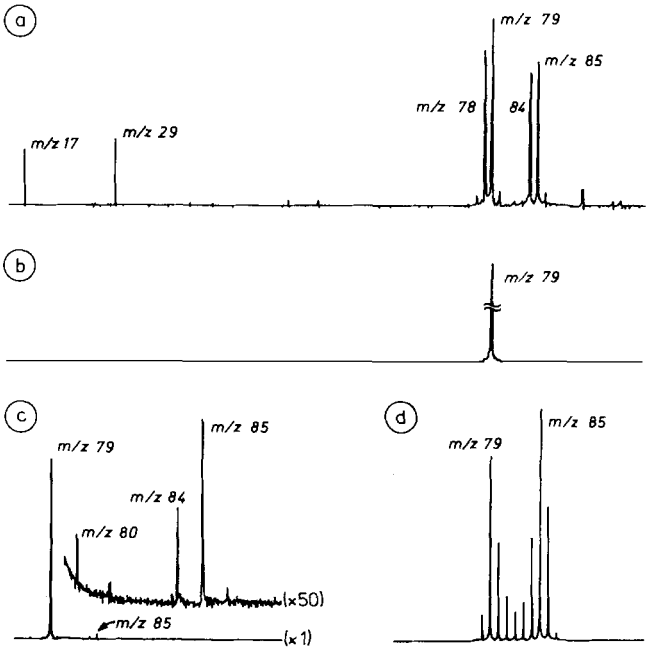

Fig. 1. a) FT-ICR mass spectrum of a mixture of CH_4, C_6H_6, and C_6D_6 [7a]; b) after ejection of all ions except $C_6H_7^{\oplus}$ (*m/z* 79) at the time $t_r = 0$; c) after $t_r = 190$ ms, and d) after $t_r = 6290$ ms.

We generated the benzenium ions $C_6H_7^{\oplus}$ and $C_6HD_6^{\oplus}$ by electron-impact ionization of a mixture of benzene, [D_6]benzene, and methane at 10^{-4} Pa (Fig. 1a).[7a] All ions except $C_6H_7^{\oplus}$ (*m/z* 79) were then removed from the ICR cell by "notch ejection"[8] (Fig. 1b); subsequently, the ion-molecule reactions of the benzenium ions isolated in this way with the C_6H_6/C_6D_6 mixture were followed as a function of time (t_r). Figures 1c and 1d show all ions present in the cell at $t_r = 190$ and 6290 ms, respectively; Figure 2 displays the dependence of the relative abundance of the *product* ions $C_6(H,D)_7^{\oplus}$ on t_r.

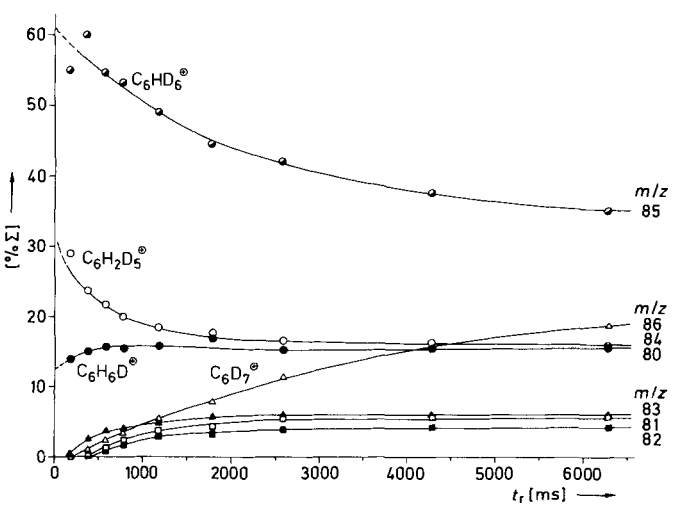

Fig. 2. Relative abundances of the product ions in the system $C_6H_7^{\oplus}/C_6H_6/C_6D_6$ as a function of the reaction time t_r given relative to the sum of all product ions and corrected for naturally occurring ^{13}C.

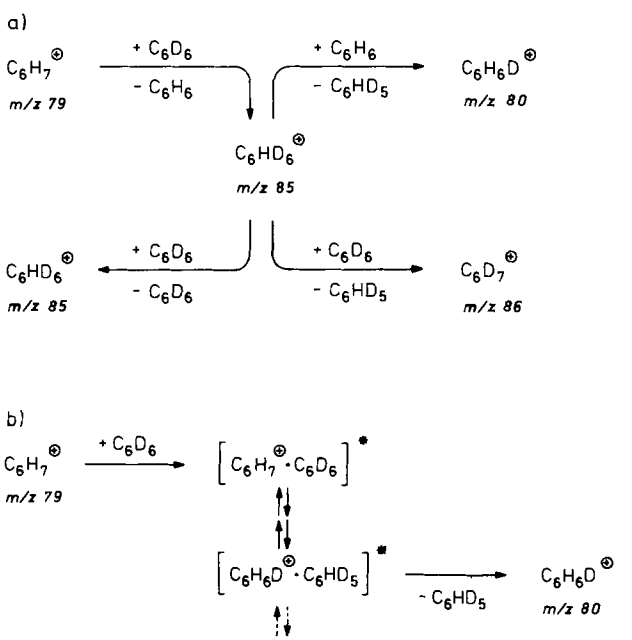
The measurements allow two conclusions to be drawn:



1. The proton exchange between benzenium ions and benzene is a surprisingly slow process (cf., for example, the system $D_3O^{\oplus}/C_6H_6$[4a]). For short reaction times t_r (under

"single collision conditions"), no isotopomers other than $C_6HD_6^{\oplus}$ (simple $H^{\oplus}$ transfer), $C_6H_6D^{\oplus}$ (simple $H^{\oplus}/D^{\oplus}$ exchange), and $C_6H_2D_5^{\oplus}$[9] are formed. The light and the heavy benzenium ions also predominate under "multiple collision" conditions ($t_r \gtrsim 300$ ms).

2. The proton exchange occurs not only by consecutive ion-molecule reactions, but also within the collision complexes (e.g., $[C_6H_7^{\oplus} \cdot C_6D_6]^*$). This follows from extrapolation of the relative abundances of the product ions to $t_r = 0$: The exchange products $C_6H_6D^{\oplus}$ (m/z 80) and $C_6H_2D_5^{\oplus}$ (m/z 84) are already present there (Fig. 2).

Similar results are obtained from the corresponding investigation of the reaction of isolated $C_6HD_6^{\oplus}$ ions with the C_6H_6/C_6D_6 mixture.

A further experiment allows a clear distinction to be made between these two exchange processes (Scheme 1). If the ions $C_6HD_6^{\oplus}$ (m/z 85) are continuously removed from the cell for the entire reaction time,[7b] the formation of all further $C_6(H,D)_7^{\oplus}$ ions is suppressed to the extent that they are formed via $C_6HD_6^{\oplus}$ (Scheme 1a). In contrast, $C_6(H,D)_7^{\oplus}$ ions that arise via $H^{\oplus}/D^{\oplus}$ exchange *within* the collision complexes $[C_6H_7^{\oplus} \cdot C_6D_6]^*$ are *not* suppressed (Scheme 1b). In Table 1 the relative abundances of the ions present in the cell after $t_r = 790$ ms—with and without continuous removal of the ions m/z 85—are compared.

Scheme 1.

Table 1. Ion abundances in the system $C_6H_7^{\oplus}/C_6H_6/C_6D_6$ after $t_r = 790$ ms without (−) and with (+) continuous removal of the ions $C_6HD_6^{\oplus}$ (m/z 85) [a].

m/z	78	79	80	81	82	83	84	85	86
(−)	30	1000	49	8.6	7.9	14.3	70	168	15.8
(+)	30	1000	40	6.4	4.2	10.4	62	0	1.0

[a] ^{13}C-corrected values. The absolute abundance of the ions $C_6H_7^{\oplus}$ (≡ 1000) was constant in both experiments. In order to continuously remove the ions $C_6HD_6^{\oplus}$, a radiofrequency pulse with an amplitude of 2.5 V peak-to-peak was used.

The data confirm that the proton exchange takes place within the collision complex: even upon ejection of the ions m/z 85, all $C_6(H,D)_7^{\oplus}$ isotopomers are formed, albeit in lower absolute abundances. Thus, for example, the abundance of the ions $C_6H_6D^{\oplus}$ (m/z 80) decreases by only a relative 19%; in contrast, the formation of the ions $C_6D_7^{\oplus}$ (m/z 86), which are formed *exclusively* by consecutive ion-molecule reactions (Scheme 1a), is completely suppressed.[10]

The proton exchange between toluenium ions and toluene ($C_7H_8/C_7D_8/CD_4$)[7a] is even slower than that between the lower homologues. Here, too, the exchange takes place partly within the collision complexes (e.g., $[C_7D_9^{\oplus} \cdot C_7H_8]^*$). Thus, a fraction of the $C_7(H,D)_9^{\oplus}$ isotopomers are still formed despite continuous removal of the ions $C_7H_8D^{\oplus}$. A possible reason is that the proton exchange in the collision complex $[C_7H_9^{\oplus} \cdot C_7H_8]^*$ only occurs between positions having the same proton affinity (primarily *para*⇄*para'*), which must lead to a considerable slowing of the reaction compared with the exchange in the collision complex $[C_6H_7^{\oplus} \cdot C_6H_6]^*$.

In fact, no proton exchange is observed for non-degenerate proton-transfer reactions, such as in the system benzene/toluene/methane.[7a] Accordingly, solely proton *transfer* is observed at all t_r in the exothermic direction of the reaction [Eq. (2a)], and no other toluene isotopomers are formed in the endothermic direction of the reaction [Eq. (2b)].[11]

$$C_6D_7^{\oplus} + C_7H_8 \longrightarrow C_6D_6 + C_7H_8D^{\oplus} \quad (2a)$$
$$\not\longrightarrow C_6(H,D)_7^{\oplus} \text{ and } C_7H_7D_2^{\oplus} \text{ etc.}$$
$$C_7H_9^{\oplus} + C_6D_6 \not\longrightarrow C_7(H,D)_9^{\oplus} + C_6(H,D)_6 \quad (2b)$$

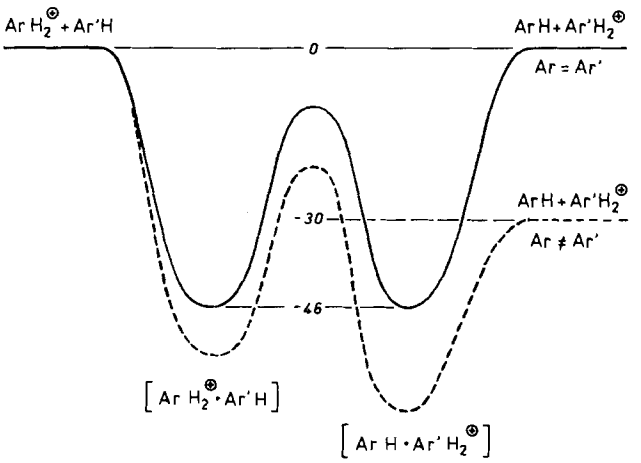


Fig. 3. Energy profiles for the $H^{\oplus}$ transfer between arenium ions and arenes (enthalpy values [11, 13] in kJ/mol^{-1}). (—): thermoneutral $H^{\oplus}$ transfer, $Ar = Ar' = C_6H_5$ or $C_6H_4CH_3$; (---): non-thermoneutral $H^{\oplus}$ transfer, $Ar = C_6H_5$, $Ar' = C_6H_4CH_3$.

These observations can be explained qualitatively by a symmetrical (Ar = Ar') or an asymmetrical (Ar ≠ Ar') double-minimum energy profile[12] (Fig. 3).[13] According to our results, the activation barrier between the minima $[ArH_2^{\oplus} \cdot Ar'H]$ and $[ArH \cdot Ar'H_2^{\oplus}]$ must be relatively high. This is especially noteworthy in comparison with the extremely fast *intra*molecular proton exchange in protonated α,ω-diphenylalkanes and related arenium ions.[3]

[6] The FT-ICR mass spectrometer was built at the University of Amsterdam. a) Electronics: J. H. J. Dawson in H. Hartmann, K. P. Wanczek: *Lecture Notes in Chemistry, Vol. 31*, Springer, Berlin 1982, p. 331; b) software: A. J. Noest, C. W. F. Kort, *Comput. Chem. 6* (1982) 111, 115; c) general methods of measurement: J. C. Kleingeld, N. M. M. Nibbering, *Org. Mass Spectrom. 17* (1982) 136; S. Ingemann, N. M. M. Nibbering, S. A. Sullivan, C. H. DePuy, *J. Am. Chem. Soc. 104* (1982) 6520.

[7] a) Experimental conditions: The magnetic field strength was 1.4 T in all experiments. The cell of the FT-ICR mass spectrometer [6] was filled with $\approx 1 \cdot 10^{-5}$ Pa of each of the two arenes and with $\approx 8 \cdot 10^{-5}$ Pa of methane. $CH_5^{\oplus}$ and $C_2H_5^{\oplus}$ ions, among others, were generated by an electron pulse (20 eV, 5 ms); they protonated the arenes in the following 200 ms to give $ArH_2^{\oplus}$ and $Ar'H_2^{\oplus}$. Subsequently, all ions except $ArH_2^{\oplus}$ (or $Ar'H_2^{\oplus}$) were removed from the cell by "notch ejection" [8] (radiofrequency pulse with a scan length of 10 ms); then, in the following reaction time ($t_r = 0$ to $t_r = 6290$ ms), the ions formed from $ArH_2^{\oplus}$ (or $Ar'H_2^{\oplus}$), ArH and Ar'H were measured. b) By applying a radiofrequency pulse for *m/z* 85 (amplitude 3.5 V peak-to-peak) during the entire reaction time t_r, all $^{12}C_6HD_6^{\oplus}$ ions were removed from the cell within $\lesssim 300$ µs after their formation. During this time, no collisions with molecules of the gas mixture took place (average rate of collision $\approx 10\ s^{-1}$).

[13] The proton-bound dimer $[C_6H_7^{\oplus} \cdot C_6H_6]$ is more stable by $\Delta H = 46$ kJ mol^{-1} than $C_6H_7^{\oplus}$ and C_6H_6; M. Mautner, P. Hamlet, E. P. Hunter, F. H. Field, *J. Am. Chem. Soc. 100* (1978) 5466.

Reaction of Ethylene Oxide with Sulfur Dioxide in the Presence of Cesium Ions: Synthesis of 1,3,6,9,2λ⁴-Tetraoxathia-2-cycloundecanone

By *Herbert W. Roesky** and *Hans Georg Schmidt*

Cyclic homologues of ethylene oxide have attracted great interest because of their unusual complexation properties in the presence of alkali metal ions and other cations.[1] Their properties can be changed by incorporation of further heteroatoms. Reactions of ethylene oxide and sulfur dioxide in the presence of catalysts have been well documented.[2] Ethylene sulfite is formed. We have now found that the reaction of ethylene oxide, sulfur dioxide,

and cesium salts[3] at room temperature leads to higher membered ring compounds, of which the title compound **1** has been isolated in 20% yield as a white solid.[4]

In the field ion mass spectrum, M^+ of **1** (*m/z* 196) is observed as sole peak. **1** polymerizes on storage at room temperature for several weeks in a sealed flask. Poor quality single crystals were obtained from ethylene oxide and examined X-ray crystallographically.[5]

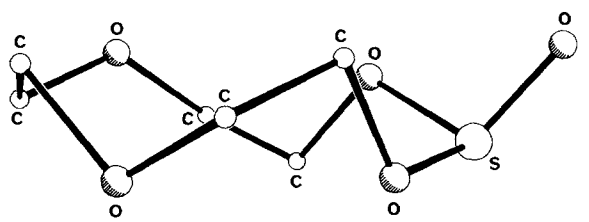

Fig. 1. Crystal structure of **1**.

The structure contains two independent conformationally isomeric molecules of **1** (Fig. 1). A final refinement was not possible owing to disorder and/or thermal motions.[6]

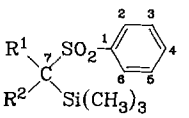
Dilithio(phenylsulfonyl)trimethylsilylmethane: Synthesis, $^{13}C/^{1}H$-NMR Characterization, and Lithium-Titanium Exchange**

By *Jürgen Vollhardt, Hans-Joachim Gais,** and *Karl L. Lukas*

Dilithioalkyl sulfones of the type $Li_2[C(R^1)SO_2R^2]$ are, as sulfonyl derivatives of n,n-dilithioalkanes,[1] of particular interest, on the one hand because of their structure in solution and in the crystalline state—whereby aggregation, number of Li atoms bound to the C atom, and its coordination geometry are of paramount importance[2]—and, on the other, because of their synthetic potential.[3] The dilithiation of alkyl(aryl) sulfones with *n*-butyllithium (*n*BuLi) has already been repeatedly described,[4] but a direct spectroscopic proof for the formation of the dilithio derivatives has not, as yet, been reported; the formation of α,α-disubstituted alkyl sulfones during the deuteration and alkylation is, according to our findings with α,*o*- and α,α-dilithiated allyl phenyl sulfones,[3] inconclusive. We have now been able to synthesize the title compound **3**, the first crystalline dilithioalkyl sulfone that is soluble in inert solvents. We have also characterized **3** by ^{13}C- and ^{1}H-NMR spectroscopy, and been able to convert it by lithium-titanium exchange into a novel organotitanium compound suitable for carbonyl olefination.[3]

Lithiation of the trimethylsilyl sulfone **1**[5] with one equivalent of *n*BuLi in tetrahydrofuran (THF) at −70°C leads quantitatively to the readily soluble lithioalkyl sulfone **2**[6] (Scheme 1), whose ^{1}H- and ^{13}C-NMR spectra characteristically differ from those of **1** (Table 1). Proof of the structure of **2** is provided, inter alia, by the upfield shift of $\Delta\delta = 1.65$ of the ^{1}H-NMR signal of H-7 and that of $\Delta\delta = 14.7$ of the ^{13}C-NMR signal of C-7;[7] remarkably, the ^{13}C-NMR signal of C-1 is shifted downfield by $\Delta\delta = 10.9$.



1 **2** **3**

Scheme 1

Further direct lithiation of **2** to the dilithioalkyl sulfone **3** was achieved smoothly with one equivalent of *n*BuLi in THF (−70°C→0°C) without prior *o*-metalation of the phenyl ring and subsequent transmetalation[3,8] (Scheme 1). On cooling the solution, **3** precipitates as pale yellow crystals of the composition $\mathbf{3}(thf)_2$. It is, e.g., readily soluble in THF, and stable under argon at 25°C. The ^{13}C-NMR signal of C-7 at $\delta = 50.5$ (Table 1) is broadened because of dynamic processes[9] and the ^{7}Li-^{13}C coupling;[10] interestingly, it is shifted by $\Delta\delta = 16.7$ downfield compared to that of **2**. The observed change in the ^{13}C chemical shift on going from the H_2- via the H,Li- to the Li_2-compound is found 'qualitatively' in the series methane, lithiomethane, dilithiomethane.[1b] Comparison of the ^{13}C- and ^{1}H-NMR spectra of **1**, **2**, and **3** also reveals an increasing downfield shift of the ^{13}C-NMR signal and an increasing upfield shift of the ^{1}H-NMR signal of the trimethylsilyl group (Table 1). The crystallinity and solubility of **3** should facilitate further investigations of its structure in the crystal and in solution, e.g. by low-temperature ^{13}C- and ^{6}Li-NMR spectroscopy[10,11] on [$^{6}Li_2$/7-^{13}C]-**3**.

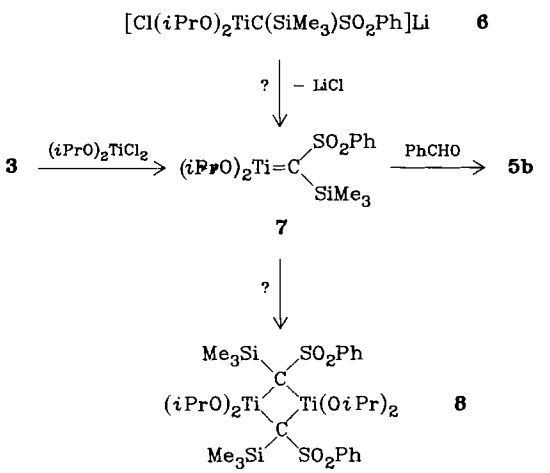
Deuteration of **3** with DCl/D_2O/THF (−30°C) affords the D_2-compound **4a** in 95% yield (≥98% deuteration), while alkylation with methyl iodide (THF, −70°C) leads to formation of 2-phenylsulfonyl-2-trimethylsilylpropane, **4b** (86%), and cycloalkylation with 1,4-dibromobutane (THF, 0°C) to formation of the cyclopentyl sulfone **4c** (81%) (Scheme 2); **4c** is desilylated with nBu_4NF in THF to cyclopentylphenyl sulfone (98%). Peterson olefination of **3** with benzaldehyde (−70°C→0°C) and reaction with DCl/D_2O/THF furnishes the styryl sulfone **5a**, deuterated in the 1-position (55%, 95% deuteration); the trimethylsilyl styryl sulfone **5b** is formed as byproduct (4%, Scheme 2).

4a, $R^1 = R^2 = D$
4b, $R^1 = R^2 = Me$
4c, $R^1, R^2 = -(CH_2)_4-$

5a, R = D
5b, R = $SiMe_3$

Scheme 2.

The lithium-metal exchange of **3** with halides of the early transition metals opens up an entry to novel functionalized organometal compounds.[3] Thus, **3** can be titanated with one equivalent of diisopropoxytitanium dichloride in THF (−90°C→−35°C); the organotitanium compound thus formed has hitherto only been generated as a deep-red THF-solution. In the titanation of [7-^{13}C]-**3**, the Li–Ti exchange manifests itself ^{13}C-NMR spectroscopically in the disappearance of the singlet of C-7 at $\delta = 50.5$; a new singlet appears at $\delta = 173$(!).



The titanium species undergoes no further reaction with methyl iodide.[3] On the other hand, on reaction with benzaldehyde in THF at −35°C, the product expected to be

Synthesis and Structure of the $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$ (n = 5, 4) Ions: Ni-Pt Clusters as Models for "Cherry" Crystallites

By *Alessandro Ceriotti, Francesco Demartin, Giuliano Longoni,* Mario Manassero,* Mario Marchionna, Gianluigi Piva,* and *Mirella Sansoni*

We report the synthesis and structural characterization of the series of clusters **1a**—**d** having the general formula $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$. These four compounds have all been isolated in a crystalline state and the structures of two, **1b** and **1c**, have been determined by X-ray diffraction studies. They constitute the highest nuclearity carbonyl clusters that have presently been fully characterized by X-ray analysis, and preliminary measurements suggest an unusual magnetic behavior.

$[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$ **1**
a, n = 3; **b**, n = 4; **c**, n = 5; **d**, n = 6

In spite of their molecular complexity, the synthesis of the cluster ions **1** is rather straightforward. Variable mixtures of **1b** and **1c** are obtained by reaction of the nickel cluster **2** in acetonitrile with either $PtCl_2$ or K_2PtCl_4 in a ca. 1:1 molar ratio; their formation probably conforms to the stoichiometry of Equation (1).

$$\underset{\mathbf{2}}{7[Ni_6(CO)_{12}]^{2-}} + 6\,Pt^{2+} \longrightarrow \underset{\mathbf{1d}}{[Ni_{38}Pt_6(CO)_{48}]^{6-}} + 2\,Ni^{2+} + 2\,Ni(CO)_4 + 28\,CO \quad (1)$$

$[Ni_{12-x}Pt_x(CO)_{21}H_{4-n}]^{n-}$ **3** $\qquad$ $[Ni_9(CO)_{18}]^{2-}$ **4**

1d is successively protonated to **1c** and **1b** [Eq. (2)] owing to the intrinsic acidity of the platinum-complex starting material. The clusters **1** can be cleanly separated from impurities (mainly the carbonyl clusters **3**[1] and **4**[2] and unreacted starting material **2**[3]) owing to the differential solubility of their tetrasubstituted ammonium or phosphonium salts in organic solvents. They are generally obtained in up to 80% yield (based on platinum) with the remaining 20% being due to the presence of variable amounts of **3** and **4** as well as some platinum metal. The salts of **1** are readily soluble in acetonitrile, only moderately soluble in acetone, and sparingly soluble or insoluble in tetrahydrofuran, alcohols, and nonpolar organic solvents.

$$\mathbf{1a} \underset{H^+}{\overset{CH_3CN}{\rightleftharpoons}} \mathbf{1b} \underset{H^+}{\overset{CO}{\rightleftharpoons}} \mathbf{1c} \underset{H_2O}{\overset{OH^-}{\rightleftharpoons}} \mathbf{1d} \quad (2)$$

Owing to the occurrence in acetonitrile solution of a rapid protonation-deprotonation equilibria [Eq. (2)], the mixture of the ions **1a**—**d** is easily converted into one of its components by controlled addition of acid or base. The derivatives **1b** and **1c** have been isolated in a crystalline state with several tetrasubstituted ammonium or phosphonium counterions by precipitation with diisopropyl ether from acetonitrile solution.[4] Isolation of **1a** is hampered by ready deprotonation of its salts on dissolution both in acetone and acetonitrile. All the crystalline sam-

ples examined gave very poor X-ray diffraction patterns and underwent rapid decay, probably owing to loss of clathrated molecules of solvent: the only exception was the $[AsPh_4]_4$ salt of **1b**. Although this sample allowed full determination of the metal framework of the cluster, the carbonyl groups and the cations could be localized only in part and exhibited very high thermal factors. The *R* structure factor progressed to a limiting value of 0.13.[5]

An X-ray analysis of a salt of **1c** containing a mixture of tetraphenylarsonium and tetrabutylammonium counterions gave the stoichiometry $[AsPh_4]_2[NBu_4]_3$ **1c**, and enabled full elucidation of the structure.[6] The combination of spherical $[AsPh_4]^+$ and spider-like $[NBu_4]^+$ counterions gave rise to good diffraction patterns and prevented rapid decay under radiation, probably because the counterions fill the holes left in the crystal lattice by the packing of big anionic molecules such as **1c**.

The unit cell of **1c** contains two independent anion molecules, which have the same structure and, after refinement, show almost identical parameters. The $Ni_{38}Pt_6$ framework in **1c** and **1b** consists of an inner octahedron of six platinum atoms fully encapsulated in a ν_3 octahedron of 38 nickel atoms (Fig. 1). The metal cluster has the same structure as a fragment of a cubic close-packed (ccp) metal lattice, and is closely related to that of the homonuclear cluster ion $[Pt_{38}(CO)_{44}H_x]^{2-}$.[7,8] The twelve Pt–Pt bond distances have a mean value of 2.719 Å; the 48 Ni–Pt bonds connecting the inner Pt_6 to the outer Ni_{38} octahedron are between 2.510 and 2.764 Å (mean value 2.630 Å). The 108 surface Ni–Ni bonds also vary in length (2.393–2.762 Å, mean value of 2.580 Å).

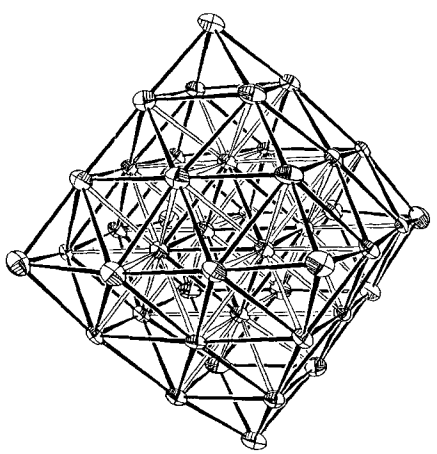

Fig. 1. ORTEP drawing of the structure of the metal framework of **1b** and **1c** in the crystal [5, 6].

The metal framework of both **1b** and **1c** provides a molecular model of bimetallic "cherry" crystallites.[9] This is further supported by the existence of a series of clusters having the more general formula $[Ni_{44-x}Pt_x(CO)_{48}H_{6-n}]^{n-}$ $(x \geqslant 6)$. We have also found an analogous series of dodecanuclear cluster ions, $[Ni_{12-x}Pt_x(CO)_{21}H_{4-n}]^{n-}$ $(x = 2, 3;\ n = 2\text{-}4)$.[1]

In both the independent molecules of **1c** in the crystal, the O_h idealized symmetry of the metal framework is reduced to a D_{3d} idealized symmetry by the presence of the 48 carbonyl ligands (18 terminal, 12 edge-bridging, and 18 face-bridging); as a result, the two opposite ν_3 triangular faces differ from the other six. The cluster **1c** with all its CO groups is shown in Figure 2.

In spite of the fact that the cluster ions **1a–c** have a relatively simple spin system, we have been so far unable to detect any ^{195}Pt- or ^1H-NMR signal due to the Pt_6 metal core or the protons. Preliminary measurements indicate

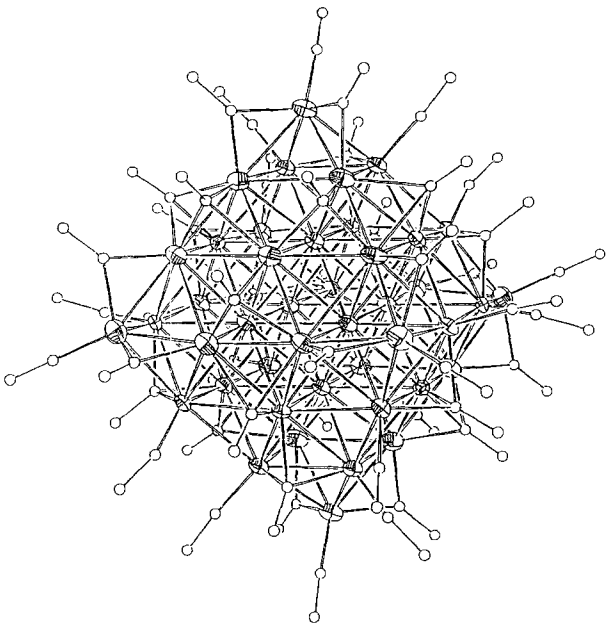

Fig. 2. ORTEP drawing of the structure of **1c** in the crystal of $[AsPh_4]_2[NBu_4]_3$ **1c** [6].

that **1b** and **1c** show peculiar magnetic behavior.[10] Unusual magnetic behavior of small metal particles,[11] and also of an even-electron molecular cluster, $[H_2Os_{10}(CO)_{24}C]$,[12] have already been documented. Such magnetic behavior could be the reason for the present failure in observing ^{195}Pt- and ^1H-NMR signals, as is also the case for platinum crystallites.[13]

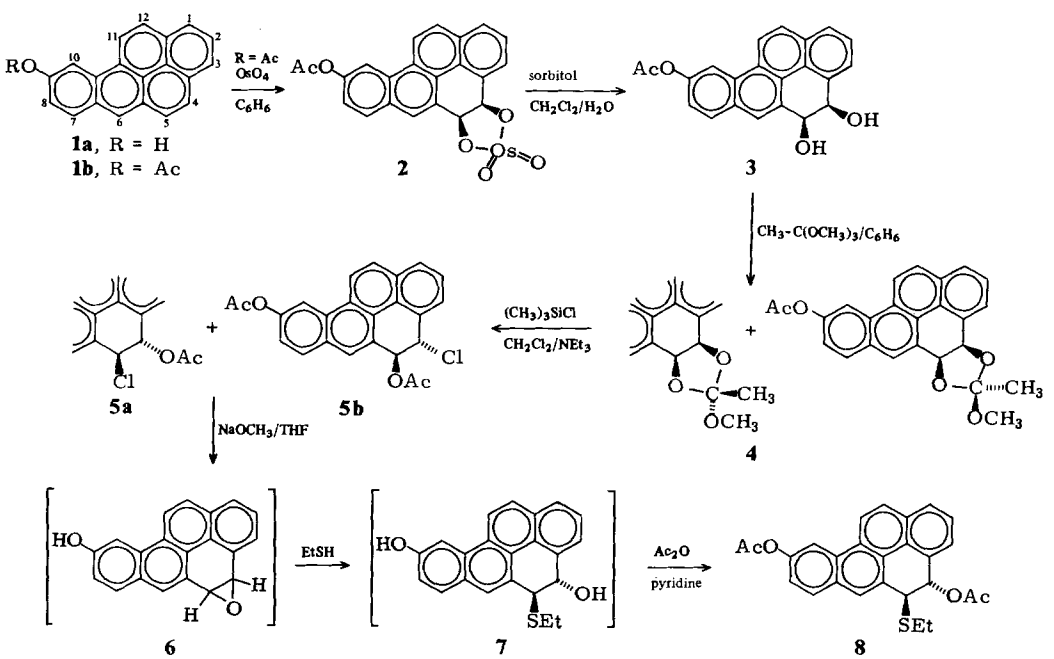
Reactive Metabolites of Carcinogenic Polycyclic Hydrocarbons: Synthesis and Trapping Reaction of 9-Hydroxybenzo[*a*]pyrene 4,5-Oxide**



By *Werner Bochnitschek, Albrecht Seidel, Horst Kunz,** and *Franz Oesch*

The carcinogenic activity of benzo[*a*]pyrene is dependent on metabolic activation by cytochrome P-450 monooxygenases[1] and was hitherto directly correlated with the DNA binding products of 7,8-dihydro-7,8-benzo[*a*]pyrenediol 9,10-oxide.[2] However, one other metabolite, 9-hydroxybenzo[*a*]pyrene (**1a**) also showed mutagenic activity in the Ames test[3] and bound with metabolic activation to nucleic acids in vivo.[4] The 4,5-oxide of **1** was regarded as the reactive species.[5] Supporting evidence for this hypothesis however was previously lacking, since all attempts to synthesize this epoxide with a free phenolic hydroxy group failed.[6]

We now describe a method for the synthesis of the ultimate carcinogen, the title compound **6**, and its trapping reaction with ethanethiol (Scheme 1). The acetate **1b** is converted with osmium tetroxide into the osmate **2** (93% yield). Subsequent transesterification with sorbitol in aqueous $NaHCO_3$/dichloromethane gives the enantiomeric *cis*-diols **3** in 54% yield. Remarkably, H-4 and H-5 appear as one singlet ($\delta = 5.15$) in the ^{1}H-NMR spectrum of **3**. Reaction of **3** with trimethyl orthoacetate affords a mixture of the two diastereomers **4**, which are purified by flash chromatography and characterized by UV, mass, and NMR spectroscopy. H-4 together with H-5, as well as the OCH_3- and CH_3-protons, give rise to a singlet for both the *exo*- and *endo*-methyl isomers ($\delta = 5.73$, 2.60, 1.79, and 5.82, 3.67, 1.58, respectively).

Reaction of the orthoacetate **4** with trimethylchlorosilane proceeds smoothly in dichloromethane/triethylamine, affording the isomeric *trans*-acetoxychloro compounds **5a** and **5b** (total yield 74% after flash chromatography). Decisive for the success of the synthesis is that no aromatization occurs in this last step by cleavage of hydrogen chloride or acetic acid. The mixture of the isomers **5a** and **5b** [m.p. 163 °C; MS: *m/z* 404 (M^+)] is characterized by its ^{1}H-NMR spectrum, which shows two doublets at $\delta = 6.59$–6.49 ($J = 3.2$ Hz) for H-4/H-5 geminal to OAc, and two doublets at $\delta = 5.68$–5.58 ($J = 3.2$ Hz) for H-4/H-5 geminal to Cl.

Reaction of **5** with sodium methoxide leads to simultaneous cleavage of the acetate and an intramolecular S_N reaction to give the desired 9-hydroxybenzo[*a*]pyrene 4,5-oxide **6**. The arene oxide **6** is unstable. Its formation is clearly detectable by thin-layer chromatography [color reagent: 4-(*p*-nitrobenzyl)pyridine].[7] Since **6** cannot be isolated as such, it is trapped with ethanethiol. The ensuing nucleophilic ring-opening reaction simulates a natural detoxification reaction for arene oxides.[8] The primary adduct **7** is further converted with acetic anhydride/pyridine into the diacetate **8**, which is isolated chromatographically on silica gel (hexane/ethyl acetate 2 : 1) in 47% yield [m.p. 172 °C, MS: *m/z* 430 (M^+)]. According to the 400-MHz ^{1}H-NMR spectrum only one isomer of 5-ethylthio-4,5-dihydro-4,9-benzo[*a*]pyrenediyl diacetate **8** is present. It follows, therefore, that both "chlorohydrin acetates" **5** react via a common intermediate **6** to give the adduct **7**. The coupling constant ($J_{4/5} = 2.5$ Hz) is consistent with a dipseudoequatorial arrangement of the two benzylic protons H-4 ($\delta = 6.44$) and H-5 ($\delta = 4.74$) in **8** and thus with the subsequent *trans* opening of the epoxide ring of **6**. Furthermore, ^{1}H-NMR NOE difference measurements show

Scheme 1. Synthesis of **6** from the acetate **1b**, trapping reaction of **6** with ethanethiol to give **7** and its conversion into the diacetate **8**. THF = tetrahydrofuran. In each case only one (arbitrarily chosen) enantiomer of the compounds **2**, **3**, **4**, **5a** and **5b**, and **7** and **8** is shown.

that the thiolate ion attacks only the 5-position of **6**. In contrast, this sulfur nucleophile reacts with unsubstituted benzo[*a*]pyrene 4,5-oxide both in the 4- as well as in the 5-position.[9] The instability and the unequivocal nucleophilic ring-opening of **6** support the hypothesis[10] that arene oxides are selectively activated by phenolic hydroxy functions.

The reaction sequence described here opens the way for the in vivo detection of adducts of **6** (to DNA or detoxifying nucleophiles) and their structural elucidation.

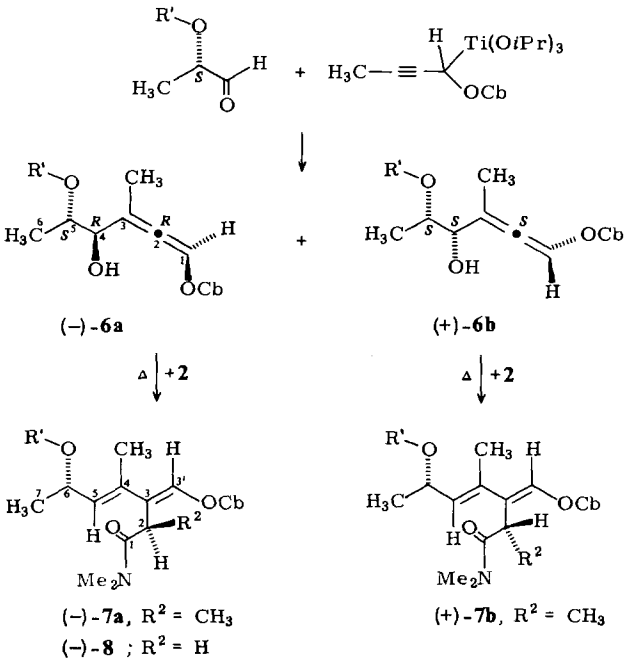
Allene Claisen Rearrangement with 1,4-Chirality Transfer**

By *Dieter Hoppe,* Charlotte Gonschorrek, Ernst Egert,** and *Dieter Schmidt*

[3,3]-Sigmatropic rearrangements of derivatives of chiral allyl alcohols often proceed with transfer of chirality—and the Claisen rearrangement is no exception; as a rule, the direction of asymmetric induction is predictable from the most favorable chair conformation of the transition state and the given topicity of the target atoms for migration.[1] Claisen rearrangements with α-allenyl alcohols that lead to 1,3-alkadienes are already well documented,[2] yet their stereochemical course has so far never been investigated.

We recently described a highly regio- and stereoselective entry to diastereomerically pure allenes[3,4] such as **1** and have now investigated their amide Claisen rearrangement.[5,6] An allene like **1** and a ketene *N,O*-acetal **2** ($R^2 \neq H$) should react to give the (*Z*)-configurated[6] intermediate **3**, whose [3,3]-sigmatropic rearrangement can proceed via four stereotopically different transition states. Which route is actually followed is revealed by the product: The chair-like transition states **A** and **B** lead to **4** (2*S*,3*Z*,4*Z*) and **5** (2*R*,3*E*,4*E*), respectively, whereas the boat-like transition states (not shown) lead to the enantiomers *ent*-**4** (2*R*,3*Z*,4*Z*) and *ent*-**5** (2*S*,3*E*,4*E*), respectively (Scheme 1).

Scheme 1. Cb = C(=O)N*i*Pr$_2$. R^1 = CH_3.



Thus, a knowledge of the absolute configuration of educt and product is indispensable for ascertaining the preferred transition state.[7] We have therefore investigated enantiomerically pure allenes of type **1** and, to simplify the synthesis and analysis, have introduced a further stereogenic, uniformly configurated reference center into the side chain R^1.

Reaction[3] of (*S*)-2-benzyloxypropanal[8] with triisopropoxytitanium *N,N*-diisopropyl-2-butynylcarbamate affords the two chromatographically readily separable, optically active diastereomers (−)-**6a**[9] and (+)-**6b**[9] (yield 71%, 37 : 63). The absolute configuration of the less polar isomer (+)-**6b** was shown by a crystal structure analysis[10] of the *p*-bromobenzoate to be (a*S*,4*S*,5*S*). (−)-**6a** is (a*R*,4*R*,5*S*) configurated, since, owing to the mode of formation[3,4] both diastereomers **6** must have the same *relative* configuration[11] at the axial-chiral and at the centrochiral stereocenter (C-4), but the same *absolute* configuration at C-5 (Scheme 2).

On heating with 20 mole equivalents of **2a** (toluene, 2 h, 50°), (−)-**6a** and (+)-**6b** afford the (*E,E*)-dienes (−)-**7a**[13] (79%) and (+)-**7b**[13] (59%), respectively, each of which contain less than 5% (^{13}C-NMR) of the other diene. According to an X-ray structure analysis (−)-**7a** has (2*R*,6*S*,3*E*,4*E*)-configuration.[14] Since 30% of (−)-(**7a**) is converted via the amide enolate into (+)-**7b** on treatment with lithium diisopropylamide (50 equiv., 1 h at −78°C in tetrahydrofuran), the stereoisomers **7** must differ only in the configuration at C-2.

[**] Metalated Nitrogen Derivatives of Carbonic Acid in Organic Synthesis, Part 30.—This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 29: E. van Hülsen, D. Hoppe, *Tetrahedron Lett. 26* (1985) 411.

Scheme 2. Cb = C(=O)NiPr$_2$, R′ = $C_6H_5CH_2$.

Consequently, the rearrangement of (−)-**6a** to (−)-**7a** proceeds via the transition state **B** and that of (+)-**6b** to (+)-**7b** via the enantiomeric transition state.[15] R^1 and the NMe_2 group thus avoid a 1,3-diaxial position, which would be accompanied by repulsion; in **B**, R^1 takes a pseudo-equatorial position. On the other hand, approach of C-2′ towards C-2 from the more strongly shielded side of the allene moiety in **B** also seems unfavorable.[16] The configuration of the two double bonds in **5** is determined by the *relative* configuration of **1** and that at C-2 in **5** by the *absolute* configuration at C-4 (for the same configuration of the enol double bond). Therefore, reaction of a mixture of (−)-**6a** and (+)-**6b** with the (at C-2′ non-prochiral) reagent **2b** affords, as expected, a uniform diene (−)-**8**[13] (70%, *ds* >98%).

This synthesis provides a simple and general entry to highly substituted diastereomerically pure 1,3-alkadienes of the type **5** in only two steps; the C-4–C-5 bond and the C-2–C-3 bond are thereby connected. The method is also well suited for the preparation of enantiomerically pure dienes such as **7**.

[9] (−)-**6a**: $[\alpha]_D^{20}$ −22.9 (*c* = 5.4, CH_3OH), R_F = 0.24; (+)-**6b**: $[\alpha]_D^{20}$ +15.0 (*c* = 3.1, CH_3OH), R_F = 0.32.—Selected NMR data (δ values, $CDCl_3$), ^{1}H-NMR: **6a**: 7.42 (qd, $J_{1,3'} = J_{1,4}$ = 2 Hz, 1-H); **6b**: 7.68 (dq, $J_{1,3'}$ = 2 Hz, $J_{1,4}$ = 1.5 Hz); ^{13}C-NMR, **6a/6b**: 114.85/114.49 (C-1), 189.81/190.62 (C-2), 112.78/112.34 (C-3), 76.51/76.36 (C-4), 74.08/75.99 (C-5), 13.71/15.82 (C-6), 17.35/17.04 (3-CH_3).

[10] Crystal structure analysis of the *p*-bromobenzoate of (+)-**6b** ($C_{28}H_{34}BrNO_5$): Space group $P2_1$, *a* = 608.1(1), *b* = 1412.3(1), *c* = 1643.2(2) pm, β = 95.69(1)°, *V* = 1.404 nm^3, *Z* = 2, μ = 1.48 mm^{-1} ($Mo_{K\alpha}$), 4844 measured intensities ($2\theta_{max}$ = 50°) including Friedel pairs, 3949 reflections with $|F| > 3\sigma_F$ classified as observed, empirical absorption correction, Patterson and Fourier methods, non-hydrogen atoms refined anisotropically, H atoms geometrically positioned, *R* = 0.050 (R_w = 0.045), values for the false absolute configuration: *R* = 0.083 (R_w = 0.081); η-refinement gave 1.00(2) [17].

[11] Contrary to our previous assumption [3] the titanium-mediated addition affords *syn*-configurated [12] 4-hydroxy-1,2-alkadienes **1**. Thus, for the racemic acetaldehyde adduct (**1**, $R^1 = CH_3$), the (a*R**,4*S**) configuration was confirmed by crystal structure analysis of the *p*-chlorophenylurethane; reversal of the relative configuration compared to **6** is only due to altered *CIP* priorities. E. Egert, D. Schmidt, C. Gonschorrek, D. Hoppe, unpublished.

[12] a) Analogously to the widely accepted proposal by *Masamune* et al. [12b] for aldol-like diastereomers, we would like to suggest the *syn/anti* notation for the facile assignment of allenes of the type **1** to diastereomeric series, on the basis of the "zig-zag conformation" **1A**. **1** and **6** accordingly belong to the *syn* series and the diastereomers (e.g. 1-H and OCb exchanged) to the *anti* series. However the *CIP* notation [12c] is recommended for the stereochemical assignment of individual compounds.—b) S. Masamune, S. A. Ali, D. L. Snitman, D. S. Garvey, *Angew. Chem.* *92* (1980) 573; *Angew. Chem. Int. Ed. Engl.* *19* (1980) 557; c) D. Seebach, V. Prelog, *ibid.* *94* (1982) 696 and *21* (1982) 654.

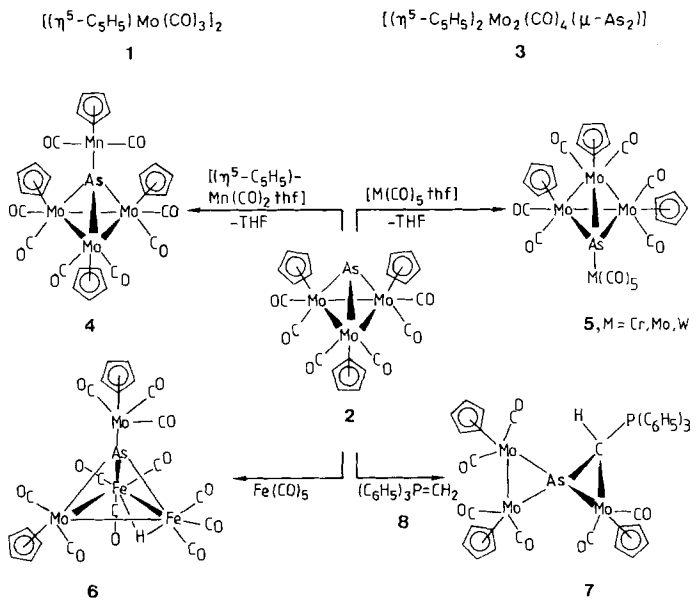
[14] Crystal structure analysis of **7a** ($C_{26}H_{40}N_2O_4$): Space group $P2_12_12_1$, *a* = 970.7(1), *b* = 1540.7(2), *c* = 1820.6(2) pm, *V* = 2.723 nm^3, *Z* = 4, μ = 0.07 mm^{-1} ($Mo_{K\alpha}$), 2721 measured intensities ($2\theta_{max}$ = 50°), 2104 with $|F| > 3\sigma_F$ significant, direct methods (SHELXTL), C, N, and O atoms refined anisotropically, H atoms geometrically positioned, *R* = 0.065 (R_w = 0.060) [17].

[15] The stereogenic center in R^1, which has no influence on the course of the reaction, is ignored here.



[16] The stereoselectivity of the rearrangement in **3** decreases with increasing bulkiness of the substituents on C-3 ($SiMe_3$ for CH_3) and on disubstitution of C-2′. The configuration of the additional isomers formed at the same time has so far not been elucidated; D. Hoppe, C. Gonschorrek, unpublished.

[17] Further details of the crystal structure investigation are available on request from Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51 506, the names of the authors, and the full citation of the journal.

Synthesis and Structure of the Spirocluster $[(\eta^5\text{-}C_5H_5)_3Mo_3As(CO)_6\{CHP(C_6H_5)_3\}]$**

By *Klaus Blechschmitt, Thomas Zahn,* and *Manfred L. Ziegler**

The Mo-complex **1** reacts with elemental arsenic to give the cluster compounds **2**[1] and **3**[2] in good yields. On investigating the reactivity of **2** we have established that, as expected, adducts like **4**[1] and **5**[3] are formed; cluster building blocks in **2** can, however, be exchanged for $Fe(CO)_5$, with formation of the species **6**.[4] Seemingly unusual to us however, is the access to the spirocluster **7** with the Wittig reagent **8**.[5]

Adducts comparable with **4** and **5** are known, e.g., in the case of $AsCo_3$ clusters;[6] this also applies in the case of the hydrido clusters **6**,[7] in which, as confirmed inter alia by an X-ray structure analysis, two $CpMo(CO)_2$ moieties are substituted by an $Fe(H)(CO)_3$ moiety and an $Fe(CO)_3$ moiety. The As atom in **6** functions as a 5-electron donor towards its neighbors. In the comparable cluster **9**,[7] the same situation exists for phosphorus.

The reaction of **2** with the phosphorus ylide **8** is surprising. Instead of a conceivable 1,2-addition to an As–Mo or a Mo–Mo bond or a transfer of the CH_2 group with formation of a μ-methylene complex,[8] the cluster is opened with cleavage of a hydrogen atom and formation of an arsenic-carbon-molybdenum three-membered ring. The chiral spirocluster **7** is unequivocally characterized by an elemental analysis, spectroscopic data,[5] and by an X-ray structure analysis (Fig. 1);[9] **7** crystallizes as a racemate.

In **7**, the arsenic is coordinated in a distorted tetrahedral fashion, all five valence electrons of the arsenic participate in bonding. The formal positive charges on the four-bonded arsenic and phosphorus are compensated by negative charges on two $Mo(CO)_2(C_5H_5)$ units. The latter must also be accounted for on the basis of the 18-electron rule, since no signals occur in the Mo–H and Mo–H–Mo regions of the ^{1}H-NMR spectrum. In the room temperature ^{1}H-NMR spectrum, three signals are observed for the C_5H_5 rings. This suggests that the molecule has the same configuration in the solid state and in solution.

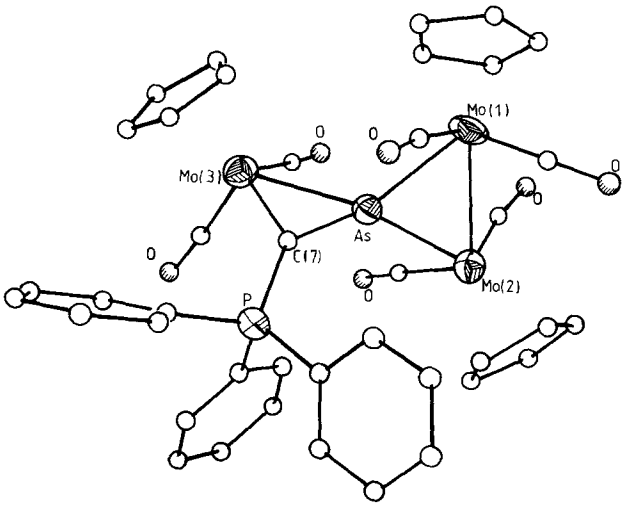


Fig. 1. Crystal structure of **7**: $P2_1$, $Z=4$, $a=965.8(5)$, $b=1805.0(9)$, $c=2331.6(7)$ pm, $\beta=95.30(3)°$, $V=4047.22\cdot10^6$ pm^3, $R_{aniso}=0.078$, $R_w=0.062$. Selected bond lengths [pm] and angles [°]: Mo(1)–Mo(2) 333.2(3), Mo(1)–As 254.4(4), Mo(2)–As 254.2(4), Mo(3)–As 257.3(4), As–C(7) 197(2), Mo(3)–C(7) 229(3), P–C(7) 175(3), Mo–C(=O) 192(3) (mean value), Mo–C(Cp) 236(2) (mean value); Mo(1)–As–Mo(2) 81.9(1), Mo(1)–As–Mo(3) 123.3(2), Mo(2)–As–Mo(3) 144.0(2), Mo(1)–As–C(7) 122.9(7), Mo(2)–As–C(7) 132.7(7), Mo(3)–As–C(7) 58.7(7), Mo(3)–C(7)–As 73.8(7), As–Mo(3)–C(7) 47.5(6), Mo(3)–C(7)–P 127(1), As–C(7)–P 132(1) [9].

In contrast to $(\mu_3,\eta^2$-methylenegermandiyl)tris[dicarbonyl-$(\eta^5$-cyclopentadienyl)manganese]*(Mn–Mn)* **10**,[10] the complex **7** described here exhibits no dynamic properties up to +100 °C (^{1}H-NMR). Between 60 and 100 °C one of the Cp signals broadens reversibly. This is explained in terms of a rotation of the phenyl rings of the $(C_6H_5)_3P$ ligand about the P–C axis. Hence, only the Cp ring on Mo(2) is affected (Fig. 1).

7 can be regarded as a μ_3,η^2-methylenearsanediyl complex, i.e. as a rare example in which a main group element and a transition element are bridged by an alkylidene group $[CHP(C_6H_5)_3]$.[11]

Cleavage of a C–C Bond in the Catalytic Hydrosilylation of Camphor Oxime**

By *Henri Brunner** and *Richard Becker*

Rhodium-catalyzed hydrosilylation of ketoximes and subsequent hydrolysis leads to formation of primary amines, e.g. in the case of acetophenone oxime to the enantiomers of 1-phenylethylamine.[1a] Thirteen other alkylaryl- and alkylbenzyl ketoximes gave exclusively the corresponding amines[1b] in the amine fraction. All the more surprising was the finding that, in the hydrosilylation of (−)-(1*R*,4*R*)-camphor oxime **1**, not only the expected bornylamines **3a** and **3b** were formed, but also, and as main product, optically pure (+)-(1*R*,3*S*)-1-(2-aminoethyl)-2,2,3-trimethylcyclopentane **4a**.

2a, R^1 = H, R^2 = Ph; **2b**, R^1 = Me, R^2 = Cl

The reaction of 1 mole equivalent of **1** with 3.3 mole equivalents of diphenylsilane **2a** in toluene is catalyzed by 1 mol-% [$RhCl(PPh_3)_3$] (Table 1).[2] Gas chromatographic analysis[3] of the distilled product revealed a mixture of three amines, which were identified by GC/MS. Besides the expected mass peaks of the trifluoroacetamide derivatives of *endo*- and *exo*-bornylamine, **3a** and **3b**, respectively, the main product, two mass units higher, indicated cleavage of a C–C bond in the camphor skeleton. That this cleavage was a hydrogenolytic cleavage between the bridgehead carbon atom and the oxime carbon atom, with formation of **4a**, followed from the ^{1}H-NMR spectrum (two methyl singlets, one methyl doublet[4]) and the ^{13}C-NMR spectrum.[5]

In the reaction of **1** to give **4a**, the (*R*)-configuration at C4 of the educt (C3 of the product) is preserved. That the configuration at C1 of **4a** is also retained was established as follows: α-campholenonitrile **5**[6] was hydrogenated with H_2/Raney nickel. The two diastereomers **4a** (1*R*,3*S*) and **4b** (1*R*,3*R*) were formed in the ratio 36:64; the base lines of their trifluoroacetamide derivatives are separated on gas chromatographic analysis.[3] Co-injections with the trifluoroacetamide derivative of **4a** obtained on hydrosilylation show that only one of the two diastereomers is formed. The retention behavior on a Chirasil-L-Val® column (shorter retention time for *R*-compounsds[7]) lends support for assignment of the (*S*)-configuration at C3 in **4a**, which is also consistent with the concept that cleavage of the C–C bond and addition of hydrogen to the two C atoms takes place at one metal center.

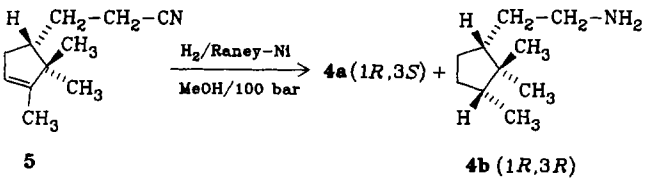

Table 1. Hydrosilylation of 2.7 g of (D)-camphor oxime **1** with the silanes **2a**, **b** in 5 mL of toluene.

[**] Asymmetric Catalysis, Part 26. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG. – Part 25: H. Brunner, A. Knott, *Z. Naturforsch.*, in press.

5 **4b** (1*R*,3*R*)

Hydrosilylation of **1** with diphenylsilane, **2a**, furnishes **4a** in 80–85% relative yield (total yield 30–40%; Table 1, entries 1 and 2). Increasing or lowering the reaction temperature reduces the selectivity with respect to **4a** in the same way as addition of $BF_3 \cdot OEt_2$, which should catalyze the Beckmann rearrangement (Entries 3–7). **4a** is also obtained with dichloromethylsilane, **2b**, on homogeneous catalysis with Zeise salt and on heterogeneous catalysis with $PtO_2 \cdot H_2O$ (Entries 8–10).

Hence, the enantiomerically pure primary amine (+)-**4a** which, hitherto, has only been described in the form of a **4a/4b** diastereomeric mixture[8] can be synthesized in one step by catalytic hydrosilylation of (D)-camphor oxime.

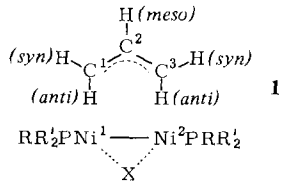
Dinuclear Nickel Complexes with Bridging Allyl Ligands**

By *Rudolf Hanko**



Dedicated to Professor Günther Wilke on the occasion of his 60th birthday

The great synthetic and catalytic potential of mononuclear η^3-allylnickel-X compounds **2** (X = halogen, allyl, H)[1] and the increasing importance of multinuclear transition metal complexes in homogeneous catalysis attracted interest in multinuclear Ni-complexes with bridging allyl ligands (type **1**). To my knowledge no such complexes have, as yet, been documented, although unsuccessful attempts at their synthesis have been reported.[2]

[**] I wish to thank Professor *G. Wilke* for his participation in and support of this work.

1

In the following communication a simple and versatile entry to this special class of compounds is described: Reaction of a 1:1 mixture of a triorganophosphane **7** and a nickel(0)-complex **4** or **5** with an η^3-allylnickel halide complex **2** [Reactions (1) and (2), respectively (Scheme 1)] or of the bis(phosphane)ethylenenickel complex **6** with the complex **3** [Reaction (3)] leads, via displacement of the olefin ligands to formation of a crystallizable dinuclear nickel compound of the type **1** in high yields. The liberated olefin can be removed under vacuum or by recrystallization. Reaction (1) affords the best yields (ca. 80%)[3] (Table 1). With exception of the PMe_3-adduct **1a**, these wine-red, dinuclear complexes **1** are stable under argon at room temperature.[4]

Scheme 1. CDT = all-*trans*-1,5,9-cyclododecatriene; COD = *cis,cis*-1,5-cyclooctadiene.

Table 1.

Product	X	PRR'_2	Educts	Reaction	Yield [%]
1a	Br	PMe_3	**2a**, **4**, **7a**	(1)	82 [a]
1b	Cl	$P(i\text{Pr})_3$	**2b**, **4**, **7b**	(1)	63
1b	Cl	$P(i\text{Pr})_3$	**2b**, **5**, **7b**	(2)	54

[a] Determined by NMR spectroscopy.

The nuclear resonance spectra[5] are reconcilable with dinuclear structures. In each case, only one signal is to be seen in the ^{31}P-NMR spectrum. In the ^{13}C-NMR spectra[6,7] the signals of the carbon atoms bound to phosphorus can be interpreted as X-parts of ABX spin systems (A,B = ^{31}P; X = ^{13}C), from which a phosphorus-phosphorus coupling constant of ca. 25 Hz can be calculated for **1b** and **1d**. According to the ^{13}C- and ^{1}H-NMR spectra the allyl groups are symmetrically bound. Particularly striking is the upfield shift of the signal ($\delta = 32$–38) of the *meso*-carbon atom of the halogen-bridged compounds compared to that of the mononuclear analogues (e.g. $\delta = 31.8$ for **1e** compared to $\delta = 107.2$[8] for **2e**). In the case of the bis(allyl) compound **1f**, the upfield shifts of the allyl carbon atoms are less pronounced compared to those of the mononuclear starting complex ($\delta = 87.1$ (*meso*), 27.6 (terminal) for **1f** compared to $\delta = 112.2$ (*meso*), 52.6 (terminal) for **2f**[9]).

From the ^{13}C-NMR spectrum of **1f**, it follows that the allyl groups are *cis* oriented. A structure with more than two nickel atoms was ruled out in the case of **1f** by spectra simulation.[5]

The structure proposed for **1e** on the basis of NMR spectra was confirmed by an X-ray structure analysis,[10] according to which the nickel atoms are separated at a distance typical for Ni–Ni bonds and are almost symmetrically bridged by an allyl group and a halogen atom.

The catalytic properties of the new Ni complex of type **1** are presently being investigated.

Selective ^{1}H,^{13}C-NOE Difference Spectroscopy for the Elucidation of Structures

By *Peter Bigler** and *Matthias Kamber*

Development of the modern technique of nuclear resonance spectroscopy has been so rapid in recent years that the spectroscopist now has a wide 'spectrum' of informative methods at his disposal. We report here on a method that has proven very useful in the solution of problems regarding structural configurations and conformations. Used in combination with other NMR methods it enables unequivocal interpretation of the mutual positions of molecular fragments. The nuclear Overhauser enhancement (NOE) effect[1] resorted to in our method has been exploited ever since the advent of ^{13}C-NMR spectroscopy. It is responsible for the enhanced intensity of the ^{13}C-NMR signals in ^{1}H broad-band decoupling. In the case of quaternary carbon atoms the total observed nuclear Overhauser effect is made up of the individual contributions of the protons in the immediate vicinity. The contributions of the individual protons differs according to their relative distances from the C-atom under observation. Selective ^{1}H-irradiation, i.e. irradiation with the resonance frequency of these protons, allows these contributions to be measured and, consequently, also the relationships to be established that are important for structure elucidation. If usually well separated ^{1}H-NMR signals have been selected for the irradiation, which severely limits the scope of the method, then the technique proposed here[2–4] can, similarly to modern homonuclear methods (Fig. 1), be used even when large signal overlapping occurs in the ^{1}H-NMR spectrum.

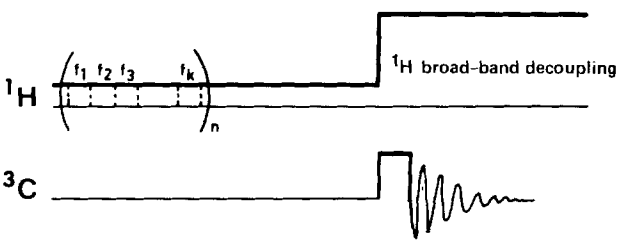

Fig. 1. Pulse scheme for the hetero-NOE experiment: During the NOE generation, the selected ^{1}H-NMR frequencies f_1 to f_k are rapidly irradiated one after the other.

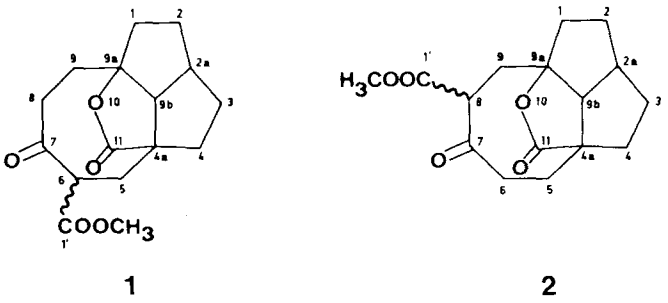
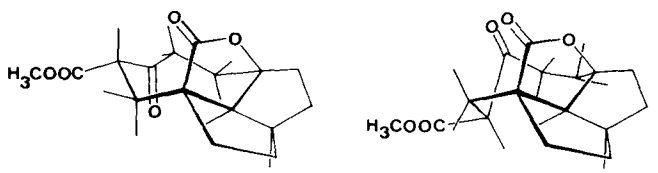


The high selectivity required for this, is achieved through the selected ^{1}H-NMR signals—more precisely associated ^{13}C satellites—being irradiated one after the other in rapid succession during the phase of the NOE generation with very small decoupler power. This also guaranties high efficiency, in that the signals of several protons, e.g. of a methylene group, with different chemical shifts, can be concomitantly saturated and the sum of several NOE contributions detected. The sensitivity of the method can be further increased by ^{1}H broad-band decoupling during the detection phase and representation of the effects in the form of difference spectra.

The NOE method has certain advantages over other methods which enable the environment of quaternary carbon atoms to be explored, e.g. the recently reported CH-shift correlation on the basis of long-range couplings:[5] As a 1D experiment, the method is favored by a relatively short measuring time. A knowledge of the coupling constants—in the case of geminal and vicinal C,H-couplings there are often uncertainties—is not required.

We have used the method for investigating the isomeric β-keto esters **1** and **2** (Fig. 2), which were formed during the synthesis of a tetraquinacane derivative.[6] An NMR spectroscopic investigation of the main components was expected to allow differentiation of the two isomers and to permit elucidation of the stereochemistry in the eight-membered ring (Fig. 3).



On the basis of signals which, due to their chemical shift and their multiplet structure, must be assigned to the H atoms on C6 and C8, the strongly overlapping signals of the other eight-membered ring protons on C5 and C9 could be located by decoupling experiments. In a prelimi-

Fig. 2. β-Keto esters **1** and **2**.

1a 1b

Fig. 3. Stereoisomers of **1**. The bonds to the H-atoms on C2a, C5, C6, C8, and C9 are shown.

nary measurement of the hetero NOE effect, the multiplet lines of the C5 protons and then of the C9 protons were, as described above, successively irradiated several times; the two spectra were (in each case at the stage of the free induction decay) subtracted from each other. The ^{13}C-NMR difference spectrum (Fig. 4a) shows a positive signal for C4a and, thus, close proximity to the protons on C5, and a negative signal for C9a, and thus, a close proximity to the protons on C9. Since the quaternary C-atoms C4a and C9a can be identified from their chemical shifts, the position of the lactone bridge relative to the methine group C6 is established and, thus, also the structure of the main component **1**.

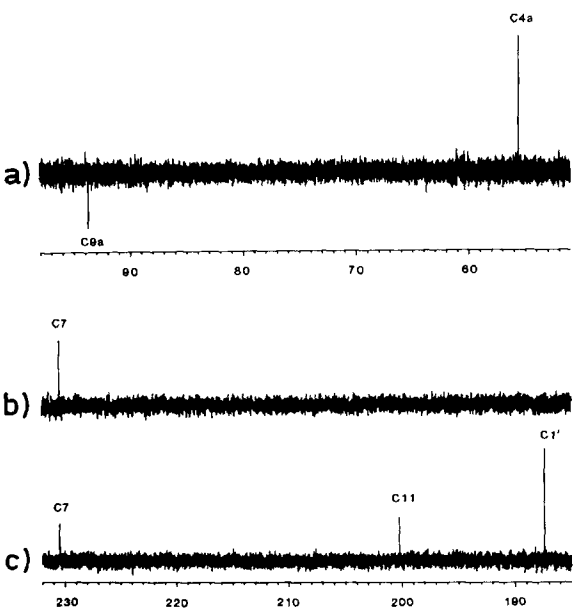

Fig. 4. Hetero-NOE difference spectra (δ values). a) Difference of the ^{13}C-NMR spectra in the region of C4a and C9a after irradiation of the protons on C5 and C9; b), c) difference of the ^{13}C-NMR spectra in the carbonyl region after irradiation of the proton on C8 (b) and of the proton on C6 (c).

For clarification of the stereochemistry in the eight-membered ring, the methine proton on C6 and one of the methylene protons on C8 were irradiated separately in a second hetero-NOE experiment. On the basis of the ^{1}H-coupling constants for their coupling with the neighboring methylene protons it could be assumed that they were the protons which lie relatively close to the lactone bridge in the case of **1a** but not so in the case of **1b** (Fig. 3).

Hence, in the presence of **1a** an NOE effect on C11 had to be expected from at least one of these protons. Indeed, the difference spectrum (Fig. 4c) shows, in the case of the irradiation of the proton on C6, a signal of C11 as well as the expected signals of C7 and C1′ (ester carbonyl-C). In the second difference spectrum (Fig. 4b), after irradiation of the one proton of the methylene group C8, only the expected signal of C7 appears. This confirms the finding of the preliminary NOE experiment and, due to the spatial proximity of the proton of the methine group C6 to C11 (lactone carbonyl-C), proves the presence of structure **1a**.

Thus, as a result of increased selectivity, the hetero-NOE experiment can be successfully employed even when strongly overlapping proton spectra are obtained.

Novel Cobalt- and Nickel-Clusters with S and PPh_3 as Ligands; Crystal Structures of $[Co_7S_6(PPh_3)_5Cl_2]$, $[Co_6S_8(PPh_3)_6]^+[CoCl_3(THF)]^-$, $[Ni_8S_6Cl_2(PPh_3)_6]$, and $[Ni_8S_5(PPh_3)_7]$**

By *Dieter Fenske,* Johannes Hachgenei,* and *Johannes Ohmer*

We recently described a simple method for the preparation of PPh-bridged clusters of Co and Ni. Reaction of MCl_2 (M = Co, Ni) with $PhP(SiMe_3)_2$ in the presence of Ph_3P leads to the formation of $SiMe_3Cl$ and $[Co_4(\mu_3\text{-}PPh)_4(PPh_3)_4]$ or **1**.[1,2] **1** contains four coordinatively unsaturated Ni atoms which are shielded in a crown-like fashion by Ph groups of the PPh- and PPh_3-ligands. As a result the cluster contains a channel of about 400–500 pm in diameter, and only small molecules, e.g. CO, can bind to the four Ni atoms with coordination vacancies.

In attempts to prepare clusters with greater coordination gaps we allowed $S(SiMe_3)_2$[3] to react with $[MCl_2(PPh_3)_2]$ (**1a**, M = Co; **1b**, M = Ni). Reactions of transition metal halides with $S(SiMe_3)_2$ have already been reported. Normally, metal sulfides are formed; only in one case could

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank co-workers at the Institut für Kristallographie der Universität Karlsruhe for help with the crystallographic measurements.

the formation of a binuclear complex be observed.[4] Reaction of **1a** with $S(SiMe_3)_2$, on the other hand, leads to formation of clusters. With tetrahydrofuran as solvent, a crystalline black precipitate consisting of **2** and **3**, separates out within a few minutes.[5]

$$[CoCl_2(PPh_3)_2] \xrightarrow[THF]{S(SiMe_3)_2} \underset{\textbf{1a}}{} [Co_6S_8(PPh_3)_6][CoCl_3(THF)] + [Co_7S_6(PPh_3)_5Cl_2]$$
$$\textbf{2} \qquad\qquad \textbf{3}$$

Reaction of the complex **2** with $[NBu_4]PF_6$ furnishes $[Co_6S_8(PPh_3)_6]PF_6$.

2 and $[Co_6S_8(PPh_3)_6]PF_6$ are paramagnetic, and, at 300 K, have magnetic moments of 4.55 and 2.49 μ_B, respectively. This manifests itself, e.g., in the ^{1}H-NMR spectrum of **2** by various isotropic shifts for the phenyl protons ($\delta = 6.60$–7.50).

The structures of **2** and **3** were determined by X-ray crystallography.[6] **2** contains isolated $[Co_6(\mu_3\text{-}S)_8(PPh_3)_6]^+$ (Fig. 1) and $[CoCl_3(THF)]^-$ ions.[7] The cluster cation consists of an almost regular Co_6-octahedron ($\bar{1}$ symmetry), whose Co_3-faces are each bridged by a μ_3-S ligand.[8, 9] In addition, each Co atom is bound to the P-atom of a PPh_3 ligand. The Co_6-cluster contains 97 valence electrons, i.e. 13 electrons more than expected according to the 18-electron rule.[10, 11] The Co–Co bond lengths (280–282 pm) correspond to those found in $[Co_6S_8(PEt_3)_8]^+$,[12] but are distinctly longer than those in $[Co_6(CO)_{15}]^{2-}$ and $[Co_6(CO)_{14}]^{4-}$ (246–254 pm).[13, 14]

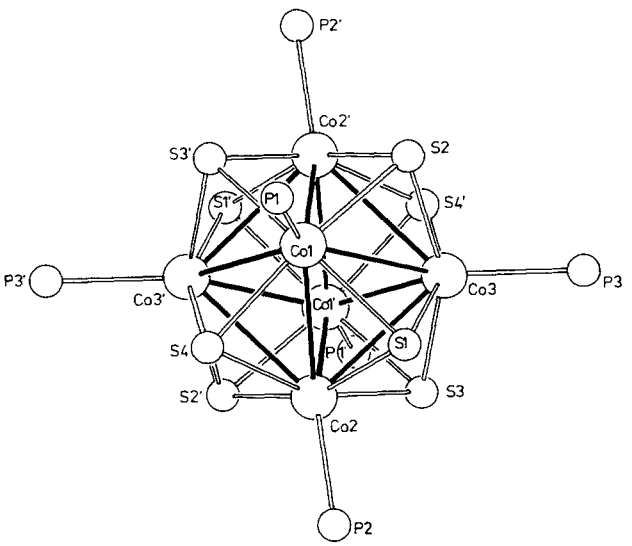

Fig. 1. Structure of the $[(Co_6(\mu_3\text{-}S)_8(PPh_3)_6]^+$ ion in the crystal of **2** (without phenyl groups) [6]. P1–P3 are the atoms of the PPh_3 ligands. (The dashed atomic positions are generated by the inversion center.) Important bond lengths [pm] (±0.2 pm) and bond angles [°] (±0.1°): Co–Co 279.8–282.8, Co–(μ_3-S) 220–223, Co–P 217.8–218.1; Co–Co–Co 59.4–60.5, 89.3–90.7, P–Co–(μ_3-S) 91–111, S1–Co1–S2 86.9, S2–Co1–S3′ 88.1, S3′–Co1–S4 87.7, S4–Co1–S1 87.8, S1–Co1–S3′ 156.8, S2–Co1–S4 156.5.

A complex containing seven Co atoms is present in **3** (Fig. 2). Formally, the Co_7-cluster can be derived from a cube from which one corner has been removed. The cluster distorts, and forms a polyhedron of three Co_4-faces and four Co_3-faces. The polyhedron faces (Co1, Co2, Co3, Co5; Co2, Co3, Co6, Co7; Co2, Co4, Co5, Co7) are not planar; the Co atoms lie 16 pm above or below the medium plane. The μ_4-S–Co ligand distances are 217–225 pm. Three of the Co_3 faces (Co1, Co3, Co6; Co1, Co4, Co5; Co4, Co6, Co7) are bound to μ_3-S ligands (Co–S 213.6–222.8 pm). The Co atoms in **3** are coordinated to a distorted tetrahedral array of three S atoms and the P atom of the PPh_3 ligand (Co1, Co2, Co4, Co6, Co7) or three S atoms and a Cl ligand (Co3, Co5). The Co–Co distances in the cluster are 257.4–263.7 pm. These values are comparable with the Co–Co bond lengths in $[Co_8S_6(SPh)_8]^{4-}$ (263–266 pm).[15] Three bonds (Co1–Co4, Co1–Co6, Co4–Co6), however, are markedly longer (286.1–289.7 pm). Presumably, this is the reason for **3** (99 valence electrons) already reacting with CO at room temperature to give $[Co_7(CO)_3Cl_2S_6(PPh_3)_5]$ (ν(CO) = 1960, 1940 cm^{-1}, 105 valence electrons).

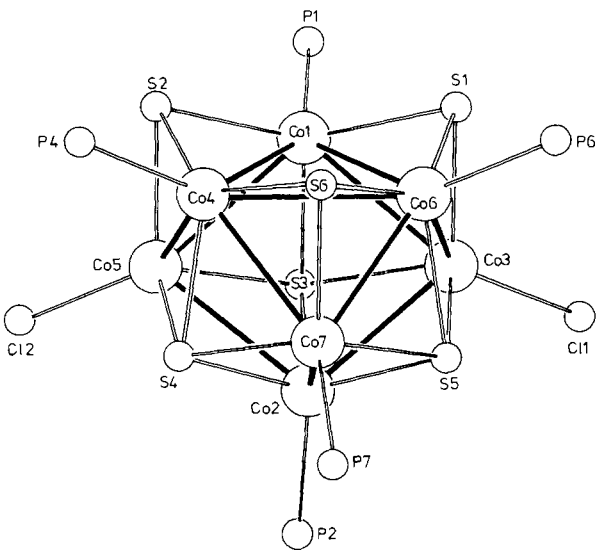

Fig. 2. Crystal structure of the cluster **3** (without phenyl groups) [6]. P1, P2, P4, P6 and P7 are the P atoms of the PPh_3 ligands. Important bond lengths [pm] and bond angles [°] (±0.1°): Co1–Co3 259.3(2), Co1–Co4 286.1(2), Co1–Co5 260.2(2), Co1–Co6 289.6(2), Co2–Co3 263.7(2), Co2–Co5 265.2(2), Co2–Co7 260.4(2), Co3–Co6 258.7(2), Co4–Co5 257.4(2), Co4–Co6 289.7(2), Co4–Co7 260.5(2), Co6–Co7 257.7(2), Co–P 220.9–227.5(4), Co–Cl 220.8–222.8(4), Co1–S 214.0–218.1(3), Co2–S 217.0–220.0(4), Co3–S 221.0–225.2(3), Co4–S 215.8–223.3(3), Co5–S 222.5–224.8(3), Co6–S 214.0–217.1(3), Co7–S 217.6–220.8(3); Co–Con–Co: Con = Co1 55.9–101.7, Co2 95.2–95.8, Co3 68.0–81.8, Co4 55.6–102.1, Co5 67.1–81.9, Co6 56.1–100.9, Co7 68.0–82.6; Co–(μ_3-S)–Co 71.8–85.3, Co–(μ_4-S)–Co 70.1–121.9, P–Co–S 94–119.4, Cl–Co–S 109.8–116.3.

The reaction of PR_3 complexes of the transition metal halides with $S(SiMe_3)_2$ also leads in other cases to S-bridged clusters. For example, reaction of $[NiCl_2(PPh_3)_2]$ with $S(SiMe_3)_2$ furnishes a mixture of **4** and a substance whose structure is so far unknwon.[16] According to analysis it is the complex **5**, which is readily soluble in THF and acetone and can be separated from the sparingly soluble **4**.

$$[Ni_8S_6Cl_2(PPh_3)_6] \qquad [NiS(PPh_3)Cl]_n \qquad [Ni_8S_5(PPh_3)_7]$$
$$\textbf{4} \qquad\qquad \textbf{5} \qquad\qquad \textbf{6}$$

A crystal structure analysis of **4** (Fig. 3) showed that a slightly distorted Ni_8 cube ($\bar{1}$ symmetry) is present which bears a μ_4-S ligand on each face.[17] In addition, the Ni atoms are bound to the P atom of the PPh_3 ligand (Ni1, Ni2, Ni4, Ni1′, Ni2′, Ni4′) or to Cl^- (Ni3, Ni3′). Consequently, the Ni is coordinated in a distorted tetrahedral fashion. **4** contains 118 valence electrons, and the Ni–Ni distances (266–270 pm) compare with those found in other Ni_8 clusters.[1, 2, 18]

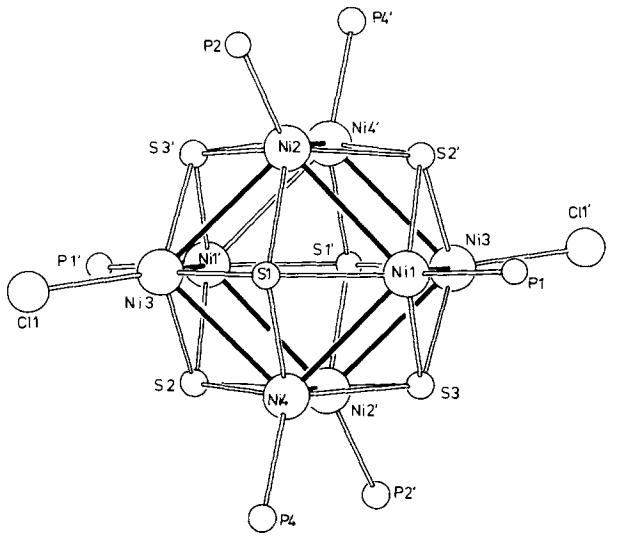

Fig. 3. Crystal structure of the cluster **4** (without phenyl groups). P1, P2, and P4 correspond to the P atoms of the PPh_3 ligands [17]. Important bond lengths [pm] (±0.1 pm) and bond angles [°] (±0.1°): Ni–Ni 265.8–271.0, Ni–(μ_4-S) 217.9–223.8, Ni–P 224.5–226.3, Ni–Cl 220.3; Ni–Ni–Ni 88.2–92.6, P–Ni–(μ_4-S) 107.9–125.8, Cl–Ni–(μ_4-S) 109.8–121.7, Ni–(μ_4-S)–Ni 74.2–76.9 (*cis*), 116.0–119.6 (*trans*).

Reduction of **4** with sodium amalgam in THF in the presence of CO affords $[Ni_8(CO)_2S_6(PPh_3)_6]$. Intercalation of metal atoms, as occurs during the reduction of $[Ni_8Cl_4(\mu_4\text{-}PPh)_6(PPh_3)_4]$, was, however, not observed.[2]

Reaction of **5** with Zn (in THF) leads to formation of **6** in 60% yield.[16]

6[19] (Fig. 4) is a Ni_8 cluster (114 valence electrons) consisting of two edge-to-edge coupled trigonal bipyramids. Owing to the large spatial requirement of the PPh_3 ligand attached to Ni1, Ni2, Ni3, Ni4, Ni5, Ni6, and Ni8, not all polyhedral faces can be occupied by S-ligands. Ni1, Ni4, and Ni6 and Ni3, Ni5, and Ni8 are bound to μ_3-S ligands. The Ni–S bond lengths (211–217 pm) and Ni–S–Ni bond angles (76.7–81.5°) are comparable with those in other complexes that contain μ_3-S ligands.[20] S3, S4, and S5 can also be regarded as μ_3-ligands (Ni–S 213–219 pm). However, the Ni–S–Ni bond angles (72.4–137.4°) are considerably larger. In addition there is still weak interaction between Ni7 and S3 (258.6 pm) and between Ni7 and S4 (268.8 pm).

The Ni–Ni distances can be classified into three groups: 1) 240–252 pm, from Ni7 to the Ni atoms bound thereto; 2) 263–268 pm; 3) 275–297 pm (Ni2–Ni6, Ni4–Ni6, Ni2–Ni5, Ni2–Ni3, Ni5–Ni8, Ni4–Ni6). Comparable bond lengths have also been observed in other Ni clusters.[20, 21]

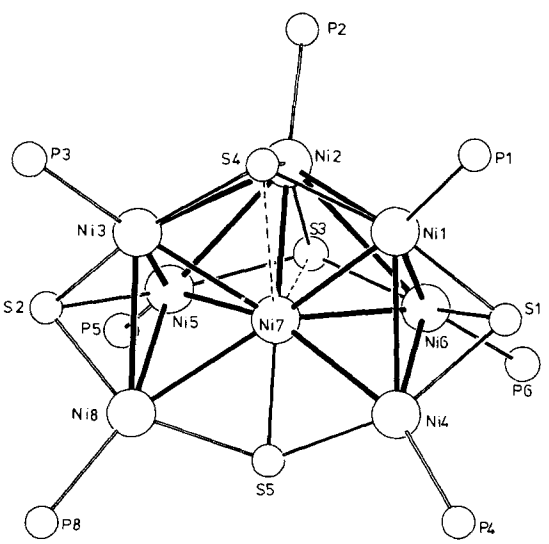

Fig. 4. Crystal structure of the cluster **6** (without phenyl groups). P1–P6 and P8 correspond to the P atoms of the PPh_3 ligands [19]. Important bond lengths [pm] (±0.3 pm) and bond angles [°] (±0.1°): Ni1–Ni2 268.0, Ni1–Ni4 268.8, Ni1–Ni6 263.0, Ni2–Ni3 276.7, Ni2–Ni5 276.6, Ni2–Ni6 295.7, Ni2–Ni7 239.5, Ni3–Ni5 267.2, Ni3–Ni7 247.2, Ni3–Ni8 267.2, Ni4–Ni6 275.5, Ni4–Ni7 250.9, Ni5–Ni7 241.6, Ni5–Ni8 282.2, Ni6–Ni7 243.9, Ni7–Ni8 252.7, Ni–P 214.8–218.5, Ni–(μ_3-S) 210.4–221.0, S3–Ni7 258.6, S4–Ni7 268.8; Ni–Nin–Ni: Nin = Ni1 55.2–110.5, Ni2 53.0–113.0, Ni3 54.1–108.6, Ni4 55.0–57.8, Ni5 54.6–61.1, Ni6 51.6–101.1, Ni7 64.6–144.7, Ni8 53.4–58.1; Ni–S1–Ni 76.2–80.1, Ni–S2–Ni 76.2–81.5, Ni–S3–Ni 78.9–118.4, Ni–S4–Ni 75.8–119.5, Ni–S5–Ni 72.4–137.4.

[5] Procedure: A solution of **1a** (16 g, 0.0245 mol) in THF (100 mL) was prepared under nitrogen and treated dropwise with 4.5 g (0.0252 mol) of $S(SiMe_3)_2$. The solution immediately changed color from blue to brown, and a mixture of **2** and **3** precipitated (yield 6.6–7.0 g). After addition of 100 mL of toluene and filtration, the residue was treated with toluene/$C_2H_4Cl_2$. About 4.1 g of **3** went into solution. (On covering the solution with pentane, **3** was obtained as long, black crystals. Crystals of the very sparingly soluble compound **2** were obtained by dissolution of the residue of crystallization in THF/$C_2H_4Cl_2$. After covering the solution with pentane, **2** separated out in the form of black crystals.
[6] **2** crystallizes with four molecules of THF per formula unit. Space group $P\bar{1}$, Lattice constants (180 K): $a = 1482.9(5)$, $b = 1603.6(5)$, $c = 2631.2(8)$ pm; $\alpha = 88.42(3)$, $\beta = 84.23(2)$, $\gamma = 76.31(3)°$, $Z = 2$, $\mu(Mo_{K\alpha}) = 11.5$ cm^{-1}. Syntex R3, $2\theta \leq 49°$, 19960 reflections, 13200 with $I > 2\sigma(I)$. Patterson methods, Co, P, S, Cl anisotropic, Ph refined as rigid group (C–C 139.5 pm). $R_1 = 0.078$, $R_2 = 0.069$.—**3**: crystals from toluene/C_2H_4Cl/pentane. **3** crystallizes with 1 mole of toluene per formula unit. Space group $P2_12_12_1$. Lattice constants (180 K): $a = 1813.7(7)$, $b = 1883.5(7)$, $c = 2896.2(10)$ pm; $Z = 4$, $\mu(Mo_{K\alpha}) = 13.5$ cm^{-1}. Syntex R3, $2\theta \leq 50°$, 10716 reflections, 8629 reflections with $I > 2\sigma(I)$. Patterson methods, Co, P, S, Cl, anisotropic, C atoms of the Ph groups isotropic (H calculated). $R_1 = 0.063$, $R_2 = 0.059$. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51402, the names of the authors, and the full citation of the journal.
[7] Important bond lengths [pm]: Co–Cl 222–223(0.2), Co–O1 206.2(10), O1–LC1 144(2), O1–LC4 145(2), LC1–LC2 155(2), LC2–LC3 151(3), LC3–LC4 151(3), (LCm and O1: C atoms and O atom of the THF ligand). Bond angles [°] (±0.2°): Cl1–Co7–Cl2 115.0, Cl1–Co7–Cl3 114.2, Cl1–Co7–O1 101.0, Cl2–Co7–Cl3 118.1, Cl2–Co7–O1 104.7, Cl3–Co7–O1 100.3.

[16] Procedure: **1b** (16.3 g, 0.025 mol) was dissolved in THF (100 mL) under N_2 and treated with 13.4 g (0.075 mol) of $S(SiMe_3)_2$. The solution rapidly turned brown, and a fine crystalline precipitate separated out. After addition of 100 mL of toluene and filtration, 6.2 g of the reaction mixture were obtained, 1.6 g of which went into solution on treatment with THF (100 mL). The residue consisted of pure **4** (66% yield based on $[NiCl_2(PPh_3)_2]$). The THF solution was treated with 2 g of zinc powder and heated to about 60°C for 2 h. After filtration the solution was covered with heptane. **6** crystallized out at the phase boundary as black, flaky crystals. Crystals of **4** were obtained on recrystallization from toluene/$C_2H_4Cl_2$.
[17] **4** crystallizes with 1 mole of $C_2H_4Cl_2$ per formula unit. Space group: $P2_1/n$, lattice constants (180 K): $a = 1683.5(5)$, $b = 1553.8(3)$, $c = 2116.4(8)$ pm; $\beta = 95.21°$, $Z = 4$, $\mu(Mo_{K\alpha}) = 16.7$ cm^{-1}. Syntex R3, $2\theta \leq 55°$, 13716 reflections, 10889 with $I > 2\sigma(I)$, empirical absorption correction. Patterson methods, all atoms (except H) refined anisotropically, $R_1 = 0.053$, $R_2 = 0.054$ [6].

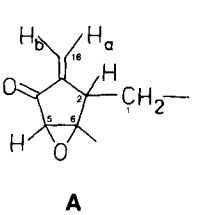
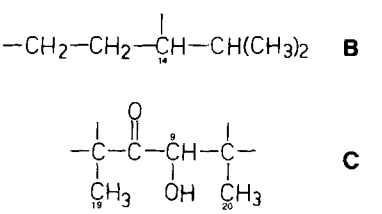
Crinipellins, the First Natural Products with a Tetraquinane Skeleton**

By *Timm Anke, Jutta Heim, Falk Knoch, Ursula Mocek, Bert Steffan,* and *Wolfgang Steglich**



Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Several years ago, we described an antibiotic that is produced by cultures of the basidiomycete *Crinipellis stipitaria* (Agaricales).[1] An investigation of several strains of this fungus has now led to the isolation of several related compounds, crinipellin A, crinipellin B, and *O*-acetylcrinipellin A, the latter of which is identical with the "crinipellin" we described earlier. In addition to these antibiotically active compounds, two inactive accompanying substances were found, dihydrocrinipellin B and tetrahydrocrinipellin A.



According to its NMR spectra (Table 1),[2] crinipellin A possesses a cyclopentane ring that contains an α-methylene ketone group and an epoxide function in an analogous arrangement to the hirsutane derivatives complicatic acid[3] and hypnophilin **4**.[4] This is shown by, among other things, the characteristic long-range coupling $^5J = 1.1$ Hz between the 5-H and the 18-H_a *trans* to the carbonyl group.[4,5] In contrast, 18-H_b exhibits a ^4J coupling of 1.4 Hz to the angular 2-H, which, along with the methylene protons on C-1, forms an ABX system. The partial structure **A** is thus obtained. From the ^{1}H,^{1}H-correlated 2D NMR spectrum, the proton sequence **B** can be derived starting from the isopropyl group, and, by selective decoupling, the acyloin moiety **C** can be recognized in the ^{13}C-NMR spectrum. Since the signal of the 20-methyl group in the ^{13}C-NMR spectrum exhibits two ^3J couplings to 9-H and 14-H, the partial structures **B** and **C** can be joined. By selective decoupling of the 19-methyl group, the multiplet of C-6 simplifies, allowing a relationship between the partial structures **A** and **C** to be obtained. Taking into consideration the presence of four carbon rings in crinipellin and the remaining quaternary C atom ($\delta = 62.3$) gives the structure **1a** for crinipellin A. The relative stereochemistry can be determined by NOE difference measurements. Acetylation of **1a** with acetic anhydride/4-(dimethylamino)pyridine affords *O*-acetylcrinipellin A **1b**, which was shown to be identical with the natural product described earlier.[1]

Table 1. ^{1}H- and ^{13}C-NMR data for crinipellin A **1a** (400 and 100.62 MHz, respectively, δ values, solvent $CDCl_3$ as internal standard). The NOE relationships are indicated. All ^{1}H- and ^{13}C-NMR assignments were confirmed by 2D NMR data.

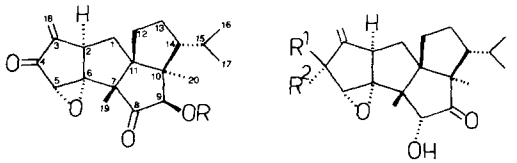
B



C

Similarly, the constitution **2a** can be derived for crinipellin B,[2] and was confirmed by an X-ray structure determination[6] (Fig. 1).

The structures **2b** and **3b** are obtained for dihydrocrinipellin B[2] and tetrahydrocrinipellin A,[2] respectively. The absence of the α-methylene ketone moiety explains the loss of biological activity.[7]

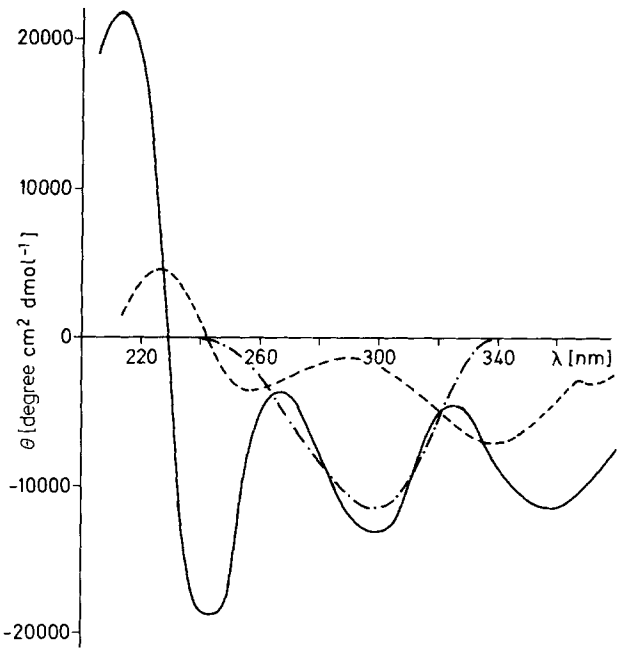

Fig. 2. CD curves of crinipellin B **2a** (—), hypnophilin **4** (------), and *ent*-3β-hydroxy-5α-androstan-17-one **5** (-·-·-). $[\theta] = 3300$ ($\varepsilon_l - \varepsilon_R$).

The crinipellins contain two isolated chromophores in asymmetric environments. We therefore attempted to derive their absolute configurations by comparison of their

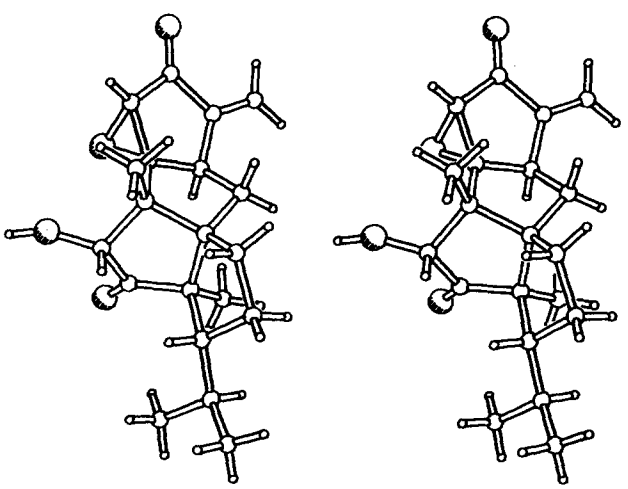

Fig. 1. Crystal structure of crinipellin B **2a**; stereograph.

CD curves with those of reference materials (Fig. 2). The CD curve of crinipellin B exhibits a negative Cotton effect at 290 nm, in accord with the CD spectrum of *ent*-3β-hydroxy-5α-androstan-17-one **5**.[8] If it is assumed that the shape of the CD curves is determined to a first approximation by the immediate environment of the CO groups, the configuration shown in Formula **2a** is obtained for crinipellin B. It is supported by comparison with the CD spectrum of hypnophilin **4**,[9] the shape of whose curve is in qualitative agreement with that of **2a**.

In recent years, sesquiterpenoids having a triquinane skeleton have especially attracted the attention of synthetic chemists since many of these compounds are biologically active natural products.[13] The discovery of the crinipellins, the first tetraquinanes of the diterpenoid type, demonstrates that the variety of possible cyclopentanoid natural products has not yet been fully explored.

Biochemically, the crinipellins undergo the same type of cyclization as the dolabellanes isolated from a moss[10] and from marine organisms.[11] Moreover, for the crinipellins, a methyl group migration subsequently takes place;[12] the carbocation formed is stabilized by formation of the tetraquinane system.

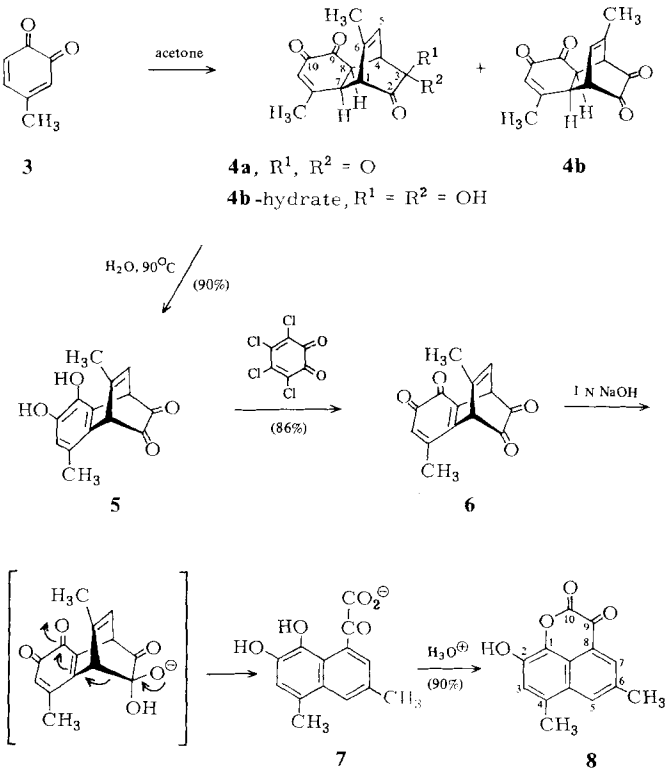
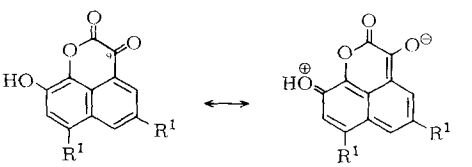
A Simple Approach to the Naphtho[1,8-*bc*]pyrandione System**

By *Wolfgang Steglich,* Hans-Theo Huppertz,* and *Bert Steffan*



The bolete pigments badione A and B, **2a** and **2b**, respectively, have a naphtho[1,8-*bc*]pyrandione partial structure,[1] which may be formed in the fungus by oxidative dimerization of the pulvinic acids **1a** and **1b**, respectively. A biosynthetic pathway involving the Diels-Alder dimerization of a 1,2-benzoquinone intermediate is conceivable.

1a, R = H
1b, R = OH



2a, R = H
2b, R = OH

In order to test this idea experimentally, we have studied the base-induced fragmentation of the model compound **6**, which is accessible from 4-methyl-1,2-benzoquinone **3** according to the procedure of *Horner* and *Dürckheimer*.[2] Thus, we have found that the dimerization of **3**[2,3] in acetone produces a 7:3 mixture of the regioisomers **4a** and **4b**, the former of which can be separated as a stable hydrate[4,5] in 36% yield by crystallization from acetone/ether. Isomerization to the diol **5**[2,5] and subsequent oxidation with tetrachloro-1,2-benzoquinone[6] gave the single tetraketone **6**.[5] When **6** is suspended in 1 N NaOH, it goes into solution within a few minutes with formation of the anion **7**. After acidification, the dark red naphtho[1,8-*bc*]pyrandione **8** is obtained in 90% yield. The formation of the naphthalene system can be rationalized according to the fragmentation shown.

3 **4a**, R^1, R^2 = O **4b**
4b-hydrate, R^1 = R^2 = OH
5 **6** **7** **8**

The spectroscopic data for **8**[5] are in good accord with those for the badione **2**.[1] The unusually high-field shift of the NMR signal ([D$_6$]DMSO) of C-9 in badione A ($\delta = 173.03$) and in **8** (172.76) may be a consequence of the importance of the dipolar resonance structure **9** in representing the ground state. **8** dissolves as the monoanion in aqueous base, turning the solution blue. After a short period of time, ring opening to **7** occurs and the solution turns green.

2, 8 **9**

The transformation of **3** into **8** can be viewed as a model for the biosynthesis of the badiones. It opens up a simple approach to the preparation of the naphtho[1,8-*bc*]pyrandiones, which have not yet been studied in detail.[7]

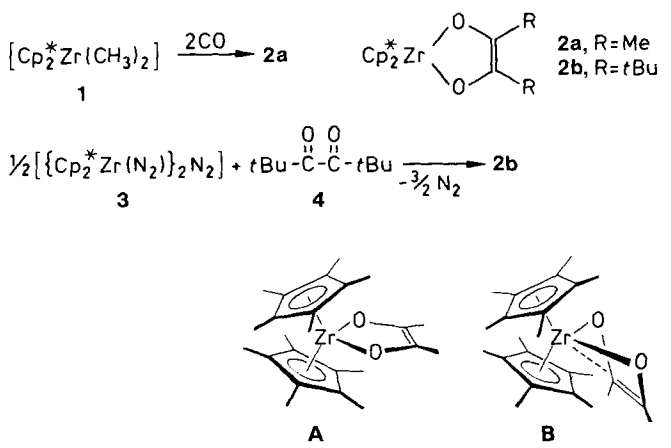
Monomeric, Mononuclear Enediolate Complexes of Zirconium: Molecular Geometry and Electronic Structure of the Products of Reductive CO Coupling on the Metal**

By *Peter Hofmann,* Martin Frede, Peter Stauffert, Wiltraud Lasser,* and *Ulf Thewalt*



Dedicated to Professor Helmut Behrens on the occasion of his 70th birthday

Insertion reactions of CO into transition-metal–carbon bonds are of great interest.[1] Carbonylation of dialkylbis(cyclopentadienyl) complexes of early transition metals [Cp_2MR_2] and [$Cp^*_2MR_2$] ($Cp = \eta^5$-C_5H_5, $Cp^* = \eta^5$-C_5Me_5; M = Ti, Zr, Hf) in some cases results in direct reductive coupling of two CO building blocks to yield mononuclear enediolate complexes (e.g. **1** → **2a**)[4]; the initially formed η^2-acyl complexes and their chemistry have been intensely studied both experimentally[2] and theoretically.[3]

The mechanism of this remarkable synthetic reaction is not yet known with certainty.[5] In order to elucidate it, among other things, a knowledge of the ground state geometry and electronic structure of complexes **2** is important. We report here relevant results for **2a** and **2b** that confirm the predictions of MO calculations.

[**] This work was supported by the Fonds der Chemischen Industrie.

2a was synthesized by the method of *Bercaw* et al.[4a] by carbonylation of **1**. The X-ray structure analysis[6] confirms the monomeric structure of the compound (Fig. 1, left). The ZrO_2C_2 chelate ring of **2a** in the crystal is not planar, but rather folded around the O–O axis so that the ZrO_2 and the O_2C_2 planes form an angle of 16.8° (Fig. 1, bottom left).

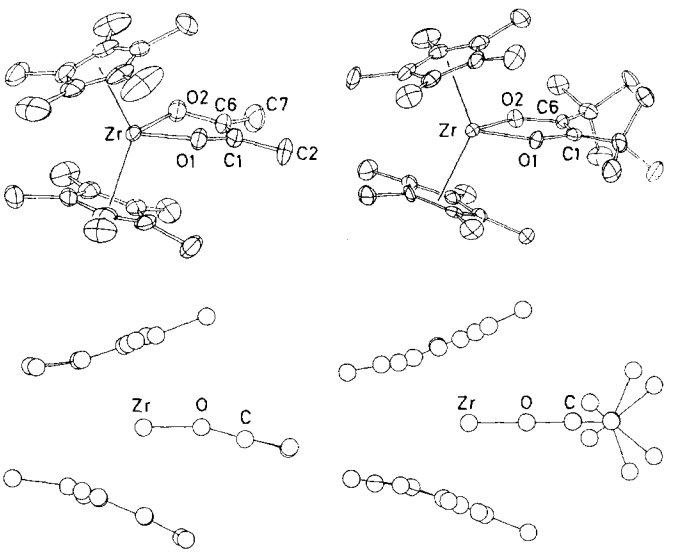

Fig. 1. Left: Structure of **2a** in the crystal; above, top view; below, side view. Selected bond lengths [Å] and angles [°]: Zr–O1 2.031(4), Zr–O2 2.048(6), O1–C1 1.371(10), O2–C6 1.367(9), C1–C6 1.315(13), Zr–C(C_5Me_5) 2.519–2.570, C–C (C_5 rings) 1.357–1.435; O1–Zr–O2 79.2(2), Zr–O1–C1 111.2(5), Zr–O2–C6 110.0(6), O1–C1–C6 117.3(7), O2–C6–C1 118.7(8), Z1–Zr–Z2 137.0(3) (Z1, Z2: centers of the C_5 rings). Right: Structure of **2b** in the crystal; above, top view; below, side view. Selected bond lengths [Å] and angles [°]: Zr–O1 2.022(6), Zr–O2 2.011(6), O1–C1 1.372(11), O2–C6 1.400(11), C1–C6 1.357(13), Zr–C(C_5Me_5) 2.525–2.616, C–C (C_5 rings) 1.372–1.458; O1–Zr–O2 75.9(2), Zr–O1–C1 118.4(5), Zr–O2–C6 118.0(5), O1–C1–C6 114.2(9), O2–C6–C1 113.5(8), Z1–Zr–Z2 136.1(4) (Z1, Z2: centers of the C_5 rings).

Thus, **2a** exhibits a geometry that deviates clearly from **A** and a σ^2 structure toward B and a σ^2,π bonding mode, in analogy to enedithiolate complexes[7] or *s-cis*-diene complexes of Cp_2Zr fragments.[8] We conclude from this finding for Cp^*_2Zr, which is a weaker Lewis acid and makes the ring folding sterically more difficult, that the nonplanar geometry is a general structural feature[10] of monomeric d°-Cp_2M enediolate complexes.[9] MO model calculations[11] for **2a**, with a planar geometry corresponding to

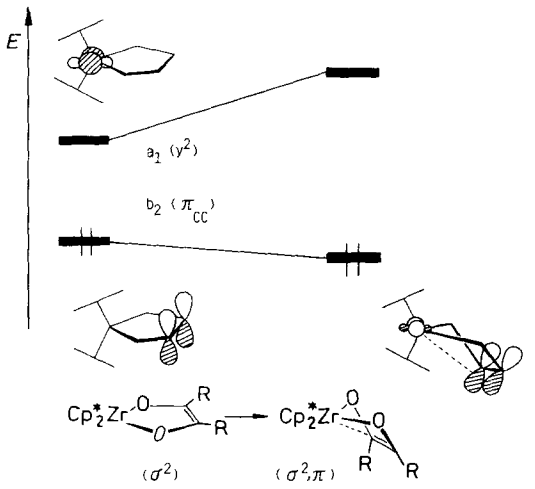

Fig. 2. Frontier orbital energies for σ^2 and σ^2,π geometries (only main contributions to the wave functions of the C=C part and on Zr shown).

Figure 2, give the π orbital of the C=C bond as the HOMO (b_2) and an MO with y^2 character (a_1) on the metal as the LUMO.

Only the folding of the ring[12] allows the π and y^2 orbitals to interact, thus causing an increase of the frontier orbital gap; the decrease in π back-bonding of the oxygen lone pairs to the metal with increasing folding of the chelate ring opposes the frontier-orbital-based trend toward a σ^2,π geometry. The deep violet color of solutions of **2a** (λ_{max}(pentane) = 495 nm, ε = 299, band extending far into the visible), which is unusual for d° systems (Zr^{IV}), may be ascribed to an electronic transition from the HOMO(π) to the LUMO (y^2) and, according to Figure 2, should be more shifted to longer wavelengths the less the ZrO_2C_2 ring is folded. In order to test this, and because explicit calculations for **2a** only gave energy differences of a few kcal between **A** and (even strongly folded) **B**, we have attempted to prepare a model system with a planar chelate ring and pure σ^2 bonding of the enediolate ligand. Accordingly, **2b** was prepared from the nitrogen complex **3**[2a] and the diketone **4**. The complex **2b** crystallizes in the form of intensely blue crystals;[13] its electronic spectrum exhibits a long-wavelength maximum with a considerable bathochromic shift (λ_{max}(pentane) = 570, ε = 120) as compared to **2a**, and its X-ray structure analysis[14] (Fig. 1, right) shows a sterically constrained, completely planar metallacycle in the crystal. The distances between the C atoms of the double bond and Zr are 0.11 Å longer than in nonplanar **2a**. It is thus shown experimentally that σ^2,π structures on d°-Cp_2M or Cp^*_2M fragments are electronically preferred also for enediolate ligands, but that the extent to which this bonding mode is found is easily influenced. The preference for such nonplanar ground-state geometries may be of significance for both stereochemistry and the mechanism of CO coupling on the metal.

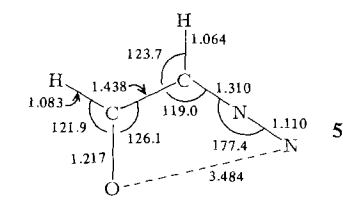
Can 1,2,3-Oxadiazole be Stable?**

By *Minh Tho Nguyen, Anthony F. Hegarty,** and *José Elguero*

Although 1,2,3-oxadiazoles **1** were first postulated as intermediates in the 1,3-dipolar cycloaddition of dinitrogen oxide (N_2O) to alkynes almost thirty-five years ago,[1] this class of heterocycles was unknown until recently. The weakness of the NO σ-bond, which provides a thermodynamic driving force for ring opening to form the more stable acyldiazomethanes **2** was considered as the main reason for the nonexistence of stable 1,2,3-oxadiazoles.[2]

1 **2** **3** **4**



In 1979, *Schulz* and *Schweig* reported spectroscopic evidence for the existence of the 1,2,3-benzoxadiazole **3** in the gas phase (by PE spectroscopy);[5] more recently, they

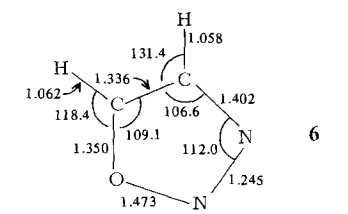
demonstrated its existence in an argon matrix as well as in solution (by IR and UV/VIS spectroscopy).[4] Both studies indicated that there is an equilibrium between **3** and the 6-diazo-2,4-cyclohexadienone **4**. In all reaction media considered, 80—90% **3** and 10—20% **4** were present as deduced from intensities of absorption bands. If an equilibrium is established between open and cyclic forms, the existence of the thermodynamically less stable isomer will be crucially dependent upon the energy difference between them. In an attempt to quantitatively assess the relative stabilities of the isomers, we have performed ab initio calculations on the interconversion pathway between the two simplest model species **5** (**2** with R=H) and **6** (**1** with R=H) via a 1,5-dipolar cyclization. Calculations have been carried out using modified Gaussian-80 programs[5] on an AMDAHL 470 computer.



The geometrical parameters of the formyldiazomethane **5**, the 1,2,3-oxadiazole **6**, and the transition state **7** connecting them were determined using the force-field method with analytical gradients and the 3-21G basis set[6] (Fig. 1).

Fig. 1. HF/3-21G-optimized geometries of formyldiazomethane **5**, 1,2,3-oxadiazole **6**, and the transition state **7**. Bond lengths in Å, bond angles in degrees. For **7**, the eigenvalue of the Hessian matrix and the imaginary frequency are -0.409 and $398i$ cm^{-1}, respectively.

The calculated CO, CC, CN, and NO bond lengths in **5** are close to the values determined by X-ray analysis for 5-diazouracil and 5-diazocyclouridine compounds.[7] Of particular interest is the NO distance in three stationary points; this distance has been used as the principal reaction coordinate for the cyclization of a number of 1,5-dipoles containing an azido group.[8] At the transition state **7**, the NO distance of 1.935 Å is found to be closer to that of 1.473 Å in **6** than of 3.484 Å in **5**. In addition, the value of 1.473 Å in the cyclic form **6** is significantly larger than that of 1.438 Å determined for H—N=N—OH at the same HF/3-21G level. The former is rather similar to the typical NO single bond (1.469 Å, HF/3-21G) in hydroxylamine, H_2NOH. This clearly indicates the particular weakness of the NO bond in 1,2,3-oxadiazole.

Figure 1 also shows that the diazo group in **5** deviates by 2.6° from linearity, adopting a slightly *cis*-bent conformation. As the NO distance compresses along the reaction pathway, the CNN bond angle becomes notably bent (50° smaller).

In order to obtain improved relative energies, we have carried out single point calculations on three stationary structures employing the HF/3-21G-optimized geometries at the Hartree-Fock level with the 6-31G and 6-31G** basis sets (including polarization functions on all atoms) as well as at the level of Møller-Plesset perturbation theory to second-, third-, and fourth-order[9] (denoted MP2, MP3, and MP4SDQ); the HF/6-31G wave functions were used as references (Table 1). The MP4SDQ/6-31G** values given in Table 1, taking into consideration both the polarization and correlation effects, are obtained from the following additivity relationship:[10]

$$\Delta E(\text{MP4SDQ/6-31G**}) = \Delta E(\text{MP4SDQ/6-31G}) + \Delta E(\text{HF/6-31G**}) - \Delta E(\text{HF/6-31G})$$

These relative values together with the correction for zero-point vibrational energies (ZPVE, Table 1) thus provide our best relative energies. The ZPVE values were computed from HF/3-21G and multiplied by a factor of 0.9.[11]

Table 1. Calculated total energies [a.u.], relative energies ([kcal/mol] values in parentheses), and zero-point vibrational energies (ZPVE, [kcal/mol]) of stationary points considered at different levels.

Method [a]	**5**	**7**	**6**	ΔE^{+}(6-7) [e]

ZPVE [c]	26.3	26.0	27.5	(3.8)
Estimated [d]	(0.0)	(12.7)	(8.9)	

[a] Using HF/3-21G optimized geometries given in Fig. 1. [b] Estimated values from MP4SDQ/6-31G, see text. [c] Zero-point vibrational energies calculated at HF/3-21G and reduced by a factor of 0.9. [d] Estimated values including MP4SDQ/6-31G** relative energies and ZPVE. [e] Energy barrier for the ring opening **6** → **7** → **5**.

One sees that at all levels of theory, the 1,2,3-oxadiazole **6** is calculated to be of higher energy than the formyldiazomethane **5**. Both polarization and correlation effects tend, however, to reduce the energy difference between them. For the transition state **7**, polarization and correlation effects cancel each other (as seen in ΔE^{+}, Table 1). According to the best values obtained in the present work, the heterocycle **6** lies 8.9 kcal/mol above its open chain

isomer **5** and undergoes ring opening with an energy barrier of 3.8 kc l/mol. These values obviously suggest that the unsubstitu ed 1,2,3-oxadiazole can not be stable in the gas phase or even in an inert matrix at low temperature.

Although the geometrical parameters were not optimized at higher levels of accuracy, we note that at the MP4SDQ/6-31G//HF/3-21G level (Table 1), **6** becomes even higher in energy than the transition-state structure **7**. Thus, the energy difference between both structures is probably very small (within a few kcal/mol) after a complete optimization of geometry at this level. In addition, recent studies of the Wolff rearrangement of some perfluorodiazoketones[12] in argon matrices do not provide any spectroscopic indication for the formation of 1,2,3-oxadiazoles, even though strong electron-withdrawing substituents such as perfluoroalkyl groups (e.g., CF_3, C_2F_5) could enhance the ring stability.

In their recent work, *Schultz* and *Schweig*[4] also reported some semiempirical MNDO results which predicted, among other things, that the cyclic 1,2,3-benzoxadiazole **3** lies about 11 kcal/mol below the open-chain form **4**. A separate MNDO calculation on the structures **5**, **6**, and **7** yields the following heats of formation [kcal/mol]: **5**: 26.6; **6**: 24.2; **7**: 69.1. It is well known that the MNDO method[13] usually overestimates the stability of rings compared with their open-chain isomers. Nevertheless, these MNDO data show that the cyclic isomer becomes significantly stabilized (by 8.6 kcal/mol) by attachment to a benzene ring.

The present ab initio study therefore suggests that the unsubstituted 1,2,3-oxadiazole **6** cannot be isolated as a discrete species even in an inert matrix at low temperature.

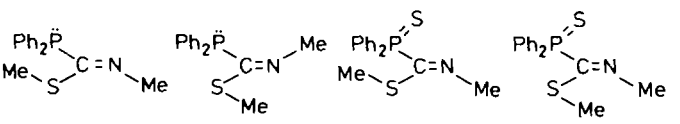
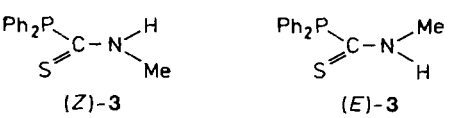
Phosphorus-Substituted Thioformamides and Thioformimidates: Molecular Structure and Solid State ^{13}C-NMR Spectra**

By *Klaus Albert, Andreas Bruns, Hans Förster, Wolfgang Hiller,* and *Udo Kunze**



In the past few years, solid-state NMR spectroscopy (CP-MAS NMR spectroscopy) has found increasing application in structural elucidation, e.g. for detecting differences in molecular conformation in the solid and dissolved state.[1,2] The results are especially valuable if the crystal structure of the molecule under investigation is already known. In the CP-MAS-^{13}C-NMR spectrum of nitrogen compounds (amino acids, peptides, nitro compounds, nitriles), an asymmetric signal splitting of the C-atoms bound to the nitrogen by quadrupole interaction is often observed which is not detectable in solution. Since the electrical quadrupole splitting of the ^{14}N isotope ($I = 1$) is of the same order of magnitude as the magnetic interaction, the Zeeman eigenstates experience a perturbation, so that an unsymmetrical three-line signal instead of the expected triplet appears in the ^{13}C-NMR spectrum of single crystals.[3] *In normal, polycrystalline material two lines* usually coincide and a field dependent, asymmetric "doublet" is formed whose splitting increases with the s-share of the carbon hybrid orbital.[4,5]

To our knowledge, no solid-state ^{13}C-NMR spectra of *simple P,N,S compounds* have, as yet, been published. We report now on some phosphorus-substituted thioformamides and the linkage-isomeric thioformimidates whose crystal structures are, in part, known[6,7] (see Table 1).



The tertiary thioformamides **1a–c** show an asymmetric doublet splitting of the *cis*- and *trans*-*N*-methyl signals at a spectrometer frequency of 75.5 MHz. At 50.3 MHz the two central lines in the spectrum of **1b** coincide, since the qua-

^{31}P-NMR [e]	21 (17.6)	47 (48.1)	31 (27.9)	[f]	[f]	12 (15.9)

[a] Spectrometer frequency 75.46 MHz; δ rel. TMS, $|^1J(PC)|$ [Hz], ^{14}N-quadrupole splitting Δ [Hz]. [b] Splitting only indicated. [c] Pseudo-triplet (50.33 MHz). [d] *c* = *cis*, *t* = *trans* to phosphorus. [e] Spectrometer frequency 121.46 MHz; δ rel. H_3PO_4. [f] Not measured.

drupole splitting is inversely proportional to the field strength.[4–6] The band shape (downfield line with lower intensity) indicates a quadrupole moment of positive sign; the amount of splitting corresponds to the literature values for amino acids.[4] In the CP-MAS-^{13}C-NMR spectrum of the thioimidate **2a** a splitting with reversed intensity ratio is observed for the *N*-methyl group ($Q<0$), whereas the *P*-sulfide **2b** shows only a singlet (cf. trimethylimidazole[4]). As has been confirmed by an X-ray structure determination,[7] **2b** is present only in the $(Z)_{sp}$ conformation in the crystalline state; in solution, an equilibrium is established between *Z*- and *E*-isomers.

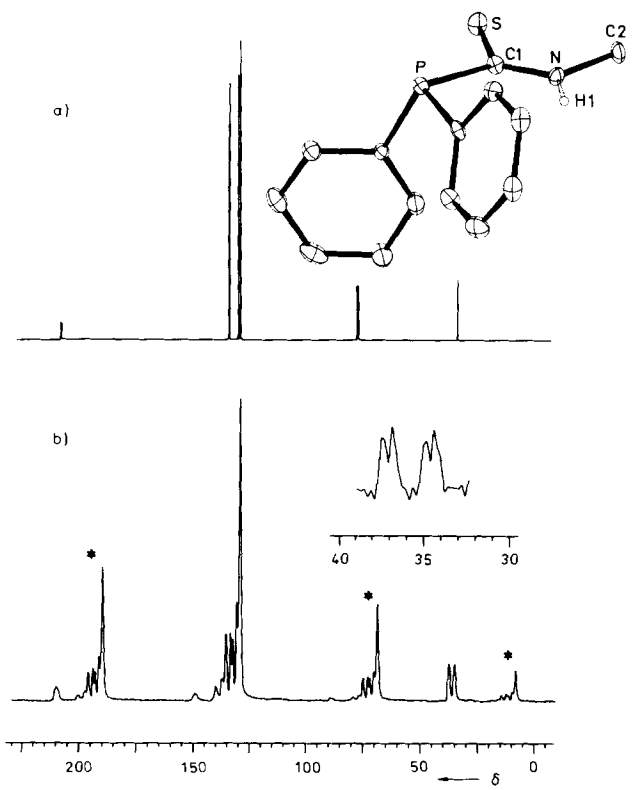

Fig. 1. (a) Crystal structure (molecule 1) [10] and ^{13}C{^{1}H}-NMR spectrum ($CDCl_3$), (b) CP-MAS-^{13}C-NMR spectrum (δ rel. TMS; * spin side bands) of **3**. Important bond lengths: S1–C1 165.6(5), P1–C1 184.8(5), N1–C1 131.5(6), N1–C2 144.7(6) pm.

Due to superposition of direct phosphorus coupling and quadrupole splitting, the NCS signal of **1b**, **c** appears as a "doublet of doublets", which, in the case of **1b**, degenerates to a pseudo-triplet at lower spectrometer frequency (50.3 MHz). The spectra of the thioimidates **2a**, **b**, on the other hand, show only the normal P–C coupling.

Surprisingly, the ^{13}C-NMR spectrum of the solid, secondary thioamide **3**[8] shows two signals in the *N*-methyl region, with $\Delta\delta=2.5$ ppm and a quadrupole splitting of 45 Hz (spectrometer frequency 75.5 MHz), whereas only a singlet appears in solution (Fig. 1). This unexpected signal doubling, however, is not to be ascribed to alternating *E*/*Z* arrangement in the crystal, but to the existence of two symmetry-independent molecules with the same *Z*-configuration, which differ only in the conformation of the phenyl rings. The situation is similar to that in crystalline *tert*-butoxycarbonylphenylalanine (Boc-Phe-OH),[2] whose unit cell likewise contains two conformers which lead to a splitting of all ^{13}C-resonance signals. An unusual finding, however, is that in **3** only a slight difference in conformation effects a relatively large signal splitting.

Polymers. Properties and Applications. Vol. 7: Introduction to Polymer Spectroscopy. By *W. Klöpffer*. Springer-Verlag, Berlin 1984. xii, 184 pp., bound, DM 98.00.—ISBN 3-540-12850-6

This book is a valuable addition to polymer literature. The range and organization make it possible to grasp the aim of the author very rapidly. This book is intended as a cohesive synopsis of the most important physical and chemical aspects of polymer spectroscopy written in the style of a second-semester lecture. An up-to-date presentation of the various modern methods is aimed at. In this sense this book is a review of and introduction to the spectroscopic methods of polymer physics and chemistry, which can be recommended to the first degree student and to the "research novice". The literature reviewed at the end of each chapter enables the interested reader to deepen his knowledge.

Electronic, vibrational and magnetic conditions are dealt with at a similar level and supplement the numerous books on polymer spectroscopy. This is revealed by the main chapters entitled "Electronic Spectroscopy", "Vibrational Spectroscopy" and "Spin-Resonance Spectroscopy" which are of almost equal length. The work is rounded off with an introduction to the definition of polymer spectroscopy, to the information contained in the spectra and the field of spectra and with rather too short a conclusion. As is to be expected from the subtitle, this book only skims the surface all the way through. The various topics in the three main chapters are only dealt with very fleetingly. On the one hand, this has the advantage that the reader can very quickly review the many spectroscopic possibilities. On the other hand, it is not possible for him to enhance his knowledge; there is no room even for explanations, which are of such great importance to the student. A deeper understanding is only possible with a lecture or by studying the literature which is cited.

There is no theoretical explanation of the material presented. The quantitative description is kept very basic and too short. Although the book is intended for teaching most of the formulae are assumed to be known and are described in too cursory a manner as are the figures.

Unfortunately this book has its weak points. The following may be quoted as examples:

—P. 73, Fig. 6.9 has three arrows but four laser lines with the wavelengths given in nanometers which the reader has to recalculate for himself in wave numbers along the axes, in order to obtain an assignment. The direction of the polymer axis is incorrectly marked.

—P. 79 "Using polychromatic radiation ... the resulting interferogram has the form of a damped oscillation." A damped oscillation is obtained with a Lorentz line.

—P. 116 "The relaxation processes deactivating the energetically higher ("excited") state ... are T_1 (spin-lattice relaxation) and T_2 (spin-spin relaxation)" and later on p. 159 "... roughly analogous to luminescence decay." T_1 and T_2 are coherence-destroying processes whereby only T_1 is to be correlated with decay of the excitation and not T_2 which describes the loss of phase.

—P. 120 (ESR Experimental) "The sample has to be introduced into the region of highest magnetic field strength." This does not refer to the static magnetic field but to the magnetic field component of the oscillating microwave field. Further: "The frequency can be precisely kept constant by modifying the tension of the reflector (AFC)". "Tension" is an error in translation, what is meant is voltage or potential. The abbreviation in brackets AFC = automatic frequency control is not explained. This circuit is not intended to keep the frequency constant but to drive the frequency of the clystrons in frequency variations especially in resonance transition.

—P. 132, Fig. 9.15. Instead of 2E only E appears in the energy level scheme, axis $\parallel B$ should be $B \parallel y$, the Zeeman splitting has an incorrect starting point. Too much importance should certainly not be attached to this list compared with the merits enumerated and the overall good impression made by this book. However the student will surely ask himself whether or not he ought perhaps to expect more of an English language book costing almost 100 DM, even if only from the point of view of scope. At this price it is not to be expected that the book will be widely sold.

Hemoglobin: Structure, Function, Evolution and Pathology. By *R. E. Dickerson* and *I. Geis*. Benjamin/Cummings Publishing Co., Menlo Park, CA 1983. 176 pp., bound, $ 40.50.—ISBN 0-8053-2411-9

The authors are known internationally amongst other achievements for their excellent book "Structure and Function of Proteins" published in 1969. Their new book is based on this in that the first chapter "The Rules of the Game" has only been changed slightly. The second chapter "Hemoglobin Structure and Function" contains sections of the previous book but also presents many details of new research results. The third chapter "Evolution of Oxygen Carriers" which reflects the authors' interests in general questions of natural history is a pleasure to read. The last chapter deals with "Abnormal Human Hemoglobins" and elegantly bridges the gaps between medicine, molecular biology and physical methods of structural analysis. The title "Hemoglobin" is too narrow judging by the contents of the book; this is particularly evident in chapters I and II.

The outstanding indefatigable life work of *Max Perutz* as well as the efforts of other scientists have led to a wealth of information on hemoglobins. As important biological and chemical concepts of protein research are based on a mosaic of experimental details, the authors of a monograph face a difficult problem. Either older results can be presented as simple and approved concepts, or new data can be offered, fresh and hence scarcely filtered. *Dickerson* and *Geis* have decided on the second alternative. Readers who are unable to review the literature on hemoglobin strewn throughout the world will find a lucid, comprehensive and exact presentation together with the original references.

In conclusion, this book is to be most warmly recommended to all scientists and physicians who are interested in the relationship between structure and function of macromolecules. Throughout the book there are general principles exemplified by hemoglobin which will fascinate

even lay persons. In addition, the book presents amazing details. The challenge cannot be ignored: All knowledge in the chemistry of natural substances, in biology but particularly in medicine, should be measured by the level of understanding which has been achieved in the case of hemoglobin.

Applications of Synthetic Peptides

By Rudolf Moser, Stephan Klauser, Thomas Leist, Hanno Langen, Thomas Epprecht, and Bernd Gutte*

Peptide chemists are increasingly concerned with the synthesis of polypeptides of biological and medical interest. This article describes several important applications of synthetic peptides in biochemistry, molecular biology, immunology, and medicine. Synthetic peptides may be useful in structure-function studies of polypeptides, as peptide hormones and hormone analogues, in the preparation of cross-reacting antibodies, and in the design of novel enzymes. Peptide chemists can actively contribute to progress in these fields if they are aware of the current problems in the life sciences.

1. Introduction—Methods of Peptide Synthesis

The goal of *peptide* synthesis is the formation of peptide bonds between amino acids (Fig. 1). Although entire *proteins* may be prepared chemically, such efforts are not very economic, since genetic engineering of bacteria is at present far superior to chemical synthesis.

Peptides can be chemically synthesized in solution or on solid supports. A comprehensive account of the former has been given by *Wünsch* et al.[1] The solid-phase method was introduced by *Merrifield*[2,3] in 1963. Although RNase A (ribonuclease A), which consists of 124 amino acid residues, has been synthesized by both methods with high specific activity[4,5] (the synthetic RNase A of *Yajima* and *Fujii*[5] was even crystallized), peptide chemists usually confine themselves to the synthesis of polypeptides not larger than about 50 residues in order to avoid misinterpretation of results obtained with inhomogeneous synthetic products. Polypeptides of high purity prepared recently by the solid-phase method include crystalline glucagon (*Mojsov* and *Merrifield*[6]) and an artificial 24-residue DDT-binding peptide that, after a single purification step, could be crys-

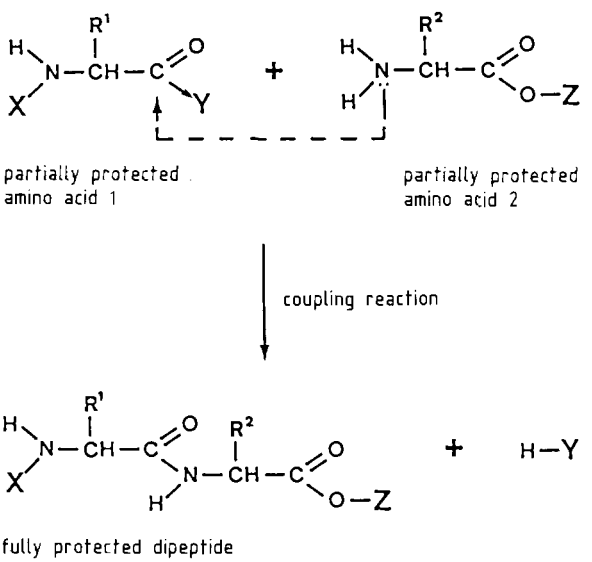

Fig. 1. Synthesis of a peptide bond. X, amino protecting group (a frequently used group is the acid-labile *tert*-butyloxycarbonyl group). CO-Y, carboxyl group activated for the coupling reaction (Y = N_3; azide method, Y = OC_6H_4-*p*-NO_2; *p*-nitrophenyl ester method, Y = O-C(-NH-C_6H_{11})=N-C_6H_{11}; dicyclohexylcarbodiimide method). Z, carboxyl protecting group. In solid-phase peptide synthesis, Z is an insoluble resin (frequently a 1% cross-linked polystyrene) to which the COOH-terminal amino acid residue is linked by an ester bond throughout the synthesis of the target peptide. The synthesis proceeds from the COOH-terminal to the NH_2-terminal end of the chain. The last step is the removal of the synthetic product from the resin by specific hydrolysis of the ester bond.

tallized and had the expected amino acid sequence based on Edman degradation (*Moser* et al.[7,8]).

2. Structure-Function Studies Using Synthetic Peptides and Proteins

2.1. Peptide Hormones, Releasing Factors, Opioid Peptides

Modification, exchange, and deletion of amino acid residues are valuable tools in studies of the conformation and mechanism of action of biologically active polypeptides. Short peptide hormones, releasing factors, and opioid peptides are particularly well suited for these studies because they can be synthesized with a high degree of purity. In fact, numerous analogues of these compounds have been described. An example of particular interest is the highly active cyclic hexapeptide analogue of the 14-residue peptide hormone somatostatin prepared by *Veber* et al.[9] in which nine residues of the somatostatin sequence were replaced by a single proline residue (Fig. 2). The resulting conformational constraint and reduced susceptibility to proteolytic digestion were most likely responsible for the high activity and the long-acting effect of this analogue.

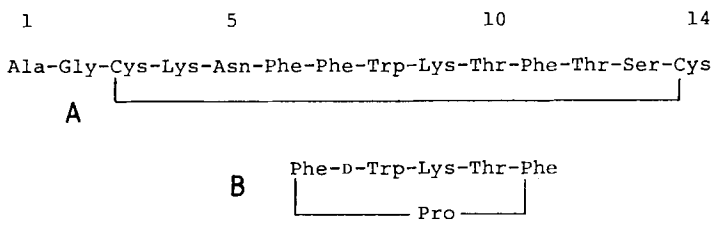

Fig. 2. Sequence of somatostatin **A** [36] and of the active cyclic hexapeptide somatostatin analogue **B** [9].

2.2. Proteins

2.2.1. Chemical Synthesis of Protein Analogues

The number of proteins that, upon chemical or enzymatic cleavage, yield biologically active complexes of the constituent fragments is increasing. In many cases fragments are formed that are small enough for chemical synthesis. Great progress has been made in recent years in the structural elucidation of both native proteins and their active complexes. This has facilitated the structure-function studies of proteins.

A classical example is RNase S, a fully active complex of two fragments (RNase 1-20 and RNase 21-124), which is obtained by subtilisin cleavage of RNase A.[10] The effects of modification, substitution, or deletion of amino acid residues in the synthetic NH_2-terminal fragment (RNase 1-20) on formation and activity of the complex with natural RNase 21-124 have been studied extensively.[11] More recent work has shown that His12, which is believed to be essential for the mechanism of action of RNase A,[11] can be replaced by β-(4-pyridyl)-L-alanine with retention of approximately 30% of the enzymatic activity of RNase A using RNA as substrate.[12] Moreover, a 63-residue analogue of RNase A comprising mainly the hydrophobic substrate binding site and lacking several surface regions of the parent protein, including residues 1 to 25, had approximately 10% activity in the transphosphorylation step of the cleavage reaction catalyzed by RNase A using poly(C) and poly(U) as substrates.[13] Recently, we synthesized RNase 1-14 and des-His-12-RNase 1-14 for further investigation of the effect of His12 on structure and function.[14] It is known that a mixture of RNase 1-14 and RNase 21-124 has full enzymatic activity.[15] When RNase 1-14 was replaced by des-His-12-RNase 1-14, the mixture showed only residual activity. There is strong evidence that des-His-12-RNase 1-14 has lost the helix-forming potential of RNase 1-14 and therefore cannot bind to RNase 21-124.[14] This seems to support the hypothesis[16] that a salt bridge between the side chains of Glu 9 and His 12 stabilizes the α-helix that extends from residue 3 to residue 13 of RNase 1-20[17] (or RNase 1-14). In des-His-12-RNase 1-14 this salt bridge does not exist. Perhaps His 12 is more important for the structural integrity of the substrate binding site than for catalysis. The properties of des-His-12-RNase 1-14 are a striking example of the dramatic consequences that deletion of a single amino acid residue may have for the structure and function of a protein.

The importance of individual residues at the COOH-terminal end of RNase A has been investigated using mixtures of natural RNase 1-118 with synthetic analogues of RNase 111-124.[18-20] The overlapping residues are essential for the formation of complexes between the two fragments.

Limited tryptic digestion of staphylococcal nuclease in the presence of thymidine 3',5'-diphosphate and Ca^{2+} yields a partially active complex called nuclease-T consisting of fragment 6-48 and fragment 49-149 or 50-149. In solution, the separated fragments do not adopt a stable structure, but a nearly native conformation is regenerated upon reconstitution of the complexes.[21,22] Furthermore, the X-ray diffraction patterns of single crystals of liganded native nuclease[23] and liganded nuclease-T complex (fragment 6-48 plus fragment 49-149)[24] are very similar, and the crystals are isomorphous. A second active complex is formed from the overlapping fragments 1-126 and 99-149 or 111-149.[25] Synthetic analogues of fragment 6-48 and fragment 99-149 have been prepared[26-28] to study the effects of truncated fragments and replacement of individual amino acid residues on formation, three-dimensional structure, and activity of the complexes.

More recently, *Juillerat* et al.[29] described a biologically active three-component complex formed from fragments of horse heart cytochrome c. The three components comprised residues 1-25 (containing the covalently bound heme), 28-38, and 56-104. With respect to their size, all three would be suitable for studies of structure-function relationships in horse heart cytochrome c using synthetic peptides.

2.2.2. Site-Directed Mutagenesis

Site-directed mutagenesis is a combined chemical-molecular biological approach to introduce specific mutations

in genes.[30-33] A circular single-stranded DNA template containing the wild-type gene is hybridized with a synthetic oligodeoxynucleotide primer that is noncomplementary to the template at the position that is to undergo mutation. The primer is then elongated and the ends spliced to form the circular complementary strand using DNA polymerase and DNA ligase. The heteroduplex formed is cloned in *E. coli*. Some of the clones contain the gene of the wild type, others that of the mutant. If the cloned genes are expressed, the gene products can be isolated and compared. Site-directed mutagenesis has already become a widely used method in structure-function studies of proteins.

3. Synthesis of Peptide Hormones

3.1. Chemical Syntheses

Numerous human polypeptide hormones are needed for therapeutic purposes. The shorter ones, like oxytocin, are easily accessible by chemical synthesis. But even larger ones such as human adrenocorticotropic hormone (ACTH, 39 residues) have been prepared in pharmaceutically pure form by conventional methods[34] as well as by the solid-phase procedure.[35] In the case of ACTH the task of the peptide chemist is made easier by the fact that the first 24 residues of the ACTH sequence are responsible for the biological activity of the hormone.

Somatostatin (14 residues, Fig. 2) is an inhibitor of the secretion of various hormones such as growth hormone, glucagon, and insulin. Since its isolation in 1973,[36] numerous syntheses have been carried out (see, for example, ref. [37] and [38]). The possible application of somatostatin analogues in the treatment of diabetes has stimulated great interest in this polypeptide hormone. Analogues that only inhibit glucagon release would be ideal.[39] Chemical peptide synthesis is the most practical way to prepare somatostatin analogues for biological assays. This approach also allows the incorporation of D-amino acids, which cause conformational changes that might increase the lifetime and the biological activity of the peptide hormone analogues.[9] In ribosomal protein biosynthesis, only L-amino acids are incorporated.

The use of synthetic peptides as drugs and for diagnostic purposes was reviewed recently by *Geiger*.[40]

3.2. Synthesis of Human Polypeptide Hormones in Bacteria

Synthetic genes for somatostatin[41] and for the A- and B-chains of human insulin[42] have been expressed in *E. coli* following transformation of the bacteria by the corresponding hybrid plasmids. Although human insulin obtained by combination[43] of bacterially produced A- and B-chains is available on the market, the interest of pharmaceutical companies in chemically synthesized somatostatin has remained strong.

4. Raising of Antibodies against Synthetic Peptides

There is great interest in antibodies that are raised against a synthetic segment of a protein chain and that cross-react with the intact native protein. Such antibodies are formed if the synthetic peptide used as immunogen corresponds to a surface region of the parent protein and adopts the native conformation at least part of the time. Figure 3 illustrates the formation of cross-reacting antibodies. Synthetic peptides shorter than about twenty residues are usually good immunogens when coupled to carrier proteins such as serum albumin. Longer peptides do not need a carrier for immunization. Often synthetic peptides corresponding to surface regions of a protein are stronger immunogens than the corresponding structures on the native protein.

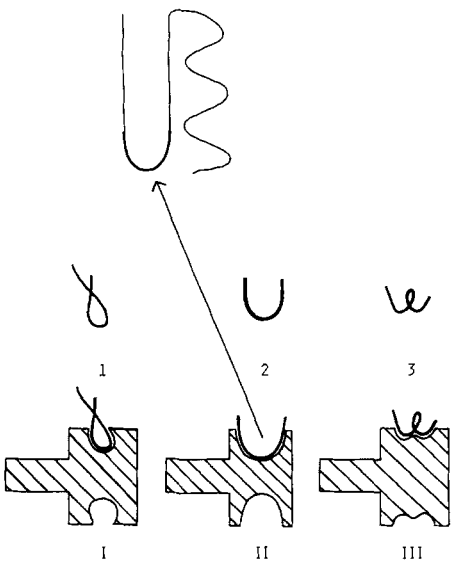

Fig. 3. Raising of antibodies against a surface segment of a native protein. Top: Assumed folding of the hypothetical protein; the segment shown in bold face is synthesized chemically. Middle: Three out of many possible interconvertible structures of the synthetic peptide in solution. Bottom: Antibody-antigen complex. If conformers 1, 2, and 3 of the synthetic peptide stimulate the production of antibodies, antibodies I and III will bind the peptide only; antibody II will also recognize the native protein because of close structural similarity of the antigenic determinants of peptide conformer 2 and the native protein (see arrow).

4.1. Antibodies for Immunoaffinity Chromatography

Affinity chromatography allows rapid and specific purification of a polypeptide from a complex mixture of products. Immunoaffinity chromatography can be used to isolate an antigen or, when pure antigen is available, to fractionate polyclonal and monoclonal antibodies. Here, we give two examples from our laboratory.

First, we synthesized the fragment 111-166 of human interferon (IFN) α1,[46] which is a largely conserved region of the IFN-α and IFN-β family.[44,45] However, the hope that this fragment might have antiviral activity was not fulfilled.[46] On the other hand, a monoclonal antibody prepared against the synthetic fragment cross-reacted with human IFN α1, IFN α2,[46] and IFN αA[47] produced by *E. coli*. It was therefore coupled to CNBr-activated Sepharose 4B for affinity chromatographic purification of human IFN α2 from *E. coli*. Purified interferon with a specific activity of approximately 10^8 units per mg of protein was obtained.[46] Further studies showed that the antigenic determinant recognized by the monoclonal antibody is lo-

cated between residues 151 and 166 of the IFN-α1 sequence.[48]

Second, we coupled the purified, artificial 24-residue DDT-binding polypeptide[7] to Affi-Gel 10 in order to resolve the IgG (immunoglobulin G) fraction of the antiserum raised against the polypeptide in rabbits. Only about 5% of the IgG isolated was bound by the immobilized peptide.[49] The remaining 95% did not recognize the antigen, which was linked to the insoluble carrier by its NH_2-terminal amino group. The specifically binding antibodies can be used to test the expression in *E. coli* of the cloned synthetic gene for the artificial DDT-binding polypeptide.[50]

4.2. Synthetic Peptides as Potential Vaccines

Recently, synthetic peptides corresponding to surface sequences of viral coat proteins or toxins have been used successfully for immunization. If the antibodies so elicited protect against viruses or toxins, the process is called active immunization. There is hope that active immunization using synthetic peptides will become generally applicable in medicine.

In 1965, *Anderer* and *Schlumberger*[51] showed that rabbit antisera to artificial antigens carrying synthetic hexa-, penta-, tetra-, or tripeptides homologous to the COOH-terminal amino acid sequence of the coat protein of tobacco mosaic virus (TMV, strain *vulgare*) readily precipitated and neutralized the intact virus. The neutralizing capacity of the antiserum toward the hexapeptide antigen was comparable to that of anti-TMV antiserum. Although TMV is a plant virus and plants do not produce antibodies, this work pointed the way to active immunization using synthetic peptides.

The sequences of these synthetic peptides have been selected in various ways. *Lerner* et al.[52] chose peptides corresponding to the amino acid sequence of the NH_2- or COOH-terminal end and to the sequences of hydrophilic segments and possible surface turns of the polypeptide chain of the hepatitis-B surface antigen (HBsAg), the major surface antigen of the 42-nm Dane particles of hepatitis-B virus. The amino acid sequences were deduced from the nucleotide sequence of the HBsAg gene. Antisera from rabbits against several peptides longer than ten residues reacted with native HBsAg and specifically precipitated the 23000- and 28000-dalton forms of the antigen from Dane particles. The peptides that elicited the formation of these antisera are potential synthetic vaccines.

Arnon et al.[53,54] and *Audibert* et al.[55] used a disulfide "loop" peptide and a peptide subtended by a disulfide bridge to raise antibodies that cross-reacted with the respective native parent proteins. Antibodies from rabbits against the natural fragment 64–83[53] and antibodies from rabbits and goats against the synthetic fragment 64–82[54] of hen egg-white lysozyme also bound intact lysozyme (all three antigens contain a disulfide bridge formed by cysteines 64 and 80), whereas they did not interact with the oxidized open-chain fragments. *Audibert* et al.[55] raised antibodies in guinea pigs against the synthetic tetradecapeptide 188–201 of diphtheria toxin. The sequence of this peptide is contained in the loop that is formed by the disulfide bridge between cysteines 186 and 201 of the native toxin. The antibodies specifically bound and neutralized diphtheria toxin. This is the first example of successful active immunization against a lethal bacterial toxin using a synthetic peptide antigen.

Since long stretches of polar amino acid residues exist only on the surface of protein molecules, *Hopp* and *Woods*[56] concluded that sequences containing mainly polar residues may correspond to antigenic determinants. They showed that the points of highest local hydrophilicity, obtained by stepwise averaging of the hydrophilicity values[57] of six successive amino acid residues along the polypeptide chain, agreed closely with the location of antigenic determinants. Twelve proteins, for which extensive immunochemical studies had been carried out, were analyzed. To test their method of identifying antigenic determinants, they synthesized fragment 138–149 of HBsAg, which contains the hydrophilic hexapeptide sequence Lys(141)-Pro-Thr-Asp-Gly-Asn(146), by the solid-phase procedure, replacing cysteine residues 138, 139, 147, and 149 by α-aminobutyric acid residues. The deprotected peptide resin was found to bind ^{125}I-labeled anti-HBsAg antibodies. This confirmed experimentally that the synthetic fragment contained all or a large part of an antigenic determinant of HBsAg.

The following steps are necessary for the development of synthetic peptide vaccines:

- Prediction of protein antigenic sites by the methods of *Hopp* and *Woods*[56] or *Pfaff* et al.[58] (the latter is discussed below)
- Chemical synthesis of these sequences
- Raising of antibodies against the synthetic peptides
- Testing of the ability of these antibodies to bind to the antigenic determinants of the native protein and to neutralize its pathogenic properties

Those peptides that elicit the formation of neutralizing antibodies are potential synthetic vaccines. Antibodies are also likely to be formed that recognize the native parent protein, but that do not neutralize its biological activity.

An antigenic determinant formed by amino acid residues belonging to an α-helix on the surface of the protein cannot be clearly detected by the method of *Hopp* and *Woods*[56] because a surface α-helix has a hydrophobic side making contact with the interior of the protein molecule and a hydrophilic side interacting with water. Consequently, it does not have a continuous sequence of six or more hydrophilic residues but rather hydrophilic and hydrophobic residues alternating approximately pairwise according to the helical wheel representation[59] of the amino acid sequence of a surface helix. Therefore, *Pfaff* et al.[58] took the following approach in order to develop a synthetic peptide vaccine against foot and mouth disease virus (FMDV). Using secondary structure prediction and helical wheel representation and taking into account the results of a serological analysis of large viral protein 1 (VP1) fragments,[60] *Pfaff* et al.[58] localized a major immunogenic site of FMDV on a predicted surface helix of VP1 between amino acid residues 144 and 159. A synthetic hexadecapeptide corresponding to this sequence elicited the formation

in rabbits of high titers of antibodies that specifically recognized and neutralized the virus. The high quality of the immune response was ascribed to the conformational stability of the immunogenic synthetic 16-residue peptide, which most likely is α-helical.

Synthetic peptides have also been used successfully to raise antibodies against polio virus.[61] Synthetic peptide vaccines against influenza virus would be of particularly great medical interest.

4.3. Antibodies for Identification of Gene Products

The availability of rapid DNA sequencing techniques has led to an exponential increase in the number of DNA sequences known. The accumulation of data is so rapid that protein chemistry can hardly keep place. In many cases it is not known whether a DNA segment with an open reading frame (i.e., a long sequence of codons uninterrupted by a stop codon) encodes a protein or not. To identify a putative protein, synthetic peptides again can be very useful. First, the sequence of this protein is deduced from the DNA sequence. Then, a fragment of the predicted protein sequence (preferably a COOH-terminal peptide[62,63] or an internal hydrophilic peptide selected by the method of *Hopp* and *Woods*[56]) is synthesized chemically and antibodies are raised against the synthetic fragment. Finally, if the putative protein exists, it can be detected immunologically provided the antibodies produced against the synthetic peptide cross-react with the gene product.

This scheme was applied by *Sutcliffe* et al.[64] to detect a new retroviral gene product. Analyzing the nucleotide sequence of the 3'-end of the Moloney murine leukemia virus genome, they found an open reading frame that extended beyond the coding region of the known viral products. Antibodies raised against a synthetic pentadecapeptide sequence of the putative protein cross-reacted with material in infected cells. In the same way, *Chomyn* et al.[63] identified the polypeptides encoded in the ATPase 6 gene and in the open reading frames 1 and 3 of human mitochondrial DNA. The antibodies produced against synthetic COOH-terminal peptides (seven to eleven residues long) of the three putative gene products immunoprecipitated specifically components 17, 12, and 24 of the mitochondrial translation products of HeLa cells. An extensive review article on antibodies against synthetic peptides has been published by *Walter* and *Doolittle*.[65]

5. Design of Novel Polypeptides

The design of novel biologically active polypeptides is a new field in protein chemistry. At the outset, two questions need to be asked: 1) Do we need novel polypeptides or proteins? 2) Is the design of novel polypeptides feasible?

The answer to the first question is unequivocally "yes." Proteins with novel enzymatic activities, for example, could be useful for research, biotechnology, and medicine. They could also play an important role in environmental protection if they were capable of degrading long-lived toxins such as DDT (Fig. 4) or dioxin.

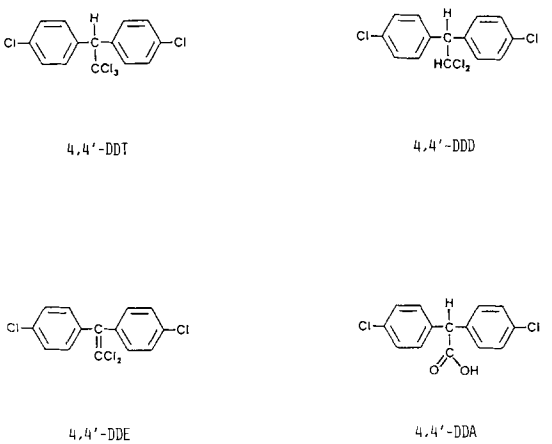

Fig. 4. 4,4'-DDT, 1,1,1-trichloro-2,2-bis(*p*-chlorophenyl)ethane; 4,4'-DDD, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane; 4,4'-DDE, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene; 4,4'-DDA, bis(*p*-chlorophenyl)acetic acid. DDD, DDE, and DDA are metabolites of DDT.

The answer to the second question is not clear at present. If a microorganism could be easily adapted to using DDT as a substrate for growth, the biological approach to the development of new enzymes would be superior to theoretical-chemical approaches. In addition, our knowledge of the folding mechanism of proteins is still incomplete.[84] We can predict, with some confidence, the location of secondary structural elements (α-helices, β-strands, and turns) on a polypeptide chain of known amino acid sequence (see *Pfaff* et al.[58] and *Gutte* et al.[66]) but not the arrangement of these structural elements relative to each other in the three-dimensional biologically active structure of a protein. This means that, at present, it is possible to design an α-helix, a β-pleated sheet, or a turn but not to construct and synthesize a novel functional protein having a complex structure. Therefore, up to now, only small biologically active polypeptides have been constructed that adopt relatively simple "one-dimensional" or "two-dimensional" structures such as a single α-helix,[67] a β-pleated sheet,[7,68] or a combination of both.[69] Despite this restriction, the results obtained are very interesting and encouraging.

5.1. Ligand-Binding Polypeptides

The preparation of biologically active models of binding sites,[68,70] peptide hormones,[9] and protein inhibitors[71] is the first step towards the design of novel polypeptides. *Lee* and *Atassi*[70] introduced "surface simulation synthesis" to confirm the location and topology of an antigenic determinant of lysozyme. This antigenic determinant is formed by amino acid residues that are adjacent in the three-dimensional structure but partly separated from one another in the amino acid sequence. A linear decapeptide was synthesized in which the amino acid residues that are adjacent to each other at the antigenic site are linked either directly or via spacer amino acids. This peptide was indistinguishable in its immunological properties from the corresponding antigenic determinant of native lysozyme. *Kullmann*[68] constructed a 40-residue peptide that mimicked the binding properties of naturally occurring opioid receptors. The amino acid sequence of this artificial receptor was deter-

mined using rules for the prediction of secondary structure and knowledge of the structure of various enkephalin and morphine derivatives. The sequence and the folding of the binding site of natural opioid receptors are not yet known. The highly active cyclic hexapeptide model of the peptide hormone somatostatin prepared by *Veber* et al.[9] was discussed already in Section 2.1.

A 13-residue competitive trypsin inhibitor was constructed by *Kitchell* and *Dyckes*.[71] This model inhibitor comprised the trypsin-binding region (two antiparallel β-strands, residues 13 to 18 and 35 to 39) of basic pancreatic trypsin inhibitor[72] and the dipeptide D-Phe-Pro, which linked the two β-strands and allowed their antiparallel alignment.

Additional synthetic peptide models of binding sites have been discussed.[66]

5.2. Construction of Polypeptides Having Enzymatic Activity

Examples of designed synthetic enzymes solely consisting of polypeptide chains and, if necessary, prosthetic groups are scarce. *Chakravarty* et al.[67] employed the known mechanism of action of lysozyme[73] and secondary structure prediction rules[74] to design and synthesize an α-helical decapeptide (Fig. 5) that had considerable lysozyme-like activity using chitin and dextran as substrates. Most likely, the spatial arrangements of the essential side chain carboxyl groups[73] were very similar in this lysozyme model and the natural enzyme. Whether the activity of the synthetic decapeptide is sequence-specific[67] or whether analogues containing the same amino acid residues in random order are also enzymatically active is still unknown.

We constructed a 34-residue polypeptide (Fig. 5) that interacts with nucleic acids.[69] This peptide and its disulfide-bridged dimer preferentially bound cytidine phosphates and had weak ribonuclease activity (0.1% and 2.5%, respectively, of the activity of ribonuclease A using tRNA as substrate) with high preference for cleavage of polynucleotide chains at the 3′-end of 3′-cytidylic acid residues. As pleasing as these results were, they once more pointed to our fragmentary knowledge of the factors that determine the folding of proteins.[84] The 34-residue polypeptide had been designed to interact specifically with the trinucleotide GAA. However, the binding of C by the synthetic product was about 100 times stronger ($K_D = 5 \times 10^{-6}$ M) than that of GAA, and the enzymatic activity of the artificial polypeptide had not been anticipated. The proposed secondary structure of the 34-residue polypeptide[69] was partly confirmed by circular dichroism measurements.[75] A more rigorous proof of the suggested folding was not possible because the crystals of the synthetic nucleic-acid-binding peptide were not suitable for X-ray studies.

5.2.1. Construction of a DDT-Binding/Degrading Polypeptide—Present State of Knowledge and Future Prospects

Model building and the secondary structure prediction rules of *Chou* and *Fasman*[76] and *Levitt*[77] were also used

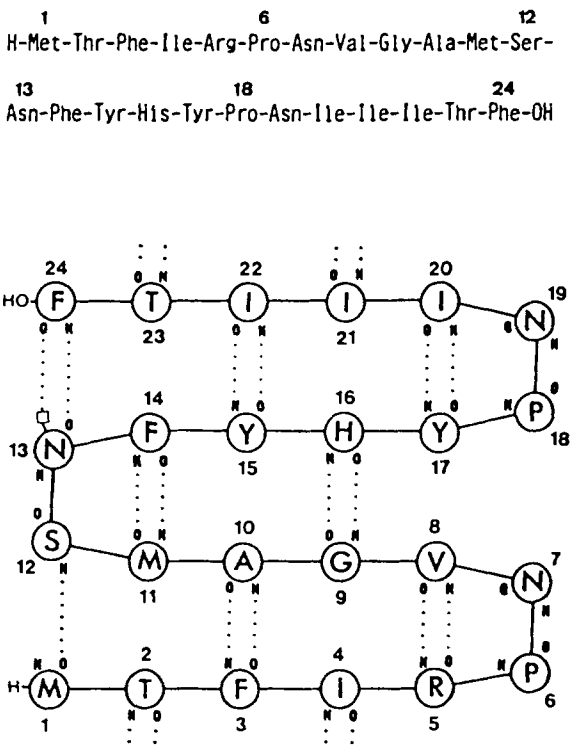

Fig. 6. Sequence and proposed secondary structure of an artificial DDT-binding 24-residue polypeptide. Dotted lines indicate hydrogen bonds between NH and CO groups of the backbone and side chains. Reprinted by permission from [7] (Copyright 1983, Federation of European Biochemical Societies).

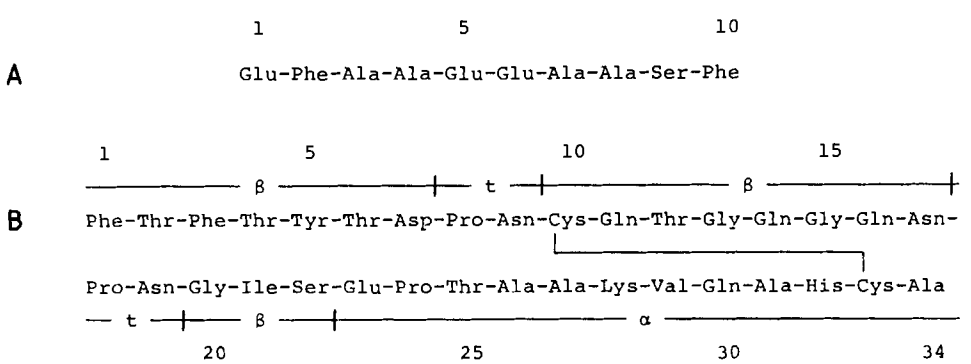

Fig. 5. Sequences of the designed α-helical decapeptide with lysozyme-like activity (**A**) [67] and of the artificial 34-residue ribonuclease (**B**) [69]. The latter is proposed to contain three β-strands (β), two β-turns (t), and one α-helical segment (α).

as the basic tools for the construction of a 24-residue DDT-binding peptide.[7] The amino acid sequence deduced seemed to be capable of producing a stable four-stranded antiparallel β-pleated sheet (Fig. 6) that could provide a DDT binding site of high complementarity involving the side chains of Phe 14, His 16, Ile 21, Met 11, and Ile 4. Since DDT is insoluble in water and, if taken up by an organism, accumulates in membranes, the artificial DDT-binding peptide had to be lipophilic as well.

The polypeptide was synthesized by the solid-phase method.[2,3] After a single gel-filtration step, the synthetic product had the expected amino acid composition, was homogeneous on thin layer chromatography, and could be crystallized.[7] Moreover, it gave a symmetrical peak on high performance liquid chromatography (HPLC) and had the correct amino acid sequence as determined by solid-phase Edman degradation.[8]

The synthetic peptide was found to bind DDT.[7] In ethanol/0.05 M NH_4HCO_3 (6 : 5, v/v), the dissociation constant K_D of the complex is about 2×10^{-5} M. Nucleotides such as 2′-CMP are not bound. The interaction of DDT with an analogue of the synthetic peptide, possessing the same amino acid residues in a random sequence, and with bovine serum albumin is much weaker ($K_D \approx 3 \times 10^{-3}$ M and 1×10^{-2} M, respectively).

It would be of theoretical and practical importance if the DDT-binding peptide could be converted into a DDT-degrading or modifying enzyme. In vivo, membrane-bound DDT is a poor substrate of cytochrome P-450 enzymes, the prosthetic group of which is a heme. Anaerobic and aerobic pathways of DDT degradation can be distinguished. An example of the former is the reductive dechlorination of DDT to DDD (Fig. 4),[78] an example of the latter the formation of DDA (Fig. 4) which is the principal urinary excretion product of DDT in mammals. Hydroxylation of the aromatic rings of DDT might also occur.

Several simple cytochrome P-450 models have been described. *Sakurai* et al.[79,80] used hemin-cysteine and hemin-glutathione complexes to carry out hydroxylations, dealkylations, and methyl migrations on aromatic substrates. We found that the hemin-cysteine complex also modified DDT. The products were more polar than DDT as shown by thin layer chromatography and HPLC of the reaction mixtures (Fig. 7A). The major products have been identified[81,82] and possible mechanisms of their formation are shown in Figure 8. In the presence of the DDT-binding peptide, the hemin-cysteine-mediated degradation of DDT was similar (Fig. 7B). Extending the 24-residue peptide to introduce a hemin binding site opposite the DDT binding site might result in a complex with increased DDT-degrading activity.

In order to study the in-vivo properties of the designed DDT-binding polypeptide, the gene for this artificial polypeptide was synthesized, inserted into a suitable plasmid, and cloned in *E. coli*. These experiments were performed in collaboration with *E.-L. Winnacker* et al.[83] If all rules of protein folding were known and all difficulties of expressing foreign DNA in bacteria or higher organisms could be overcome, designed proteins might be produced in highly pure form solely by genetic engineering methods, making their chemical synthesis superfluous.

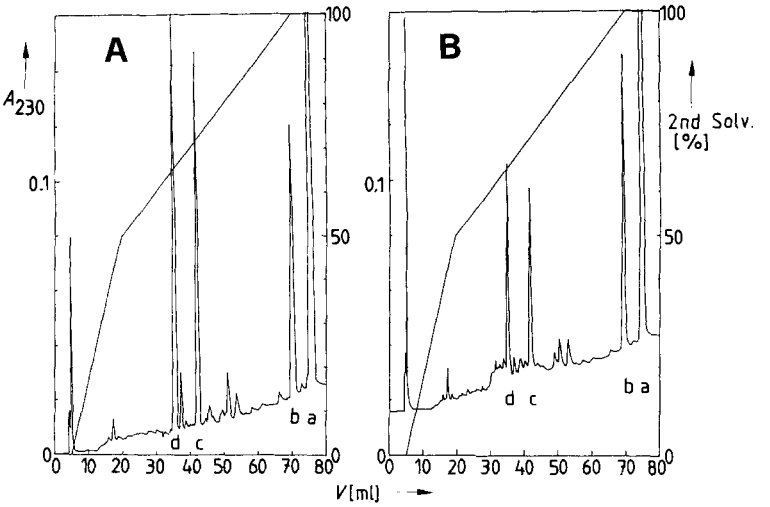

Fig. 7. HPLC separation of the DDT degradation products formed in the absence (**A**) and in the presence (**B**) of the designed 24-residue DDT-binding polypeptide. DDT, hemin, and cysteine were incubated in ethanol/0.05 M sodium acetate, pH 5.2 (6 : 5, v/v) at 37 °C for 48 h. Then the reaction mixtures were centrifuged and an aliquot of the supernatant was separated by HPLC [Aquapore RP-300 column (Brownlee), gradient elution (first solvent: 0.1% trifluoroacetic acid, second solvent: 60% acetonitrile in 0.1% trifluoroacetic acid)]. The following products have been identified: a, DDT; b, DDD; c, DDE-cysteine conjugate; d, DDA-cysteine conjugate. The millimolar extinction coefficients of DDT and DDD are $\varepsilon^{230}_{1\,cm} = 15.002$ and 19.125, respectively. A_{230}, absorption at 230 nm; 2nd solv., proportion of second solvent.

Elucidation of the structure of the artificial 24-residue DDT-binding polypeptide is essential for future work on protein design. It is important to know to what extent the folding found and that proposed agree. Furthermore, if the structure of the DDT binding site were known, the binding properties of the artificial polypeptide could be improved.

Work has begun on the raising of antibodies (preferably a monoclonal antibody) against DDT in order to compare

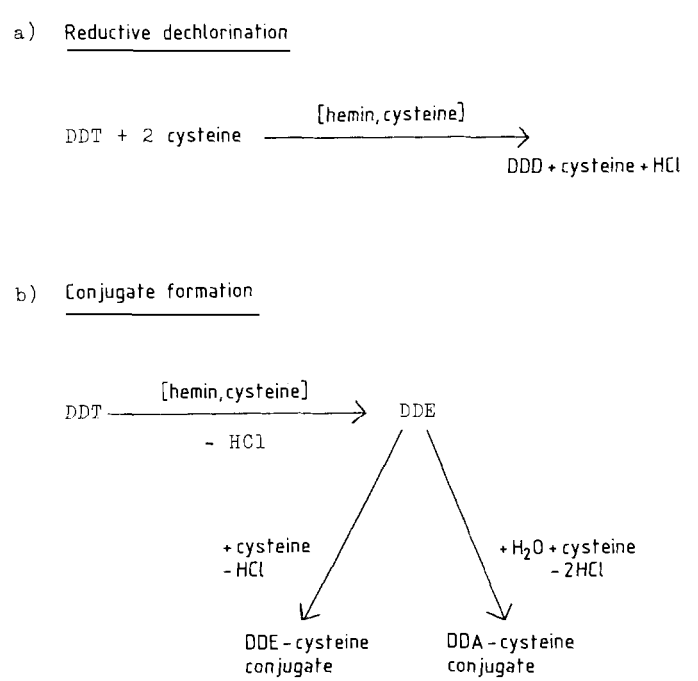

Fig. 8. Pathways of DDT degradation at pH 5.2 in the presence of the hemin-cysteine cytochrome P-450 model system.

natural and artificial DDT-binding polypeptides and to determine DDT in biological samples quantitatively.

Finally, inspection of the space-filling model of the designed peptide showed that dioxin may also fit the DDT binding site after minor adjustments of a few amino acid side chains. However, it will be difficult to test this possibility experimentally.

6. Outlook

The design of novel polypeptides still involves many unknowns, but once a workable system has been found it can be highly exciting. The future for peptide synthesis appears optimistic, especially if protein chemists collaborate with biologists. The protein chemist can play a very active role thereby if he is familiar with the modern experimental techniques of molecular biology and immunology. Moreover, the search for novel methods that allow rapid chemical synthesis of proteins in good yield and of high purity should remain a challenge for every protein chemist.

We thank M. Linden for performing DDT degradation experiments. The work from our laboratory was supported by the Schweizerische Nationalfonds. Work done before 1980 was funded by grants from the Deutsche Forschungsgemeinschaft and the Stiftung Volkswagenwerk.

Host/Guest Chemistry of Organic Onium Compounds—Clathrates, Crystalline Complexes, and Molecular Inclusion Compounds in Aqueous Solution

By Fritz Vögtle,* Hans-Gerd Löhr, Joachim Franke, and Detlev Worsch

The importance of organic onium compounds for host/guest interactions in biological processes has been long recognized. In contrast, the versatility of synthetic onium compounds as host molecules in abiotic chemistry has only been investigated in detail for the last few years. Due to their inclusion ability and selectivities, organic ammonium, pyridinium, and phosphonium salts and other organic salts with specific structural features are interesting as clathrate-forming molecules. The crystal structures of the clathrates afford insight into the conformational adaptability of onium clathrands with limited flexibility to the geometric requirements of the guest molecules. Optically active onium hosts can be used for enantiomeric enrichment. In crystalline tetracyanoquinodimethane(TCNQ) complexes and radical anion salts, the structure of the organic heterocation has a marked effect on the electrical conductivity. Macrocyclic onium compounds of the phane type with "exohydrophilic" and "endolipophilic" cavities are suitable as models of enzymes and biological receptors. They can also be used to transfer aromatic and aliphatic guest molecules selectively into aqueous solution. Catalytic activity (including H/D exchange) has already been obtained with synthetic compounds having large cavities. The further development of such host/guest systems may contribute to the understanding of biological systems and the improvement of technical processes (catalysis in molecular cavities).

1. Introduction

Onium compounds have important functions in biological processes; they contribute to the hydrophilization of the exterior surfaces of membranes and enzymes, they are involved in the transfer of one-carbon units, and they play a part in biochemical host/guest processes, for instance in the electrostatic binding of biologically active substances to receptors or of substrates to enzymes.[1]

Use of organic ammonium, phosphonium, and sulfonium salts in abiotic chemistry was for a long time limited to the fields of preparative intermediates,[2] herbicides, bactericides, and surfactants (e.g., invert soaps).[3] Only during the last few years has the versatility of onium compounds as clathrate- and complex-forming molecules and as models for enzymes and biological receptors been recognized.

This development was promoted by the introduction of new and improved solid-state research methods, such as solid-state NMR spectroscopy, X-ray crystallography, high-resolution electron microscopy, Fourier transform IR spectroscopy, and Raman difference spectroscopy, which facilitated the identification and characterization of inclusion phenomena.[4] The increasing number of scientific contributions and patents concerning inclusion compounds during the last few years documents the growing interest in such systems.

Host/guest compounds have a wide range of applications. For instance, host/guest interactions permit the separation of mixtures of substances according to molecular shape and size using reversible crystallization/solution processes,[5] chromatographic procedures,[6] or suspension methods (molecular sieves).[4e] Host/guest selectivities are sufficient to separate aromatic compounds from other compounds in multicomponent hydrocarbon mixtures,[5] to separate branched from normal hydrocarbons,[7] to fractionate isomers[8] and isotopomers,[9] and to resolve enantiomers (see Section 4). Of general interest is the use of in-

[*] Prof. Dr. F. Vögtle, Dr. H.-G. Löhr, Dr. J. Franke, Dipl.-Chem. D. Worsch
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (FRG)

clusion compounds to store and handle toxic, radioactive, or explosive substances,[10] to stabilize sensitive substances and unusual conformations of molecules,[11] as chemical reagents or specific catalysts,[12] to detoxify contaminated systems, to promote phase transfer of sparingly soluble hydrophobic or hydrophilic compounds (surfactants[13]), and as molecular templates for polymerization reactions.

Host/guest interactions also play a significant role in many medical and pharmacological processes. In the chemotherapeutic treatment of cancer, for example, the replication of DNA is inhibited in part by intercalative binding of drugs.[15]

A topological subdivision of host systems into *cavitands* having intramolecular cavities (i.e., within *one* molecule), and *clathrands* having extramolecular cavities (i.e., between different molecules) is useful[16] (Fig. 1).

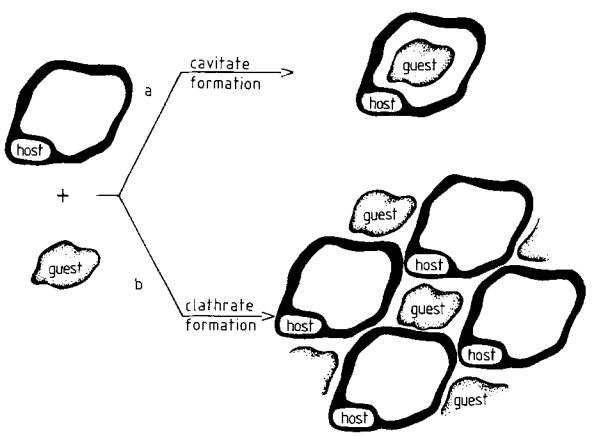

Fig. 1. Schematic differences between cavitates and clathrates: a) conversion of a cavitand into a cavitate by inclusion of the guest in the cavity of a host molecule; b) inclusion of guest molecules in cavities formed between the host molecules in the lattice; conversion of a clathrand into a clathrate.

Typical host compounds with *intra*molecular cavities are cyclodextrins, crown ethers, cryptands, calixarenes, and some cyclophanes. They form host/guest aggregates in the solid state and in solution and have been employed as models of enzymes and receptors (cf. Fig. 1a and Section 6).

Unlike cavitates, *clathrates* can form only in the crystalline state: guest molecules either are incorporated into *extra*molecular cavities already present in the lattice or, during crystallization, they induce host-lattice structures with guest-specific vacancies (Fig. 1b).

An essential feature of inclusion compounds is that the host and guest molecules are bound together by noncovalent forces. The type and strength of the bonding (ion–ion, ion–dipole, dipole–dipole, dipole–induced dipole, dispersion and electron donor-acceptor interactions, hydrogen bonding) between host and guest molecules necessitates another subdivision.[16] If predominantly electrostatic interactions between host and guest are decisive for adduct formation, the compounds are considered as complexes. If, on the other hand, aggregate formation occurs without specific bond forces between individual host and guest molecules, the term cavitate or clathrate is correct.

The driving force for the formation of crystalline clathrates and cavitates is first and foremost the thermodynamically favored, dense molecular packing (cf. ref. [4c]), which frequently is not observed when pure host lattices crystallize, owing to, for example, steric barriers or intramolecular cavities. The distinction between complexes and clathrates or cavitates is not always clear and the assignment of a host/guest compound to one or the other of these classes is left to the observer to a certain degree.[17]

Comparison of the structural formulas of known *clathrate*-forming molecules indicates that bulky molecular geometries occur frequently and that the number of possible stable conformations is limited. Replacement of single atoms or atomic groups leads frequently to further host compounds with similar or markedly changed cavity geometries and new guest selectivities, but often also to complete loss of inclusion ability.[18] Characteristics of many host compounds are the formation of intramolecular hollows as well as trigonal symmetry as in tri-*o*-thymotide (TOT) **3**,[19] cyclotriveratrylene (CTV) **4**,[20] triphenylmethane,[21] or perhydrotriphenylene.[22]

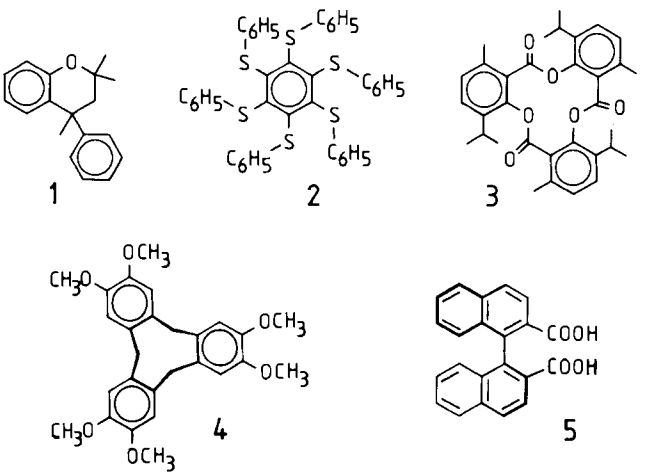

Fig. 2. Parent compounds of some "classical" clathrate-forming host systems; dianine **1** [4b, 18], hexakis(phenylthio)benzene **2** [23], tri-*o*-thymotide **3** [19], cyclotriveratrylene **4** [20], 1,1'-binaphthyl-2,2'-dicarboxylic acid **5** [26].

Predictions concerning the inclusion ability of new host compounds are still not possible or only in a limited way. Only by starting from known clathrate hosts and systematically varying their structures could clathrand families with considerable capacity and selectivity be developed. Such host systems include dianine **1** and its derivatives,[4b] the family of "hexahosts" derived from it, for example, **2**,[23] and the Schaeffer-[24] and Hofmann-type[25] inorganic transition-metal complexes.

The recently investigated hinge compounds, such as the binaphthyl derivative **5**,[26] are promising in view of the wide range of variation possible. This host system with bulky molecular structures is based on the combination of steric barriers with possible coordination via hydrogen bonds. Accordingly, polar guest molecules such as alcohols are incorporated preferentially in the sense of "coordinato clathrates."[17a]

The subject of this survey is organic onium compounds, a class of clathrate-, cavitate-, and complex-forming molecules with extensive inclusion ability, diverse selectivities, ready availability, and wide variability.

2. Clathrates of Organic Onium Salts: Properties and Guest Selectivities

As for many of the presently known clathrand systems, the discovery of the family of onium clathrate hosts was due to a chance observation. When the bisammonium compound **6** was prepared by reacting 1,3-bis(dimethylaminomethyl)azulene with excess iodomethane in ethanol, variable amounts of iodomethane and ethanol remained in the crystalline product.[27] The guest molecules could not be removed, even by "drying" in vacuum for several days. Attempts to recrystallize **6** revealed that it can incorporate a variety of solvent molecules, mostly in stoichiometric amounts. Systematic structural variations of the host compound **6** by replacement of the alkyl residues on the ammonium nitrogen, modification of the onium side arms, and exchange of the anchor group (azulene ring in **6**) and of the anions led to further clathrate-forming molecules (Fig. 3) with different guest selectivities.[28-30] Table 1 displays the clathrates of the onium compounds **6**–**22**. The "adducts" of organic onium compounds with alkyl halides that have been described in the older literature have partly been taken into consideration in Table 1.[31,32]

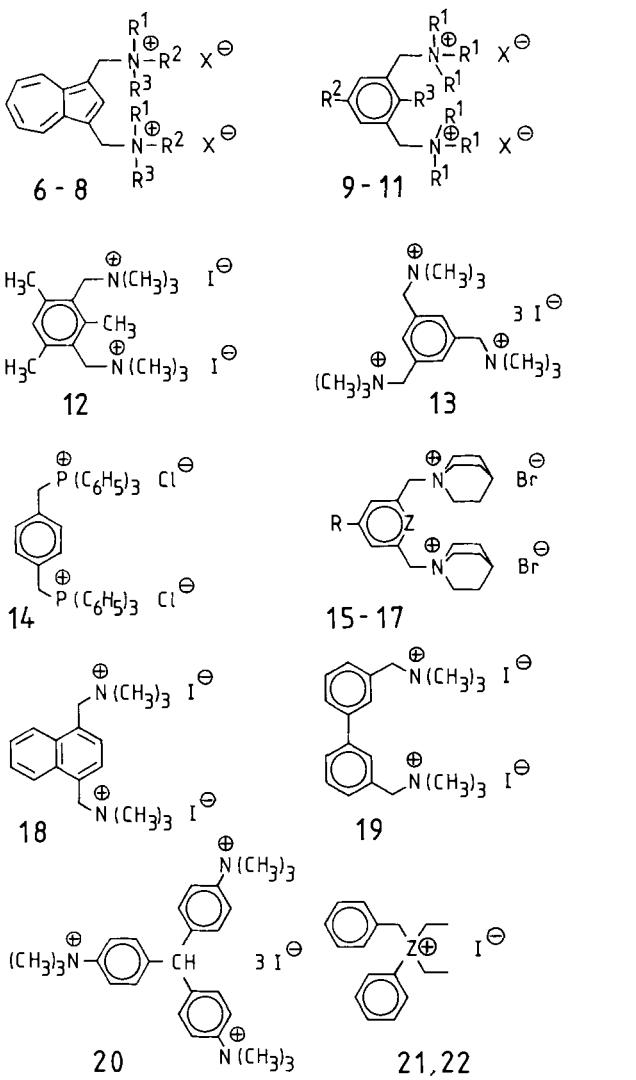

Fig. 3. Clathrate-forming onium compounds **6**–**22** [27–29, 31, 34].

	R^1	R^2	R^3	X		Z	R
6	CH_3	CH_3	CH_3	I	**15**	CH	H
7	CH_3	CH_3	CH_3	Br	**16**	CH	*t*Bu
8	CH_3	CH_3	C_2H_5	I	**17**	N	H
9	CH_3	H	H	I	**21**	N	—
10	CH_3	*t*Bu	H	I	**22**	As	—
11	C_2H_5	H	H	I			

The extensive inclusion ability of the bisammonium host **6** is clearly diminished when the anion $I^{\ominus}$ is replaced by $Br^{\ominus}$ (**7**). Whereas **6** hosts primary and secondary alcohols from methanol to pentanol, diols, and numerous halo- and nitroalkanes, the host **7** incorporates mainly smaller molecules with the exception of alcohols. In the series dichloro-, trichloro-, and tetrachloromethane, only dichloromethane is hosted selectively by bisbromide **7**. Here, the reduction in size of the anion obviously leads to smaller lattice cavities.

The naphthalene derivative **18** selectively forms clathrates with "BTX" aromatic compounds (*b*enzene, *t*o-

luene, xylene) and 1-butanol in a stoichiometry of 2 : 1. Inclusion complexes containing mesitylene, other hydrocarbons, alcohols, alkyl halides, or nitroalkanes have not been found.[29] The affinity of **6** for iodoalkanes, and of **7** for bromomethane as well as the specifity of **18** for nitromethane are considerable.

More than 30% of the onium compounds that have been synthesized to date and studied with respect to their inclusion ability have turned out to be clathrate-forming molecules. If one includes the iodoform adducts, which belong to the family of coordinato clathrates, the "hit rate" is more than 50%!

What are the causes of this remarkable variety of inclusion complexes? In addition to the general features of many clathrate hosts, such as bulkiness and limited conformational flexibility, the stability of the ionic host lattice is certainly of significance. The higher energies of ionic interactions are more important in forcing bulky molecules to crystallize than the interaction forces in molecular lattices.

Figure 4 shows some onium compounds for which, up to now, no inclusion compounds have been found. Extension or removal of the spacer unit (methylene bridge) between the anchor group (aromatic ring) and the onium group always led to a strong decrease or total loss of inclusion ability. If the "onium branches" on the benzene ring are in *o*- or *p*-positions (compare **9** with **29** and **30**) or if a small substituent is present on the anchor group (compare **10** with **24**–**28**), the effect is also negative. Apparently, these substituents fill the vacant spaces in the lattice.

What structural features are important in the design of potential onium clathrate hosts? Factors that have a favorable effect on the ability of molecules to form clathrates ("clathratogenic structural features," cf. Fig. 3) include a) a rigid molecular part such as benzene, naphthalene, azulene, or other aromatic compound as an anchor group, b) methylene bridges as spacer units, c) rigid, bulky, or voluminous substituents on the anchor group, and d) positioning of the "onium branches" on the anchor group in such a way that conformations with hollow-shaped spaces can form (for example, the 1,3-arrangement on benzene and azulene).

Molecular symmetry and flexibility play, as expected, a decisive part in determining the inclusion ability of a host compound. In the formation of crystal lattices containing cavities, a too high conformational mobility of the atomic groups counteracts the "bulkiness" of the molecules; conversely, a too low flexibility makes the adaptation of the host conformation to the requirements of the guest molecules more difficult.[28]

The stability of the onium clathrates is shown by the fact that they normally only decompose noticeably at temperatures far above the boiling points of the guest substances and that in vacuum no liberation of solvent molecules is usually observed. Predominantly cage-like lattice inclusions are presumably present. Subsequent saturation of guest-free host crystals requires channel- or layer-like cavities, and is only possible for host compound **6** (after recrystallization from methanol) with smaller guest molecules (CH_2Cl_2, CH_3OH, CH_3CN, H_2O).[28]

Owing to the ionic character of organic onium compounds, they are normally soluble to a significant extent only in polar solvents. Clathrates containing lipophilic guests can therefore only be prepared by recrystallization of the host substances from mixtures of solvents or by precipitation from alcoholic solution. In order to recover the guest substance (declathration), the clathrates are dissolved in water or methanol, and the guest is obtained by subsequent extraction from aqueous solution or vacuum distillation. By reducing the volume of the clathrand solution, the host compound can also be recovered; thus, the process is reversible (cf. ref. [5]).

3. Clathrate Lattice Structures

X-ray structure determinations of host inclusions in organic onium compounds show that multimolecular crystal-lattice cavities are present. The guest molecules are sterically constrained by the ionic lattice of the host without exhibiting strong interactions between individual host and guest molecules, such as specific ion-dipole bonding.

Thus, these structures are definitely to be classified as clathrates (cf. ref. [16]).

Figures 5–7 display the crystal structures of three different clathrates of the same host compound **6**. The guest molecules iodomethane (Fig. 5), 1-butanol (Fig. 6), and 1,4-butanediol (Fig. 7) are each surrounded by several host molecules. In all three cases, the crystal lattices differ. The conformation of the host molecule **6** is significantly adapted to the structure of each guest molecule.

In the CH_3I clathrate of **6** (Fig. 5), the "onium branches" of the host molecule are aligned in a cisoid way (C_m symmetry) and embed the guest molecule partly in the hollow-shaped space. The remaining boundary surfaces of the CH_3I cage are formed by the bulky azulene rings and the voluminous trimethylammonium units.[27]

In the 1-butanol clathrate of **6**,[34] the "onium branches" are aligned in a transoid way on opposite sides of the plane formed by the azulene ring (C_2 symmetry, Fig. 6, left). The guest molecules are in tube-shaped cavities with an alternating series of expansions and contractions in the longitudinal direction ("tubulato clathrate"[16]). The top and bottom of the tubes are formed by the planes of azulene rings aligned in parallel layers, and the lateral sides are bounded by the ammonium groups that project between the layers (Fig. 6, left).

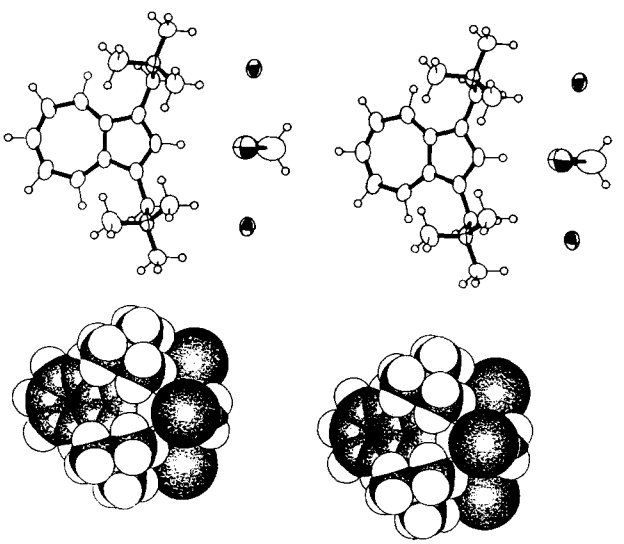

Fig. 5. Crystal structure of the CH_3I clathrate of **6** (stereoscopic pictures) [27]. Above: Molecular framework. Below: Space-filling model.

The butanol molecules are disordered in a characteristic way: although each of the CH_2 groups is located in a similar position, the OH group sometimes points in one, sometimes in the opposite direction along the tube. Thus, 1,4-butanediol appears to be present (Fig. 6, right).

Indeed, **6** forms clathrates with 1-butanol and 1,4-butanediol having the same stoichiometric ratio (1 : 1). However, the crystal lattices and the conformations of the host molecules differ clearly, even though there are no specific coordination interactions (e.g., hydrogen bonds) between host and guest or between guest molecules. In contrast to the tube-shaped 1-butanol inclusion, **6** forms a clathrate of cage type with 1,4-butanediol (Fig. 7).[35]

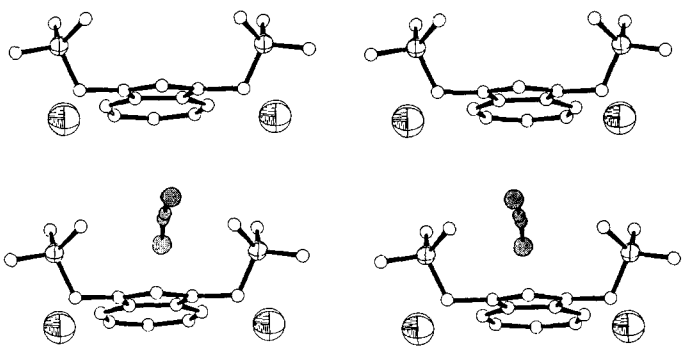

Fig. 7. Crystal structure of the 1,4-butanediol clathrate of **6** (stereoscopic picture). Butanediol shaded [35].

The shape and size of the hollows that are required by the guest molecules in the crystal lattice are similar to those of the 1-butanol inclusion. The planes formed by the azulene rings are again aligned in parallel layers and form the top and bottom of the cavity; the ammonium groups serve as lateral boundaries. The oval cavities are aligned in a longitudinal direction; as a result of the greater contraction, isolated cages rather than tubes are present.

Another difference between the butanol and butanediol inclusion is the position of the guest molecules. The plane formed by the C atoms (zigzag chain) of the butanol molecules is nearly parallel to the planes formed by the aromatic compounds; however, the middle layers of the C

[a] X-ray = X-ray structure determination.

atoms of the 1,4-butanediol molecules form planes that are perpendicular to the plane formed by the azulene rings.

The cell data of these and several other clathrates of **6**, **10**, and **16** are shown in Table 2. The crystal lattices of the 1-butanol, 2-butanol, and 1-propanol clathrates of **6** are isotypic; they differ only slightly in cell parameters and should therefore have the same cavity dimensions.

Other lattice structures of **6** with changed cavity proportions—depending on the incorporated species—are formed upon inclusion of CH_3NO_2 and $BrCCl_3$; they demonstrate the extraordinary adaptability (induced fit) of the host compound **6** to the geometry of the guest molecules.

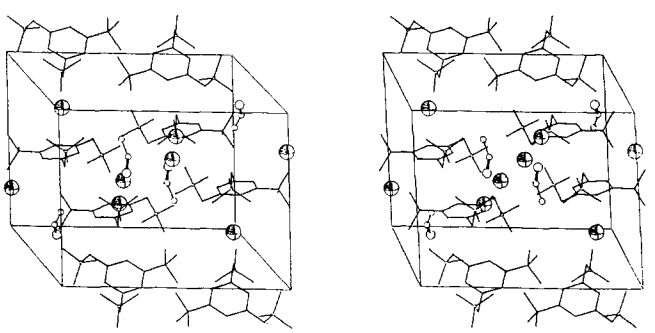

Fig. 8. Unit cell of the ethanol clathrate of **10** (stereoscopic picture) [28].

Figures 8 and 9 show the crystal structures of alcohol inclusions (ethanol, propanol) in host lattices of the compounds **10** and **16**, which have *tert*-butylbenzene as anchor group and *meta*-oriented ammonium groups. Along with the voluminous transoid-oriented trimethylammonium units, the *tert*-butyl groups also serve as cavity boundaries in the ethanol clathrate of **10**[28] (Fig. 8).

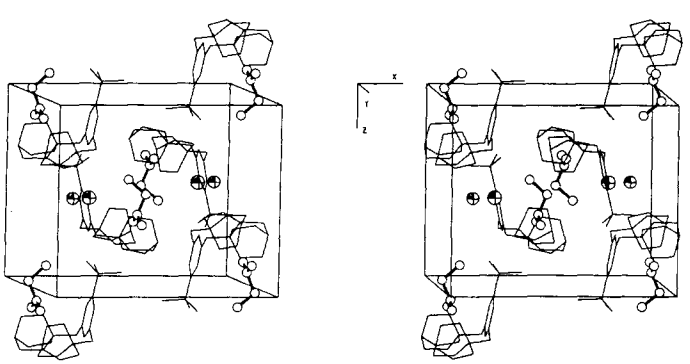

Fig. 9. Unit cell of the 1-propanol clathrate of **16** (stereoscopic picture) [29].

In the crystal of the 1-propanol clathrate,[29] the quinuclidinium branches of the host compound **16** are aligned on the same side of the *tert*-butyl anchor group (Fig. 9). In addition to the stoichiometric amounts of 1-propanol, one-half mole of water of crystallization per mole of clathrate is present in defined lattice positions. One terminal group (OH or CH_3) of propanol is disordered and is not in the plane formed by the other three C and O atoms.

X-ray analyses of the different clathrates of **16**[29] support the conceptual picture of the onium hosts: the molecular combination of voluminous onium groups with rigid, bulky anchor groups leads frequently to gaps in the crystal lattice. Only the inclusion of suitable guest molecules makes a dense molecular packing in the crystal possible—in addition, more beautifully shaped crystals are frequently produced.

The methylene bridges as spacer units permit a somewhat limited conformational flexibility which ensures a *dynamic adaptability of the conformation of the host molecules to the geometry of the guest molecules* during crystallization. A certain analogy to the induced adaptation of enzymes or receptors to substrate or ligand molecules (induced fit) is unmistakable.

A dependence of the structure of the host lattice on the incorporated species is known for only a few other synthetic clathrands. Tri-*o*-thymotide (TOT) **3**, for instance, forms trigonal cage clathrates with smaller guest molecules; with larger guests (six or more C atoms) it forms hexagonal channel-shaped inclusion lattices.[36] Urea crystallizes in its pure form in "fairly loose" tetragonal lattice structures; in urea adducts, on the other hand, a hexagonal lattice is present which makes the formation of stronger hydrogen bonds between the urea molecules, as well as a denser molecular packing, possible (cf. ref. [4c]).

Host flexibility and induced fit are found as characteristic features in numerous biochemical host/guest processes—albeit in solution. Thus, for example, the specificity of the enzyme(hexokinase)-catalyzed phosphorylation of glucose with ATP is due to a substrate-induced conformational change of the enzyme.[37]

4. Chiral Onium Host Compounds: Clathrates and Enantiomeric Enrichment

Enantiomeric resolution by means of noncovalent interactions is a further, more recent aspect of host/guest chemistry. Well-investigated examples with broad applications include enantiomeric enrichment using optically active crown ethers[38] in crystallization, extraction, or membrane transport processes,[39] chromatography on optically active adsorbents[40] involving the formation of diastereomeric electron-donor-acceptor complexes,[41] diastereomeric $Cu^{2\oplus}$-amino-acid chelates,[42] and chiroselective inclusions (e.g., in triacetylcellulose, polyacrylamides, and polymethylacrylamides).[43]

In contrast, the use of clathrate chemistry to produce precise, crystalline, chiroselective guest inclusions is still in its infancy. The basic prerequisite is the inclusion of chiral species in chiral crystal cavities. Numerous chiral clathrands are unable to resolve enantiomers. In fact, some even lose their inclusion ability in pure enantiomeric form.[18,44]

Isolated examples of enantiomeric enrichment via the formation of inclusion complexes with optically active host compounds have been described, for example, between chiral carboxylic esters and cyclodextrins,[45] between propargyl alcohols and brucine,[46] and between 1-amino-1-phenylethane and tetraacetyl-α-glucose.[47] Tri-*o*-thymotide **3** crystallizes in its pure form in an achiral lattice, one-half of which consists of plus and the other half of minus propeller conformations. In solution, the two enantiomeric conformers readily interconvert. Upon formation of an inclusion compound, spontaneous "enantiomeric resolution" occurs, so that a chiral environment is offered to the guest molecules in the crystal.[48] By co-crystallization with a chiral species, one of the enantiomers from a racemic mixture can undergo preferential inclusion. The enantiomeric excess per clathratization step is usually higher for the cage-type clathrates of tri-*o*-thymotide **3** (e.g., 2-bromobutane, 37% *ee*) than for channel-like inclusions (e.g., 2-bromononane, 5% *ee*).[49]

Achiral compounds as host crystals can also effect a discrimination of enantiomers. For instance, hexagonal urea crystallizes spontaneously in left- and right-handed helix structures, each of which preferentially forms an adduct with only one enantiomer of a racemic mixture.[51] The azulenebis(ammonium) salt **6** crystallizes, for example, with butanol in a chiral conformation (C_2 symmetry, cf. Fig. 6); the crystal lattice, however, is achiral, since both enantiomers are present.

The structural features (bulkiness, limited conformational flexibility) of the chiral onium compounds that are displayed in Figure 10 illustrate the construction principle of many effective clathrate-forming molecules (cf. Fig. 3). The modified Tröger's bases **38**–**43**[51] and the enantiomerically pure quaternized alkaloid bases **44** and **45**[52] have an extensive inclusion ability (Table 3). Particularly noticeable is the wide range of clathrates formed by the ammonium salts **38**, **39**, and **41** with *aromatic* guest substances.

The (−)-*N*-methyl- and (−)-*N*-benzylquininium salts **44** and **45**, respectively, which were obtained by quaternization of bases from the "pool" of optically active natural

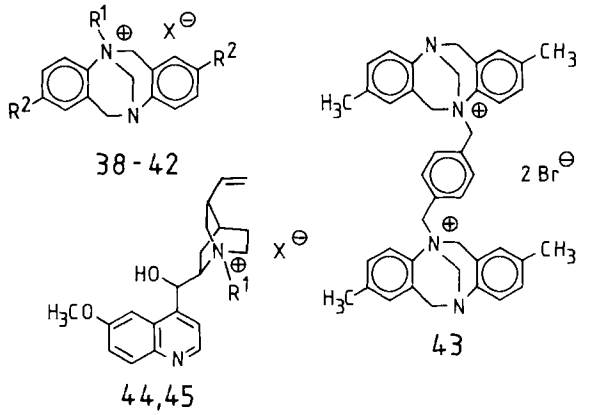

Fig. 10. Chiral onium clathrands **38**–**43** [51] and **44**, **45** [52].

	R^1	R^2	X

44	CH_3	—	I
45	CH_2–Ph	—	Cl

substances, form inclusion compounds with a chiral species (2-butanol) in the stoichiometric ratio 1 : 1, as well as with other short-chained guest compounds. Recrystallization of the enantiomerically pure clathrands from racemic 2-butanol and subsequent declathration by heating to 50 °C at 0.01 torr yields optically active distillates: **44**, (+)-(*S*)-2-butanol, 16% *ee*; **45**, (−)-(*R*)-butanol, 25% *ee*.[25] The reversibility of the clathration/declathration process and the relatively high enantiomeric excess indicate that higher enantiomer enrichments are possible.

Figure 11 shows the crystal structure of the methanol clathrate of **44**. The guest molecules are enclosed within the cage cavity of the quaternized host alkaloid. The hydroxyl group of the host compound is coordinated to the oxygen atom of the guest methanol via a hydrogen bond (coordinato clathrate[17a]).

Table 3. Clathrates of the chiral host compounds **38**–**45**.

5. Triiodomethane and TCNQ Complexes of Organic Onium Compounds Having Electrical (Semi-)Conductivity

It has been known for a long time that triiodomethane forms solid adducts with onium salts;[31] however, it also forms solid adducts with neutral molecules.[53] The crystalline products with 1,4-dioxane, 1,4-dithiane, and other π-donor substances could be identified as charge-transfer complexes.[53,54] IR and ^{1}H-NMR measurements indicate that the association of tetraalkylammonium halides and triiodomethane in weakly solvating media may also be attributed to electron-donor-acceptor interactions.[55]

Most of the onium compounds whose clathrate-forming qualities have been investigated form solid adducts with HCI_3.[33] Unlike the crystallization of "true" clathrates, which usually takes place slowly from alcoholic solution or requires the addition of inert solvents (e.g., diethyl ether), the reaction with triiodomethane to form solid adducts takes place readily, usually within a few minutes. In Table 4, the molar ratios of onium compounds to triiodomethane in the crystalline complexes are listed.

Table 4. Electron-donor-acceptor complexes of several host compounds with triiodomethane [33].

Onium compound	Molar ratio salt : HCI_3	Onium compound	Molar ratio salt : HCI_3
6	1:2	**23**	1:1
7	1:2	**29**	1:2
8	1:2	**30**	1:4
9	1:3	**31**	1:2
10	1:2	**32**	1:1
11	1:2	**33**	1:4
13	1:2		

X-ray analyses of the adducts (as well as Raman measurements) confirm the existence of electron-donor-acceptor complexes (Fig. 12–14): a) The $I^{\ominus}\cdots I$ distances are about 75 pm shorter than the calculated van der Waals distances; b) the C–I bond lengths in the complexes are slightly longer than in pure HCI_3; c) the $I^{\ominus}\cdots$I–C arrangements are in all cases roughly linear.

The crystal structures of the complexes show that the triiodomethane molecules are in all cases linked to the $I^{\ominus}$ ions via iodine atoms. Since every $I^{\ominus}$—as well as every HCI_3 unit—can be linked one, two, or three times, depending on the crystal packing, three-dimensional cross-linked structures (Fig. 12 and 14) as well as smaller $I^{\ominus}\cdots HCI_3$ units (Fig. 13) result.

An interesting anomaly appears in the NMR spectrum of the complexes in solution. Whereas, the addition of halide ions results in increased shielding of the proton in the ^{1}H-NMR spectrum of HCI_3 (in [D$_6$]DMSO), a significant deshielding of about 10 ppm is observed in the ^{13}C-NMR spectrum. This anomaly can be interpreted satisfactorily by structural changes in the HCI_3 molecule (see above) as a result of the charge transfer from the $I^{\ominus}$ donor to the HCI_3 acceptor.[33]

In the solid state, the triiodomethane complexes have specific electrical conductivities that lie at the lower end of the semiconductor scale. Interestingly, the specific conductivity increases in the sequence $\mathbf{10}\cdot 2\,HCI_3 < \mathbf{8}\cdot 2\,HCI_3 < \mathbf{32}\cdot HCI_3$ with the extent of the three-dimensional $I^{\ominus}\cdots HCI_3$ linking.

The dependence of the $I^{\ominus}\cdots HCI_3$ cross-linking in the crystal on molecular packing and the fact that a part of the onium halide is not able to form corresponding adducts indicate that, in addition to the electron-donor-acceptor interaction, structural characteristics also decisively influence the formation of adducts.

In organic conductors and semiconductors based on tetracyanoquinodimethane (TCNQ), the alignment of the TCNQ molecules or radical anions in stacks with overlapping π orbitals is of decisive importance for electrical conductivity.[57] Accordingly, the specific conductance depends sensitively on the molecular packing in the crystal and therefore on the structure of the cation. Generally, one distinguishes between simple salts $M^{n\oplus}(TCNQ^{\ominus})_n$ and complex salts $M^{n\oplus}(TCNQ^{\ominus})_n(TCNQ)_m$ ($M^{n\oplus}$ = metal or organic onium ion).[58] Planar structures like *N*-methylphenazinium **46**, protonated acridine **47**, or quinoline **48** (Fig. 15) have proved to be especially convenient counterions in TCNQ (complex) salts.[57]

How do "clathratogenic" structural features affect the molecular packing and the electrical conductivity of organic TCNQ salts? Reaction of the onium compounds with excess LiTCNQ results in typical "simple salts" as well as in complex salts (**6**, **7**, **30**) of general composition $M^{(n+m)\ominus}(TCNQ^{\ominus})_n(X^{\ominus})_m$.[59] The unusual but reproducible stoichiometry of the complex salts that contain TCNQ and radical ions in addition to halide ions may be ascribed to crystal packing effects.

The conductivity data of a small selection of onium TCNQ salts and complexes (Fig. 3, 4, 15) are listed in Table 5. The complex salt of the cation **30** has an electrical conductivity that is unusually high for simple salts.[59]

Solvent molecules often undergo inclusion in the complex TCNQ radical-anion salts (Table 5).[60,61] Upon removal of the acetonitrile from the adduct with **50** (70°C/high vacuum) and from that with **49** (103°C), the conductivities decrease to about 1.2×10^{-4} Ω^{-1} cm^{-1}. Obviously, the solvent molecules in the crystal support a stack-shaped alignment of the TCNQ molecules (cf. structure of **50**·CH_3CN in ref. [59]) which is favorable for the electrical conductivity. This example clearly demonstrates the possible effects of structural and electronic interactions on the formation of crystalline complexes and clathrates.

6. Macrocyclic Onium Compounds with Hydrophobic Cavities as Inclusion Forming Molecules in Aqueous Solution

Host molecules with intramolecular cavities capable of incorporating uncharged guest molecules are interesting with regard to their suitability as selective inclusion forming compounds and as enzyme and receptor models. Beside the well-investigated cyclodextrins,[65] synthetic and semisynthetic molecules, such as modified cyclodextrins,[66] crown compounds,[67] calixarenes,[68] and many-membered cyclophanes,[69] are able to form inclusion compounds with neutral guest molecules.

Of the abiotic host compounds, particularly macroheterocyclic onium compounds of the phane type (Fig. 16–18, 20–22) significantly reflect the basic characteristics of enzymes[1,70] such as substrate specificity, saturation kinetics, and catalysis. The ammonium centers that are already present or are formed by protonation of amine or pyridine nitrogen atoms serve the purpose of ensuring or increasing the water solubility of the host molecules. At least four positive charges are required because of the size of these host molecules and their lipophilic components.

In aqueous medium, steric adaptation (induced fit) and van der Waals, electrostatic, and hydrophobic interactions[71] play decisive roles (multiple recognition[17b,72]) as driving forces for the binding of lipophilic guest molecules inside host molecules with nonpolar cavities. The macrocyclic onium compounds shown in Figures 16 and 17 have the following advantages over open-chained analogues as model compounds (cf. **120**, **121** in Fig. 22[17b]):

a) As a result of the rigid structure units that function as spacers and the repulsion of the positive charges, cavities of strictly defined size and structure are formed in aqueous solution.
b) As a result of their polar exterior, dispersed host macrocycles are soluble in water, i.e., formation of micelles is avoided within a relatively large concentration range.
c) The host molecules have a hydrophobic interior and therefore offer the guest molecules a nonpolar microenvironment.
d) The electropositive potential allows the stabilization of anionic transition states and therefore favors catalytic activity.
e) In the compounds **78**–**82** and **85**–**87**, the hydrophobic quaternary ammonium groups point away from the cavity, so that, on inclusion of nonpolar guest molecules, no interference by water molecules occurs.

Whereas the benzene adduct of **52**,[73] which had long been considered as an intramolecular inclusion compound, turned out, on X-ray analysis, to be an extramolecular benzene inclusion in the crystal (i.e., a clathrate)[74] other host/guest compounds of cyclophanes could be identified as intramolecular inclusions of nonpolar guest molecules (i.e., as cavitates).[16] Thus, for example, the cyclic hexamer **83** with trigonal symmetry forms niches above and below the plane of the macrocycle, in which chloroform molecules are incorporated just as in a lock-key relation and the H

atom of the guest molecule points toward the center of the cavity.[75] The inclusion of chloroform was also confirmed for the adduct in solution by nuclear Overhauser effects between host and guest protons, by the splitting of the chloroform signal at −60°C in the ^{1}H-NMR spectrum, and by measurements with ion-selective liquid membrane electrodes.[76]

A dish-shaped conformation is exhibited by the azaparacyclophane **53** in its inclusion compound with 1,4-dioxane.[77]

The question arises as to how guest molecules in neutral or acidic aqueous medium are enclosed in the host molecules. The onium cyclophanes offer a cavity of sufficient depth if the aromatic compounds are in an "all-face" conformation.[78] This is favored as a result of the intramolecular π-interactions of the diphenylmethane units in the ring.[79] In its crystalline inclusion compound with durene, the tetraammonium salt **63** · 4 HCl shows a corresponding "all-face" conformation, in which the plane formed by the four benzene rings is aligned perpendicular to the main plane of the macrocycle. The durene guest molecule is found exactly in the middle of the cavity.[80]

Are the complex geometries of the crystalline intramolecular inclusion compounds (cavitates) also observed in solution? Fluorescence and nuclear magnetic resonance measurements in aqueous medium indicate this to be the case. In the presence of the cyclophanes **53**–**55**, **62**–**70**, **72**, **75**, or **78**–**82** in acidic or neutral aqueous solution, the emission spectra of 8-anilino-1-naphthalenesulfonate and other fluorescence probes undergo changes; the quantum yields increase strongly, and the shift of λ_{max} corresponds to switching to nonpolar media.[82,83,86,101] In the ^{1}H- and ^{13}C-NMR spectra of host and guest molecules, signal displacements are observed that suggest specific geometric alignments of the host/guest associates.[83] Theoretical calculations of the chemical displacement support a "pseudoaxial" inclusion of 2,7-dihydroxynaphthalene in **63**[84] (Fig. 19a), whereas in the large cavities of **67** and **70** "equatorial" alignments of naphthalene derivatives are supposedly present[78,79] (Fig. 19b).

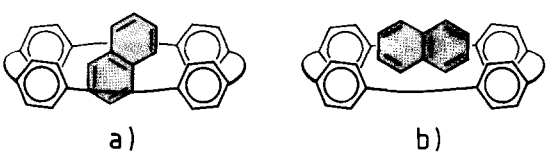

Fig. 19. a) "Pseudoaxial" and b) "equatorial" alignment of naphthalene in the cavity of a schematic cyclophane host in the "all-face" conformation.

In addition to the spectroscopic results, the comparatively high stability constants,[82b] the immobilization of guest molecules in the cavity,[85] the increased solubility of guest substances, and kinetic measurements[86] indicate an intramolecular inclusion in the host cavities.

The fact that **63** prefers β-substituted naphthalene (pseudoaxial inclusion) and **67** and **70** prefer α-substituted naphthalenes (equatorial inclusion) as well as the discrimination between benzene and naphthalene derivatives by **85**–**87** show[87] that even simple structural modifications in cyclophanes of this type result in different substrate selectivities.

Compared with **63** and **64**,[84] the octamethyl compounds **72**–**74**[101] have the advantage of being soluble in neutral aqueous solution.[89]

The inclusion capability of such hosts has been demonstrated by the high-field shifts of the protons of the guest naphthalene in the ^{1}H-NMR spectra as well as by fluorescence and NMR shifts upon titration. The energy of complexation in water decreases strongly with increasing percentage of organic solvent. Furthermore, it has been discovered that the mechanism of the binding of hydrophobic substrates in lipophilic cavities is similar to that of the dissolving of hydrocarbons in water. After immobilization of the azacyclophane **72** (n = 3) by adsorption on silica gel, chromatographic applications are possible.[89] Substrates such as naphthalenesulfonic acid, which is complexed particularly well by **72** (n = 3), are more strongly bound by the host in methanol as eluent than by untreated silica gel; this corresponds to a decreasing R_F value.

Attempts to catalyze the chlorination of hydrocarbons by binding a halide-transferring iodophenyl group to such

a tetraazacyclophane failed because of relative instability and insolubility of the hosts.[88]

In the reaction of 2-(bromomethyl)naphthalene with sodium nitrite in the presence of the 34-membered host **72** (n = 3), an acceleration of the reaction by a factor of 20 was observed compared with the uncatalyzed reaction.[90] Also, the product distribution [R-ONO]/[R-NO_2] obtained with this ambident nucleophile changes from 0.5 : 1 to 0.16 : 1. This product control can be explained by an accumulation of the nitrite ions at the positively charged centers of the host, thereby favoring S_N2 reaction and resulting in attack on nitrogen rather than on oxygen.

With host molecules such as **82**, 1 : 1 complexes could also be obtained with aromatic guest substances that are not readily soluble in water:[91] perylene, fluoroanthrene, pyrene, durene, and azulene. The highest binding constant ($pK = 7.2$) was found for the perylene complex. The weaker binding of adamantanol in methanol and the lack of complex formation in dimethyl sulfoxide as solvent indicate that hydrophobic interactions are the decisive driving forces for this type of host/guest binding.

A unique feature of the hexalactam host compounds **85**–**87** is their ability to complex aliphatic guests such as cyclohexane and adamantane derivatives, in addition to aromatic guests, in acidic aqueous solution, as shown by ^{1}H-NMR spectroscopy.[87]

By combination of the various diphenylmethane hosts (cf. **62**, **72**, **78**) according to the oligolactam concept (cf. **83**–**89**), new hosts having lactam structures (**90**–**94**, **96**, **98**, **99**, **101**–**104**) and—by reduction of the lactams—amine structures (**95**, **97**, **100**) with 30- to 48-membered rings became available[92] (cf. Fig. 18).

If the amine nitrogen atoms are in the benzylic position, as in **95**, **97**, and **100**, rather than in the aryl position, as in the hosts of *Koga* et al. (e.g., **62**–**70**), the complexation ability is completely retained. The high-field ^{1}H-NMR shifts that are observed for different aromatic guests are often very large. Besides phenols and naphthols, aliphatic guest molecules such as *trans*-1,4-cyclohexanediol and *trans*-1,4-cyclohexanedicarboxylic acid are complexed, in particular, by the *o*-terphenyl hosts **98**–**100**.

However, the host substances **102**–**104**, which have been made more rigid by the introduction of triple bonds, do not exhibit high-field shifts under comparable conditions. Fluorescence spectroscopic comparisons of the binding of the guest 8-anilino-1-naphthalenesulfonic acid (ANS) to different hosts[92] support the ^{1}H-NMR results: replacement of the diphenylmethane unit in **63** by the more lipophilic *o*-terphenyl unit in **100** results in an increase of the complexation constant from $pK = 3.8$ to 4.3. Even the rings **102**–**104**, which contain triple bonds, are possible host substances for ANS, although weaker bonding results from increasing ring size.

Like the macrocycles **85**–**87**, the pyridyl-substituted hosts **92**, **94**, and **99** strongly catalyze the H/D exchange in 2,7- and 2,6-naphthalenediol.[93]

Diederich and *Dick* studied the macrobicyclic hosts **105** and **106** with regard to their ability to complex neutral arenes such as pyrene and naphthalene in aqueous solution in cavities (Fig. 20).[94] In weakly acidic solution, **105** has a nonpolar cavity since the solvation-mediating ammonium centers lie at the periphery of the host. Pyrene and naphthalene can be dissolved by **105** in water using solid/liquid extraction. The complexation constants are $pK = 6.6$ for pyrene and 4.1 for naphthalene. In the ^{1}H-NMR spectrum, the signals of the complexed arene are strongly high-field shifted. Presumably, the guest is oriented in the plane of **105**, which includes the three spiro carbon atoms. The exchange between host and pyrene is sufficiently slow so that the ^{1}H-NMR signals of the free and uncomplexed pyrene can be recognized.

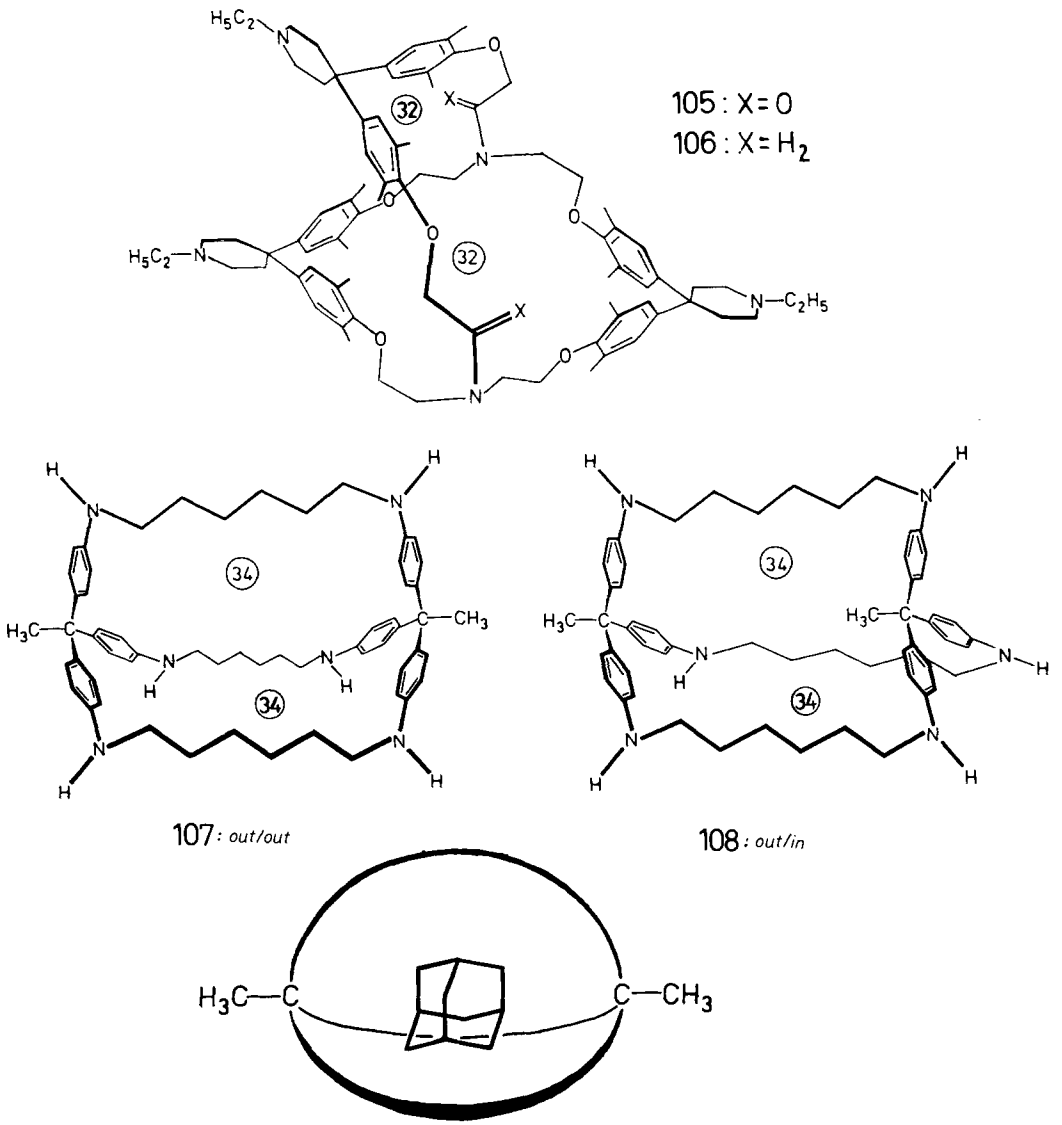
Easily available *in/out*-isomeric, spherical large-cavity compounds (**107** and **108**) were recently reported that differ only in cavity size and shape (Fig. 20);[95] their chemical constitutions and chemical properties are otherwise identical. Both hosts are able to complex polar aromatic compounds such as 2,7- and 2,6-naphthalenediol in acidic aqueous solution, as shown by the high-field ^{1}H-NMR shifts. Moreover, unsubstituted aromatic hydrocarbons such as naphthalene are complexed with similar binding constants by both hosts; however, the larger durene undergoes inclusion neither by **107** nor by **108**. Furthermore, with **107** but not with **108** it was possible for the first time to dissolve and efficiently complex a nonfunctionalized *aliphatic* hydrocarbon—adamantane—in aqueous medium by solid/liquid extraction.

This ability, which has up to now only been observed for cyclodextrins, and the marked differences in selectivity compared with the smaller and distorted cavity of the *out/in* isomer **108** are explained by the suitable size and shape of the host cavity of **107**, which is able to enclose the spherical adamantane completely. Accordingly, adamantanethiol is also complexed by **107** but not by **108**. A further confirmation of the different complexation abilities of the isomeric hosts is provided by the fact that the complexation constant of **107** with ANS ($pK = 4.6$) is considerably larger than that of **108** with ANS (4.0).

In contrast to **62**–**70** and to **108**, the *out/out* isomer **107** catalyzes the H/D exchange of the 1-protons of the guests 2,6- and 2,7-naphthalenediol. Presumably, **107** encloses the guest more favorably than **62**–**70** and **108**, resulting in activation of the 1-position.

Recently, the basket-shaped host molecules **109**–**111** were synthesized for the first time; these hosts have a bottom as well as a nearly 30-membered cyclic wall (Fig. 21).[96] The free host amine **111** forms the first inclusion complex with tetrahydrofuran (THF) in neutral water as shown by the high-field ^{1}H-NMR shifts of the THF protons and attempts to liberate the THF. ^{1}H-NMR investigations of the hexalactam **109** in deuterated glacial acetic acid as solvent with different phenols as guests did not result in any significant high-field shifts. On the other hand, an H/D exchange of each of the guest protons in the 1-position was observed for 1,3-naphthalenediol and, particularly, for resorcinol as guest substrates within a few minutes, but not for a large number of other phenols and naphthalenediols. No significant deuteration is observed with reference substances even after one day.

The water soluble paracyclophane **71**[97] permits discrimination between optically active isomers. It has a chiral hydrophobic cavity which is formed by two diphenylmethane units and by two C_4 bridges that are derived from



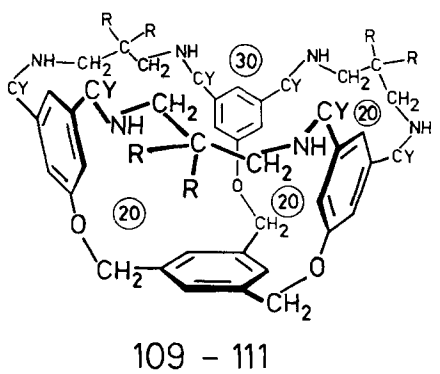


Fig. 20. Spherical large-cavity host compounds [94, 95] and drawing of the adamantane inclusion in **107**.

L-tartaric acid. Enantiomeric guest molecules containing hydrophobic moieties are selectively incorporated by the host to form diastereomeric host/guest compounds (chiral recognition[72]). Thus, for example, the ^{1}H-NMR signals of (*R*)- and (*S*)-mandelic acid or (*R*)- and (*S*)-1-amino-1-(1-naphthyl)ethane show different high-field shifts in a solution of **71** in acidic D_2O (pD = 1.2).[97]

109 - 111

Fig. 21. Basket-shaped host molecules [96]. **109**: Y = O, R = CH_3; **110**: Y = O, R = H; **111**: Y = H_2, R = CH_3.

The formation of a host/guest complex as a result of favorable steric and electronic adjustment is the first important step in enzymatic reactions (substrate discrimination). In order to go from host/guest chemistry to biomimetic chemistry, in which organic reactions are carried out analogously to enzyme-catalyzed reactions, further criteria must be fulfilled: a) suitable substrate orientation and positioning of the functional groups ("active sites") on the host; b) steric and/or electronic stabilization of transition states.[1,37,70]

A few cyclic onium compounds have been investigated with regard to their catalytic activity. Thus, for example, the tricyclic ammonium compound **77** accelerates the reactions of 2,4-dinitrofluorobenzene and iodomethane with azide ions by factors of 20 and 37, respectively, and kinetically controls the elimination of HBr from 2,3-dibromo-3-phenylpropionate.[98] The desolvation of the reaction partners and the stabilization of the anionic transition state are presumably of decisive importance here. The enzyme-like behavior of this so-called "artificial enzyme"[98] is emphasized by its substrate and reaction specificity and by the saturation kinetics.

The cyclophanes **112**–**114**, **118**, and **119** (Fig. 22) catalyze the hydrolysis of *p*-nitrophenyl esters of long-chained aliphatic carboxylic acids and sulfuric acids;[99] **54**–**56** catalyze the hydrolysis of the *p*-nitrophenyl and the α- and β-naphthyl esters of chloroacetic acid.[86, 100]

The amination of phenyl pyruvate to give phenylalanine is accelerated by the macrocycle **75** by a factor of 31 in comparison with pyridoxamine.[101]

The cyclophane **119**, with imidazole residues as functional auxiliary groups, catalyzes the extremely rapid liberation of *p*-nitrophenolate from *p*-nitrophenyl esters in neutral aqueous solution in the presence of $Cu^{2\oplus}$ ions.[102] Possibly, a $Cu^{2\oplus}$ ion is coordinated to one of the two imidazole rings and drives both the transacylation and the hydrolysis.[102]

In contrast to other cyclic ammonium salts (e.g., **63** · 4 HCl) and open-chained reference compounds,[93] the pyridyl-substituted macrocycles **85**–**87**, **92**, **94**, and **99**, the macrobicycle **107** · 6 HX, and the macrotricycle (hexalactam) **109** catalyze a substrate-selective, strongly accelerated H/D exchange in bound hydroxy aromatic compounds in acidic aqueous medium. Apparently, the flexible pyridinium side arms or the carbonyl oxygen atoms function as active sites for this catalysis. The enzymatic character of these phanes is shown clearly by their (cyclo)peptide-like structure and their ability to bind physiologically important metal cations.[87]

Finally, it should be pointed out that *onium* compounds are not only bound as hosts but also in a variety of ways as *guest* substances with suitable host compounds: *ammonium salts as guests* in crown-ether-like host compounds have been thoroughly investigated, particularly as regards enantiomeric differentiation and resolution.[103, 104] Physiologically relevant ammonium compounds could be enclosed by hosts of the crown-ether type as well as, only recently, by anionic large-cavity compounds;[104] non-heterocyclic polyanions have also been used.[105]

7. Outlook

Although host/guest chemistry of heterocationic organic compounds is still in its infancy, the results of the investigations show that this field of research offers a valuable and versatile approach for present and future ways of looking at problems. As a result of the broad applicability of the onium clathrate concept and the fact that suitable host compounds are easy to synthesize, this host family may develop into one of the most widely used clathrate-forming systems and will be useful to both basic and applied research. Furthermore, the ready availability of completely synthetic chiral onium hosts and pure enantiomeric host compounds from the "pool" of optically active natural compounds allows for the first time the application of a clathrate family in the field of enantioselective host/guest systems.

Macrocyclic onium compounds with "exohydrophilic" and "endolipophilic" cavities are already established as simple, abiotic enzyme and receptor models. Even though the "functions" of the completely synthetic catalysts still do not even begin to approach the complexity of biological enzymes and receptors, individual important features are imitated in a significant way. Substrate discrimination (selectivity) and structure changes (induced fit) are of primary interest as initial steps in imitating receptor functions and enzyme action. Substrate orientation and catalytic activity—if necessary, with the aid of functional groups as active sites—are further "minimal characteristics" of enzyme models.

But who does not think in connection with synthetic enzymes of their use in technical processes? With such specific catalysts, chemical transformations—like enzymatic reactions—can be carried out more swiftly, under milder conditions, with higher yields, and fewer by-products, and, if necessary, with stereochemical control.

We thank Prof. Dr. H. Puff and Dr. W. Schuh for numerous X-ray analyses. We are grateful to Dipl.-Chem. U. Mül-

ler, Dr. W. Bunzel, Dr. H.-P. Josel, and Dr. A. Engel for experimental data and to Dr. E. Weber for valuable suggestions.

[16] For nomenclature and classification of host/guest compounds, see a recent suggestion: E. Weber, H.-P. Josel, *J. Incl. Phenom. 1*, 79 (1983).
[17] a) In order to characterize complex/clathrate intermediate structures more clearly, the terms "coordinato clathrate" for host/guest compounds with dominant clathrate character and "clathrato complex" for inclusion compounds in which bonding coordinations dominate have been introduced [16]. Accordingly, those host/guest situations are called "coordinato clathrates" (coordination-supported clathrates) whose bond relations are intermediary between those of coordination compounds (complexes) and those of crystal lattice inclusion compounds (clathrates). b) Thus, for example, in the known phase-transfer catalaysts [13], no fixed cavities or distinct niches are present [13]. Through specific conformational folding of the molecule, however, niches can arise under certain circumstances. Compare also the introduction of lipophilic steroid units into open chained ammonium compounds in order to make them more rigid: J. P. Guthrie, P. A. Cullimore, R. S. McDonald, S. O'Leary, *Can. J. Chem. 60* (1982) 747.

