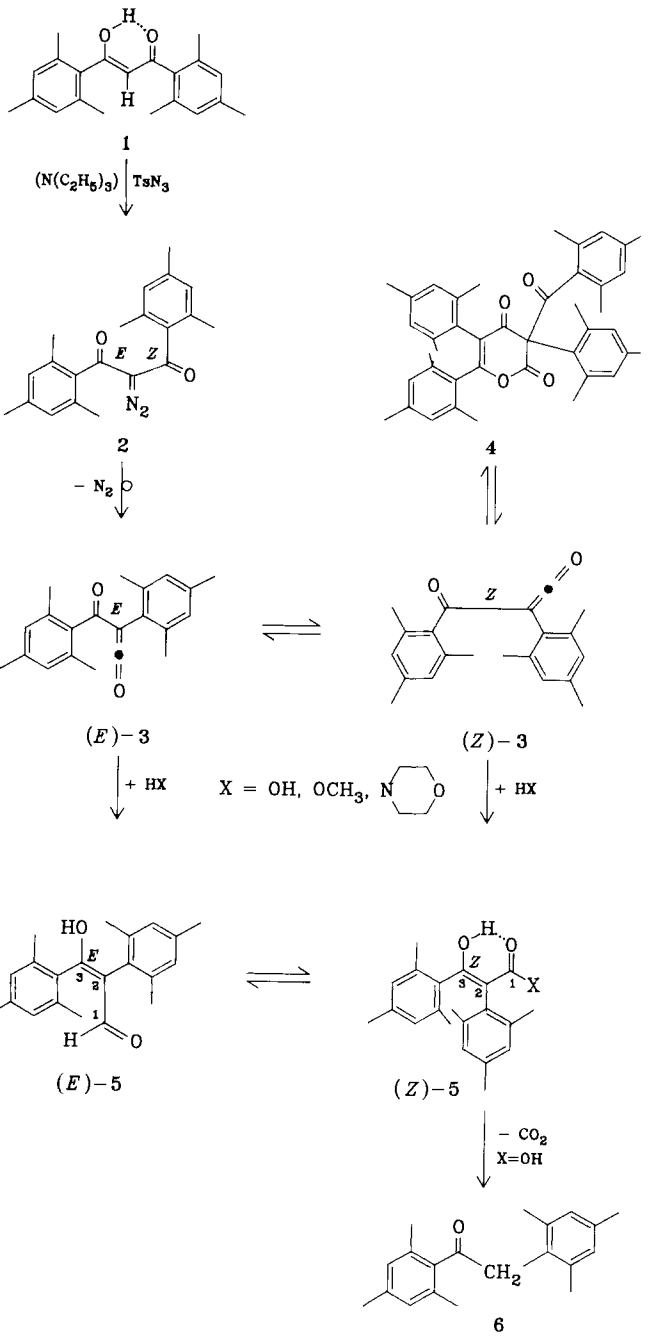
Isolation of the (*E*)-Enols of β-Ketocarboxylic Acid Derivatives**

By *Herbert Meier,* Wolfgang Lauer,* and *Friedrich Ulrich Scholter*

Dedicated to Professor Dietrich Schulte-Frohlinde on the occasion of his 60th birthday

β-Ketocarboxylic acid derivatives are of great importance as intermediates in organic synthesis.[1] The Wolff-rearrangement of 2-diazo-1,3-dicarbonyl compounds provides a facile entry;[2] the intermediary acyl ketenes rapidly add water or other nucleophiles.[3] Even in the absence of nucleophiles and cycloaddition partners, acyl ketenes cannot be isolated, since they rapidly dimerize.[4]



We have now studied the influence of increasing steric hindrance on the reaction behavior of the diazo compounds $R^1CO-CN_2-COR^2$ ($R^1=R^2=C_6H_5$; $R^1=C_6H_5$, $R^2=2,4,6\text{-}(CH_3)_3C_6H_2$; $R^1=R^2=2,4,6\text{-}(CH_3)_3C_6H_2$). The compound **2** containing two mesityl moieties, which is readily accessible from **1** by diazo group-transfer[5] (yield 81—89%, orange-yellow crystals, m.p. 94°C), gave a number of quite surprising results:

1. Photolysis ($\lambda \geq 290$ nm) of the *E,Z*-configurated diazodiketone **2** in anhydrous diethyl ether leads to formation of an acyl ketene **3**, which, as a result of steric hindrance, is partly present in monomeric form (IR spectrum, CCl_4: ketene band at 2090 cm^{-1}). It can be assumed that there is rapid rotation about the central CC single bond, since this bond shows little double-bond character. In contrast to normal ketenes, acyl ketenes such as **3** dimerize (according to their IR and NMR spectra) to six-membered lactones such as **4**.[4]

2. Photolysis in diethyl ether saturated with water leads to the β-ketocarboxylic acid **5** (X = OH), which decarboxylates to **6** only very slowly at room temperature. The half-life of **5** amounts to more than two days (decay with first order kinetics).

3. Photolysis in the presence of methanol affords the methyl ester **5** ($X=OCH_3$), which can be isolated in the *E*- and the *Z*-configuration. On termination of N_2-elimination, a mixture of 52% *Z*-form (m.p. 152°C) and 19% *E*-form (m.p. 125°C) is obtained which can be separated by column chromatography (silica gel/benzene). In an alkaline medium (e.g. triethylamine), on the other hand, the pure *E*-form is obtained.

4. Thermolysis of **2** in morpholine at 50—60°C affords the amide **5** ($X=NC_4H_8O$) in 74% yield. On completion of reaction it is present in the *E*-form (m.p. 142°C) and can be converted into the *Z*-form (m.p. 96°C) either thermally or by acid catalysis.

The existence of (*E*)-enols of β-ketocarboxylic acid derivatives has often been surmised. *Matusch*[6] was able to detect such an enol on examining ethyl acetate NMR spectroscopically. However, the handicap met with is the small amount of *E*-isomer in the mixture with the thermodynamically more favorable (*Z*)-enol (intramolecular six-membered ring hydrogen bridge) and the thermodynamically even more favorable keto-form. By introducing the mesityl moiety, it has now been possible to completely suppress the formation of the keto-form in the case of **5**; concomitantly, the steric hindrance considerably increases the energy content of (*Z*)-**5**. The rate of thermal isomerization is

[*] Prof. Dr. H. Meier, Dipl.-Chem. W. Lauer, Dr. F. U. Scholter

Johann-Joachim-Becher-Weg 18—20, D-6500 Mainz (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

so small that it was possible in the cases described here to isolate both stereoisomers in the pure form for the first time. The influence of the alkaline medium manifests itself in the enolate-form[7] being present in the *E*-configuration in the absence of H-bridges. Accordingly, the enol that is liberated therefrom has the *E*-configuration.[8]

The identification of the stereoisomers is possible by means of IR, ^{1}H-, ^{13}C-NMR spectroscopy. The intramolecular H-bridge in the *Z*-form effects a shift in the CO stretching vibration of about 50 cm^{-1} to smaller wave numbers. The reduced electron density of C-1 and C-3 due to the intramolecular hydrogen bridge gives rise to a significant downfield shift of the corresponding ^{13}C-NMR signals (Table 1). δ(C-2), on the other hand, experiences an

upfield shift on going from (*E*)-**5** to (*Z*)-**5**. The assignment of the resonances of C-1 and C-3 was established by heteronuclear double resonance. Also of interest is the observation that chemical equivalence of the corresponding nuclei in the morpholine ring caused by rapid rotation is already achieved at room temperature in the case of the amides **5** (X = NC_4H_8O). That is, in this instance, steric hindrance effects an acceleration of the rotation about the CN-bond in comparison to normal amides, because it reduces the double bond character of the CN bond! This is true, both for the *Z*- as well as the *E*-form.

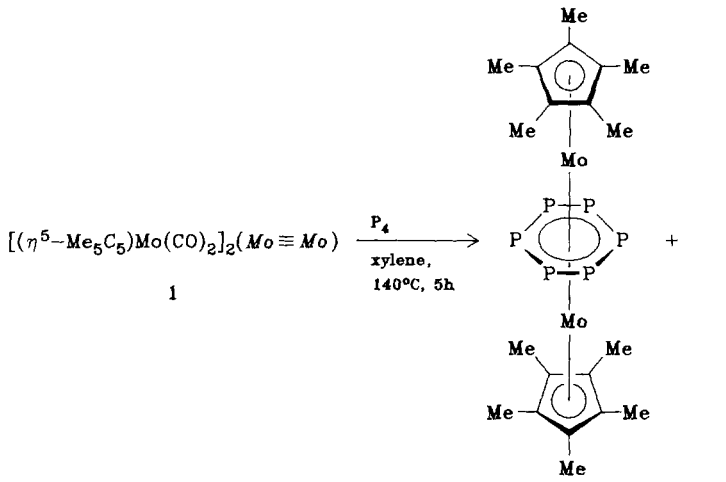
Hexaphosphabenzene as Complex Ligand**

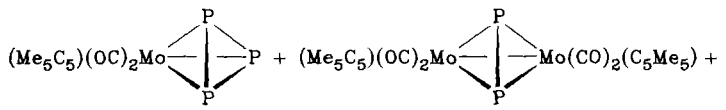
By *Otto J. Scherer,* Helmut Sitzmann,* and *Gotthelf Wolmershäuser*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The formal replacement of each CH unit in benzene **A** by an isoelectronic P atom would lead to the phosphaanalogue P_6 **B**.[1] Its synthesis was a fascinating aim. The most promising approach would be expected to be the stabilization of P_6 by complexation.



Using this approach we have now, indeed, been able to prepare the triple-decker sandwich complex [{(η^5-Me_5C_5)Mo}$_2$(μ,η^6-P_6)] **2** with hexaphosphabenzene as central bridge-ligand. The reaction proceeded analogously to that of [$CpMo(CO)_2]_2$(*Mo≡Mo*) (Cp = cyclopentadienyl) or [$CpMo(CO)_3]_2$(*Mo–Mo*) with P_4.[2] **2**[3] forms amber-colored, air stable crystals (decomp. >250 °C), which are very sparingly soluble in pentane, moderately soluble in benzene, and readily soluble in dichloromethane. The ^{1}H-NMR spectrum (200 MHz, [D_6]benzene, TMS int.) of **2** shows a septet for the CH_3-groups at $\delta = 0.47$ (standard region of the C_5Me_5 signal $\delta \approx 2$) with $^4J(PH) = 0.45$ Hz, shifted considerably upfield by the anisotropic sphere of the P_6 ring (ring current effect). The $^{31}P\{^1H\}$-NMR spectrum (80.82 MHz, CH_2Cl_2, 85% H_3PO_4 ext.) shows a singlet at $\delta = -315.6$.



Reaction of **1** with P_4 not only leads to formation of **2**, but also of complexes **3**, **4**, and **5**.[3] As in the case of its Cp-analogue,[2] no restriction to rotation of the P_3-"disk" is observed for **3**, even at ca. −80 °C (otherwise an A_2B spin system would be expected in the $^{31}P\{^1H\}$-NMR spectrum); **3** can also be prepared from **1** and P_4S_3.[4] It follows from the IR band at 1829 cm^{-1} that **4** contains a semibridging CO ligand. An X-ray structure analysis of **5** could not be carried out on the thin, yellowish-brown crystals; their composition was confirmed by elemental analysis and by the mass and NMR spectra.[5] We propose a structure consisting of two P_2Mo_2 tetrahedra with a common Mo–Mo edge and *cis* arrangement of the C_5Me_5- and CO-ligands.

Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

[+] X-Ray structure analysis.

[**] This work was supported by the Fonds der Chemischen Industrie (postgraduate grant for *H. S.*). We thank Prof. *W. Siebert*, Heidelberg, for helpful discussions.

$^{31}P\{^1H\}$-NMR spectroscopic monitoring of the reaction showed the presence, not only of **2**–**5** but also of two further products ($\delta = -118$ (s), possibly a *trans*-derivative of **5** or a (μ,η^4-P_4)-complex, and $\delta = -319$ (s), traces), which, however, could not be isolated.

The crystal structure analysis[6] shows that **2** is a centrosymmetric molecule (Fig. 1). Both five-membered rings as well as the P_6 ring are planar and parallel. The average PP distance of 2.170 Å lies in the range to be expected for such a molecule. Thus, P–P bond lengths of 2.004–2.034 Å are found for R–P=P–R,[7] 2.115–2.159 and 2.13–2.20 Å, for complexes with η^3-[2b,8a] and μ,η^3-P_3 ligands[8] and 2.149–2.155 Å for the binary compounds Rb_4P_6[9a] as well as α- and β-K_4P_6.[9b] The MoPMo angle (mean value 62.8°) reveals the interrelationship with P_4 and, in combination with the MoP distance of 2.541 (mean value) gives the Mo–Mo distance 2.647(1) Å which is somewhat shorter than that in [$(CpMo)_2(\mu,\eta^4$-$As_5)$] (Mo–Mo 2.764(2) Å).[10] On the basis of the 18e rule a metal-metal single bond can be discussed for **2**. The angles and bond lengths in the C_5Me_5-ligands show no unusual values.

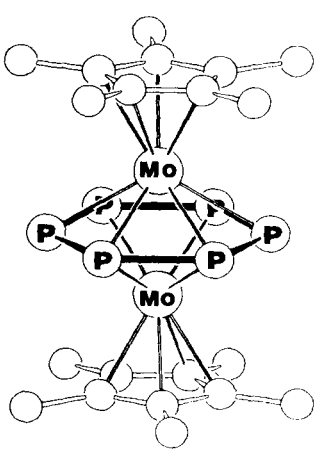

Fig. 1. Structure of **2** in the crystal. Selected bond lengths [Å] and angles [°]: P–P 2.167(3), 2.167(3), 2.175(3), P–Mo 2.541(2), 2.542(2), 2.541(2), mean value Mo–C 2.331, Mo–Mo 2.647(1). The methyl C-atoms lie, on average, 0.1079 Å above the plane of the five-membered ring (distortion about 4°); P–P–P 119.9(1), 120.1(1), 120.0(1), Mo–P–Mo 62.7(1), 62.8(1), 62.8(1).

If one regards the P_6 ring as 6π electron-donor ligand then **2** is a triple-decker sandwich complex with 28 valence electrons (cf. the analogous 26e vanadium complex with benzene as "middle deck"[11] and the 30 and 34e rule[12] for such complexes).

The synthesis of **2** poses the following questions: Can **5** be converted photochemically or thermally into the 26e triple-decker sandwich complex[11] [$\{(\eta^5$-$Me_5C_5)Mo\}_2(\mu,\eta^4$-$P_4)$]? If P_2 can be considered as an acetylene analogue, then a P_6 synthesis is possibly an analogue of the Reppe benzene synthesis ($3\,P_2 \rightarrow P_6$)?[13]

[3] Preparation of **2**–**5**: A stirred solution of $Mo(CO)_6$ (4.0 g, 15.15 mmol) and pentamethylcyclopentadiene (2.7 mL, 15.5 mmol) in xylene (150 mL) was heated under reflux for 24 h. The solution was then treated at room temperature with 2.0 g (16.1 mmol) P_4 and the mixture heated to gentle boiling for 5 h. After removal of solvent by distillation, the residue was extracted three times with 70-mL aliquots of CH_2Cl_2 and the combined extracts evaporated to 30 mL, stirred with 20 mL Florisil, and dried under an oil-pump vacuum until a freely-flowing powder was obtained. The chromatography (column diameter 3 cm, length 35 cm) was started with pentane as eluent. As soon as the eluate showed a yellow coloration, yellow **3** could be eluted from the column with pentane/toluene (2:1). Yield 290 mg (5% referred to $Mo(CO)_6$); $^{31}P\{^1H\}$-NMR: $\delta = -336.5$; IR, *n*-heptane: ν(CO) = 1990 (vs), 1938 (vs) cm^{-1}. Elution with pentane/toluene in the ratio 1:1 gave a red fraction. When this fraction was evaporated down and the residue washed with ca. 5 mL CH_2Cl_2 at room temperature, there remained **2** as a yellow powder, which could be recrystallized from CH_2Cl_2 at −80°C. On evaporation and cooling to 5°C the red solution (mainly $[Me_5C_5Mo(CO)_3]_2$ and **1**) furnished another portion of **2** (total yield 67 mg, 1.4%); $^{13}C\{^1H\}$-NMR (50.28 MHz, CH_2Cl_2): $\delta = 95.6$ (s, C_5Me_5) 11.7 (br, s, CH_3). Elution with pentane/THF (3:1) then afforded a yellowish-red fraction, which, after evaporation to dryness and recrystallization from heptane, furnished thin, yellow-brown needles of **5** (yield 340 mg, 7%). Final elution with pentane/THF (1:1) furnished a cherry-red fraction, from which **4** was isolated (recrystallization from heptane: yield 15 mg, 0.2%; $^{31}P\{^1H\}$-NMR: $\delta = -48.4$ (s); IR ν(CO) = 1980 (s), 1920 (s), 1905 (s), 1829 (s) cm^{-1}). Complications: The fractions containing **3**, **4**, and **5** also contain small amounts of **2**, which are separated as described. Small amounts of **5** are also present in the fractions containing **2** and **4**.

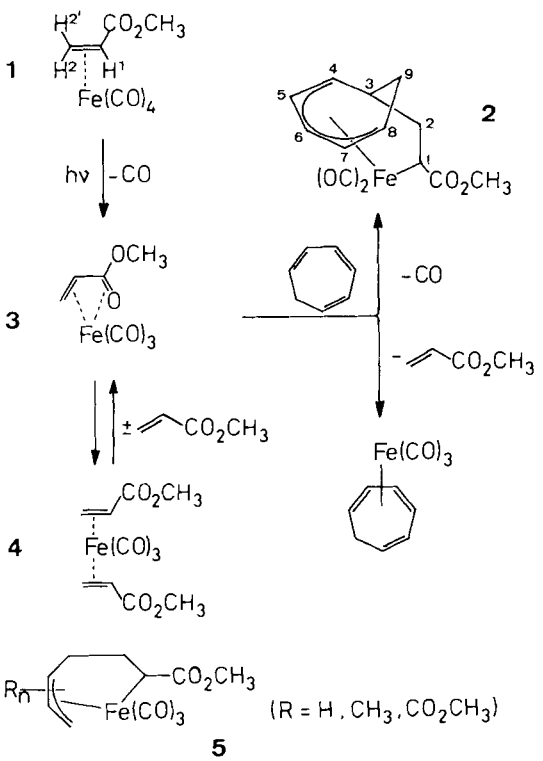
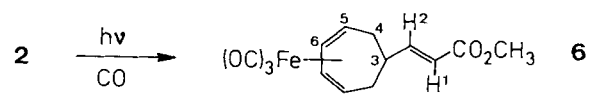
Carbonyliron-Assisted Coupling of Cyclopolyenes with Methyl Acrylate

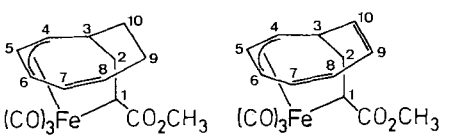


By *Richard Goddard, Friedrich-Wilhelm Grevels,** and *Rosemarie Schrader*

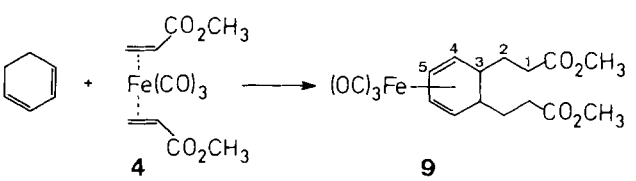


Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

In many cases, substituted cyclohexadienes and cycloheptadienes are obtainable by addition of a nucleophile to $[(\eta^5\text{-cyclohexadienyl})Fe(CO)_3]$ and $[(\eta^5\text{-cycloheptadienyl})Fe(CO)_2L]$ cations, respectively.[1] We present here another way to introduce the $RO_2C-CH_2-CH_2-$ or $RO_2C-CH=CH-$ side chains: the carbonyliron-assisted coupling of acrylic esters with a cyclodiene or cyclotriene followed by a hydrogen shift.



Irradiation of a mixture of the complex **1** and cycloheptatriene affords, in addition to $[(\eta^4\text{-cycloheptatriene})Fe(CO)_3]$ and small amounts of other products, the dicarbonyliron complex **2** (20% yield). In **2**, the adduct of the two organic substrates is σ,η^5-coordinated. The actual photoreaction consists of the dissociation of CO,[2] which is followed by a series of thermal reactions. **2** is also obtained without irradiation starting from the tricarbonyliron complex **4**[3] and introducing cycloheptatriene by thermal ligand exchange (43% yield).[4] These reactions are comparable to the synthesis of compounds of the type **5**.[5,6]



Upon irradiation under CO, **2** is converted into the derivative **6**,[4] which has a double bond in the side chain. In this process, the hydrogen atom is selectively transferred from the 2′-H position to the ring. Analogous experiments with deuterium-labeled **2** (1-H, 2-H = D, or 2′-H = D) show that, in the first case, both D atoms remain in the side chain, whereas, in the second case, D is transferred. Each of the complexes **2** labeled in this way was synthesized from the correspondingly labeled methyl acrylate (1-H, 2-H = D, or 2′-H = D).[7]

Exploratory attempts to couple cyclooctatriene or cyclooctatetraene with methyl acrylate, analogously to the synthesis of **2**, gave the complexes **7** and **8**, respectively, in 10–20% yield.[4]

In the thermal reaction of 1,3-cyclohexadiene with **4**, two acrylic ester moieties are added to the six-membered ring, forming **9**[4] (45% yield). The X-ray structure analysis of **9** (Fig. 1) shows that the $Fe(CO)_3$ group and the two side chains are on the same side of the six-membered ring. Hence it follows that, here too, complexation of the two substrates initially takes place with subsequent formation of a carbonyl(σ,η^3-organo)iron complex, which immediately undergoes rearrangement. In this case, a hydrogen atom is transferred from the ring to the side chain, so that the 1,3-diene unit is retained in the ring and the side chain, detached from the metal, is saturated. When this sequence

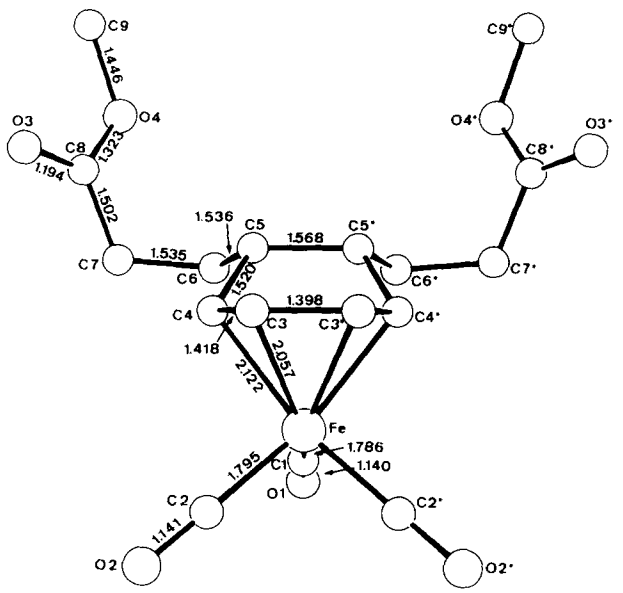
of reactions occurs once again with the second acrylic ester, **9** is formed as the final product.



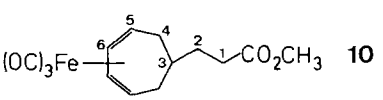


Fig. 1. Molecular structure of **9** in the crystal with selected interatomic distances [Å]. Crystal data: Pnma, $a = 13.898(1)$, $b = 17.465(2)$, $c = 7.237(1)$ Å, $V = 1756.6$ Å^3, $Z = 4$, $\rho_{calcd.} = 1.48$ g cm^{-3}; $\lambda = 0.71069$ Å, $\mu = 8.9$ cm^{-1}, $R = 0.035$, $R_w = 0.035$; 4913 measured reflections [h, k, ±l], of which 1743 were observed ($I > 2.0\sigma(I)$). 158 refined parameters. The molecule has a space-group-determined mirror plane passing through Fe, C1, and O1 and therefore cutting the C3–C3* and C5–C5* bonds. The best plane passing through C4, C3, C3*, and C4* forms an angle of 41.2° with that passing through C4, C5, C5*, and C4*. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen (FRG), on quoting the depository number CSD 51266, the authors, and the journal citation.

The analogous reaction of 1,3-cycloheptadiene with **4** likewise affords a substituted (η^4-1,3-cyclodiene)Fe(CO)$_3$ complex, **10**,[4] which, however, contains only one acrylic ester moiety (20% yield).

10

We are currently attempting to improve the yields by modification of the reaction procedure; the reaction may eventually be applied to other olefins[8] as well as to substituted cyclopolyenes.

Bioelektrochemische Membranelektroden. By *J. G. Schindler* and *M. M. Schindler*. Verlag Walter de Gruyter, Berlin 1983. xi, 340 pp, bound, DM 180.00.

The astonishing developments in the field of bioelectrochemical membrane electrodes is certainly a result of the enormous practical importance which these bioanalogous sensors are gaining in analytical biochemistry, diagnostic clinical chemistry, for biotechnological process control, and for reaction control. A (German language) summary of the fundamental principles, of the various possible applications, and of further developments of electrochemical measuring systems will, therefore, be welcome, particularly to clinical medical practitioners, biochemists, biophysicists, and process engineers.

The functional principles of bioelectrochemical membrane electrodes, such as the membrane concept, ionic selectivity, membrane-immobilized enzymes, streamline form for flow measuring sensors are copied from nature. The construction of highly specific electrochemical sensors is often bioanalogous down to the smallest detail. This is true not only for the measuring systems for the determination of the activities of metal and nonmetal ions and of dissolved gases (e.g. O_2 and CO_2), but also for biodetectors for the highly specific determination of ionic and nonionic cell metabolites.

Bioelectrochemical measuring sensors include a large number of enzyme electrodes, which are employed as the sensitive elements of gas and ion sensors. Immobilized microorganisms, cell organelles such as mitochondria, and cell tissue are employed as enzyme carriers. Highly selective immune reactions are the functional basis of immune electrodes; hormone-receptor reactions are also exploited electroanalytically in membrane electrodes.

The authors explain the bioanalytically important topic of bioelectrochemical electrodes in seven chapters. After an introduction to ion-selective measurement circuits and some physicochemical principles, quantitative electrode characteristics are discussed. Further sections cover structure and binding, electrically neutral ionophoric antibiotics and synthetic carriers (including chiroselective transport molecules), ion-selective carrier membrane systems (transport principle, membrane production), ion-selective carrier membrane electrodes (derivation, continuous flow sensors, dip electrodes), gas-sensitive electrodes (potentiometric and polarographic measuring cells), and finally membrane electrodes with sensitized detectors.

The book is clearly written and reflects the competence of the authors and their experience with bioelectrodes. But chemical thermodynamics is thin ice for them even when they only need to copy it out. The free enthalpy (Gibbs) is naturally "work potential" and not as asserted on p. 2 "the amount of heat taken up or evolved". The quantity named after *Loschmidt-Avogadro* is not a number but a constant possessing dimensions. The molar free enthalpy of reaction $\Delta\overline{G}$ is not known "as the chemical potential μ" (p. 4), but rather $\Delta\overline{G} = \Sigma\nu_i\mu_i$ is the change in free enthalpy for one stoichiometric turnover and is given by the sum of the chemical potentials of the reaction partners, whereby the stoichiometric coefficients of the educts are taken as negative.

These inadequacies in the introduction do not, however, detract from the service the authors have performed in providing a good and comprehensible presentation of a complicated topic. The book contains a comprehensive bibliography, including recent publications. It is to be recommended to beginner and expert alike as a general orientation guide.

NMR and Chemistry. An Introduction to the Fourier Transform-Multinuclear Era. 2nd Edit. By *J. W. Akitt*. Chapman and Hall, London—New York 1983. xiii, 263 pp, paperback, £ 7.95.

This introduction to modern NMR methods is aimed mainly at students of chemistry and related sciences and at NMR spectroscopists in industry.

The first half of the book comprises six chapters which contain a vivid presentation of the fundamentals of high resolution NMR spectroscopy of dissolved compounds. The basic physical background is dealt with in Chapter 1. The following chapters are devoted to the important NMR parameters, chemical shift (Chapter 2), spin-spin coupling (Chapter 3), and relaxation (Chapter 4). It is particularly pleasing that these chapters do not just refer to examples with protons and carbon-13, but also touch on the NMR properties of other nuclei such as ^{11}B, ^{15}N, ^{17}O, ^{19}F, and ^{31}P. The third chapter on the analysis of spin systems is also a successful introduction to spectral interpretation and gets by largely without formulas. The chapter on relaxation is satisfying since all the important phenomena are clearly presented, although the treatment of exchange phenomena and instrumental details at this juncture may confuse some readers, since the modern spectrometer system is not treated until the fifth chapter. The sixth chapter discusses the nature of the samples and the problems of the standardization of spectra.

In the second half of the book the author deals with more complex NMR techniques and introduces examples of multinuclear NMR methods. Many of the double resonance methods described in Chapter 7 are already outdated as a result of the rapid development of pulse spectroscopy. A more detailed treatment of ^{13}C NMR spectroscopy would have been desirable here. It is pleasing that the most recent NMR techniques are mentioned (Chapter 8). The short presentation of solid and in vivo NMR methods is particularly successful. The examples chosen to illustrate the application of two dimensional NMR spectroscopy are less fortunate; there is no mention of shift correlation diagrams, which are of great practical importance because the bonding of the C and H atoms in the organic skeleton can be derived from them without any prior information. Immediate chemical applications are discussed in the last chapter. In addition to ^{1}H and ^{13}C NMR, the chemical relevance of ^{7}Li, ^{23}Na, ^{11}B, ^{27}Al, ^{15}N, ^{31}P, ^{17}O and ^{19}F NMR spectroscopy is demonstrated on the basis of examples. The appendix contains 18 short exercises together with their solutions, a reference list that is, however, too short, and a list of contents.

This book will be of immense value to those seeking an insight into high resolution NMR spectroscopy. Its strength lies in the clear presentation of NMR phenomena. On the other hand, very little comparison material, which is of such importance for the NMR spectroscopist, is given. This reasonably priced book can be highly recom-

mended to undergraduate and postgraduate students who come into contact with NMR spectroscopy.

Radwaste Immobilization by Structural Modification—the Crystallochemical Properties of SYNROC, a Titanate Ceramic

By Timothy J. White,* Robert L. Segall, and Peter S. Turner

New studies utilizing electron microscopic techniques have revealed the immobilization of radionuclides in crystalline ceramic waste forms to be not merely a question of substituting waste elements into the appropriate crystallographic sites of a host matrix. Rather than entering the ceramic as a "continuous" solid solution it has been found that the incorporation of highly radioactive waste elements is commonly accompanied by structural modification. This may take the form of cation ordering, crystallographic shear, or twinning on a unit cell scale. Such mechanisms considerably enhance the capacity of a ceramic to immobilize (simulated) radwaste and impart to it the flexibility to respond to inevitable variations in wastestream composition.

1. Introduction

One of the major challenges confronting the nuclear power industry is to provide an enduring solution to the problem of high level waste (HLW) disposal which is both satisfying from a scientific viewpoint and convincing to the layman. The technological and environmental difficulties associated with radioactive refuse have long been recognized. In 1953 *Hatch*[1] showed remarkable prescience by outlining the likely hazards associated with the containment of spent fuel rods and recognizing the political and social responsibilities of a world embarking upon the generation of electricity by nuclear fission. It was he who coined the expression, now a cliche, "ultimate disposal" and described preliminary research associated with several disposal techniques that are under consideration today.

Currently, there is a broadly based consensus that securement of HLW is achieved most effectively by the use of nested multibarriers.[2] The barriers may be divided into two categories. The first is the immobilization barrier. Primarily, this refers to the material which has been produced by solidification of liquid waste. This matrix should be in a form that is mechanically sound and exhibits stability in the presence of groundwater. The barrier may include a corrosion resistant cannister in which the solidified waste has been placed. This "package" is then deposited in an (inaccessible) repository which can take the form of a salt dome, deep-sea clay formation, disused mine or deep bore hole; these and their surroundings constitute the geological barrier.

At present, the nuclear power establishment favors the incorporation of radwaste in borosilicate glass. The major advantage of the glass matrix is that it is "amorphous", hence the process of metamictization (or radiation induced disorder) is eliminated. However, glasses have a maximum waste load capacity of about 10 wt%, since it is difficult to maintain homogeneity during preparation, and annealing due to self-irradiation may cause devitrification.[3,4] In addition, doubts have been expressed with regard to the stability of glass under repository conditions which admit ground water.[5]

For these reasons, considerable effort is being expended to develop alternative or second generation crystalline

waste forms whose hydrothermal stability exceeds that of glass, and in addition possess the ability to effectively immobilize similar or greater waste loadings without undergoing deleterious structural change leading to inadequate leach resistance.[6] To this end, three approaches are receiving significant attention: a glass-(titanosilicate) ceramic the principal constituent of which is the mineral sphene ($CaSiTiO_5$);[7a] an alumina waste form which may be tailored to suit a variety of wastestreams;[7b] and SYNROC (*syn*thetic *rock*) a titanate ceramic based on several naturally occurring minerals.[7c]

In this article we explore the crystallochemical properties of SYNROC[8] and describe for the first time some unexpected structural characteristics which impart to the ceramic the flexibility to incorporate a great diversity of wastestream compositions and loadings.

2. The SYNROC Process

It is not the purpose of this paper to describe the techniques of SYNROC manufacture; this has been documented extensively elsewhere.[9, 10] However, some aspects of the fabrication which bear directly upon the microcrystalline properties of the ceramic are worthy of mention. At present, the favored preparative route—the Sandia process[11]—involves the hydrolysis of titanium tetraisopropoxide and zirconium tetra-*n*-butoxide in the presence of NaOH to yield a "sodium titanate—sodium zirconate" powder which behaves as a cation exchanger for an aluminum, barium and calcium nitrate solution. Simulated waste (see Table 1), also as a nitrate solution, is subsequently added to this precursor material. The slurry is dried and calcined under reducing atmosphere, then hot pressed with 2 wt.-% titanium metal added to control the redox potential. The most significant feature of this fabrication process, which distinguishes it from those employed for other ceramic waste forms, is the maintenance of low oxygen potential during manufacture. The reducing conditions ensure that molybdenum is reduced to metal, thus preventing the formation of molybdates which are highly susceptible to leaching. In addition, considerable quantities of Ti^{3+} are produced; as will be shown, this profoundly influences the crystal chemistry of the system because of its ability to substitute for Zr^{4+} (due to its size) and Al^{3+} (as a result of its valence).

Table 1. Typical composition (wt% oxide) of simulated waste (for 20 wt% loaded SYNROC) as compared to high level waste calcine.

Fission Products			Actinoids

3. The Phase Assemblage of SYNROC

Studies of the partition behavior of SYNROC phases have to date relied primarily on electron microprobe data. In order to grow crystals sufficiently large for satisfactory microprobe analyses ($>1\,\mu m$) samples must be hot-pressed at temperatures very close to the solidus ($>1200\,^\circ C$). However, during actual fabrication calcined powders are hot pressed at lower temperatures (1100—1170 °C) yielding a ceramic with grain sizes which are invariably less than 1 μm, many only a few hundred Ångstroms. Consequently, conventional methods of microstructural evaluation, viz. scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS), are unable to probe individual grains, making it impossible to unequivocally document the elemental partitioning between phases. In any case, the compositions of many SYNROC minerals are very similar, so chemical analyses alone are insufficient for definitive phase and structural identification.

Instead, it is necessary to adopt the more sophisticated technique of combining high resolution transmission electron microscopy (HRTEM), selected area diffraction (SAD), scanning transmission electron microscopy (STEM) and energy dispersive analysis to unequivocally characterize the waste form. Specimens were prepared for examination by crushing under ethanol and mounting on holey carbon films. (The more drastic preparative method of ion-beam milling was avoided since there is some evidence to suggest that structural alteration and elemental migration may result.[13])

The constituent phases of SYNROC are conveniently placed in six crystallographic categories: these are fluorite derivatives; perovskites; rutile; hollandite; magnetoplumbite/β-alumina types, and alloys. The relevant crystallographic data and approximate proportions of these phases in SYNROC are summarized in Tables 2 and 3, respectively. Their compositions are given in Figure 1.

4. Fluorite Superstructures

Fluorite (CaF_2) itself is cubic with $a = 5.463$ Å.[14] However, many nonstoichiometric derivatives containing a variety of altervalent ions are known; they are especially likely to form where the cations are relatively large, i.e. when r_{cation}/r_{anion} is about unity.[15] The effective ionic radii of the lanthanoids and actinoids are quite large[16] and so it is not surprising that several fluorite phases are observed in waste-loaded SYNROC. Most significantly, each fluorite structure may be derived from the others by the application of simple crystallographic operations on topographically similar portions of the structures. The relative abundance of these phases is determined by radwaste composition and loading.

Table 2. Unit cell parameters for SYNROC phases.

Phase Name/ Structure Type	System [a]	Cell Parameters						Ref.
		a [Å]	b [Å]	c [Å]	α [°]	β [°]	γ [°]

Alloy	$\leqslant$ 5%

4.1. Zirconolite

In 1964 *Pyatenko* and *Pudovkina*[17] showed zirconolite, nominally $CaZrTi_2O_7$, to be an anion-deficient superstructure derived from a fluorite-type substructure. Each unit cell of zirconolite consists of eight fluorite subcells ($8\times Ca_4F_8$) and contains $Ca_8Zr_8Ti_{16}O_{56}\square_8$, where $\square$ represents an oxygen vacancy. The (111) fluorite = (001) zirconolite metal planes are retained, but are occupied in an ordered fashion. However, the exact nature of the cation ordering over the subcell, crucial to our understanding of radwaste partitioning behavior, has only recently been determined.[18] It is useful to regard zirconolite in a formal way as a layer structure[18,19] in which planes of TiO_6 octahedra alternate with sheets of CaO_8/ZrO_7 polyhedra. The former are arranged in rings of three and six in the so-called hexagonal tungsten bronze type motif (Fig. 2). The larger cations are sandwiched between these layers and occur in strings of distorted Ca–O cubes (coordination number, CN = 8) or Zr–O monocapped octahedra (CN = 7). The interstice within the six-membered octahedral ring is occupied in a complicated manner. Ideally, a titanium atom would reside at the center of the ring in heavily distorted cubic coordination. However, such a polyhedron would be structurally unstable because of the large Ti–O bond lengths required. In accordance with Born theory[20] the cation moves slightly off-center such that the titanium atom is randomly located in either of two trigonal bipyramids (CN = 5).

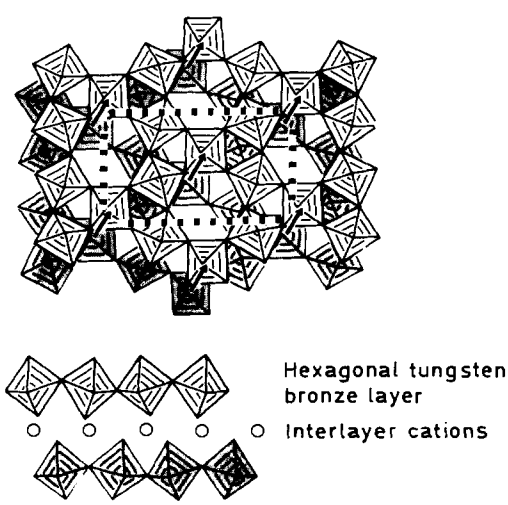

Fig. 2. Two hexagonal tungsten bronze layers as they occur in zirconolite. The upper (unshaded) is offset from the lower (shaded) by an interlayer displacement vector (arrowed). Large radionuclides are inserted between the layers. ■ ■ ■ delineates the unit cell repeat in (001).

In Figure 2 two adjacent hexagonal tungsten bronze layers in zirconolite are illustrated. The upper layer is staggered with respect to the lower (shaded); this offset is emphasized by arrows in the diagram. A third layer (not shown) would lie directly over the lowermost layer; thus, when considered sequentially, the displacement between layer pairs would be indicated by antiparallel arrows. This relationship between hexagonal tungsten bronze layers is conveniently represented by plotting the interlayer displacements upon the $a-b$ basal plane (Fig. 3). The double headed arrows, (placed at the corners of the unit cell and the C-center), indicate schematically the alternation in the direction of layer stagger (Fig. 3a). All the other fluorite structures may be derived from zirconolite by varying the pattern of layer displacement, and, as we shall see, this facilitates the incorporation of a variety of waste elements at a number of concentrations (cf. Section 10). Some other interlayer stacking sequences are shown in Figures 3b–f.

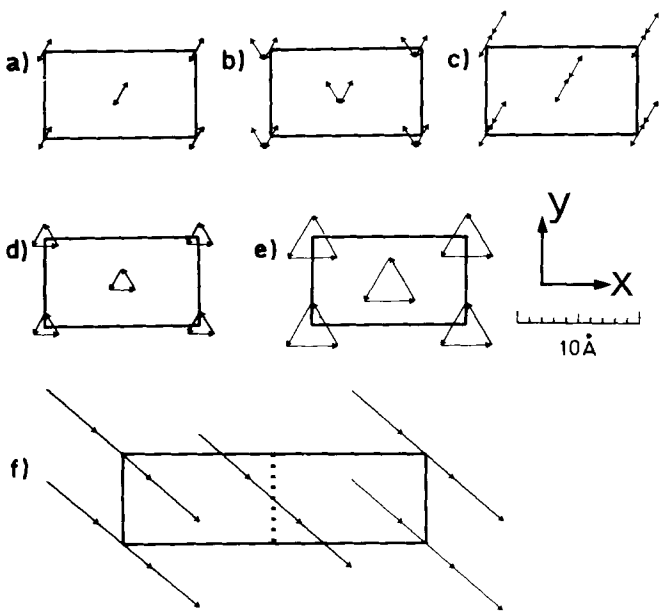

Fig. 3. Displacement vector diagrams for the fluorite derivatives plotted on the common a-b plane. (a) zirconolite, (b) zirconolite with t-type twin, (c) zirconolite with m-type twin, (d) zirkelite, (e) pyrochlore, (f) polymignyte.

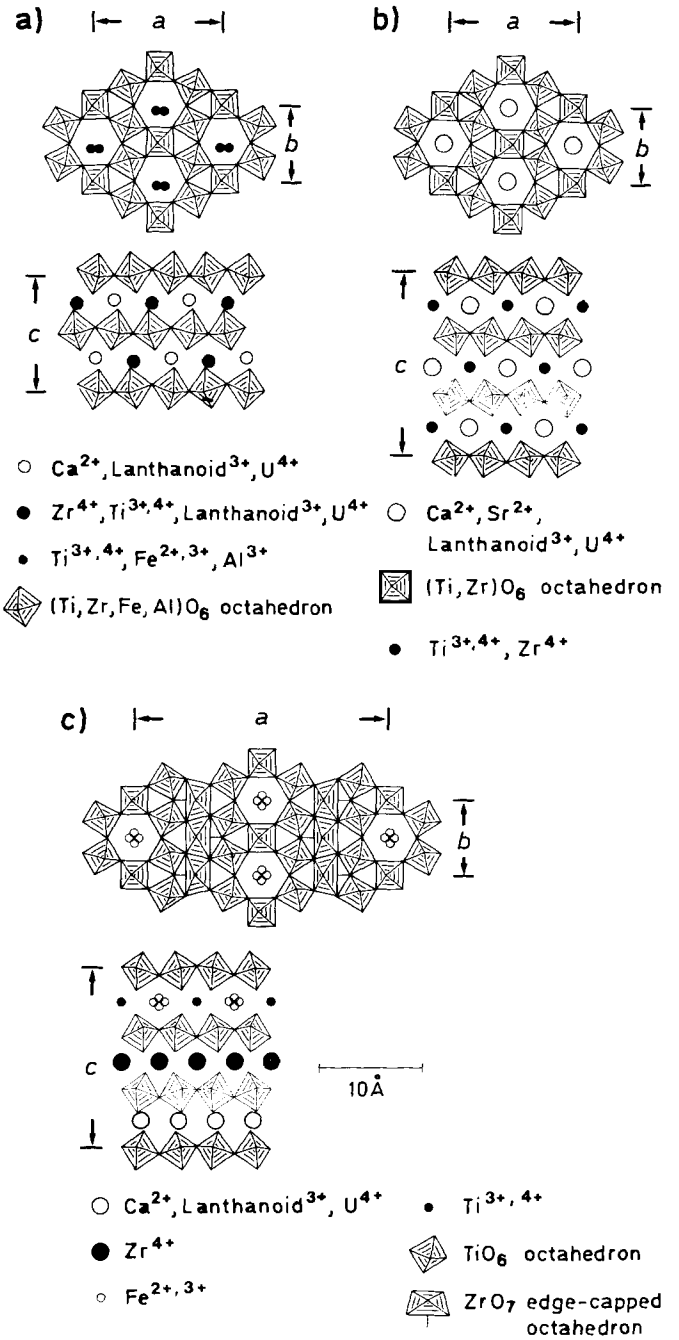

Fig. 4. Crystallochemical partitioning in (a) zirconolite and zirkelite, (b) pyrochlore, (c) polymignyte. In zirconolite-zirkelite and polymignyte the large interstice formed by the six-membered octahedral ring is filled by cations which are randomly distributed over two and four sites respectively. In pyrochlore the interstice is filled by large lanthanoids, actinoids, or Sr.

The partitioning behavior of zirconolite is quite complex (Fig. 4a). TiO_6 octahedra will accept Zr^{4+}, $Fe^{2+,3+}$, and Al^{3+}, while the smaller TiO_5 trigonal bipyramids will only accommodate the latter two of these. Trivalent lanthanoid ions and Th^{4+} are preferentially partitioned into Ca-sites whilst Zr^{4+} is replaced by U^{4+} and small, heavy trivalent lanthanoid ions.[12] The incorporation of these elements in zirconolite was confirmed by EDS (Fig. 1a).

At low concentrations the replacements are quite straightforward and radwaste is immobilized as a dilute substitutional solid solution. However, at modest concentrations—at the level of only 2.4 at% for neodymium[21]—isomorphic substitution no longer plays the primary role and the zirconolite structure is modified in a manner which greatly enhances the maximum concentration of "dissolved" radwaste. Initially, structural modification takes the form of polysynthetic (i.e. frequent) twinning on a unit cell scale. Displacement vector diagrams for the simplest twins are shown in Figure 3b,c. In t-type twins the zirconolite domains are related by rotations at 120° (i.e. a $t$riad rotation), whilst for m-type twins a 360° or $m$onad rotation is operating. Figure 5 is a typical high resolution electron micrograph of a twinned zirconolite crystal in SYNROC; different lattice periodicities result from the change in orientation across the twin boundaries.

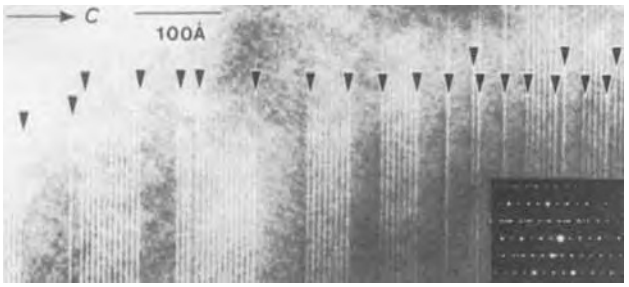

Fig. 5. High-resolution electron micrograph of SYNROC zirconolite. The frequent insertion of twin boundaries (arrowed) on the scale of a few tens of Angströms facilitates the incorporation of radionuclides. Each twin boundary can be considered as a narrow lamellar intergrowth of zirkelite, a phase stabilized by high actinoid concentrations.

4.2. Zirkelite

As the concentration of radwaste increases so does the frequency of twinning. It is not impossible for twinning to become perfectly regular and new ordered structure types produced.[21] One of these, zirkelite, has recently been analyzed using single crystal X-ray diffraction by *Mazzi* and *Munno*[22] and shown to be mimetically twinned zirconolite; mimetic twinning, as distinct from polysynthetic twinning, is perfectly regular.[23] *Mazzi* and *Munno*'s erudite interpretation of their diffraction data should not be underestimated. For many years, zirkelite and zirconolite were regarded as isotypic (i.e. structurally identical) as metamictization due to self-irradiation made diffraction studies equivocal. In the final analysis, the correct diffracted intensities could only be obtained by subtracting reflections due to other closely related species. Zirkelite was shown to have trigonal symmetry; however, the cell dimensions of the more useful C-centered unit cell are preferred and are given in Table 2. The sequence of layer displacements for zirkelite is shown in Figure 3d. Clearly, the insertion of three *t* type boundaries in zirconolite will yield a single unit cell of zirkelite. It is now obvious that the twin boundaries in zirconolite are usually very thin lamellar intergrowths of zirkelite. This is in complete agreement with other experiments which show zirkelite to have a greater capacity to incorporate actinoids than zirconolite provided that secondary cations such as Fe, Al or Mg are present.[12,21] Thus, the coherent intergrowth of zirconolite and zirkelite on a unit cell scale permits the incorporation of larger quantities of simulated radwaste (particularly the actinoids), than would be possible if simple cationic replacement was functioning alone.

4.3. Pyrochlore

The structure of pyrochlore, having the general stoichiometry (Ca, lanthanoids, actinoids)$_2$Ti$_2$O$_7$, has been extensively studied for many years.[24] It is cubic ($a = 10.1$ Å), but in the context of this discussion a direct comparison with other fluorite-related structures is facilitated by adopting the C-centered setting (Table 2). In this instance the interstices of the hexagonal tungsten bronze layers are occupied by large trivalent lanthanoid ions or tetravalent actinoid ions (Fig. 4b) in eightfold oxygen coordination. The sequence of interlayer displacements is identical to that found in zirkelite (Fig. 3e), but the offset between the layers is twice as great. In this manner CaO_8 cubes similar to those of zirkelite are retained, but the distorted monocapped octahedra are replaced by perfect (Ti,Zr)O_6 polyhedra, thus changing the interlayer cation coordination numbers from 8 plus 7 to 8 plus 6.

Pyrochlore occurs in SYNROC containing high waste loadings (i.e. >20 wt%). In crystallochemical terms this means a material with a relatively high Ca/Zr ratio, and a low concentration of Ca with respect to lanthanoids (Fig. 1a, b). The effect of doubling the interlayer displacement is to produce a fluorite derivative which has a greater capacity to immobilize lanthanoid fission fragments. In addition, pyrochlore may incorporate Sr^{2+}, U^{4+} and Th^{4+}; the partitioning behavior is summarized in Figures 4b and 1b.

4.4. Polymignyte

In a prototype SYNROC formulation containing 40 wt% simulated waste, yet another fluorite superstructure appears. The unit cell parameters of polymignyte, which is orthorhombic,[22] are given in Table 2. The octahedral motif of its layer cations is shown in Figure 4c. Clearly, large sections are still of the hexagonal tungsten bronze type, but they have been modified by crystallographic shear to yield a new type of layer interstice—an edge-capped octahedron.

This phase is favored when the concentration of Ca and Zr are simultaneously depleted relative to the amount of lanthanoids and actinoids. Iron (a processing contaminant), is a necessary constituent of this phase (Fig. 1c) being distributed statistically over four sites (two tetrahedral and two trigonal bipyramidal) which are situated around the center of the 6-membered octahedral ring.[22] These changes in the topology of the hexagonal tungsten bronze layers result in four different types of interlayer cation site. Two of them are not dissimilar to those found in zirconolite; however, in this instance the Zr-site is apparently devoid of any waste elements and the Ca-site accommodates all the U^{4+}. TiO_6 octahedra occur as in pyrochlore, and for the first time statistically occupied sites appear in the interlayer region. The interlayer stacking sequence for polymignyte is shown in Figure 3f.

Thus, zirconolite may be regarded as the structural aristotype of a group of minerals composed of (modified) hexagonal tungsten bronze layers. Providing altervalent cations are available (usually as processing contaminants) to ensure electrostatic charge balance, these layers can be stacked in a number of orientations which permit the incorporation of lanthanoids and actinoids at variable concentrations.

5. Perovskite and Related Structures

Perovskite has the composition $CaTiO_3$. Although initially thought to be cubic it was soon recognized to possess lower symmetry.[25] Subsequent X-ray crystallographic studies revealed it to be orthorhombic[26] (Table 2). The TiO_6 octahedral array of perovskite is derived from the

well known ReO_3 type (Fig. 6a); Ca atoms fill the large interstices between the octahedra and enter twelve coordinate cuboctahedral sites.

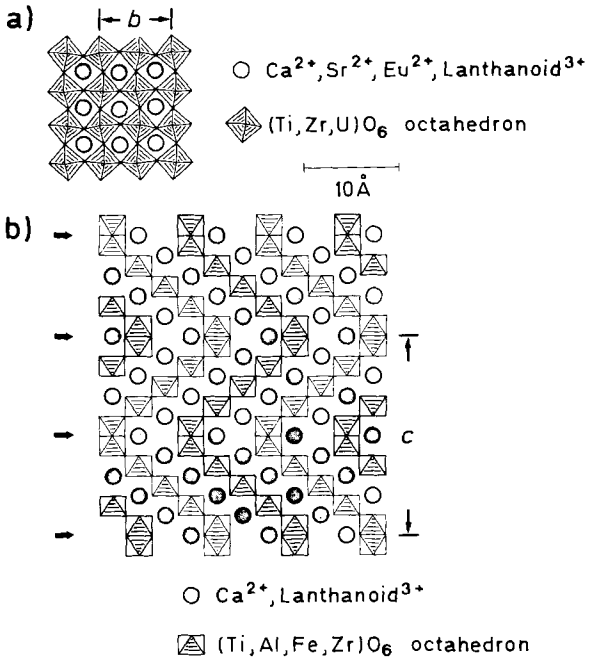

Fig. 6. (a) Octahedral array, projected down [101], and elemental partitioning in perovskite. (b) A drawing (idealized to cubic closest packing) of the most common perovskite polytype. This twinned arrangement of perovskite blocks accompanies the incorporation of neodymium and iron. Arrows indicate twin boundaries.

This mineral is the major host for Sr^{2+} and Eu^{2+}, and acts as a secondary host for trivalent lanthanoid ions; these replace Ca^{2+}. U^{4+} is also immobilized and it occupies the octahedral position.[27] The presence of these simulated waste elements was confirmed by EDS analyses (Fig. 1d). A large number of experiments have shown that radwaste generally enters perovskite by isomorphic substitution.[28]

In a special case, apparently when the local concentration of Nd and Fe are correct (see Fig. 1e), the perovskite grains begin to twin mimetically on the (approximately) close-packed atom planes. In this manner perovskite polytypes are produced. Figure 6b shows the most common structure (idealized to perfect cubic-closest-packing). Occasionally, disorder arising from variations in the width of the perovskite portion of the structure has been observed (Fig. 7).

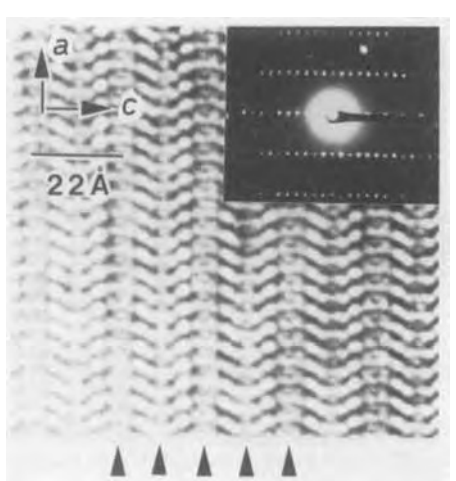

Fig. 7. High resolution electron micrograph of the perovskite polytype. Arrows indicate the same twin boundaries as those shown schematically in Figure 6b.

Infrequently, complex perovskite superstructures similar to those reported by *Nanot* et al. (1981)[29] are observed in 40 wt% waste loaded SYNROC; these phases are stabilized by high neodymium concentrations.

6. Rutile

The structure of rutile (Fig. 8a) was first determined by *Vegard* in 1916.[30] It is rather simple, being composed of TiO_6 octahedral strings that are corner connected to form tunnels one-octahedron wide. However, it has received considerable attention from crystal chemists because of its ability to accommodate nonstoichiometry by the introduction of crystallographic shear planes. At their simplest, these shear planes have the form $(hkl)_r = p(121)_r + q(011)_r$, where $1 \leqslant p/q \geqslant \infty$. This gives rise to an infinite number of crystallographic shear planes which are said to "swing" between $(121)_r$ and $(011)_r$.[31] The reducing conditions employed during SYNROC manufacture ensure that rutile invariably contains a variety of "swinging" shear planes due to the incorporation of Ti^{3+}. For all practical purposes radionuclides do not enter rutile, its major role being to buffer the redox conditions. A small amount of Zr^{4+}, typically 2 wt%[10] (Fig. 1e) does replace Ti and its stoichiometry is best regarded as $(Ti^{3+,4+}, Zr^{4+})_n O_{2n-1}$.

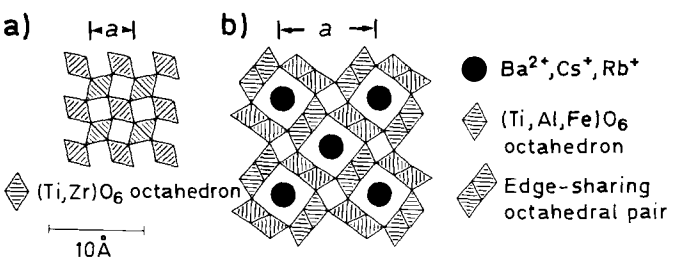

Fig. 8. Octahedral arrangement, shown along the short unit cell edge, of (a) rutile and (b) hollandite. The small octahedral tunnels of hollandite cannot accommodate simulated waste, but the larger incorporate Cs and Rb.

7. Hollandite

The structure of hollandite, *sensu stricto* $BaMn_8O_{16}$ was first determined by *Bystrom* and *Bystrom* in 1950[32] and shown to be tetragonal (Table 2). SYNROC hollandite has the ideal formula $Ba(Al^{3+},Ti^{3+})_2Ti_6O_{16}$.[33] Its structure is closely allied to that of rutile. Hollandite contains tunnels both one and two octahedra in width (Fig. 8b). The smaller of these are empty as in rutile, but the larger are occupied by Ba^{2+} which may be replaced by the radionuclides Cs^+ and Rb^+ (provided suitable altervalent cations are present). Evidence for the partitioning of the former element into hollandite is given in Figure 1g.

More recent structural refinements have shown that cation ordering along the tunnels is quite complex. The exact crystallographic positions and degree of filling of the tunnels is controlled by interactions between the occupants and the valence of the surrounding octahedrally coordinated cations.[34] These ordering effects in SYNROC hollandite are readily observed by selected area electron diffraction.[35] This is illustrated in Figure 9; stronger reflections arise due to the substructure defined by *Bystrom* and *Bystrom*, whilst weaker diffuse reflections (arrowed) are indicative of ordering along the tunnels. An extensive transmission electron microscopic study of SYNROC hollandite doped with Cs and Rb has shown that the incorporation of higher concentrations of monovalent species leads to longer range ordering sequences in the tunnel direction (Fig. 10).[36] It has been shown elsewhere[34] that the small cationic displacements, which produce these (incommensurate) superstructure reflections, yield a slightly larger cation acceptor site which is more suitable for the incorporation of Cs.

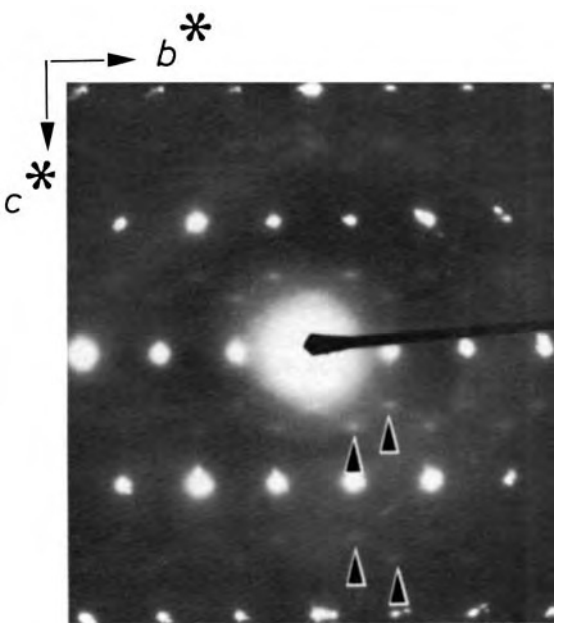

Fig. 9. Selected area electron diffraction pattern of hollandite. Diffuse reflections (arrowed) are indicative of cation ordering along c^*, the tunnel direction.

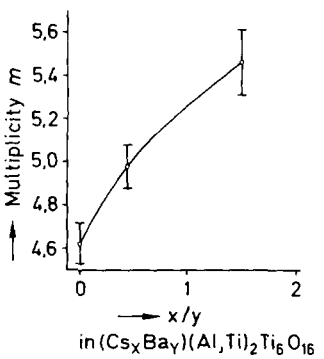

Fig. 10. The number of subcell units per supercell, or the multiplicity (m) of hollandite crystals increases as the Cs/Ba ratio is raised. That is, higher waste loadings lead to (increasingly) long range cation ordering sequences along the large hollandite tunnels. Values of m were determined from selected area electron diffraction patterns like that shown in Figure 9.

The titanium end member (*viz.* $BaTi_2Ti_6O_{16}$) has monoclinic symmetry and a doubled (pseudotetragonal) cell edge[37] (Table 2). This phase, however, has never been found in SYNROC; presumably the structure is destabilized by the presence of Fe and Al. Very occasionally "faulting" normal to the tunnel direction has been observed in a SYNROC variant (designated SYNROC E), which largely consists of rutile (80 percent by weight). This may be the result of intergrowth between the $BaAl_2Ti_6O_{16}$ and $BaTi_8O_{16}$ end members, and would certainly provide a means of incorporating some of the excess Ti^{3+}. It has been suggested that other hollandite derivatives may occur in SYNROC,[38,39] and indeed small ("defect") quantities of a number of structural variants have been recognized. One of these, $Ba_2Ti_9O_{20}$, may be of concern as it appears to be unable to take up Cs, and instead coexists with a highly soluble phase of approximate stoichiometry $Cs_2Ti_4O_9$.[40] However, the examination of many SYNROC preparations by selected area electron diffraction has failed to produce any evidence in support of the existence of single crystal $Ba_2Ti_9O_{20}$; it seems likely that this phase is not stable under the strongly reducing conditions. Nonetheless, some of the more complex defects in hollandite may contain elements of the $Ba_2Ti_9O_{20}$ structure. (Some crystallites in the SYNROC E formulation mentioned above yield diffraction patterns consistent with the $Cs_2Ti_4O_9$ phase of *Bursill* and *Kwiatkowska*.[40])

8. Magnetoplumbite and β-Alumina Structures

The structure of magnetoplumbite (Fig. 11) and β-alumina[41] are very closely related, both belonging to the same space group and having the ideal stoichiometries $AB_{12}O_{19}$ and $AB_{11}O_{17}$, respectively. They are mixed hexagonal-close-packed (h) cubic-close-packed (c) structures with the stacking sequence $(h^2c^3)^2$. Each cubic-close packed block is of the spinel type. These units are related by mirror planes at which large A atoms (Sr^{2+}, trivalent lanthanoid ions) and the appropriate number of B cations ($Ti^{3+,4+}$, Al^{3+}, $Fe^{2+,3+}$) commensurate with charge balance are inserted. The elemental contents of a magnetoplumbite crystal are given in Figure 1h. In β-alumina, the B atoms of the

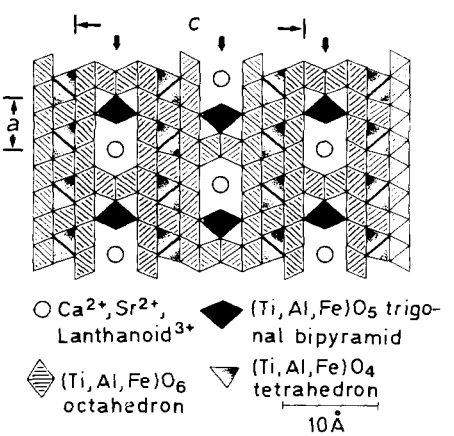

Fig. 11. Polyhedral arrangement in magnetoplumbite; mirror planes are arrowed.

inter-spinel region occupy tetrahedra, while in magnetoplumbite, octahedra and trigonal bipyramids are filled. In each instance AO_{12} twinned-cuboctahedra are present. The structures have been regarded as intergrowths between spinel and perovskite;[42] however, such a description is not convincing.

Magnetoplumbite has been extensively studied by *Morgan* et al.[7] as a possible host for a wide variety of radionuclides; it will accept most radwaste elements with the exception of the actinoids and possibly Cs. Only relatively small quantities of this phase are found in SYNROC as it provides a means of consuming residual Al^{3+} discarded from hollandite due to incorporation of Ti^{3+} produced during hot pressing.[33] This phase can be removed entirely, without deleterious effect on the performance of the ceramic, by eliminating the aluminum content of the formulation.[33]

Stacking faults in magnetoplumbite and β-alumina are well known and may arise from changes in the width of the spinel blocks[7] or from the insertion of antiphase boundaries.[7,43] These faults, which form in response to local variations in the concentration of radwaste species, should be regarded as structural intergrowths rather than "defects".

9. Other Phases

Fabrication under reducing conditions ensures that several of the waste constituents are (partially) reduced to metal; these include Tc, Ru, Rh, Pd, Cd, Fe, Ni, Mo and Ti. *Dosch* et al.[11] tentatively identified three intermetallic compounds in their experiments—a body-centered-cubic Mo-rich phase (≥80% Mo), Mo_4Ru_3 and Pd_4Te. However, the compositions of these alloys were quite variable, and their structures are unlikely to be as simple as the stoichiometries suggest.

In a ceramic as complex as fully waste-loaded SYNROC there exists the possibility for the formation of minor phases. It is perhaps surprising that these are rarely observed and probably account for less than 2 wt% of the bulk; the commonest additional phase is a Ca,Fe-titanate whose diffraction patterns are consistent with those of $CaTi_2O_4$. The only element whose crystallographic location has not been established is the processing contaminant phosphorus. Independent experiments[44] have shown the phosphate $Ca_3(PO_4)_2$ to be compatible with other SYNROC minerals, but the present study failed to identify this phase.

10. Concluding Remarks

The careful characterization of SYNROC by transmission electron microscopy has revealed the uptake of radwaste to be not only a question of inserting radionuclides into the appropriate crystallographic sites of a host matrix. We have shown the phenomenon of structural modification to very often accompany the incorporation of substantial levels of waste.

The fluorite oxides exhibit the greatest diversity of structural modification, engineered simply by varying the offset between successive hexagonal tungsten bronze layers. At low waste-loadings (< 10 wt%), zirconolite predominates. However, even at these levels, not all the waste may be accommodated directly into the "perfect" structure. Some of the elements, primarily the lanthanoids and actinoids, modify their crystallographic environment by causing zirconolite crystals to twin. The twin boundaries, rather than being regarded as crystalline defects are more rationally considered as thin lamellae of the closely related structure zirkelite. This mineral is known to be stabilized by high actinoid concentrations. If the waste is rich in lanthanoids or a 20 wt% loading is used, then pyrochlore coexists with zirconolite. At still higher waste-loadings (40 wt%) polymignyte becomes the dominant phase—zirconolite is seldom observed. It should be remarked that, with the exception of Rb, Cs, Sr, and P, all the radwaste (not reduced to metal) may be accommodated in fluorite phases. Perovskite and its polytypes are present to ensure the immobilization of Sr^{2+}, whilst hollandite and small quantities of some incompletely identified variants, which intergrow with the parent structure, take up Cs^+ and Rb^+; in both instances the incorporation of higher radwaste concentrations promotes long-range cation ordering. Little work has been done on the alloy structures, but they must also be quite complex.

It is a pleasure to acknowledge the support of an Australian Institute of Nuclear Science and Engineering Postdoctoral Fellowship and research maintenance (T. J.W.). Additional project funding was provided by the National Energy Development and Demonstration Programme of the Commonwealth Department of National Development and Energy. Specimens were provided by Dr. S. Kesson (A. N. U.), and K. D. Reeve, E. J. Ramm, D. M. Levins and J. L. Woolfrey (A. A. E. C.). Dr. D. J. H. Cockayne kindly made available EDS/STEM facilities at the Electron Microscope Unit, Sydney University. Informative critical reviews were provided by Dr. S. Kesson, Dr. H. Rossell, Dr. R. St. C. Smart, and Dr. S. Myhra.

The Glycine Receptor of Rat Spinal Cord: Exploring the Site of Action of the Plant Alkaloid Strychnine**

By Heinrich Betz*

The amino acid glycine is a major neurotransmitter in the spinal cord of all vertebrates and is involved in the control of various motor and sensory functions. By binding to specific receptors of the neuronal plasma membrane, glycine produces an increase in chloride permeability and thus a hyperpolarization, i.e., an inhibition of glycine-sensitive neurons. This inhibitory action of glycine is reversibly blocked by the plant alkaloid strychnine. We have used strychnine for the biochemical characterization and isolation of the glycine receptor of rat spinal cord. Our results show that the glycine receptor is a large membrane protein which contains three different polypeptides. Based on the currently available data we propose a structural model of the glycine receptor and discuss its relation to other proteins of the neuronal membrane that are involved in the transmission of nerve impulses.

1. Introduction

Numerous investigations over the last two decades suggest that, besides their metabolic function, amino acids serve an important role in the transmission of nerve impulses between neurons. For a long time it has been known that aromatic amino acids are the precursors for the synthesis of catecholamines and thus are important in the metabolism of signal substances (neurotransmitters) in the brain. Only recently, however, was it realized that unmodified amino acids also can serve as neurotransmitters.[1] Today, several acidic and neutral amino acids (Table 1) are generally accepted as neurotransmitters at many synapses (interneuronal communication sites) in the central nervous system. There, the amino acids are concentrated in specialized intracellular organelles, the synaptic vesicles. Upon excitation, they are released onto the plasma membrane of connecting "postsynaptic" neurons, where they bind to highly specific receptors and thus produce various responses. Acidic amino acids, such as glutamate or aspartate, excite and neutral amino acids, e.g., γ-aminobutyric

Krischke* for technical assistance, and *R. Franklin* for help with the preparation of this manuscript.

acid (GABA) and glycine, inhibit neuronal firing. Table 1 lists the amino acids that are currently considered to function as neurotransmitters or neuromodulators.

Table 1. Amino acid neurotransmitters.

Excitatory (increasing sodium conductance):
L-glutamate, L-aspartate, L-homocysteic acid [a]
Inhibitory (increasing chloride conductance):
glycine, GABA, taurine [a], β-alanine [a]

[a] Neurotransmitter function debated.

All the amino acid neurotransmitters listed in Table 1 produce selective alterations in the ion permeability of the neuronal cell membrane. Glutamate and aspartate increase the conductivity for Na^+, i.e., the influx of extracellular Na^+ into the negatively charged cytosol of the neuron. The resulting depolarization of the membrane's resting potential leads to an excitation of the nerve cell. GABA and glycine, in contrast, increase the chloride permeability: the influx of extracellular Cl^- produces a hyperpolarization of the plasma membrane, i.e., the neuron is inhibited.

The molecular structure of the plasma membrane proteins responsible for these conductance changes has only been poorly explored. In analogy with other receptor systems, amino acid receptors are thought to contain ion channels capable of assuming different protein conformations (Fig. 1). According to this model, the binding of an amino acid (or, more generally, an activator or "agonist") to the receptor induces the transition to an open, conducting conformation of the ion channel. Competitive receptor blockers ("antagonists") inhibit this conformational change by occupying the agonist binding site without activating the receptor: antagonists cannot produce the corresponding conformational alteration of the membrane protein. In other words, amino acid receptors are considered as bifunctional regulatory ("allosteric") proteins which mediate both neurotransmitter binding and ion transport. It should be noted here that the receptor activation depicted in Figure 1 implies a high molecular amplification of the primary signal: the binding of one or a few agonist molecules results within 1—5 ms in the flux of ca. 10^2—10^6 ions through the open channel of the activated receptor.

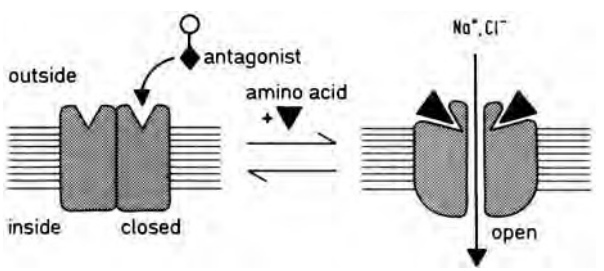

Fig. 1. Schematic representation of the closed and open conformations of an amino acid receptor.

So far, the biochemical analysis of amino acid receptors of the central nervous system has been hampered by their low concentration in the brain: a complete purification requires purification factors of ca. 10^4—10^6. However, the development of highly sensitive analytical techniques during the past three years has changed this situation. Today, the structural and functional analysis of these membrane proteins has become possible at the molecular level.

This review describes the efforts of our group to elucidate the molecular structure of an inhibitory amino acid receptor, the glycine receptor of rat spinal cord. Our results show that this chemically gated chloride channel has a complex structure which resembles that of other neuronal ion channels.

2. Strychnine—a Tool for Analyzing the Glycine Receptor

The alkaloid strychnine from *Strychnos nux vomica* has a rich history in natural products chemistry. The structural analysis of this alkaloid (Fig. 2) culminated in 1962 in its total synthesis by *Woodward*'s laboratory. In medicine, strychnine has long been popular as a stimulant and tonic. Higher doses of this alkaloid produce characteristic symptoms of poisoning which may cause pain and convulsions leading to death. Today, strychnine is still in use as a rat poison.

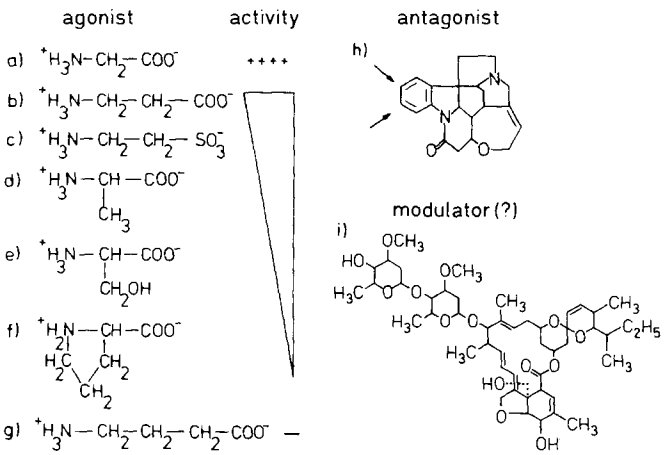

Fig. 2. Structure of glycine receptor agonists and antagonists. a) glycine; b) β-alanine; c) taurine; d) alanine; e) serine; f) proline; g) GABA; h) strychnine (the arrows indicate positions 2 and 3, which are suitable for substitution); i) avermectin B1a.

In the early 1950s strychnine was shown to disinhibit neurotransmission in the spinal cord. Meanwhile, it has been established that the toxic effects of strychnine result from a selective inhibition of the glycine receptor.[2] Strychnine binds with high affinity to this receptor (equilibrium dissociation constant ca. 10^{-8} M; see Table 2). It is thus a typical receptor antagonist. In 1973 *Young* and *Snyder*[3,4] demonstrated the existence of high-affinity binding sites for tritiated strychnine in membrane fractions of rat spinal cord. This binding was blocked by an excess of glycine and other amino acids that activate the glycine receptor.[3] Obviously these strychnine binding sites were located on the glycine receptor protein. The determination of these pharmacologically "specific" strychnine binding sites has since been used to localize and quantify the glycine receptor by a simple radioligand binding assay.[3-5]

Table 2. Equilibrium dissociation constants K_D of natural glycine receptor ligands.

Ligand	K_D [M] [a]
strychnine	9×10^{-9}
glycine	6×10^{-6}
β-alanine	5×10^{-6}
taurine	1×10^{-5}
GABA	$> 10^{-3}$

[a] The values are taken from [12] and were determined using glycine receptor purified by affinity chromatography.

3. Molecular Pharmacology of the Glycine Receptor

Not only glycine but also other amino acids inhibit neuronal firing in the central nervous system. Electrophysiological investigations have shown that β-alanine and taurine are efficient agonists of the glycine receptor. L-Alanine, serine, and proline, in contrast, have only weak agonist activity.[2-5] The binding affinities of the amino acid agonists are about 1000-times lower than that of strychnine (Table 2). GABA, which, together with glycine, is the most important inhibitory amino acid transmitter in the central nervous system, binds to a separate receptor system which is also coupled to a chloride channel.[6]

The structural formulas presented in Figure 2 show that the ionic groups of glycinergic agonists cannot be separated by more than two C atoms without destroying their activity. Side chains also inactivate their potency (Table 3). The stereoselectivity of asymmetric glycine receptor agonists is low.

Table 3. Inhibition of [^{3}H]strychnine binding to the glycine receptor by amino acids. [^{3}H]Strychnine binding to membrane-bound glycine receptor was determined in the presence of 20 mM amino acid as described in [9] (F. Pfeiffer, unpublished experiments).

Amino acid	Inhibition [%]
glycine	86.3
β-alanine	79.5
L-alanine	52.9
D-alanine	63.0
L-proline	49.0
D-proline	47.4
L-α-aminobutyric acid	<5
D-α-aminobutyric acid	16.8
L-valine	22.5
D-valine	<5

Strychnine (Fig. 2) has little structural similarity with the amino acid agonists. It is still a matter of debate whether strychnine binds to the glycine binding site of the receptor or to another site which is allosterically coupled with the former.[4] Strychnine tolerates only limited chemical modification without losing its biological activity. Substitutions in the aromatic ring system, in particular, lead to active derivatives, some of which are naturally occurring, such as brucine and other *Strychnos* compounds. The oxygen-containing seven-membered ring of strychnine can be opened without significantly impairing biological activity. In contrast, opening of the heterocyclic six-membered ring to give, for example, strychnic acid causes inactivation. Similarly, bulky substituents outside the aromatic ring system result in inactivation (Table 4). The biological activity of the different strychnine analogues does not correlate with their lipophilicity. Therefore, strychnine has been postulated to bind as a protonated base to the glycine receptor.[7]

Table 4. Biological activity and equilibrium dissociation constants K_D of receptor binding of strychnine and its derivatives.

Compounds	Biological activity [a] LD_{50} [μmol/kg]	K_D [M] [b]
strychnine	0.4	$\approx 10^{-8}$
2-aminostrychnine, 2-nitrostrychnine, 3-aminostrychnine, brucine (2-dimethylaminostrychnine), 2,3-dihydroxystrychnine, 2,3-diacetamidostrychnine, etc. (substitution in the aromatic ring system)	0.4–10	$\approx 10^{-8}$–$2.5 \cdot 10^{-7}$
21,22-dihydroxystrychnine, isostrychnine, bromodeoxyisostrychnine, etc. (substitution in the oxygen-containing seven-membered ring)	5–40	$\approx 10^{-7}$–10^{-6}
strychnic acid (9,10-secobrucin-10-ate), etc. (opening of the heterocyclic ring containing the keto function)	>50	$> 10^{-6}$

[a] LD_{50} was determined using mice [7]. [b] K_D was determined by competition experiments with [^{3}H]strychnine [7]; D. Graham, unpublished.

Figure 2 also shows a compound which is active at glycine and GABA receptors, avermectin B1a. This macrocyclic lactone, which is used as an antihelminthic agent, potentiates neurotransmission at inhibitory GABA synapses and thus causes paralysis of annelids.[8] At the isolated glycine receptor, avermectin B1a is an extremely efficient antagonist of strychnine binding.[9] Its in-vivo effect on spinal cord neurons has not, however, been investigated. In any case, this lactone represents a new class of active agents for the glycine receptor, and the elucidation of its mechanism of binding is thus of considerable interest.

4. Solubilization and Photoaffinity Labeling of the Glycine Receptor

The biochemical investigation of membrane-bound proteins requires their solubilization from the lipid bilayer of the membrane. This is usually achieved by generating micellar suspensions of the membrane components with suitable detergent mixtures. Our biochemical experiments thus began with attempts to solubilize the glycine receptor. This receptor can be efficiently solubilized with ionic and nonionic detergents (e.g., Triton X-100, sodium cholate) from membrane fractions of rat spinal cord.[10] The native (i.e., strychnine- and amino-acid-binding) conformation of the receptor, however, was only maintained in the presence of excess phospholipid in the detergent buffer. With such soluble glycine receptor preparations, a preliminary biochemical characterization of this membrane protein could be achieved. By classical methods of biochemistry, the glycine

receptor was shown to behave as a large glycoprotein with a molecular weight of about 250000 daltons.

The first identification of a subunit of the glycine receptor was based on photoaffinity labeling with tritium-labeled strychnine.[11] In the late seventies, several groups showed that photolabile low-molecular-weight compounds could be irreversibly bound to their high-affinity protein binding sites by illumination with ultraviolet (UV) light. Strychnine is light-sensitive; we therefore suspected that this alkaloid could serve as a natural photoaffinity ligand. In initial experiments, membranes from rat spinal cord were irradiated with UV light in the presence of [^{3}H]strychnine. The membrane proteins then were separated according to their molecular weight by gel electrophoresis, and the incorporated radioactivity was detected by fluorography. These experiments revealed a polypeptide that was covalently labeled with [^{3}H]strychnine; a comparison with marker proteins of known size revealed a molecular weight of 48000 daltons.[11] The labeling of this polypeptide is pharmacologically specific and occurs at or close to the high-affinity strychnine binding site of the glycine receptor.[12] The exact mechanism of this UV-induced incorporation of strychnine into the glycine receptor is not known. Kinetic studies suggest a photoactivation not only of strychnine, but also of aromatic amino acids (tyrosine) in the binding region of the 48000-dalton polypeptide.[12]

Photoaffinity labeling with [^{3}H]strychnine was also used for exploring the topology of the 48000-dalton polypeptide in the neuronal plasma membrane. Upon incubation of photoaffinity-labeled membrane vesicles of rat spinal cord with the protease trypsin, the radioactive 48000-dalton polypeptide was degraded into smaller peptides, and a final major product with an apparent molecular weight of 37000 daltons accumulated. This result indicates that the strychnine-binding subunit of the glycine receptor has a protease-accessible extracellular region of at least 11000 daltons.[12] Surprisingly, even extensive proteolytic digestion did not remove the radiolabel from the membrane fractions. Therefore, we suspect that the strychnine binding site of the glycine receptor is located at a domain of the

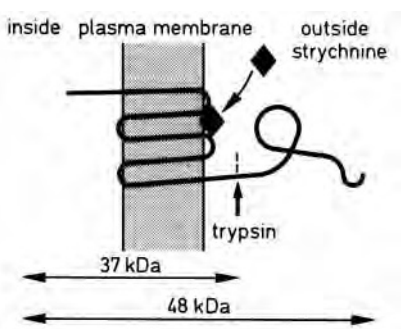

Fig. 3. Topology of the 48000-dalton polypeptide in the neuronal plasma membrane. The number of transmembrane domains is not known; five have been assumed here.

48000-dalton polypeptide which is protected from proteolytic cleavage by the hydrophobic environment of the lipid membrane (Fig. 3).

5. Affinity Chromatography and Biochemical Characterization of the Glycine Receptor

The solubilized glycine receptor was purified by affinity chromatography. A biologically active derivative of strychnine, 2-aminostrychnine (cf. Table 4), was coupled to an agarose support via a long hydrophilic spacer. Upon incubation with detergent extracts of spinal cord membranes, this aminostrychnine—agarose bound more than 90% of the soluble glycine receptor. After extensive washing with buffers of high ionic strength, about 20% of the bound receptor molecules could be recovered by elution with the competing agonist glycine (Fig. 4).[13] This simple procedure resulted in a 2000-fold purification of the glycine receptor in one step. Currently, one purification yields about

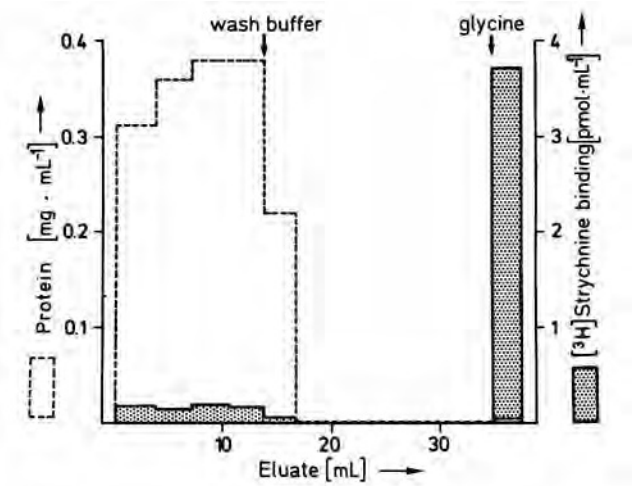

Fig. 4. Affinity chromatogram of the glycine receptor. A detergent extract of rat spinal cord membranes was pumped through an aminostrychnine-agarose column, and the column was then washed with detergent buffer. Under these conditions, 80–90% of the strychnine binding sites, but < 1% of the protein is adsorbed to the column. Subsequently, strychnine binding sites, i.e., glycine receptor, were eluted with glycine. Note the low protein content of the strychnine eluate (corresponding to a 1500-fold purification of the receptor).

25–50 μg of highly purified glycine receptor. Polyacrylamide gel electrophoresis in the presence of the denaturing detergent sodium dodecyl sulphate separated the purified glycine receptor into three polypeptides with molecular weights of 48000, 58000, and 93000 daltons.[13] The native receptor had a molecular weight of about 250000 daltons (Section 4). Using photoaffinity labeling, the 48000-dalton polypeptide of the purified glycine receptor preparations was shown to be identical with the strychnine binding subunit of the glycine receptor previously identified in membrane fractions.[13] The function of the two other receptor polypeptides is not known. These polypeptides are probably associated with the 48000-dalton subunit and form a heteropolymer which functions as the chloride ion channel.[14] This idea is also supported by structural investigations of the glycine receptor of pig spinal cord[15] and by reconstitution experiments using affinity-purified glycine receptor. Using methods developed for other receptor proteins,[16] the purified glycine receptor was incorporated into phospholipid vesicles by removal of the detergent, and these vesicles subsequently were used to form planar

lipid bilayers. The addition of glycine to these planar membranes produced an increase of membrane conductance which exhibited several characteristics of the typical glycine response.[17] These experiments indicate that the isolated glycine receptor contains all components required for ion translocation.

A model based on the currently available data is given in Figure 5. According to this model, the glycine receptor contains two copies of the 48000-dalton and one copy each of the 58000- and 93000-dalton subunits. The binding of two glycine molecules to specific binding sites on the 48000-dalton polypeptide induces a conformational change of the receptor and thus the opening of a chloride ion channel formed by all (or only the 93000-dalton) subunits. This model is compatible with the available electrophysiological and biochemical data. It should, however, be emphasized that many of its features, in particular the exact stoichiometry and topology of the subunits, have to be verified by additional experiments.

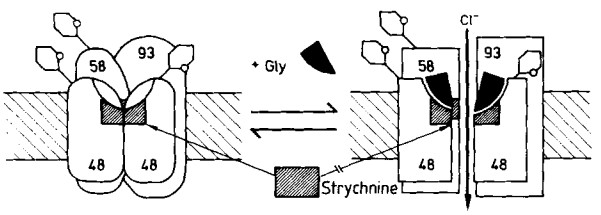

Fig. 5. A model of the glycine receptor. Here, it is assumed that the binding of glycine to the receptor alters the conformation of all receptor polypeptides via allosteric interactions, and thus opens the chloride channel. The numbers are the molecular weights [kDa] of the peptides. The carbohydrate side chains present on the 48- and 58-kilodalton polypeptides are schematically shown.

In order to produce new ligands for the further characterization of the glycine receptor, we have produced monoclonal (i.e., determinant-specific) antibodies against the glycine receptor protein by using the hybridoma technology of *Köhler* and *Milstein*.[18] Currently, nine monoclonal antibodies are available. Some of these antibodies bind to the 48000-dalton and others to the 93000-dalton subunit of the receptor.[19] Surprisingly, two of our monoclonal antibodies recognize not only one but two subunits of the glycine receptor. The subunits of this receptor therefore can be assumed to contain common antigenic determinants, probably homologous peptide structures. Peptide maps produced with different proteolytic enzymes also suggest chemical similarities between the glycine receptor polypeptides, in particular the small ones.[19] These results suggest that all subunits of the glycine receptor may be derived from a common ancestor receptor polypeptide. A divergent evolution of individual receptor polypeptides from a homopolymeric ancestor membrane protein is well established for another neurotransmitter receptor, the nicotinic acetylcholine receptor from the electric organ of fish.[20]

6. Conclusions and Perspectives

Our investigations of the glycine receptor demonstrate that the membrane proteins involved in neurotransmission are amenable to biochemical analysis provided high-affinity ligands such as strychnine are available. Suitable affinity chromatographic techniques allow the purification of these rare (<0.1—0.01% of total cell protein) membrane proteins. Today, the glycine receptor is one of the biochemically well-characterized neurotransmitter receptors of the central nervous system. This membrane glycoprotein has a native molecular weight of 250000 daltons and contains three different polypeptides. Photoaffinity labeling and reconstitution experiments showed that the purified receptor oligomer contains not only the ligand binding site but also the chloride channel of this allosteric membrane protein. We are, however, still far from a true understanding of its structure and function as a chemo-electrical signal transducer. Here, only detailed pharmacological and structural investigations can advance our knowledge. For the organic chemist, a detailed analysis of the structure-function relationship of glycinergic agonists and antagonists and their discrimination from GABA receptor ligands appears particularly appealing. The currently available data are unfortunately rather poor. At present we have only limited information on the topology of the agonist binding site of the glycine receptor; it is certain, however, that closely spaced cationic and anionic groups are required. In addition, there are restrictions on side-chain substitutions of the agonist.

The further analysis of the receptor protein requires the identification of the amino acids involved in strychnine binding via affinity ligands or specific antibodies, as well as the determination of the complete primary structure of the 48000-dalton subunit. Since only limited amounts of highly purified receptor protein are available, the latter goal must be based on gene cloning methods. Our current efforts therefore concentrate in part on the isolation of the messenger ribonucleic acid (mRNA) of this and the other glycine receptor polypeptides. This requires their amplification as complementary deoxyribonucleic acid (cDNA) in bacteria and the determination of their informational content by base sequencing. If successful, this approach may allow the expression of individual receptor polypeptides in bacteria and even of the functional heteropolymeric protein in eucaryotic cells. Specific chemical mutagenesis of the DNA should then allow the modification of individual receptor regions and thus lead to a dissection of functionally important receptor domains, such as the ligand binding region and the ion channel. Refinement of these techniques may in addition help to develop a precise structural pharmacology of the glycine receptor. This receptor definitely has considerable potential for the application of new pharmacological agents, since it is known to control not only the motor neuronal pathways, but also many sensory neuronal pathways. Efficient glycine receptor agonists and modulators thus have considerable promise as potential anticonvulsive and analgesic drugs. Furthermore, glycine receptor studies may open new possibilities for applied medicine; this protein has been suggested to induce autoimmune reactions in degenerative spinal cord diseases. A detailed analysis of receptor structure and metabolism should illuminate the pathogenesis of these syndromes.

It may be noted here that the molecular structure of the glycine receptor emerging from these studies is similar to

that of other ion-channel proteins in the electrically excitable plasma membrane. Table 5 summarizes the molecular weights and, where known, the subunit composition of the currently investigated chemically and voltage-gated ion channels. All these membrane proteins are large glycoproteins with a total molecular weight of about 250000 to 300000 daltons. In the case of the voltage-dependent sodium channel responsible for the propagation of nerve impulses, this molecular mass is located on one large glycopeptide. The nicotinic acetylcholine receptor and the glycine receptor, in contrast, contain subunits with mean molecular weights of about 50000 daltons. Several other neuroreceptors, like the GABA receptor and the nicotinic acetylcholine receptor of the central nervous system, also fit into the latter scheme; these proteins consist of polypeptides of 50000–60000 daltons and have native molecular weights of about 250000–300000 daltons (Table 5). It has therefore been proposed that the evolution of these channel proteins followed a common organizational principle.[21] Recently discovered structural homologies between the individual subunits of the nicotinic acetylcholine receptor[22] and probably also the glycine receptor[19] support this idea. Whether the different receptor proteins and ion channels of the neuronal membrane are all related, i.e., members of a large gene family, is unknown. The primary structure data that will become available during the coming years should clarify the picture.

Table 5. Molecular properties of neuronal ion channels.

	Molecular weight of native protein [kDa]	Molecular weight of subunits [kDa]	Composition of subunits
nicotinic acetylcholine receptor

The 3′-End of tRNA and Its Role in Protein Biosynthesis**

By Stanislav Chládek and Mathias Sprinzl*

In the course of protein biosynthesis, the 3′-ends of aminoacyl-tRNA (aa-tRNA) and peptidyl-tRNA specifically interact with macromolecules of the protein biosynthesis machinery. The 3′-end of tRNA consists of an invariant C-C-A single strand. Interaction of the aminoacyl-tRNA 3′-end with elongation factor Tu (EF-Tu) containing bound GTP is necessary for the formation of the aa-tRNA·EF-Tu·GTP complex and, after the complex binds to the ribosome, for the GTP hydrolysis. This process is followed by the specific binding of the aminoacyl-tRNA 3′-end to the aminoacyl (A) site of the ribosome. In this review, a model is proposed that involves Watson-Crick base pairing of the C-C sequence of the aminoacyl-tRNA 3′-end with a specific G-G sequence of the ribosomal 23S RNA. Similarly, peptidyl-tRNA binds with its 3′-end to the peptidyl (P) site of the ribosome. This binding may also involve Watson-Crick base pairing of the C-C-A sequence with a complementary sequence of 23S RNA. It is proposed that peptide bond formation is catalyzed by a functional site of the 23S RNA located near the 3′-ends of aminoacyl-tRNA and peptidyl-tRNA. A model is suggested in which two loops of the 23S RNA, brought into close proximity via folding, are involved both in binding the 3′-ends of the tRNAs and in catalyzing peptide bond formation. This model presumes a dynamic structure for ribosomal RNA, which is modulated by interaction with elongation factors and ribosomal proteins.

1. Introduction[***]

The biosynthesis of proteins, a central process in the living cell, is one of the most intensively studied topics of molecular biology. Several aspects are a focus of current interest: the regulation of protein synthesis at the translational level,[3] the processing and transport of newly synthesized proteins,[4,5] and the fidelity of protein synthesis.[6] Nevertheless, the basic questions remaining to be answered concern the mechanism of translation and the structure and function of the protein synthesis apparatus.

The most important step in protein biosynthesis, from a chemical point of view, is the formation of the peptide bond. This reaction, which is accomplished on the ribosome, takes place via the transfer of an activated peptidyl residue from peptidyl-tRNA to the amino group of aminoacyl-tRNA. The correct reading of the mRNA during translation is of utmost importance since, once the peptide bond is formed, it is energetically unfavorable for the translational apparatus to correct any errors. Since extremely few errors are observed,[6] the correction steps must take place prior to peptide bond formation. The tRNA adaptor molecule plays a central role in this process since it must, on the one hand, faithfully recognize the appropriate codon of the mRNA and, on the other hand, transfer the aminoacyl residue onto the growing peptide chain. Although recognition of tRNA by the protein biosynthesis apparatus cannot be a simple matter, two areas of the tRNA molecule are of a special significance for the translational process: the anticodon region, which specifically interacts with the mRNA codon, and the 3′-end, where the chemical reactions take place.

The 3′-end of tRNA consists of the single stranded invariant C-C-A^{76} sequence,[2] which is connected to the helix of the aminoacyl stem by an unpaired nucleotide, usually a purine nucleotide (Fig. 1). The C-C-A sequence of tRNA is not involved in tertiary interactions with other regions of the molecule. Thus, the 3′-end of tRNA should presumably be available for interactions with the components of the protein synthesis apparatus.

The aminoacyl residue is attached to the 2′(3′)-hydroxyl group of the terminal adenosine residue of tRNA via an ester linkage. Thus, the C-C-A terminus of the charged tRNA, by virtue of its specific interactions with the ribosomal components, can assist in the binding of the aminoacyl residue to the appropriate site on the ribosome.

The C-C-A sequence of tRNA has an ordered structure, which is stabilized by stacking interactions in the aminoacyl stem. This structure is probably recognized by the en-

zymes of the protein biosynthesis apparatus. 3′-Terminal adenosine is involved in the stack, and relatively small structural changes, e.g., aminoacylation, may lead to a perturbation of this ordered structure.[7,8] It is assumed that even small changes in the physical environment of the C-C-A sequence of tRNA can also modulate its structure. Thus, the 3′-end of tRNA can serve as a mobile instrument, capable of accommodating different partners of the translational machinery.

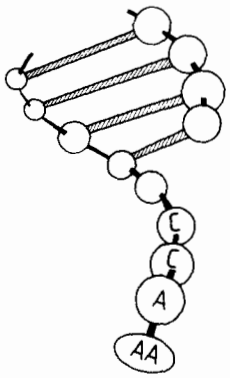

Fig. 1. Schematic drawing of the structure of the 3′-end of aa-tRNA. The last four nucleotides do not interact with the rest of the tRNA molecule; they are probably stacked on top of one another. AA = aminoacyl residue.

This article will focus on the role of the 3′-end of tRNA in protein biosynthesis. The discussion of the molecular mechanism of recognition of the 3′-end of tRNA will be based primarily on chemical results. This will hopefully lead to further stimulation of interest in this important topic and, in addition, aid efforts in understanding the events that lead to the synthesis of proteins on ribosomes.

Some aspects of this topic were recently reviewed.[9–15] The overall mechanism of protein biosynthesis has recently been discussed by several authors[16–18] and the structure of ribosomes has been reviewed by *Wittmann*.[19]

2. Properties of the Aminoacyl Ester Bond

2.1. Chemical Properties of the Aminoacyl Ester Bond

The ester bond of aa-tRNA is an activated, energy-rich bond. The free energy of hydrolysis of aa-tRNA is approximately equal to the free energy of hydrolysis of ATP.[20] The attachment site of the aminoacyl residue is the oxygen atom in the 2′- or 3′-position of the terminal adenosine of tRNA. The esterification of tRNA with the amino acid is catalyzed by a specific aminoacyl-tRNA synthetase. A simplified reaction scheme is depicted in Figure 2. In the first reaction, the amino acid is activated via formation of the aminoacyl adenylate from the amino acid and ATP in the presence of the enzyme. Pyrophosphate, which is also formed, is hydrolyzed in a further enzymatic reaction to inorganic phosphate. This coupled reaction shifts the equilibrium of the amino acid activation in the direction of the aminoacyl adenylate product. The transfer of the aminoacyl residue from aminoacyl adenylate to the 3′-terminal adenosine of the tRNA is accomplished in the second reaction, which again is catalyzed by aminoacyl-tRNA synthetase. In principle, either the 2′- or 3′-hydroxyl group of the terminal adenosine can function as an acceptor of the aminoacyl residue. However, the aminoacyl-tRNA synthetases are specific for only one hydroxyl group.[14,21] It is remarkable that the overall error rate for both reactions, i.e., activation and transfer of the aminoacyl residue, is very low. This high fidelity is achieved by an enzymatic proofreading mechanism.[22–24]

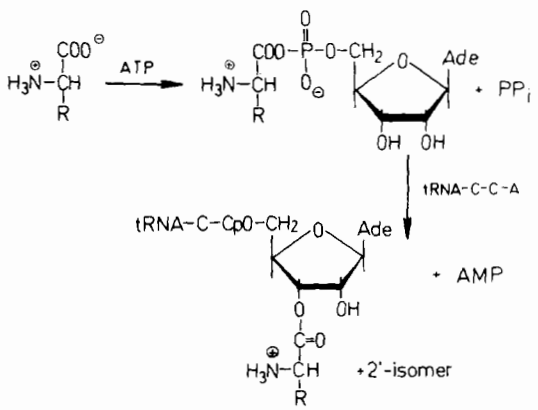

Fig. 2. Enzymatic aminoacylation of tRNA. Both steps are catalyzed by the appropriate specific aa-tRNA synthetase.

Assuming that only the pure 2′- or 3′-isomer of aa-tRNA is formed in the enzymatic reaction, two spontaneous, competing reactions can take place: a) hydrolysis with the formation of a free amino acid and uncharged tRNA and b) transacylation between the vicinal *cis*-hydroxyl groups of the 3′-terminal adenosine, resulting in the formation of an equilibrium mixture of 2′- and 3′-*O*-aminoacyl esters of tRNA (Fig. 3). Both chemical processes have been studied intensively. The hydrolysis of the aminoacyl residue of aa-

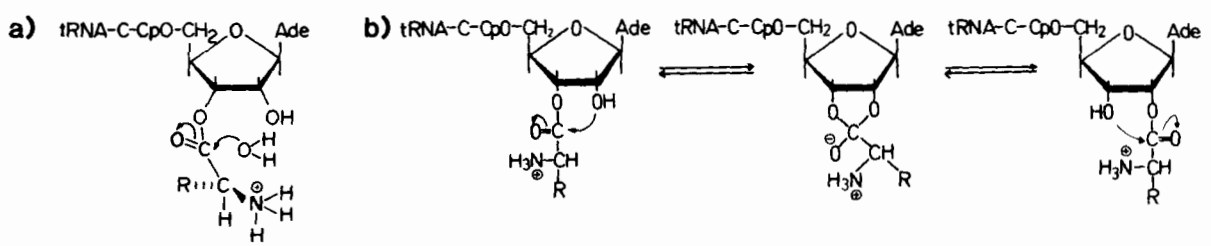

Fig. 3. a) Hydrolysis of the aminoacyl residue of aa-tRNA. b) Transacylation between 2′- and 3′-hydroxyl groups of aa-tRNA. The formation of the ortho acid intermediate is facilitated by the protonated α-amino group of the aminoacyl residue.

tRNA is facilitated by the presence of the neighboring 3′(2′)-hydroxyl group.[25] However, this effect has been often overestimated. The aminoacyl residue of native aa-tRNA terminating with adenosine hydrolyzes only about three times faster than that of aa-tRNA terminating with deoxyadenosine.[26] The 2′(3′)-hydroxyl group of the ribose residue is a poor leaving group for hydrolysis ($pK = 12.5$), but still more acidic than, e.g., ethanol ($pK = 16$). This property of the ribose hydroxyl groups is due to the electron withdrawing effect of the endocyclic oxygen of ribose. Indeed, it is known that aa-tRNA hydrolyzes about 30 times faster than aminoacyl alkyl esters. This difference can be attributed mainly to the pK difference of 3.5 for these particular leaving groups, which corresponds to a factor of ten in their rates of hydrolysis, and only to a much lesser extent (factor of 3) to the effect of the neighboring hydroxyl group.[27]

Aminoacyl-pyrimidine or -purine nucleotides and aa-tRNAs with the same aminoacyl residue have very similar rates of hydrolysis,[28,29] indicating that neither the terminal nucleobase nor the polynucleotide chain of aa-tRNA influences significantly the reactivity of the ester bond. On the other hand, there are significant differences in the rates of alkaline hydrolysis of aa-tRNAs incorporating different amino acids.[30]

The rate constants for the hydrolysis of methyl esters of amino acids can be correlated with the Taft substituent constants σ.[31] There are, however, two notable exceptions to this correlation, namely, valine and isoleucine esters, wherein the chain branching adjacent to the reaction center leads to steric hindrance which slows the rate of hydrolysis. The main factor facilitating the nucleophilic attack on the carbonyl group of the aminoacyl ester is the inductive ($-I$) effect of the protonated α-amino group. For instance, Val-tRNA with a positively charged α-amino group hydrolyzes 90 times faster than the neutral form of the same aa-tRNA.[27] The absence of a protonated α-amino group also explains the high stability of *N*-acylaminoacyl-tRNA[27] or phenyllactyl-tRNA[32] toward alkaline hydrolysis. Since the pK values of the α-amino group of aa-tRNA are in the range between 7 and 8,[33] the rate of hydrolysis at physiological pH will depend principally on the degree of protonation of the particular amino group and the differences in the rates will be largest in the physiological range (pH 7–8).

The rate of transacylation of 2′(3′)-*O*-aminoacyl esters of adenosine and adenosine 5′-phosphate was recently measured by the NMR saturation transfer method.[34] The rate constants for transformation of a 2′-*O*-aminoacyl adenosine into the 3′-derivative in aqueous buffer at pH 7.3 and 37 °C were estimated to be 3–11 s^{-1} for the 2′→3′ transacylation and 1–4 s^{-1} for the 3′→2′ transacylation. The rate of transacylation also depends primarily on the protonation of the α-amino group. The protonated aminoacyl residue migrates about 100 times faster than the unprotonated one. This is due to the inductive effect of the protonated amino group and presumably to its ability to stabilize the intermediate orthoester structure by ionic interactions (Fig. 3b). The 5′-phosphate group of the terminal adenosine and the charged functional groups of amino acids such as lysine or glutamic acid do not significantly influence the rate of transacylation. Moreover, the structures of the terminal C-C-A sequence of aa-tRNA and other structural elements of the polynucleotide chain apparently do not affect appreciably the rate of transacylation.

The overall rate of protein biosynthesis in *E. coli* corresponds to the incorporation of 15–20 amino acid residues per second.[35] Thus, the rates of spontaneous 2′⇄3′ transacylation are slow compared to the overall rate of biosynthesis. Therefore, it is conceivable that an enzymatic activity is present in the cell which catalyzes the transacylation of the aa-tRNA to give the required 2′- or 3′-isomer.[36]

2.2. Conformation of the Aminoacyl Residue

There is little information about the structure of the aminoacyl residue in aa-tRNA and its possible interactions with the polynucleotide chain of tRNA. The physicochemical studies of this problem are limited by the instability of the ester linkage of aa-tRNA and the relatively large amount of material needed for such studies. Crystallization of aa-tRNA has not yet been possible. Therefore, a crystallographic structural analysis was made only with puromycin, the stable analogue of 3′-*O*-aminoacyl adenosine[37] (cf. caption to Fig. 14). The results have not indicated any direct interaction between the aminoacyl side chain and the adenine moiety. On the other hand, some structural changes in the polynucleotide chain were detected upon aminoacylation of tRNA.[38,39] The nature of the changes is however unknown. Crystallization of stable aa-tRNA analogues[9] and high-resolution NMR studies of such compounds would be invaluable in the study of this problem.

3. Analogues of Aminoacyl-tRNA

Several aspects of the function of the 3′-end of tRNA have been clarified using analogues. Two types of analogues are used: tRNA species with modified units incorporated at a precise site of the 3′-end, and 3′-terminal fragments of aa- or peptidyl-tRNA, which may also contain modified units.

3.1. Modified Aminoacyl- and Peptidyl-tRNAs

The incorporation of modified nucleotides into the 3′-end of tRNA can be accomplished by a combination of chemical and enzymatic methods. Some synthetic nucleoside 5′-triphosphates are substrates for ATP (CTP): tRNA nucleotidyl transferase and can be incorporated into shortened tRNAs, thus replacing the natural CMP and AMP residues in the C-C-A sequence[40] (Fig. 4). This approach was used for the preparation of tRNAs **1** and **2** with terminal deoxyadenosine,[14,21] which were then converted into aa-tRNAs. In such tRNAs 2′(3′)-isomerization cannot take

$$\text{tRNA-N-C}^{74} + \text{C*TP} + \text{ATP} \longrightarrow \text{tRNA-N-C-C*-A} + 2\,\text{PP}_i$$
$$\text{tRNA-N-C-C}^{75} + \text{A*TP} \longrightarrow \text{tRNA-N-C-C-A*} + \text{PP}_i$$

Fig. 4. Enzymatic incorporation of ATP or CTP analogues into truncated tRNAs using ATP (CTP): tRNA nucleotidyl transferase. C* and A* are modified cytidine and adenosine units. N signifies any nucleotide.

place because the neighboring OH group on the terminal adenosine is absent. tRNA derivatives containing a 2′-amino-2′-deoxyadenosine **4** or a 3′-amino-3′-deoxyadenosine **3** on the 3′-end were prepared in an analogous way[40,41] (Fig. 5). Similarly, the natural cytidine unit at position 74 or 75 can be replaced by a modified nucleotide if an analogue of CTP is employed. The truncated tRNAs required for such syntheses (tRNA-N[73], tRNA-N-C[74], or tRNA-N-C-C[75]) are obtained by partial degradation of native tRNA-N-C-C-A[76] with snake venom phosphodiesterase[42] or polynucleotide phosphorylase.[43] The stepwise degradation of nucleotides via periodate oxidation, β-elimination, and phosphatase treatment has been especially used for the large scale preparation of truncated tRNAs. The disadvantage of this chemical method is the deactivation of some tRNA species during periodate treatment.[40]

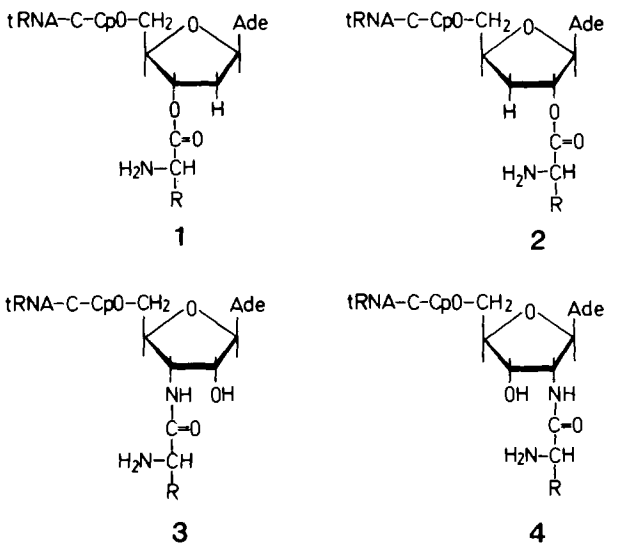

Fig. 5. Structures of non-isomerizable analogues of aa-tRNA: aa-tRNA-C-C-2′dA **1**, aa-tRNA-C-C-3′dA **2**, aa-tRNA-C-C-3′NH_2A **3**, and aa-tRNA-C-C-2′NH_2A **4**.

More recently, tRNAs modified on the 3′-end were prepared via incorporation of oligonucleotides using RNA-ligase (Fig. 6). In this reaction, truncated tRNAs are used as

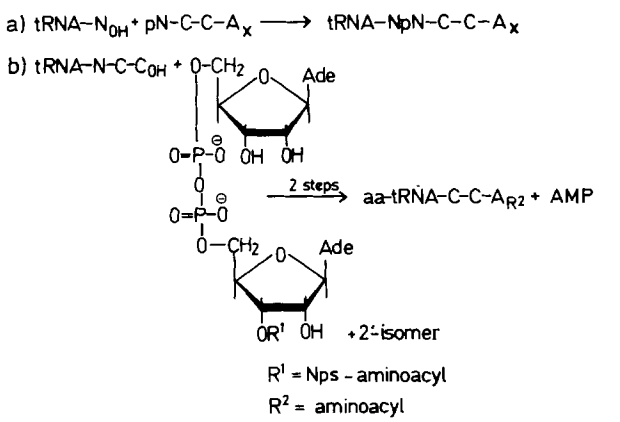

Fig. 6. Enzymatic synthesis of modified aa-tRNAs using RNA ligases. The truncated tRNA may either react with the 3′-blocked tetranucleotide donor (a) or the extension is achieved via the reaction with AppA derivatized with an *N*-protected amino acid (b). After the condensation, catalyzed by RNA ligase, the *o*-nitrophenylsulfenyl (Nps) group is selectively removed (according to [48]). N signifies any nucleoside.

acceptors;[44] donor molecules are either 5′-phosphorylated oligoribonucleotides[45–47] protected at the 3′-hydroxyl group or derivatives of diadenosine-5,5′-diphosphate (AppA-X), where X is a substituent on the 3′- or 2′-hydroxyl group of the donor adenosine residue.[48]

3.2. 3′-Terminal Fragments of Aminoacyl- and Peptidyl-tRNA

These fragments are nucleosides or oligoribonucleotides of various lengths and can be prepared by specific enzymatic cleavage of aa-tRNAs. The method is obviously limited to the sequences that occur in native tRNAs.[49] Chemical synthesis can provide analogues with any sequence, including those in which various functions, e.g., aminoacyl and carbohydrate moieties, are modified.[50]

4. Definition of the Partial Reactions of Protein Biosynthesis; Assays for these Steps

4.1. Definition of the Partial Reactions

For the purpose of our discussion, it will suffice to briefly define the partial reactions of protein biosynthesis in which the 3′-end of the aminoacyl-tRNA is involved. We will use the classical two-site model proposed by Watson[51] some 20 years ago, with a few modifications. The general features of this model are shown in Figure 7. The 70S ribosome has two functionally distinct sites, the acceptor (A) and the donor or peptidyl (D or P) site. The aa-tRNA bound at the A site can accept the peptide from the peptidyl-tRNA bound at the P site. The 3′-terminal CCA sequences of the two tRNAs are in contact with subsites A′ and P′, which are located on the peptidyl transferase center of the ribosome.[52]

In the initiation step, fMet-$tRNA^{fMet}$ (initiator tRNA) is bound to the P site in the presence of initiation factors (complex I). In the elongation cycle, several reactions take place: aa-tRNA (Phe-$tRNA^{Phe}$ in Fig. 7) first interacts specifically with EF-Tu·GTP to form a ternary aa-tRNA·EF-Tu·GTP complex. This complex next binds to the ribosome in a codon-dependent reaction, with the probable formation of the intermediate complex II in which EF-Tu·GTP is still bound to the ribosome, thus preventing reaction between aa-tRNA and peptidyl-tRNA (fMet-$tRNA^{fMet}$). Initially, the aa-tRNA C-C-A end is not properly accommodated on the A′ site (as schematically shown in complex II) and therefore must undergo a small movement to assume the positioning indicated in complex III. This occurs after hydrolysis of GTP and dissociation of EF-Tu·GDP from the ribosomal complex.[53,54] In complex III, the aa-tRNA C-C-A end is positioned on the A site and the peptidyl transferase reaction can take place. This reaction is assumed to be catalyzed by an enzymatic activity, which is an integral part of the 50S subunit of the ribosome; neither external energy nor other protein factors are required (see Section 6). As a result of the transpeptidation reaction, the peptidyl residue (or fMet) is transferred to the α-amino group of aa-tRNA to form complex IV, commonly called the pre-translocation intermediate. The

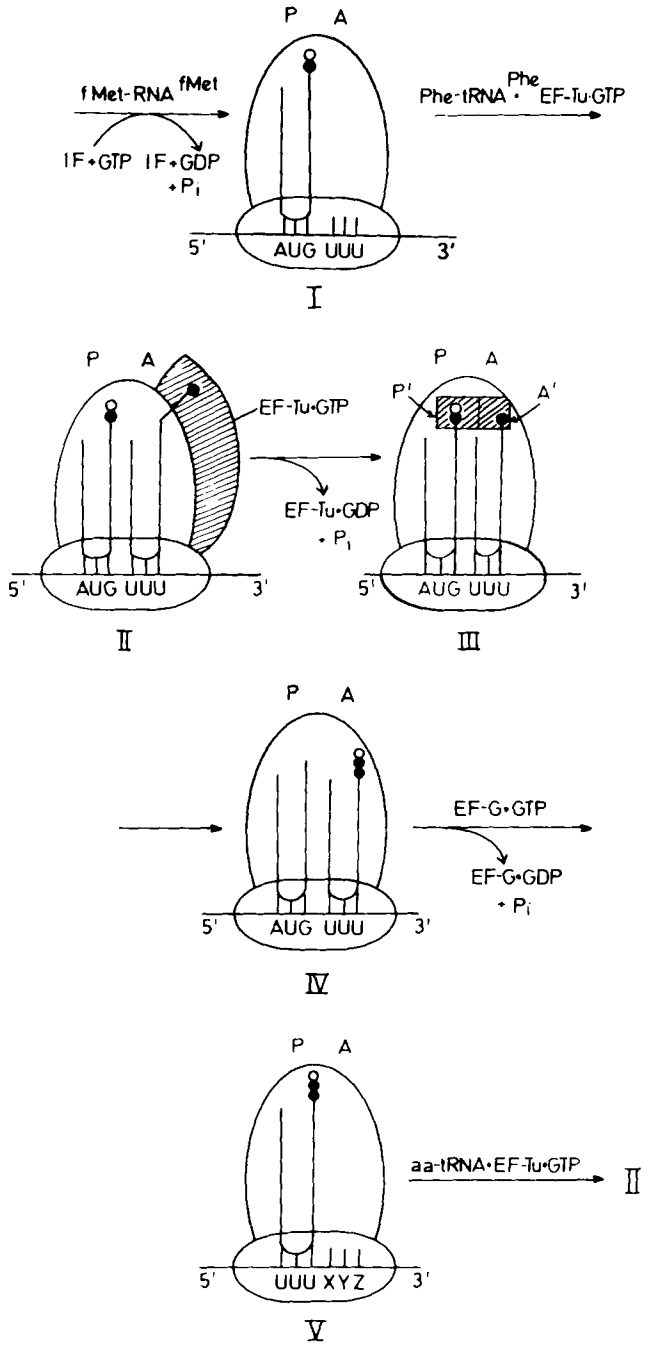

Fig. 7. Schematic drawing of the ribosomal cycle, showing the steps in the peptide chain elongation process (see text). A′ and P′ denote the subsites of the peptidyl transferase, which are parts of the A and P sites. The C-C-A terminal sequences of aa- and peptidyl-tRNA bind to the A′ and P′ sites.

newly formed peptidyl-tRNA is now located on the A site and has to be translocated to the P site in order to participate in another round of the cyclic process. The translocation step involves another protein factor, elongation factor G (EF-G); in the process one molecule of GTP is hydrolyzed. As a result, the deacylated tRNA dissociates from the ribosomal complex and the newly formed peptidyl-tRNA (fMetPhe-tRNA in Fig. 7) shifts together with mRNA to the P site, thereby exposing the next codon, X-Y-Z. When the mRNA nonsense codon (U-A-A, U-G-A, or U-A-G), which does not code for any amino acid, reaches the A site, termination of protein biosynthesis occurs in a process involving releasing factors and the hydrolysis of GTP; the peptide chain is hydrolyzed off, probably with the involvement of peptidyl transferase, and the newly synthesized protein leaves the ribosome.

Recently, *Nierhaus* et al.[55,56] proposed the three-site ribosomal model, which postulates the existence of a third site for the deacylated tRNA (E site, exit site). According to this model, deacylated tRNA is released from the E site during the binding of the ternary aa-tRNA·EF-Tu·GTP complex to the ribosome. After peptide bond formation takes place between the aa-tRNA in the A site and the peptidyl-tRNA in the P site, translocation results in the movement of newly formed peptidyl-tRNA to the P site and deacylated tRNA to the E site. However, for the sake of simplicity, we will base our discussion here on the two-site model, since this simplification does not have any effect on the conclusions stated herein.

4.2. Assay Systems for the Partial Reactions of Protein Biosynthesis

4.2.1. Interaction of aa-tRNA with EF-Tu

Various techniques, including gel filtration, affinity chromatography, and hydrolysis protection experiments, can be used to investigate the ability of aa-tRNA to complex with EF-Tu·GTP.[57-60] The 2′(3′)-*O*-aminoacyl oligonucleotides interact with EF-Tu·GTP only at very high concentrations and do not form a stable ternary complex.[61] The interaction of modified aa-tRNA species with EF-Tu·GTP can also be studied directly via the EF-Tu·GTP- and codon-dependent binding to the ribosomal A site. This assay is usually performed in the presence of deacylated tRNA bound to the P site. The binding of aa-tRNA to the A site and the EF-Tu- and aa-tRNA-dependent GTPase reaction, which accompanies this binding, may be measured simultaneously.[62]

Both aa-tRNA and 2′(3′)-*O*-aminoacyl oligonucleotides can protect EF-Tu·GTP against deactivation by the L-phenylalanine derivative (*S*)-*N*-(1-benzyl-3-chloro-2-oxopropyl)-*p*-toluenesulfonamide,[63] which reacts, in the absence of the aa-tRNA, with an essential cysteine SH group of EF-Tu·GTP.[11] The resultant blocking of the SH group can be used as an indirect binding assay.

A most convenient method for the study of the interaction of 2′(3′)-*O*-aminoacyl oligonucleotides with EF-Tu is based on the measurement of the EF-Tu-catalyzed GTPase activity induced by these oligonucleotides. In the simplest assay, the EF-Tu·GTPase is activated by the antibiotic kirromycin and further stimulated by a 2′(3′)-*O*-aminoacyl oligonucleotide.[54,64] The degree of stimulation is a measure of the extent of interaction between EF-Tu·GTP and the oligonucleotide. In a second assay, the activity of the EF-Tu·GTPase is measured in the presence of 70S ribosomes. 2′(3′)-*O*-Aminoacyl oligonucleotides promote this reaction[65] in the presence of deacylated tRNA and mRNA.[66]

4.2.2. Binding of aa-tRNA to the Ribosomal A and P Sites

The studies of the enzymatic binding of modified aa-tRNAs reveal an affinity of some of these substrates for

both EF-Tu and ribosomes. Certain modified aa-tRNAs that do not interact with EF-Tu·GTP, such as Phe-tRNA-C-C-A-3′NH_2,[57] may still bind to the ribosomal A site nonenzymatically under appropriate ionic conditions (usually higher $Mg^{2\oplus}$ concentration) and in the presence of mRNA.[67] The presence of the deacylated, correctly coded tRNA at the P site stimulates the binding of aa-tRNA to the A site.[68] The enzymatic binding of peptidyl-tRNA to the P site can be achieved via translocation in the presence of EF-G and GTP, or, for fMet-$tRNA^{fMet}$, in the presence of initiation factors and GTP. Under appropriate ionic conditions, peptidyl-tRNA will also bind nonenzymatically to the P site.[69]

The aa- and peptidyl-tRNAs can also be studied as acceptors and donors in the peptidyl transferase reaction. The formation of the peptide can be measured and the peptide can be identified chromatographically. A similar approach can also be applied to the studies of tRNA fragments. In typical systems, oligolysyl-tRNA, AcPhe-$tRNA^{Phe}$, or fMet-$tRNA^{fMet}$ are used as the donor molecules in the presence of an appropriate mRNA.[70,71]

In order to study 2′(3′)-*O*-(*N*-acylaminoacyl)oligonucleotides as potential donors in the peptidyl transferase reaction with aa-tRNA or puromycin as acceptors, the presence of ethanol and a buffer of higher ionic strength is required. However, no mRNA is necessary in this so-called "fragment reaction,"[72] and, under these conditions, the 50S subunit can replace the 70S ribosome. It was originally postulated that ethanol may promote the interaction of the substrates with their binding sites.[73] However, other authors[74,75] have suggested conformational changes of ribosomal binding sites induced by the organic solvent. Whatever role ethanol plays in the fragment assay, it does not appear to change the specificity of the peptidyl transferase reaction.[76,77]

Compounds such as C-C-A-Phe bind to the A′ site of the 70S ribosome in the presence of ethanol and high $Mg^{2\oplus}$ concentrations[78] or even without alcohol in the presence of $tRNA^{Phe}$ and poly(U).[79] Analogously, compounds such as U-A-C-C-A(AcLeu) bind to the P′ site under the conditions of the fragment reaction.[80]

Using the fragments that are derived from the C-C-A terminus of aa- or peptidyl-tRNA, it is possible to isolate and study in detail the interaction of the C-C-A terminus with the peptidyl transferase center or with the active site of EF-Tu independently of its interaction with other parts of the tRNA. It is remarkable that the results obtained with fragments are in good agreement with those with intact tRNAs.[62,81]

5. Interaction of the 3′-End of Aminoacyl-tRNA with Components of the Protein Biosynthesis Apparatus

It is important to consider at this point the interactions of the 3′-end of aa-tRNA with (a) initiation factors and the ribosome during initiation, (b) elongation factor Tu during the enzymatic binding of aa-tRNA to the ribosome, and (c) the peptidyl transferase acceptor and donor sites.

5.1. Interaction with Initiation Factors

Very little is known about the interaction of the 3′-end of initiator tRNA, fMet-$tRNA^{fMet}$, with initiation factors.[82] It is obvious that the initiation factors recognize structural features in the tRNA molecule that differ between the initiator tRNA and the other elongator tRNAs.[83] The ribosomal site to which fMet-$tRNA^{fMet}$ binds, in a process requiring IF-2 and IF-3, is probably the P site, since the bound fMet-$tRNA^{fMet}$ is reactive toward puromycin. Both this site and IF-2 distinguish between formylated and unformylated species (see Section 5.3.1). Modification of the C-C-A terminus of tRNA influences its binding to the ribosome. Thus, AcPhe-$tRNA^{Phe}_{ox\text{-}red}$ **5b** (Fig. 8), in which the 2′,3′ bond of the terminal ribose moiety is cleaved, does not bind to the P site in the initiation-factor-dependent process.[84] Moreover, fMet-$tRNA^{fMet}$-U-C-A binds very poorly to the ribosomal P site in the presence of initiation factors.[85] This is the only indication to date of the role of nucleotide 74 in binding to the P′ site.

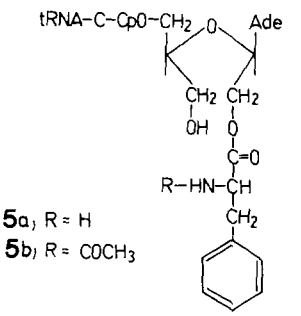

Fig. 8. Phe-$tRNA^{Phe}_{ox\text{-}red}$ **5a** and AcPhe-$tRNA^{Phe}_{ox\text{-}red}$ **5b**.

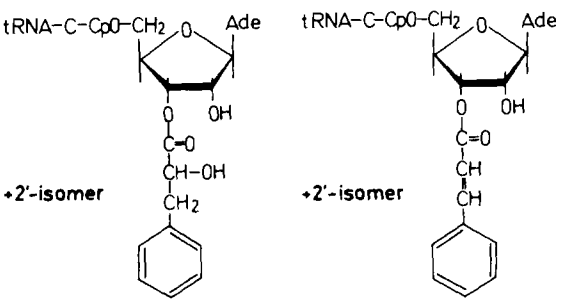
$tRNA^{fMet}$ is enzymatically aminoacylated at the 2′-OH of the terminal ribose.[14] However, the formylation of methionine, which is required for initiation, proceeds specifically only if the methionine is bound to the 3′-position of the terminal ribose. Thus, the transacylation of methionine in Met-$tRNA^{fMet}$ must take place before the formylation. Furthermore, only the 3′-isomer of fMet-tRNA can participate in the initiation process in the presence of initiation factors, mRNA, and the 70S ribosome.[86]



5.2. Interaction with Elongation Factor Tu

The ternary aa-tRNA·EF-Tu·GTP complex is a true intermediate of the enzymatic binding of aa-tRNA to the ribosome as was shown using aa-tRNA species chemically crosslinked to EF-Tu·GTP.[87] The aa-tRNA C-C-A terminus plays a crucial role in the formation of the ternary complex and its subsequent binding to the ribosome, which is accompanied by hydrolysis of GTP.[88-91] The double stranded acceptor stem, which is immediately adjacent to the C-C-A sequence of aa-tRNA, is especially involved in EF-Tu recognition.[92] This could be demonstrated in experiments in which the pC residue of the 5′-end of Met-$tRNA^{fMet}$, which is a poor substrate for EF-Tu·GTP, was chemically transformed to a pU residue. The

tRNA so modified is recognized by EF-Tu, apparently because a completely base-paired stem is formed via the modification. The absence of this important structural feature in bacterial $tRNA^{fMet}$ molecules explains the very weak interaction of the Met-$tRNA^{fMet}$ with EF-Tu·GTP.

5.2.1. *The Aminoacyl Moiety*

The amino acid residue of aa-tRNA is of considerable importance for binding to EF-Tu; only a weak interaction has been observed between deacylated tRNA and EF-Tu·GTP.[11,63,93] The amino group of the aminoacyl residue is apparently directly involved in binding to the protein, since it is protected against chemical acylation while aa-tRNA is complexed with EF-Tu·GTP.[94] The replacement of the aa-tRNA aminoacyl group with either a phenyllactoyl[95] or a cinnamoyl[96] group (**6** and **7**, respectively; Fig. 9) leads to a lowering of the efficiency of binding to EF-Tu by a factor of 300. Thus, the ester function of these analogues still contributes appreciably to the interaction with EF-Tu·GTP.

6 7

Fig. 9. Phenyllactoyl- and cinnamoyl-tRNAs, **6** and **7**, respectively.

It was postulated that the tRNA 5′-phosphate group forms an intramolecular salt bridge with the α-amino group of the aminoacyl residue and that the proposed interaction may be involved in recognition of aa-tRNA by EF-Tu·GTP.[92] However, this hypothesis was found incorrect, since there is little difference between binding of native aa-tRNA and 5′-dephosphorylated aa-tRNA to EF-Tu·GTP.[97] The aminoacyl residue of aa-tRNA in the ternary complex is protected against hydrolysis; this again demonstrates that this moiety is bound to the enzyme.[59,60]

EF-Tu interacts preferentially with L-aminoacyl-tRNA; the derivatives of D-amino acids are bound much more weakly.[66,98,99] However, this specificity is not absolute. For instance, EF-Tu can functionally interact with achiral 2′(3′)-*O*-aminoacyl oligonucleotides **8a** and **8b** (Fig. 10). These analogues contain a second substituent on the α-carbon (α-aminoisobutyric acid and cycloleucine).[54,66] This finding indicates a certain degree of flexibility in the interaction of the amino acid with EF-Tu.

The amino acid side chain also influences the strength of the interaction of intact aa-tRNA with EF-Tu·GTP.[60,100,101] The activity of aminoacylated fragments, e.g., 2′(3′)-*O*-aminoacyl nucleosides and oligonucleotides, as promoters of EF-Tu·GTPase likewise depends on the structure of the amino acid side chain.[63,66,91] It was therefore suggested[60] that EF-Tu possesses a binding site for the side chain; the interaction is strongest with basic and aromatic amino acids. The pocket for binding of the amino acid side chain of aa-tRNA was previously postulated to exist on the peptidyl transferase A′ site.[71] If a corresponding pocket exists on EF-Tu, it would provide for specificity with respect to the attachment of the aminoacyl residue to the 2′- or 3′-hydroxyl groups (Fig. 11) and only one isomer should interact with the enzyme. If the amino groups of the two isomers are assumed to interact with the same binding site on the protein, then the respective side chains would point in different directions. However, this model is incompatible with the finding that EF-Tu does not have a great preference for either 2′- or 3′-aa-tRNAs.[57,102]

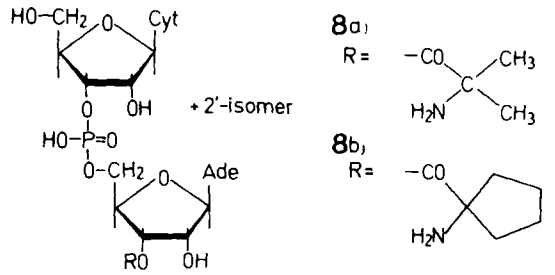


Fig. 10. Structures of 2′(3′)-*O*-(α-aminoisobutyryl) and cycloleucyl derivatives of C-A, **8a** and **8b**, respectively. Cycloleucine is 1-amino-1-carboxycyclopentane.

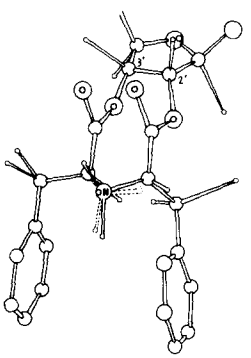

Fig. 11. A perspective view of the probable molecular conformation of 2′- and 3′-*O*-L-aminoacyl derivatives of adenosine at the 3′-end of tRNA (according to [61, 62]). The aminoacyl residues are attached to both the 2′- and 3′-positions in order to show the spatial relationship of the α-amino groups and side chains.

An alternative explanation for the role of the amino acid side chain of aa-tRNA in the ternary complex formation may be the requirement of a protonated α-amino group for the interaction of EF-Tu with aa-tRNA. The degree of protonation of the α-amino group should depend on the nature of an amino acid side chain. This assumption derives support from the observation that the pK values for the protonation of the amino groups of aminoacyl esters depend on the structure of the side chain.[33]

5.2.2. *The Carbohydrate Moiety*

EF-Tu seems to be very sensitive to modifications in the ribose moiety of the 3′-terminal adenosine. Thus, the "deoxy analogues" of aa-tRNA **1** and **2** bind more weakly to EF-Tu than the corresponding unmodified aa-tRNA.[57, 102] Low or no activity in promotion of the EF-Tu·GTPase was also observed with 2′(3′)-*O*-aminoacyl derivatives of C-A in which the 3′(2′)-hydroxyl group was replaced by either methoxy or hydrogen.[54, 66] Also, the oxidation of the *cis*-diol grouping destroys the ability of Phe-$tRNA^{Phe}_{ox\text{-}red}$ **5a** to bind to EF-Tu·GTP.[62, 103] Presumably, such chemical modification unfavorably influences the base stacking of the 3′-end of tRNA. The derivatives **3** and **4** with a 3′- and 2′-aminoacylamido linkage, respectively, do not interact with EF-Tu·GTP as observed for aa-tRNA and for fragments thereof.[57, 66] This can probably be attributed to the rigidity of the acylamido bond relative to the ester bond;[57] apparently, the aminoacylamido derivatives cannot be properly accommodated by the enzyme. It is also possible that EF-Tu recognizes the "intermediate" ortho acid structure of aa-tRNA (Fig. 12). The formation of this structure is not possible either with analogues **3** and **4** or with the deoxy compounds **1** and **2**. An alternative explanation for the decreased activity of deoxy derivatives **1** and **2** may reside in the requirement of the enzyme to bind the 2′- or 3′-hydroxyl group of the terminal ribose. The conformation of the ribose ring and the consequent orientation of the aminoacyl residue must also be taken into consideration in explaining the interaction of aa-tRNA derivatives with EF-Tu·GTP.

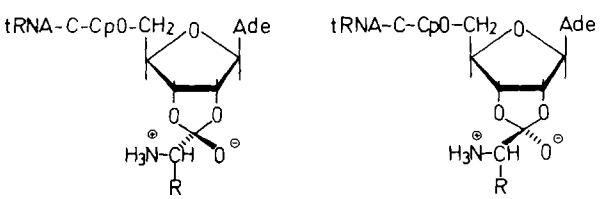

Fig. 12. The hypothetical ortho acid structure of aa-tRNA (both diastereoisomers are shown, cf. Fig. 3).

5.2.3. *The C-C-A Sequence of aa-tRNA*

There is convincing evidence that the 3′-terminal C-C-A sequence of aa-tRNA is involved in the interaction with EF-Tu. This sequence is protected against nuclease attack in the ternary complex, but, at the same time, is available for base pairing with a complementary oligonucleotide.[104, 105] Phe-$tRNA^{Phe}$-C-C-C-A reacts weakly with EF-Tu·GTP, showing that the length of the 3′-terminal sequence is also of importance for the interaction.[106] The activity of 2′(3′)-*O*-aminoacyl oligonucleotides as promoters of EF-Tu·GTPase increases with the chain length in the order A-Phe < C-A-Phe < C-C-A-Phe.[54, 63, 64, 66, 91] aa-tRNA-C-U-A (with uridine replacing cytidine in position 75 of tRNA) interacts only weakly with EF-Tu·GTP. This modification probably disturbs the base stacking of the aa-tRNA 3′-end.[92] No significant impairment of the interaction of EF-Tu·GTP occurs with aa-tRNA in which cytidine 75 is replaced by an alkylated 2-thiocytidine (Fig. 13).[107]

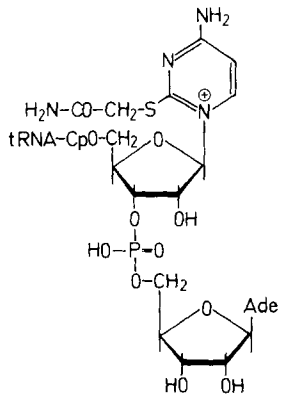

Fig. 13. Structure of the modified tRNA in which the cytidine residue 75 is replaced with 2-thiocytidine carbamoylmethylated at position 2 by iodoacetamide.

Collectively, these findings indicate that EF-Tu probably does not interact directly with the bases of the C-C-A end, but recognizes instead the overall spatial structure of the stacked C-C-A end. This stacked structure does not change appreciably when aa-tRNA is bound to EF-Tu·GTP in the ternary complex.[46] This model may subsequently prove to be an oversimplification, since U-Phe cannot substitute for A-Phe as a promoter of EF-Tu·GTPase. Thus, some base recognition, at least for the terminal adenosine, is implied.[66]

5.2.4. *EF-Tu·GTPase and Transacylation of aa-tRNA*

The ternary aa-tRNA·EF-Tu·GTP complex serves as a vehicle for the codon-dependent binding of aa-tRNA to the A site of the ribosome. This binding step is accompanied by the hydrolysis of one molecule of GTP, which results in the dissociation of EF-Tu·GDP from the ribosome and the subsequent accommodation of aa-tRNA on the A′ site. It is known that the GTPase activity resides on EF-Tu;[108] moreover, the C-C-A terminal sequence of aa-tRNA interacts with EF-Tu during the GTPase reaction.[54] Thus, the C-C-A·EF-Tu interaction persists after the ternary complex binds to the ribosome.[65]

Both isomers—the 2′- and the 3′-aminoacyl-tRNA—can be bound to the A site in the EF-Tu-dependent process.[109] If the transacylation of the 2′-aminoacyl residue to the 3′-position is hindered (cf. **1** and **2**), however, aa-tRNA can be easily displaced from the ribosomal A site.[62, 109] In this respect, Phe-tRNA-C-C-3′dA behaves similarly to natural Phe-tRNA-C-C-A bound enzymatically in the presence of the nonhydrolyzable GTP analogue GMPPCP. In the latter case, since GTP hydrolysis cannot occur and EF-Tu does not dissociate from the ribosome, the C-C-A end of aa-tRNA is probably not properly accommodated by the peptidyl transferase A′ site.[53] Presumably, the 2′-aa-tRNA, in contrast to the 3′-aa-tRNA, cannot be properly bound to the A′-site. As a result of the GTP hydrolysis (which is promoted by both aa-tRNA isomers)[109] and consequent EF-Tu·GDP dissociation, isomerization of the

aminoacyl residue occurs, producing a uniform population of 3′-aa-tRNA. Only the 3′-aa-tRNA binds firmly to the A site (since its C-C-A terminal sequence binds correctly to the A′ site of the peptidyl transferase center) and reacts in the next elongation step as an acceptor.[14, 110] However, this hypothesis still requires direct experimental confirmation. At least part of the aa-tRNA population must be bound to EF-Tu as the 2′-isomer, since EF-Tu accepts both isomers. Therefore, transacylation must take place on the ribosome prior to peptide bond formation. Whether this reaction is enzyme catalyzed is still unknown.[34]

The EF-Tu·GTPase activity can also be stimulated by parts of the tRNA molecule other than the C-C-A sequence.[91, 111] It is not known, however, whether these effects are due to interactions of other portions of aa-tRNA with EF-Tu or due to stabilization of the conformation of the C-C-A end by the rest of the aa-tRNA. The GTPase activity of EF-Tu is normally dormant and is activated only after the ternary complex binds to the ribosome in response to an appropriate codon. Several domains of the ribosome as well as the tRNA and the elongation factor Tu are probably involved in the delicate interplay that leads to GTPase activity. Although the exact structures of the EF-Tu active sites are unknown, the GTPase site is distinct from the C-C-A binding site.[112, 113] Thus, it is tempting to speculate that EF-Tu·GTPase is triggered by a specific interaction of the incoming ternary complex with specific ribosomal domains.[114, 115] At the same time, the aa-tRNA C-C-A sequence must be bound to the EF-Tu site in order to effect the conformational changes in EF-Tu that are required to induce the GTPase reaction.

5.3. Interaction with the Peptidyl Transferase Acceptor and Donor Sites

5.3.1. The α-Amino Group and the N-Acyl-α-amino Group of the aa-tRNA

The α-amino group of the acceptor substrate is required not only for the synthesis of peptide bonds, but also for binding of the aa-tRNA to the A′ site.[116, 117] It can, to a certain degree, be replaced by an OH or SH group.[118, 119]

The binding of substrates to the P′ site requires that the amino group be acylated. Thus, e.g., C-A-C-C-A(AcLeu) binds preferentially to the P′ site,[80] whereas C-A-C-C-A-Phe interacts preferentially with the A′ site.[117] Both the formyl and the acetyl groups are recognized by the P′ site, but they can be replaced in in-vitro experiments by practically any acyl group, in accord with the obvious necessity for the ribosome to accommodate the growing peptide chain of peptidyl-tRNA. It follows, therefore, that the P′ site of the peptidyl transferase must recognize at least two functional groups, the carbonyl group of the first C-terminal peptide bond and that of the ester bond in the peptidyl-tRNA.

5.3.2. The Carbonyl Group

There is an obligatory requirement for the ester carbonyl group of aa-tRNA in the binding to the A′ site. Thus, compounds **9**—**11** (Fig. 14) do not act as acceptors in the peptidyl transferase reaction.[120, 121] Compound **12** (Fig. 15), which has an ortho ester group in lieu of a carbonyl group, is inactive as an acceptor substrate.[81] Thus, the A′ site appears to recognize the definitive spatial arrangement of the α-amino and carbonyl groups while the P′ site recognizes the positions of at least two carbonyl groups at the C-terminus of the peptidyl residue of the peptidyl-tRNA.

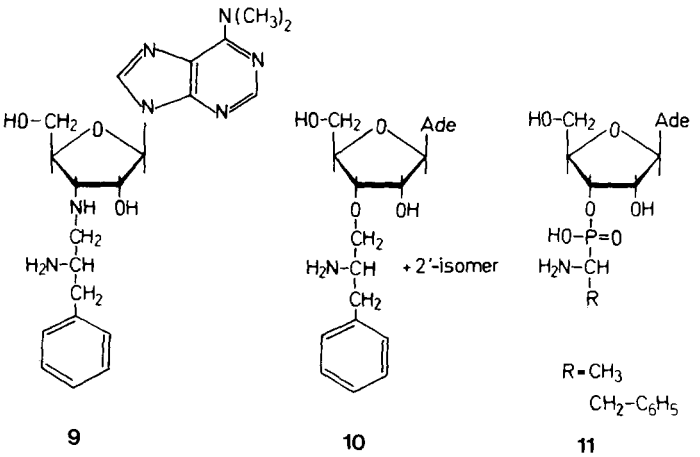

Fig. 14. Puromycin analogue **9** in which the carbonyl group of the aminoacyl residue is replaced by $>CH_2$ and the *p*-methoxy group by H; the analogues **10** and **11** of 2′(3′)-*O*-L-phenylalanyl adenosine in which the carbonyl group is replaced by $>CH_2$ and $>P(O)OH$, respectively.

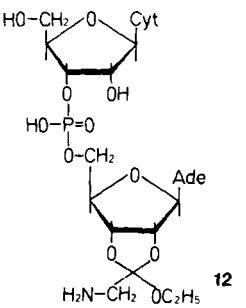

Fig. 15. 2′,3′-Ortho ester derivative **12** of C-A.

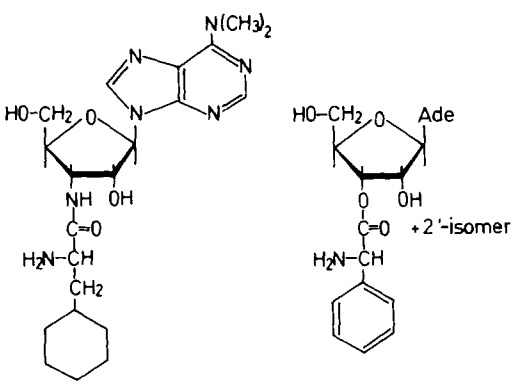
5.3.3. The Amino Acid Side Chain



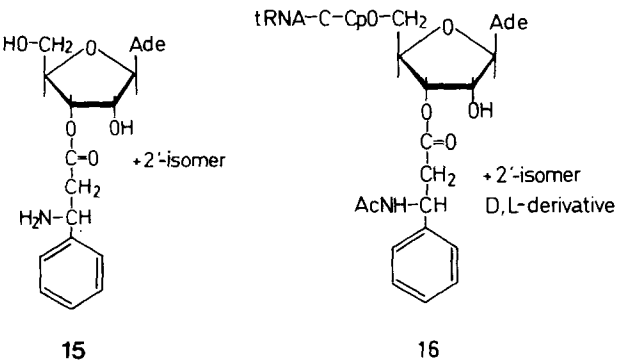
Enzymes that show stereospecificity toward substrates usually recognize them at least at three loci.[122] If this principle is applied to the binding of aa-tRNA to the A′ site of the peptidyl transferase, then, in addition to the α-amino group and the carbonyl group, the third locus is very probably the side chain of the amino acid. *Rychlík* et al.[71] originally suggested the existence of a binding locus for the side chain of an amino acid within the A′ site in order to explain the different acceptor activities of 2′(3′)-*O*-aminoacyl adenosines in the peptidyl transferase reaction. It was also observed, by other researchers,[81, 123–126] that derivatives of aromatic amino acids are the strongest acceptor substrates and derivatives of glycine or proline the weakest.[*] Similar conclusions can also be drawn from the ob-

[*] The only exception was the low activity of the tryptophan analogue of puromycin [127]. This experiment, however, is lacking an independent verification.

servations of *Lessard* and *Pestka*,[78] who studied the binding of various 2′(3′)-*O*-aminoacyl derivatives of C-C-A to the A′ site. Although the effects of the side chain are most pronounced with fragments, they are also recognizable with tRNA.[128] The side chains of all amino acids must be oriented in the same direction on the A′ site in order to account for the stereospecificity of the peptidyl transferase reaction;[81] presumably, this involves an interaction with a "protein pocket." The high binding affinity of aromatic amino acids may, however, be due to fortuitous lipophilic interactions rather than to a specific binding site.

The donor activity of various fragments was also observed to be dependent on the nature of the amino acid side chain.[129–132] However, this dependence is distinct from that of their acceptor activity. Whereas, the best acceptors are derived from phenylalanine, the derivatives of AcPhe are, by contrast, usually poor donors. The highest donor activity was observed with derivatives of fMet and AcLeu. These findings indicate that different ribosomal functionalities are involved in the interaction with the amino acid side chains at the acceptor and donor sites.

The C-A derivatives of achiral amino acids such as α-aminoisobutyric acid **8a** and cycloleucine **8b** are not acceptors.[132] These amino acids have a second α-substituent, which apparently precludes proper binding to the acceptor site. On the other hand, nonproductive binding to the A′ site is possible, and these compounds therefore function as inhibitors. It is not known whether the same phenomenon holds for the P′ site.



13 14

Fig. 16. Analogues of puromycin and 2′(3′)-*O*-L-phenylalanyl adenosine. In compound **13** the aromatic ring of puromycin is replaced by the cyclohexyl group; compound **14** incorporates L-phenylglycine.

The cyclohexyl analogue **13** of puromycin (Fig. 16) is active as an acceptor,[134] which agrees with the general model presented here, since this alicyclic residue is lipophilic and should interact rather strongly with the A′ site. Several model derivatives were studied recently to probe the distance of the hydrophobic locus from the α-amino group of the acceptor substrate.[135, 136] Moreover, the 2′(3′)-*O*-L-phenylglycyladenosine **14** is a weaker acceptor than the related A-Phe.[137]

5.3.4. *Stereospecificity*

A series of experiments with fragments and intact tRNAs conclusively shows that peptidyl transferase is stereospecific for both acceptors and donors. Only L-α-aminoacyl derivatives can participate in the peptidyl transferase reaction.[47, 81, 132] It is interesting to note that, e.g., C-A(D-Phe) or C-A(Ac-D-Met), neither of which are substrates for the peptidyl transferase reaction, are inhibitors at the respective sites.[81, 132] Thus, as is the case with the proteolytic enzymes, the stereospecificity is not achieved by preferential binding of one diastereoisomer, but by selective positioning of appropriate functionalities of the substrate (carbonyl group, amino group, and side chain) with respect to the enzyme.[138]

15 16

Fig. 17. Analogues of 2′(3′)-*O*-L-phenylalanyladenosine and AcPhe-tRNA^{Phe}. Compound **15** incorporates L-β-phenylalanine; compound **16** incorporates Ac(DL-β-phenylalanine).

Neither D- nor L-2′(3′)-*O*-(β-phenylalanyl)adenosine **15** (Fig. 16) is an acceptor in the peptidyl transferase reaction.[137] On the other hand, Ac(D,L-β-Phe)-tRNA **16** (Fig. 17) can serve as a donor.[47] It would be of considerable interest to learn whether the P′ site also displays a "reverse stereospecificity" in analogy to chymotrypsin, since *N*-acetyl-D-β-phenylalanine esters are cleaved preferentially by chymotrypsin.[139]

5.3.5. *Isomer Specificity*

The specificity of the A′ site of the peptidyl transferase for 2′(3′)-isomers of aa-tRNA was extensively investigated using both fragments and intact tRNAs. The nonisomerizable aa-tRNA derivatives **1**—**4** were used for these investigations. Since the peptidyl transferase is able to recognize tRNA derivatives with modified sugar residues (see Section 5.3.6), structures in which the 2′⇄3′ transacylation is precluded could serve as models for such studies.

The 3′-aa-tRNAs Lys-tRNA^{Lys}-C-C-2′dA (type **1**) and Phe-tRNA^{Phe}-C-C-3′NH$_2$A (type **3**)[67, 109, 140, 141] are acceptors, whereas Phe-tRNA^{Phe}-C-C-3′dA (type **2**) and Phe-tRNA$^{Phe}_{ox\text{-}red}$ are only weak acceptors.[62] A quantitative comparison with several nonisomerizable 2′(3′)-*O*-aminoacyl derivatives of C-A (**18**—**19**; Fig. 18) was performed by *Bhuta* et al.[81] They concluded that the 3′-aminoacyl derivatives of optically active amino acids are much better acceptors than the 2′-derivatives with K_m values more than 100 times smaller than those of the 2′-derivatives (Table 1).

Completely different results, however, were obtained with the isomeric glycine derivatives **20** and **21** (Fig. 19);

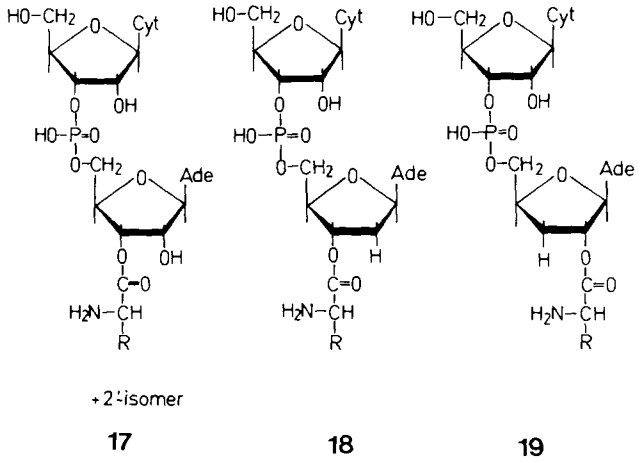


Fig. 18. 2'(3')-*O*-L-Aminoacyl derivatives **17** of C-A; 3'-*O*-L-aminoacyl derivatives **18** of C-2'dA; 2'-*O*-L-aminoacyl derivatives **19** of C-3'dA (R = amino acid side chain; see Table 1).

Table 1. Dependence of the K_m values in the peptidyl transferase reaction on the site of attachment of the amino acid. The fMet-tRNA^{fMet}·A-U-G·70S-ribosome system was used; aminoacyl derivatives of C-A **17**, C-2'dA **18**, and C-3'dA **19** functioned as acceptors [81].

Aminoacyl residues	Michaelis constants K_m [M] 2'(3') **17**	2'-isomer **19**	3'-isomer **18**	$K_m^{2'}/K_m^{3'}$
Phe	1.1×10^{-7}	2×10^{-5}	1.1×10^{-7}	182
Leu	1.0×10^{-6}	$>10^{-3}$	9.5×10^{-6}	> 100
Lys	3.4×10^{-7}	$>10^{-3}$	3.0×10^{-7}	> 1000
Ala	9.0×10^{-7}	$>10^{-3}$	1.0×10^{-5}	> 100
Gly	5.0×10^{-6}	6.4×10^{-5}	4.0×10^{-5}	1.6

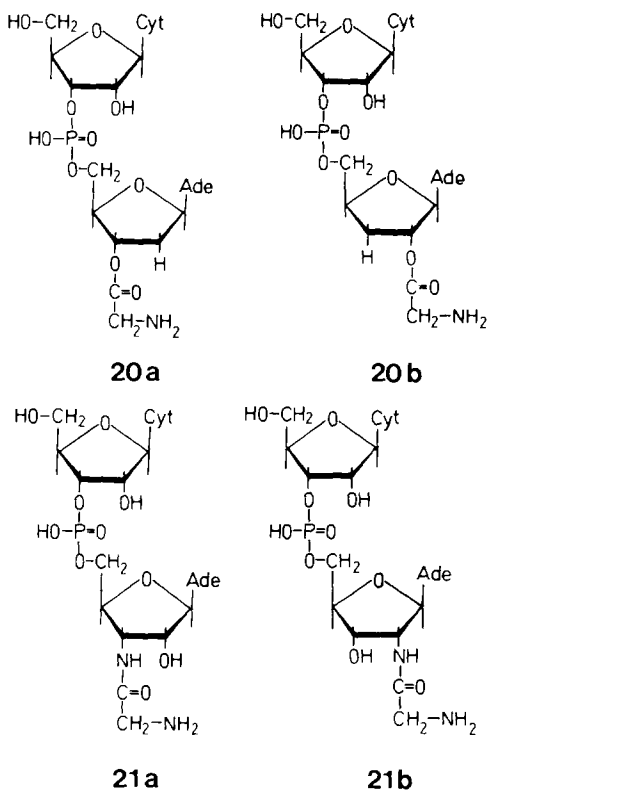

Fig. 19. Nonisomerizable analogues **20** and **21** of C-A-Gly, incorporating a modified adenosine residue.

both the 2'- and 3'-isomers were found to accept the fMet residue from the fMet-tRNA bound to the P site.[81] This is, of course, surprising and the general validity of this finding should be tested by experiments at the tRNA level.

These results can be rationalized using a model which depicts the orientation of the aminoacyl residue on the 3'-end of aa-tRNA (Fig. 11).[61,62] If the reasonable assumption is made that a definite orientation of the α-amino group of the aminoacyl residue is required for the peptidyl transferase reaction, then the side chains of the 2'- and 3'-aminoacyl derivatives extend in different directions. This is the main reason for the selectivity of the A' site with respect to positional isomers. Due to the absence of the side chain in glycine derivatives, this factor is cancelled and both compounds can serve as acceptors.

In all systems investigated, the 2'-aminoacyl derivatives are able to bind to the A' site. However, this binding, like that of D-derivatives, is nonproductive.

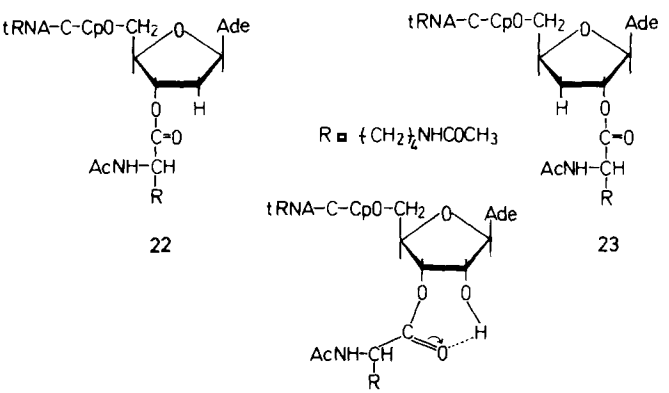

Fig. 20. Nonisomerizable analogues of Ac_2Lys-tRNA^{Lys} in which a hydroxyl group is absent: Ac_2Lys-tRNA^{Lys}-C-C-2'dA **22** and Ac_2Lys-tRNA^{Lys}-C-C-3'dA **23**. The lower structure depicts the activation of the aminoacyl ester bond of peptidyl-tRNA via the hydrogen bond from the neighboring hydroxyl group.

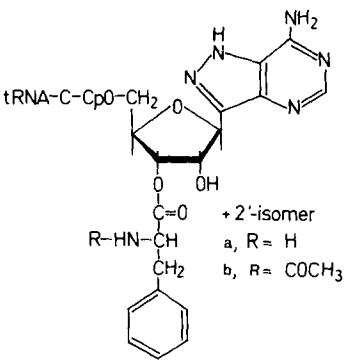
The investigation of the isomer specificity of the P' site proved to be much more difficult than that of the A' site. It was found only recently[109] that Ac_2Lys-tRNA^{Lys}-C-C-2'dA **22** (Fig. 20) can function as a donor substrate, reacting with aa-tRNA bound to the A' site, whereas the 2'-isomer **23** is inactive under the same conditions. Thus, the stereochemical requirements are similar to those of the A' site, although it is not known whether both 2'- and 3'-AcGly esters act as donors (by analogy with the A' site). These findings afford insight into the mechanism of catalysis of the peptide bond, since they show that the activation of the ester carbonyl group via hydrogen bonding with the 2'-OH, which is not possible with derivative **22**, is not an absolute requirement.

5.3.6. The Carbohydrate Moiety

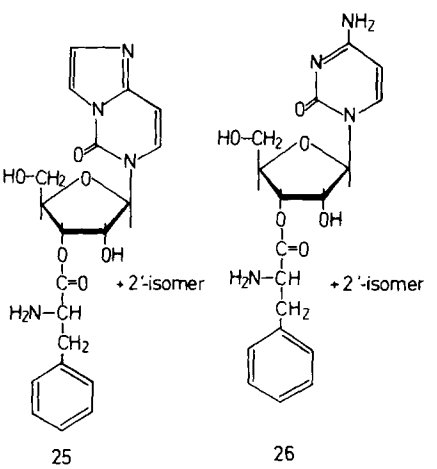


The A' site can recognize a variety of substrates incorporating modified sugar derivatives, e.g., 2'-deoxyribose, 2'-*O*-methylribose, ribose cleaved between C2' and C3', and 3'-amino-3'-deoxyribose.[67,123,142-145] The 2'-aminoacyl

derivatives are in general inhibitors of the A′ site. In this respect, the A′ site is very different from EF-Tu, which is more sensitive to ribose modification. The absence of the 2′-OH group influences the acceptor activity to a greater degree in the case of weak substrates (e.g., those containing glycine) than with the more active acceptors (e.g., those containing phenylalanine).[81] It is interesting to note that 2′dA-Phe is not an acceptor substrate, whereas the dinucleotide C-2′dA-Phe is an excellent acceptor, very similar to C-A-Phe (Table 1). This anomaly can hardly be explained by the existence of a binding locus for 2′-OH only. It is conceivable that a change in pucker of the sugar moiety and a consequent change in orientation of the aminoacyl residue plays a role in the recognition by the peptidyl transferase.[*]

5.3.7. *The Nucleotide Sequence*

The acceptor activity of 2′(3′)-*O*-aminoacyl derivatives of C-A is significantly higher than that of the corresponding adenosine derivatives (the K_m values differ by more than two orders of magnitude).[149] In fact, the observed effect is a consequence of incorporating the Cp residue since it cannot be achieved with other nucleotides.[127, 150] The acceptor activity also increases in the order A-Phe < pA-Phe < MepA-Phe, but the magnitude of increase does not approach that achieved upon incorporation of a Cp residue.[151] On the other hand, the increase of acceptor activity upon attachment of a second Cp residue to form 2′(3′)-*O*-aminoacyl derivatives of C-C-A is not as significant, particularly with highly active substrates. Thus, the acceptor activity of C-A-Phe is similar to that of C-C-A-Phe, whereas, in the case of less active glycine derivatives, the acceptor activity of C-C-A-Gly is much higher than that of C-A-Gly.[79] The second Cp residue also plays a role in binding to the A′ site.[78] Direct interaction of the C-C-A terminus of aa-tRNA with the A′ and P′ sites has been inferred from the observation[152-154] that the C-C-A sequence of the bound aa-tRNA is shielded from chemical or enzymatic attack.



The nucleosides beyond the C-C-A sequence probably do not play an important role in binding to the A′ site, as indicated by the similar binding activities of C-C-A-Phe and C-A-C-C-A-Phe.[78, 79] Detailed studies of the acceptor activity of 2′(3′)-*O*-aminoacyl nucleosides containing modified bases[155, 156] have shown that there is little base specificity for the purine ring of the acceptor; however, G-Phe is inactive. In fact, modifications at the position 6 of the purine may be made, including the introduction of some extremely bulky substituents,[157] providing that they do not significantly influence the electronic configuration of the purine moiety. Interestingly, compounds that cannot form Watson-Crick base pairs, such as puromycin and other 2′(3′)-*O*-phenylalanyl nucleosides, are all acceptors. Therefore, base pairing of the terminal adenosine of tRNA is not required for acceptor activity.[156, 158, 159] The possibility of Hoogsteen pairing from position 7 of the purine ring is also excluded, since 2′(3′)-*O*-phenylalanyl tubercidin (7-deazaadenosine) is an acceptor.[156] The terminal adenosine of tRNA can also be replaced by formycin, since Phe-tRNA^{Phe}-C-C-F **24a** (Fig. 21) functions as an acceptor.[160]

24

Fig. 21. Phe-tRNA^{Phe}-C-C-F **24a** and AcPhe-tRNA^{Phe}-C-C-F **24b**, incorporating formycin as the 3′-terminal nucleotide.

Thus, the A′ site most probably recognizes only the spatial structure of the last nucleobase of tRNA. 2′(3′)-*O*-Phenylalanyl ethenocytidine **25** (Fig. 22) is more active than the

25 26

Fig. 22. 2′(3′)-*O*-L-Phenylalanyl ethenocytidine **25** and 2′(3′)-*O*-L-phenylalanyl cytidine **26**.

corresponding cytidine derivative **26**, since the bicyclic structure of ethenocytidine is apparently more similar to that of the purine ring.[158] Presumably, the terminal adenosine has considerable freedom of motion in intact tRNA.[14] Therefore, it is possible that this nucleoside residue may be accepted in either *syn*- or *anti*-conformation by the enzyme. Model studies with nucleoside analogues **27** and **28** (Fig. 23) have shown that, for the acceptor site, the *anti*-conformation (as in **27**) is preferred.[161]

The acceptor activity of Phe-tRNA^{Phe}-C-C-A modified at cytidine 75 (cf. Fig. 13) was found to be much weaker than that of the unmodified tRNA. The ability of this mod-

[*] There are differences in the sugar conformation of ribose and deoxyribose derivatives. Puromycin is known to be in N-(3′-*endo*) conformation, whereas the 2′-deoxy nucleosides are more likely to exist in S-(2′-*endo*) conformation. The N-conformation is the only one in which stacking with other bases in the C-C-A sequence may occur. Thus, it is tempting to speculate whether the presence of the Cp residue in C-2′dA-Phe may force the N-conformation on the 2′dA moiety of the dinucleoside phosphate [145–148].

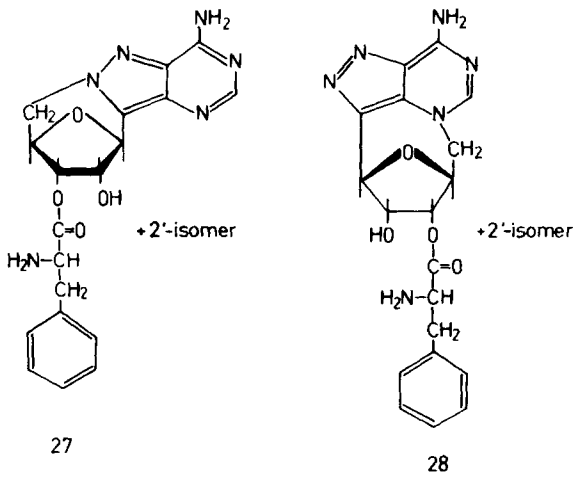


Fig. 23. 2'(3')-*O*-L-Phenylalanyl derivatives of the two cycloformycins. Compound **27** is in an *anti*-conformation and compound **28** in a *syn*-conformation.

ified tRNA to form base pairs from positions 73—75 is also strongly reduced.[107] It is thus obvious that the stacked ordered structure of the C-C-A terminus is extremely important for recognition by the A' site.[162] Accordingly, the 2'-5' dinucleotide **29** (Fig. 24) is not an acceptor, since its stacking geometry is different from that in the natural 3'-5' derivatives.[163]

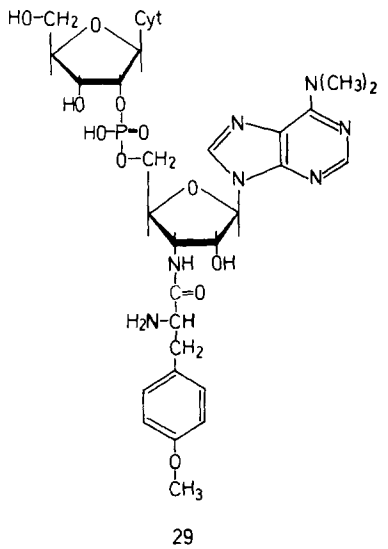

Fig. 24. Cytidylyl (2'-5')-puromycin **29**.

As is the case with aa-tRNA, the terminal C-C-A sequence of peptidyl-tRNA is also involved in specific interactions with the P' site. The donor activity can be detected with 2'(3')-*O*-(*N*-acylaminoacyl) mononucleotides, e.g., pA(fMet) **30a** (Fig. 25), albeit only at very high concentrations of the substrate.[164] The corresponding dinucleotide and, even more so, trinucleotide derivatives are much better donors.[129, 131, 132] Although no quantitative comparisons are available to date, it is apparent that there is a significant increase of donor activity in going from C-A(fMet) to C-C-A(fMet), whereas the effect of joining a cytidine residue to, e.g., pA(fMet) is not as dramatic.[129, 149] As observed for the A' site, there is no significant difference in donor activity between trinucleotide and pentanucleotide derivatives.[129, 131] Therefore, only nucleotides of the C-C-A terminus play an important role in the binding of peptidyl-tRNA to the P' site. AcPhe-tRNA^{Phe}-C-C-F **24b**, in which the 3'-terminal nucleotide is formycin, shows relatively low donor activity as compared to AcPhe-tRNA^{Phe}-C-C-A.[160] This is presumably due to a disruption of base stacking in the modified C-C-A end.[160] The donor activity

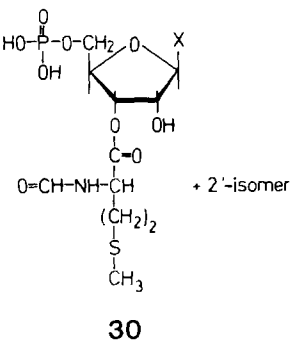

Fig. 25. 2'(3')-*O*-(*N*-Formyl-L-methionyl) nucleoside 5'-phosphate **30a**, X = Ade; **30b**, X = Hyp; **30c**, X = Cyt; **30d**, X = Ura.

of **30** (Fig. 25) decreases in the order X = Ade > Hyp > Gua; derivatives with X = Cyt and Ura are devoid of any activity.[165] Similarly, C-N(AcMet) (N = nebularin) **31** (Fig. 26) is inactive as a donor substrate, whereas C-(8-

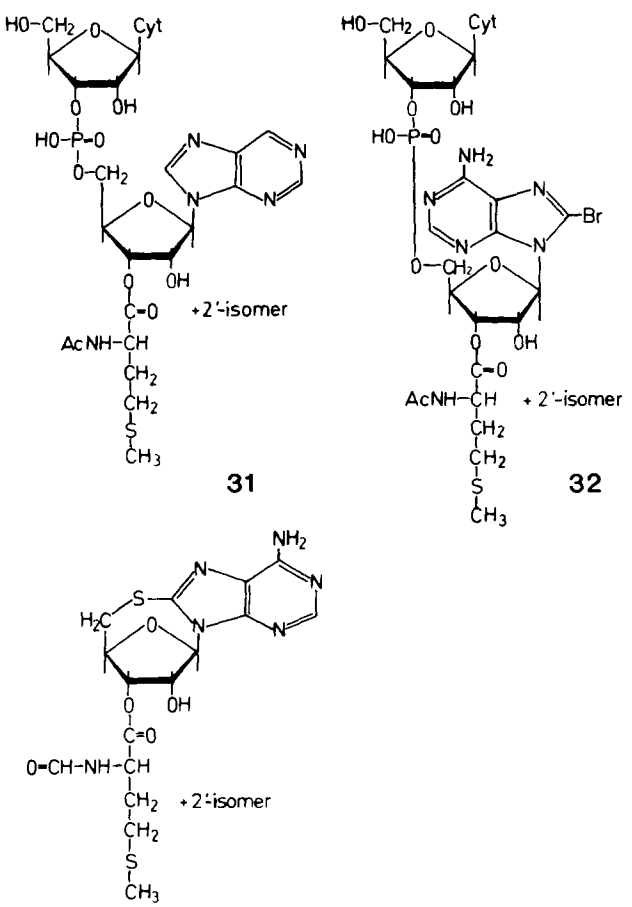

Fig. 26. Cytidylyl(3'-5')2'(3')-*O*-(*N*-acetyl-L-methionyl) purine riboside, C-N(AcMet) **31**; cytidylyl(3'-5')2'(3')-*O*-(*N*-acetyl-L-methionyl)-8-bromoadenosine, C-(8-Br)A(AcMet) **32**; (3')-*O*-(*N*-formyl-L-methionyl)-5', *S*-anhydro-8-mercaptoadenosine **33**.

Br)A(AcMet) **32** is almost as active as the unmodified C-A(AcMet).[132] These findings indicate that the P′ site exhibits greater specificity for the 3′-terminal residues of peptidyl-tRNA than the A′ site exhibits for the corresponding residues of aa-tRNA. C-N(AcMet) **31** cannot form Watson-Crick base pairs from the 3′-terminal residue; C-(8-Br)A (AcMet) **32** is expected to have the 3′-terminal nucleotide in the *syn*-conformation, but is, nonetheless, active as a donor. The latter finding is in agreement with results of other authors,[166] who also detected weak donor activity for p(8-Br)A(fMet) but no donor activity for compound **33**, which exists exclusively in the *anti*-conformation. Although the results with the latter compound have to be interpreted with caution due to the inherently very low activity of "good" peptidyl-nucleosides as donors and due to the lack of similar derivatives in the *syn*-conformation having donor activity, it is possible that the donor site may prefer a *syn*-conformation of the 3′-terminal nucleoside. Thus, peptidyl-tRNA translocation from the A to the P site may be accompanied by a rotation around the glycosidic bond of the 3′-terminal adenosine to give the *syn*-conformation.

Modified AcPhe-tRNA^{Phe}, in which cytidine 75 is alkylated in position 2, is a good donor; the modification has no effect on the rate and yield of the peptidyl transferase reaction, in contrast to its effect on the A′ site.[107] Replacement of cytidine 74 by uridine in fMet-tRNA^{fMet}, yielding fMet-tRNA^{fMet}-U-C-A, leads to the complete deactivation of this substrate as a donor in the puromycin reaction.[85] The extension of the C-C-A end by an additional Cp residue, i.e., AcPhe-tRNA^{Phe}-C-C-C-A, resulted in an approximately 20-fold reduction in the donor activity of aminoacyl derivatives of this modified tRNA relative to those of native Phe-tRNA^{Phe}.[106]

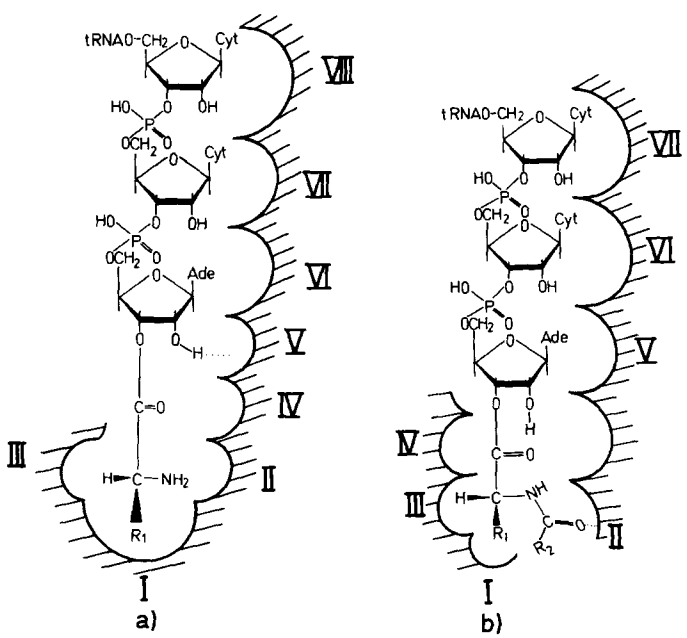

Fig. 27. a) Schematic drawing of the ribosomal A′ site showing the interactions with the 3′-end of aa-tRNA and indicating the peptidyl transferase loci which bind several moieties of the substrate. Binding site III has sufficient space only for α-hydrogen, not for a larger substituent. The loci may not be located on one molecule of a ribosomal component, but rather on one or several ribosomal proteins and a partial sequence of 23S RNA. b) Schematic drawing of the ribosomal P′ site showing the interactions with the 3′-end of peptidyl-tRNA and indicating the loci which bind several moieties of the substrate. The space is allocated for the growing peptide chain. Again, the loci are probably not located on one molecule of the ribosomal component.

It is thus evident that both A′ and P′ sites may have different requirements for the binding of adenosine 76 of tRNA. Furthermore, the results clearly show the existence of binding loci for the C-C sequence at both the A′ and P′ sites. However, despite this structural similarity, these binding sites are not functionally equivalent. The binding behavior of the C-74 and C-75 residues differs not only between the A′ and P′ sites, but also within these respective sites.[77, 107, 149, 167]

These results are summarized, in a very simplified form, in Figure 27.

5.3.8. Cooperative Effects at the Peptidyl Transferase Binding Sites

The ribosome and especially its peptidyl transferase sites have a dynamic structure. Due to the conformational flexibility of the macromolecules forming these sites, cooperative effects may, in principle, be transmitted in several ways, e.g., between the sites, within either the A′ or P′ site, or from different parts of the ribosome. In addition, cooperative effects can be transmitted within the tRNA molecule, e.g., by changing the conformation of the C-C-A end upon binding of a different part of the tRNA to a ribosomal domain.

Bound peptidyl-tRNA (P site) stimulates enzymatic binding of aa-tRNA to the A site.[68] Moreover, peptidyl-tRNA must be the 3′-isomer to provide for this stimulation; the 2′-isomer is inactive.[67] This shows that the correct occupation of the P′ site is specifically involved in this phenomenon. Moreover, the substrate affinity of the A′ site changes in response to the occupation of the P′ site by different molecules. Thus, the acceptor activity of aminoacylated fragments depends on the nature of the donor molecule.[71, 81] Similarly, occupation of the donor site with AcPhe-tRNA^{Phe} may change the affinity of the acceptor site for substrates.[79] Stimulation of the binding of C-A-C-C-A-Phe to the acceptor site by the deacylated tRNA (bound to the P site) is probably an expression of the same phenomenon.[74, 168, 169] Binding of an acceptor to the A′ site on the 50S subunit is also stimulated by tRNA or C-C-A, which interact evidently with the P′ site.[170] The results show an interesting interplay between P′ and A′ sites. Thus, the structure of the A′ site depends on the occupation of particular loci of the P′ site.

Cooperative effects can also be observed within the P′ site. *Černá*[77] has discovered the stimulating effect of pC on the donor activity of pA(fMet) under the conditions of the fragment reaction. The stimulating effect is specific for nucleotides that can form a G·C pair, whereas other nucleotides, such as pA, are inhibitory.[171] This phenomenon is undoubtedly related to the binding of a pC residue to the binding site of the penultimate residue of the peptidyl-tRNA on the P′ site. It is interesting to note that pC inhibits the donor activity of C-A(AcMet).[149] Thus, loci for binding of the second and third residues in the C-C-A ter-

minus of peptidyl-tRNA are not equivalent. Apparently, the binding site for the Cp residue on the A′ site must differ significantly from that on the P′ site, since neither pC nor other cytidine nucleotides show a stimulating effect on the acceptor activity of puromycin or C-A-Lys.[149] In contrast, pC is inhibitory in the latter case.[172]

5.3.9. *Structure of the Peptidyl Transferase*

The body of findings related to the substrate specificities of the A′ and P′ sites, together with the recent structural studies of ribosomes, allow us to draw some conclusions as to the nature of the peptidyl transferase center. The peptidyl transferase is an integral part of the larger ribosomal subunit. To date, it has been impossible to identify a single ribosomal component solely responsible for the binding of substrates or for the enzymatic activity. Affinity labeling studies with reactive derivatives of charged tRNA or other ligands for A′ and P′ sites led to the identification of several ribosomal proteins as well as parts of the 23S RNA in the neighborhood of the peptidyl transferase center. However, these observations do not necessarily imply that these macromolecules form the respective sites.[73]

It is almost certain that the 3′-terminal nucleoside of the A′-site-bound aa-tRNA is not base-paired. The situation with the peptidyl-tRNA may be different. The *N*-acylaminoacyl(peptidyl) moiety most probably binds to a protein. The 3′-terminal adenosine residue may base-pair with an appropriate U residue of ribosomal RNA, since the P′ site, unlike the A′ site, shows considerable specificity for the adenine base of the 3′-end of peptidyl-tRNA.[12, 132, 165] The ability of a donor with a 3′-terminal nucleoside in *syn*-conformation to interact functionally with the P′ site suggests the existence of an asymmetrical base pair between a nucleoside of tRNA in the *syn*-conformation and a nucleoside of ribosomal RNA in the *anti*-conformation.[174]

One of the most interesting results is the stimulating effect observed as a consequence of joining cytidine 3′-phosphate (or cytidine) residues on the activity of either 2′(3′)-*O*-aminoacyl adenosine or 2′(3′)-*O*-(*N*-acylaminoacyl)adenosine 5′-phosphate as acceptors or donors in the peptidyl transferase reaction (see Section 5.3.7). This suggests the possibility of base pairing of the C-C sequence of charged tRNA with an invariant G-G sequence of, most probably, 23S RNA.

Although it has been shown that 23S RNA is capable (unlike 16S RNA) of binding charged tRNA 3′-terminal fragments such as C-A-C-C-A-Leu and C-A-C-C-A(AcLeu),[170] more direct evidence of 23S RNA participation in the peptidyl transferase activity was obtained only recently. For instance, several nucleotide residues of 23S RNA are implicated in resistance to the antibiotics chloramphenicol and erythromycin, which are known to act on the peptidyl transferase center.[175–177] The resistance to these antibiotics derives from a modification of nucleotide residues that are all found clustered in the central loop of domain V of 23S RNA.[178] Thus, this highly conserved region of 23S RNA is likely to constitute part of the peptidyl transferase center (Fig. 28). Moreover, two uridine residues of this loop (2584 and 2585) are also sites of attachment of

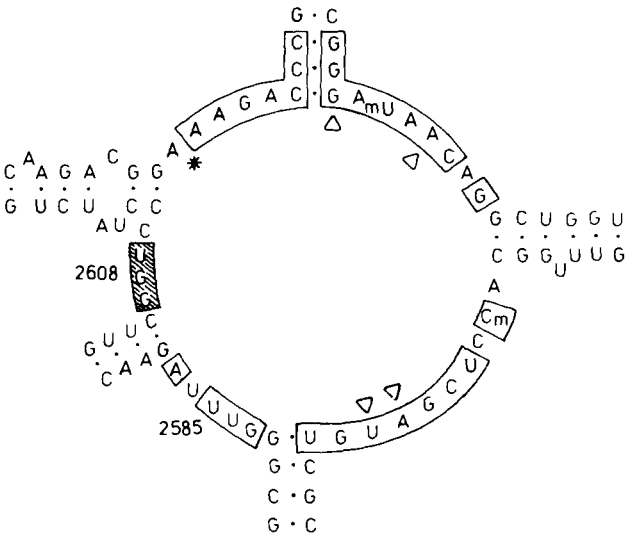

Fig. 28. Secondary structure of a part of *E. coli* 23S RNA, encompassing the central loop of domain V (according to [178, 181]). The conserved nucleotides are boxed; the asterisk denotes the site of erythromycin resistance in *B. stearothermophilus* 23S RNA: the triangles denote the sites of chloramphenicol resistance in mitochondrial RNA [177]. The shaded sequence is proposed to be part of the A′ site which could base-pair with the Pu-C-C^{75} sequence of aa-tRNA. The nucleotides 2584 and 2585 are sites of attack for the photoreactive analogue **34** of peptidyl-tRNA (see Fig. 29) [179].

the photoreactive peptidyl-tRNA analogue **34** (Fig. 29).[179] Since **34** is cleaved by irradiation at the aromatic keto group, the length of the probe is approximately 14 Å from the 3′-terminal adenosine residue. It was suggested that the

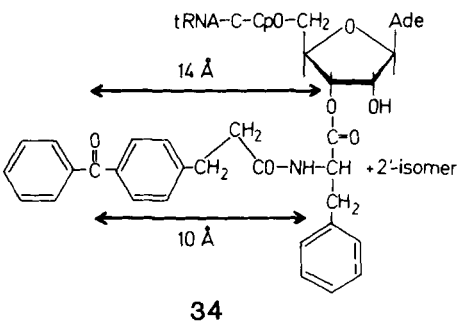

Fig. 29. Structure of the photolabile analogue **34** of Ac-Phe-tRNA^{Phe}. A residue of this compound becomes covalently linked to 23S RNA after photolysis at the site of the aromatic keto group [179].

C-C-A terminus of peptidyl-tRNA forms base-pairs with the highly conserved U-G-G^{809} sequence located in a loop of domain II of the 23S RNA (Fig. 30). The experimental evidence obtained by UV-induced crosslinking of 23S RNA shows that domain II is in close proximity with the central "peptidyl transferase loop" of domain V.[180] If this is the case, where then is the conserved G-G sequence located, which is required for binding of the aa-tRNA 3′-end? Conventional wisdom would place this site at a conserved G-G^{2608} sequence of the central loop of domain V (Fig. 28).[178, 181] There, it is possible to visualize that peptide bond formation between the two species of tRNA, bound in such fashion, is sterically possible. Thus, this sequence would be a part of the A′ site.

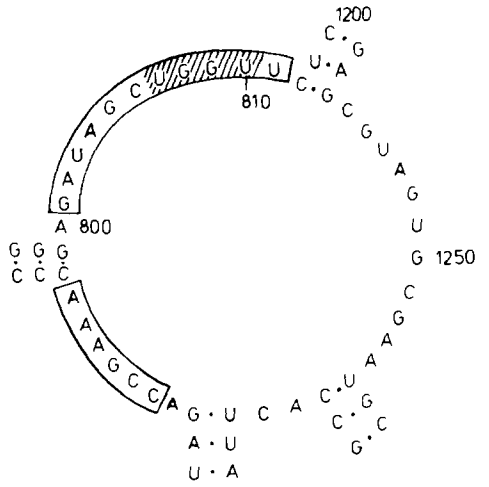

Fig. 30. Secondary structure of the part of *E. coli* 23S RNA (in domain II) which contains the invariant U-G-G-U sequence. This sequence is proposed [179] to be part of the P′ site and interacts via base pairing with the Pu-C-C-A^{76} sequence of peptidyl-tRNA. The conserved nucleotides are boxed; the shaded area denotes part of the A′ site [179].

The vicinity of the antibiotic resistance sites also supports this assignment, since chloramphenicol, for example, is known to inhibit A′ site binding.[182] Residue U^{2605} is possibly also the site of attack of a reactive puromycin analogue.[178, 183] Such a pairing scheme for both tRNA molecules would result in the formation of two coaxial helices; these stabilize the newly formed RNA·RNA hybrids, resulting in precise alignment of both tRNA molecules[178] (Fig. 31). If we allow for the base pairing of residue 73 (usually purine) of both tRNAs with invariant U residues of the 23S RNA (810 and 2609, respectively) (but see also [167]), the coaxial structures would produce two single nucleotide bulges. Such structures may provide recognition sites for the proteins[184] and in this case might modulate the interaction with ribosomal proteins or with elongation and releasing factors.

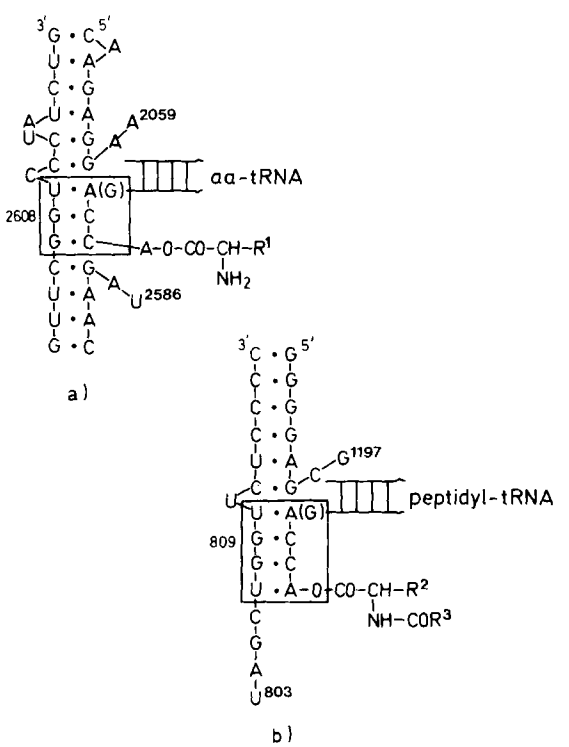

Fig. 31. Models of the coaxial stacking of tRNA with 23S RNA. a) Base-pairing scheme of the aa-tRNA Pu-C-C^{75} sequence with the complementary sequence of 23S RNA (central loop of domain V, cf. Fig. 28) on the A′ site. b) Base pairing of the peptidyl-tRNA Pu-C-C-A^{76} sequence with the complementary sequence of 23S RNA (located in a loop of domain II, cf. Fig. 30) at the P′ site.

5.3.10. *Involvement of the 3′-End of tRNA in Translocation*

Leder[185] postulated that the driving force for the translocation is the product-substrate relation of peptidyl-tRNA and deacylated tRNA in the pre-translocational and post-translocational state, respectively (cf. Fig. 7). Therefore, translocation would be driven, in principle, by the dissociation of the products, peptidyl-tRNA and tRNA, and by the binding of the substrate, peptidyl-tRNA. If this model is correct, the structure of the 3′-terminal adenosine of both peptidyl-tRNA and tRNA should be critical in triggering translocation. Indeed, translocation does not take place if modified peptidyl-tRNA **22** (Fig. 20), lacking the 2′-OH group, is bound to the A site. The EF-G-dependent dissociation of deacylated tRNA from the P site is also inhibited if tRNA-C-C-2′dA is used instead of native tRNA.[186]

These experiments indicate that in the translocation a recognition of the 3′-terminal ribose of both the A′- and the P′-site-bound tRNA is involved. Presumably, translocation is initiated by direct interaction of EF-G with the 2′-OH group of the peptidyl-tRNA and with the *cis*-diol function of the P-site-bound tRNA. Alternatively, a ribosomal protein, which is in contact with the 3′-terminal ribose moieties of both A′- and P′-site-bound tRNAs, may be directly involved in translocation (see also [187]).

During the translocation step, the coaxial helical structures (Fig. 31) would have to be disrupted in order for the newly formed peptidyl-tRNA to move from the A site to the P site. One of the factors that may facilitate such a motion is the acylation of the α-amino group of the newly formed peptidyl-tRNA, now in the A site of the pre-translocation intermediate.[188] An acylated α-amino group does not conform with the specificity of the A′ site, which requires a free α-amino group, and may thus provide a steric impetus for translocation.

6. Catalysis of the Peptidyl Transferase Reaction

Inspite of the fact that the reaction of peptidyl-tRNA with aa-tRNA is thermodynamically favored,[13] there is, to our knowledge, no example of the reaction between the two species in the absence of the ribosome. Peptidyl transferase, which normally catalyzes the synthesis of peptide bonds, is also able, albeit less efficiently, to form ester bonds,[118, 189, 190] thioester bonds,[119] thioamide bonds,[191] and phosphinamide bonds.[192] On the other hand, there is no evidence that peptidyl transferase can cleave peptide bonds. Two other ribosome-mediated reactions appear to involve the peptidyl transferase: the peptide chain termination reaction[193] and the alcoholysis of peptidyl-

tRNA.[194] In these two cases, a molecule of water or ethanol functions as the acceptor substrate.

What then is the nature of peptidyl transferase? Is it an enzymatic activity of a specific ribosomal component or does it work strictly as a template, bringing the "business ends" of two tRNAs into proper juxtaposition to allow spontaneous peptide bond formation? In the following paragraphs we consider both possibilities.

6.1. Peptidyl Transferase as a Template

According to this hypothesis, the peptidyl transferase reaction is simply the aminolysis of the activated ester bond of peptidyl-tRNA by the α-amino group of aa-tRNA via the formation of the tetrahedral intermediate **35** (Fig. 32). The ribosome is not involved catalytically in the reaction. The proposed intermediate is thermodynamically favored, since there is a sufficient energy difference between the activated ester bond of peptidyl-tRNA and the amide bond of the product. It was convincingly argued by *Nierhaus* et al.[195] that the required rates of peptide bond formation, as they are known to occur during protein synthesis, can be achieved if the substrates are properly juxtaposed. The requisite orientation is achieved by the existence of extremely well defined sites for binding of both substrates. According to this model, the functional groups of the ribosomal components do not participate in the peptidyl transferase reaction.

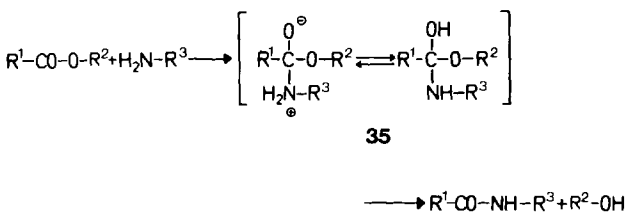

Fig. 32. Peptide bond formation in the peptidyl transferase reaction via a tetrahedral intermediate.

A relevant example of the rapid "uncatalyzed" transacylation reaction is provided by the isomerization of the aminoacyl residue after enzymatic aminoacylation of the accepting 2′-hydroxyl group of tRNA-C-C-3′NH_2A **36** (Fig. 33). The rapid isomerization of the initially formed ester **37** leads subsequently to a stable molecule **3** containing the acylamido bond. This reaction may be considered as a model of "peptide bond formation" via a reactive ester intermediate, which is facilitated by a properly juxtaposed substrate.[14]

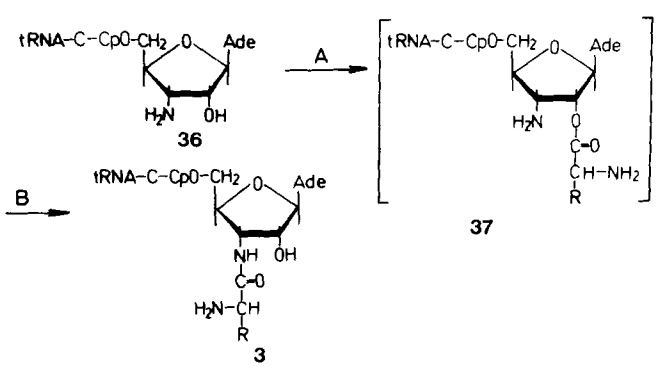

Fig. 33. The formation of the aminoacylamido bond on tRNA-C-C-3′NH_2A **36** involving the ester intermediate **37**. A: 2′-specific enzymatic aminoacylation; B: transacylation to give **3**.

6.2. Peptidyl Transferase as an Enzyme

Although the required rates of peptide bond formation can be achieved by juxtaposition of the 3′-ends of the two tRNA substrates, there are numerous observations that indicate that the ribosome functions as an enzyme for the formation of the peptide bond. The question then arises whether peptidyl transferase could function by a mechanism similar to that of proteolytic enzymes, which are also capable of synthesizing peptide bonds. Members of this class of enzymes, known as serine proteases, all appear to operate by a similar mechanism, involving a serine-histidine-aspartic acid charge relay system and the formation of a covalent acyl-enzyme intermediate. The formation of a covalent substrate-enzyme intermediate in the case of peptidyl transferase is not probable.[195, 196] On the other hand, a mechanism involving the histidine-carboxyl system was postulated for the peptidyl transferase in order to account for the repeated observation that the histidine residue of a ribosomal protein is involved in substrate binding to the A′ site.[197-199] There is no need, however, to postulate the existence of a protease-type charge relay system to explain the putative role of the ribosomal peptidyl transferase in the catalysis, since this mechanism has evolved for an entirely different reaction, i.e., cleavage of the peptide bond.

Before the peptidyl transferase reaction can take place, the α-amino group of aa-tRNA must be deprotonated by an appropriately placed proton-accepting group on the ribosome. Thus, the reaction may be considered to be a "catalyzed" reaction.[200] Moreover, the concerted mechanism of "catalyzed" peptide bond formation, which was originally proposed by *Cheney*,[201] involves the transfer of a peptidyl residue from peptidyl-tRNA to a *deprotonated* amino group of aa-tRNA, followed by a proton transfer with $Mg^{2\oplus}$ participation. It also requires the participation of a suitably oriented ribosomal function to act in "the proton relay" (Fig. 34), which would thus serve as a catalytic site. This mechanism merits serious consideration, since it accounts for the stabilization of the tetrahedral intermediate, which, obviously, is not possible in an "uncatalyzed reaction". Furthermore, this model also provides a rationale for the competitive binding of antibiotics such as lincomycin, chloramphenicol, and erythromycin, which are known to inhibit the peptidyl transferase reaction. According to this model, the antibiotics would be expected to interact directly with the catalytic center and, thereby, obviate the need to postulate allosteric effects. Additionally, the participation of a ribosomal group in the catalysis should facilitate kinetic control of the process, which is necessary in providing for the fidelity of translation.[6, 202]

If the traditional view were to hold, namely, that the enzymatic activity is harbored by a protein, then it would seem rather safe to predict, from an evolutionary point of view, that peptidyl transferase activity should be the prop-

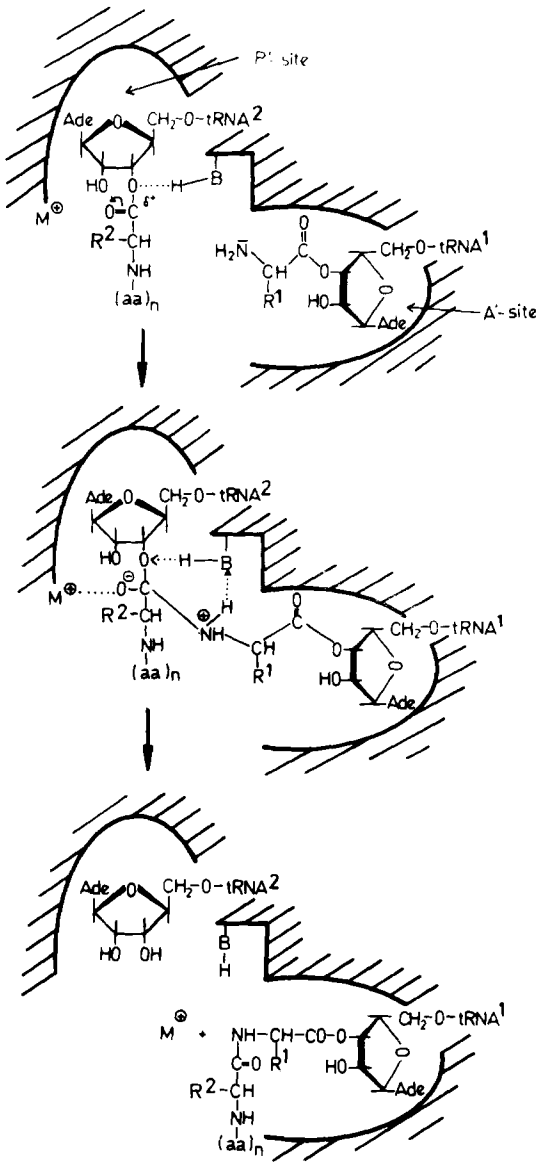

Fig. 34. The mechanism of the enzymatically catalyzed peptide bond synthesis. A metal ion $M^{\oplus}$ and a ribosomal functional group B-H are involved in the reaction. The latter functions as a proton acceptor and proton donor. $tRNA^1$ is aminoacyl-tRNA; $tRNA^2$ is peptidyl-tRNA (redrawn according to [201]).

erty of a single protein. In fact, protein L16 was long regarded as a prime candidate for the peptidyl transferase,[203] but this view is no longer tenable.[204,205] The latest potential candidate for "the peptidyl transferase protein" is the highly conserved protein L2 (see also [187]).

Since the protein synthesizing machinery must have evolved before the existence of proteins themselves, the prebiotic ribosome was most likely composed only of RNA.[206,207] Therefore, the pertinent question arises as to whether RNA alone can catalyze peptide bond formation. A short time ago this view would have been regarded as heretical, since catalytical roles were traditionally reserved for proteins, whereas nucleic acids were believed to have structural functions. This perception has changed dramatically recently. There are, to our knowledge, two examples for the catalytic role of RNA alone in the cleavage and formation of phosphodiester bonds between nucleotides.[208,209] *Garrett* and *Wooley*[200] have recently speculated that the catalysis of peptide bond formation could possibly be mediated by a properly positioned 5'-phosphate group of peptidyl-tRNA, involving a mechanism similar to that shown in Figure 34. It was shown that the rate of poly(Phe) synthesis decreased as a result of the removal of the 5'-phosphate group from tRNA.[97] This effect, however, which was measured for the synthesis of polypeptides de novo, does not seem to be dramatic enough for assigning a crucial catalytic role to this phosphate group. The suggestion of *Garrett* and *Wooley*[200] is also at variance with the donor activity of fragments such as C-C-A(fMet) in the peptidyl transferase reaction, although the fragment reaction apparently proceeds at a slower rate. Since the central loop of the domain V of 23S RNA appears to be a part of the peptidyl transferase center (Section 5.3.9), it seems plausible that some of its functionality, properly oriented, could provide for the catalysis of the peptidyl transferase reaction (or deprotonation of the α-amino group of aa-tRNA).

Indeed, it was recently demonstrated that a complex that forms between 16S and 23S RNA may act as a primitive ribosome, having lower, albeit significant activity in poly(Phe) synthesis.[210] *Burma* et al. have also shown that EF-Tu-dependent binding of $Phe\text{-}tRNA^{Phe}$ to the 16S·23S RNA complex requires the presence of 5S RNA.[210] This RNA binds to the 16S·23S RNA complex only in the presence of the 5S RNA binding proteins (L5, L18, L15/25). Accordingly, these proteins must be included in the experiment. On the other hand, it is very clear that none of these proteins is involved in peptidyl transferase activity. Therefore, peptide-bond-forming activity should most probably be attributed to 23S RNA, specifically to the central loop of domain V, in which most of the single-stranded nucleotides are highly conserved through evolution.[178,181] Furthermore, several mutations leading to ribosomal resistance to chloramphenicol and erythromycin are found in the same region. The binding site of the 3'-end of peptidyl-tRNA in the loop of domain II of 23S RNA is probably the P' site. The binding site of the 3'-end of the aa-tRNA in the peptidyl transferase loop, which includes the catalytic activity, is most likely the A' site. This configuration would provide for the separation of the catalytic activity and acceptor binding from the binding of the donor molecule. This is necessary for the regulation of peptide synthesis, the proofreading mechanism, and the fidelity of the process. Thus, the findings of *Burma* et al.[210] have far-reaching functional implications, showing for the first time that ribosomal RNAs still may retain their primitive protein-synthesizing functions, which, by virtue of evolution, have been much refined by the proteins themselves.

7. Conclusions and Outlook

The data obtained by several approaches make it possible to visualize in considerable detail the nature of the interactions of the 3'-terminal C-C-A end of tRNA with elongation factors and with the A' and P' sites. The most recent and important observations are concerned with the crucial role of 23S RNA in the peptidyl transferase reac-

tion. Since the rRNA story is just beginning to unfold, we are certain to learn more of the direct participation of rRNAs not only in the process of peptide bond formation, but also in other events encompassing overall protein synthesis on the ribosomes.

The interaction of the 3′-end of aa-tRNA with a corresponding site of EF-Tu is of primary importance for the formation of the ternary complex and for the EF-Tu-catalyzed GTP hydrolysis, which is triggered upon binding of the ternary complex to ribosomes. It seems reasonable to assume that the nucleic acid bases of the C-C-A sequence are not directly in contact with EF-Tu while aa-tRNA is complexed to the enzyme. Thus, in the process of the enzymatic binding of aa-tRNA to the ribosome, base moieties of the C-C-A sequence are available for interaction with the ribosomal A′ site. It is not clear whether EF-Tu is indeed nonspecific with respect to the 2′,3′-isomers of the aa-tRNA. Our understanding to date is based on model studies, which may not be fully adequate. The obligatory involvement of the aa-tRNA C-C-A terminal sequence in the process of GTP hydrolysis is, however, clear. Nonetheless, a larger question remains to be answered: how do conformational changes occur in the EF-Tu molecule to bring about GTP hydrolysis by this protein? The question also remains how the binding of other parts of the tRNA, to either EF-Tu or to the ribosome, influences the interaction of the 3′-end of aa-tRNA with the enzyme. Also, it remains to be clarified whether the latter phenomenon is a part of the EF-Tu·GTPase triggering mechanism.

Since the aa-tRNA 3′-end is accommodated at the A′ site upon dissociation of EF-Tu, we do not know whether the process includes, as well, some intermediary interactions. Intermediary configurations of aa-tRNA may allow for proofreading, involving possibly rRNA structure dynamics. A ribosomal protein(s) is required for the precise alignment of the aminoacyl portions of both substrates (aa- and peptidyl-tRNA) for peptide bond formation. Moreover, the protein(s) would be expected to possess binding loci to facilitate proper orientation of both substrates; this must involve, at the very least, the carbonyl group and the side chain of the aminoacyl moieties. Interactions with other moieties of the terminal adenosine unit are also conceivable. On the other hand, the α-amino group of the acceptor and the ester bond of the donor would be expected to be available to hydrogen bond with the catalytic functionality of peptidyl transferase. The acceptor and donor molecules, aa-tRNA and peptidyl-tRNA, react in the form of the 3′-isomer, while the 2′-OH group of the terminal adenosine is not required for this reaction. Gly-tRNA is probably exempt from this rule.