Transition Metal Polysulfides: Coordination Compounds with Purely Inorganic Chelate Ligands

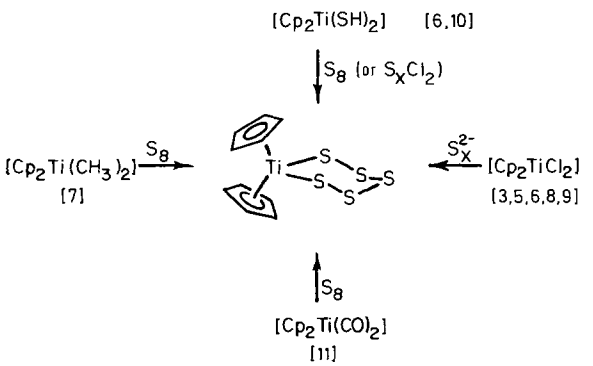
By Mark Draganjac and Thomas B. Rauchfuss*

It has been long known that certain transition metal sulfides dissolve in aqueous ammonium polysulfide. Although it was assumed that they thereby formed metal polysulfides, attention was first paid to such compounds only a few years ago. In recent years a host of new complexes with polysulfido chelate ligands have been isolated and characterized. The complexes are of interest not only regarding their structure and reactivity but also in view of their potential uses; they can be used for the directed preparation of sulfur rings of a given size, and there are indications that they will find applications in catalysis.

1. Introduction

The topic of this review, which covers an interface between main group and coordination chemistry, was officially born about 80 years ago with a report on $(NH_4)_2PtS_{15}\cdot 2H_2O$ and related compounds.[1] However, it was not until the 1960's that synthetic, spectroscopic, and structural techniques had evolved sufficiently to allow the systematic study of metal complexes of polysulfides. As coordination chemists turn increasingly toward organic chemistry in their search for new ligands, the discovery or rediscovery of a new class of inorganic chelating agents is a relatively rare phenomenon.

This review covers the syntheses, structures, and reactivity of molecular transition metal compounds containing polysulfido ligands. Important aspects of this chemistry in-



[*] Prof. T. B. Rauchfuss, Dr. M. Draganjac
School of Chemical Sciences, University of Illinois
Urbana, IL 61801 (USA)

volve compounds with disulfido ligands. The coordination chemistry of the disulfides has been reviewed recently[2] and will be discussed only insofar as it directly relates to polysulfides. The review is divided into two portions, the first half provides a survey of the syntheses and structures of the polysulfido complexes reported to date. In the second half, we discuss the reaction chemistry of two important classes of these compounds.

2. Synthetic and Structural Aspects of Transition Metal Polysulfides

2.1. The Titanium and Vanadium Triads

Cp_2TiS_5 ($Cp=\eta^5$-C_5H_5), first reported by *Samuel*[3] and *Schmidt*,[4] is one of the most easily prepared polysulfide complexes and has been the subject of numerous studies. With some refinements,[5] *Köpf* and *Schmidt*'s synthesis[6] from aqueous ammonium polysulfide and Cp_2TiCl_2 remains the most convenient way to prepare this compound on a large scale. Several other synthetic routes are available,[7-11] the diversity of which is testament to the stability of this complex and reflects the considerable level of interest in its chemistry (Scheme 1).

Scheme 1. Synthesis of Cp_2TiS_5.

Cp_2TiS_5 is a dark red, practically odorless, crystalline solid which is stable towards air and water. While this compound is sufficiently soluble for many synthetic purposes, the alkyl substituted derivatives such as the MeC_5H_4 and $iPrC_5H_4$ analogues are considerably more soluble and are also easy to prepare.

Early work suggested that the size of the polysulfide ring in the Cp_2TiS_x system could be adjusted by the nature of the polysulfide reagent.[12] Subsequently, these reports were shown to be incorrect; the reaction of Cp_2TiCl_2 with Na_2S_x ($x<5$) simply leads to diminished yields of the pentasulfide complex and negligible quantities of S_2 and S_3 derivatives.[8] This also holds in the case of many other polysulfido chelates: Very rarely can kinetically stabilized polysulfido chelates be selectively prepared through the use of sulfur transfer reagents. A possible exception to this rule, at least for a selenium system, is the reaction of Li_2Se_2 with $(MeC_5H_4)_2TiCl_2$, which affords the dimeric complex $[(MeC_5H_4)_2TiSe_2]_2$ in excellent yield with little formation of the known pentaselenido complex[13] [Eq. (1)].

$$2\ (CH_3C_5H_4)_2Ti\begin{matrix}Cl\\Cl\end{matrix} + 2\ Li_2Se_2 \xrightarrow[-4\ LiCl]{} (CH_3C_5H_4)_2Ti\begin{matrix}Se\text{–}Se\\Se\text{–}Se\end{matrix}Ti(CH_3C_5H_4)_2 \quad (1)$$

On the other hand, in the case of kinetically labile polysulfido complexes, such as those of copper and zinc, the size of the MS_x ring appears to be a function of the ratio of metal to total sulfur and cannot otherwise be controlled.

Two crystalline modifications of Cp_2TiS_5 have been characterized by single-crystal X-ray diffraction and the results of both structural studies are essentially in agreement.[14,15] The structure of this prototypal polysulfido complex is reproduced in Figure 1.

The TiS_5 ring adopts the chair conformation and the S–S distances and angles are within the range observed for other polysulfides, including S_8 itself.[16] Steric factors involving $Cp\cdots S$ interactions appear to be significant, but it has not proven necessary to invoke special electronic effects to rationalize the structural details. The stability of the S_5^{2-} chelate is a consequence of the 95° S–Ti–S angle and the Ti–S distance of 2.45 Å;[15] for comparison the S–S–S angle in α-S_8 is 107° and the S–S distance is 2.048 Å.[16]

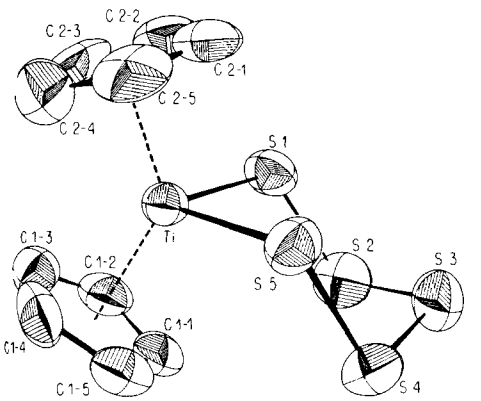


Fig. 1. ORTEP plot of $(C_5H_5)_2TiS_5$ [15].

NMR spectroscopic findings suggest that the chair conformation of the TiS_5 ring is retained in solution.[6] The energetics of this ring inversion, as analyzed by variable temperature NMR spectroscopy, is approximately 76 kJ/mol.[17]

As already mentioned, substitution of the Cp ligands generally enhances the solubility of polysulfides of the group IV elements without impinging on the structural or reactivity characteristics of the polysulfido chelate. An important exception, however, is provided by the decamethyltitanocene derivative, which is obtained as the monomeric trisulfide $(C_5Me_5)_2TiS_3$[18] (Fig. 2).

No evidence has been obtained for the S_5 or S_4 derivatives of the sterically encumbered $(C_5Me_5)_2Ti$ moiety. The barrier for ring inversion of the trisulfidotitanium complex and its zirconium analog is 40 kJ/mol, about half that for the corresponding Cp_2TiS_5 species.

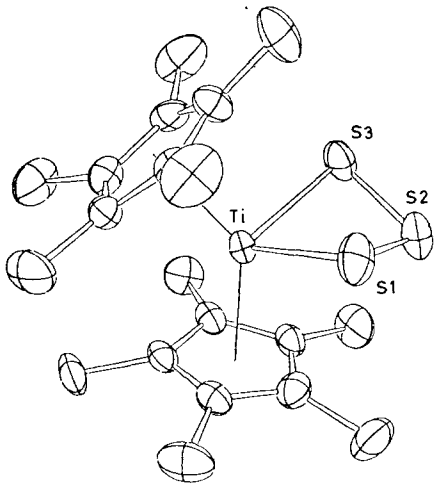

Fig. 2. ORTEP plot of $(C_5Me_5)_2TiS_3$ [18].

Steric factors and not electronic effects dictate the size of the TiS_x rings. This assertion is supported by the fact that, in contrast to the decamethyltitanocene complex, "Cp_2TiS_3" exists as a stable eight-membered Ti_2S_6 ring.[19] 1,5-$[(Cp_2Ti)_2S_6]$ and the six-membered ring compound 1,4-$(Cp_2Ti)_2S_4$ are formed upon desulfurization of the pentasulfido complex. The influence of the steric bulk of the substituents on ring size is often observed in organic systems and, to a lesser extent, in nonmetal rings as well.[20]

In the solid state, 1,5-$[\{(MeC_5H_4)_2Ti\}_2S_6]$ adopts the chiral D_2 conformation (Fig. 3). This same geometry is retained in solution. Thus, its ^{1}H-NMR spectrum shows four resonances indicative of the absence of a time-averaging of the halves of the MeC_5H_4 rings; at higher temperatures these resonances begin to merge, but coalescence has not been observed. With a visible absorption maximum of 610 nm, the blue Ti_2S_6 species somewhat resembles two well-known sulfur compounds, S_3^-[21] and S_8^{2+}.[22] $[Cp_4Ti_2S_6]$ may in fact be related to S_8^{2+} since its conformation lends itself to the formation of an incipient transannular S···S interaction as observed in S_8^{2+}. Such interactions would be induced by the electron-deficient character of the 16-electron titanium centers which possess acceptor orbitals suitably positioned for titanium-sulfur multiple bonding.

Other group IV analogues of Cp_2TiS_5 are known and do not appear to differ structurally. Since the precursor compounds Cp_2ZrCl_2 and Cp_2HfCl_2 are fairly moisture sensitive, the preparation of their polysulfides precludes the use of the aqueous reagents used for the titanium compound. *Shaver* and *McCall* solved this problem through recourse to anhydrous polysulfide reagents generated by using Li-BEt_3H ("superhydride")[23] [Eq. (2)].

$$2\,LiBHEt_3 + 5/8\,S_8 \longrightarrow Li_2S_5 + H_2 + 2\,BEt_3$$
$$Cp_2MCl_2 + Li_2S_5 \longrightarrow Cp_2MS_5 + 2\,LiCl\ (M = Ti, Zr, Hf, V) \qquad (2)$$

This superhydride methodology[24] continues to prove extremely versatile for the preparation of early transition metal polysulfido (and selenido) complexes. The free energy barriers for inversion of the three Cp_2MS_5 compounds are 76.3 (M = Ti), 48.6 (M = Zr), and 58.0 kJ/mol (M = Hf).[23]

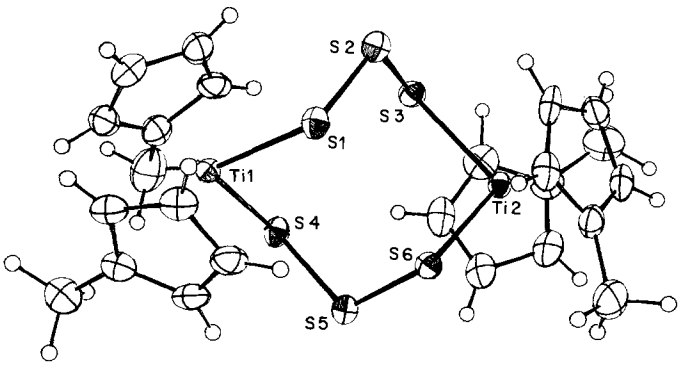

Fig. 3. ORTEP plot of $[(MeC_5H_4)_2TiS_3]_2$ [19].

There is no obvious explanation for these variations in the ring inversion barriers.

The preparation of the black Cp_2VS_5 is completely analogous to that for the titanium complex.[15,25] The structural and spectroscopic characterization of this 17-electron complex was instrumental in determining the spatial distribution of the frontier orbitals of Cp_2ML_2 compounds.[26] Structurally, this compound is isomorphous with the titanium complex, though its S-M-S angle is smaller by 5°. As a result of this angular compression, decamethylvanadocene forms a stable S_2[27] complex, unlike the analogous titanium system where the S_3 species is formed.

No molecular polysulfide chelates of niobium or tantalum have been reported so far, but further investigations in this direction are justified, for two reasons: The first monometallic S_2 complex prepared was Cp_2NbS_2Cl[28], and, as a rule, disulfido complexes presage the existence of related, stable polysulfido chelates. A second incentive for further study of niobium polysulfides derives from possible connections with the solid state chemistry of niobium and tantalum polyselenides and polytellurides, which exhibit unusual electrical properties. The one-dimensional polymer Nb_2Se_9 features Nb_2Se_4 octahedra bridged by Se_5 units.[29]

2.2. The Chromium Triad

Binary metal molybdenum sulfide chemistry represents one of the most fruitful specialties in this area of coordination chemistry.[30] The present inventory of known molecular binary molybdenum sulfides includes $[MoS_4]^{2-}$,[31] $[MoS(S_4)_2]^{2-}$,[32] $[Mo_2(\mu\text{-}S_2)_2(S_2)_4]^{2-}$,[33] $[Mo_2(\mu\text{-}S)_2(S)_2(S_2)_2]^{2-}$,[34] $[Mo_2(\mu\text{-}S)_2(S)_2(S_2)(S_4)]^{2-}$,[32b,35] $[Mo_2(\mu\text{-}S)_2(S)_2(S_4)_2]^{2-}$,[32b] $[Mo_3(\mu\text{-}S)_4(S)_5]^{2-}$,[36] and $[Mo_3(S)(S_2)_6]^{2-}$;[37] note the existence of two structural isomers of "$[Mo_2S_{12}]^{2-}$" (Fig. 4).

Three of these compounds contain S_4 ligands. All of the dimeric compounds are clearly interrelated structurally,

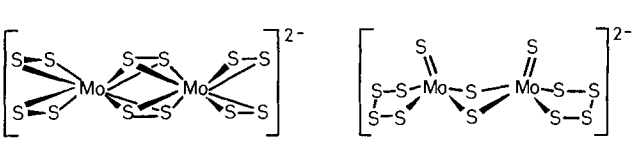

Fig. 4. Two isomers of $[Mo_2S_{12}]^{2-}$.

and, to a limited extent, they appear to be interconvertible.

The reaction of $[MoS_4]^{2-}$ with sources of elemental sulfur affords the $[MoS_9]^{2-}$ ion. The most convenient source of sulfur is dibenzyl trisulfide, and the product obtained in the reaction can be isolated as the PPh_4^+[38] or NEt_4^+[32] salt, both of which have been characterized by X-ray diffraction. Furthermore, the oxo ion $[MoOS_8]^{2-}$ can be prepared either by hydrolysis of $(Et_4N)_2[MoS_9]$[32] or by reaction of $[MoO_2S_2]^{2-}$[38] or $[MoOS_3]^{2-}$[39] with elemental sulfur. In the $[MoS_9]^{2-}$ ion, molybdenum is coordinated in a distorted square pyramidal fashion by a terminal sulfide and two bidentate S_4^{2-} ligands[32] (Fig. 5). The Mo-S1 distance of 2.12 Å is 0.20–0.25 Å shorter than the Mo-S2 (S2′, S5, S5′) distances. Although it is consistent with substantial multiple bond character it is one of the longest Mo-S(terminal) distances known.

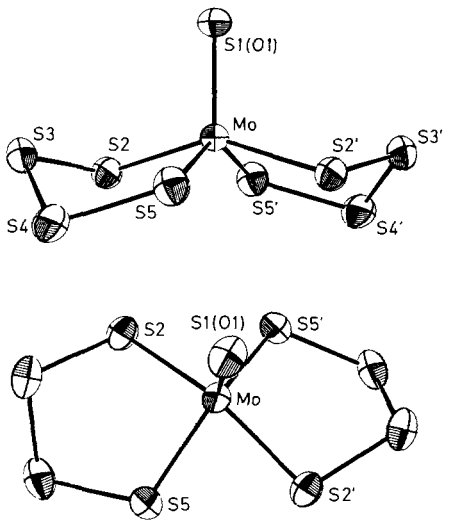

Fig. 5. ORTEP plots of $[MoS_9]^{2-}$ and $[MoOS_8]^{2-}$ [32]. Top: side view; bottom: plan view.

The Mo-S(S_4) distances are only slightly changed upon replacement of the terminal sulfide by an oxide. The S_4 ligands in $[MoX(S_4)_2]^{2-}$ exhibit the unusual envelope conformation, which appears to result from nonbonded contacts between the basal sulfur atoms. In contrast, the half-chair conformer is observed for the pseudotetrahedral species Cp_2MoS_4[40,41] and $[Zn(S_4)_2]^{2-}$, which may be less sterically crowded.

There has been some interest in elucidating the factors responsible for the alternation in S–S bond distances in tetrasulfido chelates. *Coucouvanis* et al. noted that the central S–S bond lengths in $(Et_4N)_2[MoS_9]$ are ca. 0.13 Å shorter than the remaining S–S bonds.[32] In complexes other than $[MoS_9]^{2-}$, the S2–S3 distances are typically 0.06 Å shorter than the flanking S1–S2 and S3–S4 distances.[42] In contrast, no such alternation is observed in the solid state structure of Na_2S_4, and the effect is less pronounced in Cp_2WS_4.[40b] The results of a qualitative molecular orbital calculation on $Pt(S_4)(PH_3)_2$ are consistent with the presence of a weak butadiene-like π-network in the S_4 ligand.[42] π-Donation from S_4^{2-} to the metal effectively depopulates the HOMO, thereby lessening the antibonding interaction between S2 and S3.

Reaction of $[Mo_2(\mu\text{-}S_2)_2(S_2)_4]^{2-}$ with PhS^- affords the unsymmetrical $[Mo_2(S)_2(\mu\text{-}S)_2(S_2)(S_4)]^{2-}$ ion, which can be isolated as the $AsPh_4^+$ salt (Fig. 6). In this compound the coordination sphere of the Mo_2S_4 core is completed by di- and tetrasulfido chelates. Although a crystallographic disorder problem limits the accuracy of the structural data, it is clear that the S_4 chelate adopts a puckered conformation with little bond alternation.[35]

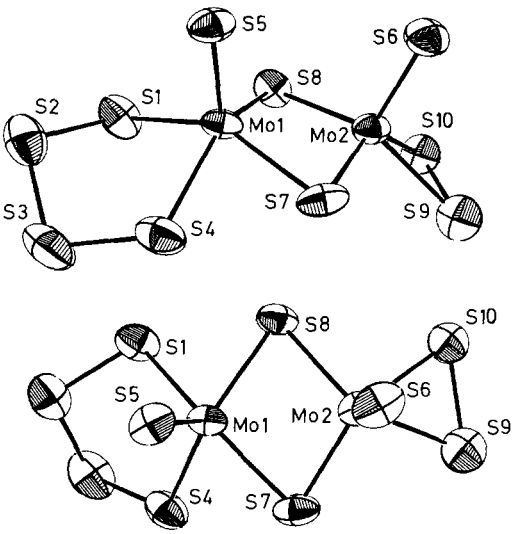

Fig. 6. ORTEP plots (two views) of $[Mo_2S_{10}]^{2-}$ in $(PPh_4)_2[Mo_2S_{10}]$ [32b].

The structure of the PPh_4^+ salt of $[Mo_2S_{10}]^{2-}$, obtained from dibenzyl trisulfide and $(PPh_4)_2[MoS_4]$, is also structurally disordered, but in a different way: here, one-fourth of the disulfido ligands are replaced by an S_4 ligand owing to cocrystallization of $[Mo_2S_{12}]^{2-}$. The Mo–S distances in $[Mo_2S_{10}]^{2-}$ appear to be similar for both ends of the molecule, suggesting that, at least in this case, the electronic effects of the tetrasulfido and disulfido ligands are comparable.[32b,35]

Müller's group has isolated a number of unusual compounds from various combinations of hydroxylamine, $[MoS_4]^{2-}$, and sulfur.[43] One such species is $[Mo_2(NO)_2(S_2)_3S_5(OH)]^{3-}$, which features an S_5 unit strapped across the Mo_2OS_2 core, forming the basket-like structure shown in Figure 7.[44]

Tetrathiomolybdate is not only reactive towards most compounds which contain S–S bonds, but also toward a host of related nonmetal rings and cages.[45] A reaction of

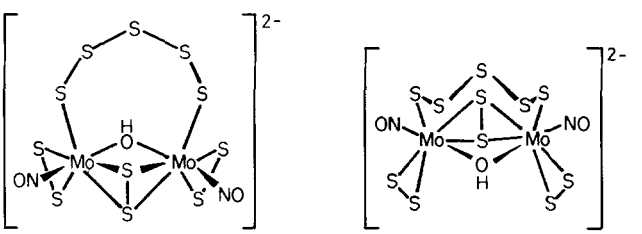

Fig. 7. Two views of $[Mo_2(\mu\text{-}S_2)(\mu\text{-}OH)(\mu\text{-}S_5)(NO)_2(S_2)_2]^{3-}$ [44].

this type, which has afforded a structurally spectacular polysulfur compound, involves As_4S_4[46] and $(PPh_4)_2[MoS_4]$. The product of this reaction is the "crowned" complex shown in Figure 8. The oxo ligands arise from hydrolysis during work-up.

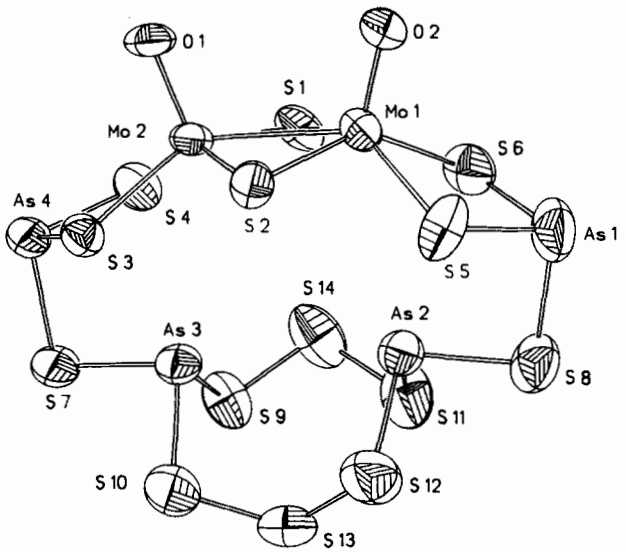

Fig. 8. Structure of the $[Mo_2O_2S_2(As_2S_{12})]^{2-}$ ion [47].

The compound, which has been characterized by X-ray diffraction, features a $Mo_2O_2S_2$ core strapped by the novel $[As_4S_{12}]^{4-}$ chelating unit. This dimolybdenum cage compound reacts readily with $[MoS_2O_2]^{2-}$ to give $[Mo_4O_4As_4S_{14}]^{3-}$, which is thought to possess a 16-membered ring.[47]

Reaction of Cp_2MH_2 or $Cp_2M(SH)_2$ (M = Mo, W) with elemental sulfur affords the tetrasulfido complexes Cp_2MS_4.[41] The rationale for this stoichiometry (vis-a-vis the Cp_2MS_5 stoichiometry observed for Ti, Zr, Hf, and V) invokes the stereochemically important, nonbonding pair of valence electrons in an orbital which leads to compression of the S-M-S angle. The same argument explains the differing metal : sulfur ratio in the sulfidodecamethylmetallocenes of titanium and vanadium.[27]

2.3. The Manganese Triad

Relatively little work has been carried out in this area. $[Mn(SPh)_4]^{2-}$ reacts with excess dibenzyl trisulfide to afford crystals of $(PPh_4)_2[MnS_{11}]$, which has been structurally characterized (Fig. 9). The X-ray structural analysis reveals a tetrahedrally coordinated Mn center bound to S_5 and S_6 ligands, the positions of which are interposed in the lattice.[48]

Herberhold et al. have described the isolation of three sulfido complexes, $CpRe(CO)_2(S_2)$, $Cp_2Re_2(CO)_4(\mu\text{-}S)$, and $Cp_2Re_2(CO)_2(\mu\text{-}S_2)(\mu\text{-}S_3)$, from the reaction of $CpRe(CO)_3$ with elemental sulfur or carbonyl sulfide. The latter complex consists of two CpRe(CO) centers bridged by both a disulfide and the relatively rare trisulfido ligand[49] (Fig. 10). This chiral dimer is formally electron-deficient but the Re-S distances are quite short,[50] indicating substantial S to Re π-donation.

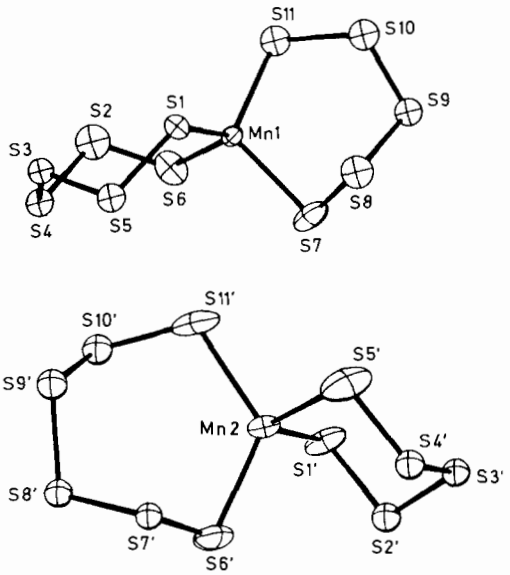

Fig. 9. Two views of the structure of the $[MnS_{11}]^{2-}$ ion [48].

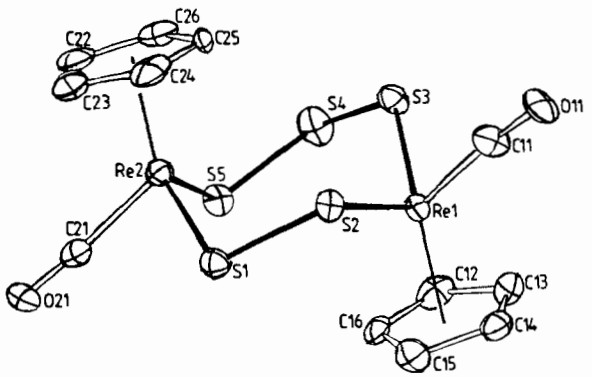

Fig. 10. ORTEP plot of $Cp_2Re_2(CO)_2(\mu\text{-}S_2)(\mu\text{-}S_3)$ [48].

2.4. The Iron Triad

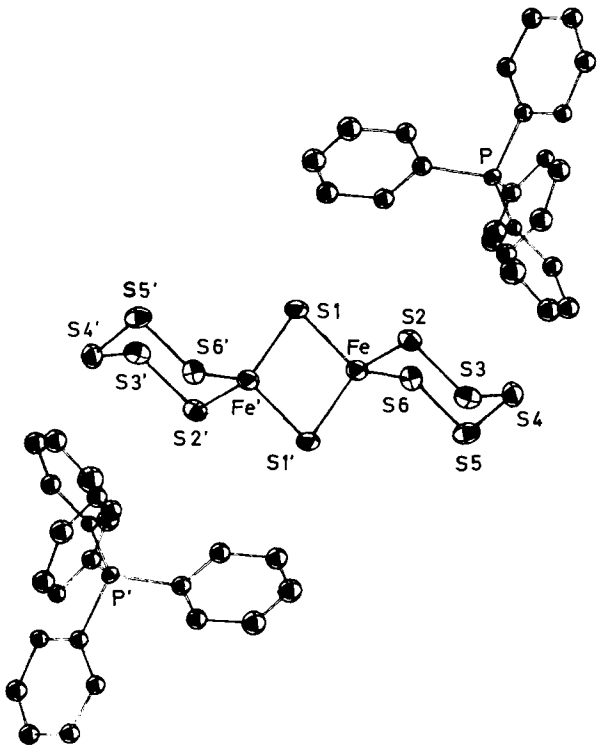
The use of dibenzyl trisulfide as a reagent for the preparation of sulfur-rich complexes is illustrated by *Coucouvanis*' preparation of the $[Fe_2S_{12}]^{2-}$ species[51a] (Fig. 11).

In this and related applications the organic trisulfide functions as a conveniently soluble source of inorganic sulfur, which oxidatively replaces labile mercaptido li-

$$[Fe(SPh)_4]^{2-} \xrightarrow{RzSz} [Fe_2(\mu\text{-}S)_2(S_5)_2]^{2-} \quad (3)$$

gands [Eq. (3)]. Each iron in $[Fe_2S_{12}]^{2-}$ is tetrahedrally coordinated to four sulfur ligands[51b] similar to that found in the naturally occurring ferredoxin dimers and their synthetic analogues.[52] A related compound is $[(S_5)Fe(MoS_4)]^{2-}$[53] (and the W analogue), which, in turn, is a close relative of $[Cl_2FeS_2MoS_2]^{2-}$,[54] emphasizing the pseudohalide character of the polysulfido ligand. An X-ray structural analysis of $(PPh_4)_2[FeMoS_9]$ revealed the presence of ca. 30% occupancy of the decasulfide, $[FeMoS_{10}]^{2-}$, which contains an S_6 chelate.[53b]

The absence of a mononuclear iron polysulfide is the major gap in the coordination chemistry of polysulfides.



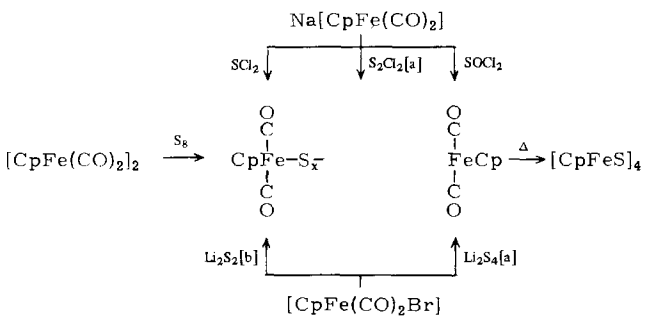


Fig. 11. ORTEP plot of $(PPh_4)_2[Fe_2S_{12}]$ [51a].

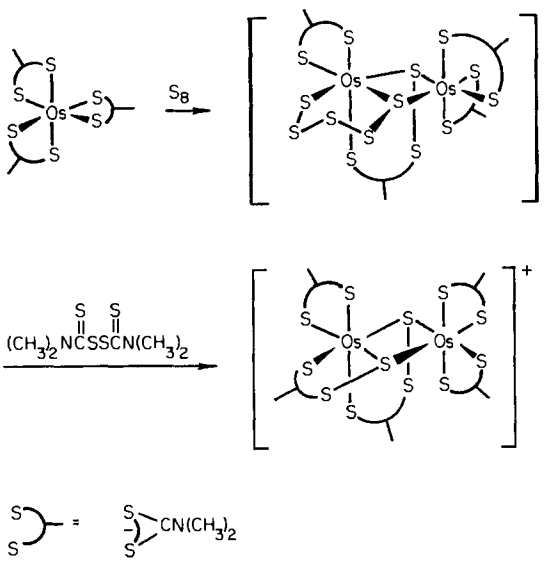
On the basis of the results discussed in this review a pseudo-tetrahedral species such as $[Fe(S_6)_2]^{2-}$ might be expected to be stable.[55] The most abundant binary iron sulfide, iron pyrite, features octahedral iron bound to six disulfide ligands. Another important sulfur-rich compound of iron is marcasite, again featuring octahedral iron bound to six disulfide ligands.[56] These minerals do not dissolve in ammoniacal polysulfide solutions.



In a simple and instructive study of organometallic polysulfides, *McAllister* et al. prepared members of the series $[CpFe(CO)_2]_2S_x$, where x = 1–4 (Scheme 2). It is necessary to conduct these reactions at low temperatures in order to minimize redox reactions. The structures of the trisulfido and tetrasulfido complexes were determined by single-crystal X-ray methods.[57] The trisulfido complex undergoes decarbonylation in refluxing toluene, affording the well known[58] cubane $Cp_4Fe_4S_4$.

The two known examples of polysulfidoosmium complexes have both set precedents. The compound

Scheme 2. Synthesis of $[CpFe(CO)_2]_2S_x$. [a] x = 3, 4. [b] x = 2, 3. Not specified: x = 3.

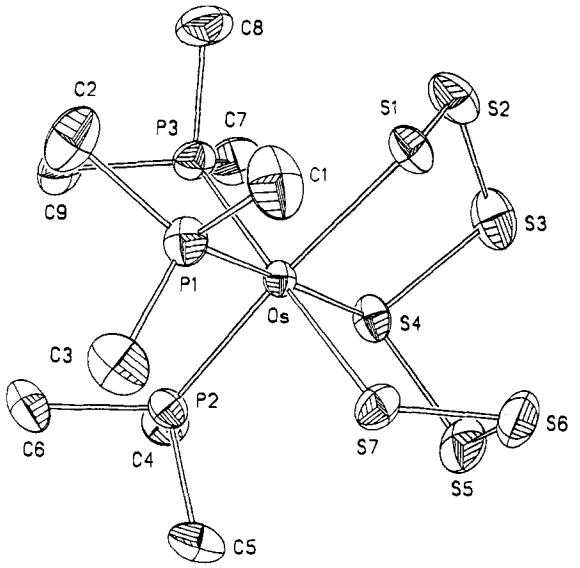
$Os_2(Me_2dtc)_3(Me_2dtcS)(S_5)$, ($Me_2dtc$ = *N*,*N*-dimethyldithiocarbamate) was obtained in high yield on reaction of elemental sulfur with $Os(Me_2dtc)_3$.[59] In the dinuclear compound one finds two octahedral Os^{III} centers bridged by one end each of the S_5^{2-} ligand and a perthiocarbamate. Judging by the structural parameters, the bridging interaction does not seem to have any major effect on the S–S bonds. The pentasulfido complex is an intermediate in the formation of the bis(trithiocarbamate) complex, $[Os_2(Me_2dtc)_3(Me_2dtcS)_2]^+$, as shown in Scheme 3.

Scheme 3. Synthesis of $Os_2(\mu\text{-}S_5)(\mu\text{-}Me_2dtcS)(Me_2dtc)_3$ and its reaction with tetramethylthiuram disulfide yielding $[Os_2(Me_2dtcS)_2(Me_2dtc)_3]^+$.

The clean formation of a trithiocarbamato complex on reaction of the pentasulfido species with thiuram disulfide (but not dithiocarbamate anion) implicates polysulfido intermediates in the formation of the sulfur-rich trithiocarbamate ligands. Related complexes may function as sulfur transfer agents in the metal-catalyzed vulcanization of polyolefins.[60]

The compounds $M(PMe_3)_3(PMe_2CH_2)H$ (M = Ru, Os) are interesting substrates for oxidative addition chemistry because they are sources of the exceptionally nucleophilic 16-electron $M(PMe_3)_4$ moieties[61] (which are isoelectronic with $[Ir(R_2PCH_2CH_2PR_2)_2]^+$). Reaction of the ruthenium and osmium phosphane complexes with elemental sulfur initially affords products of the formula $M(PMe_3)_3S_6$, which upon recrystallization give $M(PMe_3)_3S_7$. These are the only known examples of heptasulfido complexes and are particularly novel because the S_7 ligand is coordinated in a tridentate manner (Fig. 12).

The ^{31}P-NMR spectrum of the compound is indicative of an AB_2 system. However, the dynamics have not yet been studied in detail. The two S–S bonds to the central sulfur are unusually long (2.20 and 2.15 Å).[62] In contrast, even though S_8^{2+} has a similar conformation all of the S–S bond lengths are within the normal range of 2.05 Å. This osmium compound may represent a model for the early stages of the reaction of S_8 with metals. To a certain extent this S_7 ligand resembles the tridentate S_4N_3 ligand found in $[PtCl(S_4N_3)]$.[63]



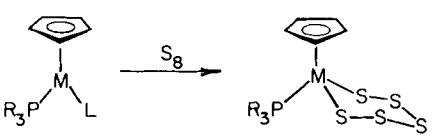


Fig. 12. ORTEP plot of $OsS_3(PMe_3)_3$ [62].

2.5. The Cobalt Triad

Several classes of polysulfido chelates have been described for the cobalt triad: anionic binary sulfides, cyclopentadienyl derivatives, and those containing phosphane chelates. Binary sulfido-cobalt complexes have not yet been reported, and, though the species $[M(S_5)_3]^{3-}$ (M = Ir, Rh)[64-66] and $[RhS_{10}]^{-}$[65] have been described, they remain poorly characterized. There is little doubt that some very novel chemistry is involved here, and increased activity in this area can be anticipated following recent reports that rhodium and iridium sulfides are good hydrodesulfurization catalysts.[67]

Reaction of $CpM(PR_3)(L)$ (M = Co,[68] R = Me, L = CS_2; M = Rh,[69] R = Ph, L = CO) with elemental sulfur furnishes the oxidative addition product $CpM(PR_3)(S_5)$ in good yields [Eq. (4)].

(4)

Both the trimethylphosphanecobalt and triphenylphosphanerhodium compounds have been structurally characterized. These compounds are relatives of Cp_2TiS_5, in which a Cp in the latter has been replaced by a phosphane ligand.

The first structurally characterized molecular S_2 complex was prepared from $[Ir(Ph_2PCH_2CH_2PPh_2)_2]^+$ and elemental sulfur;[70] related compounds containing selenium have also been described.[71] Recently, *Ginsberg* and coworkers have examined the addition of Se_8 to the very basic $[Ir(dmpe)_2]^+$ (dmpe is 1,2-bis(dimethylphosphino)ethane); $[Ir(Se_4)(dmpe)_2]^+$, which features an Se_4 chelate, is formed.[72] (A related S_4 complex is p_3CoS_4, in which p_3 is the tripod ligand 1,1,1-tris(diphenylphosphinomethyl)-ethane.[73]) Upon treatment with phosphane desulfurizing agents, $[Ir(Se_4)(dmpe)_2]^+$ is converted into the Se_2 complex.[72] These and other observations suggest that polychalcogen chelates may in fact be intermediates in the formation of other mono- and dichalcogenido complexes. In support of this theory, one observes that the kinetically stabilized products obtained from the reactions of low valent metal complexes with S_8 and Se_8 generally contain more E–E bonds (E = S, Se) than are found in thermally equilibrated systems. Some particularly notable examples of such kinetically stabilized species (in addition to $[Ir(Se_4)(dmpe)_2]^+$) are $[MoS_9]^{2-}$,[32] $[(C_5Me_5)_2Mo_2(S_2)_5]$,[74] $[(C_5Me_5)_2Mo_2(S)_2(S_2)]$,[75] and $[Mo_2(S_2)_6]^{2-}$.[33]

2.6. The Nickel Triad

Several examples of polysulfido chelates can be found in this triad, some of which date back to 1903. The structural characterization of *Hofmann*'s and *Höchtlen*'s $(NH_4)_2PtS_{15}\cdot 2H_2O$ in 1967[76] was a major turning point in the development of this area of chemistry.

There are four principal structural types for the polysulfides of this triad. Preeminent is $[Pt(S_5)_3]^{2-}$, which consists of a Pt(IV) moiety octahedrally coordinated to three bidentate S_5^{2-} ligands (Fig. 13).

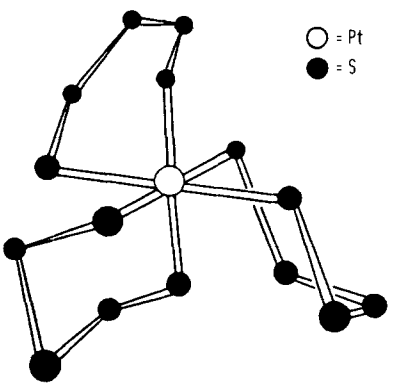

Fig. 13. Structure of the $[PtS_{15}]$ ion (see M. Schmidt, *Angew. Chem. 85* (1973) 474; *Angew. Chem. Int. Ed. Engl. 12* (1973) 445).

In the crystallographically characterized potassium[77] and ammonium[76] salts, the chelate rings adopt a chair conformation. ^{195}Pt-NMR studies on methanol solutions of $[Pt(S_5)_3]^{2-}$ indicate the presence of a 17.2 : 1 mixture of diastereoisomers which are thought to arise from the presence of both $(chair)_3$ and $(chair)_2(boat)$ conformers.[78] Unlike the situation for organic chelates, conformational diastereoisomers are expected to be common in polysulfido complexes because of the high barriers for rotation about S–S bonds. *Gillard* et al. have reported the partial optical resolution of $[Pt(S_5)_3]^{2-}$, thereby providing a very rare example of an optically active inorganic molecule.[79]

Desulfurization of $[Pt(S_5)_3]^{2-}$ with S^{2-}, SO_3^{2-}, PPh_3, and OH^- yields the $[PtS_{10}]^{2-}$ ion, which can be isolated as its water-soluble potassium and ammonium salts or its organic-soluble tetraalkylammonium salts.[80,81] It is probable that $[PtS_{10}]^{2-}$ consists of square planar Pt^{II} bound to two S_5^{2-} chelates. Should these S_5 chelates adopt the chair conformation, then the ^{195}Pt-NMR spectrum would reveal the presence of a 1 : 1 mixture of two diastereoisomers.

Further treatment of $[PtS_{10}]^{2-}$ with triphenylphosphane yields the well characterized square planar complex $Pt(S_4)(PPh_3)_2$,[80,82] which can also be prepared from elemental sulfur and $Pt(SH)_2(PPh_3)_2$[83] or $Pt(PPh_3)_3$.[42,84] There are a large number of closely related species in this class of compounds.[85]

In the early 1960's, *Schrauzer* and *Mayweg* pointed out the differing reactivities of stoichiometric and nonstoichiometric (sulfur-rich) nickel sulfides.[86] Very recently, the first binary polysulfidonickel complex, $(Et_4N)_2[Ni(S_4)_2]$, was reported by two groups[48,87] (Fig. 14).

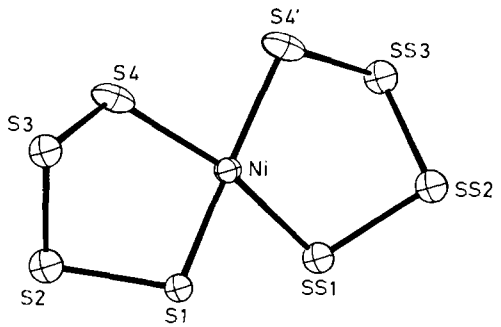

Fig. 14. ORTEP plot of the $[Ni(S_4)_2]^{2-}$ anion in $(Et_4N)_2[Ni(S_4)_2]$ [48]. The atoms marked SS belong to one of the two crystallographically disordered S_4^{2-} ligands which take up the same place and have atom S4' in common.

The complex can be prepared metathetically using polysulfide ions[87] or with the neutral sulfur transfer agent dibenzyl trisulfide.[48] The anion consists of square planar nickel; and the palladium complex[87] is presumably quite similar. The complex $[Ni(S_4)_2]^{2-}$ is quite reactive towards carbon disulfide and acetylenes, forming perthiocarbonate and alkenedithiolate complexes.[48]

2.7. The Copper Triad

The salts of CuS_4^- and AuS_3^- have been known since the beginning of the century[1], but only recently have they been examined in any detail. The structure of NH_4CuS_4,[88,89] shown in Figure 15, features a CuS_4 ring,

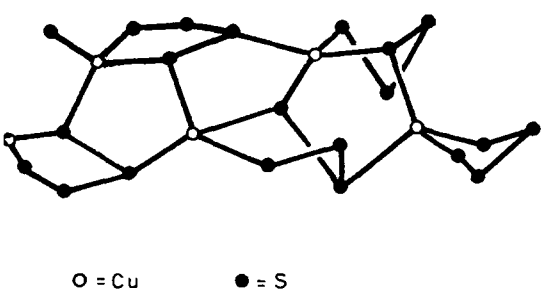

Fig. 15. Structure of the $[CuS_4]_n$ chain in $NH_4[CuS_4]$ [88].

wherein the polysulfido ligand forms bridges to other copper centers. Bridging polysulfide ligands are unusual for most elements but appear to be prevalent for the sulfido clusters of copper(I). Reaction of ethanolic polysulfide solutions with $Cu(CH_3CO_2)_2 \cdot 2H_2O$ yields crystals of $(Et_4N)_3[Cu_3(S_6)_3]$.[90] One end of each of the S_6 chelates is bridging, giving a Cu_3S_3 ring (Fig. 16).

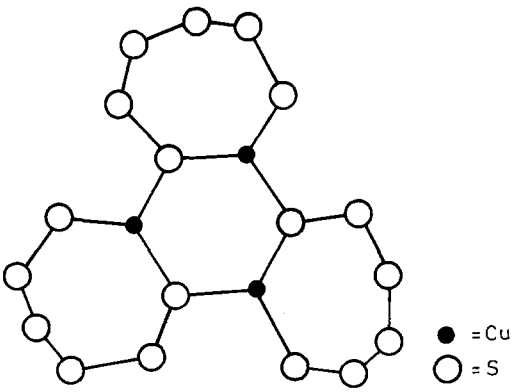

Fig. 16. ORTEP plot of the $[Cu_3S_{18}]^{3-}$ anion [90].

Closely related to $[Cu_3(S_6)_3]^{3-}$ is $[Cu_3(S_4)_3]^{3-}$.[91] The bridging nature of the S_4 and S_6 ligands in these trimetallic anions is similar to the S_5 chelate found previously in $Os_2(dtc)_3(dtcS)S_5$.[59] Three coordinate copper(I) is also found in $[Cu_2S_{20}]^{4-}$, which features two CuS_6 rings linked by an S_8 chain.[87b,91] The analogous silver complex, $[Ag_2S_{20}]^{4-}$, has also recently been prepared.[92]

A new class of inorganic sulfido clusters contain a tetrahedral Cu_4 core with S_4 and S_5 bridging chelates. There are reports of the isolation and crystallographic characterization of each member of the series $[Cu_4(S_4)_{3-x}(S_5)_x]^{2-}$ $(x=0-3)$[93-96] (Fig. 17).

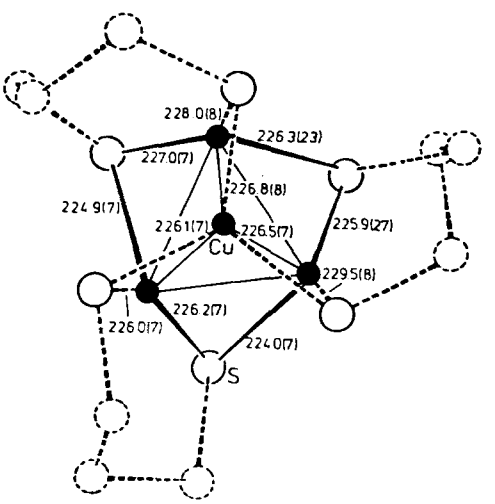

Fig. 17. ORTEP plot of the $[Cu_4S_{14}]^{2-}$ anion [93-96]. Distances [pm].

The $[Cu_4S_{15}]^{2-}$ and $[Cu_4S_{14}]^{2-}$ ions cocrystallize, a rare example of the coexistence of both S_4 and S_5 chelates.[95] Structurally, the most spectacular polysulfide cluster is $[Cu_6S_{17}]^{2-}$ (Fig. 18).

The molecule comprises an edge-shared bitetrahedral array of copper atoms with three tetrasulfido and one pentasulfido subunits. The S_4 ligands are like those seen in the aforementioned Cu_4 clusters, whereas the S_5 ligand is bound to four metal ions. The molecule contains a twofold axis through the central (non-coordinated) sulfur atom of the S_5 chelate.[97,98]

The record size for a metal polysulfide ring is currently held by the $[AuS_9]^-$ ion isolated by *Strähle* and *Mar-*

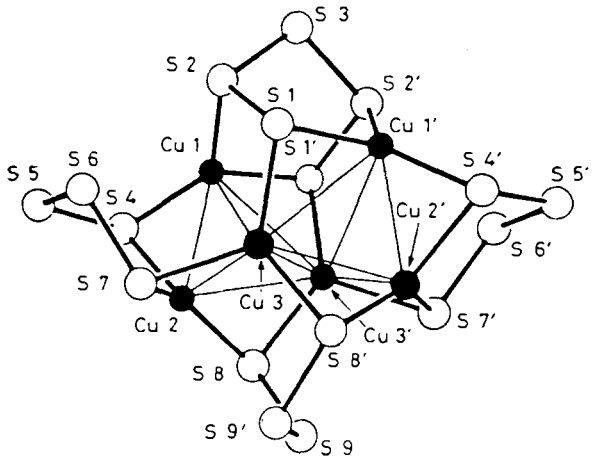

Fig. 18. ORTEP plot of the $[Cu_6S_{17}]^{2-}$ anion [97, 98].

bach.[99] In this molecule the catenating abilities of sulfur and the linear coordination geometry preferred by gold(I) stabilize the S_9^{2-} strap (Fig. 19). The S–Au–S angle is 176° and the S–S bond lengths are in the normal range of 2.03 Å.

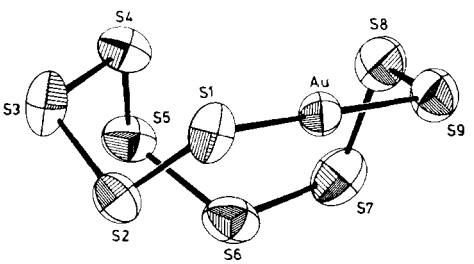

Fig. 19. ORTEP plot of the $[AuS_9]^-$ anion [99].

The bimetallic species $[Au_2S_8]^{2-}$ contains a ten-membered ring; each gold atom is again accomodated with a linear coordination environment. Here the two S_4-bridged gold centers are separated by 3.120 Å[95] (Fig. 20).

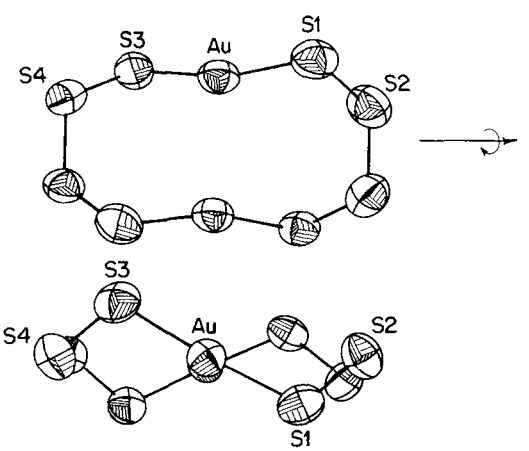

Fig. 20. ORTEP plot of the $[Au_2S_8]^{2-}$ anion [95].

The analogous $[AgS_9]^-$ ion has been prepared recently as the Ph_4P^+ salt; however, the anion is severely disordered in the crystal lattice. *Müller* et al. have also isolated the $[Ag_2(S_6)_2]^{2-}$ complex, under similar reaction conditions. The S_6 ligands coordinate in a fashion similar to that observed in $[Cu_3(S_6)_3]^{3-}$, such that a planar Ag_2S_2 ring is formed (Fig. 21).[100]

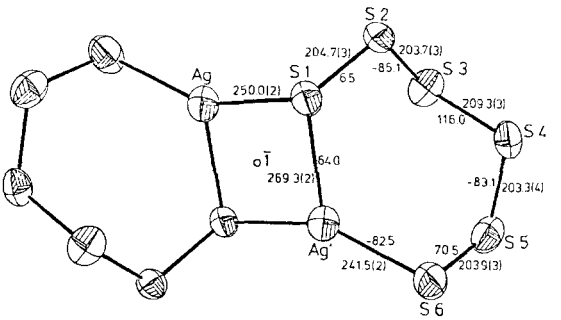

Fig. 21. ORTEP plot of the $[Ag_2(S_6)_2]^{2-}$ anion [100]. Distances [pm], angles [°].

2.8. The Zinc Triad

The stepwise reaction of dibenzyl trisulfide with $[Zn(SPh)_4]^{2-}$ has recently been reported by *Coucouvanis* et al.[48] Initially the mixed ligand complexes $[Zn(SPh)_2(S_4)]^{2-}$ and $[Zn(SPh)_2(S_5)]^{2-}$ are formed, additional sulfur gives $[Zn(S_5)_2]^{2-}$ and eventually $[Zn(S_6)_2]^{2-}$ (Scheme 4).

$$[Zn(SR)_4]^{2-} \xrightarrow{S^\circ} [Zn(SR)_2(S_4)]^{2-} \xrightarrow{S^\circ} [Zn(SR)_2(S_5)]^{2-}$$

$$\xrightarrow{S^\circ} [Zn(S_5)_2]^{2-} \xrightarrow{S^\circ} [Zn(S_6)_2]^{2-}$$

$$[Zn(S_5)_2]^{2-} \xrightarrow{Ph_3P} [Zn(S_4)_2]^{2-}$$

Scheme 4. Formation of polysulfide ligands by stepwise addition of sulfur to $[Zn(SPh)_4]^{2-}$ and its derivatives.

Under the same conditions employed for the synthesis of $(PPh_4)_2[Zn(SPh)_2(S_5)]$, $(Et_4N)_2[Zn(SPh)_4]$ is converted into $(NEt_4)_2[Zn(S_4)_2]^{2-}$ (Fig. 22).

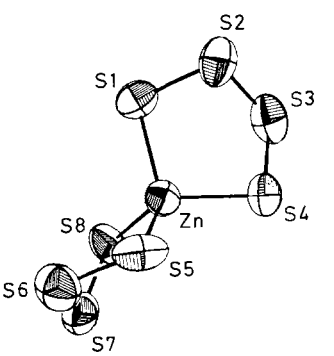

Fig. 22. ORTEP plot of the $[ZnS_8]^{2-}$ anion [48].

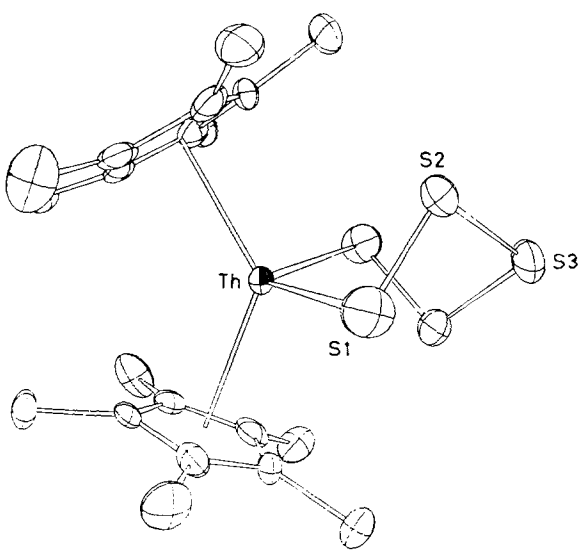
These results highlight the importance of counterion effects on the stoichiometry of compounds crystallized from solutions of such kinetically labile ions. Starting with $[Cd(SPh)_4]^{2-}$, *Coucouvanis* et al. obtained $(PPh_4)_2[Cd(SPh)_2(S_5)]$ using reactant ratios employed for

the synthesis of both $(PPh_4)_2[Zn(SPh)_2(S_x)]^{2-}$ complexes, with $x = 4$ or 5. This difference may result from the larger ionic radius of the Cd^{2+} ion which stabilizes the S_5 chelate ring. Contrary to this facile explanation, however, is the fact that the $[Cd(S_6)_2]^{2-}$ ion, unlike the situation for zinc and mercury(II), is not observed. The dianion $[Hg(S_6)_2]^{2-}$ can be prepared from mercuric acetate and aqueous polysulfide.[109] This molecule closely resembles the $[MnS_{11}]^{2-}$ ion.

2.9. f-Element Polysulfides

The compound $(C_5Me_5)_2ThS_5$ has recently been prepared from $(C_5Me_5)_2ThCl_2$ and Li_2S_5. In the solid state, the molecule features a twist conformation for the ThS_5 ring (Fig. 23). This structure is maintained in solution, as revealed by a DNMR study on $(C_5Me_4Et)_2ThS_5$, whose low temperature ^{1}H-NMR spectrum consists of four methyl singlets. The calculated $\Delta G^{\neq}$ for the ring inversion process (racemization) is 58 kJ/mol (Scheme 5).[102]



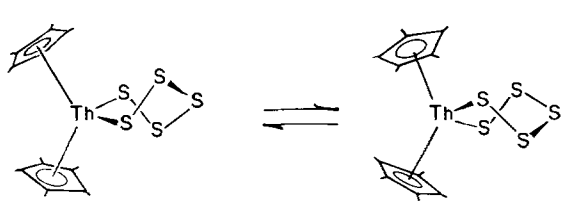


Fig. 23. ORTEP plot of $(C_5Me_5)_2ThS_5$ [102].

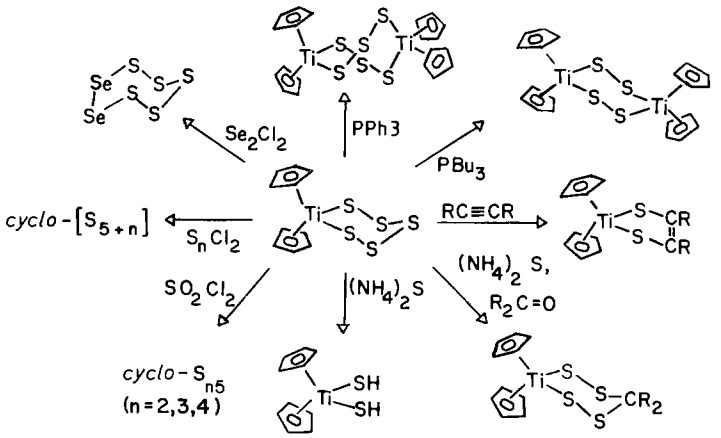
Scheme 5. Racemization of $(C_5Me_5)_2ThS_5$ via ring inversion.

Two aspects of the $(C_5Me_5)_2ThS_5$ structure warrant further discussion. First, why does this thorium complex exist as a pentasulfide while the corresponding transition metal compounds, e.g. $(C_5Me_5)_2MS_3$ (M = Ti, Zr), are trisulfides? This difference is probably due to the more open coordination environment about the actinoid. The Th–S distance of 2.77 Å is 0.33 Å longer than the corresponding distance in Cp_2TiS_5, while the C_5Me_5–Th–C_5Me_5 angle is 4° smaller than that for Cp–Ti–Cp, and the S–Th–S angle of 113.5° is 18° wider than the S–Ti–S angle. As already mentioned, the structure of Cp_2TiS_5 features short C···β-S contacts (cf. Section 2.1). These contacts would become intolerably short in the hypothetical $(C_5Me_5)_2TiS_5$, but apparently not so in its thorium analogue.

The second and more intriguing aspect of $(C_5Me_5)_2ThS_5$ is the twist conformation of the ThS_5 ring. This ring geometry had not been observed previously in any of the transition metal polysulfides and is presumed to be a consequence of bonding between Th and the β-sulfur atoms (3.04 Å). The twist conformation may be stabilized by a cog wheel effect induced by the nesting of the methyl groups.

3. Reactions of Polysulfide Complexes



Polysulfides are reactive ligands. Mechanistic studies have largely involved kinetically stable complexes, particularly those derived from titanium, molybdenum, and platinum.[80,81,85a] On the other hand, the synthetic applications of this class of compounds have thus far been restricted to titanium.

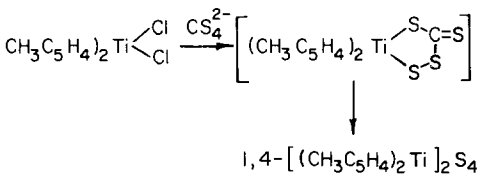
3.1. The Chemistry of the Bis(cyclopentadienyl)titanium Pentasulfides

The reaction chemistry of Cp_2TiS_5 is extensive (Scheme 6). Because of the oxophilicity of titanium, the sulfur ligand in Cp_2TiS_5 is easily displaced by oxide or, more importantly, halide. This was the basis for the S_5 transfer reaction of *Schmidt* et al., which was first demonstrated in the high yield syntheses of *cyclo*-S_6 and *cyclo*-S_7.[103] The reaction of Cp_2TiS_5 with chlorosulfanes is ideally suited for the directed synthesis of polysulfide compounds since it gives relatively few products and little S_8. Subsequent to *Schmidt*'s original report in 1968, Cp_2TiS_5 has emerged as a standard reagent in the synthesis of new polysulfur rings.[104–109]. It is interesting to note that unlike the situation with organic synthesis, organotransition metal reagents are rarely employed in the synthesis of main group compounds. Sulfur homocycles can also be obtained from the reaction of S_2Cl_2 with KI or by extraction of supercooled sulfur melts followed by careful fractional crystallization. In contrast to the titanium-mediated chemistry, however, these methods afford primarily even-numbered sulfur rings, especially S_6, S_{12}, and S_{18}, together with large amounts of S_8.[16]

Mechanistic insights into the course of chelate transfer reactions of Cp_2TiS_5 are being gained from investigations by *Steudel* et al.[5] It is found that the reaction of SO_2Cl_2 gives *cyclo*-S_{10} in good yields, some *cyclo*-S_{15}, and, depending on the rate of the addition, varying amounts of *cyclo*-S_{20}. The addition of SO_2Cl_2 to a solution containing both Cp_2TiS_5 and *cyclo*-S_7 gave no *cyclo*-S_{12}, suggesting that these reactions do not involve the coupling of small ring intermediates such as *cyclo*-S_5. Further insight into these reactions is provided from the synthesis of heterocycles from Cp_2TiS_5. Thus, oxaloyl chloride reacts with the pentasulfide to give a 14-membered C_4S_{10} ring compound.[105] Reaction of Cp_2TiS_5 with Se_2Cl_2 initially gives *cyclo*-1,2-

Se_2S_5, which was identified by Raman spectroscopy.[107] This selenasulfide appears to undergo a highly selective ring expansion reaction, giving *cyclo*-1,2,3-Se_3S_5 as the principal Se-rich product, possibly via the intermediacy of a spirobicyclic Se^{IV} species.[108] Such experiments represent a significant step towards elucidating the mechanisms of the basic reactions of inorganic sulfur.

Scheme 6. Selected reactions of Cp_2TiS_5 showing its synthetic usefulness in preparing novel titanium complexes and new *cyclo*-sulfur compounds.

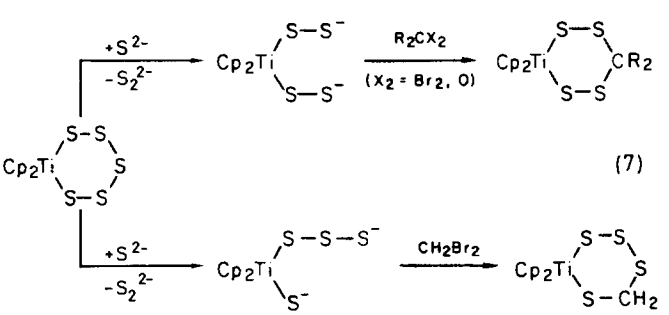


It should be noted that Cp_2TiSe_5 has also emerged as a useful chalcogen transfer reagent. This is an important development for selenium chemistry since Cp_2TiSe_5 and particularly its derivatives (i.e., $(MeCp)_2TiSe_5$) are soluble in a range of organic solvents giving thermally stable purple solutions. In contrast red selenium is only modestly soluble in a limited number of solvents. The syntheses of the following Se compounds have been accomplished using Cp_2TiSe_5: 1,3-$(IB)_2Se_3$, $(Bu_2B)_2Se_2$, $[Ir(Se_2)(Ph_2PC_2H_4PPh_2)_2]^+$, $Cp_2TiSe_2C_2R$ ($R_2=(CO_2Me)_2$; H, CO_2Me; $(CF_3)_2$), V(Se)(porphyrin), and *cyclo*-Se_7.[9, 16, 109]

The mechanism of the classic reaction of elemental sulfur with nucleophiles such as phosphanes was studied in detail several years ago by *Bartlett* et al.[110] The reaction rate obeys bimolecular kinetics consistent with nucleophilic opening of the S_8 ring and concomitant formation of a thiophosphonium intermediate. The latter decomposes to the phosphane sulfide and an undetermined, presumably labile, homocyclic sulfide. Insight into this classical reaction is provided by the products formed in the reaction of phosphanes with Cp_2TiS_5. These reactions are facile and it is unlikely that they involve direct coordination of the phosphane to the titanium atom. The two products formed in the desulfurization of Cp_2TiS_5 are not interconvertible under the experimental conditions used, and the type of products formed depends noticeably on the nucleophilicity of the phosphane employed. This chemistry highlights one of the very interesting aspects of these titanium polysulfides: the S–S bonds are reactive in the normal way but the M–S bonds are resistant to attack by phosphanes. The products of such desulfurizations are dimers of the type 1,4-$[(MeC_5H_4)_2TiS_2]_2$[111] and 1,5-$[(MeC_5H_4)_2TiS_3]_2$[19] [Eq. (5)].

These compounds could arise via either ionic (open chain) or neutral (small ring) intermediates. Ionic species would be expected to react readily with activated acetylenes; indeed, the addition of phosphanes to solutions containing both Cp_2TiS_5 and dimethylacetylenedicarboxylate (DMAD) affords the dithiolene even at 0 °C.[111] While this trapping experiment is consistent with the presence of ionic intermediates, the synthesis of the Ti_2S_4 ring in high yield via the perthiocarbonate route implies that it is neutral, strained ring compounds which actually dimerize[111] [Eq. (6)].

$$(MeC_5H_4)_2TiS_5 \xrightarrow{+3.3\ \text{equiv. } PR_3} \begin{matrix} 1,4\text{-}[(MeCp)_2Ti]_2S_4 & \mathbf{1} \\ + & \\ 1,5\text{-}[(MeCp)_2Ti]_2S_6 & \mathbf{2} \end{matrix} \quad (5)$$



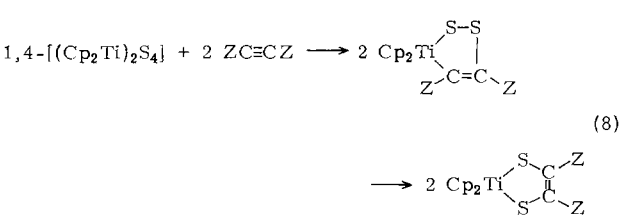
PR_3	Yield of **1** [%]	Yield of **2** [%]
$P(C_6H_5)_3$	trace	38
$P(C_6H_5)_2CH_3$	22	23
$P(C_6H_{11})_3$	35	trace
$P(C_4H_9)_3$	43	trace

(6)

Related dimerization reactions have been observed in the desulfurization of benzo-1,2,3-trithiacyclopentane, which affords the 1,2,5,6-tetrathiadibenzocyclooctane[112], and the $SbCl_5$-induced dimerization of S_6O, which yields 1,7-$S_{12}O_2$.[113]

Sulfur anions, like phosphanes, are very good thiophiles. Although Cp_2TiS_5 can be prepared from ammonium polysulfide, it is also rapidly degraded by the sulfide ion, giving $Cp_2Ti(SH)_2$ (see Scheme 5).[114] Ionic intermediates arising from the cleavage of the TiS_5 ring with sulfides can be trapped with aliphatic ketones to give perthiolato complexes.[115] Two regioisomers of the methylene derivative can be prepared from methylene bromide, Cp_2TiS_5, and ammonium sulfide [(Eq. (7)].

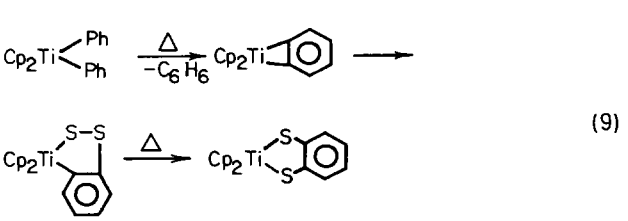
(7)



The existence of the symmetrical isomer of $Cp_2TiS_4CH_2$ has been proven by an X-ray structure analysis, while the structure of the other isomer was established by NMR studies, which revealed the absence of a plane of symmetry in the methylcyclopentadienyl derivative. In view of the numerous applications of Cp_2TiS_5 for the preparation of novel sulfur rings, it would appear that these isomeric alkylidene bisperthiolates could evolve as synthetically and mechanistically useful reagents. In general, they appear to

be more stable than the pentasulfides and are less reactive towards sulfides and phosphanes.

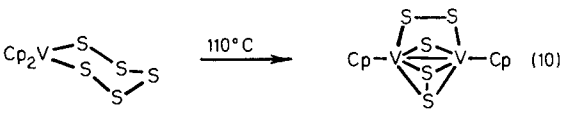
The reaction of the titanium polysulfides and polyselenides with acetylenes has been studied in some detail.[9, 111] The following rules apply:



1. Only activated acetylenes participate in these reactions; these include dimethylacetylenedicarboxylate (DMAD), hexafluorobutyne, and methyl propiolate.
2. The selenides react faster than the sulfides and the reactivity of the rings increases with decreasing E/M ratio (e.g. the Ti_2S_4 compound is much more reactive than is Cp_2TiS_5).
3. The reactions proceed via an associative pathway, the rates of the reactions being linearly dependent on the concentrations of both the acetylene and the titanium precursor.

These are beautiful reactions to witness as they involve the conversion of the red or purple chalcogenidotitanium into the brilliant green dithiolenes and diselenenes. The first methylcarboxylate substituted dithiolenes were prepared in this way. It now appears that this type of dithiolene will emerge as the most readily accessible ligand of this type. The mechanism proposed for the reaction of Cp_2TiS_5 with acetylenes is a not an obvious one and was only revealed through kinetic studies on 1,4-$[(Cp_2Ti)_2S_4]$. Reaction of the latter with DMAD proceeds at room temperature to give a green compound isomeric with the "normal" dithiolene[111] [Eq. (8)]. The rate of this reaction is first order, both for the titanium dimer and for the acetylene, and there is no evidence for a predissociation of the $Cp_4Ti_2S_4$ species into Cp_2TiS_2 fragments.

(8)



The structurally characterized vinyl disulfide isomer then rearranges in a first order reaction to give the normally observed isomer. Similar types of intermediates have been observed by *Halbert* et al.[116a] who reacted $[Mo_2O_2(S)_2(S_2)_2]^{2-}$ with DMAD, and by *Tebbe* who studied the insertion of sulfur into a titanium-benzyne species[116b] [Eq. (9)].

(9)

Many of the currently recognized metal-promoted dithiolene syntheses may proceed via similar insertion mechanisms. Furthermore, this mechanism may be applicable to the addition of sulfur to metal disulfides yielding tetrasulfides.

It has been known for several years that Cp_2VS_5 undergoes a facile thermal rearrangement[117] to give the dinuclear complex $Cp_2V_2S_5$. [By heating Cp_2VS_5 in toluene, 85% yield [Eq. (10)].]

(10)

The selenium compound behaves similarly. The structures of both products have been determined by X-ray crystallography. It is probable that these transformations involve the formation of organochalcogen intermediates. This suggestion is supported by studies on the thermolysis of Cp_2TiS_5.[118] Heating the titanium complex in boiling xylene for one day followed by gel permeation chromatography affords a black fraction which contains sulfidotitanium clusters and a red fraction containing an isomer of Cp_2TiS_5. While the red color of this isomer is (deceptively) similar to that for its precursor, its ^{1}H-NMR spectrum is decidedly more complex. The X-ray structural analysis of the compound reveals that a cyclopentadienyl fragment has migrated to the sulfur atoms (Figure 24).

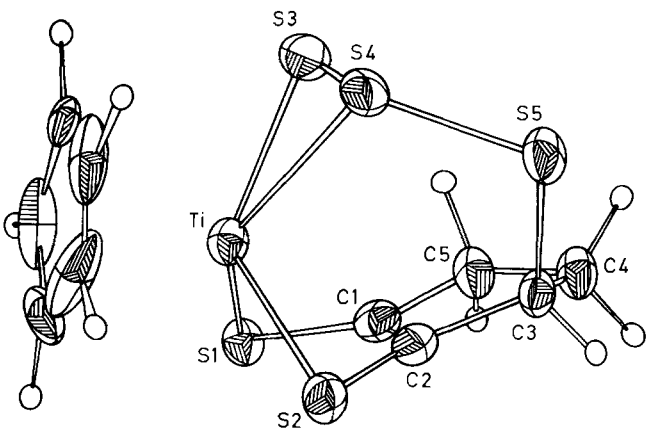


Fig. 24. ORTEP plot of β-$C_{10}H_{10}TiS_5$ [102].

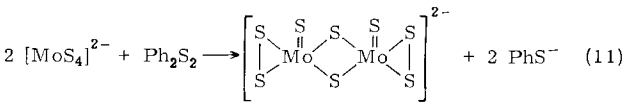


It is also interesting that this rearrangement involves both the formation of three new carbon-sulfur bonds as well as the migration of two hydrogen atoms. The tetradentate $C_5H_5S_5$ ligand binds to the titanium atom via an η^2-trisulfide and a dithiolene, whereby the latter is so distorted that it appears to be coordinated in an η^4 fashion. This rearrangement of Cp_2TiS_5 provides a further example of the migration of an organic ligand from the metal to sulfur.

3.2. Polysulfidomolybdenum Compounds

In molybdenum chemistry one observes several reactions involving interconversions between S, S_2, and S_4 ligands which proceed with a change in the formal oxidation state of the molybdenum. This novel type of redox reaction highlights the inappropriateness of the oxidation

state formalism for these compounds and suggests the near electronic equivalence of S_2 and S_4 ligands.

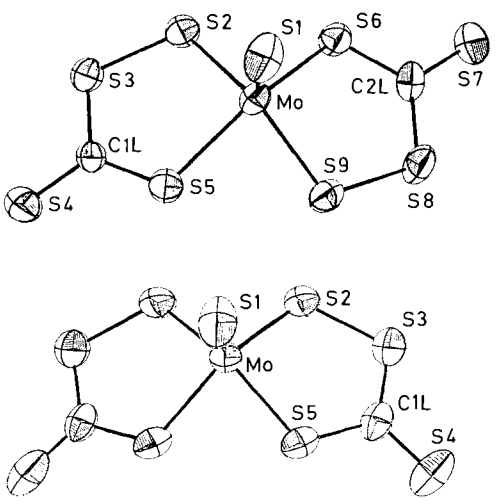
The reaction of $[MoS_4]^{2-}$ with organic disulfides affords the $[Mo_2S_8]^{2-}$ ion together with two equivalents of the reduced organosulfur compound[34] [Eq. (11)].

$$2\ [MoS_4]^{2-} + Ph_2S_2 \longrightarrow \left[\begin{array}{c}S\\ \|\\ S-Mo-S\\ |\ \ \ |\\ S-Mo-S\\ \|\\ S\end{array}\right]^{2-} + 2\ PhS^- \qquad (11)$$

Evaluation of the changes in the formal oxidation state in this and related systems can be confusing, and for "bookkeeping purposes" one can analyze this reaction by considering the valence isomer of $[MoS_4]^{2-}$, namely $[Mo(S)_2(S_2)]^{2-}$. In this way the two-electron reduction of $(PhS)_2$ is coupled with the two-electron oxidation of a pair of Mo^{IV} compounds.

In the oxidation of $[MoS_4]^{2-}$ with sulfur-rich compounds such as elemental sulfur or dibenzyl trisulfide one obtains the $[MoS_9]^{2-}$ ion.[32] Similarly, the reduction of $[MoS_9]^{2-}$ with thiolates generates the oxidized species $[MoS_4]^{2-}$.[36b] Here again, changes in the formal oxidation state of the metal ion occur concomitant with the making and breaking of sulfur-sulfur bonds. Little is known about the mechanisms of these reactions and the problem, at least as it is described in the literature, is a formidable one. For example, the addition of solutions of PPh_4Cl to acetonitrile solutions of $(Et_4N)_2[MoS_9]$ yields crystals of $(PPh_4)_2[Mo_2S_{10}]$. Similarly, it has been demonstrated that the reverse reaction occurs when solutions of Et_4NCl are added to $(PPh_4)_2[Mo_2S_{10}]$.[32b]

The $[MoS_9]^{2-}$ species has been the subject of a series of studies by the *Coucouvanis* group. $[MoS_9]^{2-}$ appears to function as a source of $[MoS(S_2)_2]^{2-}$ in its reactions with carbon disulfide, affording perthiocarbonate complexes.[119] Two isomers of $[MoS(CS_4)_2]^{2-}$ are obtained in this reaction. However, the lack of appropriate analytical techniques has precluded any mechanistic insight into the implied interconversion (Fig. 25).



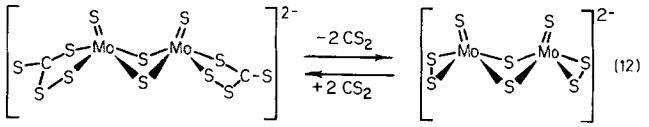


Fig. 25. Structure of the two isomers of $[MoS_9C_2]^{2-}$ formed on reaction of $[MoS_9]^{2-}$ with CS_2 [38].

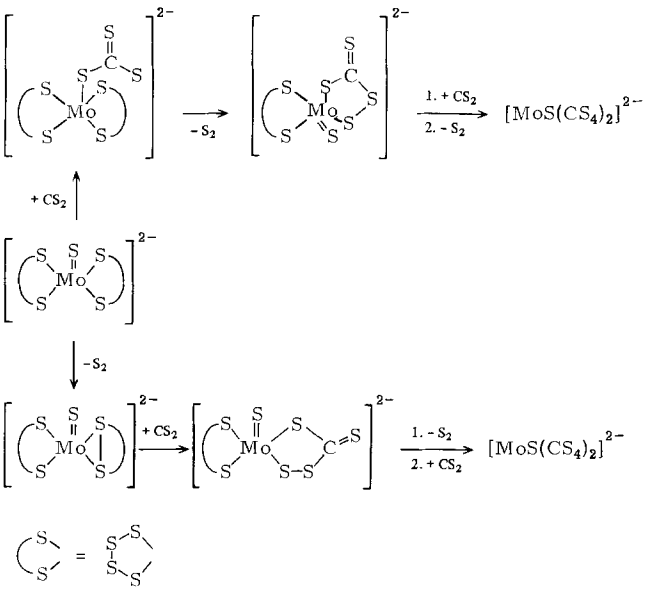

Also formed in these reactions is the dimer $[Mo_2S_4(CS_4)_2]^{2-}$, which reversibly evolves CS_2 in vacuo to give the bis(disulfido) compound $[Mo_2S_8]^{2-}$ [Eq. (12)].

$$\left[\begin{array}{c}S\\ \|\\ S-Mo-S\\ |\ \ \ |\\ S-Mo-S\\ \|\\ S\end{array}\right]^{2-} \underset{+2\,CS_2}{\overset{-2\,CS_2}{\rightleftharpoons}} \left[\begin{array}{c}S\\ \|\\ S-Mo-S\\ |\ \ \ |\\ S-Mo-S\\ \|\\ S\end{array}\right]^{2-} \qquad (12)$$

CS_2 can also be removed from solutions of the $[MoS(CS_4)_2]^{2-}$ ion, whereby $[MoS_4]^{2-}$ is formed;[38] it would be of special interest to attempt this removal of CS_2 in the solid state. As shown by *Coucouvanis* et al., this CS_2 addition reaction appears to be of some generality as it is observed with the polysulfido complexes of nickel, zinc, and manganese.[48] In the case of manganese, the product formed from the addition of CS_2 to only one polysulfido ligand, $[Mn(S_6)(CS_4)]^{2-}$, has also been characterized.

$[MoS_9]^{2-}$ reacts with DMAD to give the trigonal prismatic $[Mo(dithiolene)_3]^{2-}$.[120] It is noteworthy that $[MoOS_8]^{2-}$ does not give the tris(dithiolene) complex upon treatment with DMAD. Furthermore, this oxo complex also fails to react with carbon disulfide.[38] These observations suggest involvement of the nucleophilic terminal sulfido ligand in these addition reactions (Scheme 7).

Scheme 7. Two possible routes for the conversion of $[MoS_9]^{2-}$ into $[MoS(CS_4)_2]^{2-}$.

The oxidation of polysulfido chelates has not been examined in detail and only a few oxo derivatives of *cyclo*-S_x are known.[113] Certain disulfur complexes undergo oxidation to give S_2O or S_2O_2 complexes.[121] Recently, *Müller* has reported the structural characterization of an S_3O_2 complex $(PPh_4)_2[Mo_2(O)_2(\mu\text{-}S)(S_2)(S_3O_2)]$; crystals of this compound are obtained when solutions of simple thiomolybdates are exposed to oxygen[122] (Fig. 26).

Binary molybdenum-sulfur complexes participate in various equilibria: Treatment of $[MoS_4]^{2-}$ with $(NH_4)_2S$ is

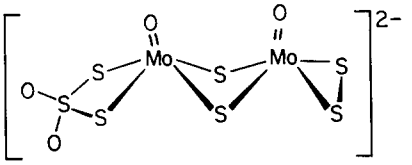

Fig. 26. Structure of $[Mo_2O_2(\mu\text{-}S)_2(S_2)(S_3O_2)]^{2-}$, the first dithiosulfate complex [122].

reported to give $[Mo_3S_{13}]^{2-}$ and small amounts of $[Mo_2(S_2)_6]^{2-}$; the addition of more sulfur to such mixtures favors the binuclear compound at the expense of the trimer. Addition of Et_4NCl to mixtures of $[MoS_4]^{2-}$ and $(NH_4)_2S_x$ yields the $[MoS_9]^{2-}$ ion in the form of a crystalline salt.[32b] PPh_4Cl reacts with solutions of $[Mo_2(S_2)_6]^{2-}$ in acetonitrile to give crystals of $(PPh_4)_2[Mo_2S_4(S_4)_2]$.[38] These few results demonstrate the complexity of this chemistry and reveal that the choice of counterions can have a decisive effect on the structure of the crystallized product. Despite the large number of structurally characterized binary molybdenum sulfides, there has never been a comprehensive study of the solution equilibria involved, primarily because of a lack of appropriate analytical techniques. ^{95}Mo-NMR spectroscopy could prove to be a useful probe for these systems.

4. Conclusions

The study of polysulfido chelates has developed rapidly in the past few years and stable derivatives have been prepared for most of the transition metals. These ligands are found in a number of ring sizes and bonding modes, but they are of special interest since they are so reactive. This area of research has already proven valuable to the transition metal chemist (how do thio- and disulfido ligands arise in the reactions of S_8) and the main group specialist (the directed syntheses of S_x rings ($x \neq 8$); Cp_2TiS_5 as a mechanistic model for S_8). Polysulfidometal compounds promise further development as synthetic reagents and as precursors to new materials[29] and catalysts.[123]

Opportunities abound for further extensions of polysulfido-transition metal chemistry. The recent preparation of $(C_5Me_5)_2ThS_5$[102] points to the f-elements as a novel source of compounds. Main group polysulfide chemistry has in large measure remained untouched.[124] No polytellurido and only very few polyselenido complexes are known. In view of the dramatic structural differences between $(NMe_4)_2Te_5$[125] and Cs_2Te_5,[126] the polytellurido chelates may prove very novel.[129] It has already been demonstrated that the ^{77}Se-NMR of metal polyselenides is structurally useful[112] and this approach could eventually resolve some of the mechanistic issues in this area of coordination chemistry. S-N[63, 127] and $(PR)_n$[128] chelates have been known for several years, but have seldom been subjected to reactivity studies.

We are indubted to many of our friends in this field for providing us with reprints and preprints. We also wish to thank Mr. Dean Giolando for his many insightful comments. Our research in this area has been generously supported by the National Science Foundation.

Synthesis of Cyclohepta[*a*]phenalene-6,12-dione

By *Shigeyasu Kuroda,* Yuriko Fukuyama, Tomohiko Tsuchida, Eishi Tanaka,* and *Syuzi Hirooka*

Although many types of nonbenzenoid quinones have been investigated, little is known about polycyclic quinones containing more than three rings.[1] Herein we report on the first synthesis and the properties of the novel tetracyclic quinone cyclohepta[*a*]phenalene-6,12-dione **8** and its dication **10** as well as the corresponding 5-bromo derivatives **9** and **11**, respectively. It is also of interest to know the tropicity of these species. They should show opposite tropicity to the unknown parent hydrocarbon cyclohepta[*a*]phenalene, which is predicted to be aromatic,[2] since an analogous alternation of tropicity is found for the heptalene system.[3]

[*] Dr. S. Kuroda, Y. Fukuyama, T. Tsuchida, E. Tanaka, Prof. Dr. S. Hirooka

Toyama University, Takaoka, Toyama 933 (Japan)

The reaction of 2-methoxy-1-naphthaldehyde **1** with 2,2-diethoxycycloheptanone **2** in the presence of NaOMe in refluxing tetrahydrofuran furnished **3** (78% yield, Scheme 1). The catalytic hydrogenation of **3** provided the satu-

Scheme 1. a) NaOMe, anhydrous tetrahydrofuran, reflux, 3 h. b) H_2/PtO_2, 2.7 atm., 3 h. c) 85% H_2SO_4, 45°C, 25 min. d) $C_5H_5NHBr_3$, $CHCl_3$. e) 2.5 equiv. *LiCl*, *dimethylformamide*, 90°C, *30 min*. f) conc. H_2SO_4 *or* D_2SO_4. g) H_2O in excess.

rated ketone **4** (>90%). The cyclodehydration of **4** gave **5** (60%), which was brominated with pyridinium tribromide in chloroform at 10°C in ca. 12 h to give **6** (93%) and **7** (traces). Under more vigorous conditions (50°C, 3 h), **7** was obtained as the major product (63%) along with **6** (23%). On treatment of **6** with LiCl in dimethylformamide,[4] the parent quinone **8** was obtained in one step as air-stable needles in 80% yield. The same treatment transformed **7** into the 5-bromoquinone **9** (73%).

Table 1. Some physical properties of quinones **8**, **9** and their dications.

8, yellow needles, m.p. = 209–212°C; IR (KBr): ν = 3040, 1640 (C=O), 1618, 1580 (C=O), 840 cm^{-1}; ^{1}H-NMR ($CDCl_3$, 90 MHz): δ = 8.67 (dd, J = 1.5, 8.5 Hz, 1-H), 8.62 (s, 7-H), 7.70 (d, J = 9.8 Hz, 4-H), 7.67 (m, 2-H), 7.54 (m, 3-H), 7.48 (d, J = 10.0, 8-H), 6.92 (m, 9,10,11-H), 6.65 (d, J = 9.8 Hz, 5-H); ^{13}C-NMR ($CDCl_3$, 90 MHz): δ = 191.2 (C=O, C-12), 184.7 (C=O, C-6), 143.1 (C-4), 137.1 (C-8), 134.5 (C-10), 133.0 (C-7), 132.7 (C-11), 131.9 (C-3), 130.4 (C-1), 128.8 (C-9), 128.4 (C-3), 127.6 (C-2), 140.0, 133.4, 130.8, 130.6, 128.4, 128.0 (quart. C); UV (hexane): λ_{max} = 416 (lgε = 3.86), 319 (3.97), 268 nm (4.14); MS: m/z 258 (M^+).—**10**, ^{1}H-NMR (conc. D_2SO_4/CH_2Cl_2, 200 MHz): δ = 10.25 (s, 7-H), 10.16 (d, J = 8.7 Hz, 1-H), 9.36 (bd, J = 10.1 Hz, 8-H), 9.34 (bd, J = 9.3 Hz, 4-H), 8.90 (dd, J = 8.8, 10.9 Hz, 10-H), 8.90 (d, J = 7.8 Hz, 3-H), 8.70 (d, J = 10.9 Hz, 11-H), 8.62 (dd, J = 8.8, 10.1 Hz, 9-H), 8.42 (dd, J = 7.8, 8.7 Hz, 2-H), 7.85 (d, J = 9.3 Hz, 5-H); ^{13}C-NMR (conc. D_2SO_4/CH_2Cl_2, 200 MHz): δ = 182.7 (C-OH, C-12), 181.9 (C-OH, C-6), 165.2 (C-4), 154.9 (C-10), 152.5 (C-8), 148.0 (C-1), 146.9 (C-3), 141.8 (C-7), 138.5 (C-5), 132.7 (C-11), 131.4 (C-9), 120.1 (C-2), 140.2, 138.1, 129.7, 127.2, 126.4, 125.0 (quart. C); UV (conc. H_2SO_4): λ_{max} = 548 (lgε = 2.25), 493 (2.98), 268 nm (3.14)

9, yellow needles, m.p. = 225°C (decomp.); IR (KBr): ν = 1655 (C=O), 1610, 1582 (C=O), 795 cm^{-1}; ^{1}H-NMR ($CDCl_3$, 90 MHz): δ = 8.85 (s, 7-H), 8.67 (dd, J = 1.8, 8.0 Hz, 1-H), 8.27 (s, 4-H), 7.78 (dd, J = 1.8, 8.0 Hz, 3-H), 7.64 (t, J = 8.0 Hz, 2-H), 7.60 (dd, J = 2.0, 10.5 Hz, 8-H), 6.98 (m, 9,10,11-H); ^{13}C-NMR spectrum could not be obtained due to low solubility of **9**. UV(CH_2Cl_2): λ_{max} = 425 (lgε = 4.08), 332 (4.08), 295 nm (4.28); MS: m/z 338 (M^+).—**13**, ^{1}H-NMR (conc. D_2SO_4/CH_2Cl_2, 90 MHz): δ = 10.39 (s, 7-H), 10.23 (d, J = 8.6 Hz, 1-H), 9.65 (s, 4-H), 9.41 (d, J = 10.0 Hz, 8-H), 9.03 (md, 3-H, 10-H), 8.72 (m, 11-H, 9-H), 8.48 (dd, J = 7.5, 8.5 Hz, 2-H); ^{13}C-NMR (conc. D_2SO_4/CH_2Cl_2, 90 MHz): δ = 182.9 (C-OH, C-12), 176.2 (C-OH, C-6), 165.9 (C-4), 155.6 (C-10), 152.5 (C-8), 150.3 (C-1), 139.0 (C-3), 138.9 (C-7), 132.1 (C-11), 131.9 (C-9), 114.8 (C-2), C-5: signal intensity too weak, 140.3, 138.5, 130.0, 127.2, 126.3, 123.9 (quart. C); UV (conc. H_2SO_4): λ_{max} = 580 (lgε = 3.76), 504 (4.26), 376 nm (4.46)

The structures of **8** and **9** were assigned on the basis of their spectra (Table 1). The ^{1}H-NMR chemical shifts of the seven-membered ring of **8** are very close to those of 5-benzocycloheptenone ("benzo[2,3]tropone")[4] and those of the phenalenone moiety are in almost the same region as those of **5** except for 1-H and 7-H, which are shifted to lower field by the deshielding effects of the carbonyl groups (Fig. 1, above). The ^{1}H-NMR spectrum of **9** is essentially identical to that of **8** but is slightly shifted to lower field. The coupling constants J (8-H, 9-H) of **8** and **9** indicate that the bond alternation of the cycloheptatrienone (tropone) moiety is smaller than that of 5-benzocycloheptenones.

The reduction potentials of **8** and **9** are $^1E_{1/2} = -1.05$, $^2E_{1/2} = -1.44$ and $^1E_{1/2} = -0.90$, $^2E_{1/2} = -1.37$ V (vs. SCE), respectively.[5] These values are similar to those of anthraquinones.[1]

The ^{1}H-NMR spectra of **8** and **9** in conc. D_2SO_4 indicate the formation of the dications **10** and **11** (Fig. 1, below). The changes in the ^{1}H-NMR chemical shifts of the seven-membered-ring protons ($\Delta\delta$ = 1.83 ppm) and of the other protons ($\Delta\delta$ = 1.35 ppm) in going from **8** to **10** are larger than those for the corresponding hydroxytropylium ion ($\Delta\delta$ = 1.50 ppm) and hydroxyphenalenylium ion ($\Delta\delta$ = 1.00 ppm),[6] respectively. This is presumably due to the diatropicity of the dications, since only small differences are observed for the corresponding $\Delta\delta$(^{13}C) values of these compounds.

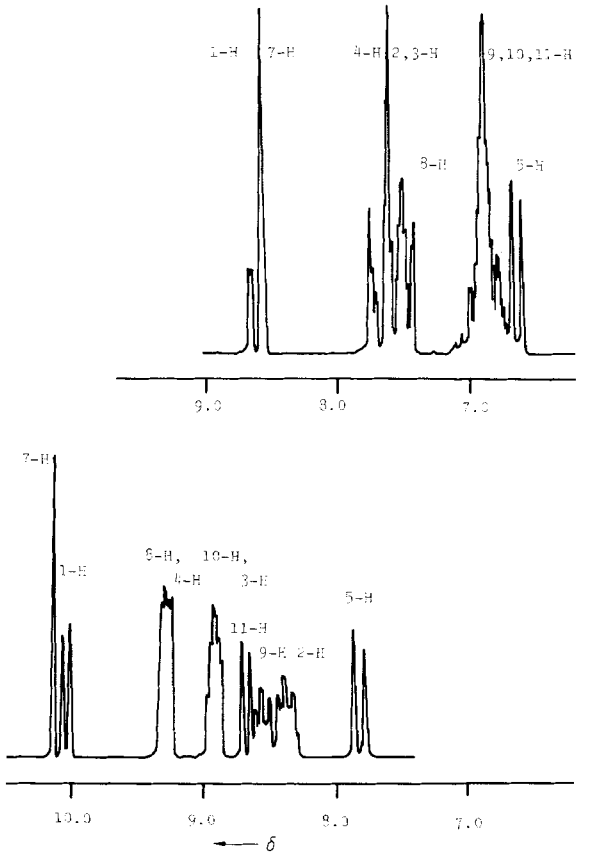

Fig. 1. Above: ^{1}H-NMR spectrum of the quinone cyclohepta[*a*]phenalene-6,12-dione **8** ($CDCl_3$, 90 MHz, δ values). Below: ^{1}H-NMR spectrum of the dication 6,12-dihydroxycyclohepta[*a*]phenalenediium **10** (conc. D_2SO_4, 200 MHz, δ values).

From the above results, it is concluded that the quinones **8** and **9** are formally composed of a tropone moiety and a phenalenone moiety; however, the dicationic species are not merely composed of hydroxytropylium and hydroxyphenalenylium ions, but are, contrary to expectation, novel dicationic diatropic compounds.

1,2-Bis(diisopropylamino)-1,2-dihydro-1,2-diborete**

By *Manfred Hildenbrand, Hans Pritzkow*, and *Walter Siebert**

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday

According to MO calculations for the $C_2B_2H_4$ system, the folded 1,3-dihydro-1,3-diborete structure **1** is the energetically favored isomer.[1] **1** has been prepared via several routes[2-5] and its structure confirmed by X-ray analysis of compounds **1c** and **1d**. Dehalogenation of the chloroboranes **2a-c** using Na/K alloy yields **1a-c**; compound **1d** is formed from **3d**, and **1e** is formed via a thermal rearrangement of the initially formed boranediylborirane **4e**. Compound **1f** is obtained, along with other compounds, from *t*Bu-C≡C-*t*Bu, $MeBBr_2$, and C_8K.[5] **1** should also be accessible via a rearrangement of the isomer of type **5**, which is 7-17 kcal/mol[1] higher in energy. After several unsuccessful attempts to synthesize 1,2-dihydro-1,2-diboretes,[3,6] we now report the preparation and structure of **5g**, the first derivative of 1,2-dihydro-1,2-diborete.[4b]

	1a, 2a [2]	1b, 2b [2]	1c, 2c [3]	1d, 3d [4a]	1e, 4e [2]	1f [5]	1g, 2g, 5g
R^1	*t*Bu	*t*Bu	NMe_2	$NiPr_2$	*t*Bu	Me	$NiPr_2$
R^2	Me	Et	*t*Bu	$SiMe_3$	$SiMe_3$	*t*Bu	H

Reaction of 1,2-bis(dichloroboryl)ethene **2** (R^1 = Cl, R^2 = H),[7] obtained from B_2Cl_4 and acetylene, with diisopropylamine affords **2g**,[8] which can be dehalogenated in refluxing benzene using Na/K alloy. Colorless crystals are obtained in 55% yield. That the product obtained, **5g**, is indeed the 1,2-dihydro-1,2-diborete is shown by the NMR data. The ^{1}H-NMR spectrum contains two septets separated by $\Delta\delta = 0.48$, two doublets for the methyl groups of the isopropyl substituents on the nitrogen atom, and a broad singlet ($\delta = 8.87$) for the olefinic protons. Only one septet is expected for a 1,3-arrangement of the boron atoms. The ring carbon atoms are found at $\delta(^{13}C) = 178.8$, whereas, for the 1,3-dihydro-1,3-diboretes, δ values of 37-126[2-5] are obtained. The ^{11}B-NMR shift ($\delta = 46.5$) also lies outside the range ($\delta = 31$-34[3,4b]) found for compounds of type **1**; it supports a dialkyldiaminodiborane(4) compound.[9] Neither in the IR nor in the Raman spectrum is a C=C band observed between 2100 and 1520 cm^{-1} and between 2100 and 1510 cm^{-1}, respectively.

The 1,2-dihydro-1,2-diborete structure derived from the NMR and MS data has been confirmed by an X-ray analysis[10] (Fig. 1).

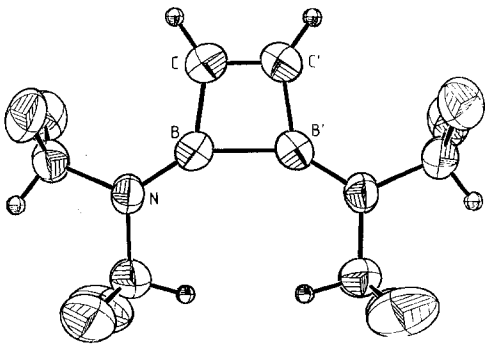

Fig. 1. ORTEP drawing of the structure of **5g** (vibration ellipsoids with 40% probability, arbitrary for the H atoms; methyl H atoms left out). Bond lengths [Å] and bond angles [°] (standard deviations 0.01 Å and 0.5°): CC' 1.31, BB' 1.75, BC 1.58, BN 1.38; CBB' 82.0, BCC' 98.0, NBB' 146.7.

The molecule lies on a crystallographically twofold axis. The C_2B_2 ring is planar (±0.007 Å) and the NC_2 atoms of the amino groups lie in the plane of the ring. The BB distance is longer than in a non-strained 1,2,4,5-tetraborinane.[11] The BC distance is in good agreement with the values for a BC single bond in a 1,3-diboretane[4a] and 1,2,4,5-tetraborinane,[11] but is significantly longer than those in **1c** (1.50 Å) and **1d** (1.52 Å). The calculations[1] for **5** predict a slightly longer CC double bond and a shorter BB single bond.

The rearrangement of **5g** to **1g**, expected on the basis of calculations,[1] takes place upon heating of a sample in [D_8]toluene to 120 °C. In the ^{1}H-NMR spectrum, a new singlet at $\delta = 2.21$ appears after 30 min and grows at the expense of the low-field signal ($\delta = 8.87$). Heating for five hours results in a conversion >95%; the singlet at $\delta = 8.87$ is barely observable and a septet at $\delta = 3.50$ has formed from the two septets originally present for **5g**. In the ^{11}B-NMR spectrum, an upfield shift from $\delta = 46.5$ to 37.3 is observed, and in the ^{13}C-NMR spectrum, an upfield shift from $\delta = 178.8$ to 37.5 for the ring carbon atoms is found. Analogous rearrangements could already take place at the temperature employed for the dehalogenation of other derivatives on account of the lower activation energies, and hence explain the formation of **1** from **2**.

Comparison of the structures of **1c** and **1d** with that of **5g** reveals that both π electrons are delocalized in the folded **1**, whereas they are localized in the CC double bond of the planar **5g**. Our results thus support the theoretical predictions[1] concerning the bonding and relative stabilities of **1** and **5**.

The X-Ray Crystal Structures of Two 1,2,4,5-Tetrathia-3,6-diazacyclohexanes**

By *Ray Jones, David J. Williams,* and *J. Derek Woollins**

Eight-membered sulfur-nitrogen rings $S_n(NR)_{8-n}$ are well known and have been extensively studied.[1] Their nitrogen atoms have planar environments and can thus be considered to be sp^2 hybridized and consequently non-basic. It is to be expected that cyclic sulfur-nitrogen compounds with other ring sizes would exist and there has been a brief report on compounds of the type $S_4(NR)_2$.[2] Here we report on the synthesis of compounds **1**–**4** and the crystal structures of **1** and **2**.[3]

1, R = C_2H_5
2, R = $CH_2C_6H_5$
3, R = n-C_6H_{13}
4, R = CH_2–CH_2–C_6H_5

Reaction of disulfur dichloride with primary amines under Ruggli-Ziegler high-dilution conditions gave **1**–**4**; use of *tert*-butylamine or aniline was unsuccessful, giving only polymeric material and the corresponding amine hydrochloride.

The crystal structures of **1** and **2** (Figs. 1 and 2) both reveal six-membered cyclohexane-type rings with the EtN and PhCH$_2$N groups in the 3,6-positions as expected. In both structures there is a crystallographic center of symmetry at the center of the ring. The structures have two unusual features. 1) All the S–N bond lengths (average 1.716 Å) are significantly longer than the previously reported values (ca. 1.67 Å) found for $S_n(NH)_{8-n}$.[4–8] 2) The angles at the nitrogen atoms, SNS = 111.3, CNS = 115.8, 116.8° (average values), reveal a substantial degree of pyramidalization; the nitrogen atoms lie 0.373 Å and 0.392 [0.379] Å from the plane of their substituents in **1** and **2**, respectively (the value in brackets refers to a second crystallographically independent molecule). This pyramidal (sp^3) geometry is in contrast to that observed for cyclic eight-membered sulfur-nitrogen compounds, which are all essentially trigonal.[4–8] The S–S bond lengths (2.054(1) Å) in **1** are marginally longer than those in **2** (2.037(2),

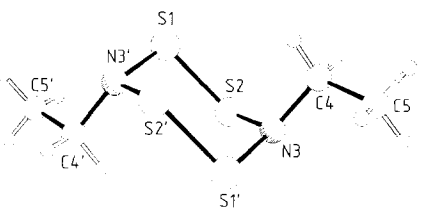

Fig. 1. Crystal structure of **1**. Important bond lengths [Å] and bond angles [°]: S1-S2 2.054(1), S1-N3' 1.714(3), S2-N3 1.716(3), N3-C4 1.475(4), C4-C5 1.506(8); S2-S1-N3' 104.8(1), S1-S2-N3 104.9(1), S2-N3-C4 115.7(3), S2-N3-S1' 111.6(2), C4-N3-S1' 117.3(2), N3-C4-C5 111.6(4).

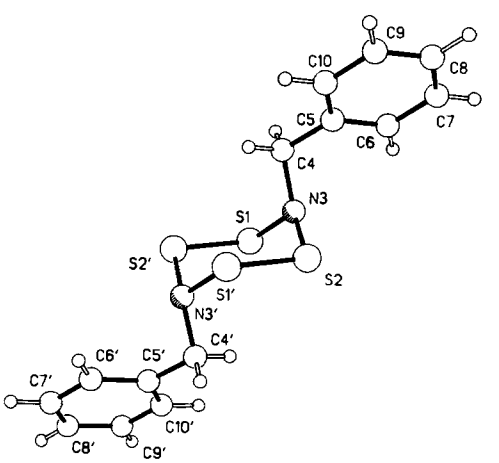

Fig. 2. Crystal structure of **2**. Important bond lengths [Å] and bond angles [°]: S1-S2' 2.037(2) [2.034(2)], S1-N3 1.713(4) [1.717(4)], S2-N3 1.720(3) [1.717(4)], N3-C4 1.479(5) [1.462(6)]; S1'-S2-N3 105.2(1) [105.9(1)]; S2-N3-S1 110.9(2) [111.3(2)], N3-S1-S2' 105.8(1) [105.3(1)], S2-N3-C4 116.7(3) [116.2(3)], S1-N3-C4 115.5(3) [116.5(3)]. Numbers in brackets are for the second crystallographically independent molecule.

[**] This work was supported by the University of London Central Research Fund.

2.034(2) Å). Although these differences are statistically significant, we are unable to rationalize them, particularly since the S–N distances are all equal in **1** and **2**. The SSN angles in both **1** and **2** are normal.

An additional notable feature is the axial substitution of the nitrogen atoms. In **1** there is a close approach (3.33 Å) of S1 to N1 of a neighboring molecule. However, in **2** there are no such close contacts; the shortest approach to N3 is 3.74 Å (to S2 of a neighboring molecule). Thus, it seems unlikely that packing forces are the determining factor in the unexpected axial substitution.

All of the above observations may be rationalized by assuming that **1** and **2** are held together by bonds with very little or no π character. The S–N bond lengths are the longest so far reported for such cyclic sulfur-nitrogen compounds. The axial substitution of the nitrogens may be a result of the importance of lone-pair repulsion between the adjacent nitrogen and sulfur atoms; this repulsion is minimized with the lone pairs of the nitrogen in the equatorial positions.

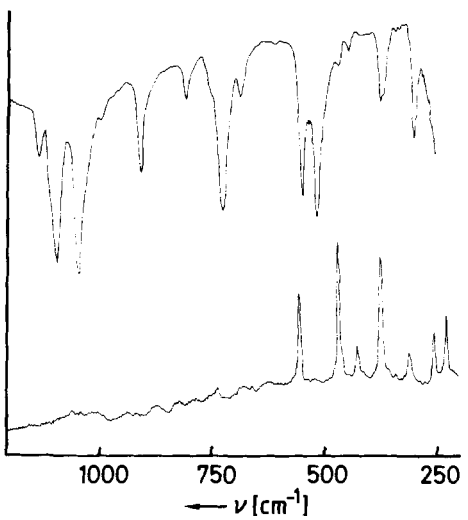

Fig. 3. Upper trace: IR spectrum, lower trace: Raman spectrum of **1**.

Vibrational spectroscopy has proved to be a useful tool for detecting S_n species with different ring sizes. The IR and Raman spectra of **1** are shown in Figure 3. The bands due to ν_{SS} have been correlated with the S–S distance in S_n rings[9] and in **1** the predicted frequency would be 470 cm^{-1}; the band at 473 cm^{-1} is thus readily assigned to ν_{SS}. By comparison with previous reports,[10] we propose that the bands at 738 and 910 cm^{-1} are largely due to ν_{SN}. **2**–**4** have very similar spectra to **1** in these regions; **2**: ν_{SS} = 479 cm^{-1}, ν_{SN} = 730, 905 cm^{-1}.

Experimental Procedure

1: Diethyl ether solutions of S_2Cl_2 (33 mmol in 20 mL) and $EtNH_2$ (100 mmol in 20 mL) were added over 16 h to 600 mL of stirred diethyl ether. The precipitate of $EtNH_3Cl$ was filtered off, and the filtrate was concentrated to ca. 20 mL and cooled (−78°C) to give **1** (1.2 g, 34%) as colorless crystals; m.p. ≈ 37°C. **2**–**4** were prepared in a similar fashion and recrystallized from ethanol or ethanol/diethyl ether; **2**: m.p. = 138°C, yield 26%; **3**: m.p. = 126°C, yield 24%; **4**: m.p. = 110°C, yield 16%.

All compounds gave good elemental analyses and showed the parent ion in mass spectra. **1**: *m/z* 214 (100%, M^+), 171 (65% S_4NEt^+), 108 (10%, S_2NHEt^+), 75 (15%, $SNEt^+$). IR spectra were recorded as KBr discs, Raman spectra were obtained using 647.1-nm excitation (50 mW) with a rotating cell arrangement; **1**, **2**, and **4** were quite stable in the laser beam, whereas **3** decomposed, making its spectrum difficult to record.

Crystals of **1** suitable for X-ray analysis were obtained by slow evaporation of a diethyl ether solution at −15°C; crystals of **2** were obtained from diethyl ether/ethanol.

UV and CD Spectroscopic Evidence of the Self-Association of a Schiff Base of all-*trans*-Retinal**

By *Ute Wingen, Lothar Simon, Michael Klein*, and *Volker Buß**

While the structural consequences of hydrogen bonding in solids may be studied directly, one usually has to rely on assumptions with regard to hydrogen bonded aggregates in solution. We have found that certain Schiff bases of all-*trans*-retinal form, in aprotic solvents, aggregates in which according to spectral data the chromophores assume fixed positions with respect to each other.

1a: $R^1 = CH(CH_3)_2$, $R^2 = CH_3$
1b: $R^1 = CH_2OH$, $R^2 = CH(CH_3)_2$

The circular dichroism (CD) of the Schiff base **1a** is practically nil down to 113 K in all solvents investigated; apparently the chiral group on nitrogen is not able to dis-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

criminate sufficiently between conformations that are oppositely twisted with respect to the C(6)–C(7) bond. In contrast, **1b** exhibits a markedly temperature-dependent CD in a mixture of 2,2-dimethylbutane and *n*-pentane. In a 2.45×10^{-4} M solution (Fig. 1, left), a pair of oppositely signed bands at 345 and 390 nm is already observed at room temperature. With decreasing temperature, the amplitudes of these bands grow dramatically and reach their maximum $\Delta\varepsilon$ values of +77 and −74 at 133 K, corresponding to rotational strengths of 210×10^{-40} and -170×10^{-40} cgs, respectively.[1] The increase of the CD upon cooling is accompanied by a long-wavelength shift of the pair of bands and the zero crossing point of about 8 nm.[2]

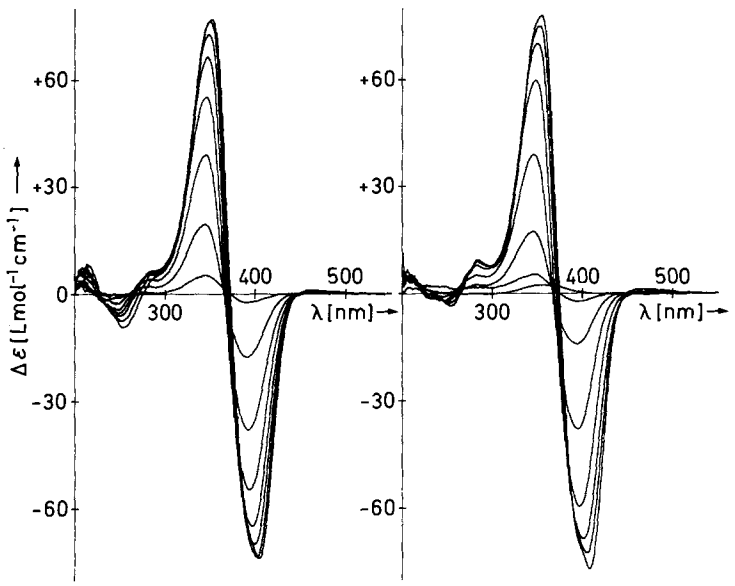

Fig. 1. Temperature- and concentration-dependent CD spectra of **1b** in Rigisolve (2,2-dimethylbutane—*n*-pentane 8:3). Concentration: 2.45×10^{-4} mol/L (left), 2.2×10^{-5} mol/L (right). The amplitude increase in the two series of spectra corresponds to cooling (starting from 283 K) first by 30, then by 20°, down to 133 K. The volume contraction of the solvent is taken into consideration in all spectra.

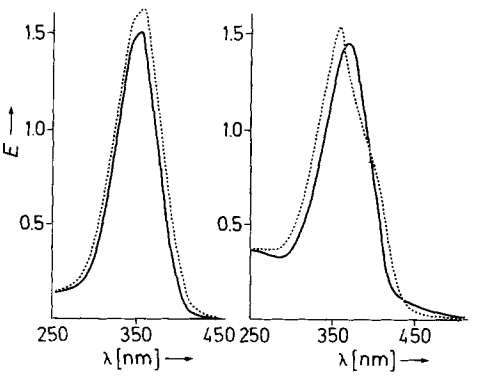
The CD is concentration dependent: in a solution diluted tenfold (Fig. 1, right), the rotational strengths increase significantly more slowly upon cooling but eventually attain the same final value as in the concentrated solution.

The temperature-dependent UV spectra also support, although less dramatically, an association of **1b** in contrast to **1a** (Fig. 2). At room temperature, the spectra of both compounds are practically identical; they exhibit an intense band with a maximum at 359 nm assigned to the longest-wavelength $\pi\pi^*$ excitation of the retinylidene chromophore. Upon cooling, only the band of **1b** undergoes splitting into an intense, short-wavelength (relative to **1a**) component and a weak component, recognizable only as a shoulder on the long-wavelength side of **1a**.

We formulate the association as a dimerization via hydrogen bonds to give **2**, which contains a ten-membered ring. The interaction of the electronic excitations of the two (identical) chromophores leads, according to exciton theory,[3] to splitting in the UV and the appearance of a pair of bands ("couplet") in the CD with a zero crossing point in the absorption maximum of the monomer **1b**.

Qualitative analysis clearly indicates that the two chromophores form an acute angle and must be arranged in an *M*-helical fashion.[4] An obtuse angle or even a linear arrangement of the retinylidene groups would result in a reversal of the intensity ratios in the UV; *P* helicity would result in the reverse sequence of signs in the CD. With these restrictions, molecular models suggest the structure of the dimer **2** given in Figure 3 with C_2 symmetry. The ten-membered ring assumes a conformation similar to the twist-boat geometry of (*Z*,*Z*)-1,5-cyclooctadiene,[5] the double bonds being replaced by two N···H–O fragments. The two retinylidene moieties extend approximately along the C_2 axis; their π-systems from C(15) to about C(11) are in close contact, which probably contributes to the stability of the aggregate. The absolute configuration of the dimer is fixed by the pattern of substitution of the two asymmetric carbon atoms. The hydrogen atoms on C(1′) and C(15) are nearly eclipsed. In analogues of **1b**, this conformation is especially favorable.[6] The isopropyl group, on the other hand, occupies the position in the dimer that offers the greater amount of space.



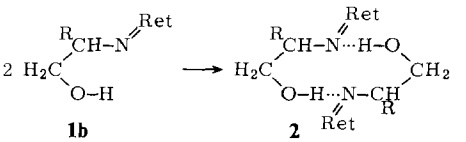


Fig. 2. UV spectra **1a** (——) and **1b** (· · · · ·) in Rigisolve at room temperature (left) and at 113 K (right). Concentrations: **1a**: 3.2×10^{-5} mol/L; **1b**: 3.6×10^{-5} mol/L.

1b **2**

R = $CH(CH_3)_2$, Ret = all-*trans*-retinylidene

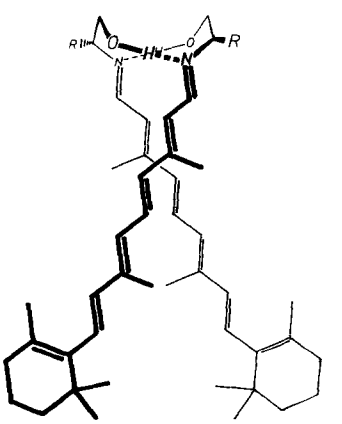

Fig. 3. Model of the structure of the dimeric aggregate **2** of **1b**, R = $CH(CH_3)_2$.

Rotational strengths calculated on the basis of this structure[7] agree well with the experimental values and support our model. The available data do not allow, at this time, a decision to be made as to whether other equilibria, apart from the dimerization, are involved in the formation of the aggregate. The factors that are responsible for the remarkable chiral discrimination and the stability of this system are the subject of further study.

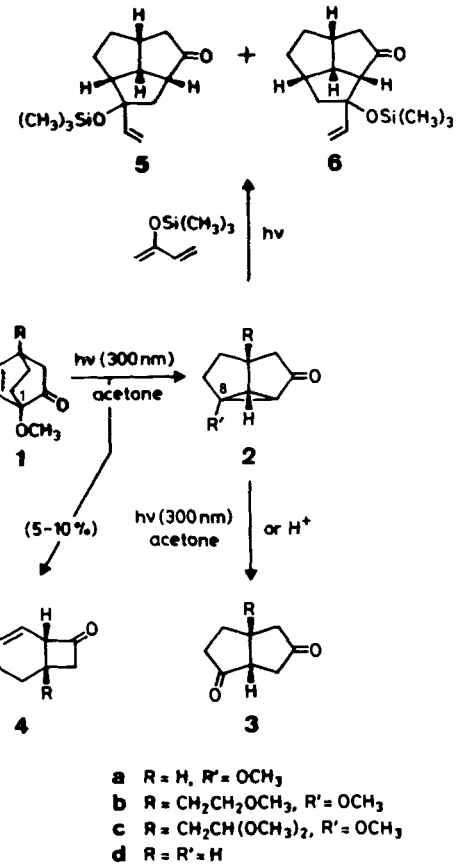
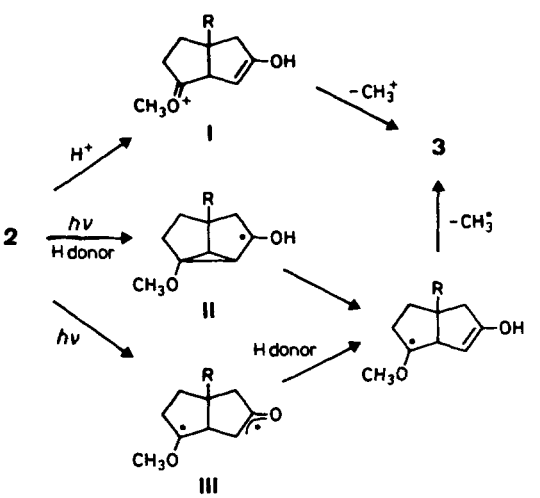
[7] For the conformation shown in Figure 3 (chromophores twisted 60° with respect to each other, separation of the two π-systems 300 pm), we calculated rotational strengths of 670×10^{-40} and -650×10^{-40} cgs for the short- and long-wavelength bands, respectively on the basis of the coupled oscillators model. Since the bands in the CD spectrum overlap strongly, the experimental rotational strengths are definitely several times larger than the values determined by integration.



Photochemistry of 1-Methoxybicyclo[2.2.2]octenones; Photolytic Cyclopropane Cleavage of the Initially Formed Tricyclo[3.3.0.0^{2,8}]octan-3-ones**

By *Martin Demuth,* Bernhard Wietfeld, Bipin Pandey,* and *Kurt Schaffner*



1-Methoxybicyclo[2.2.2]octenones **1a–c** are converted in a triplet-sensitized photoreaction into bicyclo[3.3.0]octanediones **3a–c** (Scheme 1; for **1a**→**3a** see ref. [1]). Diquinanes such as **3** are of synthetic interest.[2,3] Modified derivatives promise to serve as key intermediates for the synthesis of natural products such as the pentalenolactones.[4,5] We have investigated this reaction in order to elucidate the mechanism and to optimize the reaction conditions. We restricted this study to the analogues **1b** and **1c**,[6] which possess synthetically useful angular substituents and which are readily available, each in ca. 30% yield, from *p*-methoxyphenylacetic acid and *p*-methoxybenzyl cyanide, respectively.[2,5]

Irradiation ($\lambda = 300$ nm) of argon-flushed 1% solutions of **1b** and **1c** in 2:1 mixtures of acetone and isopropyl alcohol at room temperature gave **3b** and **3c**, respectively, in ≥75% yields[6] (quantum yields of product formation, $\Phi_{3b} = \Phi_{3c} = 0.03$[7]), along with **4b** and **4c** (5–10%).[6,8]

Rogers et al.[1] had previously postulated that the conversion **1a**→**3a** proceeds via an oxa-di-π-methane rearrangement to **2a**,[8] followed by photolytic cleavage of its three-membered ring[11,12] (Scheme 2: intermediate **III**); the reaction sequence ends with addition of H and loss of CH_3. We have now found that, upon irradiation of **1b** in acetone, **2b** is formed in low yield (ca. 5%). **2b** is also formed in benzene containing acetophenone, but not in benzene containing bicyclo[2.2.2]oct-2-en-2-yl phenyl ketone, which has a similar triplet energy (E_T(O–O) = 73.3 kcal/mol by phosphorescence in ether-isopentane-ethanol at 77 K[13]) but less readily abstractable H atoms. Whereas **2b** is stable in the dark in acetone solution, **2b** gave **3b** upon addition of methanol, isopropyl alcohol, or *p*-toluenesulfonic acid (Scheme 2: **2**→**I**→**3**). This transformation could also be effected in the absence of proton donors

Scheme 1. Photochemical transformations of the 1-methoxybicyclo[2.2.2]octenones **1a–c** and the tricyclo[3.3.0.0^{2,8}]octanones **2a–c** as well as addition of trimethylsiloxybutadiene to **2d** (all chiral compounds racemic).

Scheme 2. Protonolysis and photolysis of **2**. H donor: acetophenone, acetone, etc.

by irradiation of **2b** in acetone. Transient **2b** is thus firmly established as an intermediate in the transformation of **1b** into **3b**.

The light-induced step **2b** → **3b** is ca. 1.7 times faster in acetone than in [D_6]acetone. In *both* experiments, C_2H_6 (ca. 80%) and CH_4, but neither CH_3OH nor C_2H_4, were found in the gas phase by GC-MS. The H/D isotope effect shows that hydrogen abstraction is rate determining. The formation of ethane indicates that the 8-methoxy group is homolytically cleaved; moreover, the absence of methanol and ethylene rules out heterolytic cleavage and carbene elimination. Consequently, there are two possibilities for the primary step in the transformation of **2** into **3**: either hydrogen abstraction by the keto group (**2** → **II**) or the regioselective[11] β-cleavage of the cyclopropyl ketone following n→π* excitation (**2** → **III**). For **II**, ring opening would be expected to dominate over hydrogen abstraction from isopropyl alcohol, as has been found even for less strained α-hydroxycyclopropylcarbinyl radicals.[14]

The existence of intermediate **III** is strongly supported by an additional observation: On irradiation of **2d** ($\lambda = 300$ nm, benzene) in the presence of 2-trimethylsiloxybutadiene (spectral cut-off at ca. 290 nm), three of the four possible products with constitutions **5** and **6**[6, 15] are formed in a ratio of 1:2:4. Since direct excitation was used in this experiment, the diene most likely quenched all triplet-excited ketone by intersystem crossing. The conclusion drawn may therefore be valid only for the reaction of the singlet excited state of **2b**. That the addition occurs with poor regioselectivity is in better accord with the trapping of a biradical than a zwitterion. Furthermore, the mechanism of the transformations **2** → **3** is very likely independent of the substitution patterns **a**–**c**.

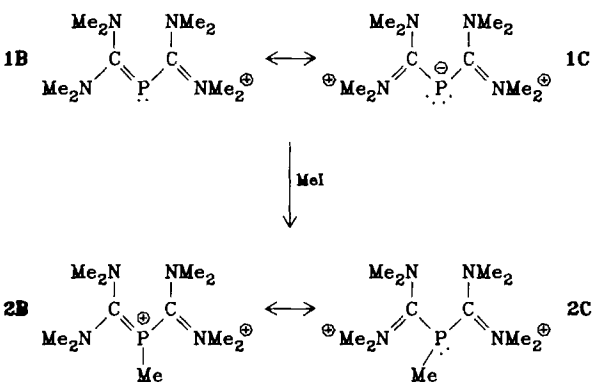
How is Phosphorus Bound in 2-Phospha- and 2-"Phosphoniaallyl" Cations?**

By *Roberta O. Day, Angela Willhalm, Joan M. Holmes, Robert R. Holmes,** and *Alfred Schmidpeter**



Dedicated to Professor Karl Dimroth on his 75th birthday

The 2-phosphaallyl cations[1, 2] are of practical interest as building blocks in the synthesis of phosphaheterocycles[2] as well as of theoretical interest as models with phosphorus in the center of a potentially conjugated chain.[3] Their bonding system may in principle be described by one of the three possibilities **A**, **B**, and **C** (E = P), which should result in different structures.

A **B** **C**

For E = N,[4] structurally investigated examples cover the range from **A** (2-azaallenium ions) to **B** (2-azaallyl cations) depending on the nature of the substituent at C. For E = P, the linear arrangement **A** was much less feasible from the outset because two-coordinate phosphorus compounds have been found to be bent (by an angle of around 100°, usually less than the tetrahedral angle) in every case up to now. Whereas description **C** would account for such a bond angle, it is consistent with neither the chemical behavior of the 2-phosphaallyl cations, nor with the strong variation of $\delta(^{31}P)$ with the C-substituents.[2] The latter is not understandable in the absence of π-interactions between the phosphide center and the carbenio ligands.

The C-substituents also govern the electrophilicity of phosphorus. Thus, only cation **1** with four amino groups can be methylated by methyl iodide to give the dication **2**. If derived from form **B**, the center in **2** should be planar, as in the homologous biguanide dications[5] and in the isoelectronic tetraaminoallyl cations.[6] On the other hand,

[**] This work was supported by the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie (*A. S.*) and by the NSF (CHE 8205411) and NIH (GM 21466, *R. R. H.*).

it should be pyramidal if derived from form **C**. With X-ray structural investigations on crystals of the perchlorate of **1**[7] and the diiodide of **2**,[8] it is now possible to compare **1** and **2** and their analogues.

The molecular structure of **1** (Fig. 1, top) shows the usual bent geometry at phosphorus, as well as PC bond lengths that are in accord with a bond order of 1.5, corresponding to **B**. Nevertheless, the coplanarity that would be optimal for **B** is not quite attained. As in the allyl cation, **1** (CH instead of P),[6] the dimethylamino groups are twisted somewhat out of the central plane as a result of their steric interaction, and the interior angles at carbon are considerably larger than the exterior angles. The CN bond lengths also agree with those found for the allyl cation (average, 135 pm).

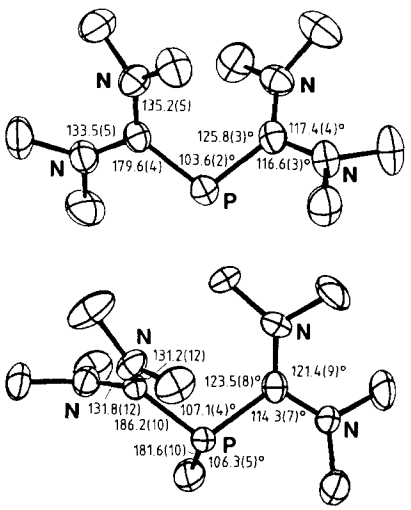

Fig. 1. ORTEP plot of the structures of **1** (top) and **2** (bottom) in the crystals of **1** ClO_4 and **2** I_2. The thermal ellipsoids are shown at the 50% probability level. Hydrogen atoms have been omitted for clarity. Bond lengths [pm] and bond angles [°] (mean values).

The C_2 symmetry that is approximately present in **1** is fully lost as a consequence of methylation to give **2** (Fig. 1, bottom). With a somewhat wider CPC angle than in **1**, the phosphorus coordination is now essentially trigonal pyramidal, and the planes of the two $C(NMe_2)_2$ groups are rotated by an angle of 69° with respect to one another. The PC bonds attain the single bond distance, while the CN bonds are clearly shorter than in **1**.[9]

Accordingly, the methylation of the phosphaallyl cation is well described by **1B**→**2C**. In **1**, where the phosphorus is bicoordinated, there is obviously a normal conjugated allylic system present. In this case, the phosphorus can best be viewed as using its p orbitals for both π- and σ-bonding, the latter of which is consistent with the small bond angle. The lone (s-)electron pair is accordingly not available to an electrophile without considerable promotion energy. It therefore remains in **2** and becomes stereochemically active. Instead, the π-electron pair is involved (at least formally)[10] in the binding of the methyl group. The dication **2**, therefore, is no longer a conjugated allylic system but merely a phosphane substituted with two independent amidinium groups. The conjugated form **2B** would require a nearly planar coordination of the phosphorus, the necessary energy for which is not sufficiently provided by the resonance stabilization. In contrast, in the isoelectronic tetraamino cations and dications with CR and NR, respectively, instead of PMe, the allylic bonds exhibit the highest barriers to rotation.[5, 11]

Allylation of Aldehydes with Etherification by Dialkoxydichlorotitanium/Allyltrimethylsilane; an Asymmetric Variant of the Sakurai Reaction**

By *Rene Imwinkelried* and *Dieter Seebach**

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

The preparation of homoallylic alcohols by $TiCl_4$-mediated allylation of aldehydes and ketones with allyltrimethylsilane was first described by *Sakurai* et al. in 1976.[1] We have now found that dialkoxydichlorotitanium reagents behave quite differently from $TiCl_4$ under the same conditions. Treatment of aldehydes with 1.1 equivalents of dialkoxydichlorotitanium at −75 °C,[2] and subsequent addition of 1.2 equivalents of allyltrimethylsilane led to the isolation in good yields of homoallylic ethers **1** (Table 1). The reagents are easily generated in situ either by mixing equimolar amounts of $TiCl_4$ and commercial $Ti(OR')_4$

[*] Prof. Dr. D. Seebach, Dipl.-Chem. R. Imwinkelried
Laboratorium für Organische Chemie

ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)
[**] Part of the projected Ph. D. thesis of *R. I.*, ETH Zürich.

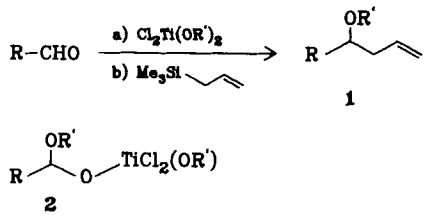

Table 1. Preparation of homoallylic ethers **1** (CH_2Cl_2, −75°C, 30 min; −75 to +20°C).

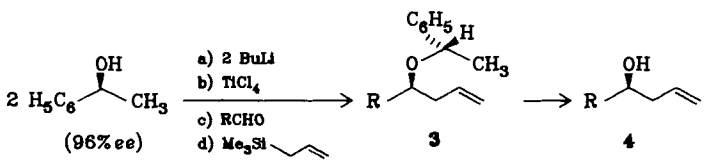
	R	R′	Yield [%]
1a	C_6H_5	$CH(CH_3)_2$	90
1b	C_6H_5	C_2H_5	95
1c	C_6H_5	CH_2–CH=CH_2	50
1d	$CH_2CH_2C_6H_5$	$CH(CH_3)_2$	65

($R' = C_2H_5$, $CH(CH_3)_2$)[3] or by allowing two equivalents of LiOR′ to react with $TiCl_4$.

In this one-step synthesis of homoallylic ethers,[4, 5] the carbonyl oxygen atom of the aldehyde is replaced by an alkoxy and an allyl group.[6] We assume that the first step is the addition of an alkoxy group to the aldehyde. The resulting (titanated) hemiacetal **2** then undergoes substitution of the former aldehyde oxygen by the allyl group. Quenching with aqueous base before addition of the allylsilane leads to complete recovery of the aldehyde, indicating that acetals $R-CH(OR')_2$ are not involved as intermediates.[5]

The synthesis of homoallylic ethers **3** from chiral, nonracemic alcohols and subsequent cleavage of the ether bond should allow the preparation of optically active homoallylic alcohols **4**. Thus, (*S*)-(−)-1-phenylethanol (96% *ee*)[7] reacted to give the homoallylic ethers **3** with a diastereoselectivity of ca. 90%[8]—racemic 1-phenylethanol produced (±)-**3a** and (±)-**3b** with 97.5% and 89% *ds*, respectively.[9] By mild cleavage of the benzylic ether bond with iodotrimethylsilane,[10] the ethers **3** were converted into the optically active homoallylic alcohols **4** (Table 2).[11]



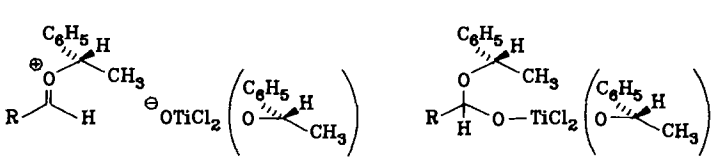


Table 2. Preparation of chiral homoallylic ethers **3** and homoallylic alcohols **4** [8, 11]. For conditions see Table 1.

	R	Yield [%]	*ds* [%]	*ee* [%]	$[\alpha]_D^{20}$ [a]
3a	$CH_2CH_2C_6H_5$	42	91.5		
3b	$CH(CH_3)_2$	50	90		
4a	$CH_2CH_2C_6H_5$	≈75		80 (*R*)	+16.9
4b	$CH(CH_3)_2$	≈75		78 (*S*)	− 2.8

[a] In $CHCl_3$, $c = 1$.

To the best of our knowledge, this is the first asymmetric synthesis of homoallylic alcohols via *open-chain* acetal derivatives.[12] It is not yet clear whether the observed asymmetric induction arises in the reaction of the oxonium ion **5** (addition) or of the hemiacetal derivative **6** (substitution).

A New Type of Sandwich Complex Formed by Ag^I and $[Pt_3(\mu_2\text{-}CO)_3(PiPr_3)_3]$**

By *Alberto Albinati, Klaus-Hermann Dahmen, Antonio Togni,* and *Luigi M. Venanzi**

Although many homo- and heteronuclear cluster compounds of gold are known,[1] silver-containing clusters are uncommon.[2] *Briant* et al.[3] recently reported the formation of a gold-platinum cluster in which $[Au\{P(c\text{-}C_6H_{11})_3\}]^+$ caps the Pt_3 fragment $[Pt_3(\mu_2\text{-}CO)_3\{P(c\text{-}C_6H_{11})_3\}_3]$.[4] Fragments of the type $[Pt_3(CO)_3L_3]$ are recurrent building blocks in platinum cluster chemistry[5] and can form sandwich-type complexes in which the central unit can be either Hg or Hg_2, e.g., **1**.[6] We describe here the preparation and X-ray crystal structure of the sandwich complex **2** in which two Pt_3 fragments are joined by Ag^+.

$[Hg_2\{Pt_3(\mu_2\text{-}CO)_3(PPh\mathit{i}Pr_2)_3\}_2]$ **1**
$[Ag\{Pt_3(\mu_2\text{-}CO)_3(P\mathit{i}Pr_3)_3\}_2](CF_3SO_3)$ **2**

Complex **2** is obtained in 65% yield as air-stable, dark-red prismatic crystals[7] on addition of ca. 1.2 equivalents of $AgCF_3SO_3$ to a CH_2Cl_2 solution of $[Pt_3(CO)_3(P\mathit{i}Pr_3)_3]$. The structure of **2**[8] consists of discrete cations and $CF_3SO_3^-$ anions. The cations (Fig. 1) consist of two Pt_3 fragments joined by a Ag^+ ion placed between them on a crystallographic inversion center. Therefore, the two Pt_3 fragments have a staggered configuration. The structure of the cation is distorted antiprismatic, since two of the Ag-Pt distances to each triangle (2.828(2) Å) are shorter than the third (2.853(2) Å). This type of distortion is observed also in the Hg_2Pt_6 cluster **1**.[6] The Pt-Pt distances within each triangular unit are not equivalent, two of them being longer than those found in the parent Pt_3 cluster[4] and in **1**.[6] The CO ligands symmetrically bridge the platinum atoms and are slightly bent towards the silver ion, while the phosphane ligands bend away from the Pt_3 plane. The mean deviations of the oxygen and phosphorus atoms from this plane are 0.8 and 0.9 Å, respectively.

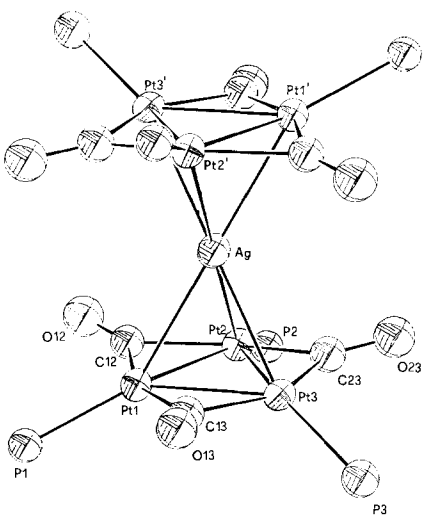

Fig. 1. ORTEP diagram of the structure of the cation of **2** in the crystal [8]. Selected bond lengths [Å] and angles [°]: Ag-Pt1 2.853(2), Ag-Pt2 2.825(2), Ag-Pt3 2.831(2), Pt1-Pt2 2.668(2), Pt1-Pt3 2.657(2), Pt2-Pt3 2.672(2), average Pt-P 2.28(1), average Pt-C 2.00(8); Pt1-Pt2-Pt3 59.68(5), Pt1-Pt3-Pt2 60.08(5), Pt2-Pt1-Pt3 60.24(5), Pt1-Ag-Pt2 56.05(3), Pt1-Ag-Pt3 55.74(3), Pt2-Ag-Pt3 56.38(3).

The ^{31}P- and ^{195}Pt-NMR data are consistent with this structure if one assumes rapid rotation of the Pt triangles on the NMR time scale. The values of the chemical shift and coupling constants[9] fall within the expected ranges.[10] The IR spectrum shows three bands in the carbonyl region.[11]

Sandwich complexes of type **2** can be obtained with several phosphanes (e.g., $PPh\mathit{i}Pr_2$), and clusters of the type $[Pt_3(CO)_3L_3]$ react also with other metal ions (e.g., Cu^+ and Cd^{2+}), giving products that are analogous to **2**.[12] Thus, there appears to be an extensive coordination chemistry based on Pt_3-cluster units.

Novel High-Nuclearity HgCoRu and HgCoFe Sandwich Complexes. Synthesis and Structure of $[Hg\{RuCo_3(\mu\text{-}CO)_3(CO)_9\}_2]$**

By *Pierre Braunstein,* Jacky Rosé, Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*

The isoelectronic character of Au^I and Hg^{II} accounts for the structural analogy found between heteronuclear metal-metal bonded complexes of these ions.[1] A particularly interesting and rapidly expanding class of mixed-metal clusters is that in which the $[AuPR_3]^{\oplus}$ ion, isolobal with $H^{\oplus}$, caps the triangular face of a transition metal cluster.[2] The first examples of a similar bonding mode for the isolobal $[HgX]^{\oplus}$ ion have recently been reported for X = Br[3] and $X=Co(CO)_4$.[4] The divalent $Hg^{2\oplus}$ ion has now been found to react with the anionic clusters $[MCo_3(CO)_{12}]^{\ominus}$ (M = Fe, Ru) with formation of the novel sandwich complexes **1** and **2**. In particular, the nonanuclear $Hg(RuCo_3)_2$ cluster is formed in 60% yield as stable black-green crystals[5] upon addition of 2 equivalents of $K[RuCo_3(CO)_{12}]$ to $HgBr_2$ in CH_2Cl_2. It is noteworthy that **2** is also formed—

along with $HgBr_2$—by ligand disproportionation of $BrHg[RuCo_3(CO)_{12}]$ (CH_2Cl_2, 7 d, 5 °C); **2** precipitates directly in the form of crystals that are suitable for X-ray structure analysis.

$[Hg\{MCo_3(\mu\text{-}CO)_3(CO)_9\}_2]$ **1**, M = Fe; **2**, M = Ru

The structure[6] of the $Hg(RuCo_3)_2$ cluster **2** consists of discrete molecules having an imposed C_i symmetry, in which two $RuCo_3$ tetrahedral units are joined by a $Hg^{2\oplus}$ ion placed sandwiched between the Co_3 planes, at 2.382(1) Å from each plane. Alternatively, this structure can be viewed as consisting of two trigonal bipyramidal metal cores $HgCo_3Ru$ sharing a common vertex. Since $Hg^{2\oplus}$ is on a crystallographic inversion center, the $RuCo_3$ units are staggered and $Hg^{2\oplus}$ is located in a strongly distorted octahedral cavity. The Co–Hg distances range from 2.777(2) to 2.816(2) Å. The other metal-metal distances and the disposition of the carbonyl ligands are similar to those found in related $RuCo_3$ clusters in which the Co_3 face is capped by $[CuPPh_3]^{\oplus}$, $[AuPPh_3]^{\oplus}$[7] or $[HgCo(CO)_4]^{\oplus}$.[4] The structure of **2** can also be compared with that of bimetallic $Hg(Pt_3)_2$ clusters.[8]

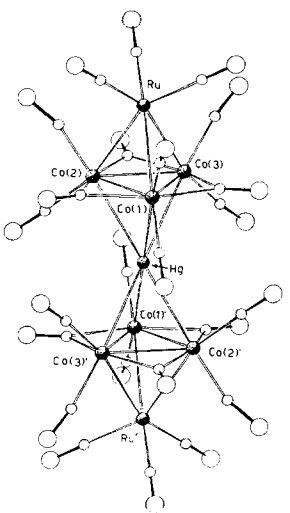

Fig. 1. Crystal structure of **2**. Selected bond distances [Å] and angles [°]: Hg-Co(1) 2.816(2), Hg-Co(2) 2.791(3), Hg-Co(3) 2.777(2), Ru-Co(1) 2.687(3), Ru-Co(2) 2.681(3), Ru-Co(3) 2.689(4), Co(1)-Co(2) 2.522(2), Co(1)-Co(3) 2.547(2), Co(2)-Co(3) 2.520(2), Co(1)-Hg-Co(2) 53.5(1), Co(1)-Hg-Co(3) 54.2(1), Co(2)-Hg-Co(3) 53.8(1), Co(1)-Ru-Co(2) 56.0(1), Co(1)-Ru-Co(3) 56.6(1), Co(2)-Ru-Co(3) 56.0(1), Co(2)-Co(1)-Co(3) 59.6(1), Co(1)-Co(3)-Co(2) 59.7(1), Co(1)-Co(2)-Co(3) 60.7.

Preliminary reactivity studies indicate that heating $Hg(FeCo_3)_2$ in toluene leads to metal-metal bond cleavage with formation of, *inter alia*, metallic Hg and $[(\eta^6\text{-toluene})Co_4(CO)_9]$.[9] Interestingly, Et_4NCl reacts with **1** in CH_2Cl_2 with extrusion of $Hg^{2\oplus}$, affording $Et_4N[FeCo_3(CO)_{12}]$[10] and $HgCl_2$. This opens the way to a number of double-exchange reactions.

$n Bu_4N[FeCo_3(\mu\text{-}CO)_3(CO)_9\{\mu_3\text{-}AuCo(CO)_4\}]$ **3**
$[RuCo_3(\mu\text{-}CO)_3(CO)_9\{\mu_3\text{-}HgCo(CO)_4\}]$ **4**

Attempts to synthesize analogous Au-complexes, using the methods developed above, by reaction of $n Bu_4N[AuI_2]$[11] with $K[FeCo_3(CO)_{12}]$ (THF/H_2O, 0 °C, molar ratio 1 : 2) led to formation of the FeCoAu-cluster **3**, the proposed structure of which is supported by the spectroscopic data presently available[12] and by analogy with the isoelectronic RuCoHg cluster **4**.[4]

Reductive Carbonylation of *o*-Nitrophenol with a Fe-Pd Cluster-Derived Heterogeneous Catalyst; CO Migration in $[FePdPt(CO)_4(Ph_2PCH_2PPh_2)_2]$**

By *Pierre Braunstein,* Jacques Kervennal,* and *Jean-Luc Richert*

Mixed-metal cluster-derived (MMCD) heterogeneous bimetallic catalysts are of great interest at present because of their improved catalytic properties over those of conventionally prepared catalysts.[1,2] We have recently reported the selective carbonylation of nitrobenzene to phenyl isocyanate,[2] using a catalyst obtained from $[Pd_2Mo_2(\eta\text{-}C_5H_5)_2(CO)_6(PPh_3)_2]$.[3] We have subsequently become interested in Fe-Pd catalysts for the carbonylation of *o*-nitrophenol **1** to benzoxazol-2-one **2**, which is a structural element of herbicides[4] and has a high synthetic potential.

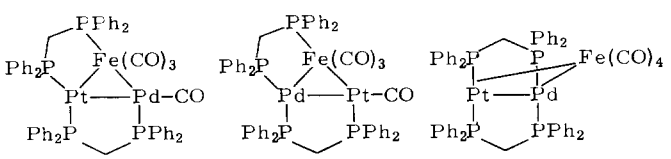
1 2

For reasons detailed previously,[2] we therefore attempted to synthesize neutral, low-valent mixed Fe-Pd carbonyl clusters stabilized by bridging ligands such as $Ph_2PCH_2PPh_2$(dppm). This stabilization should prevent cluster fragmentation during the impregnation of the inorganic support (catalyst preparation); even with thermodynamically stable clusters, modifications of the metal core can occur under very mild impregnation conditions.[5]



3 4

The reaction of the Pd_2 complex **3** with $Na_2Fe(CO)_4$ afforded the $FePd_2$ cluster **4**,[6] the structure of which was established on the basis of analytical and spectroscopic data[6] and by comparison with related systems.[8]

The catalyst derived from cluster **4** effects the reductive carbonylation of *o*-nitrophenol **1** to the benzoxazolone **2** better (i.e., with higher conversion and higher selectivity) than the conventional catalyst (prepared by mixing iron oxalate and palladium acetate) (Table 1). Addition of pyridine is found beneficial and the main properties of the MMCD catalyst are retained on repeated use. To our knowledge, this is, together with a patent,[9] the first reported use of heterogeneous catalysts for this reaction.

By analogy to the reaction **3**→**4**, the mixed-metal complex $[PdPtCl_2(dppm)_2]$ afforded a mixture of the two isomers **5a** and **5b**.[6] We and *Seddon* et al.[10] have independently found that **5a** and **5b** cannot be separated by either column chromatography or fractional crystallization. This could be due either to the very similar physico-chemical properties or to the rapid interconversion of the two isomers.

5a 5b 5c

However, if excess $Na_2Fe(CO)_4$ is used and the work-up is carried out at low temperatures,[6] **5a** can be obtained as the *only* isomer in 98% yield. In tetrahydrofuran (THF) at room temperature, **5a** immediately isomerizes to **5b**; a 1 : 1 mixture is obtained at equilibrium (18 h at 17 °C). This process can be followed using ^{31}P-NMR spectroscopy or IR spectroscopy (increase in intensity of the band at 2000 cm^{-1} due to the CO bonded to Pt in **5b**). The transformation **5a**→**5b** cannot be reversed by decreasing the temperature. Therefore, **5a** is the kinetically formed isomer and the thermodynamic preference for **5b** is only very small in view of the position of the **5a** ⇌ **5b** equilibrium.

This unique isomerization under very mild conditions may contribute to a better understanding of the chemistry of bi- and polynuclear as well as A-frame complexes. A possible (solvent-stabilized) intermediate could be the symmetrical complex **5c** in which the $Fe(CO)_4$ fragment would occupy the position of the isolobal CH_2 group in the known methylene-bridged A-frame complexes. Facile metal-phosphorus bond breaking and carbonyl migration appear to occur, allowing insertion of the $Fe(CO)_3$ group into the Pd–P (**5a**) or Pt–P bond (**5b**). The net result of this process is a very facile CO migration between two different adjacent metal centers, which is of relevance to the activation of bimetallic catalysts and CO chemistry.

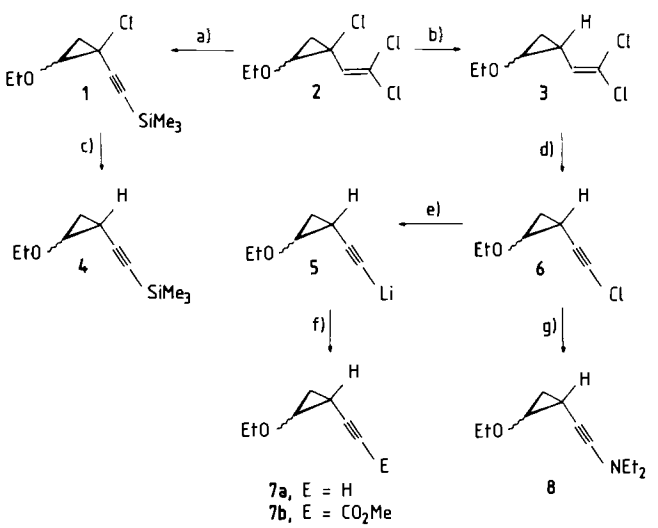
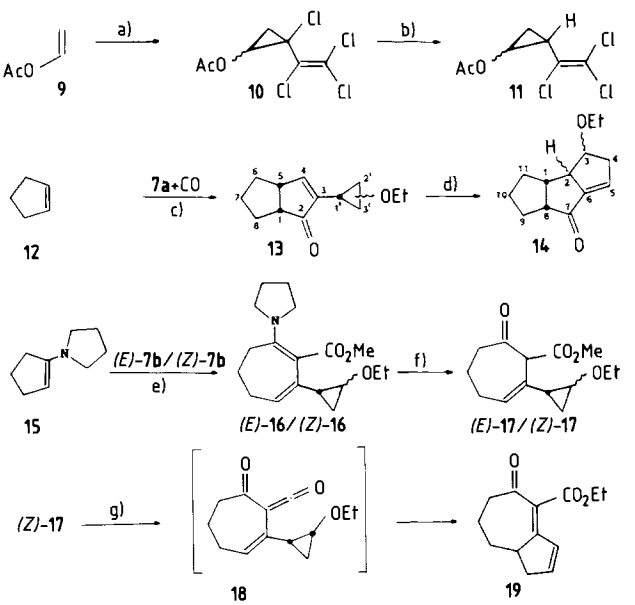
New Donor-Substituted Vinyl- and Alkynylcyclopropanes as Synthetic Building Blocks**

By *Schahab Keyaniyan, Michael Apel, Joe Pierce Richmond,* and *Armin de Meijere**



Dedicated to Professor Wolfgang Lüttke on the occasion of his 65th birthday

The vinylcyclopropane–cyclopentene rearrangement is one of the most versatile methods for the annelation of five-membered rings.[1] Enhancement of the rate of this reaction by electron-donating substituents in the 1-[2] and especially in the 2-position[3] of the cyclopropane ring is in the extreme case of 2-vinylcyclopropanolates so pronounced that cyclization occurs at room temperature. In order to extend the usefulness of the (halovinyl)-[4] and alkynylcyclopropanes[5] developed by us, we have sought access to the corresponding donor-substituted building blocks, examples of which include compounds **3**, **11** and **7**.



Ethyl vinyl ether and other enol ethers polymerize upon heating with tetrachlorocyclopropene. On the other hand, α-elimination of 1,1,3,3-tetrachloropropene produced the carbene 1,3,3-trichloro-2-propenylidene, which added to ethyl vinyl ether to give 1-chloro-1-(2,2-dichlorovinyl)-2-ethoxycyclopropane **2** (46%, $E/Z = 2.0$)[4c] (Scheme 1). As in the case of 1-chloro-1-(trichlorovinyl)cyclopropanes,[5] reaction of **2** with MeLi followed by quenching with electrophiles affords substituted alkynylcyclopropanes such as **1** (57%, with Me_3SiCl).[6] However, the yield upon reduction of **1** to **4** was disappointing (30%).

A substantial improvement was achieved by the newly developed sequence in which the ring chlorine in **2** is selectively removed by ultrasonication[7] with zinc/copper to yield **3** (82%, $E/Z = 1.0$) without retention of configuration.[8] The dehydrochlorination of **3** to give the chloroacetylene **6** was best achieved[9] (77%, $E/Z = 1.5$) with potassium hydroxide in CH_2Cl_2/dibenzo-[18]crown-6.[10] Reaction of **6** with lithium dialkylamides affords ynamines[11] such as **8** (38%, not optimized, $E/Z = 1.0$). Halogen-metal exchange followed by substitution with electrophiles converted **6** *via* **5** into synthetically interesting building blocks, the 1-alkynyl-2-ethoxycyclopropanes **7** (**7a**, 59%, $E/Z = 0.5$; **7b**, 78%, $E/Z = 0.83$).[6] The diastereomers of **7b** could be separated by chromatography on silica gel.

Surprisingly, the addition of thermally ring-opened tetrachlorocyclopropene[4a,b] to vinyl acetate was achieved *without* polymerization and afforded **10** (85%, $E/Z = 0.61$), which could be selectively reduced to 2-(trichlorovinyl)cyclopropyl acetate **11**, a potential precursor to building blocks analogous to **7** and **8** (Scheme 2).

Scheme 1. a) 1) MeLi, tetrahydrofurane (THF), −35°C; a) Me_3SiCl, −35°C→RT. b) Zn/Cu, THF/H_2O (8/1), ultrasonication, 65°C, 20 h. c) $LiAlH_4$, THF, Δ, 10 h. d) KOH, CH_2Cl_2, dibenzo-[18]crown-6, 24 h. e) *n*BuLi, THF/*n*-hexane, −78°C. f) MeOH (→**7a**); $ClCO_2Me$ (→**7b**). g) $LiNEt_2$, Et_2O, −20°C.

Scheme 2. a) Tetrachlorocyclopropene, 155°C, 36 h. b) Zn/Cu, THF/H_2O (8/1), ultrasonication, 65°C, 20 h. c) $Co_2(CO)_8$, CO, 120°C, 48 h. d) 600°C, 0.1 torr, 0.09 s. e) (*E*): 125°C, (*Z*): 135°C. f) Et_2O, 2 N HCl, RT. g) 250°C, 0.02 torr, 0.8 s.

Cycloadditions to the triple bond of such alkynylcyclopropanes afford vinylcyclopropanes[12] in which the vinyl group is incorporated into a ring and whose rearrangement to a cyclopentene should be facilitated by the 2-ethoxy or the 2-acetoxy function.

Thus reaction of (*E*/*Z*)-**7a** with cyclopentene **12** and $Co_2(CO)_8$ under CO (cf. [13]) followed by chromatographic separation gave a 1 : 1.6 mixture (30%) of both diastereomers of 3-(2-ethoxycyclopropyl)-*cis*-bicyclo[3.3.0]oct-3-en-2-

Institut für Organische Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, as well as by a NATO Research Grant, Hoechst AG, and BASF AG. We thank Prof. *I. Erden* for helpful discussions.

one, (*E*)-**13**[6] with (*E*) configuration on the 3-membered ring and a 1:1 mixture (4%) of both diastereomers of (*Z*)-**13**. Reaction of pure (*E*)-**7b** with 1-cyclopentenylpyrrolidine **15** at 125°C furnished the cycloheptadiene derivative (*E*)-**16** (55%); (*Z*)-**7b** was converted at 135°C into (*Z*)-**16** (47%). The enamines **16** can be hydrolyzed to the methyl 7-oxo-2-cycloheptene-1-carboxylates (*E*)-**17** (16%) and (*Z*)-**17** (37%),[6] respectively.

Upon flash vacuum pyrolysis, **13** is smoothly converted into the linearly annelated triquinane **14**[6] (39% after chromatography on SiO_2).[13] Product **14** consisted of three stereoisomers in a ratio of 4:2:1, whose separation thus far has been achieved only by capillary gas chromatography. According to ^{1}H-, ^{1}H,H-COSY- and ^{1}H,^{13}C-correlation-NMR spectra, the ratio of *anti*- and *syn*-configurated isomers is 5:2 or 3:4. The cycloheptene derivative, (*Z*)-**17**, rearranges especially easily; evidently the main reason for this is that the β-ketoester splits off methanol above 250°C, forming the ketoketene **18**,[14, 15] which, due to favorable stereochemistry, can cyclize with ethoxy-group migration to give ethyl 3-oxobicyclo[5.3.0]deca-1,9-diene-2-carboxylate **19**.

Heterogeneous Redox Catalysis on Ti/TiO_2 Cathodes—Reduction of Nitrobenzene**

By *Fritz Beck** and *Wolfgang Gabriel*

Reductions with low valency titanium compounds are well known in organic chemistry. Typical examples are, inter alia, the reduction of nitro compounds with Ti^{II}[1][2] and the reductive dimerization of ketones to olefins with Ti^{II}.[3] Stoichiometric quantities of reducing agent were used in these reactions. The selectivity of the processes is explained in terms of a complexation of the reactants with the titanium species. Since large amounts of reagents such as $TiCl_3$ are not easy to handle, it was suggested that the reduction be carried out on an inert cathode in the presence of a dissolved redox mediator such as $(TiO)SO_4$[4a] or $TiCl_4$.[4b] We report herein on a further simplification, namely the oxidic Ti-redox system fixed to the surface of a Ti cathode.

The Ti/TiO_2 electrode was fabricated using a method employed in the production of ceramics.[13] As shown by the cyclic voltammograms 1a, b in Figure 1, reduction of the surface layer starts at ca. $U_H = -0.1$ V with respect to a standard hydrogen electrode. This corresponds to the equilibrium potential for Reaction (a):[5]

$$Ti(OH)_4 + e^{\ominus} + H^{\oplus} \longrightarrow Ti(OH)_3 + H_2O \qquad (a)$$

At more negative potentials, further reduction processes come into operation, with a current maximum at $U_H = -0.73$ V and a shoulder at $U_H = -0.65$ V. Whether $Ti^{IV/III}$ transitions, e.g. Reaction (b),

$$TiO_2 + H_2O + H^{\oplus} + e^{\ominus} \longrightarrow Ti(OH)_3,\ U_{H,O} = -0.79\ V \qquad (b)$$

or $Ti^{III/II}$ redox processes operate,[6] both of which are possible in this voltage range, cannot be decided with certainty. At still more negative potentials, cathodic evolution of hydrogen begins to take place (Fig. 1, g). The corresponding re-oxidation processes are detected cyclovoltammetrically. The TiO_2 layer is converted up to 2–20%, a relatively high value for a solid-state reaction, the conversion decreasing with increasing voltage scan rate. The redox processes can be repeated as often as desired. At higher pH val-

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

ues all potentials shift to more negative values. Slopes of 47 to 56 mV/pH are indicative of the presence of protonated oxidized species on the electrode surface.[7]

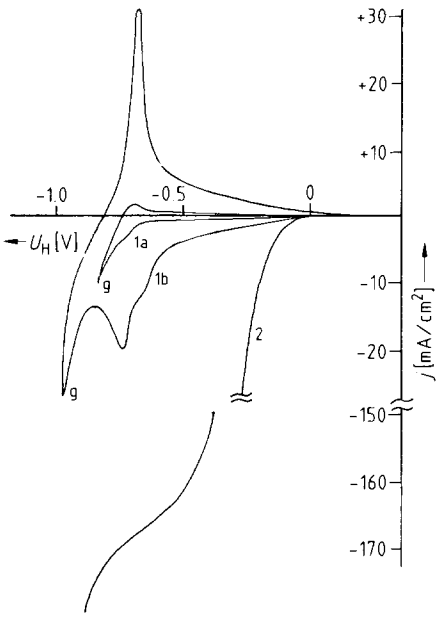

Fig. 1. Current/voltage curves at Ti/TiO_2 ceramic electrodes. 1a, b) In 1 M H_2SO_4, $v_s = 2$ and 50 mV s^{-1}, respectively. 2) 0.2 M nitrobenzene, 1 M H_2SO_4 in 70% (v/v) MeOH, $v_s = 5$ mV s^{-1}. 20 °C, stirring. v_s = voltage scan rate. H_2-evolution occurs at g.

Ti/TiO_2 electrodes prepared thermally by firing Ti metal sheet (10 min, 400–600 °C) in air do not exhibit these reversible redox processes before the evolution of hydrogen; in the same voltage range, only ca. 1% of the current density is reached, the cathode current significantly predominating.

Redox processes on Ti/TiO_2 electrodes prepared by anodization have been described in the literature;[8–11] they resemble those of the electrodes prepared by firing in air. The unusual behavior of our ceramic electrodes, particularly the much higher current densities, cannot be explained alone by a higher surface factor but rather in terms of an activation. Figure 1 also shows the current-voltage curve for the reduction of nitrobenzene on these electrodes (curve 2). The curve rises steeply at the point of reduction to $Ti(OH)_3$. It may therefore be assumed that we have here a further example of a heterogeneous redox catalysis.[7, 12] In the electrochemical step [Reaction (a)], Ti^{III} species are generated. These react in a chemical follow-up step with the organic depolarizer nitrobenzene to give aniline; $Ti(OH)_4$ is thereby recovered [Reaction (c)].

$$6\,Ti(OH)_3 + C_6H_5NO_2 + 4\,H_2O \xrightarrow{k} 6\,Ti(OH)_4 + C_6H_5NH_2 \qquad (c)$$

The limiting current in Figure 1 is a pure diffusion limiting current, so that the chemical step [Reaction (c)] is not rate-determining. The electrodes should have a long lifetime, since TiO_2 and Ti_2O_3 are insoluble in acids.

Hitherto, primarily anodic oxidations via surface fixed oxides in various redox states have been described: $Ru^{III/IV}$,[13, 14] $Pb^{II/IV}$,[15] $Ni^{II/III}$,[16, 17] and $Cr^{III/VI}$.[7, 12]

Should the redox peak immediately before the start of cathodic H_2-evolution correspond to a change in valency $Ti^{III/II}$, then this electrode process (in acidic solution) should also proceed via heterogeneous redox catalysis. The chemical step

$$2\,TiO + H_2O \xrightarrow{k_1} Ti_2O_3 + H_2 \qquad (d)$$

is very rapid.[6] $Ti^{2\oplus}$ ions are extremely unstable in aqueous media.[6] In a more recent work[18] on the mechanism of the Ti/H_2 cathode, the acid-base interaction of the species involved with surface-bound TiO is taken into consideration, not however the redox behavior.

Experimental

Preparation of the electrodes: A 1 mm-thick titanium sheet (Contimet 35, Thyssen Edelstahlwerke, Krefeld) is treated for 1 h at 95 °C with 20% hydrochloric acid. This roughening or etching is a prerequisite for obtaining a sufficiently adhering TiO_2 layer. After rinsing with water and drying, a solution of titanium acetylacetonate (2.189 g) (titanium butoxide gives similar results) in conc. HNO_3 (5 mL) and H_2O (3 mL) (made up to 50 mL with isopropanol) is transferred onto the titanium sheet (with a painting brush in the case of large surface areas) in amounts of 10 μL/cm^2. After drying at 80 °C (10 min) the sheet is baked in air in a muffle furnace at 450 °C. After a total of three activation cycles a TiO_2 concentration of 5 μmol/cm^2 is present on the electrode. According to scanning electron microscope photographs the greyish layer has a rippled structure. The layer thickness is ca. 1 μm. A porous structure results from the electrochemical behavior of the layer. According to X-ray diffraction diagrams the TiO_2 is present in the anatase form. Reduction of nitrobenzene: A stirred solution of 0.2 M nitrobenzene and 1 M H_2SO_4 in 70% v/v methanol (2 L) was electrolyzed at 20 °C for 4 h at a current density of 5 A/dm^2, corresponding to a theoretical Faradayic conversion (6 F/mol) of 33%, using an activated Ti/TiO_2 cathode (Contimet 35, expanded metal with ten mashes per cm^2 (f = 1) and a total surface area of 107 cm^2). The lead anode was separated from the cathode by a alundum diaphragm. Cathode potential: $U_H = -0.23$ V. The yellow solution was neutralized with Na_2CO_3, extracted continuously with chloroform, and dried with Na_2SO_4. Aniline was detected by gas chromatography. Current yield: 70%. Nitrobenzene conversion: 65%. Since no evolution of H_2 was observed, other products must also have been formed.

Decabenzylgermanocene: Synthesis and Structure of a Monomeric, Air-Stable Germanocene**

By *Herbert Schumann,* Christoph Janiak, Ekkehardt Hahn, Jörg Loebel,* and *Jerold J. Zuckerman**

Decaphenylstannocene[1] has S_{10} symmetry with two parallel, staggered cyclopentadienyl rings and a stereochemically inert electron pair at Sn^{II}. It has not yet been determined whether the corresponding compounds of Ge^{II}[2] or Pb^{II}[2] have similar structures. In the germanocenes studied up to now, $(\eta^5\text{-}C_5H_5)_2Ge$,[3] $(\eta^5\text{-}CH_3C_5H_4)_2Ge$,[4] and $(\eta^5\text{-}C_5Me_5)_2Ge$,[5] on the other hand, the planes of the two cyclopentadienyl rings intersect at an angle of 34 to 50°; the compounds are very reactive.

We have now obtained decabenzylgermanocene, **1**, the first germanocene that, despite nonparallel cyclopentadienyl ring planes, is stable toward air. **1** is formed as large, pale yellow crystals by addition of germanium diiodide to a freshly prepared solution of pentabenzylcyclopentadienyllithium in tetrahydrofuran (THF).[6]

$$2\,C_5Bn_5H + 2\,LiC_4H_9 + GeI_2 \xrightarrow{THF} \underset{\mathbf{1}}{(C_5Bn_5)_2Ge} + 2\,LiI + 2\,C_4H_{10}$$

Bn: $C_6H_5CH_2$

The X-ray structure determination[7] shows that **1** (Fig. 1) is monomeric, and that the two cyclopentadienyl rings are bonded in η^5-fashion to Ge^{II}. The planes of the two cyclopentadienyl rings form an angle of 31°.

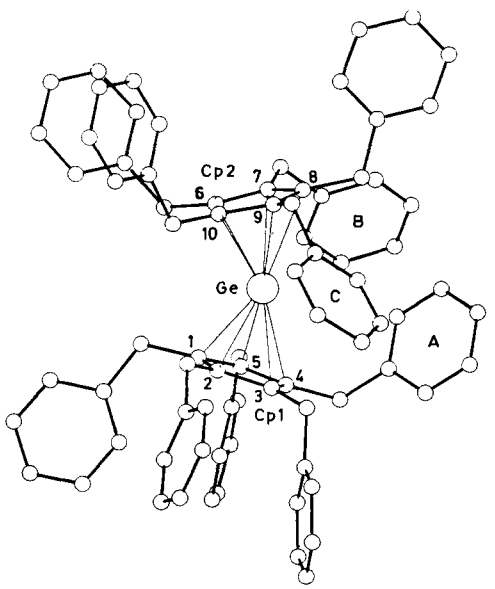

Fig. 1. Crystal structure of **1**. Selected bond lengths [Å] and bond angles [°]: Ge-Cp1 2.240(4), Ge-Cp2 2.288(4), Ge-C1 2.444(4), Ge-C2 2.429(3), Ge-C3 2.623(4), Ge-C4 2.636(4), Ge-C5 2.528(4), Ge-C6 2.489(4), Ge-C7 2.661(4), Ge-C8 2.723(4), Ge-C9 2.613(4), Ge-C10 2.441(4); Cp1-Ge-Cp2 163.1(1) (Cp: centroids of the cyclopentadienyl groups).

Of the ten benzyl (Bn) groups, seven are directed away from and three toward the central atom. The phenyl ring plane of Bn group A (distances: Ge-C_{Ph} 3.635 to 5.509 Å) is thereby intersected by the assumed vector of the lone pair of electrons on the germanium atom. The two Bn groups B and C (distances: Ge-C_{Ph} 4.107 to 5.847 and 3.739 to 5.554 Å, respectively) flank the space occupied by the lone pair electrons.

This arrangement of ligands explains the unexpected stability of **1** toward atmospheric oxygen. The Bn groups form a protective shield not only for the reactive positions of the cyclopentadienyl rings, but also, particularly, for the central germanium atom. A comparable interaction between the lone pair of electrons of a divalent element of the fourth main group and a phenyl group has been found in $[\{(PhO)_2PS_2\}_2Sn]_2$.[8] In that case, too, a phenyl group is nearly perpendicular to the postulated vector of the lone pair electrons on tin, resulting also in unusual air-stability of the compound.

Synthesis of the Immunologically Essential Saccharide Sequence of the "Enterobacterial Common Antigen"

By *Hans Paulsen,** and *Jens Peter Lorentzen*

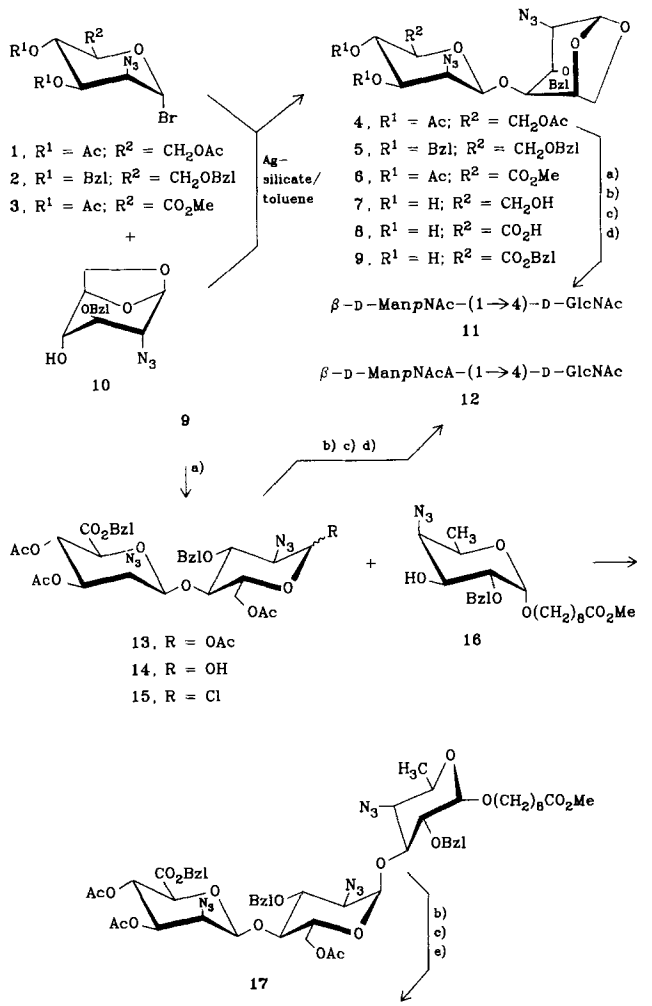
Most bacterial surface antigens contain specific saccharide sequences as immunodeterminants, which permit the serological differentiation of the different species of a genus. In contrast, the "enterobacterial common antigen"

[*] Prof. Dr. H. Paulsen, Dipl.-Chem. J. P. Lorentzen
Institut für Organische Chemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

(ECA) is wide-spread; it is a family-specific antigen of all Enterobacteriaceae, to which a large number of pathogenic bacteria belong.[1] For this reason, the detection of ECA and of ECA antibodies has become of importance for the taxonomy of bacteria and for the diagnosis of enterobacterial infections.[1,2] The oligomeric saccharide that is responsible for the immunological reactions is composed of the following repeating trisaccharide chain:[3]

[→4)-β-D-Man*p*NAcA-(1→4)-α-D-Glc*p*NAc-(1→3)-α-D-Fuc*p*4NAc-(1→]$_n$

Cyclic structures[3] and L-*glycero*-phosphatide units[2] may play a role in the anchoring of the carbohydrate chain to the outer cell membrane of gram-negative bacteria. We have now synthesized a derivative of the trisaccharide unit, which should make possible the synthesis of a corresponding synthetic antigen.



Recently, we were able to couple 2-acetamido-2-deoxy-D-mannopyranose and 2-acetamido-2-deoxy-D-mannopyranuronic acid with the poorly reactive 4-OH group of 2-acetamido-2-deoxy-D-glucose, forming a β-glycosidic linkage.[4] On reaction of the glycosyl bromides **1**, **2**, and **3**[5] with the glycosyl acceptor **10** using heterogeneous silver silicate catalysis,[6] the β-linked disaccharides **4** (48%), **5** (79%), and **6** (29%) are obtained.[4] As we expected,[7] the reactive benzyl compound **2** reacts more selectively than the less reactive triacetate **1**, while the uronic acid **3** appears to be relatively unsuitable for glycoside syntheses. It is therefore better to carry out the oxidation to the uronic acid after the glycosidation. Deblocking of **4** in four steps affords the disaccharide **11** (56%, $[\alpha]_D^{20}$ −30.0), which, in many gram-positive bacteria, is the site at which peptidoglycan and teichonic acid are linked.[8]

After deacylation of **4** to give **7**, it was possible to oxidize **7** to the uronic acid disaccharide **8** by selective catalytic oxidation with O_2/Pt[9] (turbo stirrer). **8** reacts with phenyldiazomethane to give the benzyl ester **9**, which can be functionalized again after acetylation by acetolysis with trifluoroacetic acid/acetic anhydride to form the derivative **13**. The three-step deblocking of **13** permits the synthesis of the disaccharide **12** (potassium salt; 73%, $[\alpha]_D^{20}$ −35.5); **12** is found in the capsular polysaccharide of *Haemophilus influenzae* type d.[10]

The derivative **16**, containing a spacer linked through an α-glycosidic bond, is used as the glycosyl acceptor for the trisaccharide synthesis. **16** can be synthesized via a multistep, but efficient route from selectively blocked derivatives of 4-azido-4-deoxy-D-fucose.[11] The acetate **13** cannot be transformed directly into the halide because of the acid lability of the 3-*O*-benzyl ether group. It is initially selectively deacetylated to **14** with piperidine;[12] **14** is then converted into the glycosyl donor **15** using the Vilsmeier reagent chloro-*N*,*N*-dimethylformamidinium chloride. Reaction of **15** with **16** under the conditions of the in-situ anomerization in the α-glycoside synthesis[7] ($AgClO_4$, Ag_2CO_3) affords the trisaccharide **17** (40%, $[\alpha]_D^{20}$ +7.6, $J_{1,2}$ = 3.7, $J_{1',2'}$ = 3.5 Hz).

Stepwise deblocking of **17** is achieved by reduction of the azide groups with H_2S, *N*-acetylation, cleavage of the benzyl groups by hydrogenolysis, and deacetylation. In this sequence of reactions, the ester groups of the molecule are cleaved selectively.

18 (sodium salt; 51%, $[\alpha]_D^{20}$ +83.6) is the first oligosaccharide containing an aminouronic acid moiety to be synthesized. It can be reacted, via the spacer, with proteins, e.g., with serum albumin or polylysine, to give the synthetic antigen using known methods.[13]

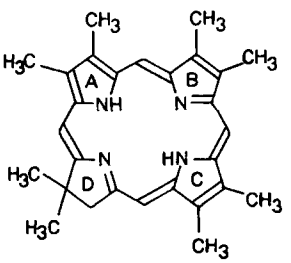
Total Synthesis of (±)-Bonellin Dimethyl Ester**

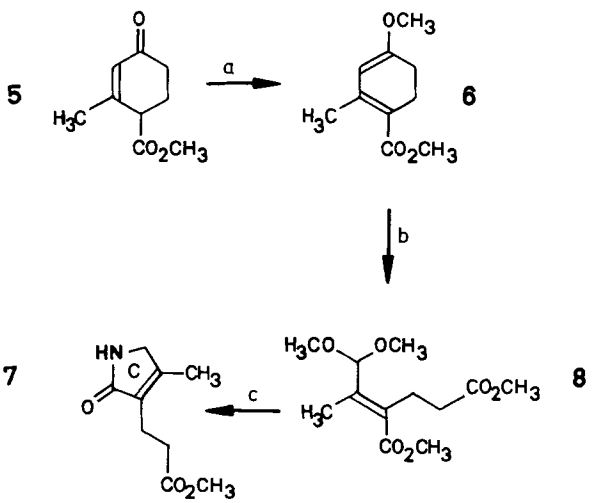


By *Franz-Peter Montforts** and *Ulrich M. Schwartz*

Dedicated to Professor Albert Eschenmoser on the occasion of his 60th birthday

Bonellin **1a** or ent-**1a**[1] is the green sex-differentiating pigment of *Bonellia viridis*, a marine animal widely distributed in the Mediterranean.[2] Initially sex-indifferent larvae which come into contact with the body wall of the female, which contains the green bonellin, develop into males of 1–3 mm in length. The larger females (15 cm) evolve from those larvae having no contact with bonellin. The unusual biological activity and antitumor properties of bonellin in vitro[3] certify it as an attractive synthetic target. During the course of our investigations, racemic bonellin dimethyl ester *rac*-**1b** was recently synthesized in another laboratory via a photochemical route.[4]

1a, $R^1 = H$
1b, $R^1 = CH_3$



2

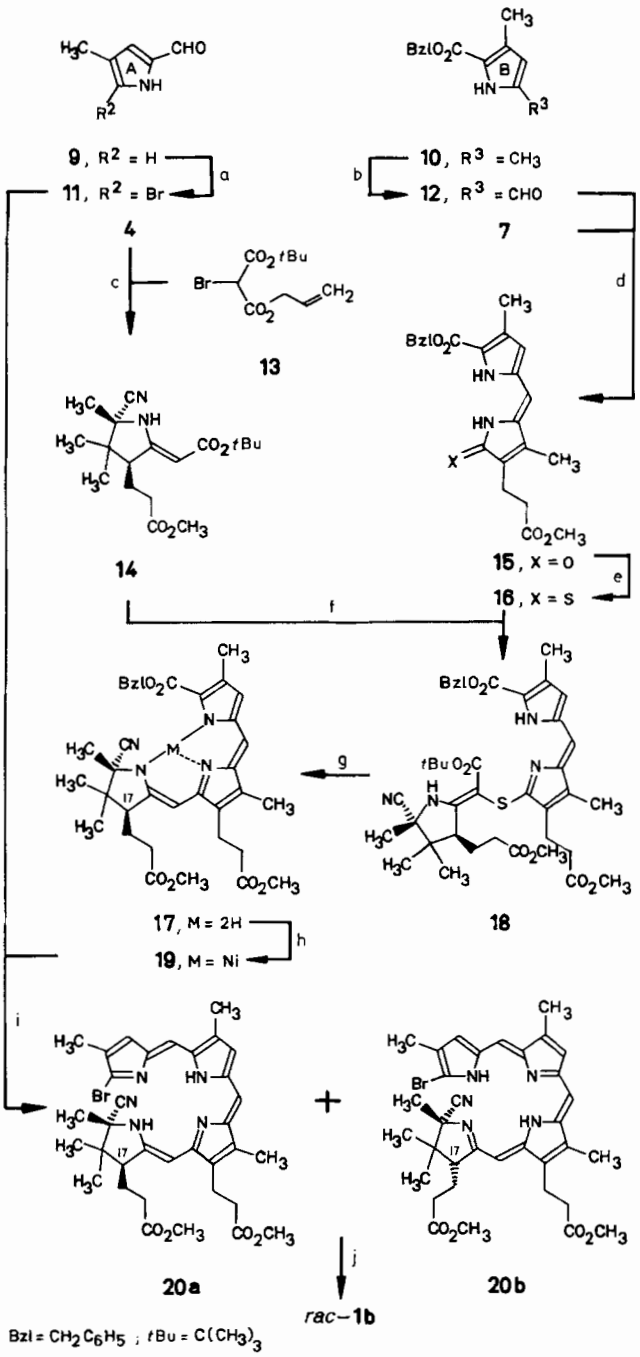
Following a model synthesis[5] of chlorin **2**, we were able to synthesize bonellin dimethyl ester *rac*-**1b** from four monocyclic building blocks—**4**, **7**, **9**, and **10**—and the selectively cleavable malonic ester **13**.

Since ring D of bonellin **1a** or ent-**1a** is constitutionally identical with ring C of vitamin B_{12} it was decided to start from the lactam **3**[6]—a building block used in the syntheses of vitamin B_{12} by *Woodward*[7] and *Eschenmoser*.[8] **3** is converted into its thia analogue **4** (Scheme 1).

A novel entry to the ring-C dihydropyrrolone **7**[9] was opened up by the use of the Hagemann ester **5** as starting material. Selective ozonolysis of the enol ether **6** produced the desired propionic acid side chain and a (protected) aldehyde function. The aldehyde group and the ester group at the double bond in **8** enabled the incorporation of nitrogen, and formation of the five-membered heterocycle **7** (Scheme 2).

5 6 7 8

Scheme 2. a) 5 equiv. $HC(OCH_3)_3$, *p*-toluenesulfonic acid (TsOH), catalytic amount, benzene, rfl., 2.5 h (71% **6**).—b) 1) O_3/O_2, CH_2Cl_2, 1.5 equiv. CH_3OH, −80°C; 1.5 equiv. CH_3SCH_3, room temperature (RT), 3 h. 2) 2 equiv. $HC(OCH_3)_3$, TsOH, catalytic amount, RT, 12 h (73% **8**).—c) 1) Raney nickel, H_2, CH_3OH, RT, 4.5 h. 2) 60% $HClO_4$, catalytic amount, CH_3CN, H_2O, RT, 2.5 h, crude producted reacted further. 3) NH_3, CH_3OH (saturated), 2 equiv. NH_4Cl, RT, 4.5 h, crude producted reacted further. 4) CH_3COOH, rfl., 5.5 h (37% crystalline **7**).



Lead tetraacetate, in the preparatively decisive solvent chloroform, oxidizes the methylpyrrole **10**[10] to the ring-B pyrrolecarbaldehyde **12**. The ring-A building block **11** is obtained by selective bromination of the α-unsubstituted pyrrolecarbaldehyde **9**.[11]

The thiolactam **4** and the malonic ester **13**[13] are converted, free of epimerization, into the vinylogous urethane **14** by sulfide contraction and subsequent Pd-catalyzed ester cleavage.[12] The dihydropyrrolone **7** and the ring-B aldehyde **12** undergo base-catalyzed reaction[14] to give the B–C bicycle **15**, which is then converted into the thiolactam **16**. Coupling **14** and **16** via a brominating agent affords the sulfur-bridged A–B–C tricycle **18**, which is converted by acid-induced sulfide contraction according to the method of *Rasetti* et al.[15] into the C–C coupled product **17**.

The complexation of **17** with nickel to give **19** stabilizes the chromophore towards atmospheric oxidation and enables the ready separation of the C-17 epimers, whose formation is unavoidable under strongly acidic conditions. For preparative purposes, however, the separation is not

Scheme 3. a) 1.1 equiv. Br_2, 2 equiv. pyridine, CH_2Cl_2, −45°C (77% crystalline **11**).—b) 1) 2.5 equiv. lead tetraacetate, $CHCl_3$, rfl., 210 h. 2) 2.5 N aq. HCl, RT, 6 h (71% crystalline **12**).—c) 1) 1 equiv. **4** + 1.1 equiv. **13**, 1.2 equiv. diazabicycloundecene (DBU), CH_3CN, 0°C, 20 min (coupling). 2) $P(OC_2H_5)_3$, 80°C, 2 h (desulfurization). 3) 5.1 equiv. piperidine, $[(C_6H_5)_3P]_4Pd$, catalytic amount, THF, argon, RT, 2 h (76% crystalline **14**).—d) 1.1 equiv. base [14], benzene, rfl., 10 h (88% crystalline **15**).—e) 1.1 equiv. "Lawesson reagent", THF, rfl., 30 min (90% crystalline **16**).—f) **14** + 1.1 equiv. *N*-bromosuccinimide, CH_2Cl_2, RT, 20 min; +0.92 equiv. **16**, 4 equiv. DBU, CH_3CN, RT, 40 min (product **18** reacted further, after chromatographic purification).—g) 7.6 equiv. $P(CH_2CH_2CN)_3$, CF_3CO_2H, benzene, rfl., 25 min (crude product **17** reacted further).—h) 20 equiv. $Ni(CH_3CO_2)_2 \cdot 4H_2O$, 70 equiv. sodium acetate, CH_2Cl_2, CH_3OH, RT, 1 h (yields referred to **16**: 57% epimeric mixture, crystalline; 21% **19** and 18% C-17 epimer of **19**, crystalline).—i) **19** + C-17 epimer, Pd/C, hydrogen, MeOH, RT, 1 h; +2.5 equiv. **11**, 15 equiv. TsOH, $CHCl_3$, rfl., 15 min (product **20a** + **20b** reacted further after chromatographic purification).—j) 1) 2.5 equiv. $Zn(CH_3CO_2)_2$, potassium *tert*-butoxide, *tert*-butyl alcohol, rfl., 1 h; 2) CH_2N_2, ether, RT (yield referred to **19** + C-17 epimer: 42% crystalline *rac*-**1b**).

necessary: The acid-catalyzed condensation of **11** (ring A) after hydrogenolysis of the benzyl ester in **19** likewise effects epimerization at C-17.

The mixture of secochlorin **20a** and its C-17 epimer **20b** undergoes base catalyzed cyclization in the presence of zinc(II), which exercises a template effect and can be readily removed from the chlorin system acidolytically, to give the racemic bonellin dimethyl ester *rac*-**1b**.

The formation of enantiomerically pure **1b** or ent-**1b** from the *pure* secochlorins **20a** or **20b**, whose separation has not yet been accomplished, should be possible under cyclization conditions that avoid epimerization.

Distortional Isomers of $[LWOCl_2]^+$ in the Solid State and in Solution; Crystal Structures of the Blue and Green Forms of $[LWOCl_2]PF_6$**

By *Karl Wieghardt,* Gabriele Backes-Dahmann, Bernhard Nuber,* and *Johannes Weiss*

The blue and green crystals of the diamagnetic neutral complex *cis-mer*-$[MoOCl_2(PMe_2Ph)_3]$[1] exhibit so-called distortional isomerism. In each case, the Mo^{IV} center is surrounded octahedrally by the monodentate ligands in identical spatial arrangement *(cis-mer)*; in the solid state, the two forms differ only in the lengths of the Mo=O bond and the Mo–Cl bond *trans* to the oxo group (Mo=O: 167.6(7) (blue), 180.3(11) pm (green); Mo–Cl 255.1(3) and 242.6(6) pm, respectively). In solution, the green form is transformed irreversibly into the blue form. *Wilkinson* et al. have described analogous blue and green crystals of $[MoOCl_2(PMe_3)_3]$, but did not characterize these as distortional isomers.[2] Recently, we were able to confirm the existence of this type of isomerism in the complex anions $[PPh_4]_2[MoO(CN)_4(H_2O)]\cdot 4H_2O$ (green) and $[AsPh_4]_2[MoO(CN)_4(H_2O)]\cdot 4H_2O$ (blue) by X-ray analysis. In this case, too, the blue form exhibits a shorter Mo=O bond than the green form. Salts of $[MoO(CN)_5]^{3-}$ ions also exist in blue and green forms.[3] Common to all of these compounds is a Mo^{IV}=O group, their diamagnetism, and the fact that, in solution, only *one* form prevails.

This type of distortional isomerism is not well understood as yet due to the limited number of firmly established examples. Is it restricted to diamagnetic Mo^{IV}=O complexes or is it a solid-state effect (packing effect, etc.)? We report here the characterization of distortional isomers, both in the solid, state *and* in solution, of the *paramagnetic* cation $[LWOCl_2]^+$ (L = *N,N',N''*-trimethyl-1,4,7-triazacyclononane), the hexafluorophosphate salt of which has been crystallized in a blue form **1** and a green form **2**.[4]

The infrared spectra of **1** and **2** (KBr) are very similar. Only in the region of the W=O stretching vibrations are significant differences apparent: **1** exhibits the ν(W=O) vibration at 980 cm^{-1}, whereas for **2** it is observed at 960 cm^{-1}. **1** and **2** are stable in the solid state and do not undergo a change in color over several months; even at temperatures up to 450 K, they are not transformed into each other.

The crystal structure determinations show that **1** and **2** crystallize in the same space group with very similar unit cell parameters.[5] The packing of the $[LWOCl_2]^+$ ions and of the disordered PF_6^- ions is also identical in the two salts. In both cases, the geometry of the ligands around the W^V center is identical (Fig. 1): the tridentate ligand *N,N',N''*-trimethyl-1,4,7-triazacyclononane occupies three facial coordination sites of a distorted octahedron; two chloro ligands in *cis* positions with respect to each other and an oxo group occupy the remaining three coordination sites. The only significant differences between the complex cations in **1** and **2** are the lengths of the W=O bond and probably of the W–N1 bond *trans* to it. In the blue form, a shorter W=O distance (172(2) pm) and a longer W–N1 distance (237(2) pm) are observed; in the green form, these distances are 189(2) and 232(2) pm, respectively. Because of the relatively large error limits, however, the significance of the difference in bond lengths of the two W–N1 bonds is experimentally unresolved.

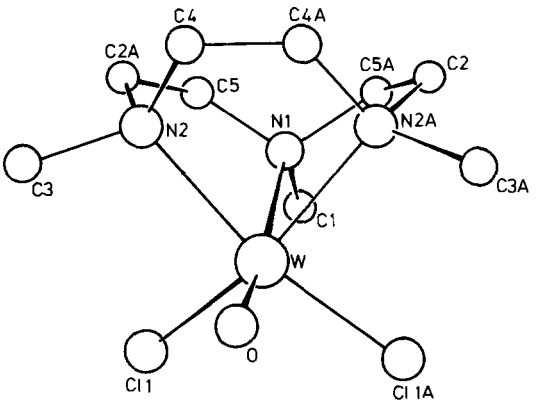

Fig. 1. Structure of the cation $[LWOCl_2]^+$ in **1** and **2**. The atoms W, C1, N1, and O lie on a crystallographic mirror plane. Selected bond lengths [pm] and bond angles [°] in **1** (corresponding values for **2** in parentheses): W-O 171.9(18) (189.3(20)), W-Cl1 232.2(5) (229.5(6)), W-N1 237.0(17) (232.1(20)), W-N2 223.9(13) (224.7(16)); Cl1-W-Cl1A 91.7(3) (93.5(4)), Cl1-W-O 102.8(8) (101.4(8)), Cl1A-W-N2 163.7(8) (164.5(8)), N2-W-N2A 78.3(6) (76.9(8)), Cl1-W-N2 93.1(5) (93.3(7)), O-W-N2 91.1(8) (90.9(8)), N1-W-N2 75.4(6) (75.8(8)).

Crystals of **1** and **2** dissolve in dry acetonitrile, affording blue and green solutions, respectively. Such solutions are stable for several days; in no case is a color change from green to blue or vice versa observed.

The electronic absorption spectra of **1** and **2** in CH_3CN (Fig. 2) show a weak-intensity d-d transition in the visible range (**1**: $\lambda = 712$ nm, $\varepsilon = 20$ cm^{-1} mol^{-1} L; **2**: 693 (40)), which is typical for oxo complexes of W^V. Interestingly, the spectrum of **2** shows a relatively strong charge transfer band (probably of the W=O group) at 419 nm ($\varepsilon = 890$ cm mol^{-1} L), which is responsible for the green color of **2** and

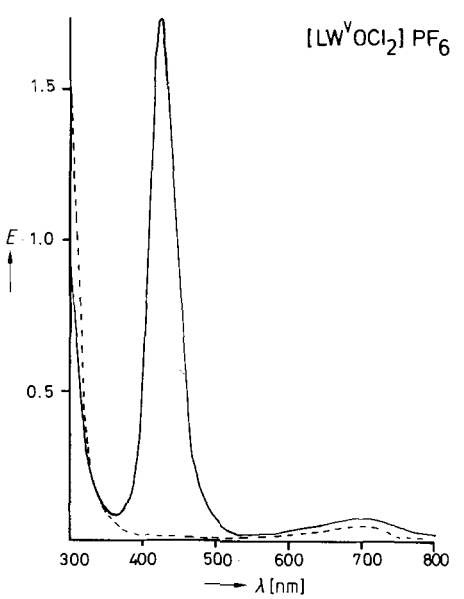

Fig. 2. Electronic absorption spectrum of **1** (----) (3.5×10^{-3} M) and **2** (—) (2.0×10^{-3} M) in dry acetonitrile (1-cm cuvette).

which, for **1**, is shifted to appreciably shorter wavelengths (286 nm). From the ESR measurements on these solutions at 293 K, g values of 1.775(3) for **1** and 1.790(3) for **2** were derived.

Both methods show that two species of the cation $[LW^{V}OCl_2]^+$ also exist *in solution*. When small amounts of water are added to the green solution of **2**, an immediate color change to blue is observed. Blue **1** can be crystallized nearly quantitatively from this solution by addition of solid $NaPF_6$. Electrochemically, **1** and **2** can be reversibly reduced to $[LW^{IV}OCl_2]$ in dry CH_3CN with 0.1 M tBu_4NPF_6 as electrolyte ($E^f = -1.14$ V vs. ferrocenium/ferrocene for **1** and **2**).[4a]

$[L_2Fe^{II}_2(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2](ClO_4)\cdot H_2O$, a Model Compound for the Diiron Centers in Deoxyhemerythrin**

By *Phalguni Chaudhuri, Karl Wieghardt,* Bernhard Nuber,* and *Johannes Weiss*

In the oxidized forms of the oxygen-transporting protein hemerythrin containing dinuclear (μ-oxo)bis(μ-carboxylato)diiron(III) structural units,[1] the two Fe^{III} centers are strongly antiferromagnetically coupled ($J = -134$ cm^{-1} in metazidohemerythrin).[2] Some low-molecular, dinuclear Fe^{III} complexes of this type have recently been synthesized and characterized.[3] The agreement between the spectroscopic properties (electronic, resonance Raman, and Mössbauer spectra) and the magnetic susceptibilities of methemerythrin on the one hand, and those of the inorganic model compounds on the other, is remarkable. This underscores the value and relevance of studies on low-molecular model complexes for an understanding of metal-containing proteins.[4]

The active form of the protein, deoxyhemerythrin, contains dinuclear Fe^{II} complexes with high-spin electron configuration. The electronic spectrum and the magnetic properties of deoxyhemerythrin have been well documented,[5] but give very little information about its structure; a crystal structure analysis has so far not been reported.

MCD-ESR measurements on deoxyhemerythrin indicate a bis(μ-carboxylato)(μ-hydroxo)-bridging for the diiron(II) centers;[6] the same structure was proposed by *Stenkamp* et al.[12] The coupling constant J was estimated to be -13 ± 5 cm^{-1}. We report here on the first low-molecular model compound for the active protein.

Reaction of $Fe(ClO_4)_2\cdot 6H_2O$ in anhydrous methanol with the cyclic triamine *N,N',N''*-trimethyl-1,4,7-triazacyclononane (L) in the presence of anhydrous sodium acetate and in strict absence of oxygen led to pale greenish-yellow crystals of $[L_2Fe^{II}_2(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2](ClO_4)\cdot H_2O$, **1**.[7]

The structure of **1** (Fig. 1)[8] consists of a μ-hydroxo-bridged diiron(II) unit containing two further acetate bridges and non-coordinatively bound, statistically disordered perchlorate ions. Two facially coordinated, tridentate amine ligands complete the distorted octahedral coordination sphere of the two Fe^{II} centers. The structure of **1** thus corresponds to the structure proposed[6] for deoxyhemerythrin. The Fe-O and Fe-N bonds in **1** are significantly longer than in **2**, the oxidation product of **1**; they are consistent with a d^6 high-spin electron configuration of the Fe^{II} centers.

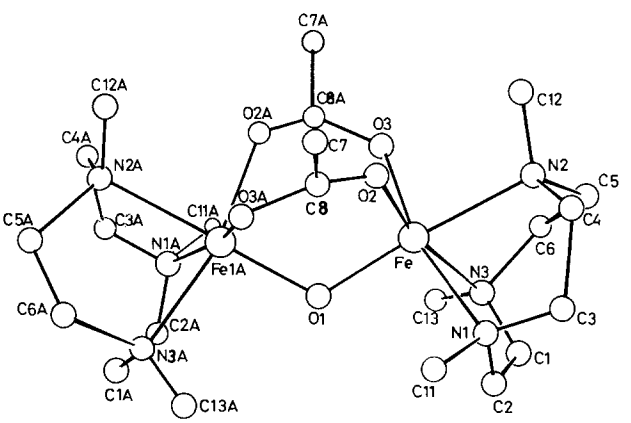

Fig. 1. Structure of the $[L_2Fe^{II}_2(OH)(CH_3CO_2)_2]^+$ cation in the crystal of **1**. Important bond lengths [pm] and angles [°]: Fe-O1 198.7(8), Fe-O2 214.2(9), Fe-O3 212.3(9), Fe-N1 225.7(10), Fe-N2 230(1), Fe-N3 231(1), C8-O2 120(2), C8-O3A 134(2), C7-C8 155(2), Fe-Fe1A 332(1); Fe-O1-Fe1A 113.2(2), O1-Fe-O2 98.2(4), O1-Fe-O3 95.6(5), O2-Fe-O3 92.6(5).

The electronic spectrum of **1** in methanol (Fig. 2, left) [$\lambda = 928$ nm ($\varepsilon = 10$ cm^{-1} mol^{-1} L); 1100 (sh) (7)] is very similar to that of deoxyhemerythrin.[5] The magnetic susceptibility data (Faraday method) for crystalline **1** in the

[**] This work was supported by the Fonds der Chemischen Industrie.

temperature range 100–298 K were readily fitted using an isotropic Heisenberg model, $H' = 2JS_1 \cdot S_2$ ($S_1 = S_2 = 2$) and $g = 2.24$. The spin exchange coupling constant J of $-14(2)$ cm^{-1},[11] which is in excellent agreement with the value derived for deoxyhemerythrin,[6] indicates weak antiferromagnetic behavior. **1** is thus a very good model for the bonding of the Fe^{II} centers in deoxyhemerythrin and confirms the structure proposed by *Solomon* et al.[6] and Stenkamp et al.[12]

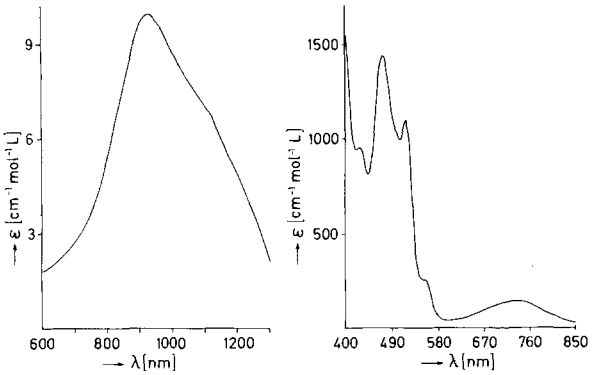

Fig. 2. Left: Electronic spectrum of **1** in methanol at 293 K; right: electronic spectrum of **2** in methanol at 293 K (a further absorption was observed at 1031 nm ($\varepsilon = 7$ cm^{-1} mol^{-1} L).

Oxidation of **1** by air yields $[L_2Fe_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](ClO_4)_2$ **2**, which has already been prepared previously via an alternative route.[9] The two Fe^{III} centers are linked via a μ_2-oxo bridge and two acetato bridges (Fig. 3). The Fe–N and Fe–O bond lengths correspond to those of other model compounds for the diiron(III) centers in metazidohemerythrin.[3] The electronic spectrum of **2** in methanol (Fig. 2, right) resembles that of metazidohemerythrin. The magnetic susceptibility data for **2** (100–298 K) yielded a J value of -115 cm^{-1}, which is very similar to the value of -134 cm^{-1} for metazidohemerythrin, and indicates strong antiferromagnetic coupling.

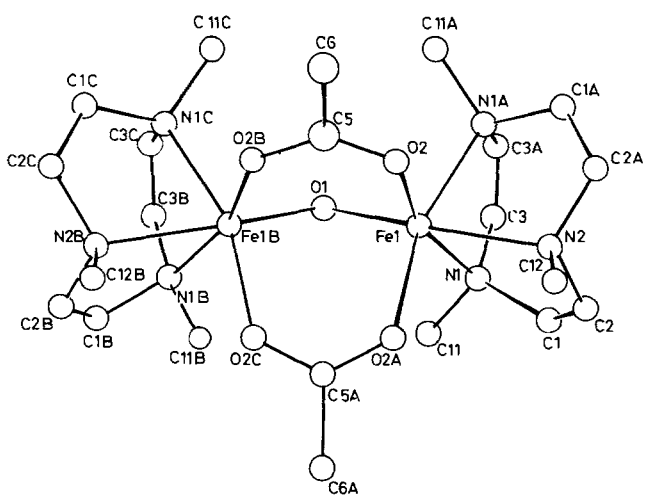

Fig. 3. Structure of the cation $[L_2Fe^{III}_2(O)(CH_3CO_2)_2]^{2+}$ in the crystal of **2**. Important bond lengths [pm] and angles [°]: Fe-O1 180.0(3), Fe-O2 203.4(3), Fe-N1 219.8(4), Fe-N2 226.8(6), C5-O2 124.6(4), C5-C6 146(1), Fe-Fe1B 312(1); O1-Fe-O2 97.2(2), O1-Fe-O2A 97.2(3), O2-Fe-O2A 96.5(2), Fe-O1-Fe1B 119.7(1).

[7] Procedure: **1**: All operations were carried out under argon. A stirred solution of *N,N',N''*-trimethyl-1,4,7-triazacyclononane (L) [10] (0.51 g, 3 mmol) in anhydrous methanol (40 mL) was treated with 0.36 g (1 mmol) of $Fe(ClO_4)_2 \cdot 6H_2O$. After 2.5 hours' stirring at room temperature, anhydrous sodium acetate (0.2 g, 2.4 mmol) was added to the solution and stirring was continued for a further 30 min. After addition of 0.4 g $NaClO_4 \cdot H_2O$ and reduction of the volume of the reaction mixture to 15 mL, 150 mg of green-yellow crystals of **1** precipitated, which were filtered off and dried in an argon atmosphere.—**2**: When air was passed through the above reaction solution, the color changed from greenish-yellow to reddish-brown, and, after allowing to stand for 48 h in the presence of air, 470 mg of reddish-brown dichroic crystals of **2** precipitated out.

[8] X-ray structure analysis of **1** and **2** (data for **2** in brackets): $P4_12_12$ (Amam); $a = 1092(1)$ (1307.8(2)), $b = 1092(1)$ (1773.2(3)), $c = 2785(3)$ (1529.0(3)) pm; $Z = 4(4)$; $\rho_{calc} = 1.416$ (1.513) g cm^{-3}; $R = 0.082$ (0.079) for 1264 (2980) independent reflections ($I > 1.5\sigma(I)$); $Mo_{K\alpha}$ radiation; Siemens AED II diffractometer. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD 51466, the names of the authors, and full citation of the journal.

Cleavage of an Ether Bond via β-Elimination of Ethanol from $[(H_2O)_5CrCH_2CH_2OC_2H_5]^{2+}$ in Aqueous Solutions; A Pulse Radiolysis Study**

By *Haim Cohen* and *Dan Meyerstein**

Dedicated to Professor Schulte-Frohlinde on the occasion of his 60th birthday

Recently it has been shown that pentaaqua(β-hydroxyalkyl)chromium(III) complexes decompose via β-elimination of the hydroxy radical to yield $[Cr(H_2O)_6]^{3\oplus}$ and the corresponding alkene.[1–4] The β-hydroxyalkylchromium(III) complexes therefore have a considerably shorter lifetime

[**] This research was supported in part by a grant from the Israel-U.S. Binational Science Foundation (Jerusalem). We wish to thank Prof. *J. H. Espenson* and Prof. *H. Pines* for helpful discussions and Mr. *D. Carmi* for technical assistance.

than the analogous alkyl- or α-hydroxyalkylchromium(III) complexes.[1,7] The β-elimination reaction has been shown to be a relatively fast acid-catalyzed process,[1-4] resulting in the formation of an unstable alkenechromium(III) complex.[3,4] The products of the reaction between $[Cr(H_2O)_6]^{2\oplus}$ and α,β-dihaloalkanes are also alkenes, indicating that pentaaqua(β-haloalkyl)chromium(III) complexes decompose via β-elimination of halides.[5] It seemed of interest to check whether ether bonds, which are considered to be kinetically considerably more stable, also decompose via β-elimination. We report here that the complex **1** (with $ClO_4^{\ominus}$ as counterion) indeed decomposes in an acid-catalyzed process to yield $[Cr(H_2O)_6]^{3\oplus}$, ethylene, and ethanol.

$[(H_2O)_5CrCH_2CH_2OC_2H_5]^{2\oplus}$ **1**

The relatively stable complex **2**[6,7] is usually prepared via Reactions (a)–(c).

$$[Cr(H_2O)_6]^{2\oplus} + H_2O_2 + H_3O^{\ominus} \longrightarrow [Cr(H_2O)_6]^{3\oplus} + {}^{\circ}OH + 2H_2O \quad (a)$$
$k(a) = 7.1 \times 10^4\ M^{-1}\ s^{-1}$ [8]

$$^{\circ}OH + (C_2H_5)_2O \longrightarrow H_2O + {}^{\circ}CH(CH_3)OC_2H_5 \quad (b)$$
$k(b) = 1.4 \times 10^9\ M^{-1}\ s^{-1}$ [9]

$$[Cr(H_2O)_6]^{2\oplus} + {}^{\circ}CH(CH_3)OC_2H_5 \longrightarrow [(H_2O)_5CrCH(CH_3)OC_2H_5]^{2\oplus} \quad (c)$$
2
$k(c) = 3.4 \times 10^7\ M^{-1}\ s^{-1}$ [1]

This synthetic route is based on the observation that the major product of reaction of hydroxy radicals with diethyl ether is the α-radical [Reaction (b)].[6] However, from the relative rates of hydrogen abstraction at the α- and β-carbons of diethyl ether by hydroxy radicals,[9] one would expect that ca. 20% of the free radicals should be formed via Reaction (d). Thus one would expect that ca. 20% of the product should be **1** [Reaction (e)].

$$^{\circ}OH + (C_2H_5)_2O \longrightarrow {}^{\circ}CH_2CH_2OC_2H_5 + H_2O \quad (d)$$

$$[Cr(H_2O)_6]^{2\oplus} + {}^{\circ}CH_2CH_2OC_2H_5 \longrightarrow [(H_2O)_5CrCH_2CH_2OC_2H_5]^{2\oplus} \quad (e)$$
1

However, the decomposition of **2** obeys a purely first-order rate law[6] suggesting that only one species is decomposing. Accordingly, **1** decomposes prior to the start of the measurement of the kinetics of decomposition of **2**. Since the hydrolysis of $[(H_2O)_5CrCH_3]^{2\oplus}$ is not fast, a plausible mechanism for the fast decomposition of **1** could be β-elimination [Reaction (f)].

$$[(H_2O)_5CrCH_2CH_2OC_2H_5]^{2\oplus} + H_3O^{\ominus} \longrightarrow [Cr(H_2O)_6]^{3\oplus} + C_2H_4 + C_2H_5OH \quad (f)$$

In order to check this mechanism, the complex **2** was prepared via two routes. In the first procedure, solutions containing 0.5 M $(C_2H_5)_2O$ and 0.05 M $[Cr(H_2O)_6]^{2\oplus}$ at pH 1.0 or 3.5 were mixed with aqueous H_2O_2 so that the final amount of H_2O_2 was 1.0×10^{-2} M. In the second procedure, He-saturated solutions at pH 1.0 or N_2O-saturated solutions at pH 3.5 containing 0.5 M $(C_2H_5)_2O$ and 5×10^{-3} M $[Cr(H_2O)_6]^{2\oplus}$ were irradiated using a ^{60}Co γ-source (4500 rad/min, total dose 67500 rad, i.e., ca. 4×10^{-4} mol free radicals formed). The reaction mixtures were analyzed by FT-IR spectroscopy (Nicolet MXs) and gas chromatography (T.C.D. Varian 1440) for possible formation of ethylene within 20 min from the start of the reaction (i.e., long before **2** had decomposed). In all the reaction mixtures ethylene was detected; the yield of ethylene was ≥ 10% of the total yield of free radicals. Since the relative rates of Reactions (b) and (d) (formation of α- and β-radicals, respectively) are not known exactly, no effort was made to determine exactly the yield of ethylene.

The formation of ethylene in these systems clearly proves that Reaction (f) indeed occurs. In order to measure the rate of Reaction (f), we used the pulse radiolysis technique. The experimental setup was identical to that described earlier.[10] N_2O-saturated solutions containing 0.5 to 0.8 M $(C_2H_5)_2O$ and 1×10^{-4} to 1×10^{-5} M $[Cr(H_2O)_6]^{2\oplus}$ in the pH range 1.0 to 4.0 were irradiated. Under these conditions the following processes occur in addition to Reactions (b) and (d):

$$H_2O \xrightarrow{e^{\ominus}} e_{aq}^{\ominus},\ {}^{\circ}OH,\ H,\ H_2,\ H_2O_2 \quad (g)$$
(the relative yields of the primary products are 2.65, 2.65, 0.60, 0.45, and 0.75, respectively [11])

$$e_{aq}^{\ominus} + N_2O + H_3O^{\oplus} \longrightarrow N_2 + {}^{\circ}OH + H_2O \quad (h)$$
$k(h) = 8.7 \times 10^9\ M^{-1}\ s^{-1}$ [12]

$$e_{aq}^{\ominus} + H_3O^{\oplus} \longrightarrow H + H_2O \quad (i)$$
$k(i) = 2.3 \times 10^{10}\ M^{-1}\ s^{-1}$ [12]
(the relative yields of Reactions (h) and (i) depend on the pH)

$$H + (C_2H_5)_2O \longrightarrow {}^{\circ}CH(CH_3)OC_2H_5 + H_2$$
$$H + (C_2H_5)_2O \longrightarrow {}^{\circ}CH_2CH_2OC_2H_5 + H_2 \quad (j)$$
$k(j) = 4.7 \times 10^7\ M^{-1}\ s^{-1}$ [13]
(the relative yields of α- and β-abstraction by H atoms are larger than those by OH radicals since the latter are more reactive)

Under the experimental conditions, Reactions (g) to (j) as well as (b) and (d) are over within the time duration of the pulse (ca. 1 μs).

These reactions are followed by Reactions (c), (e), (a), (k), (l), and probably (f).

$$[Cr(H_2O)_6]^{2\oplus} + H \longrightarrow [(H_2O)_5Cr{-}H]^{2\oplus} + H_2O \quad (k)$$
$k(k) = 1.5 \times 10^9\ M^{-1}\ s^{-1}$ [14]

$$[(H_2O)_5CrH]^{2\oplus} + H_3O^{\oplus} \longrightarrow [Cr(H_2O)_6]^{3\oplus} + H_2 \quad (l)$$
$k(l) = 1.8 \times 10^4\ M^{-1}\ s^{-1}$ [14]

We have observed three kinetic processes (Fig. 1). The first process is attributed to Reactions (c) and (e), which are expected to have similar rate constants and might hide a small contribution from Reaction (k), which is considerably faster.[14] The second process is attributed to Reaction (a) followed by reactions (b) to (e), since in this process the absorption increases somewhat due to the alkylchromium complex and since the rate is pseudo first order in $[Cr(H_2O)_6]^{2\oplus}$ and agrees with the reported rate constant of Reaction (a).[8]

The third process can be due either to Reaction (l) or to Reaction (f). We attribute it to the latter for the following reasons. First, the process obeys a pseudo-first-order rate law in $H_3O^{\oplus}$. The pH dependence of the reaction is plotted in Figure 2, from which $k(f) = (4.6 \pm 0.8) \times 10^3\ M^{-1}\ s^{-1}$ is calculated. This rate constant differs significantly from $k(l)$. Second, the percentage of decrease in the absorption caused by this process at pH 3 to 4 is nearly independent of the ratio of the concentration of $(C_2H_5)_2O$ to that of $[Cr(H_2O)_6]^{2\oplus}$ although the relative yields of Reactions (j) and (k) are linearly dependent on this ratio. Third, the percentage of decrease in the absorption caused by this pro-

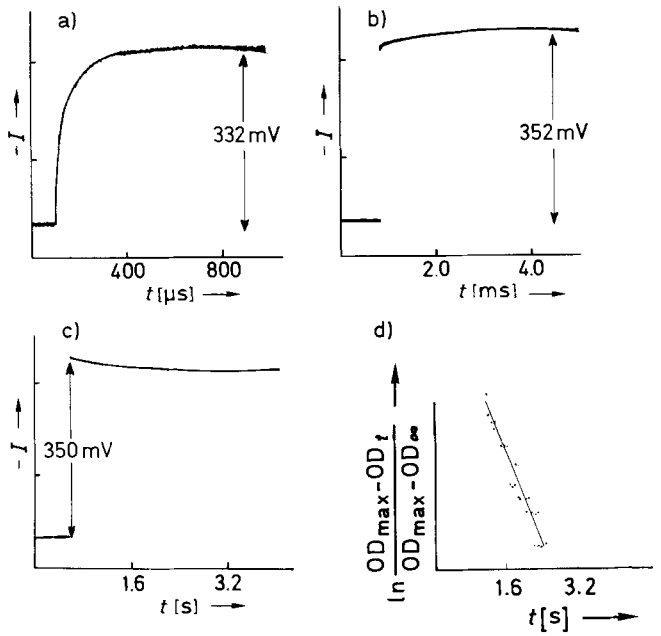

Fig. 1. Kinetic traces of absorption changes upon irradiation at 310 nm of N_2O-saturated aqueous solutions containing 0.5 M $(C_2H_5)_2O$ and 0.05 M $[Cr(H_2O)_6]^{2\oplus}$ at pH 3.5. a) Formation of **2** and **1**. b) Formation of Cr–C compounds by the reaction of H_2O_2 with $(C_2H_5)_2O$ and $[Cr(H_2O)_6]^{2\oplus}$. c) Decomposition of **1**. d) First-order decrease in the concentration of **1**. $-I_0 = 755$ mV.

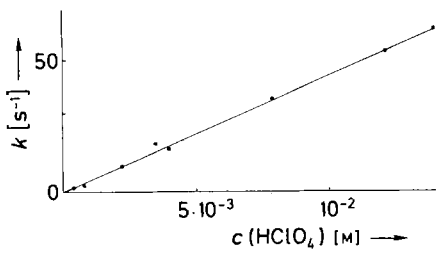

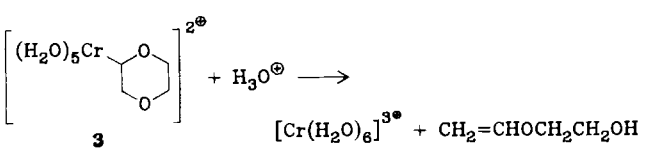

Fig. 2. Dependence of the rate of decomposition of **1** on pH, measured in N_2O-saturated aqueous solutions containing 0.5 M $(C_2H_5)_2O$ and 1×10^{-3} to 1×10^{-2} M $[Cr(H_2O)_6]^{2\oplus}$ at 315 nm. Ionic strength was not taken into consideration.

cess is nearly pH independent in the pH range 2 to 4 although the relative yields of Reactions (b) and (h) depend linearly on the pH.

The large residual absorbance remaining after the third process is that due to complex **2**.

We thus conclude that the third process responds to concentration variables as expected and, since ethylene is detected as a product, this process is indeed the β-elimination of ethanol [Reaction (f)] and $k(f) = (4.6 \pm 0.8) \times 10^3$ $M^{-1} s^{-1}$.

This is the first reported rate constant for the cleavage of an ether bond via β-elimination. The rate constant is similar to that reported for β-eliminations of the hydroxyl group from $[(H_2O)_5CrCH_2C(CH_3)_2OH]^{2\oplus}$ and related compounds,[3,4] thus suggesting a similar transition state for the two processes. It is tempting to speculate that the fast decomposition of complex **3** is not a hydrolysis reaction as suggested[1] but rather a β-elimination reaction [Reaction (m)].

3 (m)

$k(m) = 0.48$ $M^{-1} s^{-1}$ [1]

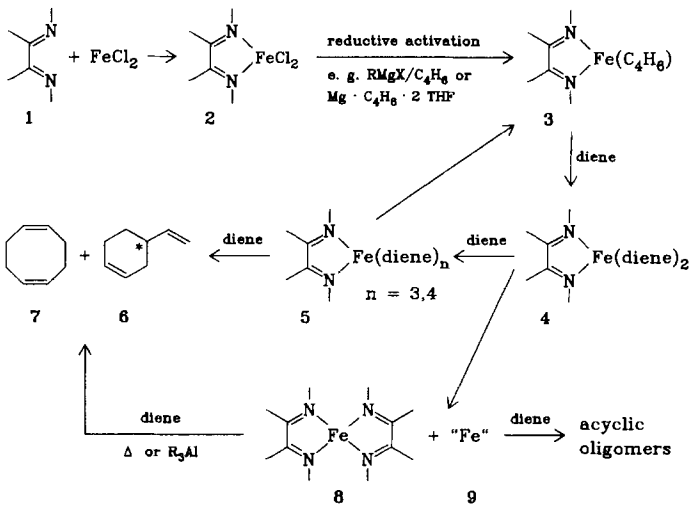
Selectivity and Mechanism of Diene Cyclodimerization on Iron(0) Complexes**

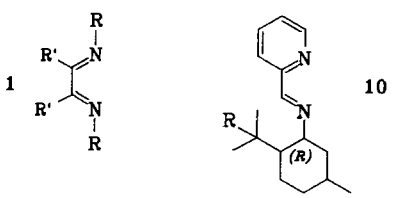
By *Heindirk tom Dieck** and *Jörg Dietrich*

Dedicated to Professor Günther Wilke on the occasion of his 60th birthday



The cyclodimerization of 1,3-dienes on "nickel-ligand" catalysts[2] is one of the most investigated homogeneous catalytic reactions, but the mechanism of the product release is still unknown. To clarify this we have carried out investigations on the diazadiene-iron system.[3]

Reaction of 1,4-diaza-1,3-dienes (dad), **1**, and iron(II) chloride leads to formation of the complexes **2**, which, for the butadiene cyclodimerization, can be reductively activated by Grignard compounds or butadienemagnesium (with $Mg \cdot C_4H_6 \cdot 2THF$ to give **3**, or with $Mg \cdot 2C_4H_6 \cdot 2THF$[4] to give **4**, stabilized by solvent). In the presence of an excess of butadiene, the reducing agent has no influence on the ratio **6** : **7** (Table 1). On complete conversion, up to 98% of **7** is formed (with **1a**) and up to 80% **6** (with **10a**). When dad is too bulky (**1c**, **1d**), the catalytic reaction is suppressed at room temperature, or (e.g. with **1e**) a disproportionation to $Fe(dad)_2$, **8**, and "Fe", **9**, is observed. Diene-stabilized iron atoms **9** (without diene, iron particles are formed!) appear to be responsible for the comparatively slow formation of linear dimers (see Table 1) and higher oligomers; **8** is only catalytically active at higher temperatures.[5]



Ligands, which—due to steric requirements—do not form $(dad)_2M$ complexes or, if so, only slowly, such as **1f**

Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (FRG)

[**] Diazadienes as Control Ligands in Homogeneous Catalysis, Part 11. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Hoechst AG. – Part 10: [1].

with nickel(0),[6] yield long-lived and rapid catalysts with Fe^0.[7] The *N*-substituent in **1g** is particularly small, and, according to an X-ray structure analysis, in **1h** the phenyl ring is turned out by ca. 70° from the dad plane and thus also counts among the sterically less demanding ligands.[8] Nevertheless, catalysts **3g** and **3h** do not convert any butadiene at room temperature, though both catalysts smoothly convert isoprene and *trans*-1,3-pentadiene into methylated cyclodimers analogous to **6** and **7**. In the case of most of the other catalysts with ligands **1** and **10** (Table 1), isoprene and 1,3-pentadiene are converted less rapidly than butadiene—similarly as in the L–Ni system.[9] If, however, isoprene (10 or 100 moles/mole Fe) is added to an "inert" butadiene/**3h** mixture (100 : 1), the cyclodimerization of *butadiene* proceeds rapidly at room temperature. Up to more than 50% conversion, codimers and isoprene dimers are not observed. On the other hand, if **2h** is activated with 1.5 equivalents of $Mg \cdot C_4H_6 \cdot 2THF$ in the presence of 100 equivalents of isoprene, 2.5% of butadiene-isoprene codimers are obtained, and, on activation of an isoprene run with bis(butadiene)magnesium, traces of **6** and **7** are also formed.

10

From these observations it must be assumed that an equilibrium is set up between butadiene and isoprene ligands on iron. Moreover, as the necessity of the isoprene as a "releaser" shows, at least three diene units must be bound to iron in **5**.

Very active catalysts such as **3f** also show a constant reaction rate (dilatometry) up to almost complete conversion of butadiene; consequently the product release (e.g. from **5**) is rate determining. In the case of the isoprene-induced butadiene dimerization on **3h** the change of the isoprene equivalents from 1 to 10 and to 100 mol per mol Fe surprisingly effects a marked change in the ratio **6** : **7**. This finding can be hardly explained in terms of an intermediate of the type **5** with n = 3, but rather in terms of a (dad)Fe^0 system containing four diene units on iron immediately before the product release. With different amounts of isoprene, different amounts of (dad)Fe"$(C_4H_6)_3$"(C_5H_8) or (dad)Fe"$(C_4H_6)_2$""$(C_5H_8)_2$" can be expected. It is virtually impossible to make any statements about the coupling of the dienes. In a (dad)Fe"$(diene)_4$" species two dienes ought to be η^2-bound, the two others already form a coupled σ,σ bound unit, so that the complex satisfies the noble gas rule and concomitantly is a meaningful precursor for the product.

3f is a slow catalyst for the dimerization of isoprene or 1,3-pentadiene, but shows a remarkable selectivity with 1 : 1 mixtures of the two dienes. Besides 3.3% of isoprene dimers 96.7% of codimers are formed, 9.5% of which being 2-methyl-4-*trans*-propenylcyclohexane and 91.5% 1,7-dimethyl-1,5-cyclooctadiene, which is thus readily accessible in an overall yield of over 88%.

The influence of the diazadienes on the course of the catalytic reaction is possibly even better demonstrated by chirality transfer. Of the numerous chiral dad and dad-like

[7] In a typical butadiene catalysis ca. 5 g (ca. 100 mmol) of dry butadiene and 12 17 mL of dry ether are condensed into a flask at −80°C and treated successively with 0.2–0.4 mmol of precatalyst **2** and then with the activator R–MgX (up to a fourfold molar amount, referred to Fe) or with MgC_4H_6 (up to a 1.7-fold molar amount). The thoroughly mixed reaction solution is then kept at room temperature in a graduated, thin Schlenk tube (NORMAG) up to the calculated maximum contraction (0.5–50 h); at higher temperatures, sealed ampules are used. The reaction solution is then treated with dilute H_2SO_4, washed with water, dried over Na_2SO_4, and distilled. Product characterization by GC, GC/MS, and preparative GC/NMR.

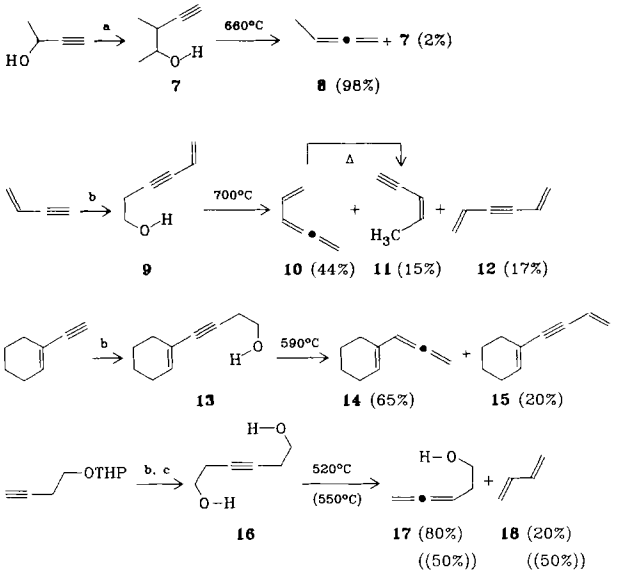
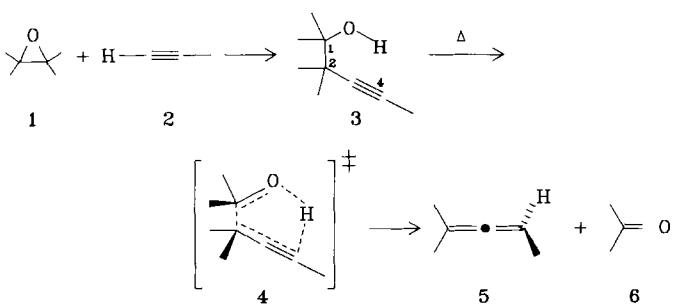
Novel Retro-Ene Reactions of β-Hydroxyacetylenes**

By *Henning Hopf** and *Reinhard Kirsch*



Dedicated to Professor Hans Musso on the occasion of his 60th birthday



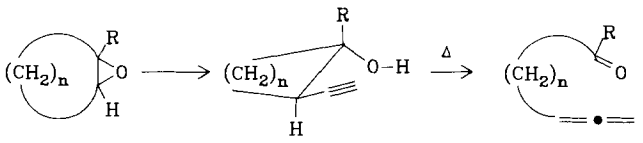
On gas-phase pyrolysis, 3-butyn-1-ols **3** decompose into allenes **5** and a carbonyl component **6**.[1]

As demonstrated by *Viola* et al. in comprehensive mechanistic investigations **5** and **6** are formed via **4** in a retro-ene type 1,5-sigmatropic rearrangement.[2] Since the alcohols **3** can be prepared, inter alia, from oxiranes **1** and 1-alkynes **2**, the two-step process **2**→**3**→**5** effects a conversion of terminal alkynes into terminal allenes with lengthening of the chain by one carbon atom.[3] In view of the growing importance of allenes in preparative chemistry[4,5] and the simplicity of the above synthesis it appeared desirable to widen its scope of application: hitherto, exclusively acyclic butynols **3** containing alkyl and phenyl substituents in the 1- and 4-position were pyrolyzed.[2,3,6] For an intended allene synthesis, however, substituents in the 1-position of *acyclic* reactants **3** are of no account, since this carbon atom is lost during thermolysis. In the pyrolysis of *cyclic* β-hydroxyalkynes, on the other hand, α,ω-allene-aldehydes or -ketones would have to result, since the fragments **5** and **6** remain connected to each other.

To supplement the acyclic series,[1] the alkynols **7**, **9**, and **13** and the diol **16** were prepared by conventional methods[7] and pyrolyzed (Table 1).

Table 1 [7]. Preparation of β-hydroxyalkynes of type **3** and their pyrolysis in a flow tube at 10^{-3} torr.—a) 1) PBr_3, 2) CH_3CHO, Al.—b) 1) $LiNH_2$, liquid NH_3, 2) oxirane.—c) H⊕.—THP = tetrahydropyranyl.—Yields, apart from those of **8** (NMR analysis), determined by GC analysis.

Whereas the expected 1,2-butadiene **8** is formed exclusively from **7**, in the case of **9** and **13** not only 1,2,4-pentatriene (vinylallene) **10** and 1-propadienylcyclohexene **14** are formed but also the dehydration products **12** and **15**. Moreover, at the temperature given, **10** isomerizes stereoselectively by a 1,5-hydrogen shift to give *cis*-3-penten-1-yne **11**.[8] In the case of the diol **16** the cleavage of a formaldehyde molecule not only generates the desired retro-ene product **17** but also concomitantly creates the prerequisite for a repetition of this fragmentation step: Indeed, 1,3-butadiene **18** is obtained as second pyrolysis product.



In the series of cyclic β-hydroxyalkynes, the *trans*-alcohols **20** were prepared from the epoxides **19**[9] and pyrolyzed (Table 2) as above (Table 1).