It is likely that the peptidyl transferase reaction is catalyzed by a functionality in the central loop of domain V of 23S RNA. The mechanism of the peptidyl transferase reaction proposed here suggests that the A′ and P′ sites are made up, in part, of the appropriate G-G and U-G-G sequences of 23S RNA, which are located in different domains of the polynucleotide. These sequences are presumably engaged in base-pairing with the C-C and C-C-A sequences of aa- and peptidyl-tRNA. The domains of 23S RNA that form parts of the A′ and P′ sites must be in close proximity for peptide bond formation to occur, but they could be separated during various stages of the ribosomal cycle. Thus, the folding of the 23S RNA chain may provide for the regulation of the protein synthesis, including proofreading.

Even though we do not envision catalysis of the peptidyl transferase reaction being mediated by a ribosomal protein, participation of proteins may not be limited to maintaining the specificity of the reaction and presumably increasing the rate of peptide synthesis. Even if we accept the unorthodox view that the ribosome is an *RNA-driven device*, we cannot deny the apparent role of protein(s) in modulation of RNA structures. Similar roles may be played by elongation and termination factors, which may effect changes in ribosomal configuration.

During the translocation step, interactions of the two tRNAs with ribosomal sites have to be disrupted in order to achieve the movement of tRNA. This might include, among other things, the breaking of at least 5 base pairs between the 3′-ends of each of the tRNAs and 23S RNA. There are indications that another important change in the structure of the tRNA C-C-A terminus may take place during translocation, namely, rotation about the glycosidic bond of the 3′-terminal adenosine. If the 3′-terminal unit of peptidyl-tRNA, bound to the P′ site, is present in a *syn*-conformation, we may expect altered base pairing of this unit as well as an altered stacking arrangement of the whole C-C-A terminus. Such a scheme may explain the different modus of operation of A′ and P′ sites.

Similarly, the termination step must involve structural changes at the peptidyl transferase center in order to allow access of a molecule of water to an otherwise "anhydrous" A′ site. This change could be again modulated by corresponding changes in the 23S-RNA structure with participation of pertinent proteins.

Thus, the dynamic structure of RNA together with specific interactions of the 3′-terminal C-C-A sequences with their respective sites may make possible a virtually foolproof process of protein synthesis.

The results reported from our respective groups could only have been accomplished through the stimulating collaboration with our colleagues Drs. A. Bhuta, P. Bhuta, T. Ott, K. Quiggle, and D. Ringer (Detroit) as well as K.-H. Derwenskus, H. Faulhammer, W. Fischer, and T. Wagner (Göttingen and Bayreuth). Our thanks are also due to our colleagues Drs. D. P. Burma, E. Cundliffe, and E. Küchler for revealing their results prior to publication. The studies from our respective laboratories were supported in part by the National Institutes of Health (NIH Grants GM-19111, GM-21151), by the National Science Foundation (NSF Grant 82-97539) (to S. C.), by an institutional grant to the Michigan Cancer Foundation from the United Foundation of Greater Detroit, and by the Deutsche Forschungsgemeinschaft (Sp 243/1-1) and the Fonds der Chemischen Industrie (to M. S.). S. C. gratefully acknowledges the award of a Visiting Professorship from the Deutsche Forschungsgemeinschaft, which made this work possible. We are further obliged to Drs. J. P. Horwitz, J. Žemlička, and E. Happ (Detroit) for a critical reading of the manuscript and stimulating discussions. Our thanks are also due to Miss B. Wagner for the preparation of the figures.

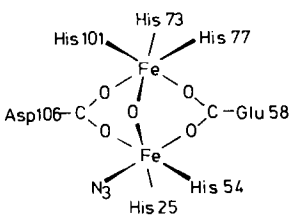
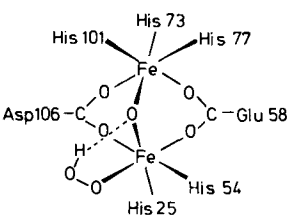
Reactivity of the $[Fe_2(\mu_2\text{-}O)(\mu\text{-acetato})_2]$ Unit in Methemerythrin Model Compounds towards $N_3^{\ominus}$ and $NCS^{\ominus}$**



By *Karl Wieghardt,* Klaus Pohl,* and *D. Ventur*

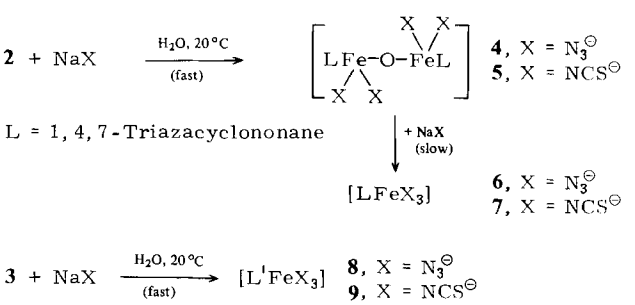
The synthesis and structure of the low-molecular-weight Fe^{III}-complexes **1** and **2**, containing the structural unit $[Fe_2(\mu_2\text{-}O)(\mu\text{-acetato})_2]$ have recently been reported.[1]



1, L = Tri-1-pyrazolylborate(1-) (n = 0)[1a]
2, L = 1,4,7-Triazacyclononane (n = 2)[1b]
3, L = *N,N',N''*-Trimethyl-1,4,7-triazacyclononane (n = 2)

These complexes, to which the complex **3** presented here also belongs, have proven to be perfect model compounds for the Fe^{III} centers in metazido-[2] and oxyhemerythrin[3] so far as bonding is concerned. Particularly remarkable is the similarity of the electronic spectra in the visible region and of the magnetic properties (antiferromagnetism) of **1**—**3** with those of the methemerythrins.[4]

Metazidohemerythrin



Oxyhemerythrin

The reactivity of the dinuclear structural unit in **1**—**3** is presently the subject of intensive study. The oxo bridge in **1** can be reversibly protonated to the corresponding μ-hydroxo bridge.[5] Furthermore, the μ-carboxylato bridges in **1** and **2** are relatively labile;[6] in **1**, they can be replaced by phosphate diesters.[6b] Aqueous solutions of **2** are stable for only about 2 h at 20°C, after which time an insoluble precipitate slowly forms.[6a] In the presence of excess acetate ions, however, aqueous solutions of **2** and **3** are stable for several hours.

We have investigated the reactivity of **2** and **3** towards $N_3^{\ominus}$ and $NCS^{\ominus}$ in aqueous solution at 20°C. Under these conditions the enzyme deoxyhemerythrin reacts in the presence of $NCS^{\ominus}$, $N_3^{\ominus}$, $CN^{\ominus}$ or $OH^{\ominus}$ and oxygen to give methemerythrin with the intact $[Fe_2(\mu_2\text{-}O)(\mu\text{-carboxylato})_2]$ structural unit with bonding of only *one* of these ligands to *one* Fe^{III} center.[4]

Addition of NaN_3 or NaSCN to freshly prepared aqueous solutions of **2** leads to immediate precipitation of microcrystalline, yellow precipitates of **4** and **5**, respectively. **4** and **5** react with excess $N_3^{\ominus}$ and $NCS^{\ominus}$ very slowly to give red **6** and **7**, respectively. Under the same conditions, **3** immediately furnishes red **8** and **9**, respectively. The formation of **4** and **5** in the presence of sodium acetate proceeds considerably more slowly. With very high concentrations of acetate, $[3\cdot(SCN)_2\cdot 5\,H_2O]$ precipitates out and no substitution reaction takes place at the Fe^{III} center.

4 and **5** are dinuclear, oxo-bridged complexes exhibiting strong antiferromagnetic coupling of the two high-spin Fe^{III} centers (Table 1). The expression for the temperature-dependent susceptibilities (98—293 K) of **2**—**5** were derived from the general, isotropic spin Hamilton operator $H' = -2JS_1\cdot S_2$ for $S_1 = S_2 = 5/2$ ($g = 2.0$, no temperature-independent paramagnetism). The values for J between -76 and $-95\ cm^{-1}$ are typical for oxo-bridged Fe^{III}-complexes. In each case, one band is observed for the ν_{as}(Fe—O—Fe) stretching vibration in the IR spectra of **4** and **5**, at 800 and 810 cm^{-1} respectively; it is shifted to higher wave numbers compared to the corresponding bands of **2** and **3** (and **1**[1a]). This is indicative of a stronger Fe—O bond and an almost linear Fe—O—Fe unit.

6—**9** are monomeric, octahedral Fe^{III}-complexes. The temperature-independent, effective magnetic moment of ca. $5.8\,\mu_B$ (98—293 K) indicates a high-spin d^5-electron configuration of the Fe^{III} centers.

The reactions of **2** and **3** with $N_3^{\ominus}$ and $NCS^{\ominus}$ are different from those of the methemerythrins—despite the very similar coordination and electronic structure of the Fe^{III}

centers. And, finally, the kinetic lability of the μ-acetato bridge[6] and, of the oxo-bridge in **2** and **3** is *not* observed in methemerythrin under the same conditions.

Table 1. Electron excitation, IR- and magnetic data of the complexes **1**—**9**.

Compound	ν_{as}(Fe–O–Fe) [cm^{-1}]	J[cm^{-1}]	μ_{eff} (293 K) [μ_B]	λ[nm] (ε[L mol^{-1} cm^{-1}]) [a]

[a] Molar absorption coefficients; solvent for **3** water, and for **4**—**9** acetone.

Experimental

3$(PF_6)_2$: To a solution of $FeCl_3 \cdot 6 H_2O$ (3.5 g) in ethanol (100 mL) was added 12 mL of 1 M ethanolic solution of *N,N',N''*-trimethyl-1,4,7-triazacyclononane (L'). A yellow precipitate of [L'$FeCl_3$] separated out. After filtration, 0.2 g of this neutral complex was dissolved in 10 mL of a saturated aqueous NH_4OAc solution. 0.25 g of KPF_6 was added to the clear brown solution and the resulting brown precipitate of **3**$(PF_6)_2$ was recovered by filtration (yield 0.2 g (75%)).

4—**7**: A solution of NaN_3 (1 g) or NaSCN (0.2 g), respectively, in H_2O (5 mL) was added at 20°C to a stirred solution of [**2**·I_2·0.5 NaI·3 H_2O] (0.10 g) [1b] in 20 mL H_2O. Ocher-yellow precipitates of **4**·H_2O (0.07 g, 92%) and **5** (0.10 g, 95%) immediately separated out. When the suspensions were stirred for a further 6 h at 20°C, red precipitates of **6** and **7**, respectively, separated out (0.07 g, 95% and 0.08 g, 98%).—All the complexes are sparingly soluble in H_2O, but moderately soluble in acetone or acetonitrile. A molecular weight determination was carried out in the case of **5** (620 ± 30).

8 and **9**: 1 g of NaN_3 or NaSCN was added to 40 mL of an aqueous solution of 0.2 g **3**$(PF_6)_2$. Red precipitates of **8** and **9** immediately separated out (quantitatively). All the compounds gave correct elemental analyses (Fe, C, H, N, S).

$(Te_2)_2(I_2)$—An Unusual Intercalation Compound**

By *Rüdiger Kniep** and *Heinz-Jürgen Beister*

In a review article on subhalides of tellurium,[1] the existence of a metastable compound Te_3I was reported. We have again synthesized this phase and determined its crystal structure. It is a compound with an unusual layer structure, which can be described as a tellurium intercalate with a phase width related to the intercalated iodine. At maximum iodine content the composition corresponds to the empirical formula Te_2I,[2] at minimum iodine content to an empirical formula $Te_2I_{0.42}$ (sample ca. 30—50 small crystals; 10 mg).

The shiny, black-metallic, air-stable crystals of $(Te_2)_2(I_2)$, **1**, are obtainable by hydrothermal synthesis[3] in concentrated HI.[4] For the structure analysis[5] we used a single, very slightly distorted crystal measuring $0.2 \times 0.07 \times 0.01$ mm^3. Intergrowths and deformations are especially pronounced in this layer-like structured crystalline substance, a factor which has hitherto prevented a satisfactory structure determination.

According to the X-ray structure analysis (Fig. 1), **1** contains planar double layers of tellurium formed from Te_2 units arranged parallel to the c axis. The Te atoms within the double layers thus exhibit a distorted tetragonal-pyramidal (1+4)-coordination with one short (d_1) and four longer bond lengths (d_2). In contrast, a distorted octahedral (2+4)-coordination is observed in the trigonal elemental structure.[6] The bond length d_1 (Te–Te) of 2.713(7) Å is distinctly shorter than that in the trigonal elemental structure ($d_1 = 2.835(2)$ Å)[6] and only slightly longer than the reported Te–Te bond length in Te_3Cl_2 (2.67 Å) with partial double bond character.[1] It may be assumed that the Te_2 units in the compound described here are stabilized by resonance (:$\ddot{T}e$–$\ddot{T}e \leftrightarrow \ddot{T}e = \ddot{T}e \leftrightarrow \ddot{T}e$–$\ddot{T}e$:). The

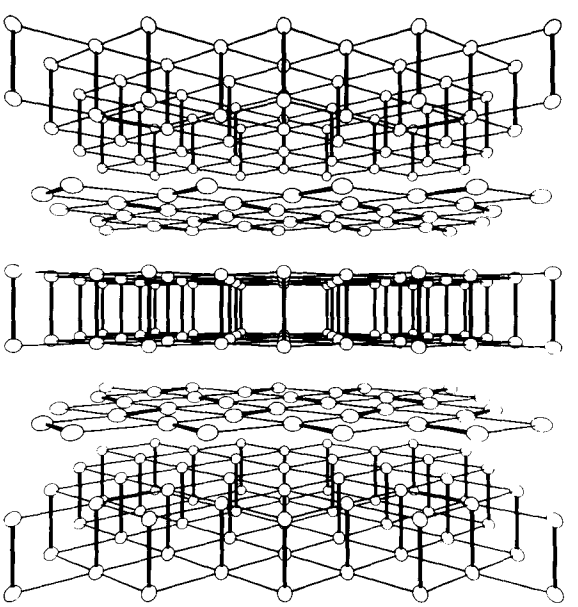

Fig. 1. Perspective representation of the layer sequence ([001]) in **1**. Te_2 pairs and I_2 molecules are accentuated by bolder lines.

distances d_2 between adjacent Te_2 units within a double layer are 3.323(1) Å and are thus likewise shorter than the intermolecular distances d_2 between the chains of the trigonal elemental structure (3.495(4) Å).[6] The ratio $d_2:d_1$ in the tellurium double layer, with a value of 1.225, is noticeably different from unity, so that little significance attaches to the comparison with a (tetragonal distorted) two-dimensional section of the cubic primitive α-Po structure, which seems reasonable at first glance.

I_2 molecules (I–I 2.866(12) Å) are located between the tellurium double layers; these are arranged via intermolecular contacts (I···I 3.324(14) and 3.841(16) Å) in monomolecular planar layers. The shortest interlayer distance I···Te is 3.812(9) Å. The orientation of the iodine molecules within the layers corresponds to the arrangement of the molecules in the (100) planes of the elemental structure;[7] here, however, the bond length in the I_2 molecule (2.715 Å) is shorter, while the intermolecular contacts (3.496 and 3.972 Å) are longer.

1 can be described as a tellurium intercalate $^2_\infty(Te_2)_2(I_2)$, in which a tellurium modification, previously unknown as an independent phase, is intercalated by elemental iodine. First attempts to obtain a new metastable elemental modification in substance, by thermal decomposition of the compound (as, e.g., in the case of *allo*-germanium[8]), were hitherto unsuccessful, and in each case led to the stable trigonal[6] modification of tellurium.

The crystal investigated by us showed an occupation of the iodine layers of only 88%. This finding can be attributed both to vacant sites within the iodine layers as well as to partial replacement of the iodine molecules by hydrogen iodide from the hydrothermal solution; in the thermal decomposition of **1** the liberation of HI is also detected mass spectroscopically.[9]

The thermal decomposition of **1** begins at ca. 100°C with chiefly elimination of I_2 and formation of small isometric crystals of trigonal tellurium at the ends of the layers of the intercalation compound. With increasing temperature (up to ca. 150 °C), TeI_2[1] is increasingly given off into the gas phase; this likewise leads, in the sense of a chemical transport reaction ($TeI_{2(v)} \rightleftharpoons Te_{(s)} + I_{2(v)}$),[10] to the formation of trigonal tellurium crystals. Under these conditions the crystals grow out parallel from the layers of the intercalation compound with a needle-like habit.

It has been demonstrated mass spectrometrically that solvent molecules are intercalated in the structural assemblage when crystals of **1** are treated with methanol.

$(Te_2)_2(I_2)$, 39449-54-2; GeTe, 12025-39-7; Te, 13494-80-9; I, 7553-56-2.

[1] R. Kniep, A. Rabenau, *Top. Curr. Chem. 111* (1983) 147.
[2] The same composition is also found for the known subhalides Te_2X (X = Cl, Br, I) [1].
[3] A. Rabenau in P. Hartmann: *Crystal Growth—an Introduction*, North-Holland, Amsterdam 1973, p. 198.
[4] Crystal growth: Quartz ampules ca. 14 cm³; 1.5 g of a 1:1 mixture of GeTe and Te; 60% degree of filling with 67% HI; temperature gradient 170→160°C ca. 18 h; duration of cooling ca. 12 h; reaction products: GeI_4, Te, $(Te_2)_2(I_2)$; yield of intercalation compound ca. 50 mg; germanium was not detected in the intercalate; the synthesis can also be accomplished in the presence of arsenic; without these "foreign elements", the compound is not formed; striking is the relatively high hydrogen partial pressure in the ampules on completion of the hydrothermal experiments.
[5] Crystallographic data of **1**: 157 (103) reflections (Syntex $P2_1$, $Mo_{K\alpha}$); $R = 0.079$; Cmmm; $a = 4.464(4)$, $b = 4.924(5)$, $c = 9.037(16)$ Å; $Z = 1$; $\rho_x = 6.39$ g/cm³ (complete occupation of the iodine positions); 6.13 g/cm³ for the observed occupation of 88%. In the space group Cmmm, two oppositely situated sites are present for each iodine atom, which are alternately occupied. The ordered iodine layers described in the text and depicted in Figure 1 follow from the occupation of only one of these sites in each case. This X-ray crystallographically established disorder can, e.g., be attributed to alternating orientation of the iodine molecules in successive layers. Superstructure reflections have not been observed photographically, even with longer exposure times. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51279, the names of the authors, and the full citation of the journal.

$[Cp_2Ti(PMe_3)_2]$—A Versatile Source of Titanocene Derivatives**

By *Lawrence B. Kool, Marvin D. Rausch,* Helmut G. Alt,* Max Herberhold, Ulf Thewalt,* and *Brigitte Wolf*

Monomeric titanocene, $TiCp_2$ (Cp = η^5-cyclopentadienyl), has so far eluded isolation as a discrete compound, since "in statu nascendi" it immediately reacts to form bi- or multinuclear species.[1] Until now, the best source for titanocene has been $[Cp_2Ti(CO)_2]$ **5**.[2] We now report the synthesis, spectroscopic characterization, and molecular structure of $[Cp_2Ti(PMe_3)_2]$ **1**, which may be considered as trimethylphosphane-stabilized titanocene. **1** is the first bis(trimethylphosphane) complex of a group 4 transition metal to be isolated and fully characterized.[3] It is synthesized in quantitative yield via the reduction of Cp_2TiCl_2 by magnesium in the presence of trimethylphosphane:

$$Cp_2TiCl_2 + Mg + 2\,PMe_3 \xrightarrow{THF} [Cp_2Ti(PMe_3)_2] + MgCl_2$$

1

1 has been characterized by elemental analysis, NMR spectroscopy, and X-ray structural analysis. The analogous zirconium derivative has similarly been obtained via magnesium reduction of the metallocene dichloride.

It was not possible to sublime **1** without decomposition. An intense peak for Cp_2Ti^+ (*m/z* 178) was observed in the EI mass spectrum; in addition, peaks of higher *m/z* appeared, which resulted from formation of binuclear titano-

cene species. In the ^{1}H-, ^{13}C-, and ^{31}P-NMR spectra, all the expected signals could be assigned.[4]

The X-ray structural analysis[4] of **1** indicates that two crystallographically independent molecules are present in the unit cell: one molecule (containing Ti1) occupies a common position while the other occupies a special position with crystallographic C_2 symmetry. Both molecules possess the same dimensions and conformations within narrow limits. All PMe_3 ligands are so oriented that one C atom always lies almost in the P–Ti–P plane (Fig. 1).

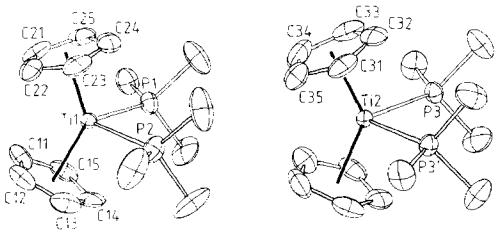

Fig. 1. The two (crystallographically) independent molecules of **1**. Important distances [Å] and angles [°]: Ti1–P1 2.527(3), Ti1–P2 2.524(4), Ti2–P3 2.527(2), Ti1–Z1 2.057(12), Ti1–Z2 2.062(14), Ti2–Z3 2.049(12); Ti–C(Cp) 2.338(13)–2.422(12); P–C(Me) 1.837(19)–1.887(11); P1–Ti1–P2 92.9(1), P3–Ti2–P3′ 91.5(2), Z1–Ti1–Z2 133.2(5), Z3–Ti2–Z3′ 134.3(6). Z1, Z2, Z3: center of gravity of the C11, C21, and C31-containing Cp rings; Z3′: center of gravity of the unnumbered Cp ring.

The Ti–P distances in **1** (2.524(4) and 2.527(3) Å) are in excellent agreement with the recently reported complex **2**.[5] They are, however, shorter than the Ti–P distance in **3** (2.585(1) Å).[6] The Cp_2Ti units in **1**, **2**, and **3** are essentially identical. The P–Ti–P angle in **1** (91.5(2) and 92.9(1)°) is, as expected, larger than in the chelated complex **2** (76.9(2)°).[5]

$[(Me-C_5H_4)_2Ti(dmpe)]$
2, dmpe = 1,2-bis(dimethylphosphino)ethane:

$[Cp_2Ti(PEt_3)(CO)]$ **3**	$[Cp_2Ti(PMe_3)(CO)]$ **4**
$[Cp_2Ti(CO)_2]$ **5**	$[Cp_2Ti(dmpe)]$ **6**
$[Cp_2Ti(SPh)_2]$ **7**	$[Cp_2Ti(PMe_3)(C_2Ph_2)]$ **8**
$[Cp_2TiC_4Ph_4]$ **9**	$[Cp_2Ti(PMe_3)(C_2H_2)]$ **10**
$[Cp_2TiC_4H_4]$ **11**	$[Cp_2Ti(PMe_3)(C_2H_4)]$ **12**
$[Cp_2TiC_4H_8]$ **13**	$[Cp_2Ti(CH_3CN)_2]$ **14**

With **1**, the titanocene unit, $TiCp_2$, has become accessible in solution with unprecedented facility, since the two PMe_3 ligands may be replaced by a large number of substrates under very mild conditions; all products are obtained in excellent yields. With carbon monoxide, it forms, within a few minutes, first the mono- and then the dicarbonyl complex, **4**[7] and **5**,[2] respectively. With the chelating ligand dmpe, **6**[5] is formed. Diphenyl sulfide reacts immediately with **1** forming **7**.[8] With diphenylacetylene, first the complex **8**[9] and subsequently the metallacycle **9**[10] are formed. Acetylene reacts with **1** affording the first C_2H_2 complex **10**, the first metallacyclopentadiene derivative of a group 4 transition metal **11**, and polyacetylene $+HC=CH+_x$. Ethylene is dimerized catalytically under pressure (60 bar) in the presence of **1** at room temperature; NMR spectroscopic studies at −50 °C indicate that, in addition, the ethylene complex **12** and the saturated metallacycle **13**[11] occur as intermediates. Acetonitrile displaces the two PMe_3 ligands of **1**, whereby the disubstitution product **14** and other, as yet unidentified, products arise. Preliminary studies indicate that **1** also reacts with isonitriles, diazoalkanes, sulfur diimides, carbon dioxide, carbon disulfide, nitrosyl chloride, hydrogen and other substrates.

Experimental Procedure

A solution of Cp_2TiCl_2 (10.0 g, 40.2 mmol) in 200 mL of tetrahydrofuran (THF) was treated under argon with 4.3 g (180 mmol) of magnesium turnings and with 19 mL (200 mmol) of trimethylphosphane and stirred. The red suspension soon turned blue, and shortly thereafter became red-brown. After 20 h, the solvent was removed at 10^{-2} bar and the residue extracted with pentane. After concentration of the orange-brown solution and cooling to −78 °C, black needles formed, which decomposed at ca. 105 °C. Yield: 13.3 g (100%).

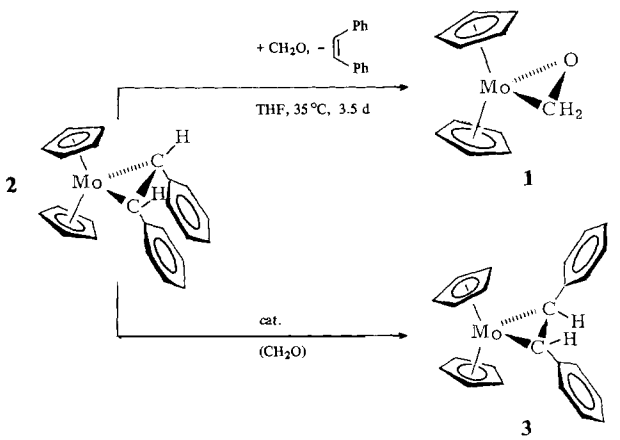
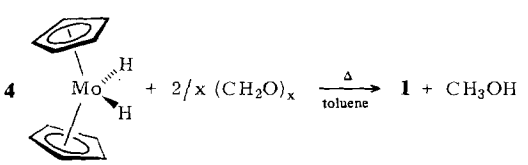
Synthesis of $[(\eta^5\text{-}C_5H_5)_2Mo(\eta^2\text{-}CH_2O)]$: A Formaldehyde Complex of Molybdenum**



By *Gerhard E. Herberich** and *Jun Okuda*

Dedicated to Professor F. Gordon A. Stone on the occasion of his 60th birthday

Organometallic complexes containing formaldehyde ligands are of considerable interest as model compounds for intermediates in the homogeneous reduction of CO.[1] The sterically compact and electronically flexible metallocene fragments $M(C_5H_5)_2$ of early transition metals are suitable for the investigation of formaldehyde coordination in complexes containing different metals but having comparable ligand environments.



Whereas vanadocene reacts with paraformaldehyde to give a mononuclear formaldehyde complex via addition of a CH_2O unit,[1b] zirconocene hydrides afford bi- and trinuclear derivatives containing bridging CH_2O ligands upon treatment with CO.[1c] We report here the molybdenocene formaldehyde complex **1**.[2]

The molybdenocene complex **2**,[3] which is labile toward substitution, reacts with formaldehyde or with paraformaldehyde in tetrahydrofuran (THF) to give the formaldehyde complex **1**; the substitution-inert (*E*)-stilbene complex **3** is simultaneously formed by catalytic isomerization of the (*Z*)-stilbene complex **2**.[4]

The reaction of molybdenocene hydride **4** with paraformaldehyde to give **1** is more convenient, affords higher yields, and exhibits practically no side reactions.[5,6] In contrast to the aforementioned carbonylation of the zirconium hydrides, the carbonylation of **4** does *not* lead to a formaldehyde complex.[7]

The spectroscopic data for **1** support a "metallaoxirane" structure with η^2-coordinated formaldehyde. The NMR signals of the H and C atoms of the CH_2O ligands are shifted to higher field relative to those of free CH_2O ($\Delta\delta(^1H)$: 6.57 ppm; $\Delta\delta(^{13}C)$: 149.2 ppm). This can be explained by strong back-bonding from the metal to the π^*-acceptor orbital of the "oxaethene". This bonding model is also in accord with the dramatic frequency shift of the ν_{CO} absorption of the formaldehyde. In the IR spectrum of **1**, in addition to the characteristic band pattern of the $Mo(C_5H_5)_2$ fragment, an intense band at 1155 cm^{-1} is observed which corresponds to the C–O bond.[8] Since the same band appears for $[V(C_5H_5)_2(CH_2O)]$ at 1160 cm^{-1},[1b] the back-bonding in both compounds is apparently of similar strength.

Synthesis, Dynamic Behavior, and Structure of $[Sn\{C(PMe_2)_3\}_2]$—a Homoleptic Tetraphosphanetin(II) Complex with Pseudo Trigonal Bipyramidal Structure**

By *Hans Heinz Karsch,** *Armin Appelt*, and *Gerhard Müller*

Complexes of main-group elements whose coordination sphere is formed exclusively or predominantly by phosphane ligands are rare, a situation contrasted by the corresponding transition-metal complexes. Recently, however, we were able to obtain phosphane lithium complexes containing *anionic* phosphane ligands, e.g., phosphinomethanides **I** or phosphinomethylaluminates **II**.[1,2] Further examples of such main-group metal complexes were not known.

[**] Phosphane complexes of main-group elements, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft. Part 3: [1b].

$[(Me_2P)_nCH_{(3-n)}]^-$ I $[Me_{(4-n)}Al(CH_2PMe_2)_n]^-$ II

In order to determine the extent to which other main-group metals are complexed by anionic phosphane ligands, we have attempted to prepare an Sn^{II} complex of **I**. Sn^{II} was chosen to be a particularly suitable complex center for the following reasons:

- The phosphinomethanide-Sn^{II} system is comparable to the analogous silylmethanide-Sn^{II} system,[3] where coordination occurs via the carbanion.
- Simple, molecular coordination compounds of Sn^{II} are rare.[4]
- Homoleptic, phosphane-Sn^{II} complexes have not yet been isolated;[5] to our knowledge, structural data for molecular P–Sn^{II} compounds are not available.

The reaction of $SnCl_2$ with LiI in diethyl ether leads, only for n = 3, to an isolable Sn^{II} complex, **1**,[6] which is stable at room temperature (84% yield).

The NMR spectra of **1** are in accord with a pseudo trigonal bipyramidal (ψ-tbp) structure if rapid pseudorotation is assumed to occur at −80 °C, which exchanges the atoms in the axial and equatorial positions of the tbp skeleton. Moreover, at room temperature, a further dynamic process becomes apparent: all phosphorus atoms equilibrate ($\Delta G^{\neq}_{20\,°C} = 12.7$ kcal/mol). In this process, however, the $^{119}Sn^{31}P$ coupling persists. Its value at 30 °C corresponds to the weighted average of the low-temperature values. The $\delta^{31}P$ value at 30 °C also corresponds to such an average of the low-temperature values, whereas $\delta^{119}Sn$ is not affected. Therefore, on the basis of the NMR spectroscopic results, a fundamental change in the coordination geometry with changing temperature can be effectively ruled out. The dynamic behavior could be explained by involvement of the carbanion and/or the free phosphino groups in the coordination sphere of tin.

Further information concerning the equilibration process can be obtained by replacement of the phosphino groups in **1** by the $SiMe_3$ group.

$$SnCl_2 + 2\,Li[C(PMe_2)_2SiMe_3] \xrightarrow[-2\,LiCl]{Et_2O} [Sn\{C(PMe_2)_2SiMe_3\}_2]$$

2[7] **3**

The NMR spectra of **3**,[8] which contains two anions of **2** as ligands, at 30 °C correspond to the low-temperature spectra of **1**. Apparently, **3** is not a fluxional system in solution—with the exception of the pseudorotation also assumed in this case. Thus, it is evident that the dynamic behavior of **1** is induced by the non-coordinating phosphino groups, with only a short life-time for the transition state.

An X-ray structure determination[9] shows the presence of a ψ-tbp geometry at Sn^{II} in the crystal (Fig. 1). The Sn^{2+} ion acts as a spiro center of two four-membered rings. Thus, it is coordinated by both P atoms of each bidentate tris(phosphino)methanide ion. One equatorial coordination site of Sn (distorted tbp geometry) is vacant, indicating that the free electron pair of Sn^{II} is probably oriented in this direction. Both the bonding angles at Sn and the axial Sn–P2/P5 bonds, which are markedly longer than the equatorial Sn–P1/P4 bonds, rule out a tetragonal pyramidal Sn coordination. Similar bonding geometries for tetracoordinated Sn^{II} are also induced by ligands with O-donor atoms.[4]

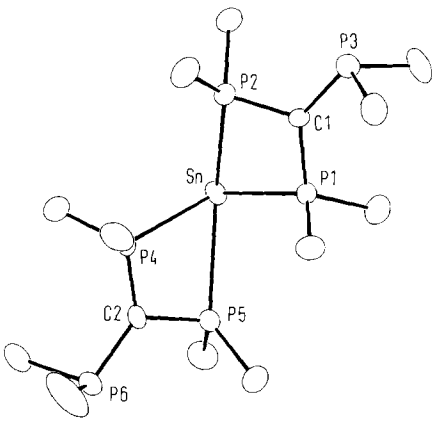

Fig. 1. Molecular structure of **1** (ORTEP, vibration ellipsoids at the 50% probability level, without H atoms). Important bond distances [Å] and bond angles [°]: Sn–P1 2.602(2), Sn–P2 2.790(2), Sn–P4 2.598(2), Sn–P5 2.839(2), C1–P1 1.733(6), C1–P2 1.754(6), C1–P3 1.792(6), C2–P4 1.735(6), C2–P5 1.765(6), C2–P6 1.791(6), Sn–C1 3.265(4), Sn–C2 3.313(4); P1–Sn–P2 62.9(1), P4–Sn–P5 62.8(1), P2–Sn–P4 95.1(1), P1–Sn–P4 105.9(1), P2–Sn–P5 142.5(1); sum of valence angles at C1/C2 359.7/360.0.

Formally, five non-bonding electron pairs (at Sn, C1, C2, P3, P6) have to be taken into consideration in **1**. Interaction between these electron pairs is apparently minimal in the arrangement found.

Thus, **1**—along with LiI[2]—is another structurally characterized main-group metal complex of the tris(dimethylphosphino)methanide ion. In contrast to LiI, the coordination of the ligands in **1** occurs exclusively via the P atoms. In this case, the exactly planar-coordinated carbanionoid centers C1 and C2 surprisingly are not used for coordination. An interaction with the Sn center is observed neither in an intramolecular nor in an intermolecular fashion.

On the Aggregation of Lithiated Bicyclobutane Derivatives in Solution**

By *Arnulf-Dieter Schlüter,* Helmut Huber,* and *Günter Szeimies*

The degree of aggregation of organolithium compounds in solution can easily be established by determination of the ^{13}C-^6Li-NMR coupling pattern.[1] *Fraenkel* et al.[2a] and *Seebach* et al.,[2b] in particular, obtained a wealth of information about the structure of monolithiated compounds from low-temperature ^{13}C-NMR spectra. We report here on the aggregation behavior of the mono- and dilithiated bicyclobutane derivatives **1b**—**4b** and **5c**, respectively, in tetrahydrofuran (THF).[3] **5c**, like the still controversial 1,2-dilithioethane,[4] is a saturated, vicinally dilithiated hydrocarbon.

The bicyclobutanes **1a**—**4a** were lithiated at C-1 with one molar equivalent of *n*Bu^{6}Li[2b] in ether at 20°C. After removal of the solvent,[5] a ca. 3 M solution of the "anion" in THF/[D$_6$]benzene was prepared with the oily or powdery residue. The appearance of a coupling fine structure was observed in the low-temperature ^{13}C-NMR spectrum beginning at $-45°C$; baseline-separated multiplets were observed throughout the spectrum at $-60°C$. In all cases a quintet with the intensity distribution 1 : 2 : 3 : 2 : 1 and a ^{13}C-^6Li coupling constant of ca. 10 Hz was obtained for the signal of the ^6Li-bearing C-atom (**1b**: 10.1; **2b**: 10.3;[6] **3b**: 9.4, **4b**: 9.6; error: ±0.6 Hz). As shown in Figure 1a by the C-1 signal of **4b** obtained by accumulation of only 300 pulses a good signal-to-noise ratio can be achieved with natural carbon isotope distribution.

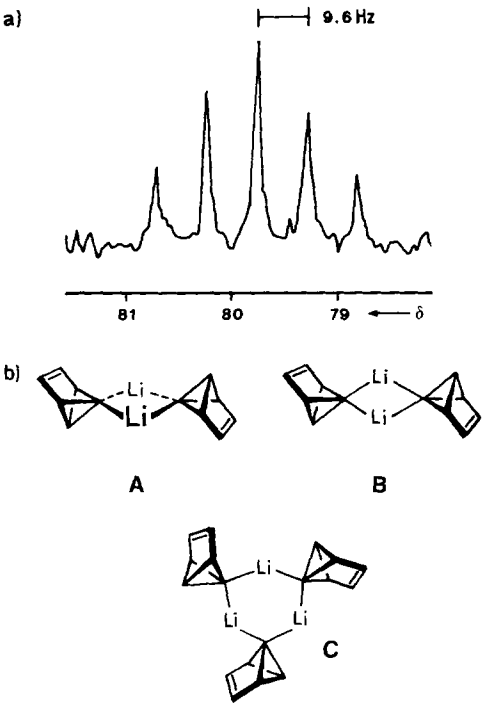

Fig. 1. a) The C-1 signal of [^{6}Li]1-lithiobenzvalene **4b** in the ^{13}C-NMR spectrum at $-76°C$ after 300 pulses; ca. 3 M in THF. b) Some of the aggregations consistent with the coupling pattern. Structure **B** is favored.

7b is present as dimer, both in the solid state[7] and in solution.[2b] On the basis of the NMR data it is also reasonable to assume dimeric structures like A or B in Figure 1b for **1b**—**4b**. But trimers of type C (Fig. 1b) or oligomers with large rings cannot be ruled out. It is remarkable that all bridgehead lithiated bicyclobutane models examined so far prefer the same degree of aggregation.

We next attempted to lithiate bicyclobutanes at both bridgehead positions[8] and to obtain information about the state of aggregation of the products. The elimination of lithium hydride from 1,ω-dilithioalkanes ($\omega = 1 - n$),[9] an unsolved problem in the synthesis of 1,2-dilithioethane,[10] should not occur in the case of the doubly metalated bicyclobutane since highly strained olefins of type **8** would be formed by loss of LiH. Indeed, the hydrocarbons **1a**—**6a** could be metalated at both bridgeheads to give the "dianions" **1c**—**6c**, in each case with 2.0 molar equivalents of *n*BuLi in ether at 20°C.[11] The work-up of the suspensions thus formed with deuterium oxide and chloro(trimethyl)silane, respectively, led to **1d**—**6d** or to **1e**—**6e**. The data listed in Table 1 show that high degrees of lithiation were obtained in a short time with those bicyclobutanes which carry sp^2-hybridized carbon atoms in the *endo-,endo*-annelated bridges and/or have small angles between the three-membered ring faces of the bicyclobutane moiety.

The ^1H- and particularly the ^{13}C-NMR spectra of the "dianions"[13] show unusually broad, unstructured bands.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Table 1. Degree of double deuteration [12] and silylation of the bicyclobutanes **1a**–**6a** as a measure of the lithiability of the two bridgeheads with 2.0 mole equivalents of *n*BuLi in ether at 20°C.

Educt	Degree of dideuteration [%] [a]	Degree of silylation [%] [b]	*t*
1a	15	15	3 d
2a	95	30	3 d
3a	100	55	1 d
4a	– [c]	21 [d]	2 h
5a	100	70	1 h
6a	95	53	3 d

[a] ^{1}H-NMR spectroscopically. [b] Determined on the isolated product. [c] The proportion of **4d** could not be determined because of signal overlapping. [d] In competition with the second metalation, **4b** rearranges to phenyllithium.

Only in the case of **5c** was it possible to assign all the signals.[14] The cause of the drastic line-broadening is, in our opinion, the intermolecular cross-linking. Greater contributions to the widths at half height ($W_{1/2}$) by dynamic effects or by spin-spin coupling are unlikely. Thus, the $W_{1/2}$ values[14] change neither with variation of temperature (−50°C to +70°C) or concentration (0.4 to 2.2 M) nor with the use of the ^{6}Li isotope. A deaggregation of the cross-linked structures by addition of up to ten molar equivalents of various donors to solutions of **5c** in THF or ether was not accomplished.[15] **5c** can be stored for several days at room temperature in solution without change.

Chain-Lengthening Difunctionalization of Grignard Compounds by Reaction with Ketenylidenetriphenylphosphorane

By *Hans Jürgen Bestmann,* Martin Schmidt,* and *Rainer Schobert*

The readily accessible ketenylidenetriphenylphosphorane **1**[1] reacts with Grignard reagents **2** to give addition compounds of still unknown structure. Such adducts, which are best formulated as in **3**, are hydrolyzed by water to acyl ylides **4**. This reaction sequence thus enables a chain-lengthening of **2** by two C atoms with concomitant introduction of a carbonyl function and an ylide function with CC coupling. Together with the secondary reactions (carbonyl olefination and saponification) a possibility is thus opened up for the acylation of Grignard compounds, i.e. for the conversion of Grignard compounds into various kinds of ketones.[2] Table 1 shows that this new methodology can be exploited for the synthesis of a wide spectrum of ylides **4**.[3]

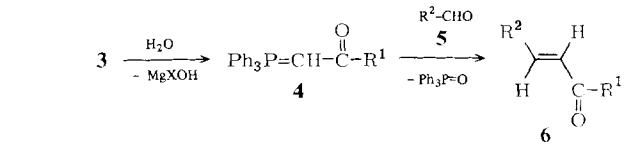

Table 1. Yields and melting points of the acyl ylides **4** obtained by reaction of **1** with **2** and subsequent hydrolysis.

4	R^1	Yield [%]	M.p. [°C]

tween 1510 and 1530 cm^{-1} in their IR spectra.[6,7] For further characterization, a Wittig reaction was carried out with aldehydes **5** to give (*E*)-α,β-unsaturated ketones **6**.[6] Table 2 lists some examples.[7]

7d: m = 1, n = 10; **7e**: m = 3, n = 9

Reaction of compounds **6d** and **6e** with acetyl chloride in glacial acetic acid[9] furnished the corresponding acetates **7** in ca. 80% yield. They are carbonyl homologues of lepidoptera pheromones,[10] which are of special interest for structure-activity investigations (**7d**, **7e**: b.p. (Kugelrohr) 105–108°C/0.01 torr and 120–123°C/0.01 torr, respectively).

Hydrolysis[5] of **4f** afforded the acetal **8** (62% yield, b.p. (Kugelrohr) 120–123°C/13 torr), which after treatment with acid to give the free 7-oxooctanal **9**[11] was allowed to react with the ylide **10**. Subsequent saponification led to formation of the queen substance **11** (57% yield based on **8**, m.p. 52°C), which is thus relatively easily accessible.[12]

11

Experimental

General procedure: **4**: A Grignard solution was prepared from magnesium turnings (0.97 g, 40 mmol) and 40 mmol alkyl halide (preferably bromide) in anhydrous tetrahydrofuran (THF) (final volume 150 mL). The boiling solution was treated dropwise over a period of 8–10 h with a solution of **1** (9.06 g, 30 mmol) in THF (150 mL) under N_2; the final mixture was then boiled under reflux for a further 2 h (in the case of **4g**: reaction temperature 40°C, addition over a period of 4 h, then stirring for 2 h at 40°C).—After cooling, the reaction mixture was poured into 60 mL of saturated ammonium chloride solution, the aqueous phase separated off, and the solvent removed from the organic phase. The residue was partitioned between 150 mL each of dichloromethane and water; the aqueous phase was extracted with dichloromethane, and the combined organic extracts were washed with a little water. After drying over magnesium sulfate, the solvent was removed by distillation and the residue was either recrystallized from ethyl acetate by addition of ether or chromatographed on silica gel 60 [column height 20 cm, diameter 4 cm; hydrocarbon impurities were first eluted with hexane/ether (3 : 1) and then **4** was eluted with ether/dichloromethane (1 : 1)].

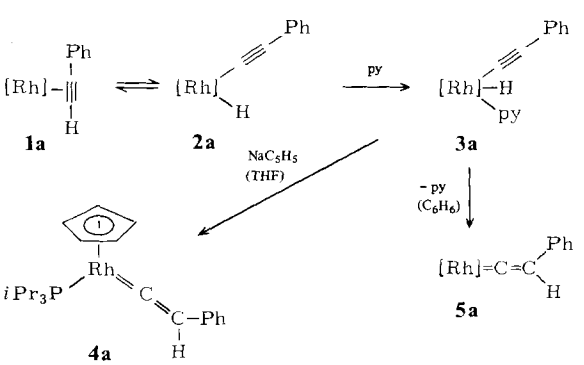
Synthesis and Structure of *trans*-[MCl(=C=CHR)(P*i*Pr$_3$)$_2$] (M = Rh, Ir): The First Square-Planar Vinylidenemetal Complexes**



By *Francisco Javier García Alonso, Arthur Höhn, Justin Wolf, Heiko Otto,* and *Helmut Werner**

Dedicated to Professor F. G. A. Stone on the occasion of his 60th birthday

Vinylidenes :C=CRR′, like carbenes :CRR′ or other highly reactive organic molecules, can be stabilized in the coordination sphere of a transition metal. However, mononuclear square-planar vinylidenemetal complexes are, as yet, unknown. Although it has been repeatedly postulated that they are formed as intermediates in reactions of d^8 compounds, e.g., of rhodium(I) with alkynes,[1] their existence has not been proved.

Recently, we have shown that an equilibrium between the alkyne complex **1a** and the alkynyl(hydrido) compound **2a** exists in solution, and that on addition of pyridine this equilibrium is completely shifted to the right.[2] Complex **3a**, which gives **4a** on reaction with NaC_5H_5 in tetrahydrofuran (THF),[2] is rather labile in solution and reacts in benzene at room temperature by elimination of pyridine to produce **5a**. This compound is also obtained almost quantitatively directly from **1a**, presumably via **2a** as intermediate.[3a] Similarly, the synthesis of **5b** and **5c**[3b] has been achieved by the use of **1b** and **1c** as starting materials.[4]

Reaction of **1b** with pyridine gives the octahedral compound **3b**, the properties of which[5] closely correspond to those of **3a**. When R = H or Me, no five-coordinate intermediate of type **2** can be detected by NMR spectroscopy.

[Rh] = RhCl(P*i*Pr$_3$)$_2$

trans-[RhCl(RC≡CH)(PR′$_3$)$_2$] ⟶ *trans*-[RhCl(=C=CHR)(PR′$_3$)$_2$]

1a–c **5a–c**

a: R = Ph; **b**: R = Me; **c**: R = H; R′ = *i*Pr

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG.

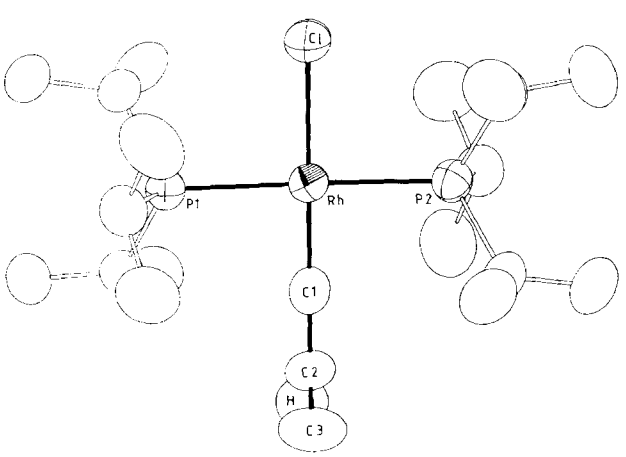
Apparently, in this case, the equilibrium between the alkyne and the alkynyl(hydrido) complex, which has been confirmed for **1a** ⇌ **2a**,[2] is strongly shifted to the side of the alkyne complex **1b**, **c**.

The composition of compounds **5a**–**c**, which are dark red solids (stable in air for a short period), has been confirmed by elemental analysis and mass spectra and by IR and NMR data.[3] The position of the ^{13}C-NMR signal of C_α of the vinylidene ligand seems to be most characteristic; it is observed in the same region (δ ca. 300 ppm) as the ^{13}C-NMR signal of a metal-bound carbene C atom.[6]

Figure 1 shows the result of the X-ray structure analysis of **5b**.[7] The metal is coordinated in a square-planar arrangement with the phosphanes in *trans* positions. The Rh–C1–C2 linkage is almost linear; together with C3 it forms a plane that is perpendicular (angle 88.39°) to the best plane containing the atoms Rh, P1, P2, Cl, C1, and C2. This structural feature is in agreement with the formation of a $d_\pi p_\pi$ bond between Rh and C1 and points to the formal analogy between allenes and vinylidenemetal complexes (i.e., "metallaallenes").[8] The Rh–C1 distance is similar to that in **4a**[2] and comparable with the Rh–C bond length in square-planar carbonylrhodium(I) compounds (e.g., $[Rh(CO)_2Cl]_2$: Rh–C = 181 pm (average value)[9]). The proposal that vinylidenes are excellent π-acceptor ligands[1] is thus amply confirmed.

We have also been successful in preparing the iridium complexes **8a**–**c** in 80–90% yield.[10] The alkynemetal compounds **6a**–**c**[11] react much more slowly than the rhodium compounds **1a**–**c**, and for **6a**, **b** the reaction is complete only after 36 h at 100°C (in toluene). In the reaction of **6a**, it has been possible to isolate a five-coordinate intermediate **7a**,[12] which is strikingly different from isomers **6a** and **8a**, particularly in its spectroscopic properties. *Thus, it has been proved for the first time that the conversion $M(\eta^2\text{-}RC_2H) \rightarrow M(=C=CHR)$ proceeds in two steps via the intermediate $MH(C_2R)$, which is formed by intramolecular oxidative addition of the alkyne to the metal.* The rearrangement of the cluster $RuCo_2(CO)_9(\mu_3\text{-}\eta^2\text{-}HCC\mathit{t}Bu)$ to give the isomer $RuCo_2(CO)_9(\mu_3\text{-}\eta^2\text{-}CCH\mathit{t}Bu)$ probably follows a similar route.[13]

8a–**c** are to the best of our knowledge the first vinylidene*iridium* complexes. Some properties of the violet (**8a**) or red (**8b**, **c**) crystalline solids deserve particular mention.



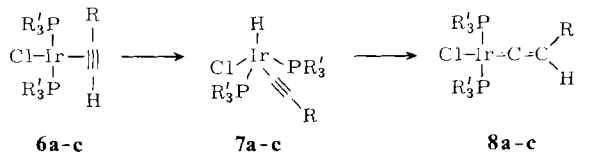


Fig. 1. Crystal structure of **5b** [7]. Selected bond lengths [pm] and angles [°]: Rh–P1 234.4(2), Rh–P2 234.2(2), Rh–Cl 236.6(2), Rh–C1 177.5(6), C1–C2 132(1), C2–C3 150(1), C2–H 107; P1–Rh–P2 173.9(1), Cl–Rh–C1 175.8(2), P1–Rh–Cl 91.9(1), P1–Rh–C1 88.2(2), P2–Rh–Cl 91.2(1), P2–Rh–C1 89.1(2), Rh–C1–C2 177.9(6), C1–C2–C3 126.2(7), C1–C2–H 124, C3–C2–H 110.

6a-c **7a-c** **8a-c**

a: R = Ph; **b**: R = Me; **c**: R = H; R' = *i*Pr

These are first the thermal stability and the inertness towards air, and secondly the unusual high-field shift of the signal of the C*H*R and CH_2 vinylidene protons in the ^{1}H-NMR spectra.[10]

Sequencing of Short Peptides Using FAB Mass Spectrometry—Increased Information via Derivatization

By *Dieter Renner* and *Gerhard Spiteller**

In 1981, *Barber* et al.[1] found that polar compounds such as peptides, which, due to their nonvolatility, cannot be studied using electron-impact mass spectrometry, are ionized upon fast atom bombardment (FAB). The resulting FAB mass spectra essentially show the masses of positive and negative ions formed by protonation and deprotonation, respectively, of the molecule. Since fragments are also observed in the spectra, there have been numerous attempts to correlate these with the structure. Such correlations can be carried out for model peptides with known structures, in part because only those fragments need to be sought which have a relationship to the structure and because other ions present can be conveniently ignored. Therefore, in the absence of additional information, a structure elucidation via interpretation of the FAB spectrum of an underivatized peptide was only possible in special cases.[2–4]

In the course of our efforts to use FAB mass spectrometry for the structure elucidation of short peptides, we had to separate, using HPLC, mixtures of peptides that contained no chromophoric groups. In order to improve detection of the peptides, we derivatized them with dansyl chloride (DnsCl).[5]

In contrast to the FAB spectra[6] of the underivatized peptides, in which the charge of the fragments is localized on the C-terminal as well as the N-terminal end of the molecule (Fig. 1), the spectra of the dansyl derivatives exhibit intense and structure-specific cleavage patterns, all of which relate to the derivatized end of the molecule and resulted from cleavage of the peptide bond (Fig. 2). The fragmentation pattern is recognizable from the formulas.

Apparently, the introduction of an electron-rich, stable aromatic system results in both a preferential ionization and an increased tendency to form fragments. Thus, the derivatization of peptides is advantageous not only for the detection in purification steps, but also for the subsequent mass spectrometric analysis. For underivatized peptides,

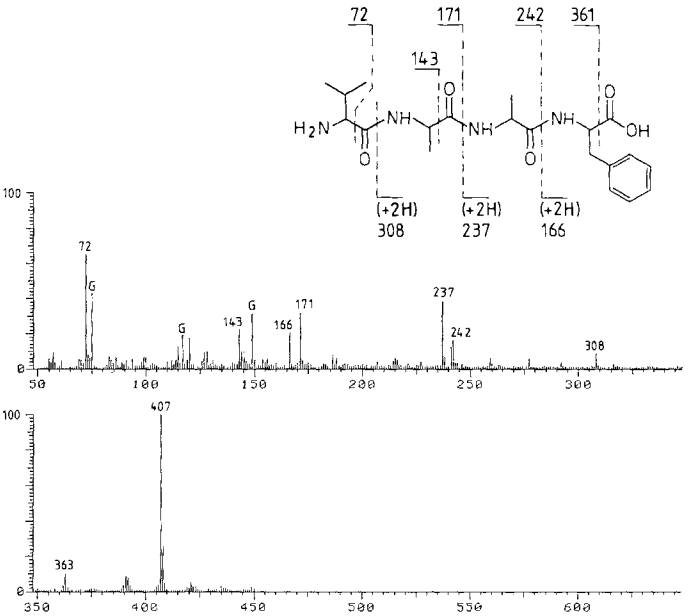

Fig. 1. FAB mass spectrum of positive ions of Val-Ala-Ala-Phe; m/z 407 = $[MH]^+$: the signals labeled "G" are due to the matrix material (glycerin).

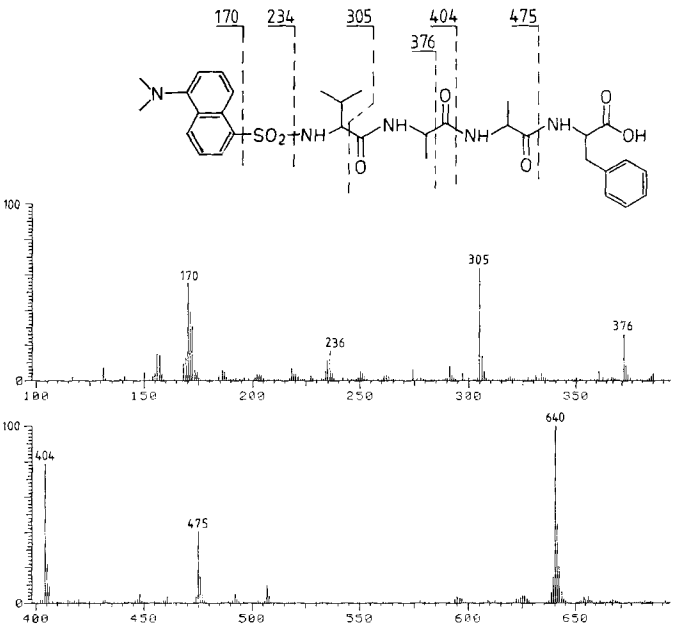

Fig. 2. FAB spectrum of positive ions of Dns-Val-Ala-Ala-Phe; m/z 640 = $[MH]^+$.

structure-specific cleavage products are hardly recognizable, and, therefore, sequence determination is difficult. For derivatized peptides, on the other hand, the amino acid sequence can be unequivocally determined.

We also reacted peptides with a bromine-containing aromatic sulfonyl chloride since the two isotopes ^{79}Br and ^{81}Br allow unequivocal labeling of the fragments. Labeling with 2-bromo-5-(dimethylamino)benzenesulfonyl chloride (Bdbs-Cl)[5] is favorable for peptides containing up to ten amino acids. For longer peptides, the isotope pattern of bromine exhibits strong overlapping due to the high content of ^{13}C. In these cases, dansyl derivatives are preferred. As already found by *Sethi* et al.,[7] the bromine-containing compounds are partly debrominated during the recording of the spectra; the bromine atom is replaced by a hydrogen

[*] Prof. Dr. G. Spiteller, Dipl.-Chem. D. Renner
Lehrstuhl für Organische Chemie I der Universität
Postfach 3008, D-8580 Bayreuth (FRG)

atom. Another series of fragments is thereby formed, whose masses are 78 and 80 amu smaller than those of bromine-containing peptide fragments (Fig. 3).

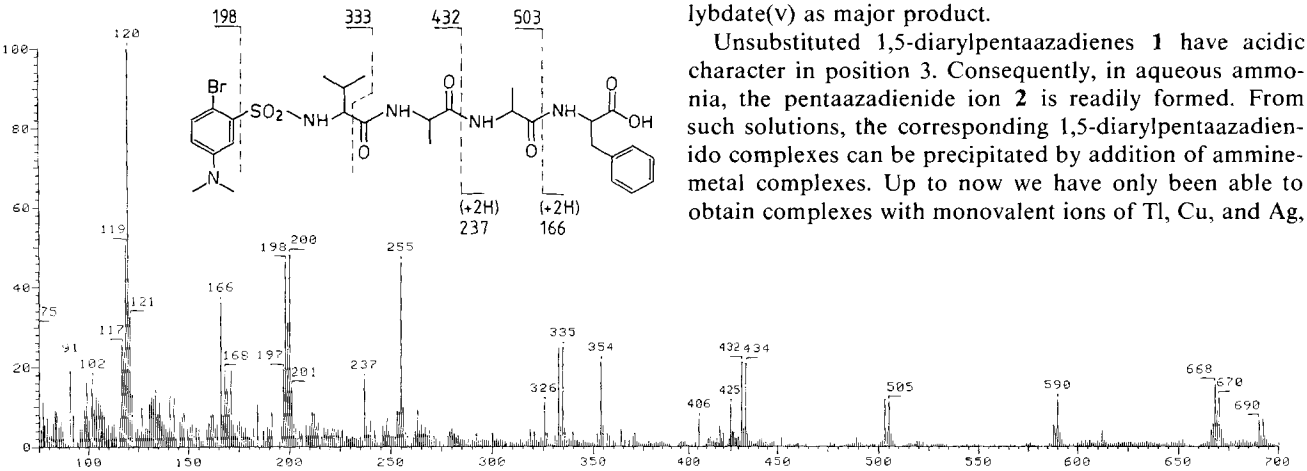

Fig. 3. FAB spectrum of positive ions of Bdbs-Val-Ala-Ala-Phe; m/z 668 = $[M\mathrm{H}]^+$, m/z 690 = $[M\mathrm{Na}]^+$. Bromine-free fragments: m/z 120, 255, 354, 425, 590.

The interpretation is more difficult for peptides whose amino acids contain side-chain functional groups. In each case studied, however, we obtained more informative spectra from the derivatized than from the free peptides.

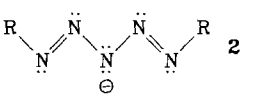
Complexes of 1,5-Di(*p*-tolyl)-1,4-pentaazadien-3-ide, Crystal Structures of [Cu(tolylNNNNNtolyl)]$_3$ and [Ni(tolylNNNNNtolyl)$_2$]$_2$**



By *Johannes Beck* and *Joachim Strähle**

Suitably substituted 1,4-pentaazadienes are stable at room temperature.[1,2] We have studied the reactions of 1,5-diaryl-3-methylpentaazadienes with compounds of molybdenum in various oxidation states. Cleavage of the N_5 chain always takes place in such reactions. In the reaction with $MoCl_5$ we obtained arenediazonium hexachloromolybdate(v) as major product.

Unsubstituted 1,5-diarylpentaazadienes **1** have acidic character in position 3. Consequently, in aqueous ammonia, the pentaazadienide ion **2** is readily formed. From such solutions, the corresponding 1,5-diarylpentaazadienido complexes can be precipitated by addition of amminemetal complexes. Up to now we have only been able to obtain complexes with monovalent ions of Tl, Cu, and Ag, divalent ions of Mn, Ni, Zn, Cd, Pd, and Cu, and trivalent cobalt. The structures of **3**, **4**, and **5** have been determined.[3]

The dimeric bis(1,5-ditolyl-1,4-pentaazadien-3-ido)nickel(II), **3**, is formed in the form of a brown, crystalline powder from ammoniacal solution.[4] It is paramagnetic; at room temperature, $\mu = 3.1$ B.M., corresponding to two unpaired electrons per metal ion. The complex decomposes at 120°C. From a tetrahydrofuran (THF)/*n*-hexane mixture, monoclinic single crystals of the composition **3** · THF crystallize out. Crystallization of a triclinic and a tetragonal modification was also observed. The structure analysis[5] (Fig. 1) shows that in **3** four N_5 zig-zag chains, whose longitudinal axes run parallel, each coordinate two Ni^{2+}

[Ni(*p*-tolyl-NNNNN-*p*-tolyl)$_2$]$_2$ **3**

[Cu(*p*-tolyl-NNNNN-*p*-tolyl)]$_3$ **4**

[Tl(*p*-tolyl-NNNNN-*p*-tolyl)]$_2$ **5**

Cu(*p*-tolyl-NNNNN-*p*-tolyl)$_2$ **6**

ions in a distorted octahedral fashion. The atoms N1, N3 and N_5 of each N_5-chain participate in the coordination. The base of the octahedron is formed by two chelate-like-bonded N_3-fragments. The mean N–Ni–N angle of 59.3° in the chelate ring is relatively small, while the neighboring angles of 117–125° in the base of the octahedron are greater than the ideal value. The Ni–N distances within the base are 213 pm. The distances to the apices of the octahedron are somewhat shorter (207 pm). The Ni–N distances indicate single bonding, as is also found in amminenickel complexes[6,7] and in dimeric bis(1,3-diphenyltriazenenickel(II)).[8]

Reaction of an ammoniacal solution of 1,5-ditolylpentaazadiene with tetraamminecopper(II) ions initially leads to formation of a brown precipitate of **6**. This Cu(II) compound is readily soluble in almost all organic solvents. Independently of the solvent employed, evolution of nitrogen and reduction to **4** takes place on heating. The color of the solution turns deep-red. From THF/*n*-hexane,

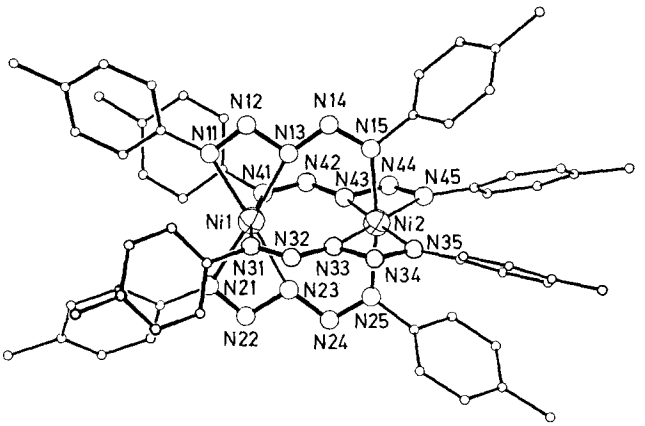

Fig. 1. Structure of **3** in the crystal. Important bond lengths [pm] and angles [°]: Ni–N 205.2(3) to 214.0(3), N1–N2 127.2(4) to 128.2(4), N2–N3 133.8(4) to 135.8(4), N3–N4 134.2(4) to 138.7(4), N4–N5 126.9(4) to 129.3(4), Ni1–Ni2 331.0(1); N–N–N 104.4(3) to 113.5(3). The first of the two figures alongside the N atoms refers to the chain, the second, the only figure given in the text, refers to the number of the N atom in the chain.

monoclinic $4 \cdot THF \cdot 0.5\,C_6H_{14}$[9] crystallizes in the form of red pseudohexagonal platelets. The complex is air-stable, and, unlike **3**·THF, it decomposes explosively on heating to 160°C. Associated with its weak paramagnetism, the magnetic moment increases between 113 and 303 K from $\mu = 0.33$ to 0.52 B.M. per Cu^+ ion.

In **4**[10] (Fig. 2), three N_5 zig-zag chains coordinate three linearly arranged Cu^+ ions with N1, N3, and N5, such that each metal atom is in a trigonal-planar environment. The Cu–N distances to the outer N1 and N5 atoms, with a mean value of 203.6 pm, are somewhat longer than the distances to the more strongly basic atoms N3 (mean distance Cu2–N3: 194.5 pm). They largely correspond to the sums of the covalent radii (202 pm[11]), and to the Cu–N distances in tetrameric (1,3-dimethyltriazene)copper(I)[12] and dimeric (1,3-diphenyltriazene)copper(I).[13] The Cu–Cu distances of 234.8 and 235.8 pm in the linear Cu_3^{3+} chain of **4** are the shortest values found so far in Cu^I complexes. Comparable Cu–Cu distances of about 242 to 246 pm are found, for example, in alkyl-[14] and arylcopper(I) compounds[15] or in the iodocuprate $Cu_3I_4^-$.[16] It is still not fully clear whether such short Cu–Cu distances can be explained in terms of bonding interactions. In the case of the Cu_3^{3+} unit, a dsp^3 hybridization of the Cu atoms is conceivable, such that two Cu–Cu bonds can be formed, with each of the outer Cu atoms still having an unpaired electron. The observed magnetic properties are consistent with this model if an antiferromagnetic coupling is assumed. The terminal atoms Cu1 and Cu3 are each bent out from the planes of the three coordinating N atoms by about 18 pm, thus indicating repulsion between the Cu atoms.

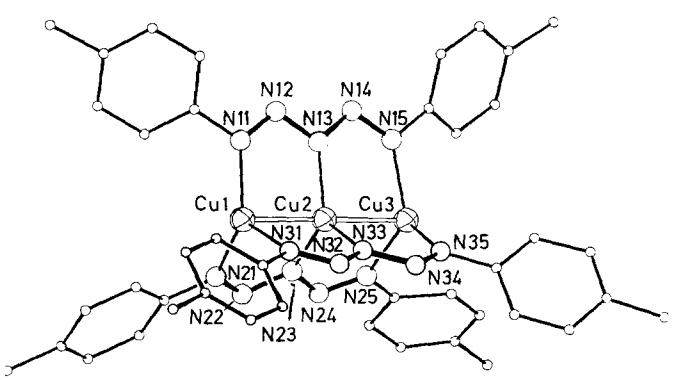

Fig. 2. Structure of **4** in the crystal. Important bond lengths [pm] and angles [°]: Cu1–N1 200.6(5) to 205.2(6), Cu2–N3 194.1(5) to 195.2(6), Cu3–N5 202.7(5) to 205.0(5), Cu1–Cu2 234.8(2), Cu2–Cu3 235.8(2), N1–N2 126.7(6) to 127.2(7), N2–N3 132.4(7) to 135.4(7), N3–N4 132.0(6) to 134.2(7), N4–N5 127.1(6) to 129.6(6), Cu1–Cu2–Cu3 180.00(1), N1–Cu1–N1 114.0(2) to 123.1(2), N3–Cu2–N3 116.6(2) to 121.7(2), N5–Cu3–N5 114.7(2) to 122.4(2), N–N–N 109.7(6) to 113.9(6). The first of the two figures alongside the N atoms refers to the respective chain, the second, the only figure given in the text, refers to the number of the N atom in the chain.

In the dimeric Tl^I complex **5**,[3] two Tl^+ ions are coordinated trigonal-pyramidally by two N_5-chains, resulting, as in **3**, in an alternating chelate-like and monodentate bonding of the metal ions.

The interatomic distances in the planar N_5 chains of all the complexes so far investigated are consistent with partial delocalization of the π-electrons. The shorter N1–N2 and N4–N5 distances of about 128 pm are slightly longer than a NN double bond, while the longer N2–N3 and N3–N4 bonds are markedly shorter than the value normally found for a NN covalent single bond.[11]

[9] Procedure: To a saturated solution of 1,5-di-*p*-tolyl-1,4-pentaazadiene in concentrated aqueous ammonia was added an excess of $[Cu(NH_3)_4]^{2+}$ (likewise in concentrated ammonia). A brown, crystalline precipitate of **6** separated out immediately. Addition of $[Cu(NH_3)_4]^{2+}$ was continued until the supernatant liquor was intense green and no further precipitate separated. The precipitate was filtered off and washed with water to remove the excess ammonia. The precipitate was then dried over P_2O_5 in vacuo. Reduction to **4** was accomplished by heating in THF: the brown Cu(II)-compound was dissolved in a little THF under N_2 and the resulting solution heated to boiling. Vigorous evolution of gas was observed and the color of the solution changed from brown to intense red. Treatment of the solution with *n*-hexane led to precipitation of deep-red crystals of $4 \cdot THF \cdot 0.5\,C_6H_{14}$.
[10] **4**: $P2_1/c$, $a = 1477.3(1)$, $b = 1478.7(4)$, $c = 2284.5(2)$ pm, $\beta = 91.06(1)°$, $R = 0.064$ for 2569 independent reflections with $I > 3\sigma(I)$ (Enraf-Nonius CAD4, $Cu_{K\alpha}$). (*Z*)-3,7-Bis(phenylsulfonyl)pentacyclo-[5.1.0.0^{2,4}.0^{3,5}.0^{6,8}]octane, an Octabisvalene Derivative**

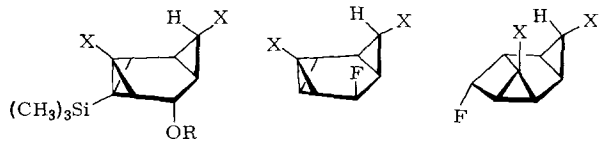
By *Christoph Rücker** and *Horst Prinzbach*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

"Octabisvalene" **A** (X = H),[1] which is still unknown, is the third saturated and highly strained (E_{st} = 130–140 kcal/mol) valence isomer of cyclooctatetraene (the others being cubane and cuneane).[2] Starting from *cis*-benzenetrioxide **1**, we have now achieved the synthesis of the first octabisvalene derivative **7** (X = $SO_2C_6H_5$).[3]



Scheme 1.

The route shown in Scheme 1 is based on the finding (cf. the preparation of the carbocyclic *cis*-tris-σ-homobenzene skeleton **B** from **1**)[4] that the bicyclic, crystalline triol **2a** can be obtained in nearly quantitative yield by reaction of **1** with five equivalents of phenylsulfonylmethyllithium[5] [tetrahydrofuran (THF), −20→20°C, 2 d, m.p. = 232°C, $J_{2,3}$ = 2.6, $J_{3,4}$ = 12, $J_{4,5}$ = 10.5 Hz]. The phenylsulfonyl groups were expected, inter alia, to favor the α-deprotonation in **3b**, **4**, and **5** (as observed in the formation of **2a**) over competing metalations. **2a** was transformed into the acetal **2b** (100%), which was then esterified to **2c** (87%). **2c** was cyclized to **3b** with two equivalents of lithium diisopropylamide (LDA) (THF, −20°C, 30 min, 90%, m.p. = 231°C, $J_{4,5} \cong 0$ Hz). The diol **3a** (100%), the bissulfonate **3c** (>90%), and (via three steps)[6] the epoxide **4** (53%, m.p. = 245°C, $J_{1,2} \cong 0$, $J_{1,9}$ = 4 Hz) can be obtained from **3b** by standard procedures.

In the *endo*-6-carbanion of **4**, the stereoelectronic situation for cyclization to **5a** (substitution at C-4) was considered, a priori, favorable:[7] indeed, this step is highly selective using four equivalents of *n*-butyllithium (THF, −78°C, 30 min, 89%, <5% addition of *n*-BuLi, m.p. = 191°C, $J_{2,4}$ = 3.5, $J_{4,5}$ = 3.5, $J_{2,5}$ = 3.8, $J_{5,6}$ = 3.5, $^1J_{C\text{-}4,H}$ = 210 Hz). Thus, there is no evidence for four-membered-ring formation (substitution at C-2 of **4**), inversion of the anion, or σ→π isomerization (which is plausible in the case of the *exo* anion).[8] Not unexpectedly, the high acidity of 4-H[9] in **5a**, **b** and of 4-H and 8-H in **7** (and also of the *o*-phenyl protons) causes complications in the ring closure to **7**. H/D-Exchange experiments with **5b** show that the deprotonation to **8b** is faster than to **9b**. The carbanion **8b** can be trapped as silyl derivative **11b** by metalation in the presence of $(CH_3)_3SiCl$[10] (2 equivalents of lithium tetramethylpiperidide, THF, −78°C, 2 h); **11b** (40% along with **5b**) is of interest as a C-4 protected precursor of **7**. **6a** ($J_{2,5}$ = 4 Hz, *endo* configuration of the silyl group confirmed by NOE) is formed from **5a** and two equivalents of *n*-BuLi after addition of $(CH_3)_3SiOSO_2CF_3$; **11a** ($J_{2,5}$ = 3.7 Hz) is formed along with several R(X)-*ortho*-silylated products from **5a** and two equivalents *n*-BuLi after addition of $(CH_3)_3SiCl$. **6a** and **11a** are isolated by chromatography (20% and 42%, respectively). Upon treatment of **5b** with sufficiently strong bases (1–2 equivalents of *n*-BuLi, LDA) under various conditions, decomposition occurs almost instantaneously. Presumably, the dicarbanion **10b** is highly labile. The monocarbanion **9b** was therefore generated by treatment of **6b** with "dry" (ca. 0.2 equivalents of H_2O) tetrabutylammonium fluoride:[11] the octabisvalene derivative **7** is formed in 20% yield [separated chromatographically (HPLC on silica gel, 33% ethyl acetate in hexane), colorless crystals, m.p. = 198°C, MS (CI, NH_3): *m/z* 402 ($M^{\oplus} + NH_4^{\oplus}$)] along with **5b** (35%) and the fluorides **12** (35%) and **13** (10%); the latter are formed from **5b** in a control experiment. Accordingly, improved yields of **7** are to be expected by more rigorous exclusion of proton sources. In the attempts thus far to obtain **7** directly from **3c** (via **5b**) (1–2 equivalents of *n*-BuLi, THF, −78 to −30°C), much polymeric material was formed along with **5b** and a small amount of **7** (β-HOR elimination?).

Photochemically Initiated, Electron-Transfer-Catalyzed Diels-Alder Reactions of Electron-Rich Dienophiles**

By *Jiri Mlcoch* and *Eberhard Steckhan**

Similarly to the endoperoxide formation between 1,3-dienes and triplet oxygen[1] or the preparation of dioxetanes,[2] Diels-Alder (DA) reactions can be catalyzed via an electron-transfer chain mechanism using radical cations of triarylamines.[3] In this way, DA products are available which otherwise are formed only with difficulty or not at all. The scope of application, however, is relatively narrow.[4] We now report DA reactions in which a chain reaction is photochemically initiated by electron transfer (Scheme 1).

$$\text{Sens}^{\oplus} \xrightarrow{h\nu} [\text{Sens}^{\oplus}]^*$$

$$[\text{Sens}^{\oplus}]^* + \text{En} \overset{\text{ET}}{\rightleftharpoons} [\text{Sens}]^{\odot} + [\text{En}]^{\odot\oplus}$$

$$[\text{En}]^{\odot\oplus} + \text{diene} \longrightarrow [\text{DA product}]^{\odot\oplus}$$

$$[\text{DA product}]^{\odot\oplus} + \text{En} \overset{\text{ET}}{\rightleftharpoons} \text{DA product} + [\text{En}]^{\odot\oplus}$$

Scheme 1. Sens = sensitizer; En = dienophile; ET = electron transfer.

2,4,6-triphenylpyrylium tetrafluoroborate, which has already proved useful for the catalysis of cycloreversions,[5] functions as sensitizer. Electron transfer to the sensitizer can be detected by fluorescence quenching.

2,4,6-triphenylpyrylium tetrafluoroborate has the advantage that only concentrations of 0.1 to 1.5 mol-% are needed and that it can be excited with light having wavelengths >345 nm ($\lambda_{max} = 354$, 404 nm).[5] It has the following advantages over 1,4-dicyanobenzene-[6] and 9,10-dicyanoanthracene-[7]sensitized [4+2]-photocycloadditions: appreciably lower concentrations of sensitizer are required; the irradiation time is drastically diminished; simple light sources, such as halogen or xenon lamps, can be used (some reactions even take place in sunlight); and the scope of application shows promise of being broader since the reaction of 1-acetoxy-1,3-cyclohexadiene, which had not yet been feasible,[6] was also performed successfully.

The DA reaction is most effectively sensitized when the olefins are dissolved in dichloromethane and irradiated with a 250-W xenon lamp ($\lambda \geq 345$ nm), and when a 0.01 M solution of the sensitizer in dichloromethane is added in such a way that a weak fluorescence is constantly maintained. If the olefins are added to the irradiated solution of sensitizer, the fluorescence is temporarily quenched. It usually returns, however, after the olefin is consumed. In acetonitrile, the reaction takes place poorly or not at all.

In the case of styrene **6a**, 1-acetoxy-1,3-cyclohexadiene **1c**, and 1-acetoxy-1,4-cyclohexadiene **3**, a stoichiometric oxidation by the excited sensitizer is observed in addition to the electron-transfer-catalyzed reaction. Thus, styrene forms phenylnaphthalene derivatives via oxidative dimerization and the acetoxycyclohexadienes **1c** and **3** are dehydrogenated to phenyl acetate. If only **3** is used, no DA dimers are obtained and phenyl acetate is the only product. The DA product **2d** from the reaction of **1c** with **3** can be explained by rearrangement of **3** to 2-acetoxy-1,3-cyclohexadiene **4** during the reaction. This could take place at the radical cation stage via sigmatropic 1,3-hydrogen shift.

Dienes that do not have a rigid *syn*-arrangement of the double bond system, such as 1-acetoxy-1,3-butadiene and 2,3-dimethyl-1,3-butadiene have not reacted thus far.

The reaction discussed here is of practical interest, since, due to the electron transfer from an electron-rich alkene to the excited sensitizer, the olefin radical cation, being a good electron-poor dienophile, is formed according to the redox "umpolung" principle.[8] The reverse process, the redox umpolung of an electron-rich diene into its electron-poor radical cation, could be a means of initiating DA reactions with inverse electron demand that are otherwise

[a] The structures and compositions of all products were confirmed by MS, 90-MHz and 400-MHz ^{1}H- and ^{13}C-NMR spectra as well as by elemental analysis. The configurations of the products were determined by analysis of their ^{1}H- and ^{13}C-NMR spectra. As expected [10], the olefinic carbon atoms and the vinylic hydrogen atoms of the bicyclo[2.2.2]octene system of the *endo* products exhibit pronounced high-field shifts. The configuration of **7b** could be assigned very well from the ^{13}C-NMR spectrum using a system of increments for substituted bicyclooctenes [11] based on bicyclo[2.2.2]octene. [b] Yield determined by gas chromatography. [c] Yield of products isolated by liquid chromatography. [d] 0.5 mmol $NaHCO_3$ was added. [e] Phenyl acetate was also a product. [f] 25% phenyl acetate as the only identified product. [g] The yields of the crossed DA products refer, in each case, to the component present in smaller amount. [h] Oxidation products of styrene are formed as side products, e.g., 1-phenyl-1,2-dihydronaphthalene, 4-phenyl-1,2,3,4-tetrahydro-1-naphthol, 4-phenyltetralone, as well as larger amounts of polymeric styrenes. [i] The total amount of the sensitizer, 2,4,6-tris(4-bromophenyl)pyrylium tetrafluoroborate, was present from the start. [j] **2c** and **2d** were isolated together and part of the product separated for analytical purposes using HPLC on silica gel Lichrosorb Si 60 (7 μm) with CCl_4/diethyl ether (10 : 1) as eluent.

not possible. In the DA reaction that is photochemically initiated by 2,4,6-triphenylpyrylium tetrafluoroborate, the suprafacial stereospecificity of the usual DA reaction is retained. This is demonstrated by the reaction of **1a** with *trans*-1-phenyl-1-propene **6b**, which leads almost exclusively to the *trans,endo* product **7b**.

The oxidizing power of the sensitizer can be varied by substitution in the *para* position of the phenyl ring. Thus, for example, 2,4,6-tris(4-bromophenyl)pyrylium tetrafluoroborate[9] was successfully used for the sensitization of the DA reaction of the mixture of **1c** and **3** (see Table 1).

General experimental procedure

The olefins, dissolved in 40 mL of dichloromethane, are placed in a glass vessel equipped with a cooling mantel (water cooling ca. 15 °C). The irradiation is carried out with a 250-W xenon lamp (Osram XBO 250 OFR; lamp housing LAX 1450, Müller Elektronik, Moosinning), filtering the light to $\lambda \geq 345$ nm (Oriel Long Pass Filter Model 5146). Under irradiation, a 0.01 M solution of 2,4,6-triphenylpyrylium tetrafluoroborate in dichloromethane is added sufficiently slowly so as to maintain a steady weak fluorescence. After termination of the reaction (consumption of one olefin component as monitored by gas chromatography; duration, see Table), the mixture is treated with a saturated solution of Na_2CO_3 and the dichloromethane distilled off. The aqueous phase is perforated with ether and the product isolated by column chromatography (silica gel, 63–200 μm, column dimensions, 60 × 2.0 and 80 × 2.5 cm; eluent, dichloromethane for **2a**, **2c**, and **2d**, pentane for **7a**, **7b**, and **7c**, and tetrachloromethane/diethyl ether (1 : 1) for **5**. The purification of **5** and of **7c**, as well as the separation of *exo*- and *endo*-**2d**, was carried out by HPLC on Lichrosorb Si 60 (7 μm) (column length 50 cm; diameter 1.6 cm) with the eluents tetrachloromethane/diethyl ether (1 : 1) for **5**, cyclohexane for **7c**, and tetrachloromethane/diethyl ether (10 : 1) for **2d**.

[4] Surprisingly, we found that the reaction only takes place in dichloromethane if triarylamine radical cations and hexachloroantimonate ions are *simultaneously* present. If the triarylamine radical cations are generated electrochemically with perchlorate as counterion, no reaction occurs. If the reaction is carried out with 2,6-dimethylpyridinium hexachloroantimonate as the electrolyte, however, the reaction occurs without difficulty.

$[\{1,3,5\text{-}(CH_3)_3H_3C_6\}_6Tl_4][GaBr_4]_4$ — Synthesis and Structure of a Mixed Mono- and Bis(arene)thallium Complex**

By *Hubert Schmidbaur,* Wolfgang Bublak, Jürgen Riede,* and *Gerhard Müller*

Complexes of neutral arenes with p block metals are still limited to very few elements of the third[1] and fourth main groups.[2] Apart from recently discovered exceptions[1a,b,e] all the reported examples are complexes in which a single arene is bound centrally to the metal. It is apparent that the tendency for this type of compound to be formed is determined by the conformity of the orbital symmetry of the HOMO of the hydrocarbon and of the LUMO of the metal—in compliance with current concepts regarding such interactions.[3] After the first entry to the complexes of divalent metals of the fourth main group (Ge^{II}, Sn^{II}, Pb^{II})[2] and analogous derivatives of monovalent metals of the third main group (Ga^{I}, In^{I})[1] we have now been able to complete this series on two scores concomitantly with the preparation of an unusual thallium(I) compound.

The existence of Tl^{I}-arene complexes had already been postulated some years ago, but final proof thereof was still lacking.[4] The complex salts $Tl[AlCl_4]$, $Tl[AlBr_4]$, $Tl[GaCl_4]$, and $Tl[GaBr_4]$ are readily soluble in hot benzene. On cooling, colorless crystals are formed, the benzene content of which, however, steadily decreases at room temperature in a stream of nitrogen, so that no defined phases can be obtained. In vacuo, the complex salts remain free of benzene. Attempted crystallization with hexamethylbenzene also met without success. With mesitylene (Mes, 1,3,5-trimethylbenzene), however, the situation is much more favorable; thus, e.g., with $Tl[GaBr_4]$ the crystalline phase of the title compound is formed, for which thermogravimetric measurements (20 to 150°C) surprisingly gave a molar ratio of mesitylene : complex salt of 1.5.

An X-ray structure analysis of the mesitylene adduct[5] revealed, as the most important finding, that a skeletal framework of tetrameric $Tl_4[GaBr_4]_4$ with crystallographic centrosymmetry is present. One or two mesitylene molecules are alternately coordinated to the $Tl^{\oplus}$ cations (Fig. 1). Accordingly, the large aggregate contains both mono- as well as bis(arene)metal moieties, which are bridged in a complicated way by $GaBr_4$ tetrahedra.

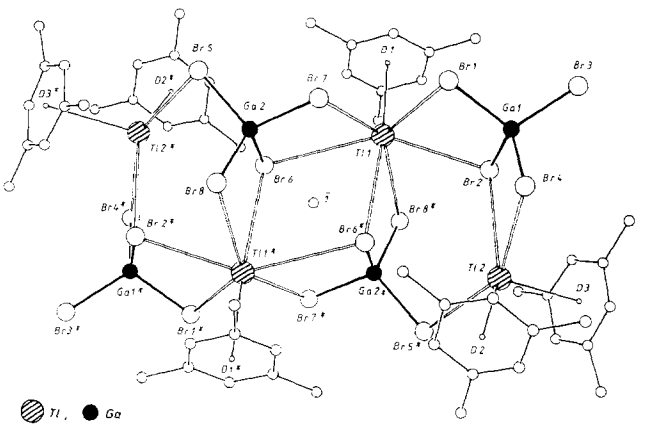

Fig. 1. Perspective diagram of the centrosymmetric tetrameric unit in the crystal (H atoms omitted) [5]. Important bond lengths [Å] and angles [°]: for Tl1: Tl1-D1 2.94, Tl1-Br1 3.520(2), Tl1-Br2 3.349(2), Tl1-Br8* 3.476(2), Tl1-Br6 3.675(2), Tl1-Br7 3.377(2), Tl1-Br6* 3.507(2), D1-Tl1-Br6* 164.8; for Tl2: Tl2-D2 3.01, Tl2-D3 3.03, Tl2-Br2 3.567(2), Tl2-Br4 3.346(2), Tl2-Br5* 3.485(2), Tl2-Br6* 4.025(2), D2-Tl2-D3 119.7.

In the $(Mes)Tl^{\oplus}$ structural unit the metal atom Tl 1 is located almost directly above the center of the ring at a distance of 2.94 Å (η^6-coordination). The coordination sphere of Tl is extended by six bromine atoms in the form of a strongly distorted pentagonal pyramid; three $GaBr_4$ anions are chelating, one apical-equatorial, the other two symmetrical and bis-equatorial. Such an arrangement has recently also been found in $[\{(CH_3)_6C_6\}_4Ga_4][GaCl_4]_4$.[1c]

The $(Mes)_2Tl^{\oplus}$ structural units are characterized by two mesitylene molecules oriented at an angle of 60.5° to each other, whereby the metal atoms Tl2 are once again located almost symmetrically (3.00 and 3.02 Å, respectively) above the ring centers (η^6-coordination). In the immediate neighborhood there are three irregularly arranged Br atoms, while a fourth Br atom (Br6*) is located somewhat further away. Once again two chelate contacts are formed. The coordination geometry thus shows similarities to that of $[(Mes)_2In(InBr_4)]$. In the latter case, however, the plane through the three bromine atoms bisects the angle between the two arene molecules.[1e] No pronounced stereochemical activity of the lone electron pair is recognizable in the coordination spheres of Tl1 and Tl2.

Thus, all heavy elements of the third group in the ns^2 valency state form both mono- as well as bis-π-complexes with neutral arenes. In principle, their geometries are obviously alike, and the differences in the measured atomic distances are regular from complex to complex.[1] Fundamentally, however, they differ from the arene complexes of the $d^{10}s^0$-configurated coinage-metal cations, in which the

metals, in accord with the change in orbital symmetry, are without exception attached to the arene acentrically.[6] Complexes of Tl^I with anionic arenes of the type $(C_5H_5)Tl$ are already well established classical organometallic reagents. Their structures are automatically governed also by an ionic bonding component.[7]

A Novel Type of Cyclotriphosphane Complex: Synthesis and Structure of $[Ni_2(\mu\text{-}P_3iPr_3)_2(CO)_4]$**

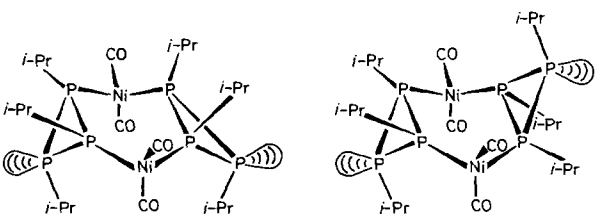
By *Marianne Baudler,* Franz Salzer, Josef Hahn*, and *Eberhard Därr*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Complexes of the series **1**,[1] **2**,[1] and **3**[2] containing triorganocyclotriphosphane ligands $(PR)_3$ have already been described. We have now synthesized the first binuclear complex of the type $[L_nM(\mu\text{-}P_3R_3)_2ML_n]$, in which the P_3 rings are linked as four-electron ligands to the ML_n moieties to give a six-membered P_4M_2 metallacycle.

Reaction of triisopropylcyclotriphosphane **4**[3] with $Ni(CO)_4$ (*n*-pentane, 10°C→room temperature) affords

1 **2** **3**



bis(μ-triisopropylcyclotriphosphane)bis(dicarbonylnickel) **5** in almost quantitative yield. The formation of **5** proceeds via the mononuclear complex $[Ni(P_3iPr_3)(CO)_3]$,

$$2\,(PiPr)_3 + 2\,Ni(CO)_4 \xrightarrow{-4\,CO} [Ni_2(\mu\text{-}P_3iPr_3)_2(CO)_4]$$

4 **5**

which is detectable at the beginning of the reaction by ^{31}P-NMR spectroscopy; on continued reaction, further, as yet not fully characterized, intermediate products appear.

5 is formed as a mixture of the isomers **5a** and **5b**, which differ from each other in the relative arrangement of the phosphorus three-membered rings. **5a** precipitates as a light-beige solid (decomposition at ca. 100°C, isomeric purity >99%), whereas **5b**, which is present in the filtrate (isomeric mixture ca. 1:1), can be enriched to ca. 90% by stepwise crystallization of **5a** at −30°C to −100°C. In solution (tetrahydrofuran (THF), benzene, *n*-pentane), **5a** rearranges into **5b** above 0°C until equilibrium (ca. 1:1) is established.

5a **5b**

The composition of compound **5**, which is only slightly sensitive to air and moisture, is confirmed by elemental analysis and cryoscopic molecular weight determination. In the mass spectrum (20 eV, 50°C), no signal is observed for the molecular ion; characteristic fragments are $M^{\oplus}-2CO$, $M^{\oplus}-3CO$, and $M^{\oplus}-Ni(CO)_4$. The IR spectrum of **5a** (*n*-pentane) shows two CO bands at 2018 (s) and 1971 (m) cm^{-1}.

The constitution of **5a,b** follows from the NMR data.[4] For both isomers, an AA'A''A'''MM' system is observed in the $^{31}P\{^1H\}$-NMR spectrum in the high field region characteristic for coordinated cyclotriphosphanes.[1] For all P atoms of **4**, the coordination chemical shift[5] is positive (downfield shift), but for the P_A nuclei (**5a**: $\Delta=55.5$; **5b**: $\Delta=55.1$) it is significantly greater than for the P_M nuclei (**5a**: $\Delta=11.3$; **5b**: $\Delta=16.2$). Accordingly, the cyclotriphosphane **4** in **5a,b** is bound as a bidentate bridging ligand.[6] The configurations of **5a,b** follow from the $^{13}C\{^1H,^{31}P\}$-NMR spectra: in the case of **5a**, two singlets (intensity ratio 1:1) are observed for the CO ligands, whereas in the case of **5b**, only one signal is observed which does not show any splitting, even at −120°C. In both isomers, the P_4Ni_2 ring should be boat-shaped and in the case of **5b** should achieve the NMR-spectroscopically observed C_{2h} symmetry in solution by rapid pseudorotation.

[**] Contributions to the Chemistry of Phosphorus, Part 153. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 152: M. Baudler, B. Makowka, *Z. Anorg. Allg. Chem.*, in press.

The formation of **5a,b** is clearly energetically favored over that of the corresponding mononuclear complex containing a P_2Ni three-membered ring.

Experimental

5a: Freshly distilled $Ni(CO)_4$ (3.24 g, 19.0 mmol) was added dropwise to a stirred solution of **4** [3] (4.2 g, 18.9 mmol) in *n*-pentane (50 mL) at 10°C under inert gas. As soon as evolution of CO had ceased, the mixture was warmed to room temperature within 30 minutes and stirred for a further 17–20 h until a total of 38.1 mmol CO had been liberated. The light-beige solid was filtered off at 10°C on a cooled frit and washed twice with 10 mL cold methanol. Yield: 3.8 g (59%) of almost colorless, isomerically pure **5a**. A further crop of **5a** could be recovered from the mother liquor.

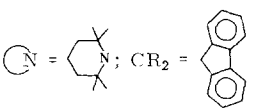
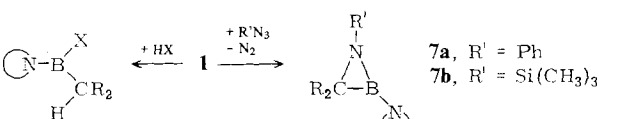
9-Fluorenylidene-2,2,6,6-tetramethylpiperidinoborane: an Allene Isoester with Two-Coordinated Boron and B=C Double Bond**

By *Bernhard Glaser* and *Heinrich Nöth**



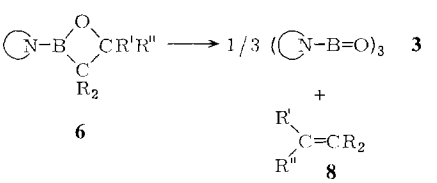
MO studies on the cation $[H_2N{=}B{-}CH_3]^{\oplus}$ suggest that its deprotonation to the amino(methylene)borane $H_2N{=}B{=}CH_2$ containing a BC double bond[1] should be possible.[2] For this allene isoester, a linear NBC skeletal structure is energetically favored over other conformers. The amino(methylene)borane will rapidly oligomerize; hence, bulky substituents are necessary for its kinetic stabilization. Especially suitable for this purpose is, for example, the 2,2,6,6-tetramethylpiperidino (tmp) group, with which stable cations of the type $(R_2N)_2B^{\oplus}$[3] or amino(imino)boranes $R_2N{=}B{\equiv}N{-}R'$[4] can be generated.

We obtained the amino(methylene)borane **1** in 60–70% yield by dehalogenation of 9-fluorenyltetramethylpiperidinoboron halides. **1** crystallizes from toluene or benzene as a 1:1 solvate; from hexane, it is obtained free of solvent.



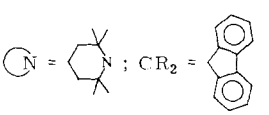
2a, X = F
2b, X = Cl

M = Li, Na; NR_2 = $N[Si(CH_3)_3]_2$, $N[Si(CH_3)_3]C(CH_3)_3$



The following results are in accord with the proposed structure for **1**: a) mass spectrometric and cryoscopic molecular weight; b) $\delta(^{11}B) = 59.2$;[5] c) $\delta(^{14}N) = -220$; this value corresponds to the shielding of the N-nucleus in the linear cations $[R_2N{=}B{=}NR_2]^{\oplus}$ ($\delta(^{14}N) = -240$));[6] d) $^4J(^{19}F^{13}C)$ coupling to the methyl groups of the tmp substituents missing (on generating **1** from **2a**); e) $\delta(^{13}C) = 83.2$ for the C-atom of the R_2C group bound to the boron atom and only observed at -30°C (this shift is found also for similarly substituted C-atoms in allenes[7]); f) no $^1J(^{13}C^1H)$ coupling in the ^{13}C-NMR spectrum of **1** for the signal of the C-atom bound to boron; g) the ^1H-NMR spectrum shows no signal in the range $\delta = 2-7$, thus clearly confirming the absence of a proton on C-9 of the fluorene system); h) two IR bands at 1717 and 1740 cm^{-1} in the intensity ratio 4:1 which we assign to $\nu_{as}(N^{11}BC)$ and $\nu_{as}(N^{10}BC)$.[8]

In addition, the high reactivity of **1** also substantiates its unsaturated character: hydrogen chloride, methanol, and dimethylamine add to **1** at -30°C to give the aminoboranes **2b**,[9] **4**,[10] and **5**,[11] respectively. Reaction of benzophenone with **1** produces the cycloadduct **6a**, a 1-oxa-2-boretane, the structure of which was confirmed by an X-ray structure analysis.[12] It decomposes quantitatively to



2b, X = Cl
4, X = OCH_3
5, X = $N(CH_3)_2$

6/8: **a**, R', R'' = Ph; **b**, R' = Ph, R'' = H

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, BASF AG, and Chemetall GmbH.

the diphenylmethylenefluorene **8a**[13] via a Wittig-like reaction. The cycloadduct **6b** of benzaldehyde[14] and **1** affords the olefin **8b** at 110°C. Finally, it is interesting that azides react with **1** at room temperature with evolution of N_2 to give the azaboriridines **7**.[15]

Experimental

1: A solution of **2a** (10.84 g, 32 mmol) in toluene (100 mL) was treated with lithium *tert*-butyl(trimethylsilyl)amide (5.25 g, 34.7 mmol) at room temperature under nitrogen. After 15 hours' stirring, the insoluble material was removed by centrifugation. On cooling the red solution to −25°C, platelet-shaped crystals precipitated. To increase the yield the solution was then cooled to −78°C and the solid isolated. The crystals, which are very sensitive to hydrolysis, effloresce on drying in a vacuum. Yield: 6.75 g (66%); m.p. 174–176°C; ^{13}C-NMR ($CDCl_3$, 243 K): δ = 16.7, 32.9, 38.0, 56.6 (tmp); 83.2 (B–C), 119.8, 120.9, 121.1, 124.8, 133.0, 144.1 (fluorenyl moiety).

Cyanogen as a Bridging Ligand—Preparation and Crystal Structure of Polymeric $[Ag\{(CN)_2\}_2]_n[AsF_6]_n$ with an Undulating Square Cationic Network

By *Herbert W. Roesky,* Hartmut Hofmann, Jürgen Schimkowiak, Peter G. Jones, Karen Meyer-Bäse,* and *George M. Sheldrick*

Dedicated to Professor Rolf Sammet on the occasion of his 65th birthday

Cyanogen has recently become of wide interest.[1] It can be used in the preparation of a variety of heterocycles, with the cyanogen usually remaining intact as an NCCN synthetic unit. In some reactions, however, cleavage of the C–C bond is observed, e.g., when cyanogen functions as a cyanation reagent in the preparation of tetracyanoethene from ethyne.[2] The reaction of cyanogen with sulfur in dimethylformamide in the presence of copper to give 1,2,4-thiadiazole-3,5-dicarbonitrile[3] is also noteworthy. Common to these and other reactions of cyanogen is the active participation of a metal center. The coordination of cyanogen to a metal and the resulting bonding must therefore be of fundamental importance for the course of the catalytic reaction. We were interested therefore in obtaining single crystals of coordination compounds of cyanogen.

Cyanogen is known to react with metal centers both to form "end-on" complexes and to undergo oxidative addition.[4,5] By the reaction of excess cyanogen with the silver salt **1** in liquid SO_2,[6] we have succeeded, as far as we know for the first time, in isolating and determining the crystal structure of a cyanogen complex.

$$[AgAsF_6]_n + 2n\,(CN)_2 \longrightarrow [Ag\{(CN)_2\}_2]_n[AsF_6]_n$$
1 **2** **3**

3 is colorless and water-sensitive and decomposes at 176°C. **2** remains as a linear unit in the reaction and is present in **3** as a bridging ligand between silver atoms. This construction makes possible a polymeric network in which each silver atom is surrounded by four nitrogen atoms in a square planar arrangement (Fig. 1). Only one other example of this coordination geometry—in $Ag_{1.8}Mn_8O_{16}$—is known for silver(I).[7] Weak contacts to the fluorine atoms (276 pm), which, however, can hardly be viewed as covalent interactions, complete a distorted octahedral coordination of the metal. The above-mentioned synthesis of 1,2,4-thiadiazole-3,5-dicarbonitrile[3] becomes more plausible on account of this study, since the planar coordination of the silver by the cyanogen molecules also facilitates coordination to sulfur. It is unknown

at present how the sulfur is transferred to the cyanogen molecule.

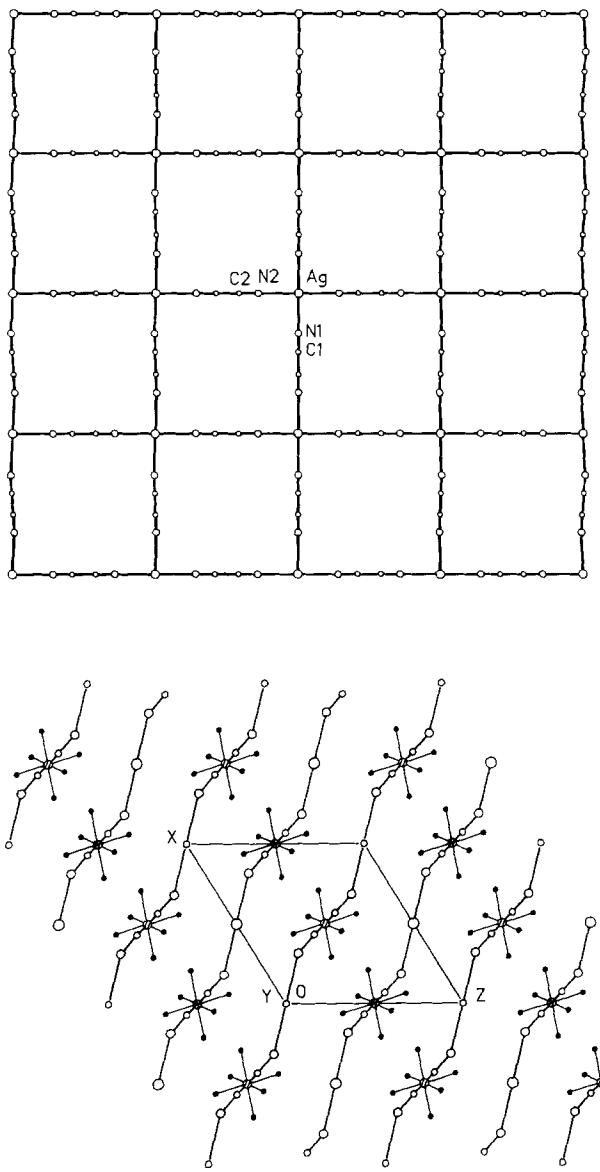

Fig. 1. Above: perspective view of the polymeric layer cation of **3** in the crystal. C2/m, $a = 866.5(4)$, $b = 836.3(3)$, $c = 819.8(4)$ pm, $\beta = 122.06(3)°$, $Z = 2$ (monomers), $T = -40°C$. $Mo_{K\alpha}$, $2\theta_{max} = 55°$. $R = 0.039$, $R_w = 0.043$ for 550 reflections (corrected for absorption) with $F > 4\sigma(F)$. All atoms of the cation lie on special positions; Ag on 0, 0, 0; C1 and N1 on x, 0, z; C2 and N2 on 0, y, 0. The refinement was difficult because of pseudosymmetry (all reflections with odd l are weak) and disorder of the anion. Important bond distances [pm] and bond angles [°]: Ag–N1 239.9(6), Ag–N2 236.4(7), N1–C1 113.8(9), N2–C2 112.8(10), C1–C1′ 138.0(12), C2–C2′ 137.9(14); Ag–N1–C1 152.3(9), N1–C1–C1′ 177.9(14), all other angles 90 or 180°. (C1′ and C2′ are equivalent atoms generated by inversion symmetry). The transformation matrix $0\,-1\,0/-1\,0\,0/-1\,0\,-2$ generates an apparently F-centered orthorhombic cell ($a' = 836.3$, $b' = 866.5$, $c' = 1389.7$ pm), which however, exhibits only monoclinic Laue symmetry. Below: projection of the structure of **3** along the b axis (N2 and C2 lie on this axis and are therefore difficult to recognize). The layers are clearly undulating with an Ag–N1–C1 angle of 152.3°. Only one orientation of the disordered anion is shown. The As atom lies on 0, 0, $\frac{1}{2}$, the F atoms, however, on general positions. Open circles: large, Ag; medium, N; small, C; cross-hatched circles, As; black points, F. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51252, the names of the authors, and the journal citation.

Gas-Phase Reactions of Organic Compounds on Raney Nickel**

By *Hans Bock** and *Hans Peter Wolf*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Raney nickel, used advantageously both in industry[2a] and in the laboratory[2b] as an active catalyst for liquid-phase hydrogenations, is prepared from Ni/Al alloys using concentrated caustic soda.[1] Physical investigations[3] have shown that the largely uniform network of pores provides surface areas of up to 100 m^2/g, depending on the method of preparation, and contains regions of ordered Ni crystals. Moreover, the Al component affects not only the texture but also functions as an electron donor to the Ni(3d) band. We report here the reactions of gaseous organic compounds on solid Raney nickel.[1] In comparison with the pyrolysis of such compounds on quartz wool or the catalytic decomposition on nickel turnings, these reactions take place *at much lower temperatures with marked selectivity*.

The following model reactions were studied in a horizontally arranged solid-bed reactor by PE spectroscopic analysis[4] of the gas flow (see Fig. 1): the dehydrogenation of 2-propanol, which competes with its dehydration; the decarbonylation of methyl formate, and the elimination of N_2 from methyl diazoacetate [Reactions (a)–(e)].

$$(H_3C)_2CHOH \xrightarrow{T} H_2 + (H_3C)_2C{=}O \quad (a)$$

$$(H_3C)_2CHOH \xrightarrow{T} H_2O + H_3C{-}HC{=}CH_2 \quad (b)$$

$$HCOOCH_3 \xrightarrow{T_1} CO + H_3COH \xrightarrow{T_2} CO + 2H_2 \quad (c)$$

$$NN{=}CH{-}COOCH_3 \xrightarrow{T} N_2 + CO + H_3C{-}CHO \quad (d)$$

$$NN{=}CH{-}COOCH_3 \xrightarrow{T} N_2 + H_3COOCHC{=}CHCOOCH_3 \quad (e)$$

[**] Gas-phase reactions, Part 50. This work was supported by the Land Hessen, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. Part 49: H. Bock, B. Solouki, G. Maier, *Angew. Chem. 97* (1985) 205; *Angew. Chem. Int. Ed. Engl. 24* (1985) 205.

2-Propanol is approximately fifty percent dehydrogenated to acetone upon passage over a 5-cm layer of Raney nickel at room temperature and 10^{-2} mbar [Reaction (a)]; the hydrogen evolved can be identified by its characteristic PES ionization pattern (Fig. 1, middle, insert) after trapping of the condensable gases in an inserted liquid nitrogen cold trap. The elimination of H_2 takes place quantitatively at 350 K (Fig. 1, bottom).

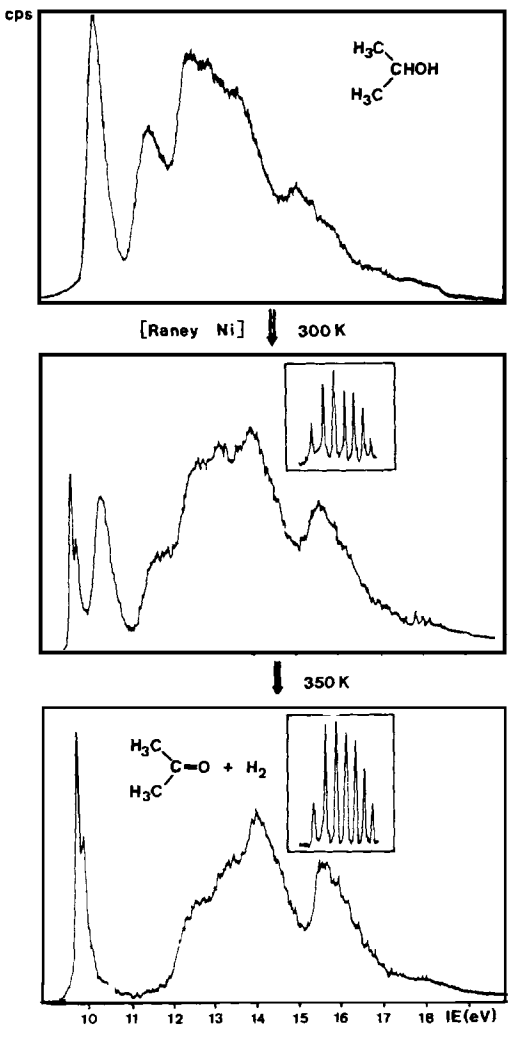

Fig. 1. He(I) PE spectra of 2-propanol (top) and of the product mixture obtained after passage over Raney nickel at 300 K and 350 K (middle and bottom, respectively). The vibrational fine structure of the H_2 band—recorded after condensation of the products at 77 K—is shown in the two inserts.

Raney nickel lowers the required temperature for the thermolysis of 2-propanol by more than 600 K compared with that on quartz wool, which begins with the elimination of water at 870 K to yield propene [Reaction (b)] and in which the dehydrogenation to acetone [Reaction (a)] can only be detected above 970 K. The catalysis by nickel turnings of comparable particle size lowers the temperature only 350 K.[1]

Even larger temperature differences are observed for the decarbonylation of methyl formate [Reaction (c); T_1] under the same reaction conditions:[1] the elimination of CO begins at 1100 K on quartz wool, at 700 K on nickel turnings, and at 370 K on Raney nickel. The methanol formed is completely decomposed to CO and H_2 upon raising the temperature only another 50 K [Reaction (c); T_2]. This enormous catalytic activity, which is also observed for other Ni_x contacts having large surface areas,[5] is due to the known, favorable chemisorption of carbon monoxide[6] and hydrogen[3,6] on the Ni surface.

The largest differences between thermal and catalytic decomposition are found for methyl diazoacetate:[1] on quartz wool, CO is eliminated along with N_2 above 523 K. Acetaldehyde can be identified in the resulting mixture of products PE-spectroscopically by the sharp band at 10.26 eV [Reaction (d)]. In contrast, on Raney nickel, N_2 is evolved already at room temperature, and, after passage of $NN{=}CH{-}COOCH_3$ for several hours at 350 K, a mixture of dimethyl maleate and dimethyl fumarate can be preparatively isolated in an inserted cold trap at 77 K [Reaction (e)]. This surprising result presumably can be explained by dimerization of methoxycarbonylcarbenes formed on the nickel surface—in analogy to the reaction of diazomethane on nickel producing ethene in the classic studies of *Pettit* on the mechanism of the Fischer-Tropsch synthesis.[7]

[1] H. P. Wolf, Diplomarbeit, Universität Frankfurt 1984, and references therein. Experimental procedure for the Raney nickel used here: Ground and sieved Ni/Al alloy (27 g, particle diameter 1 mm, Degussa, 50 wt.-% Ni) is dissolved under purified N_2 in 30 mL of water. A solution of KOH (5.6 g) in 30 mL of degassed H_2O is added slowly under cooling. After evolution of 4.7 L of H_2 (corresponding to 3.8 g of Al as $KAlO_2$), the reaction is stopped by cooling to 3°C; the suspended Raney Ni is transferred under N_2 into a reaction tube stoppered with quartz wool and dried at 350°C and 1 mbar for 5 h. The Raney nickel is then activated in a stream of H_2 for 2 h and subsequently heated at 10^{-2} mbar until the intense PES ionization peak of H_2O at 12.62 eV has disappeared. Analysis after dissolving in HCl and filtering off 6.2% Al_2O_3: Ni(electrogravimetrically) 57.4%; Al (as Al_2O_3) 36.4%.

The First Arsirane

By *Rolf Appel,* Thomas Gaitzsch,* and *Falk Knoch*

Dichlorophosphanes **1a,b** react with lithium chloro[bis(trimethylsilyl)]methanide **2** to give stable bis[bis(trimethylsilyl)methylene]phosphoranes **3**.[1,2] Further reaction to give the phosphiranes **4**, which is observed in the case of bismethylenephosphoranes substituted otherwise at the methylene C-atoms,[3,4] does not take place here because of shielding by the bulky trimethylsilyl groups.

[*] Prof. Dr. R. Appel, T. Gaitzsch, Dr. F. Knoch

Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (FRG)

On carrying out this reaction with dichloroarsanes **1c** we have now succeeded for the first time in synthesizing a bismethylenearsorane **3c**. Of the dichloroarsanes $RAsCl_2$ (R = Me, *t*Bu, Ph) tested, only the phenyl compound gave no additional reactions. NMR spectroscopic monitoring of the reaction revealed that initially only the red bismethylenearsorane **3c** is formed below −15°C; unlike the analogous phosphorane it is unstable and rearranges within a short period of time into the stable arsirane **4c**. The composition of the crystalline and colorless substance **4c** precipitating from pentane is secured by elemental analysis and mass spectrum; its structure was confirmed by an X-ray structure analysis (Fig. 1).[5]

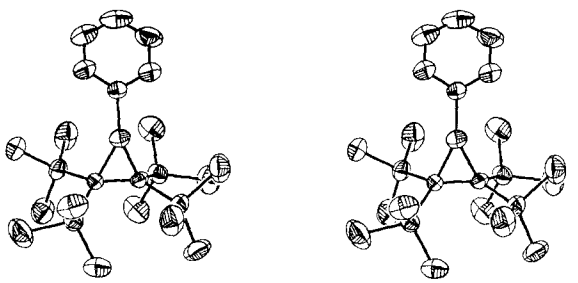

Fig. 1. Stereoview of the crystal structure of **4c**.

The arsirane **4c** is, to our knowledge, the first arsacyclopropane to have been isolated. Only one bicyclic system containing an annelated arsirane ring has so far been reported in the literature.[6]

The characteristic spectroscopic data of **3c** and **4c** are listed along with those of the phosphorus analogues in Table 1.

Table 1. Characteristic ^{13}C-NMR data of **3c** and **4c** compared with those of the corresponding phenyl- and *tert*-butylbismethylenephosphoranes; δ values rel. TMS ext., positive downfield, solvent $CDCl_3$, J [Hz].

Experimental

59 mL of a commercially available 1.6 M solution of *n*BuLi in hexane (0.09 mol) was added dropwise to a mixture of tetrahydrofuran (200 mL), diethyl ether (20 mL), pentane (20 mL), and dichlorobis(trimethylsilyl)methane (20.6 g, 0.09 mol) cooled to −110°C. The mixture was stirred for 3 h, then treated with a solution of **1c** (6.57 g, 0.03 mol) in THF (10 mL), and allowed to warm to −15°C. The solvents were then removed and the mixture was taken up in 50 mL of pre-cooled pentane and filtered. Finally, solvent and dichlorobis(trimethylsilyl)methane were condensed off as quickly as possible at room temperature in a vacuum. From the solution of the residue in 10 mL pentane, **3c** precipitated as a red solid. At room temperature, **3c** undergoes complete conversion within 12 h into **4c**, which can be recrystallized from pentane. M.p. 91°C (**4c**), yield 67%.

Tricarbonyl(1,3-diphosphaallyl)cobalt, a Phosphorus Analogue of (η^3-Allyl)tricarbonylcobalt**

By *Rolf Appel,* Winfried Schuhn,* and *Falk Knoch*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

In transition-metal complexes containing phosphaalkene ligands, η^1-(P) and η^2-(P=C) coordination[1] is observed. We have now obtained the first complex with an η^3-1,3-diphosphaallyl ligand.

The chlorophosphino-substituted methylene phosphane **1**[2] reacts smoothly with sodium tetracarbonylcobalt **2** in

[**] Lower coordinated phosphorus compounds, Part 38.—Part 37: R. Appel, J. Menzel, F. Knoch, *Chem. Ber.*, in press.

tetrahydrofuran (THF) via **3**, which cannot be detected spectroscopically, to give tricarbonyl(1,3-diphosphaallyl)cobalt **4** (correct elemental analysis); in the process, NaCl is eliminated and CO evolved.

According to the X-ray structure determination (Fig. 1), **4** can be described best as a square pyramid having two P atoms and two CO ligands at the base and a third carbonyl group at the apex, with the allyl C atom below the basal plane pointing towards the Co center. The NMR data[3] (magnetic equivalence of the two aryl-P units) are in accord with this description.

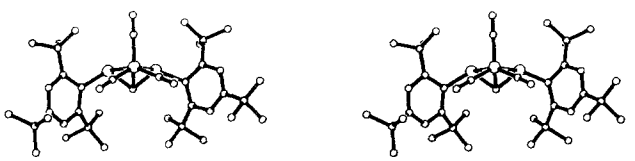

Fig. 1. Stereograph of the crystal structure of **4**.

The following findings support the classification of **4** as a 1,3-diphosphaallyl complex:[4] all three atoms of the PCP triad are bonded to the Co atom; the C1 atoms of the aryl moieties and the PCHP skeleton form a plane; the PC distances within the ligands are the same and lie between a PC single bond and a PC double bond, in contrast to the starting material.

Experimental procedure

A solution of octacarbonyldicobalt (0.85 g, 2.5 mmol) in THF (50 mL) is added to 13 g of 1% sodium amalgam. After stirring overnight at room temperature, the supernatant is decanted and treated with **1** (3.0 g, 5 mmol), then heated at 45 °C for 4 h, during which time the solution undergoes a color change from yellow to rust-brown. The solvent is removed and the residue extracted three times with 20 mL of hexane. The extracts are combined; **3** crystallizes out as orangish brown prisms. Yield: 1.9 g (53%), m.p. = 163 °C (decomp.).

Laser Photolysis of the Bisazoalkane 7-*syn*,7′-*anti*-Bis-2,3-diazabicyclo[2.2.1]hept-2-ene

By *Waldemar Adam,* Klaus Hannemann, Eva-Maria Peters, Karl Peters, Hans Georg von Schnering,* and *R. Marshall Wilson*

Recently the synthesis of the tetraradical **2** by denitrogenation of the bisazoalkane **1** was reported.[1] We have now synthesized the bisazoalkane **3**, from which we wanted to generate the tetraradical **4** by laser photolysis. Although other suitable bisazoalkanes such as the bisazoalkane **5**[2] are known, no formation of tetraradicals could hitherto be observed.[3] Should **4** be formed, then it could react further with intramolecular coupling to give the known[4] hydrocarbon **6**; that is, its formation would be an indication of the intermediary occurrence of the tetrayl **4**. By stepwise cleavage of N_2, the formation of the novel hydrazine **7** would be possible by intramolecular trapping reaction[5] of the diyl with the remaining azo group.

1 **2** **3** **4**

5 **6** **7**

The bisazoalkane **3**[6] was prepared from the known bisurazole,[7] which is formed upon double cycloaddition of 4-phenyl-4*H*-1,2,4-triazole-3,5-dione (PTAD) to 9,10-dihydrofulvalene, by catalytic hydrogenation and subsequent oxidative hydrolysis. The X-ray structure analysis of the bis-azoalkane **3** (Fig. 1, top) showed that the double PTAD cycloaddition led to the *syn,anti*-product.[8]

Both the direct as well as the triplet-sensitized laser photolysis[9] of the bisazoalkane **3** gave, besides unreacted **3**, small amounts (ca. 15%) of the four possible monoazoalkanes **8a**, **d** (major products) and **8b**, **c** (minor products). Cleavage of N_2 from the "upper" azo group led to the isomers **8a**, **b**, while cleavage of N_2 from the "lower" azo group furnished the isomers **8c**, **d**. All the isomers could be completely characterized on the basis of their spectral data and could be recovered in pure form by column and gas chromatography. The X-ray structure analysis of **8c** (Fig. 1, bottom)[8] proved to be a valuable aid for the stereochemical assignment of all isomers. The isomeric com-

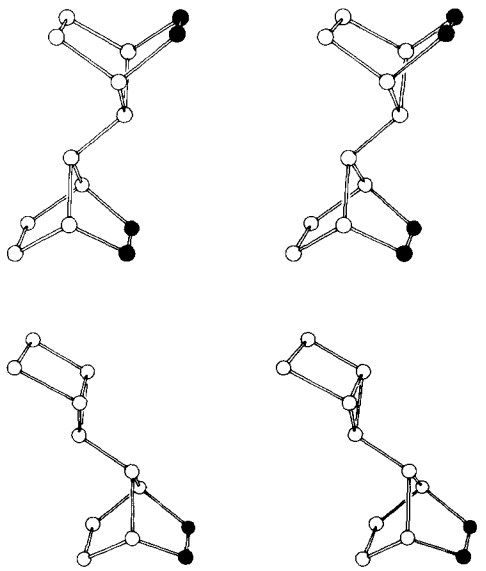

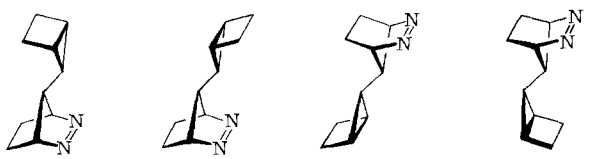

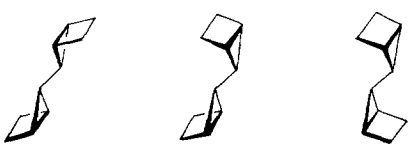

Fig. 1. Stereoviews of the crystal structures of **3** (top) and **8c** (bottom) [8]; ● N, ○ C.

position depended on the irradiation conditions (direct or sensitized); even at optimal intensity (focused laser beam at maximum power) no further products could be detected by capillary gas chromatography.

8a **8b** **8c** **8d**

The complete photolysis (direct as well as sensitized) of the bisazo compound **3** yielded the three possible bi-5,5′-bicyclo[2.1.0]pentanes **9a**—**9c** in roughly statistic amounts.

9a **9b** **9c**

The pure monoazoalkane isomers **8** each afforded a pair of the isomers **9**, namely in the photolysis of **8a**, **d** a mixture of **9b**, **c**, whereas in the case of **8b**, **c** the isomers **9a**, **b** were formed. All bi(bicyclopentane) isomers **9** could be characterized on the basis of their spectroscopic data. The isomers **9b**, **c** could be isolated in pure form by preparative gas chromatography. The photoproducts can be explained, if it is assumed that the cyclization of the 1,3-diyl intermediate proceeds with retention or double inversion; an analogous process was formulated for the photochemical decomposition of 2,3-diazabicyclo[2.2.1]hept-2-ene.[10]

For the formation of **4**, two photons have to be successively absorbed (one by each azo chromophore) ($\mathbf{3} \xrightarrow{h\nu} \mathbf{3}^* \xrightarrow{h\nu} \mathbf{3}^{**}$) within the lifetime of an n,π*-excited state (ca. 1 ns), so as to ensure a double N_2-cleavage. Although "two-photon processes" have been observed during pulsed laser irradiation,[11] no cases of a simultaneous double N_2-cleavage leading to a tetraradical has hitherto been reported. Even **2**, which should be favored by stereoelectronic factors such as ring strain and spiroconjugation, is not formed upon photolysis of the bisazo compound. Here too, instead of the required simultaneous double N_2-cleavage, a stepwise process takes place.[10] The generation and detection of polyradicals still remain a challenge.

Synthesis, Structure, and Reactivity of η^3-1-Azaallylmolybdenum Complexes**

By *Michael Green,* Richard J. Mercer, Carolyn E. Morton,* and *A. Guy Orpen*

Dedicated to Professor F. G. A. Stone on the occasion of his 60th birthday

Although the ubiquitous η^3-allyl ligand has been shown to play an important role in many transition metal mediated reactions,[1] little is known about the chemistry of η^3-1-azaallyl complexes[2] where a terminal CH_2 group of the allyl fragment is replaced by an NH group. Such compounds can be formed on reaction of the 2-substituted azirines[3] **1** and **2** with the unsaturated dimolybdenum species $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$. In toluene at room temperature, the initial red-brown color becomes dark green, and column chromatography on alumina afforded orange crys-

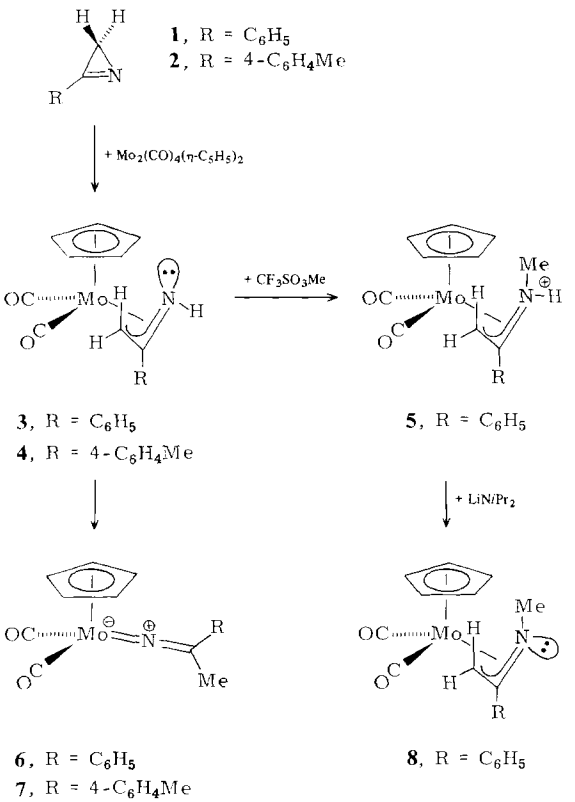
Synthesis, Structure, and Reactivity of η^3-1-Azaallylmolybdenum Complexes**

By *Michael Green,* Richard J. Mercer, Carolyn E. Morton,* and *A. Guy Orpen*



Dedicated to Professor F. G. A. Stone on the occasion of his 60th birthday

Although the ubiquitous η^3-allyl ligand has been shown to play an important role in many transition metal mediated reactions,[1] little is known about the chemistry of η^3-1-azaallyl complexes[2] where a terminal CH_2 group of the allyl fragment is replaced by an NH group. Such compounds can be formed on reaction of the 2-substituted azirines[3] **1** and **2** with the unsaturated dimolybdenum species $[Mo_2(CO)_4(\eta\text{-}C_5H_5)_2]$. In toluene at room temperature, the initial red-brown color becomes dark green, and column chromatography on alumina afforded orange crys-

tals of **3** and **4**.[4] The elemental analysis and IR, ^{1}H-, and ^{13}C{^{1}H}-NMR spectra[5] suggested that a ring-opening reaction had occurred with formation of azaallyl complexes, where the nitrogen now carries an additional hydrogen atom, which is presumed to originate from the alumina.

The X-ray structure analysis of **4**[6] shows that the $[Mo(CO)_2(\eta\text{-}C_5H_5)]$ fragment has typical dimensions and is bound to an η^3-1-azaallyl moiety. This group adopts an *endo* configuration with respect to the cyclopentadienyl ligand, presumably because this avoids unfavorable contacts involving the *p*-C_6H_4Me group on the central allyl carbon and the C_5H_5 ring. The hydrogen atom carried by the nitrogen lies close to the C_2N plane of the azaallyl ligand. This and the geometry at the nitrogen implies sp^2 hybridization, the lone pair occupying the *anti*- and the hydrogen the *syn*-position, respectively, on the azaallyl fragment. The differences in the Mo–C(8) and Mo–C(9) distances show some tendency towards flattening of the Mo–C(8)–C(9)–N unit, i.e., progression towards the planar geometry familiar for dihetero 'allyls' such as dithioacetates (for which η^2-coordination is common, of course, but η^3-coordination is known[7]).

The structural evidence is unambiguous in indicating that the nitrogen atom possesses a basic functionality. Chemical evidence for the presence of a nitrogen lone pair was provided by the observation that addition (−78 °C, THF) of methyl triflate to **3** followed by proton abstraction with the sterically hindered base lithium diisopropylamide (−78 °C, THF) afforded (70% yield) the orange complex **8**, which was characterized by NMR as the illustrated *anti*-substituted η^3-*N*-methyl-1-azaallyl complex.

It is particularly interesting that the hydrogen atom attached to the nitrogen atom is labile. In methylene chloride or benzene solution the azaallyls **3** and **4** slowly (room temperature, 12 h) rearrange to form the dark green

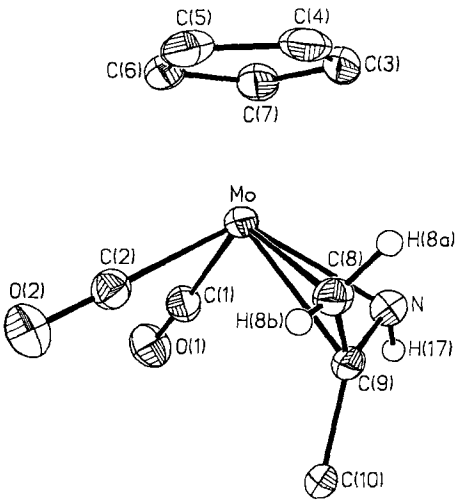

Fig. 1. Molecular structure of **4** [6]. Tolyl group and cyclopentadienyl hydrogens omitted for clarity. Important bond distances [Å] and angles [°]: Mo–C(8) 2.262(3), Mo–C(9) 2.334(3), Mo–N 2.340(3), C(8)–C(9) 1.371(4), C(9)–N 1.380(4), C(8)–H(8a) 0.91(3), C(8)–H(8b) 0.77(3), C(9)–C(10) 1.497(4), N–H(17) 0.99(4), Mo–C(Cp) 2.295(3)–2.404(4); H(17)–N–C(9) 113(2), C(9)–N–Mo 76.2(2), C(8)–C(9)–N 112.6(3).

complexes **6** and **7**. When the reaction was monitored by NMR spectroscopy[5] the N*H* and C*H*$_2$ signals of the azaallyls decreased in intensity to be replaced by a new methyl resonance. In the ^{13}C{^{1}H}-NMR spectrum the η^3-1-azaallyl quaternary carbon at $\delta = 101.02$ is replaced by a quaternary carbon at $\delta = 155.38$, characteristic of an uncoordinated azomethine carbon. It is suggested that **6** and **7** have the illustrated linear azavinylidene-like structure; a type of molecule which has previously[8] been synthesized by reaction of $LiN{=}CtBu_2$ with $[MoCl(CO)_3(\eta\text{-}C_5H_5)]$. In this connection it is interesting to note that the phosphorus analogue $[Mo\{\eta^1\text{-}P{=}C(SiMe_3)_2\}(CO)_2(\eta\text{-}C_5H_5)]$ has recently[9] been prepared by reaction of $K[Mo(CO)_3(\eta\text{-}C_5H_5)]$ with $(Me_3Si)_2C{=}PCl$. There is no precedent for the rearrangement **3**/**4**→**6**/**7**, which involves a formal 1,3-hydrogen shift and resembles an enamine→imine rearrangement.

Thus, this study has demonstrated that η^3-1-azaallylmolybdenum complexes are stable species and can be synthesized from azirines; the nitrogen lone pair can be alkylated, and a novel nitrogen to carbon H-shift provides a route to azavinylidene metal complexes.

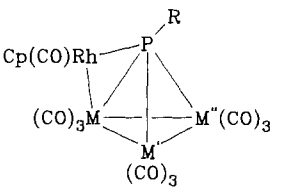
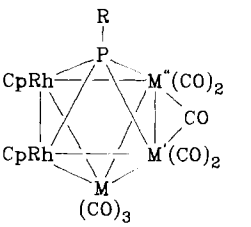
Cluster Expansion with Cp(CO)Rh Fragments**



By *Darjusch Mani* and *Heinrich Vahrenkamp**

For cluster expansion experiments to date, mainly anionic mononuclear complexes or anionic clusters, the number of which is obviously limited, have been used. For this purpose, only complexes affording $Fe(CO)_3$ units have clearly emerged as a source for neutral fragments.[1] We hoped that the RhCp unit (Cp = cyclopentadienyl), which is isovalent and isoelectronic with the $Fe(CO)_3$ unit, would be similarly useful. In order to effect cluster skeletal expansion and, at the same time, to introduce the catalytically active element rhodium, we have therefore reacted the FeCo or RuCo clusters **1** with $Cp(CO)_2Rh$.

In all five cases, the desired pentanuclear clusters **3**, all of which are new, were formed when the starting materials were allowed to react in a mole ratio of 1:2 at 80—100°C for ca. 20 h in benzene or toluene. The total turnovers were about 75% and the yields of **3a** and **b** were 70—90% (relative to the extent of the reaction), those of **3c**—**e** 6—30%; the unused starting clusters were recovered. The constitutions of the clusters **3** are assumed to be like those of known PM_5 clusters;[2] this is in accord with the spectra.[3]



1a–e

2b,c,d

	R	M	M'	M"
a	Me	Fe	Co	Co
b	Ph	Ru	Co	Co
c	Me	Ru	RuH	Co
d	Me	Ru	FeH	Co
e	*t*Bu	Ru	FeH	Co

3a–e

The reactions appear to be general: the $PFeCo_4$ cluster analogous to **3a** was formed from **1a** and $Cp(CO)_2Co$, and the cluster analogous to **1a** but containing S instead of MeP afforded a product mixture, which, according to the spectra, also contains the $SFeCo_2Rh_2$ cluster analogous to **3a**.

At low reaction temperatures (60—80°C) and after short reaction times (3—8 h), the tetranuclear clusters **2b**, **c**, and **d** were obtainable as intermediates from **1b**, **c**, and **d** in just about 90% yield; they reacted further to give **3b**, **c**, and **d**. The cluster type **2** was identified by X-ray structure determination of **2b**,[4] as well as by the usual methods.[3] The tetranuclear clusters **2** are thermally sensitive, in contrast to the pentanuclear clusters **3**. In refluxing benzene, they are mainly transformed back into **1** over the course of several hours; part of the rhodium that is thereby lost is found again in the form of **3**. Attempts to cleave CO thermally, photochemically, or oxidatively from **2**, in order to obtain, via aggregation, clusters with tetrahedral M_4 skeletons, were unsuccessful.

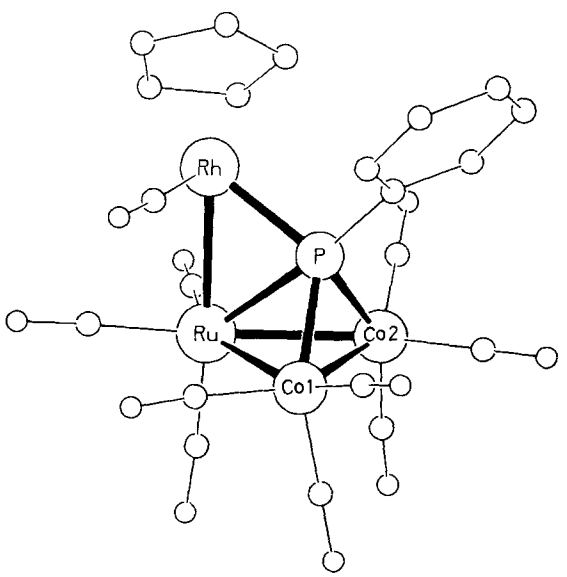


Fig. 1. Crystal structure of **2b**. Important bond lengths: Ru—Rh 279.3(1), Ru—Co1 272.0(1), Ru—Co2 268.7(1), Co1—Co2 255.8(1), Rh—P 227.3(2), Ru—P 261.9(1), Co1—P 218.1(2), Co2—P 218.5(2) pm.

[**] This work was supported by Heraeus and by the Rechenzentrum der Universität Freiburg.

Figure 1 clearly shows that the clusters **2** exhibit an unusual molecular skeleton. All components of **1** are still present; **1** as a whole acts as a two-electron ligand with respect to the Cp(CO)Rh unit. This naturally changes the electron distribution in the cluster, but the 18-electron rule remains fulfilled for all four metal atoms. The demands on the Ru–P side of **1b** are evident in the markedly longer Ru–P bond and the sideways displacement of the phenyl group on phosphorus. Clusters having organometallic fragments attached, such as **2b**, were, to be best of our knowledge, unknown. The unusual electronic nature of this configuration corresponds to the ability of the rhodium-containing fragment to be removed thermally.

The geometry of **2b** is also in accord with another description of the bonding: due to the approximate linearity of the Ru–P–C sequence (174°), the central $PhPRu(CO)_3$ molecular moiety can be viewed as a phosphanediyl complex, which, in its free form, would have a Ru–P triple bond. Analogously to an alkyne, this group can bridge the $Co_2(CO)_6$ unit and/or function as a side-on ligand with respect to the Cp(CO)Rh unit. The electron count would thus correspond to that in the μ_3-η^2-alkyne-bridged trinuclear clusters.[5] However, the triple bond surrounded by three metal atoms, which is observed here for **2b**, has no precedent.

The clusters **2d**, **3d**, and **3e** contain four different metal atoms. Therefore, studies of the chirality, in light of catalytic optical induction, are of interest, as are attempts to incorporate further heterometal atoms, which could make use of the hydride function in the clusters **c**, **d**, and **e** or of the **2** → **3** transformation.

Photosignal II as an Indicator for Damage to Forests – EPR Spectroscopic Investigation of Spruce Needles**

By *Hartmut B. Stegmann,* Hans J. Ruff,* and *Klaus Scheffler*

EPR spectroscopy is a very sensitive and selective method for the detection of paramagnetic species. For this reason, we have attempted to determine whether the pollutants SO_2 and NO_x, which are much under discussion, exert an effect on the photosynthetic apparatus and whether these effects can be detected by EPR spectroscopy. Although the relationship between photosynthesis and tree death has already been pointed out,[1] EPR studies, which are capable of very sensitively detecting disturbances in the electron transport chains, have not been carried out.

Externally undamaged whole needles from 20 spruces *(Picea abies L.)* of various ages and from a variety of locations in the vicinity of Tübingen (Schönbuch, Rammert, Alb) were studied. The EPR spectra of spruce needles, which were investigated in the dark without any pretreatment, show essentially two types of signals. About 50% of all samples studied exhibit a strong and relatively well-resolved six-line spectrum, which can be unequivocally assigned to Mn^{2+}. The other needles show only negligible Mn^{2+} signals. The factors responsible for this variation between different trees are still unclear. The further studies were carried out on needles containing very little Mn^{2+}. Independent of the manganese content, absorption at g = 2.005 is found for all samples; this absorption exhibits a significant structure over a range of ± 15 G (cf. Fig. 1).

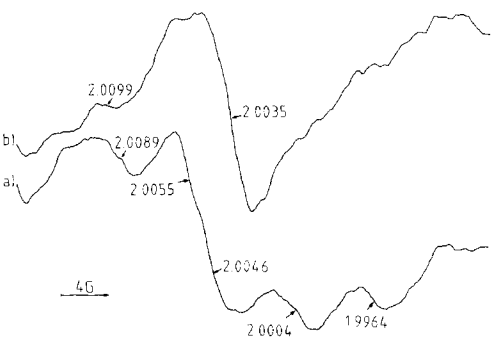

Fig. 1. EPR spectrum of various spruce needles in the g = 2.005 region. The samples were collected in October and November 1984. The signals were obtained with a Varian E-line spectrometer connected to a Bruker data system ER 140 by accumulation of 50 scans using an FF lock (5-mW microwave energy; modulation 1 G). Spectrum a): tree 17 (S 0); spectrum b): tree 15 (S 3).

Needles from trees that, according to the conventional, subjective criteria, are assigned to the damage level S 0,[2] show signals at g = 2.0089, g = 2.0100, g = 2.0055, g = 2.0046, g = 2.0004, and g = 1.9964 (cf. Fig. 1 and Fig. 2, spectrum a) in each case). In contrast, needles from trees assigned to the damage level S 3 show a completely different EPR signal (cf. Fig. 1, spectrum b)).

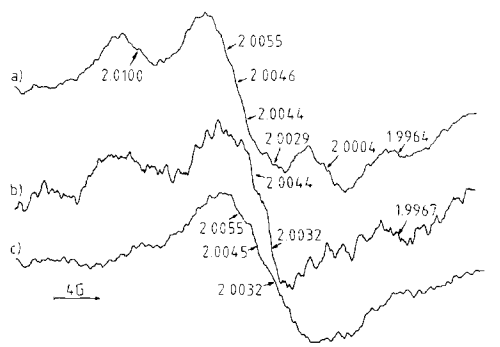

Fig. 2. EPR spectra of various spruce needles in the g = 2.005 region (same experimental conditions as in Fig. 1). Spectrum a): tree ST (S 0); spectrum b): tree 16 (S 3); spectrum c): tree ST after treatment with NO_x. In order to allow short reaction times and thus avoid aging processes, the concentration of NO_x in this very preliminary experiment was very high relative to that in the natural environment.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Spectrum b) of Figure 1 consists essentially of only one component at $g = 2.0035$, which is totally absent in a). Differences in location seem to be of secondary importance for the EPR signals of the needles of undamaged trees since the spectra a) in Figures 1 and 2 are practically identical. For needles from damaged trees, however, differences are found which could make possible a differentiation according to objective criteria and thus allow the early recognition of damage. For instance, the signal at $g = 2.0044$ is clearly recognizable in spectrum b) of Figure 2, even though the main absorption is the component at $g = 2.0032$.

When spruce needles are exposed for ca. 2 h to light in an atmosphere containing 10^{-4} mol/L NO_x, the EPR spectrum changes appreciably (cf. Spectrum c) in Figure 2). The signal at $g = 2.0100$ has practically fully vanished and the $g = 2.0055$ component has lost intensity, whereas the absorption at $g < 2.0032$ has increased in importance. Spectrum c) is therefore more like spectrum b) than spectrum a), which was recorded immediately prior to treatment with NO_x. Similar spectra are obtained upon simultaneous treatment with NO_x and SO_2.

These findings do not mean that only NO_x and SO_2 can damage the electron transport chain. Other pollutants, such as ozone and photooxidants, can possibly have similar effects. Studies of spruce needles from areas having clean air should afford further conclusions. Treatment with aqueous acids, such as sulfuric acid (pH = 1), does not lead to a change in the EPR signal, even after several hours; therefore, the needle damage occurs preferentially via the gas phase.

The EPR signals that we have recorded for undamaged spruce needles correspond largely to the signals found for isolated chloroplasts and referred to as "Signal II slow".[3] While the chloroplast signals depend strongly on the preparation procedure, only small differences are observed for different samples in the investigations of whole healthy spruce needles. Seasonal variations of these signals are not known. With regard to the assignment of Signal II (S II) in the photosynthetic processes of plants, it is at present assumed that the signal is directly associated with the water splitting reaction of Photosystem 2.[3] Much less is known about the chemical structure of the radicals responsible for S II. Whereas some authors assume the involvement of several species,[4] others prefer homogeneous redox systems of the plastosemiquinone type,[5] with the structure of S II being due to unresolved hyperfine structure. We are not in agreement with this latter point of view, since the difference spectra (light-dark) exhibit an increase in the signals at $g = 2.0055$ and $g = 2.0046$ upon irradiation. Our results indicate that NO_x and SO_2 affect to varying degrees the various paramagnetic species that are responsible for S II. For massive damage, which need not be attributed exclusively to NO_x and SO_2, practically only "one" signal with $g = 2.0035$ is still observed. Similar absorptions have been reported in connection with Photosystem 2.[6]

Synthesis of a Novel Stable Carbanion: 1,1,2-Tricyano-2-(3,4-dicyano-5-imino-2,5-dihydro-1*H*-pyrrol-2-ylidene)ethanide by Reduction of Tetracyanoethylene with Tris(2,2'-bipyridine)titanium**

By *Giulia Dessy, Vincenzo Fares, Alberto Flamini,** and *Anna Maria Giuliani*

Reduction of tetracyanoethylene (TCNE) and subsequent acidification normally furnishes tetracyanoethane.[1] In the presence of $Ti(bpy)_3$,[2] however, an anionic dihydropyrrole derivative **2**[3] was obtained which could be isolated as the salt **3** (Scheme 1). The structure of the anion (Fig. 1) was elucidated by a single-crystal X-ray structure analysis. Despite high standard deviations the tautomeric pyrrolide could be ruled out. This finding is additionally supported by IR and ^{13}C-NMR spectra.[4]

Scheme 1.

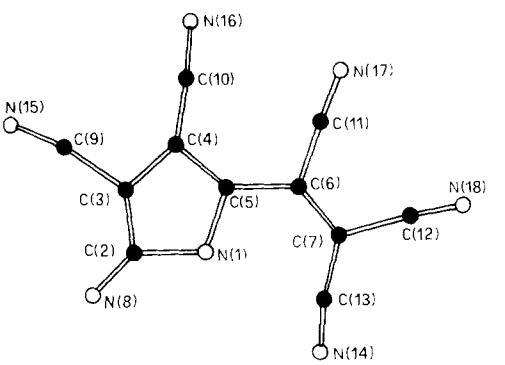

Fig. 1. Structure of the anion **2** in the crystal of **3** (hydrogen atoms have been omitted) $P2_1/c$; $a = 9.435(4)$, $b = 13.655(7)$, $c = 24.487(13)$ Å, $\beta = 106.97(4)$, $R = 0.066$ (1382 reflections). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51272, the names of the authors, and the full citation of the journal. Selected bond lengths [Å] and angles [°]: C3–C4 1.42(6), C4–C5 1.39(4), C5–N1 1.45(4), N1–C2 1.51(6), C2–C3 1.31(7), C2–N8 1.17(7), C5–C6 1.46(4), C6–C7 1.35(3), C2–C3–C4 128(4), C3–C4–C5 98(3), C4–C5–N1 109(3), C5–N1–C2 112(2), N1–C2–C3 93(4).

In order to clarify the mechanism of the reduction of TCNE in the presence of $Ti(bpy)_3$ we have studied in detail each of the individual steps (Fig. 2) shown in Scheme 1. In the first step the intermediate **1** is formed by replacement of one bipyridine ligand by TCNE, which, in the process, is reduced to tetracyanoethanediide ($TCNE^{2\ominus}$). In other words, $Ti(bpy)_3$ causes a two-electron reduction of TCNE, as is also proven by the zero magnetic moment and the IR spectrum of **1**[5] (prominent $TCNE^{2\ominus}$ bands at 2160, 2095, and 1260 cm^{-1}).[6]

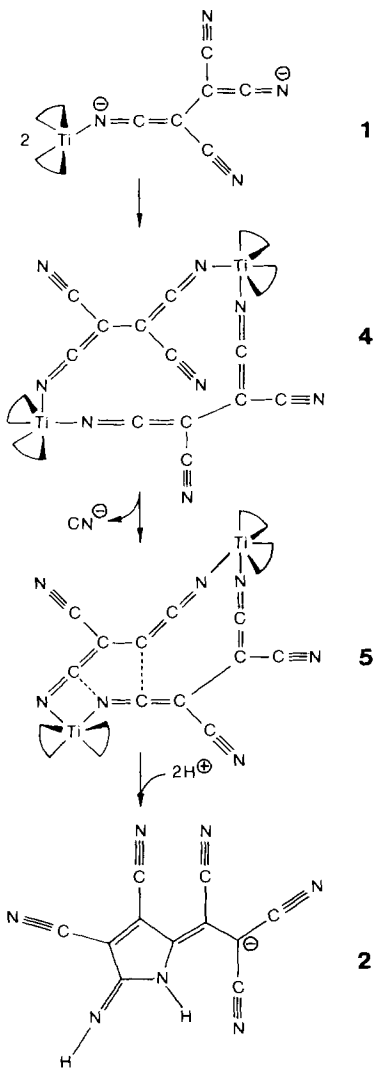

Fig. 2. Reaction scheme explaining the formation of the anion **2**. The charges are only partly indicated.

This coordinatively unsaturated species **1**, which is formed at low temperatures, can be stabilized by polymerization or dimerization. Several dimers with different conformations can be formed; one of them could be, e.g., **4**, containing two $TCNE^{2\ominus}$ bridges (*cis* and *trans* referred to titanium). If **4** is concomitantly oxidized and protonated in a second step, HCN is liberated;[7] finally, the anion **2** and the polymeric cationic titanium(IV) complex $[Ti(bpy)_2O]_n^{2n\oplus}$ are formed via the more stable complex **5**.

The anion **2** is thus formed by condensation of two TCNE molecules:

$$2\,TCNE + 4e^{\ominus} \longrightarrow 2\,TCNE^{2\ominus} \xrightarrow{+3H^{\oplus}} \underset{\mathbf{2}}{C_{11}N_7H_2^{\ominus}} + HCN$$

The formation of **2** is favored by titanium because it can bind $TCNE^{2\ominus}$ via a nitrogen atom. Such a reaction appears to be very unusual in the field of TCNE chemistry; only one similar example has previously been reported in the literature.[8] In the complex $[(CO)(PPh_3)_2M(TCNE)]$, M = Rh, Ir, the TCNE is reduced to $TCNE^{2\ominus}$ and subsequently bonded to the metal through the nitrogen. Under certain conditions a dimer is formed, which is converted by cleavage of two $CN^{\ominus}$ groups into hexacyanobutenediide.

The salt **3**, which can be prepared in reasonable yield (ca. 40%) in a one-pot synthesis, is stable toward water and oxygen. Due to the five cyano groups the salt is supposedly a strong electron acceptor toward donor molecules.[9]

The anion **2** or the readily obtainable acid $C_{11}N_7H_3$ can be used in combination with the tetrathiafulvalene cation ($TTF^{\oplus}$) or TTF, respectively, to give new organic metals.[10] Preliminary studies have shown that a novel salt exhibiting interesting electrical properties is formed by metathesis of $NaC_{11}N_7H_2$ with $[(TTF)_3(BF_4)_2]$.[11]

[2] First synthesis of $Ti(bpy)_3$: S. Herzog, R. Taube, *Z. Anorg. Allg. Chem. 306* (1960) 159.
[3] Experimental: TCNE (0.32 g; 2.5 mmol) was added under stirring at −80°C to a suspension of $Ti(bpy)_3$ (1.30 g; 2.5 mmol) in 50 mL tetrahydrofuran under N_2. The black suspension was allowed to warm to room temperature. After four hours it was cooled again to −80°C and CH_3NO_2 (50 mL) was added from a syringe with stirring under N_2. The final solution was allowed to warm to room temperature. The solvent was then evaporated at reduced pressure and the black-violet residue was washed with toluene (200 mL) and the undissolved residue filtered off. The solid was treated with acetone (200 mL) and the undissolved residue filtered off. $As(C_6H_5)_4Cl$ (1.05 g; 2.5 mmol) in H_2O (50 mL) was added to the violet solution. After concentration, the salt $[As(C_6H_5)_4 \cdot C_{11}N_7H_2]$ **3** separated as air-stable golden microcrystals, which were recrystallized from acetone-toluene (0.26 g; yield *ca.* 40%). **3** and the corresponding sodium salt have been characterized by their UV, IR, ^1H- and ^{13}C-NMR spectra and cyclic voltammograms. The molecular ion of the acid $C_{11}N_7H_3$, prepared from the sodium salt by acidification (H_2SO_4, 1 M) and extraction with ether, has been determined by MS ($m/z = 233.048 \pm 0.003$ ($C_{11}N_7H_3^{\oplus}$)).
[4] A resonance at $\delta = 67.8$, assigned to the C-7 carbon atom, strongly supports the existence of the carbanion **4**, bearing a high charge density on that atom (R. B. Bates, S. Brenner, C. M. Cole, E. W. Davidson, G. D. Forsythe, D. A. McCowly, A. S. Roth, *J. Am. Chem. Soc. 95* (1973) 926).
[5] **1** is not stable at room temperature: its IR spectrum slowly changes with time even when it is stored in a dry-box under nitrogen.

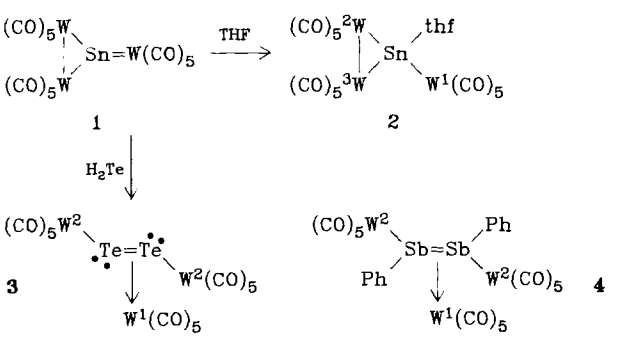
Transformation of $[\{(CO)_5W\}_3Sn]$ into $[\{(CO)_5W\}_3Te_2]$, a Compound Containing Unusually Bonded Ditellurium**



By *Olaf Scheidsteger, Gottfried Huttner,* Kurt Dehnicke,* and *Jürgen Pebler*

The complex **1** was recently synthesized. It is the first Sn analogue[1] of the class of complexes discovered by *Weiss* et al.,[2] which contain elements of the 4th main group that are trigonally planar coordinated by metals. We report here the Mössbauer spectrum of **1** as well as the use of **1** for the synthesis of the ditellurium complex **3**, in which a Te_2 unit is stabilized as a 2π-4σ ligand, a novel form of coordination.

The description of **1**[1] as a complex[3] of an unusual metallacyclic stannanediyl is supported by comparison of the ^{119}Sn Mössbauer spectrum ($IS = 2.56(4)$ mm s^{-1} relative to SnO_2; $EQ = 4.60(4)$ mm s^{-1}; asymmetry parameter $\Gamma = 0.88(5)$ mm s^{-1}; T (γ-source (SnO_2)) = 293 K; $T_{(sample)} = 84$ K; Lorentz fit) of **1** with the Mössbauer values of $[R_2SnM(CO)_5]$, M = Cr, Mo.[3a] Quadrupole splittings similar to those in **1** are only observed for stannanediyl complexes.[3a]

1 is very reactive due to the coordinatively unsaturated tin. It reacts with THF to give the expected base adduct **2** in which the Sn is tetrahedrally coordinated.[4] In the adduct, all Sn–W bonds are somewhat longer than those in **1**.

The reaction of **1** with the Lewis base H_2Te leads to **3**, in which, instead of Sn as in **1**, a Te_2 unit is coordinated in an unusual manner (Scheme 1).

Scheme 1. Synthesis of **3** and comparison of the structure of **3** with that of the distibene analogue **4** [8] (bond distances [pm], angles [°]): **3**: Te–Te 268.6(4), Te–W1 288.1(3), Te–W2 273.9(2); Te–Te–W2 106.7(1); W2–Te–Te–W2 140.0, W2–Te–Te–W1 110.0; **4**: Sb–Sb 270.6(4), average Sb–W1 288.8(19), average Sb–W2 276.2(4); average Sb–Sb–W2 129.5(11); W2–Sb–Sb–W2 124.5, W2–Sb–Sb–W1 117.

A brown-black suspension is formed from the orange-colored solution of **1** in the presence of Al_2Te_3[5] upon acidification with HCl; **3** is separated from this mixture chromatographically on diatomite. The black crystals of **3**[6] are stable in air at 20 °C and decompose only at 135 °C. **3** is insoluble in *n*-pentane but dissolves in toluene with a black-violet color, and is even more soluble in CH_2Cl_2. According to the X-ray structure determination,[4] **3** contains a Te_2 unit; the lone electron pairs on each tellurium terminally bind a $W(CO)_5$ group and, in addition, a further $W(CO)_5$ group is coordinated via the Te–Te π-system (Scheme 1).[7]

In this kind of bonding, the Te_2 unit is, in the broadest sense, isoelectronic with RSb=SbR. The comparison of the structure of the distibene complex **4**[8] with that of **3**, given in Scheme 1, makes this analogy clearer. In each case, the distance between the main-group elements is shorter than that of a single bond, despite the lengthening due to the side-on coordination. The Te–Te distance in **3** lies between the bond length of free $Te_{2(g)}$ (261 pm)[9] and that of hexagonal $Te_{(s)}$ (283.5 pm).[9] The "open" structure of **3** compared with the "closed" star-like structure of the complex $[\{(CO)_5W\}_3X_2]$ (X = As,[10] Sb,[8] Bi[11]) is a consequence of the different numbers of electrons in the diatomic ligands Te_2 and X_2, respectively.

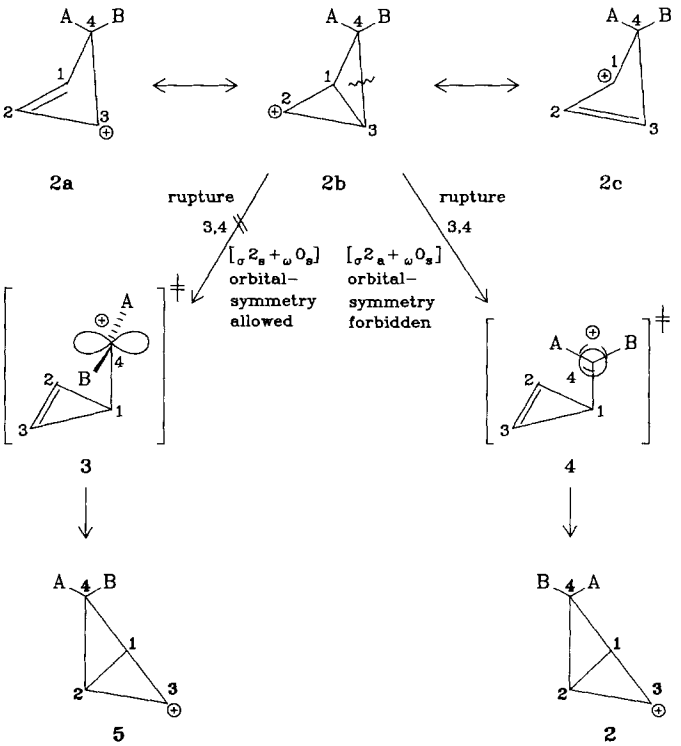
Walk Rearrangement in the 1,2,3,4-Tetra-*tert*-butylhydroxycyclobutenylium Ion**

By *Günther Maier,** *Rolf Emrich,* and *Hans-Otto Kalinowski*



The oxidative ring-opening of tetra-*tert*-butyltetrahedrane leads to stable and crystalline isolable homocyclopropenylium salts.[1] The ion **1** thus obtained, the structure of whose hexafluoroantimonate has been confirmed by an X-ray structure analysis, shows temperature-dependent NMR spectra. In the ^{1}H-NMR spectrum, only three singlets are observed at $\delta = 1.10$ (9H, *t*Bu on C-4), 1.54 (27H, *t*Bu on C-1/2/3) and 4.60 (OH) at room temperature. On cooling, the signal at 1.54 becomes broader and finally splits at +1°C into two signals in the intensity ratio 2:1 (at −10°C: $\delta = 1.50$ and 1.58). The other two singlets remain unchanged.

1A 1B 1C

In the room-temperature ^{13}C-NMR spectrum of **1** only four signals are recorded, at $\delta = 29.3$ (CH_3, *t*Bu on C-4), 30.9 (CH_3, *t*Bu on C-1/2/3), 41.2 (quaternary, *t*Bu on C-4), and 101.2 (C-4). All other absorptions (C-1/2/3 and quaternary C of *tert*-butyl groups attached thereto) are hidden under these conditions because of poor signal-to-noise ratio as a result of exchange processes. Below +17°C, the signal for the *tert*-butyl groups on C-1/2/3 separates into two signals. In this temperature range, absorptions also gradually emerge for C-1/2/3 and the quaternary C-atoms of the *tert*-butyl groups attached thereto. At −20°C the expected spectrum could finally be observed: $\delta = 29.1$ (CH_3, *t*Bu on C-4), 30.6 (CH_3, *t*Bu on C-1/3), 31.3 (CH_3, *t*Bu on C-2), 34.9 (quaternary, *t*Bu on C-2), 38.1 (quaternary, *t*Bu on C-1/3), 40.9 (quaternary, *t*Bu on C-4), 101.0 (C-4), 161.5 (C-1/3), 184.9 (C-2).

The reversible changes in the spectra demand a dynamic process in which the olefinic ring positions in **1** are equilibrated, while C-4 and the substituents attached to it do not, however, experience any change. The simplest interpretation of this process is the occurrence of the walk rearrangement **1A** ⇌ **1B** ⇌ **1C**. From the coalescence temperatures (determinable on the signals of the methyl groups in the ^{1}H- and ^{13}C-NMR spectra; a measurement of the coalescence spectrum for C-1/2/3 and the neighboring C-atoms was not possible, owing to technical reasons and because of the instability of **1**) and the magnitude of the splitting in the low temperature spectra, an activation barrier of $\Delta G^+ \approx 15$ kcal/mol could be calculated for the observed rearrangement.

Such an isomerization is known in the case of methyl-substituted homocyclopropenylium salts.[2] Still unclear, but of particular interest,[3] is the stereochemistry of this reaction. According to theory[4] the rearrangement of the homocyclopropenylium ion **2** would violate the Woodward-Hoffmann rules. Of the two alternatives—**3** and **4** represent the corresponding eclipsed and bisected transition states, respectively—not the orbital symmetry allowed reaction via **3**, but the route via **4** with inversion at the migrating C-atom is to be expected. Accordingly, the substituents A and B would always retain their orientation. This prerequisite coincides with experiment, for the signals of C-4 and of the substituents on C-4 in the coalescence spectra remain sharp over the whole temperature range. Their chemical shifts likewise remain unaffected. The presence of equal amounts of the *endo-exo*-isomeric ions and a very rapid rearrangement into each other can therefore be ruled out. There remain three possibilities: a) Because of the size of the *tert*-butyl groups the "least-motion" process is favored. b) Ring inversion leads very rapidly to an *endo,exo* equilibrium that lies totally on the side of **1** (*endo-tert*-butyl group). c) An unusually strongly pronounced secondary orbital interaction[4] ensures that the Woodward-Hoffmann rules no longer hold in this instance. We consider the latter mentioned explanation not only to be the most attractive but also the most likely.

The above example can be compared with the Berson-Willcott rearrangement of norcaradienes, which, according to investigations by *Klärner* et al.,[5] likewise proceed contrary to the requirements of the rules of conservation of orbital symmetry with inversion at the migrating C-atom.

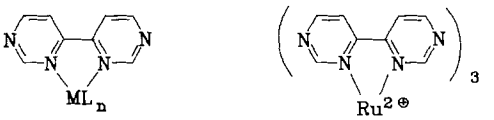
d^6-Metal Complexes of 4,4′-Bipyrimidine, an Ambident Ligand with High π-Acceptor Ability**

By *Sylvia Ernst* and *Wolfgang Kaim**

Owing to the importance of ligands of the 2,2′-bipyridine type **1** in inorganic and analytical chemistry[1a] and especially in the photochemistry of coordination compounds[1b] there have been numerous attempts at purposefully modifying this system. Besides the substitution at the heterocyclic rings[2a] and the enlargement of the α-diimine π-system,[2b] the incorporation of further nitrogen centers in **1** has recently also attracted interest;[3–5] coordination compounds of 3,3′-bipyridazine **2**,[3] 2,2′-bipyrazine **4**,[4] and 2,2′-bipyrimidine **5**[5] have been described in connection with the use of corresponding ruthenium(II) complexes as photocatalysts.[1b]



1 **2** **3** **4** **5**

We have now carried out Hückel MO calculations for all symmetrical bidiazines with α-diimine structure, including the remaining isomer 4,4′-bipyrimidine **3**.[6] Such calculations surprisingly revealed that the hitherto neglected[7] complex ligand **3** is the most π-electron deficient compound: $\varepsilon_{LUMO}^{HMO} = -0.583$ (**2**), -0.460 (**3**), -0.515 (**4**), and -0.518 (**5**).

In accordance with the specific properties of the pyrazine system,[8] 2,2′-bipyrazine **4** was considered to be a ligand with an especially low-lying π* level;[3,4] however, the π-acceptor activity expected to operate towards d^6 metal centers is compensated by the strongly reduced σ basicity of this 1,4-diazine ligand.[4b–d]

Since pyrimidines are stronger bases than pyrazines, we prepared **3** according to the method of *Effenberger*,[9a] found the pK_{a_1} to be 1.50 (pK_{a_1} (**4**) = 0.45[4c]), and were in fact able to establish a distinct red shift of the metal-to-ligand charge transfer (MLCT) absorptions for the chelate complexes **6**[9b] with tetracarbonylchromium, -molybdenum, and -tungsten and with ruthenium(II) fragments. Table 1 lists these data and some redox potentials; in Table 2, the tris(α-diimine)ruthenium(II) complexes of 2,2′-bipyridine and of the bidiazine series are compared.

[a] Measurements on bis(hexafluorophosphates) in acetonitrile. [b] Irreversible reduction [4d].

Intermediates could be isolated during the formation of complexes with the ambident, potentially bridging (N^1, $N^{1'}$) or chelate-forming (N^3, $N^{3'}$) ligand **3**. Thus, the primary coordination of photolytically generated $THF \cdot W(CO)_5$ initially takes place at the peripheral nitrogen centers N^1 and $N^{1'}$[9c] before a conversion into the chelate complex occurs [Reaction (1)].

Consistent with the HMO calculations, both the ligand **3** as well as its complexes exhibit markedly more positive reduction potentials than corresponding coordination com-

pounds of the ligands **1**,[4b] **2**,[3] **4**,[4b] and **5**;[4d] on the other hand, a comparison of the $Ru^{2\oplus}/Ru^{3\oplus}$ potentials (Table 2) indicates that **3** is a stronger σ-donor than **4**. The special position of the ligand **3** is nicely illustrated by the parameter $\Delta = E_{ox} - E_{red(1)}$, i.e. the difference between oxidation potential and reduction potential of tris(ligand)ruthenium(II) complexes, which correlates with the long-wavelength charge-transfer absorption (Table 2). In the case of **6e** there is only a difference of 2.32 V, whereas for all other complexes $\Delta = 2.62 \pm 0.04$ V.

In accord with the cyclovoltammetrically observed reversibility of the first electron uptake, the respective radical reduction products of all the 4,4′-bipyrimidine complexes described here can be generated and characterized by ESR spectroscopy.[10] In the case of compound **3d**, the partially resolved ESR spectrum of a reduced polyazineruthenium(II) complex could be obtained for the first time (Fig. 1, A). Because of the correlation between MLCT excited and reduced states of such systems (one unpaired electron in the ligand π* orbital) the formulation of such radical complexes was the subject of several studies,[11] in which ESR line-broadening caused by rapid exchange according to reaction (2) was postulated for singly reduced tris(ligand) complexes.[11b]

Due to the vastly different reduction potentials of **1** and **3** (Table 2), the unpaired electron in the reduced mixed complex $\mathbf{6d}^{\odot\ominus}$ is localized almost entirely in the π system of the bipyrimidine (Fig. 1, A and B). However, the ESR line width remains relatively large when compared to the better resolved spectrum of the tetracarbonylmolybdenum complex radical (Fig. 1, C), presumably as a result of the superposition of numerous small and unresolved hyperfine couplings with the protons and ^{14}N nuclei of the 2,2′-bipyridine ligands.[12]

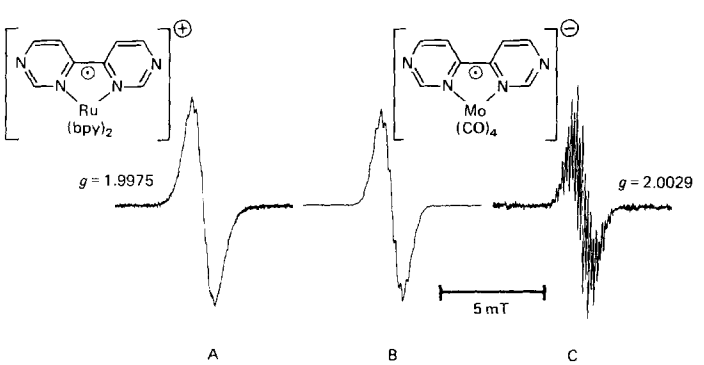

Fig. 1. Room temperature ESR spectra of the reduced complex $\mathbf{6d}^{\odot\ominus}$ in acetonitrile (A) and of the tetracarbonylmolybdenum radical complex $\mathbf{6b}^{\odot\ominus}$ at low (B) and high resolution (C) in THF. The similarity between A and B implies a localization of the unpaired electron in the π-system of the 4,4′-bipyrimidine, in accord with the formulation $[Ru^{2\oplus}(\mathbf{1})_2(\mathbf{3}^{\odot\ominus})]^{\oplus}$. Counterions $ClO_4^{\ominus}$ ($\mathbf{6d}^{\odot\ominus}$), $K^{\oplus}$ ($\mathbf{6b}^{\odot\ominus}$), modulation amplitudes 0.02 (A, C), 0.3 mT (B).

Undoubtedly, the ruthenium(II) complexes **6d**,**e** are distinguished by their ready reducibility (Tables 1 and 2); comparable effects have otherwise only been achieved after using ligands with a substantially larger π-system.[2b] Photochemical and photophysical investigations should therefore furnish information about the suitability of these complexes as photocatalysts; in any case, the 4,4′-bipyrimidine represents a relatively small but particularly π-acidic α-diimine ligand.

Synthesis and Structure of New Potassium-Gold-Tellurium Polyanions: $[KAu_9Te_7]^{4\ominus}$, $[K_2Au_4Te_4(en)_4]^{2\ominus}$, and $[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]^{2\ominus}$

By *Robert C. Haushalter**

In the Au–Te binary system, one congruently melting compound is known, $AuTe_2$,[1] as well as the minerals calverite[2] and krennerite[3] (both $AuTe_2$) as a thermally metastable mineral montbrayite, Au_2Te_3.[4] Apparently, the only structurally characterized synthetic Au–Te compounds are the gold(III) chalcogenide halides AuTeI[5] and $AuTe_2X$ (X = Cl, Br, I).[6] However, several thioaurates like $[AuS_9]^{\ominus}$,[7] $[Au_2S_8]^{2\ominus}$,[8] and $[Au_{12}S_8]^{4\ominus}$[9] have recently been characterized. We have now obtained several novel K–Au–Te polyanions from the extraction of ternary K–Au–Te alloys. In this report, we describe the structures of the following salts:

$[Ph_4P]_4[KAu_9Te_7]$ **1**

$[Ph_4P]_2[K_2Au_4Te_4(en)_4]$ **2**

$[Ph_4P]_2[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]$ **3**, dmf = dimethylformamide

During our investigation of ternary K–Au–Te alloys, we have prepared a yellow-brown material of nominal composition K_3AuTe_2, **4**, by heating a 5% excess of K with $AuTe_2$. Whereas K_3AuTe_2 dissolves readily in deoxygenated water, methanol solutions give a black precipitate on standing. However, if **4** is treated with methanol in the presence of Ph_4PBr, an orange crystalline precipitate, **5**, is immediately obtained. Dissolution of **5** in dimethylformamide (DMF), followed by dilution with additional Ph_4PBr in methanol, gives two products: red, triangular plates of **1** and red prisms of **3**.

The structure of the anion in **1**, viewed almost parallel to the pseudo threefold axis containing the unique Te and K, is shown in Figure 1 and can be approximately described as a derivative of an $[M_{12}X_8]^{4\ominus}$ cube, with one corner and three edges missing.[10] The structure of the intact thiocubanes $[M_{12}S_8]^{4\ominus}$ are known for M = Au[9] and Cu.[11] The Au_9Te_7 skeleton in the anion of **1** is distorted from a fragment of a perfect cube by compression along the pseudo threefold axis containing the unique Te and the missing corner. This compression is apparently due to a bonding interaction among the Au centers. Except for two longer contacts (367 and 338 pm), the Au–Au distances within the Au_3 triangles range from 303.9(2) to 322.1(2) pm with an average distance of 313 pm. These can be compared to Au–Au distances[12] of 288 pm in Au metal and 363 pm for the contacts in a hypothetical $[Au_{12}Te_8]^{4\ominus}$ cube with an Au–Te distance of 257 pm. The Au–Au distances between the Au_3 triangles are much longer with an average distance of 389 pm. The nine Te–Au–Te angles are close to 180° (range 173° to 180°, average 176°) as expected for Au^{I}. The compression of the cubic fragment is also reflected in the Au–Te–Au angles which fall into two groups: a) those involving the three Te atoms capping the Au_3 triangles, which are less than 90° (average angle = 77°), and b) the remaining Te atoms with average Au–Te–Au angles greater than 90° (average = 99°).

An interesting feature of the anion in **1** is the $K^{\oplus}$ imbedded in the cluster. This atom was identified as $K^{\oplus}$ as follows: 1) X-ray fluorescence analysis of **1** indicated the presence of K; 2) the observed charge of $4\ominus$ ($9\,Au^{\oplus} + 7\,Te^{2\ominus} + K^{\oplus}$); 3) satisfactory refinement of the thermal parameters, using values for K, in the X-ray data refinement. As observed in the only other structurally characterized K–Au–Te clusters, **2** and **3** (vide infra), the K–Au distances are shorter than the K–Te distances, which could be due to the fact that Au is more electronegative than Te (2.4 vs. 2.1).[13] The average of the nine K–Au contacts (364 pm) is longer than the average in the anions in **2** or **3** (359 and 349 pm, respectively) or the distances in K–Au intermetallic compounds like KAu_5,[14] which has K–Au contacts of 327 and 364 pm. $K^{\oplus}$ appears too large to be encapsulated by an intact $[Au_{12}Te_8]^{4\ominus}$ cube based on the observed Au–Te and K–Au distances.

In the solid state, the tetragonal compound CsAuO[15] has been prepared by the oxidation of CsAu. The important structural unit in CsAuO is an eight-membered $[Au_4O_4]^{4\ominus}$ ring, which is constrained to be exactly square-planar by the space group $I\bar{4}$ in which the structure was

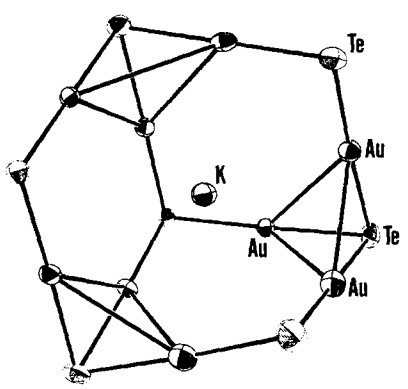

Fig. 1. Structure of the anion $[KAu_9Te_7]^{4\ominus}$ in **1** [10].

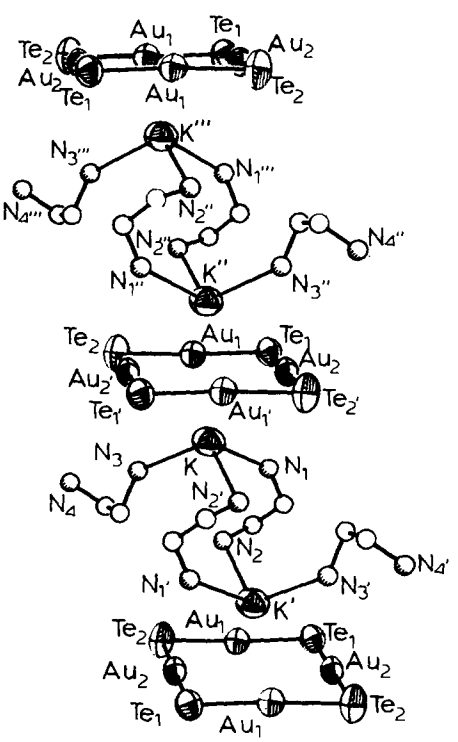

Fig. 2. Structure of the anion $[K_2Au_4Te_4(en)_4]^{2\ominus}$ in **2** [10].

Exxon Research and Engineering Company
Annandale, NJ 08801 (USA)

solved. We have found planar $[Au_4Te_4]^{4\ominus}$ rings, capped by $K^{\oplus}$ on each face, in the compounds **2** and **3**, which were prepared by the extraction of ternary K–Au–Te alloys.

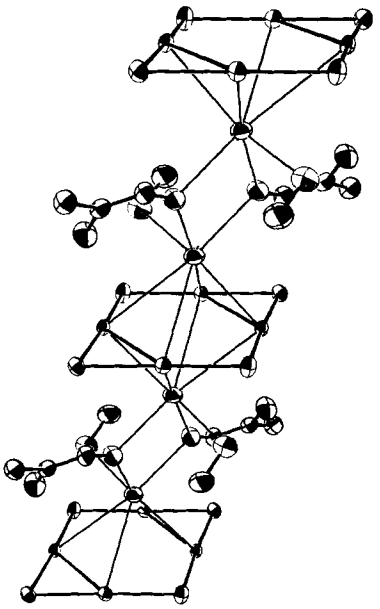

Fig. 3. Structure of the anion $[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]^{2\ominus}$ in **3** [10].

Compound **2** was prepared in high yield by dissolving the alloy KAuTe (prepared from the fusion of equimolar amounts of K and a melt of nominal composition AuTe) in ethylenediamine (en) followed by treatment with Ph_4PBr in ethylenediamine, while **3** forms as a coproduct in the synthesis of **1**. Both compounds are dark red.

Compounds **2** and **3** crystallize in the triclinic space group $P\bar{1}$[10] and exhibit similar unit cell packings. The structures of the anions in **2** and **3** are shown in Figures 2 and 3, where the similarities of the structures are obvious. Both consist of planar $[Au_4Te_4]^{4\ominus}$ rings to which two $K^{\oplus}$ ions are coordinated on opposite faces. Solvent molecules, which occupy two of the $K^{\oplus}$ coordination sites, either en in **2** or DMF in **3**, bridge the $[K_2Au_4Te_4]^{2\ominus}$ moieties into one-dimensional strings. A third $K^{\oplus}$ coordination site is occupied by en in **2** or CH_3OH in **3**. As observed in $[KAu_9Te_7]^{4\ominus}$, the shortest potassium-metal contacts are the K–Au, not the K–Te distances. The coordination mode of K to Au is slightly different in **2** and **3**. In **2**, the four K–Au contacts are approximately equal (346.3, 350.1, 343.2, 351.3 pm), whereas in **3** there are two longer (387.4, 387.3 pm) and two shorter contacts (351.2, 348.3 pm). In CsAuO, KCuO,[16] and KAgO,[17] the K–O contacts are much shorter than the K–M (M = Au, Ag, Cu) distances as expected.

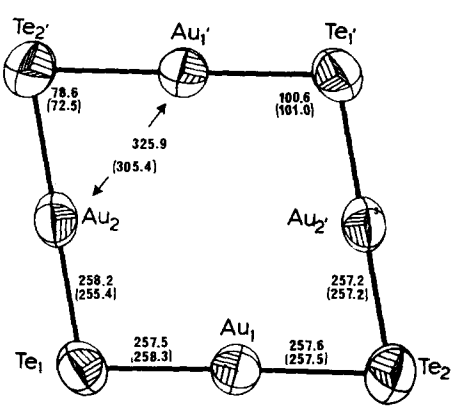

Fig. 4. Distances [pm] and angles [°] in the $[Au_4Te_4]^{4\ominus}$ rings in **2** and **3**. The values in parentheses are those of **3**.

Unlike the $[M_4O_4]^{4\ominus}$ rings in CsAuO[15] or KAgO,[17] which are perfect squares, the $[Au_4Te_4]^{4\ominus}$ rings in **2** and **3** have a rhombohedral distortion (Fig. 4). Presumably this distortion is due to the pairwise attractive interaction between the Au atoms and results in a pair of short Au–Au contacts and a pair of longer non-bonding contacts in both structures.

Synthesis and Structure of New Hg–Te Polyanions: $[Hg_4Te_{12}]^{4\ominus}$, a Cluster Containing $Te^{2\ominus}$, $Te_2^{2\ominus}$, and $Te_3^{2\ominus}$ Ligands and $[Hg_2Te_5]^{2\ominus}$, a New One-Dimensional Inorganic Polymer

By *Robert C. Haushalter**

The binary compounds HgX (X = S, Se, Te) are known to have extremely low solubilities in aqueous solutions. Al-

[*] Dr. R. C. Haushalter

though it is possible to solubilize HgS in the presence of $S^{2\ominus}$,[1] apparently only one structurally characterized binary tellurium compound, $[HgTe_2]^{2\ominus}$, has been isolated and structurally characterized.[2] We would like to report the syntheses and structural characterization of **1** and **2** from the extraction of ternary K–Hg–Te alloys with ethylenediamine (en).

$[n\mathrm{Bu_4N}]_4[Hg_4Te_{12}]$ **1** $[PPh_4]_2[Hg_2Te_5]$ **2**

The only previously known HgTe anion is contained in the yellow [crypt·K]$_2$[$HgTe_2$], which was prepared by the extraction of an alloy of composition KHgTe with ethylenediamine. The alloy KHgTe was prepared by quenching a sealed tube initially containing equivalent amounts of K, Hg, and Te at 600 °C. We have observed that, under 1 atmosphere of helium, Hg boils out of a melt of nominal composition $K_2Hg_2Te_3$ (prepared from the fusion of 1.5 equivalents of Te with KHg), at temperatures well below 600 °C. It was necessary, therefore, to keep the temperature of the melt below the boiling point during the synthesis of K–Hg–Te alloys in order to prepare compositions richer in Hg than K_2HgTe_2.

Unlike KHgTe, which is reported to give yellow ethylenediamine solutions, the alloy $K_2Hg_2Te_3$ dissolves in ethylenediamine to give very dark brown-orange solutions. Treatment of these dark extracts with solutions of $n\mathrm{Bu_4NBr}$ in methanol (MeOH) furnishes dark brown **1** in high yields. **1** was identified by elemental analysis[3] and a single-crystal X-ray structure determination.[4]

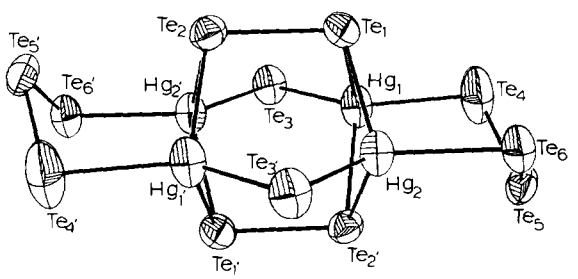

Fig. 1. The structure of the $[Hg_4Te_{12}]^{4\ominus}$ anion in **1** [4].

1 contains the novel $[Hg_4Te_{12}]^{4\ominus}$ anion which resides on a crystallographic inversion center (Fig. 1). The four Hg atoms, which are coplanar, are coordinated in a distorted tetrahedral fashion to an array of two $Te^{2\ominus}$-, two $Te_2^{2\ominus}$-, and two $Te_3^{2\ominus}$-ligands. There are no Hg–Hg bonds, as the nearest contacts are 394 pm (Hg1–Hg2) and 370 pm (Hg1–Hg2'). The Hg–Te bond lengths fall into two groups: shorter distances involving Hg to two-coordinate Te (270.6 to 277.6, average = 273.7 pm) and longer distances from Hg to three-coordinate Te (292.5 to 298.3, average 295.4 pm). These Hg–Te distances can be compared to those found in [crypt·K]$_2$[$HgTe_2$][2] (258.9 pm) and in [HgTe][5] (279 pm).

During the refinement of the X-ray data, it was observed that there is some disorder in the $Te_3^{2\ominus}$-ligand. The central Te atom (Te5) in the $Te_3^{2\ominus}$-ligand refined to an occupancy factor of ~75% while the remaining electron density (~25% of that expected for Te) was located along the line connecting Te4 and Te6. A possible explanation may be that a $Te_2^{2\ominus}$-ligand occupies the position of the $Te_3^{2\ominus}$-ligand ~25% of the time.

Using the cation $PPh_4^{\oplus}$ instead of $Bu_4N^{\oplus}$ has allowed us to isolate a different Hg–Te polyanion, $^1_\infty[Hg_2Te_5]^{2\ominus}$, a new one-dimensional inorganic polymer. Several examples of one-dimensional tellurium-containing polyanions have recently been structurally characterized. These include ternary systems such as K_2SnTe_5,[6] $LiGeTe_2$,[7] and K_2GeTe_4,[8] and binary systems like Rb_2Te_5[9] and Cs_2Te_5.[10] The ternary materials contain tetrahedral atoms bridged by Te atoms,[6–8] while Rb_2Te_5 and Cs_2Te_5 contain two variants of the $^1_\infty[(Te_4Te_{2/2})]^{2\ominus}$ chain.[9, 10]

2 was prepared from the same ethylenediamine extract, of an alloy of nominal composition $K_2Hg_2Te_3$, used for the preparation of $[Hg_4Te_{12}]^{4\ominus}$. Compound **2** forms black, spear-shaped needles with curved crystal faces, when the aforementioned $K_2Hg_2Te_3$ solution and an ethylenediamine solution of PPh_4Br are allowed to diffuse slowly (3 weeks) into each other in an H-tube.

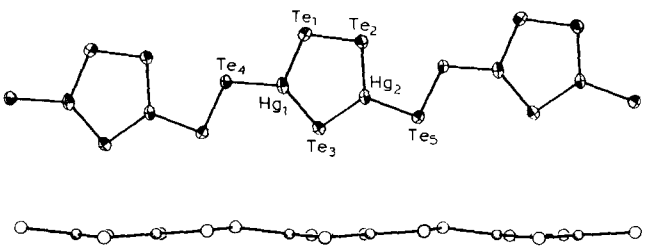

Fig. 2. Top: Structure of three repeat units of the polymeric anion $^1_\infty[Hg_2Te_5]^{2\ominus}$ of **2** [4]. Bottom: An edge-on view of the same structural unit.

The X-ray structure analysis of **2** shows that the new polymeric anion $^1_\infty[Hg_2Te_5]^{2\ominus}$ runs in one-dimensional strings parallel to the crystallographic *a* axis (Fig. 2, top). The anion chain is approximately planar (Fig. 2, bottom).

In **2**, the two crystallographically independent Hg atoms have essentially trigonal planar environments with Hg1 10 pm out of the Te1, Te2, Te3 plane and Hg2 50 pm from the Te2, Te3, Te5 plane. Although rare, other examples of species containing trigonal planar coordinated Hg atoms are known, such as $Hg_3O_2Cl_2$[11] and $(Me_3S)[HgI_3]$.[12] The average of the six Hg–Te distances in **2** is 271 pm, which can be compared to the average of the Hg to two-coordinate Te contacts in $[Hg_4Te_{12}]^{4\ominus}$ (274 pm) or the short Hg–Te distance in $[HgTe_2]^{2\ominus}$ of 259 pm. The Te–Te distances are similar to those found in many other polytellurides. The chains of $^1_\infty[HgTe_5]^{2\ominus}$ are isolated from one another in **2** by $Ph_4P^{\oplus}$ cations and there are no interchain contacts.

It should be noted that the structures of $^1_\infty[Hg_2Te_5]^{2\ominus}$ and $[Hg_4Te_{12}]^{4\ominus}$, which were prepared by extracting the same starting alloy, are somewhat related. The five-membered Hg_2Te_3 ring, with two Te atoms exocyclic to the Hg atoms, is present in both $[Hg_4Te_{12}]^{4\ominus}$ and $^1_\infty[Hg_2Te_5]^{2\ominus}$. Thus, $[Hg_4Te_{12}]^{4\ominus}$ is a face-to-face dimer of the repeat unit of $^1_\infty[Hg_2Te_5]^{2\ominus}$ with two additional Te atoms present per dimer.

BOOK REVIEWS

Cyclophanes, Vols. 1 and 2. Edited by *P. M. Keehn* and *S. M. Rosenfeld,* Academic Press, New York 1983. Vol. 1: xxx, p. 1—358, bound, $ 65.00, ISBN 0-12-403001-7/Vol. 2: xxx, p. 359—725, bound, $ 60.00, ISBN 0-12-403002-5.

This set appears as part of the excellent series of monographs chosen by its editor *H. H. Wasserman*. There may be an *embarras de richesse* in updating reviews of the chemistry of cyclophanes (a series edited by *F. Vögtle* comprising two volumes, albeit smaller, has recently appeared) but the present set is more encyclopedic.

The editors have done a fine job in choosing authors and in parcelling out the vast material to be covered. Inevitably there is some overlap but this is surprisingly minimal. I agree with the editors' claim that each chapter stands on its own. The set opens with a charming chapter by the father of the field; *Don Cram*'s personal account is a short overview, past, present, and future. The other chapters either emphasize synthesis and reactions, or properties and structure, or, in the best ones, there is a blend of the two. The more synthetic chapters are by *Rosenfeld* and *Chloe* ([n]cyclophanes, 46 pages), *Reiss* (condensed cyclophanes, 41 pages). *Hopf* (multibridged cyclophanes, 51 pages), *Misumi* (multilayered cyclophanes, 55 pages). Those emphasizing properties and structure are by *Liebman* (the conceptual chemistry of cyclophanes, 45 pages), *Keehn* (the crystal structure of cyclophanes, 169 pages), *Mitchell* (NMR properties and conformational behavior of cyclophanes, 71 pages). The chapters that, to my taste, blend all aspects and are thus the most useful in giving the reader an overall review before consulting the primary literature are those by *Paudler* and *Bezoari* (synthesis and properties of heterophanes, 82 pages) and *Itô, Fujise,* and *Fukuzawa* (non-benzenoid cyclophanes, 35 pages). Biological applications are given in two chapters by *Odashima* and *Koga* (cyclophanes in host-guest chemistry, 49 pages), and by *Sutherland* (cyclophanes as synthetic analogs of enzymes and receptors, 46 pages). The first doesn't touch upon, the second emphasizes crown ether hosts.

I have a bone to pick with *Don Cram*'s statement: "It seems that the selection of certain research problems is dominated by a subliminal aesthetic judgment." Subliminal indeed! There is little doubt that symmetry motivates many chemists in their choice of subject, in full awareness, explicitly.

Liebman's excellent chapter covers chemical concepts which have been clarified through cyclophane chemistry. *Keehn*'s very useful chapter includes a wealth of structural information accompanied by general explanatory comments. *Mitchell*'s chapter is not as exhaustive but clearly shows how NMR techniques have been used to assign rigid stereochemistry or conformation in mobile systems. *Rosenfeld* and *Chloe* include the variegated approaches for synthesis of [n]cyclophanes. *Paudler* and *Bezoari* do a good job in covering all aspects of heterophane chemistry but *Reiss* covers only synthesis of condensed benzenoid cyclophanes. Although he mentions in telegraphic style, e.g., that electronic spectra have been measured, his omission of more detail gives short shrift to important aspects of the work of *Staab* and his group. On the other hand, the *Itô* et al. chapter, albeit shorter, covers non-benzenoid cyclophanes in a much better way following *Hamlet*'s invocation: "There are more things in heaven and earth, Horatio, than are dreamt of in your philosophy." *Reiss* can learn from this. *Hopf*'s chapter, though essentially synthetic, is a gem in its general approach and pedagogic clarity. *Misumi*'s chapter covers his subject's manifold aspects. Both biochemical chapters are excellent, well-coordinated reviews with no unnecessary overlap between them.

Many of the authors (and the editors who did not correct them) do not know that one converts **52** into **51**, not to **51**. It is amusing to note that the Japanese authors (or those who do not describe synthetic steps) do not err in this respect; they do not use the word in their constructions.

This set on cyclophanes is a must in every library; even those suffering from the steep rise in Journal prices would be well advised to buy them, as would all wealthy individuals interested in the subject.

David Ginsburg [NB 667 IE]
Technion—Israel Institute of Technology, Haifa

Chemical Dynamics via Molecular Beam and Laser Techniques. By *R. B. Bernstein*. Oxford University Press, Oxford 1982. ix, 362 pp, paperback, £ 10.95.

This book is based on the Hinshelwood lecture series delivered by the author in Oxford in 1980. An introductory discussion of problems of reaction dynamics is followed by treatment of the following topics: The connection between reaction cross section and rate constant, the principle of microscopic reversibility, jet stream properties,

state-specific excitation and detection of educt and product molecules by laser and electrical multipole techniques, potential models for elastic and inelastic scattering and the classical deflection function, "glory" and "rainbow" effects, the concept of the scatter phase in the quantum theory of elastic scattering, reactive scattering problems such as product angular distributions in the laboratory and center of mass systems in complex and direct reactions, "opacity" (reaction probability as a function of the impact parameter) and "excitation functions" (reaction cross section as a function of collision energy), orientation effects, the influence of vibrational, rotational, and translational excitation on reaction velocity, and nonadiabatic (proceeding by various electronic potential surfaces) reactions. The text ends with a section covering the author's own field, the information-theoretical analysis of chemical dynamics and a survey of promising new fields such as the spectroscopy of transition states and the laser analysis of catalytic effects.

Such an enormous range of material can only be discussed in highlights in the space of 360 paperback pages. Exceptions, for example an interesting and detailed calculation for the determination of the degree of excitation of particles in molecular beams by laser techniques, only prove the rule. Thus, *Bernstein*'s book provides (aside from its price) a welcome guide for the rather confused student through the flood of specialized texts in this field.

Biotechnology. A Comprehensive Treatise in 8 Volumes. Edited by *H. J. Rehm* and *G. Reed*. Vol. 5: **Food and Feed Production with Microorganisms.** Edited by *G. Reed*. Verlag Chemie, Weinheim 1983, 631 pp., bound, DM 425. ISBN 3-527-25767-5.

This series[*] from Verlag Chemie is a welcome addition to the repertoir of resources for people in the biotechnology and allied fields. Volume 5, in some respects, continues where Volume 3 left off in the area of food related fermentations. One should look to Vol. 3 for the production of ethanol, bakers' yeast, edible mushrooms, starter cultures, acetic acid, citric acid, gluconic acid, lactic acid, amino acids and extracellular polysaccharides—all food related topics. This underlines one of the problems the editors must have faced in organizing the series. I would just caution the reader that this Volume alone will not cover the area described by its title.

It begins with a contribution by *G. Spicher*, who presents a thorough discussion on the technology of baked goods, in particular bread. *S. Lafon-Lafourcade* gives an excellent review of the science of wine and brandy production. She has included some fine photomicrographs of the yeast and bacteria involved. This chapter however, like several others in this volume, does not emphasize the commercial aspects such as production technology, economics, and regulatory information. Nevertheless, what is covered is covered well. Later on in this volume is included a discussion on distilled beverages other than brandy, i.e., whiskey, rum, vodka, tequila by *L. Bluhm*.

W. A. Hartwick describes the technology of beer including its history in a very readable chapter. The next two chapters relate to the dairy industry. *E. R. Vedamuthu* and *C. Washam* deal with cheese technology. The chapter appears to be not well integrated. For example, the involvement of microorganisms and enzymes is discussed twice in the chapter. Despite this, the chapter has a lot of good information including excellent summaries of changes occurring during the manufacture of seven different kinds of cheeses.

A very fine review of the technology of yogurt production and of lactic acid bacteria in fermented dairy products is given by *V. Bottazzi*.

The importance of lactic acid bacteria in food biotechnology is recognized through two additional chapters. One on cabbage and cucumbers *(J. R. Stamer)* and the other on olives *(M. J. Fernández Díez)*.

Starter cultures in sausage and ham production are discussed by *H.-U. Liepe*. The emphasis here is on the use of starter cultures and not on the production of the cultures. *H. Ebner* and *H. Follmann* continue their chapter on acetic acid from Vol. 3 by focussing on how raw vinegar is treated before sale. Regulatory aspects are also reviewed.

A commendable addition to the selections in this volume is made by *L. R. Beuchat* via a presentation on "Indigenous Fermented Foods". This one provides you with a chance to learn about the real "classical biotechnology" as practiced for centuries the world over. A good review of the literature on cocoa fermentation, with a somewhat sloppy section on page 556, is presented by *D. W. Lehrian* and *G. R. Patterson*. The Volume is concluded with three short chapters. These provide introductions to the manufacturing of tea *(G. W. Sanderson)*, coffee fermentation *(J. Castelein* and *H. Verachtert)*, and of fermented feeds and feed supplements *(H. J. Peppler)*. I would have preferred to see a greater consistency in the emphasis and orientation from one chapter to another, a better coverage of regulatory issues, of economic issues and of manufacturing and engineering aspects. The subjects of single cell protein for both food and feed production and solid state fermentations for feed production could have been covered here. However, the editors have a very difficult job and it seems to me they have succeeded in bringing together a great deal of useful information in this third volume released.

Enzymes Hosted in Reverse Micelles in Hydrocarbon Solution

By Pier Luigi Luisi*

Reverse micelles are spheroidal aggregates formed by certain surfactants in apolar media. In contrast to normal micelles in water, the polar head groups of the surfactant molecules are directed towards the interior of the aggregate and form a polar core which can solubilize water (the "water pool"); the lipophilic chains are exposed to the solvent. The water of the water pool exhibits properties that (depending on the mole ratio of water to surfactant) differ from those of bulk water. Surprisingly, these reverse micelles are able to solubilize in hydrocarbon solvents hydrophilic molecules, e.g., enzymes and even plasmids, that are much larger than the original water-pool diameter. These biopolymer-containing reverse micelles can be viewed as novel microreactors, whose physical properties can be controlled through the water content. Remarkable is the ability of enzyme-containing micelles to react with water-insoluble, hydrocarbon-soluble substrates, as in the example of lipoxygenase with linoleic acid.

1. Introduction

This review presents the work carried out over the last few years on enzymes solubilized in apolar solvents with the help of reverse micelles. The basic properties of reverse micelles will be described first, followed by a discussion of the physical and chemical properties of enzymes solubilized in reverse micelles.

Some common surfactants that form such aggregates in apolar solvents are summarized in Table 1. As is well known, other types of aggregates can be found in aqueous solution,[1] such as bilayers, vesicles, and liposomes; these, however, will not be considered here. Figure 1 gives an idea of the structure of normal (aqueous) and reverse micelles, as well as of the surfactant AOT, which has been mostly used in our studies. Most important is the fact that reverse micelles exhibit relatively ordered structures, characterized by a definite (although average) radius, molecular weight, and packing density. Micelles are an ideal subject of investigation for those chemists who are interested

Table 1. Aggregation of amphiphilic molecules in hydrocarbon solvents. n = average aggregation number [a].

Amphiphilic molecule	Solvent	T [°C]	Conc. range [wt.-%]	n
dodecylammonium propionate	benzene	25	0.09–0.21	3
dodecylammonium propionate	cyclohexane	20	0.023–0.034	5
dodecylammonium benzoate	benzene	25	0.20–0.33	3.6
dodecylammonium benzoate	cyclohexane	20	0.8–3	3.6–9

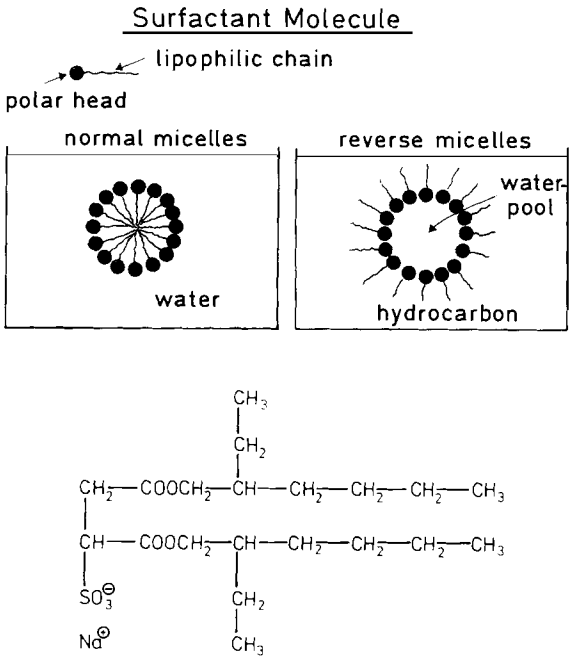

Fig. 1. An idealized representation of normal (aqueous) and reverse micelles in cross section. The structure of sodium 1,2-bis(2-ethylhexyloxycarbonyl)-1-ethanesulfonate (AOT) is also shown. Typical conditions for reverse micelles: isooctane (2,2,4-trimethylpentane), 25—100 mM AOT, 0.5—2% water. Reverse micelles are fairly monodisperse, dynamic aggregates, which can solubilize relatively large (ca. 10%) amounts of water. For mole ratios $w_0 = [H_2O]/[AOT] \gtrsim 7$, the term microemulsion should be used (see text).

in the spontaneous formation of ordered structures. Figure 1 should not, however, convey the idea that micelles are rigid structures: on the contrary, they are characterized by several dynamic processes.[2-4] For example, one important characteristic of reverse micelles is their coalescence upon collision.[4] This is assumed to take place through a "transient dimer" having a communication channel that permits rapid exchange of material. This is illustrated in Figure 2, along with the significance of this phenomenon for the enzymatic activity cycle (see Section 4).

Of considerable importance is the interaction of reverse micelles with water. Due to their polar core, reverse micelles can solubilize water in apolar solvents. This solubilized water is usually referred to as a "water pool".[2]

The reverse micelles formed by sodium 1,2-bis(2-ethylhexyloxycarbonyl)-1-ethanesulfonate (AOT) will now be considered more closely. The system we will mostly be dealing with is AOT/isooctane/water. An important parameter is the molar ratio of water to surfactant, $w_0 = [H_2O]/[AOT]$. This ratio, more than the absolute amount of water or surfactant present in the hydrocarbon solvent, determines most of the structural and physical properties of reverse micelles.[1,5,6] The water in the water pool is partly "bound" to the polar wall, and is relatively "free" only above a certain critical concentration. In the case of AOT, it appears that the molecules of water up to perhaps $w_0 = 6-8$ are tightly bound to the head groups of the surfactant[6,7] and that only above this value does "free water" exist in the water pool. In fact, reverse micelles swell when the water content increases.[5,6] Figure 3 (solid line)[5,6] illustrates this phenomenon with enzymes as guest molecules (see Section 3).

Particularly at low w_0 values, where the micelles are smaller and a relatively high amount of water is bound to

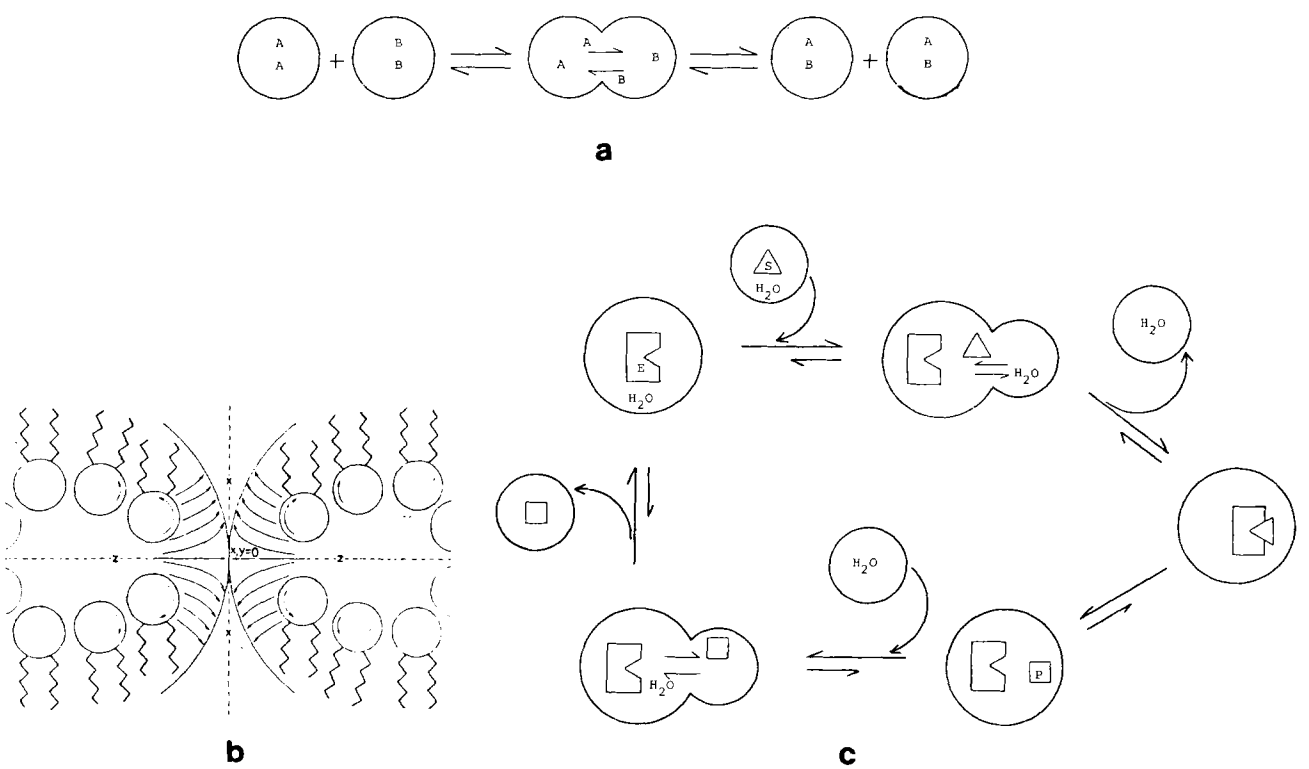

Fig. 2. Dynamic properties of reverse micelles. a) Exchange of materials between two reverse micellar solutions, which is the prerequisite for the reaction between A and B (from [2]). Coalescence between micelles and exchange of reagents takes place through a transient dimer, a concept elaborated by *Eicke* et al. [4a]. b) Schematic representation of the site of contact of two reverse micelles prior to coalescence (from [4a]). c) The proposed steady-state cycle of an enzymatic reaction in reverse micelles (from [24]).

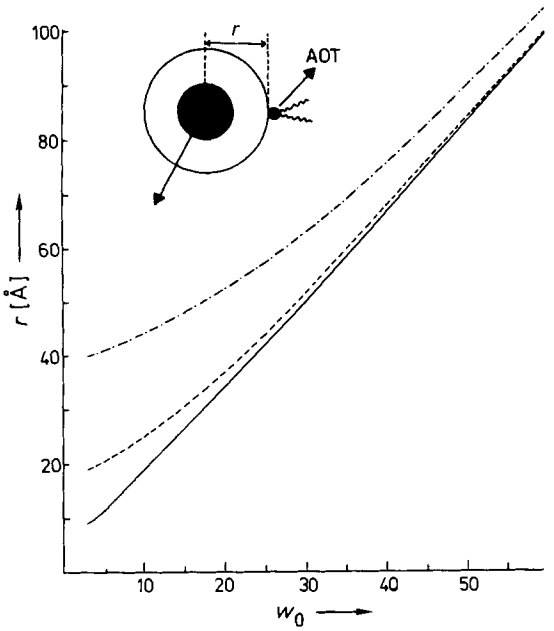

Fig. 3. The radius r of the AOT reverse micelles as a function of $w_0 = [H_2O]/[AOT]$. (—): "empty" micelles, i.e., micelles containing only water. This curve corresponds to the data of *Eicke* et al. [5, 6] (from [24]). (– – –): protein = ribonuclease (RNase); (– · –): protein = liver alcohol dehydrogenase (LADH). All data in this figure and in the following figues refer to room temperature if not otherwise stated.

the micelle walls, water in reverse micelles behaves "anomalously"—i.e., its physical properties are somewhat different from those of bulk water.[8–10] With increasing water content, the physical properties of the water pool asymptotically approach those of pure water. However, even at relatively large w_0 values, small differences may remain.

The w_0 region where water becomes free is usually taken as the dividing line between micelles and microemulsions. Microemulsions can indeed be visualized as distinct droplets of water in oil (hydrocarbon), whereas micelles form a homogeneous system, the water being used only to solvate the surfactant molecules. This distinction is usually disregarded since we generally study a large w_0 range and it would be too confusing to switch nomenclature depending upon the w_0 value—furthermore, the dividing line is not so clear. However, the difference between micelles and microemulsions should be kept in mind, because the physical properties of the system (e.g., mass transport, dynamics, reactivity and structure of guest molecules) may be different in the two w_0 ranges.

The discussion above suggests that the reactivity and conformation of biopolymers solubilized in reverse micelles changes as a function of the micellar parameters, in particular as a function of w_0. Since, with increasing w_0, the physical properties of the water pools approach those of the bulk water, the enzyme-containing micelle can be viewed as a microreactor, whose physical properties can be continuously changed by simply regulating the amount of water present in the micellar system. These new biopolymer aggregates may be of biotechnological use and may provide chemists with some basic information about the interaction of proteins with water and with membrane-like surfaces.

2. Experimental Problems

Figure 4 shows the three techniques that have been applied until now to prepare enzyme-containing micellar solutions. The first method (Fig. 4a) is the one we first used in our group for peptides[11,12] and defined as the "phase transfer" method. According to this method, the protein is present initially in an aqueous solution, which is covered with a layer of the micellar solution of AOT. Upon gentle stirring, a part of the protein is slowly transferred from the aqueous phase into the hydrocarbon phase (the process can be followed spectrophotometrically, for example at 280 nm). This method is relatively slow, but has the advantage that the final system is in thermodynamic equilibrium and the final hydrocarbon micellar solution, containing the biopolymer, is generally stable. This point is better understood if one compares the phase transfer method with the so-called injection method (Fig. 4b), whereby a few microliters of the concentrated stock solution of the protein are injected into the hydrocarbon solution of AOT (no sonication is used in this or in the other solubilization methods). If the hydrocarbon solution becomes oversaturated with protein, so that the micellar solution is metastable, a decrease of the protein absorption with time might be observed, which is indicative of protein precipitating out of the micellar system. However, the method is so fast and simple that it has become the method of choice. In most cases, we have been able to obtain stable micellar solutions of the proteins up to $w_0 = 5-30$ by simply injecting an aqueous stock solution of the protein in the pH range 7—10 into the hydrocarbon solution of the surfactant at room temperature.

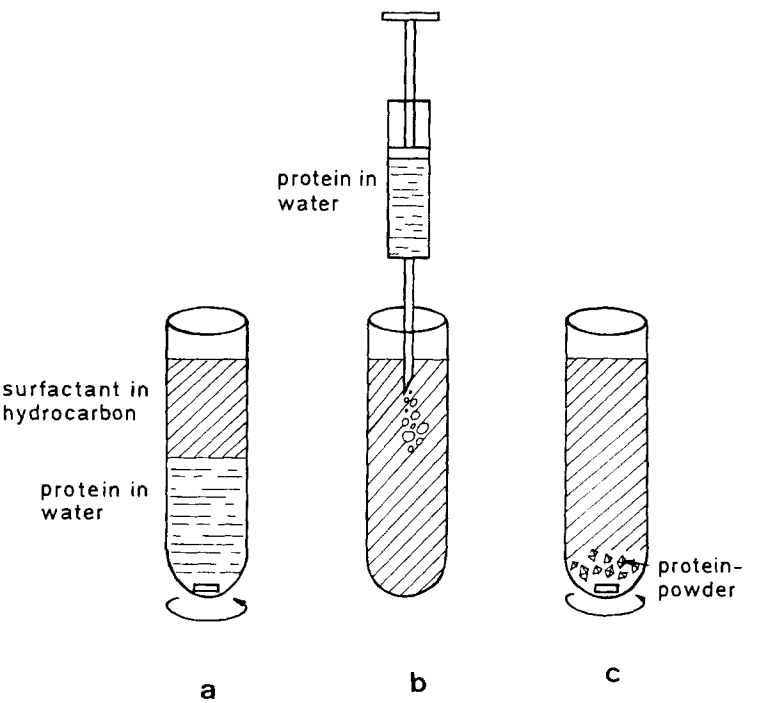

Fig. 4. The three methods used up to now to solubilize proteins in reverse micelles: a) "phase transfer" method; b) the most commonly used "injection method"; c) method for water-insoluble proteins.

Generally, it is important to characterize the stability domain of the protein-containing reverse micellar system. A simple, relatively rapid way to accomplish this is shown in Figure 5, which shows the regions of temperature and of water content in which the enzyme micellar system is thermodynamically stable. We usually do not work with micellar solutions of proteins unless they are completely transparent; an operative criterion is to measure the scattering at 330 nm and to discard all solutions having an optical density greater than 0.1.

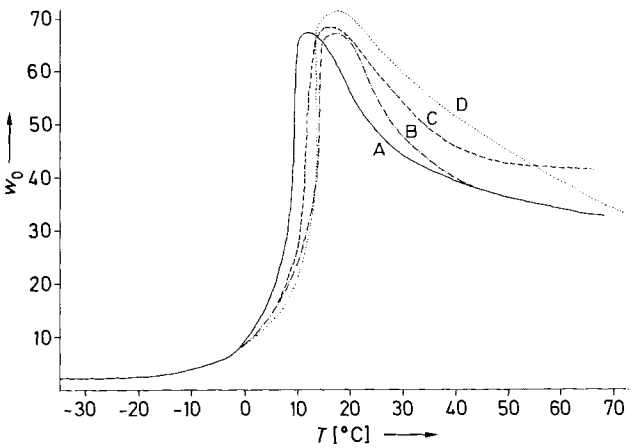

Fig. 5. Stability diagram of AOT reverse micelles in isooctane with and without enzymes. The area underneath the curve represents the stability region where hydrocarbon micellar solutions are clear. Outside this region, the preparation of micellar solutions results in cloudy and/or unstable systems. A (—) Stock solution: 0.05 M AOT with 50 mM borate buffer, pH 8.5; B (-·-·) stock solution with lipoxygenase (0.16 μM); C (----) stock solution with ribonuclease (175 μM); D (····) stock solution with ribonuclease (17.5 μM).

The methods illustrated in Figures 4a and 4b are appropriate for water-soluble proteins. Of great advantage and interest is the ability of reverse micelles to solubilize water-insoluble proteins. This is accomplished according to the method illustrated in Figure 4c, where the insoluble protein, as a powder, is gently stirred with the hydrocarbon micellar solution containing already a certain amount of water (for example, $w_0 = 3-30$). This solubilization phenomenon can perhaps be understood on the basis of the already mentioned fact that water in reverse micelles may have different physical properties from those of bulk water, so that its solubilizing ability may be changed. This method can be useful for water-insoluble membrane proteins, because the protein-containing micelles may mimic to some extent the protein-containing lipid membranes. This area of research, however, has not yet been investigated intensively, and there are to the best of our knowledge no systematic investigations on water-insoluble membrane proteins in reverse micelles. *Waks, Carol* et al. (CNRS, Paris) have been able to solubilize the Folch-pi proteolipid (or lipophyline) (Fig. 6) and are presently studying the interaction of this protein with the water-soluble myelin basic protein.[13] Both proteins ensure the lamellar structure of myelin. By the use of reverse micelles it is possible to study the interaction between the two proteins, one of which is soluble, the other insoluble in water.

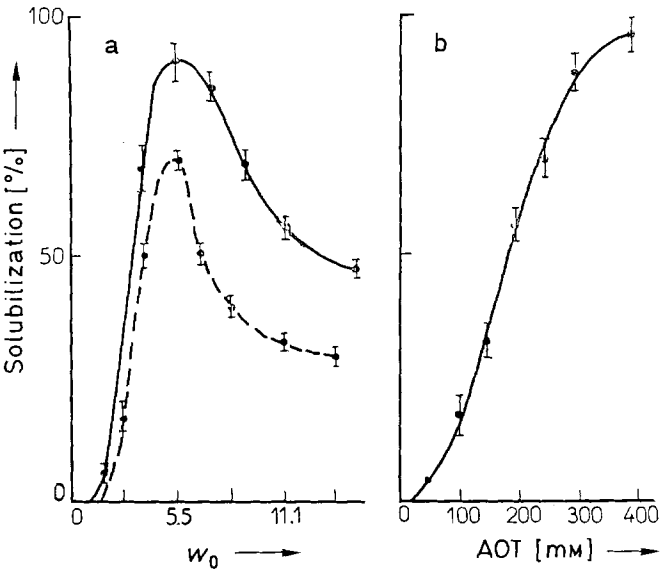

Fig. 6. Solubilization of the Folch-pi proteolipid in isooctane-AOT-water reverse micelles. The overall concentration of the proteolipid in the assay was 20 μM (20 nmoles/mL). A micellar solution of this concentration corresponds to 100% solubilization. a) The percent of solubilization plotted against $w_0 = [H_2O]/[AOT]$ at 300 (—) and 200 (---) mM AOT. b) The percent of solubilization against AOT concentration at $w_0 = 5.56$ (the bars represent experimental error) (from [13]).

Table 2 summarizes the main studies that have appeared until now on proteins solubilized in reverse micelles. The main groups active in this area at the present are those of *Martinek* in the USSR, *Robinson* in the UK, *Laane* in the Netherlands, and *Balasubramanian* in India. Several groups in France (*M. P. Pileni, M. Waks, J. F. Biellmann*) are studying related problems. Table 2 will be referred to again in Sections 4 and 5.

Although we have been able to solubilize almost all kinds of proteins, difficulties are still encountered with the heme-containing proteins: for example, hemoglobin and myoglobin are not stable in AOT/isooctane reverse micelles, probably because the heme group dissociates rapidly once the protein is solubilized in reverse micelles. Also, using AOT, we could not get reproducible data for the activity of cytochrome P-450.

An interesting practical problem concerns the definition and determination of the pH in the water pool. The difficulty stems from the fact that one cannot reliably use a glass electrode in an isooctane solution containing as little as 1% water; even if this could be done, no reliable value could be obtained, because the water of the water pool, particularly at low w_0 values, is a novel solvent with unknown properties and for which no pH calibration is available. Problems are probably less severe at high water contents (cf. [14–17]). In general, it appears that the pH of reverse micelles cannot be determined with certainty. We proposed[16] an empirical calibration based on ^{31}P-NMR data (measurement of the phosphate ion concentration on the basis of its chemical shift)—but, to obtain pH values from these experiments, we had to assume that the pK of the phosphate ion in reverse micelles is the same as in water—an arbitrary, although quite reasonable, assumption.

Another practical problem concerns the definition of the concentration of guest molecules inside reverse micelles.

Table 2. A schematic representation of the activity of various groups in the field of enzymes in reverse micelles.

Group	System	Most important studies, main results
Martinek et al. (1978) [55]	α-chymotrypsin and peroxidase in AOT/octane	activity studies, enzymes remain active

[a] CTAB = hexadecyltrimethylammonium bromide. [b] $C_{12}E_4$ = tetraethyleneglycol monododecyl ether.

For simplicity, let us consider one mole of a compound A that is soluble only in water and is present in one liter of a hydrocarbon reverse micellar solution containing 1% water ($F_w = 0.01$). The "overall" concentration (relative to the total volume, i.e., hydrocarbon plus water) is $[A]_{ov} = 1$ M; but its water-pool concentration (relative to the water "microphase" alone) is $[A]_{wp} = [A]_{ov}/F_w = 100$ M (cf. [18]). Velocities, and all other properties having dimensions of concentration, can be expressed by two different numbers. Which one is physically relevant? This question is not simply semantic, but involves the physics itself of reverse micelles. For example: is the concentration of Na^+ (the counterion of the sulfonate group) in reverse micelles 50 mM or (50/F_w) mM? This question is also important because it may generate confusion when comparing different data in the literature. In some simple instances, however, it is a moot question and the difference in the final physical property disappears when the proper normalization is consistently used throughout. An example is the Michaelis-Menten constant in enzyme kinetics.[36]

Last but not least among the practical problems is the purity of the surfactant. Three kinds of impurities are usually present, to a greater or lesser extent, in most commercial preparations of AOT. There are one or more still unidentified impurities that absorb in the ultraviolet region (Fig. 7). In addition, commercial preparations of AOT often contain an acid impurity. This may produce a significant decrease in the pH of the water pool with respect to that of the stock aqueous solution used to prepare the micelle water pools. We have found two efficient ways to considerably reduce the UV-absorbing species: HPLC and an extraction procedure.[20] The acid impurity can also be eliminated,[34] and certain commercial preparations are much better than others to start with in this regard. *Robinson* et al.[18] have pointed out another source of difficulty with AOT preparations: AOT can partly hydrolyze at alkaline pH. Finally, commercial AOT preparations may contain an indeterminate amount of common salt, which is an important determinant for the conformation of guest biomolecules.[10] In principle, therefore, one should do routine conductometric measurements to check the ionic strength of a standard aqueous AOT stock solution.

These questions of chemical purity are now more important than in the past, due to the increased level of sophistication of the research (spectroscopy, enzymatic activity, conformational properties), and should be taken into account in order to make possible the comparison of data from different laboratories. We would like to end this discussion with one example. Figure 8 shows the pH-activity profiles of α-chymotrypsin in water and in two different AOT micellar hydrocarbon solutions. The first pH-activity profile is taken from our first investigation,[19] when we were not yet completely aware of the acid impurities in the

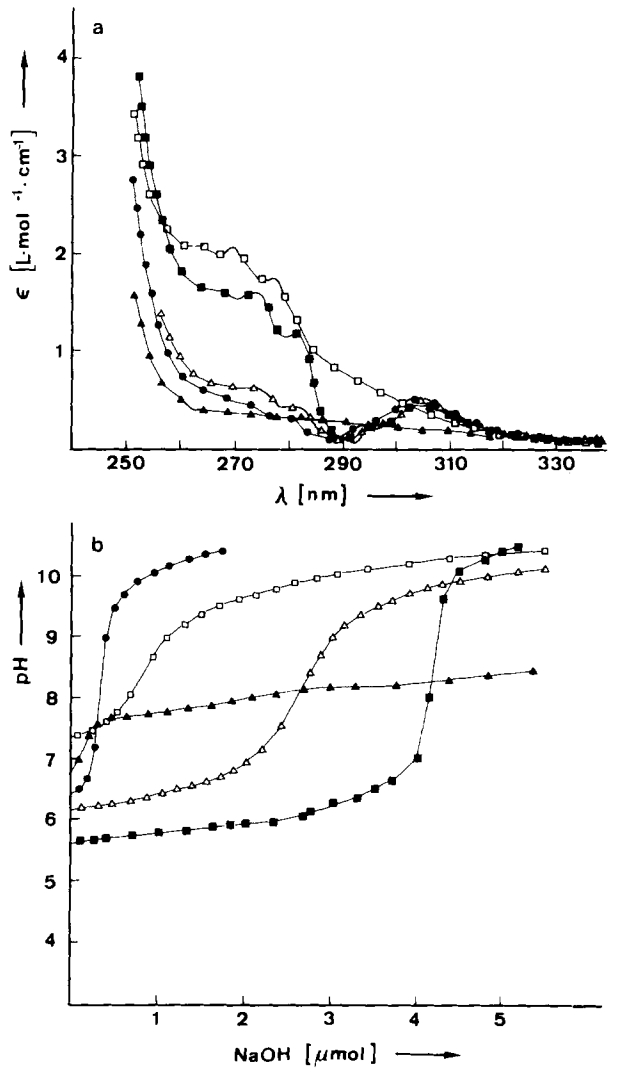

Fig. 7. UV absorption (a) and potentiometric titration (b) profiles of various AOT samples. The spectra were obtained using 50 mM AOT solutions in UV-grade isooctane, and titrations were performed with 10 mL of a 1 : 1 (v/v) water-methanol solution containing ca. 2.2 mmol of AOT, using 0.1 N NaOH as the titrating agent. The extinction coefficient, ε, was calculated as if the absorption were due only to AOT. Thus, an ε of 1 L mol^{-1} cm^{-1}, for example, refers to an absorbance of 0.05 in a 1-cm cell. (□—□): commercial AOT (SERVA); (△—△): purified according to [34]; (■—■): purified according to [54]; (●—●): see text for purification procedure; (▲—▲): purified by HPLC (from [20]).

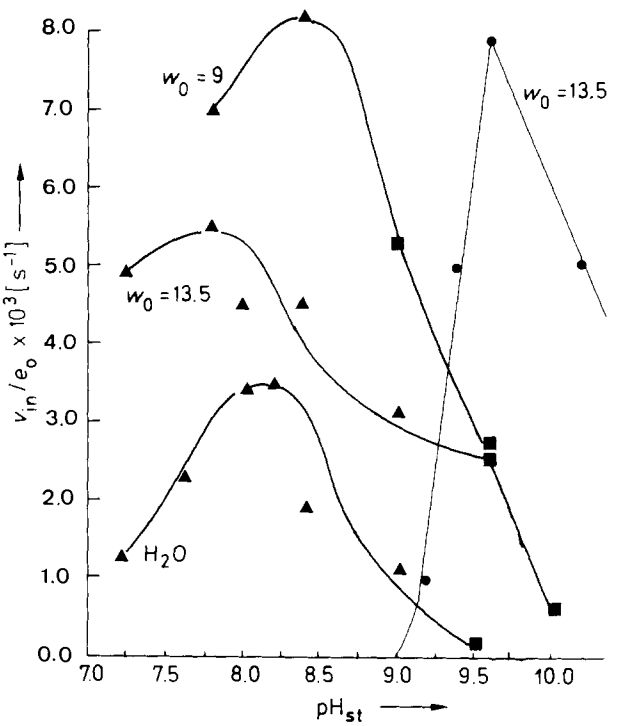

Fig. 8. The effect of AOT purity on the pH profile of enzymatic reactions: α-chymotrypsin catalysis of the hydrolysis of *N*-glutarylphenylalanine-*p*-nitroanilide. The curve on the right ($w_0 = 13.5$) is taken from our earlier work [19], in which AOT was purified according to the existing literature procedure. The two curves on the left ($w_0 = 9$ and $w_0 = 13.5$) are obtained with HPLC-purified AOT (prepared by *P. Lüthi* [30]; cf. [20]). Another such example is shown in [20]. pH_{st} = pH value of stock solution; v_{in}/e_0 = initial rate/initial enzyme concentration.

commercial preparations of AOT and only used the purification procedure described in the literature. In this case, there is a sizeable shift of the pH-activity profile towards more alkaline values, which can be explained (all or in part) by the presence of an acid impurity. The other curve is with an HPLC-purified AOT preparation;[20] in this case, the micellar solution gives about the same pH-activity profile as the aqueous solution. The result cannot, however, be generalized: lysozyme and ribonuclease, for example, continue to exhibit a shift of the pH optimum even with the purified AOT preparations.[20,21] In the case of α-chymotrypsin, the presence of acid impurities in our old AOT preparations does not seem to affect the conformational properties (e.g., enhancement of the helical structure) or the peculiar enhancement of k_{cat} at low w_0 over the value found in aqueous solution.[19]

3. Structural Aspects

Where and how is the biopolymer situated inside the reverse micelle—or more generally—what can be said about the structure of the protein-containing reverse micelles? This question is not completely clarified as yet. In fact, as depicted in Figure 9, different models are conceivable, and the answer to the above question may be different for different enzymes. We believe that most of the data for hydrophilic proteins can be interpreted on the basis of the so-called water shell model (see Fig. 9a), according to which the protein is confined to the middle of the water pool and is protected by a layer of water from the charged inner wall of the micelle and from the external organic milieu.[22,24] The evidence for this model is still indirect. For example, the conformation and activity of enzymes depend on w_0,[22-27] which indicates that the enzyme is sensitive to the amount of water surrounding it. This would not be so if the enzyme adhered with its active site region to the internal wall of the reverse micelle, or if the enzyme were predominantly exposed to the hydrocarbon solvent. In the latter case, most enzymes would be denatured. Finally, circular dichroism data for some enzymes, for example, horse liver alcohol dehydrogenase, ribonuclease, and lipoxygenase, indicate rather similar conformations in the reverse micelle and in bulk water.[25,28,23] However, lysozyme and other enzymes show marked differences.[23,19]

Additional indirect evidence in favor of the water shell model is provided by the fact that the kinetic behavior of

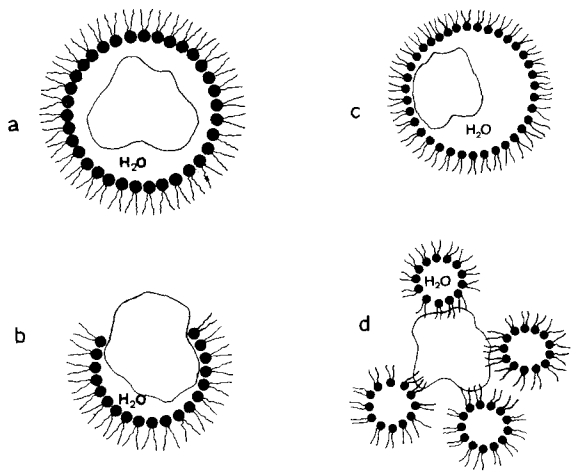

Fig. 9. Possible models for a protein hosted in a reverse micelle (see text): a) the water-shell model, in which the protein is located in the middle of the water pool and is protected from the micelle wall by a layer of water; b) the protein has a very lipophilic part, which tends to interact directly with the bulk hydrocarbon; c) the protein is adsorbed to the micelle wall; d) the protein is solubilized by several small micelles, whose hydrocarbon tails interact with the hydrophobic portions of the protein.

enzymes in reverse micelles appears to be essentially the same as in aqueous solution.[22-27] Furthermore, the pH-activity profile for enzymes in reverse micelles, although somewhat shifted with respect to bulk water, forms a very similar bell-shaped curve.[22,27,29] If the enzyme adhered to the inner wall of the micelle by electrostatic effects, one would expect rather dramatic changes of activity when the enzyme, becoming more negatively charged, dissociates from the micelle wall. For α-chymotrypsin, further circumstantial evidence comes from fluorescence studies: the fluorescence properties of α-chymotrypsin in reverse micelles for $w_0 \gtrsim 7$ (i.e., when "free" water is present) are very close to its fluorescence properties in bulk water,[19] indicating that the environment of the active protein is essentially aqueous.

Using the water shell model, we have developed a scheme, partly based on ultracentrifuge experiments,[24] which enables us to approximate the dimensions of the protein-containing micelles and to estimate the micellar parameters characterizing such aggregates. This model was based on several assumptions, the most important being that the volume of the protein-containing micelle is the algebraic sum of the volume of the protein and the volume of water molecules originally present in the "empty" micelle, and that w_0 does not change. The two dashed curves in Figure 3 show the dimensions of the protein-containing micelles as a function of w_0 according to our model.[24] Noticeably, for small proteins such as ribonuclease, there is very little difference in size between "empty" (containing only water) and "filled" micelles (containing the protein) for $w_0 \gtrsim 15$. In contrast, for small values of w_0, the protein induces an enlargement of the reverse micelles (with the consequent mass redistribution in the micellar solution). In the case of a larger enzyme like horse liver alcohol hydrogenase ($M_r = 80000$), the micelles that contain guest molecules will always be larger, even at large w_0 values, than the empty micelles. It is now doubtful whether the first approximation model is valid for all enzymes. The group of *Martinek* has presented a model, also based on ultracentrifuge studies, according to which the uptake of α-chymotrypsin does not produce any significant increase in size of the host reverse micelle.[26,31] Our own studies using neutron scattering (carried out at Oak Ridge National Laboratory in collaboration with *L. Magid*) appear, on the contrary, to give dimensions for the lysozyme-containing micelles that are at least 30% larger than those predicted by our original model. The situation is therefore still in a state of flux.

4. The Reactivity of Enzymes in Reverse Micelles

The preceding discussion provides the basis for understanding qualitatively which kind of micellar parameters may affect the activity of an enzyme hosted in reverse micelles. When there is enough "free" water (namely at $w_0 > 7-8$), the activity should be very similar to that found in bulk aqueous solution, and the steady-state cycle may be represented simply according to Figure 2c: enzyme and substrate molecules form an active complex that eventually decays to products which dissociate from the enzyme. The difference with respect to water solution is that in micellar solution each bimolecular step requires micellar collision and coalescence.[24]

At lower w_0 values, when most of the water molecules are bound to the inner surface of the AOT micelles, one may expect some interaction between the protein surface and the inner wall of the reverse micelles, which may affect the mechanism. Also, at low w_0 values, deviations from the normal activity profile can be expected because the water in the water pool is a novel solvent. Another effect that may influence the enzyme activity in this regard is the local pH. The transport rate of the substrate into the reverse micelles or the transport rate of the product out of them can also, in principle, play a role. Depending upon the structure of the micelle or upon the relative concentration of micelles and substrate molecules, these events can possibly become the rate-limiting step.

With all this in mind, we will now consider some of the enzymes studied to date. Figure 10 shows the activity of lysozyme as a function of pH in water and in reverse micelles. Notice that the maximal velocity is at about $w_0 = 10$ and not at the maximal water content. This is surprising and can be generalized to all hydrolases. Notice also the shift of the pH-optimum with respect to water, which can possibly be ascribed to a difference in pK of the amino acid residues involved in the catalysis. The turnover number at the optimal pH is not much different from that in water; it appears therefore that lysozyme, apart from the pH-shift of the activity, behaves quite normally in reverse micelles. However, things are not so simple if the conformation of the protein in reverse micelles is considered. As shown in Figure 11, there are large differences in the circular dichroism (CD) spectra on going from water to micellar solutions.[22,21] As is well known, the circular dichroism spectrum in the near-ultraviolet region reflects the environment of the aromatic amino acid residues of the protein, while the CD spectrum in the far-ultraviolet region, particularly around 220 nm, reflects the secondary structure of the protein. The near-UV region will be considered first.

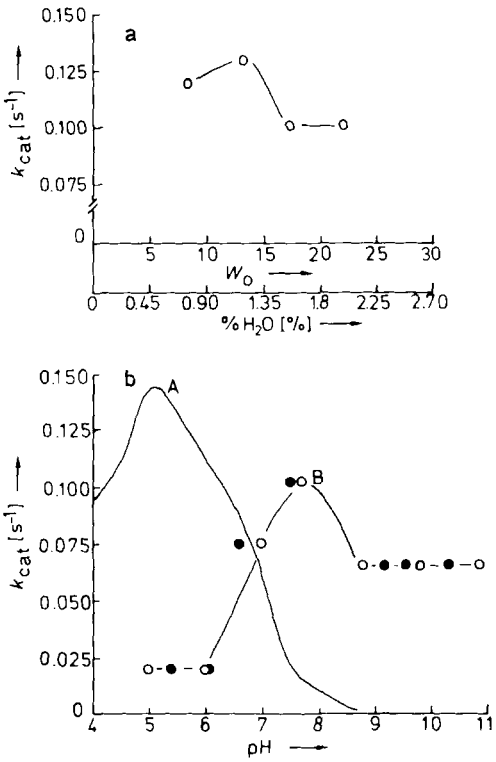

Fig. 10. Degradation of chitin with lysozyme in micellar solutions prepared from 50 mM AOT/isooctane; dependence of the rate constant k_{cat} on the water content (a) and pH (b). Curve A, for comparison, represents an aqueous solution. Curve B refers to the micellar solutions. ○: pH of the stock solutions used to prepare the reverse micelles (pH = pH_{st}); ●: pH values measured directly in the reverse micellar solutions using ^{31}P-NMR at $w_0 = 16.8$ (from [16] and [22]).

Since the ultraviolet absorption spectra of lysozyme in this region are the same in water and in reverse micelles,[22] the changes observed in the CD spectrum can be safely ascribed to conformational changes. The orientation of several aromatic side chains of lysozyme is therefore probably different in water and in reverse micelles. The CD spectrum in the lower wavelength region, where the ultraviolet absorption spectra of micellar solutions also show an increase in intensity, can be interpreted in terms of an increase in the helical structure. Thus, the CD spectra of Figure 11 show that the enzyme has lost its conformational specificity without loosing activity. In order to interprete this apparent paradox, we have proposed that the changes in the enzyme's conformation may only involve peripheral regions[22] rather removed from the active site. However, one should recognize that lysozyme has three of its five tryptophan residues adjacent to or within the active site; it is thus hard to conceive that the conformation of these aromatic residues is changed without affecting the overall active-site geometry. We are presently carrying out CD studies on the enzyme in reverse micelles in the presence of inhibitors and/or substrates in order to clarify this point[*].

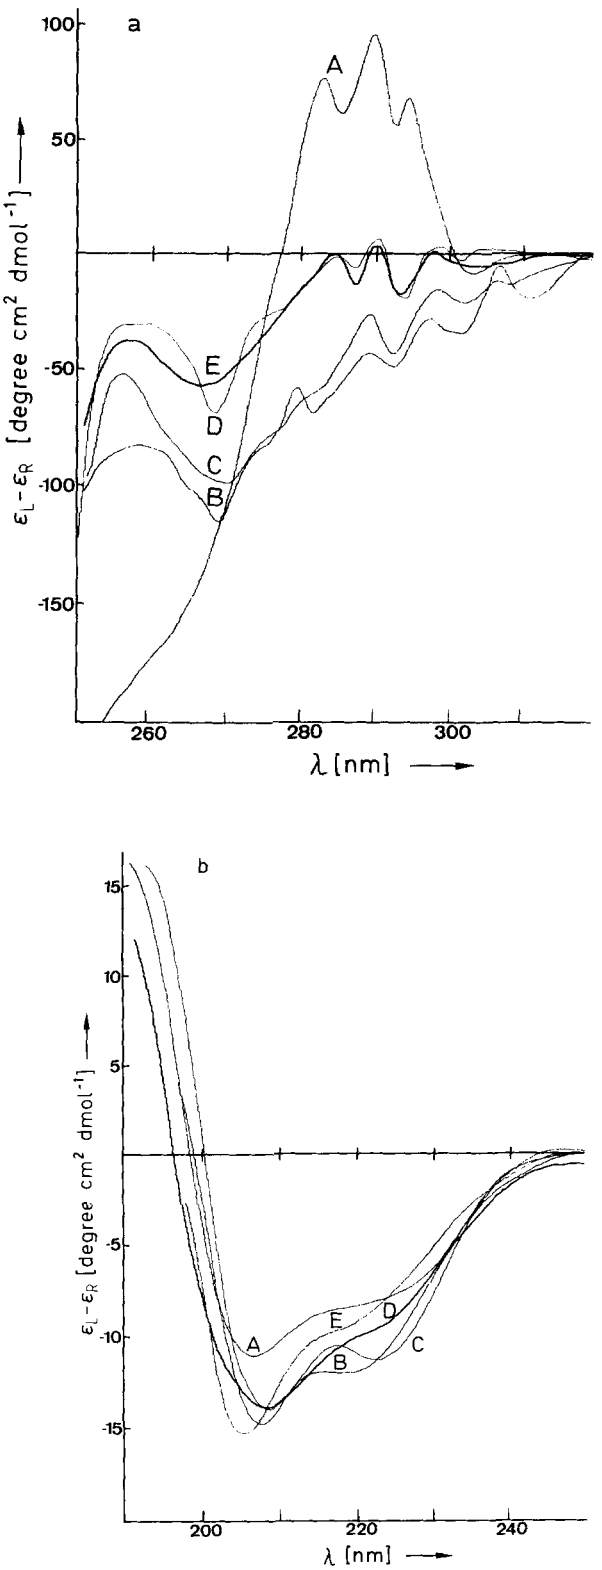

Fig. 11. Near- (a) and far- (b) ultraviolet circular dichroism spectra of lysozyme in water (A) and in AOT reverse micelles at $w_0 = 3$ (B), $w_0 = 6$ (C), $w_0 = 16$ (D), and $w_0 = 25$ (E).

[*] Note added in proof: The problem has now been clarified. The CD spectra of lysozyme in reverse micelles formed by AOT in isooctane do not change significantly with respect to water when NAG (*N*-acetylglucosamine) or NAG_3 is bound. By inference, the conformation of the enzyme in AOT reverse micelles remains the same (or nearly the same) as in aqueous solution when the substrate is present. Without the substrate, AOT brings about a rapid denaturation of the enzyme (lysozyme appears to be the only enzyme where this happens thus far), with the CD spectrum changing as shown in Figure 11. In other words, the lysozyme in the reverse micelles of Fig. 11 is denatured. The reason why our earlier investigation failed to notice this is due to the fact that the enzyme was added to a reverse micellar solution already containing the substrate, so that the enzyme did not have time to denature (B. Steinmann, P. L. Luisi, in preparation).

The situation with chymotrypsin is also very interesting. As apparent from Table 2, this case has been studied by at least four different groups. *Menger* and *Yamada*,[29] the first to study this enzyme in reverse micelles, initially failed to find activity with an ester substrate at a nominal pH of 7. The reason was that the micellar environment had markedly changed the pH-activity profile of the enzyme. In fact, they found a very good activity in the alkaline pH range. We found that, with *N*-glutarylphenylalanine-*p*-nitroanilide, the turnover number is larger at low w_0 values than in water.[19] Although the effect is not extremely large, it is certainly worthy of attention. Of particular interest in this case is the relationship between the activity and the conformation of the main chain of the enzyme, as determined again by circular dichroism. Here, too, there is an enhancement of the ellipticity at 220 nm, which can again be interpreted as an increase of helical content. The activity enhancement has been interpreted[19] by postulating that in reverse micelles the conformational equilibrium of α-chymotrypsin is shifted towards the more active form of the enzyme. α-Chymotrypsin is not the only example of "superactivity". An increase has also been found for ribonuclease and lysozyme,[21,23,24] again at low w_0 values. *Martinek* et al.[27,35] have reported a large increase of activity for peroxidase (Fig. 12).

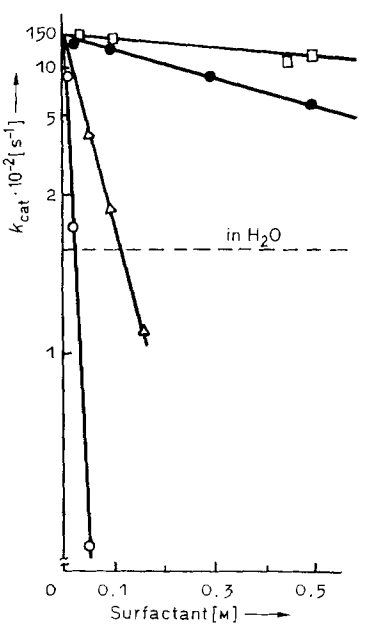

Fig. 12. Dependence of the first-order rate constant k_{cat} for peroxidase oxidation of pyrogallol on the concentration of surfactant (from [2]). (□—□): AOT in octane, 0.1 M imidazole buffer; (●—●): AOT in octane; (△—△): dodecylammonium propionate in diethyl ether/benzene (1:2); (○—○) egg yolk lecithin in methanol (2.5% v/v)/pentanol (5% v/v)/octane. 26°C, $w_0 = 13$, 0.025 M aqueous buffer (phosphate-borate-acetate), pH 7.0. The kinetic assay was carried out as described in [37].

Dehydrogenases are particularly interesting from the point of view of preparative bioorganic chemistry. As is apparent from Table 2, horse liver alcohol dehydrogenase has been investigated by several groups. In addition to the reduction of acetaldehyde, the reduction of a highly lipophilic substrate (decanal) and of a steroid hormone has also been tested.[25] An interesting finding has been reported by the Russian group of *Martinek*: the relative specificity of alcohols in reverse micellar solutions appears to be different from that found in aqueous solution.[35]

Concerning the kinetic parameters, an important question is whether K_m in reverse micelles is different from that in water. We have already indicated[36] that K_m in reverse micelles should be expressed as $K_{m,ov}$ in order to be properly compared with the values in aqueous solution. Table 3 lists typical K_m values in water and reverse micelles. Generally, there is a close agreement between the K_m values in water and in reverse micelles. The efficiency of the enzymes (usually expressed by k_{cat}/K_m) is also not impaired, therefore, when enzymes are solubilized in reverse micelles. The stability of enzymes in reverse micelles is important for kinetic studies and is also of direct relevance for the biotechnological applications (see Section 5). To date, there have been few systematic studies on this important subject. In the case of chymotrypsin,[19] the time stability depends on w_0; at low w_0, the enzyme can be more stable and more active than in water. *Martinek* et al. have studied the stability of several enzymes in reverse micelles formed by different surfactants and/or organic solvents.[37]

Table 3. Kinetic parameters for enzymatic reactions in reverse micelles (isooctane/AOT/water). pH_{st} = pH value of the stock solution [a].

System	K_m^S [μM] [b]	K_m^{NADH} [μM]	v/e [s^{-1}]
LADH in water [c], pH 7.1	110—375	10—11	114
LADH in water, pH 9	400	3	5
LADH in micelles, $w_0 = 42$, $pH_{st} = 8.8$	300	23	80
LADH in micelles, $w_0 = 19$, $pH_{st} = 9.2$	—	20	30
lysozyme in water [d], pH 5.1	10	—	0.14
lysozyme in micelles, $w_0 = 22.2$, $pH_{st} = 7.6$	2	—	0.10
α-chymotrypsin in water [e], pH 7.9	600	—	0.7
α-chymotrypsin in micelles, $w_0 = 13.5$, $pH_{st} = 9.8$	450	—	2.3
α-chymotrypsin in micelles, $w_0 = 9$, $pH_{st} = 11.8$	400	—	4.2

[a] Adapted from [53]. For further details see [19, 22, 25]. [b] Expressed as "overall" concentration. The numerical value of $K_{m,ov}$ depends on the water content of the micellar system. 5. Biotechnological Relevance

Until now we have considered hydrophilic enzymes with their water-soluble substrates. A very interesting aspect of enzyme-containing reverse micelles is their ability to accept and transform water-insoluble, hydrocarbon-soluble substrates. An example is lipoxygenase. The enzyme, although lipophilic, is readily soluble in water (and insoluble in hydrocarbons) and, as such, is probably hosted in the water pool of reverse micelles. The fact that its kinetic behavior corresponds closely to that observed in water supports this view. The substrate linoleic acid is not, or only very sparingly, soluble in water at neutral or acidic pHs. It is soluble, however, in isooctane, and can be added in its pure liquid form to a micellar solution containing lipoxy-

genase. Spectrophotometric analysis of the solution reveals that the substrate is enzymatically converted into the expected products.[28] Typical data are shown in Figure 13. The important point here is that the substrate dissolved in

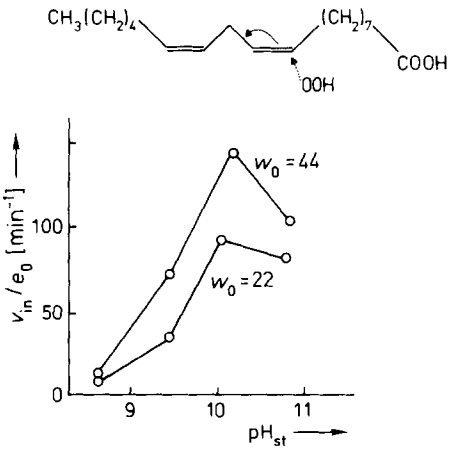

Fig. 13. pH-activity profile of the lipoxygenase reaction. Enzymes in reverse micelles react with both water-soluble and water-insoluble (hydrocarbon-soluble) substrates. An example is the oxidation of linoleic acid with lipoxygenase. [enzyme] = 2.5×10^{-8} M, [substrate] = 4×10^{-4} M, [AOT] = 10×10^{-3} M, isooctane. Overall concentrations are given (v_{in}/e_0 as in Fig. 8).

the bulk hydrocarbon finds its way to the enzymatic active site in the reverse micelle, i.e., through the layer of water that surrounds the enzyme. How this can happen is not yet clear. It may be that the particular physical properties of the water in the reverse micelles, for example, a lower dielectric constant, result in a better solubility of lipophilic substrates. The other possibility, particularly in the case of linoleic acid or analogous substrates, such as arachidonic acid, is that they are incorporated into the micellar interface as cosurfactants and that the enzyme interacts dynamically with the interior micellar wall. The solubility of lipophilic substances in reverse micelles is, however, not restricted to fatty acids; steroids,[25,39] long-chain aldehydes,[25] or water-insoluble peptides[40] are also readily accepted as substrates by their respective enzymes in reverse micelles. The fact that the mechanism of this uptake is not yet clarified does not decrease the biotechnological relevance of the finding that water-insoluble, hydrocarbon-soluble substrates can be enzymatically converted into their products (for a review on the few results available, see [28]). This may open the way to a new application of enzymes in organic chemistry and biotechnology. The interest is increased by the observation that almost all enzymes tested until now can be solubilized in reverse micelles—it is therefore a general method (by contrast, the use of enzymes in biphasic systems, for example, does not appear to be so general, since many enzymes rapidly denature under such conditions). Preliminary work involving the use of α-chymotrypsin for the synthesis of peptide bonds should also be mentioned: acetylalanylphenylalanine ethyl ester and leucinamide are coupled enzymatically to yield the water-insoluble, isooctane-soluble, protected tripeptide AcAla-Phe-LeuNH$_2$, which, after synthesis in the water pool, is expelled into the bulk hydrocarbon. The reaction is carried out in an enzyme reactor[40] with hydrocarbon-resistant, semipermeable, hollow fibers, in which the enzyme-containing reverse micelles are entrapped. Thus, the product can be obtained in pure form and physically separated from the enzyme and reagents.

Although such reactions may be interesting in organic synthesis, until now there has been no example of relevant practical applications of enzymes in reverse micelles. As apparent from Table 2, *Hilhorst, Laane,* and *Veeger*[39,41] in Wageningen (Netherlands) have come closest to such a goal. They were able to solubilize three enzymes in reverse micellar solution at the same time; in a chain reaction, these enzymes reduce regioselectively a ketosteroid. As shown in Figure 14, molecular hydrogen is transferred by a hydrogenase (H_2ase) to methyl viologen (MV), which in turn is able to recycle the system NAD/NADH with the help of lipoamide dehydrogenase (LipDH). Finally, NADH reduces the ketosteroid in a reaction catalyzed by a specific steroid dehydrogenase (HSDH).

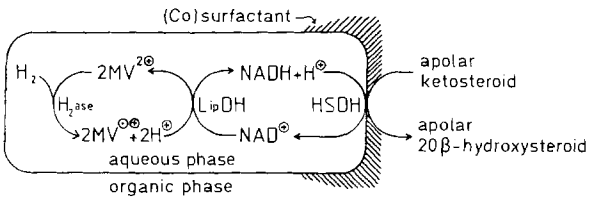

Fig. 14. The scheme of *Hilhorst, Laane,* and *Veeger* [39]: three enzymes in reverse micelles cooperate to selectively reduce a water-insoluble ketosteroid in a chain reaction (see text).

The enzymatic conversion of lipophilic substrates is not the only field where reverse micelles can be used for biotechnological applications. Another interesting aspect stems, for example, from the phase transfer of proteins and nucleic acids. Indeed, our interest in the whole field originated in the transfer of amino acids and peptides, and later polypeptides and proteins, from an aqueous to a hydrocarbon solution containing the surfactant.[11,12,42] Figure 15 shows the three possibilities of phase transfer (cf. [46]). In the "forward transfer", the protein is transferred from an aqueous solution to the supernatant micellar solution. In the "backward-transfer", the enzyme, solubilized in hydrocarbon, is recovered as an aqueous solution. In the "dou-

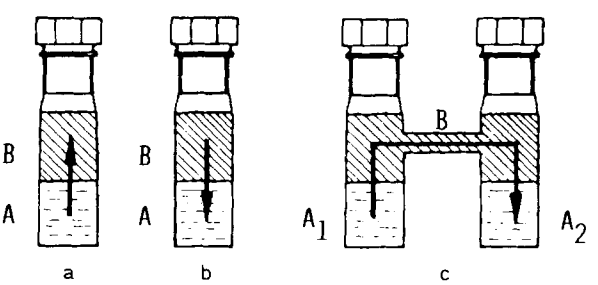

Fig. 15. Phase transfer processes. a) In the "forward-transfer" the protein is transferred from the water phase A into the micellar solution B; b) in the "backward transfer," the protein is transferred from the hydrocarbon micellar solution into the aqueous solution; c) in the "double transfer" method, the protein is vectorially transported from a first water phase A_1 into a second water phase A_2 via reverse micelles present in the hydrocarbon bridge. The vials are gently shaken during the experiment. The shaking is interrupted periodically for the removal of small aliquots to monitor the concentration of the transported biopolymer.

ble transfer" experiments, the biopolymer is present initially in an aqueous phase, and is then transferred into a second aqueous phase, which is separated from the first by a hydrocarbon bridge containing the reverse micelles. In all cases, the transfer of the protein is carried out by the micelles. We have presented until now only preliminary data, but it appears that the method can possibly be used as a chromatographic separation technique for biopolymers. There are already several groups engaged with such projects.[43,44] The separation of proteins and nucleic acids should also be possible, since the transfer of DNA is much slower than that of proteins.

The use of reverse micelles as a drug delivery system by *Speiser*'s group[45] should also be mentioned (cf. [46]).

The biotechnological relevance is actively being explored, but we will have to wait a few years to see whether and to what extent the present expectations are fulfilled.

6. Nucleic Acids

The internal wall of AOT reverse micelles is negatively charged, and although there is a stoichiometric amount of positively charged sodium ions, the solubilization of negatively charged polyelectrolytes such as RNA or DNA was somewhat of a surprise. In fact, the solubilization of nucleic acids in hydrocarbon micellar solutions occurs readily[47] and is actually easier at alkaline pHs. The mechanism of this uptake is not clear yet. We know that the solubilization of high-molecular-weight DNA can only take place at relatively high w_0 values (for example, above 14). Proteins, on the other hand, behave differently.

Does the structure of a high-molecular-weight nucleic acid change upon insertion into the reverse micelles? The solubilization is attended by a decrease of absorbance in the 260-nm region, with a corresponding increase of ellipticity.[47] This can be interpreted as an increase in the base-pair interactions (more hydrogen bonds are formed), which brings about an increase in the UV hypochromic effect and an increase in the macromolecular conformational rigidity. The picture is thus not unlike that proposed for proteins. The effect is more pronounced for RNA, which is more flexible in water solution, than for DNA, which exists already as a rigid double helix; it is not significant for low-molecular-weight oligonucleotides.

Of particular interest is the observation that the plasmid pBR 332 ($M_r = 2.7 \times 10^6$) can also be solubilized in isooctane/AOT/water reverse micelles. We are still investigating the structure of such aggregates. It is really not easy to imagine how a small micelle can accept such a large molecule. Certainly, the uptake involves an enlargement of the original micelle, with a redistribution of its components. The interest in this solubilization experiment also stems from the fact that the CD spectra of the plasmid-containing reverse micelles (Fig. 16) belong to the so-called ψ family.[48] Such spectra in turn are supposed to be diagnostic for superpackaged DNA, like that present in vivo when the long macromolecules are obliged to condense into a geometrically very restricted environment (e.g., a virus head or chromatin). The spectroscopic study of such structures in reverse micelles should be facilitated by the fact that the hydrocarbon medium does not interfere spectroscopically with water or nucleic acids. Studies in this direction are in progress in our group.[69]

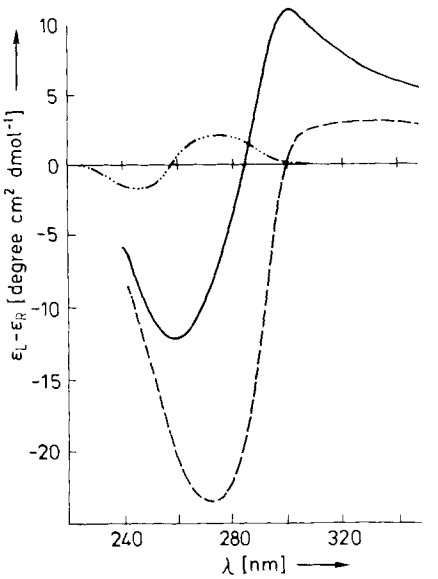

Fig. 16. CD spectra of the DNA of the plasmid pBR 322 in AOT reverse micelles (ψ-spectra). (· · · — · · ·): borate buffer; (——): AOT/isooctane, $w_0 = 18.5$; (– – –): AOT/isooctane, $w_0 = 14.8$ [69].

7. Concluding Remarks

Biopolymer-containing reverse micelles are not only interesting because of their biotechnological relevance, but also because such structures may exist in vivo in biological membranes.[49-52] Perhaps the first hint of this derives from the well-known hexagonal structure that is occasionally formed by phospholipids. The group of *de Kruijff* in Utrecht[49,50,52] has presented very convincing arguments in favor of the biological relevance of reverse micelles. However, the question of the biological relevance of reverse micelles in membrane structure remains to be definitly answered (cf. [38]). The question of the possible existence of reverse micelles in vivo bears upon the more general one of whether and to what extent reverse micelles can be considered as proper models for biological membranes. The term "biological model" is a misused one, as pointed out elsewhere (cf. appendix to [36]) and we do not want to dwell here further on this question.

Despite the uncertainty about the biological and biotechnological relevance of biopolymers in reverse micelles, this review demonstrates the fascination of the field. It stretches over quite different areas, from biotechnology to pure biology, from basic enzymology to nucleic acid structures, and touches upon a variety of important physical aspects. These include the transfer of macromolecules across interphases, or the transfer of low-molecular-weight materials across interfaces, as well as the structure and stability of novel aggregates of biopolymers.

I thank my students Ergin Imre, Peter Lüthi, and Bettina Steinmann-Hoffmann, as well as Dr. Hans Jäckle and Prof.

Lee Magid, visiting professor from the University of Tennessee, for very helpful discussions.

Combination of Chromatographic Separation Methods with Mass Spectrometry—a Modern Technique for Studying Metabolism

New Analytical Methods (26)

By Gerhard Spiteller*

Powerful separation methods developed during the past few decades, in particular glass capillary gas chromatography (GC) and high performance liquid chromatography (HPLC), can be combined with sensitive methods of detection such as mass spectrometry (MS) to provide new insights into metabolic processes. Research in a field that was long thought to be exhausted has thus been revitalized. New perspectives have been opened up for studying the metabolism of foods, spices and flavorings, drugs, and compounds produced in the body as well as for establishing the way in which the organism rids itself of harmful substances or how and when these compounds can interfere with the metabolic processes occurring in the body.

1. Introduction

If biological material is investigated with modern analytical methods, it soon becomes apparent that our knowledge of this field is still alarmingly fragmentary. Some compounds that are excreted in urine in relatively large amounts (milligrams per day) have still not been identified. The situation is even worse in the case of trace compounds, only a few of which are known.

This review shows how these compounds can be detected and identified by combining different chromatographic techniques with mass spectrometry and how chromatographic methods can contribute to solving biological and medical problems, and, moreover, demonstrates the difficulties involved in establishing this type of "biological profile."

This field is so extensive that an arbitrary selection has to be made from the wide range of literature available.

2. General Comments on the Work-Up of Biological Fluids and the Characterization of Their Individual Components

Urine and other biological fluids represent very complex mixtures that contain low- and high-molecular-weight substances with very different polarities. Only some of them can be extracted with organic solvents and are thus readily accessible for analysis. Many of the less polar substances occur in the form of "conjugates," i.e., as esters of sulfuric or glucuronic acid. If these polar conjugates are to be extracted, they must be subjected to enzymatic hydrolysis before work-up.

Polar compounds can, however, also be adsorbed onto added adsorbents, ion exchange columns, or "reversed phase" columns (Sep Pak columns) and subsequently separated after elution by HPLC. The eluates are often later cleaved enzymatically and roughly separated into acidic, neutral, and basic fractions, which are then chromatographed.

Since the individual components of a class of substances usually occur in amounts that differ by several orders of magnitude, only the most predominant compounds can be identified by means of a single chromatographic method while many trace substances escape detection (Fig. 1). The necessary enrichment of the trace substances can only be achieved by the use of a combination of different chromatographic separation methods.

With these combined separation procedures, almost all substances with molecular weights of up to about 2000 (or even higher) that are found in biological materials can be sufficiently enriched to characterize them and to elucidate their structures; the substances must, however, be convertible into volatile derivatives to allow gas chromatographic

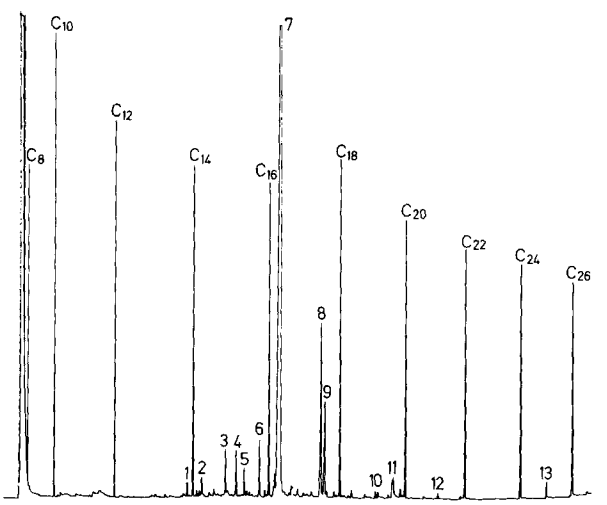

Fig. 1. Glass capillary gas chromatogram of the total acid fraction of a urine sample taken from a healthy woman (28 years old) after extraction with chloroform and reaction with diazomethane. The numbered peaks are the mono-, di-, or trimethyl esters of the following acids: 3-methoxyphenylacetic acid (1) (from 3-hydroxyphenyl acetic acid), citric acid (2), 2,4-dimethyloctanedioic acid (3), nonanedioic acid (4), *N*-acetyl-2-aminooctanoic acid (5), 3,4-dimethoxyphenylacetic acid (6), hippuric acid (7), indoleacetic acid (8), *N*-methylhippuric acid (9) (an artifact formed when hippuric acid is treated with diazomethane), palmitic acid (10), phthalic acid (11), stearic acid (12), and di(*n*-butyl) phthalate (13). Experimental conditions: Carlo Erba Fractovap 4160 gas chromatograph with a WCOT glass capillary (33 m × 0.3 mm, OV 101); hydrogen flow-rate: 2 mL/min; injector temperature: 275 °C; oven temperature: 80—280 °C (5 min isothermally, then 2 °C/min); flame ionization detector (FID); C_8, C_{10}, C_{12}, etc., are *n*-alkanes.

separation. The separation may require a great deal of time and complex instrumentation and may also necessitate experience and skill.

Quantitative detection of the individual substances has not been solved as satisfactorily. Losses are incurred during every separation step and add up if several separation steps are involved. The losses of an individual compound can be kept to a low level by skilled experimental organization, but it is generally difficult to simultaneously quantify the large number of compounds usually found in biological fluids due to their different properties.

The relationships between peaks in a chromatogram do not necessarily reflect the true relationships between substances, not only because different losses of substances have to be taken into account during the work-up, but because the peak intensities also depend on the properties of the substances concerned. If, for example, a flame ionization detector is employed to detect a substance in a GC separation, the peak height depends on the oxygen content of the compound[1]—the higher the oxygen content, the smaller the peak. Quantitative measurements thus require admixture of several standards.

Fortunately, individual substances do not always have to be quantified exactly because metabolic disorders generally produce such massive changes (sometimes reaching several orders of magnitude) in the quantities of the individual metabolic products that they cannot be overlooked.

A compound can always be clearly identified if it can be separated in the form of an appropriate derivative by gas chromatography on capillary columns and its mass spectrum is then recorded. The mass spectrum and retention index usually suffice for identification, even if isomers are present.

It is much more difficult to characterize compounds that, on account of their polarity, can only be separated by HPLC, because such compounds can only be characterized by their retention times. Attempts have been made to combine HPLC with mass spectrometry but the results obtained do not seem very convincing.[2]

GC or HPLC chromatograms of mixtures obtained from biological fluids are called "biological profiles," a term proposed by *Horning* et al.[3]

3. Work-Up of Biological Fluids for Establishing Acid Profiles

The acid profiles of urine and other biological fluids low in protein (e.g., saliva) are the easiest to obtain. The biological fluid is first acidified and then extracted with an organic solvent. The acids so obtained are converted into their methyl esters with diazomethane[4] or they are trimethylsilylated,[5] and the derivatives are separated by gas chromatography.[3b]

Some very volatile acids (e.g., isovaleric acid) and strongly polar acids (e.g., citric acid) are, however, lost during this procedure; most compounds cannot be identified by such a simple separation and only become evident after the main products have been separated (Fig. 2).

If mainly volatile acids are to be determined, the sample is acidified and subjected directly to a GC separation.[6] The acids can, however, also be obtained by vacuum distillation[7] or extraction.[8] *Zlatkis* et al.[9] and *Politzer* et al.[10] have published reviews on the investigation of volatile substances.

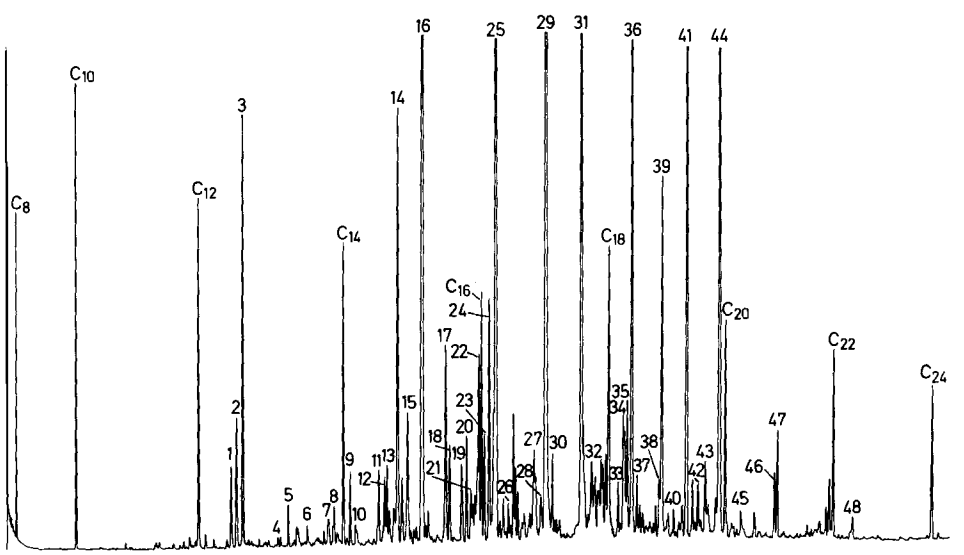

Fig. 2. Glass capillary gas chromatogram (for conditions see Fig. 1) of a fraction (methylated with diazomethane) obtained by column chromatography of the total acid fraction shown in Figure 1. The main acid components (e.g., hippuric and citric acids) have been separated and products appear that occur in small amounts in urine. The following acids in the form of their mono-, di-, or trimethyl esters represent a selection of the numbered peaks: 2-methylhexanedioic acid (1), 3-methylhexanedioic acid (2), 2-hydroxyphenylacetic acid (3), 3,5-dimethyloctanedioic acid (15), nonanedioic acid (16), 3,4-dimethyloctanedioic acid (17), hexanedioic acid (24), 5-decynedioic acid (25), 3-methylfuran-2,5-dipropanoic acid (29), 2-(3-carboxy-4-methyl-5-*n*-propylfuranyl)-*n*-propanoic acid (31), 2-(3-carboxy-4-methyl-5-*n*-pentylfuranyl)-*n*-propanoic acid (41).

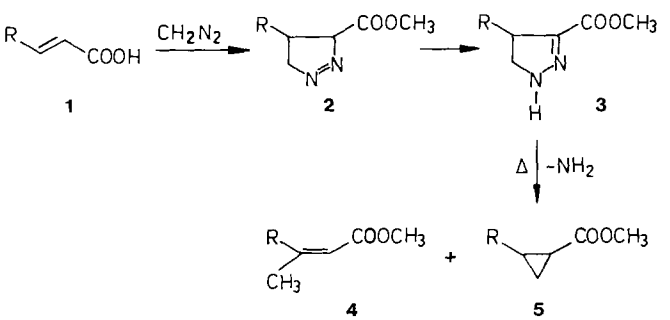
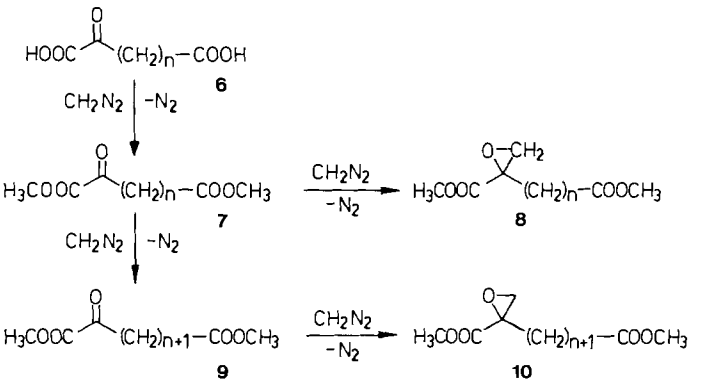


Conjugates that contain mainly phenolic acids are rapidly cleaved by β-glucuronidase/arylsulfatase.[11] The free acids can then be extracted.

Polar acids can be obtained by adsorption of the compounds present in the biological fluid onto an ion exchanger,[12] and, after desalting, elution with an organic solvent;[12] the type of solvent used has a marked effect on the appearance of the profile.

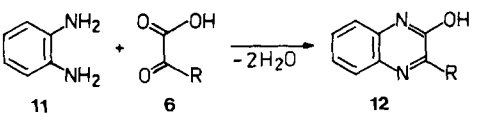
When serum and protein-rich biological fluids are processed, the peptides must first be separated because they would otherwise block the columns. Since acids are sometimes coprecipitated during precipitation, it is advisable to remove the protein by one-step[13] or, preferably, two-step[14] ultrafiltration. The filtrates can then be easily processed similarly to urine.

Complications also arise during the separation of urine on ion exchange columns. Highly polar compounds are very strongly bound to ion exchangers and gradually co-elute in subsequent runs. Complete elution of trace components that are adsorbed onto a column may require washing with many liters of solvent and may take up to 14 days.[15]



Further difficulties are encountered in the derivatization steps required for gas chromatographic separation. If diazomethane is used for esterification,[4] not only do the acidic and phenolic groups react to form the desired esters and ethers, respectively, but the nitrogen atoms of some amino acid conjugates are also methylated—e.g., hippuric acid is converted into methyl *N*-methylhippurate (Fig. 1). Diazomethane can also add to the double bonds of any α,β-unsaturated acids present[16] (Scheme 1).

Scheme 1. Reaction of an α,β-unsaturated carboxylic acid with diazomethane.



The 4,5-dihydro-3*H*-pyrazoles **2** produced from the α,β-unsaturated acids **1** rearrange to give the isomers **3**. The latter may undergo partial decomposition in the gas chromatograph to form the α,β-unsaturated esters **4**, substituted with a methyl group at the 3-position, or the cyclopropane derivatives **5**.[17]

When the α-oxo acids **6** are treated with diazomethane, they form not only the corresponding methyl esters **7** but are also converted into the epoxy compounds **8** and the homologous methyl esters **9** (Scheme 2). The resulting homologues **9** can react further with diazomethane in a similar fashion to yield **10**.[17] Accordingly, several reaction products are sometimes formed from one compound and acid profiles usually show more compounds than actually exist.

Scheme 2. Reaction of an α-oxo acid with diazomethane.

Other routes must be used if such artifacts are to be avoided. For example, the α-oxo acids **6** can be analyzed by reacting them with *o*-phenylenediamine **11** to give the quinoxaline derivatives **12** (Scheme 3), which are also highly suitable for quantitative gas chromatographic determinations.[18]

Scheme 3. Reaction of α-oxo acids **6** with *o*-phenylenediamine **11** to give the quinoxaline derivatives **12**.

Trimethylsilylation[5] is preferred, especially for the quantitative determination of known substances, due to the danger of side reactions that take place when diazomethane reacts with acids. However, compared with diazomethane derivatization, trimethylsilylation has the decisive disadvantage—in addition to the sensitivity of trimethylsilylated acids to hydrolysis—that the mass spectra of trimethylsilyl derivatives generally provide less information about the structure of a compound than the corresponding methyl esters; it is thus almost impossible to elucidate the structure of unknown compounds by this method and, in many cases, this is what is required.

Biological fluids usually contain so many acids that the peaks observed in the gas chromatograms correspond to several components if packed columns are used. Therefore, peaks cannot always be clearly identified even with the aid of mass spectrometry. Superimposed spectra can be subtracted from one another by recording a large number of spectra during the course of a run.[19] This procedure is still useful even if glass capillary columns are employed. In such cases, however, a further chromatographic method is now generally used (see Figs. 2 and 3).

4. Structure Elucidation of Unknown Compounds

The structure of unknown compounds can be deduced from the mass spectra of substances separated by GC if reference spectra are found in the large number of spectral catalogs that are available.[20] Computers can, of course, also be utilized for such searches.[21]

If a structure cannot be assigned with the aid of refer-

ence spectra, some information about the structure may usually be deduced from a spectrum, but complete structures can only be established in a small number of fortuitous cases. Generally, it can be assumed that the compound may already have been described in the literature. Since the empirical formula is needed for a literature search, it must be obtained by high-resolution mass spectrometry of the peaks observed in the gas chromatogram.[22] The measuring period for the individual ions of a peak obtained in glass capillary GC is, however, so brief that the instruments must be operated far below their optimal resolution[*] (e.g., with a "resolution of 3000" instead of a possible "resolution of 50000") in order to obtain adequate ion currents; determination of mass thus gives a large number of possible empirical formulas.[22]

Selection of the correct formula from a large number of possibilities requires a great deal of effort, a knowledge of additional parameters of the substance, and consideration of the possible routes of mass spectrometric decomposition. Despite time-consuming considerations, the empirical formula cannot always be obtained in this way. The substance then usually has to be enriched to such an extent that masses can be determined by "peak matching."[**]

Enrichment is performed by first separating the mixture of methyl esters by thin layer chromatography. The plates are arbitrarily divided into zones, the zones are then eluted, and each fraction is investigated by means of glass capillary gas chromatography. If necessary, the fraction containing the enriched, unknown compound can be located using mass spectrometry.[23] The next step involves further separation by HPLC and subdivision into arbitrary fractions which are also tested by means of gas chromatography to determine whether the separation was successful.

When the unknown compound is enriched to such an extent that it accounts for about 20% of the total material present and examination of the mass spectra of the accompanying substances shows that these contain key ions other than that of the unknown compound, the exact mass of the ions and hence the empirical formula of the compound can be determined from the mixture, and a literature search can then be made.

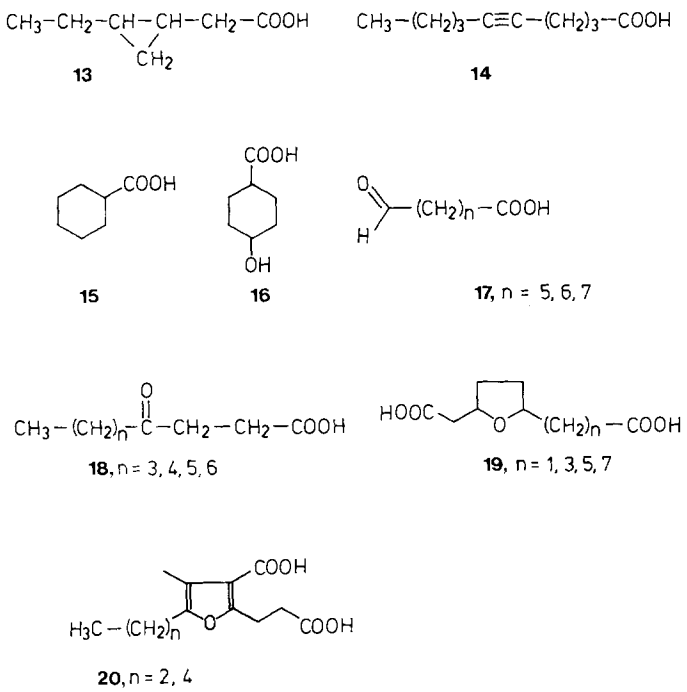
If the literature search proves to be unsuccessful, further information is often provided by determining the empirical formulas of the fragment ions. However, high-resolution data of the key ions obtained using a few micrograms of the enriched sample only allow structural determination in special cases.[24]

Proposed partial structures can then be confirmed or rejected by chemical reaction of the enriched sample on a microscale and subsequent analysis of the reaction products by GC/MS. Several micrograms of enriched material are sufficient for hydrogenation, addition of OsO_4[25] or H_3CSSCH_3[26] to double bonds, ozonolysis, acylation, methylation, etc. Approximately 5 to 10 times as much sample is required for the detection of a carbonyl group by oxime formation, for the identification of a methoxycarbonyl group by $LiAlH_4$ reduction, or for oxidative degradation reactions, because the polar reaction products formed are often strongly adsorbed.

Reactions in which the electron densities of specific parts of the molecule are modified considerably are especially advantageous, since the ionization and thus the initiation of fragmentation is shifted from one part of the molecule to another. In favorable cases, important information can first be obtained from the mass spectrum of one part of the molecule and then from that of the other.

In each of these microreactions contaminants are introduced via the solvents, filters, and materials used to coat the columns, by touching glass vessels with the fingers, and from the atmosphere,[27] etc.; the quantity of the introduced contaminants sometimes far exceeds that of the reacted sample. Separation of the contaminants by subsequent gas chromatography is thus an absolute prerequisite for the interpretation of spectra. It is often difficult to find the "right" reaction products in a gas chromatogram; many spectra have to be examined, since the smaller the reacted sample, the more often is the reaction product a small peak whose intensity is overshadowed by the much more intense peaks due to the contaminants.

It is, however, easy to establish that a reaction has failed if the starting compound remains unchanged. The retention index and the mass spectrum of this substance are known and therefore even traces of it can be recognized within the range of the known retention index by means of the key ions.



The structure of an unknown molecule can usually only be partially clarified with the aid of microreactions. For instance, the positions of substituents in aromatic and heterocyclic rings are seldom established from mass spectra. There is thus no alternative but to collect at least 1 mg of the sample of a sufficient purity to determine NMR and other spectroscopic data.

Nowadays this quantity of substance usually allows unambiguous structural determination provided that the molecule has a maximum molecular weight of about 2000, the necessary microchemical degradation experiments are carefully planned, and the reaction products (at least in the form of derivatives) can be separated by GC. The studies of *Bergström* et al. on prostaglandins are noteworthy examples of this type of structural determination[28] with the aid of microreactions.

In recent years a large number of unknown acids, some of which display unusual structures, have been identified in biological fluids. For example, the following compounds have been isolated from urine: the cyclopropanoic acid **13**,[29] the acetylene compound **14**,[30] cyclohexanecarboxylic acid **15**,[31] 4-hydroxycyclohexanecarboxylic acid **16**,[32] the aldehyde acids **17**,[33] the 4-oxo acids **18**,[33] the tetrahydrofuran acids **19**,[34] and the urofuran acids **20**[23] (Scheme 4). This indicates that we are still unaware of many metabolic pathways.

[*] Resolution means that two different masses are separated from one another by a "valley"—e.g., for a resolution of $R = M/\Delta M = 50000$, a mass of 500 daltons will be separated from a neighboring mass of 500.01 daltons by a valley. For a resolution of $R = 3000$, masses of 500.00 and 500.01 will no longer be separated; in this case, it is only possible to separate masses of 500.00 and 500.17 daltons.

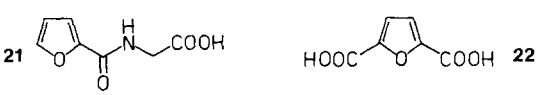
[**] The substance to be determined is introduced into the mass spectrometer together with a reference compound that affords ions of known mass. The different acceleration voltages are then measured that are needed for "identical" focusing of a reference peak of known mass and the unknown peak. The voltage ratio is the same as the ratio of the two masses. The exact mass of the unknown ion (e.g., the molecular ion) can thus be calculated with a very small degree of error (< 5 ppm).

Scheme 4. Carboxylic acids recently discovered in human urine.

5. Acids as Degradation Products of Body Substances and Foodstuffs

It is not easy to decide whether a compound is synthesized in the body or whether it passes through the body as an unmodified constituent of food. This problem can be solved as follows: if the compound in question is found in the urine of babies fed exclusively on breast milk but does not exist in the breast milk itself, it can be concluded that the substance is produced by the body.[35]

The supposition that a substance comes from a specific food can be tested by selecting a diet that does not contain the food in question; disappearance of the compound from the urine supports the hypothesis. More definitive evidence is provided by examining the urine before, during, and after a starvation diet; substances that are not changed on passage through the body (e.g., 3,4-dihydroxybenzoic acid) are no longer found in the urine after only one day of starvation. Substances of exogenous origin that undergo metabolism are found in the urine for up to one week after beginning the starvation diet (e.g., piperine metabolites), whereas metabolic products formed from depots within the body are still excreted after longer starvation periods (e.g., **19**).[15]



Up to now, physiologically active compounds were first identified on the basis of their activity and subsequently isolated so that their structures could be determined. It should now be possible to adopt the reverse approach. Physiologically active compounds are often synthesized in very small amounts and are then converted into inactive compounds which are excreted in the urine, where they accumulate. These degradation products can then be used to detect the active precursors.

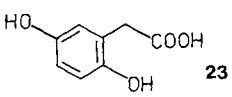
Possible precursors can be synthesized in the search for active precursors. Animal experiments then show whether these compounds are degraded to the substances found in urine.[36] Attempts to find appropriate precursors in the liver, kidney, and other organs can, however, also be made.

Such studies have demonstrated, for example, that tetrahydrofurandiacetic acid **19** (n = 1) is formed by oxidative degradation of higher homologues that are synthesized by the body.[35] The search for physiologically active precursors seems to have paid off in this case. The aldehyde acids **17** are, however, less interesting; they are oxidation products of linolenic acid and probably enter the body in the food[37] as is also the case for cyclohexanecarboxylic acid **15**.[31]

To the best of our present knowledge, most of the acids excreted in the urine are derived from foodstuffs or from spices and flavorings. Only a small proportion of the acids excreted are products that can be synthesized by the body. Our future interest should be centered on research into these compounds since this will enable us to discover unknown metabolic processes. A prerequisite for such studies is a knowledge of the substances contained in foodstuffs, but our understanding in this area is still as fragmentary as that of metabolism. Modern analytical methods are often employed to examine aroma and flavoring substances but are hardly ever used to determine all of the constituents of plant foods.

The acid contents of individual foodstuffs vary appreciably,[38] which means that mere ingestion of different foods can lead to considerable differences between the profiles. On the other hand, acids derived from food can be integrated into the metabolism of the body; an equilibrium is then set up between the ingested and the excreted acids. Few studies have been performed on this subject;[39] it is known that a diet rich in vegetables promotes the excretion of aromatic acids.[40] In spite of this, some of these acids (e.g., homovanillic acid and vanillinmandelic acid), which are also produced from catecholamines, have been employed to deduce the concentrations of these amines.[40,41] 2-Furoylglycine **21** and 2,5-furandicarboxylic acid **22** (Scheme 5) also enter the body via the food.[42]

Scheme 5. 2-Furoylglycine **21** and 2,5-furandicarboxylic acid **22**.



Since definitive results have not been obtained, the acid excretion rates of individuals are determined and these mean values are regarded as "normal profiles."[43] It would certainly be better to differentiate the acids already present in the body from the acids ingested with the food and to use only the former to determine the "normal values."

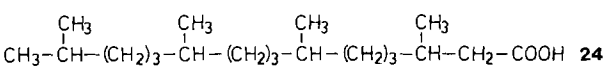
The determination of a "normal profile" implicitly assumes that acid excretion in one and the same individual does not change on a regular basis and that it is not affected by external conditions; this is, however, not always the case. Thus, marked changes in acid excretion are observed after physical exertion. The amount of propylurofuranic acid **20**, for example, decreases within three hours to 1/5th of its original amount.[44] Detailed studies in this field are, however, lacking.

6. Investigation of Metabolic Diseases that are Associated with the Excretion of Unusually High Quantities of Acids

Acid profiles are crucial for recognizing inborn errors of metabolism because, in many cases, acidic metabolites are accumulated as a result of enzyme defects, thus resulting in the excretion of abnormally high amounts in the urine.

Some of these usually rare, genetically controlled metabolic diseases have been known since the turn of the century—e.g., alcaptonuria in which the patients suffer from a lack of homogentisic acid oxidase, resulting in the excretion of 4–8 g of homogentisic acid **23** (Scheme 6) in the urine per day.[45]

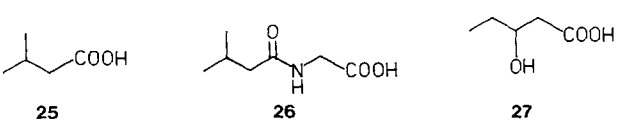
23



Scheme 6. Homogentisic acid **23**.

Many of the 1400 genetic metabolic diseases that are now known[26] soon cause serious physical and mental damage. If muscle spasms, uncontrollable vomiting, acidosis, etc., are observed after birth or in young babies, the patients should be thoroughly examined for metabolic defects.[47]

Nowadays GC/MS plays an important part in these investigations,[48] the urine profiles of the patients being compared with those of healthy individuals. Unusual peaks found in the gas chromatogram of the patient's urine may indicate a metabolic defect. Mass spectra of these peaks can then be used for structural determination.[49]



It is remarkable that an unknown metabolic product has often been discovered in this way but that subsequent, more precise studies show that the compound thought to be "specific" for the disease also occurs in the urine of healthy persons; the quantities involved are, however, so small that the compound can only be detected when special attempts are made to find it. The specific characteristic of the disease is thus not the compound itself but rather the extremely large quantities of it that are found.

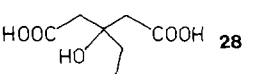
GC/MS was first used in 1963 to investigate a lipid storage disease ("Refsum syndrome"); phytanic acid **24** was identified in the urine of the patient (Scheme 7).[50]

24

Scheme 7. Phytanic acid **24**.

In 1966 *Tanaka* et al. were able to demonstrate that large quantities of isovaleric acid **25**, its glycine conjugate **26**, and 3-hydroxyvaleric acid **27** (Scheme 8) were excreted in a previously unknown metabolic disease.[51]

25 **26** **27**



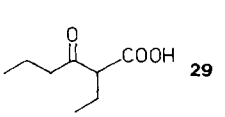
Scheme 8. Isovaleric acid **25**, its glycine conjugate **26**, and 3-hydroxyvaleric acid **27**.

Improvement of detection techniques led to the discovery of more new and unusual metabolites which are produced as a result of the isovaleryl coenzyme A dehydrogenase deficiency encountered in this disease, which has been called "isovaleric aciduria."[52]

A large number of unknown metabolic defects have been subsequently identified using GC/MS; these studies were initiated primarily by *Jellum* et al.[53a,c] These defects are all characterized by the excessive excretion of acids—e.g., methylmalonic aciduria,[53b,54] pyroglutamic aciduria,[53a] hydantoin-5-propionic aciduria,[55] propionic aciduria,[56] glutaric aciduria,[57] and glutaric aciduria II.[58] Further studies using improved methods have shown that in some cases a large number of unusual metabolic products are formed, for example, in propionic aciduria,[59] which is a result of a disorder in the metabolism of propionyl CoA, or in tyrosinuria, which is caused by a defect of tyrosine aminotransferase.[60] Disorders in the metabolism of the amino acid leucine are especially numerous; the various enzyme defects can cause a wide range of different diseases.[61]

A total of more than 50 previously unknown hereditary diseases have been shown to be caused by metabolic defects with the aid of GC/MS. Gas chromatography has proved to be a suitable method for definitively identifying an even larger number of such diseases.[62]

Acids that occur in the urine of patients suffering from metabolic diseases need not necessarily be a consequence of the disease. It was recently reported, for example, that 3-ethyl-3-hydroxyglutaric acid **28** (Scheme 9) is found in the urine of children suffering from propionic aciduria.[63]

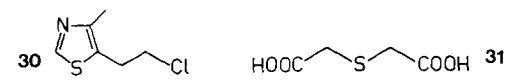


28

Scheme 9. 3-Ethyl-3-hydroxyglutaric acid **28**.

Such results should be assessed very critically for a number of reasons—packed columns were used for the gas chromatographic separations, the width of the peak indicates the presence of a mixture of compounds and the peak itself is not very large, and the same compound also occurs in the urine of healthy persons and probably originates from foodstuffs.[64]

It should also be carefully considered whether 2-ethyl-3-oxohexanoic acid **29**[65] (Scheme 10) found in the urine of diabetics is a metabolic product of the body or, instead, a degradation product of an artifact, since the corresponding alcohol is formed from dioctyl phthalate; the latter compound is an almost ubiquitous constituent of all biological materials and can reach the body via plasticizers. Diabetics still seem to have difficulty in further degrading 2-ethyl-3-oxohexanoic acid.



29

Scheme 10. 2-Ethyl-3-oxohexanoic acid **29**, which has been discovered in the urine of diabetics.

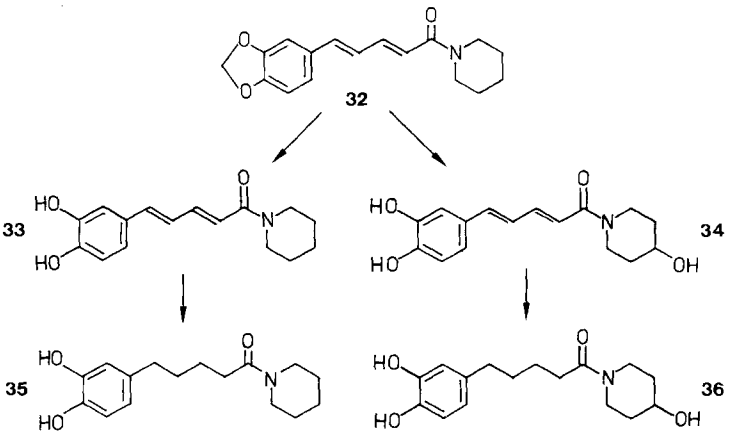
7. Investigation of Drug Metabolites

Acids are often produced during the metabolism of pharmaceuticals. If the profiles are compared before, during, and after administration of the drug, the acids formed from it can be recognized from the additional peaks that appear in the gas chromatogram of the methylated acid fraction of the urine obtained during treatment. This method can thus supplement metabolic studies with radioactively labeled compounds.

For example, the drug 5-(2-chloroethyl)-4-methylthiazole (Clomethiazol or Distraneurin®) **30**, which is often used to alleviate withdrawal symptoms in alcoholics, is degraded not only by oxidative attack at the carbon atoms of the side chain[66] but also by oxidation at C2 with subsequent ring cleavage. Since the labeled C-2 atom is thereby lost in the form of CO_2, some important metabolites escaped detection. Comparison of the profiles of untreated and treated individuals revealed, however, the presence of other metabolites that had lost the C-2 atom, e.g., thiodiacetic acid **31**[67] (Scheme 11).

Scheme 11. 5-(2-Chloroethyl)-4-methylthiazole (Distraneurin®) **30** and its metabolite thiodiacetic acid **31**, which is probably produced by reaction of the side chain with glutathione.

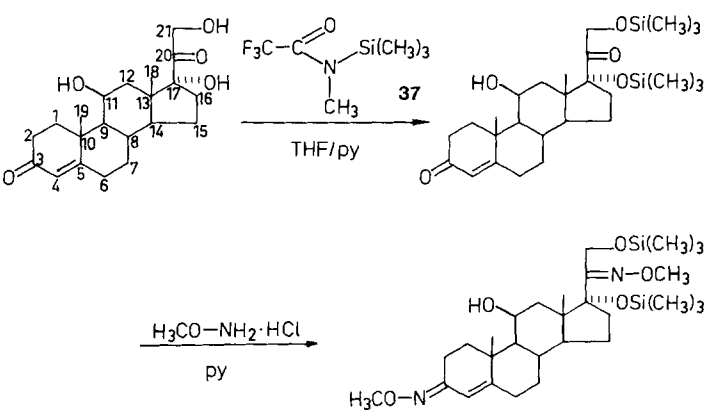
Saliva is, like urine, a biological fluid that is easy to obtain. Examination of its acids has shown that saliva contains the same metabolic products that are found in other body fluids.[68]



8. Steroid Profiles

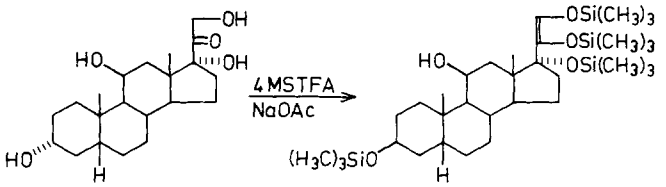
Unlike acids, which are often of exogenous origin, the steroids of biological fluids are of endogenous origin so that one does not have to contend with the problem of whether these compounds are derived from foodstuffs or spices and flavorings. It is, however, more difficult to obtain the steroid fraction than the acid fraction because the steroids mainly occur in the form of conjugates.

In routine investigations free steroids are generally not separated from steroids that are excreted as sulfate and glucuronide conjugates.[69] The conjugates are usually hydrolyzed enzymatically and then extracted with an organic solvent, e.g., ethyl acetate or ether.



Even if the acids are removed by addition of hydrogen carbonate, neutral substances originating from food are still carried over into the steroid fraction. After ingestion of sweets containing liquorice, numerous peaks appear which are derived from flavanones. Oxindole is also a common interfering substance.[70] Urine steroid profiles almost always contain the degradation products of the pepper constituent piperine **32**, which enters the body in the food. It is interesting that the metabolites **35** and **36** are lacking in approximately every tenth person; these individuals excrete the precursors **33** and **34**[24] (Scheme 12).

Steroids and their conjugates can be isolated completely and under mild conditions by extraction with XAD resins.[71] The steroids can then be eluted from the ion exchanger with methanol and subjected to further work-up. Lipophilic Sephadex is also used for this purpose.[72] One of the disadvantages of these adsorption methods is the tedious washing procedure. This disadvantage can largely be overcome by applying the biological fluid to Sep Pak C-18 cartridges which adsorb all the steroids present.[73] This method can also be utilized to obtain steroids from serum and other biological fluids.[74]



Scheme 12. Piperine **32** and its metabolites **33** and **34** or **35** and **36**, which are excreted in the urine.

A few polar steroids can be separated by gas chromatography without derivatization, as was first shown by *Horning* et al.,[75] but even simple hydroxysteroids decompose. Progress was made with the synthesis of trimethylsilyl derivatives.[76] This form of protection is not, however, sufficient to prevent steroids with hydroxyl groups at positions 17 and 21 from being decomposed to 17-oxosteroids.[77] Analysis of such steroids (e.g., cortisol) only became possible when their trimethylsilylated methoxime derivatives (MO-TMS derivatives) had been synthesized[78] (Scheme 13).

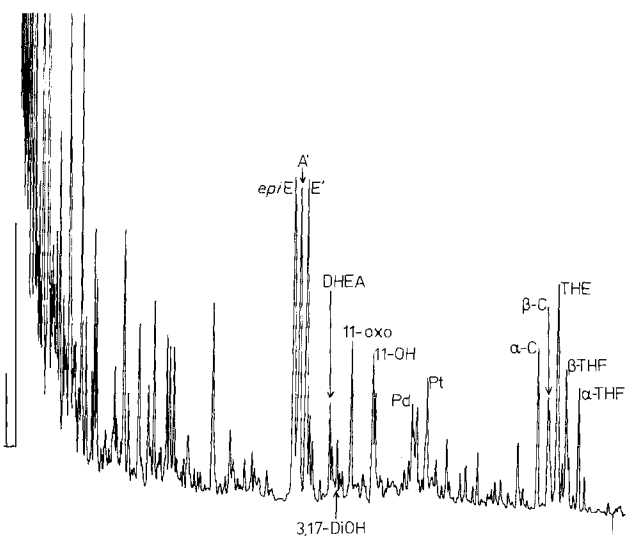
Scheme 13. Trimethylsilylation and methoxime formation of cortisol. THF: tetrahydrofuran.

Modern trimethylsilylation reagents, such as *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (MSTFA) **37** or trimethylsilylimidazole (TMSI) **38**, now permit conversion to trimethylsilylenol ethers,[79] which display gas chromatographic properties that are equally as good as those of the MO-TMS derivatives (Scheme 14).

Scheme 14. Formation of the trimethylsilylenol ether of 5β-tetrahydrocortisol.

We use such derivatives almost exclusively. The introduction of glass capillaries, which have been employed since about 1970, also led to further important developments in the field of steroid analysis.[80]

Urine steroid profiles of healthy adults are distinguished by a characteristic double peak in the androgen range, which corresponds to androsterone and etiocholanolone,[78a,81] and by an equally intense peak corresponding to tetrahydrocortisone in the range of the corticoid metabolites[3a,81,82] (Fig. 3).



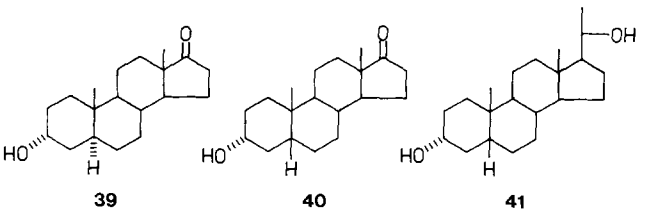


Fig. 3. Urine steroid profile of a healthy man (24 years old); *epi*-etiocholanolone (*epi*E) as an internal standard, androsterone (A'), etiocholanolone (E'), dehydroepiandrosterone (DHEA), 3,17-dihydroxyandrost-5-ene (3,17-DiOH), 11-oxoetiocholanolone (11-oxo), 11-hydroxyetiocholanolone (11-OH), pregnanediol (Pd), pregnanetriol (Pt), α-cortolone (α-C), β-cortolone (β-C), tetrahydrocortisone (THE), β-tetrahydrocortisol (β-THF), *allo*-tetrahydrocortisol (α-THF). Experimental conditions: Siemens L 402 gas chromatograph with a WCOT glass capillary (30 m × 0.3 mm, OV 101); hydrogen flow-rate: 2 mL/min; injector temperature: 270°C; oven temperature: 150–280°C (2°C/min); flame ionization detector (FID). The steroids were separated in the form of their trimethylsilylenol ethers.

If the intensity of the tetrahydrocortisone peak in profiles of healthy individuals is only a fraction of that of the androsterone and etiocholanolone peaks, it is likely that errors have been made during the work-up. This often applies to older studies.

It should be possible to differentiate steroid profiles according to sex. Although sex-specific differences are found in most cases[83]—in the urine steroid profiles of adult men, the peak for androsterone **39** is generally considerably greater than that for etiocholanolone **40** (Scheme 15), whereas in women the etiocholanolone peak is about twice as intense as the androsterone peak—the urine steroid profiles of some healthy men are similar to those of women and, moreover, women must not necessarily excrete more etiocholanolone than androsterone.[84]

In the second half of the menstrual cycle of women, there is a sharp increase in the excretion of pregnanediol **41** (Scheme 15), which is reflected in the steroid profile (Fig. 4).

39 **40** **41**

Scheme 15. Androsterone **39**, its isomer etiocholanolone **40**, and pregnanediol **41**.

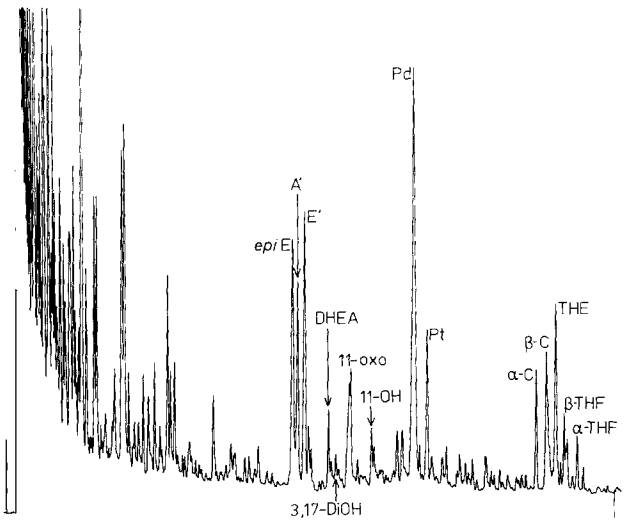

Fig. 4. Urine steroid profile of a healthy woman (27 years old, second half of the menstrual cycle). For conditions and abbreviations see Figure 3.

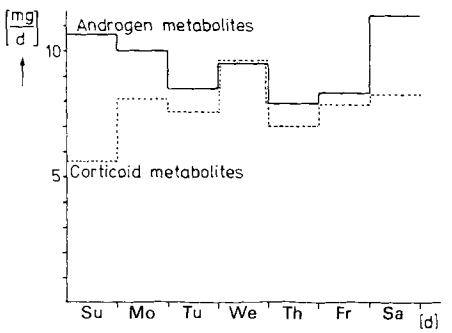
The change in hormonal balance during pregnancy can be recognized above all by a considerable increase in the excretion of pregnanediol.[85] The steroid metabolism of the fetus differs from that of the mother; the fetus passes its steroids back to the mother so that the 16-hydroxysteroids typical of the fetus can be used as a measure of the normal course of pregnancy.[86] The excretion of 6-hydroxylated pregnane derivatives is examined using GC/MS and is especially important during the last three months of pregnancy.[87]

The gradual development of a steroid metabolism in the first few months of life is reflected in the steroid profiles. The fetal zone of the adrenal cortex, which gradually recedes, produces other steroids than those typically found in adults. The steroid profiles of newborns and babies are thus characterized by the presence of steroids having a 3β-hydroxy-5-ene structure[88] and often possessing additional hydroxyl groups at positions 16, 18, and 21 as well as by corticoid metabolites with hydroxyl groups at positions 1 or 6. GC/MS has played an important part in the separation, structural examination, and elucidation of these steroids.[89]

As expected, only small amounts of androgens are excreted in the urine of children prior to puberty. Moreover, the aging process can be followed by means of the steroid profiles: the androgen content in older individuals decreases sharply in comparison with that of the corticoids.[85]

The steroid excretion rate of adults exhibits a circadian rhythm;[90] the mean excretion rate when awake is about ten times higher than when asleep. These differences can be offset by collecting "24-hour urine." This does not, however, compensate for the often large, day-to-day fluctuations in steroid excretion rates found in one and the same person, which may be as high as 50%[84] (Fig. 5).



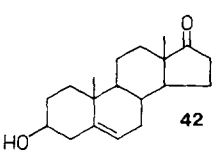


Fig. 5. Mean daily androgen and corticoid excretion rates of a healthy man (25 years old) over the course of a week.

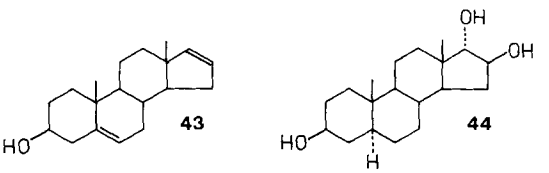
Whereas the absolute quantities of steroids vary considerably, their relative amounts only display slight differences. In healthy individuals the ratio of androsterone to etiocholanolone remains almost constant over a period of years.[84]

In chronic diseases, however, the steroid levels can gradually change (see below). The body thus works like a chemical factory: if production is increased, the by-products are also formed in correspondingly larger quantities.

The steroid dehydroepiandrosterone (DHEA) **42** (Scheme 16) occupies an exceptional position with respect to the others. The excretion rate of DHEA in most people is only 1/10th that of the main androgens androsterone **39** and etiocholanolone **40** but increases up to ten- to twenty-fold during psychological stress.[91]



Scheme 16. Dehydroepiandrosterone (DHEA) **42**.

Approximately every tenth person excretes these high levels of DHEA continuously.[84] Women who suffer from hirsutism often excrete large amounts of DHEA.[92] Increased excretion of corticoids is also associated with psychological and emotional stress.

Steroids are excreted not only in the urine but also in the feces, where they are subjected, however, to attack by microorganisms in the intestines.[93] The excretion of steroids in the feces of normal and germ-free rats was studied in detail in order to establish what happens to steroids in the intestines.[94] It was concluded that steroids are released into the intestines and are then reabsorbed. 21-Hydroxysteroids are, for example, dehydroxylated by the internal bacterial flora of rats.[95]

In contrast to humans, rats exhibit major sex-specific differences as regards the hydroxylation of the D-ring of certain androstane derivatives, e.g., 5,16-androstadiene-3β-ol **43**. 5α-Androstane-3β,16β,17α-triol **44** (Scheme 17) predominates in the urine of male rats, whereas an analogous metabolite is not found in the urine of female rats.[96]

Scheme 17. 5,16-Androstadiene-3β-ol **43** and its main metabolite 5α-androstane-3β,16β,17α-triol **44** found in the urine of male rats.

The observation that rats display different steroid profiles depending on their sex was used by *Eriksson* and other workers to show that the liver enzymes responsible for corticoid metabolism are regulated by androgens and estrogens.[97] Metabolism of a steroid in the liver can be studied by allowing the steroid to react with rat liver microsomes and then examining extracts by means of GC/MS.[98]

Since bile metabolism is related to diseases of the gastrointestinal tract, GC/MS was used at a very early stage to investigate bile acids and their precursors, especially by *Sjövall* and his group.[99] Previously unknown bile acids and other steroids were discovered with this method and determined in bile and serum.[100]

As expected, disorders in the functioning of steroid-producing glands have an extremely marked effect on steroid excretion. Lack of 11β-hydroxylase, for example, causes diminished cortisol production and thus greatly reduces the excretion of tetrahydrocortisol. A functional defect in the adrenal cortex leads to a drastic decrease in corticoid production.

A reduced ability to cleave steroid sulfates is associated with pathologically prolonged pregnancy. Drastically elevated levels of steroid sulfates are excreted in cases of sulfatase deficiency; this defect can thus be differentiated from other possible causes of deficient estrogen excretion in pregnant women by analyzing the sulfate fraction of the urine.[101]

3β-Hydroxysteroid dehydrogenase deficiency is reflected by extremely high excretion of 3β-hydroxy-4-ene steroids.[102]

Hereditary hypofunctioning of the adrenal cortex causes greatly reduced excretion of 3-hydroxy-5-ene steroids in babies;[103] a tumor in the adrenal cortex leads to greatly increased excretion of all steroids, but especially of dehydroepiandrosterone, 16β-hydroxydehydroepiandrosterone, and androstenetriol. A lack of 21-hydroxylase can be recognized by markedly reduced excretion of corticoids and elevated excretion of 17β-hydroxysteroid metabolites such as pregnanetriol and pregnanetriolone.[104]

A deficiency of enzymes that oxidize 18-hydroxysteroids to aldehydes (the pathway of aldosterone synthesis) leads to increased excretion of these steroids.[105] A deficiency in 17-hydroxylase is reflected by low excretion of androgen and cortisol metabolites; instead, large amounts of corticosterone are excreted.[106]

Atlases have been compiled for the recognition of metabolic steroid disorders. They contain typical excretion patterns and thus allow identification of the individual disorders.[107]

Unexpectedly, disturbances of steroid metabolism are also encountered in chronic diseases. It has been shown that the main steroids found in the ultrafiltrates of blood from uremic patients are 11-oxidized androsterone derivatives (Fig. 6), while production of the normal androgens is greatly diminished and the ratio of androsterone to etiocholanolone is shifted increasingly in favor of etiocholanolone.[108] The increase in the 11-oxidized steroids roughly parallels the development of hypertension.[109]

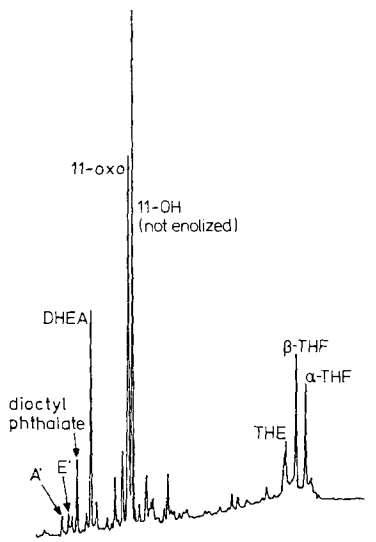


Fig. 6. Steroid profile of the ultrafiltrate of blood from a uremic patient (for conditions see Figure 3).

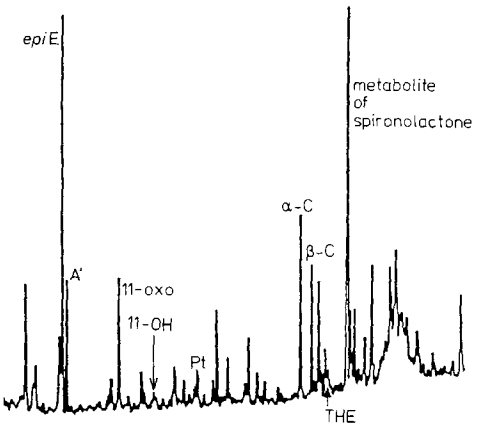
Interestingly, the blood steroid balance is different in uremia; the main steroid found in the blood of healthy individuals is, apart from cholesterol, dehydroepiandrosterone, whereas in uremia another main steroid is present—androst-5-ene-3β,17β-diol.[108]

Steroid metabolism also changes in diabetics[110] and persons suffering from liver diseases[111] (Fig. 7). Large quantities of the bile acid precursors are excreted in the form of steroid alcohols that are derived from cholesterol. They are normally only present in trace amounts.

Changes in steroid metabolism also seem to be typical of some skin diseases. For example, the blood steroid profiles of patients suffering from psoriasis resemble those of uremic patients.[112] Low levels of corticoid excretion in urine have been observed in a number of skin diseases such as psoriasis and neurodermitis;[113] this phenomenon may perhaps be related to the irritation of large areas of skin associated with such diseases.

External application of corticoid ointments should not affect the body's steroid metabolism. However, it has been



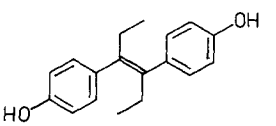


Fig. 7. Urine steroid profile in liver disease (Wilson's syndrome) (for conditions see Figure 3).

found that fluorocorticoids can apparently penetrate damaged skin[114] and thus simulate increased corticoid levels, which leads to a reduction of the body's own steroid production. The urine steroid profile then exhibits reduced steroid excretion.

GC/MS plays an important part in determining whether artificial estrogens such as diethylstilbestrol (Scheme 18) have been used to fatten livestock.[115] Traces of these substances can be detected in the bodies of animals by "selective ion monitoring"[116] or "selected metastable peak monitoring."[117]

Scheme 18. The synthetic steroid diethylstilbestrol detected in the urine of fattened beef cattle.

9. Profiles of Bases

Since biological fluids generally only contain very small quantities of bases, base profiles usually reflect the consumption of stimulants. The main peak of the base profile of urine obtained from smokers is nicotine while that for coffee drinkers is caffeine.

Polyamines such as putrescine **45**, cadaverine **46**, spermidine **47**, spermine **48**, and isoputreanine **49** (Scheme 19) are of importance for cell proliferation and growth, especially in their acetylated forms.[118]

$H_2N-(CH_2)_4-NH_2$ **45**

$H_2N-(CH_2)_5-NH_2$ **46**

$H_2N-(CH_2)_3-NH-(CH_2)_4-NH_2$ **47**

$H_2N-(CH_2)_3-NH-(CH_2)_4-NH-(CH_2)_3-NH_2$ **48**

$H_2N-(CH_2)_3-NH-(CH_2)_3-COOH$ **49**

Scheme 19. Putrescine **45**, cadaverine **46**, spermidine **47**, spermine **48**, and isoputreanine **49**.

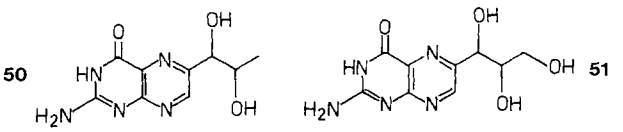
A relatively large amount of spermidine **47** is found in young tissues and relatively little in aging tissues. Increased levels of polyamines are consequently released in

tumor diseases. It was therefore hoped that cancer could be diagnosed at an early stage by determining polyamines in urine. However, high levels of polyamines were also found in other diseases.[118] Furthermore, even if amine production is increased in tumor tissue, the quantity of tumor tissue is so small when compared with the body weight that it has little effect on the total excretion of polyamines.

Polyamines and their acetyl derivatives cannot easily be extracted from biological fluids because they are highly soluble in water. One method for obtaining these compounds consists of extracting the alkalized urine with butanol, reextracting after acidification, and adsorption of the amines onto a Dowex 50W-X8 ion exchanger, from which the amines can then be washed off with HCl.[119] In another procedure, the acetyl residues initially present are cleaved by acid hydrolysis, the hydrolysate is then concentrated, buffered, and applied to a Sep Pak column, and the amines are finally eluted with acidic methanol.[120] The polyamine fraction is derivatized by acylation with heptafluorobutyric anhydride for the subsequent gas chromatographic separation.

Profiles were obtained in this way using packed[119] and capillary columns.[120] The profiles revealed the presence of many other amines in addition to the known polyamines and purine bases; only one degradation product of spermidine[119] **47** and isoputreanine[120] **49** (Scheme 19) have so far been identified. Many polyamines still remain to be identified.[121]

Since isoputreanine **49** is excreted in much smaller quantities by healthy individuals than by patients who have been successfully treated for lymphomatosis, it has been suggested that this could provide a method for analytically studying the success of the therapy used to treat such diseases.[120]



Neurophysiological processes are closely linked to the release of catecholamines. Determination of these compounds is important because the liberation of catecholamines is related to nervous diseases such as schizophrenia, Parkinson's disease, epilepsy, migraine, and depressive symptoms. Their concentrations in blood vary greatly with time. Measurement in urine is therefore often preferred because this gives the mean release values over longer periods of time.

The determination of many phenylethylamines is difficult due to their dipolar nature—they contain both basic amino groups and phenolic hydroxyl groups having acidic character. Their subsequent degradation products, such as vanillinmandelic acid, homovanillic acid, and 4-hydroxy-3-methoxyphenylethyleneglycol, are therefore often measured instead.[41a,b,122]

Many methods have been developed for measuring the catecholamines themselves.[123] The biogenic amines[124] can be determined by GC/MS or by HPLC using electrochemical detection to identify the components.[125]

Basic metabolites are often formed from pharmaceuticals. Since the amines normally present in the body hardly interfere with the base profile and usually only a few basic metabolites are produced from a single drug, GC/MS is highly suitable for routine measurements in pharmacokinetic studies even if packed columns are used.

The investigation of pterins has recently become of importance in connection with the growth of tumors. MS is very important for detecting and determining biopterin **50** and neopterin **51** (Scheme 20) in the form of their trimethylsilylated derivatives.[126]

Scheme 20. Biopterin **50** and neopterin **51**.

10. Amino Acid Profiles

Amino acids and low-molecular-weight peptides are obtained from biological fluids by acidification and adsorption on a cation exchanger. On rinsing with water, the amino acid and peptide fractions are retained by the ion exchanger and can then be eluted with NH_3. They can be separated into an amino acid fraction and a peptide fraction by using reversed phase octadecasilyl columns[127] or Chelex 100.[128]

For gas chromatographic determination of the amino acids, the amino acid fraction is esterified and acylated;[129] the butyl esters are usually prepared as suggested by *Gehrke* et al. and are then trifluoroacetylated in a subsequent step.[130] It is difficult to determine arginine, sulfur-containing amino acids, and tryptophan with this technique.[131] This problem can be surmounted, however, by preparation of the *N*-heptafluorobutyryl *n*-butyl ester derivatives.

The trifluoroacetylated amino acid butyl esters can easily be characterized by MS.[130a,132] Profiles of amino acid hydrolysates of differing biological origin were obtained using packed columns.[133] They display, in addition to the peaks corresponding to the 20 known amino acids present in proteins, other peaks corresponding to unknown basic substances.[134] Small quantities of, for example, acylated[135] and methylated[136] amino acids were identified. Since most of these studies were reported some time ago and capillary gas chromatography has only been employed recently in this field (Fig. 8),[137] little is known about the unidentified substances.

Unlike acid profiles, amino acid profiles remain highly consistent. Differences are observed between individuals but the profiles vary little with time. The quantities of the main amino acids that are excreted vary within one order of magnitude but are probably more dependent on diet than those of acids. It is known that ingestion of food rich in protein leads to an increase in the excretion of amino acids, particularly those that are branched. Stress has a similar effect in adults.[138] When meat and above all poultry are consumed, 1-methylhistidine is found in the urine;[139] homocitrulline occurs in the urine of children who drink a great deal of milk.[140] Small children excrete appreciably more glycine, histidine, glutamine, alanine, and lysine than adults.[141]

Amino acid excretion in individuals with hereditary diseases that affect amino acid metabolism[142] naturally differs considerably from that of healthy individuals.[138,141]

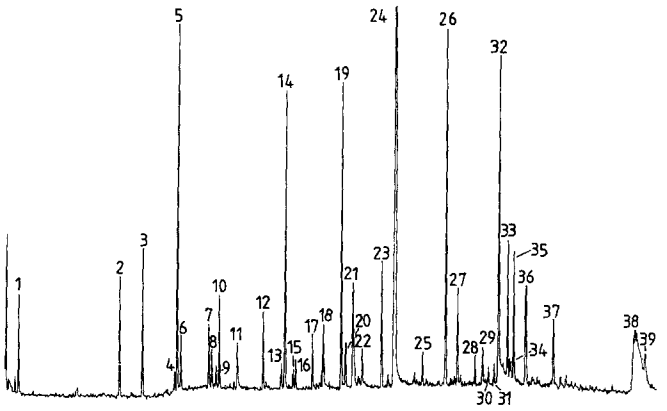


Fig. 8. Urine amino acid profile of a healthy man (29 years old). The amino acids were separated in the form of their *N*-heptafluorobutyryl *n*-butyl ester derivatives. Alanine (3), valine (4), glycine (5), threonine (6), serine (7), β-aminoisobutyric acid (8), leucine (9), isoleucine (10), cycloleucine, standard 1 (12), proline (13), cysteine (15), hydroxyproline (18), methionine (22), aspartic acid (and asparagine) (23), creatinine and phenylalanine (24), glutamic acid (and glutamine) (26), tyrosine (27), ornithine (30), 4-aminomethylenecyclohexanecarboxylic acid, standard 2 (33), arginine (34), lysine (35), 1-methylhistidine (36), 3-methylhistidine (37), histidine (38). (1), (2), (11), (14), (16), (17), (19), (20), (21), (25), (28), (29), (31), (32), and (39) are unknown. Experimental conditions: Carlo Erba Fractovap 4160 gas chromatograph with a WCOT quartz capillary (50 m × 22 mm with the chemically bound phase OV 1701); hydrogen flow-rate: 1.3 mL/min; injector temperature: 270°C; oven temperature: 130–260°C (3 min isothermally, then with 3°C/min); flame ionization detector (FID).

The kidney has the important function of resorbing much larger quantities of the essential amino acids than of other substances from the primary urine. The filter that is used for ultrafiltration of the blood of patients suffering from uremia is incapable of doing this. Consequently, uremic patients lose a much higher percentage of essential amino acids due to excretion in the urine than do healthy persons. Studies of the amino acid profiles show, for example, that the loss of methionine is 10 times higher, that of proline 100 times higher.[137b]

11. Peptides

Dipeptides can also be separated by gas chromatography in the form of trifluoroacylated butyl esters. The urine of healthy individuals contains small quantities of dipeptides.[143] Patients suffering from skin disease excrete relatively large amounts of proline-containing dipeptides.[144]

Determination of the structures of oligopeptides by mass spectroscopy proved to be unsuccessful due to the low volatility and high mass of these substances. The oligopeptides were therefore cleaved enzymatically with dipeptidyl aminopeptidases, and the mixture of dipeptides was then separated by gas chromatography after derivatization and the individual dipeptides were characterized by MS.[145] The main problem in all of these investigations was presented by the large number of dipeptides (about 400) that can be formed and whose GC and MS properties had to be known for purposes of identification. Furthermore, many dipeptide mixtures are difficult to separate on packed columns.[145d] Nevertheless, this procedure was finally applied successfully to study the *N*-terminus of spinach plastocyanin.[146]

Peptides can be sequenced by GC/MS using the method developed primarily by *Biemann*'s group. The peptides are split into smaller peptides by peptidases that act specifically on certain peptide bonds or by non-specific chemical hydrolysis. The mixture is then esterified, acylated, and reduced with $LiAlH_4$ ($LiAlD_4$) or B_2H_6 (B_2D_6). The resulting amino alcohols are trimethylsilylated and separated by gas chromatography. The structure of the hydrolysate peptides and thus of the original peptides can be deduced from the very characteristic mass spectra of the derivatized amino alcohols.[147]

Since this procedure initially required a relatively large amount of material, it could only compete with conventional sequencing procedures in special cases.[148] The many steps involved in preparing the derivatized amino alcohols can be reduced if the mixture of the esterified partial peptide hydrolysate is methylated.[149] However, C-methylation may also occur,[150] resulting in the formation of complex mixtures. This method can therefore only supplement classical degradation procedures.[151]

In recent years "soft" ionization methods, in particular "fast atom bombardment" (FAB)[152] and field desorption mass spectrometry,[153] have become increasingly important in the study of oligo- and polypeptides. In FAB-MS investigations a noble gas is ionized and the ionized atoms are then accelerated. If these atoms pass through a zone of intact gas molecules, they will transfer their charge but not their kinetic energy to these molecules. The beam of atoms then bombards a glycerol solution of the non-derivatized peptide. Peptides and solvent molecules that are hit by the beam are expelled and ionized. Protonated molecular ions are chiefly obtained. This method is thus especially suitable for determining molecular weights of even larger molecules—e.g., both fragments[155] and molecular ions were obtained from insulin[154] ($M_r \approx 6000$).

Attempts were made to determine the sequence of model peptides from the fragments formed. Basically, fragments were selected from those present whose formation could be accounted for by the given structure. Since additional ions (some being produced by reaction of the peptide with the matrix molecules) and missing ions confuse the fragmentation pattern, it is almost impossible to deduce the complete structure of unknown free peptides without supplementary information.

However, the tendency to form fragments can be greatly increased by introducing an electron-rich system into the peptide, as is demonstrated by comparing the FAB mass spectra shown in Figures 9 and 10. In the case of small peptides (up to ten amino acids), the introduction of an aromatic group containing bromine is particularly advantageous because the presence of the almost equally abundant bromine isotopes ^{79}Br and ^{81}Br in the fragments affords a label which allows simple recognition of the structurally specific fragments in the form of double peaks[155c] (Scheme 21).

Interpretation of the spectra can also be improved by establishing the decomposition pathways with the aid of the "linked scan technique."[156] After the primary production of ions, the ions of a defined mass that are to be studied are separated from the other ions by the electric field of the mass spectrometer and then excited by reaction with an

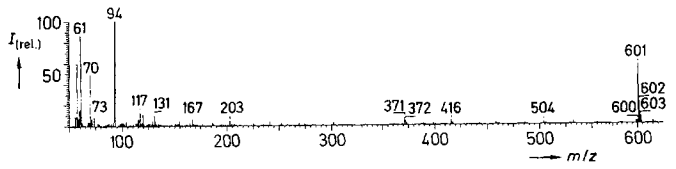

Fig. 9. FAB mass spectrum of the positive ions of the hexapeptide Pro-Pro-Gly-Phe-Ser-Pro in a glycerol matrix; m/z 601 (MH^+).

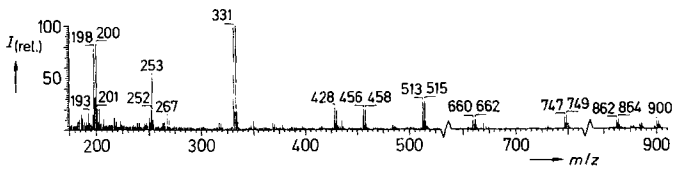

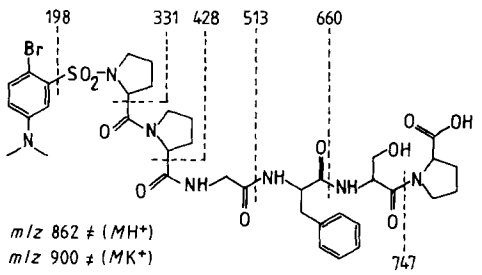

Fig. 10. FAB mass spectrum of the positive ions of the hexapeptide Pro-Pro-Gly-Phe-Ser-Pro derivatized with 2-bromo-5-(*N*,*N*-dimethylamino)benzenesulfonyl chloride.

Scheme 21. Formation of ions observed in the FAB mass spectrum (shown in Figure 10) of the derivatized hexapeptide Pro-Pro-Gly-Phe-Ser-Pro; the masses given are relative to ^{79}Br.

added auxiliary gas. The masses of the secondary fragments of the selected primary ions can now be determined and the fragmentation mechanisms investigated by varying (scanning) the magnetic field; for example, the stepwise formation of fragments can be followed and thus the sequence of a peptide can be determined.

The resolving power of the instrument and the necessary mass determination limit the usefulness of the FAB-MS method for large peptides. A procedure recently developed by *Biemann* et al. seems to be suitable for examining these peptides and combines both the sequencing of nucleic acids and that of peptides. A peptide mixture that has been partially digested with trypsin is investigated by means of FAB-MS. The molecular ions of the peptides in the mixture are easy to obtain and must correspond to molecular weights that can be predicted from DNA sequencing. If no differences are found, the DNA sequence is confirmed. If this is not the case, errors can be identified and corrected. This combined procedure seems to have a promising future.[157]

12. Concluding Remarks

The metabolism of an individual is apparently predetermined from birth. Large differences exist, however, between individuals. These are perhaps a result of undiscovered, harmless genetic defects, but may become significant if a disease has to be treated with drugs and the pharmacologically active agents are also metabolized differently, as has already been shown.[158]

If it were possible to recognize these defects at an early stage in small children and to construct a metabolic chart for each individual, drug treatment of disease could then be designed on an individual basis and preventative measures against nutritional damage could be taken if required.

The great effort involved in the use of GC/MS would probably not be necessary if key compounds typical of certain hidden defects were discovered, since radioimmunoassays could be developed to detect them. This is, however, still a dream of the future.

The question of whether such studies can be at least partially realized mainly depends on whether organic chemists will in the future attach more importance to research into biological materials and metabolic processes than they have done in the past. This is the task that faces young chemists.

The studies of my own group mentioned in this review are the results of the efforts, skill, and ideas of my coworkers. I would like to thank them for their persistence despite setbacks and the courage with which they have followed the course traced out for them. They are S. Bauer, H.-J. Egger, M. Ende, A. Grupe, A. Heindl, C. Hölzel, H. Ludwig-Köhn, M. Neupert, P. Pfeifer, J. Pfordt, O. Rau, J. Reiner, D. Renner, K. Schneider, M. Spiteller, Jr., and B. Zielinska. I am grateful to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Schering for their financial support.

Growth and Dissolution of Organic Crystals with "Tailor-Made" Inhibitors—Implications in Stereochemistry and Materials Science

By Lia Addadi,* Ziva Berkovitch-Yellin,* Isabelle Weissbuch, Jan van Mil, Linda J. W. Shimon, Meir Lahav,* and Leslie Leiserowitz*

In memoriam Gerhard M. J. Schmidt

When crystals of organic compounds are grown in the presence of growth inhibitors, there is a change in crystal morphology. A stereochemical correlation exists between the crystal structure, its modified morphology, and the molecular structure of the inhibitor. This correlation has been successfully exploited for the efficient resolution of conglomerates, the engineering of organic crystals with desired morphologies, the direct and relative assignment of the absolute configurations of chiral molecules and crystals, and for the design of a new model for the spontaneous generation of optical activity. In an analogous way dissolution of organic crystals in the presence of these growth inhibitors induces etch pits at preselected faces. The effect of solvent on crystal growth has been analyzed in some model systems. The experimental results are complemented by atom-atom potential energy calculations.

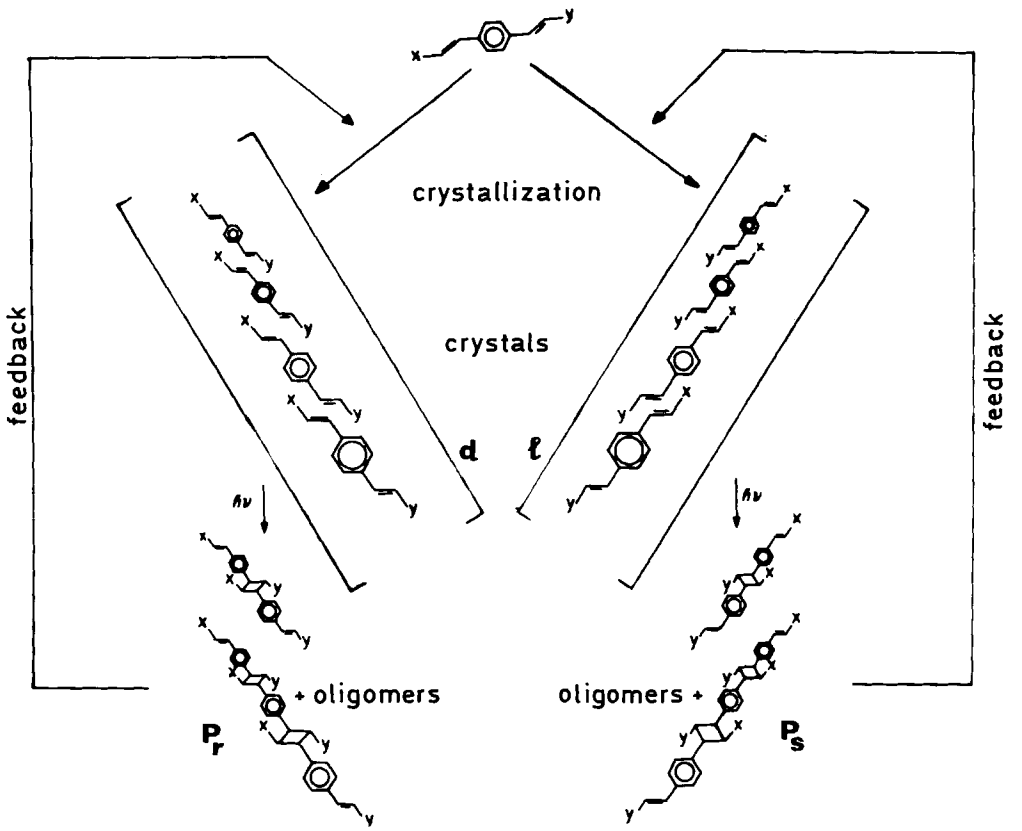
1. Introduction

The various and beautiful morphologies of crystals have attracted the attention of natural philosophers since ancient times. Crystal formation from the smallest irreducible units had already been conceived as long ago as 1611 by *Kepler*;[1] this concept played an important role in the development of molecular theory.

The relation between the morphology of a crystal and its internal symmetry at a molecular level was first demonstrated by *Louis Pasteur*[2] in 1848. In his now famous experiment he separated, for the first time, the two enantiomers of sodium ammonium tartrate, utilizing the asymmetric habit of their crystals. Over the years, however, it became evident that the morphological characteristics of the crystals of a given compound depend not only on its crystal structure, but also on external parameters of the overall crystallizing system such as solvent, supersaturation, temperature, and specifically impurities present in the system[3].

In 1931 *Miles*[4] demonstrated that crystals of $PbCl_2$, which normally crystallize with centrosymmetric point symmetry ($2/m,2/m,2/m$), assume a chiral morphology of symmetry 222 when grown in the presence of dextrin. With the advent of new and efficient methods of crystal structure determination, most efforts were devoted to such determinations and less interest was focused on correlating crystal structure and morphology. As a result, many important properties of materials which depend on this correlation were not exploited in a systematic way. On the other hand, the use of dopants for inducing a particular crystal morphology is a widespread technological tool, even though the mechanism of the effect is scarcely understood. Thus, for example, small amounts of ions such as Pb^{2+} or SO_4^{2-} have long been routinely used as crystallization moderators in the industrial production of large NaCl single crystals for IR and Raman spectroscopy.[5] Similarly, sugar technologists recognized and studied the critical role played by oligosaccharides in determining the rate of crystallization and habit of sucrose crystals on extraction from molasses.[6]

In the course of investigating the packing and growth of organic molecular crystals, we initiated a study on the systematics of the interactions between a crystallizing substrate and its environment, in general, and the solvent and stereospecific "tailor-made" growth inhibitors in particular. We shall illustrate here some mechanistic aspects of the above interactions as they have emerged during these studies and some applications thereof to the amplification of chirality by crystallization, resolution of conglomerates, the direct and relative assignment of absolute configuration of chiral molecules, the study of molecular interactions in crystals, the engineering of crystals with desired morphologies, and the selective etching of crystal surfaces upon dissolution.



2. Amplification of Chirality by Crystallization with Chiral Additives; a New Method for the Resolution of Conglomerates of Enantiomers

The synthesis of chiral enantiomerically pure materials from nonchiral reagents has been accomplished by crystallization of the (in solution) nonchiral substrate in appropriately packed chiral single crystals, followed by a lattice controlled reaction.[7] This concept is illustrated in Scheme 1 for the generation of chiral cyclobutane polymers from nonchiral dienes packing in "engineered" chiral crystals.[8]

The molecules in each chiral crystal, (denoted by $[\,]_d$ or $[\,]_l$ in Scheme 1), are related by translation such that the neighboring C=C bonds are in appropriate proximity for photodimerization. UV irradiation of a single crystal yields dimers, trimers, and oligomers of a single chirality P_r or P_s.

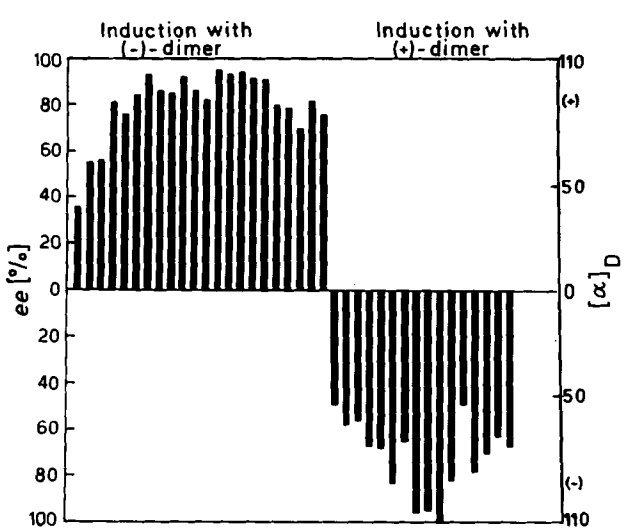
Scheme 1. Lattice-controlled generation of chiral cyclobutane derivatives (enantiomers P_r and P_s) from non-chiral dienes packing in "engineered" chiral crystals (d and l symbolize the respective enantiomeric packings). For examples of the dienes, see Table 1. The feedback leads to an inhibition of crystallization.

In a nonchiral solvent the d and l crystals are formed in equal amounts, so that no net asymmetric induction of the reaction products P_r and P_s is observed. On the other hand, a net asymmetric induction of one of the crystalline phases is achieved when chiral dimers, trimers or oligomers of a *single* chirality (i.e. P_r *or* P_s) are present during the process of crystallization. In all experiments it was observed that a large excess of that phase was formed which was enantiomorphic to the one in which the additive itself had been generated; namely, d crystals were obtained from a solution containing additives P_s and l crystals from solutions containing additives P_r (Fig. 1).



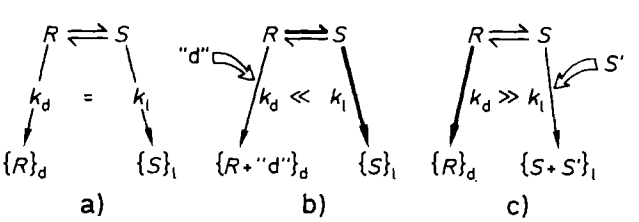


Fig. 1. Enantiomeric excess (*ee*) of the dimers obtained by lattice controlled reaction after crystallization of the monomer in the presence of chiral dimers as additives under various experimental conditions (see Scheme 1 and Table 1).

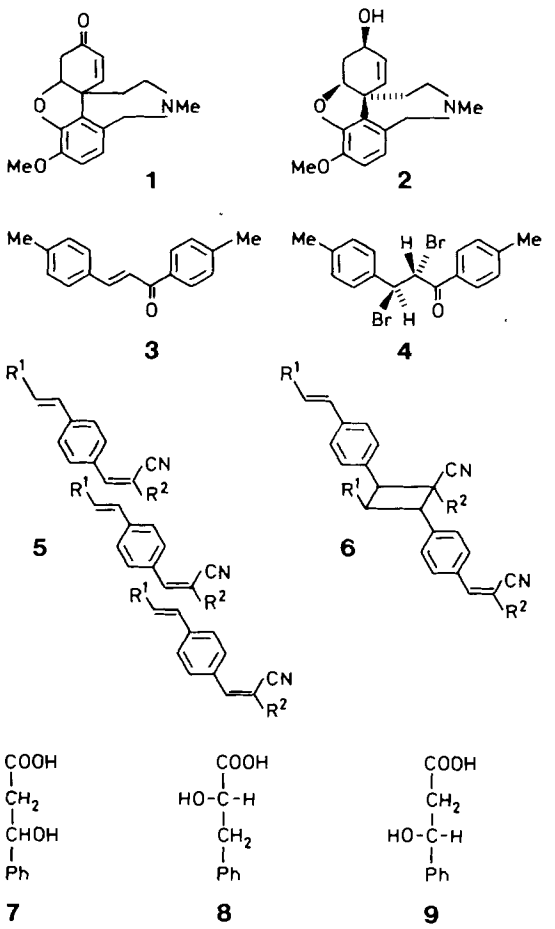
The stereochemical similarity between the additive and the respective enantiomorphous crystal of the monomer was found to be of paramount importance,[9,10] while parameters like temperature, concentration, or nature of the medium had only a quantitative effect on the observed asymmetric induction.

We suggested that, by virtue of this stereochemical similarity, a chiral dimer, trimer, or oligomer may substitute two, three, or n monomer units at a growing site of that crystal with the same absolute configuration as the parent crystal of the photoproducts. The adsorption should cause a drastic decrease in the rate of growth of this same crystal, shifting the crystallization equilibrium towards the unaffected phase. This process of crystal growth and inhibition is illustrated in Scheme 2, where the achiral monomer is

Scheme 2. (a) Spontaneous crystallization of a racemate (*RS*) to give a $\{R\}_d/\{S\}_l$ conglomerate; (b) crystallization in presence of the additive "d" (lattice-controlled product of the $\{R\}_d$ phase); preferred crystallization of $\{S\}_l$; (c) crystallization in presence of a chiral additive *S'* (with stereochemical similarity to *S*); delayed crystallization of $\{S\}_l$.

represented as a fast racemizing mixture of chiral conformations R and S in solution, and $\{R\}_d$ and $\{S\}_l$ represent the chiralities of the crystalline phases.

A natural extension of this scheme to any racemic mixture, fast racemizing or not, crystallizing in the form of a conglomerate of $\{R\}_d$ and $\{S\}_l$ crystals, led to the suggestion of a new method for kinetic resolution of such systems. It is based on selective retardation of the growth of the crystals of one enantiomorph, say S, induced by small amounts of chiral additives, say S', with related stereochemistry (Scheme 2c).[10]



In the light of this proposed mechanism we could rationalize various experimental results, describing kinetic resolutions accidentally observed in the presence of chiral additives, and where the fast crystallizing enantiomer had absolute configuration opposite to that of the additive (Table 1).[10] The predictive power of the hypothesis was further tested on other conglomerate systems including threonine, glutamic acid · HCl, and asparagine · H_2O. These were resolved with the assistance of a variety of other amino acids used as growth retarders (Table 1).[10]

The efficiency of the resolution was found to vary from one system to another, and to depend upon the nature and

[a] All amino acids that have been used as chiral additives belong to the L-series, i.e. with the exception of Cys they are (*S*)-configurated. [b] d und l arbitrarily denote the different chirality of the crystals (without reference to the absolute configuration). [c] Examples: R^1 = COOCHEt$_2$, R^2 = COOMe, COOEt, COO*n*Pr; R^1 = (*RS*)-COO*s*Bu, R^2 = COOEt, COO*n*Pr.

concentration of the additive. In the best cases, [(*RS*)-glutamic acid · HCl + (*S*)-lysine; (*RS*)-threonine + (*S*)-glutamic acid; (*RS*)-asparagine + (*S*)-aspartic acid] complete resolution (100% *ee*) was achieved. The growth of the affected crystals in these instances was delayed up to several days with respect to that of the unaffected ones. In all the systems investigated we could demonstrate that the additive is occluded throughout the bulk of the affected crystals in amounts ranging typically from 0.05 to 1.5% w/w of substrate; it is found in much smaller amounts, if any, in the crystals of the enantiomorph.

The inhibiting effect of the additive on the growth of the affected enantiomorph has also been proven by direct comparison of the size of $\{R\}_d$ and $\{S\}_l$ single crystals grown in parallel from seeds under conditions close to equilibrium (Fig. 2). Although there are indications that the same kind of inhibition may also influence the crystal nucleation rate, such an effect is more difficult to isolate and quantify.

The most convincing demonstration of the adsorption-growth inhibition mechanism is provided by the changes in the morphology of the affected crystals. The morphology of a crystal is determined by the relative rates of growth of its various faces. Since the growth rates of only those crystal faces where adsorption of inhibitor takes place are affected, crystals growing in the presence and in the absence of additives are expected to display different habits. Indeed, in the resolution experiments it was consistently observed that the appearance of crystals of normal habit was

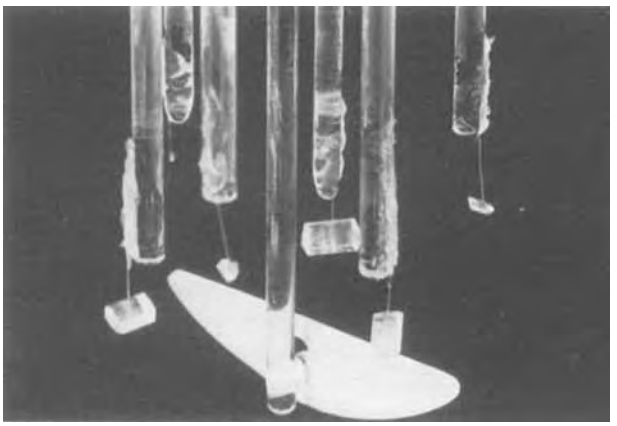

Fig. 2. Three (*R*)- and three (*S*)-crystals of asparagine·H_2O grown together for 45 days under conditions near to equilibrium in the presence of (*S*)-serine. The large crystals are (*R*)- asparagine·H_2O and the small ones are (*S*)-asparagine·H_2O.

followed (after variable time depending on the system) by that of crystals of distinctly different morphology: when the two types were separated by visual sorting, they were found to consist of the unaffected and the affected enantiomers respectively. As expected, the crystallization of asparagine in the presence of different additives consistently yielded crystals with different morphologies (Fig. 3). In the case of (*RS*)-threonine, grown in the presence of say (*S*)-glutamic acid, and (*RS*)-glutamic acid·HCl, grown in the presence of (*S*)-lysine·HCl, the inhibition of growth is so strong that the affected (*S*)-enantiomer appeared as a fine powder coating the well-formed crystals of the (*R*)-enantiomorph (Fig. 4).[17]

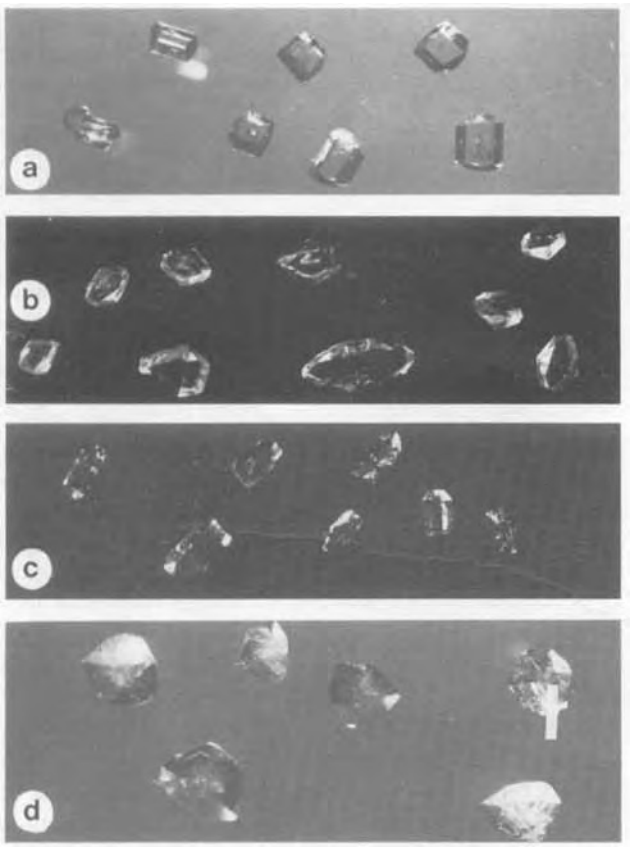

Fig. 3. Crystals of (*S*)-asparagine·H_2O grown in the presence of additives: (a) none, or (*R*)-additives; (b) (*S*)-glutamine as additive; (c) (*S*)-serine as additive; (d) (*S*)-ornithine as additive. In each case the crystals were obtained from (*RS*)-asparagine as a mixture of (*R*)-asparagine crystals displaying a morphology as in (a), and (*S*)-asparagine crystals displaying a morphology as in (b)–(d) or others, depending on the additive.

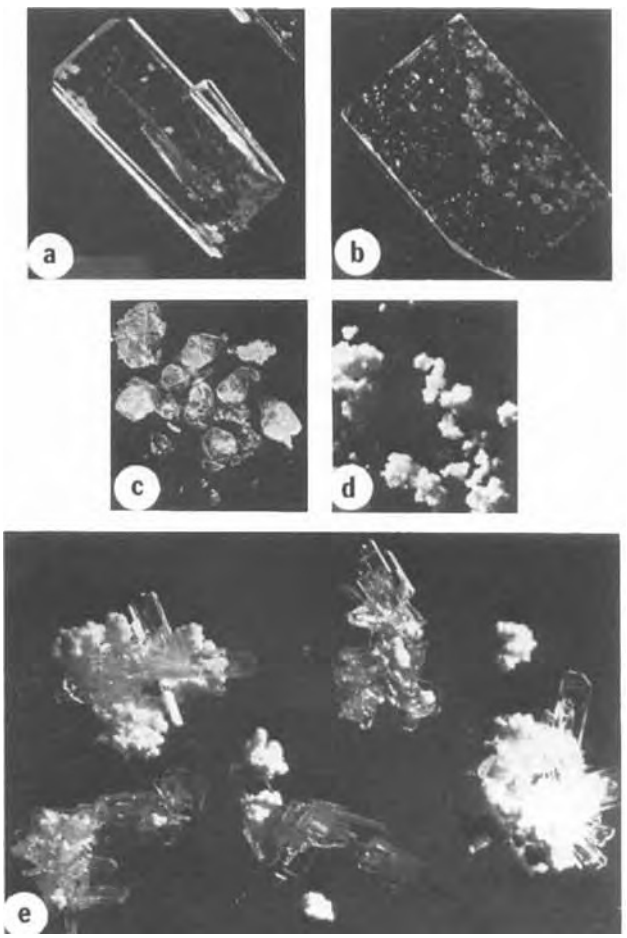

Fig. 4. Crystals of (*S*)-glutamic acid·HCl grown in the presence of increasing amounts of additive lysine: (a) no additive or (*R*)-lysine; (b) +2 mg/mL (*S*)-lysine; (c) +5 mg/mL (*S*)-lysine; (d) +50 mg/mL (*S*)-lysine; (e) crystals of (*R*)- and (*S*)-glutamic acid·HCl grown in the presence of (*S*)-lysine: the plates are the (*R*)-enantiomer while the powder is the (*S*)-enantiomer.

This phenomenon offers the possibility of modifying *Pasteur*'s classical experiment and of extending it to systems which undergo spontaneous resolution but do not display hemihedrism so that one cannot distinguish the enantiomorphous crystals by their morphologies.[18] Another kind of visual differentiation of the enantiomorphs was obtained by crystallizing a conglomerate of colorless crystals in the presence of a resolved and colored "tailor-made" inhibitor. When the plate-like crystals of (*R*)- and (*S*)-glutamic acid·HCl are grown in the presence of yellow N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine as additive, colorless crystals of (*R*)-glutamic acid·HCl precipitate first, and then yellow ones of the (*S*)-enantiomer (Fig. 5a–c).

The stereochemical correlations between the enantiomorphous crystals and their chiral inhibitors, namely that the additive only affects the enantiomer of the same absolute configuration, provides us with a new method for the determination of absolute configuration on a relative scale.

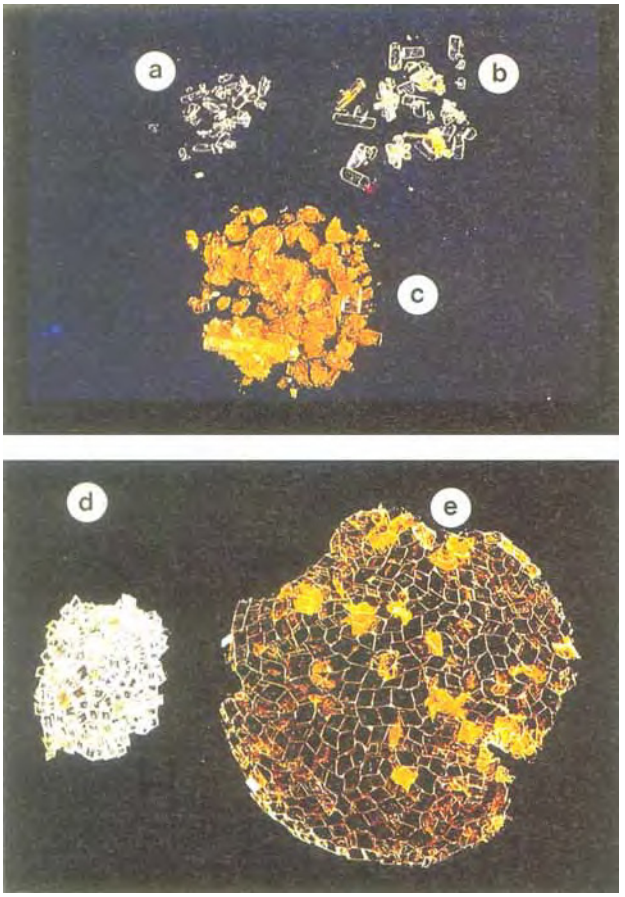

Fig. 5. Top: Crystallization of (*R*)- and (*S*)-glutamic acid·HCl in the presence of N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine. (a) First crop: colorless crystals of (*R*)-glutamic acid·HCl; (b) second crop: mixture of colorless (*R*)-glutamic acid·HCl and yellow (*S*)-glutamic acid·HCl; (c) third crop primarily contains small, yellow crystals of (*S*)-glutamic acid·HCl.—Bottom: Crystals of glycine grown at an air/water interface from aqueous solutions (concentration: 0.3 g/mL) in the presence of (d) (*S*)-leucine + N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine and (e) (*R*)-leucine + N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine (see Section 5).

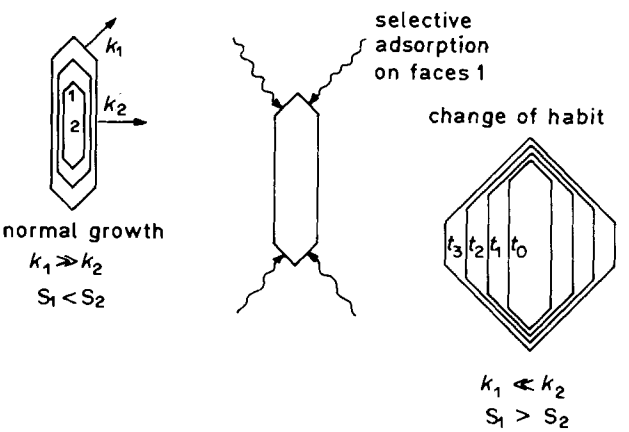

This is revealed independently by morphological changes and enantioselective occlusion of additives. The method is related to the quasi-racemate technique of *Fredga*,[19] but has the advantage of a wider applicability.

3. Morphological Crystal Engineering

The dramatic morphological changes associated with the growth of organic crystals in the presence of additives reveal the high degree of specificity in the interaction of the foreign material with the different structured surfaces of the crystalline matrix. The morphological changes have therefore a direct bearing on the mechanism of the adsorption-inhibition process on a molecular level.

In general, when growth is inhibited in a direction perpendicular to a given face, the area of this face is expected to increase relative to those of other faces of the same crystal (Scheme 3). Differences in the relative surface areas of the various faces of pure and affected crystals allow, therefore, identification of the affected faces and consequently of the crystallographic directions involved. This type of morphological analysis was carried out on a variety of organic compounds crystallized in the presence of additives of molecular structure similar to those of the corresponding substrate molecules.[17] A stereochemical correlation between the structures of the affected crystal surfaces and the molecular structure of the inhibitor could be deduced in each system. We could infer that the additive may be adsorbed only at those faces in which the part of the adsorbate that differs from that of the substrate points away from the crystal interior. Once adsorbed, the additive inhibits the regular deposition of oncoming layers of substrate molecules, slowing down the growth perpendicular to that face and leading to a concomitant relative increase in its surface area. A similar mechanism had been invoked by *Smythe*[6] in his elegant studies on the changes in habit of the crystals of sucrose grown in the presence of oligosaccharides as additives.

Once this mechanism was established, it became possible to exploit it in order to systematically modify the morphology of crystals by tailoring additives which bind at a preselected face and thus inhibit growth in a predictable manner.

Scheme 3. Formation of crystal faces f with surface area S as a function of their selative growth rates *k*. The change in habit results from selective adsorption of inhibitor on faces of type 1. Left: Habit during normal growth. Right: Change of habit by inhibition of growth of faces 1.

This approach is illustrated here for benzamide, which crystallizes from ethanol in the form of {001} plate-like crystals elongated along the *b* axis (Fig. 6a). The main packing feature of the structure (Fig. 7) consists of the typical ribbon motif[20] of hydrogen bonded cyclic dimers interlinked by NH···O bonds along the *b* axis. Retardation of growth of the {011} faces along *b* was achieved with benzoic acid as additive. The substitution of a molecule of benzamide at the end of the ribbon motif by benzoic acid results in replacement in the *b* direction of an NH···O bond by a repulsive O···O interaction, thus retarding growth in this direction and inducing the growth of bar-shaped crystals elongated in *a* (Fig. 6b). Inhibition of growth along *a* was accomplished by adding *o*-toluamide to the crystallization solution. The crystals consistently grew as bars elongated in *b* (Fig. 6c). The additive *o*-toluamide can be easily adsorbed in the hydrogen-bonding chain without interfering with growth in the *b*-direction. The *o*-CH_3 group emerges, from the $(10\bar{4})$ side face, and

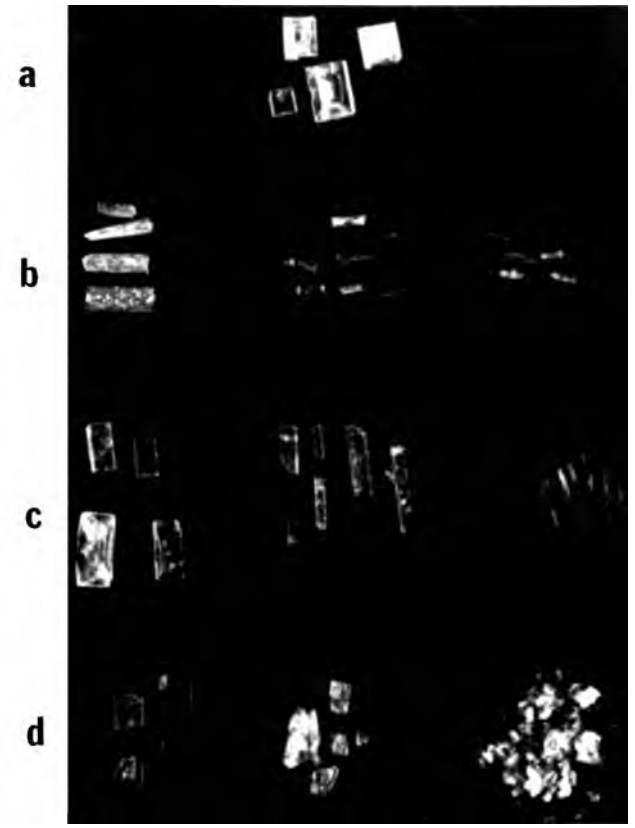

Fig. 6. Crystals of benzamide: (a) Crystallization with no additive. (b) – (d) Crystallization in the presence of increasing amounts (from left to right) of (b) benzoic acid; (c) *o*-toluamide; (d) *p*-toluamide.

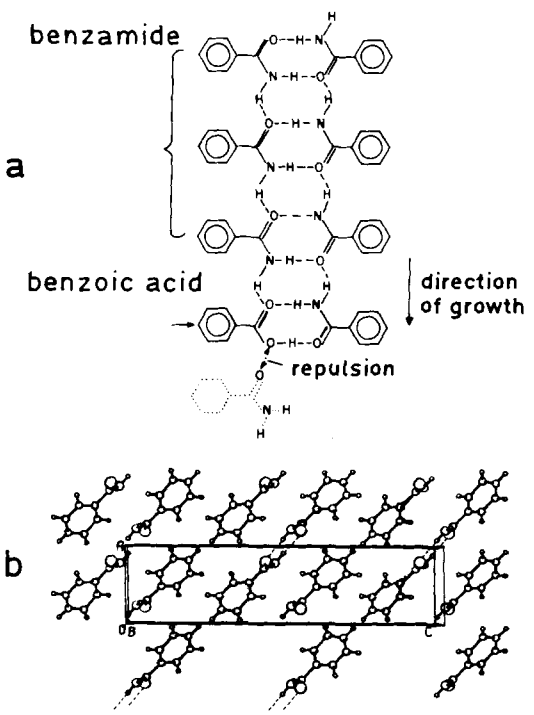

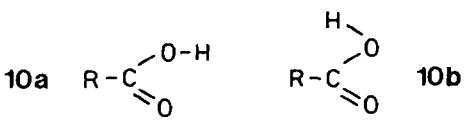

Fig. 7. (a) Schematic representation of part of the benzamide structure showing a benzoic acid molecule inserted at the end of the ribbon motif of hydrogen bonded dimers along the *b* axis. (b) Packing arrangement of benzamide viewed along the *b* axis (*b* axis perpendicular to plane of paper).

thus interferes with growth along the *a* direction, in which the dimers are stacked (Fig. 7b). Finally, thinner and thinner plates are obtained by adding increasing amounts of *p*-toluamide, whose methyl substituent perturbs the already weak van der waals interactions between the phenyl layers in the *c* direction (Fig. 6d, 7b).[21]

Similar morphological changes were induced in crystals of other primary amides and of other organic molecules, including carboxylic acids, amino acids, dipeptides and steroids.

In accounting for the effect of a carboxylic acid additive on the crystal habit of the corresponding primary amide we assumed that the carboxyl group adopts the commonly observed synplanar conformation **10a**, as against the rarely observed antiplanar conformation **10b**.[22]

This postulate was eventually demonstrated by a diffraction experiment on the host-additive system asparagine-aspartic acid[23] and confirmed by potential energy calculations on benzamide-benzoic acid.[24]

Crystals of asparagine·H_2O undergo a change in habit when grown in the presence of aspartic acid[17] (Fig. 8a). We explain this change using arguments akin to those given above for benzamide-benzoic acid. The affected crystals are {010} platelets, whose formation can be rationalized in terms of adsorption of aspartic acid on an (010) face with the condition that its hydroxyl oxygen atom emerges from the face. Further growth at such a surface site is inhibited by the replacement of an amide N–H···$O_{carboxy}$ hydrogen bond between asparagine molecules by an $O_{hydroxy}$···$O_{carboxy}$ repulsion (Fig. 8b). The adsorption-inhibition is compatible only with a synplanar O=C–O–H conformation (see **10a**) in the host crystal. The concentration of occluded aspartic acid (15%) was sufficient to allow us to establish the conformation of the acid by low-temperature X-ray diffraction (Fig. 8c).

Energy calculations were carried out on the benzamide-benzoic acid system in order to quantify the substrate-additive interactions on the basis of the established mechanism of adsorption and inhibition. To ascertain on which face the additive may be adsorbed with the least loss in energy, relative to the pure substrate molecule, we calculated the binding energies of the additive and substrate molecules at the different symmetry-related sites on the various crystal faces (Fig. 6a). It was found that benzoic acid with a synplanar O=C–O–H conformation is most easily adsorbed on the (011) face, with an energy loss of 7 kcal/mol. This loss of energy relative to benzamide originates primarily from the fact that the amide oxygen atom is a much stronger proton acceptor than the corresponding carboxy oxygen.[22] Once bound, such a benzoic acid molecule interacts with an oncoming benzamide layer with an energy loss as high as 10 kcal/mol relative to a corresponding benzamide molecule adsorbed at the site of the additive. An analogous calculation for the antiplanar conformer of

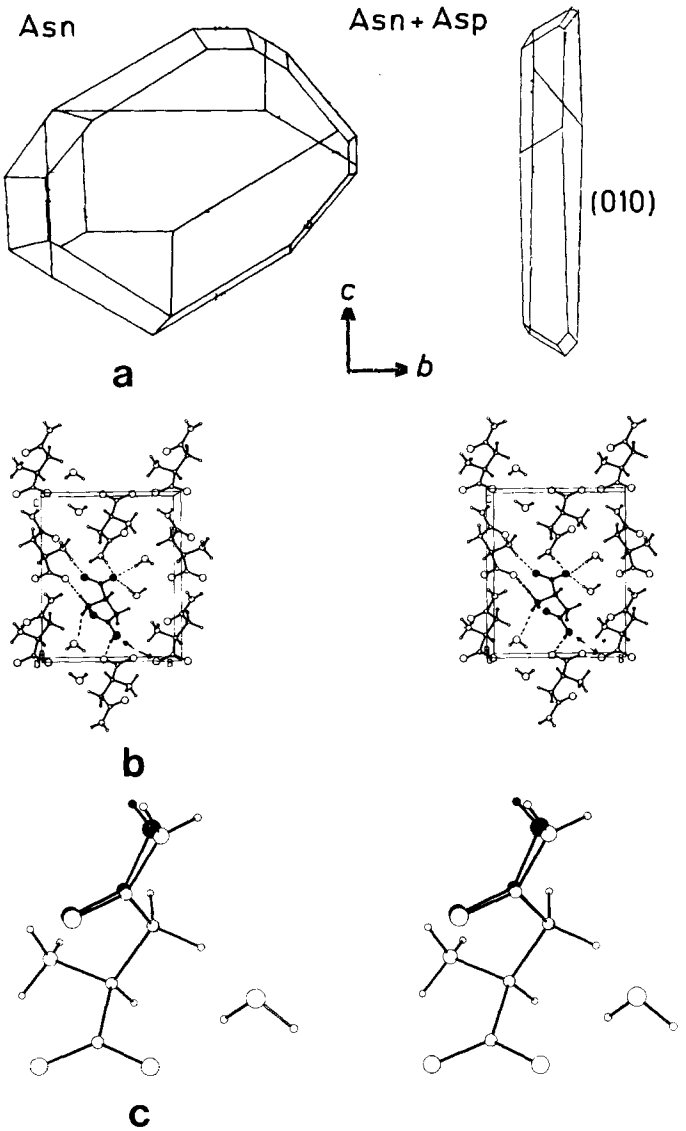

Fig. 8. (a) Crystal morphologies of pure (*S*)-asparagine·H_2O (left) and of (*S*)-asparagine·H_2O grown in the presence of (*S*)-aspartic acid (right); (b) crystal structure (stereoview) of (*S*)-asparagine·H_2O with occluded (*S*)-aspartic acid (full circles); (c) molecular structures (stereoviews) of asparagine and aspartic acid in the crystal structure of asparagine (OH group full circle).

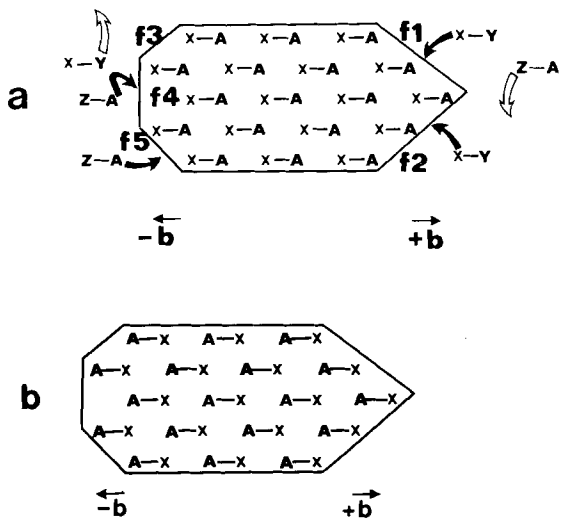

benzoic acid shows that it may be adsorbed and hinder growth only at faces which are experimentally found to be unaffected. This provides further support for the assignment of a synplanar conformation.

These theoretical and empirical considerations allow us both to understand and to predict the induced changes in crystal habit. We shall now show how this knowledge was applied to the solution of certain fundamental problems in stereochemistry.

4. Direct Determination of the Absolute Configuration of Chiral Molecules

Ever since the recognition of chirality in molecules, the direct assignment of the absolute configuration of a chiral molecule in a chiral crystal which develops hemihedral faces has challenged the chemical crystallographer.

The essence of the problem is that conventional X-ray diffraction analysis of chiral crystals (i.e. assumption of Friedel's law) does not allow assignment of the absolute orientation of the chiral molecule with respect to the crystal axes or crystal faces.[25] In other words, it is not possible to distinguish between the polar structure of Scheme 4a

Scheme 4. Schematic representation of the two possible enantiomeric crystal structures (*a*) and (*b*) of the compound X–A with respect to the polar axis *b* (space group $P2_1$); interaction of the polar faces with the additives X–Y and Z–A. a, b see text.

(where the chiral molecule is represented by X-A) and the enantiomeric structure of Scheme 4b (in which the orientation of X-A with respect to the polar *b* axis is reversed). A pictorial representation of a polar motif from a drawing by *Escher* is given in Figure 9.

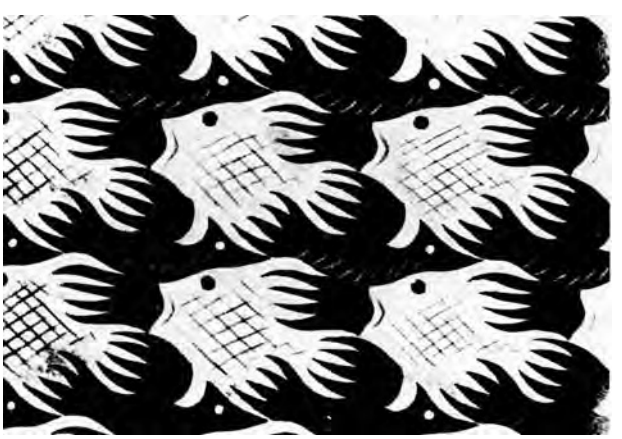

Fig. 9. Drawing by *M. C. Escher* displaying polar symmetry: the fish swim in one direction while the birds fly in the opposite one. (Copyright M. C. Escher heirs, c/o Cordon Art–Baarn–Holland.)

In 1949, *Waser*[26] tried to establish the absolute configuration of (D)-tartaric acid by correlating the relative rates of growth of the hemihedral (*hkl*) and ($\overline{hkl}$) faces with the ease of attachment of the "free" molecule at either face in terms of intermolecular distances between the crystal and the molecule to be attached. In fact, as *Turner* and *Lonsdale* pointed out,[27] given an asymmetric molecule X–A in

a polar crystal, as in Scheme 4, there is no *a priori* reason why, on the basis of intermolecular distances only, the attachment of an X to an "A face" should take place more readily than that of an A to an "X face". The observed differences in development of hemihedral faces may be explained primarily in terms of surface-solvent interactions or polarizability effects.

We developed a new method, based on controlled morphological modifications through adsorption of tailor-made additives, for the direct assignment of the absolute configurations of chiral molecules. First, we shall discuss the case of polar crystals.[28]

4.1. Polar Crystals

Scheme 4 describes an appropriate polar crystal belonging to space group $P2_1$. The unique axis of the crystal is parallel to the X–A direction. Faces f1 and f2 delineate the crystal in the polar $+b$ direction and f3, f4, f5 in the $-b$ direction. The faces within each pair f1, f2, and f3, f5, are homotopic since they are related by 2-fold symmetry. Since the crystal is polar, the structures of the faces at the $+b$ and $-b$ ends are different. By application of the two-step mechanism of adsorption-inhibition, in the crystal of Scheme 4a an inhibitor X–Y will bind selectively at faces f1 and f2, and once bound, will retard growth along $+b$ and possibly other directions but not along $-b$. In an analogous way an inhibitor Z–A will hinder the growth of faces f3, f4 and f5 but not of f1 and f2 (the opposite would happen in the structure of Scheme 4b). Such retardation will be associated either with an increase in the areas of the inhibited faces with respect to the unaffected ones or with the appearance of new faces on the affected side of the crystal. The observed morphological differences between crystals grown in the presence and in the absence of the additive thus establish the direction of the substrate molecule X–A with respect to the polar axis. Consequently, the absolute configuration of the crystal and that of its chiral molecular constituents can be derived.

We shall briefly illustrate here the case of lysine·HCl and cinnamoyl alanine.[28] (*S*)- and (*R*)-lysine·HCl crystallizes from water as a dihydrate in a monoclinic structure of space group $P2_1$. The packing arrangement delineated by the crystal faces of the unaffected crystal is shown in Figure 10 (cf. Fig. 11a). In the crystal the lysine molecules are aligned parallel to the *b* axis with the $^{\oplus}H_3N{-}CH{-}COO^{\ominus}$ moiety emerging from the $+b$ end of the crystal and the ε-$NH_3^{\oplus}$ pointing towards $-b$. In agreement with the analysis presented above, additives with a modified carboxyl or α-amino group, like lysine methyl ester, indeed inhibited growth in the $+b$ direction, inducing development of the (010) face (Fig. 11b). Conversely, additives which bear a modified ε-amino group, like norleucine or norvaline, inhibited growth along the $-b$ direction, with a concomitant pronounced increase in the areas of the $(1\bar{1}0)$ and $(\bar{1}\bar{1}0)$ faces (Fig. 11c).

The observed changes in morphology implied that the occluded inhibitor would be distributed anisotropically along the polar *b* axis of the crystal. This expectation was experimentally confirmed for the crystals of (*S*)-lysine·HCl grown in the presence of (*S*)-norleucine. According to a chromatographic analysis of the material taken from the $+b$ and $-b$ ends of the crystal, the additive was occluded preferentially at the $-b$ end (Fig. 12).

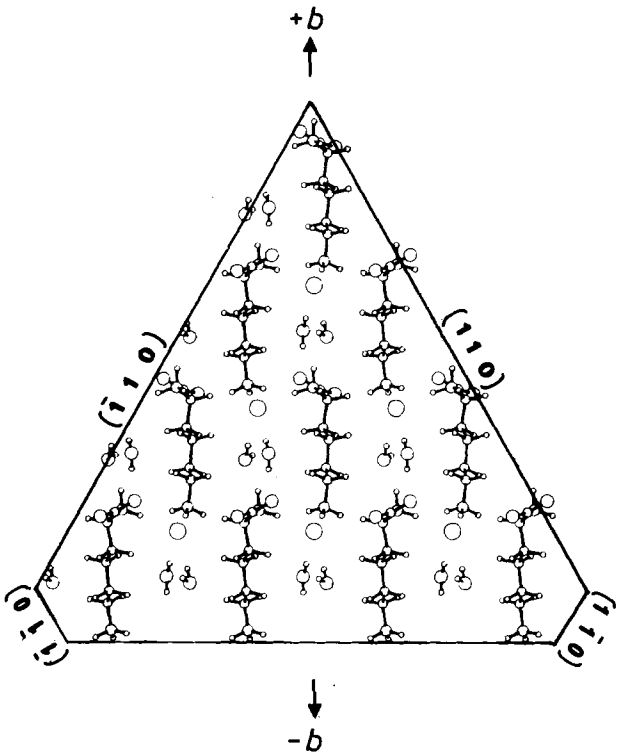

Fig. 10. Packing arrangement of the crystals of (*S*)-lysine·HCl·2 H_2O viewed along the *c* axis, as delineated by the observed {*hk*0} crystal faces.

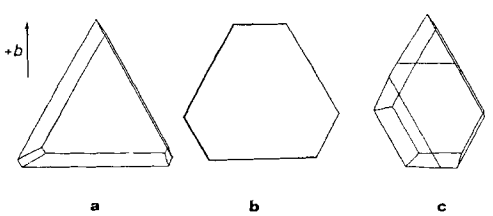

Fig. 11. Computer-drawn pictures of typical crystals of (*S*)-lysine·HCl·2 H_2O viewed along the *c* axis, grown in the presence of: (a) no additives; (b) (*S*)-lysine methyl ester; and (c) (*S*)-norleucine.

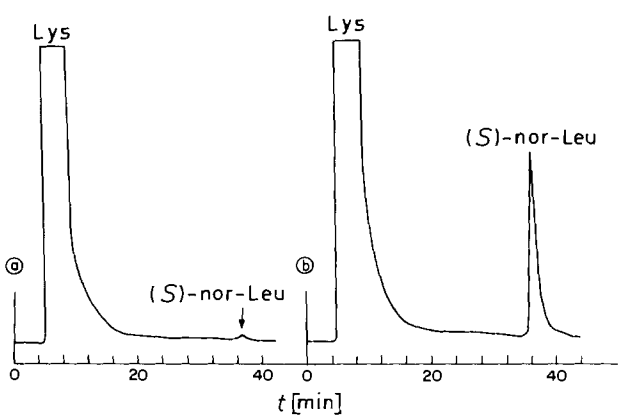

Fig. 12. HPLC analysis of (*S*)-norleucine occluded at the two opposite sides of the polar *b* axis of crystals of (*S*)-lysine·HCl·2 H_2O. In experiments ⓐ and ⓑ the analyses were performed on equal amounts of (*S*)-lysine·HCl·2 H_2O.

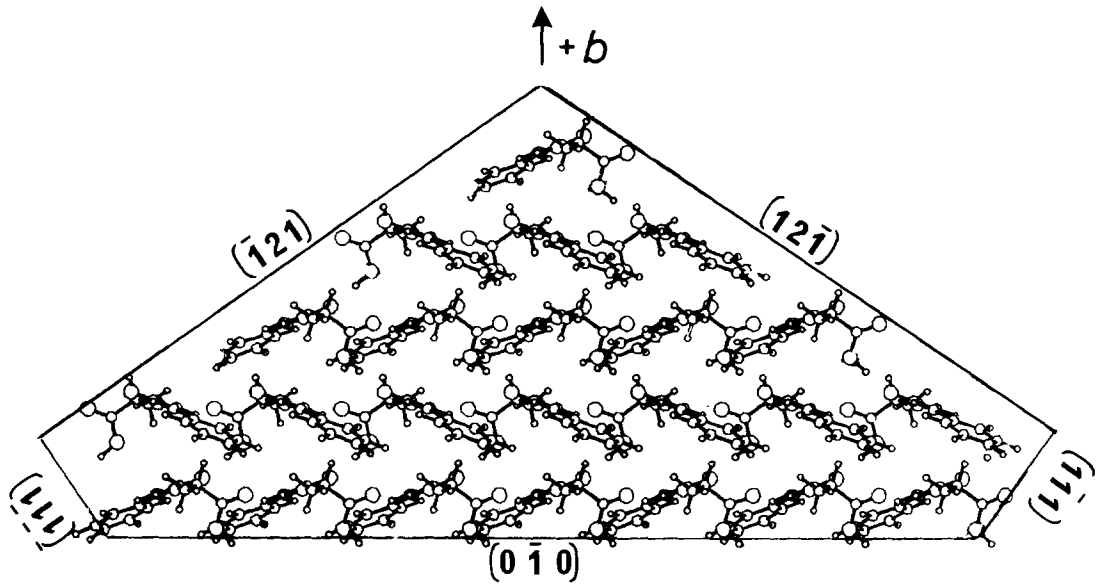

Fig. 13. Packing arrangement of the crystals of cinnamoyl-(*S*)-alanine as delineated by the observed {*hkl*} crystal faces.

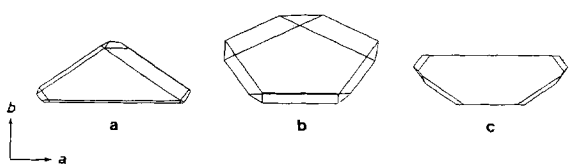
Cinnamoyl alanine crystallizes in space group $P2_1$ (cinnamoyl = *trans*-3-phenylpropenoyl). In the crystal structure of the (*S*)-enantiomer all the OH groups form hydrogen bonds with a major component along $-b$, while the C(chiral)–H bond is directed along $+b$. Figure 13 shows the orientations of the molecules with respect to the crystal faces. The pure crystals are depicted in Figure 14a.



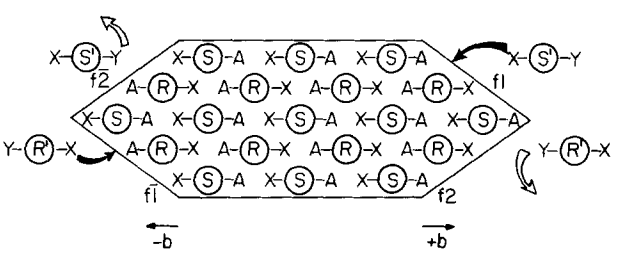


Fig. 14. Computer-drawn pictures of typical crystals of cinnamoyl-(*S*)-alanine (viewed along the *c* axis) grown in the presence of: (a) no additive; (b) methyl cinnamoyl-(*S*)-alaninate; and (c) cinnamoyl-(*R*)-alanine.

We found, as expected, that the methyl ester of the substrate with the same absolute configuration induced large ($1\bar{1}1$) and ($\bar{1}\bar{1}\bar{1}$) faces (Fig. 14b), thus fixing the absolute direction of the O–H bond with respect to the polar axis and hence also the absolute configuration of the substrate molecule. On the other hand cinnamoyl (*R*)-alanine, of configuration opposite to that of the host, induced, as expected, formation of an (010) face (Fig. 14c), because adsorption of this molecule can take place only from the $+b$ side of the crystal since the $C-CH_3$ group of the inhibitor points away from the surface along the $+b$ direction.

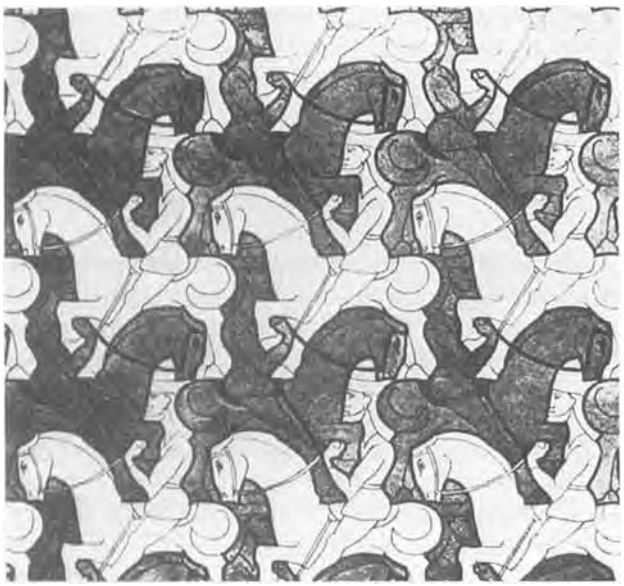
Application of the present analysis to the morphological differences observed by *Smythe*[6] in polar crystals of sucrose grown in the presence and in absence of raffinose (and other di- and tri-saccharides), enabled us to assign the absolute configurations of these sugars.

4.2. Enantiopolar Crystals

The above method of determining absolute configuration is not limited to the molecules in polar crystals, but is also applicable to chiral molecules which induce morphological changes in centrosymmetric crystals composed of racemic mixtures or meso compounds.[29,30] The method is based on the fact that, unlike chiral crystals, in centrosymmetric ones the orientations of the constituent molecules with respect to the crystal axes are unambiguously assigned by conventional X-ray analysis. The known orientation of the enantiomers in such crystals can be exploited for the direct assignment of the absolute configuration of chiral resolved additive molecules, provided this structural information can be transferred to such molecules. The absolute configuration of the resolved additives is determined through the morphological changes they selectively induce on the enantiotopic faces of appropriately selected crystals.

Scheme 5. Structure of an enantiopolar crystal and interaction of the enantiotopic faces with enantiomeric additive molecules, schematic.

A prerequisite for application of this method is that within the centrosymmetric racemic crystal a specific functional group (A) attached to an (*R*)-molecule will point towards the face f$\bar{1}$ but not towards f1 (Scheme 5). Correspondingly, the same functional group attached to an (*S*)-molecule will emerge at the enantiotopic face f1, but not at f$\bar{1}$. It is useful here to regard centrosymmetric crystals containing chiral molecules as enantiopolar. We define an enantiopolar crystal as comprising two enantiomeric sets of intermeshed polar crystal structures related to each other by symmetry elements of the second kind, e.g. a center of



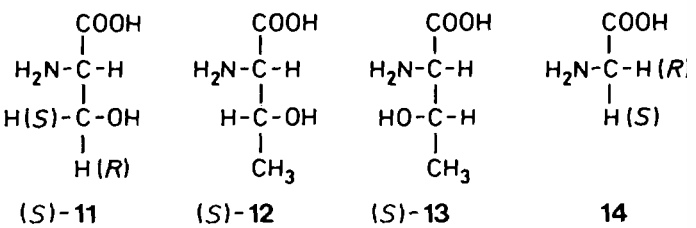


Fig. 15. Drawing by *M. C. Escher* displaying enantiopolar symmetry: treating the white and the black horses as chiral objects of opposite handedness, the two enantiomeric ensembles of the white and the black horses are enantiopolar, pointing in opposite directions along the horizontal axis. (Copyright M. C. Escher heirs, c/o Cordon Art—Baarn—Holland.)

inversion or a glide plane. This is also neatly illustrated in a drawing by *Escher* (Fig. 15). Crystallization of such compounds in the presence of a chiral additive R', appropriately designed so that it will fit in the site of an (R)-molecule on the growing crystal faces f$\bar{1}$ or f$\bar{2}$, but not on the enantiotopic faces f1 or f2, will hinder growth along the $-b$ direction but not along $+b$. By virtue of symmetry, the enantiomeric additive (S') will inhibit growth of faces f1 and f2, while the racemic additive ($R'S'$) will inhibit growth along both directions, $+b$ and $-b$.

These principles were applied to the monoclinic crystals of (RS)-serine[29] and glycine.[30] Racemic serine crystallizes in a molecular packing appropriate for this analysis, space group $P2_1/a$ (Fig. 16). Within the structure, the C–H(Si)-bond vector[*] of the rigid methylene group of (R)-serine has a major component along $+b$ and, by symmetry, the C–H(Re)-bond vector of the (S)-serine (S)-**11** along $-b$.

Thus, their replacement by a methyl, as in threonine, will inhibit growth along the b direction. Namely an (R)-threonine molecule with the side-chain β-carbon of chirality (S), will inhibit growth along $+b$, while the $-CH_3$ group of (S)-threonine will replace the pro-(Re) hydrogen of (S)-serine and hence inhibit growth along $-b$; (R)- and (S)-threonine are (2R,3S)- and (2S,3R)-configurated, respectively.

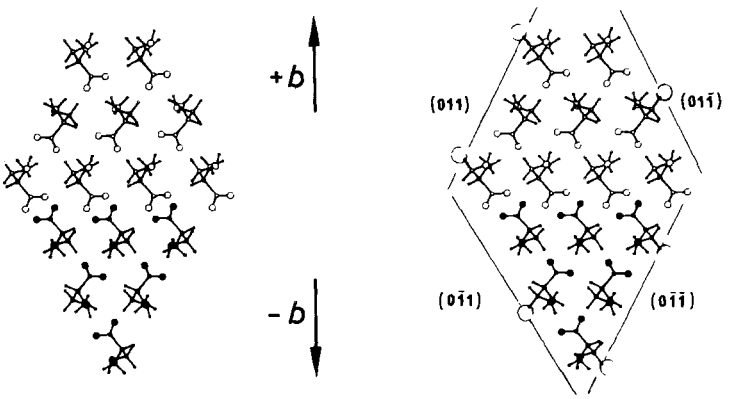

Fig. 16. Packing of (*RS*)-serine viewed along the *a* axis (stereoview). The enantiomers are packed in homochiral *bc* layers: for clarity only half of each *R* (open circles) or *S* (full circles) molecular layer is shown, delineated by the four {011} crystal faces.

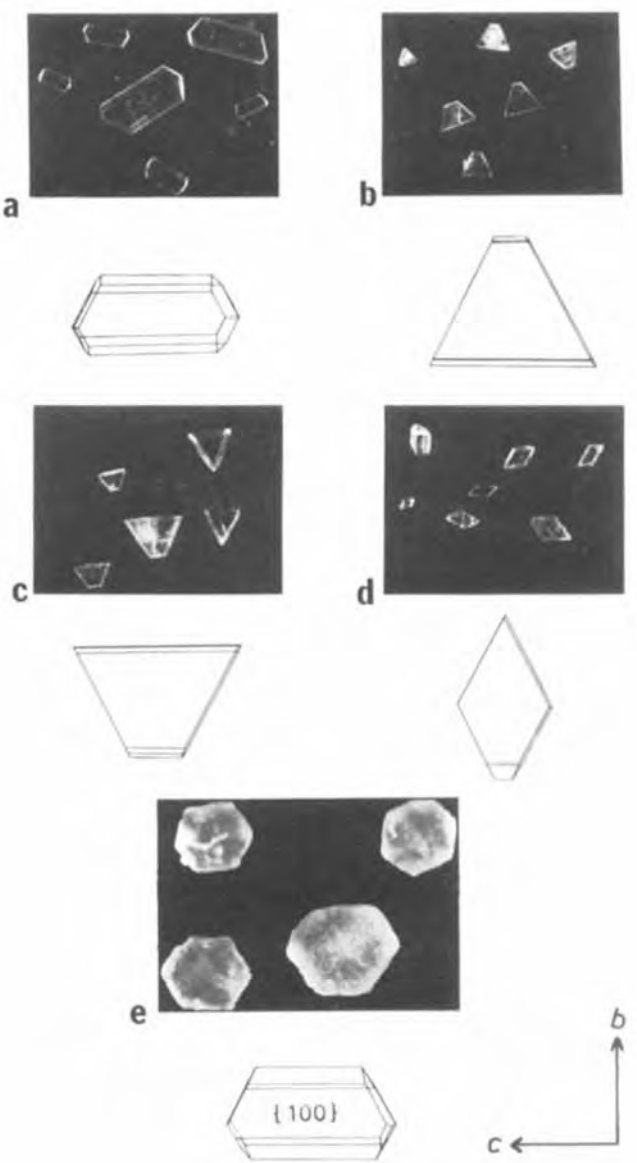

Fig. 17. Photographs and computer-drawn pictures of crystals of (*RS*)-serine grown in the presence of: (a) no additives; (b) (*R*)-threonine; (c) (*S*)-threonine; (d) (*RS*)-threonine; and (e) (*R*)- or (*S*)-allothreonine ((2*R*,3*R*)- and (2*S*,3*S*)-configurated, respectively).

[*] H(Si) denotes the *pro-S* H-atom and H(Re) the *pro-R* H-atom.

(*RS*)-serine forms tabular crystals, with point symmetry $2/m$ (Fig. 17a); the crystals affected by either (*R*)- or (*S*)-threonine exhibit reduced morphological symmetry 2 (the mirror plane is lost) and are enantiomorphous (Fig. 17b and 17c, resp.). When (*RS*)-threonine is used as additive, the morphological symmetry $2/m$ is left unchanged as a result of a combination of the effects induced by each additive separately. The crystals turn into rhombs (Fig. 17d).

The morphological changes, and our interpretation thereof, imply that in this last experiment (*RS*)-threonine must segregate along the *b*-axis during crystal growth; occluded (*R*)-threonine will prevail in the $+b$ half of the crystal, whereas (*S*)-threonine will prevail in the $-b$ half. This expectation was confirmed experimentally by HPLC analyses (Fig. 18a, b, c) through work done in collaboration with *S. Weinstein* using the chiral mobile phase of *N,N*-dimethyl-(*S*)-valine and cupric acetate.[31]

The discriminative power of the various faces of a crystal of (*RS*)-serine is further manifested by the differences

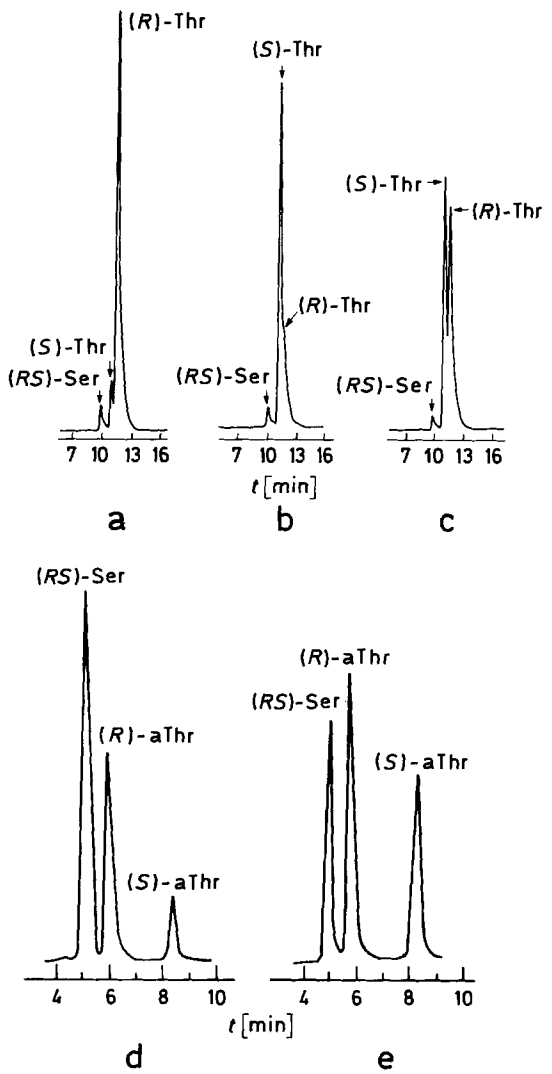

Fig. 18. Enantiomeric analysis of threonine occluded in the rhomb-like crystals of (*RS*)-serine (Fig. 17d) after separation of serine by cation exchange: Material taken from: (a) tip of the crystal at the $+b$ end; (b) tip of the same crystal at the $-b$ end; (c) whole crystal. Enantiomeric analysis of allothreonine (Fig. 17e) occluded in (*RS*)-serine crystals: (d) from the $+b$ end; (e) from the $-b$ end.

in morphology induced by the additives threonine as against allothreonine (cf. (*S*)-**13**, and Fig. 17d and 17e, resp.). The established mechanism of adsorption-inhibition allows a rationalization of this difference. The relative orientation of molecular serine *vis-à-vis* its various crystal faces, suggests that allothreonine can be adsorbed on the homotopic {100} faces as well as on the enantiotopic {011} faces[*] (Fig. 17e).

This would imply that no distinct morphological differences can be expected between (*RS*)-serine crystals grown in the presence of resolved or racemic allothreonine, as was indeed observed (Fig. 17e). Furthermore, (*R,S*)-allothreonine, in contrast to (*RS*)-threonine, should not segregate enantiomerically along the *b* axis; this was confirmed by HPLC analysis of tips of the crystal which were taken from the opposite ends of the *b* axis (Fig. 18d, e). The effect of threonine and allothreonine on the crystals of (*RS*)-serine is further independently explained by dissolution experiments (see Section 6) and by atom-atom potential energy calculations.[32]

According to the surface binding energies of the additives threonine and allothreonine relative to pure serine at several crystal faces, (*R*)-threonine may be easily adsorbed only on faces (011) and (01$\bar{1}$) and, by symmetry, (*S*)-threonine should preferably adsorb on (0$\bar{1}\bar{1}$) and (0$\bar{1}$1); in fact threonine is better bound than substrate serine by 3 kcal/mol. (*S*)-allothreonine may be easily adsorbed on {100}, (011) and (01$\bar{1}$), and, by symmetry, (*R*)-allothreonine on faces {100}, (0$\bar{1}\bar{1}$) and (0$\bar{1}$1). The binding energies of allothreonine relative to serine are -2.1 kcal/mol at {100} and -0.7 kcal/mol at {011}. These results are completely compatible with experiment. In particular, we account for the observation that the resolved and racemic allothreonine do not induce obvious changes in habit because they can each be adsorbed on two principal faces. Moreover, the possibility of occluding (*R*)- and (*S*)-allothreonine through the large {100} faces masks any enantioselective segregation along the *b* axis in accordance with the HPLC results (Fig. 18d, e).

The ability of the serine crystals to recognize the subtle differences between diastereotopic hydrogens suggested that the crystal of prochiral glycine may serve as a matrix for the assignment of absolute configuration of all the chiral α-amino acids.[30] The glycine molecule, although nonchiral, has two prochiral hydrogen atoms, H(*R*) and H(*S*). In the α-modification of the crystal with space group $P2_1/n$ (Fig. 19), the glycine molecules form two enantiopolar sets, which are represented in Figure 19 by shaded and nonshaded atoms, respectively. All the molecules in the nonshaded set have the C–H(*R*) bond aligned with the *b* axis and pointing towards $+b$, so that C–H(*R*) emerges from the (010) face, while C–H(*S*) lies almost perpendicular to it in the *ac* molecular layer. Only an (*R*)-amino acid additive, whose side chain will be parallel to the C–H(*R*) bond, can be adsorbed at the (010) face and would subsequently hinder the crystal growth perpendicular to it. By virtue of symmetry, an (*S*)-amino acid can be adsorbed only at the (0$\bar{1}$0) face.

[*] The symbol {*hkl*} represents all the symmetry related faces, e.g. in serine, {011} denotes (011), (0$\bar{1}$1), (01$\bar{1}$) and (0$\bar{1}\bar{1}$) faces. The symbol (*hkl*) represents only the specified (*hkl*) face.

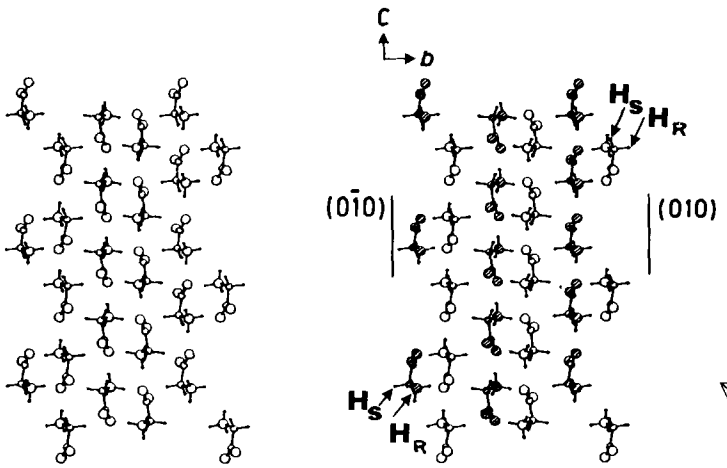

Fig. 19. Packing of glycine crystals with layers of glycine molecules parallel to the *ac* plane (stereoview along the *a* axis). The two enantiopolar sets are represented by shaded and nonshaded molecules.

Pure glycine crystallizes from water in the form of bipyramids, with the *b* axis perpendicular to the base of the pyramid (Fig. 20a). It was observed that all natural (*S*)-amino acids, apart from proline, induce a dramatic morphological change at the $-b$ side of the crystals, with the appearance of pyramids exhibiting a predominant (0$\bar{1}$0) face (Fig. 20b). All (*R*)-amino acids induce the development of a large (010) face (Fig. 20c), while a racemic additive causes crystallization of {010} platelets (Fig. 20d).

Amounts in the range 0.02 to 0.2% of the additives were found in the bulk of the glycine crystals. HPLC analysis (Fig. 21) of these occluded α-amino acids inside single

Fig. 21. S = sensitivity in arbitrary units.

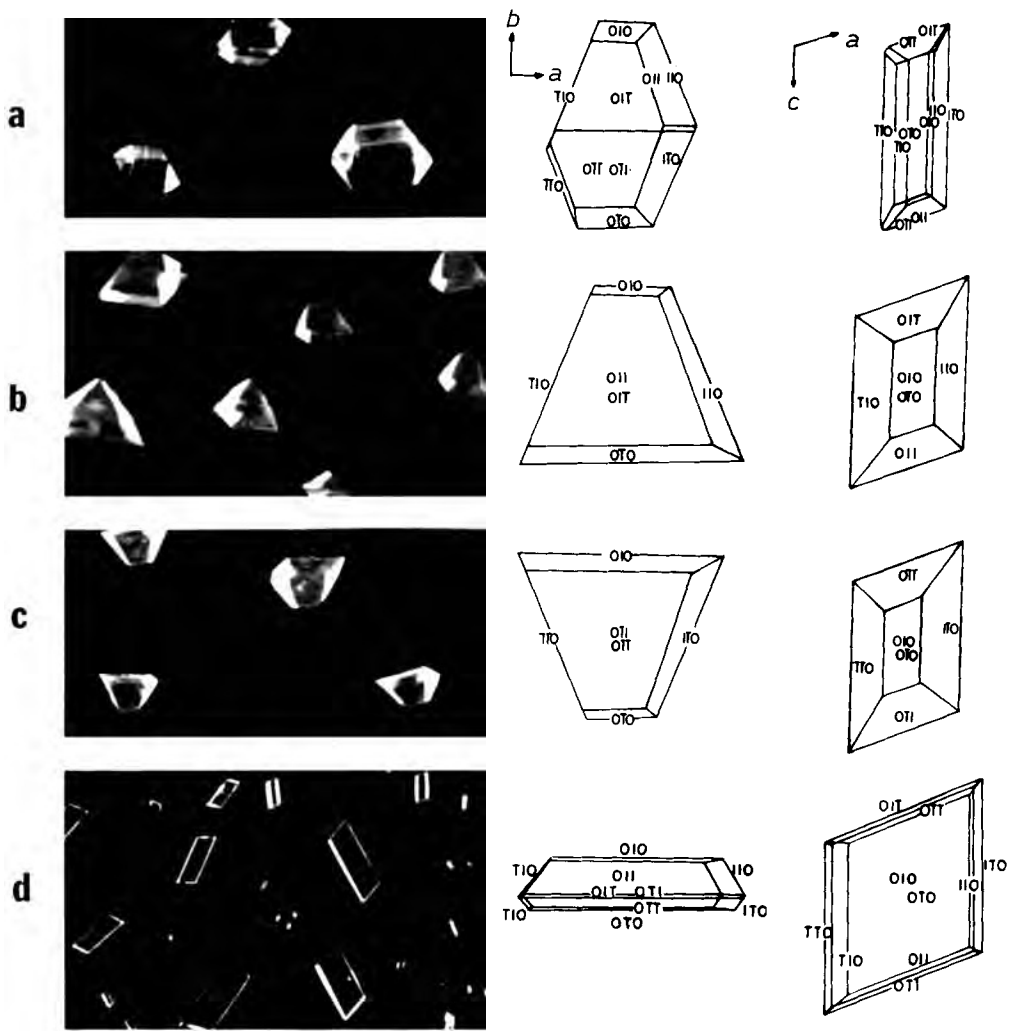

Fig. 20. Comparison between crystals of α-glycine grown in the presence of: (a) no additives; (b) (*S*)-α-amino acids; (c) (*R*)-α-amino acids; (d) racemic α-amino acids.

plate-like crystals of glycine demonstrated a total enantioselective segregation along the b axis; as expected, the (R)-amino acids predominate in the $+b$ half of the crystal and the (S)-amino acids in the $-b$ half. This segregation suggests that the overall symmetry of the crystal has been lowered from $P2_1/n$ to $P2_1$.

The changes in crystal habit of glycine as studied by potential energy calculations[30] were completely consistent with the above-mentioned observations.

5. A New Model for Spontaneous Generation of Optical Activity

The results reported on the glycine system acquire further interest as the {010} plate-like crystals of glycine, grown in the presence of other (*RS*)-α-amino acids, have a tendency to float at the air/water interface with the b-axis perpendicular to the interface.[33] Each such floating crystal will grow either along its $+b$ or $-b$ direction, depending upon whether face (010) or ($0\bar{1}0$) is pointing towards the water solution. Thus, if a single crystal of glycine exposes its (010) face to a solution of glycine containing a mixture of (*RS*)-amino acids, only the (*R*)-acids will be occluded, if the ($0\bar{1}0$) face is exposed to the solution, the (*S*)-acids will be occluded. HPLC analysis of the enantiomeric content of the occluded amino acids indeed confirmed these expectations. Such resolutions of (*RS*)-leucine and (*RS*)-valine are shown in Fig. 22a, b, c.

It is clear that in a racemic mixture there is equal probability for a given crystal to float on its (010) or ($0\bar{1}0$) face. We have observed, however, that if glycine is crystallized in the presence of small amounts of resolved amino acids bearing hydrophobic side chains, like (*S*)-leucine, (*S*)-phenylalanine, or (*S*)-α-aminooctanoic acid, the floating crystals of pyramidal shape always expose their ($0\bar{1}0$) face to the air. In fact, when crystals were grown in the presence of equal amounts of two amino acids with side chains of different character and opposite absolute configuration, for example (*S*)-leucine with (*R*)-glutamic acid or (*R*)-alanine, or (*R*)-serine, all the resulting platelets had their ($0\bar{1}0$) faces directed to the air. This indicates that stereospecifically adsorbed leucine molecules are capable, even in tiny amounts, of orienting the glycine crystals by virtue of the hydrophobic character of their side chains.

The tendency of leucine molecules to orient floating glycine crystals and the enantioselective adsorption at the face exposed to the solution were exploited to induce resolution of racemic amino acids by crystallization of glycine at interfaces in the presence of resolved leucine; for example glycine, grown in the presence of racemic hydrophilic amino acids plus small amounts of (*S*)-leucine, yielded platelets all floating with their ($0\bar{1}0$) faces pointing upwards, thus selectively occluding the (*R*)-enantiomers (Fig. 23a, b). Furthermore, even under conditions where polycrystalline crusts of glycine were formed (Fig. 23c, d) resolution occurred with an enantiomeric excess higher than 70% (Fig. 23d) in the examples studied. This effect was also demonstrated visually by the formation of polycrystalline crusts of glycine grown in the presence of (*S*)-leucine + N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine and (*R*)-leucine + N^{ε}-(2,4-dinitrophenyl)-(*S*)-lysine. We obtained respectively colorless and colored crusts of glycine (Fig. 5d, e in Section 2).

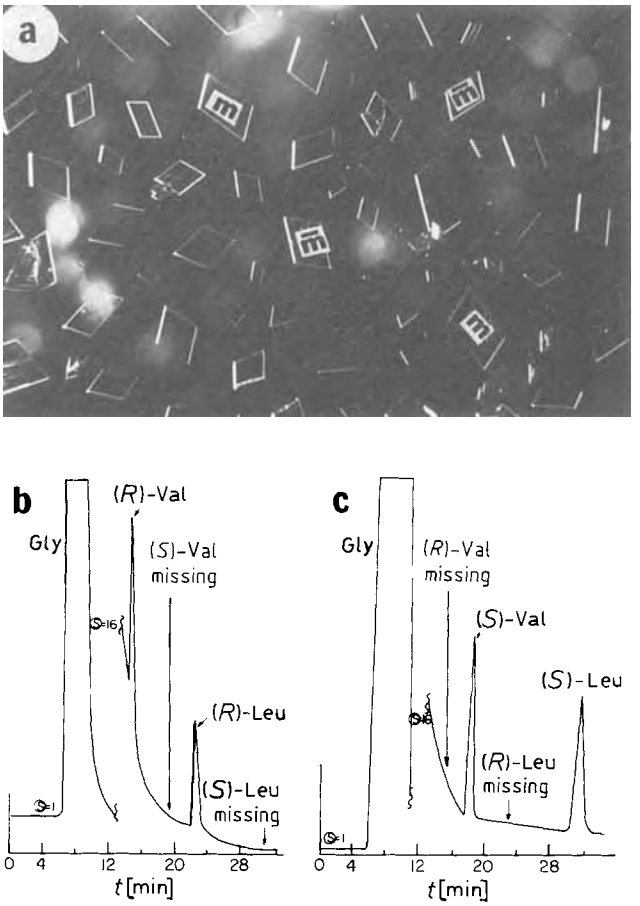

Fig. 22. (a) Floating plate-like crystals of glycine grown from a water solution (4.4 M) containing racemic 1%-w/w (*RS*) leucine and 1%-w/w (*RS*)-valine. The crystals display both enantiomorphous morphologies, labelled m and $\bar{m}$; (b) HPLC analysis of crystals m with the (010) face exposed to solution, after washing with water; (c) HPLC analysis of glycine crystals $\bar{m}$ with the ($0\bar{1}0$) face exposed to the solution after washing with water.

The experiments described above provide us with a possible model for the generation and amplification of optical activity in an initially symmetrical world. Let's assume that the first plate-like crystal of glycine formed from the 'prebiotic soup' floats with its (010) face upward. During growth the crystal will occlude exclusively the (*S*)-amino acids present in the "soup", thus leaving the solution enriched in the (*R*)-enantiomers. The excess of hydrophobic (*R*)-amino acids so generated will in turn direct the floating of later-formed crystals with their (010) faces again upward, thus ever further enriching the solution with (*R*)-enantiomers.