The allene-aldehydes **21b** and **21c** and the allene-ketone **21d** are formed as major products of the isomerization reactions from **20b–d**. Varying amounts of unsaturated hydrocarbons are also formed, which, according to GC/MS analysis, are dehydration products of the respective alkynols. The five-membered ring alcohol **20a** affords the al-

(yield determined by GC analysis). In analogy to the findings of *Conia* et al. on the thermolysis of 7-octyn-2-one, **22** and **23** can be postulated as intermediates of this cyclization.[10] The good yields obtained in the rearrangements of **20b–d** are surprising in so far as *trans*-2-(1-heptynyl)cyclohexanol resists thermal ring-opening.[1,2,11]

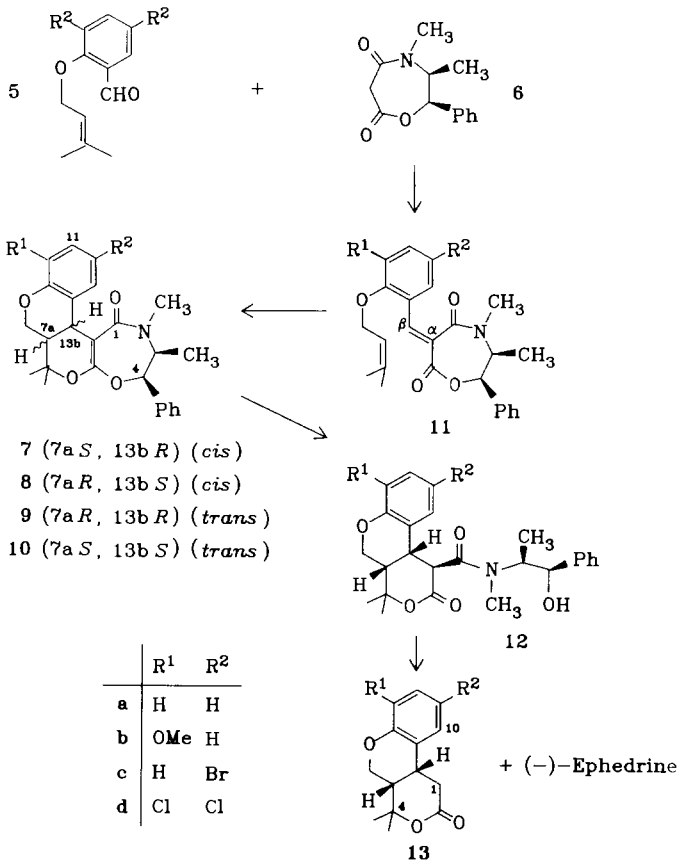
Highly Enantioselective Intramolecular Hetero Diels-Alder Reactions for the Synthesis of Enantiomerically Pure Tricyclic Lactones**

By *Lutz-F. Tietze,* Siegbert Brand,* and *Thomas Pfeiffer*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Diels-Alder reactions can be used not only for the construction of carbocycles but also for the synthesis of heterocycles ("hetero Diels-Alder reactions").[1] For example, pyran derivatives may be prepared by reaction of α,β-unsaturated carbonyl compounds with enol ethers or alkenes. The reaction is particularly valuable because the educts **4** can be prepared in an easy way by condensation of aldehydes **1** with cyclic 1,3-dicarbonyl compounds **2**. The cycloaddition leads intramolecularly to *cis*- or *trans*-annelated polycyclic compounds of the type *rac*-**3** with *de* values ≥98%.[2] This method can be employed for the synthesis of such diverse natural products as cannabinoids,[3a] iridoids,[3b] and indole alkaloids.[3c]



Here we describe the asymmetric induction[4] using the oxazepandione **6** as a chiral 1,3-dicarbonyl compound, which was prepared from methyl hydrogen malonate and (−)-ephedrine in 40% yield[6] according to the method of *Mukaiyama*.[5] The benzaldehyde derivations **5** are catalytically condensed with **6** to give the benzylidene-1,3-dicarbonyl compounds **11** (see Table 1). In the intramolecular hetero Diels-Alder reaction of **11**, the *cis*-annelated cycloadduct **7**[7–9] is obtained as the main product with often excellent *de* values (≥98%); the compounds **7** can be purified by crystallization or by chromatography on silica gel (Table 1).

A priori, eight cycloadducts can be formed in the reaction of **11**, since the educt contains two heterodiene moieties; each of them should give both *trans*- and *cis*-annelated products. The *trans*-annelated products **9** are formed in <1 to 4% yield; the *cis*-fused cycloadducts **8**,[7,8] which are diastereomeric to **7**, can be detected in amounts of <1 to 3%. The *trans* products **10** were not isolated; likewise, compounds whose formation may be explained by reaction of the amide carbonyl groups were not found. Without a catalyst, the selectivity of the reaction decreases dramatically. Thus, the reaction of **11a** in *o*-dichlorobenzene (100°C, 18 h) affords 45% **7a**, 21% **8a**, and 24% **9a** after

purification by column chromatography. Steric interactions such as in **11d** also lower the selectivity and especially the reaction rate (Table 1).

14

We assume that the conformation of the transition state **14** of the intramolecular cycloaddition of **11a** to give **7a** is an *endo*-(*E*)-*syn* arrangement with a folded oxazepandione moiety in which the C_β *si* face is sterically shielded so that the dienophile attacks almost exclusively from the C_β *re* face. The Lewis acid catalyst may cause a lowering of the LUMO energy of the heterodiene and a fixation of the conformation in the transition state. The lower reactivity of **11** in comparison with the corresponding derivatives of dimethylbarbituric acid and Meldrum's acid[2] is presumably due to the fact that the carbonyl group on C_α of the heterodiene is twisted, to a certain extent, out of the plane of the π-system. This raises the energy of the LUMO of the heterodiene and thus decreases the rate of this Diels-Alder reaction with inverse electron demand.

The cycloadducts **7** are surprisingly stable toward alkali. With methanolic HCl (3 N HCl/MeOH = 1:1, 20°C, 14 h), however, up to 89% of the amide **12a**[7] is obtained from **7a**. Compound **12a** is cleaved in the presence of 6 N NaOH (100°C, 3.5 h), undergoing decarboxylation to give the lactone **13a**[7,8] in 80% yield. In addition to **13a**, 87% (with respect to **12a**) of the (−)-ephedrine used could be recovered. By use of (+)-ephedrine, which is also commercially available, *ent*-**13a** can be prepared analogously.

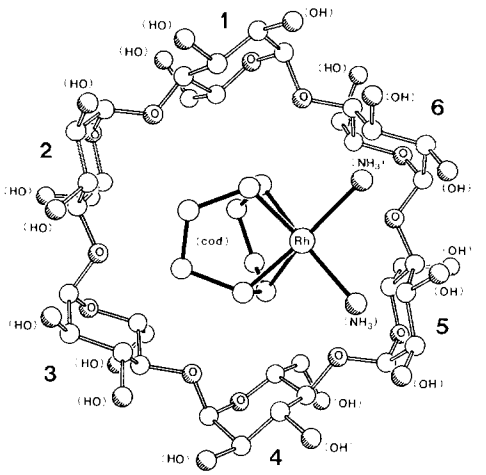

Fig. 1. A plan view of the skeletal representation of $[Rh(cod)(NH_3)_2 \cdot \alpha\text{-CD}]^{\oplus}$ in the crystal of $1 \cdot 6H_2O$. Note that the α-D-glucopyranosidic units are numbered from 1 to 6 in an anticlockwise direction.

Cyclodextrins as Second Sphere Ligands for Transition Metal Complexes—The X-Ray Crystal Structure of $[Rh(cod)(NH_3)_2 \cdot \alpha\text{-cyclodextrin}][PF_6] \cdot 6H_2O$**

By *David R. Alston, Alexandra M. Z. Slawin, J. Fraser Stoddart,** and *David J. Williams*

Transition metal complexes can be coordinated[1] in the second sphere by macrocyclic crown ethers in apolar solvents. This finding prompted us to study the potential of cyclodextrins[2] to act[3] as second-sphere ligands for organometallic compounds in aqueous media. We have discovered that cyclodextrins do indeed form stable adducts with a range[4] of transition metal complexes in H_2O. We report here on ^{1}H-NMR spectroscopic investigations of the 1 : 1 adducts **1** and **2** between α-cyclodextrin (α-CD) and $[Rh(cod)L_2][PF_6]$ (cod = 1,5-cyclooctadiene and $L_2 = (NH_3)_2$ or $H_2NCH_2CH_2NH_2$ = en), and on the structure of the crystalline hydrate of **1**

$[Rh(cod)(NH_3)_2 \cdot \alpha\text{-CD}][PF_6]$ **1**
$[Rh(cod)(en) \cdot \alpha\text{-CD}][PF_6]$ **2**

Initially, we noted that both α- and β-CDs solubilize $[Rh(cod)(NH_3)_2][PF_6]$ in water. Addition of 1 mol. equiv. of the Rh complex to a solution of α-CD in D_2O resulted in significant shifts (i) of the ^{1}H-NMR signal for H3 in α-CD to higher frequency (e.g. 20.8 Hz at 250 MHz for a concentration of 0.021 mol kg^{-1}) and (ii) of the ^{1}H-NMR signal for H5 in α-CD to lower frequency. These twelve protons are oriented inside the cavity of α-CD. The association constant K_a for 1 : 1 adduct formation could not be determined since the Rh complex slowly hydrolyzed.[5] Despite the instability of the 1 : 1 adduct, it did prove possible to obtain single crystals of the hexahydrate of **1**.[6]

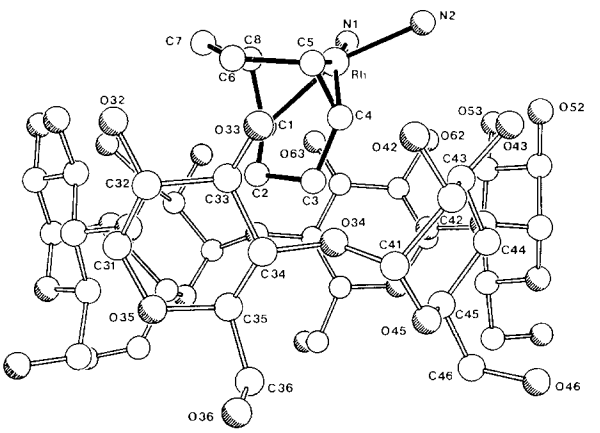

Fig. 2. A side-on view of the skeletal representation of $[Rh(cod)(NH_3)_2 \cdot \alpha\text{-CD}]^{\oplus}$ in the crystal of $1 \cdot 6H_2O$. The cod-numbering is not that recommended by the IUPAC.

An X-ray structure analysis of $1 \cdot 6H_2O$[7] (Figs. 1 and 2) showed that the cod ligand is positioned almost exactly over the center of the torus in α-CD, which adopts a characteristic tub-shaped conformation with local pseudo C_6 symmetry. One of the two ethylene groups is inserted (Fig. 2) into the α-CD cavity with C2 and C3 lying 0.88 and 1.08 Å respectively below the mean plane of the O atoms associated with the 12 secondary OH groups. Although two (C1 and C4) of the olefinic C atoms on the cod ligand lie 0.22 and 0.21 Å respectively above this plane, they clearly reside below the rim defined by the H atoms of these OH groups. The two NH_3 ligands on Rh are tilted slightly upwards and are positioned over the two α-D-glucopyranosidic units 5 and 6 (Fig. 1). There are four intra-adduct N···O contacts[8] of <3.5 Å: two are between N1 and O62 and O63 (3.46 and 3.25 Å, respectively), and the other two are between N2 and O52 and O53 (3.31 and 3.24 Å, respectively).[9]

Replacement of the two ammine ligands in $[Rh(cod)(NH_3)_2][PF_6]$ by a bidentate ethylenediamine (en) ligand afforded a stable Rh complex, **2**, in aqueous solution in the presence of α-CD. The ^{1}H-NMR spectrum of **2**

in D_2O revealed shifts[10] to higher frequencies of the signals for H2, H3 (e.g. 21.1 Hz at 250 MHz for a concentration of 0.017 mol kg^{-1}),[11] and H4 and a shift to lower frequency of the signal for H5. A K_a value of 520 ± 80 mol^{-1} kg was obtained[12] from a quantitative ^{1}H-NMR spectroscopic analysis of the 1:1 adduct in the concentration range (0.002–0.017 mol kg^{-1}) using H3 as the probe proton.

[4] E.g. [Fe(Cp)$(CO)_2NH_3$][PF_6] and [Fe(Cp)$(CO)_2C_5H_5N$][PF_6] (Cp = cyclopentadiene) form 1:1 adducts with both α- and β-CD. J. F. Stoddart et al., unpublished.

[5] The pH of the D_2O solution increases slowly with time as NH_3 is released from the first coordination sphere. The lability of the NH_3 ligands in [Rh(cod)$(NH_3)_2$][PF_6] has been observed previously (H. M. Colquhoun, S. M. Doughty, A. M. Z. Slawin, J. F. Stoddart, D. J. Williams, *Angew. Chem. 97* (1985) 124; *Angew. Chem. Int. Ed. Engl. 24* (1985) 135).

[6] Experimental: **1**·6 H_2O: 80 mg (0.20 mmol) [Rh(cod)$(NH_3)_2$][PF_6] was dissolved in H_2O (1 mL) containing 240 mg (0.25 mmol) α-CD with gentle warming. On cooling, a white precipitate formed initially followed by a crop of fine yellow crystals. On gentle warming, the yellow crystals redissolved leaving behind the white precipitate which was filtered off. *Very slow cooling* during 6 h afforded a few yellow crystals (m.p. > 200 °C, decomp.), suitable for X-ray structural investigation.

[7] Crystal data for **1**·6 H_2O: $P2_12_12_1$, $a = 14.035(4)$, $b = 19.517(6)$, $c = 23.803(6)$ Å, $V = 6520$ Å^3, $Z = 4$, $\rho_{calc} = 1.5$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 34$ cm^{-1}, 4015 independent observed reflections with [$|F_0| > 3\sigma(|F_0|)$, $\theta \leq 58°$], $R = 0.086$, $R_w = 0.077$. An empirical absorption correction was applied. The structure was solved by the heavy-atom method and refined anisotropically. Further details of the crystal structure investigations can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW. Any request should be accompanied by the full literature citation for this communication.

[8] Interestingly, there is an N-H···F interaction (3.07 Å) between N1 and one of the F atoms of the PF_6^- counterion.

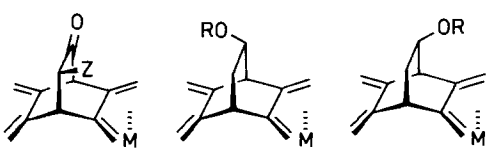
[9] Characteristically, there is an extensive network of H bonds, some involving the H_2O molecules and others linking symmetry-related α-CD ligands. The formula **1**·6 H_2O merely indicates the presence of 6 H_2O molecules in the asymmetric unit: there are, however, 7 discrete sites occupied by the six H_2O molecules—5 of these have 100% occupancy and the other 2 have 50% occupancy.

[10] Interestingly, the four ethylene protons in the en ligand of **2** resonate as an AA'BB' system in the range $\delta = 2.64$–2.78, indicating the anisochronous nature of the enantiotopic CH_2 protons in the chiral environment of α-CD. In contrast, a singlet for these protons is observed in the ^{1}H-NMR spectrum of [Rh(cod)(en)·β-CD][PF_6] in D_2O.

[11] In the ^{1}H-NMR spectrum of [Rh(cod)(en)·β-CD][PF_6] in D_2O, the signal for H3 is shifted to lower frequency relative to that observed in the spectrum of free β-CD.

[12] The chemical shift differences observed on changing progressively the concentration x [in mol kg^{-1} (D_2O)] of the 1:1 adduct were analyzed using the equation,

$$\Delta = \Delta_0 - (\Delta/x)^{1/2} \cdot (\Delta_0/K_a)^{1/2}$$



where Δ is the difference between the observed chemical shift for H3 in the solution of the 1:1 adduct (at equilibrium) and that for H3 in free α-CD, and Δ_0 is the difference between the limiting chemical shift of the 1:1 adduct (assumed fully formed) and that for H3 in the free α-CD. A plot of Δ against $(\Delta/x)^{1/2}$ gave a straight line and the K_a value was obtained from the slope, $-(\Delta_0/K_a)^{1/2}$, and the intercept, Δ_0, which equalled 29.7 Hz.

Stereoselective Nucleophilic Additions to a Bicyclic Ketone Controlled by a Remote Tricarbonyl(diene)iron Moiety**

By *Jean-Christophe Zwick* and *Pierre Vogel**

A great deal of effort has been devoted to understanding relative asymmetric induction in nucleophilic additions to chiral carbonyl compounds.[1] A variety of transition-state models based on steric factors[2] or on the interaction of the σ-orbitals of α-substituents with the π-orbital of the carbonyl group have been proposed.[3] We report on the hydride addition to the ketone **1** in which asymmetry is induced by a remote tricarbonyl(diene)iron moiety.[4]

The hydride reductions of **1** give alcohols **2** and **3**, whose ratio is dependent on the reagent, solvent, and temperature (Table 1). The hydride always prefers to attack

the CO group on its *syn* face with respect to the $Fe(CO)_3$ moiety, giving **2**, whose structure was established by 360-MHz ^{1}H-NMR spectroscopy and confirmed by lanthanide-induced shift (LIS) measurements (Table 2[5]). It is noteworthy that the base-catalyzed H/D exchange of **1** is also stereoselective, **4** being formed ca. 100 times faster than the corresponding dideuterated derivative.[6]

[a] Correct elemental analysis. [b] thd = 2,2,6,6-tetramethyl-3,5-heptanedionate.

Preliminary X-ray crystallographic data on **1**[7] showed that the two faces of the ketone offer the same steric hindrance toward nucleophilic attack. Thus, the selectivities of the reactions **1**→**2** and **1**→**4** cannot be attributed to steric factors in the ground state. Unless there is a special distortion of the bicyclic skeleton of **1** in solution,[6] electronic factors must be invoked. The field effect of the $Fe(CO)_3$ group in **1** could induce a preferred *syn* attack of the nucleophile (**1**→**2**).[8] Accordingly, the transition state with the largest dipole moment should lead to the highest stereoselectivity. This is consistent with the observation that the reduction of **1** by $LiAlH_4$ or $LiBHEt_3$, which takes place via a partially ionized transition state having a high dipole moment,[9] gives better selectivity than that with diisobutylaluminum hydride (DIBAH), the transition state of which is non-ionized and has a smaller dipole moment[10] (Table 1).

7 M=Fe(CO)$_3$ **8** **9**

Alternatively, the results could be interpreted in terms of charge delocalization involving the uncomplexed diene moiety in **1** (**7**↔**8**). The stronger the charge development, the more **8** contributes and the more reaction **1**→**2** is favored, in agreement with our results. The low stereoselectivity for the reaction of **1** with DIBAH could be attributed to the smaller charge development in the transition state (see **9**[10]).[11]

The relative ability of the uncomplexed diene and tricarbonyl(diene)iron moieties to participate in the charge delocalization in **7** has been tested by comparing the rates of solvolysis of the methanesulfonates **5** and **6** (S_N1 reaction). In $(CF_3)_2CHOH/H_2O$ (2:1, 2,6-lutidine as buffer, 25°C) **6** was hydrolyzed at least 2000 times faster than **5**.

At present neither of the possible explanations discussed above to explain the observed stereoselectivities in the reduction of **1** can be dismissed. Our work, however, demonstrates that a remote tricarbonyl(diene)iron moiety can influence the stereoselectivity of nucleophilic addition to a carbonyl function and that this effect is not due to a steric factor.

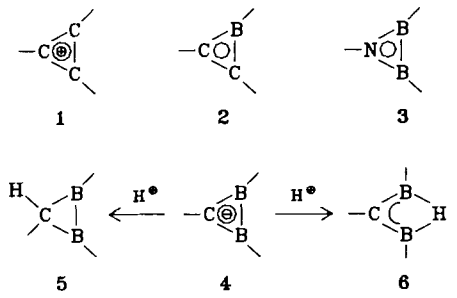
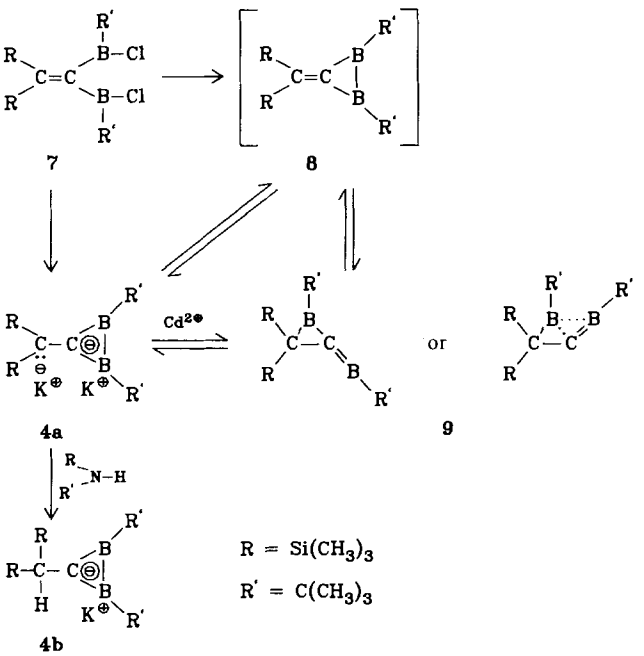
Diboriranides and a 1,3-Diboraallyl System with *B*-H-*B* Bridge**



By *Rolf Wehrmann, Harald Meyer,* and *Armin Berndt**

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday



Diboriranides, **4**, are isoelectronic with the 2π-arenes **1**–**3**;[1] protonation of **4** could lead to diboriranes **5** or to 1,3-diboraallyl systems containing a *B*-H-*B* bridge, **6**.[2] According to molecular orbital calculations unsubstituted **5** has planar geometry at the ring C atom, while the corresponding species **6** was found to be considerably lower in energy (31.7 kcal/mol) than **5**.[3] We report here on the synthesis of the first derivatives of **4** and **6**.

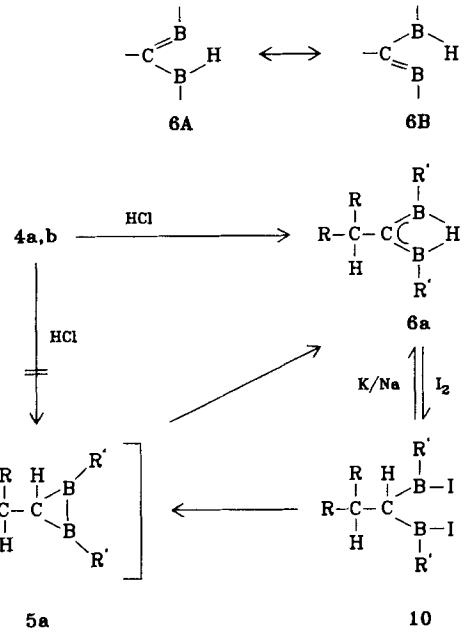
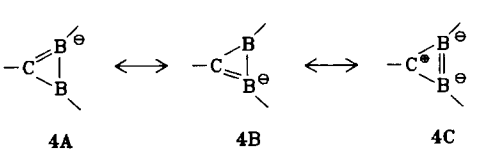
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



Reaction of the dichloride **7**[4] with four equivalents of potassium or K/Na alloy in tetrahydrofuran (THF) leads to formation of the diboriranide **4a**. Oxidation of **4a** with $CdCl_2$ leads to the boranediylborirane **9**,[5,6] which is also accessible by reaction of **7** with two equivalents of K/Na alloy in pentane. Reduction of **9** with K/Na alloy in pentane affords **4a** in ca. 20% yield.[7] These reactions can easily be explained in terms of the methylenediborirane **8** as common intermediate.

Reaction of **4a** with the very weak acid *tert*-butyl(trimethylsilyl)amine leads to formation of the diboriranide **4b**.

The structures **4a** and **4b** follow from ^{1}H-, ^{13}C-, ^{11}B-, and ^{29}Si-NMR spectra;[8] they are consistent with the formation and reactions of these compounds. The chemical shift of the boron atoms ($\delta(^{11}B) = 39$ and 45, respectively) is similar to that in borirenes **2** (36-49).[9] The ring C atoms ($\delta(^{13}C) = 162$ and 148, respectively) are shielded compared to those in borirenes with partial positive charge on these atoms ($\delta(^{13}C) = 180$-195).[9] **4a** is remarkably thermostable in the absence of solvents which can function as proton-donators (THF): heating the solid salt to 150°C for five hours does not lead to any NMR spectroscopically measurable changes.



Further protonation of **4b** with bis(trimethylsilyl)amine or reaction of **4a** or **4b** with gaseous HCl does not lead to diborirane **5a**, but to the isomeric **6a**.[8] In the undecoupled ^{13}C-NMR spectrum, the signal of the C atom bearing the two boron atoms is not a doublet but a singlet. Also its position ($\delta = 128$) is not reconcilable with **5a**, but is so with

6a. The H-bridge between the boron atoms of **6a** follows from the characteristic[10] broad IR band at 1580 cm^{-1}, which, in deuterated **6a** (reaction of **4b** with $(Me_3Si)_2N$-D), is shifted to 1185 cm^{-1}. We ascribe the appearance of two signals for the *tert*-butyl groups on cooling **6a** to hindered rotation of the $(Me_3Si)_2CH$ group[11] ($\Delta G^{+} = 13.4$ kcal/mol). An explanation in terms of a rapidly established equilibrium between **6A** and **6B** can be ruled out because of the absence of an IR or Raman band in the region for B=C double bonds.[5,6b] **6A** and **6B** are merely resonance formulas of **6a** in which two π electrons are delocalized over the three centers B-C-B; thus a 1,3-diboraallyl system is realized. The *B*-H-*B* bridge in **6a** is the first 3-center 2-electron bond with only *tri*coordinated boron atoms. The NMR signal of the proton of the *B*-H-*B* bridge appears in the region for vinyl protons at $\delta = 4.9$ (verified by ^{2}H-NMR spectroscopy of the deuterated compound). Signals of the protons of BH_2B bridges with *tetra*coordinated boron atoms appear at $\delta = 0.5$ to 1.5.[11]

6a neither reacts with the strong base **4a** nor with K/Na alloy or with strong mineral acids (HCl, HBF_4 in ether). It reacts smoothly with iodine to give **10**,[8] whereupon the hydrogen migrates from the boron to the carbon (doublet in the undecoupled ^{13}C-NMR spectrum at $\delta = 47.7$). Dehalogenation of **10** with K/Na alloy does not lead to the primarily expected diborirane **5a**, but back to **6a**. Apparently, **5a** rapidly rearranges into **6a**.

The formation of **6a** instead of **5a** via two independent routes confirms the results of the calculations,[3] according to which the unsubstituted diboraallyl compound **6** with a *B*-H-*B* bridge is considerably more stable than the corresponding diborirane **5**.

Despite the negative charge of the diboriranides **4a** and **4b**, their ring C atom (with $\delta = 162$ and 148, respectively) is deshielded compared to that of **6a** (128). This points to ap-

preciable participation of the resonance structure **4C**, and thus to considerable double-bond character of the B-B bond, which is also found from calculations.[2]

[2] In reference [3] **6** is formulated with additional σ-bonding between the boron atoms and cyclic delocalization of the π-electrons. The NMR data of **6a** are not consistent with a structure with tetracoordinated boron. In the meantime Prof. *Schleyer* has informed us that further ab initio calculations (6-31G*) have given a three-center *B*-H-*B* bridge with only weak B-B bonding (distance 1.736 Å) and a short C-B distance of 1.432 Å for unsubstituted **6**. For unsubstituted **4**, bond lengths of 1.463 Å (C-B) and 1.600 Å (B-B) have been calculated, which indicate considerable double bond character and thus cyclic delocalization (aromaticity).

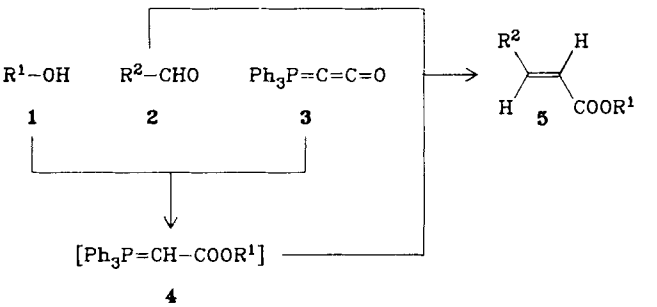
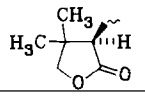
Chemoselective Multicomponent Synthesis of α,β-Unsaturated Esters and Lactones and of Their Diels-Alder Adducts

By *Hans Jürgen Bestmann** and *Rainer Schobert*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Chemoselective multicomponent syntheses, which do not require the isolation of intermediates or the use of protecting groups, are increasingly attracting the attention of preparative organic chemists. We have found that α,β-unsaturated esters **5** are obtainable in good to very good yields via a three-component reaction between an alcohol **1**, an aldehyde **2**, and the easily accessible ketenylidenetriphenylphosphorane **3**.[1] Presumably, **1** and **3** initially react to give **4**,[2] which then undergoes an *E*-stereospecific Wittig reaction[3] to give **5**.





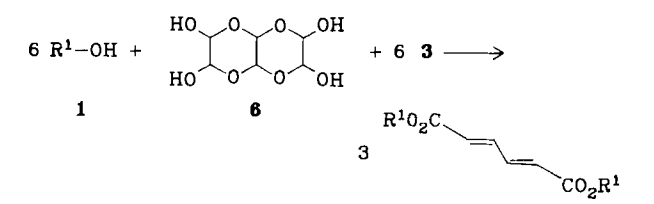


Table 1. α,β-Unsaturated esters **5** via three-component synthesis [a].

	R^1	R^2	Yield [%]	B.p. [°C/torr]	$[\alpha]_D^{25}$ [b] (EtOH)
5a	n-C_6H_{13}	n-C_4H_9	94	70/0.01	–
5b	n-C_4H_9	n-C_4H_9	92	60/0.01	–
5c	(*S*)-MeEtCHCH$_2$	n-C_4H_9	90	61/0.01	+5.2 ($c=1$)
5d	(−)-Menthyl	n-C_3H_7	81	92/0.01	−66.8 ($c=1$)
5e		n-C_3H_7	55	110/0.01	+10.6 ($c=0.2$)

[a] A solution of **1** (10 mmol), **2** (10 mmol), and **3** (3.02 g, 10 mmol) in 100 mL of dry toluene was refluxed for 12 h under inert atmosphere. After evaporation of the solvent, the residue was filtered through 20 g of silica gel with ca. 200 mL of hexane/ether (1:1), the eluate was evaporated, and the final residue was distilled in vacuum. [b] By saponification of the esters **5**, the optically active alcohols **1** are obtained, which have the same rotation as at the start of the reaction sequence.

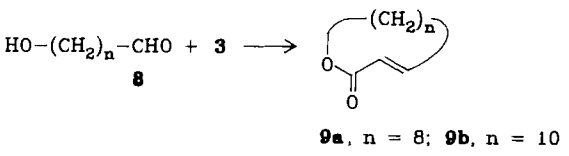

Table 1 shows that the chiral esters **5**, which are important for enantioselective diene syntheses,[4] are very easily accessible from the optically active alcohols **1**; as expected, the reaction takes place without racemization (as shown by saponification of the esters to the optically pure alcohols).

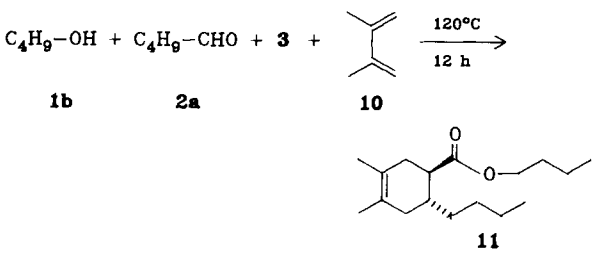
Similarly, the (*E,E*)-muconic ester **7** is formed from **1**, trimeric glyoxal hydrate **6**, and **3** in a molar ratio of 6:1:6. In this case, too, chiral compounds such as **7b**, which may be of interest for enantioselective [2+4] cycloadditions involving inverse electron demand, are easily obtainable (Table 2).



When ca. 0.1 M solutions of long-chained ω-hydroxy aldehydes **8** are added slowly to a refluxing solution of **3** in xylene (high-dilution conditions), the macrocyclic lactones **9** are formed (Table 2). The yields are similar to or better than those obtained in the lactone synthesis we described earlier,[5] in which the aldehyde group had to be protected first as the acetal.

Oxidation of α,β-Unsaturated Esters and Lactones with Selenium Dioxide to γ-Oxo or γ-Hydroxy Derivatives; Synthesis of (±)-A 26771 B and Norpyrenophorin

By *Hans Jürgen Bestmann** and *Rainer Schobert*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

γ-Oxo-α,β-unsaturated esters **2** are interesting synthetic building blocks, for example, for [2+4] cycloadditions. We have found that these compounds are easily accessible via oxidation of α,β-unsaturated esters[1] with SeO_2 in anhydrous dioxane.[2] Chiral esters such as **2c** are of particular interest for enantioselective cycloadditions.[3]

When the reaction is carried out in dioxane containing 3% water, the γ-hydroxy-α,β-unsaturated esters **3**[4] are obtained. Table 1 gives several examples.

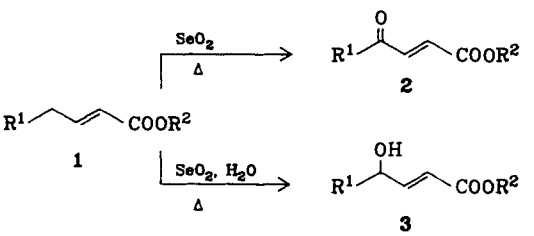

Table 1. Esters **2** [a] and **3** [b] via oxidation of α,β-unsaturated esters **1** with selenium dioxide.

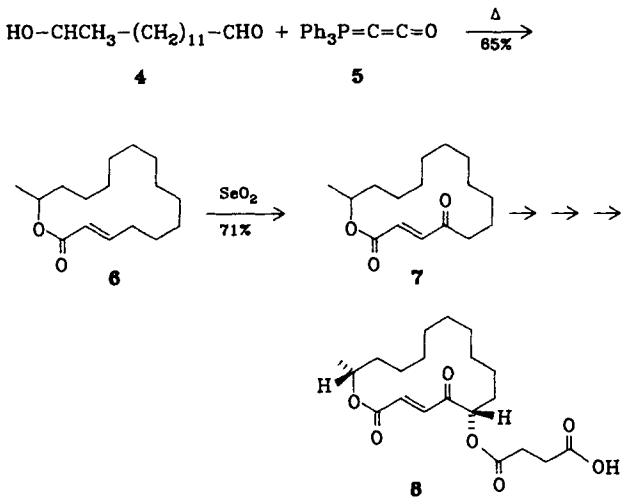
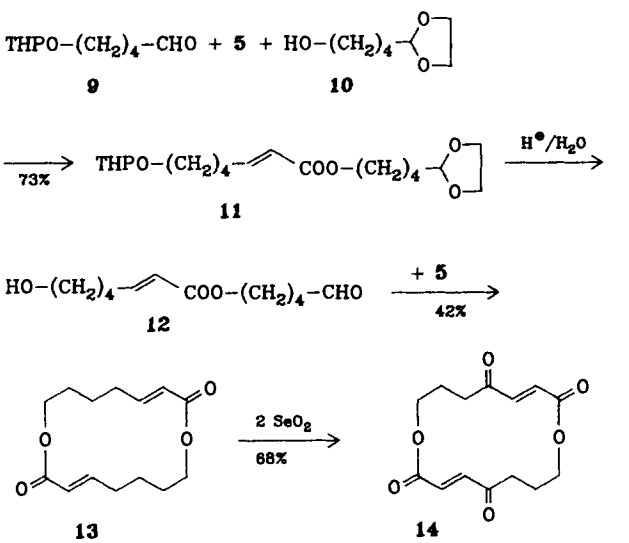
	R^1	R^2	Yield[%]	B.p.[°C/torr]
2a	n-C_3H_7	n-C_6H_{13}	89	92/0.01
2b	n-C_3H_7	n-C_4H_9	90	76/0.01
2c	C_2H_5	(−)-Menthyl	78	99/0.02 [c]
3a	n-C_3H_7	n-C_6H_{13}	52	[d]
3b	C_2H_5	CH(n-C_3H_7)$_2$	61	105/0.01
3c	CH_3	(−)-Menthyl	60	132/0.01 [e]



[a] SeO_2 (14 mmol) is added to a solution of **1** (10 mmol) in ca. 100 mL of dry dioxane, and the mixture is heated under inert atmosphere for 48 h. The selenium is filtered off, the filtrate is concentrated, and the residue is purified by distillation or chromatography. [b] The same procedure is used as in [a] except that ca. 3 mL of water is added to the reaction mixture. [c] $[\alpha]_D^{25}$ −59.6 (c = 1.0; EtOH). [d] Chromatographic purification on silica gel 60; R_f = 0.44 (hexane/ether 3 : 1). [e] $[\alpha]_D^{25}$ −77.8 (c = 1.11, $CHCl_3$).

A number of macrolide antibiotics are γ-oxo or γ-hydroxy-α,β-unsaturated lactones, e.g., cytochalasins,[5] pyrenophorins,[6] the macrocycle A26771B,[7] and brefeldin A.[8] The use of selenium dioxide oxidation in the synthesis of such compounds is illustrated by the following examples.



(±)-A26771B **8**: The hydroxy aldehyde **4** undergoes cyclization with ketenylidenetriphenylphosphorane **5** to give the α,β-unsaturated lactone **6**.[1] Oxidation of **6** with selenium dioxide gives the γ-oxo compound **7**, whose transformation into the antibiotic **8** has already been described.[9, 10] (**6**: b.p. = 100°C/0.05 torr; **7**: b.p. = 93°C/0.05 torr (kugelrohr, air-bath heating); **8**: m.p. = 131°C.)

Norpyrenophorin **14**: The α,β-unsaturated ester **11** is obtained by three-component reaction[1] of the tetrahydropyranyl ether **9** and the acetal **10** of ω-hydroxypentanal with **5** in benzene and its protecting groups are then

[*] Prof. Dr. H. J. Bestmann, Dipl.-Chem. R. Schobert
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (FRG)

cleaved in acid. The ω-hydroxy aldehyde **12** so formed is not isolated but rather cyclized to the diolide **13** by addition of a ca. 0.1 M solution of **12** in xylene to the molar equivalent amount of **5** in refluxing xylene (high-dilution conditions).[1] The subsequent oxidation of **13** with two

equivalents of selenium dioxide affords norpyrenophorin **14**[1] (**11**: b.p. = 125–128 °C/0.05 torr (kugelrohr, air-bath heating); **13**: m.p. = 55 °C (hexane), b.p. = 127 °C/0.01 torr; **14**: m.p. = 131 °C).

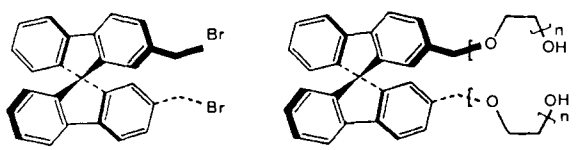
Chiral Poly(9,9′-spirobifluorene) Crown Ethers

By *Max Dobler, Miljenko Dumić, Martin Egli,* and *Vladimir Prelog**

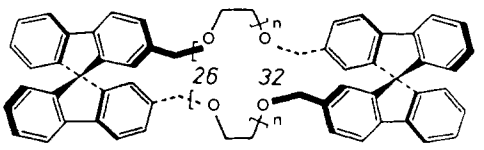
The first two members of the poly(9,9′-spirobifluorene) crown ether series, bis(9,9′-spirobifluorene)-[26]crown-4 **4** and bis(9,9′-spirobifluorene)-[32]crown-6 **5**, were initially obtained as side products in the preparation of the corresponding mono(9,9′-spirobifluorene) crown ethers from 2,2′-bis(bromomethyl)-9,9′-spirobifluorene **1** and the alkoxides of ethylene glycol and diethylene glycol, respectively.[1] Direct synthesis via condensation of **1** with alkoxides of the two dihydroxy ethers **2** and **3** in the presence of potassium *tert*-butoxide affords the cyclic products only in moderate, nonreproducible yields.



In the meantime, it has been found that the two bis(9,9′-spirobifluorene) crown ethers **4** and **5** exhibit, as ionophores, high enantioselectivity for salts of biologically active α-amino alcohols (e.g., ephedrine),[2] thus enhancing their interest. We have attempted to improve the second procedure of preparation of the compounds **4** and **5** by modifying the reaction conditions. It was finally possible to obtain **4** and **5** reproducibly in 40–50% yield by reaction of **1** with the dihydroxy ethers **2** and **3**, which may be prepared quantitatively, under the conditions of phase-transfer catalysis.[3]

Upon investigation of the crude products by thin layer chromatography, the two bis(9,9′-spirobifluorene) crown ethers **4** and **5** were found to be accompanied by several closely related compounds, which could be separated by chromatography on silica gel. These compounds were identified as poly(9,9′-spirobifluorene) crown ethers **6** to **9** on the basis of their UV, CD, NMR, and, in particular, mass spectra[4] and are summarized in Table 1.

The crown ethers **6** to **9**[5] are striking in several respects. They are well-defined cyclic compounds with a large number of ring members (52 to 104). They belong to the class of chiral yet highly symmetrical compounds (point group symmetry C_n, n = 4, 6, 8), for which only a few examples are known.[6] As crown ethers, they are potential host molecules. On account of their chirality, they are expected to be enantioselective, like the compounds **4** and **5**.[2] It is therefore advantageous that their sense of chirality, or absolute configuration, is known.



Characteristic of the poly(9,9′-spirobifluorene) crown ethers is the strong binding of solvent and crystallization

Raschdorf*, Ciba-Geigy, Basel, on a VG Micromass ZAB with high-field magnet; FAB, matrix 3-nitrobenzyl alcohol, Xe 7 kV. [f] Benzene/ethyl acetate (7 : 3).

with solvent molecules. Thus, **4** crystallizes with two molecules of benzene (m.p. = 122–124 °C) and **5** with one molecule of dichloromethane (m.p. = 153–156 °C). The results of the X-ray analyses[7] are presented in Figures 1 and 2.

The 26-membered compound **4** has a structure similar to those of other crown ethers having the same ring size.[8] The shape and size of its chiral cavity account for its complexing abilities and the observed enantioselectivity. The structure of the 32-membered compound **5** differs: the 9,9′-spirobifluorene moieties are closer to each other (separation of the two spiro atoms in **4**, 11.09 Å; in **5**, 6.65 Å) and the two oxygen-containing chains lie to the side so that no cavity for a guest molecule is present. The host molecule must first adapt itself to the guest by a significant conformational change. Such an "induced fit" has often been observed for natural as well as for synthetic ionophores.[9]

Experimental Procedure

Poly(9,9′-spirofluorene) crown ethers **4**, **6**, **8**, and **9**: (*S*)-(−)-2,2′-bis(bromomethyl)-9,9′-spirobifluorene **1** (502 mg) in 5 mL of toluene was added over 2 h with vigorous stirring to a solution of KO*t*Bu (447 mg) and CsI (259 mg) in 25 mL of ethylene glycol at 70 °C. The reaction mixture was then heated for an additional 13 h. After dilution with water and acidification, it was extracted with 500 mL of benzene. The washed benzene extracts, containing the dihydroxy ether **2** in practically quantitative yield, were concentrated to 200 mL, treated with an additional 478 mg of **1** as well as with tetrabutylammonium hydrogen sulfate (97 mg), acetonitrile (100 mL), and 200 mL of 50% sodium hydroxide solution, and vigorously stirred for 20 h at room temperature. The reaction mixture was diluted with water and acidified. The benzene layer was separated, washed, dried with $MgSO_4$, and evaporated. The residue (840 mg) afforded **4** · 2 C_6H_6 (323 mg) after recrystallization from benzene. By flash chromatography [10] of the mother liquor on silica gel 60 (Merck) with benzene/ethyl acetate (9.5 : 0.5) and (9 : 1) and recrystallization, an additional 70 mg of **4** · 2 C_6H_6 was obtained from the first fractions. The later fractions were rechromatographed and gave **6** (82.5 mg), **8** (14.1 mg), and **9** (1.0 mg). The final fractions contained the dihydroxy ethers with five (74.5 mg; $C_{147}H_{116}O_{12}$; $[M+K]^+ = 2111$) and with three (91.5 mg; $C_{89}H_{72}O_8$;

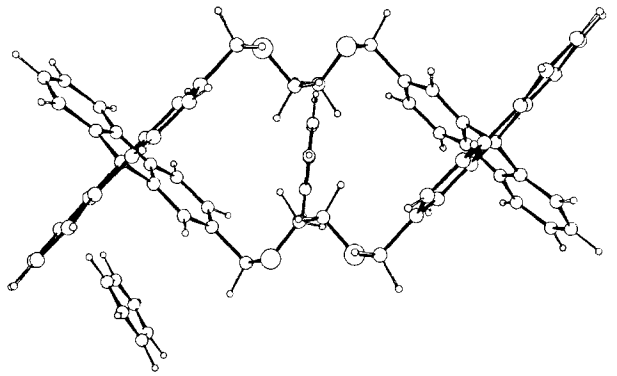

Fig. 1. Crystal structure of $4 \cdot 2C_6H_6$ along the crystallographic two-fold axis. The benzene molecule drawn in the center lies 5.7 Å below the crown ether ring. Important bond distances, bond angles, and torsion angles: spirobifluorene, six-membered ring 1.348...1.435, average 1.387 Å; 117.0...123.2°, average 120.0°. Five-membered ring, single bonds 1.443...1.556, average 1.513 Å, angles (without angles at spiro atom) 106.5...111.6°, average 109.7°, at spiro atom 100.2, 101.8°. Angle between the best planes 91.3°. 26-membered ring, values for the asymmetric moiety, beginning at the spiro atom: distances 1.542, 1.348, 1.385, 1.540, 1.443, 1.407, 1.518, 1.438, 1.425, 1.506, 1.409, 1.384, 1.509 Å; angles 113.0, 126.7, 119.4, 120.2, 111.5, 111.6, 107.8, 108.1, 111.9, 114.9, 120.4, 117.8, 126.9°; torsion angles 59.7, −172.9, 179.9, −45.6, −70.5, 176.1, 70.5, −177.7, −71.4, −32.1, −178.4, −178.3, 56.8°.

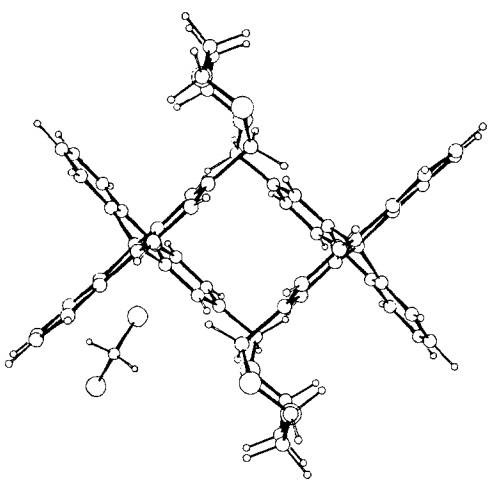

Fig. 2. Crystal structure of $5 \cdot CH_2Cl_2$ along the crystallographic two-fold axis. Important bond distances, bond angles, and torsion angles: spirobifluorene, six-membered ring 1.354...1.420, average 1.385 Å; 116.3...123.4°, average 120.0°. Five-membered ring, single bonds 1.500...1.552, average 1.522 Å, angles (without angles at spiro atom) average 109.6°, at spiro atom 101.1, 101.4°. Angle between the best planes 92.2°. 32-membered ring, values for the asymmetric moiety, beginning at the spiro atom: distances 1.552, 1.371, 1.398, 1.518, 1.402, 1.426, 1.486, 1.405, 1.443, 1.492, 1.414, 1.418, 1.569, 1.389, 1.373, 1.511 Å; angles 117.4, 128.5, 118.5, 120.2, 109.7, 110.4, 107.5, 108.7, 114.2, 107.8, 115.2, 115.8, 111.7, 118.0, 117.4, 128.3°; torsion angles 45.5, −178.8, 176.5, 36.2, 179.6, 172.3, −72.0, 174.3, −173.8, 80.7, −69.6, −64.2, 131.5, 176.7, 177.6, 59.3°.

$[M+K]^+ = 1307$) 9,9′-spirobifluorene residues as intermediate or side products along with 27 mg of unreacted **2**.

Poly(9,9′-spirobifluorene) crown ethers **5** and **7**: Analogously, $5 \cdot CH_2Cl_2$ (439 mg) and **7** (62.5 mg) were obtained from a total of 1004 mg of **1** with diethylene glycol.

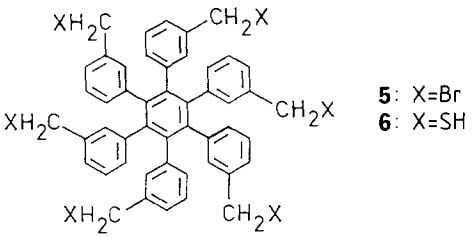
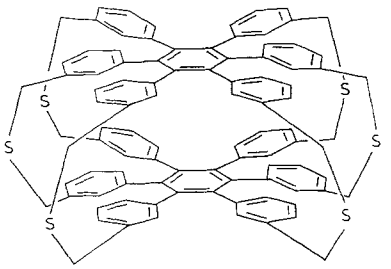
First Sixfold Bridge-Formation in One Step**

By *Wolfram Kissener* and *Fritz Vögtle**

While threefold,[1] fourfold,[2] and fivefold[2] bridging between two benzene rings in one step have all been successfully demonstrated in the past 15 years in the synthesis of the phanes **1**–**3**, the realization of a sixfold bridging, e.g. to give the ten-membered "superphane hexasulfide" **4**, in one step has not proven possible, despite numerous efforts.[1–4]



We assume that all previous attempts at achieving this aim have remained unsuccessful, not because of the number of bridges involved, but primarily because of the steric strain. Working on this basis we have now found that even six bridges can indeed be coupled intermolecularly if sterically less demanding starting materials are allowed to react with each other using the cesium effect[5] and dilution principle. An example is the reaction of hexakis[3-(bromomethyl)phenyl]benzene **5**[6] with the corresponding hexathiol **6**[7] to give **7**.



Using a general procedure previously optimized by us in earlier work,[2,5] this reaction resulted in precipitation of the 22-membered polycyclic hexasulfide **7** as pale yellow crystals (m.p. >320°C) in ca. 0.1% yield. The mass spec-

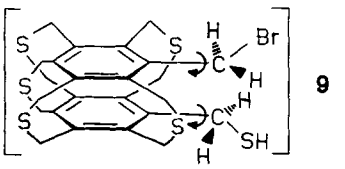
5: X=Br
6: X=SH



7

trum (m/z 1416 (M^+)) shows the molecular ion as an intense peak. The ^{1}H-NMR absorptions of the previously purified crystalline crude product are considerably broadened in CD_2Cl_2 as solvent. The polycondensation product[8] formed at the same time in the reaction, which is responsible for the broad signals, is removed by chromatography on silica gel with dichloromethane as eluent (R_F=0.61). The ^{1}H-NMR spectrum then shows an AB system for the CH_2 protons (δ_A=2.65, δ_B=3.2, J_{AB}=15 Hz) and sharp signals at δ=6.85–7.05 for the aromatic protons (in CD_2Cl_2). These findings are consistent with an all-*anti* conformation for **7**.[9] It is easily seen on comparison with the conformationally flexible 2-thia[3]*ortho*-terphenylophane **8**,[10] that **7** can be fixed conformationally, due to strain; according to model considerations the hexaphenylbenzene skeleton is present in a six-bladed propeller arrangement. This now raises the question whether **7** is sufficiently ridgid (and thus helical) in solution that it can be separated into enantiomers. Analytical separation on "Okamoto" resin[11] would indicate that this is indeed the case.

The successful one-step sixfold bridging realized with **7** throws light on the reasons why **4** was hitherto unobtainable: The last CH_2X groups in the intermediate **9** may no longer achieve the conformation requisite for the sixth bridging span.

8

9

With the synthesis of **7**, it has been shown for the first time that more than fivefold bridge formation is possible in one step if steric factors are carefully taken into account. Owing to the "six-coordination of the benzene ring", the sixfold bridging, particularly with longer bridges to give molecules with large cavities suitable for the encapsulation of organic guest molecules, opens up novel aspects: According to model considerations, the cavity of **7** is, as it were, tailor-made for the accommodation of a benzene molecule, whereas longer, flexible bridges are stretched after passage of the guest molecule; due to the widening of the cavity the guest becomes "trapped".

BOOK REVIEWS

Determination of Organic Reaction Mechanisms. By *B. K. Carpenter*. Wiley, Chichester 1984. xi, 247 pp., bound, £ 32.20.—ISBN 0-471-89369-2

This short, compactly-written, introductory textbook on the methods of investigating the reaction mechanisms of organic chemical reactions is based on a one-semester lecture course for new graduate students.

One could wish that such a lecture course were compulsory for all chemistry students at our universities after completion of their undergraduate work. It is true that the most important reaction classes and their mechanisms are treated in most general lecture courses, but additional knowledge concerning the experimental and theoretical basis of reaction mechanisms and their general limitations is needed in order to be able to understand them and their information content in a critical manner.

This book is capable of closing this gap. After a short introductory chapter, in which the scientific method of learn-

ing is generally described in brief, there are seven chapters in which the most important methods of investigating reaction mechanisms are described with brief treatments of their limitations and areas of application: isotopic labeling, chirality and stereochemistry, kinetics, isotope effects, acid-base catalysis, the interpretation of activation parameters including the elements of thermochemistry and bringing in linear free enthalpy relationships, methods of detecting reactive intermediates. Then follows a chapter which describes the combined application of these techniques with the aid of examples of investigations taken from recent literature. An appendix explains a range of mathematical techniques for the analysis of kinetics and symmetry problems; then follow tables of Benson group increments.

Almost all recent methods up to and including picosecond spectroscopy and laser methods are described briefly and in a way that is easily followed up and critically discussed upon the basis of a few chosen examples from the literature. An overemphasis on pericyclic reactions can be detected in the choice of examples, but account is also taken of classical fields, such as solvolysis and arene chemistry, while radical chemistry is dealt with too briefly. Unfortunately, little account is taken of the German literature. Topics which are omitted from the examples are steric effects including the force field method, the Curtin-Hammett principle, the interrelationships between selectivity and reactivity, and, finally, the isoselective relationship.

Is it necessary to know the treasure house of methods for studying reaction mechanisms in the era of preparative chemistry which we are now experiencing? In my opinion yes! It was the development of "physical organic chemistry" over the last 30 years that first made possible the new breakthroughs in preparative chemistry. It is only quantitative investigation methods that make possible the purposeful optimization of synthesis.

It is in this sense that the present book, which can only be criticized on the basis of a somewhat one-sided choice of examples, is thoroughly to be recommended. A German translation is to be desired.

Sources and Applications of Ultraviolet Radiation. By *R. Phillips*. Academic Press, New York 1983, xvi, 434 pp., bound, $ 60.00.—ISBN 0-12-553880-4

Normally, a book review begins with a short description of the contents. It seems more appropriate in the case of this book to start with the story of its origins. The author candidly admits in his foreword that his original intention was to write a monograph concerning (A) "Photopolymerization of Organic Surface Coatings" with emphasis on the chemical aspects. However, it soon became clear to him that there was already sufficient review literature covering this field and he thought it more useful and original to emphasize (B) "Sources of Radiation Suitable for Photopolymerization". Then that seemed to him to be too restricted and he became fascinated by the idea of writing a book entitled (C) "Radiation Sources in Applied Photochemistry". But this was also too specialized for him (or his publisher) and thus he came to the very general and sales-promoting title (D) "Sources and Applications of Ultraviolet Radiation".

The illogical construction of this book and its repetitions, shortcomings, and errors have two basic causes. Firstly, the various texts that had already been written ought to have been rewritten on going from (A) through (B) and (C) to (D). However, the author made it easy for himself and simply added sections or subsections to what had already been written. Secondly, in the course of the transition from (A) to (D) the author concerned himself with fields in which he was no longer competent. The eleven friendly helpers who checked the parts of the original manuscript and whom the author thanks in his foreword have probably avoided the worst. This help is evident in the text because of competently and fluently written passages, which pleasantly distinguish themselves from the often clumsy, imprecise or simply false formulations of the author.

One would actually expect in a book entitled "Sources and Applications of Ultraviolet Radiation" firstly to learn something about sources of UV light and afterwards something about their applications. The first chapter (37 pp., 274 refs.), however, is concerned with "Applications of Ultraviolet Radiation". It is not surprising that the applications furthest from the interests of the author consist in practice of pure enumeration, that many concepts are employed which are only explained in later chapters and that it is very seldom mentioned which UV source was employed.

The main purpose of Chapter 2 ("The Nature of Light", 10 pp., 2 refs.) is to introduce some concepts from atomic spectroscopy, which are required later for the discussion of gas discharge lamps.

Chapter 3 ("Photochemistry and Photopolymerization", 50 pp., 205 refs.) corresponds to the originally planned monograph (A). The subsection 3.1.4.3 ("The Jablonski Diagram") provides a whole range of examples of clumsy or false formulations. The keyword "UV curing" provides an example of unnecessary repetition and illogical ordering. It already appears in many places in Chapter 1 and in the titles of subsections 1.6.1, 1.6.1.10 and 1.6.11 and then it reappears in subsections 3.4.4 and 3.5. The explanation of what is understood by "cure", however, is first to be found in the *last* and obviously subsequently added section of Chapter 3 (3.6 "The Concept and Measure of Cure").

Chapters 4 ("Radiometry", 45 pp., 154 refs.), 5 ("Incandescent Sources", 8 pp., 2 refs.) and 6 ("Gas Discharges", 14 pp., 14 refs.) lead then to the main portion of the book: Chapter 7 ("The Low Pressure Mercury Lamp", 19 pp., 62 refs.), 8 ("The Medium Pressure Mercury Lamp", 66 pp., 53 refs.), 9 ("Metal Halide Lamps", 16 pp., 71 refs.), 10 ("Electrodeless Lamps", 16 pp., 16 refs.) and 11 ("Xenon Lamps", 33 pp., 91 refs.). Of these, chapter 8 is the most important because it includes results of the author's own investigations. Considerable knowhow is to be expected of the author here. But, once again one must cast doubts upon his competence, when on page 208 in connection with the Richardson-Dushmann equation $J = AT^2 \exp(-e\phi/kT)$ for thermal electron emission, it is stated "... where ... e is the electronic charge (1.60×10^{-19} e.s.u.), ϕ is the work function ... with units of electron volts, k is Boltzmann's constant (1.372×10^{23} JK^{-1} ..." It is almost a work of art to introduce an error into each of the three definitions! On page 239 of the same chapter the author reveals that he has no notion of optical spectroscopy. He maintains that the dispersion of a grating monochromator is independent of the wavelength and that the asym-

metry of the lines of an Hg spectrum recorded at low resolution is caused by pressure broadening of the lines (instead of being caused by the curvature of the image of the monochromator entry slit in the plane of the exit slit).

Chapters 12 ("Lasers", 19 pp., 120 refs.) and 13 ("Miscellaneous Sources", 9 pp., 23 refs.) are probably intended to justify the general title of the book. The inconsequence of the author in chapter 12 is quite remarkable, for he writes a relatively large amount on an infrared laser (CO_2 laser), but is satisfied in the case of the argon and krypton ion laser with the statement that both lasers can lase at various wavelengths in the UV and visible range. Chapter 13 is typical of the style of this book. Here sunlight, the deuterium lamp, synchrotron radiation and the high pressure mercury lamp all come together under the title "Miscellaneous".

Chapter 14, ("Ultraviolet Irradiators", 36 pp., 80 refs.) contains alongside 80 literature references a list of 58 chosen journal articles (with titles) concerning the design (or construction) and analysis of photochemical reactors. Finally chapter 15 (17 pp., 72 refs.) treats "Hazards of Ultraviolet Radiation".

It can be seen from these critical remarks and the contents of the book that this book—in contrast to the very generally formulated title—is only directed at a very limited circle of readers. This is clearly expressed by the author in the first sentence of his foreword: "This book has been written primarily for the benefit of those who have a responsibility for, or an interest in, the design, construction, purchase or operation of the "hardware" associated with applied photochemistry". The book is useless—whether as textbook or as reference source—for everyone else and particularly for those who work in the field of photophysics.

Finally it may be useful for the reader to know that there are two very good older books with similar titles. (I) "Ultraviolet Radiation" by *L. R. Koller* (Wiley, New York 1965, 312 pp.) and (II) "Ultraviolette Strahlen" edited by *J. Kiefer* (de Gruyter, Berlin 1977, 661 pp.). Both books were known to the author of the book that has been reviewed, but they have obviously only served him as a model for his choice of title. The application of UV radiation is described in (II) by means of examples; it is thus very suitable for use as a textbook.

Bernhard Nickel [NB 680 IE]
Max-Planck-Institut für
Biophysikalische Chemie, Göttingen (FRG)

Methods of Enzymatic Analysis. Vol. 2. Samples, Reagents, Assessment of Results. Edited by *U. Bergmeyer, J. Bergmeyer,* and *M. Grassl.* Verlag Chemie, Weinheim 1984. xvi, 539 pp., bound, DM 215.00 (when ordering all ten volumes).—ISBN 3-527-26040-4 (complete work)

Publication of Bergmeyer's 3rd edition of "Methods of Enzymatic Analysis" proceeds with volume 2 which marks the transition to practice from the theory presented in volume 1.[*] Volume 2 "covers the three steps in obtaining results from laboratory: the pre-analytical phase, the post-analytical phase, and the analysis itself." This objective is achieved in a straightforward and concise manner.

The first chapter in volume 2 deals with specimens and samples. The first section describes preparation and processing methods for samples in clinical laboratory sciences, food chemistry, cosmetics and pharmacy. The next section discusses cell and tissue disintegration and includes methods for animal tissues, subcellular fractionation, microorganisms and plant tissues. The third section describes and compares methods for protein determination. Throughout this chapter, factors which influence and interfere with these various methods are described, as well as ways to avoid potential pitfalls.

Reagents for enzymatic analysis are the focus of the second chapter. This chapter includes a section discussing the handling of reagents (nomenclature, quality requirements, storage and stability), and diagnostic kits. The compendium of reagents for enzymatic analysis found in the previous edition has been expanded and is included in this section; assays and characteristics of 143 enzymes and 119 coenzymes, metabolites and reagents are now described. A new addition is a section including descriptions and characteristics of standard reference materials for biochemistry.

The third chapter is titled "Evaluation of Experimental Results." The first section in this chapter discusses transformation of experimental data into results, end-point determinations, non-linear reaction curves, use of standard curves, standard substances and their terminology and definitions. Equations useful for calculating metabolite concentrations and enzyme activities from photometry, radiometry and related techniques are included along with specific illustrative examples. A second section covers the topic of quality control. After a discussion of errors, precision and accuracy, the principles of quality control and its applications in clinical chemistry are described. A subsection on the use of statistics in quality control covers basic concepts, evaluation of results, and curve fitting.

This volume concludes with a useful appendix with lists of symbols, quantities, units and constants; chemical and biochemical abbreviations; NAD(P)H absorption coefficients; numbering and classification of enzymes; and a table of atomic weights. This volume should find daily use in the biochemical laboratory as a handbook of both methods and data.

Harvard University, Cambridge (USA)

Einführung in die Pharmazeutische Chemie. 2nd completely revised edition. By *O.-E. Schultz* and *J. J. Schneckenburger.* Verlag Chemie, Weinheim 1984. xv, 510 pp., bound, DM 68.00.—ISBN 3-527-26098-6

At the moment, pharmaceutical chemistry is undergoing a change into medicinal chemistry. In this process the main emphasis is moving from the chemical via the biochemical into the medical field. Whether this is an advantage for the subject of pharmaceutical chemistry and the education of pharmacists really remains to be seen. This book places the medicament with its synthesis, properties and analysis in the forefront again. The compounds are summarized according to their pharmacological properties, but described from a chemical point of view. This system is occasionally abandoned, if this is practically forced by chemical analogy; thus the antitussive normethadone is treated alongside methadone which is an analgesic. This is acceptable because there is a cross-reference under the antitussives. The individual substances are specified under

[*] Cf. *Angew. Chem. Int. Ed. Engl. 23* (1984) 171.

their proprietary and international nonproprietary names, so that rapid access is available for the practitioner; then follow synthesis, analysis and details of action and application. References to metabolization are rare; interactions are not described. It should be remembered here that this book is neither intended to nor can act as a substitute for a pharmacology textbook, although physiological-anatomical comments, which make understanding of the action or application easy, preface individual chapters (e.g. diuretics, saluretics, antirheumatics, cardiac glycosides). The collaboration of a specialist for internal medicine *(Hg. Lahrtz)*, who receives the authors' thanks in the foreword, is evident in these chapter introductions. Clear synopses provide information rapidly, e.g. concerning the semisynthetic penicillins.

This introduction to pharmaceutical chemistry only deals with organic medicaments. It is true that inorganics have, in general, lost in importance, nevertheless today we understand many physiological processes that are changed by the intervention of drugs as reactions of inorganic ions. In my opinion inorganic medicaments ought not to have been ignored and the physiological chemistry of the more important inorganic ions ought to have been given more emphasis.

In the generally very clear presentation of formulas for the syntheses the authors assume a basic knowledge of organic chemistry; however, I have doubts in many cases as to whether the student will understand the reactions without any explanation. References to textbooks of organic chemistry could provide a better understanding (e.g. ketamine: comparison with pinacol and benzilic acid rearrangements, cephalosporins from penicillins: indication of sulfinic acid intermediates). Occasional references to the reaction type (e.g. as with ciclonium bromide) would not disturb the structure of the book. Original papers could be referred to in the case of complex reactions (e.g. primary amines and 1,2-naphthoquinone-4-sulfonic acid) and in other cases (e.g. the van-Urk reaction with the rearrangement of C-3 substituted indoles to C-2 derivatives) reviews could be employed. The good student would thus be led into reading the literature, a possibility also for the practicing professional to keep up to date. Such additions naturally require space and it is for the authors to consider.—On the basis of the investigations of *Neumeyer* (Boston) the apomorphine rearrangement should not be formulated any longer via a primary carbenium ion.—Enantiomers are finding increasing therapeutic employment; for this reason the formulas should be checked for stereochemical content (e.g. L-α-methyldopa described, D-form represented, (*S*)-propranolol represented, racemate employed commercially; ethambutol: (*R,R*)-form active, *meso* form represented).

If the picture of pharmaceutical chemistry that *Richard Kuhn* sketched in Berlin in 1965 is accepted, then the subject embraces so much that it is scarcely possible to cover it in a textbook. Synthesis and analysis will continue to be important viewpoints. This book is a comprehensive introduction to this part of pharmaceutical chemistry and is worthy of recommendation.

Solid Phase Synthesis (Nobel Lecture)**

By Robert Bruce Merrifield*

The proteins, as the Greek root of their name implies, are of first rank in living systems, and their smaller relatives, the peptides, have now also been discovered to have important roles in biology. Among their members are many of the hormones, releasing factors, growth factors, ion carriers, antibiotics, toxins, and neuropeptides. Herein, I wish to describe the chemical synthesis of peptides and proteins and to discuss the use of the synthetic approach to answer various biological questions.

The story begins with *Emil Fischer*[1] at the turn of this century when he synthesized the first peptide and coined the name. The general chemical requirements were to block the carboxyl group of one amino acid and the amino group of the second amino acid. Then, by activation of the free carboxyl group the peptide bond could be formed, and selective removal of the two protecting groups would lead to the free dipeptide. *Fischer* himself was never able to find a suitable reversible blocking group for the amine function, but his former student *Max Bergmann*, with *Zervas*, was successful.[2] Their design of the carbobenzoxy group ushered in a new era. When I began working on the synthesis of peptides many years later this same general scheme was universally in use and was very effective, having led, for example, to the first synthesis of a peptide hormone by *du Vigneaud* in 1953.[3] It soon became clear to me, however, that such syntheses were difficult and time consuming and that a new approach was needed if large numbers of peptides were required or if larger and more complex peptides were to be made.

Synthesis on a Solid Matrix

One day I had an idea about how the goal of a more efficient synthesis might be achieved. The plan[4] was to assemble a peptide chain in a stepwise manner while it was attached at one end to a solid support. With the growing chain covalently anchored to an insoluble matrix at all stages of the synthesis the peptide would also be completely insoluble and, furthermore, would be in a suitable physical form to permit rapid filtration and washing. Therefore, after completion of each of the synthetic reactions the mixture could be filtered and thoroughly washed to remove excess reactants and by-products. The intermediate peptides in the synthesis would thus be purified by a very simple, rapid procedure rather than by the usual tedious crystallization methods. When a multistep process, such as the preparation of a long polypeptide or protein is contemplated the saving in time and effort and materials could be very large. The fact that all of the steps just described are heterogeneous reactions between a soluble reagent in the liquid phase and the growing peptide chain in the insoluble solid phase led to the introduction of the name "solid phase peptide synthesis."

The general scheme for solid phase synthesis is outlined in Figure 1. It begins with an insoluble particle, indicated by the large circles, which is functionalized with a group X. The first monomer unit, small circles, is blocked at one end and at the reactive side chain groups (black dots) and anchored to the support by a stable covalent bond. The α protecting group is then removed and the second monomer unit is added to the first by a suitable reaction. In a similar way the subsequent units are combined in a stepwise manner until the entire polymeric sequence has been assembled. Finally, the bond holding the chain to the solid support is selectively cleaved, together with the side chain pro-

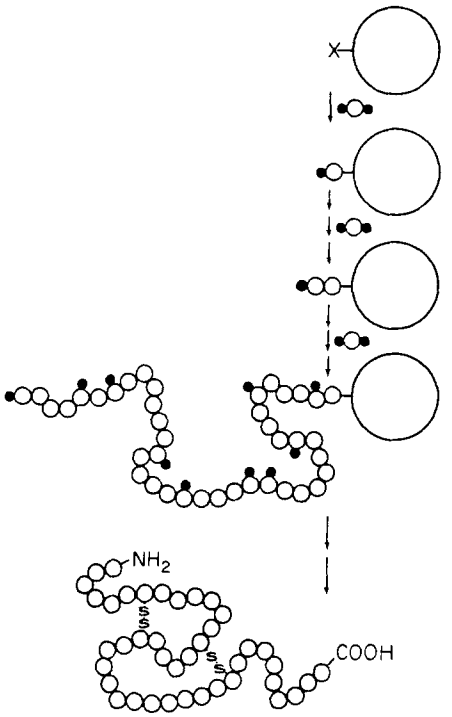

Fig. 1. The general scheme for solid phase synthesis (see text).

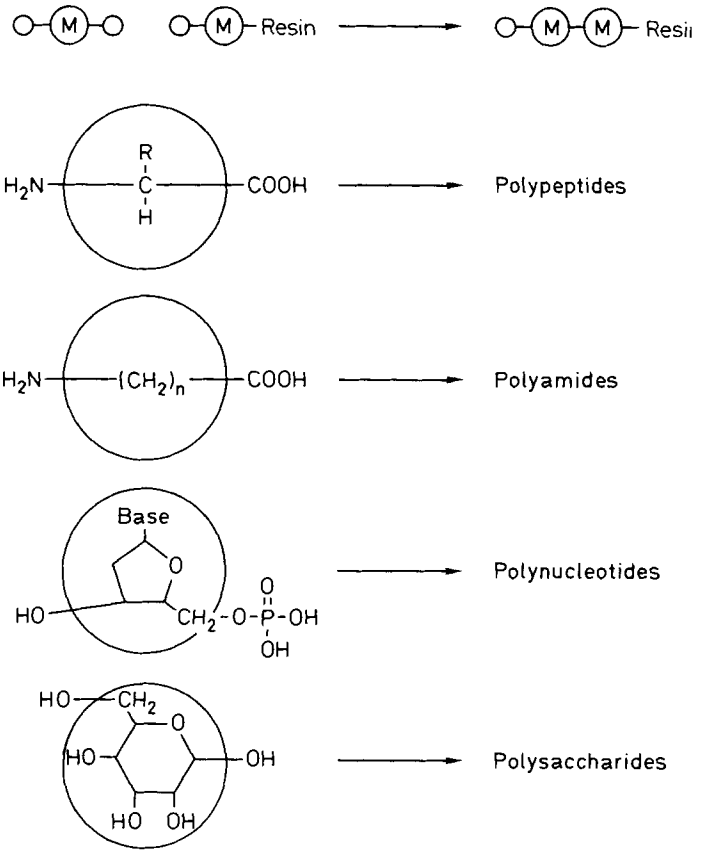

Fig. 2. Solid phase syntheses with various monomers.

tecting groups, and the product is liberated into solution. Such a system offers four main advantages:

- It simplifies and accelerates the multistep synthesis because it is possible to carry out all the reactions in a single reaction vessel and thereby avoid the manipulations and attendant losses involved in the repeated transfer of materials.
- It also avoids the large losses which normally are encountered during the isolation and purification of intermediates.
- It can result in high yields of final products through the use of excess reactants to force the individual reactions to completion.
- It increases solvation and decreases aggregation of the intermediate products.

The task now was to translate the general idea into a workable set of reactions.

Although the plan was originally conceived as a way to synthesize peptides, the general scheme does not specify the nature of the monomer units. It soon became apparent that the technique should be applicable to units other than amino acids, such as those shown in Figure 2. We extended it to the synthesis of depsipeptides[5] and other laboratories succeeded in synthesizing polyamides,[6] polynucleotides[7] and polysaccharides.[8] In principle, the monomer may be any bifunctional compound that can be selectively blocked at one end and activated at the other. In addition, the solid support idea can be applied to a variety of conventional reactions in organic chemistry to aid in directing the course of the reaction or in the separation of the products from reagents and by-products. It also led to the solid phase sequencing technique.

Solid Phase Peptide Synthesis

A detailed scheme for the synthesis of peptides is shown in Figure 3. Each of the steps has been modified in many ways, but the chemistry shown here has served well and has been applied to the synthesis of large numbers of peptides.[9] The carboxy-terminal amino acid is blocked at the amino end by a *tert*-butyloxycarbonyl (Boc) group and is covalently attached to the resin support as a benzyl ester via the chloromethyl group. Side-chain functional groups must also be blocked, usually with benzyl-based derivatives. The synthesis depends on the differential sensitivity of these two classes of protecting groups to acid, which is greater than 1000 : 1. The Boc group is completely removed with 50% trifluoroacetic acid in dichloromethane, with minimal loss of the anchoring bond or of the other protecting groups. The resulting ammonium salt is neutralized with a tertiary amine such as *N,N*-diisopropylethylamine and the free amino group of the resin-bound amino acid is then ready to couple with a second Boc-amino acid. The latter must be activated for the reaction to occur. The simplest and most often used procedure is activation with dicyclohexylcarbodiimide (DCC)[10] (Fig. 3), but active esters,[11] anhydrides,[12] and many other activated derivatives have been successfully applied. All of these reactions are carried out under non-aqueous conditions in organic solvents that swell the resin and accelerate the rates. Dichloromethane and dimethylformamide are the solvents of choice.

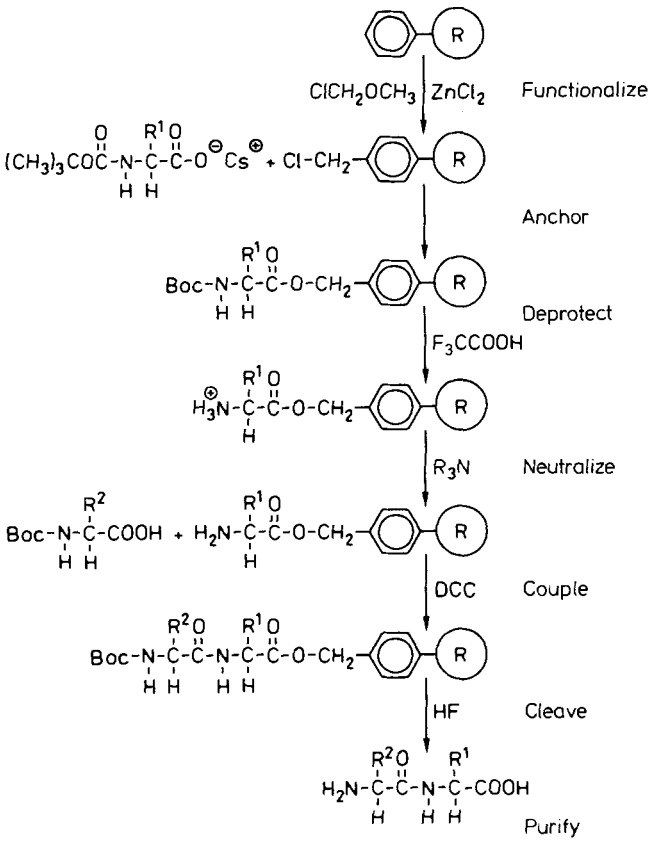

Fig. 3. Scheme for solid phase peptide synthesis (see text).

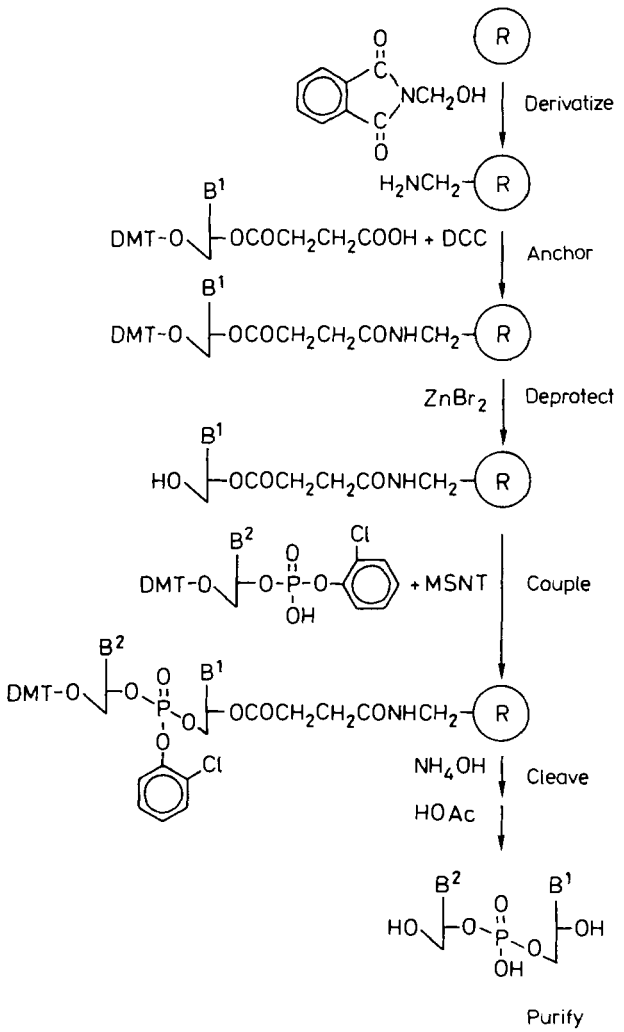
To extend the peptide chain the deprotection, neutralization and coupling steps are repeated for each of the succeeding amino acids until the desired sequence has been assembled. Finally, the completed peptide is deprotected and cleaved from the solid support. With the chemistry described here, this is accomplished by treatment with a strong anhydrous acid such as HF.[13] The free peptide is then purified by suitable procedures.

It is very important that the repetitive steps proceed rapidly, in high yields, and with minimal side reactions in order to prevent the accumulation of excessive amounts of by-products. Much of our effort has been directed toward developing and evaluating these requirements.

Solid Phase Nucleotide Synthesis

Similar schemes for the solid phase synthesis of oligonucleotides have now been developed which are rapid and give relatively high yields.[14,15] They employ protected nucleotides as monomer units and make use of either phosphotriester or phosphite triester chemistry. One such procedure is outlined in Figure 4. The resin is first functionalized with an aminomethyl group and the nucleotide derivative is coupled to it, through a spacer, by a stable amide bond. In this example the 5'-hydroxy group is esterified with the spacer and the 3'-hydroxy group is temporarily blocked with a dimethoxytrityl (DMT) group. The latter is removed with acid or $ZnBr_2$ and the chain is extended at the 3' end by coupling with the next protected nucleotide by activation with 1-(mesitylene-2-sulfonyl)-3-nitro-1,2,4-triazolide (MSNT). The completed oligonucleotide is finally cleaved from the solid support and deprotected by treatment with a base such as NH_4OH or tetramethylguanidine and then with hot acetic acid. The products are readily purified by ion-exchange chromatography or by electrophoresis where the desired product always has the greatest negative charge. I will not deal further with polynucleotides and their use in site-specific mutagenesis or with synthetic genes in this presentation but will concentrate instead on peptides and proteins.



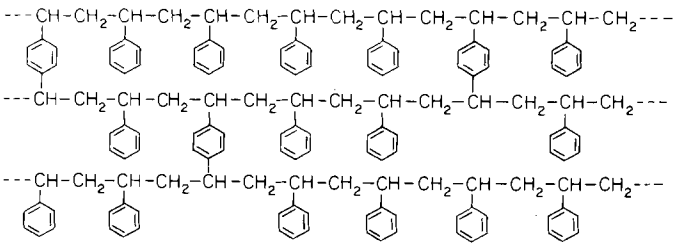


Fig. 4. Scheme for solid phase nucleotide synthesis (see text).

The Support

The first requirement for the development of solid phase synthesis was a suitable support. After examination of many potential supports it was found that the most satisfactory one was a gel prepared by suspension copolymerization of styrene and 1% of divinylbenzene as cross-linking agent.[4] The resulting spherical beads (Fig. 5) are about 50 μm in diameter when dry, but in organic solvents such as dichloromethane they swell to five or six times their original volume. Furthermore, as peptide chains grow the dry volume increases to accommodate the added mass and, most importantly, the swollen volumes continue to in-

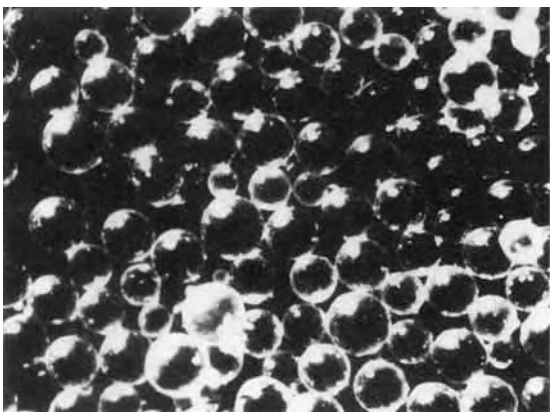

Fig. 5. Copolymer of styrene and divinylbenzene (1%). Top: structural formula. Bottom: photomicrograph of the resin beads.

crease. Values up to 25-fold have been measured and calculations indicate that the maximum expansion should be about 200-fold.[16] This means that the polystyrene matrix and the pendant peptide are highly solvated during the chemical reactions and are freely accessible to diffusing reagents. The reactions occur not only at the surface of the bead but, in major part, within the interior of the cross-linked polymeric matrix. This could be demonstrated by autoradiography of a cross section of a bead containing a synthetic tritium-labeled peptide.[17] At this resolution the silver grains were located uniformly throughout the bead, although the distribution is not known at the molecular level. Because of the solvation and swelling of the beads, the reactions are very fast, with half-times in the order of seconds for both the coupling and the deprotection steps. Current efforts to evaluate the effects of mass transfer and diffusion indicate that they are not rate determining. We believe the solid matrix not only does not have detrimental effects on the synthesis but actually has beneficial effects in certain instances.

One of the well recognized difficulties with the classical peptide synthesis in homogeneous solution is the insolubility of some intermediates. This problem can be overcome in many cases by the use of solid supports, where the peptide chain and the lightly cross-linked polymer chain become intimately mixed and exert a mutual solvating effect on one another. It becomes thermodynamically less favorable for the peptide to self aggregate and it remains available for reaction. For this to occur the solvated state of the bound peptide needs only to be favorable relative to the amorphous unsolvated state within the peptide-resin matrix.[16] Similar solubilizing properties of linear polymers for covalently attached components are known, but the effect will be greater for a lightly cross-linked polymer network. The phenomenon can be illustrated by the synthesis of oligoisoleucines.[18] The standard solution synthesis failed after the tetrapeptide stage because of aggregation and insolubility, whereas the chain could be extended up to eight residues on linear poly(ethylene glycol). A solid phase synthesis proceeded smoothly at least as far as the dodecamer, where the experiment was stopped. There is very significant polymer chain motion in these cross-linked polystyrene resins. Both ^{1}H- and ^{13}C-NMR measurements[19] have shown that the motional rates for the aromatic groups and the aliphatic backbone atoms in CH_2Cl_2 are high and equivalent to linear soluble polystyrene ($\tau_c = 10^{-8}$ s). The ^{13}C-NMR signals of the α carbon atoms of model resin-supported peptides were as sharp as the solvent peak in CH_2Cl_2 or dimethylformamide and similar to those of small molecules in solution ($\tau_c = 10^{-10}$ s). A variety of chemical experiments also have shown polymer flexibility. For example, short resin-bound peptides that were too far apart on average to reach one another if the resin were rigid could be shown to react to the extent of 99.5%, indicating considerable motion of the polystyrene segments within the matrix.[20]

Many other solid supports have also been examined and several have been satisfactory for peptide synthesis. These have included polymethylmethacrylate, polysaccharides, phenolic resins, silica, porous glass and polyacrylamides, but only the latter have seen widespread use.[21] Comparative studies with polystyrene and polyacrylamide have shown that they can be equally effective, even with difficult peptides.

Automation

The ability to purify after each reaction by simple filtration and washing and the fact that all reactions could be conducted within a single reaction vessel appeared to lend themselves ideally to a mechanized and automated process. Initially, a simple manually operated apparatus was constructed (Fig. 6). This system was first used to work out the methodology and to synthesize bradykinin,[22] angiotensin,[23] oxytocin[24] and many other small peptides. In order to accelerate the process we undertook the design

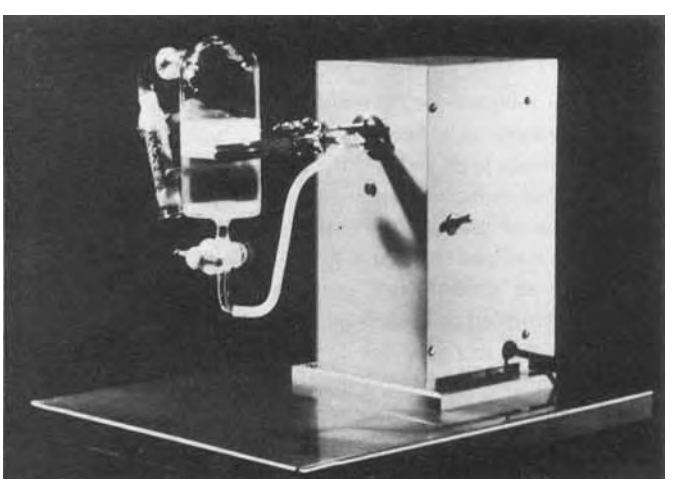

Fig. 6. Manually operated apparatus for peptide synthesis.

and construction[25] of the automated instrument shown in Figure 7. The essential features are the reaction vessel, containing the resin with its growing peptide chain, and the necessary plumbing to enable the appropriate solvents and reagents to be pumped in, mixed, and removed in the proper sequence. These mechanical events are under the control of a simple stepping drum programmer and a set of timers. In the past few years many commercial instruments have been constructed in several countries. They differ considerably in detail, particularly in the sophistication of the electronic program mechanisms but are designed to carry out the same chemistry.

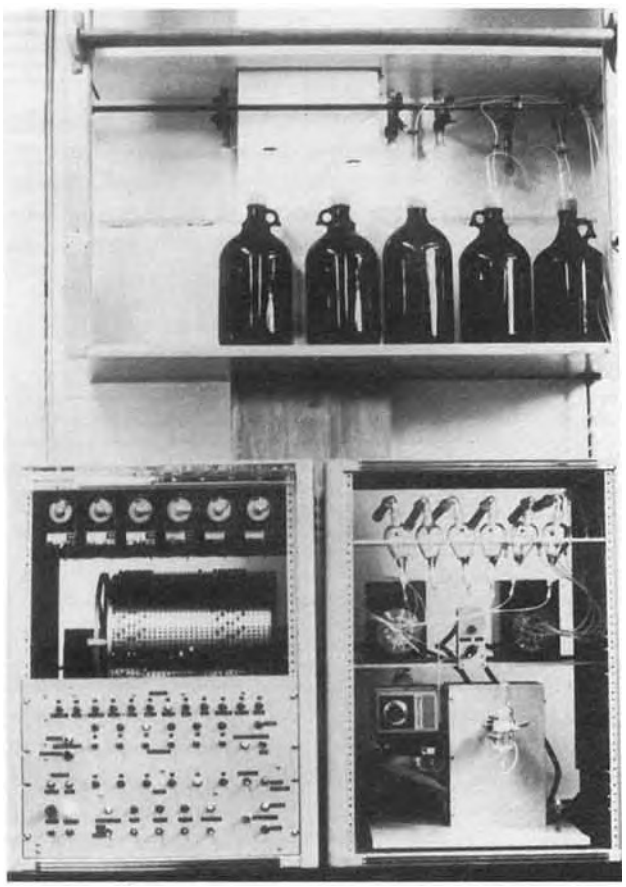

Fig. 7. Automated peptide synthesizer.

The Synthesis of Ribonuclease A

The idea of chemically synthesizing an enzyme must have occurred to many people over the years. There was a time when such a thought would have been unacceptable even on philosophical grounds, but from the period when enzymes were shown to be proteins, and proteins were shown to be discrete organic molecules, it was a goal that chemists could begin to think about. If an enzyme could be made in the laboratory, then it should become possible to learn new things about how these large and very complex molecules function. Specific changes could be made in their structures that could not be made readily by altering the native protein and data should be forthcoming that would supplement the information already obtained from the natural enzymes themselves. In this regard, a quotation from *Emil Fischer* in 1906[26] is pertinent:

> "Whereas cautious professional colleagues fear that a rational study of this class of compounds [proteins], because of their complicated structure and their highly inconvenient physical characteristics, would today still uncover insurmountable difficulties, other optimistically endowed observers, among which I will count myself, are inclined to the view that an attempt should at least be made to besiege this virgin fortress with all the expedients of the present; because only through this hazardous affair can the limitations of the ability of our methods be ascertained."

With the development of solid phase peptide synthesis and its automation the time seemed right to attempt the total synthesis of an enzyme. Dr. *Bernd Gutte* and I selected bovine pancreatic ribonuclease A because it was a small stable protein of known amino acid sequence,[27] and the three-dimensional structure was known from X-ray diffraction studies.[28] Much of the detailed mechanism by which this enzyme hydrolyzes and depolymerizes ribonucleic acid was also known. The purpose of a chemical synthesis of this 124-residue molecule was, first, simply to demonstrate that a protein with the high catalytic activity and specificity of a naturally occurring enzyme could be synthesized in the laboratory. For the long term the more important purpose was to provide a new approach to the study of enzymes. We believed it should be possible to modify the structure and to alter the activity and the substrate specificity of the enzyme.

The synthesis[29] was carried out on a copolymer of styrene and divinylbenzene (1%) using the general methods described above. The *C*-terminal Boc-Val was anchored to the solid matrix by a benzyl ester bond, the usual benzyl-based side-chain protecting groups were used and the Boc group provided the reversible N^{α} protection. The deprotection steps were carried out with trifluoroacetic acid and the coupling reactions with dicyclohexylcarbodiimide activation. Figure 8 shows the final protected derivative of ribonuclease. It contained a total of 67 side-chain protecting groups and had a molecular weight of 19791. The synthesis is summarized in Table 1. The overall yield after several purification steps was about 3% based on the original amount of valine attached to the resin. There was a large (83%) loss of chains during the assembly of the peptide chain due to partial instability of the anchoring bond, and the accumulated losses during HF cleavage from the resin and the purification steps amounted to another 80%. The crude cleaved product was air oxidized to form the four disulfide bonds and the monomer fraction was isolated by gel filtration. The monomers with incorrect disulfide pairing or incorrect folding were digested by trypsin and the small fragments were separated from the stable protein with the correct structure. An ammonium sulfate fractionation gave the final purified enzyme possessing approximately 80% specific activity compared with native ribonuclease A. We could not claim that our product was completely pure or that the synthesis constituted a structure proof for RNase, only that the molecule showed a close chemical and physical resemblance to the native protein and that it was a true enzyme. The chemical and physical comparisons were based on amino acid analysis, enzyme

RNase A	169	2.9

digestions, peptide maps, paper electrophoresis, gel filtration, ion-exchange chromatography, and antibody neutralization. At that time we did not have HPLC or an affinity chromatography system.

Table 2. Ribonuclease A activity.

Purification stage	Specific activity [%]	Total activity mg RNase / 2g resin
HF cleavage	2	14
Sephadex G-75	9	33
IRC-50	13	53
Trypsin	61	156
$(NH_4)_2SO_4$	78	132

Table 2 summarizes the activity data at various stages of purification of the synthetic enzyme. Both the specific activity and the total number of units of RNase increased as the purification proceeded, indicating either that inhibitory impurities were being removed or that the molecule was gradually refolding into a conformation that more closely resembled the native structure. The substrate specificity of the synthetic enzyme was consistent with that to be expected for RNase A: it was able to cleave both large (RNA) and small (cyclic cytidine 2′,3′-monophosphate) substrates and therefore to catalyze both the transphosphorylation and the hydrolysis steps; it was specific for D-ribose instead of D-deoxyribose and for a pyrimidine instead of a purine at the 3′ position of the phosphodiester substrate (Table 3). The K_M values toward RNA were also the same for the natural and synthetic enzymes.

Table 3. Substrate specificity of synthetic ribonuclease A.

Substrate		Activity [%]
Ribonucleic acid	(RNA)	78
Deoxyribonucleic acid	(DNA)	0
Cyclic cytidine-2′,3′-monophosphate	(C>p)	65
Cyclic guanosine-2′,3′-monophosphate	(G>p)	0
5′-(3′-Guanylyl)cytidylic acid	(GpCp)	0
5′-(3′-Adenylyl)adenylic acid	(ApAp)	0

The purified RNase A was compared on a CM-cellulose column with natural RNase A and with reduced and reoxidized natural RNase A. They were identical by this criterion, which was the one first used by *White*[30] to show that RNase A after reduction and reoxidation of the disulfide bonds was indistinguishable from the native enzyme. It was *White*'s experiments[30] that led to the hypothesis that the primary structure of the protein determined its tertiary structure.[31] Our synthesis provided a new kind of evidence for this hypothesis. The fact that the only information put into the synthesis was the linear sequence means that the primary structure must be sufficient to direct the final folding of the molecule into its active tertiary structure. The synthesis of an active enzyme containing no substituents except amino acids also provided a new proof for the now well established belief that enzymatic activity can be attributed to a simple protein containing no other components.

Structure-Function Studies on Ribonuclease

The synthesis of ribonuclease provided answers to several fundamental questions and laid the foundation for new studies on the relation of structure to function in the enzyme. The classic *S*-peptide/*S*-protein system discovered by *Richards*[32] provided an ideal way to study such re-

lations because a small peptide (residues 1–20) and a large protein component (residues 21–124) could be combined noncovalently with regeneration of nearly full enzymatic activity. The extensive work from the *Hofmann*[33] and *Scoffone*[34] laboratories on the synthesis of the *S*-peptide and its combination with the natural *S*-protein had already provided a great amount of information about the role of individual residues in the *N*-terminal region of the enzyme. We undertook to study this region of RNase by total synthesis (Fig. 9). During the initial synthesis we removed

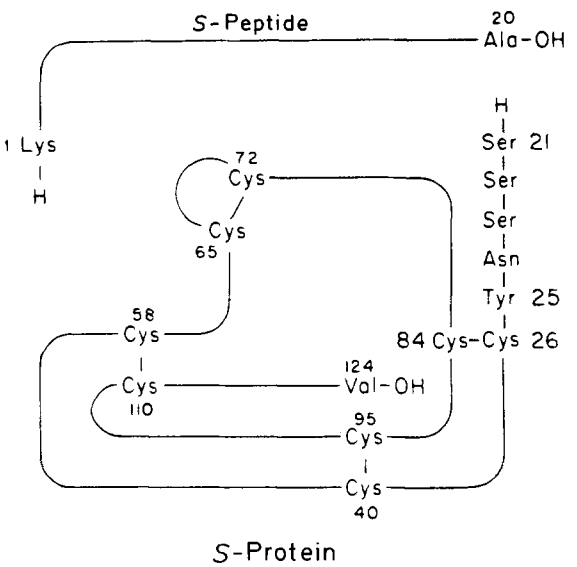

Fig. 9. The *S*-peptide *S*-protein system.

samples after coupling Cys 26 and again after Ser 21 and in that way prepared synthetic *S*-protein (21–124) and *S*-protein (26–124). The partially purified proteins were reduced at their four disulfide bonds, each mixed with synthetic *S*-peptide, reoxidized, and assayed for enzymatic activity. Each of the crude mixtures was found to have as much activity as the product derived from native *S*-protein by the same treatment. From these data it was concluded, first, that *S*-protein had been synthesized and, second, that the five residues 21–25 were definitely not necessary for the binding and reactivation to occur. Earlier X-ray data[35] had predicted that the serine residues at positions 21, 22 and 23 would probably not be necessary, but Asn 24 and Tyr 25 appeared to be involved in a total of five hydrogen bonds in RNase S and it was expected that they might be necessary for the formation of an active complex. The synthetic studies showed that they were not.

Several years earlier I had been interested in the question of whether or not a peptide from the carboxyl end of RNase might function in a manner similar to that of the *S*-peptide at the amino end. We therefore synthesized and purified the tetradecapeptide RNase 111–124. RNase was inactivated by carboxymethylation of the imidazole ring of His 119. Attempts to reactivate the enzyme by addition of the synthetic peptide were uniformly unsuccessful. Somewhat later in a separate study *Lin* et al.[36] succeeded in preparing a series of shortened RNases. They made RNase 1–120, RNase 1–119 and RNase 1–118 by enzymatic digestion. When the synthetic peptide 111–124 was assayed in the presence of these inactive proteins, high enzymatic activity was generated[37] and it became clear that a system existed at the *C*-terminus of RNase that was similar to the one at the *N*-terminus.

We then made the interesting discovery that the *C*-terminal peptide 111–124 containing His 119, the *N*-terminal peptide 1–20 containing His 12, and the central protein component 21–118 containing Lys 41 could be mixed together non-covalently and ribonuclease activity would be generated. Therefore, three components, each containing one of the known residues required for enzymatic activity could bind together and form the specific well ordered structure necessary for substrate binding and catalytic activity.

A series of synthetic studies was then undertaken to define the roles of some of the individual residues in the *C*-terminal region. These can be summarized and discussed by referring to Figure 10. When peptides shorter than 111–124 were prepared and combined with RNase 1–118, both the binding constant and the activity were progressively decreased and peptide 117–124 was inactive indicating that each residue contributed to the binding energy.[38] However, even in the complex 1–118 + 116–124 there were three overlapping residues. It was then found that the complex 1–115 + 116–124, in which there were no overlapping residues, had a binding constant 100 times larger.[39] In these experiments it could also be shown that Tyr 115 was not necessary for enzymatic activity.

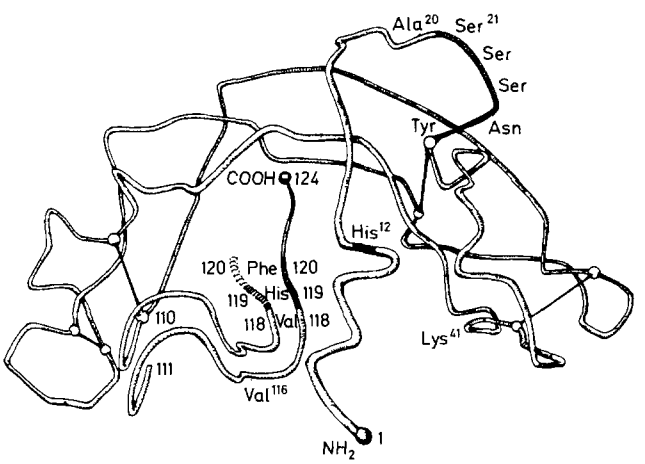

Fig. 10. A 3-dimensional representation of ribonuclease fragments 1–20, 21–118 and 111–124.

Phenylalanine-120 was shown by transition temperature studies to be important in stabilizing the ribonuclease structure and by X-ray and NMR studies to interact with the pyrimidine substrate. Our synthetic-analogue work on the 1–118 + 111–124 system showed that replacement of Phe 120 by Leu 120 or Ile 120 reduced the binding by 5- and 17-fold and reduced the maximum enzymatic activity to 10% and 5% respectively, indicating that the aromatic side chain of phenylalanine was of considerable importance in binding the peptide to the protein.[40] It could only be partially replaced by a hydrophobic aliphatic chain, indicating an inexact alignment of the catalytic site. The

small residue Ala 120 and the bulky aromatic residue Trp 120 were inactive. Replacement of Phe 120 by an aromatic residue of similar size, Tyr 120, in the 111–124 peptide gave a complex with 1–118 that was fully active toward cyclic cytidine 2′,3′-monophosphate substrate and 190% as active toward cyclic uridine 2′,3′-monophosphate.[41] A semisynthetic enzyme with enhanced activity was a novel finding. K_M and K_i data led to the conclusion that Phe 120 does not have a unique role in the binding of substrate but is important for stabilizing the peptide-protein complex and the native enzyme itself. Nevertheless, the presence of substrate increased the binding constant between RNase 1–118 and RNase 111–124 by a factor of 50.

Similar experiments with the aspartic acid residue at position 121 have shown that it can be partially replaced (ca. 20%) by glutamic acid, but the Asn 121 and Ala 121 analogues did not show measurable binding. Removal of Val 124 from RNase A does not affect the enzymatic activity and removal of Val 124 from *S*-protein does not reduce the activity of the complex with *S*-peptide. In contrast, omission of Val 124 from the *C*-terminal tetradecapeptide produced an essentially inactive complex with RNase 1–118, indicating an important hydrophobic interaction necessary for peptide-protein binding. The smaller aliphatic residue Ala 124 could only restore half of the binding energy.[41]

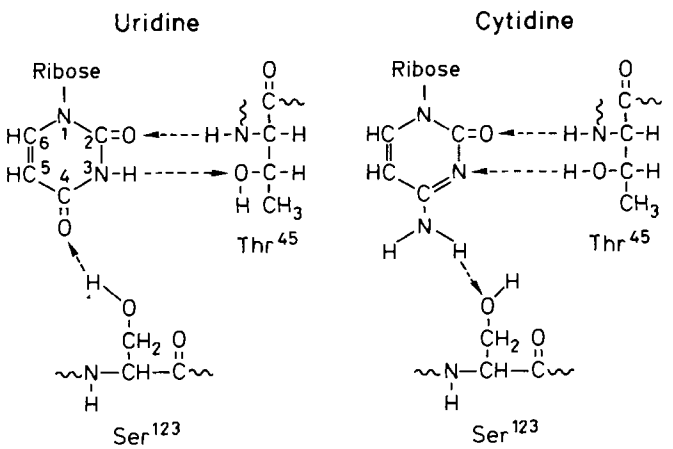

Fig. 11. Postulated hydrogen bonding of uracil and cytosine substrates to ribonuclease.

X-ray data[42] indicate that the uracil and cytosine residues of RNA and the cyclic nucleotides probably bind to ribonuclease through the series of hydrogen bonds shown in Figure 11. For uracil, the hydroxyl group of Thr 45 is a hydrogen acceptor and for cytosine it is a hydrogen donor. Conversely, the hydroxyl group of Ser 123 is a donor for uracil and an acceptor for cytosine. We reasoned that if these two hydroxyl groups were blocked as methyl ethers they could only be hydrogen acceptors and if replaced by Ala they could be neither donor nor acceptor. A suitable combination of these residues in replacement analogues might, therefore, lead to a synthetic ribonuclease with altered substrate specificity. Such analogues have been made for Ser 123.[43]

The tetradecapeptide containing Ala 123 gave a complex with RNase 1–118 that showed appreciable selectivity for substrates containing cytosine relative to those containing uracil (either the cyclic 2′,3′-nucleotides or polynucleotides) (Table 4). Replacement with *O*-methylserine did not result in differential substrate specificity. It was concluded that a hydrogen bond between the hydroxyl group of Ser 123 and the C^4 amino group of cytosine is not important for substrate binding and catalytic activity, but that the hydrogen bond between the hydroxyl group of Ser 123 and the C^4 carbonyl of uracil contributes significantly to the binding and activity; when Ser is replaced by Ala the H-bond is absent and the activity is reduced. The corresponding studies with replacement of Thr 45 by Ala 45 and *O*-Me-Ser 45 involve total synthesis of the enzyme; these much more difficult experiments have not yet been completed. We believe that the substrate binding at Thr 45 is much tighter than at Ser 123 and that changes at this residue will lead to much greater substrate selectivity.

Table 4. Substrate selectivity of [Ala[123]]-RNase complexes.

Enzyme	Selectivity (k_s/K_m) $\frac{C>p}{U>p}$
RNase A	4.6
[Ser[123]]-RNase 111–124 + RNase 1–118	5.0
[Ala[123]]-RNase 111–124 + RNase 1–118	19

Recent Improvements in Solid Phase Peptide Synthesis

Although the earlier solid phase chemistry was very useful for these studies on ribonuclease, it was clear that there was a need for improvement in several areas. One was the mode of attachment of the peptide to the resin. If the strategy of differential stability toward acid for the N^α and C^α groups was to be continued, a more acid-stable anchoring bond was needed. We predicted that the insertion of an acetamidomethyl group between the benzyl ester and the polystyrene matrix would increase the stability of the benzyl ester toward trifluoroacetic acid by a factor of approximately 25 to 400 times. When such a linkage was finally constructed it was found to be 100 times more stable.[44] A new synthesis of aminomethyl-resin was first developed in which *N*-hydroxymethylphthalimide and polystyrene resin were reacted under acid catalysis with F_3CSO_3H, HF, or $SnCl_4$.[45] This product was then coupled with a derivative of the *C*-terminal amino acid. Thus, N^α-Boc-aminoacyloxymethylphenylacetic acid was prepared and activated with dicyclohexylcarbodiimide for the reaction. The product was a copolymer of polystyrene and divinylbenzene (1%) bearing acyloxymethylphenylacetamidomethyl groups (acyloxymethyl-Pam-resin) (Fig. 12). This new preparation has the advantages that it is more acid stable, and it is made from purified, well characterized intermediates, which give a cleaner product with fewer side reactions. It is free of chloromethyl groups that can give rise to quaternization and ion-exchange reactions and is free of hy-

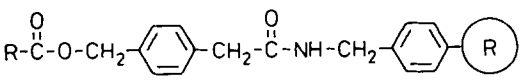

Fig. 12. Acyloxymethyl-Pam resin.

droxyl groups that can lead to peptide chain terminations via trifluoroacetylation.[46]

An alternative protecting group strategy is to make use of an orthogonal system[47] in which the N^{α}, C^{α}, and side chain groups represent three different classes of compounds that are cleavable by three different kinds of reactions. In this way any one of the functional groups can be

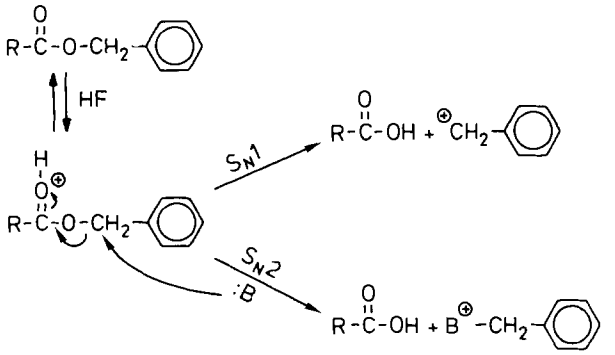

Fig. 14. The S_N1 and S_N2 acidolysis mechanisms.

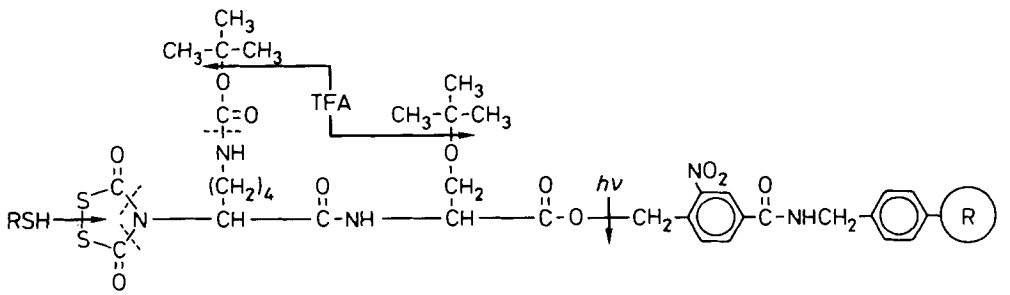

Fig. 13. A scheme for "orthogonal" protecting groups.

selectively removed in the presence of the other two. Figure 13 illustrates such a system in which the anchoring *O*-nitrobenzyl ester is photolabile but stable to acid or nucleophiles, the side chain groups are based on *tert*-butyl derivatives that are very acid labile but stable to light or nucleophiles, and the N^{α} protecting group is the dithiasuccinoyl group which is removed by nucleophilic thiols but is stable to acid and photolysis. This scheme has recently been put to the test and found to give excellent results.[48]

Anhydrous hydrogen fluoride, the usual cleavage reagent for solid phase peptide synthesis, is a very strong acid ($pK_a = -10.8$) and is known to promote a number of side reactions. In particular, it leads to the formation of carbonium ions which then can alkylate tyrosine, tryptophan, methionine and cysteine residues of the peptide. In addition, HF can protonate and dehydrate the side-chain carboxyl group of glutamic acid residues with formation of the very reactive acylium ion, which has been shown to acylate the aromatic rings of anisole and other scavengers present in the mixture. Activated glutamyl residues can also form pyrrolidone (pyroglutamic)-containing products. Aspartyl residues can close in HF to give the aspartimide derivative and subsequently open to produce β-aspartyl residues. All of these undesired reactions result from the S_N1 mechanism of the cleavage reaction under the usual conditions (90% HF + 10% anisole, 0°C, 1 h). We reasoned that if conditions could be found that would change the reactions to an S_N2 mechanism in which the acidolysis is aided by a nucleophile and carbocation is never formed (Fig. 14) it should be possible to minimize or avoid these problems. Dr. *James Tam* and *Bill Heath*, a graduate student, have succeeded in developing such conditions and in demonstrating marked improvements in solid phase peptide synthesis.[49]

The problem was to find a suitable weak base which would reduce the acidity function of the HF but which would remain largely unprotonated and nucleophilic under the resulting acidic conditions. It should be a weaker base than the groups to be cleaved so that they would be largely protonated under the same conditions. Dimethyl sulfide (DMS) was found to be an ideal base for this purpose. It has a pK_b of -6.8 compared with values of -2 to -5 for the benzyl ethers, esters and carbamates to be cleaved. It is a good solvent for HF and it is volatile and easily removed from the reaction mixture. A 1:1 molar mixture of HF and DMS (1:3 by volume) was determined by Hammett indicators to have a pK_a value between -4.6 and -5.2. The mechanisms of removal of various benzyl-based protecting groups by HF/DMS mixtures were tested by kinetic and product analysis experiments. Based on earlier work with H_2SO_4 hydrolysis of alkyl acetates,[50] a sharp upward break in the rate constant was expected when the acid concentration was increased. At the break point the mechanism changed from S_N2 to S_N1. A similar change was found in the cleavage of *O*-benzylserine by HF/DMS mixtures; above HF concentrations of 50% by volume the rate increased rapidly, indicating the change in mechanism. Product analysis for the deprotection of tyrosine benzyl ether as a function of HF concentration is shown in Figure 15. Above 15% HF in DMS the yield (after 1 h, 0°C) of tyrosine was quantitative and the other product was the benzyl(dimethyl)sulfonium salt. In the range of 40–50% HF the amount of sulfonium salt began to decrease and the level of the undesirable by-product, 3-benzyltyrosine, increased. Again, there was a change from the S_N2 to the S_N1 mechanism at an HF concentration around 40–50%. The reactions were accelerated in the presence of 5–10% of cresol. We selected 25% HF/65%

DMS/10% cresol as the best reagent and refer to it as "low HF."

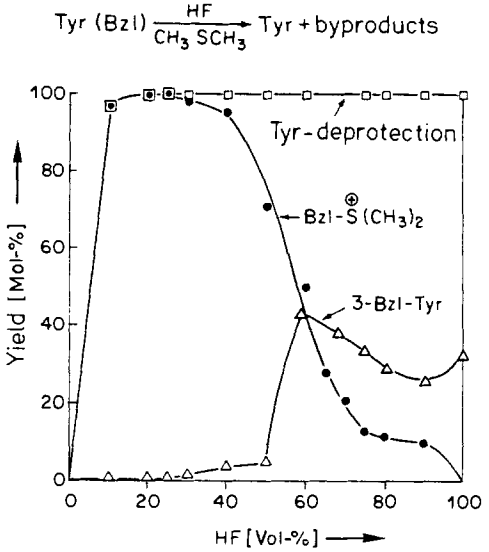

Fig. 15. Product analysis for the deprotection of tyrosine benzyl ether in mixtures of HF and dimethyl sulfide.

This reagent was also effective in preventing acylium ion formation in glutamyl and aspartyl peptides and avoided the acylation and imide side reactions. It was also found to be very effective in converting methionine sulfoxide into methionine, with formation of dimethyl sulfoxide as coproduct. Furthermore, in the presence of 5% of a thiol such as thiocresol a nearly quantitative removal of the formyl protecting group from the indole nitrogen atom of tryptophan was possible. The coproduct was $HC(SR)_3$. The last two reactions do not occur at high (90%) HF due to protonation of the reagents.

The derivatives Arg(Tos), Arg(NO_2), Cys(4-MeBzl), or Asp(OcHex) will not be deprotected under the low HF conditions, and peptides containing these and certain other residues must be re-treated in high HF (90%) after removal of the DMS. However, since most of the potential carbocations in the peptide will already have been trapped as the less reactive dimethylsulfonium salt, very few by-products will be formed even upon reaction with 90% HF.

The Need to Pay Attention to Details

I cannot emphasize enough how important it is to be attentive to even the smallest of details if one expects to synthesize a peptide of high quality. The principal by-products of solid phase peptide synthesis can be classified as termination, deletion, or modification peptides. Much effort has gone into identifying these problems, developing ways to quantitate them, and finding ways to eliminate them. First of all, it is important to begin with clean well characterized resins, clean amino acid derivatives, and clean solvents. Most of the known side reactions can now be eliminated or greatly minimized if the proper coupling methods and conditions are selected.[51] It is important to monitor coupling reactions to determine that they have proceeded to completion so that deletion peptides missing one or more residues will be avoided. The quantitative ninhydrin reaction[52] is useful for this purpose and can detect the presence of 0.1% unreacted chains (i.e., 99.9% coupling). After a peptide chain has been assembled it can be analyzed by solid phase sequencing methods[53] to quantitate the levels of preview and therefore of deletion sequences.[54] Except for special cases, racemization is not usually a problem in stepwise solid phase synthesis, but sensitive methods for its detection are available.[55] If the various precautions alluded to here are taken, satisfactory results can be expected in most instances.

Some Recent Syntheses of Peptides

Numerous peptides have been synthesized in recent years by the techniques that have been discussed and I cannot begin to cover them here. From our own laboratory we have reported recent synthetic studies on apamin,[56] thymosin α_1,[57] glucagon,[58] and cecropin A.[59,60] For this discussion I have selected examples of syntheses that serve to illustrate certain areas of interest.

An excellent example of a synthetic peptide study leading to useful drugs is that of *Manning* and *Sawyer* on the development of vasopressin analogues with high antidiuretic activity and essentially no remaining pressor activity for treatment of Diabetes insipidus.[61] The best was 1-deamino-(4-valine, 8-D-arginine) vasopressin. They have also discovered, through synthesis, arginine vasopressin analogues that are strong inhibitors of both antidiuretic and pressor activity for use in patients with hyponatremia due to excessive retention of water.[62] The best was [1-(β-mercapto-β,β-cyclopentamethylenepropionic acid), 2-D-phenylalanine, 4-valine]arginine vasopressin.

In a few instances solid phase syntheses have been scaled up for commercial purposes. A good example is salmon calcitonin.[63] It has been prepared in 50–100 g batches of highly purified peptide. This 32-residue hormone is highly effective for the treatment of Paget's disease and other conditions of hypercalcaemia.

The area of greatest current interest and activity is undoubtedly the synthesis of peptides for the elucidation of the immunogenic determinants of proteins and for the development of synthetic vaccines against viral and other infectious diseases. The work from *Lerner*'s laboratory[64] has given an important impetus to this field. Synthetic antigens are also useful for the development of diagnostics and for the production of antibodies as aids in detecting and isolating unidentified gene products.

As an illustration of my emphasis on the importance of new chemistry and the need to pay attention to the details when utilizing solid phase peptide synthesis I would mention some new work on the epidermal growth factor (EGF) by *Bill Heath*.[65] EGF stimulates cellular proliferation, inhibits gastric acid secretion, and plays a role in embryonic development. The structure of this 53-residue peptide[66] is shown in Figure 16. It is a hydrophobic, highly cross-linked, compact molecule that others have found very difficult to synthesize in the past. By using the newly developed Pam-resin support, several new protecting groups,

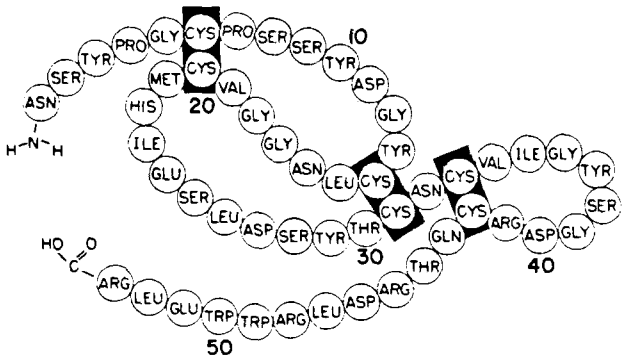

Fig. 16. Structure of mouse epidermal growth factor.

pure reagents, the quantitative monitoring procedures, the new HF cleavage methods, and by taking all the other known precautions against side reactions, he succeeded in obtaining an essentially quantitative assembly of the peptide chain and a 97% cleavage yield, leading to a crude unpurified product that contained 65% of the desired EGF. It could be readily isolated in a highly purified form which eluted from a C_{18} HPLC column at exactly the same time as natural EGF (Fig. 17). In the sensitive and discriminating Leydig cell growth assay the synthetic and natural EGF had identical activity.

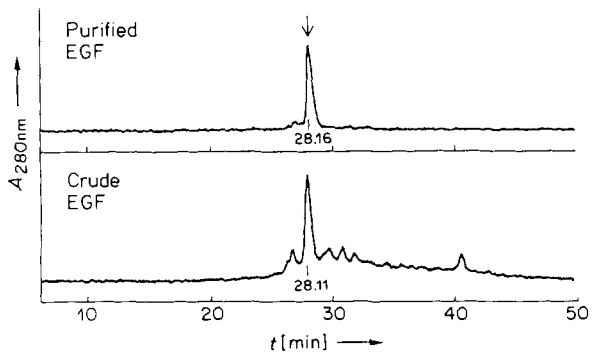

Fig. 17. HPLC analysis of synthetic EGF.

From the accumulated data presented, we conclude that the solid phase synthesis of peptides up to a length of 50 or somewhat more residues can be readily achieved in good yield and purity; and this is a far better situation than I could have expected when this technique was first proposed.

As example of a synthesis of a protein I have selected our recent studies on interferon. The sequence of human leucocyte interferon α_1 was first deduced from the DNA sequence of the cloned gene.[67] It contains 166 amino acids with five cysteine residues (Fig. 18). The amino acid sequence of the isolated protein of human leucocyte interferon α_2 was also sequenced[68] and found to have only 155 residues. There is a high degree of homology between the two, but the latter has one deletion at Asp44 and is missing the last ten residues predicted from the DNA sequence (Fig. 18). We have synthesized these two proteins and also their Ser1 analogues and purified them by reduction, gel filtration, reoxidation, gel filtration, and affinity purification on a column of supported antibodies to polyclonal human leucocyte interferon.[69] The synthetic proteins and the natural and recombinant interferon all had 10^8 to 10^9 units/mg in antiviral assays against a broad spectrum of cell lines. The development and duration of the antiviral state were also similar. Synthetic [Ser1]IFN-α_2 and natural Hu-Le-IFN-α showed similar growth inhibition of K 562 cells. [Cys1]IFN-α_2 and natural Hu-Le-IFN-α caused a similar increase of natural killer cell activity whereas synthetic [Ser1]IFN-α_2 caused a decrease. All four synthetic interferons bind to and are eluted from polyclonal anti-Hu-Le-IFN-α antibodies under similar conditions.

These results are encouraging, but much more needs to be done to assure that even small proteins can be synthesized readily in high yield and purity. I think we can be optimistic about the future.

I owe a very special debt of gratitude to my teachers, Dr. M. S. Dunn of U.C.L.A. and Dr. D. W. Woolley of The Rockefeller University. Several of the past and present members of my laboratory have been referred to here, but to the many others who have not been specifically mentioned I am equally grateful because they all have contributed to the progress of our work. Finally, I wish to acknowledge the continuing support of The Rockefeller University and of the National Institutes of Health of the United States.

The Generative Grammar of the Immune System (Nobel Lecture)**

By Niels K. Jerne*

Grammar is a science that is more than 2000 years old, whereas immunology has become a respectable part of biology only during the past hundred years. Though both sciences still face exasperating problems, this lecture attempts to establish an analogy between linguistics and immunology, between the descriptions of language and of the immune system. Let me first recall some of the essential elements of the immune system, with which I shall be concerned. In 1890, *von Behring* and *Kitasato*[12] were the first to discover antibody molecules in the blood serum of immunized animals, and to demonstrate that these antibodies could neutralize diphtheria toxin and tetanus toxin. They also demonstrated the *specificity* of antibodies: tetanus antitoxin cannot neutralize diphtheria toxin, and vice versa. During the first 30 years, or more, after these discoveries, most immunologists believed that all cells of our body are capable of producing antibodies, and it took until the 1950's before it became clear, and until 1960 before it was demonstrated,[13] that only white blood cells, named lymphocytes, can produce antibodies. The total number of lymphocytes represent a little more than 1% of the body

weight of an animal. Thus, it would not be wrong to say that our immune system is an organ consisting of about 10^{12} lymphocytes, or in a mouse that is 3000 times smaller than we, 3×10^8 lymphocytes.

(human) immune system = 10^{12} lymphocytes
(mouse) immune system = 3×10^8 lymphocytes

This brief description of the immune system disregards the fact that lymphocytes interact with most other cells in the body, which in my definition do not belong to the immune system *sensu strictu*.

Let me draw attention to the fact that this number of lymphocytes in the immune system is at least one order of magnitude larger than the number of neurons in the nervous system. Also, we should note that lymphocytes travel among most other cells of our body, that they circulate in blood and lymph, and occur in large concentrations in spleen, lymph nodes, appendix, thymus and bone marrow. Strangely enough, however, they seem to be excluded from the brain. The 1960's was a very fruitful decade of immunological discoveries, of which I shall name a few: In the beginning of the decade, the primary structure of antibody molecules was clarified;[14, 15] then followed the demonstration that the dictum of *Burnet*[2, 16] was correct, namely that all antibody molecules synthesized by one given lymphocyte are identical, and finally, towards the end of that decade, lymphocytes were shown to fall into two classes, called T cells and B cells, existing in the body in almost equal numbers.[17, 18, 5] Only B lymphocytes, or B cells, however, can produce and secrete antibody molecules.

Schematically, I could picture this as in Figure 1.

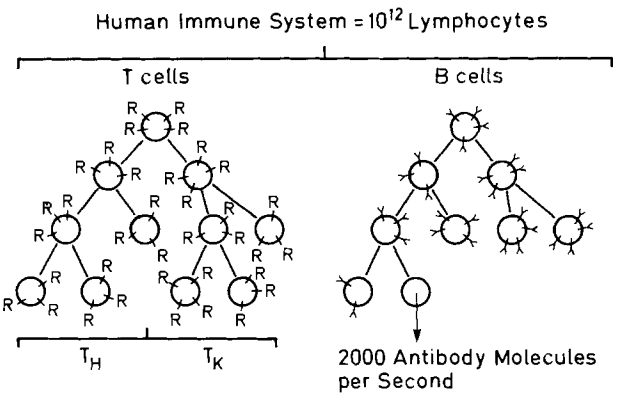

Fig. 1.

What I should like you to retain from this picture is both what we know as well as what we do not know at present. Thus, B lymphocytes are known to carry so-called receptor molecules on their surface (about 10^5 identical receptors per B cell), and when such a "resting" B cell is properly stimulated to divide and to mature, it will end up excreting about 2000 antibody molecules per second, all of which are identical, and similar or identical to the receptors that the resting B cell originally displayed. This clonal nature of antibody formation was clearly demonstrated in the early 1970's.[19, 20] The normal antibody response of an animal to a foreign antigen involves a large number of different clones, however, and is characterized by the production, usually, of several hundreds of different antibody molecules.[21] T lymphocytes are also known to carry receptor molecules on their surface, but firstly these molecules are not well known yet because they have been discovered only during the past two years and secondly, the T cells do not excrete such molecules: these T cell receptors are antigen-recognizing molecules, but they do not contribute to the population of freely circulating antibody molecules which are purely B cell products. Furthermore, there are at least two different types of T cells, one of which is called T helper cells (T_H)[22] because they help B cells to become stimulated (or, in their absence, they prevent B cells from receiving a proper stimulus); the other type is called T killer cells (T_K)[23] because they are capable of killing other cells which they consider undesirable (such as virus-infected cells); moreover, as suppressor cells, they may prevent B cells from being stimulated.[6]

Thus, in this picture, B cells have the single-minded desire to express their antibody language, but are subordinate to the T cells, which can either enhance or suppress this capacity.

Before looking at grammar, I must briefly describe the structure of an antibody molecule. No matter what you try to investigate in biology turns out to become increasingly complex—thus also the structure of antibody molecules. The basic element of all antibody molecules has been shown to be a Y-shaped protein structure[26] of about 150000 daltons molecular weight. This is a three-dimensional structure, like all molecules and cells that biology has to deal with. Three-dimensionality tends to perplex our mind, which is most at ease with one-dimensional, linear sequences, but I shall try to make a rough two-dimensional sketch of an antibody in Figure 2.

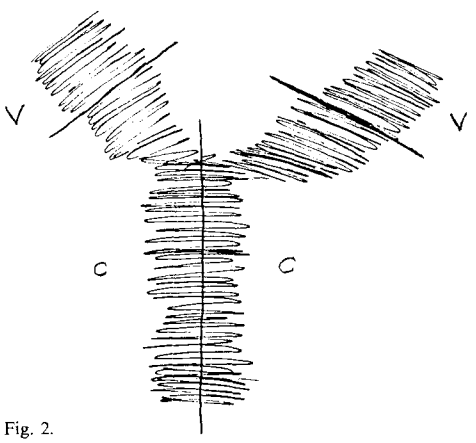

Fig. 2.

We can make some important cuts through this molecule. The vertical cut shows symmetry. It divides the antibody molecule in two identical halves. The two other cuts separate a so-called "constant" part (c) from a "variable" part (v). By constant part, we mean that molecules of different antibody specificity have this part in common (such as, for example, diphtheria antitoxin and tetanus antitoxin). By variable part, we mean that this is the region of the antibody molecule that determines its "specificity." The two variable parts are identical: that is to say that the molecule, with regard to specificity, is divalent. The difficulty

we face is not to transform this sketchy two-dimensional picture into a one-dimensional primary structure, but into a three-dimensional tertiary structure. The primary structure[14, 15] has been clarified: the half molecule is made up of a light polypeptide chain of about 214 amino acid residues, and a heavy polypeptide chain of a little more than 400 amino acid residues, as shown in Figure 3.

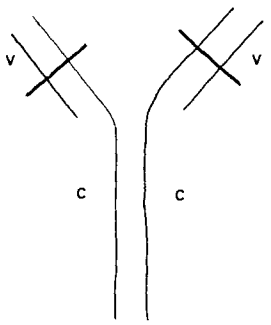

Fig. 3.

It turned out that antibody molecules of different specificity have identical amino acid sequences in their carboxyl-terminal regions, but that they vary with respect to the amino acid sequences in the amino-terminal regions of both heavy and light chains.[24] It became obvious immediately that the great diversity of antibody molecules, the great number of different molecules which antibodies can recognize, or in other words, the great repertoire of antibody specificities, must result from an enormous number of varieties in the variable regions with respect to amino acid sequences. This insight does not solve our problems, however. It is like saying that the great variety of words or sentences in a language results from the enormous number of varieties with respect to the sequences of letters or of phonemes.

The interpretation in immunology remained practically as it had traditionally been, namely that the variable region of an antibody molecule forms a three-dimensional "combining site," and that "specificity" simply means that this combining site is complementary in shape to the shape of part of the three-dimensional profile of an antigen molecule. Antigen is the word that was given, and is still in use, for molecules that can induce the immune system to produce specific antibodies which can recognize these antigens. The antibody combining site was conceived of as a cleft which recognizes a protruberance on the outer shape of an antigenic molecule, and all antibodies were named after the antigens that they recognized, such as diphtheria antitoxin, anti-sheep red blood cell antibodies, anti-TNP, etc.[25] I shall now try to give you an impression of the size of this system of antigens and specific antibody molecules. Let us first consider macromolecules of molecular weights exceeding 10000 daltons; they may be polysaccharides, proteins, lipoproteins, nucleic acids, viruses, bacteria—in fact any such molecule or particle existing in the world is an antigen to which the immune system can make specific antibodies. Moreover, molecules such as nitrophenol, or arsonate, or any inorganic molecules you care to mention are antigenic when attached to a so-called carrier molecule, for example to a protein: the immune system will then produce antibodies that specifically recognize these molecules, even if they have been synthesized in a chemical laboratory without ever before having existed in the world.[1] How is this possible? For example, the immune system of a mouse possesses no more than about 10^8 B lymphocytes, which would be the maximal available repertoire of variable regions on its antibody molecules. We realize that "recognition" need not be perfect, and that the same "combining site" might recognize, with more or less precision, a number of similar antigens.

I shall now turn to some remarkable discoveries, made during the past 25 years, showing that the variable regions of antibody molecules are themselves antigenic and invoke the production of anti-antibodies. *Kunkel*[27] showed that monoclonal myeloma antibodies, when injected into another animal, induce specific antibodies which recognize the particular myeloma antibodies used, but which do not recognize any other myeloma antibodies isolated from other myeloma patients. This work was extended by others, but mainly by *Jacques Oudin* and his colleagues in Paris, who showed that ordinary antibody molecules that arise in an immunized animal are antigenic and invoke the formation of specific anti-antibodies.[28–31] In other words, the variable region of an antibody molecule constitutes not only its "combining site," but also presents an antigenic profile (named its idiotype) against which anti-idiotypic antibodies can be induced in other animals. Moreover, it turned out that this antigenic, idiotopic profile of the variable region of a given antibody molecule is not a single site, but consists of several distinct sites against which a variety of different anti-idiotypic antibody molecules can be made. These individual sites are now named idiotopes, implying that the idiotype of one antibody molecule can be described as a set of different immunogenic idiotopes. And finally, it has been shown that the immune system of a single animal, after producing specific antibodies to an antigen, continues to produce antibodies to the idiotopes of the antibodies which it has itself made. The latter anti-idiotopic antibodies likewise display new idiotypic profiles, and the immune system turns out to represent a network of idiotypic interactions.[7–11]

I shall now show, in Figure 4, a preliminary picture of how we might vaguely try to imagine the shape of the variable region of an antibody molecule.

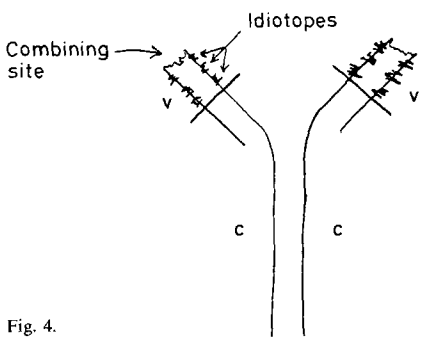

Fig. 4.

This picture is a historical compromise: we uphold our antigen-centered tradition[25] by retaining the notion of a "combining site" which enables the antibody molecule to recognize the antigenic molecule that induced its produc-

tion, and we simply add a number of idiotopes on the same variable region, which are capable of inducing the production of other antibody molecules that have "combining sites" recognizing these idiotopes.

We are now getting into trouble, however, when trying to interpret our experimental results. As I said earlier, a resting B lymphocyte displays on its surface about 100000 identical receptor molecules which are representations of the type of antibody molecules this B cell will produce if stimulated by an antigen.

Let us return to this picture for a moment, as in Figure 5, and let us make an enlargement, in Figure 6, of a small part of the surface of this B cell, focusing on one receptor molecule only, making the usual cuts between constant and variable regions.

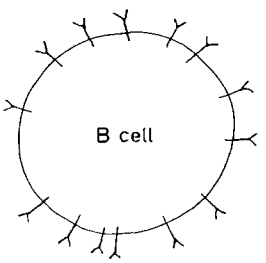

Fig. 5.

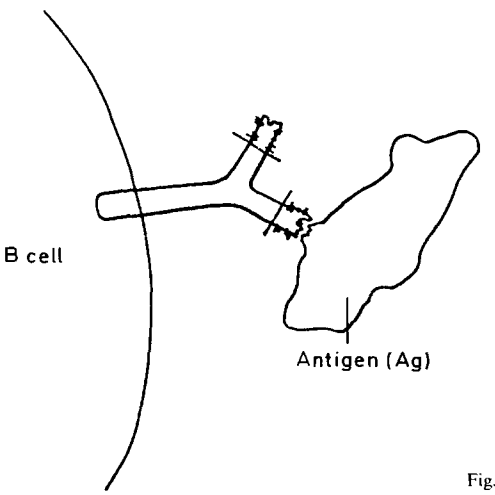

Fig. 6.

As you see, I have retained the traditional distinctions between the antigen-recognizing combining site, and a number of antigenic idiotopes (cf. Fig. 4). I have also added an imaginary profile of an antigenic molecule, part of which is recognized by the combining site of the B cell receptor. This is the basic picture of the selective theories of antibody formation, as most clearly formulated by *Burnet*.[16,2] The antigen "selects" the lymphocytes by which it is recognized, and stimulates these cells to proliferate, to mature, and to secrete antibodies with fitting combining sites. Clearly, T cell control is also involved, as well as growth factors, maturation factor, etc., but this picture remains the basic idea of antibody induction. Figure 7 shows one of these antibody molecules, which recognizes part of the surface profile ("epitope") of the antigen.

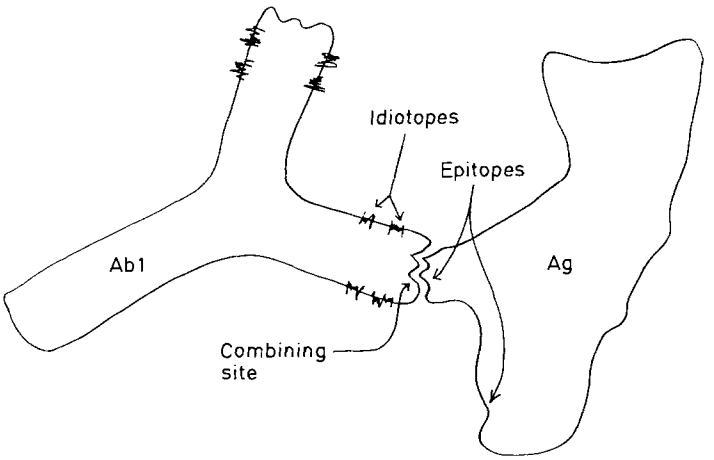

Fig. 7.

Now imagine, however, that this antibody molecule (Ab1), displaying both its combining site as well as its antigenic idiotopes, is itself used as antigen. It is then possible to envisage two situations. Figure 8 shows, schematically, a freely circulating Ab1 molecule which recognizes, and sticks to, a receptor of a B cell. The figure envisages the stimulation of two different B cells by Ab1 molecules now acting as antigens. In the α case, the combining site of the receptor on a B cell recognizes an idiotope of Ab1 and the cell may be stimulated to produce the corresponding anti-idiotopic antibodies (Ab2). In the β case, however, it is the combining site of the Ab1 molecule which recognizes an idiotope of the receptor on a B cell which may thus be stimulated to produce antibodies which possess idiotopes that have a shape that is similar to the epitope displayed by the original antigen. Experiments have shown both these situations actually to occur. For example, if the original antigen is insulin, and Ab1 is an anti-insulin antibody, then some of the anti-idiotypic antibodies (Ab2) of the β types show a similarity to insulin and can even be shown to function like insulin, as shown by *Sege* and *Peterson*.[32] Similar results in other systems have been obtained by *Cazenave* and *Roland*, by *Strosberg*, by *Urbain*, and their colleagues, and by others.[10,33-35]

The point I wish to make, however, is to consider whether the two situations α and β are fundamentally different, or not. Is there a difference between saying that Ab1 recognizes Ab2 or that Ab2 recognizes Ab1? Can we, at this three-dimensional molecular level, distinguish between "recognizing" and "being recognized"? If not, it becomes meaningless to distinguish between idiotopes and combining sites, and we could merely say that the variable region of an antibody molecule displays several equivalent combining sites, a set of idiotopes, and that every antibody molecule is multi-specific. I do not have to belabor this point which has been made repeatedly.[25,36-38] Instead, I should now like to introduce some numerology into this discussion. How large is the number of different antibodies that the immune system of one single animal (be it a human or a mouse) can make? This number, during the past few decades, has been estimated, on more or less slender evidence, to exceed ten million, and this enormous diversity has been designated as the "repertoire" of the B lym-

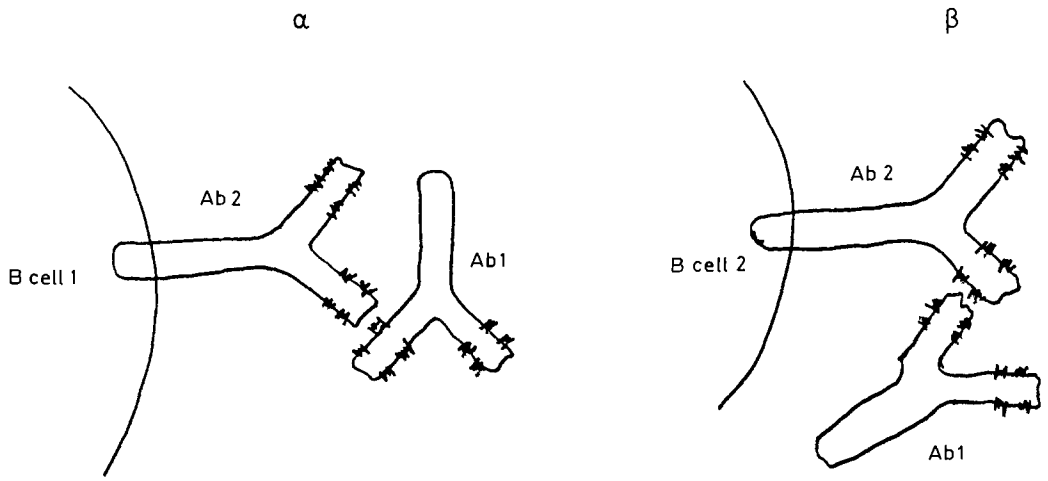

Fig. 8.

phocytes. Such a "repertoire" has been characterized by *Coutinho* as "complete."[39] "Completeness" means that the immune system can respond, by the formation of specific antibodies, to any molecule existing in the world, including, as I said earlier, to molecules that the system has never before encountered. Immunologists sometimes use words they have borrowed from linguistics, such as "immune response." Looking at languages, we find that all of them make do with a vocabulary of roughly a hundred thousand words, or less. These vocabulary sizes are a hundredfold smaller than the estimates of the size of the antibody repertoire available to our immune system. But if we consider that the variable region that characterizes an antibody molecule is made up of two polypeptides, each about 100 amino acid residues long, and that its three-dimensional structure displays a set of several combining sites, we may find a more reasonable analogy between language and the immune system, namely by regarding the variable region of a given antibody molecule not as a *word* but as a *sentence* or a phrase. The immense repertoire of the immune system then becomes not a vocabulary of words, but a lexicon of sentences which is capable of responding to any sentence expressed by the multitude of antigens which the immune system may encounter.

At this point, I shall give a few quotations from *Noam Chomsky*[3] concerning linguistics: "The central fact to which any significant linguistic theory must address itself is this: a mature speaker can produce a new sentence of his language on the appropriate occasion, and other speakers can understand it immediately, though it is equally new to them ... Grammar is a device that specifies the infinite set of well-formed sentences and assigns to each of these one or more structural descriptions. Perhaps we should call such a device a *generative grammar* ... which sould, ideally, contain a central syntactic component ..., a phonological component and a semantic component." That is the end of my quotation. For the size of the set of possible sentences in a language, *Chomsky* uses the word "open-endedness," and I now think that "open-ended" is the best description also of the "completeness" of the antibody repertoire. As for the components of a generative grammar that *Chomsky* mentions, we could with some imagination equate these with various features of protein structures. Every amino acid sequence is a polypeptide chain, but not every sequence will produce a well-folded stable protein molecule with acceptable shape, hydrophobicity, electrostatics, etc. Some grammatical rules would seem to be required. It is harder, however, to find an analogy to semantics: does the immune system distinguish between meaningful and meaningless antigens? It would seem, at first sight, that the immune response to a sentence presented by an invading protein molecule is merely to select, from amongst its enourmous preformed antibody repertoire, a suitable mirror image of part of this antigenic sentence. As you will know, *Leonardo da Vinci* wrote his private journal in the mirror image of ordinary handwriting. It is difficult, without considerable practice, to write and read mirror handscript. Let me show you an example in Figure 9.

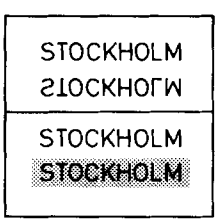

Fig. 9.

In Figures 10 and 11, as in Figure 9 (bottom), I shall use the device of showing ordinary letters in black, and of using gray zones to indicate the mirror images of these letters.

I should perhaps again emphasize that the sentences representing antibodies possess partial mirror images of an antigenic sentence. These antibodies are not echoes of the invading antigen, but were already available to the animal in its repertoire of B cells before the antigen arrived. This is the important insight that followed the introduction into immunology of the selective theories in the 1950's. Also, I

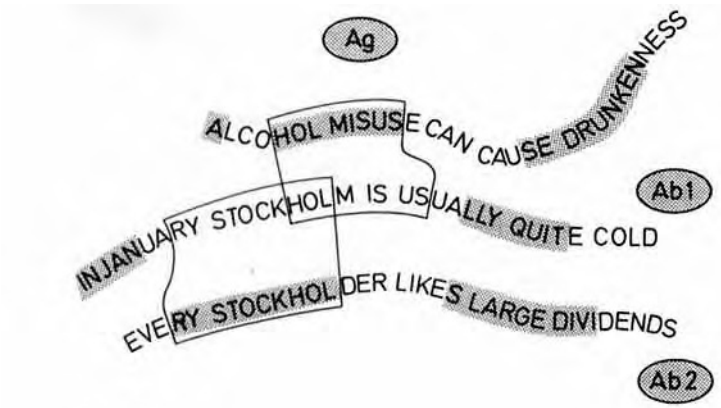

Fig. 10.

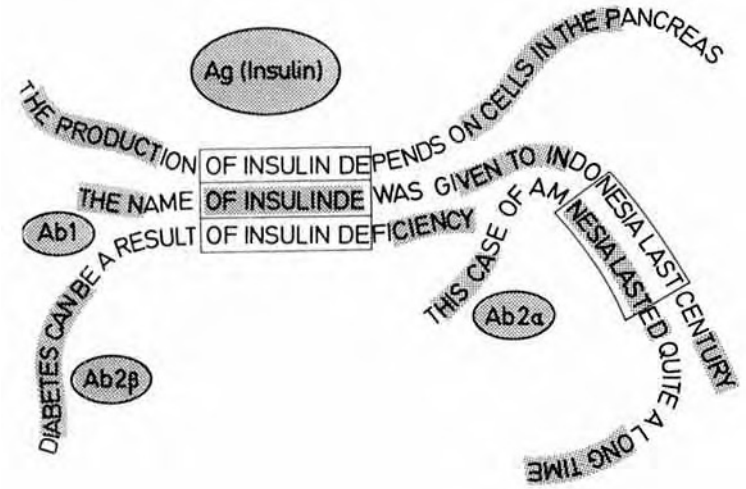

Fig. 11.

must emphasize another important quantitative aspect of the situation facing the immune system. It has been estimated that one human individual produces about 10000 different proteins, such as enzymes, hormones, cell surface proteins, etc. At the same time, we estimate that the immune system maintains a repertoire exceeding ten million different proteins, namely antibody molecules. This is a thousandfold more than all other body proteins taken together. Man and mice, normally, have about ten milligrams of antibodies in a milliliter of their blood. Thus, a normal human possesses from about 50 to 100 grams of freely circulating antibodies, called immunoglobulins. If we divide this figure by 10^7 different specificities, we are still left with an average of 5 to 10 micrograms of every specificity in the available repertoire, representing an average of about 3×10^{13} monoclonal antibodies of every specificity. For mice that are 3000 times smaller, we would have to divide these figures by 3000, which would still leave a mouse with an average of 2 to 3 nanograms of antibodies of each of 10^7 specificities. That even such nanogram quantities of monoclonal anti-idiotypic antibodies, when introduced into mice, produce remarkable effects has been shown by *Rajewsky* and his colleagues.[40–42]

I should therefore like to conclude that in its dynamic state our immune system is mainly self-centered, generating anti-idiotypic antibodies to its own antibodies, which constitute the overwhelming majority of antigens present in the body. The system also somehow maintains a precarious equilibrium with the other normal self-constituents of our body, while reacting vigorously to invasions into our body of foreign particles, proteins, viruses, or bacteria, which incidentally disturb the dynamic harmony of the system.

The inheritable "deep" structure of the immune system is now known: certain chromosomes of all vertebrate animals contain DNA segments which encode the variable regions of antibody polypeptides. Furthermore, experiments in recent years have demonstrated the generative capacities of this innate system. In proliferating B lymphocytes, these DNA segments are the targets for somatic mutations, which result in the formation of antibody variable regions which differ, in amino acid sequences, from those encoded by the stem cell from which these B cells have arisen.[43–47] The experiments showed that it was still possible, however, to identify the original stem cell genes that must have undergone these mutations. Expressed in linguistic terms, such investigations belong to the etymology of the immune system.

As immunologists, we should like to know the semantics of the inheritable gene structures. What is the meaning of the basic lexicon, or what are the specificities of the antibodies, B cell receptors, and T cell receptors as encoded in the genes of our germ cells? It is known that B cells recognize the language of the T cell receptors. I have said so little about the latter because T cell "receptorology" is still in too early a stage of development. An immune system of enormous complexity is present in all vertebrate animals. When we place a population of lymphocytes from such an animal in appropriate tissue culture fluid, and when we add an antigen, the lymphocytes will produce specific antibody molecules, in the absence of any nerve cells.[48] I find it astonishing that the immune system embodies a degree of complexity which suggests some more or less superficial though striking analogies with human language, and that this cognitive system has evolved and functions without assistance of the brain.

It seems a miracle that young children easily learn the language of any environment into which they are born. The generative approach to grammar, pioneered by *Chomsky*[4], argues that this is only explicable if certain deep, universal features of this competence are innate characteristics of the human brain. Biologically speaking, this hypothesis of an inheritable capability to learn any language means that it must somehow be encoded in the DNA of our chromosomes. Should this hypothesis one day be verified, then linguistics would become a branch of biology.

From the Structure of Antibodies to the Diversification of the Immune Response (Nobel Lecture)**

By Cesar Milstein

> *Cuando se acerca el fin,* escribió Cartaphilus, *ya no quedan imágenes del recuerdo; sólo quedan palabras.* Palabras, palabras desplazadas y mutiladas, palabras de otros, fue la pobre limosna que le dejaron las horas y los siglos.
>
> *J. L. Borges*

When an animal is infected, either naturally or by experimental injection, with a bacterium, virus, or other foreign body, the animal recognizes this as an invader and acts in such a way as to remove or destroy it. There are millions of different chemical structures that the animal has never seen and yet which it is able to recognize in a specific manner. How is this achieved? Scientists have been fascinated by this question for most of this century, and we continue to be fascinated by the intricacies and complexities that still need to be clarified. Even so, looking back over the years since I myself became involved in this problem, progress in the understanding of the process has been phenomenal. Suffice it to remind our younger colleagues that 20 years ago we were still trying to demonstrate that each antibody differed in its primary amino acid sequence.

What attracted me to immunology was that the whole thing seemed to revolve around a very simple experiment: take two different antibody molecules and compare their primary sequences. The secret of antibody diversity would emerge from that. Fortunately at the time I was sufficiently ignorant of the subject not to realize how naive I was being.

Back in 1962, when I had by accident become the supervisor of *Roberto Celis* in Argentina, it occurred to me that antibody diversity might arise from the joining by disulfide bridges of a variety of small polypeptides in combinatorial patterns. I don't know whether anybody else had the same idea at that time, but of all the prevailing theories about antibody diversity that I am aware of, this is one that was widest of the mark. I hold it to my credit that I never put it into print. But it was of great value to me as it provided an intellectual justification to work on disulfide bonds of antibodies. By the time I joined the Laboratory of Molecular Biology in 1963, the model of two heavy and two light chains joined by disulfide bonds (Fig. 1) had been established,[1] and I was eager to accept Dr. *Sanger*'s proposal that I should engage in studies of antibody combining sites.

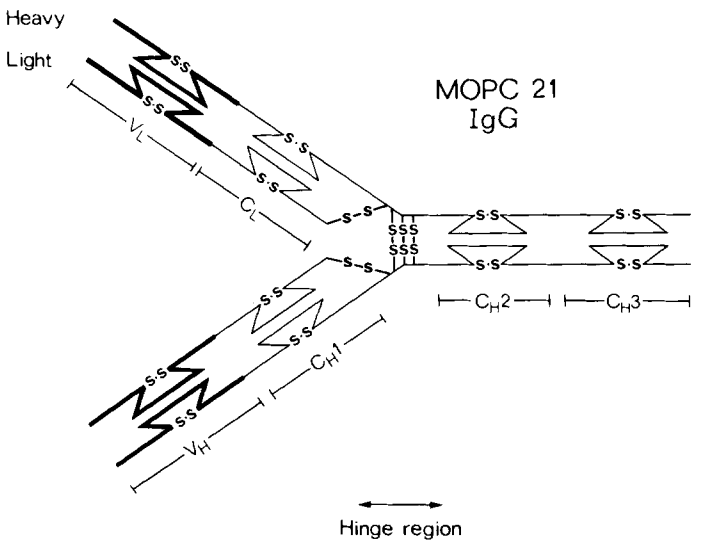

Fig. 1. Antibodies are made of two or more pairs of heavy and light chains joined by disulfide bonds. Each chain has two regions. The variable region differs in structure from one antibody to another and contains the combining site. The antibody combining site is located at the tips of a Y-shaped three-dimensional structure. The constant region is invariant within a given class or subclass, and is responsible for effector functions (complement binding, attachment to and transport across membranes, etc.). The number and position of the interchain disulfide bonds is characteristic for the different classes and subclasses. In this figure, the structure depicted is the mouse myeloma protein MOPC 21 which was the subject of much research in our laboratory.

The Nature of Antibody Diversity

At first I looked for differences in fingerprints of digests of iodinated antibodies directed against different antigens. The pattern that emerged from those studies implied that purified antibodies were too complex and differed only in a subtle quantitative way from the totally unfractionated immunoglobulin. I never published those results, which only led me to the conviction that the protein chemistry of antibodies at that level was too difficult to tackle, and that a different approach was needed.

The study of the amino acid sequence around the disulfide bonds of the immunoglobulins was my own short-cut to the understanding of antibody diversity. I soon recognized the existence of what appeared to be a variable disulfide bridge and a common disulfide bridge,[2,3] but the full meaning of that observation only became obvious when *Hilschmann* and *Craig* described the variable and constant halves of antibody light chains.[4] The variable half contained one disulfide bond, and the constant half the other. This was followed, in later studies with *Pink, Frangione, Svasti,* and others, by the observation of the repeating pattern of similar S-S loops as a distinctive common architectural feature of the different classes and subclasses of immunoglobulin chains. What distinguished them from each other was the diversity of interchain S-S bonds.[5]

The period between 1965 and 1970 was full of excitement, both at the experimental and theoretical level. How were these variable and constant regions going to be explained? It was now not only a problem of millions of antibody structures, but that in addition those millions of structures were part of a polypeptide which otherwise had an invariant primary sequence encoded by only one or very few genes. How to solve the puzzle? *Dreyer* and *Bennett*[6] suggested that there were thousands of genes in the germ line and that the paradox was easy to solve if we postulated a completely unprecedented scheme. This became known as the "two genes-one polypeptide" hypothesis. At the time we did not like that, and proposed a mechanism of hyper-mutation operating on selected segments of a gene.[7] There were other ideas at the time to generate antibody diversity. One of them, widely discussed in a Cold Spring Harbor Symposium in 1967, was based on a mechanism of somatic cross-over between gene-pairs.[8] It was very exciting for me when soon after the symposium I could show that in the human kappa chains at least three genes must be involved.[9] The predicted thousands of V-regions could be grouped into a small number of families or subgroups. The fact that these families were encoded by non-allelic V-genes[10]—coupled to the genetics of the C-region, which indicated a single Mendelian C-gene—provided the experimental evidence that convinced me and many others that the "two genes-one polypeptide" hypothesis was inescapable.

After that, there was a period of consolidation and extension of the results. The concept of V-gene families or subgroups became firmly established, as was the existence of hypervariable residues within the variable segment.[9,11] Crystallographic data showed that such hypervariable residues were near to each other, justifying the idea that they were part of the antibody combining site. This was directly shown with crystals of myeloma protein-antigen complexes.[12] The work with myelomas was not only totally vindicated, but also generally accepted. The idea of separate pools of V- and C-genes that were under continuous expansion and contraction was the last element added to the picture. By 1970 we became convinced that "the section of the genome involved in the coding of immunoglobulin chains undergoes an expansion-contraction evolution: that the number of individual genes coding for basic sequences is not large, and that it varies in different species and even within species at different stages of its own history. The task of providing for the endless variety of individual chains is left to somatic processes."[13]

Light Chain mRNA and the Signal for Secretion

I now began to feel a bit restless. It seemed that protein chemistry alone was not going to get us much further. Furthermore, there was a lot of excitement in the laboratory with the new methods for sequencing RNA being developed by *Sanger* and his group. Perhaps even more important, one of my closest friends at the laboratory, *George Brownlee*, was beginning to feel that the time was ripe to attack molecules more complicated than 5S or 6S RNA. So we joined forces in an attempt to isolate immunoglobulin mRNA. This was a difficult problem and when *George*'s new research student, *Tim Harrison*, joined us we decided to move from solid tumors[14] to cell lines in culture which were kindly provided by colleagues from the Salk Institute.[15] The first important breakthrough in the field was a paper reporting in vitro synthesis of immunoglobulin light chains.[16] We immediately set to work to follow up that approach, and to our delight ran into the unexpected observation of the existance of a biosynthetic precursor of light chains. Further experiments led us to propose that the extra *N*-terminal sequence was a signal for vectorial transport across membranes during protein synthesis. That was the first evidence which indicated that the signal for secretion was an *N*-terminal segment, rapidly cleaved off during protein synthesis.[17,18]

However, our major concern remained the sequence of the messenger RNA for the light chains. In those days there was no DNA sequencing, only mRNA sequencing via elaborate fingerprints of radioactive mRNA. Every radioactive messenger preparation on which we could do sequence analysis involved the labeling of cells with inorganic ^{32}P-phosphate at levels of 100 mCi. So there we were, dressed up in our new-style laboratory coats (namely heavy lead aprons), behind a thick plastic screen, labeling cells and then frantically working up our messenger purification procedures and performing fingerprinting experiments, before the inexorable radioactive decay. Although we didn't go very far in our sequencing, we could isolate oligonucleotides that corresponded to the protein sequences.[19] Among these were oligonucleotides spanning the V- and C-regions, demonstrating that the protein chain was made from a single messenger RNA and that therefore integration of the V- and C-genes did not take place during or after protein synthesis. At this stage the radioactive approach was stopped and we tested alternative methods for the sequencing of mRNA, using synthetic primers and cDNA synthesis. This approach went on in the background while our main efforts were moving in a different direction. Eventually however, it paid off.[21] I will come back to that later, because it forms part of my story.

Spontaneous Somatic Mutants of a Myeloma Protein

The introduction of tissue culture methods to our laboratory had a major impact on the direction of our research. With my new research student, *D. S. Secher*, and soon after with *R. G. H. Cotton*, we decided to embark on an analysis of the rate and nature of somatic mutation of myeloma cells in culture. We were hoping that we might reveal a high rate of mutation of the hypervariable segments. (The protocol is described in Figure 2.) A continuous culture was grown for a minimum of three months to allow mutants to accumulate, and individual cells were taken and grown as colonies. These were incubated with labeled amino acids and the radioactive immunoglobulin analyzed to detect mutants with altered electrophoretic properties. Our first structural mutant appeared after a few thousand clones,[22] and the final analysis of 7000 individual clones gave us a pool of mutants which are described in Table I. We were relieved that this elaborate experiment provided the first evidence at the protein and nucleic acid

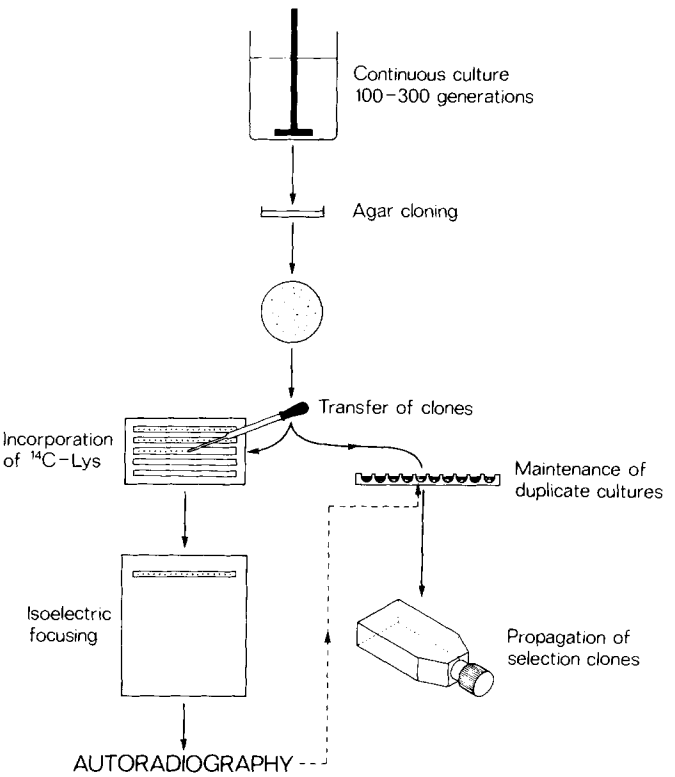

Fig. 2. Protocol used for the screening of the isoelectric focusing pattern of the immunoglobulin secreted by 7000 clones of P3 myeloma cells. Mutants were detected and their primary defect analyzed by amino acid and mRNA sequence analysis. The results are described in Table 1 (taken from ref. [23]).

Table 1. Spontaneous structural mutants of MOPC 21 heavy chains.

Mutant	Protein defect	Genetic defect
IF1	Last 82 residues of CH3 missing; carbohydrate difference	Ser(387)→Ter [a] small deletion?
IF2	Whole CH1 deleted	5.5 K bases deleted including CH1 exon. Aberrant switch?
IF3	Altered sequence of residues 367-380. Deletion of rest of CH3	Frameshift (−2). Premature "ochre" termination
IF4	Asparagine 452 to aspartic acid	A to G transition ("missense")
NSI1/1	Deletion of last 67 residues	Trp (406)→Ter G to A transition ("nonsense")

[a] Ter = termination.

levels of the existence of somatic mutations of mammalian cells.[23] Furthermore, the rate at which these mutations occurred suggested an important role in the generation of diversity.[24] But the mutations were not in the variable region, and we were forced to conclude that in the cells we were studying, there was no evidence for a hypermutable segment. So that in a sense we were back to square one.

Hybrid Myelomas

While this work was going on, *Cotton* was preparing another type of experiment which turned out to be more important than we anticipated.[25] This involved the fusion of two myeloma cells in culture (Fig. 3). That fusion demonstrated that the phenomenon of allelic exclusion was not dominant. On the contrary, fusion of two myeloma cells gave rise to a hybrid co-dominantly expressing the antibody chains of both parents. In addition, we proved that the expression of V- and C-regions was *cis*, probably because the V- and C-segments were already integrated at the DNA level by a translocation event in the precursors of plasma cells. This was in contrast to the assembly of heavy and light chains, which combined with each other to give rise to hybrid molecules.

Armed with these results, I went to Basel to give a seminar, and the important consequence was that *Georges Köhler* came to Cambridge. He joined in our main research project of looking at somatic mutants in immunoglobulin-producing cells, and in the other minor project concerning the phenotypic expression of somatic cell hybrids prepared between myelomas and myeloma mutants. It became increasingly clear that we could not go on looking for mutants by the procedure we had employed before, and the only way ahead was to use a culture of a myeloma cell line capable of expressing an antibody. Mutants from that cell could then be made based on the antibody activity. Although at that time there had been reports in the literature of myeloma cells capable of fulfilling that role, none proved suitable in our hands. The myeloma cell line P3 (MOPC 21) would have been ideal from a chemical point of view, because at the time the sequencing of the protein was a major undertaking and we knew how to deal with MOPC 21. But we were unable to find a suitable antigenic binding activity to this myeloma protein. We failed, but others who were pursuing similar types of experiments succeeded. *Scharff* and his co-workers were the first to demonstrate that one can isolate somatic mutants of a variable region in that way.[26]

And yet in a funny way our lack of success led to our breakthrough; because, since we could not get a cell line off the shelf doing what we wanted, we were forced to construct it. And the little experiment being done in the background concerning hybridization between myeloma cells developed into a method for the production of hybridomas. Thus, as illustrated in Figure 4, instead of hybridizing

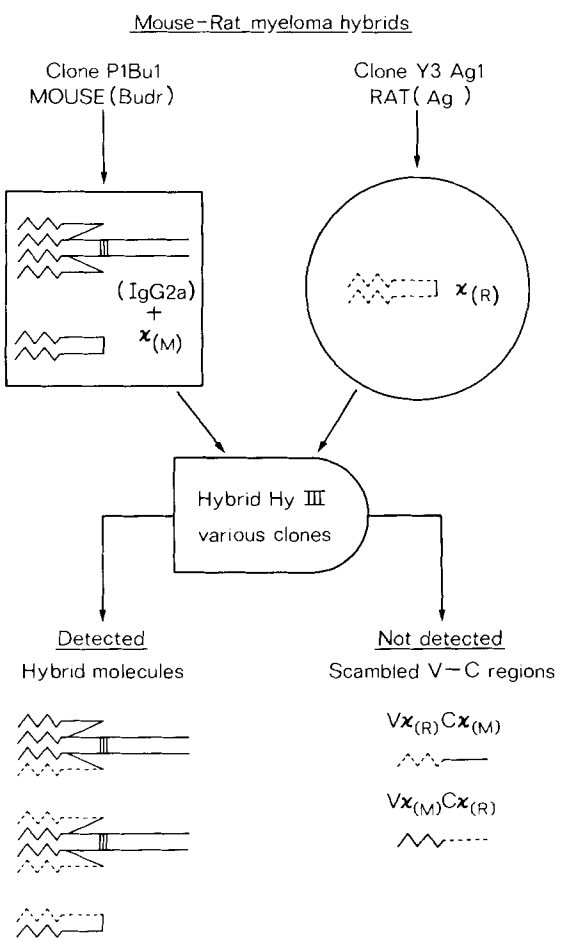

Fig. 3. Co-dominant *cis* expression of antibody genes in hybrids of myeloma cells. The diagram describes data taken from ref. [25].

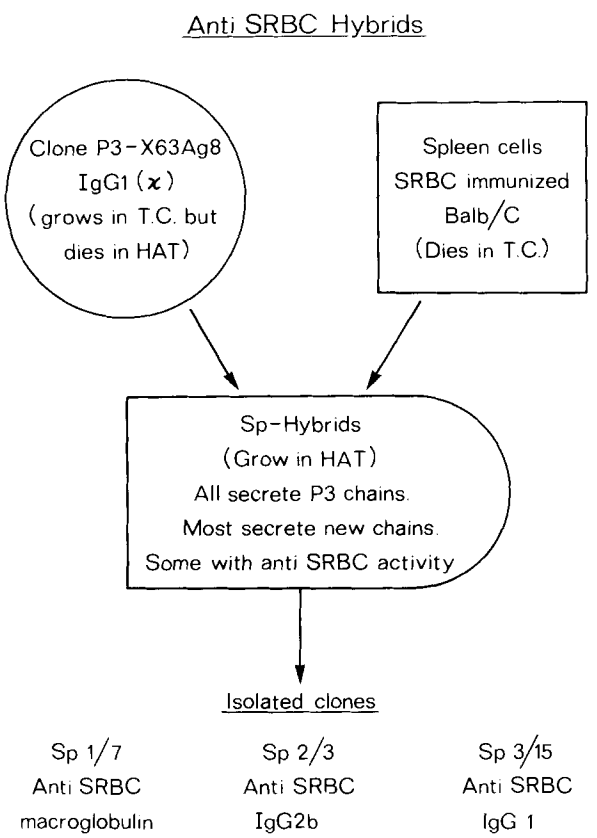

Fig. 4. The first successful hybridoma was prepared from cells from a mouse immunized with sheep red blood cells (SRBC) [56]. These were fused to a myeloma cell line producing the IgG protein MOPC 21 (see Fig. 1) growing in tissue culture and made resistant to azaguanine. Hybrids were selected by growth in HAT medium [57].

two myelomas, we hybridized a myeloma and an antibody producing cell. The resultant hybrid was an immortal cell capable of expressing the antibody activity of the parental antibody-producing cell, the immortality being acquired from the myeloma.

So finally, we were able to obtain a continuously growing cell line expressing a specific antibody and use it to search for mutants of the hypervariable region. This was undertaken by my research student, *Deborah Wilde*. While she got more and more discouraged by her lack of success in what she called "looking for a needle in a haystack," it dawned on me that it was up to us to demonstrate that the exploitation of our newly acquired ability to produce monoclonal antibodies "a la carte" was of more importance than our original purpose. After our early success we ran into technical difficulties and could not get our fusion experiments to work for quite some time. Then *Giovanni Galfré*, who had recently joined us, got us out of the deadlock when he discovered that one of our stock solutions had become contaminated with a toxic substance. After this an improved reliable protocol was developed (Fig. 5) and

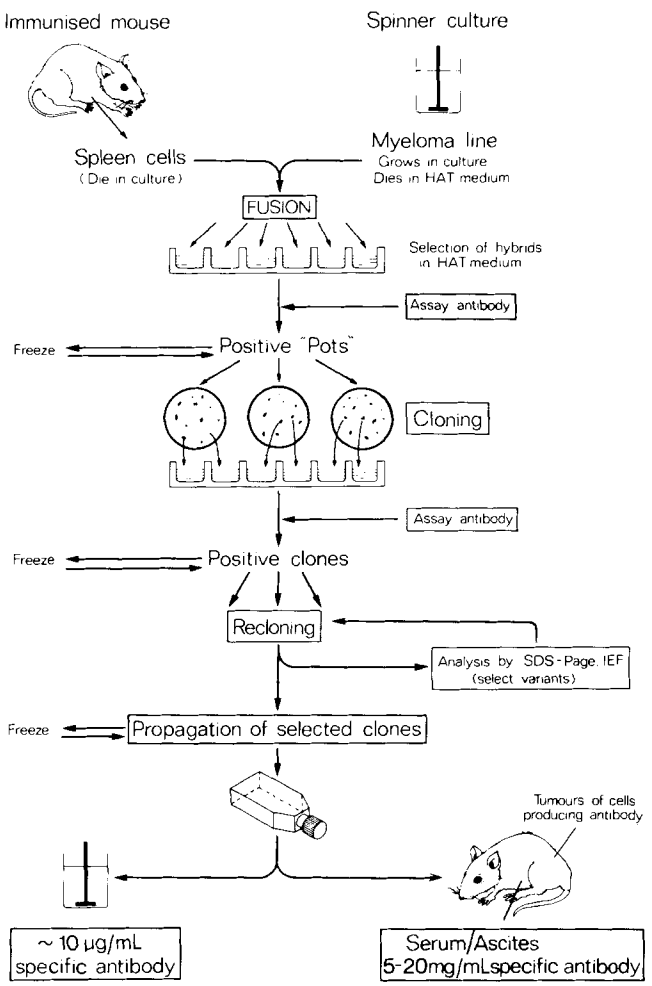

Fig. 5. Most generally used protocol for the derivation of hybridomas (taken from ref. [58]).

quick progress made towards the first practical applications of the technology. For several years I shelved the antibody diversity problem to demonstrate the practical importance of monoclonal antibodies in other areas of basic research and in clinical diagnosis (Table 2). We were able to show that the hybrid myelomas were capable of being used for the production of standard reagents such as anti-histocompatibility antigens[27] and anti Ig-allotypes.[28] The procedure was ideally suited to the study of cell surface and tumor antigens and to providing reagents for cell fractionation.[29-31] Monoclonal antibodies produced in this way were suitable for radioimmunoassays and for neuropharmacology,[32] as blood group reagents,[33] and for large-scale purification of natural products.[34] We also extended the hybrid myeloma technology to a second species—the rat[35]—and to the production of bi-specific immunoglobulins (hybrid-hybridomas).[36]

Genetic Origin of Antibody Diversity

In the period 1970-1975, a considerable effort was being made to measure the number of germ-line genes coding for the variable regions of immunoglobulin chains. Our own

contributions started when we persuaded *Terry Rabbitts* to join us. After considerable effort and a lot more radioactivity we obtained results indicating that the number of germ line genes was not much higher than would be predicted from our understanding of subgroups, and this view was shared and reinforced by parallel work being conducted by others.[37,38] By 1976 this view was gaining general support.[39] But then the impact of the recombinant DNA revolution began to be very strongly felt. Within a few years, and largely through the work of *Tonegawa, Leder, Rabbitts, Hood, Baltimore,* and others, a coherent picture of the arrangement and rearrangement of immunoglobulin genes and their involvement in the generation of diversity began to emerge.[40] The precursors of the antibody-producing cells do not express an immunoglobulin, but during their differentiation into pre-B cells and B cells, they express first the heavy chain and then the light chain (Fig. 6). The first antibody produced is membrane bound and this functions as the receptor molecule, which receives antigenic signals. Triggered cells divide and differentiate to antibody-producing cells and memory cells.

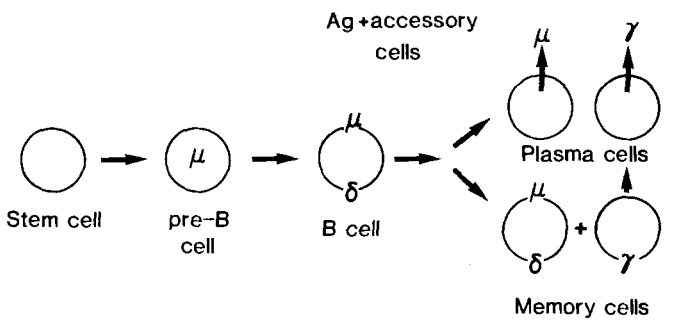

Fig. 6. Differentiation of B cells.

These events at the cellular level are correlated with changes in the DNA structure (Fig. 7). The germ-line DNA contains the V- and C-genes on different DNA fragments, as predicted. But in addition, there are further fragmentations, and only some of them are shown in Figure 7. Light and heavy chains can only be transcribed and translated when certain fragments (any one of the V and J in light chains; V, D, and J in heavy chains) are integrated by a deletion mechanism. During this process of integration, enormous diversity is generated.

To theorize about the genetic origin of antibody diversity was a "must" among molecular immunologists for quite a number of years. How do those theories contrast with the reality of today? The hard experimental facts made possible by the methodological advances in molecular biology show that, while none of them was right, most of them contained at least a grain of truth. There were two major currents of opinion. One consisted of germ-line theories whereby all the diversity was inherited as genes present in the germ line. The other included somatic diversification theories, whereby somatic processes were responsible for the generation of diversity, starting from a small number of germ-line genes. As it turns out, the genetic mechanisms responsible for the generation of diversity include a little bit of everything (Table 3). There are between

Table 3. Mechanisms that generate antibody diversity.

1. Germ line: multiple V-gene segments
2. Combinatorial: a) Different combinations of V-(D)-J
   b) Different combinations of V_H and V_L
3. Junctional: variation at V-J, V-D, and D-J boundaries
4. Somatic point mutation: nucleotide substitutions throughout the V region

50 and 300 gene fragments in the germ line encoding the light or the heavy chains. The number varies from species to species. So there is a considerable germ-line contribution. Recombination and gene conversion are probably important genetic events in the evolution and maintenance of that germ-line gene pool. We still do not know whether these events are significant as somatic generators of diver-

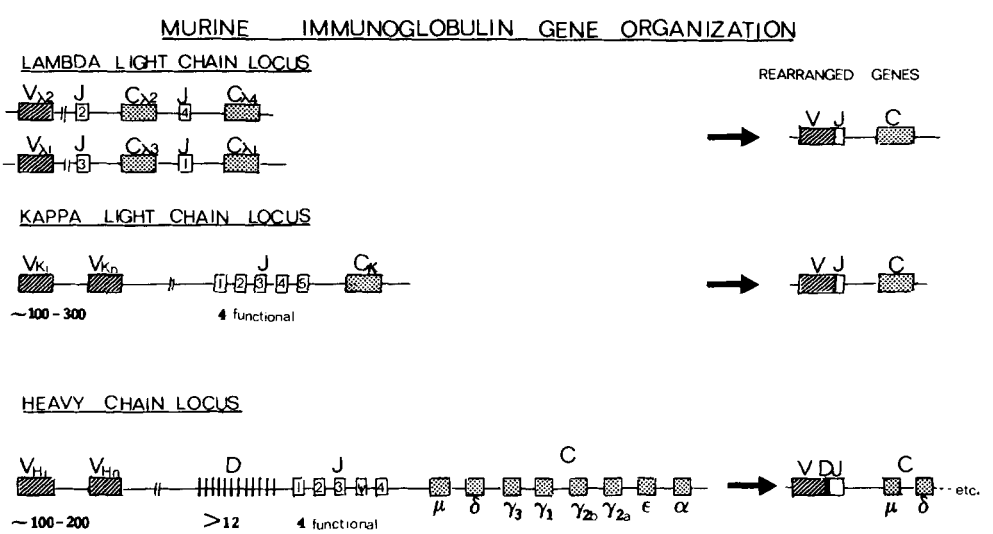

Fig. 7. Genetic arrangement of immunoglobulin genes in the germ line. During differentiation into pre-B cells and B cells large deletions of DNA lead to the integration of fragments (rearranged genes). Further proliferation leads to somatic mutation of the integrated gene and this is of major importance in the maturation of the response.

sity.[41] As shown in Figure 7, the V-region is encoded by V, D, and J segments (heavy chain) and V and J segments (light chain). Their combinatorial integration into a single gene, although an important component of the generation of diversity, is not the critical mechanism predicted by the mini gene hypothesis.[42] Also important is the diversity generated during the joining process, and this contains an element of the errors and aberrations during repair predicted by other theories.[43] And then there are the somatic point mutations for which a mechanism remains to be elucidated. It may involve error-prone repair enzymes,[7] genetic hot-spots,[24] appropriate selection either by antigen[44] or by other network elements,[45] or quite possibly by a mixture of all or some of these. The instructional theories were largely forgotten as soon as the chemical diversity of antibodies was established.[46] Yet they also may contain a grain of truth. It has recently been proposed that peptide segments of the antigen which appear to be mobile are better immunogens, presumably because they adapt their structure to a predefined antibody structure.[47,48] It is also possible that to some extent the antibody combining site itself has a certain degree of mobility, which has a limited capacity to accommodate its own structure to that of the antigen. Of course dynamic adaptation has a price to pay in terms of affinity. Adaptability should not be confused with the generation of specificity. As I discuss below, an improved fit of binding to the ligand is the result of somatic mutation and antigenic selection.

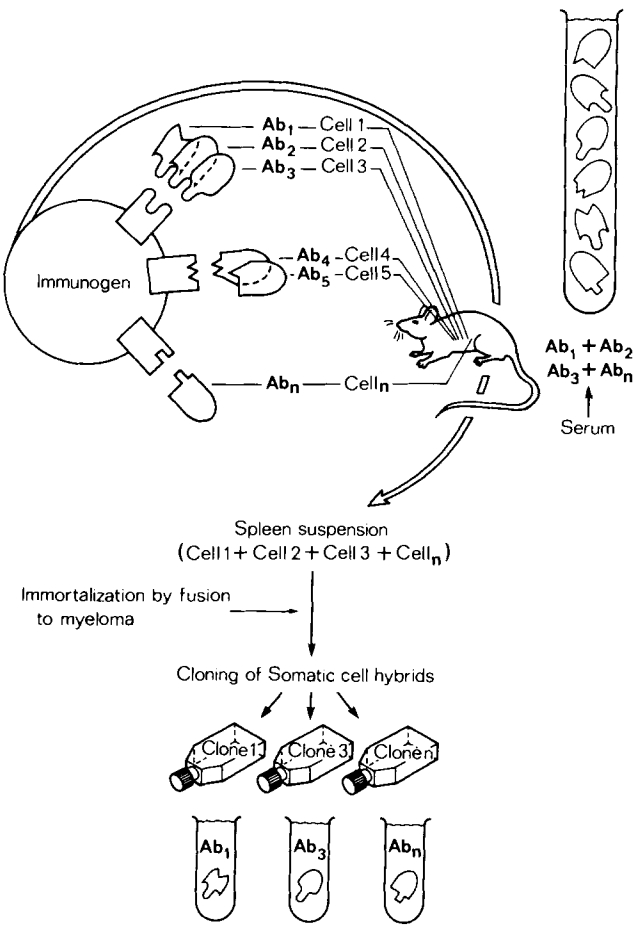

Fig. 8. The dissection of the immune response by the hybridoma technique. When an animal is injected with an immunogen the animal responds by producing an enormous diversity of antibody structures directed against different antigens, different determinants of a single antigen, and even different antibody structures directed against the same determinant. Once these are produced they are released into the circulation and it is next to impossible to separate all the individual components present in the serum. But each antibody is made by individual cells. The immortalization of specific antibody-producing cells by somatic cell fusion followed by cloning of the appropriate hybrid derivative allows permanent production of each of the antibodies in separate culture vessels. The cells can be injected into animals to develop myeloma-like tumors. The serum of the tumor-bearing animals contains large amounts of monoclonal antibody.

Molecular Analysis of an Immune Response Using Monoclonal Antibodies and mRNA Sequencing

Let us return to an animal that is being immunized with a certain substance. The immune system recognizes the substance as foreign, and the B cells are triggered to produce antibody (Fig. 8). The different antibodies are secreted and mixed in the serum. The individual antibody molecules are extremely similar and once mixed cannot be separated from each other. For this reason, and until the advent of the hybridoma technology, it was impossible to study the diversity of the antibody response to a given immunogen. The derivation of immortal cell hybrids solved this problem, because it affords individual antibodies separately produced, on culture vessels and as mouse myelomas. This permits dissection of the individual components of the antigen. Monoclonal antibodies prepared against hitherto undefined cellular components can themselves be used to identify the chemical nature of those components, to probe for their function, and later for use as reagents for diagnostic and therapeutic purposes. These are the fundamental properties behind the most important of the general applications of monoclonal antibodies. When we started to explore these applications, and until some years ago, it was possible to some extent to summarize the main results obtained.[49] In recent years their application to basic research, clinical biochemistry, medical therapy, and in industry has been so widespread that I do not intend even to attempt to discuss it any further here.

Different antibodies recognize different antigenic determinants of the immunogen, and the recognition of each determinant is complex in itself (Fig. 8). It has been known for a long time that even the simplest antigenic determinants are recognized by an unknown variety of antibody molecules. Monoclonal antibodies can be made pure and used to answer the old questions of how complex the collection of antibody molecules produced by the animal as a response to a particular antigen is, and how the individual molecules differ from each other. This brings me back to sequencing messenger RNA.

While in the late '70s the excitement about monoclonal antibodies and DNA recombinant methods was simmering, *Pamela Hamlyn* was quietly adapting *Sanger*'s fast DNA sequencing methods to the sequencing of light chain mRNA. Her eventual success[21] added to our capacity to derive cell lines secreting monoclonal antibodies to a predefined antigen, and to our ability to sequence quickly the

messenger RNA of the antibody molecule they produce. So, instead of asking the question "What is the nature of antibody diversity?", we were now in a position to ask the question "How do antibodies diversify during an immune response?" In other words, how, in real life in the animal, do all those genetic events capable of producing antibody diversity actually operate in response to an antigenic stimulus?

In collaboration with *Matti Kaartinen, Gillian Griffiths,* and *Claudia Berek,* we have been conducting a study of the response to the hapten phenyl oxazolone.[50,51] The essence of the experiment is described in Figure 9. The

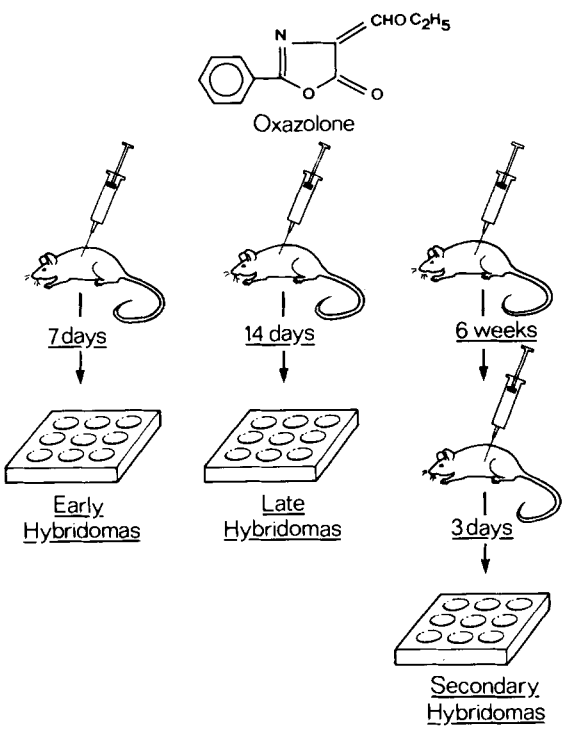

Fig. 9. Derivation of monoclonal antibodies at the onset and during the maturation of the response to oxazolone.

hapten conjugated to chicken serum albumin as carrier is injected into mice, and 7 days and 14 days later animals are sacrified, hybridomas are prepared, and a number of random clones isolated in each case. Other animals are left for a couple of months, and hybridomas of the secondary response are prepared.

Hybridomas prepared 7 days and 14 days after primary immunization are compared in Figure 10. Each point on the figure represents the avidity of each one of 32 monoclonal antibodies. The mixture of antibodies at each stage, as a first approximation, represents a cross section of the complexity of a typical antiserum. The average titers of the antibodies at both stages are not very different, although the day-14 average is slightly higher. This is as expected. The antibody titer of an antiserum, as well as its average avidity, increases during the course of an immunization. It is what we refer to as the maturation of the response. What distinguishes the results of the day 7 and day 14 is that while the day 7 results cluster around the average, the scatter at day 14 is much wider.

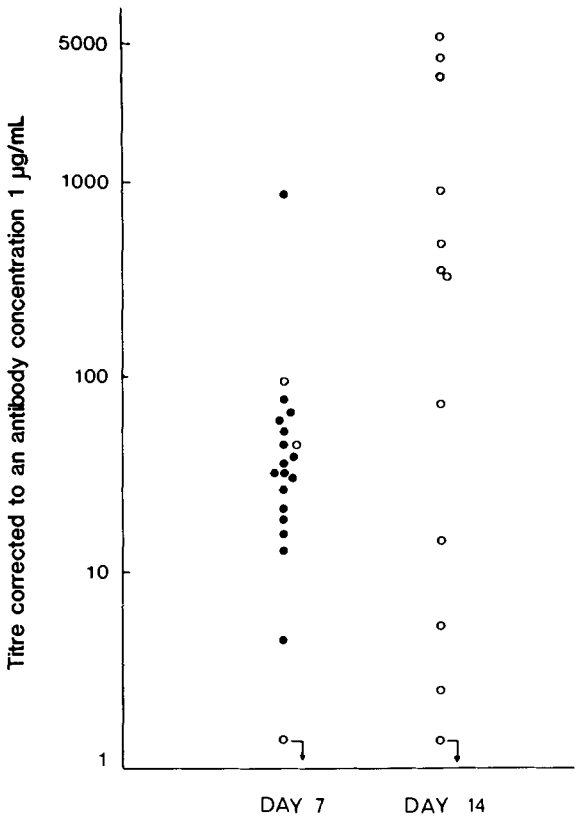

Fig. 10. Avidity of monoclonal antibodies 7 and 14 days after immunization. Haptenated phage inhibition (HPI) per µg of anti-phOx immunoglobulin from supernatants of IgG-secreting hybridomas. Those on the left were from day 7 and those on the right from day 14 fusions. Black circles represent oxazolone idiotype-positive IgG and open circles represent idiotype-negative IgG (taken from ref. [50]).

Since each monoclonal antibody was the product of an immortal hybridoma, we could go one step further and study the total amino acid sequence of each one of these monoclonal antibodies. Better still, we could study the sequence of the mRNA coding for each amino acid sequence. This not only provided more information, but was also technically simpler. To do so, RNA was prepared from the hybridoma cells and direct sequencing done on the impure messenger preparations, as shown in Figure 11. In this way, sequences of antibodies at different stages of the immune response could be compared.

What we have learned from this is that the majority of anti-oxazolone antibodies at day 7 express a single set of germ-line V-genes taken from the total pool of over 100 for each of the two chains (Fig. 12). This pair of term-line genes (which we refer to as V_H-Ox1 and V_k-Ox1) are at this stage expressed in their unmutated form. The few differences between them arise by junctional diversity—that is, the variations introduced during integration of the DNA fragments V, D, and J which make up the variable region of the antibodies. At day 14 the same germ-line genes V_H-Ox1 and V_k-Ox1 still seem to dominate the response. However, in sharp contrast to day 7, the day-14 antibodies express a small number of point mutations which are responsible for a significant increase in affinity for the same hapten. In other words, as the response matures, new somatic mutants appear in a seemingly endless variety.

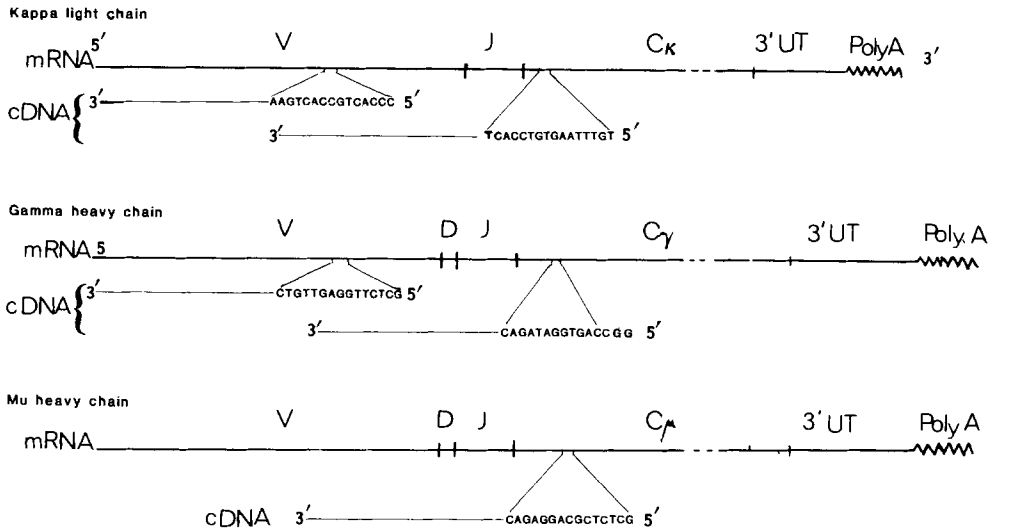

Fig. 11. mRNA sequencing strategy. Synthetic oligonucleotide primers designed to pair with defined bases within segments of mRNAs were used to initiate reverse transcription. Using dideoxynucleotides, specific stops in the cDNA can be generated and the nucleotide sequence determined by gel methods (taken from ref. [59]).

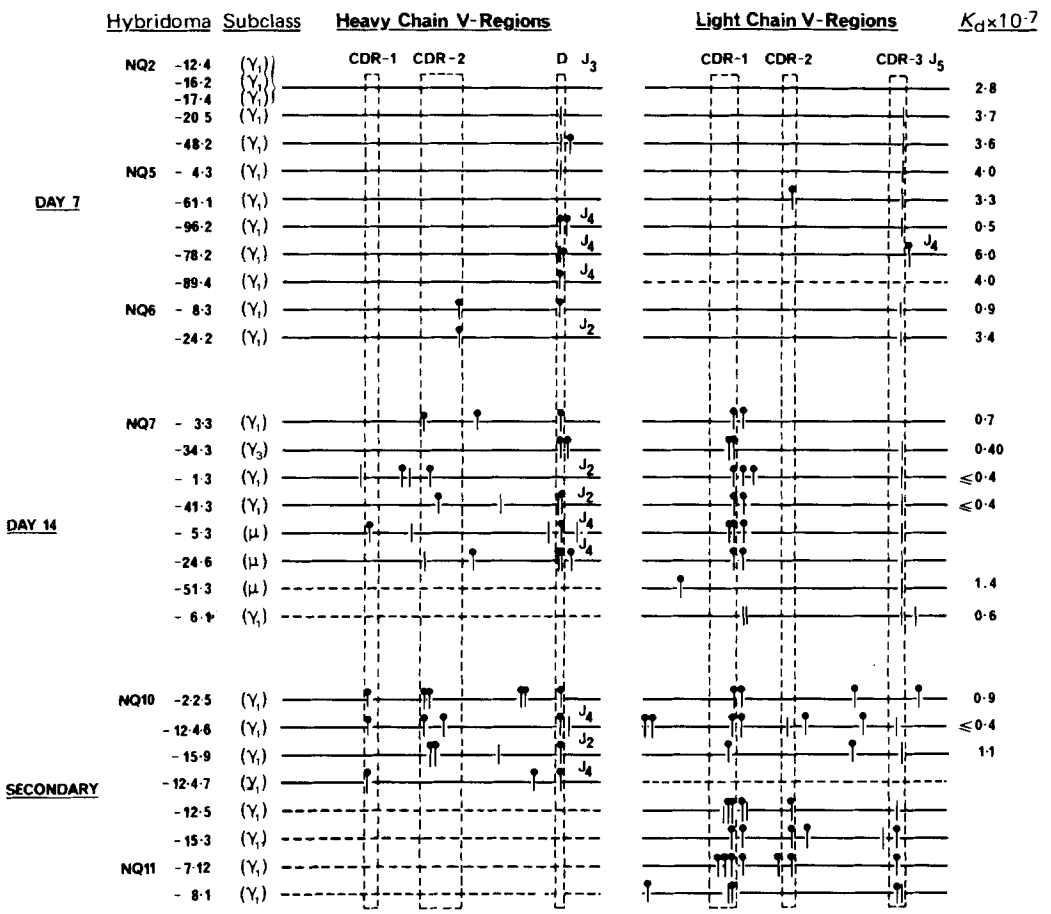

Fig. 12. Diagrammatic comparison of the mRNA sequences from anti-phOx-secreting hybridomas derived at different stages after immunization with Ox-CSA. Only sequences closely related to the prototype are shown. The variable region sequences of each hybridoma have been compared with the sequences of V_H-Oxl and V_k-Oxl, respectively. Unbroken horizontal lines denote identical sequences, broken lines represent extensive sequence differences. A black circle indicates that these changes predict an amino acid difference at this position. Complementary determining regions (CDR-1, -2, -3) have been marked as have the D and J regions. Where different J segments are observed these are represented accordingly. Dissociation constants determined hy fluorescence quenching (K_d) are shown on the right (taken from ref. [51]).

The antibodies obtained during the secondary response, expressing the germ-line gene combination characteristic of the primary response, show a further small increase in point mutations (Fig. 12). However, the most important feature of the secondary response is a shift towards other germ-line genes (see Table 4).

It appears therefore that the development and maturation of the immune response to oxazolone—which we take

Table 4. Expression of germ-line V-genes in the maturation of the response to oxazolone.

	V_HOxl-V_kOxl combination	Other combinations	V_HOxl-V_kOxl [%]
Day 7	11	4	73
Day 14	6	5	54
Secondary	4	18	18

as a model system—proceeds basically in three stages. In the first, the majority of the antibody reflects a very restricted choice from a vast repertoire of germ-line gene combinations, self-selected for their capacity to bind the antigen. In the second stage, cells expressing these combinations proliferate, and during this proliferation mutants arise which improve the affinity of the antibody for the antigen. In the third stage, as the first type of germ-line gene combinations and their mutants reach a certain limit of dissociation constants, new germ-line gene combinations and somatic mutants are selected for further improvements. Of course, the three stages are not absolutely separate and all three processes overlap to a certain extent. In many ways, the system behaves as a Darwinian system, where adaptation is an improvement in antigen binding. It remains to be seen to what extent other regulatory constraints are critical to the process.

From Monoclonal Antibodies to Antibody Engineering

The immortalization of antibody-producing cells not only allows the permanent supply of an antibody of a constant chemical structure but, more important, affords all the advantages that can be derived from the techniques of cell culture and somatic cell genetics. The most obvious is cell cloning, and this has been at the root of the explosion in the use of this technology. And yet the derivation of cell lines producing specific antibodies cannot go beyond the immortalization of what already exists. We select hybrids producing monoclonal antibodies of desired properties, but if the immunized animal does not make it, there is no way of immortalizing it. Fortunately we can go further.

Hybridomas are established cell lines and are therefore capable of other "in vitro" manipulations using somatic cell genetic and molecular engineering techniques. We are at the beginning of a new era of immunochemistry, namely, the production of "antibody based" molecules. The derivation of hybrid hybridomas is one example of the utilization of such methods for the biosynthesis of bi-specific antibodies.[36] Another example is the derivation of class switch mutant antibodies.[52]

Some years ago I discussed the eventual use of recombinant DNA techniques to make more drastic changes.[53] Recent developments have shown the feasibility and potential of the approach. Antibody genes have been put into suitable vectors, propagated, modified, and re-introduced into myeloma cells which will then secrete recombinant antibodies possessing novel properties. For instance, in my laboratory *Neuberger* has developed a cell line which secretes a mouse-human antibody molecule with a mouse anti-nitrophenacyl variable region and a human epsilon heavy chain constant region.[54] In another example, the Fc portion of the mouse antibody was replaced by staphylococcal nuclease.[55] A novel antibody was thus made which contains an antigen-specific Fab portion joined to an enzymatic effector function replacing the normal Fc portion.

More elaborate modifications will be made possible by the fast-developing techniques of site-directed mutagenesis. These will allow well-planned specific modifications of antibody combining sites. In this way we will be able to test the contribution of individual point mutations to the generation of high-affinity antibody during the process of the maturation of the response. This brings us back to the problems of the diversity of molecular recognition and the maturation of the immune response.

Exciting as these prospects are, they still require the basic starting genes taken from a hybridoma line. With them, we can introduce changes at the amino acid sequence level but with the exception of simple changes, the ultimate folding pattern and their effect on protein-ligand interaction cannot yet be reliably predicted. This will remain so for the time being. Total construction of antibody molecules to suit specific needs depends on a much better understanding of protein folding.

While selection is the strategy of the antibody response of an animal, the immunochemistry of the future will revert to an instructional approach where the antigen will tell us what antibody structure we should construct. Although this is not science fiction, we need to overcome the theoretical problems involved in the translation of one-dimensional reality into a valid three-dimensional prediction. Although the way ahead is full of pitfalls and difficulties, this is indeed an exhilarating prospect. There is no danger of a shortage of forthcoming excitement in the subject. Yet, as always, the highlights of tomorrow are the unpredictabilities of today.

The hybridoma technology was a by-product of basic research. Its success in practical applications is to a large extent the result of unexpected and unpredictable properties of the method. It thus represents another clear-cut example of the enormous practical impact of an investment in research which might not have been considered commercially worthwhile, or of immediate medical relevance. It resulted from esoteric speculations, for curiosity's sake, only motivated by a desire to understand nature. It is to the credit of the Medical Research Council in Britain to have fully appreciated the importance of basic research to advances in medicine. We are delighted to belong to the small, lucky group of those who are at the window-dressing end of the justification for the wisdom of that policy.

I learned what research was all about as a research student of Stoppani in Argentina, and then with Sanger in the Department of Biochemistry at Cambridge. I owe an enormous debt to the atmosphere of the Laboratory of Molecular Biology, where all the work I have described here was done, mostly under the Chairmanship of Max Perutz, and within the Division of Protein and Nucleic Acid Chemistry, of which Fred Sanger was the Head. From them, I always received an unspoken message which in my imagination I translated as "Do good experiments, and don't worry about the rest."

During my lecture I have tried to acknowledge those of my collaborators whose contributions were critical at specific stages of the work. In addition, so far unmentioned, is John Jarvis, my personal assistant for well over 20 years—only months less than my involvement with immunology. Since this prize mentions the discovery of the principles of the hybridoma technology, I would like to acknowledge specifically the importance of the contributions of Dick Cotton and David Secher, with whom preliminary work leading to that discovery was made, and my tissue culture assistant, Shirley Howe, who was directly involved not only in the preliminary work but also in some of the specific experiments conducted with Georges Kohler. I would also like to acknowledge other

collaborators who were concerned in our own contributions to the demonstration of the practical potential of the hybridoma technology in a variety of fields, particularly G. Galfré, A. R. Williams, and A. C. Cuello, and the technical assistance of Mr. B. W. Wright. The list of acknowledgements is certainly much longer, but I wouldn't like to end it without recording my indebtedness to my secretaries, Margaret Dowding and Judith Firth. Their handling of the press in the immediate period after the announcement of this prize ranks high among my memories of that exciting moment.

Derivation and Diversification of Monoclonal Antibodies (Nobel Lecture)**

By Georges Köhler*

A mouse can make ten million different antibodies, each synthesized by its own B-lymphocyte. About 1000 different antibodies are able to recognize one single antigenic determinant. When a conventional mouse response to such a determinant is analyzed, only 5–10 different antibody species are seen, representing probably a random sample of the total repertoire. So even when appropriate absorptions or allogenic immunizations have confined the antibody heterogeneity to one single determinant, the sera obtained have four disadvantages: (1) the titers are low, (2) the antibodies, while specific for a single determinant, are nevertheless heterogeneous, (3) the supply is limited, and (4) the same combination of specific antibodies is impossible to reproduce in a new animal.

The method of lymphocyte fusion developed together with *C. Milstein,* MRC, Cambridge (England), provides a tool to overcome these limitations (Fig. 1). Mouse myeloma tumor cells are fused to spleen cells derived from a mouse which previously had been immunized with antigen. About 50% of the hybrid cells combine the hoped for parental traits: vigorous growth in tissue culture derived from the myeloma tumor cell and antibody production coming from the splenic B cell. A relatively high proportion of the hybridoma cells secrete antibody specific to the immunizing antigen.[1,2]

The advantages of this technique are:

1) Single specificity. Each hybrid produces only one antibody.
2) Unlimited supply of antibody. The hybrids are immortal like tumor cells, can be frozen, secrete 10–50 μg/mL antibody into the culture fluid, and upon injection into mice produce titers as high as 1–10 mg antibody per mL body fluid.
3) Impure antigens lead to pure antibody reagents. The monoclonal antibody by definition characterizes only one antigen of the many injected into the mouse.
4) All specificities can be rescued. The empirical observation seems to be that if an immune response can be elicited in the mouse also specific hybridomas can be derived.
5) Enrichment of specific hybridomas. Specific B cells are rare even in the spleen cell population of an immunized mouse. They are found to be enriched 10–100 fold in the corresponding hybridoma population.
6) Dominance of antibody secretion. B-hybridomas secrete a high level of antibodies, irrespective of whether or not the normal B cell was a high producer.
7) Antibodies become manipulable. The hybridoma cell lines can be mutated to produce antibodies not found in nature.
8) It is a general method. The only generalization so far was to apply cell fusion for the rescue of T-cell functions, where T-hybridoma lines secreting different lymphokines and exerting killer function or helper and suppressor activities have been generated.

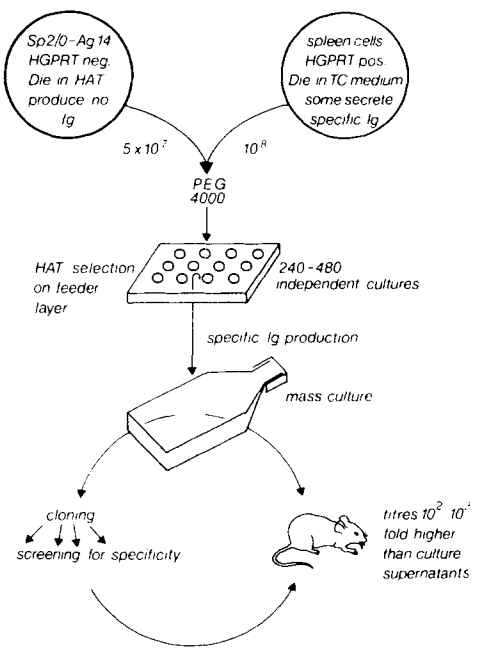

Fig. 1. The hybridoma technique. The fusion line Sp2/0-Ag14 comes itself from a hybridoma line and is devoid of endogenous immunoglobulin production [61]. HGPRT = hypoxanthine-guanine phosphoribosyltransferase, an enzyme necessary in DNA synthesis, when the normal pathway is blocked by aminopterin. HAT = hypoxanthine, aminopterin, thymidine [1, 62, 63]. PEG = polyethylene glycol.

Some selected applications are summarized in Table 1.

In the past, conventional sera have been used to define, purify, detect, quantify, map, modify, select, and localize antigen. Thus, with few exceptions,[18,19] the monoclonal antibodies have not led to applications unthought of previously. However, as pure chemicals of higher precision and unlimited supply, they are replacing the conventional sera and thereby contributing to a worldwide standardization of antibody-mediated reactions.

One of the great advantages of the hybridoma lines lies not only in the production of monoclonal antibodies but also in the availability of the machinery which produces

them. One can diversify a single antibody molecule by selecting mutant molecules, by introducing new immunoglobulin heavy and light chains, and by cloning and mutating its genes by "reverse genetics" techniques and reintroducing them into cell lines or into the germ line of a mouse.

Table 1. Uses of monoclonal antibodies.

Use	Application	Success, example	Ref.
to *define* antigen	- on bacteria	classification	[3]
	viruses	becomes easier	[4]
	parasites		[5]
	- on cells	11 human T-cell antigens established	[6]
		histocompatibility antigen typing	[7]
		tumor antigens	[8, 11]
purify	- factors, hormones	5000-fold enrichment of interferon	[9]
	- cell membrane	200-fold enrichment of Ia antigen of rat	[10]
detect and *quantify*	- in crude mixtures	human chorionic-gonadotropin in pregnancy tests	[11]
map	- epitope characterization	7 determinants on mouse μ chain (constant region)	[12]
modify	- infectivity	sporozoite of *Plasmodium berghei*	[13]
	- toxicity	digoxin overdose	[14]
	- function	αLy2 suppresses T-cell killing	[15]
	- immunogenicity	α Rhesus factor	[16]
select	- α idiotype	enhancement and suppression of anti-NP immune response	[17]
	- mutations	histocompatibility antigen	[18]
		influenza A virus	[19]
localize	- in organs	nervous system of leech	[20]
	- in body	tumor imaging in humans	[21]

The variants give some insights into the structure-function relationships of immunoglobulin proteins, their RNA, and genes. The analysis of variants has also led to a more speculative hypothesis about the interaction of H and L chains in multigene families.

Diversification of Monoclonal Antibodies

Many investigators have generated variant forms of monoclonal antibodies (Table 2), with perhaps more interesting properties than the ones I will describe here. But this is a somewhat personal account of this development, and not meant to be a review. It is focused, where possible, on experiments using one hybridoma cell line, Sp6/HLGK. The line is derived from a Balb/c mouse immunized with trinitrophenyl-lipopolysaccharide (TNP-LPS). It secretes an immunoglobulin mu heavy chain associated with a kappa light chain of anti-TNP specificity (designated HL in Sp6 and equivalent hybridomas) together with a gamma and kappa chain derived from the fusion myeloma line X63-Ag8 (designated GK in Sp6 and equivalent hybridomas).[2]

Table 2. Mutations and alterations in cell lines producing monoclonal antibodies.

Selection	Mutation/alteration	Frequency	Ref.
loss of isotype	loss of H- or L-chain	$1/10^2$	[22]
	domain deletions	$1/10^3$	[23, 24]
	loss of λ-chain secretion due to point mutation	$>1/10^4$	[25, 26]
change in isoelectric focusing (IEF)	domain deletions frameshift, point mutation	$1/10^3$	[27]
cell sorter, positive selection for different isotype	change of isotype often associated with deletions	$\approx 1/10^5$-$1/10^7$	[28–30]
loss of idiotype, loss and gain of antigen binding	possible gene conversion point mutations	$1/10^2$-$1/10^3$	[31–33]
loss of lytic activity	deletions, frameshifts insertions	$1/10^3$-$1/10^4$	[34–36]
reverse genetics	chimaeric antibodies V_H-C_α		[37, 38]
	V_{mouse}-C_{human}		[39, 40]
	antibody-enzyme		[41]
secondary hybrids	monovalent antibodies		[41a]
	two specificities		[41b]
	complementation of specificity		[49]

Immunoglobulin Chain-Loss Variants Lead to the Heavy-Chain Toxicity Hypothesis

The first hybridomas all produced two immunoglobulins, the specific lymphocyte-derived one and the myeloma-derived one, and were therefore, like Sp6, of the HLGK-type. To obtain pure specific antibodies, sublines were selected which had lost the production of the nonspecific G and K chains of the myeloma fusion partner.[2,42] It was observed that heavy chains are more easily lost than light chains. The sequence of chain loss as exemplified with Sp6 was Sp6/HLGK→Sp6/HLK→Sp6/HL and not Sp6/HLGK→Sp6/HLG→Sp6/HL. This was reminiscent of results of *Coffino* and *Scharff*,[22,43] who, using the myeloma line MPC11, found that H-chain loss was observed at a rate of $1\text{-}2\times10^{-3}$ per cell and generation but L-chain loss was not observed even at a 100 times lower rate. After H-chain loss, however, L chains were lost at a rate similar to H chains.

To test the generality of the observation, a series of hybridoma lines were established making three, two, and one antibody and their chain-loss variants were monitored (Table 3[42]). L-chain loss was inhibited with increasing sever-

Table 3. H-Chain toxicity.

3H+3L	⟶	2H+3L / 3H+2L	≈ 2/1
2H+2L	⟶	1H+2L / 2H+1L	≈ 8/1
1H+1L	⟶	0H+1L / 1H+0L	≳ 100/1

2H+3L, 1H+2L, 0H+1L } L-loss as frequent as H-loss

ity only in those combinations resulting in an increasing excess of H-chain production. It is concluded that heavy chains not counterbalanced by enough light chains are toxic for the cells. Excess H-chain producers have a growth disadvantage and cannot be cloned out from the cell population. Additional support for the H-chain toxicity hypothesis came from the analysis of Sp6 variants. A subline (Sp6/HLk) was derived producing a variant K chain, which combined less efficiently with the H chain (this property is symbolized by the lower k in Sp6/HLk). The Sp6/HLk line lost L at a 1000 times lower frequency than the original Sp6/HLK line.[34,42] We concluded that the variant k could not substitute for the parental K chain to avoid toxic accumulation of free H chain. We have cloned the H- and L-chain genes of Sp6 and reintroduced them separately or physically linked into the Ig non-producing myeloma line X63Ag8.6.5.3 (Table 4). If production of free heavy chain is toxic for the cell, we would expect that μ-alone transformants are selected which produce lower amounts of μ when compared to (μ and κ) transformants. A 5- to 13-fold difference was observed between these two groups of transformants. On average, about 100 times less μ RNA or protein is found in the μ-alone transformants. This low amount is comparable to the amount of μ alone found in pre-B cells[44] and may no longer be toxic for the cells. In proteins consisting of two different subunits such as H and L in immunoglobulins, often one chain is produced in excess (L chains in Ig-producing cells). Potentially toxic effects of free light but not free heavy chains will therefore be selected against. In the multigene Ig-family with about 5000–10000 H and 250 L chains, elimination of cells producing H-L pairs with too low affinities to form antibody molecules may be an important control mechanism.

Table 4. Expression of cloned Sp6 μ and κ genes in X63Ag8.6.5.3 B-myeloma cells [a].

Gene	DNA Copy Number	RNA (% of Sp6 parent)		Protein (% of Sp6 parent)	
		μ	κ	μ	κ
κ	50 (41)	—	62 (10)	—	50 (4)
μ	7 (8)	1.3 (9)	—	1 (9)	—
μ+κ	5 (11)	6 (8)	4 (8)	13 (12)	13 (12)
$\frac{\mu+\kappa}{\mu}$	≈1	5		13	

[a] Data from *J. McCubrey*, unpublished. In parenthesis: the number of stable transformants analyzed.

Somatic mutants of H and L chains dominate late immune responses.[45,46] It is conceivable that mutations occurring in the variable regions of low-affinity H and L pairs enhance their pairing affinity. Such cells avoid elimination caused by free H-chain toxicity and contribute to the somatic diversification of antibody molecules. Scaling up Ig production or switching Ig-classes may induce new rounds of selections (Fig. 2). Preferential association of original H-L pairs in competition experiments[47,48] are easily explained by this intracellular selection mechanism.

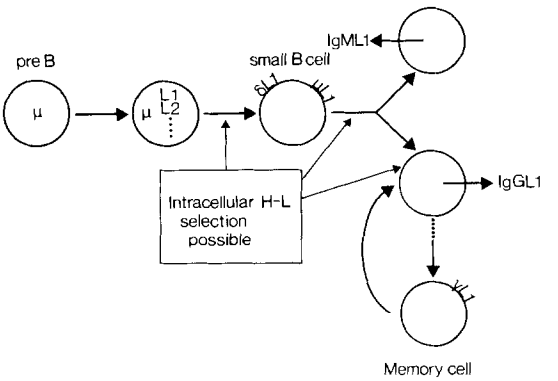

Fig. 2. Schematic representation of B-cell development. The points at which increased production of heavy chains or production of different heavy-chain isotypes might become toxic for the cells are indicated. Variable region mutations increasing heavy(H)- and light(L)-chain pairing affinities may avoid toxicity of free heavy chains and be enriched.

Arrays of Antibodies with One Specificity Generated by Secondary Fusions

The Sp6/HK and Sp6/LK lines (chain-loss derivatives of Sp6/HLGK) are no longer producing antibodies with anti-TNP specificity (a property confined to the HL combination). Both lines were fused to unimmunized mouse spleen cells stimulated for four days with the mitogen lipopolysaccharide. The resulting hybrids were screened for restoration of the original anti-TNP specificity.[49] In about every 100th hybridoma the anti-TNP activity of the Sp6/HK line was restored. In about every 2000th hybridoma the anti-TNP activity of the Sp6/LK line was restored, which was indistinguishable from values obtained with the line Sp2/0, which does not contribute any Ig chain. The generality of this observation was confirmed by using three other pairs of hybridomas of the HK- or L-type, with similar results. The HK-lines could easily be complemented, the L-lines gave "background" complementation. From these experiments the following conclusions were drawn:[49]

1) Around 40 light-chain variable-region genes contribute to the light-chain repertoire of the mouse.
2) Around 250 different light chains are found in unstimulated spleen cells, due to the combination of 40 V-region genes with 4 J (joining) segments and their early somatic diversification.
3) About 20–40 fold more heavy than light chains are expressed in early, unstimulated spleen lymphocytes.
4) A statistical analysis of the data leads to the generalization, that, could one screen through all heavy chains with a given light chain, one would find any given antibody specificity. Could one screen through all light chains with a given heavy chain, a given antibody specificity would only be found in every 20th case.

The above points have to be considered with caution, since they are based on limited numbers of hybridomas. Nevertheless, I think hybridomas have opened a new way to analyze the problem of antibody diversity, by analyzing H and L chains separately, thereby avoiding the enormous

heterogeneity created by the combination of heavy and light chains in antibody molecules. The Sp6 line has been diversified to 10 different sublines, each of which makes a different light chain, which together with the Sp6 heavy chain gives rise to the original anti-TNP specificity. Such lines will provide insights into the heavy- and light-chain variable-region interactions necessary to create a given antigenic combining site. A more practical aspect of such secondary arrays of antibodies with one specificity would be the isolation of low-affinity antibodies, which for certain antigen purification procedures may be advantageous.

Diversification by Mutant Selection

We have studied mutants of the Sp6 and PC 700 (IgM anti-phosphorylcholine (PC)) line. The selection method was simple. The hapten TNP or PC was covalently attached to the membranes of the cells. The cells were diluted and incubated in the presence of complement. Cells secreting wild type IgM preferentially bind their own antibody and are killed. Cells secreting less or less lytic IgM are enriched. Three to four selection rounds lead to an almost "pure" mutant-cell population. Table 5 summarizes

Table 5. Mutations affecting Sp6 immunoglobulin M.

Defect	Number	Description	Ref.
not determined, possibly point-mutations	2	10-fold lower affinity 200-fold reduced lytic activity	[34]
insertion	2	loss of L production or reduced L production	[36]
deletion	4	loss of Cμ1, Cμ2, Cμ3 [a]	[35]
frameshift	16	loss of *C*-terminal portions	[50]

[a] Found in the PC 700 system [52] only.

the mutants so far characterized for the Sp6 line. The deletion variants were used to map a panel of monoclonal antibodies.[12] Figure 3 shows the IgM structure of some of the deletion variants and the mapping of monoclonal antibodies to each of the five μ-domains. The monoclonal antibodies against eight-defined, non-cross-reacting determinants of mouse μ chains were used to define new IgM variants,[50] to map C1q binding to the area of binding of C2-23 monoclonal antibody (ref. [38], unpublished) and to define the quaternary structure of some of the IgM-mutants.[12]

Diversification by Reverse Genetics

The light-chain gene of Sp6 has been cloned and sequenced.[36] The Sp6 heavy-chain variable-region gene was placed into the V_κ-C_κ intron using the HindIII and XbaI restriction sites. After transfection into the X63Ag8.6.5.3 (X63/0) myeloma line,[51] a V_μ-C_κ chimaeric protein was revealed (Fig. 4). Fusing this line to Sp6/L (igm10) resulted in hybrids producing covalently linked dimers containing the V_κ-C_κ and the chimaeric V_μ-C_κ chain. Binding of the heavy-chain-dependent anti-idiotypic antibody 20-5

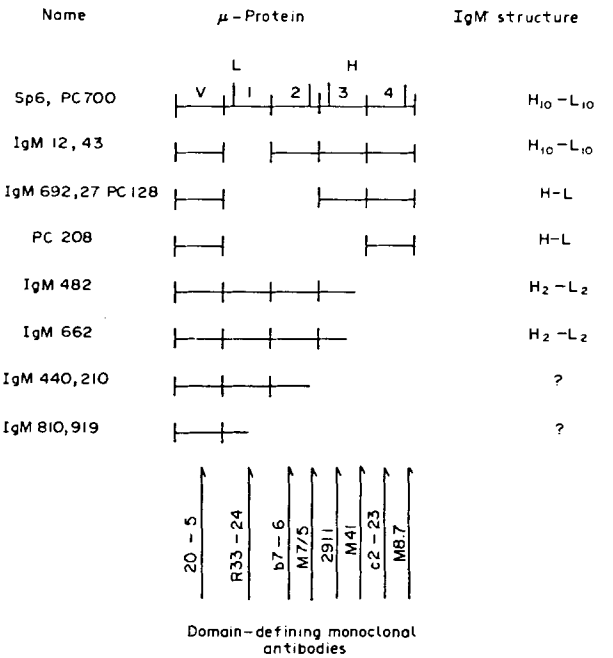

Fig. 3. Deletions in mouse μ chains. The wild-type μ-protein (Sp6 and PC700) is drawn in its domain structure and disulfide bridges to the light (L) or heavy (H) chains are indicated. The light chain of igm 12 and igm 43 is not covalently bound to μ, whereas it is in all other mutants with known IgM structure. The monoclonal rat anti-mouse μ-antibodies were selected from about 20 antibodies and define independent binding sites. The line 20-5 makes a mouse anti-idiotypic antibody reacting with Sp6 but not PC 700 IgM.

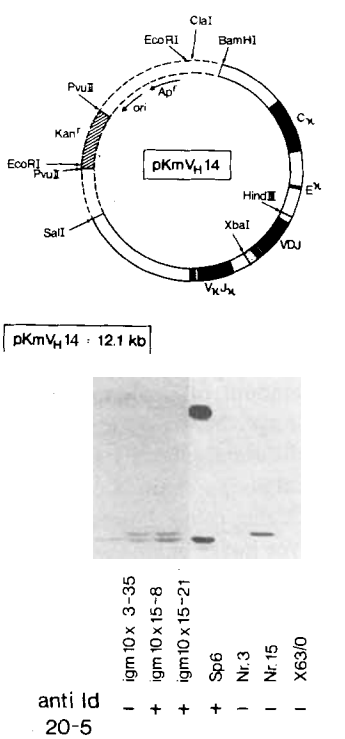

Fig. 4. Production of chimaeric antibodies. Top: The plasmid pK_mV_H14 carries the kanamycin-resistance gene (shaded), pBR322 sequences (dashed), and an insert of the Sp6 kappa gene from the BamHI to the SalI restriction sites. The Sp6 variable heavy-chain gene (VDJ) was inserted into the XbaI and the Hind3 restriction sites in front of the kappa enhancer element (E^κ). Bottom: SDS-gel electrophoreses under reducing conditions of products formed after transfection of pK_mV_H14 plasmid into X63/0 myeloma cells. Stably transformed lines No. 3 and No. 15 show a band with slightly slower mobility than the Sp6 light chain. Light-chain- and pK_mV_H14-directed production of V_HC_κ in (No. 15 × igm 10) hybrids 8 and 21 is observed. Only in these hybrids is the heavy-chain-dependent idiotype 20-5 restored.

was restored in these dimers. We could not measure antigen binding activity, because of the low anti-TNP affinity of the Sp6/IgM (10^{-4} M[34]). A similar chimaeric protein with antigen binding for arsonyl was however described.[37] Small, antigen-binding molecules lacking the heavy-chain constant-region determinants might be useful when only one binding site is required (to avoid modulation of cell surface antigens), and when a smaller molecule with fewer non-specific interactions (via Fc-receptors) and possibly a higher elimination rate is needed. Also such molecules might be less immunogenic. Since most therapeutically interesting antibodies are of mouse origin, the construction of chimaeric antibodies using human constant regions and mouse variable regions would be a solution, avoiding immunogenicity but keeping effector functions of the antibody. That this is possible has recently been shown with the Sp6 IgM.[39] The mouse heavy- and light-chain variable regions were placed in front of human μ- and κ-constant regions, respectively. Mouse-human chimaeric IgM was recovered from supernatants of a plasmid-carrying myeloma line. The IgM was pentameric and functional in terms of being able to lyse TNP-coupled sheep erythrocytes.

The Transgenic Mouse Model

So far three groups have introduced rearranged immunoglobulin genes into the germ line of the mouse. A μ and a κ gene alone as well as a combination of both genes derived from the Sp6 line have been used (Table 6).

Table 6. Immunoglobulin genes introduced into mouse germ line cells.

Gene (specificity)	Molecules injected	Zygotes implanted	Offspring (with transgene)	Number of copies per genome	Gene in germ line	Ref.
μ (NP)	50	284	13 (5)	17–140	3	[53]
κ_{21} (?)	440	197	11 (6)	20–200	6	[54–56]
μ, κ (TNP)	50	13	5 (1)	4	1	[57]

In the Sp6 case about 50 molecules of the heavy- and light-chain genes both cloned into a pBR322 plasmid vector ($pRHL_{TNP}$) were injected into fertilized eggs from Swiss albino mice. From 13 implanted zygotes, 5 offspring mice were obtained, one of them carrying the gene. Analysis of the germ-line transmission pattern indicated integration of 4 copies of the $pRHL_{TNP}$ plasmid into one autosomal chromosome.

Expression of Trans-Immunoglobulins

In all cases, along with germ-line transmission of the immunoglobulin genes, also expression of the respective chains was observed. Expression of κ_{21} chains was confined to the B-cell lineage excluding Abelson-virus-transformed pre-B cell lines.[65] Expression of μ_{NP} chains was observed in B- and in T-cells.[53] Other tissues, like kidney, brain, heart, lung and liver, did not transcribe the genes. By fluorescence analysis, the Sp6 μ_6 and κ_6 chains were expressed on the membrane of B- but not T-cells, although the μ_6 chain (κ_6 was not testable) was expressed in around one-quarter of Con-A-stimulated, splenic T cells. The Sp6 immunoglobulin was found as pentameric, functional IgM in the sera of the transgenic mice where it represented around one-fifth to one-third of the total IgM. It will be interesting to see whether such massive production of one specificity induces changes in idiotypic network interactions. Introducing antibodies with anti-self specificities into the germ line of the mouse may give some insight into how self-tolerance is achieved at the B-cell level. With the genes introduced so far, another immunological question, the one of allelic exclusion, was analyzed. How is it possible that B cells produce heavy and light chains from only one of the two homologous chromosomes, a prerequisite of effective clonal selection?

Influence of Transgenic μ and κ Chains on Allelic Exclusion

In order to create a functional heavy-chain gene, three spatially separated DNA segments, the variable region, the diversity, and the joining (V, D, J_H) segments have to juxtapose. To create a functional light-chain gene, a V_L and a J_L segment have to join. In roughly one-quarter of the B cells, allelic exclusion is achieved by having functionally rearranged VDJ_H^+ and VJ_L^+ units in one allele and non-functionally rearranged VDJ_H^- and VJ_L^- units in the other allele, which due to mistakes during the joining process are unable to produce the respective chains. In about 75% of the B cells, either the heavy- or the light-chain variable region or both have not been completely rearranged. In order to explain this finding a regulatory feedback mechanism of the immunoglobulin chains on the rearrangement process was postulated.[58]

To study the effect of rearranged and expressed immunoglobulin transgenes on the rearrangement process of endogenous Ig genes, a series of B-cell hybridomas were made and their endogenous heavy- and light-chain expression monitored. In Table 7 our results and those obtained from transgenic mice carrying a rearranged kappa gene

Table 7. Allelic exclusion in trans hybridomas.

κ_{21} [56]:	24 Hybrids			
	11	$H_{\kappa_{21}}$ - (germ line) [a]		
	2	H–L		
	7	$-\kappa_{21}$L		
	2	$-\kappa_{21}$ - (germ line) [a]		
	2	$-\kappa_{21}$ - (rearranged) [a]		
$\mu_6\kappa_6$ [57]:	11 Hybrids			
	3	$\mu_6\kappa_6$–HL		
	8	$\mu_6\kappa_6$–L [b]		
5 lines still have both H-encoding chromosomes	⟶ 10 alleles:	VDJ⁻	DJ	germ line
		1	8	1

[a] H = endogenous heavy chain; L = endogenous light chain; in parenthesis, light-chain gene configuration. [b] Heavy-chain gene configuration of 5 of the 8 H-minus hybrids is shown.

alone[56,57] are summarized (results from the μ-alone transgenic mice are not yet available). Of 24 hybridomas derived from κ_{21} transgenic mice, none expressed a heavy

chain with two light chains. In seven cases where no heavy chain production is observed, two light chains, the endogeneous and the transgenic one are expressed. These results are compatible with a negative feedback mechanism of H-L molecules on the light-chain gene rearranging process.

Expressing the transgenic μ_6 and κ_6 chains should therefore inhibit endogeneous light-chain gene rearrangement, which in none of the eleven hybridomas was observed. However, the trans-κ_6 chain was expressed at one-tenth the level of the endogeneous light chains whereas the μ_6 chain was made in excess. Thus, low amounts of μ_6-κ_6 molecules in an excess of free μ_6 chains are not a feedback signal to stop light-chain gene rearrangement. This observation is well in agreement with the exceptional light-chain double producers found in myeloma cell lines such as S107 where one of the kappa light chains was unable to combine with the alpha heavy chain,[59] or such as in the MOPC315 line where a truncated λ_1 chain unable to bind to its heavy chain is found together with a functional λ_2 light chain.[60] A high proportion (8/11) of hybridomas derived from the $\mu_6\kappa_6$-expressing mouse did not express a second endogenous heavy chain. Five of these lines still retained both heavy-chain-encoding chromosomes. Only in one of the ten heavy-chain alleles was a complete (though inactive) VDJ_H^- unit found. One allele apparently was frozen in the germ-line configuration and eight stopped rearrangement at the immature DJ_H state. Thus again, the result is compatible with a (leaky) feedback regulation of the heavy-chain gene rearrangement process by the mu chain itself. Whether also the light chains are involved in this process has to be clarified by analyzing pre-B cell lines. Other interpretations, however, such as different cellular selection processes in transgenic versus normal mice are possible. Nevertheless, the power of the transgene approach to study immunological phenomena is clearly demonstrated.

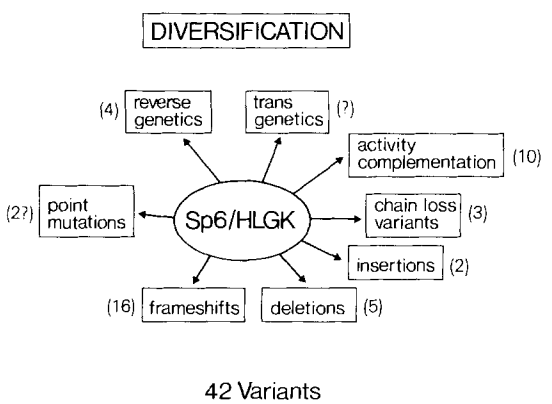

Fig. 5. Summary of Sp6 variants.

Let me now go back to the general theme of this paper and ask whether or not diversification of our Sp6 antibody could be achieved by having introduced its genes into the mouse. At the moment one can only speculate. A somatic mutation mechanism operates on immunoglobulin light- and heavy-chain genes at an approximate rate of 10^{-3} per base and generation.[45,46] It seems possible that the introduced genes will profit from this mechanism and that we will generate a whole series of somatically mutated Sp6 IgM molecules. Figure 5 summarizes the variants obtained so far from the Sp6 line using different techniques and underlines my belief that a single monoclonal antibody will only be the starting point of a variety of man-made secondary antibodies, each manufactured to fulfill a special requirement.

Dinuclear Complexes with Predictable Magnetic Properties

By Olivier Kahn*

When two paramagnetic transition metal ions are present in the same molecular entity, the magnetic properties can be totally different from the sum of the magnetic properties of each ion surrounded by its nearest neighbors. These new properties depend on the nature and the magnitude of the interaction between the metal ions through the bridging ligands. If both ions have an unpaired electron (e.g. Cu^{2+} ions), then the molecular state of lowest energy is either a spin singlet or a spin triplet. In the former case, the interaction is said to be antiferromagnetic, in the latter case ferromagnetic. The nature and the order of magnitude of the interaction can be engineered by judiciously choosing the interacting metal ions and the bridging and terminal ligands, and, thus, by the symmetry and the delocalization of the orbitals centered on the metal ions and occupied by the unpaired electrons (magnetic orbitals). The first success in this "molecular engineering" of bimetallic compounds was in the synthesis of a $Cu^{2+}VO^{2+}$ heterobimetallic complex in which the interaction is purely ferromagnetic. The same strategy could be utilized for designing molecular ferromagnets, one of the major challenges in the area of molecular materials. Another striking result is the possibility of tuning the magnitude of the interaction through a given bridging network by modifying the nature of the terminal ligands, which, in some way, play the role of "adjusting screws". By careful selection of the bridging and terminal ligands, a very large antiferromagnetic interaction can be achieved, even if the metal ions are far away from each other. Some sulfur-containing bridges are especially suitable in this respect.