6. "Tailor-Made" Etchants for Organic Crystals

Growth and dissolution of crystals are considered reciprocal processes that can be interchanged by altering the degree of saturation of the solution. This implies that an inhibitor of growth of a given crystal face must in principle affect the rate of dissolution of that same face.[5] In order to

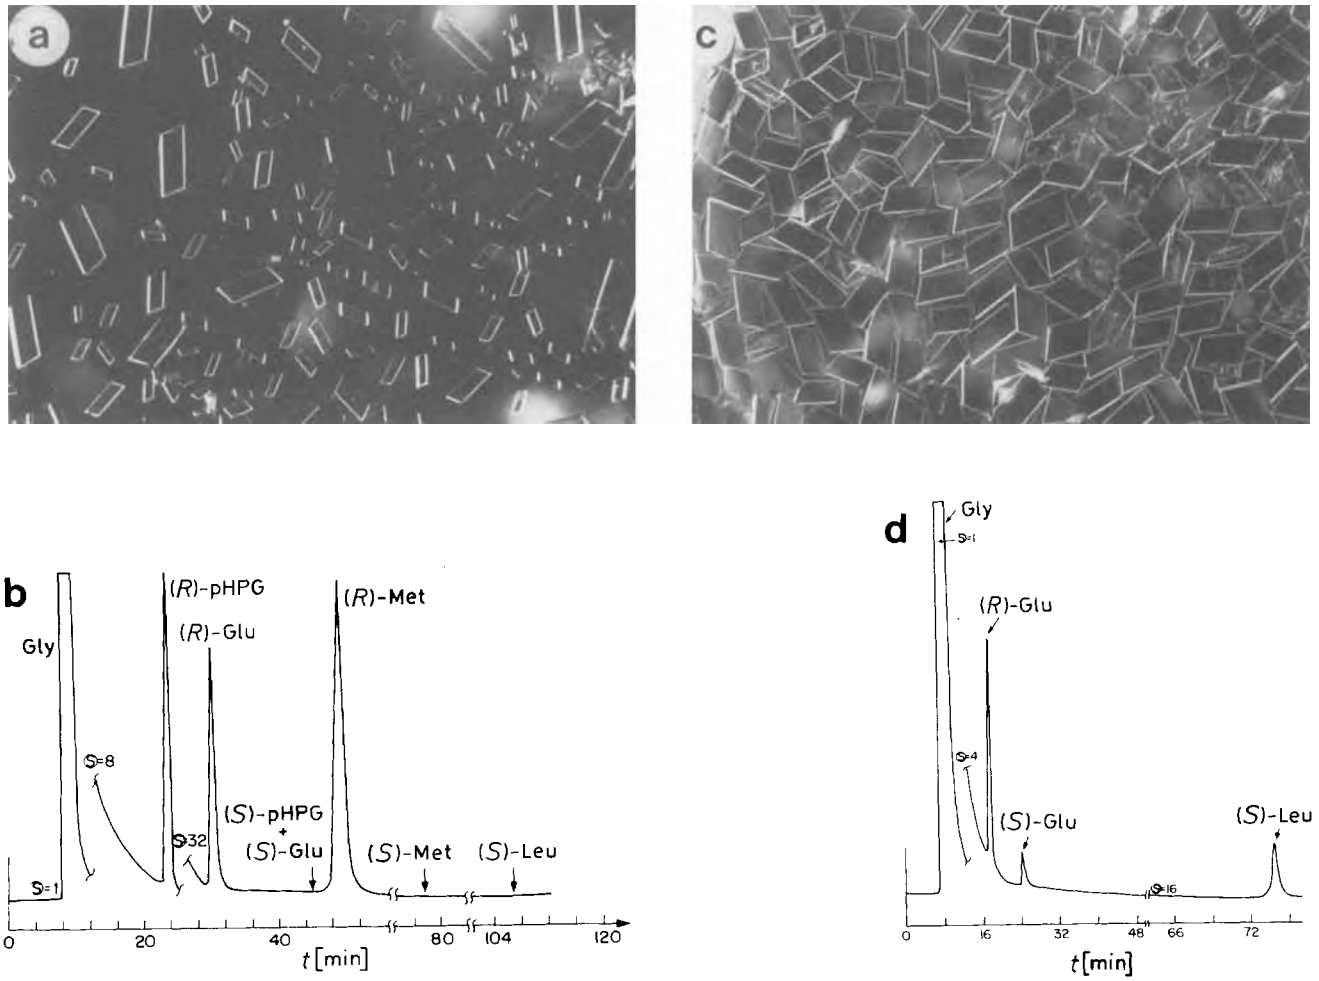

Fig. 23. (a) Floating plate-like crystals of glycine grown in the presence of 1%-w/w (*S*)-leucine and racemic *p*-hydroxyphenylglycine (0.5% w/w), racemic glutamic acid (1%) and racemic methionine (0.5%). All the crystals float with their $(0\bar{1}0)$ faces exposed to air and exhibit the same enantiomorphous morphology; (b) HPLC analysis of the enantiomers of *p*-hydroxyphenylglycine (pHPG), glutamic acid, methionine and leucine occluded inside the crystals; only the (*R*)-enantiomers of pHPG, glutamic acid and methionine are found; (c) crystalline crust of glycine grown at the air/water interface. The aqueous solution (4.4 M) contains 1%-w/w (*S*)-leucine and 3%-w/w racemic glutamic acid; (d) HPLC analysis of the same crust, indicating an *ee* of 70% of occluded (*R*)-glutamic acid.

test this reciprocity, a systematic study was undertaken on crystal dissolution in the presence of "tailor-made" growth inhibitors. As models, we investigated some of the systems we described above for crystal growth.[34]

Plate-like crystals of glycine (see Sections 4 and 5) with well-developed {010} faces were submitted to partial dissolution in an undersaturated solution of glycine containing variable amounts of other α-amino acids. When resolved (*R*)-alanine was present in the solution, well-developed etch-pits were formed only on the (010) face. These pits exhibit twofold morphological symmetry with surface edges parallel to the *a* and *c* axes of the crystal (Fig. 24a). The enantiotopic $(0\bar{1}0)$ face dissolved smoothly (Fig. 24b), exactly as it does when the crystal is dissolved in an undersatu-

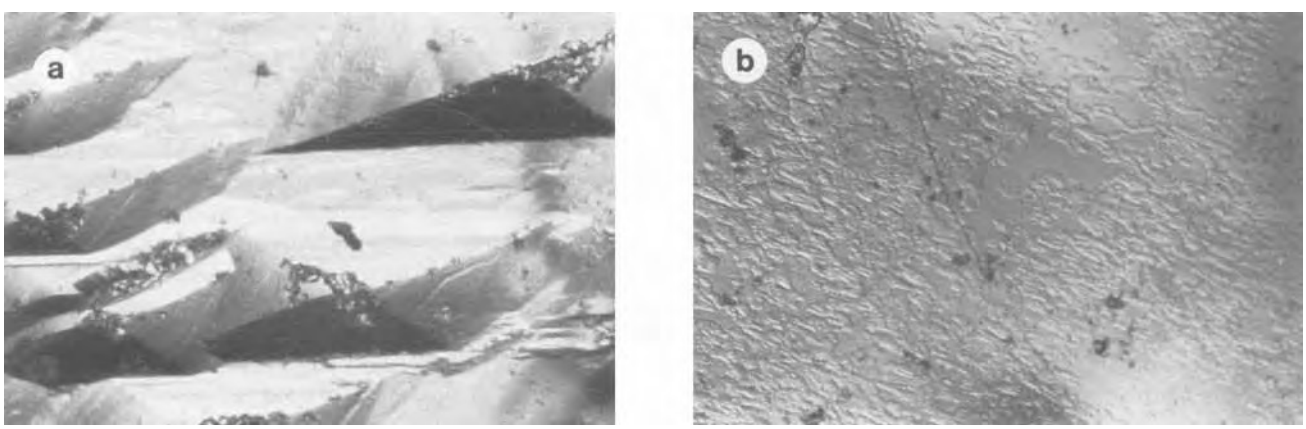

Fig. 24. Optical microscope pictures (×50) of the {010} faces of a glycine crystal after partial dissolution in the presence of (*P*)-alanine: (a) the (010) face; (b) $(0\bar{1}0)$ face.

rated solution of pure glycine. As expected, (*S*)-alanine induced etch-pits on the (0$\bar{1}$0) face. Racemic (*RS*)-alanine etches both {010} faces.

An explanation of these, and other similar results, takes into consideration that dissolution from a given surface is considered to begin at sites of emerging dislocations.[35] At these sites, more than one type of facial surface is exposed to the solvent (Scheme 6). The dissolution front propagates

Scheme 6. Formation of etch pits at the sites of emerging dislocations as a result of selective binding of additive to the horizontal faces.

from these centers in various directions, at the same relative rates as for their growth. Under such circumstances the overall shape of the crystal is preserved. On the other hand, when an additive which binds selectively to a given face of the crystal is present in the solution, the crystal will dissolve in different directions with rates which differ from those in pure solvent. As a result, the rate of dissolution in a direction perpendicular to the affected face will decrease relative to that perpendicular to the unaffected ones, and etch pits will be formed at the dislocation centers on the former faces.

The generality of the above stereochemical correlation was tested for all the systems described above, including serine/threonine and serine/allothreonine (see Section 4) and for the enantiomorphous pairs of glutamic acid·HCl and of asparagine·H_2O. When rhomb-like crystals of (*RS*)-serine are partially dissolved in the presence of (*R*)-threonine, well formed etch-pits develop at the (011) and (01$\bar{1}$) faces (see Figs. 16, 17). By virtue of symmetry, similar etch-pits form at the (0$\bar{1}$1) and (0$\bar{1}\bar{1}$) faces when (*S*)-threonine is present in the solution. In neither experiment were etch-pits formed at the {100} faces. On the other hand, both resolved and racemic allothreonine etch primarily the {100} faces, in keeping with the results of the morphological and segregation studies and with theoretical calculations.

The present method was also exploited for the manual separation of a pair of enantiomorphous crystals. For example, when a crystalline conglomerate of asparagine·H_2O was partially dissolved in a solution of (*S*)-aspartic acid, well formed etch-pits were formed only on the {010} faces of the (*S*)-crystals, but not on the (*R*)-enantiomorph (Fig. 25). The treated enantiomorphous crystals are thus visually distinguishable and, therefore, separable.

In several ways the etching experiments yield results complementary to those obtained from the studies on morphological changes and enantiomeric segregation. On the other hand, etching provides a unique probe for differentiating between the two steps of binding of inhibitor and retardation of growth. Furthermore, the etching experiments should provide a decisive insight into those systems where the inhibitors appear to bind at one face but retard growth at another. In addition, increase of the surface area upon etching by the additives should influence the overall rate of the crystal dissolution. This approach is currently

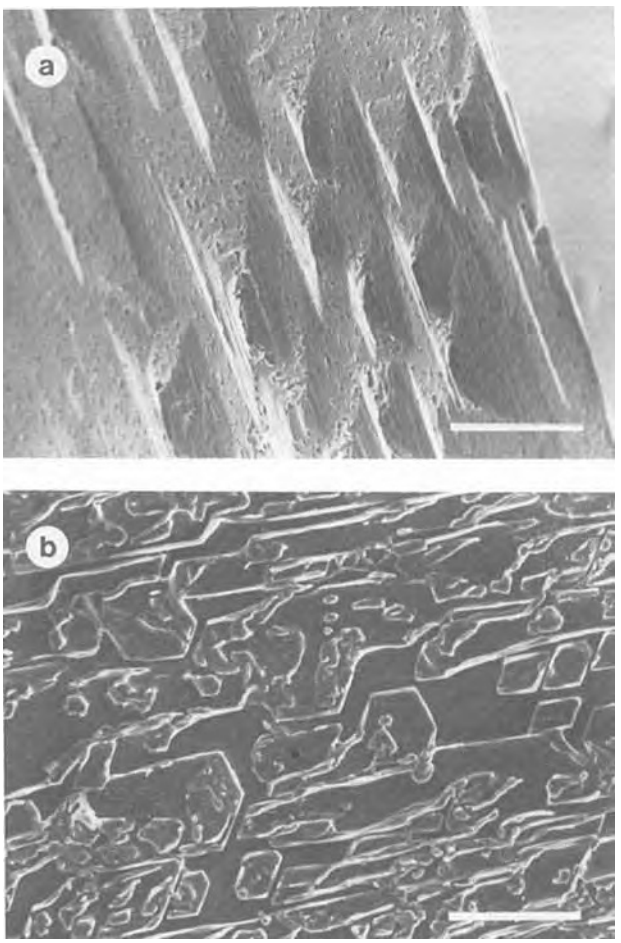

Fig. 25. Scanning electron micrograph of the (010) face of crystals of asparagine partially dissolved in the presence of (*S*)-aspartic acid; (a) (*S*)-asparagine crystal; (b) (*R*)-asparagine crystal. White line: 100 μm.

being resorted to for increasing the rate of dissolution of organic crystals in general, and of sparingly soluble drugs in particular.

7. Simulation of Crystal Morphology by Energy Calculations

Atom-atom potential energy calculations were undertaken in order to gain an understanding of crystal morphology in terms of the intermolecular interactions between substrate molecules in the crystal bulk, and between substrate and solvent or substrate and additive at the crystal solvent interface.

A controlling factor in crystal growth is the energy of the interactions between neighboring molecules. According to *Hartman* and *Perdok*,[36] the crucial relationship is between the attachment energy E_{att}, the energy per molecule released when a new layer is attached to the crystal face, and the layer energy E_l which is defined as the energy per molecule released when a new layer is formed. E_l measures the stability of a layer and E_{att} controls the growth rate perpendicular to this layer. Studies on the relationship between the internal structure of the crystal and its morphology led to the working hypothesis that the morphological importance of a crystal face decreases with increasing at-

tachment energy. From the known crystal structure it is possible to calculate the corresponding values of E_{att} for various low-index faces. This information is used to derive the theoretical form, i.e., the calculated morphology of the crystal which best represents the crystal habit obtained by sublimation.[37,38] To derive the habit of the crystal grown from solution in the presence or absence of additives, substrate-solvent and substrate-additive interactions at the crystal-solution interface must be taken into account.

7.1. The Theoretical Form of Glycine and the Solvent Effect

The theoretical crystal form of glycine, depicted in Figure 26 (left), is in nice agreement with the morphology of glycine crystals obtained by sublimation (Fig. 26, right). Its habit is distinctly different from that of glycine grown from aqueous solution. The most striking differences between the two forms (Fig. 26 and Fig. 20, resp.), are the complete disappearance in the latter of the {001} and {10$\bar{1}$} faces, the formation of {011}, and the drastic reduction in relative area of {010}. We account for these differences in terms of the higher affinity of the water solvent for the crystal faces {110} and {011} than for {010} and {001}.

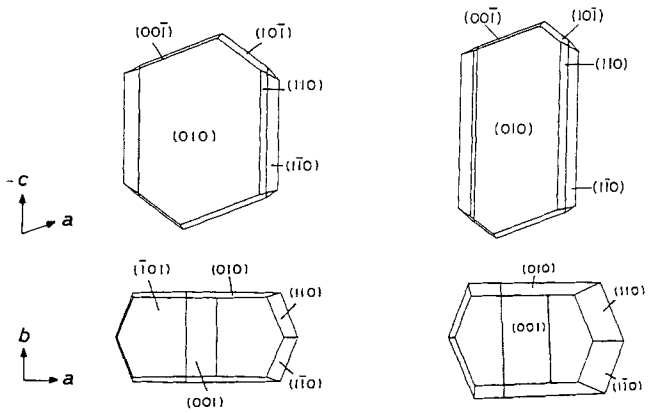

Fig. 26. left: Theoretical crystal form of glycine; right: morphology of glycine crystals obtained by sublimation.

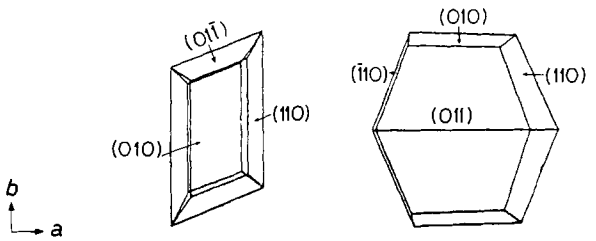

Fig. 28. Calculated crystal form of glycine incorporating the solvent effect.

To establish the relative hydrophilic affinities of these faces the Coulomb potential energy was calculated at closest approach distances from the surface of each of the four faces (Fig. 27). From these maps we may conclude that the {010} face is the least polar and (011) the most polar face. Thus, preferential adsorption of water molecules on the polar faces, primarily on {011}, causes a reduction in the growth rate normal to these faces relative to that of {010}, with a concomitant increase in their surface areas. When this solvent effect was simulated in the calculation of the theoretical form[37,38] we obtained the habit shown in Figure 28, which is in agreement with the observed morphology (Fig. 20a). Several other systems were studied, in-

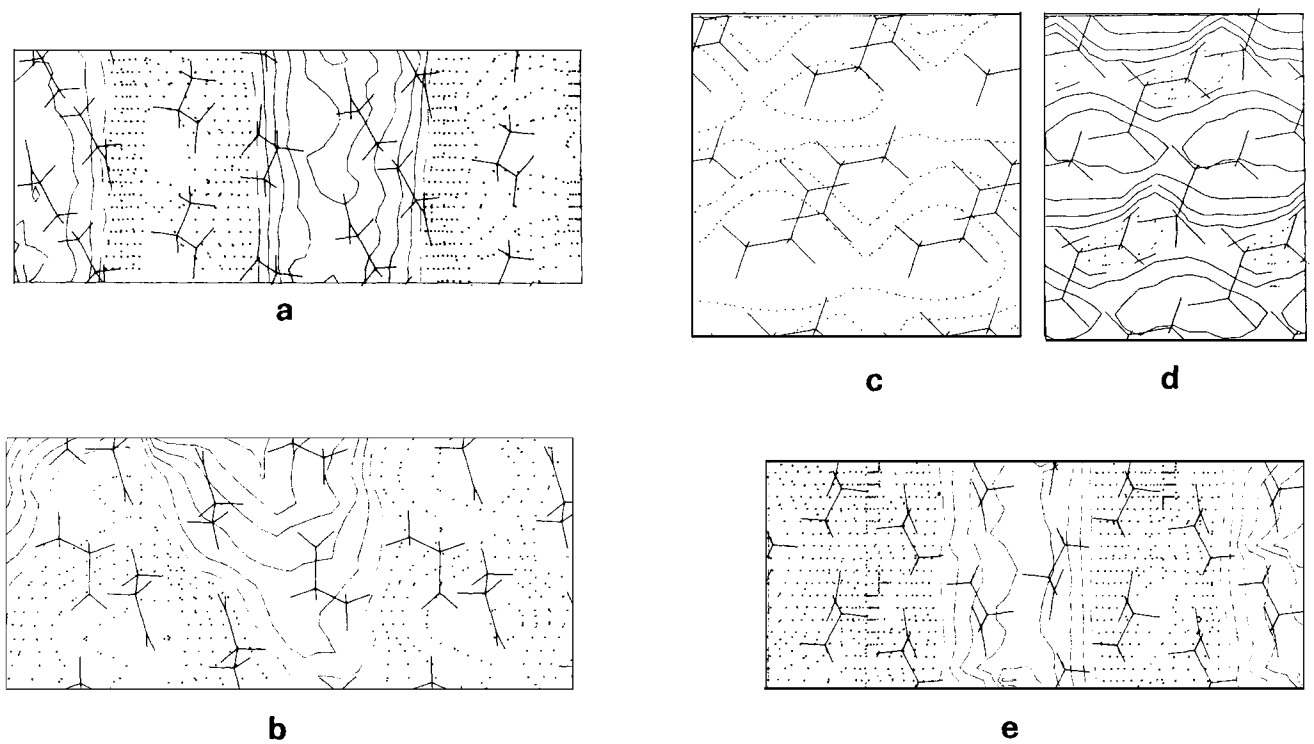

Fig. 27. Electrostatic potential energy maps at closest approach distances of a unit positive charge from the surfaces of various glycine crystal faces. Solid contour lines represent repulsive energies, and broken lines attractive energies. (a) {011} faces; (b) {110} faces; (c) {010} faces at the layer exposing the C–H bonds (i.e. unshaded molecules at the (010) surface in Fig. 19). (d) {010} faces at the layer exposing the NH bonds (i.e. the shaded molecules at the (010) surface in Fig. 19). (e) {001} faces.

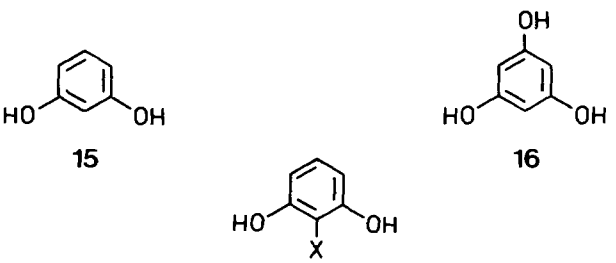

cluding benzamide, cinnamide[24,38], and serine[29,32], and yielded theoretical forms consistent with the observed habits.

7.2. The Riddle of Resorcinol

Polar crystals are ideal for elucidating the effect of solvent on crystal growth, because the difference in growth rates of opposite faces (*hkl*) and ($\bar{h}\bar{k}\bar{l}$) along a polar direction originate primarily from the differences in their solvent-surface interactions. However, due to the practical difficulty in determining the absolute polarity of crystals, in particular for crystals composed of nonchiral molecules and containing light atoms only, this approach has been somewhat neglected to date. Our technique of "tailor-made" additives for the determination of the absolute configuration of crystals, allowed us to tackle such a problem and clarify the influence of solvent on growth of the polar crystal of α-resorcinol, **15**.

In 1949, *Wells*[39] found that in an aqueous solution the α-form of resorcinol (space group $Pna2_1$) grows unidirectionally along the polar *c* axis. The crystal (Fig. 29, left) exhibits "phenyl-rich" (011) and ($0\bar{1}1$) faces at one end of the *c* axis and "hydroxy-rich" ($01\bar{1}$) and ($0\bar{1}\bar{1}$) faces at the other end (Fig. 29, right). The absolute direction of growth along the polar axis with respect to the crystal structure could not be fixed at that time, however, so that *Wells* did not know which end of a given crystal was phenyl-rich and which end hydroxy-rich. *Wells* interpreted this unidirectional growth along *c* to take place at the phenyl-rich faces as a result of stronger adsorption of water to the hydroxy-rich {$0\bar{1}\bar{1}$} faces, so inhibiting their growth relative to the phenyl-rich {011} faces.

Recently, *Davey*[40] has proposed that strong surface-water interactions should enhance crystal growth. By use of oriented growth on silica surfaces, *Davey, Bourne,* and *Milisavljevic*[41] deduced that indeed the OH-rich {011} faces are those that grow quicker in aqueous solution. The assignment by this technique is, however, not unambiguous. In order to resolve the controversy between the two hypotheses we assigned the absolute direction of growth of the resorcinol crystal in aqueous solution by employing the additives **16** to **19**, and independently by the Bijvoet method.[42]

We found that the unidirectional growth in water takes place primarily at the oxygen-rich faces in accordance with the findings of *Davey, Bourne,* and *Milisavljevic*.[41] We tend to the paradoxical view that the unidirectional growth at the hydroxy-rich {$0\bar{1}\bar{1}$} faces is due to inhibition of growth at the phenyl-rich {011} faces because of a higher affinity of water for the latter face. We base our arguments on the relative structures and on the van der Waals and Coulomb energy potentials of these surfaces.

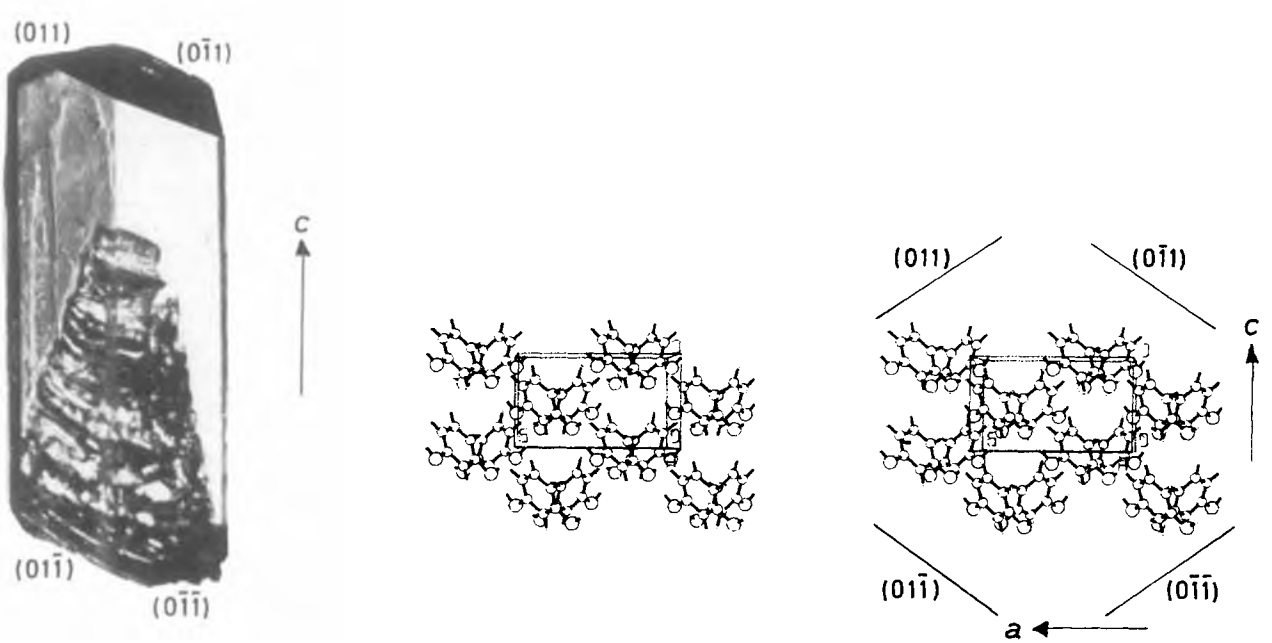

Fig. 29. Left: Typical crystal of α-resorcinol grown from water. The end faces {011}, i.e. (011) and ($0\bar{1}1$), and {$01\bar{1}$}, i.e. ($01\bar{1}$) and ($0\bar{1}\bar{1}$), are marked; right: packing arrangement of α-resorcinol, stereoview along the *a* axis. The planes parallel to the phenyl-rich {011}- and hydroxy-rich {$01\bar{1}$}-faces are denoted.

The {011} face is criss-crossed with grooves forming pockets at their intersections, whereas the hydroxy-rich $\{0\bar{1}\bar{1}\}$ face is relatively flat (Fig. 30). In order to obtain a

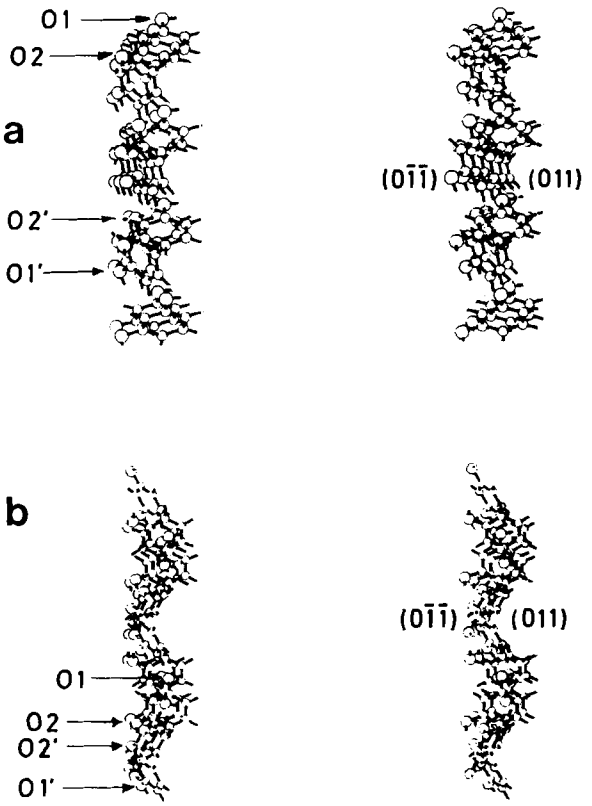

Fig. 30. Resorcinol. Two different stereoviews of an 011 molecular layer showing the surface structures at the (011) and $(0\bar{1}\bar{1})$ faces: (a) along the a axis; (b) along the direction $-b+c$.

measure of the relative affinity of these two faces for water in terms of van der Waals forces, their surface energy potentials were calculated as sensed by a pseudo van der Waals' water atom' brought into best attractive contact along each surface. The result indicates a higher (14%) affinity of the solvent for the {011} face than for $\{0\bar{1}\bar{1}\}$ in accordance with their relative 'roughness'. The relative polarity of these two faces in terms of their Coulomb potential energy surfaces is shown in Figure 31.

The positive potential values at the {011} face indicate that this face best interacts with negative ions or the oxygen of water, whereas $\{0\bar{1}\bar{1}\}$, which is characterized by negative potential values, interacts best with positive ions or with the hydrogen of water. Thus, for solvent water, it is preferable to consider the {011} and $\{0\bar{1}\bar{1}\}$ faces as acidic and basic faces, respectively, rather than as 'phenyl-rich' and hydroxy-rich'. The acidic nature of the {011} face is also evident in so far as it exposes the O1–H bond as well as aromatic C–H bonds (see Fig. 30) which may participate in attractive C–H···O interactions.[43] The proton-acceptor properties of the opposite $\{0\bar{1}\bar{1}\}$ face arise from the fact that three out of four resorcinol oxygen atoms O1, O2, O1′, O2′ are accessible to water (see Fig. 30). The contour values of the two energy maps indicate that the basic face has a deeper potential than the acidic face. Thus, the van der Waals and Coulomb forces appear to balance out in

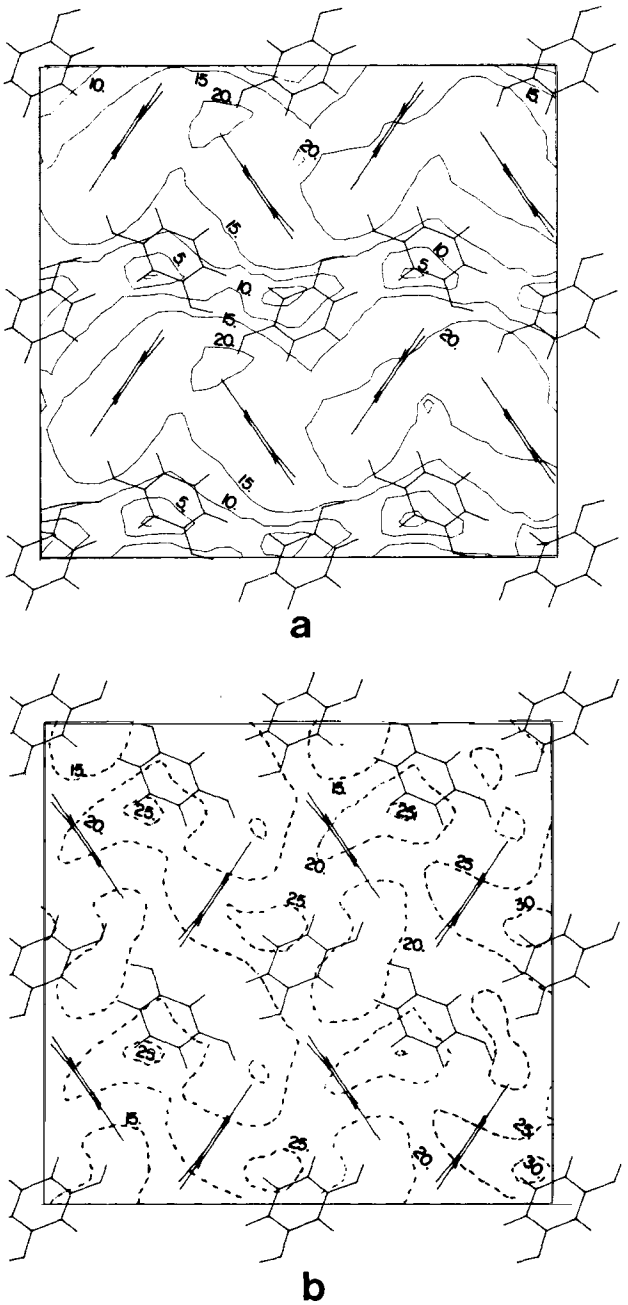

Fig. 31. Electrostatic potential energy maps at closest approach distances of a unit positive charge from the surfaces of: (a) a {011} face; (b) a $\{0\bar{1}\bar{1}\}$ face. Solid contour lines represent repulsive energies and broken lines attractive energies. Contour interval 5 kcal/mol.

terms of preferential binding of water; on the other hand, it is clear that water can bind to both sides. In the light of the experimental data we tend to believe that van der Waals forces play the determining role. Thus, we maintain that *Well*'s interpretation, that growth of a crystal face is inhibited by strong adsorption of solvent, is essentially correct, although in the case of resorcinol he drew the incorrect conclusion about the growth direction, by assuming that water is adsorbed preferentially on the hydroxy-rich face.

This approach in studying solvent-surface interactions is encouraging. Indeed, it may eventually lead to a quantitative unraveling of the relative roles played by internal crys-

tal structure and solvent-surface interactions in determining crystal morphology.[38]

8. Outlook

In the present article, we have attempted to show that it is possible with the assistance of tailor-made additives to control both growth and dissolution of organic crystals. A remarkable aspect of this process is that it provides us with the ability to navigate a given additive through a given face into a selected subset of the symmetry-related sites of the crystal. Thus, for example, in the case of benzamide, benzoic acid may be occluded at only one of the two centrosymmetrically related sites at the end of the ribbon motif (Fig. 7a); the overall symmetry of the crystal is thus reduced from the centrosymmetric space group $P2_1/c$ to the chiral space group $P2_1$. Such "induced chirality" is currently being exploited for the performance of spontaneous asymmetric syntheses. Furthermore, this type of chiral discrimination in centrosymmetric crystals is presumably manifested also in inorganic crystals, including minerals, which might have a bearing on the spontaneous separation of enantiomers in Nature.

The present approach might further provide an effective method for pinpointing fine intermolecular interactions in crystals, (e.g. O···O repulsion in the benzamide-benzoic acid system, (see Section 3) as revealed by the morphological changes they induce.

The role of the tailor-made additives is probably not limited to the growth stage, but includes prenucleation aggregates which are expected to structurally resemble the mature crystal. An extension in this direction might be of importance in the resolution of enantiomers by crystallization.

So far we have confined ourselves to additives which resemble the host molecule. This was done in order to facilitate the extraction of detailed mechanistic information. We can now reduce systematically this similarity, provided strong specific interactions are preserved at interfaces between substrate and additive. This approach provides a unique entry to the study of solvent effects on crystal morphology. It is of particular relevance for the better understanding of crystallizations taking place at structured biological interfaces, such as bones, teeth and shells,[44,45] and in the inhibition of ice formation in fish living at temperatures below the freezing point of water.[46]

In summary, we see that the old, but until recently empirical, technique of modifying crystal growth by addition of impurities has a wide range of consequences in both theoretical and practical chemistry and materials science.[47] This field of research may be expected to expand rapidly in the future.

We thank the U.S.-Israel Binational Foundation, Jerusalem, the donors of the Petroleum Research Fund administered by the American Chemical Society, the Volkswagen Stiftung, and the Israel Academy of Science and Humanities for financial support of this work. One of us (L. A.) is the recipient of the Helena Rubinstein Career Development Chair. We are indebted to Prof. M. D. Cohen for a critical reading of the manuscript, and are grateful to Edna Gati and Marianne Idelson for carrying a heavy load of the experimental work. We are also grateful to Dr. S. Weinstein for his important cooperation in the HPLC analyses, and to Prof. A. van Hook for bringing to our attention the work carried out on the change of morphologies of sugars.

Great Fear of Small Amounts of Elements—The Significance of Analytical Chemistry in our Modern Industrialized Community as Exemplified by Trace Element Analysis

By Günther Tölg* and Rainer P. H. Garten

Dedicated to Professor Rudolf Bock on the occasion of his 70th birthday

Analytical chemistry is consolidating an important position within the framework of our modern industrial community; the frontiers of trace (and ultra-trace) analysis have expanded into new territories, thus demanding a constant change in our mode of thinking in a substance-related manner in analytical chemistry. An outline of the development of analytical chemistry during this century reveals a period of underdeveloped research and education followed by a current phase of impetuous advancement. However, as a result of increasingly antagonistic sectional convictions in the public mind concerning reservations against, as well as efforts towards, efficient technological progress, this advancement evokes new existential risks for analytical chemistry—viz. either to be used in an uncritical way or to fall into discredit following slogans like 'high-performance analytical chemistry is to blame for it all!' A much more constructive consideration says that risks can be estimated and evaluated solely by means of a highly efficient analytical chemistry, when used with a sense of responsibility. Analysts may help to clarify and to cope with the increasing fear of decreasingly smaller amounts of trace elements—in both adverse groups in our community. Strategies necessary to gain this end are outlined with regard to a methodological as well as a political platform.

1. The Role of Analytical Chemistry in our Modern Industrial Society

The chemical, biological, and physical properties of materials and—what is of interest to us in connection with our environment—of complex systems of substances are often dependent upon very small alterations in composition. This dependence forms the basis of many fields of research, e.g. in the life sciences, in the earth sciences, and in materials science; but, as we are learning more and more each day, it also has direct serious consequences for man and his environment in terms of health, working conditions, and other factors determining the quality of his life. Thus, this research and public policy are entering progressively into closer relationships with which not only every responsible, forward-looking scientist and politician, but also every individual citizen must come to an understanding.

In an effort to comprehend these very complicated interrelationships, it is very easy to come to false conclusions

concerning the function of scientific disciplines for the common good, such as is the case, for example, in analytical chemistry. Even many scientists are scarcely aware of the importance of analytical chemistry for the future development of our quality of life.

All the natural events in our biosphere occur in a multitude of extremely complicated regulated cycles, which in turn are interdependent on very sensitive equilibria. We are increasingly realizing the difficulty, not only of understanding their interactions in detail, and of affecting them only so that the human race can survive intact, but also of assuring the disturbances of these equilibria are limited as much as possible. Very often we do not even recognize the consequences on the affected ecosystems.[1-3]

Our trust in technical progress, built up slowly and with difficulty over the centuries, is shaken nowadays by fast-reacting, alarming reports, which are very often sensationally, but inaccurately presented by the media. The human need for security then motivates some to defend themselves against that which is incomprehensible and even sinister. The anxiety arising from such uncertainty is another only too natural response. The widespread aversion to chemistry ("Modern Inquisition"), will unfortunately not promote the solution of pressing problems. What we need is an accelerated elucidation of the role of chemistry in order to learn factually and circumspectly its advantages and disadvantages (see, e.g., [4]). This, however, presupposes reliable information and data concerning complex processes in the material field. In other words, whenever synthetic or anthropogenically mobilized substances impinge on our lives, both in a positive and in a negative sense, analytical chemistry faces the challenge to make available reliable data for a critical evaluation of changes in material systems. Only in this way, will we make any possible risks calculable. This is also indispensable if we wish to terminate some absurd endeavors either to turn back the wheel of progress or to ignore the fear-provoking consequences of our progress by burying our heads in the sand. Only this will help to lessen the conflict between these two extreme schools of thought, a conflict which is continually becoming more threatening. Thus, analytical chemistry is today taking on an interdisciplinary and society-relevant role;[5,6] this requires for the future—particularly in teaching—an accelerated change of attitude concerning its standing, which has been stagnating for decades (cf. [7,8]). However, an unsatisfactory system can only be improved if its weaknesses are known.

2. Changes in the Catalogue of Functions

As the oldest branch of chemistry, the first functions of analytical chemistry were concerned with the composition of terrestrial materials for the sake of a basic understanding of nature. Its intrinsic value was at first undisputed (cf. [1,9,10]) and led to an extraordinarily successful development in the classical-chemical age. In more recent times, its standing has gradually diminished, in particular as a result of the following developments:[5,7]

1. In the chemical industries it took over more and more of a quality control function whereby routine tasks had the upper hand and scarcely any capacity remained for further methodological developments.
2. Chemical analytical methods had to endure more and more competition from physical methods. This led to further uncoordinated parallel development on both sides, i.e. chemical and physical. But since the teaching of analytical chemistry was mainly in the hands of chemists, the new blood that was recruited was mainly chemically orientated (cf. [8,11]), whereby the synopsis of chemical and physical methods was increasingly lost. The triumphal incursion of physical methods, which proved themselves to be more economical for routine work, into industrial laboratories dominantly in the hands of the self-taught, occurred largely outside the framework of analytical chemistry. It was subsequently sought to replace the fine art of analysis, by instruments or tools, more and more of which were becoming available on the burgeoning instrument market.

   The original unity of methodological development and strategic application of these methods to the solving of problems has been increasingly lost. Physically or technically oriented method specialists and highly specialized instrument manufacturers established themselves, on the one hand, while, on the other, there were more and more "measurement slaves" who tackled problems with "black boxes". From an economical point of view this process could even be justified in the short term because the difficulty of the analyses remained practically the same for a long period of time.
3. The fact that the solution to analytical problems could be, as it were, bought, released research policy makers from the necessity of educating analysts in sufficient numbers and reinforced the view that analytical chemistry was no longer topical as an independent scientific discipline. This opinion is unfortunately still so widely held today that, in spite of the superfluity of constantly perfected methods, the solution of difficult analytical problems has become more and more intractable, because the challenge imposed by the degree of difficulty and scope has risen dramatically.

   The very first environmental problems indicated that it was not just the major and minor components of a synthetic product that were of interest, but the anthropogenically mobilized trace components too.

3. Ambivalent Thinking as a Requirement for the Increasing Employment of Trace-Analytical Information

Our usual, very successful, reductionistic, linear cause-and-effect thinking based on *Newton* and *Descartes*, that at first had only to be extended by dualistic models in quantum mechanics, is revealing itself over a wide area to be too one-sided.[3,9,12,13,14] Here is not the place to lay down why it is necessary to learn to think cybernetically or in cross-linked dynamic systems, but some simple examples will show that the chemistry of trace components encounters the boundaries of all too one-sided thought processes, both with respect to the production of analytical information and to its interpretation.

At least 26 of the naturally occurring elements are now regarded as necessary for life (Fig. 1). Of these, 15 are present in the organism at concentrations of $<0.01\%$. These are collectively categorized under the heading "trace elements" in the biochemical sense. All other elements are ubiquitous in biogenic systems below certain concentration levels, which are laid down within a certain range of scatter by nature; it has not yet been possible to establish physiological effects at these natural concentrations. However, if given concentration thresholds are exceeded, usually because of anthropogenic activities, then, with only a few exceptions, negative effects can be detected on the living conditions of individuals or ecosystems (see, for example, [3, 15–17]).

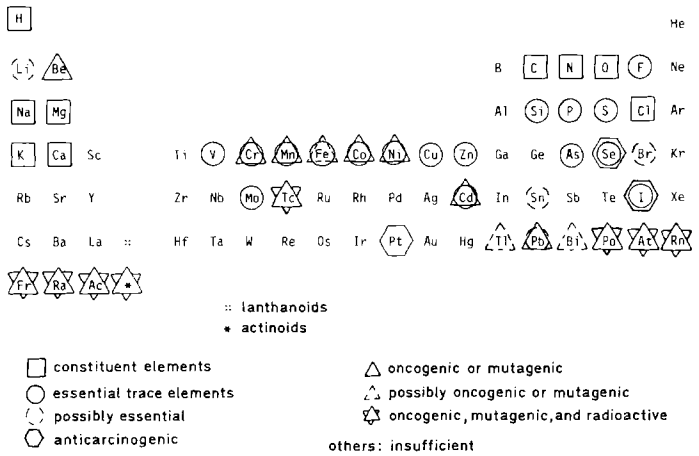

Fig. 1. Periodic table of the elements with essential, oncogenic, and mutagenic trace elements (after [61]).

Each essential trace element only exerts its vital function over a certain concentration range (Fig. 2);[18] too little leads to just as serious a biological problem as too much—under certain conditions either state can lead to mortality. In other words, a natural equilibrium of element concentrations has been set up during the course of evolution between animate and inanimate matter and this setting is restricted in each case to a very narrow range of trace element concentrations for optimal living conditions.

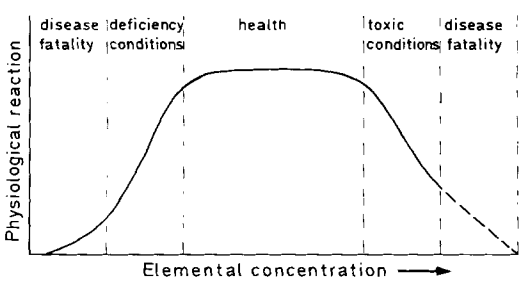

Fig. 2. Ambivalent physiological dose-effect relationship of an essential trace element (after [18]).

This poses the question as to whether the lower limits, below which symptoms of deficiency occur, ought to be defined more closely in future, in order to avoid not only man-made overdosage but also to allow for natural and man-made deficiencies.[19, 20]

Probably the most impressive example at present for demonstrating the ambivalent effects of a trace element, is selenium, the concentration limits of which in the physiologically optimal range differ only by about one order of magnitude.[21] There have also been found distinct indications of such ambivalent behavior for As, Cd, and Pb.[22] It is highly likely that further elements will follow, as analytical techniques improve. Already under discussion is a protective effect of selenium (cf. [21]) against the heavy metals Hg, Cd, or Pb via the formation of physiologically less active compounds. Thus, in order to evaluate the toxicity of heavy metals, which react with selenium yielding extremely stable compounds, it is not only necessary to have a detailed knowledge of the various types of toxic bonding (cf., e.g., [23, 24]) of metals, but also of their concentration in relation to that of selenium, just as, vice versa, the concentration of heavy metals in the system must be taken into account for the evaluation of a selenium deficiency. By analogy, corresponding protective effects by "detoxification", i.e. immobilization of toxic substances, are to be expected for a range of other trace substances, whose damaging effect on living organisms is known at higher dosages if they are observed in isolation.

If it is assumed that all naturally occurring elements have acquired physiological activity during the course of evolution, which is by no means impossible, then there is a considerable degree of obscurity concerning all those elements whose natural concentrations in living systems are too low for their ambivalent function to be demonstrated, because they cannot be determined analytically or because the analysis is very unreliable.

At the moment we can only observe the toxic upper concentration levels of these elements, since these are generally analytically controllable. An exception here is found in the concept of homeopathy, which postulates a positive physiological effect for the smallest possible concentrations of an element and employs these therapeutically. Without wishing here to question the success of such treatments, this one-sided point of view is irrelevant for the trace analyst, at least as far as higher degrees of dilution are concerned (powers > D 10). This has nothing to do with the controversy between conventional medicine and homeopathy, as to whether such low element concentrations can possibly exert any effect. This dispute is pointless, since even the most uncommon elements in the earth's crust, such as for instance Hg, Ag, Au, are present in every organism and every preparation in concentrations that are many orders of magnitude greater than the reported concentrations. For instance, a commercially available preparation purporting to contain silver at a dilution of D 19 ($10^{-17}\%$) actually contained Ag in a concentration of ca. $10^{-7}\%$,[19] i.e. equivalent to the natural concentration of silver in blood serum. The ubiquitous concentration of gold is about one order of magnitude lower. We are on the verge of greatly increasing the ubiquitous concentration of the even less common platinum in the environment (cf. [25, 26]), without being able to predict the consequences.

The next example has deliberately been chosen from the bordering fields of contention between conventional and alternative thinking in chemistry. It ought to demonstrate that not everything is as "healthy" as ideologists assume.

As early as 1967 *Weinig* and *Zink*[27] observed that the concentration of thallium in the urine of vegetarians and smokers is significantly higher than that in control samples from "normally" nourished subjects; it is up to one order of magnitude higher in vegetarian smokers. Tl(I) accompanies potassium, whose atomic radius is very similar. It is therefore preferentially enriched in plants. This finding is of analytical relevance, because the authors determined the concentration of Tl by the very reliable technique of isotope dilution analysis using mass spectrometry, and checked their results by a second independent method. Accordingly, vegetarian smokers are at greater risk than "normal consumers" so far as chronic Tl intoxication is concerned, at least until we know the concentration interval for Tl provided by nature. In the case of selenium, and possibly beryllium,[28] this range most likely lies within only one order of magnitude.

Beryllium provides a further example which illustrates the inadequacies of our conventional way of thinking. A large-scale systematic study of the distribution of beryllium in the environment led certain authors, who shall remain anonymous here, based on their one-sided way of thinking, to the conclusion that beryllium did not constitute a risk for smokers. Their chain of arguments was completely logical. They found that tabacco ash contained very little beryllium. According to the textbooks BeO cannot be volatilized in the combustion process. The analytical methods employed were impeccable; in spite of this the authors made a grave error of judgement.

Had they investigated the urine or the blood of smokers they would have discovered a significant enrichment of volatilized beryllium (cf. Fig. 3), which can on no account be neglected as a risk factor, at least until the toxicology of beryllium and the chemical behavior of Be traces have been fully explored.[28,29]

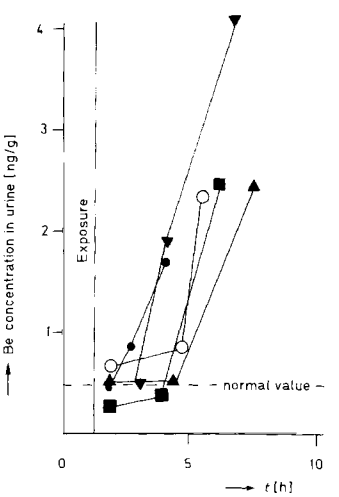

Fig. 3. Time course of Be concentration in the urine of active (●, ■, ▲, ▼) and passive (○) smokers after each hour's inhalation of dense cigarette smoke [29].

4. Criteria of Analytical Quality—Aims and Limits

This section is devoted to a discussion of some significant factors arising from different viewpoints regarding the environmentally related tasks of the trace analyst. The universal analytical method that is ultimately sought for is one that ensures an economical optimal combination of sample preparation, decomposition, separation, and detection, and yields reliable results for all trace elements in all samples; a method with such a degree of universality has not, as yet, been discovered and is unlikely to be so, even in the future. Thus, the major task of the trace analyst is to focus his attention on improving the methodological criteria of quality, that is power of detection, sensitivity, reliability[30-32] and economy,[6,33,34] in order to provide efficient solutions for the innumerable, interdisciplinary problems that exist. He should also recognize today what complicated analytical problems will emerge tomorrow in all fields in which materials are investigated, so as to be able to develop suitable methods in advance. It is only in this way that he will be able to establish himself as a partner of many colleagues in a very wide interdisciplinary field who are dependent on analytical progress, but who are out of their depth in the development of ever more demanding analytical methods.

While the problem of detection power and sensitivity is inherent in the analytical problem, the other two quality criteria, namely reliability and economy, are parameters that depend on the power of detection. Basically the improvement of the detection power and sensitivity of analytical determination has to be looked at from several points of view.

Increasingly sensitive methods of determination also lead to the danger of their misuse. Those who would like to turn back the wheel of history, employ sophisticated analytical procedures to hunt for more pollutants, often in a very uncritical manner. The main effect is to create uncertainty and anxiety and this provokes many of the antagonistically thinking group to believe, in accord with the motto "analytical chemistry is to blame for it all", that there is no sense in developing analytical methods offering higher power of detection. It is to be hoped that those will succeed, both in general and in research policies in particular, who will look at the problem as as whole and will realize that unbiased, efficient analytical chemistry is an indispensable prerequisite for evaluating risks and making them calculable.

But many analysts who honestly try to employ analytical progress as a driving force in the quest for new knowledge, better products, and a healthier life, are also in danger of slowing down necessary progress by false attitudes. Because of their training, many analysts are inclined to oversimplify, to standardize, to generalize, or to fall into the trap of extrapolating data. We should therefore make ourselves more conscious of the fact that it is just these useful, even indispensable human facilities which can be the more dangerous the lower the concentration of the elements to be determined. Obviously, we are constrained to standardize our analytical methods and to make them as simple as possible for economic reasons, in order to guarantee broad compatibility in routine application. But it must be ensured that these methods already function reliably and that each user, who follows the standardized instructions, can also guarantee the accuracy of his results in all the envisaged areas of application. The results obtained in many interlaboratory comparisons (round robin analyses) carried

out in the last few years reveal very impressive interrelationships between the power of detection and the reliability of the results.

The lower the concentration of the elements to be determined in an actual sample, the greater the systematic error that occurs.[5,6,35] Despite the good agreement sometimes found for results obtained by one particular method for a particular sample, normally statistically distributed about the true value, results can be obtained that are very different from the true concentration, as has been shown by round robin analyses comparing various methods and/or various laboratories' results on analyzing the same sample.

A further problem resulting from these systematic errors in the determination of very small traces of an element is illustrated in Figure 4. A large number of determinations have been made of the normal concentration of trace elements in the matrix "human serum", so that the results can be evaluated statistically. The mean concentrations recorded for some essential trace elements by various authors over periods up to 1976 and after 1976 reveal two groups of trace elements:

1. Elements, for which values were obtained which were practically in agreement with each other over both periods. These are the elements Cu, Zn, and also Se, whose determination is unproblematical nowadays. With slight reservations, this also holds for their determination in other biotic matrices. Thus, it is meaningful in these instances to develop standard procedures for their routine analysis.
2. Elements, whose measured normal concentration in the blood serum has been tending to drop to ever lower values up to the present time. They are real problem elements which demand continual attention by the experienced trace analyst.

As long as the systematic errors involved in the determination of these elements prevail over the statistical errors, standard procedures may only be designed with the employment of extreme analytical expert knowledge and critical understanding.

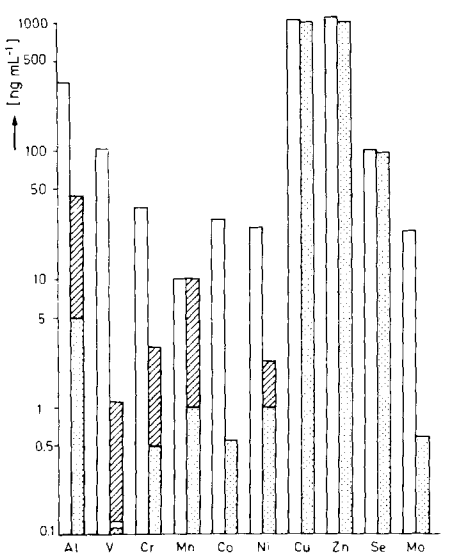

Fig. 4. Comparison of the means of some elemental concentrations in serum, determined in the period before 1976 and after 1976 (according to data assembled by *Versieck* et al. [62]); □ before 1976, ▨ after 1976, ▩ realistic.

5. Pathways to Accuracy in Trace Analysis

Long years of experience and thought concerning the causes and the avoidance of systematic errors in ultratrace analysis can be summarized in one sentence: "Systematic errors of combined procedures are minimized if only absolutely essential unit steps are carried out in closest combination in reaction spaces with the smallest surface areas at the lowest temperatures possible, all apparatus materials are as inert as possible and only a minimum of easily highly purified reagents and additives are employed, all contamination by laboratory air is avoided, and each unit step of such a procedure is carefully investigated for its analytical yield—using radioactive tracers if possible."

This fundamental sentence summarizes our methodological strategy;[35] it therefore requires some comment. The largest systematic errors are expected to arise from impurities, which are introduced into the analytical system from components of the apparatus, from the reagents, and from the atmosphere in the laboratory. They are the greater the more common an element is in the environment (ubiquitous concentration). Irreversible adsorption of trace elements occurs on the vessel walls and losses due to evaporation occur during the whole analytical procedure, which begins with sampling. Some of these errors are in opposite directions and can sometimes compensate each other. Since it is primarily the blank value that limits the power of detection, it must be remembered that it is the ratio of the concentration of the element to be determined in the sample to its concentration in the environment of the analytical system which is decisive rather than the sensitivity of the detector system itself. Thus, in present day ultratrace analysis, it is more meaningful to keep the blank concentration as low as possible than to search for new and more sensitive detectors.[35–38]

Basically, it is only possible to achieve an optimal power of detection for each analytical method when the element to be determined has been isolated. We do not, as yet, possess any methods of determination where the excitation of an analytical signal for the element is not affected in a positive or negative sense by other accompanying elements above a certain threshold concentration. All economical direct instrumental methods (cf., e.g., [31,39]), in which the sample itself is analyzed directly, not only fail to yield optimal detection power, but, under certain circumstances, are also subject to considerable interference by other elements. It is possible to compensate for such interferences, however, but only if reliably investigated standard reference samples are available for calibrating the method[32,40] which are as similar as possible to the analytical samples. In ultratrace analysis, however, this applies in only very few cases (cf. [41]). Consequently, one must resort to less economical and more complicated combined procedures, in which the element of interest is separated as far as possible from other accompanying elements before being determined.[5,37] In contrast to routine methods where systematic errors have already been removed, in ultratrace analysis, only complex combined procedures lead to reliable results, and, in end effect, are more economical than direct instrumental methods yielding inadequate or even false results and their consequences. Systematic errors naturally

occur also in these procedures; they may have different origins which are distributed with different importance over the various individual steps of the procedure.[6, 35, 42]

This catalogue of tasks in modern trace analysis can be extended by some specific examples from our own investigations. They are considerably complex examples involving complicated interdisciplinary problems. We were therefore only able to make modest contributions towards obtaining reliable analytical information and optimal solutions to individual problems. For a scientific interpretation of the data we always seek the cooperation of other suitably qualified colleagues who may not be in a position to develop the analytical part by themselves, while we for our part often feel overtaxed with the scientific interpretation of our results.

5.1. Example: Species and Distribution Analysis of Mercury

Along with Cd, Pb, Tl, and As, mercury, in particular, counts among the most important problem elements which pollute the environment as a result of anthropogenic activities—apart from the not inconsiderable basic emissions caused by volcanism and the weathering of rocks.[43]

In certain industrial areas relatively large amounts of mercury are emitted into the atmosphere during the production and use of its compounds. Much more mercury is emitted, however, by its release from all materials removed by mankind from the earth's crust, during combustion and heating processes (Table 1). Its ubiquitous concentration in these materials is in the middle ng/g range. The growth in industrialization has led to a cumulative increase in these emissions, so that it is not possible with our present state of knowledge to say unequivocally how this increasing Hg-emission, which is unavoidable in our industrial society, will affect the health of living individuals in the next generations; this also applies, but not to such a serious degree, for all other relatively volatile elements. The risks involved are probably more difficult to calculate than the risk which is involved in the peaceful use of nuclear energy. The main reason for this is that the ecological circulation of mercury is exceedingly complex and that mercury behaves biologically very differently in the various compounds in which it appears (see Fig. 5).

Table 1. Comparison of global mercury emissions of natural and anthropogenic origin [43] (based on data from 1970 and 1974).

	Globally released mercury [t/year]
Natural origin:	
Volcanism and weathering in the hydrosphere	500– 5000
Gaseous form from the earth's crust into the atmosphere	25000–150000
Hg-reserve in the oceans: 2×10^8 t	
Evaporation from sea water	23000
Rivers and glaciers	3800
Anthropogenic origin:	
Hg-processing industry	6000– 10000
Preparation of ores and minerals	1500– 20000
Combustion of fossil fuels	100– 8000

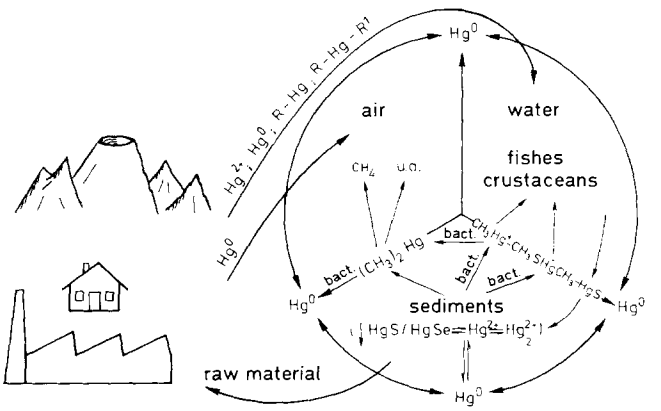

Fig. 5. The circulation of mercury in the environment (according to [63]); u.a. = and other gases.

The route by which organomercury compounds in particular enter the human nutritional chain via water is relatively well understood as a result of the impetus given by the catastrophe in Minimata Bay in Japan in 1954. The methylmercury compounds are greatly enriched by fish in particular (cf. [43, 44]). On the other hand, we understand very little about the mobility of mercury and its compounds in soils, which take the mercury up again from the atmosphere. It is only known that there is a high degree of enrichment in the upper horizons of all soils (cf. Fig. 6).[45] The question as to whether and in what form Hg can be transported into the human nutritional chain via water, has not been investigated sufficiently enough for it to be possible to estimate future risks.

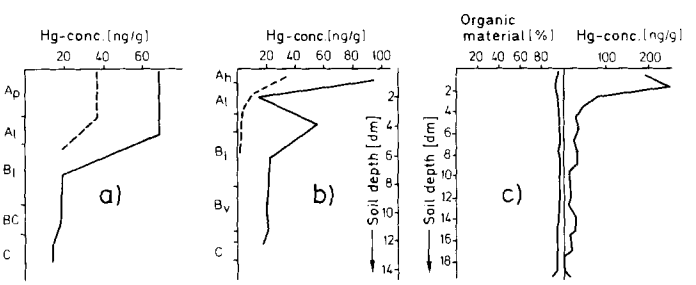

Fig. 6. Typical vertical profiles of mercury concentration in various soils: a) arable; b) forest; c) high bog (broken line: humus content in g/kg) soil horizons: A_p: ploughed top soil; A_h: humus-containing mineral soil; A_l: leached para brown soil; B_l: mean soil horizon with argillaceous illution; B_v: mean soil horizon of mineral weathering; BC: transition horizon; C: living rock [45].

The first, very crude step in our analytical strategy was to learn how to determine as reliably as possible the total Hg-content of all environmentally relevant matrices, i.e. in rocks, soils, water, air, plants, animal organs, tissues, and even in the individual serum protein fractions. It was necessary to strive for a detection power down to the lower pg/g range, at least for the organic matrices, in order to distinguish natural concentrations from anthropogenically originating concentrations. The aforementioned problems of systematic errors due to contamination, adsorption and evaporation were encountered during the solution of this

supposedly relatively simple task. In order to overcome them it was necessary to adhere strictly to our strategy for the ultratrace analysis of elements; combination procedures were designed that were as compact as possible, and performed in a closed system.

As starting point for the combined procedure several decomposition methods were investigated which had been specially developed for ultratrace analysis and which were considered to be practically free from systematic errors.[33,46,47] Combustion or heating the sample in an oxygen plasma excited by microwaves proved almost ideal. The mercury vapor produced during decomposition of the sample (cf. Fig. 7, left) is quantitatively absorbed on a gold absorber (Fig. 7, center) before it is transferred for the actual determination (Fig. 7, right) by pulse heating the Au-absorber. This compact combination of decomposition, enrichment, and actual determination methods in a closed system provides the basis for a very universal, extremely sensitive and reliable determination of the mercury isolated from the sample by a newly developed spectroscopic detector (microwave-induced plasma optical emission spectrometry, MIP-OES), which makes it possible to detect absolute quantities of less than 1 pg Hg.[2,48] With the experience gained so far (several man years) it was possible to commence the following briefly reviewed investigations on the mobility of mercury in soils.

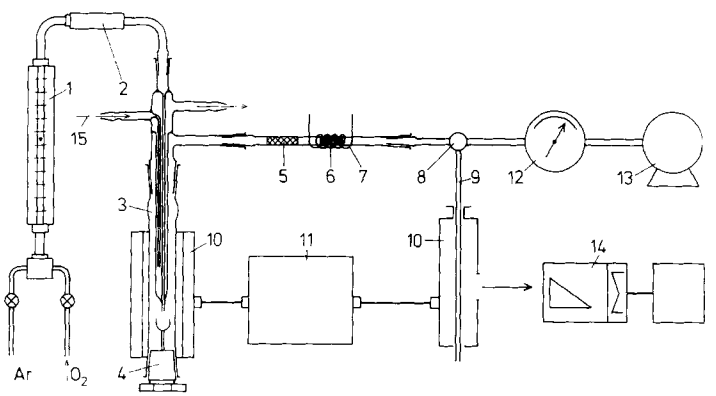

Fig. 7. Combined procedure for mercury determination in biological material and rocks by sample decomposition in microwave induced oxygen plasma (3), enrichment of Hg on an Au absorber (6) and excitation of the optical Hg emission spectrum in a microwave induced argon plasma (Kaiser et al. [48]): 1 rotameter, 2 gas purification, 3 decomposition chamber (quartz), 4 sample container support, 5 quartz wool, 6 Au absorber, 7 heating spiral, 8 three-way cock, 9 quartz capillary, 10 hollow resonator, 11 microwave generator, 12 manometer, 13 vacuum pump, 14 spectrometer, 15 cooling water).

Since soil is exceedingly complex from a chemical point of view we searched, in collaboration with a soil scientist, for a suitable model soil which would be relatively simple to understand, particularly with respect to transport mechanisms.

In the case of upland high bogs, mercury can only be taken up from the atmosphere. Analysis of samples from various depths always gave similar profiles for the distribution of Hg-concentration, which made it possible to recognize the natural background, the anthropogenic portion, and an equilibrium between input from the atmosphere and return of Hg from the upper soil layers into the atmosphere (Fig. 6c).[45]

Using radioactively labeled Hg it was possible to demonstrate that ca. 15% of the mercury taken up by the high bog was released again in the form of metal vapor or methylmercury. It was more difficult to answer the question as to how the mercury behaved that was retained by the peat bog soil. Was it completely fixed in an insoluble form, or did stable soluble complexes form, with humic acids for instance, which could be transported away by drainage water and thus gain access to the water circulation?

It proved possible to isolate the mercury compounds formed in the peat bog soil by employing a complicated separation system (cf. Fig. 8) using HPLC with MIP-OES

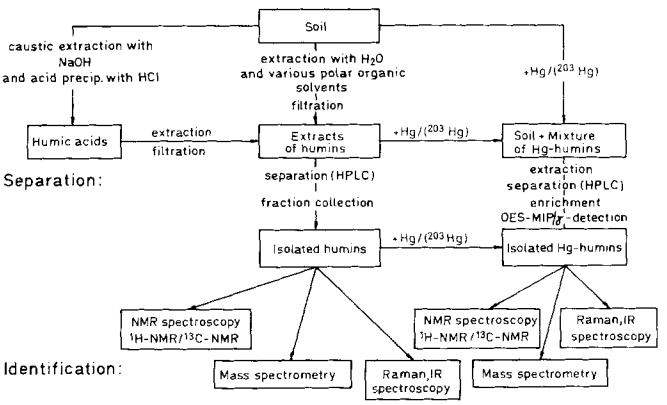

Fig. 8. Isolation and identification of Hg species in soils (after [64]).

as detector. The real breakthrough was the element-specific MIP-OES detector system, which enabled a differentiation between the Hg-containing and the remaining fractions separated chromatographically (Fig. 9).[49]

Furthermore, it was possible to identify the most common mobile Hg-compound occurring in the peat bog soils. According to ultramicro elemental analysis, UV, IR and ^{1}H-NMR spectroscopy it is unequivocally Hg humate.[49] The other four Hg-containing substances detected are present in such minute quantities that their identification will only be possible after further very expensive enrichment processes.

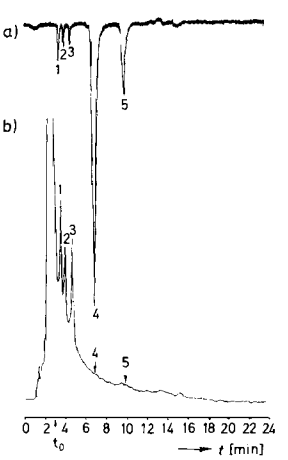

Fig. 9. Chromatographic separation of Hg-species after extraction of Hg-contaminated high peat bog with ethanol. a) MIP-OES detection: Hg(I), $\lambda = 253.6$ nm; b) UV/VIS detection, absorption at $\lambda = 250$ nm, reference wavelength $\lambda = 430$ nm. Details: [49].

About 15% of the total Hg taken up by the peat bog soil is returned to the atmosphere by evaporation within a very short time of residence; ca. 10% is transported away by water as soluble species, mainly humates, and, according to our present knowledge, ca. 75% remains fixed in the peat bog soil. Thus, profile analysis of peat bog soils with suitable corrections can significantly differentiate and make a balance of the anthropogenic input of the Hg in comparison with the natural background.

In spite of these analytical improvements this Hg-problem will be with us for some time until it will be possible to make a realistic estimate of the risks involved, since other relationships are as yet incompletely clarified. One important point is that until now the evaluation of the toxicity of heavy metals has always been focussed on the consideration of a single element, without taking into account its interaction with other elements. But many antagonistic or synergistic effects occur in this field, and they always ought to be taken into account.[50] Hg reacts, in particular, with selenium and sulfur to form selenides or sulfides with virtually no solubility. It is of utmost importance concerning the biological activity of mercury at the site of its action to know the ratio of uptake of antagonistic elements and their species transported in the organism.

5.2. Example: Traces of Selenium between Toxic and Essential

Concentrations of selenium of more than 1 μg/g taken up in the daily nutrition lead to selenosis.

On the other hand, Se-deficiency in the food intake (probably <0.2 μg/g) also causes severe damage to health, since not only does selenium fulfill important enzymatic functions, but, as described previously, it can also bind mercury and render it biologically inactive.[cf. 50,51]

In the case of selenium the analyst must be in a position to be able to make an unequivocal distinction as to whether the very narrow selenium concentration limits, laid down by nature for optimal biological effect, are maintained, exceeded, or not reached. Above all, the remaining uncertainties in the analytical data for the very low relevant concentration range make it difficult to evaluate the risks involved in selenium deficiency. Even the normal natural concentration range is difficult to determine satisfactorily, as has been confirmed by recent round robin analyses.[50]

Consequently, an analytical procedure has been sought which is economically acceptable for routine work and which enables the determination of selenium in a wide spectrum of matrices, in the ng/g range and below, as reliably as possible. Many methods promised success here because selenium can be detected very sensitively using any of the common analytical techniques (Fig. 10). The real difficulty lies in the employment of a critical comparison to find the starting point for a method which is as sensitive and reliable as possible while at the same time economical and universally applicable to all matrices of interest in an ecological survey, from geological to biological materials, so as to yield results that are as comparable as possible.

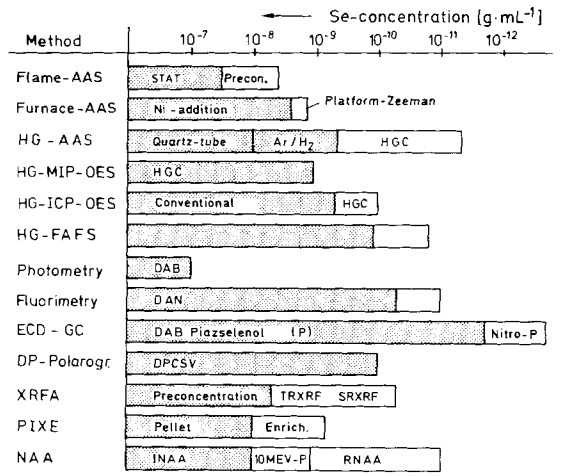

Fig. 10. Concentration ranges of the most sensitive methods for the trace determination of selenium (according to Tölg [50]): STAT: slotted tube atomic trapping; HG-AAS: Hydride generation atomic absorption spectrometry; HGC: Hydride generation and condensation; HG-MIP-OES: HG-microwave induced plasma-optical emission spectrometry; HG-ICP-OES: HG inductively coupled plasma-OES; HG-FAFS: HG flame atomic fluorescence spectrometry; DAB: 3,3'-diaminobenzidine; DAN: 2,3-diaminonaphthalene; ECD-GC: electron capture detector gas chromatography; DPP: differential pulse polarography; DPCSV: differential pulse cathodic stripping voltammetry; XRFA: X-ray fluorescence analysis; TRXRF: total reflection XRFA; SRXRF: synchrotron radiation XRFA; PIXE: proton induced X-ray emission spectrometry; INAA: instrumental neutron activation analysis; 10MEV-P: proton activation analysis ($E_P = 10$ MeV); RNAA: radiochemical neutron activation analysis.

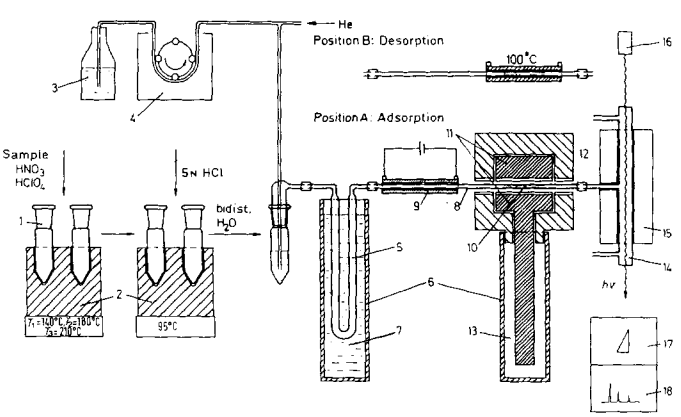
Just as in our experiences with the determination of Hg and many other elements, we found confirmation of the principle that the most sensitive and reliable analysis can only be achieved after prior isolation of the selenium. The strategy followed for selenium determination is comparable with that for the determination of mercury, since selenium is easily separated by evaporation during the decomposition of the sample.

Once again it is a matter of an optimal combination of decomposition, separation, and determination methods. This combination has been achieved in many different ways. Only one of them will be described briefly here which possesses the optimal quality criteria for determin-



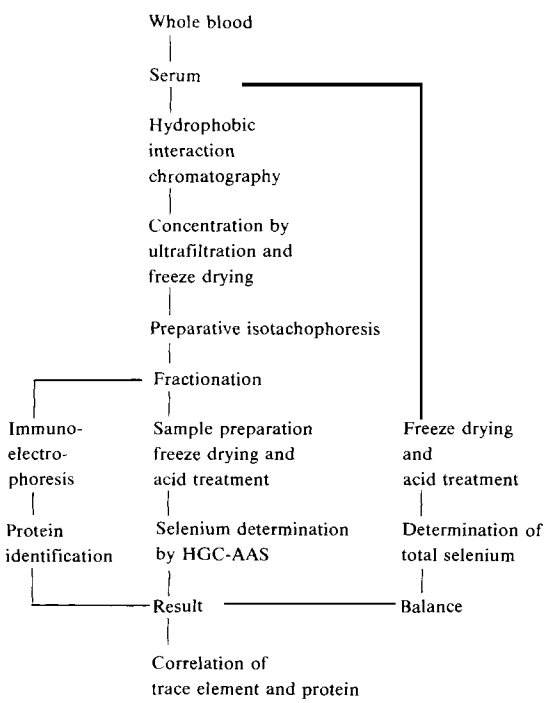


Fig. 11. HGC-AAS apparatus for the determination of selenium in the pg·mL^{-1} range (according to J. Piwonka [52]): 1. Quartz flask, 2. heating block, 3. reducing solution, 4. peristaltic pump, 5. quartz U tube, 6. Dewar flask, 7. cold trap (−70°C), 8. quartz adsorption tube, 9. heater, 10. adsorption trap Chromosorb W30/60, 11. cold block (Al, −196°C), 12. insulation, 13. liquid N_2, 14. quartz cuvette, 15. furnace, 16. EDL-lamp, 17. atomic absorption spectrometer, 18. recorder.

ing selenium reliably in all biotic matrices in the lower pg-range. The high detection power of the AAS method, which is only exceeded by the gas-chromatographic determination of selenium as piazselenol using the electron capture detector, is based on a simple preconcentration step. As a supplement to conventional hydride AAS, after a special decomposition of the sample in oxygen, hydrogen selenide is released and collected in an absorber tube by freezing onto Chromosorb (HGC-AAS). The hydrogen selenide collected can then be transferred in a pulse-like fashion to the atomization cuvette by simply heating up the absorber tube (Fig. 11).[52]

It is now possible to determine selenium in blood serum protein fractions by a complicated combined analytical procedure (cf. Scheme 1).[53] Thus, very sensitive procedures are available for the determination of Hg and Se, and their antagonistic effects can be investigated even in the serum protein fractions.

Scheme 1. Flow diagram for the separation and determination of selenium in the protein fractions of blood serum (after [53]).

The procedure is even suitable for the micro-distribution analysis of selenium in sections of a single hair or in finger nails. Very good reproducibility was obtained in the investigation of different hairs from a single subject, but when the selenium content of hairs from various subjects was determined surprisingly large variations were found. The cause of this could be traced to selenium contamination[50] (cf. [54]), which could only be incompletely removed by even the most careful cleansing process. Other authors[55] revealed in a gradient analysis, scanning a proton microprobe (PIXE) across the hair's cross section that selenium was strongly enriched at the surface of the hair, and definitely originated from selenium-containing shampoos (cf. Fig. 13). It was concluded from the thickness of the layer that the selenium had diffused into the hair. However, the detection power of PIXE does not suffice for the determination of selenium in the interior of the hair strand.

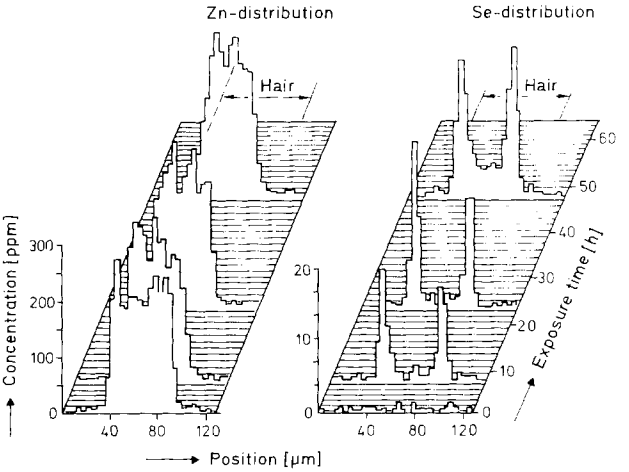

Fig. 12. Concentration distribution of Zn and Se across the cross-section of hair segments (distances in µm) after various periods of treatment with a selenium-containing shampoo. X-ray emission analysis with a proton microprobe PIXE (after [55]).

6. Future Challenges

The problems discussed here as examples are similarly imposed in other fields of analysis also, for example in the analysis of semi-conductors, metals, ceramics and plastics; here also, the positive and negative effects caused by previously ignored impurities are recognized.[56] In all these fields, interest centers not only on ever decreasingly lower concentration ranges of a total impurity but also on its distribution in samples and on sample surfaces.[57–59] The decisive question is often the mode of bonding of an element,[23,60] the formation of the compound, or the metabolism of active agents in very complex systems, which can only be elucidated by including analyses of microstructures, surfaces, and bonding properties. There is danger arising, whenever a single-minded course is followed without observing critically the sum total. This also applies to the interpretation of analytical data; and here, in particular, it can be said that the whole is more than the sum of its parts. Once again, an appeal must be made for closer partnership between specialized analysts and scientists of all spheres who need reliable data. Only such cooperation will lead to the urgently required progress which can repair the currently disturbed relationship between man and his environment.

The inter-methodological approach in basic analytical research itself urgently needs intensification. This presupposes, apart from an improvement in research capacity, a high degree of critical and creative thought concerning analytical strategies, which can only be worked out by highly qualified analysts—both chemically and physically orientated—with the necessary background knowledge (see [11]). The primary task is the furtherance of junior analytical scientists. However, this will only succeed, if a concerted effort is made to promote efficient analytical chemistry; and this will call on those responsible for research policies as well as those interested in reliable analytical

data, viz. all users of such data, expert colleagues in universities, in civil authorities, in industry, and in scientific and medical institutes.

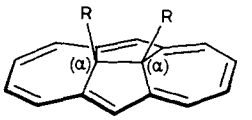
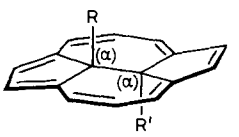
Hyperfine Coupling to ^{13}C Nuclei in Alkyl Substituents—A Contribution to the Problem of C–C and C–H Hyperconjugation**

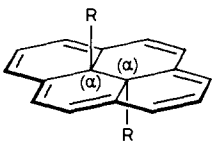


By *Fabian Gerson** and *Walter Huber*

The concept of "hyperconjugation" was introduced by *Mulliken*[1] to describe the interaction between a π-MO and a σ-MO of appropriate symmetry (pseudo-π-MO). The theoretical foundations of this interaction were recently discussed by *Radom*.[2] Of particular interest is hyperconjugation in ions that occur as intermediates in chemical reactions. The course of the reaction often depends on the preferred conformations of such ions which, in turn, are determined by the relative "hyperconjugative abilities" of the C–X σ-bonds. According to MO calculations of rotational barriers in simple alkyl cations[3] and anions[4] as model systems, these "abilities" are greater for C–C than for C–H bonds. ESR spectroscopy is especially suitable for testing predictions of this kind, since the hyperfine coupling constants of the β-^{13}C atoms ($^{13}C(\beta)$-hfc's), like those of the β-H atoms ($^{1}H(\beta)$-hfc's), predominantly arise from hyperconjugation of the singly occupied π-MO (SOMO) with the σ-MO of the C(α)–X(β) bond.



An insight into the relative "hyperconjugative abilities" of the C–H and C–C σ-bonds can thus be gained from the corresponding $^{1}H(\beta)$- and $^{13}C(\beta)$-hfc's. With the exception of a recently reported value for the radical cation of $(^{13}CH_3)_2CO$,[5] however, no hfc's of $^{13}C(\beta)$ have so far been available to provide a comparison with those of $^{1}H(\beta)$. Ideally suited model systems are the three pairs of radical ions of bridged [14]annulenes, the cations **1a**$^{\oplus\ominus}$ and **1b**$^{\oplus\ominus}$,[6] as well as the anions **2a**$^{\ominus\ominus}$, **2b**$^{\ominus\ominus}$[7] and **3a**$^{\ominus\ominus}$, **3b**$^{\ominus\ominus}$.[8]



These radical ions, which have been characterized by their ^{1}H-hfc's, offer several advantages. The carbon framework is fairly rigid. On going from **a** to **b** within each pair, there is no change either in the π-spin distribution or in the orientation of C(α)–X(β) bonds relative to the cyclic π-system (X = H for R = H in **a** and X = C for R = CH_3 in **b**). Furthermore, these radical ions are a typical example of a particularly favored hyperconjugation. Not only are the

1a, R = H(β)
1b, R = C(β)H_3

2a, R = H(β), R' = C(β)H_3
2b, R = R' = C(β)H_3

3a, R = H(β)
3b, R = C(β)H_3

C(α) atoms simultaneously bound to two π centers having large LCAO coefficients of the same sign for the SOMO, but also the directions of the C(α)–X(β) bonds are almost parallel to that of the $2p_z$ axes at the two centers.[9] The strong hyperconjugative interaction is manifested by the exceptionally large $^{1}H(\beta)$-hfc's, $a(^{1}H)$, for **1a**$^{\oplus\ominus}$, **2a**$^{\ominus\ominus}$, and **3a**$^{\ominus\ominus}$ (Table 1). A reexamination of the ESR spectra of **1b**$^{\oplus\ominus}$, **2b**$^{\ominus\ominus}$, and **3b**$^{\ominus\ominus}$[10] reveals the existence of satellite lines stemming from ^{13}C isotopes in two equivalent sites. The corresponding, unusually large ^{13}C-hfc's, $a(^{13}C)$, are assigned to the C(β)-nuclei (Table 1). For **2b**$^{\ominus\ominus}$, the assignment is confirmed by the ESR spectrum of the radical anion enriched (90%) with ^{13}C isotopes in the C(β) positions ($^{13}C_2$-**2b**$^{\ominus\ominus}$).[11] In the case of **1b**$^{\oplus\ominus}$, the assignment is supported by the fact that the corresponding satellite lines are missing in the ESR spectrum of **1a**$^{\oplus\ominus}$. Unfortunately, an analogous argument cannot be used for **3b**$^{\ominus\ominus}$, because ^{13}C-satellite lines in the spectrum of **3a**$^{\ominus\ominus}$ cannot be examined due to the instability of the radical anion.[8a]

Table 1. $^{1}H(\beta)$- and $^{13}C(\beta)$-hfc's, $a(^{1}H)$ and $a(^{13}C)$, respectively, in mT [a] for the radical ions **1a**, **b**$^{\oplus\ominus}$, **2a**, **b**$^{\ominus\ominus}$, and **3a**, **b**$^{\ominus\ominus}$.

	1a$^{\oplus\ominus}$	**2a**$^{\ominus\ominus}$	**3a**$^{\ominus\ominus}$
$a(^{1}H)$	2.81 [6]	2.14 [7]	1.91 [8a]
	1b$^{\oplus\ominus}$	**2b**$^{\ominus\ominus}$	**3b**$^{\ominus\ominus}$
$a(^{13}C)$	2.74	1.72	1.43

[a] Experimental error: ±1%.

The $^{13}C(\beta)$-hfc's, $a(^{13}C)$, are almost as large as the corresponding $^{1}H(\beta)$-hfc's, $a(^{1}H)$ (Table 1).[12] With respect to the relative "hyperconjugative abilities" of the C–C and C–H bonds, it is, however, more informative to compare the spin populations ρ_C and ρ_H at the C(β) and H(β) atoms in question. Whereas conversion of $a(^{1}H)$ into ρ_H is straightforward, calculation of ρ_C requires an exact measurement of the anisotropy parameter $B(^{13}C)$ in addition to the isotropic value $a(^{13}C)$.[13] This requirement is met in the case of **2b**$^{\ominus\ominus}$ by the use of the labeled derivative $^{13}C_2$-**2b**$^{\ominus\ominus}$.

Figure 1 shows the ESR spectrum of $^{13}C_2$-**2b**$^{\ominus\ominus}$ in a liquid solution, along with the ENDOR signals associated with $a(^{13}C)$.[14] The second-order splitting observed for these signals is, to our knowledge, the first such finding in a ^{13}C-ENDOR experiment. In view of the small width of the ESR and ENDOR lines, the anisotropy of the $^{13}C(\beta)$-

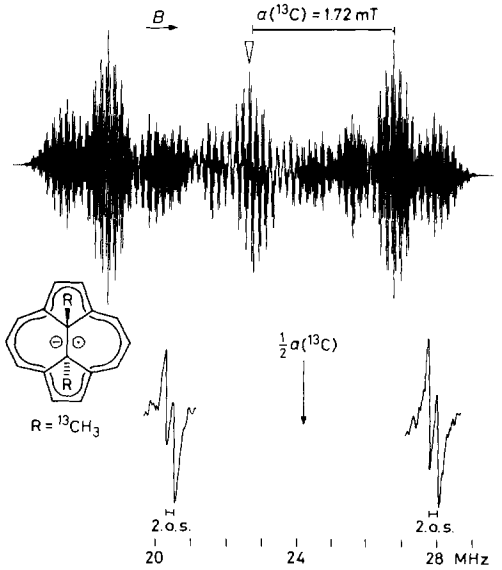

Fig. 1. ESR (top) and ^{13}C-ENDOR (bottom) spectra of $^{13}C_2$-**2b**$^{\ominus\ominus}$ in liquid solution. Solvent: 1,2-dimethoxyethane; counterion: $K^{\oplus}$; $T = 193$ K. The triangle in the ESR spectrum indicates the position for the ENDOR experiment. 2.o.s. = second-order splitting. Recorded with a Varian E-9 ESR spectrometer and a Bruker ER-252 ENMR system connected to a Bruker ER-200-D-SRC-9 spectrometer. [14]

hfc's should be rather small. This conclusion is confirmed by the ESR and ENDOR spectra of $^{13}C_2$-**2b**$^{\ominus\ominus}$ in a glassy solution (Fig. 2). The difference $A_{\parallel}(^{13}C) - A_{\perp}(^{13}C) = 3.4_5$ MHz (0.12_3 mT), which is derived from the ENDOR signals, gives an anisotropy parameter $B(^{13}C)$ of only $\frac{1}{3}0.12_3$ mT $= 0.04_1$ mT.[13] From the experimental ^{13}C(β)-hfc's ($a(^{13}C) = 1.72$ and $B(^{13}C) = 0.04_1$ mT)[12] and the atomic parameters for the C-2s- and C-2p-orbitals[15] (135 and 3.8 mT, respectively)[15] the partial populations $\rho_C(2s) = 1.72$ mT/135 mT $= 0.013$ and $\rho_C(2p) = 0.04_1$ mT/3.8 mT $= 0.011$ are calculated. This result is compatible

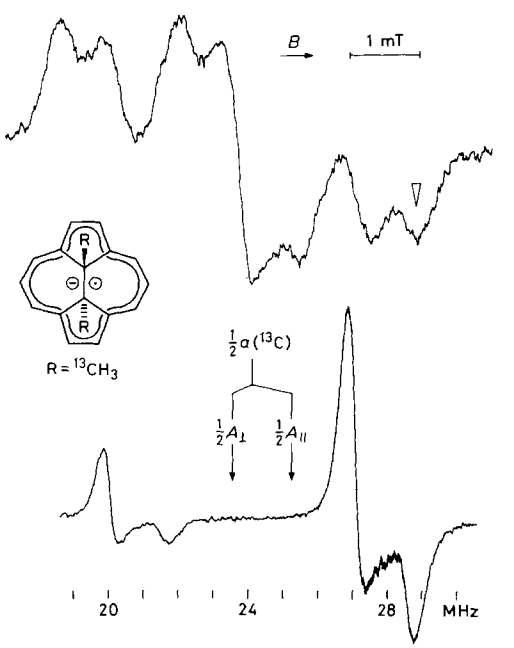

Fig. 2. ESR (top) and ^{13}C-ENDOR (bottom) spectra of $^{13}C_2$-**2b**$^{\ominus\ominus}$ in glassy solution. Solvent: 2-methyltetrahydrofuran; counterion: $K^{\oplus}$; $T \approx 113$ K. The triangle in the ESR spectrum indicates the position for the ENDOR experiment. Taken with a Varian E-9 ESR spectrometer connected to a Varian EN-DOR-1700 system.

with an sp-hybridization rather than with the sp^3-hybridization expected for a methyl C atom. Interestingly, it is reminiscent of the formulation $-C{\equiv}H_3$ used for a methyl substituent by *Mulliken*[1] nearly 50 years ago.

The total spin population ρ_C at a C(β) atom in **2b**$^{\ominus\ominus}$ thus amounts to $0.013 + 0.011 = 0.024$, while the corresponding value ρ_H for the H(β) atom in **2a**$^{\ominus\ominus}$ is $\rho_H(1s) = 2.14$ mT/50.7 mT $= 0.042$,[12] where 2.14 and 50.7 mT are the hfc's of ^{1}H(β) in **2a**$^{\ominus\ominus}$ (Table 1) and of the ^{1}H nucleus in atomic hydrogen,[16] respectively. Should the spin populations, $\rho_C = 0.024$ and $\rho_H = 0.042$, be interpreted in terms of the "hyperconjugative abilities" of the C–C bonds being markedly smaller than those of the C–H ones, which is at variance with the previous predictions of MO models?[3,4] Or, do the radical ions **1a,b**$^{\oplus\ominus}$, **2a,b**$^{\ominus\ominus}$, and **3a,b**$^{\ominus\ominus}$ represent a special case, so that the conclusions drawn from the present results are not general? An answer to these questions demands further investigations.

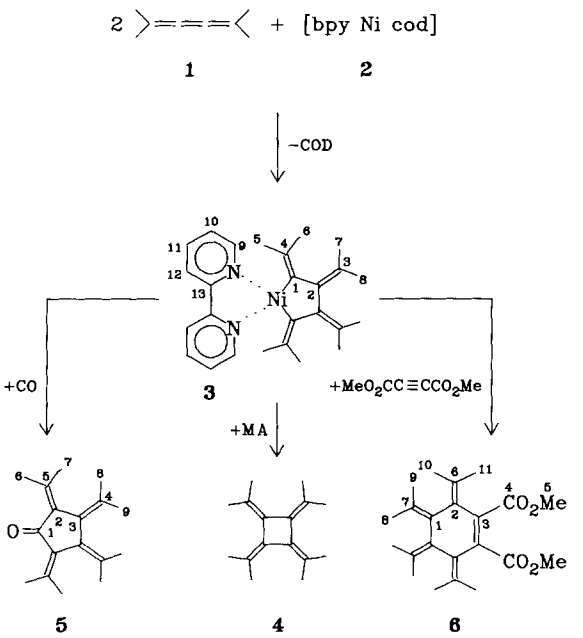
An Intermediate and Its Secondary Products in a Nickel-Catalyzed Synthesis of [4]-Radialenes

By *Ludwig Stehling* and *Günther Wilke**

Dedicated to Professor Schulte-Frohlinde on the occasion of his 60th birthday



1,2,3-Butatrienes can be catalytically cyclodimerized to [4]-radialenes[1] or cyclotrimerized to [6]-radialenes in the presence of $[(Ph_3P)_2Ni(CO)_2]$.[1,2] In the cyclotrimerization of butadiene on "naked" nickel it was possible for the first time to trap an intermediate of a catalytic cyclooligomerization.[3] Subsequently, numerous other intermediates, in general metallacycles,[4] have been isolated from related

[*] Prof. Dr. G. Wilke, L. Stehling
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

catalytic reactions. Thus, metallacyclopentanes are formed on reaction of 2,2'-bipyridyl-1,5-cyclooctadienenickel(0) **2** with 3,3-dimethylcyclopropene[5] or methylcyclopropane;[6] the structure of the former metallacycle was determined X-ray crystallographically.[5]

2,5-Dimethyl-2,3,4-hexatriene **1** reacts smoothly with **2** in tetrahydrofuran (THF) at 5 °C with displacement of 1,5-cyclooctadiene (COD) to give the nickelacyclopentane **3**, which can be isolated in crystalline form in over 80% yield. The structure of **3** was confirmed by ^{1}H- and ^{13}C-NMR spectra and X-ray structural analysis.[7,8]

3 is formed by the oxidative addition of two triene molecules to nickel(0) with concomitant CC coupling. In the presence of maleic anhydride (MA) a reductive elimination takes place, leading to formation of the [4]-radialene **4**.[9] The Ni–C σ-bonds in **3** take part in insertion reactions followed by reductive elimination. Thus, reaction of **3** with CO leads to formation of 2,2'-bipyridyldicarbonylnickel and the cyclopentanone derivative **5**, whose structure is confirmed by IR/Raman, NMR, and mass spectra.[10] On reaction of methyl acetylenedicarboxylate with **3**, insertion and reductive elimination leads to the cyclohexene derivative **6**, which has also been unequivocally characterized.[11]

In the catalytic cyclooligomerization[1] of 2,5-dimethyl-2,3,4-hexatriene **1** mentioned initially, **4** is formed in only 11% yield along with 38% cyclotrimers.[2] The reaction described here in contrast, affords **4** in yields of more than 90% without necessitating a separation from by-products.

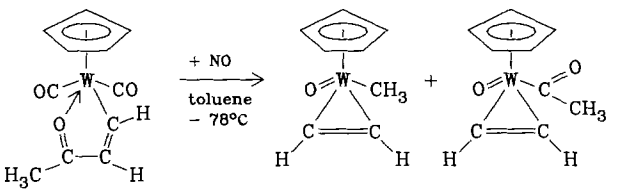
Unit cell data: $a = 9.602(1)$, $b = 25.239(3)$, $c = 20.127(2)$ Å, $\beta = 97.34(1)°$, $Z = 8$ with $\rho = 1.18$ g cm^{-3}; 9880 reflections, 3834 unobserved ($I \leq 2\sigma(I)$); $R = 0.039$, $R_w = 0.047$. Distorted planar coordination to the nickel (interplanar angle N–Ni–N/C–Ni–C: 33°), Ni–N 1.952(3), NiC 1.926(5) Å; N–Ni–N 82.1, C–Ni–N 84.7°.
[8] **3**: 15.65 g (48.44 mmol) of **2** was dissolved in THF (350 mL) under argon and treated with a solution of **1** (10.48 g, 96.88 mmol) in THF (150 mL). After ca. 12 hours' stirring at 5 °C, the solution was evaporated to 40 mL, treated with 200 mL of pentane, cooled to −78 °C, and the resulting precipitate filtered cold on a frit, and dried. Yield: 17.4 g (40.35 mmol), 83.3%. ^{13}C-NMR ([D$_8$]THF, TMS, 75.5 MHz): $\delta = 151.17$, 150.52 (s, C-1, C-2); 108.32 (s, C-3); 121.69 (s, C-4); 26.47 (q, C-5); 23.12, 22.40, 22.08 (q, C-6, C-7, C-8); 152.33 (d, C-9); 127.20, 121.84 (d, C-10, C-12); 135.92 (d, C-11); 153.74 (s, C-13); MS: *m/z* 430 (M^+, decomp.).
[9] **4**: 2.11 g (4.89 mmol) of **3** was dissolved in THF (40 mL) under argon and treated with solid maleic anhydride (MA) (0.96 g, 9.78 mmol). Reaction was allowed to proceed for ca. 12 h, the THF removed by evaporation, and the residue taken up in pentane. After filtration through a frit, the filtrate was evaporated to dryness. Yield of crude product: 0.9 g (4.62 mmol) 94%. After sublimation in vacuo (60–80 °C): 0.75 g (3.47 mmol), 78.8% pure product. ^{1}H-NMR ([D$_8$]toluene): $\delta = 1.83$ ([2] ($CDCl_3$): $\delta = 1.80$); ^{13}C-NMR ($CDCl_3$): $\delta = 138.3$, 115.5, 23.8 ([2]: $\delta = 138.3$, 115.5, 23.8); MS: *m/z* 216 (M^+); UV (*n*-hexane): $\lambda_{max} = 269$ nm ($\lg\varepsilon = 4.62$), 259 sh (4.16), 280 sh (4.21), 304 sh (3.83) ([2]: UV (cyclohexane): $\lambda_{max} = 272$ nm ($\lg\varepsilon = 4.279$), 260 sh (4.176), 283 sh (4.230), 307 sh (3.857)).
[10] **5**: 2.94 g (6.82 mmol) of **3** was dissolved in THF (80 mL) and treated with 458.3 mL (20.46 mmol) CO. The THF was then removed and the residue was taken upon in pentane, filtered through a frit, and the filtrate evaporated to dryness. The residue was sublimed in a vacuum (80–100 °C): 1.1 g (4.5 mmol), 66% pure product. ^{13}C-NMR ($CDCl_3$, TMS, 75.5 MHz): $\delta = 194.05$ (s, C-1); 136.51, 136.05 (s, C-2, C-3); 125.07 (s, C-4); 140.89 (s, C-5); 25.97, 23.06, 22.72, 20.38 (q, C-6, C-7, C-8, C-9); MS: *m/z* 244 (M^+, 63%); IR (KBr): $\nu = 1696$ (s) (CO), 1661 (w), 1644 (w), 1619 (s) (C=C) cm^{-1}; m.p. 111 °C.
[11] **6**: 1.21 g (2.8 mmol) of **3** was dissolved in toluene under argon and treated with methyl acetylenedicarboxylate. After 4 hours' stirring the mixture was filtered through a frit. The filtrate was evaporated to dryness and the residue was taken up in pentane, filtered through a frit, and the solvent removed from the filtrate. Yield: 0.6 g (1.67 mmol), 59.8%. ^{13}C-NMR ($CDCl_3$, TMS, 75.5 MHz): $\delta = 133.42$, 133.35, 129.51, 126.18 (s, C-1, C-2, C-6, C-7); 132.38 (s, C-3); 169.87 (s, C-4); 52.12 (q, C-5); 25.05, 21.47, 20.93, 20.30 (q, C-8, C-9, C-10, C-11); MS: *m/z* 358 (M^+, 29%); IR (KBr): $\nu = 1734$ (s), 1721 (s) (CO), 1609 (m), 1537 (m) (C=C) cm^{-1}; m.p. 159 °C.

Nitrogen Monoxide as a Source for Oxo Ligands—Acetylene-Oxo Complexes of Tungsten**

By *Helmut G. Alt** and *Heidi I. Hayen*



The conventional way to prepare organometallic oxo complexes involves the thermally or photochemically induced reaction of carbonyl complexes with air or with oxygen.[1-4] In special cases, the hydrolysis of alkyl transition-metal complexes is also suitable.[5]

We report here the reaction of the alkenyl ketone complex **1** with nitrogen monoxide in toluene. Nitrogen monoxide is not coordinated to the metal as an intact complex ligand, but rather provides its oxygen for the formation of a terminal oxo ligand. Simultaneously, the alkenyl ketone ligand fragments into an acetylene and a methyl or acetyl ligand.

Universitätsstrasse 30, D-8580 Bayreuth (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The mechanism of this instantaneous reaction is still unclear. Nitrogen monoxide, which is readily reduced, could react via a transient hyponitrito complex to form dinitrogen monoxide,[6, 7] thus acting as a source of oxygen.[8] However, no N_2O is detected in the reaction gas. Complex **1** does not react with NO_2 to form **2a** and **3a**. With air, only a small amount of **3a** is formed after 30 min.

1 **2a** (25%) **3a** (47%)

In order to prepare acetylene-oxo complexes of type **2**, the reaction of the acetylene-alkyl-carbonyl complexes **4a**–**c** with NO (as a source of oxygen) can also be used.

$$[LW(CO)(C_2H_2)Me] \xrightarrow[-CO]{+NO} [LW(O)(C_2H_2)Me]$$

4 **2**

a: L = η^5-C_5H_5, 37%, **b**: L = η^5-C_5H_4Me, 17%, **c**: L = η^5-C_5Me_5, 74%

For L = C_5H_5 and C_5H_4Me, the acetylene-nitrosyl complexes **5**[9] are formed in 38 and 61% yield, respectively. No oxo complexes result from the reaction of the chromium and molybdenum analogues of **1** with NO under the same reaction conditions. The reaction of **6a** with NO did not afford a tractable product; complex **6b** reacts with NO to give the dinitrosyl complex **7**.

$[LW(CO)(C_2H_2)NO]$
5, L = η^5-C_5H_5, η^5-C_5H_4Me

$[(C_5R_5)(CO)_2M\{HC{=}CH{-}C(O)Me\}]$
6; **a**, R = H, M = Mo; **b**, R = Me, M = Cr

$[(C_5Me_5)Cr(NO)_2(NO_2)]$ **7** $[W(O)(C_2H_2)(S_2CNR_2)_2]$ **8**, R = Me, Et

$[Re(O)(C_2Me_2)I]$ **9** $[(C_5H_5)W(NO)_2(HC{=}CHCOMe)]$ **10**

$[(C_5H_5)W(CO)_3]_2$
11

In the IR spectra (cf. [10]) of the acetylene-oxo complexes **2a**–**c** and **3a**, a relatively intense band is observed at 940 cm^{-1}, which is characteristic of the W=O vibration.[1–5] The ν(CC) absorption of the C_2H_2 ligand appears as a strong band in the region 1580–1630 cm^{-1}. Similar values have been reported for the alkyne-oxo complexes **8**[4] and **9**.[11] Especially noticeable in the ^{1}H-NMR spectra[10] is the large downfield shift of the signals of the methyl ligands. This is due to the positive charge induced on the central metal atom by the oxo ligand. A similar effect is observed for the chemical shifts of the C_2H_2 hydrogen atoms in the ^{1}H-NMR spectrum and for those of the C_2H_2 carbon atoms in the ^{13}C-NMR spectrum.

The alkyne ligand in the oxo complex **8**, R = Me,[4] has a relatively low barrier for rotation around the metal-alkyne bond ($\Delta G^{\neq}$ = 66.4 kJ/mol); the C_2H_2 signals of the complexes **2a**–**c** and **3a** do not change upon heating of the samples to 130 °C (in [D_8]toluene under pressure). This indicates that the complexes **2a**–**c** and **3a** exhibit high tungstacyclopropene character and that tungsten is present in its highest formal oxidation state +6.

Selective nitrosylation of **1** is achieved when nitrosyl-chloride is used as a nitrosylation reagent: in this case, equal proportions of the stable alkenyldinitrosyl complex **10**[13] and the known compound **11** are formed.

Experimental Procedure

All operations were carried out under inert atmosphere with dry solvents. Reaction of **1** with NO: **1** (0.24 g, 0.64 mmol) [12] was dissolved in 20 mL of toluene. The solution was cooled to –78 °C and allowed to react with excess NO gas. The solution immediately changed from dark red to orange. Subsequent column chromatography (silica gel/pentane) afforded the yellow oxo complex **2a** (eluted with ether) and the orange acetyl compound **3a** (eluted with tetrahydrofuran). Both solutions were evaporated to dryness under high vacuum. **2a**: m.p. = 77–80 °C (under argon), *m/z* 306 (relative to ^{184}W), yield 0.05 g (25%). **3a**, oil at room temperature, *m/z* 334 (relative to ^{184}W), yield 0.10 g (47%).

Reduction of Ketones by Alkali Metals in Tertiary Alcohols: Unexpected Cation Effect on the Stereochemistry**

By *Claudio Giordano,** *Giulio Perdoncin,* and *Graziano Castaldi*

Although the reduction of ketones by alkali metals is a classical process, the overall mechanism and the factors that govern the stereochemistry of the products are not completely understood.[1] The stereochemical course of the reduction has practical applications: for example, the reduction of 3α-hydroxy-7-oxo-5β-cholanic acid **1** by alkali metals is the key step in the industrial production of 3α,7β-dihydroxy-5β-cholanic acid **2**. The reduction of **1**, carried out using a large excess of sodium in alcohols, provides **2** and **3** in the ratio 80—85/20—15 in almost quantitative yield.[2] In order to increase the stereoselectivity toward the formation of **2**, we have investigated the factors that influence the stereochemistry of this reduction.[3]

1

2, R^1 = H, R^2 = OH
3, R^1 = OH, R^2 = H

We describe here the stereochemistry of the reduction of **1** by alkali metals in tertiary alcohols (see Table 1). When the reduction is carried out in *tert*-amyl or *tert*-butyl alcohol, higher stereoselectivity toward the formation of **2** is observed with potassium, rubidium, and cesium than with sodium. This effect is not observed in primary and secondary alcohols.

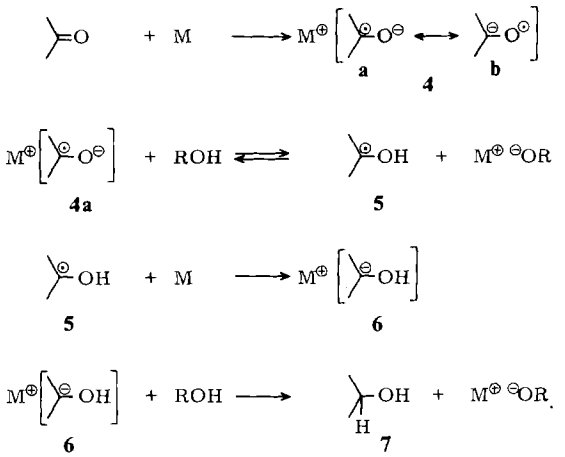

Table 1. Reduction of **1** by alkali metals M in *tert*-amyl alcohols [a].

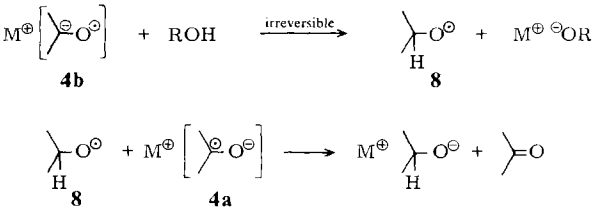
1 [mmol]	MO*t*Am [mol] [b]	*t*AmOH [mL]	M [mmol]	**2** : **3** [c]
25.60	—	200	Na [0.217]	80 : 20
25.60	—	200	K [0.141]	94 : 6
2.56	—	20	Rb [0.025]	96 : 4
2.56	—	20	Cs [0.025]	96 : 4
25.60	M = K [0.136]	200	Na [0.436]	94 : 6
2.56	M = Rb [0.014]	20	Na [0.044]	95 : 5
2.56	M = Cs [0.014]	15	Na [0.044]	95 : 5

[a] The reduction was carried out with vigorous stirring, under nitrogen, and at reflux temperature. The metal was added in 10 minutes in the amount required to reach conversion higher than 90%. [b] Alkali metal *tert*-amylates were obtained by dissolving the desired amount of the metal in *tert*-amyl alcohol before adding **1**. [c] The product ratio was determined by HPLC analysis [2].

The reduction with sodium in tertiary alcohols in the presence of potassium, rubidium, or cesium salts gives the same stereoselectivity as observed for the reduction with potassium, rubidium, or cesium metals, respectively. In contrast, the stereoselectivity in the reduction of **1** with potassium, rubidium, or cesium is only slightly affected by the presence of sodium salts. This interesting cation effect in alcoholic medium has not been previously reported for the reduction of ketones by alkali metals.



How can the mechanism of the reduction accomodate these experimental results? The first step of this reduction is the transfer of an electron to the ketonic carbonyl group generating the ketyl **4**.[4] The ketyl exists in equilibrium with a dimeric (or higher) species, which for aliphatic ketyls strongly favors dimeric or polymeric ion pairs.[5] In the presence of a relatively acidic proton donor (e.g., a tertiary alcohol) an α-hydroxyalkyl radical **5** is formed, according to the classical mechanism, via protonation of the ketyl on oxygen.[1,5] Subsequently, **5** undergoes a second electron transfer leading to the carbanion **6**, which is rapidly protonated to form **7**[1] (Scheme 1).

Scheme 1. Classical mechanism for the reduction of ketones with alkali metals in tertiary alcohols.

As an alternative to this mechanism, we would like to consider the possibility that the radical anion **4** is protonated on a different site. It has been reported that the protonation of the ketyl **4** occurs on oxygen rather than on carbon.[6] However, the observation that a stable ketyl dimer of 2,2,6,6-tetramethylcyclohexanone, on quenching with water, rapidly disproportionates to a molecule of alcohol and a molecule of ketone[7] suggests that the protonation might occur on carbon. Obviously, the protonation on oxygen is favored. However, it is a reversible process, whereas the protonation on carbon is irreversible under our experimental conditions. The latter protonation would lead to the formation of an electrophilic alkoxy radical **8**, which could be easily reduced by the ketyl **4** (Scheme 2). On the other hand, the protonation on oxygen would lead to a nucleophilic α-hydroxyalkyl radical **5**, which could not be reduced by the ketyl **4** so easily.[8]

The radical **5** is much more acidic (5 pK_A units lower) than the parent alcohol.[9] The ketyl **4** will be present in

Scheme 2. Alternative mechanism for the reduction of ketones with alkali metals in tertiary alcohols (first step as in Scheme 1).

[**] We thank Prof. *F. Minisci* for helpful discussions.

higher concentration in tertiary alcohols than in primary or in secondary ones,[10] thus favoring the reduction of **8**. In the classical mechanism,[1] the stereochemistry of the product is determined by the protonation of the carbanion **6**, which is a strong base, whereas, in our proposed mechanism, it is determined by the protonation of the more weakly basic ketyl **4** on carbon. Thus, the new mechanism better accomodates the observed cation effect in the reduction of **1** by alkali metals in tertiary alcohols.

NaGe—High-Pressure Formation of the NaPb-Type Structure**

By *Jürgen Evers,* Gilbert Oehlinger, Gerhard Sextl,* and *Armin Weiss*

The 1:1 compounds of the alkali metals Na, K, Rb, and Cs with Si, Ge, Sn, and Pb crystallize at normal pressure (NP) in four structure types. In the monoclinic NaSi-type structure,[1] the monoclinic NaGe-type structure,[1] and the cubic KGe-type structure,[2] 6:6 coordination is observed, in contrast to the tetragonal NaPb-type structure with 7:7 coordination.[3] Recently, the six binary phases with the KGe-type structure were transformed under high pressure (maximum 4 GPa) into the NaPb-type structure.[4] The NP phases are approximately 4% less densely packed than the high-pressure (HP) phases. This increase in density is in agreement with the pressure-coordination rule that the HP phases exhibit higher coordination (7:7) than the NP ones (6:6). We report here on the high-pressure transformation of NaGe, the only known binary phase with the NaGe-type structure, into the NaPb-type structure.

NaGe was prepared at NP under argon by fusion of stoichiometric amounts of the elements in a molybdenum crucible equipped with a cover. In order to prevent the evaporation of sodium during the synthesis, the Mo crucible was placed in a vacuum-tight iron crucible fitted with a copper gasket. The crucibles were heated in a high-vacuum furnace to 800—850°C. NaGe is rapidly decomposed by air and water. Therefore, all preparative operations involving the open iron crucible must be carried out under purified argon in a glove box. A belt-type apparatus was used to generate high pressures and high temperatures (maximum 4 GPa, 500°C, boron nitride crucibles). After rapid cooling to room temperature and subsequent release of pressure, the HP phase of NaGe can be metastably quenched to ambient conditions. Heating of this phase to 300°C results in quantitative retransformation into the NP phase.

The X-ray Guinier pattern (Huber G 644 with computer control, $Cu_{K\alpha 1}$ radiation) can be tetragonally indexed. It shows the characteristic sequence of reflections for the NaPb-type structure.[3] Best agreement between observed and calculated intensities was achieved with the positional parameters given in Table 1 (32 reflections, $R = 0.07$). In the ternary phases $NaGe_xSn_{1-x}$, which were studied in steps of $\Delta x = 0.25$ from $x = 0$ to $x = 1$, the NaPb-type structure is stable at NP for $0.00 \leq x \leq 0.25$ and at HP over the whole range $0.00 \leq x \leq 1.00$.

The crystallographic data for the monoclinic NP phase of the NaGe-type structure and for the tetragonal HP phase of the NaPb-type structure are summarized in Table 1. NaGe (HP) is isotypic with NaSn[5] and NaPb.[3] For these three sodium compounds, the axial ratio c/a changes continually. It is 1.64 in NaGe (HP), 1.66 in NaSn ($a = 1046$, $c = 1739$ pm),[5] and 1.68 in NaPb ($a = 1058$, $c = 1775$ pm).[3] Furthermore, the corresponding silicides and germanides of the larger alkali metals K, Rb, and Cs[4] as well as their stannides and plumbides[6] crystallize in the NaPb type at NP. In this case, c/a remains constant at 1.63.

Tetragonal NaGe (HP) with the NaPb-type structure has an approximately 5% higher density than monoclinic NaGe (NP) with the NaGe-type structure (Table 1). This increase in density involves an increase in the coordination number from 6:6 to 7:7. Nevertheless, the Ge partial structures of both polymorphs of NaGe consist of isolated tetrahedra of tricoordinated germanium atoms. Possibly, the semiconducting properties of these phases will be lost when 8:8 coordination in NaGe is stabilized at pressures very much higher than 4 GPa. Such a coordination is already present at NP in LiGe,[7] LiSn,[8] and LiPb.[9] In

LiGe, the Ge partial structure consists of a three-dimensional network of tricoordinated germanium atoms. However, the electric conductivity now shows metallic behavior. In LiSn and LiPb, no tricoordinated arrangement of the Sn and Pb atoms, respectively, is found. The Sn atoms still have four Sn neighbors in LiSn; the Pb atoms in LiPb have even six Pb neighbors. In this case, metallic phases are present.

A Nucleolipid with Antiviral Acycloguanosine as Head Group—Synthesis and Liposome Formation**

By *Helmut Rosemeyer, Michael Ahlers, Brigitta Schmidt,* and *Frank Seela**

Nucleoside analogues in which the glyconic moiety is replaced by an acyclic side chain exhibit strong antiviral activity. 9-(2-Hydroxyethoxymethyl)guanine (acycloguanosine, acyclovir), **1**, which bears only the C-1′–O–C-4′–C-5′ chain of D-ribofuranose is one of the most potent antiviral substances, especially against herpes simplex (type I and II.)[1] Depot and/or transport forms of acycloguanosine[2,3] have to ensure the release of the unchanged pharmacon in vivo. The selective toxicity of **1** for virus-infected cells is based on the fact that it acts as a substrate for a virus-coded thymidine kinase which phosphorylates specifically the 5′-hydroxyl group. A modification of this hydroxyl group abolishes the activity almost completely, while structural alterations of the nucleobase lead to strongly reduced activity.[4]

An anionic acycloguanosine-phospholipid conjugate has recently been described.[5] We report here the synthesis and liposome formation of the nucleolipid **3** which carries acycloguanosine as head group and the likewise antiviral *N,N*-dioctadecyl-1,3-propanediamine as lipid moiety. Between the lipid and acycloguanosine, a succinate spacer is incorporated which can be cleaved at the head group by the action of either esterases or dilute base with liberation of the pharmacon.[2,3] This hydrolyzable amphiphilic acycloguanosine derivative can be solubilized in the form of liposomes bearing the drug as a hydrophilic head.[6,7] Amphiphilic drug conjugates show altered resorption characteristics and body distribution, and liposomes of such conjugates can be taken up by tumor cells via various mechanisms.[8]

3

Reaction of acycloguanosine, **1**, with succinic anhydride leads to the crystalline succinate **2a**, which can be converted into its activated ester **2b** by reaction with *N*-hydroxysuccinimide in the presence of dicyclohexylcarbodiimide. Compound **2b** was isolated or coupled in situ with the primary amino group of *N,N*-dioctadecyl-1,3-propanediamine. The latter was obtained by alkylation of dioctadecylamine with acrylonitrile and subsequent reduction with $LiAlH_4$.[9] The reaction of this lipid with the activated ester **2b** was complete within 6 h; pure **3** was obtained after silica gel chromatography in 62% yield as a colorless wax.

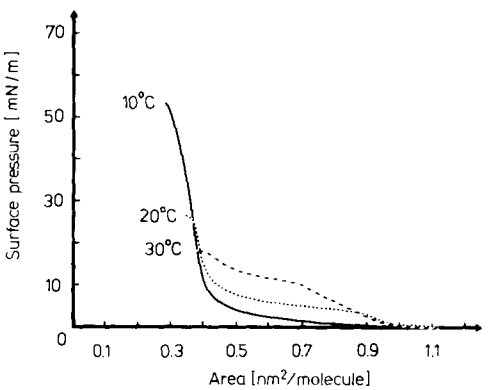

Fig. 1. Surface pressure–area isotherms of the nucleolipid **3** at three different temperatures.

For the characterization of the amphiphilic behavior of **3**, the nucleolipid was spread as a monolayer at the gas-water interface on a Langmuir film balance.[10] Figure 1 shows the resulting surface pressure–area isotherms at three temperatures. Whereas below 10°C the nucleolipid forms only a condensed film with a collapse pressure of about 53 mN/m, the 20°C and 30°C isotherms also show a liquid-like phase. The area value at the collapse point of the condensed phase amounts to 0.42 nm^2/molecule and is in the normal range of double-tailed lipids. Along an isobar with a surface pressure of 10 mN/m phase transition appears at 22°C.

Ultrasonication of mixtures of **3** with either cholesterol (30 mol-%) or dicetyl phosphate (100 mol-%) in water (15 min, 50°C) or manual shaking results in the formation

of opaque solutions.[6] After filtration (millipore-filter, 0.45 μm), about 80% of the nucleolipid can be separated as liposomes from low-molecular-weight material by gel chromatography and obtained as an opaque, UV-active solution ($\lambda_{max} = 262$ nm), which is stable for at least four weeks. Electron micrographs show their spherical structure. Liposomes obtained by the "handshaking method" have a mean diameter of about 2000—5000 Å, those obtained by ultrasonication approximately 300—1000 Å.

The finding that the nucleolipid **3** forms liposomes only in the presence of cholesterol or dicetyl phosphate as mediator may be due to the relatively low hydrophilicity of the head group. A steric hindrance of liposome formation by acycloguanosine can be excluded because the area value of the condensed film of **3** (0.42 nm^2/molecule) is in the normal range of double-tailed lipids.

Experimental Procedure and Physical Data

2b: The succinate **2a** [2] (325.3 mg, 1 mmol) and *N*-hydroxysuccinimide (115.3 mg, 1 mmol) are dissolved in dry, amine-free dimethylformamide (10 mL) and cooled to about 5 °C. Dicyclohexylcarbodiimide (206 mg, 1 mmol) is then added and the reaction mixture stirred for 24 h at room temperature. During this time the precipitated dicyclohexylurea is occasionally removed by filtration. The solvent is evaporated in vacuo, the residue dissolved in water (100 mL), and the precipitated crude product filtered. Recrystallization (2-propanol) afforded 312 mg (79%) of the crystalline ester **2b**; m.p. 130—133 °C. Thin layer chromatography (TLC) (silica gel, $CHCl_3$/MeOH, 8:2, v/v) $R_f = 0.6$; UV (MeOH) $\lambda_{max} = 253$, 272 nm (sh) ($\varepsilon = 14300$, 9800 M^{-1} cm^{-1}); ^{1}H-NMR (250 MHz, [D$_6$]Me_2SO) $\delta = 10.64$ (s, 1H, NH), 7.80 (s, 1H, H-8), 6.51 (s, 2H, NH_2), 5.37 (s, 2H, H-1'), 4.12 (t, 2H, H-4' or H-5', $J = 4.0$ Hz), 3.66 (t, 2H, H-4' or H-5', $J = 4.1$ Hz), 2.91 (t, 2H, CH_2-succinate, $J = 5.9$ Hz), 2.80 (s, 4H, 2 × CH_2-succinimide), 2.65 (t, 2H, CH_2-succinate, $J = 5.9$ Hz); ^{13}C-NMR (62.9 MHz, [D$_6$]Me_2SO) $\delta = 170.6$, 169.6, and 167.8 (3C=O), 156.4 (C-6), 153.6 (C-2), 151.2 (C-4), 137.2 (C-8), 116.4 (C-5), 71.7, 66.2 and 62.9 (CH_2N-9, CH_2O, CH_2CO_2), 27.9 and 25.6 (2CH_2-succinate), 25.2 (2CH_2-succinimide).

3: The succinate **2a** (325.3 mg, 1 mmol) and *N*-hydroxysuccinimide (230.6 mg, 2 mmol) are dissolved in 15 mL of dry dimethyl sulfoxide (DMSO) and converted into the ester **2b** as described above. When the reaction is complete (TLC) about 10 mL of the solvent is removed in vacuo and the residue is diluted with $CHCl_3$ (20 mL). After addition of *N,N*-dioctadecyl-1,3-propanediamine (650 mg, 1.12 mmol), the reaction mixture is stirred for 6 h at room temperature. Silica gel chromatography (6 × 40 cm, $CHCl_3$/MeOH, 95:5, v/v) gave a main zone, which, after pooling the appropriate fractions and evaporation of the solvent, afforded 550 mg (62%) of **3** as a colorless wax; m.p. 67—68 °C (not corrected). TLC (silica gel, $CHCl_3$/MeOH, 9:1, v/v) $R_f = 0.45$; UV ($CHCl_3$) $\lambda_{max} = 257$, 272 nm (sh) ($\varepsilon = 13700$, 9300); ^{13}C-NMR (62.9 MHz, $CDCl_3$) $\delta = 172.9$ and 170.6 (2C=O), 158.7 (C-6), 154.2 (C-2), 152.0 (C-4), 137.6 (C-8), 117.2 (C-5), 72.6, 67.2, and 63.1 (CH_2N-9, CH_2O, CH_2CO_2), 48.0, 46.3, and 41.1 (NCH_2), 31.9—22.6 (aliphatic CH_2), 13.9 (2CH_3).

Synthesis, Structure, and Ligand Motion of $[Cr(CO)_2\{P(OCH_3)_3\}(\eta^4\text{-}2,4\text{-dimethyl-}1,3\text{-pentadiene})]$, a Complex with a C—H—Cr Bridge**

By *Günther Michael, Jürgen Kaub,* and *Cornelius G. Kreiter**

Organotransition-metal complexes that, in addition to σ- or π-bonds, exhibit 3z2e bonding between a C—H moiety of the ligand and the central metal atom[1] are models for the attack of a coordinatively unsaturated complex fragment on a C—H bond. Such complexes are crucial for the understanding of the activation of C—H bonds by transition metals.

The photochemical reaction of the chromium complex **1** with 2,4-dimethyl-1,3-pentadiene (**2**) in *n*-pentane at 203 K does not yield a $[Cr(CO)_3\{P(OCH_3)_3\}(\eta^4\text{-diene})]$ complex, as is the case with other dienes,[2] but rather the product **3** containing one CO ligand less.[3] In **3**, the diene is coordinated to the central chromium atom through both its π-bond system and a methyl group.

$$\underset{\mathbf{1}}{[Cr(CO)_5\{P(OCH_3)_3\}]} + \underset{\mathbf{2}}{C_7H_{12}} \xrightarrow[-3CO]{h\nu} \underset{\mathbf{3}}{[Cr(CO)_2\{P(OCH_3)_3\}(\eta^4\text{-}C_7H_{12})]}$$

The reaction mixture must be rapidly separated by chromatography on silica gel at 230 K, since spontaneous decomposition of **3** sometimes occurs upon longer standing. Pure **3** forms deep red crystals, which are soluble in *n*-pentane or toluene. In toluene, **3** is stable for a short period at temperatures of up to 390 K.

The IR spectrum of **3** exhibits two CO stretching vibrations having the same intensity (1915, 1840 cm^{-1}; *n*-pentane), which indicate an angular $Cr(CO)_2$ group.

The ^{1}H-NMR spectrum of **3** is temperature dependent (Table 1). The low-temperature spectrum is obtained at 124 K. Particularly noticeable is the fact that the resonances of the 5-methyl protons are split into three multiplets, a, b, and c (Table 1), with geminal coupling constants of $J_{ab} = 10.0$, $J_{ac} = 15.0$, and $J_{bc} = 18.0$ Hz. The strong shielding of one of these methyl protons shows its interaction with chromium. At 240 K, the methyl protons in the 5-position are apparently equivalent due to rapid exchange ($\Delta G^{\ddagger}_{200} = 28.6 \pm 0.3$ kJ/mol). Increasing the temperature to 390 K results in collapse of the signals of the methyl groups in the 2- and 4-positions and of those of the methylene protons in the 1-position and the methyl protons in the 5-position ($\Delta G^{\ddagger}_{300} = 68.1 \pm 0.1$ kJ/mol).

The X-ray structure determination of **3** (Fig. 1) supplements the spectroscopic results. Complex **3** has a distorted octahedral ligand sphere. The 2,4-dimethyl-1,3-pentadiene ligand occupies three facial coordination sites with its π-system (b and c) and with a C—H bond of the methyl group in the 5-position (a). The bulky $P(OCH_3)_3$ ligand is found in the d position.

CAD4 (Enraf-Nonius) ω-scan ($2\theta \leq 55°$), $Mo_{K\alpha}$. 2658 independent, 3228 measured reflections, $R = 0.054$, $R_w = 0.043$. The positions of the hydrogen atoms on C10 were calculated; all remaining protons were located by X-ray analysis and freely refined. Selected distances [pm] and angles [°]: Cr–C1 224.6(4), Cr–C2 219.9(4), Cr–C3 216.0(4), Cr–C4 214.0(4), Cr–C5 239.9(4), Cr–H51 194(3), Cr–P 225.3(1), Cr–C6 179.3(4), Cr–C7 182.4(4), C1–C2 138.7(5), C2–C3 141.4(5), C3–C4 137.3(6), C4–C5 148.8(5); P–Cr–H51 80.3(8), C6–Cr–H51 169.9(9), Cr–Cr–H51 91.8(9), P–Cr–C6 91.9(1), P–Cr–C7 92.1(1), C6–Cr–C7 82.0(2), Cr–H51–C5 101.1. C1–C4 extend across a plane (±2.2 pm); C5 directed towards the Cr out of the plane (+29.8 pm), C21 and C41 are directed away (−30.2, −12.8 pm). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51353, the names of the authors, and the journal citation.

The temperature-dependent ^{1}H-NMR spectra of **3** show two hindered ligand motions which are independent of each other. One is a hindered rotation of the terminal methyl group, which was similarly observed for $[\{P(OCH_3)_3\}_3Fe(\eta^3\text{-butenyl})]^+$.[4] The activation barrier of $\Delta G^{\ddagger}_{200} = 28.6 \pm 0.3$ kJ/mol is a measure for the strength of the Cr–H–C bond.

3 is chiral and is present as an enantiomeric pair. Owing to the second dynamic process (Scheme 1), an apparent C_s symmetry is observed on a time average; this means that enantiomerization takes place.

Thus, the position of the diene skeleton changes relative to the three other ligands and a 1,5-sigmatropic hydrogen shift occurs in the 2,4-dimethyl-1,3-pentadiene ligand. Since the energy barrier of $\Delta G^{\ddagger}_{300} = 68.1 \pm 0.1$ kJ/mol is much lower than that for free conjugated dienes,[5] the chromium is presumably involved in the 1,5-hydrogen shift. The ^{1}H-NMR spectroscopic results can be explained by the existence of the species **3'**, a transient intermediate. On the basis of the experimental data it cannot be determined whether the $P(OCH_3)_3$ ligand and the two CO ligands undergo synchronous def-efd positional exchange during the 1,5-hydrogen shift or whether the three facial ligands are rotated more quickly with respect to the rest of the molecule.

Scheme 1. L: $P(OCH_3)_3$.

Complex **3** shows that the steric demands of organic ligands are apparently the determining factor in the formation of organotransition-metal complexes containing C–H-metal bridges. The 5-methyl group of the 2,4-dimethyl-1,3-pentadiene ligand in **3** displaces a CO ligand in the a position and reduces the electron deficiency on chromium by formation of the C–H–Cr bond. Although this bond to the metal can be easily broken, the C–H bonds of the 5-methyl group are strongly activated, thereby enabling a facile 1,5-hydrogen shift to occur, presumably via chromium.

[1] Review: M. Brookhart, M. L. H. Green, *J. Organomet. Chem.* 250 (1983) 395. The authors suggest the term "agostic" for compounds containing C–H-metal bridges. Since C–H–M bridges are comparable to B–H–B or M–H–M bridges, we have decided not to use this terminology.

[2] M. Kotzian, C. G. Kreiter, G. Michael, S. Özkar, *Chem. Ber.* 116 (1983) 3637.

[3] *Experimental procedure:* An *n*-pentane solution (500 mL) containing **1** (500 mg, 1.58 mmol) and **2** (1.5 mL) was irradiated at 203 K for 1 h with a UV lamp (TQ 150, Original Hanau Heraeus Quarzlampen GmbH). A stream of nitrogen was vigorously bubbled through the solution in order to remove the photochemically evolved carbon monoxide. The dark red reaction mixture was filtered through filter flakes, treated with 50 mL of ether, and evaporated at 253 K. The residue was dissolved in 5 mL of

pentane/ether (1:3) and chromatographed at 230 K on silica gel with pentane/ether (3:1). Unreacted **1** was eluted initially followed by **3**. The red solution containing **3** was evaporated; the product was dissolved in pentane/ether (4:1) and the resulting solution slowly cooled from 252 K to 193 K. The deep red crystals that separate out were washed several times with 1 mL portions of pentane at 193 K and dried under high vacuum (188 mg, 36%).

P_7tBu_5—The First Bicyclo[3.2.0]heptaphosphane**

By *Marianne Baudler,* Michael Michels, Josef Hahn,* and *Manfred Pieroth*

Dichloro(organo)phosphanes react with metals in the presence of phosphorus(III) chloride to give polycyclic organophosphanes P_nR_m ($m < n$).[1] In the case of small alkyl groups (R = Me, Et, *i*Pr), with $RPCl_2$ and PCl_3 in the molar ratio 5:2, the 2,3,5,6,7-pentaorganobicyclo[2.2.1]heptaphosphanes **1**[1,2] are formed. We have now found a novel P_7R_5 structure type in the penta-*tert*-butylheptaphosphane **2**, and at the same time the first polycyclic phosphane skeleton containing an annelated four-membered ring.[1a]

P_7R_5

1, R = Me, Et, *i*Pr

2, R = *t*Bu

2 is formed in about 20% yield on dehalogenation of a mixture of *tert*-butyl(dichloro)phosphane and PCl_3 with magnesium.

$$5\,tBuPCl_2 + 2\,PCl_3 + 8\,Mg \longrightarrow \underset{\mathbf{2}}{P_7tBu_5} + 8\,MgCl_2$$

In addition, mainly $(PtBu)_4$,[3a] $(PtBu)_3$,[3b] P_6tBu_4,[4] P_8tBu_6,[5] P_4tBu_3H,[6a] and P_5tBu_4H[6b] are formed. The best initial yield of **2** (ca. 25%) is obtained when $tBuPCl_2$ is allowed to react with PCl_3 in the molar ratio 2:1 (not 2.5:1!) in boiling tetrahydrofuran (THF). **2** can be isolated in analytically pure form by chromatographic separation of the product mixture.

The heptaphosphane **2** is a pale yellow solid (m.p. 132°C, decomp. sealed tube) which is stable at room temperature and is sensitive to light and oxidation; it is readily soluble in hydrocarbons and THF, and moderately soluble in methanol. The mass spectrum (10 eV, 70°C) shows, aside from the M^+ ion (*m/z* 502; 100%), only $(M-C_4H_9)^+$. The IR spectrum[7] is distinctly different from that of **1** (R = Me[2]) in the region of the P–P stretching and deformation vibrations.

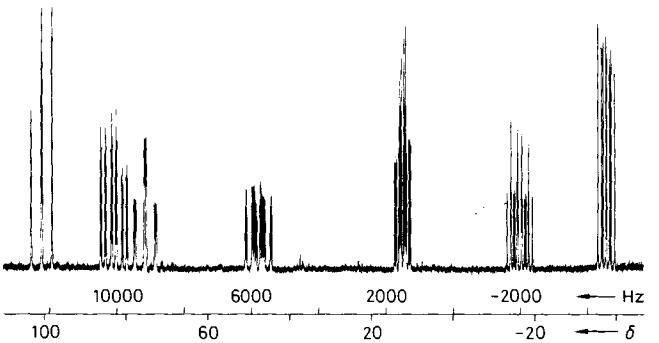
[**] Contributions to the Chemistry of Phosphorus, Part 155. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 154: M. Baudler, G. Germeshausen, *Chem. Ber.*, in press.

The constitution and spatial structure of **2** follow from detailed NMR studies. The $^{13}C\{^1H,^{31}P\}$-NMR spectrum[8] provides proof of the nonequivalence of the five *tert*-butyl groups. The ^{31}P- and ^1H-signals[8] belonging to identical $>PtBu$ groups were assigned on the basis of a "reverse ^{31}P-^1H shift-correlated" 2D-NMR spectrum,[9] which also indirectly characterizes the ^{31}P signals of the bridgehead atoms. The complete analysis of the $^{31}P\{^1H\}$-NMR spectrum (Fig. 1) is additionally based on a COSY 45 experiment,[10] by which the relative signs of the coupling constants have been determined (RMS value of the spectrum calculation: 0.3; all transitions assigned).



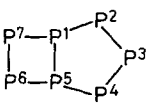


Fig. 1. Observed 121.497-MHz $^{31}P\{^1H\}$-NMR spectrum of **2** in [D$_6$]benzene at 27°C.

Table 1. ^{31}P-NMR parameters [a] of **2** in [D$_6$]benzene (15%) at 27°C.

[a] *J* [Hz]; signs assuming negative ^1J(PP)-couplings.

The positions of the signals and, above all, the values of the ^1J(PP) coupling constants (Table 1) identify **2** as a bicyclic compound containing a five-membered ring and an annelated four-membered ring. The large positive $^2J(P^4P^6)$ coupling indicates that the lone pairs of electrons at the respective P atoms are directed towards each other.[4,11] Accordingly, the four-membered ring is strongly inclined towards the five-membered ring and the *t*Bu group at P^6 is in the *exo* position. The relationships $^2J(P^5P^7) \gg {}^2J(P^1P^6)$ and $^3J(P^2P^6) \gg {}^3J(P^4P^7) \approx {}^3J(P^3P^6)$ reveal the *endo* position of the *t*Bu group at P^7 and the arrangement of the substituents of the five-membered ring. Due to steric interactions between the *t*Bu groups in the 3,7 position, the four-membered ring and five-membered ring are distorted with respect to each other at the zero-bridge P^1–P^5. This mani-

fests itself in the different values of $^2J(P^1P^3)$ and $^2J(P^3P^5)$ and, in particular, in the large coupling constants $^2J(P^5P^7)$ and $^3J(P^2P^6)$ caused by the resulting folding of the four-membered ring; the five-membered ring is assumed to have a twisted envelope conformation. Due to the asymmetry of the molecule, **2** exists as an enantiomeric mixture. Transformations between (+)- and (−)-form by concomitant inversion at P^6 and P^7 do not take place at room temperature.

That **2** is a 2,3,4,6,7-penta-*tert*-butylbicyclo[3.2.0]heptaphosphane[12] can be explained by a destabilization of the structure type **1** as a result of increasing steric interactions with increasing bulkiness of the substituents at P^6 and P^7. Differing skeletal structures for R = Me, Et, *i*Pr, and R = *t*Bu have already been found in the P_8R_6 class of compounds.[1a] In the case of **2**, for the first time a molecular polycyclic phosphane is forced to form an annelated four-membered ring as structural unit for steric reasons.[1a] A framework consisting of two annelated P_4 rings, on the other hand, is so unfavorable energetically that the compound P_6tBu_4 related to **2** is not a bicyclo[2.2.0]- but a bicyclo[3.1.0]hexaphosphane.[4]

Experimental

A solution of $tBuPCl_2$ (50.9 g, 0.32 mol) and PCl_3 (22.0 g, 0.16 mol) in THF (200 mL) is added dropwise within 2 h to 500 mL of vigorously stirred boiling THF containing magnesium turnings (14.0 g, 0.58 mol; previously etched by evaporating a few grains of iodine). The yellow mixture is refluxed for a further 1 h, and, thereafter, allowed to cool to room temperature before complete removal of the solvent under reduced pressure. The residue is then taken up in 800 mL of *n*-pentane and the undissolved material filtered off, washed with pentane (3 × 400 mL) and the solvent removed from the combined filtrates. The yellow, viscous residue is dissolved in 100 mL of pentane, and P_8tBu_6 allowed to separate out by crystallization at room temperature (1 d). After filtration, the filtrate is evaporated down to 40 mL and then chromatographed twice on Al_2O_3 using pentane with ^{31}P-NMR spectroscopic control. Final purification is achieved by preparative HPLC (Nucleosil-5-C18 column, methanol, receiver: −78 °C). The solvent is rapidly condensed off (bath: −30 °C, cooling trap: −196 °C, pressure: 0.3 torr), leaving 0.59 g of pure **2** (2% referred to $tBuPCl_2$; not optimized).

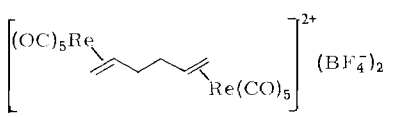
Pentacarbonylolefin- and Pentacarbonyldiolefinrhenium Complex Cations; Synthesis and Structure of the 2-Butene-1,4-diyl-Bridged Carbonyldirhenium Complex *trans*-$[(OC)_5ReCH_2CH{=}CHCH_2Re(CO)_5]$**

By *Wolfgang Beck**, *Klaus Raab*, *Ulrich Nagel*, and *Wolfgang Sacher*

Dedicated to Professor Helmut Behrens on the occasion of his 70th birthday



Reaction of pentacarbonyltetrafluoroboratorhenium(I) with ethene and propene under very mild conditions (1 bar, 20 °C) affords the olefin complexes $[(OC)_5Re(olefin)]^+BF_4^-$.[1] We have now found that the Lewis acid "$Re(CO)_5^+$" can add to the C=C bond of various mono- and diolefins.

$$[(OC)_5ReFBF_3] + L \xrightarrow[20\,^\circ C]{CH_2Cl_2} [(OC)_5Re(L)]^+BF_4^-$$
1

a, L = 1-pentene; **b**, L = cyclohexene; **c**, L = 1,5-cyclooctadiene; **d**, L = 1,3-butadiene; **e**, L = 1,4-cyclohexadiene

With 1,5-hexadiene and 1,5-cyclooctadiene we could also isolate the diolefin-bridged complexes **2**, which, because of their sparing solubility in acetone, can be separated from the monomeric compounds **1**. Compared to the ν(C=C) bands of the free olefins, those of the coordinated olefins in the IR spectra of **1** and **2** are, as expected, shifted by ca. 100 cm^{-1} to lower wave numbers (Table 1).

preparation of ethanediyl-bridged complexes.[1,3] A novel example of this type of reaction is the addition of pentacarbonylrhenate(1−) to the η^2-coordinated 1,3-butadiene in **1d**, which leads to the formation of the 2-butene-1,4-diyl-bridged complex **4** as stable product.

At low temperatures (−40°C), a complex **3** is first formed, which, according to the IR- and ^{1}H-NMR-spectrum,[4] can be formulated as a product of kinetically controlled 1,2-addition with CO insertion.[5] The structures of **3a** and **3b** are both consistent with the spectroscopic data of **3**. Complex **3** already isomerizes in solution at room temperature to give **4**. Elimination of CO does not occur under these mild conditions. In the direct photochemical reaction of $Re_2(CO)_{10}$ and $Mn_2(CO)_{10}$ with butadiene, the CO-deficient compounds $[(OC)_5MC_4H_6M(CO)_4]$ and $[(OC)_4MC_4H_6(CO)_4]$ (M = Mn, Re)[6,7] were isolated; here, butadiene functions as a σ-η^1-, π-η^3- or η^2,η^2-bridge. Thus, in **4** the previously unknown σ-η^1,σ-η^1-type C_6H_4-bridge is realized.

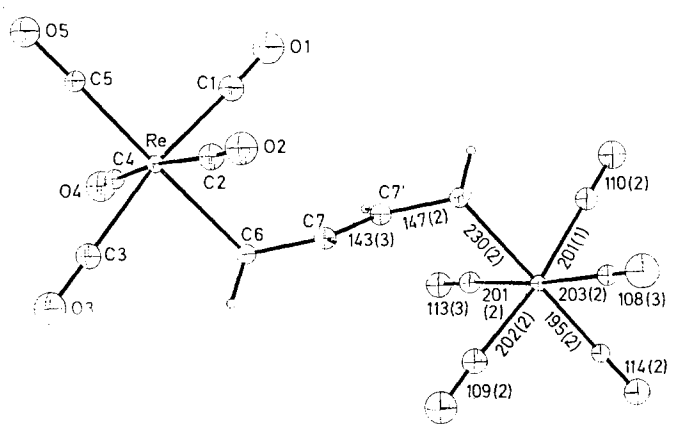

Fig. 1. Low-temperature molecular structure (at −90 °C) of **4**, 50% probability level (H atoms only schematic), atomic distances [pm]. $P\bar{1}$, $a = 612.6(3)$, $b = 660.1(3)$, $c = 1244.0(6)$ pm, $\alpha = 83.44(4)$, $\beta = 88.85(4)$, $\gamma = 61.47(3)°$, $V = 0.4387(3)$ nm^3, $Z = 1$, $\lambda(Mo_{K\alpha}) = 71.069$ pm; ω scan, $\Delta\omega = 0.8°$, $2° \leq \omega \leq 29.3°$ min^{-1}; $4° \leq 2\vartheta \leq 55°$; 4299 measurements, 2001 independent ($I \geq 2\sigma(I)$) reflections, 53 parameters. The absorption ($\mu = 140.2$ cm^{-1}) was corrected (crystal dimensions $0.08 \times 0.3 \times 0.3$ mm^3; Parametral face indexes: {001} 72 Friedel pairs as measured values). $R = 0.111$, $R_w = 0.115$, $w = [\sigma^2(F_0) + 0.001\,F_0^2)^{-1} \cdot (1 - \exp[-5(\sin\vartheta/\lambda)^2]]$. The hydrogen atoms are located at calculated sites and not refined. A refinement of the structure with anisotropic thermal parameters gave $R = 0.072$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51 195, the names of the authors, and full citation of the journal.

4 (Fig. 1) has a center of symmetry corresponding to a crystallographic center of symmetry. The four C-atoms of the *trans*-2-butene bridge lie in a plane, from which the rhenium atoms are located at a distance of 198 pm; this corresponds to a C7′−C7−C6−Re torsion angle of 109°. The C7−C7′ bond is apparently longer than normal C=C double bonds, while the C6−C7 bonds are shorter than normal C−C single bonds. The angles C7′−C7−C6 (124(2)°) and C7−C6−Re (114(1)°) are widened; as in the case of $[(CO)_5Re-CH_2-CH_2-Re(CO)_5]$,[1] this can be attributed to the bulkiness of the $Re(CO)_5$ moiety.

Experimental:

1d: A Schlenk tube containing $[(OC)_5ReFBF_3]$ [8] (0.58 g, 1.40 mmol) was evacuated and then filled with anhydrous 1,3-butadiene gas (1 bar). 10 mL CH_2Cl_2 was then added to the contents of the tube through counterflowing butadiene and the resulting suspension stirred for 2 d at 1 bar. The colorless **1d** was centrifuged off, washed with CH_2Cl_2 (2 × 10 mL), and dried in a high vacuum. Yield 96%. **3**, **4**: 1.24 g (2.65 mmol) **1d** was dissolved with stirring in ca. 30 mL acetonitrile (previously cooled to −40°C). The solution was then treated dropwise with a tetrahydrofuran solution of $Na[Re(CO)_5]$ (prepared from 0.89 g (1.36 mmol) $Re_2(CO)_{10}$ and 2.5 mL 0.8% sodium amalgam in 7 mL THF at 0°C, reaction time 90 min). After a short while a yellow precipitate started to separate out. During the addition the temperature was slowly lowered to −45°C and on completion of addition the mixture was kept at −50 to −45°C. After 3 hours' stirring, the precipitate was recovered at this temperature (either by centrifugation or by filtration on a frit), washed twice with acetonitrile/THF (4:1; pre-cooled to −50 to −45°C) at ca. −50°C, and then dried in a high vacuum, firstly at −40°C and then at room temperature. The yellow substance consisted mainly of **3**. Yield 42–63%. **3** and **4** were separated chromatographically at −10°C (stationary phase: silica gel 60). Yellow **4** was completely eluted with CH_2Cl_2. Thereafter, **3** (also yellow), which hardly moved in CH_2Cl_2, was eluted with acetone.

Polymerization of Propene and Butene with a Chiral Zirconocene and Methylalumoxane as Cocatalyst**

By *Walter Kaminsky,* Klaus Külper, Hans H. Brintzinger,* and *Ferdinand R. W. P. Wild*

Hitherto, only atactic polypropylene could be prepared with soluble bis(cyclopentadienyl)zirconium(IV)/methylalumoxane Ziegler-Natta catalysts.[1,2] *Ewen*[3] has recently shown that mixtures of, e.g., 63% isotactic and 37% atactic polypropylene are formed with the sterically rigid ethylenebis(1-indenyl)titanium dichloride (mixture of meso form and racemate).[4]

If, however, the chiral ethylenebis(4,5,6,7-tetrahydro-1-indenyl)zirconium dichloride **1** (Fig. 1) is used in combination with methylalumoxane ($[Al(CH_3)-O]_n$) as cocatalyst, highly isotactic polypropylene is obtained. The racemate of **1** was used for this polymerization. The fraction of polymer soluble in toluene can be reduced to 0.2 wt.-%, which is considerably lower than the 2—7% achievable with heterogeneous $TiCl_4/MgCl_2/Al(C_2H_5)_3/C_6H_5CO_2C_2H_5$-based catalysts.[6]

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Hoechst AG for help with the polymer analysis.

Remarkable is the high activity of the chiral catalyst **1** (Table 1). Thus, less than 10^{-5} mol/L suffices for the production of 7700 kg polypropylene per mole of Zr per hour at 60°C.

Under comparable conditions only 2730 kg of atactic polypropylene is formed per mole of Zr per hour with bis(cyclopentadienyl)dimethylzirconium. That is, the chiral zirconocene **1** affords not only isotactic polypropylene, but also has a polymerization activity 2—3 times greater than catalysts that form only atactic polypropylene. The rates of polymerization of ethylene : propene with bis(cyclopentadienyl)zirconium compounds are of the order of 25 : 1, whereas with zirconocene this ratio drops to ca. 10 : 1.[7,8] This means that propene is polymerized relatively far better by zirconocene **1** than by bis(cyclopentadienyl)zirconium compounds.

Table 2. Composition of some polypropylenes prepared with **1** (see Table 1).

M_η	M_w	M_w/M_n [a]	Atactic fraction [%] [b]	Isotacticity index [%] [c]	Viscosity number [cm³/g] [d]

130000	144000	2.4	0.2	88.1	132
55000	62000	2.0	0.7	87.3	110
41000	45000	1.9	1.0	86.0	76

[a] GPC measurements at 135°C in trichlorobenzene. [b] Fraction soluble in saturated hydrocarbons (b.p. 130°C) according to *Kloos* et al. [9]. [c] IR spectroscopically, according to *Luongo*. [10] [d] At 135°C in decalin.

Besides the high activity of **1** towards propene, which reaches values at least equal to those achieved by heterogeneous catalysts, the properties of the polypropylene thus formed are also remarkable (Table 2). In contrast to industrial polypropylene, which has a molecular weight distribution M_w/M_n of at least 5, with **1** we have produced products with molecular weight distributions of only 1.9 to 2.6. The fraction soluble in hydrocarbons amounts to less than 1% in all cases. The IR-spectroscopically determined isotacticity index of 86 to 91% is also very high. The crystallinity of the highly isotactic polypropylene is largely determined by the stereochemical uniformity of the polymerization. High-resolution ^{13}C-NMR spectroscopy affords an insight into the pattern of the sequences in the polymer chain. Isotactic sequences (mm triads) are found to be present to the extent of 95%, heterotactic sequences (mr triads) to the extent of 3.2%, and syndiotactic sequences (rr triads) to the extent of 0.9%. Notable is the very small amount of rr triads compared to mr triads. In the case of commercially available polypropylene the mr/rr ratio is of the order of 1, and rr is greater by a factor of about 5.

This means that the propene molecules are inserted highly stereospecifically with this homogeneous Ziegler-Natta catalyst. Defects in the insertion are minimal, as is confirmed by the high isotaxy of 97.5% and an average length of the isotactic sequences of more than 60 monomer units.

1-Butene can also be polymerized highly effectively with the zirconocene **1**/methylalumoxane catalyst (cf. Table 1). Thus, polymerization activity is still 2640 kg of polybutene per hour per mole of Zr at 20°C. Although the polymers have molecular weights of 150000 or 50000, they are soluble in toluene. The consistency is wax-like to crystalline, but not clear and viscous like atactic polybutane, which was produced with bis(cyclopentadienyl)zirconium compounds and measured ^{13}C-NMR spectroscopically.

Hence, both unusually highly isotactic polypropylene as well as isotactic polybutene can be produced with **1** and methylalumoxane; the activity of the catalyst is high. The narrow molecular weight distribution, an additional effect, might be of interest from an industrial processing point of view.

Experimental

1: Tetrahydrofuran (THF) (60 mL) was distilled into a three-necked flask at −196 °C and treated, with stirring, with 4.9 g (21 mmol) of $ZrCl_4$. A solution of the dilithium salt of bis(1-indenyl)ethane (21 mmol) in THF (50 mL) was then added dropwise to the mixture under N_2, at room temperature. After 2 hours' stirring, hydrogen chloride was passed into the mixture and, immediately thereafter, the excess HCl was removed *in vacuo*. The mixture was then treated with diethyl ether (20 mL) and petroleum ether (10 mL). The resulting light-yellow, crystalline product was filtered off and washed successively with 4N hydrochloric acid, water, ethanol, and diethyl ether and dried *in vacuo*; yield 3.1 g of (*R,S*)-ethylenebis(1-indenyl)zirconium dichloride. 1 g of this substance was hydrogenated, as described for the analogous titanium compound [4], for 30 min with 75 mg PtO_2 and 25 mL CH_2Cl_2 at 100 bar H_2; yield 650 mg of **1** (characterized by X-ray structure analysis [5]).

Polymerization of propene: A solution of methylalumoxane (320 mg, 5.6 mmol Al) and **1** (3.3×10^{-6} mol) in 1 mL of toluene was added to 330 mL toluene contained in a 1 L glass autoclave fitted with a thermostat and magnetic stirrer and previously dried out and purged with argon. After 20 minutes' ageing, purified propene (70 mL) was distilled into the contents of the autoclave at 20 °C. The solution gradually clouded, and white polypropylene precipitated out. After 120 min the contents of the autoclave were treated with ethanol, filtered, and the filter cake washed with dilute HCl and dried in vacuo; yield 31.3 g of isotactic polypropylene. On removal of toluene from the filtrate there remained a further 0.3 g of polypropylene.

Electrochemical Oxidation of Anthracene and 9,9′-Bianthryl to the Respective Dication and Tetracation**

By *Michael Dietrich, John Mortensen,* and *Jürgen Heinze**

The electrochemical reduction of unsubstituted arenes to stable, highly charged anions was recently described for the first time.[1] Thus, for example, it was possible to detect electrochemically the tetraanion of 9,9′-bianthryl **1** and the hexaanion of decacyclene. Independently, *Müllen* et al.[2] had previously converted **1** as well as a series of annulene derivatives to their tetraanions by the use of alkali metals and, on the basis of NMR spectroscopic results, found new applications of the Hückel $4n+2$ rule for such highly charged perimeter systems.

Until now it had not been possible to obtain the corresponding tetracations either chemically or via electrochemical oxidation. The highly charged cations react easily with nucleophilic impurities or, as is usually the case, with the nucleophilic solvent. The proper choice and purification of the solvent is therefore even more crucial than for the cathodic reduction. In 1979, *Tinker* and *Bard*[3] described the anodic oxidation of thianthrene and other arenes in liquid SO_2 and were able to show that this solvent is excellently suited to the generation of reactive cations owing to its low nucleophilicity.

It has now been possible, using an optimized sample preparation procedure (purification of SO_2 solely with Al_2O_3),[1,4] to generate anodically in liquid SO_2 the extremely reactive dication of anthracene $\mathbf{2}^{2+}$[5] as well as, for the first time, the tetracation of **1** and to characterize these species by cyclic voltammetry.

All measurements were carried out in SO_2/Bu_4NPF_6 with a Pt electrode. The potentials were calibrated using an internal ferrocene standard and then referred to the standard Ag/AgCl reference electrode.

Owing to the high reactivity of $\mathbf{2}^{+}$, only quasi-reversible voltammograms of the $\mathbf{2}/\mathbf{2}^{+}$ redox pair have been observed for scan rates of 100 mV/s at −70 °C. A mean life-time of 0.5 s for the cation was derived from the peak-current ratios.[7]

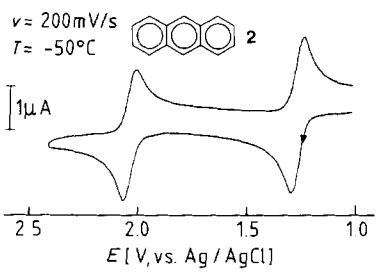

Fig. 1. Cyclic voltammogram of the oxidation of **2** in SO_2 (working electrode: Pt).

Figure 1 shows the voltammogram for the oxidation of **2** at −50 °C. Two clearly defined reversible steps are apparent; a ΔE^0 of 770 mV (−50 °C) for these two steps gives a semiquinone formation constant of 2.48×10^{17}. The peak-current ratios indicate a radical cation life-time that extends far beyond the time scale of cyclic voltammetry; for the dication, the average life-time under the experimental conditions was estimated to be ca. 10 s. The extremely high reactivity of the dication is shown by the observation that, in SO_2 dried with P_2O_5, $\mathbf{2}^{2+}$ always reacts via irreversible subsequent reactions. Remarkably, the peak height for the dication formation is somewhat smaller than that for the monocation formation; this indicates a reversible dimerization ($K \approx 50$ L·mol^{-1}) of the radical cation with the substrate, as is also found for pyrene and other arenes.[1]

The oxidation of **1** leads, in four reversible redox steps (Fig. 2), to what is, to the best of our knowledge, the first tetracation of an unsubstituted arene.[8] Since formation of the tetracation also involves the transfer of four electrons, **1** represents, in principle, an eight-step redox system. The standard potential difference ($E_1^0 = 1.267$; $E_2^0 = 1.482$;

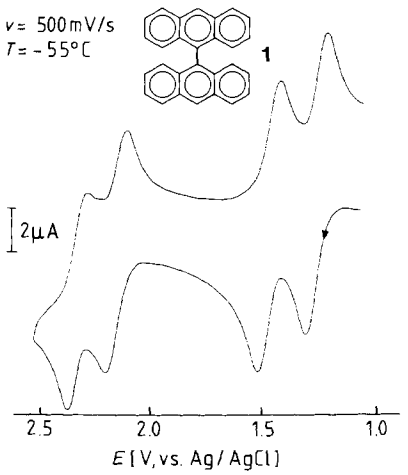

Fig. 2. Cyclic voltammogram of the oxidation of **1** in SO_2 (working electrode: Pt).

$E_3^0 = 2.170$; $E_4^0 = 2.348$ V vs. Ag/AgCl) between the first and the fourth redox step of **1** amounts to 1.080 V at $-50\,^{\circ}C$. This correlates very well with the value of 1.070 V that is observed for the reduction of **1** in tetrahydrofuran in the presence of Na^+/[15]crown-5. The effective ionic radii of the counterions PF_6^- and Na^+/[15]crown-5, namely, 3.5 and 3.6 Å, respectively (perpendicular to the plane of the crown ether), are similar; this indicates that the electrostatic shielding effects (ion pair effects) are the same in positively and negatively charged redox systems.

The life-time of the electrochemically generated tetracation $\mathbf{1}^{4+}$ is about 1 s under the experimental conditions. We presume that traces of nucleophilic impurities, such as F^-, initiate subsequent reactions.

[5] The chemical oxidation of **2** to $\mathbf{2}^{2+}$ in SO_2ClF with SbF_5 has been described several times [6]. However, the NMR spectroscopic results presented to support the structure are not totally convincing in comparison with the unequivocal data for the dianion of **2** [2]. In particular, the measured ^{1}H-NMR chemical shifts are very similar to those of the neutral species, in contrast to what is expected. A further discrepancy emerges from the fact that $\mathbf{2}^{2+}$ should be stable in SO_2ClF at 0°C, whereas the electrochemical measurements in highly pure SO_2 at $-50\,^{\circ}C$ indicate a life-time on the order of seconds.

[8] Since, in **1**, two anthryl groups are joined at the 9,9'-positions, $\mathbf{1}^{4+}$ can also be formally viewed as a double dication. This presumes, however, that the two charged anthryl groups do not interact with each other, an assumption that is not supported by the experimental results. The electronic interaction energies of the tetracation and the tetraanion of **1** [1] attain values of up to 0.6 eV depending on the type of counterion, which determines the charge deshielding in the anthryl moiety.

Comparison of Theoretical and Experimental Deformation Densities in S–O Bonds**

By *Hartmut Fuess,* Jan W. Bats, Durward W. J. Cruickshank,* and *Miriam Eisenstein*

The distribution of electrons in a chemical bond between atoms may be studied by careful X-ray structure analysis.[1a] In such investigations, deformation densities are determined as differences between the total measured electron density and that of a set of spherical atoms whose positions in a crystal lattice are known. A comparison between experimental and theoretical densities has to take into consideration the fact that atoms or molecules in a crystal are influenced by intermolecular forces and by thermal vibrations. The quantum-chemical calculations, however, are usually carried out for an atom or molecule at rest. Therefore, the experimental results have to be corrected for thermal vibrations before a meaningful comparison between the theoretical and experimental densities can be made. The electron densities obtained by this procedure are called static deformation densities.[1b] Alternatively, inclusion of thermal motion in the theoretical static densities gives results that may directly be compared with the experimental results. These thermally smeared electron densities are called dynamic densities.

The comparisons reported up to now have dealt essentially with organic molecules containing C–H, C–O, and C–C bonds.

We report here on quantum-chemical calculations and experimental determinations of the deformation density in the sulfur-oxygen bond, which is present in several different anions. Marked similarities are found between the experimental electron-density maps for $Na_2S_2O_3$ and the theoretical maps for H_3NSO_3 (Fig. 1).

The experimental work[2a] on $Na_2S_2O_3$, space group $P2_1/a$, forms part of a series of careful crystallographic studies on sulfur-oxygen bonds in thiosulfates[2] and in a sulfite.[3] The densities for $Na_2S_2O_3$ are static deformation densities based on a multipole refinement[4] of 3456 reflections up to a resolution of $\sin\theta/\lambda = 1.0$ Å^{-1}. Position parameters for oxygen were obtained from neutron diffraction data. The reported densities were obtained by a Fourier transform of calculated structure factors. In addition, the densities for the three chemically equivalent sulfur-oxygen bonds were averaged.

The theoretical work forms part of a series of careful studies[5] on sulfur-oxygen bonds in H_3NSO_3, SO_3^-, and SO_2 and its ions. The theoretical electron-density maps shown here were calculated for sulfamic acid using extended double-zeta basis sets, which included two sets of d functions for each S, O, and N atom and two sets of p functions for each hydrogen.

Comparison of the experimental and theoretical maps (Fig. 1) shows, in particular, that the shapes of the respec-

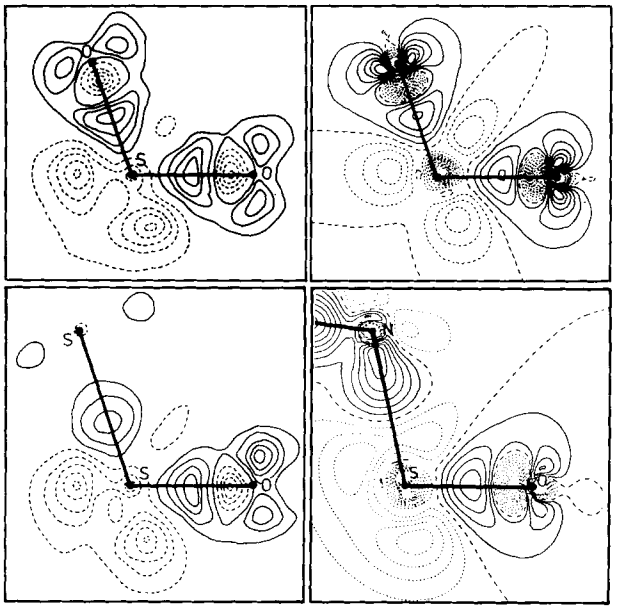

Fig. 1. Left: experimental static deformation density in $Na_2S_2O_3$, resolution 1.0 $Å^{-1}$. Right: theoretical static deformation density in H_3NSO_3. Contour interval 0.1 $e/Å^{-3}$. The zero contour (dashed) is omitted in the experimental map but included in the theoretical map. Top: electron deformation density in the O–S–O plane. Below: electron deformation density in the X–S–O plane (X = S, N). Solid lines and dotted (or dashed) lines represent positive and negative densities, respectively.

tive maxima in the S–O bond and the minima near sulfur are similar in all maps. Also, the deformation density in the vicinity of the S–O bonds shows approximate axial symmetry in both experimental and theoretical maps.

In the molecular XSO mirror planes (Fig. 1, bottom), the maxima and minima in $Na_2S_2O_3$ and H_3NSO_3 are similar. The S–O bond maxima even have similar slight skewnesses, and the asymmetry of the lone pairs of electrons on oxygen in $Na_2S_2O_3$, with the higher density on the S–S side, is also apparent in the theoretical maps.

The biggest difference between theory and experiment is that in the theoretical maps for sulfamic acid the theoretical maxima for the nonbonding electrons on oxygen are appreciably higher in the OSO plane than in the XSO plane, whereas in the experimental maps for thiosulfate this is not the case. The difference between sulfamic acid, which may be regarded as the zwitterion $(H_3N)^+(SO_3)^-$, and $S_2O_3^{2-}$ is not unexpected. First, it is consistent with differences we have found theoretically between SO_2^- and SO_2^{2-} (the maps for H_3NSO_3 and SO_3^- being very similar). Secondly, it is consistent with the differing bond character in the two molecules. In sulfamic acid the S–N bond length corresponds to that of a single bond, while the S–O length of 1.441 Å shows considerable double-bond character. This explains the non-uniform distribution of nonbonding electrons on the oxygen atom. In the thiosulfate anion the S–S bond length of 2.007 Å indicates some double-bond character, and the S–O length of 1.479 Å is typical for that in a sulfate group. Thus, a more uniform distribution of non-bonding electrons is to be expected near the oxygen atom in the thiosulfate.

In the experimental maps the densities of the oxygen non-bonding electrons are nearly as spread out as those of the bonding electrons, whereas in the theoretical maps the densities of the oxygen non-bonding electrons exhibit small sharp peaks. The method of experimental analysis, however, does not permit resolution of such sharp features near the atoms.

Quantum-chemical calculations on a double-zeta basis (omitting the p functions on hydrogen and all d functions) give poor agreement with the experimental results.

Exhaustive *tert*-Butoxycarbonylation of Peptide Nitrogens**

By *Leif Grehn* and *Ulf Ragnarsson**

We have recently described an efficient and convenient method for the preparation of Boc-pyrroles and Boc-indoles (Boc = *tert*-butoxycarbonyl) using Boc_2O in dry acetonitrile or dichloromethane[1] with 4-dimethylaminopyridine (DMAP) as catalyst.[2,3] By this procedure we have also synthesized tryptophan derivatives protected on the indole nitrogen and shown that such compounds may be useful for peptide synthesis in solution.[4] However, when excess Boc_2O was used in these preparations, several byproducts were frequently obtained. Spectral evidence indicated that these crude mixtures contained substances with Boc groups on amide nitrogens. To elucidate the scope of this reaction, we have now investigated the action of Boc_2O/DMAP on some simple model substrates.

It was found that the urethane moiety in Boc-Gly-OBzl was completely acylated using only a slight excess of Boc_2O/DMAP in acetonitrile, affording the *N,N*-diacyl compound **1** in high yield. **1** is surprisingly stable and could be handled without special precautions. Since diacylation of amino nitrogens is relatively difficult to accomplish in most cases, this novel approach may prove useful for the preparation of diacylamino derivatives in general. In particular, mixed diacyl analogues might be available by stepwise synthesis.

When Boc-Pro-Gly-OMe was treated with 1.1 equivalent of the reagent mixture, acylation occurred smoothly at the only available nitrogen atom, giving **2** in excellent yield.

[**] This work was supported by the National Swedish Board for Technical Development and the Swedish Natural Science Research Council.

The outcome of this reaction thus appears to open up new possibilities for the facile protection of peptide bonds with Boc groups. In the same way, both amide hydrogens in Z-Pro-NH_2 (Z = benzyloxycarbonyl) could easily be replaced by Boc employing 2.2 equivalents of Boc_2O. The product **3**, like **1** and **2**, was sufficiently stable to withstand normal workup including aqueous extractions (Table 1). Both Boc groups were smoothly removed from **3** with 33% trifluoroacetic acid in dichloromethane within 45 min (TLC) at room temperature.

Table 1. Yield and physical data of the Boc derivatives **1**—**3**. All new compounds gave satisfactory elemental analyses (C, H, N). The yields are based on the crude product, which was pure by TLC (toluene:acetonitrile, 2:1). ^{13}C-NMR ($CDCl_3$, $\delta(CDCl_3) = 77.0$).

1: 95% yield, m.p. = 30.5—31.0°C (petroleum ether, 10 mL/g, active charcoal, −70°C); ^{13}C-NMR: 169.0 (ester CO), 151.8, 83.1, 27.9 (Boc), 135.4, 128.5, 128.3, 66.8 (benzyl), 47.4 (Gly CH_2)

2: 100% yield, m.p. = 93.0—93.5°C (as for **1** but 50 mL/g); $[\alpha]_D^{25}$ −41.2 ($c = 1$, DMF); ^{13}C-NMR: 175.6/175.2 (peptide CO), 169.5/169.2 (ester CO), 154.4/153.8, 84.2/84.0, 28.4/28.2 (peptide Boc), 151.8/151.7, 79.4, 27.8 (α-Boc), 61.0/60.8 (Pro, αC), 30.9/30.2 (Pro, βC), 23.5/22.8 (Pro, γC), 46.9/46.5 (Pro, δC), 52.1 (ester Me), 45.3 (Gly CH_2) [a]

3: 87% yield; oil (as for **1**, but 25 mL/g). The white precipitate melts below 0°C but later solidifies at room temperature; $[\alpha]_D^{25}$ −31.2 ($c = 1$, DMF); ^{13}C-NMR: 173.5/173.2 (amide CO), 149.1, 85.0, 27.5 (Boc), 154.6/154.1, 136.8, 128.3, 127.8, 127.3, 66.9 (Z), 60.6/59.8 (Pro, αC), 30.8/29.9 (Pro, βC), 23.6/22.9 (Pro, γC), 47.1/46.6 (Pro, δC) [a]

[a] Doubling of signals due to the presence of two conformers [8].

Acyclic diacylamines have been reported previously but such compounds are often unstable and may revert to monoacylamines.[5,6] Peptide bonds carrying trifluoroacetyl groups are known but they are also sensitive to hydrolysis.[7] With respect to stability, therefore, the new Boc compounds are superior to earlier diacylamines. Moreover, their lipophilic properties enhance their solubilities in solvents frequently used in peptide synthesis.

Experimental Procedure

DMAP (12 mg, 0.1 mmol) was added to a stirred solution of the peptide derivative (1.0 mmol) in dry acetonitrile (2—3 mL) followed by Boc_2O (240 mg, 1.1 mmol). After stirring for 5 h at room temperature, all peptide starting material was consumed (TLC, toluene:acetonitrile, 2:1). The brownish reaction mixture was evaporated at room temperature and the oily residue partitioned between ether (50 mL) and 1 M aqueous $KHSO_4$ (25 mL). The organic extract was thoroughly washed in turn with 1 M aqueous solutions of $KHSO_4$ and $NaHCO_3$ and finally brine and dried over $MgSO_4$. Evaporation to complete dryness (high vacuum, room temperature) left a light yellow oil, which was chromatographically pure. Recrystallization from petroleum ether (decolorizing carbon) gave an analytically pure product (see Table 1).

Azahexamethineneutrocyanines from a *N*-(Tetramethylformamidinio)pyridinium Salt**

By *Gerhard Maas** and *Bernhard Feith*

Nucleophilic ring-opening reactions of quaternary pyridinium salts which initially involve α-addition of the nucleophile are always likely to succeed if the heterocycle bears a strong electron-attracting substituent on the nitrogen atom.[1] It would appear that pyridinium salts bearing a cationic substituent, have—with the exception of one (2-pyridinio)pyridinium salt[2]—so far never been used for such rearrangements.

We have now found that the *N*-(tetramethylformamidinio)pyridinium salt **2**, which is readily accessible from the "dication ether" salt **1**[3] and pyridine, is also attacked at the α-C atom by the anions of active methylene compounds **3**; as usual the primary product **4** undergoes ring-opening to give **6**. *N*-protonation of the isolated compound **6b** was verified by a weak vicinal coupling with H-6. On reaction with bases the deep-colored azaneutrocyanines **7a**—**d** are formed. Their all-*trans* configuration is proven by the X-ray structure analysis of **7a** (see Fig. 1)

and also follows from the $^3J_{H,H}$ coupling constants, which—as far as recognizable—differ by less then 1.5 Hz (see Table 1).

Table 1. Some physical and spectroscopic data of **7a—d** and **6b** [a].

7a: dark red crystals with shiny violet surfaces; m.p. 164°C; ^{1}H-NMR ($CDCl_3$): $\delta = 1.70$ (s, 6H, CMe), 2.96 (s, 12H, NMe), 6.10 (t, H-5), 7.33 (t, H-4), 7.48 (t, H-3), 7.53 (d, H-6), 7.94 (d, H-2); $J(2,3) = J(3,4) = 12.7$, $J(4,5) = J(5,6) = 11.7$ Hz; IR: 1703, 1616, 1520 cm^{-1}; UV/VIS [b]: 525 nm ($\lg\varepsilon = 4.94$), 527 (5.07), 521 (5.16), 471 (5.21)

7b: dark red crystals with shiny bluish-violet surfaces; m.p. 174—175°C; ^{1}H-NMR ($CDCl_3$): $\delta = 2.95$ (s, 12H, NMe_2), 3.32 (s, 6H, NMe), 6.12 (dd, H-5, $J(5,6) = 11.7$, $J(4,5) = 12.7$ Hz), 7.34 (dd, H-4, $J(3,4) = 13$, $J(4,5) = 12.7$ Hz), 7.46 (d, H-6, $J(5,6) = 11.7$ Hz), 7.75 (t, H-3, $J(2,3) = J(3,4) = 13$ Hz), 8.00 (d, H-2, $J(2,3) = 13$ Hz); IR: 1703 (m), 1622 cm^{-1} (br, s); UV/VIS [b]: 541 nm ($\lg\varepsilon = 5.00$), 546 (5.06), 539 (5.15), 535 (4.90)

7c: dark red crystals with shiny metallic-green surfaces; m.p. 152°C; ^{1}H-NMR ($CDCl_3$): $\delta = 1.05$ (s, 6H, CMe), 2.43 (s, 4H, CH_2), 2.96 (s, 12H, NMe_2), 6.15 (t, H-5), 7.34 (m, H-4), 7.41 (d, H-6), 7.64—7.82 (AB part of ABX, H-2 and H-3); $J(4,5) = J(5,6) = 12.2$ Hz; IR: 1612 cm^{-1} (br, s); UV/VIS [b]: 544 nm ($\lg\varepsilon = 4.84$), 552 (4.94), 546 (5.01), 5.41 (4.90)

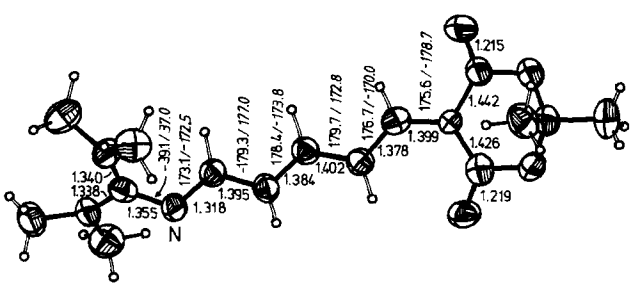
7d: dark red crystals with shiny metallic-green surfaces; m.p. 116°C; ^{1}H-NMR ($CDCl_3$): $\delta = 2.94$ (s, 12H, NMe_2), 5.99 (t, H-5), 6.41 (dd, H-3), 7.07 (dd, H-4), 7.28 (d, H-2), 7.35 (d, H-6); $J(2,3) = 12.6$, $J(3,4) = 13$, $J(4,5) = 12.2$, $J(5,6) = 12.2$ Hz; IR: 2215/2200 (s, C≡N), 1600 (m), 1495 cm^{-1} (s); UV/VIS [b]: 506 nm ($\lg\varepsilon = 4.75$), 510 (4.81), 511 (5.00), 506 (4.93)

6b: orange powder; m.p. 265°C; ^{1}H-NMR (CD_3CN): $\delta = 3.00$ (s, 12H, NMe_2), 3.25 (s, 6H, NMe), 6.35 (dd, H-5, $J(5,6) = 13.5$, $J(4,5) = 12.5$ Hz), 6.78 (d, broadened by NH-coupling, H-6), 7.25 (t with long-range coupling, H-4), 7.86—8.04 (AB part of an ABX system, H-2, H-3), 8.45 (br, NH); IR: 1655, 1530 cm^{-1} (both s)

[a] ^{1}H-NMR: 200 MHz, TMS as standard. IR: KBr pellet. All compounds gave correct elemental analyses. [b] The longest wavelength absorption bands in benzene, chloroform, acetone, and ethanol (95%) are given. IR: ν; UV/VIS: λ.

The products of γ-addition to the pyridinium ring **5c** and **5d** could be detected in the reaction solution by NMR spectroscopy. Under kinetically controlled conditions, **5d** is formed almost exclusively, but rearranges into **4d** or **6d**.[4]

The equal possibility of carbanionic attack at the formamidinium carbon of **2**, which would lead via elimination of a pyridine molecule to a push-pull olefin or a *O*-(formamidinio)enol,[5] surprisingly does not take place in the cases presented here.



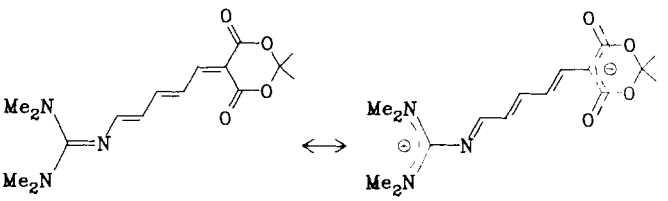


Fig. 1. ORTEP plot (50% probability) of a molecule of **7a**. The second independent molecule has almost a mirror-image configuration. The torsion angles [°] for the molecule (italics: corresponding values for the second molecule) and the average bond lengths [Å] are shown. The mean errors of the average values are 0.004—0.005 Å. The *NCN* fragment of the formamidinium group is rotated by 42° (in the second molecule by 35°) and the *CCC* plane of the heterocyclic acceptor by 5° (14°) with respect to the least-squares plane of the polyene chain (NC_5).

The bonding in neutrocyanines can, in general, be described in terms of a mesomerism of the type **7aA** ↔ **7aB**. The X-ray structure analysis of **7a**[6] (see Fig. 1) clearly shows that almost complete bond equalization has taken place (dipole moment $\mu = 5.66$ D in dioxane). It follows from the weak alternance that the resonance structure **7aB** even dominates. This bonding is favored in the crystal by a relatively large twisting of the NCN plane of the formamidinium group with respect to the least squares plane of the (in the second independent molecule not quite planar) NC_5 polyene chain.

7aA **7aB**

Consistent with their polymethine-like character, **7a—d** show only a slight solvatochromism of the longest wavelength absorption bonds, which, with increasing polarity of the solvent are shifted, first bathochromically and then hypsochromically.

Experimental

A solution of **1** [3] (3.0 mmol) and pyridine (7.5 mmol) in acetonitrile (25 mL) was stirred for 2 h at room temperature and then treated with 3.0 mmol of the CH-acidic compound **3**. On completion of reaction [**3a**: 3.5 h; **3b**: 30 min (**6b** crystallizes from the solution and can be isolated, yield 96%); **3c**: 2.5 h; **3d**: 60 h] the solvent was removed in vacuo and the residue taken up in 100 mL of chloroform. The solution was washed with 2 × 10 mL of NaOH (10%) or with aqueous ammonia (25%), whereupon it turned red-violet in color. It was then washed with water until neutral and finally dried over magnesium sulfate. After evaporation to dryness the residue was recrystallized from tetrahydrofuran (yield: **7a**: 70%; **7b**: 72%; **7c**: 69%; **7d**: 77%); for further data, see Table 1.

On the Absolute Configuration of (+)-Tartaric Acid

By *Hartmuth Buding, Bertold Deppisch, Hans Musso,** and *Günther Snatzke*

The absolute configuration of (+)-tartaric acid from grape juice was determined in 1951 by *Bijvoet* et al.[1] for the rubidium salt using the anomalous dispersion of zirconium K_α X-rays. This result was questioned by *Tanaka* et al.[2] in 1972, but *Dunitz*[3] has shown it to be correct. In the meantime new structure determinations on tartrates[4] have appeared and there is independent evidence that macroscopic crystal forms can be related to molecular chirality by X-ray methods.[5] According to *Prelog* et al.[6] each new example that reconfirms Bijvoet's method is welcome. Therefore, we present results that led us unintentionally to the determination of the (*R,R*) configuration for (+)-tartaric acid **1**.

(+)-2,3-Butanediol **2** was obtained from (+)-**1** by reduction of the carboxy groups according to a conventional procedure,[7] and was then transformed into (−)-2,3-butanedithiol **3** by the method of *Corey* and *Mitra*.[8] The reaction of **3** with the racemic diketone **4** yielded a mixture of diastereomeric bisdithioacetals. The second component eluting on chromatography was shown by *Bijvoet*'s X-ray diffraction analysis to be the enantiomer **5**.[9] The chiral centers in (−)-**3** therefore have the (*R,R*) configuration. Since the formation of **3** from (+)-**2** must involve a Walden inversion, (+)-**2** has the (*S,S*) configuration and the starting material is therefore (*R,R*)-(+)-**1**.

Independently, the (*S,S,S,S*) configuration was determined for the carbon framework of the tricyclic ketone (+)-**4** (obtained by hydrolysis of **5**) from the negative Cotton effect that is observed.[9] The (*R,R*) configuration of (+)-**1** and the (*S,S,S,S*) configuration of (+)-**4** are linked here by the structure determination of **5**. In this way (*R,R*)-(+)-**1** is reconfirmed through the optical activity of (*S,S,S,S*)-**4**.

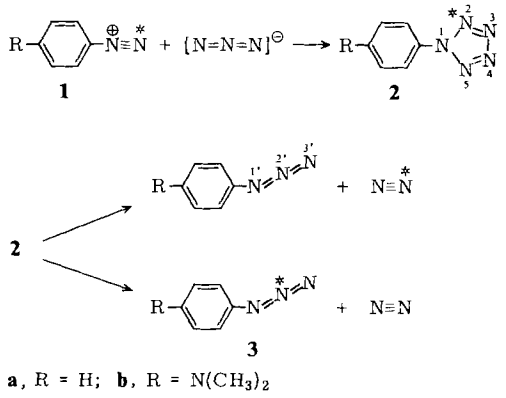
Direct Structural Proof for the Pentazole Ring System in Solution by ^{15}N-NMR Spectroscopy**



By *Raffaello Müller, John D. Wallis,* and *Wolfgang von Philipsborn**

Benzenediazonium chloride **1a** reacts with lithium azide in methanol to produce phenyl azide **3a** and molecular nitrogen. *Huisgen* and *Ugi*[2] discovered that the reaction proceeds by two mechanisms. For one of them it was proposed that phenylpentazole **2a** is an intermediate.[3] Its symmetry accounts for the equal distribution of an ^{15}N label, originally in the terminal N atom of the diazonium salt, between the decomposition products phenyl azide **3a** and molecular nitrogen (Scheme 1). Subsequently, a series of crystalline *p*-substituted phenylpentazoles was isolated[4] at low temperature (−30 °C), and recently the structure of the most stable of these, *p*-dimethylaminophenylpentazole **2b**, was confirmed by X-ray crystallography at 128 K.[5] We have now used ^{15}N-NMR spectroscopy to observe this unstable compound in solution at 238 K and to monitor its decomposition at higher temperatures.

The natural abundance ^{15}N-NMR spectrum of a solution of a crystalline sample of **2b** in $CDCl_3$ measured at 40.56 MHz (9.4 T) and 238 K is shown in Figure 1a. Even at this temperature the pentazole has partially decomposed during the long measurement time (40 h) to molecular nitrogen and *p*-dimethylaminophenyl azide **3b**. The nitrogen

[**] ^{15}N-NMR Spectroscopy, Part 14. This work was supported by the Royal Society of London (*J. D. W.*) and the Swiss National Science Foundation. We thank Prof. *J. D. Dunitz* for his interest.—Part 13: [1].

Scheme 1.

produces a broad resonance at $\delta = -73$[6,7] and the presence of **3b** is confirmed by comparison with the spectrum of an authentic sample (Fig. 1b). The assignment of the four resonances of **3b** is based upon literature data on phenyl azides.[8] These were the only resonances observed when the spectrum was remeasured after the sample had been left at room temperature for 24 h. The four remaining signals in Figure 1a are ascribed to the pentazole derivative **2b**, one to the $-N(CH_3)_2$ group ($\delta = -324.6$) and three to the all-nitrogen five-membered ring (N-1: $\delta = -80.0$, N-2,5: $\delta = -27.1$, N-3,4: $\delta = +4.9$, Table 1).

The resonance at $\delta = -80.0$ is assigned to the only tricoordinated N atom N-1, by analogy with other azoles.[9] Using additive shielding increments[10] evaluated from

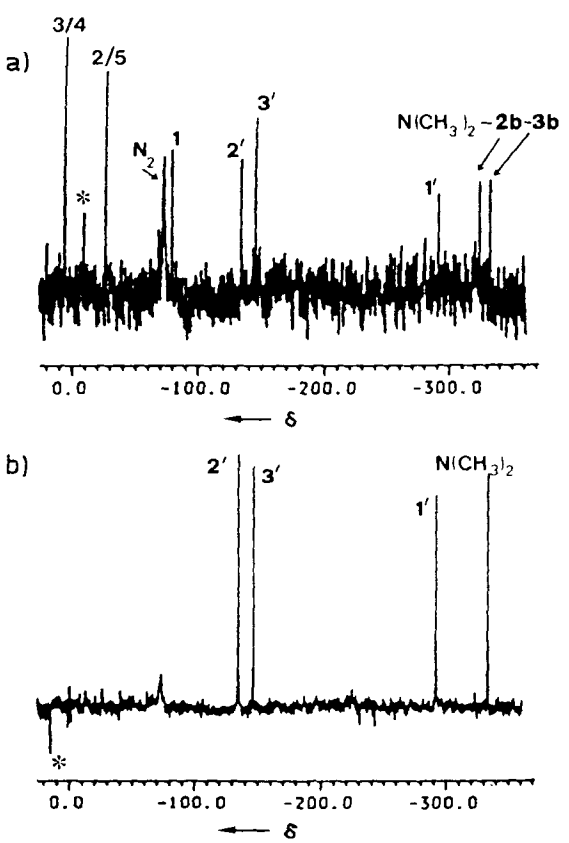

Fig. 1. ^{15}N-NMR Spectra (40.56 MHz) of a) pentazole **2b**, 0.04 M in $CDCl_3$, 238 K (see also Table 1 [a]) and b) authentic azide **3b**, 0.21 M in $CDCl_3$, 253 K (see also Table 1 [b]). The weak signal at $\delta = -73$ is probably due to N_2 originating from decomposed azide; the asterisk indicates electronic spikes.

Table 1. ^{15}N chemical shifts in δ values (± 0.3 ppm) relative to external $CH_3{}^{15}NO_2$; solvent $CDCl_3$ [15].

	T [K]	N-1	N-2,5, N-2′	N-3,4	$N(CH_3)_2$
2b	238	− 80.0	− 27.1	+ 4.9	− 324.6 [a]
3b	238	− 292.2	− 134.6	− 146.2	− 333.2 [a]
	297	− 292.7	− 134.4	− 147.0	− 335.0 [a, b]
^{15}N-**2b**	253		− 27.5		[c]
^{15}N-**3b**	273		− 135.3		[d]
	295		− 135.0		[d]

[a] Data from a solution of 80 mg of crystalline **2b** dissolved in 10 mL of $CDCl_3$, 0.07 M in $Cr(acac)_3$. [b] Data of an authentic sample of **3b**, 348 mg in 10 mL $CDCl_3$, 0.07 M in $Cr(acac)_3$. [c] Data from a crystalline sample of [2(5)-^{15}N]-pentazole **2b**, 99% ^{15}N, 25 mg in 10 mL of $CDCl_3$, 0.06 M in $Cr(acac)_3$. [d] Same sample as in [c], after decomposition.

azoles, a range of $\delta = -70$ to -90 for N-1 is predicted. The shielding of the tricoordinated N atoms decreases in the series 1-methylpyrazole ($\delta = -180.8$),[11] 2-methyl-1,2,3-triazole ($\delta = -134.0$),[9] 2-methyltetrazole ($\delta = -105.3$),[9] and the pentazole **2b** ($\delta = -80.0$). The assignments of N-2,5 and N-3,4 were made on the basis of the spectrum (Fig. 2a) of a sample of **2b** labeled with ^{15}N at N-2, which was prepared from the corresponding diazonium salt **1b** labeled at the terminal nitrogen.[12] The resonances of N-2,5 and N-3,4, while in the expected range predicted by extrapolation from triazoles and tetrazoles, could not be reproduced by application of additive shielding increments.[10] On decomposition of **2b**, the ^{15}N label appeared as expected in the central position of the N_3 group of **3b** and in the molecular nitrogen[13] (Fig. 2b).

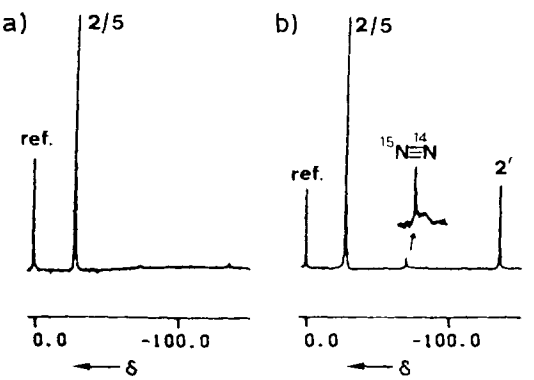

Fig. 2. ^{15}N-NMR Spectra (40.56 MHz) of a) [2(5)-^{15}N]-pentazole **2b**, 0.013 M in $CDCl_3$, 253 K (see also Table 1 [c]) and b) labeled pentazole **2b** (0.013 M, $CDCl_3$) during decomposition to [2-^{15}N]-**3b** and labeled $^{15}N \equiv {}^{14}N$ [13] at 273 K.

It is thus confirmed that **2b** also contains a pentazole ring in solution. The electron-attracting power of the pentazole group is demonstrated by the deshielding of the dimethylamino N atom ($\delta = -324.6$) compared to that in *N,N*-dimethylaniline ($\delta = -338 \pm 2$). A similar effect is observed when the pentazole group is replaced by CN ($\delta = -325.4$) or CHO ($\delta = -323.1$), and an even greater effect is produced by an NO_2 group ($\delta = -316.5$).[14] The crystallographic results indicate that the inductive effect of the pentazole group is similar to that of the nitro group. Hence, it may be concluded from the ^{15}N-NMR data that the pentazole substituent is not as good a π-acceptor as the nitro group.

[12] Treatment of *N,N*-dimethyl-1,4-diaminobenzene in CH_3OH/H_2O (5:1) at -10°C with a molar equivalent of $Na^{15}NO_2$ (99% ^{15}N) in a minimum volume of H_2O gave, after stirring for 4 h, a solution of the corresponding diazonium chloride labeled with ^{15}N at the β-N atom. Cooling to -30°C, dilution with an equal volume of cold CH_3OH, and treatment with methanolic LiN_3 yielded the desired pentazole as previously described. [4]
[13] The signal of the labeled $^{15}N \equiv {}^{14}N$ appears as a sharp line at $\delta = -70.1$ in good agreement with [7]. It is assigned to truly dissolved N_2 and is only observed with labeled material because of the low concentration. The broad N_2 absorption centered at $\delta = -73$ in Figures 1 and 2b probably results from gaseous N_2 in micro-bubbles and the associated local field inhomogeneity.
[14] J. Dorie, B. Mechin, G. Martin, *Org. Magn. Reson. 12* (1979) 229. The published chemical shift data were recalculated relative to $CH_3{}^{15}NO_2$ as an ext. standard.
[15] The ^{15}N-NMR spectra were measured on a Bruker AM-400 w.b. spectrometer at 40.56 MHz in 20-mm tubes with $Cr(acac)_3$ as a relaxation reagent (AT = 0.8 s, α = 23°, no proton decoupling).

Disulfur Monoxide as Complex Ligand—Preparation and Molecular Structure of $[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(S_2O)]$**

By *Max Herberhold,* Bertram Schmidkonz, Manfred L. Ziegler,* and *Thomas Zahn*

Dedicated to Professor Helmut Behrens on the occasion of his 70th birthday

Free disulfur monoxide, S_2O, which is stable in the gas phase below 1 torr for several days, decomposes to SO_2 and polysulfur oxides.[1] Like the isovalent and isoelectronic SO_2, it is non-linear.[1]

S_2O can be formed as a complex ligand by the oxidation of S_2 ligands. However, the S_2O complexes reported so far only allow tentative conclusions to be made regarding the coordinating properties of S_2O, since no structural investigations are available for the mononuclear complexes **1**[2] and **2**,[3] and since the binuclear complex **3**,[4] whose structure has been confirmed by X-ray analysis, contains S_2O bridges.

$6(dppe)_2Ir(S_2O)]Cl$ **1**, dppe: bis(diphenylphosphino)ethane

$[Cp_2Nb(S_2O)Cl]$ **2**, Cp: η^5-cyclopentadienyl

$[Mo(S_2O)(S_2C-NEt_2)_2]_2$ **3**

We have prepared the brown disulfur complex **5** by reaction of the tetrahydrofuran(THF)-stabilized complex fragment $[Cp^*Mn(CO)_2]$ ($Cp^* = \eta^5$-pentamethylcyclopentadienyl), which is formed via photolysis of **4** in THF,[5] with excess sulfur. **5** was then converted to the red complex **6** by air oxidation.[6] The mononuclear neutral complex **6** is a suitable model compound for the study of the S_2O ligand.

[a] In THF. [b] Calculated according to F. A. Cotton, C. S. Kraihanzel, *J. Am. Chem. Soc. 84* (1962) 4432. [c] In $CDCl_3$, 0°C.

Table 1 summarizes the characteristic IR and NMR data of the complexes **4**—**6**. According to the force constants k(CO) of the carbonyl vibrations, which can be calculated from the ν(CO) frequencies, the back-bonding from the metal to the CO ligands decreases upon replacement of a CO group in **4** with S_2 or S_2O. The acceptor character of S_2 is higher than that of CO; this observation was also made in an earlier study on $[CpRe(CO)_2S_2]$.[7] Apparently, S_2 is able to withdraw more charge from the complex fragment $[Cp^*Mn(CO)_2]$ than carbon monoxide. A further, but somewhat smaller increase in the acceptor ability occurs upon oxidation of the S_2 ligand to S_2O.

According to the X-ray structure determination of **6** (Fig. 1), the disulfur monoxide ligand is coordinated to the metal via both sulfur atoms. The Mn—S bonds are long and somewhat different; the sulfur atom bearing the oxygen, S(2), exhibits pyramidal geometry and is further away from the metal than the terminal S(1). The S—S axis is roughly parallel to the ring plane of the Cp* ligand. The oxygen atom of the S_2O ligand is directed away from the Cp^* ring; the dihedral angle S_2O/C_5Me_5 is 54.3°. In comparison to free S_2O, the S—S and S—O bonds of coordi-

nated S_2O in the complex **6** are longer, whereas the SSO angle remains unchanged. The S–S distance (201.3(8) pm), however, is markedly shorter in **6** than for the S_2O bridges in **3** (mean value 210.0(5) pm), which were interpreted tentatively as S_2O anions in a molybdenum(III) complex.[4] In the manganese complex **6**, S_2O can be looked upon as a side-on π-bound ligand.

Scheme 1. Left: part of **6**; right: part of $[CpMn(CO)_2SO_2)]$ **7** [8].

In contrast, the SO_2 ligand in **7** is only bonded via the central sulfur atom. The involvement of multiple bonding must be assumed for the Mn–S bond because of the trigonal-planar sulfur geometry and the short Mn–S distance.[8,9] The SO_2 plane lies perpendicular to the ring plane of the Cp ligand. The S–O distances are somewhat shorter than those of free SO_2 and the OSO angle is smaller.[8]

[6] *Experimental procedure:* A solution of **4** (600 mg, 2.2 mmol) in 150 mL of anhydrous N_2-saturated THF was irradiated with a high-pressure mercury lamp (Q700 Original Hanau) until the ν(CO) absorptions of **4** had vanished (ca. 3 h). After addition of sulfur (200 mg, 6.3 mmol), the solution was stirred for 1 h, its color changing from the original wine-red to dirty green. Subsequently, air was passed through the solution for 30 min, followed by an additional 5–8 h of stirring under air. The resulting brownish red solution was evaporated and the residue chromatographed on a silica gel column (CCR 60 Grace, 20 × 1.5 cm). The column was first washed with pentane and then the sulfur-containing complexes (including **5**) were eluted as a greenish brown band with CH_2Cl_2 and **6** as a red band with THF. Recrystallization from THF/diethyl ether at −78 °C afforded red crystals of **6** (150 mg, 21%), which decompose at 140–145 °C. — IR (KBr) 1995 (vs), 1950 (vs) (ν(CO)), 1056 (m) (ν(SO)), 546 (m) (ν(SS)) cm^{-1}. — FD-MS: m/z 326 (M^+). — EI-MS: m/z 326 (4%, M^+), 310 (6%, $Cp^*Mn(CO)_2S^+$), 270 (36%, $Cp^*Mn(S_2O)^+$), 254 (16%, $Cp^*MnS_2^+$), 238 (3%, Cp^*MnSO^+), 222 (37%, Cp^*MnS^+), 206 (17%, Cp^*MnO^+), 190 (4%, Cp^*Mn^+), 119 (100%, $C_9H_7^+$). — Correct elemental analysis (C, H, O, S, Mn).

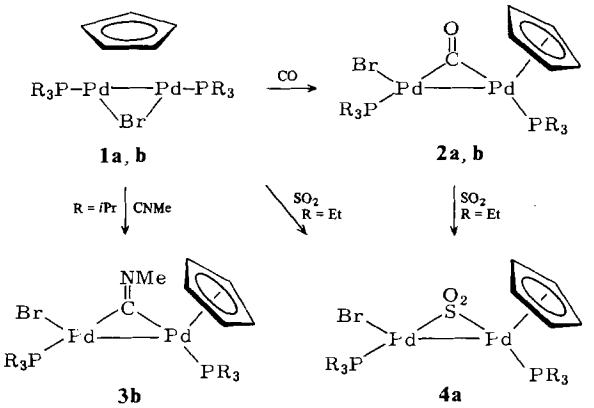
Reaction of Small Molecules with the Binuclear Complex $[(\mu\text{-}C_5H_5)(\mu\text{-}Br)Pd_2(PR_3)_2]$: Addition without Cleavage of the Metal-Metal Bond**

By *Peter Thometzek, Karin Zenkert,* and *Helmut Werner**

The addition of small molecules such as CO, CO_2, or SO_2 to compounds containing metal-metal bonds and the possible reversibility of this process is of current interest, e.g., in connection with the removal of these molecules from gas mixtures. We chose as a model system the sandwich-type binuclear complexes **1a**, **b**,[1] in which the bridging bromide can be easily replaced, for example, by a thiolate or carbonylmetalate anion.[2]



The reaction of **1a**, **b** with CO in pentane or toluene produces nearly quantitatively in a few minutes the novel CO-bridged binuclear complexes **2a**, **b**.[3] These ruby-red, rather air-stable solids are soluble in all the standard organic solvents except alkanes. In contrast to the reactions of $[(\mu\text{-dppm})_2M_2X_2]$ ($dppm=CH_2(PPh_2)_2$; M = Pd, Pt; X = Cl, Br)[4a] and $[(\mu\text{-dppm})_2Rh_2(CO)_2]$[4b] with CO, the addition of carbon monoxide to **1a**, **b** is not accompanied by cleavage of the metal-metal bond; however, the cyclopentadienyl and bromide ligands rearrange from bridging to terminal positions. A similar rearrangement also occurs in the addition of allene to **1b**, but with cleavage of the Pd–Pd bond.[5]

The reactivity of methyl isocyanide and SO_2 towards **1b** and **1a**, respectively, is similar to that of CO. The reaction of **1b** with $CNCH_3$ occurs rapidly in toluene even below 0 °C to give **3b** in high yield.[3] The spectroscopic data for **3b** are consistent with a structure similar to that of the CO-bridged complexes **2a,b** and **2b**, Cl instead of Br.[6] According to the ^1H- and ^{13}C-NMR spectra of **2a,b** and **3b**

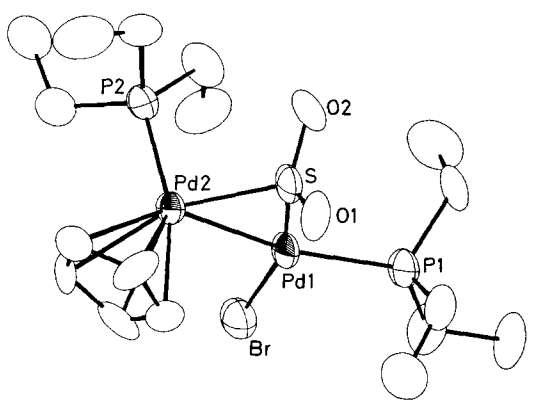
(as well as of **4a**),[3b] the phosphane ligands are non-equivalent. Compound **4a** is formed quantitatively by bubbling SO_2 into a solution of **1a** in toluene. The chemical properties of **4a** and the carbonyl complex **2a** are similar; owing to the oxidation state +1 of the palladium, the most noteworthy feature of these compounds seems to be their stability in air.

The differing nature of the two fragments $[Pd(PR_3)Br]$ and $[Pd(PR_3)C_5H_5]$ present in **2a,b**, **3b**, and **4a**, whose anionic ligand is a *two*-electron and a *six*-electron donor, respectively, should be reflected in the structure of the bridging unit. On the basis of a comparison with binuclear cobalt and rhodium complexes in which one of the metals formally has 16 and the other 18 electrons in the valence shell,[7,8] we expected the bridging ligand in **2a,b**, **3b**, and **4a** to be more firmly bonded to the electron-deficient part of the molecule. This is confirmed by the results of the X-ray structural analysis of **4a** (Fig. 1).[9] The SO_2 ligand



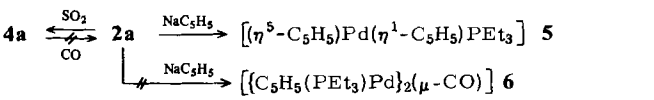


Fig. 1. Structure of **4a** in the crystal. Selected bond lengths [pm] and bond angles [°]: Pd1–Pd2 274.7(2), Pd1–Br 247.8(3), Pd1–P1 225.1(6), Pd1–S 215.6(6), Pd2–S 227.9(6), Pd2–P2 226.7(5), S–O1 144(2), S–O2 148(2), Pd2-midpoint of the C_5H_5 ring 196.6(2); Pd2–Pd1–P1 149.4(2), Pd2–Pd1–Br 107.3(1), P1–Pd1–Br 102.0(1), Pd1–Pd2–P2 101.7(2), Pd1–S–Pd2 76.5(2), Pd2–Pd1–S 53.8(2), P1–Pd1–S 97.2(2), O1–S–O2 116.0(1).

bridges the Pd–Pd bond in an unsymmetrical fashion, the Pd–S bond lengths differing by 12.3 pm. The bond angle Pd1–S–Pd2 is relatively small and similar to that in $[\{C_5H_5(CO)Rh\}_2(\mu\text{-}SO_2)]$, which contains a symmetrical $Rh–SO_2–Rh$ bridge.[10] Owing to the size of the sulfur atom, the Pd–Pd distance in **4a** (274.7(2) pm) is significantly larger than that in **1b** (260.9(1) pm)[11] and comparable to the Pd–Pd distance in palladium metal (274 pm). To the best of our knowledge, there is only one other known example of a polynuclear metal complex, having an unsymmetrical SO_2 bridge, namely, $[(\mu\text{-}C_6H_5)(\mu\text{-}PPh_2)(\mu\text{-}SO_2)Pt_3(PPh_3)_3]$; in this case, the Pt–S distances are 217.0(6) and 227.2(6) pm.[12]

The preference of SO_2 to form the $Pd(\mu\text{-}SO_2)Pd$ unit is also manifested in the reaction of **2a** with SO_2 to produce **4a** which is complete in benzene at 25 °C in a few minutes. Ligand exchange in the reverse direction is not detectable under the same conditions. Treatment of **2a** with NaC_5H_5

in toluene at −78 °C does not lead to the formation of the symmetrical binuclear compound **6**, but gives instead the complex **5**[13] by cleavage of the metal-metal bond.

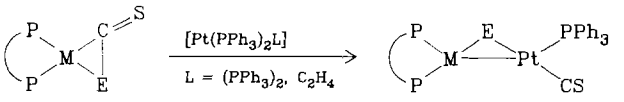
Fragmentation and Recombination of CS_2 and CSSe in the Coordination Sphere of Platinum Metals**

By *Martin Ebner, Heiko Otto,* and *Helmut Werner**

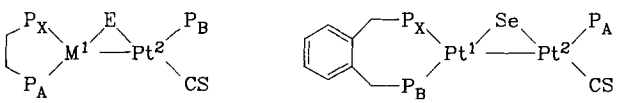
Whereas drastic reaction conditions are needed to split CS_2 into CS and sulfur,[2] such a process occurs readily in the coordination sphere of transition metals. A striking example is the formation of the Co_3 cluster **3** from **1** and the 16-electron fragment $[C_5H_5Co(PMe_3)]$ generated from **2**, which proceeds in benzene at ca. 80 °C in 82% yield.[3]



1 **3**

$[C_5H_5(PMe_3)Co(\mu\text{-}CO)_2Mn(CO)C_5H_4Me]$ **2**

We have now observed that it is possible to reverse the metal-initiated fragmentation of CS_2 (or of CSSe) into CS and S (or CS and Se). Two platinum atoms or one platinum and one palladium atom are involved in this process.