1. Introduction

Since the beginning of this century, and following the pioneering work of *Werner*, an enormous amount of relevant information has been collected concerning the physical and chemical properties of transition metal complexes. In particular, the magnetic properties of these systems have been well documented, and are rather well understood today.[1-7] In this respect, the main points deserving attention are the following:

(1) When all the thermally populated states are spin and orbital singlets, the complex is diamagnetic with temperature-independent, weakly negative magnetic susceptibility. When one of these states has an angular momentum, the complex is paramagnetic. Its magnetic susceptibility is positive and generally increases upon cooling.

(2) When the ground state has a spin momentum S without first order orbital momentum and is largely separated in energy from the first excited states, the molar magnetic susceptibility, χ_M, follows the Curie law, except perhaps at very low temperature.

$$\chi_M = (N\beta^2 g^2/3kT)S(S+1) \quad (1)$$

In Equation (1), N is the Avogadro number, β the Bohr magneton, k the Boltzmann constant, and g the Zeemann factor. χ_M is almost always very weakly anisotropic. Thus, for example, all the monomeric copper(II) complexes obey the relationship given in Equation (1), with $S=1/2$; indeed, Cu^{2+}, with d^9 configuration, has one unpaired electron. When S is larger than 1/2, at very low temperature, χ_M may substantially deviate from the values given by Equation (1) and become anisotropic owing to the zero field splitting of the magnetic ground state. This is the case, for instance, for octahedral nickel(II) complexes.[8]

(3) When the ground state has an orbital momentum or is close in energy to a state with an orbital momentum, the magnetic susceptibility no longer obeys the Curie law (1) and may be strongly anisotropic. This occurs, for instance, in the case of octahedral cobalt(II) complexes with $^4T_{1g}$ ground state.

(4) Finally, in the case of some complexes with ions like Fe^{2+}, Fe^{3+}, or Co^{2+}, the ground state may be either high spin or low spin or even may undergo high spin-low spin transitions.[9] This is the only case where the magnetic behavior of a monomeric complex of known structure cannot be estimated a priori. A small modification of the environment of a given ion may drastically modify the magnetic properties.[10]

To summarize, one can say that so far as the magnetic properties of isolated monomeric complexes are concerned, the only problem deserving new thorough investigation is that of high spin-low spin duality.

For one or two decades, the inorganic chemist has been more and more interested in polynuclear compounds. When the metal ions are not isolated from one another, these systems can acquire new physical properties or a new reactivity. Thus, the magnetic properties of a polynuclear complex are, in general, totally different from the sum of the magnetic properties of each metal center surrounded by its nearest neighbors.[11-12] It was for a long time consid-

[*] Prof. Dr. O. Kahn

Unité Associée au C.N.R.S. n 420, Université de Paris Sud
F-91405 Orsay (France)

ered impossible to estimate a priori the magnetic properties of a polynuclear complex, since such complexes can be extremely sensitive to very small structural modifications. The main aim of this review article is to present evidence of the fact that the situation is quite different today. It is possible, from a small number of basic concepts, to predict the nature of the transition ions and of the terminal and bridging ligands which must be utilized and the whole geometry which has to be achieved in order to obtain compounds with certain magnetic properties. In other words, we are attempting to lay the foundations of a molecular engineering of magnetic polynuclear systems.[12-13]

The studies on magnetic polynuclear complexes started in 1952, when *Bleaney* and *Bowers* demonstrated that the magnetic and ESR properties of copper(II) acetate were due to the dimeric nature of the molecule.[14] These authors established a theoretical expression for the magnetic susceptibility of such a system as a function of the temperature and the energy parameter J characterizing the interaction between the Cu^{2+} ions inside the same molecular entity (see Section 2). By the end of the sixties, numerous polynuclear complexes had been synthesized, whose parameters J were determined by comparing the observed magnetic data with the theoretical laws.[15-17] More and more researchers then attempted to rationalize the sign and the value of J in the light of structural data. This allowed correlations between structural and magnetic properties to be made, and constituted quite an important step toward an understanding of the mechanism of interaction between metal centers.[12] The most elegant of these correlations was established by *Hatfield* and *Hodgson* who showed that the magnitude of the interaction in planar dihydroxo-bridged copper(II) dimeric complexes depends on the CuOCu bridging angle.[18-19] Other correlations concerning di-μ-chlorocopper(II) dimers[20-22] and di-μ-hydroxochromium(III) dimers[23-25] were also established. Despite their undoubted interest, however, such correlations cannot be regarded as actual contributions to the molecular engineering mentioned above. Indeed, except maybe in very few cases, it seems extremely difficult to control the value of the structural parameters during the synthetic process. Thus, in di-μ-hydroxocopper(II) dimers,[18] the value of the CuOCu angle, which plays a key role regarding the sign and value of J, depends in an almost unforeseeable fashion on the terminal ligands and on the counterion. Our first attempt to synthesize a new complex exhibiting definite magnetic properties dates back to the late seventies when we prepared a $Cu^{2+}VO^{2+}$ bimetallic complex in which the interaction is purely ferromagnetic (see Section 4).[26,27] The present paper is divided up as follows: In the next section, we shall recall very briefly the basic principles of the electronic structure and the magnetic properties of polynuclear complexes, then we shall present some fundamental concepts concerning the mechanism of the interactions. In some way, these concepts are our tools for designing new systems having desired magnetic properties. Then, in the sections to follow, we shall present several examples selected from the work carried out in our group. Namely, we shall outline the strategy leading to a purely ferromagnetic interaction. This outline will be kept rather brief since this facet of our work has already been reviewed elsewhere.[28] We shall then focus our attention on bimetallic complexes with bisbidentate extended ligands. The first ab initio calculations concerning complexes of this kind will also be presented. Finally, we shall give some insights into the ESR spectroscopic properties of this class of compounds before discussing the vast perspectives of this area of coupled systems.

This review has been written with the hope that it will be read by a large audience of chemists, and not just by those who are already active in this field. Accordingly, the reader does not need to have any previous knowledge of the subject. All the concepts and formulas used will be explained in detail.

The electronic structure of the coupled polynuclear systems has attracted the attention of a very large number of research workers.[12] The main reason is probably that the phenomenon of interaction between metal centers lies at the crossover point of two widely separated areas, namely the physics of the magnetic materials and the role of polynuclear reaction sites in biological processes.[29] This paper is intended to convince the reader that there are still many activities in this field and that important new developments may be expected in the near future.

2. Electronic Structure and Magnetic Properties of Dinuclear Complexes

Let us consider the simplest case of a dinuclear copper(II) complex, denoted A-B, having spins $S_A = S_B = 1/2$. The interaction between the metal centers gives rise to a molecular spin singlet ($S = 0$) and a molecular spin triplet ($S = 1$) with a singlet-triplet (S-T) energy gap, conventionally denoted by J. When the ground state is the singlet state ($J < 0$), the interaction is said to be antiferromagnetic. When the triplet state is the lowest ($J > 0$), the interaction is said to be ferromagnetic. The situation concerning the triplet state is, however, more complicated owing to the second order spin-orbit coupling. The three components of the $S = 1$ state may be split in the zero field, so that the spectrum of the low lying states in A-B is as shown in Figure 1, where the effects are arranged according to decreasing magnitude.

Generally, the absolute value of J is much larger than D and E and the spectrum in Figure 1 may be described in

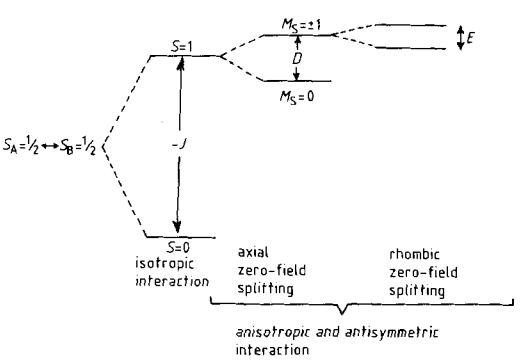

Fig. 1. Spectrum of the low lying states in a dinuclear copper(II) complex A-B.

quite a simple form by the Hamiltonian operator [Eq. (2)], in which only the local spin operators $\hat{S}_A$ and $\hat{S}_B$ occur:[30,31]

$$\mathcal{H} = -J\hat{S}_A \cdot \hat{S}_B + \hat{S}_A \cdot D \cdot \hat{S}_B + \vec{d} \cdot \hat{S}_A \cdot \hat{S}_B \quad (2)$$

J is a scalar, D a tensor, and $\vec{d}$ a vector. The first term in Equation (2) leads to the S-T splitting, the second term splits the triplet state, and the last term, which vanishes when the complex is symmetrical, couples the singlet and triplet states. This Hamiltonian operator is easy to handle; however, it does not provide any information about the mechanism of the phenomenon. Indeed, the first term, J, is related to the electrostatic interactions between the electrons of the system. Therefore, the only way to obtain information on the mechanism of the interaction is to work with the original electrostatic Hamiltonian (cf. next section).

We now want to establish the theoretical expression for the molar magnetic susceptibility of A-B. In a magnetic field H, one mole of any compound acquires a molar magnetic moment M_M given by

$$M_M = \chi_M H \quad (3)$$

where χ_M is the molar magnetic susceptibility. In classical mechanics, the magnetic moment is related to the free energy of the system by

$$M = -\partial E/\partial H \quad (4)$$

The expression for one mole of a quantized system with discrete energy levels changes to

$$M = \frac{N \sum_n (-\partial E_n/\partial H) \exp(-E_n/kT)}{\sum_n \exp(-E_n/kT)} \quad (5)$$

with summation over all thermally populated states. In A-B, n is 4 and the E_n's are:

$$E_1 = -g\beta H; \quad E_2 = 0; \quad E_3 = g\beta H; \quad E_4 = J \quad (6)$$

where E_1-E_3 refer to the triplet state taken as origin and E_4 to the singlet state. D and E have been neglected with regard to J. Substituting Equation (6) in Equation (5) gives[14]

$$\chi_M = \frac{2N\beta^2 g^2}{kT} [3 + \exp(-J/kT)]^{-1} \quad (7)$$

if we assume that H/kT is small. When the complex A-B is dissymmetrical, a very small additional term arising from the coupling of the $M_S = 0$ components of the singlet and the triplet occurs in the expression of χ_M.[28,32] This term is negligible when $|J|$ is larger than a few wave numbers. In the case of antiferromagnetic interaction, χ_M exhibits a maximum on changing the temperature T. The smaller the maximum susceptibility and the further this maximum is displaced toward high temperatures, the larger is the stabilization of the singlet state. In the case of ferromagnetic interaction, χ_M increases upon cooling down faster than $1/T$. The best way to demonstrate a ferromagnetic interaction is to plot the product $\chi_M T$ versus T.[33,34] For $J = 0$, $\chi_M T$ is constant and equal to $N\beta^2 g^2/2k$. For $J < 0$, $\chi_M T$ decreases upon cooling and tends to zero (or more exactly toward a value close to zero, owing to the presence of monomeric impurities). For $J > 0$, $\chi_M T$ increases upon cooling and reaches a plateau with $\chi_M T = 2N\beta^2 g^2/3k$, corresponding to the temperature range where only the ground triplet state is populated. At very low temperature, say below 10 K, $\chi_M T$ can deviate from this plateau owing to very small effects like zero field splitting of the ground state or intermolecular interactions, which, in most cases, couple the molecular triplet states in an antiferromagnetic fashion.[35] Moreover, whatever care is taken in the purification of the samples, a coupled dinuclear complex always contains a small amount ρ of uncoupled species, the magnetic susceptibility of which obeys the Curie law. This uncoupled species may be either an actual monomeric impurity, or merely defects at the surface of the microcrystallites. To account for this effect, the experimental susceptibility χ_M^{exp} is expressed as

$$\chi_M^{exp} = \chi_M(1-\rho) + \rho \cdot C/T \quad (8)$$

where C is the Curie constant of the uncoupled species. J is then determined by least squares fitting of the experimental data. Actual examples of ferromagnetic or antiferromagnetic behavior will be given in Sections 4–8.

3. Basic Concepts

Let us consider again the dinuclear copper(II) complex A-B where A (or B) now symbolizes one of the metal ions surrounded by its ligands. A and B are therefore monomeric fragments. Some of the ligands are common to A and B; they constitute the bridging zone. In the fragment A (or B), we have an unpaired electron which occupies the highest molecular orbital Φ_A (or Φ_B) for this fragment. These semi-localized orbitals Φ_A and Φ_B are defined as the magnetic orbitals. From the ground state configuration $\Phi_A\Phi_B$ with one unpaired electron in A and the other in B, two low lying states arise: a spin singlet state and a spin triplet state, separated by J. To a first approximation, the orbital parts of the wave functions that are suitable for describing these low lying states are given by[36]

$$\Psi_{S \atop T} = [2(1 \pm S^2)]^{-1/2} [\Phi_A(1)\Phi_B(2) \pm \Phi_A(2)\Phi_B(1)] \quad (9)$$

where the + sign holds for the singlet and the − sign for the triplet. S is the overlap integral between the magnetic orbitals.

$$S = \langle \Phi_A(1) | \Phi_B(1) \rangle \quad (10)$$

Above the ground state configuration $\Phi_A\Phi_B$, there are metal-metal charge transfer configurations $\Phi_A\Phi_A$ and $\Phi_B\Phi_B$ with the two electrons in the same fragment. These excited configurations form two spin singlet excited states, which, in principle, may interact with and stabilize the

low-lying singlet state. In fact, these excited configurations of the $Cu^{+}Cu^{3+}$ type are very high in energy and, so far, have never been unambiguously detected, so that it is reasonable to assume that this second order stabilization of the low-lying singlet state is generally a very small effect, which, in a qualitative approach, may be neglected.

The electrostatic (non-phenomenological) Hamiltonian for this problem is

$$\mathscr{H} = h(1) + h(2) + r_{12}^{-1} \tag{11}$$

where only the two electrons in Φ_A and Φ_B are taken into account. h(i) is a one-electron Hamiltonian containing the kinetic energy of the electron i and the potential energy exerted by the nuclei and the other electrons in A–B, which are assumed to be passive. r_{12} is the distance between the two magnetic electrons. The energies of the low-lying states are[37]

$$E_{S \atop T} = (\alpha_A + \alpha_B \pm 2\beta S + 2k \pm 2j)/(1 \pm S^2) \tag{12}$$

where again + holds for the singlet and − for the triplet. The integrals in Equation (12) are defined as

$$\begin{aligned} \alpha_A &= \langle \Phi_A(1) | h(1) | \Phi_A(1) \rangle \\ \beta &= \langle \Phi_A(1) | h(1) | \Phi_B(1) \rangle \\ k &= \langle \Phi_A(1)\Phi_B(2) | r_{12}^{-1} | \Phi_A(1)\Phi_B(2) \rangle \\ j &= \langle \Phi_A(1)\Phi_B(2) | r_{12}^{-1} | \Phi_A(2)\Phi_B(1) \rangle \end{aligned} \tag{13}$$

The S-T energy gap, J, may be expanded in increasing powers of S.

$$J = 2j + 4tS + \text{terms in } S^2 \ldots \tag{14}$$

with

$$t = \beta - [(\alpha_A + \alpha_B)/2] \cdot S \tag{15}$$

If J is small enough for the two low-lying states to be thermally populated, then the upper limit for $|J|$ is about 0.1 eV (800 cm^{-1}). In other words, the interaction in A–B is weak, compared for instance to the metal-metal bond in organometallic complexes. It follows that the overlap integrals S will also remain small, so we can limit the expansion of J in Equation (14) to the term linear in S.[38,39] At the same level of approximation, J may also be expressed by[39,40]

$$J = 2j - 2S(\Delta^2 - \delta^2)^{1/2} \tag{16}$$

where Δ is the difference in energy between the two singly occupied molecular orbitals γ_1 and γ_2 for the triplet state of A–B, built from the magnetic orbitals Φ_A and Φ_B. δ is the energy difference between these magnetic orbitals as specified in Figure 2. If the fragments A and B in A–B are related by a symmetry operation, Φ_A and Φ_B have the same energy and δ is zero.

In Equations (14) and (16), the first term, $2j$, is always positive. This term stabilizes the triplet state and represents the ferromagnetic contribution J_F. Each of the second terms are negative or zero. They stabilize the singlet state and represent the antiferromagnetic contribution J_{AF}. In the Wolfsberg-Helmholtz approximation,[41] the one-electron transfer integral t is assumed to be proportional to S, so that J_{AF} becomes proportional to S^2. Therefore, we can say that the S-T splitting results from a competition

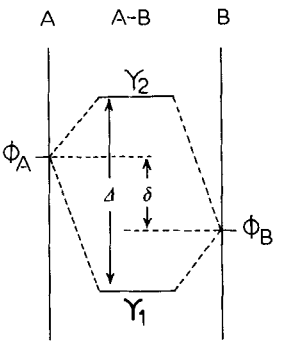

Fig. 2. Relative energies of the magnetic orbitals Φ_A, Φ_B and molecular orbitals γ_1, γ_2 built from these magnetic orbitals in a dissymmetrical dinuclear copper(II) complex.

between two antagonist terms, the one, the ferromagnetic contribution, is proportional to the two-electron exchange integral between the magnetic orbitals, the other, the antiferromagnetic contribution, is proportional to the square of the overlap integral of the magnetic orbitals. Both terms depend on the overlap density, ρ(i), in the bridging network:[42]

$$\rho(\mathrm{i}) = \Phi_A(\mathrm{i})\Phi_B(\mathrm{i}) \tag{17}$$

j is the self-repulsion of the overlap density. The zones of strong overlap density, irrespective of their sign, will give the main contributions to j. As for S, it is the integral of the overlap density, so that J_{AF} will depend on the balance between the positive and negative zones of overlap density. When positive and negative zones compensate exactly, S is zero. The magnetic orbitals are then said to be orthogonal and the interaction is ferromagnetic. In this case, the more pronounced the extrema of ρ(i), the greater is the stabilization of the triplet state (see Section 4).

Finally, we shall discuss the problem of the possible magnitudes of j and S when the two metal centers are bridged by extended ligands. In such cases, each magnetic orbital is delocalized over a large number of bridge atoms. Consequently, the overlap density is spread over the whole bridge without any pronounced maximum (Fig. 3, right). In contrast, the maximum of the overlap density in the case of a monoatomic bridge may be very pronounced (Fig. 3, left). It follows that, in the case of extended bridges, the overlap integral $S = \int_{space} \rho(\mathrm{i})\, d\tau$; may eventually be large if the magnetic orbitals are properly oriented to give an overlap density of the same sign over the whole bridging network, but the self-repulsion of the overlap density

$$j = \int_{space} \frac{\rho(\mathrm{i})\rho(\mathrm{j})}{r_{ij}}\, d\tau_i\, d\tau_j$$

remains weak. In other words, it can be expected that the main factor governing the magnitude of the interaction in dinuclear complexes with extended bridges will be the overlap of the magnetic orbitals, which favors the antiferromagnetic interaction. Of course, such a topological approach is purely qualitative and is open to criticism. In Section 6 an example will be shown in which the ferromagnetic component J_F is actually very small when the metal centers are bridged by an extended ligand.

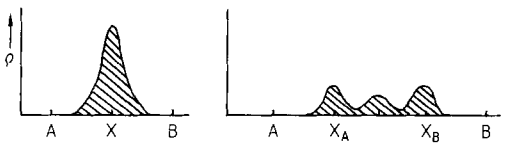

Fig. 3. Schematic representation of the overlap density ρ in the case of monoatomic bridges (left) and extended bridges (right).

4. The Symmetry of the Magnetic Orbitals and Nature of the Interaction

Quite a spectacular way of demonstrating the influence of the symmetry of the magnetic orbitals on the nature of the interaction is to compare the two complexes $[CuVO(fsa)_2en \cdot CH_3OH]$ **1** and $[Cu_2(fsa)_2en \cdot CH_3OH]$ **2**, where $(fsa)_2en^{4-}$ is the dinucleating ligand derived from *N,N'*-bis(4-carboxy-3-hydroxybenzyl)ethylenediamine.[27,43] In **1** and **2** (Figs. 4 and 5, respectively) the inner coordination site of the ligand is occupied by a Cu^{2+} ion. It is coordinated in a square pyramidal fashion by the nitrogen atoms and the phenolic oxygen atoms of the $(fsa)_2en^{4-}$ ligand in the basal plane and by the CH_3OH ligand at the apex. The outer coordination site is occupied by a VO^{2+} ion in square pyramidal surroundings (**1**) or by a Cu^{2+} ion in planar surroundings (**2**). The plane containing the metal ions, perpendicular to the plane of the dinucleating ligand, is almost a mirror plane.

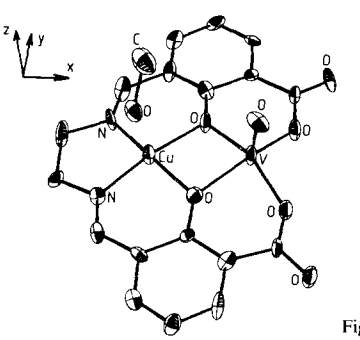

Fig. 4. Crystal structure of **1**.

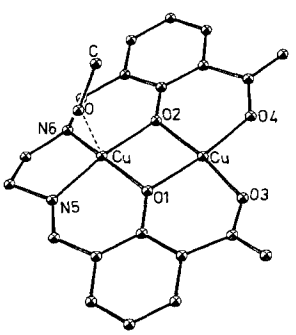

Fig. 5. Crystal structure of **2**.

In a 4+1 environment, the most destabilized orbital occupied by the unpaired electron of Cu^{2+} is of the d_{xy}-type. It points from the metal toward the four nearest neighbors in an antibonding fashion (Fig. 6). The unpaired electron of the VO^{2+} ion (configuration d^1) occupies a $d_{x^2-y^2}$ type orbital, pointing along the bisectrices of OVO angles involving the phenolic and carboxylic oxygen atoms. Consequently, the magnetic orbitals Φ_{Cu} in $Cu^{2+}VO^{2+}$ and $Cu^{2+}Cu^{2+}$ complexes are antisymmetric with regard to the mirror-plane, while the magnetic orbital Φ_{VO} is symmetric with regard to the mirror-plane. Thus, the overlap integral $\langle\Phi_{Cu}|\Phi_{VO}\rangle$ in $Cu^{2+}VO^{2+}$ is equal to zero. The magnetic susceptibilities (Fig. 7) confirm that the interaction is actually ferromagnetic with a triplet ground state 118 cm^{-1} below the singlet state. In contrast, the overlap integral $\langle\Phi_{Cu}|\Phi_{Cu}\rangle$ in $Cu^{2+}Cu^{2+}$ is different from zero. The antiferromagnetic contribution J_{AF} in the expression for J becomes preponderant and the singlet state is now the lowest with a S-T gap of -650 cm^{-1}. This comparison between the $Cu^{2+}VO^{2+}$ and $Cu^{2+}Cu^{2+}$ pairs is shown schematically in Figure 8.

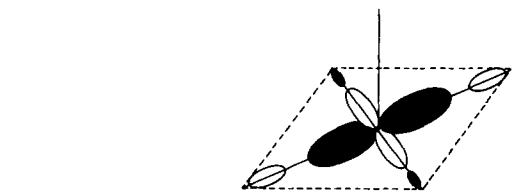

Fig. 6. Singly occupied orbital of a Cu^{2+} ion in a square pyramidal environment.

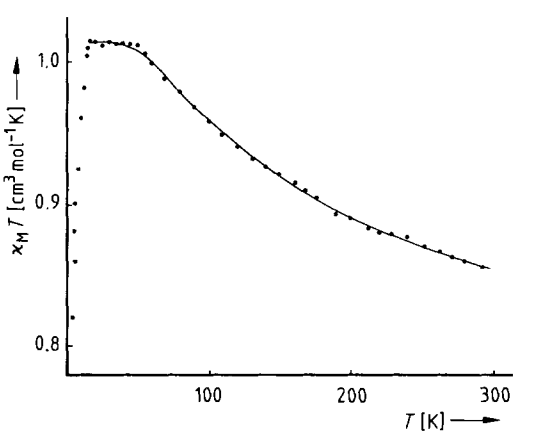

Fig. 7. Experimental (···) and theoretical (—) temperature dependence of $\chi_M T$ for **1**.

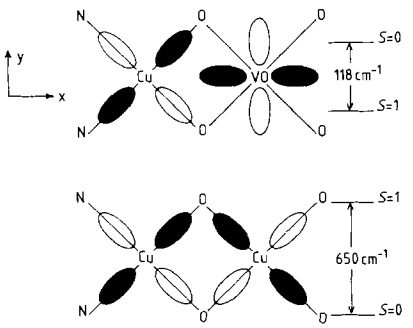

Fig. 8. Symmetries of the magnetic orbitals and the nature of the interaction in 1 (above) and 2 (below).

The symmetry of the magnetic orbitals Φ_{Cu} and Φ_{VO} in the $Cu^{2+}VO^{2+}$ complex **1** imposes the ferromagnetic nature on the interaction; their shape enables a qualitative understanding of why $J=2j$ is relatively large. Figure 9 shows in detail the two magnetic orbitals in the bridging network and Figure 10 gives two representations of the overlap density in the plane of the macrocycle. The overlap density exhibits two strongly positive lobes in one of the bridges and two strongly negative lobes in the other. Positive and negative lobes cancel exactly and the overlap integral is zero. However, the strong values of the extrema of the overlap density in each bridge lead to a significant self-repulsion of the overlap density, and hence to a large stabilization $2j$ of the triplet state.

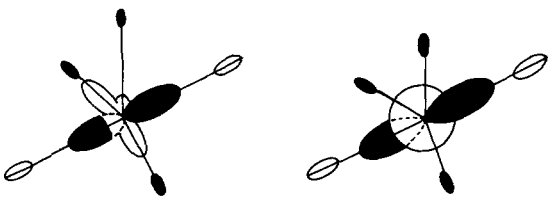
5. Magnetic Orbitals in Dinuclear Copper(II) Complexes with Extended Ligands

In this and the following sections, attention will be focused on complexes in which two Cu^{2+} ions are bridged by ligands of the type $C_2X_2Y_2^{2-}$, where the X and Y atoms bound to the metal ions may be oxygen, nitrogen, or sulfur. A highly symmetrical ligand of this kind is the oxalate ion $C_2O_4^{2-}$, which forms complexes with L and L′ as neutral terminal ligands. In dinuclear complexes of this kind, we can define the two monomeric fragments A and B considered in Section 3 as

Very often, these monomeric fragments can actually be synthesized. $[LCu(C_2O_4)CuL]^{2+}$ complexes are therefore particularly good candidates for application of the basic concepts introduced in Section 3.[44]

Owing to the Jahn-Teller effect the coordination sphere of a Cu^{2+} ion in a fragment A (or B) is remarkably flexible.[45,46] Hence, the environment of the Cu^{2+} ion will be strongly influenced by the nature of the L or L′ ligand. The Cu^{2+} ion most often adopts a coordination 4 or 4+1 or 4+2 with four nearest neighbors in the basal plane and eventually one or two next nearest neighbors in apical position. The orbital which the unpaired electron occupies is shown in Figure 6. When the symmetry of the coordination sphere is such that the xz plane is no longer a mirror plane, there is a mixing of the d_{xy} and d_{z^2} metal orbitals. The unpaired electron is then described by a $d_{xy}+\lambda d_{z^2}$-type orbital which is slightly delocalized toward the eventual apical sites. In a 4+1 coordination, the environment of the metal is not necessarily rigorously square pyramidal, it may adopt some trigonal bipyramidal character with a singly occupied orbital delocalized toward all five ligands. The

orientation of the singly occupied orbital for an intermediate case between the square pyramid and the trigonal bipyramid as well as for a pure trigonal bipyramid is shown in Figure 11.



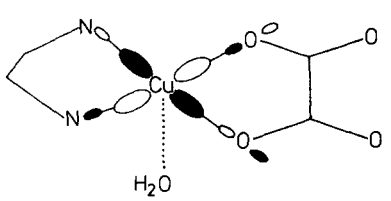


Fig. 11. Singly occupied orbital of a Cu^{2+} ion in an environment intermediate between square pyramidal and trigonal bipyramidal (left) and of a Cu^{2+} ion in a pure trigonal bipyramidal environment (right).

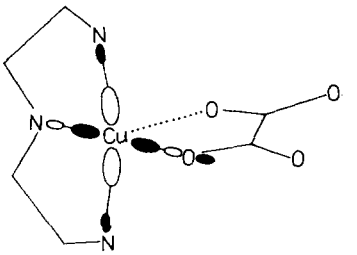
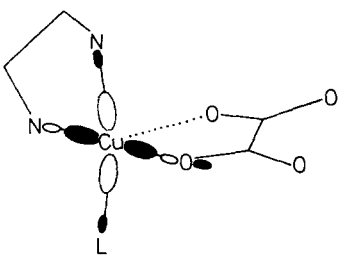


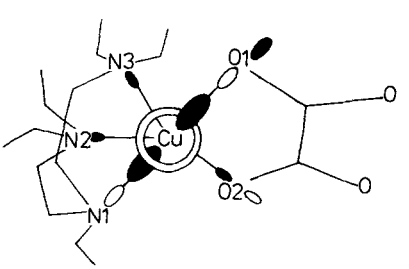
In order to decide whether oxygen or nitrogen takes over the role of nearest neighbors one must, if conclusions cannot be drawn from simple theoretical considerations, resort to the examination of a large number of structural data. Almost without exception, the Cu^{2+} ion first chooses the nitrogen atoms as nearest neighbors, then eventually completes its basal plane with oxygen atoms. If this finding is taken as a rule, then one is in a position to influence the orientation of the magnetic orbital in a $LCu(C_2O_4)$ fragment by appropriate selection of L. For example, if one wants the magnetic orbital to lie in the plane of the oxalato group, then a diamine is chosen for L. For instance, in the mononuclear complex $[(tmen)Cu(C_2O_4)\cdot 4H_2O]$ **3**, with tmen = *N,N,N',N'*-tetramethylethylenediamine, the four nearest neighbors of the Cu^{2+} ion are the two nitrogen atoms of tmen and two oxygen atoms of the oxalato group. They lie in the base of the square pyramid, with a water molecule occupying an apical position.[47] The unpaired electron is then described by the orbital shown in Scheme 1.

Scheme 1. Magnetic orbital of **3**.



If, on the other hand, it is desired that the magnetic orbital lie in a plane perpendicular to the plane of the oxalato group, then a triamine is chosen for L. Thus, in $[(dien)Cu(C_2O_4)\cdot 4H_2O]$ **4** (dien = diethylenetriamine), the four nearest neighbors are the three nitrogen atoms of dien and only one of the oxygen atoms of the oxalato ligand, with another oxygen atom occupying the apical position.[48] It follows that the unpaired electron is now described by an orbital as shown in Scheme 2.

An alternative way of achieving the same orientation of the magnetic orbital as that depicted in Scheme 2 is to start



Scheme 2. Magnetic orbital of **4**.

from $[(tmen)Cu(C_2O_4)\cdot 4H_2O]$ **3** and to incorporate a new monodentate nitrogen-containing ligand L which reverses the orientation of the orbital in complex **5** (Scheme 3).

Scheme 3. Magnetic orbital of **5**.

In the case of 4 + 1 coordination, the environment of the Cu^{2+} ion may acquire some trigonal bipyramidal character. The bulkier the ligands bound to the metal, e.g. on replacing dien in **4** by *N,N,N',N'*-pentamethyldiethylenetriamine (pmedien) and by *N,N,N',N'*-pentaethyldiethylenetriamine ($[LCu(C_2O_4)\cdot 4H_2O]$ **6**; L = pmedien, petdien), the more pronounced the distortion from the square pyramidal toward the trigonal bipyramidal character of the N_3O_2 coordination,[49] whereby the admixture of the d_{z^2} metal orbital in the singly occupied orbital progressively increases. In the hypothetical borderline case of a pure trigonal bipyramidal symmetry with N1CuO1 as trigonal axis and N2N3O2 as equatorial plane, the magnetic orbital can be represented as in Scheme 4.

Scheme 4. Magnetic orbital of **6**.

How can the relative magnitudes of the interactions in dinuclear μ-oxalatocopper(II) complexes be predicted

from the orientations of the orbitals in **3** to **6**?[50] **3** represents the monomeric fragments of the complex $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)](ClO_4)_2 \cdot 1.25\,H_2O$ **7**,[50] and the orbital shown in Scheme 1 may be regarded as one of the two magnetic orbitals of the dinuclear system. These magnetic orbitals are suitably oriented for interaction on both sides of the bridge, since the σ orbitals of the oxygen atoms bound to the same carbon atom of the oxalato bridge overlap each other. **4** represents the monomeric fragments of $[(dien)Cu(C_2O_4)Cu(dien)]^{2+}$[51] and, as above, the orbital shown in Scheme 2 may be considered as one of the two magnetic orbitals of the dinuclear complex. The two short Cu–O bonds must be in the *trans* position with respect to the C–C bond of the oxalato ligand. It follows that the two magnetic orbitals are unfavorably oriented for interaction and, in the absence of d_{z^2} admixture, the overlap integral may be assumed to be zero. In the case where the CuN_3O_2 coordination sphere acquires some trigonal bipyramidal character, owing to the admixture of the d_{z^2} orbital and the associated delocalization of the spin density on the apical site, the overlap integral between magnetic orbitals is no longer zero. Such a situation may be expected in $[(pmedien)Cu(C_2O_4)Cu(pmedien)]^{2+}$ and, to a greater extent, in $[(petdien)Cu(C_2O_4)Cu(petdien)]^{2+}$.[49] In $[(tmen)(L)Cu(C_2O_4)Cu(L)(tmen)]^{2+}$, owing to the orientation of the magnetic orbital being as shown in Scheme 3, the overlap integral is again zero or close to zero, depending on eventual trigonal bipyramidal distortion.

Because of the relative orientation of the magnetic orbitals of the dissymmetrical dinuclear complex $[(dien)Cu(C_2O_4)Cu(tmen)]^{2+}$ (Schemes 1 and 2), the overlapping takes place only on one side of the bridge. Consequently, the overlap integral is approximatively half of what it is in $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)]^{2+}$. Replacement of dien by pmedien, and then by petdien, leads to increased trigonal bipyramidal coordination, but the magnitude of the overlap nevertheless remains smaller than in $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)]^{2+}$.

To sum up, our predictions concerning the relative magnitudes of the interactions in a series of μ-oxalatocopper(II) complexes are:

(1) In $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)]^{2+}$, in spite of the large separation between the metal centers, the interaction is expected to be strongly antiferromagnetic.

(2) The antiferromagnetic interaction is expected to be negligible in $[(dien)Cu(C_2O_4)Cu(dien)]^{2+}$ and to increase slightly on varying the tridentate terminal ligands in the series dien < pmedien < petdien.

(3) Similarly, the interaction is expected to be negligible or very small in $[(tmen)(L)Cu(C_2O_4)Cu(L)(tmen)]^{2+}$, where L is a nitrogen-containing monodentate ligand.

(4) In the complex $[(dien)Cu(C_2O_4)Cu(tmen)]^{2+}$, the interaction should be about a quarter of what it is in $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)]^{2+}$ since the ratio of the overlap integrals is close to 1/2. The magnitude of the interaction is expected to increase in the hypothetical complexes in which dien is replaced by pmedien, then by petdien.

6. Structures and Magnetic Properties of μ-Oxalatocopper(II) Complexes

Most of the complexes considered in the previous Section have actually been synthesized. Generally, their crystal structures have also been refined. In all cases, the temperature-dependence of their magnetic properties have been investigated, and the S-T energy gaps are accurately known.

The synthesis of symmetrical complexes is straightforward and is carried out according to the following reaction scheme.

$$2Cu^{2+} + 2L + C_2O_4^{2-} \longrightarrow [LCu(C_2O_4)CuL]^{2+}$$

Dissymmetrical complexes, $[LCu(C_2O_4)CuL']^{2+}$, are prepared in two steps. First, a monomeric fragment is obtained according to the following reaction:

$$Cu^{2+} + L + C_2O_4^{2-} \longrightarrow LCu(C_2O_4)$$

Then, this fragment is used as a ligand:

$$LCu(C_2O_4) + Cu^{2+} + L' \longrightarrow [LCu(C_2O_4)CuL']^{2+}$$

The compound $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)](ClO_4)_2 \cdot 1.25\,H_2O$, **7**, contains centrosymmetrical dinuclear cations in which the Cu^{2+} ions have a square pyramidal environment with a water molecule in the apical position (Fig. 12). The $Cu(C_2O_4)Cu$ network has a flattened chair configuration, the Cu···Cu separation being 5.15 Å. The magnetic properties of **7** (see Fig. 16) are characteristic for a strong antiferromagnetic interaction with maximal magnetic susceptibility at 300 K. The S-T energy gap was found to be $J = -385.4\ cm^{-1}$.

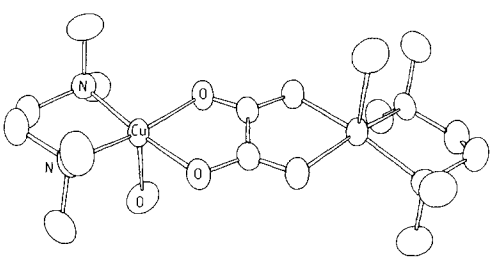


Fig. 12. Structure of the dinuclear cation $[(tmen)(H_2O)Cu(C_2O_4)Cu(H_2O)(tmen)]^{2+}$ in the crystal of **7**.

The compounds $[LCu(C_2O_4)CuL]^{2+}$, where L is a tridentate ligand, have been synthesized by *Waters* et al.,[51] by *Hendrickson* et al.,[49,52,53] and by *Sletten*.[54] When L = dien, the environment of the metal ions is square pyramidal; the basal plane is perpendicular to the plane of the bridge. In the perchlorate $[(dien)Cu(C_2O_4)Cu(dien)]^{2+}$ **8**[51] the Cu···Cu separation is 5.43 Å (Fig. 13). Down to 4.2 K, the temperature-dependence of the magnetic susceptibility obeys the Curie law for two uncoupled Cu^{2+} ions. J is very close to zero. As expected, replacement of

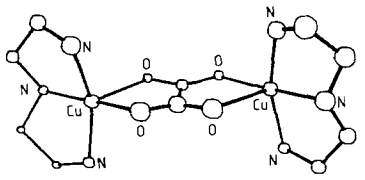

Fig. 13. Structure of the dinuclear cation $[(dien)Cu(C_2O_4)Cu(dien)]^{2+}$ in the crystal of **8**.

dien by pmedien and petdien, progressively increases the trigonal bipyramidal character, as well as the S-T energy gap. When the counterion is the perchlorate, J is $-4.5\ cm^{-1}$ for the pmedien derivative and -20 cm for the petdien derivative.[52] For a given dinuclear cation, J also depends on the counterion. For instance, for $[(petdien)Cu(C_2O_4)Cu(petdien)](BPh_4)_2$, J is as large as $-75.8\ cm^{-1}$. The dinuclear complex cation $[(tmen)(L)Cu(C_2O_4)Cu(L)(tmen)]^{2+}$, with L = 2-methylimidazole (2-Melm), which could be isolated as the PF_6^- salt **9**, is centrosymmetric (Fig. 14). Each Cu^{2+} ion is coordinated in a distorted square pyramidal fashion, the distortion introducing some trigonal bipyramidal character. The basal plane contains the two nitrogen atoms of tmen, one of the nitrogen atoms of 2-Melm, and one of the oxygen atoms of the oxalato bridge; the other oxalato oxygen atom occupies the apical position. The $Cu(C_2O_4)Cu$ network has a flattened chair configuration with a Cu···Cu separation of 5.43 Å. The magnetic susceptibility of **9** exhibits a maximum at 10.8 K; this corresponds to a S-T splitting of $-13.8\ cm^{-1}$.

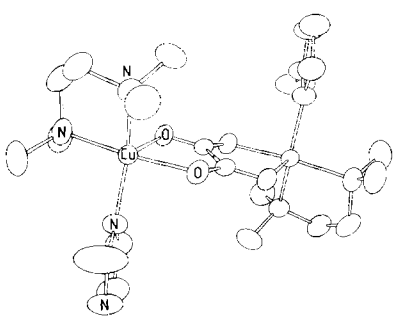

Fig. 14. Structure of the dinuclear cation $[(tmen)(2\text{-}Melm)Cu(C_2O_4)Cu(2\text{-}Melm)(tmen)]^{2+}$ in the crystal of **9**.

Only one dissymmetrical complex has been synthesized so far in the series $[LCu(C_2O_4)CuL']^{2+}$, namely $[(dien)Cu(C_2O_4)Cu(H_2O)_2(tmen)](ClO_4)_2$, **10**. The structure of the dinuclear cation is given in Figure 15. On the tmen side, the Cu^{2+} ion is in a 4+2 environment. The four nearest neighbors are the nitrogen atoms of tmen and two oxygen atoms of the oxalato bridge; the two apical positions are occupied by water molecules. On the dien side, the Cu^{2+} ion is again in a 4+2 environment. The four nearest neighbors are the three nitrogen atoms of dien and an oxygen atom of the bridge. They occupy the basal corners of a square pyramid whose apex is occupied by a second oxygen atom of the oxalato group. An oxygen atom belonging to the bridge of a neighboring dinuclear cation occupies the second apical site 2.75 Å from the metal. The magnetic susceptibility of **10** with a maximum at 62 K corresponds to a S-T splitting of $-75.5\ cm^{-1}$. The magnetic susceptibility curves of **7**, **9**, and **10** are shown in Figure 16.

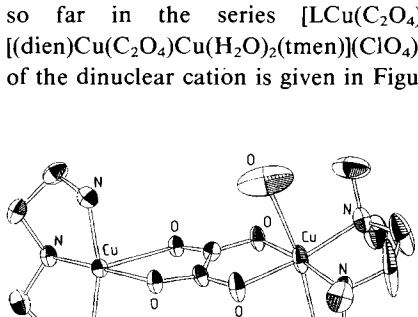

Fig. 15. Structure of the dinuclear cation $[(dien)Cu(C_2O_4)Cu(H_2O)_2(tmen)]^{2+}$ in the crystal of **10**.

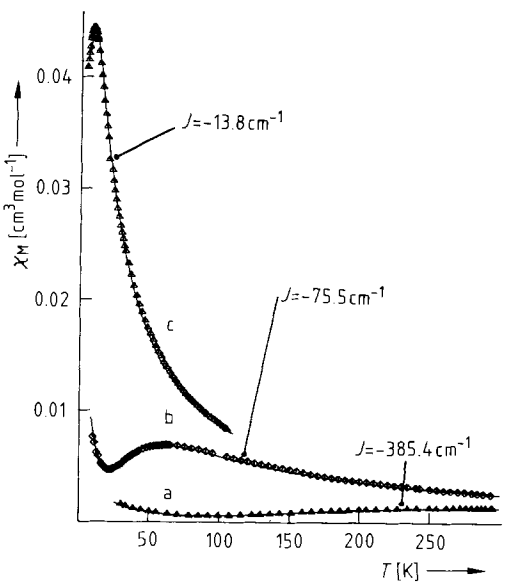

Fig. 16. Magnetic susceptibilities of 7(a), **9** (c), and **10** (b). (▲) experimental data; (—) calculated curves.

Let us now compare the experimentally determined S-T splittings with the predictions made in the previous section: As expected, owing to the favorable orientation of the magnetic orbitals, **7** exhibits a strong antiferromagnetic interaction. Again, as expected, the interaction in **8** is negligible, but increases with increasing trigonal bipyramidal character of the coordination spheres. By coordination of the 2-Melm ligand to the metal ion in **9**, we succeeded in reversing the orientation of the magnetic orbitals and in drastically diminishing the magnitude of the interaction. Finally, in **10** the S-T splitting is about five times smaller than in **7**, whereas we predicted a ratio of four. The essence of this discussion is summarized in Figure 17, where the relative orientations of the magnetic orbitals in **7**, **8**, and **10** are shown.

The monomeric fragments which are taken into consideration in the theoretical model presented in Section 3 do actually exist. In $[(bpy)(H_2O)Cu(C_2O_4)Cu(H_2O)(bpy)][(bpy)Cu(C_2O_4)](NO_3)_2$, **11** (bpy = 2,2'-bipyridyl), the binuclear complex and the monomeric fragment coexist in the same crystal lattice.[55] In the dinuclear cation, bpy plays

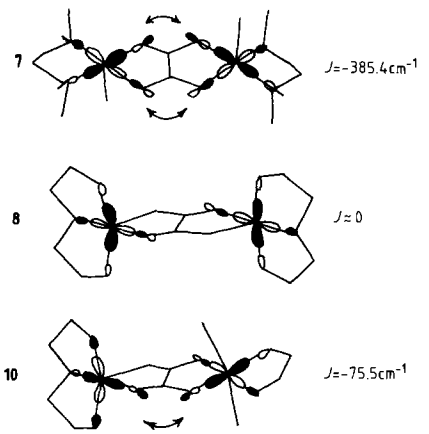

Fig. 17. Relative orientations of the magnetic orbitals in **7**, **8**, and **10**.

much the same role as tmen in **7**. Like the monomeric unit, it is almost planar (Fig. 18). The magnetic orbitals are also favorably oriented to give a strong antiferromagnetic interaction. The magnetic susceptibility of **11** corresponds to that of the monomeric fragment, which obeys the Curie law, and that of the dinuclear complex with a S-T energy gap of $-385.9\ cm^{-1}$ (equal to the value found in **7**).

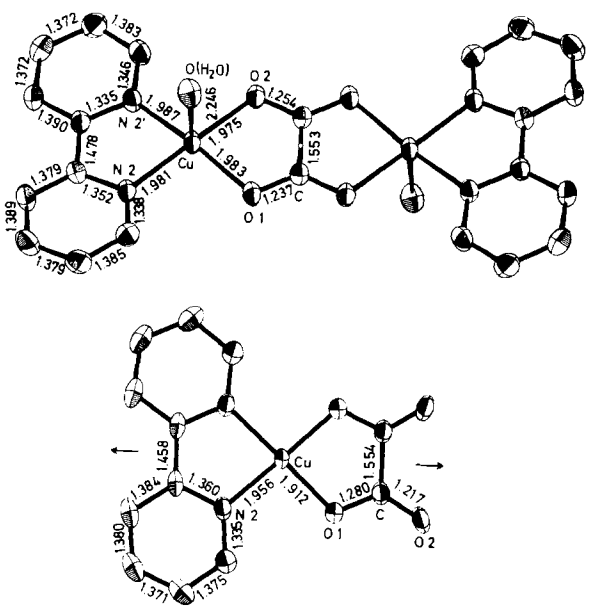

Fig. 18. Structure of the dinuclear cation $[(bpy)(H_2O)Cu(C_2O_4)\text{-}Cu(H_2O)(bpy)]^{2+}$ and of the neutral mononuclear unit $[(bpy)Cu(C_2O_4)]$ in the crystal of **11**. Distances [Å]. The arrows denote a twofold axis of symmetry.

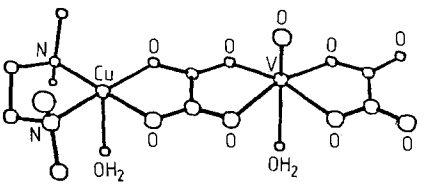
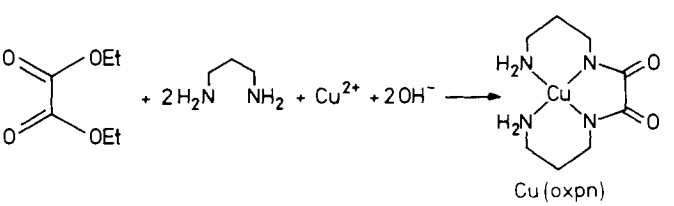
All our predictions in the previous Section on the magnitude of the interaction were based on the assumption that the ferromagnetic contribution $J_F = 2j$ is very weak when the metal ions are bridged by extended ligands. This assumption is substantiated by the magnetic behavior of the compound $[(tmen)(H_2O)Cu(C_2O_4)VO(H_2O)(C_2O_4)]$, **12**, the most likely structure of which is shown in Figure 19.[56] A Cu^{2+} ion and a VO^{2+} ion are bridged by oxalate. The magnetic orbitals of Cu^{2+} and VO^{2+} (Scheme 1 and Fig. 9, respectively) are, as in the case of $[CuVO(fsa)_2en \cdot CH_3OH]$, **1**, orthogonal, and the antiferromagnetic contribution vanishes. Therefore, the interaction should be ferromagnetic with a triplet ground state. From the magnetic and ESR data, it is found that J is in the range 0.3–1 cm^{-1}. The ferromagnetic contribution of the oxalato bridge is effectively negligible.





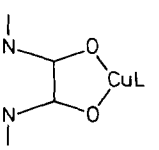


Fig. 19. Crystal structure of **12**.

7. Tunable Interaction in μ-Oxamidocopper(II) Complexes

The concepts developed in Section 3 have been applied to another series of dinuclear copper(II) complexes where the metal ions are bridged by an oxamide derivative. The monomeric fragment Cu(oxpn) can be synthesized according to the following reaction:[57]

The metal center has square planar coordination, so that the unpaired electron occupies an orbital pointing toward the nitrogen atoms, similarly to that shown in Scheme 1. The other monomeric fragment, of the type

may be modified by changing L.

For very large interactions, a nitrogen-containing bidentate ligand, bpy, is chosen for L. The structure of the dinuclear cation $[Cu(oxpn)Cu(bpy)](ClO_4)_2$, **13**, is essentially planar with very weak interactions between the Cu^{2+} and the perchlorate ions (Fig. 20). The $Cu \cdots Cu$ separation is 5.19 Å. The S-T gap is as large as $-439.7\ cm^{-1}$. We shall see in the next section why the antiferromagnetic interaction is even larger than in **7**.

To minimize the interaction, a nonbulky nitrogen-containing tridentate ligand must be chosen for L; dien would appear to be particularly promising for this purpose; unfortunately, however, all attempts to synthesize $[Cu(oxpn)Cu(dien)](ClO_4)_2$ failed. Instead, $[Cu(oxpn)Cu(pmedien)](ClO_4)_2$, **14**, was prepared, whose crystal structure has not yet been refined. On the pmedien side, the Cu^{2+} ion is most likely in a distorted square planar environment with the three nitrogen atoms of pmedien and an oxygen atom of oxpn in the basal plane, the other oxygen atom of oxpn occupying the apical position. The S-T energy gap is only $-82.8\ cm^{-1}$.

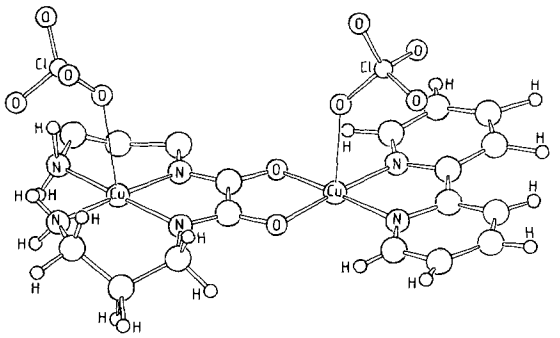

Fig. 20. Structure of the dinuclear cation $[Cu(oxpn)Cu(bpy)]^{2+}$ in the crystal of **13**.

For an interaction of intermediate magnitude, a bulky nitrogen-containing tridentate ligand can be chosen for L so as to enhance the trigonal bipyramidal character. This has been achieved with L = petdien, in the compound $[Cu(oxpn)Cu(petdien)](ClO_4)_2$, **15**. The environment of one of the Cu^{2+} ions is planar, that of the other, on the petdien side, is in an environment intermediate between a square pyramid and a trigonal bipyramid (Fig. 21). A square pyramidal description places the three nitrogen atoms of petdien and an oxygen atom of the bridge in the basal plane, the other oxygen atom of the bridge being in the apical position. A trigonal bipyramidal description, on the other hand, places the central nitrogen atom of petdien and an oxygen atom of the bridge along the trigonal axis and the three other atoms around the metal in the equatorial plane. The Cu···Cu separation is 5.25 Å. The S-T gap J, with a value of $-242.0\ cm^{-1}$, lies between the values for **13** and **14**. The magnetic susceptibilities of **13**, **14** and **15** are compared in Figure 22.[58]

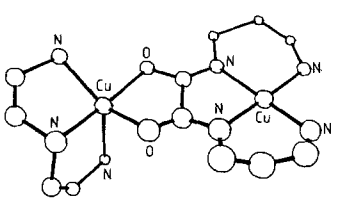

Fig. 21. Structure of the dinuclear cation $[Cu(oxpn)Cu(petdien)]^{2+}$ in the crystal of **15**.

8. Maximization of the Interaction Through a Bis-Bidentate $C_2X_2Y_2$ Bridge

Despite a separation of 5.15 Å between the metal centers in the dinuclear copper complex **7**, the interaction is very strong ($J = -385.4\ cm^{-1}$). The questions posed then are: Is it possible to do better? Is it possible to achieve a larger interaction between two metal ions that are separated as much as or more than in **7**? The answer is in the affirmative, for we have already mentioned the compound **13** in which the metal-metal distance is much the same as in **7** and the S-T splitting is equal to $-439.7\ cm^{-1}$.

The strong interaction in **7** is due to the relative orientation of the magnetic orbitals and to their delocalization from the metal toward the oxygen atoms of the bridge bound to the metal. Both the orientation and the delocalization of the magnetic orbitals favor their overlapping, and thus the antiferromagnetic interaction. Consequently, there are in principle two ways in which to enhance this interaction: either by improving the orientation of the magnetic orbitals or by increasing their delocalization. The possibilities of the former way are very limited since the magnetic orbitals are already located in the plane containing the bridging network, and, moreover, point to each other. One can only improve the planarity of the dinuclear cation, by weakening the apical copper-water bond which pulls the metal from the basal plane. For instance, in **7**, the metal is displaced from the N_2O_2 basal plane toward the apical water molecule by 0.16 Å. It has been found, however, that displacement of the apical water molecules has almost no effect on the magnitude of the interaction. Is it, on the other hand, possible to increase the delocalization? Here, the answer is quite positive. By replacing the oxygen atoms of the oxalato bridge by less electronegative atoms, one can diminish the energy gap between the metal orbital and the ligand orbitals. In the monomeric fragment, the metal orbital-ligand orbital interaction is strengthened, giving rise to a low energy bonding molecular orbital with en-

hanced metal character and a high-energy antibonding molecular orbital with enhanced ligand character, the magnetic orbital (Fig. 23).

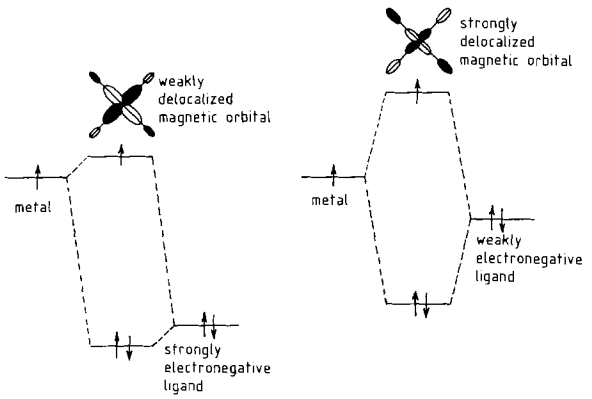

Fig. 23. Electronegativity of the ligands and delocalization of the magnetic orbitals.

This strategy for increasing the interaction has been tested by replacing the oxalato bridge in **7** by an oxamido bridge.[59,60] The compound $[(tmen)(H_2O)Cu(C_2O_2N_2H_2)Cu(H_2O)(tmen)](ClO_4)_2$ **16** was obtained. Each Cu^{2+} ion in the dinuclear cation is coordinated in a square pyramidal fashion with the two nitrogen atoms of tmen, a nitrogen atom, and an oxygen atom of the oxamido bridge in the basal plane (Fig. 24). A water molecule occupies the

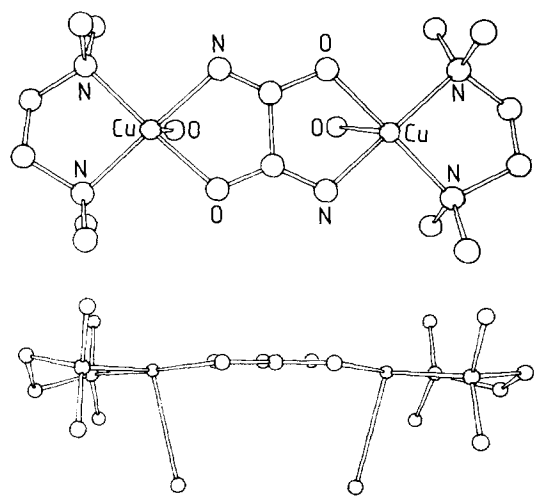

Fig. 24. Structure of the dinuclear cation $[(tmen)(H_2O)Cu(C_2O_2N_2H_2)Cu(H_2O)(tmen)]^{2+}$ in the crystal of **16**.

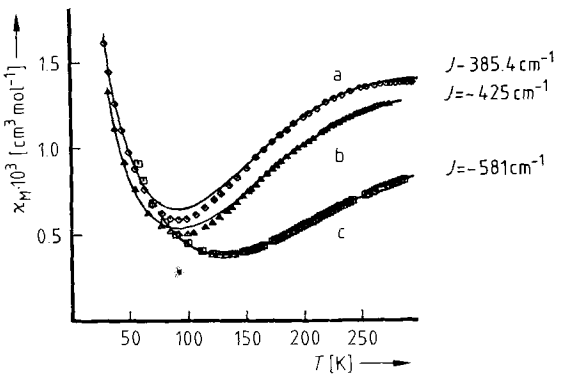
apical position. Surprisingly, the two water molecules are on the same side of the molecular plane, so the $Cu(C_2O_2N_2H_2)Cu$ network has a flattened boat configuration with a Cu···Cu separation of 5.17 Å. The maximum of the magnetic susceptibility occurs well above room temperature, which is consistent with a very large S-T energy gap. J was found to be equal to $-581\ cm^{-1}$. A value of J lying between those for **7** and **16** might be expected for the compound $[(tmen)Cu(C_2O_3NH)Cu(tmen)](PF_6)(NO_3)\cdot H_2O$, **17**, where the Cu^{2+} ions are bridged by the oxamato ligand $O_2C-C(O)NH^{2-}$; Indeed, a value of $J = -425\ cm^{-1}$ was found. The magnetic susceptibilities of **7**, **16**, and **17** are compared in Figure 25.[59,60]



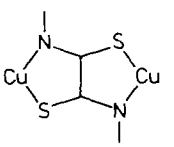


Fig. 25. Magnetic susceptibilities of **7** (a), **16** (c) and **17** (b). (◇, △, □) experimental data; (—) calculated curves.

What kind of X or Y atoms in the bridges $C_2X_2Y_2^{2-}$ could lead to even further improvement of the interaction? Sulfur is less electronegative. The tetrathiooxalate ion $C_2S_4^{2-}$[61] has not as yet been employed for the bridging of metal centers. On the other hand, the chemistry of dithiooxamide derivatives with a bridging network has been studied extensively in the past few years.[62-66].

Only a few examples can be cited here. The compound $[Cu_2\{S_2C_2(NCH_2CH_2OH)_2\}(H_2O)_2]_2(SO_4)_2$ **18** has been prepared from *N,N'*-bis(2-hydroxyethyl)dithiooxamide.[62] The dinuclear complex cation is almost planar. The Cu···Cu separation is 5.61 Å, i.e. 0.46 Å larger than in **7** and 0.42 Å larger than in **16**. In spite of this much larger metal-metal separation, the S-T energy gap $J = -594\ cm^{-1}$

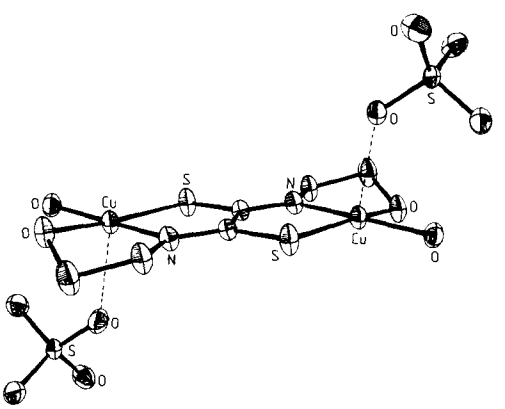

Fig. 26. Crystal structure of **18**.

in **18** is increased considerably compared to that in **7** and slightly increased compared to that in **16**. In other compounds with the same bridging network, J may even be more negative. This is the case, for example, in $[Cu_2\{C_2S_2[NCH(CH_2CH_2SCH_3)COOCH_3]_2\}Br_2]$, **19**, the structure of which is shown in Figure 27. The $CuS_2C_2N_2Cu$ network resembles very closely the network found in **18**, in that the corresponding bond lengths deviate less than 0.03 Å from each other and the Cu···Cu separation is 5.67 Å.[66] The S-T energy gap deduced from the magnetic properties is $J=-730\ cm^{-1}$. In **19**, the environment of each Cu^{2+} ion is far from being a pure square pyramid with a basal plane almost coplanar with the bridging network. Indeed, in **19**, the sulfur atom S2 of the methionine group is displaced by more than 2 Å from the N-S1-Br plane, S1 being the sulfur atom of the bridge (see Fig. 27). This distortion is, however, not sufficient to reverse the orientation of the magnetic orbital, which remains delocalized toward the nitrogen and sulfur atoms of the bridge.

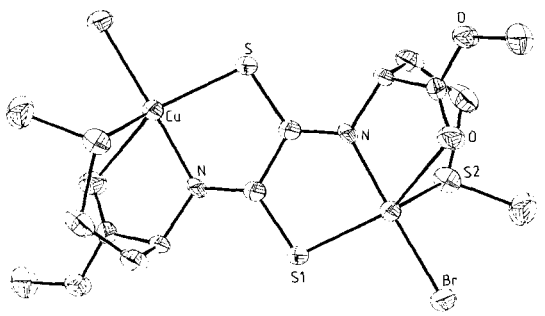

Fig. 27. Crystal structure of **19**.

In **19**, the delocalization is, as in **18**, particularly significant, because of the small energy difference between the 3d metal orbitals and the sulfur valence orbitals. Another way of expressing this is to say that the 3s and 3p valence orbitals of the sulfur are quite diffuse, which favors both the delocalization of the magnetic orbitals as well as overlapping of the orbitals of the S- and N-bridging atoms bound to the same carbon atom. It is interesting to note that all attempts to achieve a reversal of the magnetic orbital and thus a drastic decrease in the interaction in μ-dithiooxamidocopper(II) complexes have been unsuccessful. Such an orbital reversal would require significant lengthening of the Cu-S (dithiooxamide) bond length. Apparently, the affinity of the Cu^{2+} ion for the sulfur atoms of the dithiooxamide is too pronounced.

9. Ab Initio Calculation of the S-T Energy Gap in Complexes 7 and 18

In Section 3 we have defined the magnetic orbitals Φ_A and Φ_B as the singly occupied molecular orbitals for the monomeric fragments. Generally, the magnetic orbitals are not orthogonal; in fact, we have seen that the overlap between them is the key factor governing the magnitude of the antiferromagnetic interaction. This approach is justified by its heuristic character, and a strategy could be proposed for obtaining a purely ferromagnetic interaction and for tuning the magnitude of the antiferromagnetic interaction through extended bridges of the type $C_2X_2Y_2^{2-}$ in the range $-730\ cm^{-1}<J<0$. Probably its main advantage is its simplicity; it uses a language familiar to the inorganic chemist, for whom the overlap between orbitals is considered the cornerstone of the chemical bond. However, this approach is apparently not appropriate for quantitative theoretical calculations, owing to the difficulty arising from the non-orthogonality of the magnetic orbitals. In 1959, *Anderson* proposed a model using orthogonalized magnetic orbitals as basis set for extended lattices,[67] and, in 1975, *Hay, Thiebault,* and *Hoffmann*[68] presented its molecular variant. A brief formulation of this model is given here for the case of a symmetrical dinuclear copper(II) complex A-B. First, a molecular orbital calculation for the triplet state of lowest energy is performed. The two singly occupied molecular orbitals are γ_1 and γ_2 (cf. Fig. 2) and the two orthogonalized magnetic orbitals Φ'_A and Φ'_B are obtained according to:

$$\Phi'_A=\sqrt{2}/2(\gamma_1+\gamma_2)$$
$$\Phi'_B=\sqrt{2}/2(\gamma_1-\gamma_2) \qquad (18)$$

Φ'_A and Φ'_B are not perfectly localized in the A and B monomeric fragments, respectively. Due to the orthogonalization, Φ'_A has a residual contribution in B, outside the bridging region between A and B. The larger the overlap integrals $S=\langle\Phi'_A|\Phi'_B\rangle$, the more important is this residual contribution. From the ground configuration with one unpaired electron per magnetic orbital a singlet and a triplet state arise. From the excited configuration with the two electrons in the same magnetic orbital, two singlet states arise. One of them interacts with the low lying singlet state and stabilizes it. J is then calculated by a perturbational treatment and found to be

$$J=2j'-\Delta^2/U \qquad (19)$$

where Δ, as already mentioned, is the energy difference between γ_1 and γ_2, and U the energy difference between the configurations of the excited state and the ground state.

$$U=\langle\Phi'_A(1)\Phi'_A(2)|r_{12}^{-1}|\Phi'_A(1)\Phi'_A(2)\rangle$$
$$-\langle\Phi'_A(1)\Phi'_B(2)|r_{12}^{-1}|\Phi'_A(1)\Phi'_B(2)\rangle \qquad (20)$$

j' is given by:

$$j'=\langle\Phi'_A(1)\Phi'_B(2)|r_{12}^{-1}|\Phi'_A(2)\Phi'_B(1)\rangle \qquad (21)$$

Two calculations of this kind have been performed, one for compound **7**,[69] the other for compound **18**.[70]

The values of j', Δ and U are given in Table 1 together with the J values derived from Equation (19) and the final J value obtained from an extended configuration interaction (see below). The electronic isodensity curves $[(\Phi'_A)^2=\text{const.}]$ of **7** and **18** are shown in Figure 28.

Table 1. Ab initio calculation of the S-T splitting J [cm^{-1}] in the oxalato complex **7** and the dithiooxamido complex **18**.

	7	**18**
j'	360	192
Δ	7572	6694
U	126600	87800
J from Eq. (19)	270	−124
Additional contribution to J	−565	−434
Final J value	−295	−558
Experimental J value	−385.4	−594

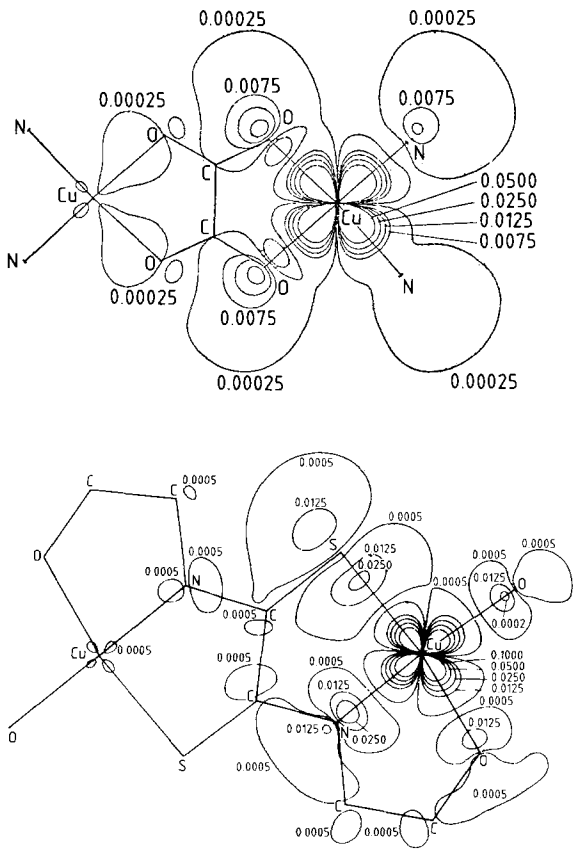

Fig. 28. Electronic isodensity curves [$(\Phi'_A)^2$ = constant] of the orthogonalized magnetic orbitals in **7** (top) and **18** (bottom). Electron density [eÅ^{-3}].

The following conclusions can be drawn from Figure 28 and Table 1:

(1) As expected, the magnetic orbital is less concentrated on the metal for the dithiooxamido complex than for the oxalato complex.

(2) j', which stabilizes the triplet state, is larger in **7** than in **18**; both Δ and U are larger in **7**, but Δ^2/U, which stabilizes the singlet state, is more important in the dithiooxamido complex **18**.

(3) The S-T splittings deduced from Equation (19) deviate widely from the experimentally determined values. J at this level of approximation has even the wrong sign for **7**. At first sight, this result is discouraging. Both *de Loth* et al.[71] and later *Charlot* et al.[69] showed great foresight in having searched for the mechanism which, beyond the formalism of *Anderson* and Equation (19), effects stabilization of the singlet state. Equation (19) is based implicitly on a configuration interaction limited to the two configurations $|\gamma_1\bar{\gamma}_1|$ and $|\gamma_2\bar{\gamma}_2|$ for the singlet state and on the only configuration $|\gamma_1\gamma_2|$ for the triplet state. To go beyond this formalism necessitates a more extended configuration interaction being carried out. By using a perturbational approach of the configuration interaction problem,[69-71] additional negative contributions of $-565\ cm^{-1}$ for **7** and $-434\ cm^{-1}$ for **18** were found, so that J was finally calculated as $-295\ cm^{-1}$ for the oxalato complex and $-558\ cm^{-1}$ for the dithiooxamido complex. The agreement between theory and experiment now appears quite satisfactory. In the latter case, in fact, this agreement is probably somewhat fortuitous.

This kind of sophisticated calculation raises problems for the chemist engaged in the challenge of designing polynuclear systems with predictable magnetic properties. It is extremely difficult to visualize the additional contributions arising from the configuration interaction, and it is even more difficult to predict their sign and their relative magnitude. In some way, these calculations resemble a "black box" which apparently is able to reproduce roughly the experimental data. This black box does not, at the present time, appear suitable enough for providing really useful information on the strategy to follow for a given interaction. Moreover, a further complication should be noted: the definition of the orthogonalized magnetic orbitals in Equation (18) is valid only when the dinuclear system is symmetrical. Dissymmetric complexes have so far never been treated according to *Anderson*'s formalism.

10. Anisotropic and Antisymmetric Interactions, and ESR Spectra

In addition to the S-T splitting, which is by far the main phenomenon, the interaction between two local doublet states may also lead to a splitting within the triplet state which is generally detectable in ESR spectroscopy. It may also lead to a coupling between singlet and triplet states (see Fig. 1).[72,73] This problem will now be briefly discussed in the light of the results established in the previous sections. The basic scheme of an ESR spectrum for a triplet state split in zero field is reproduced in Figure 29,

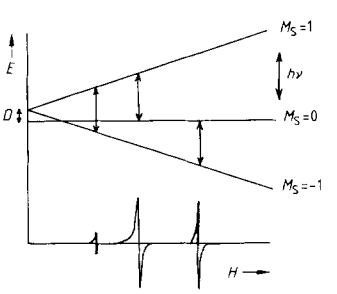

Fig. 29. Zero field splitting and ESR spectrum for a triplet state.

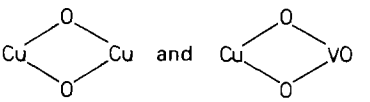
where the magnetic field is assumed to be parallel to the z axis of the axial symmetry. This spectrum exhibits two allowed transitions $\Delta M_S = \pm 1$, the separation of which depends on the axial zero field splitting parameter D, and a forbidden transition $\Delta M_S = 2$ at half field.

The zero field splitting within the triplet state has two origins, namely the dipolar interaction between magnetic dipoles, which varies roughly as d^{-3} (d being the distance between the metal centers) and the sum of the anisotropic and antisymmetric interactions.[74,75] In the case of symmetrical systems, for which the antisymmetric interaction is zero, the anisotropic interaction is due to the combined effect of the local spin-orbit coupling and of the interaction itself. To find appropriate expressions for the zero field splitting parameters, we must replace the magnetic orbitals Φ_A and Φ_B as defined in Section 3 by new orbitals which take into account the coupling between local ground state and excited states through the spin-orbit coupling.[72] The calculation of the relative energies of the low lying states becomes tedious, and, generally, the final expressions are very complicated. Since the aim of this paper is merely to present the general philosophy of the problem, only the simple case of a symmetrical copper(II) complex like **7** will be described here. The axial zero field splitting parameter D may then be approximated by

$$D \simeq \frac{1}{32}(\Delta g_z)^2 J_{xy,x^2-y^2} \tag{22}$$



Δg_z is the deviation of the component g_z of the Zeeman factor for the monomeric fragment referred to $g_e = 2.0023$. This deviation comes from the second-order effect of the spin-orbit coupling. J_{xy,x^2-y^2} is the magnitude of the interaction between the xy-type ground state of an ion and the x^2-y^2 type excited state of the other ion, this interaction being assumed to be much larger than the other interactions between ground state and excited state. The important point in Equation (22) is that the interaction to be taken into account is not the interaction between the local ground states characterized by the S-T splitting J. In other words, it is in principle possible to deduce from D an order of magnitude for the interaction between the ground state of an ion and the excited state of the other ion.[35] This information cannot be derived from the magnetic data.

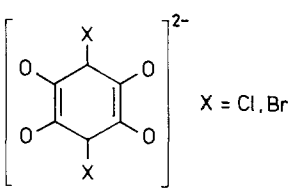
In the case of compound **7**, D is too small to be detected from the ESR spectrum.[56] This value of D, close to zero, is surprising at first sight, since interaction between the local ground states is large, with $J = -385.4\ cm^{-1}$. In fact, if the dipolar interaction between two metal ions separated by 5.15 Å is clearly negligible, the anisotropic interaction which involves the xy- and x^2-y^2-type orbitals located in the plane of the oxalato bridge can hardly be expected to be negligible. An interaction of the type J_{xy,x^2-y^2} through an oxalato bridge has already been described (cf. Section 6). It occurs between the local ground states of the Cu^{2+} and VO^{2+} ions in [(tmen)(H_2O)Cu(C_2O_4)VO(H_2O)(C_2O_4)], **12**. Symbolically, we may therefore write

$$\underset{\text{in [CuCu]}}{D} \approx \tfrac{1}{32}(\Delta g_z)^2 \cdot \underset{\text{in [Cu–] in [CuVO]}}{J} \tag{23}$$

where [CuCu] and [CuVO] denote the dinuclear complexes **7** and **12**, respectively, and [Cu–] denotes the monomeric fragment **3**. J in [CuVO], **12**, was found to be close to zero, which explains why D in [CuCu], **7**, is also close to zero. In all the other complexes with an extended bridge and exhibiting a strong antiferromagnetic interaction (for instance **13**, **16**, **18** and **19**), D was also found to be close to zero.[76]

A similar comparison between $Cu^{2+}Cu^{2+}$ pairs and $Cu^{2+}VO^{2+}$ pairs can be carried out with the networks:

In **1**, the ferromagnetic interaction is large with $J = 118\ cm^{-1}$. *Gatteschi* and co-workers extensively investigated the ESR spectra of doubly bridged hydroxocopper(II) dimers.[77,78] They found that, whatever the sign and the value of the S-T energy gap between the low lying states may be, D is much larger than what would be expected if only the dipolar interaction were operative. In fact, in these doubly hydroxo-bridged dimers, the anisotropic interaction is significant owing to the strong ferromagnetic interaction between the ground state of an ion and the x^2-y^2 excited state of the other. This interaction has the same orbital character as that occurring between the local ground states in **1**.



For dissymmetrical complexes, there is an additional contribution to the zero field splitting within the triplet state, namely for the antisymmetric interaction. In fact, the origin of this new contribution is the same as that of the anisotropic interaction, namely the synergic effect of the spin-orbit coupling and of the interaction.[79] The antisymmetric interaction is a first order term in $\Delta g J_{ij}$ instead of $(\Delta g)^2 J_{ij}$, which vanishes when the two monomeric fragments are related by a symmetry center. The antisymmetric interaction not only contributes to the zero field splitting, but also mixes the singlet and the triplet states. This mixing effect has been detected in many extended lattices. It leads to weak ferromagnetism.[79,80] The singlet-triplet interaction in dinuclear copper(II) complexes has not yet been detected. Dissymmetrical complexes like **10** and **15** are potentially suitable candidates for observing this phenomenon for the first time.

11. Conclusion and Outlook

The inorganic chemist also can be likened to Prometheus: He can transform matter, not only for pleasure or to prove his power, but in order to design new systems exhibiting desired physical or chemical properties. Such an ambition, when dealing with the magnetic properties of polynuclear systems, necessitates going many times through the steps of a cycle. These steps are: (i) the synthesis of a new compound, which one thinks will exhibit given magnetic properties; (ii) the determination of its crystal and molecular structure; (iii) the investigation of its magnetic properties and of its ESR spectrum, and—on the basis of these data—the determination of the nature and the relative energies of the low lying energy states; (iv) lastly, and not least, conceptual reflections on the real (non phenomenological) mechanism of the observed phenomena,

so that it is possible in the following cycle to synthesize a novel compound whose magnetic properties will be even closer to what is expected. In the last few years, we have shown that by working according to this scheme, it is actually possible to impose the nature and the order of magnitude on the interaction between the two magnetic centers of a dinuclear compound. The first success achieved in this way was the design of ferromagnetically coupled complexes, using the strategy of orthogonality of the magnetic orbitals. One of the greatest challenges in the sector of molecular materials is the synthesis of molecular ferromagnets, in which a ferromagnetic order would occur up to as high a critical temperature as possible. With spin moments there is no one- or two-dimensional magnetic order. Consequently, in the design of molecular ferromagnets three-dimensional ferromagnetic interactions between neighboring magnetic centers must be realized. This can be most effectively achieved by orthogonality of the magnetic orbitals. For instance, a chromium(III)-nickel(II) lattice is well suited for ferromagnetic behavior. Thus, there are three unpaired electrons occupying the three $t_{2g}(d_{xy}, d_{yz}, d_{zx})$ orbitals around a Cr^{3+} ion in an octahedral environment, and around a Ni^{2+} ion, also in octahedral surroundings, there are two unpaired electrons occupying the two $e_g(d_{z^2}, d_{x^2-y^2})$ orbitals. Since the overlap integrals $\langle t_{2g} | e_g \rangle$ are zero,[81] the ground state of such a Cr(III)-Ni(II) system should exhibit parallel spins of respectively 3/2 for chromium(III) and 1 for nickel(II). This orthogonality of the magnetic orbitals could also be realized with organic radicals such as nitroxide.[82] Several groups over the world are engaged in the search for the first molecular ferromagnet with a Curie temperature that is not too low.

Another challenge is the design of coupled systems with strong interactions between distant metal centers. The efficiency of the dithiooxamido-bridge in this respect has already been mentioned; significant interactions can also occur between more distant metal ions. For instance, through the chloranilato and the bromanilato bridges,

X = Cl, Br

singlet-triplet energy gaps of about -24 cm^{-1} were recently found.[83, 84]

Is there a limit beyond which no interaction is detectable? Our feeling (and it is still only a feeling) is that this limit, if it does exist, has not yet been reached. The synthesis of novel bridging ligands which are especially efficient at transmitting electronic effects over long distances is certainly a field of research deserving further development. An understanding of the mechanism of the interaction and skilful organic synthesis are invaluable tools in this sector. Useful information can also be gleaned from natural processes. In some biological systems the electronic information is apparently transmitted over distances as large as 10 Å or more.[85]

The ability to tune the interaction through a given bridging network by 'playing' on the nature of the terminal ligands L and L' is a noteworthy achievement in the area of molecular magnetism. Two examples of this achievement were given. The strategy used could, of course, be extended; a key factor is the synthesis of dissymmetrical complexes with $L \neq L'$, which provide two "adjusting screws" for tuning the interaction. In fact, at the moment the main difficulty lies in the synthesis of the complex; not all of the desired dissymmetrical systems could be prepared, probably because of the high strain that would be involved with some complexes.

Despite all the results obtained so far, the field of molecular magnetism is still largely open. Many problems remain unsolved or must first be specified:

(1) Compared to isotropic interactions very little is known about anisotropic interactions, and even less is known about antisymmetric interactions. Demonstration of the singlet-triplet interaction in dissymmetrical complexes would constitute a great step forward.

(2) The concept of magnetic orbitals and of overlap density between magnetic orbitals can only be visualized by carrying out polarized neutron diffraction studies and obtaining spin density maps. The few investigations of this kind that have already been reported in the literature are far from satisfactory.[86]

(3) So far, the influence of the molecular vibrations on the magnetic properties has been completely neglected. Two effects could be expected, namely a temperature-dependence of the energy gaps between low lying states[87] and phase transitions with drastic modification of the interactions. This latter effect has only recently been observed,[88] and absolutely deserves further investigation.

Finally, the challenge presented by the design of molecular ferromagnets should be emphasized once again. Today, the strategy to follow is known. The problem, and it is not an easy problem, is the application of this strategy in three-dimensional space. It is also conceivable that the magnitude of the interaction could be tuned by L, L' adjusting screws. In any case such systems represent quite important milestones on the way to molecular electronics.

The work presented in this paper is the result of a collective adventure initiated by my co-workers and myself. Together, we reflected on the basic concepts, we imagined the strategies, we chose the systems to be investigated, we performed the syntheses and the physical measurements. We then analyzed the results. I wish to express my deepest gratitude to M. F. Charlot, J. J. Girerd, Y. Journaux, M. Julve, I. Morgenstern, R. Veit and M. Verdaguer, and would also like to thank my colleagues involved in the structural aspects of this work, namely J. Galy, A. Gleizes, J. Gouteron, J. Jaud, S. and Y. Jeannin, A. Michalowicz and J. Sletten. The work was financially supported by the CNRS, the Université de Paris Sud, and the SNEA.

Synthesis of 1,2,3-Butatrienecarboxylic Acids**

By *Franz W. Nader** and *Claus-Dieter Wacker*

Owing to their bond system, the cumulenes represent a separate entity in the class of unsaturated compounds. Whereas numerous derivatives of the allenes have been prepared and investigated,[1] in the butatriene series only very few derivatives with functional groups have been reported,[2] among them no butatrienecarboxylic acids. Since we were interested, inter alia, in the solid state chemistry of such butatrienes and their complexes with amides,[3] we decided to search for a general entry to this class of compounds.

The conventional methods of butatriene synthesis[4] such as dehydrohalogenations (of 2-halogenobutadienecarboxylic acid derivatives) with bases,[5] dehalogenations (of 2,3-dihalogenodienecarboxylic acid derivatives[5]) with Zn or other reducing agents, and 1,4-elimination reactions (on 1,4-dihydroxy-2-butynecarboxylic acid derivatives[6]) with $SnCl_2$, P_2I_4 etc., failed. Finally, a successful strategy proved to be that based on the concept of constructing the butatriene system stepwise from homologous allene derivatives[7] (Scheme 1).

As starting material we used the 1-phenylallenyl ester **1**, which was formed in 75–79% yield by Wittig reaction of (α-methoxycarbonylbenzylidene)triphenylphosphane[8] with acetyl chloride using the method of *Lang* and *Hansen*.[9] Reaction of **1** with equimolar amounts[10] of lithium hexamethyldisilylamide at −78 °C afforded the mesomerically stabilized anion, which reacted with benzophenone **2a** and the keto esters **2b** and **2c** to give the allene alcohols **3a–c**.[11] The isomeric alkynols **4**[12] are not formed, obviously for steric reasons. The *p*-toluenesulfinyl residue proved to be a suitable leaving group for the subsequent 1,2-elimination. In the preparation of the sulfinyl ester of **3a**, elimination and formation of the desired butatrienecarboxylate **5a** already occurs at $T < -20$ °C. The *p*-toluenesulfinyl esters could therefore not be isolated and characterized. The extreme easiness of this elimination[13] enabled a one-pot variant of the reaction sequence **1** → **5**, thus circumventing the high losses in yield during purification of the alcohols **3**:[11] a solution of *p*-toluenesulfinyl chloride in THF was added dropwise at −78 °C to the reaction mixture containing the lithium alkoxides of **3** which had previously been treated with an equimolar amount of triethylamine; finally, the mixture was allowed to warm to room temperature.

Scheme 1. a) *p*-$MeC_6H_4S(O)Cl$, NEt_3, $T = -78$ °C. b) KOH/[18]crown-6, H_2O/THF (phase transfer catalysis).

Purification by column chromatography furnished intense yellow crystals (m.p. 94–95 °C) of **5a** in 31% yield (referred to **1** and with maximally 50% conversion of **2a**). Slow crystallization at −20 °C yielded a second, orange-colored modification of **5a** (m.p. 112–113 °C). Both crystal forms are storable in the dark, but are photolabile.

In an analogous way the keto ester **2b** affords a *Z/E* mixture of the butatriene diester **5b**. Treatment of the reaction mixture with ethanol leads to crystallization of isomerically pure *E*-**5b** (no cumulene band in the IR spectrum; strong butatriene band at 2040 cm^{-1} in the Raman spectrum) in 52% yield. Crystalline *E*-**5b** can be stored at room temperature, even when exposed to light; in solution at room temperature, the *Z/E* equilibrium already observed by *Kuhn* et al.[14] with unsymmetrically substituted butatrienes is established. From the second fraction obtained on column chromatographic separation of such an equilibrium mixture at −20 °C, *Z*-**5b** can be isolated as an orange colored powder, the *Z*-stereochemistry of which follows from the IR butatriene band observed at 2033 cm^{-1}. *Z*-**5b** is thermolabile and photoactive, but can be stored for long periods of time at −78 °C when not exposed to light. The equilibrium constant for the isomerization *E*-**5b** ⇌ *Z*-**5b** was determined ^{1}H-NMR spectroscopi-

cally:[15] The *E*-isomer (with $K = 1.9$, in $CDCl_3$) is favored.

The keto ester **2c** furnishes the *Z*/*E* mixture of the butatrienediester **5c**. In contrast to **5b**, **5c** is configurationally stable at room temperature. Consequently, the isomers could be separated by conventional column chromatography. *E*-**5c** and *Z*-**5c** were obtained in 33% and 9% yield, respectively, in each case as pale yellow, crystalline and stable compounds (m.p. 87–88 °C and 71–73 °C, respectively). All the butatriene derivatives **5** prepared were characterized by accurate analytical and spectroscopic data.

The esters **5** can be converted into the carboxylic acids **6**–**8**. Since they have a pronounced tendency to undergo nucleophilic addition,[6] protic conditions had to be avoided. The hydrolysis was carried out with [18]crown-6 as phase transfer catalyst of the THF/KOH system. **5a** thus furnished the acid **6** in 83% yield as an orange-yellow crystalline substance. *E*- and *Z*-**5c** yielded the isomerically pure dicarboxylic acids *E*- and *Z*-**8**, respectively, in 65% yield as bright-yellow crystals. In contrast, *E*-**5b** forms a *Z*/*E* mixture of the dicarboxylic acids **7**, from which isomerically pure, orange-colored *E*-**7** precipitates in 71% yield upon crystallization. *Z*-**7**, on the other hand, could—due to sparing solubility—only be obtained by a very tedious chromatographic separation.

Upon determination of the melting points, still in the crystalline state, *Z*-**7** and *Z*-**8** rearranged into the *E*-isomers.

The dicarboxylic acids *E*- and *Z*-**7**, like their esters **5b**, have different ^{1}H-NMR spectra;[16] the equilibrium constant *K*, with a value of 2.9 (in $[D_6]$DMSO) in favor of the *E* isomer, is significantly higher than in the case of **5b**.

[10] An excess of metalating agent leads to dimetalation, which causes substantial losses in yield.
[11] According to ^{1}H-NMR spectra the reaction mixtures contain ca. 50% **3a**, 75–80% **3b**, and 75% **3c**. The chromatographic purification afforded **3a** in only 30–35% yield as a readily decomposable oil. **3b** and **3c** (diastereomeric mixtures) were isolated in 40 and 45% yield, respectively, as viscous yellowish oils that decompose at room temperature. **3a**–**c** are characterized by accurate analytical and spectroscopic data.

[13] This reflects the relatively high acidity of the γ-H atom of **1** [9]. In the case of the diphenylallene alcohols analogous to **3** (Ph instead of COOMe), the crystalline sulfinates can be isolated; the elimination can be achieved only with strong bases such as lithium diisopropylamide.

On the Thermal Behavior of Butatrienecarboxylic Acid Derivatives: Crystal and Molecular Structure of a [4]Radialene Tetracarboxylic Ester**

By *Franz W. Nader,* Claus-Dieter Wacker, Hermann Irngartinger, Ursula Huber-Patz, Rainer Jahn,* and *Hans Rodewald*

The cycloaddition reactions of cumulenes are of special interest, both from the preparative as well as the mechanistic point of view. The thermal behavior of numerous allene derivatives has been studied in detail.[1] Some relatively stable butatrienes have been thermally converted, via [2+2]-cycloaddition at the central cumulene bond, into [4]radialenes.[2–4] One exception so far is the unsubstituted butatriene, which already reacts thermally at 0 °C—sometimes explosively. The [4+4]-cycloaddition product 1,5-cyclooctadiyne could be isolated in 2% yield from the reaction mixture.[5]

The synthesis of the stable, crystalline butatrienecarboxylic acid derivatives **1**–**3** in isomerically pure form[6] enabled, inter alia, the investigation of its thermal behavior in the crystalline state and in solution.

The esters *Z*-**2a** and *E*-**2a** and the carboxylic acids *Z*-**2b** and *E*-**2b** were investigated.[7] The two *Z*-isomers were converted almost completely into the *E*-forms in the solid state, already slowly at room temperature, but much faster on heating (*Z*-**2a**: no longer detectable in the ^{1}H-NMR spectrum after two days at 70–75 °C).

1, $R^1 = R^2 = C_6H_5$, $R^3 = CH_3$

2a, $R^1 = C_6H_5$, $R^2 = COOCH_3$, $R^3 = CH_3$
2b $= COOH$ $= H$

3a, $R^1 = C(CH_3)_3$, $R^2 = COOCH_3$, $R^3 = CH_3$
3b $= COOH$ $= H$

Crystals of the carboxylic acid *E*-**2b** proved to be stable up to 110–120 °C; at 140–150 °C, a black viscous mass is slowly formed (after ca. 14 days), from which no well-defined products could be isolated. On the other hand, crystals of the ester *E*-**2a** underwent complete reaction within 5 days without any observable melting during conversion. Aside from a small amount of polymeric material (< 5%), only a bright yellow substance was formed, which, after column chromatographic separation of the polymeric material, could be isolated in crystalline form[9] in 75% yield.[8, 9] Its mass spectrum was consistent with a dimeric structure [*m/z* 625 ($M - CH_3$), CI(CH_4): *m/z* 641 ($M + 1$)]. The absence of a cumulene band in the IR spectrum indicated presence of a [4]radialene, which is consistent with the ^{13}C-NMR data.[9] Complete elucidation of the structure was accomplished by X-ray diffraction[10] (Fig. 1).

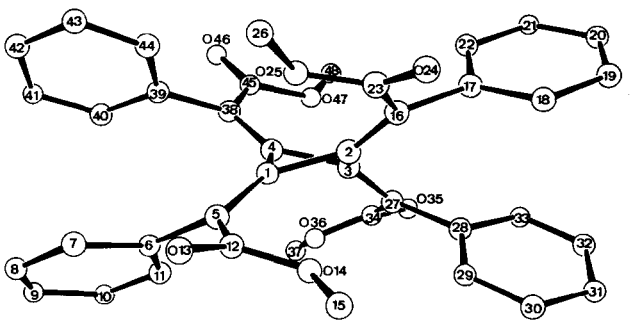
[**] This work was supported by the Fonds der Chemischen Industrie.

Surprisingly, the results of this analysis revealed that the species formed was not the [4]radialene **4**, as would have been expected from the configuration of the starting compound *E*-**2a**, but its (1*Z*,2*Z*,3*Z*,4*Z*) diastereomer[11] **5**.

In the [4]radialene **5** the four-membered ring is considerably more puckered (puckering angle 142.6(4)°) than in any of the previously reported [4]radialenes.[12] The torsion angles of the four-membered ring are on average 26.3(2)°



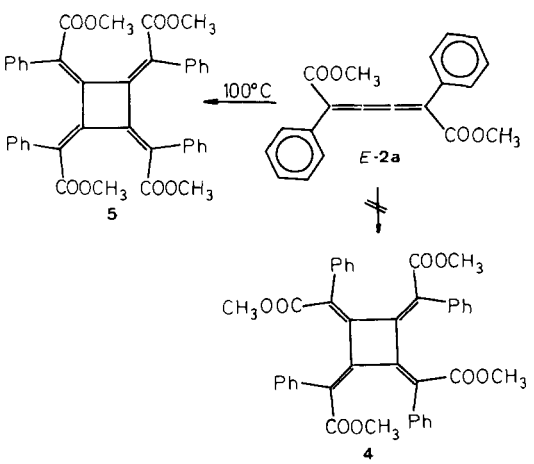


Fig. 1. Crystal structure of **5**. Selected bond lengths [Å] and angles [°]: C1-C2 1.494(4), C2-C3 1.498(4), C3-C4 1.499(4), C1-C4 1.494(4), C1-C5 1.336(4), C2-C16 1.334(4), C3-C27 1.342(3), C4-C38 1.336(4); averaged values: C_{Ph}-C_{sp^2} 1.484(8), C_{sp^2}-COOMe 1.485(12), (C-C)$_{aromat.}$ 1.377(11), C=O 1.197(9), C_{sp^2}-O 1.322(4), O-CH_3 1.449(6); C1-C2-C3 86.6(2), C2-C3-C4 87.1(2), C1-C4-C3 86.5(2), C2-C1-C4 87.4(2), C2-C1-C5 137.4(3), C4-C1-C5 132.2(3), C1-C2-C16 138.0(2), C3-C2-C16 132.3(3), C2-C3-C27 131.8(3), C4-C3-C27 137.6(3), C3-C4-C38 138.3(3), C1-C4-C38 131.2(2), C1-C5-C6 121.7(3), C1-C5-C12 120.2(3), C6-C5-C12 118.1(3), C2-C16-C23 121.3(3), C2-C16-C17 121.5(2), C17-C16-C23 117.0(3), C3-C27-C28 121.3(3), C3-C27-C34 120.9(3), C28-C27-C34 117.6(2), C4-C38-C39 120.4(3), C4-C38-C45 123.4(3), C39-C38-C45 116.0(3).

(internal) and 65.6(5)° (external). In addition to the puckering, the radialene double bonds are inclined at 13.8° to the plane of the three attendant carbon atoms of the four-membered ring. Due to steric hindrance of neighboring substituents the radialene double bonds are twisted. The angles of twist are between 12.6° and 18.3° on the "ester side" and between −5.2° and −11.1° on the "phenyl

side". The phenyl and ester groups are twisted counter to each other relative to the double bonds (46.5° to 67.7° and −2.6° to −47.9°, respectively), such that no regular propeller arrangement results.

Within the limits of experimental error, the bond lengths in the four-membered ring are equal (1.496(4) Å), as are also the lengths (1.337(4) Å) of the double bonds, and in each case they lie in the expected range (see Fig. 1).

The high stereospecificity of the solid state reaction is indicative of a crystal lattice control, whereby the stereochemical result requires that both molecules have to assume a *Z*-type rotational form during the course of the dimerization (possibly via a diradical mechanism), since the radialene **5** is made up of two *Z*-configurated butatriene units.

Compared to the solid-state reaction, the corresponding reaction in solution (boiling toluene) proceeds very inhomogeneously. Aside from 20% monomer (*E*/*Z* mixture), only ca. 32% of the dimer **5** could be detected (by ^{1}H-NMR spectroscopy) after five days. The remaining product was an inseparable mixture, which presumably contained the isomeric [4]radialenes[8] such as **4**.

[7] The uncatalyzed thermolyses of butatrienes usually require temperatures in excess of 100°C, a reason for having initially ruled out the lower melting compounds **1** (m.p. 94–95°C), *Z*-**3a** (m.p. 71–73°C), and *E*-**3a** (m.p. 87–88°C) as candidates for solid-state reactions.

[8] The substance is stable in the solid state; in solution, however, novel compounds are formed, which, on grounds of the similar ^{1}H-NMR and ^{13}C-NMR spectra, are presumably isomers. The solution contains only ca. 80% of the original product after two days, thus explaining the losses observed on chromatographic purification.

[11] In the case of the radialenes described here, four *cis-trans* isomers are possible. Owing to the equivalence of the ring atoms, the usual *Z*/*E* convention fails. Even recourse to the more recently recommended sequence rule 3 (V. Prelog, G. Helmchen, Section 5.3.1 in *Angew. Chem. 94* (1982) 614; *Angew. Chem. Int. Ed. Engl. 24* (1985) 567) does not provide unambiguous descriptors for this problem. An invariant designation of the isomers is achieved, however, if the stereochemistry of the butatrienes on which the [4]radialenes are based is taken into consideration. In **5**, this is likewise the *Z*-butatriene for the 1,2, the 2,3, the 3,4 and the 4,1 bonds. **4** is correspondingly built up of *E*-units, and therefore has the descriptors 1*E*,2*E*,3*E*,4*E*. The two remaining isomers, each of which are formed from one *Z*- and one *E*-butatriene, are to be designated as 1*Z*,2*Z*,3*E*,4*E* and 1*Z*,2*E*,3*Z*,4*E*, respectively.

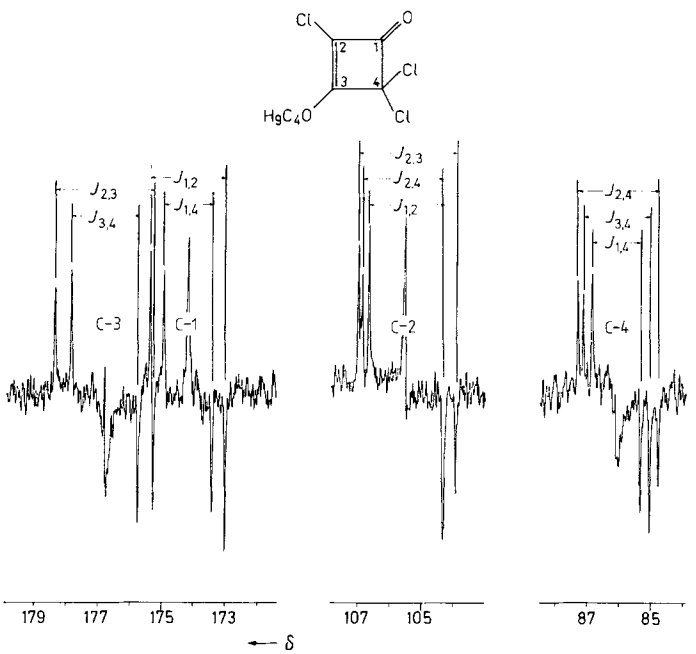
Misinterpretation of CC Bonding through Unusually Large $^2J_{CC}$ Values—a Caveat for the Use of INADEQUATE-^{13}C-NMR Spectroscopy**

By *Hans Bauer, Joachim Buddrus,* Wolfgang Auf der Heide,* and *Wolfgang Kimpenhaus*

Dedicated to Professor Robert Kosfeld on the occasion of his 60th birthday

Recourse is increasingly being made to ^{13}C-^{13}C couplings for the structural elucidation of organic compounds;[1-6] thereby, double quantum coherence NMR spectroscopy with the INADEQUATE pulse sequence has proven especially helpful.[7] One presupposes that a CC coupling above a certain value arises from a CC bonding. It now emerges, however, that this does not always hold true.

The one-dimensional INADEQUATE-^{13}C-NMR spectrum of 3-butoxy-2,4,4-trichlorocyclobutenone **2d** shows, in addition to the expected ^{13}C-^{13}C couplings, an inexplicably large coupling between C-2 and C-4 (64.1 Hz) (Fig. 1); this value is typical for couplings between directly bonded C-atoms. Since there is no doubt about the structure,[8] this value can only be reconciled with a coupling over two bonds. $^2J_{CC}$ values[9] are generally not greater than 5 Hz; and even in exceptional cases, for instance the coupling in ketones via the carbonyl group, the values do not exceed 20 Hz. We have therefore investigated further compounds exhibiting the structural characteristics of **2d**.



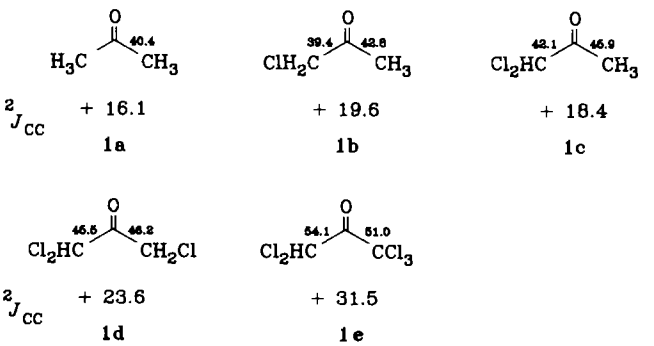


Fig. 1. INADEQUATE-^{13}C-NMR spectrum of **2d** at 25 MHz (three sections). Solution: 1.5 g of **2d** and ca. 10 mg of Cr(acac)$_3$ (relaxation reagent) in 1 mL of C_6D_6. Recording conditions: 3000 Hz, 16 K. The delay τ in the pulse sequence [7] corresponds to $J_{CC}=58$ Hz. 35404 scans with 5 s repetition time.

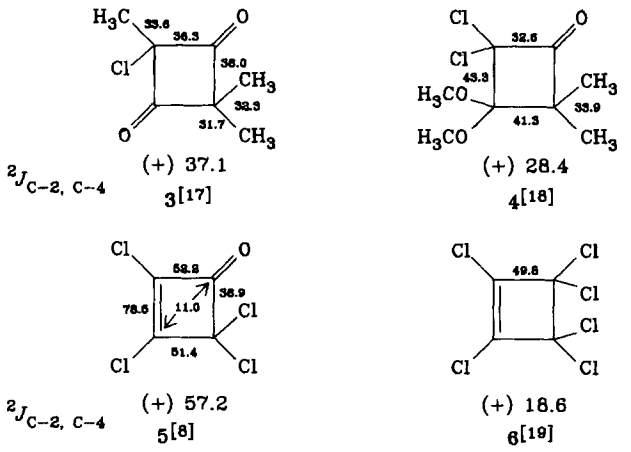
[**] We thank Herr *H. Herzog*, Dortmund, for his help in preparing and measuring the NMR spectra of some of the compounds; thanks are also due to Priv.-Doz. Dr. *K. Roth*, Berlin, for some helpful discussions.

In the case of acetone, **1a**, and the chlorinated derivatives **1b**-**1e** (Scheme 1) $^2J_{CC}$ increases from +16.1 Hz in **1a**[10] to 31.5 Hz in **1e**. The positive signs of **1b**-**1e** follow from the steady increase in the absolute values, an increase being interrupted only in the case of **1c**. The substituent effect of a chlorine atom on $^2J_{CC}$ is on average ca. ±2.5 Hz.

Scheme 1. $^1J_{CC}$ and $^2J_{CC}$ in Hz. For ^{13}C chemical shifts see [11].



In the 3-alkoxycyclobutenone series **2a**-**2d** (Scheme 2) $^2J_{C\text{-}2,C\text{-}4}$ increases from (+)20.5 Hz in **2a** to (+)64.1 Hz in **2d**. The signs are most likely also positive, since the influence of the chlorine atoms should be the same as in the case of the acetone compounds. A comparison of the values for **2a** and **2b** and for **2c** and **2d** shows that the substituent effect of the chlorine atoms on $^2J_{CC}$ is, in these instances, respectively, ca. 13 and 26 Hz, i.e. distinctly greater than in the acetone series.

Scheme 2. $^1J_{CC}$ and $^2J_{CC}$ in Hz. For ^{13}C chemical shifts see [14].

The coupling constants $^2J_{C\text{-}2,C\text{-}4}$ of **2a**-**2d** result, in each case, from the contributions of two couplings (via the C-2/C-1/C-4 and C-2/C-3/C-4 bonds).[15,16] For comparison, the compounds **3**-**6** were investigated (Scheme 3).

The coupling constant $^2J_{C\text{-}2,C\text{-}4}$ in **3**, which has two identical coupling pathways, in each case via a carbonyl group, is 37.1 Hz; each coupling contributes 18.5 Hz to the total coupling. Since the corresponding coupling constant in **2b**-**2d**, and also in **4** and **5**, is considerably larger, a substantial portion of the same sign of the coupling must arise from the coupling via the CC double bond; this coupling also exists in **6**, so the coupling constant of 18.6 Hz is not surprising.

Scheme 3. $^1J_{CC}$ and $^2J_{CC}$ in Hz. For ^{13}C chemical shift see [20].

As yet, there is no explanation for the unusually large $^2J_{CC}$ values sometimes observed in chlorinated ketones. Regardless of this they indicate that care must be taken in determining the CC connectivities of unknown compounds via ^{13}C-^{13}C couplings: *not every coupling constant that is greater than ca. 25 Hz is an indication of CC bonding.*

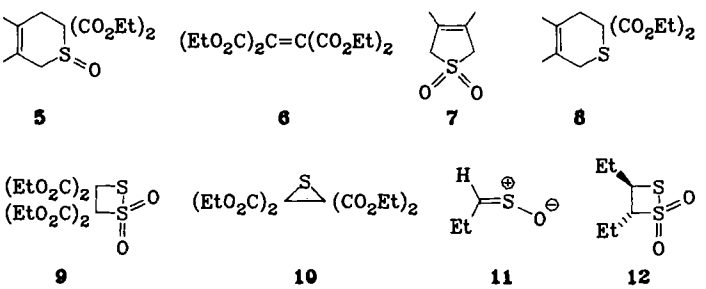
Diethyl Thioxomalonate *S*-Oxide; a Sulfine as Reactive Intermediate**

By *Rolf W. Saalfrank** and *Walter Rost*



Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 60th birthday

1,3-Bis(dialkylamino)-1,3-diethoxyallenes—malonamide dianion equivalents—react with disubstituted malonyl chlorides to give allene-1,1-dicarboxamides.[1] By the choice of appropriate combinations of substituents, this transallenation[2] has wide scope. Tetraethoxyallene—a malonic ester dianion equivalent—reacts with phosgene and thiophosgene to give bis(ethoxycarbonyl)ketene and bis(ethoxycarbonyl)thioketene, respectively.[3]

We have now been able to generate diethyl thioxomalonate *S*-oxide **4** as an intermediate by reaction of tetraethoxyallene **1**[4] with thionyl chloride **2**. The ketene acetal **3**, formed in the first step with elimination of ethyl chloride, spontaneously eliminates ethyl chloride again to afford the heteroallene **4**.

4 can be trapped with 2,3-dimethyl-1,3-butadiene in a Diels-Alder reaction, forming diethyl 3,6-dihydro-4,5-dimethyl-2*H*-thiopyran-2,2-dicarboxylate 1-oxide **5** (42% yield).[7,8] Surprisingly, tetraethyl ethylenetetracarboxylate **6** (31%), 2,5-dihydro-3,4-dimethylthiophene 1,1-dioxide **7** (21%), and diethyl 3,6-dihydro-4,5-dimethyl-2*H*-thiopyran-2,2-dicarboxylate **8** (22%) are also formed (Table 1). We assume that the dimerization of **4** to tetraethyl 1,2-dithietane-3,3,4,4-tetracarboxylate 1,1-dioxide **9**[9] competes with the trapping of **4** by 2,3-dimethyl-1,3-butadiene. By elimination of sulfur dioxide, **9** affords the intermediate tetraethyl thiiranetetracarboxylate **10**, which finally eliminates sulfur[11] to give the olefin **6**. The intermediacy of **9** and its

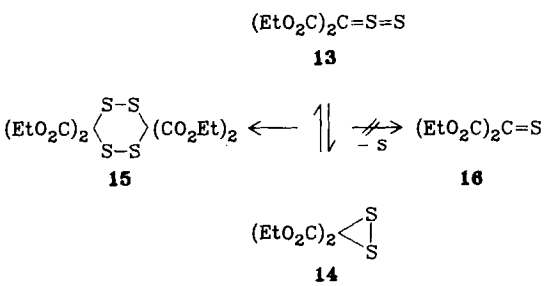
decomposition explain in a simple manner the product **7**, which is formed in a cheleotropic reaction from 2,3-dimethyl-1,3-butadiene and the sulfur dioxide already present.[12] The formation of **8** has not yet been unequivocally explained. **8** is probably formed by reduction of **5** by the elemental sulfur that was formed earlier.[13] The intermediacy of **9** is supported, moreover, by the fact that the lachrymatory factor of onions, *Z*-thiopropionaldehyde *S*-oxide **11**, dimerizes to the stable *E*-3,4-diethyl-1,2-dithietane 1,1-dioxide **12**.[10] Furthermore, it was possible to demonstrate the existence of **9** in the crude product by mass spectroscopy [*m/z* 412 (M^+)]. All attempts to obtain pure **9** have been unsuccessful and have led exclusively to **6**. When the reaction of **1** and **2** is carried out in the absence of a trapping agent for sulfine, **6** is again the only product isolated in pure form.

Table 1. Physical data for the compounds **5**, **6**, **7**, **8**, and **15**.

5: IR (film): $\nu = 1730$ cm^{-1} (C=O); ^{13}C-NMR ($CDCl_3$): $\delta = 13.92$ and 13.98 (CH_3), 19.26 and 20.32 (CH_3), 28.15 and 51.57 (CH_2), 62.55 and 63.07 (OCH_2), 70.53 (C_q), 116.33 and 125.43 (C=), 165.36 and 165.75 (C=O); b.p. = 117 °C/0.1 torr



6: IR (KBr): $\nu = 1735$ cm^{-1} (C=O); ^{13}C-NMR ($CDCl_3$): $\delta = 13.83$ (4CH_3), 62.52 (4OCH_2), 135.35 (2C=), 162.29 (4C=O); m.p. = 56 °C

7: IR (KBr): $\nu = 1300$ and 1110 cm^{-1} (SO_2); ^{13}C-NMR ($CDCl_3$): $\delta = 14.56$ (2CH_3), 60.61 (2CH_2), 125.50 (2C=); m.p. = 135 °C

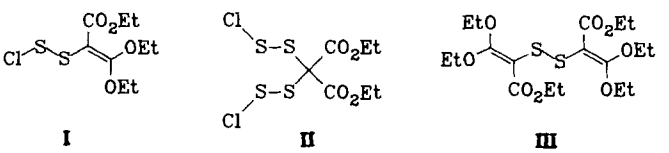
15: IR (KBr): $\nu = 1720$ (C=O); ^{13}C-NMR ($CDCl_3$): $\delta = 13.92$ (4CH_3), 62.52 (2C_q), 63.77 (4CH_2), 165.84 (4C=O); m.p. = 56 °C



If tetraethoxyallene **1** is reacted with disulfur dichloride[14] instead of with thionyl chloride **2**, no diethyl thioxomalonate *S*-sulfide **13** can be trapped with 2,3-dimethyl-1,3-butadiene. (**13** possibly exists in equilibrium with the isomeric diethyl dithiiranedicarboxylate **14**[15, 16].) Instead, tetraethyl 1,2,4,5-tetrathiane-3,3,6,6-tetracarboxylate **15**[17] is isolated in 83% yield (Table 1). We assume that **15** is formed by dimerization of the isomers **13**/**14**.[18] Apparently, **13** and/or **14** do not eliminate sulfur, since no diethyl thioxomalonate **16** or its dimer can be detected.[15, 19]

Do $Cp(CO)_2Mn$ Fragments Stabilize Radicals?**

By *Renate Gross* and *Wolfgang Kaim**

$Cp(CO)_2Mn$ fragments [Cp = η^5-C_5H_5(Cp^0), η^5-C_5H_4Me (Cp^1), η^5-C_5Me_5(Cp^5)] can stabilize diamagnetic, unstable molecules.[1] Three recent studies were concerned with the formation of radical complexes involving these metal fragments,[2–4] and although each of the complexes described has one unpaired electron, they differ significantly in the distribution of spin. For anionic, binuclear coordination compounds of pyrazine, the unpaired electron was shown by ESR spectroscopy to be localized largely in the π-system of the heterocyclic ligand;[3] for the complexes $[Cp(CO)_2(L)Mn]$ (L = NH(*m*-$C_6H_4CH_3$),[2] S*t*Bu, and SePh[4]), only a large ^{55}Mn coupling constant was ob-

served. We report here on the ESR spectroscopic distinction between genuine radical complexes and those compounds that must be described as low-spin Mn^{II} systems.

We were able to obtain the radical anions of 4-cyanopyridine **1**, 4,4'-bipyridine **2**, and terephthalonitrile **3** with coordinated $Cp^{1}(CO)_2Mn^{I}$ fragments[5] analogously to the preparation of pyrazine radical complexes.[3] At room temperature, $\mathbf{1}^{\odot\ominus}$ forms an N^1-coordinated[5b] mononuclear radical complex (Fig. 1). $\mathbf{2}^{\odot\ominus}$ and $\mathbf{3}^{\odot\ominus}$ yield binuclear complexes, even though the neutral ligand **3** only affords the mononuclear complexes $[Cp(CO)_2(\mathbf{3})Mn]$;[5c] this is due to the increased basicity of reduced ligands.[6] In all these cases, the ESR data (Table 1) indicate that radical complexes are present, i.e., the spin distribution is little changed compared with that in the free radical anions[7] and the g factors are only slightly smaller than $g_{electron} = 2.0023$.[3]

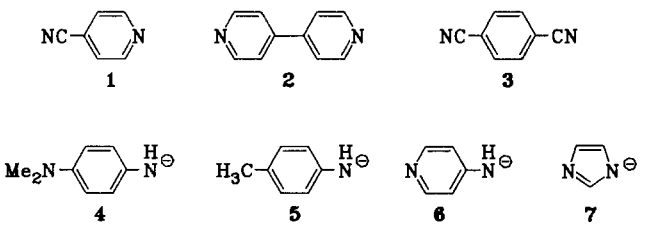

Table 1. ESR data of paramagnetic $Cp(CO)_2Mn$ complexes [a].

[a] Coupling constants a [mT]. [b] In THF, counterion $K^{\oplus}$. Coupling constants determined by computer simulation. [c] Insufficiently resolved super-hyperfine coupling.

The complexes of $Cp(CO)_2Mn$ fragments with the deprotonated amine ligands **4**–**7**,[8] prepared according to the method of *Sellmann, Müller* et al.,[2] and the corresponding sulfur and selenium systems[4] show much larger ^{55}Mn coupling constants than do radical complexes (Fig. 1), exhibit no detectable interaction of the unpaired electron with the coordinated ligands, except for the special case $[Cp^{1}(CO)_2(\mathbf{4})Mn]$,[9] and have isotropic g factors that are significantly larger than $g_{electron}$ (Table 1). These results do not support their formulation as "radical complexes,"[2,4] but rather indicate the presence of low-spin manganese(II),[1,11] i.e., d^5 configuration of the metal. Further arguments in favor of this interpretation are provided by comparison with other cyclopentadienyl manganese(II) complexes: $[CpCl(D)_2Mn^{II}]$ (D = amine or phosphane) are high-spin complexes[10] and a high-spin/low-spin equilibrium is observed in the manganocenes, Cp_2Mn,[11] so that a low-spin complex is expected for $[Cp(CO)_2(L)Mn^{II}]$ with the strong ligands CO and L. Electrochemical investigations[3,12] show that the one-electron oxidation of $[Cp(CO)_2(L)Mn^{I}]$ is extremely facilitated by nucleophilic ligands L: the difference between $E_{ox} = +1.24$ V for L = CO and $E_{ox} = +0.09$ V for L = piperidine[12] suggests that the extremely strong nucleophiles $^{\ominus}NR_2$ and $^{\ominus}SR$ should effectively stabilize the oxidized state, that is, Mn^{II}; indeed, negative potentials relative to the saturated calomel electrode are found for $[Cp^{5}(CO)_2(L)Mn^{II/I}]$: $E = -0.87$ V (L = **5**[13]) and $E = -0.98$ V (L = $^{\ominus}S$*t*Bu[4]).

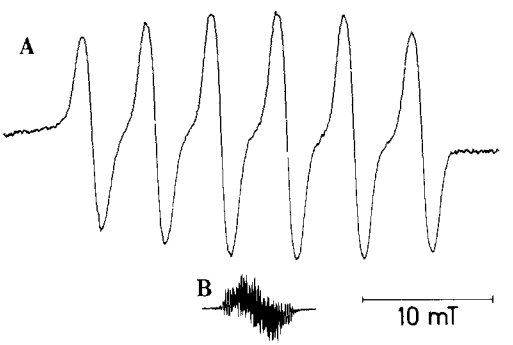

Fig. 1. The ESR spectra of $[Cp^{5}(CO)_2(\mathbf{5})Mn]$ (**A**) and $[Cp^{1}(CO)_2(\mathbf{1}^{\odot\ominus})Mn]$ (**B**) at room temperature in toluene and THF, respectively, illustrate the difference between localization of the unpaired electron on the metal and in the π-system of the radical ligand. In **A**, only a large ^{55}Mn coupling constant is observed ($I = 5/2$, 100% natural abundance), whereas spectrum **B** exhibits extensive hyperfine coupling of the numerous magnetically active nuclei of the radical ligand (486 theoretical lines).

Further evidence for strongly differing electronic configurations is provided by the opposite deviations of the g factors from $g_{electron}$ (Table 1): whereas the radical anion complexes experience only a small lowering of the g factor, on account of low-lying unoccupied metal orbitals,[3] the manganese(II) complexes exhibit significantly higher g values, which—in agreement with theoretical investigations on $Cp(CO)_2M$ complexes[14]—indicate doubly occupied levels close to the singly occupied orbital.[3,15] The relatively strong absorptions of some of these Mn^{II} compounds in the visible[2,4,8] can accordingly be interpreted as LMCT (ligand-to-metal charge-transfer) transitions, in analogy to corresponding Cu^{II} and Ru^{III} systems.[16] It is only in this charge-transfer excited state ($d^6/5\pi \leftarrow d^5/6\pi$) that the unpaired electron is localized on the ligand (radical complex) and, as expected, the LMCT excitation energies, the g factors, and the ^{55}Mn coupling constants decrease as the electrons on the ligands become more available, such as in the series **7**, **6**, **5**, **4**. In the compound $[Cp^{1}(CO)_2(\mathbf{4})Mn]$, the separation between the ground state and the LMCT excited state has already decreased to $\approx 11\,500$ cm^{-1}, so that the first evidence of a super-hyperfine interaction with the ligand **4** is recognizable (Table 1). This, species, which is stabilized by the extreme donor effect of a deprotonated *p*-phenylenediamine ligand, must nonetheless be viewed as a Mn^{II} system.

The $Cp(CO)_2Mn$ fragments thus form two different classes of stable paramagnetic complexes: as neutral and diamagnetic Mn^{I} fragments with d^6 metal configuration, they can stabilize radical anion ligands by π back-bonding.

In contrast, the less common oxidized form of the organometal fragment with the metal center present as low-spin Mn^{II} is stabilized[17, 18] if very nucleophilic diamagnetic ligands are employed.

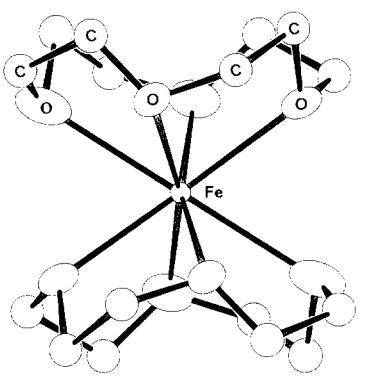
Reactions in the Ligand Sphere of Iron(II): Synthesis of Crown Ethers

By *Kurt Meier** and *Grety Rihs*

Cationic arene-iron complexes are thermally and chemically very stable, but, upon excitation with light, can undergo ligand exchange reactions with high quantum yields.[1–3] Thus, irradiation of the toluene complex **1** in aprotic solvents in the presence of the ligands L = CO, RNC results in the formation of the isolable complexes **2**; in the absence of suitable ligands, one-half molar equivalent of both ferrocene **3** and iron(II) hexafluorophosphate **4** are formed.

The Lewis acids generated by irradiation are active for the polymerization of bi- and multifunctional epoxides to give insoluble polyethers.[4, 5] These photoinitiator properties of arene-iron complexes have found technical applications in resist and surface-protection technology.

When complex **1** is irradiated in dichloromethane in the presence of a tenfold excess of ethylene oxide, one-half molar equivalent of ferrocene **3** is again formed along with



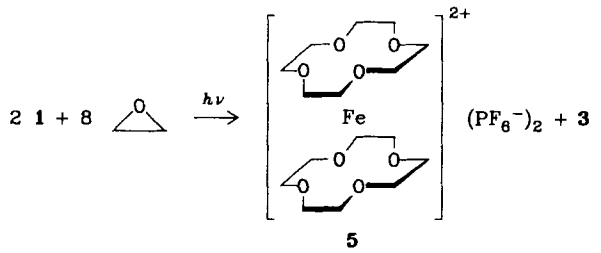


Fig. 1. ORTEP plot of the structure of the cation of **5**. Aba 2, $a = 17.819$, $b = 20.663$, $c = 8.882$ Å, $Z = 4$; $R = 0.112$ for 1910 observed reflections ($I > 2\sigma(I)$). The cation has C_2 symmetry. The mean Fe–O bond length is 2.40 Å. The relatively poor R factor is due to disorder of the $-CH_2-CH_2-$ bridges. Further details on the crystal structure investigation are available from the director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England) by giving the full journal citation.

a white crystalline product, which, after a single recrystallization, affords fine needles of the [12]crown-4 complex **5**.[6] Addition of 2,2'-bipyridine (bpy) to the solution of the recrystallized complex **5** gives $[Fe(bpy)_3]$ $(PF_6)_2$ and two molar equivalents of [12]crown-4. The single-crystal X-ray structure determination of **5** (Fig. 1) shows a sandwich-like arrangement of the crown ether ligands around the central iron atom. The coordination geometry at iron corresponds to that of a cube twisted by 19°, in which the eight ligating oxygen atoms occupy the corner positions. For the $[Ag([12]crown\text{-}4)_2]AsF_6$ complex formed from ethylene oxide and $AgAsF_6$ in SO_2,[7] the faces of the cube are twisted by 30°, while the analogous manganese[8] and sodium complexes[9] exhibit the coordination geometry of a regular square antiprism.

When 2,2'-bipyridine is added to a solution of non-recrystallized **5**, 85% [12]crown-4 and 15% [15]crown-5 are obtained. When (η^5-cyclopentadienyl-η^6-toluene)iron(II) tetrafluoroborate is used as starting material, the 12- and 15-membered crown ethers are formed in a ratio of 10:1; for the analogous hexafluoroantimonate complex, the ratio is 3:2. The irradiated solution contains, in addition to ferrocene and unreacted ethylene oxide, traces of 1,4-dioxane.

Lithium-Coordinated α-Sulfonyl Carbanions: Synthesis and X-Ray Structure Determination of $[\{CH_2(SO_2C_6H_5)\}Li(tmeda)]_2$**

By *Hans-Joachim Gais,* Hans Jörg Lindner,** and *Jürgen Vollhardt*

α-Sulfonyl carbanions $[R^1R^2C{-}SO_2R^3]^-$ are important, asymmetrically reacting ($R^1 \neq R^2$) intermediates in organic synthesis.[1] Their structure is the topic of considerable controversy, and definitive information is still lacking. Whereas experimental[2a] and theoretical[2b] studies on cation-free α-sulfonyl carbanions postulate a chiral structure without free rotation around the CS bond, a planar configuration at the C atom, and stabilization via (n_C-d_S) or (n_C-$\sigma^*_{SR^3}$) π-overlap, corresponding investigations of the lithium-coordinated species suggest chiral four- or five-center chelate structures with intramolecular coordination of the Li, O, and C atoms and a nonplanar configuration at the C atom.[3] We present here the X-ray structure determination of the $[\{CH_2(SO_2C_6H_5)\}Li(tmeda)]$ dimer **1** (tmeda = N,N,N',N'-tetramethylethylenediamine)—the first X-ray analysis of a lithiated alkyl sulfone[4]—which provides decisive information regarding the structure of lithium-coordinated α-sulfonyl carbanions.

1 was prepared by metalation of methyl phenyl sulfone with *n*-butyllithium (*n*BuLi) in TMEDA.[5] The single-crystal X-ray structure determination of **1**[6] shows dimers with a crystallographic center of inversion (Fig. 1).

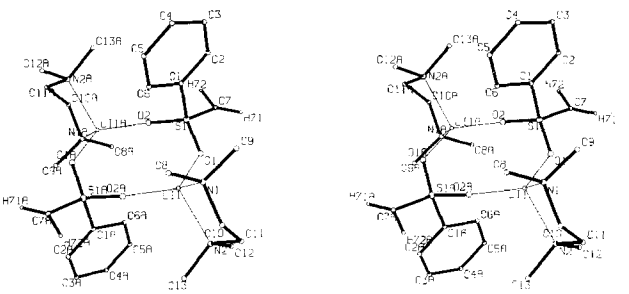

Fig. 1. Stereoscopic view of the structure of **1** in the crystal (H atoms, with the exception of those on C7 and C7A, not shown). Important distances [Å] and angles [°]: S1-C7 1.608(3), S1-C1 1.812(2), S1-O1 1.464(2), S1-O2 1.456(2), Li1-O1 1.908(4), Li1-O2A 1.864(4), Li1-N1 2.148(4), Li1-N2 2.123(4); H71-C7-H72 137(3), C7-S1-C1 114.5(1), O1-S1-C1 102.1(1), O1-S1-C7 111.4(1), O1-S1-O2 114.9(1), O1-Li1-N1 114.8(2), O1-Li1-N2 108.0(2), O2A-Li1-N1 108.1(2), O2A-Li1-N2 112.1(2), N1-Li1-N2 87.6(2), O1-Li1-O2A 121.2(2), S1-O1-Li1 134.1(2), S1-O2-Li1A 155.0(2); H71-C7-S1-C1 81(3), H72-C7-S1-C1 −81(3), C2-C1-S1-C7 −14.0(6), H71-C7-S1-O1 −34(3), H72-C7-S1-O2 34(3).

Li, S, and O atoms form a flat, chair-like, eight-membered ring with the S atoms above and below the plane formed by the Li and O atoms. On the ring, the methylene groups are in equatorial and the phenyl rings in axial positions. The two TMEDA molecules are so arranged that the Li atoms are tetrahedrally coordinated by two O and two N atoms. The methylene group bonded to the sulfur lies *outside* the coordination sphere of Li. Within the limits of

[**] This work was supported by the Fonds der Chemischen Industrie.

experimental measurement, this is nearly planar. The deviation of C7 from the plane S1-H71-H72 is only 0.12 Å, and the hydrogen atoms are slightly directed toward the phenyl ring. The unusually short S1-C7 bond (1.608 Å) suggests a true CS double bond. It is nearly the same length as that in the sulfine [1.610(4) Å][8a] and in its derivatives.[8b] This result, along with the orthogonality of the C7-S1-C1 and H71-C7-H72 planes, is in agreement with the results of ab initio calculations on cation-free α-sulfonyl carbanions[2b] as well as with investigations of $[\{CH_2(SO_2C_6H_5)\}Li]$[3b] by IR spectroscopy, and confirms their stabilization by an effective π overlap. However, the theoretically[2b] and experimentally[3b] predicted lengthening of the S1-O1(2) and S1-C1 bonds is not supported. Their bond lengths in **1**, 1.464 (1.456) Å and 1.812 Å, respectively, are nearly the same as in methyl phenyl sulfone [S-O1(2) 1.465 (1.453), S-C1 1.832, S-C7 1.761 Å].[9] **1** is a compound comparable to the lithium enolates.[10]

Novel C–O Bond Formation via [3+2] Cycloaddition of Diphenylketene to a Dioxo Metal Moiety**

By *Wolfgang A. Herrmann,* Ulrich Küsthardt, Manfred L. Ziegler,* and *Thomas Zahn*

The Re^{VII} complex trioxo(η^5-pentamethylcyclopentadienyl)rhenium **1** has proved to be a valuable starting material for the preparation of high-valent organorhenium compounds.[1-3] Whereas all previously described functionalizations have proceeded with partial deoxygenation of the ReO_3 fragment, we have now discovered a novel cycloaddition reaction in which the integrity of this group is retained.

When compound **1** is reacted with excess diphenylketene in tetrahydrofuran (THF) at room temperature, the violet cycloadduct **2**[4] is formed rapidly and nearly quantitatively.

A single-crystal X-ray structure determination afforded the initially surprising result that the heterocumulene is not bonded to the ReO group via the CO moiety, as in the known complex $[(\eta^5\text{-}C_5Me_5)ReO\{\eta^2\text{-}O_2C{=}C(C_6H_5)_2\}]$,[2b] but rather via the CC double bond. This results in a nearly planar five-membered ReO_2C_2 metallacycle (sum of angles 539.4°). As a consequence of the formation of two carbon-oxygen bonds [C1-O3, 133; C2-O2, 147 pm], the two oxygen-rhenium bonds involved are lengthened to very different extents. The Re-O3 distance (202 pm) corresponds to that of a single bond; the Re-O2 distance (184 pm) is between that of a single bond and that of a double bond. The length of the exocyclic Re-O1 bond (168 pm) is typical for a double bond. As a result of the cyclization, the C1-C2 distance (151 pm) is markedly increased compared with that in free and π-coordinated ketenes (127-135 pm)[5] and therefore best looked upon as a single bond. In accord with this interpretation, compound **2** eliminates carbon dioxide upon thermolysis of the solid at 180 °C. The other MO_2C_2 metallacycles known up to now exhibit different bonding arrangements.[6]

The reaction described here is the first example of a [3+2] cycloaddition of a ketene to an organometallic dioxo metal moiety, and is one more indication of the high stability of the rhenium-oxygen bonds in complex **1** if oxy-

gen-abstracting reducing agents (e.g., phosphanes[2]) are absent.

The marked oxyphilicity of rhenium in higher oxidation states allows two types of reaction to occur. The [2+2] cycloaddition to give the four-membered ring **B** apparently occurs only when the metal center is capable of attaining an even higher coordination number. This is the case for all reactions of the Re^V compound $[(\eta^5\text{-}C_5Me_5)ReO_2]_2$,[2a] since this is always found as the mononuclear fragment $(\eta^5\text{-}C_5Me_5)ReO_2$ in the subsequent products. In contrast, **1** already contains the stable, pyramidal ReO_3 fragment, the metal center of which is not readily accessible, and therefore undergoes the type **A** reaction described here.

A **B**

Despite the very different geometries in **A** and **B**, the products always contain the ReO_3 moieties, which, taking into consideration the π-bonded cyclopentadienyl ligands, form (distorted) trigonal pyramids. The oxo ligands that are not involved in the cycloadditions remain largely unchanged with respect to their bonding relationships to the transition metal (double bonds), whereas the lengths of the Re-O bonds incorporated into the four- and five-membered structures **B** and **A**, respectively, are increased, approaching those of single bonds. The significance of the [2+3] cycloaddition reaction described here, the first of its type, lies in the oxidation of carbon-carbon multiple bond systems, like those that have been carried out with oxo derivatives of higher-valent osmium.[7]

Skeletal Isomerization of the $[Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2]$ Cluster by Recrystallization in Various Solvents

By *Robert Bender, Pierre Braunstein,* Antonio Tiripicchio,* and *Marisa Tiripicchio Camellini*

The long-standing interest in polymetallic chemistry involving bridging μ-PR_2 groups arises from both the electronic properties of this three-electron donor ligand and its unique geometrical flexibility. The M-P-M angle can vary from ca. 70 to 110° depending on whether metal-metal bonds are present or not.[1] A rich chemistry is being developed using this and other related ligands[2] and it can be anticipated that the class of phosphane-/phosphido-rich clusters, as yet little studied, will display new features and properties, not encountered in their analogues containing better π-accepting ligands (e.g., CO).

We report here a unique example of a cluster having two structural isomers, whose formation is dependent on the solvent used for crystallization. Heating a solution of $[Pt(C_2H_4)(PPh_3)_2]$ in acetone affords a red solution from which the Pt_3 cluster **1a** is isolated as bright red needles.[3]

$$3\,[Pt(C_2H_4)(PPh_3)_2] \xrightarrow[\text{acetone}]{\Delta} [Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2] + 3\,C_2H_4 + PhH + \cdots$$

1a

1a has imposed m symmetry[4] (Fig. 1). The same complex was obtained as a C_6H_6 solvate (C_2 symmetry) by *Carty* et al.[5] During the numerous attempts to grow crystals of **1a** suitable for X-ray analysis, we surprisingly found that dark red crystals of an isomer of **1a** (**1b**·$2CH_2Cl_2$, Fig. 2) formed in CH_2Cl_2/pentane at −20 °C.[4] Interestingly, recrystallization of **1b**·$2CH_2Cl_2$ in toluene/pentane at room temperature affords **1a**. The solvent used for crystallization is therefore of considerable

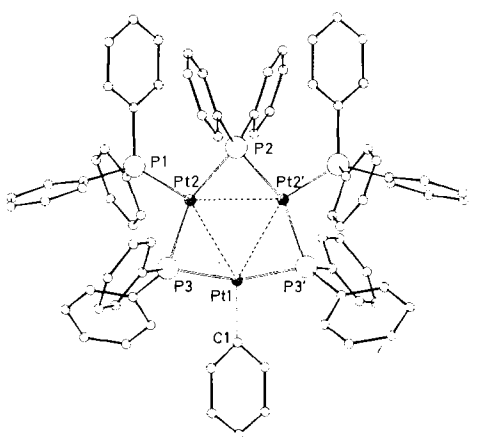

Fig. 2. Molecular structure of $\mathbf{1b}\cdot 2CH_2Cl_2$. Selected bond lengths [Å] and angles [°]: Pt1···Pt2 2.956(3), Pt2···Pt2′ 3.074(4), Pt2-P1 2.244(4), Pt2-P2 2.252(3), Pt1-P3 2.250(4), Pt2-P3 2.297(3), Pt1-C1 2.011(17); P3-Pt1-P3′ 159.8(1), P2-Pt2-P3 148.5(2), Pt1-P3-Pt2 81.1(1), Pt2-P2-Pt2′ 86.1(1), Pt2-Pt1-Pt2′ 62.6(1), Pt1-Pt2′-Pt2 58.7(1).

The two isomers differ in their Pt-Pt distances and Pt-P-Pt angles. **1a** contains a bent Pt_3 chain with two short Pt-Pt distances (2.758(3) Å) and a long Pt2-Pt2′ separation (3.586(2) Å). The Pt atoms are connected by three μ-PPh_2 ligands, their P atoms being roughly coplanar with the Pt atoms (deviations 0.17(5) Å for P1 and P1′, 0.08(7) Å for P2). In $\mathbf{1b}\cdot 2CH_2Cl_2$, the C_2 axis passes through Pt1 and P2: the three Pt atoms form an isosceles triangle with edges of 2.956(3) and 3.074(4) Å. These values are greater than conventional Pt-Pt distances,[6] but do not rule out the existence of Pt-Pt interactions.[7] Whereas P2 is coplanar with the Pt atoms, P3 and P3′ are displaced ±0.627(4) Å from this plane. The value of 86.1(1)° for the Pt2-P2-Pt2′ angle in $\mathbf{1b}\cdot 2CH_2Cl_2$ contrasts with that of 103.1(1)° in **1a**. Whereas the phenyl ring bonded to Pt1 is orthogonal to the Pt3 plane in **1a**, it makes an angle of 59.2(3)° with it in $\mathbf{1b}\cdot 2CH_2Cl_2$. No interaction involving the solvent was found in the structure of $\mathbf{1b}\cdot 2CH_2Cl_2$.

These 44e-clusters formally contain two Pt^{I} centers and one Pt^{II} center. The 4-electron-3-center bonding results in either two short and one long or in three medium Pt-Pt distances. **1** is the only example of a Pt cluster to display easy skeletal isomerism, a feature of great interest but rarely encountered in cluster chemistry.[1] Preliminary MO calculations indicate that this can be related to the presence of strong σ-donor ligands and that the energy difference between the two isomers is very small.[8] The flexibility of the μ-PR_2 ligand allows very large variations in metal-metal separations; even packing forces or solvent interactions are sufficient to induce major structural changes. Great care must be exercised when correlating ^{31}P-NMR chemical shift values of phosphido ligands (in solution) with values of the M-PPh_2-M angle (in the solid state).

1a and $\mathbf{1b}\cdot 2CH_2Cl_2$ are valuable precursors for the synthesis of phosphido-bridged mixed-metal clusters, as shown by their reaction with $Co_2(CO)_8$ in toluene, which affords Pt-Co clusters.[9]

Polymorphism of an Organolithium Compound: Dilithium 1,2-diphenylbenzocyclobutadienediide · 2 Tetramethylethylenediamine**

By *Gernot Boche,* Heinz Etzrodt, Werner Massa,* and *Gerhard Baum*

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday

Numerous cyclobutadiene transition metal complexes have been prepared and characterized;[1] the first derivatives of dilithium cyclobutadienediide, however, were prepared only recently.[2] We report here on X-ray structure investigations of dilithium 1,2-diphenylbenzocyclobutadienediide · 2 tmeda **1** (tmeda = *N,N,N′,N′*-tetramethylethylenediamine). Polymorphism has been observed for the first time in organolithium compounds, whereby the Li atoms in particular, and the TMEDA molecules in the two modifications I and II of **1** take on different positions (lithiotropism). The two phenyl substituents at C1 and C1′ in both modifications are bent outwards (Fig. 1). This has not been observed in comparable organolithium compounds.

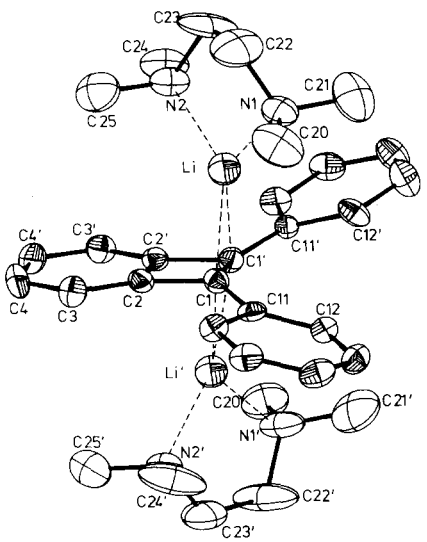

Fig. 1. ORTEP diagram of the crystal structure of **1-I** (thermal ellipsoids are depicted at the 30% probability level). Atomic numbering accounts for the pseudo-C_2 symmetry. $P2_1/n$, $a = 17.05(1)$, $b = 19.73(1)$, $c = 20.20(1)$ Å, $\beta = 113.5°$, $V = 6232$ Å^3, $Z = 8$, $\rho_{calc} = 1.071$ g/cm^3 at 213 K. $Mo_{K\alpha}$ radiation, graphite monochromator, $\lambda = 0.71069$ Å. 6003 independent reflections, 3165 observed, with $F_0 > 3\sigma(F_0)$, four-circle diffractometer (Enraf-Nonius CAD4). Direct methods (MULTAN 80 [3]), anisotropic temperature factors for all atoms except Li (isotropic) and H (at calculated positions), SHELX 76. [4] $w = 1.9/\sigma^2(F_0)$, $R_w(F) = 0.058$, $R_g = (F^2) = 0.058$. The asymmetric unit contains two independent molecules, the symmetry of which approaches C_2. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51563, the names of the authors, and the full citation of the journal.

Surprisingly, the Li atoms in **1-I** (Fig. 1; see also Fig. 2, left) are arranged unsymmetrically above and below the four-membered ring. The distances to C1 and C1′ are slightly different, but both are noticeably shorter than those to C2 and C2′. The Li atoms lie almost directly above and below the C1C1′ bond.[5,6b] The phenyl rings deviate strongly from the almost ideal plane (maximum deviation 0.02(2) Å) of the "benzocyclobutadienediide" C atoms: C11 lies 0.27(2) Å below and C11′ 0.32(2) Å above this plane. This means that the phenyl rings are bent away from the Li atom adjacent to the C1 or C1′ atoms, respectively. Calculations on 1,2-dilithioethane, which compares with the situation here, revealed that its C_{2h} structure is the stablest.[7]

For such a bonding the two Li atoms should be of special importance, since in neutral compounds of the "*cis*-stilbene" type the two phenyl rings always evade mutual steric hindrance by twisting of the rings (40–70°)[8,9], and MNDO calculations for 1,2-diphenylbenzocyclobutadienediide gave a twisting of about 22° for the phenyl rings.[2a] In the TMEDA molecules the N–N bonds run almost parallel to the two four-membered ring diagonals.

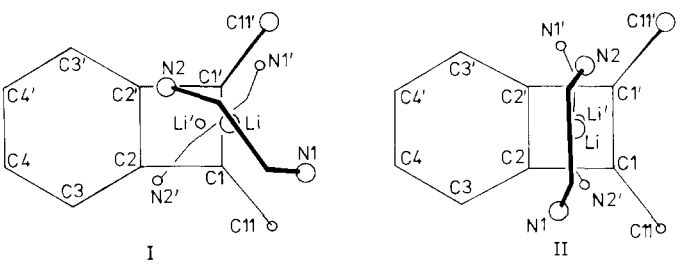

Fig. 2. Projection of a part of the structure of **1-I** (left) and **1-II** (right) onto the plane of the benzocyclobutadienediide C atoms. Important bond lengths [Å], bond angles, and dihedral angles [°] of **1-I** (average) and **1-II** (in square brackets): LiC1 2.14(1) [2.23(4)], LiC1′ 2.20(1) [2.35(4)], LiC2 2.66(1) [2.37(4)], LiC2′ 2.69(1) [2.36(4)], Li′C1 2.22(1) [2.35(4)], Li′C1′ 2.15(1) [2.23(4)], Li′C2 2.45(1) [2.36(4)], Li′C2′ 2.41(1) [2.37(4)], LiN (mean value) 2.044 [1.94], C1C1′ 1.53(1) [1.45(3)], C1C2 1.46(1) [1.48(1)], C1′C2′ 1.45(1) [1.48(1)], C2C2′ 1.44(1) [1.44(3)], C1C11 1.42(1) [1.48(2)], C1′C11′ 1.42(1) [1.48(2)]; C1C1′C11′ 138(1) [138(2)], C1′C1C11 138(1) [138(2)]; C3C2C1C11 15(4) [16(5)], C3′C2′C1′C11′ 20(3) [16(5)]. **1-II**: C2/c; $a = 14.11(1)$, $b = 13.33(1)$, $c = 16.58(1)$ Å; $\beta = 91.98(7)°$, $Z = 4$, $\rho_{calc} = 1.042$ g/cm^3 at 295 K. Lower density and higher—here also crystallographically realized—C_2 symmetry points to a high-temperature modification, but a phase-transition **1-II** → **1-I** could not be observed. Instead, a reversible phase transition into a third modification **1-III** occurs between 273–225 K [10], so that the measurements had to be made at 295 K. Only an incomplete set of low quality data has so far been obtained ($R_w(F) = 0.13$ and $R_g(F^2) = 0.12$ for 536 independent reflections) because of the attendant rapid decomposition of the crystals in the X-ray beam [11].

In **1-II** (Fig. 2, right[11,12]) the distances of the Li atoms to the four-membered ring C atoms differ less from each other than in **1-I**; in **1-II** they lie more over the center of the four-membered ring. An "asymmetry" of the Li atoms referred to C1 and C1′ is indicated also in the case of **1-II**. The phenyl rings at C1 and C1′ are once again bent away from the neighboring Li atom: C11′ and C11 respectively lie 0.24(1) Å above and below the plane of the four-membered ring. The N–N axes of the TMEDA molecule run parallel to C1–C1′.

Calculations suggest that the potential hypersurface for the position of lithium ions on delocalized "carbanions" is very flat.[5a,6d–f,13] Consequently, packing effects in the crystal could influence the structure of organolithium compounds considerably. The polymorphism and lithiotropism found in **1** provide the first experimental support. It emerges that—at least with delocalized charge in the "carbanion"—particular care must be taken when discussing

[9] In the case of **1**-I, the mutual steric hindrance of the two phenyl rings should be minimal compared to that in *cis*-stilbenes, since the C1–C1′ distance in **1**-I (1.53 Å) is very long and the C1C1′C1′ and C1′C1C11 angles are quite large (138°).
[10] Since **1**-III is twinned—as a result of the phase transition—its structure could not be elucidated.
[11] This result shall be improved by an X-ray investigation of further crystals of **1**.

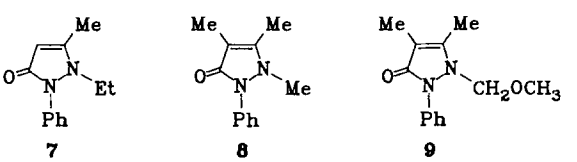
Electrochemical Methoxylation of Antipyrine**

By *Gerd Kaupp,* Fatih Köleli,* and *Eleonore Gründken*

Dedicated to Professor Hans-Jürgen Bestmann on the occasion of his 60th birthday

Anodic methoxylations of alkyl- and arylamines and of amides have been known for a long time and have been used in organic synthesis, even though the regioselectivity cannot always be predicted.[1] We report here the electrochemical methoxylation of antipyrine **1**, an *N*-methyl heterocycle with delocalized π-electrons. Antipyrine (1,2-dihydro-1,5-dimethyl-2-phenyl-3-pyrazolone) is of broad significance, for example, as a pain-killer,[2] a reagent for heavy-metal ions and nitrite,[3] and a substrate for pharmacokinetic studies.[4] Despite the high functionality of **1**, **4** is selectively obtained.

When **1** is oxidized at the platinum anode in methanolic potassium hydroxide in an undivided beaker cell, the unstable methyleneammonium ion **3** is formed apparently selectively via the radical cation **2** in which the π-electrons are delocalized. **3** undergoes solvolysis to give the derivative **4**, which is methoxylated on the *N*-methyl group. For 87% conversion of **1**, the yield of **4**, determined by NMR spectroscopy, is 85%; after complete conversion, crystalline **4** is isolated in 71% yield.[5]



No competing reactions at the *C*-methyl group or at the unsubstituted ring C atom of **1** occur although these possibilities are largely preferred in chemical oxidations[6] and are realized, to a large extent, in human metabolic pathways (along with demethylation at the nitrogen).[7] The phenyl group, too, remains intact.

Although the anodic oxidation of **1** competes with the oxidation of the solvent (formaldehyde was detected) and thus proceeds with comparatively lower current yields (28% for 87% conversion),[8] it is especially simple and preparatively useful and affords the derivative **4**, which is functionalized at the *N*-methyl group.

Compound **4** may be viewed as a model compound for the metabolism of **1**, which results partially in demethylation (presumably via the *N*-hydroxymethyl derivative of **1**, i.e., **4** with OH instead of OCH_3).[7] Treatment of **4** with hydrochloric acid effects solvolytic cleaving off of methanol and formaldehyde. Norphenazone **5**[9] is formed, which undergoes condensation with the formaldehyde to form the methylene-bridged **6** (together 99%).[10]

The *N*-methyl methoxylation of antipyrine **1** without control of the potential leads selectively to **4**. Further oxidation of the methylene group to the dimethoxy derivative in methanolic potassium hydroxide fails because of the too high oxidation potential of **4**.[8] The first anodic peak potentials of the cyclovoltammograms (200 mV/s, CH_3CN, 0.1 M $LiClO_4$, Pt vs. SCE) of **1** and **4**, as well as of the related derivatives **7**,[11] **8**,[11] and **9** (1.22, 1.36, 1.22, 1.09, and 1.24 V, respectively) also support this interpretation. However, not only the potential determines the success of the electrochemical methoxylation. Thus, **7** (same first

peak potential as **1**) cannot be converted into a derivative that is methoxylated on the *N*-methylene group (analogous to **4**) either under the conditions described here for **1** (mainly recovery of **7**) or by a tenfold increase in the current passage employed. It appears that one of the subsequent chemical and/or electrochemical steps (cf. scheme) is not possible.[12]

The *N*-methyl selectivity remains the most striking criterium of our synthesis to the extent that the initially formed radical cation (cf. **2**) is not particularly effectively stabilized by additional dialkylamino groups.[13] Thus, **9** is obtained nearly quantitatively from **8**[11] when the electrolysis is carried out as for **1**.

The simple preparation of compounds **4** and **9** opens up the possibility of extending the synthetic potential of *N*-(α-methoxyalkyl)amides[1] to these cyclic, vinylogous derivatives (Lewis-acid-catalyzed reaction with nucleophiles).

Experimental Procedure

1 (5.8 g, 0.031 mol), KOH (6 g) and methanol (300 mL) were subjected to electrolysis (full conversion, DC control) in a beaker at a cylindrical platinum anode (50 cm^2, wire thickness 0.125 mm, mesh size 1.00 mm) using a cylindrical V4A steel-net cathode (100 cm^2, electrode separation 9.1 mm) for 4.5 h at 2 A with magnetic stirring. The terminal voltage was 5.7 V. The solvent was rotovapped in vacuum, 50 mL of water was added, and the solution was extracted five times with 50 mL of diethyl ether. After chromatography on basic Al_2O_3 (activity III) with ethyl acetate and crystallization of the product fraction from *n*-heptane, 4.8 g (71%) **4**, m.p. = 67–68 °C, was obtained.

4 (1.00 g) was dissolved in 6 mL of methanol and treated with 4 mL of 1 N HCl. The solution was refluxed for 10 min and then cooled; 0.43 g (53%) **6**, m.p. = 149–151 °C. At pH 7, 0.37 g (46%) **5** was isolated from the mother liquor.

[11] L. Knorr, *Justus Liebigs Ann. Chem. 238* (1887) 137; *293* (1896) 1; ^{1}H-NMR ($CDCl_3$): **7**: δ = 7.5–7.2 (m, 5H), 5.36 (q, 1H, J = 1 Hz), 3.52 (q, 2H, J = 7 Hz), 2.20 (d, 3H, J = 1 Hz), 0.85 (t, 3H, J = 7 Hz); **8**: δ = 7.5–7.2 (m, 5H), 2.93 (s, 3H), 2.14 (q, 3H, J = 1 Hz), 1.84 (q, 3H, J = 1 Hz); **9**: δ = 7.5–7.2 (m, 5H), 4.78 (s, 2H), 3.23 (s, 3H), 2.25 (q, 3H, J = 1 Hz), 1.87 (q, 3H, J = 1 Hz); yield of **9** determined by ^{1}H-NMR spectroscopy for 53% conversion of **8**: 96%.

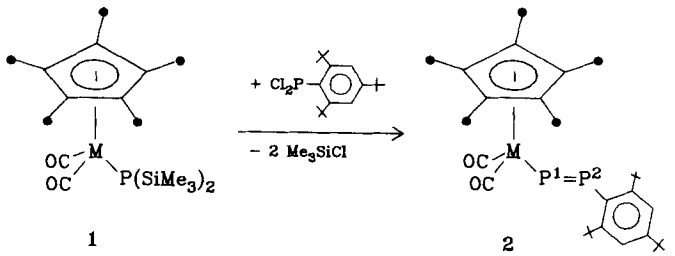
[12] A striking parallel is found in the electrochemical methoxylation of amides. Thus, in the review [1], no methoxylations of *N*-ethylamides are described; the numerous examples are for *N*-methylamides, cyclic acylated amines, and lactams.

[13] H. Sayo, M. Masui, *Chem. Pharm. Bull. 24* (1976) 2137; *J. Chem. Soc. Perkin Trans. 2 1973*, 1640: By cyclovoltammetry (6 V/s, CH_3CN, 0.1 M $NaClO_4$ vs. SCE) anodic potentials of 1.22 and 1.65 V for **1** were measured; in contrast, the anodic potentials of 4-dimethylamino- and 4-diethylaminoantipyrine are, as expected, lower (0.34, 0.85, 1.32 and 0.39, 0.88, 1.18, 1.38 V, respectively) and it was possible to detect spectroscopically the blue-violet radical cations, from which (with the involvement, this time, of the *C*-methyl group and not the *N*-methyl group), the decomposition products acetaldehyde and diethylamine were formed in low yield.

[(η^5-C_5Me_5)(CO)$_2$M–P=P(2,4,6-*t*$Bu_3C_6H_2$)] (M = Fe, Ru), the First Diphosphenyl Complexes**

By *Lothar Weber** and *Klaus Reizig*

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday



Since the preparation of bis(2,4,6-tri-*tert*-butylphenyl)diphosphene, the first stable phosphorus analogue of the long known azo compounds,[1] there has been a rapid development in the chemistry of diphosphenes and their higher homologues.[2] Diphosphenes can act not only as terminal σ-bonded ligands and as π-bonded ligands,[2] but also as bridging groups[2,3] and as building blocks for clusters.[2,4] In all of these cases, the diphosphene complexes contain an intact $R^1P{=}PR^2$ fragment. Conceivably, the groups R^1 and R^2 of a diphosphene could be replaced by transition-metal complex fragments, leading to the types of complex **A** and **B**. Here, we report the first type **A** diphosphenyl complexes of iron and ruthenium.

We have extended the syntheses of diphosphenes[5] from disilylphosphanes and dichlorophosphanes to disilylphosphido complexes of iron **1a**[6] and ruthenium **1b**[7] as starting materials. **1a**, **b** smoothly react with 2,4,6-tri-*tert*-butylphenyldichlorophosphane[1] (mole ratio 1 : 1) in tetrahydrofuran (THF) at 20 °C to give the orange-yellow title compounds **2a**, **b**.[8]

1 2

• — = CH_3; a, M = Fe; b, M = Ru

The constitutions and configurations of the isolated complexes were confirmed by elemental analysis, molecular weight determinations, and spectroscopy. The $M(CO)_2$ groups are indicated by the two intense ν(CO) bands in the IR spectrum. The presence of unsymmetrically substituted diphosphenes is confirmed unequivocally by the ^{31}P-NMR spectra of **2a**, **b**. Two doublets at very low field with very large coupling constants[8] are diagnostic for unsymmetrical diphosphenes.[2] The largest low-field shift to date for uncomplexed diphosphenes was recorded for $(Me_3Si)_3C-P=P-C(SiMe_3)_3$ ($\delta = 599.7$).[9] The largest coupling constant up to now for an unsymmetrical diphosphene was reported by *Niecke* et al. for $(Me_3Si)_2N-P=P-N(t\text{Bu})(SiMe_3)$ ($^1J_{PP} = 670$ Hz).[10] The X-ray structure determination of **2a** shows that the complex exists in the *E* configuration like most diphosphenes [P-P 2.019(15) Å; Fe-P1-P2 109.9(4)°, P1-P2-C(aryl) 103.5(8)°].[11] The title compounds can be viewed as transition-metal-substituted diphosphenes or as the first diphosphenyl complexes. They are accordingly the phosphorus homologues of those diazenyl complexes in which the ligand functions as a 1e donor and in which, therefore, a doubly bent M–N=N–R geometry is present.[12] Attempts to synthesize diphosphenyl complexes from **1** and the less bulky mesityldichlorophosphane failed.[13]

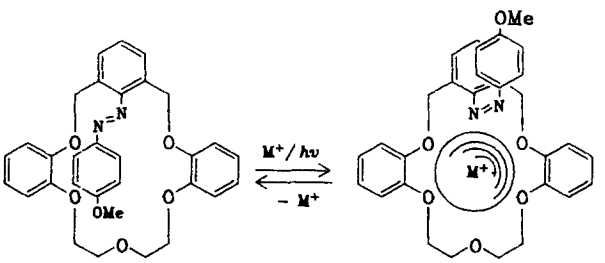
A Photochemically "Switched-on" Crown Ether Containing an Intraannular 4-Methoxyphenylazo Substituent

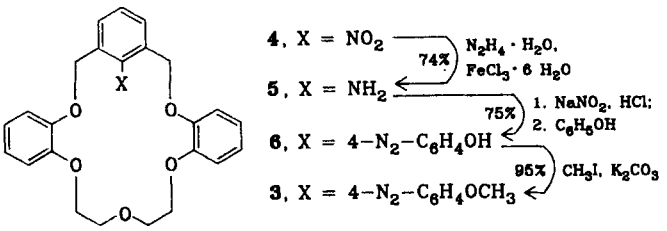


By *Seiji Shinkai*,* *Kiminori Miyazaki*, and *Osamu Manabe*

Crown ethers of type **1**, bearing an intraannular substituent X, bind metal ions to different extents, depending on the nature of X.[1–3] When X has no metal-coordination ability (X = methyl, phenyl, halides, etc.), the association

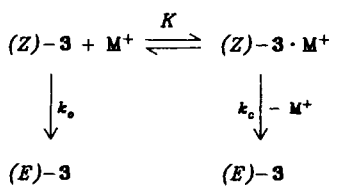
1 **2**

constant decreases.[1–4] In contrast, when it has a metal-coordination ability (X = OH, COOH, NH_2, etc.), it not only increases the association constant but may act as a pH-responsive "switch" governing the metal-binding phenomena.[1–7] Crown ethers whose intraannular substituent can change position (**1** ⇄ **2**), e.g., upon photolysis, are of particular interest since this allows specific modification of the binding properties of the crown ether.



(E)-**3** *(Z)*-**3**·M^+

[*] Prof. Dr. S. Shinkai, K. Miyazaki, Prof. Dr. O. Manabe
Department of Industrial Chemistry, Faculty of Engineering
Nagasaki University
Nagasaki 852 (Japan)



We report here the synthesis and properties of the crown ether **3**, which contains a photochemically "switched-on," intraannular 4-methoxyphenylazo substituent. By photochemically induced *E/Z* isomerization of the azo group of (*E*)-**3**, the substituent is taken out of the ring. Furthermore, one of the two azo nitrogens in (*Z*)-**3** may contribute to the binding of metal ions.

3 was synthesized from the nitro compound **4** via **5** and **6** (Scheme 1)[1-3] and identified by IR and ^{1}H-NMR spectroscopy[8] and by elemental analysis. Photoisomerization of (*E*)-**3** (λ_{max} = 352 nm, *o*-dichlorobenzene) to (*Z*)-**3** (λ_{max} = 440 nm, *o*-dichlorobenzene) was effected by irradiation (100-W high-pressure Hg lamp, color-glass filter $330 < \lambda < 380$ nm (Toshiba UV-D35)). The fraction of (*Z*)-**3** in the photostationary state is 59%.

Scheme 1.

The rate of the thermal *Z/E* isomerization was estimated spectrophotometrically at 30 °C in *o*-dichlorobenzene/methanol (5:1, v/v). The first-order rate constant ($k_0 = 9.05 \times 10^{-3}$ min^{-1}) is efficiently suppressed in the presence of Na^+ or K^+ ions (added as perchlorate salts: $[MClO_4] = 1 \times 10^{-5}$ to 5×10^{-4} M). The rate is not affected by Li^+ and only weakly by Cs^+. These findings suggest that (*Z*)-**3** shows selectivity for Na^+ and K^+ (Scheme 2).

Scheme 2.

From plots of the rate constant k vs. $[M^+]$ we determined the association constant K and the rate constant k_c:[9] $K = 64600$ M^{-1} and $k_c = 1.26 \times 10^{-3}$ min^{-1} for Na^+; $K = 46000$ M^{-1} and $k_c = 2.18 \times 10^{-3}$ min^{-1} for K^+. The rate constants for *Z/E* isomerization of the Na^+ and the K^+ complex are 7.2 and 4.2 times smaller, respectively, than those for pure **3**. The K values for complexation of Na^+ and K^+ by (*Z*)-**3** ($\lg K = 4.81$ and 4.65, respectively) are comparable to those for [18]crown-6 and dibenzo[18]crown-6.[10] This suggests that one of the azo nitrogens in (*Z*)-**3** contributes to metal coordination. In fact, the absorption spectrum of (*Z*)-**3** changes significantly on the binding of Na^+ ion (λ_{max} shifted to shorter wavelength by 5 nm).

The ion-binding ability was evaluated by solvent extraction of alkali picrates from water ([MCl] = 0.10 M, [MOH] = 1.00×10^{-4} M, [picric acid] = 1.00×10^{-4} M) into organic solvent (*o*-dichlorobenzene/1-butanol (80:20 v/v), [**3**] = 3.01×10^{-3} M), the decrease in the picrate concentration in the aqueous phase being determined. Neither (*E*)-**3** nor (*Z*)-**3** could extract Li^+. The dramatic photoirradiation effect was observed only for Na^+: (*E*)-**3** extracts no Na^+, whereas (*Z*)-**3** (52% mixed with (*E*)-**3**) extracts Na^+ (14.1%). This all-or-nothing behavior is explained as follows; the 4-methoxyphenylazo substituent in (*E*)-**3** acts as a steric spacer nesting in the crown ether ring and interferes with the interaction between Na^+ ion and the crown ether ring; it is removed by the photoinduced *E/Z* isomerization. We have found, however, that K^+ ion is bound not only to (*Z*)-**3** (21.1% extractability) but also to (*E*)-**3** (17.9%). Since the 4-methoxyphenylazo substituent in (*E*)-**3** acts as a "shallow floor"[11] of the crown ring, it is probably difficult for metal ions to bind deeply within the crown ring. Conceivably, the interaction between (*E*)-**3** and K^+ may be accommodated by the "perch-on-type" complexation. On the other hand, Na^+, which is smaller than K^+, cannot interact with (*E*)-**3** by the "perch-on-type" complexation. Therefore, the all-or-nothing change in ion-binding ability would be effected only when the cavity size of the crown ring fits the metal ion.

The 4-methoxyphenylazo substituent in (*E*)-**3** thus acts as an obstruction for metal ions, but when it is taken out by a light trigger, a metal ion is complexed deeply within the cavity. This concept should be useful in the designing of other novel "switched-on" host molecules. We are now applying the photoinduced interconversion of **3** to light-driven active transport across membranes.

[**] We thank Professor Dr. *A. Gossauer* for support of this work.

B_{12} chromophore, metal chelates of corrinoids have hitherto only been accessible either by total synthesis[1] or by complexation of metal-free corrinoids that are isolated from the culture media of phototrophic bacteria.[2] The demetalation and/or transmetalation of cobalt-containing corrinoids is therefore of interest from both a theoretical and practical point of view.

All attempts to replace directly the complex-bound cobalt ion by other metal ions have so far failed[3] because of the extremely high stability of corrin-cobalt complexes.

An alternative route, developed by *Inhoffen* et al., consists in the *regioselective* cleavage of the corrin ring, subsequent demetalation of the resulting *seco*-corrinoid, remetalation, and, finally, recyclization to the new metal complex. In the heptamethyl dicyanocobyrinate series, ring closure was possible in the case of the cobalt complex,[4] but not in the case of the rhodium and palladium analogues.[5]

In earlier studies on the reactivity of the corrin chromophore we found that thermolysis of **1** afforded the "pyrocobyrinate" **2a**[6] in 60% yield,[7] and that *regioselective* oxidation of **2a** with photochemically generated singlet oxygen led to formation of the dioxomono-*seco*-compound **3a** in 95% yield.[8] In the present communication we report on the first transformation of **2a** into the nickel complex **2b**.

Initially, all attempts to demetalate **3a** failed. Neither reaction with H_2S in pyridine/methanol[4] nor reaction with dithiols in presence of acids[9] yielded any satisfactory results. Success was first achieved upon reaction of **3a** with P_4S_{10} in acetonitrile, which furnished unstable **3c** in good yields (ca. 80% of crude product). The *seco*-corrinoid **3c** was converted by reaction with nickel perchlorate into the corresponding complex **3b** (overall yield **3a**→**3b**: 80%), which could be cyclized under the conditions of the

McMurry reaction.[10] Reaction of **3b** with $TiCl_3/Zn$ in dioxane at room temperature led initially to formation of a lemon-yellow compound (41% yield) whose structure **4** could be assigned on the basis of spectroscopic data. When the reaction was carried out at 100°C, perchlorato-7-de(carboxymethyl)-7,8-didehydronickelobyrinic acid hexamethyl ester **2b** was formed in 43% yield.

The structure of **2b** was confirmed by comparison of the spectroscopic data with those of **2a** (UV/VIS; IR; FAB-MS; ^1H and ^{13}C NMR) (Table 1).

Cl_2C-Cl-$Cl^{\odot\oplus}$, Cl_2C-Cl-$Br^{\odot\oplus}$, and Br_2C-Br-$Cl^{\odot\oplus}$ by Gas-Phase Decarbonylation of $CX_3COY^{\odot\oplus}$**

By *Thomas Drewello, Thomas Weiske,* and *Helmut Schwarz**

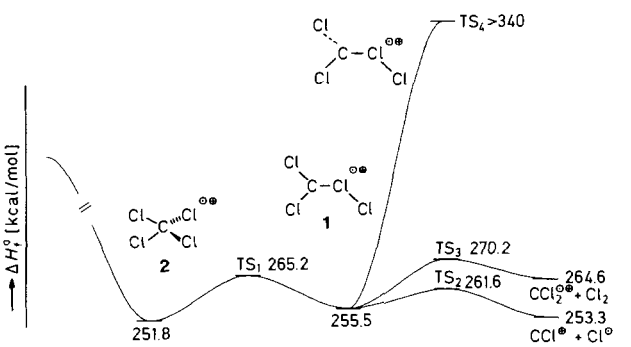
Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Whereas carbon tetrachloride and its dication $CCl_4^{2\oplus}$ (C_{2v})[1] are very well known, no stable radical cation $CCl_4^{\odot\oplus}$ has so far been generated and characterized. Electron impact ionization,[2a,b] charge-exchange mass spectrometry[2c] or radiolysis of CCl_4 do not afford any detectable molecular ion, but exclusively fragments such as $CCl_n^{\oplus}$ (n = 1–3), $Cl^{\odot}$ or doubly charged ions of the type $CCl_m^{2\oplus}$ (m = 1, 2). Although according to semi-empirical molecular orbital calculations[3] (MINDO/3) at least seven minima should exist on the energy hypersurface of $CCl_4^{\odot\oplus}$ (the global minimum corresponding to a $CCl_4^{\odot\oplus}$ with C_{2v} symmetry, followed by isomers of the following point groups: C_{3v}, D_2, T_d, D_{2d}, D_{2h} and D_{4h}), it is not surprising that vertical ionization of CCl_4 with generation of $\tilde{X}(^2T_2)CCl_4^{\odot\oplus}$ does not lead to a stable radical cation; Reaction (1) is exothermic (5–6 kcal/mol), and an activation energy of 1.4 kcal/mol (referred to $\tilde{X}(^2T_2)CCl_4^{\odot\oplus}$) is calculated for the decomposition.[3] A lifetime of $t \leqslant 2 \times 10^{-10}$ s is assigned to the radical cation generated by direct ionization of CCl_4.[2d] The lifetime for metastable $CCl_4^{\odot\oplus}$ in the gas phase is estimated to be $t \leqslant 10^{-5}$ s.[2e]

$$\tilde{X}(^2T_2)CCl_4^{\odot\oplus} \longrightarrow \tilde{X}(^1A_1')CCl_3^{\oplus} + Cl^{\odot} \quad (1)$$

We report here on a simple experiment[4] for the generation of $CCl_4^{\odot\oplus}$ with a lifetime $t \geqslant 10^{-5}$ s. Electron impact ionization (70 eV) of CCl_3COCl affords $CCl_3CO^{\oplus}$ and $CCl_3^{\oplus}$ (100%), and a further weak (intensity 0.5%) but clearly detectable signal in the range *m/z* 152–158. According to the isotope pattern (0.330 : 0.407 : 0.200 : 0.009) this signal arises from the decarbonylation product of $CCl_3COCl^{\odot\oplus}$; that is, a stable $CCl_4^{\odot\oplus}$ radical cation must have been formed. Upon collisional activation,[5] $CCl_4^{\odot\oplus}$ decomposes to $CCl_3^{\oplus}$ (95.8% total ion current), $CCl_2^{\odot\oplus}$ (3.1), $CCl^{\oplus}$ (0.5), and $Cl^{\oplus}$ (0.6). What is the constitution of $CCl_4^{\odot\oplus}$? It has been demonstrated mass spectrometrically that a chlorine radical is readily split off (generation of $CCl_3^{\oplus}$), whereas the elimination of Cl_2 (formation of $CCl_2^{\odot\oplus}$) should require more energy. These results are fully consistent with structure **1**. We have calculated the most important reaction paths on the hypersurface of $CCl_4^{\odot\oplus}$ for **1** using RHF-MNDO[6] (Fig. 1): The reaction **1** → $CCl_3^{\oplus} + Cl^{\odot}$ requires ca. 6 kcal/mol, the process **1** → $CCl_2^{\odot\oplus} + Cl_2$ ca. 15 kcal/mol. The isomerization of **1** to the radical cation **2** of carbon tetrachloride ($CCl_4^{\odot\oplus}$, C_{2v}), which corresponds to the global minimum on the MINDO/3-[3] and MNDO-hypersurfaces, requires ca. 10 kcal/mol. The *direct* decomposition path **2** → $CCl_3^{\oplus} + Cl^{\odot}$ with by-passing of **1** is, according to both MINDO/3[3] as well as MNDO, energetically more demanding than the reaction sequence **2** → **1** → $CCl_3^{\oplus} + Cl^{\odot}$.

1, which could be regarded as an ion/dipole complex of Cl_2 with $CCl_2^{\odot\oplus}$,[7] is better described as a $CCl_3^{\oplus}$ cation interacting with a chlorine atom. The resulting Cl–Cl bond is the weakest in the whole radical cation (bond order (*BO*)[8] 0.56); the bond between carbon and the hypervalent chlorine, with a *BO* = 0.76, is indeed markedly stronger, but



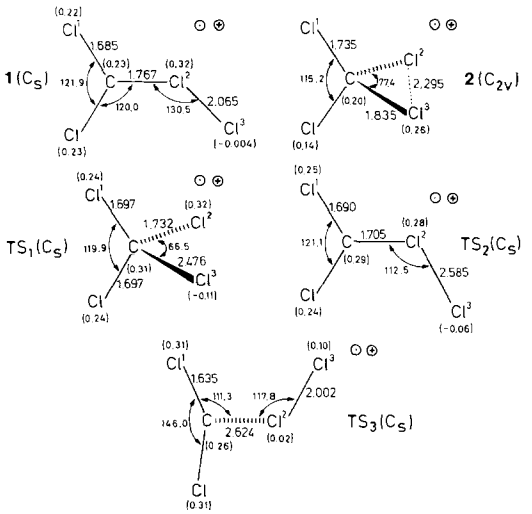


Fig. 1. MNDO reaction path for $CCl_4^{\odot\oplus}$.

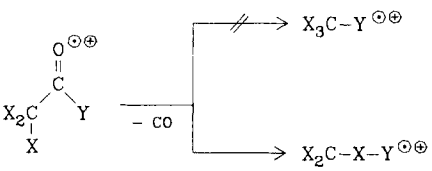
still considerably weaker than the two remaining C–Cl bonds ($BO = 1.24$ and 1.22). The positive charge is carried almost quantitatively by the CCl_3 unit (see Scheme 1); the fourth chlorine atom, which has been transferred intramolecularly from the acid chloride moiety in the course of the cleavage is practically neutral.



Scheme 1. Geometry (angles [°], bond lengths [Å]) and charge distribution (in brackets) of **1**, **2**, and the transition states TS_{1-3} (TS_4, which is irrevelant for the discussion, could not be characterized).

All attempts to analyze the reaction path $CCl_3COCl^{\odot\oplus} \rightarrow CCl_4^{\odot\oplus} + CO$ computationally, and thus to be able to decide whether **1** and **2** are generated independently of each other were thwarted by the fact that we could not cleanly localize the molecular ion. In the course of the geometric optimization, decomposition to $CCl_3^{\oplus}$ occurs, which also dominates in the mass spectrometer. In view of the fact that, with one (explainable) exception,[9] the dissociative ionization of carboxylic acid derivatives (cleavage of CO or CO_2) always leads to ion/dipole-like ions such as **1** and the isomeric ions with normal valence are not generated, we think that decarbonylation of $CCl_3COCl^{\odot\oplus}$ also preferably yields **1**. The following observations also lend support to such an interpretation: On using an extremely sensitive tandem mass spectrometer (Vacuum Generator type ZAB-3F) we were able for the first time to detect an, admittedly, weak (intensity $< 0.01\%$) but, nevertheless, clearly recognizable signal for $CCl_4^{\odot\oplus}$ when CCl_4 was ionized with 70 eV. The kinetic energy T_k released on cleavage of $Cl^{\odot}$ from the mass-selected $CCl_4^{\odot\oplus}$ ion is, with a value of 160 meV, significantly greater than the T_k value for the analogous reaction of those $CCl_4^{\odot\oplus}$ ions that have been generated from $CCl_3COCl^{\odot\oplus}$ ($T_k = 7.8$ meV). This finding, and the fact that the line shapes of the corresponding transition signals are characteristically different ("dished" in the first case and pure gaussian[10] in the second) unquestionably require that the two $CCl_4^{\odot\oplus}$ ions are structurally different. Furthermore, the different T_k values support the reaction profile described by MINDO/3[3] and MNDO calculations: Direct decomposition of **2** to $CCl_3^{\oplus}$ and $Cl^{\odot}$ is not possible; instead, in the energy-determining step isomerization to excited **1** takes place and, finally, **1** decomposes with liberation of a larger amount of translational energy to $CCl_3^{\oplus}$ and $Cl^{\odot}$, as is the case when **1** is generated directly by decarbonylation.[11]

Loss of CO is also observed with $CCl_3COBr^{\odot\oplus}$,[4] whereas no decarbonylation takes place in the case of $CCl_3COF^{\odot\oplus}$.

Remarkable in the case of $CCl_3Br^{\odot\oplus}$ is that the dominating mode of decomposition corresponds to the elimination of $Br^{\odot}$. This could indicate that here, analogously to $CCl_4^{\odot\oplus}$, a hypervalent radical ion (Cl_2C–Cl–$Br^{\odot\oplus}$) has once again been generated from which Br can be readily cleaved. Since, however, preferred cleavage of the C–Br bond is to be expected also in the radical cation of CCl_3Br, we have studied $CBr_3COCl^{\odot\oplus}$, the spectrum of which shows a signal for $[M-CO]^{\odot\oplus}$ with the correct isotope pattern. If this decarbonylation product corresponds to a $CBr_3Cl^{\odot\oplus}$ ion, then a preferred loss of $Br^{\odot}$ ought to be observed here also, whereas $Cl^{\odot}$ ought to be eliminated from the hypervalent Br_2C–Br–$Cl^{\odot\oplus}$ in analogy to Cl_2C–Cl–$Cl^{\odot\oplus}$ with cleavage of the Br–Cl bond. Experimentally, it is observed that the mass-selected decarbonylation product with *m/z* 288 (which corresponds to an isotope mixture of 25% $^{12}C^{79}Br_2{}^{81}Br^{37}Cl$ and 75% $^{12}C^{79}Br^{81}Br_2{}^{35}Cl$) decomposes on collisional activation *exclusively* with loss of ^{37}Cl and ^{35}Cl in the ratio 1 : 3. It therefore follows that loss of CO from $CBr_3COCl^{\odot\oplus}$ leads specifically to Br_2C–Br–$Cl^{\odot\oplus}$ and that also in the usual decarbonylation processes only the hypervalent radical cations **1**, **3**, and **4** are generated [Eq. (2)].[12]

Reactions of Per(chloro,fluoro)ethanes with Aryloxide and Alkoxide Ions—Evidence for Chlorophilic Attack on C–Cl Bonds

By *Xing-ya Li,* He-qi Pan, Xi-kui Jiang,* and *Zheng-yun Zhan*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Reactions of nucleophiles with per(fluoro,halo)alkanes (halogen = iodine or bromine) have been intensively studied,[1,2] and most likely the C–I or C–Br bonds are always attacked in the initial steps. However, only a few cases have been reported for nucleophilic reactions of per(chloro,fluoro)alkanes,[3–6] which are well-known for their inertness.[7] As to reactions involving oxygen nucleophiles, we know of only two instances.[5,6] Recently, *Sawyer* et al.[6] suggested that the degradations of substrates containing trichloromethyl groups by the hyperoxide ion ($O_2^{\ominus}$) are initiated by electron transfer. *McBee* et al.[5] used phenoxide ions in butanone; these reactions, however, are most likely initiated by carbanions (from butanone) rather than by oxygen nucleophiles. We report here evidence for direct attack on C–Cl bonds by oxygen nucleophiles, as well as a useful method for the preparation of aryl and alkyl per(chloro,fluoro)ethyl ethers of the type **2** from the per(chloro,fluoro)ethanes **1** (see Table 1).

$$\underset{\mathbf{1}}{ROK} + XCF_2{-}CCl_2Y \longrightarrow \underset{\mathbf{2}}{RO{-}CF_2{-}CCl_2Y} + \underset{\mathbf{3}}{RO{-}CF_2{-}CClHY}$$

X,Y = Cl,F

yield depend strongly on the nature of the solvent. The reactions are usually faster in polar aprotic solvents like dimethylsulfoxide (DMSO), dimethylformamide (DMF), and hexamethylphosphoric triamide (HMPA), which also give higher yields of **2** for aryloxides. For alkoxides, better yields are obtained in weakly polar solvents, such as diglyme or triglyme. If ROH/KOH is used instead of ROK, the reaction becomes dramatically slower, but, in some cases, good yields can still be obtained. The reaction is sensitive to water and other proton-donating species, but light, oxygen, and dinitrobenzene do not seem to have any effect.

In all the products, the aryloxy or alkoxy groups are attached to CF_2. Since direct S_N2 attack of $RO^{\ominus}$ on a carbon of the CF_2–X type (X = Cl, F) is improbable[9a] and the formation of the hydrogen-containing product **3** is also incompatible with this sort of attack, our results are best rationalized by an anionic chain mechanism (Scheme 1).

$$RO^{\ominus} + \mathbf{1} \longrightarrow ROCl + XCF_2{-}CClY^{\ominus} \quad (1)$$

$$XCF_2{-}CClY^{\ominus} \longrightarrow CF_2{=}CClY + X^{\ominus} \quad (2)$$

Compounds **1** react spontaneously with potassium alkoxides at room temperature or below to afford the ethers **2** in fair to good yields. The carefully purified and dried reactants are usually used in molar ratios of 2:1 to 3:1. Distillation after work-up furnishes the products **2**, usually in high purity. Small amounts of hydrogen-containing products **3** were found in all cases.[8] The reaction can take place in a wide variety of aprotic solvents, but its rate and

This mechanism is similar to two previously reported reactions involving chlorophilic attack by $PhS^{\ominus}$ ions[3] and bromophilic attack by $PhO^{\ominus}$ ions;[2] it is the first confirmed chlorophilic attack on C–Cl bonds by oxygen nucleophiles. The proposed propagation steps (2) and (3) are supported by GC detection of small amounts of olefins $CF_2{=}CClY$ and, especially, by the exclusive linkage of the entering RO groups to the CF_2, because it is well established that all nucleophiles add regiospecifically to that end of polyhalogenated double bonds.[9b] The fact that the same product $RO{-}CF_2{-}CCl_3$ is obtained from either **1b** or **1c** is also good evidence for the intermediacy of $CF_2{=}CCl_2$. The chain process is supported by the ability

345 Lingling Lu, Shanghai (China)

of added CF_2=CClY to greatly accelerate the reaction. For example, in diglyme, **1a** reacts with C_6H_5OK so slowly that only trace amounts of **2a** can be detected after 24 h, but when 5 mol-% CF_2=CClF (relative to C_5H_5OK) is added, **2a** (15%) and **3a** (3%) are formed in 20 min.

The reactions described here afford a facile route to ethers, one of whose alkyl groups is fully halogenated; such ethers are not readily available via other preparative methods. More interestingly, these observations are the first good evidence for a chlorophilic attack on C–Cl bonds by oxygen nucleophiles.

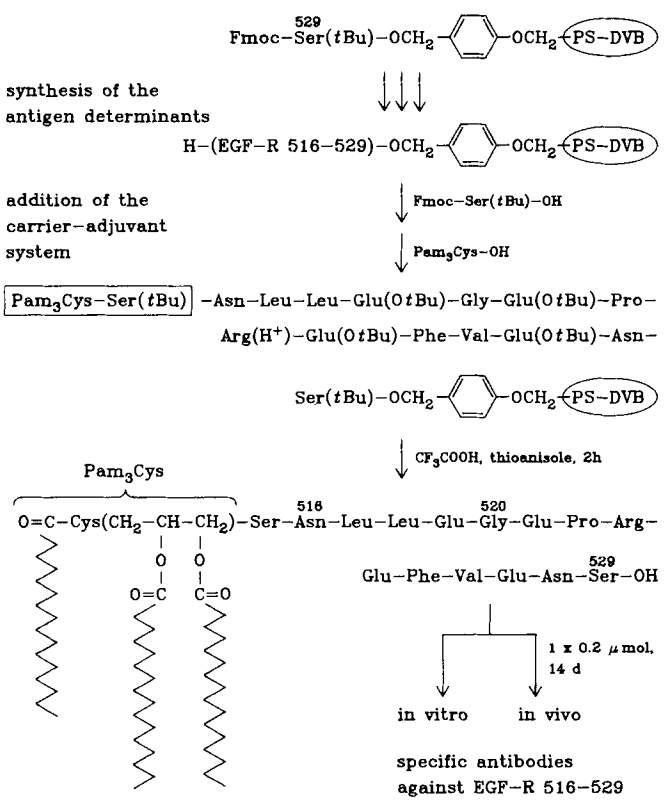
Increased Production of Specific Antibodies by Presentation of the Antigen Determinants with Covalently Coupled Lipopeptide Mitogens



By *Günther Jung,* Karl-Heinz Wiesmüller, Gerhard Becker, Hans-Jörg Bühring,* and *Wolfgang G. Bessler*

In the conventional methodology for the production of antisera against antigenic determinants (epitopes) of a protein, synthetic partial sequences are coupled with high-molecular carriers such as serum albumin; subsequently, immunization is carried out with addition of *Freund*'s adjuvant. The reproducibility, both of the preparation of the conjugate as well as of the immunization, is frequently unsatisfactory. With the concept described herein, long immunization times, multiple administrations, high titers of undesired antibodies, and serious inflammations of the immunized animals can be avoided.

The initiating process in antibody formation is the endocytosis and processing of antigens by leukocytes and their subsequent "presentation" on cell surfaces, the molecular details of which are largely unknown. Our concept is based on the idea of employing for the immunization a chemically unequivocally defined *low molecular* conjugate such as **2** in which the carrier-antigen-adjuvant principles are coupled with one another. Such a conjugate was designed as a potential synthetic vaccine in connection with the "Pam_3Cys-antigen-helix" system.[1] Our conjugate differs in essential points from the high molecular polylysine conjugates with antigens and muramyl dipeptide[2] as well as from other adjuvants[3] that were merely admixed but cannot perform any special carrier function. Most of the systems developed so far require multiple antigen administrations in vivo.

We have, for the first time, covalently coupled a B-cell mitogen, which is an excellent carrier and concomitantly a strongly active adjuvant, with a synthetic antigenic determinant. To do this we used the synthetic lipopeptide *N*-palmitoyl-*S*-[(2*RS*)-2,3-bis(palmitoyloxy)propyl]-cysteinyl-serine (Pam_3Cys-Ser),[4] which constitutes the *N*-terminal of the lipoprotein from the outer membrane of *Escherichia coli*.[5] The covalently bonded conjugate of Pam_3Cys-Ser and antigen exhibits pronounced amphiphilic properties. They guarantee, on the one hand, a stable anchoring of the three fatty acid residues in the lipid layer of the cell membrane (Scheme 1) and, on the other, that the usually stronger polar antigen (hapten) is 'presented' in the outer hydrophilic layer of the membrane. A decision on the pos-

Scheme 1. Production of antibodies using the covalently bound carrier and adjuvant Pam_3Cys-Ser. Fmoc = fluorenylmethoxycarbonyl; *t*Bu = *tert*-butyl; PS-DVB = styrene-divinylbenzene (1%) copolymer with 4-(hydroxymethyl)phenoxymethyl anchor groups; EGF-R = receptor of the epidermal growth factor (cf. synthetic example).

sible micellar/monomeric distribution of the conjugate in the cell culture medium can probably be made by spin- and fluorescence-labeling.

Since the activating effect of the lipoprotein is brought about by its *N*-terminal moiety,[6] in all conjugates which contain the Pam_3Cys-Ser or analogues its immunostimulating action remains preserved. Pam_3Cys-Ser-antigen-conjugates can be routinely prepared in the last step in Merrifield syntheses of partial sequences (Scheme 1). Preferably an alkoxybenzyl alcohol-resin as well as N^{α}-fluorenylmethoxycarbonyl-, *tert*-butyl-, and *tert*-butoxycarbonyl protective groups are used in the peptide segment.[7] Since Pam_3Cys is stable towards trifluoroacetic acid,[4] the conjugate can be cleaved from the carrier without problem free of protective groups. The conjugate, which is usually readily soluble in aqueous organic systems or liposomes, can be chromatographed and can be characterized unequivocally by all analytical methods including NMR spectroscopy.

As example we cite the use of our concept for the generation of specific antibodies against the receptor of the epidermal growth factor (EGF-R).[8] The extracytoplasmic region 516–529 was selected by computer-supported epitope search, built up by Merrifield synthesis, and finally coupled with Fmoc-Ser(*t*Bu)-OH.[4] After cleavage from the resin, the analytically pure conjugate **2** was administered, *without further additives,* intraperitoneally to mice in a *single* dose. High titers of specific antibodies (IgM and IgG) against the tetradecapeptide EGF-R 516–529 could be established by ELISA assays[9] after two weeks (Fig. 1). The vital point is that no significant antibody titers were obtained by the tetradecapeptide alone in control experiments. A conventional immunization by a tetradecapeptide-serum-albumin conjugate required multiple antigen administration with addition of *Freund*'s adjuvant, in order to achieve comparable antibody production. With the Pam_3-Cys-Ser-antigen conjugate **2** we were already able to prepare monoclonal antibodies that were detectable in cell culture supernatants and as ascites.

Pam_3Cys conjugates are also strongly immunogenic in cell cultures[9] (Fig. 1). Hence, conventional and monoclonal antibodies against weakly immunogenic compounds can also be obtained in a rapid and elegant way by in-vitro immunization. The antibody titers shown in Figure 1 reflect the well-known finding that only a minor immune response can be elicited by primary in-vitro immunization.

The advantages of our concept are: simple preparation of chemically unambiguously defined antigen-adjuvant-conjugates in any desired amount; in contrast to other conjugates single administration without multiple boosting; high efficiency in vivo and in vitro. A considerable saving of experimental animals, often a complete elimination of in-vivo immunizations, and a drastic saving of time, especially for gene-technological studies are evident. Experiments with other antigens are presently being carried out in mouse cell and human cell cultures to demonstrate the general applicability of our system.

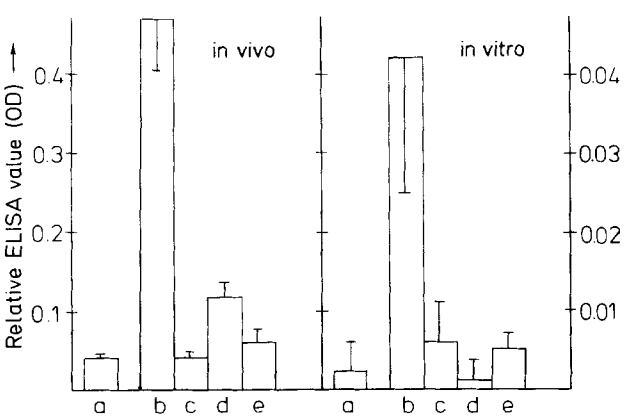

Fig. 1. Formation of specific antibodies against the tetradecapeptide EGF-R 516–529. In-vivo experiment: Control (a), immunization (single i.p. 0.2 μmol, groups of 3–5 mice (Balb/c)) [9] with the conjugate Pam_3Cys-Ser-(EGF-R 516–529) **2** (b), with the tetradecapeptide EGF-R 516–529 (c), with the adjuvant Pam_3Cys-Ser alone (d), and with a mixture of EGF-R 516–529 and Pam_3Cys-Ser (e). 14 days after the immunization the serum antibody titer was determined by ELISA (enzyme-linked immunosorbent assay) [9]. As a measure of the antibody production (specific antibody titer against EGF-R 516–529 coupled to bovine serum albumin), in each case the mean values ± standard deviation of three measurements (OD at 405 nm) are quoted; the values of the serum albumin-specific antibody (OD 0.000–0.034) are subtracted from these values.—In-vitro experiments: The experiments were carried out in microtiter plates (Falcon Plastics, Los Angeles) at a cell density of 2.5×10^6 cells/mL (37 °C, 5% CO_2, 5 days) [6c]. Concentration of the reagents used: 5×10^{-7} mM.

Synthetic example

Following the usual stepwise synthesis (Merrifield synthesis with N^{α}-Fmoc/(*t*Bu)-protection with dicyclohexylcarbodiimide/hydroxybenzotriazole (DCC/HOBt) and symmetrical anhydrides) of the EGF-R segment 516–529 [10], Fmoc-Ser(*t*Bu)-OH was incorporated as the last amino acid. After cleavage of the Fmoc group with piperidine/dimethylformamide (DMF) (1 : 1, 15 min) the resin-bound pentadecapeptide protected in the side chain by *t*Bu (1 g, loading 0.5 mmol/g) was coupled with Pam_3Cys-OH **4a** (2 mmol, in DMF/CH_2Cl_2 (1 : 1)) and DCC/HOBt (2 mmol, preactivated for 20 min at 0 °C) (16 h, then 2nd coupling, 4 h). The protected lipohexadecapeptide **1** was removed from the polymeric carrier with trifluoroacetic acid (5 mL) in the presence of thioanisole (0.25 mL) within 2 h and thereby freed also from protective groups. Yield: 960 mg (76%) **2** x CF_3COOH (correct amino acid analysis, no racemization).

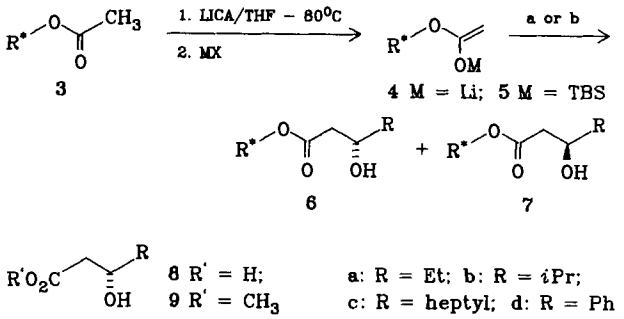
Enantio- and *anti*-Diastereoselective Aldol Additions of Acetates and Propionates via *O*-Silyl Ketene Acetals**

By *Günter Helmchen,** *Ulrich Leikauf,* and *Irmtraud Taufer-Knöpfel*

The structural units **1a–c** are present in numerous natural products. For their direct construction by enantio- and diastereoselective aldol addition, usually via carboxylic acid derivatives, excellent solutions have been found for the case of **1c**.[1] Methods for the direct synthesis of **1a**[2] and **1b**[3] have only recently been reported; as a rule, circuitous routes are chosen that can be tedious.[4] In the course of our investigations of asymmetric syntheses with enolates of esters of the alcohols **2a** and **2b**[5] we have now found that the structural units of **1a** and, albeit judged on the basis of one example only, of **1b** can be obtained highly selectively by $TiCl_4$-catalyzed addition of aldehydes to *O*-silyl ketene acetals (Mukaiyama reaction).[6]



1a **1b** **1c**

2a **2b**

Reaction of the acetates **3**, R*-OH = **2a** or **2b**, with lithium cyclohexylisopropylamide (LICA) in tetrahydrofuran (THF) affords the lithium enolates **4**, which on subsequent reaction with *t*-butyldimethylsilyl chloride (TBSCl) furnish the *O*-silyl ketene acetals **5** in good yields.[7] The latter react with $TiCl_4$-complexes of achiral aldehydes to give the crystalline β-hydroxycarboxylates **6** and **7** with a diastereoselectivity of >93:7 (yield: 50–70%),[8] whereas the lithium enolates **4** react unselectively with aldehydes (Table 1). The diastereomers **6** and **7** can be separated by liquid chromatography, thus enabling determination of the diastereomeric ratio by high performance liquid chromatography (HPLC) and purification by medium pressure liquid chromatography. In the case of the Mukaiyama reaction the main product **6** can also be obtained in essentially pure form by recrystallization. Hydrolysis of the esters **6** (1.5 N methanolic KOH, room temperature) affords the carboxylic acids **8a–d** with known absolute configuration in quantitative yield. As was to be expected,[5] the esters of the alcohols **2a** and **2b** yielded enantiomeric carboxylic acids.

Scheme 1. Aldol addition of the acetate of **2a** or **2b** (R*–OH) to give β-hydroxycarboxylic acid derivatives; a: RCHO, THF, –60°C (M = Li); b: RCHO/$TiCl_4$ (1:1.1), CH_2Cl_2, –80°C (M = TBS).

Table 1. Conversion of the acetates **3** of the reagents **2a** or **2b** via lithium enolates **4** or *O*-silyl ketene acetals **5** [a] into β-hydroxycarboxylates **6** and **7** (Scheme 1) [b].

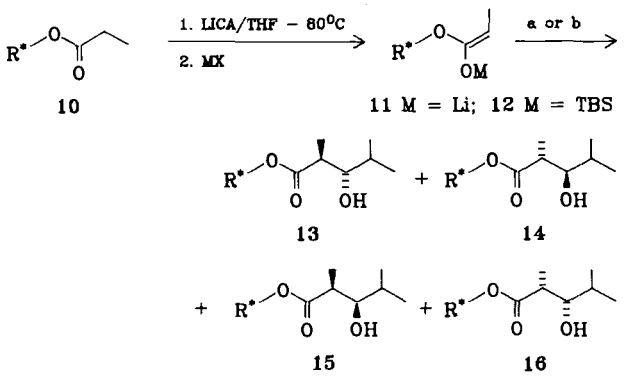
[a] Preparation: reaction of the lithium enolates **4** with 2.2 equivalents *t*BuMe$_2$SiCl/2 equivalents hexamethylphosphoric triamide (HMPT) (THF, –63°C→0°C) followed by extractive work-up (pentane/water). [b] Mukaiyama reaction: dropwise addition of a solution of *O*-silyl ketene acetal **5** in CH_2Cl_2 at –80°C to a mixture of aldehyde and $TiCl_4$ (molar ratio 1:1.1). [c] HPLC peak area ratios (silica gel, petroleum ether/ethyl acetate 9:1). [d] In brackets: corrected with respect to recovered reactant **3**. [e] **9a**: $[\alpha]_D^{20}$ +20.4 (undiluted); T. Tannabe, Y. Izumi, *Bull. Chem. Soc. Jpn. 46* (1973) 1550, (*S*)-**9a**: $[\alpha]_D^{20}$ +18.6 (undiluted). **8b**: $[\alpha]_D^{25}$ +40.2 (c = 1.2, $CHCl_3$); D. A. Evans, T. R. Taber, *Tetrahedron Lett. 21* (1980) 4675, (*R*)-**8b**: $[\alpha]_D$ +40.5 (c = 0.6, $CHCl_3$). **8c**: $[\alpha]_D^{20}$ +21.3 (c = 1, $CHCl_3$); M. Nakahata, M. Imaida, H. Ozaki, T. Harada, A. Tai, *Bull. Chem. Soc. Jpn. 55* (1982) 2186; (*S*)-**8c**: $[\alpha]_D^{20}$ –20.8 (c = 1, $CHCl_3$). **8d**: $[\alpha]_D^{25}$ –17.9 (c = 2.2, 95% EtOH) [2c]; (*R*)-**8d**: $[\alpha]_D^{25}$ +17.9 (c = 2.3, 95% EtOH).



According to *Chan* et al.[9] the Mukaiyama reaction with (*E*)-*O*-silyl ketene acetals leads preferably to *anti*-3-hydroxy-2-methylcarboxylates. Since, under the conditions employed for acetates, the propionates **10** of the alcohols **2a** and **2b** furnish (*E*)-*O*-*t*-butyldimethylsilyl ketene acetals with a selectivity of 98:2, the *O*-silyl ketene acetal **12** was reacted with isobutyraldehyde-$TiCl_4$ complex in order to test the diastereoselectivity. The four diastereomeric adducts **13–16** can be readily separated by chromatography. In this case also, the Mukaiyama reaction is remarkably diastereoselective, whereas the reaction of the corresponding lithium enolate **11** once again proceeded unselectively (Table 2).

Surprisingly, the reactions of the *O*-silyl ketene acetals **5** and **12** proceed with configuratively inverse enantioface-differentiation of the aldehyde, i.e. with Re attack in the case of **5** and Si attack in the case of **12**. The diastereoface-differentiation at C-2 of **12** corresponds configura-

[a] For reaction conditions see Table 1. [b] [c] as in Table 1.

tively to that of the alkylation of the corresponding lithium enolate **11**. If one assumes a transition state of the Zimmermann-Traxler type and addition of the electrophile from the sterically more favorable half space of C-2, the configurational relationships can be rationalized on the basis of the transition states **17** and **18**.

The assignment of configuration with regard to C-2 and C-3 of the adducts **13**–**16**[10] was combined with an application in natural product synthesis, in that the TBS derivative of the ester **14** was reduced to the alcohol **19**, which, as building block for a synthesis of avermectin, was recently prepared via a different route.

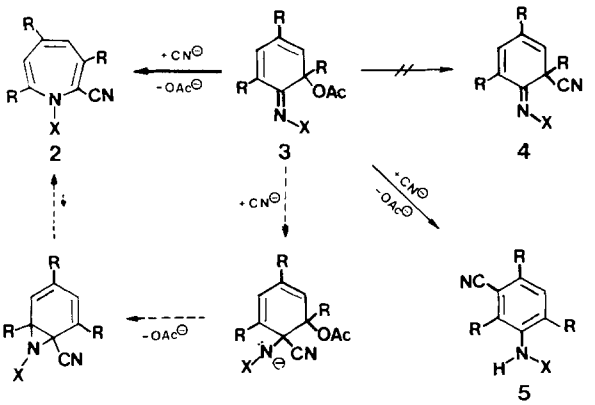
A Previously Unrecognized 1*H*-Azepine Synthesis**

By *Hartwig Perst,* Werner Massa, Michael Lumm,* and *Gerhard Baum*

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday

In 1963 the *N*-ethoxycarbonyl derivative **1** was described as the first monocyclic, 1-substituted 1*H*-azepine.[1]



An entry to the monocyclic 1*H*-azepine **2a** first reported as long ago as 1956 by *Adams* and *Brower* seems to have been overlooked, because the authors could not, at the time, elucidate the structure of **2a**. Upon reaction of triethylammonium cyanide with the linearly conjugated 6-benzenesulfonyliminocyclohexadienyl acetate **3a** they obtained—apart from the expected 3-cyanoanilide derivative **5a** (18.5% yield)—a pale yellow compound (55% yield).[2] The structure 6-cyanocyclohexadienylideneamide **4a** proposed for this substance[3] should, according to our recent findings, be replaced by the 1*H*-azepine structure **2a**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

On further investigation we were able to confirm the ready formation of **2a** (58% yield); furthermore, we were also able to extend this convenient entry to 2-cyano-1*H*-azepines **2** to the imines **3b**–**3d**,[4] which can be smoothly generated by oxidation of the corresponding anilides with lead tetraacetate.[5]

Attack by cyanide at the imine carbon atom of **3** followed by nitrogen neighboring-group participation with loss of the acetate residue results in formation of the 1*H*-azepines **2a**–**d** (via azanorcaradiene intermediates).[6] The competing Michael addition of the cyanide ion leads to 3-cyanoanilides **5** and, starting from **3a**–**c**, proceeds only up to a maximum of 20%, whereas in the case of **3d** it is the preferred reaction (ca. 75%).[7] In no case could a 6-cyanocyclohexadienylideneamide **4** be detected.

2–5	R	X	Yield **2** [%]
a	Me	Ph-SO_2	58
b	Me	*p*-$MeC_6H_4SO_2$	61
c	Me	Me-SO_2	59
d	Ph	*p*-$MeC_6H_4SO_2$	22

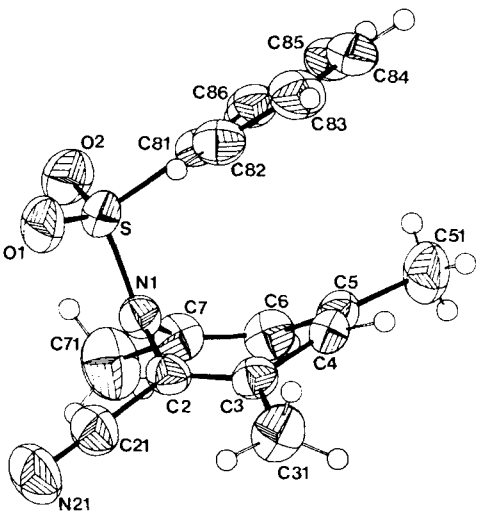

Fig. 1. Crystal structure of **2a**. ORTEP diagram, thermal ellipsoids depicted at the 50% probability level. Selected bond lengths [pm] and angles [v]: N1-C2 143.1(3), C2-C3 134.2(3), C3-C4 144.8(3), C4-C5 134.8(3), C5-C6 145.5(3), C6-C7 133.1(3), C7-N1 144.1(3), N1-S 165.1(2), S-O1 142.6(2), S-O2 142.5(2), S-C81 176.0(2), C2-C21 144.0(3), C21-N21 113.9(3); C2-N1-C7 115.9(2), N1-S-C81 106.9(1), O1-S-O2 121.1(1), C2-C21-N21 177.8(3).

The 1*H*-azepine constitutions of the compounds **2a**–**c** (pale yellow) and **2d** (deep yellow) have been confirmed by an X-ray structure analysis of **2a** (see Fig. 1).[8] ^{1}H- and ^{13}C-NMR data ruled out a cyclohexadienylideneamide formulation **4**, yet at the same time did not provide unequivocal evidence in favor of **2**.[9]

The seven-membered ring in **2a** has a boat-shaped configuration typical for 1*H*-azepines;[1c,6] the angles between the C2, C3, C6, C7 plane and the N1, C2, C7 and C3, C4, C5, C6 planes are 128.7 and 154.4°, respectively. The slightly pyramidal nitrogen center N1 lies 18 pm outside of the C2, C7, S plane; the N1–S bond is bent at an angle of 20° (towards the axial position). The phenyl ring in the *endo* position to the seven-membered ring is oriented almost parallel to the C3, C4, C5, C6[11] plane (deviation 6.8°).

Photochemical Synthesis of an L-Erythrose Building Block and Its use in the Preparation of Methyl 2,3,*O*-Isopropylidene-β-L-apio-L-furanoside**

By *Alfred Nehrings, Hans-Dieter Scharf,** and *Jan Runsink*

The addition of electronically excited chiral phenylglyoxylates **1**[1] to electron-rich olefins (e.g. **2**) in the sense of a Paterno-Büchi reaction[2,3] leads to oxetanes in high diastereomeric excesses.[4,5]

Thus, the oxetane **4a** is formed exo- and diastereoselectively (*de* ≥ 96%, *exo* ≥ 99%) by photochemical addition of (1*R*,3*R*,4*S*)-(−)-8-phenylmenthyl phenylglyoxylate **1a** to 2,2-dimethyl-1,3-dioxole **2**.[6] When the menthyl esters **1b** or **1c** are used, the *de* values are 57 and 56%, respectively (see Table 1). The exoselectivity is not a result of the chiral ester grouping, for it is also observed with the achiral methyl ester (**1**, R* = Me),[7] which leads to the racemate of the oxetanes **3** and **4** (R* = Me).

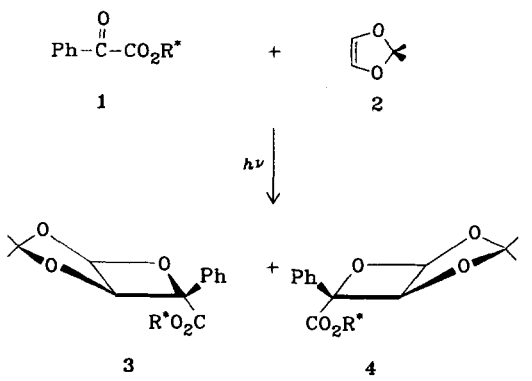

Table 1. Chemical yields and diastereomeric excesses (*de*) in the Paterno Büchi reaction of the phenyl glyoxylates **1a**–**1c**.

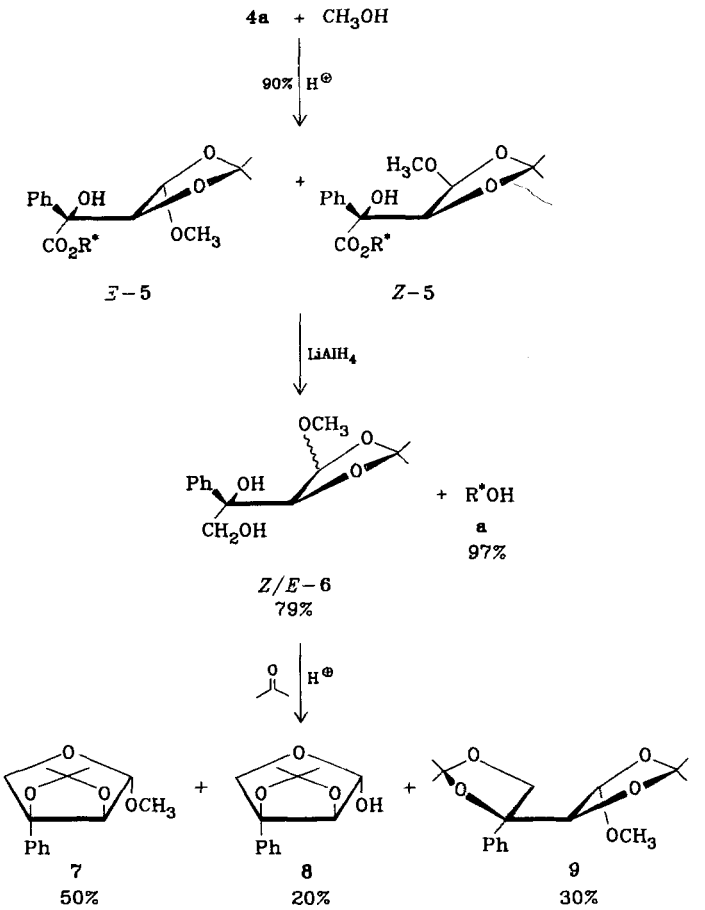
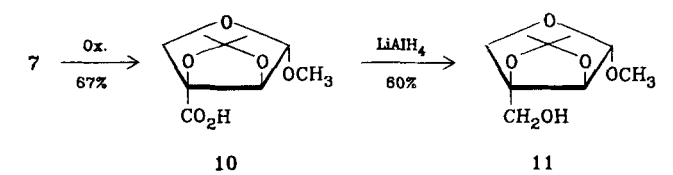
Alcohol R*OH	R*	Chem. yield of oxetane	*de* [a]	Excess oxetane
a	(−)-8-Ph-Menthyl [9]	99%	≥ 96%	**4a**
b	(−)-Menthyl	99%	57%	**4b**
c	(+)-Menthyl	99%	56%	**3c**



[a] Determined by ^{13}C-NMR spectroscopy.

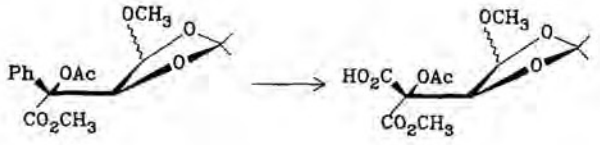
Three chiral centers are established in a single face-differentiating reaction step. Of these three centers, two remain when the oxetane **3/4** is considered as a masked aldol[8] (photo-aldol reaction).



The oxetane **4a** can, for example, be used for the preparation of the apiose derivative **11**. The oxetane ring of **4a** is opened in an intermolecular transacetalization with methanol.[8] An ion-exchanger is employed as catalyst, thus facilitating easy work-up: The liquid is decanted off, filtered over silica gel, and the *Z*/*E* mixture (1:12) of the 1-*O*-methyl-1,2-*O*-isopropylidene-3-*C*-phenyl-L-*erythro*-tetruronic acid (1*R*,3*R*,4*S*)-(−)-8-phenylmenthyl ester **5** is obtained in 90% yield.[10] The reduction of this mixture *Z*/*E*-**5** with $LiAlH_4$[11] leads to recovery of the chiral alcohol in 97% yield (87% overall yield based on all reaction steps).

The *Z*/*E* mixture of 1-*O*-methyl-1,2-*O*-isopropylidene-3-*C*-phenyl-L-erythrose **6** is formed in 79% yield.

Z/*E*-**6** is cyclized by intramolecular transacetalization to the furanoside **7**, the vic. diol being protected at the same time. The furanose **8**[12] and the diacetonide **9** are obtained as by-products. The furanoses **7** and **8**, which are suitable for further syntheses are formed together in 70% overall yield.



Methyl-2,3-*O*-isopropylidene-3-*C*-phenyl-β-L-*erythro*-furanoside **7**[13a] should, by way of example, serve for the synthesis of methyl-2,3-*O*-isopropylidene-β-L-apio-L-furanoside **11**.[13b] The phenyl group **7** is oxidized according to the method described by *Sharpless* et al.[14] to the carboxy group (67%) and reduced with $LiAlH_4$ in ether to give the apiose derivative **11** (60%). The structure of the apioside **11** was determined by ^{1}H- and ^{13}C-NMR spectroscopy.

In addition, a comparison with data in the literature is possible, since *Ball et al.*[15] have recorded the ^{1}H-NMR spectrum as well as measured an optical rotation ($[\alpha]_D^{25} = -108$ ($c = 3.9$, $CHCl_3$)) for the enantiomer, a derivative of D-apio-D-furanose—the naturally occurring form. The ^{1}H-NMR spectra were identical, while the synthetic product was found to have an optical rotation of $[\alpha]_D^{25} = +105$ ($c = 1.5$, $CHCl_3$).

[**] Chiral Induction in Photochemical Reactions, Part 3. The firms Bayer AG and Haarmann & Reimer GmbH supported this work by gifts of basic chemicals.—Part 2: [5].

12 13

Degradation (or oxidation) of the phenyl group in the acetal **12**, chemoselective reduction of the carboxylic acid **13** to the alcohol, and subsequent cyclization affords access also to the *threo*-configurated derivative of the apiose, an L-apio-D-furanose derivative. It is thus shown, by way of example, that this chiralic controlled photo-aldol reaction is suitable for the general synthesis of branched carbohydrates starting from "non-sugar building blocks".[16]

Experimental

1a: A solution of pyridine (13.5 g) and (−)-8-phenylmenthol (alcohol **a**) in toluene (100 mL) was added dropwise at 0–5 °C to a solution of PhCO-COCl (20.2 g) in toluene (100 mL). After ca. 12 hours' stirring the reaction mixture was washed with 10% HCl, 5% $NaHCO_3$, and water, then dried with $MgSO_4$, and finally evaporated to dryness. Subsequent recrystallization (three times, hexane-ether 6:1) of the residue furnished 22 g of the ester **1a** (51%), m.p. 90–91.5 °C. It should be noted that, unless the alcohol **a** has been purified via its chloroacetic acid ester, a separation of diastereomers is carried out during the recrystallization, since the (−)-8-phenylmenthol synthesized according to the method given in the literature[9] contains up to 15% of an isomer.

4a: A solution of **1a** (16.4 g) and **2** (4.5 g) in anhydrous benzene (500 mL) was irradiated for 6 h with a T718Z2 (Hanau Heraeus) lamp in a falling-film apparatus. The solution was then evaporated, filtered over silica gel (CH_2Cl_2), and the residue remaining after the removal of solvent was dried. Yield 20.7 g (99%) of oxetane **4a**, m.p. 73 °C; $[\alpha]_D^{25} = -9.1$ ($c = 0.98$, EtOH). Since the volume of the irradiation vessel was ca. 1000 mL, up to 40 g of oxetane could be synthesized in one batch.

Catalytic Hydroboration with Rhodium Complexes

By *Detlef Männig* and *Heinrich Nöth**

The catalytic hydrosilylation,[1] hydrocyanation,[2] and metal-catalyzed additions of element-hydrogen compounds to unsaturated functional groups of organic substrates, in particular to CC double and triple bonds, have long been known and are of industrial importance. The hydroboration of unsaturated CC systems with hydroboration agents such as H_3B/tetrahydrofuran (THF), $H_3B \cdot S(CH_3)_2$, disiamylborane, thexylborane, or $H_2BCl \cdot O(C_2H_5)_2$ proceeds even in the absence of catalysts with a high rate. Probably for this reason, no catalytic hydroborations using simple borane derivatives[4] have been described up to now despite the broad scope of hydroboration in organic synthesis.[3] There are, however, a number of hydroboration agents, such as 1,3,2-benzodioxaborole **1**, whose low activity could be considerably increased catalytically.

We have now found that hydroboration with 1,3,2-benzodioxaborole (catecholborane) **1** is catalyzed by rhodium complexes—i.e., the hydroboration of alkynes and alkenes with **1**, which requires temperatures of 70 and 100 °C (2–4 h), respectively, without a catalyst,[5] occurs without difficulty at room temperature in the presence of a catalyst. It has thereby been possible to activate the CC double bonds of olefins so strongly that they are preferentially hydroborated even in the presence of the much more reactive keto group (Table 1). For example, without a catalyst, 5-hexen-2-one reacts rapidly and quantitatively to give 2-(1-methyl-4-pentenyloxy)-1,3,2-benzodioxaborole **2**, whereas, in the presence of Wilkinson's complex, $[ClRh\{P(C_6H_5)_3\}_3]$, the ketone **3** is preferentially formed.

1 2 3

This rhodium complex is characterized by particularly high activity. The complexes $[RhCl(CO)\{P(C_6H_5)_3\}_2]$, $[RhCl(CO)\{As(C_6H_5)_3\}_2]$, and $[RhCl(cod)]_2$ (cod = 1,5-cyclooctadiene) are also suitable as catalysts for the hydroboration with **1**. Significantly lower activity is observed for $[HRuCl(CO)\{P(C_6H_5)_3\}_3]$; complexes of platinum, palladium, iridium, and cobalt exhibit no or only minor catalytic effects.

The order of reactivity of the olefins studied (Table 1) is the same as that found for $BH_3 \cdot THF$. In the case of ketones containing CC double bonds, only the keto group is reduced by **1** in the absence of $[ClRh\{P(C_6H_5)_3\}_3]$. In the presence of the catalyst, however, the CC double bond is preferentially hydroborated. The two hydroboration products formed can be separated by distillation. In contrast to the keto group, the aldehyde group is so reactive[6] that, even in the presence of the catalyst, it is not possible to activate the CC double bond sufficiently for it to compete with the CHO group.

We were also able to enhance the reactivity of 2,2,4-trimethyldioxaborinane catalytically, although less effec-

[a] Reaction conditions: 45 mmoles of substrate and of **1**, 7.5 mL of benzene, 0.05 mol-% $[ClRh nP(C_6H_5)_3]_3]$, 20°C; distillative workup after 25 min. Hydroboration does not occur under these conditions without a catalyst. [b] Only hydroboration of vinyl groups. [c] Reaction to give the alkenyl compound. [d] Reaction conditions: 22.5 mmoles of substrate and of **1**, 70 mL of benzene, 0.5 mol-% $[ClRhnP(C_6H_5)_3]_3]$ or no catalyst, 0°C. Distillative workup after 2 h. Product distribution determined by ^{11}B-NMR spectroscopy before distillation. [e] Mixture of *exo-endo* isomers, 72:28. [f] Mixture of *exo-endo* isomers, 80:20. [g] Mixture of 3- and 1-cyanopropyl compound (60:40).

tively than **1**; however, 1,3-dimethyl-1,3,2-diazaborolidine or dialkylboranes could not be activated. We suggest as an explanation that only sufficiently acidic borane components can be catalytically activated. **1** adds oxidatively to Wilkinson's complex, and the adduct formed, $[\{(C_6H_5)_3P\}_2Rh(H)Cl(BO_2C_6H_4)]$,[7] which had not previously been characterized in detail, reacts stoichiometrically with olefins, resulting in hydroboration and formation of $[\{(C_6H_5)_3P\}_2RhCl]_2$.[8]

The catalytic hydroboration of olefins by **1** is at least as good as the standard hydroboration with hydroboration agents that are more reactive than **1** and superior in the case of thermally labile olefins. Moreover, the method has the advantage that the CC double bond is preferentially hydroborated even in the presence of reactive functional groups and thus is an additional method of selective reduction.[8]

[**] Chemistry of the Tricyclopentadienyluranium(IV) Cation in Aqueous Solution, Part 4. We thank *J. P. Jacobsen* for his assistance. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 3: [1a].

(ψ-T_d) and trigonal-bipyramidal (tbp) configuration, respectively (M = U, R = η^5-C_5H_5 = Cp; M = Sn, R = alkyl or aryl; X and Y = halide, pseudohalide; q = 0, +1, −1), exhibit similar chemical behavior.[1] Various observations[2–6] suggest that such tbp fragments of either metal (e.g., with X = Y = CN^-) might be able to incorporate d-transition-metal ions M'^{n+} (M') into one-, two-, and three-dimensionally linked coordination polymers, $\{M'[(CN)_2MR_3]_n\}_\infty \triangleq \{(R_3M)_nM'(CN)_{2n}\}_\infty$ (n = 1–3). Compounds with n = 3 deserve particular interest since large cavities "padded" by organic groups could be generated in their lattices.

The air-stable compound **1** forms spontaneously and quantitatively in aqueous solution.[7]

$$3\,Me_3SnCl + K_3[Co(CN)_6] \xrightarrow[-3\,KCl]{H_2O} [(Me_3Sn)_3Co(CN)_6]_\infty \quad \mathbf{1}$$

The fine, white precipitate can be easily purified; **1** is nonvolatile and insoluble in commonly used solvents.[8] The relatively simple vibrational spectra of **1** are devoid of H_2O bands; the spectral behavior in the ν(CN) range suggests weakly distorted O_h symmetry for the $Co(CN)_6$ units, while the Sn atoms appear to be uniformly tbp-coordinated (ψ-D_{3h} symmetry).[9,10] The ^{59}Co-NMR spectrum of the solid[11] shows one broad singlet, the high-field shift of which, along with the higher ν(CN) values of **1** (as compared with those of $K_3[Co(CN)_6]$) indicate the formation of Co−C≡N→Sn bridges.[12] In the ^{119m}Sn Mössbauer spectrum,[13] a doublet is observed which is, also in view of ΔE,[14] in accord with tbp coordination. The X-ray powder diffraction pattern[15] shows noticeably sharp reflections, the positions of which rule out a cubic lattice.

The single-crystal X-ray structure determination[16] confirms the presence of distorted octahedral $Co(CNSn)_6$ fragments (C_i microsymmetry) and tbp-configurated N_2SnMe_3 units within a strictly three-dimensional network (Fig. 1). Surprisingly, only one-third of all $(Co-C\equiv N-Sn-N\equiv C)_\infty$ chains are linear (angle between nonparallel, linear $(CoCNSnNC)_\infty$ chains, 80°); the remaining Co−C≡N−Sn sections are bent at the N atom (157.7 or 146.2°[17]). The two non-identical *trans*-$(CN)_2SnMe_3$ units (i.e., the components of linear and zigzag $(CoCNSnNC)_\infty$ chains, respectively) cannot be differentiated by vibrational spectroscopy.[18]

Apparently, compound **1** does not form an equally plausible, quasi-cubic isomer with exclusively linear $(CoCNSnNC)_\infty$ chains ("super Prussian blue" analogue; for Co_8 cubes with an edge length of 10.62 Å, $\rho_{calcd} = 0.978$ g·cm^{-1}[16]). The relatively short C···C distances between methyl groups bonded to different Sn atoms (e.g., C4···C8, C4···C7, C5···C8; 3.65–3.70 Å) along with the markedly distorted C_3 symmetry of the Sn2-C4-C5-C6 fragment (Fig. 1) do not rule out the possibility that increasing steric bulk of the group R (R ≠ Me) might force all CNSn angles to become 180°, resulting in a marked expansion and simplification of the lattice.

The extremely air-sensitive uranium complex $[(Cp_3U)_3Co(CN)_6]_\infty$ **2**, which is formally analogous to **1**, separates out as a light green, colloidal precipitate after mixing concentrated aqueous solutions of Cp_3UCl and $K_3[Co(CN)_6]$.[19] A likewise polymeric structure for **2** is suggested by its nonvolatility in high vacuum,[20] considerable thermal stability,[21] and low solubility in a variety of solvents.[22] The NIR/VIS absorption spectrum[23] shows the f-f ligand-field transitions that are very characteristic for tbp-configurated $[Cp_3UX_2]^q$ systems. The occurrence of only one ν(CN) absorption in the IR spectrum[23] is fundamentally in accord with a conceivable structure of a "super Prussian blue" analogue. Inspection of space-filling models of **1** and **2** clearly indicates that the rather expanded Cp ligands are likely to fill, and even to stabilize, the inner surfaces of the individual Co_8 cubes (with, on the average, nine Cp units per Co_8 cube) better than methyl ligands, and that UNC angles smaller than 180° should hardly be possible.[24] From an equimolar solution of Me_3SnCl and Cp_3UCl, a light green, surprisingly Sn-deficient (Sn : U ≈ 1 : 3) precipitate **3** forms (m.p. = 250 °C (decomp.)) upon addition of $K_3[Co(CN)_6]$; **3** is stable to air for several minutes but hardly differs **2** IR spectroscopically.

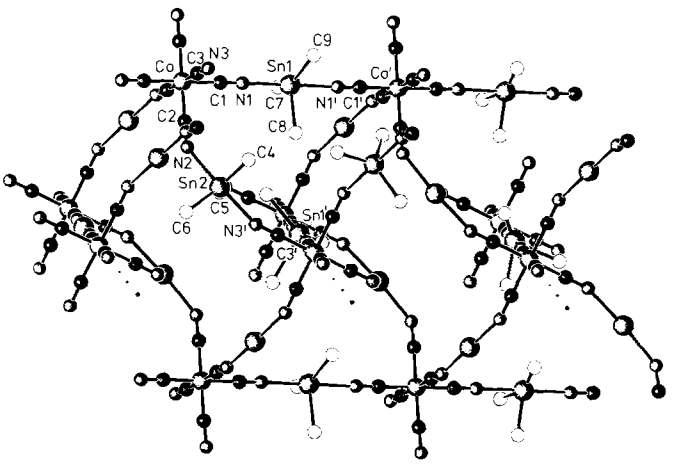

Fig. 1. SCHAKAL plot of a section of the lattice of **1**. Regiospecific α-Alkylation of α-Haloalkylidenamines ("α-Haloketimines")

By *Norbert De Kimpe,* Paul Sulmon,* and *Niceas Schamp*

α-Heterosubstituted carbanions are powerful reagents for the synthesis of a large variety of compounds.[1] They may be generated from a variety of precursors, including nitriles, sulfides, sulfoxides, phosphonates, and silanes, which contain halogens, S, O, P, N, Ge, or Si in the α position. Only rarely are they prepared from α-halocarbonyl compounds, with the exception of α-haloesters (cf. Darzens reaction) and α-halocarboxylic acids. α-Haloketones are usually not susceptible to the generation of stabilized α-anions because of their high reactivity (e.g., Favorskii rearrangement, tar formation). Some α-haloenolate anions of type **2** have been described,[2–4] but most of them lack hydrogen atoms in the α′ position. Very recently, α-fluoroenolates were used in directed aldol condensations with high diastereoselectivity.[5] The remarkable progress in α-lithioimine chemistry in recent years[6] prompted us to investigate the chemical behavior of α-lithio-α-haloalkylidenamines ("α-haloketimines") **5**.[7]

The α-chloroalkylidenamines **4a,b** are readily deprotonated with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) at 0°C (1–2 h) to give 3-chloro-1-azaallylic carbanions **5a,b**, which are stable for at least one day at

0 °C under N_2 and react with alkyl halides at room temperature to afford *C*-alkylated products **6** exclusively. Primary and secondary as well as functionalized alkyl halides can be used (Table 1) without giving side products. In most cases the use of hexamethylphosphoric triamide is not necessary. When the phenyl-substituted azaallylic anion **5b** is treated cautiously at 0 °C with water, protonation occurs exclusively on nitrogen to generate the fairly stable β-chloroenamine **7b** (one stereoisomer), which slowly rearranges to the α-chloroalkylidenamine **4b**. An analogous reaction sequence has been observed recently for aldimines.[7] The alkylation **4** → **6** also takes place for α-bromo- and α-fluoroalkylidenamines, **4c** and **4d**, respectively (Table 1).

The new strategy developed here allows the α-alkylation of α-haloketones **1**, even when there are hydrogen atoms in the α′ position (direct treatment of such α-haloketones with strong bases often results in tar formation). By masking the α-haloketones as α-haloalkylidenamines,[10] this transformation (**1** → **3**) becomes possible. For example, 3-chloro-2-butanone **1a** was converted via **4a** and **5a** into 3-chloro-3,4-dimethyl-2-pentanone **3a**, $R^3 = i$Pr, in 65% yield. This masking strategy demonstrates the usefulness of α-haloimines in synthetic organic chemistry.[11]

Photoreactions of *N*-(1-Pyridinio)amidates in Monolayers and Liposomes

By *Michael Haubs* and *Helmut Ringsdorf**

The variation of membrane properties via excitable assemblies is one of the essential features of cell membranes and is often triggered by photoreactions.[1] In connection with the investigation of membrane models,[2] we have studied the photochemical modification of liposomal surfaces and of monolayers using the synthetic amphiphiles **1**–**8** with the mesoionic chromophore $C_5H_5\overset{\oplus}{N}-\overset{\ominus}{N}-CO-$ as hydrophilic head group (Table 1). The photoreaction of *N*-(1-pyridinio)amidates, $C_5H_5\overset{\oplus}{N}-\overset{\ominus}{N}-CO-R$, leads to 1,2-diazepines,[3] which are markedly less polar. This opens up interesting possibilities to drastically vary the surface character of organized assemblies, such as micelles,[4] mono- and multilayers,[5] and liposomes.[6]

Table 1. Single- and double-chain amphiphiles **1**–**8** [a] with the photoreactive pyridinioamidate group $C_5H_5\overset{\oplus}{N}-\overset{\ominus}{N}-CO-$ as head group.

Compound	R	M.p. [°C]
1	C_9H_{19}	67
2	$OCH_2CH_2OCOC_{11}H_{23}$	50
3	$C_{17}H_{35}$	90
4	$C_{25}H_{51}$	100.5
5	$OC_{18}H_{37}$	92
6	$CH_2CH_2CON(C_{18}H_{37})_2$	60
7	$N(C_{18}H_{37})_2$	56
8	$N(CH_2CH_2OCOC_{15}H_{31})_2$	75

[a] The pyridinioamidates **1**–**8** were synthesized by adding the corresponding activated carbonyl component in tetrahydrofuran to a solution of 1-aminopyridinium chloride in ethanol or acetonitrile in the presence of excess K_2CO_3 [7]. The products were purified by recrystallization from acetone and hexane or by column chromatography on silica gel using chloroform/methanol (10:1) as eluent (yields: 50–90%). The 1,2-diazepines were prepared by photolyses (λ = 366 nm) of the corresponding pyridinioamidates (1% solutions in chloroform) and purified by column chromatography on silica gel using chloroform/ethanol (100:1) as eluent (yields: 40–95%). All compounds were characterized by elemental analysis and by ^{1}H-NMR, UV, and mass spectra.

Ultrasonication of the single-chain amphiphile **4** and of the double-chain amphiphiles **6**–**8** in water yields liposomes as shown by electron microscopy and dye inclusion experiments (Azure A, Rhodamine B). Formation of liposomes was also confirmed by fluorescence microscopy on large (1–10 μ) vesicles containing 1 mM Rhodamine B. Liposomal suspensions are stable at room temperature for months when kept in the dark. Liposomes are only formed in slightly acidic solution (pH 3), whereas sonication in pure water leads to a suspension of microcrystals. This may be rationalized by partial protonation of the head group, rendering it more hydrophilic. The extent of protonation is approximately 15% (at pH 3) as calculated from pH measurements and from the UV spectra, which for the protonated form do not show the long-wavelength absorption band of pyridinioamidates (Fig. 1).

The photoreactions of pyridinioamidates in organized assemblies show marked differences compared with those in solution: the quantum yield of the rearrangement is considerably lower, and the photoreaction strongly depends on the structure of the lipids and on the wavelength of ir-

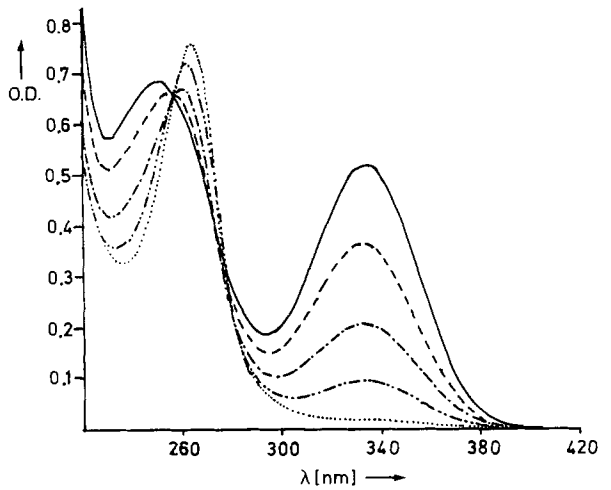

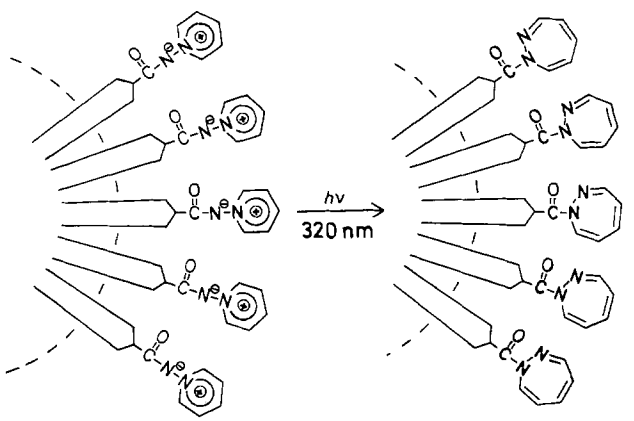

Fig. 1. UV spectra of liposomes from **8** at pH 4.1 (—), pH 2.7 (---), pH 2.2 (-·-·-), pH 1.8 (-··-··-), and pH 1.4 (····); $c = 1.8 \times 10^{-4}$ mol/L.

radiation. The lipid **8**, which contains a flexible spacer between the hydrophilic head group and each of the hydrophobic alkyl chains, is photoisomerized in the liposome to a lipid with 1,2-diazepine head groups in high yield upon irradiation with long-wavelength UV light ($\lambda = 366$ nm) (Scheme 1).

Scheme 1. Photochemical transformation of liposomes prepared from **8**.

This transformation of the polar into a nonpolar head group strongly influences the stability of the liposomal membrane. The photolyzed vesicles are metastable and collapse on mechanical stress (shearing, ultrasonication, filtration). In contrast, the photoreaction of liposomes prepared from **4**, **6**, or **7** yields a complex reaction mixture with only minor amounts of the corresponding diazepine.

Compounds **1** and **2** dissolve in water to form micelles. The foaming solutions solubilize hydrophobic dyes and chloroform, which precipitate or are released on photolysis. Compounds **3**–**8** are water-insoluble and give stable monolayers at the air-water interface. Single-chain derivatives exhibit typical collapse areas of 0.34 nm^2/molecule (packing of the head groups), whereas the monolayers of double-chain derivatives collapse at 0.45 nm^2/molecule (chain-packing).

Upon irradiation with 254-nm UV light the films prepared from **3**–**7** form stable, solid-analogue monolayers. The collapse areas of single-chain compounds decrease by approximately 40% (transition from head-packing to chain-packing). Kinetic studies with intermittent irradiation show that the decrease in area at constant surface

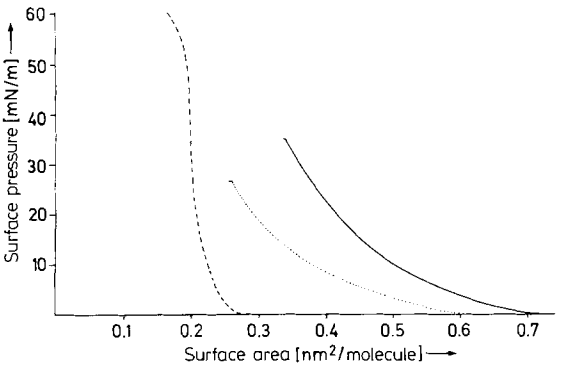

Fig. 2. Surface pressure-area isotherms of monolayers at the air-water interface at 22°C; single-chain derivative **3** (—), 254-nm photoproduct (---), and pure 1,2-diazepine (····). The compounds were spread from a 0.1% solution in $CHCl_3$ on a Langmuir film balance.

pressure solely takes place during exposure to UV light. This indicates a change in monolayer structure rather than a partial solubilization. As expected, the double-chain derivatives exhibit only slight differences in collapse areas upon irradiation because the monolayer packing is determined by the hydrophobic alkyl chains, which are not involved in the photoreaction. Figure 2 shows the spreading behavior of the single-chain compound **3**, its 254-nm photoproduct, and the corresponding pure diazepine.

TLC analyses of the photoproducts of **3**–**7** ($\lambda = 254$ nm) reveal a complex mixture in which the diazepine is just one of many components. By exposing the monolayer of **5** to 302-nm UV light, however, the corresponding diazepine is formed as the main product.

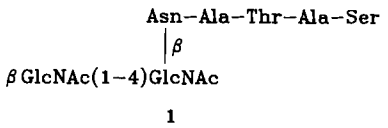
Construction of Disaccharide *N*-Glycopeptides—Synthesis of the Linkage Region of the Transmembrane-Neuraminidase of an Influenza Virus**

By *Horst Kunz** and *Herbert Waldmann*



Dedicated to Professor Günter Viktor Schulz on the occasion of his 80th birthday

Glycoproteins play an important role in biological recognition processes on cell membranes, as occur in im-

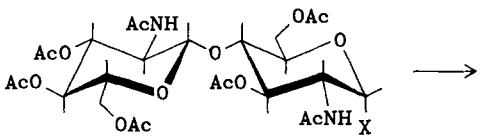
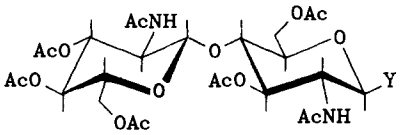
Institut für Organische Chemie der Universität
Johann-Joachim-Becher-Weg 18-20, D-6500 Mainz (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

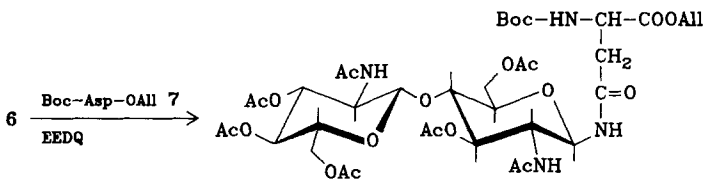
mune reactions and infection processes.[1] Important for an exact study of and the directed influence on these processes are well-defined model compounds which correspond to characteristic structural elements of glycoproteins that participate in these recognition processes. We now describe the synthesis of two such partial structures of *N*-glycoproteins, a glycopentapeptide of the linkage region **1** of the transmembrane-neuraminidase of the influenza virus strain A/Tokyo/3/67[2] and a glycopeptide of the linkage region **2** of the factor B of the human complement system.[3] Both structures contain the disaccharidic core of the di-*N*-acetylchitobiose which is characteristic for *N*-glycoproteins and which is bound *N*-glycosidically to the amide function of the asparagine of the peptide chain.



1

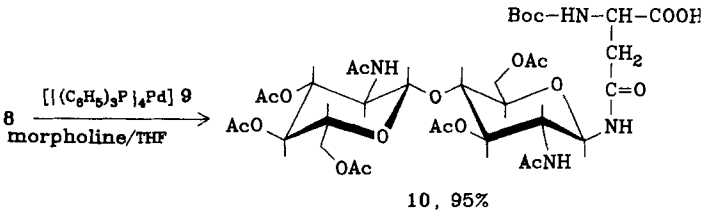


2

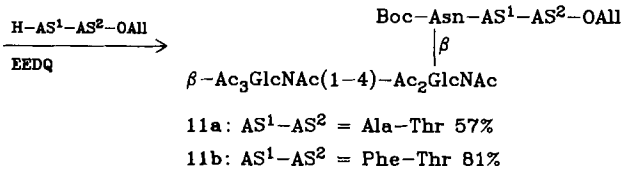


For construction of the target structures **1** and **2** the octaacetate of the chitobiose **3** is first obtained from chitin by acetylating acid hydrolysis and is converted by reaction with HCl in acetyl chloride into the peracetylated chitobiosyl chloride **4**.[4] The conversion of **4** into the β-azide **5** carried out hitherto with the aid of the sensitive silver azide was accomplished smoothly as a phase-transfer catalyzed S_N2 reaction with sodium azide in the presence of tri-*n*-caprylmethylammonium chloride in chloroform/water. Hydrogenolysis of the azide furnished the chitobiosylamine **6**, which was coupled in the presence of ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ)[5] with allyl *N*-*tert*-butyloxycarbonyl aspartate **7** in high yields to give the fully protected chitobiosylasparagine unit **8**.

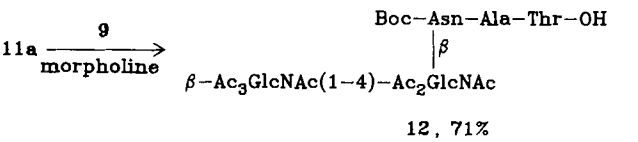
3: X = OAc **4**: X = Cl, 88%



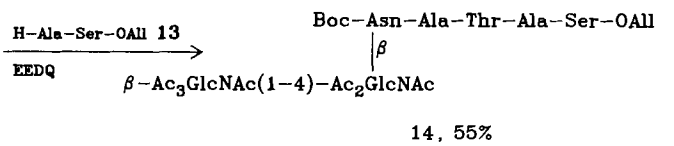
5: Y = N_3, 75% **6**: Y = NH_2, 60%



All = Allyl 8, 91%

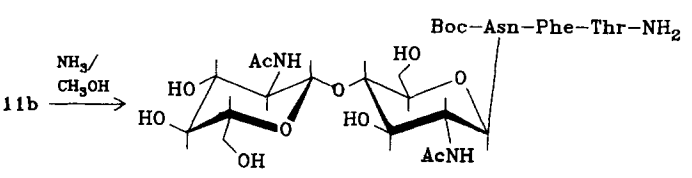


Decisive for further success of the synthesis is that the complex compound **8** containing *N*- and *O*-glycosidic bonds can be almost specifically and quantitatively *C*-terminally deblocked by palladium(0)-catalyzed allyl ester cleavage.[5] Chain lengthening at the *C*-terminal with dipeptide allyl esters[6] is then possible.



10, 95%

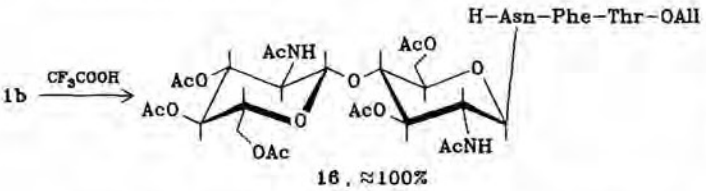
11a: AS^1–AS^2 = Ala–Thr 57%
11b: AS^1–AS^2 = Phe–Thr 81%



12, 71%

14, 55%

With EEDQ as condensation agent in dichloromethane the protected chitobiosylasparagine tripeptides **11** are formed, whereby the yield of **11a** is reduced due to cyclization of the less hindered dipeptide ester to the diketopiperazine during the course of the reaction. This disaccharide glycopeptide **11a** can also be selectively deblocked at the carboxyl group by Pd(0)-catalyzed allyl transfer to morpholine in dioxane at room temperature. Chromatographic separation affords the analytically pure compound **12**.[7] With the dipeptide allyl ester **13**,[6] which once again tends to undergo cyclization, the chitobiosylasparagine pentapeptide **14** is formed, which corresponds to the protected partial structure **1** of the influenza virus neuraminidase. Chromatographic separation (chloroform/ethanol 9 : 1) afforded pure **14**, which was then characterized spectroscopically.[8]



The carbohydrate hydroxyl groups of the synthetic glycopeptide can be removed under very gentle conditions with ammonia in methanol at room temperature, as was demonstrated with the compound **11b**, the protected partial structure **2** of the human complement factor B.[9] The allyl ester is concomitantly aminolyzed. The compound **15** can be isolated directly as pure crystals from methanol/chloroform and can be used for model biochemical and immunological reactions.

15, 86%

If removal of the *tert*-butyloxycarbonyl group from the glycopeptide is also desired, this does not succeed in the mainly deblocked molecule **15**. The *O*-glycoside bond of

the chitobiose is partially cleaved, both with anhydrous trifluoroacetic acid as well as with aqueous hydrochloric acid. In contrast, *N*-terminal deblocking in the fully protected glycopeptide **11b** to give **16** proceeds readily and selectively with anhydrous trifluoroacetic acid.

The hydro salt of the *N*-deblocked compound **16** opens up the possibility of both directed *N*-terminal chain lengthening as well as further deblocking in the sense outlined above.

[6] Preparation according to: H. Waldmann, H. Kunz, *Liebigs Ann. Chem. 1983*, 1712.
[7] Procedure: A solution of **11a** (0.28 g, 0.26 mmol) in anhydrous dioxane (10 mL) was treated under argon and in the absence of light with 30 mg (0.026 mmol) of tetrakis(triphenylphosphane)palladium(0) and then dropwise with 0.26 g (3 mmol) of morpholine. The mixture was stirred for 12 h at room temperature, evaporated to dryness, and the resulting *C*-terminally deblocked di-*N*-acetylchitobiosaminyl tripeptide **12** purified chromatographically on silica gel, the impurities being first removed with chloroform/ethanol (9:1) and **12** then being eluted with methanol. Yield 0.19 g (71%); m.p. 218–220°C; $[\alpha]_D^{22} = 6.2$ ($c = 0.2$, DMSO).—270-MHz ^{1}H NMR ([D$_6$]DMSO): $\delta = 8.51$ (d, $J = 10$ Hz, 1H, γ-NH Asn), 8.05 (d, $J = 10$ Hz, 1H, NH), 7.94 (d, $J = 8.5$ Hz, 1H, NH), 7.87 (d, $J = 9$ Hz, 1H, NH), 7.53 (d, $J = 7.5$ Hz, 1H, NH), 6.86 (d, $J = 9.2$ Hz, 1H, NH urethane), 5.11 (dd, J(H1/NH) = 10, J(H1/H2) = 9.5 Hz, 1H, H1), 4.68 (d, J(H1'/H2') = 8.3 Hz, 1H, H1'), 2.49 (dd, $J_{gem} = 11.9$, $J_{vic} = 7.5$ Hz, 1H, β-CH$_a$ Asn), 2.03, 2.0, 1.94, 1.93 and 1.91 (5s, 15H, 5CH$_3$-COO), 1.74 (s, 6H, 2CH$_3$-CONH), 1.38 (s, 9H, (CH$_3$)$_3$C), 1.20 (d, $J = 6$ Hz, 3H, CH(OH)-CH$_3$), 0.95 (d, $J = 6.2$ Hz, 3H, CH-CH$_3$).
[8] M.p. 202°C; $[\alpha]_D^{22} = -3.3$ ($c = 0.1$, DMSO).—FAB mass spectrum: m/z_{calc} 1219, m/z_{obs} 1258 ($(M+K)^+$).—270-MHz ^{1}H NMR ([D$_6$]-DMSO): $\delta = 8.5$–8.4 (m, 2H, NH), 8.22 (d, $J = 7.6$ Hz, 1H, NH), 8.02 (d, $J = 9.1$ Hz, 1H, NH), 7.83 (d, $J = 7.5$ Hz, 1H, NH), 7.24 (d, $J = 7.8$ Hz, 1H, NH), 5.9 (ddt, 1H, CH=CH$_2$), 5.31 (dd, $J_{trans} = 17.3$, $J_{gem} = 1.7$ Hz, 1H, CH=CH$_{2\,trans}$), 5.19 (dd, $J_{cis} = 9.6$, $J_{gem} = 1.7$ Hz, 1H, CH=CH$_{2\,cis}$), 4.68 (d, J(H1'/H2') = 8.2 Hz, 1H, H1'), 4.57 (d, $J = 4.8$ Hz, 2H, CH$_2$-CH=CH$_2$), 2.04, 2.01, 1.95, 1.94 and 1.90 (5s, 15H, 5CH$_3$-COO), 1.74 (s, 6H, 2CH$_3$CONH), 1.35 (s, 9H, (CH$_3$)$_3$C).
[9] Procedure: A solution of fully protected chitobiosyl tripeptide ester **11b** (0.45 g, 0.39 mol) in a cold saturated solution of ammonia in methanol (20 mL) was stirred for 2 d at room temperature. The reaction mixture was then evaporated to dryness and the residual product (**15**) purified by two recrystallizations from methanol/chloroform. Yield 0.3 g (86%), m.p. 267°C; $[\alpha]_D^{22} = -14.4$ ($c = 0.1$, H_2O).—FAB mass spectrum: $m/z_{calc} = 885.8$, $m/z_{obs} = 887$ ($M+1$), 909 ($M+Na$)$^+$.—470-MHz ^{1}H NMR (D_2O): $\delta = 7.38$ (d, $J = 7.3$ Hz, 2H, 2*o*-H C$_6$H$_5$), 7.33 (t, $J = 6.7$ Hz, 1H, *p*-H C$_6$H$_5$), 7.29 (t, $J = 6.2$ Hz, 2H, 2*m*-H C$_6$H$_5$), 5.05 (d, J(H1/H2) = 9.5 Hz, 1H, H1), 4.59 (d, J(H1'/H2') = 8.4 Hz, 1H, H1'), 3.13 (dd, $J_{vic\,a} = 7.9$, $J_{vic\,b} = 8.4$ Hz, 2H, β-CH$_2$ Phe), 2.72 (dd, $J_{vic} = 16$, $J_{gem} = 5.6$ Hz, 1H, β-CHa Asn), 2.6–2.55 (m, 1H, β-CHb Asn), 2.06 and 2.02 (2s, 6H, 2CH$_3$-CONH), 1.41 (s, 9H, (CH$_3$)$_3$C), 1.16 (d, $J = 6.2$ Hz, 3H, CH(OH)-CH$_3$).

The First [2.1] Phane: a New Helical Molecular Skeleton**

By *Karl-Heinz Duchêne* and *Fritz Vögtle**

Of the chemically and optically stable helical molecules,[1] we have been interested in the low-molecular-weight compounds with rigidly twisted structures. Whereas several families of compounds of the helical [2.2]cyclophane type[2] have been described in the last few years,[3] the synthesis of phanes with shorter bridges, e.g., [2.1]phanes, has apparently not been seriously pursued[4] because of the expected ring strain. Interest in axially and helically chiral compounds has increased in connection with the transformation of nematic liquid-crystal phases into cholesteric phases.[5]

The route to the new 6,7-dihydrobenzo[*bc*]naphtho[2,1,8-*ghi*]oxecine **8** (m.p. = 94–96°C), which is highly strained according to molecular models, proceeds via six steps starting from **1**. The crucial cyclization could not be achieved directly by C–C bond formation (using phenyl or *n*-butyllithium), but rather indirectly via the sulfide **6** (m.p. = 115–118°C), obtained using Na_2S[6] with the assistance of Cs_2CO_3, and its photochemical ring contraction using triethylphosphite (with elimination of S).[7] The pyrolysis of the sulfone **7** [m.p. > 200°C (decomp.)] has not led to **8** under the standard conditions employed so far.

NBS: *N*-bromosuccinimide; DMF dimethylformamide

In the ^{1}H-NMR spectrum of **8**, the inner protons H_i (benzene ring) and H_i (naphthalene ring) are found, as anticipated, at high field strengths ($\delta = 4.66$ and 4.75, respectively). As expected, **8** is chiral: the complete enantiomeric

[**] New Helical Molecules, Part 12. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank *A. Aigner* and *W. Kissener* for help, in particular for the racemic separation, and Dr. *G. Eckhardt* for help in interpreting the mass spectra.—Part 11: [1].

resolution was achieved by HPLC on a column packed with (+)-poly(triphenylmethylmethacrylate) (PTrMA).[8] The pure (−)-enantiomer of **8** has a rotation of $[\alpha]_D^{20}$ −59.1. The UV and CD spectra are shown in Figure 1.

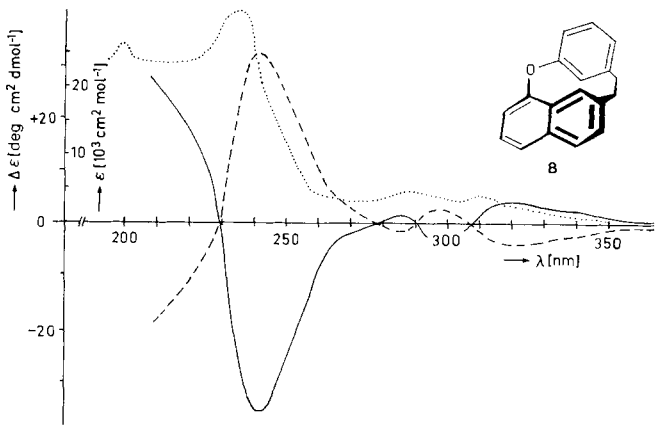

Fig. 1. CD spectra of (+)-**8** (---) and (−)-**8** (—) and UV spectrum (···) (in ethanol).

The enantiomers are stable to 200°C; only upon heating for 30 minutes at 250°C is **8** transformed into an optically inactive substance; according to the NMR and mass spectra, a transannular ring closure with loss of the two inner protons H_i and formation of benzophenanthrene and dihydrobenzophenanthrene rings occurs under these conditions.

Thus, a new framework[9] of highly strained and yet remarkably enantiomerically stable phanes and low-molecular-weight helices is available, which can be varied structurally for systematic chiroptical studies (heteroatoms S, NR, CR_2 instead of O; heterocycles instead of benzene and naphthalene; intra-annular substituents). The structural rigidification obtained here, namely, by annelation between molecular core and bridge, can be extended to other phane rings, especially in order to increase ring strain and racemization barriers.

[9] Elemental analysis and mass spectrum are in accord with the structure of **8**. An X-ray structure analysis has not yet been possible due to the low quality of the crystals.

Primary Adduct, γ-Ketoketene, and Some Subsequent Products of the Reaction of Methyl 6-Oxo-5-phenyl-1,3,4-oxadiazinecarboxylate with Norbornene**

By *Manfred Christl,** *Ulrike Lanzendörfer, Maria M. Grötsch,* and *Joachim Hegmann*

2,5-Diaryl-1,3,4-oxadiazine-6-ones undergo Diels-Alder addition with activated olefins.[1] We have explained the remarkably rapid elimination of nitrogen from the primary adducts of type **2** in terms of a Diels-Alder cycloreversion with formation of dihydropyrylium 2-olates of type **3**,[1c] which, just like the primary adducts, could not be detected, and which should be in equilibrium with the frequently observed γ-ketoketenes of type **4**. Depending upon the nature of the olefin employed, the products isolated are derived either from intermediates analogous to **3** or to **4**. We report here on the first isolable primary product (**2**) and on unexpected reactions of the system **3** ⇌ **4**.

We have prepared the title heterocycle **1** from phenylglyoxylic acid and methyl oxalate-hydrazide according to the method described by *Steglich* et al.[2] for the diphenyl compound. That **1** is considerably more reactive than the diphenyl compound[1a,c] is demonstrated by the fact that it added norbornene in tetrachloromethane within 16 hours at 20°C, whereupon **2** crystallized. Due to this favorable circumstance, it was possible for the first time to isolate such a compound with two groups highly prone to elimination (N_2 and CO_2). Being dissolved in $CDCl_3$, **2** lost nitrogen with a half-life of about one hour at 24°C. On mechanistic grounds the intermediate **3** should be the precursor of the ultimate product **4**,[1c] which is stable in solution.

The γ-ketoketene **4**, a tri- or tetrachloromethane solution of which was employed in the following reactions, is attracting attention by virtue of the variety of transformations it can undergo. Reaction with anhydrous hydrogen chloride furnished, apparently via 1,4-addition to the intermediate **3**, the chloro substituted lactone **5**, which, upon heating in CH_3OH/H_2SO_4, was converted into the ketobisester **6**.

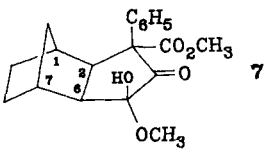
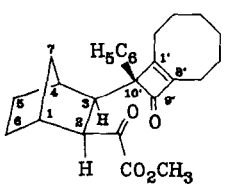
[a] Correct elemental analyses and mass spectra have been obtained for **1**, **2**, **5**–**9**. The isolation of **4** from the solution was not attempted. [b] The chemical shifts vary, but the multiplicities of the other signals are very similar to those of the corresponding signals of **2**. [c] Measurement at −50°C, since the restricted rotation of the phenyl group at 20°C gives rise to very broad phenyl signals.

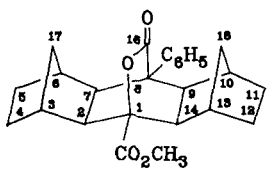


On reaction with methanol, **4** was transformed into a mixture, which, according to the number of OCH_3 signals in its ^{1}H-NMR spectrum, must consist of at least six components. So far it has only been possible to identify **6** (present in a relative amount of 10%) and the 1,2-cyclopentanedione derivative **7** (21%). Compound **7** crystallized on treatment of the mixture with CH_3OH/H_2O; the nature of **7** was disclosed by an X-ray structure analysis.[3] The ester enol presumably formed by addition of methanol to the ketene functionality of **4** could, on the one hand, isomerize to **6** and, on the other, undergo a Dieckmann condensation with the ester group that is present and thus finally give rise to **7**.

5



6



7

Cyclooctyne preferably reacted with the ketene moiety of **4** and afforded, in a [2+2]-cycloaddition, the cyclobutenone **8**, the nature of which could be confirmed by an X-ray structure analysis.[3] By way of contrast, when **4** was heated for twelve days in the presence of an excess of norbornene at 60°C the symmetrically *saturated* δ-lactone **9**

8

9

was obtained. Most likely, the well-known sluggish ketenophile norbornene[4] intercepts the heterodiene **3** in the equilibrium **3** ⇌ **4** in terms of a previously unknown variant of the Diels-Alder addition.—Some physical data of the compounds **1**, **2**, and **4** through **9** are listed in Table 1.

Methods of Enzymatic Analysis. Vol. 3: Enzymes 1. Oxidoreductases, Transferases. xxiv, 605 pp., bound, DM 224.00; **Vol. 4: Enzymes 2. Esterases, Glycosidases, Lyases, Ligases.** xxiv, 426 pp., bound, DM 198.00; **Vol. 5: Enzymes 3. Peptidases, Proteinases and Their Inhibitors.** xxvii, 558 pp., bound, DM 235.00 (prices when ordering all ten volumes). Edited by *H. U. Bergmeyer, J. Bergmeyer,* and *M. Grassl.* Verlag Chemie, Weinheim 1984.—ISBN 3-527-26040-4 (complete work)

Volume III follows the general trend of the two previous volumes and has been updated and considerably expanded.[*] It is the first volume in the 3rd edition to describe specific enzymes in detail, covering oxidoreductases and transferases.

Volume III begins with a general chapter—the first of seven chapters—which consists of three sections. The first section in Chapter I discusses enzyme determinations by various approaches and the limitations of these approaches. The second covers an area of increasing importance in clinical chemistry: determination of catalytic activities in body fluids other than blood. The third section discusses the principles and techniques of isoenzyme analysis.

Chapters 2 through 7 present detailed information on oxidoreductases and transferases. Each enzyme section begins with a general introduction to the enzyme and its history (general available assay methods for the enzyme, special applications of the enzyme, basic assay procedures, international reference methods and enzyme effectors or inhibitors). This information is followed by a detailed discussion of assay conditions, definitions of units of activity, temperature conversion factors for activity, equipment, preparation of reagents and stability of reagent solutions. These sections thus contain detailed descriptions of procedures for conducting assays and for analyzing the resulting data. Each section is completed by a part discussing the validity of the assay method; these sections are considerably expanded from the 2nd edition of "Methods of Enzymatic Analysis." The discussion of information concerning individual enzymes ends with approximately 20 literature references for each enzyme. These references provide the user ample opportunity for updated literature sources. Oxidoreductases are covered in detail in Chapters 2 and 3: assays available only in this edition include 3-hydroxy-3-methylglutaryl-coenzyme A reductase, "malic" enzyme, glutamate semialdehyde dehydrogenase, monoamine oxidase, glutathione reductase, cytochrome C oxidase and superoxide dismutase. Chapters 4 through 7 cover 21 transferases. New procedures are given for one-carbon group transferases (methionine synthase, thymidylate synthase), an acyltransferase (lecithin-cholesterol acyl transferase), glycosyl transferases (galactosyl transferase, purine-nucleoside phosphorylase, adenine phosphoribosyl transferase, hypoxanthine-phosphoribosyl transferase, sialyl transferase), an aminotransferase (tyrosine aminotransferase) and a phosphotransferase (adenylate kinase).

Even the enlarged 3rd edition of "Methods in Enzymatic Analysis" is not complete, and volume III has omitted detailed coverage of some enzymes described in the corresponding chapters in the 2nd edition: 6-phosphogluconate dehydrogenase, transketolase and D-glucose-1-phosphate phosphotransferase. The lack of extensive cross-references to the previous volumes can cause difficulties when attempting to obtain information on enzymes or reagents which are not described in volume III (6-phosphogluconate is covered in the reagent section of volume II). Several useful appendices, however, are maintained in each volume such as a list of symbols, abbreviations, mathematical formulae and NAD(P)H extinction coefficients.

Volume III of the 3rd edition of "Methods of Enzymatic Analysis" is a clearly written, amply referenced source of information focused on oxidoreductases and transferases and their assay procedures. The first chapter covering various kinds of enzyme determinations in water and body fluids other than blood is particularly useful. The section on isozymes is clear and well written. This volume has the form of an extensive handbook, whose size, organization and index system may cause problems for those less familiar with enzymology. Volume III provides an enormous amount of information which is not accessible in any other single source. This volume should be regarded as a basic reference on oxidoreductases and transferases. It is strongly recommended for everyone who uses enzymatic analysis.

Volume IV describes analyses for esterases, glycosidases, C–N and anhydride splitting enzymes, lyases and ligases. It continues in the spirit of volume III by providing descriptions of enzyme assays in a well-organized, strict format. Each section concerning a specific enzyme begins with a general introduction of the enzyme and its history, and continues with descriptions of available assay methods for the enzyme, special applications of the enzyme, international reference methods and enzyme effectors or inhibitors. Information concerning assay conditions, definitions of units of activity, temperature conversion factors for activity, equipment, preparation and stability of reagents follows.

The literature on each enzyme in the General Section, although expanded and updated from the previous edition, still provides information relevant only to analysis—enzyme structure and mechanisms are not discussed. A new section entitled "Enzyme Properties Relevant in Analysis" emphasizes pitfalls dependent on variables such as the source of the enzyme. The Methods of Determination section provides a new emphasis on comparison of methods, describing the limitations and applications of each. The heart of each section is a detailed, step-by-step description of the enzyme assays. The language is concise and frank; the authors reassure readers with comments such as "these assays are precise, cheap and quick" as well as providing caveats where needed. Assays which are apparently cumbersome and outdated, such as the photometric assay for lipase, are omitted from the 3rd edition. Additional sections are added where appropriate, such as "Details for Measurement in Other Body Fluids, Cells and Tissues."

Chapter I describes esterases and is divided into nine sections, each section describing one enzyme. A few new enzymes are included in the 3rd edition including cyclic nucleotide phosphodiesterase and serum ribonuclease. Chapter 2 presents glycosidases and is split into 13 sections, each section describing one enzyme or enzyme group. This chapter has been considerably expanded from the 2nd edition and now includes specific descriptions of α-amylases, cellulase, lysozyme, β-galactosidase, α-D-mannosidase, β-D-mannosidase, β-D-glucuronidase, α-L-fucosidase and β-*N*-acetylhexosaminidase. Chapter 3 covers C–

[*] Cf. *Angew. Chem. Int. Ed. Engl. 24* (1985) 797.

N bond and anhydride splitting enzymes. It consists of five sections of which three are an expansion from the 2nd edition. The newly included enzymes are arginase, β-lactamase and adenosine triphosphatases. Urease is described separately in the 3rd edition.

The final chapter consists of seven sections. This chapter is expanded with six new enzymes; two enzymes previously covered are omitted. The enzymes described in this chapter are orotidine-5-phosphate decarboxylase, citrate synthetase, fumarase, δ-aminolaevulinate dehydratase, adenylate cyclase, guanylate cyclase and fructose-1,6-biphosphate aldolase (the only enzyme also described in the 2nd edition). The two enzymes omitted are 1-phosphofructoaldolase and tetrahydrofolate formylase.

The enlarged 3rd edition provides extensive coverage of esterases, glycosidases, lyases and ligases. It is not a complete handbook; it is, however, an updated and enlarged improvement of the 2nd edition. Useful appendices follow each volume, and the lack of cross-referencing is somewhat made up for by the clear sectioning of the volumes. Volume IV is a basic source of information and is strongly recommended for everyone who uses enzymatic analysis.

Volume V describes analytical procedures for assaying proteolytic enzymes. The format is similar to the previous two volumes. Each section covering a specific enzyme begins with some general background (source and function of the enzyme, applications, special properties relevant in analysis, methods of determining activity, international reference methods and standards, and known enzyme effectors). One or two assay procedures, chosen on the basis of simplicity and reliability are then described in detail. The assays are presented in a uniform, rigidly organized, format, making them easy to follow. In many cases, a procedure for assaying enzyme inhibitors is also included.

The strength of the text lies in the attention to detail. Each assay procedure includes a discussion of the principles behind it. Information on assay conditions, equipment, preparation and stability of reagents and samples, temperature conversion factors, and calculation of results are also included. A validation of methods section following each assay discusses the reliability of the procedure, clearly warning the reader about possible sources of error or problems involving specificity.

The volume is divided into four chapters. Chapter I covers peptidases and their inhibitors. Three enzymes not discussed in the 2nd edition (angiotensin I converting enzyme, proline carboxypeptidase, and carboxypeptidase N) have been added to this edition, and angiotensinase and glycyl-glycine dipeptidase have been dropped. In total, procedures are given for assaying eight different peptidases. Chapter 2 covers proteinases and their inhibitors. Besides the sections dealing with specific enzymes, a general review is provided, covering unique features of proteinase analysis, for example: quantitation of pro-enzymes design of synthetic substrates, and differentiation of related enzymes by inhibitors. Many of the specific assays include methods for assaying pro-enzymes and inhibitors. The reader is warned when the existence of iso-enzymes or related enzymes can affect results. Eighteen proteinases are covered in this chapter. Sections on enterokinase, gelatinase, subtilisin, and the cathepsin have been added in this edition, as have sections on proteinase determination by hydrolysis of proteins and active site titrations of proteinases. Another improvement in this edition has been the replacement of a general assay for elastases with assays specific for pancreatic and leukocyte elastase as well as for the elastase-α_1-proteinase inhibitor complex.

Chapters 3 and 4 cover blood coagulation factors and complement enzymes respectively. Both of these chapters are new, neither topic being covered in the 2nd edition. Probably for this reason the introductions to these two chapters go into much more biological detail than is usual for the series. Concise descriptions of activation and regulation of the haemostatic process and the complement system are provided, as are discussions of their biological significance.

In addition to assays for fourteen enzymes and pro-enzymes involved in haemostasis, Chapter 3 provides assays for heparin, fibrinogen, and various important effectors. Two coagulation methods are also described.

Chapter 4 includes assays for six components of the complement system. For those readers interested in assaying for complement enzymes, an important caveat is included in the editor's preface to the volume. Bergmeyer notes that procedures in this rapidly growing field are too new to be proven by time and use, therefore, "these methods represent a departure from the principle of describing only well-proven methods suitable for routine use." However, the importance of the field clearly merits inclusion of the chapter.

Volume V greatly expands the coverage given peptidases and proteinases in the 2nd edition. The number of enzymes discussed is more than doubled. The increase in scope has fortunately not led to any decrease in clarity or ease of use. Volume V is the obvious first reference to turn to for analysis of proteolytic enzymes and their inhibitors.

Polymers. Properties and Applications. Vol. 8: Polymer Degradation and Stabilization. By *W. L. Hawkins*. Springer-Verlag, Berlin 1984. xii, 120 pp., bound, DM 88.00.—ISBN 0-540-12851-4

This book[*] deals in eight main chapters with the problems of polymer degradation under various influences and possible methods of polymer stabilization. Each main chapter begins with a short introduction, in which the synoptic and clearly related subsections are summarized for the reader in an easily comprehensible fashion.

A short review of the historical development of the stabilization of rubber is the subject of the introduction for example. Quite early on it is pointed out that the explanation of the degradation mechanism of polymers is a necessary prerequisite for the development of suitable stabilizers. Thus, as a result, the following most comprehensive chapter is devoted to polymer degradation.

Pyrolysis reactions, i.e. thermal degradation in the absence of oxygen, is discussed for some chosen polymers and the mechanisms are explained. In this the hydrocarbon polymers polyethylene and polypropylene are treated preferentially. A deal of space is devoted to thermal oxidation and photooxidation, which are naturally of particular importance for the behaviour in applications. Degradation by high energy radiation, ozone, and physical effects is also dealt with briefly. Some comment about the energetic situation which leads to the coupling of two radical chains in the crystalline areas of polyolefins would have been apposite. The chapter closes with some new results on the

[*] Cf. *Angew. Chem. Int. Ed. Engl. 24* (1985) 717.

oxidative degradation of polyolefins, polystyrene, polyethylene-polypropylene blends, polycarbonates and polyacetals. On the other hand, only the hydrolytic degradation is discussed for the polyamides which serve as examples of polycondensates.

A further short chapter describes stabilization by means of structural changes, copolymerization and cross-linking, demonstrating that there are very few possibilities for stabilization in cases of purely thermal degradation without drastically changing the structure of the polymer. In this book the author quite rightly places most emphasis on stabilization against thermal oxidation and UV radiation. The mode of operation of short-term and long-term antioxidants, peroxide decomposers, metal deactivators, of antioxidant combinations, of non-migrating antioxidants such as carbon black and incorporable antioxidants is explained using polyolefins as an example. Amongst the light stabilizers an exhaustive discussion is devoted to the hindered amines as the most recent radical quenchers. Naturally the reader also obtains a quick look at the mechanism of photostabilization by benzophenones and benzotriazoles (without the Jablonski diagrams which are usually employed for this purpose). The practising synthetic organic chemist is provided with the structural modifications to UV absorbents and their effects.

The discussion of the mode of operation of anti-ozone agents is worthy of mention in the chapter on stabilization against ozone, which is the last of the stabilization chapters.

The importance of test processes as well as their advantages and disadvantages when used to determine the thermo-oxidative and photo-oxidative degradation are brought together in a separate section. Information is also given about the importance of tests which are not yet in use for the recognition of degradation in the early stages by employing chemoluminescence tests.

This book is of less use to the stabilization researcher who is not working in the polyolefin field. On the other hand the compact and logical format of the book make it very suitable for readers who wish to become familiar with the field of stabilization and degradation of polymers with polyolefins as an example.

Practical Analytical Electron Microscopy in Materials Science. By *D. B. Williams*. Verlag Chemie International, Deerfield Beach, FL, USA 1984. vii, 153 pp., bound, $ 34.95.—ISBN 3-527-26224-5

The term Analytical Electron Microscopy (AEM) is in use for the analysis of elemental composition and crystal structure in submicron areas by means of a transmission electron microscope (TEM). This book is an introduction to elemental analysis by energy-dispersive X-ray spectrometry (EDS) and by electron energy-loss spectroscopy (EELS) and to crystal structure analysis by microdiffraction methods.

Chapter 1 introduces the different modes of AEM; it gives an overview of electron sources and detectors for X-ray quanta. Illustrative examples demonstrate AEM capabilities. Chapter 2 deals with alignment procedures for different imaging modes and for EDS and EELS. The success of AEM in the last decade has its origin in the development of the production of small electron probes with diameters of 2–100 nm by means of the prefield of the objective lens in front of the specimen foil. For localizing the electron probe, the scanning transmission electron microscope (STEM) mode has been introduced as an additional imaging mode of a TEM. Therefore, Chapter 3 compares the conventional TEM and the STEM modes for bright and dark field imaging. Quantitative X-ray microanalysis is first introduced in Chapter 4 with a brief review of the physics of X-ray production. The author discusses the optimization of an AEM for X-ray microanalysis, including the elimination of spurious X-ray signals. Quantification by the k-factor method and by thin film standards is then outlined and is followed by a discussion of the limits for minimum detectable masses and concentrations and for spatial resolution. Chapter 5, concerning EELS demonstrates the possibilities of getting information from the low-loss region (plasmon losses) and from the high-loss region (ionization edges), including the fine structure of the ionization edges. Background subtraction and deconvolution methods are discussed for both EDS and EELS. Chapter 6, which deals with microdiffraction, concentrates mainly on convergent beam diffraction patterns, including the fine structure from Bragg diffraction with reciprocal lattice points at high-order Laue zones (HOLZ). It is demonstrated how much more information is available from these HOLZ patterns than from conventional selected-area diffraction patterns.

Considering that the book has only 150 pages, it contains a wealth of information. The reference lists at the end of the Chapters are also representative and up to date. Because of its size, one cannot expect such a book to give a complete discussion of the physics of these methods. For example, the book contains nothing about the dynamic theory of electron diffraction, and one has to ask how one can understand and use convergent beam patterns, not being familiar with the basic physics of dynamic theory. Furthermore, the formation of Kikuchi lines and bands is oversimplified.

The book is expensive when compared with other text books about TEM which run to a few hundred pages and give more detailed information for the same price. It does not require just the copyright (by Philips Electronic Instruments) to give one the feeling of advertizing on many of the pages.

Nevertheless, the book is well written and contains many practical examples and excellent illustrations.

Ludwig Reimer [NB 695 IE]
Physikalisches Institut der
Universität Münster (FRG)

Beilstein Handbook of Organic Chemistry, 4th Edition, 5th Supplementary Series, Volume 17/1. Edited by *R. Luckenbach*. Springer Verlag, Berlin 1984, lxxxvii, 858 pp., bound, DM 1620.00.—ISBN 3-540-13418-2

In this volume are covered heterocyclic compounds of class 10, parent compounds $C_nH_{2n}O$, $C_nH_{2n-2}O$, $C_nH_{2n-4}O$, $C_nH_{2n-6}O$ and $C_nH_{2n-8}O$. But that is not what matters and that is not why this particular Beilstein volume is singled out for review. What matters and what makes this volume of signal importance is that it is the first Beilstein volume to appear in the English language. Since World War II, like it or not, English has become the *lingua franca* of science. In general, those national journals not published in English have had diminishing impact, in large part because of the language problem outside of their home country. It has become a common complaint of

those scientists who publish in such journals that their work is insufficiently cited.

For the preparative chemist as well as for those scientists who have a need to know about the properties and reactivities of chemical compounds, three handbooks of chemistry which were published in German have been indispensable almost from the day of their respective founding: the "Beilstein Handbuch der Organischen Chemie", the "Gmelin Handbuch der Anorganischen Chemie" and "Houben-Weyl Methoden der Organischen Chemie". Of these, the Gmelin Handbook already has made the switch from German to English. And now the Beilstein Handbook has done so as well. A comparison of the present volume with a previous one written in German shows that this is not really such a very great change. There is little text in a Beilstein volume and for many of the German scientific words the English counterparts often are quite similar. Nonetheless, this change from German to English will be welcomed by all Beilstein users whose native language is not German for it will facilitate their use of the Handbook. It will be welcomed especially by the, alas, many who cannot read German at all.

The Beilstein Handbook celebrated its 100th birthday in 1981: in 1881 the first volume of the initial two volume set appeared. With the publication of the second volume in 1883 the organic chemists of the day had available a register of about 15,000 compounds. In these two volumes which totaled about 2200 pages they could find carefully selected information about the preparation and properties of these organic compounds, together with references to the original literature, an immense help to anyone active in organic research. *F. K. Beilstein,* the founder of the Handbook, born in Russia of German parents, spent his student and early professional years in Germany, but returned to Russia in 1866, at age 27, to become the successor of *Mendeleev* at the Imperial Technical Institute in St. Petersburg. However, his Handbook was published in Germany in the German language. By the time of his death in 1906, the third edition of his Handbook had just been published. There is no doubt that it fulfilled an important need when it first appeared and it won immediate acceptance by the organic chemists of that time. Chemists of the latter part of the 19th century were more literate in foreign languages than the chemists of today and that the Beilstein Handbook was written in German presented no problems.

In the succeeding years, through good times and bad, the Beilstein Handbook has continued and grown. Its impact in the world of chemistry has been, right from the start, considerable and it has become an indispensible aid to the organic chemist. It is no exaggeration to say that no library that services organic chemists can be considered complete without a set of "Beilstein". Nowhere else can one find such a comprehensive coverage of critically selected data of organic compounds of all kinds. It would appear that no stone is left unturned in this search for facts. These are culled from original research publications, patents, the review and monograph literature and theses. The information provided for a given organic compound may include its preparation, occurence in nature and isolation, physical properties, an indication of what spectroscopic properties have been reported, chemical reactivity and transformations, key literature references. It is important to note that this coverage is not exhaustive in the sense that *all* such information on a given compound is provided. As the present director of the Beilstein Institute has pointed out, it is the task of the Beilstein workers to clarify the inconsistencies found in the original research literature and omit incorrect data, to critically note ambiguous results, to ignore reported findings that are trivial in nature. Thus, the Beilstein Handbook has as its commendable objective a *critical* evaluation of the organic literature. And what a task this is! As noted already, the first two-volume edition of the Beilstein Handbook of 1883 contained about 15,000 compounds. By 1940 about 400,000 compounds had been reported in the research literature; in the 50's, already one million. Today, one may estimate a count of nearly five million! The Beilstein Institute at this point is nearing completion of the Supplementary Series IV of the Fourth Edition which covers the literature of the period 1950–1959. The next Supplementary Series V, which will cover the period 1960–1980, will truly be a challenge since these two decades have seen a veritable explosion of the organic literature. We may be certain that the members of the Beilstein Institute will rise to this difficult challenge. The continuation of the life's work of *Friedrich Beilstein* is in good hands!

Dietmar Seyferth [NB 692 IE]
Massachusetts Institute of Technology (USA)

Smectic Liquid Crystals, Textures and Structures. By *G. W. Gray* and *J. W. Goodby,* Leonard Hill, Glasgow 1984. xvi, 162 pp., bound, £ 46.00.—ISBN 0-249-44168-3

Textbooks on the liquid crystalline state or on liquid crystals are a rarity. It is thus even more pleasing that this new publication gives the first comprehensive survey. The book has been written by internationally recognized experts for the practically oriented reader and for those interested in working with liquid crystals. It will contribute significantly towards ending the uncertainty still dominating the original literature concerning the nomenclature of smectic phases and thus could become the standard work on smectic liquid crystals.

The book consists of a textual section of 157 pages and another portion with 124 photographs of the characteristic textures of liquid crystalline phases taken under the polarizing microscope.

The text is clearly arranged. Nine chapters treat smectic phases A to J and the 10th chapter additionally deals with the most recent developments in phase classification and structure. The nine chapters are largely uniformly set out. A short *introduction* gives a general overview of the particular smectic phase followed by a description of the historical development of the investigations. The intelligibility of the detailed discussion of the *structure* of the phase that then follows is made easier by the large numbers of very clear schematic presentations. Finally, there is a description of the *textures* of the phase with a direct reference to the diagrams in the second part of the book. It is here that the intention of the authors is particularly clearly expressed: Reading this part of the book encourages one to sit at a polarizing microscope with the book and to investigate a known or new liquid crystal. Finally under the heading "*Identification and Classification*" significant aspects of the textures are summarized, standard substances are introduced for mixture experiments, the characteristics of X-ray diffraction data are mentioned briefly, and details are given of the thermochemical data of phase transformations. A detailed list of references is attached to each chapter.

The polarization micrographs reproduce typical texture pictures that were obtained without specific preparation techniques. The colored plates are of good quality.

This book is recommended without any reservations to all those who are concerned with or wish to concern themselves with liquid crystals. It will be an indispensable laboratory manual for the classification and identification of smectic phases.

Arene Complexes of Univalent Gallium, Indium, and Thallium

By Hubert Schmidbaur*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Arene complexes of main-group metals were, until recently, rare species—in contrast to the now classical, analogous complexes of transition metals. In systematic investigations, it has been possible to prepare and structurally characterize arene complexes of the univalent elements gallium, indium, and thallium, which directly follow the d-block elements in the periodic table. This new type of compound is characterized by centric (η^6) coordination of the metal to the arene; both mono- and bis(arene) complexes are known. The interaction can be explained by the perfect agreement between the HOMO/LUMO symmetry of the arene and of the low-valent metal. The electronic states of the $nd^{10}(n+1)s^2$ configuration, which are partially modified by relativistic effects, play a particularly important role. The relationship to the few known complexes of the neighboring elements (Sn^{II}, Pb^{II}) becomes plausible via the isoelectronic principle. The arene/Ga^I, In^I, Tl^I systems are of potential significance as homogeneous reducing agents and as agents for the activation of aromatic compounds, the purification of metals, and the separation of metals from non-aqueous media.

1. Introduction

Common alkali metal salts are virtually insoluble in aromatic hydrocarbons, which, of course, is not unexpected. The rule of thumb for solvation processes, as well as detailed thermodynamic calculations, make it very unlikely that the ionic lattices of alkali metal salts should yield to hydrocarbon solvation. It is only in the presence of very bulky anions having complicated substructures or after efficient anion chelation that uncomplexed alkali metal cations are dissolved readily as solvated ion pairs in an organic liquid phase. The salts that can be precipitated from such solutions may contain, e.g., "crystal benzene." These solvent molecules,[1,2] however, are distributed more or less randomly in the lattice with no specific coordination to the alkali metal component. In such cases, alkali metal cations are rarely found in what is referred to as η^6 coordination to arenes, i.e., perpendicular to the ring center. On the contrary, the crystal benzene appears non-centered, most frequently η^2 or η^3 bonded[1,2] (cf. **A1**, **A2**).

It is therefore very intriguing that salts of low-valent metals of the third main group, such as Ga^I, In^I, or Tl^I, are often readily soluble in aromatic solvents.[3–6] For instance, $Ga[GaCl_4]$ forms a 7% (w/w) solution in benzene at room temperature, whereas $K[GaCl_4]$ is insoluble. Since the ionic radii of univalent gallium, indium, and thallium are very similar to those of the heavier alkali metals (Table 1), the coulombic terms of the lattice energy and the classical

Table 1. Ionic radii r of univalent alkali metals and of heavy metals of the third main group.

M	r [Å]	M	r [Å]
Li	0.76		
Na	1.02		
K	1.38	Ga	1.20
Rb	1.52	In	1.40
Cs	1.67	Tl	1.50

solvation energies are unlikely to be responsible for this difference in solubilities. Other factors, specific for the electronic configuration of the low-valent post-transition metals must be invoked, but until recently a complete lack of information regarding stoichiometry and structure made theoretical approaches difficult if not impossible.

A1 **A2** **A3**

A similar discrepancy exists between alkaline earth metals and divalent metals of the fourth main group. Complex halides of the latter exhibit surprisingly high solubility in aromatic hydrocarbons, whereas analogous calcium, strontium, or barium salts are completely insoluble in such solvents.[7-9]

In contrast to research in gallium, indium, or thallium chemistry, structural work on the benzene adducts of compounds like $Sn[AlCl_4]_2$ was initiated as early as 1957 by *Rundle* et al.[11] and continued later by *Amma* et al.[10] The results of these studies have established that tin(II) and lead(II) form discrete 1:1 arene complexes exhibiting η^6 coordination (cf. **A3**). No 1:2 complexes, i.e., bis(arene) complexes, were detected with metals of the fourth main group, however. On the basis of the isoelectronic principle, predictions were made as to the structures of the related hypothetical In^I or Tl^I compounds, but none of these were substantiated by experimental evidence.[11b]

Like the ions Ge^{2+}, Sn^{2+}, and Pb^{2+}, the Ga^+, In^+, and Tl^+ ions have the electronic configurations $3d^{10}4s^2$, $4d^{10}5s^2$, and $5d^{10}6s^2$, respectively. Their filled d shells require a description of bonding in arene complexes quite different from that for the d-block elements, in which incompletely filled d orbitals are available as acceptor orbitals.[12] Moreover, they also differ from the d^{10} metal ions of the elements at the end of the transition series, like Ag^+ ($4d^{10}5s^0$) or Hg^{2+} ($5d^{10}6s^0$) in that their outer s orbital is also filled (Table 2).

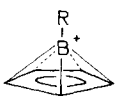

Table 2. Electronic configuration of metal cations on the borderline between p-block and d-block elements and the resulting arene coordination.

Electronic configuration	$d^{10}s^0$		$d^{10}s^2$	
Metal ions	Cu^+	Zn^{2+}	Ga^+	Ge^{2+}
	Ag^+	Cd^{2+}	In^+	Sn^{2+}
	Au^+	Hg^{2+}	Tl^+	Pb^{2+}
Arene coordination	η^2 (η^3)		η^6	

For the coinage metals (copper, silver, and gold), η^2 (or η^3) coordination is known to be the exclusive mode of arene complexation.[13] This observation is consistent with the findings for the alkali metals. It is easily explained on the basis of the analogous LUMO configurations: an empty (alkali metal) or filled (coinage metal) d shell, is followed by vacant s and p orbitals, respectively.

On account of their filled outer s orbitals, the univalent metals and divalent metals of the third and fourth main groups, respectively, are left with the outer p orbitals as the vacant acceptor orbitals (LUMO's), the energy and symmetry characteristics of which determine the strength and orientation of the arene interaction. There is little doubt, therefore, that, e.g., In^I and Sn^{II} coordination will be similar, but many questions remain unanswered, including the number of arenes that can be bonded, the relative strength of bonding, the geometrical details of the complexes, and the role of the counterions.

Of the lighter homologues, aluminum has never been observed in the univalent state, with the exception of a few high-temperature species. Boron, however, is known to form *nido*-clusters,[14a] which could also be referred to as arene complexes of boron(I) (cf. **B**). Sandwich clusters with a larger number of carbon atoms remain to be prepared.

$[BF_4]^-$ **B**

In the course of preparative and structural studies, the first mono- and bis(arene) complexes of Ga^I, In^I, and Tl^I have now been isolated and structurally characterized. The gap existing between the two blocks (Table 2) has thus been closed. Moreover, the first "bent" arene sandwich compounds of non-transition elements have also been detected. Their structural features are particularly important, since no such complexes had been reported for the neighboring isoelectronic metals of the fourth main group, or for any other main group element.

2. Practical Aspects

Solutions of low-valent gallium and indium compounds in aromatic hydrocarbons are of great interest for several reasons. First, these solutions are powerful reducing agents for a large variety of substrates. In this connection it is important that gallium, like aluminum, is neither a poisonous, hazardous element, nor an element of environmental concern. In contrast to the situation with thallium, there are no reservations about the laboratory or large-scale use of gallium. Moreover, the price of gallium metal is in an acceptable range. There also exist recent reports on the oxidation of arenes with gallium(III) to give gallium(I) complexes.[15a] Second, it is reasonable to assume that gallium(I) complexation to arenes should activate the hydrocarbon for nucleophilic substitution reactions. It is only due to the reactivity of the counterions present in most of the conventional systems (e.g., $[GaCl_4]^-$) that this possibility has not yet been exploited. The changes in the elec-

tronic states of the arene complexes have not yet been studied by, e.g., spectroscopic techniques, whereas extensive information is available on arene adducts of other metal halides.[14b] Finally, current trends in electrical conductor, semiconductor, and superconductor technologies are responsible for a growing demand for ultrahigh-purity metals. Gallium and indium are important in this context. The unusual solubility behavior of Ga^{I} and In^{I} salts may well be significant for new purification processes involving redistribution and extraction in nonaqueous solvents. Electrolytic recovery of the metal from these solutions is an established method.[15b]

3. Crystal Structures of the Arene-Free Gallium Subhalides, and ^{69}Ga,^{71}Ga-NMR Spectra of the Solids and Melts

A starting point for the discussion of the structures and NMR spectra of the arene complexes is an examination of the data for the arene-free subhalides. Of the $M^{I}[M^{III}X_4]$ phases, the structures of $In[InI_4]$,[16] $Ga[GaCl_4]$,[17] and $Ga[GaI_4]$[18] have been determined so far. Of these, the first two crystallize in the same orthorhombic space group Pnna. M^{I} occupies the center of an only slightly distorted dodecahedron formed by eight halogen atoms. M^{III} occupies the positions of a distorted tetrahedron. The Ga^{I}–Cl and In^{I}–I distances are relatively large, indicating large ionic radii for the univalent cations. $Ga[GaI_4]$ crystallizes rhombohedrally (acentric space group R3c). There is a hexagonal close packing of tubes formed from $[GaI_4]$ tetrahedra, the interstices of which are filled by the Ga^{+} ions. The environment of the Ga^{+} ions consists of eight nearest I neighbors with a large spread of Ga···I distances (3.281 to 3.020 Å). This geometry approximates a bicapped trigonal prism.

Only the last of the three structures is compatible with stereochemical activity of the lone pair of electrons of the M^{+} ions. The dodecahedra, in particular, give no indication for such an effect, since the very minor reduction in their symmetry is not directed towards the generation of a halogen-free corner in the polyhedron, where such a lone pair of electrons could be accommodated.

The small deviation from dodecahedral symmetry observed for $Ga[GaCl_4]$ is just sufficient to allow observation, even in the solid state, of surprisingly intense Ga^{I}-NMR signals without the use of special procedures such as magic angle spinning.[19] The appearance of a complex ^{69}Ga signal (Fig. 1a, b) is in agreement with the theoretical resonance calculated for asymmetry parameters $\eta > 1/3$. Signal-form analysis according to this model yields a quadrupole coupling constant $e^2qQh^{-1}(^{69}Ga) = 1.7 \pm 0.1$ MHz and an η value of 0.44 ± 0.05.[20] In contrast, the ^{71}Ga resonance shows no resolvable structure (Fig. 1c), as expected from the relations $Q(^{69}Ga) > Q(^{71}Ga)$ and $\eta(^{69}Ga) < \eta(^{71}Ga)$: The value calculated for $e^2qQh^{-1}(^{71}Ga)$ from the existing data is only 1.1 ± 0.1 MHz. The resulting maximum splitting (1500 Hz) is well below the experimental line width ($\Delta B = 3070$ Hz).

The quadrupole coupling constants found for crystalline $Ga[GaCl_4]$ therefore confirm that there is only a very small distortion of the dodecahedral environment of the Ga^{+} ions. It also follows from the asymmetry parameter that the symmetry of the tensor of the electric field gradient at the Ga^{+} centers is reduced only according to the orthorhombic crystal symmetry. Both results are in agreement with the notion that the $4s^2$ lone pair of electrons deviates only very little from spherical symmetry. Any significant hybridization should lead to much more drastic effects. Resonances of the Ga^{III} nuclei cannot be observed in the ^{69}Ga,^{71}Ga-NMR spectra of crystalline $Ga[GaCl_4]$. The distortion of their tetrahedral environment is too strong, so that the condition for the NMR experiment $e^2qQh^{-1} \ll \mu B$ is no longer fulfilled.[20]

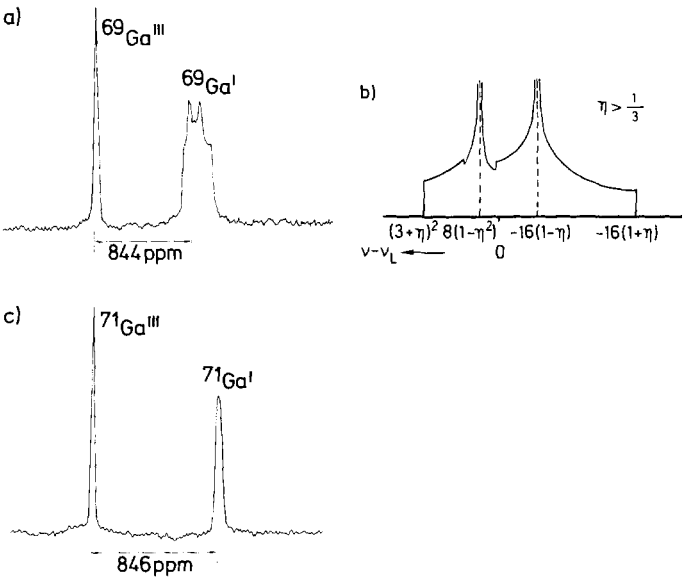

Fig. 1. a) Solid-state ^{69}Ga-NMR spectrum of $Ga[GaCl_4]$. Crystal powder at 30°C, Larmor frequency $\nu_L = 47.987$ MHz, sweep width 180 kHz, pulse 4 μs. Reference: $GaCl_3$ in aqueous hydrochloric acid. b) Calculated spectral pattern for the central transition ($m = 1/2, -1/2$) for half integral spin I in frequency units $\nu_Q^2(144\nu_L)^{-1}[I(I+1)-0.75]$ with $\nu_Q = 3e^2qQ[2I(2I-1)h]^{-1}$ [20]. c) Solid-state ^{71}Ga-NMR spectrum of $Ga[GaCl_4]$. Conditions as in a), $\nu_L = 60.790$ MHz.

The $Ga[GaCl_4]$ melt (at 200°C), in contrast, shows an extremely noteworthy ^{71}Ga-NMR spectrum:[21] Not only are separate signals detected for Ga^{I} and Ga^{III}, but the resonance of the univalent ion is characterized by its sharpness and large high-field shift (Fig. 2). These observations again suggest a very symmetrical environment of the Ga^{I} nuclei in the melt and an extremely strong shielding due to a reduction of paramagnetic effects through the presence of the $4s^2$ lone pair of electrons. The results for $Ga[GaBr_4]$

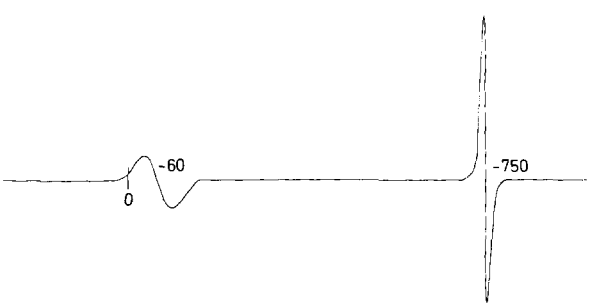

Fig. 2. ^{71}Ga-NMR spectrum of the $Ga[GaCl_4]$ melt at 200°C. Reference: $[Ga(H_2O)_6]^{3+}$ in aqueous solution. δ values.

melts are qualitatively analogous, but broader resonances and smaller shift differences are to be noted. These differences are not unexpected because of the lower electronegativity and higher polarizibility of the bromine atoms. Both spectra provide important reference data for the Ga-NMR spectra of the arene complexes.

4. Earlier Studies on Ga^I, In^I, Tl^I/Arene Systems

The discovery more than 50 years ago that $Ga[GaCl_4]$ dissolves readily in benzene prompted investigations of the colligative properties of the resulting solutions. Cryoscopic molecular weight determinations indicated a pronounced concentration dependence with the value for the undissociated monomer being reached only at infinite dilution.[22] Between 0.05 and 0.1 M, dimeric species appear to prevail.[22] The dielectric constants of the solutions are strongly temperature-dependent, indicating solvated ion pairs and a high dipole moment for the solute.[22] The solutions are electrically nonconducting, again strong evidence for tight ion-pair formation.[23, 24]

For $Ga[GaBr_4]/C_6H_6$,[25] phase diagram studies showed the existence of two discrete phases, with compositions $Ga_2Br_4 \cdot C_6H_6$ and $Ga_2Br_4 \cdot 3\,C_6H_6$. The complete phase diagram of the $Ga[GaCl_4]/C_6H_6$ system is not known, but a phase 1 : 1 with a molar ratio could also be identified under certain work-up conditions.[26] Preliminary X-ray analysis of one of these phases gave the approximate cell constants $a = 11.89$ and $c = 30.05$ Å ("pseudohexagonal," $Z = 12$), but the structure could not be solved.[10]

Vibrational spectroscopy was successfully employed to verify the presence of quasitetrahedral $[GaX_4]^-$ anions (X = Cl, Br). However, no definite conclusions could be drawn regarding the mode of interaction between Ga^+ and the benzene molecule.[22] Nevertheless, the η^6 model was favored, and it was pointed out that *Mulliken*'s charge transfer concept could be used to account for such a ring-centered metal/arene interaction.[10, 27, 28]

^{71}Ga-NMR spectra of solutions of $Ga[GaCl_4]$ and $Ga[GaBr_4]$ in benzene[21] exhibit separate signals for Ga^I and Ga^{III}. Conclusions drawn from the analyses of line widths and chemical shifts, however, were limited by the small number of known examples. Among other models, an anion-association with benzene was also considered.

For indium(I) the experimental investigations were comparatively meager and evidence for benzene complex formation was only mentioned in passing.[11b] For thallium(I), however, the isolation of two compounds, $2\,Tl[AlCl_4] \cdot C_6H_6$ and $Tl[AlCl_4] \cdot 2\,C_6H_6$, was reported (supported by elemental analysis data). The materials were described as extremely labile, the benzene being partly lost on drying. For these species, a "ferrocene sandwich-type structure" and an "inverted ferrocene structure," respectively, were discussed, again with reference to *Mulliken*'s theory, but could not be supported by further details.[11b]

Thus, there has been ample evidence for over half of a century for compounds having the compositions $[M^+(C_6H_6)M^+]$, $[(C_6H_6)M]^+$, and $[(C_6H_6)_2M]^+$ for all three elements of the third main group in their univalent state.

5. Structural Chemistry of the Arene Complexes

5.1. The Bis(benzene)gallium(I) Tetrachlorogallate(III) Dimer 1[5]

When crystals are grown at 20 °C from an anhydrous benzene solution saturated previously with $Ga[GaCl_4]$ at elevated temperatures, a transparent colorless material is obtained which loses benzene rapidly under vacuum or when purged with dry nitrogen or argon. According to elemental analysis, this phase contains benzene in excess of a 3 : 1 molar ratio C_6H_6/Ga_2Cl_4. (The alleged 1 : 1 complex is reported to be formed upon removal of the solvent by pumping at −5 °C[11]).

An X-ray diffraction study of the benzene-rich phase revealed the presence of the dimeric units $[\{(C_6H_6)_2Ga\}^+\{GaCl_4\}^-]_2$, **1**, with three additional molecules of benzene trapped in the triclinic lattice. The overall stoichiometry is thus 3.5 : 1, in good agreement with the analytical data. There is also a remarkable parallel to the 3 : 1 phase detected in the phase diagram of the system C_6H_6/Ga_2Br_4.[25] The two Ga^+ centers in **1** form two "bent" sandwich moieties with the benzene molecules (Fig. 3), which are linked together by two bridging

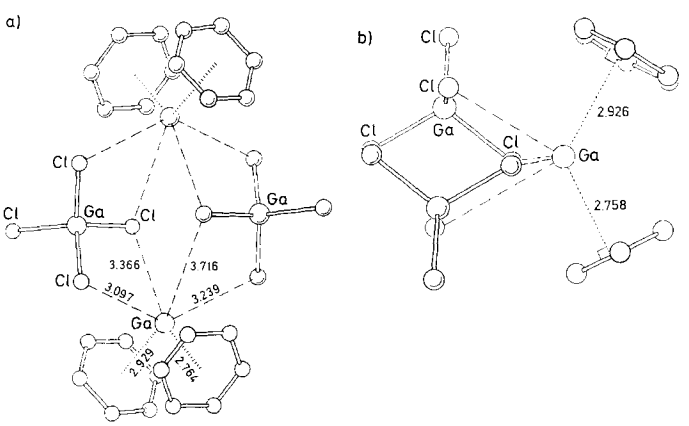

Fig. 3. a) The centrosymmetric unit of $[\{(C_6H_6)_2Ga\}(GaCl_4)]_2$ **1** projected perpendicular to the plane of the four gallium atoms. b) View showing the arrangements of ligands around the Ga^I center in **1**. Distances [Å].

$[GaCl_4]^-$ tetrahedra. Most important, the Ga^+ ions are located over the centers of the benzene rings. The normals to the rings form angles of only 2.8 and 3.7°, respectively, with the corresponding lines connecting the metal atom and the ring centers. Four chlorine atoms surround Ga^+ irregularly, two of which lie roughly in the plane that bisects the angle between the benzene rings. This structure is probably also present in solution. At high dilution, however, solvated monomers are more likely, as suggested by the colligative properties.[22–24]

The bis(benzene)–metal coordination is an unexpected and unparalleled phenomenon for p-block elements. The two benzene rings are not equidistant, however, from the Ga^+ center. If no other corroborative example had been found, the results would therefore have remained in doubt.

5.2. The Bis(1,3,5-trimethylbenzene)gallium(I) Tetrachlorogallate(III) Chain Polymer 2[29]

$Ga^+[GaCl_4]^-$ also dissolves readily in hot mesitylene, which on cooling affords monoclinic, colorless, transparent crystals. Elemental analysis indicates a 2 : 1 molar ratio mesitylene/Ga_2Cl_4, which is retained even after exposure to a vacuum at 20°C. The single-crystal X-ray analysis of **2** showed that "bent" sandwich moieties are again present in this phase; however, they are linked by $[GaCl_4]^-$ tetrahedra into chains rather than rings (Fig. 4a). As in **1**, the bridging chlorine atoms approach the Ga^+ centers in a plane bisecting the angle between the two arenes (Fig. 4b). In **2**, these arenes are equidistant from the Ga^+ ion (Fig. 4c), and thus there is no ambiguity about equivalent bond-

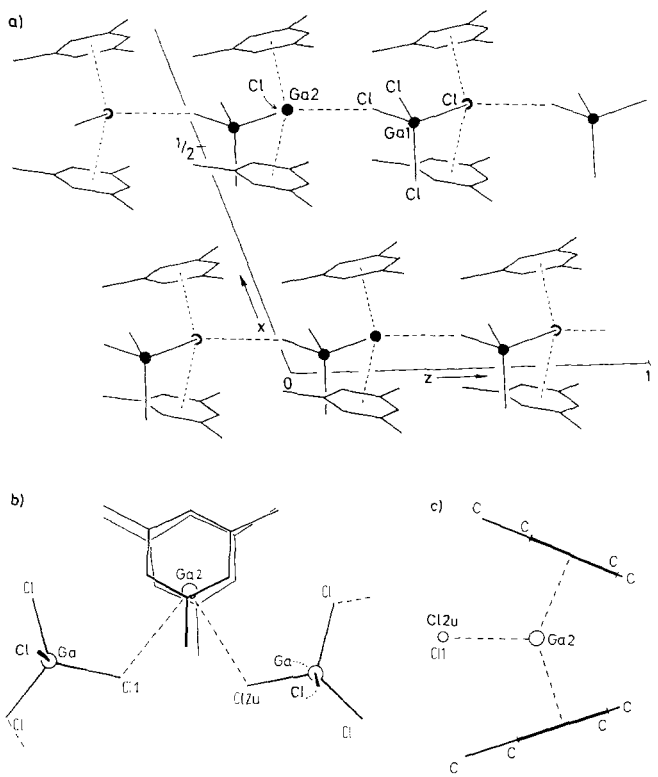

Fig. 4. a) Crystal structure of $[\{1,3,5\text{-}(CH_3)_3C_6H_3\}_2Ga(GaCl_4)]$ **2**. Projection along the *y* axis. b, c) Environment of the Ga^1 center in **2**. Projection onto the Ga2C11Cl2u plane (b). Projection along the Cl1–Cl2u vector (c).

ing of the two hydrocarbon rings. The metal is again centered over the mesitylene rings as in the benzene analogue. The sterically more demanding mesitylenes prevent a closer approach of the $[GaCl_4]^-$ tetrahedra and the coordination number of Ga^+ is essentially 4.

In mixtures of benzene or toluene with mesitylene, only the latter is taken up as a ligand by the Ga_2Cl_4 solute. Apparently, increasing methyl substitution strongly favors the Ga^+ complexation.

5.3. The (Hexamethylbenzene)gallium(I) Tetrachlorogallate(III) Tetramer 3[30]

Solutions of Ga_2Cl_4 in a mixture of toluene and hexamethylbenzene yield a crystalline phase on cooling, which has the analytical stoichiometry of a 1 : 1 complex of $[(CH_3)_6C_6]$ and Ga_2Cl_4 [m.p. = 168°C (decomp.)]. Purging with dry nitrogen does not change the composition. The rhombohedral crystals are very soft and extremely difficult to manipulate. The X-ray diffraction analysis showed the presence of four formula units in the unit cell in the form of a tetrameric cluster with crystallographic C_{3v} symmetry (Figs. 5a, b). One unique Ga^+ ion lies on the threefold axis and is coordinated to a hexamethylbenzene ring that is perpendicular with respect to the C_3 axis. The distance from the metal to the ring center is only 2.43 Å. The inner core of the cluster is composed of four $[GaCl_4]^-$ tetrahedra, from which, altogether, seven chlorine atoms in the form of a regular hexagonal pyramid are directed toward the unique Ga^+. The three remaining symmetry-related Ga^+ ions are also attached to a hexamethylbenzene molecule, each at a distance of 2.51 Å, and are coordinated to six chlorine atoms which form a cap in the shape of a pentagonal pyramid (Fig. 5c).

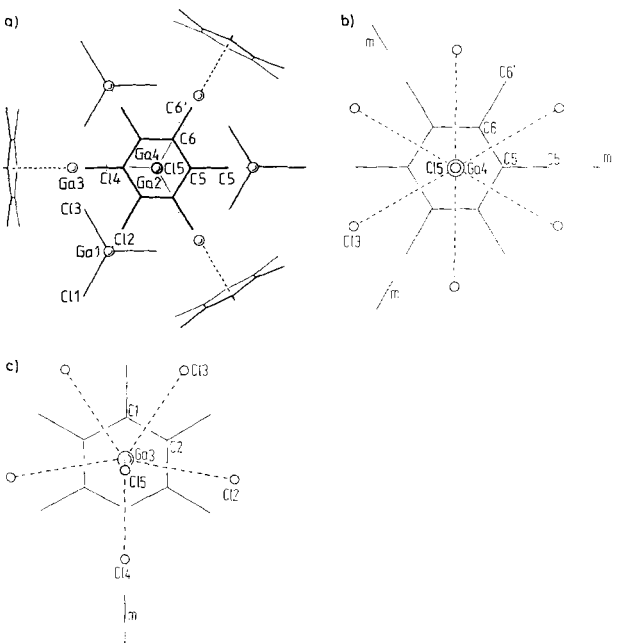

Fig. 5. a) Crystal structure of $[\{(CH_3)_6C_6\}Ga(GaCl_4)]_4$. Projection of a unit of **3** along the [111] axis (Ga2, Ga4, and Cl5 lie on this axis). b) Projection of the coordination sphere of Ga4 (cf. a) onto the corresponding hexamethylbenzene plane. A hexagonal pyramid of seven chlorine atoms is staggered relative to the hydrocarbon. c) Projection of the coordination sphere of Ga3 (cf. a) onto the corresponding hexamethylbenzene plane. Six chlorine atoms form a distored pentagonal pyramid.

The overall structure may be described as consisting of four $[(CH_3)_6C_6]Ga^+$ cations and four $[GaCl_4]^-$ anions, generating a hydrocarbon surface around an inorganic Ga_8Cl_{16} skeleton. Each arene can be assigned to a discrete Ga^+ center as an η^6 ligand.

5.4. The (Hexamethylbenzene)gallium(I) Tetrabromogallate(III) Network 4[31]

A solid phase of composition $[\{(CH_3)_6C_6\}Ga]^+[GaBr_4]^-$ **4** can be crystallized from solutions of Ga_2Br_4 in a mixture

of toluene and hexamethylbenzene. The colorless, transparent material, which is stable at room temperature in a vacuum (m.p. = 146 °C), contains no toluene. Hexamethylbenzene is therefore clearly preferred as a ligand for Ga^+, regardless of whether $[GaBr_4]^-$ or $[GaCl_4]^-$ counterions are present (**3** and **4**, respectively).

The X-ray analysis of the monoclinic phase **4** revealed a complicated network of interacting $[(CH_3)_6C_6]Ga^+$ and $[GaBr_4]^-$ ions. In the former the metal atoms are located perpendicularly above the arene ring center at a distance of 2.52 Å, which is shorter than in the bis(arene) complexes (**1** and **2**) and similar to that in the tetrameric cage of the $[GaCl_4]^-$ analogue **3**. The coordination sphere around Ga^+ is completed by a distorted tetragonal pyramid of five bromine atoms (Fig. 6). This geometry complements the pentagonal and hexagonal pyramids detected in **3**, in which the smaller chlorine atoms permit higher coordination numbers. One monodentate and two bidentate $[GaBr_4]^-$ tetrahedra are the origins of the five nearest bromine atoms.

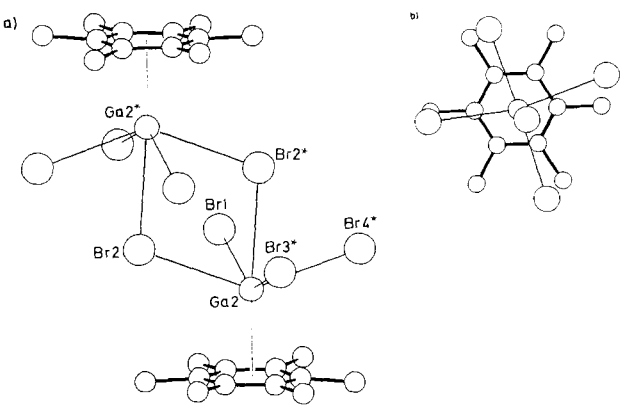

Fig. 6. a) Crystal structure of $[\{(CH_3)_6C_6\}Ga]^+[GaBr_4]^-$ **4**. The gallium(III) atoms of the $[GaBr_4]^-$ tetrahedra have been omitted for clarity. b) The coordination sphere of Ga^1 in **4**, projected onto the hexamethylbenzene plane. Five bromine atoms form a distorted tetragonal pyramid.

5.5. The Bis(1,3,5-trimethylbenzene)indium(I) Tetrabromoindate(III) Chain Polymer 5[32] and Related Compounds

Arene-indium(I) complexes are more difficult to obtain than their gallium analogues. With many complex subhalides and many hydrocarbons, no reaction takes place.[33] However, a combination was found in the system In_2Br_4/mesitylene, from which a 1:2 phase was easily obtained.

The structure of the bis(1,3,5-trimethylbenzene)indium(I) tetrabromoindate(III) **5**, which precipitates from saturated In_2Br_4 solutions containing excess hydrocarbon, is closely related to the mesitylene/Ga_2Cl_4 analogue **2**. The crystalline phase contains chain-like coordination polymers of $[InBr_4]^-$-linked bis(arene)indium(I) moieties (Fig. 7a). The aromatic rings are positioned nearly equidistantly from the metal (at 2.83 and 2.89 Å, respectively), and form an angle of 47.3°. In the plane bisecting this angle, there are three bromine atoms contributed from monodentate and bidentate $[InBr_4]^-$ tetrahedra (Fig. 7b, c). The In^+ ions in **5** are thus pentacoordinate, whereas only tetracoordinate Ga^+ ions are found in **2**. The difference of the ionic radii (Table 1) offers a straightforward explanation for this structural difference.

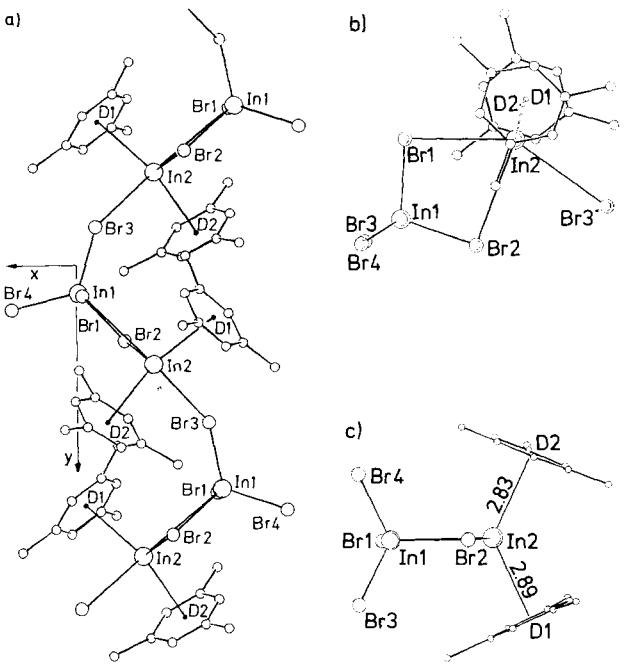

Fig. 7. a) Crystal structure of $[\{(CH_3)_3C_6H_3\}_2In(InBr_4)]$ **5**. Projection onto the xy plane. b, c) The coordination sphere of In^1 in **5**. Projection onto the In2Br1Br2Br3* plane (b). Side view of the same unit (c). Distances [Å].

A hexamethylbenzene complex of In_2Br_4 has also been obtained, but not yet structurally characterized. Benzene forms only very labile adducts with the subhalides of indium, and no discrete products could be isolated. There is little doubt, however, that the arene coordination chemistry of indium resembles that of the gallium congener; however, both the higher lattice energies of the indium halides and the reduced tendency of indium to complex with arenes are responsible for the more limited scope of its chemistry.

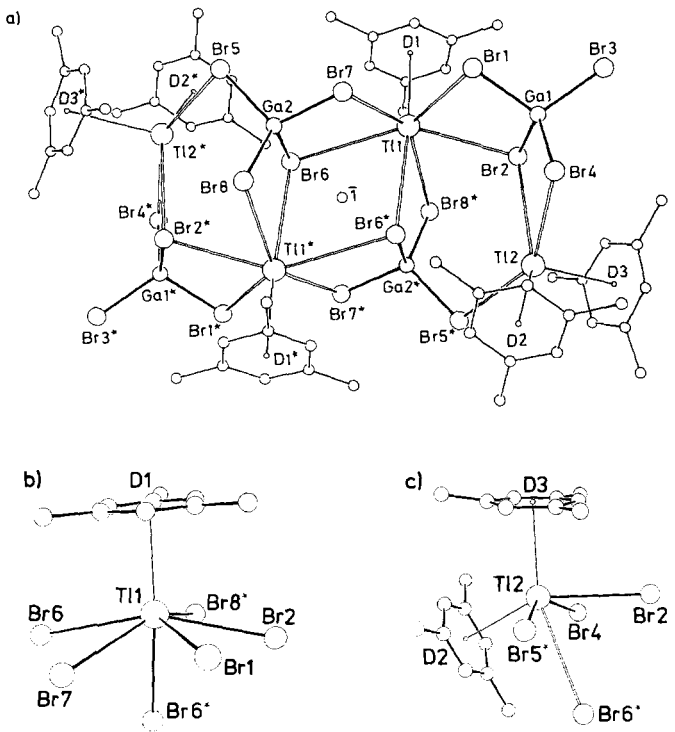
5.6. The Mixed Mono- and Bis(arene)thallium(I) Complex $[\{1,3,5\text{-}(CH_3)_3C_6H_3\}_6Tl_4(GaBr_4)_4]$ 6[34]

Thallium(I) tetrahalometalates(III) such as $Tl[AlCl_4]$, $Tl[AlBr_4]$, $Tl[GaCl_4]$, and $Tl[GaBr_4]$ are soluble in hot benzene, mesitylene, or hexamethylbenzene. The arene complexes that are present in solution are very unstable, and isolation of discrete phases often involves enormous experimental difficulties. To date only the title compound **6** has been fully characterized.[35]

The X-ray diffraction analysis of the triclinic crystals obtained from mesitylene in hot benzene or toluene gave a very unexpected result: centrosymmetric tetrameric units were found in which both mono- and bis(arene)thallium moieties are present in the same cluster (Fig. 8a). In the monoarene ions, the metal atom is located 2.94 Å above the ring center of the mesitylene, while in the bis(arene) ions, the two arenes are displaced by 3.00 and 3.02 Å, respectively, with a mutual inclination of 60.5° (Fig. 8b, c).

The cationic units are linked via tetrahedral $[GaBr_4]^-$ ions into a complicated network of thallium-bromine contacts.

An analogy to the mono(arene)gallium(I) species **3** and **4** exists only insofar as the metal atom of the (mesitylene)thallium units is also coordinatively saturated by a pentagonal pyramid of six bromine atoms, donated from three chelating $[GaBr_4]^-$ ions, two bisequatorial and one axial/equatorial (Fig. 8a, c). The bromine contacts of the metal atom in the bis(mesitylene)thallium(I) unit are irregular, but the geometry of **6** is reminiscent of that of **1**.[5]



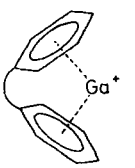


Fig. 8. a) Projection of the centrosymmetric unit of $[(1,3,5\text{-}(CH_3)_3C_6H_3)_6Tl_4(GaBr_4)_4]$ **6** onto the plane of the thallium atoms. b, c) View of the coordination sphere of the Tl^I atoms in **6**: cationic monoarene unit (b), cationic bis(arene) unit (c).

6. Relative Stabilities and Possible Modifications

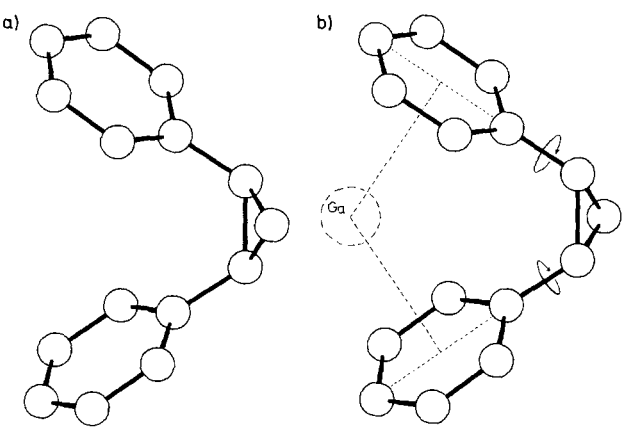
The addition of the arenes to the Tl^I salts is based on relatively weak interactions and is therefore readily reversible. Thermogravimetric analyses proved that the hydrocarbon is liberated completely and unchanged from the solid on heating at temperatures below 150°C. Experiments with the gallium(I) and indium(I) analogues gave similar results.

Semiquantitative observations suggest that the arene complex stability decreases as the radius of the metal increases from gallium to thallium. The role of the counterion is less obvious, but it is particularly noteworthy that no examples have been found with anions other than tetrahalometalates. All attempts to synthesize species with (thio)phosphates, halophosphates, halosilicates or other anions have failed. This situation is not unlike the state of affairs with the subvalent arene complexes of the fourth main group, with the exception of a tin(II) diphenyldithiophosphate, in which an intramolecular coordination of one of the phenyl rings to the Sn^{II} center was observed.[8]

Increased arene substitution with electron releasing groups provided the expected stabilization of the arene complexes, as shown in numerous reactions in which different arenes were allowed to compete for the M^I centers (see above). In order to exploit additional entropy effects, linked bis(arenes) were reacted with Ga^+ salts. Surprisingly, the introduction of a hydrocarbon bridge between the two phenyl rings did not increase the stability of the bis(arene)metal complexes (*cf.* **C**). Experiments carried out with the potentially chelating arenes $C_6H_5\text{-}(CH_2)_n\text{-}C_6H_5$ (where $n = 1\text{-}4$) as ligands for Ga^I, In^I, or Tl^I gave no well-defined products.[33,35] Cleavage reactions or intermolecular bridging led to intractable materials. Formula **C** is a possible model for the desired structures, as yet unrealized.

C

Due to the flexibility of the alkyl chains, the position of the two arene substituents in α,ω-diphenylalkanes is not fixed. In experiments aimed at positioning the arenes in a sandwich-type arrangement in the free ligand, the ligand *cis*-1,2-diphenylcyclopropane was chosen, based on the optimum dimensions derived from the complexes **1** and **2**, and experimentally tested. The ligand, which is accessible via a known procedure,[36] was first structurally investigated,[35] and the expected geometry confirmed (Fig. 9). On



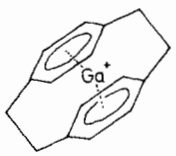


Fig. 9. a) Molecular structure of *cis*-1,2-diphenylcyclopropane; b) expected geometry of the corresponding gallium(I) complex; The calculated distances and angles are in excellent agreement with those in other bis(arene)gallium complexes.

introduction of a Ga^+ ion between the two phenyl rings, metal-ring bonds should be formed that are in satisfactory agreement with those observed for **1** and **2**. However, no crystalline products could be isolated from solutions containing the ligand and $Ga[GaX_4]$ salts, although, according to NMR data, complex formation must indeed have occurred.[35]

Experiments with cyclophanes appeared to be more successful.[35] Colorless, microcrystalline 1:1 complexes are formed immediately on addition of [2,2]paracyclophane to

solutions of Ga_2Cl_4 or Ga_2Br_4 in benzene, toluene, or xylenes. These complexes are much less sensitive to air and moisture than the analogous complexes with non-bridged arenes. (Hydrolysis with coloration to brown takes place only after hours.) In the solutions treated with the cyclophane, no gallium(I) can be detected. Complex formation with the cyclophane is specific for Ga^I, since no In^I or Tl^I can be precipitated from benzene solutions of In_2Cl_4 or $TlGaCl_4$. Attempts to crystallize a product yield again the benzene complexes. These results suggested that the Ga^I complexes of the cyclophane have a double-bridged sandwich structure (Formula **D**), one already proven for the chromium(0) complex.[37,38] The estimated atomic radii for Cr^0 and Ga^I are, in fact, almost equal.[39]

D

The X-ray structure analysis of the Ga_2Br_4 complex showed very surprisingly, however, that the gallium(I) ions have not entered the cyclophane interstices, but have become attached from the outside to the bridged arene rings of the hydrocarbon. Each Ga^I center is thereby coordinated to two different cyclophane molecules, and each cyclophane bears two η^6-coordinated gallium atoms. In the resulting endless, slightly folded stacks, the centers of the cyclophane molecules represent centers of symmetry (Fig. 10a). The two benzene rings of each cyclophane remain parallel to each other (as required by symmetry) and form an angle of 56.7° with the benzene rings of the following cyclophanes in the "polydecker" arrangement. This folding corresponds to the geometry found in other bis(arene)metal complexes (**1**, **2**, **5**, and **6**). The coordination sphere of Ga^I is complemented by two bromine atoms which belong to two different $[GaBr_4]^-$ tetrahedra. These bromine atoms lie on a crystallographic mirror plane together with the Ga^{III} centers (Fig. 10b), and they form bridges between the Ga^I atoms. Consequently, coordination polymer chains $-Ga^I-Br-Ga^I-Br-$ are formed perpendicularly to the (cyclophane)Ga^I stacks and interconnect the system to give a three-dimensional lattice (Fig. 10c). It is conceivable that other cyclophane complexes, e.g., of silver(I), obey a similar structural principle. However, no structural data are available as yet.[40]

It is hoped that cyclophanes with larger arene-arene separations will be able to accommodate the gallium(I) cations within the molecular cavity.

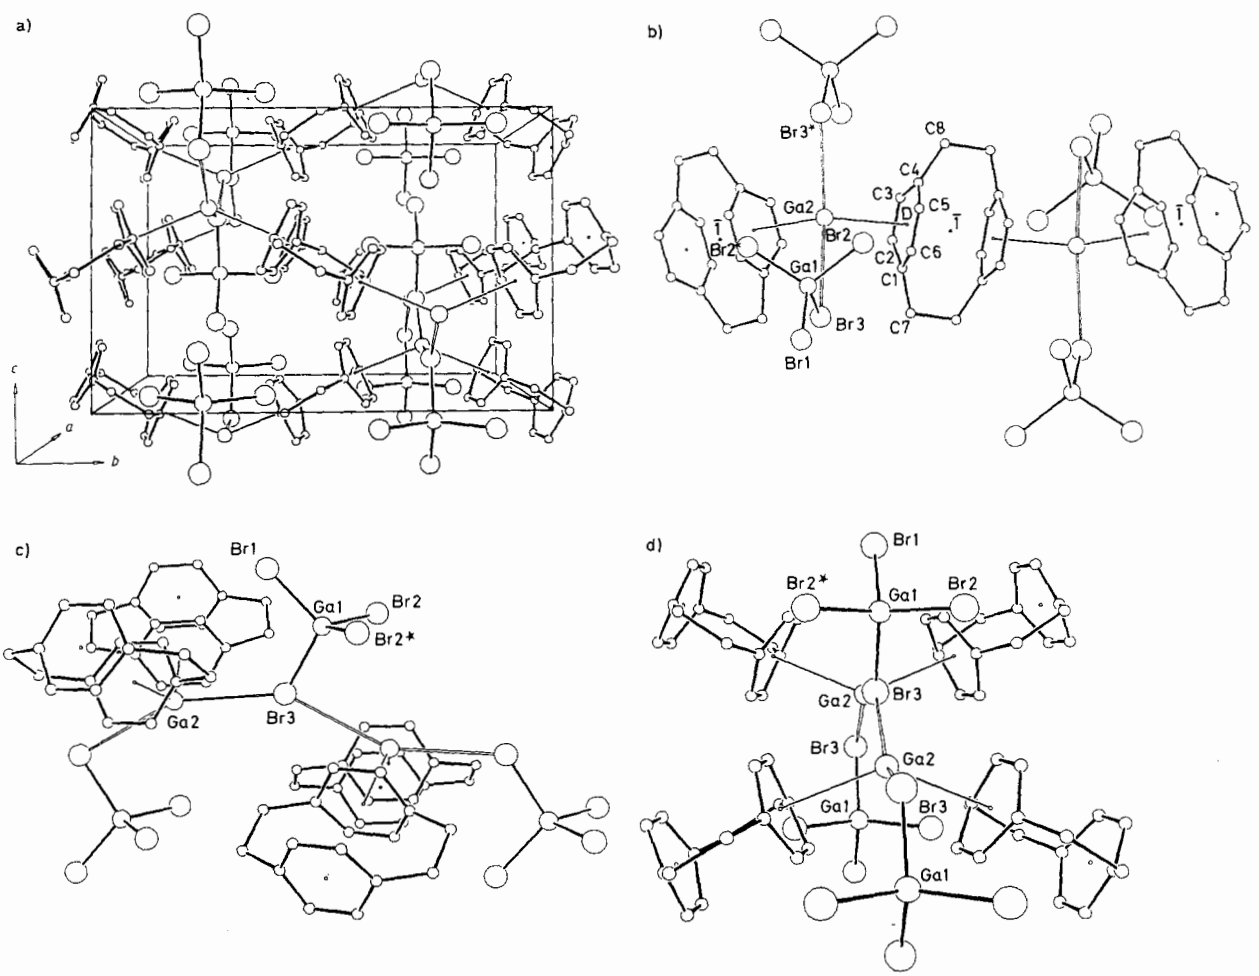

Fig. 10. a) View of the crystal structure of [2.2]paracyclophane-gallium(I) tetrabromogallate(III). b) View along the stacks formed from alternating cyclophane and gallium(I) units. The chains are folded periodically at the metal centers. c) View down the cyclophane/gallium(I) stacks, but perpendicular to the mirror planes formed by the gallium and the bromine atoms Br1 and Br3. d) View almost perpendicular to the cyclophane stacks and almost parallel to the mirror plane referred to in c (d).

7. ^{71}Ga-NMR Spectra of Solutions of Gallium(I) Compounds in Aromatic Hydrocarbons

The isolation of crystalline arene complexes and the elucidation of their crystal structure provided a much better basis for the discussion of the solution NMR spectra of these materials. From a variety of measurements on solutions of Ga_2Cl_4 and Ga_2Br_4 in benzene, toluene, p-xylene, and mesitylene, and in mixtures of these solvents, in suitable ranges of temperature and concentration, the following new and essential aspects emerged:[41]

a) The ^{71}Ga nucleus (abundance 39.6%, spin 3/2, quadrupole moment 0.112×10^{-24} cm^2) affords sharp signals with high sensitivity for Ga^I-containing structural elements (and, therefore, for the arene complex moieties) of all systems investigated. These signals show the largest high-field shift ever observed for a gallium compound. The δ values (Table 3) are higher (more negative) by 200 ppm than those of the molten Ga[GaX$_4$] salts.[21] The introduction of arenes into the coordination sphere of the metal, which had contained only GaX_4 tetrahedra in the melt, leads to a further reduction of paramagnetic contributions to the chemical shift. Since the arenes are clearly kept at a considerable distance, only weak interactions are possible (Fig. 11).

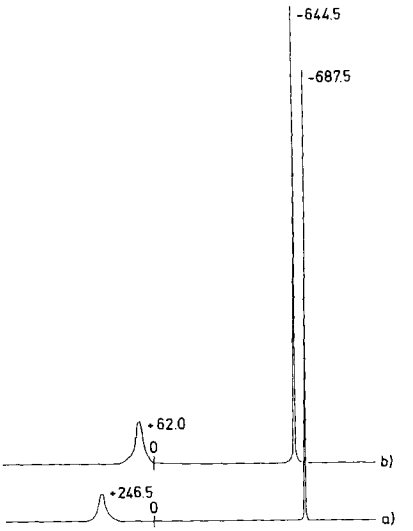

Fig. 11. ^{71}Ga-NMR spectra of benzene solutions of a) Ga[GaCl$_4$] and b) Ga[GaBr$_4$] at 30°C. δ values.

Table 3. ^{71}Ga-NMR spectra of solutions of the salts Ga[GaX$_4$] in aromatic hydrocarbons [41] [a] (Bruker CXP 200, ν=60.99 MHz; standard 1 M Ga(NO$_3$)$_3$, in diluted aqueous HNO$_3$, corresponding to [Ga(H$_2$O)$_6$]$^{3+}$).

	Solvent [a]	Conc. [wt. %]	δ(Ga$^+$)	δ(Ga^{3+})
Ga[GaCl$_4$]	benzene	1	−650	+247
	benzene [b]	3	−669	+247
	toluene	1	−668	+247
	toluene [b]	4	−673	+247
	p-xylene [b]	7	−674	+247
	mesitylene	sat.	−675	br.
	mesitylene/benzene	sat.	−675	+247
Ga[GaBr$_4$]	benzene	3	−609	+ 62
	mesitylene	sat.	−624	br.

[a] The line widths for Ga$^+$ lie between 50 (127°C) and 100 Hz (27°C), for Ga^{3+} between 1700 und 4700 Hz. [b] With too little solvent, two-phase mixtures are formed, the heavier of which show δ(Ga$^+$) = −687 for Ga[GaCl$_4$] in benzene, −686 in toluene, and −688 ppm in *p*-xylene (at constant δ(Ga^{3+}) = +247).

b) In mixed solvents a chemical shift is observed for Ga$^+$ that corresponds to a complex with the better donors among the arenes present in the mixture (hexamethylbenzene > mesitylene > xylene > toluene > benzene). Thus, there is also a preference for specific components in solution.

c) The line width of the ^{71}Ga$^+$ resonance of arene complexes, which typically is ca. 100 Hz at 20°C and 50 Hz at 130°C, is of the same order of magnitude as that of the highly symmetrical [Ga(H$_2$O)$_6$]$^{3+}$ ion. Since the environment of Ga$^+$ in arene complexes cannot attain the high symmetry of point group O$_h$, it is necessary to assume that the conservation of spherical symmetry of the outer electron shell, combined with the large distances to the ligand, is responsible for a relaxation behavior which corresponds to that of complexes of high symmetry.

d) The resonances of the [GaX$_4$]$^-$ anions are largely constant in their δ value and have large line widths (Table 3). It follows that these counterions do not attain their full tetrahedral symmetry in solutions of Ga[GaX$_4$] salts in arenes even at high dilution, but remain coordinated to the (arene)Ga^I centers. It has been noted repeatedly that other M$^+$[GaX$_4$]$^-$ salts, when fully dissociated in polar solvents, do indeed give rise to sharp signals. This is because the relaxation behavior of ^{71}Ga^{3+} is modified by the T$_d$ symmetry of the free GaX_4^- anions so that small line widths result.[41-43] This conclusion is also in agreement with the colligative properties of the solutions, which show no significant dissociation of the ions.[23,24]

e) The ^{71}Ga-NMR spectra give no indication of the simultaneous presence of mono- and bis(arene)Ga^I complexes in solution. Even at low temperatures (−50°C), only one Ga$^+$ resonance is observed. Similarly, only one Ga$^+$ signal is detected in mixed arene solvents. Arene exchange processes between Ga$^+$ centers probably have very low activation barriers, so that a separate recording of the individual states is not possible. This result supports the view that the bonding of the arenes to the metal is weak. ^{1}H- and ^{13}C-NMR spectra lead to the same conclusion.

f) Two separate liquid phases are formed if an excess of a Ga[GaX$_4$] salt is dissolved in benzene, toluene, or mesitylene. This phenomenon is especially apparent with *tert*-butyl- and trimethylsilylbenzenes.[41] Even if the phase boundary remains invisible to the naked eye, because phase separation is incomplete, this situation becomes immediately obvious in the NMR spectra through a doubling of all signals. These additional signals disappear as more solvent is added, until homogeneity is reached.

8. The Nature of the Bonding in Arene Complexes of the Third Main Group

Arene complexes of metals are best referred to as donor-acceptor adducts, the hydrocarbon π-system being the donor component. Qualitative observations have also consistently shown that, for metals of the third main group, an increased arene donor strength through electron-releasing substituents leads to enhanced stability of the complexes. The resulting metal-ring bond distances are shorter for hexamethylbenzene or mesitylene than for benzene (Table 4). The interactions are not strong enough, however, to induce significant distortions of the six-membered ring, or to bend hydrogens or methyl groups out of the ring planes. None of the deviations from the original ligand symmetry exceeds the standard deviations of the X-ray diffraction analysis. These findings are in accord with the extremely low thermal stability of the complexes and with the exchange processes observed by NMR.

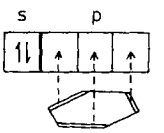

Table 4. Metal-carbon bond lengths [Å] and hydrocarbon interplane angles [°] in arene complexes **1**–**6**.

M	M–C in [(arene)M]$^+$ (average)		M–C in [(arene)$_2$M]$^+$ (average)		Angles
Ga	**4**: 2.887		**1**: 3.08	3.23	55.6
	3: 2.79	2.88	**2**: 3.01	3.02	39.7
In	—		**5**: 3.15	3.21	47.3
Tl	**6**: 3.28		**6**: 3.32	3.34	60.5

A molecular orbital description of the mono(arene) complexes can use a model previously suggested for (benzene)tin(II)[9] analogues. In Figure 12, the MO's of a benzene molecule and the valence orbitals of a Ga^+ ion are combined under the assumption of local C_{6v} symmetry. The lowest unoccupied atomic orbitals of the metal and the highest occupied molecular orbitals of the arene have the same symmetry (e_1) and lead to bonding and antibonding linear combinations. The four HOMO electrons of the arene are thus just sufficient to fill the two new bonding MO's of the complex (e_1 symmetry). This situation accounts for the ligand-metal bonding. Owing to the significant energy gap between arene and metal orbitals, however, the energy of complex formation is limited. It is therefore not surprising that the stability of the metal-arene bond is hardly high enough to compete with other metal-ligand interactions.[44]

The metal-halogen coordination in complexes **3**, **4**, and **6** does not appear to be geometrically specific, as evidenced by the very different arrangement of chlorine or bromine atoms in the coordination sphere. Therefore, it is probably pointless to include details of this coordination in the MO diagrams. A largely electrostatic description of this part of the coordination should lead to at least equally acceptable predictions.

A simple picture of the arene-metal interaction, in which the six electrons of the benzene π system fill the three vacant p orbitals of the metal, is of little value since symmetry criteria are ignored in such a model of localized bonding.[45] Although an inert gas shell is formally reached in

this formalism, a closed-shell state is not present.[46] This reasoning is further supported by the fact that more than one arene can engage in bonding to the same metal atom, as in compounds **1**, **2**, **5**, and **6**. The MO scheme for these bis(arene) complexes with local C_{2v} symmetry is, on the other hand, straightforward (Fig. 13).

A closely related scheme has previously been proposed for bent bis(cyclopentadienyl) complexes of germanium(II) and tin(II).[47] For these prototypes the origin of the interplane angle between the two cyclopentadienyl rings has

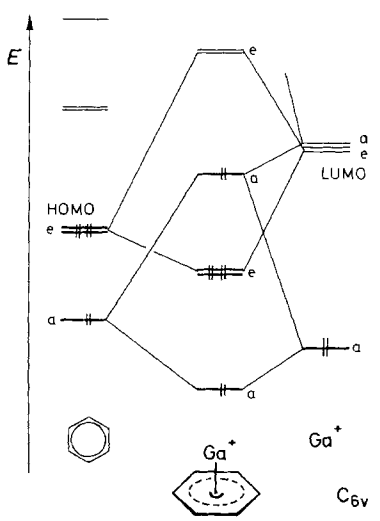

Fig. 12. Qualitative MO diagram of [(arene)Ga]$^+$ complex ions (C_{6v} symmetry) [48].

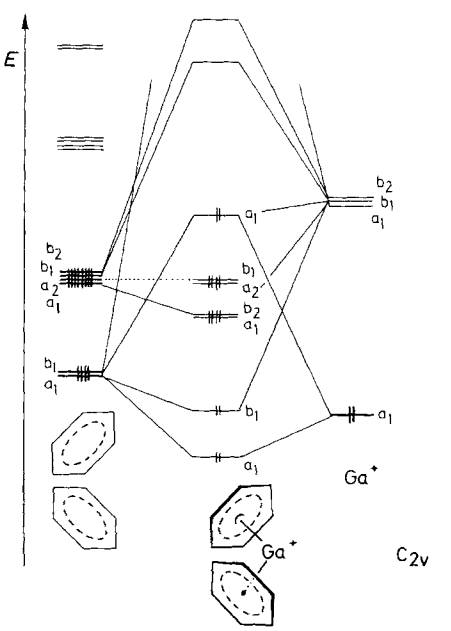

Fig. 13. Qualitative MO diagram of [(arene)$_2$Ga]$^+$ complex ions (C_{2v} symmetry) [48].

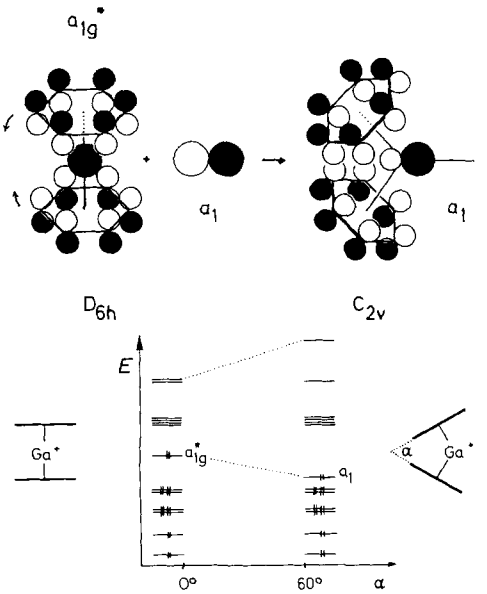
been considered in some detail. It was pointed out that mixture of the s orbital into the relevant metal p orbitals leads to a significant gain in energy, even in the absence of stabilizing ligands. In the case discussed here, the bis(arene)metal tetrahalometalates (Fig. 14), direct metal-halogen coordination, which is made possible by the increased interarene angle, is likely to afford additional stabilization.[48]



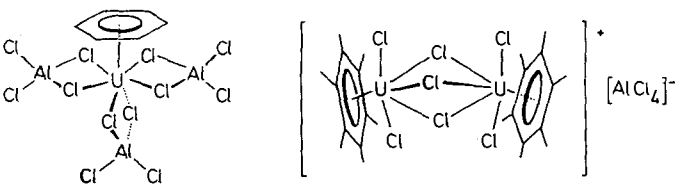


Fig. 14. Dependence of the MO diagram of $[(arene)_2Ga]^+$ complex ions on the angle α between the two arene planes [48].

In summary, the qualitative MO schemes can account for most of the new experimental data. The metal complexes of the third main group can be viewed as the missing links in the existing series of arene-metal complexes. They are unique in that the LUMO set of p orbitals of the low-valent metal can interact perfectly with the HOMO set of an arene, whereas in most classical cases the d orbitals play the key role.[12]

Both the (Ga)-NMR data and the structural features of the arene complexes indicate only a slight deviation from a spherical arrangement of the two outer electrons of the univalent M^+ cations. Due to large shielding effects and lack of stereochemical activity, these electrons appear to be in a "dehybridized" state.[49-51] In fact, indications of directed effects of the free electrons are rarely found in the structural chemistry of trivalent elements of the third main group.[18] However, this effect becomes pronounced with the divalent (Ge, Sn, Pn) and trivalent (As, Sb, Bi) neighboring elements, indicating a lowering of the energy through hybridization. Especially in the case of heavy atoms (Tl, Pb, Bi), the stabilization of the $6s^2$ state, known as the "inert pair effect," may be interpreted as a relativistic phenomenon.[51] After completion of the two d shells of Zn ($3d^{10}$) and Cd ($4d^{10}$), a significant influence on $4s^2$ and $5s^2$ of gallium and indium, respectively, seems to be present, manifested by an unusually strong binding of these electrons. Therefore, hybridization becomes more unfavorable as the p states become higher in energy, and directed bonds arise only with less electronegative and more polarizable partners. Experiments in this direction have always led to rapid disproportion of the Ga^I and In^I compounds, however, and as a consequence, almost no distinctly covalent Ga^I, In^I, or Tl^I compounds are known so far.

Recent reports on the first complexes of actinide metals with neutral arenes show that these elements, in low oxidation states, are also capable of η^6-arene coordination.[52,53] In the two compounds **E** and **F**, which have been studied by X-ray diffraction, tri- and tetravalent uranium is bound to arene and halide ligands in a very similar way as in the low-valent third and fourth main-group metal ions of the complexes presented above.

E **F**

9. Outlook

Several decades after the discovery of the polar In^I and Tl^I cyclopentadienyl complexes, the coordination chemistry of these metals with neutral arenes is now being developed. The arene complexes of p-block metals differ from the analogous complexes of d-block metals, especially in the strongly decreased binding interaction between metal and hydrocarbon. This is evident not only in the easy cleavage of the complexes into their components, but also in the large metal-ring separations and the apparently small change in the electronic states of the arenes. For example, no absorption in the visible region is observed, and the IR bands and NMR signals are changed only slightly. Although thermodynamic data are lacking, these observations place these complexes in the class of substances exhibiting "weak interactions." Both the dissolution of gallium(I) compounds in aromatic hydrocarbons and their separation from these media involve only small energy changes, which means that solution, extraction, and recovery processes can be carried out reversibly with a minimum amount of energy under mild conditions. The position of the equilibrium can be easily influenced by modifications of the ligands. These considerations can also be of considerable advantage for stoichiometric reductions using low-valent metals of the third main group.

The author wishes to express his gratitude to Dr. Th. Zafiropoulos, J. Ebenhöch, W. Bublak, and M. Usòn-Finkenzeller, who carried out most of the fundamental experiments with great skill and enthusiasm, Prof. U. Thewalt, Dr. G. Müller, B. Huber, and J. Riede for their expert solution and discussion of all the crystal structures, Prof. F. H. Köhler and Priv. Doz. P. Burkert for NMR measurements, and Prof. P. Hofmann for theoretical discussions. Financial sup-

port from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Siemens AG, and Preussag AG is also gratefully acknowledged.

Mechanisms of Biological Ion Transport— Carriers, Channels, and Pumps in Artificial Lipid Membranes

By Peter Läuger*

The cell membrane contains specific systems for passive and active transport of ions between the cytoplasm and the extracellular medium. For a number of small and medium-sized transport molecules like valinomycin and gramicidin A, extensive structural and kinetic data are available and it is possible in these cases to understand the transport function on the basis of their molecular structure. Incorporation into artificial bimolecular lipid membranes opens up the possibility of studying the kinetic properties of biological transport systems in detail.

1. Introduction

The basic structure of biological membranes consists of a bilayer of lipid molecules with their polar head groups oriented toward the aqueous phase and their hydrophilic hydrocarbon chains forming the interior of the membrane (Fig. 1). The lipid structure contains protein molecules, some of which span the whole membrane. A particular feature of biological membranes is the fact that their structure is predominantly held together by noncovalent bonds such as van der Waals and coulombic interactions, so that a high degree of flexibility with respect to their chemical composition and dynamic properties is achieved.

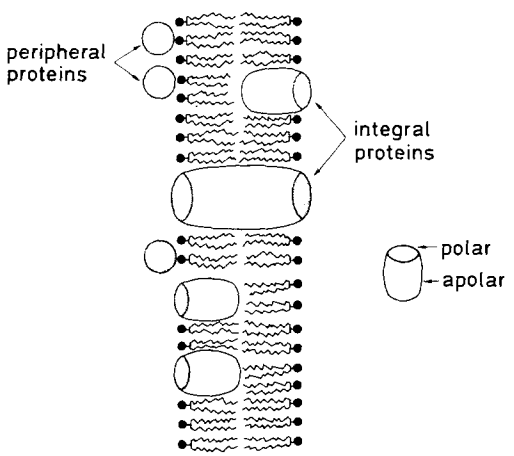

Fig. 1. The structure of a biological membrane (schematic). The basic structure of the membrane consists of a lipid bilayer. Peripheral proteins are bound to the membrane mainly by electrostatic interactions. Integral proteins are incorporated into the lipid matrix.

At physiological temperatures cell membranes are in a *fluid* state.[1] Exchange of lipid molecules between neighboring positions within a monolayer takes place in the time range of 10^{-8}–10^{-7} s.[2] (The exchange of lipid molecules in *transversal* direction, i.e., between two adjacent monolayers is, however, much slower, from seconds to days.) For some proteins a high diffusion rate within the plane of the membrane was observed[3] (diffusion coefficients of 10^{-11}–10^{-9} cm^2/s); other membrane proteins are probably fixed in the membrane by interactions with the cytoskeleton.

Lipid membranes are extremely impermeable to small ions such as Na^+ or Cl^-. A protein-free bilayer of phosphatidylcholine (lecithin) in 0.1 M NaCl has a specific conductance of 1–10 nS/cm^2,[4] a value that corresponds (at a membrane thickness of 5–10 nm) to the conductivity of an excellent insulator. The origin of the small ion permeability is the high energy necessary to transfer an ion from the aqueous phase into the apolar, hydrocarbon-like interior of the membrane. This barrier is important for the functioning of the cell membrane, since it allows the selective passage of certain types of ions and enables the cell membrane to regulate the ionic permeability by chemical or electrical means.

2. Ion Carriers and Ion Channels

The ionic permeability of cell membranes depends on certain specialized transport molecules. With respect to mechanism it is possible to distinguish two classes of transport systems: carriers and channels.[5] An ion carrier is a molecule that binds the ion and transports it in its bound form through the membrane (Fig. 2). The binding site is

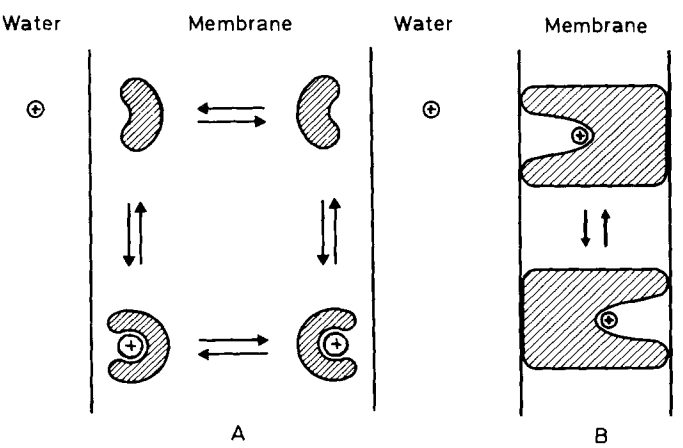

Fig. 2. Two mechanisms of carrier-mediated ion transport through lipid membranes. A: Translation of the carrier molecule relative to the membrane; B: alternation between a left-exposed and right-exposed form of the ion binding site due to conformational changes.

accessible alternately from the left-hand or from the right-hand side but not from both sides simultaneously. The transition between states with left-exposed and right-exposed binding sites is achieved either by movement of the entire carrier molecule relative to the membrane or via a conformational change of the carrier molecule (Fig. 2).

An ion channel is a protein molecule that spans the entire membrane and contains in its interior a tunnel-like pathway for ions (Fig. 3). Entry of ions into the channel is

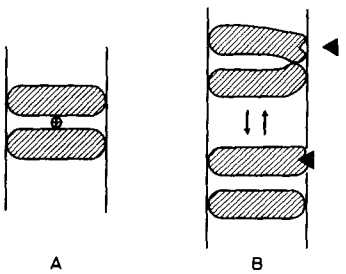

Fig. 3. A: Permanently opened ion channel; B: regulation of an ion channel by binding of an effector molecule.

energetically favored by electrostatic interactions with polar groups of the protein (e.g., peptide carbonyl groups). Certain ion channels in cell membranes are either open always or open and close at statistically determined time intervals. In other cases the channel opens only upon binding of an effector molecule (Fig. 3). This mechanism for regulating ion channels is the basis of signal transmission at neuromuscular synapses; the presence of transmitter molecules at nerve junctions results in an activation of ion channels in the muscle membrane.[6] The opening and closing of Na^+ and K^+ channels in the nerve membranes is regulated by the electrical field in the membrane.[7]

3. Artificial Lipid Membranes

Numerous laboratories are presently engaged in the isolation and purification of transport proteins from biological membranes. In the study of isolated transport proteins a fundamental difficulty arises since the transport function can no longer be tested once the protein is present in homogeneous solution. This is quite different from the situation for an enzyme, whose activity can easily be studied in vitro. This difficulty can be overcome by incorporating the isolated transport molecule into an artificial lipid membrane.[8] For this purpose, two artificial membrane systems may be used: planar lipid bilayers and lipid vesicles.

3.1. Planar Lipid Bilayers

Planar lipid bilayer membranes with diameters up to 10 mm can be formed in aqueous solution by a variety of techniques.[9,10] The method introduced by *Montal* and *Mueller*[10-12] starts with the formation of monomolecular lipid films on the water surfaces in a cell containing two compartments separated by a teflon diaphragm with a circular opening in the middle. After formation of the monolayers the liquid is raised, first in one chamber then in the other, above the level of the opening. In this way a lipid bilayer is formed across the opening in a zipper-like manner (Fig. 4). By the use of different lipids for the formation of the two monolayers, asymmetric membranes may be obtained.[13,14]

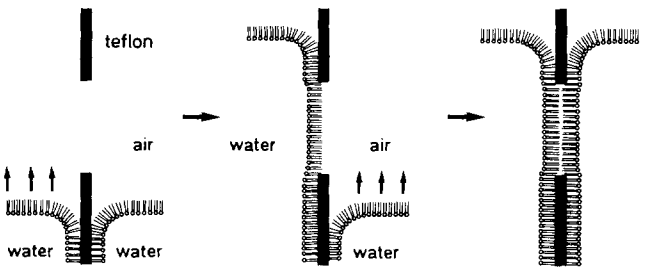

Fig. 4. Formation of artificial lipid bilayers. A monomolecular lipid film is formed on the water surface by spreading from an *n*-hexane solution. By subsequent raising of the aqueous solutions, a bimolecular lipid membrane is formed across the opening of the teflon support.

The electrical properties of lipid bilayers can be investigated in the measuring cell illustrated in Figure 5. The specific electrical capacitance of a dioleoyl phosphatidylcholine membrane formed according to the method of *Montal* and *Mueller* is $C_m = 0.72\ \mu F/cm^2$.[15] Using the relationship for a plate condensor, $C_m = \varepsilon_0 \varepsilon / d$, one can calculate the membrane thickness d ($\varepsilon_0 = 8.85 \times 10^{-12}\ CV^{-1}\ m^{-1}$ is the electrical field constant and ε is the dielectric constant of the membrane). Using $\varepsilon = 2.1$, a value appropriate for a hydrocarbon, one obtains a membrane thickness of $d = 2.6$ nm. This value is smaller than twice the chain length $2l$ of oleic acid ($2l \simeq 4.0$ nm), which indicates that the hydrocarbon chains are not completely extended within the membrane.

The electrical conductivity of simple lipid bilayers is, as already mentioned, very small. Thus it is possible to measure changes in conductivity that are caused by incorporation of biological ion transport systems with high sensitivity. A further considerable advantage of using planar lipid membranes is the small series resistance between electrodes

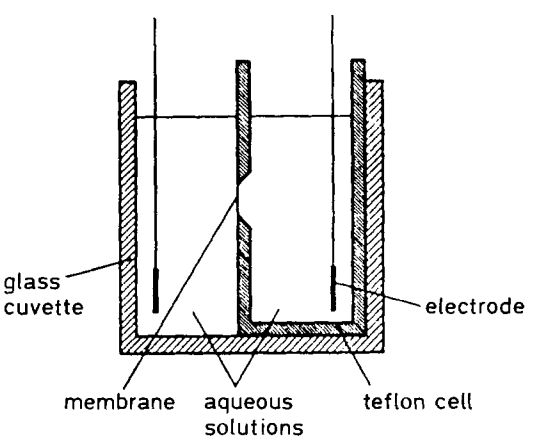

Fig. 5. Measuring cell for the investigation of the electrical properties of lipid bilayers. Platinized platinum electrodes or silver/silver chloride electrodes are used.

and membrane. This makes it possible to investigate fast electrical processes within the membrane by relaxation techniques with high time resolution (Section 4.1).

Recently *Hanke* et al. described a method of producing membranes with a small surface area (a few μm^2) which are ideally suited for the incorporation of proteins.[16-19] A glass micropipette (tip diameter ca. 1 μm) filled with an electrolyte solution is placed with its tip beneath the water surface (Fig. 6). After formation of a lipid monolayer on

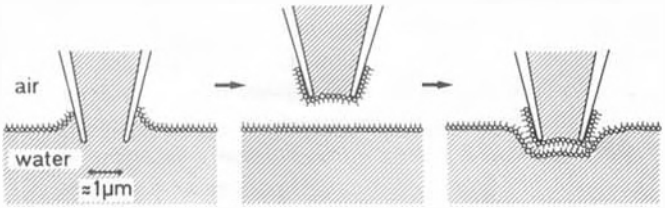

Fig. 6. Formation of lipid bilayers having small areas. The tip of a glass micropipette is initially located below the water surface. After formation of a monomolecular lipid film, the pipette is pulled out of the aqueous phase and then reinserted.

the water surface, the pipette is lifted out of the water, resulting in the formation of a monolayer on the pipette tip. Reinsertion of the pipette into the liquid results in the apposition of two monolayers and the formation of a bimolecular membrane. Ion channels isolated from biological membranes may be incorporated into the monolayer, and thus subsequently into the bimolecular membrane by spreading protein-containing lipid vesicles on the water surface.[16-20] Since the membrane area is fairly small, it is possible to achieve the incorporation of only one channel molecule into the artificial membrane. Thus it is possible to measure single-channel currents with high sensitivity.

3.2. Lipid Vesicles

Planar lipid membranes, which have a limited area, are not well suited for the study of transport systems with small rates of transport. Such systems can be more easily studied using suspensions of artificial lipid vesicles, which may be produced with diameters of between 30 nm and 1 μm in aqueous electrolyte solutions.[21,22] Lipids such as phosphatidylcholine swell in contact with water and form so-called liposomes consisting of concentric layers of lipids. Ultrasonic treatment of these large liposomes (with diameters of several μm) results in the formation of single-shelled spherical vesicles with an outer diameter of approximately 30 nm. Such single-shelled vesicles have an aqueous core in which water-soluble substances can be trapped.

Another method of producing single-shelled lipid vesicles consists in solubilizing the lipid in micellar form in water by detergents with subsequent removal of the detergents by dialysis or gel chromatography. The diameter of the vesicle may be varied in the range of 50–200 nm by the proper choice of the detergent and by the experimental conditions used to remove the detergent. Dialysis of cholate leads to dioleoyl phosphatidylcholine vesicles with a mean outer diameter of 90 nm.[23] 1 mL of a vesicle suspension with a lipid concentration of 10 g/L corresponds to a membrane area of $\approx 3\ m^2$; the enclosed aqueous volume is approximately 1% of the total volume of the suspension.

Interesting possibilities arise through the use of synthetic amphiphilic compounds in the formation of vesicles. Using polymerizable lipid analogues or analogues containing functional groups, membrane vesicles with novel properties can be obtained.[24-26]

Transport proteins isolated from biological membranes can be introduced into artificial lipid vesicles.[27] This is achieved by adding the detergent-solubilized protein to a lipid/detergent mixture and subsequently removing the detergent by dialysis. In this way, the protein is incorporated into the membrane of the lipid vesicles. Ion fluxes through the vesicle membrane can be studied either using radioactive isotopes or with optical indicator molecules.

4. Ion Carriers

A variety of compounds are now known that function in biological membranes or artificial lipid membranes as mobile ion carriers (Fig. 2A).[24-28] Best characterized are macrocyclic compounds such as valinomycin and enniatin B and macrotetrolides like monactin (Fig. 7). Valinomycin and enniatin B are depsipeptides formed from alternating amino acids and α-hydroxy acids. Valinomycin forms a 1:1 complex with K^+ ions in which the ion is surrounded by the six oxygen atoms of the ester carbonyl groups[31] (Fig. 8). The exterior of the complex, formed by methyl and isopropyl groups, is strongly hydrophobic.

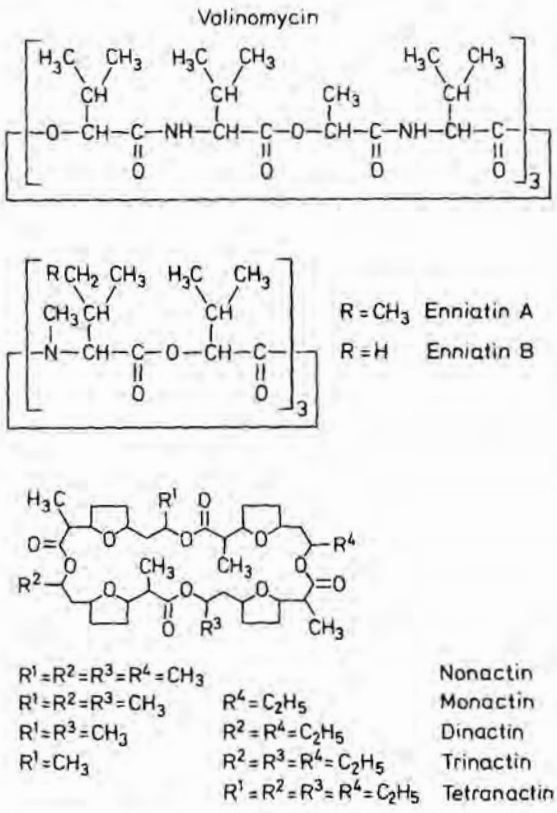

Fig. 7. Macrocyclic ion carrier. Valinomycin, enniatin A, and enniatin B are depsipeptides which consist of alternating α-amino acids and α-hydroxy acids.

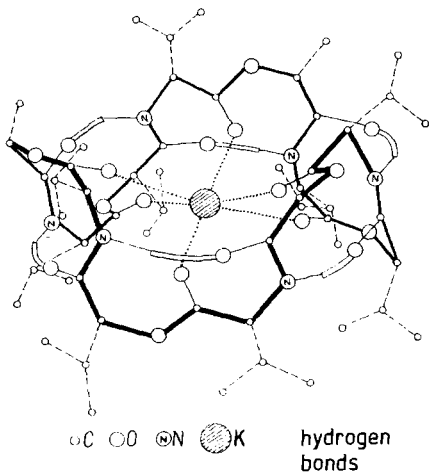

Fig. 8. Structure of the valinomycin/K^+ complex [31]. The central K^+ ion is encaged by six oxygen atoms of the ester carbonyl groups. The complex is stabilized by six hydrogen bonds between NH and CO groups of the six amino acids.

The structure of the valinomycin/K^+ complex (Fig. 8) was determined by X-ray analysis[32–36] as well as from spectroscopic data.[31,37–48] The backbone of the molecule is folded into six loops which are held together by six hydrogen bonds between NH and C=O groups of the amino acids. UV, IR, circular dichroism (CD), and NMR studies have shown that the noncomplexed valinomycin molecule can adopt a variety of conformations in solution, depending on the nature of the solvent. In nonpolar solvents the molecule exhibits a closed conformation similar to that of the K^+ complex, whereas in polar solvents an open conformation with a smaller number of intramolecular hydrogen bonds predominates (Fig. 9).[29,30] Transitions between these two conformations take place in the time range of 10^{-9}–10^{-7} s, as was shown by ultrasound absorption measurements.[29] Fast conformational equilibria seem to be a necessary precondition for the high rates of complexation of macrocyclic ion carriers in homogeneous solution.[41,49–52]

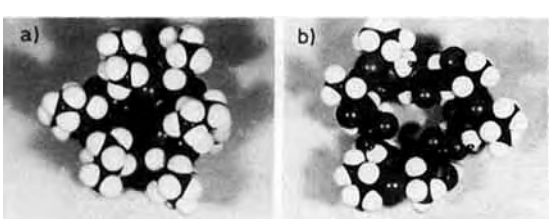

Fig. 9. Structure of valinomycin in solution. (a) Closed conformation with six intramolecular hydrogen bonds; (b) semi-open conformation with three intramolecular hydrogen bonds. Conformation (a) predominates in apolar solvents, whereas conformation (b) is adopted in polar solvents (from *Grell* et al. [29]).

The mechanism of carrier-mediated transport of alkali-metal ions through membranes has been studied in detail using planar lipid bilayers.[53–82] In a 1 M KCl solution containing 0.1 μM valinomycin, the membrane conductivity is about 10 mS/cm^2, six orders of magnitude greater than the conductivity of the membrane in the absence of valinomycin.[59] This enormous increase of the conductivity is practically solely due to the transport of K^+ ions; this is deduced from the observation that the membrane potential in asymmetric KCl solutions agrees with the Nernst potential for K^+.[53] The specificity of valinomycin is extremely high; the ratio of the membrane conductivity in a solution containing K^+ to that in a solution containing an equivalent concentration of Na^+ is about 2000.[84,85] Valinomycin may be added to the aqueous phase or directly to the lipid. It then undergoes distribution between the aqueous phase and the membrane with a partition coefficient of about 5×10^4 in favor of the membrane.[60]

The observed concentration dependence of the membrane conductivity can be explained by the assumption that both valinomycin and enniatin B as well as macrotetrolides act according to a translational mechanism as illustrated in Figure 2A. The transport process consists of four steps: 1) formation of a complex between the ion M^+ and the carrier molecule S at the membrane surface; 2) translocation of the complex MS^+ to the opposite side of the membrane; 3) liberation of the ion; 4) back-transport of the free carrier molecule S. The kinetics of the transport process can be described in a first approximation by the introduction of rate constants for each reaction step (Fig. 10). This is self-evident in the case of association and dissociation steps (rate constants k_R and k_D); k_R and k_D are overall rate constants which may include several intermediate reactions (e.g., conformational changes of the carrier or stepwise replacement of water molecules by ligand atoms of the carrier within the hydration shell). The description of the translocation steps of MS^+ and S by the unimolecular rate constants k_{MS} and k_S is only an approximation which is based on the assumption that the residence times of MS^+ or S in the membrane–solution interfaces are much longer than the time required for the actual translocation.[60]

The reaction scheme illustrated in Figure 10 leads to a number of interesting questions. Is there a rate-limiting step that determines the rate of the overall reaction? Is the high specificity of valinomycin dominated by thermodynamic factors (equilibrium constants of complex formation) or by kinetic parameters? Which kinetic factors are important for the optimal functioning of a carrier? In order to answer these questions the kinetics of the transport system must be studied in detail. Such an analysis is made possible by the use of relaxation measurements.

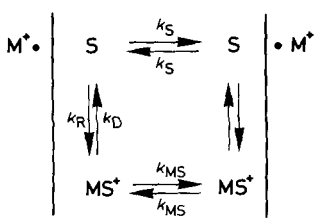

Fig. 10. Transport of an ion M^+ by the carrier S. k_R and k_D are the association and dissociation rate constants, k_{MS} and k_S the rate constants for translocation of the complex MS^+ and the free carrier S.

4.1. Relaxation Methods for the Study of Ion Transport Processes in Membranes. Kinetic Analysis of Carrier Systems

Relaxation methods were first developed for the study of fast chemical reactions in homogeneous phase.[83] The system under investigation is perturbed by the sudden change of an external parameter such as pressure or temperature, and the time course of the approach to a new equilibrium state is followed. Relaxation methods have also proved to be useful tools for the kinetic study of ion transport processes in membranes.[60-63, 67-72, 75-81]

The voltage-jump relaxation method (Fig. 11) consists in rapidly applying a voltage to the membrane and then recording the current relaxation.[60, 78, 79] For the carrier mechanism illustrated in Figure 10 it is possible to describe the time dependence of the membrane current by the sum of three (or, in some simple cases, two) exponential functions. From the experimental time constants and the amplitudes of the exponential functions, the rate constants k_R, k_D, k_S, and k_{MS} can be calculated.

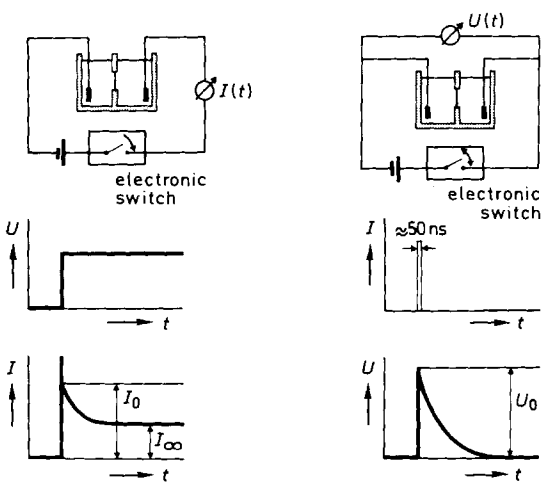

Fig. 11. Electrical relaxation methods for the study of ion transport processes in membranes. In the voltage-jump method (left), a voltage is rapidly applied to the membrane and the relaxation of the membrane current I is measured. In the charge-pulse method (right), the membrane capacitance is charged by a 50-ns electrical pulse to a starting potential of U_0. At the end of the pulse the outer electrical circuit is interrupted and the decrease in voltage due to charge transport within the membrane is recorded.

The time resolution of the voltage-jump method is limited by the charging time of the membrane capacitance and is approximately 1 μs. A considerably better time resolution is obtained with the charge-pulse relaxation method (Fig. 11).[68, 78, 86] In this case, the membrane capacitance is charged to starting voltage of approximately 10 mV by a current pulse of 10–50 ns duration. The outer electrical circuit is then interrupted and the relaxation of the voltage resulting from the movement of ions within the membrane is monitored. Using the charge-pulse relaxation method it is possible to achieve a time resolution of 40 ns.[87]

A further relaxation method consists in changing the temperature of the membrane and the surrounding solutions in a stepwise fashion. The temperature jump can be achieved by absorption of an intense flash of light.[88, 89] If a light source emitting in the visible region is used, an appropriately absorbing dye has to be added to the external medium.[71] Because of its small thickness, the membrane responds to the temperature changes in the medium within less than 1 ns. An improved version of this method makes use of an IR laser pulse to heat the solution (Fig. 12).[76] For the wavelength of the Nd glass laser ($\lambda = 1.06$ μm) the absorption coefficient of water is 0.063 cm^{-1}. This allows temperature jumps of approximately 0.3–0.4 K within 0.4 ms using the fixed Q-mode of the laser. In practice, a constant voltage is usually applied to the membrane prior to the temperature jump. The T-jump leads to an almost instantaneous increase in membrane conductivity, corresponding to the temperature dependence of the ion-transport system. This rapid increase in the membrane current is followed by a slower relaxation process due to translocation of carrier molecules within the membrane and changes in the degree of complexation.

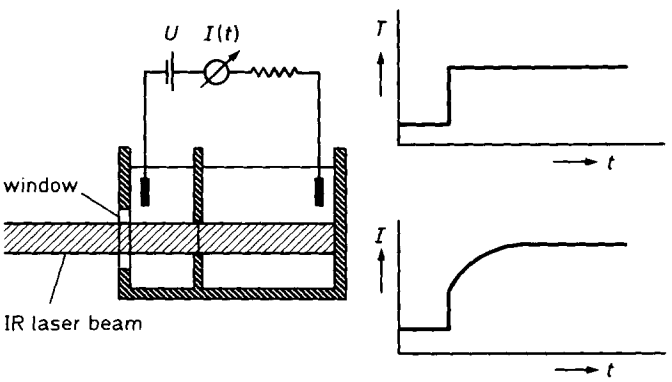

Fig. 12. Principle of the temperature-jump relaxation method. The membrane and the surrounding solutions are rapidly heated by absorption of an infrared laser pulse. A voltage U is applied to the membrane prior to the T-jump. The T-jump leads to a practically instantaneous increase in membrane conductivity (according to the temperature dependence of the rate constants), followed by slow relaxation processes.

The kinetic analysis of a carrier system such as valinomycin (Fig. 10) involves the determination of four rate constants (k_R, k_D, k_S, and k_{MS}). By the use of the voltage-jump method[60, 62, 63, 65, 67, 75, 90, 91] and the charge-pulse relaxation method,[68-70, 73] the ion carriers valinomycin, enniatin A and B, and beauvericin as well as the macrotetrolides have been studied in artificial lipid membranes. As a typical example, the rate constants for valinomycin-mediated K^+ transport through monooleate membranes at 25°C are given below:

$k_R \approx 3 \times 10^5\ M^{-1}\ s^{-1}$
$k_D \approx 3 \times 10^5\ s^{-1}$
$k_{MS} \approx 2 \times 10^5\ s^{-1}$
$k_S \approx 4 \times 10^4\ s^{-1}$

At a K^+ concentration of 1 M ($c_M = 1$ M) the rate constants for the association ($c_M k_R$), dissociation (k_D), and translocation of the charged carrier (k_{MS}) are approximately equal (2×10^5–$3 \times 10^5\ s^{-1}$). The rate-limiting step in this case is determined by the back-transport of the free carrier ($k_S \approx 4 \times 10^5\ s^{-1}$). $k_{MS} \approx 2 \times 10^5\ s^{-1}$ is the frequency with which the charged carrier crosses the membrane; its

reciprocal value, $1/k_{MS} \simeq 5\ \mu s$, is the average residence time of the complex in the energy minimum at the membrane-solution interface.

A useful parameter for the kinetic description of carriers (and other transport systems) is the maximum turnover number f, which is defined as the limiting value of the transport rate reached under short-circuit conditions with an infinitely high ion concentration on the left-hand side and a negligible ion concentration on the right-hand side of the membrane.[61] f is the maximum number of transport cycles that a carrier molecule can carry out per second. From the known values of the rate constants, the turnover number can be calculated using the following equation:

$$f = \left(\frac{1}{k_{MS}} + \frac{1}{k_S} + \frac{2}{k_D}\right)^{-1} \quad (1)$$

For the above example, $f \simeq 2 \times 10^4\ s^{-1}$ is obtained, which means that a single valinomycin molecule is able to transport 10^4–$10^5\ K^+$ ions per second through the membrane. The high efficiency of valinomycin as an ion carrier is mainly determined by its high turnover number. In contrast, the stability constant $K = k_R/k_D \simeq 1\ M^{-1}$ of the K^+ complex in the membrane-solution interface is remarkably small. Considerably higher values for the stability constant ($K \simeq 3 \times 10^4\ M^{-1}$) were found in methanol.[29] In methanol/water mixtures, however, K is smaller and at 70% (v/v) water in methanol reaches a value of approximately $1\ M^{-1}$.[29] A mixture of 30% methanol and 70% water is thus comparable to the membrane interface with respect to complex stability.[30] The same is true for the association and dissociation rate constants. In pure methanol $k_R \simeq 4 \times 10^7\ M^{-1}\ s^{-1}$ and $k_D \simeq 1.2 \times 10^3\ s^{-1}$ are found,[29] while for 70% water in methanol the extrapolated values are $k_R \simeq 1.4 \times 10^5\ M^{-1}\ s^{-1}$ and $k_D \simeq 1.8 \times 10^5\ s^{-1}$, similar to those found for the membrane.[30] From CD measurements, the stability constant of the valinomycin/K^+ complex in artificial dimyristocyl lecithin vesicles was found to be $K \simeq 1\ M^{-1}$.[29] This value agrees with that determined from relaxation experiments with planar lipid membranes.

4.2. Optimization Principles for Carrier Systems

The kinetic analysis described above leads to the general question of how to optimize carrier systems. In particular, it is interesting to ask how close nature has come to an optimal solution in the evolution of ion carriers. In order to achieve high transport rates it is advantageous to make all rate constants large, within the physical limits imposed on the system. The translocation rate constant k_S of the free carrier is limited by its size, by the microviscosity of the membrane, and by the binding of the amphiphilic carrier molecule at the membrane-solution interface. k_{MS} is also limited by membrane viscosity as well as by the height of the dielectric energy barrier of the membrane. It is therefore unlikely that, for a mobile carrier, k_S and k_{MS} will exceed the value of ca. $10^5\ s^{-1}$ observed for valinomycin. The association rate constant k_R, however, lies far below the limiting value for a diffusion-controlled reaction. The small value of k_R probably results from the fact that the carrier molecule at the membrane interface is stabilized in an open conformation which is less favorable for complex formation.

How large is the optimum value of the dissociation rate constant k_D for a given set of values of k_R, k_{MS}, and k_S? A very large value of k_D would obviously be a disadvantage since it would result in a decrease of the stability constant $K = k_R/k_D$. For a very small value of k_D, on the other hand, the transport rate would be limited by the slow dissociation of the complex MS^+ at the membrane interface. The optimum value of k_D can be calculated under the condition that for given values of k_R, k_{MS}, and k_S the membrane conductivity induced by the carrier should reach a maximum. This results in the following equation:[78]

$$k_D^* = [c_M k_R k_{MS}(2 + c_M k_R/k_S)]^{1/2} \quad (2)$$

Using the experimental values for k_R, k_{MS}, and k_S given above, $k_D^* \simeq 1 \times 10^5\ s^{-1}$ for $c_M = 0.1\ M$ is obtained, which agrees approximately with the observed value of $k_D \simeq 3 \times 10^5\ s^{-1}$. All macrocyclic peptide and depsipeptide analogues of valinomycin synthesized up to now have been found to be less efficient carriers than valinomycin itself.[27,72,92,93]

4.3. Influence of Membrane Structure on the Kinetics of Carrier Systems

Biological membranes contain a variety of lipids, which differ in the structures of their polar head groups, the lengths of their hydrocarbon chains, and the number of C=C double bonds. The functional significance of this diversity is not yet well understood. Using artificial bilayers prepared from chemically uniform lipids, it is possible to study the influence of membrane structure on the kinetics of carrier systems.[62,63,69,70,72,73,94–96]

The electrical charges and dipole moments of the headgroups influence the ion transport rates. Membranes consisting of phosphatidylserine or phosphatidylinositol have a negative interfacial potential; this results in an accumulation of cations at the membrane interface and in an increase in cation transport rates.[96] Oriented dipole layers at the interface result in an additional difference in the potential between the interior of the membrane and the aqueous solution.[95,97] From experiments with positively and negatively charged lipophilic ions, for example, it may be estimated that the potential of the interior of a phosphatidylcholine membrane is about +0.3 V relative to the external solution.[97] This electrostatic energy barrier inhibits the transport of cations and favors that of anions.

Variation in the length of the hydrocarbon chains of the lipid molecules and in the number of double bonds has a marked effect on the rate constants of ion carriers. Table 1 summarizes the kinetic parameters for the valinomycin/Rb^+ system in membranes formed from different monoglycerides.[69] An increase in chain length from C_{16} to C_{22} results in a decrease of the translocation rate constants k_S and k_{MS} by a factor of 8 to 10, whereas k_R and k_D remain almost constant. Increasing the number of C=C double bonds from one to four results in a marked increase of k_S

Table 1. Influence of the chain length and the number of double bonds of lipids on the rate constants for the valinomycin-mediated Rb^+ transport [69]. The membranes were formed from α-monoglycerides (MG) containing the following fatty acid residues: palmitoleoyl (16:1), oleoyl (18:1), 11-eicosenoyl (20:1), erucoyl (22:1), 11,14-eicosadienoyl (20:2), 11,14,17-eicosatrienoyl (20:3), and arachidonoyl (20:4). The membranes were spread from *n*-decane. $T=25°C$.

Lipid	k_R [10^4 M^{-1} s^{-1}]	k_D [10^4 s^{-1}]	k_{MS} [10^4 s^{-1}]	k_S [10^4 s^{-1}]
Variation of the chain length				
(16:1)-MG	43	13	74	8.5
(18:1)-MG	37	24	27	3.5
(20:1)-MG	23	12	10	1.8
(22:1)-MG	24	13	7	1.1
Variation of the number of double bonds				
(20:1)-MG	23	12	10	1.8
(20:2)-MG	34	9	39	3.2
(20:3)-MG	34	5	136	9.4
(20:4)-MG	42	3	240	12

and k_{MS}. This increase in translocation rate constants is probably due to the decreased order and smaller microviscosity of membranes consisting of highly unsaturated lipids.

5. The Gramicidin Channel

The simplest known molecule that forms ion channels in a lipid membrane is gramicidin A (Fig. 13), a linear pentadecapeptide with the sequence

HCO-NH-L-Val-Gly-L-Ala-D-Leu-L-Ala-D-Val-L-Val-D-Val-L-Trp-D-Leu-L-Trp-D-Leu-L-Trp-D-Leu-L-Trp-CO-NHCH$_2$CH$_2$OH

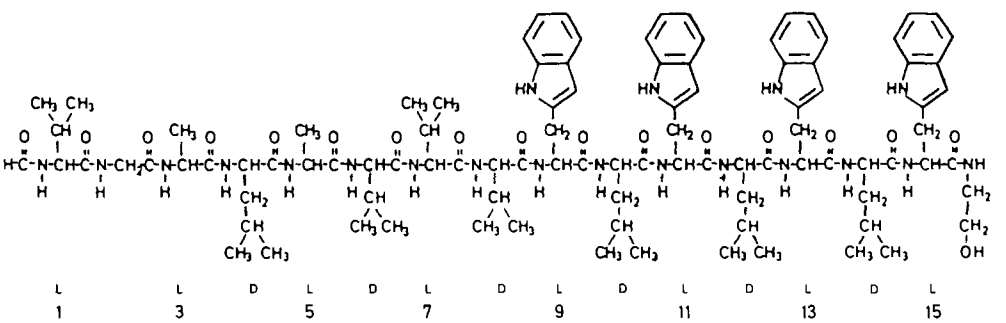

Fig. 13. Structure of valine-gramicidin A [98].

isolated from *Bacillus brevis* and exhibiting antibiotic activity.[98] Gramicidin A consists mainly of hydrophobic amino acids, and the end groups are blocked. In the presence of gramicidin A the permeability of biological membranes or artificial lipid membranes is strongly increased for small monovalent cations such as alkali metal ions, Ag^+, Tl^+, NH_4^+, and H^+.[53,54,99-102]

5.1. Single-Channel Experiments

The first evidence that gramicidin A acts as an ion channel and not as a carrier came from experiments in which an extremely small amount of the peptide was added to a lipid bilayer. Under these conditions, when a constant electrical voltage is applied to the membrane, discrete, stepwise variations of the membrane current are observed with amplitudes of approximately 8×10^{-12} A in 1 M Cs^+ solution and at 0.1 V (Fig. 14).[103] When increasing amounts of gramicidin A are added to the membrane, more and more current fluctuations superimpose until eventually the membrane reaches a macroscopic conductivity. The simplest explanation of these observations is to assume that the observed current fluctuations result from the formation and disappearance of single ion channels. The height of the current step corresponds to a single-channel conductivity of 80 pS (in 1 M Cs^+ solution), which is equivalent to the transport of 5×10^7 Cs^+ ions per second (at a voltage of 0.1 V). This transport rate is 3-4 orders of magnitude greater than the maximum transport rate of an ion carrier of the valinomycin type (Section 4.1). Therefore, gramicidin A presumably does not act as a carrier; the high transport rates observed, however, are perfectly compatible with a channel mechanism.[103]

The possibility of directly observing single molecular events within a membrane by current measurements is a consequence of the extremely small intrinsic conductivity of a lipid membrane. Recently, it has been possible to electrically isolate small areas of cell membranes with the aid of glass micropipettes and to monitor single-channel currents through biological ion channels.[105]

Detailed analysis of the experiment illustrated in Figure 14 shows that the amplitudes of the fluctuations in conductivity are not completely uniform but rather distributed about a mean value. The width of the distribution depends on the nature of the lipid.[106] Furthermore, gramicidin channels occasionally show single-channel events with much smaller amplitudes.[107] A possible explanation for these observations is to assume that the gramicidin channel may adopt several long-lived conformations (see Section 5.2) which have different ionic permeabilities.[107-110]

Single-channel experiments yield, apart from the channel conductivity, the life-time of the open state of the channel. Experimentally, one obtains for the probability dP of finding a channel with a lifetime between t and $t+dt$ the relation $dP=\exp(-t/\tau)dt$ as one would expect for a system of independent particles with a constant rate of decay.[103] The constant τ is the mean lifetime of the channel.

Although the channel conductivity is almost independent of the nature of the lipid (if the lipid is electrically neutral), the mean lifetime τ decreases rapidly with increasing chain length of the lipid (i.e., with increasing membrane thickness).[102, 111, 112] τ varies from milliseconds to seconds. A further parameter influencing the mean lifetime is the interfacial potential of the membrane.[112, 114–116]

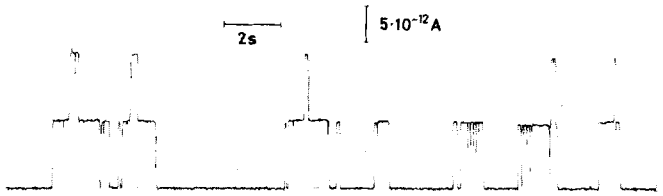

Fig. 14. Fluctuations in membrane current at very low gramicidin concentration [104]. 1 M CsCl, 25°C, membrane potential 0.1 V. The membrane was formed from monoolein. The base line represents the membrane conductivity in the absence of gramicidin.

5.2. The Structure of the Gramicidin Channel

A structural model for the gramicidin channel has been proposed by *Urry* based on calculations of the conformational energies.[117–119] It consists of a hydrogen-bond-stabilized helical dimer in which the two monomers are connected head-to-head at their formyl ends (Fig. 15 and 16). The hydrophobic amino acids side chains are located on the outside of the helix.[120] In the center of the helix, along the axis, a 0.4-nm-wide tunnel is present which is lined with the oxygen atoms of the peptide carbonyl groups. The diameter of 0.4 nm is sufficient to allow the passage of non-hydrated alkali metal ions. The total length of the dimer is 2.5 to 3.0 nm, which is somewhat less than the thickness of the hydrocarbon layer of a bimolecular lipid membrane. Conformational energy calculations show that the peptide carbonyl groups can tilt with their oxygen end toward the helix axis.[117–119] This "libration" allows the channel width to adjust to the diameter of the ion; the close approach of the negative end of the carbonyl dipole to the cation results in an energetically favorable interaction between ion and channel.

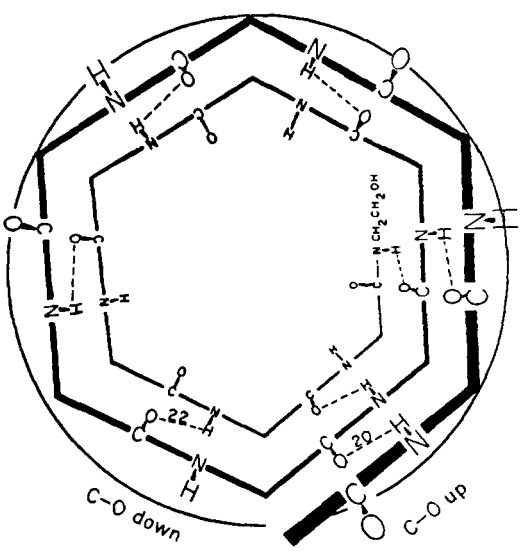

Fig. 15. Helical structure of the gramicidin A channel [121]. The 0.4-nm wide channel along the helix axis is lined with the oxygen atoms of the peptide carbonyl groups. The amino acid side chains, which are located at the outside of the helix, are not shown. The transmembrane channel consists of two helixes joined at their formyl ends.

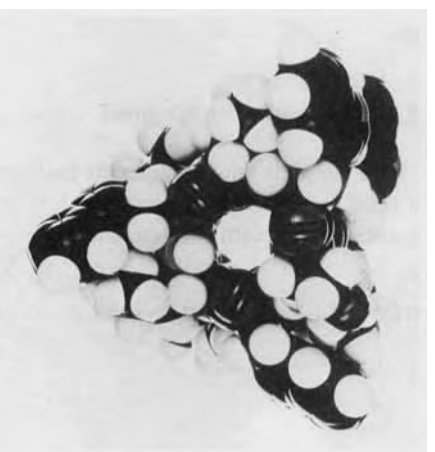

Fig. 16. Space-filling model of the gramicidin channel, according to *Urry* [118]. Left: the outside of the dimeric channel. The two monomers are joined by hydrogen bonds. Right: view along the helix axis. The central tunnel has a diameter of 0.4 nm.

Energy considerations also indicate that the channel can adopt a variety of stable conformations which differ in the orientation of the amino acid side chains.[108–110] The channel conformation may influence the channel conductivity, for example, due to the dependence of the electrostatic energy of the ion inside the channel on the orientation of the dipolar tryptophan residues. In addition, the libration of the carbonyl groups may be restricted to different extents for different side chain conformations.

X-ray diffraction studies of gramicidin have been possible to date only at low resolution,[122, 123] the results being compatible with a helical structure. It is interesting to note that the structure is different for the free dimer and the dimer occupied by a cation (K^+ or Cs^+). The helix diameter increases from 0.5 to 0.68 nm upon binding of a cation, and the length decreases from 3.2 to 2.6 nm.

Evidence for the dimeric structure of the channel was obtained from kinetic studies of channel formation (Section 5.3) as well as from experiments with pyromellityl derivatives of gramicidin (Section 5.4). A further test of the dimer hypothesis was performed by combining fluores-

cence and conductivity studies on membranes containing dansylated gramicidin.[133] In these experiments, a quadratic dependence of the membrane conductivity on the fluorescence intensity, and thus the concentration of the incorporated gramicidin, was observed, in accordance with the dimer model.

Spectroscopic investigations show that gramicidin A forms helical dimers in organic solvents.[124-132] Apart from head-to-head dimers, double-stranded helixes are observed in which both peptide chains are wound around a common axis and joined by intermolecular hydrogen bonds. The double-stranded helix was originally proposed as an alternative to *Urry*'s channel model.[127] The evidence for *Urry*'s model is based on measurements of membrane conductivity (Section 5.4) as well as on nuclear magnetic resonance experiments.[134-136] In particular, it was possible to prove via distance measurements based on spin-spin interactions that the carboxyl terminal end of the peptide is localized at the membrane interface whereas the amino terminal end is buried deep inside the hydrophobic part of the membrane.[134] Nuclear magnetic resonance experiments in which ^{13}C-NMR chemical shifts were measured in the presence of cations in the channel support the model of a left-handed β-helix.[136, 137]

5.3. Kinetics of Channel Formation

On the basis of the dimer model (Section 5.2) it is possible to describe channel formation as a bimolecular reaction:

$$G + G \underset{k_D}{\overset{k_R}{\rightleftharpoons}} G_2 \qquad (3)$$

The kinetics of this reaction can be investigated by relaxation measurements.[138, 140] The basis for the application of the voltage-jump or charge-pulse relaxation method lies in the fact that the number of active channels in the membrane is dependent on the transmembrane electrical field strength. If a voltage is rapidly applied at time $t=0$ to a membrane doped with gramicidin, an initial current is observed which is determined by the number of channels initially present. Subsequently, the current increases asymptotically toward a limiting value which corresponds to the voltage-induced shift in the equilibrium constant of channel formation. For the channel-formation reaction given by Equation (3), the reciprocal of the time constant τ_c for the increase in current should be linearly related to the square root of the stationary membrane conductivity λ_∞:

$$1/\tau_c = k_D + 4\sqrt{k_R k_D \lambda_\infty / L\Lambda} \qquad (4)$$

L is Avogadro's number and Λ the conductivity of a single channel. Equation (4) has been experimentally verified: measurement of τ_c and λ_∞ for a variety of gramicidin concentrations and plotting of $1/\tau_c$ versus $\sqrt{\lambda_\infty}$ results in a straight line.[138] Channel formation thus can be described as a second-order reaction in agreement with Equation (3). This does not exclude, however, more complicated mechanisms such as an equilibrium between inactive and active forms of the dimer or the association of inactive dimers to form an active tetramer.[142]

On the basis of the dimer model [Eq. (3)], the rate constants k_R and k_D can be determined from a plot of $1/\tau_c$ versus λ_∞. $1/k_D$ agrees within experimental error with the mean lifetime τ of the channel determined by single-channel experiments.[138, 139]

A totally independent method of studying the kinetics of channel formation consists in the analysis of electrical noise.[113, 143, 144] A bimolecular lipid membrane is thermodynamically a small system and is therefore subject to large fluctuations. In accordance with the statistical nature of channel formation, the number of channels and thus the membrane conductivity varies with time. Measurement of the correlation function or the spectral intensity of the current fluctuations allows the kinetic parameters of the channel system to be determined. Noise analysis provides the same information as a combination of relaxation experiments and single-channel measurements; furthermore, this method yields information on single-channel conductivity at high channel density. Thus, noise analysis offers the possibility of studying interactions between neighboring ion channels.[113]

5.4. Derivatives and Analogues of Gramicidin A. Effects of Electric Charges at the Channel Opening

Experiments with gramicidin channels open up the possibility of studying the relationship between structure and permeability properties of ion channels. To this end, a variety of derivatives and analogues of gramicidin A have been investigated.[104, 121, 141, 145-161] Synthetic analogues with a simplified sequence, e.g., HCO-NH-(L-Trp-D-Leu)$_7$-L-Trp-CO-NHCH$_2$CH$_2$OH, also form ion channels, but these exhibit different conductivities and altered selectivities.[152] Replacement of a single amino acid may lead to a considerable change in single-channel conductivity. For instance, replacement of tryptophan in position 11 by phenylalanine (see Fig. 13) results in a decrease in K^+ conductivity by a factor of 1.4.[106] Simultaneous changes in two different positions change the conductivity even more.[158] The variations in conductivity are likely to result from local effects of amino acid side chains on the geometry and flexibility of the ligand system. Furthermore, as discussed above, the potential energy of the ion inside the channel can be influenced by the introduction of side chains with electrical dipole moments.

Of particular interest are gramicidin derivatives carrying charged groups at the carboxyl or amino terminal ends.[148, 152, 154, 159, 162] Esterification of the ethanolamine residue at the carboxyl terminal end with pyromellitic acid results in the introduction of three negative charges at the mouth of the channel opening.[148] *O*-Pyromellitylgramicidin A (Fig. 17) forms ion channels in planar lipid membranes that exhibit opening and closing behavior similar to gramicidin A itself. Other properties of the neutral and negatively charged gramicidins, however, differ considerably, as described below.

Addition of *O*-pyromellitylgramicidin to one of the aqueous solutions bathing the membrane results in only a mar-

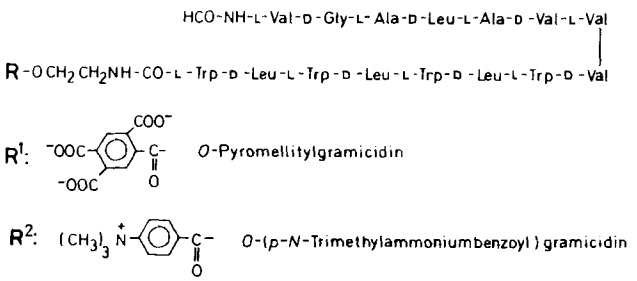

Fig. 17. Gramicidin derivatives with positively and negatively charged groups at the carboxyl terminal end, which is located at the opening of the channel.

ginal change in membrane conductivity. If the compound is subsequently added to the other solution, however, an increase in conductivity by several orders of magnitude is observed.[148] This result is in marked contrast to the behavior found for neutral gramicidin, where addition of the peptide to one side or to both sides simultaneously results in almost the same conductivity. These observations can be explained on the basis of the dimer model, assuming that both half-channels can combine only if they are located on opposite sides of the membrane. Unmodified gramicidin A can probably cross the membrane easily due to its highly hydrophobic character, whereas the negatively charged derivative remains on the side of the lipid bilayer to which it has been added. Simultaneous addition of *O*-pyromellitylgramicidin to both outer solutions leads to an increase in membrane conductivity proportional to the square of the peptide concentration,[148] in accordance with the dimer model.

Marked differences between neutral and negatively charged gramicidin are also observed in their single-channel conductivity Λ.[148] Whereas at high ion concentrations (1 M) the Λ values of the neutral and negatively charged channels are almost equal, at low ion concentrations (0.1 M) the conductivity of the negatively charged channel is 5 to 6 times higher (Fig. 18). This result is consistent with the notion that the negative charges at the channel opening should lead to an accumulation of cations capable of permeating the membrane. This accumulation effect is most pronounced at low ionic strength according to the Debye-Hückel theory of ionic interactions. Even greater electrostatic effects are observed when neutral gramicidin A is introduced into a negatively charged membrane.[163]

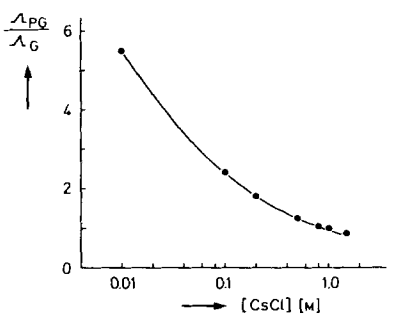

Fig. 18. Single-channel conductivity Λ_{PG} of the negatively charged *O*-pyromellitylgramicidin channel divided by the channel conductivity Λ_G of neutral gramicidin [148]. At low ionic strength, the negatively charged channel has a five- to sixfold greater conductivity than the neutral channel.

In the presence of a mixture of neutral and negatively charged gramicidin three types of channels with different conductivities are observed.[148] The channel with the highest conductivity is identical to the *O*-pyromellitylgramicidin channel and that with the smallest conductivity to the normal gramicidin channel. Presumably, therefore, the channel with intermediate conductivity is a hybrid consisting of one neutral and one negatively charged half-channel. Such hybrid channels, whose existence is predicted from the dimer model, have also been observed with other derivatives and analogues of gramicidin.[151,158]

A gramicidin derivative with a positive charge at the channel opening may be prepared by introduction of a *p*-trimethylammoniumbenzoyl group (Fig. 17). In this case the conductivity is less than that of the neutral channel.[152]

Channels exhibiting novel properties can be obtained by adding the positively charged peptide to one aqueous phase and the negatively charged peptide to the other. In this case hybrid channels, which consist of one positive and one negative half-channel, are formed inside the membrane.[152] This structural asymmetry is reflected in an asymmetric current-voltage behavior (Fig. 19). The channel

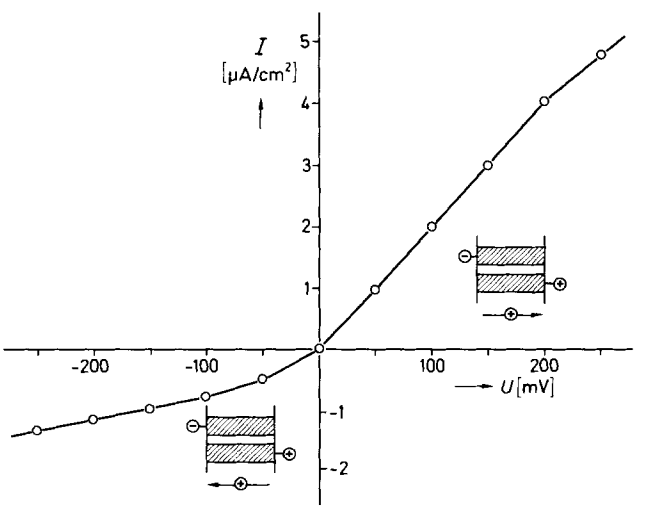

Fig. 19. Asymmetric current-voltage characteristic of hybrid channels, which are formed from a positively and a negatively charged half-channel (Fig. 17) [152]. The membrane current I was measured 1 ms after the voltage U was applied. The current is larger in the forward direction (cation flux from the negative to the positive channel end) than in the backward direction.

current increases much more in the "forward" direction (cation flux from the negative to the positive end of the channel) than in the "backward" direction. Chemical modifications thus allow preparation of ion channels with intrinsic rectifying properties.

Experiments with ionic derivatives of gramicidin may also be used to distinguish between different channel models. To this end, the membrane activity of the *N*-pyromellityl derivative of desformylgramicidin A, in which the formyl group at the amino terminus is replaced by a pyromellityl residue was studied.[162] In a double-stranded helix, both the amino terminal ends as well as the carboxyl terminal ends should lie at the membrane interface. Since the *O*-pyromellityl derivative is able to form channels, one

would expect, on the basis of the double-strand model, the *N*-pyromellityl derivative also to be active. For the *Urry* model, in which the amino terminal ends are located in the interior of the membrane (Section 5.2), a membrane activity would not be predicted since the localization of the negatively charged pyromellitic acid group in the apolar interior of the membrane is energetically unfavorable. Experimentally, channel formation is not observed with the *N*-pyromellityl derivative, in agreement with *Urry*'s model.[162]

5.5. Mechanism of Ion Transport through the Channel

Compared to an ion carrier such as valinomycin, the gramicidin channel exhibits a much smaller selectivity. Within the series of alkali-metal ions, the order of permeability is identical with the order of mobility of these ions in water ($Li^+ < Na^+ < K^+ < Rb^+ < Cs^+$). The permeability ratio $P(K^+)/P(Na^+)$ is only 3–4,[102] whereas for valinomycin $P(K^+)/P(Na^+)$ is greater than 10^3. The channel is virtually impermeable to anions and higher-valent cations. Ca^{2+} and Ba^{2+}, at high concentrations, block the passage of monovalent cations.[164–166]

The selectivity of an ion channel is influenced by the geometry and flexibility of the ligand system.[167] The preference for cations over anions can be explained by the favorable electrostatic interactions of the cation with the negatively charged oxygen atoms of the carbonyl groups. The fact that all alkali metal ions have comparable permeabilities (within a factor of 10) is probably connected to the aforementioned libration of the carbonyl groups. Presumably, a cation entering the channel loses only part of its hydration shell and migrates together with two water molecules, one preceding and one following, through the channel.[168, 179, 180]

Permeation experiments suggest that the gramicidin channel normally contains several water molecules. The water permeability of a gramicidin-doped membrane can be measured in two ways, either by application of an osmotic gradient or by isotope flux experiments.[169, 170] For small pores in which water molecules cannot exchange positions, the theory predicts that the ratio of the two permeability coefficients P_{osm}/P_{iso} is equal to the number N of water molecules inside the pore.[170] Experimentally, $N=6$ is obtained. This value of N was independently confirmed by measuring the so-called streaming potential.[170–172] A pore that simultaneously contains water molecules and ions should exhibit coupling between ion transport and water transport, and in a narrow pore such as the gramicidin channel (0.4 nm) the coupling should be rather strong.[178, 179] Any osmotically induced transport of water should therefore result in a transport of charge and should create (under open-circuit conditions) an electrical potential difference across the membrane. The experimentally measured streaming potential yields, under appropriate assumptions, a value for N of 6–7.[170]

The interaction of the ion with the ligands results in a series of local minima and maxima of potential energy along the transport pathway in the channel.[173–177] Superimposed on this potential is the dielectric interaction of the ion with the aqueous phase and the lipid. The dielectric interaction creates a broad energy barrier with a maximum in the middle of the membrane.[181, 182] This analysis gives a potential profile with one binding site at either end of the channel (Fig. 20). The energy barrier at the channel opening takes into account the existence of energetically unfavorable transition states between the fully hydrated and the ligand-bound states of the ion.

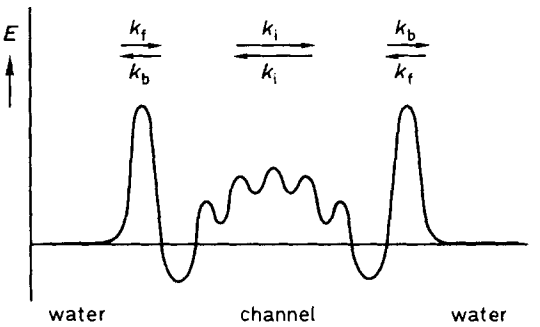

Fig. 20. Hypothetical potential-energy profile of a cation in the gramicidin channel. The potential profile results from a superposition of a broad dielectric energy barrier and local potential variations caused by interactions with the ligand system. The energy barriers at the openings take into account the (probable) existence of energetically unfavorable transition states between the completely hydrated and the ligand-associated states of the ion. k_i is the rate constant for ion jumps across the central barrier; k_f and k_b are the on and off rate constants for ion binding (when the second binding site is unoccupied).

The model illustrated in Figure 20 leads to the following predictions: if one binding site is occupied, the on and off rates for the other binding site should be altered by electrostatic ion-ion interaction. Furthermore, an ion should be able to leave one binding site and cross over the central barrier only if the other binding site is free. In fact, several experimental observations indicate ion-ion interactions inside the channel, e.g., the concentration dependence of permeability ratios,[102, 183] the blocking by Tl^+ ions,[183, 186] the exact form of the concentration dependence of channel conductivity,[103, 183, 185, 187] isotope interactions in flux experiments,[188] and the conductivity of short-chain gramicidin analogues.[189] Important information on the transport mechanism can also be deduced from the current-voltage characteristics of the channel.[103, 173, 190] These observations can be largely explained on the basis of the model in Figure 20 if one assumes that at high ion concentrations both binding sites can be occupied. The model is characterized by five rate constants (Fig. 20): k_i (crossing of the central barrier), k_f and k_b (on and off rate when the second binding site is unoccupied), and k_f^* and k_b^* (on and off rate when the second binding site is occupied). The values for the kinetic parameters summarized in Table 2 were obtained by fitting the model to the experimental data.[191, 192] According to the data given in Table 2, the first binding site is already occupied at ion concentrations of 1–10 mM ($k_b/k_f \simeq 8$ mM for Na^+). An interesting result is the large increase in the dissociation rate constant after occupancy of the second binding site ($k_b^*/k_b \simeq 600$). This agrees with the predicted electrostatic repulsion between the two ions. It is unclear, however, why a similar effect is not found for the association rate constants k_f and k_f^*. The data listed in Table 2 show that for high ion concentrations the channel

Table 2. Rate constants for ion transport through the gramicidin channel according to the model illustrated in Figure 20 [191]. k_i: rate constant for crossing over the central energy barrier; k_f, k_b: on and off rate constants when the second binding side is unoccupied; $k\dagger$, $k\ddagger$: on and off rate constants when the second binding site is occupied. The values in the first three columns were determined from conductivity and permeability measurements [191], the values in the last column from nuclear magnetic resonance studies [194].

	Cs^+	K^+	Na^+	Na^+ (NMR)
k_f [10^8 M^{-1} s^{-1}]	1.8	1.6	0.55	0.3
k_b [10^5 s^{-1}]	2.9	3.9	4.5	3
$k\dagger$ [10^8 M^{-1} s^{-1}]	1.6	1.4	0.53	0.12
$k\ddagger$ [10^8 s^{-1}]	1.6	2.1	2.6	0.4
k_i [10^7 s^{-1}]	8.2	2.7	1.3	>0.03

conductivity is limited by the rate constant for crossing the central barrier ($k_i \cong 10^7\ s^{-1}$). Values for k_i of this order of magnitude were also obtained from dielectric relaxation experiments.[196]

Nuclear magnetic resonance spectroscopy can also be used to study the transport kinetics of ions in the gramicidin channel.[193-195] For this purpose gramicidin A was introduced into lysolecithin micelles. From the concentration dependence of the rate of longitudinal relaxation of $^{23}Na^+$, the presence of one high-affinity and one low-affinity binding site for Na^+ was deduced. From the chemical shift of the ^{23}Na resonance and from relaxation data, an estimate for the binding constants $K = k_f/k_b$ and $K^* = k\dagger/k\ddagger$ was obtained. As shown in Table 2, the rate constants obtained by nuclear magnetic resonance agree within an order of magnitude with those obtained by conductivity measurements.

6. Introduction of Channel Proteins into Artificial Lipid Membranes

Biological membranes contain ion channels that are regulated by the electrical field in the membrane or by effector molecules such as acetylcholine. Examples are the Na^+ channel[197] of nerve membrane and the acetylcholine-activated channel in neuromuscular synapses.[6] The Na^+ channel of the nerve membrane is a glycoprotein whose main polypeptide chain has a molecular weight of $M \approx 260000$ g/mol. The acetyl-choline-activated channel has a molecular weight of 270000 g/mol and consists of five polypeptide subunits.

Channel proteins can be isolated from biological membranes by detergent solubilization. During the last few years methods have been developed to incorporate isolated membrane proteins into artificial lipid membranes.[8, 198] A phospholipid is added to the detergent-solubilized protein and the detergent is subsequently removed by dialysis. In this way, closed lipid vesicles are formed in which the protein is incorporated into the membrane. Addition of these lipid/protein vesicles to the external medium of a planar lipid membrane results, under appropriate conditions, in fusion of the vesicles with the membrane and incorporation of the protein. If the vesicle membrane and the planar membrane contain negatively charged lipids, the fusion can be induced by the addition of Ca^{2+} ions. An osmotic pressure inside the vesicle further promotes fusion.[199] An increased rate of fusion is observed at the characteristic temperature of the transition between the liquid crystalline phase and the gel-like phase of the membrane lipid.[200, 201]

An alternative to the fusion method consists in spreading lipid/protein vesicles on a water surface. From the monolayer obtained in this way, a bimolecular membrane can be formed by the technique described in Section 3.1. This method was applied to the incorporation of the acetylcholine-activated channel into planar bilayer membranes.[202-205]

It is also possible to incorporate channel proteins into planar lipid membranes without previous purification. This is achieved by mechanical fragmentation of cells followed by density gradient centrifugation. A membrane-vesicle fraction is thus obtained that can be fused with a planar membrane. Since, in general, a large number of different membrane proteins are incorporated into the planar membrane by this method, the desired channel protein must be identified either by its electrical properties or by its pharmacological behavior. This technique was used for the incorporation of Cl^- channels from the electric organ of the electric eel into an artificial membrane[206, 207] as well as for the incorporation of K^+ channels from sarcoplasmic reticulum[208-211] and from nerve endings,[212, 213] Ca^{2+}-dependent K^+ channels from muscle,[214, 215] and Na^+ channels from nerves.[216, 217] By the use of highly sensitive measurements of current (Section 5.1), the electrical properties of single channels can be studied after incorporation into the membrane (Fig. 21). Such reconstitution experiments also allow channels to be studied that are not accessible in situ due to an unfavorable cell geometry. This is the case, for instance, for the voltage-dependent Ca^{2+} channel from nerve endings (Fig. 21).[218] In the future, experiments using artificial membrane systems may become increasingly important for the study of structurally modified ion channels.

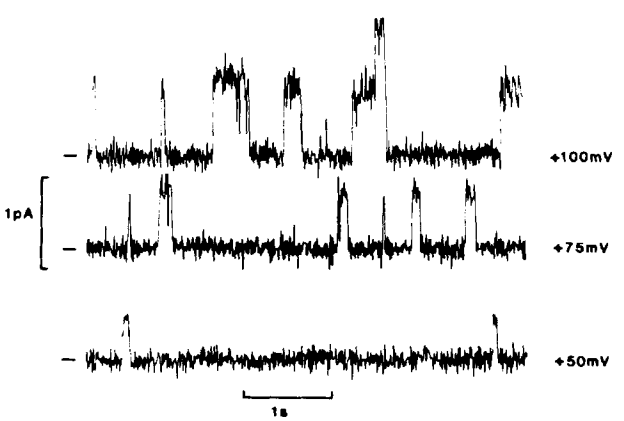

Fig. 21. Single-channel currents of Ca^{2+} channels from nerve endings at three membrane potentials [218]. The ion channels were incorporated into planar lipid membranes by fusion of nerve membrane vesicles. The probability for spontaneous opening and closing of channels depends on the applied voltage. The current level of the closed channel is marked by the horizontal line. The channels are permeable for Ca^{2+}, Sr^{2+}, and Ba^{2+}; in the experiment shown here, 0.25 M $BaCl_2$ was present in the aqueous phase.

7. Ion Pumps

The ion carriers and channels discussed so far are strictly passive transport systems; net transport is observed when a difference $\Delta\tilde{\mu}$ in the electrochemical potential of the permeable ion is present across the membrane as a driving force. $\Delta\tilde{\mu}$ can either be a concentration difference and/or a difference in electrical potential. Most biological membranes also contain active transport systems, which have the ability to transport ions against a thermodynamic potential gradient when energy is supplied. Depending on the kind of energy source, several types of active transport systems may be distinguished. In secondary active transport systems, the "uphill" transport of one substance is thermodynamically made possible by coupling it to the "downhill" transport of a second substance. The following discussion will only deal with primary active transport systems (ion pumps), which either use light, redox processes, or the free energy generated by the hydrolysis of adenosine triphosphate (ATP) as energy sources.

7.1. Light-Driven Proton Transport: Bacteriorhodopsin

Bacteriorhodopsin, a protein with a molecular weight of 26000 g/mol in the cell membranes of halobacteria, contains retinal as a chromophore and acts as a light-driven proton pump.[219,220] The protein is integrated into the bacterial membrane in the form of distinct patches which are two-dimensional protein lattices. These membrane areas can be isolated from the cells in the form of "purple-membrane fragments." After absorption of a photon, bacteriorhodopsin undergoes a cycle of conformational changes in the course of which one to two protons are transported from the cytoplasm into the extracellular medium. At the end of the cycle (after ca. 10 ms) the protein is again present in its initial state.

The individual states of the protein were at first characterized spectroscopically.[219] For instance, a fast *cis/trans* transition of the retinal was observed as an early event in the cycle. Still open is the question how the spectroscopically detected intermediates are correlated with the actual transport steps. Information about the transport kinetics is provided by experiments in which the purple membrane is associated in an oriented manner with a planar lipid membrane (Fig. 22).[221-227] After laser-pulse excitation at 575 nm (pulse length 10 ns), transient current signals are observed in the external circuit which originate from a charge redistribution within the bacteriorhodopsin molecule.[226] The first detectable signal has a time constant of $\tau \simeq 1$ µs and corresponds to a shift of the positive charge inside the purple membrane from the extracellular to the cytoplasmic side, i.e., in a direction opposite to that of stationary proton transport under constant illumination. This negative signal probably results from intrinsic charge displacements within the protein associated with a conformational change.[226-232] It is followed by charge displacements in the positive direction (from the cytoplasmic side to the extracellular medium) with time constants $\tau_2 \simeq 20$, $\tau_3 \simeq 60$, and $\tau_4 \simeq 400$ µs. On the basis of the pH dependence and H/D isotope effects, it is possible to assign the different charge displacements to specific spectroscopically detected transitions. From the amplitudes of the observed photoelectric signals, information can be obtained about the relative contributions of the individual events to the total charge displacement.

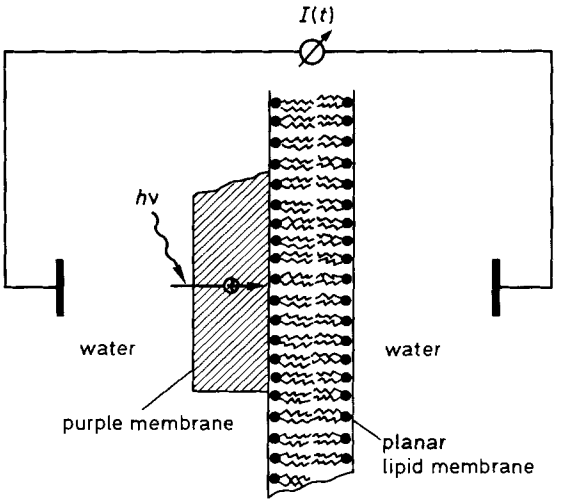

Fig. 22. Arrangement for carrying out photoelectric experiments with bacteriorhodopsin [226]. The purple membrane contains bacteriorhodopsin in the form of a two-dimensional lattice. After addition to the aqueous phase, the purple membrane binds with the extracellular side to the lipid bilayer. Charge transport within the bacteriorhodopsin molecule after flash excitation creates a current signal in the outer circuit.

7.2. Reconstitution of the Sodium-Potassium Pump

Most animal cells have the ability to maintain a high K^+ concentration and a low Na^+ concentration in the cytoplasm relative to the concentration of these two ions in the external medium. Responsible for the active transport of Na^+ and K^+ ions is a protein embedded in the cell membrane, the Na^+,K^+-ATPase, which transports K^+ into the cytoplasm and Na^+ into the extracellular medium at the expense of the free energy of ATP hydrolysis.[233-235] Under physiological conditions, the hydrolysis of one ATP molecule leads to the transport of three Na^+ ions to the outside and two K^+ ions to the inside. The Na^+,K^+ pump is thus (like bacteriorhodopsin) electrogenic, i.e., the pumping activity is associated with net charge transport. Using detergents it is possible to isolate the Na^+,K^+ pump from the cell membrane. The protein, which consists of an α subunit ($M \simeq 110000$ g/mol) and a β subunit ($M \simeq 40000$ g/mol), most likely has the dimeric structure $\alpha_2\beta_2$ inside the membrane.

Reconstitution of the Na^+,K^+-pump in planar lipid membranes has not yet been achieved. It is possible, however, to incorporate the Na^+,K^+-ATPase in a functional form into lipid vesicles.[236-246] Solubilization of the protein in a detergent (e.g., cholate) and removal of the detergent by dialysis after addition of a phospholipid (e.g., phosphatidylcholine) leads to the formation of lipid vesicles formed from monolayers and containing the protein incorporated into the membrane (Fig. 23). Whereas the Na^+,K^+-ATPase is always present in the cell membrane with its ATP binding site oriented toward the cytoplasm, it exhibits both orientations in reconstituted vesicles. Addition of ATP to the external medium leads only to activa-

tion of those ATPase molecules whose ATP binding site faces toward the outside (Fig. 23).

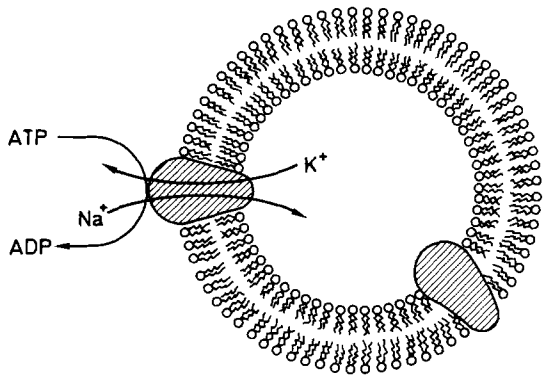

Fig. 23. Reconstitution of the Na^+, K^+ pump in artificial lipid vesicles [246]. Protein-containing vesicles form spontaneously when the detergent is removed by dialysis from a mixture of protein, lipid, and detergent in water. The outer diameter of the lipid vesicle is approximately 90 nm. After addition of ATP to the external medium, only those ATPase molecules are activated that are orientated with their ATP binding site toward the outside.

Reconstituted systems open up the possibility of varying the composition of both aqueous phases as well as the lipid composition of the membrane. In this way, many experiments can be carried out that would be difficult or impossible to perform with whole cells. In particular, the ATP-driven Na^+ and K^+ fluxes may be measured over a wide range of concentrations of ATP, adenosine diphosphate (ADP), P_i, K^+, and Na^+. For the measurement of Na^+ and K^+ fluxes radioactive ions may be used. The time resolution of such isotope experiments, however, is only of the order of seconds since it is limited by the time required to remove the samples. Better time resolution can be achieved using a recently developed optical method.[246] This method consists in monitoring the K^+ concentration inside the vesicle via the Nernst potential. Addition of valinomycin makes the vesicle membrane selectively permeable for K^+; an electrical potential is thus formed across the membrane (the Nernst potential U) which is dependent on the ratio of the K^+ concentration outside to that inside the membrane, c_K^o/c_K^i.

$$U = \frac{RT}{F} \ln \frac{c_K^o}{c_K^i} \tag{5}$$

R is the gas constant, T the absolute temperature, and F Faraday's constant). Since it is impossible to introduce an electrode into a vesicle having a diameter of 100 nm, the potential U has to be measured indirectly. This is achieved by introducing into the vesicle membrane a fluorescent dye whose absorption and emission properties depend on the transmembrane electrical field.[247] After calibration using a known concentration ratio c_K^o/c_K^i, the membrane potential can be determined from the measured fluorescence intensity. In the experiment illustrated in Figure 24, ATP was added to the external medium at time $t=0$. From the time dependence of the membrane potential U, the time course of the K^+ concentration inside the vesicle can be obtained and thus the ATP-driven K^+ flux can be determined for a given c_K^o using Equation (5).[246]

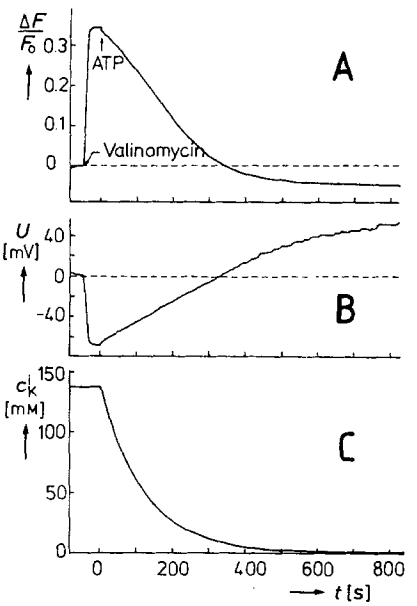

Fig. 24. Optical measurement of ATP-driven transport of K^+ in artificial lipid vesicles [246]. Each vesicle contains on the average three to five ATPase molecules, which are oriented with their ATP binding site facing outward. The initial concentrations inside and outside were: $C_{Na}^i = 10$ mM, $C_K^i = 140$ mM, $C_{Na}^o = 140$ mM, $C_K^o = 10$ mM. At time $t=0$, 250 μM ATP was added to the outside. A: Relative fluorescence change $\Delta F/F_0$ of the dye (1,3,3,1',3',3'-hexamethylindodicarbocyanine); B: Membrane potential U; C: internal K^+-ion concentration c_K^i. T = 16 °C.

8. Theoretical Concepts for the Description of Ion Transport through Channels

For the microscopic description of ion transport through channels, it is useful to introduce the potential profile of an ion along its transport pathway, which consists of a series of potential minima and maxima. Potential minima are located at positions where the ion is surrounded in an energetically favorable manner by ligand atoms. The movement of an ion through the channel may thus be described as a series of thermally excited jumps across energy barriers.[173-175,248] According to the theory of absolute reaction rates,[248] the rate constant k' for jumps across an energy barrier of height E is approximately given by the following relationship:

$$k' = \nu \cdot \exp(-E/kT) \tag{6}$$

where $\nu \simeq 10^{12}$–$10^{13}\ s^{-1}$ is the oscillation frequency of the ion in the potential minimum and k the Boltzmann constant. From the rate constants for the jumps across the individual barriers it is possible to calculate the total rate of transport through the channel.[173]

8.1. Channels with Multiple Conformations. Relationship between Carrier and Channel Mechanisms

The traditional application of reaction-rate theory is based on the (implicit) assumption that the potential profile of a channel is fixed, i.e., independent of both time and the movement of ions inside the channel. This corresponds to a purely static view of channel structure. Recent investi-

gations, however, have shown that proteins can adopt a variety of different conformations and that at physiological temperatures they can rapidly undergo transitions between different states.[249,250] Evidence for the dynamic nature of protein structure comes from X-ray diffraction and Mössbauer studies,[251,252] fluorescence depolarization experiments,[253] and nuclear magnetic resonance measurements.[254] These and other studies have shown that the time scale for the internal motions of proteins covers an extremely wide range, from picoseconds to seconds.

Of special interest is the coupling between conformational transitions of a channel protein and ion movements inside the channel.[255–258] Such coupling may arise, for example, from the electrostatic interactions between the ion and the ligand system. Binding of an ion to a binding site may result in a reorientation of the neighboring ligand dipoles due to the strong coulomb field of the ion. Coupling between conformational changes and movement of ions will occur when the time required for the conformational change is similar to or greater than the mean residence time of the ion at the binding site. In this case, the channel conductivity explicitly depends on the rate constants for the conformational transitions.[256–258]

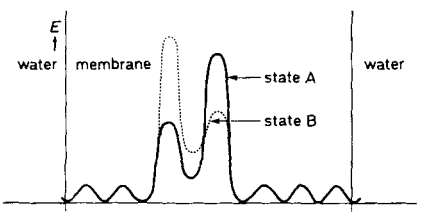

Fig. 25. Potential profile of an ion inside a channel that fluctuates between two states A and B. The channel contains a single (main) binding site which is separated from the aqueous phases by rate-limiting barriers. Further, low-energy barriers (not rate limiting) are located near the channel openings.

The example illustrated in Figure 25 depicts a channel with a single binding site which is separated from the aqueous phases by two rate-determining barriers. The conformation of the channel protein fluctuates between two states A and B having different potential profiles. State A may be the preferred state of the channel when the binding site is unoccupied and state B the preferred polarized state when the binding site is occupied. The dependence of the average conductivity Λ on the ion concentration c is given by the following equation:[256]

$$\Lambda(c) = \frac{z^2 e_0^2}{kT} \cdot \frac{\alpha c + \beta c^2}{\gamma + \delta c + \varepsilon c^2} \tag{7}$$

z is the valency of the ion, e_0 the elementary charge and α, β, γ, δ, and ε concentration independent combinations of the rate constants for transitions between the different states of the channel. Thus, the channel conductivity is a nonlinear function of the ion concentration c containing terms proportional to c^2. For a channel with only one binding site and a fixed potential profile, theory predicts a simple saturation behavior:[173]

$$\Lambda(c) = \frac{z^2 e_0^2}{kT} \cdot \frac{pc}{q + rc} \tag{8}$$

p, q, and r are concentration-independent constants. Deviations in channel behavior from that described by Equation (8) are commonly interpreted by the assumption of ion-ion interactions inside the channel or by the introduction of regulatory ion binding sites. For the case discussed here of a channel with conformational fluctuations, the appearance of the quadratic terms in Equation (7) results from coupling between ion transport and conformational transitions.

A particularly strong coupling occurs if in one conformational state the barrier on the right-hand side is very high (binding site accessible only from the left-hand side) and in the other conformational state the barrier on the left-hand side (Fig. 26). In this case, the channel conductivity is extremely small for either state; however, ion transport is possible by a cyclic sequence of ion jumps and conformational changes, which lead to an alternating exposure of the binding site to the right- and left-hand side.[257,259–261] In this case the channel approaches the kinetic behavior of a carrier. This means that carrier and channel mechanisms cannot be strictly distinguished. Carrier-like behavior and the behavior of channels with a fixed structure should be regarded as limiting cases of a more general transport mechanism represented by a channel with multiple conformational states.

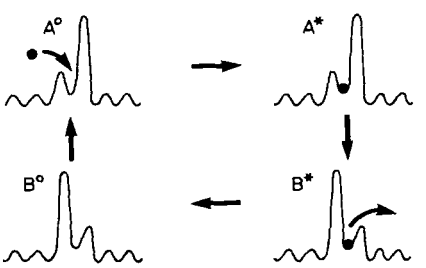

Fig. 26. Carrier-like behavior of an ion channel. In conformation A, the barrier towards the right is high (binding site mainly accessible from the left side), while in conformation B the left-hand barrier is high. During the cycle $A^\circ \rightarrow A^* \rightarrow B^* \rightarrow B^\circ \rightarrow A^\circ$, an ion is transported from the left to the right.

8.2. Energy-Driven Cyclic Conformational Transitions: Ion Pumps

The concept of a channel exhibiting multiple conformational states can also be applied to the description of active ion transport. An ion channel acts as a pump if the potential profile is transiently modified in an appropriate way by an energy-supplying reaction.[259–263] Absorption of a photon or phosphorylation of the channel protein can change the affinity of an ion binding site and simultaneously alter the height of the neighboring energy barriers. In this way an ion can leave the binding site preferentially in one direction; after the protein has returned to the initial state, another ion may enter the binding site from the opposite direction.

Figure 27 illustrates the simplest model of an ATP-driven proton pump. (H^+-transporting ATPases have been found, for example, in plant cell membranes.[264,265]) In the dephosphorylated state (HC) of the pump, the binding site, which is accessible from the left-hand (cytoplasmic) side, is occupied by a proton. Phosphorylation of the protein

leads to the state HE in which the energy barriers are altered in such a way that the proton is released preferentially to the right-hand (extracellular) side. After dissociation of H^+, the protein is dephosphorylated and adopts conformation C, which exhibits a low barrier on the cytoplasmic side. The ground state HC is reached again after binding of H^+ from the cytoplasmic side. During the cycle HC→HE→E→C→HC, a proton is transported from the cytoplasm to the extracellular medium.

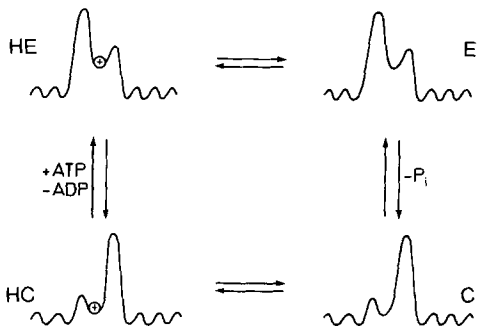

Fig. 27. Minimal model for a proton pump driven by ATP hydrolysis. In the dephosphorylated state (HC/C) of the pump, the proton-binding site is accessible from the left (cytoplasmic) side; in the phosphorylated state (HE/E), from the right (extracellular) side. During the cycle HC→HE→E→C→HC, a proton is transported from the cytoplasm to the extracellular medium (for abbreviations see text).

The ATP-driven ion pump thus represents a thermodynamic "machine" which uses the free energy of the reaction ATP→ADP+P_i to build up a concentration gradient (and/or a potential gradient). For maximum efficiency of energy conversion, two conditions have to be fulfilled. First, the energy barriers on both sides of the binding site have to be very different so that the ion cannot leave the binding site in the "wrong" direction, and, second, a spontaneous dephosphorylation (cleavage of P_i from the phosphorylated protein) is only permitted in the deprotonated state E and not in the protonated state HE. If these conditions are met, the free energy ΔG of ATP hydrolysis can be completely converted into osmotic or electrical energy. Since proton transport is associated with charge transport, the maximum possible concentration ratio $[H^+]_e/[H^+]_c$ is dependent on the membrane potential $U=\psi_c-\psi_e$ (the subscripts c and e refer to the cytoplasmic and the extracellular side, respectively; ψ is the electrical potential). For a proton pump with a stoichiometric ratio of 1 H^+ : 1 ATP, the maximum possible concentration ratio is given by the following equation:

$$\frac{[H^+]_e}{[H^+]_c} = \exp\left(\frac{UF-\Delta G}{RT}\right) \qquad (9)$$

For $\Delta G \simeq -50$ kJ/mol and $U=-0.1$ V, $[H^+]_e/[H^+]_c = 1\times10^7$ is obtained. In practice, the observed values for $[H^+]_e/[H^+]_c$ are considerably lower than this thermodynamic maximum; this results from the existence of parallel passive transport pathways for H^+ through the membrane as well as incomplete coupling between ATP hydrolysis and proton transport.

9. Summary and Outlook

The basic structure of biological membranes consists of a bilayer of oriented lipid molecules, which is almost impermeable to ions. Ion transport across the membrane depends on the presence of specialized transport molecules that are integrated into the lipid layer. Two limiting cases for such transport mechanisms can be distinguished: ion carriers and ion channels. An ion carrier is a transport molecule with an ion binding site that is accessible (due to a conformational change or a movement of the carrier relative to the membrane) from one side or the other in an alternating fashion, but not from both sides simultaneously. An ion channel, on the other hand, is a transmembrane pathway that is simultaneously open at both ends. Ion transport across the channel can be linked to a conformational change of the channel protein; in this way an ion channel may approach the kinetic properties of a carrier. Since the membrane is only about 5 nm thick, the electrical field inside the membrane is extremely large (of the order of 10^7 V/m) at physiological membrane potentials (≈ 0.1 V). In nerve excitation, the permeability of ion channels is modulated by field-induced conformational changes.

Carriers and channels are passive transport pathways; net ion transport occurs only if the electrochemical potential of the ion is different on both sides of the membrane. Active transport systems, on the other hand, have the ability to transport ions against a thermodynamic potential difference at the expense of energy. In the case of primary active transport systems (ion pumps), the energy is supplied by the hydrolysis of ATP or the absorption of light. The mechanism of active transport systems such as the Na^+, K^+ pump is only partly understood at present; a number of experiments indicate that the transport protein undergoes an energy-driven cycle of conformational changes during which an ion is bound in a first step from one side and is released in a later step to the other side.

In the investigation of biological transport systems, artificial lipid membranes have been widely used. Planar lipid bilayers with areas of 10 μm^2 to 10 mm^2 can be formed from chemically homogeneous lipids in aqueous medium. After incorporation of a biological ion transport system into the artificial membrane, the electrical properties of the transport system can be studied under defined conditions. A number of small to medium-sized transport molecules that act as ion carriers or ion channels have been studied in detail. For the K^+-specific carrier valinomycin, transport rates of 10^4–10^5 s^{-1} per single molecule have been found from electrical relaxation experiments. The rate of the individual transport steps depends strongly on the structure of the membrane lipid.

Substantially higher transport rates (10^7–10^8 s^{-1}) are observed for ion channels. A model compound for the study of the mechanism of ion transport through channels is gramicidin A, a hydrophobic pentadecapeptide isolated from *Bacillus subtilis*. Gramicidin A forms helical channels in lipid membranes, which are generated by a head-to-head association of two monomers. Along the helix axis a "tunnel" of 0.4 nm diameter is present which is lined by carbonyl oxygen atoms. The gramicidin channel is permea-

ble to small monovalent cations (alkali metal ions, NH_4^+, H_3O^+). Because of the high rates of ion transport, it is possible to detect the formation and decay of single gramicidin channels by sensitive current measurements. Investigations on gramicidin channels open up the possibility of studying the relationship between chemical structure and transport properties of an ion channel. Gramicidin analogues with modified amino acid sequences show changes in both transport rates and ion specificity. Introduction of charged residues at the channel openings permit the formation of ion channels with rectifying properties.

Methods are now available for the incorporation of large membrane proteins such as ion channels from nerve membranes or ion pumps into artificial lipid membranes. This permits the use of a variety of methods which previously have been applied to small transport molecules. Interesting prospects result from the possibility of incorporating membrane proteins obtained by cell-free protein synthesis directly into an artificial lipid membrane. Gene technology allows the synthesis of transport proteins with specific amino acid substitutions at particular positions in the sequence. The functional characterization of such modified transport proteins is likely to make substantial contributions to the understanding of ion transport mechanisms.

The results presented in this article are based on the work of numerous colleagues and collaborators. Special thanks go to H. Alpes, H.-J. Apell, E. Bamberg, R. Benz, A. Fahr, E. Frehland, K. Janko, H.-A. Kolb, M. Marcus, G. Stark, and W. Stephan. The work from my laboratory was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Phosphorus, Arsenic, Antimony, and Bismuth Multiply Bonded Systems with Low Coordination Number— Their Role as Complex Ligands

By Otto J. Scherer*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Multiply bonded systems with low coordination number (one to three) involving phosphorus and its homologues, whether isolable or generated *in situ* at a metal complex, are versatile ligands that can function as two-, four-, six- or eight-electron donors to transition metal fragments and that may be coordinated in η^1 (terminal), η^2 (side-on), edge- or face-bridging modes. The (p-p)π bonding system of the ligand is thereby rendered capable of addition and intra- or intermolecular cycloaddition reactions. Some of the polycyclic species thus generated represent novel, polydentate ligands.

1. Introduction

The textbook theories explaining the nonexistence of certain groups of compounds[1] (noble gas compounds, N_2-complexes, isolable compounds with multiple bonds between 2p-elements and those lower in the periodic table or between the latter only) disappeared gradually in the early 1960's as these compounds began to be discovered. It is obvious from the new (fourth) edition of the standard text of *Cotton* and *Wilkinson*[2] that the necessary changes of attitude are not easy; nitrogen is ascribed very strong (p-p)π bonds, phosphorus unstable (p-p)π bonds. However, the following multiply bonded systems (Scheme 1) with low coordination number, all stable at room temperature, have been known for many years (phosphorus compounds are presented as representative of these compounds).

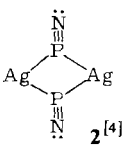
:P≡	R–C≡P	trivalent phosphorus, coordination number 1 (σ^1, λ^3–P)
	A	R = CMe_3, adamantyl, $SiMe_3$ etc.
=P:	X=P–R	trivalent phosphorus, coordination number 2 (σ^2, λ^3–P)
	B	X = R'_2C, C=O, C=NR' etc., R'E (E = N, P, As, Sb)
–P=	R–P(=X)–Y	pentavalent phosphorus, coordination number 3 (σ^3, λ^5–P)
	C	X = R'_2C, O, S, Se, R'N etc. Y = R'_2C, S, R'N etc.

Scheme 1. Low-coordination number multiply bonded systems of phosphorus.

The preferred substituents R and R' are often the sterically demanding groups *tert*-butyl, trimethylsilyl, mesityl, tris(*tert*-butyl)phenyl, adamantyl, bis(trimethylsilyl)amino, *tert*-butyl(trimethylsilyl)amino, and bis- or tris(trimethylsilyl)methyl. In contrast to classes **A** and **C**, **B** is represented also by acyclic or cyclic compounds in which the P-atom is replaced by its homologues. There are few current research topics to which so many and so varied review articles[3] have been dedicated in so short a time, but these have been concerned predominantly with the synthesis, reactivity, and structure of such compounds; the associated ligand behavior, intensively studied for about five years, has been poorly covered. It is the purpose of this review to present the chemistry of ligands of the types **A** to **C** and also of derivatives that can only be generated and stabilized at a metal center.

2. Multiply Bonded Systems with Ligand Coordination Number One

2.1. Terminal and Bridging Coordination of PN and E_2 (E = P, As, Sb, Bi)



These ligands, characterized in the gas phase or in an inert matrix, can be stabilized in a complex in various ways.

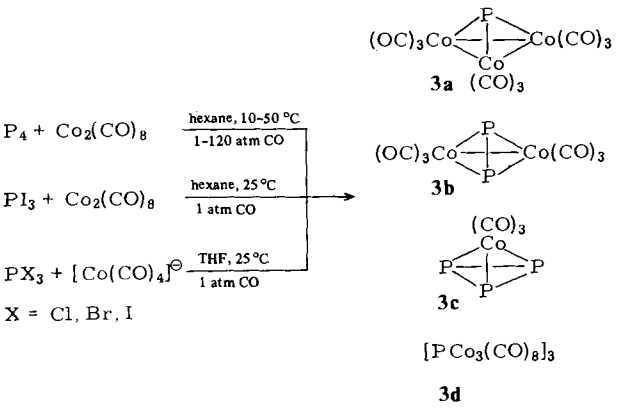
2.1.1. 2e-Donor Ligands

$$P_3N_5 \xrightarrow{\Delta} :P{\equiv}N: \xrightarrow[10\ K,\ krypton]{Cu,\ Ag,\ Au\ atoms}$$

:N≡P: →M← :P≡N:

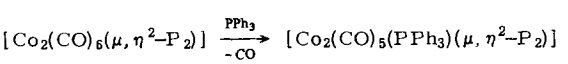
1, M = Cu, Au[4]

2[4]



IR-spectroscopic measurements formed the basis for the suggested structures: **1** with terminal, **2** with μ-P coordination.[4]

2.1.2. 4e-Donor Ligands

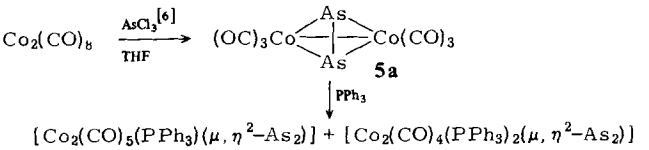


These most intensively studied μ,η^2-coordination types of the P_2 or As_2 molecule can be synthesized by a wide range of reactions.

[*] Prof. Dr. O. J. Scherer
Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (FRG)

The first metal-phosphorus tetrahedranes **3a–d** were synthesized using $Co_2(CO)_8$ or $[Co(CO)_4]^{\ominus}$ and P_4 or PX_3 (X = Cl, Br, I) as the source of $(OC)_3Co$ and P_x respectively[5a,b] (THF = tetrahydrofuran).

The Co_2P_2 tetrahedrane structure was demonstrated by an X-ray structure analysis (Table 1) of **3e**,[5c] the Ph_3P substitution product of **3b**.



3b **3e**[5a,c]

The reaction of **3b** with $W_2(OiPr)_6(py)_2$ allows the transfer of the P_2 unit to tungsten at room temperature with the elimination of pyridine.[5d]

3b **4**[5d]

The pioneering experiment that stabilized an N_2 homologue at a metal complex goes back to 1969. **5a** was synthesized from $Co_2(CO)_8$ and $AsCl_3$ (excess) and characterized by X-ray methods as the Ph_3P derivatives **5b** and **5c**[6] (Table 1).

5b[6] **5c**[6b]

The transformation of $[(CO)_4Fe]_3(P_4)$ to the polymeric P_2-complex $[(CO)_3Fe(P_2)]_n$ can be brought about thermally or photochemically.[7]

A further 15e metal-ligand fragment suitable for constructing M_2E_2 clusters is $Cp(CO)_2M$ (M = Mo, W). The As_2-compounds **6a, b** are formed by the co-thermolysis of $(AsC_6H_5)_6$ and $[Cp(CO)_3Mo]_2$(*Mo–Mo*) or $CpW(CO)_3H$,[8a] or by the reaction of a trinuclear μ_3-As metal complex with

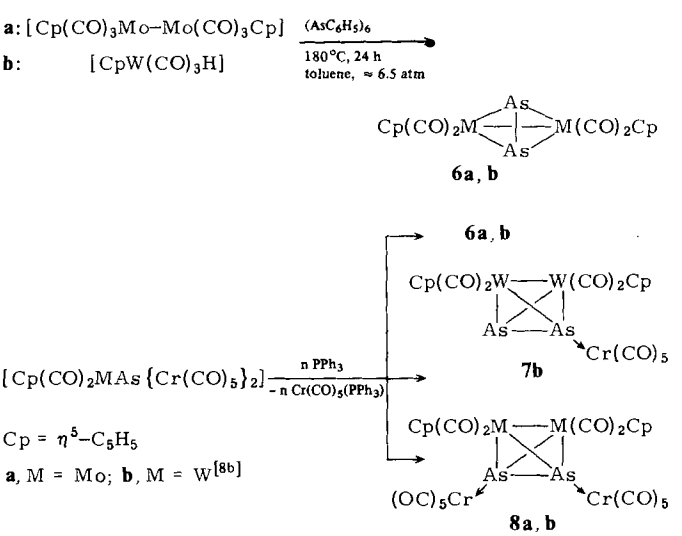


Table 1. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz), metal-metal and E-E bond lengths [Å] in complexes with an M_xE_y framework. Cp = η^5-C_5H_5, Cp* = η^5-C_5Me_5. Gas-phase bond length of P_2 for comparison: 1.875 Å (D. E. C. Corbridge, *The Structural Chemistry of Phosphorus*, Elsevier, New York 1974).

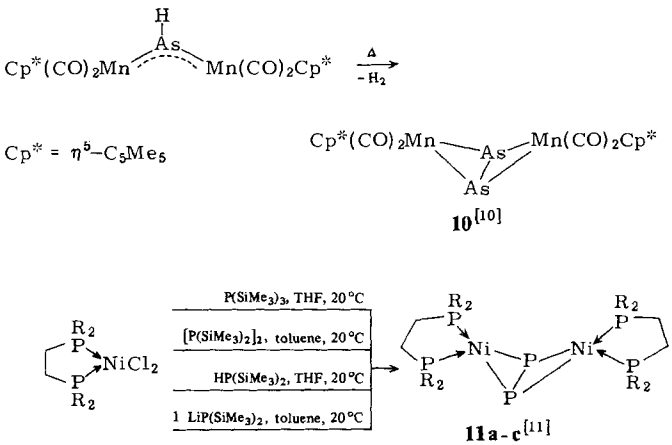
[a] Two independent molecules in the asymmetric unit. [b] AA'XX' spin system.

triphenylphosphane; the latter reaction also permits the isolation of **7** and **8**, products showing further complexing of the As_2 ligand.[8b]



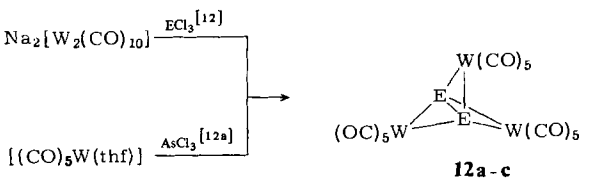
The C_5Me_5 analogue of **6a** is formed by the reaction of $[(C_5Me_5)(CO)_2Mo]_2(Mo{\equiv}Mo)$ with As_4S_4.[8c]

White phosphorus and $[Cp(CO)_2Mo]_2(Mo{\equiv}Mo)$ are suitable reactants for the preparation of molybdenum-phosphorus tetrahedranes **9**.[9a]

9a[9] **9b**[9a]

The butterfly form of the M_2E_2 framework is obtained by employing a 16e- or 14e-fragment M as partner for the As_2 or P_2 ligand, as for **10**[10] and **11**.[11]

10[10] **11a-c**[11]

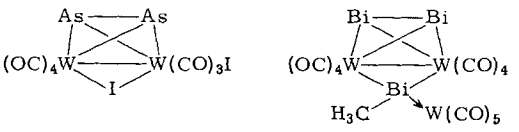


a, R = C_2H_5; **b**, R = C_6H_5; **c**, R = *c*-C_6H_{11}

The X-ray structure analysis (for E-E and M-M bond lengths see Table 1) confirms the butterfly structure for **10** and **11** and the tetrahedrane structure for **3e**,[5a,c] **4**,[5d] **5b**, **c**,[6] **6a**, **b**,[8a,b] and **9b**.[9a]

2.1.3. 6e-Donor Ligands

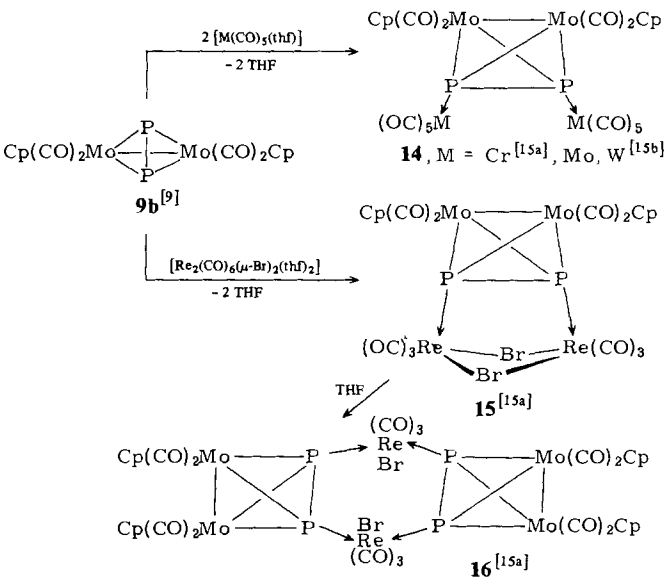
The most interesting variant of this coordination mode was realized in the chemically and aesthetically striking, star-shaped molecules **12**;[12] the E≡E unit is side-on bonded.



EHT calculations[12a] (cf. the investigations of π-bonded N_2 complexes[13]) on $(L_5W)_3As_2$ model compounds show that a strong π-acceptor interaction of the As_2 molecule

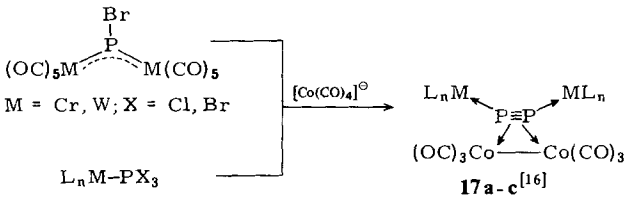
12a-c

a, E = As[12a]; **b**, E = Sb[12b]; **c**, E = Bi[12c]



with the ligand fragments of the metal is of importance. In **12** all six bonding electrons of the axial E_2 ligand take part in the coordinative bonding. The E-E bond lengths point to a bond order greater than 1 (Table 1).[12] Reaction of iodine with **12** (E = As)[8b] leads to formation of the E_2M_2 cluster **13a** with an additional bridging iodide; similarly, the bismuth-bridged **13b** and **12** (E = Bi) are formed from $(Me_3Si)_2CHBiCl_2$ and $Na_2[W(CO)_5]$.[14]

13a[8b] **13b**[14]

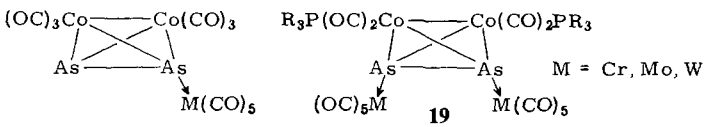


2.1.4. 8e-Donor Ligands

The non-bonding electrons of certain P_2M_2 complexes can be utilized for further terminal (complexes **14**,[15] **17**[16]) or bridging (complexes **15**, **16**[15a]) coordination to transition metal fragments.

9b[9] **14**, M = Cr[15a], Mo, W[15b] **15**[15a] **16**[15a]

The molybdenum clusters **14**–**16**[15] are obtainable directly from the Mo_2P_2 precursor **9b**;[9a] the cobalt clusters **17** are generated in the coordination sphere of the metals.[16]

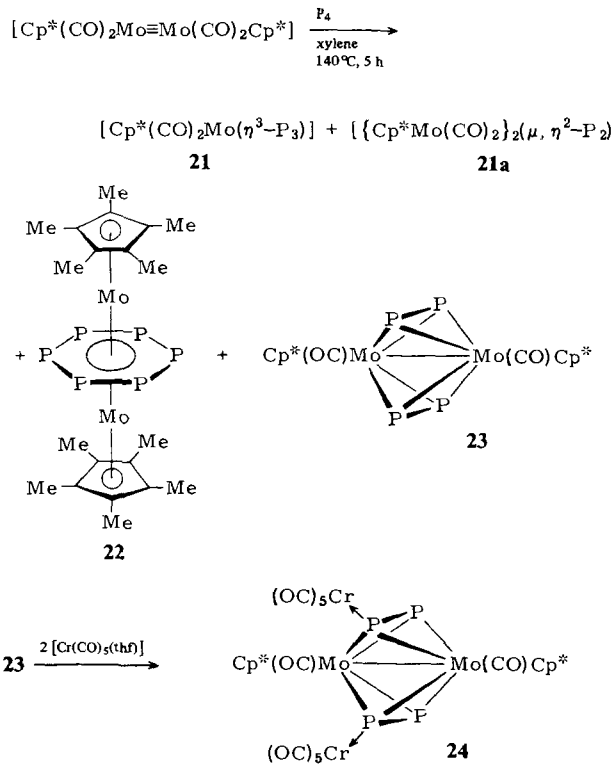


17a-c[16]

17a, L_nM = $Cr(CO)_5$; **17b**, L_nM = $W(CO)_5$; **17c**, L_nM = $CpMn(CO)_2$

The less pronounced donor properties of the $Co_2(CO)_6As_2$ unit are illustrated by the complexes **17** and **18** (cf. **7b** and **8a**, which are also directly obtainable from **6b** or **6a** and $Cr(CO)_5(thf)$[8b]). In contrast to **17**,[16] **18**[17]

shows only the very unstable mono-coordination (6e-donor ligand, as for **7b**) of the As_2 unit. Appreciably more stable complexes **19**[17] are formed if the basicity of the As_2Co_2 tetrahedrane is increased by the introduction of R_3P ligands.



[{Cp(CO)$_2$Mn}$_4$As$_2$] **20**

The As–As single bond length of 2.445 Å and the planar environment of the As atoms in **20**[8b,10] suggest the presence of a diarsinidene (Äs–Äs) 8e-donor ligand.

2.1.5. Complexes with More Than One E_2 Unit

If the η^5-C_5H_5 ligand in $[CpMo(CO)_2]_2$(*Mo≡Mo*) is replaced by η^5-C_5Me_5, the reaction with P_4 not only leads to formation of **21**, **21a**, and the triple-decker sandwich complex **22** but also **23**,[18] which in turn reacts with $Cr(CO)_5$(thf) to give **24**, a complex with two 6e-donor μ,η^2-P_2 units.[19]

The X-ray structure analysis shows **22** to be a centrosymmetric molecule (Fig. 1), in which all the rings are planar and parallel. The average P–P distance is 2.170 Å. In the ^{1}H-NMR spectrum (^{31}P, Table 1) the CH_3 signal is shifted to high field ($\delta = 0.47$, septet, $^4J(PH) = 0.45$ Hz; cf. the usual range $\delta \approx 2$ for C_5Me_5); this is caused by the anisotropic cone of the P_6 ring (ring current effect). **23** can be converted into **22** with P_4;[19] it probably occupies a key position in the formation of the hexaphosphabenzene ligand P_6, which may be formally regarded as being composed of three P_2 units (cf. the isoelectronic pair P_2/C_2H_2 and the benzene synthesis of *Reppe*). X-ray studies have shown that the bond lengths and angles of the M_2E_2 unit are not significantly altered on further complexing (Table 1). If we use Figures 2 and 3 as models for **23**, then it can be seen from the P2···P4 and P1···P3 distances[19] and the orientation of the $Cp^*_{center}MoMoCp^*_{center}$ moiety [Cp^*_{center}

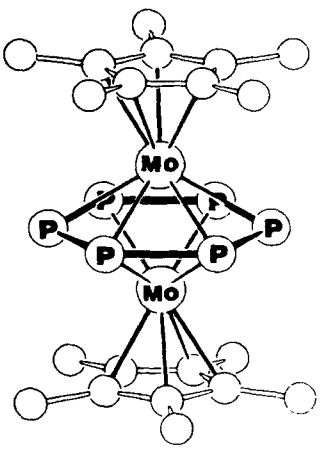


Fig. 1. Molecular structure of **22** in the crystal [18].

MoMo 160.8 and 161.1°, dihedral angle 1.3°] that a similar trapezoid arrangement of the P_4 unit in **23** could lead to formation of the P_6 "middle deck" of **22** by introduction of a further P_2 unit with CO elimination.

The thermolysis of $[CpMo(CO)_3]_2$(*Mo–Mo*) and $(CH_3As)_5$ forms (amongst other products) **25**, in which the great differences in As–As bond lengths (Table 1) suggest

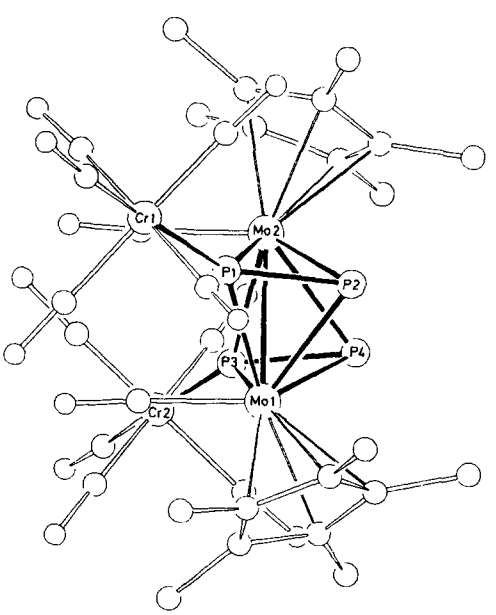

Fig. 2. Molecular structure of **24** in the crystal [19].

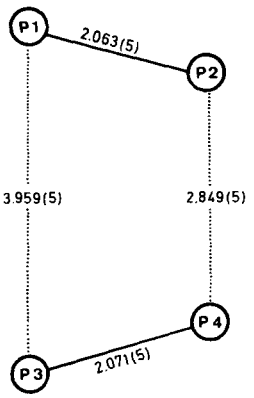

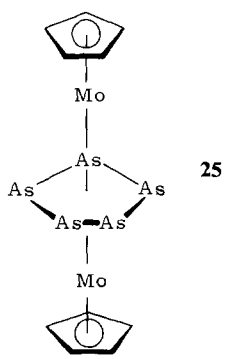

Fig. 3. The planar $(P_2)_2$ unit of **24** with PP distances [Å].

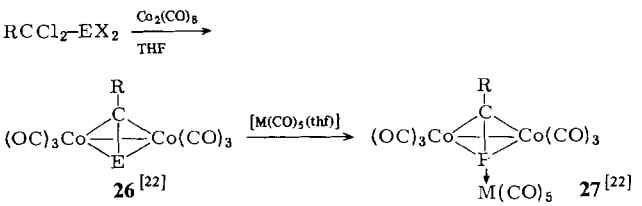
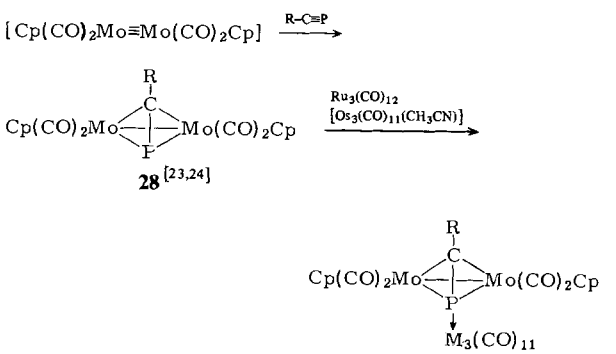
the formulation of the ring as μ,η^2-As_3 and μ,η^2-As_2 ligand fragments[20a] (cf. the μ,η^3-As_3, coordination type in [(triphos)Co(As_3)Co(triphos)]$(BPh_4)_2$,[20b] triphos = $MeC(CH_2PPh_2)_3$).



25

$^{31}P\{^1H\}$-NMR data for complexes of the form $M_2P_2[M'(CO)_5]_2$ show a clear shift to higher field on going from M′=Cr to W (**14**, M=Mo, M′=Cr: −36.7; M′=Mo: −64.9; M′=W: −105.1;[15a,b] **17a**, M=Co, M′=Cr: 146; **17b**, M′=W: 44[16]). The transition from the 4e- to the 8e-donor E_2 ligand (e.g. **3e/17a**; **9b/15**, **16**; **5b**, **c/19a**; **6a/8a**) causes only minor changes in the E–E bond lengths. Comparison of the E_2M_2 butterfly complexes **10**[10] and **11a**[11] with the "normal" As_2- and P_2-complexes, respectively, shows a definite shortening of the E–E distance for the As derivative **10**, but a lengthening in the P derivative **11a**. The unusually long P–P distance in **4** is mirrored in the C–C distance of the isoelectronic μ,η^2-C_2H_2 complexes.[5d] The complexing of the P_2 molecule causes its bond to be lengthened by 0.14 (**3e**) to 0.28 Å (**4**) from its original value of 1.875 Å (cf. Table 1).

2.2. Bridging Phospha- and Arsa-alkynes

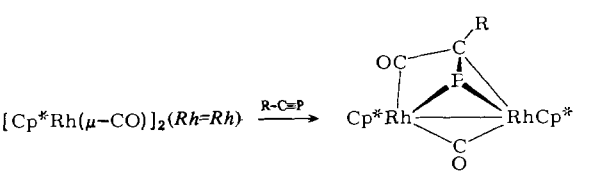


The ligand of choice is (for phosphorus) $Me_3C-C\equiv P$,[21a] which is stable at room temperature (cf. adamantyl-C≡P and other derivatives[21b]). Less sterically demanding R–C≡P ligands can also be generated in the coordination sphere of the transition metal; for R–C≡As ligands this is the only method (as in complexes of the type **26** and **27**[22]).

26[22] **27**[22]

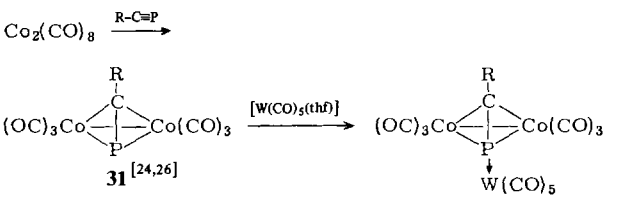
X = Cl, Br; E = P, As; R = H(As), CH_3, C_6H_5, $SiMe_3$; M = Cr, Mo, W

2,2-Dimethylpropylidinephosphane, $Me_3C-C\equiv P$, adds to the Mo≡Mo bond like an acetylene to give complexes of the type **28**, which possess an organometallic tetrahedrane skeleton.[23,24] **28** reacts further with trinuclear carbonylmetal compounds, forming polyhedral metal clusters **29**.[25]



28[23,24]

29a,**b**[25]

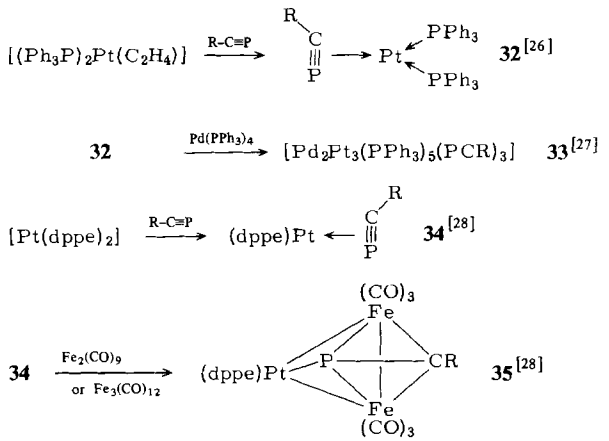


R = CMe_3; **a**, M = Ru; **b**, M = Os

The regiospecific formation of **30** is based on the addition of $Me_3C-C\equiv P$ to the Rh=Rh bond and an insertion into one of the Rh–CO bonds of the starting material.[23]

R = CMe_3 **30**[23]

The ligand properties of the Co cluster **31** (analogous to **28**) are seen in its reaction with $W(CO)_5$(thf) to give **31a** ($Me_3C-C\equiv P$ as 4e-donor ligand).[24]



31[24,26] **31a**[24]

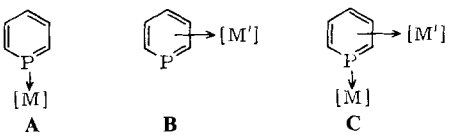
R = CMe_3

The reaction of $Me_3C-C\equiv P$ with $(Ph_3P)_2Pt(C_2H_4)$ or $Pt(dppe)_2$ proceeds with elimination of C_2H_4 or dppe to give the Pt complexes **32**[26] and **34**,[28] which show classi-

cal side-on coordination of the phospha-alkyne ligand (2e-donor). Both compounds are suitable for cluster-building reactions.