The chelate complexes **4**—**7**[4] react with $[Pt(PPh_3)_4]$ and with $[Pt(C_2H_4)(PPh_3)_2]$ in acetone at room temperature by displacement of triphenylphosphane and ethylene, respectively, to produce the binuclear μ-sulfido or μ-selenido compounds **8**—**11**.[5] The addition of $[Pt(PPh_3)_2]$ to the exocyclic sulfur atom, which was originally expected to occur (see [6]), does not take place. *Walker* et al. have independently described the synthesis of the Pt_2 complex **8**.[7] A similar cleavage of CS_2 by phosphane-platinum compounds has recently been reported by *Scherer* et al.[8] who isolated the complex $[\{PtL(CS)\}_2(\mu\text{-}S)_2]$ ($L=tBuN{=}P{-}N(SiMe_3)tBu$) on reaction of PtL_3 with CS_2. In this product, however, platinum is in the +2 oxidation state and thus the two metal atoms are *not* linked by a metal-metal bond.

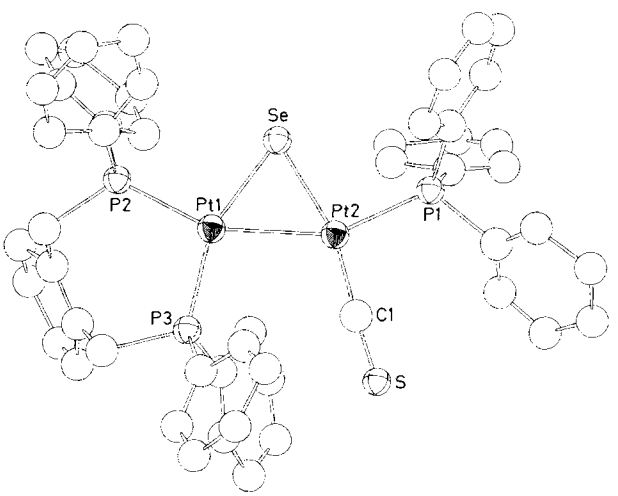
The evidence for the proposed structures of complexes **8**—**11** was obtained from the ^{31}P-NMR spectra which confirm the presence of ABX spin systems.[5b] The assignment is based on reference data which allow for the size of the chelate ring.[9]

8, 9, 11 **10**

The molecular structure of compound **10** is shown in Figure 1.[10] The selenium and platinum atoms form an isosceles triangle to which the CS ligand is coordinated in *trans* position to Se. The metal atoms and the non-metal atoms bonded to them are nearly coplanar, the dihedral angles formed between the planes [Pt1, Pt2, Se] and [Pt2, P1, C1] and between [Pt1, Pt2, Se] and [Pt1, P2, P3] being 5.5 and 4.5°, respectively. The Pt–Pt distance is nearly the same as in other platinum(I) complexes.[11]



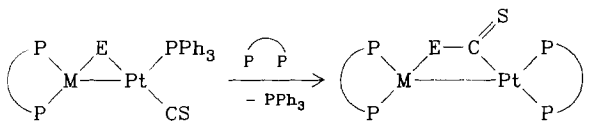


Fig. 1. Structure of **10** in the crystal; only one of the two independent molecules present in the asymmetric unit is shown. Selected bond lengths [pm] and angles [°] of the molecule illustrated in the figure (the values of the second molecule are the same within the standard deviations): Pt1–Pt2 266.1(3), Pt1–Se 238.5(7), Pt2–Se 238.0(7), Pt1–P2 229(2), Pt1–P3 223(2), Pt2–P1 230(2), Pt2–C1 183(4), C1–S 152(4); Pt1–Pt2–Se 56.1(2), Pt2–Pt1–Se 56.0(2), Pt1–Se–Pt2 67.9(2), Se–Pt2–P1 95.8(5), Se–Pt2–C1 163(1), Se–Pt1–P2 99.2(4), Se–Pt1–P3 156.6(4), Pt2–C1–S 177(3), Pt1–Pt2–P1 151.5(4), P2–Pt1–Pt2 155.1(4), P3–Pt1–Pt2 101.0(4), P2–Pt1–P3 103.8(6), Pt1–Pt2–C1 107(1), P1–Pt2–C1 102(1).

[**] Complexes with Carbon Sulfides and Selenides as Ligands, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG.—Part 15: [1].

An attempt to displace the two monodentate ligands at the platinum atom Pt^2 in **8**—**11** by a second chelating diphosphane led to an unexpected result. On treatment of **8**, **10**, and **11** with diphos or dpmb, the complexes **12**—**14** are formed, which, according to the IR spectra, contain a bridging CS_2 or CSSe ligand.[12] The position of the CS stretching frequency at ca. 900 cm^{-1} is very similar to that of the compound $[Pt_2Cl_2(\mu\text{-}Ph_2P\text{-}CH_2\text{-}PPh_2)_2(\mu\text{-}CS_2)]$, the structure of which has been determined by X-ray structural analysis.[13] The ^{31}P-NMR spectrum of **13** consists of two AB pairs which correspond to two pairs of phosphorus atoms (P_A, P_B and P_X, P_Y) located in a similar chemical environment.[12b]

8, 10, 11 **12–14**

	M	E	P⌒P
8, **12**	Pt	S	diphos
10, **13**	Pt	Se	dpmb
11, **14**	Pd	Se	diphos

The reaction of **9** with diphos does not lead to the formation of a product comparable to **12**—**14**. Although displacement of PPh_3 by the chelating ligand occurs, a band at 1055 cm^{-1} in the IR spectrum corresponding to a ν(CS) stretching frequency points to the presence of a CS bridge in the binuclear complex. Thus, the tendency of the two fragments CS and S or CS and Se to reform the corresponding heteroallene depends both on the metals and on the ligands.

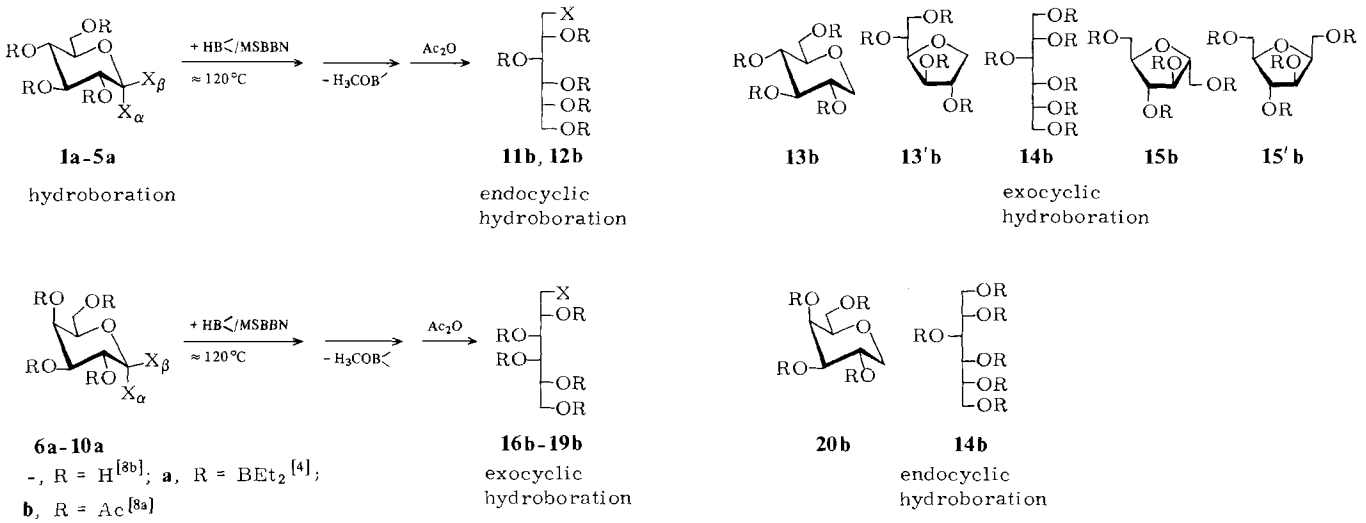
Catalyzed Acetal Reduction with >BH Boranes — 1-*O*-Alkyl(aryl)alditols, Anhydroalditols, and 1-*O*-Alditylalditols from *O*-Glycopyranosides**



By *Roland Köster,** *Soledad Penadés-Ullate,* and *Wilhelm Volker Dahlhoff*

In contrast to semiacetals, acetals are completely stable towards >BH-boranes and ≥BH-borates up to ≳130°C. In the course of our investigations on the analytical uses of organoboron reagents we found that open-chain and cyclic *O,O*-acetals can be quantitatively reduced with aliphatic-substituted >BH boranes in the presence of certain electrophiles, e.g. ether-trifluoroboranes or alkane- and arenesulfonyloxy(diorgano)boranes, respectively.[1] We report here on the preparation of open-chain and cyclic polyhydroxyethers from *O*-gluco- and *O*-galactopyranosides[2] with alkyldiboranes(6) in the presence of the activator 9-methanesulfonyloxy-9-borabicyclo[3.3.1]nonane (MSBBN).[3] Apart from 1-*O*-methylalditols, 1-*O*-phenylgalactitol and various anhydroalditols, also 1-*O*-alditylalditols can now be prepared from disaccharides.

The per-*O*-diethylboryl derivatives **1a** to **10a**[4] of the *O*-glycopyranosides **1** to **10** (cf. Scheme 1 and Table 1) are especially suitable for the reduction with alkyldiboranes(6) (alkyl = ethyl, propyl)[5a] in the presence of MSBBN[3] at

[a] Standard conditions: 5—6 h heating of **1a** to **10a** in boiling, neat ethyldiboranes(6) [12—15% $H^\ominus$] [5] with addition of MSBBN **3** in the ratio educt: >BH : MSBBN ≈ 1 : 4 : 0.1; in the case of **4a** and **9a**: 1 : 4 : 0.8. [b] The mixtures of **11b** to **20b** [8a] were separated gas-chromatographically; GC [12]: Siemens instrument glass capillary column (25—55 m, OV-1), He (1.5 bar), column 100—320 °C (10/min); injection block: 250 °C. [c] 1-, 2-, 3- or 5-D-glucityl-substituent. [d] Not determined.

100 °C. Hydroboration of the endocyclic acetalic C—O bond takes place, leading to open-chain *O*-ethylboron-protected[5b] polyhydroxy ethers, e.g. **11a**, **12a** and **16a** to **19a**.[6] Hydroboration of the exocyclic acetalic C—O bond leads to cyclic *O*-ethylboron-protected polyhydroxyether, e.g. **13a** and **20a**. *O*-Diethylboryl-, and the *O,O'*-ethylbo-

ranediyl-protective groups formed therefrom in the presence of ethyldiboranes(6) can readily be removed with methanol/glycol.[7] The per-*O*-acetyl derivatives[8a] **11b** to **20b** are prepared from the product mixture and can be separated chromatographically and characterized spectroscopically (MS, NMR).[8b]

The *O*-glycopyranosides **1a** to **10a** react with varying rates on reduction with ethyldiboranes(6); **4a** and **9a** are reduced especially slowly. By increasing the amount of MSBNN (cf. Table 1, footnote [a]), the formation of pyranosylalditols in the product mixture can be avoided. The composition of the polyhydroxyether mixtures is influenced by the anomeric configuration of the D-glucopyranosides **1** to **4** and the D-galactopyranosides **6** to **10**. The methyl β-pyranosides **2a** and **7a** and the phenyl β-D-galactopyranoside **8a** afford highly selectively, via endocyclic C–O hydroboration, 1-*O*-methyl-D-alditols (**11**, **16** with 80% selectivity) and 1-*O*-phenyl-D-galactitol (**17**, 98%), respectively. Octakis-*O*-(diethylboryl)cellobiose **4a** and octakis-*O*-(diethylboryl)lactose **9a** preferentially yield the 1-*O*-alditylalditols[9] **12** (52%) and **18** and **18'** (72%), respectively. In contrast, octakis-*O*-(diethylboryl)maltose **3a** affords **12** and **13** practically non-selectively, while octakis-*O*-(diethylboryl)melibiose **10a** gives only 20% **19**, and mainly 1,5-anhydro-D-galactitol **20** and D-glucitol **14**, both of which are formed as a result of exocyclic C–O bond cleavage (cf. Scheme 1 and Table 1).

The "trehalose" moiety of the octakis-*O*-(diethylboryl)sucrose **5a** is not reduced at the endocyclic acetal bonds. The quantitative reduction of **5a**, however, takes place regioselectively (88%), showing preference for the exocyclic C–O bond of the furanoside ring. In each case, 44% glucitol **14** and a ca. 1:6 mixture of the 2,5-anhydroalditols **15** and **15'** formed via an oxycarbenium intermediate are obtained. Reductive pyranoside-cleavage of **5a** affords a further 6% of D-glucitol **14** and 6% of 1,5-anhydro-D-glucitol **13** (cf. Scheme 1).

Experimental

Penta-*O*-acetyl-1-*O*-phenyl-D-glucitol **17b**: MSBBN [3] (0.1 g, 0.38 mmol) was added under protective gas at ≈20°C to 1.94 g (3.67 mmol) **8a** [prepared from 1 g (3.9 mmol) of phenyl β-D-galactopyranoside **8** and 4 mL (28.4 mmol) of activated triethylborane [4]] and 1.27 g ethyldiboranes(6) [5a] (11.86% $H^{\ominus}$, i.e. 15.1 mmol >BH-borane) and the mixture stirred for 4 h at 120°C. After evaporation of the colorless solution in vacuo (10^{-3} torr; bath: 70–80°C) the residue was treated with ≈7 mL methanol/1,2-ethanediol (≈5:2) and all volatile components were removed in vacuo (10^{-3} torr). The procedure was repeated. The boron-free residue was then treated at 20°C with 5 mL of acetic anhydride in 5 mL pyridine and, after stirring for 1 hour, the mixture was evaporated to dryness. The solid residue was washed with a little ethanol, then with diethyl ether. The colorless, solid product (m.p. 129–131°C) was recrystallized from 20 mL diethyl ether/5 mL ethanol: 1.6 g (93%) pure **17b**; m.p. 133°C; $[\alpha]_D^{20} = 20$ ($c = 0.3$, $CHCl_3$); HZ (Hydridzahl = hydride number) [8b, 10] = 9.9.

1-*O*-Phenyl-D-galactitol **17**: A mixture of **17b** (404.4 mg, 0.86 mmol) and ethyldiboranes(6) (952.9 mg, 11.96 mmol >BH-borane) was heated for 2 h at ≈120°C. The excess >BH-borane was destroyed by addition of 20 mL of methanol (>BH-borane consumed: 8.53 mmol). After removal of volatile components by distillation in vacuo the residue was treated with a further 20 mL of methanol and the resulting solution evaporated to dryness, giving 225 mg (≈100%) **17**; m.p. 202°C; $[\alpha]_D^{20} = 7.2$ ($c = 0.4$, $(H_3C)_2SO$).

Bis(tricarbonyliron)-*para*-quinodimethanes: Preparation and Molecular Structure

By *Ali R. Koray, Claus Krieger,* and *Heinz A. Staab**

The stabilization of highly unstable organic molecules as tricarbonyliron complexes is well-known in several cases including cyclobutadiene, trimethylenemethane, and *ortho*-quinodimethane.[1] Other highly unstable molecules are *para*-quinodimethanes like **1** and **2** which have attracted a great deal of interest as intermediates in chemical reactions[2] and have been studied spectroscopically at low temperatures.[3] In this paper we would like to report on bis(tricarbonyliron) complexes of **1** and **2**, which, to our knowledge, are the first examples of *para*-quinodimethanes stabilized as ligands in transition metal complexes.

1: R = H **3**: R = H
2: R = CH_3 **4**: R = CH_3

3 and **4** were obtained by rapid dropwise addition of solutions of 1,4-bis(bromomethyl)benzene and 1,4-bis(bromomethyl)-2,5-dimethylbenzene, respectively, in benzene (≈0.01 mol/250 mL) into a suspension of $Fe_2(CO)_9$ in benzene (≈0.05 mol/250 mL) at 40–45°C. Evaporation of the solution, rapid chromatography (silica/cyclohexane), sublimation and recrystallization from hexane yielded **3**[4] (orange microcrystals, dec. >150°; 1.1% yield) and **4**[4]

Jahnstrasse 29, D-6900 Heidelberg 1 (FRG)

(red crystals, dec. > 160°C; 3.4% yield). All spectroscopic data of **3** and **4** agree well with the assumption of bis(tricarbonyliron) complexes of **1** and **2**, respectively.[4]

With regard to the bonding sites of the two tricarbonyliron units the molecular structure obtained for **4** by X-ray analysis was of special interest. Figure 1a shows a side-view of the C_i structure of the complex, from which the positions of the tricarbonyliron groups above and below the *para*-quinodimethane unit and the deformation from planarity of the latter can be seen. The complex consists of two trimethylenemethane-like sections with short distances between Fe and C(1), C(4), C(3i) and C(2) [195.2(1), 209.7(1), 220.5(1) and 230.8(1) pm, resp.]. This type of bonding is also supported by the carbon-carbon bond-lengths of the quinodimethane moiety which shows equal distances for C(1)···C(4), C(1)···C(2) and C(1)···C(3i) (Fig. 1b). Furthermore, the subdivision into two trimethylenemethane parts is impressively demonstrated by the long bond length of 146.2(1) pm found for the bonds C(2)···C(3) which are the formal double bonds of the *para*-quinodimethane ligand. Theoretical calculations (EHT-MO) agree well with the complex structure found.[6]

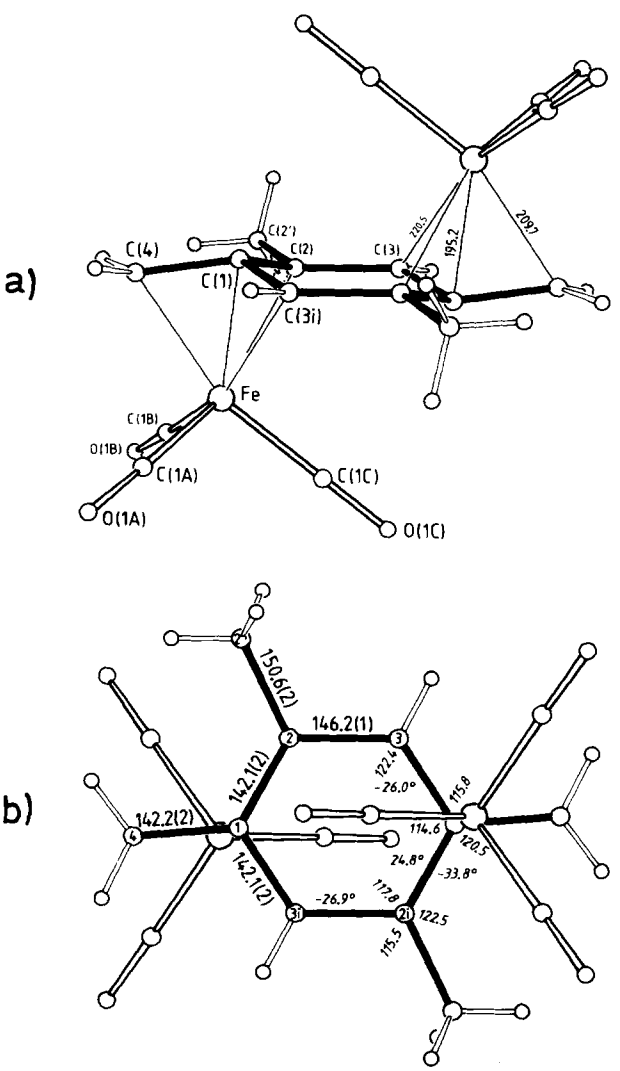

Fig. 1. Side-view (a) and top-view (b) of **4** with bond lengths [pm] and bond angles [°]. $a = 643.6(1)$, $b = 746.6(1)$, $c = 919.6(1)$ pm, $\alpha = 103.31(2)$, $\beta = 108.77(2)$, $\gamma = 91.42(2)°$; space group $P\bar{1}$, $Z = 1$; number of reflections measured 2061, number of reflections with $I \geq 1.96\sigma(I)$ 1827; $R = 0.021$. Further details of the X-ray structure analysis of **4** are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the registry number CSD 51246, the names of the authors, and the full citation of this journal.

As was to be expected on the basis of structures **3** and **4** both compounds react readily with bromine (tetrachloromethane, 0°C) to yield 1,4-bis(bromomethyl)benzene (67%) and 1,4-bis(bromomethyl)-2,5-dimethylbenzene (63%), respectively. Further reactions which can be rationalized as 'in-situ' generation of the *para*-quinodimethanes from bis(tricarbonyliron) complexes are under investigation.

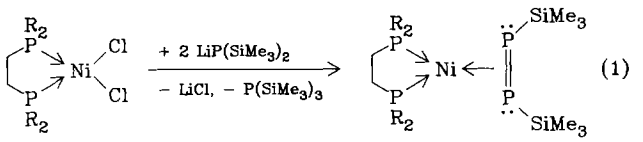
Chelate-Stabilized Diphosphene and Diphosphorus Complexes of Nickel**

By *Hans Schäfer,* Dieter Binder,* and *Dieter Fenske*



Diphosphenes R–P̈=P̈–R have two lone pairs of electrons and a double bond and can therefore coordinate in different ways to transition metals.[1] We are interested in complexes of the η^2-type in which only the double bond is formally bonded to a metal center.[2] This coordination pattern corresponds to the bonding of olefins to transition metals.

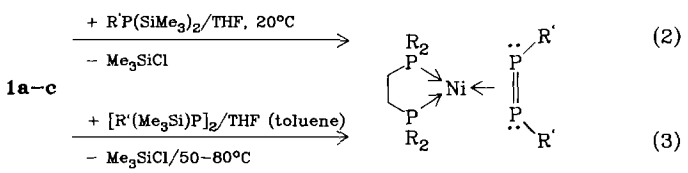
[**] Transition-Metal Phosphido Complexes, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The crystal data were collected at the Institut für Kristallographie der Universität.—Part 9: H. Schäfer, J. Zipfel, B. Gutekunst, U. Lemmert, *Z. Anorg. Allg. Chem.*, in press.

The use of two resonance structures, **A** and **B**, to describe such complexes is supported by the P–P distances (212–215 pm)[1a-d,2] and the ^{31}P-NMR spectra (see below). We are interested exclusively in complexes which formally contain diphosphene ligands that are not stable as free species. We obtained the first P-functional compounds of this kind from *trans*-$(R_3P)_2NiCl_2$ (R = alkyl) and $LiP(SiMe_3)_2$.[2] This method can be extended to the synthesis of the chelate-stabilized diphosphene complexes **2a** and **2b** [Reaction (1)].

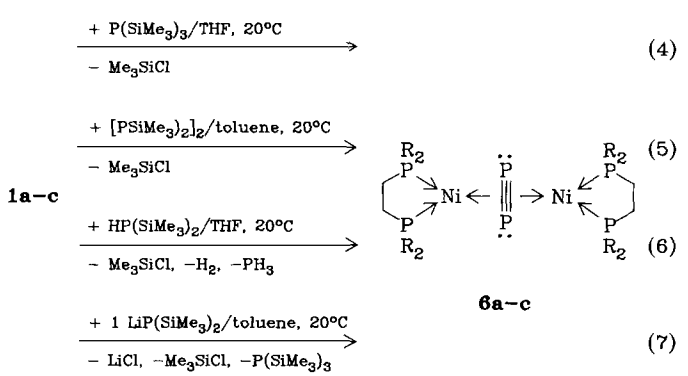


(1)

1a–c **2a, 2b**

a, R = Et; **b**, R = c-C_6H_{11}; **c**, R = Ph

In these reactions, some of the intermediates were shown by NMR spectroscopy to be nickel complexes containing terminal $P(SiMe_3)_2$ groups. For **1c**, however, redox reactions predominate, forming $(Me_3Si)_2P-P(SiMe_3)_2$ and $(chelate)_2Ni$. When **1a–c** are reacted with $LiP(R')SiMe_3$ (R' = Me, *t*Bu, Ph), redox reactions are also mainly observed, yielding diphosphanes and $(chelate)_2Ni$. Complexes containing diphosphene $(PR')_2$ ligands are accessible, however, via the simple reaction (2) and, in some cases, even better, starting from silylated diphosphanes [Reaction (3)].

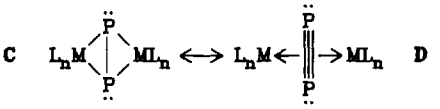


(2)

(3)

3, R' = Me; **4**, R' = *t*Bu;
5, R' = Ph

Surprisingly, attempts to synthesize complexes containing $(PSiMe_3)_2$ ligands in an analogous way from **1a–c** and $P(SiMe_3)_3$ or $(Me_3Si)_2P-P(SiMe_3)_2$ or complexes containing (PH_2) ligands from **1a–c** and $HP(SiMe_3)_2$ yielded the P_2 complexes **6a–c**.



6a and **6b** can also be identified by NMR spectroscopy for Reaction (1) when a 1:1 stoichiometry is used. Even the cleavage of the Me_3Si groups in **2a** and **2b** with methanol leads to **6a** and **6b**, presumably via $(PH)_2$ complexes.

(8)

In Reactions (1)–(8), variable amounts of $(chelate)_2Ni$ are always formed, making the isolation of the diphosphene or diphosphorus complexes somewhat difficult. Reaction (6) proved to be the preparatively most convenient synthetic method for **6a–c**.

According to *Hoffmann*,[3] the (chelate)Ni group, viewed as a 14-electron fragment, is isolobal with the CH_2 group. The complexes **6a–c** are therefore formally bicyclobutane derivatives according to the resonance structure **C** and thus represent a new class of P_2 complexes, analogous to the As_2 complexe $[(C_2Me_5)(CO)_2Mn]_2As_2$ of *Herrmann* et al.[4]

In all P_2 complexes known so far, the P_2 group is bonded to two 15-electron fragments, which, as units isolobal to the CH group, are connected by a metal-metal bond, resulting in a closed tetrahedron.[5] **6a** crystallizes with two crystallographically independent molecules in the asymmetric unit.[6] The two molecules primarily differ only in the fold angle between the (NiP_2) planes (95.4 and 98.3°, see Fig. 1). This is presumably due to packing effects and causes a marked difference in the Ni–Ni distances (291 and 296 pm, respectively; no Ni–Ni bonding). Comparison of the structure of **6a** (see Fig. 1) with the tetraphosphabicyclobutane derivative $P_4[N(SiMe_3)_2]_2$[7] reveals the analogy to main-group chemistry. Both the P–P distance and the fold angle are very similar to those in the P_4 derivative (P–P = 213 pm, fold angle 95.2°). The Ni–Ni distance in **6a** corresponds to the transannular P–P distance (281 pm) of the open P_4 tetrahedron. The P–P distance of the P_2 group of **6a** (212 pm) lies, as in other P_2 complexes,[5] between the typical values for a single bond

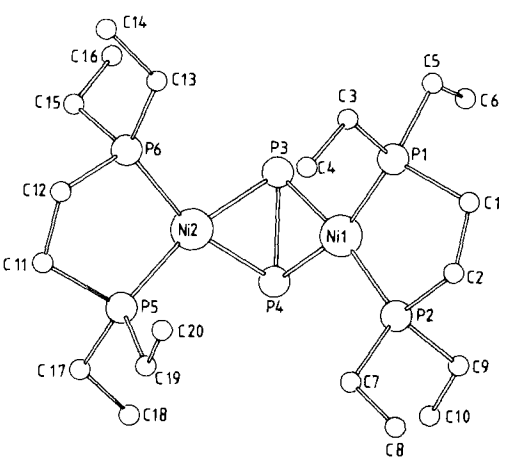


Fig. 1. Molecular structure of **6a** (molecule 1). The Ni atoms are surrounded by a nearly planar array of four P atoms and lie 9 pm below the mean plane. Fold angle (Ni1-P3-P4–Ni2-P3-P4) 95.4°. Important distances [pm] and bond angles [°]: Ni1–P1 212.5(5), Ni1–P2 213.1(4), Ni1–P3 223.8(5), Ni1–P4 223.1(5), Ni1–Ni2 290.8(3), P3–P4 212.1(6), Ni2–P3 223.3(3), Ni2–P4 223.3(3), Ni2–P5 213.4(4), Ni2–P6 214.9(5), P–C 182–186(1); Ni1–P3–P4 61.5(2), P3–P4–Ni1 61.8(2), P3–Ni1–P4 56.7(2), P1–Ni1–P2 91.5(2), P3–Ni1–P1 101.9(3), P4–Ni1–P2 109.6(2), P3–Ni1–P2 165.7(2), P4–Ni1–P1 158.3(2), Ni1–P3–Ni2 81.1(2), Ni1–P4–Ni2 81.3(2). The distances in molecule 2 correspond to the values given above within the standard deviation.

(220—225 pm) and the values for a P—P double bond in sterically protected free diphosphenes (200—205 pm).[8] This is analogous to the C—C bond in alkyne complexes such as $[(cod)Ni]_2(CPh)_2$[9] and supports the resonance structure **D**.[10]

Table 1. $^{31}P\{^1H\}$-NMR data for the diphosphene and phosphorus complexes. Standard: 85% H_3PO_4, high-field signals have negative signs, $\delta \pm 1$ ppm; $J \pm 1$ Hz.

	Solvent [a]	$\delta(^{31}P)$ (chelate)	$\delta(^{31}P)$ (P_2R_2)	J(PNiP) [b]
2a	Tol	+58 (t)	−101 (t)	28
2b	Tol	+76 (t)	−103 (t)	24
3b	THF	+72 (t)	− 30 (t)	28
4a	Tol	+53 (t)	+ 55 (t)	25.5
4b	THF	+68 (t)	+ 39 (t)	20
4c	THF	+52 (t)	+ 66 (t)	21
5a	Tol	+58 (t)	− 19 (t)	30
5b	Tol	+75 (t)	− 34 (t)	27
		$\delta(^{31}P)$ (chelate)	$\delta(^{31}P)$ (P_2)	J(PNiP) [c]
6a	Tol	+55 (t)	+133 (q)	33
6b	Tol	+67 (t)	+135 (q)	27.5
6c	Tol	+48 (t)	+161 (q)	28

[a] Tol = toluene, THF = tetrahydrofuran. [b] AA'XX' spectra, $J(PNiP) = 1/2|cis\text{-}^2J(AX) + trans\text{-}^2J(AX')|$; since $^1J(PP) \gg$ all $^2J(PNiP)$, two pseudo triplets result, which do not allow a further calculation of the coupling constants. [c] $A_2A'_2XX'$ spectra, J(PNiP) as for [a], pseudo triplet and pseudo quintet; further calculation of the coupling constants not possible.

The $^{31}P\{^1H\}$-NMR spectra are most useful for the characterization of the diphosphene and diphosphorus complexes.[11] As shown in Table 1, **2**—**6** exhibit simple splitting patterns. The signals of the diphosphene ligands show significant downfield shifts relative to those of P-containing three-membered rings,[12] which correspond to the resonance structure **A**. However, the signals of the diphosphene ligands lie at much higher field than those of free diphosphenes.[8] The signals of the P_2 ligands (see Table 1) exhibit a downfield shift of 350—450 ppm relative to those of $P_4[N(SiMe_3)_2]_2$.[7] Thus, the resonance structure **D** should not be neglected.

Experimental Procedures

2a [Reaction (1)]: A solution containing 4.7 g (15 mmol) of $LiP(SiMe_3)_2 \cdot 1.8\,THF$ (THF = tetrahydrofuran) is slowly added under argon to a stirred suspension of **1a** (2.5 g, 7.5 mmol) in 50 mL of toluene at −30°C. After 2 d at −20°C, the reaction mixture is slowly warmed to 20°C and filtered, and the solvent is removed *in vacuo*. Fractional crystallization from pentane at −78 and −20°C affords reddish brown crystals of **2a** (1.31 g, 37%). **2b** is synthesized analogously from **1b** (2 g, 3.6 mmol) and $LiP(SiMe_3)_2 \cdot 1.8\,THF$ (2.26 g, 7.2 mmol). After evaporation of the solvent, the residue is washed with pentane until a yellow powder remains. Recrystallization from toluene at −20°C gives yellow crystals of **2b** (0.69 g, 28%).

4c [Reaction (3)]: A suspension of **1c** (2 g, 3.8 mmol) in 20 mL of THF and $[(t\text{Bu})(Me_3Si)P]_2$ (1.22 g, 3.8 mmol) is heated under argon to 50°C for 20 h. After removal of the solvent in vacuo at 20°C, the residue is recrystallized from toluene at −20°C. Yield: 1.45 g **4c** (60%), orange crystals.

5b [Reaction (2)]: A suspension of **1b** (2 g, 3.6 mmol) in 60 mL of THF and $PhP(SiMe_3)_2$ (1.83 g, 7.2 mmol) is stirred under argon for 10 d at 20°C. The solvent of the suspension (green solid, greenish yellow solution) is evaporated in vacuo at 20°C. Recrystallization of the residue from CH_2Cl_2 at −20°C affords **5b** (1.12 g, 44%), yellow crystals.

6a [Reaction (6)]: A suspension of **1a** (2 g, 6 mmol) in 60 mL of THF and $HP(SiMe_3)_2$ (2.13 g, 12 mmol) is stirred under argon for 2 h. After removal of the solvent in vacuo at 20°C, the residue is recrystallized from pentane at −20°C. Yield: **6a** (1.04 g, 59%), brown crystals.—**6c** is obtained analogously from **1c** (5 g, 9.5 mmol) and $HP(SiMe_3)_2$ (3.37 g, 19 mmol) in 130 mL of THF. The reaction mixture is concentrated to half of its volume in vacuo at 20°C, cooled to −78°C for 2 d, and filtered. The mother liquor is evaporated in vacuo at 20°C and the residue recrystallized from toluene at −20°C. Yield: 1.86 g **6c**·**3toluene** (31%), brown crystals.

Chem. Soc. Chem. Commun. 1977*, 930.

[10] The Ni—Ni distance in **6a** is appreciably longer than in $[(cod)Ni]_2(CPh)_2$ (262 pm),[9] since the fold angle in **6a** is larger and the Ni—P bond is longer than the Ni—C bond in $[(cod)Ni]_2(CPh)_2$. Thus, no direct Ni—Ni interaction needs to be assumed in **6a**.

[11] All diphosphene complexes isolated so far can be evaporated in vacuo without noticeable decomposition, so that the molecular peaks in the mass spectra show reasonable relative intensities. The P_2 complexes **6a**—**c** exhibit the molecular peaks with only minor intensities, if at all.

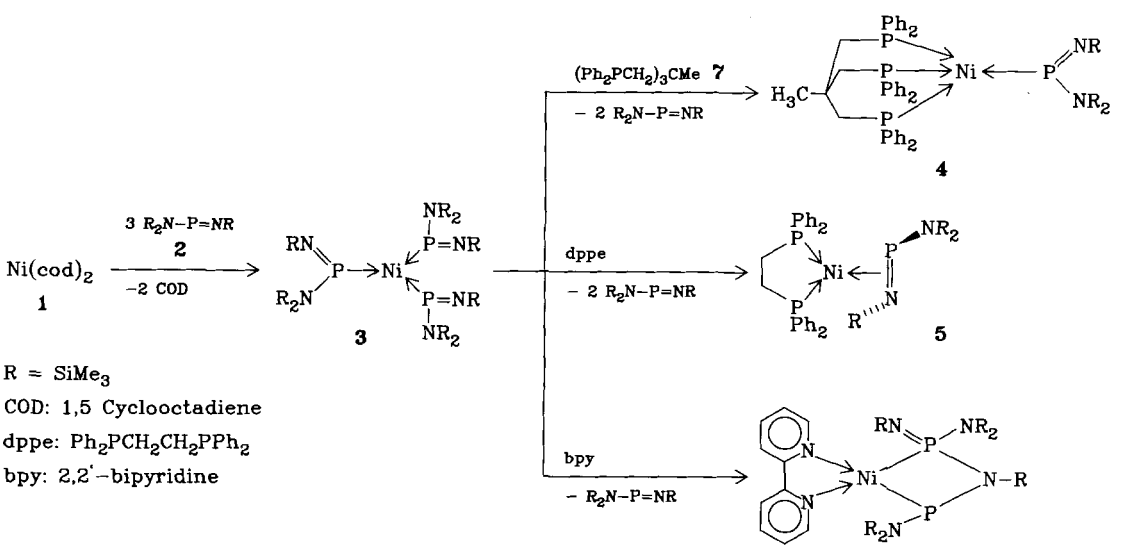
Chelate Ligand-Controlled η^1-η^2 Change of Coordination in Amino(imino)phosphane Ligands and Their Conversion into a Nickelaazadiphosphetidine

By *Otto J. Scherer*,* *Richard Walter* and *William S. Sheldrick*

Amino(imino)phosphanes, compounds containing triply bonding phosphorus of coordination number two, are versatile ligands.[1,2]

Reaction of the nickel complex **1** and the amino(imino)phosphane **2** (molar ratio 1:3) affords the synthetic building block **3** with terminal P-coordination of the ligand **2**. The tridentate ligand **7** reacts with **3** such that the η^1-type coordination of the amino(imino)phosphane ligand is retained in **4**, whereas in the reaction of **3** with dppe to give **5**, a change of coordination from the η^1- to the η^2-type of coordination takes place.[3] **5** is the first example of a compound containing a classical side-on coordinated P=N ligand.[4,12] The reaction is steered in a completely different fashion by bpy. Two P=N functions form, via coupling of a P–N bond, the nickelaazadiphosphetidine **6**, the first P_2N_2 four-membered ring[5] in which a nitrogen atom is replaced by a metal atom (Ni). **3**, **4**, and **6** form dark red to brownish-black crystals, while **5** forms yellowish-orange crystals;[6] in each case the crystals are readily soluble in benzene, moderately (**3** and **4** readily) soluble in pentane, and only very sparingly soluble in acetonitrile.

The $^{31}P\{^1H\}$-NMR signal (Table 1) of the π-bonded –P=N– ligand in **5** is shifted upfield by about 260 ppm compared to that of free **2** ($\delta = 327$), the largest shift so far observed in the case of coordinated amino(imino)phosphane ligands (cf. the upfield shift of ca. 155 pm in the case of μ_3-η^2 coordination[2]). One of the two R_2N groups of **6** exhibits hindered P–N rotation at room temperature.



The crystal structure analysis[7] shows that **2** is side-on coordinated in **5** (Fig. 1) and that its *trans* arrangement at the P=N-bond is retained. The characteristic structural data of the free ligand **2** (P=N 1.545(2), P–N 1.674(1) Å, NPN 108.4(1), PNSi 129.9(1)°[8]) are changed by the coordination as follows: P=N(P1–N2) is about 0.101 Å longer, P–N(P1–N1) about 0.063 Å longer. The N1–P1–N2 angle, with a value of 109.1(1)°, remains virtually unchanged; P1–N2–Si2 (125.2(2)°) is ca. 5° smaller. The Ni–P distance differs only very slightly from that of the side-on coordinated R–P=P–R ligand to the Ni.[9] The bending angles between P1,N2 and the planes Si2,N2,P1 and N1,P1,N2 away from the nickel atom are 42.3° and 12.3°, respectively. Ni is almost planar coordinated (dihedral angle P1,Ni1,N2/P3,Ni1,P4 3.4°).

In the case of **6** (Fig. 2) the crystal structure data[7] indicate a somewhat more pronounced tetrahedral distortion (P1,Ni1,P2/N5,Ni1,N6 8.8°). The ring-P–N distances and angles are comparable with those of *trans*-$(R_2N-PN-R)_2$,[10] the dimer of **2**, whereas the corresponding exocyclic distances and angles lie in the normal range found for diazadiphosphetidines.[5] The N2–Si2

[6] Preparation of **3**–**6**; **3**: A solution of **2** [11] (1178 mg, 4.23 mmol) in toluene (1 mL) was added dropwise at room temperature to a stirred suspension of **1** (388 mg, 1.41 mmol) in toluene (4 mL) and the mixture stirred for a further 20 min. Such solutions were then used for further reactions. **3** crystallizes out (sometimes difficult) in 8 d at –78 °C in the form of red crystals. These were washed with 2 mL of cold toluene and dried under vacuum (oil-pump). Yield 416 mg (33%). **4**: **1** (262 mg, 0.95 mmol) was allowed to react with **2** (796 mg, 2.85 mmol) in benzene—under the same conditions as for **3**—and then the solution was treated with 594 mg (0.95 mmol) of 7 at room temperature. The reaction mixture was stirred for a further 20 min, the solvent and COD removed in vacuo, and the residue recrystallized from 4 mL acetonitrile/1 mL toluene at ca. –20 °C (2 d). The reddish-black crystals thus obtained were washed twice with 4 mL CH_3CN and dried in vacuo. Yield 705 mg (77%). **5**: **1** (280 mg, 1.02 mmol) and **2** (853 mg, 3.06 mmol) were allowed to react under the conditions described for **3** and the reaction mixture was then treated with a solution of 406 mg (1.02 mmol) of dppe in benzene (3 mL) at room temperature. The work-up procedure was the same as in the case of **4**. The residue was treated with 10 mL pentane, with stirring, whereupon **5** precipitated as a yellow powder. Subsequent washing of the precipitate with ca. 20 mL pentane and recrystallization from CH_2Cl_2/CH_3CN (1:1, ca. –20 °C, 2 d) furnished 532 mg of **5** (71%). **6**: **1** (215 mg, 0.78 mmol) and **2** (653 mg, 2.34 mmol) were allowed to react, as described for **3**, and then treated with 123 mg (0.78 mmol) bpy at room temperature. After work-up—in the same way as for **4**—the brownish-black residue was taken up in 5 mL pentane and allowed to stand for 1 d at –78 °C. The brownish-black crystals that separated out (yield 512 mg (85%) of **6**) were recrystallized from toluene/acetonitrile (5:2, 3 d, ca. –20 °C).
[7] **5**: $P2_1/n$, $a = 11.543(3)$, $b = 10.655(2)$, $c = 32.074(4)$ Å, $\beta = 91.87(2)°$, $Z = 4$, $\rho_{calc} = 1.24$ g cm^{-3}. 5141 independent reflections, 3960 observed ($Mo_{K\alpha}$, $F_0^2 \geq 2.0\sigma(F_0^2)$, $2\theta \leq 45°$); $R = 0.049$, $R_w = 0.042$. **6**: $P\bar{1}$, $a = 13.270(2)$, $b = 14.185(2)$, $c = 11.599(2)$ Å, $\alpha = 92.55(1)$, $\beta = 91.61(1)$, $\gamma = 96.99(1)°$, $Z = 2$, $\rho_{calc} = 1.18$ g cm^{-3}. 5843 independent reflections, 3754 observed ($Mo_{K\alpha}$, $F_0^2 \geq 2.0\sigma(F_0^2)$, $2\theta \leq 45°$); $R = 0.053$, $R_w = 0.041$. Wood Chemistry, Ultrastructure, Reactions. By *D. Fengel* and *G. Wegener*. de Gruyter, Berlin 1984. xiii, 613 p., bound, DM 245.00.–ISBN 3-11-008481-:

This book by the Munich wood researchers fills a gap. Since the appearance of *Wenzl*'s "The Chemical Technology of Wood" in 1970 and of *Sjöstrom*'s short "Wood Chemistry" in 1981 no competent author has produced a comprehensive treatment of the chemistry and ultrastructure of wood.

This work by *Fengel* and *Wegener*—without any other coauthors—consists of a presentation of the latest state of the subject area named in the title. This effort alone, backed up by many references (up to 1983), commands respect. The English text is clear and understandable. The numerous tables, diagrams and excellent electron micrographs increase the vividness.

The content and emphasis of the work can be seen from its division into 18 chapters: 1. Introduction (5 p.), 2. Structure and ultrastructure (20 p.), 3. Chemical composition and analysis of wood (40 p.), 4. Cellulose (40 p.), 5. Polyoses (hemicelluloses) (26 p.), 6. Lignin (50 p.), 7. Extractives (45 p.), 8. Distribution of the components within the wood cell wall (13 p.), 9. Constituents of bark (28 p.), 10. Reactions in acidic medium (28 p.), 11. Reactions in alkaline medium (23 p.), 12. Influence of temperature (26 p.), 13. Degradation by light and ionizing rays (28 p.), 14. Microbial and enzymatic degradation (28 p.), 15. Aging and fossilization (7 p.), 16. Pulping processes (68 p.), 17. Derivatives of cellulose (44 p.), 18. Utilization of wood and wood components for chemicals and energy (41 p.). The very comprehensive index (19 p.) is completed by a compilation of wood types categorized according to the properties treated in the text (26 p.) and a list of the bacteria and fungi described (2 p.).

The size of the book is just sufficient to cover the topics adequately according to their importance. Students of wood science are presented with sufficient information for graduation and the specialist is aided by an almost complete reference list of the newer literature. The clear division of the material allows a rapid familiarization with specialist areas and makes the book of utility to non-specialists who wish to inform themselves about an area of wood chemistry. The treatment is deliberately not historical, that is, most of the references cited come from the years after 1960. The interested reader must come indirectly to earlier pioneering publications. The authors are very sparing in their evaluations and occasionally leave the beginner in some confusion, as for instance when the various models of the organization of cell wall components (Figs. 8-5 to 8-7) or the gas yields on pyrolysis (Figs. 12-20 and 12-21) are presented without commentary. In general it would have been of advantage to differentiate the fundamental somewhat more emphatically from the preliminary and speculative.

This book contains an astonishingly small number of printing errors and few mistakes and deficiencies: Thus it would have been preferable to reproduce the structural formulas of all the compounds mentioned. The formation of condensed tannins (p. 209/211) and the peeling-off reaction (p. 297) remain unclear to non-chemists. The role of B_2O_3 in the modified sulphate process (p. 446) and the importance of crosslinking reactions for the textile industry (Chapter 17) are worthy of a more comprehensive treatment. Individual mistakes (particularly confusing "preceded" instead of "succeeded" on p. 430) should be corrected in a later edition.

The above remarks apply only to a small fraction of the book. All in all this work is greatly to be recommended and should be included in every specialist library. It is to be hoped that, despite its high price, it also comes into the hands of all who are interested in wood and wood chemistry.

Principles of Peptide Synthesis. By *M. Bodanszky*. Springer-Verlag, Berlin 1984. xvi, 308 pp., bound, DM 148.00.—ISBN 3-540-12395-4

It should be said right from the start—this book is a welcome enhancement of the literature available in the highly topical field of peptide chemistry. This enhancement can best be substantiated by a comparison:

The chemistry student learns to estimate the reactivity of molecules by formulating the mesomeric structures from which the reactions can be deduced. But, at the same time, he learns that every mesomeric structure is of itself only a formalism—the molecular reality lies somewhere between all these mesomeric forms.

This collection of principles from the field of peptide synthesis represents such a mesomeric form for the presentation of the topic—important and admissible alongside many other more topical reviews which for their part mostly only describe the newest advances or one single aspect, e.g. the Merrifield Synthesis. It is all these contributions taken together which yield a proper picture of the state of the art in the field of peptide chemistry.

Judging by the method of presentation "Principle Problems of Peptide Synthesis" would have been an apt title for the book. The author describes a wealth of beautiful organic chemistry, side reactions and the limits of peptide synthesis, not only in the chapters intended for this but scattered throughout most of the specialist sections. The experienced peptide chemist finds an excellent collection of information about the problems, plentifully supplied with mostly older references in which a certain egocentricity and one-sidedness in the choice is unmistakable. However, a novice coming to this book will be turned away from peptide chemistry rather than drawn to it because of the numerous, certainly technically correct discussions of problems. It would certainly have been more useful to have clearly emphasized a few essential principles, perhaps furnished with short, quantitative experimental details. For the rest the text is precise and the discussions comprehensive. The fact that the mechanistic arrows have occasionally been omitted from the formulas even though they are necessary for instructional purposes (e.g. p. 14) does not do justice to the clarity of the rest of the book. In addition, a whole range of typographical errors, and that not just in the text, ought to have been removed from the monograph.

Finally, it must be said that this work should be included in the libraries covering the sphere of activity which includes peptide synthesis if only because this book emphasizes the often misunderstood, delicate and easily rearranged nature of peptides—a facet to which at the moment only cursory attention is paid by many molecular biologists.

Consequences of Strain for the Structure of Aliphatic Molecules

By Christoph Rüchardt* and Hans-Dieter Beckhaus

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

The chemist is accustomed to deriving structures and preferred conformations of organic compounds from rigid molecular models and standard values for bond lengths, bond angles, and torsional profiles. In the case of strained compounds, this rigid structural model has to be abandoned and replaced by a flexible one which takes individual conditions of strain into consideration. It is shown, on the basis of new experimental structural data, that the force field method is suitable and highly reliable for the calculation of structural parameters and preferred conformations of strained compounds. It is, therefore, capable of replacing the rigid molecular model. Furthermore, the systematic analysis of strain induced angle and bond deformation gives a new pivot for the development of a qualitative discussion of deformation in strained molecules and hence for improved conformational analysis.—In the course of this work we were able to isolate two rotamers of D,L-3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexane; this is the first isolation of a rotamer pair of an aliphatic hydrocarbon.

1. Introduction

Probably the most important concept in the whole of chemistry is that of molecular structure. The properties of matter are connected with it, and discussions of reactivity are based on the molecular structures of the reaction partners.[1, 2] Hence, the development of structural models is of central importance.

Additivity rules have been developed for a uniform description of the structural data[3] and thermodynamic quantities of numerous organic compounds.[4, 5] These enable a calculation of molecular properties from increments for the atoms and groups involved. In this context, standard bond lengths and bond angles are used, and ideal conformations with a staggered arrangement of the groups on neighboring tetracoordinated carbon atoms with a 60° torsional angle are assumed. Individual deviations from the standard values caused by conjugational effects can be taken into account with the aid of correction factors[5] as regards both geometry and thermodynamic properties.

Structural models based on this simple concept allow the discussion of reactivity without having to analyze experimentally the structures of whole series of compounds. However, this simple additive and hence rigid structural model rapidly reaches its limits when used to explain steric effects on reactivity.[6–8] The deliberately pragmatic concept "steric effects" incorporates phenomena arising from individual structural properties of the reactants and the activated complexes. If the result of a steric effect is a change in the activation enthalpy,[9] it can be described by the model quantity "strain enthalpy H_s".[10] This is defined as the difference between the enthalpy of formation of a real

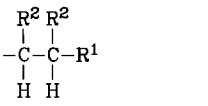
molecule, ΔH_f° (g), and a norm or standard value ΔH_f^N calculated from group increments.[10]

Strain can result, for example, from ring formation or repulsion between non-bonded atoms and is associated with changes in the geometric parameters of a molecule, i.e. bond lengths, bond angles, and torsional angles, with respect to the standard values.[11,12] Therefore, the rigid structural model breaks down in the treatment of steric effects,[13] and the question is posed as to the alteration of bond lengths and bond angles under the influence of strain.[6-8,11,12] Consequences for the conformational behavior can also be expected as a result of the deformability of the molecular framework; the fundamental rules of conformational analysis are based on the rigid structural model.

The study of steric influences is of increasing importance not only in organic chemistry. Studies of the relationships between structure and activity of drugs attest to intermolecular effects as one of the reasons for the high selectivity of biochemical recognition processes, which have been described, inter alia, as docking processes between an active substance and its receptor.[14,15] As another example, special material properties of polymers resulting from preferred conformations in a polymer chain should be mentioned. These in turn are determined by steric effects.[16] In these and many other cases only a flexible structural model which requires variation of the structural parameters as well as knowledge of the dynamic behavior of organic molecules subjected to internal or external strain, is applicable.



Hitherto, the investigation of highly strained compounds has largely been confined to monocyclic and polycyclic small ring compounds,[11] the rigid skeletons of which permit the evaluation of angle deformations and preferred conformations. In this review we summarize the structural investigations of highly branched open chain carbon skeletons, which are in part characterized by very high strain enthalpies. Therefore, the extent and consequences of the deformability of these molecular structures are particularly readily perceived.[17-31] Because of the inherent flexibility of the open chain framework, predictions about the extent and nature of the deformation can hardly be made in the realm of classical conformational analysis.[13]

In order to answer the question posed, experimentally derived structural parameters of strained compounds are required. These also permit an extension of the parameter basis of empirical force field methods[32-34a] to include strongly deformed and highly strained compounds. Their application to strongly deformed molecules permits an evaluation of the usefulness of the various empirical force fields as regards dynamic behavior and deformability of molecular structures under the influence of strain. Therefore, these evaluations will also answer the question whether the rigid structural and thermodynamical increment model for aliphatic molecules can be replaced. In this context *Mislow*'s comparison of the X-ray structure of the propeller-like molecules trimesitylmethane and the result of a force field calculation was a pioneer work[34b]. The increasing use of empirical force field (EFF) calculations in the quantitative analysis of structure reactivity relationships[35] makes a demanding test all the more essential. We will use the experimental structural data of strained representatives of the classes of compounds **1**—**8** (Table 1) as test cases.

2. Synthesis

The sixfold (C_q–C_q) and fourfold (C_t–C_t) symmetrically substituted ethanes **1**—**8** were mostly synthesized by dimerization of the "half" molecules. These were obtainable either by Wurtz type reactions[26,36-39] [e.g. Reaction (a),[26] (b),[19]] or by dimerization of thermally or photochemically

In general, the yields were higher for phenyl-[19,39] or cyano-substituted[28] compounds than for unsubstituted alkanes[36] because in the latter case radical disproportionation often predominated. The highest yields were obtained when β-hydrogen atoms were absent in the radicals concerned, because in these cases disproportionation was no longer possible.[20,40] The peroxide-induced oxidative dimerization gave, as expected, particularly good yields of dimers when capto-datively substituted radicals were involved.[43] The *oxidative* dimerization of enolates or enol ethers proved less broadly applicable than expected.[29] The reductive dimerization of geminal dibromides [Reaction (h)[44]] proved to be an excellent strategy for the synthesis of the highly strained molecules tetra-*tert*-butylethane (3,4-di-*tert*-butyl-2,2,5,5-tetramethylhexane), **5g**,[44] [H_s(exp) = 66.3 kcal/mol] and 1,2-diadamantyl-1,2-di-*tert*-butylethane (3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexane) [**5**, R^1 = 1-adamantyl, R^2 = *t*Bu; H_s(MM2) = 72.9 (*meso*) or 73.3 (D,L) kcal/mol].[40]

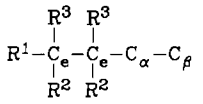
3. Force Field Calculations of Strained Molecules

Strain enthalpies of interest for the discussion of strain effects on structure were obtained by force field calculations[7b] on numerous representatives of compound classes **1**–**8** and compared with experimental values derived from combustion calorimetry.[7b] In general, the agreement between calculated and experimental values was excellent; only in the case of the most highly strained compounds, e.g. tetra-*tert*-butylethane **5g**,[44] was a discrepancy of a few kcal/mol found. The validity of the calculated strain enthalpies was also seen in the successful quantitative analysis of the thermal decomposition of the compound classes **1**–**8**.[6,7] Here, radical formation is associated with a decrease in strain and a gain in conjugational energy. These results have been reported elsewhere.[7]

Force field calculations not only give heats of formation, ΔH_f°(g), but also predict structural data for organic compounds.[32] The reliability of the computational results is well documented within the range of parametrization, not however for compounds which, because of high strain, fall outside this range. This is the case for most of the compounds given in Table 1.[7]

The potential of the force field method in structure determination can be evaluated by comparison of its predictions with the experimental structural data for highly strained compounds; these have been worked out in recent years by crystal structure analyses. In Table 1, only selected characteristic structural parameters are given from which the influence of strain on the structure can be derived. These are, on the one hand, the bond lengths from the central carbon atom in the ethane skeleton (C_e), and, on the other, the bond angles at the central atoms C_e and the carbon atoms in the α position C_α. The bond lengths C_e–C_e and C_e–C_α are lengthened to up to 164 pm—in the record case, 2,3-di(1-adamantyl)-2,3-dimethylbutane **1d**, there are three neighboring bonds of this length. The bond angles at the tetracoordinated carbon atoms in these positions are also increased to a maximum of 123°. These are clear signs of significant molecular strain.



We have carried out calculations of the strain and structures for all compounds in Table 1 using the MM2 force field of *Allinger*.[45] Of the several force fields tried for **1b**, this one gave results in closest agreement with the experimental data.[22] We have extended the force field with the necessary parameters to include alkyl benzenes,[46] nitriles,[28] and carboxylic acid esters,[29] and correspondingly modified the MM2 program for alkylcyclopropanes.[18]

The structural data obtained with the extended MM2 force field just described are given in Table 1 together with the experimental results. Furthermore, for each compound the calculated strain enthalpy H_s is given.[7b] A comparison shows that even pronounced molecular deformations created through high molecular strain are well reproduced by the calculation. Only the values calculated for extremely elongated bonds are somewhat too short (see e.g. **2d**, **4a**, **4b**, **5c**). If packing effects on the crystal structure are also taken into account (this, of course, not being possible in the force field calculations on isolated molecules) the data in Table 1 demonstrate the high reliability of the EFF calculations for the structural types investigated here. This could not have been predicted, since up until now highly strained compounds such as those given in Table 1 had not been used in the parametrization of the MM2 force field.[32,45] The reliability of the MM2 force field in calculating structures of sterically strongly deformed compounds justifies the use of computational structural data in the discussion of the relationships between structure and strain.

4. The Breakdown of the Additive Structural Model through Strain Induced Deformation

The results in Table 1 clearly show that in the case of strained compounds whose heats of formation no longer can be verified by simple increment calculations, also the

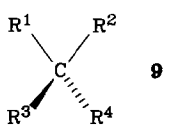
[a] Computational value using the MM2 force field according to *Allinger* et al. [45] with extensions [28, 29, 46]. [b] Experimental values from enthalpies of combustion and sublimation (MM2 computational values in parentheses) [49]. [c] C_α belongs to the group R^1 unless otherwise indicated. [d] Electron diffraction experiments. [e] C_α belongs to the group R^2. [f] Ring strain is subtracted: H_s(cyclopropane) = 28.12, H_s(adamantane) = 7.9 kcal/mol. [g] Two independent molecules are present in the crystal. [h] Derived from the *p-tert*-butyl derivate. [i] See Figures 4 and 5 for a designation of the rotamers **5e** and **5f**. [k] Calculated using the force field described in reference [49].



structural parameters strongly deviate from the norm, i.e. bond angles, bond lengths, and torsional angles. However, common traits can be perceived from the structures of the strained four- and six-fold substituted ethanes. These can be used as guidelines in the interpretation of the structures of other branched molecules. The generalizations reached

in the rigid structure model by the standardization of bond lengths and bond angles have been lost again in favor of individual structural parameters for each molecule. Such phenomena are successfully taken into account by the force field method, which therefore pragmatically becomes the basis for a flexible structural model. The realization that molecular strain can be spread over large areas rather than localized in individual bond lengths or angles, is almost trivial but extremely important in this context. Many internal coordinates change in order to evade repulsive van der Waals interactions between neighboring atoms within the molecule. Each individual deformation is compensating for only a small part in the total strain. For example, the elongation of a C–C bond to 160 pm is calculated as requiring an energy of less than 2 kcal/mol.[50]

4.1. Angle Deformation

From vibrational spectroscopy it is known that angle deformation is energetically more favorable than bond elongation: the stretching vibrations have larger force constants. Furthermore, and more importantly, a bending vibration is more effective in separating two groups than is simple bond stretching. *The preference for angle deformation over bond stretching* is impressively demonstrated in Table 1 by comparison of the fourfold substituted ethanes (C_t–C_t series **5**–**7**), with the sixfold substituted ethanes (C_q–C_q series **1**–**4**). In the first series the four residues evade mutual repulsion by increasing the C_e–C_e–C_α angle at the central tertiary carbon atom and simultaneously decreasing the C_e–C_e–H angle. This is much more difficult to achieve for the six residues in the C_q–C_q systems **1**–**4** because each C–C–C angle enlargement results in compression of another C–C–C angle in the center of the molecule (see however **1d**). The C_q–C_q systems, therefore, evade repulsion by more pronounced bond extension.

Table 2. Strain and angle opening caused by geminal repulsion in methanes **9** with two, three or four substituents (EFF calculations) [a].

9

	R^1	R^2	R^3	R^4	α [°]	H_s [kcal/mol]
9a	Me	Me	Me	Me	109	0.0
9b	Me	Me	H	H	113	0.0
9c	Ph	*t*Bu	H	H	114	0.7
9d	Et	*t*Bu	H	H	117	1.6
9e	*t*Bu	*t*Bu	H	H	125	7.4
9f	*t*Bu	*t*Bu	Me	H	121	13.9
9g	*t*Bu	*t*Bu	Me	Me	118	21.6

[a] Calculated according to the MM2 force field [45, 53, 54] extended to include alkyl benzenes [46].

The interplay between the relative space-filling property of the four residues at a four-coordinated carbon atom and the deformation of its geminal bond angles is seen in the case of the alkylated methanes **9** in Table 2. It is noteworthy that the central carbon atom in neopentane, **9a**, having four identical residues (R^1–R^4 = CH_3), adopts the ideal tetrahedral structure. The central C–C–C angle in propane, **9b**, is increased to 113° by the small repulsion between the two methyl groups. Thus, the C–C–C angle deformation in **9** depends less on the total strain and more on the difference in size between the four residues R^1–R^4. Di-*tert*-butylmethane (2,2,4,4-tetramethylpentane), **9e**, has a relatively small strain energy of 7 kcal/mol and has a C–C–C angle of 125° (according to crystal structure analysis: 124–126°).[51, 52] **9e** represents a rare case of a single internal coordinate carrying a high proportion (ca. 40%) of the total strain; according to MM2 ca. 3 kcal/mol is required for this degree of angle deformation.[45b]

The space-filling property of a group, which is decisive in geminal repulsion, is strongly dependent on shape, as seen in the comparison between ethyl and phenyl groups in **9c** and **9d** (Table 2). The larger and heavier phenyl group leads to less strain and a smaller C–C–C angle than does the smaller ethyl group in the presence of a geminal *tert*-butyl group.

The result is that the bond angles of the tetravalent carbon atom easily adapt to the space-filling requirements of the four substituents.

If the angle deformations of the highly branched ethanes shown in Table 1 are considered in this context, then again a clear correspondence with size and shape of the substituents R^1, R^2, and R^3 is seen. The large difference in size between H and an alkyl group results in the particularly large angle deformations already mentioned in the C_t–C_t-ethanes. It is somewhat smaller in the diarylethanes **6** and in dicyclohexenylethane **7**. Thus, the 1-cyclohexenyl residue, which is joined through a trigonal carbon atom, is more similar to the planar phenyl group than to the cyclohexyl ring as regards geminal repulsion. The quaternary centers in the C_q–C_q series **1**–**4** are, in general, less distorted, but here, too, differences in size determine the distortion pattern. In the most strongly strained compound **1d** the central bond angle is increased to almost 120°.

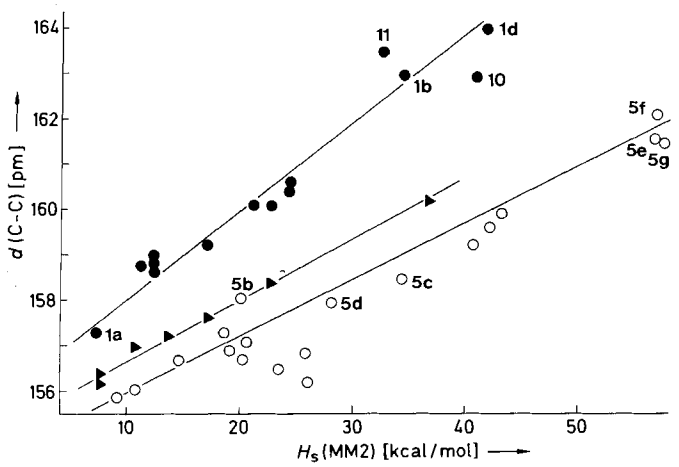
As shown for di-*tert*-butylmethane **9e** in Table 2, a secondary CH_2 center is particularly easily deformed as a result of steric pressure from geminal groups. The large C–C–C angles at the α-carbon atoms in the alkyl side chains of **1** are also a consequence of this phenomenon.

Increased angles caused by geminal repulsion decisively determine the conformational behavior of branched hydrocarbons. This will be further elaborated in depth in Section 5.

4.2. Bond Elongation

The steric repulsion in compounds **1**–**7** leads not only to angle deformation but also to bond lengthening. As expected from the preceding discussion, bonds between more highly alkylated, e.g. quaternary, carbon atoms are more strongly affected than those between tertiary or even secondary carbon atoms. This is shown in the graph in Figure 1. The correlation between central C–C bond length and strain enthalpy shows a steeper slope for C_q–C_q than

for C_q-C_t alkanes, and the smallest slope is found for the C_t-C_t series.



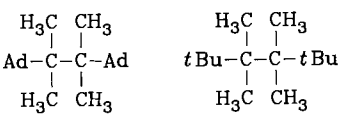


Fig. 1. Dependence of C–C bond length, d(C–C), on molecular strain, H_s(MM2), in various alkanes. ○ $R^1R^2CH-CHR^1R^2$ (C_t-C_t) [37, 40], ● $R^1R^2R^3C-CR^1R^2R^3$ (C_q-C_q) [36, 40], ▲ $(CH_3)_3C-CHR^1R^2$ (C_q-C_t) [53].

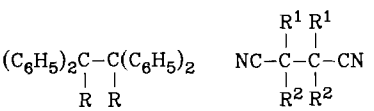
In the first two of these series, the length of the central C–C bond is surprisingly linearly dependent on the total strain of the system. Apparently, the two molecular halves constitute approximately equal steric domains and lead to qualitatively similar and only quantitatively different deformation of the molecules within each series. The proportion of the total strain manifested in the form of bond elongation is either constant or linearly related to the total strain within each series. Exceptions are found in the C_q-C_q series only for most highly strained compounds, viz. 2,2,3,3,4,4,5,5-octamethylhexane **10**, 3,3,4,4-tetraethylhexane **11**, and 2,3-di(1-adamantyl)-2,3-dimethylbutane **1d**. This is not surprising considering that in these C_q-C_q alkanes strongly deformed $C_q-C_q-C_\alpha$ or $C_q-C_\alpha-C_\beta$ bond angles are also present (see Table 1 and Section 4.1).

1d **10**



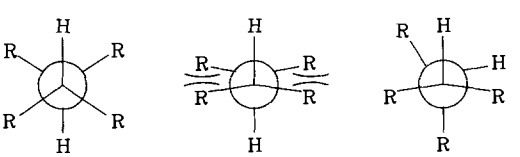
$(C_2H_5)_3C-C(C_2H_5)_3$ **11**

Ad = 1-adamantyl

The longest C–C bonds ever measured experimentally in acyclic systems are found in 2,3-di(1-adamantyl)-2,3-dimethylbutane **1d** (164.7, 164.0, and 163.9 pm).[12] Moreover, these bonds are immediate neighbors[26] (Table 1). The good agreement between experimental and calculated (MM2) values is noteworthy. The central C_q-C_q bond in the structurally related octamethylhexane **10**[36] is comparatively shorter (MM2 value 162.9 pm). Apparently, the more flexible *tert*-butyl group permits a stronger molecular deformation by means of angle opening than does the polycyclic adamantyl skeleton. The question as to the inherent limit of bond elongation has often been posed and finds a general answer here: the multifarious deformability of alkyl chains prevents further elongation of bonds in acyclic molecules. Of the total strain in **1d** (over 40 kcal/mol) only about 3 kcal/mol is manifested in the form of elongation of the central bond to a total of 164 pm.[45b,50] Thus, even in the C_q-C_q ethanes, only a very small part of the total strain is reflected in the lengthening of the central bond.

In contrast to the C_q-C_q and C_q-C_t series, a less direct relationship between central bond length and strain enthalpy is found in the C_t-C_t series[37] (Fig. 1). In particular, the compounds with linear side chains have shortened central bonds because strain is readily relieved through angle deformation at the methylene groups in the side chains (see Section 4.1).

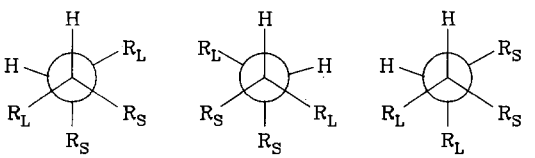
As already shown in another connection, the linear correlation for the C_q-C_q series (Fig. 1) is also valid for phenyl, cyano, and otherwise substituted compounds,[7] although with a somewhat larger spread. In this context it is of interest that comparatively short central C–C bonds are found in the compound classes **3** and **12** with planar phenyl or linear nitrile groups. Apparently, these substituents increase the opportunities for angle deformation.



12 **3**

In view of these findings it is understandable that the length of a bond is no criterion for its strength.[7] The bond broken in a homolysis reaction is the one leading to the less strained and more stabilized radical, as evidenced by us in detailed kinetic studies. Also in compound **1d** the somewhat shorter central bond is clearly weaker than the longer neighboring C_e-C_α bond.[26]

5. Preferred Conformations



Angle deformation caused by repulsion between geminal groups has direct consequences for the preferred conformations.[6,37] Although the angle deformations typical for the C_t-C_t alkanes **5** (see Section 4.1) decrease geminal repulsion, they increase vicinal repulsion in the *anti* conformation as seen from the Newman projection of the en-

13 **14** **15**

vironment of the C_t-C_t bonds in **13** and **14**. In the conformation **15** with *gauche* hydrogens, the groups R can adopt positions minimizing both vicinal and geminal repulsion. Thus, according to force field calculations, the *anti* ro-

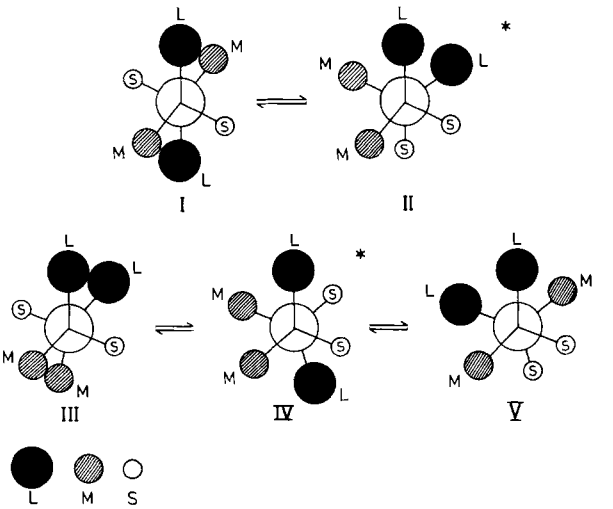
tamer of 1,2-di-*tert*-butyl-1,2-dicyclohexylethane (3,4-dicyclohexyl-2,2,5,5-tetramethylhexane) is 10 kcal/mol less stable than the preferred *gauche* conformation.[22,37] This difference is even more extreme in the case of tetra-*tert*-butylethane **5g**[33,44,55] or the isomeric 3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexanes,[40] which prefer *gauche* conformations similar to **15** in which vicinal hydrogens and R-groups are almost eclipsed. It is still an open question why structures with non-alternating Newman projections have not been found so far. Their occurrence in tetra-*tert*-butylethane, **5g**, was suggested originally by *Mislow* et al. on the basis of earlier force field calculations.[55c] Even in 2,3-dimethylbutane, **5a**, the *gauche* conformation **15** ($R=CH_3$) is slightly preferred.[37,48] If the two residues in a C_t-C_t alkane **5** differ in the space-filling properties, the D,L diastereomer **16** turns out to be more stable than the *meso* form **17**.

16 (D,L) **17** (*meso*)

This is because in the preferred conformation of the D,L diastereomer **16** the two large substituents R_L are flanked by the steric vacancy caused by the small hydrogen atoms. In the *meso* compound **17** only one of the large groups R_L can adopt this preferred position, the other one being in a *gauche* relationship to two R residues. Accordingly, D,L-1,2-dicyclohexyl-1,2-di-*tert*-butylethane, **5d**, is thermodynamically more stable than the *meso* diastereomer **5c** by 6 kcal/mol.[22] These conformation-controlling factors, which have already been identified earlier for C_t-C_t alkanes and phenyl-substituted analogs,[6,37] are more generally applicable than hitherto believed.

With respect to the central bond, a total of five staggered, alternating rotamers are possible for a symmetrically substituted ethane[56] having three substituents of different steric requirement (R^1, R^2, and R^3, designated L, M, and S). Two of these rotamers (**I** and **II**) correspond to the *meso* form (*erythro*), and three (**III**—**V**) to the D,L (*threo*) form. These are shown in Newman projections with a schematic representation of the steric requirements in Figure 2. The expected increase of the L–C–M angle, and decrease of the L–C–S and M–C–S angles at the central carbon atoms (cf. Section 4.1) have been taken into account in these projections.

The consequences of this angle increase are readily seen in Figure 2. Judging from the repulsion between the groups, rotamer **I** in the *meso* series clearly appears less favorable than rotamer **II**. The deformation of the central carbon atom in **I** causes a closer approach of the medium-sized substituents, M, to the large ones, L. In **II**, however, the increased bond angle between the L and M substituents leads to relief of vicinal interaction between these groups.



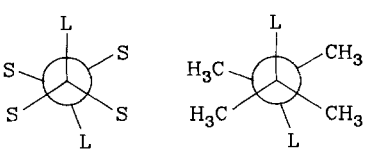


Fig. 2. Model for conformational analysis of C–C single bonds taking into account geminal repulsion between groups of different sizes (L = large, M = medium, S = small). **I**—**II**: *meso*; **III**—**V**: D,L. In each case, only one enantiomer of **III**—**V** is shown. * Denotes the preferred conformation.

Thus, although conformer **I** with the large substituents L *anti* to each other is slightly preferred as long as ideal tetrahedral geometry is maintained, this conformer becomes less favorable when increasing differences in size cause an increased deformation of the central bond angles.

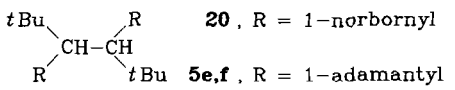
By analogy, **IV** is seen to be the preferred conformation in the lower row of Figure 2. Here, too, the two large substituents L profit from less vicinal repulsion of the smallest substituents as a result of opening of the L–C–M bond angle. Of all the rotamers shown, **IV** should be the most stable. Consequently, the D,L diastereomer becomes more stable than the *meso* form.

Further predictions can be made for particular combinations of groups. If two of the groups are identical or effectively identical, the differences between **II**, **IV**, and **V** vanish (see **5e** and **5f** in Table 1 and Fig. 2).

The differences between the conformers become less pronounced as the differences in size between the groups R diminish. This is particularly true for **IV** and **V**, the *meso*-2,3-diisobutyl-2,3-diphenylsuccinic ester **4b** (L = *i*Bu, M = Ph, S = COOMe) exists in the *gauche* conformation **II** in clear agreement with the model.[29,30] Also, with respect to the total strain, the methoxycarbonyl group proved to be "smaller" than the phenyl group.[29] Force field calculations indicate that the *anti* form **I** is less stable by 1.7 kcal/mol.[29]

18 **19**

Another special case obtains in the C_q-C_q series when two large substituents R^1 are combined with two small ones, R^2 and R^3. Here, conformation **18** is, of course, preferred, because the large groups L are *anti*, but the torsional angle between these groups is not 180° but signifi-



cantly less (165–175°; see Fig. 2). Thus, conformations corresponding to **IV** are present, and surprisingly enough this is also the case when R^2 and R^3 are methyl groups, as in **1a** and **1d** (cf. **19**). Apparently, the methyl groups in **19** differ as regards their vicinal repulsion. A sterically less demanding pair (Fig. 2) gets closer together and reduces the total strain, as shown earlier.[57] This is due to the fact that methyl groups do not behave as spheres; in contrast, their interlocking ability allow them to reduce repulsion pairwise.

Phenyl groups influence the conformations of substituted ethanes in a different manner. Their disk shape allows them to avoid geminal repulsion more easily, and hence the bond angles at the ethane carbons are much less deformed (see Table 2). In the C_q–C_q series the 1,2-diphenylethanes **2** with *n*-alkyl side chains adopt the *anti* conformations **I** or **III** with normal torsional angles of 180° between the phenyl groups. Similarly, in the C_t–C_t series, the diarylethanes **6** carrying smaller alkyl groups (methyl to isopropyl), follow the usual conformational rules: *meso* and D,L configurations prefer the conformations **I** and **III**, respectively, the hydrogen atoms being *anti*; the *meso* form is somewhat more stable than the D,L form.[13] Only *tert*-alkyl groups (**6a**–**6d**) increase the geminal repulsion to such an extent that the *gauche* conformation **IV** becomes preferred in the D,L series because of increased angle deformation. In contrast, the *meso* form maintains the *anti* conformation **I** and remains more stable than the D,L form.[13, 14]

6. Rotational Barriers and the Isolation of Stable Rotational Isomers

The height of the barrier toward rotation around the central bond of an ethane is not a simple function of the total strain or the sum of the volumes of the groups. Six-fold substituted C_q–C_q ethanes show rather uniform rotational profiles, and the rotational barriers are generally not high ($\Delta G^* \leq 13$ kcal/mol; see Fig. 3). Secondary groups can co-rotate (like cogwheels) in the course of a rotation around the central bond. This can result in a complex change of the enthalpy as a function of the inner movements during rotation.[58] This is very nicely illustrated by the rotation profile of the isopropyl derivative in Figure 3.

C_t–C_t ethanes with large substituents have very steep torsional profiles.[23, 24] In tetra-*tert*-butylethane, **5g**, the barrier toward rotation around the central bond is even higher than that for dissociation.

20, R = 1-norbornyl

5e,f, R = 1-adamantyl

Starting with this phenomenon and using a strategy based on orienting force field calculations, the compounds **20** and **5e**, **f** were synthesized[40] [see Reaction (h)]. NMR-spectroscopy demonstrated that in both cases three isomers were formed, assigned as the three rotamers **II** (*meso*), **IV**, and **V** (D,L) (Fig. 2). The two conformationally stable rotamers D,L-**5e** and D,L-**5f** could even be separated by manual crystal selection, and after purification by fractional crystallization were subjected to crystal structure analysis[30, 40] (see Fig. 4). **5e** corresponds to the *anti* conformation **IV** and **5f** to the *gauche* conformation **V** when L = 1-adamantyl, M = *tert*-butyl, and S = H.

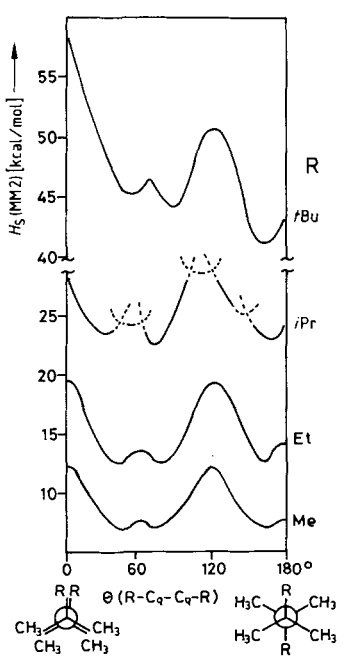


Fig. 3. Rotational potentials for the C_q–C_q bonds in hydrocarbons $R(CH_3)_2C$–$C(CH_3)_2R$ according to MM2 calculations [57].

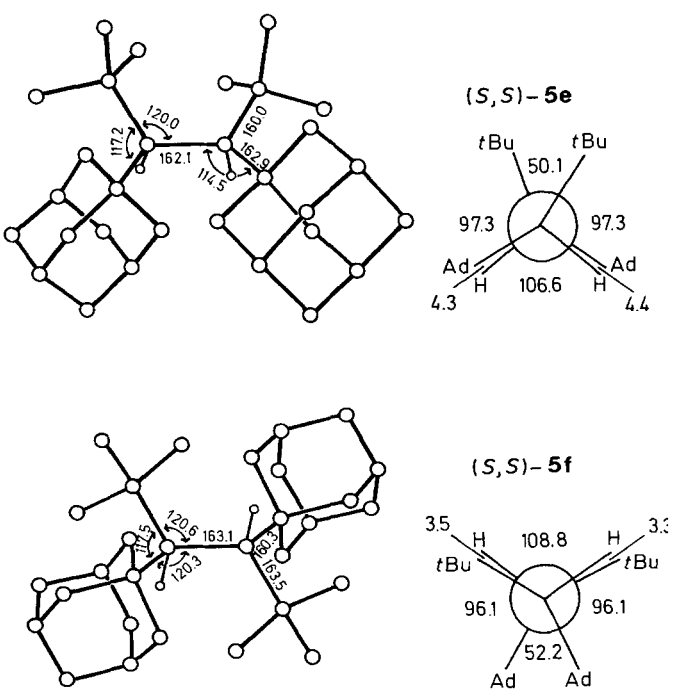

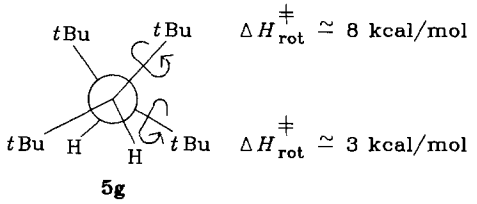

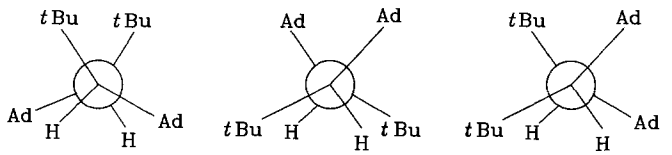

Fig. 4. Structures and Newman projections of the two rotamers of D,L-3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexane with important bond lengths [pm] and angles [°] derived from crystal structure analysis [30, 40]. Ad = 1-adamantyl. The (*S*,*S*)-enantiomers are shown.

The assignment of the rotamers made previously by NMR was based on a characteristic difference between the *tert*-butyl groups *gauche* or *anti* to the methine C–H bond. The former possess lower rotational barriers ($H_{rot} = 3$ kcal/mol), as is also observed for tetra-*tert*-butylethane, **5g**; the latter have higher barriers ($H_{rot} = 8$ kcal/mol), both being MM2 calculated values[40, 44, 55] (Fig. 5).

5g

(*R*,*R*)-**5e** (*R*,*R*)-**5f** *meso*

Fig. 5. Newman projections of tetra-*tert*-butylethane (**5g**), the two rotamers of D,L-3,4-di(1-adamantyl)-2,2,5,5-tetramethylhexanes [40, 59] (illustrated: (*R*,*R*)-enantiomers) and the corresponding *meso*-compound. Ad = 1-adamantyl.

To the best of our knowledge, **5e** and **5f** are the first examples of stable rotameric aliphatic hydrocarbons.[60] Their strongly deformed structures, in particular the Newman projections, eminently confirm the rules for conformational analysis of C–C single bonds, derived for C_t–C_t hydrocarbons in the present work, and applicable also to other compounds.

7. Conclusion and Outlook

Starting with the work of *D. H. R. Barton*,[61] the development of general rules of conformational analysis with the aid of geometrically standardized molecular models has made possible a unifying description of an unusual wealth of questions relating to structure and reactivity. Strained molecular structures, however, are at the limit of applicability of simple conformational analysis, and standard bond lengths, bond angles, and torsional profiles are no longer valid. The conformational analysis of each strained molecule becomes an individual problem, in the solution of which the force field method has proved well suited.

The knowledge of structural data for a variety of strained compounds also makes it possible to give new and refined guidelines for qualitative conformational analysis. Here, the consequences of angle enlargement caused by geminal repulsion between large groups are particularly decisive for the conformation. If angle enlargement is energetically unfavorable, bond lengthening will be the dominating outcome of strain. However, strain is always distributed over many structural coordinates, so that the degree of distortion of individual bond angles and bond lengths is limited. The influence of a substituent on the conformation depends less on the size than on the shape of the substituent.

The possibility of calculating unusual molecular geometries using the force field method is of importance not only for the determination of intramolecular but also intermolecular interactions. After all, van der Waals interactions can influence the nature of the accessible reaction channels[62] and hence the selectivity, e.g. in radical recombination[63] or in asymmetric synthesis.[35] Their importance should be even more far reaching in biological recognition processes.[14, 15, 64–65]

We are indebted to numerous co-workers, whose names are given in the references, for excellent cooperation. Prof. H.-G. von Schnering and Dr. K. Peters (Stuttgart) and Prof. H. J. Lindner (Darmstadt) are thanked for the execution of numerous crystal structure analyses, and Prof. H. Fritz and Dr. D. Hunkler (Freiburg) for their help with the NMR investigations. We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support of this work.

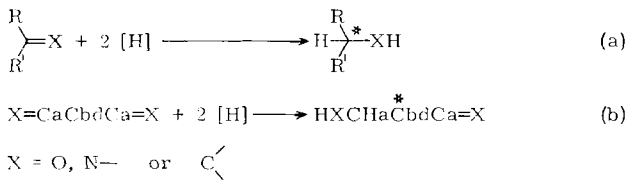
Chiral Compounds Synthesized by Biocatalytic Reductions



New Synthetic Methods (51)

By Helmut Simon,* Johann Bader, Helmut Günther, Stefan Neumann, and Jordanes Thanos

It has been known for many decades that chiral compounds can be obtained by stereospecific biocatalytic reduction. Further significant methodological developments in this field have, however, only been made during the past ten years; they include the application of previously unused microorganisms and electron donors, the discovery of additional substrates for the known reductases, the development of methods for regenerating reduced pyridine nucleotides, and the discovery of new reductases which were sought for specific preparative purposes. Many chiral compounds can now be synthesized by microbial hydrogenation using H_2 and hydrogenase-containing microorganisms as well as by electromicrobial or electroenzymatic reduction. In the two latter methods, anaerobic or aerobic organisms are supplied with electrons from electrochemically reduced, artificial mediators, e.g., methyl viologen. Reductases that do not require pyridine nucleotides and can accept electrons directly from reduced viologens are especially useful. Two examples of this type of enzyme are described which are of preparative interest. Many cells contain methyl viologen-dependent NAD(P) reductases, a large number of which have still not been characterized. A productivity number is proposed which allows different methods of bioconversion with microorganisms to be compared. The productivity numbers of compounds synthesized by the methods described in this review are often 10- to 100-fold higher than those of substances obtained by conventional techniques.

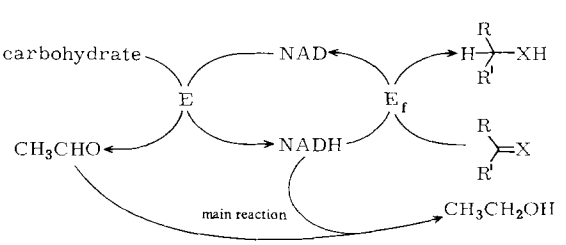
1. Introduction

A large number of chiral products can be obtained by stereospecific reduction of appropriately substituted unsaturated compounds according to Reaction (a) or (b):

(a)

(b)

In Reaction (a), the biocatalyst only has to differentiate between the *Re* and *Si* faces of a π system. Two alternatives are possible in Reaction (b). If the originally sp^2-hybridized C atom does not become chiral after reduction,



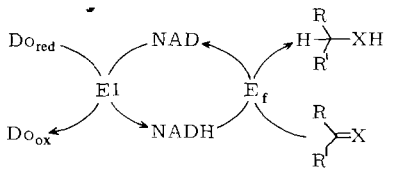
then only the pro-*R* or pro-*S* group ($-C=X$) has to be differentiated. If, however, substituent a is such that a chiral group is formed from the π system after hydrogenation, this raises the question of diastereomeric purity, since the *Re* and *Si* faces must be differentiated in addition to the pro-*R* and pro-*S* groups.

Reaction (a) is more important than (b). The reduction of carbonyl groups has been described much more frequently than that of CC double bonds. The reduction of CN double bonds has rarely been described but plays an important part in the reductive amination of oxo compounds (e.g., in the synthesis of amino acids). A review of the microbial enantioselective reduction of ketones has recently been published[1] (for reviews and literature surveys see ref. [2–8]).

The reduction of phenylglyoxylic acid to mandelic acid by fermenting yeast was reported more than 70 years ago.[9] The reduction of ketones to chiral alcohols was described in about 160 publications in the mid-1950s. Microbial reductions of systems of the type $-CH=C<$ were the subject of only about 20 studies.[2] Later, in addition to microorganisms, enzymes of various purities were used for the preparative reduction of unsaturated compounds.[4, 10, 11] The reductases that have so far been employed, however, require reduced pyridine nucleotides (nicotinamide adenine dinucleotide = NAD or nicotinamide adenine dinucleotide phosphate = NADP), which cost several thousand marks per mole. The nucleotides must therefore be regenerated if they are to be used in catalytic quantities.

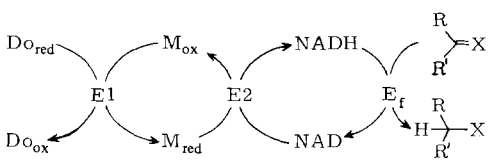
Six different methods of biocatalytic reduction can be differentiated according to the nature of the donor and the route of electron transport from the donor to the substrate:

– Up to now carbohydrates have usually been employed as electron donors for the microbial reduction of unsaturated substrates. NADH and an electron acceptor such



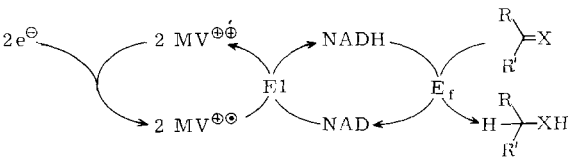
(I)

[*] Prof. Dr. H. Simon, Dr. J. Bader, Dr. H. Günther, Dr. S. Neumann, Dr. J. Thanos
Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (FRG)



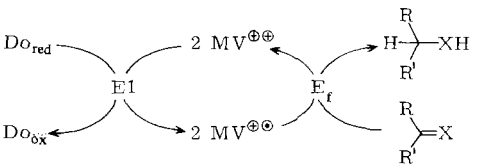
as acetaldehyde or pyruvate are formed from NAD and the carbohydrate in a series of enzyme-catalyzed steps (Route I). The desired reaction catalyzed by the "final" reductase E_f is usually a side reaction.

—It is better to have a system in which the electron donor Do_{red} converts NAD into NADH in a single, practically irreversible step, the NADH then being consumed in the reaction catalyzed by E_f (Route II). Two enzymes isolated from different sources can be combined for this route.



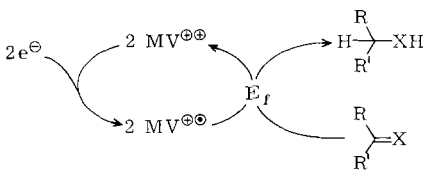
II

—Systems can also be very advantageous in which a natural electron mediator M_{red} (e.g., reduced ferredoxin) is formed from the primary electron donor (e.g., H_2 or formate); M_{red} then converts NAD into NADH in a reaction catalyzed by E2 (Route III.1). In this case, electron transport can often be accelerated if, instead of a natural mediator, an artificial mediator such as viologen can be used (Route III.2).



III. 1, III. 2

—Route IV has proved to be of value in many cases, because viologens (e.g., methyl viologen = $MV^{\oplus\ominus}$, 1,1'-dimethyl-4,4'-bipyridinium dication) can be electrochemically reduced in a defined manner and, according to our results, methyl viologen-dependent NAD reductases seem to be widely distributed.



IV

—Further studies performed by our group have shown that preparatively useful reductases are available which can accept electrons directly from reduced viologens. Routes V and VI thus become accessible. In Route V, enzymatically reduced methyl viologen is produced with, for example, H_2 or formate as an electron donor. In Route VI, the shortest and simplest electron transport system, the enzyme E_f is supplied with electrons electrochemically (i.e., using electricity) via the mediator $MV^{\oplus\ominus}$.

V

VI

These six pathways are briefly described in Table 1 and will be discussed from a practical point of view in Section 2.2.

Table 1. Possible pathways of biological reductions.

Description	Electron donor	Catalyst(s) for NAD(P)H regeneration or reduction of the final reductase	Scheme of electron flow	Comments
NAD(P)H is produced after a series of enzyme-catalyzed steps and the formation of competing electron acceptors	Glucose or other carbohydrates	Whole cells, e.g., yeasts or bacteria	I	Used most often; productivity numbers are usually low
Direct NADH formation	HCOOH, H_2, CH_3CH_2OH	Whole cells, e.g., *Pseudomonas ovalis, Arthrobacter spec.*, or *Clostridium kluyveri*	II	Seldom used; cells are employed for NADH regeneration
Reduction of NAD(P) via natural or artificial mediators	H_2, HCOOH	Whole cells, e.g., clostridia or *Proteus vulgaris;* with or without mediators such as viologens	III.1; III.2 or V	Numerous α,β-unsaturated carboxylates and 2-oxocarboxylates are reduced to chiral compounds
Two-enzyme system	HCOOH or other substrates of an NAD-dependent dehydrogenase, e.g., isopropanol or cyclohexanol	Dehydrogenase and final reductase	II	In some cases successful on a pilot scale with NAD of increased molecular weight in membrane reactors
Electromicrobial	Cathode of an electrochemical cell	Cells with methyl viologen-dependent NAD(P)H reductase and pyridine nucleotide-dependent final reductase	IV	Examples are to be found in this review
Electroenzymatic or electromicrobial	Cathode of an electrochemical cell	Cells with final reductase that can accept electrons directly from mediators such as viologens or isolated final reductase	VI	Examples known so far are enoate reductase and 2-oxocarboxylate reductase. Both react with a wide range of substrates

As shown in this review, the methodology of biocatalytic reduction can be considerably extended by employing microorganisms that have not so far been generally applied together with the new types of enzymes found in them; a second approach is to utilize coenzyme regeneration methods which until now have been used either very rarely or not at all.

2. What Has Been and Can Be Improved by New Methods?

2.1. Criteria for Evaluating the Conversion of Substances Using Microorganisms

The efficiency of the conversion of substances using microorganisms can be characterized by a so-called productivity number (PN):[12, 13]

$$PN = \frac{\text{amount of product [mmol]}}{\text{dry weight of catalyst [kg]} \times \text{time [h]}}$$

High productivity numbers mean better volume-time yields and usually easier isolation of the product. If, for example, 500 mmol of a product is to be synthesized in 24 h, approximately 1000 g of catalyst is required for a productivity number of 20 (which is frequently the case), whereas only 10 g is needed if the productivity number is 2000. Moreover, it is much simpler to separate 100 g of a product from 10 g of a catalyst (i.e., microorganisms) than from 1000 g. If a microorganism consists of 50% protein, the productivity numbers and the enzyme units (U) customarily used in biochemistry are related as follows: if a crude extract of an organism contains the enzyme that is rate-limiting for the conversion with a specific activity of 1 U/mg protein (1 μmol substrate transformed per mg protein per min), a productivity number of 30000 can be attained. This assumes, however, that other factors, such as transport processes, concentration limits, and inhibition by the substrate and/or product, do not have any effect on the reaction. (So far, activities have seldom been expressed in SI units, according to which a quantity of an enzyme has an activity of 1 katal if it transforms 1 mol of substrate per second. 1 U $\triangleq 16.7 \times 10^{-9}$ katal.)

The following factors are also important for biocatalytic conversions in addition to satisfactory productivity numbers:

- —Availability of the cells. Are the cells or is the material for inoculation commercially available from a microorganism collection? Is cell culture simple and reproducible?
- —Reaction specificity. Is the substrate only converted into the desired product or do the substrate and/or product react further?
- —High stereospecificity of the enzyme (or the same high stereospecificity of each of the enzymes catalyzing the reaction). Many enzymes display a high degree of stereospecificity but there are a large number of exceptions.[14] Furthermore, a microorganism may possess two or more enzymes that react with the substrate in stereochemically different ways. For a discussion of this topic see ref. [1].
- —Michaelis-Menten constant (K_m) for the substrate and inhibition constants (K_i) for the substrate and product of the catalyzing enzyme. Low K_m values allow rapid conversion even of the last 5—10% of the substrate, i.e., the reaction does not end "gradually." Low K_i values for the substrate may mean that the substrate has to be added continuously, which is usually not difficult if the reaction rate and thus the actual substrate concentration is known. Low K_i values for the product require selective separation of the product, which is in most cases a complicated task.
- —Stability of the biocatalyst. Here, a distinction has to be made between whether resting or multiplying cells are used. In the former case, the activities of the required enzymes or the concentrations of the cosubstrates, such as NAD(P) or NAD(P)H, can decrease sharply (for example, within 24 h) before the substrate has been transformed. If growing cells are used, product isolation is usually impeded by the large quantities of biocatalyst, and, depending on the microorganism, the substrate and/or product may be converted further.
- —Suitability for immobilization. In order to facilitate product isolation and to stabilize (and eventually reuse) the biocatalyst (intact cells, crude extracts, or enzymes), it may be advantageous to immobilize it. The suitabilities of different biocatalysts for immobilization vary.
- —Storage stability. It is advantageous if the enzyme activities of a prepared biocatalyst remain stable for a long period of time (e.g., when frozen).

2.2. Evaluation of Older and More Recent Procedures

Bakers' yeast *(Saccharomyces cerevisiae)* is the biocatalyst most commonly used for reductions based on Route I (see Table 1); according to the criteria described above, however, it is not a very suitable catalyst even though it is readily accessible and stable. High productivity numbers cannot be achieved via Route I for fundamental reasons. Carbohydrates as electron donors must undergo five or six consecutive, enzyme-catalyzed reactions before NADH is formed. Also, the uptake of carbohydrate may be rate-limiting.[15] Furthermore, acetaldehyde is formed in alcoholic fermentation and competes for the reduction equivalents; formation of ethanol is usually the main reaction; it has been reported that for every mole of ketone produced 200—2000 moles of ethanol are formed.[16, 17]

The experimental data in many published studies do not allow the calculation or estimation of productivity numbers. Examples that permit calculation[17–25] show that the majority of reactions performed with microorganisms and carbohydrates have productivity numbers of 5—50, values of about 200 being very rare. To the best of our knowledge, the highest value, approximately 1000, has been reported for the reduction of 2,2,6-trimethyl-5-cyclohexene-1,4-dione to (6*R*)-2,2,6-trimethyl-1,4-cyclohexanedione with yeast.[24] The special problems associated with the use of non-standardized bakers' yeast or non-standardized methodology are illustrated by the studies published during the

past 50 years on the synthesis of chiral 3-hydroxybutyric acid esters.[22,25,26] Even if only studies reported during the last seven years are considered, *ee* (enantiomeric excess) values of between 80 and 97% have been reported for the synthesis of ethyl (*S*)-3-hydroxybutyrate with bakers' yeast.[22,25] Productivity numbers of about 100 were found. The *ee* values of 95–97% for the (*S*) enantiomer can, however, only be obtained if the concentration of the 3-oxo ester does not exceed 1 g/L; if the concentration is 5 g/L, the *ee* values only amount to 72%. Reductions with *Mucor javanicus*[27] and *Geotrichum candidum*[22] yield the (*R*) enantiomers. The investigations of *Sih* et al.[1,21,27] on the synthesis of esters of 4-chloro-3-hydroxybutyric acid, which is of interest as a precursor of carnitine, have helped to clarify the various factors involved in reductions with bakers' yeast (see Section 3.2).

Seldom and only recently have electron donors that are not carbohydrates (e.g., ethanol) been used for whole cells. Ethanol would also perhaps be a better electron donor than glucose for yeast. Furthermore, it has been suggested that ketones can be reduced by yeast without adding carbohydrates or another electron donor by the use of appropriately larger quantities of cell material.[17]

The different results obtained in a large number of investigations demonstrate that the biochemical fundamentals of reductions are not always well thought out and that the investigators are sometimes not aware of the fact that the bakers' yeast used is not always the same. Even if the same strain is used, the behavior of the yeast in reductions may depend strongly on the culture conditions (culture medium, temperature, stage of growth). An example is given by the reduction of the 5-oxo group of the monothioacetal of methyl 5,6-dioxocaproate. *Takaishi* et al.[29] found specific rotation values of between +5.4 and −21.1° for the products obtained with different strains of *Saccharomyces cerevisiae*. This applies of course to more or less all microorganisms.

According to our findings,[12,13,30–34] H_2 is an especially good electron donor (Routes III.1, III.2, or V) for reductions with organisms containing hydrogenases. In these cases, Do_{red} is H_2; this applies particularly if Route V is possible. Formate could presumably also be of advantage in cases in which the cells contain an NAD-dependent formate dehydrogenase. *Allais* et al.[35] found such an enzyme with a specific activity of 0.16 U/mg protein in a crude extract of *Pichia pastoris*. *Schütte* et al.[36] isolated a formate dehydrogenase from the yeast *Candida boidinii* which proved to be highly suitable for NADH regeneration in the enzyme membrane reactor of the groups led by *Kula* and *Wandrey* (see below). *Izumi* et al.[37] employed the NAD-dependent formate dehydrogenase from methanol-metabolizing bacteria to regenerate NADH with formate, whereby productivity numbers of up to about 6000 were obtained for regeneration.

Examples of the use of ethanol (Table 1) are given by the reductions of (+)- and (−)-carvone with *Pseudomonas ovalis* performed by *Noma* et al.[38] We have reduced various allyl alcohol derivatives with *Clostridium kluyveri* and ethanol to chiral alcohols such as (*R*)-2-methyl-1-butanol, (*R*)-3-methyl-1-pentanol, and (2*R*,3*S*)-2-methyl-3-phenyl[2,3-^{2}H]-1-propanol.[39] The advantages of ethanol over H_2 for this special case will be discussed in Section 3.1 (see also ref. [40]).

In the case of NAD(P)H-dependent reductases, if enzymes are utilized on a preparative scale instead of cells, NAD(P)H must be regenerated *enzymatically* (Table 1, Route II). It has not so far been possible to reduce NAD(P) chemically or electrochemically with practically useful recyclization numbers (for more recent experiments see *Wienkamp* and *Steckhan*[41,42]). The groups of *Kula* and *Wandrey* reported that NAD bound to polyethylene glycol in an enzyme membrane reactor could be used for the preparation of amino acids with the aid of formate dehydrogenase,[43] and could be recycled up to 80000 times. Numerous reports have appeared during the past few years on other possible ways of enzymatically regenerating NAD(P)H[44–47] (see also Section 4.2).

NADH regeneration, especially with formate dehydrogenase or one of the more recently described methods, is now a routine operation on a laboratory scale. Many chiral compounds have already become accessible by the use of this technique in combination with a small number of reductases. In the course of the past few years *Jones* et al.[11,48] and *Nakazaki* et al.[49] have, for example, found a large number of additional substrates for liver alcohol dehydrogenase, an enzyme that has been known for several decades. *Lamed* et al.[50] have drawn attention to some interesting applications of an alcohol/aldehyde/ketone oxidoreductase from the thermophilic bacterium *Thermoanaerobium brokii*. *May* and *Padgette*[51] have reported on the possible applications of oxidoreductases. It is likely that further preparatively or even industrially useful oxidoreductases will be discovered since an intensive search for these enzymes with a view to their possible applications only began a few years ago. (*S*)-Phenylalanine and (2*S*)-2-hydroxy-4-methylpentanoate dehydrogenase are recently discovered examples of such enzymes.[52,53]

Nonpolar compounds can also be enzymatically reduced in conjunction with NADH regenerating systems. *Hilhorst* et al.[54] regenerated NADH in reverse micelles with hydrogenase, methyl viologen, and lipoamide dehydrogenase. 20β-Hydroxysteroid dehydrogenase was used to reduce progesterone dissolved in hexanol/octane to 20β-hydroxy-4-pregnen-3-one at the boundary to the aqueous phase. Routes IV and VI can be utilized for the continuous reduction of catalytic quantities of artificial electron carriers by employing electrochemical cells; NAD(P)H can thus be regenerated with the NAD(P) reductases frequently encountered in microorganisms (Route IV) or electrons can be directly transferred to the final reductase E_f.

3. Hydrogenation with Microorganisms

3.1. Reduction of the CC Double Bond of α,β-Unsaturated Aldehydes and Carboxylic Acids

According to our studies, H_2 can be employed as an electron donor with some microorganisms.[12,13,30–34,55] This has the following advantages: 1) The equilibrium of Reaction (c) lies strongly to the right. 2) In resting cells the

(c)

electron donor can be used solely for the desired reaction. Side reactions, which can occur, for example, with acetaldehyde or other products that are formed from carbohydrates, do not take place. 3) The reaction can be monitored continuously by following the H_2 consumption. 4) The productivity numbers are often 10—100 times higher than those found for reductions with yeasts, which considerably simplifies isolation of the products. According to our findings, productivity numbers of 1000—3000 are often achieved, particularly if catalytic quantities (1—4 mM) of an artificial electron donor such as methyl viologen are added. The electron flow in reductions with clostridia can be described by Route III.1 or III.2.

Hydrogenation with *Clostridium spec. La1* (DSM 1460), *Clostridium kluyveri* (DSM 555), *Proteus mirabilis* (DSM 30115), and *Proteus vulgaris* (DSM 30118) will now be described. Many α,β-unsaturated carboxylic acids or aldehydes (Tables 2 and 3) can be hydrogenated with *C. La1*

Table 2. Enoates of the type $R^2R^3C{=}CR^1CO_2^{\ominus}$ that can be hydrogenated with *Clostridium La1* and H_2 [a]. The last five compounds are allene derivatives.

[a] If not otherwise stated, $X = COO^{\ominus}$. [b] Relative rate with respect to (*E*)-2-methylbutenoate (100%). Purified enoate reductase displays a specific activity of 20 U/mg for this substrate with reduced methyl viologen at 25°C. [c] K_m values in mM. [d] Only the α,β double bond is hydrogenated. [e] X = CHO. [f] 90% *E* and 10% *Z* isomer. [g] Marked substrate inhibition above 40 mM. [h] Marked substrate inhibition above 10 mM.

found to apply: R^1 should not be too large; if R^2 is a phenyl ring, $NHCOCH_3$ and OC_2H_5 residues are not accepted in place of NHCHO and OCH_3, respectively. The halogens

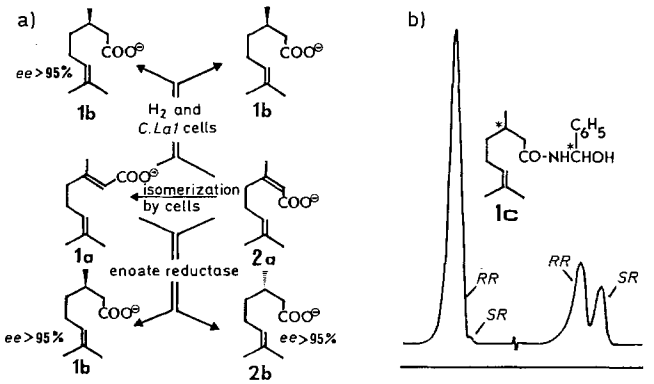
(d)

(e)

X = $COO^{\ominus}$, $\overset{H}{\underset{|}{C}}{=}O$; R^1, R^2, R^3 see Tables 2 and 3

F, Cl, and Br are tolerated in the α position but are reductively eliminated in the β position.[62, 63] The choice of R^2 is subject to the least number of restrictions. Branching in the β position leads to reduced activities. If R^2 and R^3 are interchanged (i.e., if the *E* and *Z* isomers of substrates of the type $R^3R^2C{=}CHX$ are used), different enantiomers are produced. Therefore, *E/Z* mixtures of substrates in which the β-C atom becomes chiral on reduction cannot be employed. Complications can arise, however, if whole cells are used, as we observed in the hydrogenation of (*E*)- and (*Z*)-geraniate (**1a** and **2a**). As shown in Figure 1, **1a** yields

pure (*R*)-citronellate **1b**, but **2a** is largely isomerized to the thermodynamically more stable (*E*) isomer **1a** by clostridia (presumably enzymatically) and thus also converted into the (*R*) enantiomer. The *ee* value is lower because some of **2a** is also reduced directly. Isolated enoate reductase must be used in this case (see Section 3.6 and Fig. 1).



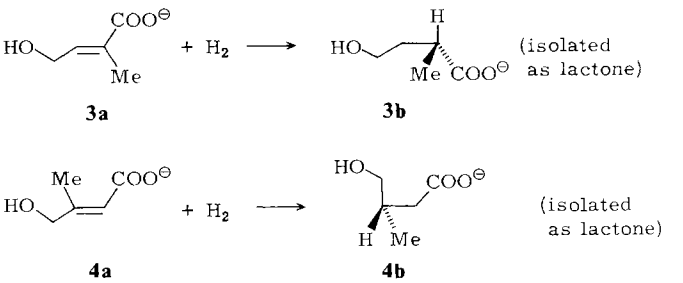


Fig. 1. Bioreduction of (*E*)- and (*Z*)-geraniate (**1a** and **2a**, respectively) to (*R*)- and (*S*)-citronellate (**1b** and **2b**, respectively). a) **1a** is hydrogenated to enantiomerically pure **1b** by *C. La1* cells with a productivity number of approximately 3000. The (*Z*) compound **2a** is reduced much more slowly and most of it is isomerized to **1a** prior to hydrogenation so that **1b** is formed with *ee* values between 60 and 85%. Pure **2b** can, however, be obtained if isolated enoate reductase is used for reduction. b) **1b** obtained after hydrogenation of **1a** with *C. La1* cells was derivatized to **1c** and then separated on 7-μ Lichrosorb columns by HPLC. (J. P. Lecomte et al., unpublished).

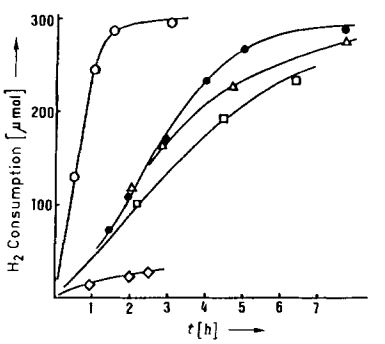
The high productivity numbers allow reactions to be carried out in small volumes. Products that are only chiral due to the stereospecific replacement of ^1H by ^2H on one or two methylene groups can therefore be obtained relatively easily by means of hydrogenation.[12,64] The cells are freeze-dried and then used in ^2H_2O buffer. H_2 can be used as an electron donor since 10^2—10^3 times more ^2H is present in the buffer than ^1H in the amount of hydrogen gas required. A preparative example has been described.[64]

Some of the hydrogenations that have so far been carried out are summarized in Tables 2 and 3. All compounds given in Table 3 had already been hydrogenated. It should be noted that nitro groups are reduced by whole cells but not by enoate reductase and NADH.[65] Figure 2 shows the time course of hydrogenation. Electron flow in the hydrogenation of α,β-unsaturated carboxylates and other carbonyl compounds with *C. La1* proceeds according to Route V (Table 1). (Hydrogenations without methyl viologen are possible but usually proceed slower.) There are two alternatives. If the rate at which the unsaturated substrate reacts with enoate reductase is greater than that at which the hydrogenase (E1) can reduce methyl viologen, the hydrogenation mixture is not initially blue. The solution only becomes blue due to reduced methyl viologen toward the end of the hydrogenation when the substrate concentration decreases and the enoate reductase is no longer saturated. If, however, the unsaturated substrate reacts relatively slowly so that the hydrogenase can reduce the methyl viologen rapidly enough, the solution remains blue throughout the entire reaction. Figure 2 shows that the hydrogenations of **3a** and **4a** with *C. La1* proceeded at about the same rates, although, according to Table 3, **3a** is reduced approximately twelve times more rapidly by enoate reductase than **4a**. Thus, the reduction of methyl viologen must be rate-limiting for the hydrogenation of **3a**. If **3a** is hydrogenated with a mixture of *C. La1* and *C. kluyveri* (the latter displays a considerably higher hydrogenase activity), the hydrogenation rate of **3a** can be increased by a factor of approximately 5. In the case of **4a**, this measure reduces the rate of hydrogenation because, although *C. kluyveri* has a higher hydrogenase activity than *C. La1*, its enoate reductase activity is lower. As will be demonstrated in Section 4.4, the conditions in an electrochemical cell are significantly different if the reduction of methyl viologen is not rate-limiting.



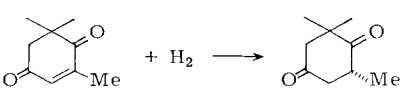


Fig. 2. Hydrogenation of a favorable (**3a**) and an unfavorable (**4a**) substrate of enoate reductase. 100 mM substrate was shaken at about 100 cycles per minute with 400 mg of cells (wet sediment) in 3.0 mL of phosphate buffer under 1 atm H_2 at 35 °C in a Warburg flask with a capacity of approximately 25 mL (manometer filled with Hg). ○—○ Hydrogenation of **3a** with 250 mg of *C. La1* and 150 mg of *C. kluyveri*; ●—● **3a** with only *C. La1*; △—△ **4a** with *C. La1*; □—□ **4a** with 250 mg of *C. La1* and 150 mg of *C. kluyveri*; ◇—◇ **4a** with only *C. kluyveri*. (The measurements were performed with *C. La1* cells that had been stored for 15 months and whose hydrogenase activity was about half of the normal value).

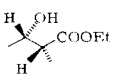
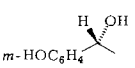
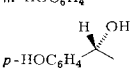
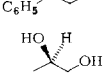
Although the pH maximum of Reaction (e) occurs at 5.2,[13] a pH of between 6.5 and 7.0 has proved to be optimal for the overall hydrogenation reaction. The hydrogenation of the diketone **5a** can also be carried out on a preparative scale—however, without methyl viologen (cf. Section 4.3).

In addition to α,β-unsaturated carboxylates and other carbonyl compounds, the CC double bonds of allyl alcohol derivatives can also be hydrogenated with *C. La1* or *C. kluyveri* cells. Enoate reductase does not, however, reduce allyl alcohol derivatives and the cells do not possess any other enzymes capable of catalyzing this reduction. It has been shown that the allyl alcohol derivatives are initially dehydrogenated to the corresponding aldehydes, and the CC double bonds of these compounds are then quickly reduced by enoate reductase. The aldehyde group is subsequently reduced back to an alcohol group. This is the reason why methyl viologen inhibits reduction in such cases; the entire NAD is rapidly reduced to NADH by H_2 and methyl viologen, and NAD is therefore not available for dehydrogenation of the allyl alcohol derivative. Ethanol is a more suitable electron donor in these cases.[39,40]







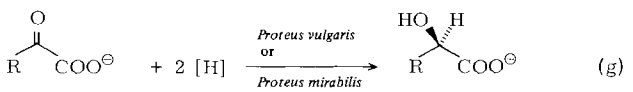


3.2. Hydrogenation of Ketones

Ketones can also be reduced to chiral secondary alcohols with clostridia such as *C. La1* or *C. kluyveri* [Reaction (f)]. Examples are given in Table 4. Excellent *ee* values can be obtained in a number of cases but low values are also encountered.

$$R{-}\overset{O}{\overset{\|}{C}}{-}R' + 2\,[H] \longrightarrow RCHOHR' \qquad (f)$$

Table 4. Reduction of ketones with clostridia. If not otherwise stated, H_2 was used as an electron donor.



Microorganism	Product	*PN*	Enantiomer	*ee* [%]
C. kluyveri		1500	(*S*)	95[a]

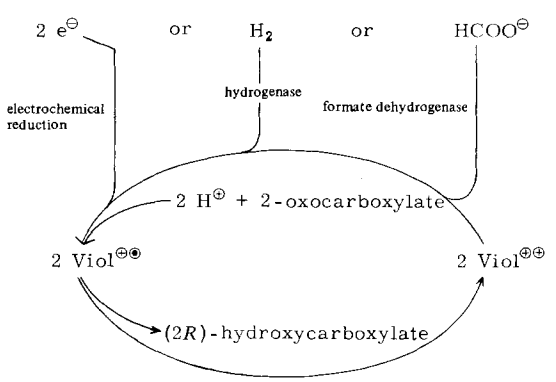
C. kluyveri		350	(*R*)	99[c]
C. kluyveri		6	(*R*)	94[c]
C. La1		4	(*R*)	96[c]
C. La1		22	(*R*)	94[c]
C. La1		11	(*R*)	91[c]
C. kluyveri		12	(*R*)	99[c,d]
C. kluyveri		3	(*R*)	98[c,d]
C. kluyveri and *Candida utilis*		3800	(*R*)	94
C. kluyveri and *Enterobacter agglomerans*		3300	(*S*)	—

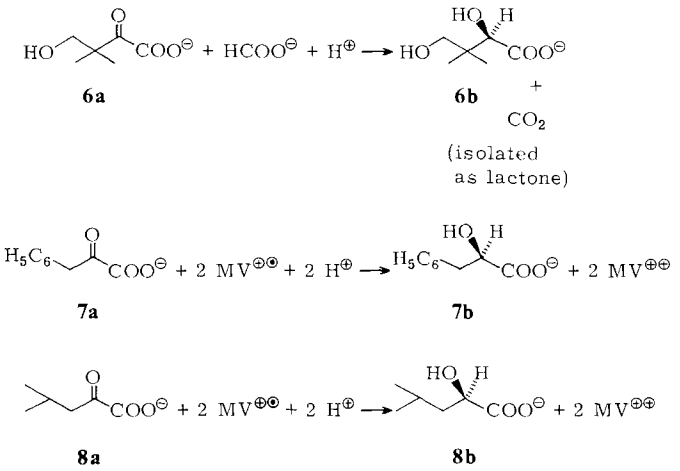
[a] Determined by enzymatic analysis. [b] A racemic mixture of ethyl 2-methyl-3-oxobutyrate was used. The reaction mixture consisted of 81% ethyl (2*R*,3*S*)-3-hydroxy-2-methylbutyrate, 13% of the (2*R*,3*R*) form, 4% of the (2*S*,3*R*) form, and 2% of the (2*S*,3*S*) form. [c] Analysis: B. Koppenhöfer et al., unpublished. [d] 10% ethanol was used as an electron donor.

Sih et al.[1,21,27] have found that in the reduction of 4-chloro-3-oxobutyrate esters with bakers' yeast the *ee* value is a function of the size of the ester group. The methyl ester is hydrogenated to the (*S*) enantiomer with an *ee* value of 65%, whereas the octyl ester is converted to the (*R*) enantiomer with an *ee* value of 97%. For other alkyl residues of the type $(CH_2)_nH$ (n=2—7), the *ee* values lie between these two values. *C. kluyveri* hydrogenates the ethyl ester of 4-chloro-3-oxobutyrate to the (*R*) enantiomer with an *ee* value of >99% and an approximately 50-fold higher productivity number (*H. Simon* et al. and *B. Koppenhöfer* et al., unpublished). The enantiomeric purities of the phenylethyl and phenylpropyl alcohols obtained with *C. kluyveri* do not seem to have been reached yet by other means. In other cases (e.g., phenylglycol) the *ee* values are poor, but this has so far been seldom observed in clostridia. The very low productivity numbers also seem to be more of an exception.



3.3. Hydrogenation of 2-Oxocarboxylates

A surprisingly wide range of 2-oxocarboxylate substrates can be reduced to (2*R*)-hydroxycarboxylates by *Proteus mirabilis* or *Proteus vulgaris* in the presence of methyl or benzyl viologen with very high enantiomeric purities.[47,66,67]



$$R{-}\overset{O}{\overset{\|}{C}}{-}COO^{\ominus} + 2\,[H] \xrightarrow[\text{or}]{\textit{Proteus vulgaris}} R{-}\overset{HO}{\overset{|}{C}}{-}H\ (COO^{\ominus}) \qquad (g)$$

This reaction is also based on an unknown type of enzyme which we have partially characterized (see Section 3.6). Instead of H_2, formate can be used as an electron donor in combination with a viologen. Since viologens (Section 4) can also be easily regenerated electrochemically, (2*R*)-hydroxycarboxylic acids may be obtained in three ways (Scheme 1), corresponding to Route V with

Scheme 1. *Proteus vulgaris* can be used with three different electron donors to synthesize (2*R*)-hydroxycarboxylic acids. $Viol^{\oplus\bullet}$ = oxidized methyl or benzyl viologen; $Viol^{\oplus\ominus}$ = reduced viologen. The mediator can be reduced either electrochemically or by H_2 gas and a hydrogenase present in the microorganism or by formate and a formate dehydrogenase also found in the microorganism.

$Do_{red} = H_2$ or $HCOO^{\ominus}$ and Route VI. Examples are the reductions of **6a**—**8a** to **6b**—**8b**.

6a **6b** **7a** **7b** **8a** **8b**

Figure 3 shows the time course of the reduction of 4-methyl-2-oxopentanoate **8a** to the corresponding (2*R*)-hydroxy acid **8b** with formate and H_2. As described in Section 4.4, productivity numbers of > 100000 can be obtained by determining and exploiting the kinetic parameters of the electrochemical reduction.

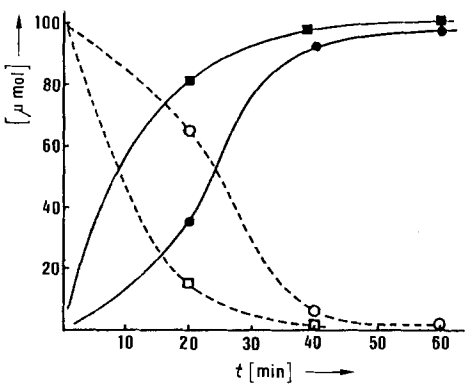


Fig. 3. Reduction of 4-methyl-2-oxopentanoate with *P. vulgaris* and H_2 or formate as an electron donor. Decrease in 4-methyl-2-oxopentanoate on reduction with H_2 ○--○--○ and with formate □--□--□ and formation of the product with H_2 ●—●—● and with formate ■—■—■.

Table 5. Relative rates for the reduction of 2-oxocarboxylates by a reductase found in *P. mirabilis* and *P. vulgaris*.

Substrate	Relative rate [%]	
	P. mirabilis	*P. vulgaris*
phenylpyruvate [a]	100	100
pyruvate [a]	92	85
2-oxobutanoate	40	65
indolylpyruvate	35	67
5-benzyloxyindolylpyruvate	30	—
3-fluoropyruvate	22	20
4-methyl-2-oxopentanoate	81	83
(*S*)-3-methyl-2-oxopentanoate	28	25
(*R,S*)-3-methyl-2-oxopentanoate	63	46
4-hydroxy-3,3-dimethyl-2-oxopentanoate [a]	7	4
phenylglyoxylate [a]	16	5
2-oxononanoate	83	93
2-oxododecanoate	27	46
2-oxotridecanoate	23	26
oxaloacetate [a]	73	50
2-oxoglutarate	78	62
2-oxoadipate	70	73
4-hydroxymethylphosphinyl(2-oxo)butanoate	24	6

[a] The enantiomeric purity of the products of these substrates was investigated by various methods. (*S*) enantiomers were not detected.

Table 5 provides a list of the substrates that can be reduced by *Proteus mirabilis* or *Proteus vulgaris* according to Scheme 1. Glyoxylic acid is so far the only 2-oxocarboxylate that does not react with this enzyme.

3.4. Hydrogenation with Two Microorganisms

As described in more detail in Section 4.2, crude extracts of *C. kluyveri* exhibit high activities for Reaction (h) in the presence of 1—2 mM methyl viologen. Reaction (h) corresponds to part of Route III.2 (Table 1). Yeasts, in particu-

$$H_2 + NAD(P)^{\oplus} \longrightarrow NAD(P)H + H^{\oplus} \qquad (h)$$

lar, demonstrate high reductase activities with certain carbonyl compounds, but the availability of NADH can be limiting. It therefore seemed reasonable to combine lysates from two species of cells; cell type 1 rapidly produces NADH using H_2 (or another electron donor): the NADH is then used by cell type 2 to reduce the unsaturated substrate. An example of this principle will be described in Section 4.4. 2(*R*)-Propanediol can, for example, be obtained in this way with a productivity number of up to 5700.[44] 3-Hydroxy-3-methyl-2-butanone can be hydrogenated to (*S*)-2,3-dihydroxy-2-methylbutane with a productivity number of 3300 (Table 4) by combining *C. kluyveri* and *Enterobacter agglomerans*. Aerobically cultured *Enterobacter agglomerans* cannot metabolize hydrogen, and *C. kluyveri* alone does not react with the ketone.

This method has the previously described advantages of high productivity numbers and simple control of the reaction (manometrically). In addition to *C. kluyveri*, *Alcaligenes eutrophus* can, for example, also be used for producing NADH according to Reaction (h). We found that crude extracts of cells that had been cultured according to *Schlegel* et al.[68] and then stored for 5 years at −15 °C still had a specific activity for NADH formation of 1 U/mg protein. Substrates for which the hydrogenase is rate-limiting (see Section 3.1) can also be more rapidly hydrogenated by employing a combination of *C. kluyveri* and *C. La1*.

3.5. Hydrogenations with Immobilized Cells

According to our experience,[69] clostridia can readily be immobilized with acrylic acid derivatives. These so-called photopolymerizable prepolymers introduced by *Tanaka* et al.[70] do not noticeably damage the cells. The observed decrease in activity can be accounted for solely by inhibition of diffusion. We have performed hydrogenations at room temperature for 63 d with immobilized *C. La1* cells in the presence of 2 mM methyl viologen. After 12 d the rate of H_2 uptake was still 50% of the starting rate. These immobilized preparations are highly suitable for storage. *C. kluyveri* stored in tris buffer with 50% glycerol did not show any decrease in activity after 150 d; under the same conditions *C. La1* cells lost 40% of their activity.[69] Purified enoate reductase can also be immobilized with photopolymerizable prepolymers. These substances are not, however, suitable for the immobilization of *Proteus mirabilis*, *Proteus vulgaris*, or the 2-oxocarboxylate reductases obtained from

these microorganisms. Ionotropic gels, such as alginates cross-linked with calcium ions, can be employed for these biocatalysts.[71] Since gels composed of photopolymerizable prepolymers are not very suitable for electrochemical cells in which rapid stirring is necessary, we have coated filter paper with alginate films containing immobilized enzymes. These systems have proved to be of value both for cells and for more or less purified enzymes. We have been able to increase the half-life of enoate reductase from approximately 6 h to 150 h in rapidly stirred electrochemical cells by using this approach.[61]

3.6. Kinetic Data for Enoate and 2-Oxocarboxylate Reductases

The pH optimum of enoate reductase with reduced methyl viologen is 5.2;[13] at pH 4.5 and 6.2 the rate is two-thirds that of the maximal value. A pH value of less than 5.2 should be avoided in an electrochemical cell. On the other hand, pH values of up to 8.0 do not seem to have a detrimental effect on the stability of the enzyme. A pH value of between 6.0 and 6.2 is recommended as a compromise between the stability of methyl viologen and the reaction rate of enoate reductase. A number of V_{max} and K_m values for substrates of enoate reductase are given in Table 3. The K_m values for reduced methyl viologen and NADH are 0.4 mM and 0.012 mM, respectively. A concentration of approximately 2 mM $MV^{\oplus\odot}$ thus seems appropriate for an optimal rate of Reaction (e). The K_i values for reduced and oxidized methyl viologen are so high that the rate is not affected when the total methyl viologen concentration is 3—4 mM. The K_m values for enoates vary over a range of two orders of magnitude. The smaller the K_m value, the later will the reaction rate be limited by the falling substrate concentration. The K_i values for aliphatic enoates and the reaction products are high (e.g., ca. 500 mM); hence, they are suitable for preparative purposes. The K_i values of aromatic products are, however, lower; the value for 3-phenylpropionate (15 mM) is the lowest that we have encountered so far. We have already reported in detail on the mechanisms and kinetics of the reductions of enoates with NADH.[58] The question arises, however, whether some of the values reported therein are different in the case of reduction with $MV^{\oplus\odot}$, as is found, for example, for the pH dependency of the reaction rate.

Table 6. Some typical K_m and K_i values for 2-oxocarboxylate reductase.

Substrate	K_m [mM]	Substrate/products	K_i [mM]
reduced methyl viologen	<0.05 [a]	reduced benzyl viologen	0.7 [b]
reduced benzyl viologen	0.1	benzyl viologen	10.0
phenylpyruvate	0.15	(*R*)-phenyllactate	100
4-methyl-2-oxopentanoate	2.1	(*R*)-2-hydroxy-4-methylpentanoate	100
4-hydroxy-3,3-dimethyl-2-oxobutanoate	7.5	4-hydroxy-3,3-dimethyl-2-oxobutanoate	50
2-oxoglutarate	2.5	phenylpyruvate	12
		4-methyl-2-oxopentanoate	70

[a] The hydrogenase of *Proteus vulgaris* has a K_m value of approximately 0.3 mM for reduced methyl viologen. [b] Concentration at which the reaction rate is half that found with 0.1 mM reduced viologen.

The 2-oxocarboxylate reductase from *Proteus vulgaris* displays a broad pH optimum with reduced methyl viologen. The maximum activity occurs at pH 7.0; the activity is still 80% of the maximal value at pH 6.0 and 8.0. Some typical K_m and K_i values are compiled in Table 6. The dependence of the reduction rate of 2-oxocarboxylates on the concentration of methyl viologen does not exhibit Michaelis-Menten behavior. The rate of reduction of a 2-oxocarboxylate increases with decreasing concentration of reduced methyl viologen until a concentration of <0.05 mM is reached! The behavior at lower concentrations cannot be followed due to experimental difficulties. Michaelis-Menten behavior was observed in the determination of the K_m values of various 2-oxocarboxylates. The K_m values vary greatly for different substrates but are suitable for preparative purposes. The K_i values of aliphatic substrates and products are favorable. The value for phenylpyruvate is relatively low but that of the product is again suitable. In practice this is of little importance. For instance, 100 mM solutions of phenylpyruvate can be reacted in the electrochemical cell with productivity numbers of >100000. The surprising behavior of 2-oxocarboxylate reductase toward oxidized methyl viologen plays an important part here. As shown in Table 7, oxidized methyl viologen is a positive effector—i.e., depending on the concentration of the reduced methyl viologen, the enzyme activity can be augmented by a factor of three to six by adding oxidized methyl viologen. The $MV^{\oplus\odot}/MV^{\oplus\oplus}$ ratio can easily be adjusted in an electrochemical cell by means of the cathode potential, thus allowing very high enzyme activities to be achieved.

Table 7. Influence of oxidized methyl viologen on the rate of reduction of a 2-oxocarboxylate.

0.14 mM $MV^{\oplus\odot}$ with increasing concentrations of $MV^{\oplus\oplus}$ [mM]	Ratio $MV^{\oplus\odot}/MV^{\oplus\oplus}$	Relative rate	1.6 mM $MV^{\oplus\odot}$ with increasing concentrations of $MV^{\oplus\oplus}$ [mM]	Ratio $MV^{\oplus\odot}/MV^{\odot\odot}$	Relative rate
0.02	7	18.1	0.02	80	10.2 [a]
0.07	2	41.9	0.8	2	29.3
0.14	1	46.0	1.6	1	33.7
0.7	0.2	62.0	8.0	0.2	53.1
			17.8	0.09	61.5

[a] The different rates obtained with the same $MV^{\oplus\odot}/MV^{\oplus\oplus}$ ratio are presumably due to the inhibitory effect of high $MV^{\odot\odot}$ concentrations.

4. Electromicrobial Reductions

4.1. Principles

The enoate reductase of *C. La1* and 2-oxocarboxylate reductase are enzymes that do not have to or cannot accept electrons from NADH or NADPH, but can accept them from reduced viologens. Since viologens can be reduced in electrochemical cells, unsaturated substrates can be stereospecifically reduced electrochemically with the aid of microorganisms containing enzymes such as enoate reductase or 2-oxocarboxylate reductase. Only one enzyme is

then required. The electron flow is described by Route VI.

We have also discovered that a large number of microorganisms catalyze Reactions (i) and (j) (see Section 4.2):[44,72]

$$2MV^{\oplus\ominus} + H^{\oplus} + NAD^{\oplus} \longrightarrow 2MV^{\oplus\oplus} + NADH \quad (i)$$

$$2MV^{\oplus\ominus} + H^{\oplus} + NADP^{\oplus} \longrightarrow 2MV^{\oplus\oplus} + NADPH \quad (j)$$

Reductions can thus be performed electrochemically with a variety of different microorganisms. Figure 4 shows a current-time curve for such a reaction. The reactions that occur are described by Equations (k), (i), and (l), which can be added together to give Equation (m):[72]

$$2MV^{\oplus\ominus} + 2e^{\ominus} \xrightarrow{\text{electrochemical}} 2MV^{\oplus\ominus} \quad (k)$$

$$H^{\ominus} + 2MV^{\oplus\ominus} + NAD^{\oplus} \xrightarrow[\text{other microorganisms}]{\text{yeast or}} 2MV^{\oplus\oplus} + NADH \quad (i)$$

$$H^{\oplus} + NADH + CH_3COCH_2OH \xrightarrow{\text{yeast}} NAD^{\oplus} + CH_3CHOHCH_2OH \quad (l)$$

$$CH_3COCH_2OH + 2H^{\oplus} + 2e^{\ominus} \longrightarrow CH_3CHOHCH_2OH \quad (m)$$

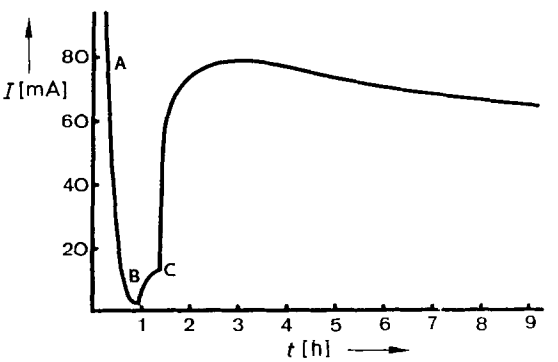

Fig. 4. Hydroxyacetone (40 mmol), methyl viologen (1.2 mmol), and NAD (0.1 mmol) were reduced in 200 mL of potassium phosphate buffer solution (0.1 M, pH 7.0). *Candida utilis* (175 mg, dry weight) was added at B and *C. kluyveri* (7.6 mg, dry weight) at C at -792 mV vs. the saturated calomel electrode. A current of 93 mA was obtained after adding a further 350 mg of *Candida utilis*, 3.8 mg of *C. kluyveri*, and 0.1 mmol of NAD. After a total of 140 h, 33 mmol of propanediol had formed and 2 mmol of hydroxyacetone was still present.

(2*R*)-1,2-Propanediol can be obtained by this method[47,72,73] with a 20- to 50-fold higher productivity number than that found for a procedure published in Organic Synthesis.[74]

4.2. Types, Sources, and Applications of Methyl Viologen-Dependent NAD and NADP Reductases for NAD(P)H Regeneration

Table 8 shows that many microorganisms catalyze Reactions (i) and (j).[44,47] These activities are of interest for the regeneration of NADH and NADPH, although their values vary by several orders of magnitude in different organisms. In order to evaluate these numbers it should be remembered that 0.1 U/mg protein corresponds to a productivity number of 3000 (see Section 2.1).

Table 8. Specific activities of methyl viologen-dependent NAD(P) reductases in crude extracts of various microorganisms (room temperature if not otherwise stated).

[a] DSM = Deutsche Sammlung Mikroorganismen, Göttingen. ATCC = American Type Culture Collection, Rockville, MD, USA. NCTC = National Collection of Type Cultures, London, England. [b] Determined manometrically by measuring the H_2 consumption. [c] Test at 80°C.

Four groups of microorganisms can be distinguished in Table 8:

1. Anaerobic eubacteria, in particular clostridia: These organisms contain NAD(P) reductases with high activities. If they contain a hydrogenase, the formation of hydrogen [Reaction (n)] may compete with Reactions (i) and/or (j).

$$2H^{\oplus} + 2MV^{\oplus\ominus} \xrightarrow{\text{hydrogenase}} 2MV^{\oplus\oplus} + H_2 \quad (n)$$

C. kluyveri is particularly advantageous at room temperature. This organism exhibits very high NAD(P) reductase

activities and the hydrogenase activity only amounts to about 10% of the value for the NAD reductases.

2. Archaebacteria: Methanogenic bacteria oxidize reduced methyl viologen mainly with production of H_2. The three thermophilic, sulfur-reducing archaebacteria that have so far been tested contain surprisingly high levels of NADP reductase activity. In two cases these activities are one order of magnitude higher than that for NADH formation.

3. Yeasts: They display lower NAD(P) reductase activities but do not contain any hydrogenases, which is of advantage for electromicrobial reductions.

4. Aerobic eubacteria: The majority of the aerobic eubacteria tested contain lower activities than the anaerobic bacteria.

The nature of the methyl viologen-dependent NAD(P) reductases is not always clear. A number of NAD(P)H-dependent flavoproteins catalyze these reactions. Diaphorase has already been used in practice.[54] In addition, Reactions (i) and (j) are known to take place with the hydrogenase from *Alcaligenes eutrophus*[76] and plant ferredoxin-NADP oxidoreductase,[77] respectively. Reactions (i) and (j) do not, however, seem to have been studied quantitatively so far. The measured activities of a series of enzymes for Reactions (i) and (j) are given in Table 9 and compared with the physiological activities of these enzymes. The following enzymes, which might have been expected to catalyze Reactions (i) and (j) on account of their structure, display low activities and are of little interest for practical purposes: glutathione reductase from yeast, NAD(P)H FMN reductase from *Photobacterium fisheri* and NADH dehydrogenase from the thermophilic bacterium *Bacillus spec* DSM 406. A very stable, methyl viologen-dependent NAD reductase can, however, be obtained from the latter microorganism; its activity as an NADH dehydrogenase with 2,6-dichlorophenolindophenol as an acceptor is low. This clearly shows that NADH dehydrogenase activity does not necessarily parallel the activity as a methyl viologen-dependent NAD reductase. The activity of the methyl viologen-dependent NAD reductase from *Bacillus spec.* DSM 406 remains practically constant over 50 d at 35 °C in a dilute solution.

In all entries in Table 9 in which the stereochemistry of [4-^{2}H]NAD(P)H formation is not accompanied by a literature reference, we prepared NADH or NADPH in an electrochemical cell using ^2H_2O buffer and determined which enantiomer was produced by means of NMR spectroscopy.[44] The method used to determine the stereochemistry has already been described.[78]

4.3. Construction of an Electrochemical Cell

Cathodes with a high overvoltage for hydrogen formation must be used for electrochemical reductions in water. Only the mediator and not the substrate must be electrochemically reduced; this can be checked by means of cyclovoltammetry.[81] Moreover, the mediator must not react spontaneously with the substrate. So far we have observed spontaneous reactions between reduced methyl viologen and the following substrates: phenylglyoxylate, ethyl 4-chloro-3-oxobutyrate, and **5a**. Phenylglyoxylate can be reacted in the presence of benzyl viologen; the two other compounds are reacted with H_2 and *C. kluyveri* without a mediator.

Gold, silver, carbon, and particularly mercury are suitable for use as cathode materials when working in the neu-

Table 9. Enzymes that have been tested for the reduction of NAD(P) with reduced methyl viologen. Initial rates for Reactions (i) and (j) and comparison of this activity with the physiological reduction or dehydrogenation of NAD(P)H in the presence of an artificial acceptor. All specific activities are for two electron transfers (μmol/mg protein × min). If not otherwise stated the tests were performed at pH 7.0 and room temperature in 0.1 M tris acetate buffer. The NAD(P) concentration was 2.5 mM, that of $MV^{\oplus\odot}$ was 1.8 mM. In order to determine the stereochemistry, NAD(P) was reacted with the relevant enzyme in an electrochemical cell (Fig. 5a) in ^2H_2O buffer [44].

Enzyme (EC number)	Physiol. reaction or NAD(P)H dehydrogenase reaction	Specific activity	$MV^{\oplus\odot}$/NAD	$MV^{\oplus\odot}$/NADP	Stereochemistry of [4-^{2}H]NAD(P)H [ref.]

[a] We are grateful to Prof. *V. Ulrich*, Constance, for this preparation. [b] The preparation had been stored for about 1 year. [c] Enzymes were isolated by *S. Nagata* in our laboratory (unpublished).

tral pH range and with potentials of approximately −450 mV versus the saturated calomel electrode (all potentials in this review are given versus this electrode). In the case of more negative potentials (e.g., −640 V), lead, bismuth, antimony, and tin cathodes are suitable. The potential is fixed in a standard three-electrode arrangement (Fig. 5). If cathode surface areas of <250 cm^2 are used, 200-mA potentiostats with a maximal terminal voltage of 15 volts are suitable.

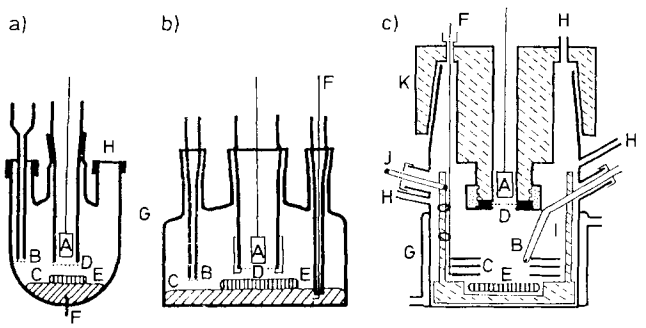

Fig. 5. Different electrochemical cells. a) 50-mL three-necked flask; b) 200-mL five-necked flask (two necks not shown); c) 70-mL cell with multiring carbon electrodes. A, platinum electrode; B, Luggin-Haber capillary for the reference electrode (saturated calomel electrode); C, mercury cathode in a) and b); D, diaphragm; E, stirring rod; F, cathode contact; G, glass vessel, in c) it can be thermostated; H, opening for taking samples and gassing with N_2; I, device for holding the cathode; J, device for preventing I from rotating; K, PVC lid and anode chamber.

Nafion membranes with a thickness of 0.5 mm have proved to be suitable for use as diaphragms in cells of over 50 mL. Vycor tips are also suitable for smaller cells (Fig. 5a). The diaphragm must satisfy the following requirements: it must allow proton transfer from the anolyte to the catholyte in which the protons are consumed (e.g., in Reaction (m)); it must be sufficiently conductive and prevent oxygen from passing from the anolyte to the catholyte. Oxygen reacts with reduced methyl viologen at a diffusion-limited rate. The superoxide radical anion formed[82,83] and its subsequent products can react with the enzymes, substrates, products, and mediator. Furthermore, the presence of oxygen results in an apparent rate of enzyme reaction that is too high. Potential differences of $> \pm 30$ mV should be avoided by means of proper design of the symmetry of the cathode.

Cells with mercury cathodes are especially easy to handle in the laboratory. A current of approximately 1 mA can be produced per cm^2 mercury surface area in solutions which contain 3 mM oxidized methyl viologen when the cell is in the stationary operational state. A current of 3.2 mA reduces 1 μmol of substrate per minute with two reduction equivalents.

Since it is easy to accomodate 10^2–10^4 U of enzyme activity in 100 mL of catholyte, especially if the enzyme is enriched, the preparative capacity of the operating cells is usually limited by the reduction of methyl viologen. The cells should therefore be operated under diffusion-controlled conditions. The diffusion layer on the cathode should be kept as thin as possible by, for example, efficient stirring (magnetic stirrer) or rotation of the cathode; this also results in thorough mixing of the reaction solution.

4.4. Practical Aspects of Performing Electromicrobial and Electroenzymatic Reductions

The optimal concentrations of oxidized and reduced methyl viologen, as well as the substrate concentration, depend on the kinetic parameters of the enzymes. For instance, enoate reductase and 2-oxocarboxylate reductase differ considerably in this respect (see Section 3.6). This also applies if cells or cell extracts are used that contain these enzymes. In the case of enoate reductase, 2–3 mM reduced methyl viologen should be present; the concentration of oxidized methyl viologen does not affect this enzyme.

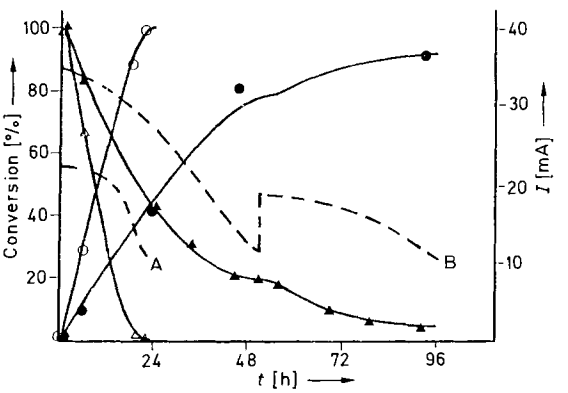

Fig. 6. Time course of the electromicrobial reduction of 30 mM (*Z*)-2-fluorocinnamate and 30 mM **4a** by 122 mg of *C. La1* and 184 mg of *C. La1*, respectively, in the cell shown in Figure 5c. Δ—Δ, Decrease in fluorocinnamate; O—O, formation of (2*R*)-2-fluoro-3-phenylpropionate; A, the observed current-time course in this reaction. ▲—▲, decrease in **4a**; ●—●, formation of **4b**; B, current-time course in this reaction. After 50 h, a further 70 mg of *C. La1* was added. The methyl viologen concentration was 3 mM, $T = 28$ °C, 36 mL of 100 mM phosphate buffer (pH 6.3), cell dry weights.

Figure 6 shows the reduction of (*Z*)-2-fluorocinnamate and of **4a** in an electrochemical cell (Fig. 5c) with *C. La1*. (*Z*)-2-Fluorocinnamate has a higher V_{max} value than **4a** and a much smaller K_m value (Table 3). This has the following consequences: (*Z*)-2-fluorocinnamate is reduced considerably faster than **4a** and the current yield is appreciably higher; this applies particularly to the reaction of the last third of the substrate and is mainly a result of the approximately 100-fold more favorable K_m value of fluorocinnamate. H_2 is produced from reduced methyl viologen (Reaction (n)) by the hydrogenase present and this reaction competes with the reduction of both substrates. Fluorocinnamate is reduced with a current yield of approximately 50%, whereas the current yield for the reduction of **4a** is ca. 10% during the first 5 h, ca. 7% after 24 h, and merely 4.5% after 72 h. The current is therefore mainly used for H_2 formation.

The current-time course during the reduction of phenylpyruvate with *Proteus vulgaris* is shown in Figure 7. The reaction is started by adding oxidized methyl viologen. The potential is adjusted in such a way that the optimal ratios given in Table 7 are obtained. A solution containing <0.1 mM reduced methyl viologen is sky blue. The subsequent current-time course can be qualitatively interpreted from the kinetic data given in Table 6. Phenylpyruvate causes substrate inhibition and has a low K_m value. As the

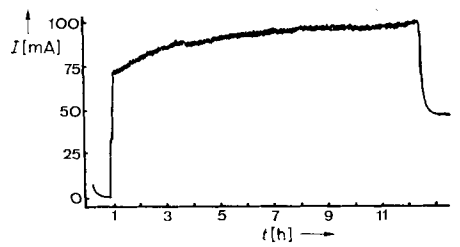

Fig. 7. Current-time course during the electromicrobial reduction of **7a** to **7b**. For further details see Experimental Procedure.

total concentration decreases, the enzyme activity and thus the current increase. Because of the K_m value, the reaction rate only begins to fall when substrate conversion is >98%, but then decreases very sharply. The solution becomes dark blue within one minute. The reason for this is that the steady state of the consecutive reaction sequence—the electrochemical reduction of methyl viologen and its reoxidation by the enzyme—collapses due to lack of substrate. The current does not fall to zero because *Proteus vulgaris* possesses hydrogenase. This reaction is of no importance until the phenylpyruvate is exhausted because the hydrogenase has the relatively large K_m value of 0.3 mM for reduced methyl viologen and up to this point the concentration of reduced methyl viologen is <0.05 mM. The product of current and time between the current increase and decrease shown in Figure 7 corresponds to the quantity of phenyllactate formed.

Typical Experimental Procedures

The cultivation of *C. La1*, *C. kluyveri*, *P. mirabilis*, and *P. vulgaris* has been described [57, 66, 67]. After the stationary growth phase has been reached, the cells are centrifuged off at ca. 5000 g and stored at approximately −15 °C under exclusion of air without being washed. The dry weight of the sediment amounts to about 20% of the wet weight. Hydrogenations are performed in 0.1 M potassium phosphate buffer (pH 7.0) under normal pressure in an H_2 atmosphere with shaking (approximately 200 cycles per min) at 35 °C and carried out in the presence of 0.4 mg tetracycline/10 mL buffer to prevent growth of other microorganisms. All experiments are performed under strict exclusion of oxygen. The H_2 consumption is read from a Warburg manometer that is filled with mercury and connected to the hydrogenation vessel. Quantities of cells are expressed as dry weights.

1. Hydrogenation of **1a** to **1b** with *C. La1*: The substrate (0.70 mmol) was completely hydrogenated in 4.5 h in 26 mL of buffer containing the cells (150 mg) and 1 mM methyl viologen (see Fig. 1).

2. Hydrogenation of **3a**, **4a**, and **5a**: *C. La1* cells (1.6 g), methyl viologen dihydrochloride (12 mg), and **3a** (6.0 mmol as the sodium salt) in 40 mL of buffer were hydrogenated for ca. 3—4 h in a shaking flask with a capacity of approximately 200 mL which was connected to a 2.5-L H_2 reservoir. **3b** was isolated in the form of a lactone; no contaminants could be detected by gas chromatography after distillation. **4b** was prepared from **4a** in an analogous fashion. The enantioselectivity of both reactions was >96%. **5a** (6 mmol) was hydrogenated with *C. kluyveri* cells (1.6 g) in 52 mL of buffer without methyl viologen in 3.5 h (*ee*>96%). (We are grateful to Dr. *H. G. Leuenberger* and Dr. *M. Schmid*, Hoffmann-La Roche, Basel, for the analyses.)

3. Reduction of **6a** to **6b** with *Proteus vulgaris* and formate: a mixture (90 mL) containing 85 mM phosphate buffer, 33.3 mM **6a** (as the sodium salt), 65 mM sodium formate, *Proteus vulgaris* (600 mg), and 1.0 mM benzyl viologen was shaken for 21 h at 35 °C under N_2. The resulting solution contained 32 mM **6b**; no **6a** could be detected. **6b** was isolated as the pantolactone. $[\alpha]_D^{25}$ −51.1 (H_2O, c=30 mg/mL). *ee*>99.5% (determined by gas chromatography). (We are grateful to BASF AG for this analysis).

4. Electromicrobial reduction of **7a** to **7b**: 0.1 M potassium phosphate buffer (200 mL, pH 7.0) containing 100 mM **7a** was flushed free of oxygen with N_2 in the cathode compartment of an electrochemical cell (Fig. 5b) and mixed with a suspension of *Proteus vulgaris* (15 mg dry weight). The cathode potential was set to −900 mV with respect to a saturated calomel electrode. A current of 70 mA flowed after addition of sufficient methyl viologen to give a 6 mM solution. The maximum current (100 mA) was obtained shortly before the end of the reaction, and the subsequent drop in current showed that the substrate was totally consumed (Fig. 7). The quantity of charge taken up at this point corresponded to a conversion of 99%. No remaining substrate could be detected by HPLC. The productivity number was 117000.

5. Electromicrobial reduction of **8b** to **8a**: The cathode compartment of the electrochemical cell contained 0.1 M potassium phosphate buffer (41 mL, pH 7.0) and 0.6 M **8a**. The diaphragm consisted of a 3.6-cm^2 Nafion cation exchange membrane; 10 mL of the above phosphate buffer served as an anolyte. Oxygen dissolved in the catholyte was removed by flushing with N_2. *Proteus vulgaris* (15.1 mg) was then added and the cathode potential set to −760 mV. After addition of sufficient methyl viologen to give a 6 mM solution and stirring at a rate of 400—500 rpm, a current of 120 mA was obtained. According to HPLC, 96% of the expected quantity of **8b** was formed after 12 h. $[\alpha]_D^{25}$ +11.1 (H_2O, c=20.7 mg/mL). If the concentration dependence is taken into consideration, this corresponds to the reported values [84, 85]. The productivity number was approximately 125000.

5. Outlook

The methodology of biocatalytic, enantioselective reductions of unsaturated compounds has undergone considerable development over the past few years. A number of efficient procedures for NADH regeneration are now available. The groups led by *Whitesides*[45] and *Jones*[48] have synthesized a variety of compounds on a laboratory scale using NADH regeneration. Amino acids can even be prepared on a commercial scale with kg prices of approximately 50 DM as a result of the studies performed by the groups of *Kula*, *Wandrey*, and *Leuchtenberger*.[43,86] This new battery of methods is, however, still used relatively seldom in preparative organic chemistry.

It can be assumed that further microorganisms and reductases will be found for reductions. These methods must, however, compete with other developments: namely, synthetic chiral hydrogenation catalysts and enzymes other than reductases. The latter include esterases that have recently often been employed to selectively cleave the esters of secondary alcohols;[87-89] also noteworthy are the syntheses of chiral secondary alcohols by biocatalytic condensation reactions.[90] Syntheses in which a center of chirality obtained by biocatalysis is utilized in subsequent sterically controlled reactions will probably also be developed further. For instance, *Reetz*[91] recently demonstrated the possibilities that are opened up by addition reactions with chiral α- and β-alkoxycarbonyl compounds.

We assume that many applications will also be found for the microbial hydrogenation and electromicrobial and electroenzymatic reductions that we have investigated during the past few years. It would also be interesting if other reductases such as enoate and 2-oxocarboxylate reductase could be discovered that are highly stereoselective, can react with a wide spectrum of substrates, and can also accept electrons from artificial mediators which can be electrochemically regenerated. We believe electrochemical regeneration, e.g., of reduced methyl viologen, to be superior in many respects to that obtained with the system light/[Ru(bpy)$_3$]/ethylenediaminetetraacetic acid.[92]

The results described in this report were obtained with the help of a large number of people and institutions. In addition to the persons mentioned in the text and references, we are especially grateful to Dr. P. Rauschenbach for providing appropriate HPLC methods, to the technicians R. Feicht, H. Leichmann, L. Riesinger, C. Stuber, and F. Wendling for

pare the manuscript. We would also like to thank BASF, the Fonds der Chemischen Industrie, and especially the Deutsche Forschungsgemeinschaft ("Sonderforschungsbereich 145, Biokonversion") for their financial support.

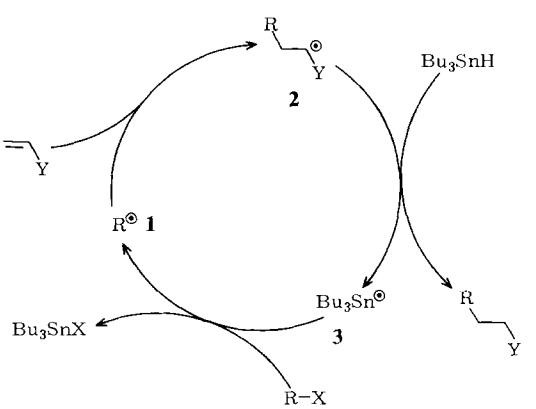
Syntheses with Radicals—C-C Bond Formation via Organotin and Organomercury Compounds

New Synthetic Methods (52)



By Bernd Giese*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

C–C bond formation is one of the most important synthetic steps in the construction of organic molecules. In the last few years it has been increasingly achieved by radical addition to alkenes. In such reactions the adduct radicals have to be trapped by an donor subsequent to the C–C bond formation in order to prevent polymerization. This task can be accomplished with organotin and organomercury hydrides, the use of which has led to new synthetic methods. The occurrence of radical chain reactions in which reactions take place between radicals and nonradicals is decisive for the success of the synthesis. In these cases small amounts of radical initiators suffice and numerous functional groups may be used in the C–C bond-forming reactions. The yields and selectivities of these radical reactions are often very high.

1. Introduction

Until a few years ago radicals were still a domain for mechanistically oriented research; a wealth of experimental data has led to a deeper understanding of their chemistry. Nowadays radical reactions are increasingly employed in synthesis, wherein the product is formed through reactions of radicals either with other radicals or with molecules whose electron spins are paired. In radical-radical reactions, the radicals must be continuously generated, so that at least equivalent amounts of radical initiators are required. Examples are the coupling reactions of electrochemically generated radicals[1] or the dimerization of capto-dative stabilized radicals developed by *Viehe* et al.[2] in recent years. Methods in which the products are produced in reactions between radicals and nonradicals are fundamentally different. These syntheses, occurring via radical chain reactions, require only small amounts of radical initiators, as shown, e.g., by the radical addition of alkyl halides to alkenes in the presence of tributyltin hydride.[3] The radicals **1**–**3** react with nonradicals (alkenes, tributyltin hydride, alkyl halides) with the formation of new radicals.

Radical chain reactions such as the $S_{RN}1$ reactions,[4] the additions of molecules with activated carbon-halogen[5] or carbon-hydrogen bonds,[6] the Minisci alkylations,[7] and the Meerwein arylations[8] have already been described in detail. The subject of this review is the C–C bond-forming reactions developed in recent years using organotin or organomercury compounds.

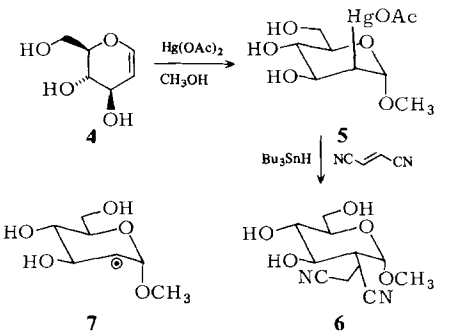
2. Conditions for Radical Chain Reactions

In order that a radical chain reaction be synthetically useful, as little radical initiator as possible should be required and few side products should form. This is possible only if the chain propagating radicals meet certain conditions of reactivity and selectivity.

2.1. Reactivity Requirements



Chain reactions are terminated by combination or disproportionation of the radicals. Therefore, the rate of reaction, r_c, between radicals and nonradicals should be higher than that of the chain termination step, r_t. Equations (a) and (b) are the analytical expressions for these reactions, where k_c and k_t are the rate constants for chain propagation and chain termination, respectively; $R^{\odot}$ represents all occurring radicals, X any added reagents. The reactivity requirement that must be satisfied for the use of the radical chain reaction in synthesis is given by Equation (c).

$$r_c = k_c[R^{\odot}][X] \quad (a)$$

$$r_t = k_t[R^{\odot}][R^{\odot}] \quad (b)$$

$$1 < \frac{r_c}{r_t} = \frac{k_c \cdot [X]}{k_t \cdot [R^{\odot}]} \quad (c)$$

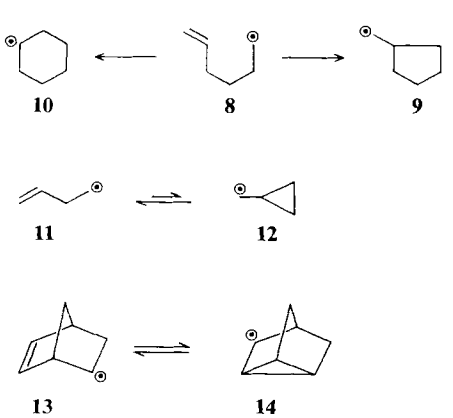
In most cases, carbon radicals react with each other in a diffusion-controlled manner; the rate constants k_t are about 10^9 L·mol^{-1}·s^{-1}, and only a very small temperature dependence is observed.[9] The concentration of the added reaction partner X is dependent on the reaction conditions. In order to evaluate the magnitude of k_c necessary for synthetic purposes, [X] = 1 mol·L^{-1} should be chosen. The concentrations of radicals in chain reactions also depend on the reaction conditions which, e.g., determine the rate of decomposition of the initiators. Typically, the radical concentrations in chain reactions are around 10^{-7} mol L^{-1}.[9] Inserting these values of [X] and [$R^{\odot}$] into Equation (c), it is seen that in radical chain reactions k_c has to be larger than 10^2 L·mol^{-1} s^{-1}. Accordingly, rate constants greater than 10^2 L·mol^{-1} s^{-1} are required for synthetically useful reactions between carbon radicals and nonradicals. This limiting factor can be of advantage in the planning of a synthesis because it means that a range of functional groups can be tolerated without protection. Thus, the homolysis of O–H and N–H bonds in aliphatic alcohols and amines by alkyl radicals,[9] as well as the addition of alkyl radicals to the C=O groups[10] of ketones and esters, takes place with rate constants k_c that are smaller than 10^2 L·mol^{-1} s^{-1} at room temperature. Therefore, these functional groups are not attacked in intermolecular radical C–C bond-forming reactions. In other words, carbon radicals exhibit high chemoselectivity and their employment in reactions with more complex molecules should be considered. For example, the C-branched carbohydrate **6** can be synthesized from the glucal **4** without the use of protecting groups. The carbon-carbon bond formation, via homolysis of the C–Hg bond in **5**, attack of fumaronitrile on the radical **7**, and subsequent hydrogen transfer, affords the product **6** in about 50% overall yield.[11]

2.2. Selectivity Requirement

The second condition that must be fulfilled in radical chain reactions concerns the selectivities of the radicals. Only when these differ sufficiently from each other will synthetically useful radical chain reactions result. Thus, the formation of products from alkyl halides and alkenes in the presence of tributyltin hydride takes place in good yields when the selectivity of the adduct radicals **2**, due to the substituent Y, is markedly different from that of the radical **1**. If **1** is a nucleophilic alkyl radical, then electron-deficient alkanes, e.g., acrylonitrile, are suitable for use in synthesis. Nucleophilic alkyl radicals, such as the cyclohexyl or *tert*-butyl radical, add to acrylonitrile at 20 °C with rate constants of about 10^6 L·mol^{-1}·s^{-1}.[12] The adduct radical **2** thus formed is much less nucleophilic because of the nitrile group. Accordingly, it adds to acrylonitrile with a rate constant of approximately 10^2 L·mol^{-1} s^{-1}.[12] This is so slow that **2** is trapped by tributyltin hydride before it can react further with acrylonitrile. Hydrogen transfer to alkyl radicals occurs with rate constants of the order of 10^6 L·mol^{-1} s^{-1} at 20 °C,[13] which are only slightly dependent on substituents on the alkyl radical. Accordingly, the ratio of the rate constants for the competing reactions of the radicals **1** and **2** are 1 and 10^4, respectively, thereby fulfilling the requirement of differing selectivity. However, a value of one for radical **1** could lead to the assumption that it reacts completely unselectively with acrylonitrile and tributyltin hydride. This is not the case if the concentration of the alkene is higher than that of tributyltin hydride. However, the concentration ratio acrylonitrile/tributyltin hydride also influences the fate of the adduct radicals **2**. If the excess of acrylonitrile is too large, then **2** would also react noticeably with acrylonitrile. An essential task, therefore, is to find the optimum concentration ratio for the synthesis in question. This is necessary because the alkene substituents exert a strong influence on the rate of addition.[12] Thus, the rate of addition of the cyclohexyl radical increases by four orders of magnitude on going from 1-hexene to acrolein.[14]

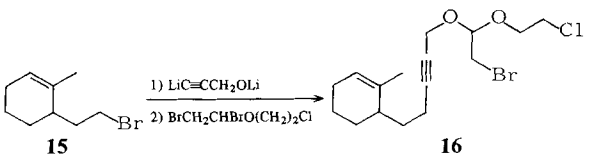
The competition between addition to an alkene and H-capture is of no importance for the tributyltin radical **3** because **3** is formed anew upon hydrogen transfer from tributyltin hydride to **3**. In the case of **3**, the competition between addition to the alkene and halogen abstraction from

the alkyl halide is much more decisive synthetically. In fact, alkyl bromides[15] and electron-poor alkenes,[16] such as acrylonitrile, react at comparable rates with **3**. Since a relatively large amount of acrylonitrile is used in these syntheses, the undesired addition of **3** to this alkene cannot be greatly influenced by varying the concentration. It is better to switch from the alkyl bromide to the 10—100 times more reactive alkyl iodide.[15] In contrast to **3**, halogen transfer from monohaloalkanes to the carbon radicals **1** and **2** is unimportant because their rate constants are relatively small.[17]

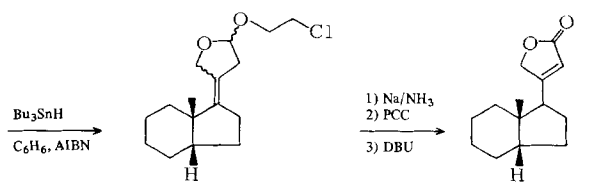


This analysis is typical for the development of radical chain reactions in synthesis. In order to evaluate whether specific reactions are synthetically useful, the magnitudes of the rate constants must be known. Many rate constants for radical reactions have been determined in recent years so that the most important are known.[18] Moreover, neutral radicals have a great advantage over ionic ones in that the solvent has little effect on the reaction.[19]

3. The Tin Method

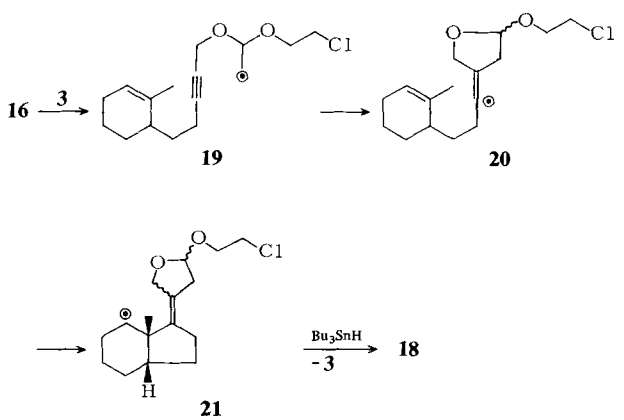


It has been known for over 20 years that the reduction of alkyl halides with trialkyl- and triaryltin hydrides leads to alkyl radicals[20] which undergo all the typical radical reactions. Only C—C bond-forming reactions will be dealt with in this review. We shall distinguish between intramolecular cyclization reactions and intermolecular C—C bond-forming reactions.

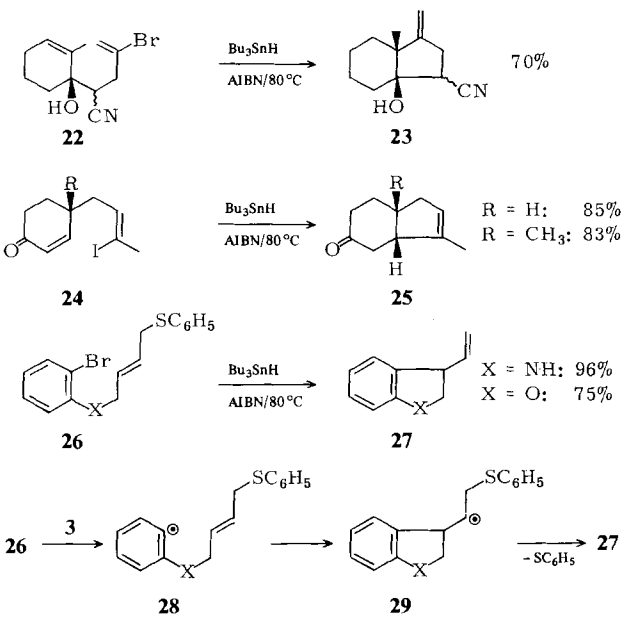


3.1. Intramolecular C—C Bond Formations (Cyclizations)

From the studies of *Lamb* et al.[21] and *Walling* et al.,[22] it is known that in a kinetically controlled reaction the 5-hexenyl radical **8** preferably cyclizes to the five-membered ring **9**, whereas under thermodynamic conditions the six-membered ring **10** is formed.[23] Radical cyclizations have been particularly thoroughly studied by *Beckwith*,[24] *Ingold*,[24b] *Wilt*,[25] *Julia*,[26] and *Surzur*[27] and reviewed in several articles. In the radical addition to alkenes[12,24b] the thermodynamically less stable cyclopentylmethyl radical **9** is rapidly formed via an unsymmetrical transition state, which is sterically more favorable for the formation of a five-membered ring. Also, Baldwin's rules[28] require that five-membered-ring formation (5-*exo-trig* reaction) be faster than six-membered-ring formation (6-*endo-trig* reaction). 6-Heptenyl radicals give the six-membered ring as well as the seven-membered ring. However, simple three- and four-membered rings cannot be formed in this way. Although the homoallyl radical **11** rapidly cyclizes to the cyclopropylmethyl radical **12**, this reverts back very rapidly to the more stable **11**.[29] Only in systems where a large proportion of the ring strain of the three-membered ring is already present in the homoallyl radical, such as the norbornenyl radical **13**,[30] can a cyclic radical such as **14** be trapped.[30,31]

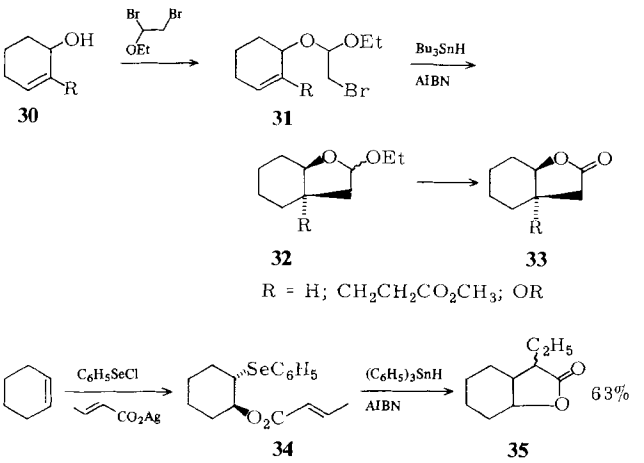


The applications of these cyclization reactions were studied before 1980 in particular by *Julia* and *Beckwith*. Since 1981 these methods have been applied to the synthesis of target molecules almost simultaneously in several laboratories. *Stork*'s work, in which both alkyl and vinyl radicals were used and cyclizations with both open-chain and cyclic double- and triple-bond systems were carried out, was pioneering. The synthesis of the butenolide **18** is a particularly elegant example (PCC: pyridinium chlorochromate, DBU: 1,8-diazabicyclo[5.4.0]undec-7-ene).[32] The radical chain reaction takes place in boiling benzene with the bromide **16** (which is easily obtained from **15**) using 2,2′-azabis(isobutyronitrile) (AIBN) as chain initiator and Bu_3SnH as H-transfer agent.



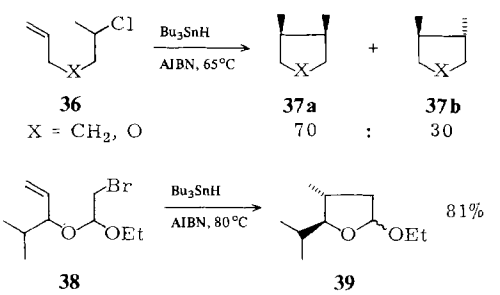
The tributyltin radicals **3** abstract the bromine atom in **16**, leaving the less reactive C—Cl bond intact. The alkyl radical **19** thus formed attacks the triple bond in an *exo-dig* reaction[28] with formation of the vinyl radical **20**, which then reacts with the double bond of the cyclohexene in an *exo-trig* reaction (**20** → **21**). It is only at this stage that

the intermolecular H-transfer from Bu_3SnH intervenes, giving the product **18** and the chain-propagating Bu_3Sn radical; the latter once again cleaves the C–Br bond in **16**.

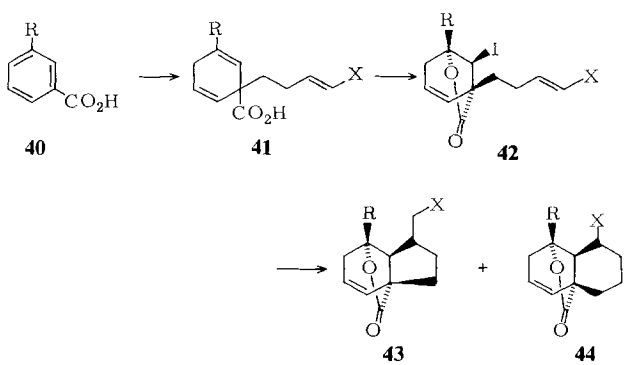


In this reaction, stereoselective *cis* annelation of the five-membered ring occurs to give the six-membered ring. In contrast, the attack of the alkyl radical on the open-chain alkyne (**19** → **20**) is unselective with respect to the β-chloroethoxy group. The vinyl radical **20** thus formed also reacts at both faces with the same rate.

Vinyl radicals can also be formed from vinyl bromides and iodides and afford products with exocyclic (**22** → **23**)[33] as well as endocyclic double bonds (**24** → **25**).[34] The OH group in **22** is not attacked owing to the high chemoselectivity of radical reactions. The facile formation of the quaternary C atom in **23** is also worth mentioning. The use of phenyl bromides such as **26** provides benzoannelated bicycles such as **27**.[35] In this case, an additional step takes place in the formation of the product **27**, namely, a β-bond cleavage (**29** → **27**). Such unimolecular homolyses are particularly fast when sulfur, bromine, iodine, or metal substituents are present in the position β to the radical center.[36] In contrast, the cleavage of the stronger C–O, C–N, C–C, or C–H bonds is much slower than hydrogen transfer from Bu_3SnH.

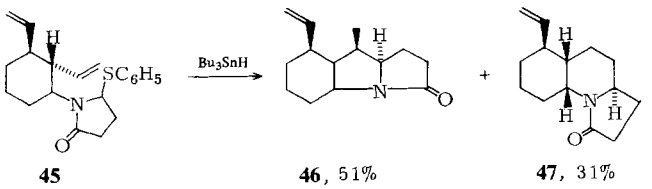


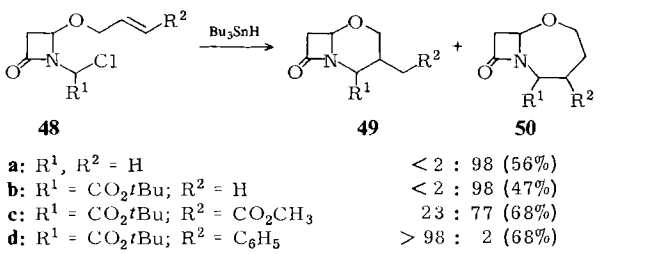
γ-Lactones can be elegantly prepared from alkenes using these radical reactions. Thus, **33** is formed by cyclization of the bromide **31** (obtained from **30**) to **32** and its subsequent oxidation.[37] In the synthesis of the γ-lactone **35**, the radical is generated from the selenide **34**.[38]



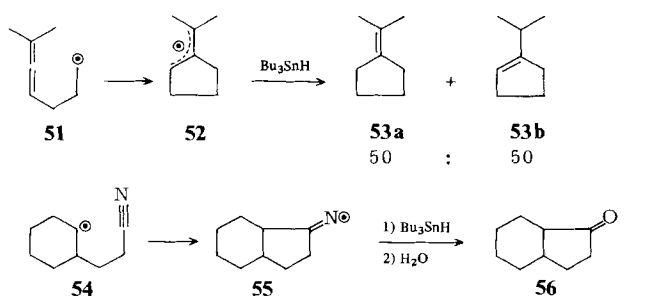
It is typical of these five-membered-ring radical cyclizations that for steric reasons the annelation to cyclic alkenes gives *cis* products. Work by *Beckwith* et al.[39] has shown that also the cyclization of open-chain 5-hexenyl radicals substituted in positions 1 or 3 gives preferentially *cis*-disubstituted pentanes (**36** → **37**). This *cis* cyclization is interpreted in terms of attractive interactions between the methyl group and the π-bond, which can occur in the very

early transition states of radical addition to alkenes. In contrast, with 2- or 4-substituted "5-hexenyl radicals," the *trans*-disubstituted products are preferentially formed, as seen in the formation of **39** from **38**.[37a]





The syntheses of the cyclization products **43** and **44** developed by *Hart* et al.[40] demonstrate that not only five-membered but also six-membered rings can be formed in these radical reactions. Birch reduction and alkylation of **40** followed by iodolactonization of **41** gives **42**, which affords the six-membered-ring compound **44** as well as the five-membered-ring compound **43**. The ratio **43**/**44** can be influenced by substituent variation. Thus, the introduction of a *tert*-butyl ester group at the terminal double bond increases the proportion of the five-membered ring. Presumably, the *tert*-butyl ester group sterically hinders the formation of the six-membered ring, while the formation of the five-membered ring is facilitated by the increased LUMO coefficient at the vinylic C atom in the β position.[12]

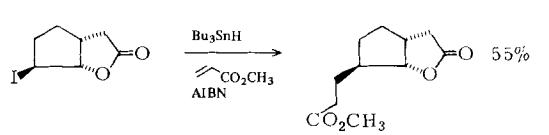


X = H; R = CH_3 70 : 30 (87%)
X = CO_2tBu; R = H > 95 : 5 (93%)

Heterosubstituted alkyl radicals can also be employed in these syntheses. Thus, the amidoalkyl radical formed as an intermediate in the desulfurization of **45** gives rise to the five- and six-membered-ring products **46** and **47**, respectively.[41] A comparison with the work of *Bachi* et al.[42] indicates that the higher proportion of the larger ring may be typical for amidoalkyl radicals. Thus, only the seven-membered-ring compound **50a** is formed from **48a**. Once again, it is possible to favor the formation of the smaller ring by the introduction of sterically demanding, polar, and radical-stabilizing substituents at the terminal olefinic C atoms.

Apart from alkenes and alkynes, also allenes[43] (**51**→**52**) or nitriles[44] (**54**→**55**) can be employed as intramolecular radical traps in C–C bond-forming reactions. In contrast, the C=O bond is not suitable for C–C bond formation, probably because the alkoxy radical undergoes rapid β-bond cleavage.[45]

3.2. Intermolecular C–C Bond Formations



Because of the unfavorable activation entropies, intermolecular reactions are noticeably slower than intramolecular cyclizations. Thus, the activation entropy for the addition of ethyl radicals to 1-hexene is more negative by 14 e.u. than that for the cyclization of the 5-hexenyl radical.[46] In contrast, these two reactions do not differ significantly in their activation enthalpies. This unfavorable entropy effect can be compensated for by electron-withdrawing substituents on the alkene, which lower the activation enthalpy.[47] The rate of addition of cyclohexyl radicals to acrolein at 20°C is almost four orders of magnitude higher than for addition to 1-hexene.[12, 14] The rate constant is about 10^6 L·mol^{-1} s^{-1}.[12] Accordingly, electron-poor alkenes are reactive enough to be employed in these syntheses. Furthermore, the polarity of the radicals changes after addition of nucleophilic alkyl radicals to electron-poor alkenes; consequently, the selectivity condition for radical chain reactions is also fulfilled. The C–C bond-forming reactions of some typical alkenes with primary, secondary, and tertiary alkyl halides are summarized in Table 1.[3, 48]

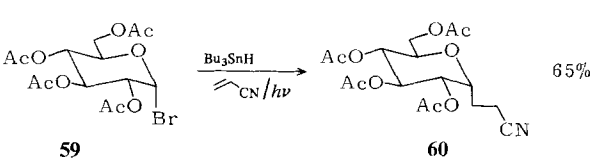


Table 1. Photochemically initiated C–C bond formation between alkyl halides and alkenes (5 molar equivalents) with tributyltin hydride (0.2 molar equivalents) and $NaBH_4$ (1.3 molar equivalents).

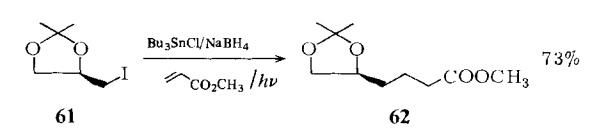
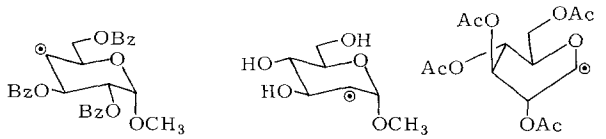
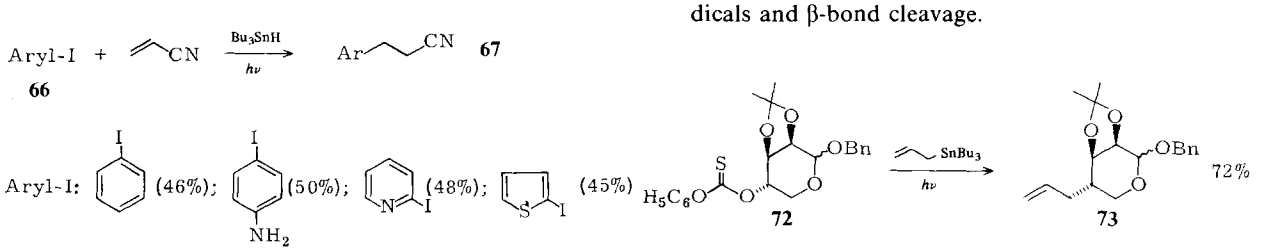


Alkyl halide	Alkene	Product [%]
n-$C_6H_{13}I$	H_2C=CHCN	80
n-$C_6H_{13}Br$	H_2C=CHCN	68 [c]
cyclo-$C_6H_{11}I$	H_2C=CHCN	95
cyclo-$C_6H_{11}I$	H_2C=CHCOCH$_3$	85
cyclo-$C_6H_{11}I$	H_2C=CHCHO	90 [c]
cyclo-$C_6H_{11}I$	H_2C=CHCO$_2$CH$_3$	85
cyclo-$C_6H_{11}I$	H_2C=CHC$_6$H$_5$	83
cyclo-$C_6H_{11}I$	H_2C=CClCN	80 [c]
cyclo-$C_6H_{11}I$	H_2C=C(CH$_3$)CN	91
cyclo-$C_6H_{11}I$	H_2C=CCl_2	87; 90 [c]
cyclo-$C_6H_{11}I$	NCCH=CHCN [a]	72 [c]
cyclo-$C_6H_{11}I$	$H_5C_2O_2CCH$=$CHCO_2C_2H_5$ [a]	78
cyclo-$C_6H_{11}I$	CH$_3$CH=CHCN [b]	86 [d]
cyclo-$C_6H_{11}Br$	H_2C=CHCN	80 [c]
t-C_4H_9I	H_2C=CHCN	87; 98 [c]
t-C_4H_9Br	H_2C=CHCN	62

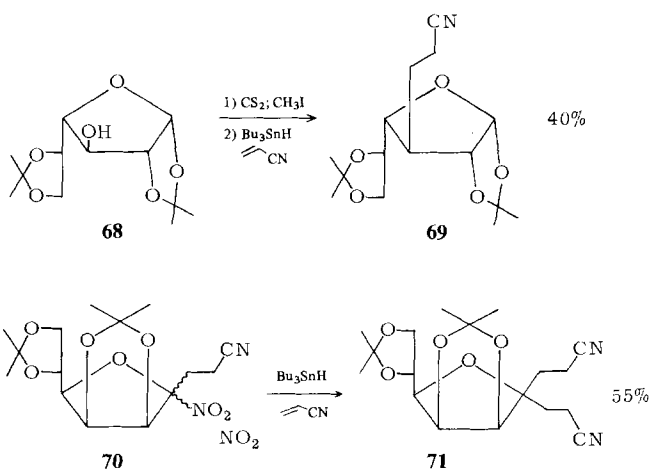
[a] *trans*-Alkene. [b] 45 : 55 *cis-trans* mixture. [c] Reaction in boiling toluene with 1.2 molar equivalents of tributyltin hydride and AIBN as initiator. [d] Photochemical reaction with 10 molar equivalents of alkene.



With iodides and bromides, the products are formed in high yields, and it is often possible to work with catalytic amounts of tin hydrides by reducing the tributyltin halide formed with $NaBH_4$ to regenerate the tin hydride. C–C bond-forming reactions do not take place with alkyl chlorides, since these are not capable of competing with the electron-poor alkene for the tributyltin radicals. Examples of the use of this tin method are shown by the C–C bond-forming reactions with the iodolactone **57**,[49] the glucosyl bromide **59**,[50] and the chiral iodide **61**.[51]



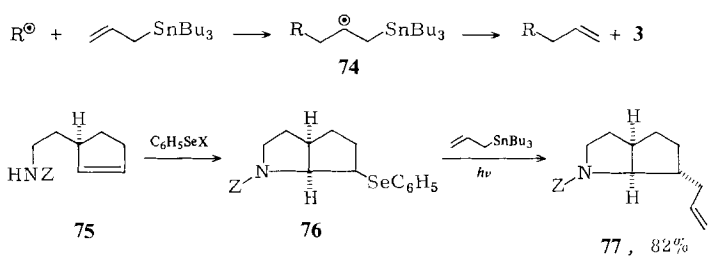
The halides **57**, **59**, and **61** have β C–O bonds that remain intact during the formation and reactions of the radicals, so that no racemization occurs at the chiral center neighboring the radical center during the radical reaction. Moreover, the C–C bond formations take place with high stereoselectivity with the radicals generated from **57** and **59**. The formation of the *C*-deoxyglucoside **60** is surprising in that the new C–C bond is axial even though the carbohydrate radicals **63** (Bz: benzoyl) and **64** are preferably attacked in the equatorial position by acrylonitrile and, particularly, by fumaronitrile.[3,52] According to ESR measurements, the glucosyl radical exists in the boat conformation **65**;[53] thus, **60** is also formed by equatorial attack.



63 **64** **65**

Reaction with the iodides **66** shows that these C–C bond-forming reactions also can be applied to aromatic systems.[48]

In the tin method, alcohols, selenides, and tertiary nitro compounds can be used in place of halides in the C–C bond forming reactions. The alcohols must be transformed into xanthogenates or other thio derivatives as in the reduction according to *Barton* et al.[53] For instance, **69** is exclusively formed from the galactose derivative **68**.[3] Another example from carbohydrate chemistry, the transformation of **70** into **71**, shows the C–C bond-forming reaction with tertiary nitro compounds. In this case, ESR measurements have shown that the sugar radical is only formed after one-electron transfer from the tin radical and elimination of $NO_2^{\ominus}$.[55] Thus, the $S_{RN}1$ reaction typical for many nitro compounds takes place, whereby the tin radical is the electron donor.

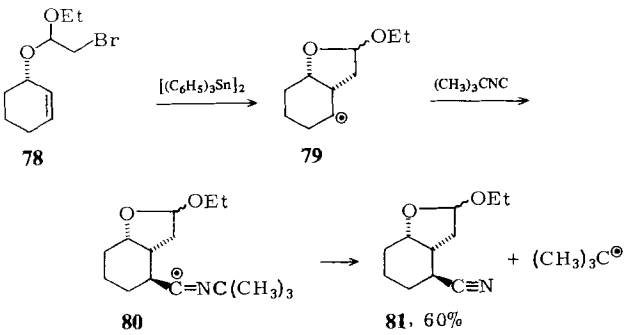


68 **69** **70** **71**

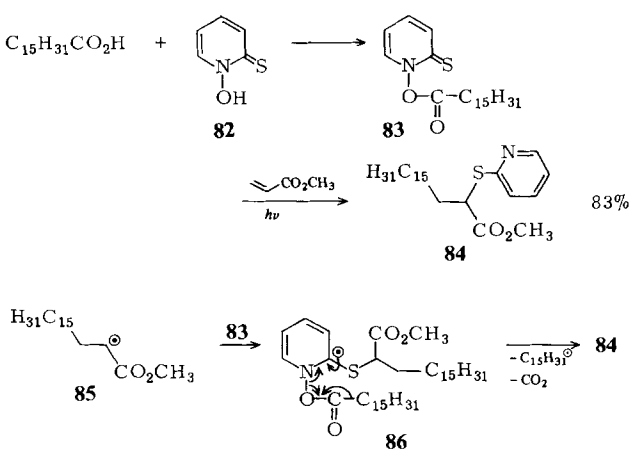
It has so far not been possible to use isocyanides for these C–C bond formations, even though they are readily reduced to hydrocarbons with tributyltin hydride via radical intermediates.[56] As for the chlorides, the reason is that they cannot compete with the added alkene for the tin radicals.

Radical chain reactions taking place via organotin compounds, but which do not involve hydrogen donors, have been worked out by *Keck*, *Danishefsky*, *Baldwin*, and *Stork*. Thus, the reaction of the pentose derivative **72** with the allyltin compound gives the pseudomonic acid derivative **73** (Bn: benzyl).[57] The reaction proceeds via the carbohydrate radical $R^{\odot}$ and the adduct radical **74**, which eliminates a trialkyltin radical by β-bond cleavage. This then attacks the thio group in **72** to regenerate the carbohydrate radical $R^{\odot}$.

Danishefsky et al.[58] used this method on the selenide **76** (Z: benzyloxycarbonyl). The C–Se bond of **76** is homolytically cleaved prior to the formation of the coupling product **77**. *Baldwin* et al.[59] used vinylstannanes, which afforded the substitution products after addition of alkyl radicals and β-bond cleavage.



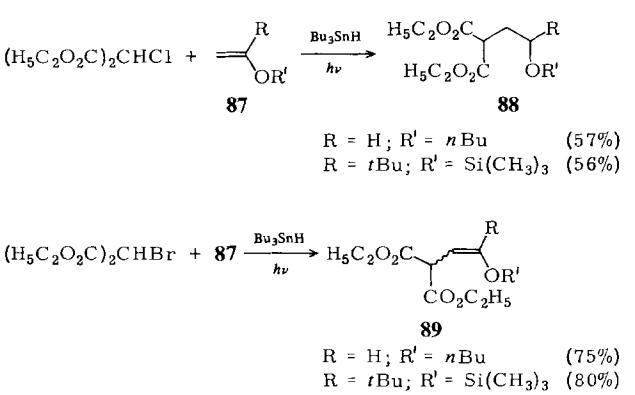
72 **73**



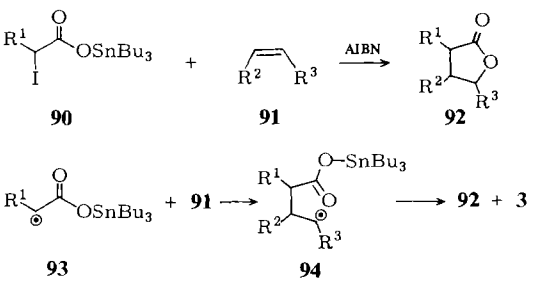
74 **75** **76** **77**, 82%

Stork et al.[60] used equimolar amounts of hexaphenylditin in the synthesis of the nitrile **81**. After homolysis of the hexaphenylditin and abstraction of a bromine atom from **78**, spontaneous cyclization gave the radical **79**, which then reacted with *tert*-butyl isocyanide to give the adduct radical **80**. Subsequent elimination of the *tert*-butyl radical gives the product nitrile **81**. The fate of the *tert*-butyl radical has not been investigated. It is unlikely, however, that it attacks the primary C–Br or Sn–Sn bonds. It is presumably consumed by radical combination and disproportionation reactions so that the synthesis of the nitrile **81** does not involve a radical chain reaction.

Barton et al.[61] have developed a method that avoids the use of tin compounds. It starts with a carboxylic acid, e.g., palmitic acid, which is converted into the mixed anhydride **83** with a thiohydroxamic acid such as **82**. Photolysis in

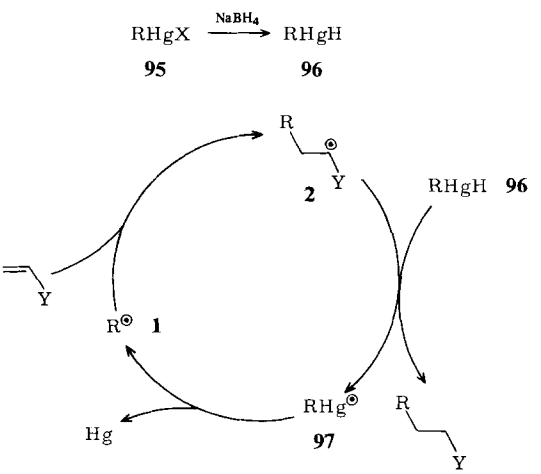


the presence of acrylic ester gives the product **84** possessing a new C–C as well as a C–S bond. This product is formed by attack of the alkyl radical on the alkene and reaction of the adduct radical **85** with the thio compound **83**. Double β-cleavage in **86** generates the product **84** and the chain-propagating alkyl radical.



3.2.1. *Electrophilic Radicals*

Intermolecular C–C bond-forming reactions with electrophilic radicals are possible in radical chain reactions if electron-rich alkenes are used. Only then is the reaction rate large enough and the difference in selectivities of the carbon radicals sufficiently pronounced. Thus, the reaction of chloromalonic ester with the enol ethers **87** gives the addition products **88**.[62] In contrast, bromomalonic ester and the enol ethers **87** give the substitution products **89**

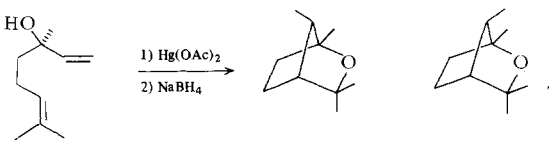


because now the adduct radicals abstract a bromine atom from the bromomalonic ester more rapidly than a hydrogen atom from tributyltin hydride.[62] Subsequent HBr elimination gives the substituted enol ethers. Therefore, photochemically initiated radical reactions can be carried out with bromomalonic esters in the absence of tin hydrides.

An interesting variation of this procedure has recently been carried out by *Kraus* et al.[63] The γ-lactones **92** are formed in good yields by reaction of the α-iodo esters **90** with alkenes in the presence of AIBN as radical initiator. The radicals **93** and **94** are intermediates; **93** adds to the alkenes **91** to give **94**, which undergoes cyclization.

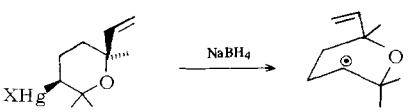
4. The Mercury Method

In addition to organotin compounds, organomercury compounds have proved particularly useful for C–C bond formation in radical chain reactions in recent years. Here, the alkyl radicals are formed by reaction of alkylmercury salts **95** (particularly halides and acetates) with boron[64] or tin hydrides.[11] Stereochemical,[65] polarographic,[66] and kinetic[67,68] studies suggest that an organomercury hydride **96** is formed, which, via hydrogen abstraction, gives the labile alkylmercury radical **97**. This decomposes spontaneously to mercury and an alkyl radical.[69] The alkylmercury hydride **96** plays the role of the hydrogen donor, trapping the adduct radicals **2** prior to their polymerization.



The advantage of the mercury method over the tin method lies in the mild reaction conditions (room temperature, absence of light) and very short reaction times (of the

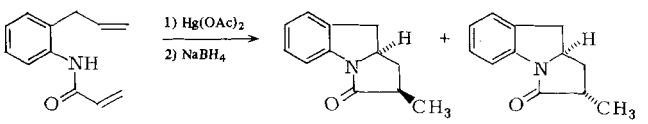
order of minutes), as well as the unproblematic separation of the mercury. However, since the alkylmercury hydride is a better hydrogen donor[67] than trialkyltin hydride, the mercury method can only be employed in syntheses involving very reactive alkenes.



4.1. Intramolecular C–C Bond Formations (Cyclizations)

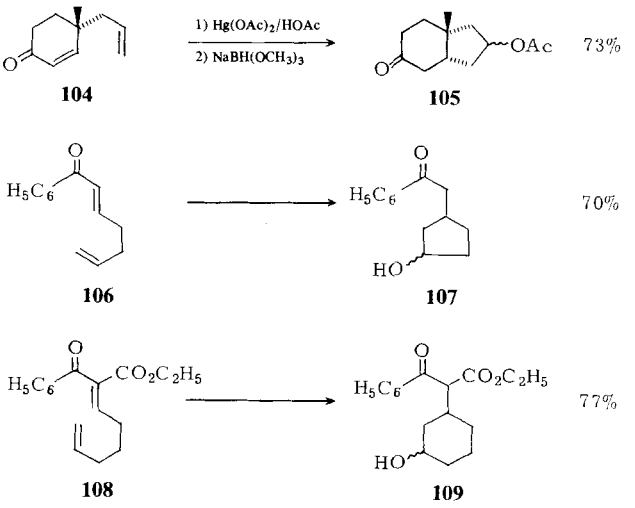
The 5-hexenyl radical generated from mercury salts behaves just as the radical produced with the aid of **3** and cyclizes to give mainly the five-membered ring. This reaction has been used in kinetic studies of hydrogen abstraction[68] and C–C bond formation.[67] The following examples illustrate some synthetic applications.

The bicyclic compound **99** is formed in 68% yield by mercuration of linalool, **98**, and subsequent reduction.[70] The reaction proceeds via the monocyclic organomercury compound **100**, which is formed by electrophilic attack of mercury acetate on the electron-rich double bond in **98** followed by intramolecular attack by the OH group. Homolysis of the C–Hg bond gives the radical **101**, which is converted into the bicyclic compound **99** after cyclization and hydrogen capture.

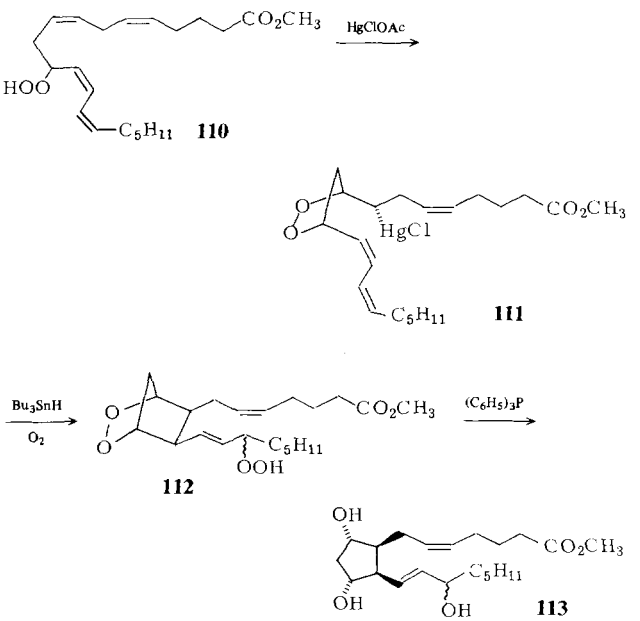


98 **99a**, 52% **99b**, 16%

100 **101**



Danishefsky et al.[71] used the diene **102** in the synthesis of the benzoannelated bicyclic compound **103**, whereby the amide function acts as a nucleophilic neighboring group in the mercuration step.

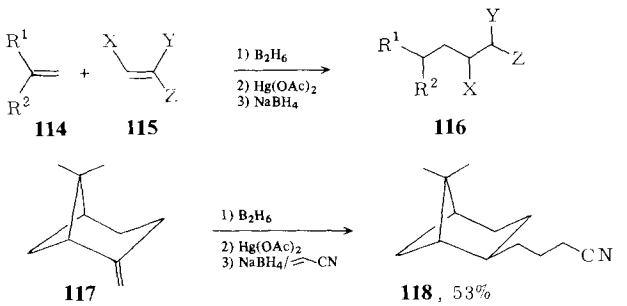


102 **103a**, 34% **103b**, 11%

The different reactivities of double bonds in the electrophilic solvomercuration have also been employed in the syntheses of the cyclization products **105**, **107**, and **109**.[72] However, in these cases, acetic acid or water function as intermolecular nucleophiles in the mercuration step.

In the course of a prostaglandin synthesis it was recently found by *Corey* et al.[73] that the organomercury compound **111** gives the bicyclic compound **112** in which the two

substituents are *cis*. In this radical cyclization reaction the attractive interaction between the double bond systems apparently predominates in the early transition state.

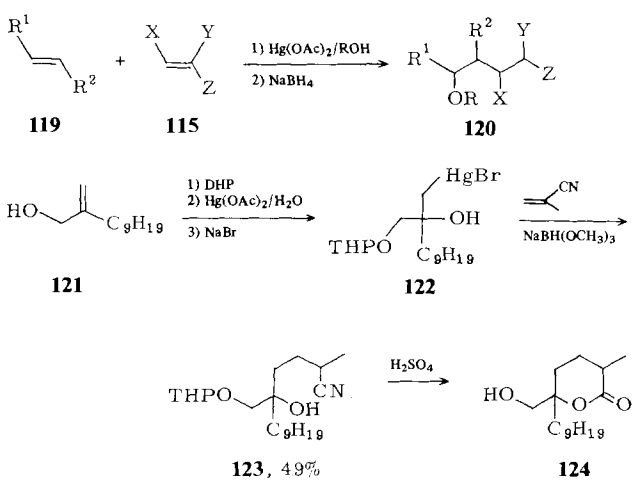


4.2. Intermolecular C–C Bond Formations

The versatility of the mercury method lies in the fact that organomercury salts are easily accessible from alkenes, cyclopropanes, and ketones.

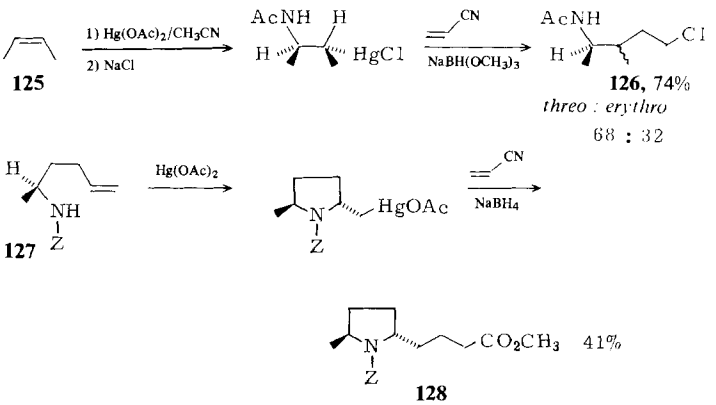
4.2.1. The Use of Alkenes

Alkenes with electron-rich terminal double bonds, **114**, can be reductively coupled with electron-poor alkenes, **115**, in a one-pot reaction.[74] The reaction proceeds via hydroboration of the electron-rich double bond, transformation of the boron-carbon bond into a mercury-carbon bond, and reduction to radicals, which on reaction with **115** give the product **116**. A wide variety of substituents



R^1 and R^2 can be present on the double bond of **115**. Acrylonitrile, acrylic esters, α-chloroacrylic esters, and maleic anhydrides are particularly effective radical traps. Thus, for example, β-pinene, **117**, reacts stereo- and regioselectively with acrylonitrile to give the C–C coupling products **118** in 53% overall yield.[74]

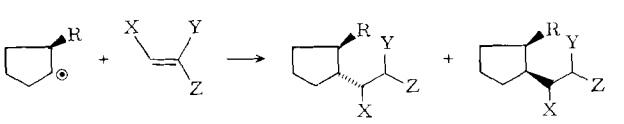
114 **115** **116** **117** **118**, 53%



In cases where the attacked alkene contains a group that can be eliminated by rapid β-cleavage, photoinitiated reaction with alkylmercury salts leads to the substitution products.[75] It is possible to introduce an additional functional group in the coupling reaction by generating the organomercury salts through solvomercuration of electron-rich alkenes, **119**.[76] These syntheses can also be carried out as one-pot reactions. After solvomercuration, the reaction mixture is diluted with dichloromethane, the electron-poor alkene is added in about a threefold excess, and the C–C bond in **120** is formed in a radical process by addition of a hydride donor. As shown by *Barluenga* et al.,[77] it is often advantageous to carry out the process as a two-phase reaction in water/dichloromethane using Trilon B as the phase-transfer catalyst.