The framework of **33**[27] is structurally analogous to that of the star-shaped molecules **12**;[12] a Pd_2 axis (instead of E_2) is symmetrically bridged by three metal fragments (Pt). Each metal atom is also coordinated to one PPh_3 ligand. The three RCP ligands then bridge this trigonal bipyramidal Pd_2Pt_3 unit in such a way as to form a hexagonal bipyramid (*closo* cluster) with P_3Pt_3 in the equatorial plane.[27] **35** is the first example of μ_3-P-coordinated R–C≡P.[28]

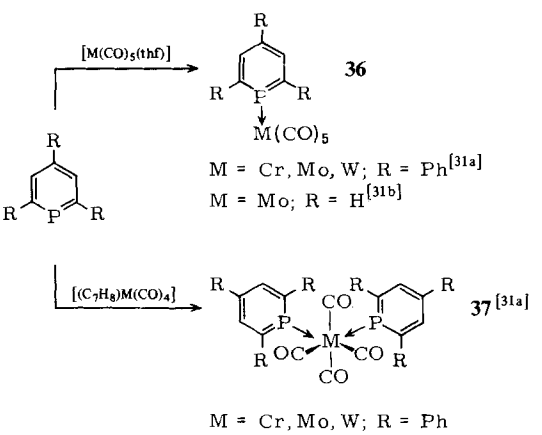
An extremely high-field shift of the ^{31}P-NMR signal is observed on going from **28** to **29b** (Table 2). **32** and **34** show distinct differences in the chemical shift and the ^1J(PtP) coupling of the R–C≡P ligand (Table 2).



Complex **29b**[25] shows an unusually long P–C bond [1.86(1) Å; cf. 1.536(2) Å in the free ligand and the values for the other complexes (Table 2)]; this is considered to be a typical single-bond length, the other values lying in the double-bond region.

He(I)-photoelectron spectroscopic studies[29] of R–C≡P (R = CMe_3, Ph) show a greater π-n separation than the nitrile analogues; this is a quantitative indicator of reduced overlap for a $2p_\pi$-$3p_\pi$ interaction and it also suggests that side-on coordination of the R–C≡P ligand will usually be preferred. Complexes of the type R–C≡P:→M remain unknown.

3. Multiply Bonded Systems with Ligand Coordination Number Two



3.1. Phosphinines (λ^3-Phosphorins)

The following coordination types are known for these cyclic representatives of trivalent phosphorus:

3.1.1. 2e-Donor Ligands (σ-Complexes)

Some years after the discovery[30] of 2,4,6-triphenylphosphabenzene (2,4,6-triphenylphosphinine), its terminal P-coordination mode **A** was demonstrated.[31]

Apart from the complexes **36** (some characterized by X-ray structure determination)[31a,b] (Table 3), representatives of the elements Mn,[31g] Ni,[31h] Ag,[31e] and Au[31d] are known and have been characterized by ^{31}P{^{1}H} NMR.

The chemical behavior of the phosphinine σ-complexes has not been studied to any great extent. The complex **38** was shown spectroscopically to be an intermediate in the synthesis of λ^5-phosphinines by oxidative addition of nucleophiles to λ^3-phosphinines.[31e] The reaction of 2,4,6-triphenylphosphinine→AuCl with sodium methoxide in the presence of methanol is said to lead to an Au_3 cluster.[32]

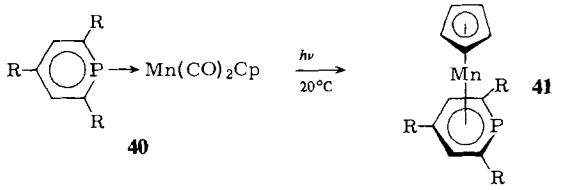


Table 2. ^{31}P{^{1}H}-NMR data (δ values, J in Hz) and M-M and P-C bond lengths [Å] in phospha-alkyne complexes. R = CMe_3. Cp = η^5-C_5H_5. PC bond length (gas phase) in Me_3C–C≡P 1.536(2) Å (H. Oberhammer, G. Becker, G. Gresser, *J. Mol. Struct.* 75 (1981) 283).

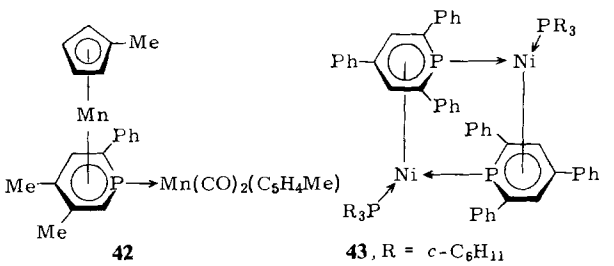
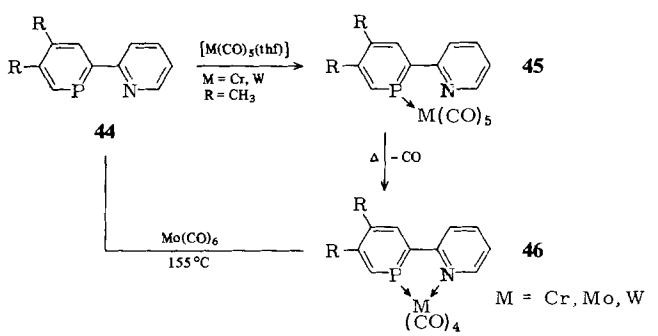
Compound		^{31}P{^{1}H}	M–M	P–C	Ref.
28	$[Cp_2Mo_2(CO)_4(PCR)]$	– 42.5 (s)	3.014(0)	1.719(3)	[23]
29b	$[Cp_2Mo_2(CO)_4(PCR)\{Os_3(CO)_{11}\}]$	–287.4 (s)	2.860(1), 2.892(1) (Os–Os)	1.86(1)	[25]
	$[Cp_2Mo_2(CO)_4(PCR)\{W(CO)_5\}]$	[a]	[a]	1.733(12)	[25]
31a	$[Co_2(CO)_6(PCR)\{W(CO)_5\}]$	[a]	[a]	1.695(6)	[24]
32	$[(Ph_3P)_2Pt(PCR)]$	56.9 (dd), ^1J(PtPCR) 62		1.672(17)	[26]
33	$[Pd_2Pt_3(PPh_3)_5(PCR)_3]$	[a]	2.679(2) (Pd–Pd)	1.62(2)	[27]
34	[(dppe)Pt(PCR)]	– 53.3, ^1J(PtP) 166			[28]
35	[(dppe)PtFe$_2$(CO)$_6$(PCR)]	–192.8 (m), ^1J(PtPCR) 128	2.518(1) (Fe–Fe), 2.669(1), 2.671(1) (Pt–Fe)	1.703(6)	[28]

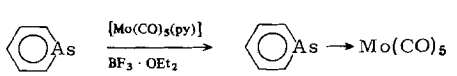


[a] Not given.

$[2,4,6\text{-}(C_6H_5)_3C_5H_2P\{Hg(OOCCF_3)_2\}]$ **38**
$[2\text{-}C_6H_5\text{-}4,5\text{-}(CH_3)_2C_5H_2P\{W(CO)_5\}]$ **39**

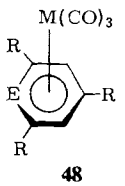


The complex **39** reacts with 2,3-dimethylbutadiene as a dienophile in the 1,6-position, but with *N*-phenylmaleimide, dimethyl acetylenedicarboxylate and cyclopentadiene in the 1,4-position.[31i]

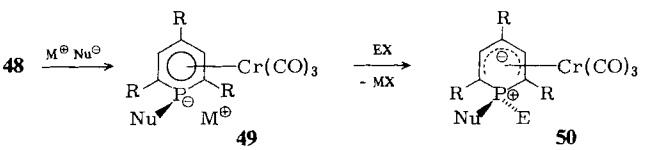


The photochemical CO elimination from the σ-phosphinine complex **40** causes a change of coordination mode from η^1 to η^6, forming a sandwich complex.[31g,39] The transition from **40** to the X-ray structurally characterized **41** (type **B**) is accompanied by a drastic high field shift of the ^{31}P-NMR signal ($\Delta\delta = 293$ ppm). Small changes in the Cp ring and the R groups of **40** lead instead to the formation of the σ,π complex **42** (type **C**), where the phosphinine acts as an 8e-donor.[31g]

A further interesting example of this coordination type is seen in **43** (a 16- or 18-electron configuration, with Ni coordinated by a double bond or a diene fragment of the phosphabenzene ligand, might also be thought feasible).[31h]



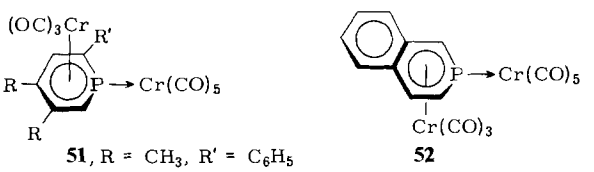
Preliminary studies of **44**, the phosphorus analogue of a 2,2'-bipyridyl derivative, promise to reveal remarkable ligand properties.[33] **47** is so far the only representative of σ-complexes of λ^3-arsinines.[34]



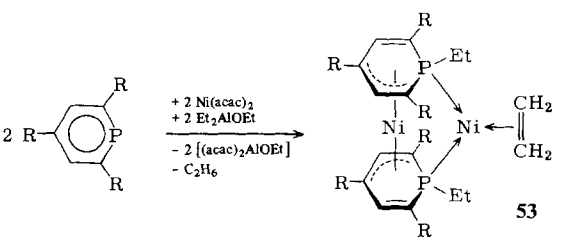
3.1.2. 6e-Donor Ligands (π-Complexes)

The use of $M(CO)_6$ or $L_3M(CO)_3$ ($L = CH_3CN$, py) as transition metal source allows the synthesis of the η^6-coordination type **48** (cf. **B**).

E	M	R	Ref.
P	Cr, Mo	Ph	[35a, b]
P	Cr	CMe_3	[35c]
As	Mo	e.g. H(2), Ph(4), H(6)	[36]
As, Sb	Mo	H	[34]



The addition of nucleophiles (Nu) such as alkyl or aryl anions or alkoxide ions to **48**, E = P, leads via the spectroscopically characterizable **49** to isolable tricarbonylchromium λ^5-phosphorus ylide complexes **50** on treatment with electrophiles (e.g. ethyl halides).[35c]



R = C_6H_5, CMe_3

3.1.3. 8e-Donor Ligands (σ,π Complexes)

Simultaneous σ- and π-coordination is possible if sterically suitable λ^3-phosphinines are allowed to react with e.g. $Cr(CO)_6$, forming **51** and **52** (see also **42**, **43** and Ref.

[31f]).[37] Phosphinines can be converted into phosphininyl ligands[38a] according to the method of *Lehmkuhl* et al.[38a]

To comply with the 18e rule at nickel in **53** (each phosphininyl ligand is both a 2e- and 3e-donor), the Ni–Ni bond (2.498(1) Å) can be ascribed double bond character (Table 3).[38a] In the iron complexes **54**, which possess structures related to **53**,[38] the double bond of the phosphininyl ligand is probably also bonded to the iron atom. **54b** is a structurally dynamic system.

$[\{(C_6H_5)_3C_5H_2PR\}_2Fe]$ **54a**, $R = CH_3$[38b]; **54b**, $R = C_2H_5$[38a]

The change from a σ- to a π-complex (**36a** → **48a**) causes an upfield shift of 193.5 ppm in the $^{31}P\{^1H\}$-NMR spectrum (Table 3). The P-C bond length (Table 3) of phosphinine(yl) complexes lies in the range 1.695–1.816 Å.

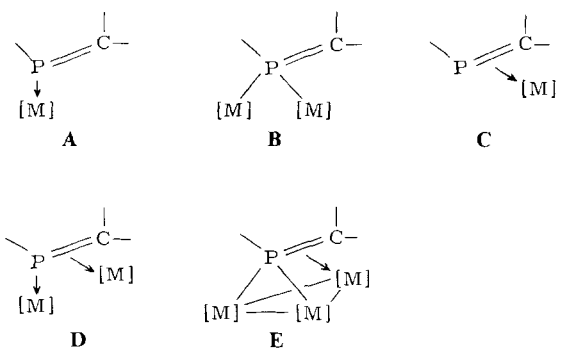


Table 3. $^{31}P\{^1H\}$-NMR data and P-C bond lengths [Å] in complexes with phosphinine ligands. Cp = η^5-C_5H_5.

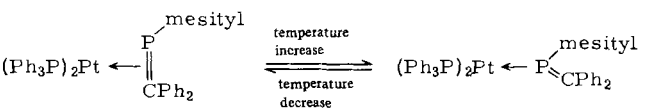
3.2. Phospha-alkenes

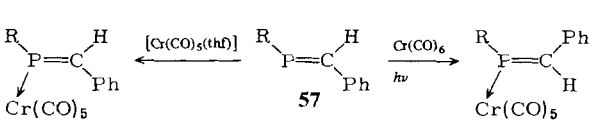
Of the many possible coordination types, **A**–**E** have so far been realized.



3.2.1. *Terminal P-Coordination*

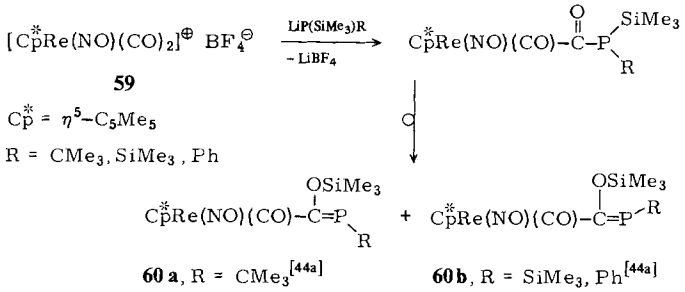
This preferred coordination mode (type **A**, 2e-donor ligand) allows in **55** a great variety of R, R′ groups and of metal fragments [M] (see also Table 4).[40]

To prepare the complexes **55**, readily available transition metal compounds can be used, for example $M(CO)_6$, [$M(CO)_5$(thf)], M = Cr, Mo, W, R = C_6H_5, R′ = mesityl,[40a, b] R, R′ = diazaphosphole derivative[40c, d] (M = Cr, Mo); $CpMn(CO)_3$, $Fe(CO)_5$, $Fe_2(CO)_9$, R, R′ = diazaphosphole derivative[40c] (M = Mn, Fe); R = $SiMe_3$, R′ = $(Me_3C)_3C_6H_2$[40e] (M = Fe); R = $SiMe_3$, C_6H_5, R′ = $(Me_3C)_3C_6H_2$[40f] (M = Fe); R = $SiMe_3$, R′ = $N(SiMe_3)_2$[40g] (M = Fe); R = H, R′ = $(Me_3C)_3C_6H_2$[48b] (M = Fe); $RhCl(PPh_3)_3$;[40b] $Ni(CO)_4$, R = C_6H_5, R′ = mesityl;[40h] R = H, R′ = $(Me_3C)_3C_6H_2$[48b] (M = Ni); PtL_x (L = R_3P, x = 3, 4), $PtL_2(C_2H_4)$, $Pt(cod)_2$, $Pt_2Cl_4(PR_3)_2$, R, R′ = diazaphosphole derivative;[40i] R = C_6H_5, R′ = mesityl;[40j, 41] ClAu(CO), $[Me_2AuCl]_2$, R, R′ = diazaphosphole derivative[40k] (cod = 1,5-cyclooctadiene).



56 exhibits a temperature-dependent equilibrium between side-on and end-on coordination.[41]

56a **56b**



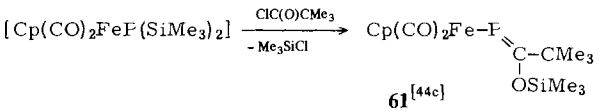
DNMR studies[41a, b] show that, in solution at −40 °C, 75% **56a** and 25% **56b** are present. Solid state ^{31}P-NMR data[41b, c] and a crystal structure analysis[41a] confirm the η^1-coordination (**56b**) in the solid state. Hartree-Fock-Slater (LCAO-X_α) calculations[41b] on the model system $(H_3P)_2Pt(HP{=}CH_2)$ provide qualitative agreement with these experimental results. Theoretical[42] and photoelectron spectroscopic[42h, k, l] investigations on the parent substances H–P=CH_2,[41b, 42a–d] H–P=N–H,[42b, c, e, l] H–P=P–H,[42f–l, 62a] H–P=O,[42b] and derivatives[42a, c, m] furnish the first satisfactory explanation for its reaction behavior.

57 is converted thermally into **58a** with retention of configuration, but photochemically into the *Z*-isomer **58b**.[43]

58a R = 2,4,6-$(Me_3C)_3C_6H_2$ **58b**

Phospha-alkenyl complexes (compounds in which a transition metal fragment is a C- or P-substituent) can be generated directly in a complex.[44] Thus, the reaction of the cationic complex **59** and monosilylated lithium phosphides at low temperature forms at first phosphinocarbonyl complexes (demonstrated by ^{31}P NMR), which then isomerize in a 1,3 migration of the Me_3Si group to the phospha-alkenyl complexes **60**.[44a]

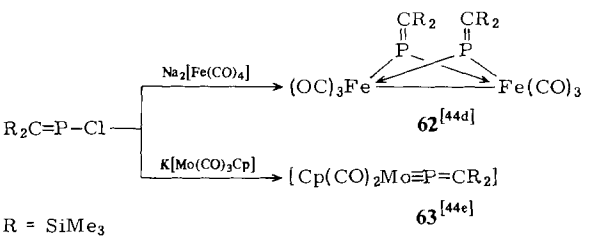
59



$Cp^* = \eta^5\text{-}C_5Me_5$

R = CMe_3, $SiMe_3$, Ph

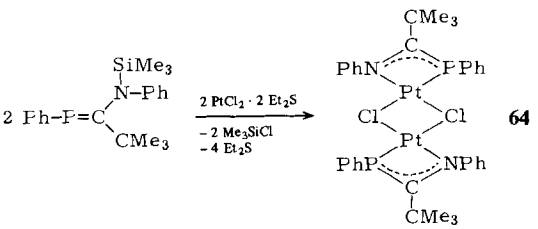
60a, R = CMe_3[44a] **60b**, R = $SiMe_3$, Ph[44a]



60a (*Z* form) is formed instead as **60a'** (*E* form) (Table 4) if η^5-C_5H_5 is employed instead of η^5-C_5Me_5.[44b]

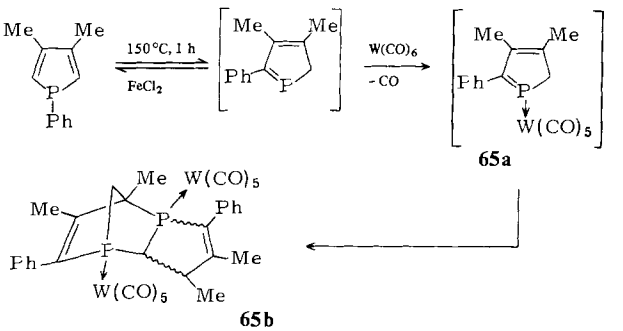
The phospha-alkenyl complex **61** (Table 4), with an Fe–P single bond and *Z*-configuration, is formed directly in the reaction of a disilylphosphido-iron complex with pivaloyl chloride.[44c]

61[44c]



A further route to this class of compound ($L_nMP{=}CR_2$) is the reaction of $(Me_3Si)_2C{=}PCl$ with $Na_2[Fe(CO)_4]$[44d] or $K[Mo(CO)_3Cp]$.[44e]

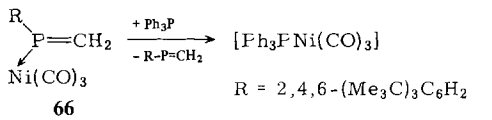
62[44d] **63**[44e]



R = $SiMe_3$

The 18-electron rule requires a le-donor ligand for **61**,[44c] and a 3e-donor ligand for the linear phosphavinylidene complex **63**,[44e] the bridging variant of which is seen in **62**[44d] (Table 4). Allyl-type coordination has been suggested for the ambidentate phosphaamidine anion in complex **64**.[45]

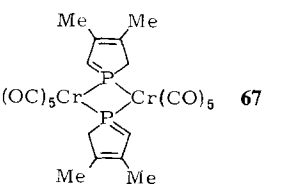
64



The chemistry of phospha-alkene or -alkenyl complexes with terminal P-coordination has hardly been investigated. Isomerization, formation of the complex **65a** and [4+2] cycloaddition have been discussed for the reaction of 3,4-dimethyl-1-phenylphosphole with $W(CO)_6$ to give the isomer mixture **65b**.[46]

65a

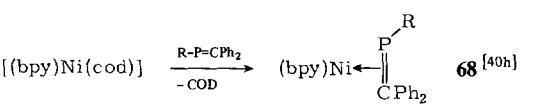
65b



Triphenylphosphane displaces the phospha-alkene ligand from **66**.[48b]

66

3.2.2. *Bridging P-Coordination*

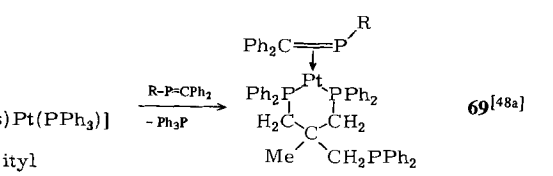


This rare coordination mode (cf. **B**) has been postulated for the isomer mixture **67** ($^{31}P\{^1H\}$-NMR: $\delta = 45.7$, 45.9)[47] (cf. also the complex **62**[44d]).

67

3.2.3 η^2-*Coordination (Side-on Coordination)*

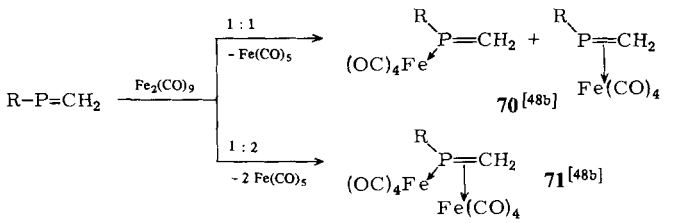
The η^2-coordination of the P=C-π-bond (cf. **C**) can be verified both by the reaction of an isolated phospha-alkene with a suitable transition metal fragment and also by formation at a complex.



68[40h]

R = 2,6-$(CH_3)_2C_6H_3$

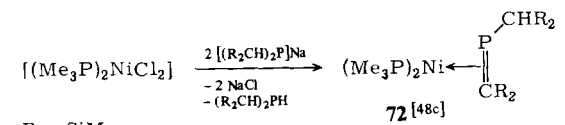
The starting material of choice is (bpy)Ni(cod) for the nickel complex **68** (Table 4),[40h] (triphos)Pt(PPh_3) for the platinum compound **69**[48a] (see also compound **56**[41]). The reaction of (triphos)Pt(PPh_3) with $Me_3C{-}C{\equiv}P$ leads to the phospha-alkyne complex analogous to **69**.[48a] $^{195}Pt\{^1H\}$-NMR studies show **69** to be a mixture of isomers.[48a]



According to the stoichiometry employed, the reaction of $Fe_2(CO)_9$ with the stable methylene(2,4,6-tri-*tert*-butyl-

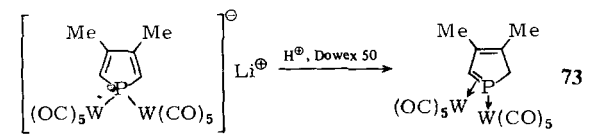
69[48a]

R = mesityl

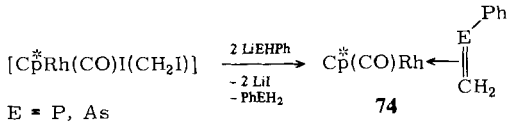


phenyl)phosphane leads to either the non-separable isomer mixture **70** (demonstrated by $^{31}P\{^1H\}$ NMR) or the crystallographically characterized product **71** (Table 4) with η^1,η^2-coordination (type **D**).[48b]

R = 2,4,6-$(Me_3C)_3C_6H_2$

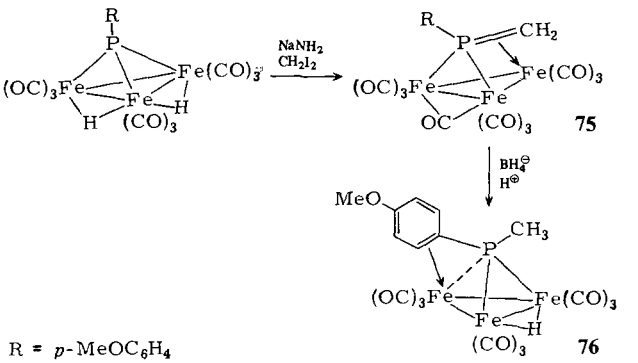


In **71** the η^1-P moiety occupies the axial site and the η^2-P=C moiety the equatorial site of the respective trigonal bipyramids.



The reaction of $(Me_3P)_2NiCl_2$ with a highly substituted phosphide ion provided unexpected access to the chemistry of η^2-coordinated phospha-alkenes by leading, inter alia, to the nickel complex **72** (Table 4).[48c]

R = $SiMe_3$



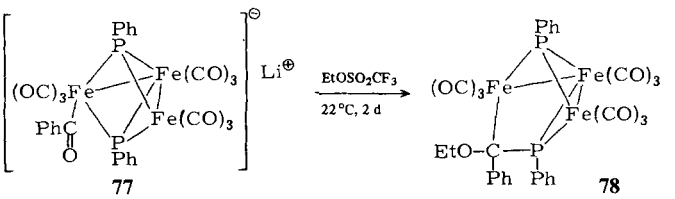
The 4e-donor type (as in **71**) was discovered in **73** (Table 4).[47]

The ligands Ph–E=CH_2 (E = P, As), unknown in the free state, were generated in the coordination sphere of rhodium and stabilized by η^2-coordination.[48d]

Cluster-stabilized R–P=CH_2 caps the Fe_3 triangle of **75** (Table 4) as a μ_3,η^2-ligand; it can be reduced to the μ_3,η^2-phosphino ligand $RPCH_3$ in **76**.[49] **75** is an example of a *type* **E** *complex*.

R = p-$MeOC_6H_4$

The coupling of a phosphanediyl and a carbene ligand to form μ-PhP=C(OEt)Ph is observed in the generation of **78** from **77** (Table 4), a complicated series of reactions.[50]



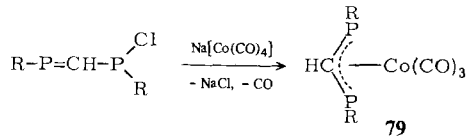


Table 4. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz) and some molecular dimensions (from X-ray studies) of complexes with acyclic and cyclic phospha-alkene or -alkenyl ligands. Cp = η^5-C_5H_5. Cp* = η^5-C_5Me_5. Comparative PC distance in mesitylP=CPh_2 1.692(3) Å [42d].

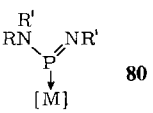
79

R = 2,4,6-$(Me_3C)_3C_6H_2$

The first phosphorus analogue of an (η^3-allyl)tricarbonylcobalt complex, **79** (Table 4), is formed as described in Ref. [51] from a chlorophosphino-substituted methylenephosphane.

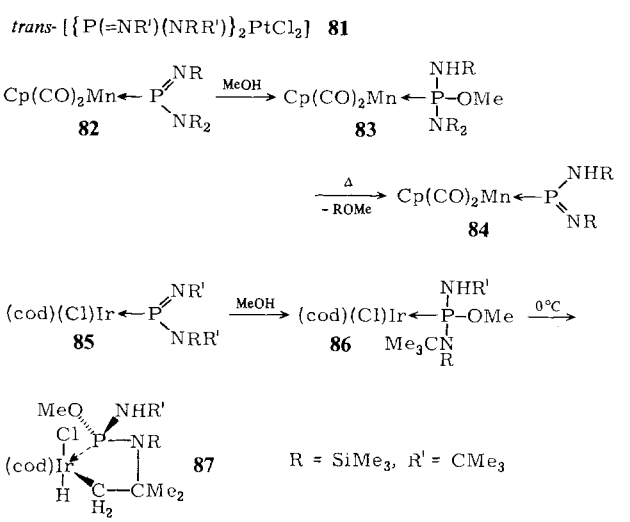
A particularly marked downfield shift of the $^{31}P\{^1H\}$-NMR signal of phospha-alkenes is observed in those cases where the P atom bonded to the transition metal fragment can be ascribed 3e-donor character (**62** and **63**, Table 4); the η^2-coordination mode, in contrast, causes a large upfield shift (cf. Ref. [41]). The P=C bond length for terminal coordination or metal-C- or metal-P-substitution falls in the range 1.649(4) (**63**) to 1.701(4) Å (**61**); in **55a,b** and **56** this bond length is slightly shorter than in the free ligand (Table 4). For η^2-coordination, longer bonds are observed (up to 1.832(6) Å in **68** (Table 4)).



F G

3.3. Iminophosphanes

In addition to the coordination types **A**–**E** discussed above for phospha-alkenes (Section 3.2), iminophosphanes display the N,P 4e- and 6e-donor types **F** and **G**.



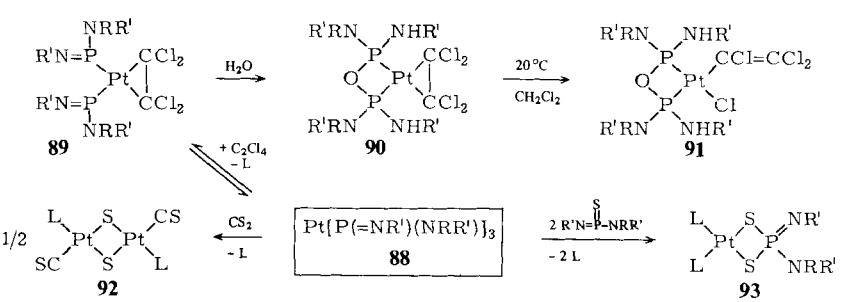
3.3.1. 2e-Donor Ligands

η^1-P Coordination: The terminal coordination **80** is preferred; for acyclic ligands it has been observed for the metals Cr,[52a,54] Mn,[52b] Ir,[52c] Ni,[56] and Pt.[52d-g] Compounds characterized by X-ray structure determination are shown in Table 5. N- and/or P-coordination is found in di- and triazaphosphole complexes of Au,[40k] Pd,[53] Pt,[40i,53] and Cr, W.[40c]

80

The reactivity of the P=N unit bound to the metal is of particular interest. Water and methanol addition were discovered in the case of **81**[52d] and successfully extended to **82** and **85**.

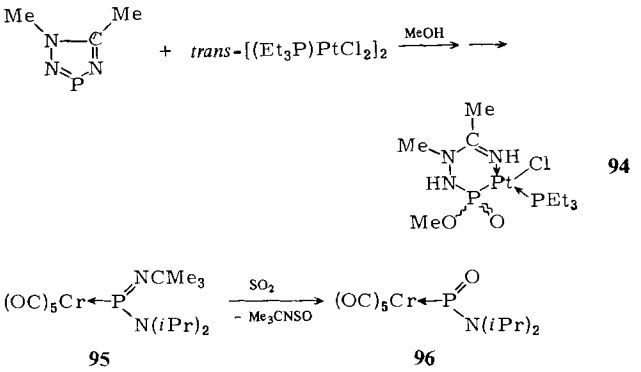
trans-[{P(=NR')(NRR')}$_2$PtCl$_2$] **81**



82 83 84 85 86 87

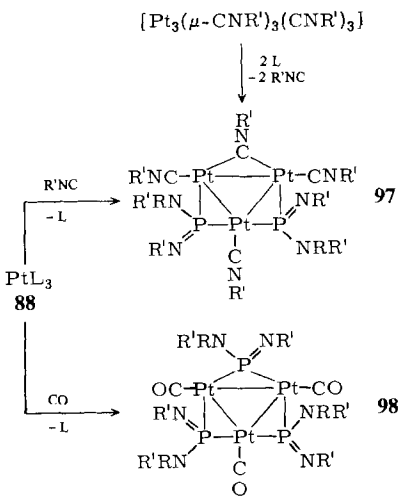
R = $SiMe_3$, R' = CMe_3

While **83** eliminates Me_3SiOMe at 60 °C to give **84** (containing $Me_3SiNH-P=NSiMe_3$, unstable in the free state)[52b] (cf. Ref. [52a] and **80b**, Table 5), **86** undergoes diastereoselective intramolecular oxidative addition of C–H (CMe_3 group) at 0 °C, forming the crystallographically characterized iridium(III) heterocycle **87**.[52c]



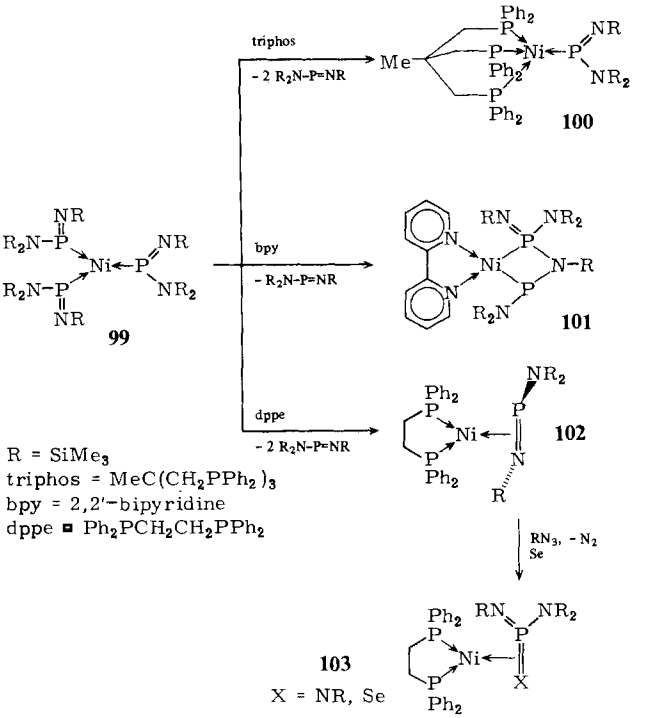
The reactions of $Pt(PPh_3)_3$ with alkenes and alkynes are very well known; some interesting reactions of the ligand were found to occur with the analogous phosphazene complex **88**.[52g] If (as in **89**) the phosphazene ligands are adjacent to each other, then the addition of a water molecule forms the platinum four-membered ring complex **90**, containing a P-O-P chelate ligand. **90** isomerizes quantitatively in CH_2Cl_2 in a few hours to the vinyl complex **91**, characterized by X-ray structure analysis.[52g] The reaction of **88** with CS_2 splits the latter into CS and S fragments, forming **92**.[52g] The synthesis of **93** from **88** may formally be regarded as the oxidation of platinum(0) to platinum(II) coupled with reduction of one molecule of the double ylide (by sulfur transfer) from phosphorus(V) to phosphorus(III) (σ^2-phosphazene).[52g] The formation of **94** in a multi-step reaction has also been described[53]

The stabilization of an aminooxophosphane as metal complex is achieved by the reaction of **95** with SO_2, forming **96**.[54]



89 90 91 92 88 93

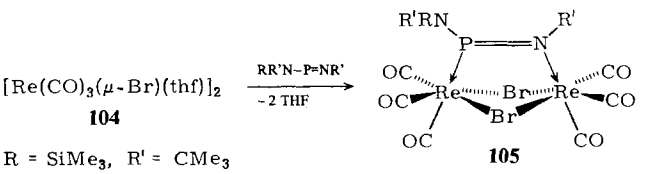
L = R'N=P–NRR'; R = $SiMe_3$, R' = CMe_3



μ-P Coordination: Edge-bridging μ-P coordination of the phosphazene ligand is realized in the trinuclear platinum clusters **97** and **98**.[52f,55] The Me_3Si groups of these clusters undergo intramolecular 1,3-exchange. The constitution of **97** and **98** is established from ^{1}H-, ^{13}C{^{1}H}-, ^{31}P{^{1}H}- and ^{195}Pt{^{1}H}-NMR studies and X-ray structure analyses (Table 5).[52f,55]

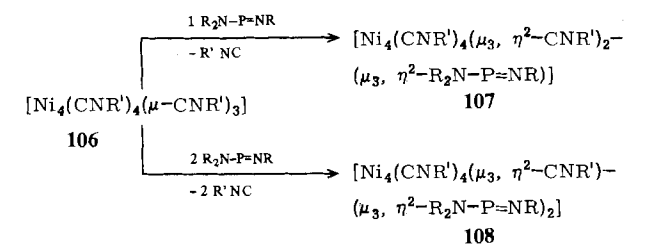
L = R'N=P–NRR'; R = $SiMe_3$, R' = CMe_3 etc.

η^2-Coordination: Complex **99**, prepared from $Ni(cod)_2$ and $R_2N-P=NR$ (R = $SiMe_3$), is a versatile synthetic reagent.[56]



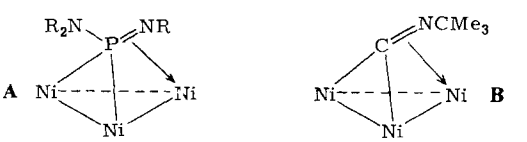
Its reaction with a tripod ligand to form **100** leaves the η^1-P coordination intact, but with bpy, transformation to the nickelaazadiphosphetidine **101** takes place (formally by formation of a P–N bond from two P=N units). The chelating ligand dppe causes a change of coordination mode from η^1 to η^2 (**102**). The classical side-on coordination in **102** has been proven by NMR studies and X-ray structure analysis (Table 5). Its oxidation by, e.g., Me_3SiN_3 or selenium leads to **103**, X = $NSiMe_3$ and Se, respectively, with side-on coordination of the P=X moiety of a σ^3,λ^5-phosphazene.[56]

R = $SiMe_3$
triphos = $MeC(CH_2PPh_2)_3$
bpy = 2,2'-bipyridine
dppe = $Ph_2PCH_2CH_2PPh_2$



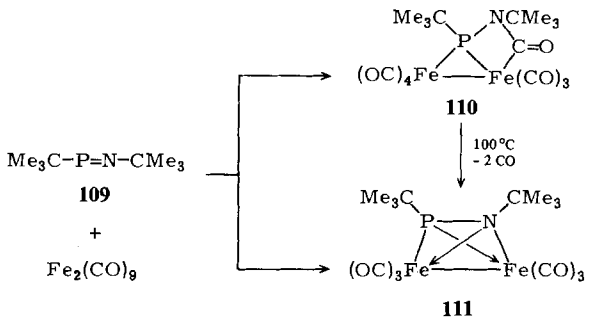
3.3.2. 4e-Donor Ligands

μ,η¹,η¹-N=P Coordination: This coordination type (cf. **F**) is represented by the dinuclear rhenium complex **105**.[57] The short P=N bond (1.56 Å, Table 5) means that the two distorted, edge-sharing octahedra in **105** tend towards face-sharing. The introduction of the P=N ligand changes the *trans*-**104** to the *cis*-**105**.[57]



R = $SiMe_3$, R' = CMe_3

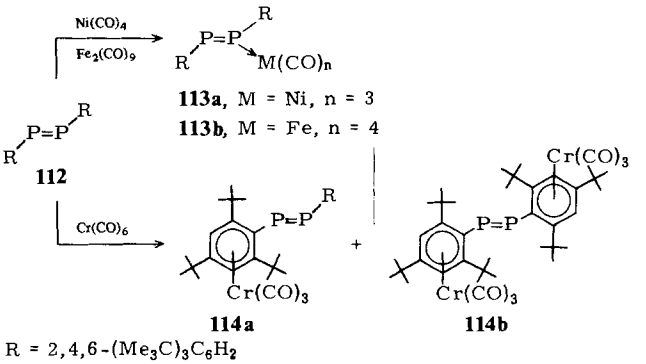
μ_3,η^2-N=P Coordination: The Ni_4-clusters **107** and **108** are formed by the displacement of the bridging isocyanide ligands of **106** by amino(imino)phosphane ligands.[58]



R = $SiMe_3$, R' = CMe_3

The crystal structure analysis (Table 5) shows that, in the flattened trigonal Ni_4-pyramid of **108**, two triangular faces are capped by μ_3,η^2-$R_2N-P=NR$ units and one by a μ_3,η^2-$C\equiv N-CMe_3$ ligand (see **A** and **B**; R = $SiMe_3$).

3.3.3. 6e-Donor Ligands



The reaction of **109** with $Fe_2(CO)_9$ leads to **110** and **111**.[59] It is possible that **110** arises from $[(OC)_8Fe_2\{\mu\text{-}P(=NCMe_3)CMe_3\}]$ by intramolecular nucleophilic attack of the imino nitrogen on a CO ligand. According to a crystal structure analysis (Table 5) the P-N bond length in **111** (cf. G) corresponds to the PN single bond length required for this coordination type[59] (see, in contrast, P-P in the isoelectronic **125**, Table 6[67a]).

$^{31}P\{^1H\}$-NMR data are also a useful indication of coordination type for the iminophosphane ligands; thus a significant upfield shift is observed on going from the terminal P- or NP- to the P=N side-on coordination. Associated with this is the expected increase of the P=N bond length (cf. also the acyclic complexes **80** with **102** and **108** and with the free ligand, Table 5).

3.4. –E=E- and –P=E-Ligands (E = P, As, Sb)

3.4.1. Diphosphenes (R–P=P–R)

The isolation and X-ray structural characterization of the first diphosphene **112**[60] showed how to stabilize these ligands in the free state by using sterically demanding groups (see summary of the literature in Refs. [3o, p]). The reaction of **112** with carbonylmetal compounds leads with nickel and iron to terminal P-coordination (**113**)[61a,63], but with chromium (reflux, dioxane) to η^6-coordination (**114**).[61b]

If one tri(*tert*-butyl)phenyl group of **112** is replaced by the sterically less demanding mesityl group, the E→Z photoisomerization **115** → **115a** can be carried out at the metal complex.[62a]

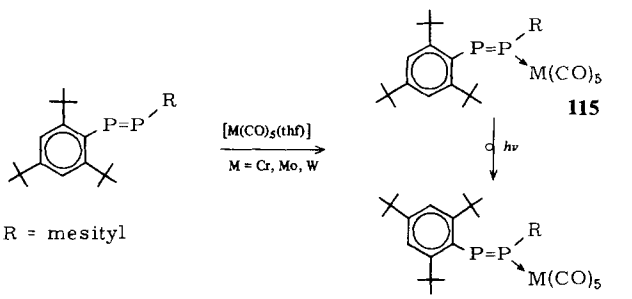


Table 5. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz) and selected molecular dimensions (from X-ray studies) of complexes with acyclic and cyclic iminophosphane ligands. $(Me_3Si)_2N-P=NSiMe_3$: NPN 108.4(1)°, P–N 1.674(1), P=N 1.545(2) Å; $(Me_3Si)(Me_3C)N-P=NCMe_3$; NPN 104.9(2)°, P–N 1.658(4), P=N 1.544(4) Å (S. Pohl, *Chem. Ber. 112* (1979) 3159).

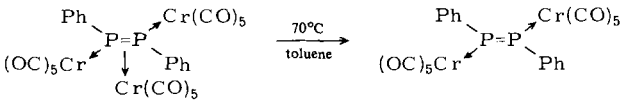
The rate of isomerization decreases in the order Cr ≫ Mo > W. Ab initio calculations suggest that the activation energy for the isomerization of HP=PH is very high (whereby rotation is preferred to inversion in the formation of the transition state). The energy barrier is lowered, sterically and electronically, by the formation of a complex[62a] (cf. Refs. [42f–l]).

Fenske-Hall MO calculations[62b] on $H_2P_2[Cr(CO)_5]$ (coordination type **113**, **115**, **117**) show that the end-on coordination cannot be described as a pure σ-donor bond, but that delocalized σ- and π-interactions play an important role.

η^1-P coordination of the less sterically shielded phosphorus atom has also been suggested for the complex **116**.[61a,63] The 2e-donor coordination type **113** can, as with **117**, be synthesized at a metal complex; this is the only known method for the 4e-donor type.

$[\{2,4,6\text{-}(Me_3C)_3C_6H_2P{=}PCH(SiMe_3)_2\}\{Fe(CO)_4\}]$ **116**

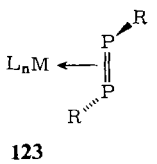
a, R = $CH(SiMe_3)_2$; **b**, R = $N(SiMe_3)_2$



Reaction of $(Me_3Si)_2CHPCl_2$ with $Na_2[M_2(CO)_{10}]$ (M = Cr, W) leads, after initial formation of deep-colored phosphanediyl complexes, to isolable compounds of the type **118a** in which $Fe(CO)_4$ is replaced by $Cr(CO)_5$ or $W(CO)_5$. Upon heating to 60 °C (toluene), these compounds yield **117a** or its tungsten analogue **117a''**.[65b] The molybdenum analogue **117a'** has been characterized X-ray crystallographically (Table 6).[65b]

Dichloro(mesityl)phosphane reacts with $Na_2[M_2(CO)_{10}]$, M = Cr, Mo, W, in such way that the compounds **119a–c** are formed alongside the isolable phosphanediyl complexes $[RP\{M(CO)_5\}_2]$, M = Cr, W. The structure of compounds of the type **119a–c** (cf. also complex **115a**) is confirmed by an X-ray structure analysis of the molybdenum derivative **119b** (Table 6).[65b]

cis-$[\{(mesityl)P\}_2\{M(CO)_5\}_2]$
119a, M = Cr; **119b**, M = Mo; **119c**, M = W



The stabilization of *trans*-Ph–P=P–Ph in a metal complex can be achieved using the method described by *Huttner* et al.[65] (X-ray data of **120**, **121**, Table 6).

Compound **120** is prepared from $Na_2[Cr_2(CO)_{10}]$ and $(OC)_5Cr(PPhCl_2)$;[65] the comparable Pd complex **122** can be prepared directly from the η^2-precursor and $W(CO)_5(thf)$.[66d] The classical side-on coordination **123**, the longest-known coordination mode of diphosphenes, has been achieved exclusively in the coordination sphere of a transition metal; compounds **123a–e** have been characterized by X-ray structure determination (Table 6).

120 **121**

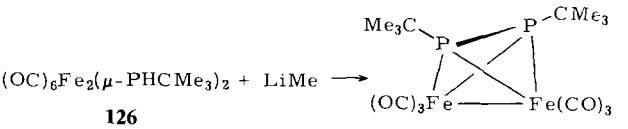
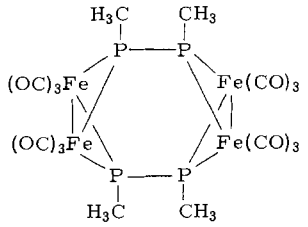
e	Ni	[a]	C_6H_5	[66e]



[a] 3,4-Bis(diphenylphosphino)-1-methyl-2,5-bis(trimethylsiloxy)pyrrole.

The thermolysis of $(\eta^5\text{-}C_5H_5)_2MoH_2$ and P_4[66a] or $M(PPh_3)_3$ and $(EC_6F_5)_4$ (M = Pd, Pt, E = P, As)[66b] gives **123a**, **b**. $[PdCl_2(dppe)]$ reacts with $Li_2(PhP{-}PPh)$ to give **123d**; the compounds with M = Pt, L_n = dppe, $(PPh_3)_2$, are also known.[66d] $[(Et_3P)_2NiCl_2]$ reacts with $LiP(SiMe_3)_2$ to give (amongst other products) **123c**; the Me_3P- and nBu_3P-compounds have been prepared analogously[66c] (cf. also Ref. [11]). **123e** and its arsenic analogue **134d** can be obtained from the 2,3-bis(diphenylphosphino)-*N*-methylmaleimide complex of $NiCl_2$ and $PhE(SiMe_3)_2$, E = P, As.[66e]

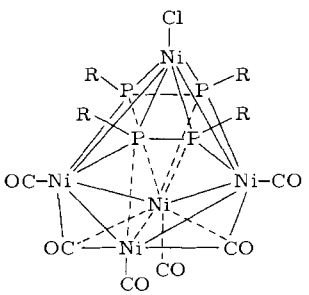
The 4e- and 6e-donor coordination modes of a diphosphene ligand (**124**[64c] and **125**[67a]) can be attained by the reactions of $2,4,6\text{-}(Me_3C)_3C_6H_2OPCl_2$ with $Na_2[Fe(CO)_4]$ or of $(OC)_6Fe_2(\mu\text{-}PHCMe_3)_2$ (**126**) with LiMe, respectively.



124

126 **125**

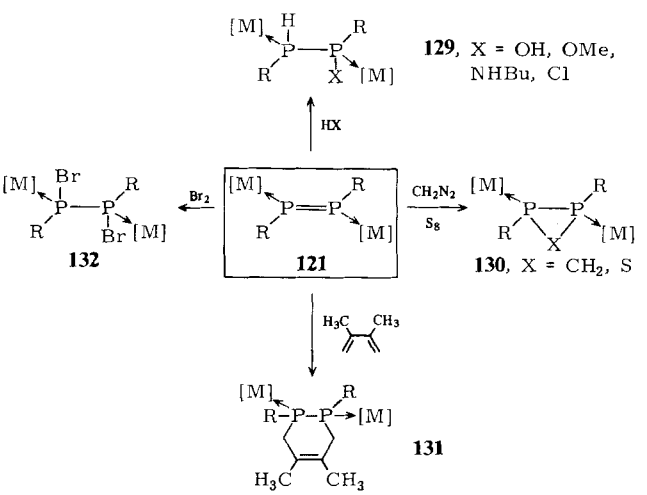
R = $2,4,6\text{-}(Me_3C)_3C_6H_2$



If the CMe_3 group of **126** is replaced by a methyl group, **127** (an organometallic analogue of octabisvalene) is formed rather than the methyl derivative of **125**. The P–P

127

bond length of **127** (2.226(4) Å) suggests that the ligands should not be described as diphosphene units.[67b]

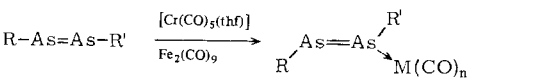


RPPR ligands are part of a Ni_5 cluster in **128**, prepared from $(Me_3Si)_2CHPCl_2$ and $Na_2[Ni_6(CO)_{12}]$[68] (Table 6).

128, R = $(Me_3Si)_2CH$

Temperature-dependent $^{31}P\{^1H\}$-NMR studies of the systems RP=PR/$Ag(SO_3CF_3)$ and RP=PR/$[Et_3PAu][PF_6]$ provide evidence for the formation of the cationic complexes $[R(Ag)P=P(Ag)R]^{2\oplus}$, $[RP=P(Ag)R]^{\oplus}$, and $[RP=P(AuPEt_3)R]^{\oplus}$, where R = 2,4,6-$(Me_3C)_3C_6H_2$.[69]

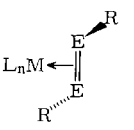
The addition and cycloaddition reactions carried out on complex **121**[70] show in striking fashion the versatile reactivity of diphosphene ligands.



[M] = $Cr(CO)_5$, R = Ph

129 and **130** are formed stereoselectively, while **132** is a mixture of racemate and *meso*-form. The [4+2]-cycloaddition of **121** with cyclopentadiene is analogous to the formation of **131** (one isomer, in each case). **129** (X = OH, NHBu), **130** (X = CH_2), and **131** were additionally characterized by X-ray structure analysis.[70]

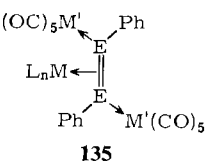
3.4.2. *Diarsenes (R–As=As–R), Distibenes (R–Sb=Sb–R)*



For the few diarsene derivatives R–As=As–R′ (R, R′ bulky groups) that are isolable in the free state, only the 2e-donor coordination type is known (**133**).[63,71]

R = 2,4,6-$(Me_3C)_3C_6H_2$ **133a**, M = Cr, n = 5[63,71]

R′ = $(Me_3Si)_2CH$ **133b**, M = Fe, n = 4[71]



η^2-Coordination (**134**, **135**) can be generated in the coordination sphere of a transition metal.

[a] $Me_3CSb{=}SbCMe_3$ instead of PhE=EPh.

134a, **b** and **134d** are prepared analogously to the diphosphene complexes **123b** and **123e**. The metathetic reaction of $Na_2[Fe(CO)_4]$ with $C_6H_5AsCl_2$[72] or $(Me_3Si)_2CHSbCl_2$[73] leads to **134c** and **134e**; **135a** is formed from $C_6H_5AsCl_2$ and $Na_2[Cr_2(CO)_{10}]$, or $(OC)_5Cr(AsPhLi_2)$ and $(Cl_2PhAs)Cr(CO)_5$;[74a] **135e** from $C_6H_5SbCl_2$ and $Na_2[W_2(CO)_{10}]$.[75] **135e** reacts with phosphanes with formation of adducts of the stibanediyl complex $PhSb[W(CO)_5]_2$.[75b] When Me_3CSbCl_2 is allowed to react with $Na_2[Cr_2(CO)_{10}]$ in $CHCl_2$, not only the stibanediyl complex $[Me_3CSb\{Cr(CO)_5\}_2]$ is obtained but also the distibene complex **135f**,[75b] the structure of which has been confirmed by an X-ray structure analysis (Table 6). Starting material for the synthesis of **135b–d** is $[(OC)_5CrAs(Ph)(H)]_2$; this is allowed to react with Pd/C/2L or Pt/C/L, when the required products are formed by H_2 elimination, probably via the intermediate **136**.[74b]

The transition from terminal to η^2-coordination is in most cases accompanied by the expected change in PP or AsAs bond length in the direction of a single bond (e.g. **113b/124**, **133a/135a**; Table 6). An exception is furnished by **125**,[67a] the short P–P bond of which can be contrasted with the long P–N bond of the isoelectronic **111**[59] (Table 5). The η^1-P- or η^1-As-coordination in **113b** and **133a** has the effect of lengthening the P=P or As=As bond by ca. 0.02 Å compared with the free ligands (Table 6), which also have the *trans* configuration.

Table 6. $^{31}P\{^1H\}$-NMR data (δ values, J in Hz) and E-E bond lengths [Å] for complexes with R–E=E–R(R') ligands. Comparative distance of the free ligand in **113b**: P=P 2.034(2) Å [60]; in **133a**: As=As: 2.224(2) Å (A. H. Cowley, J. G. Lasch, N. C. Norman, M. Pakulski, *J. Am. Chem. Soc. 105* (1983) 5506).

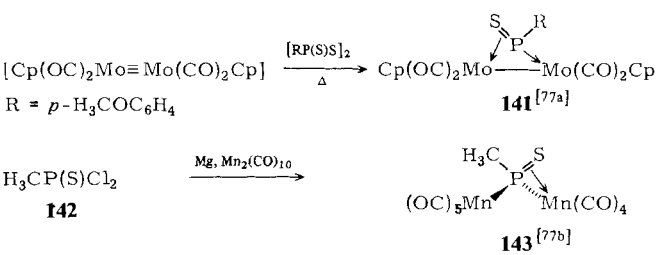
[a] AB spin system.

[{$(OC)_5Cr$}(Ph)As=As(Ph){$Cr(CO)_5$}] **136** $Te_2[W(CO)_5]_3$ **137**

An interesting structural analogy is seen in $(PhSb)_2[W(CO)_5]_3$ (**135e**) and $Te_2[W(CO)_5]_3$ (**137**).[76] The Te–Te bond length of 2.686(4) Å and also the Te–W bond lengths correspond almost exactly with their counterparts in the "isoelectronic" **135e**[75a] (Table 6).

3.4.3. *Phosphaarsaethenes (R–P=As–R')*

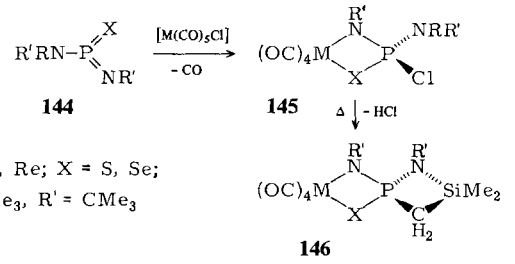


The isomers **139** and **140** are formed on reaction of $Fe_2(CO)_9$ with **138**; their separation proved impossible, but $^{31}P\{^1H\}$-NMR data suggested the structures shown.[63]

R = 2,4,6-$(Me_3C)_3C_6H_2$, R' = $(Me_3Si)_2CH$

3.4.4. *Thioxophosphanes (R–P=S)*

Compounds of this type (with a σ^2,λ^3-phosphorus atom) have not yet been isolated in the free state at room temperature, but have been stabilized in complexes.

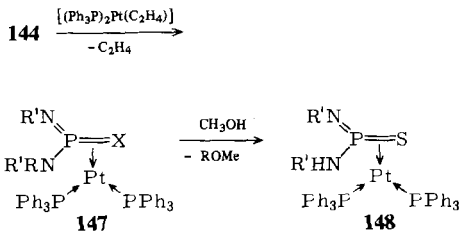


In both cases (**141** and **143**) the R–P=S ligand is coordinated side-on to the metal atom; the PS bond lengths are very similar [2.022(1) Å in **141**,[77a] 2.033(2) Å in **143**[77b]]. The non-bonding electron pair of the phosphorus of RPS is formally a 2e-donor to Mo in **141**, but a 1e-donor to both Mn atoms of **143**. If, instead of $Mn_2(CO)_{10}$, $[Mn(CO)_5]^{\ominus}$ is allowed to react with **142**, then **143** is formed only in trace amounts; this has been interpreted as evidence for the role of H_3C–P=S as an intermediate of **142** leading to **143**.[77b] The terminal P-coordination of an amino(oxo)phosphane is revealed by the crystal structure of **96**.[54]

4. Multiply Bonded Systems with Ligand Coordination Number Three

4.1. Aminoiminothioxophosphoranes and Aminoiminoselenoxophosphoranes

The isolable ligand **144**, a pentavalent phosphorus compound with coordination number 3 (σ^3,λ^5-P), adds, e.g., to



$M(CO)_5Cl$ to form the four-membered ring chelate complexes **145**, thermolysis of which leads to the spiro systems **146**.[78] **146** is also formed directly from, e.g., $Mn(CO)_5Br$ and **144**.[78]

144 **145** **146**

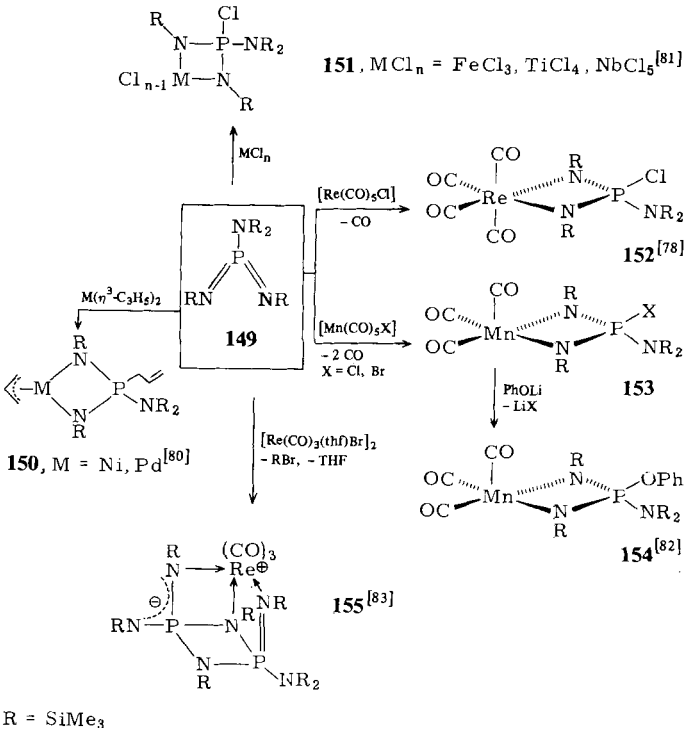
M = Mn, Re; X = S, Se;
R = $SiMe_3$, R' = CMe_3

The η^2-coordination of the P=S or P=Se unit of **144** is achieved in the platinum complexes **147**.[79] Methanolysis of the Si–N bond of **147** furnishes an aminoiminothiophosphorane $Me_3CNH-P(S)=NCMe_3$, unknown in the free state but stabilized at the metal center.[79] The X-ray structure analysis of **147** (X = S) reveals the side-on coordination (P–S 2.073(3) Å) and also a weak N→Si donor-acceptor interaction of 2.629(6) Å.[79]

147 **148**

X = S, Se; R = $SiMe_3$, R' = CMe_3

Coordination type **147** for nickel (see compound **103**) can be achieved by oxidation of an η^2-$R_2N-P=NR$ ligand.[56]



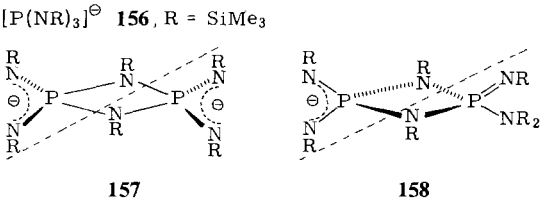
4.2. Aminobis(imino)phosphoranes

The persilylated compound **149** surpasses **144** in its versatility as a ligand.

149 reacts with bis(η^3-allyl)nickel and bis(η^3-allyl)palladium to form the four-membered ring framework **150** by allyl migration.[80] With transition metal halides[81] or carbonyl halides,[78,82] the chelate complexes **151**–**153** are formed; the formation of the five-coordinate Mn^I complex **153** is particularly notable, and the square pyramidal coordination at Mn was proved by an X-ray structure analysis of the derivative **154**.[82]

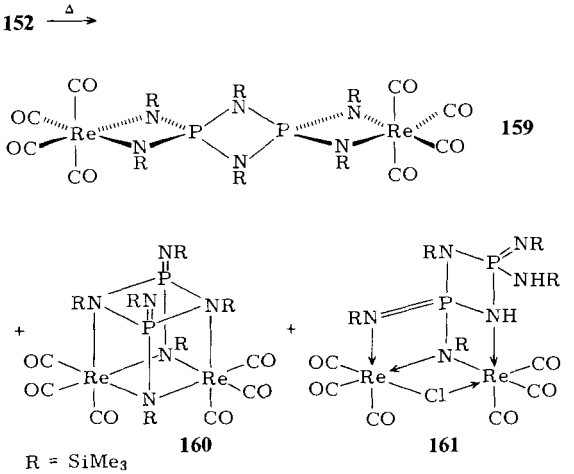
The removal of an R group from the amino nitrogen of **149** would formally produce **156**, a derivative of the monomeric metaphosphate ion; **156** could react with itself or with **149** by [2+2] cycloaddition to form the polydentate ligands **157** and **158**, which in turn (as **155** and the following examples show) can be synthetic units for mono- and dinuclear rhenium complexes.

The tricyclic **155** contains the anion **158** acting as a 6e-donor, whereas in **159** and **160**, the dianion **157** is an 8e- and 12e-donor, respectively, to Re^I. Starting material for



151, MCl_n = $FeCl_3$, $TiCl_4$, $NbCl_5$[81]

152[78] **153** **154**[82] **155**[83]

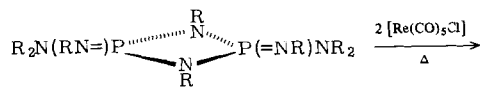


150, M = Ni, Pd[80]

R = $SiMe_3$

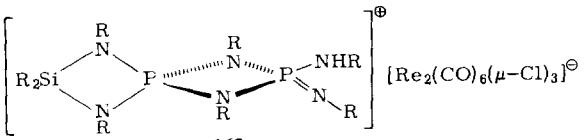
the synthesis of the polydentate ligand system **157** is the chelate complex **152**, thermolysis of which leads to the polycyclic phosphorus-nitrogen-rhenium compounds **159**–**161**.[84]

157 **158**



159 **160** **161**

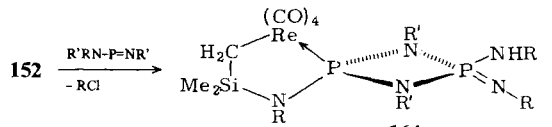
R = $SiMe_3$



The centrosymmetric dispiro compound **159** (a derivative of a dimeric metaphosphate, stabilized at a metal complex) contains PN_2Re four-membered rings slightly bent about the N···N axis.[84] **161** (identified by crystal structure analysis) is probably formed from the "cubane" **160**

($M_2A_4B_2$ structure type) and the HCl formed by the thermolysis (cf. the formation of **146**), with simultaneous elimination of Me_3SiCl.[84]

Attempts to synthesize **159** ($^{31}P\{^1H\}$-NMR control) by reaction of **162** (dimeric **149**[85]) with $Re(CO)_5Cl$ lead instead to the ionic **163**.[84]



162

163

R = $SiMe_3$

A no less surprising reaction is the co-thermolysis of **152** with amino(imino)phosphanes.

164

R = R' = $SiMe_3$; R = $SiMe_3$, R' = CMe_3

The spirocycle **164** formed in this way is of structural interest for the novel linkage of the P–N–Re units and also for the formation of a Re–C bond, probably by oxidative addition of a $SiMe_3$ methyl group (cf. the iridium complex **87**[52c]). An approximately linear P=N–R unit has been established for **163** (173°) and **164** (168°) by X-ray structure determination.[84] Me_3SiN_3 oxidizes (dppe)Ni(η^2-R_2N–P=NR) **102** to **103**, X = $NSiMe_3$, which contains the aminobis(imino)phosphorane **149** side-on bonded to the metal via one of its phosphorus-nitrogen double bonds.[56]

5. Concluding Remarks and Outlook

The chemistry of complexes of multiply bonded systems of phosphorus, arsenic, antimony and bismuth with low coordination number has so developed, especially in the last few years, as to be a connecting link between main group and transition metal chemistry; notwithstanding its diversity, there are clearly many more important discoveries to be made. Ligands with triple or double bonds, analogous to alkyne, alkene, benzene, and diazene derivatives, can also display novel coordination modes and variants. The coordination sphere of transition metals allows the generation and stabilization of ligands such as PN, E_2 (E = P, As, Sb, Bi), P_6, As_5, HP=PH (the simplest diphosphene), PhAs=AsPh, RSb=SbR, RPCHPR (the diphosphorus analogue of the allyl group), insufficiently sterically protected trivalent phosphorus and arsenic compounds with coordination number 1 (E≡) and 2 (–E=) and pentavalent phosphorus of coordination number 3 (=P–); transition metal-phosphorus units of the type L_nM–P= and L_nM⇆P= can similarly be synthesized in stable form.

It is to be expected that new ligand systems and coordination types (cluster units) will be discovered and that our knowledge of the reactivity of the coordinated ligands will be extended. Studies of catalytic activity will certainly be worthwhile. Further valuable help for our understanding of the bonding involved in these compounds will be provided by the theoreticians.

I should especially like to thank the following: my co-workers (mentioned by name in the references) for their enthusiasm and commitment to their research; Prof. C. Krüger (Mülheim), M. L. Ziegler (Heidelberg), W. S. Sheldrick and Dr. G. Wolmershäuser for X-ray structure determinations; and the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.

2,3-Dihydro-1,3-diborole-Metal Complexes with Activated C–H Bonds: Building Blocks for Multilayered Sandwich Compounds

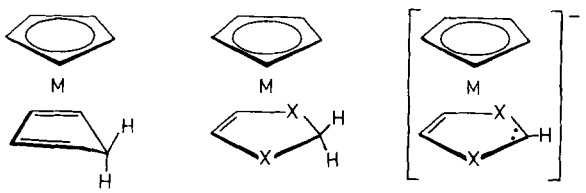
By Walter Siebert*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Derivatives of 2,3-dihydro-1,3-diborole acting as four-electron ligands form various metal complexes in which the ring-methylene carbon atom is pentacoordinated. The resultant activation of the C–H bond can be used to prepare triple-decker to hexadecker sandwich complexes. Bis(2,3-dihydro-1,3-diborole)nickel complexes undergo a spontaneous stacking and formation of tricarbahexaboranyl oligodecker complexes with stacks of 2,3-dihydro-1,3-diborolylnickel. These findings finally led to the synthesis of the first polydecker sandwich complex which was obtained by vacuum thermolysis of a tris(allyl)(μ-2,3-dihydro-1,3-diborolyl)dinickel complex. The black polymer possesses remarkable semiconductor properties.

1. Introduction

In the last few years various papers dealing with the interaction between the C–H bonds of saturated (sp^3) and unsaturated (sp^2) carbon atoms and the metal atoms in complexes have appeared.[1] *Brookhart* and *Green* have suggested the term *agostic* to describe the three-center, two-electron bond (3c/2e) between a carbon, hydrogen, and metal atom (C–H→M). Such systems are characterized by longer C–H and M–H bonds, ^{1}H-NMR shifts to higher fields, and smaller ^{13}C-^{1}H coupling constants. For the formation of an agostic 3c/2e-bond it is necessary to create a complex with two valence electrons (VE) less, which can then electronically stabilize itself by an intramolecular C–H→M bond. As a result of an oxidative addition of the C–H bond to the metal atom, these interactions often lead to organometallic hydrides (C–M–H), which is usually observed in an intermolecular reaction.



Recently, *Saillard* and *Hoffmann*[2] have analyzed the activation of the C–H bond of methane by transition metal complexes and metal surfaces in detail. This field of research has attracted broad interest regarding catalytic processes.[1,2] Not only spectroscopic and structural data

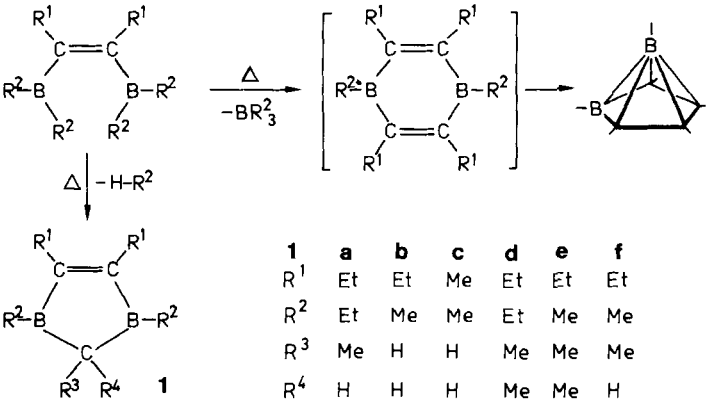
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

but especially stoichiometric reactions involving the activated C–H bonds yield important information. Hence, we are interested in new kinds of sandwich complexes,[3] which contain a pentacoordinated carbon atom with at least one C–H bond in a terminal cyclic ligand and which are also expected to exhibit an enhanced reactivity.

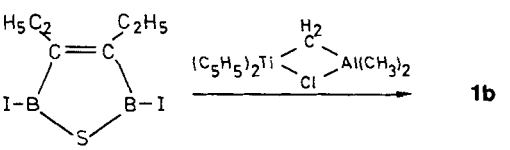
Cobalt compounds of type **I** containing carbacyclic ligands are known to easily lose a hydrogen from the methylene moiety.[4] The axial C–H group exhibits a strong peak at $\approx 2750\ cm^{-1}$ in the IR-spectrum. However, no C–H→Co bond is involved, since the cobalt atom already possesses an 18 VE shell. In the analogous manganese compound (**I**) a C–H→Mn interaction is to be expected at lower temperatures.

Substituting the CH-groups adjacent to the methylene carbon atom in **I** by electron-deficient X atoms (see **II**) could (with M = cobalt) lead to a C–H→Co bond. Such postulated complexes based on the 18-VE rule should exhibit an increased CH-acidity and should be easily deprotonated to **III**.



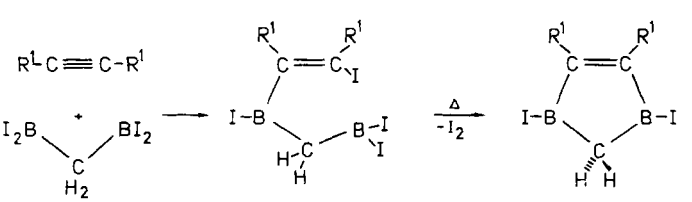
The first example of such a complex was obtained in the reaction of $(C_5H_5)Co(CO)_2$ with the 2,3-dihydro-1,3-diboroles **1**. In this report, iron, cobalt, nickel, rhodium, and platinum complexes will be described, which exhibit a preparatively widely used reactivity of the methylene bridge of the monofacially coordinated ligand **1**. However, instead of the expected 3c/2e interaction C–H→M,[5a] a new type of bonding system which will be introduced in Section 4, is observed.

This C–H-acidity as well as the donor/acceptor properties of complex-bonded **1** open the door to new compounds which in turn can serve as educts for the construction of many-layered sandwich complexes with stacked structures. One-dimensional polydecker complexes should possess anisotropic properties. Especially the electrical conductivity along the stacking axis is of theoretical[6] and practical interest. The preparative possibilities of the 2,3-dihydro-1,3-diborole-metal complexes become apparent when the isolobal principle[7] is applied. In the 18-VE complexes of **1** the heterocycle is isolobal with cyclopentadiene; thus, a new dimension of organometallic and complex chemistry can be developed.



2. Synthesis of 2,3-Dihydro-1,3-diboroles

The heterocycle **1** was first prepared by *Binger*[8] in the thermal ring closure of hexaalkyl-*cis*-diborylethene with simultaneous elimination of alkane (Scheme 1). From the hexaethyl derivative, **1a** is obtained in 35–40% yield, while hexamethyldiborylethene yields, instead of **1c**, the permethylated 2,3,4,5-tetracarbahexaborane(6) practically quantitatively via the 1,4-diboracyclohexadiene. These and other rearrangements of organoboranes into carbaboranes have been studied by *Lipscomb* et al.[9] using PRDDO calculations.

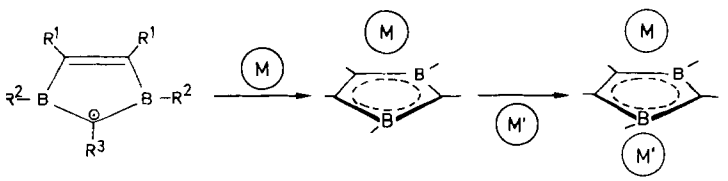


Scheme 1. Thermal ring closure of 3,4-bis(diethylboryl)-3-hexene to the heterocycle **1a** [8]. 2,3-Bis(dimethylboryl)-2-butene yields only the C_4B_2-carbaborane. The synthesis of **1b** and **1c** takes place according to Schemes 2 and 3, respectively, while **1d–f** can be prepared by methylating the complexed ligands **1a** or **1b** [3, 20].

The reaction of 3,4-diethyl-2,5-diiodo-2,5-dihydro-1,2,5-thiadiborole[10] with $(C_5H_5)_2Ti(Cl)CH_2Al(CH_3)_2$,[11] in which methylation and S/CH_2-exchange took place, led to a direct synthesis of **1b** (Scheme 2).[12] The disadvantage of this dihydro-diborole synthesis, besides the meager yield, is that it is limited to the 3,4-diethyl-2,5-diiodo-2,5-dihydro-1,2,5-thiadiborole, since the corresponding 3,4-dimethyl compound is difficult to synthesize.

Scheme 2. Synthesis of the heterocycle **1b** from 3,4-diethyl-2,5-diiodo-2,5-dihydro-1,2,5-thiadiborole and $(C_5H_5)_2Ti(Cl)CH_2Al(CH_3)_2$ [12].

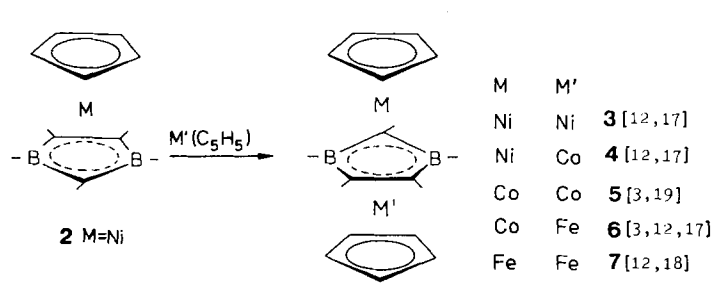
The redox reaction between dialkylacetylenes and bis(diiodoboryl)methane[13] (Scheme 3) offers a new reaction pathway to the heterocycle **1**. Elimination of iodine and ring closure leads to formation of the corresponding diiodine derivative ($R^2 = I$) in 80% yield. Subsequent alky-



Scheme 3. Synthesis of 4,5-dialkyl-1,3-diiodo-2,3-dihydro-1,3-diborole derivatives using the redox reactions between dialkylalkynes and bis(diiodoboryl)methane [13]; **1c** and other derivatives by alkylation of the diiodine compounds with AlR_3.

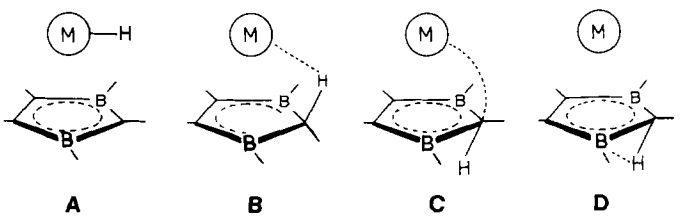
lation using trialkylaluminum yields the air-sensitive organoboranes.

Attempts to synthesize penta- und hexaalkyl derivatives are presently being carried out. **1d** (**1f**) can be prepared in poor yields upon allowing the brown solution obtained from **1a** (**1b**) and potassium to react with methyl iodide.[14]



3. Donor/Acceptor Properties of 1

2,3-Dihydro-1,3-diboroles can act as three- or four-electron donors. Cleavage of a hydrogen atom from the methylene bridge leads to an intermediate 2,3-dihydro-1,3-diborolyl radical $(1-H)^{\odot}$, which can react with metal complex fragments mono- or bifacially as a 3e ligand to form mono- or dinuclear complexes[5] (Scheme 4).



Scheme 4. Mono- and bifacial coordination of the 3e ligand 2,3-dihydro-1,3-diborolyl$(1-H)^{\odot}$ with metal-complex fragments.

The 15e fragments $Ni(C_5H_5)$ and $Co(CO)_3$ yield the 18 VE complexes **2**[15] and $(CO)_3Co(\mathbf{1a}-H)^{\odot}$,[16] in which the heterocycle acts as a 3e donor. The electron deficiency of the ligand is mainly compensated by the π-back bonding between occupied d-orbitals of the metal and acceptor orbitals of the C_2B_2C ligand. However, the remaining acceptor properties are often strong enough for a bifacial coordination of the ligand. With the complex fragments $Ni(C_5H_5)$ and $Co(C_5H_5)$ the Lewis-acidic nickel sandwich **2** (M = Ni) undergoes an almost quantitative stacking to the triple-decker sandwich complexes **3** and **4**, respectively (Scheme 5). The three-component reaction between **1a**, $[(C_5H_5)Fe(CO)_2]_2$ and $(C_5H_5)Co(CO)_2$ led to the triple-decker sandwich complex **6a** in poor yields, whereas **5a** is formed from $(C_5H_5)Co(CO)_2$ and **1a**.[17] It can thus be assumed that the mononuclear complex $(C_5H_5)Co(\mathbf{1a})$ is the primary product in the synthesis of **5a** and **6a**. Since $Co(C_5H_5)$ is a 14 VE fragment, **1a** should act as a 4e ligand in the complex if a C–H bond is involved in the bonding. For the latter, several possible structures (**B**–**D**) have been discussed.[3] In **A** a hydrogen atom has migrated to the metal, so that the ligand acts as a 3e donor as in the complexes **2** to **7**. Until now we have had no concrete evidence of the existence of hydride complexes;[3] however, recent results have identified a complex of type **A** as a labile primary product.[20] In the intact heterocycle **1**, the 3c/2e bonds could be present in **B**, M←H–C, in **C**, M←C–H, or in **D**, B←H–C. Type **B** represents an agostic interaction, while **C** represents a M←C–H bond between the axial C–H group and the metal; **D** represents a part of the 4c/4e bond made up of the 3c/2e bonds B←H–C and B–M–C (similar to the bridging bond in diborane). Each of these electronic interactions between the intact 2,3-dihydro-1,3-diborole **1** and the metal in **B**, **C**, and **D** is expected to activate the C–H bond.

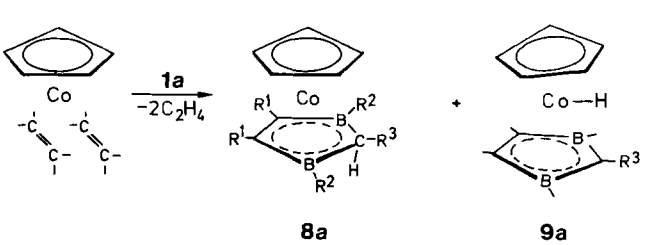
Fe	Fe	**7** [12,18]

Scheme 5. Stacking of sandwich complexes (M = Ni, **2**; M = Co, Fe) with $M'(C_5H_5)$ complex fragments to give the triple-decker sandwich complexes **3**–**7** [3, 12].



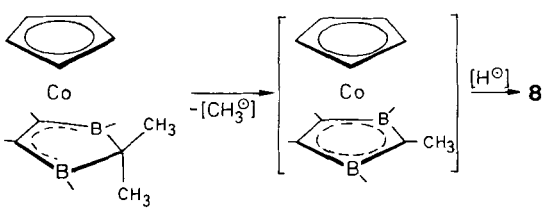
Scheme 6. Possible interactions between the ligand **1** and a metal-complex fragment with the formation of **A** (M–H bond), **B** (C–H→M bond), **C** (H–C→M bond), and **D** (C–H→B bond) [3].

4. Synthesis of 2,3-Dihydro-1,3-diborole-Metal Complexes

4.1. Cyclopentadienylcobalt Complexes

The photolytic reaction between $(C_5H_5)Co(CO)_2$ and **1a** leads to traces of the red, diamagnetic complex **8a**.[17b] The poor yield is related to the reactivity of the released carbon monoxide, which can insert itself into the B–C bond of **1a** (see Scheme 11). Rearrangement results in the formation of compounds with boron-oxygen bonds, which are no longer capable of bonding to the $Co(C_5H_5)$ fragment. The crystalline complexes **8** containing the ligands **1a**–**1c** and **1f** are obtained in up to 80% yields[3,22] using the *Jonas*-reagent[21] $(C_5H_5)Co(C_2H_4)_2$ (Scheme 7).

The side of the C=C double bond of **1a** that attacks the $Co(C_5H_5)$ fragment plays an important role in the synthesis of **8a**. If the methyl group of the methylene bridge faces the cobalt atom, **8a** is obtained. Otherwise, the yellow complex **9a** containing a Co-hydride bond [^{1}HNMR: $\delta = -10.6$ (Co–H)] is formed via a C–H→Co interaction. **9a** can only be isolated if the reaction mixture (20°C/1 h)

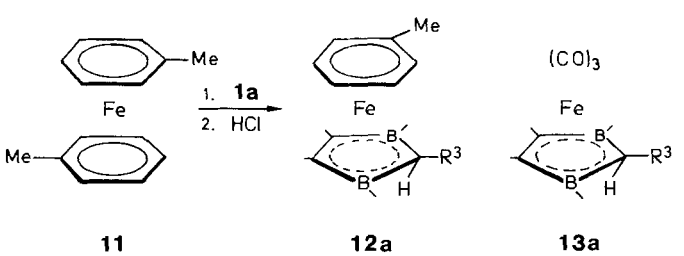


Scheme 7. Replacement of ethylene in $(C_5H_5)Co(C_2H_4)_2$ by **1a** with formation of the red complex **8a** [3, 22] and the yellow complex **9a** [20].

is quickly worked up (yields of **8a** : **9a** ≈ 4 : 1). At room temperature **9a** is transformed into **8a** by migration of the hydrogen atom from the cobalt to the axial position of the methylene carbon atom.[20]

The triple-decker **5b** and the tetradecker **41b** are formed as by-products in the preparation of **8b**.[3] This increased reactivity of **8b** with respect to stacking can be ascribed to the decreased shielding in the ligand **1b** compared to **1a**. A characteristic property of the cobalt sandwich complexes is the upfield ^{1}H-NMR shift of the axial proton at $\delta = -8.3$. The ^{11}B-NMR shifts ($\delta = 25$–30) indicate that the boron atoms are well shielded by the metal atom, which is not consistent with an agostic arrangement. A decrease in the ^{13}C-^{1}H coupling constant for the methylene carbon atom from 115 Hz in the free ligand **1a** to 81 Hz in the complex **8a** is observed in the ^{13}C-NMR spectrum. An unequivocal decision as to which of the possibilities **B**, **C** or **D** correctly describes the bonding situation cannot be made on the basis of these NMR data.

Reaction of the hexaalkyl derivatives **1d**,**e** with $(C_5H_5)Co(C_2H_4)_2$ yields the violet, wax-like complexes **10d**, **e**, which decompose to **8a**, **f** above 60 °C (Scheme 8). The blue 1,3-diphenyl-1,3-diborole complex is thermally more stable.[20] **9a** reacts with methyl iodide at 20 °C with formation of **10d**. Complex **10** probably contains a 16 VE configuration which does not involve a $H_2C{-}H \rightarrow Co$ bond. The much lower ^{11}B-NMR upfield shift ($\delta = 42$) strongly suggests that the interaction between metal and ligand must be weaker (see Section 6.1).



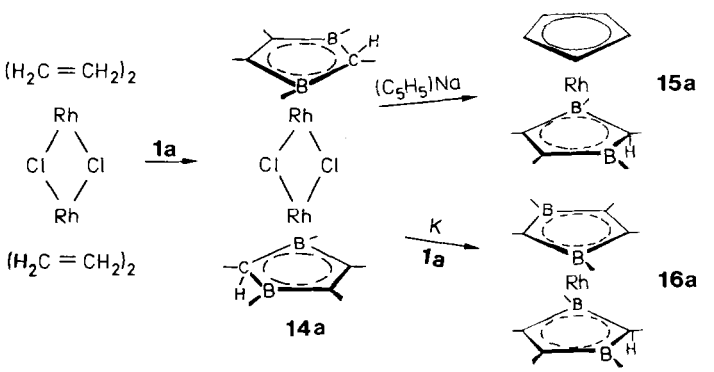
Scheme 8. Thermal conversion of the violet complex **10** into red **8** [3, 20].

4.2. Areneiron and Tricarbonyliron Complexes

To prepare arene(2,3-dihydro-1,3-diborole)iron complexes the reaction of bis(toluene)iron **11** with **1a** was investigated.[23] At first, a brown, impure product containing finely divided iron was obtained, which after treatment with hydrogen chloride yielded the red, crystalline sandwich complex **12a** (Scheme 9).

The ^{1}H-NMR spectrum of **12a**, like that of **8a**, exhibits a high-field quartet at $\delta = -8.6$ due to coupling between

Scheme 9. Synthesis of the iron sandwich complex **12a** from bis(toluene)iron **11** and **1a** [23].



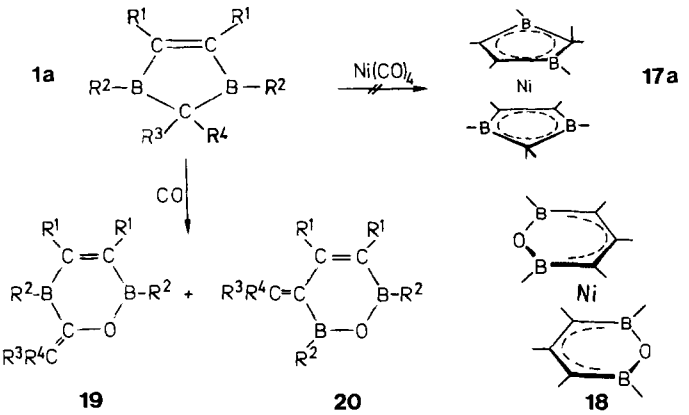
the proton of the pentacoordinated carbon atom and the methyl group.

The ^{11}B-NMR shift of $\delta = 24$ also suggests that the bonding relationships in **12a** and **8a** are similar. The corresponding toluene-iron complexes with the ligands **1b**, **c** could not be obtained, probably because of their increased reactivity.

The tricarbonyliron fragment, isolobal with arene-iron, reacts with **1a** to yield the yellow complex **13a**.[23] Due to CO-insertion into **1a** the reaction is not successful with $Fe(CO)_5$ or $Fe_2(CO)_9$ but with tricarbonylbis(π^2-cis-cyclooctene)iron.[24] The MS and NMR data provide strong proof for the structure of **13a**: the high-field quartet for the acidic proton appears at $\delta = -6.52$, the ^{11}B-NMR signal at $\delta = 26.6$. The compound decomposes above 60 °C; the corresponding complexes **13b**, **c** are no longer stable at 20 °C.

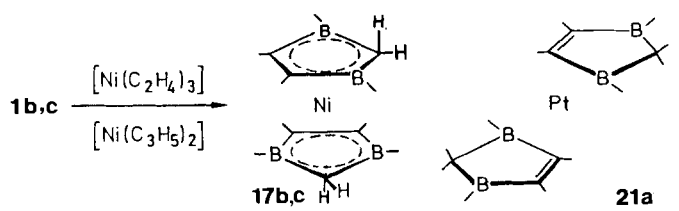
4.3. 2,3-Dihydro-1,3-diborole-Rhodium Complexes

The reactions of $(C_5H_5)Co(C_2H_4)_2$, $Ni(C_2H_4)_3$, and $Pt(C_2H_4)_3$ (see Section 4.4) with the ligands **1** have clearly demonstrated the advantage these reagents have over the carbonyl complexes. Thus, the analogous reactions with $[(C_2H_4)_2RhCl]_2$ were carried out to determine, among other things, whether diborolerhodium complexes with 16 VE are stable. The reaction with **1a** in THF results in the formation of the chloro-bridged dinuclear complex **14a** in 70% yield (Scheme 10). **14a** reacts with C_5H_5Na to yield the sandwich complex **15a**, which exhibits a high-field ^{1}H-NMR signal ($\delta = -6.9$) with a ^{103}Rh-^{1}H coupling constant of 7 Hz.[25] The new sandwich complex **16a**, in which for the first time both the 2,3-dihydro-1,3-diborole **1a** and the 2,3-dihydro-1,3-diborolyl $(\mathbf{1a} - H)^{\odot}$ are complexed, is formed in the reaction of **14a** with potassium in the presence of **1a**. In this 16 VE complex the high-field ^{1}H-NMR signal appears at −3.7 ppm with $^2J_{Rh-H} = 5$ Hz.



Scheme 10. Replacement of ethylene in $[(C_2H_4)_2RhCl]_2$ by **1a** with formation of the dinuclear complex **14a**, and its reaction with $(C_5H_5)Na$ or with potassium and **1a** to yield the sandwich complexes **15a** and **16a**, respectively [25].

4.4. 2,3-Dihydro-1,3-diborole-Nickel and -Platinum Complexes



Reaction of **1a** with $Ni(CO)_4$ did not yield bis(diborole)nickel **17a**; instead the unusual bis(allyl)nickel com-

plex **18** (15% yield) was obtained, the constitution of which was proven by an X-ray structure analysis.[26] Carbon monoxide insertion into **1a**, rearrangement of the primary products to **19** and **20**, and the complexation of **20** to $Ni(CO)_4$ leads to the reddish-orange complex **18** (Scheme 11).

Scheme 11. Reaction of the heterocycle **1a** with CO to give **19** and **20**. Reaction of **20** with $Ni(CO)_4$ leads to formation of the bis(allyl)nickel complex **18** [26].

The reduction of $NiBr_2$ with $NaHBEt_3$ in the presence of **1a** led to the isolation of the yellowish-brown compound **17a**, whose ^{1}H-NMR spectrum showed that it is indeed a bis(diborole)nickel complex.[27] This synthetic route cannot be used to prepare **17b**, **c**. The latter, yellowish orange crystalline compounds can be obtained, however, by allowing the ligands **1b**, **c** to react with $Ni(C_2H_4)_3$ or $Ni(C_3H_5)_2$[27-29] (Scheme 12). The ^{1}H-NMR spectrum of **17c** exhibits a doublet for the axial proton ($\delta = -2.3$) and the equatorial C–H group. A *gauche*-arrangement of the rings is consistent with the ^{11}B-NMR chemical shifts of $\delta = 45.1$ and 39.4. The interaction between boron and nickel is weaker than that observed in the cobalt complexes **8**.

Scheme 12. Formation of the nickel sandwich complexes **17b**, **c** from **1b**, **c** and $Ni(C_2H_4)_3$ or $Ni(C_3H_5)_2$, resp. [28, 63].

The analogous platinum compounds **21** can only be prepared with **1a** and $Pt(C_2H_4)_3$.[19] **21a** exhibits a temperature-dependent ^{1}H-NMR spectrum; an increase in the ^{195}Pt-^{1}H coupling constants and upfield shift are observed with decreasing temperatures. These findings are in agreement with a dynamical sandwich arrangement.

5. Structure and Bonding

X-ray structure analyses were carried out in order to elucidate the bonding relationships in the Co-, Fe- and Ni-complexes **8a**, **12a** and **17c**. Figure 1 shows the result for the cobalt sandwich **8a**. Based on the position of the CH_3-group on C4, an agostic hydrogen atom in a C–H→Co bond can be ruled out. The hydrogen atom on C4 is located on the side of the ligand that faces away from the cobalt atom. A crystallographic mirror plane passes through the atoms Co, C4, C7, and C1. From the data available, it is not possible to decide whether the hydrogen atom H4 lies in the mirror plane and is involved in a H–C→Co bond or whether it is disordered and forms C–H→B bridging bonds. Several factors suggest that the latter possibility is more likely to be the correct one. As is to be expected the geometry about C4 of the 2,3-dihydro-1,3-diborole ring in the cobalt complex differs from that of the 2,3-dihydro-1,3-diborolyl ring in the nickel sandwich complex **2a**: C4–B5 (1.63 Å) is significantly longer than the corresponding bond in **2a** (1.55 Å).

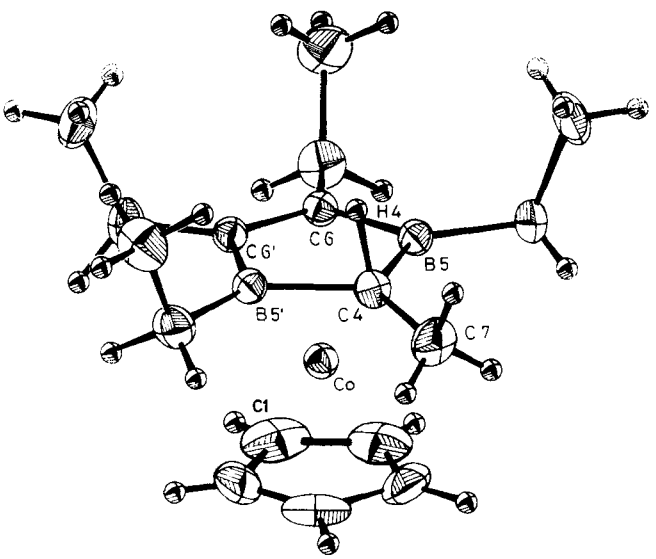


Fig. 1. Crystal structure of the cobalt sandwich complex **8a** [3, 22].

The iron sandwich complex **12a** exhibits a structure similar to that of **8a**, but without the uncertainty with respect to the position of the hydrogen atom caused by the mirror plane. As shown in Figure 2 the hydrogen atom H6 is dis-

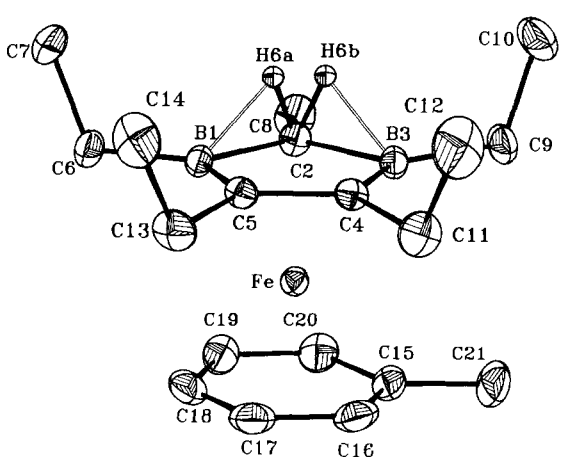

Fig. 2. Crystal structure of the iron sandwich complex **12a** [23, 30]. The axial hydrogen atom H6 at C2 is disordered (H6a, H6b) and forms asymmetric C–H→B bridging bonds (see Fig. 3).

ordered and occupies two independent positions above the plane of the ring, each of which allows an interaction with one of the two boron atoms. Assuming a disorder for H4 in the cobalt sandwich **8a**, both structures exhibit 3c/2e bonds (C–H→B).

The C–H and B–H bond lengths are 0.93 and 1.36 Å, respectively for **8a** and 1.13, 1.14 and 1.53, 1.51 Å, respectively, for **12a**. In order to locate H6 exactly, a neutron structure analysis was carried out for **12a**;[30] the data, however, did not allow a complete refinement of the structure. A combined structure refinement using the X-ray and neutron intensity data confirmed the result of the X-ray structure analysis. The positions of all of the hydrogen atoms were more reliable. The hydrogen atom is disordered and forms asymmetric C–H→B bridges to both boron atoms (Fig. 3).

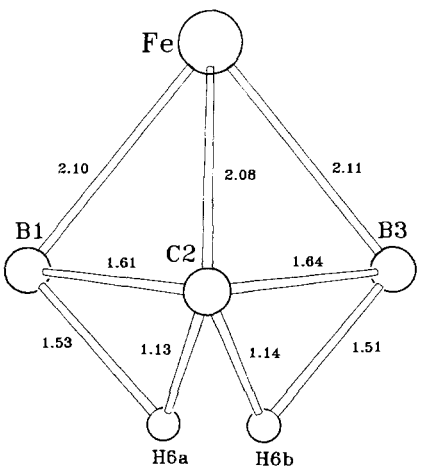

Fig. 3. Section of the structure of the iron sandwich complex **12a** (see Fig. 2). Bond lengths [Å].

The positions of the equatorial (H4) but not of the axial hydrogen atoms were located in an X-ray structure analysis of the nickel sandwich complex **17c** (Fig. 4). The *gauche*-confirmation of both rings as well as the NMR and MS spectra indicate that compounds **17** are nickel(0) complexes containing two 2,3-dihydro-1,3-diborole rings. It is assumed that complexes **17** also contain C–H→B bridges with 3c/2e bonds.

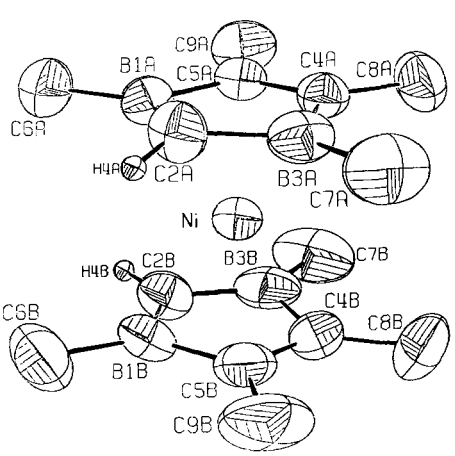

Fig. 4. Crystal structure of the nickel sandwich complex **17c**. The axial hydrogen atoms at C2A and C2B could not be located [29, 62].

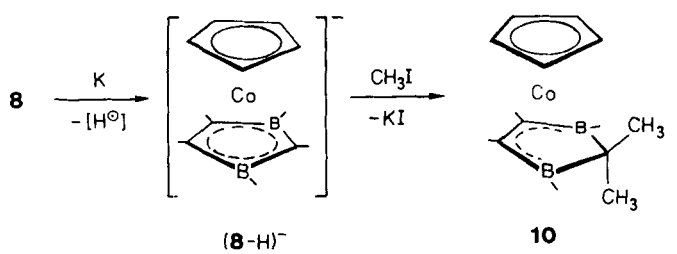
Summarizing, one can say that the exact position of the methylene hydrogen atom in the above complexes, except for the iron sandwich complex **12a**, is uncertain. Based on the present data it is assumed that the axial hydrogen atom is involved in C–H→B bonding in each of the complexes.

Hoffmann and *Böhm*[3] have carried out MO-studies (EH and INDO) in order to find out more about the electronic source for the deformation of the ligand **1** in the sandwich complex **8**. Both methods predict a frontier orbital strongly localized at Co–C4–H4 (3c-bond) in the equilibrium geometry. This coupling between Co and C4 results in a weakening of the C4–H4 bond. The nature of the Co←C–H interaction is only slightly changed by the formation of a C–H→B bridge. The LCAO-amplitude is reduced at the carbon atom, while it is increased at the boron atom. The frontier orbital is the result of a linear combination of the $3d_{xz}/3d_{yz}$ of the metal and contributions from C, B and H. Both oligo-center interactions are closely related topologically, since Co and H4 are coupled with one another through fragment orbitals of the ligand.



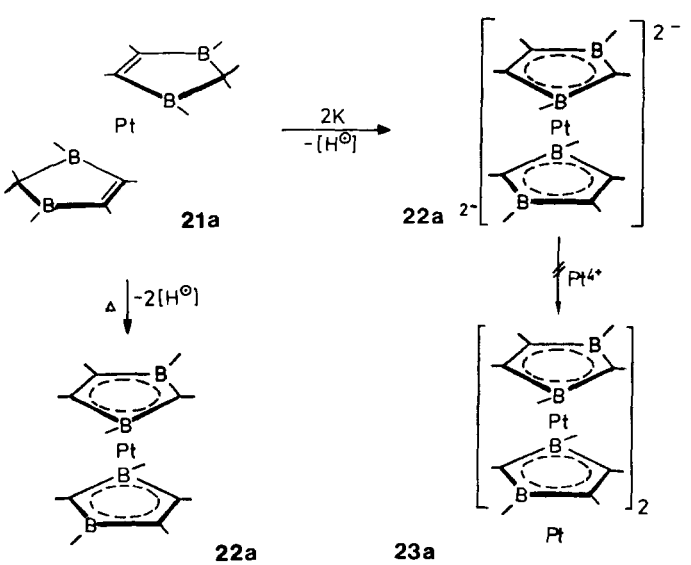
6. Reactivity of the Complexes

The pentacoordination of the methylene carbon atom and the C–H→B three-center bond in the complexes increase the acidity of the C–H bond, which can be taken advantage of preparatively. One can differentiate between two basic types of reactions: 1) formation of sandwich anions and their reaction with MX_2 or RX, and 2) direct reaction between metal complexes and different reagents. In the following sections, characteristic reactions of the cobalt, nickel, and platinum sandwich compounds shall be discussed.

6.1. Deprotonation

Deprotonation of **8** with potassium in THF yields a yellow, extremely air-sensitive anion,[3] in which the boron atoms are more strongly shielded ($\delta(^{11}B) = 19$). With methyl iodide, the violet complex **10d** is formed. Its ^{11}B-NMR signal is shifted 15 ppm downfield relative to **8a**. Hence, a non-parallel arrangement of both rings due to the steric influence of the second methyl group is assumed. Deuteration of the methyl groups confirmed the non-existance of a C–H→Co bond. Two CH_2D groups can be successively introduced into the deprotonated complex **8b**.[20] Due to D–H coupling, one of them appears as a triplet in the ^1H-NMR ($J = 1.8$ Hz, $\delta = 0.35$). The other gives an unresolved signal ($\delta = -0.14$) and can be assigned to the *exo*-position. An isotope effect cannot be observed in the chemical shifts of the bis(CH_2D)-complex. This finding is incompatible with an agostic hydrogen atom (Co←H–CHD). In contrast to the 18 VE complexes **8a**, **b**, the dimethyl derivatives **10d**, **e** can be reversibly reduced electrochemically at 1.38 V[31] (Scheme 13).

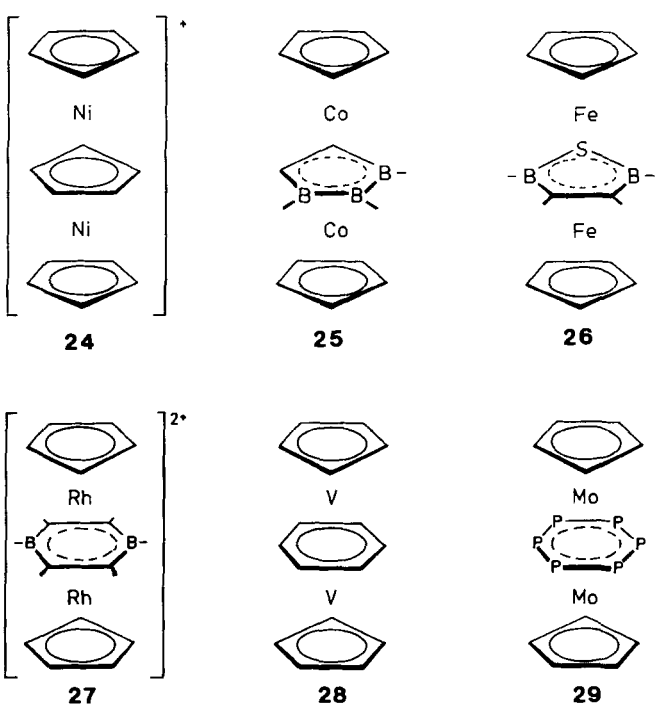
Reaction of the anion of **8c** with methyl iodide yields the yellow cobalt hydride **9f**, which can rearrange through a hydrogen shift to **8f**. The formation of **9f** affords evidence of an electrophilic attack at the methylene carbon



Scheme 13. Deprotonation of the sandwich complex **8** to give the anion $(8-H)^-$ and reaction of the latter with CH_3I to yield **10** [3, 20].

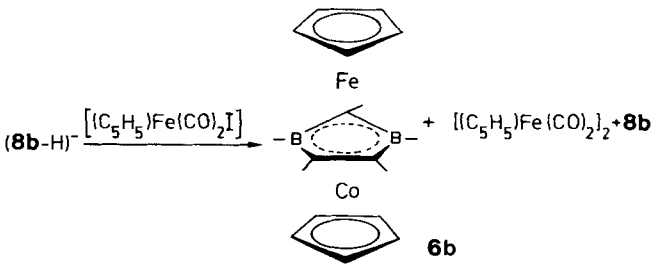
atom by CH_3I from the *exo*-position, since only an *exo*-attack yields **9f**.[20] The reactions of the potassium salts of **8a**, **b** with Me_3SiCl, designed to introduce the silyl group, were unsuccessful, although the formation of potassium chloride was always observed.[3] Since the starting materials **8** could always be recovered, it is most likely that the desired Me_3Si-derivatives of **8** decompose to the 17 VE sandwich radicals, which take up hydrogen atoms from the solvent to form the diamagnetic complexes **8**. An analogous reaction mechanism is assumed to explain the formation of **8a** from **10d**.[20]

The nickel sandwich complexes **17** react like **8** with potassium; however, definite salts or products from the subsequent reactions with methyl iodide could not be isolated. Attempts to eliminate hydrogen from the 18 VE complex **17a** did not yield a 16 VE sandwich complex. However, the postulated 16 VE complexes formed from **17b**, **c** react with the starting material with methylboranediyl abstraction to yield new carbaboranyl nickel complexes (see Section 6.6).[28]



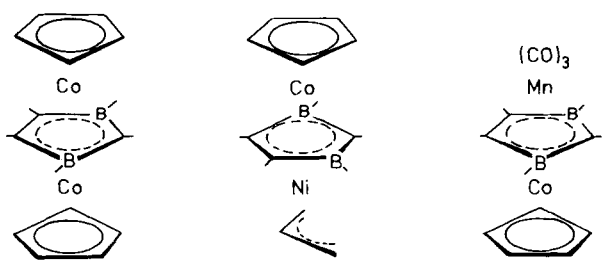
The platinum complex **21a**, the analogue to **17**, can be deprotonated with potassium to the dianion $\mathbf{22a}^{2-}$, whose ^{11}B-NMR signal is shifted 34 ppm upfield relative to **21a** ($\delta = 58$). However, the reaction of $\mathbf{22a}^{2-}$ with Pt^{4+} yields the sandwich complex **22a** instead of the tetradecker **23a**. This sandwich complex can also be directly obtained from **21a** through an elimination of hydrogen in refluxing benzene.[32] The transition from $\mathbf{22}^{2-}$ to **22** takes place via the radical anion $\mathbf{22}^{\odot -}$, which can be observed ESR spectroscopically (Scheme 14).

Scheme 14. Deprotonation of the platinum complex **21a** to the dianion $\mathbf{22a}^{2-}$ and the dehydrogenation of **21a** to the sandwich complex **22a** [19, 32].



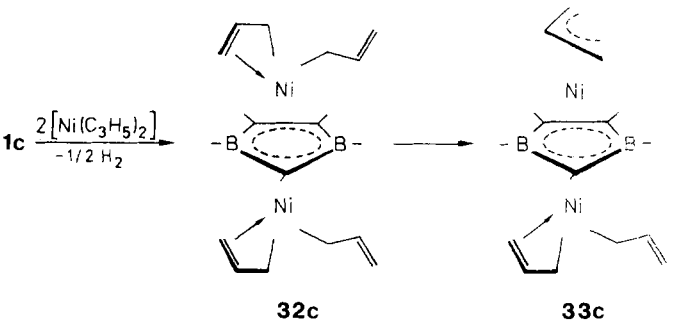
6.2. Formation of Dinuclear Complexes

1 always acts as a 3e donor when it is complexed bifacially. The triple-decker sandwich complexes **3**–**7** are obtained from **1** and the complex fragments $M(C_5H_5)$ (M = Fe, Co, Ni) possessing 13–15 VE. This first complete series with 33 to 29 VE exhibits the magnetic properties and structural changes predicted by the MO-scheme[33] in going from the diamagnetic complex **6** (30 VE) to the paramagnetic, dinickel complex **3** (33 VE). Reduction of the green complex **3** with potassium yields the red, diamagnetic anion $\mathbf{3}^-$, which is isoelectronic with the first triple-decker sandwich complex **24** obtained by *Werner* and *Salzer*.[34,35] The maximum number of valence electrons for triple-deckers is 34, while the optimal number corresponding to the 18 VE of mononuclear complexes is 30. Examples of this rule are **6**, the 1,2,3-triboracyclopentene complex **25** and its 1,2,4-isomer prepared by *Grimes* et al.,[36] the 2,5-dihydro-1,2,5-thiadiborole complex **26**,[37] and the μ-1,4-diboracyclohexadiene complex **27** described by *Herberich, Huttner* et al.[38] *Jonas, Krüger* et al.[39] have reported the first triple-decker containing C_6H_6 as a bridging ligand. According to the EH-MO calculations and PE-data this 26 VE dinuclear complex possesses four unpaired electrons.[40] Recently *Scherer* et al.[41] were successful in synthesizing the unusual 28 VE triple-decker sandwich complex **29**, in which the (in the free state nonexistent) hexaphosphabenzene P_6 acts as a π^6-arene (see p. 924ff).



In order to synthesize triple-decker complexes one can use the cobalt sandwich **8** as well as its anion. In the reaction of the anion with $(C_5H_5)Fe(CO)_2I$ a redox reaction

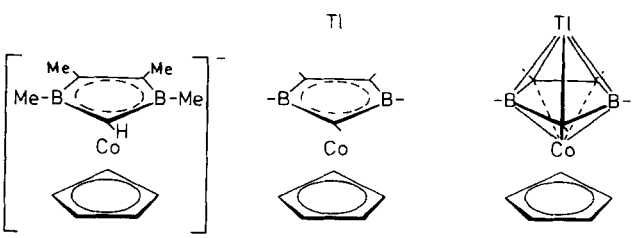
takes place, in which very little **6b** besides **8b** (50%) is formed,[12] presumably because of steric hindrance of the $(C_5H_5)Fe(CO)_2$-group. The redox reaction mainly leads to the formation of $[(C_5H_5)Fe(CO)_2]_2$ (Scheme 15). In contrast, the reaction of $(\mathbf{8b}-H)^-$ with $FeCl_2$ in the presence of $C_5H_5^-$ affords **6b** in 68% yield.



Scheme 15. Reaction of the anion $(\mathbf{8b}-H)^-$ with $(C_5H_5)Fe(CO)_2I$ to give the triple-decker sandwich complex **6b** [3].

Instead of using ions one can synthesize triple-deckers by letting **8** react directly with various complexes. At higher temperatures, however, the starting material **8** can react with itself to form the triple-decker **5** as well as the tetradecker sandwich complex **41** (cf. Scheme 18). **6b** (28%), the tetradecker **40b**, and ferrocene are obtained in the reaction of **8b** with $(C_5H_5)Fe(C_8H_{12})$[42]. The stacking of **8b** with $(C_5H_5)Co(C_2H_4)_2$, $Ni(C_3H_5)_2$, and $Mn_2(CO)_{10}$ to give the dinuclear complexes **5b**,[12] **30b**,[29,43] and **31b**[3] in yields of 54, 96, and 80%, respectively, takes place much more readily. Hence, the substitution of the axial hydrogen atom in **8** by the 13 VE complex fragments $Fe(C_5H_5)$, $Ni(C_3H_5)$, and $Mn(CO)_3$ leads to the diamagnetic 30 VE triple-deckers **6**, **30**, and **31**, respectively. The paramagnetic complexes **5** can be prepared using the 14 VE fragment $Co(C_5H_5)$. This proves that the sandwich **8a** is an intermediate in the reaction of $(C_5H_5)Co(CO)_2$ with **1a** to form **5a**.[12]

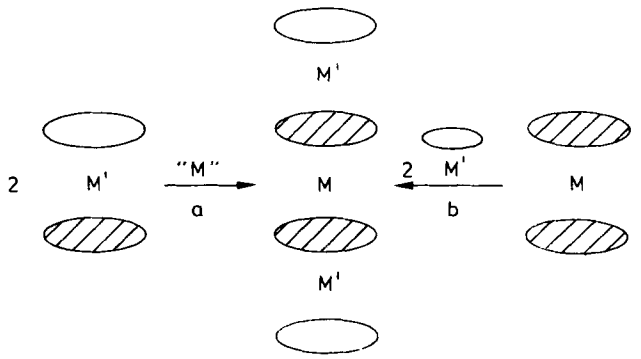
5 **30** **31**



The ease of formation and the high reactivity of **30b** make this allyl triple-decker a valuable starting material[43] for oligodecker complexes. Another allyl complex with triple-decker structure is obtained in the low-temperature reaction of $Ni(C_3H_5)_2$ and **1b**, **c** in the ratio 2:1.[29] It is assumed that the initial product is the tetraallyl triple-decker **32b**, **c** (31 VE), which then eliminates an allyl group to yield the diamagnetic complex **33c** (Scheme 16). Its ^{1}H-NMR spectrum exhibits only two different types of allyl groups due to the rapid interconversion between η^1 and η^3 coordination. **33c** dissociates relatively easily. The liberated $Ni(C_3H_5)_2$ may be removed by vacuum and the remaining $(C_3H_5)Ni$(1,3-diborolyl) complex polymerizes by eliminating hexadiene (see Section 6.7).

Scheme 16. Synthesis of the tris(allyl)(μ-2,3-dihydro-1,3-diborolyl)dinickel complex **33c** from **1c** and bis(allyl)nickel [29].

Another class of dinuclear compounds is obtained in the stacking of a bifunctional acceptor sandwich with a $M(C_5H_5)$ fragment (see Section 6.3).

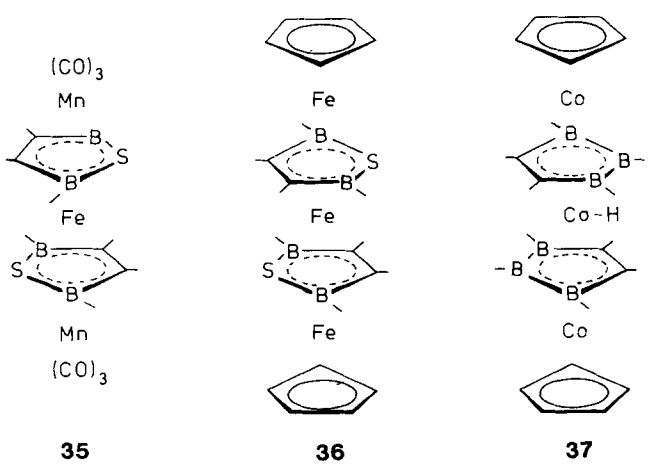


Since the potassium salts of **8** could not be characterized, the more stable Tl^I-compounds were investigated. **8c** reacts with $Tl(C_5H_5)$ to yield the dinuclear complex **34c**, which consists of a molecular unit both in solution and in the crystal.[44] Although $C_5H_5^-$ and the side of the heterocyclic ring of the anion $\mathbf{8c}^-$ are isolobal, **34c** does not exhibit the polymeric zig-zag structure of $Tl(C_5H_5)$.[45] Instead, it possesses a head-to-tail arrangement of the individual molecules without intermolecular contacts. The bonding in this complex with a capping Tl-atom is described by a seven membered *closo*-cluster according to *Wades'* rules.[46] The required $2n+2=16$ electrons for the framework are supplied by the carbon ($3\times3e$), boron ($2\times2e$), cobalt (2e) and thallium (1e) atoms.

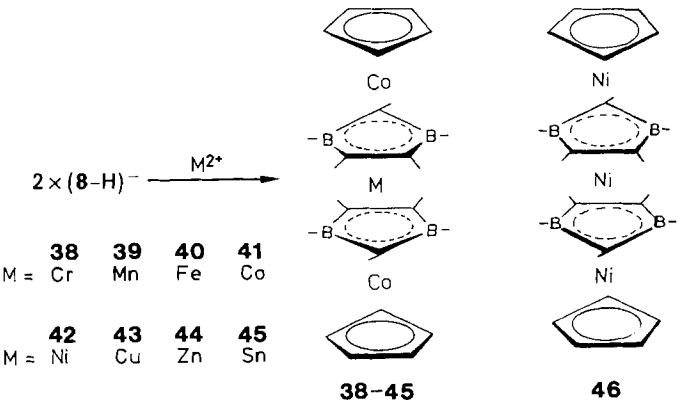
6.3. Synthesis of Trinuclear Complexes

Sandwich complexes with acidic C–H bonds are suitable for the synthesis of tetradecker complexes.[47] In Scheme 17 route a describes the coupling of two sandwich units by a central metal and route b the stacking of a sandwich with two $M'(C_5H_5)$ complex fragments.

Within the series of triple-decker complexes, examples containing 26 and 28–34 VE are known; the family of tetradeckers should involve complexes with 36–46 VE. The maximum number is attained by combining two 18 VE sandwich complexes with a d^{10}-metal according to route a;



Scheme 17. Formation of tetradecker sandwich complexes by a) the reaction of two acceptor sandwich complexes with a metal and b) the stacking on both sides of an acceptor sandwich complex with M'(C_5H_5)-complex fragments [19, 58].



the optimum number of 42 is reached by formally inserting two 12 VE fragments (bridging ligand and metal) into the 18 VE complex ferrocene. Trinuclear complexes having 36 VE should contain beryllium or magnesium as the central metal.

Another way of determining the number of valence electrons is indicated in route b. A 16 VE sandwich with two potential acceptor ligands can be stacked on both sides with the 15 VE fragment Ni(C_5H_5) to yield a 46 VE complex. The analogous reaction with the 18 VE complex bis(2,5-dihydro-1,2,5-thiadiborole)nickel did not yield the 48 VE tetradecker [(C_5H_5)Ni(C_2B_2S)]$_2$Ni. Instead the 19 VE complex (C_5H_5)Ni(C_2B_2S) was obtained as a result of ligand exchange.[51]

The first two trinuclear complexes **35**[52a] and **36**[52b] whose structures have been determined, contain two 2,5-dihydro-1,2,5-thiadiborole ligands which act as 4e donors. While the tetradecker complex **35** is only obtained in poor yields, the tetradecker sandwich complex **36** can be prepared in several steps from [(C_5H_5)Fe(C_8H_{12})]$_2$Zn[42] in good yields. *Grimes*[48] reported a trinuclear complex **37**, in which the central cobalt atom carries a hydrogen atom. The complexes **35**-**37** all possess 42 VE.

As shown in Sections 6.1 and 6.2 the reactions of the anions of **8** with Me_3SiCl and (C_5H_5)Fe($CO)_2$I lead, if at all, to only poor yields of the desired products. The anions of **8** do, however, react with metal salts in high yields to give the corresponding tetradecker sandwich complexes **38**-**44**[3, 19, 53] (Scheme 18).

Scheme 18. Synthesis of the tetradecker sandwich complexes **38**-**45** by reaction of the deprotonated cobalt sandwich complex **8** with metal ions [19, 53].

In this manner, with the exception of the zinc complex **44**, paramagnetic complexes are obtained. The magnetic data of **38**-**41** are in agreement with high-spin configurations. The X-ray structure analyses of **38b**-**44b** have shown that the geometry of the Co-sandwich units is the same in all of the complexes and that the 2,3-dihydro-1,3-diborolyl rings are antiperiplanar.[3, 19, 53] The distances between metal and (C_2B_2C) correlate well with the *Shannon-Prewitt* ionic radii for octahedrally coordinated M^{2+} ions.[54] Two maxima as well as a minimum are observed for the central metals M = Mn, Zn and M = Ni, respectively. Each metal atom M is shifted (slip Δ) from a position above the centroid of the heterocyclic ring. This slip (Δ) takes place along the vector ring-centroid-C2 towards C2. Figure 5 shows the molecular structure of the CoCuCo te-

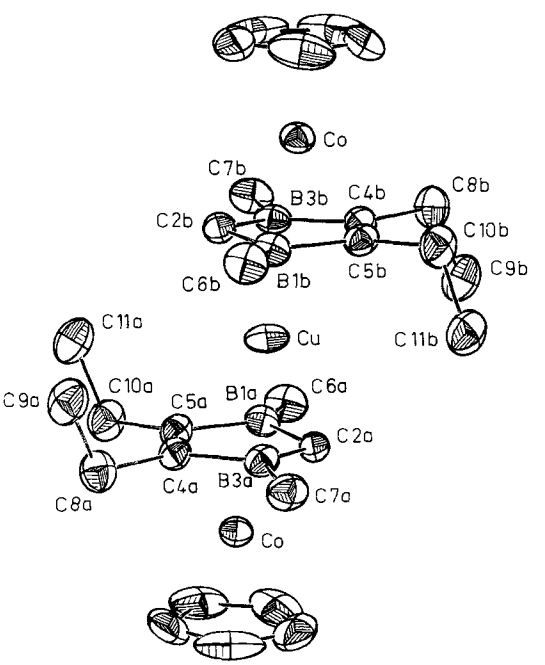


Fig. 5. Crystal structure of the tetradecker sandwich complex **43b** [19].

tradecker sandwich **43b**. The change in the structural parameters d, r and Δ for the complexes **38b**–**44b** as well as the ionic radii of the hexacoordinated metals Cr^{2+}–Zn^{2+} are shown in Figure 6. Electronic factors are primarily responsible for the slip.

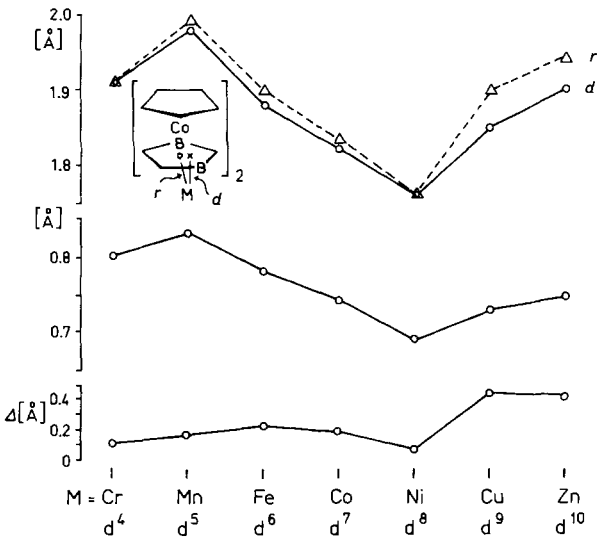

Fig. 6. Top: Distances (r,d) between central metal atom (M) and bridging ligand $(\mathbf{1b}-H)^-$ in the tetradecker sandwich complexes **38b**–**44b**. Middle: Ionic radii of high-spin M^{2+} ions. Bottom: Slip Δ as a function of the central metal in **38b**–**44b** [19].

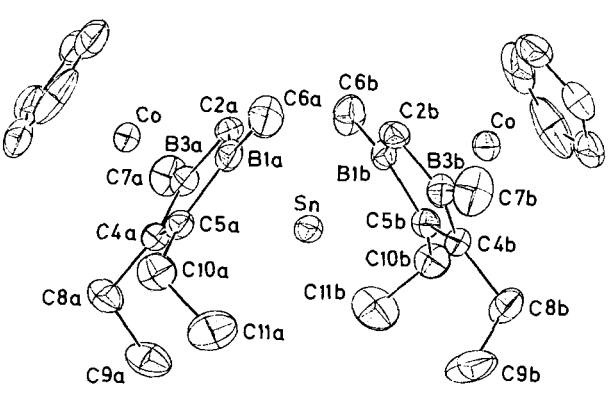
The CoNiCo tetradecker **42a** was first obtained as a product of the reduction of the NiCo triple-decker **4a** with potassium.[53] It reacts further with potassium via the diamagnetic dianion (46 VE) to yield elemental nickel and the sandwich anion $(\mathbf{8a}-H)^-$. Reaction of $(\mathbf{8b}-H)^-$ with $SnCl_2$ leads to a stannocene analogue **45b** (Fig. 7), the first "bent" tetradecker sandwich complex with bending angles of 112 and 114°, respectively.[55] **45b** is also formed in the reaction of **8b** and stannocene with elimination of cyclopentadiene. This is again proof of the acidity of the axial hydrogen in **8b**.



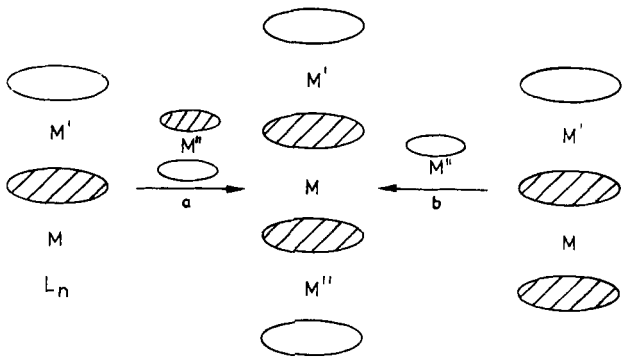


Fig. 7. Crystal structure of the bent tetradecker sandwich complex **45b** [55].

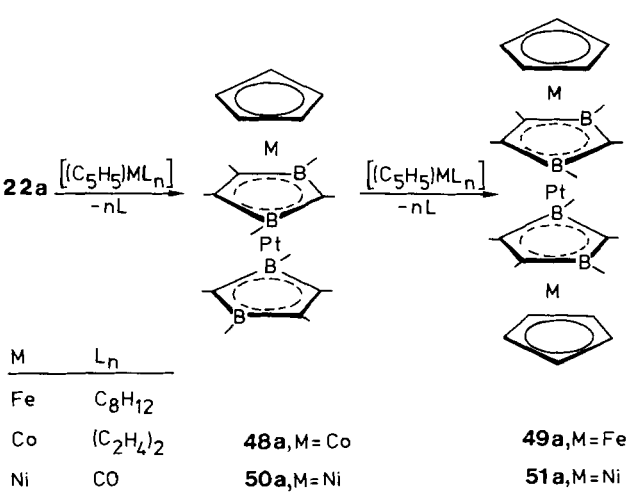
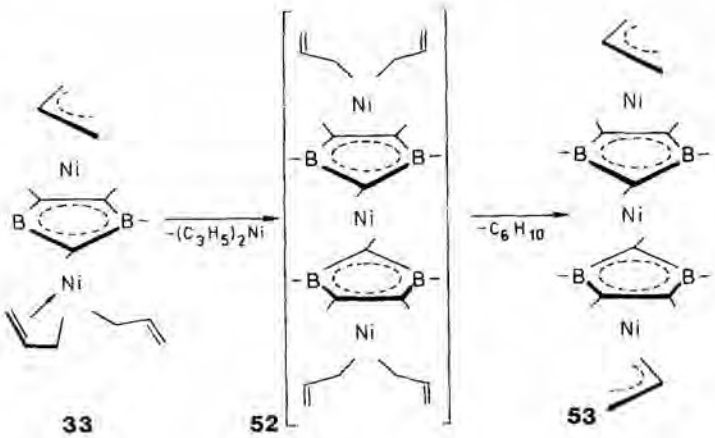


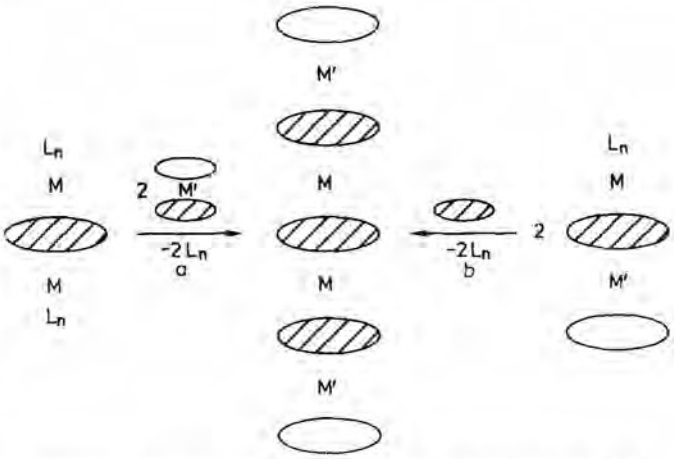
Diamagnetic 46 VE tetradecker complexes **46** containing three nickel atoms are obtained in the reaction of $NiBr_2$ with the anions of the nickel sandwich complexes **2a**,**b**, and in the reaction of **2b** with $[H_2AlOCMe_3]$.[56,57] The attempted preparation of a CoNiNi-tetradecker (**47**) from **53** met without success.[59]

The alternative synthetic route b (Scheme 17, 19) involves complexes with two acceptor ligands. With $M(C_5H_5)$ fragments these complexes can be stacked to give unsymmetric triple-deckers in the first step and then react further to give tetradeckers.

Scheme 19. Formation of tetradecker sandwich complexes by a) the reaction of a triple-decker with a sandwich complex and b) the stacking of a triple-decker sandwich complex with a cyclopentadienylmetal-complex fragment [19].



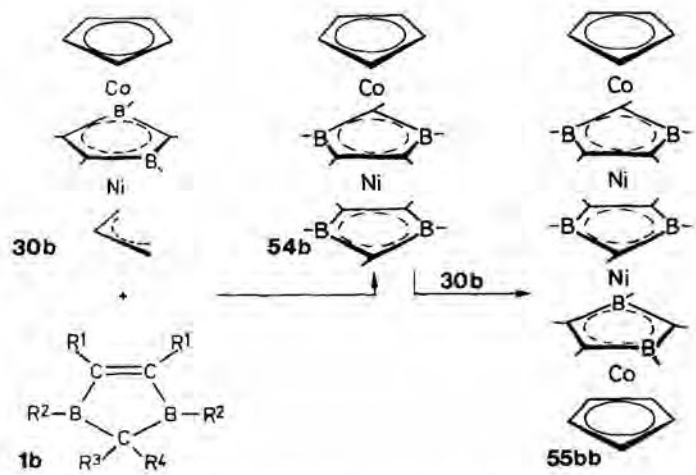
The platinum sandwich complex **22a**, formed upon elimination of hydrogen from the dihydro-complex **21a** and $(C_5H_5)Fe(C_8H_{12})$ yields the FePtFe tetradecker **49a**; the reaction with $(C_5H_5)Co(C_2H_4)_2$, however, stops at the unsymmetrical triple-decker stage (**48a**).[58] On the other hand, the triple-decker **50a** (31 VE) as well as the tetradecker **51a** can be isolated from the stacking reaction with $[(C_5H_5)Ni(CO)]_2$ (Scheme 20). The NMR spectra of the diamagnetic complexes **48a** (30 VE), **49a** (42 VE), and **51a** (46 VE) are indicative of highly symmetrical conformations or a free rotation of the ligands. The X-ray structure



Scheme 20. Stacking of the platinum sandwich complex **22a**, obtained in the elimination of hydrogen from **21a**, with $M(C_5H_5)$-complex fragments to give the triple-decker sandwich complexes **48a** and **50a** and the tetradecker sandwich complexes **49a** and **51a** [58].

analyses of **48a** and **50a** show an antiperiplanar arrangement of the heterocycles, while the tetradeckers **49a** and **51a** are the first of their kind to exhibit synclinal conformations.[58]

Reaction of the allyl triple-decker **30** with the Co-sandwich complex **8** according to Scheme 19a represents another approach to the synthesis of trinuclear complexes. Elimination of propene leads to formation of the CoNiCo-tetradecker **42**.[59] The above-mentioned tetradecker sandwich complexes **38**–**44** with 40–46 VE each possess terminal C_5H_5 ligands, which do not allow a further stacking with complex fragments. The formal replacement of a cyclopentadienyl by an allyl ligand yields reactive complexes, which allow the synthesis of oligodecker complexes. Deeply colored products are obtained upon reaction of bis(allyl)nickel with **1** in refluxing toluene. The red tetradecker complex **53** can be isolated in 4–15% yield.[60] However, the main products are higher oligodeckers, which, although not yet separated, have been observed in the mass spectra.[29] They are probably formed via the tris(allyl) triple-decker **33** and the tetrakis(allyl) trinuclear complex **52**, which upon elimination of hexadiene leads to **53** (Scheme 21).

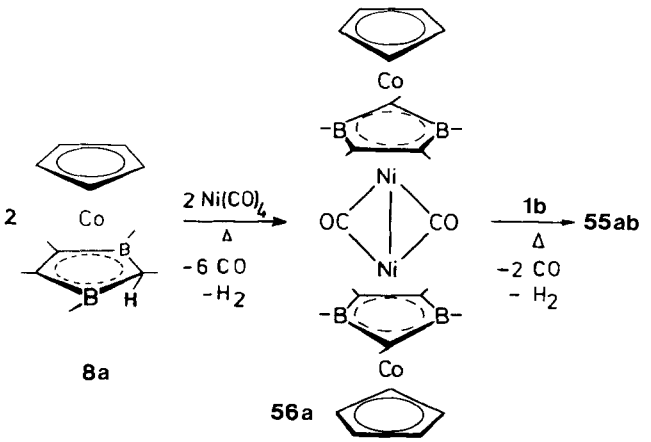


Scheme 21. Conversion of the dinickel complex **33** into the tetradecker complex **53** [29].

Scheme 22. Formation of pentadecker complexes by a) the reaction of a triple-decker with two sandwich complexes and b) the reaction of two triple-deckers with a heterocycle [29].

(Scheme 23). The main product of this reaction is the tetradecker **42b**.[29]

Scheme 23. Reaction of the heterocycle **1b** with the triple-decker **30b** to give the triple-decker sandwich complex **54b**, and the stacking of the latter with **30b** to the pentadecker complex **55bb** [29].



6.4. Synthesis of Tetranuclear Complexes

The above-mentioned reactions of the C–H-acidic sandwich complexes clearly demonstrate their synthetic potential. One of our goals is to use these compounds to prepare polydecker sandwich complexes, which are expected to exhibit interesting anisotropic properties. The pentadecker complexes (Scheme 22) are the first complexes in which a stack $M(C_2B_2C)$ has two analogous units as neighbors. The construction of such systems can take place via reactive triple-deckers according to route a or b (Scheme 22).

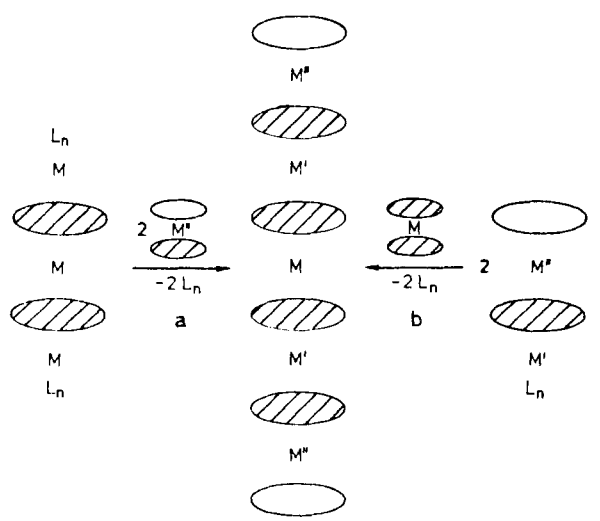
In the first step the unsymmetrical triple-decker **30b** reacts with the ligand **1b** to form triple-decker sandwich **54b**, which, in contrast to the analogous PtCo-compound **48a**, is still reactive and can further react with the starting material to yield the pentadecker sandwich complex **55bb**

The pentadecker **55ab** was first obtained in 45% yield upon reaction of the tetranuclear complex **56a** with the ligand **1b**.[61] At first, a cleavage of the carbonyl complex **56a** and formation of the unsymmetrical triple-decker **54ab**, which can be isolated in 7% yield, takes place. Stacking of **54ab** with the $(C_5H_5)Co(C_2B_2C)Ni$-fragment, formed in the elimination of CO from **56a**, then yields the pentadecker sandwich complex **55ab** containing the bridging ligand **1b** (Scheme 24).

The red-violet 57 VE complexes **55** are paramagnetic. They can be reduced with potassium to the diamagnetic anion **55**$^-$. The ^{1}H-NMR spectra of **55**$^-$ and the mixture **55/55**$^-$ behave almost completely analogous to those of the triple-decker pair **3/3**$^-$ (33/34 VE). However, the outer ligands (C_5H_5) of **55** remain almost unaffected by the paramagnetism. Proof of a pentadecker sandwich arrangement is given by the X-ray structure analysis of **55ab**, in which two neighboring C_2B_2C-ligands are *trans* to each

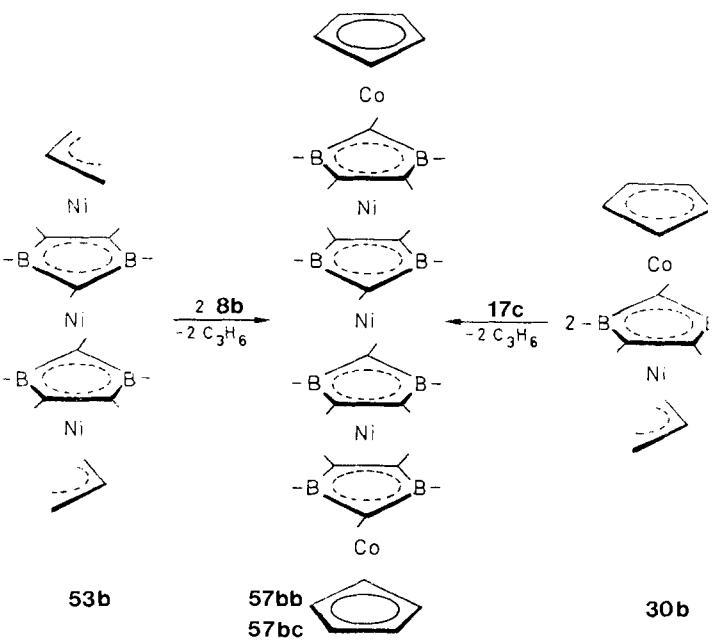
Scheme 24. Reaction of the sandwich complex **8a** with $Ni(CO)_4$ to give the tetranuclear complex **56a** and the reaction of the latter with **1b** to give the pentadecker sandwich complex **55ab** [61].

other while the third is rotated through approximately 70° (Scheme 23).[61]



The formation of the carbonyl complex **56a** ($\nu_{CO} = 1852$ cm^{-1}) from **8a** and $Ni(CO)_4$ is another example of the isolobal analogy and chemical similarity between **8a** and cyclopentadiene. Formally, **56a** is the result of the insertion of the 12VE stack $Co(C_2B_2C)$ into the (C_5H_5)-Ni bond of $[(C_5H_5)Ni(CO)]_2$.

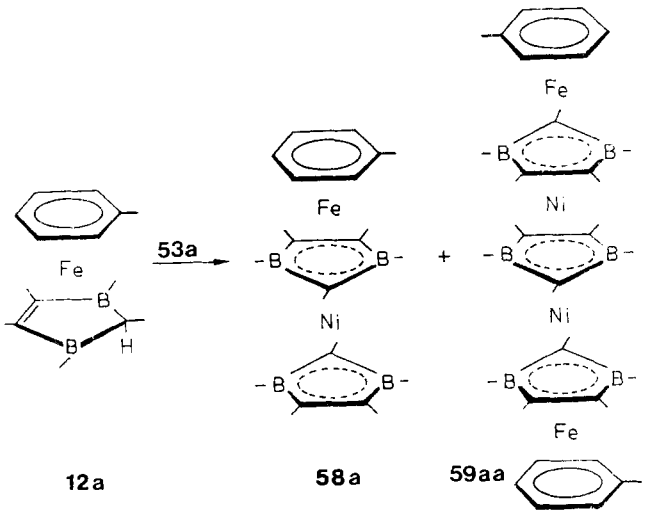
The steric influence of the ligand **1** plays an important role in the formation of **56**. With **1a** the synthesis of **56** is possible, while **1b** yields the CoNiCo-tetradecker **42b**.



6.5. Synthesis of the First Hexadecker Complexes

With increasing stacking, not only do the number of synthetic routes that lead to oligodecker complexes increase (through the combination of mono-, di- and trinuclear complexes) but also the formation of side products. So far the two reaction pathways shown in Scheme 25 have been studied. The addition of a sandwich unit to both ends of a reactive tetradecker according to route a should be possible. Route b describes the synthesis of a pentanuclear complex in which a triple-decker fragment is added to both sides of a central sandwich unit. The combination of allyl complex building blocks with the C–H-acidic sandwich complexes **8** or **17** should take place with elimination of propene.

Reaction of the allyl tetradecker **53b** with the cobalt sandwich **8b** in refluxing mesitylene yields a mixture from which the red-violet hexadecker sandwich **57bb** can be isolated in 7% yield by column chromatography at −20°C (Scheme 26).[43] The paramagnetic triple- and tetradeckers **5b** and **41b** are by-products formed from **8b** at high temperatures. Furthermore, **42b** is the result of a coupling of **8b** with nickel. The diamagnetic 70 VE complex **57bb** sublimes at 200°C/10^{-5} torr. Its constitution was determined from MS and NMR data.

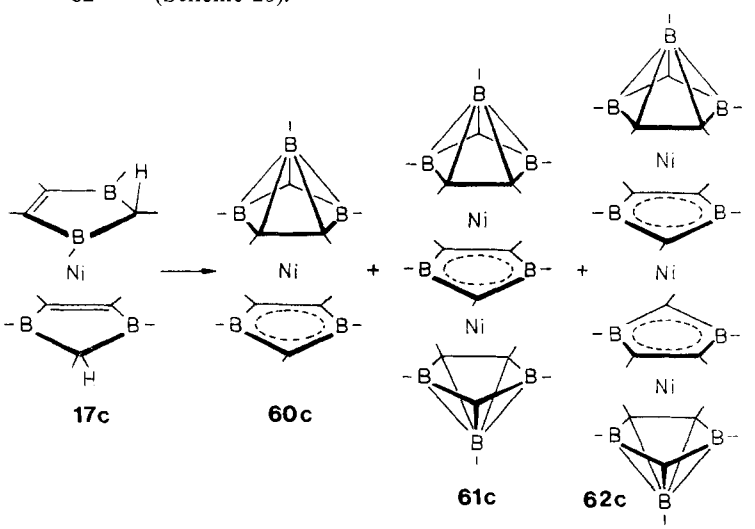


Scheme 25. Formation of hexadecker sandwich complexes by a) the reaction of a tetradecker with two sandwich complexes and b) the stacking of a sandwich complex with two triple-decker complexes [43].

Scheme 26. Synthesis of the hexadecker sandwich complexes **57bb** from the tetradecker **53b** and the sandwich complex **8b** as well as **57bc** from the triple-decker **30b** and the sandwich complex **17c** [43].

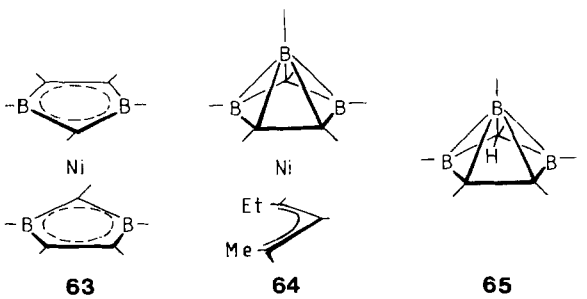
If the above reaction is carried out with **53a** and **8a**, the pentadecker **55aa** is obtained instead of the hexadecker. Similarly, reaction between the toluene-iron sandwich complex **12a** and **53a** stops at the triple-decker **58a** and pentadecker **59aa** stage[29] (Scheme 27). This indicates that the steric hindrance of the four ethyl groups in each ligand does not allow a fourfold stacking of **1a** with metal atoms.

A second route leading to a hexadecker involves twofold stacking of the bis(2,3-dihydro-1,3-diborole)nickel sandwich **17c** with the allyl triple-decker **30b** at 160°C. The main product (67%) is the green tetradecker **42b** formed by reaction of **30b** with itself. The hexadecker **57bc** containing two different ligands is obtained in 21% yield. Crystals



Scheme 27. Formation of the pentadecker sandwich complex **59aa** from the sandwich complex **12a** and the tetradecker **53a** [29].

of **57bb** and **57bc** that are suitable for X-ray structure analyses have not yet been grown[62].



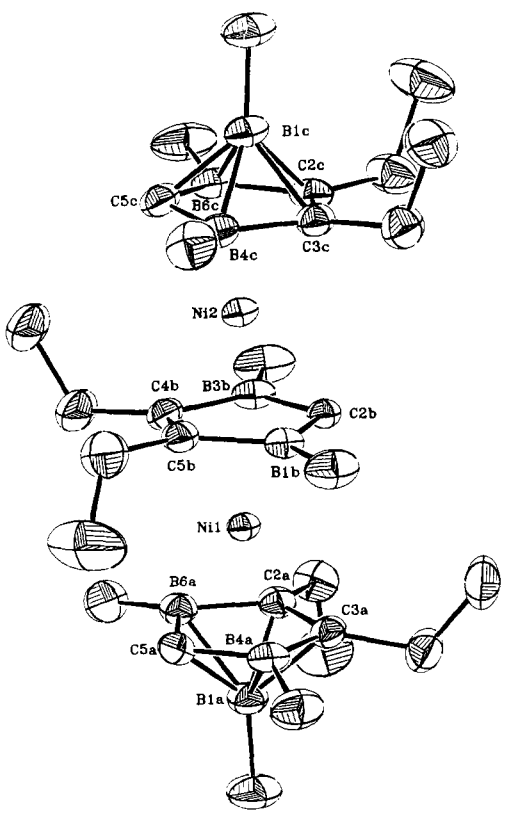
6.6. Carbaboranyl Sandwich Complexes

The bis(2,3-dihydro-1,3-diborole)nickel sandwich complexes **17b, c** already described in Section 4.4 are characterized by a remarkable reactivity. At room temperature they are slowly transformed into a series of carbaboranylnickel complexes, whose first three members are **60–62**[28,63] (Scheme 28).

Scheme 28. Conversion of the nickel sandwich complex **17c** into the carbaboranylnickel sandwich complex **60c** and the bis(carbaboranyl)nickel complexes **61c** and **62c** [28, 29].

This transformation probably takes place via the elimination of hydrogen from **17**. The resulting hypothetical 16 VE complex **63** (an analogue of the platinum complex **22**) immediately yields the 18 VE carbaboranyl sandwich complex **60** through the transfer of a methylboranediyl fragment. If a boranediyl fragment is abstracted from **17**, a boracyclobutenyl complex should be formed. Trace amounts of the η^3-allyl-η^5-carbaboranyl complex **64b**[57] were isolated from the transformation reaction of **17b**. This complex is probably the result of an elimination of both boranediyls as well as the methylene group from **63b** and the capping of the C_2B_2C-ring by a Me–B moiety. The η^3-allyl ligand must be formed from the diethylethylene portion of the complexed ligand **1b**. The formation of the new η^5-2,3,5-tricarbahexaboranyl ligand **65** – H in the complex is the first access to the *nido*-2,3,5-tricarbahexaborane(7) **65**, which has not, as yet, been isolated in the free state. Alkyl derivatives of the isomeric 2,3,4-tricarbahexaborane as well as tricarbonylmanganese complexes $[(\eta^5\text{-}C_3B_3H_4R_2)Mn(CO)_3]$ (R = H, CH_3) are known.[64]

The complexes **60** (reddish orange), **61** (green) and **62** (turquoise) are the electronic analogues of the (η^5-cyclopentadienyl)(η^5-2,3-dihydro-1,3-diborolyl)nickel complexes **2**, **3**, and **46** since the isolobal ligands $C_3B_3H_6^{\ominus}$ and $C_5H_5^{\ominus}$ each contribute five electrons to the complexation. A com-



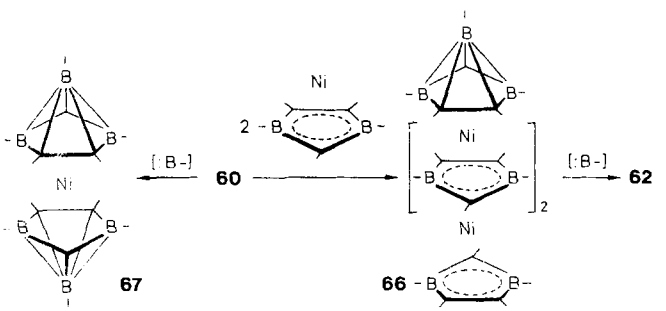


Fig. 8. Crystal structure of the bis(carbaboranyl) triple-decker **61b** [28].

parison of their physical and chemical properties as well as their spectroscopic data (color, stability, NMR, cyclovoltammetry) underline this analogy. The bond lengths and angles in the carbaboranyl sandwich **60b** are similar to those in the bis(carbaboranyl) triple-decker sandwich complex **61b** (Fig. 8). The planes passing through the central ring and the base of the carbaboranyl ligand (deviations ≤ 0.04 Å) are parallel. The nickel atoms are somewhat closer to the carbaboranyl rings than to the μ-ligand (1.69, 1.70 and 1.73, 1.74 Å, respectively). The structure and composition of the 46 VE trinuclear complex **62b** follow from the spectroscopic data.[63]

The formation of **62** can take place via the combination of two 18 VE complexes **60** with nickel or via the unsymmetrical carbaboranyl tetradecker **66**. The latter is capped by a methylboranediyl group to yield the bis(carbaboranyl) complex **62**. Two main reactions take place, of which the stacking of the 13 VE stack $Ni(C_2B_2C)$ must be faster than the capping with Me–B. Otherwise, only the formation of the complexes **60** and **61** is to be expected. It is interesting to note that the 18 VE complex is hardly capped to form the 20 VE complex **67** (Scheme 29); we only have MS evidence for **67b**.[31]

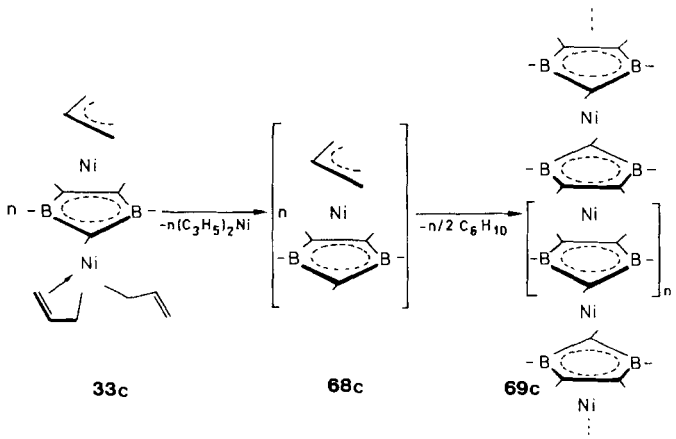
Scheme 29. Stacking of the carbaboranylnickel sandwich complex **60** with two (2,3-dihydro-1,3-diborolyl)nickel stacks to give **66**, the capping of the latter with methylboranediyl to give the bis(carbaboranyl)tetradecker sandwich complex **62** [29], and the capping of **60** to give **67** [31].

The stacking and capping reactions with **17c** take place with higher yields than with **17b**. After removal of **60c–62c** and the green bis(carbaboranyl) pentadecker complex, a dark-green residue is obtained. According to the EI-, FD- and FAB-mass spectra this residue contains oligomers up to and including the decadecker with differences in mass of 177 ($\triangleq {}^{58}Ni(C_3{}^{11}B_2Me_4H)$, stacking unit of the oligodeckers.[29,63]

6.7. Polydecker Sandwich Complexes

The synthesis of oligodecker complexes containing nickel atoms between the 2,3-dihydro-1,3-diborolyl ligands proves that the stacking unit $Ni(C_2B_2C)$ is a suitable building block for the construction of oligodeckers. Mass-spectral evidence of higher-molecular species formed in the synthesis of the bis(allyl) tetradeckers **53** also confirms this finding. The distillation residues contain oligodecker complexes with up to seven nickel atoms and six dihydrodiborolyl rings.[60,65] Furthermore, the isolation of the bis(carbaboranyl) complexes **61c** and **62c** as well as the mass-spectral evidence of pentadecker to decadecker complexes containing up to nine nickel atoms, eight dihydrodiborolyl ligands, and two terminal carbaboranyl groups, shows that these oligomers are formed under relatively mild conditions by a stacking of $Ni(C_2B_2C)$ units.

A single stacking unit contributes 13 VE ($d^{10}+\pi^3$) to the bonding, which in combination with the 5e ligands $C_5H_5^{\ominus}$ or $C_3B_3H_6^{\ominus}$ and an odd number of nickel atoms (for example n = 3: 46 VE, n = 5: 72 VE) yields the maximum number of valence electrons. 59 VE pentadecker complexes, which can be reduced to their diamagnetic anions, are formed with four nickel atoms and the ligands. In this connection it should be mentioned that the 13 VE stacking unit $Fe(C_5H_5)$ (Scheme 30) is completely unsuitable as a building block for polydecker complexes because of the weak acceptor properties of the bridging ligand and the high stability of ferrocene.



Scheme 30. 13 Valence-electron stacking unit (2,3-dihydro-1,3-diborolyl)nickel with donor properties of the metal and acceptor properties of the ligand. $Fe(C_5H_5)$ as a one-electron donor fragment.

Grimes et al.[36] were the first to predict that it should be possible to synthesize "multiple-decked stacked compounds" from metals and carbaborane rings $C_2B_3H_5$ (see **25**). Without a doubt the boron heterocycles[5,12,48–50,66] employed in the triple-decker sandwich complexes can also be used to synthesize oligodecker complexes.

The band structure of eleven one-dimensional polydecker sandwich compounds containing the metals Mn–Zn and different five-membered rings has been analyzed by *Böhm*[6] using a semi-empirical crystal-orbital method. Nine polydeckers contain 12 VE per stacking unit; two systems contain 14 VE. The 13 VE unit $Ni(C_2B_2C)$ described in this report is presently being studied.[67]

The yellowish brown tris(allyl) triple-decker **33c** was chosen as starting material for the synthesis of a $[Ni(C_3B_2)]_n$ polymer, since this complex already decomposes at room temperature with the elimination of bis(allyl)nickel and hexadiene to yield the bis(allyl) tetradecker **53c**.[29] The vacuum polycondensation of **33c** at temperatures > 120 °C produces bis(allyl)nickel, which is removed from the reaction zone, and the postulated η^3-allyl-η^5-diborolyl-nickel complex **68c** reacts with itself with elimination of allyl or secondary products to yield a black, film-like polymer **69c**. This product is characterized by an unusual thermal stability (Scheme 31).

The film cracks upon cooling and loosens itself from the sides of the glass. A C,H,B,Ni-analysis of the polymer yielded the empirical formula $C_7H_{13}B_2Ni$, which corresponds to a single stacking unit. The compound absorbs approximately two O_2 molecules per stacking unit.[68] Its

Scheme 31. Formation of the first polydecker sandwich complex **69c** from the tris(allyl)(μ-2,3-dihydro-1,3-diborolyl)dinickel triple-decker **33c** [29].

insolubility in inert organic solvents indicates a higher molecular arrangement. Mass spectral studies[69] up to 350°C have shown allyl to be the only fragment of any intensity. Solid-state ^{13}C- and ^{11}B-NMR studies show signals in the diamagnetic region although the polymer is paramagnetic.[76] Electrical conductivity measurements at 2500 bar using the two-point method[71,72] have yielded values of approximately 1 Siemen/cm, the four-point measurements[73] 10^{-2} S/cm. The observed temperature-dependency characterizes the polymer as a semiconductor. An EXAFS analysis supports a polydecker sandwich structure. However, two Ni–Ni and Ni–(C,B) distances (3.35, 3.8 Å and 2.17, 2.56 Å) indicate no regular stacking of $Ni(C_3B_2)$ units but most likely a Peierls distortion.[74]

7. Concluding Remarks

Thirteen years ago the first triple-decker sandwich complex opened up the field of classical sandwich chemistry towards "sky-scraper" molecules.[35] However, their predicted synthesis was not realized with carbacyclic bridging ligands. It was only the use of Lewis-acidic boron heterocycles that finally gave this field the necessary crucial impulses, which led to the synthesis of a wide range of oligodecker molecules using new synthetic strategies and theoretical models. Among the boron heterocycles the derivatives of 2,3-dihydro-1,3-diborole **1** described here occupy an exceptional position. On the one hand they can act as three-electron donors similar to an allyl ligand in the form of the 2,3-dihydro-1,3-diborolyls, while on the other they possess the necessary acceptor properties required to bind electron-rich metal atoms in a sandwich-like fashion with one another.

The previously introduced building blocks used to synthesize multilayered sandwich complexes contain the intact boron heterocycle **1** which acts as a four-electron donor. The synthetic potential of these compounds is based on the acidic C–H-bond of the ring-methylene group. We are convinced that the synthesis of oligodecker complexes containing more than six ligand planes is possible using C–H acidic triple-deckers. As already mentioned in this progress report, separation problems are often encountered. These difficulties are to be overcome with the help of middle pressure/low temperature chromatography.

The 2,3-dihydro-1,3-diborolyl metal complexes could someday attain practical significance as catalysts, as the recently published results of a 2,3-dihydro-1,3-diborolylcobalt complex-catalyzed pyridine synthesis by *Bönnemann* have shown.[75]

With the synthesis of the first polydecker sandwich complex, we have proven that the stacking of 2,3-dihydro-1,3-diborolylnickel units to a new type of semi-conducting polymer is possible. The optimization of the above-mentioned polycondensation as well as the introduction of other metals between the heterocyclic bridging ligands are the goals of further studies.

I would like to thank my co-workers M. Bochmann, D. Büchner, J. Edwin, U. Ender, K. Geilich, W. Herter, Th. Kuhlmann, H. Pritzkow, W. Schütz, K. Stumpf, H. Wadepohl, M. W. Whiteley, U. Zenneck, and J. Zwecker for their enthusiasm and their valuable contributions in the development of this field of research. I also wish to thank Prof. Dr. C. Krüger, Dr. H. Pritzkow, and Prof. Dr. J. Weiss, and their co-workers for the numerous X-ray structure analyses, and Dr. S. Berger (Marburg), Dr. P. Kunzelmann, Dr. R. Geist, Dr. K. Steinbach (Marburg), and their co-workers for the NMR and MS spectra. Discussions with Dr. M. C. Böhm, Prof. Dr. R. Hoffmann, and Dr. K. Jonas have contributed significantly to the development of this sandwich chemistry, for which I am also heartily thankful. The research reported here was generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and by BASF AG and Degussa.

[47] Trinuclear complexes with four parallel cyclic ligands have been labeled tetradecker sandwich complexes. In analogy to the nomenclature of the tripledeckers [34, 35], which can also be described as tridecker sandwich complexes, the terms "Quadrupeldecker" [35] and "quadrupledecker" [12], as well as "quadruple-decked complexes" [48, 49] are used. The term "tetradecker" is also used in Houben-Weyl [50].

The Revised Structure and Absolute Configuration of Chaksine**

By *Wolfgang Voelter,* Werner Winter, Viquar Uddin Ahmad,* and *Mohammad Usmanghani*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Chaksine was first isolated by *Siddiqui* and *Ahmad*[1] from the seeds of the plant *Cassia absus* (var. *Chaksa*) in 1935. Since then the natural product has been the subject of several structural[2] and pharmacological studies.[3] In 1958, Wiesner et al. proposed the monoterpenoid alkaloid structure **1** with an eight-membered lactone ring for chaksine iodide, which has been accepted till now.

1

2

For the isolation of chaksine, seeds of *Cassia absus* were extracted with ethanol and the extract was neutralized with aqueous ammonia, acidified with acetic acid, and evaporated under reduced pressure. The syrupy concentrate was suspended in distilled water and extracted successively with *n*-hexane, benzene, and ethyl acetate. The aqueous layer was acidified with dilute HCl, potassium iodide added, and the solution allowed to stand at +4°C. Chaksine iodide separated as a thick, whitish, crystalline mass, which was filtered, washed with 5% potassium iodide solution, ethanol, and acetone, and recrystallized from a mixture of ethanol and water (1 : 1).[4]

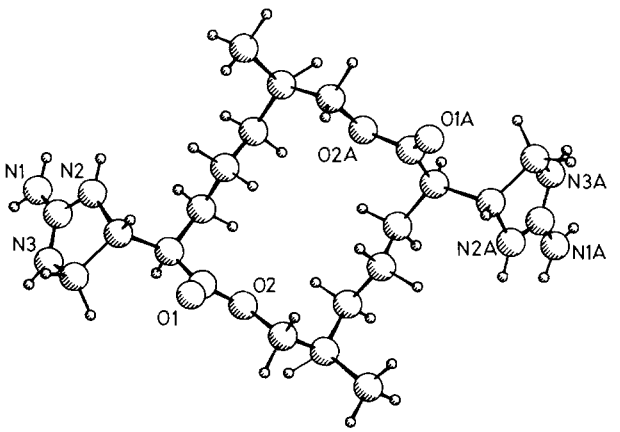

Fig. 1. Perspective view of the chaksine dication in **2** [5].

Although the elemental analysis and ^{1}H- and ^{13}C-NMR spectra were in agreement with the structure suggested by *Wiesner* et al.,[2] the field desorption mass spectrum, which showed a molecular ion of m/z 579, corresponding to the ionic species $(M^{2\oplus}I^{\ominus})^{\oplus}$, was not. This discrepancy prompted us to perform an X-ray crystallographic study. The results revealed that the structure of this alkaloid should be revised to **2**. Chaksine iodide consists of a 16-membered bislactone ring with two imino-imidazolidinyl groups at C-2 and C-2A, which form hydrogen bonds to both iodide anions. The molecule has a crystallographically imposed C_2 symmetry with *R,R,R* configuration at C-2, C-6, and C-9 as well as C-2A, C-6A, and C-9A.

Synthesis and Structure of 1,4-Dimethylanthracenemagnesium·3thf and μ-Trichlorodimagnesium·6thf(1+) Anthracenide

By *Borislav Bogdanović,* Nikolaus Janke, Carl Krüger, Richard Mynott, Klaus Schlichte,* and *Uwe Westeppe*

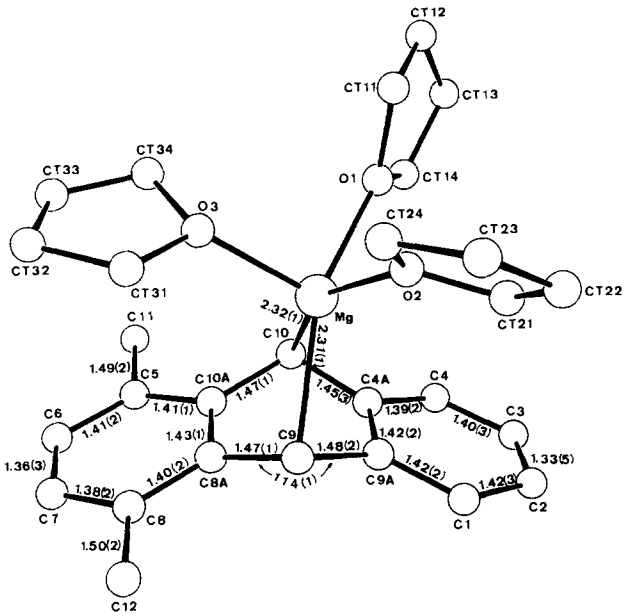
Magnesium-anthracene systems are of interest owing to their catalytic properties.[1] We report here the synthesis, chemical and spectroscopic characterization, and crystal structure of 1,4-dimethylanthracenemagnesium·3thf **2** and of μ-trichlorodimagnesium·6thf(1+) anthracenide **6** (thf = tetrahydrofuran).

2 is prepared analogously to anthracenemagnesium·3thf[1c,2] **5**, from 1,4-dimethylanthracene **1** and magnesium in THF. Protolysis of the orange solid affords solely 1,4-dimethyl-9,10-dihydroanthracene **3**, along with THF and traces of **1**.

1 2 3

In the ^{13}C-NMR spectrum of **2**, eight signals are observed in addition to those of **3**; on the basis of their multiplet structure and relative intensities in the proton-coupled spectrum, they could be assigned to the 1,4-dimethylanthracene skeleton.[2] A detailed analysis of the ^{13}C-NMR spectrum of the analogous **5** has already been presented.[1c] Comparison of the NMR data of **2** with that of **5** shows that the methyl groups on the aromatic ring cause only small changes in the chemical shifts of C1/C4 and C11/C12. As in the case of **5**, the largest interaction of magnesium occurs with the carbon atoms C9 and C10 of the anthracene skeleton ($\delta = 54.1$, $^1J_{CH} = 137.3$ Hz). The signals for C9/C10 in the spectrum of **2** are shifted slightly to higher field ($\Delta\delta = 3.6$) compared with those of **5** on account of the γ-methyl groups. The corresponding coupling constants $^1J_{C\text{-}9,H}$ are the same in both spectra within the limits of detection and indicate the rehybridization of this carbon atom from sp^2 toward sp^3.

In contrast to **5**, compound **2** is sufficiently soluble in THF to obtain single crystals for an X-ray structure determination.[3] In the crystal, a monomeric structure is present, which was suggested earlier[1c] on the basis of nuclear magnetic resonance data for **5** (Fig. 1). Three coordination sites of the pentacoordinated magnesium are occupied by oxygen atoms of the THF molecules. The two independent molecules differ mainly in a slightly different folding of the solvate molecules. The geometries of the two independent anthracene moieties are identical, however, within the experimental accuracy. The folding angle of the two halves of the anthracene along the C9–C10 line has a mean value of 40.95°; the C9–Mg–C10 angle in the bicyclic metallacycle is 72.6°. The metal-carbon distances in this system were determined to be 2.32 Å (average). The structure of **2** and that of 9,10-bis(trimethylsilyl)anthracenemagnesium·3thf,[4] which exhibits the same structural features, suggest that **5**, with similar structural elements, is also present as a monomer, taking into consideration the nearly identical ^{13}C-NMR spectra.



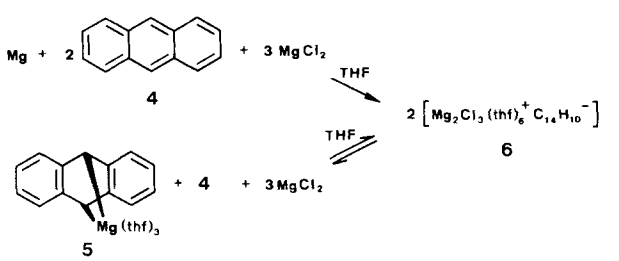


Fig. 1. Crystal structure of **2** (averaged over two independent molecules). Distances [Å], angles [°]. $P2_1/c$; $a = 8.090(1)$, $b = 21.301(4)$, $c = 29.992(5)$ Å, $\beta = 92.21(1)°$, $V = 5164.42$ Å^3, $Z = 8$, $\rho_{calcd} = 1.15$ gcm^{-3}, $\lambda = 0.71069$ Å, $\mu = 0.89$ cm^{-1}, $R = 0.088$, $R_w = 0.087$, 2632 observed reflections ($I \geq 2\sigma(I)$), 9046 unobserved reflections; 577 refined parameters [10].

The catalytic synthesis of magnesium hydride[1a] is improved by addition of $MgCl_2$.[5,6] For this reason, we studied the reaction of magnesium with anthracene **4** in THF in the presence of $MgCl_2$. The reaction, carried out in a solution saturated with $MgCl_2$, results in dark blue solutions, from which **6** separates out as a blue precipitate. **6** is also obtainable from **5** and **4** in the same solvent.[7]

4 6 5

UV and ESR spectroscopy show that anthracene radical anions are present in **6**. Hydrolysis of **6** results in disproportionation and the formation of a 1:1 mixture of **4** and 9,10-dihydroanthracene. **6** is present in equilibrium with **4** and **5**, the position of which is dependent on both the temperature and the concentration of $MgCl_2$.[5a] Accordingly, the Lewis acid $MgCl_2$ favors, at room temperature, the electron transfer from the dianion to **4**. Of interest is the elucidation of the structure of **6** and the comparison of its structure with that of **2** (Fig. 1) as well as with 9,10-bis(trimethylsilyl)anthracenemagnesium,[4] in which magnesium intramolecularly bridges the 9- and 10-positions of the anthracene skeleton. Crystals for a high-resolution structure determination[8] of **6** could be obtained by crystallization from a $MgCl_2$-saturated solution of **6**. In the crystal lattice,

[*] Prof. Dr. B. Bogdanović, Dipl.-Chem. N. Janke, Prof. Dr. C. Krüger, Dr. R. Mynott, K. Schlichte, Dr. U. Westeppe
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Patz 1, D-4330 Mülheim a. d. Ruhr (FRG)

6 is present as distinct ions; a twofold axis of symmetry (as required by the space group) intersects a $Mg_2(thf)_6$ structural unit bridged by three chlorine atoms,[9] while the anthracene skeleton is characterized by a center of inversion (Fig. 2).

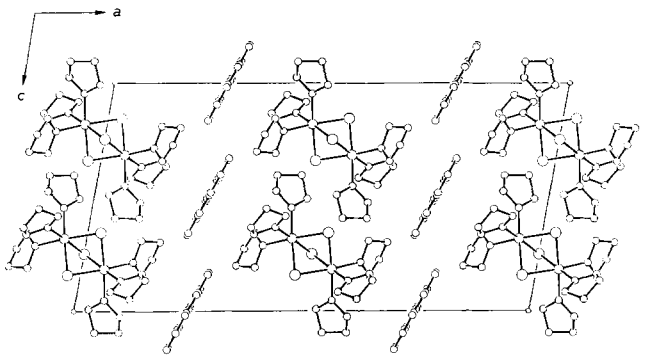

Fig. 2. Packing of **6** in the crystal lattice. C2/c, $a=28.212(3)$, $b=9.947(1)$, $c=14.520(3)$ Å, $\beta=100.043(9)°$, $Z=4$, $T=-173°C$, $\rho_{calcd}=1.27$ gcm^{-3}, $\lambda=0.71069$ Å, $\mu=2.99$ cm^{-1} (analytical absorption correction), $\theta_{max}=36°$, 44049 measured reflections, averaged to 6213 observed reflections ($R_{av}=0.027$), ($I\geq 2\sigma(I)$), 2301 unobserved reflections, 337 refined parameters, $R=0.039$, $R_w=0.039$, $R_{HO}=0.027$, $\sin\theta/\lambda\geq 0.65$ Å^{-1} [10].

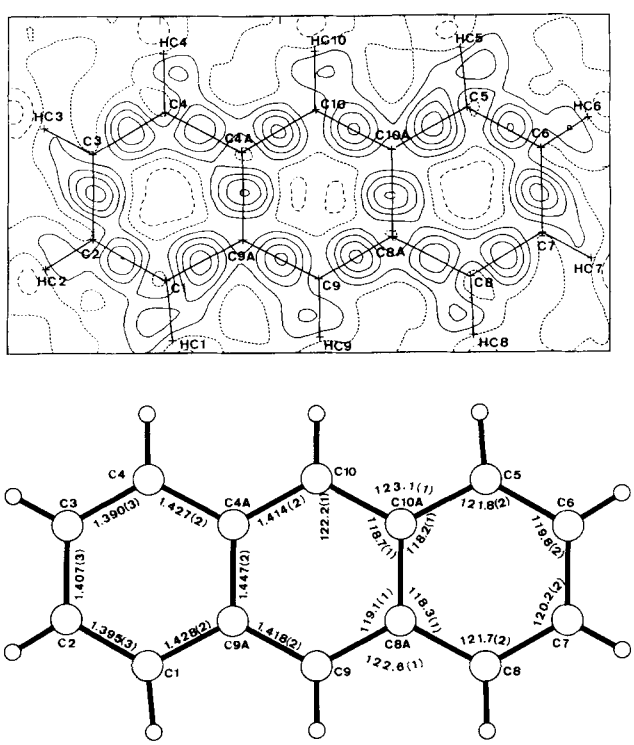
Both the bond lengths and the electron deformation density (EDD) (Fig. 3) of the skeleton of the radical anion of anthracene, which, in this case, is present in a lattice as a distinct species for the first time, show unequivocally that in **6** the LUMO of anthracene is occupied by one electron. Thus, the C2–C3 (C6–C7) bonds are shortened by 0.02 Å, the EDD in this region being increased, whereas the C1–C2 and C3–C4 bonds are lengthened by 0.02 Å with decrease in the EDD. No changes were observed for the central C4A–C9A bond.



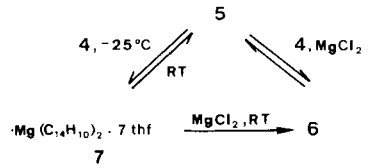


Fig. 3. EDD in the skeleton of the radical anion of **6** as well as the corresponding bond lengths.

Even in the absence of $MgCl_2$, **5** can transfer an electron to **4** in THF at −30°C. The insoluble magnesium bis(anthracenide)·7thf **7** is formed, which, after addition of $MgCl_2$ at room temperature (RT), affords **6**.

Compounds **5**, **6**, and **7** can accordingly be converted into one another.[5a]

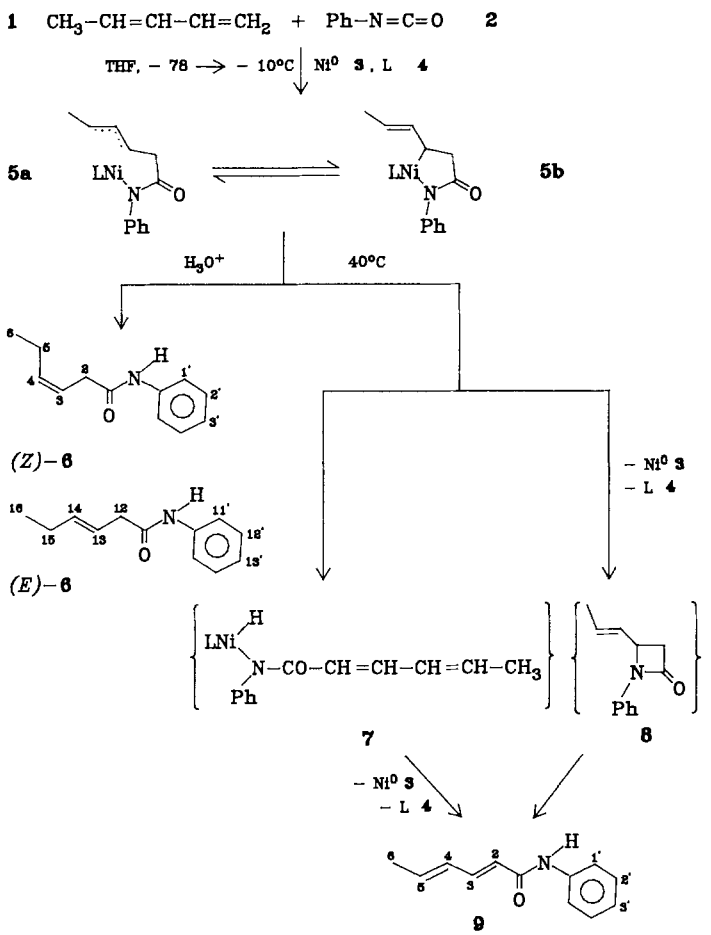
Nickel(0)-Catalyzed Synthesis of Sorbanilide from 1,3-Pentadiene and Phenyl Isocyanate



By *Heinz Hoberg** and *Elisa Hernandez*

We recently reported the preparation of acrylamides from ethylene and isocyanates on nickel(0) complexes in a

[*] Prof. Dr. H. Hoberg, Dr. E. Hernandez
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1
D-4330 Mülheim a. d. Ruhr 1 (FRG)

stoichiometric sequence of reactions.[1] The corresponding 1:1 CC coupling reactions of 1,3-dienes and isocyanates with retention of the diene skeleton were unknown up to now.[2] We have now been able to obtain sorbanilide from 1,3-pentadiene (piperylene) and phenyl isocyanate using nickel compounds as catalysts.

Piperylene ($Z/E = 33:67$ mixture) **1** reacts with phenyl isocyanate **2** on nickel(0) complexes **3**[3] in the presence of a strongly basic, bulky ligand L such as (*cyclo*-$C_6H_{11})_3P$ **4** (mole ratio 2:1:1:1) with 1:1 CC bond formation to give the nickel complex **5** regioselectively[4] in 63% yield.[5] Protonolysis of **5** with 2 N H_2SO_4 affords **6** ($Z/E = 71:29$) in 55% yield.[6]

The mass spectrum of **5** shows no peak for the molecular ion, but does exhibit, along with the expected fragment ions of **4** and **6**, a peak that, as the molecular ion of the sum of **1** and **2** [*m/z* 187 (M^+)] indicates the formation of sorbanilide **9**. Under the conditions of mass spectrometric measurement, a reductive elimination thus takes place for **5**.

9 is also formed when **5** is heated. When **5**, which is only sparingly soluble in the conventional solvents (**5a** corresponds to a 14e and **5b** to a 16e complex, so that **5** is presumably present as an aggregate in the solid), is heated at 60°C for 24 h in tetrahydrofuran (THF), the protonolysis affords **9** in ca. 11% yield.

The stoichiometric synthesis of **9** can be made catalytic if special reaction conditions are employed. When a mixture of **1**, **2**, **3**, and **4** (mole ratio 10:5:1:1), initially prepared in a steel autoclave at −78°C in THF, is warmed with stirring to 20°C over ca. 10 h and then heated for ca. 48 h at 40°C, **9** is obtained in ca. 250% yield[7] (based on **3**) after hydrolytic work-up.[8]

The catalysis presumably begins with formation of a CC bond between **1** and **2** at L–Ni^0 in an oxidative addition reaction ($Ni^0 \rightarrow Ni^{2+}$) to give the nickel complex **5**, which, upon heating, forms **9** and the regenerated L–Ni^0 complex via intermediates **7** and/or **8** (with reductive elimination and H shift).

The formal addition of a vinylic C–H bond of 1,3-pentadiene to the CN double bond of phenyl isocyanate is the first metal-induced synthesis of a conjugated dienoic acid derivative.

[2] Dienoic acids can also be prepared from the corresponding 1,3-dienes and carbon dioxide on nickel complexes in a stoichiometric reaction; cf. H. Hoberg, D. Schaefer, B. W. Oster, *J. Organomet. Chem. 266* (1984) 313; H. Hoberg, D. Schaefer, *ibid. 255* (1983) C 15; D. Walther, E. Dinjus, H. Görls, J. Sieler, O. Lindqvist, L. Anderson, *ibid. 286* (1985) 103.

[3] Ni^0: e.g., (cdt)Ni where cdt = 1,5,9-cyclododecatriene or $(cod)_2Ni$ where cod = 1,5-cyclooctadiene.

[4] **2** reacts exclusively at the C^1 atom of **1** to give **5**; the other three possible products of CC coupling could not be detected.

[5] **5**: A mixture of **1** (1.1 g, 15 mmol), **2** (0.95 g, 8 mmol), $(cod)_2Ni$ (1.96 g, 7.3 mmol), and **4** (1.97 g, 7.3 mmol) prepared under argon at −78°C in 30 mL of diethyl ether was warmed to −10°C within 48 h, forming an orange-brown suspension. After addition of ca. 30 mL of pentane, the precipitate was collected on a sintered glass filter and dried. Yield: 2.4 g (4.57 mmol) 62%. M.p. = 115°C (decomp.). IR (KBr): ν = 1532 (C=O) cm^{-1}. Correct elemental analysis.

[6] **6**: **5** (1.0 g, 1.9 mmol) was suspended in 20 mL of diethyl ether and treated with ca. 5 mL of 2 N H_2SO_4. After ca. 20 h, the reaction mixture was extracted with diethyl ether, the organic phase was dried with magnesium sulfate, the ether was removed, and the residue was chromatographed on silica gel 60 (eluent: toluene/diethyl ether 1:1). Yield: 199 mg (1.05 mmol) 55%. M.p. = 39°C. MS: *m/z* 189 (M^+). IR (KBr): 3247 ν(NH); 1548 δ(NH); 1657 ν(C=O); 1620 ν(C=C); 966 γ(CH,CC(*E*)); 760 γ(CH,CC(*Z*)) covered by C_6H_5 bands, cm^{-1}. The *E*/*Z* ratio was determined by ^{1}H-NMR spectroscopy. ^{1}H-NMR: the signals of (*Z*)-**6** and (*E*)-**6** were not completely resolved in the 200-MHz spectrum (except for H-2 and H-12, respectively, and H-6 and H-16); the integration gave $Z/E = 71:29$. ^{1}H-NMR ($CDCl_3$, TMS): [(*Z*)-**6**], δ = 1.01 (t, 3 H, H-6); 2.11 (quint, 2 H, H-5); 3.16 (d, 2 H, H-2); 5.7 (m, 2 H, H-3, H-4); 7.08 (t, 2 H, H-2'); 7.51 (d, 2 H, H-1'); 7.78 (s, 1 H, NH). [(*E*)-**6**] as for (*Z*)-**6** except for δ = 1.02 (H-16) and 3.08 (H-12).

[7] That only ca. 2.5 catalytic cycles occur is apparently due to inactivation of L–Ni^0 by **2**, forming nickel-containing six-membered rings; cf. H. Hoberg, B. W. Oster, C. Krüger, Y. H. Tsay, *J. Organomet. Chem. 252* (1983) 365.

[8] **9**: 1.88 g (20.3 mmol) **1**, 1.21 g (10.14 mmol) **2**, 0.56 g (2.03 mmol) $(cod)_2Ni$ and 0.57 g (2.03 mmol) **4** in 30 mL of THF were mixed at −78°C and warmed to 40°C (stirring) in a steel autoclave. The THF was subsequently distilled off and the residue hydrolyzed with 2 N H_2SO_4, diethyl ether being added. The organic phase was dried over magnesium sulfate and then chromatographically purified (silica gel 60, eluent: toluene/diethyl ether 1:1). Yield: 930 mg (4.93 mmol) 250% based on **3** [9]. M.p. = 143°C [10]. IR (KBr): 3303 ν(NH), 1534 δ(NH), 1656, 1630, 1611 ν(C=O,C=C), 1010 γ(CH,C=C–C=C) cm^{-1}. ^{1}H-NMR [$(CD_3)_2CO$, δ = 2.04, 200 MHz]: δ = 1.81 (d, 3 H, CH_3), 6.15 (m, 3 H, H-2, H-4, H-5), 7.02 (t, 1 H, H-3'), 7.28 (m, 4 H, H-3, H-2', N–H), 7.72 (d, 2 H, H-1').

[9] **1** was used as an $Z/E = 33:67$ mixture. If 97% (*Z*)-**1** or (*E*)-**1** is employed, the yield of **9** remains practically unchanged.

[10] O. S. Stepanova, D. A. Mazurenko, V. T. Nguyen, N. Ya. Derka, *Fiziol. Akt. Veshchestva 8* (1976) 86; *Chem. Abstr. 86* (1977) 189422d.

Reactivity of Bis(η^6-benzene)chromium(0) toward Sulfur Dioxide: Formation and Structure of $[(\eta^6\text{-}C_6H_6)_2Cr]_2S_4O_{10}$, a Salt Containing the Anion $[S_2O_6 \cdot 2SO_2]^{2\ominus}$**

By *Christoph Elschenbroich,* Rolf Gondrum,* and *Werner Massa*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

An investigation of the reaction of bis(η^6-benzene)chromium **1** with SO_2 is of interest since the redox couples $\mathbf{1}/\mathbf{1}^{\oplus}$ and $2SO_2/S_2O_4^{2\ominus}$ ($E_{1/2} = -0.81$ and -0.79 V, respectively, DMF, versus SCE[2]) have nearly identical redox potentials, and since **1** reacts with liquid SO_2, undergoing extensive oxidation to $\mathbf{1}^{\oplus}$.[3] We have been concerned, above all, with the question whether, upon controlled addition of SO_2 to **1**, charge-transfer complexes $\mathbf{1}(SO_2)_n$ or, as for acceptors with more positive redox potentials,[4] radical salts $\mathbf{1}^{\oplus}SO_2^{\ominus}(SO_2)_{n-1}$ would be formed. In the latter case, the subsequent fate of the radical anion $SO_2^{\ominus}$ was of interest.

When dry, oxygen-free SO_2 gas is bubbled through a solution of **1** in toluene, a precipitate forms, which is initially red but subsequently turns black, and whose analytical composition corresponds to $\mathbf{1}(SO_2)_2$, the central metal atom of which, according to ESR spectroscopy, is present as Cr^I. At room temperature under high vacuum, this substance releases one equivalent of SO_2 and turns lighter in color. At temperatures above 80 °C, **1** sublimes from the precipitate. Recrystallization of the product from acetonitrile or direct reaction of **1** with SO_2 in acetonitrile affords brown crystals, whereby the solution transiently turns green. These crystals are only stable under SO_2; they also contain Cr and S in a ratio of 1:2 (approximately 60% yield from **1**). This substance, too, loses SO_2 in high vacuum; the residue has the composition $\mathbf{1}(SO_3)$.

Since the IR spectra do not allow unequivocal identification of the product, its structure was determined by X-ray analysis of the crystals obtained from acetonitrile.[5] To our surprise, the results showed that an $S_4O_{10}^{2\ominus}$ species is present as the counterion of two $\mathbf{1}^{\oplus}$ ions (Fig. 1). On the basis of the S2–O11 distance (243 pm), which lies between that corresponding to the sum of the van der Waals radii (330 pm) and that of an S–O single bond (176 pm), the $S_4O_{10}^{2\ominus}$ structural unit can be viewed either as a Lewis adduct with two extremely long S–O bonds or as a charge-transfer complex $S_2O_6^{2\ominus} \cdot 2SO_2$ of a dithionate ion with two molecules of SO_2. The interaction between SO_2 and $S_2O_6^{2\ominus}$ is fundamentally different from that between SO_2 and $SO_3^{2\ominus}$, which results in the formation of the unsymmetrical disulfite ion $S_2O_5^{2\ominus}$, in which, both in solution[6] and in the crystal,[7] SO_2 is bound covalently by an S–S bond. The formulation $S_2O_6^{2\ominus} \cdot 2SO_2$ places this structural unit in the class of "solvates," which have been frequently observed for SO_2[8] but only rarely characterized by X-ray analysis.[9] In the region of SO_2 coordination, the $S_2O_6^{2\ominus} \cdot 2SO_2$ structural unit exhibits similarities to the species 1,4-$(Me_2N)_2C_6H_4 \cdot 2SO_2$,[9f] the ion $ISO_2^{\oplus}$,[9g] and the ligand-bound SO_2 in $[Ru(CO)_2(PPh_3)_2(\eta^2\text{-}SO_2 \cdot SO_2)]$:[9d] the lengths of the donor-acceptor bonds lie, in each case, between those of van der Waals contacts and that of a covalent single bond; the pyramidal geometries around the S atom and the contractions of the bond angle O–S–O are comparable. An aggravating circumstance in the discussion of the S–O bond lengths is the strong thermal vibration of the loosely bound SO_2 molecule. However, correction for the effect of vibration using the "riding" model[11] leads to plausible, significantly longer S–O distances (Fig. 1), which are employed in the following discussion.

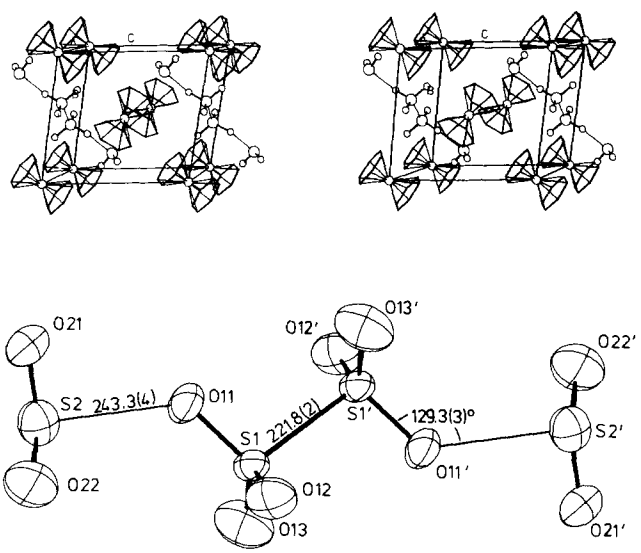

Fig. 1. Above: Stereoscopic view of a unit cell of $\mathbf{1}_2^{\oplus}S_2O_6^{2\ominus} \cdot 2SO_2$. Below: ORTEP plot of the anionic groups $S_2O_8^{2\ominus} \cdot 2SO_2$ (the ellipsoids of vibration represent 30% probability). A center of symmetry is present on the S1–S1′ bond. Bond lengths [pm]. Other important bond lengths [pm] (including values corrected for the effect of thermal vibration in brackets) and angles [°]: S1–O11 147.5(5) [153], S1–O12 142.1(6) [146], S1–O13 137.3(6) [143], S2–O21 137.9(7) [146], S2–O22 135.6(9) [144]; O12–S1–O13 113.4(4), O21–S2–O22 112.9(6). In $\mathbf{1}^{\oplus}$: mean value Cr–C 212.9, C–C 139.4.

The form and orientation of coordinated SO_2 in $S_2O_6^{2\ominus} \cdot 2SO_2$ can be explained in terms of the interaction between an occupied σ-donor orbital of the dithionate ion and the LUMO $2b_1(\pi)$ of SO_2, which is dominated by the contribution of the $3p_x$-AO on sulfur ($x \perp SO_2$ plane).[10] Since the O11–S2 bond is nearly perpendicular to the O21–S2–O22 plane, S2 is probably only slightly rehybridized. The LUMO $2b_1$ of SO_2 is S–O antibonding and O–O bonding. The contraction of the O21–S2–O22 angle and the lengthening of the S–O bonds of SO_2 in $S_2O_6^{2\ominus} \cdot 2SO_2$ can thus be viewed as a result of the charge transfer $S_2O_6^{2\ominus}(n) \rightarrow SO_2(\pi, 2b_1)$. The coordination of the acceptor SO_2 also influences the shape of the dithionate ion, which manifests itself primarily in the lengthening of the central S–S bond from 214 pm in $S_2O_6^{2\ominus}$[12] to 222 pm in $S_2O_6^{2\ominus} \cdot 2SO_2$ and of the S1–O11 bond from 145 to 152 pm. A significant interaction $SO_2/\eta^6\text{-}C_6H_6$ is not evident, the shortest S2–C(arene) separation (362 pm) being larger than the van der Waals distance.

The analysis of the IR spectrum of $\mathbf{1}_2^{\oplus}S_2O_6^{2\ominus} \cdot SO_2$ is complicated by the fact that the absorptions of the oxo anions of sulfur fall in a narrow range, the contribution of solvate formation to the shift cannot be predicted, and the counterion $\mathbf{1}^{\oplus}$ exhibits absorptions in the region around 1000 cm^{-1} where several of the IR bands for $S_2O_6^{2\ominus}$ are

[**] Metal π Complexes of Benzene Derivatives, Part 25. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 24: [1].

found.[13] Nevertheless, the bonding of the SO_2 molecule to the $S_2O_6^{2\ominus}$ ion causes shifts to lower wave numbers of the SO_2 vibrations ($\nu_{as} = 1314\ cm^{-1}$ [$\nu_{as}(SO_2, free) = 1340\ cm^{-1}$]) as well as of the dithionate ion vibrations ($\nu = 1209\ cm^{-1}$ [$\nu(Na_2S_2O_6, E_u) = 1235\ cm^{-1}$ [13a]]). Upon release of SO_2 in high vacuum, the band at 1314 cm^{-1} disappears and the band at 1209 cm^{-1} is displaced to 1224 cm^{-1}). These IR results are in accord with the structural data for $1_2^{\odot\oplus}S_2O_6^{2\ominus} \cdot 2SO_2$ as well as with earlier IR studies on the SO_2 solvates.[14]

The formation of two oxidation products, $1^{\odot\oplus}$ and $S_2O_6^{2\ominus}$, from the educts **1** and SO_2 requires the inclusion of a disproportionation step. As we were able to demonstrate by means of a flow experiment in which ESR spectra were recorded immediately after mixing solutions of **1** and SO_2 in acetonitrile, the reaction sequence is initiated by an electron transfer from **1** to SO_2, since, along with the ESR signal for $1^{\odot\oplus}$ ($\langle g \rangle = 1.9862$), the signal for $SO_2^{\odot\ominus}(SO_2)_n$ ($\langle g \rangle = 2.0068$[15]) is observed. The elucidation of the consecutive reactions leading to the product $1_2^{\odot\oplus}S_2O_6^{2\ominus} \cdot 2SO_2$ is the subject of further study. However, the formation of dithionate in the reduction of SO_2 is not without precedent. Thus, $S_2O_6^{2\ominus}$ was also found as a product of the discharge of Li/SO_2 cells and its formation ascribed to the following sequence of reactions.[16]

$$2SO_2 + 2e^{\ominus} \longrightarrow S_2O_4^{2\ominus} \xrightarrow{SO_2} S_3O_6^{2\ominus} \longrightarrow S_2O_6^{2\ominus} + S$$

β-$(ET)_2AuI_2$: An Organic Volume Superconductor with $T_c = 3.2$ K at Ambient Pressure**

By *Eberhard Amberger,* Helmut Fuchs,* and *Kurt Polborn*

Inorganic superconductors have been produced on an industrial scale for more than a decade.[1] The highest transition temperature T_c (transition from the metallic to the superconducting state) hitherto recorded, namely 23.2 K in the case of metastable Nb_3Ge, could not even be surpassed by A 15-Nb_3Si.[2] It would now appear, from theoretical considerations, that organic superconductors may offer more prospects of achieving higher critical temperatures.[3] The first organic ambient-pressure superconductor, the perchlorate of the radical-cation dimer of tetramethyltetraselenafulvalene $(TMTSF)_2ClO_4$ ($T_c = 1$ K), was discovered in 1981.[4] In 1983 the radical-cation salt $(ET)_2ReO_4$, obtained from bis(ethylenedithio)tetrathiafulvalene **1** ("BEDT-TTF" or "ET"), was found to be superconducting ($T_c \sim 2$ K), but only at high pressures ($p > 4.5$ kbar). Meanwhile,[***] four ambient-pressure superconductors of ET have been synthesized: β-$(ET)_2I_3$ ($T_c = 1.2$–1.6 K),[7, 8] γ-$(ET)_3(I_3)_{2.5}$ ($T_c \sim 2.5$ K),[7] ε-$(ET)_2I_3(I_8)_{0.5}$ ($T_c \sim 2.5$ K),[7] and β-$(ET)_2IBr_2$ ($T_c = 1.7$–2.8 K).[9, 10]

1

It would seem that superconductivity occurs in ET compounds only with certain layer arrangements of the nearly flat ET molecule. The ET radical cations are stacked in a fashion which is typical for all quasi one-dimensional "organic metals." However, the loosely packed ET stacks are not arranged along the shortest period of the crystal.[7b] Thus, the $(ET)_2X$ system belongs to a structurally novel class of organic conductors, in which the S···S interstack contact distances of the side-by-side arrangement of ET molecules are shorter than the intrastack S···S packing distances. The anions reside in channels and cavities between the ET stacks. We report here on the synthesis of $(ET)_2X$ compounds containing the anions $IBr_2^{\ominus}$, $I_2Br^{\ominus}$, and $AuI_2^{\ominus}$, which, like the isostructural $(ET)_2I_3$, are two-dimensional organic conductors (see Table 1).

Replacement of the linear $I_3^{\ominus}$ in β-$(ET)_2I_3$ by the smaller linear $IBr_2^{\ominus}$ anion leads to an increase in T_c from 1.2–1.6 K to 1.7–2.8 K. The design strategy described here for achieving still higher transition temperatures consists in the replacement of the interhalide ions by linear metal halide or

[**] We wish to thank Dipl.-Phys. *C. P. Heidmann, H. Veith,* and *Prof. Dr. K. Andres,* Walther-Meissner-Institut für Tieftemperaturforschung, D-8046 Garching, for the T_c measurements.

[***] Almost concomitantly with the submission of this manuscript *Williams* et al. reported on β-$(ET)_2AuI_2$ as a superconductor at ambient pressure and quoted an onset temperature of 3.93–4.98 K [16].

cyanide ions $(X-M-X)^{\ominus}$, e.g. $AuI_2^{\ominus}$, $AuBr_2^{\ominus}$, and $Au(CN)_2^{\ominus}$. By electrocrystallization, the most important method for preparing single crystals of organic superconductors, we have obtained β-$(ET)_2AuI_2$, which is superconducting at $T_c = 3.2$ K at ambient pressure. This is the highest T_c recorded for any ambient-pressure organic superconductor without subsequent doping (e.g. with I_2 vapor) or tempering (see [16]). β-$(ET)_2AuI_2$, which was obtained as black, canted crystals in 1,1,2-trichloroethane (TCE), proved to be a volume superconductor. Besides strict adherence to the experimental conditions, especially important in the electrocrystallization is that $AuI_2^{\ominus}$ is synthesized chemically and not electrochemically. Non-superconducting, thin, black platelets were isolated from tetrahydrofuran (THF).

Table 1. Crystallographic data and T_c of superconducting and non-superconducting β-$(ET)_2AuI_2$ crystals and of polyhalide-ET compounds.

In the case of $(TMTSF)_2FSO_3$, less than 2% of the crystal volume is superconducting.[8] ET salts containing the centrosymmetric $(Br-I-Br)^{\ominus}$ anion and those containing the asymmetric $(I-I-Br)^{\ominus}$ anion, which have also been prepared by electrocrystallization, behave completely differently: Only β-$(ET)_2IBr_2$ is superconducting,[9b] thus verifying the importance of a centrosymmetric and crystallographically ordered anion. For the first time volume superconductivity has been observed in our β-$(ET)_2IBr_2$ with a T_c of 1.7 K. β-$(ET)_2I_2Br$, on the other hand, is not superconducting at ambient pressure nor under hydrostatic pressure. By electrocrystallization, we also obtained α- and β-like ET salts with the dibromoaurate ion $AuBr_2^{\ominus}$, but no superconductivity was observed up to the measured temperature of 1.2 K. As to whether superconducting crystals are obtained or not often depends very strongly on the experimental conditions.

Replacement of the $I_3^{\ominus}$ anion in the isostructural β-$(ET)_2X$ system by the ~7% shorter $IBr_2^{\ominus}$ anion leads to a decrease in the interstack S...S distances. Whether this is also true in the case of β-$(ET)_2AuI_2$ with the higher T_c and a unit cell volume about 11 Å^3 larger than that in the IBr_2 salt will have to be established by an X-ray structure analysis. Upon electrocrystallization of ET with halide ions ($F^{\ominus}$, $Cl^{\ominus}$, $Br^{\ominus}$) we have hitherto obtained only whiskers or thin, scaly-like platelets. Apparently, anions that are too small rarely yield useful single crystals.

Experimental

ET was prepared as previously described in the literature [11] and was recrystallized twice from toluene. The supporting electrolyte salt nBu_4NAuI_2 was synthesized chemically from AuI [12] and nBu_4NI [13] or from nBu_4NAuBr_2 and nBu_4NI. [14] The electrocrystallization of β-$(ET)_2AuI_2$ (2×10^{-3} M ET) was carried out galvanostatically at a current density of 0.5 μA/cm^2 in 25 mL of TCE at platinum electrodes in the presence of nBu_4NAuI_2 (3×10^{-3} M) using an H-type cell with two small porosity frits between cathode and anode vessels. After six days, black, canted needles with typical dimensions of maximally $3 \times 1 \times 1$ mm^3 were obtained. After electrocrystallization, the cathode was always found to be covered with a thin gold film. At current densities in excess of 1 μA/cm^2, compact separation of elemental gold took place at the anode and partial separation on the crystals. We have also succeeded in preparing thin, black platelets of $(ET)_2AuI_2$ from tetrahydrofuran (THF) by electrocrystallization (gold electrodes, 0.5 μA/cm^2, 2×10^{-3} M ET and 3.6×10^{-3} M nBu_4NAuI_2, room temperature). Preliminary X-ray crystallographic investigations indicate that only α-phases are obtained from THF.—Electrochemical synthesis of $(ET)_2AuI_2$ and its electrocrystallization: Stoichiometric oxidation of a gold wire in a solution of nBu_4NI in TCE furnished nBu_4NAuI_2. Neutral ET, dissolved in TCE, was then added. Electrocrystallization: 2×10^{-3} M ET, 5×10^{-3} M nBu_4NAuI_2, 23 °C, 2 μÅ/cm^2. The crystals have unit cell parameters similar to those of the β-$(ET)_2AuI_2$ crystals from chemically prepared nBu_4NAuI_2, but have a ca. 10 Å^3 larger unit cell (Table 1) and are not superconducting up to 1.2 K.—α- and β-$(ET)_2IBr_2$ and β-$(ET)_2I_2Br$ were crystallized from THF at 1–2 μA/cm^2 and 1 μA/cm^2, respectively. The supporting electrolyte salts nBu_4NIBr_2 and Et_4NI_2Br were prepared according to procedures given in the literature [15].—Superconductivity has been demonstrated in various batches of crystals using two samples of three crystals in each case and using a superconducting quantum interference device (SQUID magnetometer). The ratio of the Meissner effect to diamagnetic screening current of 38% and 67%, respectively, showed, analogously to the conclusions drawn from measurements with β-$(ET)_2I_3$ [8], that both β-$(ET)_2AuI_2$ and β-$(ET)_2IBr_2$ are volume superconductors.

The large difference in the transition temperature may primarily be due to the different experimental conditions under which the crystals were isolated. The higher T_c (4.98 K) also results from the definition of T_c as the onset temperture and not as the linear tangent extrapolation of the resistivity jump onto the temperature scale.

$(i\text{-}C_3H_7SGaI_2)_2$, the First "Butterfly" Molecule with Tetracoordinated Gallium**

By *Gerhard Georg Hoffmann** and *Christian Burschka*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Four-membered rings containing two tetracoordinated elements of the boron group are mostly planar. Only for aluminum have some folded ("butterfly") four-membered-ring structures been confirmed.[1] In contrast, no such example is known for gallium; all known four-membered rings containing sp^3-hybridized gallium atoms are strictly planar.[2] Folded systems are only found for pentacoordination of the metal.[3] We have now succeeded in synthesizing, along with further planar GaSGaS four-membered rings,[2b] the first compound of this kind that exhibits a "butterfly" structure in the crystal, bis[diiodo(isopropylthio)gallane].

A solution of diiodo(methylthio)gallane[4] reacts rapidly with 2-propanethiol in refluxing benzene, resulting in exchange of the alkylthio groups [Reaction (a)].[5]

$$CH_3SGaI_2 + i\text{-}C_3H_7SH \longrightarrow \underset{\mathbf{1}}{i\text{-}C_3H_7SGaI_2} + CH_3SH \qquad (a)$$

The gallane formed, **1**, is very sensitive to moisture and decomposes at 352 K. In the ^{1}H-NMR spectrum, the proton signal of the methine group is markedly shifted downfield compared with that of the free thiol; that of the methyl groups, on the other hand, is shifted upfield somewhat.[4] In contrast to the analogous compounds I_2GaSR ($R=CH_3$, C_2H_5, and n-C_3H_7), in which, already at room temperature, two (broad) groups of signals are present in the ^{1}H-NMR spectrum for both the methylene and the methyl groups,[4] no significant splitting is observed for **1**, even down to 200 K (400-MHz spectra), which would have indicated the presence of isomers. However, when **1** is stored for ca. 24 h at 213 K and its ^{1}H-NMR spectrum subsequently recorded, an additional signal for the methine protons appears at higher field. All signals are broadened and barely resolved. Recording of the spectrum once again at room temperature results in only one well-resolved signal for each type of proton.

Osmometric molecular weight determinations in benzene (318 K) using various concentrations of **1** (13 to 162 mmol/L, based on the empirical formula of the monomer) always give a molecular weight three times that calculated. The same degree of association is also found for the analogous compounds I_2GaSR ($R=CH_3$, C_2H_5, and n-C_3H_7), whereas the phenylthio derivative is present as a monomer in the same solvent.[4]

The X-ray structure analysis of the crystals obtained from $CHCl_3$/n-hexane, which are up to 3 mm in size, shows, however, that **1** adopts a folded four-membered-ring structure (Fig. 1) in the crystal, the two isopropyl groups being in *syn* positions. The molecule has C_2 symmetry in the crystal but deviates only slightly from C_{2v} symmetry. With a fold angle of 143.3(2)° on the diagonal Ga···Ga', the deviation from planarity (36.7(2)°) is more pronounced than in all folded four-membered-ring systems of aluminum and gallium known up to now. In the homologous series, only the "butterfly" ion $(Tl_2Te_2)^{2-}$[6] with 49.9° shows a greater folding; in this case, however, a Tl^I compound is involved. Both the Ga-S and the Ga-I bond lengths in $(\mathbf{1})_2$ are four to five standard deviations smaller than in the planar GaSGaS four-membered ring of $(CH_3SGaI_2)_2$, whose structure we[2b] and others[2c] have also elucidated recently.

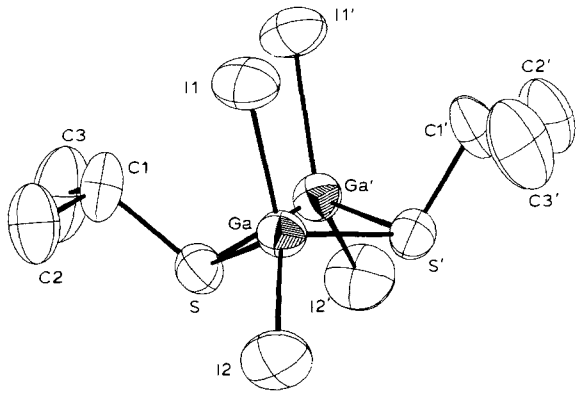

Fig. 1. Crystal structure of $(\mathbf{1})_2$: C2/c, $a=956.1(2)$, $b=1253.0(3)$, $c=1724.3(5)$ pm, $\beta=104.80(2)°$, $Z=4$, $\rho_{calcd}=2.65$, $\rho_{exp}=2.62$ gcm^{-3}, $R_1=0.053$ for 1303 independent reflections ($I_0 \geq 3\sigma(I_0)$), $Mo_{K\alpha}$ radiation. Atomic distances [pm]: Ga-S 232.7(3), Ga-S' 233.1(3), Ga-I1 248.2(2), Ga-I2 247.9(2), Ga···Ga' 313.7(2), S···S' 326.8(4); bond angles [°]: S-Ga-S' 89.1(1), Ga-S-Ga' 84.7(1), I1-Ga-I2 114.58(6). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD-51366, the names of the authors, and the journal citation.

A satisfactory explanation of the striking differences in the degree of association of **1** in solution and in the crystal demands that an equilibrium between dimer and trimer

$$3(i\text{-}C_3H_7SGaI_2)_2 \rightleftharpoons 2(i\text{-}C_3H_7SGaI_2)_3 \qquad (b)$$

be established [Reaction (b)] by breaking of the four-membered-ring structure upon solvation of the substance; the equilibrium must be quickly established and lie strongly to the side of the trimer. Moreover, either only one conformer of the trimeric form is formed preferentially or an exchange between the various conformers takes place so rapidly, even at 200 K, that no significant additional groups of signals can be observed in the NMR spectrum.

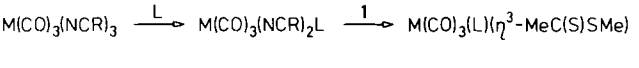
A Dithioester as Allylic-Type 4e Ligand**

By *Wolfdieter A. Schenk,* Doris Rüb,* and *Christian Burschka*



Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

The coordination chemistry of simple organic thiocarbonyl compounds recently has attracted considerable attention. Thus, the normally unstable thioaldehydes and thioketones can be both stabilized[3,4] and activated to undergo novel reactions[4,5] by η^1- or η^2-coordination to a transition metal. Other C=S functional compounds, e.g., thioamides and thioureas, have frequently been employed as ligands;[6] their reactivity in the coordinated state, however, has not been investigated in detail. Herein we report on complexes of the simplest stable dithioester, methyl dithioacetate **1**, in which the ester acts as a four-electron donor toward the same metal center through both the C=S double bond and the second sulfur atom.[7]

1

The synthesis starts from the well-known tris(nitrile) complexes **2**–**4** with replacement of one nitrile ligand by a bulky phosphane, followed by replacement of the other two by the dithioester **1**. Complexes **5**–**7** are obtained as orange crystalline solids (correct elemental analyses).

2 – **4** **5** – **7**

2: M = Cr, R = Me **5**: M = Cr, L = PPh_3

3: M = Mo, R = Me **6**: M = Mo, L = PPh_2iPr

4: M = W, R = Et **7**: M = W, L = $PiPr_3$

The high CO stretching frequencies (Table 1) confirm the high π-acceptor ability of the dithioester ligand. In the ^{13}C-NMR spectra the dithiocarboxylate carbon gives rise to a resonance at approximately $\delta = 100$, well separated from the resonances for both the free ester ($\delta = 234.1$)[8] and the known η^2-complexes ($\delta = 47$–60).[2,9] An X-ray structure determination of **7** conclusively shows that the dithioester acts as an allylic-type four-electron ligand. The

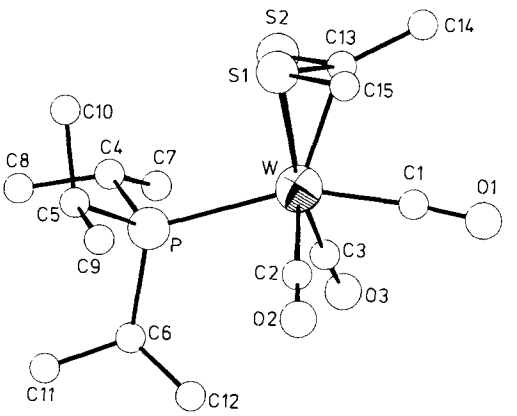
[a] Resonance of the dithiocarboxylate carbon.



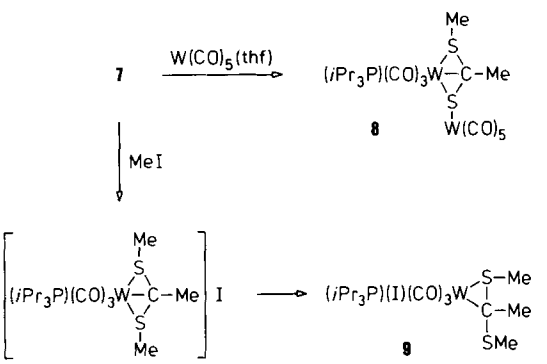


Fig. 1. Structure of **7** in the crystal. Space group $P2_1/c$ (No. 14), $Z = 4$, $a = 8.629(5)$, $b = 16.395(7)$, $c = 14.889(6)$ Å, $\beta = 104.22(4)°$, $\rho_{calcd} = 1.74$, $\rho_{exp} = 1.7$ mg/mm^3, $R_1 = 0.032$ (0.057), $R_2 = 0.029$ (0.031) for 2083 (3101) reflections ($I_{obs} \geq 3\sigma(I)$). Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-51496, the names of the authors, and the journal citation.

atoms C15, S1, C13, and S2 are exactly coplanar. The bond lengths C13–S1 (1.79 Å), C13–S2 (1.75 Å), and W–C13 (2.154 Å) equal those of single bonds (Fig. 1).

The η^3-coordinated dithioester is still susceptible to electrophilic attack. Thus, **7** reacts with $W(CO)_5$(thf) to give the binuclear complex **8**.

With methyl iodide, **7** is converted into the yellow addition product **9**, which, surprisingly, is a nonelectrolyte. In the ^{13}C-NMR spectrum of **9**, the resonance of the dithiocarboxylate carbon is found at $\delta = 56.2$, a value typical for η^2-coordination. Apparently, the iodide ion produced in the first step nucleophilically attacks the metal center with displacement of one of the coordinated sulfur atoms. **9** contains a stabilized dithiocarbenium ion as two-electron

donor and is thus analogous to the previously reported ionic compounds $[W(CO)_3(dppe)(RSC(H)SR')]X$ ($dppe = Ph_2P(CH_2)_2PPh_2$).[2]

Experimental procedure

5: A solution of **2** (1.30 g, 5.0 mmol) in acetonitrile (40 mL) was allowed to react at 20°C with Ph_3P (1.30 g, 5.0 mmol). After 16 h, the volume was reduced to 10 mL and diethyl ether (30 mL) was added to give a yellow precipitate. This was collected by filtration, washed with ether, and suspended in ethanol (50 mL). Upon addition of **1** (0.50 mL, 5.0 mmol), the mixture turned deep red. After 1 h, the volume was reduced to 25 mL and water (5 mL) was added to precipitate the orange product **5**. Yield 1.65 g (65%), decomp. p. 85°C.

6, **7**: **6** (80%, m.p. = 90°C (decomp.)) and **7** (70%, m.p. = 103–105°C (decomp.)) were obtained analogously.

8: A solution of $W(CO)_6$ (0.46 g, 1.30 mmol) in THF (100 mL) was irradiated until 1 equiv. of CO was liberated. After addition of **7** (0.64 g, 1.20 mmol), the volume was reduced to 5 mL and hexane (15 mL) was added to precipitate **8** as a yellow-orange powder. Yield 0.68 g (66%), m.p. = 107–110°C (decomp.).

9: A solution of **7** (1.44 g, 2.70 mmol) in acetone (20 mL) was treated at 20°C with methyl iodide (1.0 mL, 16.0 mmol). After 24 h, the solution was filtered and evaporated to 2 mL. Upon addition of diethyl ether (10 mL), **9** separated as a yellow crystalline powder. Yield 0.52 g (29%), m.p. = 115–120°C (decomp.).

New Bicyclic Ketones and the Stereochemistry of Their Reaction with Carbanions**

By *Petra Baierweck, Detlef Hoell,* and *Klaus Müllen**

Dedicated to Professor Rolf C. Schulz on the occasion of his 65th birthday

Knowledge of the reaction profile of nucleophilic attack on carbonyl compounds is of great theoretical and practical importance.[1] If ketones of type **1** or **2** are allowed to react with carbanions, the question arises whether the transient associative interaction of the organometallic compound with the ethylene or benzene π-system can result in a diastereoselective addition. We have directed our attention to the ketones **2** and **3** since the results for **1a**[2] did not provide a clear picture. We describe here a remarkably simple preparation of the new ketones **2b** and **3** (Table 1) and report on the stereochemistry of their reaction with organometallic compounds.

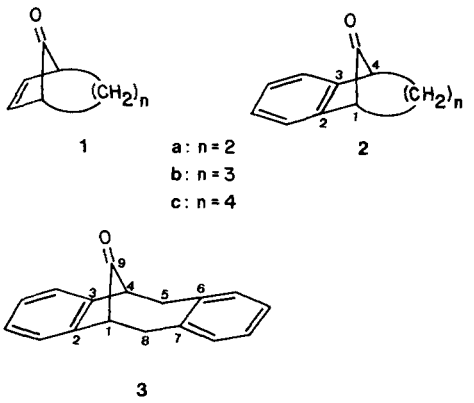

Table 1. Spectroscopic data for some of the new compounds [a].

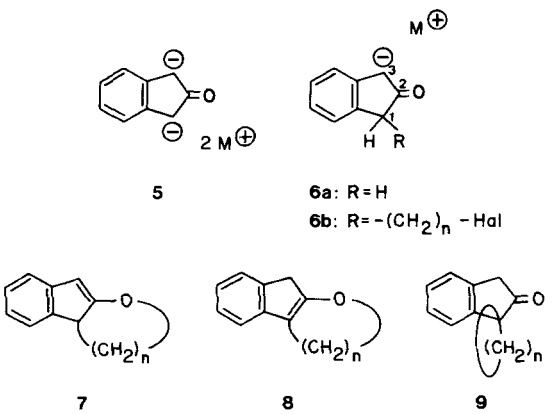
2b: ^{13}C-NMR ($CDCl_3$, 20 MHz): δ = 217.4 (C-carbonyl), 139.1, 127.5, 122.6 (C-arom.), 52.4 (C-1, C-4), 34.3 (C-5, C-7), 17.4 (C-6); ^{1}H-NMR ($CDCl_3$, 90 MHz): δ = 7.25 (4H, arom.), 3.37 (2H, m), 2.15–1.90 (4H, m), 1.57–0.78 (2H, m); IR (KBr): ν(CO) = 1760 cm^{-1}

3: ^{13}C-NMR ($CDCl_3$, 100 MHz): δ = 219.0 (C-9); 140.3, 136.0, 131.5, 127.5, 126.9, 123.7 (C-arom.), 52.2 (C-4, C-1), 41.1 (C-5, C-8); ^{1}H-NMR ($CDCl_3$, 60 MHz): δ = 7.05 (4H, arom.), 6.90 (4H, arom.), 3.65 (2H, m), 3.20 (4H, m); IR (KBr): ν(CO) = 1750 cm^{-1}; m.p. = 153.5°C



12a: ^{13}C-NMR ($CDCl_3$, 20 MHz): δ = 146.6 (*ipso*-phenyl), 143.6 (C-2, C-3); 127.7, 126.7, 126.5, 122.5 (C-arom.), 82.0 (C-8), 49.2 (C-1, C-4), 24.5 (C-5, C-7), 16.7 (C-6); ^{1}H-NMR ($CDCl_3$, 90 MHz): δ = 7.4–7.1 (9H, arom.), 3.32 (2H, m), 2.46–2.09 (2H, m), 1.99 (1H, s), 1.79–1.20 (3H, m), 1.02–0.5 (1H, m); m.p. = 70°C.

[a] All compounds gave correct elemental analyses.

Our most recent studies of the reductive alkylation of unsaturated hydrocarbons show[3] that the reaction of dianions with difunctional alkylating agents, e.g., 1,n-dihaloalkanes **4**, makes accessible a wide range of new cy-

$Hal-(CH_2)_n-Hal$ **4**

cloannelation and bridged products. In order to synthesize **2**, these results suggested the reaction of the dianion **5**, prepared by deprotonation of 2-indanone (1. NaH, 1.2 equiv., 0°C; 2. *n*-butyllithium, 1 equiv., tetrahydrofuran (THF), −78°C→0°C), with **4** (both **6a** and **5** were characterized by NMR spectroscopy[4]). The central question was

[*] Prof. Dr. K. Müllen, Dipl.-Chem. P. Baierweck, Dipl.-Chem. D. Hoell

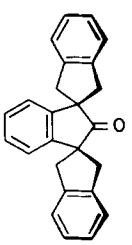
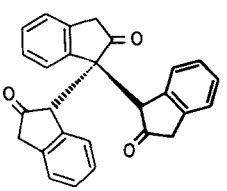
J.-J.-Becher-Weg 18–20, D-6500 Mainz 1 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.



whether the monoanion **6b**, obtained by the first alkylation in the 1-position would tend to react via *C*-alkylation in position 3 (product **2**), by *O*-alkylation (products **7** and **8**), or—after proton migration—by *C*-alkylation in position 1 (product **9**).

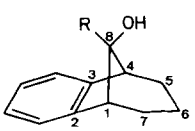
We investigated this reaction as a function of the chain length of the alkylating agent, the halide leaving group, and the ion-pair structure:[5]



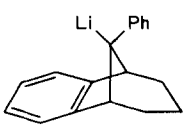
- 1,2-dibromoethane reacts with the dianion of 2-indanone to give solely the spiroannelated product **9a**; 1,3-dibromopropane affords a mixture of **2b** and **8b**;[6] 1,4-dibromobutane gives a complex mixture of products, which cannot be separated, but in which, according to NMR, no enol ether is present.
- The ratio of *C,C*- to *C,O*-alkylation products (**2b/8b**) increases in going from dibromo- to diiodopropane (a "softer" electrophile) from 2:1 to 5:1.
- This product ratio, observed in THF solution, is increased by addition of hexane and reduced by addition of hexamethylphosphoric triamide;[5] the product ratio **2b/8b** is 20:1 if THF/hexane (6:4) is used as solvent.

Even in dilute solution, considerable amounts of oligomeric products are formed; in a typical experiment (1,3-dibromopropane, THF), the yield of **2b/8b** is 31%. The separation of the products is achieved by column chromatography.

The variation of the alkylating agent demonstrates the limitations of the reaction. α,α'-Dibromo-*o*-xylene affords the ketone **3** (18%; side product, dispiro compound **10** (5%)), which is analogous to **2**; no *C,C*-alkylation product is formed with 1,2-bis(β-bromoethyl)benzene. When 1,2-dibromo-1,2-dihydrobenzocyclobutene is used, an electron transfer occurs. The trimer **11** is formed as the product of oxidative coupling.[7]



10



11

The reaction of the ketone **2b** with organometallic compounds (phenyllithium, phenylmagnesium bromide, methyllithium) exhibits pronounced diastereoselectivity: in the alcohol formed, **12**, the carbanion has always added *syn* to the benzene moiety. The configuration of the alcohol **12a** (Table 1) has been confirmed by an X-ray structure determination.[8] These results are in marked contrast to the results obtained for **1a**;[2] in the latter case, only a small amount of diastereoselectivity is observed, which, moreover, depends on the nature of the organometallic agent. Attack of phenyllithium on **3** also affords only the alcohol in which the phenyl group is *syn* to the neighboring benzene system.

The newly accessible ketones and alcohols described here are of further importance for the study of unusual carbanion structures. For example, the alcohol **12a**, formed from **2b**, can be transformed into the corresponding methyl ether. The reductive cleavage of the ether with lithium leads to the benzyllithium system **13**, which exhibits intramolecular "through-space" interaction between the carbanion moiety and the separated benzene π-system.[9]

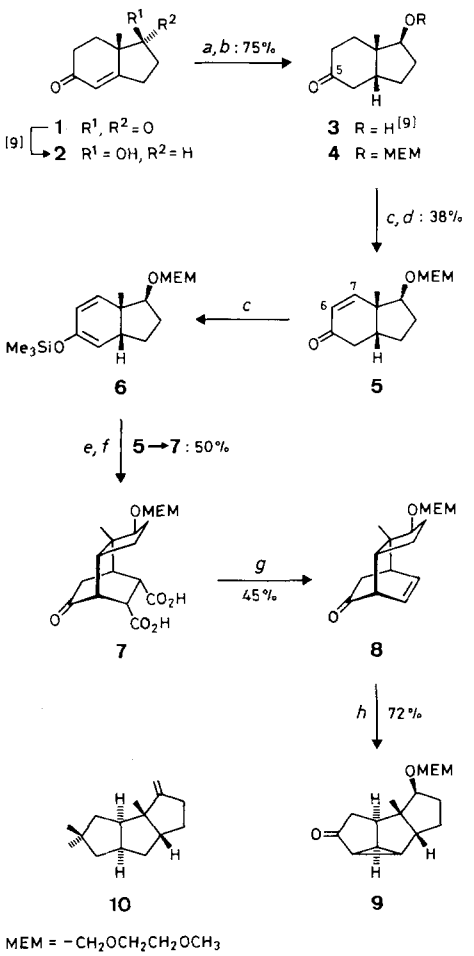
Extensions of the Tricyclooctanone Concept. A General Principle for the Synthesis of Linearly and Angularly Annelated Triquinanes

By *Martin Demuth** and *Werner Hinsken*



As an extension of our tricyclooctanone concept[1] for the synthesis of enantiomerically pure cyclopentanoid natural products, we present here a variant,[2] which leads to target structures that, using the original concept, would be difficult to obtain. Applying the new strategy, the linear *anti*-annelated triquinane skeleton **9**[3] and its isomer **15** with angularly joined rings are accessible in only a few steps.[4] They are, in our opinion, suitable precursors for hirsutene **10** and 5-oxosilphiperfol-6-ene **16**, respectively.[5]

The light-induced oxadi-π-methane rearrangement of bridged β,γ-unsaturated ketones again serves as the key step. Instead of constructing this type of chromophore via a Diels-Alder reaction of 1,3-dienes with ketene equivalents,[1] the addition of an acetylene equivalent (e.g., maleic anhydride) to siloxy-substituted dienes (**6** and **12**) is used.[6] From the adducts (**7** and **13**, respectively) the photoreactive substrates (**8** and **14**) are obtained and subsequently undergo triplet-sensitized rearrangement to **9** and **15**, respectively. The use of optically active dienes in this new route is advantageous. Both **6** and **12** are derived from a compound (**1** in Scheme 1) whose enantiomers are accessible in very good yields and high optical purities.[7] At first, racemic **1** was employed.

The *cis*-hydrindenone **5**[8] (Scheme 1, hirsutene project) could be prepared in good yield in four steps starting from the known compound **2** (**1** → **2**).[9] The *cis* configuration is

[*] Priv.-Doz. Dr. M. Demuth, W. Hinsken

Stiftstrasse 34-36, D-4330 Mülheim a. d. Ruhr (FRG)

established in the first step, a highly selective Birch reduction (**2**→**3**).[9] The introduction of the 6,7 double bond (→**5**) was achieved, after protection of the alcohol **3** (→methoxyethoxymethyl ether **4**),[8] by oxidative transformation of the trimethylsilyl C-5,6 enol ether of **4** (main product at −78 °C, 2 min). The method of kinetic formation of enol ethers[10] proved valuable both in this and in the following step. Thus, it was possible to synthesize the siloxydiene **6**[8] nearly quantitatively from **5** at −78 °C in 5 min and to react it, without purification, with maleic anhydride at room temperature. This addition took place in an *endo* manner, which is usual for Diels-Alder additions, and exclusively on the α side of **6** — thus determining the desired *anti* junction of the rings in the final product **9**. After hydrolysis of the resulting anhydride adduct, the diacid **7**[8] could be isolated in crystalline form and easily (in comparison, e.g., to the lead tetraacetate method) decarboxylated electrolytically to **8** (carbon electrodes, 200 V potential) (Table 1). In agreement with previous experience with simpler substrates, the β,γ-unsaturated ketone **8** underwent photochemical rearrangement to **9** upon irradiation at $\lambda = 300$ nm accompanied by the formation of a negligible amount of a side product[11] (reaction time 3 h, 72% yield after purification on silica gel) (Table 1).

Scheme 1. Synthesis of **9**. The sequence was carried out first with racemic material [14]. a) Li/NH_3, −78 °C [9]. b) Methoxyethoxymethyl chloride, ethyldiisopropylamine, CH_2Cl_2, room temperature. c) Lithium diisopropylamide, trimethylsilylchloride, −78 °C, analogous to [10]. d) 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone, benzene, room temperature, 24 h. e) Maleic anhydride, no solvent, room temperature, 4 h. f) H_2O. g) 90% aqueous pyridine, triethylamine, 4-*tert*-butylcatechol, electrolysis, analogous to [12]. h) Acetone (1% solution), irradiation at $\lambda = 300$ nm (Rayonet apparatus with RPR-3000 lamps), room temperature, 3–4 h.

[a] Correct elemental analyses.

The reaction sequence for the synthesis of the angularly fused isomeric triquinane **15** (Scheme 2, oxosilphiperfo-

Scheme 2. Synthesis of **15**. The sequence was carried out first with racemic material [4]. *b*, *c*, and *e*–*h* have the same meaning as in Scheme 1.

lene project) began with the facile synthesis of the diene **12**.[8] **12** could be prepared by kinetic deprotonation of **11**,[8] which gave, as expected,[13] exclusively the 5,6-enolate, and subsequent trapping of the enolate with trimethylsilyl chloride according to the method of *Corey*.[10] **12** was directly used for the subsequent step. The introduction of the etheno bridge [**12** → **13** (exclusively *endo* adduct) → **14** (Table 1)][8] was achieved analogously to the synthesis of **8** (from **6**) in comparable yields. The photorearrangement **14** → **15** (Table 1) (4 h irradiation time, 70% yield after purification on silica gel)[11] confirmed, along with the spectroscopic results, the structure of the enone chromophore of **14**. The possible isomeric arrangement in which the oxoethano and etheno bridges are interchanged would have resulted in a stereoisomer of **15** with an unrealistically strained *trans* ring junction for ring A. The successful oxadi-π-methane rearrangement of **14** to **15** was not predictable a priori. For instance, a few examples of bridgehead-substituted β,γ-enones have been found that are unreactive upon irradiation.[1, 14]

The efficiency and ease of the photorearrangements presented here further support the preparatively interesting applications of specific light-induced processes. The remaining functionalization of **9** to **15** and of **10** to **16** should be realizable using relatively simple procedures.[15]

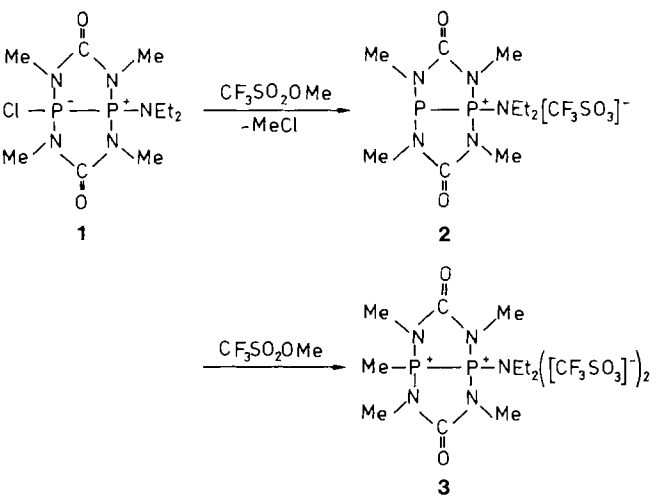
[15] According to preliminary experiments the crucial step, the lateral opening of the cyclopropane ring of **9** and **15**, can be achieved selectively under Birch-type conditions; moreover, **15** can be methylated regioselectively in the α-position to the keto group.



Preparation and Structure of a Diphosphorus Compound with Positive Charges on the Two Directly Bonded Phosphorus Atoms**

By *Dietmar Schomburg, Gerhard Bettermann, Ludger Ernst,* and *Reinhard Schmutzler**

The P–P single-bond distance in diphosphorus compounds varies only slightly, depending on the oxidation state and/or coordination number of the phosphorus atoms involved, and is usually around 220 pm.[1–4] It was therefore of particular interest to determine whether this constant P–P bond length is also observed when both phosphorus atoms bear a formal positive charge. Two opposing effects should be operative in this case: on the one hand, the electrostatic repulsion of the positive charges should lead to a lengthening of the P–P distance; on the other hand, the orbital contraction resulting from the proximity of two positive charges could lead to a shortening of the P–P distance.

To the best of our knowledge, the double quaternization of two directly bonded phosphorus atoms, for example, by alkylation of a $\lambda^3P\lambda^4P^+$ species, has not yet been achieved.[1] Presumably, the nucleophilicity of the λ^3 phosphorus atom is strongly decreased by the proximity of the positive charge.[1, 5] In studies carried out by *Nöth* et al.[6] and *Seidel*,[7] attempts to alkylate several diphosphanes with alkyl iodides resulted in cleavage of the P–P bond and disproportionation rather than quaternization of directly bonded phosphorus atoms. In the case of **2**, however, the bridging of the two phosphorus atoms by the *N,N'*-dimethylurea groups should render cleavage of the P–P bond more difficult.

We have developed a simple synthesis of compound **1** (and of its dimer resulting from chloride bridging).[8] The positive charge in **1** can, as part of the assumed zwitterionic system, presumably be delocalized optimally over three directly neighboring nitrogen atoms. Consequently,

the nucleophilic properties of the low-valent phosphorus atom in **1** may be more strongly pronounced than in $\lambda^3P\lambda^4P^+$ compounds.

The validity of this assumption was confirmed by reaction of **1** with the strong methylating agent methyl trifluoromethanesulfonate.[9] The reaction proceeds via two steps, the first of which, the removal of the chlorine in **1** to form the salt **2**, takes place at 30°C.[10] The simultaneous formation of methyl chloride was demonstrated by IR spectroscopy. Upon heating of the reaction mixture in a heavy-walled glass tube, the quaternization of the λ^3P atom occurs with formation of the bis(trifluoromethanesulfonate) **3**.[11] **3** is the first compound to contain two directly bonded quaternary phosphorus atoms.

The structure of **3** was confirmed by elemental analysis, by ^1H-, ^{19}F-, and ^{31}P-NMR spectroscopy,[12] and by an X-ray structure determination (Fig. 1).

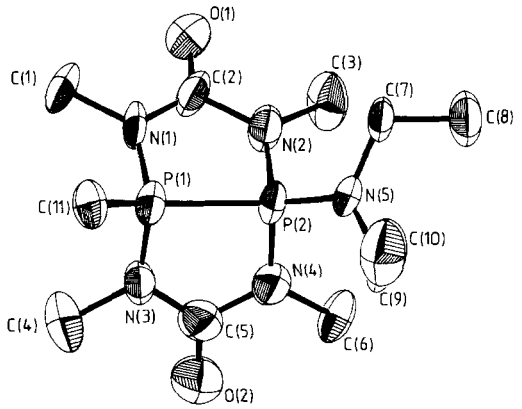

Fig. 1. Crystal structure of the cation of **3**.

The X-ray structure analysis[13] of **3** shows that the P^+–P^+ bond length (average value in the two crystallographically independent molecules 218.9 pm) exhibits, indeed, no significant deviation from the value normally found in diphosphorus compounds. On the other hand, the increased charge on the phosphorus atoms effects a marked shortening of the endocyclic P–N bonds to an average value of 163.7 pm, the corresponding bonds in uncharged phosphorus compounds being ca. 171 pm long.[3,4] The distance of the urea nitrogen atoms to phosphorus atoms bearing a formal negative charge is in the range of 174–176 pm.[3,4]

The bond between the phosphorus atom and the diethylamino nitrogen atom (158.7 pm) is significantly shorter than those to the urea nitrogen atoms. In particular, this very short bond indicates strong multiple bond character with delocalization of the positive charge over both phosphorus atoms and the amino nitrogen atom.

The geometry at both tetracoordinated phosphorus atoms exhibits a strong deviation from the ideal tetrahedral structure because of their incorporation into a bicyclic structure. Thus, the endocyclic N–P–P angle is reduced to 91.3–94.2° while the P–P–X angles (X = Me, NEt_2) are between 132.3 and 136.9°.

Photoreaction of Thiones with Bromoketene Acetals

By *Pieter H. J. Ooms** and *Willy Hartmann*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

Thiocarbonyl compounds such as **1** combine with ketene acetals upon n,π* excitation to give 2,2- or 3,3-dialkoxythietanes.[1] We have now investigated the photoreactions of the thiones **1**[2] with the bromoketene acetals **2**[3] and found an unexpected course of reaction.

1 **2a**, $R^2 = CH_3$ **3** **4**
2b, $R^2 = C_2H_5$

When a solution of xanthione and bromoketene dimethyl acetal **2a** or bromoketene diethyl acetal **2b** in benzene is irradiated at room temperature the corresponding acrylates **3** are obtained in high yield. Thioxanthione and 4,4′-

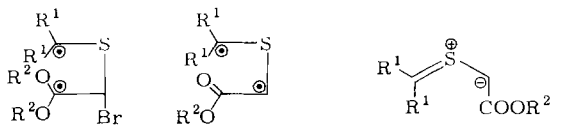
	C_2H_5	33	oil	1718 [c]	7.26 (d, 2H), 7.15 (d, 2H), 6.90 (d, 2H), 6.80 (d, 2H), J=8.3 Hz, arom. H, 6.22 (s, 1H, =CH), 4.05 (q, 2H, J=7.2 Hz, OCH_2), 3.82 (s, 3H, OCH_3), 3.79 (s, 3H, OCH_3), 1.14 (t, 3H, CH_3)
	CH_3	23	oil	1721 [c]	7.24 (d, 2H), 7.16 (d, 2H), 6.90 (d, 2H), 6.83 (d, 2H), J=8.8 Hz, arom. H, 6.22 (s, 1H, =CH), 3.83 (s, 3H, OCH_3), 3.79 (s, 3H, OCH_3), 3.61 (s, 3H, OCH_3)

[a] All compounds give correct elemental analyses. [b] KBr pellet. [c] Thin film.

dimethoxythiobenzophenone react similarly (Table 1). If the irradiation of xanthione and **2a** in toluene is carried out at −70°C, besides **3** the stereoisomeric tetrahydrothiophenecarboxylates **4** can be isolated in small yields.[4]

Upon reaction of electronically excited adamantanethione **5** with **2a** or **2b**, the formation of acrylic acid esters **3** does not take place. Instead, a 1,3-dithiolanecarboxylate is obtained in yields of 60-65%. Reductive desulfurization



5 **6a, b** **7a, b**

a, R^2 = CH_3; **b**, R^2 = C_2H_5

of the ethyl ester with Raney nickel in methanol furnishes adamantane and (2-adamantyl)acetic acid ethyl ester;[7] thus, it is confirmed that **6b**[8] and not its isomer **7b** is formed. **6b** is also obtained via an alternative route by reaction of **5** with ethyl diazoacetate (ether, 50°C, 1 h, 60%).

For the reaction of n,π*-excited thiones **1** and **5** with bromoketene acetals **2**, we propose the formation of the diradical **8** as the first step.[1] By subsequent heterolytic dissociation[9] of the C-Br bond and dealkylation, the 1,3-diradical **9**, a resonance structure of the thiocarbonyl ylide **10**,[10] is formed.

8 **9** **10**

In the case of the aromatic thiones **1** the main reaction of the thiocarbonyl ylide **10** is cyclization and extrusion of sulfur to give the unsaturated esters **3**.[11] Concomitantly, **10** reacts with **2** leading to the tetrahydrothiophene **4**. Upon reaction of the cycloaliphatic thione **5** with **2**, the 1,3-dipolar cycloaddition predominates. The ylide **10** is trapped by **5** to give the 1,3-dithiolane **6**. We regard the independent synthesis of **6** from **5** and diazoethyl acetate as substantial support for the formulated mechanism. For this type of reaction the intermediate formation of thiocarbonyl ylides is established.[11]

Experimental

3: A solution of **1** (0.01 mol) and **2** (0.05 mol) in benzene (100 mL) was irradiated for 4 to 6 h at room temperature under N_2. A mercury high-pressure lamp (Philips HPK 125W) mounted in a water-cooled shaft (FW161 glass, Glasshütte Wertheim) transparent to light of wavelength $\lambda > 500$ nm was used as light source. After complete decoloration the solution was evaporated to dryness; the acrylates **3** were isolated by column chromatography (Merck silica gel 60F 254, petroleum ether/ethyl acetate 15:1).

6: In the reactions with **5**, a solution of **5** (0.01 mol) and **2** (0.20 mol) in pentane (100 mL) was irradiated for 14 h using a GWV glass filter (Glashütte Wertheim) transparent to light of wavelength $\lambda > 400$ nm. After evaporation to dryness the 1,3-dithiolanes **6** are obtained by recrystallization from ether.

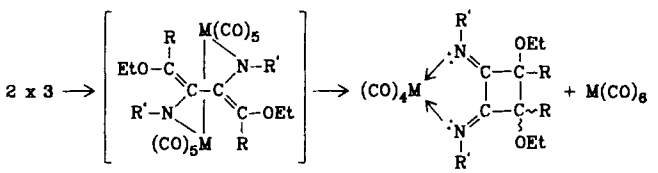
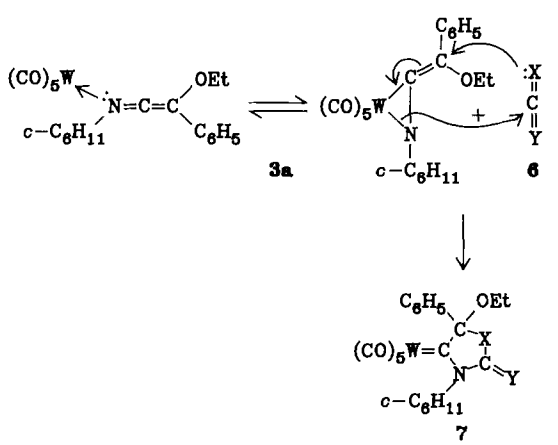
3-Aminoindoles, Imidazolidines, and Oxazolidines from Isocyanides and Carbene Complexes by Metal-Induced [4+2]- and [3+2]-Cycloadditions**

By *Rudolf Aumann,* Eberhard Kuckert,* and *Heinrich Heinen*



Carbene complexes **1** react with isocyanides **2** to give ketenimine complexes **3**[2] in good yields. Complexes **3** prove to be versatile synthons for organic reactions.[3,4] They are capable of undergoing novel [2+2]-,[3] [3+2]-, and [4+2]-cycloadditions, all of which are characteristically controlled by the carbonylmetal fragment.

1 **2** **3**



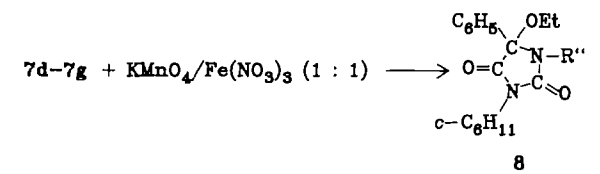
M = Cr, Mo, W; R = C_6H_5, 2-Thienyl;
R' = C_6H_5, o-CH_3O-C_6H_4, c-C_6H_{11}

In inert solvents, **3** is slowly converted at 40–70°C into 1,2-bis(imino)cyclobutane complexes **5** and $M(CO)_6$ by a template-controlled symmetric [2+2]-cycloaddition of two C=C bonds, presumably via the intermediates **4**.[3]

4 **5**

3a reacts rapidly with the C=O and C=N-groups of aldehydes **6a** and isocyanates **6b**, respectively, undergoing [3+2] cycloaddition[5] to give the oxazolidine complexes **7a–c** and imidazolidine complexes **7d–i**, respectively. In each case formation of a M=C bond to the central C atom of the CCN moiety takes place (Table 1).

3a **6**



a: X = O, Y = R", H; **b**: X = N–R", Y = O; **c**: X = Y = N–R"

Table 1. Synthesis and physical data of the complexes **7**.

	X	Y	Yield [%]	$\delta(^{13}C_{carbene})$	ν(C=O) [cm^{-1}]	M.p. [°C]

[a] As diastereomeric mixture (for composition see below). [b] Not determined.

7 is synthesized in a one-pot process by reaction of **1**, **2**, and **6** in ether. The ketenimine complex **3a**, which is formed in the first step of the reaction, does not need to be isolated. With increasing bulkiness of **6** the [2+2]-cycloaddition to give **5** supersedes the [3+2]-cycloaddition leading to **7**. **7a–7c** each have two chirality centers and accordingly are obtained as diastereomeric mixtures (*S,R*)/(*R,S*):(*S/S*)/(*R/R*) = 1:2 (**7a**), 1:1 (**7b**), 1:1 (**7c**), which can be separated on silica gel. The hydantoins **8** are obtained in high yields by oxidative decomposition of **7d–7g** with $KMnO_4/Fe(NO_3)_3$ in acetone/water (Table 2).

8

Table 2. Synthesis and physical data of the hydantoins **8**.

	R"	Yield [%]	M.p. [°C]	ν(C=O) [cm^{-1}]
8a	C_6H_5	73	128	1770, 1705
8b	CH_3	78	95	1770, 1715
8c	*n*-C_4H_9	80	Oil	1775, 1706
8d	*t*-C_4H_9	84	118	1764, 1708

The ketenimine complexes **3b** prepared from aromatic isocyanides react differently to the aliphatic derivatives. Complexes **3b** rapidly add two further molecules of aryl isocyanide;[6] cycloaddition by *ortho*-attack at the *N*-aryl groups leads to formation of the 3-aminoindole derivatives **11** and **12** – presumably via the intermediates **9** and **10** (Table 3).

The dipolar intermediate **10** dimerizes in anhydrous ether to the pyrazinodiindole **11**, which precipitates as colorless crystals (50%, m.p. 250°C). In the presence of water, **10** hydrolyze to 3-arylamino-2-arylcarbonylindoles **12a–c**, which are readily accessible in this way in a one-pot process.

Experimental:

7a: A solution of cyclohexyl isocyanide (95 mg, 0.87 mmol) in ether (1 mL) was added dropwise to a vigorously stirred solution of $[(CO)_5W{=}C(OEt)C_6H_5]$ (400 mg, 0.87 mmol) and benzaldehyde (250 mg, 2.36 mmol) in anhydrous ether (4 mL) under an inert gas (N_2). After 20 h at 25°C, the reaction mixture was evaporated to dryness and the residue taken up in a small volume of toluene and chromatographed on silica gel (column 10 × 2 cm, petroleum ether/ether 4:1). The yellow main fraction contained **7a**. The separation of the diastereomers was carried out on a 40 × 2 cm column with petroleum ether/dichloromethane 5:1 (1st fraction 137 mg (23%), m.p. 164°C; 2nd fraction 270 mg (47%), m.p. 150°C).

Table 3. Synthesis and melting points of the 3-aminoindole derivatives **12**.

	R	R'''	Yield [%]	M.p. [°C]
12a	C_6H_5	H	72	143
12b	C_6H_5	OCH_3	65–70	oil
12c	2-Thienyl	H	71	138

7d: A solution of $[(CO)_5W{=}C(OEt)C_6H_5]$ (500 mg, 1.09 mmol) and phenyl isocyanate (650 mg, 5 mmol) in anhydrous ether was treated (under the same conditions as given above) with 120 mg (0.13 mL, 1.09 mmol) of cyclohexyl isocyanide. After work-up and column separation **7d** was isolated from the orange fraction. Yield 520 mg (69%), m.p. 168 °C.

12a: $[(CO)_5Cr{=}C(OEt)C_6H_5]$ (326 mg, 1 mmol) was dissolved in tetrahydrofuran (1 mL; ca. 5% water) in an air-tight 5-mL glass vessel and treated dropwise with vigorous stirring with a solution of phenyl isocyanide (309 mg, 3 mmol) in tetrahydrofuran (3 mL) (ca. 30 min). After 4 h at 70 °C the reaction mixture was evaporated to dryness and the residue taken up in a small volume of benzene and chromatographed on silica gel (2 × 20 cm column, elution with petroleum ether/ether 7:3 with continually increasing proportion of ether). **12a** was isolated from the yellow main fraction. Yield 224 mg (72%), m.p. 143 °C (from dichloromethane/petroleum ether at − 15 °C).[7] The colorless first runnings contained ca. 250 mg of $[(C_6H_5NC)Cr(CO)_5]$.

[6] Both addition steps proceed almost equally rapidly; hence, two equivalents of aryl isocyanide are required for complete reaction of **3b**. As to whether the isocyanide-ketenimine coupling is metal-induced or takes place after previous removal of ligand cannot be answered by simply changing the stoichiometric ratios.

Isocyanomethylenetriphenylphosphorane**

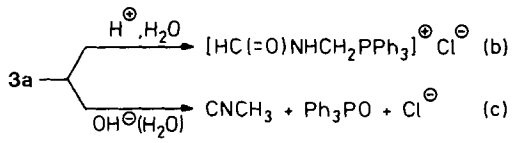
By *Gerhard Zinner* and *Wolf Peter Fehlhammer**

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Among the numerous reactions of 'in situ' generated α-metalated isocyanides is carbonyl olefination, which supplements the Wittig reaction without really competing with it.[1] We became interested in isocyanomethylenetriphenylphosphorane **1**, which combines the structural elements (and thus the reaction possibilities) of both synthons; in view of its internal stabilization, this α-carbanionic isocyanide was expected to be isolable. Its *N*-analogue **2** is known and has proved to be a key substance in *N*-isocyanide chemistry.[2]

1 **2**

As a consequence of the unavailability of suitable α-halo isocyanides,[3] the most straightforward synthetic route to **1**, namely, nucleophilic substitution, was blocked. Surprisingly, however, the reaction of trimethylsilylmethyl isocyanide[4] with Ph_3PCl_2 or with PPh_3 and C_2Cl_6[5] in tetrahydrofuran (THF) under very mild conditions was successful [Reaction (a)]: After only 1 h, the phosphonium salt **3a** starts to crystallize out.[6] Its conversion into the hexafluorophosphate **3b** was carried out in neutral aqueous solution



$$CNCH_2SiMe_3 + PPh_3 + C_2Cl_6 \longrightarrow [CNCH_2PPh_3]^{\oplus}\,X^{\ominus} + C_2Cl_4 + SiMe_3Cl \qquad \text{(a)}$$

3a, X = Cl
3b, X = PF_6

by reaction with NH_4PF_6.[6] In acidic media, addition of water takes place to give the corresponding formamide [Reaction (b)]; in basic media, on the other hand, fast

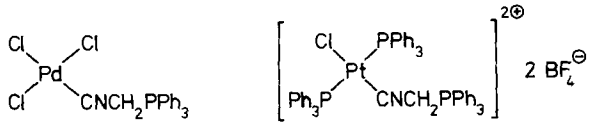
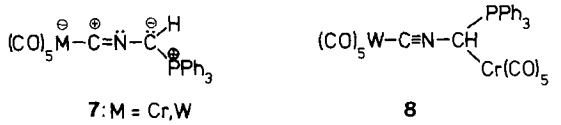
[**] Metal Complexes of Functionalized Isocyanides, Part 12. This work was supported by the Fonds der Chemischen Industrie.—Part 11: [14].



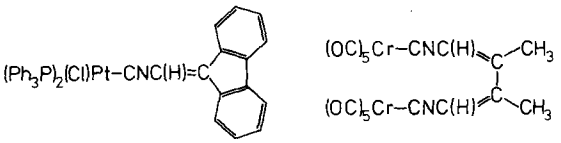
cleavage of the P-C bond occurs with formation of triphenylphosphane oxide and methyl isocyanide [Reaction (c)].

Deprotonation of **3a** by sodium amide in THF gives the yellow neutral compound **1**, which, even in the coordinated form, is extremely sensitive to moisture, decomposing in analogy with Reaction (c). The α-isocyanocarbanionic nature of **1** becomes particularly obvious by comparing its spectroscopic data with those of **3a**.[7]



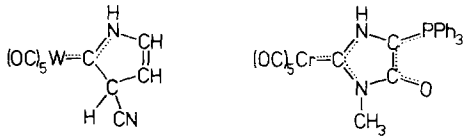
1 and its "storable" form **3** are unusually reactive. For instance, upon heating in toluene to 70°C, **1** undergoes isomerization to the corresponding cyanide, which may be detected by its ν(CN) band at 2139 cm^{-1}. Despite its positive charge, **3** exhibits a pronounced tendency to undergo coordination (formation of **4** and **5**), even with cationic metal complex fragments (formation of **6**).[8]

4a: M = Cr
4b: M = W



5 **6**

7: M = Cr, W **8**



The complex-bound cation of **3** may also be deprotonated; the ylides **7a**, **b** thus formed from **4a**, **b** can coordinate to a second Lewis acidic metal center via the ylide carbon atom (formation of **8**).[8, 9] With carbonyl compounds such as fluorenone or 2,3-butanedione, **1** and **3** as well as their metal complexes (e.g., **4a** or **6**) react to give free and coordinated vinyl isocyanides (e.g., **9**)[10] and bis(vinyl isocyanides) (e.g., **10**[10] (mixture of isomers)); in this respect, **1** and **3** are similar to *Schöllkopf*'s $CNCH_2P(O)(OEt)_2$.[11]

9 **10**

Finally, coordinated **1** undergoes [3+2] cycloadditions with reactive multiple bond systems such as heteroallenes, nitriles, acetylenes, and olefins to give metal-*C*-bonded five-membered heterocycles, PPh_3 being cleaved (e.g., formation of **11**[12]) or remaining bonded (e.g., formation of **12**[12]). In each case, only one product is formed both rapidly and in good yield, i.e., the reactions proceed regiospecifically and (with unsymmetrical heteroallenes) chemoselectively.

Pentacarbonyl(isocyanomethylenetriphenylphosphorane)chromium and -tungsten, **7a**, **b**, are the first stable

11 **12**

1,3-dipoles of the metal nitrile ylide type. Their representation by resonance structure **7**, however, indicates that they are more similar to organic nitrile oxides (or nitrile imines) than to alkyl- or aryl-substituted nitrile ylides, the HOMOs of which, in complete contrast, have the largest coefficient on the twofold coordinated carbon atom.[13]

[6] *Experimental procedure*: **3a**: Trimethylsilylmethyl isocyanide (3.0 mL, 21.2 mmol) [4], PPh_3 (3.5 g, 13.4 mmol), and C_2Cl_6 (3.2 g, 13.4 mmol) were stirred in 100 mL of THF under argon for 18 h at room temperature. The pale yellow precipitate was filtered off, washed with 2 × 10 mL of cold CH_2Cl_2, and dried under vacuum. After recrystallization from CH_2Cl_2/petroleum ether, colorless and odorless crystals were obtained (3.3 g, 73% based on PPh_3).—**3b**: On combination of concentrated aqueous solutions of **3a** and NH_4PF_6 (1 : 1), **3b** precipitated quantitatively.—**1**: **3a** (2.0 g, 5.9 mmol) and $NaNH_2$ (0.7 g, 17.9 mmol) were dispersed in 100 mL of THF at −78°C over 1 h (Ultra-Turrax, 20000 rpm). The filtered solution was concentrated to ca. 1/3 of its original volume under oil-pump vacuum and treated with 15 mL of *n*-hexane. At −15°C yellow **1** crystallized (1.65 g, 93%).

$[\mu\text{-}N_2H_2\{Ru(PPh_3)dttd\}_2]$, the First Diazene Complex with Sulfur-Coordinated Transition Metal Centers (dttd = 2,3,8,9-Dibenzo-1,4,7,10-tetrathiadecane(2 –))**

By *Dieter Sellmann,** *Elmar Böhlen, Michael Waeber, Gottfried Huttner,* and *Laslo Zsolnai*

The coordination of N_2 and reduction products N_2H_2 and NH_3 to sulfur-coordinated transition-metal centers is a central problem in the elucidation of the molecular course of N_2-fixation in nitrogenases. Numerous findings indicate that activation and subsequent reduction of the N_2-molecule are achieved by coordination to the sulfur-coordinated iron and/or molybdenum centers of the nitrogenase; nevertheless, all attempts to detect N_2 or N_2H_2 in complexes with metal-sulfur centers have hitherto met without success.[1]

In the search for model compounds for nitrogenase we have now isolated a complex in which diazene HN=NH is bound to sulfur-coordinated ruthenium centers. Diazene is extremely unstable in the free state;[2] it is probably the key compound of the reduction of N_2 in N_2-fixation,[3] but it has so far only proven possible to demonstrate its formation from molecular nitrogen indirectly.[4] As we have previously been able to show, diazene can be stabilized considerably by complexation; however, this has so far only been accomplished with the organometal complex fragments $M(CO)_5$, M = Cr, Mo, W and $C_5H_5M(CO)_2$, M = Mn, Re.[5]

In the reaction

$$[Ru(N_2H_4)(PPh_3)dttd][6] \xrightarrow[20\,^\circ C/1\,d]{O_2/CH_2Cl_2} [\mu\text{-}N_2H_2\{Ru(PPh_3)dttd\}_2] + \cdots$$
1

the color of the solution gradually changes from yellow to deep green. Filtration and subsequent concentration and cooling of the filtrate afford blackish-green crystals whose composition according to an elemental analysis is consistent with the compound $\mathbf{1}\cdot 2CH_2Cl_2$. A spectroscopic confirmation of this formulation was not possible.[7] Besides the intense color, a weak signal in the ^{1}H-NMR spectrum ($CDCl_2$) at $\delta = 14.5$ alone indicated that a diazene unit was formed from the N_2H_4 ligand of the starting complex.

An X-ray structure analysis of the crystals confirmed this indication.[8] A *trans*-N_2H_2 ligand couples two Ru centers, which are additionally surrounded pseudooctahedrally by four S atoms and one P atom (Fig. 1).

The molecule has a crystallographically established inversion center in the mid-point of the N=N bond. The structure could be determined accurately enough to establish the positions of all H atoms and to refine the parameters of the diazene hydrogen atoms. Accordingly, the Ru, N, H_N and the S1 and S4-thiolate atoms lie in a plane, to which the (S2RuP)- and (S2′Ru′P′)-axes are oriented orthogonally. The bond lengths and angles characterize **1** as a *trans*-diazene complex. The N=N distance (130.1 pm) is slightly larger than the corresponding distance in $[\mu\text{-}N_2H_2\{Cr(CO)_5\}_2]\cdot 2thf$ (125 pm),[9] but nevertheless still much shorter than is to be expected for a N-N bond; the Ru-N distance is relatively short (202.6 pm). (The corresponding distances in the methylhydrazine complex $[Ru(CH_3NHNH_2)PPh_3(dttd)]$ are N-N = 143 and Ru-N = 217 pm.[10]) The angles too are consistent with sp^2 hybridized N atoms; consequently, the Ru-diazene moiety is best described in terms of a Ru=N=N=Ru 4c-π-system. The intense color typical for diazene complexes is also in agreement with this description.

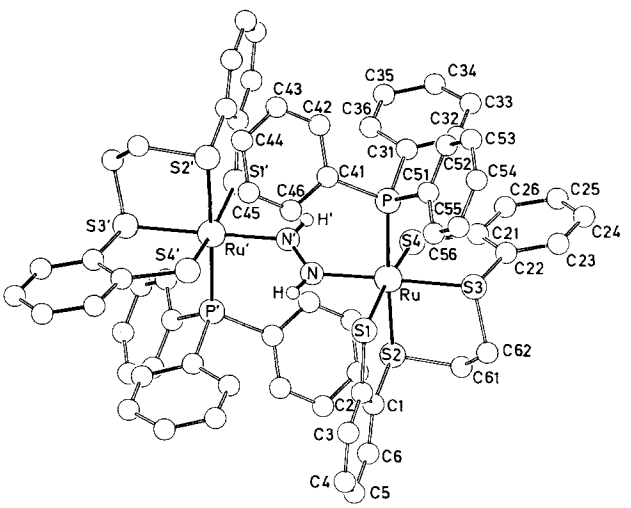

Fig. 1. Structure of **1** in the crystal of $\mathbf{1}\cdot 2CH_2Cl_2$.

These results show that the unstable HN=NH can be stabilized also by coordination to sulfur-coordinated metal centers. Generally, the formation of the M=N=N=M four-center system might be responsible for this stabilization. A second stabilizing factor in the case of **1** is certainly the good steric shielding of this system. The third stabilizing factor is caused by the sulfur ligand. As is shown in Figure 2, the mean $S\cdots H(N_2H_2)$ distances are ≈288 pm (Fig. 2). They are thus about 20 pm shorter than the sum of the corresponding van der Waals radii (≈305 pm[11]), indicating H-bridges between the diazene H-atoms and thiolate S-atoms.

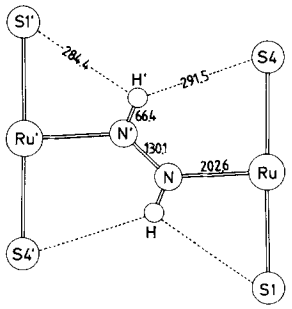

Fig. 2. View onto the $Ru\text{-}N_2H_2\text{-}Ru$ coordination plane in **1** with $S\cdots H(N_2H_2)$ distances [pm].

Such an interaction between diazene and sulfur ligands—observed here for the first time—should favor the formation of diazene upon N_2-reduction at sulfur-coordinated metal centers and lower the energy that is necessary

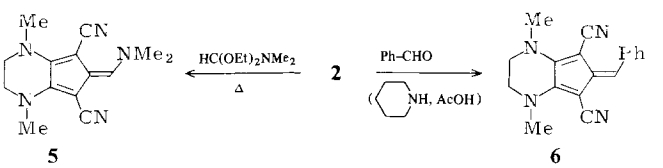
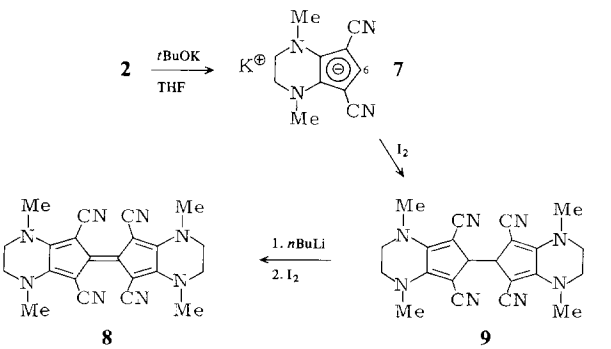
Donor-Acceptor Substituted Anions and Cations in the Cyclopentadienyl System**

By *Rudolf Gompper** and *Thomas Gessner*

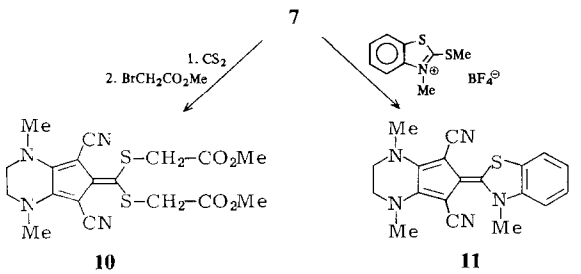


In connection with studies on the color and reactivity of pyridiniocyclopentadienides[1] we have concerned ourselves with the preparation of donor-acceptor substituted cyclopentadienes, since the pyridiniocyclopentadienides obtained from them should absorb at longer wavelengths than analogues without substituents in the five-membered ring. Donor-acceptor substituted derivatives should at the same time, however, be more stable than donor-substituted derivatives, which are likewise expected to exhibit bathochromism.

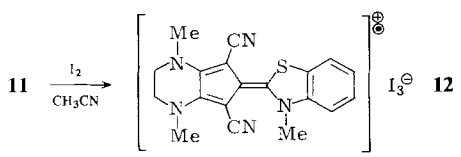


The well known reaction of glutaric acid dinitrile with diethyl oxalate[2] can be considerably improved by the use of potassium *tert*-butoxide/tetrahydrofuran (THF). The dipotassium salt **1** is formed in quantitative crude yields. It reacts with *N,N'*-dimethylethylenediamine dihydrochloride to yield the ammonium salt, which can be converted by heating in ethylene glycol into the desired donor-acceptor substituted cyclopentadiene **2** (yield 52%, colorless needles, m.p. 248 °C (decomp.)). Protonation of **1** provides the dihydroxy compound **3** (colorless powder, m.p. 222 °C (decomp.)). The analogous reaction of **1** with *o*-phenylenediamine dihydrochloride affords the cyclopentadiene derivative **4** (yield 57%, orange-yellow crystals, decomp. above 250 °C).

Like other cyclopentadienes, **2** is suitable for the preparation of fulvenes. Reaction with dimethylformamide di-



ethyl acetal affords the 6-dimethylaminofulvene **5** (yield 65%, orange-yellow needles, m.p. 128–130 °C), while reaction with benzaldehyde furnishes the 6-phenylfulvene **6**



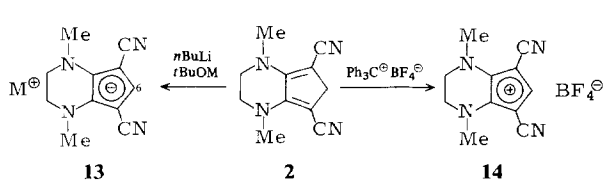
[*] Prof. Dr. R. Gompper, Dipl.-Chem. T. Gessner
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(yield 51%, orange-yellow needles, m.p. 228–230°C). Fulvalenes are also accessible from **2**. The yellowish potassium salt **7** [^{1}H NMR (CD_3CN): $\delta = 2.66$ (s; 6H, NCH_3), 2.79 (s; 4H, NCH_2), 6.05 (s; 1H, 5-ring-H)], obtained from **2** with potassium *tert*-butoxide, reacts with iodine to give the colorless dihydrofulvalene **9** (m.p. 190°C (decomp.)), from which the donor-acceptor substituted fulvalene **8** is formed by reaction with *n*-butyllithium and then with iodine [yield 66%, shiny green prisms, m.p. 317–318°C; UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 230$ (4.44), 265 (sh, 3.94), 301 (sh, 3.68), 335 (sh, 3.33), 520 nm (4.47)].

7 also reacts with carbon disulfide. The resulting dithiocarboxylic salt reacts, e.g. with methyl bromoacetate to give the bis(methoxycarbonylthio)fulvene **10** (yield 71%, orange-yellow needles, m.p. 190°C). Treatment of **7** with 3-methyl-2-methylthiobenzothiazolium tetrafluoroborate leads to the thiaazafulvalene **11** [yield 57%, shiny metallic green prisms, m.p. 248–250°C; UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 225$ (4.52), 520 nm (4.58)], which can be oxidized with iodine to the blackish-violet radical cation salt **12**

[yield 91%, m.p. 156°C; UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 212$ (4.53), 236 (4.36), 291 (4.71), 365 (4.50), 424 (4.39), 568 (sh, 3.66), 609 (3.79), >900 nm].



The distinctive effect of the combination of donor- and acceptor-substituents in **2** is illustrated in a dramatic way by the fact that not only can the (yellow) cyclopentadienides **13** be prepared (e.g. **7**, M = K), which contain the "aromatic" 6π system of the cyclopentadienide anion, from **2**, but also the green cyclopentadienylium tetrafluoroborate **14**, which contains the "antiaromatic" 4π system of the cyclopentadienylium cation [yield practically quantitative, m.p. 160°C (decomp.); UV/VIS (CH_3CN): $\lambda_{max}(\log\varepsilon) = 225$ (4.25), 307 (4.13), 350 (sh, 3.59), 426 (sh, 2.46), 810 nm (2.52); ^{1}H NMR (CD_3CN): $\delta = 3.65$ (s; 6H, NCH_3), 4.00 (s; 4H, NCH_2), 8.15 (s; 1H, 5-ring-H)]. The signal of the five-membered ring H atom in the anion of **7** (δ(H-6) = 6.05) is shifted somewhat downfield compared to that of the (unsubstituted) cyclopentadienide anion[3] ($\delta = 5.49$). This difference, taking into account the relationship between charge density (according to PPP: $q_{C\text{-}6} = -0.128$[4]) and chemical shift ($\Delta\delta_q = (10.7\,\Delta q_\mu)$ ppm[5]) shows **7** to be a typical aromatic compound with diamagnetic ring current. As expected, the substituents in **7** do not influence the aromatic properties of the anionic cyclopentadienide system. The signal of the corresponding proton in the cation of **14** ($\delta = 8.15$) appears between the proton signals of the tropylium ion ($\delta = 9.26$[6]) and of benzene ($\delta = 7.27$[7]) and not, as one would expect from the size of the ring, between those of the cyclopropenylium ion ($\delta = 11.1$[8]) and of the tropylium ion. The charge-induced shift on going from **13** to **14** ($\Delta\delta_q = 3.58$ ppm) calculated from the charge density on C-6 of **14** (according to PPP: $q = +0.207$[4]) using the above equation is considerably larger than that observed ($\Delta\delta = 2.10$ ppm) and leads to a calculated paratropic shift of $\Delta\delta_p = 1.48$ ppm in **14**. This value is actually smaller than, for instance, that in the bicyclo[5.4.1]dodecapentaenide anion (3.7–6.8 ppm),[9] but is comparable with that observed in tri-*tert*-butylcyclobutadiene (1.04 ppm).[10] Like other paratropic compounds (cf., e.g.,[11]) **14** may therefore be counted among the antiaromatic systems. The yellow salt **15**[12] ($\lambda_{max} = 421$ nm) can be regarded as a non-aromatic compound for comparison with **14**.

Compared to this model (^{1}H NMR: δ(H-3) = 8.3; PPP: $q_{C\text{-}3} = +0.129$[4]) the signal of H-6 in the ^{1}H NMR spectrum of **14** shows a small upfield shift. Particularly striking is the enormous difference in color (green/yellow, $\Delta\lambda_{max}$ ca. 400 nm) between **14** and its open-chain analogue **15**.

As in **13**, the substituents in **14** also change the properties of the parent compound only slightly. **14** is more stable than the unsubstituted cyclopentadienylium cation (inter alia because of the removal of degeneration of the frontier orbitals), but the paratropic and thus antiaromatic properties are retained, albeit to a lesser extent.

There are only very few fully conjugated monocyclic systems which, with the same ring size and same substituents, exist both as a cation as well as an anion, with the latter possessing two additional π-electrons. In the case of the pentachloro- and pentaphenylcyclopentadienide derivatives, the (aromatic) metal cyclopentadienides are stable,[14] whereas the (antiaromatic) cyclopentadienylium salts could previously only be obtained in solution.[13] **13** and **14** are, in contrast, the first pair of carboxylic ions in which the partners have comparable stability.

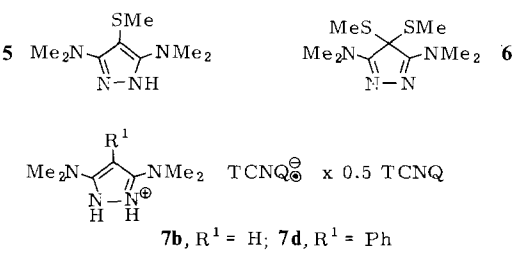
Dimethylamino-Pyrazoles and Pyrazolylium Salts**

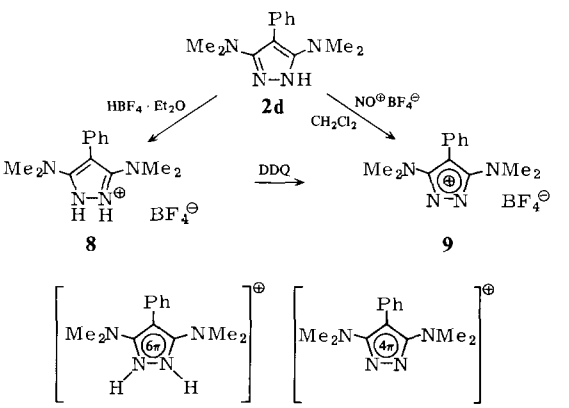


By *Rudolf Gompper,* Rainer Guggenberger,* and *Rolf Zentgraf*

In investigations into stable five-membered ring cations which are formally to be counted among the antiaromatic species, we have previously prepared imidazolylium salts,[1] pyrrolylium salts,[2] and finally also crystallized cyclopentadienylium salts.[3] The gradation in the color of these compounds (yellow/red/blue to green) is consistent with the HOMO-LUMO distances calculated by HMO. According to these calculations the longest wavelength absorption maxima in the electronic spectra of pyrazolylium salts, i.e. of 1,2-diazacyclopentadienylium salts, should approach the maxima of the cyclopentadienylium salts, and the stabilities of the two systems should also be comparable. Since dialkylamino groups had proven to be stabilizing groups for the previously prepared five-membered ring cations, it seemed to us that 3-dialkylamino- and 3,5-bis(dialkylamino)pyrazoles would be the most suitable starting materials. Due to their richness in electrons, they ought to be more susceptible to electrophilic substitution than simple pyrazoles, and, moreover, they ought to be easily oxidizable.

1-Substituted dialkylaminopyrazoles have long been known,[4] while compounds not substituted in the 1-position are relatively new.[5-7] *Viehe* et al.[8] have prepared 3,5-dichlorovinamidinium salts, but only in the case of one 4-phenoxy derivative has a corresponding 1-unsubstituted pyrazole been reported.

We have now found that the 5-dimethylamino- and 3,5-bis(dimethylamino)pyrazoles **2a–d**[9] are readily accessible in good yields by reaction of the 1-chloro- and 1,3-dichloro-vinamidinium tetrafluoroborates **1a–d**, respectively, with hydrazine in dichloromethane. The chlorides **1**, $Cl^{\ominus}$ instead of $BF_4^{\ominus}$, are sensitive to hydrolysis and are therefore unsuitable for this reaction.



Upon coupling **2a** and **2b** with benzenediazonium chlorides in dilute mineral acids and subsequent addition of sodium acetate, or benzenediazonium tetrafluoroborates in acetonitrile (in the case of **2b** this usually leads to improved yields), the azo dyes **4** and their salts **3**[10] are obtained. **2b** reacts with dimethyl(methylthio)sulfonium tetrafluoroborate[11] in dichloromethane to give, depending on the molar ratio, either the 3,5-bis(dimethylamino)-4-methylthio-1*H*-pyrazole **5** (yield 82%, m.p. 101–102 °C) or the 3,5-bis(dimethylamino)-4,4-bis(methylthio)-4*H*-pyrazole **6** (yield 70%, m.p. 151 °C).

7b, R^1 = H; **7d**, R^1 = Ph

When a hot saturated solution of tetracyanoquinodimethane (TCNQ) in acetonitrile is treated with **2b** or **2d** the solution immediately turns deep-green, the color typical for the TCNQ radical anion, and upon cooling, blackish-blue needles of **7b** and **7d**, respectively, crystallize out (**7b**: m.p. 234 °C (decomp.); **7d**: m.p. 216–218 °C (decomp.)). The electrical conductivities (two-electrode measurement, $P = 1800$ kp/cm^2) of pellets of these salts at room temperature are $\sigma = 1.6 \times 10^{-3}$ S/cm and 6.1×10^{-3} S/cm, respectively.

Attempts to eliminate a methylthio group from **6** to give a pyrazolyl cation met without success. However, oxida-

tion of **2d** with nitrosyl tetrafluoroborate furnishes 3,5-bis(dimethylamino)-4-phenylpyrazolium tetrafluoroborate **9** in 72% yield as dark blue crystals.[12] On a preparative scale it was found that protonation of **2d** with tetrafluoroboric acid and subsequent oxidation of the isolable pyrazolium salt **8**, with dichlorodicyano-*p*-benzoquinone (DDQ), was more favorable.

The electronic spectrum of **9**[12] is, as expected, similar to that of a structurally related cyclopentadienylium salt (6-dimethylamino-1,4-dimethyl-5,7-diphenyl-1,2,3,4-tetrahydrocyclopentapyrazine-6-ylium tetrafluoroborate: $\lambda_{max} = 624$ nm[3]). Also informative with respect to the electronic properties of the 4π system **9** is a comparison with the 6π system **8**: In the ^{1}H-NMR spectrum of **9**, two signals appear at $\delta = 3.91$ and 2.90, which are assigned to the protons of the dimethylamino groups. Upon increasing the temperature these signals broaden and the coalescence temperature is 121°C. From this, an energy barrier of $\Delta G^* = 19.45$ kcal/mol is calculated for the rotation about the ring-NMe_2 bond. The ^{1}H-NMR spectrum of **8**, on the other hand, shows only one signal for these protons, indicative of a rapid rotation of the dimethylamino groups. Apparently—and as expected—the 4π system of **9** is a very much stronger electron acceptor than the 6π system of **8**.

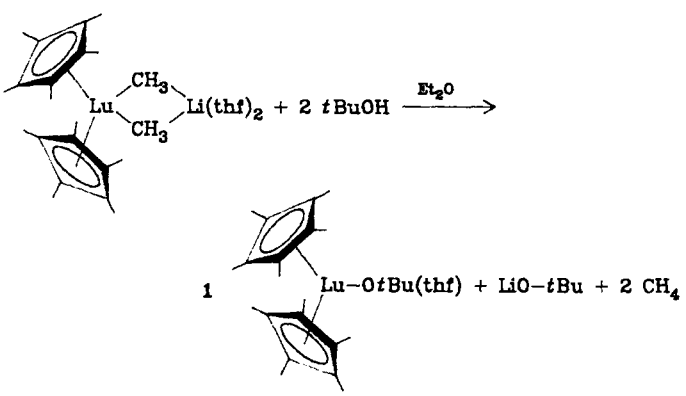
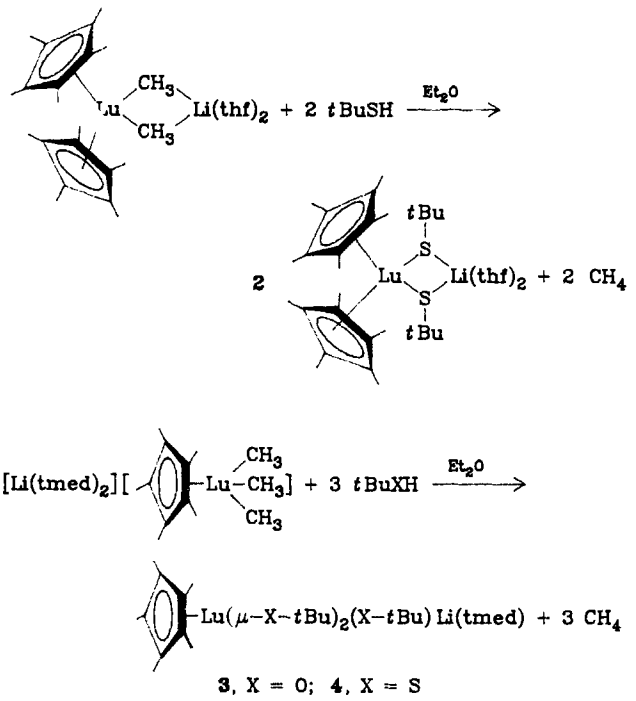
A Novel Route to Pentamethylcyclopentadienyllutetium Alkoxides and Thiolates**



By *Herbert Schumann,* Ilse Albrecht,* and *Ekkehard Hahn*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Only very few organometallic compounds of the "hard" electropositive metals of the lanthanoid series are known in which, aside from organic groups, other ligands are bonded via "soft" atoms such as sulfur, phosphorus or silicon.[1] Such compounds are, however, of particular interest as reagents for organic syntheses because of their very reactive, and possibly strong covalent Ln–X bonds. To our knowledge only one organolanthanoid-sulfur compound, $(C_5Me_5)_2YbS_2CNEt_2$,[2] has so far been characterized, whereas several bis(cyclopentadienyl)lanthanoid-phosphane derivatives have been described.[3] However, their unequivocal characterization by X-ray structural determination was, in contrast to that of the first organolanthanoid-silicon complex, $[Li(dme)_3][(C_5H_5)_2Sm(SiMe_3)_2]$[4] (dme = 1,2-dimethoxyethane), hitherto not possible.



We have now found a simple, versatile route to this interesting class of compounds. Bis(pentamethylcyclopentadienyl)lutetiumdi(μ-methyl)bis(tetrahydrofuran)lithium[5] reacts in ether with *tert*-butyl alcohol at −78°C with formation of bis(pentamethylcyclopentadienyl)lutetium *tert*-butylate, **1**, whereas with *tert*-butyl hydrosulfide the compound **2** (thf = tetrahydrofuran) is obtained with retention of the bridged structure. $[Li(tmed)_2][C_5Me_5Lu(CH_3)_3]$[6] (tmed = tetramethylethylenediamine), which exists as an ion pair, reacts with both *t*BuOH and *t*BuSH with formation of the bridged organolanthanoid compounds **3** and **4**, respectively.[7]

Both **3** and **4** are also assumed to contain a $Lu(\mu\text{-}X)_2Li$ unit since in each case only one molecule of tmeda is bound to lithium. The NMR spectra of both compounds, however, show only one signal for the three *tert*-butyl ligands, which can be explained in terms of a rapid exchange of the terminal X*t*Bu group with the two bridging ligands. An analogous process was observed in the case of $[Li(tmed)]_3[Th(CH_3)_7]$ where six bridging CH_3 groups and

[**] Organometallic Compounds of the Lanthanoids, Part 32. This work was supported by the Fonds der Chemischen Industrie, by the Deutsche Forschungsgemeinschaft, and special funds from the Technische Universität Berlin.—Part 31: H. Schumann, W. Genthe, E. Hahn, M. B. Hossain, D. van der Helm, *J. Organomet. Chem.*, in press.

one terminal CH_3 group give only one CH_3 signal in solution.[8]

The X-ray structural analysis (Fig. 1) shows that **2** is a bis(*tert*-butylthio)-bridged, dinuclear lutetium-lithium complex. The lutetium atom is in a distorted tetrahedral environment consisting of the centroids of two cyclopentadienyl rings and the two bridging sulfur atoms, whereas the two sulfur atoms, and the oxygen atoms of two THF molecules form the coordination sphere of the lithium. In the bis(cyclopentadienyl)lanthanoid complexes so far investigated X-ray crystallographically, $[Cp_2Ln(\mu\text{-}X)_2Li(B)_{1,2}]$, $Cp = C_5Me_5$, $Ln = Yb$, $B = Et_2O$, $X = Cl$, I,[10] $Cp = C_5H_5$, B = tmed, $X = CH_3$, $Ln = Er$,[11] Lu[11] a planar four-atom unit $Ln(\mu\text{-}X)_2Li$ was observed. In **2**, on the other hand, a dihedral angle of 168.1(7)° is found between the S1-Lu-S2 and S1-Li-S2 planes. To our knowledge, a puckered $Ln(\mu\text{-}X)_2Li$ unit with two Cp ligands on the Ln atom is unique and does not even occur in the four-membered rings of $(C_5Me_5)Yb(\mu\text{-}Cl)_2AlCl_2$,[10] $(C_5Me_5)_2Lu(\mu\text{-}CH_2)_2P(CH_3)_2$[12] or in the one other crystallographically characterized organolanthanoid-sulfur compound $(C_5Me_5)_2YbS_2CNEt_2$.[2]

The Cp1-Lu-Cp2 angle (Cp signifies the centroid of a cyclopentadienyl group) and the mean value of the ten $LuC(\eta^5)$ distances (2.66(2) Å) lie in the expected range. The cyclopentadienyl rings are planar (maximum deviation from the medial plane 0.015 Å). The Lu-S distance (2.709(3) and 2.723(3) Å) is comparable with the Yb-S distance in $(C_5Me_5)_2YbS_2CNEt_2$ (2.70(1) Å[2]) (ionic radii for Yb and Lu with coordination number 8 : 0.985 and 0.977 Å, respectively[13]). The S1-Lu-S2 angle is, of course, larger than the S-Yb-S angle in the dithiocarbamate.[2]

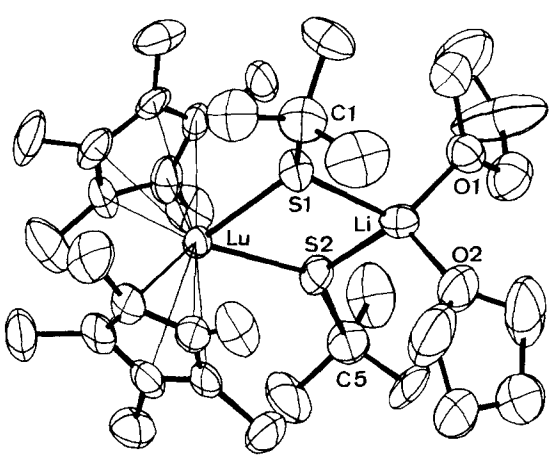

Fig. 1. ORTEP-plot of $[(C_5Me_5)_2Lu(\mu\text{-}S\text{-}t\text{Bu})_2Li(thf)_2]$ in the crystal [9]. Selected bond lengths [Å] and angles [°]: Lu···Li 3.89(2), S1···S2 3.252(4), Lu-S1 2.709(3), Lu-S2 2.723(3), Lu-Cp1 2.364(10), Lu-Cp2 2.370(10), average Lu-C(η^5) 2.66(2), S1-C1 1.853(12), S2-C5 1.863(12), S1-Li 2.41(2), S2-Li 2.48(2), Li-O1 1.95(2), Li-O2 1.95(2); Cp1-Lu-Cp2 131.5(3), S1-Lu-S2 73.6(1), Lu-S1-Li 101.8(4), Lu-S2-Li 99.7(4), S1-Li-S2 83.5(6), O1-Li-O2 102.6(10); dihedral angle between the S1-Lu-S2 and S1-Li-S2 planes 168.1(7) (Cp1 and Cp2 signify the centroids of the top and bottom cyclopentadienyl groups.

The Structure of the Lichen Macrolide (+)-Aspicilin**

By *Gerhard Quinkert,* Nana Heim, Jan W. Bats, Hartmut Oschkinat,* and *Horst Kessler*

Dedicated to Hans Musso on the occasion of his 60th birthday

(+)-Aspicilin **1** (Scheme 1) was first isolated in 1900 from a crustose lichen belonging to the genus *Lecanora*.[2] It took nearly 75 years to realize that the substance was a macrolide: the constitution is that of a 4,5,6-trihydroxy-17-methyl-2-heptadecenolide, and the orientation of the ligands on the C(2)–C(3) double bond is *E*.[3] We have now determined its configuration to be 4*R*,5*S*,6*R*,17*S* (Fig. 1).

Scheme 1. a) Conversion of **1** into the acetonides **2** and **3**: 2,2-dimethoxypropane, PPTS, room temperature, 7 h. b) Degradation of **1** to **4**: $NaIO_4$, $MeOH/H_2O$ (9:1), room temperature, 5 h; $LiAlH_4$, ether, room temperature, 12 h. c) Synthesis of **4** from **5** and **6**: aq. HBr, petroleum ether, 80°C; dihydropyran, PPTS, CH_2Cl_2, room temperature, 4 h; Mg, tetrahydrofuran; 1,5-cyclooctadiene/CuCl [4], **6** [9]. *ent*-**6** is analogously converted into [10] *ent*-**4**. PPTS: pyridinium *p*-toluenesulfonate.

The relative configuration was established by single-crystal X-ray analysis of **1** (with respect to C(4), C(5), C(6), and C(17); see Fig. 1A)[5] as well as by ^{1}H-NMR spectroscopy of **2** and **3** (with regard to C(4), C(5), and C(6); see Fig. 2 and Table 1).

In order to obtain unequivocally interpretable NMR data, it is necessary to reduce the conformational flexibility of **1** at centers C(4), C(5), and C(6) by acetonide formation. The constitution of the acetonide moiety for **2** and **3** is obtainable provided the signals for H-C(2) to H-C(6) can be assigned for both substances. This is achieved by determination of the homonuclear coupling (H,H-COSY),[7] in which the coupling between the exchangeable OH proton and the vicinal CH proton makes it possible to distinguish between the acetonides. This coupling depends both on the water content and the temperature of the sample. The NOE build-up rates for **2** and **3** were determined by NOESY spectroscopy (with shorter mixing time than

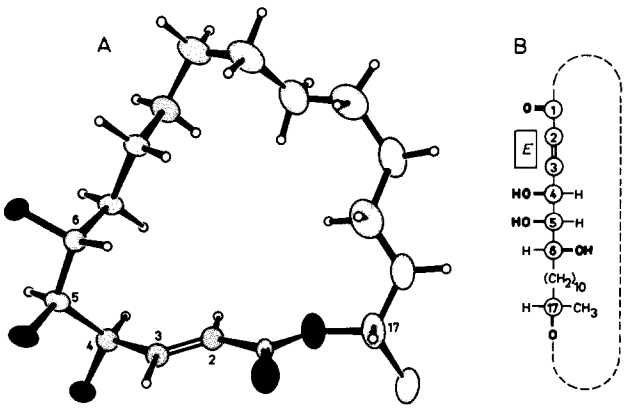

Fig. 1. A) Conformation and B) absolute configuration of (+)-aspicilin **1** (Fischer projection).

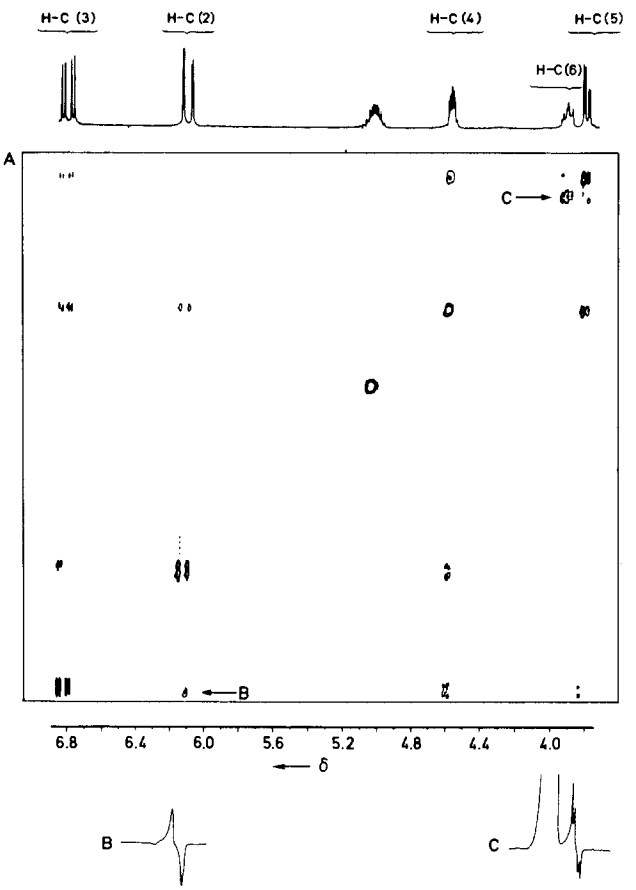

Fig. 2. A) Phase sensitive NOESY spectrum [6] of **3** in $CDCl_3$ at room temperature, recorded at 300 MHz by the TPPI method; the mixing time was 1.2 s ≈ 1.1 T_1). The signals along the diagonal from bottom left to top right have positive intensities and all cross peaks negative intensities. The cross peaks of H-C(4) and H-C(5) exhibit a strong NOE, while only weak artifacts occur between H-C(5) and H-C(6). B) Cross-section through the cross peak of H-C(3) and H-C(2) along the arrow marked with B in Fig. 2A. The antiphase structure arises due to scalar coupling; no NOE is observed. C) Cross-section through the cross peak marked with C in Fig. 2A; antiphase magnetization due to scalar coupling.

Reaction of Phenylcarbene with Oxygen

By *Wolfram Sander**

Since 1958, when *Horner* and *Kirmse* et al.[1] described the reaction of diphenylcarbene with oxygen, the mechanism of the oxidation of free carbenes has been in dispute. Frequently, a carbonyl oxide is postulated to be the primary product.[1,2] The carbonyl oxide reacts with O_2 to give ozone and the carbonyl compound[2,9] or with unreacted carbene to give two molecules of the carbonyl compound,[1] or it rearranges to give a carboxyl compound.[5,6,9] In some cases, chemiluminescence has been observed during the oxidation of carbenes.[2–5] Direct observation of the carbonyl oxide was achieved in the case of cyclopentadienylidene by matrix isolation in argon[6] and in the case of diphenylcarbene by time-resolved spectroscopy.[7]

We have studied the oxidation of phenylcarbene **2** in an O_2-doped argon matrix. The O_2 content of the matrix was varied between 0.5% and 15%; the carbene **2** was generated by photolysis of matrix-isolated phenyldiazomethane **1**.[8]

$$\underset{\mathbf{1}}{PhCHN_2} \xrightarrow{h\nu} \underset{\mathbf{2}}{{}^3PhHC:}$$

After irradiation ($\lambda > 475$ nm, 8 K) of **1**, phenylcarbene **2** (IR: $\nu = 747$, 668 cm^{-1}), benzaldehyde **3** (1717, 830 cm^{-1}), and benzoic acid **4** (1757, 712 cm^{-1}) were found along with small amounts of unreacted starting material. The ratio of these products depends on the O_2 content and on the thermal treatment of the matrix. For an O_2 content of 0.5%, **2** was the main product; only traces of **3** and **4** were formed. At this O_2 content, the probability is low that an oxygen molecule is present near the carbene formed upon photolysis. The rate of diffusion of O_2 in solid argon at 8 K is too small for significant reaction to occur. At an O_2 content of 4%, the conversion was almost complete; in the IR spectrum, the characteristic band of **2** at 668 cm^{-1}[8] was absent. At 1% O_2, free carbene and oxidation products were present in roughly equal amounts and could be simultaneously detected by IR spectroscopy.

The ratio of **3** to **4** depends on the thermal treatment of the matrix. For short irradiation times (1 h) and the lowest temperature possible (8 K), **3** was the only detectable oxidation product. For longer irradiation times (15 h), which were necessary for complete conversion of **1**, some **4** was also formed (Fig. 1). By warming the matrix over a short period of time to 27 K following irradiation, the proportion of **4** increased significantly and that of **2** and of **3** decreased.

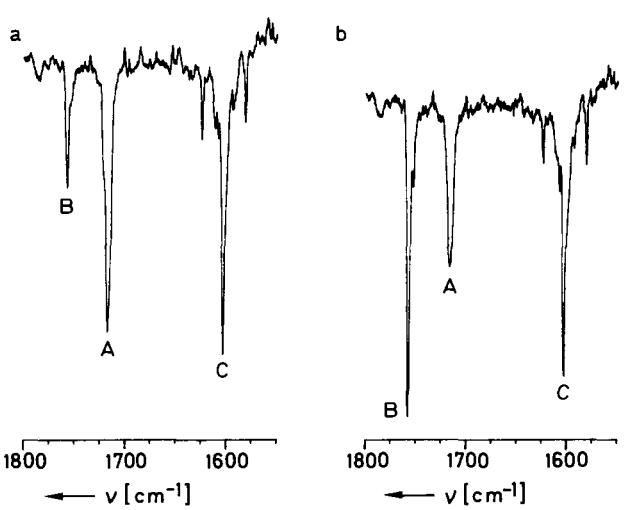

Fig. 1. Thermal reaction of benzaldehyde **3** and $O(^3P)$ to give benzoic acid **4**. IR spectra in the region of the carbonyl vibrations of **3** (A, 1717 cm^{-1}) and **4** (B, 1757 cm^{-1}). A band of unreacted phenyldiazomethane (C, 1603 cm^{-1}) serves to compare intensities. a) 5 h irradiation ($\lambda > 475$ nm, 8 K) of **1** in Ar with 1% O_2; b) as in a) but with subsequent annealing at 27 K for 15 min.

[*] Dr. W. Sander
Organisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. I thank Prof. Dr. *R. Gleiter* for his support.

The maximum in the rate of reaction for the conversion **3** → **4** was found at 27 K. After several minutes of annealing at this temperature, no further reaction was observed to take place. Unreacted **2** only underwent significant oxidation at $T > 35$ K by the O_2 present in excess.

$$^3\text{PhHC:} + {}^3O_2 \longrightarrow [{}^*\text{PhHC}{=}\overset{\oplus}{O}{-}\overset{\ominus}{O}] \longrightarrow \underset{\mathbf{3}}{\text{PhCHO}} + O(^3P) \quad (1)$$
$$\mathbf{2}$$

$$^3\text{PhHC:} + O(^3P) \longrightarrow {}^3\text{PhCHO} \longrightarrow \underset{\mathbf{3}}{\text{PhCHO}} + h\nu \quad (2)$$
$$\mathbf{2}$$

$$\underset{\mathbf{3}}{\text{PhCHO}} + O(^3P) \longrightarrow \underset{\mathbf{4}}{\text{PhCOOH}} \quad (3)$$

$$^3O_2 + O(^3P) \longrightarrow O_3 \quad (4)$$

Atomic oxygen is the only oxidizing agent in question that has a sufficiently high rate of diffusion at 27 K.[10] The oxygen atoms are trapped by phenylcarbene **2** or benzaldehyde **3** [Reactions (2) and (3)]. For an O_2 content of 15%, **3** was also obtained as the main product; however, larger proportions of ozone were also formed. Warming the matrix to 27 K following irradiation resulted in no changes in the IR spectrum; accordingly, O_2 in large excess can compete successfully with **2** and **3** for the oxygen atoms[11] [Reaction (4)]. In an N_2 matrix containing 1% O_2, we obtained no N_2O, which is formed from $O(^1S)$ and N_2 but not from $O(^3P)$ and N_2.[12] Thus, the oxygen atoms are formed in the $O(^3P)$ electronic state.

The reaction of **2** with $O(^3P)$ can be followed directly by observing the chemiluminescence upon warming the matrix. The temperature dependence of the total emission of the matrix (glow curve) was recorded using a photomultiplier (Fig. 2). Spectra at several points along the curve were obtained using an optical multichannel analyzer. In all cases, the phosphorescence spectrum of benzaldehyde[13] with maxima at 401, 430, 462, and 500 nm was found, independent of oxygen content and temperature.

For an O_2 content of the matrix of 1%, the glow curve exhibits an initial increase at 20 K followed by a plateau and a maximum at 44 K (Fig. 2a). If the matrix is warmed to 27 K for several minutes before recording the glow curve the initial increase is absent, the maximum remaining unchanged (Fig. 2b). The emission in the region between 20 and 32 K is due to the reaction of free $O(^3P)$ with phenylcarbene **2** [Reaction (2)], which was also observed by IR spectroscopy. At higher temperatures, the diffusion of O_2 and thus the formation of new $O(^3P)$ begins to take place [Reaction (1)]. This reaction is not sufficiently exothermic to generate **3** in a triplet state.[14] The excess energy of the reaction is partly transferred to $O(^3P)$, which thus receives sufficient translational energy to leave the matrix cage.

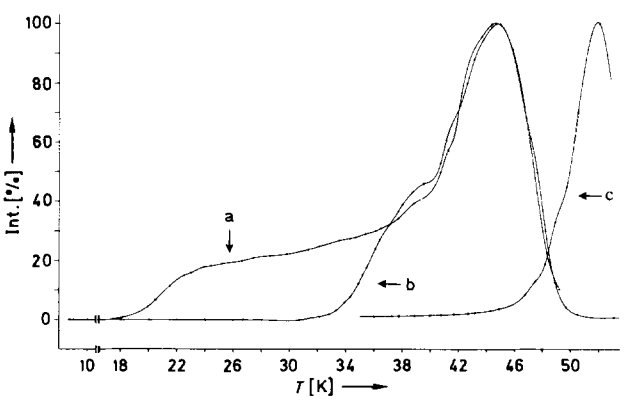

Fig. 2. Chemiluminescence intensities as a function of temperature (glow curve) normalized to the highest intensity (100%). Rate of warming ca. 1 K/min. a) Warming experiment directly after the irradiation; b) warming experiment after 15 min of annealing at 27 K and subsequent cooling to 8 K; c) control experiment as in a) but without O_2 in the matrix. The chemiluminescence on evaporation of the matrix (51 K) is caused by reaction of phenylcarbene **2** with a layer of air (from small leaks) on top of the matrix.

A carbonyl oxide as intermediate could not be detected either directly after irradiation of **1** or after annealing the matrix. This contrasts with the behavior of cyclopentadienylidene[6] and diphenylcarbene[15] upon oxidation with O_2 under comparable conditions; in these cases, the corresponding carbonyl oxide could be detected by UV or IR spectroscopy. The dependence of the stability of the initially formed carbonyl oxide on the substituents may be based on differing mechanisms of deactivation of the excess energy, leading either to cleavage of the O–O bond or, primarily, to vibrational excitation of the substituents.

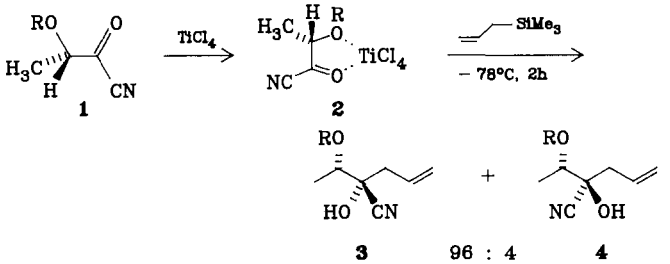
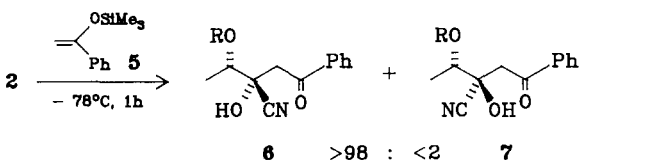
Chelation-Controlled Stereoselective Synthesis of Cyanohydrins**

By *Manfred T. Reetz,* Kurt Kesseler,* and *Alfred Jung*

Dedicated to Professor Karl Dimroth on the occasion of his 75th birthday



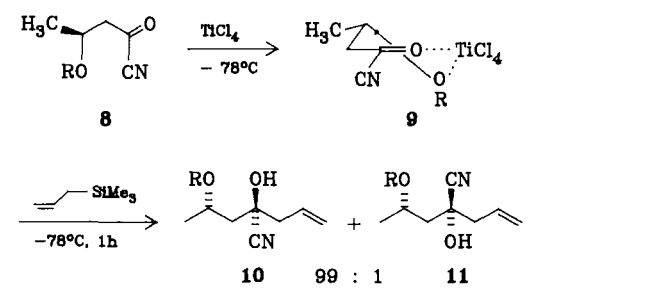
Effective chelation-control in nucleophilic additions to chiral alkoxycarbonyl compounds has become possible in recent years by the use of suitable organometallic compounds.[1] The reagents of choice are often Lewis-acidic titanium compounds of the type $RTiCl_3$ or $TiCl_4$ in combination with soft *C*-nucleophiles such as allylsilanes or silyl



[*] Prof. Dr. M. T. Reetz, Dipl.-Chem. K. Kessler, Dipl.-Chem. A. Jung
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

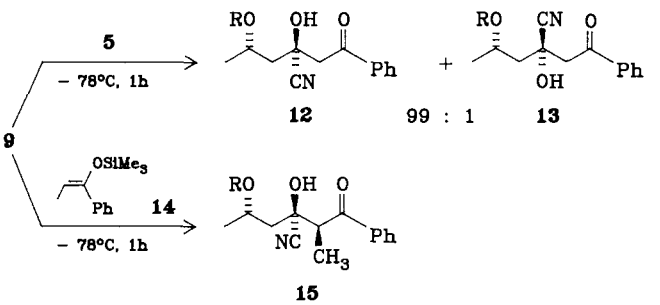
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

enol ethers. In the case of α- and β-alkoxyaldehydes, intermediate five- and six-membered chelates are formed, respectively, which are attacked stereoselectively from the sterically less hindered side. Herein, we report a preparatively useful extension of this concept, namely the diastereoselective synthesis of secondary and tertiary cyanohydrins.

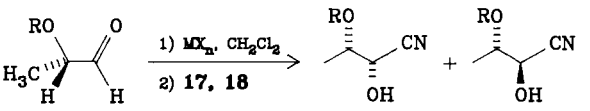


When the chiral acyl cyanide **1**[2] is treated at low temperatures with $TiCl_4$ in CH_2Cl_2, the chelate **2** is presumably formed, since subsequent addition of allyltrimethylsilane affords essentially only adduct **3** (conversion 98%).[3] $SnCl_4$ is not as effective (**3** : **4** = 85 : 15). Aldol addition of the silyl enol ether **5** to **2** takes place with even greater 1,2-asymmetric induction (conversion >90%). The tertiary cyanohydrins **3**, **4**, **6**, and **7** are configurationally stable.[4]

R = CH_2Ph



The observed complete 1,3-asymmetric induction in the addition of allylsilane to the β-chiral acyl cyanide **8**[2] (conversion >98%) is also remarkable.[3]



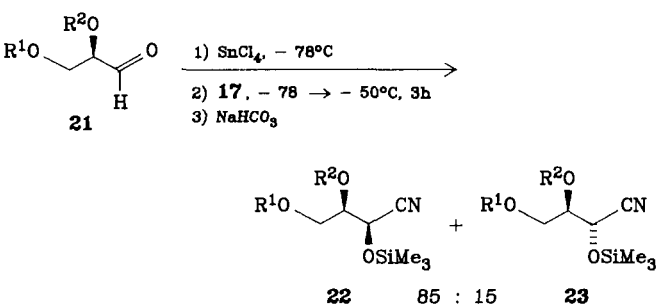
R = CH_2Ph

Furthermore, we found that aldol additions to **9** proceed quantitatively with strict chelation-control to give, e.g., **12**.[3] Reaction of the *E*-configurated prochiral silyl enol ether **14** from propiophenone with **9** leads to the formation of only one (**15**) of four possible diastereomers (ratio 99 : 1).[3] This unusual effect was observed previously in reactions of α- and β-alkoxyaldehydes and can be explained in terms of an open-chain transition state.[1,5]

A different strategy is necessary for the synthesis of secondary cyanohydrins. The compounds can be synthesized stereoselectively by addition of the cyanosilanes **17**[6] or **18**[7] to complexed aldehydes; however, the 1,2- and 1,3-asymmetric induction is not complete (Table 1). In some cases *O*-silylated derivatives are formed. They can be converted into the free cyanohydrins upon acidic work-up

(2 N HCl, tetrahydrofuran, 22°C, 2 h). In order to make configurational assignments, **19** and **20** were converted into the corresponding acetonides and examined by ^{13}C-NMR spectroscopy.

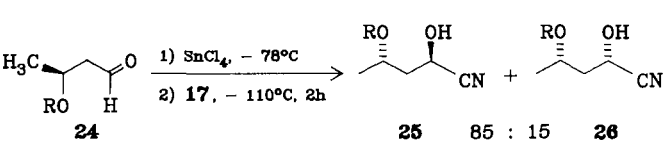
16 **19** **20**



R = CH_2Ph; Me_3SiCN **17**; *t*$BuMe_2SiCN$ **18**

Table 1. Diastereoselective formation of cyanohydrins **19**/**20**.

Cyanating reagent [a]	Lewis acid [a]	*T* [°C]	*t* [h]	Conversion [%] [b]	**19** : **20**
17	$TiCl_4$	–78 → –30	3	63	74 : 26
17 [c]	$TiCl_4$	–78 → –30	3	91	77 : 23
18	$TiCl_4$	–78	1	>98	80 : 20
17	$SnCl_4$	–78	1.5	>98	78 : 22
17	$BF_3 \cdot OEt_2$	–78	2	86	57 : 43
18	$BF_3 \cdot OEt_2$	–78	3	0	—
17	ZnI_2 [d]	0	3	>98	60 : 40
17	ZnI_2 [d]	–30	24	>98	59 : 41
17	$MgBr_2$	–30	24	87	80 : 20



[a] Normally one equivalent. [b] In the case of >90% conversion into **19**/**20** the isolated yield is about 76%. [c] Two equivalents. [d] 0.05 equivalents.

The method can be employed in carbohydrate chemistry, as documented by the reaction of aldehyde **21** obtained from mannitol[8] with formation of **22**/**23** (conversion 95%; unoptimized yield: 62%). Besides **22**/**23**, about 10% of the free cyanohydrins are formed in the same diastereomeric ratio.

R^1 = *t*$BuMe_2Si$; R^2 = CH_2Ph

Finally, we have investigated the 1,3-asymmetric induction in the synthesis of cyanohydrins from the β-alkoxyaldehyde **24** (conversion >90%).[9]

R = CH_2Ph

Since cyanohydrins are useful synthetic building blocks, the importance of a general stereoselective synthesis is obvious. The addition of HCN to L-arabinose described by *Kiliani* and *Fischer* about 100 years ago was one of the first examples of 1,2-asymmetric induction in organic chemistry.[10]

Int. Ed. Engl. 21* (1982) 36. Normal acyl cyanides undergo $TiCl_4$-mediated additions with allylsilanes and silyl enol ethers: G. A. Kraus, M. Shimagaki, *Tetrahedron Lett. 22* (1981) 1171.

[3] For work-up, the cold reaction mixture was added to water under acidic conditions. The chromatographic purification of **3/4** (silica gel/petroleum ether 40–60/ether (1:3) gave 69% analytically pure product. The assignment is based on analogy to the $TiCl_4$-controlled allylsilane-addition to aldehydes [1] and was supported by conversion of **3/4** into the acetonides, whose ^{13}C-NMR spectra confirmed the assignment. The assumption of chelation-control [1] in the other reactions seems justified on grounds of plausibility; X-ray structure analyses are presently under way.

[4] Basic conditions should be avoided since the cyanohydrins decompose or undergo configurational equilibration. **6** slowly loses HCN on standing (22 °C).

$As_{12}tBu_8$—a Tricyclo[6.4.0.0^{2,6}]dodecaarsane**

By *Marianne Baudler** and *Stefan Wietfeldt-Haltenhoff*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

In contrast to the corresponding phosphanes,[1] polycyclic arsanes are still hardly known. Only in the past few years could the nortricyclene-analogue $As_7(SiMe_3)_3$[2] as well as the *tert*-butylarsanes As_8tBu_6[3] and As_4tBu_2[4] analogous to pentalane and bicyclobutane, respectively, be synthesized as the first representatives[5]. According to more recent findings,[6] arsenic, like phosphorus, is capable of forming polycyclic molecular structures. We have now succeeded in synthesizing octa-*tert*-butyldodecaarsane **1**, the first compound with twelve arsenic atoms in the molecule.

1, R = *t*Bu

[*] Prof. Dr. M. Baudler, Dr. S. Wietfeldt-Haltenhoff
Institut für Anorganische Chemie der Universität
Greinstrasse 6, D-5000 Köln 41 (FRG)

[**] Contributions to the Chemistry of Arsenic, Part 7. This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie.—Part 6: [4].

1 is formed on dehalogenation of a mixture of *tert*-butyl(dichloro)arsane and arsenic(III) chloride with magnesium in boiling tetrahydrofuran (THF).

$$8\,tBuAsCl_2 + 4\,AsCl_3 + 14\,Mg \longrightarrow \underset{\mathbf{1}}{As_{12}tBu_8} + 14\,MgCl_2$$

In addition, mainly As_9tBu_7,[6] As_8tBu_6,[3] As_6tBu_4,[6] $As_{16}tBu_{10}$,[6] $(AstBu)_4$,[7] and $(AstBu)_5$[8] are formed together with small amounts of further *tert*-butylarsanes containing up to 20 arsenic atoms in the molecule.[6] The product pattern is strongly dependent on the reaction conditions (molar ratio and concentration of the reactants, reaction rate, duration of additional stirring). Under suitable reaction conditions (optimized by ^1H-NMR spectroscopic monitoring), **1** can be obtained as major product and isolated in analytically pure form.

The dodecaarsane **1** is a bright yellow, crystalline solid (decomposition with browning above 237 °C), which is stable at room temperature in the absence of air and light. It is readily soluble in aliphatic hydrocarbons and THF, moderately soluble in arenes, and only very sparingly soluble in methanol;the solutions are, in contrast to the solid substance, thermally decomposable and extremely sensitive to oxidation and light. The composition of **1** is confirmed by an accurate elemental analysis and by a molecular weight determination (MS). The IR spectrum, unlike those of the other *tert*-butylarsanes, shows an intense band at 348 cm^{-1}.

Since we have so far been unable to obtain single crystals for an X-ray structure analysis, the structure proposed for **1** is based on NMR and mass spectroscopic findings. The ^1H-NMR spectrum[9a] shows eight, partially overlapped signals at $\delta = 1.54$, 1.59, 1.60, 1.61, 1.63, 1.65, 1.69, and 1.75 (in [D_6]benzene, 24 °C), the intensity ratio of which indicates the presence of two configurational isomers[10] with C_1 symmetry in the ratio 5:1. The chemical shifts lie in the region characteristic for *tert*-butyl-substituted five- and six-membered arsenic rings,[3,6] while three- and four-membered rings[6,7,12]—and thus also seven-membered rings—can be ruled out as structural units. This is confirmed by the $^{13}C\{^1H\}$-NMR spectrum[9b], which shows two slightly structured signal humps at $\delta = 32.3$ and 33.5 (in [D_6]benzene, 24 °C) for the primary and tertiary C-atoms, respectively, of the *tert*-butyl groups. Of the possible isomers, whose skeletal frameworks consist only of arsenic five- and/or six-membered rings, only a tricycle of an As_8-skeleton analogous to pentalane with an annelated six-membered ring comes into question for **1** on taking into consideration the steric interactions of the substituents and the observed C_1 symmetry. This is further supported by the mass spectrum (10 eV, 180 °C), in which, aside from the $(M-Bu)^{\oplus}$ ion, primarily five-membered ring/six-membered ring and five-membered ring/five-membered ring fragments of comparably high intensity occur. **1** is thus a 3,4,5,7,9,10,11,12-octa-*tert*-butyltricyclo[6.4.0.0^{2,6}]dodecaarsane.

The configuration and conformation of the structural unit analogous to pentalane should be the same as in As_8tBu_6,[3] with the substituents in the *exo*-coupled six-membered ring arranged predominantly in the *trans* position in both isomers.

Due to its "open" tricyclic As_{12} skeleton, compound **1** decomposes on heating in solution with formation of mono-, bicyclic, and higher annelated polycyclic *tert*-butylarsanes.

According to mass spectroscopic investigations, the element-homologous phosphorus compound $P_{12}tBu_8$ likewise exists; however, because of difficulties encountered in its isolation, the structure of this homologue has not yet been elucidated.[13]

Experimental

A solution of tBuAsCl$_2$, (22.36 g, 0.11 mol) and AsCl$_3$ (13.32 g, 0.073 mol) in THF (95 mL) is added dropwise within 90 min to a vigorously stirred suspension of magnesium turnings (5.36 g, 0.22 mol; previously etched by evaporating a few grains of iodine) in boiling THF (120 mL). The black mixture is refluxed for a further 35 min and then the solvent completely removed at room temperature under reduced pressure. The brown residue is treated with 450 mL of *n*-pentane and the resulting mixture stirred for 3 h. The undissolved material is separated off by suction filtration, washed with 2 × 20 mL of pentane, and the solvent is again removed from the combined filtrates. The remaining yellow solid is dissolved in 15 mL of pentane and chromatographed on Al_2O_3 using pentane at −50 °C with ^{1}H-NMR spectroscopic monitoring [9-cm column, 4.5 cm internal diameter; packing: neutral Al_2O_3 (according to Brockmann), particle size 0.063–0.200 mm, heated in vacuo and gassed with argon; amount of solvent: 4000 mL; duration 5.5 h]. After combination of the fractions containing the largest amounts of **1**, final purification is accomplished by crystallization at −25 °C or by preparative HPLC [11] (Nucleosil-5-C8 column, methanol/*n*-pentane (91.5:8.5); receiver: −78 °C); yield 1.3 g of pure **1** (7% w.r.t. tBuAsCl$_2$; not optimized).

Decamethyl-7-thiahexasilanorbornane $(CH_3)_{10}Si_6S$**

By *Wiesław Wojnowski, Bogusław Dręczewski, Aleksander Herman, Karl Peters, Eva-Maria Peters,* and *Hans Georg von Schnering**

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

We have recently investigated intensively the relationships between the structures and properties of silicon-sulfur compounds.[1–3] For this purpose, polysilane-sulfur systems appeared to be particularly attractive, allowing the properties of the polysilanes to be combined with those of the silathianes. Nothing was known about these substances up to now, even though there has been a surge of interest in recent years in acyclic and cyclic polysilanes as well as in Si–S chemistry (3400 and 1850 compounds, respectively, although structure analyses are available for only 40 and 11, respectively[14]).

1,2,2,3,3,4,5,5,6,6-Decamethyl-7-thia-1,2,3,4,5,6-hexasilanorbornane $(CH_3)_{10}Si_6S$ **1**[5] is formed in a surprisingly simple and straightforward reaction from 1,4-dichlorodecamethylcyclohexasilane and H_2S with elimination of HCl. **1** crystallizes as colorless needles, which are very sensitive to moisture and decompose thermally above 240 °C without melting. IR measurements had to be carried out in CS_2 since **1** reacts even with CCl_4.

1 has a very slightly distorted mm2-C_{2v} symmetry. Immediately apparent in the X-ray diffraction structure (Fig. 1) is the size and orientation of the ellipsoids of thermal vibration, which, at first glance, indicate a separate vibration of the Si–S–Si structural unit. The analysis, using the model of a rigid body,[6] shows, however, that the entire molecule behaves like a rigid body, which has important consequences for the analysis of bond lengths. If the vibrations are initially ignored, then the distances and angles shown in Figure 1 are obtained.

The mean Si–S (216.9 pm) and Si–Si bond lengths (234.2 and 234.6 pm) fall in the usual range. This also holds for the Si–C distances (187.4, 187.3, 188.0 pm), which are not significantly influenced by the position of the substituents in the molecule. The notable ellipsoids of all the atoms can be described very well using the model of a rigid body ($R = 0.07$), especially those of the ring atoms ($R = 0.03$). In the crystal, the molecule vibrates about a center on the twofold axis (Fig. 1) that does not coincide with the center of gravity. The maximum values of the librational and

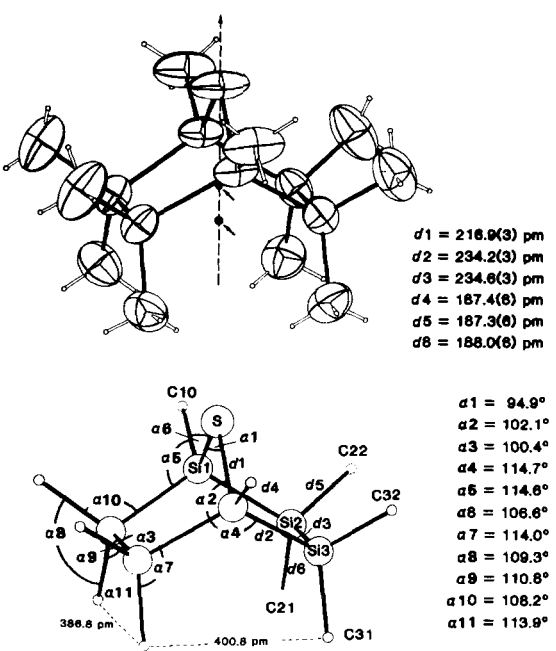

Fig. 1. Crystal structure of **1** with ellipsoids of thermal vibration (above) and the average bond lengths $d1$–$d6$ and bond angles $\alpha1$–$\alpha11$ (below). The position of the twofold axis (dashed line), the center of gravity (•, and the center of vibration (○) are shown (arrow). The position of the H atoms is given in the upper part.

[**] Contributions to the Chemistry of Silicon-Sulfur Compounds, Part 37.—Part 36: [1].

translational components of the motion are 5.4° and 26 pm. The vibration-corrected bond lengths are about 1 pm longer. $d1^* = 217.8$, $d2^* = 235.6$, $d3^* = 235.5$, and $d^*(\text{Si-C}) = 188.1$–189.0 pm.

The bond angles (Fig. 1) exhibit a noticeable deviation from those of tetrahedral angles. The angle at the S bridge, $\alpha 1 = 94.9°$, is very small, but the other endocyclic angles $\alpha 2$ and $\alpha 3$ at the Si atoms are also strongly reduced. In contrast, $\alpha 4$ and $\alpha 3$ at the Si atoms are also strongly reduced. In contrast, $\alpha 4$, $\alpha 5$, $\alpha 7$, and $\alpha 11$ are considerably expanded. Such deformations should be due, on the one hand, to the topology of the bicyclic ring system and the steric effects between the CH_3 substituents. On the other hand a valence effect must be considered in accounting for $\alpha 1$. If a simple framework molecular model with ideal tetrahedrons as centers and flexible bonds is used as a *S*tructure *M*odel *A*nalogue *C*omputer (SMAC)[7] and the resulting distances between the tetrahedral centers are measured, then surprising values for the angles α^* between the connecting vectors are obtained: $\alpha 1^* \simeq 96$, $\alpha 2^* \simeq 104$, $\alpha 3^* 100$, $\alpha 4^* \simeq \alpha 5^* \simeq 109$, $\alpha 6^* \simeq 115$, and $\alpha 7^*$-$\alpha 11^* = 109.5°$.

The small endocyclic angles $\alpha 1$-$\alpha 3$ are, therefore, a result only of the ring strain of the bicycle. The observed angles $\alpha 4$ and $\alpha 5$ (115°), $\alpha 6$ (107°), $\alpha 7$ and $\alpha 11$ (114°) apparently contain the essential deformations. Accordingly, an increase in $\alpha 4$ and $\alpha 7$ or $\alpha 11$ results in an increase of the van der Waals separations between the methyl groups C21–C31 of 339 to 401 pm and of 360 to 387 pm, respectively. Changes in $\alpha 5$ and $\alpha 6$ result from bending of the methyl group on C10 in the direction of the free space around the S atom.

Experimental procedure:

By reaction of dodecamethylcyclohexasilane $Me_{12}Si_6$ [8] with $SbCl_5$ in CCl_4 [9] in a molar ratio of 1:4, equal amounts of 1,4-dichlorodecamethylcyclohexasilane and monochloroundecamethylcyclohexasilane were formed. 10 g of this mixture was dissolved in 200 mL of pentane containing 3.4 mL of triethylamine, and H_2S was bubbled through the solution. After 6 h, the reaction forming **1** was complete (monitored by gas chromatography). After filtration of Et_3NHCl and evaporation of half of the pentane, **1** crystallized out at 6°C (yield 30%).

Crystallographic data:

Fdd2, $a = 1835.6(12)$, $b = 3231.9(20)$, $c = 727.3(3)$ pm, $Z = 8$. Syntex $P\bar{1}$ diffractometer; $Mo_{K\alpha}$ radiation; 1230 reflections (1178 with $F > 3\sigma(F)$); $R_{iso} = 0.150$; $R_{aniso} = 0.032$. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD-51523, the names of the authors, and the journal citation.

New Co and Ni Clusters with Se and PPh_3 as Ligands: $[Co_4(\mu_3\text{-Se})_4(PPh_3)_4]$, $[Co_6(\mu_3\text{-Se})_8(PPh_3)_6]$, $[Co_9(\mu_4\text{-Se})_3(\mu_3\text{-Se})_8(PPh_3)_6]$, and $[Ni_{34}(\mu_5\text{-Se})_2(\mu_4\text{-Se})_{20}(PPh_3)_{10}]$**

By *Dieter Fenske,** *Johannes Ohmer*, and *Johannes Hachgenei*

Dedicated to Professor Klaus Krogmann on the occasion of his 60th birthday

We recently described the synthesis of *S*-bridged Co and Ni clusters **1**–**4** in high yields from $[MCl_2(PPh_3)_2]$ (M = Co, Ni) and $S(SiMe_3)_2$.[1]

1 $[Co_7S_6(PPh_3)_5Cl_2]$ $[Co_6S_8(PPh_3)_6]^{\oplus}$ **2**
3 $[Ni_8S_6(PPh_3)_6Cl_2]$ $[Ni_8S_5(PPh_3)_7]$ **4**

We have now carried out analogous reactions with $Se(SiMe_3)_2$.[2] When $[CoCl_2(PPh_3)_2]$ is allowed to react with $Se(SiMe_3)_2$ in toluene; a crystalline, black precipitate consisting of **5** and **6** was obtained within a few minutes; large, black crystals of 7 crystallize from the filtrate.[3] **5** is readily soluble in tetrahydrofuran (THF), thus allowing its separation from the sparingly soluble **6**.

$[Co_4Se_4(PPh_3)_4]$ $[Co_6Se_8(PPh_3)_6]$ $[Co_9Se_{11}(PPh_3)_6]$
5 **6** **7**

5 and **6** are diamagnetic; 7 is paramagnetic. The PPh_3 ligands of **5**–**7** give signals in the ^{31}P-NMR spectrum (in dimethyl sulfoxide) at $\delta = 35.67$ (**5**), 35.8 (**6**), and 36.0 (70.3) (**7**) and in the ^{1}H-NMR spectrum in the region 7.35–7.60 (**5**) 7.13–7.7 (**6**), and 6.95–8.10 (**7**). The IR spectra of **5**–**7** are very similar and differ only below 450 cm^{-1}. These results are in agreement with those of X-ray crystal structure analyses.[4]

The structure of the Co_4Se_4 cluster **5** (Fig. 1) consists of a slightly distorted Co_4 tetrahedron with μ_3-Se ligands

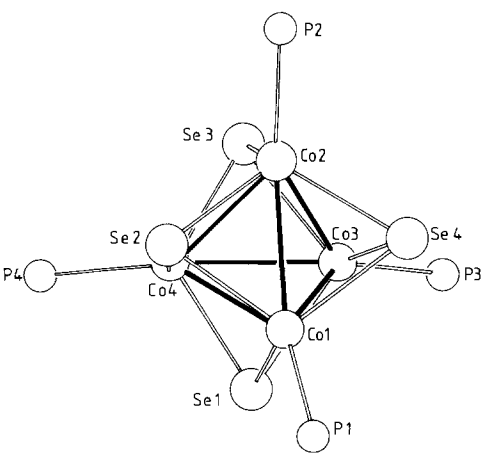

Fig. 1. Crystal structure of **5** (without phenyl groups) [4]. Most important distances (±0.2 pm) and angles (±0.1°): Co-Co 261.6–268.3, Co-Se 233.7–237.5, Co-P 220–224, Se···Se 377–384; Co-Co-Co: 58.6–61.2, Co-Se-Co 67.4–69.4, P-Co-Se 106.5–114.4, Se-Co-Se 105.7–110.1.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. We thank the co-workers of the Institut für Kristallographie der Universität Karlsruhe for help in the crystal structure investigations.

bonded to the faces; the Co atoms are each further coordinated by one PPh_3 ligand. The structure of the 60e Co_4Se_4 cluster resembles that of other heterocubanes, such as $[Fe_4Se_4(NO)_4]$.[5] The Co-Co distances (261.6–268.3 pm) are significantly longer than those in $[Co_4(PPh)_4(PPh_3)_4]$ (257.1–258.6 pm).[6]

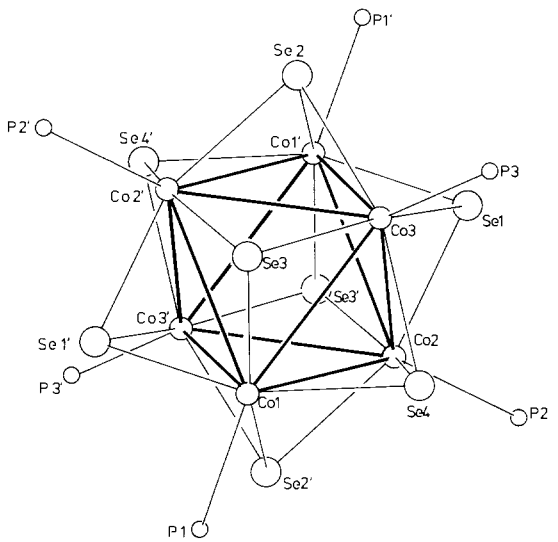

Fig. 2. Crystal structure of **6** (without phenyl groups) [4]. The atomic positions marked with ' are generated by reflection through a center of symmetry. Most important distances (±0.2 pm) and angles (±0.1°): Co-Co 299–302, Co-(μ_3-Se) 233–237, Co-P 216.2–217.5; Co-Co-Co 59.3–60.5, 89.8–90.6, P-Co-(μ_3-Se) 91.2–113.9, Se-Co-Se 87.2–87.8, 154.0–156.2, Co-(μ_3-Se)-Co 79.1–80.9.

The Co_6Se_8 cluster **6** (Fig. 2) has $\bar{1}$ symmetry; the Co_3 faces are each bridged by one μ_3-Se ligand,[4] and each Co atom is coordinated by one PPh_3 ligand. Complexes having the same structure have already been synthesized via a different route, e.g., **2** and $[M_6S_8(PEt_3)_6]^{n\oplus}$ (M = Co, n = 1, 0; M = Fe, n = 2).[7] The Co-Co bonds in **2** (280–282 pm) and in $[Co_6S_8(PEt_3)_6]$ (279–282 pm) are considerably shorter than those in **6** (299–301 pm); the S-S and Se-Se distances are 307–310 pm (**2**) and 324–326 pm (**6**), respectively. Thus, the Se-Se contacts in **6** are significantly shorter than in Mo_3Se_4 (350–374 pm)[8,9] and considerably less than the van der Waals contacts in selenium or $Se_8^{2\ominus}$.[10] This can be explained by the addition of more electrons into antibonding states of the Co_6 cluster in going from E = S to E = Se in $[Co_6E_8(PPh_3)_6]$ and by the increase in the interaction between the Se ligands. Alternatively, **6** could be described as a cubic Se_8 cluster that is coordinated by six $Co(PPh_3)$ groups, the Co atoms lying 49 pm above the faces of the cube. The 98e cluster **6** obeys neither the 18-electron rule nor the Cotton-Haas model.[11]

In the Co_9Se_{11} cluster **7** (Fig. 3), the Co atoms form two face-joined octahedra. Each of Co1,4,9 and Co 6,7,8 is coordinated to a PPh_3 ligand. The faces of the polyhedron are bridged by μ_3-Se (Se 1, 4, and 6–11) and μ_4-Se (Se 2, 3, 5) (Se···Se: 318–346 pm). The Co-(μ_3-Se) and Co-(μ_4-Se) distances, 228–236 and 232–247 pm, respectively, differ. Of the 21 Co-Co bonds (271–298 pm), those of the Co_3 polyhedron faces Co1, 4, 9 and Co6, 7, 8 are 10 pm longer (291–298 pm) than the remaining ones. **7** is formally formed by addition of a Co_3Se_3 group to **6**. This type of structure is known for, e.g., $K_2Mo_9S_{11}$,[12] $In_xMo_{15}Se_{19}$ ($x \leq 3$),[13] $[Rh_9(CO)_{19}]^{3\ominus}$, and $[Ni_9S_9(PEt_3)_6]^{2\oplus}$.[14] The 137e cluster **7** contains 17 and 13 electrons more than are expected on the basis of the 18-electron rule and the topological electron-counting rule,[15] respectively.

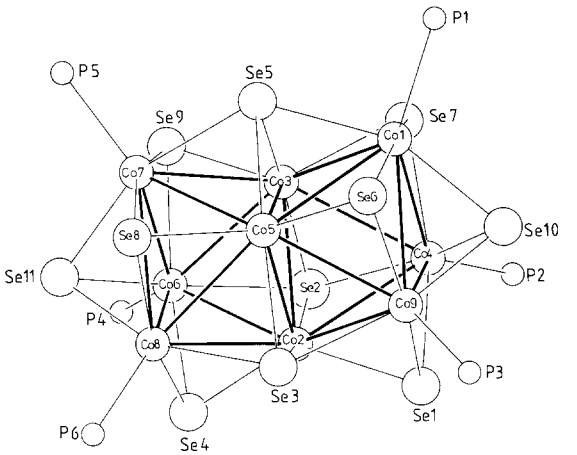

Fig. 3. Crystal structure of **7** (without phenyl groups) [4]. Most important distances (±0.2 pm) and angles (±0.1°): Co-Co 271–298, Co-(μ_3-Se) 228–236, Co-(μ_4-Se) 232–247, Co-P 218–221; Co-Co-Co 56.3–64.8, 88–92.2, 106.2–108.0, 144.6–150.1, Co-(μ_4-Se)-Co 68.2–74.4 and 129.8–132.8, Co-(μ_3-Se)-Co 71.1–78.5.

When $[NiCl_2(PPh_3)_2]$ is allowed to react with $Se(SiMe_3)_2$ in toluene, an insoluble residue of unknown structure is formed in 70% yield (based on Ni). The black $Ni_{34}Se_{22}$ cluster **8** crystallizes from the filtrate (yield 30%).[16] **8** is diamagnetic; in the ^{31}P- and ^1H-NMR spectra, signals are observed at $\delta = 28.0$ (39.8) and at 7.0–7.7, respectively.

$[Ni_{34}Se_{22}(PPh_3)_{10}]$ **8**

In the center of the $Ni_{34}Se_{22}$ cluster **8** (Fig. 4) ($\bar{1}$ symmetry)[17] is a pentagonal Ni_{10} antiprism (black), which is

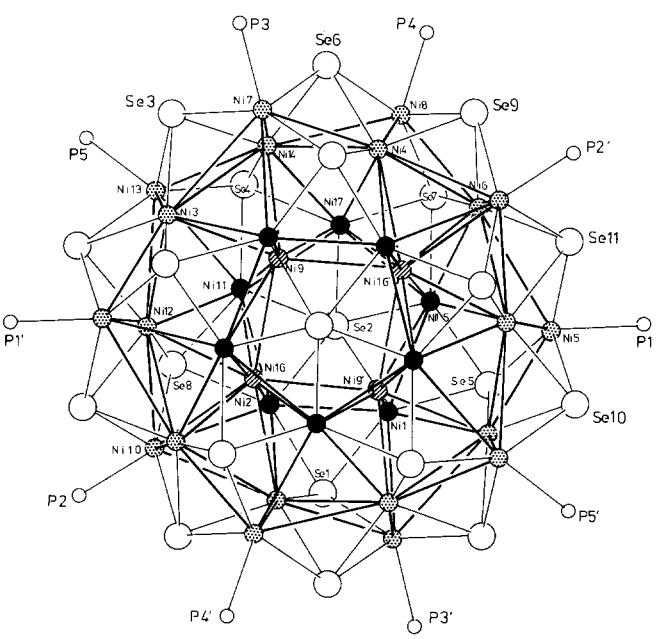

Fig. 4. Crystal structure of **8** (without phenyl groups) [17]. The atomic positions marked with ' are generated by inversion through a center of symmetry. Ni-Ni bond lengths are given when the Ni-Ni distance is ≤312 pm. Most important distances (±0.2 pm) and angles (±0.1°): Ni-Ni distances to the atoms Ni1 236–282, Ni2 239–275, Ni3 260–302, Ni4 260–310, Ni5 252–307, Ni6 241–310, Ni7 256–307, Ni8 260–301, Ni9 236–312, Ni10 260–293, Ni11 247–286, Ni12 256–312, Ni13 257–297, Ni14 258–313, Ni15 250–313, Ni16 242–293, Ni17 247–277. Ni-P 221–222, Ni-(μ_4-Se) 226–246, Ni-(μ_5-Se) 236–246; Ni-(μ_4-Se)-Ni 63–93, 114–129, Ni-(μ_5-Se)-Ni 62–63, 114–116.

coordinated by a μ_5-Se ligand at each of the terminal faces (Ni-(μ_5-Se): 236–246 pm). Between the two Ni_5 faces (distance: 448–456 pm) lies an intervening Ni_4 face (hatched); Ni9 is disordered. **8** formally arises by addition of five Ni_4 clusters to the pentagonal antiprism. Five distorted, connected Ni_8 cubes are thereby formed, the polyhedron faces of which are occupied by μ_4-Se ligands (Ni-(μ_4-Se): 226–246 pm). With the exception of Ni9, 9′, 16, and 16′, the Ni atoms are each bonded to three μ_4-Se ligands. Furthermore, a PPh_3 ligand is coordinated to each of ten Ni atoms (Ni 5, 7, 8, 10, 13 and the positions generated by reflection through an inversion center) (Ni-P: 221 pm).

The differing Ni-Ni distances (236–312 pm) complicate a description of the bonding situation. The *P*-coordinated Ni atoms are bonded to four other Ni atoms (distance: 252–307 pm). On the other hand, the remaining Ni atoms on the periphery of the cluster each exhibit four short (252–272 pm) and three long (297–313 pm) contacts. The Ni-Ni distances in the pentagonal antiprism vary from 236 to 275 pm and from 280 to 312 pm. **8** contains 448 valence electrons, a value that is in good agreement with the number of electrons calculated for M_n clusters ($n > 13$) using the electron-counting concept based on the Hume-Rothery rules.[18]

[3] *Experimental procedure:* $[CoCl_2PPh_3)_2]$ (15.13 g, 0.023 mol) was suspended in 100 mL of toluene and treated with 5.25 g (0.023 mol) of $Se(SiMe_3)_2$. The blue solution immediately turned black. After 4 d, the mixture of **5** and **6** was filtered off (yield 6.0 g). When the residue was treated with THF, **5** was dissolved. Addition of a layer of pentane afforded crystalline **5** (2.8 g, 30% yield). By dissolving the residue in dichloroethane and adding a layer of pentane, crystalline **6** was obtained in the form of black crystals (yield: 2.0 g, 20%). From the filtrate of the reaction solution, 7 precipitated as large, black rhomb-shaped crystals (yield: 1.8 g, 25%).

[4] **5** (from THF), space group $P2_1/n$, lattice constants (180 K): $a = 1347.2(6)$, $b = 2560.1(11)$, $c = 1908.6(9)$ pm; $\beta = 100.40(3)°$, $Z = 4$, $\mu(Mo_{K\alpha}) = 33.9$ cm^{-1}, empirical absorption correction. Syntex R3, $2\theta \leq 55°$, 12264 reflections, 7472 with $I > 2\sigma(I)$. Patterson methods, Co, P, Se, C anisotropic, H positions calculated and isotropically refined. $R_1 = 0.078$, $R_2 = 0.069$.—**6** (from $C_2H_4Cl_2$), **6** crystallizes with four molecules of $C_2H_4Cl_2$, space group $P2_1/n$, lattice constants (180 K): $a = 1422.9(11)$, $b = 2000.0(20)$, $c = 1926.4(14)$ pm; $\beta = 102.29(4)$, $Z = 2$, $\mu(Mo_{K\alpha}) = 41.0$ cm^{-1}, empirical absorption correction. Enantioselective Hydrosilylation of Prochiral 3,4-Dihydro-2*H*-pyrrole Derivatives**

By *Richard Becker, Henri Brunner,* Siavosh Mahboobi,* and *Wolfgang Wiegrebe**

Dedicated to Professor Hellmut Hartmann on the occasion of his 90th birthday

Pyrrolidine alkaloids, a class of compounds to which nicotine belongs, contain an asymmetric center (C-2 of the five membered ring). We report here on the Rh-catalyzed enantioselective hydrosilylation of the five-membered ring imines **1a**–**5a** with up to 64% optical induction, whereby a new acylating work-up procedure enables isolation of the products **1c**–**5c** in yields between 80 and 90%. In the cata-

[a] Without solvent. [b] Catalyst: $[Rh(cod)Cl]_2$/(+)-diop. [c] 1 mmol imine employed. [d] Reproducibility ± 1.5% *ee*.

lytic hydrosilylation of the six-membered ring imine 3,4-dihydropapaverine an enantiomeric excess (*ee*) of 39% with only low chemical yields was achieved.[1]

The 3,4-dihydro-2*H*-pyrrole derivatives **1a**–**5a** were prepared from acetophenone and its derivatives via Mannich reaction with formaldehyde/dimethylamine.[2] The Mannich base was allowed to react with KCN; the resulting nitrile[3] was then hydrogenated with Raney nickel, whereupon cyclization to give **1a**–**5a** took place.[4, 5] The substrates **1a**–**5a** were dissolved in toluene together with the in-situ-catalysts prepared from $[Rh(cod)Cl]_2$/(−)-diop.[6] After 10 min stirring at room temperature the mixture was cooled (Table 1) and the reaction initiated by addition of diphenylsilane. The reaction was then allowed to continue with steady warming to room temperature. One of the Si–H bonds of the diphenylsilane adds to the C=N bond of the imines **1a**–**5a** with formation of the silylamines **1b**–**5b**. Isolation of the secondary amines could not be accomplished by hydrolysis with aqueous hydrochloric acid. The trifluoroacetamides **1c**–**5c** formed upon reaction of the silylamines **1b**–**5b** with trifluoroacetic anhydride, however, can, after neutralization with $NaHCO_3$, be extracted with ether and separated by distillation.[7]

The optical purity of the trifluoroacetamides **1c**–**5c** was determined by capillary gas-chromatography on Chirasil-L-Val®,[8] while the configuration was deduced from the retention behavior, according to which the *R*-enantiomers have shorter retention times.[9] When (−)-diop is employed as cocatalyst, the preferred configuration for all compounds **1c**–**5c** is uniformly *R* configuration.

The optical induction of the imine **1a** unsubstituted in the phenyl moiety can be increased from 59 to 61% *ee* if the reaction is carried out at −6 °C instead of at room temperature (Table 1, Entries 1–3). The best result (64% *ee*) is achieved when the reaction is carried out in the absence of solvent; the solid imine **1a** and the catalyst slowly dissolve in the diphenylsilane which is added at 0 °C (Entry 4). In the hydrosilylation of **2a**, whose *o*-methoxy group could coordinate intramolecularly to Rh, the optical induction drops to 31% *ee* (Entry 5). Since the optical inductions for the imines **3a** and **4a**, whose *m*- and *p*-methoxy groups cannot react intramolecularly with the rhodium, are likewise only 33 and 31% *ee*, respectively (Entries 6–8), an intermolecular effect, favored by the 50- to 100-fold excess of the substrate, must be responsible for such a drop in induction; this is even more pronounced in the hydrosilylation of the *p*-Br derivative **5a**, where 60% *ee* with the same enantiomeric yield as in the case of the unsubstituted imine **1a** is achieved (Entries 1, 2, 9), so that electronic effects cannot play any significant role. Catalyses with (+)-diop as cocatalyst preferably yield the *S*-enantiomer with the same optical purity as (−)-diop the (*R*)-isomer (Entries 6, 7).

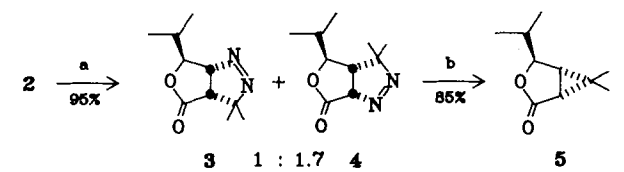
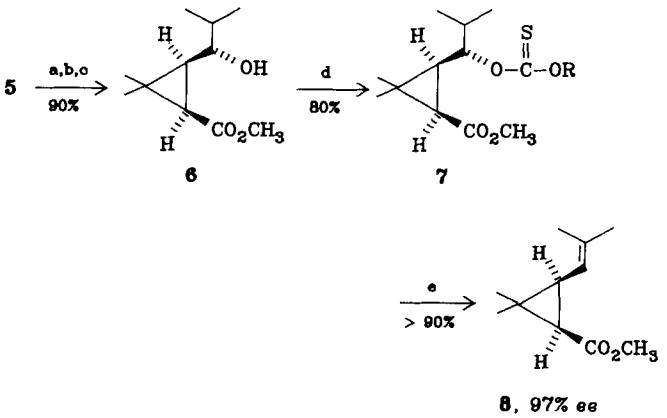
[**] Pyrethroids, Part 5.—Part 4: M. Franck-Neumann, M. Miesch, *Bull. Soc. Chim. Fr. II 1984*, 362.

acids, are highly effective insecticides.[1] The physiological activity of such esters strongly depends on the absolute configuration, so that stereospecific and, if possible, enantioselective syntheses are necessary, especially in the *cis*-series.



We report herein on a stereo- and enantioselective synthesis of both enantiomeric *cis*-chrysanthemic acid methyl esters: these compounds, which serve also as very important precursors for the synthesis of caronaldehyde acid esters,[2] are obtained in high yields and almost optically pure by stereospecific cyclopropanation of the corresponding chiral butenolides (cf. **2**). The key step of our synthesis is the 1,3-dipolar cycloaddition of 2-diazopropane with subsequent photolysis of the adducts (cf. **5**).[3]

The unsaturated, optically active lactone **2** was synthesized according to the method described for the preparation of similar chiral lactones[4] from the chiral alcohol **1**[5,6] (Scheme 1).



Scheme 1. a) *n*BuLi (2 equiv.), tetrahydrofuran (THF), −78°C; b) CO_2, −78 to +20°C; c) HCl, two recrystallizations from benzene; d) H_2/Lindlar catalyst (Pd/$BaSO_4$/quinoline), MeOH; e) HCl, ether.

The 1,3-dipolar addition of 2-diazopropane to **2**, which does not proceed regiospecifically but completely stereospecifically, furnishes the diastereomerically free 4,5-dihydro-1*H*-pyrazoles **3** and **4** (overall yield 95%)[7] (Scheme 2).

Scheme 2. a) $(CH_3)_2CN_2$ (2 equiv.), ether/ethylbenzene, −10°C [8]; b) *hv*, $(C_6H_5)_2CO$, benzene.

In contrast to **3**, the thermolysis of **4**, as expected, does not lead to a three-membered ring, despite loss of nitrogen. However, this does take place upon photolysis, preferably in the presence of a triplet-sensitizer such as benzophenone.[9] The cyclopropanated lactone **5** can be obtained directly in pure form and in at least 85% yield by irradiation of the mixture of **3** and **4**.[10] Hydrolysis of **5** under mild conditions and subsequent esterification with diazomethane finally afford the *cis*-cyclopropanecarboxylic acid methyl ester **6** (>90%), which could not however be dehydrated under mild conditions. Under drastic conditions, mainly opening of the three-membered ring was observed. Thermal elimination according to the method of *Gerlach* and *Müller*[13] proceeds quite differently when performed in 1,2,4-trichlorobenzene. **6** was first esterified to the thiocarbonate **7**, whose thermolysis in 1,2,4-trichlorobenzene led exclusively to the *cis*-chrysanthemic acid methyl ester **8** (Scheme 3).

Scheme 3. R = *p*-tolyl. a) KOH in EtOH/H_2O (2 : 1), 20°C, 12 h; b) HCl 5%; c) CH_2N_2, ether; d) R-OC(S)Cl, pyridine, CH_2Cl_2, 0°C, 48 h; e) 1,2,4-trichlorobenzene, 140°C, 15 min.

The pure *cis* ester **8** is separated from the sparingly volatile solvent by filtration through silica gel. Its optical purity is at least 97%, determined by direct comparison of the optical rotation with that of the authentic (1*R*,3*S*)-*cis*-ester.[14] The (1*R*,3*S*)-(+)-chrysanthemic acid methyl ester **8** depicted here, which leads to the physiologically most effective *cis* analogues, is formed from the (*S*)-(+)-butenolide **2**, which is obtained via the (*S*)-(−)-hydroxy acid from the (*S*)-(−)-alcohol **1**. This enantioselective total synthesis is also applicable to the (1*S*,3*R*)-*cis*-ester *ent*-**8**.

Microbiological or enzymatic reactions or resolution and separation of diastereomers are thus not necessary; this synthesis requires only cheap optically active auxiliary substances that can be readily recovered.

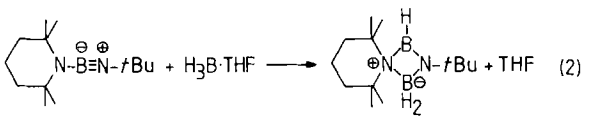
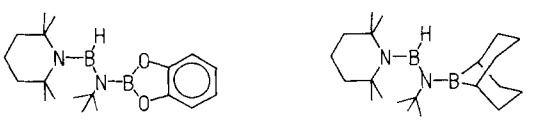
Hydroboration and Hydrozirconation of *tert*-Butylimino-2,2,6,6-tetramethylpiperidinoborane



By *Detlef Männig, Heinrich Nöth,* Manfred Schwartz, Siegfried Weber,* and *Ulrich Wietelmann*

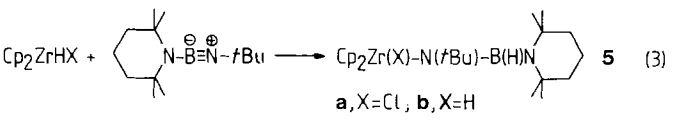


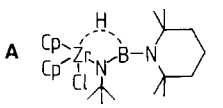
Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

In many respects the chemistry of the iminoboranes[1–3] is similar to that of the isoelectronic alkynes: they oligomerize or polymerize,[2] add HX,[3] and form complexes with transition metals.[4] However, the polarity of the BN bonds confers enhanced reactivity on iminoboranes. This is exemplified by their rapid organoboronation to diborylamines according to Eq. (1).[1]

$$R-\overset{\ominus}{B}\equiv\overset{\oplus}{N}-R' + BR_3'' \longrightarrow RR''B-NR'-BR_2'' \qquad (1)$$

Alkynes undergo a *cis*-hydrometalation.[5] We have now investigated the hydrometalation of iminoboranes using *tert*-butylimino-2,2,6,6-tetramethylpiperidinoborane **1** as an example.[6] If $H_3B\cdot THF$ (THF = tetrahydrofuran) is used, the reaction at −65 °C and high dilution proceeds according to Eq. (2) to give the four-membered ring diborylamine **2** as the main product.[8] In contrast to this, hydroboration with 1,3,2-benzodioxaborole and with 9-borabicyclo[3.3.1]nonane leads to the BN chain compounds **3**[9] and **4**,[10] respectively, since electronic and (particularly) steric effects prevent ring closure.





Whether the hydroboration of **1**, like that of the alkynes, proceeds stereospecifically by *cis*-addition, could not be confirmed in the above three examples by monitoring the reactions NMR spectroscopically at low temperatures. The reason for this is that the rotation barrier of the CC double bond is markedly higher than that of the BN bond of aminoboranes (40–100 kJ/mol).[11] For formation of **2**, a rotation about the central BN bond of a *cis*-hydroboration product is necessary.

Whereas the NMR data of **2**–**4** are consistent with the proposed structures, the two hydrozirconation products **5a**, **b** obtained according to Eq. (3) (Cp = cyclopentadienyl)[12] showed ^{11}B-NMR signals which are not reconcilable with an *N*-metalated bis(amino)borane (**5a**: $\delta = 21.5$; **5b**: $\delta = 16.8$; $HB(NR_2)_2$: $\delta = 26$–28; $RN(NR_2)NRLi$: $\delta = 25$). The IR spectra do not contain any stretching modes of terminal BH-bonds. Medium strength bands in the region 1865–1910 cm^{-1} suggest the presence of hydride bridges. The proposed structure **A** is based on this finding (for **5b**: Cl replaced by H).

An X-ray structure analysis of **5a** confirms this postulate (cf. Fig. 1). The zirconium atom is coordinated in a distorted trigonal-bipyramidal fashion if one takes into consideration the centroids C_x and C_y of the η^5-bonded Cp ligands and the atoms H1, Cl, and N1. Each Cp ring shows two longer and three shorter CC bond distances. The thermal parameters of the C(F)–C(K) ring suggest disorder; its CC bonds are on average shorter (1.352(9) Å) and subject to larger standard deviations than the CC bonds of the Cp ring C(A)–C(E) (1.395(4) Å).

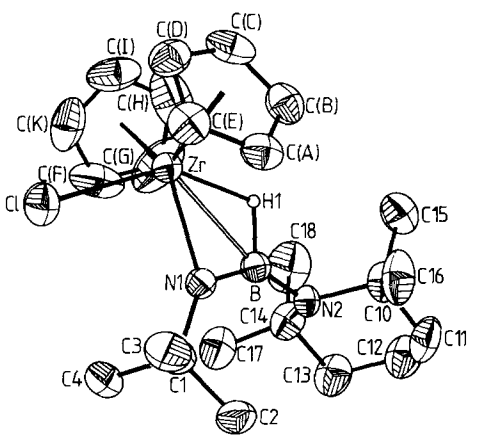

Fig. 1. ORTEP plot of the molecular structure of **5a** [13]. For clarity, C-bonded hydrogen atoms have been omitted. Selected bond lengths and angles ([Å] and [°], standard deviations in brackets): Zr-Cl 2.551(1), Zr-N1 2.211(2), Zr-H1 1.96(2), Zr-B 2.627(2), B-N1 1.360(3), B-N2 1.459(4), B-H1 1.25(2), N1-C1 1.497(3), N2-C10 1.499(4), N2-C14 1.493(4); Cl-Zr-H1 146.3(6), Cl-Zr-B 119.4(2), Cl-Zr-N1 88.7(1), Zr-N1-B 91.5(2), Zr-N1-C1 137.8(2), C1-N1-B 130.5(2), N1-B-N2 140.3(3), N1-B-H1 102.3(9), N2-B-H 117.4(9), B-N2-C10 115.9(2), B-N2-C14 120.1(3), C10-N2-C14 117.7(2), B-H1-Zr 107.7(12); C_x-Zr-Cl 99.8, C_y-Zr-Cl 98.3, C_x-Zr-C_y 122.3, C_x-Zr-N1 114.1, C_y-Zr-N1 120.6 (C_x, C_y: centroids of the Cp rings).

Characteristic for **5a** is a ZrHBN four-membered ring system. A short BN bond of only 1.360 Å is present which may be regarded as a double bond (1.37 Å in $(CH_3)_2NBCl_2$,[14] 1.33 Å in $(R_2N)_2B^{\oplus}$[15]). The ZrN bond is only slightly longer than in compounds of Zr^{IV} with sp^2 hybridized N atoms (2.070 Å in $ClZr[N(SiR_3)_2]_3$ (R = CH_3),[16] 2.167 Å in $Cp_2Zr(NC_4H_4)_2$, and 2.198 Å in

$[Zr(NC_4H_4)_6]^{2-}$[17]). Both the BH as well as the ZrH distances are consistent with H-bridges (1.25 and 1.35 Å in μ-aminodiboranes[18] and 1.73–1.88 Å in H-bridged Cp_2Zr-compounds[19]). The tetramethylpiperidino group is strongly twisted towards the four-membered ring plane: the C10–N2–C14 plane is inclined at an angle of 77° to the plane of the four-membered ring. Consistent with this is the relatively long BN2 bond (1.459 Å), indicating single bonding.[20]

The ZrB distance is only 0.18 Å longer than would be expected for a covalent ZrB bond (2.45 Å). This finding is compatible with a Zr–H–B multicenter bonding, and the resulting ZrB interaction could be responsible for the good shielding of the boron atoms in the NMR experiment.

5a thus contains a novel bonding system reminiscent of that of a μ-H-metallaborane. However, it differs from the latter in that the boron atom is only three-coordinated. Thus, *N*-metalated aminoboranes, whose structural chemistry promises new and interesting aspects of bonding, are accessible by hydrometalation of **1** (and presumably also of other iminoboranes).

Experimental

Bis(η^5-cyclopentadienyl)-μ-hydridozirconium-*tert*-butyl(2,2,6,6-tetramethylpiperidinoboryl)amide chloride **5a**: A stirred suspension of Cp_2ZrHCl (0.52 g) in toluene (5 mL) was treated dropwise with a solution of **1** (0.44 g) *in toluene (4.4 mL) in the absence of light.* After 24 h the clear solution showed ^{11}B-NMR signals at $\delta = 30.2$, 21.1, and 18.4 in the ratio 15 : 70 : 15. The toluene was removed by distillation and the residue was dissolved in a small amount of dichloromethane. Hexane was then added to the resulting solution until it turned turbid. The Cp_2ZrHCl which crystallized out on cooling to −15 °C was removed by filtration and the solution concentrated to a third of its volume by evaporation. Subsequent cooling to −78 °C afforded 0.4 g of **5a** (42%).

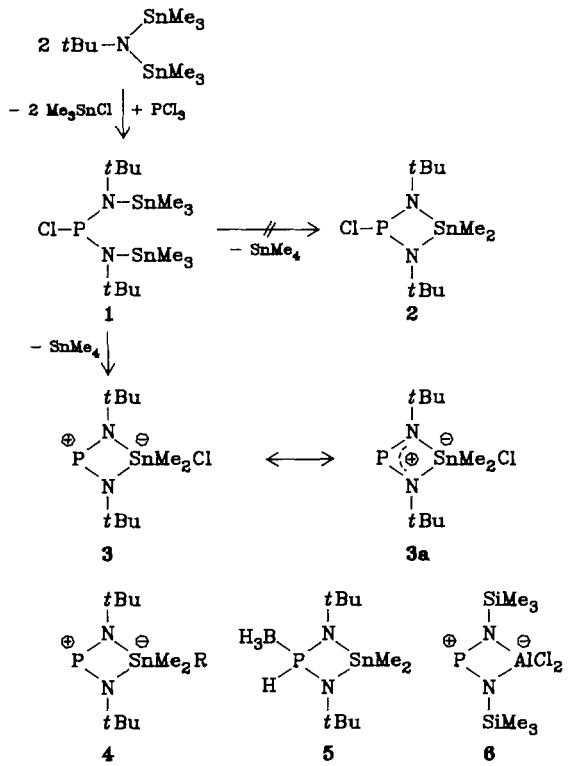
Synthesis and Structure of a Diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane

By *Manuela Bürklin, Elisabeth Hanecker, Heinrich Nöth,* and Wolfgang Storch**



Stannazanes are attracting increasing interest as versatile synthons for main group element-nitrogen compounds,[1] e.g., for the synthesis of phosphazanes.[2,3] They are also suitable, as reported here, for the synthesis of a novel ring system.

Phosphorus trichloride reacts with the stannazane *tert*-butylbis(trimethylstannyl)amine in the molar ratio 1 : 2 to give the diaminochlorophosphane **1**, which has only been detected NMR-spectroscopically; **1** decomposes slowly below 0 °C and quantitatively within 5 h at room temperature. Cyclocondensation, which surprisingly involves formation of tetramethyltin, does not, however, lead to the diazaphosphastannetidine **2** but to the zwitterion diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane **3**. In contrast, the *N*-silylated diaminophosphane $ClP(NCR_3SiR_3)_2$, a homologue of **1**, decomposes with elimination of Me_3SiCl.[4,5] Compound **3** undergoes substitution at the Sn-bonded chlorine atom on reaction with organolithium compounds: The zwitterionic derivatives **4** are formed. By way of contrast, the reaction of **3** with $LiBH_4$ in ether leads to formation of **5**. Apparently a positively charged λ^3-phosphorus center is unstable; its expectedly pronounced electrophilicity therefore favors a hydride migration from the tin atom to the phosphorus atom.[6]

The structures of **3**–**5** follow from the NMR spectra.[7] Thus, the ^{119}Sn chemical shifts confirm pentacoordination[8] in **3** and **4a** and tetracoordination of the tin atom in **5**, whose BH_3 group, according to the BP coupling, is bound to the P atom. The ^{14}N-nuclei in **5** are better shielded ($\Delta\delta(^{14}N) = 130$) as compared to those in **3** and **4a**. This is not only an indication of trigonal planar coordinated N atoms but is also a strong argument for pro-

a, R = Ph; **b**, R = Bu; **c**, R = Me

nounced (pp)π interactions between the phosphorus center and the amino nitrogen atoms,[9] leading to stabilization of the positive charge (cf. **3a**). The $\delta(^{31}P)$ values lend support to the phosphanylia-character of **3** and **4**.[10] The two *tert*-butylamino groups in **3** and **4** should be magnetically non-equivalent, since one nitrogen atom is expected to be bonded equatorially and one axially to the pentacoordinate Sn atom. However, they cannot be differentiated by NMR spectroscopy; no signal splitting is observed, even at −60°C. This suggests fluctional behavior, which is favored by pentacoordination.

An X-ray structure analysis of **3** confirms the constitution derived from NMR data.[11] Figure 1 shows the pentacoordination at the tin atom and the dicoordination at the phosphorus atom. The PN_2Sn four-membered ring lies on a crystallographic mirror plane and is thus planar. Its N atoms show angle sums of 360°. As a result, the tertiary C atoms of the *tert*-butyl groups also lie in the ring plane. In this respect **3** resembles the zwitterion **6**.[12] The apical positions are occupied by the Cl atom and one N atom,[13] while two methyl C-atoms and one nitrogen atom are found in the equatorial positions. The trigonal bipyramidal coordination polyhedron is somewhat distorted. The apical SnN bond is about 0.20 Å longer than the equatorial one. As a consequence, two PN distances are observed: The PN bond to the equatorial N atom is longer than that to the axial N atom. They are short compared to other PN distances,[12] so that (pp)π bonding, which is to be expected from the ^{14}N-NMR spectra, is also supported by the X-ray structure analysis. Finally, also the relatively short transannular SnP distance (2.983 Å), which lies well below the sum of the van der Waals radii, corresponds with the large value for $^2J(^{119}Sn^{31}P)$.

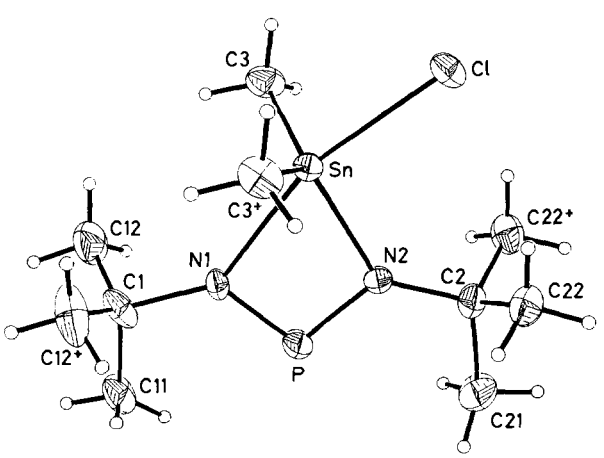

Fig. 1. ORTEP plot of the crystal structure of **3**. Selected atomic distances [Å] and bond angles [°] (with standard deviations): PN1 1.586(9), PN2 1.643(7), SnN1 2.359(6), SnN2 2.156(7), SnCl 2.489(3), SnC3 2.114(8); N1PN2 96.6(4), N1SnN2 64.4(3), PN1Sn 96.3(3), PN2Sn 102.7(4), N2SnCl 97.5(2), N1SnCl 161.8(2), C3SnC3$^+$ 128.6(5).

Experimental

1,3-Di(*tert*-butyl)-4-chloro-4,4-dimethyl-1,3,2λ^2,4λ^5-diazaphosphanyliastannatacyclobutane **3**: A solution of PCl_3 (2.9 mL) in CH_2Cl_2 (12 mL) was added dropwise at −78°C to a stirred solution of *tert*-butyl-bis(trimethylstannyl)amine (20 mL) in 60 mL CH_2Cl_2. After allowing the solution to warm up to 25°C, stirring for 12 hours, and refluxing for an additional hour, $(CH_3)_3SnCl$ and CH_2Cl_2 were removed from the light-brown solution by condensation into a trap cooled to −78°C. 11.7 g (97%) of **3**, mp. 84°C, was obtained by sublimation of the residue at 90°C/10^{-2} torr.

1,3-Di(*tert*-butyl)-4,4-dimethyl-4-phenyl-1,3,2λ^2,4λ^5-diazaphosphanyliastannatacyclobutane **4a**: A 2 M solution of PhLi in benzene (3.1 mL) diluted with ether (3 mL) was added dropwise at −78°C to a stirred solution of **3** (2.2 g, 6.15 mmol) in 50 mL of a 1:1 ether-pentane mixture. After the suspension had slowly acquired ambient temperature and after 24 hours' stirring at room temperature, the insoluble material was removed by filtration (G4 frit). The solvent was then removed from the filtrate at 25°C/10^{-2} torr and the viscous residue was fractionally distilled. 2.1 g (85%) of **4a** was obtained as a slightly yellow liquid, b.p. 108–109°C/10^{-2} torr.

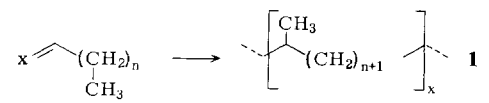
Novel Polymerization of α-Olefins with the Catalyst System Nickel/Aminobis(imino)phosphorane



By *Volker Michael Möhring* and *Gerhard Fink**

Polymerization of ethene with the catalyst system nickel(0) compound[1]/bis(trimethylsilyl)aminobis(trimethylsilylimino)phosphorane[3] leads, according to *Keim* et al.[4] to short-chain, branched polymers. We have found that this system polymerizes α-olefins: surprisingly the structure of the products is consistent not with the usual 1,2 coupling of the monomers to give a comb-like branched product but with a 2,ω-coupling.

With the homogeneous catalyst system nickel(0) compound/aminobis(imino)phosphorane, linear α-olefins (experimentally tested range: C_3 to C_{20}) and singly branched α-olefins can be polymerized, but not α-olefins with quaternary C-atoms in the chain or olefins with vinylene or vinylidene groups. Besides α-olefin homopolymers, copolymers with ethene or other α-olefins can be prepared, whereby random copolymers or block copolymers are obtained, depending on the method employed. The catalyst components—preferably in equimolar ratio—are employed in situ in the pure liquid monomer or in aromatic solvents. The nature of the ligand of the Ni^0 compound (see[11]) has no influence on the structure of the α-olefin polymer.

This finding and results of kinetic investigations[5] suggest that the rate-determining step in the formation of the polymerization-active species is the release of the ligand from Ni^0.[5]

The structure of the poly-α-olefins is unusual. When a linear α-olefin is polymerized, the polymer (see **1**) contains only methyl branches, regularly spaced along the chain with a separation corresponding to the chain length of the monomer.

1

Thus, in the polymer of a linear α-olefin with n CH_2 groups the distance between two methyl branches is (n+1) CH_2 groups. Because their structure is well defined and can be predetermined by selection of the appropriate α-olefin, these products are suitable as model substances for physical investigations. Thus, for example, the structure of the polymer synthesized from 1-pentene corresponds to that of a rigidly alternating copolymer of ethylene and propylene.

The structure of the products was confirmed ^{13}C-NMR spectroscopically (for examples, see Figs. 1 and 2). The assignment of the signals was carried out with the help of the increment rules of *Lindemann* and *Adams*.[6] All the signals to be expected for 2,ω-linked α-olefin polymers were found in the spectra in the corresponding intensity ratios. The additional signals arise from the difference between the beginning and the end of the polymer chains: at the beginning there are not (n+1) but (n+3) CH_2 groups between the first two methyl branches (Fig. 1).

Analysis of the ^{13}C-NMR spectra of polymers of deuterated α-olefins revealed that the growing chain is bound to the next α-olefin via $C_\omega \rightarrow C^2$ linking; C^1 forms the later methyl branch in the polymer.

The average molecular weight and the molecular weight distribution are strongly dependent on the reaction temperature. Below ca. 273 K characteristic features of a "living polymer" are observed; that is, the molecular weight can be regulated by the ratio of monomer to catalyst-concentration, and the molecular weight distribution remains narrow. Above ca. 273 K the average molecular weight decreases with increased polymerization activity; at the same time the molecular weight distribution becomes broader and the double bonding in the polymer (vinylene, vinyl, vinylidene groups) is increased. This finding indicates that transfer reactions to the monomer take place via β-H elimination.

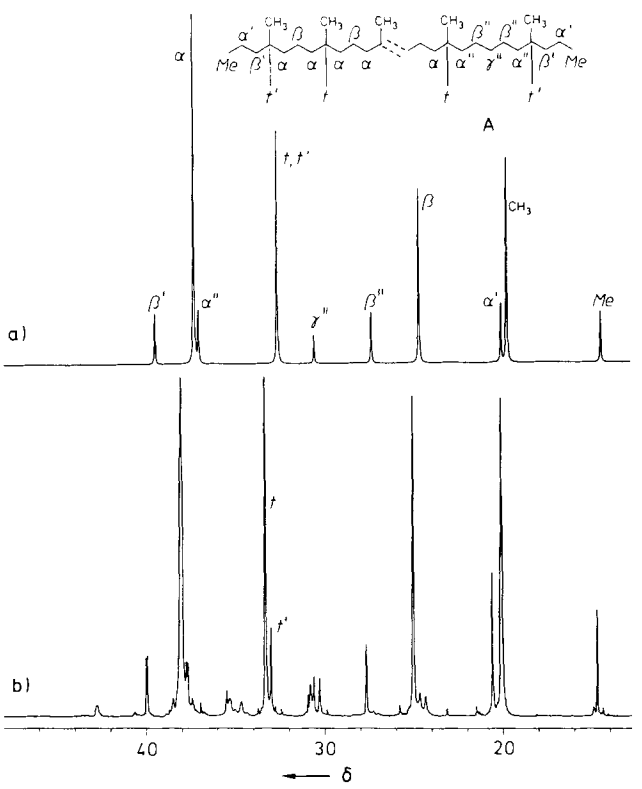


Fig. 1. a) Simulated $^{13}C\{^1H\}$-NMR spectrum of a polymer with the given structure obtained from 1-pentene (with A beginning of the chain); b) $^{13}C\{^1H\}$-NMR spectrum of poly-2,5-(1-pentene)[poly(1-methyltetramethylene)] (75.5 MHz, [D_6]benzene 30°C).

[*] Priv.-Doz. Dr. G. Fink, Dipl.-Chem. V. M. Möhring

Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (FRG)

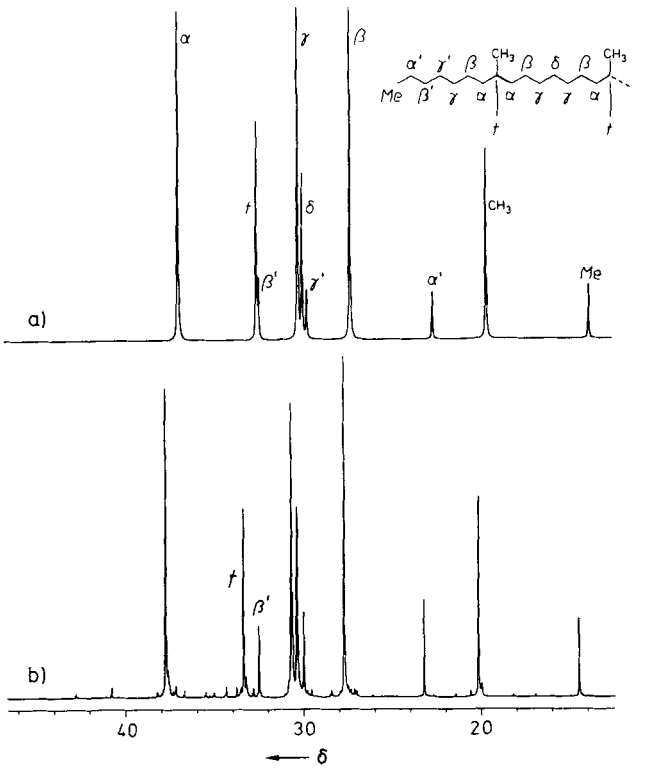

Fig. 2. Simulated $^{13}C\{^1H\}$-NMR spectrum of a polymer of the given structure (with chain ends) obtained from 1-nonene; b) $^{13}C\{^1H\}$-NMR spectrum of poly-2,9-(1-nonene)[poly(1-methyloctamethylene)] (75.5 MHz, [D_6]benzene, 30°C).

In addition, it emerges that, under otherwise equal reaction conditions, the average molecular weight always has the same value independent of the C-number of the monomer (e.g. at 298 K: ca. 1000 g/mol[7]). The degree of polymerization decreases linearly with increasing chain length of the α-olefin.

Taking all the results into account, a reaction scheme was developed with which the origin of the special structure of the poly-α-olefin can be explained (Fig. 3). The main points of the scheme are:

- The monomer can only insert into a CH_2–Ni bond at the end of the growing chain;
- the insertion is regioselective; only $C_\omega \rightarrow C^2$ coupling of the growing chain with the next monomer takes place;
- the nickel-catalyst complex "migrates" along the polymer chain between two insertions. During this "migration" transfer reactions to the monomer can occur, but not insertions.

These processes are represented schematically in Figure 3 for the polymerization of the 1-butene. The "migration" can be explained in terms of an addition-elimination mechanism via allylnickel/nickel hydride species with 1,2-hydride shift. The nickel hydride could also function as a transferring species, whereby the various types of detectable double bonds would be formed via β-H elimination corresponding to the momentary position of the nickel-catalyst complex in the chain.

If each step of the "migration" is reversible, then statistically the nickel-catalyst complex not only moves forward to the "correct" end of the chain but also back in the direction to the beginning of the formed polymer chain. The ever increasingly longer chain being formed in the polymerization is so structured that the "migrating" nickel-catalyst complex always finds a similar chemical environment after a certain chain length. That is, any possible influence of the chain end will progressively get smaller, so that there is equal probability of migration in both directions. The dependence of the degree of polymerization on the length of the linear α-olefin could be explained in terms of a limiting chain length after which the probability of formation of a Ni–CH_2 grouping at the end of the chain, and thus the possibility of insertion of a further monomer, tends to zero under the particular reaction conditions.

The formation of all structural features (short- and long chain branches) which are detectable in polyethylene prepared with this catalyst system can likewise be explained in terms of an extended "migration mechanism".[8]

[7] The average molecular weights of the polymers were determined from the ^{13}C-NMR spectra, i.e. from the ratio of the signal intensities of the sums of all C atoms to those of the chain terminal C-atoms. They therefore correspond to the number average molecular weights.

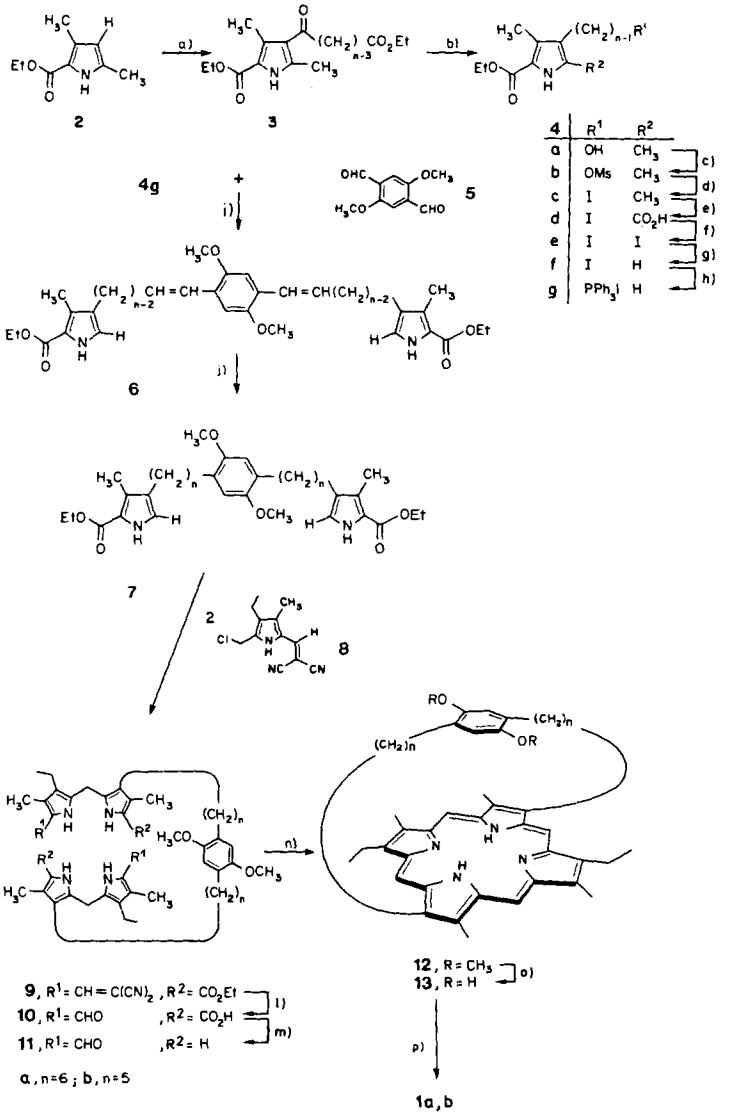
The Synthesis of Porphyrins Doubly Linked to Quinones by Hydrocarbon Chains**

By *Brian Morgan* and *David Dolphin**



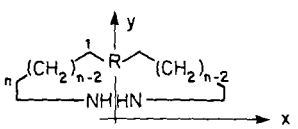
Electron transfer from an excited ((bacterio)chlorophyll through a series of intermediate compounds (bacterio)pheophytin, Fe-S clusters) to a quinone acceptor (ubiquinone, plastoquinone) is a key step in bacterial and plant photosynthesis.[1] Not surprisingly, attempts have been made to mimic this light-induced separation of charge using various model complexes in which a quinone is covalently attached to the periphery of a porphyrin macrocycle.[2] However, meaningful results depend on a knowledge of the relative orientation and separation of the two reaction centers. For those complexes in which the porphyrin electron donor and the quinone acceptor are linked by a *single*, flexible chain, observation of intramolecular charge transfer may be obscured by intermolecular reaction.

1a, n=6
1b, n=5

We report here on a general route for the synthesis of porphyrin-*p*-benzoquinone systems such as **1a**, **b** in which the quinone ring is held in position above one face of the porphyrin by *two* oligomethylene straps. *Staab* et al. recently described the synthesis of a porphyrin related to **1** which is doubly capped by *p*-benzoquinone.[3] Postponement of the porphyrin ring-forming reaction until the final stages of the synthesis of **1** (Scheme 1) ensures good yields of the product even for relatively short straps. The compounds **1a** and **1b** prepared by us contain two hexa- and pentamethylene straps, respectively, and it is anticipated that also variants of **1** with $n \geq 4$ can be obtained in this way.

The key step of the synthesis is the double Wittig reaction of the pyrrolephosphonium salt **4g** and the dialdehyde **5**,[4] both compounds being easily prepared from readily available starting materials, the β-free pyrrole **2**

Scheme 1. Synthesis of the capped porphyrins **1a** and **1b**. The yields [%] are given in parentheses. (a) $SnCl_4$, CH_2Cl_2, 0°C, $ClOC(CH_2)_{n-3}CO_2Et$ (n = 6 and 5, resp.) (84, 73); (b) $BF_3 \cdot Et_2O$, $NaBH_4$, tetrahydrofuran (85, 72); (c) CH_3SO_2Cl, Et_3N, CH_2Cl_2, 0°C (92, 88); (d) NaI, acetone, reflux (92, 88); (e) SO_2Cl_2, CH_2Cl_2, Et_2O; H_2O, acetone, reflux (83, 91); (f) $NaHCO_3$, KI, I_2, $ClCH_2CH_2Cl$, reflux (84, 86); (g) HI, EtOH (88, 43); (h) PPh_3, $C_6H_5CH_3$, reflux (97, 86); (i) $K_2CO_3 \cdot 1.5\,H_2O$, dioxane, reflux; (j) 10% Pd/C, cyclohexene, EtOH, reflux, (two steps: 83, 42); (k) ACOH, 80°C (88, 90); (l) KOH, PrOH, H_2O, reflux; (m) dimethylformamide, reflux; (n) TosOH, high dilution (three steps: 49, 39); (o) BBr_3, −78°C → room temperature; (p) PbO_2, CH_2Cl_2 (two steps: 60, 70).



and 1,4-dimethoxybenzene, respectively. Phase transfer reaction[5] of **4g** and **5** in refluxing dioxane in the presence of potassium carbonate yielded the diolefin **6**, which was reduced to the oligomethylene-bridged bis(pyrrole) **7**.[6] This was then condensed with two equivalents of the α-chloromethylpyrrole **8** to provide the highly substituted bis(dipyrromethane) **9**. Base hydrolysis and thermal decarboxylation gave the unstable α-free, α′-formyl chain-linked bis(dipyrromethane) **11**. Acid-catalyzed cyclization of **11** was carried out under high dilution conditions to encourage intramolecular condensation, and the strapped porphyrin **12** was isolated chromatographically (**12a**, 20–60%; **12b**, 40%). Compounds **12a** and **12b** were recrystallized from CH_2Cl_2/hexane (m.p. 271–274°C and 264–267°C, resp.) and characterized by elemental analysis, high resolution mass spectrometry (*m/z* 724.4695 (M^+) and 696.4365 (M^+), resp.), and ^1H- and ^{13}C-NMR spectroscopy.

[*] Prof. D. Dolphin, B. Morgan
Department of Chemistry, University of British Columbia
Vancouver, B.C., V6T 1Y6 (Canada)

[**] This work was supported by the National Institutes of Health (USA) and the National Sciences and Engineering Research Council (Canada).

The methoxy functions could be removed under mild conditions by treating **12** with excess boron tribromide in CH_2Cl_2 at $-78°C$, and then warming to room temperature. The crude porphyrin-hydroquinone **13** was then oxidized to **1** by stirring with lead dioxide in CH_2Cl_2. Chromatography (neutral Al_2O_3) furnished the desired porphyrin in excellent yield (**1a**, 82%; **1b**, 96%). The structures of **1a**, **b**, like those of **12a**, **b** were confirmed by elemental analysis, high resolution mass spectrometry (*m/z* 694.4249 (M^+) and 666.3984 (M^+), resp.), and ^{1}H- and ^{13}C-NMR spectroscopy.

That the dimethoxybenzene or quinone rings are held in place above the porphyrin was dramatically illustrated in the ^{1}H-NMR spectra. All protons of the two oligomethylene straps experience the effect of the porphyrin ring current and since this effect decreases along both x- and y-axes (Scheme 2), the chemical shifts of the strap protons depend on the length and conformation of the strap. For example, protons directed into the cavity bounded by the strap and the porphyrin ring experience large upfield shifts. The internal shift reagent effects a spread in the chemical shifts over a wide range, thus allowing identification of each resonance by simple decoupling experiments.

Scheme 2.

Table 1. ^{1}H-NMR data of **12** and **1** (δ values, $CDCl_3$).

Group	12a	12b	1a	1b
10,20 Methine H's	9.98	9.93	10.02	10.05
5,15 Methine H's	10.00	9.97	10.03	
CH_2CH_3	4.12 4.04	4.17 4.07	4.12	4.08–4.24
Phenyl 3,6-H	3.91	3.80	—	—
CH_3	3.60 3.59	3.62 3.54	3.68 3.60	3.70 3.57
Quinone 3,6-H	—	—	2.76	2.94
CH_2CH_3	1.87	1.88	1.89	1.93
Phenyl OCH_3	1.58	1.91	—	—
N-H	−3.99	−3.90	−4.00	−3.91
Chain 1-CH_2	0.70 0.21	0.53 0.96	0.27 −0.70	0.65 0.0
Chain 2-CH_2	−0.10 0.11	−1.13 −0.31	0.05–0.15 —	−1.29 −0.32
Chain 3-CH_2	0.82 —	0.88 1.07	0.95 1.11	1.14 1.25
Chain 4-CH_2	1.22 1.50	1.91 2.22	1.51 1.73	1.93 2.33
Chain 5-CH_2	2.32 —	3.93 4.25	2.51 —	3.97 4.30
Chain 6-CH_2	3.72 4.43	—	3.63–3.75 4.40	—

The larger upfield shift of the quinone protons in **1a** ($\delta = 2.76$) compared to that in **1b** ($\delta = 2.95$) suggests that the longer, more flexible oligomethylene chain can accommodate a shorter porphyrin-quinone distance, and this was reinforced by examination of space-filling models. A similar situation was observed by *Baldwin* in his "cap" and "homo-cap" porphyrins,[7] and also by *Sanders* et al.[2i] The situation is less clear for the porphyrin-dimethoxybenzene complexes **12**, with the shifts of the phenyl and the methoxy protons offering conflicting estimates of the separation of the porphyrin and phenyl rings. However, when the ^{1}H- and ^{13}C-NMR spectra of **12a** are recorded in trifluoroacetic acid (10%)/$CDCl_3$ a broadening or disappearance of the phenyl protons and some of the strap protons is observed. It would appear that for the free base form of **12a** the straps can rotate freely among a number of conformations, resulting in sharp signals for the average conformation. On protonation this rotation is restricted and the signals for the phenyl ring and some of those of the straps are broadened. Observation of all resonances for **12b**, both in the free base and the protonated forms, suggests that again the longer, more flexible chain in **12a** accommodates a shorter separation between the phenyl and the porphyrin rings.

Metalation and electron-transfer studies on complexes **1** and the corresponding hydroquinones **13** are presently in progress. The extension of this synthetic route to the preparation of other porphyrins bearing bulky groups and potential ligands in the strap will be subsequently communicated.

Comprehensive Heterocyclic Chemistry. The Structure, Reactions, Synthesis and Uses of Heterocyclic Compounds. Cochairmen of the editorial board: *A. R. Katritzky* and *C. W. Rees*. Pergamon Press, Oxford 1984, bound, $ 2200.00.—ISBN (complete work) 0-08-026200-7

Vol. 1: Part 1: Introduction, Nomenclature, Review Literature, Biological Aspects, Industrial Uses, Less-common Heteroatoms. Editor: *G. Meth-Cohn*. xvi, 731 pp.—Vol. 2: Part 2a: Six-membered Rings with One Nitrogen Atom. Editors: *A. J. Boulton, A. McKillop*. xiv, 689 pp.—Vol. 3: Part 2b: Six-membered Rings with Oxygen, Sulfur or Two or More Nitrogen Atoms. Editors: *A. J. Boulton, A. McKillop*. xiv, 1210 pp.—Vol. 4: Part 3: Five-Membered Rings with One Oxygen, Sulfur or Nitrogen Atom. Editors: *C. W. Bird, G. W. H. Cheeseman*. xiv, 1195 pp.—Vol. 5: Part 4a: Five-Membered Rings with Two or More Nitrogen Atoms. Editor: *K. T. Potts*. xiv, 994 pp.—Vol. 6: Part 4b: Five-Membered Rings with Two or More Oxygen, Sulfur or Nitrogen Atoms. Editor: *K. T. Potts*. xiv, 1171 pp.—Vol. 7: Part 5: Small and Large Rings. Editor: *W. Lwowski*. xiv, 867 pp.—Vol. 8: Part 6: Indexes. Editor: *C. J. Drayton*. xiv, 1111 pp.

A great, and still rapidly increasing, number of heterocyclic compounds is known; this makes it progressively more difficult to obtain a survey of particular aspects of this field, which is so important in synthesis, in biochemistry and in its many practical applications. Attempts at orientation in this mass of material by means of textbooks often founder on account of the selective or even uninterested coverage given to heterocycles. As far as specialized literature goes, "Elderfield", which largely stems from the 1950's, can only be conditionally considered and even the 60+ volumes of "Weissberger-Taylor" are not all up to date. The present monumental work sets out to fill an obvious gap in the market. Formally, it complements the series "Comprehensive Organic Chemistry" and "Comprehensive Organometallic Chemistry" (cf. *Angew. Chem. Int. Ed. Engl. 22* (1983) 797). Heterocyclic chemistry is dealt with here in more than 6000 pages by over 120 authors, predominantly from English speaking countries. From the FRG *K. Dimroth, W. Flitsch, W. Friedrichsen, H. Gotthardt, H. Neunhoeffer, W. Pfleiderer, I. Ugi*, and *H. Wamhoff* have contributed and from the GDR *G. W. Fischer, E. Schmitz*, and *T. Zimmermann*.

The numerous applications and biological aspects of heterocycles are prominent in the first volume. Observations on the toxicity of chlorinated dibenzodioxins (p. 118) provide an indication of how up to date the work is. Beside this there is a section on nomenclature (36 pages), a literature survey of heterocyclic chemistry (34 pages) and a very informative chapter on the synthesis of non-heterocycles from heterocycles (79 pages). The volume concludes by treating boron containing rings (35 pages), rings containing higher elements of groups 4 or 5 (phosphorus: 45 pages, arsenic, antimony, bismuth: 23 pages), rings containing halogens (10 pages) and rings containing a transition metal (8 pages).

The mass of material on heterocycles containing nitrogen or a group 6 element requires clear arrangement of the content. As is usual, ring size, together with the number and type of heteroatoms, serves as the general criterion of organization. To emphasise common properties, however, annelated systems are discussed with the corresponding monocycle. Parts 2 to 5 (Vols. 2 to 7) are each introduced by a general chapter which gives a condensed survey and, above all, draws out relationships between the ring systems to be dealt with. Then follow extensive sections on the individual ring systems. Whenever possible, general and specialized chapters are subdivided as follows:

- structure, especially molecular structure, as well as spectroscopic data and problems of tautomerism
- reactivity of ring positions and substituents of aromatic compounds as well as non-aromatic derivatives
- synthesis from non-heterocycles, arranged according to the number of newly formed bonds, or from heterocyclic precursors
- applications.

In the second volume pyridine and benzo-annelated pyridines are dealt with according to this general plan (95 pages survey and 422 pages specialized material). The volume is completed by short sections on quinolizinium ions (55 pages) and pyrido-pyridines (46 pages).

The third volume is a compilation, in 17 chapters, of the chemistry of 6-rings with at least two nitrogen atoms or with oxygen or sulphur. Apart from (benzo)pyridazines (57 pages), -pyrimidines (98 pages), and -pyrazines (41 pages), amongst others pteridines (64 pages), (benzo)triazines (altogether 160 pages), pyranes (306 pages) and thiopyranes (58 pages) are dealt with in depth.

The fourth volume begins with a general introduction to 5-rings with one heteroatom (153 pages). Amongst others (benzo)pyrroles (221 pages), -furans (181 pages), -thiophenes (219 pages) and -selenophenes (36 pages) are handled in individual chapters. Porphyrins, corrins and phthalocyanins (66 pages) belong in this volume too.

In volumes 5 and 6 the treatment of 5-rings is extended to those with at least two heteroatoms. After the introduction (162 pages), the following receive substantial sections of their own: (benzo)pyrazoles (135 pages), -imidazoles (153 pages), purines (105 pages), (benz)isoxazoles (130 pages) and (benzo)thiazoles (95 pages).

The seventh volume contains 15 contributions on heterocyclic 3- and 4-rings and 7 sections on rings with at least seven members. Individual chapters are devoted to penicillins (41 pages), cephalosporins (14 pages), crown ethers and cryptands (32 pages) and heterophanes (18 pages).

Without reference to the organizational structure, the entire work is accessible via the four indexes of volume 8. A "physical data index" contains sources of quantitative information on more than 4000 heterocycles, e.g. for "furan, tetrahydro" information is supplied on the dipole moment, ^{1}H-, ^{13}C-, ^{17}O-NMR spectra, microwave spectrum, pK_a value and the photoelectron spectrum. The subject index contains 40,000 entries; the author index lists 30,000 names in 35,000 references. A ring index, analogous to the "Chemical Abstracts" register, names 4000 ring systems.

A striking characteristic of the work is that literature references are given as an alphanumeric code derived from the year of publication, an abbreviated designation of the journal and the page number. Thus the reference [*Angew. Chem. 95* (1983) 819] would appear as ⟨83AG819⟩. This method enables the reader to identify the most recent reference directly in the text and, after a little practice, to find the original straightaway. The complete references are given at the end of each volume, arranged by year of publication. The literature references reach up to 1982; in places publications from 1983 are also included.

All in all this is a successful work; the external appearance is pleasing and every page is strewn with useful information. The rigorous arrangement of the individual volumes enables quick orientation, even without recourse to the index, and means that cross references can largely be dispensed with. The numerous clear formula diagrams and informative tables are very helpful. Preparative chemists will particularly welcome the tabular grouping of the "best methods of synthesis".

The production of this work must have been a Herculean task for authors and editors alike. This deserves recognition and makes detailed criticism mere niggling. Spot tests indicate that printing errors have been carefully expunged and that transcription errors do not exceed the sadly inevitable limits. One striking example of this is the citation of two different (by 1.98 eV) ionization potentials for oxetane on the same page (Vol. 7, p. 368). It is unfortunate that "oxete", the correct name for the unsaturated 4-ring ether, is replaced even in a chapter heading by "oxetene" (Vol. 7, p. 363). In a few cases the chapters have turned out to be pretty eclectic, as, for example, when 1,2- and 1,3-dioxolanes as well as 1,2- and 1,3-oxathiolanes are discussed in tandem, although they are cyclic derivatives of quite different classes of compounds (Vol. 6, p. 749ff).

The selection of material by authors and editors is naturally subjective and some readers will find particular aspects missing or inadequately dealt with. Obviously, however, exhaustive treatment cannot be expected even in 42 cm of shelf space. Even so a survey of the subject and an entry into further literature are provided. The general chapters enable interested students to find their bearings and could also serve as the basis for a lecture; for this reason this work should enable heterocyclic chemistry to find a place in the curriculum that corresponds to its importance. The specialized chapters are available to meet the demand for more detailed information. Even experts—in universities or industry—will find useful references here. Interested parties from neighboring disciplines will appreciate the extensive sections on applications and biochemical aspects. Quite apart from searching for particular information, the book is interesting territory for the browser; even in the age of machine readable data this "semi-systematic" access to information is indispensable and will ensure a large readership for "Comprehensive Heterocyclic Chemistry".

Gene und Klone. Eine Einführung in die Gentechnologie. By *E.-L. Winnacker*. Verlag Chemie, Weinheim 1984. xii, 454 pp., bound, DM 70.00.—ISBN 3-527-26061-7

Textbooks dealing with topics in molecular biology have a very short half-life and become rapidly outdated. Courage and the ability to foresee future developments are therefore required when one sets out to write a detailed introduction into the concepts and techniques of gene technology. *Ernst-Ludwig Winnacker*, with his book "Gene und Klone", has succeeded in making a contribution that will not only be of value to novices in the field of molecular biology. In didactically exemplary fashion, the fundamental principles of molecular biology are combined with the concepts and techniques of gene technology. The sequence of chapters reflects the experimental procedures routinely followed in cloning experiments. Research in molecular biology always involves genuine craftsmanship that has to be mastered and modified daily on the basis of the most recent developments. This practical aspect has also been adequately dealt with by *Ernst-Ludwig Winnacker*'s presentation. The combination of theoretical considerations and practical instructions renders the book readable for newcomers; accuracy in detail and the author's efforts to cover current findings make the book useful and worthwhile reading for advanced students as well. Essentials for daily work are readily available by the inclusion of numerous, clearly drawn illustrations presenting genetic and structural maps. In the appendix, the guidelines of the "Zentrale Kommission für die Biologische Sicherheit" are also included. The reader should, however, be aware of the fact that these guidelines are currently being revised.

Shortly before writing this book review, I wanted to leaf through "Gene und Klone" again. I had to search for my two copies in the laboratory. Only after days of questioning, however, was I able to find them. One copy had been extensively used and showed it. Apparently, the book has been consulted frequently by my younger colleagues. This observation is perhaps the best recommendation for the book.

In Munich, it must be difficult to compete with the "Schönheitengalerie" of the first Ludwig.[*] Although the gallery of molecular biologists presented by the Ludwig who writes about genes and clones may render the cold scientific facts more likeable, its attraction is in general far inferior to the collection of the first Ludwig.

This book is highly recommended above all to students in the field. I hope that the book goes through many, carefully rewritten editions and will be translated into English after having been brought up-to-date.

Walter Doerfler [NB 724 IE]
Institut für Genetik der Universität Köln (FRG)

Hydrazine and its Derivatives. Preparation, Properties, Applications. By *E. W. Schmidt*. Wiley, Chichester 1984. xxv, 1059 pp., bound, £ 87.00.—ISBN 0-471-89170-3

The major sections of this book are: the production of hydrazine (including the anhydrous compound), together with details of the capacities of and processes employed by western manufactures; physical properties; chemical properties of hydrazine and its salts with a detailed section on hydrazine analysis; the handling of hydrazine with a very important subsection on its toxicology; the decomposition of hydrazine; utilization of hydrazine, especially its use as a rocket propellant whose description occupies more than 100 pages.

Organic derivatives are described only very briefly and, essentially, only insofar as they are of importance to the field of rocket propellants.

As the author, who is a senior staff scientist of the Rocket Research Corporation and obtained his doctorate in Tübingen, correctly states, this is the first comprehensive survey of hydrazine in an occidental language for the last 30 years. For all who are doing work in the field of hydrazine the absence of such a book has been a significant handicap.

Here too, as in many other fields, the literature has exploded. The reference list contains more than 4400 citations on 194 pages. The references are listed "lexically", that is alphabetically according to the name of the first author, so that the list fulfills some of the functions of an author index.

[*] Ludwig I., King of Bavaria (1825–1848), had portraits of the most beautiful Munich women painted for his "Schönheitengalerie", which is now exhibited in Schloss Nymphenburg. Go and see it.

Because of the professional activities of the author, the emphasis of the book is on the chapters concerned with the application of hydrazine as a rocket propellant. A new technology has been developed here that is rarely reviewed in the normal chemical literature. Who, for example, is aware that the anhydrous hydrazine employed for the Viking landing on Mars had to be freed from organic impurities by fractional crystallization because of apprehensions that hydrazine cyanide, occurring in the exhaust gases, might interfere with the biological experiments?

In the important section on the toxic properties of hydrazine and its compounds the author points out that investigations are still in progress and that there is no lack of contradictory results.

The reviewer has several reservations in spite of the many positive aspects of this book. For instance, the almost 60 lines per page and the relatively small type make reading difficult. However, the following objections are of more importance: Today, three processes are employed for the production of hydrazine on an industrial scale, whereas one process was formerly employed, the urea process. Each of these processes are, of course, described (flow diagrams are also provided) but one also finds a host of irrelevant details from the patent literature. Some statements are even incorrect. In the Bayer process their is no hydrazine formed which is intercepted as the ketazine. Diaziridine is a feature of the (not practised) Bergbau process and not of the Bayer process. Since these processes are to be found under the heading "Bergbau-Bayer-Whiffen Process" this section can only confuse readers who are unfamiliar with the matter. It is also questionable if a ketone imine is an intermediate in the PCUK process.

In the discussion of the large number of processes that are not employed for the synthesis of hydrazine on an industrial scale, e.g. the fixation of nitrogen in complexes with subsequent reduction or electrochemical methods, one misses a short account as to why these interesting variants are not employed industrially. The description of the application of hydrazine in fuel cells is a positive example where it is clearly stated that technical application is not to be expected (and why).

In all, a necessary book for all who have anything to do with hydrazine; but care must be taken by those searching in the chemistry part of the book for rapid up todate information concerning the present state of the art in this field.

Selenium in Natural Products Synthesis. By *K. C. Nicolaou* and *N. A. Petasis*. CIS Inc., Philadelphia 1984, 300 pp., bound, $ 39.50.—ISBN 0-914891-00-6

It is well-known that the usefulness of novel synthetic methods depends on their application to the synthesis of complex natural products. In the last 15 years the efforts of several groups with organoselenium compounds have led to the development of many preparative methods. This book documents the fact that these have found frequent use up till now in the synthesis of natural products and evaluates this, rightly, as evidence for the breadth of application of selenium chemistry.

The introductory chapter reports very briefly on the particularities of organoselenium compounds; then the most important reagents are listed in tabular form, together with the comment that many are now commercially available. Details of the preparation of the non-commercially available substances would have been desirable here.

The following chapters describe, according to reaction type, a wide range of natural product syntheses with selenium reagents. In the second chapter entitled "Selenium-mediated oxygenations" the reader finds alongside allylic oxidation with selenium dioxide also examples of the modern variations of this well-known reaction which have been introduced especially by *Sharpless* and *Barton*. In Chapters 3 and 4, which deal with dehydrogenations, a—somewhat arbitrary—distinction is made between "Selenium-mediated Dehydrogenations" (= Dehydrogenations without the isolation of an intermediate) and "Organoselenium-mediated Olefinations". By this the authors understand the synthesis of olefins by the preparation of selenium oxides followed by elimination, a method which has become known under the names of *Sharpless* and *Reich*. Chapter 5 briefly covers reductions with selenium reagents. Chapter 6 is concerned with selenium-stabilized carbanions which were first described by *Seebach* at the end of the 1960s and have since found extensive application by *Krief* and *Reich*. Unfortunately the expression "synthetic equivalent" is employed in the review at the commencement of the chapter when "synthon" was what was meant. The electrophilic addition of selenium reagents to CC double bonds and their subsequent cyclization by intramolecular reaction of the selenium ion (e.g. "selonlactonization") is described in the seventh chapter with many examples including some from *Nicolaou* himself. Finally, a potpourri of reactions, some of which have not (yet) been employed in natural product synthesis, is included under the title "Miscellaneous Applications of Selenium Compounds".

Before going into the numerous examples of applications, the key reactions are presented in generalized form in the individual chapters by means of clear formula graphics. The target molecules range from terpenes via steroids and alkaloids to prostaglandins and macrolides. In accordance with the intensions of the book only the relevant steps of multistep syntheses are reported. Unfortunately the yields of the individual steps are not always included in the clearly presented reaction schemes.

The authors have been able to provide a comprehensive insight into the potential of selenium reagents which is, nevertheless, understandable even to the advanced student. A successful book in spite of the flaws mentioned.

Dusseldorf (FRG)

Non-Benzenoid Conjugated Carbocyclic Compounds. By *D. Lloyd*. Elsevier, Amsterdam 1984. xvi, 431 pp., bound, HFl. 260.00—ISBN 0-444-42346-X

This book communicates a feeling of the fascination which has brought synthetic chemists, spectroscopists and theoreticians together in a unique manner. The chemistry of non-benzenoid conjugated carbocycles has years of hectic development behind it; this is reason enough for the stock-taking that *Lloyd* planned. The author has also succeeded in representing the continuous, the living force of his subject which transcends the ups and downs of fashion, particularly by the inclusion of original work up to 1983.

The concept of aromaticity and its unchanging importance is dealt with in an introductory chapter. This section impresses with its historical completeness; it has a strongly narrative character, but suffers from the absence of a dis-

cussion of, for instance, the theory of the fixation of double bonds. The following chapters are devoted to cyclopentadienes and cyclopentadienide ions (2.), cycloheptatrienes and tropylium ions (3.), cyclopropenes and cyclopropenium ions (4.), cyclobutadienes (5.), cyclooctatetraenes and cyclononatetraenes (6.), annulenes (7.), and bicyclic and polycyclic compounds (8.). The descriptions of the results are always comprehensive; thus, in the case of the seven-membered ring compounds, the coverage ranges from tropylium ions to tropones, tropolones, heptafulvenes up as far as the cycloheptatrienylidenes and cycloheptatrienide ions. The description of the individual substance types is always under the headings "Synthesis", "Spectra and Structure" and "Chemical Reactions".

The book is convincing in the care and specialist knowledge with which the relevant literature has been collected and pithily reviewed. The sympathetic "devotion to the literature" which is the real strength of the book becomes an unintentional disadvantage in instances were a criticism of the original work or a discussion of discrepant results is called for. The text also remains a little conventional because the beginnings of newer developments within the chemistry of conjugated carbocycles such as, for example, "aromaticity and electrical conductivity" or "multilayered π systems and properties of stacks" remain unmentioned. Taking this into account it remains a resumee which will be of great value to every interested chemist who makes use of the material collected in it.

The publishers must be excluded from the recognition awarded to the author. The author deserved better support in the large quantities of graphics. The print and graphics have an improvised appearance and are at great variance with the exaggerated price.

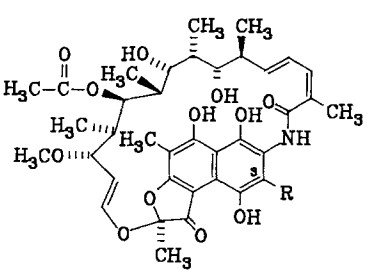
Molecular Mechanism of Action of the Antibiotic Rifampicin



By Guido R. Hartmann,* Peter Heinrich, Margit C. Kollenda, Bernhard Skrobranek, Maximilian Tropschug, and Wolfgang Weiß

Dedicated to Professor Wolfram Zillig on the occasion of his 60th birthday

The lipophilic antibiotic rifampicin is successfully used in the treatment of tuberculosis. On the molecular level it interferes with the metabolism of Eubacteria by blocking RNA synthesis. This effect is the consequence of the tight binding of the drug to a single and highly specific binding site on the DNA-dependent RNA polymerase. The enzyme-bound drug strongly inhibits RNA chain initiation and chain elongation. This inhibition can be explained by the influence of enzyme-bound rifampicin on binding sites for the reaction products diphosphate and RNA. In order to reach its target the antibiotic must penetrate into the cytoplasm of the bacteria. Mutants have been discovered which are resistant to rifampicin because its uptake from the medium is significantly reduced. The gene responsible for this effect has been cloned. It confers on bacterial cells with highly sensitive RNA polymerases a remarkable resistance to the drug.

1. Introduction

Rifampicin, an antibiotic with a wide antibacterial spectrum, has proved particularly effective in the treatment of tuberculosis. Chemically, it is a semisynthetic member of the class of rifamycins, which are produced by the bacterium *Nocardia mediterranei*. The productive strain was discovered in a sample of soil collected by *Hermes Pagani*, a technician of the pharmaceutical company Lepetit in Milan, from a pine arboretum close to the seaside resort of Saint Raphaël in southern France where he had spent his vacation. The antibiotic was named after "Rififi," the title of a well-known movie.[1,2] *Sensi*, *Oppolzer*, and *Prelog*[2,3] elucidated the chemical structures of the rifamycins and showed that they are naturally occurring ansa compounds.[4] Many derivatives of the parent compound, rifamycin SV, have been prepared semisynthetically. Most of them are effective only after parenteral application. The

derivative rifampicin, also known under the trade names rifa, rifampin, or rimactan, is fully effective after oral application and is therefore the commercially most successful form of the rifamycins.[5] The drug is well tolerated because the metabolism of human cells is not disturbed at antibiotically effective concentrations whereas the metabolism of Eubacteria such as *Mycobacterium tuberculosis*, the causative agent of tuberculosis, is drastically impaired.[6]

2. RNA Polymerase as Target

Of the metabolic processes in bacteria, RNA synthesis is most strongly inhibited by rifampicin, even at very low concentrations (0.5 μg/mL in cell culture).[7] Protein synthesis ceases as a consequence of this inhibition, resulting in the termination of bacterial replication.[8] Termination of RNA synthesis is caused by the inhibition of the enzyme that catalyzes DNA-directed RNA synthesis, namely, DNA-dependent RNA polymerase (EC 2.7.7.6).[9] Only the eubacterial enzyme and not the corresponding RNA polymerase from eukaryotic cells contains a single and specific binding site for the antibiotic. It binds rifampicin even at concentrations as low as 8 μg/L.[4] These observations explain the excellent toleration of the drug at low concentrations by human cells. The drug is very hydrophobic and at 1000-fold higher concentrations also binds to many other proteins, causing various side effects.[4,10-12] The primary effect of rifampicin can therefore be investigated only if higher concentrations are strictly avoided.

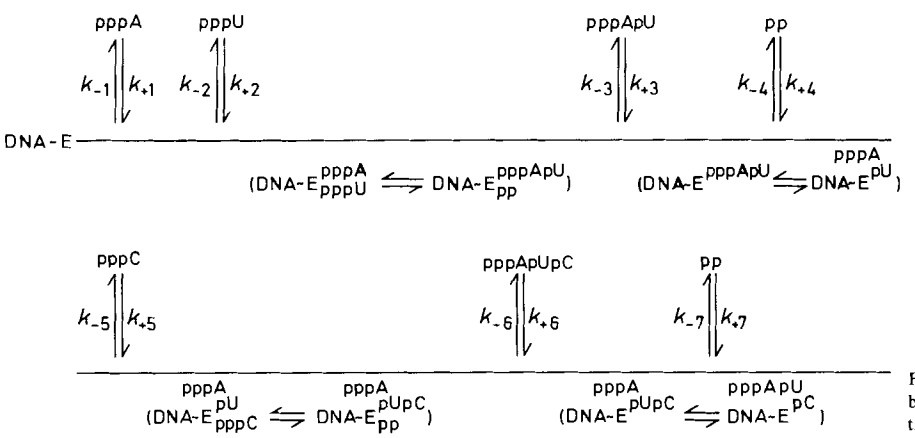
Since DNA-dependent RNA polymerase has not been crystallized, the X-ray crystallographic analysis of the antibiotic-enzyme complex has not yet been carried out. Therefore, we do not know which part of the drug molecule is directly involved in the binding. With the exception of residues in position 3 of the naphthohydroquinone ring system, not much can be altered in the structure of the drug without concomitant loss of the tight binding to the eubacterial enzyme.[4] In vitro the enzyme-rifampicin complex dissociates immediately in the presence of agents such as guanidinium chloride that disrupt the three-dimensional structure of proteins.[13] Accordingly, the drug does not bind covalently to the protein.

Bacterial strains resistant to rifampicin as a consequence of a mutation have been known for a long time.[14] Two classes of mutants have been characterized. In the first class, all mutations occur in the bacterial gene that codes for the β subunit of RNA polymerase.[15,16] This is independent evidence for RNA polymerase being the immediate target of rifampicin since, otherwise, such mutations would not lead both to the loss of the tight binding between the drug and the enzyme and, simultaneously, to the loss of rifampicin sensitivity of the bacterial cells.[4] The DNA-dependent RNA polymerase from Eubacteria is a large protein with a relative molecular weight of about 0.5 million. The enzyme from the intestinal bacterium *Escherichia coli* has been studied most thoroughly. It consists of four different polypeptide chains, α, β, β′, and σ, of known amino acid sequence which form a stable complex with the stoichiometric composition $\alpha_2\beta\beta'\sigma$. Most mutations of the first class that lead to rifampicin resistance are located in a single region of the gene. This region codes for a sequence of about 50 amino acids[17,18] close to the center of the β polypeptide chain, which is 1342 amino acids in length.[19] Presumably, this region of the β subunit forms an essential part of the rifampicin binding site. This assumption is supported by observations from our laboratory which demonstrate that this region of the β subunit is protected against proteolytic cleavage by bound rifampicin.[20]

3. Inhibition of RNA Synthesis

E. coli RNA polymerase catalyzes the stepwise chemical condensation of ribonucleoside triphosphates to form RNA using DNA as a template. The formation of a phosphodiester bond is accompanied by the release of a molecule of diphosphate (Scheme 1). The sequence of bases in the RNA synthesized is complementary to the transcribed strand of the DNA template as required by the base-pairing rule. A careful analysis of the individual steps of the reaction has shown that the substrates associate in an ordered sequence on the enzyme-DNA complex.[21,22] If a template coding for an RNA with the sequence ApUpCp... is used, then the first substrate that binds to the enzyme-DNA complex is ATP (≡pppA), which acts as a primer. Binding of UTP (≡pppU) follows (Fig. 1).

In the next step, the first phosphodiester bond is formed and the intermediate dinucleoside tetraphosphate pppApU is produced. If the next nucleotide is absent from the reaction mixture, this product is released and diphosphate dis-



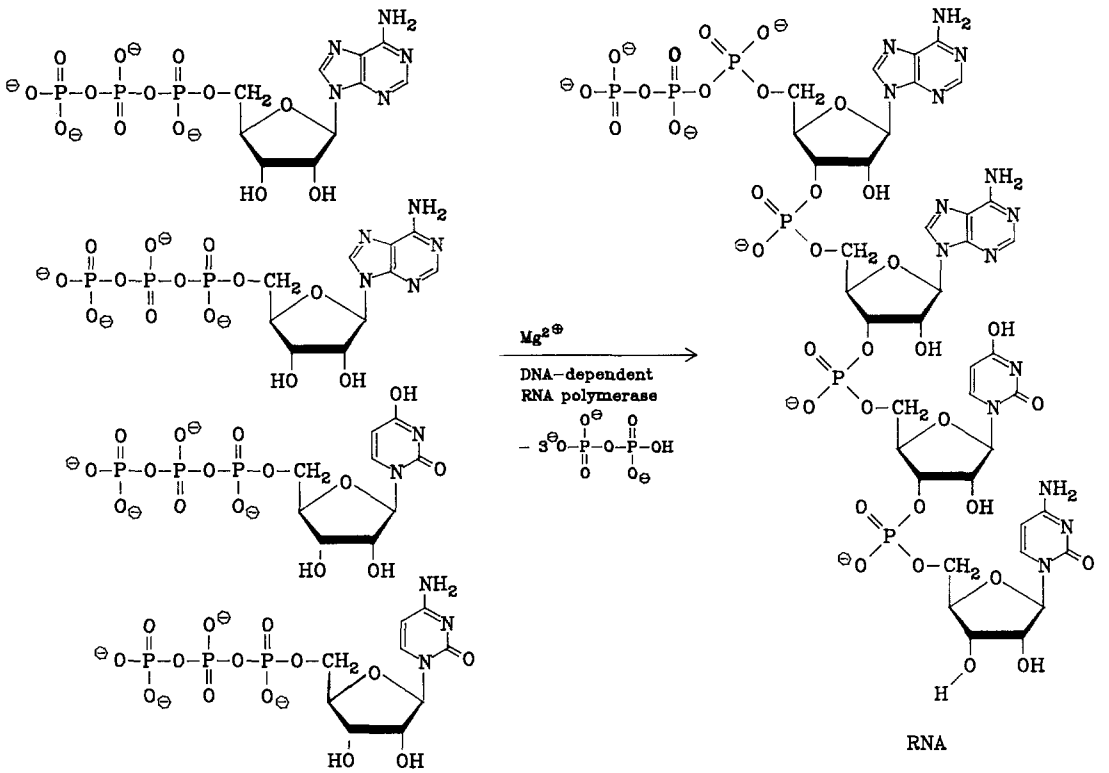


Fig. 1. Mechanism of initiation of RNA synthesis by *E. coli* RNA polymerase (see text). DNA~E is the DNA-enzyme complex.

Scheme 1.

sociates from the enzyme.[22] In this case, termed abortive initiation,[23] the initiation is continuously repeated, leading to the accumulation of pppApU.

If suitable nucleotides are available for further reactions, the dinucleoside tetraphosphate undergoes translocation. The uridine moiety of pppApU then occupies the binding site formerly occupied by the adenosine residue of the priming ATP. Simultaneously, the enzyme must move by one base along the template strand. The former binding site of UTP is free to accept the next substrate molecule, CTP(≡pppC), and the second phosphodiester bond is formed. Continuous repetition of these steps leads to the synthesis of long-chain RNA. This scheme describes a minimal mechanism for the catalytic process, all details of which are not yet known. However, its essential points suffice for the discussion of the effects of the association of rifampicin on the enzyme.

If antibiotic is added to the enzyme in vitro followed by addition of template and a complete set of ribonucleoside triphosphates, the rate of RNA synthesis rapidly decreases with increasing concentration of the antibiotic (Fig. 2). At a concentration of 0.06 μg/mL (0.1 μM), an inhibition of 50% is already observed. At a tenfold higher concentration, RNA synthesis is barely detectable. Simultaneously with the decrease in the rate of RNA synthesis, an increase in the rate of formation of the dinucleoside tetraphosphate pppApU is observed.[24] Half of the maximum rate is obtained at the same drug concentration that depresses RNA synthesis by 50%. Thus, the enzyme–rifampicin complex can still catalyze the synthesis of pppApU but not that of long-chain RNA.[23] In this context it is important to note that rifampicin does not alter the apparent Michaelis constant for the reaction of the substrates ATP and UTP on the enzyme.[25]

The inhibition of RNA synthesis may be explained by several different hypotheses. The simplest one assumes steric blocking of that part of the product binding site required for binding intermediate products longer than di- or trinucleotides.[26,27] Another hypothesis postulates an increase in the rate constant k_{-3} for dissociation of the intermediate dinucleotide (Fig. 1). This assumption is based on results obtained mainly with the synthetic template poly[d(A-T)].[28]

Both hypotheses assume that the drug does not inhibit the formation of dinucleotides. This can be tested experimentally. Abortive initiation is possible with a large num-

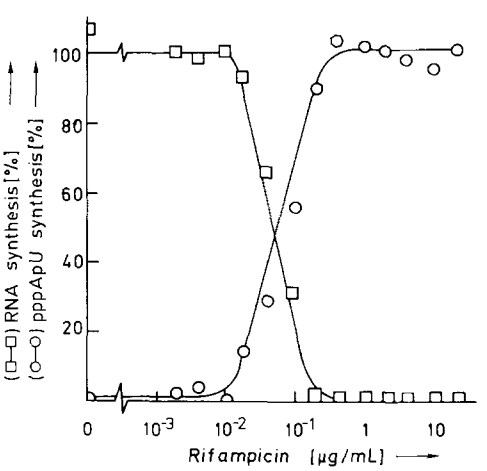

Fig. 2. Influence of rifampicin on the RNA or pppApU synthesis catalyzed by *E. coli* RNA polymerase. The experiments were carried out at 25°C with bacteriophage T4 DNA as template [36]. 100% pppApU synthesis (○—○) in the presence of 2 μg/mL rifampicin corresponds to an incorporation of 1830 cpm per hour of incubation. 100% RNA synthesis (□—□) in the absence of rifampicin corresponds to an incorporation of 2380 cpm per hour of incubation.

ber of adenosine derivatives (e.g., adenosine, 5′-AMP, 5′-ADP, ATP) as priming substrates[21,26,29] [Eq. (1)]. The rate

$$R-A + pppU \rightleftharpoons R-ApU + pp \quad (1)$$
$$R = HO, p, pp, ppp$$

of synthesis depends on and varies with the priming substrate. At 25 °C it is highest with 5′-AMP, followed by ATP and ADP. Adenosine is the poorest substrate (Table 1). Similar results have been obtained with RNA polymerase from the gram-negative *E. coli* and the gram-positive *Micrococcus luteus*. Low concentrations of rifampicin have noticeable effects on these reactions at 25 °C. The synthesis of the dinucleoside monophosphate ApU is inhibited by 85%. The synthesis of pApU and ppApU is also strongly reduced. Such an inhibition violates the assumptions of the hypotheses mentioned above. Different effects of rifampicin on dinucleotide synthesis catalyzed by the enzymes from *E. coli* and *M. luteus* are only observed when the highly charged, anionic pppApU is the product. Whereas its synthesis by the enzyme from *M. luteus* is inhibited by 27%, the rate observed with the *E. coli* enzyme is increased by 27% under identical conditions (Table 1).[30] This surprising effect is not only observed when the enzyme is preincubated with the antibiotic in order to form the complex but also when rifampicin is added during abortive initiation (Fig. 3). Similar results have been obtained with different templates. At temperatures above 30 °C, the rate of pppApU synthesis is also inhibited when the *E. coli* enzyme is used.[26,30]

Table 1. Relative rate (v_{rel}) of dinucleotide synthesis at 25 °C in the presence and absence of 2μM rifampicin. Abortive initiation was carried out with 1.5 mM primer and [α-^{32}P]UTP on bacteriophage T7 D111 DNA as template with RNA polymerase from *E. Coli.* or *M. luteus* as described in [36].

Primer	Product	v_{rel}		v_{rel} (2μM rifampicin)	
		E. coli [%]	*M. luteus* [%]	*E. coli* [%] [a]	*M. luteus* [%] [a]
5′-ATP	pppApU	100	100	127	73
5′-ADP	ppApU	60	79	47	34
5′-AMP	pApU	124	124	42	18
Adenosine	ApU	51	32	15	15

[a] 100% = rate in the absence of rifampicin (columns 3 and 4).

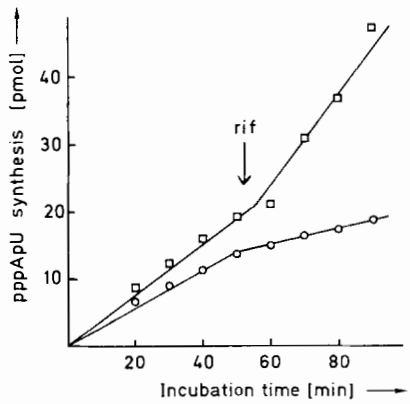

Fig. 3. Influence of rifampicin at 26 °C on pppApU synthesis catalyzed by the RNA polymerase from *E. coli* (□—□) and *M. luteus* (○—○) on bacteriophage lambda DNA. After 52 min of incubation, 2 μg/mL rifampicin (rif) was added.

The inhibitory effect of rifampicin apparently decreases with the increasing overall charge of the dinucleotide formed. However, it is still observed even if pppApU or pppppApU are formed.[26] Therefore, the drug cannot inhibit RNA synthesis in general by increasing the rate of dissociation of the intermediate dinucleotide or by blocking the product binding site for longer intermediate products. Since the RNA polymerase from *E. coli* and *M. luteus* differ in several details of their structure,[31] it is not surprising that the action of rifampicin differs slightly for these two enzymes.

4. Competition between Diphosphate and Rifampicin

So far, the influence of the enzyme-bound rifampicin has been discussed only for the forward reaction [Equation (1)]. Is the backward reaction inhibited similarly? In order to determine the rate of diphosphorolysis, radioactively labeled diphosphate was added to an incubation mixture containing enzyme, template, ATP, UTP, and Mg^{2+}. The rate of the backward reaction was determined by measuring the formation of radioactively labeled UTP, which was separated from the labeled diphosphate by adsorption on charcoal.[31] The backward reaction is strongly inhibited by rifampicin. This effect is independent of the number of phosphate groups at the 5′ end of the dinucleotide. At a diphosphate concentration of 0.34 mM, 50% inhibition is observed with 0.08 μM rifampicin. The rate of diphosphorolysis is strongly dependent on the concentration of diphosphate (Fig. 4). Interestingly, rifampicin changes the

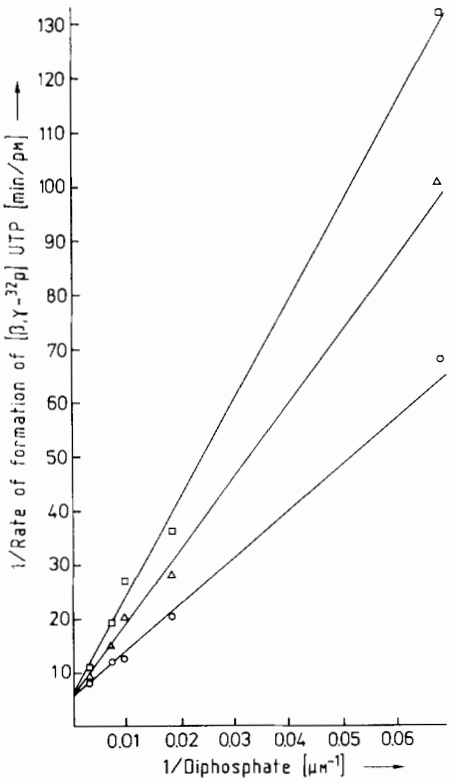

Fig. 4. Influence of rifampicin and diphosphate on the enzyme-catalyzed diphosphorolysis of pppApU on bacteriophage T7 D111 DNA as template (Lineweaver-Burk plot). Diphosphorolysis was measured at 25 °C similarly to the procedure in [32] in the absence (○—○) or presence of 0.05 (△—△) and 0.10 (□—□) μg/mL rifampicin.

rate of reaction competitively to diphosphate as is evident from the Lineweaver-Burk plot of the data (Fig. 4). This suggests that the binding of diphosphate to the enzyme-DNA complex is altered by the drug and vice versa. An increase of the diphosphate concentration should therefore decrease the binding of rifampicin to the enzyme-template complex.[33] This is indeed the case (Fig. 5). In the presence of the template, the influence of the diphosphate concentration is more pronounced. The binding site of diphosphate is apparently altered by the association of the enzyme with the template. The rate of the backward reaction does not change with the concentration of pppApU in the range of 0.03 nM–10 μM and is independent of the presence of the antibiotic. An inhibition is only observed at higher concentrations and is probably due to the formation of a kinetic dead-end complex.[22]

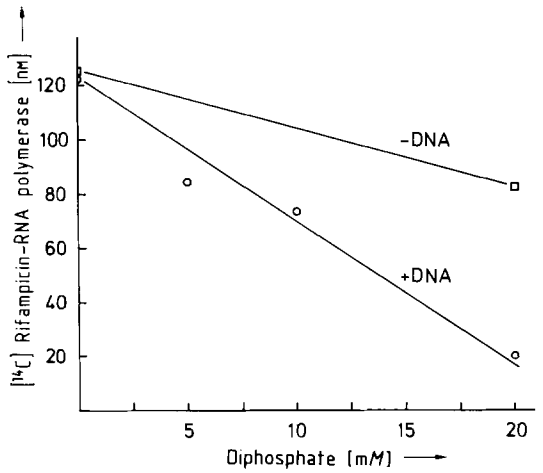

Fig. 5. Influence of diphosphate on the binding of [^{14}C] rifampicin to *E. coli* RNA polymerase at 37 °C in the absence (□—□) and presence (○—○) of 70 pmole/mL bacteriophage T7 D111 DNA. The enzyme-bound [^{14}C] rifampicin was determined similarly to the procedure in [33].

5. Competition between RNA and Rifampicin

RNA strongly inhibits the catalytic activity of the enzyme when added prior to the template.[34,35] Interestingly, the inhibition of pppApU formation by RNA is strongly reduced if the enzyme is preincubated with 0.1 μM rifampicin before the addition of RNA.[36] This protecting effect of the drug may be explained by a competitive effect of the antibiotic on the binding of RNA and vice versa, similar to the observations reported for diphosphate. Indeed, it is well known that RNA strongly inhibits binding of rifampicin to RNA polymerase.[37] It is more difficult to demonstrate the inhibitory effect of the drug on the binding of RNA since the enzyme contains two binding sites for nucleic acids, namely, one for the product and one for the template. For further analysis, therefore, it is necessary to physically separate these two sites. The subunits of RNA polymerase form several complexes with each other: $\alpha_2\beta\beta'\sigma$ (holoenzyme), $\alpha_2\beta\beta'$ (core enzyme), α_2 (dimer), and the subassembly $\alpha_2\beta$. Fortunately, $\alpha_2\beta$ is able to bind both RNA[20] and rifampicin[38,39] with rather high affinity,[40] while DNA is only loosely bound.[20] Rifampicin inhibits the binding of RNA to the subassembly[20] and, vice versa, RNA that of rifampicin.[36] These observations strongly support the notion that the drug and RNA compete for binding to RNA polymerase. This would explain why RNA polymerase does not bind rifampicin during RNA synthesis.[13,41] For the same reason, the antibiotic cannot terminate RNA chain elongation if added to the reaction mixture after initiation. It prevents, however, the start of RNA synthesis if added to the enzyme before the substrate.[42] Originally, these observations led to the hypothesis of rifampicin being a specific inhibitor of RNA chain initiation, which has been widely propagated even in textbooks.[43] This hypothesis, however, explains the plethora of observations concerning the molecular effects of rifampicin much less convincingly than the hypothesis of an indirect interference of the bound drug with the binding of the reaction products.

6. Penetration of Rifampicin into Bacteria

The activity of rifampicin on the metabolism of bacteria must also be discussed with respect to the process of penetration of the drug into the bacterial cell, which allows it to reach its target in the cytoplasm. It has been postulated that rifampicin does not require a special mechanism of penetration since it is so lipophilic. Rifampicin is thought to dissolve readily in the lipid-rich cell wall and membranes of bacteria and therefore to reach the cytoplasm via an equilibrium distribution.[44] In fact, *M. tuberculosis*, the causative agent of tuberculosis, contains very high amounts of complex lipids in its cell wall, which should facilitate the solubilization and penetration of rifampicin. However, recent observations indicate that the penetration of the drug is controlled by additional factors.[45] After mutagenesis of *E. coli* AB1157[46] with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, clones that contain an RNA polymerase highly sensitive to the drug but that are able to grow in its presence were isolated by an appropriate selection procedure. No evidence for the degradation of the drug by the mutants was found. The rate of rifampicin uptake in the mutant cells is extremely reduced (Fig. 6). These mutants are only resistant to rifamycins, while their sensitivity to other toxins, such as phenol, acriflavin, malachite green, neomycin, tetracycline, or chloramphenicol, remains unchanged.

The mutated gene can be transduced into sensitive strains with bacteriophage P1kc. Mapping of the mutation with the help of bacteriophage mu[47] has shown that the gene is located between the loci cysB (28 min) and aroD$_6$ (37 min) of the *E. coli* standard gene map far away from the gene loci of the RNA polymerase subunits. The mutated gene has been cloned in pBR322. *E. coli* DH1 or HB101 cells harboring this plasmid are resistant to up to 200 μg/mL of rifampicin in the growth medium, whereas the RNA polymerase activity is as sensitive to the drug as in the plasmid-free host. In vitro expression of the cloned gene[48,49] resulted in the appearance of a protein with a relative molecular weight of 49000 in dodecylsulfate-containing polyacrylamide gels. The cloned DNA fragment

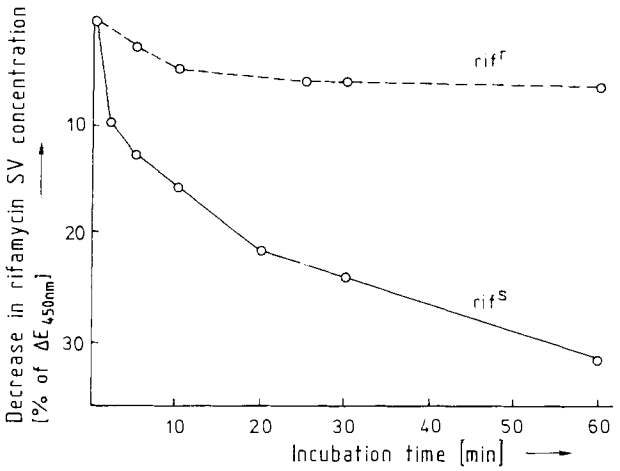

Fig. 6. Uptake of rifamycin SV by *E. coli* CR 34 thy ("rif") and by the rifampicin-resistant rif 41 ("rif") mutant at 37°C. The decrease of the rifamycin concentration in the supernatant was determined spectrophotometrically [44].

with a length of 2145 base pairs has been sequenced. It contains two open reading frames starting with a methionine codon close to a Shine-Dalgarno-like sequence. The larger one has a coding capacity for a protein of 452 amino acids length until to the next stop codon. It may code for the protein observed upon in vitro gene expression. More work will be required to elucidate the function of these gene products in the uptake of such a lipophilic compound as rifampicin by *E. coli* cells.

7. Outlook

Thanks to improved hygiene and healthier nutrition, better methods of early detection, and—last but not least—more effective drugs such as rifampicin, the formerly widespread disease tuberculosis has today become, at least in the industrialized countries, a seldom and specifically treatable illness. The times are forgotten when every seventh human being died of tuberculosis. Transients and drug addicts, that is, those social groups that are difficult to treat therapeutically, are still afflicted by the disease. Furthermore, there is the ever-present danger that bacterial strains will appear that are resistant toward antibiotics such as rifampicin. It was surprising to discover that such resistance can also arise from the blocking of the uptake of a hydrophobic drug, which ought to be able to penetrate easily the lipophilic membranes of microorganisms. The natural function of the gene that determines this behavior is still unknown. Further research is necessary to elucidate the specificity and extent of this kind of resistance.

We greatly appreciate the generous help and advice of Professor A. Böck and Professor H. Schmieger, München, Dr. D. Kamp, Martinsried, and Dr. J. E. G. McCarthy, Braunschweig-Stöckheim, in various stages of this work. The investigations from our laboratory mentioned in this paper have been supported by the Deutsche Forschungsgemeinschaft, by the Fonds der Chemischen Industrie, and by Dr. A. Pohl, Bayrol Chemische Fabrik GmbH, Martinsried.

Error Rates of the Replication and Expression of Genetic Information

By Uwe Englisch,* Dieter Gauss, Wolfgang Freist, Sabine Englisch, Hans Sternbach, and Friedrich von der Haar

Dedicated to Professor Friedrich Cramer

Biological evolution is based on continual changes in the genomes of cells. If stable organisms are to develop nonetheless in the course of this process, low error rates (high accuracy) in both the replication of genes and their transcription and translation into proteins have to be assured. The overall error rates of these processes are measurable and can be estimated: they result from the error rates of the individual enzyme-catalyzed steps. In many cases, for example in the discrimination of the amino acids valine and isoleucine during protein biosynthesis, it is not possible to achieve a sufficient accuracy only on the basis of the difference of the free energies of binding of the correct and incorrect substrates (the two amino acids differ only in a CH_2 group). The necessary low error rate is maintained by an additional proofreading step, which is carried out by the enzymes involved after formation of the enzyme-substrate complex, either during catalysis or before product release. In this step, an incorrect intermediate or product is hydrolyzed. The energy input necessary for the synthesis of the incorrect intermediate or product, which is provided by hydrolysis of adenosine or guanosine triphosphate, is the price paid for the low error rates. In this article, the proofreading mechanisms of several enzymes—mainly those involved in DNA replication and the aminoacylation of transfer RNA during protein biosynthesis—are discussed.

1. Introduction[**]

The specificity of enzymes has fascinated chemists and biologists since the early days of bioorganic chemistry. *Emil Fischer*'s "lock and key" theory of enzyme-substrate recognition was the first mechanistic model of this interaction.[1] The rapid development of biochemistry in the last few decades has resulted in increasingly detailed models of enzymatic reactions,[2-4] such as the "induced fit" theory (fitting of the active site of an enzyme to the substrate) and the "strain" theory (activation of the substrate by the enzyme). At the same time the principles of enzymatic catalysis have been evaluated using low-molecular-weight organic compounds.[5,6] The elucidation of the basic molecular mechanisms of heredity and the formation of phenotypes has stimulated the search for enzyme systems responsible for DNA replication and protein biosynthesis[7,8] (see Fig. 1). Shortly after their discovery it was demonstrated that these enzymes exhibit greater specificity[9,10] than most of the known enzymes of such important metabolic pathways as the Calvin, citrate, or urea cycles.

Phoenix, *Can. J. Biochem. Cell Biol. 62* (1984) 231.

In 1963 *Loftfield* investigated the accuracy of ovalbumin biosynthesis in hen oviduct tissue[11] and showed that the misincorporation of valine in place of isoleucine occurred with a frequency of $\approx 1:3000$. This overall error rate includes all possible errors in protein biosynthesis, from the transcription of DNA through the esterification of amino acids to transfer RNAs up to peptide bond formation at the ribosome.

The error rates of DNA replication in prokaryotic and eukaryotic cells, on the other hand, are orders of magnitude lower, as indicated by the rates of spontaneous mutation.[12,13] They occur in the range of one mutation per $\approx 10^8$ to 10^{12} incorporated nucleotides, which reflects the extreme accuracy with which the genetic code is conserved. However, this error rate does not only include the errors of the DNA polymerase, but also all other changes of the DNA sequence[14-17] that are not corrected by repair enzymes before replication starts.[18] Such changes can be caused, for example, by UV radiation (dimerization of neighboring thymidines to form a cyclobutane derivative) or by mutagenic compounds (alkylation, deamination of nucleosides.

The extremely low error rate of DNA replication, however, need not be achieved in gene expression, since in replication each nucleic acid strand is replicated only *once*, whereas in gene expression one gene is transcribed to give many copies of messenger RNA, which, in turn, serve as templates for the synthesis of many protein molecules. Both the messenger RNAs and the proteins are degraded after a short lifetime. Moreover, proteins with a wrong amino acid sequence often have a different tertiary structure which favors fast proteolytic cleavage.[19]

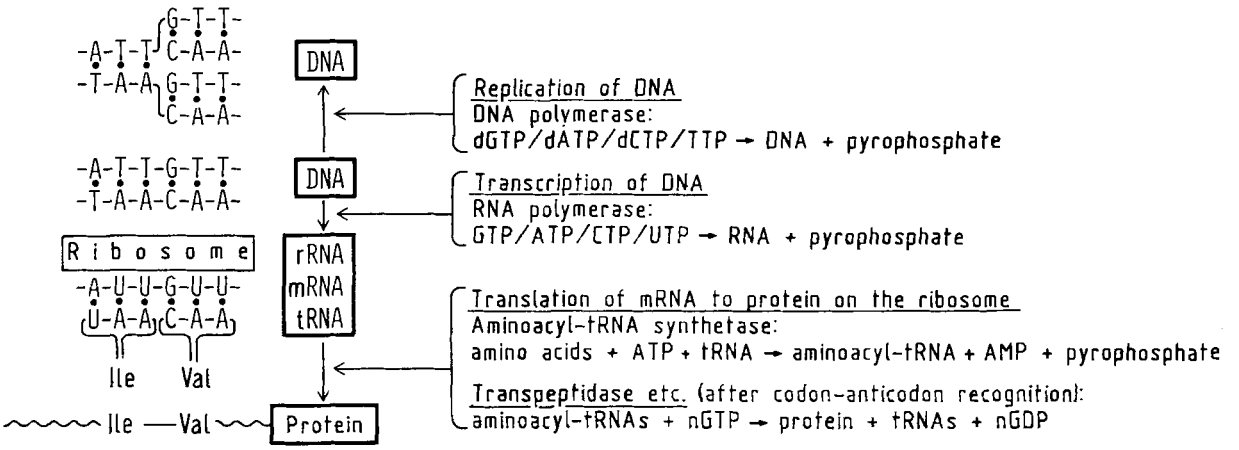

Fig. 1. Scheme of replication, transcription, and translation; some key enzymes and their reactions with energy-rich substrates are given with the reaction steps.

The expression of the genetic information is a multistep system optimized for economy and efficiency. Accordingly, the error rates of the single steps are always expected to be slightly lower than the overall error rate, which is obtained (to a first approximation) by the addition of the single error rates. However, if the accuracy of any one step is improved by a proofreading mechanism, the resulting error rate (again to a first approximation) is the product of the initial discrimination of the substrates and a proofreading factor, which is the inverse ratio of the number of errors before and after the proofreading.

2. Relevance of Error Rates in the Replication and Expression of Genetic Information

High error rates during DNA replication and protein biosynthesis would have two important consequences. First, a high (but not lethal) exchange rate for single nucleotides during DNA synthesis would generate many different mutants. This would enable organisms to adapt faster to changing environmental conditions, assuming a sufficient number of cell divisions occur. Second, the stability of the genome would be impaired and useful mutations would not be conserved. In gene expression high error rates would lead to large amounts of heterogeneous, nonspecific, functionally impaired, or even nonfunctional proteins. The consequences would range from metabolic disturbances to possible breakdown of the cell metabolism.

The accuracy of DNA replication and protein biosynthesis are coupled to each other. On the one hand, error-prone DNA replication results in a direct change of the genotype, leading to defective proteins, even if the protein biosynthesis is free of errors. On the other hand, error-prone protein biosynthesis results in DNA polymerases and other proteins that interact with DNA with low specificity. The necessity of maintaining intact replication units and simultaneously permitting a certain level of mutations led in the course of evolution to an optimized range of mutation rates. Slow and fast mutating species of one organism are known[20-23] in which the mutation rate is genetically determined or in which a specific regulation mechanism is responsible for an increased rate of mutation in a rapidly changing environment.[24]

A low accuracy in protein biosynthesis plays a major role in one of the theories of biological aging, the "error catastrophe theory" of *Orgel*.[25] Since all reaction steps of the protein biosynthesis are catalyzed by enzymes, errors in the synthesis of these enzymes lead to the biosynthesis of increasingly defective proteins, resulting finally in cell death. The error catastrophe is definitely not the only source of cell aging, but a decrease in enzyme activities and specificities might play an important role in this process.[26-31]

The severe effect of *one* point mutation in a large genome is exemplified in sickle cell anemia:[32] persons carrying homozygotic chromosomes have a shorter lifetime due to a change in the shape of their erythrocytes. This phenomenon is the result of an amino acid exchange in position 6 of the β-chain of hemoglobin, where a valine is inserted in place of a glutamic acid. The sequence CTC in the gene, which is transcribed into GAG in mRNA, codes for glutamic acid.[33] Since valine is coded for by GUG in mRNA, the corresponding sequence in the gene is CAC, indicating a T→A exchange.

Recent studies on tumor cell lines show a connection between point mutations and tumor induction: in cell lines of human bladder carcinoma, one uncorrected point mutation changes a silent proto-oncogene into an active oncogene. This one mismatch produces a glycine/valine exchange in the expression product,[34-37] which is a key factor for the transformation of the cell.

3. Error Rates of DNA Replication

The synthesis of a daughter strand of the DNA double helix is catalyzed by DNA polymerase with the assistance of many other proteins. The polymerase uses the deoxynucleotides dATP, dCTP, dGTP, and TTP as substrates, while the mother strand serves as template (Fig. 1). The enzyme does not recognize single deoxynucleotides, only base pairs formed with the pyrimidine and purine residues of the template.[38] The accuracy of this selection process is

not perfect, as the shapes and properties of the correct base pairs can be mimicked. *Watson* and *Crick*[39] suggested that amino/imino and keto/enol tautomerism of the nucleobases can reduce the specificity of DNA polymerases. The imino form of cytosine can establish the same hydrogen bonding pattern as thymine and the enol form of thymine that of cytosine, resulting in A : C(imino) and G : T(enol) base pairs. Additionally, the interatomic distances in these mismatch base pairs are the same as in the correct A : T and G : C base pairs (Fig. 2).

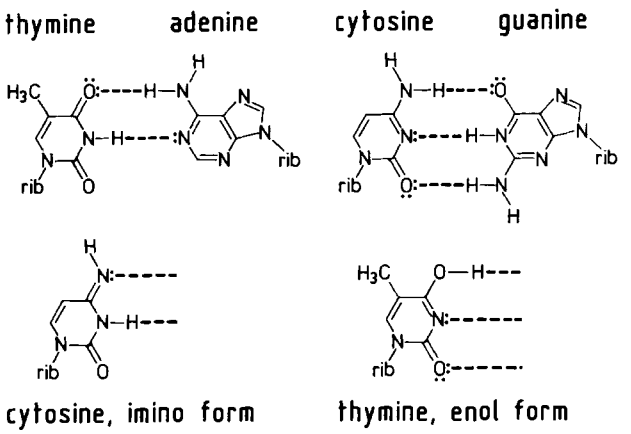

Fig. 2. Structures of thymine·adenine and cytosine·guanine base pairs in comparison with the imino form of cytosine and the enol form of thymine, which are suitable for mispairing. rib = ribosyl.

This mispairing occurs with a frequency of $\approx 1:10^4$ to $1:10^5$.[40,41] This rate is by 3 to 6 orders of magnitude higher than the frequency of in-vivo mutation of *E. coli* ($\approx 1:10^8$ to $1:10^{10}$).[42] The mutation rate in eukaryotic cells is thought to be even lower by a factor of about 100. The slower rate of replication (30 nucleotides/s versus 1000 nucleotides/s in *E. coli*) may be an indication that eukaryotic cells use more sophisticated proofreading steps before a nucleotide is finally incorporated into the daughter strand.[43,44]

3.1. Mechanism of Proofreading in DNA Replication

To maintain a low error rate of DNA replication, prokaryotic DNA polymerases have an exonuclease activity in addition to their polymerizing activity. In the case of a recognized mismatch, excision of the incorrect nucleotide takes place. Only after this proofreading step and, if necessary, incorporation of the correct nucleotide does replication continue.[44–46] The connection between polymerase and exonuclease activities was demonstrated for the first time when fast- and slow-mutating species of bacteriophage T4 ("mutator" and "antimutator" strains) were examined.[47] The exonuclease activity of DNA polymerase isolated from "mutator" phages is much lower than its polymerase activity. Therefore, the proofreading activity of this enzyme is low in comparison with that of the wild-type enzyme. Exactly the opposite phenomenon was observed with the "antimutator" phages. In further studies with DNA polymerase III from a mutator *E. coli* strain it could be shown that a mutation in the gene of the ε-subunit of the enzyme, which seems to control the exonuclease activity, is responsible for the observed high rates of mutation.[48,49]

The quantitative measurement of error rates in DNA replication—using as templates either synthetic polynucleotides in in-vitro biochemical assays[45] or DNA in in-vivo molecular genetics assays[50,51]—has shown that the error rate is reduced by a proofreading system to one mistake per $\approx 10^6$ to 10^9 polymerized nucleotides.[51–56] The proofreading system of prokaryotic DNA polymerases therefore decreases the error rate by a factor of $\approx 10^2$ to 10^4 compared with the rate of mispairing but this is still not sufficient to explain the observed rates of spontaneous mutations. A further reduction is achieved by the action of a second system, the post-replicative proofreading.

Until recently, it was thought that error correction could only occur before the incorporation of the next nucleotide because the proofreading enzyme cannot distinguish afterwards which nucleotide in the mismatch base pair was the original correct one. However, it has been shown in the meantime that specific methylation of the DNA strand, which occurs in all cell systems examined so far,[57] provides a recognition signal to differentiate between mother and daughter strands. The methylation of adenine (N^6 atom) in the sequences G-A-T-C of *E. coli* (Fig. 3) lags behind replication,[58] such that newly synthesized strands are transiently unmethylated or undermethylated. The mismatch repair system moves along the undermodified daughter strand, removes the mismatches, and replaces them with the correct nucleotides.[59–61] This mismatch repair system reduces the error rate of replication by a factor of ≈ 100 to 10000, resulting in an overall error rate of one mistake in $\approx 10^9$ to 10^{11} polymerized nucleotides.

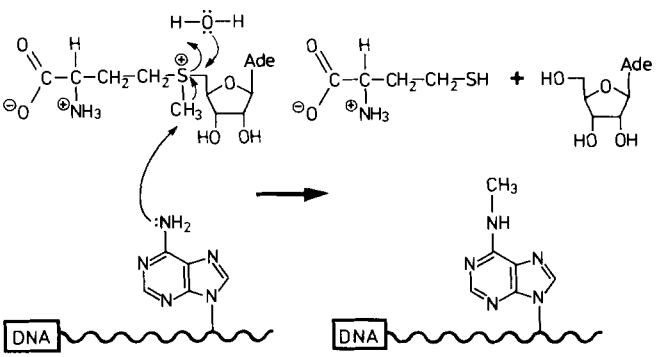

Fig. 3. Enzymatic methylation of DNA; this reaction allows the template DNA strand to be discriminated from the newly synthesized strand.

4. Error Rates of Transcription

The transcription of the genetic information from DNA into mRNA by DNA-dependent RNA polymerase does not appear to involve a proofreading system.[62–64] The observed in-vitro error frequencies with synthetic polynucleotides are in the range of one mistake per $\approx 10^3$ to 10^5 polymerized ribonucleotides;[62] for example, in an in-vivo *E. coli* system the transcriptional error of a nonsense muta-

tion is one mistake per 10^4 polymerized ribonucleotides.[64] This error frequency is the same as that predicted from the intrinsic tautomerism of the heterocyclic bases, and thus no evidence for a proofreading mechanism is detectable.

5. Error Rates of Aminoacylation of Transfer RNA

The main task of the enzymes involved in replication and transcription is to assure the correct base-pairing of nucleotides. In protein biosynthesis, on the other hand, three nucleotides (triplet or codon) of the messenger RNA (mRNA) have to be correlated to one amino acid (cf. Fig. 1). The links between these two systems are the transfer RNAs (tRNAs),[65-67] which consist of 50 to 100 ribonucleotides. In Figure 4 (bottom left), the schematic structure of phenylalanine tRNA is shown. The binding of the tRNA to the mRNA occurs by base-pairing of the three nucleotides of the anticodon with the codon of the mRNA; the corresponding amino acid is esterified to the 3′-terminal adenosine of the tRNA (cf. Fig. 1 and Fig. 4). The aminoacylation of each tRNA species is catalyzed by a specific aminoacyl-tRNA synthetase.[68-72] In this reaction, the following two selection problems arise for each of the twenty enzymes: the accurate selection of the correct tRNA from a population of at least 20—but usually ca. 70—species, and the accurate selection of the correct amino acid from 20 possibilities.[73]

The aminoacylation takes place via two successive steps known as activation and transfer (Fig. 4). The intermediate after activation of the amino acid by ATP, the aminoacyl adenylate, is a mixed anhydride. Thermodynamic considerations show that the free energy of hydrolysis of the α,β-phosphoric acid anhydride bond of ATP is largely conserved in the free energy of hydrolysis of the aminoacyl-tRNA.[71] This large amount of energy[74,75] may be necessary for the subsequent transformation of the ester linkage into a peptide linkage at the ribosome. Although the exact details of this process are still unknown, energy might be necessary for providing the correct stereochemical orientation of the macromolecules, and for assuring the high rate of elongation of the peptide (≈ten aminoacyl residues per second).

5.1. Selection of Transfer RNA

Each aminoacyl-tRNA synthetase has to select its cognate tRNA, carrying the amino-acid-specific anticodon. However, the anticodon does not seem to be the recognition site—at least not the only one—of the tRNA for the synthetase. Although many studies have been carried out, e.g., aminoacylations of chemically or enzymatically modified tRNAs, the addition of cross-linking reagents to aminoacylation reactions, the misaminoacylation of tRNAs, or the comparison of the ca. 1000 known tRNA sequences,[76] no specific recognition site on the tRNA (Fig. 4) has been unambigously identified.[65,67,68,73,77] This clearly demonstrates the complexity of the selection process, which probably changes in terms of both the recognition site and the selection mechanism from tRNA to tRNA and from organism to organism. The enzyme (consisting of 500 to 1000 amino acids) and the tRNA (50 to 100 nucleotides) offer a large number of possibilities for recognition. Taking into consideration the informational content of an anticodon or codon, a recognition sequence of six steps is reasonable if, for each of the three base pairs, two questions must be posed: Is the opposite base a purine or a pyrimidine? In the former case, is it A or G, and in the latter, U or C? Accordingly, six questions arise for a sequence of three base pairs. The results of biochemical experiments[78-80] and theoretical studies[81,69] suggest that a similar number of steps are involved in the recognition process. Probably, step by step, the cognate tRNA docks more and more tightly to the enzyme.[78-80] An important role—at least in some systems—is played by the terminal adenosine of the

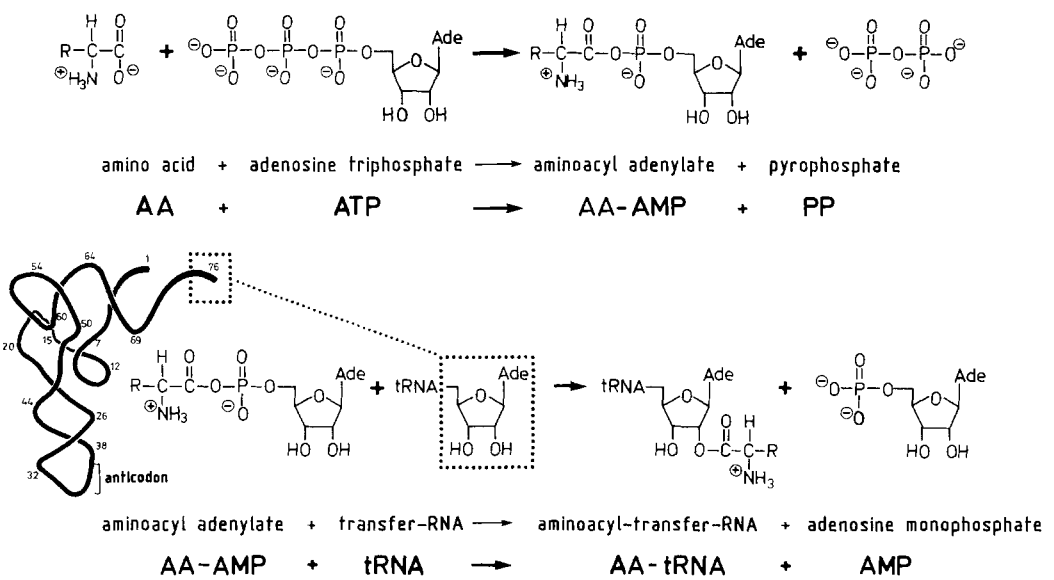

Fig. 4. The coupling of tRNAs with amino acids (aminoacylation), catalyzed by aminoacyl-tRNA synthetases, is a two-step process: the formation of an aminoacyl adenylate from an amino acid is called activation (upper reaction); aminoacyl-tRNA formation is called transfer (lower reaction). Bottom left: sugar-phosphate backbone of yeast $tRNA^{Phe}$ (76 nucleotides).

tRNA and its 2′- or 3′-hydroxyl groups,[82,83] to which the aminoacyl residue is transferred.[84-87] In most cases, this transfer specifically involves one of these hydroxyl groups; the other one—at least in several cases (see Section 5.2)—is important for the error rate of the aminoacylation. In most experiments, an error rate of one mistake per $\approx 10^4$ to 10^5 tRNA-enzyme recognitions is observed, which is in the range of the other steps of gene expression and therefore does not seem to require a proofreading step. As early as 1972/1973, however, it was demonstrated that phenylalanyl-tRNA synthetase from *E. coli* could hydrolyze misaminoacylated Ile-tRNA^{Phe}, the product of a misaminoacylation reaction using isoleucyl-tRNA synthetase;[88,89] this hydrolysis was called "verification." Detailed examination of the recognition process in the system isoleucyl-tRNA synthetase + tRNA^{Ile} + tRNA^{Val} from yeast (the close relationship of the two tRNAs is quantified by the number and kind of the ribonucleotides) recently showed that the initial discrimination of the tRNA is only $\approx 1:10$ and that an additional proofreading step is necessary to decrease the error to $\approx 1:100$.[90] In vivo the error is then diminished to $\approx 1:10^4$ to 10^5 by the presence of the tRNA^{Val}-complexing valyl-tRNA synthetase. Nothing is known yet about the mechanism of this proofreading.

5.2. Selection of the Amino Acid

In comparison to tRNAs, amino acids are very small cell constituents. In addition to their small size, some of them, e.g., glycine and alanine, phenylalanine and tyrosine, or isoleucine and valine (Fig. 5), are very similar. Therefore, it may be especially difficult for the enzyme to differentiate very accurately between the closely related amino acids.

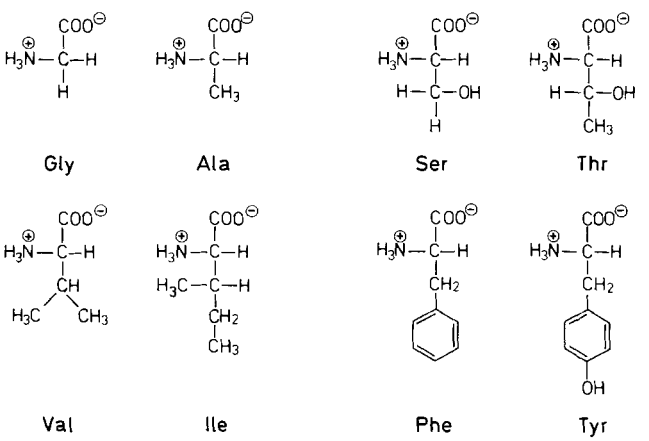

Fig. 5. Satisfactory discrimination of some amino acids by aminoacyl-tRNA synthetases requires proofreading steps. Structures of some related amino acids: glycine and alanine, serine and threonine, valine and isoleucine, phenylalanine and tyrosine.

The decisive parameter determining the ability of an enzyme to discriminate between two substrates (A and B) is the difference in the free energy of binding of the two substrates in the transition state. Under the assumption that the reaction steps involved are energetically the same for both substrates, this parameter can be calculated from relatively easily measurable kinetic parameters:[3,91]

$$(k_{cat}/K_m)_A/(k_{cat}/K_m)_B = \exp(-\Delta\Delta G/RT)$$

where k_{cat} and K_m are the turnover numbers and the Michaelis constants, respectively, of the substrates and $\Delta\Delta G$ is the difference between their free energies of binding in the transition state. According to calculations based on the London theory of electronic dispersion forces and on measurement of energy differences in binding of chemically related compounds to antibodies, *Pauling*[92,93] demonstrated in the 1950s that the free energy for the hydrophobic interaction of a methylene group with a molecule is about 4 kJ/mol. Using this result, he calculated, years before the discovery of the molecular mechanism of protein biosynthesis, that the error rate for the incorporation of glycine instead of alanine, or valine instead of isoleucine, must be about 1 : 10.[93] Although another calculation in the 1970s gave a lower error rate,[94] these numbers are very far from the error rates necessary in protein biosynthesis.