The introduction of an additional group in this reaction permits subsequent reactions, e.g. lactonization,[78] when the solvomercuration is carried out in the presence of acetic acid or water. *Kozikowski* et al.[79] used this method to synthesize the antibiotic malingolide, **124**, as a racemic mixture of diastereomers from the allyl alcohol **121**, whereby **122** and **123** are intermediates (DHP: dihydropyran, THP: tetrahydropyranyl).

119 **115** **120** **121** **122** **123**, 49% **124**

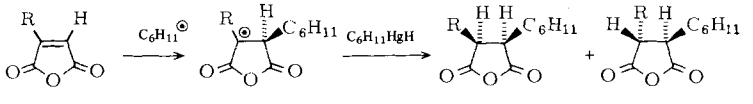


A C–N bond is formed when nitrogen nucleophiles are used. The nucleophile can enter in the reaction either in-

125 **126**, 74% *threo* : *erythro* 68 : 32 **127** **128** 41%

termolecularly,[80] e.g., **125** → **126**,[81] or intramolecularly,[82] e.g., **127** → **128**.[83]

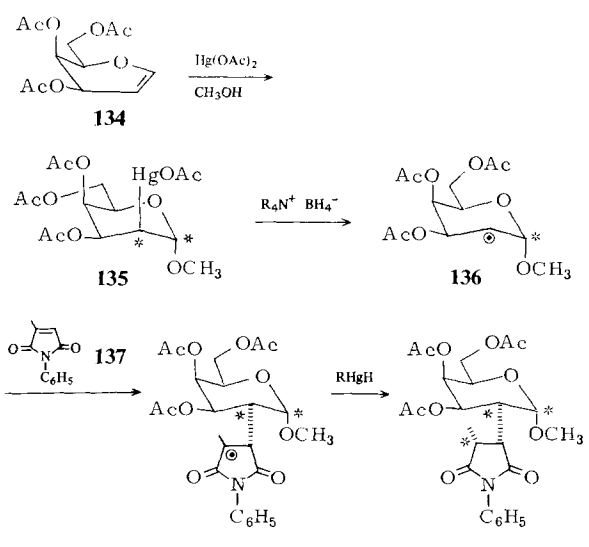
Up to four centers of chirality are created in the formation of **120** from the alkenes **115** and **119**. The first chiral center is introduced in the solvomercuration, a reaction that takes place with quite high diastereoselectivities with both cyclic[84] and open-chain[85] alkenes via asymmetric induction. The homolysis of the C–Hg bond gives radicals; cyclic radicals react selectively. Thus, the C–C bond-forming reaction with α-ethoxy-substituted cyclopentyl radicals **129** ($R = OC_2H_5$) shows that the proportion of *trans* addition increases from 72 to 90% on going from α-chloroacrylonitrile to styrene.[86] This is explained by the decreasing reactivity of the alkenes,[12] because steric effects are more pronounced in the slower reaction with a later transition state than in the earlier transition state of the faster reaction. The introduction of a substituent on the vinyl atom in the alkene to be attacked also leads to an increased stereoselectivity[87] because this substituent increases the steric repulsion during the radical addition.[12] The substituent in the radical also influences the *trans* : *cis* ratio. In this respect an amide group[88] shields the neighboring radical center more strongly than a methyl group.[89] The latter, in turn, exerts a larger influence than an ethoxy group.[86] The selectivities are somewhat smaller for substituted six-membered-ring radicals,[86-89] although in isolated cases, e.g., carbohydrate radicals,[3,11,50,52] they can be quite pronounced.



129 **115** **130a** **130b**

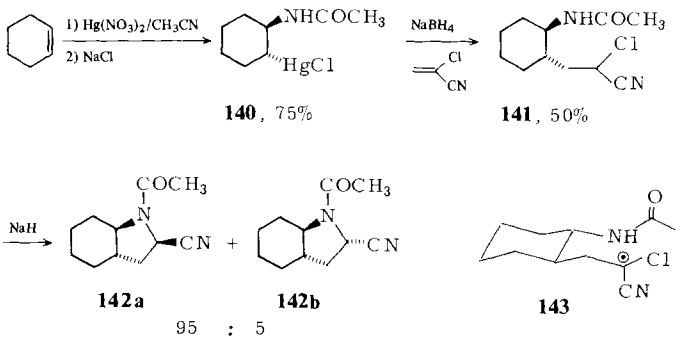
R	X	Y	Z	**130a** : **130b**
OC_2H_5	H	Cl	CN	72 : 28
OC_2H_5	H	H	CN	77 : 23
OC_2H_5	H	H	CO_2CH_3	88 : 12
OC_2H_5	H	H	C_6H_5	90 : 10
OC_2H_5	$CO_2C_2H_5$	H	$CO_2C_2H_5$	98 : 2
CH_3	H	H	CN	92 : 8
CH_3	$CO_2C_2H_5$	H	$CO_2C_2H_5$	98 : 2
$NHCOCH_3$	H	Cl	CN	>98 : 2

The last center of chirality is generated by hydrogen abstraction, whereby once more the different shielding of the



radical centers by the neighboring substituents plays a decisive role. Since, however, the small hydrogen atom is transferred in this process, the thermodynamically less stable *cis* product is preferentially formed. This is illustrated by the hydrogen abstraction reactions of the radicals **132**, generated from cyclohexyl mercury salts and maleic anhydrides **131** in the presence of $NaBH_4$; the *cis* proportion reaches 95%.[90]

131 **132** **133a** **133b**



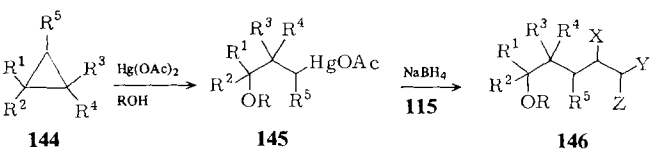
R = CH_3 : 89 : 11
R = *t*Bu : 95 : 5
R = OAc: 94 : 6

The C–C bond formation between the galactal **134** and the methyl maleimide **137** is an example of the asymmetrically induced formation of four centers of chirality.[52] The mercuration takes place *cis* to the directing OAc substituents in the galactal **134**. Subsequent *trans* attack by the nucleophile leads to the organomercury salt **135**, which, via the radical **136**, undergoes equatorial coupling with **137** with over 95% stereoselectivity to give **138**. A *trans* hydrogen transfer to **138** then gives the product **139** in which each of the three indicated centers of chirality were created with over 90% asymmetric induction. Only the fourth center of chirality (on the five-membered ring) consists of roughly equal parts of *R* and *S*. In this one-pot reaction, two diastereomers, each with four new centers of chirality, are obtained in a yield of 55%. The separation of the two diastereomers is readily achieved by column chromatography.

134 **135** **136** **137** **138** **139**

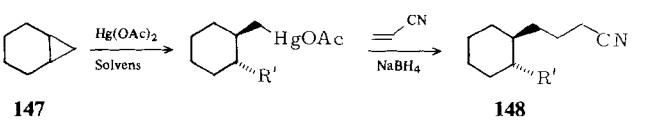
Another example of the high selectivity of this synthetic sequence is given by the preparation of the α-aminonitrile derivative **142** by solvomercuration of cyclohexene to **140** in acetonitrile followed by C–C coupling of **140** with α-chloroacrylonitrile.[88] As shown by the *trans*-annelation of

140, 75% **141**, 50%



142a **142b** **143**

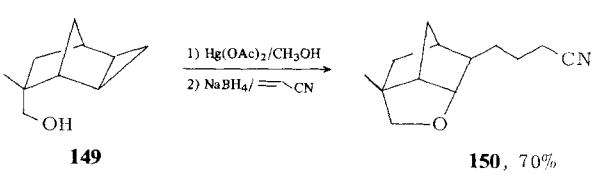
95 : 5



the rings in **142**, the six-membered-ring radical undergoes *trans* C–C coupling. Also, the high selectivity of the hydrogen capture seen in the cyclization of **141** is interesting. The ratio **142a** : **142b** (95 : 5) can be interpreted in terms of a preferred conformation **143** of the adduct radical, which is attacked from the less hindered side.

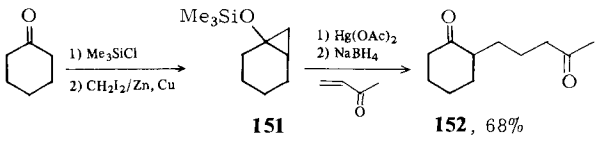
4.2.2. *The Use of Cyclopropanes*

Cyclopropanes are solvomercurated in an analogous way to alkenes.[91] Here, the mercury salt attacks at the least substituted carbon atom of the cyclopropane **144** to give γ-substituted organomercury salts **145** upon reaction with a nucleophile, e.g., the solvent ROH. The salts **145** react via the corresponding radicals with electron-poor alkenes **115** to give the products **146**.[92] This reaction can also be carried out as a one-pot synthesis,[93] and differently substituted products are obtained in different solvents.[94,95] Starting with norcarane, **147**, the *trans*-disubstituted cyclohexane derivative **148** is obtained.[93b,95]

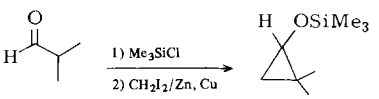


144 **145** **115** **146**

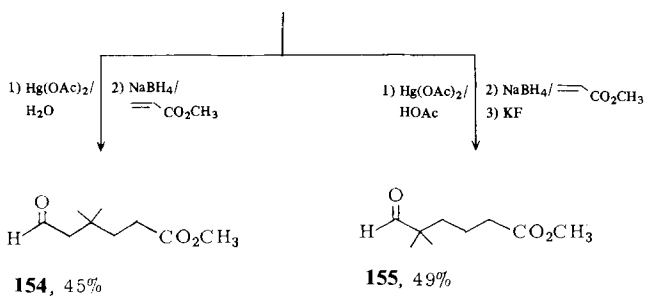
147 **148**



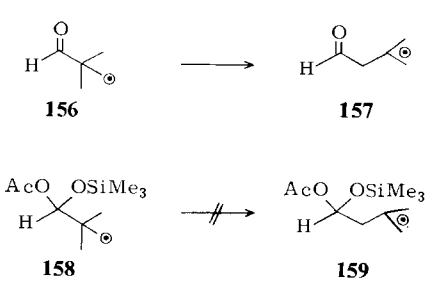
Solvent	R′	**148** [%]
CH_3OH	OCH_3	82
H_2O	OH	62
HOAc	OAc	65
CH_3CN	$NHCOCH_3$	65



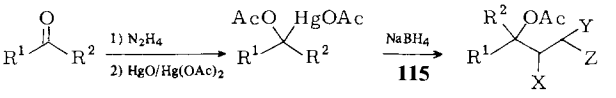
An intramolecular reaction is also possible using cyclopropanes as seen in the formation of **150** from the cyclopropane **149**, which contains a nucleophilic neighboring group.[95]



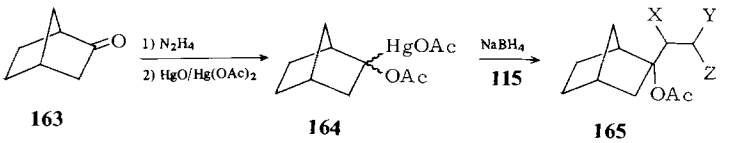
149 **150**, 70%

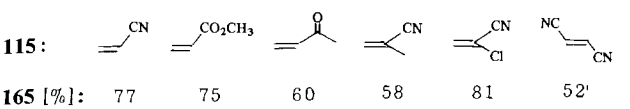


A variation of this cyclopropane method involves the use of ketones or aldehydes to give products of increased chain length via silyl enol ethers, cyclopropanation to siloxycyclopropanes, mercuration, and C–C coupling.[96] In this way the diketone **152** can, for example, be synthesized from cyclohexanone via the cyclopropane **151**. This example shows that 1,6-disubstituted C–C chains can be produced in radical reactions using cyclopropanes—i.e., the products of reactivity umpolung are obtained.[97]



Rearrangements take place when aldehydes are used. Thus, the rearranged product **154** is obtained from isobutyraldehyde via the cyclopropane **153**.[98] If the solvomercuration is carried out in acetic acid rather than water, rearrangement is avoided and **155** is formed. The rearrangement occurs in the case of the β-keto-substituted alkyl radical and is reminiscent of the homoallyl rearrangement (**156** → **157**).[24b] When the aldehyde group is protected by working in acetic acid, the rearrangement (**158** → **159**) can no longer take place.





4.3.2. The Use of Ketones

Ketones **160** can be transformed into α-substituted organomercury salts **161** via the hydrazones.[99] The C–C coupling products **162** are formed via reaction of **161** with alkenes.[100] The scope of this synthesis is illustrated by the transformation of norcamphor **163** to **165** via the organomercury salt **164**.[101]

The reaction with methyl vinyl ketone exemplifies the synthesis of 1,4-disubstituted C–C chains, i.e., the products of umpolung, in this radical reaction.[97] In the radical **166**, the *O*-substituted C atom is nucleophilic, in contrast to the corresponding C atom in the starting ketone **160**; it therefore rapidly attacks electron-poor double bonds[12, 102].

5. Outlook

Radical chain reactions in which the decisive reactions are between radicals and nonradicals have proven to be of particular value for the employment of radicals in synthesis. The syntheses take place, in part, with good yields and high selectivities. The mild reaction conditions and the high chemoselectivity are remarkable and permit the use of radical chemistry in reactions with complex molecules. This can give a fresh impetus to, for example, carbohydrate chemistry. Here, a knowledge of the stereochemistry, which should depend on the substituents on both the carbohydrate and the radical trap, is important. Experiments carried out so far have demonstrated surprising conformations and high stereoselectivities of these carbohydrate radicals.[53]

Mechanistic studies have generated a wealth of kinetic data in recent years. Considering the reactivity and selectivity conditions delineated in Section 2, it should be possible, therefore, to find new radical chain reactions for use in synthesis. Thus, for example, it would be desirable to replace the mercury salts by ecologically acceptable hydrogen transfer agents. Also, the search for starting materials that, upon radical formation, can be incorporated into these chains is by no means complete. Furthermore, bonds other than C–C and C–H bonds can be created by varying the radical trap.

Radical chemistry thus opens up a wealth of possibilities for synthesis. It gives the preparative chemist the opportunity to develop new synthetic methods, provided that the fear of kinetic data is overcome.

Our own work in this area was made possible by the generous support of the Deutsche Forschungsgemeinschaft and

the Fonds der Chemischen Industrie. In particular, my co-workers, whose names are found in the references, are thanked for their energetic efforts.

New Silacycloalkynes with up to Four 1,4-Disila-2-alkyne Units in the Ring**

By *Else Kloster-Jensen** and *Gudveig Aamdal Eliassen*

The replacement of C by Si in the α,α′ position of the C≡C bond of 3,3,n,n-tetramethylcycloalkynes involves the consideration of the following factors: the greater steric demand of the $Si(CH_3)_2$ group, the greater length of the Si–C bond, and the smaller force constant for deformation of the C–Si–C angle. Accordingly, such disilacycloalkynes (number of chain links <8) should be more stable than the corresponding cycloalkynes. We have now synthesized low-membered disilacycloalkynes in order to determine the minimum number of chain links.

The syntheses of angle-strained cycloalkynes are all based on the introduction of the triple bond into the final ring system and cannot be transferred to 1,4-disila-2-cycloalkynes. An alternative approach is the coupling twice of an acetylene with an α,ω-disilaalkane of sufficient chain length that is reactive at both ends.

In analogy to the synthesis of 3,3,8,8-tetramethylcyclooctyne,[1,2] the smallest stable[3] cycloalkyne, 2,7-dichloro-2,7-dimethyl-2,7-disilaoctane **1d**[4] was reacted with bis(bromomagnesium)acetylide **2** (Scheme 1). However,

Scheme 1. **a**, n=1; **b**, n=2; **c**, n=3; **d**, n=4; **e**, n=0.

1,1,4,4-tetramethyl-1,4-disila-2-cyclooctyne $^4[1+1]$[5] **6d**, which is formed from one pair of reactants, could be isolated in very small yield only; it was identified by its mass spectrum (*m/z* 196 (M^+)). The main product was $^4[2+2]$ **3d**, which is formed from two pairs of reactants (Scheme 1).

Furthermore, we have investigated the dependence of ring formation ability on the chain length of **1** (n=0–3).

[**] *E. K.-J.* thanks Professor *W. Lüttke* (Göttingen) for stimulating discussions and Dr. *D. Grace* (Oslo) for recording the NMR spectra.

We were thereby able to isolate cyclic products containing various numbers of coupled reactant pairs. However, 2,6-dichloro-2,6-dimethyl-2,6-disilaheptane **1c**,[4] in analogy to **1d**, yielded mainly ^{3}[2+2] **3c**, formed from two pairs of reactants, along with traces of 1,1,4,4-tetramethyl-1,4-disila-2-cycloheptyne ^{3}[1+1] **6c**, identified by its mass spectrum (*m/z* 182 (M^+)). In contrast, **1b**[4] afforded ^{2}[2+2] **3b** as well as ^{2}[3+3] **4b** and a very small amount of ^{2}[4+4] **5b**. Analogously, **1a**[4] gave the products ^{1}[2+2] **3a**,[6] ^{1}[3+3] **4a**, and ^{1}[4+4] **5a**.

The last member of the **1** series, **1e** (n=0), 2,3-dichloro-2,3-dimethyl-2,3-disilabutane,[4] produced, as expected, octamethyl-1,2,5,6-tetrasila-3,7-cyclooctadiyne ^{0}[2+2] **3e**, which is analogous to 1,5-cyclooctadiyne,[7] as well as ^{0}[3+3] **4e**. These two silacycloalkynes have recently been synthesized in an alternative way by *Sakurai* et al.[8] The compounds synthesized by us are summarized in Table 1.

Table 1. Synthesized silacycloalkynes of the type ^{n}[m+m] [5]. For experimental procedure see [14].

	^{n}[1+1]	^{n}[2+2] mp [°C]	^{n}[3+3] mp [°C]	^{n}[4+4] mp [°C]	Σ Yields [%]
n=4	**6d** (traces)	**3d** 86–87			15
n=3	**6c** (traces)	**3c** 162–162.5			35
n=2		**3b** 122–123	**4b** 153–154	**5b** 135–137	25
n=1		**3a** 103–104	**4a** 107–108	**5a** 118–119	15
n=0		**3e** 139 (139 [8a])	**4e** 146–147 (146–147 [8c])		5

The silacycloalkynes described here are easily crystallizable and sublimable solids; they were obtained in a pure state as shown by mass spectrometry. They are stable in air and can be subjected to gas chromatography without decomposition. An oily residue, which makes up a considerable portion of the crude products, could not be further analyzed.[14]

The high-resolution IR spectra of the isolated silacycloalkynes are very similar to each other and exhibit the bands characteristic for these highly symmetrical compounds. The ^{1}H- and ^{13}C-NMR spectra (Table 2) of ^{n}[2+2] **3a**–**d** are also very similar to one another and are in accordance with the structure given (**3e**[8a]). An X-ray structure determination[9a] of ^{0}[2+2] **3e** confirmed the results of *Sakurai* et al.,[8a] which showed that the ring is planar, as in 1,5-cyclooctadiyne.[7] The homologue ^{1}[2+2] **3a** at −133° adopts a conformation analogous to cyclohexane; both chair and boat forms are present in the same crystal.[9b] Low-temperature NMR spectra of **3a** show conformational changes. The photoelectron spectra of ^{0}[2+2] **3e** and ^{0}[3+3] **4e** were recorded by *Heilbronner* et al.;[10] they are in accord with those of *Gleiter, Sakurai* et al.[11]

Table 2. ^{1}H- and ^{13}C-NMR spectra of silacycloalkynes of the type ^{n}[2+2] **3** (300 MHz, $CDCl_3$ (standard), δ values). **3e**: ^{1}H-NMR: δ=0.25; ^{13}C-NMR: δ=119.46 (−C≡C−), 3.07 (CH_3) [8a].

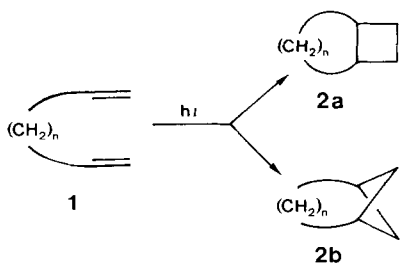
[14] *Experimental procedure:* The reactions were carried out in anhydrous tetrahydrofuran (THF) under nitrogen on a 10- to 20-mmol scale. The yields are unoptimized crude yields. **1a**–**d** and **1e** were synthesized by chlorodemethylation [4] of **7a** [4], **7b** (Fluka), **7c** [12], **7d** [13], and **7e** (Fluka), respectively. To **2** in THF at 55–60°C were added equivalent amounts of **1** over 15 min with stirring. After stirring for 2 h at this temperature, the reaction mixture was hydrolyzed with 10% NH_4Cl solution and extracted three times with pentane. The combined pentane extracts were washed ten times with saturated NH_4Cl solution and dried over $MgSO_4$. Removal of the solvent left a partly crystalline residue, which was fractionally sublimed at ca. 10^{-2} torr. In some cases, additional recrystallization was necessary. The purity was checked by gas chromatography (3% SP-2100, 190–260°C). **6c** and **6d** were characterized by MS (isotope distribution corresponds to 2 Si); the other products were characterized by IR, ^{1}H-NMR, and ^{13}C-NMR spectroscopy.

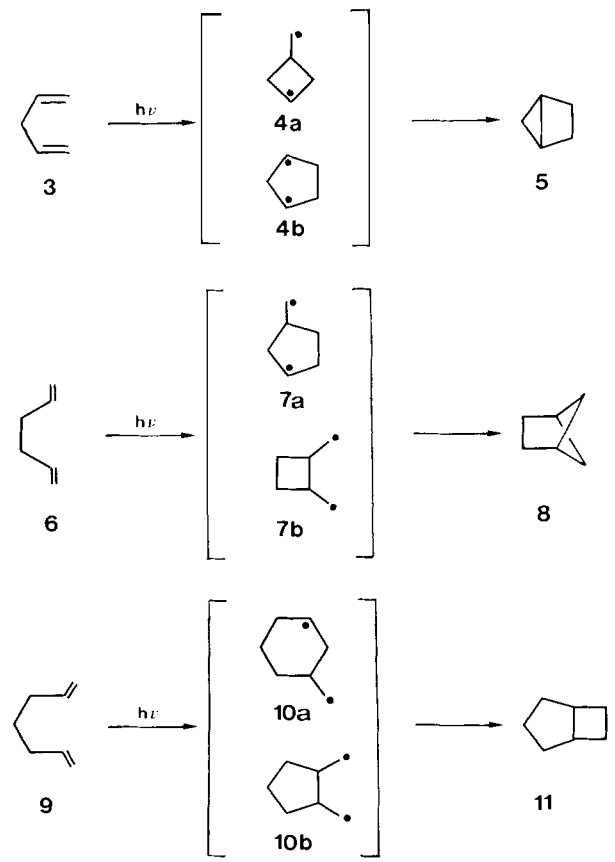
Light-Induced [2+2] Cycloaddition Reactions of Nonconjugated Dienes—the Effect of Through-Bond Interaction**

By *Rolf Gleiter** and *Wolfram Sander*



Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Light-induced intramolecular [2+2] cycloaddition reactions of nonconjugated dienes, **1**, lead via parallel cycloaddition to 1,2-bridged cyclobutanes, **2a**, or via cross cycloaddition to 1,3-bridged cyclobutanes, **2b**.[1] As pointed out by *Srinivasan* et al.,[1] the ratio of **2a** to **2b** de-



[*] Prof. Dr. R. Gleiter, Dr. W. Sander

[**] This work was supported by the Fonds der Chemischen Industrie and BASF AG, Ludwigshafen. *W. S.* thanks the Studienstiftung des Deutschen Volkes for a stipend.

pends on the number (n) of methylene groups between the double bonds in **1**. For n = 1 and 3, **2a** predominates, while for n = 2, **2b** is mainly formed. The dependence of the product ratio on n is even more drastic in cyclic dienes. Here, in almost all cases, only one product is formed.[1,2]

To rationalize these observations, *Srinivasan* et al. suggested that the initial step, which gives a diradical, involves preferential formation of a five-membered ring ("rule of the five").[1] Scheme 1 shows three examples. The postulated diradical intermediates **4b**, **7a**, and **10b** contain two, one, or no radical centers in the five-membered ring and thus have very different structures. In order to explain the stereochemistry of the reaction, it is assumed that these diradicals are more stable than the other possibilities **4a**, **7b**, and **10a**.

Scheme 1.

We present here an alternative explanation in which electronic factors (as well as steric factors[3]) in the educts and transition states are stressed instead of the relative stabilities of the primary intermediates (e.g., five-membered-ring vs. six-membered-ring diradicals). To demonstrate these electronic factors we constructed a molecular orbital and state correlation diagram, as introduced by *Woodward*

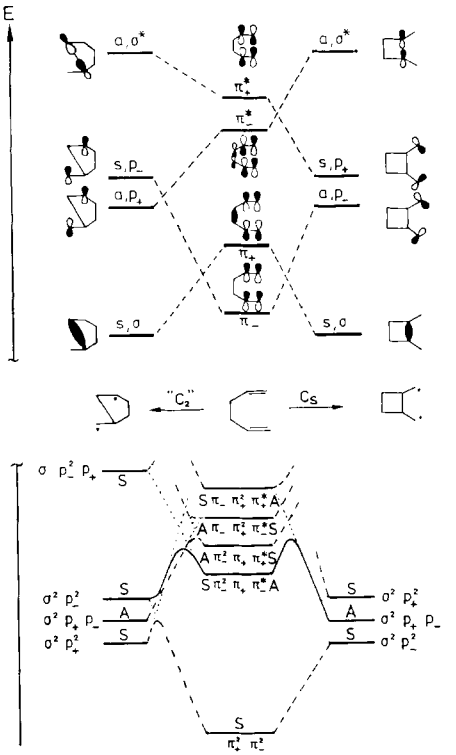

Fig. 1. Orbital (top) and state (bottom) correlation diagrams for the intramolecular cycloaddition of **6** to give **7a** (left) and **7b** (right) assuming local C_2 and C_s symmetry, respectively. The sequence of the frontier orbitals of **7b** is obtained if through-bond effects are assumed to predominate.

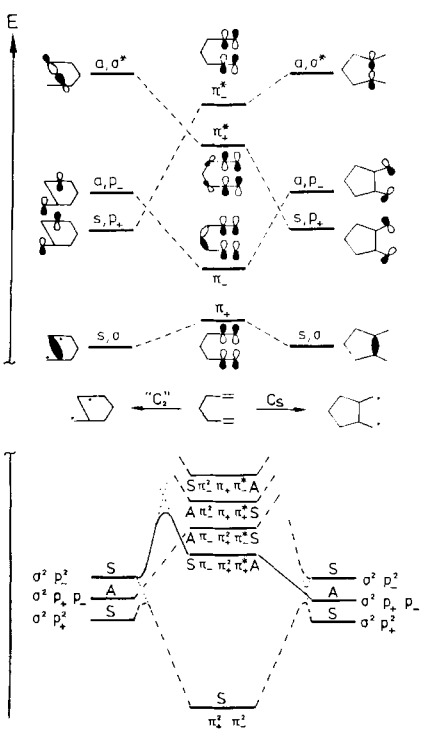

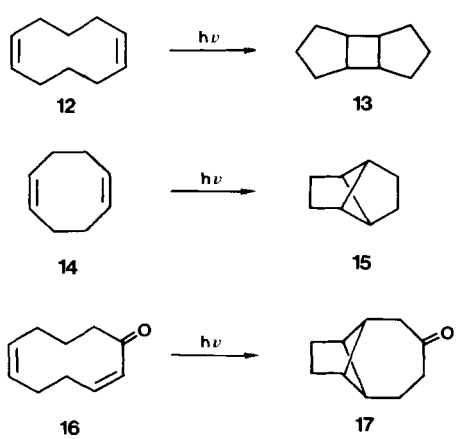

Fig. 2. Orbital (top) and state (bottom) correlation diagrams for the intramolecular cycloaddition of **9** to give **10a** (left) and **10b** (right) assuming local C_2 and C_s symmetry, respectively.

and *Hoffmann*[4] and further developed by *Dauben, Salem,* and *Turro*,[5] for **6**→**8** (via **7a** or **7b**) and for **9**→**11** (via **10a** or **10b**). We assume that the photochemical ring closure occurs via exciplex formation which forces the double bonds of **1** on top of each other.[6] To understand the difference between the two reactions it is important to note that the sequence of the frontier orbitals in **6** and **9** is different (Fig. 1 and 2). For **6**, through-space and through-bond interactions are opposed and, due to the dominance of the latter, the sequence is reversed compared with that obtained for two interacting ethylenes. For **9**, however, the orbital sequence is predicted to be the same as for two interacting ethylenes since through-space and through-bond interactions act in the same direction.

To understand the effect of the sequence of the frontier orbitals on the photochemistry we consider the molecular orbital and state correlation diagrams for the nonconcerted intramolecular cycloaddition (Fig. 1 and 2) of **6** to give **7a** and **7b** and of **9** to give **10a** and **10b**, assuming local C_2 and C_s symmetry, respectively.[8,9] As shown in the lower part of the two figures, both dienes have four excited states of similar energy arising from four $\pi^*_{+,-} \leftarrow \pi_{+,-}$ transitions. Whereas the lowest excited state of **9** correlates with a low-energy state of **10b** without any electronically determined activation barrier, the correlation with **10a** exhibits a barrier. The lowest excited state of **6** correlates with low-energy states of both **7a** and **7b**, but activation barriers are present. The activation energy for **6**→**7a** is lower than that for **6**→**7b** due to the correlation of the lowest excited state of **6** with a lower-energy excited state of **7a** ($\sigma p^2_- p_+$). The corresponding state of **7b** (p^2_-, σ, σ^*, not shown in Fig. 1) is much higher in energy. Thus, the magnitude of the through - bond interaction in **6** and **9** influences strongly their reactivity in the excited state.

The correlations suggest that light-induced parallel [2+2] cycloaddition of nonconjugated dienes should occur if the two double bonds are bridged by an odd number of carbon atoms. If an even number of carbon atoms connect the two double bonds, other reactions of the excited state, such as the cross [2+2] cycloaddition or radiationless transition, are likely to occur. Examples of the latter possibility are shown by *syn*-tricyclo[4.2.0.0^{2,5}]octadiene, which does not yield cubane on irradiation,[3,10] and by hypostrophene, which does not react to give pentaprismane.[3,11] A strong through-bond interaction has been postulated for both dienes on the basis of PE-spectroscopic data.[11,12]

If the two double bonds are connected by two aliphatic chains as in the cyclic dienes **12**, **14** and **16**, larger through-bond interactions are expected. This is in accord with the experimental findings[2] that, in almost all cases, these compounds undergo exclusively parallel [2+2] cycloaddition for odd bridges (**12**→**13**[2a]) and cross [2+2] cycloaddition for even bridges (**14**→**15**[2b] and **16**→**17**[2d]).

^{15}N-^{29}Si Coupling Constants and ^{15}N Isotope Effect on ^{29}Si Chemical Shifts in Compounds with Natural Isotopic Abundance

By *Ēriks Kupče, Edvards Liepiņš,* and *Edmunds Lukevics**

Coupling constants provide information concerning the structure, bonding, and dynamic processes of molecules.[1] Until recently, ^{15}N-^{29}Si coupling constants have received only scant attention in the literature,[2] mainly because of the necessity for isotopically enriched samples. In an earlier paper[3] we have shown that $^1J(^{15}N\text{-}^{29}Si)$ may be measured from ^{29}Si satellites in ^{15}N-NMR spectra at the natural abundance level of isotopes using an INEPT pulse sequence for accumulation. However, this method is limited by the small values of long-range ^{15}N-^{1}H couplings; therefore, practically only compounds bearing an NH group can be investigated.

We show here that $^1J(^{15}N\text{-}^{29}Si)$ can be easily measured from ^{15}N satellites in ^{29}Si-NMR spectra[4] with ca. 100-fold greater sensitivity. Indeed, for compound **1**, only eight scans (25-s measuring time instead of ca. 1 hour in the case of ^{15}N-NMR spectra) were necessary to obtain the required information (Fig. 1). Since polarization transfer occurs via the methyl groups on the silicon atom, the pres-

ence of NH protons is no longer necessary. Furthermore, the ^{29}Si-NMR spectra provide additional information on $^1J(^{13}C\text{-}^{29}Si)$, the ^{29}Si-NMR chemical shifts, the ^{15}N-isotope effect on ^{29}Si chemical shifts, and the quadrupolar relaxation time of ^{14}N nuclei.[5]

[a] Bruker WM-360 spectrometer (71.55 MHz); ca. 50% (vol-%) solutions in $CDCl_3$ at 303 K, INEPT pulse sequence [4], relaxation time: 2 s, 100—200 scans. [b] ±0.1 Hz. [c] ±0.0005. [d] Relative to TMS (±0.1). [e] Line width at half height (±0.2 Hz). [f] In C_6D_6. [g] Measured in ^{15}N-NMR spectrum.

The results obtained (see Table 1) demonstrate that the $^{15}N\text{-}^{29}Si$ coupling constants depend strongly on the nitrogen hybridization and the nature of the N–Si bond. Within the series of cyclic amines **3**—**7**, there is a significant decrease in $^1J(^{15}N\text{-}^{29}Si)$ with diminishing ring size. The same drop in $^1J(^{15}N\text{-}^{31}P)$ had been observed earlier for analogous phosphorus compounds[6] and can be rationalized by the increased pyramidal geometry of nitrogen in smaller rings. Relatively small $^1J(^{15}N\text{-}^{29}Si)$ values were found in compounds **8** and **9**, which contain a C=N bond. This can be possibly attributed either to an increase in the negative contribution of the non-contact terms to ^1J[1] or simply to an increased length of the N–Si bond in **8** and **9**.[7]

We were not able to detect ^{15}N satellites in the ^{29}Si-NMR spectra of trimethylsilyl amides such as **10** and **11**. This may be due to a fast inter- and intramolecular exchange of the trimethylsilyl groups in such compounds.[8]

We have measured for the first time the ^{15}N isotope effect on the ^{29}Si chemical shift (Table 1). The isotope effect depends on the bond length, order, and energy.[9, 10] The high-field shift ($\Delta J = 0.006$—0.015 ppm) of the ^{29}Si-NMR signal of the molecules bearing an ^{15}N isotope is about half the value of the analogous ^{13}C chemical shift.[11]

[5] The signals of silicon nuclei bonded to the nitrogen are broadened due to $^{14}N\text{-}^{29}Si$ spin-spin coupling and fast quadrupolar relaxation of ^{14}N nuclei having spin $I = 1$ (natural abundance of ^{14}N 99.6%). Since $^1J(^{14}N\text{-}^{29}Si)$ can be calculated from $^1J(^{15}N\text{-}^{29}Si)$ using magnetogyric ratios (γ) of ^{14}N and ^{15}N nuclei, line-shape analysis of the ^{29}Si-NMR spectra allows the quadrupolar relaxation time of ^{14}N nuclei to be estimated. Total Synthesis of Ulicyclamide**

By *Ulrich Schmidt** and *Peter Gleich*

Dedicated to Professor Gerhard Billek on the occasion of his 60th birthday

Peptides containing thiazole rings have often been found as fungal metabolites. Cancerostatic cyclopeptides containing thiazole and dihydrooxazole rings have been

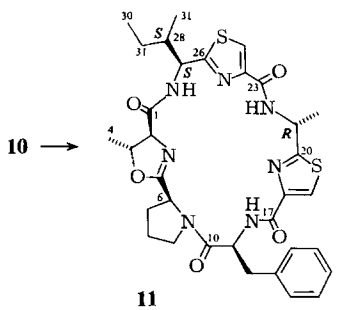
[**] Amino Acids and Peptides, Part 52. This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and BASF AG.—Part 51: U. Schmidt, J. Wild, *Liebigs Ann. Chem.*, in press.



isolated from lower marine organisms (e.g., *Lissoclinum patella*). The biosynthesis of these compounds takes place via cysteine-containing or via threonine- and serine-containing peptides, respectively.

We report here the first total synthesis of a cyclopeptide that contains thiazole *and* dihydrooxazole rings. This compound, ulicyclamide, **11**, was isolated and its structure elucidated by *Scheuer* and *Ireland*.[1,2]

In our synthesis of dolastatin isomers,[3] we prepared (*R*)-(aminoalkyl)thiazolecarboxylic acids from (*S*)-amino acids. This route led, via protected (*S*)-α-hydroxycarbothioamides, to (*S*)-(hydroxyalkyl)thiazolecarboxylic acids, which were transformed with inversion into (*R*)-(aminoalkyl)thiazole compounds. This sequence can also be employed in the synthesis, from (*S*)-alanine, **1a**, of the thiazole compound **4**, which has the (*R*) configuration and is contained in ulicyclamide, **11**. For the construction of the (*S,S*)-2-(1-amino-2-methylbutyl)-4-thiazolylcarbonyl fragment of **7** from (*S*)-isoleucine, **1b**, two inversions were required at the C atom bearing the amino group. The synthesis of ulicyclamide, **11**, is shown in Schemes 1 and 2.

Scheme 1. Synthesis of the linear educt **10** for the ring closure to ulicyclamide. *a*: Analogous to [3]; *b*: diethyl azodicarboxylate, Ph_3P, PhCOOH (inversion); *c*: NaOH, H_2O; *d*: diethyl azodicarboxylate, Ph_3P, HN_3 (inversion); *e*: Pd/H_2; *f*: dipyridyl disulfide, Ph_3P; *g*: Boc-Thr(*t*Bu)-S-pyridyl; *h*: CF_3COOH; *i*: imidic ester of Boc-Phe-Pro; *k*: NaOH, H_2O; *l*: C_6F_5OH, dicyclohexyl carbodiimide, ethyl acetate; *m*: CF_3COOH.

Scheme 2. Ring closure of **10** to ulicyclamide **11**. **10**·4CF_3COOH (0.1 mmol) was added over 8 h to a solution containing 0.4 mmol of 4-pyrrolidinopyridine in 500 mL of dioxane at 95 °C.

The (*R*)-2-(1-aminoethyl)-4-thiazolecarboxylic ester **4** is accessible via a known route from (*S*)-alanine, **1a**.[3] (*S,S*)-2-(1-hydroxy-2-methylbutyl)-4-thiazolecarboxylic acid was prepared analogously from (*S*)-isoleucine, **1b**, and converted via a Mitsunobu reaction[4] with inversion into the thiazole compound **5** containing a side chain having (1*R*,2*S*) configuration. The two thiazoles **4** and **5** are combined to give the amide **6** by redox condensation.

The transformation of the hydroxyl group of **6** into an amino group was achieved in turn via a Mitsunobu reaction[4] with inversion. The compound **7** so obtained is acylated with a protected threonine and, after cleavage of the two protecting groups, the amino alcohol **8** is condensed with Boc-phenyl-alanyl-proline imidic ester to give the dihydrooxazole compound **9**. Hydrolysis of the ester group on the thiazole ring, conversion into the pentafluorophenyl ester,[3,5] and cleavage of the Boc group with trifluoroacetic acid furnishes the tetrakis(trifluoroacetate) of the ω-aminopentafluorophenyl ester **10**. This ester is cyclized under high-dilution conditions to ulicyclamide, **11**, which can be isolated by medium pressure chromatography (20%).[6]

2,3-Dilithio-1,3-butadienes via Addition of Lithium to Butatrienes**

By *Adalbert Maercker** and *Ralf Dujardin*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

In the deuterolysis of (dilithiomethylene)cyclohexane **5a**,[2] which was synthesized from **1a** by direct mercury-lithium exchange, we often obtained up to 7% of the butadiene derivative **6a**[3] as a side product. This suggested the intermediacy of the 2,3-dilithio-1,3-butadiene derivative

a: R^1R^2 = $-(CH_2)_5-$; **b**: R^1 = R^2 = CH_3

[*] Prof. Dr. A. Maercker, Dipl.-Chem. R. Dujardin

[**] Polylithium organic compounds, Part 4. This work was supported by the Fonds der Chemischen Industrie. *R. D.* thanks the Studienstiftung des Deutschen Volkes for a Promotionsstipendium.—Part 3: [1].

4a, which might have been formed from the mercury compound **3a**. That **3a** is in fact an intermediate in the transformation of **1a** to **5a** could be shown by interrupting the reaction after 10 min: **3a**[4] was formed in 95% yield and could be cleaved to **5a** with additional lithium powder. **4a** is formed as a side product in yields of up to 8%.

In order to synthesize a 2,3-dilithio-1,3-butadiene such as **4** by an independent route, we have attempted to add lithium to the central double bond of the readily accessible tetramethylbutatriene **2b**.[5] Indeed, **4b** was formed in 97% yield.[6,7] It was characterized by deuterolysis to **6b** (yield 86%),[8] reaction with mercury(II) chloride to give **3b** (yield 70%),[9] and reconversion to **2b** with iodine (yield 75%).[10]

Evidence for a doubly bridged structure **4b** or similarly structured aggregates was provided by the ^{13}C-NMR spectrum (100.6 MHz)[11] of the ^{6}Li-labeled compound: the two α-carbon atoms (C-2) exhibit a quintet in [D_8]tetrahydrofuran at -100 °C, $\delta(^{13}C)$ = 188.7, $^1J(^6Li,^{13}C)$ = 6.7 Hz. A second species of the compound **4b** is also detectable in the solution and exhibits only a broad, unresolved signal at $\delta(^{13}C)$ = 187.9 for C-2. Moreover, all remaining ^{13}C-NMR signals appear twice with nearly the same intensity: the singlet of the β-carbon atom (C-1), $\delta(^{13}C)$ = 109.2, 100.9, and the signals of the pairwise differing methyl groups, $\delta(^{13}C)$ = 32.0, 29.6, 23.4, 22.0 (R^1, R^2). A non-bridging, dimeric structure would also be in accord with the ^{13}C-NMR spectroscopic results.[12] An X-ray structure determination of **4b**, which is obtained in crystalline form from diethyl ether, and ab initio calculations are being carried out.[13]

However, 2,3-dilithio-1,3-butadienes **4** are not only of theoretical interest, but also have considerable synthetic potential. Thus, hexamethylbutadiene **7b** (yield 80%)[14] is obtained by reaction of **4b** with dimethyl sulfate, and the 2,3-bis(methylthio)-1,3-butadiene derivative **8b** (yield 75%)[15] by reaction of **4b** with dimethyl disulfide. Interestingly, **4b** is stable towards excess lithium. Only after addition of mercury(II) chloride is it cleaved to 1,1-dilithio-2-methyl-1-propene **5b**.

An Organoboron Model System for the Fischer-Tropsch Synthesis**

By *Roland Köster** and *Mohamed Yalpani*

Dedicated to Professor Heinz Hoberg on the occasion of his 60th birthday

Since the discovery of the Fischer-Tropsch synthesis[1] there have been numerous and extensive studies, not only from the standpoint of its technology[2] but also with regard to the reaction mechanism involved[3a,c] and the other variants[3b] of the still very interesting C_1-growth reaction. However, in contrast to the many investigations of assumed part steps, the overall chain formation reaction cannot be followed with a suitable model system.

Herein we report on a quantitative,[4] reductive C_1-polymerization of carbon monoxide, present as mono-, di- or trinuclear metal carbonyl, with 9-borabicyclo[3.3.1]nonane (9-H-9-BBN)[5] to give 9-alkyl-9-borabicyclo[3.3.1]nonanes (9-alkyl-9-BBN). The reaction proceeds according to Eq. (a), giving 9-BBN derivatives with mainly linear alkyl moieties. These have so far been identified up to 9-decyl-9-BBN (n = 10).

[**] Boron Compounds, Part 67. We thank Mrs. *F. Sagheb* (Dept. Dr. *Schomburg*) for the gas-chromatographic separations and Mr. *W. Schmöller* (Dept. Dr. *Henneberg*) for the mass spectrometric measurements. – Part 66: R. Köster, S. Penadés-Ullate, W. V. Dahlhoff, *Angew. Chem. 97* (1985) 508; *Angew. Chem. Int. Ed. Engl. 24* (1984) 519.

1 Mole of pentacarbonyliron with ≈11 moles of 9-H-9-BBN[6] in e.g. mesitylene or *n*-nonane leads in a strong exothermic reaction within a few minutes on heating at ≈140°C to the formation of a black precipitate, whose composition corresponds to the empirical formula $FeC_2H_{3.5}$. Referred to 9-H-9-BBN, about one equivalent of gas, consisting of ≈2/3 H_2 and ≈1/3 CH_4, is liberated. Small amounts of ethane (<2%) as well as traces of C_3/C_4-hydrocarbons are also detectable (MS analysis). A colorless liquid fraction and a white solid can be recovered from the reaction mixture.[7] The liquid can be separated gas-chromatographically into numerous 9-alkyl-9-BBN compounds whose retention volumes and MS fragmentograms are consistent with those of authentic samples. The solid product is the diboroxane $(9\text{-BBN})_2O$,[8] an organoboron equivalent of the water formed in the Fischer-Tropsch synthesis.—9-Alkyl-9-BBN mixtures of varying composition, as well as the oxide $(9\text{-BBN})_2O$, can also be obtained in an analogous way with $Fe_2(CO)_9$ (≳140°C), with $Fe_3(CO)_{12}$ (≳130°C) or with $Co_2(CO)_8$ (≳90°C) according to Eq. (a).

The reaction mixtures contain, apart from the major products with unbranched alkyl residues, also derivatives with straight alkane chains not bound to C-1 (e.g. 9-*sec*-butyl-9-BBN) and compounds with methyl-branched alkyl groups (e.g. 9-isobutyl-9-BBN) (cf. Table 1).

Table 1. Relative yields [%] of 9-R-9-BBN from metal carbonyls and 9-H-9-BBN [a]. Procedure: [7].

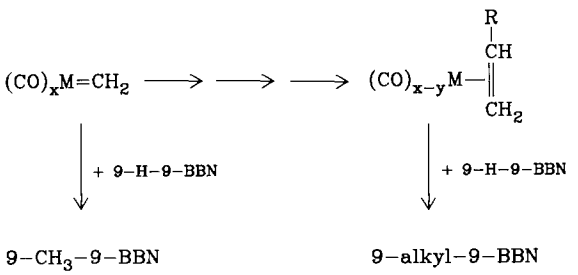
[a] GC/MS analyses; GC peaks <0.3% ignored; n. d. = not determined. [b] Separation from the highly viscous residue by cooling its pentane solution to –78°C, and filtration. [c] $\sum C_x$ isomers include all alkyl moieties with x carbons, but with the exception of straight chain alkyl residues bonded to the boron atom via C-1.



$Fe_2(CO)_9$ reacts with 9-deuterio-9-borabicyclo[3.3.1]nonane[5d] (9-D-9-BBN) in mesitylene >140°C to give 9-alkyl-9-BBN compounds, whose 9-alkyl moieties contain only very little deuterium[9]. Reaction of 9-D-9-BBN with $Co_2(CO)_8$ in heptane at ≈90°C, however, leads to formation of 9-perdeuterioalkyl-9-BBN compounds (degree of deuteriation of the alkyl moieties: >95%). The alkyl groups of the 9-alkyl-9-BBN compounds must therefore be generated by reduction of the metal-coordinated CO ligands. Presumably metal carbenes and/or metal-alkene π-

[a] GC peaks; conditions for separation: capillary column (36 m); dexsil 300; injection block: 150°C; column: 40—280°C (6°/min). [b] Standard conditions: carbonylmetal compound and 9-H-9-BBN in mesitylene (M) or in nonane (N) heated for ≈1 h at ≥140°C. [c] Portionwise addition (≈3 h) of solid 9-H-9-BBN to the solution of $Fe(CO)_5$ at 140°C. [d] Heated at ≈90°C.

complexes are formed as intermediates in the synthesis (cf. Scheme 1).

Scheme 1. Possible mode of the 9-alkyl-9-BBN formation.

Different rates of the reduction and CO-insertion reactions lead, depending upon the amount of monomeric 9-H-9-BBN available in solution, to varying amounts of 9-methyl-, 9-ethyl-, and higher 9-alkyl-9-BBN homologues. Thus, at low >BH/CO ratios the amount of 9-methyl-9-BBN drastically decreases, e.g. on slow addition of 9H-9-BBN (cf. Tables 1 and 2).

We presume that the higher 9-alkyl-9-BBN compounds (alkyl ≳ C_2H_5) are only formed on polynuclear metal clusters or on the surfaces of metal particles which separate from the original homogeneous solutions of the metal carbonyls.

The composition of the 9-alkyl-9-BBN mixture depends on the molar ratio of the reactants and on the reaction conditions, i.e. the temperature, the heating rate, or additives, e.g. alkali metal alkoxides. The metal carbonyl/9-H-9-BBN system is thus suitable as a readily variable, easily accessible reaction mixture for the investigation of the Fischer-Tropsch synthesis.

[**] This work was supported by the Fonds der Chemischen Industrie.

the corresponding CH compounds and the fact that optically active α-sulfonyl "carbanions" can be prepared from optically active sulfones led early to numerous experimental[2] and theoretical[3] studies into the nature of the stabilization of a negative charge by a neighboring sulfonyl group ($-SO_2R^3$) and the origin of the chirality in the "carbanion." The central question was whether the anionic C atom was pyramidal or planar, and, if planar, what conformation the substituents on the S atom adopted with respect to those on the anionic C atom. The position of the counterion $M^{\oplus}$ is of particular current interest.

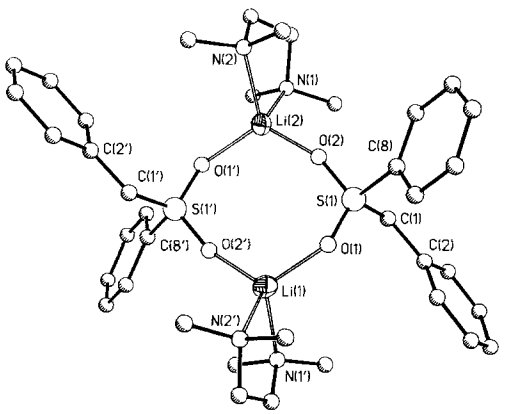

Fig. 1. Crystal structure of **1**. Space group $Pna2_1$, $a = 1705.1(6)$, $b = 1001.7(2)$, $c = 2375.9(30)$ pm, $Z = 8$ (one dimer per asymmetric unit). $R = 0.064$ for 3103 reflections with $F > 3\sigma(F)$. The dimer has approximately C_i symmetry, but could not be brought into accord with an inversion center of a centrosymmetric space group. The probable direction of the polar axis was determined by the use of an η-refinement [6]. The hydrogen atoms were refined according to a riding model with C–H 96 pm. An attempt to refine freely the H atoms on C(1) and C(1') gave only approximate positions with large standard deviations. Important distances (mean values) [pm] and bond angles (mean values) [°]: C(1)–S 164.1(5); C(8)–S 178.4(5); S–O 146.5(4); Li–N 213.6(10); Li–O 189.0(9); C(1)–C(2) 143.7(8). O–S–O 115.4(2); S–C(1)–C(2) 125.8(4). Dihedral angles (mean value) [°]: O–S–C(1)–C(2) ±45.6(6) and ±175.4(5); C(8)–S–C(1)–C(2) ±70.4(6); S–C(1)–C(2)–C ±3.1(9) and ±176.8(30). Further details of the crystal structure investigation may be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51257, the names of the authors, and the journal citation.

We report here the X-ray structure investigation of α-(phenylsulfonyl)benzyllithium-tetramethylethylenediamine **1** (Fig. 1).[4, 5]

1 crystallizes as a dimer in which the Li atoms are coordinated only by the tetramethylethylenediamine (TMEDA) molecules and the O atoms of the sulfonyl group, but not by the "anionic" C atoms! IR and Raman studies on $C_6H_5SO_2CH_2Li$ in solution indicate a contact to the C atoms as well.[2o] In the polymeric benzyllithium-triethylenediamine complex, the Li atom bridges three carbon atoms (corresponding to C(1), C(2), and C(3) in Fig. 1)[7] and in the monomeric 2-lithio-2-phenyl-1,3-dithiane-tetrahydrofuran-tetramethylethylenediamine, a C–Li bond to the benzylic C atom is present.[8] Ab initio calculations on $LiCH_2SO_2CH_3$ give two different Li positions as minima on the potential surface.[3c]

The C(1)–S distance (164.1 pm) is appreciably shorter than the corresponding distance in sulfones (mean value of 58 bond lengths: 180.6 pm).[9] By comparison, the CS double bond in thioformaldehyde is 161.08 pm,[10] which is only 3 pm shorter than C(1)–S in **1**! The increased CS bond order in **1** is in accord with an increased force constant in $C_6H_5SO_2CH_2Li$,[2o] as determined by vibrational spectroscopy.

The S–O distance in **1** (146.5 pm) is only a little larger than that in sulfones (mean value of 53 bond lengths: 143.4 pm).[9] A larger S–O distance was indicated by the force constants of α-sulfonyl "carbanions" as determined by IR spectroscopy.[2o] The S–C(1)–C(2)–C dihedral angles show that the short CS bonds lie in the plane of the phenyl ring, in accord with sp^2 hybridization of the carbon atom C(1) as well as with the results of most of the studies (mainly kinetic)[2m–o] on α-sulfonyl "carbanions" in solution. The chirality of an α-sulfonyl "carbanion" could therefore be due to a chiral conformation and hindered rotation around the C(1)–S bond, rather than to a tetrahedral configuration of the anionic C atom.[11] Up to now, kinetically controlled anion formation has been presumed to be responsible for the formation of a chiral conformation.[2a, e, k, l] The dihedral angles around the C(1)–S bonds (see above and Fig. 2) indicate that a local chiral conformation is thermodynamically favored in the crystal of **1**; the p orbital on C(1) is approximately *gauche* to the two O atoms on the sulfur.

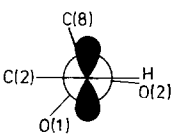

Fig. 2. Dihedral angles around the C(1)-S bonds.

[11] Since we could not locate the H atom on C(1) with sufficient accuracy, only a suitable substitution would allow a definitive statement to be made regarding the configuration of this C atom.

Solvent Exchange on Magnesium([15]Crown-5) Complexes—a First- and Second-Order Reaction**

By *Franz L. Dickert** and *Manfred F. Waidhas*

Dedicated to Professor Helmut Behrens on the occasion of his 70th birthday

Solvent molecules (S) in the first coordination sphere of metal ions M^{2+} can be distinguished from the free solvent by NMR spectroscopy.[1] The use of DNMR, in particular, allows the dynamics of the exchange process to be studied:

$$[M(S)_6]^{2+} + S^* \rightleftharpoons [M(S)_5S^*]^{2+} + S \qquad (1)$$

Variations in temperature and pressure indicate, in terms of activation entropy[1] and activation volume,[2] that this reaction has mainly dissociative character. In order to study the mechanism of Eq. (1), it would be desirable, in addition, to vary the concentration of the solvent molecule (S). The limited solubility of solvated metal ions in non-coordinating cosolvents, such as CH_3NO_2 and CH_2Cl_2, can be overcome by the use of crown ethers to make the metal ions hydrophobic. Thus, [15]crown-5 (15C5) forms 1:1 complexes[3] with metal ions M^{2+}, in which, in addition to the macrocycle, two solvent molecules are coordinated in *trans* positions[4] (Fig. 1). The investigations of the mobility of the solvent molecules described here were carried out on the complex $[Mg(15C5)(DMF)_2](ClO_4)_2$ (DMF = dimethylformamide). In this system, no complications arise due to formation of the complex $[Mg(15C5)(DMF)]^{2+}$.

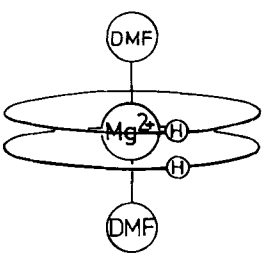

Fig. 1. Structure of $[Mg([15]crown-5)(DMF)_2]^{2+}$; the fluctuational crown ether [3] is indicated by the two ellipses.

The kinetic studies can be performed particularly advantageously with the DNMR method, using the HCO proton absorption of DMF: this absorption is shifted downfield by 0.17 ppm upon coordination of DMF to the Mg complex. As shown in Figure 2, the reciprocal residence time

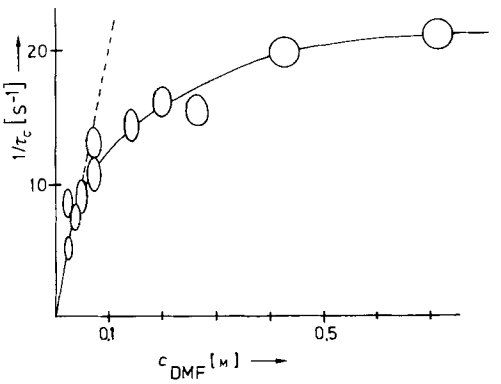

Fig. 2. Reciprocal residence times $1/\tau_c$ of DMF, coordinated in the complex $[Mg([15]crown-5)(DMF)_2]^{2+}$, as a function of the concentration of free DMF in CD_3NO_2 at 40°C.

$1/\tau_c$ of the DMF molecules in the first coordination sphere of the magnesium ion increases with increasing concentration of the uncoordinated DMF in CD_3NO_2/DMF mixtures and finally reaches a plateau value. In order to interpret this result, Equation (1) must be modified. The solvated and hydrophobic ion $[Mg(15C5)(DMF)_2]^{2+}$ forms an aggregate with free DMF in the inert solvent CD_3NO_2. However, the displacement of DMF from the first coordination sphere of the magnesium ion[5] [Eq. (2)] is rate-determining:

$$\begin{array}{l} [Mg(15C5)(DMF)_2]^{2+} + DMF^* \\ \qquad\qquad K^0 \uparrow\downarrow \\ [Mg(15C5)(DMF)_2]^{2+}\cdots DMF^* \\ \qquad\qquad k_1 \uparrow\downarrow k_1 \\ [Mg(15C5)(DMF)(DMF^*)]^{2+}\cdots DMF \\ \qquad\qquad K^0 \uparrow\downarrow \\ [Mg(15C5)(DMF)(DMF^*)]^{2+} + DMF \end{array} \qquad (2)$$

The life-times τ_c for the coordinated DMF molecules are obtainable directly from the NMR spectra and can be described by Eq. (3);[6] c_{DMF} is the concentration of free DMF, which is bound neither in the complex $[Mg(15C5)(DMF)_2]^{2+}$ nor in the aggregate $[Mg(15C5)(DMF)_2]^{2+}\cdots DMF$:

$$1/\tau_c = \frac{k_1 \cdot K^0 \cdot c_{DMF}}{1 + K^0 \cdot c_{DMF}} \qquad (3)$$

The experimental results in Figure 2 can be explained by the reaction scheme in Eq. (2) using Eq. (3). For high concentrations of DMF ($c_{DMF} \cdot K^0 \gg 1$), a first-order rate constant (k_1) is obtained, which is characteristic for the solvent exchange process in a coordinating solvent. From this kinetic viewpoint, the solution of 0.5 M $[Mg(15C5)(DMF)_2]^{2+}$ and 0.8 M DMF in CD_3NO_2 already behaves remarkably

like such a system due to the strong hydrophobic interaction between the complex and DMF (K^0 in Eq. (2)). When the concentration of free DMF is decreased, on the other hand, the transition to a second-order rate law is observed ($c_{DMF} \cdot K^0 \ll 1$, Eq. (3)), the rate constant of which, k_{12}, can be derived from the slope of the tangent to the curve through the origin of $1/\tau_c$ (Fig. 2). The constants defined by Eq. (3) have the following values ($T = 40\,^\circ C$):

$k_1 = 24.7 \pm 2\,s^{-1}$; $\Delta H_1^{\neq} = 81 \pm 44\,kJ\,mol^{-1}$;
$\Delta S_1^{\neq} = 41 \pm 5\,J\,K^{-1}\,mol^{-1}$

$K^0 = 7.8 \pm 2\,L\,mol^{-1} \longrightarrow k_{12} = K^0 \cdot k_1 = 193 \pm 40\,L\,mol^{-1}\,s^{-1}$

The DMF exchange in the complex $[Mg(15C5)(DMF)_2]^{2+}$ is therefore 10^4 times slower than in $[Mg(DMF)_6]^{2+}$.[7] This phenomenon is general[3] and is due to an increased interaction between Mg^{2+} and DMF caused by the coordination of 15C5.[8]

Solvent exchange and complex formation with macrocyclic ligands is very important for the understanding of ion transfer through biological membranes. Thus, according to the carrier mechanism,[9] in which the ions are made hydrophobic, the coordinated solvent molecules must be displaced in an initial step.

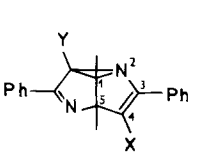
1,5-Diazocines**



By *Christoph Schnieders, Walter Huber, Johann Lex,* and *Klaus Müllen**

Diazocines, diaza derivatives of cyclooctatetraene, are not well known.[1] The thermolysis of semibullvalenes carried out by *Paquette* et al. has provided access to specifically substituted cyclooctatetraenes.[2] The 2,6-diazasemibullvalenes **1**[3] recently described by us, now also open up a route to 1,5-diazocines **2**. Herein, we describe the synthesis, structure, and reduction of the first representative of this class of compounds.

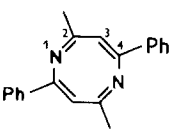
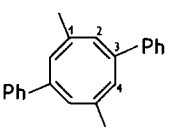
When a degassed solution of the diazasemibullvalene **1a** in tetrahydrofuran (THF) is kept at 90 °C for 8 h, the 2,6-dimethyl-4,8-diphenyl-1,5-diazocine **2a** is formed quantitatively. The kinetics of this transformation can be monitored by NMR spectroscopy. The activation parameters are $\Delta G^{\neq} = 27 \pm 0.5$ kcal/mol (25 °C) and $\Delta S^{\neq} = 2 \pm 2$ cal $K^{-1}mol^{-1}$ (25 °C). **1b** and **1c** are transformed increasingly more rapidly [$t_{1/2}$(25 °C) ca. 12 h] into **2b** and **2c**, respectively. The thermal instability of **1b** and **1c** is consistent with observations made by *Gompper* et al. when synthesizing a tetrazocine.[4] Compound **2c**, yellow rectangular crystals, melts at 105 °C with decomposition.



1a: X = Y = H
1b: X = Br, Y = H
1c: X = Y = Br



2b: X = H
2c: X = Br

2a'

2a''

3

The 1,5-diazocine **2a** exists in the form of two double-bond isomers,[5] **2a'** and **2a''**, which (irrespective of the temperature) are generated in the ratio 3 : 2 in the thermolysis.[6] Differentiation of the two isomers is based on the finding that a pronounced allyl coupling $^4J_{HH} = 2.5$ Hz between the ring protons and the methyl protons occurs only in the case of **2a'**. The isomers cannot be separated, but the synthesis of pure **2a'** is possible if the dianion $\mathbf{2a}^{2\ominus}/2\,K^{\oplus}$ is reoxidized with oxygen or iodine at low temperatures. On warming the solution to room temperature the equilibrium between **2a'** and **2a''** is rapidly reestablished.

According to the NMR spectra, the bromodiazocines **2b** and **2c** exist only in the form of one of the double-bond isomers. The X-ray structure analysis[7] of **2c** leads to the same conclusion, and, moreover, shows that the ring is tub-shaped and contains alternating double and single bonds.

Characteristic for **2a** and **2c** are the low-field resonances of C-2 and C-4 and the high-field resonance of C-3.[8]

We were able to prepare the carbon analogue of **2a**, 1,4-dimethyl-3,7-diphenylcyclooctatetraene **3**,[9] by flash thermolysis of the semibullvalene[10] corresponding to **1a**. However, this reaction requires substantially higher temperatures (340–360 °C) than the reaction **1a** → **2a**.

On reduction with alkali metal, **2a** and **3** are converted into stable anions, which, on the basis of their spectroscopic data,[11] can be described as bond-delocalized, diatropic 10π systems.[12, 13]

Considering the structure of $\mathbf{2a}^{2\ominus}/2\,K^{\oplus}$, the product of the one-electron reduction of **2a**, the radical anion $\mathbf{2a}^{\odot\ominus}/K^{\oplus}$, behaves in a surprising manner. Here, the number and multiplicity of the ESR-spectroscopically determined ^1H-

and ^{14}N-coupling constants[14] are consistent with an unsymmetrical structure which arises as a result of localization of spin (or charge) density in one part of the ring. The ^1H-ENDOR-spectroscopically determined coupling constants of the protons sensitively depend upon changes in the counterion-solvent system (and, hence, the ion-pair structure).[15]

Stepwise Formation of a Dinuclear μ-Aminocarbyne- and a μ-Formimidoyl-Metal Complex by Insertion of Methyl Isocyanide into an MHM Bridge**

By *Ralf Zolk* and *Helmut Werner**

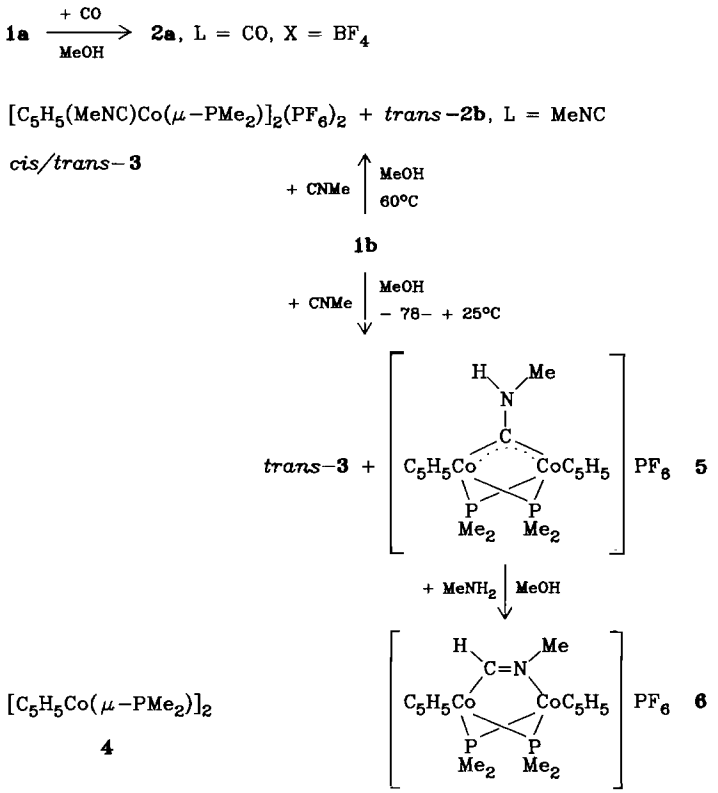
Dedicated to Professor Helmut Behrens on the occasion of his 70th birthday

The cation of the dinuclear complex **1** contains a closed CoHCo-three-center bond which can be split by trimethylphosphane or trimethylphosphite.[1] The hydride ligand in **1** is thereby transferred from a bridging to a terminal position in **2**.

1 *cis/trans*-**2**

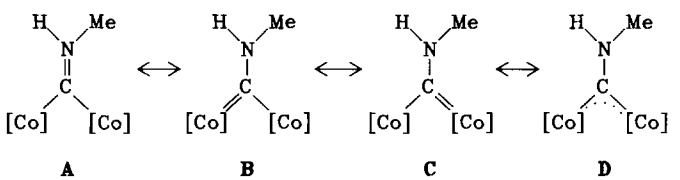
a, X = BF_4; **b**, X = PF_6
L = PMe_3, $P(OMe)_3$

We were interested to know whether such a reaction is also possible with CO or CNMe and, if so, whether the complexes **2** with L = CO and CNMe react by *intramolecular* reduction of carbon monoxide or methyl isocyanide, respectively. Studies of this type are of current importance in connection with the proposed mechanism of the Fischer-Tropsch synthesis.[2]



Compound **1a** reacts with CO in methanol at 40°C to produce the dinuclear carbonyl(hydrido) complex **2a**, L = CO, which after chromatography on Al_2O_3 (Woelm, activity grade V, acetone) and recrystallization from acetone/ether is isolated in 67% yield.[3] Warming a solution of **2** or photolysis does *not* lead to the formation of a bridged formyl complex; decomposition occurs instead of a hydride transfer.

The reaction of **1b** with methyl isocyanide in methanol at room temperature gives a mixture of products which contains compounds *trans*-**2b**, L = MeNC, and **5** as well as minor amounts of the neutral complex **4**[1] and the PF_6 salts **3** with *cis*- and *trans* cations.[4] At 60°C (in MeOH), the main product is the hydrido(methylisocyanide) complex **2b**, L = MeNC, for which by comparison with reference data[5] a *trans*-orientation of the cyclopentadienyl ligands is proposed;[6] a small quantity of **3** (*cis* and *trans*, yield 7%) is also formed. Under the same reaction conditions, a rearrangement of complex **2b** into **5** or **6** cannot be observed.



Addition of methyl isocyanide to a solution of **1b** in methanol at −78°C followed by warming to room temperature gives compound **5** containing a bridging aminocarbyne ligand in excellent yields.[7] Similar insertions of isocyanides into the MHM bridge of Fe_3- or Os_3-clusters are known and have recently been discussed elsewhere.[8] The structure proposed for **5** is based mainly on ^1H-NMR data (e.g., a doublet-of-triplets for the NCH_3 protons caused by coupling with the adjacent NH proton and the two equivalent ^{31}P nuclei) and the IR spectrum.[7] The ν(CN)

Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

stretching frequency lies between that of a C=N double bond and a C–N single bond, indicating that the resonance forms **B** – **D** must be considered in addition to **A** for the bonding of the bridging unit ([Co] = $C_5H_5Co(\mu\text{-}PMe_2)$).

In the presence of methylamine (in MeOH) the aminocarbyne complex **5** rearranges *quantitatively* to produce the μ-*N*-methylformimidoyl complex **6**.[9] We assume that an abstraction of the N*H*Me proton occurs initially, followed by protonation of the carbon atom of the transiently formed μ-isocyanide compound by NH_3Me^+; subsequent cleavage of one Co–C bond and coordination of the nitrogen at the second cobalt atom leads to the Co–CH=NMe–Co bridge. It should be noted that the formation of bridging *N*-alkyl- and *N*-arylformimidoyl ligands by insertion of isocyanides into M–H and M–H–M bonds has previously been observed[8,10] but there was no evidence that this process could occur via aminocarbyne complexes as intermediates. A thermal rearrangement of **6** to give (or *trans*-**2b**, L = MeNC) does not take place. We assume that the *cis* isomer of **2b** is a short-lived intermediate in the reaction of **1b** and CNMe to form **5**, whereas at higher temperature *trans*-**2b** is formed as the thermodynamically preferred product.

The structure of the cation of **6** is shown in Figure 1.[11] The midpoints of both cyclopentadienyl rings and the Co1, C1, N, and Co2 atoms are nearly coplanar and define a non-crystallographic mirror plane; C2 is displaced by 9(2) pm out of this plane. The distance C1–N (126(2) pm) is very slightly shorter than the C=N double bond in protonated methaneimine (129 pm)[12] and comparable to the C–N distance in other μ-formimidoyl complexes.[8] The Co···Co separation of 319.1(3) pm is significantly larger than in the cation of **1** (251.7 pm)[1] and is evidence against the existence of a metal-metal bond.

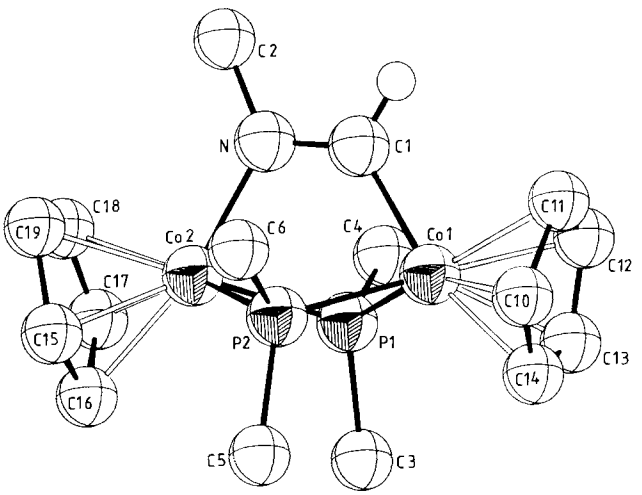

Fig. 1. Structure of the cation of **6** in the crystal. Selected bond lengths [pm] and angles [°]: Co1···Co2 319.1(3), Co1–C1 191.0(14), Co1–P1 216.8(4), Co1–P2 217.2(5), Co2–N 195.8(12), Co2–P1 219.1(5), Co2–P2 217.3(5), C1–N 126(2), C2–N 144(2), Co1–C1–N 123.8(13), Co2–N–C1 116.2(11), Co2–N–C2 126.0(10), C1–N–C2 117.6(14), Co1–P1–Co2 94.1(2), Co1–P2–Co2 94.5(2).

The formation of a formimidoyl bridge during the reaction of **1b** with isocyanides probably depends on the substituent R. This follows from preliminary results which indicate that CNPh behaves similarly to CN*t*Bu seems to prefer a different reaction path.

[3] **2a**, L = CO: Brown crystals, dec. temp. (DTA) 142°C; equivalent conductivity (CH_3NO_2): $\Lambda = 70\ cm^2 \cdot \Omega^{-1} \cdot mol^{-1}$; IR [KBr]: $\nu(CO) = 2010\ cm^{-1}$; ^{1}H-NMR (CD_3NO_2): $\delta(C_5H_5) = 5.34$ (s) and 4.94 (s), $\delta(PCH_3) = 2.19$ (vt, $N = 12.4$ Hz) and 1.90 (vt, $N = 14.6$ Hz), $\delta(CoH) = -13.45$ (t, $J_{PH} = 64.0$ Hz); ^{31}P-NMR ([D$_6$]acetone, −23°C): $\delta(PCH_3) = -22.87$ (s).
[4] The mixture of *cis*/*trans* **3** as well as the pure *trans* isomer have also been prepared by a different route using $[(C_5H_5Co)_2(\mu\text{-}PMe_2)_2(\mu,\eta^2\text{-}ONO)]PF_6$ as the starting material [5].
[5] R. Zolk, Dissertation, Universität Würzburg 1985.
[6] *trans*-**2b** (L = MeNC) is prepared by stirring a suspension of **1b** (520 mg, 1.0 mmol) and CNMe (70 μL, 1.2 mmol) in methanol (20 mL) at 60°C for 2 h. After removing the solvent and extraction with pentane to remove **4**, the residue is dissolved in 10 mL acetone and the solution chromatographed on Al_2O_3 (Woelm, activity grade V). Recrystallization from acetone/ether/pentane (1 : 2 : 2) gives brown crystals; yield 285 mg (51%). Dec. temp. (DTA) 260°C; equivalent conductivity (CH_3NO_2):

$\Lambda = 86$ cm$^2 \cdot \Omega^{-1} \cdot$mol^{-1}; IR [KBr]: ν(CN) = 2202 cm^{-1}; ^{1}H-NMR ([D$_6$]acetone): $\delta(C_5H_5) = 5.23$ (t, $J_{PH} = 0.3$ Hz) and 4.91 (t, $J_{PH} = 0.3$ Hz), $\delta(NCH_3) = 3.78$ (s), $\delta(PCH_3) = 2.14$ (vt, $N = 11.5$ Hz) and 1.76 (vt, $N = 14.8$ Hz), δ(CoH) = −13.12 (t, $J_{PH} = 64.0$ Hz); ^{31}P-NMR ([D$_6$]acetone, −23 °C): $\delta(PCH_3) = -29.34$ (s), δ(PF) = −145.02 (sept, $J_{PF} = 708.6$ Hz).

[7] **5** is prepared by addition of CNMe (25 μL, 0.45 mmol) to a suspension of **1b** (205 mg, 0.40 mmol) in methanol (10 mL) with stirring at −78 °C. The mixture is slowly warmed to room temperature over a period of 4 h. After stirring for 20 h, the reaction mixture is worked up as described in [6]; yield 165 mg (75%). Orange crystals, dec. temp. (DTA) 285 °C; equivalent conductivity (CH_3NO_2): $\Lambda = 94$ cm$^2 \cdot \Omega^{-1} \cdot$mol^{-1}; IR [KBr]: ν(NH) = 3327, ν(CN) = 1511 cm^{-1}; ^{1}H-NMR ([D$_6$]acetone): $\delta(C_5H_5) = 5.02$ (t, J(PH) = 0.4 Hz) and 4.88 (t, J(PH) = 0.3 Hz), $\delta(NCH_3) = 3.61$ (dt, J(HH) = 3.6 Hz, J(PH) = 2.5 Hz), $\delta(PCH_3) = 2.17$ (vt, $N = 11.6$ Hz) and 1.81 (vt, $N = 12.2$ Hz), δ(NH) not exactly assignable; ^{31}P-NMR ([D$_6$]acetone, −33 °C): $\delta(PCH_3) = -69.37$ (s), δ(PF) = −145.02 (sept, J(PF) = 708.6 Hz).

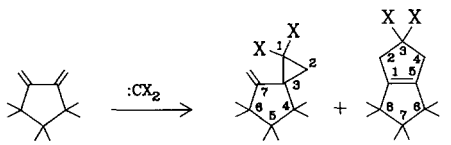
1,4-Additions of Dihalocarbenes**

By *Herbert Mayr** and *Ulrich W. Heigl*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday



Singlet carbenes usually undergo 1,2-addition with 1,3-dienes to give vinylcyclopropanes.[1] Theoretical studies indicate that the transition state of the likewise orbital symmetry allowed concerted 1,4-addition is destabilized by closed-shell repulsions,[2a] particularly the four-electron interaction between ψ_1(diene) and σ(carbene).[1,2] This type of reaction is preferred only in exceptional cases, for example in the homo-1,4-additions of dihalocarbenes to norbornadiene[3a] or the benzvalene synthesis via intramolecular carbene addition.[3b] Apart from some compounds which have been interpreted as sequential products of 1,4-adducts,[4a] so far the only indication of an intermolecular 1,4-addition of a singlet-carbene to a 1,3-diene comes from 0.6% 1,4-adduct isolated in the reaction of dichlorocarbene with 1,2-bis(methylene)cycloheptane.[4b]

[*] Prof. Dr. H. Mayr, Dipl.-Chem. U. W. Heigl
Institut für Chemie der Medizinischen Universität zu Lübeck
Ratzeburger Allee 160, D-2400 Lübeck (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Dr. *I. Löffler* for carrying out a gas-phase thermolysis.

1,1,2,2,3,3-Hexamethyl-4,5-bis(methylene)cyclopentane, **1**, which can readily be prepared by bromination and twofold HBr-elimination from octamethylcyclopentene,[5] is a predestined model for 1,4-additions, since it contains a *cis*-fixed 1,3-diene system in which access to the 2- and 3-positions is sterically hindered.

Treatment of **1** in petroleum ether with chloroform and potassium *tert*-butoxide for four hours at 0 °C leads to formation of a mixture of **2a** and **3a** (73 : 27) in 76% yield (Table 1). **2a** is stable under the reaction conditions, since the

1 **2a, b** **3a, b**

Table 1. 1,2- and 1,4-addition of CX_2 to the 1,3-diene **1**.

	X	Reaction conditions	**2** : **3**
a	Cl	KO*t*Bu/$CHCl_3$/petroleum ether/0 °C	73 : 27
a	Cl	$PhHgCCl_3$/toluene/100 °C/1 h	79 : 21
b	Br	KO*t*Bu/$CHBr_3$/petroleum ether/0 °C	70 : 30
b	Br	$PhHgCBr_3$/toluene/80 °C/1 h	73 : 27

same product ratio is observed even after 30 hours' reaction time. The analogous reaction with bromoform leads to formation of the adducts **2b** and **3b** (70 : 30) in 80% yield. **2a** and **3a** can be separated chromatographically and unequivocally characterized by their NMR spectra (Table 2).[6] Pure **3a** is also obtained by flash thermolysis of the mixture **2a/3a** in a quartz tube at 350 °C.

Table 2. ^{13}C-NMR data of the carbene addition products **2** and **3**. The assignment of the values in parentheses is unclear.

	C-1	C-2	C-3	C-4	C-5	C-6	C-7	=CH_2 or C-8

2b	38.18	27.85	(45.39)	(46.37)	(46.68)	(49.58)	160.37	107.98
	methyl signals at 20.38, 20.41, 23.49, 27.90, 28.51, 29.85							
3a	145.00	51.39	92.22	51.39	145.00	(46.35)	(51.02)	≙C-6
	methyl signals at 21.78 and 23.84 (doubled int.)							
3b	145.97	54.12	65.83	54.12	145.97	(46.41)	(51.33)	≙C-6
	methyl signals at 21.84 and 23.84 (doubled int.)							

If the two carbenes are generated from phenyl(trihalomethyl)mercury[7] in toluene at 100 °C (CCl_2) and 80 °C (CBr_2), respectively, a ratio **2** : **3** of 79 : 21 and 73 : 27, respectively, is observed after one hours' heating. Hourly analysis of the reaction mixtures shows that **2a** and **2b** slowly decompose under these reaction conditions to hitherto unidentified products. Within 5 h the ratio **2** : **3** falls to 72 : 28 and 65 : 35, respectively. The slow change of the product pattern clearly demonstrates, however, that the adducts **3a**, **b** observed after one hours' reaction time cannot be interpreted as rearrangement products of **2a** and **2b**.

Since the reaction of CCl_2 and CBr_2 with **1** yields 1,2- and 1,4-addition products in comparable amounts, diene **1**

is a suitable model to check theoretical predictions about 1,4-additions[2] and to examine proposals on the two-step mechanism of certain carbene additions.[8] It is obvious that **1**, a 1,3-diene with normal 1,4-reactivity but greatly reduced 1,2-reactivity, may also be used as a mechanistic probe for other reactions in which 1,3-dienes usually participate as $_{\pi}2$-units.

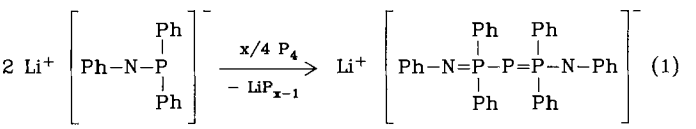
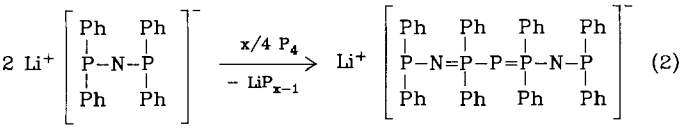
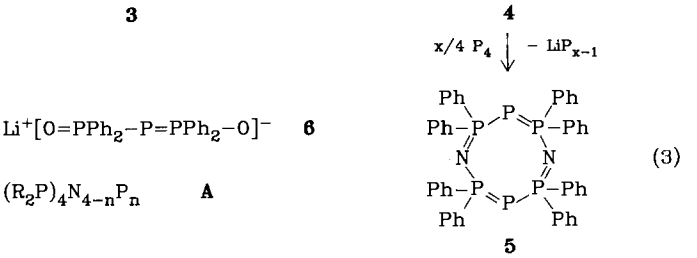
Octaphenyl-1,5,2λ^5,3,4λ^5,6λ^5,7,8λ^5-diazahexaphosphocine**



By *Alfred Schmidpeter** and *Günther Burget*



Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday



Two-coordinated nitrogen in organic aromatic heterocycles such as pyridine or the azoles can be replaced by two-coordinate phosphorus with retention of the bonding system. We now wanted to know whether this exchange is also possible in the case of inorganic ring systems with delocalized double bonds, such as cyclotetraphosphazenes; that is, whether compounds of the series **A** can be prepared.

Nucleophilic P_4-degradation analogous to that with alkali metal phosphinites[1] was considered a promising synthetic strategy. Thus, for example, lithium diphenylphosphinoanilide **1** also effects the disproportionation of white phosphorus according to equation (1) on boiling under reflux in tetrahydrofuran (THF). Tetramethylethylenediamine (TMEDA) accelerates the reaction. According to the reaction stoichiometry and C,H-analysis, the insoluble black polyphosphide that separates during the reaction has the composition $(thf)_2LiP_{13}$.[2] The oxidation product **2** can be isolated from the reaction solution as analytically pure crystals.

The corresponding reaction (2) with lithium bis(diphenylphosphino)amide **3**[3] proceeds rapidly enough even without the aid of TMEDA and leads to formation of the lithium salt **4** containing a seven-membered anion; **4** is again a lithium phosphinoamide and therefore reacts further in a second step (3) with white phosphorus to give the eight-membered ring **5** ≡ A, n = 2.[5] The reaction cannot be stopped just at the stage of the intermediate product **4**, even by a high $3/P_4$ ratio (7:2). For the polyphosphide precipitate, the reaction stoichiometry gives a Li/P ratio of 1:8 corresponding to Li_2P_{16};[4] excess P_4 remains unchanged.

An iterative spectral analysis confirms the spin-system AA'A''A'''MM' of **5**, but does not allow a satisfactorily accurate enough determination of the remaining coupling constants. The ^{31}P-upfield shift and PP coupling constant correspond to those in anionic[1] and cationic[6] systems consisting of a central twofold coordinated phosphorus atom and two tetrahedrally coordinated phosphorus atoms. **5** is thermally stable up to at least 200°C. In hydrous THF, **5** hydrolyzes within a few days with formation of $(Ph_2P)_2NH$. It is slowly degraded by $Li^+Ph_2PO^-$ at 60°C, reforming **4** and **3** and yielding the salt **6**.[1] Like the crystals of many cyclophosphazenes,[7] those of **5** also incorporate solvent molecules.

Attempts to prepare the end member of the series of compounds **A**, namely **9** with n = 4, remained unsuccessful. It is thermodynamically less stable than the mixture of tetraphenyldiphosphane **10** and P_4. Formally, **9** could be formed by disproportion of P_4 with the nucleophile lithium diphenylphosphide **7** according to equation (4). Indeed, the reaction does proceed in the desired direction but only up to the first (corresponding to **3**) stage **8**.[8] Compound **8** does not formally take up P^+ from further P_4 (**8** ↛ **9**), but gives up P^- to P_4 according to equation (5). The reaction proceeds the same with sodium or potassium salts instead of lithium salts.[8]

A hexaphosphocine **12**, in which the two nitrogen members of **5** are replaced by NCC members in the sense of the cyano-displacement principle, could be detected in the

Experimental procedure and physical data

2: A vigorously stirred mixture of **1** (40 mmol) and P_4 (9.91 g, 80 mmol) in THF (100 mL) was heated under reflux for 24 h. A black precipitate separated from the orange-red solution; it was separated from the hot reaction mixture by filtration on a frit and washed with THF. The filtrate and washings were evaporated down to 80 mL and diluted with 80 mL of *n*-hexane. A colorless, crystalline precipitate of **2**·THF separated out; this was recovered by filtration and washed with *n*-hexane (yield: 5.70 g (43%). ^{31}P NMR (THF/TMEDA): A_2M, $\delta(A) = +31.7$, $\delta(M) = -119.6$, $J(AM) = 410$ Hz.

4: ^{31}P NMR (THF): A_2B_2M, $\delta(A) = +45.7$, $\delta(B, \text{terminal}) \approx +49.6$, $\delta(M) = -122.5$, $J(AM) = 410$, $J(AB) = 68$ Hz.

5: A vigorously stirred mixture of **3** (11.74 g, 30 mmol) and P_4 (8.43 g, 68 mmol) in THF (200 mL) was heated under reflux for 24 h. The solution turned deep-red in color and a violet-black precipitate separated out. The hot solution was filtered on a frit and the precipitate was washed with THF. On cooling the filtrate and washings to room temperature, **5**·THF separated out as light yellow, fine needle-like crystals (first fraction); after filtration, the filtrate was evaporated down to 100 mL and treated with 100 mL of *n*-hexane. This provided a second crop of **5**·THF. Total yield of **5**·THF (m.p. 220°C (dec.)): 65%; ^{31}P NMR (THF): AA'A''A'''MM', $\delta(A) = +35.0$, $\delta(M) \approx -141.5$, $J(AM) = 429$ Hz. On using benzonitrile, crystals of **5**·C_6H_5CN having the same appearance were obtained.

12: ^{31}P-NMR (THF): AA'A''A'''MM', $\delta(A) = 36.3$, $\delta(M) = -141.2$, $J(AM) = 425$ Hz.

A Macrobicyclic Receptor Molecule for the Diquat Dication**

By *Billy L. Allwood, Franz H. Kohnke, J. Fraser Stoddart,* and David J. Williams**

Recently, we have demonstrated[1] that, although the macrobicyclic receptor molecule **6** provides enhanced complexation of the diquat dication ([Diquat]$^{2+}$) relative to that exhibited by dibenzo-[30]crown-10, **1**,[2] and its derivatives **2**—**4**,[3] its [Diquat]$^{2+}$ receptor site is larger than is necessary for a good supramolecular match. In view of the biological significance of [Diquat]$^{2+}$, and its relevance and importance in redox processes and photochemical systems,[4] synthetic modifications of **6**, so as to achieve an improved receptor molecule, constitute one of our prime objectives.

[Diquat]$^{2+}$

	1	2	3	4	5
R	H	CH_3	CH_2OH	CHO	CH_2Br

	6	7
R–R	CH_2-O-CH_2 	CH_2-O  O-CH_2

We (1) describe here the synthesis[5] of the macrobicyclic receptor molecule **7** from **5**, (2) report on ^{1}H-NMR spectroscopic investigations in solution (Fig. 1, Table 1), designed to probe the kinetics and thermodynamics of its complexation with diquat bishexafluorophosphate[6] in relation to its conformational behavior and mode of binding (Fig. 2), and (3) provide, from X-ray crystallographic investigations, details of the solid-state structures of both the free (i.e., **7**) and complexed ([Diquat]$^{2+}$) states[5,7] (Fig. 3 and 4).

At room temperature in the ^{1}H-NMR spectrum of [Diquat·**7**][PF_6]$_2$ recorded[8] at 400 MHz in [D_6]acetone, all the signals for the diquat and *O*-methylene protons are very broad. On cooling the solution, the spectrum becomes well resolved, until, by −20°C (Fig. 1), all eight bipyridinium protons and two sets of *N*-methylene protons in the complexed [Diquat]$^{2+}$ can be identified as separate signals in addition to the AB system arising from the benzylic methylene protons of **7**. Analyses of the temperature-dependent spectra afforded the kinetic and thermodynamic data listed in Table 1 for the processes illustrated in Figure 2:

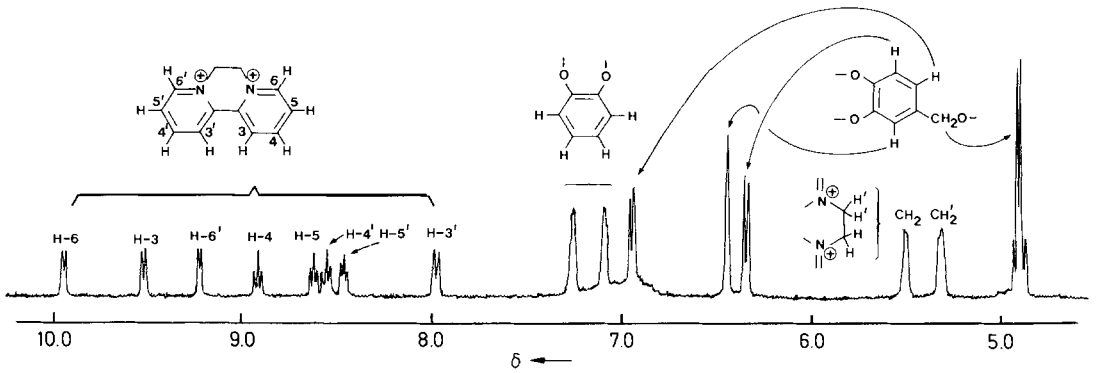

Fig. 1. The partial 400-MHz ^{1}H-NMR spectrum of [Diquat·7][PF_6]$_2$ recorded at -20°C in [D_6] acetone [8]. Although the assignment of signals to primed and unprimed protons is arbitrary, the two sets of pyridinium ring protons have been identified by double irradiation experiments.

the assumption was made[9] that the exchange processes for [Diquat·7]$^{2+}$ depend solely upon a unimolecular dissociation-recombination mechanism.[10] The temperature-dependent behavior of the ^{1}H-NMR spectrum of [Diquat·7][PF_6]$_2$ can most reasonably be interpreted in terms of a 1:1 molecular complex in which the substrate becomes desymmetrized ($C_{2v}\rightarrow C_s$) within the dissymmetric cavity of the receptor.

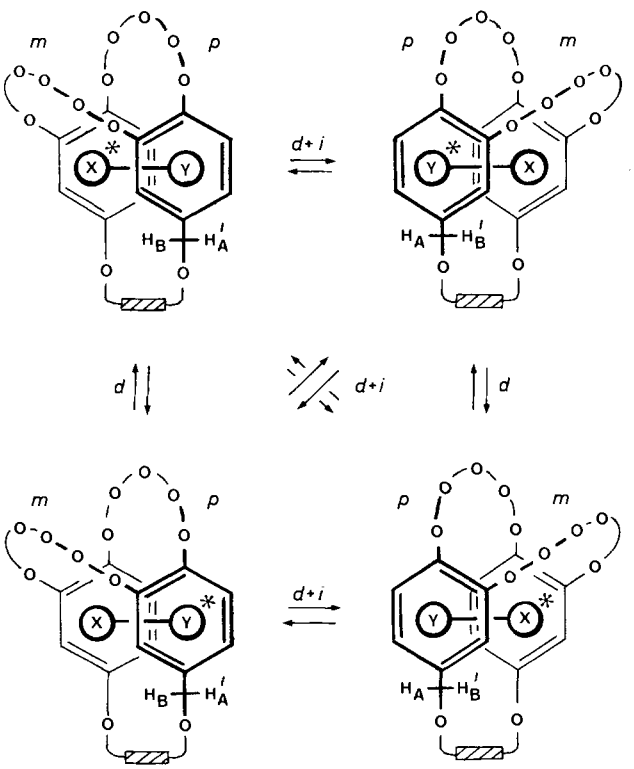

Fig. 2. Exchange processes [($d+i$) and d] for the complex of [Diquat]$^{2+}$ with 7 (schematic). d is dissociation with recombination, i is conformational inversion of 7 (see [c] in Table 1). The site exchanges for the benzylic methylene protons (A⇄B) and for the constitutionally homotopic protons (X⇄Y) on the bipyridinium nucleus (X–Y) of [Diquat]$^{2+}$ are shown (m = *meta* and p = *para* polyether chain). The prime is replaced by an asterisk for X and Y.

Confidence in this interpretation of events in solution comes from the following observations: (1) The degenerate conformational change proposed for the receptor molecule in Figure 2 can be detected (Table 1), employing the benzylic methylene protons as probes, at much lower temperatures in the ^{1}H-NMR spectrum of the free receptor **7** recorded in CD_2Cl_2. (2) A charge-transfer absorption band is observed in the UV spectrum of [Diquat·7][PF_6]$_2$ in acetone and a quantitative analysis of it provides evidence for the 1:1 stoichiometry of the solution complex, together with a value of $>9\times10^5$ M^{-1} for its stability constant.[11] (3) X-Ray crystallography[5,7] of **7** and [Diquat·7][PF_6]$_2$ demonstrates (Fig. 3) that the receptor molecule undergoes a conformational change[11] in order to encapsulate [Diquat]$^{2+}$. A consequence of the shortening of the diether

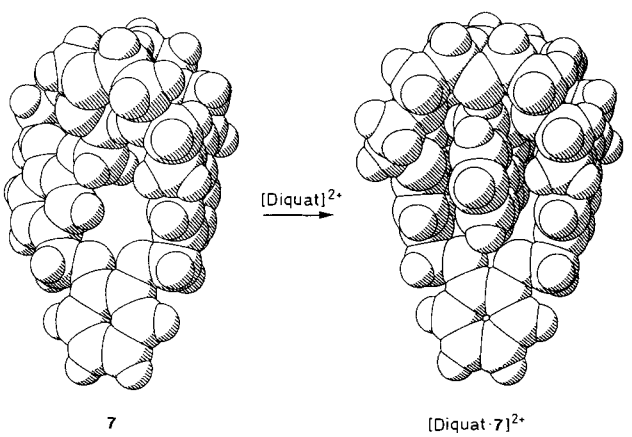

Fig. 3. The conformational change experienced by 7 in the solid state when it complexes [Diquat]$^{2+}$ (space-filling models).

bridge in [Diquat·7]$^{2+}$ relative to that of [Diquat·**6**]$^{2+}$[1] is a better match between [Diquat]$^{2+}$ and the host cavity. This is reflected in a loss of structural disorder in the two bridging polyether chains. As in [Diquat·**6**]$^{2+}$, there is approximate alignment of the bipyridinium nitrogen atoms with the catechol oxygen atoms O1, O13, O16, and O28 (Fig. 4). Uncharacteristically, the O1–C2 bond is nearly orthogonal to the plane of the attached benzo rings and the associated N1···O1 distance[12] (2.89 Å) is shortened dramatically compared with the other constitutionally related $N^+\cdots O$ distances in both [Diquat·**6**]$^{2+}$ and [Diquat·7]$^{2+}$. This N1···O1 distance is comparable with that normally found for $N^+-H\cdots O$ hydrogen bonds and is very much shorter than we have previously observed for

Table 1. Temperature-dependent ^{1}H-NMR spectroscopic data and kinetic and thermodynamic parameters for **7** and its 1:1 complex [Diquat·**7**][PF_6]$_2$ [a].

Species	^{1}H-NMR signal	Spectral changes [b]	T_c, ±3 [°C]	$\Delta\nu$, ±2(°C) [Hz]	J_{AB}, ±0.5 [Hz]	k_c [s^{-1}]	$\Delta G_c^{\neq}$, ±0.3 [kcal mol^{-1}]	Process [c]

[a] All spectra were recorded at 400 MHz on a Bruker WH400 spectrometer with Me_4Si as internal standard. The spectra of the 1:1 complexes were obtained in [D_6]acetone. In this solvent, the low temperature spectra for **7** showed no temperature dependence of the signal for the benzylic methylene protons other than line broadening: however, in CD_2Cl_2, an AB system separated out below −59°C with a chemical shift separation for the A and B protons that is strongly temperature dependent and results in the signal assuming a singlet character again below −90°C. Abbreviations: T_c, coalescence temperature; $\Delta\nu$, frequency separation for the appropriate ^{1}H-NMR signal with the temperature at which it was measured in parenthesis (in the case of **7**, $\Delta\nu$ was obtained by extrapolation of ν_A and ν_B below T_c back to this temperature); J_{AB}, coupling constant between the benzylic protons H_A and H_B; k_c, exchange rate constant at T_c calculated from the approximate expressions $k_c = \pi[\Delta\nu^2 + 6J_{AB}^2]^{1/2}/(2)^{1/2}$ when the protons undergoing exchange are mutually coupled, and $k_c = \pi\Delta\nu/(2)^{1/2}$ when the protons undergoing exchange are not mutually coupled; $\Delta G_c^{\neq}$, free energy of activation at T_c calculated from the Eyring equation. [b] Sites are designated X/Y for uncoupled two-site systems (H-3/3′, H-4/4′, H-5/5′, and H-6/6′ in Fig. 1). Sites that represent two time-averaged signals are designated XY. Sites are designated A/B for coupled AB systems (CH_2-Aryl in Fig. 1). Sites that represent two time-averaged signals from such systems are designated AB. Since the broadened singlets observed for the $CH_2N^{\oplus}$ protons at −60°C constitute an AA′BB′ system, the half-peak width was equated with J_{AB}. [c] Process *i* is ascribed to the degenerate conformational inversion of **7** in which the polyether chain *meta* to the diether bridge passes through the macrocyclic ring formed by the bridge and the polyether chain *para* to it. Processes *d*+*i* and *d*, respectively, refer to dissociation-recombination of [Diquat·**7**]$^{2+}$ with and without conformational inversion of **7**.

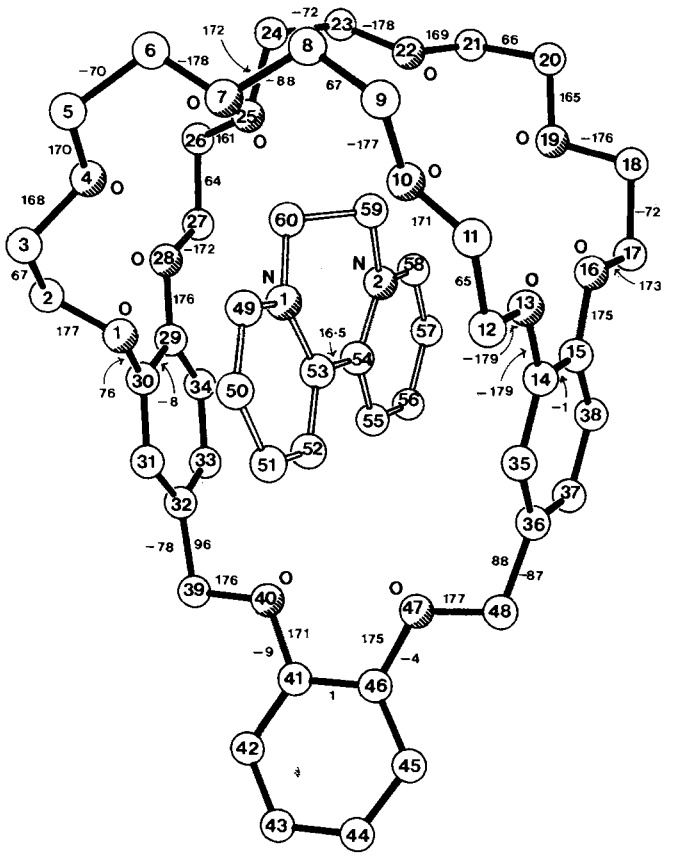

Fig. 4. Structure of [Diquat·**7**][PF_6]$_2$ in the crystal (anion not shown). Torsional angles [°] (O–C–C–O and C–C–O–C) associated with the polyether chains and the diether bridge are shown beside the relevant C–C and C–O bonds in the structure. Selected hydrogen contact distances, C···O, H···O [Å], and C–H···O angles [°] at H atoms assuming normal trigonal or tetrahedral geometry: C49···O4 3.20, H49···O4 2.69, 114; C49···O7 3.12, H49···O7 2.25, 150; C49···O10 3.07, H49···O10 2.89, 92; C58···O19 3.16, H58···O19 2.47, 128; C59···O25 3.27, H59···O25 2.63, 124; C60···O4 3.20, H60···O4 2.88, 101; C60···O7 3.24, H60···O7 2.35, 154; C60···O10 3.24, H60···O10 2.78, 109; C60···O25 3.29, H60···O25 2.69, 121. Separation [Å] between pyridinium ring nitrogen atoms in the guest and phenolic oxygen atoms in the host: N1···O1 2.89; N2···O16 3.45. Twist angle between the pyridinium rings in the guest: 17°. Separation of the overlapping regions between the benzo rings in the host; 6.15 Å with a 17° departure from a parallel alignment of their mean planes.

electrostatic interactions of this type. The conformational change undergone in **7** during complexation entails more than a 60° rotation of one of the benzo rings relative to the other. Although the conformation of **7** is not totally preorganized prior to complexation, a substantial portion of the macrobicyclic receptor is correctly arranged for binding [Diquat]$^{2+}$. This investigation demonstrates the need[13] to introduce at least one further bridging unit between the two benzo rings of **1** in order to provide a more rigidly defined receptor site for the diquat dication.

[5] Experimental: Bromination (PBr_3, C_6H_6) of **3** [1] afforded **5** [83%, m.p. 96—97°C, ^{1}H-NMR ($CDCl_3$, 220 MHz): δ = 3.67, 3.73, 3.86, 4.13 (32H, 4×m, δ/δ′-, γ/γ′-, β/β′-, and α/α′-OCH_2 protons, respectively), 4.42 (4H, s, 2×CH_2Br), 6.75—6.95 (6H, m, arom. H)]. Reaction of **5** (NaH, THF) with equimolar amounts of catechol gave **7** [22%, m.p. 127—128°C, ^{1}H-NMR ([D_6]acetone, 400 MHz): δ = 3.60—3.68 (20H, m, δ/δ′-, γ/γ′-, β- or β′-OCH_2), 3.70—3.73 (4H, m, β- or β′-OCH_2), 3.81—3.84, 4.13—4.16 (8H, 2×m, α/α′-OCH_2), 6.83 (2H, d, J = 8 Hz, H-4, 18), 6.87 (2H, d×d, J = 2, 8 Hz, H-3, 19), 7.02 (2H, d, J = 2 Hz, H-1, 21), 6.97, 7.12 (4H, AA′BB′ V system, remaining aromatic protons)]. Single crystals of **7** suitable for X-ray analysis were grown by very slow vapor diffusion of pentane into a $CHCl_3$ solution of **7**. To obtain single crystals (m.p. 216°C) of [Diquat·**7**][PF_6]$_2$, [Diquat][PF_6]$_2$ (7 mg, 0.015 mmol) and **7** (10 mg, 0.015 mmol) were dissolved in acetone (0.5 mL) and the solution was subjected to vapor diffusion with petroleum ether. All new compounds and the 1:1 complex gave satisfactory elemental analyses and spectroscopic data.

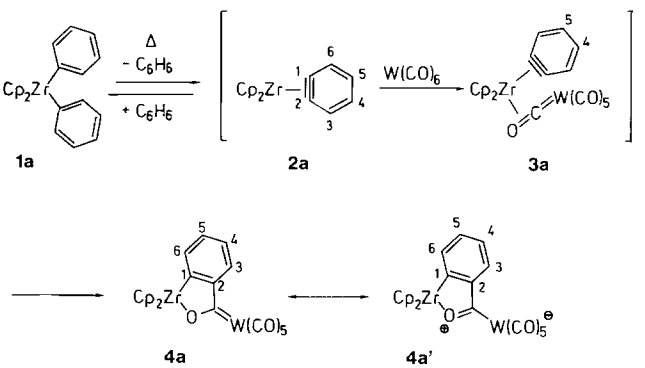
[11] $K_a > 9 \times 10^5$ M^{-1} corresponds to a free energy of complexation of > 8.1 kcal mol^{-1}. Comparing this complex strength with the value of 13.8 kcal mol^{-1} (Table 1) found for the free energy of activation for dissociation of the complex suggest that the association of the complex is not diffusion controlled. A free energy of activation for association of up to 5.7 kcal mol^{-1} indicates a somewhat slower recombination process which is probably associated with an energy-demanding conformational change within **7**, prior to it complexing with the diquat dication.

[12] The angle between the N1···O1 vector and the C30–O1–C2 plane is 21°. This is consistent with a pole-dipole interaction between the positively charged N1 atom and an O1 lone pair.



[13] From a comparison of the complexation strength ($K_a = 2 \times 10^5$ M^{-1}) of [Diquat·**6**]$^{2+}$ (see [1]) with that ($K_a > 9 \times 10^5$ M^{-1}) of [Diquat·**7**]$^{2+}$, it is clear that, although shortening of the diether bridge has increased the thermodynamic and kinetic stabilities of the diquat complex, the question of making the receptor site more rigid has still to be addressed.

Reaction of Thermally Generated (η^2-Aryne)zirconocene with $W(CO)_6$, a Novel Route to Carbene Complexes**

By *Gerhard Erker,* Ulrich Dorf, Richard Mynott, Yi-Hung Tsay,* and *Carl Krüger*

Variations of *Fischer*'s original route to heteroatom-substituted transition-metal carbene complexes are probably still the most widely used approach to this important class of compounds.[1] In some cases, however, the classical two-step pathway is unsuitable because side reactions at the stage of the acylmetalate intermediate can prevent or interfere with the otherwise smooth course of the carbene complex synthesis.[2] The formation of the carbene complex via concerted CC bond formation to a coordinated CO ligand would solve this general problem. A possible way of realizing such a one-step synthesis is a reaction analogous to the presumably concerted bis(olefin)metallocene→bis(cyclopentadienyl)metallacyclopentane ring closure reaction using an "oxyphilic" early transition metal.[3] We selected the (η^2-aryne)zirconocene **2** as a very reactive (η^2-olefin)metal complex precursor for this proposed reaction sequence. Compound **2a**, which cannot be isolated as such, may be generated easily as a reactive intermediate by elimination of benzene from diphenylzirconocene, **1a**, at 80 °C.[4]

1a reacts smoothly with hexacarbonyltungsten at 80 °C to give the zirconiumoxycarbenetungsten complex **4a**. The coupling of the *ortho*-phenylene moiety at the bent metallocene with the CO ligand is established unequivocally from the spectroscopic data[5]. The formation of **4a** via an aryne intermediate is supported by a classical experiment:[6] The thermolysis of di-*para*-tolylzirconocene **1b** affords the unsymmetrically substituted arynezirconocene complex **2b** (Me on C4),[4a] which should react with $W(CO)_6$ to give two intermediates **3** (**b**: Me on C5; **c**: Me on C4). We observed the formation of a 60:40 mixture of the correspondingly substituted, isomeric zirconiumoxycarbene complexes **4b** (Me on C5) and **4c** (Me on C4) in the reaction of **1b** with $W(CO)_6$ at 80 °C.[7]

While the X-ray structure analysis[8] shows that **4a** exhibits the characteristic properties of a Fischer-type carbene complex[1] with a large W–C(carbene) distance, the C(carbene)–O bond is remarkably short. The corresponding Zr–O bond is long. Two crystallographically independent molecules of **4a** are present in the unit cell. They mainly differ in the conformation of the bent metallocene fragment: in one molecule, the two cyclopentadienyl ligands are, to a first approximation, staggered, while in the other one, they are eclipsed (Fig. 1).

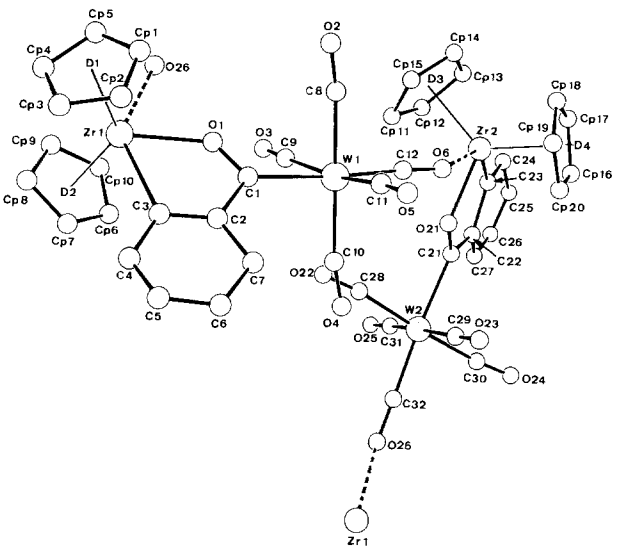


Fig. 1. Crystal structure of **4a**: geometry of the two crystallographically independent molecules: intermolecular interactions between Zr1 and O26 and between Zr2 and O6 are indicated.

The most noticeable feature of the solid-state structure of **4a** is the intermolecular linkage of the crystallographically independent units via the CO ligands *trans* to the car-

bene carbon. Although the resulting interaction (Zr2–O6: 2.49(2) Å) is weak (and certainly unstable in solution) in comparison with that in the metallocyclic five-membered-ring skeleton (Zr1–O1 2.16(2) Å), it is sufficient to connect the monomeric zirconiumoxycarbene–$W(CO)_5$ units in the solid specifically to give a polymeric helical molecular chain. The two independent units of **4a** together form the repeating structural unit of the helix (see Fig. 2). Solvent molecules (in this case, toluene) occupy positions between the chains in a disordered fashion. However, the incorporated solvent is only weakly bound. It is rapidly released, with destruction of the crystal structure, upon passing a stream of inert gas over the solid.

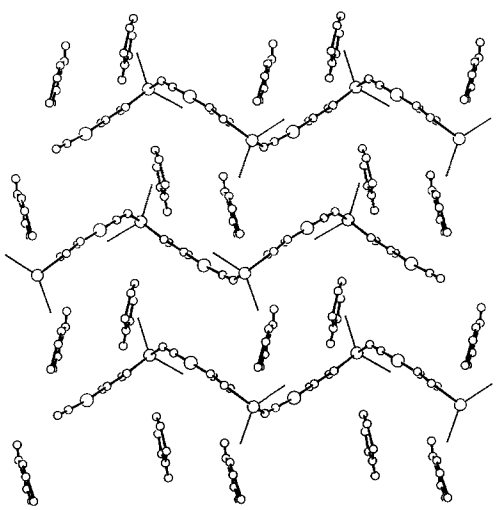

Fig. 2. Crystal structure of **4a**: a view of the helical molecular chains. For simplification, only the $-Zr(C_3O)-W-(CO)-$ skeletal units are drawn.

The formation of the polymeric helix structure of **4a** in the solid state is possibly an indication of the importance of a dipolar resonance structure **4a'** in describing the properties of this zirconiumoxycarbene complex:[9] The unusually electrophilic Zr center is attacked by the negative end of the dipole, the oxygen of the carbonyl group, in a manner that is typical[10] of a carbonylmetalate ion.

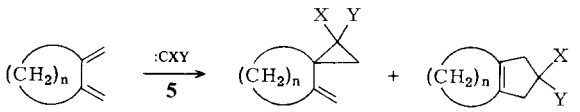
1,4-Addition of Dihalocarbenes to 1,3-Dienes**



By *Leonardus W. Jenneskens, Willem H. de Wolf,* and *Friedrich Bickelhaupt**

The 1,4-addition of singlet carbenes to 1,3-dienes is not ruled out on the basis of theoretical calculations even though it may be difficult in comparison with the known 1,2-addition.[1] However, until now, it has been observed directly[2] or indirectly[3] in only a very limited number of cases.[4,5] Earlier, we found the first example of an unequivocal intermolecular 1,4-addition in the reaction of dichlorocarbene with 1,2-bis(methylene)cycloheptane and explained this on the basis of the cisoid conformation of the 1,3-diene.[2b] We report here a new investigation which had as its goal the more exact determination of the scope of this novel reaction.

[**] This work was supported by the Netherlands Foundation for Chemical Research (SON) with a grant *(L. W. J.)* from the Netherlands Organization for the Advancement of Pure Research (ZWO).

For this purpose, we allowed the 1,2-bis(methylene)cycloalkanes **1–4** to react with dihalocarbenes CXY **5** under largely standardized conditions.[6] In addition to the expected main products **6**, the 1,2-adducts, we found varying amounts of the 1,4-adducts **7** (Table 1), depending on the ring size and the halogen substituents.

1–4 **6** **7**

Table 1. 1,2- and 1,4-additions of CXY, **5**, to 1,2-bis(methylene)cycloalkanes **1–4**. Both diastereomers of **6c** are formed in the additions of **5c**.

[a] According to *Skattebøl* [7] from CHX_2Y and *t*BuOK in *n*-pentane at 25°C (cf. [6]). [b] According to *Dolbier* and *Sellers* [8] from $[Ph_3PCF_2Br]^{\oplus}Br^{\ominus}$ with KF at 25°C (20 h). [c] According to *Seyferth* [9] from $PhHgCBr_3$ in benzene at 80°C (2 h). [d] According to *Seyferth* [9] from $PhHgCBr_3$ in toluene at 110°C (2 h). [e] According to *Baird* [10] from CHI_3 and *t*BuOK in *t*BuOH at −20°C and 16 h stirring at room temperature.

Control experiments with 2,3-dimethylbutadiene and the same dihalocarbenes gave exclusively 1,2-adducts; no 1,4-adducts were observed within the limits of experimental error (^{1}H NMR, GLC: <0.1% **7**). As we have already shown earlier, **6b** (n = 5) does not rearrange to **7b** (n = 5) under the reaction conditions used; similarly **6d** (n = 5) does not afford **7d** (n = 5), even at 110°C. The surprisingly general 1,4-addition that occurs for **1–4** must be ascribed to their cisoid conformation. A radical mechanism or a nucleophilic addition of a trihalomethane anion is very unlikely since, in these cases, 1,4-adducts of 2,3-dimethylbutadiene would also be expected. The only alternative is thus a more or less concerted addition; whether a short-lived common intermediate[11] is involved cannot be determined on the basis of our experiments.

An analysis of the results in Table 1 allows the following preliminary conclusions to be drawn:

1) The relative yields of **6** and **7** are not strongly dependent on the mode of generation of the dihalocarbenes. This conclusion results from the roughly constant molar ratio of **6d** and **7d** formed from **3** and **4** when dibromocarbene, **5d**, is prepared by either the Skattebøl[7] or the Seyferth[9] method. Although minor differences are observed, they may be ascribed to temperature effects, as shown by the monotonic decrease in the amount of **7d** with increasing temperature (e.g., **7d** from **3**: 0.19/25°C, 0.13/80°C, 0.11/110°C). One may therefore assume that free carbene is involved in these reactions.

2) Electronic factors play an important role in the 1,4-addition. Difluoro- and diiodocarbene, **5a** and **5e**, respectively, do not engage in 1,4-addition; the optimal reaction occurs for dibromocarbene, **5d**. Remarkably, difluorocarbene tends to engage most strongly in homo 1,4-addition to norbornadiene;[4,5] different factors are apparently decisive in the two types of reaction.

3) Steric factors also have a major influence on the competition between 1,2- and 1,4-addition. However, caution is urged here since rate comparisons using a variety of substrates would be necessary before drawing definite conclusions; the product ratios of Table 1 reflect only the competition with respect to the same substrate. It is noticeable, however, that for the relatively small dichlorocarbene, **5b**, there is hardly any dependence on the ring size, whereas for bromochlorocarbene, **5c**, such a dependence is evident and for dibromocarbene, **5d**, it is strongly pronounced. Furthermore, it is noteworthy that, especially for dibromocarbene, the highest yield of the 1,4-adduct is obtained for the seven-membered ring **3** even though its 1,3-diene system is not coplanar and the distance between the carbon atoms 1 and 4 of this system is less favorable than, for example, in the five-membered ring **1**.

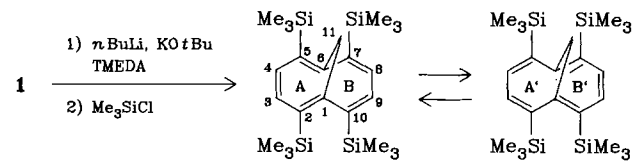
2,5,7,10-Tetrakis(trimethylsilyl)-1,6-methano[10]annulene, a Fluxional Valence Tautomer with Cyclopolyolefin Structure**



By *Richard Neidlein,* Wolfgang Wirth, Alfred Gieren, Viktor Lamm,* and *Thomas Hübner*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

1,6-Methano[10]annulene **1** has an aromatic structure with a Hückel 10π-electron system in the perimeter.[1,2] Depending on the substituents, isolable valence tautomers

can occur; thus, the derivative **2** with dicyano-substituted methano-bridge and having a norcaradiene crystal structure has already been reported.[3]

3

The compound 2,5,7,10-Tetrakis(trimethylsilyl)-1,6-methano[10]annulene **3** has been shown by an X-ray structure analysis to be the first cycloheptatriene/cycloheptadiene valence isomer with a cyclopolyolefin structure. If **1** is lithiated in the presence of tetramethylenediamine (TMEDA) and potassium *tert*-butoxide and subsequently trimethylsilylated, **3** can be isolated in 6% yield as colorless crystals.

One of the two equivalent resonance structures representing the aromatic character of 1,6-methano[10]annulene is present as valence tautomer in **3**. In solution at room temperature, a fluctuation between single and double bonding takes place. This manifests itself in the appearance of only one signal in the ^{1}H-NMR spectrum for the perimeter protons and only one signal in the ^{13}C-NMR spectrum for the perimeter carbon atoms 2, 5, 7, and 10. At lower temperatures, a diminution in the fluctuation leads to a broadening, and, below 155 K, a doubling of the proton signals is observed.

The molecule **3** (Fig. 1)[4] has a well-fulfilled non-crystallographic mirror plane through the bridge carbon atom C11 and the midpoints of the C3–C4 and C8–C9 bonds. The tendency of the bulky trimethylsilyl groups in the "*peri*" positions to make way for each other not only determines the bonding behavior and conformation of the molecule but also removes the aromaticity of 1,6-methano[10]annulene. In the [10]annulene perimeter of **3**, there are alternating single and double bonds, as in a cycloolefin. The single bonds have a length of 1.45–1.47 Å, while the double bonds have a length of 1.35–1.36 Å. The two seven-membered rings do not have the same conformation: the cycloheptatriene ring A has a boat conformation, while the cycloheptadiene ring B has an envelope conformation. In ring B, the silyl-substituted atoms C7 and C10 are noticeably rehybridized from sp^2 to sp^3 (sum of angles: 356.2°). The Si3 and Si4 atoms lie 0.75 Å outside of the plane of the six coplanar C atoms of ring B. The rehybridization of the analogous C-atoms of the boat-shaped ring A is comparatively slight (sum of angles: 358.9°). In both cases, however, steric strain between the "*peri*" silyl groups is reduced by the rehybridization. The silyl groups on ring A, on the one hand, and on ring B, on the other, are located on opposite sides of the [10]annulene ring (Fig. 1b). The aromaticity of the 1,6-methano[10]annulene is removed by the steric effects of the substituents, which lead to a strong torsion about the C6–C7 and the C1–C10 bonds. The torsional angle C5–C6–C7–C8 is −127.5°, the mirror symmetry equivalent angle 126.7°. If the rehybridization at C7 and C10 is still taken into account then the p_z orbitals of these bonds are rotated through 61.4° with respect to each other. The transannular C1–C6 distance is 2.298 Å.

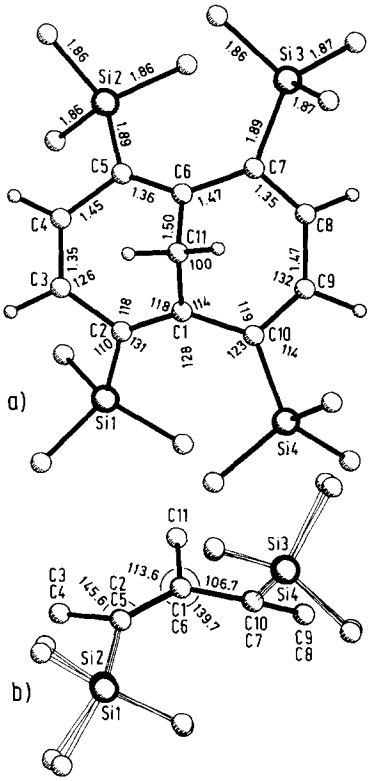


Fig. 1. Molecular structure of **3**. a) Plan view, without H-atoms of the $Si(CH_3)_3$ groups. b) Side view, without H-atoms, with interplanar angles. The given bond lengths [Å] and angles [°] are averaged over the molecular mirror symmetry, and, for clarity, given with one digit less than the least significant one (standard deviations of the individual values: 0.004–0.008 Å and 0.2–0.5°, respectively).

The reversible valence isomerization in solution leads to a mutual transformation of the conformations of the seven-membered rings; this results in the structures being the same.

Experimental

TMEDA (20 mL) was treated with **1** (5 g, 33 mmol), potassium *tert*-butoxide (1 g), and a 2.5M solution of *n*-butyllithium in hexane (84 mL, 210 mmol). The mixture was heated for 1 h at 50°C and then treated, with ice-cooling, with 25 g (230 mmol) of trimethylsilyl chloride, stirred for a further hour at room temperature, and finally hydrolyzed with dilute hydrochloric acid. Subsequent extraction with ether, drying over anhydrous $MgSO_4$, removal of the solvent, and column-chromatographic purification (silica gel, 30 cm, Ø 3 cm, hexane as eluent) afforded 910 mg (6%) of **3** (colorless crystals, m.p. 128°C).—UV (hexane): λ_{max} (lgε) = 240 (4.15), 320 nm (3.88).—^{1}H NMR (250 MHz, CCl_2F_2/[D$_6$]acetone): 293 K: δ (referred to [D$_6$]acetone) = 0.30 (s, CH_3), 1.53 (s, CH_2), 6.84 (s, H-3,4,8,9). 128 K: δ = 0.11, 0.31 (CH_3), 0.82, 1.66 (CH_2), 6.47, 7.03 (perimeter-H).—^{13}C NMR (62.89 MHz, $CDCl_3$): δ = 1.87 (q, CH_3), 39.7 (t, C-11), 132.4 (d, C-3,4,8,9), 138.3 (s, C-2,5,7,10).

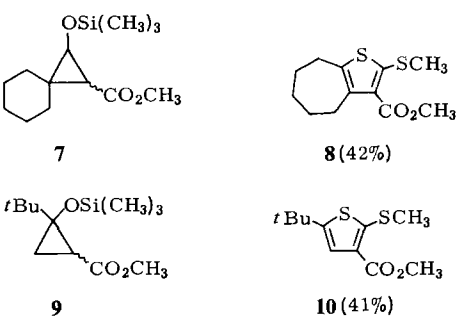
Thiophene Derivatives by Novel Rearrangements of Siloxy-substituted Cyclopropanecarboxylates**

By *Christiane Brückner* and *Hans-Ulrich Reissig**

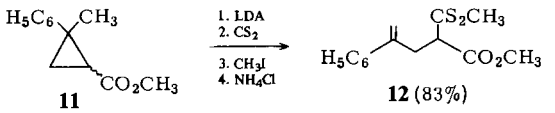
Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday



Siloxy-substituted cyclopropanecarboxylates are, as synthetic equivalents of 1,4-dicarbonyl compounds, versatile building blocks for the preparation of heterocycles; after having already used such intermediates for the synthesis of furan,[1] pyrrole,[1c] and pyridazine derivatives,[2] we have now found that the "cyclopropane trick"[3] can also be exploited for a surprisingly easy access to thiophene derivatives.

Generation of the ester enolate by reaction of **1** in tetrahydrofuran (THF) with lithium diisopropylamide (LDA)[4] followed by successive addition of carbon disulfide (1 h, −78°C/3 h, 20°C) and methyl iodide (16 h, 20°C) does not lead to formation of a cyclopropanedithiocarboxylate, as would be expected, but to the dihydrothiophene **2**. We presume that the ring expansion takes place at the stage of the anionic CS_2-adduct. The driving force behind this novel rearrangement[5] could arise from the release of strain in the cyclopropane ring and better stabilization of the negative charge in the ring expanded intermediate.

The siloxy compound **2** can be smoothly desilylated with $Et_3N \cdot 3HF$ (THF, 1 h, 20°C) to the hydroxy compound **3**, which, in turn, can be oxidized with pyridinium dichromate (PDC) (CH_2Cl_2, 3 d, 20°C) to give the thiolactone **4**. On attempting to reduce **3** with $HSiEt_3/Et_2O \cdot BF_3$ (CH_2Cl_2, 1 h, 0°C/3 h, 20°C)[6] to the dihydrothiophene derivative **6**, not only **6** but also the 3-thiophenecarboxylate **5** was formed (**6** : **5** ≈ 1 : 3). Treatment of **3** (or **2**) with $Et_2O \cdot BF_3$ (CH_2Cl_2, 30 min, 0°C/3 h, 20°C) provides exclusively **5** in high yield (overall yield **1** → **5**: 36%). The formation of **5** can be explained in terms of ionization by the Lewis acid, Wagner-Meerwein migration of a methyl group, and deprotonation with aromatization. The bicycle **8** is formed in a completely analogous way from **7** (overall yield in three steps: 42%). Two ring expansion steps (**3** → **5**, **6** → **7**) lead from a spirocyclic to an annelated ring system.



The example **9** shows that siloxycyclopropanes unsubstituted in position 3 are also capable of forming thiophene derivatives. Deprotonation of **9**, addition of CS_2 and MeI, and treatment of the crude product with catalytic amounts of CF_3CO_2H (3 h, 20°C) leads directly to **10** [overall yield (not optimized): 41%].

In the absence of a trimethylsiloxy group on the cyclopropane ring, another reaction takes place: in an analogous procedure, **11** affords the ring-opened dithio ester **12**.[7]

11 12 (83%)

The SCH_3-group in the 2-position in 3-thiophenecarboxylates ought to be substitutable;[8] hence, new possibilities are opened up for the synthesis of highly-substituted thiophene derivatives.[9,10]

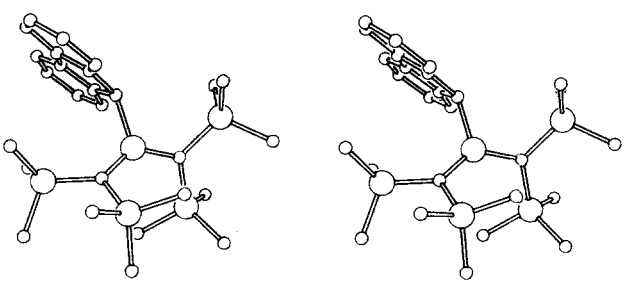
The First Tris(methylene)phosphate Ion $[P(=C<)_3]^-$ **

By *Rolf Appel,* Elisabeth Gaitzsch,* and *Falk Knoch*



Pentavalent phosphorus has mainly the coordination numbers 4, 5, and 6. Compounds in which P^V is coordinated by only three or two ligands have only become known in recent years. Currently, they are being intensively investigated. Recent examples of such systems, which are characterized by double or triple bonds, exhibit the structure types **A**,[1] **B**,[2] and **C**.[3] We report here the first synthesis of a salt of the anion type **D**.

The *P*-chlorobis(methylene)phosphorane **1**,[4] the starting material, is first converted into the bis(methylene)phosphorane **2**[5] by reaction with fluorenyllithium. **2** is converted into the corresponding anion **3** by treatment with *n*BuLi or lithium dimethylamide in tetrahydrofuran (THF). According to the X-ray structure determination and spectroscopic data in solution, **3** can be described as a discrete anion with fourfold THF-coordinated lithium[7] as counterion in the solid state and in solution.[6]

The following structural parameters—particularly in comparison with those of the neutral compound **2**—justify the characterization of **3** as tris(methylene)phosphate: The fluorenyl C9-P distance (167 pm) is shorter in **3** than in **2**, corresponding to a double bond. The $P{=}C(SiMe_3)_2$ bond

[**] Low-Coordinated Phosphorus Compounds, Part 39.—Part 38: R. Appel, W. Schuhn, F. Knoch, *Angew. Chem. 97* (1985) 421; *Angew. Chem. Int. Ed. Engl. 24* (1985) 420.

lengths remain essentially the same on going from **2** (mean 166 pm) to **3** (169 pm); the angle $(SiMe_3)_2C{=}P{-}C(SiMe_3)_2$ is decreased by 6° due to the introduction of the third double bond. The central PC_3 group is planar and the CPC angles are almost identical. The three double-bonded C atoms with their substituents surround the central phosphorus atom in a propeller-like manner (sp^2 hybridization). These results do not allow conclusions to be drawn about the ylene or ylide character of the three PC double bonds. Phosphorus may be bonded similarly to the sulfur in tris(imino)sulfur compounds.[8]

syn- and *anti*-Bishomoperylene

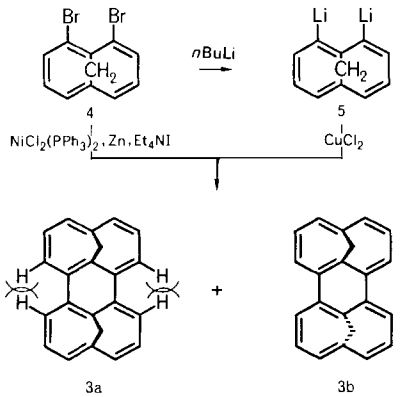
By *Emanuel Vogel,* Klaus-Dieter Sturm, Aderson de Farias Dias, Johann Lex, Hans Schmickler,* and *Fred Wudl**

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

Perylene **1** has gained importance as a key molecule in the construction of organic solids exhibiting unconventional properties. The radical-cation salts of **1** and some other low molecular arenes, which are to be regarded as charge transfer complexes, qualify as organic metals,[1] while perylene-3,4:9,10-bis(dicarboximides) are pigments[2] that have recently been shown to be versatile fluorescent dyes.[3] The hitherto hypothetical polyperylene (poly-*peri*-naphthalene) is of interest since, according to theoretical calculations, it ought to exhibit metallic conductivity without requiring the presence of a dopant.[4] Arene-radical salts and perylene pigments have in common that their macroscopic properties are associated with a stacked arrangement of the arene moieties in the molecular crystals—thus enabling charge transfer or intermolecular π-electron interactions.[5]

1 **2** **3a**: *syn* **3b**: *anti*

In the light of these findings it seemed attractive to us to include the homoperylenes (derived from **1**), i.e. monohomoperylene **2** and the *syn-anti* isomeric bishomoperylenes **3a** and **3b** (and their analogues with hetero-atom bridges), in research studies on organic solids.



The question as to what extent the molecular geometry of homoperylenes still permits stacking in the crystal due to intermolecular electronic interactions is of special interest in this respect. We now report on the synthesis of the stereoisomeric bishomoperylenes **3a** and **3b**.

Reductive coupling of 2,10-dibromo-1,6-methano[10]annulene **4**[6] with triphenylphosphane-nickel(0) complexes generated in situ seemed to be the most promising strategy for a facile entry to **3a** and/or **3b**. However, the use of methods[7] customarily resorted to for such couplings led to formation of very complex reaction mixtures. In view of the ready metalation of **4** with butyllithium to give 2,10-dilithium-1,6-methano[10]annulene **5**[6] it therefore seemed worthwhile to investigate the oxidative coupling of **5** with copper(II) chloride.[8]

For the coupling reaction, a solution of **5**—prepared from **4** (3 g, 10 mmol) and a 2 M solution of butyllithium in ether (10 mL)—was added to a cooled suspension of anhy-

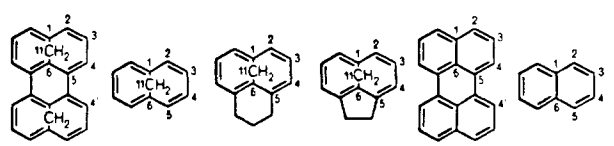
drous $CuCl_2$ (2.7 g, 20 mmol) in ether (300 mL) at −78 °C. The deep-brown mixture was stirred for 6 h at −78 °C and 1 h at room temperature. Chromatographic work-up on alumina (Woelm, activity III, neutral) with chloroform-hexane (1:3) afforded a hydrocarbon which crystallized from dichloromethane as orange-colored platelets, m.p. 250–252 °C (decomp.), yield 25–30%. Physical investigations of the compound showed the presence of *anti*-bishomoperylene **3b** as the only isomer.



The ^{1}H-NMR spectrum of **3b**, which shows an ABX system at low field for the annulene protons and a singlet at high field for the bridge protons, is similarly related to that of 1,6-methano[10]annulene **6** as the spectrum of perylene **1** is to that of naphthalene **7** (see Table 1). That the signals of H-4 (X part of the ABX system)—analogously to the situation in the perylene spectrum—are shifted to lower field compared to those of H-2 and H-3 (AB part) is ascribed primarily to non-bonding interactions[9] between H-4 and H-4', similarly as in the case of **1**. Since this steric effect is distinctly more pronounced in **3a** than in **3b**, the position of the H-4 resonance signals—a knowledge of both stereoisomers prerequisite—permits an assignment of configuration, which, due to the symmetries of **3a** and **3b**, is not possible by other NMR-spectroscopic means.

The existence of **3b** as annulene valence tautomer is supported not only by the ^{1}H-NMR and ^{13}C-NMR spectra (Tables 1 and 2) but also by the finding that the dihydrohomophenalene **8**,[10] which can serve as a model for **3a**/**3b** with regard to the *peri*-bridging, is fully consistent with 1,6-methano[10]annulene **6** so far as the NMR parameters that can be used for a comparison are concerned (see Table 1). In the case of homoacenaphthene **9**,[11] on the other hand, the relatively short *peri*-bridge appears to confer some weight on the norcaradiene valence tautomer.

The UV/VIS spectrum of **3b** may be qualitatively interpreted in terms of a bathochromically shifted perylene spectrum. For the longest wave band (L_a band), which could correspond to a HOMO-LUMO transition, the red shift is relatively slight (ca. 15 nm), but sufficient to give **3b** a vivid orange color.

The presence of the *anti*-isomer **3b**, with a center of inversion, was confirmed by an X-ray structure analysis[12] (Fig. 1). The geometry of the 1,6-methano[10]annulene halves of the molecule shows no unusual alterations compared to **6**; this seems understandable, since the formation of the C^5–$C^{5'}$ and C^7–$C^{7'}$ bonds is almost strain-free if relatively weak non-bonding H–H interactions are disregarded. The central six-membered ring in **3b** is strikingly similar to that in **1** regarding the C–C bond lengths,[13] but

Table 2. Some spectral data of **3a** and **3b**.

3a: ^{13}C NMR (75.5 MHz, CD_2Cl_2): δ = 137.01 (C-5), 128.63 (C-3), 126.26 (C-2), 123.57 (C-4), 119.34 and 111.09 (C-1, 6), 34.78 (C-11); MS (75 eV): *m/z* 280 (M^+, 85%), 279 (M^+ − H, 82), 264 (M^+ − CH_2, 100), 252 (M^+ − $2CH_2$, 26); IR (CsI): 3034, 2946, 1889, 1520, 757 cm^{-1}; UV/VIS (cyclohexane): λ_{max} = 223 nm (ε = 50700), 263 (16700), 301 (24400), 468 (17800) sh, 476 (18500)

3b: ^{13}C NMR (75.5 MHz, $CDCl_3$): δ = 139.21 (C-5), 127.70 (C-3), 124.83 (C-2), 121.20 (C-4), 116.13 and 113.47 (C-1, 6), 36.32 (C-11); MS (70 eV): *m/z* 280 (M^+, 45%), 279 (M^+ − H, 53), 264 (M^+ − CH_2, 77), 252 (M^+ − $2CH_2$, 31), 132 (100); IR (KBr): 3041, 2967, 1904, 1532, 764 cm^{-1}; UV/VIS (cyclohexane): λ_{max} = 228 nm (ε = 64500), 258 (32600) sh, 268 (36300), 290 (34700), 310 (8750) sh, 440 (21500)

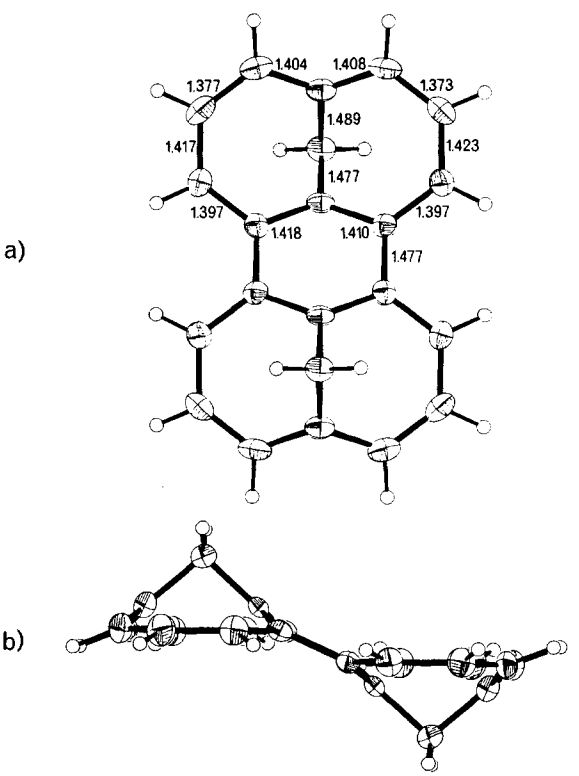

Fig. 1. Molecular structure of *anti*-bishomoperylene **3b**. Bridge-bond angle: 96.7°, transannular C–C distance in the 1,6-methano[10]annulene moieties (C^1–C^6): 2.216 Å. a) Plan view, bond lengths [Å] in the centrosymmetric molecule; b) side view.

differs from the latter in that it has a flat chair conformation. The median planes of the two [10]annulene rings in **3b** are at a slightly different level (difference ca. 0.6 Å) which can be explained in terms of the geometry of **6**.[14]

In the meantime, it has been shown that the *syn*-isomer **3a** (*syn/anti*-isomeric ratio 1:4) is also formed in the oxidative coupling of **5**. **3a** initially escaped detection, because it polymerized on the carrier material during chromatography. The isolation of **3a** has now been made possible by the surprising finding that the dibromide **4**, on reaction with $NiCl_2(PPh_3)_2$, zinc, and tetraethylammonium iodide in tetrahydrofuran[15] (1 h at 50°C) forms *syn*- and *anti*-bishomoperylene in the ratio of 4:3. After chromatographic separation on silica gel (hexane), **3a** is recrystallized from ethanol to give fine, red crystals [decomp. above 200°C; yield 7%]. **3b** is obtained in 18% yield via this route.

3a was identified mainly by its ^{1}H-NMR spectrum, since this is almost identical to the spectrum of **3b**, except for the resonance signals of H-4, H-4′ and H-8, H-8′, which, as expected, are shifted further downfield (by 0.3 ppm) (see Table 1).

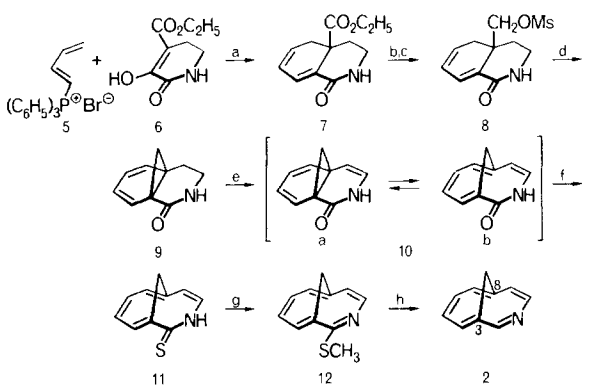
3,8-Methanoaza[10]annulene (Homoisoquinoline)

By *Werner Tückmantel, Gertraud Andree, Andreas Seidel, Hans Schmickler, Johann Lex, Elfi Kraka, Michael Haug, Dieter Cremer*, and *Emanuel Vogel**



2,7-Methanoaza[10]annulene **1** and 3,8-methanoaza[10]annulene **2**, the two bridged aza[10]annulenes formally derived from the Hückel-arene 1,6-methano[10]annulene, can, on the one hand be regarded as 10π-homologues of pyridine and, on the other, as homoquinoline and homoisoquinoline, respectively. This characterization definitely applies to **1**,[1] first described in 1978: It is a stable aromatic compound, which, in many of its properties, is reminiscent of pyridine or quinoline **3**. Several derivatives of **2** are known,[1a,2] but all attempts to synthesize the parent heterocycle have hitherto failed. The presumption consequently fostered, that **2** is less stable than **1**, finds support from theoretical considerations. According to semiempirical MNDOC and ab initio calculations[3] **2** has an enthalpy of formation (ΔH_f^0) 5 kcal/mol lower than that of **1**, whereas isoquinoline **4** is only slightly energetically less favored than quinoline **3** ($\Delta\Delta H_f^0 = 1.1$ kcal/mol).

1 2 3 4

We have now succeeded in synthesizing **2**. The isomers **1** and **2** very closely resemble each other in many respects, yet at the same time exhibit some remarkable differences.

The expectation that **2** could be prepared analogously to **1** did not materialize. It was only by an unconventional route involving **10** as strategic intermediate that the target compound yielded to synthesis (Scheme 1).

Scheme 1. a) Diazabicyclo[5.4.0]undecene (DBU), tetrahydrofuran (THF), RT, 5 h; b) diisobutylaluminum hydride (DIBAH), CH_2Cl_2, −78°C, 5 h; c) MsCl, NEt_3, CH_2Cl_2, RT, 3 h; d) DBU, THF, reflux, 12 h; e) di-*tert*-butyl peroxalate, C_6H_6, RT, 5 h; f) Lawesson reagent, C_6H_6, reflux, 30 min; g) trimethyloxonium tetrafluoroborate, CH_2Cl_2, K_2CO_3, RT, 1 h; h) 1 mmol **12**, 20 mL 75% C_2H_5OH, 1–1.5 mL Raney nickel (suspension in C_2H_5OH), RT, ca. 15 min (see text).

Reaction of the readily accessible pyridone derivative **6**[4] with butadienyltriphenylphosphonium bromide **5**[5] in

[*] Prof. Dr. E. Vogel, Dr. W. Tückmantel, G. Andree, A. Seidel, Dr. H. Schmickler, Dr. J. Lex, Dr. E. Kraka, M. Haug, Prof. Dr. D. Cremer

the presence of DBU led, via successive terminal nucleophilic addition and intramolecular Wittig reaction, to formation of the bicyclic ester **7** [m.p. 162–164°C (from benzene); yield 65%]. Selective reduction of the ester group of **7** with DIBAH furnished the corresponding alcohol, which was converted, as crude product, into the mesylate **8** [m.p. 144–146°C (from methanol); yield 67% referred to **7**]. Consistent with the theoretically established rule that kinetically controlled alkylations of enolate ions of conjugatively unsaturated carbonyl compounds preferentially occur at the α-position rather than at the vinylogous positions,[6] reaction of **8** with DBU afforded the tricycle **9** [m.p. 109–111°C (from ether/pentane 10:1); yield 70–75%], which, according to the chemical shifts and coupling constants of the CH_2-bridge protons ($^2J_{H,H}=4.8$ Hz; $^1J_{^{13}C,H}=165$ Hz), is present solely as the norcaradiene valence tautomer. The conversion of **9** into **10** [existent as **10a** and/or **10b**], i.e. the dehydrogenation of a lactam to an enelactam with the double bond adjacent to the nitrogen, appears to be without precedent in the literature.[7] This crucial step was realized by a radical reaction employing di-*tert*-butyl peroxalate[8] as the agent. The chromatographically isolated (silica gel, pentane/ethyl acetate 2:1) **10** [yellow needles, m.p. 90–92°C (first from acetonitrile, then from hexane/dichloromethane 8:1); yield 5–10%], shows changes in the coupling constants of the bridge protons compared to **9** ($^2J_{H,H}=7.2$ Hz; $^1J_{^{13}C,H}=155$ Hz), from which, in combination with other NMR findings, it can be concluded that it is present as the fluxional norcaradiene-cycloheptatriene system **10a/10b**. After exploratory experiments had shown that the 2-azabicyclo[4.4.1]undeca-4,6,8,10-tetraene-3-one[1] isomeric with **10b** (3-azabicyclo-[4.4.1]undeca-4,6,8,10-tetraene-2-one) can be converted without problem into **1** by the reaction sequence of thiolactam formation, *S*-methylation, and desulfurization, the same procedure was used for **10**. Whereas **10** on reaction with Lawesson reagent readily underwent replacement of oxygen by sulfur to give **11** [orange needles, m.p. 158°C (decomp.) (from acetonitrile); yield 65%], and **11** could be routinely methylated with trimethyloxonium tetrafluoroborate to give **12** [yellow liquid, b.p. 50°C/4×10^{-5} mbar; yield 72%], the desulfurization of **12** with Raney nickel yielded the desired **2** only under strictly controlled conditions. It was found expedient to treat **12** with Raney nickel (activity grade W2)[9] in ethanol at room temperature until ca. 50% conversion was achieved. After chromatography on silica gel (pentane/ether 2:1) and distillation at 4×10^{-5} mbar (receiver cooled to −78°C), 3,8-methanoaza[10]annulene (3-azabicyclo[4.4.1]undeca-2,4,6,8,10-pentaene) **2** was obtained as a bright yellow liquid. In striking contrast to **1**, compound **2** rapidly polymerizes even in the absence of air.—The spectroscopic data of the new compounds are listed in Table 1.

Proof of the structure of **2** is based on the spectra as well as on the X-ray structure analysis of the methanesulfonyl derivative **13**. Particularly informative is the ^{1}H-NMR spectrum [300 MHz (CCl_4, CD_2Cl_2): $\delta=-0.18$ and -0.01 (AX system, $^2J=8.56$ Hz, 2H, H-11a and H-11b[10]), 7.01 (1H, H-5), 7.12 (1H, H-6), 7.31 (1H, H-7), 7.45 (1H, H-4) (ABCD system, $^3J_{H\text{-}4,H\text{-}5}=9.10$ Hz, $^3J_{H\text{-}5,H\text{-}6}=9.01$ Hz, $^3J_{H\text{-}6,H\text{-}7}=9.13$ Hz), 7.04 (1H, H-9), 8.19 (1H, H-10) (AX system, $^3J_{H\text{-}9,H\text{-}10}=6.40$ Hz), 8.43 (s, 1H, H-2)]. The data are consistent with **2** having aromatic character, like the stable isomer **1**, even though its instability would rather suggest an olefinic molecule.[11] As in the spectrum of **1**, the resonances of the annulene and bridge protons appear at relatively low and high field, respectively, while the vicinal H,H couplings are found to be nearly equal. The absorption pattern of the annulene protons of **2** is qualitatively the same as that of the corresponding isoquinoline protons, but, as in the case of the **1/3** pair, the signals appear on average ca. 0.5 ppm further upfield.

Table 1. Some spectral data of the new compounds.

2 [a]: ^{13}C NMR (75.5 MHz, $CDCl_3$): $\delta=34.10$, 112.77, 113.68, 120.74, 126.74, 128.69, 129.27, 129.37, 143.58, 149.75; MS (75 eV): *m/z* 143 (M^+, 100%), 115 (M^+-H_2CN, 86); IR (CH_3CN): 3030, 2960, 1579, 1523, 1446 cm^{-1}

7: ^{1}H NMR (300 MHz, CD_2Cl_2): $\delta=1.22$ (t, 3H), 1.95 (m, 1H), 2.17–2.24 (m, 2H), 2.96 (m, 1H), 3.29 (m, 2H), 4.14 (m, 2H), 6.04 (m, 1H), 6.14 (m, 1H), 6.83 (br. s, 1H), 7.11 (d, 1H); MS (70 eV): *m/z* 221 (M^+, <1%), 148 ($M^+-COOEt$, 89), 105 ($M^+-COOEt-HNCO$, 100); IR (KBr): 3182, 1720, 1676 (C=O) cm^{-1}; UV/VIS (MeOH): $\lambda_{max}=285$ nm ($\varepsilon=8500$)

8: ^{1}H NMR (300 MHz, CD_2Cl_2): $\delta=1.80$ (m, 1H), 2.17–2.25 (m, 2H), 2.61 (dd, 1H), 2.99 (s, 3H), 3.34 (m, 1H), 3.56 (m, 1H), 4.12 (s, 2H), 6.06 (m, 1H), 6.17 (m, 1H), 6.58 (br. s, 1H), 7.13 (d, 1H); MS (70 eV): *m/z* 258 (M^+ + H(^{32}S), <1%), 148 (M^+-CH_2OMs, 30), 105 ($M^+-CH_2OMs-HNCO$, 100); IR (KBr): 3300, 1663, 1650 (C=O), 1352, 1172 (SO_2) cm^{-1}; UV/VIS (MeOH): $\lambda_{max}=208$ nm ($\varepsilon=4790$), 268 (2570)

10: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta=0.27$ and 2.16 (AX, 2H, $^2J=7.2$ Hz), 5.81 (d, 1H), 6.00 (dd, 1H), 6.37 (dd, 1H), 6.49 (t, 1H), 6.58 (t, 1H), 7.02 (d, 1H), 8.35 (br. s, 1H); MS (70 eV): *m/z* 159 (M^+, 100%); IR (KBr): 3225, 1647, 1614 (C=O) cm^{-1}; UV/VIS (cyclohexane): $\lambda_{max}=226$ nm ($\varepsilon=12300$), 245 (8130) sh, 268 (5130) sh, 300 (2090) sh, 348 (910)

11: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta=0.14$ and 2.09 (AX, 2H, $^2J=9.75$ Hz), 6.32–7.23 (m, 5H), 7.69 (d, 1H), 10.80 (br. s, 1H); MS (70 eV): *m/z* 175 (M^+ (^{32}S), 100%); IR (CsI): 3153, 1602 cm^{-1}; UV/VIS (cyclohexane): $\lambda_{max}=232$ nm ($\varepsilon=21200$), 315 (10900), 395 (7100)

12: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta=-0.32$ and 0.83 (AX, 2H, $^2J=9.06$ Hz), 2.54 (s, 3H), 6.89 (d, 1H), 7.01–7.22 (m, 3H), 7.54 (d, 1H), 7.67 (d, 1H); MS (70 eV): *m/z* 189 (M^+ (^{32}S), 15%), 115 (M^+-SCH_3-HCN, 100); IR (film): 3032, 2929, 1572, 1532 cm^{-1}; UV/VIS (cyclohexane): $\lambda_{max}=235$ nm ($\varepsilon=21770$), 290 (6130) sh, 330 (5700), 390 (1300) sh

13: ^{1}H NMR (300 MHz, CD_2Cl_2): $\delta=-0.29$ and -0.06 (AX, 2H, $^2J=9.31$ Hz), 3.21 (s, 3H), 7.24 (t, 1H), 7.31 (t, 1H), 7.48 (d, 1H), 7.51 (d, 1H), 8.26 (d, 1H), 8.28 (d, 1H); MS (70 eV): *m/z* 221 (M^+ (^{32}S), 7%), 115 ($M^+-SO_2CH_3-HCN$, 100); IR (CsI): 3010, 2932, 1313, 1133 (SO_2) cm^{-1}; UV/VIS (CH_3CN): $\lambda_{max}=240$ nm ($\varepsilon=22000$), 263 (17800) sh, 320 (3800), 363 (1500) sh

2·HCl: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta=-0.01$ and 0.29 (AX, 2H, $^2J=9.6$ Hz), 7.30 (t, 1H), 7.40 (t, 1H), 7.63 (d, 1H), 7.87 (d, 1H), 7.93 (d, 1H), 8.17 (t, 1H), 9.13 (d, 1H), 16.65 (br. s, 1H); IR (KBr): 3013, 2713, 1602 cm^{-1}; UV-VIS (0.1 N HCl): $\lambda_{max}=250$ nm ($\varepsilon=23940$), 260 (21840) sh, 310 (3140), 372 (2840)

[a] ^{1}H NMR and UV/VIS see text.

The UV/VIS spectrum of **2** [(cyclohexane): $\lambda_{max}=240$ nm ($\varepsilon=22500$), 260 (sh, 8900), 310 (2000), 375 (650)[12]] is comparable with that of **1**. It corresponds in its type to that of 1,6-methano[10]annulene and thus provides a further argument in favor of **2** being regarded as an aromatic system.

Even before **2** had been synthesized, its basicity was already the subject of theoretical calculations, for it was found that **1** ($pK_a=3.20$) is significantly more weakly basic than pyridine and quinoline ($pK_a=5.23$ and 4.92, respectively).[1] If the theoretically determined values for the electron densities in the region of the lone pair on nitrogen in **1**–**4**[13] are correlated with the pK_a values of **1**, **3**, and **4**, a pK_a value of 4.8 ± 0.1 can be predicted for **2**, i.e., **2** should be more basic than its isomer **1**.

We have now been able to confirm this prediction; a pK_a value of 4.7 has been determined experimentally for **2**

(isoquinoline **4**: $pK_a = 5.14$). On reaction with HCl in ether, **2** readily forms a hydrochloride [dark yellow crystals, m.p. 160°C (decomp.) (from acetonitrile)].

The reason for the relatively weak basicity of **1** lies in the stereoelectronic conditions prevailing in the molecule. The lone pair orbital on the nitrogen and the 2pπ orbital on the neighboring bridgehead carbon atom deviate in their alignment pronouncedly from orthogonality so that the lone pair electrons can, to a certain extent, delocalize into the aza[10]annulene ring.[14]

The aromaticity of **2** deduced from the spectra is further substantiated by the X-ray structure analysis of the crystalline 2-methanesulfonyl-3,8-methanoaza[10]annulene **13** [bright yellow platelets, m.p. 86°C (from ether); yield 58%] obtained from **12** by oxidation with potassium peroxomonosulfate ("Oxon")[15] in dichloromethane in the presence of [18]crown-6.[16] As shown in Figure 1, the

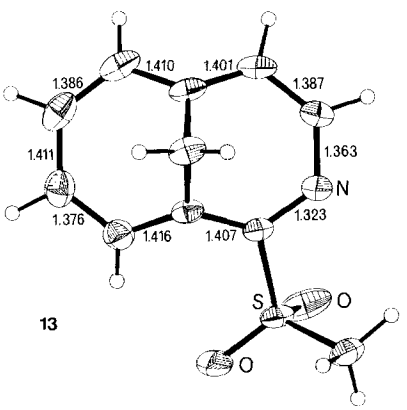

Fig. 1. Molecular structure of **13** in the crystal. Selected bond lengths [Å].

aza[10]annulene ring of **13** exhibits C–C and C–N bond lengths that correspond to those found in heteroarenes. The stretching of the $N-C^{10}$ bond compared to that of the $N-C^{2}$ bond is understandable, when one considers that the $C^{3}-C^{4}$ bond and the oppositely situated $C^{8}-C^{9}$ bond in 1,6-methano[10]annulene are relatively long.[17] Interestingly, the transannular C–C distance ($C^{3}-C^{8}$: 2.222 Å; bridge-bond angle 97°) in **13** is shorter than in 1,6-methano[10]annulene ($C^{1}-C^{6}$: 2.235 Å; 97.6°);[17] the same holds for the 3-bromo derivative of **1** ($C^{2}-C^{7}$: 2.202 Å; 95.5°) analyzed by *Simonetta et al.*[18] The introduction of a nitrogen atom into the peripheral ring of the 1,6-methano[10]annulene system (particularly at the α-position) thus appears to favor the homoconjugative transannular interaction. Consequently, there is in fact some justification for alternatively considering the aza[10]annulenes **1** and **2** as homoquinoline and homoisoquinoline, respectively.

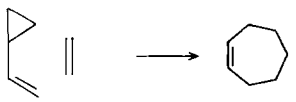
Synthesis of Seven-Membered Rings by $[(_\sigma 2 + _\pi 2) + _\pi 2]$ Cycloaddition to Homodienes**

By *Rainer Herges* and *Ivar Ugi**



Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Most thermally allowed pericyclic reactions, such as the Diels-Alder reaction, the electrocyclic reactions of hexatrienes, the [1,5] sigmatropic shift, and the Cope rearrangement, proceed via an aromatic six-center transition state.[1, 2] According to our studies using the artificial intelligence program IGOR,[4] one of the twelve possible types of reactions[3] with six carbon atoms as reaction centers that should be realizable, the $[(_\sigma 2 + _\pi 2) + _\pi 2]$ cycloaddition [Reaction (a)], has not been investigated in detail. In fact,

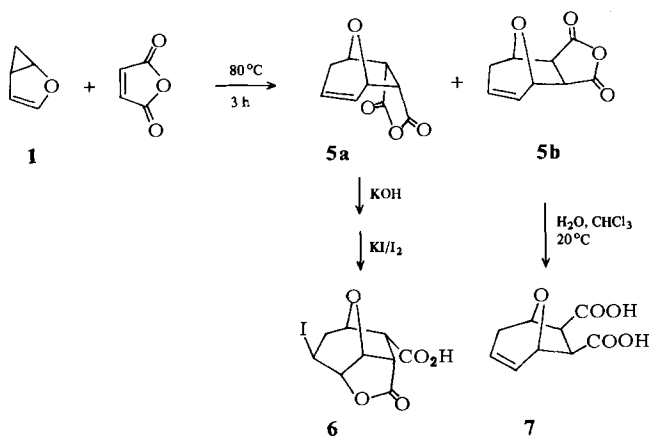
only four examples are known,[5-8] one of which[7] could not be reproduced by other investigators.[9-11] This reaction is related to the Diels-Alder reaction, one of the double bonds of the diene being replaced by a single bond. The most well known analogous reaction is the ene reaction, which, however, has a hydrogen atom as a component of the four centers.

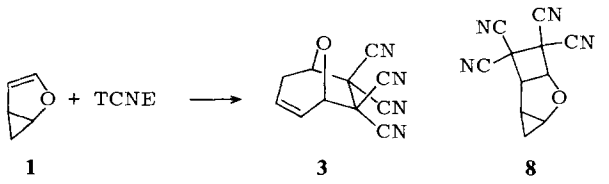
(a)



Homofuran **1** and homothiophene **2**, which are almost as reactive toward dienophiles as furan, have proved to be suitable dienes. They react quantitatively with tetracyanoethylene (TCNE) at 20°C in a few minutes to give the corresponding [3.2.1] bicyclic compounds **3** and **4**, respectively (activation parameters of the reaction of **3**: $\Delta H^{+} = 54.0 \pm 0.81$ kJ/mol, $\Delta S^{+} = 110.9 \pm 1.7$ J mol^{-1} K^{-1}). The course of the reaction can be easily monitored by following the change in the color of the reaction mixture; the initially formed charge-transfer complex is deep red for homofuran and blue for homothiophene.

1, X = O
2, X = S

3, X = O
4, X = S



Homofuran (like furan[12]) reacts with maleic anhydride to give the *endo* and *exo* cycloadducts **5a** and **5b**, respectively, in a ratio of 1 : 1. They can be easily separated after hydrolysis to give **6** and **7**, respectively. The activation parameters, determined by ^{1}H-NMR spectroscopy, are $\Delta H^{+} = 58.6 \pm 3$ kJ/mol and $\Delta S^{+} = -165.3 \pm 37$ J mol^{-1} K^{-1}. Only the *exo* isomer **5b** reacts with water to give the dicarboxylic acid **7**. After hydrolysis and iodolactonization, the *endo* isomer **5a** affords **6**.[13]

1 **5a** **5b**

6 **7**

In polar solvents, homofuran reacts with TCNE not only to give **3**, but also to give the $[\pi 2 + \pi 2]$ cycloadduct **8**. The product ratio is very strongly dependent on the solvent[14] (Scheme 1).

1 **3** **8**

CH_2Cl_2	100	:	0
THF	43	:	57
acetone	37	:	63
acetonitrile	23	:	77

Scheme 1.

Since, to a first approximation, two irreversible parallel reactions are involved, the reaction rates and activation parameters can be determined separately for each reaction. Whereas the activation energy of the $[(\sigma 2 + \pi 2) + \pi 2]$ cycloaddition in very strongly polar acetonitrile is almost identical to that in CH_2Cl_2, the rate of the $[\pi 2 + \pi 2]$ cycloaddition in acetonitrile is just measureable. On going from CH_2Cl_2 to acetonitrile, the rate increases by at least a factor of 1000.

1 + TCNE $\xrightarrow{\text{acetonitrile}}$	**3**	+	**8**
$\Delta H^{+} =$	57.3 ± 0.8		29.3 ± 0.4 kJ/mol
$\Delta S^{+} =$	-110.5 ± 2		-195.0 ± 2 J mol^{-1} K^{-1}

Similar results are obtained for the addition of TCNE to homothiophene. In chloroform, exclusively the [4+2] cycloadduct is formed; in acetonitrile, the [2+2] cycloadduct is formed in 83% yield. In this case, the different yields are also attributable only to the change in the rate of the [2+2] cycloaddition, the [4+2] cycloaddition not being affected by solvent polarity. The activation entropies of the $[(\sigma 2 + \pi 2) + \pi 2]$ cycloaddition of TCNE (-54 J mol^{-1} K^{-1}) and of maleic anhydride (-165 J mol^{-1} K^{-1}) to homofuran are approximately the same order of magnitude as those of other pericyclic bimolecular reactions—e.g., the ene reaction ($\Delta S^{+} = -134$ J mol^{-1} K^{-1}),[15] the Diels-Alder reaction (-146 J mol^{-1} K^{-1}),[16] and the [1,3] dipolar cycloaddition (-105 to -150 J mol^{-1} K^{-1}).[17] The very negative activation entropy supports an ordered transition state and at least does not rule out a concerted mechanism. The small influence of solvent polarity on the reaction rate is also in accordance with a concerted $[(\sigma 2 + \pi 2) + \pi 2]$ cycloaddition. The increase of the activation energy with increasing solvent polarity even renders a mechanism with a polar intermediate unlikely.

Most vinylcyclopropane systems react with strong dienophiles with formation of the [2+2] cycloadduct, rearrangement of the initially formed dipole,[18] or reaction of the dipole with the solvent.[19] In order for the $[(\sigma 2 + \pi 2) + \pi 2]$ cycloaddition to be successful, additional strain in the cyclopropane ring[6,8] or activation of the cyclopropane bond via a heteroatom appears to be necessary.

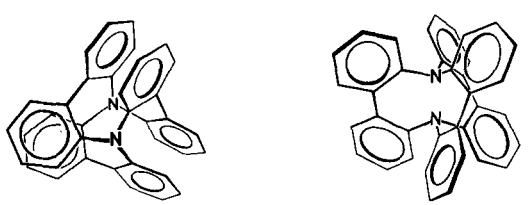
A Triphenylamine Double-Decker**

By *Franz A. Neugebauer** and *Sigrid Kuhnhäuser*

Bicyclic diamines are perfect models for intramolecular n(σ)-electron interactions.[1] We report here on the synthesis and spectroscopic properties of the double layered triphenylamine 9,18-dihydro-9,18-[2,2']biphenylotetrabenzo-[*b,d,g,i*][1,6]diazecine **1**.



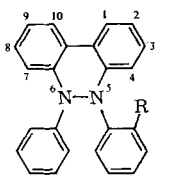


Fig. 1. Conformations of the triphenylamine **1**. Top: planar. Bottom left: out,out. Bottom right: in,in.

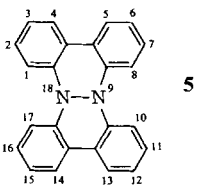
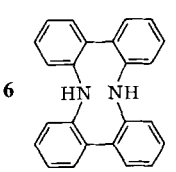


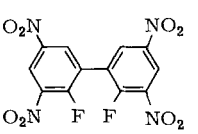
[*] Prof. Dr. F. A. Neugebauer, Dipl.-Chem. S. Kuhnhäuser
Abteilung Organische Chemie,
Max-Planck-Institut für medizinische Forschung
Jahnstrasse 29, D-6900 Heidelberg 1 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Addition of phenyllithium to benzo[*c*]cinnoline and subsequent reaction with 1-fluoro-2-nitrobenzene led to formation of 5,6-dihydro-5-(2-nitrophenyl)-6-phenylbenzo[*c*]-cinnoline **2** (35%, m.p. 241°C), which was converted by catalytic hydrogenation (Raney nickel, 3 equivalents of H_2) into the corresponding amine **3** (84%, m.p. 201–202°C). Diazotization of **3** and subsequent thermal decomposition yielded, surprisingly smoothly, benzo[*c*]benzo[3,4]cinnolino[1,2-*a*]cinnoline **5** (53%, yellow needles, m.p. 194–195°C).[2] Immediate reduction of the diazonium salt of **3** in phosphinic acid[3] afforded 5,6-dihydro-5,6-diphenylbenzo[*c*]cinnoline **4** (80%, m.p. 160–161°C). **4** and **5** are derivatives of tetraphenylhydrazine in which *N,N'*-phenyl residues are coupled at one or both sides in the *o*-position.

2, R = NO_2
3, R = NH_2
4, R = H



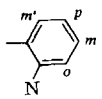


5

The central N–N bond in **5** can be opened by catalytic hydrogenation (Raney nickel, H_2) to give 9,18-dihydrotetrabenzo[*b,d,g,i*][1,6]diazecine **6** (60%, colorless needles, m.p. 268–269°C[4]). **6** is sensitive to oxidation and is dehydrogenated by oxygen in the presence of bases to give, inter alia, the starting compound **5** again.

Twofold reaction of the dilithium compound of **6** with the activated 2,2'-difluorobiphenyl **7** led to formation of the 19,21,24,26-tetranitro derivative of the desired compound **1** [17%, orange crystals, m.p. > 330°C; MS: *m/z* 664 ($M^{\oplus}$, 100%)]. Catalytic hydrogenation (Raney nickel, 12 equivalents of H_2) afforded the corresponding tetraamino compound [MS: *m/z* 544 ($M^{\oplus}$, 100%)], extremely sensitive to oxidation, which was immediately diazotized in phosphinic acid and reduced to **1**[3] [8%, bright pink crystals, m.p. > 330°C; MS: *m/z* 484 ($M^{\oplus}$, 100%), *m/2z* 242 (14%)].[5]

6



7

The proton resonances of **5** lie in the arene region and show typical chemical shifts corresponding to the substitution. In the case of **1** and **6**, on the other hand, upfield shifts of ca. $\Delta\delta = 0.2$–1 ppm are observed for three sets of protons (Table 1). These protons are apparently located within the shielding region of aromatic systems above or below the protons. According to model considerations, the conformation of the inner ten-membered ring of **6** is highly flexible. Of the four phenylene moieties, alternatingly each pair of oppositely situated rings can approach each other, and, as in a [3.3]paracyclophane, eventually lie one above the other. The extreme case of this arrangement is found for all six phenylene rings in the *out,out*-arrangement of **1**, for which considerably larger upfield shifts in

the ^{1}H-NMR spectrum are to be expected than in the case of **6**. Since the chemical shifts of **1** and **6** differ only very slightly, an *out,out*-arrangement is highly improbable in the case of **1**. The alternative *in,in*-form is already highly improbable because of repulsion between the lone electron pairs. The ^{1}H-NMR spectrum is also not reconcilable with such an arrangement, since, as in the case of **5**, the proton resonances should then appear in the usual arene region. The ^{1}H-NMR data of **1** agree best with an almost planar propeller-like arrangement of the phenyl moieties at the nitrogen atoms, as is known in the case of triarylamines.[6] The threefold *o,o'*-coupling of two such oriented triphenylamine moieties would result in a triphenylamine double decker (**1**, planar), with a N···N distance of ca. 2.5 Å.

Table 1. Chemical shifts of the protons in the phenylene segment.

	o	*m*	*p*	*m'*
5	6.77	7.2–7.3	7.2–7.3	7.90
6	6.73	7.01	6.87	7.08
1	6.63	6.79	6.91	6.97

The dication with *m/2z* 242 (14%) is observed in the mass spectrum of **1**. Its constitution can correspond to an *in,in*-arrangement with a N–N σ bond. In comparison to triphenylamine [dioxane, $\lambda_{max_1}=299$ nm ($\lg\varepsilon=4.41$)], **1** shows an electron spectrum shifted markedly to longer wavelength [dioxane, 357 nm (4.21)], which we ascribe to the extended conjugation of the system. **1** is very sensitive to oxidation and immediately forms a deep-violet, extremely persistent radical cation. Studies on its properties and those of the radical cations $\mathbf{4}^{\oplus\ominus}$ and $\mathbf{5}^{\oplus\ominus}$ are currently under way.

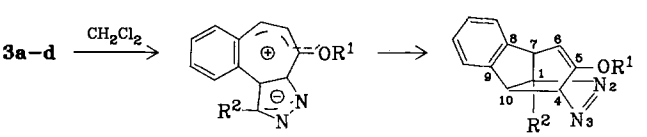
Intramolecular [4+3]-Cycloaddition to 5-Diazomethyl-5*H*-benzocycloheptenes—a Step in a New Benzosemibullvalene Synthesis**

By *Manfred Böhshar, Heinrich Heydt, Gerhard Maas, Helmut Gümbel,* and *Manfred Regitz**

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

The preparative significance of aliphatic diazo compounds lies partly in their ability to undergo [3+2]-cycloaddition.[1] In addition, examples of intramolecular [2+1]-cycloaddition are known in which the terminal nitrogen adds like a nitrene to a CC double bond.[2] The intramolecular [4+3]-cycloaddition of the title compound **3** represents a new type of cycloaddition involving unsaturated diazo compounds; this reaction makes possible a new synthesis of benzosemibullvalenes.

The starting materials are the 7-alkoxy-5-diazomethyl-5*H*-benzocycloheptenes **3a–d**, which are obtained in 35–60% yields via electrophilic diazoalkane substitution[3] of **2a, b** by the 7-alkoxybenzocycloheptenylium perchlorates **1a, b**.[4] Only **3c** (orange oil) and **3d** (yellow crystals, m.p. 78 °C) can be purified via chromatography on silica gel with ethyl acetate; under such conditions, **3a, b** isomerize to **5a, b**.



1 **2** **3**

	R^1	R^2
1a + 2a → 3a	CH_3	$PO(C_6H_5)_2$
1a + 2b → 3b	CH_3	$PO(OCH_3)_2$
1b + 2a → 3c	CH_2–C≡CH	$PO(C_6H_5)_2$
1b + 2b → 3d	CH_2–C≡CH	$PO(OCH_3)_2$

3a–d exhibit strong diazo stretching vibration bands in the IR spectra (KBr or film, $\nu=2070-2090$ cm^{-1}); according to the ^{1}H-NMR spectra of **3a–d**,[5] C-5 of **1** is the reaction center.

The diazo compounds **3a–d** are only stable at −20 °C for longer periods of time. In dichloromethane at 20 °C, they undergo intramolecular [4+3]-cycloaddition of the diazo dipole to the 1,3-butadiene moiety of the seven-membered ring within a few hours (**3a, b**) or days (**3c, d**)

4a–d **5a–d**

[**] In estigations on diazo compounds and azides, Part 64. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 63: T. Allspach, H. Gümbel, M. Regitz, *J. Organomet. Chem.*, in press.

to give quantitatively the azo isomers **5a—d**. Such additions are formally of the [4π+4π]-type, concerted reactions of this kind being thermally not allowed; to the best of our knowledge, they have been unknown up to now.[6]

Even though the solvent has only a modest effect on the rate of cycloaddition [**3d** → **5d**: $k = 3.0 \times 10^{-6}$ (C_6D_6), 1.26×10^{-5} (CD_3CN), 2.1×10^{-5} s^{-1} (CD_3OD), ^{1}H-NMR spectroscopy], we assume that the reaction proceeds in two steps via the betaine **4**, which is stabilized by the donor groups in the cationic part of the molecule and the acceptor groups in the anionic part. In the absence of donor groups (**3**, Br in place of OR^1), the isomerization does not occur.

In the IR spectra of **5a-d**, the diazo vibration of **3a-d** is replaced by the −N=N− absorption (1505—1520 cm^{-1}); in the ^{1}H- and ^{13}C-NMR spectra, only one olefinic hydrogen atom and two olefinic carbon atoms, respectively, can be detected (Table 1). An X-ray structure determination was carried out for **5d** (Fig. 1).[7]

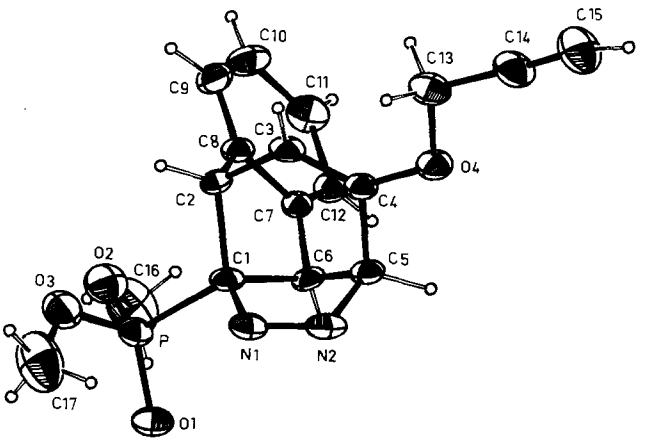

Fig. 1. ORTEP diagram of **5d** [7]. The ellipsoids of vibration correspond to 38% probability.

Table 1. Melting points and characteristic NMR data for the diazatricyclodecatrienes **5a-d**.

[a] 90-MHz spectrum. [b] Signal not resolved. [c] In addition, ^4J(10-H/7-H) ≈ 0.8 Hz; the coupling only causes broadening of the 7-H signal.

When **5a, b** is refluxed in xylene for 10–15 min, N_2 is eliminated and the benzosemibullvalenes **6a, b** (100%) are formed. For **5c, d**, moreover, a hetero-Cope rearrangement takes place in the propargyl enol ether moiety of the molecule; the 4-propadienyl-3,4-dihydrobenzosemibullvalen-3-ones **7a, b** (60 and 85%, respectively) are thereby formed.

The rearrangement can be recognized by the CO (**7a, b**: 1750 and 1730 cm^{-1}, respectively) and allene bands (**7a, b**: 1970 and 1945 cm^{-1}, respectively) in the IR spectra.

6a, $R^2 = PO(C_6H_5)_2$ **7a**, $R^2 = PO(C_6H_5)_2$

6b, $R^2 = PO(OCH_3)_2$ **7b**, $R^2 = PO(OCH_3)_2$

The NMR data of **6** and **7** confirm the structure of the tricyclic systems.[8] The *exo* arrangement of the propadienyl residues in **7a, b** is evidenced indirectly in the finding that 5-H (necessarily in the *exo* position) is not coupled with 4-H (dihedral angle ≈90°).

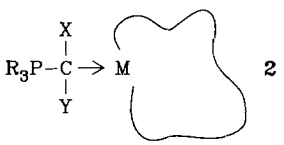
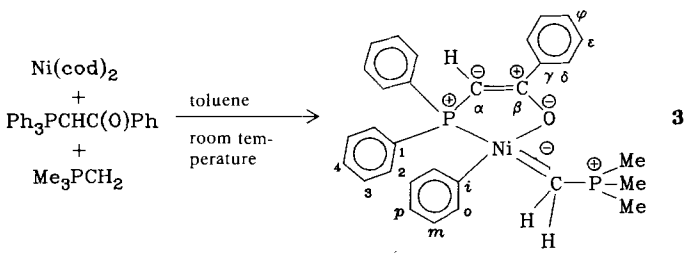
Highly Active Ylide-Nickel Catalysts for the Polymerization of Ethylene



By *K. Alexander Ostoja Starzewski** and *Josef Witte*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Ylides are characterized by extremely low first ionization energies and ylide C-atom ^{13}C-NMR signals that are shifted strongly upfield; this is due to a high-energy occupied MO, usually the HOMO that is strongly localized on the ylide C atom.[1]



1

2

The reaction of the stabilized ylide benzoylmethylenetriphenylphosphorane with Ni(0) in the presence of triphenylphosphane leads to the oligomerization catalyst **1**, which catalyzes the reaction of 6000 moles of ethylene per mole of complex at 50 bar and 50 °C.[2] The ylide ligand is practically no longer present in **1**. Complexes such as **2**,[3,4] in which the ylide ligand remains largely intact, are of interest concerning their properties as polymerization catalysts, but in this respect had not been studied up to now.

3

cod: cyclooctadiene

We have now found that the reaction of bis(cyclooctadiene)nickel(0) with benzoylmethylenetriphenylphosphorane and trimethylmethylenephosphorane in toluene yields a highly active homogeneous catalyst for the polymerization of ethylene. The spectroscopic data for this catalyst are in accord with the structure **3**, which formally arises via oxidative addition of the Ph_3P group of the stabilized ylide and nucleophilic attack of the carbonyl oxygen atom and of Me_3PCH_2 on Ni. The reaction can be followed by ^{31}P-NMR spectroscopy. After a few minutes, a product has formed that exhibits two doublets (J = 7 Hz) in the ^{1}H-decoupled ^{31}P-NMR spectrum (Fig. 1a); the assignment of the signals was made by analyzing the undecoupled spectrum (Fig. 1b). Concentration of the solution affords a yellow solid whose elemental analysis is in accord with the composition of **3**.

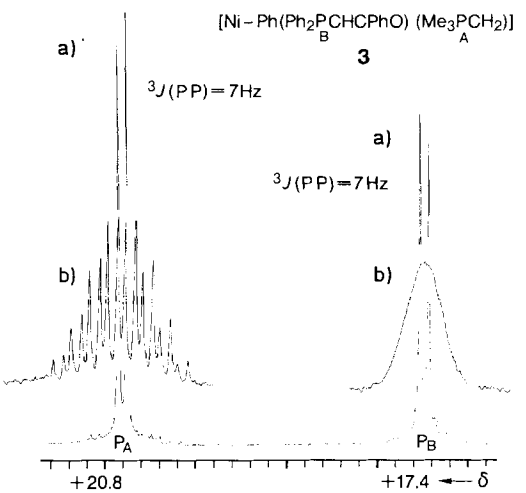


Fig. 1. ^{31}P-NMR spectrum of the ylide complex **3** ([D_6]benzene, room temperature). a) Broad-band ^{1}H-decoupling; b) undecoupled.

3 is stable up to ca. 90 °C in toluene (NMR). Above 130 °C, $M^{\oplus}$ as well as characteristic fragments are observed in the mass spectrum.[5] In the ^{1}H-NMR spectrum of **3**, the resonances of the methylene protons are shifted downfield by nickel complexation (δ = 0.65 in the complex; δ = −0.78 in the free ylide[6]). The double doublet structure (13.1/5.4 Hz)[7] is explained by interaction of the two protons with two different P atoms. The ^2J(PH) coupling in the carbonyl-stabilized ligand is < 0.5 Hz; such small values are typical for free and complexed phosphanes.

The high-resolution room-temperature ^{13}C{^{1}H}-NMR spectrum exhibits sixteen resonances—as expected for **3**—which are partly split due to ^{31}P-^{13}C couplings (Table 1). The Ni-bound ylide C atom is the most strongly shielded C atom of the molecule (δ = 7.2). Noticeable in this case, too, is the double doublet splitting. By comparison with other ylide-metal complexes,[1f,8] the smaller 31-Hz coupling can be assigned to ^1J. We ascribe the 64-Hz coupling to the special *trans* arrangement of ylide and phosphane ligands on square-planar-coordinated nickel. ^1J(CH) (129 Hz, from the undecoupled ^{13}C-NMR spectrum) supports a pyramidalization of the ylide C atom[1d,f,8] due to coordination to the Ni atom. The position of the signals of *o*- and *p*-C atoms on the Ni-bound phenyl group (Table 1) is charac-

teristic for a phenyl group that is bound to an electron-rich center (benzyl Grignard compound,[9] benzylidenephosphorane[11]). C-α is still trigonal planar after complexation according to ^1J(CH) (163 Hz).

The double bond in **3** is strongly polarized. The C-α atom, which bears a partial negative charge, exhibits a signal ($\delta = 78.9$) that is shifted upfield relative to those of "normal" sp^2-hybridized C atoms ($\delta = 128$). The signal of C-β is correspondingly strongly shifted downfield ($\delta =$ 182.5). In comparison, the values for benzoylmethylenetriphenylphosphorane are $\delta = 50$ and 185, respectively.[10]

The ylide complex **3** catalyzes the oligomerization of ethylene at 10 bar and 90 °C with an activity of ca. 0.5×10^5 moles of ethylene per mole of **3**. The polyethylene so formed has a higher molecular weight than that obtained with **1**. We have also synthesized the ylide complexes **4** and examined their ability to catalyze the polymerization of ethylene. We have observed, among other things, the marked effect of substituents on the activity of the catalyst. The activity increases in changing the chelate ligand from formyl to acetyl and finally to benzoyl (**4a**—**c**). The activity of the catalyst can also be influenced by variation of the intact ylide ligand; this is shown by the complexes **4d**—**f**, whose activity increases with decreasing first ionization energy of the ylide (IE_1 of $Me_3PCH_2 = 6.81$, of $Ph_3PCH_2 = 6.62$, of Me_3PCHPh as a model for the ylide ligand in **4f** = 6.19 eV). Accordingly, the metal-ylide bond determines the positions of the highest occupied molecular orbitals, which are metal-d- and metal-C-localized, and thereby the catalyst's (re)activity.

Experimental Procedure

3: Bis(cyclooctadiene)nickel(0) (13.75 g, 50 mmol) in ca. 250 mL of anhydrous N_2-saturated toluene is mixed under inert gas with 19.02 g (50 mmol) of benzoylmethylenetriphenylphosphorane and 4.50 g (50 mmol) of trimethylmethylenephosphorane. A dark yellowish brown solution is formed upon intense stirring and is then heated for ca. 1 h at 40 to 60 °C. After subsequent Schlenk filtration, the solution is evaporated under vacuum to half its volume. Upon cooling to 0 to −20 °C, an initial fraction of yellow crystals forms, which is isolated by Schlenk filtration, washed with hexane, and dried under vacuum. The filtrate is then treated similarly, affording the pure nickel-ylide complex in 90% yield already in the first three crystalline fractions. Impure fractions can be purified by recrystallization, e.g., from toluene/hexane. M.p. = 117—120 °C (decomp.). ^{1}H-NMR (CD_2Cl_2, TMS int.): $\delta = 0.65$ (dd, ^2J(PH) = 13.1, ^3J(PH) = 5.4 Hz, 2 H), 1.56 (d, ^2J(PH) = 13.9 Hz, 9 H), 4.93 (br., ^2J(PH) < 0.5 Hz, 1 H), 6.56—7.83 (m, 20 H).

Polymerization of ethylene with **4f** as catalyst: **4f** (2 mmol) in 250 mL of toluene is injected into an autoclave containing 4 L of toluene at 80 °C under a constant pressure of 10 bar of ethylene parallel to the consumption of ethylene (multipulse injection), air and water being excluded. After ca. 1 h, the autoclave is allowed to cool down, the pressure released, and the solid polyethylene (PE) isolated. In the filtrate, $(C_2H_4)_n$ for n = 2 to ca. 20 can be identified by gas chromatography. The amount of oligomers is determined by solvent evaporation (rotary evaporator), the low-boiling fractions being ignored. The polymer consists of monoolefins having over 90% terminal double bonds and high linearity (ratio $-CH_3/-CH=CH_2 \approx 1$ by IR spectroscopy). Total yield: 1366 g (5% oligomers); catalyst activity: 24393 moles of ethylene converted per mole of nickel; m.p. of the PE ≈ 116 °C; intrinsic viscosity of the PE in tetralin at 120 °C: 0.11 dL/g.

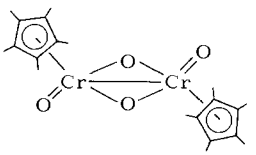
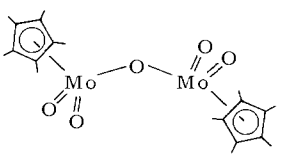
[(η^5-C$_5$Me$_5$)CrO$_2$]$_2$— A Dinuclear Oxo-Complex of Chromium(v)**

By *Max Herberhold,* Walter Kremnitz, Abbas Razavi, H. Schöllhorn,* and *Ulf Thewalt**



The photoinduced oxidation of [Cp*Re(CO)$_3$] to [Cp*ReO$_3$] **8**[1–4] has demonstrated that cyclopentadienyl ligands (η^5-C$_5$H$_5$ (Cp), η^5-C$_5$Me$_5$ (Cp*)) can tolerate both low as well as high oxidation states of a metal. Oxygen attack ought to be favored if the metal in the low oxidation state bears strong acceptor ligands. We have therefore investigated the oxidation of the nitrosyl complexes **1a–c** with oxygen.

On stirring an oxygen-saturated solution of **1a** in toluene (without irradiation), a red dinuclear complex **2**[5] is slowly formed, the structure of which has been elucidated by X-ray crystallography (Fig. 1). In the complex **2**, chromium does not attain its highest possible oxidation number, +6; nevertheless, the formal oxidation state of +5 is two oxidation states higher than in the antiferromagnetic tetranuclear pseudocubane cluster [CpCrO]$_4$,[6–8] prepared by mild oxidation of CrCp$_2$ in organic solvents[6,7] and likewise characterized by an X-ray structure analysis.[7]



In contrast to **1a**, the molybdenum complex **1b** is oxidized by oxygen to a yellow dinuclear complex **3**,[5] which, according to its IR spectrum (ν(Mo=O) 908 and 879 cm^{-1}), contains two *cis*-oriented terminal oxo-ligands per metal atom, i.e. the characteristic unit [Mo$_2$O$_5$]$^{2+}$ with molybdenum in the oxidation state +6. No simple oxo-complex has been isolated from **1c** under comparable conditions.

Table 1 contains characteristic data of the new oxo-complexes **2** and **3** and of some reference compounds. **2** and **3** are diamagnetic. In the ^{13}C-NMR spectrum, the signal of the Cp* ring atoms is shifted by $\Delta\delta \approx 15$ ppm downfield as a result of the oxidation of the nitrosyl complexes **1a** and **b**; the methyl groups, however, are barely influenced. In the IR spectrum, the very strong absorptions of the terminal oxo-ligands appear in the region 850—950 cm^{-1}.

Dinuclear oxo-complexes of chromium(v) were hitherto unknown. On the other hand, some oxo-complexes have been isolated in the oxidation of cyclopentadienylmolybdenum compounds;[9] these include, inter alia, the brown molybdenum(v) complex **4** analogous to **2**,[9,10] and the bright-yellow molybdenum(vi) complex **5** analogous to **3**[9] (Table 1).

An X-ray structure analysis[11] of **2** reveals a centrosymmetric molecule with a planar Cr$_2$O$_2$ four-membered ring, the chromium atoms of which have a distorted tetrahedral environment (Fig. 1). The two Cp*-rings and the two terminal oxo-ligands are each arranged *trans* to each other. In contrast, both in the structurally similar complex **6**[12] as well as in **4**[10] the five-membered rings are in the *cis* posi-

Bis(dihydro-1,2-azaborolyl)tin—a Novel Boron-Nitrogen Stannocene**

By *Günter Schmid,* Dagmar Zaika,* and *Roland Boese*

Dihydro-1,2-azaborolyl ligands provide transition metals with a more diverse range of electronic possibilities than the isoelectronic cyclopentadienyl(Cp) systems. In addition to η^5-coordination, η^4- and η^3-coordination are observed.[1] Corresponding to its electron configuration, the metal seeks stronger contact to the acceptor atom boron, to the donor atom nitrogen, to the C_3 allyl moiety, or equally to all five ring atoms. Interestingly, in the stannocenes that have been synthesized and structurally investigated in the last few years, relatively marked deviations from the η^5 arrangement of the Cp ligands have been found. Moreover, the Cp rings are usually not coplanar but rather are at an angle with respect to each other.

With the synthesis of bis(1-*tert*-butyl-2,3-dimethyldihydro-1,2-azaborolyl)tin **1**, we have succeeded for the first time in binding a main group metal to a dihydro-1,2-azaborolyl ligand (apart from Li in 1-*tert*-butyl-2,3-dimethyl-

[**] Azaborolinyl Complexes, Part 19. This work was supported by the Fonds der Chemischen Industrie. Comment on the nomenclature: the traditional name "azaborolinyl" has been replaced by "dihydroazaborolyl" according to IUPAC rule RB-1.2 (*Pure Appl. Chem. 55* (1983) 409).—Part 18: G. Schmid, G. Barbenheim, R. Boese, *Z. Naturforsch. B*, in press.

dihydro-1,2-azaborolyl, **2**). **1** has enabled us to study the behavior of the metal with respect to its preferred coordination site and to make comparisons with stannocenes.

The reaction of **2** with $SnCl_2$ at $-45°C$ in tetrahydrofuran (THF) afforded orange-yellow **1** in 49% yield; **1** decomposes above $-20°C$ with formation of tin.[2] The molecular structure of the BN/NB isomer[3] (Fig. 1) shows

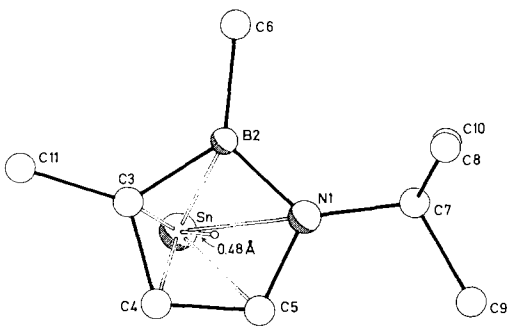

Fig. 1. Crystal structure of **1**. Selected bond lengths [Å]: Sn–C3 2.489(9), Sn–C4 2.592(10), Sn–B2 2.742(10), Sn–C5 2.810(10), Sn–N1 2.917(9), N1–B2 1.480(7), B2–C3 1.511(7), C3–C4 1.422(6), C4–C5 1.377(8), N1–C5 1.399(4).

planar rings lying at an angle with respect to each other and thus resembles most of the stannocenes studied so far.[4–7] Only in the sterically highly hindered $[(Ph_5C_5)_2Sn]$ are the rings arranged in a coplanar fashion.[8] The molecule exhibits C_2 symmetry, which is due to the crystallographic axis in $0/Y/0.25$.

The angle of aperture between the two rings in **1** is 46.5°, thus lying between the corresponding angles in stannocene (55°)[4] and decamethylstannocene (36°).[5] According to MO calculations, the angled structure is energetically favorable (energy minimum at 60°) compared with the coplanar geometry.[5] Figure 2 shows the displacement

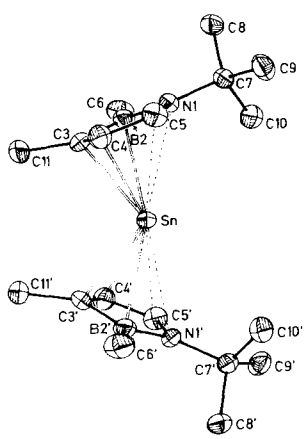

Fig. 2. Displacement of the tin atom from the ring center in **1**.

of tin from the center of the ring by 0.48 Å in the direction of the atoms C3 and C4. Accordingly, the Sn–C5 and Sn–N1 distances, 2.810 and 2.917 Å, respectively, are unusually long. This observation is in accord with the bonding relationships in stannocenes or stannocene-like complexes, in which marked differences in the Sn–C bond angles also exist: 2.56–2.85 Å in **3**,[4] 2.59–2.74 Å in **4**,[5] or 2.53–2.81 Å in **5**.[6] In the boron-containing complexes **6**[9] and **7**[10] the tin atoms are clearly displaced from the center of the ring in the direction of the boron atoms.

$[(C_5H_5)_2Sn]$ **3** $[(C_5Me_5)_2Sn]$ **4** $[\{C_5H_4(iPr_2N)\}_2Sn]$ **5**

$[\{CpCo(C_3B_2R_5)\}_2Sn]$ **6** $[(C_2Me_2B_9H_9)SnL]$ **7**

Whereas metal-boron bonds in transition-metal complexes result in upfield shifts of the ^{11}B-NMR signals compared with those in the free ligands, a shift downfield from $\delta = 24.5$ (in **2**) to $\delta = 31.5$ is observed for **1**. This is due to the reduced ability of main group metals to engage in back-bonding because of a lack of available d electrons.

As is the case for the dihydro-1,2-azaborolyl complexes with transition metals, the two expected diastereomers of **1** can be observed by ^{1}H-NMR spectroscopy; their formation is due to the prochiral character of the rings. The proton signals of the diastereomers have an intensity ratio of ca. 10:1. It is not yet known whether the enrichment of one of the forms occurs only during the course of the work-up, or, instead, whether one isomer is already formed preferentially during the formation of the complexes. In the case of the transition-metal complexes, an isomer ratio of ca. 1:1 is usually found. Possibly, the special bonding and structure relationships play a role in the example discussed here. The ^{1}H-NMR signals lie in the expected ranges, the ring protons H4 and H5 each appearing as a doublet due to the mutual coupling.

[2] Experimental procedure: 1-*tert*-Butyl-2,3-dimethyl-1*H*-2,3-dihydro-1,2-azaborole **8**: 1-*tert*-butyl-2-methyl-1*H*-2,3-dihydro-1,2-azaborolyllithium (8.55 g, 59.8 mmol) [11] was dissolved in 90 mL of THF and treated dropwise at $-50°C$ with a solution of iodomethane (8.49 g, 59.8 mmol) in pentane. The solution was warmed slowly to room temperature and stirred for 1 h. LiI was separated by suction filtration through a sintered-glass filter. Distillation at 163–165°C afforded 6.86 g (75.9%) of colorless **8**. ^{1}H NMR (200 MHz, [D$_6$]benzene): $\delta = 0.69$ (s, 3H, BCH_3), 1.15 (d, $J \approx 7$–8 Hz, 3H, CCH_3), 1.16 (s, 9H, $C(CH_3)_3$), 1.78 (m, 1H, H3), 5.41 (dd, $J = 4$ Hz, $J = 2$ Hz, 1H, H4), 6.47 (dd, $J = 4$ Hz, $J = 2$ Hz, 1H, H5); ^{11}B NMR (200 MHz, [D$_6$]benzene): $\delta \approx 50.8 \pm 1$; ^{13}C{^{1}H} NMR (200 MHz, [D$_6$]benzene): $\delta = 0.8$ (br. s, BCH_3), 13.01 (s, CCH_3), 31.35 (s, $C(CH_3)_3$), 35.6 (br. s, C3), 53.52 (s, $C(CH_3)_3$), 118.21 (s, C4), 136.4 (s, C5). Correct C–H–N analysis. **2**: Similarly to the synthesis of other dihydroazaborolyllithium salts from lithium tetramethylpiperidide and **8** [11]. Yield: 76.0%. ^{1}H NMR (200 MHz, [D$_8$]THF): $\delta = 0.47$ (s, 3H, BCH_3), 1.34 (s, 9H, $C(CH_3)_3$), 1.82 (s, 3H, CCH_3), 5.54 (d, $J = 2.7$ Hz, 1H, H4), 5.73 (d, $J = 2.7$ Hz, 1H, H5); ^{11}B NMR (200 MHz, [D$_8$]THF): $\delta = 24.5 \pm 1$; ^{13}C{^{1}H} NMR (200 MHz, [D$_8$]THF): $\delta = 0.6$ (br. s, BCH_3), 15.25 (s, CCH_3), 32.56 (s, $C(CH_3)_3$), 53.64 (s, $C(CH_3)_3$), 103.28 (s, C4), 113.31 (s, C5). The signal for C3 cannot be observed due to the neighboring boron atom. Correct C–H–N–Li analysis. **1**: Anhydrous $SnCl_2$ (0.74 g, 3.9 mmol) in 25 mL of THF was slowly added dropwise to a solution of **2** (1.23 g, 7.8 mmol). After 1 h, the solvent was removed without heating. The residue was treated with 20 mL of cold pentane. Filtration through a sintered-glass filter cooled with dry ice afforded an orange-yellow solution. The solvent was removed at $-20°C$. Repeated washing with pentane at $-20°C$ and subsequent drying in vacuum yielded 0.79 g (48.6%) of analytically pure **1** as a mixture of diastereomers, which was stored at $-78°C$. According to the ^{1}H NMR spectrum, the sample contains both diastereomers in a ratio of 10 (**a**):1 (**b**). Assignment of **a** and **b** to the BN/BN- or BN/NB isomer was not achieved since a preparative separation was not possible. ^{1}H NMR (200 MHz, [D$_8$]toluene, $-40°C$): δ = (**a**) 1.02, (**b**) covered by $C(CH_3)_3$, (s, 6H, BCH_3), 1.10 (1.16) (s, 18H, $C(CH_3)_3$), 2.28 (2.42) (s, 6H, CCH_3), 5.39 (5.52) (d, $J = 3$ Hz, 2H, H4), 6.80 (6.70) (d, $J = 3$ Hz, 2H, H5); ^{11}B NMR

(200 MHz, [D$_8$]toluene, -40°C): $\delta = 31.5 \pm 1$ (**a** = **b**); ^{13}C{^{1}H} NMR (200 MHz, [D$_8$]toluene, -40°C): δ = (**a**) 13.41 (s, CCH_3), 31.22 (s, $C(CH_3)$), 54.22 (s, $C(CH_3)_3$), 103.89 (s, C4), 117.94 (s, C5). The signals for C3 and C6 cannot be observed due to their position next to the boron atom. Owing to the poor signal-to-noise ratio, the ^{13}C-NMR signals of **b** can no longer be observed. Correct C–H–N–Sn analysis.

[3] In the BN/NB isomer, the same sides of the rings are coordinated to tin; in the BN/BN isomer, different sides. BN/NB **1** (-120°C): from pentane at low temperature: C2/c; $Z = 4$; $a = 20.972(4)$, $b = 9.266(2)$, $c = 18.137(5)$ Å; $\beta = 144.01(1)$°; $V = 2071.2(9)$ Å^3; $\rho_{calcd.} = 1.34$ g/cm^3; $3° \leq 2\theta \leq 60°$ ($Mo_{K\alpha}$, $\lambda = 0.71069$ Å, graphite monochromator), $\mu = 12.4$ cm^{-1}; 2469 independent intensities, 2320 with $F \geq 3.5\sigma(F)$. Structure solution using Patterson and difference Fourier methods, refinement according to the block cascade method with SHELXTL. The hydrogen atoms of the CH_3 groups were refined as "riding groups" and the ring hydrogen atoms were obtained from a difference Fourier synthesis and refined to $R = 0.066$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51413, the names of the authors, and the journal citation.

Z-[(η^5-C_5H_5)(CO)$_2$Fe–P=C(OSiMe$_3$)(*t*Bu)], a Phosphaalkenyl-Complex with FeP Single Bond**

By *Lothar Weber,* Klaus Reizig, Roland Boese,* and *Michael Polk*

Multiple-bond systems with elements of higher periods ($n \geq 3$) are of current interest, not only from the preparative and the theoretical point of view,[1] but also with regard to the ligand properties of compounds containing such structural units.[1e,2] Thus, for example, η^1- and η^2-complexes of phosphaalkenes and phosphaalkynes have recently been the subject of intensive studies; phosphaalkenes can be terminal or bridging ligands.[3] All phosphaalkene complexes reported so far contain an intact $R^1P{=}CR^2R^3$ structural unit.

In principle, it should be possible to replace the R^1, R^2 and R^3 groups of a phosphaalkene by transition metal-complex fragments to give complexes of the type **A**—**E**.

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

We recently reported the synthesis and structure of rhenium complexes of type **B**,[4] while *Cowley* et al. have described the first phosphavinylidene complex **4**.[5] In this communication we present for the first time a phosphaalkenyl complex of iron, which represents a complex of type **A**.

The synthetic strategy chosen here is an extension of that developed by *Becker* for the synthesis of phosphaalkenes from disilylphosphanes and pivoloyl chloride[6] to the disilylphosphidoiron complex **1**.[7] The complex **1** reacts with pivaloyl chloride to give the brown title compound **3**.[8] No intermediate, such as, e.g., **2**, could be detected in the reaction between -70°C and 22°C by ^{31}P-NMR spectroscopy.

2

$$[(\eta^5\text{-}C_5H_5)(CO)_2FeP{=}C(OSiMe_3)(t\text{Bu})]$$

3

$$[(\eta^5\text{-}C_5H_5)(CO)_2Mo{=}P{=}C(SiMe_3)_2]$$

4

The constitution and configuration of the isolated complex **3** were confirmed by elemental analysis and spectroscopic methods.[8] The Fe(CO)$_2$-group gives rise to two intense ν(CO) bands in the IR spectrum. The characteristic downfield shifts of the resonances of the (C=P) unit and the M^+ ion in the mass spectrum are reconcilable with the monomeric structure of the complex. The configuration at the P=C bond was ascertained by analysis of the ^{1}H- and ^{13}C-NMR spectra. The protons of the Me_3SiO unit gave rise to a singlet at $\delta = 0.44$, while the resonances of the *tert*-butyl protons appear as a doublet due to coupling with the phosphorus atom. The doublet at $\delta = 4.15$ is assigned to the

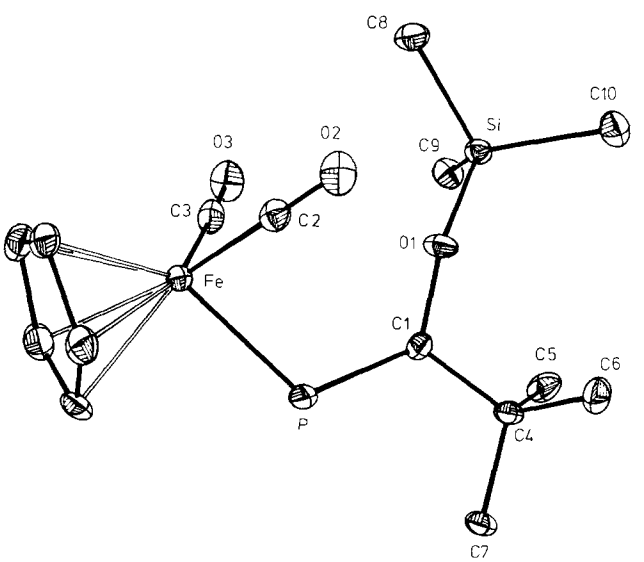

Fig. 1. Crystal structure of **3**. Selected bond lengths [pm] and angles [°]: Fe–P 229.8(1), P–Cl 170.1(4), Cl–O1 136.5(5), Cl–C4 152.9(6), Fe–C2 175.3(5), Fe–C3 178.3(5), C2–O2 115.1(6), C3–O3 110.8(7), Fe–C(ring) 211.2(3) to 211.9(3). C2–Fe–P 86.2(1), P–Fe–C3 88.8(2), C2–Fe–C3 96.5(2), Fe–P–Cl 113.8(2), P–Cl–O1 123.9(3), P–C1–C4 120.5(3), O1–C1–C4 115.3(4), C1–O1–Si 144.7(3).

cyclopentadienyl ligand. On the basis of reference data,[9] and the fact that couplings to moieties which are oriented in the eclipsed position with respect to the free electron pair of the phosphorus atom are larger, a *Z*-configuration must be assumed for **3**. This finding is confirmed by the X-ray structure analysis of **3** at −162°C (Fig. 1).[10] The P=C bond length (170.1(4) pm) lies in the range (168 to 172 pm) characteristic for phosphaalkenes.[11] The iron atom lies in a plane with the atoms P, C1 and O1 and is linked to the phosphorus via a single bond (229.8(1) pm). The C1–O1 distance (136.5(5) pm) is markedly shorter than the length calculated for a C(sp^2)O single bond (141 pm).[12] The angle at the phosphorus is 113.8(2)°, while that at O1 is considerably widened (144.7(3)°). Complex **3** differs from the phosphavinyl complex **4** in that the lone pair on the phosphorus is not required for electronic saturation of the metal; hence, **3** can be regarded as a transition metal-substituted phosphaalkene or as an η^1(Fe–P)-phosphaalkenyl complex.

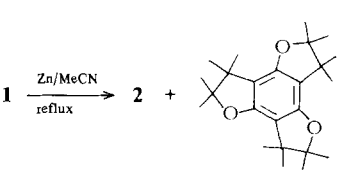
Novel Carbonylcyclopropane Dimers and Trimers—Free Ketenes or Organometallic Intermediates?**

By *Jan-Michael Wulff* and *H. M. R. Hoffmann**

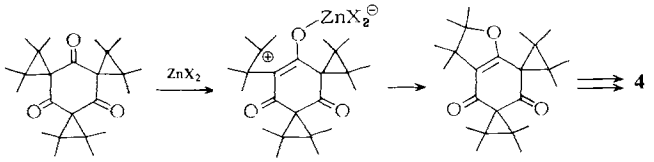


We have previously reported on the preparation of dispiro[2.1.2.1]octane-4,8-diones via dehalogenation of 1-bromocyclopropanecarbonyl chlorides with zinc in tetrahydrofuran (THF), e.g. **1** → **2**.[1]

We have now investigated other 1-bromocyclopropanecarbonyl chlorides and also expanded the experimental conditions for dehalogenation, by using magnesium in addition to zinc as a reducing agent and acetonitrile in addition to tetrahydrofuran as a solvent.

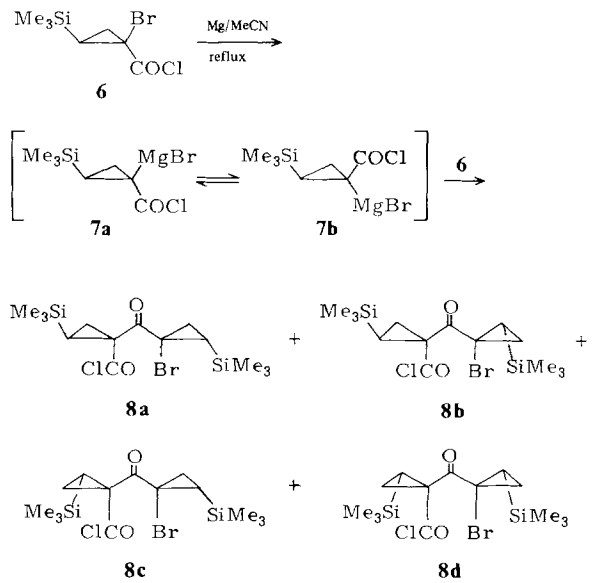
For example, when magnesium was added to **1** in THF and the reaction solution was scanned by IR after 5 min, the band of the acid chloride **1** (1780 cm^{-1}) and that of **2** (1708 cm^{-1}) were visible in a ratio of 1:1 in addition to a new absorption at 2115 cm^{-1}, which we assign to the cumulated system of double bonds of the free carbonylcyclopropane **3**.[2] This band had an intensity of ca. 10% with respect to the dominating acid chloride band and had disappeared after ca. 10 min. Hence, permethylated **3** has a considerably longer lifetime than parent carbonylcyclopropane, which stays monomeric at liquid nitrogen temperatures only.[3] Magnesium and THF are also optimum for preparing the cyclic dimer **2** (70–75% isolated yield) from **1**.

With zinc as metal and absolute acetonitrile as solvent not only **2** was formed, but also dodecamethylhexahydrobenzo[1,2-*b*:3,4-*b'*:5,6-*b''*]trifuran **4** (**2**:**4** = 77:23; 56% combined yield).[4]



A rational precursor of **4** is the novel trispiro compound **5a**, which, on contact with the zinc halide generated, will

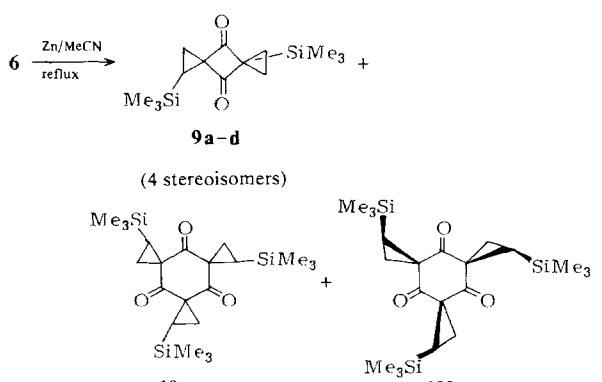
[*] Prof. H. M. R. Hoffmann, Dr. J.-M. Wulff
Institut für Organische Chemie der Universität
Schneiderberg 1B, D-3000 Hannover (FRG)



[**] We thank the Fonds der Chemischen Industrie for support of this work.

first form the tertiary homoallylic cation **5b** and eventually the arene **4**.

5a **5b** **5c**



Since 1,3,5-trihydroxybenzene (phloroglucinol) is known to exhibit ketonic properties, we felt that trispirotriketones other than the hypothetical permethylated **5a** might actually be isolable. Surprisingly, dehalogenation of **6**[4] with magnesium in acetonitrile gave the β-ketoacid chlorides **8a–d** as a mixture of four stereoisomers. Dimers of the dispiro[2.1.2.1]octane-4,8-dione type (cf. **9a–d**) were formed only in traces (GC). Attempts to cyclize **8** to **9** with zinc in THF and acetonitrile remained unsuccessful.

6 **7a** **7b** **8a** **8b** **8c** **8d**

However, dehalogenation of **6** with zinc in boiling acetonitrile gave four stereoisomeric dimers, **9a–d**,[5] and two stereoisomeric trimers, **10a**, **b** (60% combined yield; **9** : **10** = 88 : 12; **10a** : **10b** = 2 : 1). After sublimation of the dimers **9a–d** the remaining trimer fraction was separated by chromatography (basic Al_2O_3, pentane/ether = 10 : 1).

The cyclic trimer, formed in only small amounts, could be identified clearly as **10b** by virtue of its C_3 axis. In the 90-MHz and 270-MHz ^{1}H-NMR spectra **10b** showed only *one* Me_3Si signal at $\delta = 0.09$ and only *one* ABM system.[4]

9a–d

(4 stereoisomers)

10a **10b**

The major trimer **10a**[4] had an IR spectrum identical to that of **10b**, showing, inter alia, a carbonyl band at 1670 cm^{-1}.

While there can be little doubt that free carbonylcyclopropanes occur on reaction with magnesium in tetrahydrofuran (cf. **3**), the formation of coupling products such as **8a–d** in acetonitrile is in better agreement with organometallic intermediates such as 1-chloroformylcyclopropyl Grignard compounds **7a**, **b**. Similarly, since the formation of cyclic trimers of the 1,3,5-cyclohexanetrione type (cf. **10a**, **b**) is unknown in conventional ketene chemistry[6] we propose that a corresponding organozinc intermediate is involved in the cyclotrimerization. The hypothetical 1-chloroformylcyclopropylmetal compounds should be both nucleophilic and electrophilic and thus enter into multiple coupling, including polymerization. Their finite existence can be ascribed to several factors, including covalency of the cyclopropylmetal bond, solvation—or lack thereof—of the metal atom and impeded enolate resonance due to developing methylenecyclopropane and carbonylcyclopropane strain.

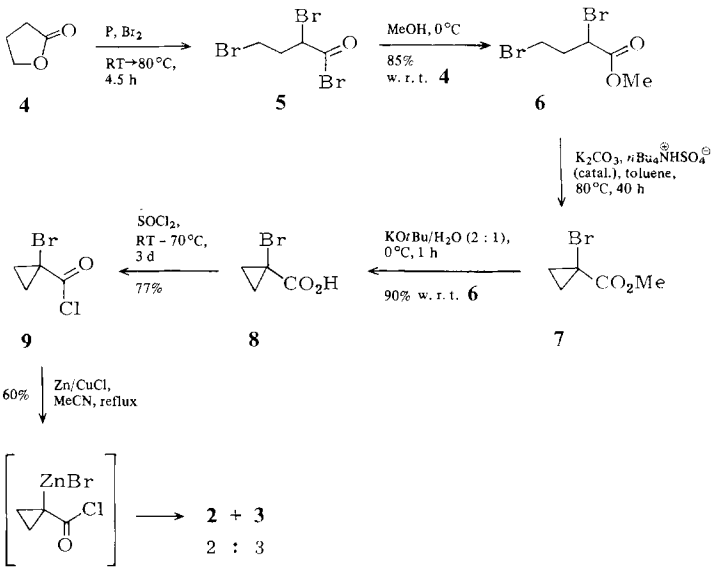
Trispiro[2.1.2.1.2.1]dodecane-4,8,12-trione**

By *H. M. R. Hoffmann,* Angela Walenta, Ulrike Eggert,* and *Dietmar Schomburg*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

The title compound, **2**, is a new, simple, and potentially highly symmetric D_{3h} molecule which merits preparative and theoretical interest. We have confirmed that *free* carbonylcyclopropane, **1b**, which was generated by flash vapor thermolysis (FVT) from **1a** as described by *Brown* et al.,[1] cyclodimerizes to the dispirodiketone **3**.[1] There was no evidence for the formation of **2**.[2a] Similarly, attempts to prepare **2** by treatment of **3** with bases[3] remained unsuccessful.



We have suggested that the novel formation of substituted 1,3,5-cyclohexanetriones from potential ketene precursors does not involve traditional ketenes, but rather organometallic intermediates, presumably 1-chloroformylcyclopropylzinc compounds.[2b] Accordingly, an attempt at the direct dehalogenative cyclotrimerization of 1-bromocyclopropanecarbonyl chloride, **9**, was of interest.

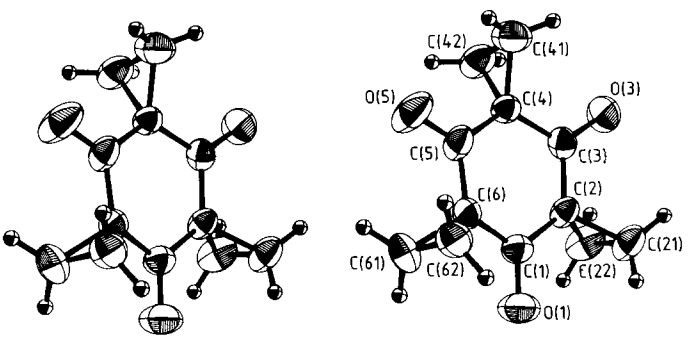
The preparation of 1-bromocyclopropanecarboxylic acid, **8**, by α-bromination of cyclopropanecarboxylic acid was not promising.[4] However, **8** could be synthesized readily from γ-butyrolactone, **4**. All the steps in Scheme 1 are simple and give high yields. Typically, 1-bromocyclopropanecarboxylic acid, **8**,[5a] (m.p. 78—80°C) and **9** (b.p. 80°C/~15 torr) were obtained in batches of 83 g and 60 g, respectively.

Earlier, dehalogenation of derivatives of **9** with zinc or magnesium in tetrahydrofuran under a wide variety of experimental conditions gave at best traces (<1%, GC) of cyclic trimer.[2b] However, dehalogenation with zinc-copper couple in dry, boiling acetonitrile furnished **2** and **3** in 61% yield (molar ratio 2:3): 1.9 g of **2** (m.p. 143—145°C) and 1.9 g of **3** after liquid-liquid extraction of the acetonitrile mother liquor with pentane.[6,7] The more lipophilic compound **2** was readily soluble in $CHCl_3$, whereas **3** was more polar and could be separated, e.g. by sublimation.

Our procedure for preparing trispirotriketone **2** is simple and efficient. Similarly to **2**, dione **3** is easily accessible in multigram quantities.

Scheme 1.

The X-ray crystal structure of **2**[8] shows that the presence of the trispirocyclopropane system necessitates a drastic flattening of the six-membered ring, as can be seen clearly from the six ring torsion angles (−10.9, 14.0, −5.0, −7.3, 10.4, −1.1°) and their absolute sum of 48.7°.



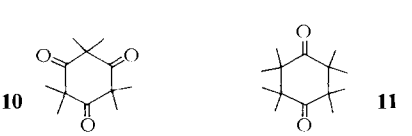


Fig. 1. Stereoview of **2**. Selected mean bond lengths [pm] and angles [°], ranges in brackets: C–C (internal) 147.5 (146.9—148.2), C–C (cyclopropyl, vicinal) 153.2 (151.1—154.4), C–C (cyclopropyl, distal) 144.6 (143.7—145.1), C–O 121.5 (121.4—121.8), C–H 92—99; C–C(O)–C 118.6 (118.4—118.9), C(O)–C–C(O) 120.7 (120.4—120.9), $C(H_2)$–C–$C(H_2)$ 56.3 (56.3—56.4), standard deviations for bond lengths are between 0.2 and 0.4 pm, for bond angles 0.2°.

By comparison, triketone **10** and diketone **11** have completely different geometries. In boat-like **10** the six ring torsion angles sum to 192°[9] and in chair-like **11** to 272.5°.[10] Note also that the six ring torsion angles in cyclohexane, which is slightly flattened, sum to 336°[11] compared with a value of 6 × 60° = 360° for "ideal" cyclohexane. Furthermore, the largest deviation from the least-squares plane of the six-membered ring in **2** is 8.6 pm; O(5) lies practically in the plane, whereas O(1) and O(3) are only 14 and 26 pm below and above the plane, respec-

tively. The six internal angles are all within $119.7 \pm 1.2°$ and sum up to 718.1°, compared to 120° and 720° in benzene. Hence the six electrons of the C(21)–C(22), C(41)–C(42), and C(61)–C(62) cyclopropane backbone are well placed for a circumannular, conjugative interaction via the three carbonyl groups.

In this respect it should be mentioned that the distal cyclopropane bonds in **2** (mean value 144.6 pm) belong to the shortest single bonds so far found in cyclopropane ring systems.[12] These bonds, if shortened by interaction with an electron acceptor are usually in the range 145–150 pm, whereas the mean bond length in cyclopropane derivatives, calculated from 115 examples is 150.9(2) pm.[12] The bond lengths in the six-membered ring of trispirotriketone **2** are also very short when compared to the standard C–C bond length of 154 pm or the comparable mean internal C–C length of 152.1 pm in **10**.

[7] *Experimental procedure:* A solution of **9** (17.5 g, 95 mmol) in absolute acetonitrile (25 mL) was added dropwise to a suspension of zinc (18.7 g, 0.29 mol) and copper(I) chloride (0.28 g, 2.9 mmol) in acetonitrile (25 mL), previously warmed to 40°C. During addition of **9** the reaction mixture was allowed to reflux. The mixture was refluxed for a further 30 min, allowed to reach room temperature and the products were extracted with pentane. Column filtration (silica gel, pentane) furnished white crystals (3.9 g, 61%) of **2** + **3** (molar ratio **2** : **3** = 2 : 3 by ^{1}H-NMR). The bulk of **3** was removed by sublimation, leaving **2** which was purified by chromatography on silica gel. Spectroscopic data of **2**: IR (KBr): 3120 (w), 3020 (w) (cyclopropane C–H), 1668 (s) (C=O), 1358 (s), 1110 (s) cm^{-1}. ^{1}H-NMR ($CDCl_3$): $\delta = 1.98$ (s). ^{13}C-NMR ($CDCl_3$): $\delta = 29.26$ ($6CH_2$), 40.68 (3 spiro C), 202.22 (3 C=O); $^1J_{C,H} = 169$ Hz.

[8] *X-ray structure analysis:* $P2_1/c$, $a = 8.550(2)$, $b = 15.665(6)$, $c = 8.408(2)$ Å, $\beta = 118.49(3)°$, $\rho_{calc} = 1.370$ g cm^{-3}, 1355 observed of 1746 independent reflections [$I \geq 1.25\sigma(I)$], $R = 0.048$, Syntex-$P2_1$-diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $2\theta_{max} = 50°$. First 1,4-Dipolar Cycloadditions of 6-Oxo-3,6-dihydro-1-pyrimidinium 4-Olates to Ketenes and Other Carbonyl Compounds**

By *Hans Gotthardt** and *Karl-Heinz Schenk*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

6-Oxo-3,6-dihydro-1-pyrimidinium 4-olates of type **3** are capable of undergoing [4 + 2]-cycloadditions to certain CC-multiple bond systems,[1] and even to singlet oxygen;[2] such additions have opened up interesting entries to pyridone derivatives and heterobicycles. In contrast, analogous [4 + 2]-cycloadditions of **3** to CO double bonds have so far never been described. We report here on an improved synthesis of **3** and on the first 1,4-dipolar cycloadditions of **3** to ketenes, formaldehyde, hexafluoroacetone, and mesoxalates. These reactions lead to the formation of novel stable primary adducts in high yields.

The synthesis of compounds **3a**, **b**[3] unsubstituted in position 5 has hitherto only been accomplished by reaction of the amidines **2** with carbon suboxide. The preparation of carbon suboxide from malonic acid, however, is somewhat expensive and yields of only 10–20% are obtained.[4] More advantageous is the synthesis of **3a**, **b** via modification of the known method[5] of heating a dry equimolar mixture of **2** and bis(2,4,6-trichlorophenyl) malonate **1** to 140–170°C/< 0.01 torr, whereby the liberated 2,4,6-trichlorophenol is immediately distilled off from the melt. Recrystallization of the melt from ethanol affords **3a** or **3b**. The new compounds **3c–e** (Table 1) and **7**[6] are obtained analogously from **2** or **6**, respectively, and bis(2,4,6-trichlorophenyl) methylmalonate **1**.

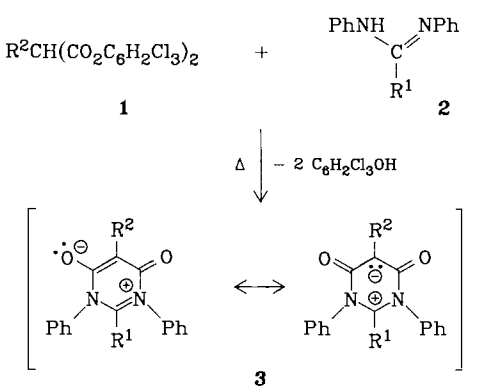

Table 1. 6-Oxo-1,3-diphenyl-3,6-dihydro-1-pyrimidinium 4-olates **3** from bis(2,4,6-trichlorophenyl) malonates **1** and *N,N'*-diphenylamidines **2**.

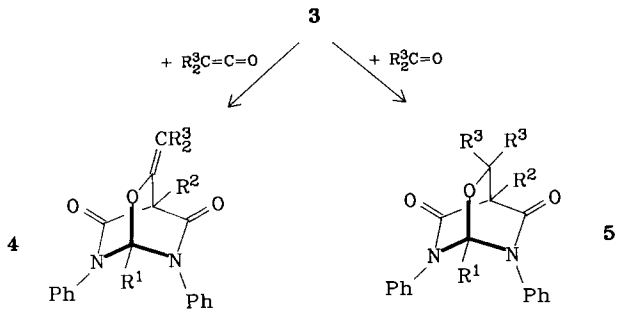
When **3a** is allowed to react with diphenylketene (molar ratio 1 : 1.27) in acetonitrile at 20°C, colorless needles of **4a** crystallize out whose structure and composition are consistent with the elemental analysis and spectroscopic data.[7] The mode of addition of the ketene in **4a** follows quite clearly from the ^{13}C-NMR spectrum, which shows the resonances of C-1 and C-4 at $\delta = 101.11$ and 58.24, respectively. The opposite mode of addition would lead to bonding of the oxygen with the unsubstituted C-atom, and the ^{13}C-resonance would then be shifted downfield to $\delta = 84.80$.[2] In an analogous way, **3b** and diphenyl ketene or dimethyl ketene afford, after crystallization from ethyl acetate/hexane, **4b** and **4c**,[7] respectively (Table 2).



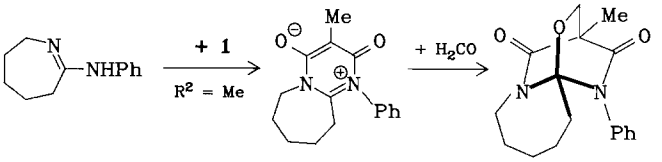


Table 2. 6,7-Diphenyl-2-oxa-6,7-diazabicyclo[2.2.2]octane-5,8-diones **4** and **5** as primary adducts from **3** and carbonyl compounds.

	R^1	R^2	R^3	Yield [%]	M.p. [°C]

5f	Ph	Me	CO_2Et	74	149.5—150 [a]

[a] Decomposition. [b] On heating, decomposes into hexafluoroacetone and **3b**, recognized by its melting point.

The solvent has very little influence on the rate constant k_2 of the cycloaddition of **3a** to diphenyl ketene; k_2 shows an inverse dependence on the solvent polarity, as indicated by the ratio k_2(dioxane)/k_2(acetonitrile) = 2.5. This suggests a diminution in charge in the transition state and is consistent with a concerted mechanism. Analogous inverse solvent dependencies of the same order of magnitude have also been observed in the [3 + 2]-cycloadditions of the sydnones to alkynes,[8] whereas the k_2 values in the multistep [2 + 2]-cycloadditions of tetracyanoethene, which proceed via dipolar intermediates, increase with increasing solvent polarity by factors of up to 63 000.[9]

The 1,4-dipolar cycloadditions of **3a**, **b** to the CO-double bond of ketenes are remarkable, since reaction of ketenes with 1,3-dienes usually yields cyclobutanone derivatives according to a [$_\pi$2$_s$ + $_\pi$2$_a$] process, with the CC double bond of the ketene functioning as antarafacial component.[10, 11] Since the concerted [4 + 2]-cycloadditions of 1,3-dienes to the ketene CC double bond are thermally forbidden as a [$_\pi$4$_s$ + $_\pi$2$_a$] process according to the rules of conservation of orbital symmetry,[11] ketenes apparently do not react with the CC double bond, but specifically and regioselectively with the CO double bond of **3a**, **b** in the sense of a thermally allowed [$_\pi$4$_s$ + $_\pi$2$_s$]-cycloaddition to give the sterically more demanding adducts **4a–c**.

6 **7** **8**

Even formaldehyde—generated in situ from paraformaldehyde by depolymerization at 110°C—reacts with **3b–d** or **7** regiospecifically to give the adducts **5a–c** and **8**,[12] while hexafluoroacetone already combines with **3d** at 0°C to give **5d**.[13] Furthermore, diethyl mesoxalate cycloadds to **3c**, **e** at 110°C with formation of **5e**, **f**.[14] The uniform regiochemistry in the adducts **5** follows from the ^{13}C-NMR spectra.

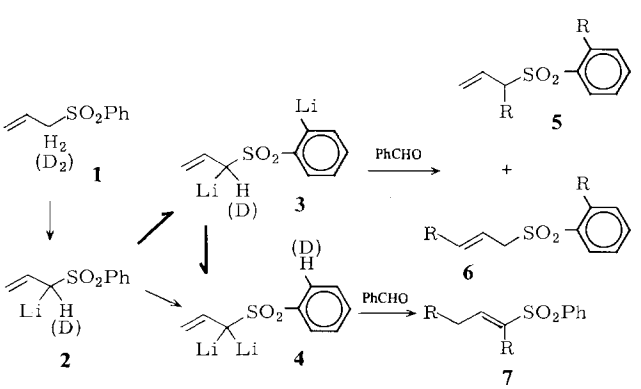
1,1- and 1,*o*-Dilithioallyl Phenyl Sulfone: Synthesis, Geminal Cycloalkylation, and Lithium-Titanium Exchange**

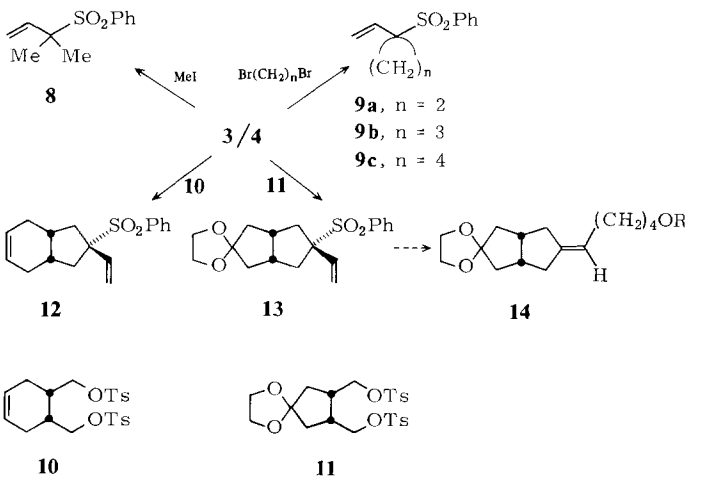


By *Jürgen Vollhardt, Hans-Joachim Gais,** and *Karl L. Lukas*

Ab initio calculations for monomeric 1,1- and 1,3-dilithiopropene gave as an energy minimum an unusual doubly lithium-bridged structure, characterized by *Streitwieser* et al.[1] as an "ion triplet of two lithium cations and a propenylidene dianion." 1,1-Dilithiopropenes containing a sulfonyl group in the 1-position, which is capable of complexing lithium and which is preparatively useful in a variety of ways, are of great interest with regard to their structure in solution and in the crystal as well as their synthetic potential. We describe here the synthesis of 1,1-dilithioallyl phenyl sulfone **4**, the first compound of this type, and that of its isomer **3** as well as their geminal cycloalkylation and lithium-titanium exchange.

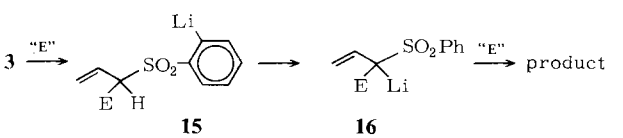
The second lithiation of 1-lithioallyl phenyl sulfone **2**, prepared from phenyl 2-propenyl sulfone **1**, proceeds in a remarkable fashion: in tetrahydrofuran (THF) at low temperatures, one equivalent of *n*BuLi metalates **2** in the position *ortho* to the sulfonyl group[2] to give **3** in a kinetically controlled reaction with high selectivity; metalation in the 1-position to give **4** occurs as well. The selectivity decreases with increasing temperature. Upon warming **3** to 50°C in THF, complete transmetalation to the thermodynamically more stable 1,1-dilithio species **4** takes place. The metalation of **2** and the transmetalation of **3** can be followed by ^{1}H-NMR spectroscopy.

In THF at −50°C, **3** reacts with excess benzaldehyde to give the 1,*o*- and 3,*o*-(*E*)-diadducts **5** (74%) and **6** (4%), respectively, while **4** affords the 1,3-(*E*)-diadduct **7** in nearly the same yield (77%).



When [1-D_1]-**2** is lithiated, a mixture of [1-D_1]-**3/4** is obtained, which upon warming to 50°C is completely converted into [*o*-D_1]-**4/4** within 2 h; after protonation with HCl/H_2O/THF, [*o*-D_1]-**1/1** is obtained and its composition determined by ^{1}H-NMR spectroscopy. At −35°C in THF, **2** is lithiated with 90% selectivity and [1-D_1]-**2** with 97% selectivity by *n*BuLi.[3]

Scheme 1. R = PhCH(OH).



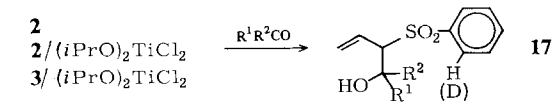
4 is only sparingly soluble in THF and remarkably stable. After 4 h at 50°C, deuteration with DCl/D_2O/THF (0°C) still afforded 82% [1,1-D_2]-**1** (degree of deuteration ≥98%). Interestingly, **4** reacts with CF_3CO_2D in THF (0°C), undergoing both 1,1- and 1,3-dideuteration, to give a 1:1 mixture of [1,1-D_2]-phenyl 2-propenyl sulfone ([1,1-D_2]-**1**) and [1,3-D_2]-phenyl 1-propenyl sulfone (*E*:*Z* = 17:1) (degree of deuteration ≥95% in each case).

The dialkylation of **4** with methyl iodide (THF, −50°C) proceeds regioselectively (≥98%) to give the 1,1-dimethylallyl sulfone **8** (80%). The same is observed for the cycloalkylation of **4** with 1,ω-dibromoalkanes (THF, 0°C) to give the carbocyclic compounds **9a** (44%), **9b** (80%), and **9c** (89%). By geminal cycloalkylation of **4** with the ditosylates **10** and **11**[4] (THF, 25°C), it is possible to synthesize the new bicyclic compounds **12** (77%, *ds* = 70%) and **13** (82%, *ds* = 90%), respectively, in high yield and with high diastereoselectivity (*ds*); these compounds are geminally disubstituted with a vinyl and a phenylsulfonyl group. **13** could eventually be converted by "γ-substitution" with lithium dialkylcuprates[5] into the 6a-carbaprostacyclin[6] precursor **14** (Scheme 2).

Scheme 2.

Surprisingly, nearly the same results are obtained for the methylation and the cycloalkylation of the 1,*o*-dilithio compound **3**. The initial alkylation of **3** in the 1-position to give the *o*-lithiophenyl sulfone **15** is followed by complete transmetalation to the 1-lithioallyl sulfone **16** (Scheme 3), which affords **8**, **9**, **12**, or **13** upon a second alkylation or upon cycloalkylation.[7]

Scheme 3.



2 reacts regioselectively with benzaldehyde and cyclopentanone (THF, −70°C) to give the 1-adducts **17a** (85%, 1:1 diastereomeric mixture) and **17b** (92%), respectively. Very similar results are obtained when **2** is first converted into the allyltitanium species with one equivalent of $(iPrO)_2TiCl_2$ (THF, −50°C), which is then allowed to react with the carbonyl compound (THF, 0°C): 82% **17a** and

91% **17b**. The titanation[8] of the 1,*o*-dilithio compound **3** with one equivalent of $(i\mathrm{PrO}_2)\mathrm{TiCl}_2$ (THF, −40°C; color change from orange to red) affords a reactive titanium species, which gives [*o*-D_1]-**17b** (degree of deuteration 85%) in 76% yield upon reaction with cyclopentanone (THF, 0°C) followed by DCl/D_2O work-up.

a: R^1 = Ph, R^2 = H; **b**: $R^1 - R^2$ = $-(CH_2)_4-$

The lithium-titanium exchange is achieved for the 1,1-dilithio species **4** if it is allowed to react with $(i\mathrm{PrO})_2\mathrm{TiCl}_2$ at −70°C in THF and the solution is then warmed to −10°C; a novel organotitanium compound is formed, which until now has only been prepared as a deep red solution. It is deuterated to [1,1-D_2]-**1** (78%, degree of deuteration ≥98%) similarly to **4** with DCl/D_2O; however, in contrast to **4**, it does not react with methyl iodide under the same conditions. With aldehydes (THF, −50°C) and ketones (THF, −50 to 0°C), on the other hand, both the dienes **18** and the 3-adducts **19** are obtained, which, upon trapping with DCl/D_2O, are shown to contain deuterium in the 1-position (e.g., [1-D_1]-**19a**, degree of deuteration 90% (Scheme 4).

	R^1	R^2	[%]	[%]

Scheme 4.

The fact that sterically hindered aldehydes react with **4**/$(i\mathrm{PrO})_2\mathrm{TiCl}_2$ to form selectively the 3-(*E*)-adducts **19** could be synthetically useful since **2** and **2**/$(i\mathrm{PrO})_2\mathrm{TiCl}_2$ as well as **3**/$(i\mathrm{PrO})_2\mathrm{TiCl}_2$ give selectively the 1-adduct **17**. The reaction of **4**/$(i\mathrm{PrO})_2\mathrm{TiCl}_2$ with cyclopentanone to give the carbonyl olefination product **18f** in good yield is also promising.

The following finding deserves attention in connection with the structure of the titanium species formed by metal exchange on **4**: when one equivalent of lithium diisopropylamide is added at −50°C to the allyltitanium species formed from **2** (one equivalent $(i\mathrm{PrO})_2\mathrm{TiCl}_2$, THF, −50°C) and the mixture warmed to −10°C, a deep red solution (color change from orange to red) is obtained, from which, after addition of benzaldehyde, 34% of the 1-adduct **17a**, 4% of the diene **18a**, and 47% of the 3-adduct **19a** (*E*:*Z* = 3:2) are obtained. The results of the reaction of **4**/$(i\mathrm{PrO})_2\mathrm{TiCl}_2$ with carbonyl compounds can be explained by the presence of a titanium species that contains the partial structures **20A** and **20B**, which are interconvertible;[9] another possibility is the alkylidenetitanium complex **21**.

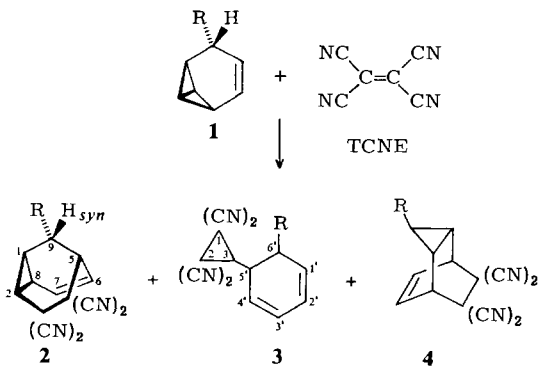
Reaction of Homobenzvalene with Tetracyanoethylene; Formation of a Tetracyanodihydrobarbaralane Derivative and a Tetracyanocyclopropane Derivative**

By *Manfred Christl,* Reinhard Lang, Clemens Herzog, Roland Stangl, Karl Peters, Eva-Maria Peters,* and *Hans Georg von Schnering*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday



The reactions of tetracyanoethylene (TCNE) and 5,6-dichloro-2,3-dicyano-*p*-benzoquinone with benzvalene recently reported by us constitute the first documented examples of the long sought after one-step 1,4-cycloaddition of an alkene to a vinylcyclopropane.[1a] As a

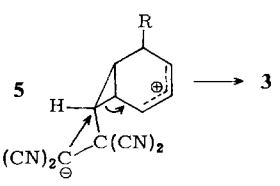
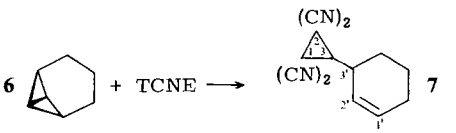
$[(\sigma 2_s + \pi 2_s) + \pi 2_s]$ process, this reaction is closely related to the Diels-Alder addition.[1b] However, the TCNE adduct concerned, a dihydrosemibullvalene derivative, is formed in a yield of only a few percent. The major products arise from a zwitterionic intermediate which is formed by addition of TCNE to the benzvalene π-bond.



We have now obtained a 5.0 : 1.2 : 1.0 mixture of the 1 : 1 adducts **2a**—**4a** in 43% yield by reaction of homobenzvalene **1a**[2] with TCNE in acetonitrile at −15 to 20°C. **2a** and **3a** were isolated in pure form by extraction and crystallization. Reaction of 5-methylhomobenzvalene **1b**[3a] and TCNE under the same conditions afforded a 10 : 1 mixture of **2b** and **3b** in 50% yield, from which pure **2b** was isolated by recrystallization.[*]



a, R = H; **b**, R = CH_3

The structure of the compounds **2** was deduced from the NMR spectra (Table 1). The ^{13}C-NMR data of **2a**, in particular, indicate the presence of a double bond and a cyclopropane moiety; the H,H-coupling constants rule out other possible combinations of the structural units, e.g. those with the CH_2-group adjacent to the double bond. The structure of **3a** was elucidated by X-ray analysis.[3b] The identity of **4a** was established by comparison of its NMR signals with those of the authentic substance.[4]

Other than in the case of benzvalene,[1a] in the case of homobenzvalene the 1,4-cycloaddition is the main reaction. However, because of the lower symmetry of **1a**, it is not possible to demonstrate the one-step mode of this reaction by labeling with deuterium. If zwitterionic intermediates are taken into consideration, then, because of the localization of the HOMO of **1a**,[5] it must be assumed that TCNE does not attack the double bond but rather the bicyclo[1.1.0]butane system, with rupture of a lateral bond.[6] The species **5** thus formed could then cyclize to **2**. Since, however, the product of the second possible mode of ring closure, namely at the other end of the allyl-cation system, was not found, even though this route would not be disfavored as regards ring strain, and the formation of a five-membered instead of a seven-membered ring would even be favored entropically, we consider the route to **2** via **5** as unlikely and prefer the $[(\sigma 2_s + \pi 2_s) + \pi 2_s]$ process.

On the other hand the formation of **3** from **5** via intramolecular nucleophilic substitution with making and breaking of a cyclopropane bond is plausible. The zwitterion **5a** is possibly also the precursor for **4a**. As such, **5a** would then have to decompose to TCNE and cycloheptatriene, which could then react further to give the known Diels-Alder adduct **4a**.[7] However, the possibility that a radical-ion pair of **1a** and TCNE serves as precursor for cycloheptatriene cannot be ruled out.

In the proposed mechanism for the formation of **3**, the double bond of **1** is inessential; it merely stabilizes the cationic center. Thus, the dihydro derivative of **1**, tricyclo[4.1.0.0^{2,7}]heptane **6**,[6a,8] reacts with TCNE in acetonitrile at 20°C to give the analogue of **3**, compound **7**, as the sole homogeneous product in 38% yield.

If benzvalene and homobenzvalene react with TCNE to give the rearranged products according to the mechanism

3b: ^{1}H NMR: $\delta = 1.13$ (d, $J_{6,CH_3} = 7.2$ Hz; CH_3), 3.74 (d, $J_{3,5'} = 11.0$ Hz; 3-H); 5.89 (ddq, $J = 9.4$, 5.5, 0.8 Hz), 5.96 (ddm, $J = 9.5$, 5.5 Hz), 6.05 (ddt, $J = 9.5$, 5.1, 0.8 Hz), 6.27 (ddt, $J = 9.4$, 5.2, 0.8 Hz) (1'-H–4'-H); the signals of 5'-H and 6'-H are superposed by signals of **2b**

7: m.p. 176°C (dec., from ethanol). ^{1}H NMR ($CDCl_3$): $\delta = 1.61$—1.88 (m; 3H), 2.07—2.18 (m; 3H), 2.32 (m; 3'-H), 2.66 (d, $J_{3,3'} = 11.4$ Hz; 3-H), 5.61 (dq, $J_{1',2'} = 10.0$ Hz, $J_{2',3'} = J_{2',6'cis} = J_{2',6'trans} = 2.3$ Hz; 2'-H), 6.11 (dtd, $J_{1',6'cis} = J_{1',6'trans} = 3.8$, $J_{1',3'} = 2.0$ Hz; 1'-H). ^{13}C NMR: $\delta = 20.43$, 25.14, 26.70 (in each case t; C-4'–C-6'); 21.90, 21.99 (in each case s; C-1,2); 35.87 (d; C-3'); 44.15 (d; C-3); 109.32, 109.51, 110.71 (double signal) (in each case s; 4CN); 123.81 (d; C-1'); 133.23 (d; C-2').

[a] Elemental analyses and IR and MS spectra of **2a**, **2b**, **3a**, and 7 are consistent with the proposed structures. Solvent for NMR measurements (if not otherwise stated): [D_6]acetone.

[*] The numbering in **3** and **7** do not comply with the IUPAC rules; it merely serves for assignment of the NMR signals (Table 1).

described in ref. [1a] and proposed in this communication then the site of attack of the electrophile would differ in both substrates. This would, in addition to the reaction of thiophenol, in which radical-chain processes take place,[9] be a further case in which regiochemistry is determined by the localization of the HOMOs.[5]

BOOK REVIEWS

New Pathways for Organic Synthesis. Practical Applications of Transition Metals. By *H. M. Colqhoun, J. Holton, D. J. Thompson* and *M. V. Twigg*. Plenum Press, New York—London 1984. xiv, 454 pp., bound, $ 59.50.—ISBN 0-306-41318-3

A retrospective glance at the Nachrichten aus Chemie, Technik und Laboratorium for 1983 indicates, amongst other things, how vigorously organometallic chemistry is developing. The results from organometallic chemistry fill 16 columns while those of classical organic chemistry only account for 9. The demand for information and teaching material is considerable in this field. Therefore many books have appeared in recent years dealing with organotransition metal chemistry. With few exceptions the disappointed reviewer has laid them aside. This book is one of the exceptions.

Organic molecules or residues bonded to a transition metal often display reactions which do not fit into the classical organic chemical picture. Surprisingly little attention is paid to these new reactions by organic chemists or by the authors of organic chemistry textbooks or laboratory manuals. Starting from this point the authors, four industrial chemists, address themselves to the practical organic chemist and present an extensive collection of catalytic and stoichiometric organic syntheses in which transition metals play a part. The emphasis is—as the authors say in the introduction—on processes which are not possible using classical methods, which are generally applicable, which do not require a great deal of apparatus or much financial outlay and which—where possible—do not deter people by their toxicity. In order to ease the application of the methods described they present in the final chapter brief instructions for the handling of air-sensitive compounds, give instructions for the preparation of 18 important transition metal catalysts and educts and list sources for such compounds.

Between the introduction and the final chapter the material is divided up as follows: Formation of CC bonds (single bond, double bond) (55 p.); Synthesis of carbocyclics (69 p.); Synthesis of heterocyclics (25 p.); Isomerization of alkenes (20 p.); Direct introduction and removal of carbonyl groups (65 p.); Reduction (73 p.); Oxidation (31 p.). The description—product-oriented—is in the Houben-Weyl style, i.e. brief, with formulas reduced to the most important, taking account of stereochemical aspects, giving warning of sources of danger and interspersed with concrete experimental data (in all 147). Only occasional reference is made to theoretical and mechanical details; however, the reader can easily obtain additional information from the carefully chosen references (in all 976).

Since the carbonyl group is the most important functional group in organic chemistry the chapter "Direct introduction and removal of carbonyl groups" is worthy of special interest. On reading this it will become clear to many chemists for the first time that the chemistry of organic carbonyl compounds after its great leap forward in the 19th century has been experiencing a great renaissance since the middle of this century. The chapter on heterocyclics offers the specialist in organotransition metals or heterocyclic chemistry surprising information and an exciting glimpse of a new field. On the other hand criticism must be made of the chapter "Formation of CC bounds". The more recent developments such as the important application of alkyltitanium compounds as alkylation agents with high chemoselectivity, the stereoselective addition reactions of organotransition metal compounds to carbonyl groups or the transition metal-containing reagents for carbonyl olefination are not mentioned (on the other hand, non-oxidative alkene dimerization, cross coupling according to *Kumada*, the McMurry reaction, the Semmelhack method, CC linkage via π-allyl complexes, alkyl cuprate reagents and alkene metathesis are all covered). Such gaps, also to be found in other chapters, and the list of references show that the book was completed some time ago (1978—1980). However, the authors used the intervening period to check the text and formulas carefully.

This book, which is fluently written, may be recommended: a) To the mentally and practically flexible organic chemist searching for new methods of synthesis. b) For use with a textbook containing the theoretical and

practical basics of organotransition metal chemistry (*Collman, Hegedus:* Principles and Applications of Organotransition Metal Chemistry is recommended), to bring university organic chemistry tuition up to date, especially in the practical field—The book deserves to sell, to be improved by its authors by the making good of the gaps which have been mentioned and to be continually updated by the inclusion of new methods.

Organisch-chemisches Institut
der Universität Münster (FRG)

Die Bleibelastung des Menschen. By *G. Lehnert* and *D. Szadkowski*. Verlag Chemie, Weinheim 1983. vii, 96 pp., DM 28.00,—ISBN 3-527-26096-X

This booklet describes in 80 pages the important sources of lead uptake (described here as lead burden) and their regulating boundary conditions, the functional changes initiated ("stresses") and the public health measures necessary (in essence tolerance levels). The actual effects of lead and therapeutic questions are only touched on cursorily. The descriptive mode of presentation makes the work suitable for use as an introduction to the field for non-specialists and less useful for medical and toxicological experts. Its value lies in the long list of literature references covering the occurrence and possibilities of uptake of lead from industry, technology, foodstuffs and confections and beverages, in the home and in the air. Daily and annual variations and the possibilities of mobilizing lead in the individual are devoted particular attention. There are no references to guide the interested reader to the larger, more comprehensive monographs on lead and the effects of lead, although they are continually borrowed from both for the text and the diagrams. The MAK for lead is erroneously quoted as 150 $\mu g/m^3$; since 1977 the value has been 100 $\mu g/m^3$.

Selectivity—A Goal for Synthetic Efficiency. Workshop Conferences Hoechst. Vol. 14. Edited by *W. Bartmann* and *B. M. Trost*. Verlag Chemie, Weinheim 1984. xi, 423 pp., bound, DM 85.00.—ISBN 3-527-26142-7

Selectivity is a conditio sine qua non for efficiency in chemical synthesis. The discovery of new, more efficient regio-, chemo- and stereoselective methods is thus of particular importance. The advances in this field are so breathtaking that several selective syntheses are often available now for complex structures that were previously only difficultly accessible. The Achilles heel of many selective methods and syntheses is, however, their lack of practicability. Biological synthesis is still better than chemical for many complicated natural products of wide application such as penicillins, cephalosporins, steroids and macrolides. The challenge to chemical synthesis is increased by the development of gene technology. It is greatly to be welcomed that the papers presented by internationally acknowledged specialists at the 14th Workshop Conference Hoechst are now available in book form and have thus been made available to a wider, interested public. The following individual topics are treated:

Stereoselectivity in the Synthesis of Cyclic Ethers *(P. A. Bartlett)*; Some Uses of Silicon-Nitrogen Bonds in Organic Synthesis *(R. J. P. Corriu* and *J. J. E. Moreau)*; Designed Complexes—Science and Applications *(D. J. Cram* and *J. M. Cram)*; Asymmetric Synthesis of Carbonyl Compounds and Primary Amines *(D. Enders)*; Stereoselection by Allylboronates. The Highs and the Lows *(R. W. Hoffmann)*; Palytoxin *(Y. Kishi)*; Tris(dialkylamino)sulfonium Enolates and Phenoxide *(R. Noyori)*; Regio-, Diastereo- and Enantioselective Carbon-Carbon Bond Formation—Recent Studies and Applications in Organic Synthesis *(W. Oppolzer)*; Selectivity and Reactivity in Oligosaccharide Synthesis *(H. Paulsen)*; Organotin Reagents for Selective Reactions: Synthesis and Applications of α-Heterosubstituted Organotins *(M. Pereye, B. Elissondo* und *J.-P. Quintard)*; Chiral Building Blocks in Natural Product Synthesis *(G. Quinkert)*; Regioselectivity in Metal-Promoted Carbon-Carbon Coupling Reactions *(M. F. Semmelhack)*; Strategies for Controlling the Stereochemical Course of Yeast Reductions *(C. J. Sih, B. Zhou, A. S. Gopalan, W.-R. Shieh* and *F. Van Middlesworth)*; Conformational Control of Chemical Reactions *(W. C. Still)*; Radical-Mediated Cyclisation Processes *(G. Stork)*; Diastereoselectivity and Asymmetric Induction in the Diels-Alder Reaction with Inverse Electron Demand *(L. F. Tietze)*; New Palladium-Catalyzed Reactions of Allylic Compounds via π-Allylpalladium Complexes *(J. Tsuji)*; Selectivity in Excited State Chemistry *(P. A. Wender)*; Chiral Building Blocks in Alkaloid Synthesis *(E. Winterfeldt)*; Selectivity in Organic Synthesis *(H. Wynberg)*; On the Mechanism of Titanium-Tartrate Catalyzed Asymmetric Epoxidation *(K. B. Sharpless, S. S. Woodard* and *M. G. Finn)*; Selectivity in Chemical and Enzymatic Synthesis *(J. E. Baldwin)*.

The contributions, of which several have been published in the meantime in other places in this or even in an extended form, are in their majority very clearly and synoptically written. Comprehensive reference lists make it possible to become further engaged in the widely ranging topics. The book is to be recommended to all who stand somewhat at a distance from this field and wish an overview—albeit incomplete—of the present state of this most topical field of organic chemistry. The purchase of this book which offers valuable stimulation with its collection of the latest results from twenty-two research groups would also pay the preparative organic chemist working in this field. However, the price seems rather high for an extract-like "snapshot" of a rapidly developing field.

Immuno Enzyme Techniques in Cytochemistry. By *W. D. Kuhlmann*. Verlag Chemie, Weinheim 1984. xiii, 162 pp., bound, DM 128.00.—ISBN 3-527-26078-1

Advances in fundamental biological and medical research are based to a large extent on the introduction of new methods. Nowadays, no laboratory working in cell biology can manage without gene manipulation and/or immunological techniques. Scientists are always being confronted anew with the problem of choosing and/or

meaningfully adapting the right methods for their particular purposes from the wealth of possible choice. Therefore practical handbooks fulfill an important purpose and every new publication is eagerly awaited. The work in question—written in English—is divided into eight chapters: 1) Basic Methods and Aspects in Immunological Reagent Preparation, 2) Preparation of Immunohistological Reagents, 3) Histological Immuno Enzyme Techniques, 4) General Preparation of Biological Specimens, 5) Immunoperoxidase Histology in the Light Microscope, 6) Immunohistological Assays for Electron Microscopy, 7) Immunohistological Specificity, 8) Practical Aspects.

The book claims to provide a review of the concepts and practical aspects of immunohistological methods, in particular those of immuno enzyme techniques, it promises a detailed description of the preparation and purification of the necessary reagents, wishes to warn the reader about making false interpretations and to be a trustworthy manual for all who have to become conversant with immunohistological methods.

Does it fulfill what it promises? The answer, unfortunately, is a very definite no. The reader who attempts to work through the instructions is confronted with insuperable problems. Who knows offhand what protein A is used for (p. 28, 44, 45, the explanation follows on p. 62, only p. 45 is mentioned in the index), or what an epitope is (p. 32, an antigen determinant), what type of ape is hiding behind the name *Cercopithecus aethiops* (p. 122, long-tailed monkey) and how one obtains its kidney cells, because they are required for one of the experiments.

The presentations are sometimes too trivial and sometimes too specialized for the scientist with years of laboratory experience. Unfortunately there is no general review of the immuno enzyme techniques, but merely a glimpse of the work being carried out in the author's laboratory. No details are given of how the results he has obtained may be applied to other systems; the results were sometimes obtained under extremely lavish conditions. Many of the details are imprecise; for example, it is not clear from the text nor from the legends to Figures 1—10 and 1—15 what protein is yielded by the kinetics or separation illustrated. Yet this information is essential, for these results only hold for a particular protein; they cannot be applied to others. In addition, data are given about the acrylamide concentrations to be used in producing gels (p. 26), but no mention is made of the fact that gels with these concentrations are only suitable for proteins of a particular size range. Nowadays, apparatus for polyacrylamide gel electrophoresis (often home-made) is part of the standard equipment but what laboratory has the chamber made of vitreous silica sheet? Normal glass or plate glass are usual. Vitreous silica is much too expensive. The suggested dimensions ($18 \times 9 \times 0.3$ cm^3, p. 26) are intended for special cases. As shown by the results in Figure 1—19 these proved to be quite unsuitable for the separation presented since the voltage drop over 18 cm is much too high to achieve an optimal separation of the material to be separated. A "slot-former" is a chamber-shaped piece of plastic which looks quite different than is shown in Figure 1—18.

It remains unclear as to why the section "... lectin binding technique" (p. 50/51) has been inserted. It is to be expected that the reader will know that concanavalin A (a lectin) binds glucosyl and/or mannosyl residues and that as a result these must be exposed on the surface of peroxidase molecules. The mention of GOT staining (p. 65) is just as incomprehensible. There is a lack of information about the particular advantages of the methods and their field of application. On the other hand, pure gastrin (p. 85) is used in the performance of an investigation without it being explained how this is obtained. The choice of reagents is not "a matter of personal preference" (p. 62), but depends quite definitely on the aim and the questions posed. Remarks such as "Then, alternative procedures must be elaborated" (p. 98) or "Antibody concentrations and incubation times were chosen by trial and were within the limits of immunohistological assays" (p. 120) are of very little value and serve to frustrate the reader.

Every chapter ends with a comprehensive list of references. There are no critical comments concerning the methods reported in the literature. Neither are there any persuasive arguments for the superiority of immuno enzyme techniques over other immunological methods, e.g. the indirect immune fluorescence with FITC as marker. This process is employed throughout the world and has led to spectacular results in recent years. Why was this not honored by even one single mention in the list of references?

The resolution of the figures is frequently disappointing. Figure 5-4 is incomprehensible. There are no points of reference or orientation. It is not possible to make out what is supposed to have been tagged. In many other figures (5-1, 5-2, 5-7 etc.) comparable tissue sections (partial figures) are reproduced at different magnifications—which is also confusing. What a pity—an opportunity has been wasted. Here it has only been possible to highlight a few of the aggravating deficiencies. One thing remains to be said: the price cannot in any way be justified.

Enzymes as Catalysts in Synthetic Organic Chemistry

New Synthetic Methods (53)

By George M. Whitesides* and Chi-Huey Wong

Enzymes have great potential as catalysts for use in synthetic organic chemistry. Applications of enzymes in synthesis have so far been limited to a relatively small number of large-scale hydrolytic processes used in industry, and to a large number of small-scale syntheses of materials used in analytical procedures and in research. Changes in the technology for production of enzymes (in part attributable to improved methods from classical microbiology, and in part to the promise of genetic engineering) and for their stabilization and manipulation now make these catalysts practical for wider use in large-scale synthetic organic chemistry. This paper reviews the status of the rapidly developing field of enzyme-catalyzed organic synthesis, and outlines both present opportunities and probable future developments in this field.

1. Introduction

Synthetic organic chemistry now faces important challenges derived from, and concerning, biology. The stunning recent advances in molecular and cellular biology—in genetics, immunology, endocrinology, neurobiology, and receptor and membrane biochemistry—have outlined broadly the course of many processes important in life. Understanding these processes in full molecular detail and using this understanding to produce chemically well-defined compounds useful in medicine, agriculture, and biology requires the preparation of classes of substances that have traditionally not been the major foci of activity in organic synthesis. Proteins, polypeptides, sugars, oligosaccharides, polysaccharides, nucleic acids, and combinations, analogues, and derivatives of these species are all centrally important in molecular biology. Their syntheses have received a relatively small fraction of the creative effort of modern synthetic organic chemistry. For chemistry to participate fully in molecular biology, it must be able to make these classes of compounds with the same high degree of skill with which it now makes hydrocarbons, heterocycles, and related classes of compounds. For molecular biology to contribute most effectively to society, its discoveries must be reduced to molecular detail and manipulated in ways that produce useful substances. Improved techniques from synthetic organic chemistry for the synthesis of biologically relevant compounds—especially those useful in modern molecular biology and biotechnology—would be of broad benefit.

The community of synthetic organic chemists has moved relatively slowly to explore many of the important synthetic problems posed by molecular biology for four reasons:

1) Many of the substances important in biology have physical properties which are unfamiliar and inconvenient. These compounds are often soluble in water, charged, nonvolatile, and high molecular weight. They may be unstable, impractical to obtain in quantity, and difficult to purify. Spectroscopy may be of limited utility in defining their structures.

2) Certain of the important generic problems encountered in the synthesis of these substances—e.g., the formation of amide, phosphodiester, and glycosidic linkages in the repetitive processes required to make macromolecules, or the manipulation of carbohydrates—have been considered in some senses to be "chemically uninteresting."

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1985 0570-0833/85/0808-0617 $ 02.50/0

3) Classical synthetic organic technology does *not* provide the best approach to certain of these problems—e.g., fermentation, tissue culture, and recombinant DNA technology are more useful than chemical techniques for the production of proteins, and fermentation is presently the only practical route to polysaccharides—and for many others the relative value of classical chemical and biologically derived synthetic methods remains undefined.

4) These problems have not been fashionable within the synthetic community.

Thus, for organic synthesis to function most effectively in the preparation of biologically relevant substances, modifications are required in the experimental techniques it uses, in the types of scientific problems it addresses, and in the scientific community it serves. These modifications to the scope and style of synthesis are substantial. Nonetheless, the central challenge—the synthesis of pure, well-defined molecular entities—is one at which synthetic chemists have (at least in the past) always been preeminent.

This article reviews one of the areas of synthesis which lies at the border between organic chemistry and biochemistry: the use of enzymes as catalysts in organic synthesis.[1-12] This area is the one which is the most "chemical" or "molecular" of the biologically derived synthetic technologies. Chemists comfortably use platinum as a catalyst; they will eventually use lipase with no more hesitation. Enzymology provides a class of catalysts genuinely useful in the synthesis of biologically relevant substances, and requires a less drastic change in experimental approach than does, for example, fermentation using obligate anaerobes or mammalian cell culture. Enzymology is also, in some sense, the most fundamental of the synthetic techniques derived from biology: the less familiar (to chemists) synthetic technologies based on living cells also, of course, ultimately depend on enzymes. We emphasize that enzymatic synthesis (whether biologically based or abiological) is not necessarily the most useful synthetic technique for the solution of an arbitrarily chosen biologically derived synthetic problem,[9, 10] and one function of this article is to try to define the areas of synthesis in which enzymatic methods are those of choice.

2. Areas of Current Application

Enzymes are catalysts which have already demonstrated high utility and potential in certain areas of current importance in organic and pharmaceutical chemistry.

2.1. Preparation of Chiral Synthons

The first area in which enzymes have found important, broad application is in the preparation of chiral synthons, commonly by kinetic resolution. The practical importance of this area to the pharmaceutical industry is based in part on the desire for efficient syntheses and in part on regulatory constraints: regulatory pressures increasingly favor the production of enantiomerically pure substances, rather than racemates. Chiral synthesis using optically active transition-metal catalysts is also, of course, an area of current intense activity,[13-17] and the competition between biological and transition-metal-based methods is one of real strategic interest. To date, from a practical point of view, biologically based routes to chiral substances have proved more broadly useful than catalytic methods using transition metals.

2.2. Specialty and Fine Chemicals

Enzymes have established utility in the manipulation of sugars, nucleic acids, amino acids, and lipids, and in fact the major applications of enzymology in process chemistry all lie within these areas.[18] The quantities of materials produced using enzymatic catalysis establish that, in appropriate circumstances, enzymes can be practical catalysts for large-scale processes:[9] for example, high-fructose corn syrup is produced on a scale of $> 10^5$ t per year in the USA, and aspartic acid, malic acid, and guanosine 5′-phosphate (GMP), which is used as a flavoring, are all produced in substantial quantity by enzymatic methods.

A wide variety of substances used for research in biochemistry, metabolism, and pharmacology have been best produced using enzymatic methods.

2.3. "Biological" Pharmaceuticals

One of the areas of greatest activity in modern pharmaceutical research is concerned with complex, biologically derived substances—especially proteins, polypeptides, and related materials obtained by, or stimulated by, the techniques of molecular genetics.[7, 9] Enzymology is now playing an increasingly important role in modification of materials derived from fermentation synthesis: for example, peptidases are used to cleave selectively (and, perhaps, to form selectively) peptide links, and other enzymes to attach oligosaccharide moieties to proteins or to modify those of glycoproteins. The recent commercialization of a process for conversion of porcine to human insulin by Novo Industrie provides the first large-scale example of this type of application.

2.4. Biotechnology[9, 10]

Many of the range of applications of biology subsumed in the word "biotechnology" require chemical manipulation of complex, biologically derived or biologically related substances. Clinical analysis, biologically derived sensors, and the preparation of flavor and odor compounds, for example, involve compounds which may require enzymatic synthesis or modification.

We note explicitly that the area of enzymatic catalysis in organic synthesis is, as are most areas of practical catalysis, fundamentally a process chemistry. That is, its principal objective is the efficient and economical (both in terms of money and time) synthesis of specific compounds (Fig. 1). In this sense it differs from a substantial amount of the work in organic synthesis presently carried out in universities, in which the compound that is the specific objective of the synthesis is less important than is the value of the individual steps (or the overall synthetic strategy) in demon-

strating new and often broadly generalizable chemical principles.

Synthesis

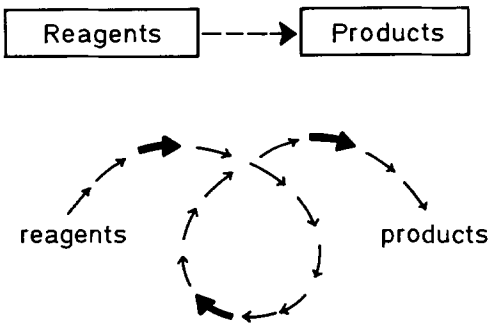

Fig. 1. Two approaches to synthesis. One (upper) is concerned with the development of practical, efficient routes to specific products. The second (lower) uses synthesis primarily to illustrate principles of reactivity and synthetic strategy. Enzyme-catalyzed synthesis (together with much of catalysis) is concerned primarily (although not exclusively) with the former objective.

3. Characteristics of Enzymes as Catalysts

Enzymes have three distinguishing characteristics as catalysts:

1) They accelerate the rates of reactions.

2) They are selective: the rate of reaction of a particular substance may be accelerated dramatically, while that of a structurally closely related substance is not.

3) They may be subject to regulation: that is, catalytic activity may be strongly influenced by the concentrations of substrates, products, or other species present in solution.

The selectivity of enzymes is the basis for much of their utility in organic synthesis. Enzymes offer the opportunity to carry out highly selective transformations—a feature of great value in working with chiral and polyfunctional molecules. The feature of regulation is critically important to the functions of enzymes in metabolic systems, but is most commonly an inconvenience in applications in organic synthesis. The most important manifestation of regulation for applications of enzymes in organic synthesis is product inhibition: that is, a decrease in the catalytic activity of an enzyme when the concentration of a product of the reaction catalyzed by that enzyme reaches a certain value.[19,20] Overcoming product inhibition may require removing the product as it is formed[20] (often an inconvenience), accepting low concentrations of product in the final reaction mixture (thereby complicating workup), or using large quantities of enzymes (with attendant increases in cost). No close analogy to regulation exists in transition-metal-based catalysis, although poisoning by product or starting material represents a loose analogy.

Enzymes have certain other characteristics which are important in considering their applications in organic synthesis:

1) Their availability, cost, and lifetime in use vary widely. A typical enzyme will contain one active site per 20000–50000 molecular weight. This high-molecular-weight equivalent per active site may be balanced by a high catalytic turnover number (moles of product produced per mole of enzyme per unit time), but is not always. The economics of enzyme use depend upon a number of factors: the cost of the enzyme, its specific activity, and its operating lifetime. Table 1 summarizes costs of research quantities of representative, commercially available enzymes useful in syn-

Table 1. Specific activities and costs of some commercially available enzymes of use in organic synthesis [a].

Enzyme [b]	E.C. Number	Specific Activity [U/mg protein]	Cost [US $/ 1000 U] [c]
Horse Liver ADH	1.1.1.1	2	50
Yeast ADH	1.1.1.1	400	0.2
ADH (*T. brockii*)	1.1.1.2	15	53
Glycerol DH (*Cellulomonas sp.*)	1.1.1.6	50	56
L-Lactic DH	1.1.1.27	1400	0.5
D-Lactic DH	1.1.1.27	300	26
Malic DH	1.1.1.37	3000	1.3
6-Phosphogluconate DH	1.1.1.44	50	280
Glucose DH (*B. cereus*)	1.1.1.47	250	160

Glucose Isomerase	5.3.1.5	30	0.005
Phosphoglucoisomerase	5.3.1.9	800	3

[a] Prices vary widely with source and quantity. [b] Abbreviations: ADH, Alcohol Dehydrogenase; DH, Dehydrogenase. [c] 1000 U of enzymatic activity will generate approximately 1 mol of product per day under favorable conditions. [d] Pancreatin is a crude, inexpensive (US$ 20/kg) mixture of enzymes which often provides the least expensive source of activities for lipases, cholesterol esterase, and certain proteases and glycosidases. [e] A variety of relatively crude proprietary proteases (Pronase, Thermolysin, Subtilisin Carlsberg, Subtilisin BPN, Newlase, Papaya, and others) are available at low cost (US$ 0.1—1/1000 U).

thesis, together with the specific activities of these enzymes. For reference, one International Unit (IU) of catalytic activity is defined as that amount which generates 1 μmol of product per mg of enzyme per min; 700 U of enzymatic activity produces ca. 1 mol of product per day. The last column of Table 1 thus indicates roughly the cost of a quantity of enzyme sufficient to generate a mole of product per day when operating under ideal—that is, V_{max}—conditions. (In fact, few synthetic reactions are run under ideal conditions, and the quantities of enzyme required to achieve this level of synthetic productivity may be greater than the theoretical by factors of between 2 and 10^2.)

2) Enzymes may require cofactors for activity. The economics of consumption or regeneration of the cofactor may be as important as that of the enzyme itself.

3) Most enzymes are water-soluble, and are most active in aqueous solution at pH 7–8 and room temperature. The importance of water solubility in limiting the applicability of enzymes in organic synthesis has probably been overestimated by organic chemists. While most enzymes are not active with truly water-insoluble substrates, it is often possible to carry out enzyme-catalyzed reactions in heterogeneous reaction mixtures in which only a small amount of the organic substrate is present in the aqueous solution containing the enzyme.[21–24] In certain cases enzymes will tolerate modest concentrations of organic cosolvents such as ethylene glycol, glycerol, dimethyl sulfoxide (DMSO), and dimethylformamide (DMF).[25–27]

4) Several enzymes can often be used in combination to carry out processes involving sequential or parallel enzyme-catalyzed transformations. This characteristic of enzymes stems from the common environment in which they function in vivo. The development of corresponding multicatalyst systems for non-enzymatic catalysts is less common.

5) Enzymes may be degraded under relatively mild conditions. Chemists are accustomed to storing metallic catalysts for long periods of time without loss in activity. Enzymes may denature on storage by a number of mechanisms:[28–33] for example, destruction by small amounts of proteases present as contaminants in the enzymatic preparation, temperature- or medium-induced changes in conformation, microbial contamination, autoxidation. All of these characteristics render the handling of enzymes, both on storage and in use, a relatively more delicate process than the handling of many other types of catalysts.

4. Enzymatic Kinetics and Mechanisms: Relevance to Synthesis

The subject of the mechanism of action of enzymes is, of course, a major field in its own right. Knowledge of characteristic kinetic constants for enzymatic reactions (especially Michaelis-Menten and inhibition constants and pH dependencies)[19,20] is very useful although not required for synthetic application. In fact, one of the major advantages of enzymatic catalysis (relative to, for example, homogeneous and heterogeneous catalysis by metals) is that a relatively small investment of time in obtaining kinetic constants for an enzyme-catalyzed reaction yields a very large return in terms of ability to control rationally the activity of that enzyme in synthetic applications. Figure 2 and Equations (a) and (b) outline essential terms. For the simplest case in which a substrate S is converted into a product P by an enzyme E in a process following Michaelis-Menten kinetics [Eq. (a)], without inhibition by products or other species, the rate of reaction is given by the familiar Equation (b).

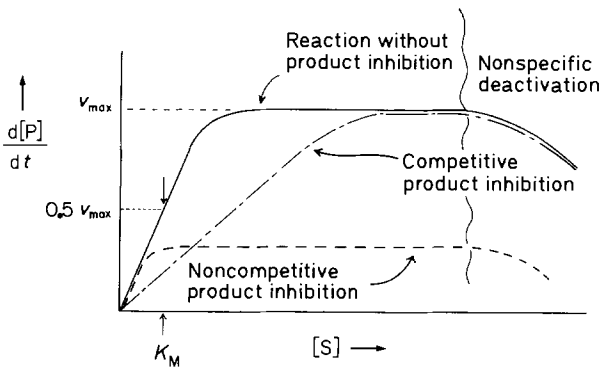

Fig. 2. Schematic representation of the relation between the reaction rate d[P]/dt and the substrate concentration [S] for a simple reaction following Michaelis-Menten kinetics (——) in the absence of inhibition by product. Curves for competitive (– – –) and noncompetitive (– – –) inhibition by product illustrate the influence of an arbitrary fixed concentration of product on the relation between d[P]/dt and [S], relative to that observed in the absence of inhibition. The slope of the curve at low [S] for an enzyme subject to competitive inhibition, and the height of the plateau for that subject to noncompetitive inhibition are determined by the concentration of the product and the inhibition constants. At high concentrations of substrate, enzymatic reactivities commonly decrease due to nonspecific deactivation.

$$S + E \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} S \cdot E \xrightarrow{k_2} P + E \qquad (a)$$

$$\frac{d[P]}{dt} = \frac{k_2[E]}{1 + \frac{K_m}{[S]}} = \frac{V_{max}}{1 + \frac{K_m}{[S]}} \qquad (b)$$

From the vantage of synthetic application, for a given quantity of enzyme, the rate of reaction increases as [S] is increased until all of the available enzyme active sites are occupied. Further increase in [S] does *not* increase the rate of reaction. In fact, if the substrate concentration is increased sufficiently, most enzymes are eventually deactivated (as the character of the solvent becomes markedly different from that of water). Maximum efficiency of use of the enzyme (usually the most expensive component of the reaction mixture) is achieved in the region of substrate concentrations in which the concentration of enzyme limits the rate (V_{max} conditions). If substrate concentrations are too low, a certain fraction of enzyme active sites are vacant at equilibrium; if substrate concentrations are too high, the enzyme is deactivated. The Michaelis constant K_m is thus invaluable in judging the *minimum* concentration of substrate which must be maintained in solution to achieve efficient use of enzyme; V_{max} is useful in indicating the most rapid rate of production of product which can be achieved for a given quantity of enzyme under ideal circumstances. Both K_m and V_{max} are measured under assay conditions.

In practice, values of K_m are often roughly the same under assay conditions and conditions used in synthesis, although higher apparent values of K_m may be observed in synthesis using immobilized enzymes if mass transport limitations are important; V_{max} under assay conditions is often much larger than the maximum rate of operation observed for the enzyme under synthetic conditions, because inhibition of enzymatic activity is common.

The discrepancy between the catalytic activity of an enzyme obtainable under ideal (assay or V_{max}) conditions and the lower value often observed under synthetic conditions is a major source of frustration to inexperienced users of enzymatic catalysis for synthetic applications. This discrepancy may have several origins: nonspecific deactivation of the enzyme by high or inappropriate concentrations of substrates, products, buffers, or ions; loss of activity on immobilization due to chemical modification or mass transport limitations; or reversible kinetic inhibition by product. The importance of product inhibition is only now beginning to be appreciated. Specific examples are given later, and a complete kinetic discussion is unnecessarily complex for synthetic applications.[20] It is, however, important to recognize that there are several important classes of inhibition (Fig. 2). The first—competitive inhibition—reflects competitive binding of substrate and product at the enzyme active site. This type of inhibition influences only K_m; its effects can, in principle, be overcome by increasing the concentration of substrate. The second—noncompetitive inhibition—leaves K_m unchanged and decreases V_{max}. This type of inhibition *cannot* be overcome by increasing substrate concentration: the only generally effective strategy is to decrease the concentration of product (e.g., by removing it continuously during reaction or by limiting the total quantity of substrate processed).[21] Yet other types of inhibition—mixed inhibition and uncompetitive inhibition—influence V_{max} and K_m simultaneously.

The important data to extract from kinetic analysis of an enzyme in order to optimize its use in synthesis are two: first, the values of K_m and V_{max} are critical in choosing values of the concentrations of substrate and enzyme; second, the product inhibition must be recognized, if present, and approximate values of K_i determined in order to choose the correct strategy—increasing substrate concentration and/or decreasing product concentration—to limit its unfavorable influence on rates of reaction.

5. Solved Problems; Current Activities; Future Problems and Opportunities

Because application of enzymes as catalysts in organic synthesis is a relatively new field, a substantial number of technical problems require solution before these applications become routine. Table 2 summarizes the status of several generic problems in this area. Those problems classified as "solved" do not necessarily have *optimal* solutions at present. The solutions now available are, however, sufficient that these problems no longer limit progress in the field. For example, many methods are now available for immobilization of enzymes.[34–39] The best strategy for immobilization of any particular enzyme is not necessarily clear, without substantial trial and error. Particularly for process applications involving long-term stability and good performance in fixed-bed reactors, improved immobilization technology would be very useful. Nonetheless, for laboratory and pilot-plant scale, existing technology is probably such that more difficult problems will be found elsewhere.

Several of the topics listed in Table 2 are discussed more fully below, but a few of the items listed in the table deserve brief comment here:

— The general thrust of *current* research in this area of applied enzymology is to establish the real practicality of

Table 2. Status of certain generic problems in enzymatic catalysis.

Solved	Current Research	Immediate Future	More Distant Fuuture
Immobilization	Development of new laboratory-scale uses of enzymes, especially simple enzymes (eaterases, amidases, isomerases)	Uses of recombinant DNA for large-scale production of enzymes	Development of new types of enzymatic activities using genetic engineering
Cofactor Regeneration AMP or ADP→ATP NAD(P)H ⇌ NAD(P)		Site-specific mutagenesis for changes in properties (K_m, K_i, selectivity, stability)	
Deactivation Thiol Autoxidation Protease Action	Use with unnatural substrates; definition of the generality of synthetic applicability of readily available enzymes	Exploration of enzymes from thermophilic and halophilic organisms for synthetic utility	
	Use with organic cosolvents; one- and two-phase systems	Evaluation of complex multienzyme systems in synthesis; comparison with whole-cell systems; "artificial metabolism"	
	Overcoming product inhibition	Applications in synthesis of fine and specialty chemicals	
	Cofactor regeneration Acetyl CoA; PAPS [a]	Chemical modification of enzymatic activities: "semisynthetic enzymes"	
	Scale-up in pharmaceutical synthesis		

[a] PAPS: 3′-phosphoadenosine-5′-phosphosulfate.

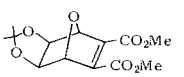
enzymes as catalysts in organic synthesis. How broadly applicable are they? Can they be used with substrates very different from their natural substrates? To what extent can their activity be changed by adding organic cosolvents? How should they be used: immobilized, in membrane reactors, or in free solution? In general, in what circumstances do they provide methods superior to existing or easily developed classical techniques for the solution of problems in organic synthesis?

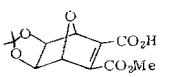
— The *immediate future* will see the application of the techniques of site-specific mutagenesis and recombinant DNA technology to the large-scale production of uncommon enzymes (if warranted by the development of important processes requiring large quantities of these enzymes), the discovery of new enzymatic activities from new sources, and modest modification of enzymatic properties (for example, changes in Michaelis-Menten constants, substrate selectivities, or thermal stabilities). The first useful examples of site-specific mutagenesis are now appearing (for example, generation of T4 lysozyme containing an engineered disulfide bond to improve stability[40a] and of tyrosyl-tRNA synthetase altered to lower K_m values[40b]). The immediate future will also see the exploration of complex multienzyme systems for synthesis. In principle, the complexity of these systems may approach that of major metabolic paths (and, since these systems may not exist in nature, the phrase "artificial metabolism" seems appropriate for them). A major question in this area concerns the degree of complexity required before cell-free enzymology becomes inferior to whole-cell synthesis. The chemical modification of existing enzymes and proteins to change activity, stability, or selectivity—that is, the generation of "semisynthetic enzymes"—also holds promise.[41]

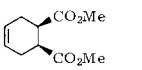
— The *distant future* holds out the potential of using highly developed structure-reactivity reactions for protein chemistry to "design" new enzymes to catalyze new reactions, and of using molecular genetics to produce these new enzymes. The prospect of being able to design and produce new catalysts is an alluring one. Its realization is, however, very far away, and even the basic principles on which the design of a new protein catalyst might be built are still being explored at the level of basic research.

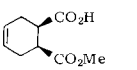
With these generalities in hand concerning the use of enzymes as catalysts in organic synthesis, we turn to a discussion of specific classes of enzymes, and illustrations of their use in synthesis. In this discussion, we will consider specific enzymes, rather than generalities concerning classes of enzymes. The discussion will proceed in terms of the present ease of use of these enzymes, although not necessarily in order of the ultimate usefulness of the enzymes.

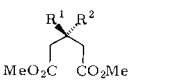
6. Specific Applications

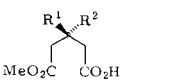






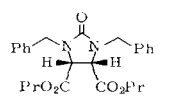


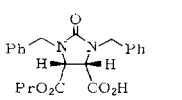


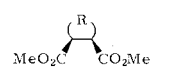


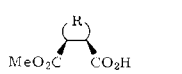
6.1. Enzymes Not Requiring Cofactors

Certain of these enzymes are among the most readily available, least expensive, and most stable. They have seen the most widespread use by synthetic organic chemists, and probably comprise the group which will first become a standard part of the synthetic organic repertoire (especially for the preparation of chiral synthons).









6.1.1. Esterases: Pig Liver Esterase and Lipases

A large number of examples exist illustrating the use of these classes of enzymes for kinetic resolutions.[42-68] The hydrolysis of *meso*-diesters has proved a particularly attractive strategy for obtaining chiral synthons, and both examples and theoretical analysis of this strategy are well-developed.[42-53] Table 3 gives representative examples.

Table 3. Enantioselective hydrolysis of *meso* substrates catalyzed by pig liver esterase and hog pancreatic lipase (last example).

Substrate	Product	*ee* [%]	Ref.
		77	[43]
		96	[51, 52]
		100	[42, 47, 49]

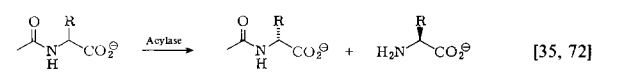
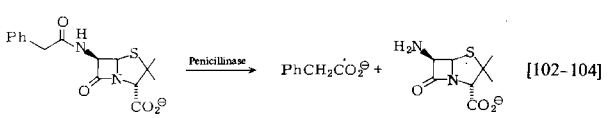
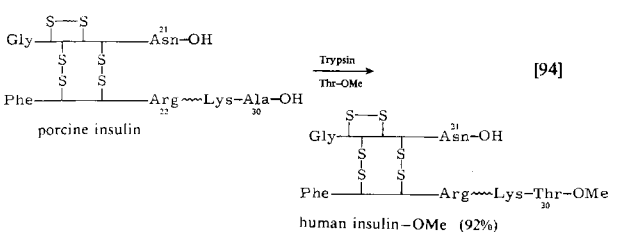
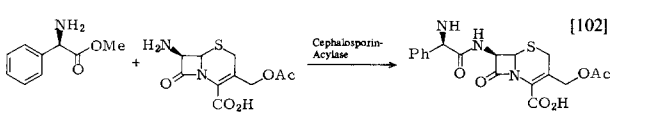
R^2	CH_3	H	CH_2Ph	NH_2	CH_3	C_2H_5	C_3H_7	$CHMe_2$	⬡	CH_2Ph	H

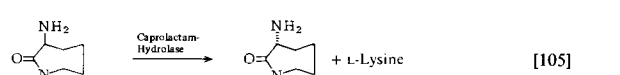
		87	[46]
		90	[50]
		95	[53]
		90	[53]

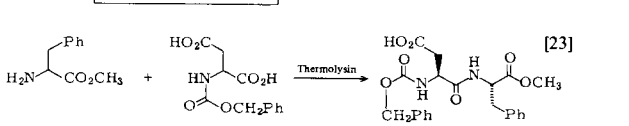












Several recent studies with these enzymes deserve further comment, since they point to certain generally useful features and problems. The lipases are rapidly developing into an extremely useful class of enzymes, especially for chiral synthesis. They have the characteristics of low cost, high stability, and high tolerance for variation in substrate structure.[53-57] They have the additional attractive feature that they do not require water-soluble substrates: They operate best at water-organic interfaces, and recent work suggests that they retain a high degree of activity in strongly dehydrating and organic systems.[60,69,70] When operating with *meso* substrates, they can generate chiral products in high yield. The utility of lipases as catalysts for the preparation of chiral substances has been demonstrated in a number of types of systems. In addition to kinetic resolution by hydrolysis, transesterification is a useful procedure.[60,61]

A recent study has compared the utility of lipase-catalyzed hydrolysis as a route to enantiomerically enriched epoxy alcohols[21] with transition-metal-catalyzed epoxidation.[17] The enzymatic hydrolysis suffers from the disadvantage that it is a kinetic resolution: that is, it relies on the selective hydrolysis of one enantiomer in the presence of the second to achieve separation, and thus, in principle, yields a maximum of 50% of product based on racemic starting material. Even given this disadvantage, however, it is in certain instances a more practical route to large quantities of an optically active epoxy alcohol than the transition-metal-catalyzed system. The enzymatic and transition-metal catalysts now available show very different substrate selectivities, and are thus, in a broad sense, complementary rather than competitive.

6.1.2. Amidases

A second broadly applicable class of hydrolytic enzymes is the amidases. The most important applications for these enzymes to date have been in kinetic resolutions of amino acids[35,72-80] (typically by hydrolysis of *N*-acylamino acids)[35,72] and in formation of amide bonds[12,81-83] in polypeptides and proteins (Table 4).[11,84-101]

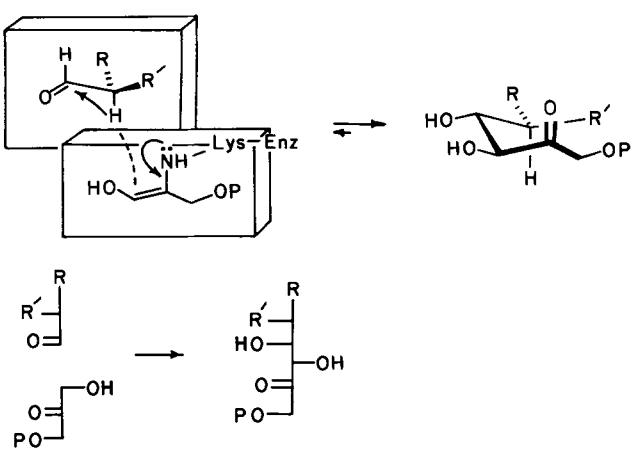


Table 4. Illustrations of uses of amidases.

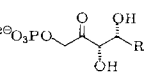
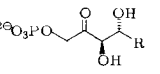
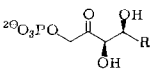
	[94]
	[102]
	[105]
	[23]

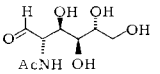
A substantial body of work has been devoted to the development of methods for formation of amide bonds between unprotected amino acids and amino acid esters using amidases. The several successful demonstrations of this type of enzyme-catalyzed dehydration establish that this type of process will be important in specific circumstances.[83] It is also clear, however, that the development of the specific reaction conditions required to effect a given dehydration demand patience and skill, and will be worthwhile only in instances in which substantial quantities of the product are desired. The most spectacular example of this technology to date is certainly the semisynthesis of human insulin from porcine insulin by Novo.[94] Future applications will rest in routine kinetic resolutions of amines, in the preparation of di- or oligopeptides,[23] in reactions incorporating organic media or reversed micelles,[101] and in the post-translational modification of proteins[106,107] obtained either by isolation from natural sources or by recombinant DNA methodology.

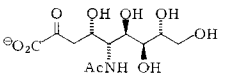
6.1.3. Aldolases

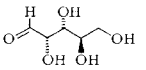


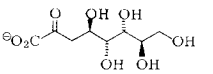


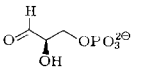


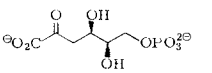


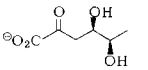


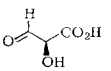


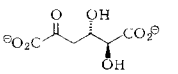


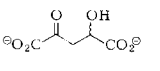


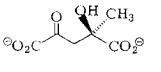


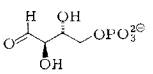


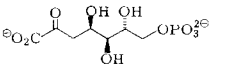


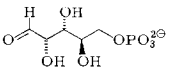


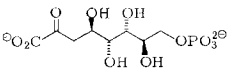












Rabbit muscle aldolase is a readily available enzyme that catalyzes the condensation of dihydroxyacetone phosphate (and a few close analogues) with aldehydes (Scheme 1).[108] This enzyme accepts a number of aldehydes as substrates, and has proved useful in the preparation of a number of rare, unnatural, and isotopically labeled sugars.[109,110] The preparation of 6-deoxyfructose-1-phosphate (a precursor to the flavoring agent Furaneol) provides one example.[109]

Scheme 1. Stereochemistry of carbon-carbon bond formation catalyzed by rabbit muscle aldolase. R is widely variable. R′ must be H or OH. Dihydroxyacetone phosphate is only slightly variable. $P = PO_3^{2\ominus}$.

Although rabbit muscle aldolase is the only enzyme in this class which has been explored for synthetic application, a large number of relatively readily available enzymes display the ability to catalyze aldol and reverse aldol reactions (Table 5).[111-121] Given the current interest in synthetic organic chemistry in directed aldol reactions,[122-126] and in the synthesis of carbohydrates,[127-130] we expect that the aldolases will be one class of enzymes which will experience substantial development as synthetic catalysts over the next years.

Table 5. Enzymes that catalyze aldol reactions.

Donor	Acceptor	Enzyme [a]	Product	Ref.
		FDP-Aldolase		[108–111]

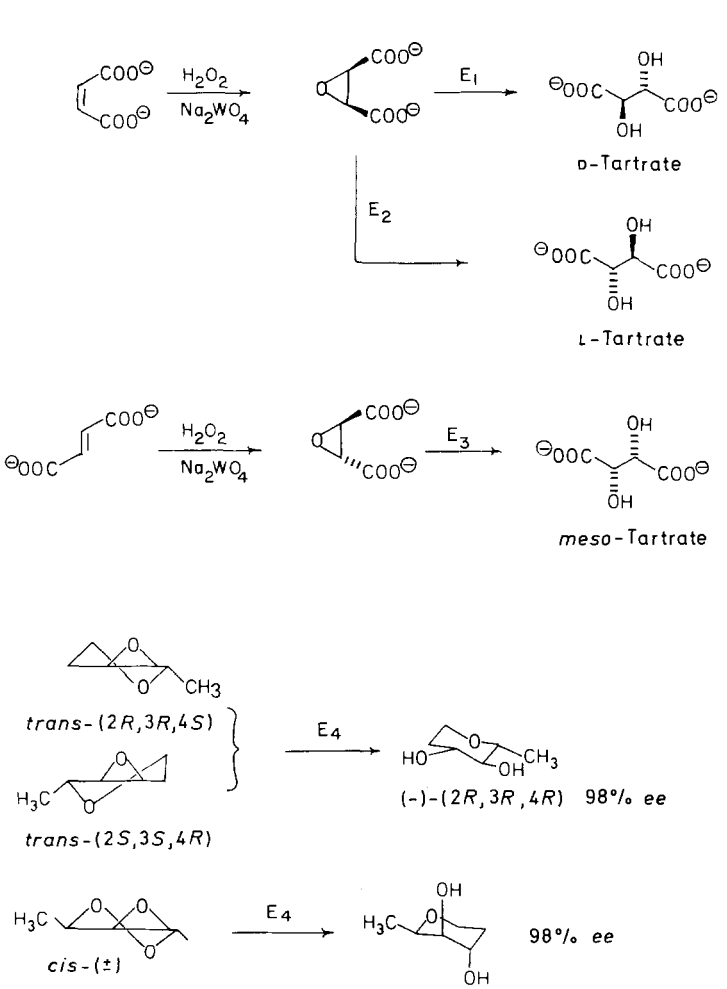
		KDO-8-P-Synthase		[119]
		Desoxyribose-Aldolase		[120, 121]

[a] Abbreviations: FDP, D-fructose-1,6-diphosphate; Fuc-1-P, L-fuculose-1-phosphate; Rha-1-P, L-rhamnulose-1-phosphate; KDO, 3-deoxy-D-mannooctulosonate; KDPG, 2-keto-3-deoxy-6-phosphogluconate; KDF, 2-keto-3-deoxy-D-fuconate; KDG, 2-keto-3-deoxy-D-glucarate; KHG, 2-keto-4-hydroxyglutarate; MHKG, 4-methyl-4-hydroxy-2-ketoglutarate; KDHA, 2-keto-3-deoxyheptonate.

6.1.4. Isomerases and Lyases

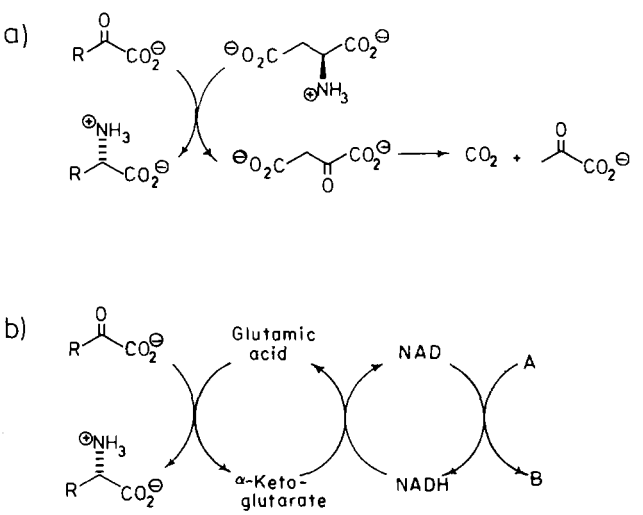


Several important commercial applications of enzymes rest on these types of enzymes. For example, glycosidases are used in large quantity in conversion of cornstarch to glucose,[131–134] and glucose isomerase catalyzes the equilibration of glucose and fructose.[135–141] Aspartic acid is prepared by addition of ammonia to fumaric acid in a reaction catalyzed by aspartase,[142] and malic acid by hydration of fumaric acid catalyzed by fumarase.[143] These transformations, by themselves, are not of major interest to synthetic chemists. The enzymes responsible for them are, however, readily available, and the range of substrates that they will accept has not been explored in detail.

6.1.5. Other Enzymes

Cyanohydrolases from several sources catalyze the enantioselective condensation of HCN with aldehydes.[144] *S*-Adenosylhomocysteine hydrolase catalyzes the synthesis of *S*-adenosylhomocysteine (or analogues) from homocysteine and adenosine (or analogues).[145–149] NADase catalyzes exchange of the nicotinamide residue of NAD with nicotinamide analogues. This enzymatic process provides a useful route to analogues of NAD.[150–152] Different phospholipases are available for selective hydrolysis of phospholipids. Phospholipases A_1 and A_2, for example, catalyze the hydrolysis of the ester groups at *sn*-1 and *sn*-2 positions of the glycerol moiety, respectively.[153–155] Phos-

pholipase D catalyzes transphosphatidylation using phosphatidylcholine and other amino alcohols as substrates.[153-155] These three enzymes have been used to prepare different types of phospholipids.[156] Glycosidases (for example, β-galactosidases) are useful in preparing glycosides and oligosaccharides.[157,158] 1-Deoxy-1-fluorosucrose—a compound which is stable to hydrolysis by invertase and which is recognized by sucrose carrier protein—has been prepared from UDP-glucose and 1-deoxy-1-fluoro-D-fructose in a reaction catalyzed by sucrose synthetase.[159]



Enzymes catalyzing addition of ammonia or hydrolytic removal of amino groups also have potential application. L-Phenylalanine has been synthesized by addition of isotopically labeled ammonia to cinnamic acid catalyzed by phenylalanine ammonia lyase.[4] Large-scale production of L-citruline from L-arginine provides a representative example of hydrolytic deamination.[35] Regiospecific epoxide opening catalyzed by epoxide hydrases may have potential in the preparation of polyhydroxy compounds.[160] Scheme 2 illustrates the use of this class of enzymes in the synthesis of D-,[161] L-,[162] and *meso*-tartaric acid,[163] and hydroxypyran derivatives.[164,165] Another potentially useful group of hydrolytic enzymes is the nitrile hydratases.[166] One such enzyme catalyzes the hydrolysis of acrylonitrile to acrylamide.[167]

Scheme 2. Reactions involving epoxide hydrolases. Abbreviations: E_1, D-tartrate epoxidase; E_2, L-tartrate epoxidase; E_3, *meso*-tartrate epoxidase; E_4, epoxide hydrolase from rabbit liver microsomes.

6.2. Enzymes Not Requiring Added Cofactors, Especially Enzymes Containing Flavins, Pyridoxal Phosphate, Porphyrins, and Coordinated Metals

In these cases, cofactors are either covalently attached to or tightly non-covalently bound to the enzymes. They are regenerated automatically during the catalytic cycle. The pyridoxal phosphate-dependent transaminases catalyze the synthesis of amino acids via transfer of the amino group from an amino acid to an α-keto acid. In most cases L-glutamate is the amine donor and is converted into α-ketoglutarate. A useful strategy for the synthesis of α-amino acids is based on transaminase-catalyzed amine transfer between an α-keto acid and L-glutamate and coupled in situ regeneration of the glutamate by reductive amination of α-ketoglutarate in a reaction catalyzed by glutamic dehydrogenase. Another group of transamination reactions using L-aspartic acid as an amine donor has the possible advantage for synthetic application that the keto acid produced (oxaloacetic acid) decarboxylates spontaneously in situ to pyruvate; this decarboxylation drives the transamination reactions[168] (Scheme 3). These methods are particularly useful for the preparation of compounds containing isotopes of short half-life, such as ^{11}C (20 min) or ^{13}N (10 min), in high purity.[169,170]

Scheme 3. Procedures for enzyme-catalyzed transamination involving an α-keto acid and a) aspartic acid or b) glutamic acid as the amine donor. Compound A is a hydride donor (for examples, see Table 7) used for in situ regeneration of NADH from NAD.

The pyridoxal phosphate-dependent enzymes tyrosinase and tryptophanase catalyze the synthesis of L-tyrosine and L-tryptophan, respectively, by condensation of three small molecules: phenol (indole for tryptophanase), pyruvate, and ammonia. By replacing the aromatic components with other phenolic analogues, new amino acids can be prepared. L-DOPA, for example, can be prepared by replacing phenol with catechol. A similar approach has been used to prepare tryptophan analogues.[171,172] An efficient synthesis of porphobilinogen from δ-aminolevulinate using catalysis by the pyridoxal phosphate-containing enzyme δ-aminolevulinate dehydratase has been demonstrated.[173,174] The flavoenzyme glucose oxidase is widely

used in the food industry as an antioxidant.[175] Under anaerobic conditions, glucose oxidase also catalyzes the transfer of electrons from glucose to acceptors such as benzoquinone.[176] In addition to determination of the optical purity of amino acids,[177] L- and D-amino acid oxidases have been used to produce α-keto acids.[35]

The $Cu^{2\oplus}$-containing enzyme galactose oxidase catalyzes the oxidation of D-galactose to D-galactaldehyde; this enzyme also catalyzes the stereospecific oxidation of glycerol and 3-halo-1,2-propanediols to L-glyceraldehyde and L-3-haloglyceraldehydes.[178] Investigations of the substrate specificity of this enzyme using a number of polyols has permitted the development of a model of the enzyme active site which rationalizes the stereospecific transformation of polyhydroxy compounds to aldehydes.[179] Several unusual L-sugars have been prepared using this method.[179] Another potentially useful $Cu^{2\oplus}$-containing enzyme, dopamine β-monooxygenase, catalyzes the stereospecific hydroxylation of the *pro-R* benzylic hydrogen of dopamine to give norepinephrine. It also catalyzes the stereoselective oxidation of heteroatoms such as S and Se, and of certain olefins.[180]

The $Fe^{2\oplus}$-containing peroxidases are able to catalyze the addition of the elements of HOX to olefin substrates starting with H_2O_2 and $X^{\ominus}$;[181-184] they also catalyze oxidation of primary alcohols and heteroatoms.[185-187] Mixtures of organic dihalides are generated by reaction between olefins, H_2O_2, and a mixture of inorganic halides; the products include compounds containing C–F bonds.[188] Horseradish peroxidase also catalyzes the selective hydroxylation of aromatic compounds at 0°C in the presence of dihydroxyfumarate, and several pharmaceuticals including L-DOPA have been prepared using this enzyme on a millimolar scale.[189] Peroxidase appears to generate highly reactive and unselective species such as singlet oxygen and hydroxy radicals during its catalytic reactions.[190,191] Whether these enzyme-based hydroxylation processes are competitive with those using fermentation[192] or organometallic catalysis[14] remains to be demonstrated. In recent, interesting work horseradish peroxidase has been modified with 2-chloro-4,6-bis[ω-methoxypoly(oxyethylene)]-*s*-triazine.[193] The modified enzyme is soluble and still active in benzene. This technique allows manipulation of apparently homogeneous solutions of the enzyme in an organic solvent. The same immobilization procedure has been used to prepare hydrophobic lipase for use in synthesis in organic media.[62]

Lipoxygenase has been used to prepare a hydroperoxy derivative for use in the synthesis of prostaglandins.[194,195] The $Fe^{2\oplus}$-containing enzyme isopenicillin cyclase has been isolated and used to prepare several analogues of isopenicillin N.[196-199] Such enzymatic reactions may be useful in generating new β-lactam antibiotics.

Another class of iron and copper monooxidases that incorporate molecular oxygen into organic substances also has been explored with interesting results, but so far without real practical utility. These enzymes convert saturated hydrocarbons to alcohols, olefins to epoxides, and heteroatoms such as N and S to oxides. They also cleave aromatic rings and steroid derivatives and dealkylate *N*- or *O*-alkyl groups.[180] Of the presently known oxygen-incorporating enzymes, bacterial methane monooxygenase[200-202] (catalyzing the hydroxylation of saturated hydrocarbons), ω-hydroxylase (catalyzing the selective epoxidation of olefins),[203-206] hepatic hydroxylase (catalyzing the oxidation of heteroatoms for preparation of drug metabolites),[207,208] and steroid hydroxylases[209,210] are in principle attractive for synthetic development. Practical use of these enzymes is limited by severe technical problems: the instability and low specific activity of the enzymes; the requirement for multiple interacting enzymes to couple NAD(P)H oxidation to reduction of O_2; the inefficient coupling of NAD(P)H oxidation to oxygen activation (with production of hydrogen peroxide and superoxide as the undesirable competing side reactions); the requirement for NAD(P)H regeneration. Certain of these problems will not be easily solved, and although these monooxygenases are potentially attractive catalysts, procedures based on fermentation and other whole-cell processes[211] are presently more practical. The problems associated with these systems are discussed in more detail below. Other oxidative enzymes—particularly cyclohexanone monooxygenase[212] (which catalyzes enzymatic Baeyer-Villager oxidation) and lipoxygenase[213]—have seen some applications in synthesis, and deserve development.

6.3. Enzymes Requiring Added Cofactors

6.3.1. Enzymes Requiring Nucleoside Triphosphates, Especially ATP

A substantial fraction of the enzymes involved in complex biosynthesis (as opposed to biodegradation) require as cofactor a nucleoside triphosphate (especially ATP) or a nicotinamide cofactor (NAD(P)H). These enzymes have not been widely used in practical-scale organic synthesis, in large part because of the cost of the cofactors when used as stoichiometric reagents. ATP costs approximately US $ 800/mol. It is, however, a relatively stable substance: in solution, the most important degradation reaction is usually the hydrolysis of the ribose triphosphate group to a di- or monophosphate (probably by traces of ATPases present in solution).[214] Thus, an efficient strategy for regeneration of ATP from ADP and AMP renders enzymatic systems requiring these cofactors practical for use. The problem of ATP regeneration is now effectively solved.[215-221] The general strategy is to use a readily obtained phosphate donor, and to regenerate ATP from ADP or AMP in situ enzymatically.[222-224] Table 6 summarizes the most

Table 6. Procedures for ATP regeneration [a].

Procedure	$\Delta G'^{\circ}_{hyd}$ [kcal/mol]	Ref.

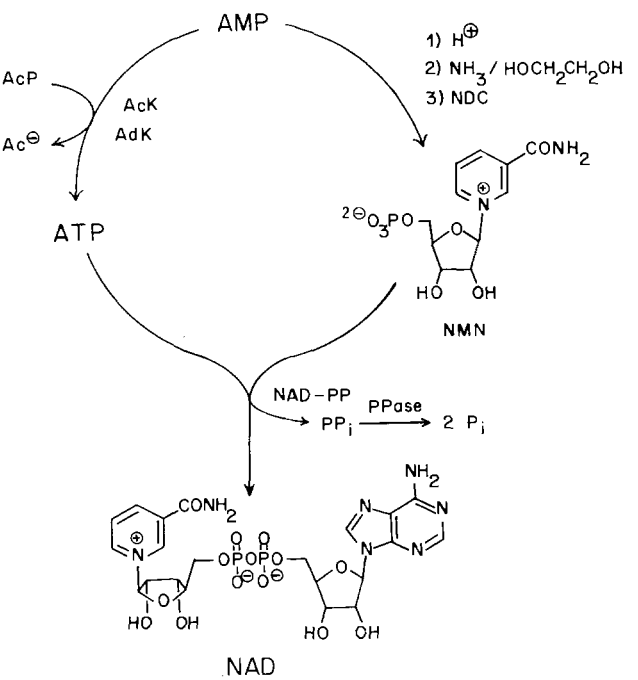
$CH_3OCOPO_3^{2\ominus}$ + ADP $\xrightarrow{AcK}$ ATP + CH_3OH + CO_2	−12.4	[221]

[a] Abbreviations: AcK, acetate kinase; PK, pyruvate kinase.

useful procedures now available for ATP regeneration. Procedures based on different phosphate donors (e.g., carbamoyl phosphate), fermentation, and other techniques are not presently practical.[225]

The most generally useful of the procedures using high-energy phosphate donors is based on acetyl phosphate. This material is readily obtained,[218,221] and two acetate kinases are commercially available. Although most of the published work has involved *E. coli* acetate kinase, the *Bacillus stearothermophilus* enzyme may be superior: the *E. coli* enzyme contains an SH group close to the active site, and is sensitive to autoxidation; the *B. stearothermophilus* enzyme is thiol-free.[219] Acetyl phosphate has two disadvantages: it is only a moderately strong phosphorylating agent (as judged by its free energy of hydrolysis, $\Delta G^{\circ\prime}$ at pH 7, see Table 6) and it is relatively hydrolytically unstable in aqueous solution. The hydrolytic instability both destroys acetyl phosphate and produces phosphate ion in solution; this phosphate complexes with and sometimes precipitates the $Mg^{2\oplus}$ required for kinase activity, and may render slow reactions difficult to control.

Regeneration systems based on phosphoenol pyruvate (PEP) are more stable: PEP is resistant to hydrolysis, and is also a very strong phosphorylating agent. Its synthesis is, however, more complex than that for acetyl phosphate.[220] A newly developed reagent, methoxycarbonyl phosphate, is as easily prepared as acetyl phosphate and roughly as strong a phosphorylating agent as PEP; it has, however, the disadvantage of even more severe hydrolytic instability than acetyl phosphate.[221] A number of other systems for regeneration of ATP have also been suggested,[35,225] but do not seem to be practical.

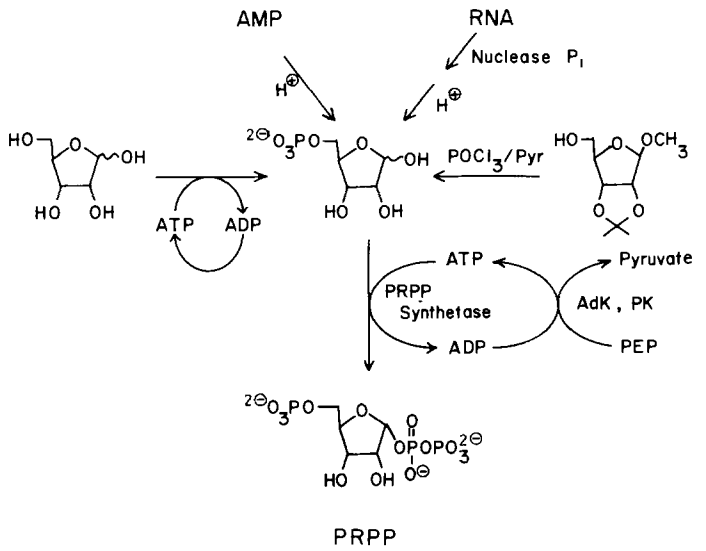


For certain large-scale applications, even given a good regeneration system for in situ reconversion of AD(M)P to ATP, the initial cost of the ATP may be significant. AMP can be purchased inexpensively in kilogram quantities and converted to ATP either in situ or in a separate step.[226] Alternatively, an efficient preparation of crude ATP from RNA has been developed.[226-228] These syntheses should render the cost of the adenosine mononucleotide moieties required for this type of synthesis unimportant on a process scale.

The other nucleoside triphosphates (GTP, UTP, CTP) and the deoxynucleoside triphosphates (dATP, dGTP, dUTP, TTP) are less important in most plausible organic synthetic applications than is ATP. Fortunately, acetate kinase and pyruvate kinase will accept all of these species as cofactors,[218,229] and thus the acetyl phosphate (methoxycarbonyl phosphate)/acetate kinase and PEP/pyruvate kinase systems will regenerate all of these nucleoside and deoxynucleoside triphosphates from the corresponding diphosphates.

Most of the simple applications of ATP regeneration systems have been to the preparation of sugar phosphates using kinases. Glucose-6-phosphate is a useful reagent for reduced nicotinamide cofactor regeneration;[230] dihydroxyacetone phosphate is a reagent for use in aldol reactions catalyzed by rabbit muscle aldolase;[108,109] *sn*-glycerol-3-phosphate[233] has the correct absolute configuration to serve as the basis for the synthesis of phospholipids; arginine phosphate[221,231] and creatine phosphate[224] illustrate the synthesis of materials which themselves have high phosphate-donor potentials, and are therefore thermodynamically difficult to prepare. These kinases are also useful in the preparation of modified nucleoside triphosphates (e.g., ATP-γ-S[232] and ATP-α-S[233]).

Of these simple kinase-based systems, the most broadly applicable in synthesis is, at present, that using glycerol kinase. This enzyme accepts a number of three- and four-carbon substrates, and yields enantiomerically enriched products.[234] It can be used in kinetic resolutions.



More complicated processes requiring regeneration of ATP are illustrated by syntheses of NAD(P) and phosphoribosyl pyrophosphate (PRPP). The synthesis of NAD(P) (Scheme 4)[235,236] illustrates a practical procedure which successfully combines classical organic and enzymatic synthetic methods. The reaction sequence avoids the use of protecting groups, chromatographic separations, and complicated purifications. This preparation still does not compete with isolation as a source of NAD,[237-239] but it does provide sufficient chemical flexibility to permit synthesis of a number of isotopically and structurally modified analogues of NAD(P).

Scheme 4. Synthesis of NAD from AMP. Abbreviations: AcP, acetyl phosphate; AcK, acetate kinase; AdK, adenylate kinase; NAD-PP, NAD pyrophosphorylase; PPase, pyrophosphorylase; PP_i, pyrophosphate; NMN, nicotinamide mononucleotide; NDC, *N*-(2,4-dinitrophenyl)-3-carbamoylpyridinium chloride.

The synthesis of 5-phospho-D-ribosyl-1-pyrophosphate (PRPP)—a key intermediate in the biosynthesis of nucleotides—is another example which involves the use of an ATP regeneration system in a large-scale preparation of a substance difficult to synthesize using classical techniques.[240] This procedure should open new routes to nucleotides and other analogues.

One feature of the syntheses summarized in Schemes 4 and 5 deserves special comment: the use of enzymatic selectivity to circumvent the normal requirement for purifi-

Scheme 5. Synthesis of 5-phospho-D-ribosyl-1-pyrophosphate (PRPP). Abbreviations: Pyr, pyridine; PK, pyruvate kinase; PEP, phosphoenolpyruvate.

cation of intermediates. In classical multistep synthesis, it is important to purify intermediates, because impurities present in them will react in subsequent steps and, ultimately, generate mixtures of products which can be purified only with difficulty. In enzyme-catalyzed synthesis, requirements for purification of an intermediate may be less strict, because the enzyme will only accept its substrate. Processing of a crude reaction mixture through an enzyme-catalyzed step thus constitutes a form of purification. In Scheme 4, for example, the conversion of AMP to NAD was carried through with essentially no purification of intermediates at any point; the final crude NAD was accepted as a substrate by enzymes. Since purification of these types of molecules is often a major nuisance, the ability to use crude reaction mixtures directly in enzymatic synthesis may be a major practical advantage of an enzyme-based strategy.

6.3.2. *Enzymes Requiring Reduced Nicotinamide Cofactors (NADH or NADPH)*

The problem of cofactor regeneration involving the nicotinamide cofactors is more complex than that for the nucleoside triphosphates: the nicotinamide cofactors are more expensive than ATP (the least expensive is NAD: ca. US$ 1000/mol), and are, more importantly, intrinsically unstable in solution. The reduced nicotinamide cofactors are destroyed by several processes, the most important of which is a Lewis acid-catalyzed protonation on the dihydronicotinamide ring, followed by addition of water to the resulting iminium salt and further irreversible degradation.[230, 241] Thus, even given the existence of a good regeneration system, it is still important to keep the rate of the enzymatic reaction high, since the ratio of productive turnover of the nicotinamide cofactor by enzyme-catalyzed reaction to nonproductive hydrolytic destruction depends upon this rate. A very large amount of work has been devoted to developing and testing various types of systems for NAD(P)H reduction;[36, 230, 242–255] examples are summarized in Table 7. Of these, three now seem useful for synthetic applications.

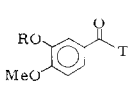
Table 7. Systems for in situ regeneration of NAD(P)H from NAD(P) [a].

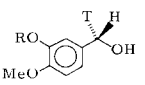
Regeneration Reaction	Ref.
$HCOO^{\ominus} + NAD \xrightarrow{FDH} CO_2 + NADH$	[36, 244]
G-6-P + NAD(P) $\xrightarrow{\text{G-6-PDH}}$ 6-PG + NAD(P)H	[230]
Glucose + NAD(P) $\xrightarrow{GDH}$ Gluconate + NAD(P)H	[255]
$H_2 + NAD(P) \xrightarrow[MV, LipDH]{H_2ase} H^{\oplus} + NAD(P)H$	[247]
$C_2H_5OH + NAD(P) \xrightarrow{ADH/AldDH} CH_3CO_2^{\ominus} + NAD(P)H$	[251]
$CH_3OH + NAD \xrightarrow{ADH/AldDH/FDH} CO_2 + NADH$	[251]
$H_2 + NAD \xrightarrow[MV]{Proteus\ mirabilis} H^{\oplus} + NADH$	[252]

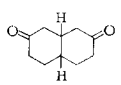
[a] Abbreviations: FDH, formate dehydrogenase; G-6-P, glucose-6-phosphate; G-6-PDH, glucose-6-phosphate dehydrogenase (*L. mesenteroides*); 6-PG, 6-phosphogluconate; GDH, glucose dehydrogenase (*B. cereus*); H_2ase, hydrogenase; MV, methyl viologen; LipDH, lipoamide dehydrogenase; ADH, alcohol dehydrogenase; AldDH, aldehyde dehydrogenase.

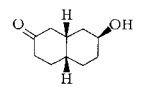
Formate/Formate Dehydrogenase has two advantages as a regeneration scheme: formate is a strong reducing agent, and the product of reaction, CO_2, causes no complications in workup. Formate dehydrogenase (from yeast), although commercially available, is still relatively expensive; a good preparation has been reported by *Kula* et al.[36]

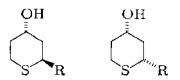
Glucose/Glucose Dehydrogenase is also an attractive system.[255] The enzyme (from *B. cereus*) is commercially available, thermally stable, and applicable to both NAD and NADP. The major disadvantages of the system are the expense of the enzyme and the requirement to separate product from glucose and gluconic acid.

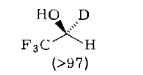


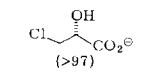


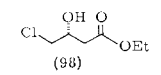








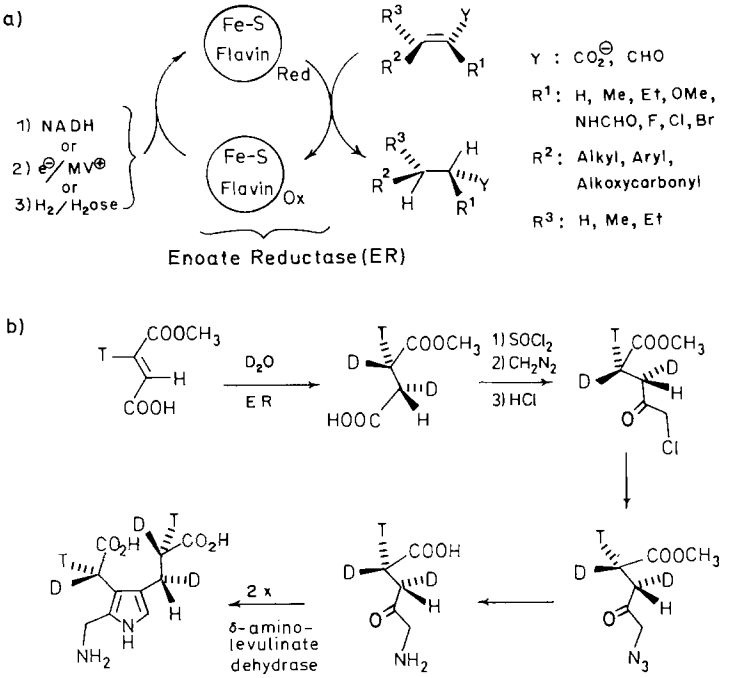




Glucose-6-phosphate/Glucose-6-phosphate Dehydrogenase has the advantage that the enzyme is very inexpensive and stable, and that the enzyme system accepts both NAD and NADP as substrates.[230] The glucose-6-phosphate must, however, be prepared (by hexokinase-catalyzed phosphorylation of glucose with in situ ATP regeneration) and the product must be separated from the 6-phosphogluconic acid produced as product.

A scheme starting with methanol and using a coupled enzyme system of methanol dehydrogenase, formaldehyde dehydrogenase, and formate dehydrogenase probably represents the most economical system available from the vantage of the ultimate hydride donor.[251] The system is not convenient to use for small-scale work, because it requires three enzymes. For large-scale work, however, it might well be worth the effort to develop a single microbial source for the three enzymes which could be used in a whole-cell package. The remaining systems for reduced nicotinamide cofactor regeneration are presently primarily of academic interest, although electrochemical procedures continue to attract attention.[252] In practice, schemes that use inexpensive reducing agents (H_2, electrons) emphasize the wrong feature: the expense in the reaction lies in the enzyme and the cofactor, not in the ultimate reducing

agent. These systems should not be discounted: with appropriate development, they may ultimately prove useful. They are not, however, the systems which are presently the most useful in organic synthesis.



Synthetic application of the enzymes requiring reduced nicotinamide cofactors has so far been restricted to research applications. The most highly developed process is that described by *Kula* et al. for the production of amino acids.[136] Other applications have involved asymmetric reductions of carbonyl compounds, and production of isotopically labeled species (Table 8).[256–259] (A system based on deuterated formate and formate dehydrogenase provides the best system presently available for the introduction of deuterium through a nicotinamide-cofactor-catalyzed process.)[259] It is, however, important to emphasize that the problem of cofactor regeneration is only one of several that must be solved in utilization of the NAD(P)H-requiring oxidoreductases. At least as important are the problems of enzyme cost, enzyme stability, and product inhibition. This last problem is particularly difficult to solve in a general way, and is important because it places constraints on the ultimate concentrations of products attainable and on the rates of reaction.[260]

Table 8. Alcohol dehydrogenase-catalyzed reductions of carbonyl compounds using NAD(P)H as the hydride donor.

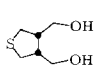
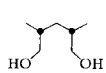
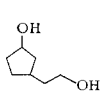
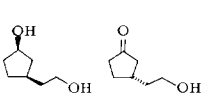
Another reducing enzyme that shows promising synthetic utility is the enoate reductase from the anaerobe *Clostridium kluyvery*.[252,263] The enzyme reduces different α,β-unsaturated carboxylate anions stereospecifically to the saturated carboxylate anions using NADH as a cofactor (Scheme 6a). A preliminary study regarding the reaction mechanism indicated that the reducing equivalent was transferred from NADH through the enzyme-associated iron-sulfur-flavin cluster to the substrate, and proton exchange between the reduced cluster and water was observed. The iron-sulfur cluster can be reduced with reduced methyl viologen produced electrochemically, and large-scale organic synthesis using a reactor suitable for electro-enzymatic reductions has been demonstrated.[264] Regeneration of NADH using H_2 and an anaerobic microorganism that contains hydrogenase has been developed and the regeneration system has been coupled with the *Clostridium* reduction of enoates.[252,265] The enoate reductase has also been used to prepare isotopically labeled chiral δ-aminolevulinic acid (Scheme 6b).[4] Similar asymmetric reduction of the CC double bond of α,β-unsaturated carbonyl compounds catalyzed by fermenting yeast has also been reported, but the enzyme responsible has not been isolated.[266] The reaction proceeds with formal *trans* addition of hydrogen across the double bond, with a *pro-R* hydrogen being introduced at the position α to the electrophilic substituent. It is unlikely that the yeast enzyme contains an oxygen sensitive iron-sulfur cluster because fermenting yeast is aerobic.

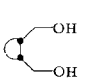
Scheme 6. Asymmetric reduction of carbon-carbon double bonds catalyzed by enoate reductase (ER). a) General reaction scheme; b) synthesis of isotopically labeled, chiral δ-aminolevulinic acid.











6.3.3. *Enzymes Requiring Oxidized Nicotinamide Cofactors (NAD or NADP)*

The problem of regeneration of *oxidized* nicotinamide cofactors is still not completely solved. The same constraints apply in this system as to those involving the reduced nicotinamide cofactors, but, in addition, the problem of product inhibition (especially kinetically mixed and uncompetitive inhibition[20]) is often severe.[260,267] The oxidized nicotinamide cofactors are also hydrolytically un-

stable in solution, and are subject to destruction in several types of enzyme-catalyzed processes. The most widely used procedure for in situ regeneration of NAD from NADH is that developed by *Jones* et al.[268] This system is based on the (non-enzyme-catalyzed) reoxidation of NADH by oxidized flavin; the reduced flavin is in turn oxidized by molecular oxygen. The disadvantage of this system is that large quantities of flavin are required to achieve useful rates, and that the separation of product from flavin is inconvenient. A number of other systems have been proposed for this regeneration.[2,242,243,269,270] Probably the most general involves oxidation of NADH to NAD coupled with enzyme-catalyzed reduction of α-ketoglutarate and ammonia to glutamic acid.[267,269] This system has the advantage that it avoids the exposure of the enzymatic system to dioxygen, with the concomitant risk of oxidation of enzymes or substrates. It has the disadvantage that glutamic acid must be separated from the product at the conclusion of the reaction. An enzyme-catalyzed system based on diaphorase and methylene blue is also useful for reoxidation of NADH to NAD when dioxygen (the ultimate oxidizing agent) can be tolerated by the system.[243,267,270,271] The flavin mononucleotide (FMN) reductase (E.C. 1.6.8.1) from photobacterium species catalyzes the reaction of NAD(P)H with dioxygen and FMN;[271] this enzyme has satisfactory specific activity (ca. 100 U/mg) and markedly improves the efficiency of the regeneration system developed by *Jones* et al.

The most important body of work devoted to synthetic applications of enzymes requiring oxidized nicotinamide cofactors has been that of *Jones* and coworkers, and of other groups,[272-277] concerning applications of horse liver alcohol dehydrogenase. Examples of these transformations are given in Table 9. These reactions, although highly practical on the scale of several grams, have not been carried to large-scale work. Several problems have hindered this stage of development. First, until recently, the available regeneration systems have not been truly practical for large-scale work. Second, horse liver alcohol dehydrogenase is particularly subject to product inhibition. Many of the most successful examples of *Jones* et al. are based on the oxidation of *meso*-diols to optically active lactones. These systems seem to be relatively free of product inhibition. Attempts to achieve kinetic resolutions of simple alcohols by oxidation of one enantiomer have, in general, been relatively unsuccessful on large scale. The active site of alcohol dehydrogenase appears to be hydrophobic, and to bind the product ketone more strongly than the reactant alcohol.[274,278,279] This specific system has been analyzed in some detail. There appears to be no general strategy to deal with product inhibition, other than to remove the product as it is formed by extraction or by some other technique.[21,30] When extraction is feasible (using, for example, a two-phase water-organic system to remove the ketone selectively as it is produced), the problem can be circumvented. In other circumstances, it is more troublesome.

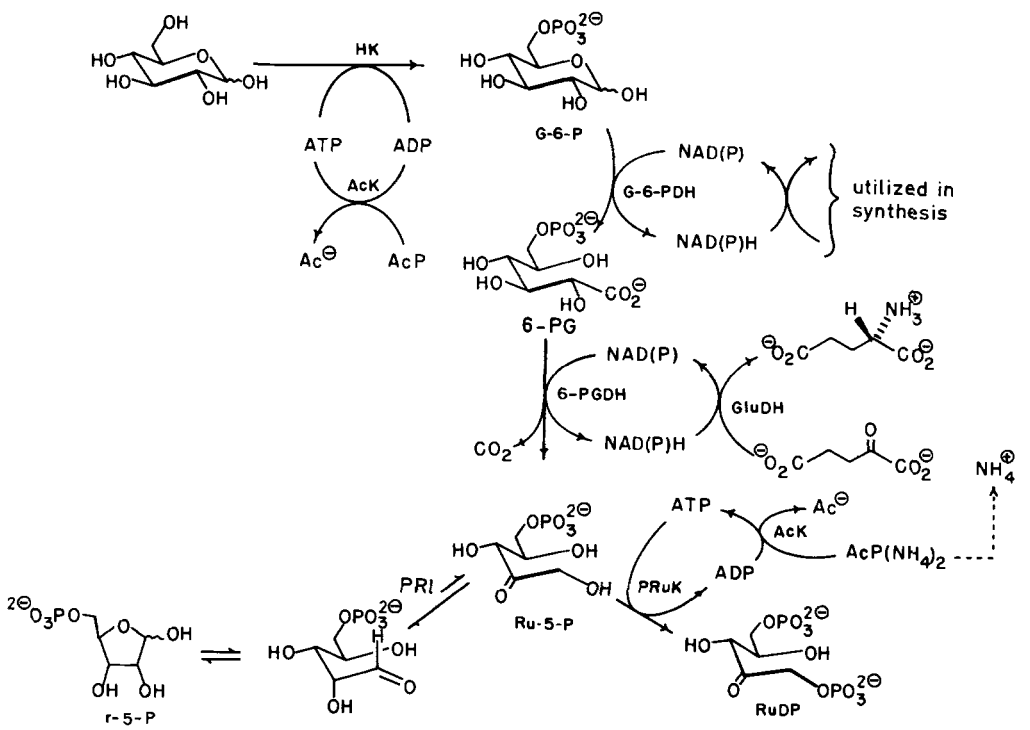
6.3.4. *Enzymes Requiring S-Adenosyl Methionine, Acetyl-CoA, PAPS, or Other Cofactors*

S-Adenosylmethionine (SAM) is an important one-carbon donor in many enzyme-catalyzed reactions.[280-282] A study of the enzymatic synthesis of SAM from ATP and methionine catalyzed by SAM synthetase from yeast concluded that the practicality of the reaction hinged upon the availability of SAM synthetase.[282] The preparation of substantial quantities of homogeneous SAM synthetase from a genetically engineered strain of *E. coli* has been described.[283] This enzyme is, however, seriously inhibited by product. The inhibition constant (K_i) of SAM vs. ATP (a competitive inhibitor) or methionine (a noncompetitive inhibitor) is ca. 0.01 mM.[282] The corresponding K_i values for the enzyme from yeast are ca. 6 mM.[284] If the *E. coli* enzyme could be modified using site-specific mutagenesis and recombinant DNA technology to increase the K_i values significantly, this procedure for the preparation of SAM could form the basis for a practical method for preparation of quantities of SAM for *stoichiometric* use in enzyme-catalyzed synthesis. No strategy for in situ regeneration of SAM is now evident. In a transmethylation using SAM as methyl donor, the product of SAM is *S*-adenosylhomocysteine (SAH). At present, there is no enzyme known which catalyzes the selective methylation of SAH to SAM. Although chemical procedures are available for the synthesis of SAM from SAH,[285] they produce racemic products and enzymes only accept the (−)-isomer.[280,286] In an alternative route to (±)-SAM, which does not require ATP as a starting material, L-homocysteine and adenosine are converted into SAH chemically[287] or enzymatically,[145-149] and SAH is methylated chemically. If resolution of SAM could be accomplished conveniently, this procedure might be valuable.

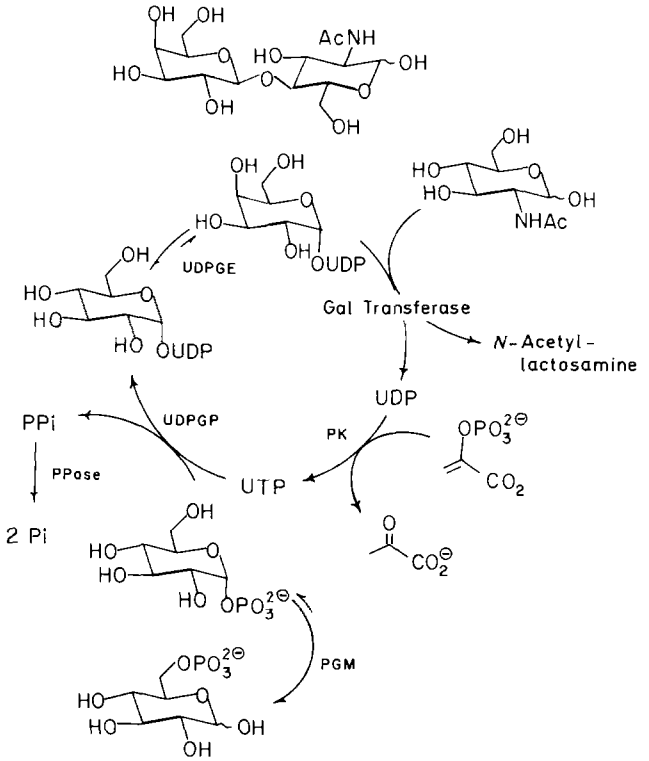
Little work has been devoted so far to synthetic applications of reactions requiring acetyl-CoA and its analogues as cofactors. Although CoASH is a broadly important cofactor in biochemistry, from a strategic viewpoint it is unclear that reactions involving it will be as important in enzyme-catalyzed synthesis as are reactions involving other

cofactors. Acetyl-CoA is central in reactions leading to fatty acids, polyketides, and derived species.[288] It is precisely these classes of compounds which classical organic synthesis is most successful in preparing. Whether enzymatic procedures offer advantages relative to chemical or fermentation routes to these compounds remains to be established.



3′-Phosphoadenosine-5′-phosphosulfate (PAPS) is a sulfate donor, universally used in biochemistry for sulfation of polysaccharides and for activation of sulfate. It is regenerated in vivo by a complex set of reactions involving the enzymes ATP-sulfurylase and adenylsulfate kinase.[289,290] Although sulfation of polysaccharides is an interesting and potentially important target reaction for enzyme-catalyzed synthesis (for example, in the modification of heparin[291] or the synthesis of chondroitin sulfate[292]), no straightforward method now exists to achieve either the synthesis or regeneration of PAPS.

7. Syntheses Involving Multienzyme Systems



A potentially important characteristic of enzymes as catalysts in organic synthesis is that, because most enzymes operate with reasonable efficiency at values of pH between 6.5 and 8.5 and at temperatures around room temperature, it is often possible to assemble complex systems containing multiple enzymes cooperating in sequence or in parallel to achieve multi-step processing of substrates. The synthesis of ribulose-1,5-diphosphate (RuDP), an important substrate in plant biochemistry (Scheme 7),[217] provides an example of a synthesis for which enzymatic catalysis provides the best solution. This synthesis, despite its apparent complexity, is actually quite straightforward, and several hundered grams of RuDP has been prepared in the course of the several reactions devoted to developing it. The point of technical interest in this synthesis is the final conversion of 6-phosphogluconate to RuDP. The kinase that converts ribulose-5-phosphate to RuDP is oxygen sensitive. Thus, the in situ regeneration of NAD from NADH required in conversion of 6-phosphogluconate to ribulose-5-phosphate cannot be carried out using an oxygen-based regeneration system. This regeneration is, however, conveniently carried out anaerobically using the α-ketoglutarate/glutamate dehydrogenase system. This part of the synthesis requires the cooperative action of four enzymes: 6-phosphogluconate dehydrogenase and 5-phosphoribulokinase for the principal conversions, and glutamate dehydrogenase and acetate kinase for in situ regeneration of cofactors.

The conversion of glucose-6-phosphate and *N*-acetylglucosamine to lactosamine provides a more complex example.[293] Lactosamine is a core disaccharide, common in glycoproteins. This synthesis (Scheme 8) illustrates the cooperative interaction of six enzymes, and establishes the utility (howbeit on a small scale) of the Leloir pathway enzymes for oligosaccharide synthesis. This type of procedure has subsequently been extended to trisaccharides.[294]

The conversion of glucose to ethanol provides a final example of a coupled multienzyme system (Scheme 9; in this scheme, several enzymes required to regulate the concen-

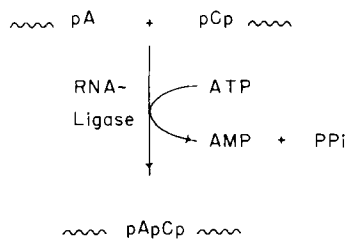
tration of ATP are omitted for simplicity). This system was not developed for synthetic purposes—there are simpler ways of obtaining ethanol—but rather to study the mechanism of ethanol toxicity in yeast and to examine the kinetic characteristics of a regulated multienzyme system.[295] Nonetheless, it establishes that it is practical to construct processes requiring sequential operation of many cooperating enzymes.

8. More Difficult Enzymatic Systems: Oxygenases and Systems for Syntheses of Macromolecules

The practicality of using monooxygenase systems has been the subject of speculation in applied enzymology for some years. Certain enzyme systems, operating in vivo, catalyze hydroxylation, epoxidation, and related oxidation reactions with selectivities that cannot be matched using classical synthetic technology. These in-vivo systems are widely important in the oxidative functionalization of steroids and other hydrocarbons (using fungal systems), and interesting isolated examples having emerged from other areas of fermentation chemistry.[211,296–299] An important recent example is the conversion of benzene to *cis*-3,5-cyclohexadiene-1,2-diol by fermentation.[300] Many of these transformations are accomplished by cytochrome P450 or non-heme iron-sulfur enzymes.[301,302] The cytochrome P-450's have been widely studied mechanistically, because of their importance in steroid metabolism and carcinogen production; the non-heme iron-sulfur proteins are less well understood.

From a practical point of view, microbial systems based on non-heme iron-sulfur and copper-sulfur enzymes are the most interesting.[200–202,303] Although these systems have been extensively examined, current indications suggest that they will not be useful for enzymatic transformations in vitro in the immediate future. They suffer from several disadvantages. First, in vitro, operating lifetimes of the enzymes are short. Many of the cytochrome P450 enzymes are membrane-bound or membrane-associated, and it is conceivable (although not yet practical) that appropriate use of surfactants or model membranes might provide valuable stabilization. The in-vivo lifetimes of the simpler microbial monooxygenases have not been carefully examined, but they also seem to be short. Perhaps more importantly, these enzymes require accessory enzyme systems as a source of reducing equivalents, ultimately used to convert dioxygen to a more reactive species at the

Scheme 9. Enzymatic pathway from glucose to ethanol. Enzymes: E1, hexokinase; E2, phosphoglucomutase; E3, phosphofructokinase; E4, aldolase; E5, triosephosphate isomerase; E6, 3-phosphoglycerate dehydrogenase; E7, 3-phosphoglycerate kinase; E8, phosphoglycerate mutase; E9, enolase; E10, pyruvate kinase; E11, pyruvate decarboxylase; E12, alcohol dehydrogenase.

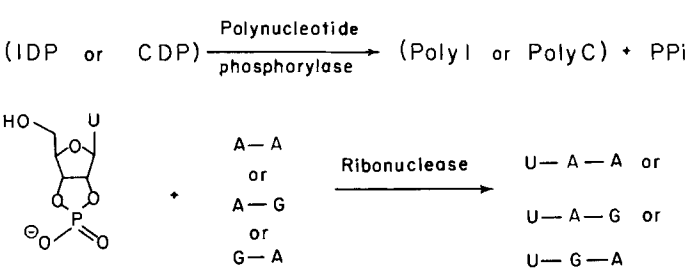


hydrogen peroxide oxidation level. These accessory enzymes typically require NADH or NADPH as the ultimate reducing agent. Thus, the final system contains a number of sensitive enzymatic components. Further, the efficiency of the coupling of oxidation of NADH to reduction of dioxygen has, so far, been poor in vitro: the majority of NAD(P)H is "wasted" in production of hydrogen peroxide or superoxide, both themselves species capable of reacting with and inactivating enzymes. It may be that the problems associated with these potentially valuable monooxygenases will ultimately be solved, but for the immediate future, these systems do not represent practical methods for oxidative functionalization of hydrocarbons.

A second class of enzymes that is attracting interest is that responsible for the synthesis of polysaccharides, oligosaccharides, and proteins.[304-306] Each of these systems represents a different set of problems. Cell-surface oligosaccharides are of substantial interest as, inter alia, disease-associated antigens and histocompatibility markers, and as reagents of possible interest in drug delivery.[304,307] In most systems, they are assembled by enzymes utilizing the Leloir pathway and localized in the Golgi apparatus.[308] These membrane-bound enzymes are usually obtainable only in small quantities. It is unresolved whether it will be more practical to base synthetic schemes on isolated enzymes or to rely on isolation from natural sources or screening for high-producing mutants for fermentation synthesis. The enzymatic systems involved in synthesis of many polysaccharides (especially those of microbial origin) are, in principle, more straightforward. Since polysaccharides cannot presently be prepared by any classical chemical technique, and because these substances have properties valuable in modification of the rheological properties of aqueous solutions and in pharmacological applications,[304-306] enzyme systems that synthesize polysaccharides may prove valuable. Again, however, no practical example yet demonstrates the utility of such systems.

Cell-free protein synthesis might provide a technique complementary to DNA methodology for certain applications.[309,310] At present, however, the complexity of the systems of enzymes required to accomplish this type of process is such that it is impractical on scales larger than micrograms.

The central scientific discoveries that have focused interest on biologically based syntheses are those leading to recombinant DNA (rDNA) technology. This technique depends on a number of enzymes that make it possible to implant desired genes into a foreign organism to produce desired proteins.[311,312] Of the enzymes used in rDNA technology, DNA ligase and restriction endonucleases are two of the most important. DNA molecules can be cleaved specifically with specific restriction endonucleases and joined with another restriction-enzyme-modified DNA fragment in a reaction catalyzed by DNA ligase. These chemical transformations cannot be accomplished by classical synthetic techniques, and the enzymatic methods might be useful in practical-scale nucleic acid chemistry. The enzymes used in rDNA research are, however, expensive. Technical problems concerning stabilization and large-scale production of enzymes need to be solved if this type of enzymology is ever to be used for preparative chemical synthesis (large-scale work is unnecessary for use in genetic engineering, because microbial growth provides large amplification). We note also that since the condensation reactions involved in forming phosphodiester links require either NAD (in reactions catalyzed by NAD ligase from bacteria, and generating AMP and NMN) or ATP (catalyzed by T_4 DNA ligase from phage-infected bacteria or from eukaryotes, and generating AMP and pyrophosphate),[310] cofactor regeneration may be required for large-scale production.



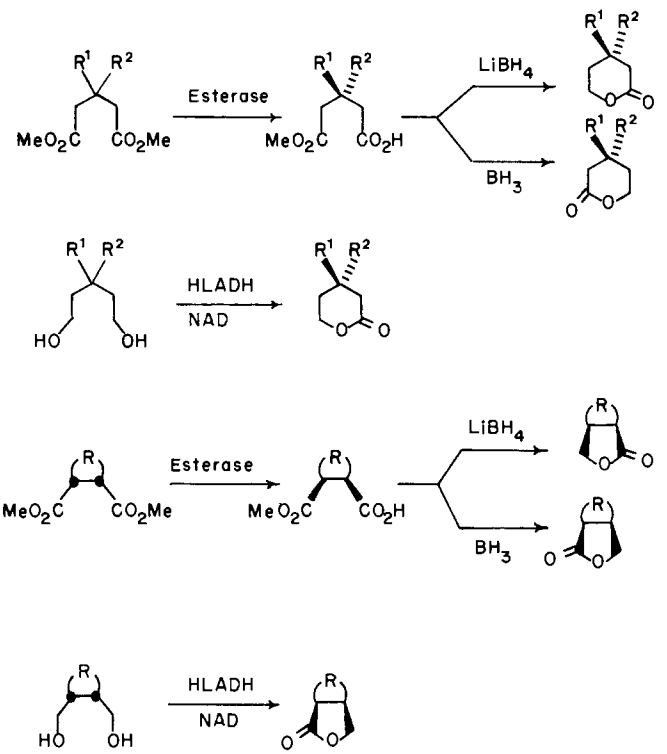
Another ligase that has been used increasingly is RNA ligase.[311,313-315] The enzyme T_4 RNA ligase catalyzes the synthesis of single-stranded oligonucleotides of different lengths from a 3′-terminal hydroxyl acceptor and a 5′-terminal phosphate donor oligoribonucleotide through the formation of a 3′→5′ phosphodiester bond, with hydrolysis of ATP to AMP and pyrophosphate. The 5′-terminal phosphate donor can be nucleotides as small as monomer units and the 3′-terminal hydroxyl acceptor can be a dimer, trimer, or oligomer.[311] The enzyme also accepts single-stranded DNA as a substrate (Scheme 10). This enzyme

Scheme 10. A representative scheme for the RNA-ligase-catalyzed formation of a 3′→5′ phosphodiester bond between oligonucleotides containing terminal A and pC.

has been used to couple short, chemically synthesized oligonucleotides to longer oligomers.[313] It also has been used for modification of nucleic acids by introducing radioactive probes and by replacing nucleotide residues.[311-316] Since applied biology based on rRNA technology may be important for the future, and since chemical methods for the synthesis of RNA are not as well developed as those for DNA, RNA ligase could play an important role in this area.

Two other examples of polynucleotide synthesis deserving mention are the polynucleotide phosphorylase-catalyzed synthesis of polyI:C[317] (an inducer of interferon) and the ribonuclease-catalyzed synthesis of trinucleotide codons[318] (Scheme 11). These two enzymes have a broad

Scheme 11. Synthesis of polynucleotides catalyzed by polynucleotide phosphorylase, and of trinucleotides catalyzed by riconuclease.



range of specificity; they can thus be useful for the synthesis of other polynucleotides.

9. Summary and Outlook

Enzymes are catalysts that are useful in a variety of synthetic problems: synthesis of chiral fragments; transformations of sugars, nucleotides, and related species; synthesis of compounds important in metabolism and analogues of these metabolites (amino acids, sugar phosphates, etc.); transformations of peptides and proteins; transformations of compounds present in foods and other transformations in which classical chemical methodology is constrained by regulation. What are the technical problems that must be solved to consolidate and extend these uses? What are the barriers that a synthetic organic chemist must overcome in order to use enzyme-catalyzed synthesis?

The two major barriers to the use of enzymes are probably educational. The first is that of learning the basic techniques of enzymology and biochemistry, especially the specialized techniques of analysis and isolation of enzymes. Neither is difficult, but both require skills that are not familiar to most classically trained synthetic chemists. Standard biochemistry textbooks are helpful in learning these techniques; *Bergmeyer*'s series provides an indispensible reference for enzymatic assays.[319] A short apprenticeship in a biochemistry laboratory is exceedingly helpful. A second, more serious problem (at least in considering the feasibility of including enzymology in a proposed synthetic sequence) is finding out whether an enzyme is known (or, better yet, commercially available) that can plausibly carry out the transformation of interest. This problem is a difficult one to solve. There is presently no reference that describes enzymology from the vantage of a synthetic chemist, that outlines the types of synthetically useful transformations which might be expected from a given class of enzymes, or that details the enzymes capable of conducting a particular type of transformation. Most enzymes have not, in fact, been examined for their utility in synthesis, and the nomenclature of enzymology is not helpful in establishing activity for new transformations. This article lists several of the enzymatic systems that have been explored in sufficient detail to be helpful in organic synthesis; the series *Methods in Enzymology* and *Bergmeyer*'s series give sample procedures involving enzymes (usually on an analytical scale) that are helpful in suggesting new applications. In the absence of specific solutions from these sources, the synthetic chemist can only consult his biochemical colleagues, and test enzymes known to operate on substrates analogous to those of interest in the proposed process.

If an enzyme can be found that effects the desired transformation, what determines the practicality of a process based on this enzyme? Clearly, technical features—the availability of the enzyme, its specificity, specific activity, and stability, its cofactor requirements—are of primary importance in evaluating the practicality of a specific enzyme. Of greater interest to most organic synthetic chemists is a broader question of strategy. Enzymes should be regarded simply as one more type of catalyst, and the best synthetic procedures will be those that make the most efficient and best integrated use of all of the available techniques—classical organic synthesis, homogeneous and heterogeneous catalysis by metals, catalysis by enzymes, fermentation, electrochemistry, conventional resolution, and other methods. In certain instances—for example, the use of DNA ligase and restriction endonuclease to close and open nicks in DNA—enzymes have no competition from other techniques. In production of chiral synthons for use in synthesis of pharmaceuticals, the range of options open to the synthetic chemist is much larger. The optimal strategies for using enzymes are still evolving. For example, is it more efficient to use horse liver alcohol dehydrogenase to oxidize a *meso*-diol to a lactone (taking into account the problems of cofactor regeneration and product inhibition) or to use an esterase in combination with a chemical oxidation (Scheme 12)? For resolution of a new epoxy alcohol, is it better to use asymmetric epoxidation[17] or an esterase? For production of large quantities of short oligopeptides, is catalysis by selected amidases starting from minimally protected amino acids in dehydrating media preferred, or are conventional chemical coupling procedures superior? None of these questions presently have categorical answers. The general point is, however, that the range of plausible applications of enzymes in organic synthesis is much larger than might be supposed by the range of their present use. Enough experimental background is now available that many of the generic problems involved in applying enzymes as catalysts have been solved.

Scheme 12. Alternative routes to optically active lactones.

Certain problems in synthesis will unquestionably benefit from use of enzymatic catalysis. Synthetic chemists capable of using this class of catalysts will have a clear advan-

tage in their ability to tackle the new generation of problems in synthesis appearing at the border between chemistry and biology. Those unwilling to use these and other biologically derived synthetic techniques may find themselves excluded from some of the most exciting problems in molecular science.

Work at Harvard University was supported by the National Institutes of Health (Grant GM 30367); that at Texas A & M University was supported by the National Science Foundation (Grant CHE-8318217). We wish to thank our many colleagues for their essential contributions to the planning, execution, and analysis of our own research in this area; the names of these persons are listed individually in the references.

The Construction of New Proteins and Enzymes—a Prospect for the Future?**

By Manfred Mutter*

Dedicated to Professor Paul J. Flory on the occasion of his 75th birthday

Only a vanishingly small proportion of the almost infinite number of possible proteins occur in nature. Can this remaining potential of structural and functional diversity be used in the construction of new proteins? Is a "second evolution" of proteins and enzymes about to occur? These questions have suddenly become of interest because the recombinant DNA technique allows the synthesis of any given amino acid sequence. Examples of enzyme models demonstrate clearly that the unusual catalytic properties of enzymes are associated with the presence of a specifically folded polypeptide chain which has a complex three-dimensional form. The critical hurdle in the path of artificial proteins is thus the design of amino acid sequences which are able to fold into *tertiary structures*.—Recent studies on the topology and the mechanism of folding have provided considerable insight into the occurrence of, and the rules governing the three-dimensional architecture of proteins. Secondary structures apparently play a key role in the folding process; helices and "β-structures" act as nucleation centers directing folding and account for the surprisingly small number of different folding topologies. The problem of secondary structure formation can be investigated directly by means of conformational studies on model peptides. Oligopeptides with tailor-made physicochemical, structural and conformational properties can already be designed. The theoretical and experimental basis for the construction of polypeptides with stable tertiary structures is therefore established. The path to macromolecules with an immense variety of novel properties lays before us.

1. Introduction

The unusual catalytic properties of enzymes are the focus of interest in diverse research activities. The capability of enzymes to accelerate reactions specifically and selectively is being increasingly exploited by chemists, as it far exceeds that of synthetic catalysts.

Of the astronomical number of possible amino-acid sequences, only an incredibly small proportion occurs in nature. Those chains which can fold to produce a globular, three-dimensional structure (tertiary structure), and can thus perform biological functions, have been selected in the evolutionary process. Proteins and enzymes are thus optimized systems for performing specific biological functions and this is reflected by a complexity of structures and functions that is still poorly understood. In the light of this background the following question arises: Can new molecules with enzyme-like structural and functional properties be created? This problem could be approached in two ways:

—by transferring enzyme-specific characteristics to more easily accessible molecules,

—by designing new proteins with unnatural amino acid sequences ("artificial proteins"[*]).

What are the possibilities and limits of the scientific and practical uses of the construction of new proteins and enzymes?

Critical analysis of the "enzyme-like" catalysts that have so far been developed shows that the complex relationships between enzyme-specific structural features and properties (such as the spatial orientation of reactive groups, specific ligand and substrate binding, creation of a local hydrophobic environment, or allosteric control) only occur with multifunctional, *macromolecular* structures.[1,2,10] On the other hand, the imitation of *individual* enzyme-typical properties by simple structures is of considerable importance for practical applications. The following questions must be answered in connection with the construction of artificial enzymes:

Is the complex, *three-dimensional* architecture of proteins a prerequisite for enzyme-analogous functions? Has nature created 'surplus' complexity—in the sense of 'molecular tinkering'?[45]

These questions will be dealt with in Section 2 of the present progress report; the problem will be illustrated using the hydrolytic activity of "enzyme models" based on polymers, particularly polypeptides.

St.-Johanns-Ring 19, CH-4056 Basel (Switzerland)

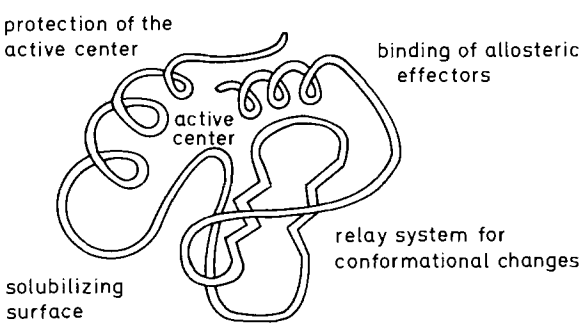
[**] Extended version of a lecture given on being awarded the Max Bergmann Prize, 3rd Max Bergmann Conference, October 7—9, 1982, Bolzano (Italy).

[*] "Artificial proteins" are defined here as polypeptide chains, containing an amino acid sequence non-homologous to one in nature, that are able to fold into a tertiary structure and thus possess features typical of proteins; "artificial enzymes" are artificial proteins with catalytic activity.

The idea of constructing new proteins with tailor-made functional properties has become of topical interest due to the development of the DNA recombination technique (genetic engineering).[3] In principle, it is already possible to reliably construct any given amino acid sequence. The almost unlimited number of sequence permutations provides an immense potential of structural and functional diversity for designing new proteins. The problem that has to be solved is therefore not so much the synthesis of the primary sequence but rather the understanding of how proteins acquire their spatial structures. The "tertiary structure puzzle" is thus the real obstacle hindering the construction of artificial proteins. Even though the "folding code" still has to be deciphered,[4] X-ray structural analysis has at least thrown considerable light on the rules governing the spatial construction of proteins.[4-6] In Sections 3 and 4 of this report a discussion of these fundamental considerations is followed by a discussion of a strategy for constructing new proteins based on current knowledge of the relationships between primary, secondary, and tertiary structures.

2. Must Enzymes Have a Tertiary Structure?

A look at the sometimes surprisingly clearly organized and comparatively simple structures of the active centers of enzymes[7-9] suggests that perhaps an enzyme-analogous function could be obtained by developing much more simple molecules. The formation of an active center in which, for example, functional groups interact specifically as a result of spatial fixation does not seem in principle to be limited to peptide structures (i.e. to a backbone consisting of amino acid building blocks). This likewise applies to other typical structural features of enzymes e.g. to a hydrophobic nucleus within a hydrophilic solubilizing surface (Fig. 1).[10]



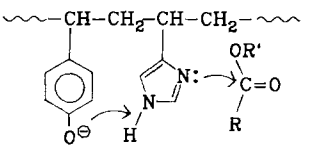


Fig. 1. General structural and functional characteristics of enzymes. The different properties of an enzyme are based on its complex three-dimensional structure which results from the characteristic folding of the polypeptide chain.

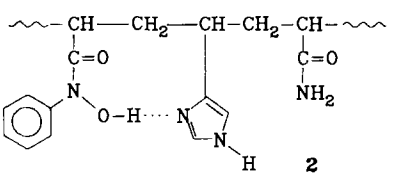
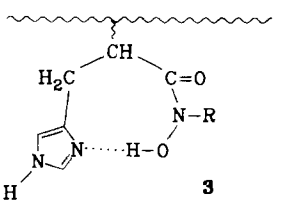
The selection of models which follow aim to imitate these features of enzymes.



2.1. Polymeric Catalysts as Enzyme Models

The range of possibilities for the synthesis, functionalization, and derivatization of synthetic polymers gives the imagination of almost unlimited scope for imitating enzyme-specific properties. The majority of publications on polymeric catalysis are concerned with the influence of hydrophobic and cooperative effects on the catalytic activity of imidazole as a model for enzymes containing histidine.[1,2,11-13] A copolymer composed of 4-vinylimidazole and *p*-vinylphenol accelerates the reaction rate of the hydrolysis of active esters significantly compared with the monomeric starting compounds. This can be explained in terms of a cooperative mechanism.[14,15]



1

Cooperative effects of spatially neighboring functional groups are also found in copolymers of the type **2**, in which the nucleophilicity of the hydroxamic acid group is

2

enhanced by hydrogen bond formation (in a similar manner to the serine-OH of α-chymotrypsin).[16,17] Compounds of type **2** react according to a typical two-step mechanism in which the deacylation step is accelerated by the neighboring imidazole group and is two orders of magnitude higher than with the monomers. The catalytic activity can be increased further if the functional groups participating in cooperative interactions are covalently fixed in the basic building block **3**.[13,18,19]

3

However, the catalytic activity of these systems is sometimes appreciably reduced by polymer effects which are caused by conformational and sterically controlled interactions within the tangled polymer.[1]

Polymeric catalysts with a random-coil structure have randomly orientated functional groups due to the high flexibility of the chain.[20,83] Moreover, the structure is generally heterogeneous so that experimentally determined rate constants are often difficult to interpret. This applies particularly to "enzyme models" which are based on statistical functionalization or polymer-analogous derivatization of cross-linked or branched polymers (e.g. polyethyleneimine).[21-24] Due to the complex interactions between the catalyst, substrate and solvent, systematic investigation of the individual parameters of critical importance for catalysis is

only possible in models with a well-defined structural organization. This requirement is satisfied in "single center" models[2, 25, 26, 28] (Fig. 2).

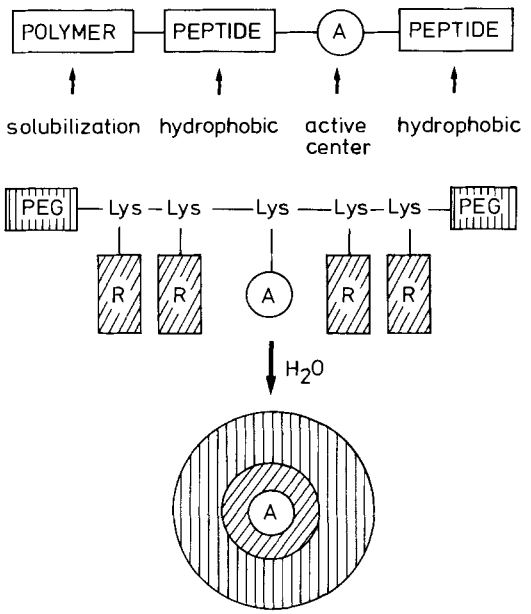


Fig. 2. Single-center model for the study of enzyme-like catalysis. The peptide (e.g. oligolysine) with a hydrophobic side chain R (e.g. a mesogenic N^{ε}-amino protecting group) is synthesized stepwise on soluble polymers (e.g. PEG, polyethyleneglycol) so that the active center A (e.g. NH_2, imidazole, histidine hydroxamic acid) can be incorporated selectively. In contrast to polyfunctional models, the macromolecule only possesses *one* active center in a well-defined environment. In an aqueous medium aggregation of the side chains results in the formation of micelle-like structures in which A is located in the hydrophobic core and the solubilized PEG chain imitates the enzyme surface [25, 26, 28].

The differential functional and structural characteristics of an enzyme are copied here using a block copolymer. The polymer block aids solubilization and also allows stepwise synthesis of the peptide block[27, 81, 89] whose functional and physicochemical properties can be modified in a specific way.[26, 28, 161] In the system shown in Figure 2 for example, the hydrolytic activity with *p*-nitrophenyl laurate can be increased by a factor of up to 10^4 by micelle-like inclusion of the active center in a hydrophobic environment.[26] The selective synthesis of oligopeptide chains in the *side-chain* of polyfunctional supports represents a variation of this principle[29, 169, 170] (Fig. 3).

An important step in the direction of enzyme-like catalysis is the spatial fixation of functional groups by stiffening

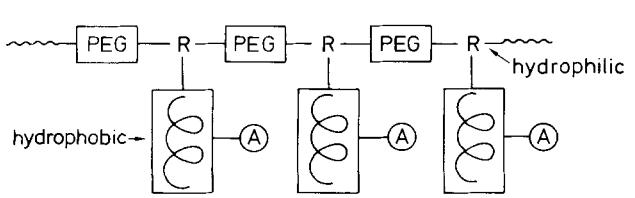

Fig. 3. Polymeric catalysts as enzyme models: Oligopeptides which tend to form secondary structures are built up in the side chains of sequential polyether blocks (PEG). In an aqueous environment the amphiphilic character of the macromolecule results in the formation of cluster-like structures in which the active centers A are located in the hydrophobic peptide layer [29].

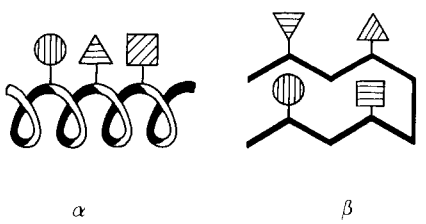
the flexible backbone. Polypeptide chains are suitable candidates for this as they can form hydrogen bonds. Polymerization of amino acids of the active center of α-chymotrypsin produces, however, polypeptides with a random-coil structure and consequently very low catalytic activities.[30–32]

Chain flexibility can be reduced by cyclization of the peptide.[53–149] However, hydrolysis experiments using cyclic model peptides of type **4**, in which cooperative inter-

cyclo(-Gly-L-His-L-Ser-Gly-L-His-L-Ser-) **4**

actions between the side chains of Ser and His can be expected, demonstrate that the rate of hydrolysis of *p*-nitrophenyl acetate is only slightly affected.[33–35] The synthesis of peptide sequences with secondary structure opens up completely new possibilities for modelling enzyme activities; catalytically active groups can be immobilized and specifically positioned with respect to each other by selectively incorporating trifunctional amino acids in α-helix- or β-structure-forming host peptides[36–38] (Fig. 4).



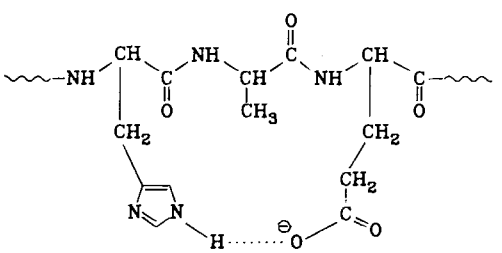


Fig. 4. Secondary-structure-forming peptides as enzyme models: Specifically incorporated functional groups can be positioned with respect to each other due to the formation of α-helix and β-structures or β-hairpins; these groups thus exhibit enzyme-like cooperative effects.

Formation of a partial α-helix structure in the sequence **5** produces a cooperative effect between the His and Glu side chains.[37]

Poly(L-His-L-Ala-L-Glu) **5**

Similarly, stabilization of the helix structure is observed for the sequence **6** (which serves as a model for the active

H-(L-Met)$_6$-L-Glu-(L-Met)$_2$-L-His-(L-Met)$_3$-L-Ser-(L-Met)$_6$-OH **6**

center of α-chymotrypsin) as a result of the formation of a hydrogen bonding system between the Ser, His and Glu side chains.[39]

The sequence **7**, designed on the basis of CPK model studies, is a novel variation.[40] The functional groups are

Ac-His-Phe-Gly-Cys-D-Phe-Ser-Gly-Glu-Cys-NH_2 **7**

orientated and fixed by incorporating a β-turn and by S–S bridge formation. The hydrophobic pocket required for substrate binding is provided by the strong interactions of the Phe side chains. The low catalytic activity of this model indicates that formation of a hydrogen bonding system is a necessary but not sole condition for α-chymotrypsin-like hydrolytic activities.[41] This finding seems to be confirmed by recent studies.[42,43]

2.2. What can "Synthetic Enzymes" Learn from Natural Enzymes?

The examples selected from the large number of enzyme models show that synthetic catalysts are indeed "capable of learning"; enzyme-specific properties such as reaction acceleration as a result of cooperativity or modification of the microenvironment of active groups, saturation kinetics, substrate affinity and specificity, can, within certain limits, be conferred on functional polymers and polypeptides. However, the effects are found to be several *orders of magnitude* smaller than those of natural enzymes. It is therefore debatable whether terms such as "enzyme-like polymers" or "synthetic enzymes" ("synzymes") are justified.[1] Any improvements of synthetic catalysts are, however, of practical importance for applications in organic synthesis: although this has not yet been successfully achieved,[1,2,44] studies on the significance of hydrophobic and cooperative effects have yielded results that point the way for further investigations. On the other hand, the examples given demonstrate that the simplified model concepts for enzymatic catalysis are far removed from reality. *Morawetz*'s remark[167] that synthetic macromolecular catalysts have produced "no new information whatsoever for the enzyme chemist" is a logical consequence and still largely applies today. The mechanism of the catalytic function is often less easy to understand in model systems than in the enzyme itself; this is particularly true of polymeric catalysts (both homogeneous and heterogeneous) whose active groups are arranged statistically.[1,2,11,12]

Enzymatic catalysis involves the complex interplay of individual effects[48–52] and is thus dependent on a macromolecular structure whose backbone and reactive groups exhibit a definite spatial architecture. The ability to fold specifically to form a rigid backbone conformation with crystal-like packing[9] would, however, appear to be a privilege of polypeptide chains.[10,20] Consequently the *first step* on the way to artificial proteins and enzymes must be the development of amino acid sequences that can fold into tertiary structures. The infinite diversity of potential primary sequence variations reflects both the complexity and the degree of difficulty of this undertaking. The question "How do proteins acquire their tertiary structure?" must therefore be dealt with first.

3. The Puzzle of "Tertiary Structure"

The questions as to "why" and "how" proteins fold still remain unanswered despite the enormous amount of information on their folding mechanism, topology and structure-activity relationships.[4,5,46,47,163] *Jaenicke* has recently published a clearly presented article on the problem of protein folding.[5] Only those aspects of this subject that are of importance for the present problem will therefore be discussed here.

3.1. Why Does a Polypeptide Fold into a Tertiary Structure?

It has been possible to answer this question from the point of view of the energy balance of a single polypeptide chain in a defined medium ever since *Anfinsen*'s fundamental renaturation-denaturation studies on ribonuclease.[54,55,64] The energy balance of the entire system for the thermodynamically controlled equilibrium between the unfolded (denatured) and folded (native) conformations

$$\Delta G = \Delta H - T\Delta S_{SOL} - T\Delta S_{CH}$$

proves to be a relatively small difference between large values. The chain entropy ΔS_{CH} that predominates in the denatured state must be compensated in the native conformation by the sum of the intramolecular interaction energies ΔH (hydrogen bonds, Van der Waals forces, and Coulomb forces) and the (positive) solvation entropy ΔS_{SOL} ("hydrophobic interaction"). A stable tertiary structure is thus an optimized system in which the driving forces for folding are the minimization of hydrophobic areas of contact with the hydrophilic solvent and the optimization of intramolecular interactions.[55–57] The formation of a stable tertiary structure in solution is a specific property of polypeptides, which possess structure-stabilizing components formed by intramolecular hydrogen bonding in addition to the highly restricted conformational space of the individual amino acid building blocks[168] (reduction of ΔS_{CH}). Synthetic polymers, with their much more flexible chains, cannot emulate this. The ability of a polypeptide chain to form a stable tertiary structure is, however, more of an exception than a rule. Presumably, only very few of the large number of possible peptide chains (a peptide chain with n amino acids can have 20^n different sequences) can produce a stable tertiary structure (estimated number of proteins found in nature $\sim 10^9 - 10^{10}$). It is thus clear that the statistical synthesis of primary sequences yields polypeptides with random coil conformations.

3.2. How Does a Polypeptide Fold into Its Tertiary Structure?

All the information that a polypeptide requires to fold into its unique, native conformation is stored in its primary sequence. It can now be assumed that the native conformation represents a thermodynamically favorable conformation with a minimum free energy.[9,55,58–60] This is the only way of explaining why the polypeptide chains belonging to one species fold to select a single, native conformation from a multitude of starting conformations (a peptide chain containing 150 amino acids has $\sim 10^{45}$ potential conformations!). Whether this conformation represents the *overall* minimum of the multidimensional hypersurface of the conformational space is still a matter of debate.[4,5,46,50]

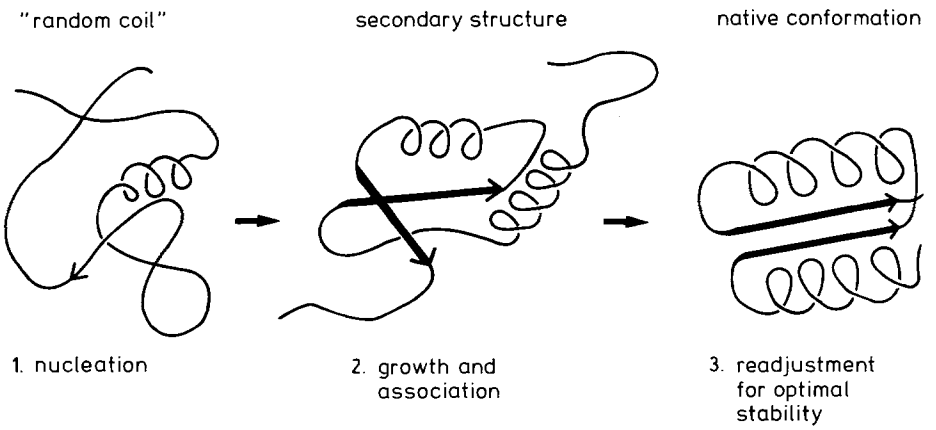

Fig. 6. Hypothetical mechanism of the folding of a linear polypeptide chain into its native conformation [4, 6, 46]. In a first nucleation step the unfolded, disordered polypeptide chain (random coil) forms regions with secondary structure (especially α-helices, β-hairpins, β-sheets) as a result of short-range interactions; these regions, which are stabilized by medium-range interactions, control folding into the tertiary structure by means of aggregation. The native conformation is then formed as a result of long-range interactions, whereby the protein assumes a crystal-like density due to optimal intramolecular readjustment of the side chains.

Experiments with the aim of predicting the native conformation from the primary sequence by means of empirical conformational energy calculations have so far failed due to the "multi-minima problem".[55,60-64] A multitude of local minima occurs in the minimization of the conformational energy of even medium-sized peptides[60-63], so that it is almost impossible to find the overall or lowest-energy minimum without other starting assumptions (e.g. the starting conformation for energy minimization in the vicinity of the overall minimum[60-62]) (Fig. 5).

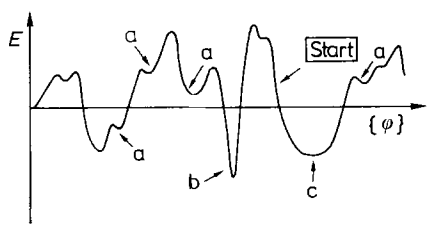

Fig. 5. Multidimensional hypersurface of the conformational energy: During minimization of the conformational energy E (sum of the Van der Waals, Coulomb, and rotation potential terms [20]), a large number of local minima (a) is found. This so-called "multi-minima problem" means that the conformation of the biologically active protein cannot be calculated solely from the amino acid sequence without preliminary experimental information about its structure (which would, for example, result in a *starting* conformation close to the overall minimum (c)). Whether the native molecule occurs in a local (a), absolute (b), or overall (c, with inclusion of the chain entropy) minimum is still a matter of controversy [5, 46].

Current concepts of the folding mechanism presume that the molecule does not try out all the possible folding pathways (and thus all the potential conformations—a peptide chain of 150 amino acids residues would require $\sim 10^{26}$ years to do this) but that a kinetically controlled, multistep folding process is adopted[4,6,46,65-68] (Fig. 6).

Fluctuating nucleation centers are formed in the first step of a single-chain, single-domain protein as a result of short-range interactions; these centers consist mainly of α-helices, β-structures, and β-bends (folding sites).[6,69-71] It is assumed that these nucleation centers are not stationary but rather distribute themselves along the peptide chain in rapid equilibrium with the disordered (random coil) conformation in accordance with their initiation enthalpies. In the second stage, secondary structure blocks associate under the influence of medium- and long-range interactions. Finally, specific readjustments are made to the side chains within the molecular chain in a slow process which involves optimization of all the intramolecular interactions; the areas of secondary structure formed originally may disappear.[183] The last folding step consists of the association of domains or subunits. The intermediary formation of *secondary structures* thus occupies a key position in the folding process.

3.3. The 'Anatomy' of the Tertiary Structure

X-ray structural analyses of a rapidly growing number of proteins have led to the surprising result that the number of different topologies is very small. After extensive study of the recurring features of protein structures, the proteins so far investigated can be divided into a small number of groups that exhibit similar patterns of tertiary structure.[6,9,69,72-74] Structural order principles within the hierarchical organization of proteins provide the basis for this type of protein classification (Fig. 7).

Folding units with characteristic organization of the secondary structure blocks (supersecondary structures)[75,76] appear to be *the* building element of proteins. The central importance of secondary structure blocks in the formation of tertiary structures is ultimately due to the folding mechanism itself. During the folding process only sufficiently stable intermediate structures are relevant for the kinetics of protein folding. Energetic consideration of the initiation and growth of potential intermediate structural units (α-helices, β-hairpins, β-bends, hydrophobic clusters) shows that α-helices and β-hairpins are especially suitable as nucleation centers for folding.[7] It can be deduced from these considerations that

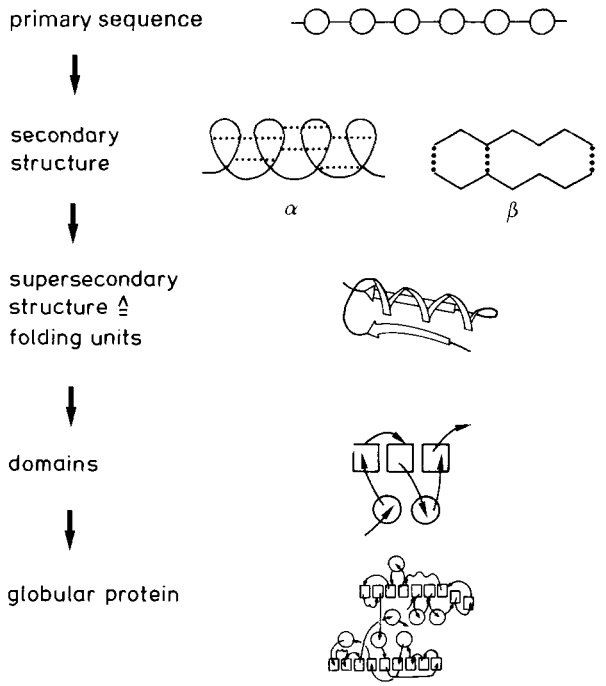

Fig. 7. Hierarchy of protein topology [69, 72]: Secondary structures such as α-helices and β-sheets associate to form characteristic supersecondary structures (e.g. βαβ folding units) via loops, these structures can be considered as the smallest building elements of domains. The globular structure is a result of intramolecular interactions between independently foldable domains.

1) the nucleation centers formed in the first stage of folding determine the topology and thus the structural type of the protein;
2) frequently occurring folding units that are independent of the primary sequence and the function of the protein are energetically preferred types of structure (Fig. 8).

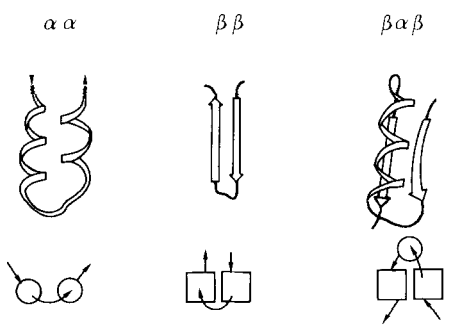

Fig. 8. Folding units (supersecondary structures) as the smallest building elements of a tertiary structure [6, 75, 76]; αα: two helical segments are connected by a loop; ββ: antiparallel pleated sheet that is linked to a β-hairpin via a β-turn or loop; βαβ: a helix lies above, and antiparallel to a β-sheet. The special stability of this folding unit is due to the amphiphilic character of the secondary structure blocks which produces a hydrophobic cluster inside the molecule and a hydrophilic surface.

In view of these aspects, it is not surprising that in many cases the tertiary structures of proteins are largely unaffected by exchange of amino acids.[77,78] On the other hand, systematic alteration of the primary sequence within the active center by means of point mutations provides insight into the structure-activity relationship of enzymes and permits the selective modification of specific properties ("protein engineering"[79]). Degeneration of the folding code is of critical importance for the construction of artificial proteins; a given tertiary structure is not bound to a specific primary sequence. The modification or complete exchange of the primary sequence with retention of the tertiary structure thus provides guidelines for the construction of artificial proteins.

4. The Secondary Structure as the Key to the Construction of New Proteins

A review of the current knowledge of the tertiary structures of proteins shows that the "folding code" is still far from being deciphered.[5] At the moment the multi-minima problem and the complexity of the folding mechanism seem to obstruct insurmountably the prediction of tertiary structures (3°) from primary sequences (1°) without prior assumptions:

$$1° \not\longrightarrow 3°$$

The deciphering of the folding code is not, however, a prerequisite for the construction of new proteins. The critical question here is: Can a coding primary sequence be found (from many potential sequences) for a given tertiary structure?

$$3° \xrightarrow{?} 1°$$

4.1. Protein Topology as a Starting Basis

Analysis of protein topologies and the postulated folding mechanism indicates the central importance of *secondary structure* in the formation of the tertiary structures of proteins.[69,72] Comparison of common topologies in proteins with different functions gives surprisingly good agreement of the spatial constructions of folding units.[80,164-166] Although the 'βαβ' type folding units shown in Figure 9 do not correspond with one another as regards their function and primary sequences, their geometrical projections[80] (length and arrangement of the helix and β-sheet blocks) are almost identical.

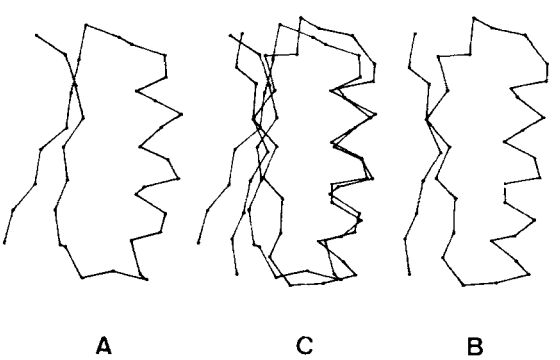

Fig. 9. Comparison of the spatial architecture of βαβ folding units [80]: Despite their different amino acid sequences the two peptide segments (A = 5-lactate dehydrogenase, sequence D47-D84; B = l-arabinose binding protein, sequence L3-P41) possess a characteristic folding unit of the βαβ type with an almost identical spatial structure as is shown by superposition of the two peptides (C).

The formation of the same spatial structures despite different coding of the peptide chains indicates that independently foldable regions within the protein are involved. Accordingly, these "supersecondary" structures represent the smallest polypeptide chains that are capable of folding and are possibly a measure of the "critical size" required for a tertiary structure. However, long-range interactions are still usually needed to stabilize the entire structure; this is due to the lability of the secondary structure blocks which form the tertiary structure.

Conformational studies on partial sequences have revealed that isolated segments do not usually have the same conformations as those found in the complete protein. A transition from a secondary structure to a random-coil conformation is often observed. The development of peptide segments with *stable secondary structures* thus represents a decisive hurdle on the way to constructing a tertiary structure with minimal size and maximal stability:

$$3^\circ \xrightarrow{\text{topology}} 2^\circ \xrightarrow{?} 1^\circ$$

4.2. Primary Sequence and Secondary Structure

Systematic conformational studies on model peptides are especially informative for the determination of the relationship between primary sequence and secondary structure. During the past few years investigations on monodisperse homo- and co-oligopeptides have in particular provided considerable insight into the formation, stability and sequence-dependence of secondary structures.[81, 82, 84, 85, 89, 90–95, 106]

4.2.1. Critical Chain Lengths of α-Helices and β-Structures

Circular dichroism measurements[82, 84, 86, 87] show that in the stepwise synthesis of helix-forming homooligopeptides there is a continuous transition from the disordered (random-coil) conformation to the α-helix structure. The critical chain length for inducing a helical structure is seven amino-acid residues in helix-promoting solvents such as trifluoroethanol and complete formation of a helical structure in solution is observed with fifteen amino-acid residues (Fig. 10).

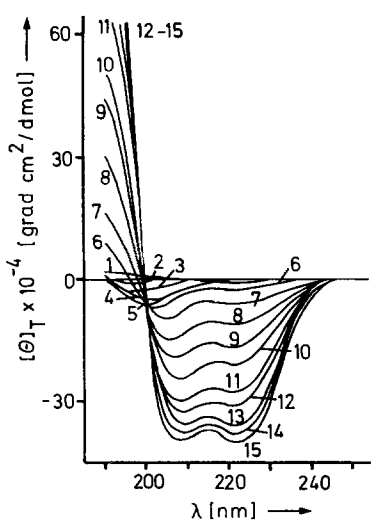

Fig. 10. Critical chain length c_n for α-helix formation: On extending the chain length, the homooligopeptide Boc-(Met)$_n$-PEG in trifluoroethanol gradually changes from a disordered conformation (n = 6) to an α-helical structure which is completely established when there are approximately 15 amino acid residues (characteristic Cotton effects in the CD spectrum at λ = 207 nm and 222 nm) [87].

β-Structures are generally formed with shorter chain lengths (n ≈ 6), the random-coil→β-conformation transition being sometimes very sharp (Fig. 11).[88, 96, 125] These

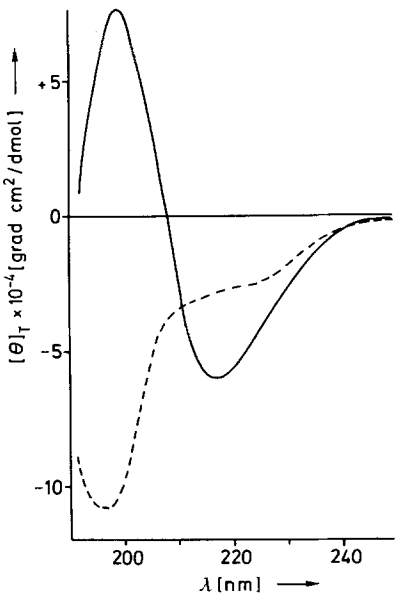

Fig. 11. Critical chain length c_n for the formation of β-structures: CD spectrum of (Ser-Leu)$_4$-Gly-PEG (—) in H_2O and Leu-(Ser-Leu)$_3$-Gly-PEG (---). The amphiphilic peptide with eight amino acid residues exhibits a sharp conformational transition from the disordered conformation to the β-structure (negative Cotton effect at λ = 218 nm). The C-terminal PEG chain solubilizes the otherwise poorly soluble peptide [125].

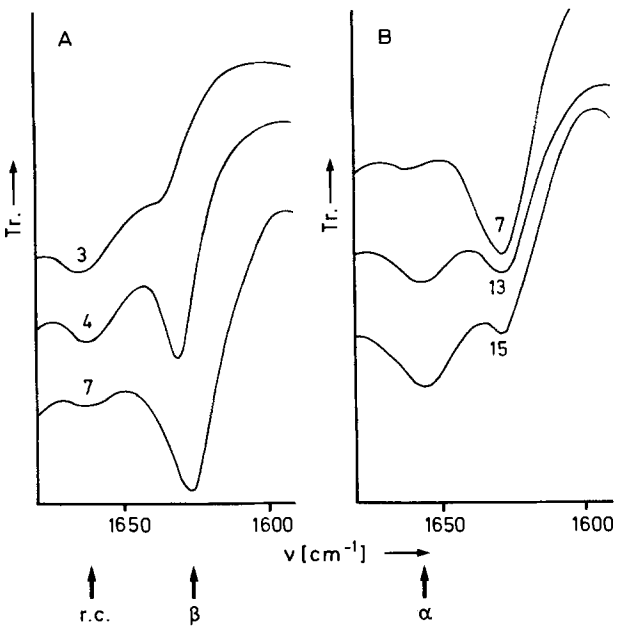

Fig. 12. IR spectrum of [Lys(Z)]$_n$-PEG in the solid state [96]. The oligopeptide shows a conformational transition from the random coil (r.c.)→β-structure→α-helix which can be clearly seen using the amide I absorption band. The band at ν = 1656 cm^{-1} (n = 3, 4), which is typical of the r.c. conformation decreases on chain extension in favor of the band at ν = 1635 cm^{-1} (n = 7, β-structure) (A); the transition to the α-helix is characterized by the reappearance of an absorption band at ν = 1655 cm^{-1} (n = 13–15) (B). (Tr = transmission.)

experimental findings reflect the different free energies for the initiation and growth of α-helices and β-structures.[64, 71] This also accounts for the random coil→β-structure→α-helix conformational transition that is frequently observed in the stepwise chain extension of homooligopeptides[81, 86, 87, 96] (Fig. 12).

The critical chain lengths for the formation of α-helices and β-structures are significantly smaller for *homo*oligopeptides than for *sequential* peptides. Interestingly, these critical chain lengths required for obtaining stable secondary structures correspond to the lengths of secondary structure blocks often observed in proteins despite the absence of long-range interactions which contribute to stabilization in the protein.[6, 69] *Homooligopeptides* are therefore potential candidates for stable nucleation centers in the construction of proteins.

4.2.2. *The Stability of Secondary Structures*

The stability of secondary structures is determined by a combination of short-range (side chain with its own backbone) and medium-range (neighborhood-dependent) interactions within the peptide chain. It is now accepted that short-range interactions determine the initiation of α-helices, β-structures, and β-hairpins.[60, 97, 98] Studies on host-guest peptides (Fig. 13) have shown, however, that the stability of β-structures is significantly affected by neighborhood interactions.[81, 99–101] The incorporation of guest amino acids in a β-structure-forming host homooligopeptide leads to destabilization of the secondary structure regardless of the specific conformational properties of the guest amino acid.[36, 81, 102] Accordingly, the stability of secondary structures is determined by the internal symmetry of the peptide side chains and is greatest in *homooligopeptides*. Incorporation of merely one guest amino acid with a voluminous side group (e.g. L-Val) into the center of a host peptide (e.g. oligo-L-Ala) can result in complete destruction of the secondary structure.[36, 102, 103] This information can only be obtained experimentally and is of fundamental importance for the design of sequences with functional properties, which form secondary structures.

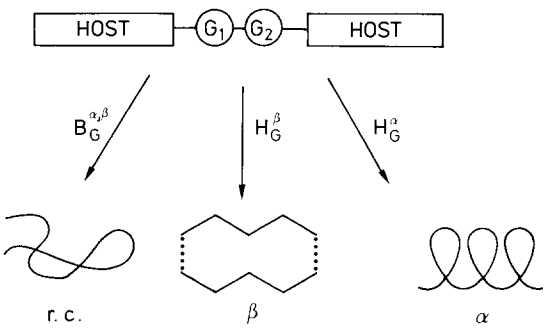

Fig. 13. Host-guest model for the study of the conformational preferences of amino-acids and peptides [36, 102]. The incorporation of guest amino-acids (G) influences the tendency of the host peptide to form secondary structures (e.g. oligo-Ala, -Val, -Met) in a characteristic fashion. The introduction of secondary-structure-breaking amino-acids (B = hydrogen-bond breaker [105]) produces the random coil (r.c.) conformation. In contrast, the incorporation of α-helix- or β-structure-forming amino acids (H = hydrogen-bond former [105]) stabilizes the secondary structure of the host-guest peptide. These model peptides can be used to determine the conformational parameters of individual amino acids (and their derivatives with protected side-chains) under different experimental conditions as well as to establish the role of short- and medium-range interactions in the formation of secondary structures.

4.2.3. *The Prediction of Secondary Structures*

Prediction of secondary structures for given primary sequences with the aid of statistically determined conformational parameters and empirical rules ("prediction codes") is already one of the standard methods used to investigate the conformation-dependent properties of peptides and proteins.[104–116] The empirical prediction schemes originally developed by *Chou* and *Fasman*[104, 105] were clearly presented and thus useable by the protein chemist in his daily work; they have, however, been continually modified due to the rapidly expanding amount of data available (from X-ray structural analyses of proteins). The improvements made to the accuracy of prediction hardly seem, however, to justify the increased complexity of the various prediction algorithms.[81, 109, 114] The statistical-mechanical method of *Scheraga* and *Tanaka* serves as a symptomatic example of this;[107] this method was the first to include neighborhood-dependent interactions in the computer-assisted calculations. The α-helix regions and—with greater uncertainty—the β-sheets and the β-bends can be located in proteins but the position of the ends of periodic secondary structures still presents considerable difficulties. Significant improvement of empirical prediction algorithms is not to be expected due to the inherent limitations of the method (e.g. long-range interactions are not considered quantitatively).[81, 109] Prediction of the secondary structures of *short-chain* peptides with a *given primary sequence* with the aid of these statistical algorithms is even more difficult on account of the effects exerted by solvents and by terminal groups on the preferred conformation in solution. The experimental information obtained from studying model peptides yields considerably more reliable insight into the relationship between the primary sequence and the secondary structure.[36, 81] Empirical prediction methods are consequently only of limited value for the present problem.

4.3. Peptides with Secondary Structure as "Building Elements"

The availability of tailor-made oligopeptide blocks with stable secondary structures for use as building elements (having specified chain lengths and physical properties) is a strategic prerequisite for the construction of artificial proteins. Systematic studies on model peptides have revealed that homooligopeptides of medium chain length tend to form secondary structures. The preferred type of conformation is determined by the side chains. Although the hydrophobic aliphatic amino acids produce stable β-structures in the order Ala < Leu < Val < Ile even with chain lengths of n = 6–8, the values of n for helix formation are considerably higher, particularly in aqueous systems. A 'trick' can be used to regulate the length of the helix block: incorporation of a strong helix-inducing amino acid such

as aminoisobutyric acid (Aib) reduces the critical chain length for helix formation as desired depending on the incorporated Aib.[117-121] Even pentapeptides containing Aib can form a helical structure.[122]

The amphiphilicity of secondary-structure-forming peptide blocks plays a critical role as the driving force for the folding of a linear polypeptide chain into a tertiary structure. Alternating hydrophobic and hydrophilic amino acid residues in the primary sequence produce layer structures[123-125] which are characterized by the formation of hydrophobic clusters (with release of solvation entropy ΔS_{SOL} (Fig. 14). Interestingly, the critical chain lengths for

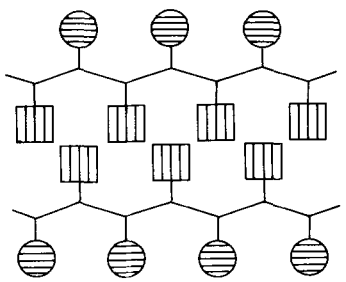

Fig. 14. Formation of a hydrophobic cluster due to the production of layer structures in amphiphilic peptides [123, 125]. The repetitive structure results, if β-sheets are formed (cf. Fig. 11), in a conformation in which the hydrophobic (▥) and hydrophilic (⊜) side chains are orientated on different sides of the peptide backbone.

the formation of amphiphilic β-structures lie in the same order of magnitude as those for homooligopeptides.[125] The sequence $(Ser\text{-}Leu)_n$ forms, for example, a complete β-structure in water even when n = 4 (Fig. 11).

Amphiphilic helices can be produced in a similar fashion by repetitive incorporation of hydrophilic amino acids (Glu, Gln, Lys) in basic hydrophobic structures.[126,127] A continuous transition to a helical structure, similar to that observed in homooligopeptides, is also found for the sequence $(Ala\text{-}Aib\text{-}Glu\text{-}Glu)_m$[127] (Fig. 15).

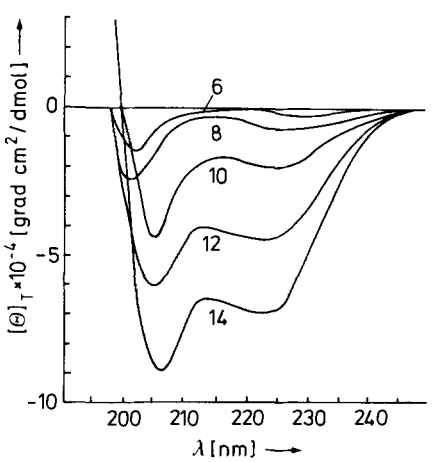

Fig. 15. Critical chain length c_n of amphiphilic helical structures: CD spectrum of $(Ala\text{-}Aib\text{-}Glu\text{-}Glu)_m$-PEG in H_2O [127]. The transition from a disordered conformation (random coil) to a helical structure occurs when there are approximately 10 amino acid residues. The amphiphilic helix in which the hydrophilic (Glu) and hydrophobic (Ala, Aib) amino acid residues are situated on different sides of the helix cylinder is completely established when the chain length is n ≈ 14.

The production of hydrophobic interactions along the helical axis generally seems to be a critical driving force for helix formation. A method (helical wheel) for predicting α-helices is thus based on the concept of determining amphiphilic structures along the peptide chain.[108,115]

β-Turns (β-bends) play an outstanding role as nucleation centers; they are produced as a result of short-range interactions. This dominance of short-range interactions is reflected in the differing coding tendencies of the individual amino acids to form β-turns. Empirically[128,129] and experimentally[130-132] determined parameters can be used to predict β-turns. The examples selected show that secondary-structure-forming peptide blocks with tailor-made structural, conformational and physico-chemical properties can, in principle, already be designed and synthesized.

4.4. From Secondary to Tertiary Structure

Analysis of the topology, folding mechanism and the relationship between the primary and secondary structures forms the basis of a general strategy for constructing polypeptide chains that can fold into tertiary structures (Fig. 16). The starting point for the design of a tertiary structure is provided by tailor-made oligopeptides with a secondary structure, which act as stable nucleation centers and determine the topology of the chain backbone. The laws governing the folding topology of natural proteins serve as "building plans" for the three-dimensional architecture whereby frequently observed folding units should be regarded as the smallest domains of an artificial protein (Figs. 7, 8). The primary sequence is designed bearing in mind

—the maximum stability of the secondary structure blocks (homooligopeptides) and
—the optimum intramolecular interaction energy of the folded polypeptide (amphiphilic sequences).

It is an advantage to have hydrophilic amino acids in the loops, as these are less important for the overall stability.

Functional amino acids or active centers must be inserted into the backbone of the host peptide without reducing the stability of the tertiary structure. Experimental results[36] show that the following priorities should be chosen: loops > α-helix > β-sheets. Suitable modifications of the primary sequence can be made in order to stabilize the tertiary structure (e.g. by S—S bonds, Coulombic contacts, complex formation). These changes can be planned most efficiently by molecular modeling in conjunction with conformational energy calculations.

The concept described here for the construction of foldable polypeptide chains is closely related to the current understanding of the protein folding mechanism. The tertiary structure results from the association of rigid secondary structure blocks in a kind of intramolecular aggregation. This strategy thus differs fundamentally from the concept of changing given *primary sequences* of proteins by replacing amino-acids while retaining the secondary or tertiary structure;[79,150] such modeling of peptides and proteins with the aim of altering their physicochemical or func-

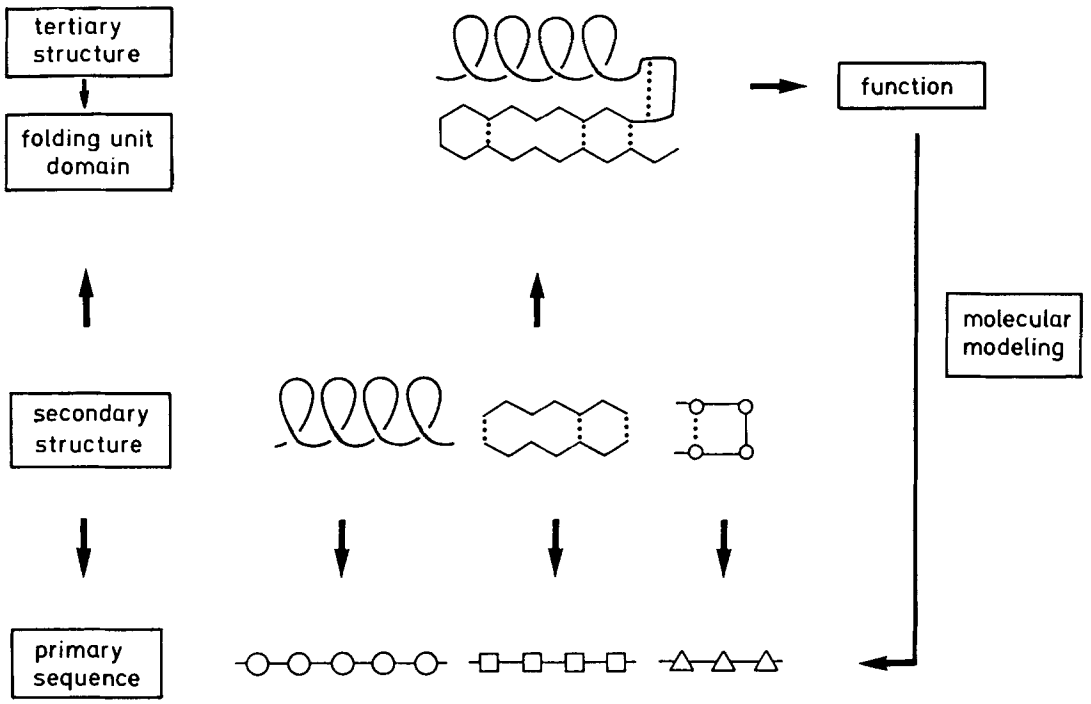

Fig. 16. General strategy for the construction of polypeptides with tertiary structure: Secondary structure blocks (stable nucleation centers) associate to form characteristic folding units and domains. The primary sequence is chosen such that the secondary structure (helix, β-sheet, β-turn; e.g. homo- or co-oligopeptide) of the peptide segments are most stable and ensure that optimum intramolecular interactions of their side chains are formed during the folding process. The overall stability of the three-dimensional structure must be maintained, if functional groups or active centers are selectively incorporated into the primary sequence; the necessary changes of sequence can be planned by "molecular modeling" [80].

tional properties can, however, be regarded as a special test for the general strategy used to construct artificial proteins that is described here.

4.5. Energy Balance of Model Proteins

The folding mechanism of model proteins (e.g. βαβ unit) can be considered as a two-step process (Fig. 17): I) Formation of the secondary structure; II) folding into the tertiary structure.

Unlike natural proteins (which have a fluctuating secondary structure), the equilibrium in the first folding step of model proteins lies almost completely on the side of the thermodynamically *stable* secondary structure. As a result of the stiffening of the peptide chain (restriction of conformational space), this rapid nucleation step provides the critical energy contribution for the formation of a tertiary structure and directs the subsequent folding process. The driving forces for folding into a tertiary structure (2nd step) are hydrophobic interactions resulting from the amphiphilic nature of the secondary structure blocks. In the case of natural proteins, the large loss of chain entropy in the folding step must be compensated by optimum intramolecular interactions and a high gain of solvation entropy (liberated solvent). However, in model proteins with a stable secondary structure a much smaller energy contribution is sufficient to overcome the much lower loss of chain entropy after the first nucleation step (ΔG = difference between small numbers). In natural proteins, where stabilization of secondary structure blocks by long range interactions is essential, "isolation" of these segments most often causes a transition to a disordered conformation. On the other hand, it can be concluded from a comparison of the energy balances that artificial proteins should have a

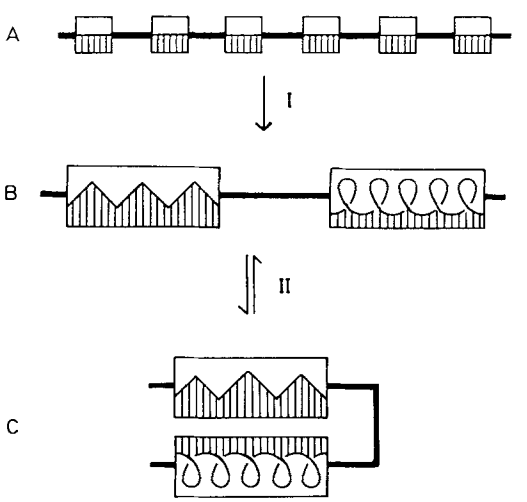

Fig. 17. Folding scheme of artificial proteins: In contrast to the folding process of natural proteins, the first nucleation step (I) leads from a disordered conformation (A) to *stable* secondary structures which act as nucleation centers (B) and thus determines the subsequent folding pattern as well as the overall topology of the molecule. The driving force for folding (II) into a stable tertiary structure (C) is the formation of hydrophobic clusters inside the polypeptide with release of solvation entropy) as a result of the amphiphilic nature of the secondary structure blocks. The molecule attempts to minimize its hydrophobic areas of contact with the solvent (H_2O).

more stable tertiary structure as a result of the higher stabilities of the secondary structure elements.

It is not yet known which is the critical chain length for the formation of a tertiary structure. Experiments on enzymatically cleaved proteins indicate a minimum length of approximately 40 amino-acid residues.[133-135] Interestingly, this number is of the same order of magnitude as is found for βαβ folding units.

4.6. Synthesis of Peptides

The chemical synthesis of longer peptide chains is still a central problem of protein chemistry despite the considerable progress that has been made in the strategy of the various synthetic methods and protecting group techniques.[136-139, 180] On a long-term basis the development of the recombinant DNA technique undoubtedly opens up entirely new possibilities for the construction of novel peptides and proteins.[3, 140] The aim of constructing peptides and proteins of any given chain length and primary sequence reliably, still unobtainable in chemical peptide synthesis, has suddenly become feasible due to this development. It is therefore evident that in the future the synthesis of *proteins* clearly belongs to the field of genetic engineering. On the other hand, the *combination* of biotechnological and chemical synthetic strategies opens up new perspectives for the modification and construction of artificial proteins. This approach has the special advantage that the entire potential of chemical peptide synthesis can be exploited for the functional and structural modification of peptide sequences (e.g. the incorporation of unnatural or of D-amino acids). Semisynthesis in which naturally and synthetically prepared segments are linked enzymatically[141-143, 155] will be of great importance in the future.

The synthesis of folding units with chain lengths of approximately 30–40 amino-acid residues seems to be the limit of chemical peptide synthesis when efficiency and reliability are considered; even this goal can only be achieved if the entire potential of the current synthetic strategies is used. Stepwise peptide synthesis on polymer supports is regaining importance due to the recent improvements made in protecting group strategy,[172, 173] anchoring techniques,[138, 139, 173-175, 181] and support properties.[138, 173, 176, 177] The development of efficient separation methods, especially preparative high pressure liquid chromatography (HPLC), has led in particular to an important breakthrough in solid-phase synthesis. Medium-sized peptides of up to 20 amino-acid residues can be purified reliably by using the HPLC technique.[172, 178] Although the synthesis of higher peptides on polymeric supports still appears to be difficult, it has often provided valuable preliminary information about the physicochemical and structural properties of the desired peptide. The combination of stepwise synthesis on a support and subsequent condensation of the segments, either in solution or on polymeric supports, could prove to be the best method for synthesizing longer chain peptides. The superstructure of an amphiphilic peptide sequence with alternating amino acid sequences is drastically destabilized by errors in the sequences:[171] this can be avoided by the coupling of dipeptides during stepwise synthesis.

The use of soluble polymeric supports[27, 138] offers special advantages for the synthesis of folding units: the preferred conformation of the solubilized peptide chain can be determined spectroscopically[89, 179, 182] in each step of the synthesis. The peptide segments with a secondary structure employed to construct folding units can be structurally *and* conformationally characterized in this way *prior to* fragment condensation.

The construction of oligopeptides which form secondary structures is a special challenge to the synthetic chemist because the conformation and the physicochemical properties of a peptide are closely related:[144-148, 162] the poor solubility of individual segments is a limiting problem; the formation of β-sheets which are associated intermolecularly causes aggregation and thus insolubility of both hydrophobic and latently amphiphilic peptide chains (Fig. 18).[26, 148] This solubility minimum can be overcome with

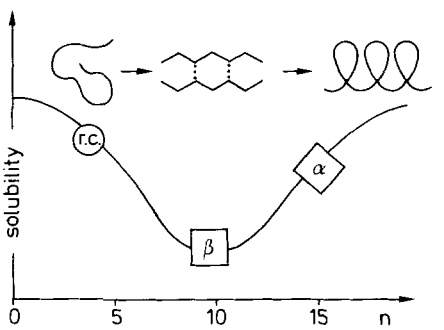

Fig. 18. Relationship between the conformations and physicochemical properties of peptides: When the chain length of a peptide (e.g. Oligo-Lys(Z), -Glu(Bzl), -Leu) is extended, a conformational transition from the disordered (r.c.) conformation to a β-structure is often observed; this is accompanied by a drastic decrease in the solubility of the peptide and accounts for the poor solubility of medium-length peptide segments. When the critical chain length for the α-helix is reached the solubility increases due to the formation of *intra*molecular hydrogen bonds. This close relationship between the preferred conformation and the properties of the peptide such as its solubility behavior, aggregation tendency or reactivity is of fundamental importance for the synthesis of higher peptides [144, 145, 162].

medium-length peptide sequences by extending the chain length since the tendency of the peptide to undergo intramolecular interactions increases (transition to a helical structure or folding).[81, 144, 145] Such conformational transformations are of considerable importance for the strategy used to construct folding units; for example, the solubility problem can be partially overcome by synthesizing the β-structure-forming peptide block on polyethyleneglycols[27, 138] and subsequently attaching the readily soluble helical segment. Enzymatic linkage of unprotected (and thus readily soluble) segments also provides another promising possibility, but this technique still requires further practical development.

In addition to the normal analytical characterization of the primary sequence (purity criteria), the identification of the tertiary structure is a special problem as biological activity tests cannot be used to check the purity and structure. Since X-ray structural analysis can only be employed in exceptional cases, a wide spectrum of spectroscopic methods (particularly CD, IR, NMR, fluorescence measurements), chemical methods (e.g. catalytic effects and complex formation), physicochemical methods (e.g. aggrega-

tion behavior, light scattering, Kerr effect), and, if possible, biochemical methods must be used to characterize the spatial structure. Another aspect deserves attention: folding into the tertiary structure only proceeds spontaneously under special conditions.[110] In addition to the design and synthesis of the primary sequence, the study of the optimum conditions for folding is therefore also important.

4.7. State of the Art in the Construction of Artificial Proteins

The relationship between the primary sequence and the secondary structure of peptides described in this report has been the focus of experimental and theoretical studies for many years; it seems that the time has now come for the investigation of a difficult, but equally fascinating, problem: the transition from the secondary to the tertiary structure. At the moment, the border area between the secondary and the tertiary structures is the center of active studies: experiments on modeling the *secondary structure* of biologically active peptides and proteins is a first important step in this connection. Substitution of helix-forming sequences in medium-sized peptides by amphiphilic model peptides with more stable secondary structures has already produced interesting results, e.g. modification of biological activity in substrate-receptor binding.[150, 151] It has been shown that the biological activity of the ribonuclease-S peptide is largely retained if a secondary structure block is replaced by a model peptide.[152] A model peptide which is capable of interaction with DNA has been developed on the basis of empirical conformational predictions.[153, 154] Studies on the modeling of the domains of natural proteins and enzymes as well as on the synthesis of folding units with novel catalytic and functional properties are in progress in the author's own laboratory. All the secondary structure blocks (α-helix 36-50, β-sheets 22-29 and 53-58) of the βαβ folding unit of the thioredoxin sequence 22-58 have, for example, been replaced by simple model sequences with retention of the active center (Cys^{32}-Gly-Pro-Cys^{35}) (Fig. 19); further small changes have no effect. Spectroscopic data indicate that the tertiary structures of the model and natural sequences (as isolated structural units and within the complete protein) are the same.[127]

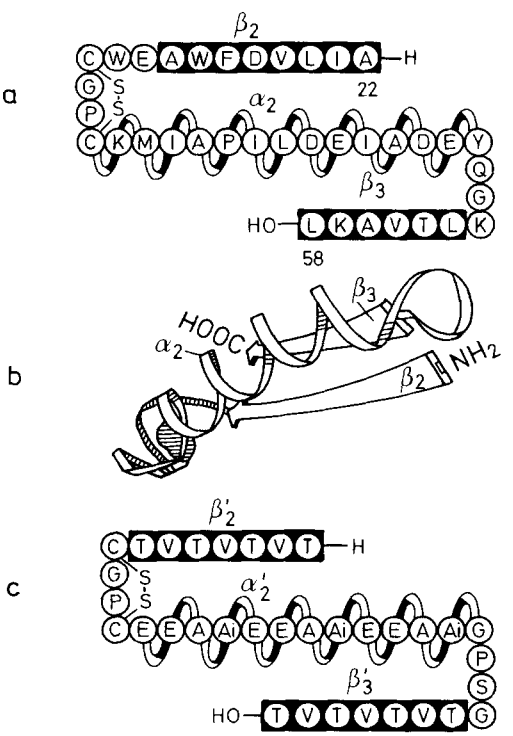

Fig. 19. Modeling of the partial sequence 22-58 of thioredoxin. The active center Cys^{32}-Gly-Pro-Cys^{35} is retained when the natural amino acid sequence (a) is replaced by an amphiphilic model helix (Glu-Glu-Ala-Aib)$_3$(α_2') and by two amphiphilic β-structure blocks containing the sequence (Thr-Val)$_3$-Thr(β_2' and β_3') (c). The spatial structure of this partial sequence corresponds to a βαβ folding unit (b) and is also retained in the model peptide despite the radical modification of the primary sequence [127].

Despite these encouraging beginnings in the construction of artificial proteins, many questions still remain unanswered. Little is known, for example, about the competition between the aggregation of polypeptide chains and their intramolecular folding. It can be shown that the amphiphilic helical and β-structure blocks used as building elements tend to aggregate in aqueous systems.[26, 148] This aggregation tendency of amphiphilic secondary structures is the driving force for intramolecular folding. Preliminary experiments on βαβ folding units appear to confirm this hypothesis.

5. Concluding Remarks

Albert Einstein's statement that "The religiousness of the research worker is founded in his delighted amazement at the harmony of natural laws which reveal such a superior reasonableness that, in comparison, all meaningful human thinking and systems represent nothing more than a feeble reflection"[156] could be used to describe the situation outlined in the present report. On the one hand we are trying to construct new proteins, "*amazed*" by the tertiary structures of proteins, and on the other hand the enzyme models that have so far been synthesized seem to be a "*feeble reflection*" of reality. In this context an attempt to construct new proteins may be regarded as a tremendous *interdisciplinary* learning process (Fig. 20) in which the curriculum is dictated by the study of the enzymes: "The molecule knows how to fold, so we may learn how it does it".[157]

The general strategy developed here employs the method of *deduction*.[158] A primary sequence is derived from the "idea of tertiary structure"[184] which has been borrowed from nature. According to *Popper*,[159] success ("verification") and failure ("falsification") in building new proteins are test criteria for our theory as to how tertiary structures are formed.

As is often the case in research, the range of potential applications and possibilities is growing more rapidly than the fundamental aims can be realized:

—tailor-made catalysts
—immunological and biochemical applications,
and last but not least
—the deciphering of the folding code

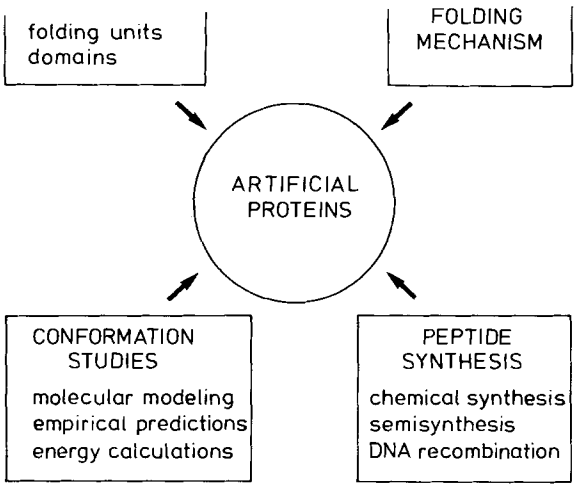

Fig. 20. The construction of artificial proteins as an interdisciplinary task. The experimental findings obtained on the *topology* (from X-ray structural analyses) and the *folding mechanism* (from denaturation-renaturation studies) of naturally occurring proteins provide the starting point for the construction of artificial proteins. Experimental *conformational studies* on model peptides supply the basis for designing peptide sequences with tailor-made conformational and physicochemical properties; theoretical studies are also useful. Finally, the possibility of *synthesizing* any given amino acid sequence is a prerequisite for the realization of the overall concept. The combination of chemical and biotechnological synthetic strategies is becoming increasingly important in this context. Access to new proteins is thus equally challenging for the conformation analyst, the biochemist, and last but not least for the peptide chemist.

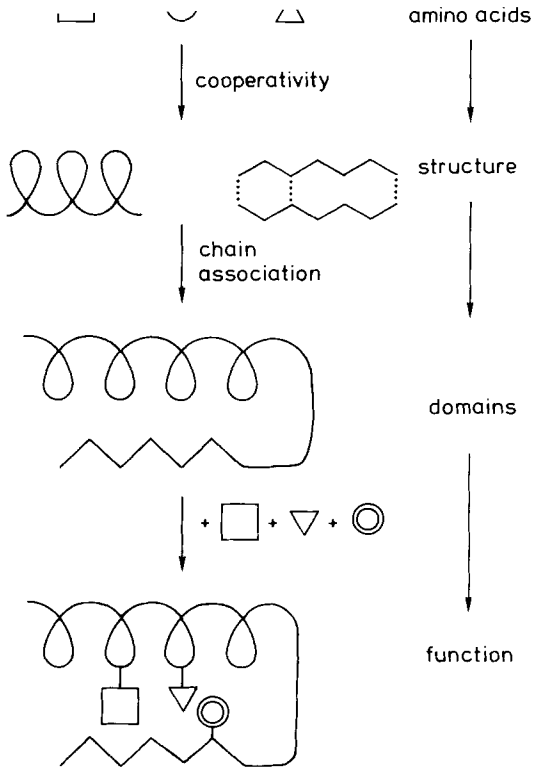

Fig. 21. Hypothetical evolution of natural proteins. According to this hypothesis, cooperative effects during the condensation of amino acids result in the preferential formation of homooligopeptides with a stable secondary structure; these peptides can then associate to form large domains (proteinoids) as a result of mutual interactions. A functional potential of increasing complexity is finally obtained by stepwise incorporation of functional amino acids within the chain backbone ("structure before function" hypothesis).

are hopes that are associated with the synthesis of artificial proteins. In view of the complexity of the problem to be solved, socratic modesty is called for—at least as far as the time scale of development is concerned. The construction of artificial proteins is thus a *prospect for the future.*

The real fascination for the peptide chemist is the inclusion of a new dimension in planning syntheses—the three-dimensional architecture of polypeptides. It may thus be possible to develop a "new quality" of synthetic macromolecules which manifests itself in enzymatic catalysis and can be recognized schematically in enzyme models.

Following this look into the future we will finally take a look at the question: How did proteins originate? On the basis of experimental data it is conceivable that the formation of homooligopeptides with secondary structure was favored by cooperative effects. Simple forms of tertiary structure ("proteinoids") were then produced due to association of these blocks as in the folding mechanism of proteins. These proteinoids were "functionalized" while retaining their three-dimensional structures by incorporation of "guest amino acids" and thus gradually acquired catalytic activity ("structure before function", Fig. 21). If the strategy for building artificial proteins and the hypothesis described here were to correspond with the natural origin of proteins, this would be a necessary consequence of the nature of the problem rather than just a coincidence.[160]

Research by the author referred to in this review has been supported by the "Deutsche Forschungsgemeinschaft", the "Fonds der Chemischen Industrie", Hoffmann-La Roche Inc., Basel, the Ciba Research Fund as well as the Swiss National Science Foundation. My special thanks are due to all my co-workers cited here. Important results in the field of conformational analysis of model peptides are the fruit of collaboration with Prof. C. Toniolo, University of Padua, over many years. I also wish to thank Dr. K. Müller, Hoffmann-La Roche Inc., for his great interest in the area of molecular modelling, and Dipl.-Chem. K.-H. Altmann for valuable assistance in preparing the manuscript. I am grateful to Professor Max Brenner for his constructive criticism. Finally, I would like to thank Professor Paul J. Flory who introduced me to the field of conformation calculations on biopolymers.

Phase Behavior of Ternary Systems of the Type H_2O–Oil–Nonionic Amphiphile (Microemulsions)

By Manfred Kahlweit* and Reinhard Strey

Liquid multicomponent systems of the type H_2O–oil–amphiphile–electrolyte are of growing interest, both in industry and in research. In applications technology, there are two problems to solve: 1. To prepare stable homogeneous solutions of H_2O and nonpolar liquids with as little amphiphile as possible which can be diluted with H_2O in all proportions without phase separation; e.g., concentrated solutions of drugs, herbicides, or insecticides. 2. To prepare stable mixtures of an aqueous, an amphiphile, and an oil phase with as little amphiphile as possible which are employed in tertiary oil recovery and in the pharmaceutical industry. Furthermore, such systems may be used for performing chemical reactions in heterogeneous liquid mixtures with continuously variable properties. In research, such systems are of interest for both experimental and theoretical studies of critical phenomena, especially near so-called tricritical points. Last but not least, their properties may stimulate further research in the field of associated solutions. In this paper we summarize the results of our studies on the phase behavior of ternary systems with nonionic amphiphiles, in particular with respect to the evolution of liquid three-phase bodies. The results suggest that the tricritical points in such systems should be regarded as kinds of pivot points from which the phase behavior evolves. If this were an approach to reality, the phase behavior would be governed in more or less good approximation by universal scaling laws, irrespective of the particular microstructure of the solutions. Finally, we discuss the effect of electrolytes on the phase behavior both in a quaternary phase tetrahedron and a pseudoternary phase prism representation. Although in practice most systems consist of mixtures of oils, amphiphiles, and electrolytes, an understanding of the phase behavior of truly ternary and quaternary systems with chemically well-defined components permits at least qualitative predictions with respect to the phase behavior of the multicomponent mixtures encountered in practice.

1. Introduction

In order to increase the mutual solubility between two partially miscible substances, a third component must be added that is equally well soluble in the two other substances.[1] In the case of H_2O and oil this is evidently an amphiphile, either nonionic or ionic, or a combination of the two. To illustrate the problem one may represent the phase diagrams of the two ternary systems

$$\underset{\mathbf{A}}{H_2O} - \underset{\mathbf{B}}{\text{oil}} - \underset{\mathbf{C}}{\text{nonionic amphiphile}} \qquad (1)$$

$$\underset{\mathbf{A}}{H_2O} - \underset{\mathbf{B}}{\text{oil}} - \underset{\mathbf{D}}{\text{ionic amphiphile}} \qquad (2)$$

at constant temperature T and pressure p in Gibbs triangles as shown schematically in Figure 1. The composition may be expressed either in mole, volume, or weight fractions. In this paper we shall use weight fractions, although, when considering molecular interactions, mole fractions are the more appropriate composition variables.

The upper triangle in Figure 1 shows the idealized phase diagram of system (1), the lower one that of system (2). Both triangles join at their common H_2O–oil side. The mutual solubility between **A** and **B** is very low. However, if one adds an appropriate amphiphile, either nonionic (**C**) or ionic (**D**), the solubility increases until the two phases eventually merge at a plait point. For reasons of clarity, the lyotropic mesophases at high concentrations of **C** and **D** have been omitted in Figure 1.

One may construct two tetrahedra by taking either the upper **A**–**B**–**C** triangle as base and placing **D** on top, or vice versa. Which of the two tetrahedra is the more conve-

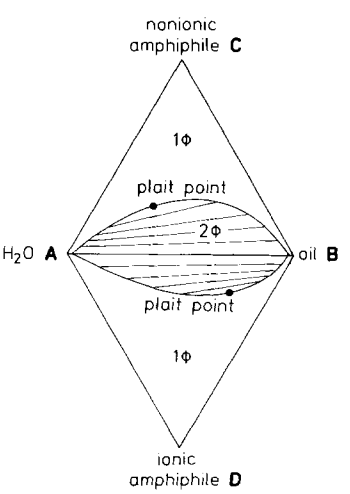

Fig. 1. Top: Phase diagram of system (1): H_2O–oil–nonionic amphiphile. Bottom: Phase diagram of system (2): H_2O–oil–ionic amphiphile (schematic). Both amphiphiles are equally well soluble in H_2O and oil. 1ϕ and 2ϕ signify one-phase and two-phase systems, respectively.

nient depends on which of the amphiphiles is considered as major and which as minor component. In both cases the body of heterogeneous phases within the tetrahedron has the shape of an orange segment the edge of which is the **A**–**B** edge of the tetrahedron. The problem is then to find, for a given oil in a given temperature and pressure range, an amphiphile or a combination of amphiphiles the addition of which makes this segment as small as possible.

The phase diagrams of such systems depend strongly on temperature (cf. Section 5). In order to study the effect of temperature on the phase behavior of these quaternary systems, one, therefore, first has to study the temperature dependence of each of the four ternary systems. This is done by representing the sides of the tetrahedron in upright prisms with the corresponding Gibbs triangle as base and temperature as ordinate. If each of these four prisms is known, one may readily construct the tetrahedron at each temperature of interest.

The systems that have been studied previously are best divided into three classes: class (1) and (2) as above, and class (3):

$$\underset{\mathbf{A}}{H_2O} - \underset{\mathbf{B}}{\text{oil}} - \underset{\mathbf{C}}{\text{nonionic amphiphile}} - \underset{\mathbf{D}}{\text{ionic amphiphile}} \qquad (3)$$

each, if necessary, including inorganic electrolytes (**E**) as fourth or fifth component. If an inorganic salt is included as fifth component, one can attempt to represent the quinary system in a pseudoquaternary tetrahedron by combining two of the components into a pseudocomponent. Which combination is chosen as pseudocomponent, is again a question of convenience.

From the vast literature, one may take the following studies as representative examples: Systems of class (1): among others, studies by *Shinoda* et al.,[2] *Friberg* et al.,[3] *Scriven* et al.,[4] and *Kahlweit* et al.[5] Systems of class (2): among others, studies by *Eckwall*,[6] *Shinoda* et al.,[7] *Schechter* et al.,[8] and *Ninham* et al.[9] Systems of class (3): first studies by *Schulman* et al.[10] and thereafter in particular by French groups.[11]

The phase behavior of systems of class (1), including electrolytes as fourth component, can be considered as being clarified.[5] In the case of systems of class (2), *Eckwall* employed ionic surfactants which are much more readily soluble in water than in oil, whereas the other authors[7–9] chose ionic surfactants with comparable solubility in water and oil in that they employed surfactants with either double-tailed or branched carbon chains. As a consequence, the phase diagrams of their systems look more similar to that shown on the lower triangle in Figure 1.

In the case of systems of class (3), *Schulman* et al. chose—in our opinion—a rather inappropriate combination of nonionic and ionic amphiphiles, namely alcohols that are more readily soluble in oil than in water, and ionic surfactants that are much more readily soluble in water than in oil (Fig. 2).

In view of *Bancroft*'s rule, however, we presume that a combination of two amphiphiles which are both equally well soluble in water and oil is most efficient in preparing stable homogeneous solutions of water and oil. It is essential, therefore, to study the temperature dependence of the phase behavior of systems of class (2), **A**–**B**–**D**, with ionic amphiphiles with 'balanced' hydrophilic and hydrophobic groups. If the prisms of these systems are known, one may combine them with appropriate nonionic amphiphiles and study the efficiency of the quaternary systems of class (3). With this goal in mind, we shall, in this review,

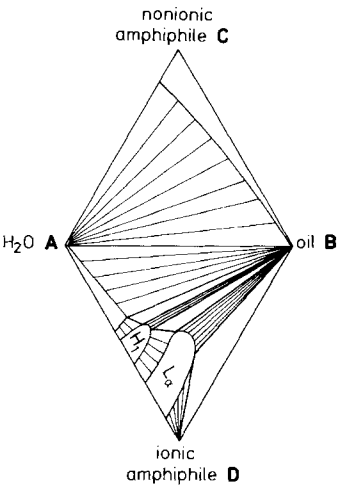

Fig. 2. Phase diagram of systems (1) and (2) [10] (schematic). The alcohol (as nonionic amphiphile) is much more readily soluble in oil than in H_2O, whereas the ionic detergent is more readily soluble in H_2O than in oil. H_1 and L_α are lyotropic mesophases (schematic, after [6]).

summarize the results of our studies of the phase behavior of systems of class (1), **A**–**B**–**C**, with an inorganic electrolyte as fourth component. In Sections 3 and 4, we shall discuss the phase diagrams of the three binary systems **A**–**B**, **B**–**C**, and **A**–**C**, while in Sections 5 and 6, we shall demonstrate the interplay of these three binary systems as it determines the phase behavior of the ternary system. Finally, in Section 7 we shall consider the effect of an added inorganic electrolyte.

2. Statement of the Problem

Multicomponent liquid systems of the class H_2O–oil–nonionic amphiphile–electrolyte are of growing interest, both in industry and in research. In practice, there are two problems to be solved that are closely related to each other:

1. To prepare a stable homogeneous solution of H_2O and oil with as little amphiphile as possible (Fig. 3). H_2O

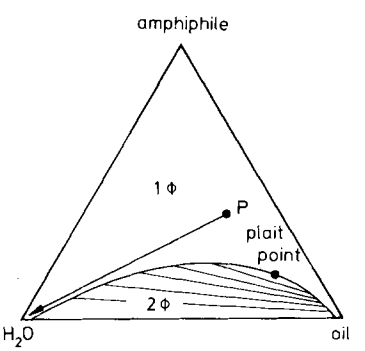

Fig. 3. An example from practice: Dilution of a homogeneous oil-rich solution of composition P with H_2O without phase separation (schematic).

and oil are almost insoluble in each other. Their 'central' miscibility gap extends into the Gibbs triangle. Since the addition of an appropriate nonionic amphiphile increases their mutual solubility, the gap shrinks with increasing concentration of the third component until the two phases, the compositions of which are connected by the 'tie lines', merge at the isothermal critical point or 'plait point'. The declination of the tie lines is determined by the distribution coefficient of the amphiphile between water and oil. The problem then, is to find, for a given oil in a given temperature and pressure range, an amphiphile which makes the central gap as small as possible, so that a homogeneous oil-rich solution (e.g. point P) can be diluted with H_2O in all proportions without phase separation.

2. A mixture having a composition within the central gap may separate into three phases instead of two phases (Fig. 4). The interfacial tension between these phases is, in general, very low. This slows down the coarsening of emulsions, a property which is not only of interest for chemical flooding in tertiary oil recovery, but also for the pharmaceutical industry and for performing chemical reactions in heterogeneous liquid mixtures.

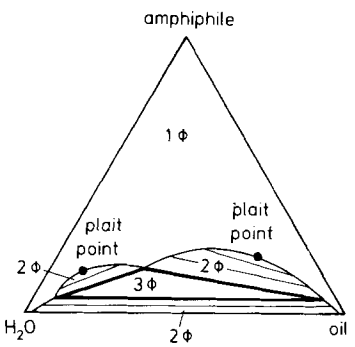

Fig. 4. An example from practice: Formation of a three-phase triangle within a central miscibility gap with low interfacial tensions between the three phases (schematic). 3 Φ: three-phase system.

The separation into three phases occurs, however, only within a certain temperature interval. Again, the problem is to find, for a given oil (mixture) and a given aqueous salt solution (the 'brine') in a given temperature and pressure range, an amphiphile which enforces the formation of such a 'three-phase triangle' as close as possible to the H_2O–oil side of the Gibbs triangle and with an area as large as possible.

Such systems are of interest for experimental and theoretical studies of critical phenomena, in particular near tricritical points. Last but not least, their properties may stimulate further research in the field of associated solutions. With respect to the properties of such mixtures, one should distinguish between their macroscopic equilibrium and dynamic properties, and their microstructure. With respect to their microstructure, the homogeneous solutions of such mixtures, in particular the amphiphile rich phase of the three-phase triangle, are frequently called 'microemulsions'. This term originates from the work of *Schulman* et al. in the fifties, who considered such mixtures as 'optically isotropic, fluid, transparent oil and water dispersions, consisting of uniform droplets of either oil or water in the appropriate continuous phase'[12] stabilized by an interfacial layer of nonionic and ionic amphiphile molecules. Since then, quite a number of other models for the microstructure have been proposed. A discussion of these models goes beyond the scope of this review, for we shall show that the macroscopic equilibrium properties can be readily understood on the basis of the theory of phase diagrams developed by the Dutch[13] and the German[14] schools at the beginning of this century without assuming any particular microstructure of the solutions.

In Sections 5 and 6 we shall discuss the phase behavior of ternary systems of class (1), while the effect of an added electrolyte will be considered in Section 7. As nonionic amphiphiles we have chosen *n*-alkylpolyglycol ethers C_iE_j (i denotes the number of carbon atoms in the hydrophobic alkyl chain and j the number of hydrophilic ethoxy groups: C_iE_j: $H(CH_2)_i(OCH_2CH_2)_jH$, $j=0$), also including short chain alcohols (C_iE_0: $H(CH_2)_iOH$). Even 'simple' systems of this class show all the qualitative features found with the more complex systems (Section 6). This holds, in particular, for the formation of the three-phase bodies within the phase prism.

The formation of the three-phase triangles has been described qualitatively by *Schreinemakers*:[13] They originate from the interplay of the miscibility gaps of the three binary systems representing the sides of the prism, provided these gaps are in the appropriate position with respect to temperature. A semiquantitative treatment, based on earlier considerations by *Meijering*,[15] has been published by *Griffiths* et al.[16] The formation of a three-phase body within the phase prism is thus not a peculiar property of systems with water and amphiphile as components, but can also be found in many other ternary systems, e.g. in metallic alloys. These systems, and such systems with water and amphiphile as components, differ insofar as hydrogen bond formation between H_2O and amphiphile molecules leads to complete miscibility between these components at ambient temperatures. With rising temperature, however, these hydrogen bonds break and the miscibility gap appears again, being, for thermodynamic reasons, a closed upper loop.[17] Since the lower gap generally lies below the melting point of the mixture, it is the upper loop which, by interacting with the lower miscibility gaps of the two other binary systems, causes the formation of the three-phase body in systems of the class **A**–**B**–**C**. Apart from this difference, the evolution of the three-phase triangles and the change of their shape with temperature corresponds to that in any other ternary system with a three-phase body.

The classification of the phase diagrams of such systems by *Winsor*[18] may be somewhat misleading, insofar as it may create the impression that his classification holds for systems with water and nonionic amphiphiles only. *Winsor* distinguished three types of phase diagrams:

I) two phases with the amphiphile dissolved mainly in the aqueous phase,
II) two phases with the amphiphile dissolved mainly in the oil phase,
III) three phases.

The type of phase diagram observed in such systems changes systematically with temperature (Section 5). At

low temperatures one finds type I, at high temperatures type II. In between, one may or may not find type III, depending on the chemical nature of the oil and the amphiphile.

3. The Three Binary Systems

An appropriate way in which to interpret the phase behavior of a ternary system is to first consider the phase diagrams of the three binary systems representing the sides of the phase prism. For thermodynamic reasons, each of these systems shows a lower miscibility gap with an upper critical point. Both the critical temperature and the critical composition depend on pressure. The effect of pressure on the phase diagrams of binary systems has recently been described in a review article by *Schneider*.[19] At the low pressures normally used in practice, the effect is rather weak.

Figure 5 shows the unfolded phase prism with schematic diagrams of the three binary phases. The phase diagram of the H_2O–oil system is the simplest of the three. The upper critical point of its (lower) miscibility gap lies well above the boiling point of the mixture, so that the very low mutual solubility between the two liquids increases only slightly between melting and boiling point.

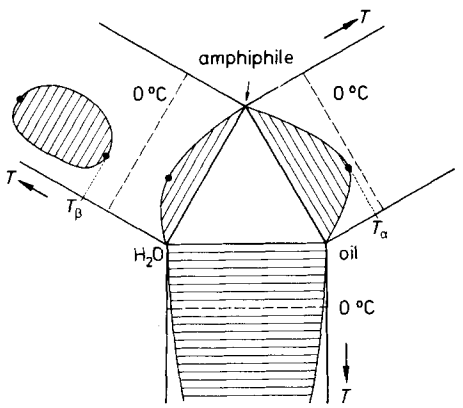

Fig. 5. Unfolded phase prism of the ternary system H_2O(**A**)–oil(**B**)–nonionic amphiphile (**C**) with the phase diagrams of the three binary systems **A**–**B**, **B**–**C**, and **A**–**C** (schematic).

The phase diagram of the binary system oil–nonionic amphiphile appears to be almost as simple. Its upper critical point lies, in general, not too far from the melting point of the mixture, with its critical composition on the oil-rich side. Its upper critical temperature, T_α, depends on the chemical nature of both the oil and the amphiphile: the more the two substances 'dislike' each other, i.e. the more hydrophobic the oil and the more hydrophilic the amphiphile, the higher T_α. As example, Figure 6 shows the miscibility gaps for C_6E_5 and some *n*-alkanes. T_α rises with increasing carbon number k of the oil by about 10° per $\Delta k = 2$.

The phase diagram of the binary system H_2O–nonionic amphiphile is the most complicated of the three, and, furthermore, fascinating. The lower miscibility gap lies, in general, below the melting point of the mixture. At ambient temperatures and low concentrations of the amphiphile, the solutions are molecular disperse. Above a critical concentration, the amphiphile molecules form association colloids (micelles). At even higher concentrations, the system shows lyotropic mesophases (liquid crystals). These

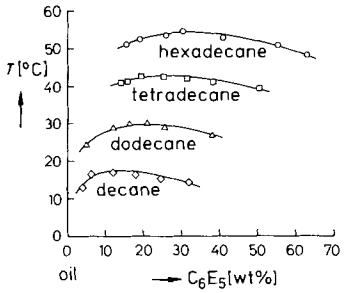

Fig. 6. Lower miscibility gap between some *n*-alkanes as oil and C_6E_5 as nonionic amphiphile. The upper critical temperature T_α rises with increasing hydrophobicity of the oil.

mesophases show up, however, only with the more amphiphilic substances. 'Simple' C_iE_j molecules, i.e. those with low i and j, form no mesophases at all. Irrespective of the existence of these mesophases most of the systems show an upper miscibility gap (at 1 bar) which is a closed loop with an upper as well as a lower critical point. Position and shape of this loop depend on the chemical nature of the amphiphile. This loop, in particular its lower critical temperature, T_β, plays an important role in the phase behavior of the ternary system (cf. Section 4).

4. The Upper Loop in the System H_2O–C_iE_j

Amphiphilic molecules can be looked upon as 'chemical dipoles' which differ from electrical dipoles in that the 'charge' of each pole can be changed independently of the other, and, furthermore, that equal charges attract each other. In the literature, their 'dipole moment' is frequently expressed in terms of a *HLB* value (*H*ydrophilic-*L*ypophilic-*B*alance; hydrophilic-hydrophobic equilibrium), which, for nonionic amphiphiles, is evaluated from

$$HLB = 20\ (M_H/M)$$

where M_H is the molar mass of the hydrophilic group, and M the total molar mass of the substance. It appears, however, that the *HLB* value is not the appropriate measure for the amphiphilicity, since two amphiphiles with quite different molar masses may have similar *HLB* values. Experience, on the other hand, shows that the efficiency of amphiphiles with respect to the increase of the mutual solubility between water and oil increases with their molar mass (Table 1).

The minimum amount of amphiphile (c_{min}) needed to emulsify the H_2O–oil mixture decreases strongly with increasing 'dipole moment' of the amphiphile, whereas the *HLB* value remains almost constant. An apparent relation exists between c_{min} and c_β, whereas T_β remains almost constant.

With respect to the upper loop of the H_2O–C_iE_j system, one can visualize it as a vertical section through a 'nose' in *c*-*T*-*p* space at constant *p*.[20] Figure 7 (left) shows the loop

Table 1. Solubilization capacity of some *n*-alkylpolyglycol ethers.

Amphiphile	*HLB*	c_{min} [a] [wt %]	T_β [°C]	c_β [b] [wt %]
C_4E_1	10.3	58.9	48.7	29.0
C_6E_3	12.7	47.4	45.4	13.5
C_8E_4	12.6	29.6	39.6	6.9
$C_{10}E_5$	12.5	19.7	40.3	3.5
$C_{12}E_6$	12.4	10.6	48.0	2.2

[a] Least concentration of the amphiphile for the homogenization of a 1 : 1 mixture (wt %) of H_2O and *n*-decane at ca. 40°C. [b] Critical concentration of amphiphile in the upper loop.

of the $H_2O-C_4E_1$ system as it shrinks with increasing pressure and disappears at about 800 bar. Figure 8 shows the corresponding 'nose' schematically.

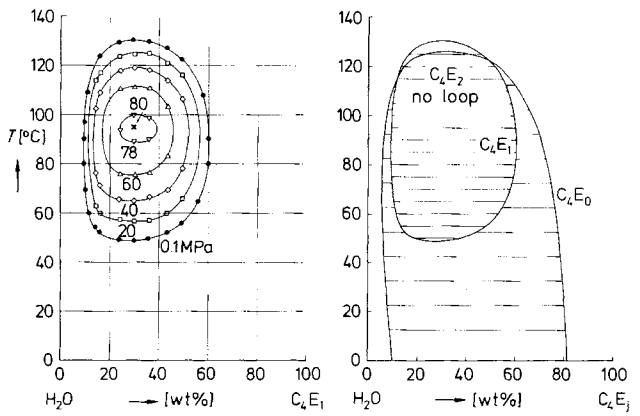

Fig. 7. Left: Shrinking of the upper loop of the system $H_2O-C_4E_1$ with increasing pressure [20]. Right: Shrinking of the upper loop of the system $H_2O-C_4E_j$ with increasing hydrophilicity (j).

The same effect can be achieved by either decreasing the hydrophobicity of the amphiphile (decreasing i at constant j) or by increasing the hydrophilicity (increasing j at constant i). A simple example of the latter is shown in Figure 7 (right): for C_4E_0 (1-butanol), the lower critical temperature T_β lies well below the melting point of the mixture at 1 bar. As one increases the hydrophilicity, by proceeding to C_4E_1, T_β rises to 48°C. As one increases the hydrophilicity further, by proceeding to C_4E_2, the loop disappears altogether. The nose has become too short to show up at 1 bar. However, the nose may still 'lurk' behind the *c*-*T* plane at 1 bar (Fig. 8), and may thus still influence the phase behavior of the ternary system.

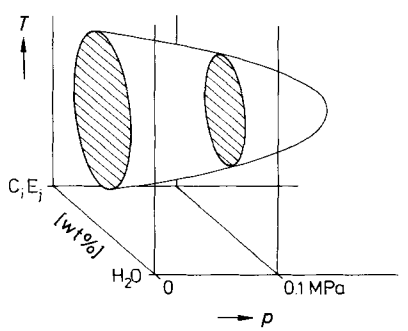

Fig. 8. Upper closed loop of the binary system $H_2O-C_iE_j$ as vertical section (constant pressure) through the 'nose' in the *c*–*T*–*p* space (schematic, after [20]).

A simple example for the effect of decreasing the hydrophobicity of the amphiphile (decreasing i at constant j) is shown in Figure 9. Here, we have chosen the system $H_2O-C_4E_1$ and then decreased the hydrophobicity of the amphiphile by replacing pure C_4E_1 by a mixture of C_3E_1 and C_4E_1 with gradually increasing ratio C_3E_1/C_4E_1. The profile of the nose (full line) has the same shape as that of the pressure nose found by *Schneider*[20] (broken line), its axis being just a little lower on the temperature scale. Both sections were measured at 30 wt% amphiphile.[21]

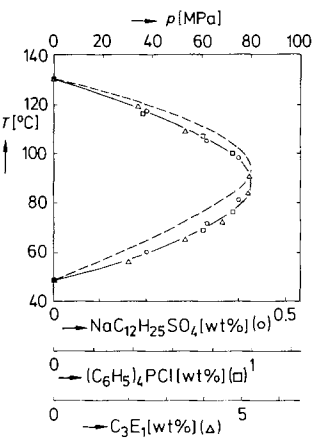

Fig. 9. Profile of the $H_2O-C_4E_1$ nose at 30 wt% C_4E_1. Dashed line: Increase of mutual solubility by increasing the pressure [20]. Full line: Increase of mutual solubility by adding a more hydrophilic amphiphile (C_3E_1), a hydrotropic non-surfactant salt [$(C_6H_5)_4PCl$], and an ionic surfactant ($NaC_{12}H_{25}SO_4$) (after [21]).

The effect of an added electrolyte on the mutual solubility between H_2O and amphiphile was first studied systematically by *Hofmeister*[22] in 1888. He chose the system H_2O–globulin, and employed mainly inorganic electrolytes. *Neuberg*[23] extended these studies to electrolytes with an organic and an inorganic ion. The results of these authors also hold for mixtures of H_2O and nonionic amphiphiles. In the following we shall, for historical reasons, call all electrolytes which decrease the mutual solubility between H_2O and nonionic amphiphiles 'lyotropic', and all electrolytes which increase the mutual solubility 'hydrotropic'.

If one applies the *HSAB* (*H*ard–*S*oft–*A*cid–*B*ase) principle,[24] the results may be summarized as follows:[21] Salts of hard acids and hard bases are lyotropic, i.e. they widen the upper loop, whereas salts of soft acids and hard bases and of hard acids and soft bases are hydrotropic, i.e. make the loop shrink. Salts of soft acids and soft bases appear to be weakly hydrotropic. Accordingly, salts like NaCl, $CaCl_2$, or Na_2SO_4 decrease the mutual solubility between H_2O and amphiphile, whereas salts like $(C_6H_5)_4PCl$, and sodium alkylsulfates ($NaC_kH_{2k+1}SO_4$) increase the mutual solubility. One major exception is the ClO_4^- ion, which, although classified as a hard base, increases the mutual solubility when combined with a hard acid ($NaClO_4$).

At constant salt concentration, the effect decreases with increasing 'dipole moment' of the amphiphile, i.e. with increasing amphiphilicity. Of particular interest is the effect of ionic surfactants. Experiments shows that the hydrotropic effect of such salts increases gradually with increas-

ing carbon number, k, of the alkyl chain,[21,25] and reaches a plateau at high k values. From this point of view, ionic surfactants can be regarded as very efficient hydrotropic salts which differ from the rather effective hydrotropic $(C_6H_5)_4PCl$ only insofar as they are surface active, whereas the latter is not. Adding a hydrotropic salt is, accordingly, equivalent to adding a more hydrophilic nonionic amphiphile (Fig. 9). The profiles of the noses for both $(C_6H_5)PCl$ and $NaC_{12}H_{25}SO_4$ are almost identical with the profile for C_3E_i, if one chooses the concentration units on the abcissa such that the tips of the three noses coincide. Adding a lyotropic salt, on the other hand, is equivalent to adding a more hydrophobic amphiphile. Accordingly, binary systems $H_2O-C_iE_j$ which do not show an upper loop at 1 bar separate into two phases after addition of a sufficient amount of lyotropic salt: the lurking nose shows up. For an example, we refer the reader to the investigation of the system $H_2O-C_3E_0$ (1-propanol)–KCl by *Schneider* and *Russo*[26] (see also [21]).

One may thus push the nose into the phase prism by either adding a more hydrophobic nonionic amphiphile or by adding a lyotropic salt. On the other hand, the nose may be pushed out of the prism by either adding a less hydrophobic amphiphile, by adding a hydrotropic salt, or by increasing the pressure. This property of the nose will be of importance when it comes to discussing the effect of electrolytes on the phase behavior of the ternary system **A–B–C**. With this information at hand we are now in a position to discuss the phase behavior of the ternary system in detail.

5. Phase Behavior of the Ternary System A–B–C

Let us assume for a moment that the binary **A–C** system does not show an upper loop, not even a lurking nose. In this case, the body of heterogeneous phases within the phase prism has a shape resembling that of an apse (Fig. 10). The critical line, connecting the plait point, starts at the upper critical point of the (lower) **B–C** gap, ascends on the oil-rich side of the prism, and finally terminates at the upper critical point of the **A–B** gap. According to *Winsor*'s classification, such a system shows a phase diagram of type I in the entire temperature range between melting and boiling point of the mixture.

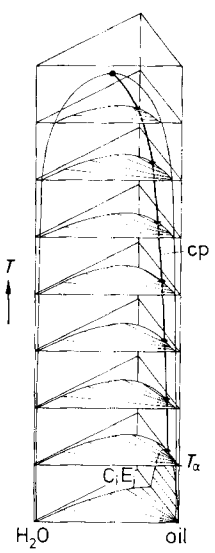

Fig. 10. Phase prism of a ternary system without upper loop between H_2O and amphiphile (schematic). The critical line ascends from the (upper) critical point of the binary **B–C** gap on the oil-rich side to the (upper) critical point of the binary **A–B** gap.

Let us now replace component **C** by a nonionic amphiphile which shows a nose lurking behind the **A–C**–T side of the prism. Since the position of the plait point indicates which of the binary mixtures would separate, if the entropy does not prevent this, the critical line will, at low temperatures, again ascend on the oil-rich side of the prism. With rising temperature, however, the system gradually approaches the lurking nose. Accordingly, the amphiphile will gradually dislike water more than the oil. As a consequence, the critical line will change from the oil-rich side around the surface of the apse to the water-rich side of the prism (Fig. 11). Such a system thus shows a phase diagram of type I at low temperatures which changes to one of type II at high temperatures.

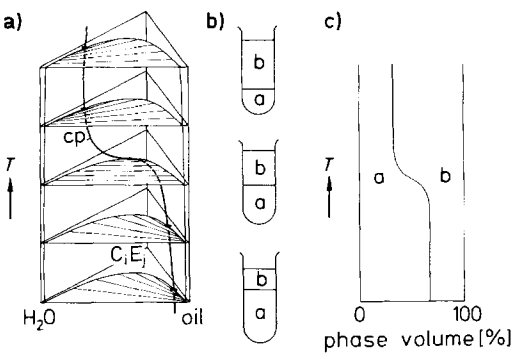

Fig. 11. (a) Phase prism of a ternary system with 'lurking' upper **A–C** nose but connected critical line (schematic). The critical line changes from the oil-rich to the water-rich side as temperature approaches the nose. (b) and (c) Phase volume ratio with $H_2O/oil = 1:1$ [wt%] versus temperature (schematic). At low temperatures, the amphiphile is dissolved mainly in the aqueous phase (type I), at high temperatures mainly in the oil-rich phase (type II). a and b denote aqueous phase and oil phase, respectively.

This change of the critical line from the oil-rich to the water-rich side can be readily demonstrated by measuring the phase volume ratio of the two phases as a function of temperature. At low temperatures, the amphiphile dissolves mainly in the lower aqueous phase, whereas at high temperatures, it dissolves mainly in the upper oil phase (Fig. 11b). Accordingly, the phase volume ratio—if measured at an appropriate composition—shows a sigmoidal dependence on temperature (Fig. 11c), the inflection point indicating that temperature at which the influence of the upper lurking **A–C** nose on the phase behavior overcomes that of the lower **B–C** gap. For an experimental demonstration see, e.g., Figure 4 in Ref. [5c]. This phase volume ratio curve (Fig. 11c) should not be mistaken for the projection of the critical line (Fig. 11a) from the **A–B**–T plane of the prism onto some parallel plane in the rear, although the two curves look rather similar.

The critical line can be looked upon as an elastic spring. Its bending tension can now be increased by either pushing the upper critical point of the **B–C** gap upwards, i.e. by increasing the hydrophobicity of the oil, or by pushing

the lurking **A**–**C** nose closer to the prism by either increasing the amphiphilicity of the amphiphile or by adding a lyotropic salt. The increase of the bending tension of the critical line manifests itself by the observation that the tangent at its inflection point becomes increasingly horizontal—until it eventually breaks (Fig. 12c). The point at which the critical line breaks is called a 'tricritical point'.[27]

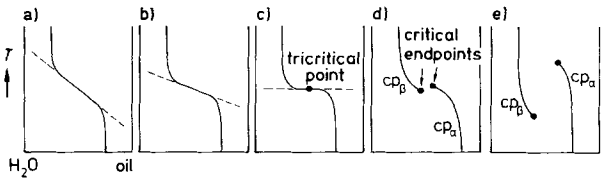

Fig. 12. Transition from a connected critical line, (a) and (b), to a broken critical line, (d) and (e): projection of the critical lines from the **A**–**B**–T plane of the prism onto some parallel plane in the rear (schematic). With increasing 'bending tension' the tangent at the inflection point of the connected critical line tends more and more to the horizontal, until the critical line breaks at a tricritical point (c).

In a ternary system the tricritical point is defined by temperature, pressure, and composition, i.e. by four parameters. To find a tricritical point in a truly ternary system at fixed pressure (e.g. 1 bar), is thus a 'lucky accident'.[28] Either the oil is not sufficiently 'oily' (Fig. 12b), or it is too oily (Fig. 12d), or the amphiphile is not sufficiently amphiphilic (Fig. 12b), or too amphiphilic (Fig. 12d). Therefore, to reach the tricritical point at a pressure of 1 bar, one has to mix either an oil of the type in Figure 12b with one of the type in Figure 12d, or an amphiphile of the type in Figure 12b with one of the type in Figure 12d. Another way to reach a tricritical point is to push the nose of an amphiphile of the type in Figure 12b into the prism by adding a lyotropic salt, or to push the nose of an amphiphile of the type in Figure 12d out of the prism by adding a hydrotropic salt, or—by increasing the pressure.

In a system with a connected critical line (Fig. 11), the amphiphile is transferred continuously from the water-rich to the oil-rich phase as the temperature rises. In a system with a broken critical line, this is achieved by means of a three-phase triangle (Fig. 13). At low temperatures, the amphiphile is dissolved mainly in the water-rich phase. As one raises the temperature, the system approaches the **A**–**C** nose. If the nose is sufficiently close to the prism or even shows up as upper loop on the **A**–**C**–T plane, H_2O and amphiphile separate into two phases on the water-rich side of the prism at the (lower) 'end point' of the critical line cp_β, which descends (or ascends) from the lower critical point of the loop into the prism. As one raises the temperature, the **A**–**C** loop widens. Consequently, the aqueous phase (a) and the 'surfactant' phase or middle phase (c) move further apart. The aqueous phase moves on an ascending line towards the H_2O-edge of the prism, whereas the surfactant phase moves on an ascending line around the surface of the central gap towards the oil-rich side. The oil phase (b), on the other hand, moves on an ascending line counterclockwise towards the surfactant phase until both merge on the oil-rich side of the prism at the (upper) end point of the critical line cp_α, which ascends from the upper critical point of the **B**–**C** gap into the prism. The surfactant phase thus acts like a 'ferry', transporting the amphiphile from the water-rich to the oil-rich side. The three-phase triangle appears as a 'lower critical tie line' at temperature T_l and disappears as an 'upper critical tie line' at T_u. In this temperature range from T_l to T_u, the triangle changes its shape such that the top of the triangle, phase (c), moves clockwise from the end point of cp_β to the end point of cp_α (Fig. 14, top). According to *Winsor*'s classification, such a system thus shows a phase diagram of type I below T_l, one of type III between T_l and T_u, and one of type II above T_u. If one measures its phase volume ratio at an appropriate composition versus temperature, one accordingly finds the behavior shown schematically in Figure 13c. The position and width of the three-phase temperature interval (T_u–T_l) on the temperature scale depends on the chemical nature of both the oil and the amphiphile. For a given oil, the three-phase interval lies the lower the more hydrophobic the amphiphile, i.e., the lower T_β, whereas—for a given amphiphile—it lies the higher the more hydrophobic the oil, i.e., the higher T_α. As a consequence, for some systems the three-phase interval may lie even below the melting or above the boiling point of the mixture.

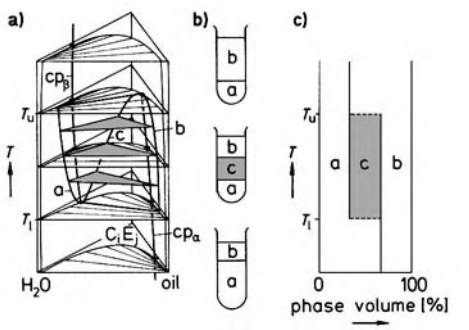

Fig. 13. (a) Phase prism of a ternary system with broken critical line and three-phase body (schematic). For discussion see text. (b) and (c) Phase volume ratio as a function of temperature (schematic). Between type I and type II one finds type III in the three-phase temperature interval T_u–T_l.

The fact, that the three-phase triangle emerges from the end point of the critical line cp_β and disappears at the end point of the critical line cp_α can be readily demonstrated by measuring the dynamic light scattering of the corresponding phases (for experimental details see Ref. [5a]): If one prepares a solution of the composition U of the intersection of the projections of the two critical lines (Figure 11 in Ref. [5b]) and approaches T_l from below, the water-rich solution shows an increasing critical opalescence which reaches its maximum at T_l (black circles in Fig. 14b, left). At T_l, the solution separates into the aqueous and the surfactant phase. A little above T_l, these solutions are still 'near critical'. Accordingly, they still show critical opalescence. If one now follows the opalescence in the surfactant phase (white circles in Fig. 14b), the composition of which is, at each temperature, well defined, the opalescence first decreases with rising temperature, i.e., increasing distance of phase c from the critical line cp_β. However, as soon as the composition of phase c has passed '12 o'clock' on its way around the central gap, opalescence increases again as

phase c starts to approach the critical line cp_α. As the temperature approaches T_u, both the oil phase and the surfactant phase become near critical, because they are to merge at the end point of cp_α. Consequently, both phases show increasing critical opalescence which reaches its maximum at T_u (as shown for the surfactant phase in Fig. 14b). At T_u the two phases merge at the end point of cp_α. With further rising temperature, this now homogeneous solution shows a decreasing opalescence as its distance from the end point of cp_α increases (black circles in Figure 14b, right). From this, it follows that the light scattering frequently observed in such systems must not necessarily stem from aggregates (e.g. microemulsions), but may also stem from critical fluctuations, provided the composition of the corresponding solutions lies sufficiently close to either one of the critical lines.

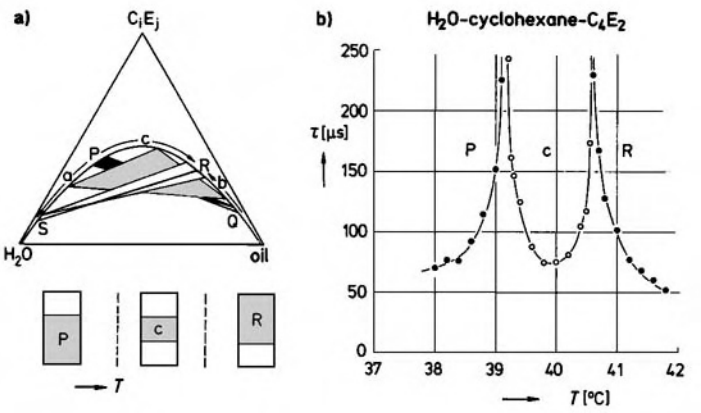

Fig. 14. (a) Change of shape of the three-phase triangle with rising temperature (schematic). The amphiphile-rich middle phase (c) moves clockwise from the (lower) end point (P) of critical line cp_β to the (upper) end point (R) of critical line cp_α. (b) Divergence of the correlation length, determined by dynamic light scattering in the homogeneous solutions of the system H_2O–cyclohexane–C_4E_2: correlation time constant τ versus temperature. (For details see text.)

Another important consequence concerns the temperature dependence of the interfacial tensions between the aqueous phase and the surfactant phase (a/c) and the oil phase and the surfactant phase (b/c). Since phase a and phase c emerge from the end point of critical line cp_β, the interfacial tensions (a/c) will rise from zero at T_l according to the scaling law for the interfacial tension between near critical phases (Fig. 15c). The oil phase and the surfactant phase, on the other hand, merge at the end point of the critical line cp_α. Consequently, interfacial tension (b/c) will vanish at T_u according to the scaling law. The very low interfacial tensions between these phases are, therefore, an inevitable consequence of the phase behavior of the ternary system, irrespective of the particular microstructure of the solutions.

We have thus learned that the phase behavior of a ternary system is determined by its 'distance' from a tricritical point. If its components are such that it lies 'beyond' a tricritical point, it will not show a three-phase body, whereas, if it lies 'this side' of a tricritical point, it will. The three-phase body emerges from the tricritical point on the surface of the central gap. With systems close to the tricritical point, the three-phase body is small, being located close to the surface of the central gap (Fig. 15a). Correspondingly,

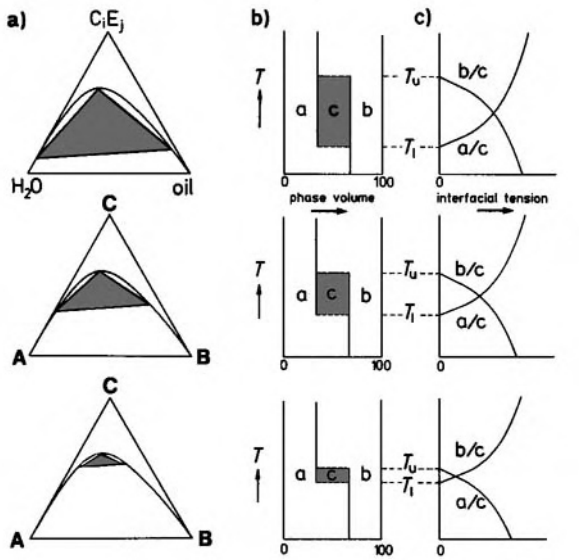

Fig. 15. Alteration of (a) the three-phase triangle, (b) the phase volume ratio, and (c) the interfacial tension with increasing distance from a tricritical point (schematic). (For details see text.)

the three-phase temperature interval is narrow and the interfacial tension between the phases low. With increasing distance from the tricritical point, the three-phase body grows into the central gap and the relative area covered by the three-phase triangles increases, as does also $(T_u - T_l)$ and the interfacial tension (Fig. 15b, 15c).

If one wishes to have a large three-phase triangle and a wide temperature interval, one has to pay with relatively high interfacial tensions. On the other hand, if one wishes to have very low interfacial tensions, one has to pay with relatively small triangles and a narrow interval. Hence, for a given temperature (or temperature range) and a given oil (or oil mixture) the problem is to optimize these properties by choosing the appropriate amphiphile (or combination).

6. Concentration-Temperature Diagrams

An instructive procedure to learn more about the shape of the central miscibility gap and the three-phase body within this gap is to draw vertical sections through the phase prism, i.e. so-called *c-T* diagrams (Fig. 16), as they are frequently employed by metallurgists. Among the

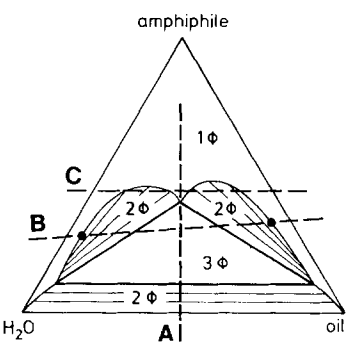

Fig. 16. *c-T* diagrams: vertical sections through the phase prism. (For details see text.)

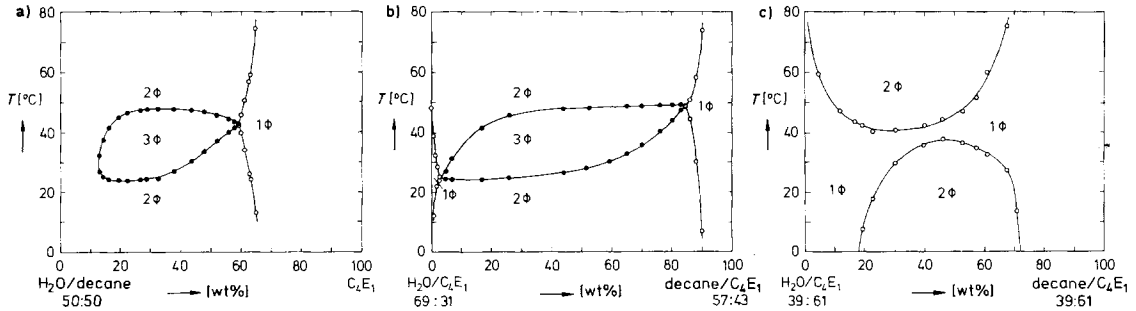

Fig. 17. (a) Section A, (b) section B, and (c) section C through the phase prism of the system H_2O–decane–C_4E_1 with three phase bodies (sections A and B), and homogeneous channel from the water-rich to the oil-rich side (section C).

many possible sections the following are particularly instructive.

Section A: erected on the center line of the Gibbs triangle, i.e. on the line connecting the point H_2O/oil = 1 : 1 on the **A**–**B** side with the **C** corner.

Section B: erected on the line connecting the end point of the critical line cp_β with that of cp_α.

Section C: erected on a line passing the 'groove' close to the surfactant phase c in its '12 o'clock' position (for details see below).

Figure 17 shows these sections for the system H_2O–*n*-decane–C_4E_1. Looking at section A from the **B**–**C** side of the prism, one can see the profile of the central miscibility gap as well as a section through the three-phase body floating within that gap like a 'fish' (Fig. 17a). The 'tail' of this fish, i.e. the groove at that point at which the three-phase body touches the surface of the central gap is a consequence of Schreinemakers' rule, which requires that—for thermodynamic reasons (!)—the boundaries of each homogeneous phase must intersect at the corner of the three-phase triangle in such a way that both their extensions either pass into the triangle (Fig. 18a) or into the adjacent two-phase regions (Fig. 18b).[29]

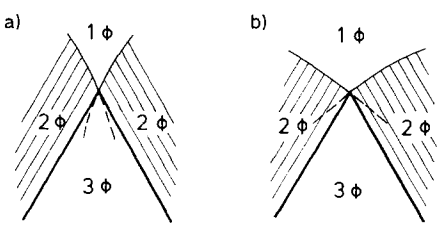

Fig. 18. Origin of *Schreinemakers'* grooves on the body of heterogeneous phases (schematic). For details see text.

Looking at the B section from the **A**–**B** side of the prism (Fig. 17b), one can see a section cutting through the three-phase body more or less parallel to the **A**–**B**–*T* plane. It again shows Schreinemakers' grooves at the end points of the critical line cp_β (on the left) and cp_α (on the right).

On its way from the end point of cp_β to that of cp_α the surfactant phase c thus cuts a groove into the body of heterogeneous phases, which ascends like a 'waist' from the water-rich to the oil-rich side. It is in this waist where one finds the highest mutual solubility of H_2O and oil in the presence of an amphiphile, and it is the groove in the A section from which the data in Table 1 were taken. Figure 19 shows the model of the body of heterogeneous phases of a 'simple' system.

This waist enables one to find an isotropic homogeneous channel from the water-rich to the oil-rich side of the prism, passing along the groove of the central gap (section C) and, like the waist, ascending with temperature from T_l on the water-rich to T_u on the oil-rich side (Fig. 17C). This channel offers a unique possibility to study the microstructure of the homogeneous solution close to the body of heterogeneous phases as it changes from an 'oil in water' to a 'water in oil' emulsion. This does not only hold for systems

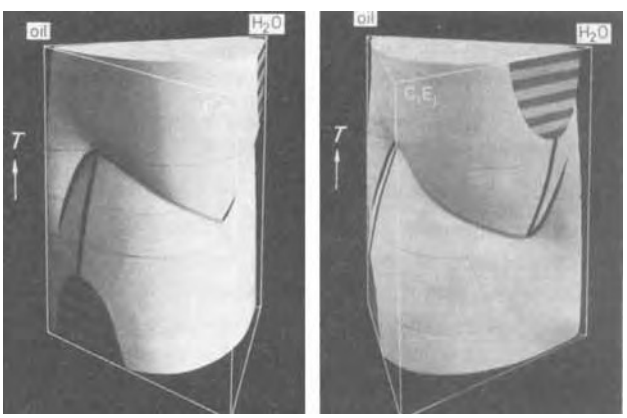

Fig. 19. Model of the body of heterogeneous phases for a 'simple' system with 'waist'. Left: seen from the **B**–**C** side with lower miscibility gap and ascending critical line cp_α; right: seen from the **A**–**C** side with upper gap and descending critical line cp_β.

with 'simple' amphiphiles, but also for systems with long chain amphiphiles (see below).

We shall now discuss some representative experimental examples: The first example demonstrates the transition from a connected to a broken critical line. The system chosen is H_2O–phenylalkane $(C_6H_5)(CH_2)_kH$–C_4E_2. The binary system H_2O–C_4E_2 shows no upper loop at 1 bar, but a lurking nose. Figure 20 shows the A sections of these systems, in which only the hydrophobicity of the oil was increased by increasing the carbon number k. The critical line is thus fixed by the lurking nose of the H_2O–C_4E_2 sys-

tem on the water-rich side, and by the upper critical point of the oil–C_4E_2 gap on the oil-rich side. For the less hydrophobic oils with low k, one finds a connected critical line, with no three-phase body within the prism. If one increases k, i.e. makes the oil more oily, one pushes the upper critical point of the oil–C_4E_2 gap upwards (see Fig. 6). This increases the bending tension of the critical line, until it breaks between k = 6 and k = 7. The tricritical point of this particular system thus lies at about 52 °C and 1 bar, with an oil having k between 6 and 7.

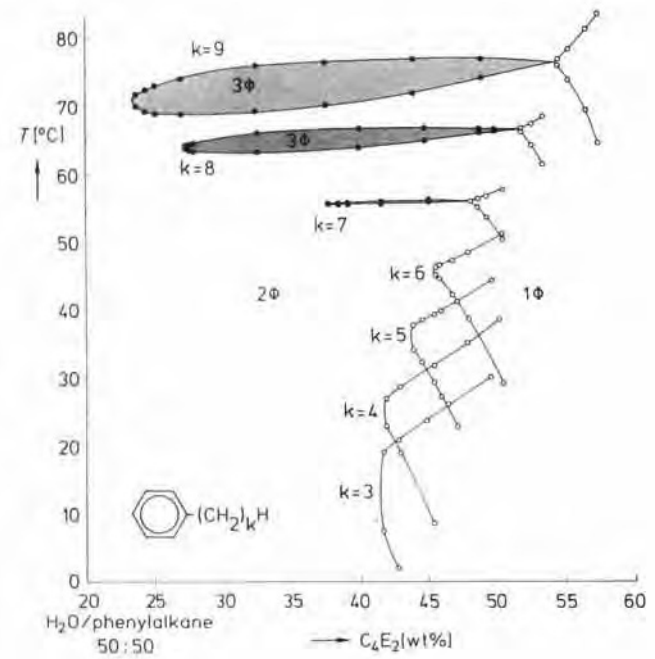

Fig. 20. Section A through the phase prisms of the systems H_2O–phenylalkanes $(C_6H_5)(CH_2)_kH$–C_4E_2. Transition from a connected (k = 3, 4, 5, 6) to a broken (k = 7, 8, 9) critical line by increasing the hydrophobicity of the oil. The three-phase body grows with increasing distance from the tricritical point (between k = 6 and k = 7) (see Fig. 12).

Interestingly, even the connected critical lines cut a groove into the central gap, which becomes increasingly sharper as one approaches the tricritical point. As expected, a system shows the highest mutual solubility between H_2O and oil at that temperature at which either the connected critical line changes from the water-rich to the oil-rich side, or the broken critical line causes the formation of a three-phase body. As further expected, this temperature rises—for a given amphiphile—with increasing hydrophobicity of the oil, i.e. increasing carbon number k.

This general feature is again demonstrated in Figure 21, which shows the change of the three-phase temperature interval $(T_u - T_l)$ for four classes of C_iE_j (i = 4, 6, 8, 12) with the carbon number k of *n*-alkanes. It also demonstrates again that the interval $(T_u - T_l$ shrinks with decreasing carbon number, shaping a 'cusp' which appears to originate in the common tricritical point of each of the series at low carbon numbers.

Unfortunately, due to the high vapor pressure of these short chain alkanes it is not possible to reach these tricritical points at 1 bar; to do so, one would have to increase the pressure (see Figure 11 in [5d]). Nevertheless, these results again suggest considering the tricritical point as a kind of pivot point from which the phase behavior of a system evolves. If this were an approach to reality, the phase behavior would be governed by universal scaling laws for 'near tricritical' systems in more or less good approximation. The closer a system to its tricritical point, the better the description—the further apart, the poorer. This would also explain why the phase behavior of all these systems is qualitatively similar, irrespective of their microstructure: amphiphiles of class C_4E_j form neither micelles nor lyotropic mesophases, those of class C_6E_j apparently only micelles, whereas the higher classes form both. The universal scaling laws, on the other hand, are independent of the particular microstructure, since that is what makes them 'universal'.

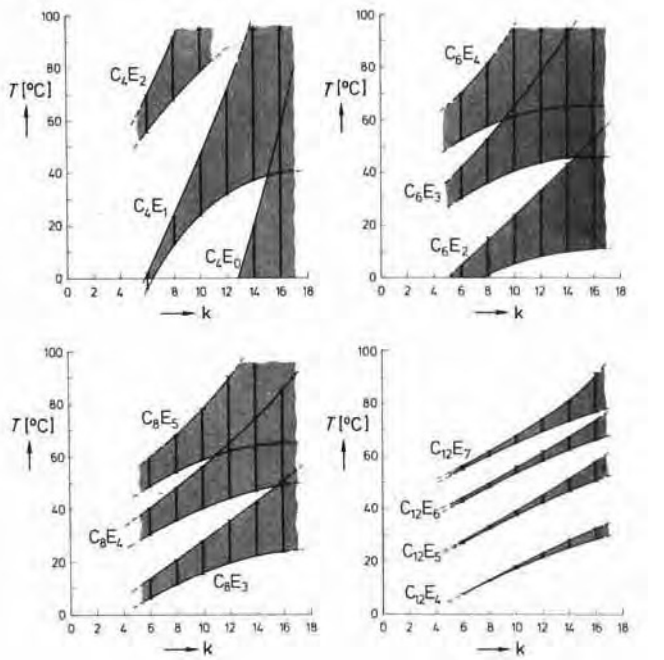

Fig. 21. Three-phase temperature intervals $(T_u - T_l)$ for the systems H_2O–*n*-alkanes C_kH_{2k+2}–C_iE_j (i = 4, 6, 8, 12). Each homologous series shapes a cusp, the tricritical point of which appears to be located at the short-chain alkanes.

Accordingly, the difference between short-chain and long-chain amphiphiles manifests itself not so much in the phase behavior but rather in their efficiency in solubilizing H_2O and oil. This is demonstrated in Figure 22, which shows the change of shape of the three-phase triangles with temperature for the three systems: H_2O–decane–C_4E_1, H_2O–decane–C_8E_3[30] and H_2O–tetradecane–$C_{12}E_5$.[31] The evolution of the three-phase triangles is quite similar.

But, the more amphiphilic the amphiphile, the closer the triangles to the **A**–**B**–*T* plane of the prism and the deeper the grooves, i.e., the less amount of amphiphile needed to achieve a homogeneous solution. This holds, however, only for the groove (!). Below and, in particular, above the three-phase temperature inverval the solubilization efficiency of the amphiphiles differs much less (Fig. 23). This is not surprising, since, at higher temperatures, the central gap merges with the upper loop of the binary H_2O–C_iE_j system. Below the groove, short chain amphiphiles show a rather wide central gap, whereas with long chain amphi-

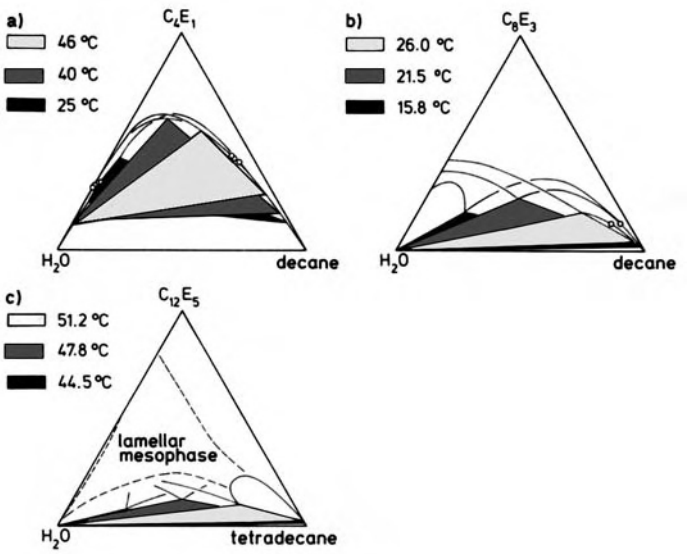

Fig. 22. Change of shape of the three-phase triangles for the system (a) H_2O–decane–C_4E_1, (b) H_2O–decane–C_8E_3, and (c) H_2O–tetradecane–$C_{12}E_5$ with rising temperature: The phase behavior is quite similar, and apparently independent of the particular microstructure of the solutions.

philes part of this gap is somewhat 'replaced' by highly viscous lyotropic mesophases.

The binary **A**–**C** system with long chain amphiphiles shows a number of mesophases (Fig. 24a). On the water-rich side one finds below the upper loop (2Φ) isotropic micellar solutions. With increasing concentration of the amphiphile, first a cubic (I_1), then a hexagonal (H_1), then a viscous isotropic (V_1), and finally, a lamellar (L_α) mesophase appear. All these mesophases extend into the narrow region of an optically isotropic though opalescent homogeneous phase. The existence of this region enables one to find a narrow isotropic homogeneous channel from the water-rich to the oil-rich side of the phase prism (section C in Fig. 23; cf. section C in Fig. 17). *Nilsson* and *Lindman*[34] were apparently the first to recognize the significance of these channels for the investigation of the microstructure of such systems.

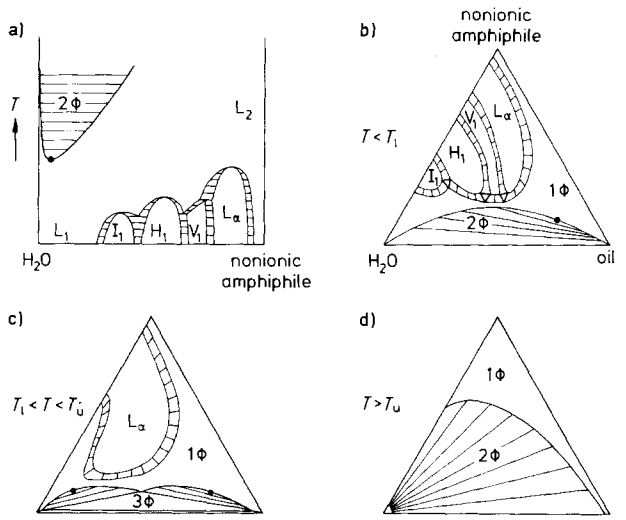

Fig. 24. (a) Lyotropic mesophases in the binary system H_2O–C_iE_j (schematic, notation after ref. [36]; see text, L_1 and L_2 are isotropic phases). (b) Extension of the lyotropic mesophases into the Gibbs triangle below T_l (schematic); (c) extension of the lyotropic mesophases into the Gibbs triangle in the three-phase temperature interval (T_u–T_l) (schematic); (d) phase diagram above T_u (schematic).

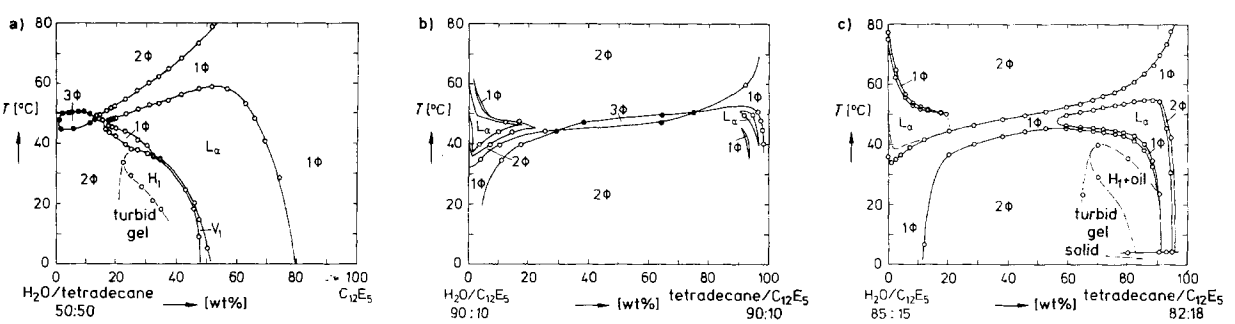

Fig. 23. (a) Section A, (b) section B [32], and (c) section C through the phase prism of the system H_2O–tetradecane–$C_{12}E_5$ with three-phase body (**A** and **B**) and homogeneous isotropic channel from the water-rich to the oil-rich side (**C**). H_1 hexagonal, L_α lamellar mesophase. Section B at 10 wt% $C_{12}E_5$; hence, it does not lie on the line between the two end points of the critical lines but parallel to the **A**–**B** side. The three-phase body, and thus also the groove (c_{min} in Table 1), lie much closer to the **A**–**B**–T plane of the prism than with C_4E_1 as amphiphile (Fig. 17).

A–**B**–**C** prism (Fig. 24b) and may even overlap with the central miscibility gap.[33]

As a rule, the three-phase body within the **A**–**B**–**C** prism appears at a temperature which lies above that for the hexagonal mesophase. Accordingly, in the three-phase temperature interval (T_l–T_u) only the lamellar mesophase is found (Fig. 24c). At sufficiently high temperatures this vanishes and, in general, one finds only isotropic solutions (Fig. 24d). The lamellar phase points at the three-phase body like a signboard (section A in Fig. 23). Between the lamellar phase and the central gap one finds, in general, a

7. Phase Behavior of Quaternary Systems **A**–**B**–**C**–**E**

In this section we shall discuss the phase behavior of quaternary systems **A**–**B**–**C**–**E**, where **E** denotes the fourth component, being either a second oil, a second nonionic amphiphile, or a lyotropic or a hydrotropic salt. The phase behavior of a quaternary system is represented in a phase tetrahedron at constant temperature and pressure (cf. Section 1). As base we choose the Gibbs triangle of the **A**–**B**–**C** system, the phase behavior of which has been

discussed in the preceding sections, and place the fourth component on top of the tetrahedron. Again, the appropriate procedure to discuss the phase behavior of the quaternary system is, first, to consider the phase diagrams of the three other ternary systems **A–B–E**, **B–C–E**, and **A–C–E**. In the following we restrict the discussion to inorganic lyotropic salts as fourth component.

To discuss the phase behavior of the quaternary system as function of the temperature, one has to move the tetrahedron within the **A–B–C–***T* phase prism upwards or downwards like an elevator (Fig. 25). The position of the **A–B–C** base of the tetrahedron then defines the temperature at which the phase behavior of the quaternary system is discussed.

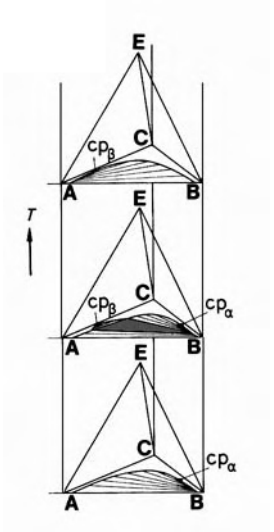

Fig. 25. Illustration of the temperature dependence of the phase behavior of the quaternary system **A–B–C–E**: Alternative positions of the phase tetrahedron **A–B–C–E** within the phase prism **A–B–C–***T* (schematic).

Accordingly, one may place the tetrahedron below, within, or above the three-phase body of the **A–B–C** system. The phase diagram on the base of the tetrahedron will then look like either one of the diagrams shown in Figure 25.

From this, it follows that the phase behavior of a quaternary system crucially depends on the temperature at which it is studied, and, furthermore, that a knowledge of the phase prism of the **A–B–C** system is a prerequisite for an understanding of the quaternary system. The same holds for the phase prisms of the three other ternary systems. Figure 26 shows schematically the unfolded tetrahedron at a temperature below T_l of the **A–B–C** system, i.e. below the temperature of its three-phase body. Accordingly, the base, i.e. the central triangle, shows a phase diagram of type I in *Winsor*'s classification.

Let us now consider the three other triangles:

Triangle **A–B–E**: The miscibility gap **A–B** extends into the **A–B–E** triangle. On the **A–E** and the **B–E** side, one finds homogeneous solutions of **E** in the corresponding mixtures. Since the solubility of a lyotropic salt, e.g. NaCl, is much higher in water than in oil, the tie lines of the two-phase region between the homogeneous regions decline steeply towards the **B** corner. Between this two-phase region and the **E** corner one finds a three-phase triangle with solid **E** as third phase. This phase diagram will change only slightly with temperature.

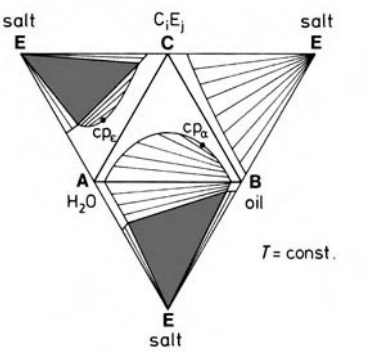

Fig. 26. Unfolded phase tetrahedron for the system H_2O–oil–nonionic amphiphile–lyotropic salt at a temperature below T_l (of the ternary system **A–B–C**). For discussion see text.

Triangle **B–C–E**: If the temperature of the system lies above the critical temperature T_α of the (lower) **B–C** gap, one finds a homogeneous solution along the **B–C** side of the triangle and a two-phase region between this region and the **E** corner with solid **E** as second phase. Since the solubility of the lyotropic salt is higher in the amphiphile than in the oil, the boundary between the homogeneous solution and the two-phase region declines from **C** to **B**.

Triangle **A–C–E**: If the temperature lies below the critical temperature T_β of the upper loop of the **A–C** system, one finds a homogeneous solution along the **A–C** side of the triangle. Since, however, the lyotropic salt enforces a phase separation between **A** and **C** at temperatures below T_β, a two-phase region with two liquid phases is found between the homogeneous region and the **E** corner. The two phases merge at a plait point cp_c. Between this two-phase region and the **E** corner there is a three-phase triangle with solid **E** as third phase.

The phase behavior of such a system can be readily understood on the basis of the considerations presented in the preceding sections,[5b] with the lyotropic salt playing the role of temperature and the plait point cp_c that of the lower critical point of the upper **A–C** loop. The three-phase triangle appears at the salt concentration c_l (instead of T_l) at the end point of the critical line cp_c, which descends from the **A–C–E** triangle into the tetrahedron. With increasing salt concentration, the surfactant phase c moves clockwise around the surface of the central gap to merge at salt concentration c_u (instead of T_u) with the oil phase b at the end point of critical line cp_α, which ascends into the tetrahedron on the oil-rich side. Since the salt is more readily soluble in H_2O than in the amphiphile or the oil, the tie lines as well as the three-phase triangles are not parallel to the **A–B–C** base, but tilted as shown schematically in Figure 27 (top).

Again, one may erect a vertical section A along the center line of the **A–B–C** base, and again one finds the three-phase body floating within the tetrahedron like a fish, now slightly tilted with respect to the base (Fig. 27). If one projects the three-phase triangles from the **E** corner onto the **A–B–C** base, one finds the same change of shape of the triangles with increasing salt concentration as

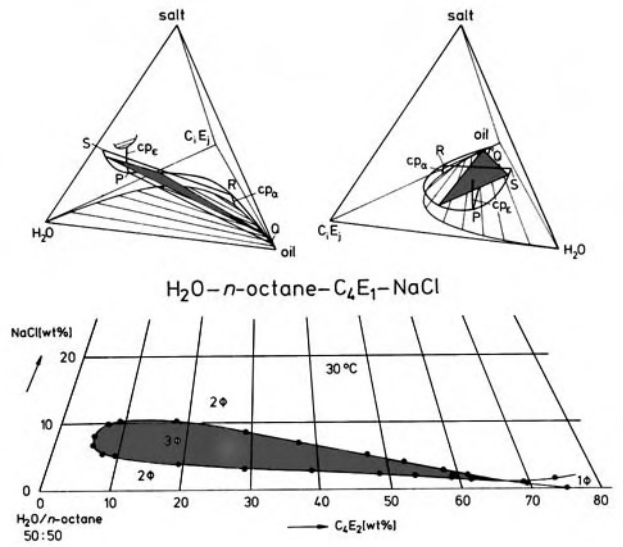

Fig. 27. Top: Position of a three-phase triangle within a phase tetrahedron of the system **A**–**B**–**C**–**E** (schematic). P, Q, R, and S are the endpoints of the two critical tie lines. Bottom: Section A through the phase tetrahedron of the system H_2O–octane–C_4E_2–NaCl at 30 °C.

is found in the ternary **A**–**B**–**C** system with rising temperature (cf. Fig. 22). Figure 28 shows this change of shape for the system H_2O–benzene–C_2E_0(ethanol)–$(NH_4)_2SO_4$ at 21 °C.[35] Accordingly, one finds the same change in the phase volume ratio and interfacial tensions with increasing salt concentration and rising temperature (Fig. 28, bottom; cf. Fig. 15).

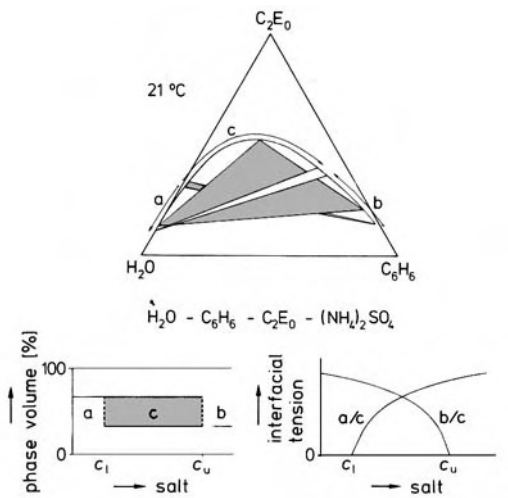

Fig. 28. Top: Change of shape of the three-phase triangle for the system H_2O–benzene–ethanol–$(NH_4)_2SO_4$ with increasing salt concentration at 21 °C (after [35], cf. Fig. 22). Lowest (dark gray), medium (gray), and highest (light gray) concentration. Bottom: Phase volume ratio and interfacial tension as a function of the salt concentration at constant temperature (schematic, cf. Figs. 13 and 15).

Such quaternary systems are frequently represented in pseudoternary phase prisms with H_2O and salt combined as pseudocomponent. The transcription of the phase behavior from a tetrahedron into a prism may lead to considerable quantitative errors insofar as the lower and the upper critical tie lines as well as the three-phase triangles may no longer be parallel to the base of the phase prism as they are in a truly ternary system. Nevertheless, such a representation in a pseudoternary phase prism may simplify the qualitative discussion. It permits, in particular, a rather transparent discussion of the effect of salts on the phase behavior of a ternary system. For this purpose one plots the three-phase temperature interval versus the salt concentration (Fig. 29). At zero salt concentration one finds

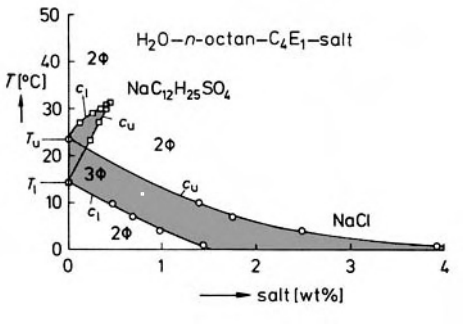

Fig. 29. Three-phase cusps for the system H_2O–octane–C_4E_1–salt (cf. Fig. 21). Lower cusp (○) for NaCl as lyotropic salt with tricritical point at a 'negative' salt concentration. Upper cusp (□) for $NaC_{12}H_{25}SO_4$ as hydrotropic salt with tricritical point within the pseudoternary phase prism.

the interval $T_u - T_l$ of the ternary system. As one adds a lyotropic salt (NaCl), the upper **A**–**C** loop widens. As a consequence, the end points of the two critical lines move further apart (cf. Fig. 12), and $T_u - T_l$ is both lowered and widened. Now consider a temperature below T_l of the truly ternary system. At this temperature the base of the tetrahedron shows a phase diagram of type I (Fig. 25). As one adds salt, one proceeds from the base towards the E corner of the tetrahedron. If the composition of the ternary mixture is properly chosen (for details see Ref. [5b]), one will cross the lower critical tie line of the three-phase body at salt concentration c_l. The three-phase triangle appears. With further increasing salt concentration, one proceeds through the three-phase body until one leaves it at its upper critical tie line at salt concentration c_u. In this representation the three-phase interval has the shape of a cusp, the tip of which lies on the negative salt scale.

Accordingly, one may again visualize a hypothetical tricritical point defined (at 1 bar) by its temperature and a composition with a negative salt concentration, from which the phase behavior of the quaternary system evolves.

In order to move the tricritical point into the pseudoternary prism, one simply has to choose an amphiphile which does not show a three-phase body with that particular oil at zero salt concentration. Such a ternary system shows a connected critical line. If one pushes the **A**–**C** nose into the prism by adding a lyotropic salt, one will eventually break the line: a three-phase body appears (transition from Fig. 12b to 12d). Such an experiment was first performed by *Lang* and *Widom*[35] with the system H_2O–benzene–ethanol–$(NH_4)_2SO_4$. Figure 14 in [5b] shows the cusps with tricritical points found in corresponding experiments with the systems H_2O–*n*-alkanes–NaCl with C_3E_0 or *tert*-C_4E_0 as amphiphile.

Since a connected critical line can be broken by adding a lyotropic salt, one can also mend a broken line by adding a hydrotropic salt or a more hydrophilic nonionic amphiphile (transition from Fig. 12d to 12b). The upper cusp in Figure 29 shows the corresponding experiment with sodium dodecyl sulfate (SDS) as very efficient hydrotropic salt. At zero concentration, one again finds the three-phase temperature interval $T_u - T_l$ of the ternary system. On adding the hydrotropic SDS, the upper **A**–**C** loop shrinks. As a consequence, the end points of the two critical lines approach each other, and $T_u - T_l$ both rises and narrows until the two end points merge at the tricritical point (Fig. 12c): The broken critical line is mended and the three-phase body has, accordingly, disappeared.

Another way of reaching a tricritical point is by decreasing the hydrophobicity of the amphiphile C_iE_j by decreasing i at constant j. Figure 30 shows the result of such an experiment with the system H_2O–hexane–$(C_3E_0 + C_2E_0)$. Here, the **A**–**C** nose is pushed further apart from the prism by gradually replacing pure C_3E_0 by a mixture of C_3E_0 and C_2E_0. Shown are the sections A through the pseudoternary phase prism (cf. Fig. 20).

The system with pure C_3E_0 shows a large three-phase body close to the melting point of the mixture (lowest fish in Fig. 30). On increasing the ratio C_2E_0/C_3E_0, the fish rises and shrinks to disappear at about $C_2E_0/C_3E_0 = 0.05$: The two critical lines cp_α and cp_β have merged at a tricritical point.

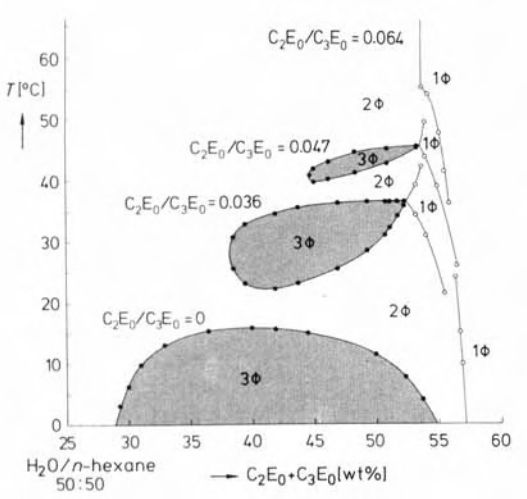

Fig. 30. Transition from a broken critical line ($C_2E_0/C_3E_0 = 0$) to an unbroken critical line ($C_2E_0/C_3E_0 = 0.064$) by increasing the hydrophilicity of the amphiphile: Section A through a pseudoternary phase prism of the system H_2O–hexane–$(C_3E_0 + C_2E_0)$ (cf. Fig. 20).

Neither C_3E_0 nor C_2E_0 show an upper loop with H_2O. On going to long chain amphiphiles C_iE_j with upper loop, one finds that the tricritical point can also be reached by increasing i at constant j, the reason being that with these amphiphiles the lower critical temperature, T_β, of the upper loop drops only slightly with increasing i at constant j, whereas the upper critical temperature, T_α, of the **B**–**C** loop drops steeply. Accordingly, the end points of the two critical lines, cp_β and cp_α, rapidly approach each other.[37]

8. Conclusion

We have shown that the phase behavior of ternary systems of class (1), H_2O–oil–nonionic amphiphile including an electrolyte as fourth component, can be readily understood on the basis of the theory of phase diagrams first developed at the turn of the century. We have, furthermore, suggested that the tricritical points in such systems be regarded as kinds of pivot points from which the phase behavior evolves. This would not only explain the fact that the phase behavior of such systems varies little, irrespective of the chemical nature of the amphiphile, but would also help to systematize its features.

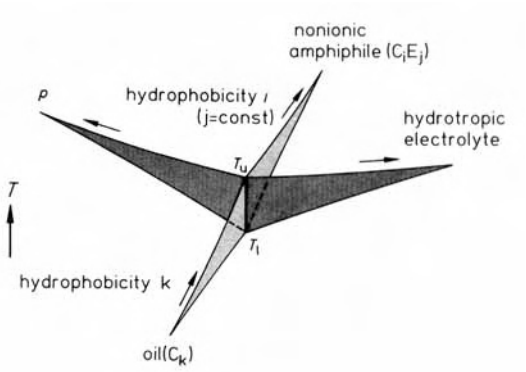

Fig. 31. Three-phase temperature interval ($T_u - T_l$) of a ternary system (center) as evolution from four tricritical points (schematic). For discussion see text.

Figure 31 summarizes our results: It shows in the center the three-phase temperature interval ($T_u - T_l$) of a ternary system of class (1). Its phase behavior evolves from four different tricritical points. These can be reached, at least in principle, by either increasing the pressure, by decreasing the hydrophobicity of the oil within a homologues series, by increasing i at constant j of the amphiphile C_iE_j within a homologues series, or by adding an appropriate hydrotropic salt. Since the thermodynamic properties of the (central) ternary system are functions of state, this suggests that the scaling laws which govern the evolution of its phase behavior from any of these four tricritical points, must be equivalent, if expressed in the appropriate order parameters.

This work is based on contributions by Dr. P. Firman, Dr. C.-U. Herrmann, Dr. G. Klar, Dr. E. Lessner, Dr. K.-H. Pospischil, Dr. U. Wuerz, and Herr D. Haase. We are indebted to Dr. M. Teubner for introducing us to the theory of critical phenomena. We are furthermore indebted to Herr B. Faulhaber and Herr T. Lieu for their assistance with the experiments, to Herr D. Luckmann for drawing the figures, and to Frau S. Schalner for typing the manuscript. The work was, in part, supported by the Bundesministerium für Forschung und Technologie (BMFT), the Fonds der Chemischen Industrie, and the 'Max-Buchner-Stiftung'.

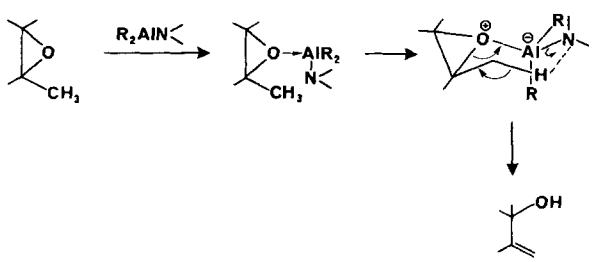
Selective Reactions Using Organoaluminum Reagents



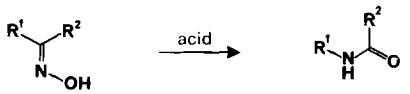
New Synthetic Methods (54)

By Keiji Maruoka and Hisashi Yamamoto*

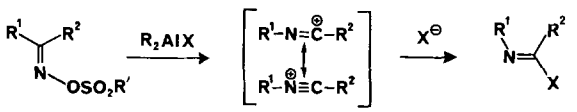
In addition to their high oxyphilicity, organoaluminum compounds are endowed with ambiphilic character. These properties can be successfully utilized in developing new synthetic reactions with unique selectivities. Especially noteworthy are the organoaluminum-promoted Beckmann rearrangement of oxime sulfonates, new syntheses of polyamino macrocycles via reductive cleavage of aminals and amidines by diisobutylaluminum hydride, the diastereoselective cleavage of chiral acetals by organoaluminum compounds leading to optically active secondary alcohols, allylic alcohols, and β-substituted carbonyl compounds, and biomimetic terpene syntheses. These and other examples, which illustrate the characteristics of organoaluminum chemistry, are used to demonstrate the distinct advantages of organoaluminum reagents in selective organic synthesis.

1. Introduction

During the past seven years since the publication of our first review[1] on organoaluminum compounds, these have found increasing application as reagents for selective organic synthesis.[2] Their chemistry has so far been simply understood in terms of the high Lewis acidity of their monomeric forms, which is directly related to the pronounced tendency of the aluminum atom to build up an octet of electrons. Organoaluminum compounds can interact strongly with various heteroatoms in organic molecules, particularly oxygen, to generate 1:1 coordination complexes. However, in sharp contrast to typical Lewis acids such as $BF_3 \cdot OEt_2$, $AlCl_3$, $SnCl_4$, and $TiCl_4$, they are endowed with a latent nucleophilic character, which can emerge prominently on coordination of an oxygen-containing functional group. The aluminum atom serves primarily as the coordination site for the substrate. The nucleophilic center attached to aluminum can be activated by the formation of the coordination complex, facilitating the nucleophilic attack on the substrate, as illustrated in the isomerization of oxiranes to allylic alcohols by organoaluminum amides.[1]



[*] Prof. Dr. H. Yamamoto, Dr. K. Maruoka
Department of Applied Chemistry, Nagoya University
Chikusa, Nagoya 464 (Japan)



Organoaluminum compounds thus possess both electrophilic and nucleophilic character, and can therefore be viewed as "ambiphilic" reagents rather than as ordinary Lewis acids.[3] These properties are of great value in the design of selective reactions. Our recent studies on the development of new synthetic reactions using organoaluminum reagents are described in this review.

2. Organoaluminum-Promoted Beckmann Rearrangement

The Beckmann rearrangement is the skeletal rearrangement of ketoximes in the presence of certain acids to give amides or lactams.[4] Its mechanism consists essentially of the formation of an electron-deficient nitrogen atom by polarization of the oxygen-nitrogen bond of the oxime with simultaneous intramolecular migration of the group *anti* to the departing hydroxyl group, producing the iminocarbocation, which then reacts with water to give the corresponding amide.

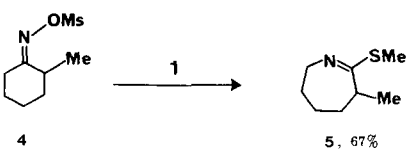
Reexamination of this reaction led us to expect that organoaluminum compounds might be employable as ambiphilic reagents to induce the Beckmann rearrangement of oxime derivatives as well as to capture the intermediary iminocarbocation or alkylidyneammonium ion[5] by the nucleophilic part of the molecule. This proved to be the case.

The realization of this concept opens new synthetic applications of the classical Beckmann rearrangement.[6] Furthermore, it has made possible the highly stereoselective synthesis of naturally occurring alkaloids.

As oxime derivatives, oxime sulfonates are preferred for the following reasons: 1) ready availability from oximes using *p*-toluenesulfonyl chloride (TsCl) or methanesulfonyl chloride (MsCl) in the presence of base in almost quantitative yields; 2) ease of handling because of their fine crystalline properties; 3) high enough reactivity toward organoaluminum reagents to initiate the rearrangement.

2.1. Synthesis of Esters of Thio- and Selenoimidic Acids

The concept discussed in the previous section was first tested using organoaluminum reagents of the type R_2AlX (X = SR', SeR') with the object of developing a new and general approach to thio- and selenoimidic esters,[6] which are an important class of compounds as activated forms of amides in alkaloid synthesis.[7]



A series of dialkylaluminum thiolates was prepared in situ from diisobutylaluminum hydride (DIBAH) and dimethyl disulfide, or from trimethylaluminum and thiols.[8]

$$2i\mathrm{Bu_2AlH} + \mathrm{MeSSMe} \longrightarrow \underset{\mathbf{1}}{2i\mathrm{Bu_2AlSMe}} + \mathrm{H_2}$$

$$\mathrm{Me_3Al} + \mathrm{RSH} \longrightarrow \mathrm{Me_2AlSR} + \mathrm{CH_4}$$

Reaction of the 2-methylcyclohexanone oxime methanesulfonate **2** with diisobutylaluminum methanethiolate **1** in dichloromethane proceeded smoothly within 1 h at 0 °C to furnish the thioimidic ester **3** in good yield. None of the substitution product at the nitrogen was detected.

By contrast, the isomeric oxime **4**[9] gave exclusively the thioimidic ester **5** under the same conditions. Thus, the regioselectivity of the reaction follows the general rule for the Beckmann rearrangement, which predicts that the group *anti* to the oxime sulfonate migrates preferentially.

Most oxime sulfonates react readily with 1–2 equivalents of organoaluminum thiolates at or below 0 °C to furnish the corresponding thioimidic esters (Table 1); an exception is cyclopentanone oxime *p*-toluenesulfonate **6**,

which under the usual conditions gives the unrearranged substitution product **7** as the sole isolable product.

In a similar fashion, selenoimidic esters can be prepared by reaction of oxime sulfonates with dialkylaluminum selenolates ($Me_2AlSeMe$ and $iBu_2AlSePh$)[10] in synthetically useful yields (Table 2).

2.2. Synthesis of α-Alkylated Amines

Trialkylaluminum compounds were studied in order to find the ultimate methodology for regio- and stereoselective α-alkylation of amines in alkaloid synthesis. Reaction of oxime sulfonates with several equivalents of an alkylaluminum reagent in dichloromethane resulted in the formation of imines, which were directly reduced with excess DIBAH to furnish the corresponding amines.[11] Furthermore, the intermediary imines were directly treated with Grignard reagents producing the α,α-dialkylated amines.[12] The carbon framework of a substrate can thus be elaborated in a flexible manner with regiospecific incorporation of a nitrogen functional group.

This reaction sequence has a wide scope of application as illustrated in Tables 3 and 4. Linear and cyclic oxime sulfonates are equally employable. Diethylaluminum alkynide can be utilized for introduction of the alkynyl moiety into a substrate, leaving the ethyl group intact. Thus, a new entry to propargylic amino derivatives is available in a simple operation. Halogenated hydrocarbons (e.g., dichloromethane, chloroform, or 1,2-dichloroethane) are suitable solvent systems. In tetrahydrofuran (THF), which strongly coordinates to aluminum, little or no α-alkylated amines are formed. Rigorous regioselectivity is also observed here, as in the synthesis of thio- or selenoimidic esters.

Since the discovery of the Beckmann rearrangement/alkylation sequence, we had hoped to apply the reaction to the synthesis of physiologically active alkaloids such as

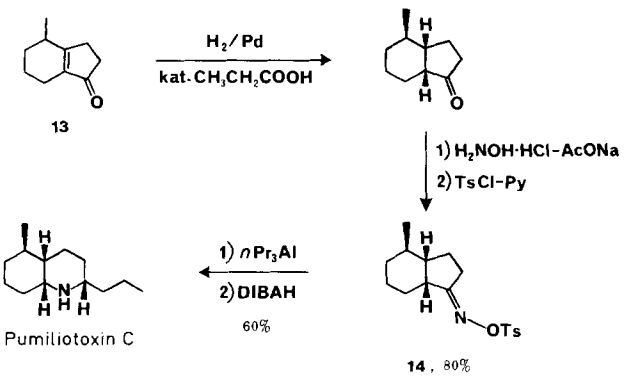
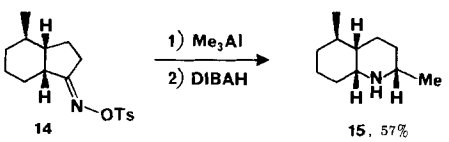
pumiliotoxin C and solenopsin A. Initially, we studied the piperidine ring formation by Beckmann rearrangement in aprotic media and attempted to prepare the simple piperidine alkaloid coniine **9**[12] by reaction of cyclopentanone oxime *p*-toluenesulfonate **8** with nPr_3Al (Scheme 1). This approach, however, was unsuccessful. Thus, treatment of **8** with nPr_3Al at −78 to 0°C followed by reduction with DIBAH gave a mixture of the unrearranged amine **10** (23%) and piperidine in addition to 4% of the desired **9**. Moreover, using hexane as solvent, the amine **10** was produced exclusively. Surprisingly, increasing the initial temperature from −78° to 40–80°C favors the normal rearrangement product **9** at the expense of **10**. The pronounced effect of temperature on the course of the reaction may be attributed to the rapid dissociation of dimeric nPr_3Al at high temperature, which would enhance its Lewis acidity toward **8** (thereby promoting the rearrangement) as well as the nucleophilicity of the *n*-propyl group toward the intermediary iminocarbocation.

In contrast to **8**, 2-alkylcyclopentanone oxime sulfonates cleanly rearrange at initially high temperatures (25–40°C) even in hexane, as exemplified by the synthesis of

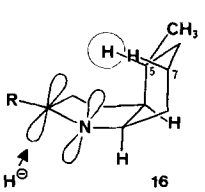


Scheme 1. A: nPr_3Al (2 equiv.) in CH_2Cl_2 (−78°C, 5 min; 0°C, 1 h); B: DIBAH (1.5 equiv.) (0°C, 1 h); C: nPr_3Al (2 equiv.) in hexane (0°C, 1 h); D: nPr_3Al (3 equiv.) in CH_2Cl_2 (40°C, 30 min); E: nPr_3Al (2 equiv.) in $ClCH_2CH_2Cl$ (80°C, 15 min).

dihydropinidine **12** from 2-methylcyclopentanone oxime *p*-toluenesulfonate **11**. The rearrangement of five-membered carbocyclic systems is thus highly dependent on both the nature of the organoaluminum reagents in solution and the substrates.

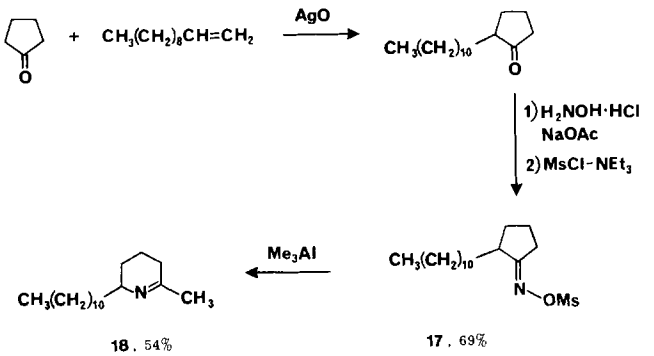


11 **12**, 67–≈70%

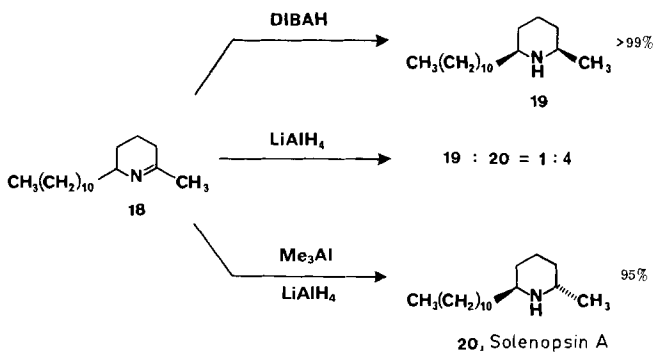


With the modified procedure for the synthesis of α-alkylpiperidine systems in hand, we have successfully developed a simple and highly stereoselective route from the ketone **13**, via the oxime sulfonate **14** as intermediate, to pumiliotoxin C,[12] a physiologically active alkaloid isolated from the skin of the neotropical frogs *Dendrobates pumilio* and *Dendrobates auratus*.

Furthermore, the preparation of other pumiliotoxin analogues was possible. Reaction of **14** with Me_3Al followed by DIBAH afforded the 2-methyl-*cis*-decahydroquinoline **15** in a stereoselective fashion.

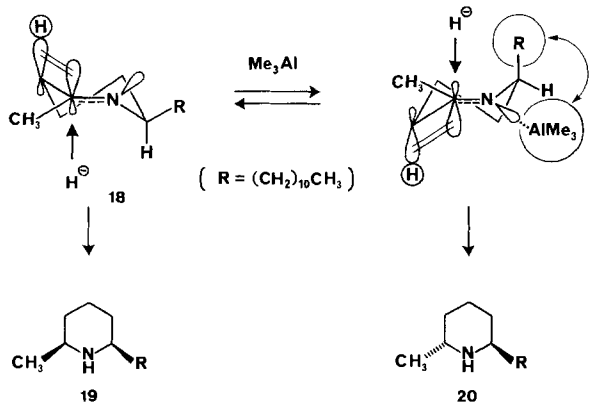


The remarkably high stereoselectivity in the DIBAH reduction of the imine **16**, the precursor of **15**, can be ascribed to steric effects (Scheme 2). In the stable conformation of **16**, the carbocyclic ring, especially its C5 and C7 axial hydrogens, shields one side of the imino group so that *exo* attack by the hydride is preferred.



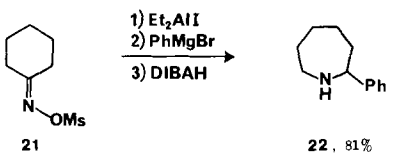
Scheme 2. Preferential *exo* attack $H^{\ominus}$ on **16**.

In addition to the *cis*-2,6-disubstituted piperidine structure in pumiliotoxin C, there are a number of physiologically active alkaloids, such as solenopsin A, that possess a characteristic *trans*-2,6-disubstituted piperidine unit. Nevertheless, none of the existing methodologies is generally applicable for synthesizing the *trans*-2-alkyl-6-methylpiperidine structure in solenopsin A, simply because specific introduction of an alkyl group to form the *trans* structure is not easy to achieve. For example, reduction of imine **18** (prepared by a multi-step synthesis from cyclopentanone and 1-undecene via the oxime methanesulfonate **17** with



DIBAH gave the *cis* isomer **19** exclusively. Reaction with $LiAlH_4$ in ether produced a mixture of **19** and **20** in a ratio of 1:4. In contrast, coordination of the imino nitrogen atom in **18** to the Lewis acid Me_3Al followed by reduction of the resulting 1:1 complex with $LiAlH_4$ in THF afforded solenopsin A **20** in 90–95% yield with excellent stereoselectivity.[13]

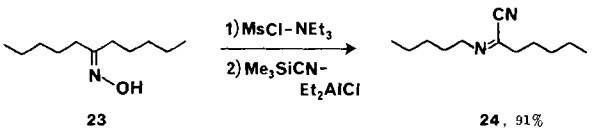
The high degree of stereoselectivity observed for the reduction of the imine using the Me_3Al-$LiAlH_4$ system can be rationalized by the theory of *Houk* et al.[14] as well as by the theory of charge-transfer stabilization of the transition state for nucleophilic addition to a carbonyl group.[15] Both theories predict the strong preference for antiperiplanar attack of the hydride ion with respect to the σ_{C-H} bond vicinal to the imino functional group (Scheme 3).



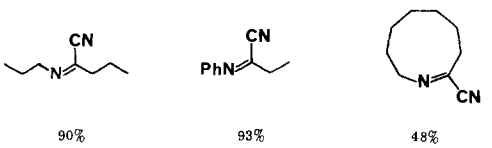
Thus, in the hydride reduction of **18**, the underside approach of the incoming hydride ion toward the π bond is preferred by the stabilization of the σ* orbital (low-lying unoccupied orbital of the imine) through electron delocalization from the σ_{C-H} bond (stereoelectronic control), producing the *cis* isomer **19**. On the other hand, in the presence of Me_3Al as Lewis acid, the alkyl group R of **18** would occupy the axial position because of the stereic repulsion between R and Me_3Al coordinated to the nitrogen

Scheme 3. Stereoselective reduction of **18** with DIBAH or $Me_3Al/LiAlH_4$.

lone-pair electrons ($A^{(1,2)}$ strain).[16] Such a conformational change should facilitate the stereoelectronically favored topside approach of the hydride ion toward the π bond to furnish the desired *trans* isomer **20**.



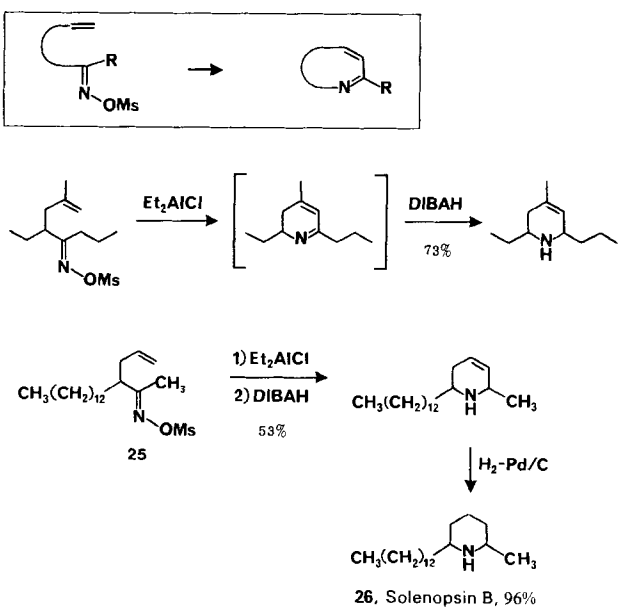
The Beckmann rearrangement/alkylation sequence cannot be utilized for introduction of less reactive nucleophiles containing sp^2-hybridized carbon such as aryl or vinyl groups. A route to α-arylated amines via imidoyl iodides was found to be promising,[17] since these are highly susceptible toward nucleophilic attack.[18] Thus, reaction of cyclohexanone oxime methanesulfonate **21** in dichloromethane with diethylaluminum iodide (2 equivalents) furnished the imidoyl iodide, which was directly arylated by the use of phenylmagnesium bromide (3 equivalents) and then reduced with DIBAH (4 equivalents), producing the α-phenylated amine **22** in high yield. Other oxime derivatives such as cyclohexanone oxime carbonate and acetate gave less satisfactory yields (0–17%).



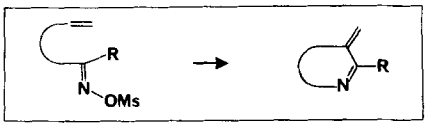
2.3. Synthesis of Schiff Bases Containing an α-CN Group

As a result of extensive investigations into the introduction of other nucleophiles by organoaluminum-promoted Beckmann rearrangement, the combination of diethylaluminum chloride with trimethylsilyl cyanide (*Utimoto*'s method as a substitute for diethylaluminum cyanide)[19] was found to provide a new method of preparing Schiff bases containing α-CN groups from oxime sulfonates.[6] These compounds are viewed as a masked form of α-amino acids, and the presence of the sp^2-prochiral center (the C=N bond) could be used to prepare optically active α-amino acids.[20] Thus, 6-undecanone oxime **23** was converted in the usual manner into its methanesulfonate, which was treated successively with Et_2AlCl and Me_3SiCN at −78 °C to afford the Schiff base **24** in high yield.

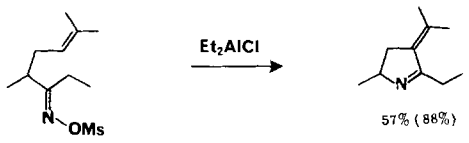
Similarly, several other oxime sulfonates were transformed into the corresponding Schiff bases (Scheme 4).



Other Lewis acids, such as $SnCl_4$, $BF_3 \cdot OEt_2$, or trimethylsilyl trifluoromethanesulfonate (Me_3SiOTf), failed to give the desired Schiff bases in the presence of Me_3SiCN.

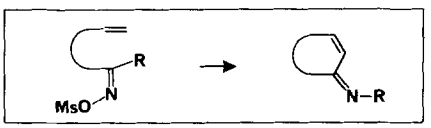


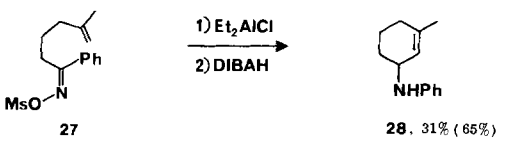
Scheme 4. Schiff bases with α-CN groups, obtained analogously to the reaction **23** → **24**.



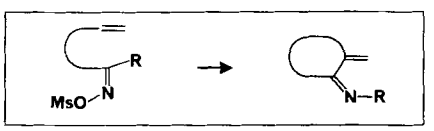
2.4. Olefinic Cyclization Promoted by Beckmann Rearrangement of Oxime Sulfonates

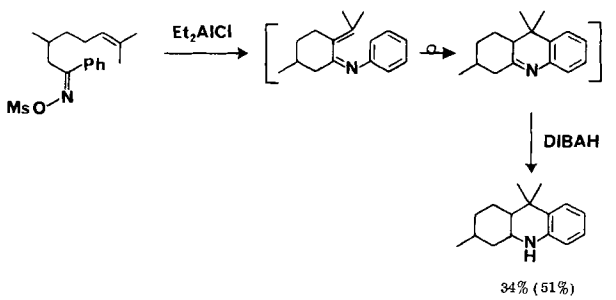
The efficient activation of oxime sulfonates by organoaluminum reagents[21] offers the opportunity to explore the intramolecular cyclization of olefinic oxime methanesulfonates, which involves the electrophilic addition of the intermediary iminocarbocation to the double bond.[22] This would result in the direct formation of a wide variety of structurally diverse carbocyclic as well as heterocyclic systems. A priori, four distinct cyclization modes are possible in these systems. Since the Beckmann rearrangement proceeds by endocyclic or exocyclic migration of the group "*anti*" to the departing sulfonate group, we refer to these as *endo*(B) and *exo*(B) rearrangements, respectively. Furthermore, we denote the endocyclic and exocyclic relationship of the bond being broken to the ring being formed by the suffixes *endo* and *exo*, respectively. Thus, the four possible cyclization modes are *endo*(B)-*endo*, *endo*(B)-*exo*, *exo*(B)-*endo*, and *exo*(B)-*exo*, as depicted in Schemes 5–8, each of which also illustrates representative examples. The values in parentheses refer to the yields obtained using $SnCl_4$.



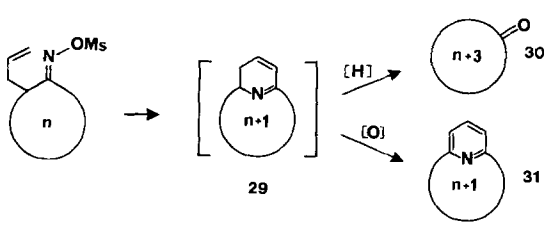


Scheme 5. *endo*(B)-*endo* cyclization.

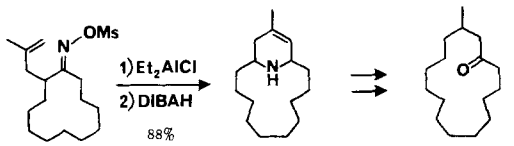




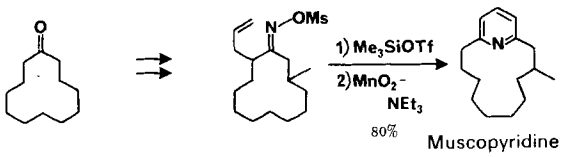
Scheme 6. *endo*(B)-*exo* cyclization.



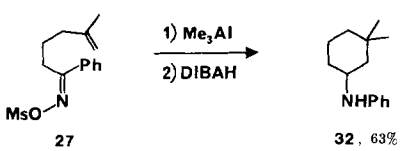
Scheme 7. *exo*(B)-*endo* cyclization.



Scheme 8. *exo*(B)-*exo* cyclization.

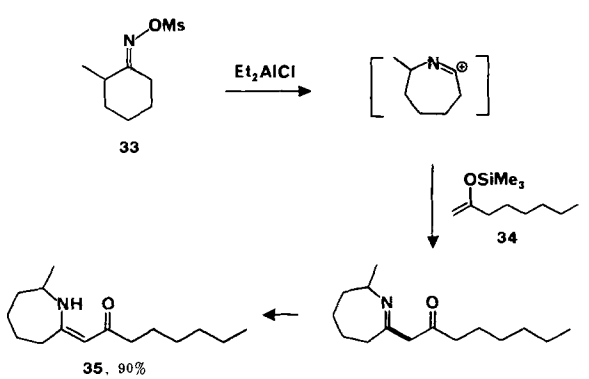


Solenopsin B **26** can be prepared via the *endo*(B)-*endo* cyclization in two steps from the simple acyclic precursor **25** (Scheme 5). Moreover, analogous *endo*(B) cyclizations were found to be key steps in synthetically important ring transformations.[23] Thus, the enimine **29** that is formed

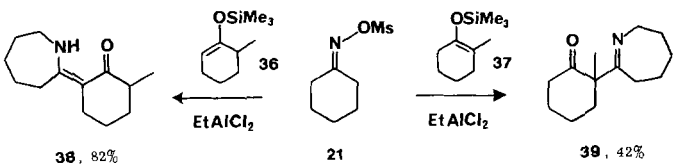


might be reductively cleaved to the ring-expansion product **30**, or oxidized to the heterocycles **31**, as illustrated in the facile syntheses of muscone and muscopyridine, respectively.

It is noteworthy that Me_3SiOTf was the reagent of choice for a new pyridinophane synthesis,[24] and that Et_2AlCl was less satisfactory in the following oxidation step.

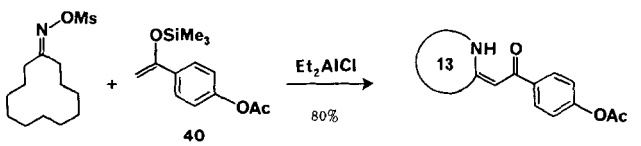


The cyclizations in the reactions described above were terminated by deprotonation, yielding α,β-unsaturated imines. The intermediary cations, however, may also be captured by carbon nucleophiles to afford saturated imines.[25] For example, treatment of the oxime methanesulfonate **27** with Me_3Al followed by reduction with DIBAH produced the methylated product **32** (63%) along with the product of deprotonation **28** (8%).



2.5. Synthesis of Enamino Ketones

In the reaction of oxime methanesulfonates with olefinic groups, silyl enol ethers **34** are extremely useful for efficient trapping of the intermediary iminocarbocation as well as for the termination of the reaction. This finding has led to a facile entry to a variety of enamino ketones (N–C=C–C=O),[26] which are useful as building blocks for the preparation of fused carbocycles and polyheterocycles.[27] Thus, in the presence of Et_2AlCl at −78 to 25 °C, the oxime methanesulfonate **33** reacted with 2-(trimethylsiloxy)-1-octene **34** in methylene chloride to give the enamino ketone **35** in high yield. Of all the Lewis acids examined, Et_2AlCl and $EtAlCl_2$ (2–3 equivalents) were the most effective; for other Lewis acids ($AlCl_3$, $SnCl_4$, $FeCl_3$,



$TiCl_4$, Me_3SiOTf, Me_3SiI, etc.), the yields were between 0 and 35%.

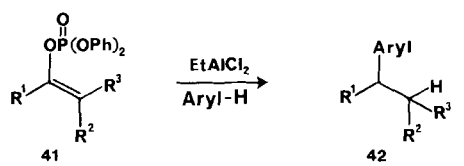
Notably, this condensation takes place with retention of regiochemical integrity in both substrates. Reaction of 6-methyl-1-(trimethylsiloxy)-1-cyclohexene **36** and 1-methyl-2-(trimethylsiloxy)-1-cyclohexene **37** with **21** furnished **38** and **39**, respectively, as the sole isolable products.

Another striking feature of the reaction is the high chemospecificity. The condensation of the silyl enol ether **40** derived from *p*-acetoxyacetophenone occurred in a chemospecific fashion with oxime methanesulfonates, the acetoxy moiety remaining intact.

Oxime sulfonates of aromatic ketones and cyclopentanones are not employable, since complex reaction mixtures are formed.

2.6. Reductive Arylation of Enol Esters

In analogy to the electrophilic addition of the cationic center generated by Beckmann rearrangement of oxime sulfonates to olefins, reductive arylation of enol esters, a new Friedel-Crafts-type reaction, is also possible.[28] Reaction of enol phosphate **41** in an aromatic solvent with excess $EtAlCl_2$ (10 equivalents) at room temperature gave the product of reductive arylation **42** in high yield (Table 5).



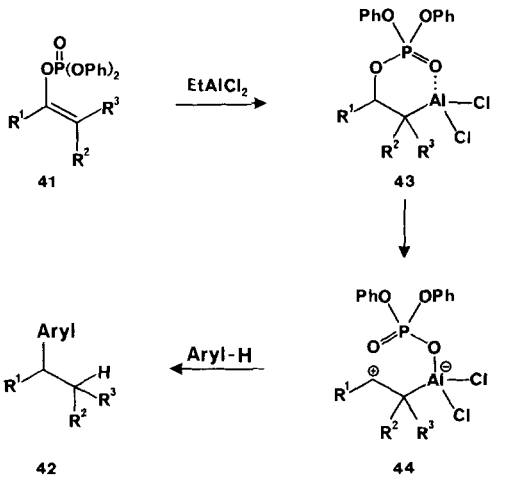


Table 5. Selected reductive arylation reactions of enol phosphates **41** in aromatic solvents in the presence of excess $EtAlCl_2$ at room temperature.

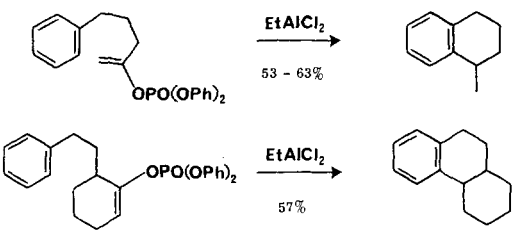
R^1	R^2	R^3	Solvent	Yield [%]
$-CH_2CH_2CHtBuCH_2-$		H	benzene	82
			toluene	97
$-CHCH_3(CH_2)_3-$		H	toluene	86
Ph	H	H	benzene	54
			toluene	90



This method is advantageous over typical electrophilic aromatic substitutions in that no polyalkylation is observed. The reaction is also highly regioselective: arylation takes place exclusively at the O-substituted carbon atom.

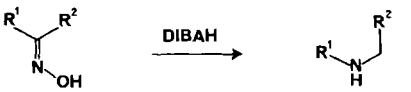
A possible mechanism is outlined in Scheme 9. The initial step of the reaction is probably hydroalumination of the double bond to form the adduct **43**, which in turn rearranges to the intermediate **44**. Electrophilic addition of the carbocation in **44** to the aryl group then takes place to give the product **42**.

Scheme 9. Mechanism of the reductive arylation of enol esters.

Intramolecular reductive arylation has also been achieved using enol phosphates of aliphatic ketones possessing a phenyl group in the γ or δ position.

2.7. Reduction of Oximes

Oxime sulfonates have been utilized so far as activated oximes. However, the pronounced reactivity of DIBAH enables the smooth cleavage of the N–O bond in the parent oxime, thereby providing a simple, yet highly convenient procedure for obtaining rearranged secondary amines from oximes (Table 6).[29]



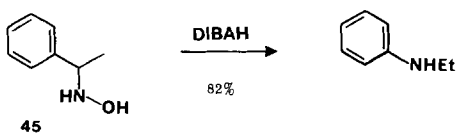


Table 6. Reduction of the oxime $R^1R^2C{=}NOH$ with DIBAH in CH_2Cl_2 at 0°C to room temperature.

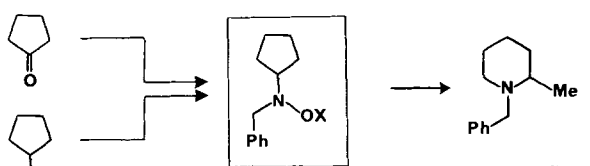
R^1	R^2	Yield [%]
Ph	Me	92
$CH_3(CH_2)_4-$	$CH_3(CH_2)_4-$	85
$-(CH_2)_{11}-$		70
$PhCH_2$	$PhCH_2$	71

Dichloromethane is the solvent of choice for the exclusive formation of the secondary amines: use of ethers affords a mixture of primary and isomeric secondary amines.[30]

Two mechanisms can be tentatively proposed for this reductive rearrangement: 1) initial reduction of the C=N bond and subsequent rearrangement of the resulting hydroxylamine; 2) Beckmann rearrangement promoted by cleavage of the N–O bond, followed by reduction of the imine. In order to determine the reaction mechanism, we prepared hydroxylamine **45** and reduced it with DIBAH, producing *N*-ethylaniline exclusively. Exposure of the corresponding oxime to trialkylaluminum produced none of the rearranged products. These results support the first mechanism.[31]

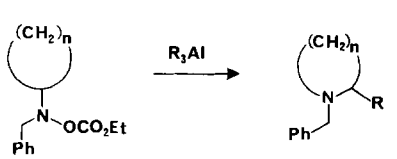


45

2.8. Rearrangement of Hydroxylamine Derivatives

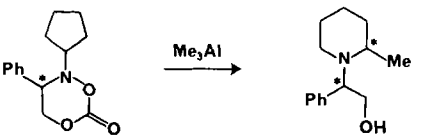
Since the hydroxylamine **45** rearranges to *N*-ethylaniline in the presence of DIBAH, it seemed logical to expect that other hydroxylamines might also undergo rearrangement under these conditions.[32]

The required hydroxylamines were conveniently prepared from a series of carbocyclic ketones, amines, or their precursors. The ethyl carbonate **47** of benzylcyclopentyl-



46, X = H
47, X = COOEt

48, 79%

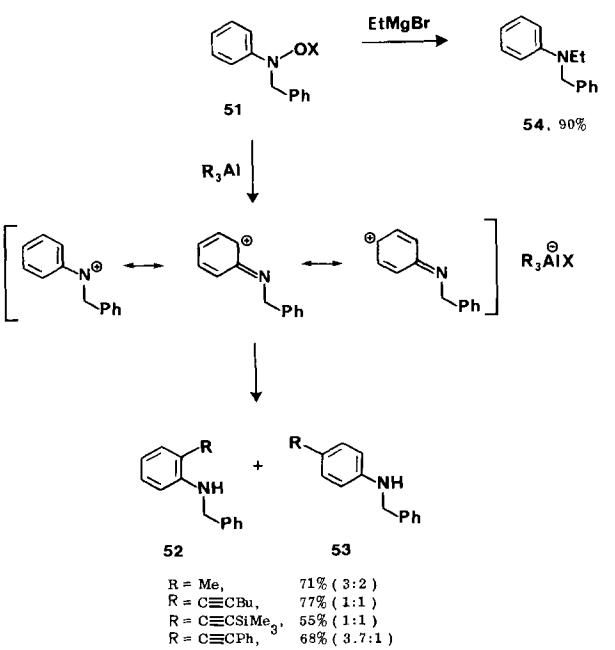


hydroxylamine **46** reacts with Me_3Al in dichloromethane to give exclusively the α-methylated piperidine **48** in high yield. The reaction is applicable to a variety of carbocyclic hydroxylamines (Table 7).

Table 7. Rearrangement of hydroxylamine carbonates using trialkylaluminum in CH_2Cl_2.

n	R	Yield [%]
3	Me	71
	C≡CSiMe$_3$	98
4	Me	74
	C≡CBu	89
	C≡CSiMe$_3$	71
7	Me	62

In contrast to the Beckmann rearrangement of oxime sulfonates, this method opens up the possibility of introducing a new carbon-carbon bond in a diastereoselective manner at the α position of amines, thus allowing the asymmetric synthesis of α-alkylated amines. A simple illustration of the potential of the reaction for asymmetric synthesis is shown by the rearrangement and subsequent alkylation of the cyclic carbonate **49**, in which the conformational mobility is reduced and the free energy difference between diastereomeric transition states in the reaction is increased. Thus, reaction of **49** with excess Me_3Al (6 equivalents) in dichloromethane at 0°C for 10 h afforded the desired amine **50** in 22% diastereomeric excess.



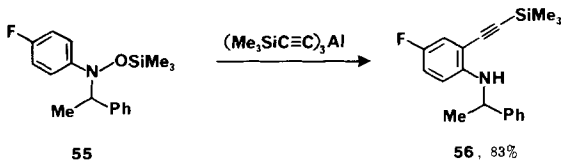
49

50, 61%

2.9. Nucleophilic Aromatic Substitution

Arylhydroxylamines behave in a completely different manner from alkylhydroxylamines on reaction with organoaluminum compounds.[33] For instance, reaction of the phenylhydroxylamine derivative **51** (X = Ac, $SiMe_3$) with trialkylaluminum in dichloromethane gave a mixture of *ortho*- and *para*-substituted methylanilines **52** and **53**, respectively, in high yield. The more nucleophilic Grignard reagent EtMgBr afforded mainly the *N*-alkylation product **54**.

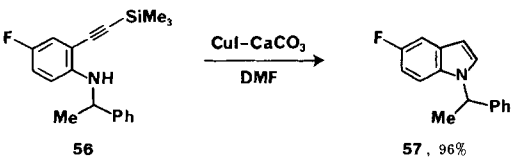
51



54, 90%

52 **53**

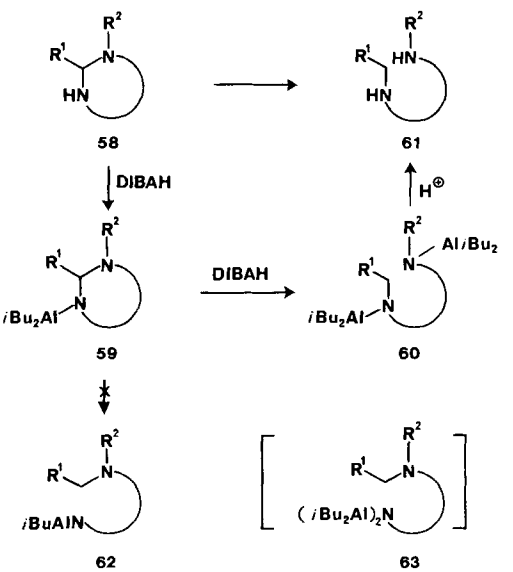
R = Me, 71% (3:2)
R = C≡CBu, 77% (1:1)
R = C≡CSiMe$_3$, 55% (1:1)
R = C≡CPh, 68% (3.7:1)



Accordingly, the highly oxyphilic organoaluminum reagent is capable of cleaving the N–O bond heterolytically to yield a phenylaminyl cation,[34] which is readily susceptible toward nucleophilic attack of trialkylaluminum at either the *ortho* or *para* position of the phenyl group. Dou-

ble alkylation products were not detected. This represents a distinct advantage over the classical Friedel-Crafts reaction. The *para*-substituted arylhydroxylamine **55** yielded solely the desired *ortho* alkylation product **56** in high yield.

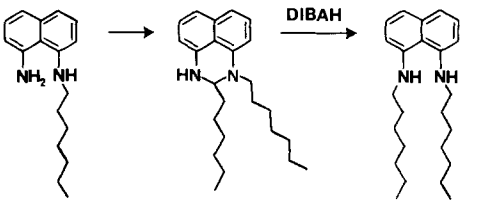
55 **56**, 83%



The availability of aromatic amines bearing an *ortho* alkynyl moiety allowed the development of a convenient synthesis of indoles. Reaction of **56** with copper(I) iodide (0.5 equivalents) and calcium carbonate (1 equivalent) in dimethylformamide (DMF) at 120 °C for 2 h[35] led to a smooth cyclization with concurrent elimination of the trimethylsilyl group to furnish indole derivative **57** in excellent yield.

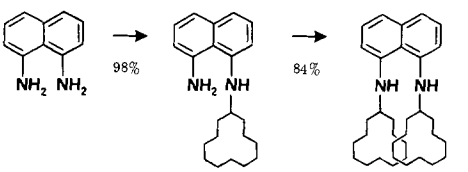
56 **57**, 96%

3. Reductive Amination by DIBAH



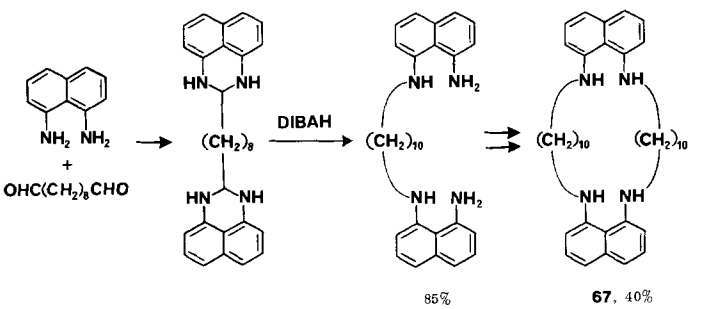
The high reduction potential of DIBAH (see Section 2.7) has also played an important role in the reductive cleavage of cyclic aminals, which provides a new and mild approach to selective *N*-alkylation of polyamines.[36] The general type of transformation is summarized in Scheme 10.[37]

58 **61** **59** **60** **62** **63**



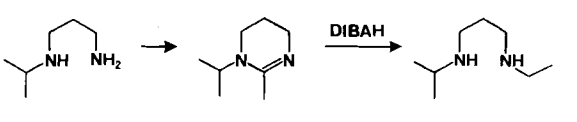
Scheme 10. Mechanism of the reductive cleavage of cyclic aminals.

DIBAH is an effective and selective reducing agent that cleanly converts the diisobutylaluminio compound **59**, prepared from the animal **58** with DIBAH, to the bis(diisobutylaluminio) compound **60**, which, in turn, gives the diamine **61** after hydrolysis. The reaction should proceed regioselectively since the formation of **62** or **63** is energetically much less favorable.



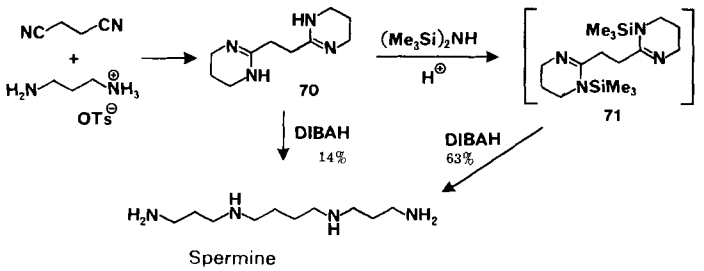
64 **65** **66**, 88%

The conversion of 8-(heptylamino)-1-naphthylamine **64** to 1,8-bis(heptylamino)naphthalene **66** is a typical example of this reaction. Reaction of **64** in benzene with heptaldehyde (1 equivalent) gave the 1-heptyl-2-hexyl-2,3-dihydropyrimidine **65** in quantitative yield.[38] Reduction of **65** with DIBAH (6 equivalents) in refluxing hexane for 1 h afforded the diamine **66** in high yield. Even bulky cyclododecyl moieties can be cleanly introduced with rigorous regioselectivity.

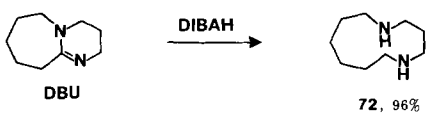


An application of this novel reductive cleavage process is the selective synthesis of the macrocyclic polyamine **67**.

85% **67**, 40%



Since DIBAH is an effective reducing agent for conversion of imines to amino derivatives, the new process can be readily extended to the reductive cleavage of the amidine system.[37] Reaction of 1-isopropyl-2-methyltetrahydropyrimidine **68** with DIBAH in hexane at 25 °C for 24 h and under reflux for 30 min gave *N*-ethyl-*N'*-isopropyl-1,3-diaminopropane **69** in almost quantitative yield.



68 **69**, 97%

This method was employed in a facile synthesis of spermine, which is widely distributed in the animal kingdom

and in microorganisms and forms the basic skeleton of spermine plant alkaloids.[39] The direct transformation of 1,2-bis(tetrahydro-2-pyrimidinyl)ethane **70**[40] into spermine did not proceed smoothly under vigorous reaction conditions (neat DIBAH, 150 °C, 11 h). However, protection of the amino function with the trimethylsilyl group,[41] which can be easily introduced and removed, enabled **70** to be converted in situ into the disilylated species **71**. After evaporation of excess hexamethyldisilazane, **71** was directly subjected to reductive cleavage by DIBAH (20 equivalents) in refluxing xylene for 3 d to furnish spermine in good yield.

In the case of bicyclic amidine systems, the reaction should result in a ring expansion, thus providing a selective and suitably mild approach to cyclic polyamines.[37] This is exemplified by the transformation of commercially available 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) to the eleven-membered cyclic diamine **72** by reaction with excess DIBAH (6 equivalents) in refluxing toluene for 7 h.

Other examples presented in Table 8 illustrate the generality and flexibility of this new approach. Indeed, this reaction was recently utilized to synthesize medium-ring

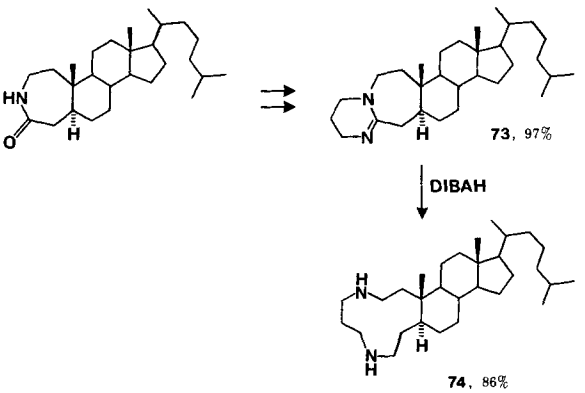


Table 8. Synthesis of cyclic polyamines from bicyclic amidines with DIBAH.

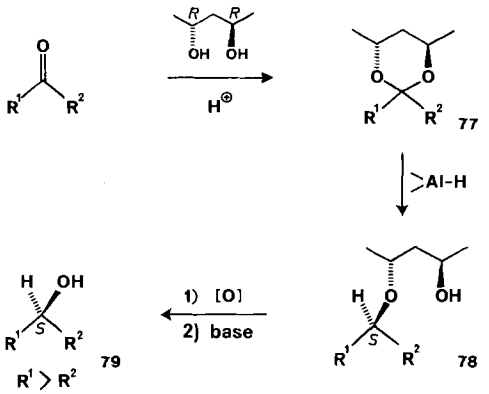
bicyclic bridgehead diamines[42] and to confirm the structure of the product of the chemical or enzymatic oxidation of spermine.[43] In addition, the optically active cyclic diamine **74** is readily accessible from the tetrahydropyrimidine derivative **73** using this procedure.

Although a large number of interesting guest compounds are available,[44] the synthesis of the corresponding host structures (e.g., macrocyclic polyethers and polyamines)[45] is rendered difficult by the limited utility of most

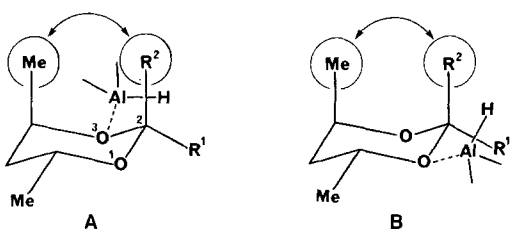


of the existing methods. The introduction of new synthetic methodology for chiral host molecules could be of crucial importance for the development of asymmetric synthesis. Accordingly, we have set out to investigate briefly the synthesis of the chiral ligand **75** and the chemistry of its metal-cation inclusion complexes.[46] Addition of *n*-butyllithium to a solution of **75** in *n*-pentane at low temperature produced the 1 : 1 complex **76**, which, on treatment with benzaldehyde, gave (*S*)-1-phenyl-1-pentanol in moderate optical yield.[47]

4. Cleavage of Chiral Acetals

The selective reducing ability of DIBAH observed in the reductive cleavage of aminals and amidines (Section 3) led us to expect that the optically active acetals might be cleaved regio- and stereoselectively by organoaluminum reagents under appropriate conditions.[48] Were this found to be the case, this might provide a new methodology for asymmetric reduction of prochiral ketones. Indeed, reduction of the chiral acetal **77** derived from (−)-(2*R*,4*R*)-2,4-pentanediol with DIBAH (5 equivalents) gave the hydroxy ether **78** diastereoselectively.[49] Removal of the chiral auxiliary by Swern oxidation[50] followed by β-elimination with methanolic K_2CO_3 afforded the optically active alcohol **79**.

Reagent, temperature, and solvent, the three variables in the reductive cleavage process, were explored in detail. Among the readily available aluminum hydrides tried, only DIBAH, Cl_2AlH,[51] and Br_2AlH gave satisfactory re-



sults. Tetrahydrofuran and other basic solvents were not satisfactory. Lower reaction temperatures resulted in better diastereoselectivities. Table 9 summarizes the results obtained with four different ketones. Since one of the major

Table 9. Selective reduction of chiral acetals 77 with aluminum hydrides.

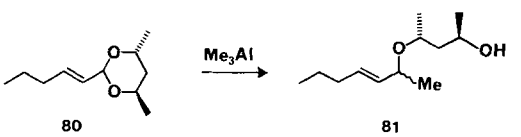
Ph	*n*Pr	DIBAH	72	20 : 1



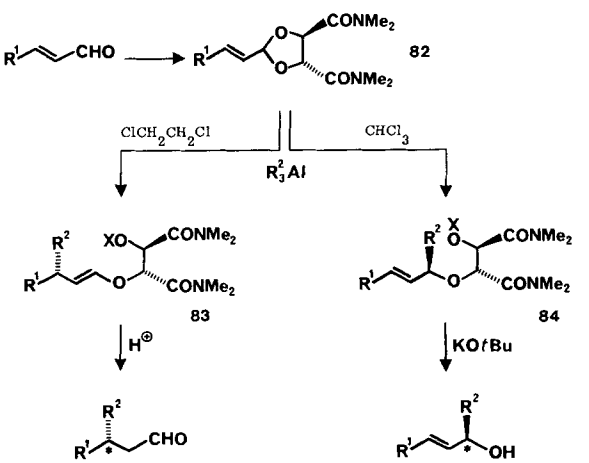
drawbacks of most existing methods for asymmetric reduction of ketones is that they are limited to aromatic or α,β-unsaturated ketones,[52] the present method serves as a practical solution to the asymmetric reduction of saturated ketones. The use of chiral 1,3-dioxanes as acetal substrate is essential for obtaining excellent diastereoselectivity. Reduction of 1,3-dioxolane systems with $LiAlH_4/AlCl_3$ was previously reported to give the corresponding hydroxy ethers with lower diastereoselectivity.[53]

Scheme 11. Complexes **A** and **B** formed from the acetal 77 and an aluminum reagent.

Scheme 11 shows the two complexes **A** and **B** formed between the aluminum reagent and the acetal **77**. Steric effects should influence the reactivity of the acetal oxygen atoms and hence their relative ease of coordination to aluminum. Accordingly, the least sterically conjested structure, the complex **A** should be favored. Due to the steric relief from the severe 2,4-diaxial interaction between methyl and R^2 as well as the anomeric effect in the 1,3-dioxane system,[54] the C2–O3 bond should be longer than a normal C–O ether bond, whereas the C2–O1 bond should have a partial double-bond character because of electron donation from O1. The transient species arising from **A** can undergo smooth cleavage of the C2–O3 bond by attack of aluminum hydride from the direction *syn* to the departing oxygen, leading to the (*S*) configuration at the newly formed ether carbon.

Utilizing a strategy based upon a chiral protecting group that is subjected to activation by ambiphilic aluminum reagents, we next focus our attention on the behavior of organoaluminum reagents toward chiral α,β-unsaturated acetals **80** and **82**. Reaction of the chiral α,β-unsaturated acetal **80** with Me_3Al resulted in formation of the 1,2-adduct **81** without any diastereoselectivity. However, by switching

the chiral auxiliary to optically active tartaric acid diamide,[55] unprecedented regio- and stereochemical control was observed in the addition of organoaluminum reagents to **82**.[56] This finding provides an easy access to optically active β-substituted aldehydes or allylic alcohols. Thus, reaction of **82** ($R^1 = n$Pr) in 1,2-dichloroethane with Me_3Al (5 equivalents) at room temperature for 12 h gave, after acetylation with acetic anhydride-pyridine, the 1,4-adduct **83** ($R^1 = n$Pr, R^2 = Me, X = Ac) preferentially in 84% yield (88% enantiomeric excess *ee*) accompanied by 13% of the



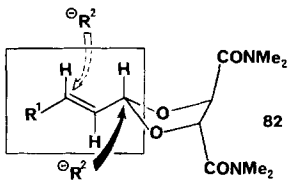


Table 10. Asymmetric 1,4- and 1,2-additions of organoaluminum reagents to α,β-unsaturated acetals **82**.

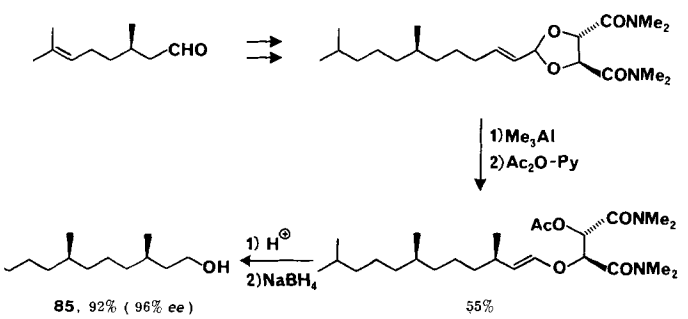
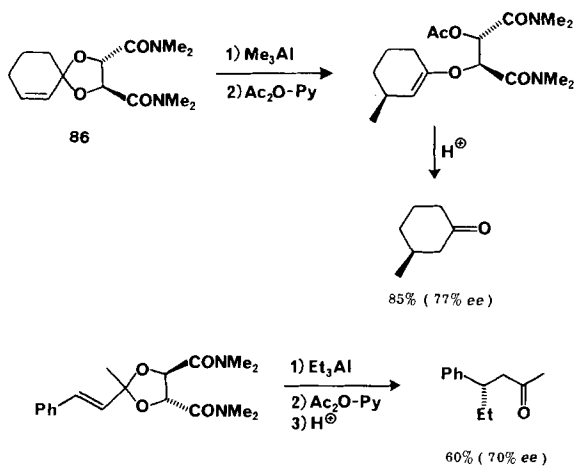
R^1	R^2	Solvent	*T* [°C]	Yield [%] [a]	*ee* [%]
*n*Pr	Me	$ClCH_2CH_2Cl$	−15	92 (2.8 : 1)	94
		*n*PrCl	RT	96 (6.5 : 1)	91
		CH_2Cl_2	RT	91 (3.3 : 1)	95
		toluene	5	81 (1.7 : 1)	96
Me	*n*Pr	CH_2Cl_2	5	96 (2.1 : 1)	87
		toluene	5	83 (1 : 1)	93
Ph	Me	CH_2Cl_2	5	62 (1 : 0)	94
		toluene	5	91 (5.7 : 1)	98

[a] In parentheses: ratio of 1,4- to 1,2-adduct.



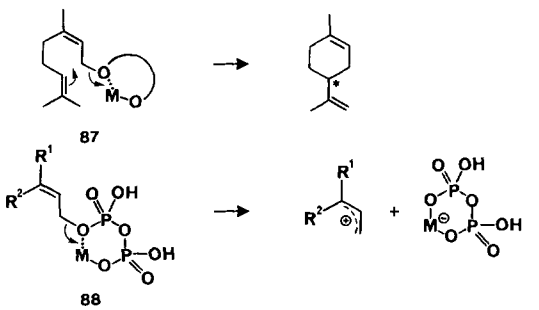
1,2-adduct **84**. In sharp contrast, the use of chloroform as solvent under comparable conditions afforded the 1,2-adduct **84** ($R^1 = n$Pr, R^2 = Me, X = H) exclusively in 85% yield (88% *ee*). The course of the reaction appeared to be strongly influenced by the nature of substrates, solvents, and temperature (Table 10).

Since both (*R,R*)- and (*S,S*)-tartaric acid diamide are readily obtainable in optically pure form,[55] this method allows the synthesis of the two enantiomers of both β-substituted aldehydes and allylic alcohols from α,β-unsaturated aldehydes in a predictable manner (Scheme 12).

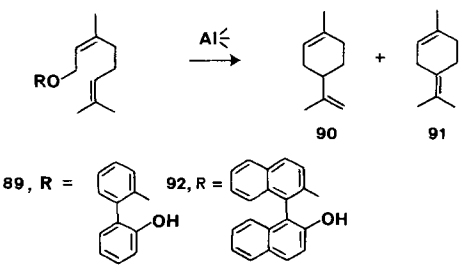


Scheme 12. Addition of the alkyl group R^2 to the chiral α,β-unsaturated acetal **82**.

This reaction has a vast potential in natural product synthesis as illustrated by the short synthesis of the branched alcohol **85**, which is present in the biologically important vitamins E and K.[56]

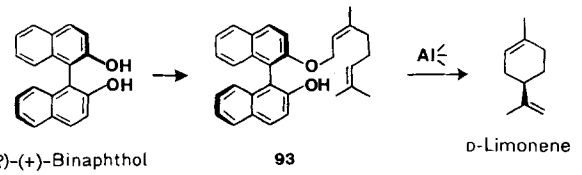


The α,β-unsaturated ketals, on the other hand, exclusively underwent 1,4-addition with moderate diastereoselectivities.[57] Surprisingly, the optical yield tends to decrease upon lowering the reaction temperature (65% *ee* at −15°C in the case of the ketal **86**).

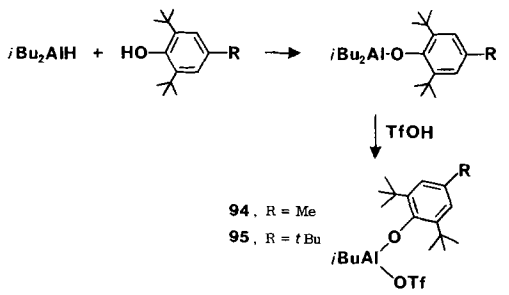


5. Biomimetic Terpene Synthesis

Since organoaluminum compounds have a great tendency to form 1 : 1 complexes, even with neutral bases such as ethers, we have sought to utilize this property ("oxyphilicity") in biomimetic terpene synthesis. Our strategy is based on the anchimerically metal-accelerated cyclization of alkoxide **87** to limonene,[58] for the biochemical transformation of these pyrophosphate derivatives could be profoundly related to the metal-assisted C–O heterolysis of allylic pyrophosphates **88**.



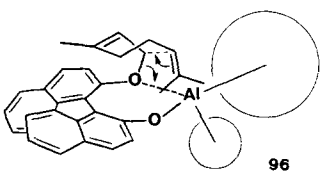
The concept was first examined with ether **89**. It was soon apparent that aluminum compounds can serve as crucial reagents for such allyl-cation-promoted cyclization reactions. When **89** in dichloromethane was treated with DIBAH at −78°C for 30 min and at 20°C for 10 h, limonene **90** and terpinolene **91** were produced in a ratio of 8 : 1 in 81% yield. Similarly, the reaction of **93** with aluminum reagents [DIBAH, 77% (9 : 1); Me_3Al, 72% (7.5 : 1)] produced **90** and **91**.



By contrast, the cyclization of neryl phenyl ether proceeds much more slowly than those of **89** and **92** under similar conditions. Thus, the remarkable rate acceleration observed here should be ascribed to the novel metal-anchimeric assistance of the aluminum reagent, which, by binding to the neighboring hydroxyl group, favors the ionization of the allylic substrates.

The enantioselective cyclization of neryl precursors is a reaction that would provide access to a variety of terpenes in enantiomeric form. The reaction of (*R*)-(+)-binaphthol mononeryl ether (**93**) with DIBAH under the conditions described above gave naturally occurring D-limonene and **91** (5 : 1 ratio) in 58% yield with only moderate enantioselectivity (≈ 12% *ee*). Since the optical yield tends to increase by lowering the reaction temperature, we sought to design more "oxyphilic" aluminum reagents than DIBAH in order to conduct the reaction at low temperature. The tri-

fluoromethanesulfonyl group was found to be promising as a ligand that, in organoaluminum reagents, decreases the electron density on aluminum. The bulky, substituted phenoxy group was also incorporated to ensure the formation of a monomeric aluminum species (**94** and **95**) in solution[60] and thus further enhance the oxyphilicity.

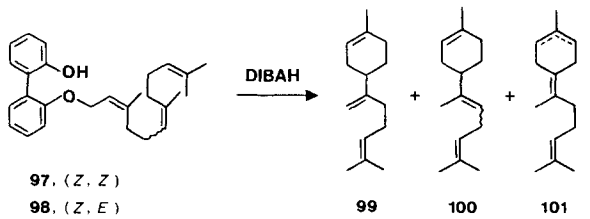


Treatment of **93** with several modified organoaluminum reagents in $CFCl_3$ at low temperature (-130 to -78 °C) produced D-limonene in high optical yield (Table 11).[59]

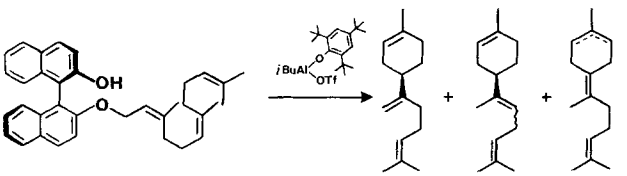
Table 11. Asymmetric synthesis of D-limonene from **93** with organoaluminum reagents.

Aluminum reagent	Yield [%] [a]	*ee* [%] [b]
iBu_2AlOTf	36 (3 : 1)	39
$iBuAl(OTf)_2$	27 (4 : 1)	40
94	29 (5.2 : 1)	64
95	58 (14 : 1)	77

[a] In parentheses: ratio of limonene to terpinolene. [b] Optical yield of D-limonene.



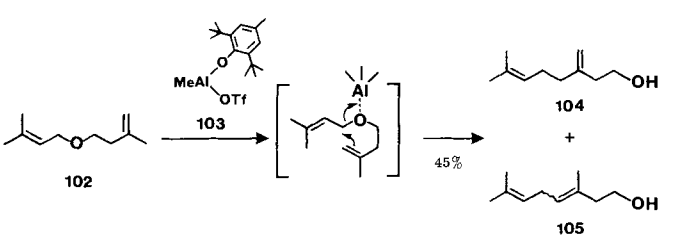
The high asymmetric induction observed here may be rationalized by the intermediacy of **96**, in which the neryl cation cyclizes via a preferential *anti-endo* conformation[61] (Scheme 13).



Scheme 13. Postulated intermediate in the asymmetric cyclization of **93** in the presence of an organoaluminum compound.

The present results have been successfully applied to the synthesis of bisabolenes from biphenyldiol (*Z,Z*)-monofarnesyl ether **97** and its *Z,E* isomer **98**. Reaction of the *Z,Z* isomer **97** with DIBAH (-78 °C, 30 min; 20 °C, 4.5 h) furnished β-bisabolene **99** preferentially in 60% yield accompanied by 16% of α-bisabolene **100** and 9% of γ-bisabolene **101**.

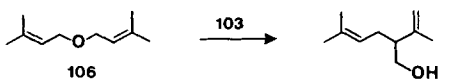
On the other hand, the *Z,E* isomer **98**, under similar conditions, was transformed into **99** (34%) and **100** (30%) along with 7% of **101**. Noteworthy is the preferential formation of **99** from the *Z,Z* isomer **97** and not from **98**, since it implies that during deprotonation the aluminum reagent may be responsible for determining the stereochemistry of the farnesyl moiety.



Furthermore, by replacing the biphenyl group with a chiral auxiliary and using other organoaluminum reagents, chiral bisabolenes can be obtained in high optical yields.

(+)-β-Bisabolene, 92% (76% *ee*)

With oxyphilic aluminum reagents at hand for terpene cyclizations, we have further extended the investigation to an intramolecular version of the prenyl transfer reaction,[62,63] which is accomplished by the rearrangement of isopentenyl prenyl ether **102**.[64] Treatment of **102** with the aluminum reagent **103** in dichloromethane at 25 °C afforded a mixture of the expected C_{10} alcohols **104** and **105** in moderate yield. The choice of catalyst is crucial for the rearrangement. For example, the strong Lewis acids usually used ($TiCl_4$, $SnCl_4$, $BF_3 \cdot OEt_2$, etc.) attack both the ether oxygen and the double bonds in **102**, leading to a number of side products. With weaker acids, it would be difficult to cleave the C–O bond of **102**. Clearly, the oxyphilic aluminum reagent **103** is strong enough to coordinate to the ether oxygen, but not to double bonds; it could thus play a key role in promoting a combined C–O bond fission/rearrangement. In addition, the bulky 2,6-di-*tert*-butyl-4-methylphenoxy group in **103** would assist anchimerically the through-space interaction of the π-electron orbital of the isopentenyl group with a developing empty orbital of the prenyl cation via a six-membered transition state.



The analogous rearrangements of isopentenyl geranyl ether and isopentenyl farnesyl ether occurred equally well to give the C_{15} and C_{20} alcohols, respectively.

42%, R = Prenyl
33%, R = Geranyl

In addition to the head-to-tail condensation, the alternative head-to-head terpene synthesis was also realized by the organoaluminum-promoted intramolecular rearrangement of diprenyl ether **106**. Thus, reaction of **106** with the reagent **103** at 0°C for 1.5 h furnished only lavandulol.[63]

106

Lavandulol, 33%

6. Closing Remarks

With the aid of selected examples the present review demonstrates that organoaluminum compounds exhibit unique properties, especially their ambiphilic character and their high oxyphilicity, that are capable of considerably extending the scope of organoaluminum chemistry in organic synthesis. In particular, the concept of ambiphilic systems should be applicable to other organometallic compounds such as magnesium, boron, and titanium reagents.[65] However, even with the promising experimental findings so far obtained, it is difficult to predict how many other chemical properties will emerge in the field of organoaluminum chemistry. The synthetic potential of organoaluminum reagents in selective organic synthesis is therefore expected to increase still further.

We express our sincere appreciation to our outstanding students who have made significant contributions to the various developments of organoaluminum chemistry outlined in this review: Kazunobu Hattori, Kensuke Umeyama, Soichi Sakane, Yasushi Matsumura, Mamoru Ando, Tohru Miyazaki, Atsunori Mori, Yoshihiro Yamamura, Yasuko Ishida, Satoru Sasatani, Junya Fujiwara, Yoshimi Fukutani, Hiromi Sano, Masaichi Hasegawa, and Terence L. Schull. Financial support from the Ministry of Education (Japan), the Naito Science Foundation, the Yamada Science Foundation, Kuraray Co., Ltd., Toyo Stauffer Chemical Co., Ltd., and the Petroleum Research Fund administered by the American Chemical Society is gratefully acknowledged.

Tridentate Oxygen Ligands as Cyclopentadienyl Equivalents: Structure and Properties of $[LRh(\mu\text{-}CO)_3RhL]$, $L^- = [(C_5H_5)Co\{P(O)R_2\}_3]^-$**

By *Wolfgang Kläui,* Mario Scotti,* Mauricio Valderrama,* Soledad Rojas, George M. Sheldrick,* Peter G. Jones,* and *Tina Schroeder*

Dedicated to Professor F. Gordon A. Stone on the occasion of his 60th birthday

Complexes of the type L^-, which are anionic tridentate oxygen ligands, are formally isoelectronic with the cyclopentadienide ion.

L^-

$[LRh(CO)_2]$ **1**

$[LRh(\mu\text{-}CO)_3RhL]$ **2**

a, R = OMe; **b**, R = OEt

We have recently observed that the oxygen tripod ligand L^-, R = OEt, can be incorporated similarly to a cyclopentadienyl (Cp) ligand into metal carbonyl complexes of Cr, Mo, W,[1] Mn, Re,[2] and Ru.[3] This is surprising insofar as L^- is a very much weaker ligand according to ligand field spectroscopy and is most closely comparable to the fluoride ion. Since no Rh^I carbonyl complex with three oxygen donors has, to the best of our knowledge, been reported, we have attempted to synthesize complexes of type **1**, which are oxygen analogues of $[CpRh(CO)_2]$.

A reaction is immediately observed on treatment of $[\{Rh(CO)_2Cl\}_2]$ with NaL (R = OMe, OEt) in hexane or dichloromethane at 25 °C; the formation of the dicarbonyl complexes **1a**, **b** can be followed by IR spectroscopy. The $\nu_{C\text{-}O}$ frequencies are observed at 2080 and 1990 cm^{-1} (CH_2Cl_2). The compounds are stable in air but dimerize in solution in a few hours with partial decarbonylation to form the title compounds **2a**, **b**.[4] Crystals of **2b** suitable for X-ray structure determination were obtained by recrystallization from dichloromethane.

2b (Fig. 1) possesses crystallographic twofold symmetry. The three carbonyl groups serve as bridging ligands. It is notable that the formal analogue $[Cp_2Rh_2(CO)_3]$ has only one bridging CO ligand.[5] If the L^- ligand is viewed as the equivalent of three CO groups, the molecule is analogous to "$[(OC)_3Rh(\mu\text{-}CO)_3Rh(CO)_3]^{2+}$," which is isoelectronic with $Fe_2(CO)_9$. Since an Fe–Fe single bond is present in $Fe_2(CO)_9$, the Rh–Rh interaction (254.6 pm) can likewise be viewed as a single bond. Although such bonds normally have lengths of 270–280 pm,[6] Rh–Rh single bonds exist that are appreciably shorter, e.g., 238.6 pm in $[Rh_2(O_2CCH_3)_4(H_2O)_2]$.[7]

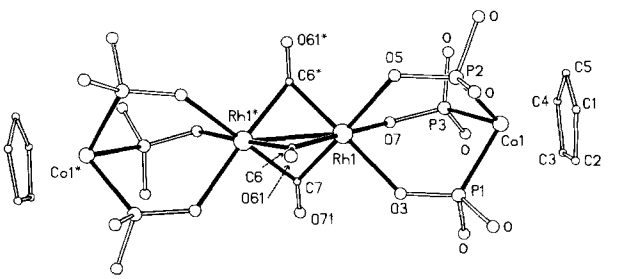

Fig. 1. Crystal structure of **2b**. The ethyl groups of the POEt moieties are omitted for clarity. Space group C2/c, $a = 1013.3(3)$, $b = 1967.0(10)$, $c = 2951.2(6)$ pm, $\beta = 92.71(3)°$, $V = 5.577$ nm^3, $Z = 4$, $\mu(Mo_{K\alpha}) = 2.8$ mm^{-1}; $R_w = 0.055$, $R = 0.078$ for all 3642 absorption-corrected reflections; $Mo_{K\alpha}$ radiation, $2\theta_{max} = 45°$. Two ethyl groups are disordered. C7 and O71 lie on a twofold axis. Important bond lengths [pm]: Rh1–Rh1* 254.6(2), Rh1–O3 218.1(5), Rh1–O5 217.2(5), Rh1–O7 217.7(5), Rh1–C6 199.4(7), Rh1–C7 198.9(9), Rh1–C6* 199.3(7), Co1–P1 216.9(3), Co1–P2 216.6(3), Co1–P3 215.9(3). The asterisk indicates symmetry-equivalent atoms. Apart from the RhRh bond, the coordination geometry at rhodium is nearly octahedral. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51411, the names of the authors, and the journal citation.

Preliminary experiments have shown that **1** and **2** form compounds of the type $[LRh(CO)PR'_3]$ with tertiary phosphanes PR'_3, R' = Et, *c*-C_6H_{11}, Ph. **2** reacts in refluxing dichloromethane over several hours, more slowly than $[Cp_2Rh_2(CO)_3]$.[8] Such differences in reactivity have also been observed for $[(C_4H_4)_2Fe_2(CO)_3]$[9] and $[(C_4Ph_4)_2Fe_2(CO)_3]$,[10] which differ similarly in the arrangement (bridging, terminal) of the CO ligands. The CO substitution in **1**, on the other hand, proceeds very fast, more rapidly than in the isoelectronic cyclopentadienyl complex $[CpRh(CO)_2]$.[11] This means that, since the CO substitution in both dicarbonyl complexes takes place via an associative mechanism, the intermediary transition from tridentate to bidentate coordination is energetically more favorable for the oxygen tripod ligand L^- than the "slipping reaction" η^5-Cp/η^3-Cp.[12] An interesting aspect of the chemistry of this rhodium complex is the fact that the oxygen tripod ligands remain bonded to rhodium. It is completely atypical for oxygen ligands to form inert complexes with metals in low oxidation states. This complex opens up the possibility, therefore, of studying the effect of a type of ligand that, in its steric and electronic properties, clearly differs from the isoelectronic C_5H_5 and C_5Me_5 ligands that are ubiquitous in organometallic chemistry.

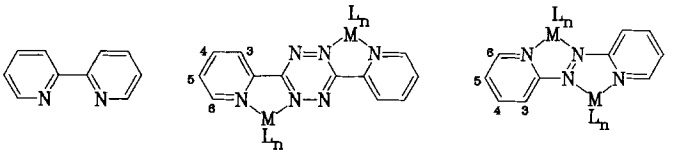
Extremely Long-Wavelength Charge-Transfer Absorptions of Binuclear Complexes with Azo-Modified 2,2′-Bipyridyl Ligands**



By *Stephan Kohlmann, Sylvia Ernst,* and *Wolfgang Kaim**

The controlled synthesis of complexes with very long-wavelength charge-transfer absorptions is of interest owing to their potential applications in the chemical use of solar energy, since a major fraction of the solar radiation that reaches the earth's surface is in the near-infrared (NIR).[1] In view of the advantageous photophysical properties of complexes containing α-diimines of the 2,2′-bipyridine (bpy) type,[2] we have modified this system by introducing coordinatively bifunctional π-acceptor moieties, which should allow coordination of more than one π-electron-rich metal fragment and thus produce particularly strong effects.[3]

We chose the bridging bis(chelate) ligands 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine **1**[4] and azo-2,2′-bipyridine **2**,[5] which incorporate the π-electron-deficient azo function $-N=N-$,[6] and report here the binuclear complexes **1a–d** and **2a**, **d** containing low-spin d^6 metal-complex fragments[7] (see Table 1).

[a] Measurements in dimethylformamide/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$, cyclovoltammetry at a glassy carbon electrode. [b] Irreversible step. [c] Measurements not possible because of insolubility. [d] Measurements in acetonitrile/0.1 M $Bu_4N^{\oplus}ClO_4^{\ominus}$. [e] Absorption maximum at 952 nm in isooctane.

The long-wavelength absorption maxima, which, for the ligands, are already in the visible region due to n→π* transitions and lie between 550 and 700 nm for the mononuclear complexes,[8] reach the NIR region in the binuclear complexes (Fig. 1, Table 1).

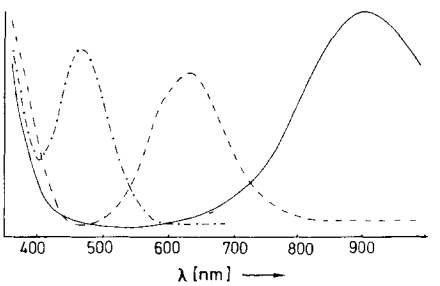

Fig. 1. Absorption spectra of the ligand **2** (·–·–·), the mononuclear complex [**2** $Mo(CO)_4$] (– – –), and the binuclear complex [**2** $\{Mo(CO)_4\}_2$] **2a** (——) in toluene (arbitrary intensity units). Solutions of the mononuclear complex are deep blue, solutions of **2a** have a faint green color because of the absorption gap in the visible (band tails from the NIR and UV regions).

Both the extinction coefficients ($\varepsilon = 10^4 - 10^5$ M^{-1} cm^{-1}) and the characteristic solvent dependence (negative solvatochromism[9]) indicate metal-to-ligand charge-transfer (MLCT) transitions; ESR studies of reduced species[10] confirm the π* character of the lowest unoccupied molecular orbital (LUMO) for the complexes **1a**, **d**.

The extremely low energy levels of the complex LUMOs are illustrated by electrochemical data (Table 1). The binuclear complexes **1a**, **b**, **d**, and **2a** are reduced at ca. 0 V relative to the saturated calomel electrode, and the binuclear ruthenium(II) complex **2d** is an even stronger acceptor than tetracyanoethylene (TCNE, $E_{red} = +0.24$ V[11]) and thus clearly superior to all known polyazine ruthenium(II) complexes.[3, 12]

The redox potentials suggest how to obtain further complexes with even smaller energy differences between the frontier orbitals and correspondingly longer-wavelength charge-transfer absorptions. On the one hand, the ligands must be easily reducible, while, on the other hand, the oc-

cupied metal d levels should be energetically destabilized by the loss of ligands capable of back-bonding. In the complexes **1** and **2**, this strong charge-transfer interaction is possible through coordination to the azo nitrogen centers; chelate coordination via the basic but less strongly back-bonding 2-pyridyl substituents stabilizes the complex toward dissociation.

The steric crowding in the coordination-induced *trans* conformation of the ligand **2** has several interesting consequences. Thus, mononuclear[8] but no binuclear complexes of this ligand could be obtained containing tetracarbonyltungsten or bromo(tricarbonyl)manganese; examination of models as well as the marked low-field ^{1}H-NMR shift for the pyridyl protons H-3 in **2a**[7] indicate non-bonded interactions between these protons and the equatorial substituents L in binuclear complexes with coplanar conformation of the ligand **2**.

Also remarkable is the similarity of the complexes **1a** and **2a** and the fact that the π-acceptor level of **2d** is lower than that of **1d** even though the ligand **1** is more easily reduced than **2** (Table 1). One reason is that the smaller system **2** exhibits a stronger reaction upon *N*-coordination;[13] on the other hand, it is also important to note the relative proximity of the two metal centers in binuclear complexes of **2**. Application of the model of *Richardson* and *Taube*[14] to this case yields an even smaller metal-metal distance (ca. 460 pm) than for N_2-bridged binuclear systems ($d_{M-M} = 500$ pm[14]).

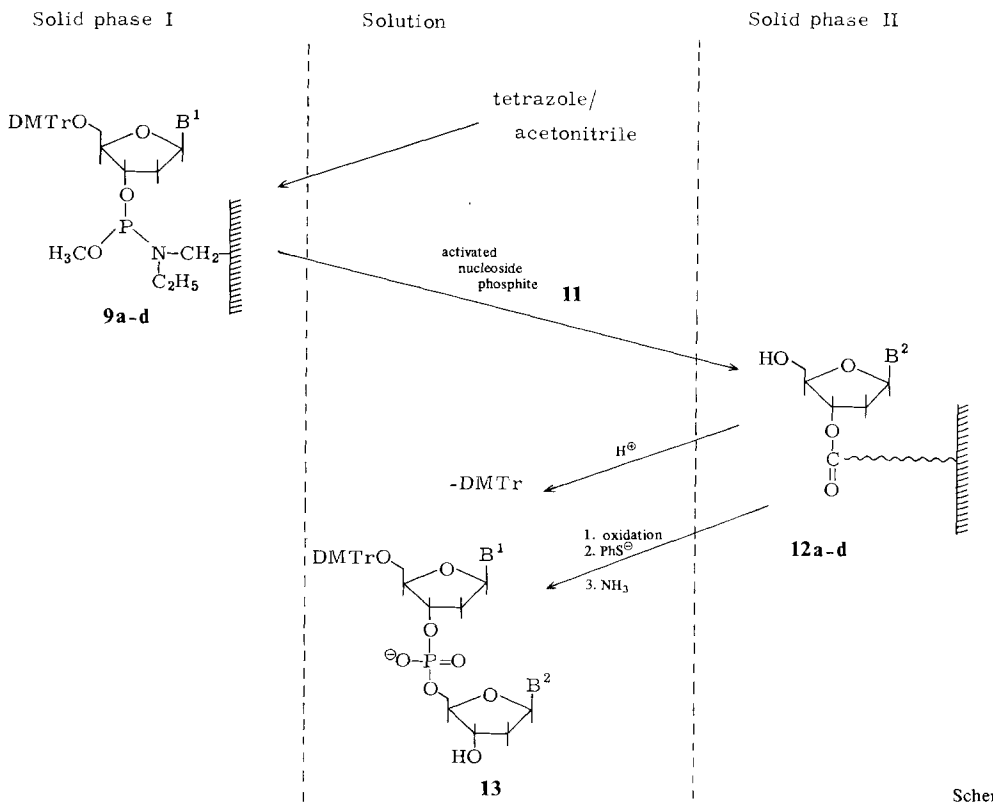
Three-Phase Synthesis of Oligonucleotides**

By *Hartmut Seliger** and *Kailash Chand Gupta*

In the synthesis of oligonucleotides via phosphite triesters[1] using the solid-phase method,[2] the nucleoside *N,N*-dimethylphosphoramidites[3] activated by tetrazole have proved particularly useful as highly reactive intermediates. However, since they are relatively unstable, we have investigated polymeric reagents of the nucleoside phosphoramidite type. We describe here their preparation and their application to the synthesis of oligonucleotides.

The polystyrene **3**, substituted with *N*-ethylaminomethyl groups, was prepared from the commercially available



Scheme 1. P = Merrifield resin, P' = silica gel; DMTr = dimethoxytrityl. **a**, B = N^6-Benzoyladenin-9-yl; **b**, B = N^4-benzoylcytosin-1-yl; **c**, B = N^2-isobutyrylguanin-9-yl; **d**, B = thymin-1-yl.

[**] Carrier Syntheses, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft. *K. C. G.* thanks the Deutscher Akademischer Austauschdienst for a fellowship.—Part 10: [16].

Merrifield resin **1**; piperazino-substituted silica gel **6** was synthesized according to a reported procedure.[4] We reacted **3** with the phosphorochloridite esters **8a—d** (prepared from **7a—d** according to a known route[1]) to give **9a—d**; **6** was analogously converted into **10a—d** (Scheme 1).

The solutions of the activated nucleoside phosphites **11**, which were prepared by treatment of **9** with tetrazole in anhydrous acetonitrile, were reacted with the immobilized nucleosides **12** followed by the usual[5b] oxidation and detritylation. The intense red-orange color of the solution showed that, in every case, a nucleoside transfer from **9** to **12** had occurred. Work-up[5b] gave the dinucleotide **13** (Scheme 2).

Scheme 2. For abbreviations see Scheme 1.

After these preliminary experiments, the solution prepared from **9d** with tetrazole/CH_3CN was used in an automatic synthesizer[6] for fourfold chain extension[5b] of **12a**; the sequence dTTTTA was thus obtained in a yield of 77%. Similarly, dT_8 could be synthesized in a total yield of 68% from **10d** and **12d**. In both cases, the individual condensation steps must have occurred with >95% average yield (taking into consideration losses during work-up). Both nucleotides were characterized by the "wandering spot" method.[7]

9 and **10** are thus excellently suitable as reagents for the chemical synthesis of oligonucleotides. Since sensitive low-molecular-weight compounds are known to be stabilized by immobilization,[8b] **9** and **10** should be more stable upon storage than the low-molecular-weight nucleoside *N,N*-diisopropylphosphoramidite esters or the corresponding morpholides.[9, 10] Accordingly, their in-situ preparation would no longer be necessary.[11, 12] Indeed, **9d** still reacts after 15 months in the same yield; less than 10% of the bound nucleoside was lost during this period by hydrolysis or oxidation. In this respect, **9** and **10** undergo "self-purification" since no oxidation or hydrolysis products appear in **11**; the former remain bound to the carrier, the latter are removed by prewashing.

Analogously to the concept of three-phase catalysis,[13] our results demonstrate that, in the synthesis of oligonucleotides via phosphoramidite ester intermediates, tetrazole not only serves as a proton donor[14] but also reacts with **9** and **10** with formation of an intermediate (**11**). Whether the highly reactive **11**, which is stable for hours, is the postulated[15] tetrazolylphosphane or instead a subsequent product remains to be clarified.

Experimental Procedure

3: **1** (5 g; 2% divinylbenzene, 2.3 mmol Cl/g) was refluxed for ca. 15 h with **2** (100 mmol), filtered, and then shaken an additional 24 h with 150 mL of dioxane/triethylamine (1:1). **3** was washed three times with 100 mL each of dioxane, dioxane/H_2O (3:1), dioxane, toluene, and methanol, and dried in vacuum.

9a—d: **8a—d** (1 mmol) [1] and ethyl(diisopropyl)amine (5 mmol), dissolved in 10 mL of dry tetrahydrofuran (THF), were added by syringe to **3** (1 g). After 30 min, unreacted **8** was removed by suction filtration under argon, and the polymer was washed with 20 mL each of $CHCl_3$ + 5% triethylamine, dry CH_3CN, and ether, and stored under argon. Load: 0.25—0.3 mmol nucleoside/g reagent (determined by VIS spectroscopy after detritylation [5b]).

Oligonucleotide synthesis

a) Manual experiment: **9** (150 mg) prewashed with 2 mL of CH_3CN was treated in a reaction syringe [16] for 10 s with 1 mL of 0.1 M tetrazole in CH_3CN. The resulting solution of **11** was injected through a septum directly into a sintered glass vessel [5b] containing 100 mg of **12** (40—50 μmol nucleoside/g). After 15 min, the mixture was filtered and the carrier was washed, oxidized, and detritylated according to established procedures [5b].

The cleavage of **13** from the carrier and its work-up were carried out as described in [5b].

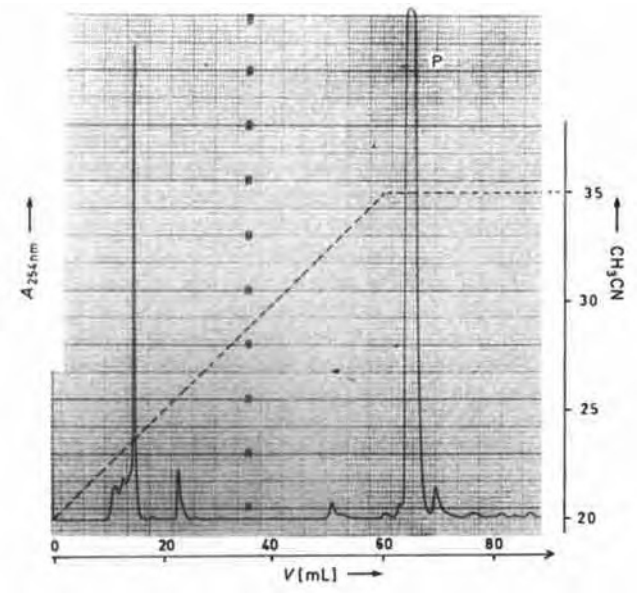

Fig. 1. HPLC separation of the product of the solid-phase synthesis of DMTrdTTTTA. A = absorption; V = elution volume; P = main product. Column: μ-Bondapak C_{18} (Waters; 7.8 × 240 mm); eluent: 0.1 M triethylammonium acetate buffer (pH 7.0) + 20–35% acetonitrile; flow rate: 2 mL/min; detection: UV (254 nm).

b) Experiment with an automatic synthesizer:

9d (1.2 g) prewashed with 15 mL of CH_3CN was treated as described in a) with tetrazole in CH_3CN. The solution of **11** was poured into the reservoir of an automatic synthesizer [6]. Four chain extensions [5b] of **12a** (4.5 μmol dA^{bz}) were carried out (cycle time 23 min). Work-up of the solid phase [5b], HPLC of the product on silica gel C_{18} (Fig. 1), and detritylation and desalting of the product fraction (P in Fig. 1) [5b] gave dTTTTA (174 $O.D._{254}$) in a yield of 77%.

Calculation of the Charge Distribution in Conjugated Systems by a Quantification of the Resonance Concept**

By *Johann Gasteiger** and *Heinz Saller*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

The resonance theory has become a fundamental part of the basic training in organic chemistry.[1] Although it has a quantum mechanical basis in the valence bond method, it has remained only a qualitative concept in the hands of the organic chemist. Even though individual resonance structures are assigned different weights, there has been no simple method so far to express these weights quantitatively.

We have now developed an empirical procedure that does just this and enables the charge distribution in π-systems to be calculated on the basis of the assignments of weights to the resonance structures. From these charges, predictions can then be made as to the physical and chemical properties of compounds. The weight w of each resonance structure consists of a formal (topological) part and an electronic part. In order to assign the topological weight w_t, the resonance structures are classified according to whether (a) a reduction in the number of covalent bonds, (b) a decrease in the number of aromatic systems, or (c) a charge separation occurs.

Each of these formal situations is assigned a factor, whose value was determined as described below. The total topological weight w_t of a resonance structure is given by Equation (d).

$$w_t = f_a \cdot f_b \cdot f_c \qquad (d)$$

The electronic weight w_e must express how well, for example, the atom A in Equation (c) can donate its lone pair of electrons and how stable a negative charge on atom C is. In order to determine this, we used the electronegativity concept.

According to Mulliken's definition,[2] the electronegativity χ is determined by the ionization potential IP and the electron affinity EA [Eq. (e)].

$$\chi = 1/2(IP + EA) \qquad (e)$$

[*] Priv.-Doz. Dr. J. Gasteiger, Dipl.-Chem. H. Saller
Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft; computer time was provided by the Leibniz Rechenzentrum München.

In order to further refine these ideas, the concept of orbital electronegativity was introduced.[3,4] According to this concept, the electronegativity is no longer a purely atomic property, but is also dependent on the type of orbital. An sp orbital, for example, has a higher electronegativity than an sp^3 orbital. Furthermore, the orbital electronegativity is dependent on the occupation number of the orbital;[4,5] an unoccupied orbital attracts electrons more strongly than a singly or doubly occupied orbital. We selected a second degree polynomial [Eq. (f)] to express the dependence of the orbital electronegativity on the occupation of an orbital (or, equivalently, on the charge q).

$$\chi_v = a_v + b_v \cdot q + c_v \cdot q^2 \qquad \text{(f)}$$

The coefficients a_v, b_v, and c_v could be calculated[6,7] from published data on valence-state ionization potentials and electron affinities.[3,4]

On the basis of the partial equalization of orbital electronegativities, we had already developed a procedure for the calculation of charge distribution in σ-bonded molecules,[6] which has proved suitable for the reproduction of a variety of physical and chemical data.[6,8,9]

The two resonance structures in each of the equations (a) to (c) differ by electron transfers between the π orbitals of two atoms. The availability of the electrons in these orbitals is characterized by the corresponding π-orbital electronegativity χ^π; the coefficients a_v, b_v, and c_v in Equation (f) that are necessary for its determination have been published already.[7] The value of the charge q in Equation (f) is obtained from Equation (g), in which the different effect of σ and π charges must be taken into consideration in determining the factor f_{sp}.

$$q = q_\pi + f_{sp} \cdot q_\sigma \qquad \text{(g)}$$

The determination of the electronic weight w_e is based on the classical idea that those resonance structures are more important ("have lower energy") in which the negative charge is localized on the more strongly electronegative atom. This can be incorporated into the calculation by the use of the difference of the π electronegativities of the two atoms i and j, which have differing formal charges, e.g., A and B in (a) or A and C in (c). In addition, the second term of Equation (h) takes into consideration the electrostatic potential of the neighboring atoms N_i of the atom i and N_j of the atom j. This potential is assumed to be proportional to the sum of the charges q_k, q_l on these neighboring atoms.

$$w_e = (\chi_i^\pi - \chi_j^\pi) + f_e \cdot \left(\sum_k^{N_i} q_k - \sum_l^{N_j} q_l \right) \qquad \text{(h)}$$

The total weight of each resonance structure is calculated from the topological weight and from the electronic weight according to Equation (i).

$$w = w_t \cdot w_e \qquad \text{(i)}$$

By adding the changes in charge of the individual resonance structures and taking into consideration the scaling factor f_s, which is the same for all resonance structures, the charge distribution is obtained. The two terms in Equation (h), however, are themselves dependent on the charge distribution [cf. Eq. (f)]. In order to take this into consideration, the charge transfer was distributed over several cycles, n_c, so that only a certain part of the charge, q_c, is displaced per cycle. New electronegativity values χ [Eq. (f)] are calculated in the next cycle using the resulting charges.

$$q_c = \frac{1}{n_c} \cdot w \cdot f_s \qquad \text{(j)}$$

Eight cycles have proved to be a good compromise between computing accuracy and computing time; the computing times are then always extremely short.

The six factors f were fixed using properties that directly depend on the charge distribution. This is true, for example, of ^{13}C-NMR shifts as long as one class of compounds is used (constant mean excitation energy[10]), or of ESCA shifts, which can be easily interpreted using a potential model.[11] Three sets of physical data were used to optimize the factors by the Simplex procedure:[12] A) the ^{13}C-NMR shifts of the *para* C atom in twelve monosubstituted benzenes; B) the ^{13}C-NMR shifts of twelve C atoms in nine substituted pyridines; C) the C 1s ESCA shifts of eleven C atoms in seven fluorinated olefins.

This gave the following factors: $f_a = 0.65$; $f_b = 0.30$; $f_c = 0.133$; $f_e = 1.00$; $f_{sp} = 0.50$; $f_s = 0.33$. The charge values calculated from them reproduced these three sets of data well (r = correlation coefficient; s = standard deviation): A) r = 0.986, s = 1.04 ppm (see Fig. 1); B) r = 0.991, s = 1.36 ppm; C) r = 0.987, s = 0.34 eV.

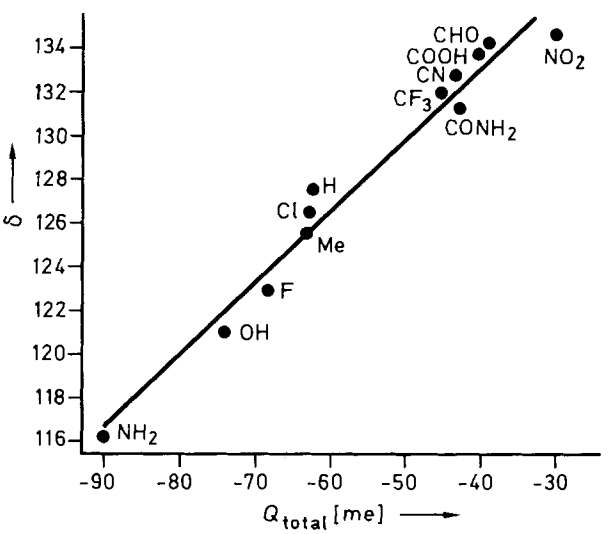

Fig. 1. ^{13}C-NMR shifts (δ values) of the *para* carbon atom in monosubstituted benzenes versus the total charge, Q_{total}, of this carbon atom.

The charge values are also helpful for the calculation of other physical data. Thus, for example, a good correlation was found between the charge of the *para* C atom of monosubstituted benzene derivatives and the chemical shift of the protons bonded to it. Furthermore, for a large data set of molecules (48 points) comprising conjugated olefins, acetylenes, and carbonyl compounds, a linear relationship between charges and C 1s ESCA shifts was obtained. In addition, good agreement between experimental and calculated dipole moments was observed (see Table 1). This emphasizes the broad general significance of the charge values.

The accuracy of the charge values has been demonstrated here on the basis of physical properties. Resonance theory is most important, however, for the interpretation of chemical reactivity, in particular, of aromatic substitution.

The weighting of the resonance structures now enables quantitative statements to be made. They are used in the program system EROS[13] for the prediction of reactions and the planning of syntheses. Use of the procedure presented here, along with methods to determine the inductive effect[14] and the polarizability,[15] allows the reactivity of complex organic molecules to be estimated automatically. The course of organic reactions can thereby be predicted.

$(NEt_4)_2[Cl_3Mo(\mu\text{-}S_2)(\mu\text{-}Cl)_2MoCl_3]$, a Paramagnetic Molybdenum(IV) Compound with a Metal-Metal Bond

By *Ulrich Müller,* Paul Klingelhöfer, Claus Friebel,* and *Jürgen Pebler*

Many compounds are known in which two transition-metal elements are joined via sulfur or halogen atoms and which further contain metal-metal bonds.[1] The metal-metal bond is recognized, apart from its length, by the existence of diamagnetism or only a very weak paramagnetism. Paramagnetic species occur when an odd number of electrons are present—e.g., in **1**–**3**,[2–4] in which the metal atoms have two different oxidation states.

$[(NC)_4Mo(\mu\text{-}S_2)(\mu\text{-}SO_2)Mo(CN)_4]^{5\ominus}$ **1**[2]

$[Cl_3W(\mu\text{-}SPh)_2(\mu\text{-}Cl)WCl_3]^{2\ominus}$ **2**[3]

$[Mo_2Cl_9]^{2\ominus}$ **3**[4]

We have now obtained the title compound, a paramagnetic compound with an even number of electrons, in which a Mo–Mo single bond is present and in which, at the same time, each molybdenum atom possesses an unpaired electron.

When a suspension of molybdenum pentachloride in CH_2Cl_2 is added to an equimolar solution of NEt_4SH in CH_2Cl_2 frozen at 77 K, and the mixture is allowed to thaw, the following reaction occurs with formation of HCl.

$$(MoCl_5)_2 + 2\,SH^{\ominus} \longrightarrow \underset{\mathbf{4}}{[Cl_3Mo(S_2)Cl_2MoCl_3]^{2\ominus}} + 2\,HCl$$

After ca. 15 h of stirring, an insoluble, greyish green product, which has not yet been identified, is filtered off; after addition of CCl_4 to the filtrate, the tetraethylammonium salt of **4** (27%) crystallizes out at 278 K.

A sulfido complex containing pentavalent molybdenum is not present, in contrast to what the composition NEt_4MoSCl_4 might lead one to suppose. As observed for other thiomolybdates,[5] the sulfido ligand is oxidized to the disulfide and the molybdenum is reduced to Mo^{IV}. The presence of a disulfide in **4** follows from the IR spectrum (ν(SS) = 609 cm^{-1}) and by the X-ray structure determination (Fig. 1).[6] The disulfide group links the two molybdenum atoms, which, in addition, are bridged by two chlorine atoms. If the disulfide group is viewed as only a single ligand, then **4** consists of two face-sharing octahedra; the bond angles Mo–Cl–Mo (68.0°) and Mo–S–Mo (69.2°) are only slightly smaller than the ideal value (70.5°) for regular face-sharing octahedra.

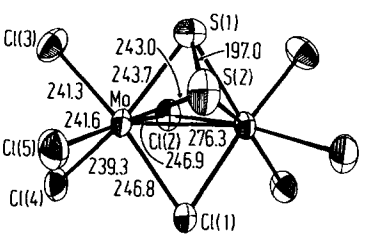

Fig. 1. Structure of **4** in the crystal of $(NEt_4)_2[Cl_3Mo(S_2)Cl_2MoCl_3]$ with ellipsoids of thermal vibration (50% probability at 295 K). Distances [pm]; standard deviations: Mo–Mo 0.2, Mo–Cl 0.3, Mo–S 0.4, S–S 0.7 pm. The ion is situated on a crystallographic mirror plane that intersects the atoms S(1), S(2), Cl(1), and Cl(2).

The Mo–Mo distance (276.3 pm) supports the existence of an Mo–Mo bond. Even though two d electrons are available per molybdenum atom, it can only be a single bond since, according to the magnetic susceptibilities and the electron spin resonance spectrum, each Mo atom still has available an unpaired electron.

Between 4 and 160 K the magnetic susceptibility approximately obeys the Curie-Weiss law. The fitting of the measured data gives a magnetic moment of 1.40 μ_B per

[*] Prof. Dr. U. Müller, Dipl.-Chem. P. Klingelhöfer, Doz. Dr. C. Friebel, Doz. Dr. J. Pebler

Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

atom and a Curie-Weiss temperature of $\theta \approx 0$ K. Taking into consideration the spin-orbit coupling constant for molybdenum, the magnetic moment corresponds to a localized $4d^1$ electron. This is in accord with the electron spin resonance spectrum, which was recorded between 130 and 298 K for the powder and for the oriented single crystal at 9.5 and 35 GHz. Although two unpaired electrons are present in **4** no triplet state with recognizable zero-field splitting is observed. The small anisotropy of the ESR powder spectrum, however, indicates a coupling of two molecular g tensors, whose axial components should be oriented parallel to the Mo–S_2 directions. Accordingly, in the direction of the crystallographic b axis, with respect to which all Mo–Mo vectors are directed parallel, the two molecular $g_{\parallel}$ components are seen at an angle of approximately 55°:

$$g_b \approx \tfrac{1}{3} g_{\parallel} \pm \tfrac{2}{3} g_{\perp} = \bar{g}$$

The observed parameter $g_b = 1.94_6$ agrees surprisingly well with the literature values for isolated octahedral Mo^V complexes such as $[MoCl_6]^{\ominus}$ ($\bar{g} = 1.95_0$) and $[MoOCl_5]^{2\ominus}$ ($\bar{g} = 1.94_5$).[7] This result supports the assumption of an Mo–Mo single bond between the two Mo^{IV} centers in **4**, which reduces the paramagnetism to that of two d^1 systems.

Simplification of Spectra for the Determination of Coupling Constants from Homonuclear Correlated 2D NMR Spectra**

By *Horst Kessler** and *Hartmut Oschkinat*

Indirect spin-spin coupling (J coupling) is one of the most important parameters in NMR spectroscopy. In complicated ^{1}H-NMR spectra it is often difficult to determine the coupling constants of importance for a structure elucidation because the proton signals to be analyzed show a complex multiplet structure or are covered by other signals.

Herein, we will show with the aid of a special method (*D*ifferences and *S*ums COSY spectra, DISCO), how coupling constants can be obtained from phase-sensitive homonuclear-correlated proton spectra (H,H-COSY)[1] without additional measurements having to be made. Difficulties that can occur in conventional methods such as double resonance spectroscopy[2] and 2D-J,δ-spectroscopy,[3] by falsification of the coupling values ("boosting"[2]) or in the assignment of the measured values, are avoided.

As example of the possibility of simplifying complex multiplet structures with the aid of the DISCO technique[4,5] we have investigated the compound **1**, R = tBuMe$_2$Si, formed during a natural product synthesis.[6]

1

Our intention was to use the proton coupling constants together with nuclear Overhauser enhancement values (NOE) for elucidation of the structure at the ring connection site of the seven-membered ring/five-membered ring

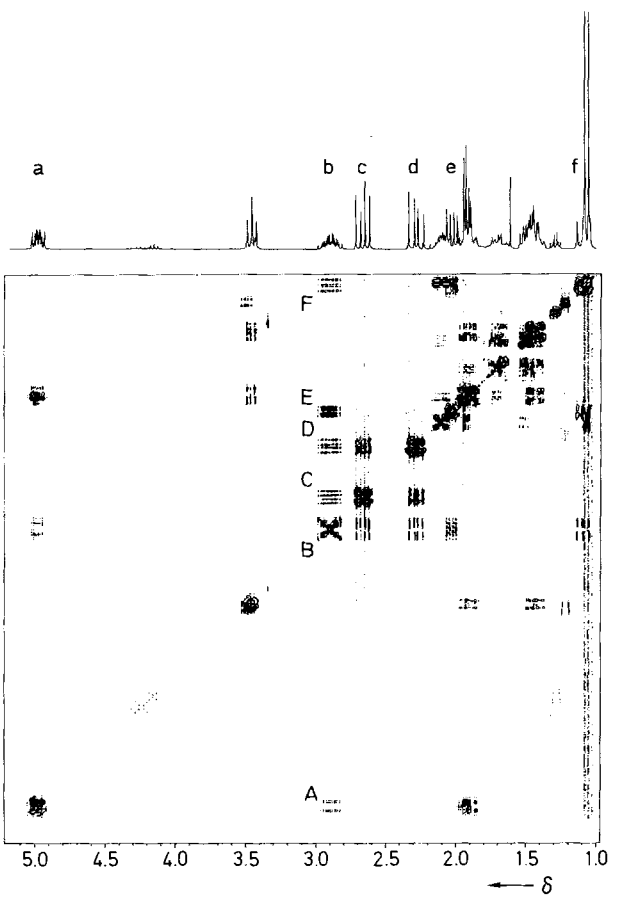

Fig. 1. Section of the phase-sensitive H,H-COSY spectrum (with double quantum filter) [7] of **1** at 300 MHz in $CDCl_3$, recorded via the TPPI method [8]. 616 increments were recorded, each with 16 scans of 8 K in t_2. Before the Fourier transformation, zero-filling to 2 K data points in t_1 was applied. The total recording time was 14 h, the computation time ca. 30 min.

lactone. For this purpose we were interested in the five coupling constants which are contained in signal b at $\delta = 2.89$. Conclusions about the position of the coupling partners can be drawn from the H,H-COSY spectrum (Fig. 1). All ten of the expected cross peaks due to coupling of b to a, c, d, e, and f are observable. In no case is there a strong coupling to b and between the signals a, c, d, e, and f. The "active" coupling giving rise to an individual cross peak is also responsible for the so-called anti-phase structure of this particular cross peak.[1, 4, 5] This means that lines with positive and negative intensity appear within a cross-section through a cross peak. The difference between the centers of the positive and negative groups of signals within this cross-section is equal to the "active" coupling constant. A direct evaluation, however, is often very difficult or impossible, owing to cancelling effects [Fig. 2 (a–e)].

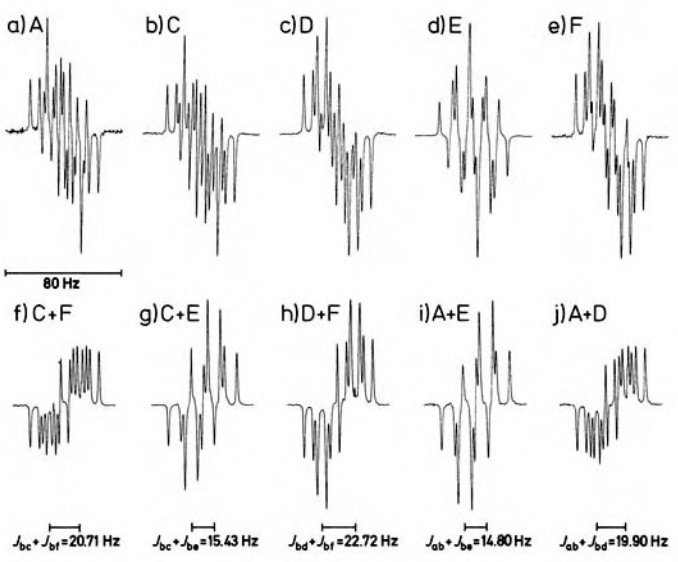

Fig. 2. (a–e). Pseudo one-dimensional spectra from the cross peaks to b. The spectra were obtained by co-addition of the individual traces of the respective cross peaks. Their resolution was improved by retro-Fourier transformation, zero filling to 32 K data points, Lorentz-Gauss transformation, and renewed Fourier transformation. The resolution was 0.4 Hz beforehand and 0.2 Hz afterwards. (f)–(j): DISCO spectra by addition of the untreated 8 K pseudo one-diemensional spectra. The resolution of the spectra thus obtained was improved as described above.

The structure of the pattern in a cross-section can be simplified by a simple trick. When the cross-sections of two different cross peaks are added, a pattern results which contains only half as many lines as originally. The anti-phase structure is still present but less perturbing, since the distance between the two groups of signals with positive or negative intensity is now the *sum* of the two active coupling constants [Fig. 2 (f, g)].

Hence, the desired coupling constants are not obtained directly but by solving a set of linear equations with n unknowns (where n is the number of participating cross peaks). If, for example, there are three cross peaks A, B, C, and they are combined to give A+B, A+C, B+C, then the difference between the centers of the positive and negative groups of signals in the individual DISCO spectra gives the sum of the coupling constants active in both cross peaks. A set of three linear equations with three unknowns is obtained which is just determinate ($J_A + J_B = X$, $J_A + J_C = Y$, $J_B + J_C = Z$) and can be solved. If there are four cross signals, then six DISCO spectra are possible, and the system is already overdeterminate. This makes it possible to minimize the errors and to forgo DISCO spectra in which the position of the centers of the in-phase multiplet cannot be established unequivocally.

To achieve good signal-to-noise ratio of the cross-sections one can add *all* traces of *one* cross peak corresponding to the signs of individual lines such that the intensity for the signals will be maximal and the signal-to-noise ratio correspondingly improved.[9] In this way T_1-noise and dispersional contributions from the diagonal peaks can be reduced. Such "pseudo one-dimensional" spectra were derived from the cross peaks labeled A, C, D, E, F in Figure 1 [see Fig. 2 (a–e)] and appropriately combined. Five of the ten possible combinations are reproduced in Figures 2f–j. Partly occurring cancellation effects do not prevent the localization of the centers of these groups of lines. In Figures 2f–j the values for the sums of the corresponding coupling constants are also quoted; solution of the linear expression with five unknowns gives $J_{ab} = 8.3$, $J_{bc} = 9.2$, $J_{bd} = 11.3$, $J_{be} = 6.2$, and $J_{bf} = 11.4$ Hz. The same values for the coupling constants J_{bc} and J_{bd} are obtained from the one-dimensional spectrum.

An intense cross peak between the signals d and f in the phase-sensitive NOESY spectrum[10, 11] enables assignment of the diastereotopic methylene ring protons e, f and c, d. A large coupling constant of 11.3 or 11.4 Hz, respectively, to signal b is found for these signals, thus proving the antiperiplanar position of their protons to proton b. The coupling of proton b to e lies in the expected range while that to c appears unusually large. The coupling constant between b and a (8.3 Hz) is compatible with an almost eclipsed arrangement. The strong NOE effect between a and b, and of proton a to both methyl groups, unequivocally confirms the *cis* ring coupling. Proton b exhibits a NOE effect only to the methyl group on the quaternary C-atom, thus indicating an incompletely eclipsed arrangement (see formula). Altogether an unambiguous picture of the configuration and conformation at the ring connection site is obtained.

The advantage of the DISCO technique is that the values for the coupling constants can also be taken from a *routinely recorded,* phase-sensitive H,H-COSY spectrum with or without double quantum filter, without other experiments being necessary. In our example, ca. 15 minutes are required for evaluating all the ten possible DISCO spectra using a data station ASPECT 3000 with an array processor. Even when the computation time of ca. 30 min for the Fourier transformation of the stored FID's is added to this, the method is still quicker than conventional experiments on a spectrometer with renewed measurement of the sample. Since only a good resolution in ω_2 is required for the use of the DISCO technique, the necessary better resolution does not demand any increase in recording time. The method can also be used when the signals to be evaluated in a one-dimensional spectrum are covered by other signals. If, however, the diagonal signals are free, the coupling constants can also be determined by DISCO spectra between cross peaks and diagonal signals calculated on the absorption phase.[5]

Marked Increase in the Regioselectivity of Radical Substitution: Minisci Reaction in a Two-Phase System**

By *Gottfried Heinisch** and *Gerhard Lötsch*

Dedicated to Professor Franz Vieböck on the occasion of his 85th birthday

Protonated π-electron-deficient N-heteroarenes are attacked by nucleophilic carbon radicals with pronounced regioselectivity (Minisci reaction[1]). This procedure is of great preparative value if the heteroarene has only *one* free position that can be attacked by radicals. Otherwise, unless the first substituent introduced by radical reaction deactivates the ring system, polysubstitution occurs to a significant extent, as observed, for example, in homolytic acylations[2] and, especially, in alkoxycarbonylations.[3,4] We have now found a simple method to significantly increase the regioselectivity of radical ethoxycarbonylation which thus provides an easy access to useful heteroaromatic synthetic building blocks.

According to *Minisci* et al.,[3] 4-pyridinecarbonitrile **1** is attacked by ethoxycarbonyl radicals—employing a ratio of **1** : peroxide = 3 : 1—preferentially at the α-carbon atom; in addition to ethyl 4-cyano-2-pyridinecarboxylate **2**, **3** and disubstitution products, which were not further identified, were observed.[5] Although, by reversing the ratio of **1** to peroxide, the conversion could be increased from 19 to 76% (see Table 1), disubstitution predominated as expected; this is shown by the increased formation of the pyridinetricarboxylic acid derivatives **4**–**6**.[6]

5	COOEt	H	COOEt	H
6	COOEt	H	H	COOEt

Since, in general, an alkoxycarbonylated heteroarene should exhibit increased lipophilicity and reduced basicity, we investigated (cf. ref. [4]) the homolytic ethoxycarbonylation of protonated **1** in the presence of variable amounts of dichloromethane. In each case, **2** was formed as the main product. As shown in Table 1, it is possible to react **1** practically quantitatively, so that analytically pure **2** can be obtained in >80% yield.[7]

Table 1. Product distribution [mol-%] in the reaction of **1** with the ethoxycarbonyl radical (GLC analysis: 25 m 3% OV 17 WCOT, FID). For reaction conditions, see [7].

Also in the case of 3-pyridinecarbonitrile **7**, it is possible to suppress multiple substitution, even at high conversions, by carrying out the reaction in a two-phase system.[8] The resulting, expected mixture of the three esters **8**,[9] **9**,[10] and **10**[11] can be smoothly separated by chromatography. Similarly, this reaction principle enables the product ratio in the homolytic ethoxycarbonylation of pyrazine **11** (cf. ref. [3]) to be decisively influenced in favor of the monosubstitution; ethyl 2-pyrazinecarboxylate **12**[12] is formed in 80% yield.[8] Furthermore, the reaction of 4-phenethylpyridazine to give ethyl 5-phenethyl-4-pyridazinecarboxylate, which proceeds smoothly under these conditions (70% yield) is noteworthy.[4]

Proton Exchange between Arenium Ions and Arenes in the Gas Phase**

By *Dietmar Kuck,* Steen Ingemann, Leo J. de Koning, Hans-Friedrich Grützmacher,* and *Nico M. M. Nibbering*

Proton transfer reactions are known to be extremely fast in general.[1] In the gas phase, they can be studied by modern, time-resolved mass spectrometry. Thus, MIKE spectrometry of metastable ions[2] (time scale 10^{-5} to 10^{-4} s) is used for the investigation of *intra*molecular hydrogen migration reactions, e.g., the proton exchange in protonated α,ω-diphenylalkanes [Eq. (1a)],[3] while, for *inter*molecular exchange reactions,[4] Fourier transform ion cyclotron resonance (FT-ICR) spectrometry[5] is becoming increasingly important (time scale 10^{-3} to 10^{+1} s). We report here on the intermolecular proton exchange [Eq. (1b)] between simple arenium ions and arenes[4c] in the cell of a FT-ICR mass spectrometer[6] (Ar, Ar′ = aryl).

$$ArH^{\oplus}-(CH_2)_n-Ar' \rightleftharpoons Ar-(CH_2)_n-Ar'H^{\oplus} \quad (1a)$$
$$2 \le n \le 20$$

$$ArH_2^{\oplus} + Ar'H \rightleftharpoons ArH + Ar'H_2^{\oplus} \quad (1b)$$