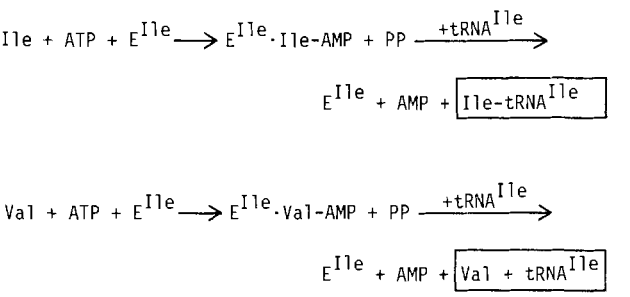

Fig. 6. Aminoacylation of tRNA^{Ile} with isoleucine by isoleucyl-tRNA synthetase (E^{Ile}, above) and misactivation of valine by the same enzyme (followed by hydrolysis to valine and tRNA^{Ile})

The difficulties predicted by *Pauling* for the discrimination between isoleucine and valine by the isoleucyl-tRNA synthetase of *E. coli* were confirmed experimentally some years later: valine is actually misactivated by the enzyme to give enzyme-bound valyl adenylate[95,96] (Fig. 6, cf. Fig. 4, top). *Berg* et al.[9,95,97,98] showed that, despite this activation, no Val-tRNA^{Ile} is obtained in the presence of tRNA^{Ile} (Fig. 6). In 1972, however, Val-tRNA^{Ile} was demonstrated to be the probable intermediate.[99] The mechanism of this reaction remained unclear for some time. The product is apparently proofread by the enzyme, and a misactivated amino acid is eliminated by hydrolysis and not released as aminoacyl-tRNA from the enzyme. The cost of this proofreading is the hydrolysis of one ATP molecule to AMP per misactivation (Fig. 6).

5.2.1. *Proofreading Mechanism of Aminoacylation*

Numerous experimental results and theoretical arguments on the mechanism of proofreading by aminoacyl-tRNA synthetases have led to different models for this phenomenon. Each of these, however, was only developed for one or a few of the aminoacyl-tRNA synthetases and, therefore, should not be regarded as general or valid in all cases. In 1974, *Hopfield* et al.[100,101] proposed a correction mechanism, called "kinetic proofreading." The main principle of this mechanism is that the discrimination between two competing substrates, according to Michaelis-Menten

kinetics, can be repeated on the level of the intermediates, resulting in an error rate that is the product of the error rates of the two steps. This argument is only valid if there is an irreversible step between the Michaelis-Menten complex and the intermediate (Fig. 7, step 2) and if this intermediate can in principal be processed in two different ways (Fig. 7, step 3 or 3'). In the aminoacylation reaction, the hydrolysis of ATP (and the subsequent hydrolysis of pyrophosphate) is regarded as an irreversible step (Fig. 7, step 2), and the enzyme-aminoacyl adenylate complex can either react to give product (Fig. 7, step 3) or dissociate from the complex and undergo hydrolysis in solution (Fig. 7, step 3'). This model is very convincing and is supported by the experimental fact that significantly increased ATP consumption is observed in aminoacylation of tRNAs with noncognate amino acids. For instance, 270 molecules of ATP are hydrolyzed before one molecule of Val-tRNA^{Ile} *(E. coli)* is formed, whereas the formation of the cognate Ile-tRNA^{Ile} only requires 1.5 ATP molecules.[100, 102–104] So far, the most persuasive experimental support for such a model is the discrimination between tyrosine and phenylalanine by phenylalanyl-tRNA synthetase.[105] This mechanism of selection is probably also of importance for other amino acids (cf. Section 5.2.2). The obvious weakness of the model is that it only deals with a proofreading mechanism on the level of the aminoacyl adenylate and does not explain what happens on the level of enzyme-bound transient misaminoacylated tRNAs, which have been detected by several groups.[99, 103, 106–108]

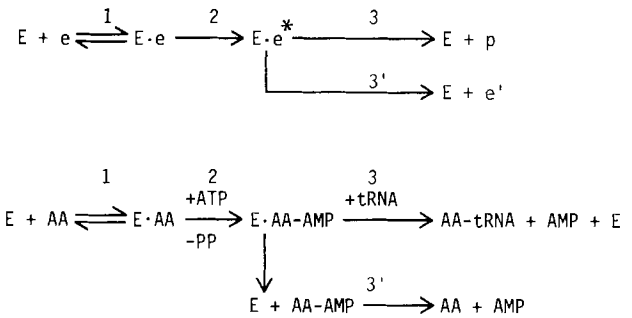

Fig. 7. A reaction scheme suitable for "kinetic proofreading" (above, taken from *Hopfield*) and aminoacylation according to this scheme (below, E = aminoacyl-tRNA synthetase).

Two other proofreading models do take into consideration these species. The double sieve model of *Fersht* et al.[109–112] is a two-step mechanical model, in which the active site acts twice as a sieve for the selection of the correct amino acid. The first sieve, the binding pocket, which perfectly accomodates the amino acid, blocks the binding of more voluminous amino acids by steric repulsion. However, smaller or isosteric amino acids are bound (albeit with lower affinity) and can react to give the aminoacyl adenylate. The second sieve acts in the following way: after transfer of the aminoacyl residue to the accepting hydroxyl group of the terminal adenosine of tRNA (cf. Section 5.1 and Fig. 4), isomerization to the nonaccepting hydroxyl group (which is close to a hydrolytic site of the enzyme) occurs if the aminoacyl residue is smaller than the correct one. The cognate aminoacyl residue cannot reach this site for stereochemical reasons and remains bound to the tRNA. The double sieve model is the result of experiments[113, 114] in which fast kinetics were used to detect the intermediates. Proofreading could be found with methionyl-,[110] valyl-,[109, 111, 115] and isoleucyl-tRNA synthetases[104, 107] from *E. coli* and *Bacillus stearothermophilus*. The authors concluded that, in the case of isoleucine,[111] threonine,[109] and α-aminobutyric acid,[115] the proofreading mechanism acts mainly after transfer of the aminoacyl residue to the tRNA, whereas valyl adenylate is hydrolyzed before the transfer step. The model could not explain, however, the activation, transfer to tRNA^{Val}, and final hydrolysis of the valine-isosteric threonine by the valyl-tRNA synthetase without further assumptions. The discrimination of more voluminous amino acids in the first sieve has been cast in doubt by the observation of a misactivation of cysteine by alanyl-tRNA synthetase.[116]

Using chemically modified tRNAs, in which either the 2'- or 3'-hydroxyl group was missing or replaced by an amino group,[117, 118] *Cramer, von der Haar,* et al.[119–121] were able to show that, at least in yeast, both hydroxyl groups act together in the proofreading.[122, 123] Besides the esterification of isoleucine with tRNA^{Ile} to Ile-tRNA^{Ile}-C-C-A (Fig. 8a), isoleucyl-tRNA synthetase also catalyzes the formation of misaminoacylated Val-tRNA^{Ile}-C-C-3'dA, which is likewise released from the enzyme. In contrast, Val-tRNA^{Ile}-C-C-A is hydrolyzed by the enzyme before release can occur.[103, 124] The model of chemical proofreading explains the hydrolysis of Val-tRNA^{Ile}-C-C-A by the assumption that the nonaccepting 3'-hydroxyl group and a water molecule—which replaces the missing methylene group—together with a nucleophilic group of the enzyme are responsible for the hydrolysis of Val-tRNA^{Ile}-C-C-A (Fig. 8b). Although the fact that one ester is hydrolyzed and the other is not can be explained quite simply for this specific case, this model cannot be easily generalized to other systems. Investigations of the valine system (Fig. 8c) showed that the hydrolysis of a mistransferred threonyl residue by valyl-tRNA synthetase (Fig. 8d) is not directly mediated by the 3'-hydroxyl group of the terminal adenosine of the tRNA.[106, 109] A possible explanation for this phenomenon would be the transient lactonization of threonine (Fig. 8d), but since the four-membered lactone product is unstable, no direct chemical proof is possible. Although a stable five-membered lactone could be formed from γ-hydroxyvaline (which is roughly the same size as isoleucine) by isoleucyl-tRNA synthetase, the enzyme does not accept this analogue as a substrate.[125, 126] However, lactones are formed in two cases where the substrate is too voluminous (in the sense of the double sieve) by one methylene group, namely from γ-hydroxyvaline by valyl-tRNA synthetase (Fig. 8e)[125, 126] and from γ-hydroxyisoleucine by isoleucyl-tRNA synthetase.[127, 128] Both reactions are enzyme-catalyzed in yeast as well as in *E. coli*. In addition, homocysteine, a precursor of methionine, is released as a thiolactone by methionyl-tRNA synthetase *(E. coli)*[108] (Fig. 8g). These examples show that an intramolecular nucleophilic attack of the hydroxyl group of the amino acid on the carboxyl group is involved in the ester hydrolysis.

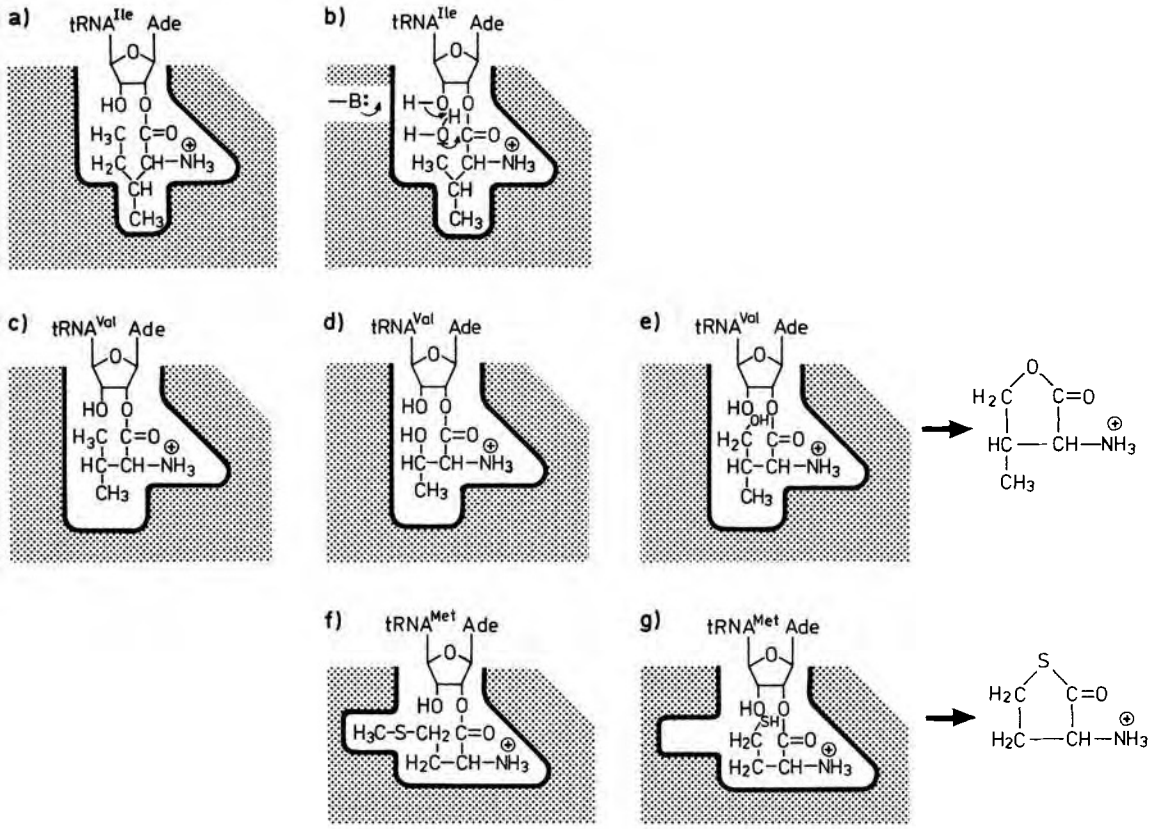

Fig. 8. Schematic representation of aminoacyl-tRNAs in the active sites of aminoacyl-tRNA synthetases: isoleucyl-tRNA synthetase and $tRNA^{Ile}$ with the amino acids isoleucine (a) and valine (b); valyl-tRNA synthetase with the amino acids valine (c), threonine (d), and γ-hydroxyvaline (e); methionyl-tRNA synthetase and $tRNA^{Met}$ with the amino acids methionine (f) and homocysteine (g).

Many other suggestions regarding the mechanism of proofreading are found in the literature, in which specific points of the reaction pathway,[129] the stability of intermediates and products,[130] the interaction of the subunits of aminoacyl-tRNA synthetases,[131] and the interaction of two tRNA molecules simultaneously bound to the enzyme are discussed[132] or high-energy conformational states of the enzyme are postulated[133] as possible ways to differentiate between correct and incorrect substrates. However, there is no conclusive experimental support for these ideas.

All measurements and calculations have in common a final error rate of about one mistake in 10^5 aminoacylations, a frequency which is ten times smaller than the overall error rate in protein biosynthesis. This is achieved by multiplication of error rates at three points: the initial discrimination of the amino acids by the synthetase, the proofreading of the aminoacyl adenylate (pre-transfer correction), and the proofreading of the aminoacyl-tRNA (post-transfer correction). Not every enzyme necessarily uses both pre- and post-transfer proofreading to select its cognate substrate. Recent investigations have shown, however, that isoleucyl-tRNA synthetase from yeast uses both steps in the discrimination between isoleucine and valine. The overall error rate, after the initial discrimination and both proofreading processes, is about 1:40000 ($10 \times 20 \times 200$).[102]

Probably, the error rates in protein biosynthesis are in the same range for all organisms, although detailed data are still lacking. What is known, on the other hand, is that the mode and extent of the proofreading step has undergone change during evolution: phenylalanyl-, isoleucyl-, valyl-, and leucyl-tRNA synthetases from different organisms show various combinations, ranging from very accurate initial discrimination and less-expressed proofreading up to sluggish initial discrimination and very accurate proofreading, which itself can be pre- or post-transfer only or a combination of both.[127, 128, 134–136] The different proofreading capacities of synthetases from *E. coli*, fungi, and mammals with respect to amino acid analogues is one possible starting point for the directed synthesis of therapeutic agents with protein biosynthesis as the specific target.[137]

5.2.2. *Aminoacylation without Proofreading*

Besides those aminoacyl-tRNA synthetases that have proofreading mechanisms (which include, according to *Fersht*,[112] those specific for alanine, valine, threonine, isoleucine, methionine, and, perhaps, phenylalanine and leucine), another class of synthetases exists for which no proofreading steps have been detected up till now. The reason for the lack of such proofreading systems is a very high initial discrimination of the amino acids, which already reduces the error rate below the overall error frequency of protein biosynthesis ($\approx 1:3000$). Examples of this type of synthetase are the histidyl-,[138] tryptophanyl-,[139] cysteinyl-,[113] lysyl-,[127] and tyrosyl-tRNA synthetases.[140] The observed error rates are in the range of $\approx 1:10^4$ to $1:10^5$ for the incorporation of tryptophan and

proline instead of histidine by the histidyl-tRNA synthetase, or of phenylalanine instead of tyrosine by the tyrosyl-tRNA synthetase. The error rate found for the activation of serine or alanine by the cysteinyl-tRNA synthetase was even lower, in the range of $\approx 1:10^8$.[113]

In the course of evolution, structures that differ sharply from those of other amino acids may have been selected for the amino acids that are directly involved in catalytic processes, e.g., histidine, tryptophan, or cysteine. The incorporation of the wrong amino acid, leading to an inactive enzyme, would thereby be avoided. Nevertheless, the above-mentioned amino acids are activated to a small extent by other synthetases.[141] In the course of evolution, therefore, the optimal balance of energy cost versus accuracy has been established for every amino acid in every protein.

6. Error Rates of Peptide Formation at the Ribosome

After release from the aminoacyl-tRNA synthetase, the aminoacyl-tRNA forms a ternary complex with the elongation factor Tu and GTP and diffuses to the ribosome. When the correct anticodon is present, the tRNA binds to the vacant aminoacyl-tRNA site with release of EF-Tu and hydrolysis of GTP to GDP. The peptidyl-tRNA, which carries the growing protein fragment, occupies the adjacent peptidyl-tRNA site. It transfers the polymer by peptide bond formation to the aminoacyl-tRNA (cf. Fig. 1). In the next step, called translocation, the deacylated tRNA leaves the peptidyl-tRNA site and the new peptidyl-tRNA binds to this site with movement of the mRNA by one triplet. After this reaction sequence, a new elongation cycle can start. Many proteins are involved in the ribosomal protein synthesis, which also requires energy provided by the hydrolysis of GTP. It is not fully known what fraction of the energy input is used for the peptide bond formation, the codon-anticodon binding, the regeneration of the helper proteins to active conformations, or for the other steps involved.[142-145]

In the course of protein synthesis errors can occur. First, the movement of the mRNA on the ribosome by two or four nucleotides instead of the usual three causes a shift in the reading frame, resulting in a completely different translation product. Second, the binding of a noncognate aminoacyl-tRNA to the mRNA leads to the incorporation of an incorrect amino acid in the translation product.

The frequency of a frameshift mutation is of the order of $\approx 1:10^4$ to $1:10^5$, a value that is in the range of the overall error rate and does not seem to require a proofreading step.[146, 147]

The binding of tRNAs that carry an anticodon with *one* mismatch with respect to the codon of the mRNA, e.g., binding of Leu-tRNA^{Leu} to a mRNA that codes for Phe-tRNA^{Phe}, however, occurs with a frequency of $\sim 1:10$ to $1:100$.[148] This unspecific binding is equivalent to the error rate in the formation of a complex of two tRNAs by base-pairing of their anticodons in ribosome-free in-vitro experiments.[149] Two proofreading models, the "time-delay" model of *Ninio*[130, 150] and the "kinetic proofreading" model of *Hopfield*[100, 101] propose dynamic processes for the rejection of incorrect aminoacyl-tRNAs after complexation to the ribosome and the mRNA. The key step in the first model is a conformational change of the tRNA, which occurs as a result of the codon-anticodon interaction; in the second model, the energy provided by GTP hydrolysis plays the major role. The experimentally proven increase in GTP consumption upon binding of noncomplementary tRNAs, which is regarded as an indication for the abortion and restart of the whole process with irreversible loss of the energy input, favors the kinetic proofreading model, but does not exclude the "time-delay mechanism" (Fig. 9).[151, 152]

In addition to these models, a third correction mechanism has been discussed, which takes place after the translocation step on the level of the peptidyl-tRNA. According to this model, incorrect peptidyl-tRNA dissociates quickly from the ribosome and is hydrolyzed by peptidyl hydrolase.[153-155] This type of correction, however, would result in a considerable energy loss, determined by the length of the fragment already synthesized: e.g., the hydrolysis of a protein containing 250 aminoacyl residues entails the loss of roughly 1000 GTPs (Fig. 9).

From the GTP hydrolysis data obtained by *Thompson* et al.[148, 151] and by *Kurland* et al.,[156] a reduction of error

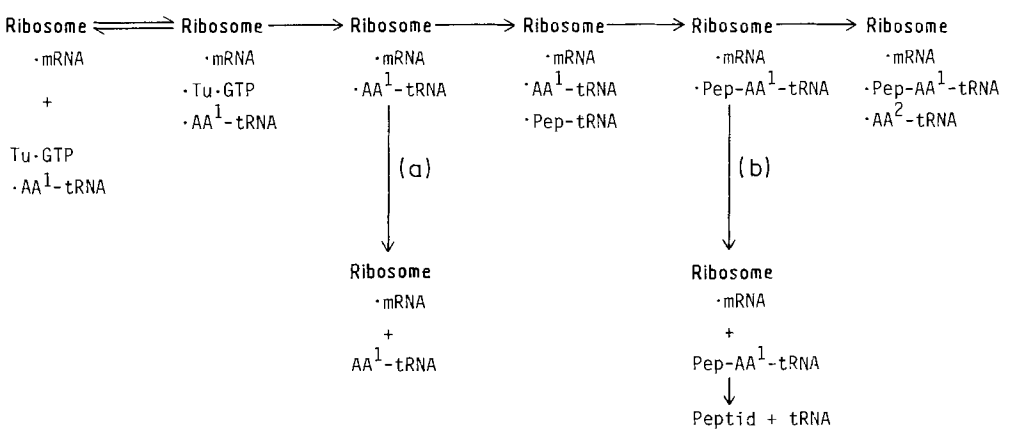

Fig. 9. The individual steps of prokaryotic ribosomal peptide synthesis including proofreading and correction steps before (a) and after (b) peptide bond formation (mRNA = messenger RNA, Tu·GTP = elongation factor·GTP complex, AA-tRNA = aminoacyl-tRNA, Pep-tRNA = peptidyl-tRNA).

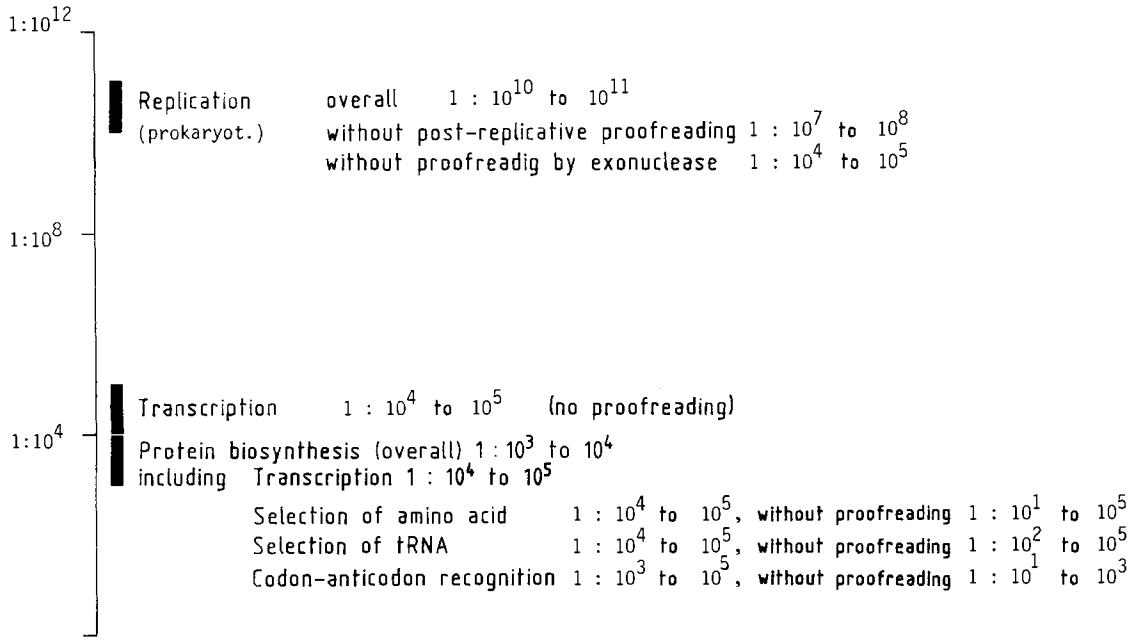

Fig. 10. Schematic display of average error rates of some reactions of replication and gene expression. The error rates given are averages of in-vitro measurements; error rates measured for a particular enzyme and a particular substrate may deviate considerably. The corresponding in-vivo error rates may also deviate considerably.

rates by a factor of ≈ 100 to 1000 may be ascribed to the proofreading, resulting in an overall error frequency for the peptide bond formation of $\approx 1:10^4$ to $1:10^5$.[157-159] The proofreading system of the ribosomes can be blocked by antibiotics, leading to increased error rates and a loss of GTP hydrolysis.[160] Furthermore, different ribosomal mutants exist which allow the binding of incorrect aminoacyl-tRNAs or inaccurate peptide bond formation to occur owing to mutations in ribosomal proteins.[161,162] However, nothing is known yet about the structural changes of the ribosomal proteins induced by the binding of antibiotics or by specific mutations.

7. Outlook on Solved and Unsolved Problems

In the absence of an efficient proofreading mechanism, DNA polymerases would work with error rates of $\approx 1:10^4$ to $1:10^5$; aminoacyl-tRNA synthetases, which have to discriminate between very similar amino acids, would work with error rates of $\approx 1:10^1$ to $1:10^2$, and the ribosomal protein synthesis apparatus would work with error rates of $\approx 1:10^1$ to $1:10^2$ (Fig. 10). The proofreading systems lower the error rates of prokaryotic DNA replication to $\approx 1:10^9$ to $1:10^{11}$, and in eukaryotic cells even to $\approx 1:10^{12}$. All reactions involved in the expression of the genetic information show error rates of $\approx 1:10^3$ to $1:10^5$. The overall error rate of protein biosynthesis, 1:3000, determined by *Loftfield*[11] in 1963, has been confirmed in different systems.[163-165] The latest data seem to indicate an additional dependence of the error rates on the speed of protein synthesis and on the codon used.[166-169]

In all cases examined so far, the energy-dependent correction systems lead to a reduction of error rates by a factor of ≈ 100 to 1000. If an even higher factor is necessary, an additional system, requiring further energy, has to be established, like the postreplicative proofreading of DNA replication.

The basic mechanisms accounting for the extremely high accuracy of DNA replication and protein biosynthesis were phenomenologically discovered, but there is still a lack of information about the chemistry of these mechanisms. Preliminary results of the X-ray analysis of a tryptic fragment of methionyl-tRNA synthetase *(E. coli)* and of tyrosyl-tRNA synthetase *(Bacillus stearothermophilus)* have been published.[170,171] In both structures, the shape of the amino acid binding site is clearly visible, but the carboxy terminus of nearly 100 amino acids is either missing or disordered in the electron density map. Although a high degree of homology in the amino acid binding sites of these aminoacyl-tRNA synthetases is present, the correlation of amino acids with the correction systems is still impossible. Deeper insight is expected from "site-directed mutagenesis" experiments,[172] such as those already carried out with tyrosyl-tRNA synthetase.[173] However, the tRNA binding site and the mechanism of transfer of the aminoacyl residue to the tRNA remain unclear due to the lack of the carboxy terminus in the X-ray structures.[174,175] For $tRNA^{Phe}$ and $tRNA^{Asp}$, however, the enzyme-binding regions have been characterized thoroughly.[176]

All experimental examinations and theoretical considerations of error rates of enzymes lead to the following principle: sufficient accuracy is not possible without energy input; infinite accuracy would require infinite amounts of energy. Data measured so far, showing an economic compromise between these extremes, correlate increasingly better with detailed mathematical models.[63,177-180] The flux of components, energy, and information has many characteristics of a system that works far from chemical equilibrium.[181]

The authors wish to thank Professor Dr. R. B. Loftfield and Dr. J. Taylor for critically reading the manuscript.

The Role of Hydrothermal Synthesis in Preparative Chemistry

By Albrecht Rabenau*

"Hydrothermal synthesis" usually refers to heterogeneous reactions in aqueous media above 100°C and 1 bar. The previously common distinction between hydrothermal conditions below and pneumatolytic conditions above the critical point is no longer made, since no discontinuities are observed upon exceeding the critical conditions. Under hydrothermal conditions, reactants otherwise difficult to dissolve go into solution as complexes, in whose formation water itself or very soluble "mineralizers" can participate. Thus, one can obtain the conditions of chemical transport reactions,[1] of which hydrothermal syntheses can be considered a special case. During recent decades in the geological sciences—in which the method is also historically rooted—it has received a strong impulse, whose effect on preparative solid state chemistry is discussed here.

1. Introduction

An excellent example of hydrothermal conditions, i.e. an aqueous medium over 100°C and 1 bar, is supplied by nature. Numerous minerals have formed under these circumstances. Through simulations in the laboratory, geologists and mineralogists have already been able to determine the conditions necessary for mineral formation and have thus contributed to the knowledge of geological processes. Even today hydrothermal investigations remain important in the field of geological sciences. In industry hydrothermal processes play a role in the concepts of hydrometallurgy, e.g. the classic Bayer process for the decomposition of bauxite. Hydrothermal conditions occur also in heating power stations and are the cause of many corrosion phenomena. The method was introduced into modern solid state research after World War II. Encouraged by the industrial preparation of quartz oscillator crystals, which was stimulated by *Nacken*, interest centered on the growth of extremely pure crystals with interesting physical properties and of sufficient size for the measurement and utilization of these properties. These requirements have left the unusual possibilities of this method for preparative solid state chemistry in the background, despite the great success of this concept in the past. Here the extreme requirements for purity, size, and perfection, e.g. those demanded in semiconductor physics, are avoided; i.e. the size necessary for a crystal structure determination, as a rule, lies orders of magnitude lower than that required for the measurement of other properties. Through the use of synchrotron radiation sources the volume necessary for crystal structure determinations has recently been lowered still further.[2] The present article deals with the use of hydrothermal synthesis in materials synthesis. It is shown that hydrothermal synthesis can be considered as a special case of chemical transport reactions. Thus, as a rule, a chemical reaction is combined with a transport process, as in SiO_2 transport:

$$SiO_{2(s)} + n\,H_2O_{(g)} \rightleftharpoons (SiO_2 \cdot n\,H_2O)_{(g)}$$

For sparingly soluble compounds with high melting points, a highly soluble transport substance ("mineralizer" in hydrothermal terminology) is added to increase the "solubility".

Hydrothermal synthesis, in contrast to conventional synthetic methods, offers a number of advantages, as can be shown by a few typical examples:

1. Compounds with elements in *oxidation states that are difficult to attain*, especially important for transition metal compounds, can be obtained in closed systems by hydrothermal synthesis. Ferromagnetic chromium(IV) oxide (Section 5) is produced by the oxidation of Cr_2O_3 with an excess of CrO_3 as follows:

$$Cr_2O_3 + CrO_3 \xrightarrow[H_2O]{350\,^\circ C,\ 440\ bar} 3\,CrO_2 \quad \text{and}$$

$$CrO_3 \xrightarrow[H_2O]{350\,^\circ C,\ 440\ bar} CrO_2 + 1/2\,O_2\uparrow$$

The decomposition of the excess CrO_3 leads to a build-up in the oxygen pressure, which stabilizes CrO_2 in relation to water at the high reaction temperature (Section 7). The product is produced in one step; it is very pure, since the only other reaction product is oxygen, and it forms uniform crystals.[3]

2. The hydrothermal method is also useful for the so-called *low-temperature phases*. Crystals of the zinc blende (γ)-phase of CuI (m.p. 605°C), important for its optical-electronic properties, can be obtained from solutions containing HI below the transformation temperature of 390°C. At these low temperatures chemical transport reactions through the gaseous phase are no longer a concern.[4]

3. *Metastable compounds*, such as the subiodides of tellurium Te_2I and β-TeI, are formed by the tempering of tellurium-rich probes in hydriodic acid *in a temperature gradient* of 265/280 or 192/198°C, respectively, and subsequent lowering of the temperature. Characteristic of the structure of the needle-forming crystals are infinite chains of tellurium atoms, which are obviously formed in the solution.[5] The syntheses of these low-temperature phases and metastable compounds can be conducted quite simply in glass or quartz glass ampoules. Numerous other examples are given in the text.

In recent decades a series of review articles have appeared that treat hydrothermal synthesis chiefly from the point of view of the geological sciences or crystal growth,[6] through which the original works can be followed. In this article, original papers are cited only insofar as they relate directly to the theme at hand.

2. Historical Development

Dates important in the development of hydrothermal synthesis are listed in Table 1. Probably the first clue was found by *Schafhäutl*,[7] when he observed quartz microcrystals upon transformation of freshly precipitated silicic acid in a Papin's digestor. *Bunsen*[8a] described the use of thick-walled glass (or barometer) tubes; "*so that in liquids an easily measurable pressure of 100–150 atmospheres can be generated without any danger.*"[8b] In this way, through cooling an ammoniacal solution from 200°C and 15 bar, he obtained millimeter-long crystalline needles of $BaCO_3$ and $SrCO_3$.[8b] Thus, this experiment was the forerunner of visual hydrothermal synthesis, which has acquired still greater significance today. The introduction of hydrothermal synthesis in its modern form into geological science is ascribed to *de Sénarmont*.[9] As a method for laboratory investigations of the hydrothermal formation of minerals, it plays an important role to this day. For a reaction vessel he used sealed glass ampoules (Fig. 1), which were placed in

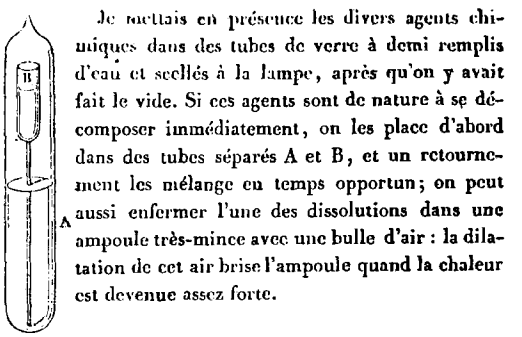

Fig. 1. Excerpt from the publication of *de Sénarmont* [9]. The ampoule B prevents the solutions from mixing with each other before A is sealed off.

an autoclave to avoid explosion. For autoclaves he used gun barrels (partially filled with water), which after being welded can be heated to a dull red glow. In spite of numerous breakdowns, he synthesized in this fashion a great number of oxide, carbonate, fluoride, sulfate, and sulfide minerals, including proustite, Ag_3AsS_3, which, because of its electronic properties, plays a role in modern solid state physics.

In the following years the method became widely used, especially in France.[10] By 1900 about 80 silicate minerals were synthesized in this way.[11] The use of sealed glass ampoules, which are heated in an autoclave to protect against explosions, was subsequently developed further by *Allen, Crenshaw*, and *Johnston*,[12] and by *Rau* and *Rabenau*,[13] and is especially suited for preparative work in neutral to acidic solutions. The introduction of corrosion-resisting and thermostable alloys was decisive in the development

Table 1. Hydrothermal Synthesis: Dates.

Year	Name	Arrangement	Comments	Ref.
1845	*Schafhäutl*	Papin's digestor	quartz microcrystals	[7]
1848	*Bunsen*	thick-walled glass tubes	carbonates; forerunner of the visual autoclaving	[8b]
1851	*de Sénarmont*	glass ampoules in autoclave	mineral carbonates, sulfates, sulfides, fluorides; founder of hydrothermal synthesis in geological sciences	[9]
1873	*von Chrustschoff*	noble metal lining	protection against corrosive solvents	[15]
1914	*Morey*	Morey-type autoclave	"closed" system; standard	[14]
1923	*Smith, Adams*	internally heated autoclave	very high pressures and temperatures: ≥ 10 kbar, ≥ 1400°C	[35a]
1943	*Nacken*	foundation for the industrial quartz growth	introduction of hydrothermal synthesis into solid state physics	[61]
1949	*Tuttle*	"cold seal" or test tube arrangement	external pressure regulation and measurement. More extensive working range than *Morey*. Standard	[16]
1973	*Capponi*	modified belt apparatus	extremely high pressures and temperatures: ≥ 100 kbar, ≥ 1500°C	[36a]

of apparatus for hydrothermal synthesis, and led to the version suggested by *Morey*,[14] which was to become the prototype of the so-called "closed" system. *von Chrustschoff*[15] had already introduced the autoclave lined with non-ferrous or noble metals (which in many cases cannot be dispensed with) by furnishing the autoclave with a galvanic gold lining. Besides the Morey principle, the "cold seal" technique[16] is a standard method today, while the techniques developed for the highest pressures and temperatures have remained confined to specialized laboratories. With the appearance of better materials, special techniques have been developed, such as those for the growth of large crystals (*Spezia*[17]). Around the turn of the century the focal point of activity shifted to Germany, Austria, and the USA, but remained the domain of geological scientists until the beginning of World War II.[18]

3. Water as a Reaction Medium

The physical and chemical properties of water and aqueous solutions in the pressure and temperature ranges required for hydrothermal syntheses are well known. These have been discussed in numerous review articles that have appeared in the last few decades, from which the original works are easily accessible.[19] This paper limits itself to a discussion of the properties which are important for the characterization of water and aqueous solutions. The pVT data for water up to 1000°C and 10 kbar are known accurately enough—to within 1% error.[19i, 19j] Figure 2 shows a temperature-density diagram of water, with pressure as a parameter. Within this range the ion product increases sharply with pressure and temperature. At 1000°C and 10 kbar, $-\log K_w = 7.85 \pm 0.3$, and there is evidence that water

at 150—200 kbar and 1000°C has a density of 1.7–1.9 g cm^{-3} and is completely dissociated into H_3O^+ and OH^-, behaving like a molten salt, isoelectronic with NH_4F or NaOH.[19i]

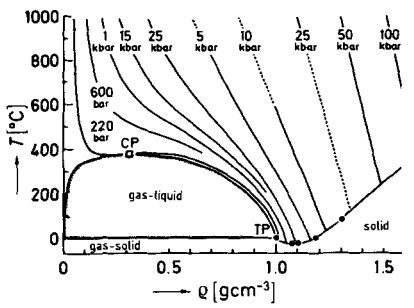

Fig. 2. Temperature-density diagram of water. The dotted isobars are interpolated. To maintain a density of 1 g·cm^{-3} at 500°C, a pressure of 9 kbar is required; at 1000°C, 20 kbar is required [19f]. CP and TP signify critial point and triple point, respectively.

The viscosity decreases with temperature, at 500°C and 100 bar amounting to 10% of its value under normal conditions.[19f] Hence, the mobility of molecules and ions in the supercritical range is much higher than under normal conditions.[19d] When using water as a solvent the dielectric constant is important. This decreases with rising temperature and increases with rising pressure, the temperature effect predominating[19e] (Fig. 3). The high dielectric constant typical of water is confined to a small region of rather low temperatures and high densities (pressures), although even in the supercritical region there is a large range where the dielectric constant is between 10 and 25–30.[19h,20] Electrolytes which are completely dissociated under normal conditions will therefore tend to associate with rising temperature,[21] and for a large number of substances this transition lies between 200 and 500°C.[22]

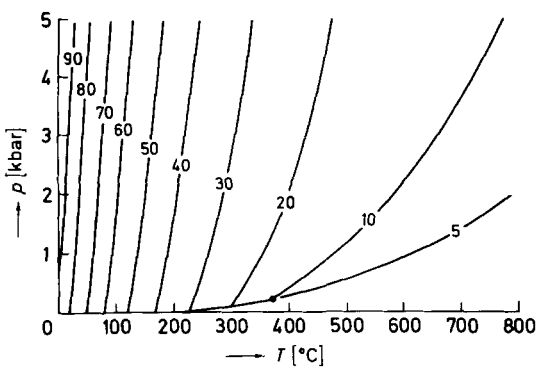

Fig. 3. Variation of the dielectric constant of water with temperature and pressure. The point • is the critical point of water [25].

Figure 4 shows a plot of the dissociation constants of NaBr. Under constant pressure they decrease with rising temperature, while with constant temperature they increase with rising density—and thus with pressure. Since in this region the ion product of water increases sharply,

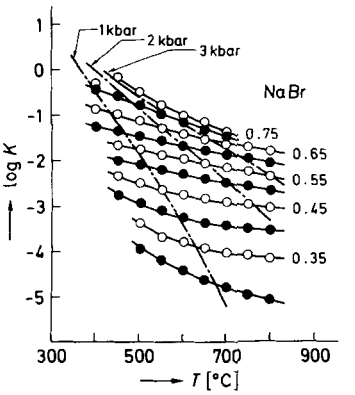

Fig. 4. Logarithm of the dissociation constant of NaBr as a function of temperature at constant density (g·cm^{-3}) or pressure [21]. The black circles denote the intensities 0.30–0.70.

hydrolytic reactions are favored. Thus, the equilibrium constant of the reaction

$$Cl^- + H_2O \rightleftharpoons HCl + OH^-$$

at 500°C and 2 kbar is about nine orders of magnitude greater than under normal conditions.[19j]

For experimental hydrothermal synthesis the PT diagram of water is important (Fig. 5). The pressure prevailing under working conditions is determined by the degree of fill, i.e. by the volume of the reaction vessel that was originally filled with solvent. With a degree of fill above 32%—0.32 g cm^{-3} is the critical density—the fluid-gas meniscus is curved upwards and the reaction vessel is completely filled with the fluid phase below the critical temperature of 374°C; e.g. with a degree of fill of 80% at 245°C. With a degree of fill below 32% the behavior is reversed, although such low degrees of fill are only seldom used, e.g. in dehydration processes (Section 4.3).

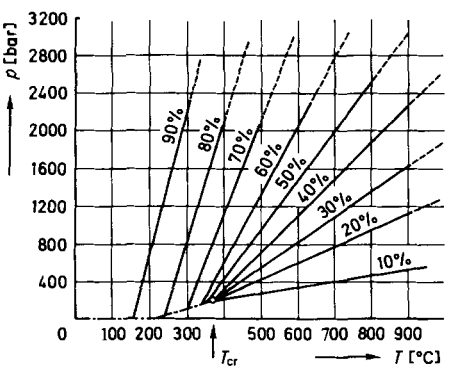

Fig. 5. The diagram relates to pure water, and shows pressure as a function of temperature, with the filling factor (degree of fill) of the autoclave as a parameter. The filling factor is usually between 50 and 80% and the pressure between 200 and 3000 bar. The chain-dotted line is the equilibrium line of vapor and liquid, T_{cr} is the critical temperature [6j].

Today, the concept of hydrothermal synthesis covers the entire region above room temperature and 1 bar. The distinction formerly made in geology between a hydrothermal regime below the critical temperature and a pneumatolytic one above it has been discarded, since scarcely any discontinuities in the behavior of the solution at the transition have been observed.[23a,23b] Moreover, the vapor pressure

over aqueous solutions is in general less than that over pure water, and the critical point is shifted to higher temperatures. With concentrated solutions the critical temperature can be several hundred degrees above that of pure water.[24] Because these critical temperatures are not known for the usually complex solutions at hand, one cannot distinguish between sub- and supercritical systems for reactions below 800 °C.

For hydrothermal reactions a minimum solubility of 2–5% for the least soluble component is necessary.[6d] Figure 6 shows an isobaric section of the pressure-temperature-concentration diagram of water and a very slightly soluble component A with a melting point much higher than that of ice. The region of conventional hydrothermal syntheses is shaded. The reason for the comparatively low temperature region arises from the limits imposed by the autoclaves. Under these conditions the required solubility in pure water is usually not obtained. Therefore, readily soluble components such as acids, bases, or other complex-forming substances are also added. These substances, known in geology as "mineralizers", form other, more soluble complexes than does pure water.[6d,i,o,s,25]

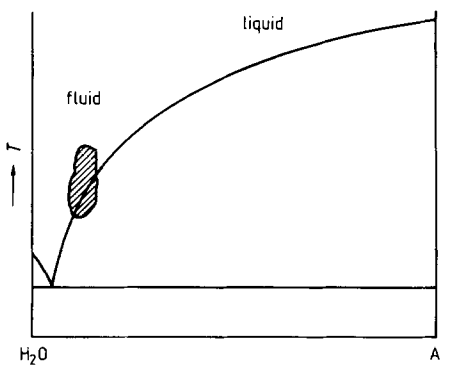

Fig. 6. Isobaric section from the pressure-temperature-concentration diagram of water and a very slightly soluble substance A above the critical pressure (schematic). The region of conventional hydrothermal synthesis is shown cross-hatched [6g].

Our current knowledge of the thermodynamic properties of aqueous solutions at high temperatures and pressures is summarized in review articles by *Helgeson*,[21] *Cobble*,[26a] and *Khodakovsky*;[26b] in the last-mentioned article numerous Russian contributions, often difficult to obtain, are treated.

4. Experimental

4.1. Autoclaves

To withstand the pressures involved in hydrothermal syntheses, the use of autoclaves is usually required. They serve to protect the reaction vessel; often the autoclave itself assumes the role of reaction vessel. A great number of papers exist concerning accessories for hydrothermal syntheses at high pressures and temperatures. The early summaries of *Eitel*[27a] and *Koenigsberger*[27b] contain many useful suggestions; the state of the art is summarized in a number of more recent reviews.[6c,l,p,r,28] Although there are numerous types of autoclaves for specialized uses, for preparative purposes they are limited to a few basic types.

The type first devised by *Morey*[14,29a] and subsequently further developed by him and his co-workers[29b] is the most suitable arrangement for work up to 400 °C and 400 bar because of its easy manipulation. The entire autoclave, including the joint, is placed within the oven; it can be operated with temperature gradients as well as isothermally. The autoclaves are best made of tool steel, with flat sealing surfaces (Fig. 7). This allows a complete lining with noble metals, so that the autoclave itself can serve as the reaction vessel. If the experiment is to be conducted with an ampoule inserted into the autoclave, then conical joints can also be used, which suffice up to 500 °C. Simple models for noble-metal linings have been described.[30] Appropriate arrangements for insertion of glass or quartz ampoules are dealt with in Section 9.

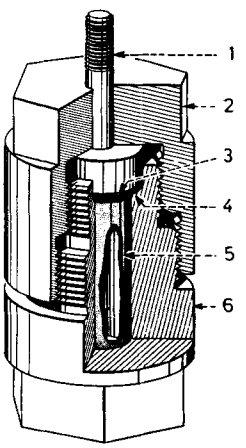

Fig. 7. Autoclave with flat sealing surface. 1) Upper part of the plunger-shaped lock (tools to withdraw the plunger have to be screwed on the thread); 2) hexagonal lock part, attached by wrench (for this the lower hexagonal head at the bottom of the autoclave is inserted into a stationary mount); 3) gasket ring; 4) bulging support on the reaction chamber for the gasket ring; 5) reaction chamber (diameter: 2.5 cm); 6) autoclave mantle [6p].

The simple arrangement of the Tuttle "cold seal" device[16] consists of a steel cylinder, into which an axial opening is drilled. The closed end is inserted in the oven, while the seal—in the simplest case with a conical joint—remains on the outside (hence the term "cold seal", although the temperature of the seal can still be several hundred °C). In order to ensure a tolerable temperature at the seal—and without making the autoclave too long—it can be provided with a water cooler.[6g,31] In contrast to the Morey arrangement, ampoules serve as reaction vessels and the pressure in the autoclave must be regulated externally, e.g. by a compressor system (Fig. 8). Autoclaves based on this principle,[6a,g,r,32,33] by utilizing Stellit 25, are operable up to 5000 bar at 750 °C, and also at somewhat higher temperatures with lower pressures. The use of René 41 enabled an extension of the working range (900 °C, 2 kbar). The names refer to cobalt- or nickel-based alloys.[6r,33] Commercial equipment[34a] for serial experiments up to 1100 °C and 3 kbar, with the name TZM-Apparatus, originate from an arrangement devised by *Williams*[34b] (Fig. 9).

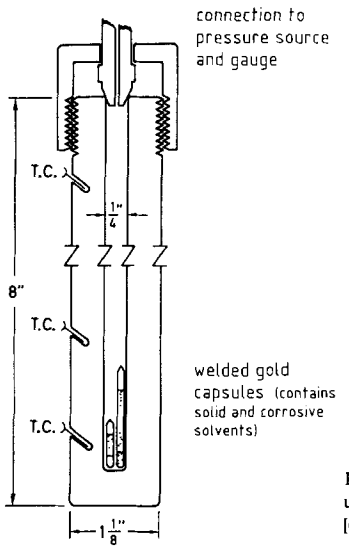

Fig. 8. "Cold seal" autoclave. The upper part lies outside the furnace [6g]. T.C.: thermoelement.

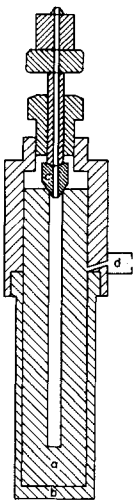

Fig. 9. TZM-autoclave with inert gas flushing. a) Autoclave body of TZM-(molybdenum) alloy; b) protective mantle of Inconel 750 (nickel alloy); c) conical seal; d) inlet vent for inert gas [6r].

For most practical purposes, the arrangements of *Morey* and *Tuttle* are satisfactory. More demanding requirements necessitate considerably greater experimental effort.

At higher temperatures it becomes necessary to cool the autoclave; therefore the heater, in the form of a small oven, is placed in the interior of a water-cooled steel jacket. One such arrangement was described by *Smyth* and *Adams* in 1923[35a] and was subsequently developed further by other workers.[35b] The pressure and temperature conditions which are thus achievable usually require a gas as the pressurizing medium. A detailed description of an internally heated autoclave, including pressurizer, was given by *Holloway*.[35c] Commercial devices with pressurizers, capable of being operated at 1400°C and 10 kbar, are available.[34a]

In recent years, the Belt technique has been used for conducting hydrothermal syntheses up to 1500°C and 100 kbar.[36a] Cylindrical platinum cells, 4 mm in diameter and 6 mm high, serve as the reaction vessels. Under these extreme conditions a series of new crystalline phases have been produced.[36b] A further variation using Teflon as a material was designed by *Herdtweck*[36c] for studies with hydrofluoric acid at 250°C and 30 kbar.

A great number of special autoclaves have been developed,[6m, u, 19e, 20, 37, 38] chiefly for investigations in physical chemistry. Generally, however, they play a minor role in preparative studies, and, as a rule, they necessitate considerable experimental effort.

4.2. Material Selection

The materials chosen for the vessel play an important role in hydrothermal reactions.[6c] Thus, the corrosive properties of the solution under the desired conditions, as well as the danger of undesirable contamination of the reaction product must be considered. Only in a few propitious cases, when using low-carbon steels, can the autoclave walls themselves serve as the reaction vessel. In NaOH-containing solutions this comes about through the formation of a protective surface layer of almost insoluble acmite, $NaFe(Si_2O_6)$. This is of importance for growing industrial quartz crystals, since in this environment the quality of the crystal is not affected. The liberation of hydrogen, associated with the formation of iron oxides, can lead to a build-up of hydrogen pressure (which must be remembered when opening the autoclave) as well as to hydrogen corrosion. As a rule, other materials must be considered. Unfortunately, the corrosion behavior of materials under hydrothermal conditions is not well known. Thus, it has been found that at 400°C copper and nickel in particular, and also titanium, vanadium, chromium, and iron are attacked by alkaline solutions. In the presence of solutions which contain sulfur, selenium, tellurium, arsenic, antimony, or bismuth, glass and quartz glass (in neutral or acidic medium), as well as graphite, titanium, and especially Teflon have been found suitable.[31] In the insertion of vessel materials a distinction is made between a lining and the so-called "floating insert".[6t] In the first case, the interior walls of the autoclave are completely lined with the vessel materials, generally a metal of sufficient ductility. Thus, the autoclave directly bears the pressure arising in the reactor chamber. The use of ampoules is required with nonductile materials such as glass, quartz glass, carbon, etc., and is also preferred with the insertion of metallic vessel materials. However, only a part of the autoclave volume is thereby used. Therefore, care must be taken that a large gradient between the pressure within the reaction container and that existing in the autoclave does not come about.

Borosilicate and quartz glasses are quite stable towards neutral and acidic solutions with the exception of hydrogen fluoride. This is also true for corrosive oxidizing media. The redox potential (Section 8) is hardly affected, and the danger of contamination by metallic impurities is slight. This last point plays an especially important role if the reaction product is to be subjected to physical measurements. Thus, in a neutral or acidic medium, glass or quartz glass are well-suited for hydrothermal syntheses, provided the pressure and temperature conditions permit it, and their possibilities have by no means been exhausted.

Glass and quartz glass have a great advantage in that, within a limited pressure and temperature range, the experiment can be directly observed. The maximum pressure

depends on the diameter of the ampoules, the strength of the walls, the temperature, and the mechanical properties of the glass being used.[39a] Thick-walled glass tubes can withstand a pressure of several hundred bars;[39b] this was exploited by *Bunsen*.[8a] The useful range for borosilicate glasses at higher temperatures is limited to 250–300°C. Quartz glass—despite its high softening point of around 1200°C—is only usable up to about 500°C, since at higher temperatures the walls are attacked. For visual autoclaving, safety precautions should be taken, such as working sufficiently below the bursting pressure—tabulated in [39b]—and the use of a safety shield of bulletproof glass or Plexiglass. For the observation of processes in the ampoules under specific temperature conditions, a suitable apparatus developed for the control of crystal growth can be used.[40a, 40b]

If the pressure-temperature range for visual hydrothermal synthesis is exceeded, the ampoule must be placed in an autoclave along with a pressure compensation, in order to prevent an explosion. Although the observability is thereby lost, the other advantages remain. An arrangement especially suited for preparative purposes, based on the method of *de Sénarmont*, was developed in the Philips Research Laboratory[13] and was used for the synthesis of a great number of previously unknown compounds[6j] (Section 9).

Experimental details of this method are described elsewhere.[41] Quartz glass ampoules for hydrothermal investigations are also described by *Speed* and *Filice*.[42] With the dimensions reported by the authors the experimental bursting points at 500°C lie above 300 bar. Although developed for batch experiments—ten or more ampoules heated simultaneously under the same conditions in the oven—the ampoules should also be suitable for visual hydrothermal synthesis. The pressure characteristics for sealed quartz glass ampoules up to 1000°C are reported by *Holland*.[43]

From the standpoint of behavior towards corrosion, Teflon is the ideal container material.[6r] Besides its resistance to hydrofluoric acid, Teflon is, in contrast to glass and quartz glass, also stable in alkaline media. Unfortunately, Teflon is only usable within a limited pressure-temperature range. Since it tends to be porous, only isostatically treated, potentially pore-free material (PTFE) can be used. Above 150°C the creep behavior becomes a problem.[44a] Autoclaves with Teflon inserts[44b] have found numerous uses as digestion bombs and are commercially available: they can be used at 200°C and 200 bar.[44c] There are units based on the same principle capable of operating at 275°C and 350 bar.[44a] Temperatures of 300–350°C can be reached if Teflon is used as a floating insert.[6m, 31, 45] Teflon seals are also used in combination with metallic inserts.[37, 46]

Inserts of pyrolytic graphite should prove useful for sulfur-containing solutions.[31] Glassy carbon[47a, 47b] has shown even better properties (permeability, etc.).[47c]

The choice of metal for the reaction vessel depends primarily upon its compatibility with the reactions being studied and, under some circumstances, upon its permeability towards hydrogen (platinum and silver-palladium alloys). Ductile metals are suitable for lining autoclaves, with no problems of mechanical stability arising. This use is limited to autoclaves of the Morey type (Section 4.1), in which the seal can also be lined. Thus, a tight seal is obtained through the cold weld effect. More common is the use of floating inserts, either as a closed crucible—in which the autoclave lid can be the cover—or as an ampoule. In both cases the possibility of a pressure gradient between the interior and the exterior must be considered; such a gradient can lead to explosion of the reaction vessel. In the case of ampoules, a simple bend is sufficient only in cases where the escape of just the solid components is to be prevented; usually the volatile constituents can equalize themselves. Complete sealing of the ampoule requires material-specific practice. Welding equipment and techniques have been described.[33] In many cases the internal pressure arising from the filling causes problems. This can be minimized by thorough freezing during the welding process[48a] or can be eliminated through the use of the cold weld technique.[48b] Ampoules of aluminum and copper can be sealed relatively simply by this last method. In addition to the works cited in the previous sections concerning the use of metals, mention should also be made of titanium,[37, 45, 46] platinum,[6c, 46] silver,[6c] and gold.[49]

4.3. Methods of Hydrothermal Synthesis

The methods developed in the last couple of decades for hydrothermal synthesis served chiefly for single crystal growth, but they are also of significance regarding preparative aspects. They are dealt with in several articles,[6m, t, u] wherein it is stated that hydrothermal crystal growth is a special type of chemical transport reaction,[1] the principles of which are immediately perceivable.

Isothermal methods include all arrangements in which no temperature gradient is deliberately introduced. This method is usually adequate for preparative purposes which do not require great transport efficiency and is of simple experimental application.

In the standard method for crystal growth, the *temperature gradient method*, the reaction products are transported from a region of higher solubility to one of lower solubility, usually from hot to cold. In the case of retrograde solubility the direction of transport is reversed, as for instance with elements.[50] A reverse in the direction of transport upon change of solvent has also been observed, as in the transport of ZrO_2 and TiO_2 in NaF (or KF) compared to that in NH_4F.[51] Since a temperature gradient leads to the separation of the reaction products, which facilitates their isolation, this method is also quite suitable for preparative work. It has been observed that certain—metastable—phases are formed only in temperature gradients.[5, 52] An arrangement for extreme temperature differentials[6t, 53] and for a spatial separation of the solution zones[54] has been described.

The *temperature-decrease method* is a variation of the temperature gradient method. The desired phase (saturated at a higher temperature) is separated from solution upon cooling. It is used primarily in crystal growth, but it is also useful, for example, if a modification stable only in a certain temperature range is desired, as in the formation of γ-CuI.[4a, 55]

Usually, the autoclaves are set up vertically or slightly inclined. In the case of retrograde solubility a *horizontal arrangement* is preferred. Also, in this arrangement the reaction products can be repeatedly transported from one zone into another, resulting in a purification effect.[51a] A further application exists in cases in which the starting materials are placed in separate zones. In hydrothermal synthesis reactions of solid starting materials take place by way of a fluid medium, which requires a degree of solubility on the part of the reactants. If the substances participating in the reaction exhibit strikingly different solubilities, it is preferable to separate these and thus to adjust the parameters *(separated charge method)*. Figure 10 shows the arrangement that was used for the preparation of ferrite from the binary oxides.[6c, 56] For the formation of $PbTiO_3$,

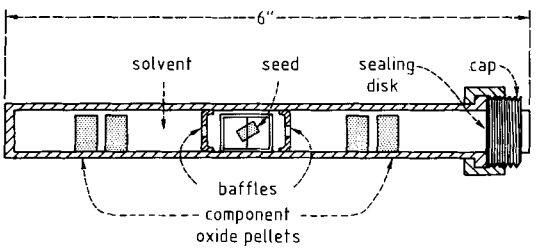

Fig. 10. Horizontal arrangement with separation of initial product. The reaction product—here on a crystallization nucleus—is formed through reaction of the diffusing species [6c].

TiO_2 was placed in the lower (hotter) part of the autoclave and PbO in the upper part.[51a, 57] $PbTiO_3$ is formed in the upper section. Compounds having the garnet structure were also synthesized as in Figure 10; Y_2O_3 was placed in the upper section, and Al_2O_3 (sapphire) was placed in the lower section. The resulting garnet (yttrium-aluminum garnet, YAG) forms between the two zones.[58] A relatively new variant is the so-called "two zone process", in which the starting materials are placed in different solvents in independent solution zones. This method was developed for the preparation of Sb_2O_4,[59] where Sb occurs in the +3 and +5 oxidation states (Fig. 11).[6s, t] Besides Sb_2O_4, the compounds ABO_4 ($A = Sb^{III}$, Bi^{III}; $B = Nb^{V}$, Ta^{V}, Sb^{V}) were obtained.[53, 60a, 60b] $Pb_7S_2Br_{10}$ was prepared analogously; the starting materials $PbBr_2$ and PbS were placed in different concentrations of HBr.[60c]

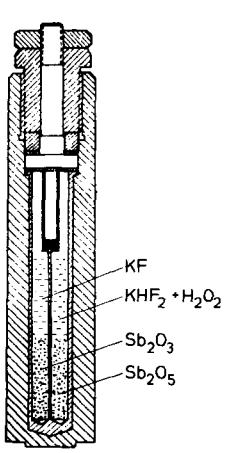

Fig. 11. Two-section liner for separation of starting materials in different solvents [6s, t].

A saturated solution of a *metastable phase* under given hydrothermal conditions is supersaturated relative to the stable phase. This can lead to the conversion of the metastable phase into the phase stable under the experimental conditions. For kinetic reasons, the presence of a seed crystal of the latter phase may be necessary. Examples are the transformation of quartz glass into quartz[61a] and the formation of α-Al_2O_3 (sapphire) from $Al(OH)_3$ (gibbsite) in temperature gradients,[62] whereby hydroxides are generally used for the synthesis of oxides. Besides crystal growth from a seed crystal of the same material, as is frequently used—the industrial preparation of quartz is an example—*deposition on another substrate* can be used to force the formation of certain compounds or crystal structures. *Roy* and *Theokritoff* have obtained cm-size GeO_2 crystals below 200°C on a quartz base,[63] while *Kolb* and *Laudise*[64] have prepared magnetic garnets on $Gd_3Ga_5O_{12}$ starting from $NaFeO_2$ and the corresponding rare earth hydroxides.

Doping the solution or starting material *with isotopes* has been used for elucidating reaction mechanisms, as with ^{18}O- and ^{17}O-enriched water in quartz preparation,[65a] or for the preparation of deuterated probes for structure determinations (ScOOD).[65b]

In *hydrothermal dehydration*, water is withdrawn from the hydrothermal solution through a spatially separated metal having a higher oxidation potential than that of hydrogen. Magnesium and zinc, which bring about the dehydration through formation of the corresponding hydroxide or oxide and hydrogen, have been used for this purpose. In such cases the degree of fill should be as low as possible (cf. Section 3). The method was used in the synthesis of chrysolite fibers, $Mg_6(OH)_8Si_4O_{10}$ (fibrous serpentine), from $Mg(OH)_2$, $MgBr_2$, and SiO_2,[66a] and of potassium hexatitanate, $K_2Ti_6O_{13}$, from TiO_2 in KOH.[66b]

A *sinter reaction* is the reaction of a metal powder with water under hydrothermal conditions. A sintering process is associated with the formation of the corresponding oxide,[67] and, just as in the dehydration process, hydrogen is liberated. Compact Cr_2O_3[68a] and ZrO_2[68b, c] have been formed this way, as well as brookite, TiO_2.[68d] Single crystals of magnetite, Fe_3O_4,[68e] and of iron titanium bronzes from TiO_2 and Fe,[68f] have been synthesized by this process.

5. Hydrothermal Synthesis in Industry

The most significant use of hydrothermal crystal growth is the industrial preparation of quartz crystals for oscillators (Fig. 12). Following the works of *Spezia*,[17] who first obtained crystals up to a cubic centimeter in size, *Nacken* et al. developed (during the second World War) processes serviceable on an industrial scale.[61] These works were stimulated by the shortage of natural crystals from Brazil. Accordingly, after the war commercial installations were developed, first in the USA and later in other countries. The crystals were grown in alkaline media in a temperature gradient of about 400° to 380°C and at a pressure of 1 kbar. In 1982, world production amounted to 600–700 tons, chiefly in the USA, USSR, Japan, France, and Czechoslovakia.

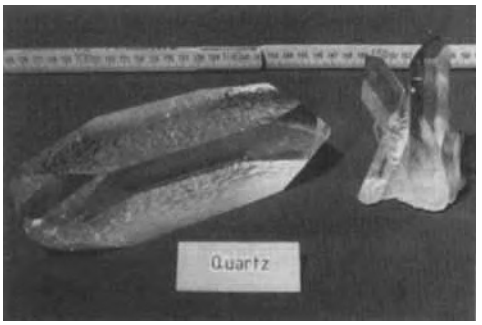

Fig. 12. Synthetic quartz crystal (left), ca. 1 kg, with natural quartz (right) (*R. Diehl*, Freiburg).

Hydrothermal crystal growth plays a certain role in the production of artificial gems,[69a-d] e.g. the quartz variants amethyst (+Fe and irradiation), citron ($+Fe^{3+}$), smoky quartz (+Al and irradiation), sapphire (or ruby), and emerald.[70] Because of the high cost of hydrothermal processes, only the production of emeralds has attained significance; synthetic emeralds, are produced almost without exception, by hydrothermal growth at 500–600°C and 1 kbar.[71] The cost of optical-quality synthetic emeralds is ca. \$300/g, compared to ca. \$7000–\$14000/g for the natural crystal.

Another area of application for hydrothermal crystal preparation lies in the field of magnetic oxides for information storage. Because of its favorable magnetic properties, chromium(IV) oxide has been employed for several years in magnetic tapes.[72] Starting compounds with tri- or hexavalent chromium are converted in a hydrothermal process at 300–400°C and 50–800 bar into microcrystalline needles of CrO_2.[3,73] Another large group of oxides useful for magnetic recordings such as γ-Fe_2O_3,[74] ferrites and garnets of the rare earths,[75] and barium ferrite, $BaFe_{12}O_{19}$,[76] can also be obtained by hydrothermal routes.

Hydrothermal processes have also found a place in chemical industrial processing.[19g,77a] Synthetic zeolites, used in great quantities as molecular sieves, require temperatures above 100°C in a closed hydrothermal system for their crystallization, especially the silicate-rich variants such as mordenite.[78] The processes employed for the pressure-decomposition of ores are listed under the designation "hydrometallurgy".[6b,77]

6. Nonaqueous Solvents

Besides water—the most important solvatothermal reaction medium for transformations above the boiling point and 1 bar—there are a great number of nonaqueous solvents which, in principle, also come into consideration for preparative purposes.[79a,79b] As long as a century ago *Hannay* and *Hogarth*[80] observed that an alcoholic solution of cobalt chloride does not change from its characteristic blue color above the critical point and thus they demonstrated the solubility of inorganic substances in a fluid medium of nonaqueous systems.[81] Although nonaqueous solvents (with the exception of ammonia) have until now attained little significance for solvatothermal transformations[6f] (Table 2), they can be considered in cases in which the required solubility cannot be reached in an aqueous medium, in which the solvent itself participates in the synthesis, and, most importantly, in cases where the reaction product reacts with water. Critical temperatures and pressures are often lower than those of water (Table 3). Formic acid is a limiting case, decomposing at elevated temperatures to CO and H_2O (or CO_2 and H_2). In this reducing and CO_2-rich reaction medium numerous oxides and carbonates are synthesized.[82a,82b] For nonaqueous solvents, arrangements with glass or quartz glass as reaction vessels are especially suitable (Section 4.2).

Table 2. Syntheses in Nonaqueous Solvents.

Solvent	Examples	Ref.
NH_3	nitrides, imides, amides, CsOH, Cs_2Se_2	[86]
HF	$MO_{3-x}F_x$ (M = Mo, W)	[119c]
HCl, HBr	$AuTe_2Cl$, AuSeCl, AuSeBr	[116]
	$Mo_3S_7Cl_4$	[141b]
Br_2	SbSBr, SbSeBr, BiSBr, BiSeBr	[124]
	$MoOBr_3$	[141b]
S_2Cl_2	MoS_2Cl_3, $Mo_3S_7Cl_4$	[141]
S_2Br_2	$Mo_3S_7Br_4$	[141b]
$SeBr_2$	SbSeBr, BiSeBr	[124]
$H_2S+(C_2H_5)_3-NHCl$	β-Ag_2S	[125]
C_2H_5OH	SbI_3, BiI_3	[60b]
CS_2	monoclinic Se (metastable mod.)	[110]
CCl_4	$SeCl_4$, $TeCl_4$	[60b]
C_6H_6	hexagonal Se	[60b]
CH_3NH_2	CH_3NHLi	[126]

Table 3. Critical data for selected solvents.

Solvent	Critical temperature [°C]	Critical pressure [bar]
Water	374.1	221.2
Ammonia	132.3	111
Chlorine	144	77.1
Hydrogen chloride	51.4	83.2
Carbon dioxide	31.3	73
Sulfur dioxide	157.8	78.7
Carbon disulfide	279	79
Hydrogen sulfide	100.4	90.1
Ethanol	243	63.8
Methylamine	156.9	40.7
Methanol	240	81
Formic acid	308	—

6.1. Ammonothermal Synthesis

While chemical reactions in liquid ammonia have long had their place in preparative chemistry,[83] investigations concerning such reactions at high pressures were first reported in the sixties,[84] as also was the first review article concerning special apparatus and the preparation of a series of amides, imides, and nitrides.[85] Although ammonia has a low dielectric constant with respect to water (Fig. 13), it can be considered, especially at high pressures, as a polar solvent. The rapid development of this method and nearly all the contributions in this field are due essentially to one research group, whose results are summarized in a review by *Jacobs* and *Schmid*, which appeared in 1982.[86]

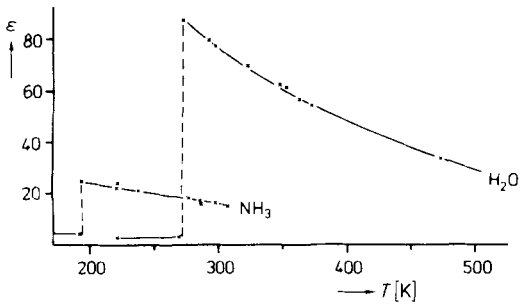

Fig. 13. ε-T Diagram for ammonia and water [86].

Two systems are in use; one is a closed system, in which the autoclave of high-alloyed steel (Vacumelt ATS 340) serves as the reaction-vessel. In this, pressures up to 6 kbar and temperatures up to 500 °C can be attained. The other system works with an adjustable nitrogen counter-pressure. Ampoules of Supremaxglas serve as reaction-vessels which are operable up to 200 °C and 2.8 kbar, or welded gold or silver ampoules, which are also operable at 2.8 kbar but with higher temperatures. With the adjustable counter-pressure the pressure in the ampoule can be compensated. Especially important and of general interest for preparative purposes are the detailed instructions concerning manipulation of the often extremely moisture- or oxygen-sensitive substances. Teflon-lined autoclaves have also been found useful for work up to 200 °C and 1 kbar in liquid ammonia.[87]

In the following section the broad preparative spectrum of the method will be demonstrated; original works will be cited only in cases which are not contained in Ref. [86].

Compounds which arise through reaction with the solvent include a great number of binary and ternary amides, including deuterated forms, such as $RbND_2$, $Mg(NH_2)_2$, $Li_3Na(NH_2)_4$,[88a] $RbBa(NH_2)_3$,[88b] $Rb_2[Mg(NH_2)_4]$,[88c] $Rb_3Y(NH_2)_6$,[88d] $Cs_2[Mg(NH_2)_4]$,[88e] and $Cs_2(NH_2)N_3$.[88f] There are also imides and nitrides such as BaNH, $Ce_3(NH)_3N$, and EuN. The size of the crystals is in many cases sufficient for a structure determination. A beautiful example of transport inversion is the preparation of Mn_3N_2 with iodine (hot→cold) or potassium (cold→hot).[88g]

Hydroxides and hydrogen sulfides are formed without participation of the solvent; in this way they were for the first time obtained free of water. The crystals are in a form suitable for structure determinations.

$$CsOH \cdot H_2O + CsNH_2 \rightleftharpoons 2\,CsOH + NH_3$$
$$CsOH \cdot H_2O + Cs \rightleftharpoons 2\,CsOH + 1/2\,H_2$$

Potassium hydrogen sulfide was obtained by reaction of KNH_2 with H_2S. The extremely water-sensitive chalcogenides such as Cs_2Se and polychalcogenides such Rb_2Te_5[89] can be synthesized in an analogous way.

7. *Eh*-pH Diagrams

Reactions in which elements that are capable of appearing in various oxidation states participate are dependent on the oxidation potential of the solution and also frequently simultaneously on the pH value. So-called *Eh*-pH diagrams,[6m,o,90] in which the reaction equilibria are plotted in relation to the redox potential and the pH,[91] can give considerable insight into these relationships. These diagrams were first devised in 1928 by *Clark* and subsequently have found a limited use in analytical chemistry.[92] They acquired significance in their application to corrosion problems; this was essentially due to the work of *Pourbaix*[93] and thus in the literature they are occasionally designated as Pourbaix diagrams. While *Eh*-pH diagrams are used increasingly in the geological sciences (for hydrothermal mineral syntheses), they have hardly been introduced into preparative chemistry. The construction of such diagrams is discussed in numerous papers.[23b,94]

The basic principles will be described with the Fe-H_2O system as an example. In Figure 14a the dash-and-dot lines enclose the region of thermodynamic stability for water. Outside this region, liberation of oxygen (or hydrogen) occurs. An increase in $p(O_2)$ or $p(H_2)$ by a power of ten displaces the lines by about 0.03 volts upwards or downwards, respectively. In practice the region for hydrothermal synthesis is not limited to this range, since the decomposition of water often proceeds very slowly and an overvoltage of up to 0.5 volts is observed. Three types of lines occur. Reactions without a change of oxidation number, such as the $Fe^{3+}(aq)/Fe(OH)_3$ equilibrium, lead to vertical lines; those which proceed independently of the pH, such as $Fe^{2+}(aq)/Fe^{3+}(aq)$, lead to horizontal lines. A depend-

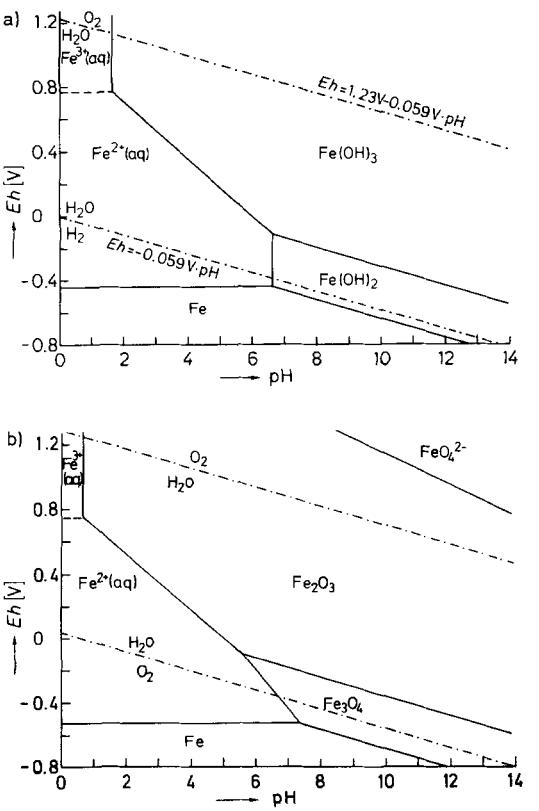

Fig. 14. Fe-H_2O system: a) *Eh*-pH diagram of the ions and hydroxides. The dash-and-dot lines correspond to the equilibrium between water and oxygen (or hydrogen). For the ions the activity is set at 1. $T=25$ °C, $p=1$ bar; b) *Eh*-pH diagram in thermodynamic equilibrium. Parameters as in a) [92a].

$Mn-S-H_2O$	25-300	[127]		0-300	[128]
$Fe-H_2O$	25-300	[95]			
	25-200	[130]			

ence of the reaction potential on the pH value occurs when hydrogen ions participate in the reaction, e.g.

$$Fe^{2+} + 3\,H_2O \rightleftharpoons Fe(OH)_3 + 3\,H^+ + e^-$$

($Eh = 1.47\,V - 0.177\,V\ pH$).

The familiar situation, shown in Figure 14a, of the precipitation of hydroxides does not correspond to the thermodynamic equilibrium, according to which only hematite (Fe_2O_3) and magnetite (Fe_3O_4) occur (Fig. 14b). While the necessary thermodynamic data for the situation at room temperature are tabulated, necessary experimental data for hydrothermal synthesis at higher temperatures is scarce.[26a] The required data for the free energy of reaction (ΔG) is obtained by extrapolation of the room temperature data using entropy and heat capacity functions.[26a, 95] ΔG is related to *Eh* through the equation $\Delta G = nFEh$ (where F is the Faraday constant). Numerous element-H_2O systems have been calculated (and tabulated) in this way, mostly with the aid of computer programs (Table 4). As shown in Figures 15a and 15b for the $Mn-H_2O$ system, the shift in the equilibrium with temperature is considerable, and at the expense of the lower oxidation states of manganese. Despite the uncertainty in the extrapolated data they are useful for experimental formulations, since they show the "trend" and also allude to kinetic aspects.[96] Examples in use are the $Sb-H_2O$[59, 97] and $A^V-B^{VI}-C^{VII}-H_2O$[45] systems. *Eh*-pH diagrams of more complicated systems, e.g. the region of existence of SbSI in the $Sb-S-I-H_2O$ system (Fig. 16), are obtained by superposition of binary data. With the decrease in effort of computing the *Eh*-pH diagrams, their use should become well-established in preparative chemistry just as it has in the geological sciences. For many-component systems and at higher temperatures, the use of diagrams in which the logarithm of the oxygen activity is plotted against the pH has proven effective. These $\log a(O_2)$-pH diagrams are topologically identical to *Eh*-pH diagrams, but more comprehensible.[23b, 98]

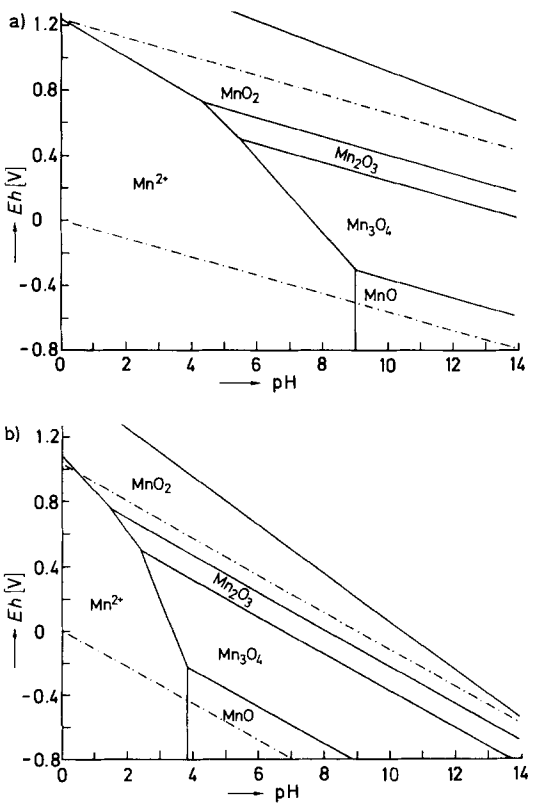

Fig. 15. *Eh*-pH diagram of the $Mn-H_2O$ system at a) 25°C; b) 300°C [129].

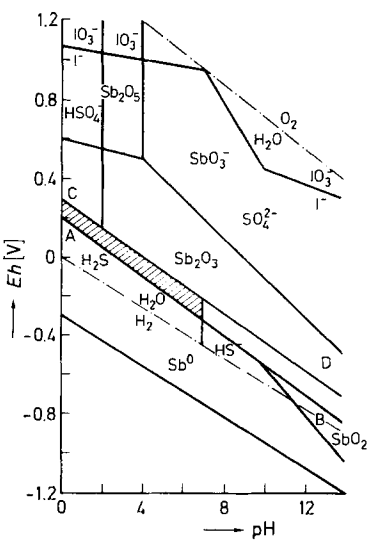

Fig. 16. *Eh*-pH diagram of the $Sb-S-I-H_2O$ system, with the region of existence for SbSI (shaded) [45].

8. Oxidation Potentials and Buffer Systems

From the preceding section it is clear that the oxidation potential plays an important role in hydrothermal syntheses and therefore warrants further discussion.[6d, h, m, o, u] The redox conditions are determined by the interactions between the reaction vessel—autoclave walls or ampoules—the solvent, and the solid reaction phases. Thus, reducing conditions prevail, largely by contact with metals, and even more so the higher the temperature.[99] Nor is the problem solved over longer periods by employing noble metals, since even silver and gold show some (albeit slight) permeability to hydrogen. For the stabilization of lower oxidation states, the reaction of the participating metal with water is called upon, e.g. vanadium for $VO(OH)_2$[100] and iron for magnetite, Fe_3O_4,[68e] iron titanium bronze,[68f] and fayalite, Fe_2SiO_4.[101] Besides the use of formic acid as

a reducing additive for Fe_3O_4,[102] a great number of oxidants have also been used as additives for achieving oxidizing conditions. While this presents no problem in vessels of inert materials such as glass, quartz glass, or Teflon, the capacity of the oxidants in metallic surroundings gradually becomes exhausted. Among those used are: $HClO_4$ for TbO_2,[103a] RhO_2 and PtO_2,[36b] TeO_2;[103b] $KClO_3$ for oxides $A^{VI}B_2^{III}O_6$;[103c] HNO_3 for PrO_2;[103d] $Ce(NO_3)_3$ for CeO_2;[103d] Cl_2 and Br_2 for complexes with trivalent gold as a transport agent;[50b] O_2 (or H_2O_2) for $BaMnO_3$,[103e] $SbTaO_4$, and $SbNbO_4$.[103f]

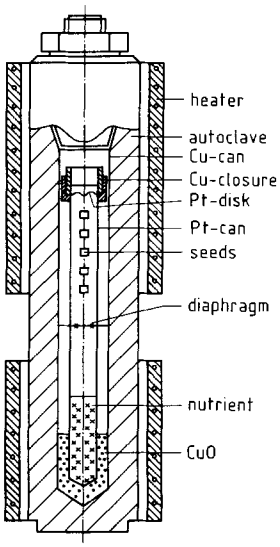

Fig. 17. Arrangement for growth of magnetic $REFe^{III}O_3$ crystals. The CuO buffer, separated from the reaction space by a hydrogen-permeable Pt partition prevents the formation of Fe^{2+} [75].

For the production of Fe^{2+}-free magnetic oxides of the type $REFeO_3$ (RE = rare earth), hydrogen evolved in a two-zone arrangement (Fig. 17) is trapped by CuO with formation of Cu_2O and H_2O.[75] This is an example for a solid state buffer system that was introduced by *Eugster* in 1957 for hydrothermal mineral synthesis[104a] and since then has been further developed in the geological sciences.[22, 104b-d] It was next a question of oxygen buffers, which could fix the oxygen potential at a given temperature through the equilibrium of two solid phases (Table 5). Thus, the buffer is separated from the reaction mixture by a semipermeable wall, which is permeable to hydrogen (Fig. 18). The reactants are placed in an ampoule of Pt or Ag—Pd alloy,[104e] while the buffer is arranged in a surrounding ampoule of gold or silver. Hydrogen diffuses through the wall of the inner ampoule, where the constant $f(H_2)$ is maintained, as long as the capacity of the buffer is not exhausted. Reactions in which O_2, H_2, or H_2O participate can be controlled with these buffer systems. The limitations of this method lie in the limited buffer capacity and also in the temperatures required to attain equilibrium within a reasonable length of time. The length of the experiment is limited, since as mentioned previously gold and silver are not completely impermeable to hydrogen. For these reasons the method is rarely employed for lengthy crystal-growth processes. It should, however, be suitable for problems of solid state chemistry, similarly as it is for mineral syntheses.

Table 5. Buffers.

Oxygen (H_2O)	Acid - Base
MnO - Mn_3O_4 [33, 133]	Ag - AgCl [105, 135]
Mn_3O_4 - Mn_2O_3 [33]	Ag - AgBr [136]
Mn_2O_3 - MnO_2 [33]	Ag - AgI [136]
Fe - $Fe_{1-x}O$ [33, 134]	Nitrogen (NH_3)
Fe - Fe_3O_4 [33, 134]	Cr - CrN [137]
Fe_3O_4 - Fe_2O_3 [133, 134]	Sulfur (H_2S)
Co - CoO [133]	Ag - Ag_2S [104c]
Ni - NiO [33, 133, 134]	$Fe_{1-x}S$ - FeS_2 [33, 104c]
Cu - Cu_2O [33]	
Fluorine (HF)	
$CaSiO_3 + 2HF \rightleftharpoons CaF_2 + SiO_2 + H_2O$ [138]	
$CaAl_2Si_2O_8 + 2HF \rightleftharpoons CaF_2 + Al_2SiO_5 + SiO_2 + H_2O$ [138]	

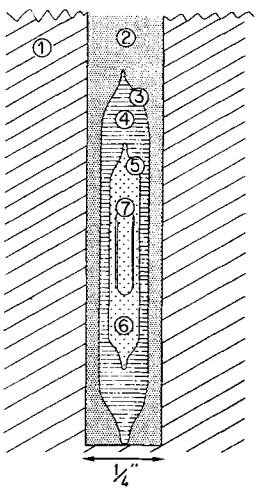

Fig. 18. Oxygen buffer assembly. 1) Pressure vessel; 2) pressure medium (H_2O); 3) sealed gold tube; 4) oxygen buffer; 5) sealed platinum tube; 6) charge. The open silver crucible 7 protects the charge before contact with the Pt wall [104b].

Adjustment of the redox potential alone, however, is not sufficient in many cases and additional buffer systems are required, such as acid/base buffers for pH-dependent reactions. The Ag-AgCl pair has proven useful as such a buffer,[105] and Figure 19 shows one such combined buffer system. Because of the low solubility of Ag under these reaction conditions, this buffer does not need to be separated from the reaction mixture. A series of additional buf-

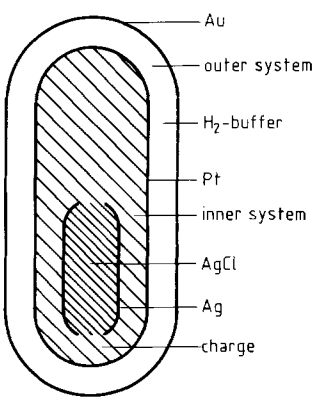

Fig. 19. Combined buffer system to maintain $f(O_2)$ and pH. The pH buffer consists of a mixture of Ag and AgCl in a silver foil [135].

fer systems is listed in Table 5. A detailed description of the buffer techniques is given by *Huebner*.[33] One disadvantage of the buffer systems is that the fugacity of, say, oxygen can only be altered gradually, and lower $f(O_2)$ values are especially difficult to maintain. *Shaw*[106] used an experimental arrangement described by *Tuttle* (Section 4.1), in which the autoclave interior is separated via a wall of $Pd_{30}Ag_{70}$, and on one side of which is hydrogen and on the other a hydrogen/argon mixture. In the H_2/Ar region the $f(H_2)$ can be adjusted exactly. Another suggestion by *Carapezza*[107] makes use of the fact that in solid solutions of oxides the $f(O_2)$ can change over a large range with composition. In the example cited, a series of (Ni,Mg)O-mixed crystals was employed. For the control of $f(S_2)$ in hydrothermal sulfide systems the work of *Barnes* should be noted,[108] along with the methods for its determination by *Kulonin*.[109]

9. Applications

Although crystal growth has hitherto stood in the foreground in preparative applications outside of the geological sciences, today several hundred compounds—excluding mineral syntheses—have been obtained by solvatothermal methods (Table 6). The following considerations should underscore the merits of the method for preparative purposes in the light of recent works.

Table 6. Reviews.

Author	Year	Comments	Ref.

Demianets, Lobachev	1980	RE germanates	[139]
Demianets, Lobachev	1981	no silicates, crystals ≥ 1 mm	[6t]

Elements. Numerous elements are obtained as single crystals hydrothermally:[50a] as a rule the metals are transported to the higher temperature region. Metastable modifications, such as monoclinic selenium in carbon disulfide, are also obtained in this way.[110]

Oxides. Here the oxides of the transition elements are especially important: hydrothermal synthesis has proven effective in attaining prescribed oxidation states (see Sections 7 and 8). To attain lower oxidation states, reaction of the transition metal with water is exploited (Section 8), or also reaction of a metal with a compound in higher oxidation state. $K_2Mo_8O_{16}$, a molybdenum hollandite, is formed from a solution of K_2MoO_4 in KOH by reaction with molybdenum at 500–700°C in gold tubes.[111] Ferrimagnetic $YCu_3Mn_4O_{12}$ $[YCu_3(Mn_3^{IV}Mn^{III})O_{12}]$ is obtained from YCl_3, $CuSO_4 \cdot 5H_2O$, and $KMnO_4$ at 500–800°C above 1.5 kbar. The resulting reaction product occurs in a form that can be magnetically separated.[112] Preferred solvents for oxides are alkaline and alkali-metal halide solutions, especially fluorides for ternary and quaternary oxides. Salts of oxoacids are obtained from the corresponding acids, e.g. $AlPO_4$ from H_3PO_4 solution. Laser-active neodymium pentaphosphate crystals can be produced from phosphoric acid solutions at 300–700°C in vitreous carbon. The troublesome OH^- content decreases with increasing growth temperature and can be brought below 10^{19} per cm^3.[47c, 113]

Chalcogenides. The preparation of anhydrous alkali-metal chalcogenides via the ammonothermal route is cited in Section 6.1. In order to avoid hydrolysis in the hydrothermal method, neutral or acidic solutions are preferred, either in Teflon or glass (or quartz glass). An especially simple and reliable experimental arrangement is shown in

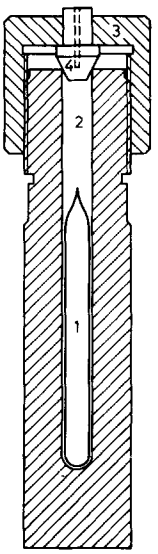

Fig. 20. Equipment for the hydrothermal method, using hydrohalic acids as solvent. The sealed quartz ampoule 1 is filled with the material to be converted and the solvent. A counter-pressure, produced by filling 2 with solid CO_2, prevents the ampoule from bursting. 3: Screw cap. 4: Sealing cone with hole for thermocouple [6j].

Figure 20. It is suitable for conditions up to 500°C and 1–2 kbar internal pressure. Upon filling the ampoule, the solvent is frozen in liquid nitrogen prior to the addition of the solid starting materials. This arrangement is not only suitable for the preparation of chalcogenides but also of chalcogenide-halides[114]—also with participation of the solvent—and for elucidation of the phase diagrams. The latter is demonstrated by the example of the chalcogenide-halides of copper and gold. At the beginning of these investigations only the silver ion conductors Ag_3SI and Ag_3SBr were known.[115] Instead of a methodical investigation of the copper or gold system, respectively, ternary phases (Fig. 21) were produced by the hydrothermal method from the elements and/or from binary boundary

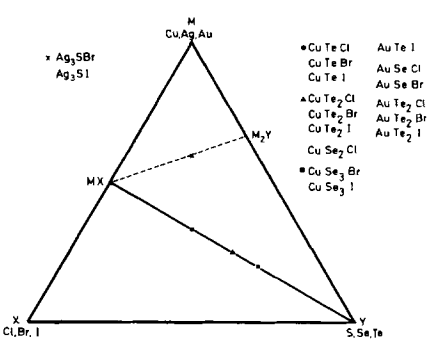

Fig. 21. Chalcogenide halides in the ternary system with the components: group 1B, Cu, Ag, Au; the chalcogens S, Se, Te and the halogens Cl, Br, I. The copper and gold compounds have been prepared for the first time using the arrangement in Figure 20 [6j].

phases. The reaction products appear as small crystals which can easily be sorted and identified (Fig. 22). The quasi-binary sections can easily be determined in the usual way from the information for the ternary phases. This is a real advantage over powder preparations, in which the presence of ternary phases but not their quantitative composition can be determined by X-ray diffraction. Products sensitive to hydrolysis can be obtained with anhydrous solvents such as HCl and HBr.[116] Under conditions similar to those for the metastable subiodides Te_2I and β-TeI (see Section 1), $(Te_2)_2I_2$ is formed, whose unusual intercalation structure was recently elucidated by *Kniep* and *Beister*.[117] Here the presence of "foreign elements" such as germanium or arsenic is required, although their presence in the reaction product cannot be detected.

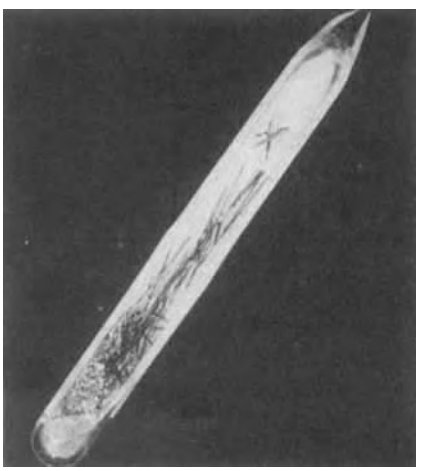

Fig. 22. Quartz-glass ampoule in which crystals of $AuITe_2$ together with gold have been grown. This result was obtained by bringing together gold and tellurium in equal numbers of gramme-atoms in 10-molar HI at a temperature of 450°C and then allowing it to cool for 10 days to 150°C (size of ampoule 15 cm) [6j, 140].

An example where the lower end of the temperature range is extended with respect to chemical transport reactions, is the transport of CuS and CuSe. While for CuS, with a decomposition temperature of 507°C, transport *via* the gas phase with HBr is still possible,[118a] for CuSe (decomposition temperature 379°C) this can only be achieved with the hydrothermal method, because of the low vapor pressure of CuBr.[118b]

Halides. Fluorides, fluoride hydroxides, and oxide fluorides are produced on a large scale from hydrofluoric acid solutions[119a] using gold ampoules as reaction vessels (Fig. 23). $In(OH)F_2$ is formed in this way from $InF_3 \cdot 3H_2O$ at 200°C. A variation of this is the transformation of a metal oxide with the corresponding metal into oxide fluorides.

$$n\,M + (m-n)\,M_nO_m \xrightarrow[\text{pressure}]{HF} m\,M_nO_{m-x}F_x$$

$V_2O_{5-x}F_x$ ($x \leq 0.025$), $VO_{2-x}F_x$ ($x \leq 0.2$) (500–600°C, 1 kbar)[119b] as well as $WO_{3-x}F_x$ ($0.17 \leq x \leq 0.66$) and $MoO_{3-x}F_x$ ($0.74 \leq x \leq 0.97$) with cubic ReO_3 structure[119c] were obtained in this way. Single crystals of blood-red $Fe^{II}Fe^{III}_2F_8 \cdot H_2O$ were produced at 250°C and 30 kbar in a modified Belt apparatus in Pt crucibles.[36] $Cs_2FeF_5 \cdot H_2O$, which has a paramagnetic-antiferromagnetic phase transition at 2.4 K, is formed at 200–450°C and 1 kbar in an autoclave lined with PTFE.[120]

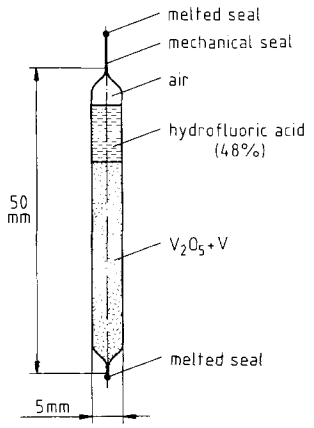

Fig. 23. Gold capsule for the preparation of oxide fluorides [119b].

Polyiodides of the type $Tl_6I_6M_2I_4$ (M = Ag, Au, Pb) were first obtained hydrothermally in hydriodic acid at 250–330°C.[121] Hexaiodoplatinate(IV), M_2PtI_6 (M = K, Rb, Cs, NH_4, Tl), is formed from PtI_4, MI, and I_2 in aqueous solutions in the presence of HI at 160°C in glass ampoules.[122] Finally, a new method for the synthesis of osmium(III), ruthenium(III), iridium (III), and rhodium(III) complexes with ethylenediaminetetraacetic acid (EDTA) and propylenediaminetetraacetic acid (PDTA) was developed through the transformation of the platinum-metal halides with EDTA or PDTA in water in a PTFE-clad vessel and heating to 150°C.[123]

10. Conclusion

The preparative possibilities of hydrothermal synthesis in solid state chemistry are by no means exhausted, as the relatively great success of ammonothermal synthesis in this field shows. From the beginning, this was oriented towards preparative work and played no role in the growth of large, perfect, single crystals. It should also be considered, that for modest requirements of pressure and temperature, the expense for the apparatus is kept within limits (see Visual Hydrothermal Synthesis, Section 4.2). Also, through judicious inclusion of *Eh*-pH diagrams and buffer systems, the state of pure empiricism can be abandoned, and hydrothermal synthesis should attain a significance in solid state chemistry similar to that already possessed by chemical transport reactions.

I thank my colleagues F. Liebau, H. Schäfer, and K. Tödheide for their valuable suggestions.

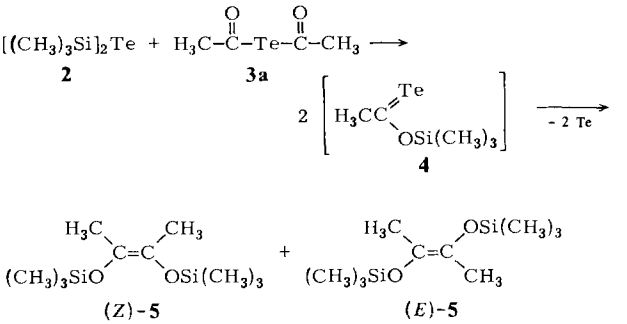
Novel Reactions of Acyl Halides with Bis(trimethylsilyl) Telluride: C,Te and C,C Bond Formation**

By *Tevfik Severengiz, Wolf-Walther du Mont,* Dieter Lenoir,** and *Heike Voss*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday



Telluro esters with C=Te groups should be of interest both as 1,2-dipoles and as soft ligands, but little is known about them. Only compounds with bulky substituents of the type *t*BuC(=Te)OR have been identified, the *tert*-butyl group being decisive for their stability.[1] In the course of seeking new tellurium reagents[2] and new olefin syntheses,[3] we found that bis(trimethylsilyl) telluride **2** does not react with simple ketones,[4] but does undergo spontaneous reaction with acyl halides.

a, R = CH_3; **b**, R = $C(CH_3)_3$

Diacetyl telluride **3a** is obtained in practically quantitative yield when acetyl chloride **1a** is allowed to react at -30 °C with a less than stoichiometric amount of **2**; in the same way, pivaloyl chloride reacts with **2** at -10 to -20 °C to give **3b**.[5,6] In the IR spectra of **3**, the characteristic pair of bands for each of the ν(C=O) appears; the mass spectra exhibit peaks for the molecular ions (correct isotopic distribution) as well as peaks for the fragments formed by loss of CO and acyl groups. In contrast to the dialkyl species, the diacyl tellurides **3** are extremely sensitive to air and moisture; the hydrolysis products include the corresponding diacyl ditellurides (identified by MS).[7]

Noteworthy is the reaction of **3a** with **2**: upon mixing of the two tellurium compounds (-20 °C, without solvent), the mixture rapidly turns intense blue and, simultaneously, tellurium starts to separate out. A mass spectrum (recorded immediately after mixing) shows the complete consumption of **3a** (no group of signals around *m/z* 216[6]); instead, new peaks appear which we ascribe to the trimethylsilyl telluroacetate **4** (*m/z* 246, $M^{\oplus}$ for ^{130}Te). The decomposition of **4** and the formation of the final products, (*E*)- and (*Z*)-**5**, can be followed by mass spectroscopy.[8]

The intermediacy of **4** is favored by the formation of the Si–O bond.[9] After 12–15 h at room temperature, the yield of **5** (mixture of isomers, (*E*)-**5** : (*Z*)-**5** ≈ 55 : 45), determined by NMR spectroscopy, is nearly quantitative (yield after distillation (b.p. = 68–78 °C/20 mbar): 60–70%).[10] The 2-butene derivatives **5** are also formed when **2** is allowed to react with molar equivalent amounts of acetyl chloride **1a** (yield after distillation: ca. 70%); tellurium separates out in an exothermic reaction and a blue color appears. Accordingly, acetyl chloride **1a** reacts with **2** in the sense of an acyloin condensation, leading (as in the system $(CH_3)_3SiCl/Na$) to the disilyl enediol ether.[11] The deep blue color is due to the labile intermediate **4**, which has a C=Te bond. In the reaction of **2** with equimolar amounts of pivaloyl chloride **1b** (or with **3b**), the corresponding telluro ester *t*BuC(=Te)OSi$(CH_3)_3$ was identified in the mixture;[12] in the UV/VIS spectrum, the absorptions characteristic for the C=Te group at $\lambda = 624$ and 350 nm (blue solution in *n*-pentane) are observed.[1] In this case, no acyloin-like C,C bond formation occurs, probably for steric reasons.[12]

The spontaneous breakdown of the ester **4** (which is free of bulky substituents) at room temperature with formation of a C=C bond and elimination of an elemental chalcogen has no precedent in carbonyl chemistry. Formally, this reaction is similar to the photochemical desulfurization of thioesters RC(=S)OR′.[13,14]

Experimental Procedure

3a: **2** (2.26 g, 8.3 mmol) was added dropwise to **1a** (3.58 g, 45.6 mmol) at -30 °C under argon. The brown suspension was then stirred for 30 min at -30 °C, and chlorotrimethylsilane and excess acetyl chloride were removed under reduced pressure. 1.3 g (74%) of **3a** remains as a yellow-orange liquid [6].—Correspondingly, **3b** (1.4 g, 85%) is obtained as a turquoise liquid from **1b** (3.2 g, 26.5 mmol) and **2** (1.5 g, 5.5 mmol) at -10 to -20 °C [6].

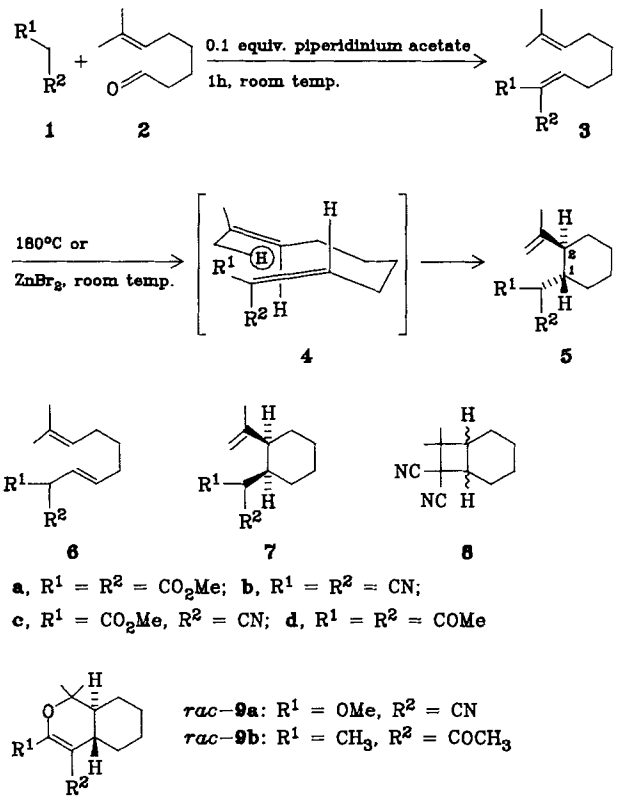
Non-Induced, Highly Diastereoselective Intramolecular Ene Reactions of 1,7-Dienes to *trans*-1,2-Disubstituted Cyclohexanes

By *Lutz F. Tietze** and *Uwe Beifuss*



Dedicated to Professor Hans Jürgen Bestmann on the occasion of his 60th birthday

Compared with the mechanistically related Diels-Alder reaction, the ene reaction has so far been considered as less important with respect to the formation of C–C bonds, which may be attributed in many cases to lower stereoselectivity and poorer yields. The intramolecular mode, which has not yet been investigated in any depth, often leads to unsatisfactory results, too, especially in the case of 1,7-dienes.[1]

We have been able to show recently that in highly diastereoselective (*de* > 95%) hetero-Diels-Alder reactions alkylidene and arylidene derivatives of cyclic 1,3-dicarbonyl compounds afford either enantiomerically pure or racemic, *trans*- or *cis*-fused dihydropyrans.[2] This paper will show that alkylidene-1,3-dicarbonyl and analogous compounds also provide very reactive enophiles if the hetero-Diels-Alder reaction is prevented; this can be achieved by using C=C bonds bearing electron-accepting substituents that do not undergo cycloaddition reactions. In this way, the alkylidene derivatives **3** of acyclic 1,3-dicarbonyl and analogous compounds may be converted into the *trans*-substituted cyclohexane derivatives *rac*-**5** by a *non-induced diastereoselective* ene reaction.[3]

The term *non-induced diastereoselective* will henceforth be used to describe reactions that preferably form one of several possible diastereomeric chiral (racemic) products from achiral educts in an achiral environment. For transformations under the influence of one or more chiral elements, the term *induced diastereoselective* will be used. It is all the more reasonable to distinguish between these two types as both of them (*non-induced* as well as *induced*) often occur simultaneously in a single reaction with different diastereomeric excess.[4]

The educts **3** are easily obtainable in nearly quantitative yields by Knoevenagel condensation of **1** with the aldehyde **2**[5] in the presence of piperidinium acetate (20°C, 1 h). Heating of **3a–3c** in refluxing *o*-dichlorobenzene (180°C) leads to the *trans*-fused ene products *rac*-**5a–5c**;[6] the amount of the *cis*-fused cyclohexane derivatives *rac*-**7a–7c** lies between 1 and 8% (Table 1). **4** is assumed to be the conformation of the transition state[7] of the ene reaction leading to *rac*-**5**.

In the presence of Lewis acids[1c] the reaction temperature is lowered; with $ZnBr_2$ (1.1 equivalents) quantitative conversion is obtained within 15–45 min at 20°C. As by-products of the reaction of **3a** and **3b** the isomeric product **6a** (4%) and a mixture of the isomeric bicyclooctanes *rac*-**8**

Tammannstrasse 2, D-3400 Göttingen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Studienstiftung des Deutschen Volkes (fellowship for *U. B.*). We thank Dr. *Pape*, BASF AG, Ludwigshafen, for a gift of methyl 5-formylpentanoate.

(14%), respectively, are found. For **3c**, the Diels-Alder adduct *rac*-**9a** (60%) is preferably formed under Lewis acid catalysis, while only 29% of the ene product *rac*-**5c** is obtained. The amount of *cis*-substituted cyclohexane derivatives is always less than 1%; for **3a**; no *cis*-fused ene product was detected. The alkylidene compound **3d**, though, behaves differently; in both the thermal and the Lewis-acid-catalyzed reaction, *rac*-**9b** and not the corresponding ene compound is formed[8] (Table 1).

Table 1. Thermal and Lewis-acid-catalyzed reactions of **3a**–**3d**.

Educt	Main product (yield [%]) [a] 180°C	Selectivity **5** : **7** [b]	Products (yield [%]) [a] $ZnBr_2$, room temp.	Selectivity **5** : **7** [b]
3a	*rac*-**5a** (73)	99 : 1	*rac*-**5a** (88) **6a** (4)	> 99 : 1
3b	*rac*-**5b** (71)	92 : 8	*rac*-**5b** (68) *rac*-**8** (14)	> 99 : 1
3c	*rac*-**5c** (89)	96 : 4	*rac*-**5c** (29) *rac*-**9a** (60)	> 99 : 1
3d	*rac*-**9b** (80)	—	*rac*-**9b** (89)	—

[a] Yield of isolated products. [b] The diastereomeric ratio **5** : **7** was determined by ^{13}C-NMR spectroscopy, HPLC, and GC-MS of the crude product mixture.

The *trans*-arrangement of the substituents in the ene products *rac*-**5a**–**5c** was shown by ^1H-NMR and ^{13}C-NMR spectroscopy. Thus, for *rac*-**5c** a value of 11 Hz is found for $^3J_{1\text{-H},2\text{-H}}$ as is usual with *trans*-diequatorially substituted cyclohexane derivatives.[6] The good yields and the high selectivity of the ene reaction of the 1,7-dienes are surprising since analogous triply activated compounds decompose upon heating.[9]

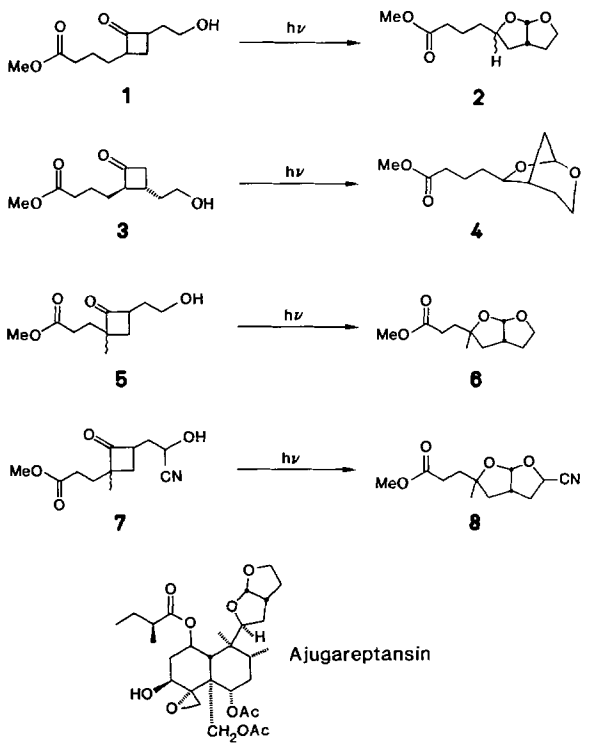
Bicyclic Acetals from Oxacarbenes**

By *Michael Pirrung**

The photochemical ring expansion of cyclobutanones to 2-tetrahydrofuranylidenes has been extensively studied mechanistically[1] but synthetic applications are few. A proposed mechanism involves α-cleavage followed by the establishment of an equilibrium between the singlet acyl-alkyl biradical and the oxacarbene, but a concerted mechanism may also operate.[2] Accordingly, the formation of products may be explained by the known reactions of the biradical or the carbene. We report here on the intramolecular trapping of photochemically generated oxacarbenes to provide bicyclic acetals.



Compounds **1** (3 : 1 mixture of diastereomers) and **3** were prepared by *Ikeda*'s route.[3] Compounds **5** and **7** were prepared by modifying this method in order to begin with 2-hydroxy-3-methylcyclopentenone.[4]

4-Hydroxyethylcyclobutanone **1** provides a stringent test of this methodology, since (considering the stability of the resulting acyl-alkyl biradicals) either α-bond could be expected to cleave. In fact, irradiation (0.02 M CH_2Cl_2 solution, 450-W Hanovia lamp, Pyrex filter) results in complete conversion of **1** into **2** within two hours. Examination of the ^1H-NMR spectrum of the crude reaction mixture shows only two products (3 : 1), which may be isolated by chromatography (1 : 1 EtOAc/hexanes). Their structures were assigned from spectral data, particularly MS and ^1H-NMR, and comparison with literature data for ajugareptansin.[5] The major isomer shows data essentially identical to those of this diterpene natural product. In ether the reaction is extremely sluggish. The importance of the intramolecular trapping reaction is emphasized by the irradiation of the acetate of **1** in methanol. Complete consumption of starting material requires 24 h, and at least five products are observed by ^1H-NMR. Compound **1** is also consumed very slowly in methanol, producing **2** and a complex mixture of methyl acetals. These data suggest that an important control element may be the intramolecular hydrogen bonding evident in the IR spectrum of **1**.[6] The yield, while only 30% at room temperature, increases to 50% at −60°, consistent with the findings of *Miller* et al. that 1,4-acyl-alkyl diradicals undergo β-cleavage more readily at higher temperatures.[7]

With compounds **3** and **5**, no ambiguity exists regarding the preferred direction of bond cleavage, and irradiation at room temperature provides the bicyclic acetals **4** and **6** in 45 and 70% yield, respectively. The homothromboxane ring system[8] is embodied in the former structure. Finally, in order to provide an entry into the more highly oxidized skeletons of the aflatoxins[9] and caryoptins,[10] cyanohy-

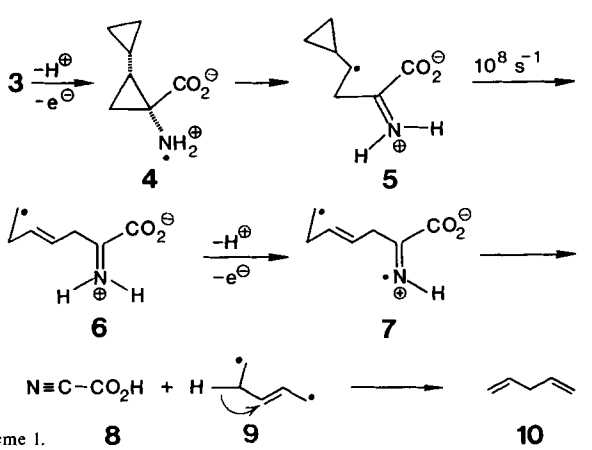
Cyclopropyl-Substituted Aminocyclopropane Carboxylic Acid (Cyclopropyl-ACC) —an Investigation of the Mechanism of Ethylene Biosynthesis**



By *Michael Pirrung** and *Gerard M. McGeehan*

We report here the synthesis of 1-amino-2-cyclopropylcyclopropane carboxylic acid (cyclopropyl-ACC) **3** and its use in investigating the mechanism of ethylene biosynthesis in plants. The application of the *Schöllkopf*[1] procedure to 1,2-dibromides has proven the method of choice for synthesis of ACC analogues.[2] In this case, ethyl isocyanoacetate reacts with 1',2'-dibromoethylcyclopropane **1**[3] in the presence of NaH in ether/dimethylsulfoxide (DMSO) to give the protected bis-cyclopropane **2** in 20–27% yield. A two-step hydrolysis procedure and ion-exchange chromatography gives cyclopropyl-ACC **3**[4] as a mixture of stereoisomers (> 7 : 1) in 85–95% yield. The structure shown was assigned to the major isomer by comparison of its ^{13}C-NMR spectra with those of the known methyl-ACC[2] and by bioassay.

Yang et al. have established that in alkyl-ACC derivatives the alkyl and carboxyl groups must be in *trans* positions to be metabolized by plant tissue.[5] The *trans*-methyl-ACC serves as a good inhibitor of ethylene production ($K_I = 0.5$ mM) and is a substrate for propylene production in mungbean hypocotyl segments.[2] A Dixon analysis of the inhibition of ethylene biosynthesis in mungbean by cyclopropyl-ACC **3** shows a K_I of 1.5 mM.[6] The bulkier cyclopropyl group probably makes it more difficult for **3** to penetrate to the active center of ethylene biosynthesis.

Based on the previously proposed mechanism of ethylene biosynthesis,[7] it was anticipated that the radical **5**, in

Scheme 1.

[**] Ethylene Biosynthesis, Part 4. This work was supported by the U.S.-Israel Binational Agricultural Research and Development Fund.—Part 3: *Bioorg. Chem. 13* (1985) 219.

which the radical center is adjacent to a cyclopropane ring, would be generated via **4** during the metabolism of **3** by plants, and that this species might undergo a second ring opening. Incubation of apple tissue with **3** results in slow evolution of 1,4-pentadiene **10** (identified by GC/MS). In contrast, treatment of **3** with NaOCl, a reagent known to convert ACC into ethylene by a concerted mechanism,[8] provides only vinylcyclopropane.

Because **3** is a good inhibitor of ethylene biosynthesis but 1,4-pentadiene is generated only slowly, it seemed likely that an intermediate radical was being diverted by another reaction, perhaps with the ethylene-forming system. An assay for time-dependent inactivation was conducted by incubating mungbean hypocotyl segments with various concentrations of **3**. Samples were periodically removed and incubated with excess ACC. A decrease in the rate of ethylene production[6] with time was observed (Fig. 1). While not strictly first order, the rate constant for the inactivation was estimated to be $1.7 \times 10^{-5}\ s^{-1}$. Excess ACC protects against inactivation and oxygen is required but it was impossible to determine an inactivation/turnover ratio for **3** since the yield of 1,4-pentadiene was too low. Mechanism-based inactivation of ethylene biosynthesis in plants is thus shown for **3**.

Mechanistically, this study provides further evidence for the presence of a "half-opened" radical and the sequential

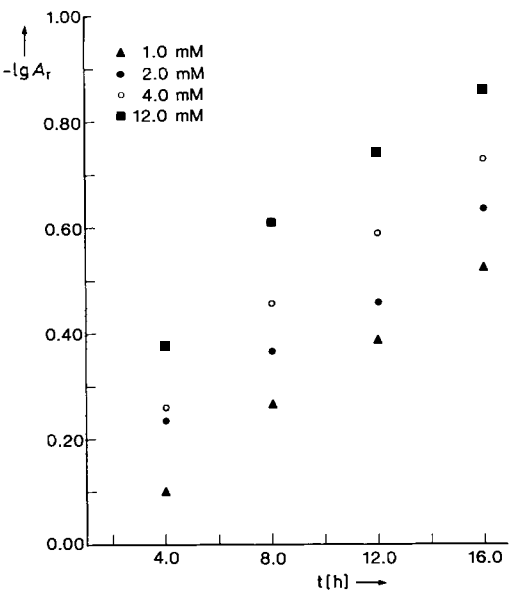

Fig. 1. Plot of the negative logarithm of the activity remaining ($-\lg A_t$) versus the incubation time. Top left: concentrations of **3**. See text.

single electron transfer pathway in ethylene biosynthesis. The formation of 1,4-pentadiene **10** is best accomodated by a mechanism involving a 1,2-hydrogen migration in a radical intermediate such as **9** (Scheme 1). It seems likely that the divergent reactivity of the "half-opened" radical formed from ACC and from **3** is responsible for the low conversion as well as the "suicide" inactivation.

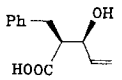
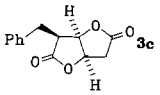
Pd^{II}-Catalyzed Stereoselective Bis-Lactonization

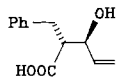
By *Y. Tamaru, H. Higashimura, K. Naka, M. Hojo,* and *Z. Yoshida**

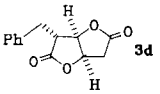
Compared with the vast development of Pd^0-catalyzed organic reactions,[1] the Pd^{II}-catalyzed ones, despite their high potential for multifunctionalization accompanied by a change in the oxidation level of a substrate, have been less exploited.[2]

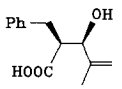
Here we describe a Pd^{II}-catalyzed, stereoselective, intramolecular double cyclization of 3-hydroxy-4-pentenoic acids **1** (X = H) to the bis-lactones **3**, carried out under CO (1 atm) (Scheme 1).[3] The *cis*-selective reaction is reminiscent of the *cis*-selective iodolactonization of **1** (X = H), which affords *cis*-3-hydroxy-4-iodomethyl-γ-butyrolactones.[4,5] The stereochemistry may be rationalized by assuming that attack of Pd^{II}[2e,2f] on the olefin is directed by the allylic OH group, forming the intermediate **2**. The results are summarized in Table 1.

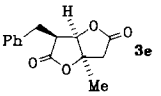


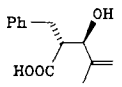


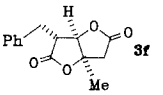


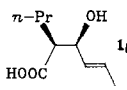


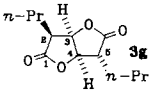


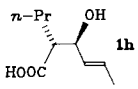


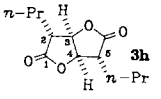


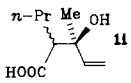


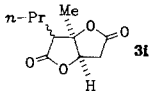












Scheme 1.

The reaction is characterized by several features. First, substitution at C-2 of **1** (X = H) increases the reactivity. Thus, the reaction of **1a** is slow, giving the bis-lactone **3a** in 18% yield (30°C, 2 days); the main products are the isomeric allyl acetates **6** (Scheme 2). *Trost* et al.[6] have shown that **1** (X = Ac) undergoes decarboxylative elimination to the *trans*-1,3-dienes **5** by the use of Pd^0 as catalyst (Scheme 1). In the case discussed here, the isolation of **6** (which is the reactant in *Trost*'s reaction) demonstrates the dramatic dependence of the reaction course on the catalytic species. The low yield formation of **3a** from **1a** is countered, however, by the reasonable yield of formation of **3b** (≡**3a**) from **1b** (room temperature, 3 d). Second, as shown by the reactions of **1c**–**1h**, substituents on the double bond do not significantly affect the yields—in contrast to other Pd^{II}-catalyzed reactions.[2f] Third, pairs of diastereomers show similar reactivities when the terminal double bond is unsubstituted (**1c**/**1d** and **1i**) and large differences

[a] **1** (1 mmol), $PdCl_2$ (0.1 mmol), $CuCl_2$ (3 mmol), NaOAc (3 mmol) in AcOH (5 mL) under CO (1 atm) [b] Yield of isolated product, based on the conversion of starting material Unless otherwise noted, the conversion is 100%. [c] From a 1 : 1 diastereomeric mixture of **1i**, a 1 : 1 diastereomeric mixture of **3i** was obtained.

of reactivity when it is substituted (**1e** and **1g** being more reactive than the corresponding diastereomers **1f** and **1h**, respectively). Fourth, and most important, the reaction is highly *cis*-selective, the *trans* products not being detected.

As shown by the reactions of **1g** and **1h**, carboxylate groups and Pd^{II} add to the double bond in a *trans* fashion. The C_2 symmetry and the *cis* configuration of the two propyl groups of **3h** are confirmed by the ^{13}C-NMR spectrum (six lines) and the ^1H-NMR spectrum ($2J_{H\text{-}2,H\text{-}3} = J_{H\text{-}4,H\text{-}5} = 0$ Hz). In the ^{13}C-NMR spectrum of **3g** the resonance of C-2 is shifted to high-field compared with that of C-5. The coupling constant $^3J_{H\text{-}2,H\text{-}3}$ is 5.4 Hz.

Experimental Procedure

3a≡**3b**: A solution of **1b** (167 mg, 1.1 mmol) in 5 mL of acetic acid was added under CO (balloon) to a flask containing $PdCl_2$ (17 mg, 0.1 mmol), $CuCl_2$ (405 mg, 3.0 mmol), and NaOAc (246 mg, 3.0 mmol) and the heterogeneous mixture was stirred at room temperature for 3 d. After dilution with benzene, the mixture was filtered through a cellulose column. The filtrate was neutralized with aqueous $NaHCO_3$, dried over $MgSO_4$, and the solvent was evaporated to give spectroscopically homogeneous **3a** as a colorless oil. ^1H-NMR ($CDCl_3$): $\delta = 1.00$ (br. t, $J = 7$ Hz, 3 H), 1.64 (m, 4 H), 2.88 (m, 3 H), 4.86 (d, $J = 4.9$ Hz, 1 H), 5.15 (m, 1 H); IR (neat): 1780 (vs), 1180 (s), 1040 (s).

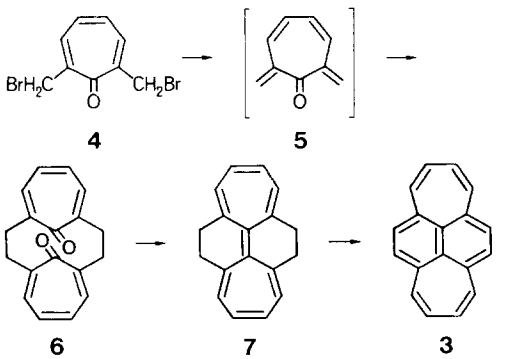
Synthesis of Dipleiadiene by "Serendipity"

By *Emanuel Vogel,* Brigitte Neumann, Wolfgang Klug, Hans Schmickler,* and *Johann Lex*



Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Pyracylene **1**,[1] acepleiadylene **2**,[2] and the previously unknown dipleiadiene **3**[3] are theoretically interesting hydrocarbons, since—formally—they can be regarded, on the one hand, as *peri*-bridged naphthalenes, and, on the other, as "peripheral" [4n]- or [4n+2]annulenes with a central C=C bridge as a perturbation.[4] *Platt*'s model[5] suggests that **2** possesses [4n+2]annulene character, and this supposition is indeed borne out by the NMR spectra (diamagnetic ring current),[6a-c] the physical properties,[6d-g] and the chemical stability[2] of the compound.

On the basis of PMO- and PPP-SCF calculations and especially on the basis of the paratropism revealed in the ^1H- and ^{13}C-NMR spectra, the strained hydrocarbon **1**, which is stable only in solution, is looked upon as a perturbed [12]annulene.[1,7] Accordingly, the [4n]-perimeter in **1**, similarly to the [4n+2]-perimeter in **2**, would appear to be capable of governing the π-electronic structure of the molecule. A deeper insight into the bonding situation in "[4n]-perimeter molecules" should be provided by dipleia-

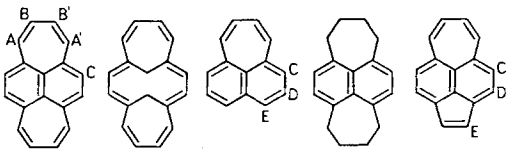
Greinstrasse 4, D-5000 Köln 41 (FRG)



diene (dicyclohepta[*de,ij*]naphthalene) **3**, which has now been obtained as a relatively stable compound in connection with an entirely different study.

The primary target of the present investigation was the still unknown 2,7-dimethylene-3,5-cycloheptadien-1-one **5** and its utilization for the synthesis of 11-oxo-1,6-methano[10]annulenes via [8+2]-cycloaddition with acetylenes. 2,7-Bis(bromomethyl)tropone **4**[8] appeared to be the most suitable starting compound available for the generation of the presumably very reactive tetraene **5**. Treatment of **4** with zinc in dimethylformamide or with sodium iodide in acetone leads, in each case, to formation of the 17,18-dioxo[16]annulene derivative **6**[9] as the sole isolable product (from ether, pale yellow crystals; decomposition above 195°C; yield 15–30% and 25%, respectively), most likely formed from the hitherto undetected intermediate **5** by radical dimerization. The expectation of being able to trap **5** with acetylenes or maleic anhydride did not materialize.

It did not escape our notice that **6** is formally only two simple steps—an intramolecular reductive C=C coupling (e.g. McMurry reaction)[10] and dehydrogenation— removed from the much discussed dipleiadiene **3**, which defied all previous attempts at its synthesis. Indeed, **6** can be converted remarkably easily into **3**. Obviously favored by the intramolecular course of the reaction, **6** undergoes coupling almost quantitatively with titanium tetrachloride/zinc[11] in tetrahydrofuran to give the heptafulvalene **7**, which proves to be a very reactive compound [violet-black crystals (platelets) from ether; decomposition above 140°C; yield 90–95%]. While **7**, on reaction with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone in benzene/hexane (3:1) at 0°C, failed to afford a defined product, it smoothly furnishes **3** when treated with the milder dehydrogenating reagent chloranil (under otherwise the same conditions). Hydrocarbon **3** is air-stable and crystallizes from ether in the form of reddish-black needles of m.p. 154–155°C (yield 80%).

Proof of the structure of **3** is based both on the spectra (see Tables 1 and 2) and on the X-ray structure analysis. A striking feature of the ^{1}H-NMR spectrum is the extremely high field location of all the signals. This is especially apparent when the ^{1}H-chemical shifts of **3** are compared with those of 1,6:9,14-bismethano[16]annulene **8**,[12] which, qualitatively, can be regarded as a model for the [16]annulene partial structure of **3**. The resonances of the "aromatic protons" of **3** are as close as 0.53 ppm to those of the corresponding protons of **8**, while the resonances of the seven-membered ring protons of **3** even appear by 0.44 and 0.63 ppm at higher field, respectively, than those of **8**. A comparison of the ^{1}H-NMR spectrum with those of the reference compounds **9**,[2,13] **10**,[3] and **2**[6a–c] also evidences the pronounced shielding in **3** (Table 1). In analogy to pyracylene **1**, **3** is thus distinguished by a paramagnetic ring current in the periphery of the molecule.

6: ^{1}H NMR (300 MHz, $CDCl_3$): δ=2.42 and 3.59 (AA′XX′ system, 8H), 6.63 and 6.94 (AA′BB′ system, 8H); ^{13}C NMR (75.5 MHz, $CDCl_3$): δ=38.40, 131.02, 131.35, 150.62, 189.55; MS (70 eV): m/z 264 (M^+, 36%); UV/VIS (MeOH): λ_{max}=234 nm (ε=40000), 320 (10500); IR (KBr): ν=1622 cm^{-1} (C=C), 1591, 1580 (C=O)

7: ^{1}H NMR [300 MHz, $CS_2/(CD_3)_2CO$]: δ=2.25 (s, 8H), 5.48 and 5.60 (AA′BB′ system, 8H; J(AB)=7.43, J(AB′)=1.05, J(AA′)=0.12, J(BB′)=11.04); ^{13}C NMR [75.5 MHz, $CS_2/(CD_3)_2CO$]: δ=36.00, 123.92, 129.29, 131.52, 143.55; MS (70 eV): m/z 232 (M^+, 100%), 202 ($M^+-C_2H_2$, 62); UV/VIS (EtOH): λ_{max}=236 nm (ε=28900), 388 (19300), 403 (16100) sh; IR (CsI): ν=3021, 2955, 2904, 2848, 1551, 731 cm^{-1}

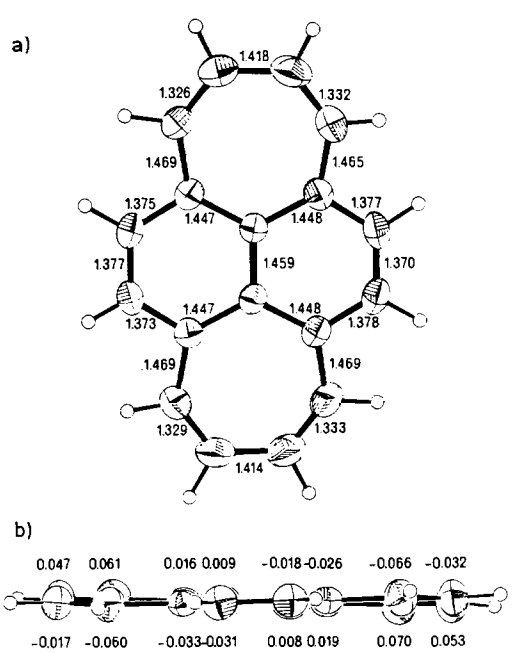

Fig. 1. Crystal structure of **3**: a) top view, bond lengths [Å]; b) longitudinal profile, distances [Å] of the carbon atoms from the mean ring plane. The values at the top refer to the rear series of atoms, those at the bottom to the front series of atoms. Atoms with negative values are located below the plane of the molecule.

The paratropism inferred from the ^{1}H-NMR spectrum of **3** would also seem to manifest itself in the ^{13}C-NMR spectrum, for, if naphthalene and pleiadiene **9** are taken as model compounds, a ring current contribution $\Delta\sigma$ of -3.2 ppm [**1**: $\Delta\sigma = -7.9$ ppm; **2**: $\Delta\sigma = +6.8$ ppm (mean value)] is obtained for the chemical shift of the central carbon atoms.

The electronic spectrum of **3** (see Table 2) is qualitatively consistent with the predictions made by *Yamaguchi* and *Nakajima*[4c] and by *DasGupta* and *Birss*[4g,14] on the basis of theoretical calculations.

Unlike **1** and **2**, dipleiadiene **3** was found to be amenable to an X-ray structure analysis.[15] The molecule shows a slight puckering of all rings (Fig. 1b; maximum distance of the carbon atoms from the mean plane: 0.07 Å), caused by non-bonding H,H-interactions. The naphthalene nucleus has, according to the C–C bond lengths, essentially maintained its integrity. In the case of the *peri*-bridges, the analysis (Fig. 1a) confirms the strong bond alternation already deduced from the ^{1}H-NMR spectrum on the basis of the magnitudes of the vicinal H,H-coupling constants J_{AB} and $J_{BB'}$ (Table 1).

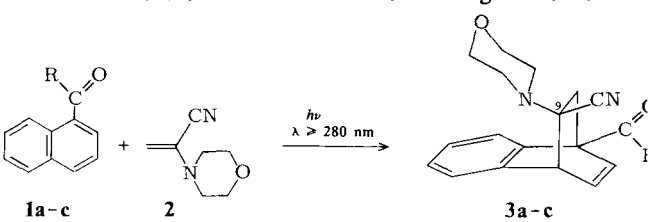
1,4-Photocycloaddition of α-Morpholinoacrylonitrile to 1-Acylnaphthalenes**

By *Dietrich Döpp,* Carl Krüger, Hamid Reza Memarian,* and *Yi-Hung Tsay*



Dedicated to Professor Hans Musso on the occasion of his 60th birthday

In the course of investigations of the cycloaddition reactions of captodative[1] olefins, we found that α-morpholinoacrylonitrile **2**[2] can undergo smooth addition to electronically excited 1-acylnaphthalenes **1** with formation of 1-acyl-9-morpholino-1,4-dihydro-1,4-ethanonaphthalene-9-carbonitriles **3** (Table 1).

This is remarkable insofar as light-induced cycloadditions of alkenes to the naphthalene skeleton have—with one exception[3]—hitherto been unknown for acylnaphthalenes but are well known for naphthalene,[4] 1- and 2-naphthonitrile,[5] and naphthyl methyl ethers.[6] Both 1,2- and 1,4-additions are observed,[4] and the results for the additions to naphthonitriles support a mechanism involving the intermediacy of singlet exciplexes.[5]

Equimolar amounts of **1a–c** and **2** were irradiated for periods of time sufficient to obtain the conversions given (Table 1);[7] the yields of the thermally labile product **3** (which could not be recrystallized without loss of material) are based on the converted (i.e., non-recovered) starting material **1**. The photoaddition of **2** to 1-acetonaphthone **1b** is particularly convenient since the product **3b**[8] precipitates in fairly pure form during the irradiation, even at low conversions. Neither the mother liquors nor the crude precipitates of the product show evidence of other products in the ^{1}H-NMR spectrum.

The solvent effects observed are not large. The use of

1a–c **2** **3a–c**

Table 1. Photocycloaddition of **2** to **1** to give **3**. t = irradiation time. For conditions see [7]. Yields are based on unreacted **1**.

[**] This work was supported by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

methanol results in a slight increase in the conversion of **1**. In this solvent, a maximum quantum yield of $\Phi = 0.02$, depending on the concentration of **2**, may be achieved for the consumption of **1b** at 313 mm. Tetramethyl-3,4-dihydrodiazete dioxide[9] inhibits the addition, which indicates the involvement of the triplet excited state of **1b**. A plot of Φ^{-1} against $[2]^{-1}$ results in a straight line and thus suggests a bimolecular interaction between electronically excited **1b** and **2**. The rate constant for the quenching of the triplet excited state of **1b** by compound **2** was estimated to be $k = 1.8 \times 10^8$ L mol^{-1} s^{-1}.[10]

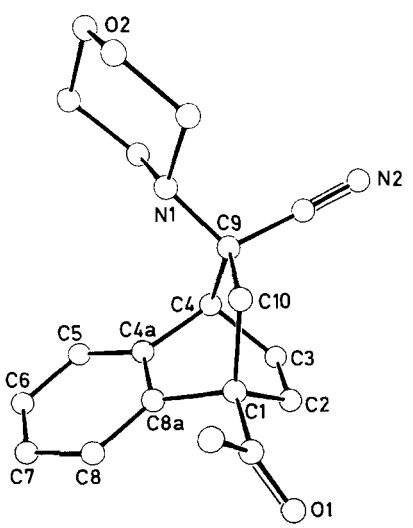
The *endo* position of the morpholino group was confirmed for **3b** by an X-ray structure determination[11] (Fig. 1). Noteworthy are the significantly elongated bond distances between C1 and C10, C4 and C9, and C9 and C10. By analogy, the same configuration is also assumed to be valid for **3a** and **3c**.

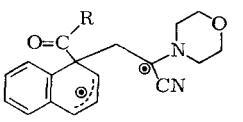
In chloroform at 50°C, **3b** decomposes with a half-life of 6 d to give the educts **1b** and **2**.

Although 1-acylnaphthalenes can in principle undergo a Paterno-Büchi reaction,[12a] the formation of oxetanes with **2** was not observed. This and the finding that **1a–c** each form only a single photoadduct with **2**, along with the preferred *endo* orientation of the morpholino group, as established for **3b**, render the intermediacy of diradicals **4**, **5** (captodative stabilized at one terminus[1]) unlikely, but do not rigorously exclude this possibility.

Apparently, in the photocycloaddition described here, the radical-stabilizing properties ascribed to the captodative terminus in **2**[1] are less important than the ability of **2** to undergo complex formation. Nevertheless, **2**, with a first ionization potential of 8.68 eV,[13a] is more like an enamine such as cyclopentenylmorpholine (7.60 eV[13b]) than an α,β-unsaturated nitrile (acrylonitrile: 10.91 eV[13c]). A (triplet) exciplex, in which the lone electron pair of the morpholino group or the entire enamine portion of **2** lies above the π-system of **1a–c**, is therefore conceivable.

2-Acetonaphthone does not give a photoadduct with **2**, nor are oxetanes formed.[12b] Instead, a dimer of **2** is formed in low yield. The captodative-substituted olefin α-*tert*-butylthioacrylonitrile also can undergo photoaddition to **1a**, **b** and to 2-naphthaldehyde.[14]





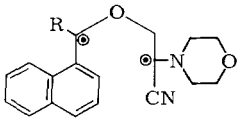


Fig. 1. Molecular structure of *rel*-(1*S*,4*S*,9*S*)-1-acetyl-9-morpholino-1,4-dihydro-1,4-ethanonaphthalene-9-carbonitrile **3b** in the crystal. Oxidation of 2-Propanol at Ti/Cr_2O_3 Anodes**

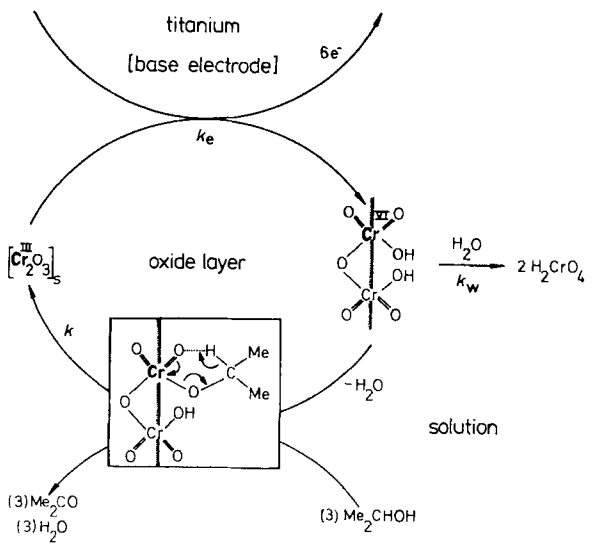
By *Harry Schulz* and *Fritz Beck**



Chromic acid is a very important and frequently selective oxidizing agent in organic chemistry,[1,2] but separa-

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

tion of the Cr^{III} salts formed in stoichiometric amounts when it is used, and their electrolytic reoxidation,[3] present problems. The mechanism of the homogeneous redox reaction has been elucidated by *Westheimer* et al.[4] (cf. [5]). Our interest was aroused in the possibility of developing an electrochemical method analogous to the chromic acid-oxidation method. Some 20 years ago, *Beer* first described the use of activated titanium electrodes in electrolysis[6] where they now play an important role in inorganic chemistry.

We have now developed a method for preparing Ti/Cr_2O_3 electrodes on the basis of a technique used for the production of ceramics.[7] The dark-green, excellently adhesive, microporous α-Cr_2O_3 layer, ca. 1 μm thick, can be stabilized by other oxides. Anodic polarization of the Ti/Cr_2O_3 electrode in 1 M H_2SO_4, leads to formation of a layer of CrO_3 on the surface, which after hydration (rate constant k_w) goes into solution (cf. Scheme 1). The rate

Scheme 1. Electrochemical oxidation of 2-propanol via heterogeneous redox catalysis at Ti/Cr_2O_3 anodes (schematic). The complex between surface-fixed chromic acid and 2-propanol is shown in the box.

constant of the $Cr^{III} \rightarrow Cr^{VI}$ electrochemical oxidation (k_e) increases exponentially with the anodic overvoltage. The possibility of using the resulting CrO_3 as an oxidizing agent for the oxidation of 2-propanal to acetone was tested (rate constant k); CrO_2 was formed, which either directly reoxidized electrochemically or, as in solution, rapidly underwent further follow-up reactions[4,5] to give Cr_2O_3. Turnover numbers of 100–10000 can be realized with catalytic amounts of Cr_2O_3 ("heterogeneous redox catalysis"[8,9]). The lifetime of the electrode is limited by the dissolution of CrO_3 and decreases with increasing k_w, but increases with k.[8]

The Cr_2O_3, which adheres as a very thin passive layer to the surface of chromium or chrome steels, has *no* catalytic properties. In the anodic polarization of such electrodes in sulfuric acid solutions of 2-propanol chromium dissolves transpassively with 6 F/mol.[10]

The initial reaction in the homogeneous oxidation of sterically unhindered alcohols with chromic acid is a rapid esterification; the rate-determining step is then a hydrogen shift, in which significant H/D isotope effects occur.[4b,5,11] Upon oxidation at Ti/Cr_2O_3 anodes, the esterification takes place on the electrode surface (cf. Scheme 1); this can be regarded as a special case of chemisorption. The following experimental findings prove that the rate-determining step is that of homogeneous oxidation:

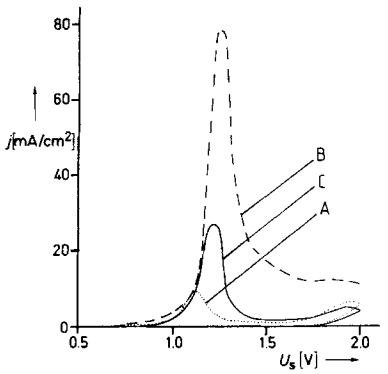

Fig. 1. Quasistationary current voltage curves for a Ti/Cr_2O_3 electrode [6, 8]. A in 1 M H_2SO_4, B in 1 M H_2SO_4 + 1 M 2-propanol, and C in 1 M H_2SO_4 + 1 M [D_8]2-propanol. Voltage scan rate: 5 mVs^{-1}. j = current density. U_s = potential referred to the Hg/Hg_2SO_4 electrode in 1 M sulfuric acid.

1) A comparison of curve B with curve A in Figure 1 shows the characteristic increase in current for the heterogeneous redox catalysis.[8,9] At higher overvoltages, a limiting current density j_{lim} of 78 mA cm^{-2} is established for the oxidation of 2-propanol. If the rate constant k_{hom} found for the homogeneous case[12] is used in Equation (a) then a

$$j_{lim} = z F k_{hom} [CrO_3]_s \qquad (a)$$

value of only ca. 0.1 mA cm^{-2} is obtained ($z = 2$, $Cr^{VI/IV}$, $[CrO_3]_s$ = surface concentration of CrO_3[8]). The discrepancy cannot be explained in terms of a roughness factor alone, and, furthermore, the medium effect—k_{hom} was determined in glacial acetic acid[12]—only lowers the limiting current to ca. 20 mA cm^{-2}. The activation entropy plays the decisive role:[13] Whereas ΔS in the homogeneous reaction is approximately -24 cal K^{-1} mol^{-1},[14] ΔS at the electrode must be larger. We obtain the observed limiting current density of the reaction j_{lim} using a value of -13.4 cal K^{-1} mol^{-1} for ΔS.

2) As shown by the curve C in Figure 1, a strong isotope effect is found with [D_8]2-propanol. j_{lim}, and thus also k,[8] decreases by a factor of 2.9. Primary isotope effects of 6.5–7 were found for the homogeneous oxidation.[4b,5,11,12] Isotope effects were also established in the reaction at the alkaline nickel oxide anode.[15]

3) We have converted 2-propanol into acetone on a preparative scale with 100% current efficiency at $j = 0.5$ mA cm^{-2}. This high selectivity is also obtained upon oxidation with chromic acid. In complete contrast, a current yield of only 70% is achieved on platinum.[16] The by-products of the oxidation include, inter alia, acetic acid.

4) When oxidation at the anode is carried out in the presence of 0.43 M $MnSO_4$, the limiting current density is reduced to 25% of the normal value. In the homogeneous reaction, a marked decrease in the conversion was established upon trapping the Cr^{IV} products formed in the first

$$Cr^{IV} + Mn^{II} \longrightarrow Cr^{III} + Mn^{III} \qquad (b)$$

oxidation step [Equation (b)], so that Cr^{IV} cannot be used for the oxidation.[17] The decrease in j_{lim} could also be attributed, in part, to a partial coating of the electrode with MnO_2.

5) Addition of acrylamide to the electrolyte (0.5 M) leads to a decrease of j_{lim} to 40% of the original value. The formation of polyacrylamide in the oxidation with chromic acid has been regarded as proof for the occurrence of radical intermediates.[18] In the oxidation at the Ti/Cr_2O_3 anode, however, the possibility that layers of polymers on the electrodes leads to a decrease in current cannot be ruled out.

Summarizing, it has been established that 2-propanol is oxidized to acetone at a Ti/Cr_2O_3 anode via a mechanism analogous to that postulated by *Westheimer* for homogeneous oxidation with chromic acid. The lifetimes of the electrodes are still too short for use on an industrial scale, but we have already been able to achieve substantial improvements by using Sb_2O_4 as additional oxide component.[8]

Elucidation of the Structure of Epidermin, a Ribosomally Synthesized, Tetracyclic Heterodetic Polypeptide Antibiotic

By *Hermann Allgaier, Günther Jung,* Rolf G. Werner, Ursula Schneider,* and *Hans Zähner*

From the culture filtrate of *Staphylococcus epidermidis* Tü 3298, we have isolated a novel active compound which is highly effective, especially against the pathogen *Propionibacterium acnes* occurring in acne disease and against staphylococci and streptococci (Fig. 1). After adsorption on Amberlite XAD-8 and chromatography on Sephadex LH-20 the antibiotic could be isolated in pure form via two purification steps, by multiplicative countercurrent distribution.

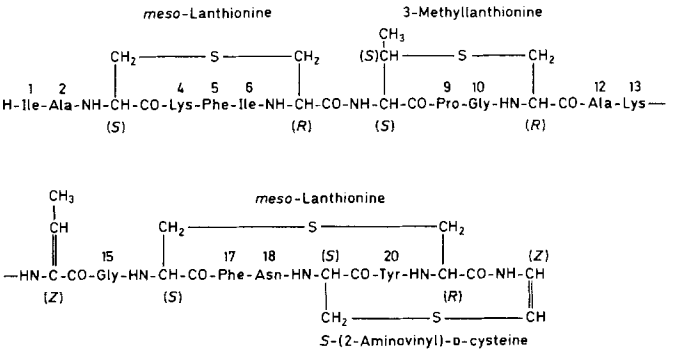

Fig. 1. Sequence of the tetracyclic heterodetic 22-peptide antibiotic epidermin. Trypsin cleaves behind Lys^{13} into the fragments P1 and P2 (cf. Fig. 2). All chiral amino acids without indicated configurations have the L-configuration, i.e. they belong to the (*S*)-series (exceptions are sulfur-containing amino acids such as cysteine: L-Cys is (*R*)-configurated).

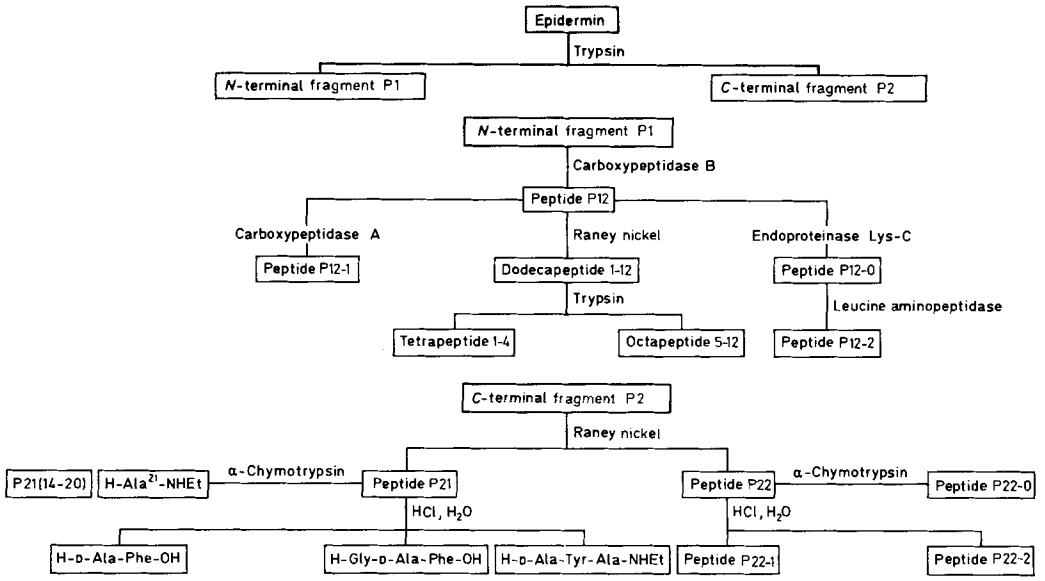
The acidic total hydrolyzate of epidermin contained thirteen protein amino acids, two lanthionines, and one 3-methyllanthionine. The *meso*- and (2*S*,3*S*,6*R*)-configurations of lanthionine and 3-methyllanthionine, respectively, were determined by gas chromatography on chiral stationary phases.[1] In the nuclear resonance spectra of the antibiotic, two unsaturated amino acids could be detected; these were completely destroyed upon acidic total hydrolysis (Table 1).

Table 1. Characterization of epidermin. Dhb = dehydroaminobutyric acid (2-amino-2,3-didehydrobutyric acid).

Amino acid composition: L-Asn (1), L-Pro (1), Gly (2), L-Ala (2), L-Ile (2), L-Tyr (1), L-Phe (2), L-Lys (2), Dhb (1), *meso*-lanthionine (2), (2*S*,3*S*,6*R*)-3-methyllanthionine (1), *S*-(2-aminovinyl)-D-cysteine (1)



Thin-layer chromatography (silica gel $60F_{254}$ plates, Merck): chloroform/methanol/17% ammonia (2:2:1), $R_F = 0.73$; 1-butanol/glacial acetic acid/water (4:1:1), $R_F = 0.05$

Mass spectra: Fragment P1 $[M+H]^+$: *m/z* 1302 (FAB-MS), fragment P2 $[M+Na]^+$: *m/z* 904 (FD-MS)

UV spectrum ($c = 0.15$ mg/mL, water, pH = 7): $\lambda_{max} = 267$ nm, $\varepsilon_{max} = 11000$

Starting point of the sequencing of the complex basic polypeptide was the tryptic cleavage into an *N*-terminal fragment P1 and a *C*-terminal fragment P2. These fragments could be separated from each other, since P2 precipitated upon enzymatic cleavage of epidermin. *C*-terminal lysine could be cleaved from the tryptic fragment P1 by reaction with carboxypeptidase B (Fig. 2). A subsequent desulfurization with Raney nickel[2] afforded a bridge-free dodecapeptide 1–12, which was sequenced by FAB-MS and Edman degradation in a gas-phase sequencer. A further fragmentation of the dodecapeptide into the peptides 1–4 and 5–12 was achieved by further tryptic cleavage. The positions of the sulfur bridges in P1 could be determined by reactions with carboxypeptidase A and B, trypsin, and endoproteinase Lys-C, in combination with Edman degradation and FAB-MS (Fig. 2).

The tryptic fragment P2, which is insoluble in water, was *N*-terminally blocked with 2-oxobutyric acid and *C*-terminally blocked by the ε-amino group of the amino acid *S*-(2-aminovinyl)-D-cysteine. Tryptic cleavage furnished the 2-oxobutyryl residue, in which the dehydroaminobutyric acid (Dhb) after Lys^{13} was converted.[3] *S*-(2-Aminovinyl)-D-cysteine (Cys(Avi)), which is likewise labile under the conditions of acidic total hydrolysis, could be converted by

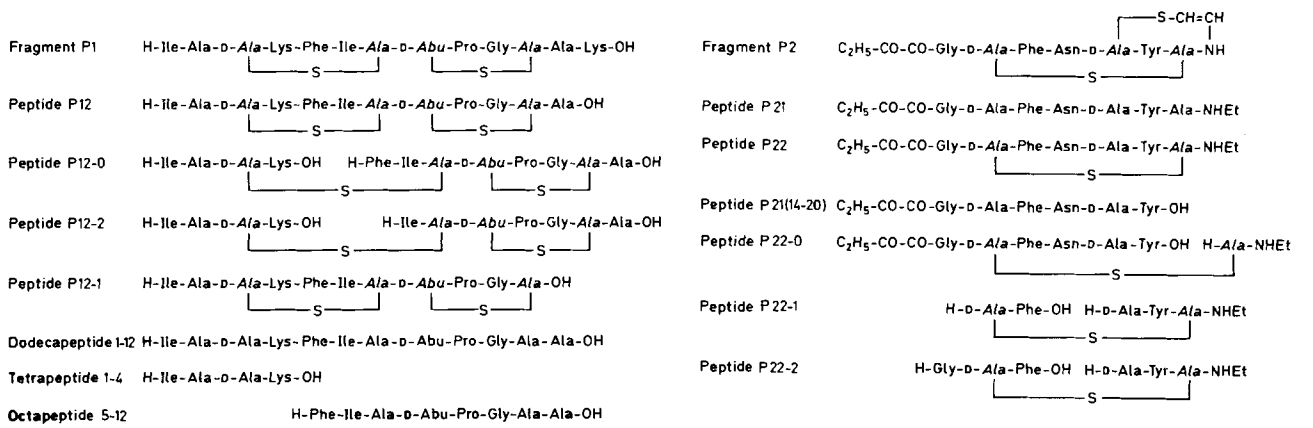


Fig. 2. Elucidation of the structure of epidermin. The halves of the thioether amino acids nearest to the *N*-termini are each D-configurated at C_α (cf. Fig. 1). Without this excessive fragmentation of the molecule, an assignment of the thioether bridges is impossible. D-Ala—S—Ala: *meso*-lanthionine; D-Abu—S—Ala: (2*S*,3*S*,6*R*)-3-methyllanthionine; D-Ala—S—CH=CH–NH_2: *S*-(2-aminovinyl)-D-cysteine).

hydrogenation of the native antibiotic into the stable amino acid *S*-(2-aminoethyl)-D-cysteine (Cys(Aet)), which was detectable by amino acid analysis and by mass spectrometry.

The key reaction for the elucidation of the structure of P2 was desulfurization with Raney nickel.[2] *S*-(2-Aminovinyl)-D-cysteine was thereby completely converted into D-alanine and *C*-terminal *N*-ethylamide. Under the chosen reaction conditions, *meso*-lanthionine could only be partly desulfurized, so that the bridge-free peptide P21 and the peptide P22 resulted, which still contained one *meso*-lanthionine bridge (Fig. 2). The sequencing of the *C*- and *N*-terminally blocked peptide P21 was accomplished by acidic partial hydrolysis. The assignment of the sulfur bridges in P2 was achieved by a combination of enzymatic and acidolytic cleavages with FAB-MS.

The 22-peptide (docosapeptide) epidermin, like nisin[4] and subtilin,[5] belongs to the polycyclic heterodetic class of peptide antibiotics. It differs from the latter mentioned peptides, however, not only in the primary structure but also by its extremely rigid conformation, as shown by comparative CD investigations. The recently described polycyclic heterodetic peptide ancovenin[6] is not antibiotically active, but it inhibits the angiotensin I-converting enzyme ACE.

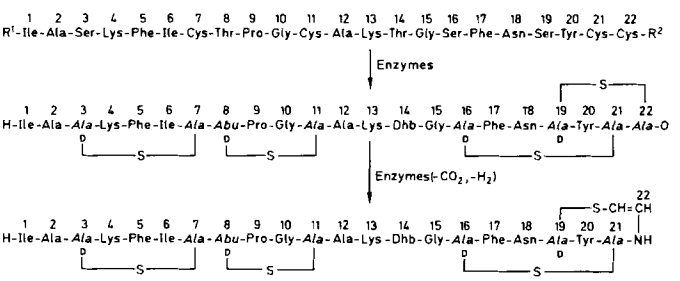

Fig. 3. Possible biosynthesis of epidermin from a postulated ribosomal precursor. The sequence of the steps—dehydration of serine and threonine, addition of the SH groups of cysteine with formation of the sulfur bridges, cleavage of CO_2 and H_2, thereby *C*-terminal formation of *S*-(2-aminovinyl)-D-cysteine—is presently being tested by isolation of the respective intermediates (see text). R^1 and R^2 have not been defined; *meso*-lanthionine and 3-methyllanthionine are abbreviated as in Figure 2; however, the configuration symbol D has been placed below "Ala".

The addition of inhibitors of the protein synthesis or RNA synthesis (erythromycin, rifampicin) to cultures of *Staphylococcus epidermidis* completely prevented the production of antibiotics. Epidermin thus belongs to the few antibiotics that are formed from a ribosomally synthesized precursor (Fig. 3) by posttranslational, enzymatic modification.[7] Dehydration of Ser^3, Thr^8, Thr^{14}, Ser^{16}, and Ser^{19} leads thereby to formation of dehydroalanine (Dha) and dehydroaminobutyric acid (Dhb). The subsequent or synchronous addition of thiol groups of the cysteine residues in the positions 7, 11, 21, and 22 to the CC double bonds of Dha and Dhb leads, with formation of sulfide bridges to *meso*-lanthionine and (2*S*,3*S*,6*R*)-3-methyllanthionine. The new *C*-terminal amino acid *S*-(2-aminovinyl)-D-cysteine is presumably formed by enzymatic oxidative decarboxylation, whereas the central dehydroaminobutyric acid remains unsaturated. We are at present attempting to detect and isolate precursor proteins with the aid of antibodies against synthetic segments of the postulated prosequence in order to prove this biosynthesis experimentally.

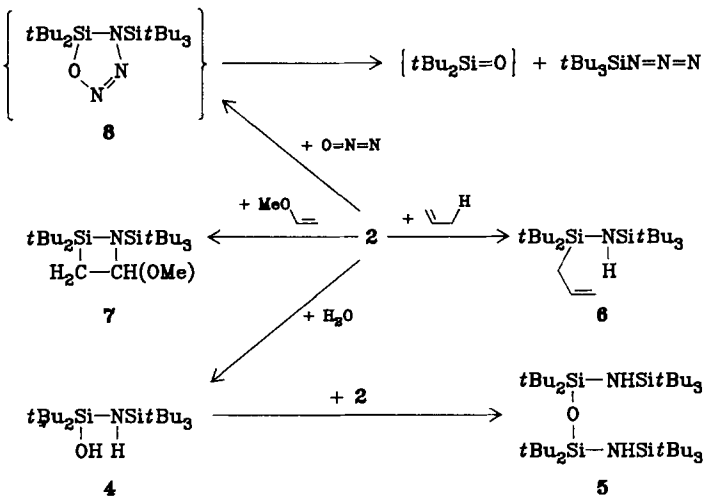
Isolation of the Stable Silaketimine tBu$_2$Si=N–SitBu$_3$**

By *Nils Wiberg,* Klaus Schurz,* and *Gerd Fischer*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday



We were recently able to isolate the silaethene **1**, which is stable at room temperature.[1] We have now succeeded in preparing the first stable silaketimine **2**.

1 **2** **3**

2, like **1**, can be obtained by "thermal elimination of salt." The tetrahydrofuran (THF) adduct of compound **3**[2] serves as the precursor, which slowly eliminates LiCl upon heating.[3] In the presence of $CF_3SO_3SiMe_3$, **3** is transformed rapidly, even at room temperature, into the unsaturated system **2**, which can be crystallized from pentane at −78 °C.[5] The silaketimine **2** gives the expected ^{1}H-NMR, ^{29}Si-NMR, and mass spectra (see Experimental Procedure).

The unsaturated character of **2** is exhibited in a number of addition reactions (cf. Experimental Procedure). With water, **2** forms the addition product **4** (the product of insertion of **2** into an OH bond of H_2O), which, in turn, can react with **2** to form **5**. With propene, the ene reaction product **6** is formed, with methyl vinyl ether, the [2+2] cycloadduct **7**. Dinitrogen oxide also reacts with **2**; the primary product is probably the [2+3] cycloadduct **8**, which, however, is unstable and decomposes with formation of tri-*tert*-butylsilylazide and further products of tBu$_2$SiO, which have not yet been identified.

Experimental Procedure

Preparation of **2**: MeLi (15.99 mmol) in 17 mL of THF was added to tBu$_2$SiCl-NH(SitBu$_3$) **9** (6.27 g, 15.98 mmol) dissolved in 50 mL of THF at −78 °C. The mixture was allowed to react at −60 °C for 70 h (quantitative conversion according to ^{1}H-NMR spectroscopy). After removal of all volatiles in vacuum at room temperature, the residue was dissolved in 100 mL of pentane and the resulting solution treated with 2.9 mL (16 mmol) of $CF_3SO_3SiMe_3$. After 1 d, the solution was filtered to remove all precipitate formed (CF_3SO_3Li) and concentrated to 50 mL; THF-containing **2** crystallized out at −78 °C (80%). MS (15 eV): *m/z* 355 (M^+, 0.1%), 298 ($M^+ - t$Bu, 100%), 256, 214, 172, 130 (298$^+$ − n × propene, 3, 14, 7, 25). ^{1}H-NMR (THF, 28 °C): δ = 1.178 (tBu$_2$Si), 1.107 (SitBu$_3$). ^{29}Si-NMR (THF, 28 °C): δ = −2.555 (tBu$_2$Si), −16.571 (tBu$_3$Si).

Reactions of **2**: **2** (0.427 g, 1 mmol), dissolved in benzene, was allowed to react at room temperature with 0.5 or 1 mmol of H_2O and at 60 °C with 10 mmol of propene or 10 mmol of methyl vinyl ether. After removal of all volatiles in vacuum at room temperature, the analytically pure products **4**–**7** were obtained. The following melting points and ^{1}H-NMR signals (C_6D_6) were obtained for the samples characterized by elemental analysis and mass spectroscopy. **4**: m.p. = 130 °C; δ = 1.099 (s, SitBu$_2$), 1.216 (s, SitBu$_3$), 1.443 (s, OH).—**5**: m.p. = 344 °C (decomp.); δ = 1.279 (s, SitBu$_3$), 1.380 (s, SitBu$_2$).—**6**: m.p. = 121 °C; δ = 1.176 (s, SitBu$_2$), 1.192 (s, SitBu$_3$), 2.074 (m, SiCH$_2$), 5.129 (m, CH$_2$), 6.070 (m, CH).—**7**: m.p. = 114 °C (decomp.); δ = 1.148, 1.214 (s, SitBu$_2$), 1.290 (s, SitBu$_3$), 2.907 (s, CH$_3$), 4.934 (m, CH).

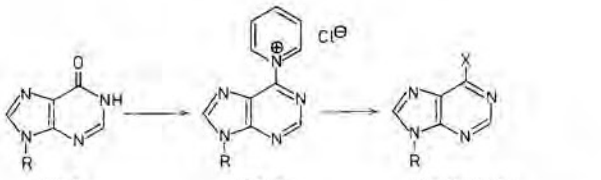
Synthesis of 6-Substituted Purines and Ribonucleosides with *N*-(6-Purinyl)pyridinium Salts**

By *Ryszard W. Adamiak,* Ewa Biała,* and *Bohdan Skalski*

The synthesis of 6-substituted purines and nucleosides—target compounds for biological and pharmaceutical studies—has usually been achieved by nucleophilic displacement reactions at C-6 of the purine ring. 6-Chloropurines, which can be prepared from hypoxanthines by reaction with $POCl_3$ in the presence of *N,N*-diethylaniline,[1] and the more reactive trialkyl(6-purinyl)ammonium salts,[2] or 6-alkylsulfonylpurines derived from them,[3] have proven to be the most suitable synthetic intermediates for such reactions.

We recently reported[4] on a virtually quantitative transformation of 2′,3′,5′-tri-*O*-acetylinosine **1a** and 9-methylhypoxanthine **1b** into fluorescent, water-soluble *N*-(6-purinyl)pyridinium salts **2a** and **2b** (87% and 75% yield), respectively, during pyridine assisted phosphorylations with 4-chlorophenyl phosphorodichloridate. Aqueous solutions of **2a** and **2b** are stable in the pH range 1.5–6.5 in the absence of light.[5]



Easy access to these purines, equipped with a good leaving group at C-6, prompted us to study their reactivity towards nucleophiles. Herein, we report on a highly efficient, two-step synthesis of the 6-azido- **3a**, **b**, 6-alkylthio- **4a**, **5a**, and 6-methoxy-derivatives **6a**, **b** (Table 1).

Both **2a** and **2b** react with sodium azide in anhydrous dimethylformamide within a few minutes to give 6-azido-9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)purine **3a** and 6-azido-9-methylpurine **3b**, which could be isolated in 94 and 90% yields, respectively. Displacement with azide ion, although much slower, is also possible in aqueous solution.

When an aqueous solution of **2a**[4] was treated with 2-mercaptoethanol the purine derivative **4a** was formed within 1 h and could be isolated in 90% yield. The ethylthio derivative **5a** can be obtained directly from **1a** in an overall yield of 85% in a one-pot reaction.

The methoxy derivatives **6a** and **6b** are formed within a few hours upon reaction of **2a** and **2b**, respectively, with sodium methoxide in anhydrous methanol.

All the reactions described above proceed quantitatively under very mild conditions (checked by thin-layer chromatography on silica gel plates in chloroform containing 1–10% methanol). The products can be isolated in over 95% purity by simply concentrating the reaction mixture, if necessary, and water/chloroform extraction (with the exception of **6a**) - checked by thin-layer chromatography, elemental analysis, and ^{1}H-NMR spectra.

b: R = Methyl

Table 1. Some data of the products **3a**, **b**, **4a**, **5a**, and **6b**.

3a: λ_{max} (MeOH) = 252, 260, 287 nm (ε = 4200, 4600, 8100); λ_{min} = 240, 255, 264 (3400, 4100, 4300); ^{1}H NMR ($CDCl_3$): δ = 9.65 (1 H, s), 8.66 (1 H, s), 8.45 (1 H, s), 8.24 (1 H, s), 6.40 (1 H, d, J = 5.2 Hz), 6.25 (1 H, d, J = 5.1 Hz), 6.02–5.90 (2 H, m, 5.74–5.63 (2 H, *m*), 4.45 (6 H, *m*), 2.17–2.10 (9 H, 3 s) [a]

3b: m.p. 197°C; UV similar as for **3a**; ^{1}H NMR ([D_6]DMSO): δ = 10.10 (1 H, s), 8.60 (1 H, s), 4.01 (3 H, s); ^{1}H NMR ($CDCl_3$): δ = 9.50 (1 H, s), 8.69 (1 H, s), 8.17 (1 H, s), 7.97 (1 H, s), 4.08 (3 H, s), 3.90 (3 H, s) [a]

4a: λ_{max} (MeOH) = 286, 290 nm (ε = 18200, 18200); ^{1}H NMR ($CDCl_3$): δ = 8.68 (1 H, s), 8.18 (1 H, s), 6.22 (1 H, s, J = 5.0 Hz), 5.96 (1 H, t), 5.66 (1 H, t), 4.42 (3 H, s), 3.99 (2 H, t), 3.55 (2 H, t), 2.15, 2.11, 2.08 (9 H, 3 s)

5a: λ_{max} (MeOH) = 284, 290 (ε = 18300, 18300); ^{1}H NMR ($CDCl_3$): δ = 8.71 (1 H, s), 8.18 (1 H, s), 6.24 (1 H, d, J = 5.1 Hz), 5.97 (1 H, t), 5.74 (1 H, t), 4.43 (3 H, br. s), 3.38 (2 H, q, J = 7.3 Hz), 2.15, 2.11, 2.08 (9 H, 2 s), 1.45 (2 H, t, J = 7.3 Hz)

6b: m.p. 147°C; λ_{max} (H_2O) = 253 nm (ε = 11000); λ_{min} = 222 nm (ε = 2300); ^{1}H NMR ($CDCl_3$): δ = 8.56 (1 H, s), 7.89 (1 H, s), 4.19 (3 H, s), 3.89 (3 H, s)

[a] The ^{1}H-NMR spectrum in $CDCl_3$ is consistent with an equilibrium between the 6-azide and a tetrazole (see [3]).

The two-step synthesis of **3a**, **b**, **4a**, **5a**, and **6a**, **b** has a great advantage over the older methods[2,3], in that it requires fewer steps and affords higher overall yields.

As might be expected, the lack of substituents at the α-positions of the pyridinium ring of **2a**, **b** makes these sites likewise vulnerable to nucleophilic attack; this results in some limitations of the range of application of *N*-(6-purinyl)pyridinium salts. Strongly basic nucleophiles such as the hydroxide ion or some amines react with **2a**, **b** with quantitative formation of 6-aminopurine derivatives[4] (Zincke reaction).[6]

Experimental

3a, **b**: A solution of **2a** (983 mg, 2 mmol) or **2b** (495 mg, 2 mmol) in anhydrous dimethylformamide (10 mL) was treated with sodium azide (195 mg, 3 mmol). The resulting mixture was stirred at room temperature for 5–10 min, concentrated under vacuum at 35°C, and subsequently partitioned between water (10 mL) and chloroform (3 × 15 mL). The organic layer was dried over $MgSO_4$ and then evaporated down: yield 788 mg (94%) of **3a** and 315 mg (90%) of **3b**, respectively.

5a: A solution of **1a** (788 mg, 2 mmol) in anhydrous pyridine (10 mL) was treated with 4-$ClC_6H_4OP(O)Cl_2$ (0.56 mL, 3 mmol), initially at +5°C (10 min) and then at room temperature overnight in the dark. After removal of pyridine at 35°C the resulting residue was treated with ice-cold water (10 mL). After 10 min, dioxane (5 mL) and ethanethiol (0.70 mL, 10 mmol) were added and the emulsified mixture was stirred overnight. The reaction mixture was concentrated to half the volume, saturated with NaCl and extracted with chloroform (3 × 5 mL). The organic layer was dried over $MgSO_4$, concentrated, and passed through a layer of silica gel (Merck H60) in chloroform containing methanol (0–5%). Appropriate fractions were collected, concentrated to a small volume (2 mL), and added dropwise to hexane (150 mL); yield 745 mg (85%) of **5a** as precipitate.

6a, **b**: A solution of **2a** (983 mg, 2 mmol) or **2b** (495 mg, 2 mmol) in anhydrous methanol (50 mL) was treated portionwise with 0.1 M sodium methoxide in methanol (100 mL, 10 mmol) under stirring. After 6–8 h the reaction

mixture was neutralized with acetic acid (ca. 0.6 mL) and evaporated to dryness under vacuum. – **6a**: The residue was dissolved in dry pyridine (50 mL) and, after concentration to ca. 20 mL, was treated with acetic anhydride (10 mL). After 1 h the mixture was treated with cold water and ethanol. Upon evaporation an oily residue was obtained; this was taken up in ethanol and treated with hexane, whereupon **6a** precipitated out: yield 702 mg (86%). – **6b**: The residue was partitioned between water (10 mL) and chloroform (3 × 15 mL). The organic layer was dried over $MgSO_4$, evaporated down, and **6b** was crystallized from chloroform; yield 280 mg (92%).

Selectivity of the Anodic Oxidation of CH- and CH_2-Groups; Selective Oxidation of Steroids at C-6**

By *Annegret Hembrock, Hans J. Schäfer,** and *Gesine Zimmermann*

Chemo- and regioselective functionalizations of CH- and CH_2-groups are especially useful in preparative chemistry, since they enable valuable products to be obtained in few steps from inexpensive starting materials. This is impressively exemplified by microbiological[1] and template-directed[2] oxidations of steroids. Hence, we became interested in studying the chemoselectivity of the anodic oxidation,[3,4] the possibility of inductively controlling the regioselectivity, and the oxidation of steroids.

Chemoselectivity: Anodic oxidation of methylcyclohexane in dichloromethane/trifluoroacetic acid affords 60% methylcyclohexyl trifluoroacetate. The statistically corrected reactivity of the hydrogen atoms on C-1, C-2, C-3, and C-4 of the educt is 10 : 2 : 2 : 1. Under the same conditions, *trans*-decalin affords 20–26% 1- and 2-decalyl trifluoroacetates and 54% oligomers (according to the mass spectrum, presumably tetramers and pentamers of decalin). In the less acidic electrolyte acetic acid/dichloromethane/Bu_4NBF_4 the oligomerization can be largely suppressed; decalyl acetates (43%) and fluorodecalins (32%) are obtained. With Bu_4NPF_6 as supporting electrolyte, 67% decalyl acetates and only 10% fluorodecalins are formed. The chemoselectivity of the acetoxylation at C-4a, C-1, and C-2 is 12 : 1 : 1. With Bu_4NOAc as supporting electrolyte, 77% decalyl acetate is obtained with equal selectivity without fluorination, but 35–40 F/mol are required for complete conversion; presumably because of a competing Kolbe electrolysis.

Regioselectivity by inductive effects: In the case of halogenations[5] or ozonolysis in superacids,[6] the site of reaction can be shifted by inductive effects; this also holds for the anodic oxidation. In dichloromethane/trifluoroacetic acid, chlorocyclohexane affords 23% 2-, 3-, and 4-chlorocyclohexyl trifluoroacetate in the ratio 1 : 1.7 : 3.2; cyclohexyl trifluoroacetate (16%), trifluoromethylcyclohexane (4%), and dichlorocyclohexane (30%, isomeric mixture) are additionally formed. In 2,2,2-trifluoroethanol the yields of byproducts are lower; 47% of the corresponding chlorocyclohexyl trifluoroethyl ethers are formed in the ratio 1 : 1.7 : 2.5. *trans*-1,2-Dichlorocyclohexane **1** affords 49% 3,4-dichlorocyclohexyl trifluoroacetate in dichloromethane/trifluoroacetic acid. A trifluoroacetoxylation in the α-position to the C–Cl groups is not observed.

Fatty acids **3** are preferentially trifluoroacetoxylated at the (ω – 2)- to (ω – 4)-CH bonds; no attack at C-2 to C-6 is observed, or, if at all, only very rarely (Table 1). The remarkable regioselectivity could be due to the inductive effect of the carboxyl group, which can also be protonated in the more strongly acidic region at the anode surface. In hydrogen abstractions from protonated substrates by radical cations, the methylene group furthest removed from the protonated position is preferentially attacked.[5] In the anodic oxidation of the CH-bond[3] the transition state is undoubtedly more positively charged than that in the radical abstraction and consequently is much more sensitive towards inductive effects. Skeletal rearrangements as in the oxidation in fluorosulfonic acid[7] do not appear to occur.

Table 1. Anodic oxidation [a] of fatty acids **3** to oxocarboxylic acids **4** [b].

[**] Anodic Oxidation, Part 33. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. – Part 32: M. Huhtasaari, H. J. Schäfer, L. Becking, *Angew. Chem. 96* (1984) 995; *Angew. Chem. Int. Ed. Engl. 23* (1984) 980.

pounds, presumably oligomers. In glacial acetic acid ($CH_3CO_2H/CH_2Cl_2 = 3:2$, $i = 40$ mA/cm^2, $T = 20$°C, Pt electrode) 17% androstanyl acetate is obtained and 38% androstane is recovered. Remarkable is the selectivity of the oxidation: We found that the 6- (**6a**), 7-, and 12-acetates are formed in the ratio 35 : 1 : 2.5; other acetates could not be detected by us. Assignment of the structures was accomplished by hydrolysis, oxidation to the ketone, and comparison of the mass spectra with those given in the literature. The main product was characterized ^{13}C-NMR spectroscopically as 6α-acetoxy-5α-androstane (**6a**). The electrolysis in methanol (methanol/dichloromethane, 0.1 M $NaClO_4$, glassy carbon electrode) proceeds even more selectively. At a 53% conversion (47% androstane recovered) 14% 6-methoxyandrostane (**7a**) and 27% 6-(methoxymethoxy)androstane (**8a**) were formed.

5

a, R = H; **b**, R =

6, X = OAc; **7**, X = OCH_3; **8**, X = OCH_2OCH_3

In glacial acetic acid, cholestane affords 15% cholestanyl acetates; the 6-(**6b**), 7-, and 12-acetates are formed in the ratio 40 : 1 : 2. In methanol, 50% conversion was observed with formation of 15% 6-methoxycholestane (**7b**) and 25% 6-(methoxymethoxy)cholestane (**8b**). These findings reveal a surprising and remarkable selectivity. Of the 32 hydrogen atoms in androstane and the 48 in cholestane, predominantly only those on C-6 are oxidized. Acetates or methyl ethers originating from attack at the reactive tertiary hydrogen atoms on C-5, C-9, C-14, and, in the case of cholestane, also those on C-17, C-20, and C-25 are not found. An explanation for this would seem premature, but the selectivity could be effected by an association of the steroid molecules. In stacked androstane and cholestane, the tertiary hydrogen atoms would be shielded, while on the front and rear side of the stack the hydrogen atoms on C-6, C-7, and C-12 would be exposed to the electrode for the electron transfer.

The methoxymethyl ethers **8** could be formed by secondary oxidation of the methyl ethers **7**.[8] That the less reactive but obviously more easily accessible methyl group is hereby oxidized, and not the methine hydrogen, could be a further indication of the formation of stacked associates.

Thus, the anode is a cheap and easily employable reagent for the oxidation of CH-bonds. The chemoselectivity of the anode compares favorably with other reagents; R_s^t, the ratio of the rate of attack at tertiary and secondary CH bonds, is 12 for decalin.[9] The regioselectivity can be controlled by inductive effects. The steroid hydrocarbons androstane and cholestane are remarkably regioselectively oxidized at C-6.

Experimental

A solution of 5α-androstane (**5a**) (260 mg, 1 mmol) in CH_2Cl_2 (20 mL), methanol (30 mL), and $NaClO_4$ (0.612 g, 0.1 M) was electrolyzed at 20°C with a current density of 30 mA/cm^2 at a glassy-carbon anode (21 cm^2) in an undivided cell until consumption of 965 As. Gas chromatographic analysis (60 m capillary column, 0.3% SE 52) of the crude product revealed the presence of 14% **7a**, 27% **8a**, and 47% **5a** (calibrating standard: *n*-octadecane). The crude product was treated with sodium methoxide and, after removal of the solvent, the residue was taken up in cyclohexane and the supporting electrolyte removed by filtration. HPLC separation (CH_2Cl_2:*n*-hexane, 1 : 1) yielded 98 mg (38%) **5a**, 29 mg (10%) **7a** (^{13}C-NMR, INEPT), and 67 mg (21%) **8a**. **8a** was hydrolyzed with HCl in methanol to 5α-androstan-6α-ol (^{13}C-NMR comparison with 6α-androstanol [10]).

Bis(2,4,6-tri-*tert*-butylphenyl)bicyclotetraphosphane

By *Ralf Riedel, Hans-Dieter Hausen,* and *Ekkehard Fluck**

So far, approximately twenty polycyclic organophosphanes have been isolated and characterized;[1,2] in addition, a few further representatives of this class of compounds have been detected spectroscopically.[1-3] We have now been able to synthesize bis(2,4,6-tri-*tert*-butylphenyl)bicyclotetraphosphane **1**, a derivative of the simplest bicyclic phosphane P_4H_2. **1** is formed along with bis(2,4,6-tri-*tert*-butylphenyl)diphosphene **2**[4] upon reaction of 2,4,6-tri-*tert*-butylphenyllithium and 1-bromo-2,4,6-tri-*tert*-butylbenzene with white phosphorus. Thus, it has been possible for the first time to isolate a product of the reaction of white phosphorus whereby only one bond of the P_4 tetrahedron is opened.

$$4\,RLi + 4\,RBr + 3\,P_4 \longrightarrow \underset{\mathbf{1}}{2\,R_2P_4} + \underset{\mathbf{2}}{2\,R_2P_2} + 4\,LiBr$$

R = 2,4,6-tBu$_2$C$_6$H$_2$

1 is ivory-colored, slightly sensitive to oxidation, stable at room temperature, and soluble in chloroform. The ^{31}P{^{1}H}-NMR spectrum ($CDCl_3$; standard: 85% H_3PO_4) of

Institut für Anorganische Chemie der Universität
Pfaffenwaldring 5, D-7000 Stuttgart 80 (FRG)

1 shows two multiplets, $\delta = -272$ (bridgehead P atoms) and $\delta = -130$, while the $^1H\{^{31}P\}$-NMR spectrum contains two singlets at $\delta = 1.27$ (4-*t*Bu) and 1.74 (2,6-*t*Bu) as well as a multiplet at $\delta = 7.0$. These findings are consistent with the results of an X-ray structure analysis (Fig. 1).[5]

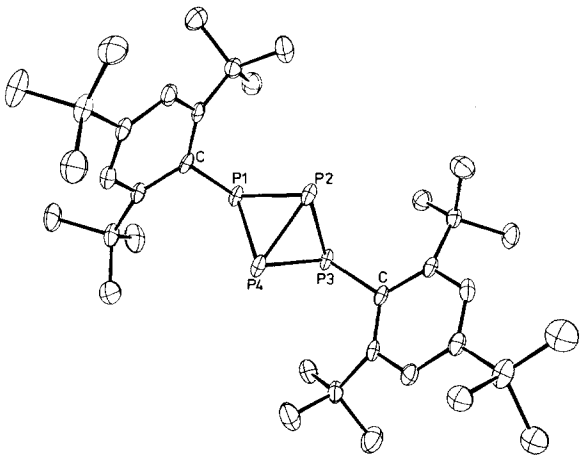

Fig. 1. ORTEP plot of the crystal structure of **1** (vibration ellipsoids at the 50% probability level). Bond lengths [pm] and bond angles [°]: P1-P2 222.3(4), P1-P4 223.5(7), P2-P3 222.2(3), P2-P4 216.6(2), P3-P4 223.6(9), P1-C 189.2(8), P3-C 188.5(1); P2P1P4 58.1(1), P1P2P4 61.2(1), P1P2P3 80.9(1), P3P2P4 61.3(1), P2P3P4 58.1(1), P3P4P2 60.6(1), P3P4P1 80.4(1), P2P4P1 60.7(1), CP1P2 98.2(1), CP1P4 97.3(1), CP3P4 99.2(1), CP3P2 97.8(1). The numbering of the P atoms is arbitrary.

The two 2,4,6-tri-*tert*-butylphenyl moieties in **1** are *cis* oriented. The folding angle of the P_4 bicycle, 95.5°, is just about the same as that in bis(trimethylsilylamino)bicyclotetraphosphane (95.2°), which has been synthesized from diphosphanes.[6] The P-P bonds in both compounds are (with exception of the central bond) about the same length as normal P-P single bonds (in **1** 222.2-223.6 pm); only the central P-P bond in **1** is slightly longer (216.6 pm) than in the bis(trimethylsilylamino) derivative (213 pm).

Experimental

All operations were carried out under argon. A solution of 1-bromo-2,4,6-tri-*tert*-butylbenzene [7] (61.55 g, 189.3 mmol in ether (500 mL) was treated at room temperature with 85 mL (212.6 mmol) of a 2.5 molar solution of *n*-butyllithium in *n*-hexane. The mixture was stirred for 3 h and then treated with 12.4 g (100 mmol) of white phosphorus. After 10 min, the resulting red solution began to boil and was then heated at the boiling point for a further 60 min. After 24 h, the mixture was hydrolyzed. A reddish-brown oil was obtained (72 g), from which an air-stable orange-red solid crystallized which was collected on a frit and washed with acetone. After recrystallization from benzene, 3 g of a coarsely crystalline mixture of **1** and **2** (ca. 3 : 1) was isolated. The crystals of **1** obtained by a second recrystallization were selected for the X-ray structure analysis.

Computer-Controlled Precipitation of Metal Hydroxides and Hydrous Oxides—Preparation of Manganese Dioxide Having Uniform Particle Sizes**

By *Dieter H. Buss, Gottfried Schaumberg,* and *Oskar Glemser**

It is difficult to precipitate metal hydroxides and hydrous oxides[1] that always have the same properties from aqueous solution. Recently, we were able to obtain cobalt, nickel, and manganese hydroxides, as well as their double hydroxides with aluminum,[2-4] by computer-controlled precipitation at a constant pH value. Their compositions, structures, and discharge capacities could be well reproduced. We report here on the application of this technique to the Guyard reaction,[5] the formation of manganese dioxide from manganese(II) salts and potassium permanganate in acidic solution.

The precipitations were carried out at the potential that is established at an electrographite electrode (measured as U_{max} versus a Ag/AgCl//3 M KCl reference electrode), for a given pH value of the solution, after the manganese dioxide begins to precipitate and while a small excess of $MnO_4^{\ominus}$ is still visible. The excess or deficiency of $MnO_4^{\ominus}$ ions is controlled with this potential, which remains relatively stable (±5 mV) during the course of the precipitation (hours). The upper control limit is U_{max}, the lower, the approximately 20 mV more negative potential. Between these limits, nearly stoichiometric amounts of $KMnO_4$ and $Mn(NO_3)_2$ solutions are added simultaneously during the precipitation. When the lower limit of the potential is exceeded, $KMnO_4$ solution is added; when the upper limit is exceeded, $Mn(NO_3)_2$ solution is added.[6,7]

Using this procedure, it has been possible, for the first time, to prepare manganese dioxide having nearly uniform

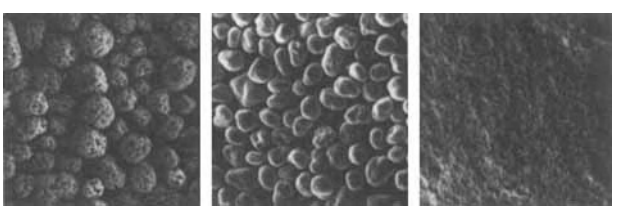

Fig. 1. Scanning electron micrograph of manganese dioxide that was precipitated with computer control at pH 0 and 1 (left and middle, respectively) or without computer control at about pH 1 (right). Left: Enlargement 110 times; potential limits 1407/1432 mV; 87.1 wt.-% active MnO_2; particle size 70 μm; bulk density 0.72 g/cm^3; BET surface: 169 m^2/g; discharge capacity $q_{max} = 73.9$ mA h/g.—Middle: Enlargement: 119 times; potential limits 1347/1357 mV; 80.1 wt.-% active MnO_2; particle size 45 μm; bulk density 1.53 g/cm^3; BET surface: 0.4 m^2/g; discharge capacity $q_{max} = 81.3$ mA h/g. —Right: Enlargement: 122 times; without control of potential; 85.7 wt.-% active MnO_2; bulk density 0.41 g/cm^3; BET surface: 108 m^2/g; discharge capacity $q_{max} = 11$ mA h/g.

particle sizes at pH 0, 1, and 2; the precipitates settle quickly and are easy to wash. Particle size, surface characteristics,[9] bulk density, and electrochemical properties[10] of the product depend strongly on the pH value during the precipitation (Fig. 1, left and middle). The properties of the samples obtained at pH 2 and pH 1 are nearly identical. At the same pH values, uncontrolled precipitation affords precipitates that are difficult to filter and wash and that, after drying, are present as nonuniform agglomerates (Fig. 1, right). The preparations obtained by controlled precipitation belong structurally to the δ-MnO_2 group:[8] those prepared by uncontrolled precipitation are primarily amorphous.

Particularly noteworthy is the possibility of obtaining uniform particles with very large surface areas (169 m^2/g) and also with much smaller surface areas (0.4 m^2/g) by controlled precipitation of manganese dioxide at pH 0 and at pH 1 and 2, respectively. The latter are somewhat similar in appearance to the manganese nodules found in the ocean.

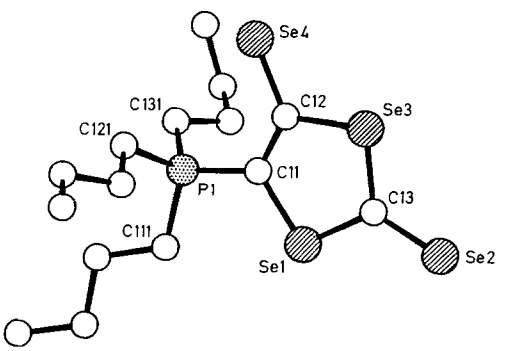
[10] Determination of the electrochemical charge capacity: A paste prepared from 3 g of the sample being tested, 1.5 g of graphite, 3.5 g of Ni powder, and 1 mL of water was pressed into a 11-cm tube made of nickel wire mesh. This test electrode was galvanostatically cyclized in cylindrical plexiglass cells with a Cd sintered sheet as counter electrode using 30% KOH solutions as electrolyte. Discharge procedure: charging of the cell with 25 mA current, subsequent discharge with 25 mA countercurrent to a cell voltage of 0.8 V (vs. $Cd/Cd(OH)_2$ in 30% KOH solution).

4-[Tri(*n*-butyl)phosphonio]-2,5-diselenoxo-1,3-diselenacyclopentanide**

By *Heinz P. Fritz,* Gerhard Müller, Gabriele Reber,* and *Michael Weis*

The search for electronically or ionically conducting nonmetallic compounds has focused on charge-transfer salts, highly conjugated polymers, and graphite intercalation compounds.[1-4] A chainlike structure [-Se-C(Se)-]$_n$ has been postulated for poly-CSe_2,[5] which should be electronically conducting[5,6] and which is obtained from CSe_2 by polymerization under normal conditions or, better still, under high pressure. We have been able to characterize the two previously described[5,6] $(CSe_2)_n$ modifications as different polymers; the electrically conducting polymer is $(C_2Se_3)_n$.[7] The composition and structure of the amorphous polymerizate are unknown. Accordingly, it appeared to us worthwhile to seek possible routes for the uniform polymerization of CSe_2.

Trialkylphosphanes react with CSe_2 to form zwitterionic, partly oligomeric adducts of the type $R_3P(CSe_2)_n$,[8] which may be used as building blocks for a selective reaction to give a linear polymer. The reaction of nBu$_3$P with CSe_2 affords dark red, flat prisms,[9] which are readily soluble in the conventional organic solvents and which are not very sensitive to air and moisture. Elemental analysis and mass spectroscopy gave the unexpected formula nBu$_3$PC$_3$Se$_4$. IR absorptions at 1465, 968, 902, and 750 cm^{-1} indicate the presence of C=C, two different C=Se, and P–C bonds. The ^{31}P-NMR signal at $\delta = +20.78$ (relative to H_3PO_4) suggests a phosphorus ylide type structure; nBu$_3$P=Se and nBu$_3$P=O exhibit ^{31}P-NMR signals at $\delta = +37$ and 43.2, respectively.



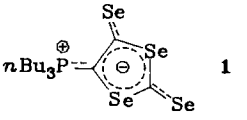


Fig. 1. Structure of one of the two crystallographically independent molecules of **1** (PLUTO). Important bond lengths [Å] for both molecules. P1-C11 1.77(1)/1.78(1), C11-C12 1.42(2)/1.38(2), C12-Se3 1.91(1)/1.88(1), C13-Se3 1.86(1)/1.87(2), C13-Se1 1.88(1)/1.88(1), C11-Se1 1.89(1)/1.91(1), C12-Se4 1.82(1)/1.87(1), C13-Se2 1.79(1)/1.77(1).

The X-ray structure analysis[10] shows the presence of planar C_3Se_2 five-membered rings in both crystallographically independent molecules in the crystal (Fig. 1). The ylide-like character is supported by the length of the P–C_{ring} bond (1.78(1) Å). The lengths of the exo- and endocyclic C–Se bonds (1.77(1)–1.91(1) Å) indicate a bond order between that of a formal double bond and that of a formal single bond.[11] The nearly identical C–Se distances and the slightly shorter (compared to single bonds) C–C bond in the ring suggest partial delocalization of the electron pairs at the ylidic carbon and the Se atoms. This is further supported by the ylidic P–C bond which is significantly longer than that in simple alkylidenephosphoranes. The compound is best described, therefore, by formula **1**.

Apart from the known, spontaneous oligomerization of CSe_2, the chalcogen abstraction and adduct formation of

the phosphane apparently determines the course of reaction in this case. In agreement with this hypothesis, nBu$_3$P reacts with CS_2 to give only the zwitterion nBu$_3\overset{\oplus}{P}-\overset{\ominus}{C}S_2$.[7] An X-ray structure analysis of the corresponding triethyl derivative is available.[12]

1 represents a new type of phosphorus ylide which is readily accessible in high yields. The arrangement of the Se atoms in the five-membered ring is similar to that in tetraselenabisfulvalene derivatives, in which the intermolecular interactions between the heteroatoms are decisive for the (super)conductivity. In dibenzotetraselenafulvalenes, intermolecular Se···Se separations of 4.03 to 4.09 Å[13] are found; in $(TMTSF)_2AsF_6$ (TMTSF = tetramethyltetraselenafulvalene), 3.87 to 4.98 Å[14] (van der Waals radii for Se: 2.0[15] or 1.9 Å[16]). The shortest intermolecular Se···Se distances in **1** are 3.49(1) and 3.91(1) Å (Se1 and Se4, respectively). The specific conductivities measured with direct and alternating current on pellets, are small (10^{-9} and 10^{-8} S/cm, respectively, at room temperature), which may be due to the non-coplanar packing of the ring systems. However, derivatives of **1** might have the properties of "organic metals."

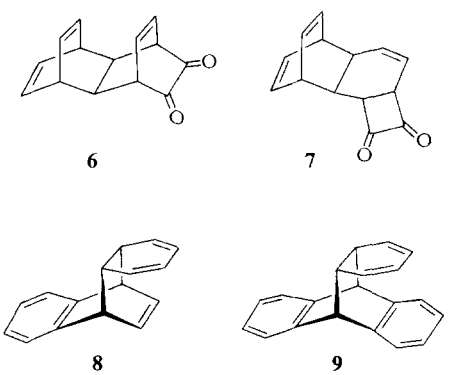
o,p'-Dibenzene**



By *Ralf Braun, Matthias Kummer, Hans-Dieter Martin,** and *Mordecai B. Rubin**

The family of $(CH)_{12}$ hydrocarbons includes a number of formal dimers of benzene, among which are the [2+2] dimers **1** and **2**, the [4+4] compound **3**, ansaradiene (**4**), and the [4+2] dimer tricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene ("*o,p'*-dibenzene") **5**. While these dimers have been of theoretical interest[1], the only compounds described in the literature to date are **2**[2a] and **4**.[2b] An organometallic complex of **5** has been reported;[3] however, attempted liberation of **5** from the complex resulted in isolation of benzene and not of its dimer. This result was attributed to the anticipated low thermal stability of **5**, which can revert to monomer by a thermally allowed, retro-Diels-Alder reaction. We report here on the successful preparation of **5** by low-temperature photolysis and the study of its thermal decomposition to benzene.

1 **2** **3** **4** **5**

The unsaturated diketone **6**, prepared in yields of 10% by [4+2]-cycloaddition of barrelene to *o*-benzoquinone in anhydrous tetrahydrofuran (THF) at room temperature[4] [UV (methylcyclohexane): λ_{max} = 456 nm (ε = 145); IR (methylcyclohexane: CH_2Cl_2 1:1) ν_{max} = 1740 cm^{-1}; m.p. 126–129°C (dec.); ^{1}H NMR (60 MHz, $CDCl_3$): δ = 2.45 (s, 2H), 3.43 (t, 2H), 3.61 (m, 2H), 5.93 (t, 2H), 6.14 (t, 2H),

6.57 (t, 2H)], underwent the expected[5,6] photoisomerization to cyclobutanedione **7** [UV (methylcyclohexane): $\lambda_{max}=496$ nm (110); IR (methylcyclohexane : CH_2Cl_2 1:1) $\nu_{max}=1770$, 1795 cm^{-1}] upon irradiation at 404 or 436 nm, with isosbestic behavior in the early stages of the reaction (305, 374 and 482 nm).

Irradiation of **7** in methylcyclohexane at room temperature ($\lambda=496$ nm) resulted in its conversion into benzene, presumably via the intermediacy of **5**. The quantum efficiency for this reaction is greater than the maximum value observed for formation of **7** from **6**. When the irradiation was performed at $-80°C$, the spectrum of a new compound was obtained with maxima in the ultraviolet at 294, 282, 271 and 260 nm (sh). The extinction coefficients were of the order of 3000. The new compound is stable indefinitely at $-80°C$ (cf. Fig. 1).

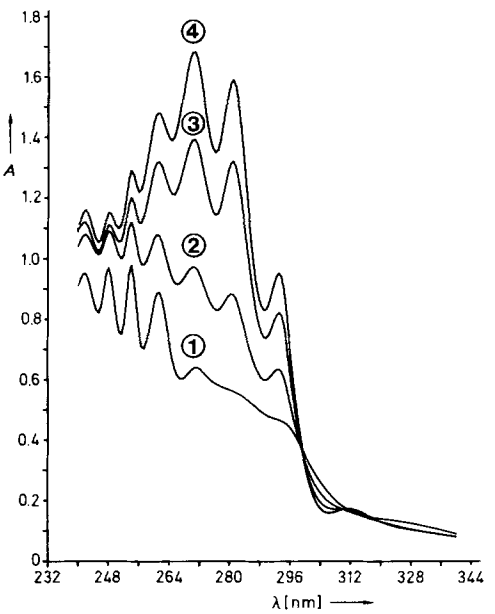

Fig. 1. UV spectroscopic monitoring of the generation of **5** from **7** at $-80°C$. Spectra after 10 ②, 30 ③, and 60 min ④ irradiation at $\lambda>380$ nm. ①: Spectrum after warming to $-50°C$ (complete decomposition of **5** to benzene).

The above absorptions are assigned to *o,p'*-dibenzene (**5**), on the following grounds: On the one hand, the spectrum is almost identical to that of the benzene-naphthalene adduct,[7,8] and, on the other, benzene is formed rapidly and quantitatively upon warming. The kinetics of this retro-Diels-Alder reaction were measured by following the disappearance of the maxima mentioned above at five temperatures in the range -68 to $-52°C$. Good first-order behavior was observed in all cases and identical rate constants were obtained from measurements at different wavelengths at a given temperature. The results obtained fit the Arrhenius expression:

$$\lg k\,[s^{-1}] = (11.78\pm0.5) - \frac{(14.7\pm0.4)}{2.303\,RT}\,[\text{kcal mol}^{-1}]$$

with $\Delta H^{\neq}=14.3$ kcal mol^{-1}, $\Delta S^{\neq}=-6$ cal mol^{-1} K^{-1}, $\Delta G^{\neq}=15.6$ kcal mol^{-1} (errors are double standard deviations). The minimal entropy change observed is consistent with a rigid transition state for this highly exothermic reaction. Comparison of the activation parameters for the thermolysis of **5** with those reported for the thermal decomposition of the formal [4+2] addition products of benzene and naphthalene **8**[7] or anthracene **9**[8] is instructive. The entropies of activation (25°C) for **8** and **9** are -5 and -3 cal mol^{-1} K^{-1}, respectively but the activation energies (19.5 kcal mol^{-1} for **8** and 24.9 kcal mol^{-1} for **9**) differ markedly, reflecting the difference between formation of two molecules of benzene from **5** vis-à-vis one of benzene and one of naphthalene from **8** or one of benzene and one of anthracene from **9**. We also note that the reported[2a] half-life of **2** at 40°C is 5.75 h, while $t_{1/2}$ for **5** is of the order of 5 ms at this temperature. Irradiation of **5** through quartz at $-80°C$ resulted in almost quantitative conversion (>95% by UV spectroscopy) into benzene. In addition, poorly defined bands of low intensity were observed at 355, 379, and 390 nm. Thus, the excited state of **5**, which has, a priori, many reaction paths available to it, proceeds to the same product as the thermal reaction (possibly in a stepwise fashion).

$[(\eta^5\text{-}C_5Me_5)_2Fe_2S_4]$ and $[(\eta^5\text{-}C_5Me_5)_2Co_2S_4]$, Two Novel Bis(pentamethylcyclopentadienylmetal) Complexes Rich in Sulfur

By *Henri Brunner, Norbert Janietz, Walter Meier, Gertrud Sergeson, Joachim Wachter,* Thomas Zahn,* and *Manfred L. Ziegler*

The electronic and structural properties of $[Cp_2M_2S_4]$ complexes (Cp: C_5H_5, MeC_5H_4 or C_5Me_5) depend, like their reactivity, upon the transition metal M. Each of the elements V,[1] Cr, Mo, W,[2] and Fe[3] can be assigned to a particular structural type. So far, nothing has been reported about a corresponding Co compound.

The complex $[C_5Me_5(CO)Co)]_2$, containing a Co=Co bond, reacts with sulfur in toluene at room temperature with formation of the green complex **1** in 23–39% yield.[4]

$$[C_5Me_5(CO)Co]_2 + 1/2\,S_8 \xrightarrow[20°C]{\text{toluene}} [(C_5Me_5)_2Co_2S_4] \quad \mathbf{1}$$

Elemental analyses and mass spectrum (dominating ions in the 70 eV spectrum: M^+, $[M-S]^+$, $[M-S_2]^+$) support this formulation. Compound **1**, which according to its ^{1}H-NMR spectrum ($\delta(CH_3)=1.62$, in $CDCl_3$) is symmetrical and is configurationally stable in solution, at least at room temperature. An IR absorption at 502 cm^{-1} is characteristic for disulfide ligands, whose multiple coordination possibilities have already been described in detail.[5] According to an X-ray structure analysis,[6] **1** has a center of inversion, the two Co atoms are bridged by two disulfide ligands (Fig. 1). These η^1,η^2-S_2 ligands are indeed primarily known as bridging elements,[5] but not in this step-like (*anti*-) arrangement of two such moieties. A relatively large Co–Co distance (3.38 Å) supports the assumption that the Co atoms achieve noble gas configuration without the necessity of Co–Co bonding. Hence, **1** represents a novel type of structure within the $[Cp_2M_2S_4]$-class of compounds.

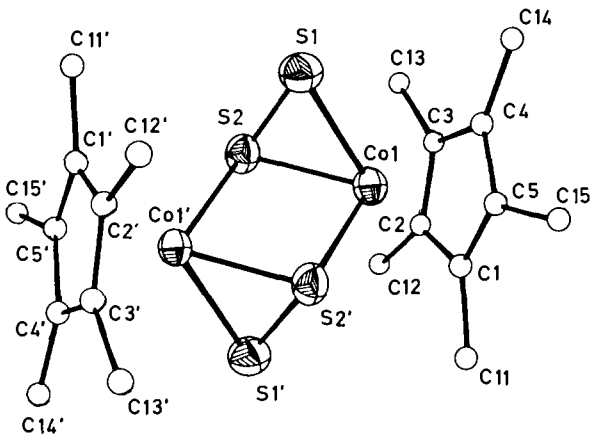

Fig. 1. Molecular structure of **1** (ORTEP plot). Selected bond lengths [Å] and angles [°] Co1-S1 2.247(4), Co1-S2 2.245(4), Co1-S2′ 2.244(4), S1-S2 2.062(6), Co1···Co1′ 3.38; S1-Co1-S2 54.7(2), S2-Co1-S2′ 83.1(2), Co1′-S2-Co1 96.9(1), Co1′-S2-S1 102.6(2).

Common to all compounds of this type is that their structures can only be elucidated with the aid of an X-ray structure analysis. Thus, the synthesis of two isomers of the composition $[(C_5H_5)_2Fe_2S_4]$, which are formed in moderate yields upon photolysis of $[C_5H_5(CO)_2Fe]_2$ with S_8 has recently been reported.[3] We have now found a high-yield synthesis of the permethylated derivative **2** by reaction of $[C_5Me_5(CO)_2Fe]_2$ with an excess of sulfur in boiling toluene.[7]

$$[C_5Me_5(CO)_2Fe]_2 + 1/2\,S_8 \xrightarrow[115\,°C]{\text{toluene}} [(C_5Me_5)_2Fe_2S_4] \quad \mathbf{2}$$

2 is formed as the sole isomer in 55–78% yield. Extension of this method to $[C_5H_5(CO)_2Fe]_2$, however, leads to formation of $[(C_5H_5)_4Fe_4S_4]$.[8] Owing to a lack of unequivocal IR spectroscopic data for comparison, an X-ray structure analysis also had to be carried out on **2**.[6] Complex **2** contains two disulfide ligands oriented perpendicularly to each other (Fig. 2). The bond lengths and bond angles are essentially in accord with those in $[(C_5H_5)_2Fe_2(\eta^1\text{-}S_2)(\eta^2\text{-}S_2)]$.[3] The influence of the pentamethylcyclopentadienyl moiety manifests itself in only a slight extension (0.01–0.03 Å) of the Fe–Fe, Fe–S, and S–S distances. Interestingly, in the two complexes **1** and **2**, both of which contain no direct metal-metal bond, the methyl residues of the two C_5Me_5 rings are staggered, whereas in $[(C_5Me_5)_2Mo_2S_4]$ they are eclipsed.[2c]

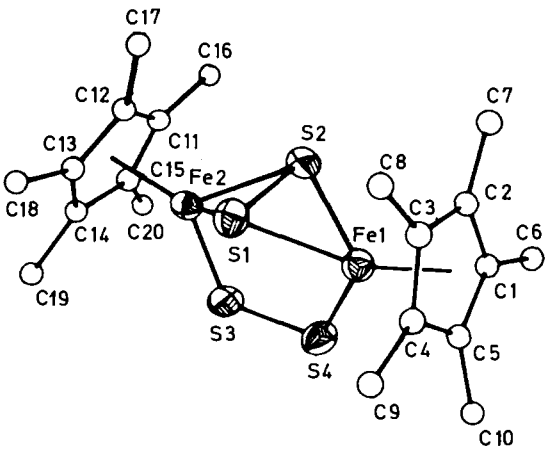

Fig. 2. Molecular structure of **2** (ORTEP plot). Selected bond lengths [Å] and angles [°]: Fe1-S1 2.282(1), Fe1-S2 2.273(1), Fe1-S4 2.129(1), Fe2-S1 2.269(1), Fe2-S2 2.268(2), Fe2-S3 2.122(2), S1-S2 2.055(2), S3-S4 2.021(2), Fe1···Fe2 3.53; S1-Fe1-S2 53.6(0), S1-Fe2-S2 53.9(0), Fe1-S1-Fe2 101.6(1), Fe1-S2-Fe2 101.9(1), Fe2-S3-S4 110.7(1), Fe1-S4-S3 110.8(1).

A comparison of **1** and **2** strikingly reveals the same overall contribution of eight valence electrons by the sulfur ligands in both cases. Nevertheless, the difference in the ligand combinations, as is also reflected in compounds of the 5th and 6th subgroups,[1,2] is impressive, and should also be observable in other systems.

Multiple Bonds between "Naked" Lead and Transition Metals—The First Example**

By *Wolfgang A. Herrmann,* Heinz-Josef Kneuper,* and *Eberhardt Herdtweck*

Dedicated to Professor Max Schmidt on the occasion of his 60th birthday

Methods for the directed synthesis of complexes containing multiple bonds between transition metals appeared, until recently, to be better developed than those for the synthesis of analogous compounds between transition metals and substituent-free ("naked") main-group elements. This is true, above all, for compounds with the more electropositive elements of the fourth to sixth main groups.[1] From the pioneering investigations of *Huttner* et al., *Weiss* et al., *Herberhold* et al., and *Legzdins* et al.,[1,2] it was expected that a strong tendency of formation should exist for this class of compounds and that such compounds might undergo a wide variety of reactions.[1,3] At present, the elements germanium, tin, arsenic, antimony, sulfur, selenium, and tellurium (coordination numbers 2 and 3 with linear, bent, or trigonal-planar frameworks) are known to exist without substituents in the bridge position of organometallic complexes and to be bonded through multiple bonds to organometallic fragments. We have succeeded, for the first time, in binding divalent lead via two cumulative double bonds to a transition metal.

Whereas the hydride route is suitable for the coupling of substituent-free germanium atoms with organometallic fragments,[1,3b,3d] this strategy fails for the heavier homologue lead, probably on account of the instability of the binary hydride. Lead(II) dichloride appeared to be a more promising precursor, even though it was not expected to be completely transformed into the substituent-free main-group ligand in the presence of organometallic complexes. We therefore allowed the substitutionally labile solvent-complex $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(thf)]$ (thf = tetrahydrofuran) to react with lead(II) chloride. After column chromatographic work-up of the crude product (silica gel, +15 °C), we obtained the Mn_2Pb complex **2** in ca. 20% yield.[4] **2** is

1 **2**

a relatively light- and oxygen-sensitive deep reddish brown compound which is nonetheless stable in air up to ca. 130 °C for a short period of time. Conclusive statements regarding the mechanism of formation of **2** are not yet possible, particularly since the reaction occurs with the precipitation of appreciable amounts of finely divided lead.

2 is not formed upon reaction of the organometallic presursor with elemental lead, even when the lead is transformed into a reactive form by high-performance ultrasound dispersion.[5] Possibly, dichloroplumbanediyl complexes are formed in the first step; in the case of germanium(II) chloride, the mono- and binuclear dichlorogermanediyl complexes $[(\eta^5\text{-}C_5H_5)Mn(CO)_2(GeCl_2)]$ (as solvent adduct) and $[(\mu\text{-}GeCl_2)\{(\eta^5\text{-}C_5H_5)Mn(CO)_2\}_2]$ (solvent free) are isolable species.[6] In the present case, **2** might result from consecutive halogen abstraction from labile intermediates of this type.

According to a single-crystal X-ray structure determination, **2** is the first complex containing a substituent-free lead atom that is bonded to a transition metal via multiple bonds. The three-atom MnPbMn structural unit is essentially linear (177.2(1)°), so that no contact exists between the manganese atoms, and the bridging element lead is dicoordinated (Fig. 1).

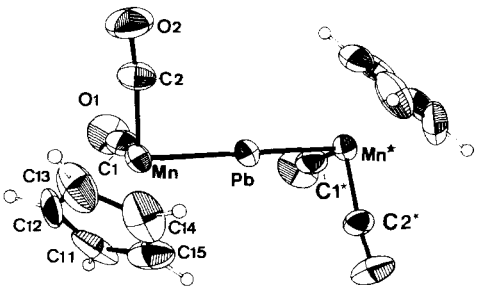

Fig. 1. ORTEP plot of the molecular structure of μ-lead-bis[dicarbonyl(η^5-cyclopentadienyl)manganese] **2** in the crystal. The ellipsoids of thermal vibration correspond to 50% probability; the positions of the hydrogen atoms are calculated. Crystals obtained from diethyl ether/dichloromethane, 294 K, I$\bar{4}$2d, $Z=8$, $a=1585.4(2)$, $c=1210.3(2)$ pm; $V=3042\times10^6$ pm^3; Enraf-Nonius CAD4, VAX 11/730; $R=0.022$, $R_w=0.028$.—Selected distances [pm] and angles [°]: Mn-Pb 246.3(1), Mn-C1 185.7(8), Mn-C2 181.3(7), C1-O1 111.1(8), C2-O2 113.6(7); Mn-Pb-Mn* 177.2(1), Mn-C1-O1 174.1(6), Mn-C2-O2 173.9(7), C1-Mn-C2 93.0(3), Pb-Mn-C1 89.9(2), Pb-Mn-C2 91.3(2), torsion angle C1-Mn-Mn*-C1* −22.2(5), C2-Mn-Mn*-C1* −115.2(5).—Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Energie, Physik, Mathematik GmbH, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 51613, the names of the authors, and the journal citation.

On the basis of the bonding proposed for the formally analogous germanium complexes $[(\mu\text{-}Ge)\{(\eta^5\text{-}C_5R_5)Mn(CO)_2\}_2]$ (R = H, CH_3; Mn-Ge 218-220 pm),[3a,c,d] cumulative multiple bonds having triple-bond character and involving the lead atom should be present.[7] The MnPb distances (245.9(1) pm) justify this view: MnPb single bond lengths (ca. 265-270 pm) may be fairly reliably estimated by extrapolation of known structural data.[8] For the MnPb double bonds, distances at least 20 pm shorter are expected, which should, at the same time, be about 20 pm longer than analogous MnGe double bonds. This

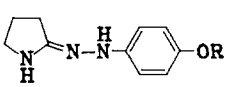
Wells, *Structural Inorganic Chemistry*, 5th ed., Clarendon Press, Oxford, England 1984.—Estimated covalent radii in organomanganese(I) complexes of the $[(\eta^5\text{-}C_5R_5)Mn(CO)_x]$ series: 130–133 (1°), ca. 120 (2°), ca. 109 pm (3°), cf. [3d], footnote 19).

The Chemistry and Antibiotic Activity of the Toadstool *Agaricus xanthoderma* (Agaricales)**

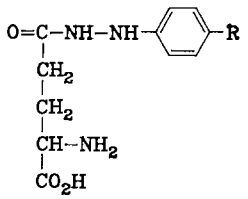


By *Sabine Hilbig, Thomas Andries, Wolfgang Steglich,** and *Timm Anke*

Dedicated to Professor Hans Grisebach on the occasion of his 60th birthday

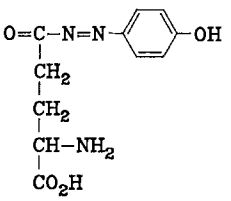
Fruit-bodies of the toadstool *Agaricus xanthoderma* Gen. stain intense chrome-yellow when bruised and develop a phenol like odor. Treatment with alkalis turns the flesh orange-yellow. Extracts of the toadstool exhibit a strong antibiotic activity, which *Atkinson*[1] ascribed to a photolabile compound "psalliotin". Later, work-up of the methanolic extract in the presence of sodium sulfite afforded "agaricin", which exhibits strong antibiotic and cancerostatic properties.[2] In neither case was the active substance chemically characterized in detail. First insights into the chemistry of *A. xanthoderma* were gained by *Gill* and *Strauch*,[3] who were able to isolate phenol, hydroquinone, 4,4′-dihydroxyazobenzene, and 4,4′-dihydroxybiphenyl from the ethanol extract. In this communication we describe the elucidation of the structures of compounds which are responsible for the antibiotic activity and the yellow discoloration of the fungus. When fruiting bodies of *A. xanthoderma* are extracted with cold ethyl acetate and the extracts are carefully concentrated by evaporation and chromatographed at 0–3°C, an intense yellow zone can be separated. Further chromatographic separation furnishes agaricone **1**[4] (yield 5×10^{-4}%), which according to its mass spectrum has the empirical formula $C_{10}H_{11}N_3O$ and which in its ^{1}H-NMR spectrum shows signals typical of a $-(CH_2)_3-$ unit, as well as signals in the aromatic region.[5] The characteristic MS fragments *m/z* 107 (C_6H_5NO), 106 (C_6H_4NO), 94 (C_6H_6O), 93 (C_6H_5O), 84 ($C_4H_8N_2$), and 83 ($C_4H_7N_2$) indicate structure **1**, which has been confirmed by synthesis. The butyrolactim methyl ester was allowed to react with *N*-(4-benzyloxyphenyl)hydrazine hydrochloride in methanol to give the hydrochloride of the pyrrolidonehydrazone **2** (yield 75%), which upon hydrogenolysis with Pd/carbon in methanol afforded the crystalline hydrochloride of **3**.[4]

1



2, R = $CH_2C_6H_5$
3, R = H

When **3** is dissolved in water and treated with sodium hydrogencarbonate the solution immediately turns yellow in color on being exposed to air. Oxidation proceeds especially smoothly upon addition of sodium periodate; **1** can be recovered by extraction with ethyl acetate; it is identical in all respects with the yellow pigment from *A. xanthoderma*. It can therefore be assumed that the toadstool contains leucoagaricone **3** which is oxidized to **1** by atmospheric oxygen (oxidases) when the fruiting body is damaged.[6]



When fresh fruit-bodies are extracted with SO_2-saturated methanol and all chromatographic steps are carried out under argon at 0–3°C, a colorless chromogen (yield 1×10^{-3}%) can be separated from large amounts of mannitol after chromatography on Sephadex LH 20 (eluent methanol/water 9:1) and repeated further chromatography on LichroPrep RP8 (eluent: water). The separation can be monitored by spot testing with $K_3[Fe(CN)_6]/NaHCO_3$ solution (orange-yellow color reaction!). The chromogen, called xanthodermin by us,[4] gives a positive ninhydrin reaction and shows signals typical for a glutamic acid residue as well as a signal in the aromatic region of the ^{1}H-NMR spectrum. This finding and the fact that ions containing three nitrogen atoms occur in the mass spectrum of the peracetyl derivative would suggest the structure of a γ-glutamyl-*N*′-(4-hydroxyphenyl)hydrazide **4** for the chromogen. This has been confirmed by synthesis. In the case of the α-benzyl ester of *N*-(benzyloxycarbonyl)-L-glutamic acid the γ-carboxy group was converted in 70% yield into

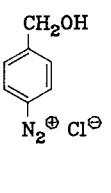
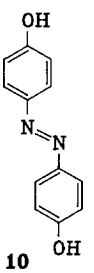
6

the *N'*-(4-benzyloxyphenyl)hydrazide with *N*-(4-benzyloxyphenyl)hydrazine according to the 4,6-diphenylthieno[3,4-*d*][1,3]dioxol-2-one 5,5-dioxide method.[7] Removal of the protecting groups with H_2/Pd-C afforded **4** in quantitative yield, which proved to be identical with the natural product. Treatment of an aqueous solution of **4** with $K_3[Fe(CN)_6]$/sodium hydrogencarbonate or sodium hydroxide leads to an intense yellow coloration of the solution. The same phenomenon is observed with the aqueous extract of the fungus.

The anion of the acylazo compound **6** is responsible for this color reaction. Hence, the fungus contains two chromogens, **3** and **4**, which participate in the yellow discoloration of the fruiting body and its color reaction with sodium hydroxide.



In the initial separation on Sephadex the last fractions contain the yellow solid sodium 4-hydroxybenzenediazosulfonate **7**[8] (yield 5×10^{-3}%). **7** is an artefact which is formed from the 4-diazo-2,5-cyclohexadien-1-one **8** present in the fruiting bodies. **8** can be detected in the methanolic extract of the fungus by azo coupling with resorcinol or β-naphthol[9] and, after work-up of the fungus with cooling and exclusion of light, but without addition of SO_2, can be identified by TLC comparison with the authentic compound.[10]



7

8

9

10

Interestingly, neither phenol nor 4,4'-dihydroxyazobenzene **10** are detectable during the work-up of the fungi with methanol containing SO_2, so these compounds isolated by *Gill* et al. are probably formed from the precursors described by us during the work-up.[11]

Merocyanines of the agaricone type, **1**, had already been obtained by *Hünig* et al.[12] by oxidative azo coupling, but have so far never been found in Nature. In contrast, **4** and **8** find a parallel in the compounds agaritine **5**[13] and 4-(hydroxymethyl)benzenediazonium chloride **9**,[14] which have been isolated from other *Agaricus* species.

1, **4**, **7**, and **8** are antibiotically active against *Bacillus subtilis* (Table 1). Especially active against bacteria and fungi are the diazo compounds **7** and **8**, whose minimal inhibitory concentrations are comparable with those of established antibiotics. Using the same assay as described in Table 1, 1 μg of penicillin G or streptomycin sulfate gave inhibition zones of 25 and 11 mm diameter, respectively, with *Bacillus subtilis* as test organism. Using *Mucor miehei* as test organism, 10 μg of the antifungal nystatin yielded an inhibition zone of 16 mm diameter. As gleaned from a comparison of the IR and UV spectra with those in Ref. [2], **7** is identical to "agaricin".[15] The antibiotic activity of "psalliotin"[1] observed by *Atkinson*, as well as its sensitivity to light, lend support to its identity with **8**.

Simply Substituted Boraethenes**

By *Günther Maier,* Jochem Henkelmann,* and *Hans Peter Reisenauer*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

Starting from silacyclohexadienes we were able to synthesize both silabenzene[1] as well as silaethene.[2] This sugested that the method might possibly be extended to the synthesis of borabenzene **1** and boraethene **3** from 1-bora-2,4-cyclohexadiene **2**. Following our recent successful isogen-exchange with antimony trifluoride, **5c** yields the fluoride **5e**, while reaction of **5c** with *N,N*-dimethyl(trimethylsilyl)amine affords a mixture of the two isomeric boracyclohexadienes **5f** and **6f** (see Table 1). In all cases an isomerization of **5** to **6** can be achieved by passing the 2,5-isomer through a quartz tube at 800 °C (8 × 65 mm; 10^{-3} torr) and condensing the product on a "cold finger" cooled with liquid nitrogen. The product ratio **5** : **6** (determined NMR spectroscopically; a clean separation of the conjugated isomer **6** is not possible) is then ca. 1:2 (**a, b, c, d**) or 1:1 (**e, f**).

If the product mixture **5/6** is allowed to react with hexafluoro-2-butyne then only the boracyclohexadienes **6** un-

[**] Hetero π-Systems, Part 14. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 13: G. Maier, K. Schöttler, H. P. Reisenauer, *Tetrahedron Lett. 26* (1985) 4079.

dergo a Diels-Alder reaction. The adducts **7**, however, are only stable when they bear methoxy- or dimethylamino-substituents (Table 1).

Do the adducts **7** yield the corresponding boraethenes upon thermal cycloreversion? The answer is yes! On the one hand, co-pyrolysis of **7b** and **7f** with benzophenone (the solutions of the components in [D_6]benzene were added dropwise into a quartz tube (13 × 240 mm, Raschig rings) heated at 400 °C) not only lead to formation of hexafluoro-*o*-xylene (17 and 41% yield, respectively) but also of 1,1-diphenylethene **9**, which could be the product of a Wittig-type reaction between benzophenone and the intermediary boraethenes **8b** and **8f**. On the other hand, the pyrolysis products (quartz tube (hot zone 8 × 50 mm), 600–800 °C, ca. 10^{-4}–10^{-5} torr) can be isolated in an argon matrix at 10 K and identified IR spectroscopically; besides the bands for hexafluoro-*o*-xylene, other bands occur which can be assigned to the boraethenes **8b** and **8f**. This is further supported by the appearance of pairs of absorptions in the intensity ratio 1 : 4 (**8b**: 1765/1721, 1542/1508, 1441/1411 cm^{-1}; **8f**: 1829/1780 cm^{-1}), as are to be expected on the basis of the $^{10}B/^{11}B$ ratio. We assign the latter, very intense pair to the antisymmetric stretching vibration of the $N^{10}BC$ and $N^{11}BC$ units—consistent with the IR spectrum of the stable 9-fluorenylidene-2,2,6,6-tetramethylpiperidinoborane (ν_{as} = 1740 and 1717 cm^{-1}) recently isolated by *Nöth* et al.[7] Accordingly, **8f** also has an allene structure. Both boraethenes **8b** and **8f** are extremely reactive; upon thawing the matrix, the characteristic IR bands already disappear at 40 K (**8b**) or 80 K (**8f**).

Summary: The existence of electroneutral compounds with a B=C bond[8] at the doubly coordinated boron atom[7] is not limited to derivatives with bulky substituents. Also simply substituted derivatives of the type **8b/8f** are detectable. The question remains, whether the presence of a donor group at the boron is indispensable for the existence of such derivatives.

Experimental

5f/6f: A solution of *N,N*-dimethyl(trimethylsilyl)amine (580 mg, 5 mmol) in pentane (5 mL) was treated at −78 °C with 450 mg (4 mmol) of **5c**; the mixture was stirred for 1.5 h at room temperature (RT), and, after removal of the volatile components in a vacuum (RT/0.5 torr), the isomeric mixture **5f/6f** was condensed in a cold trap.

7f: A solution of the isomeric mixture **5f/6f** (500 mg) in $CHCl_3$/pentane (1 : 1) (4 mL) was treated with 5.0 g of hexafluoro-2-butyne and the mixture stirred for 48 h at −30 °C; the excess hexafluoro-2-butyne was condensed in a cold trap and the solvent was removed in a vacuum. The unreacted compound **5f** was separated from the adduct by fractional recondensation. Pure **7f** was obtained by sublimation at 10^{-2} torr.

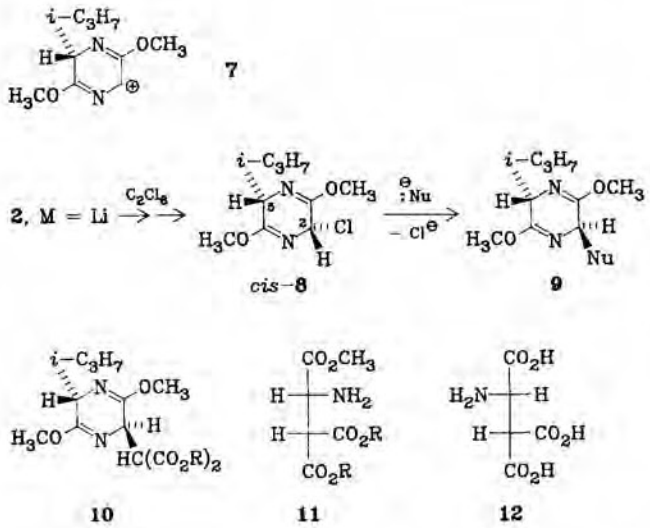
Asymmetric Synthesis of (*R*)-β-(Alkoxycarbonyl)aspartic Diesters (Derivatives of (*R*)-Asa) with a Chiral Cationic Amino Acid Synthon**

By *Ulrich Schöllkopf,* Hans-Jürgen Neubauer,* and *Manfred Hauptreif*

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

During the last few years, we have developed an asymmetric synthesis of nonproteogenous amino acids of type **6**, which consists in metalating the bislactim ether **1** of cyclo(L-Val-Gly), reacting the metal derivative **2** with electrophiles **3**, and hydrolyzing the adducts **4**.[1] Upon hydrolysis, the amino acid esters **6** are released (along with L-valine methyl ester **5**). Since the reaction **2** + **3** → **4** usually occurs with very high diastereoselectivity,[1] the amino acid esters **6** are often nearly optically pure.[1]



It was therefore of interest to modify the educts **1** in such a way that the ring CH_2 group becomes a cationic acceptor center[2] (see **7**) at which nucleophiles can be introduced diastereoselectively. Since the chloride **8** is a synthetic equivalent for **7**, we attempted its stereospecific synthesis.

When we added a solution of the lithium compound **2** (M = Li)[3] in tetrahydrofuran (THF) at −78 °C to a solution of hexachloroethane, we obtained a 94 : 6 mixture of the *cis/trans* isomeric chlorides **8** in ca. 90% yield, in which, surprisingly, the (2*S*,5*S*)-*cis*-chloride is the predominant diastereomer.[4] Since compound **8** can epimerize and/or undergo elimination of HCl, we carried out the reaction with nucleophiles in situ immediately after its formation.[5] The compound undergoes S_N2 reaction with inversion at C-2 to give the compounds **9**; however, the yield is only satisfactory for "soft" nucleophiles such as thiolates, borohydrides, water, or resonance-stabilized anions of carbon acids.[6]

A typical reaction is, for example, that of **8** with sodium dialkyl malonates (in THF in the presence of 5 mol-% [18]crown-6; 0 °C), which leads to the products **10** with primarily (2*R*) configuration (ca. 65% yields; (2*R*) : (2*S*) = 25 : 1 for **10a**, 32 : 1 for **10b**, and 60 : 1 for **10c**).[7] These were hydrolyzed with two equivalents of 0.25 N hydrochloric acid for **10a**, **b** and with 0.1 N hydrochloric acid for **10c** (at room temperature in ca. 7 d) to **5** and (*R*)-β-(alkoxycarbonyl)aspartic diesters **11**. In the

[**] Asymmetric Synthesis via Heterocyclic Intermediates. Part 29.—Part 28: R. Gull, U. Schöllkopf, *Synthesis 1985* 1052

a, R = CH_3; **b**, R = i-C_3H_7; **c**, R = t-C_4H_9

case of **11b** and **11c**, we distilled off **5** (kugelrohr distillation at 0.005 torr, room temperature) and isolated **11b** and **11c** by low-pressure chromatography[8] in 63 and 72% yield, respectively, and with *ee* > 95% in each case.[9] In the case of **11a**, after the hydrolysis, we acetylated the mixture of **5**·HCl and **11a**·HCl on nitrogen,[10] separated *N*-acetyl-**5** by chromatography, and obtained (*R*)-*N*-acetyl-**11a**. This compound has already been prepared in racemic form.[11] For (optically pure) (*R*)-*N*-acetyl-**11a**, we found $[\alpha]_D^{20}$ −86.9 (*c* = 2.0, methanol).

β-Carboxyaspartic acid (Asa) is—presumably in the (*S*) form **12**—a constituent of ribosomal bacterial proteins.[11] Syntheses of the racemic triesters of Asa have been described,[11,12] but no asymmetric syntheses are known.

With the bislactim ether of cyclo(D-Val-Gly),[13] the (*S*) enantiomer **11** is obtained.

[4] In the reaction of **2** with **3**, *trans*-**4** is the main diastereomer formed. Accordingly, the reactions of **2** with electrophiles and the chlorination take place via different mechanisms. For the chlorination, a radical pathway is likely; for the reactions with electrophiles, a polar one [1].

[5] Typical experiment for the in-situ preparation of **8**: **1** (0.92 g, 5.0 mmol) was lithiated according to [3]: the solution of **2** (in THF) was injected at −78 °C under nitrogen into a solution of hexachloroethane (1.42 g, 6.0 mmol). In one experiment, **8** was isolated and characterized [6].

[6] H.-J. Neubauer, *Dissertation*, Universität Göttingen 1984.

[7] Determined by capillary GC (WCOT Chrompack column, 50 m, 210 °C).—The diastereomeric ratio of **10** differs from that of **8** since the sodium dialkyl malonate causes elimination of HCl to a different extent from *trans*-**8** (in competition with the S_N reaction).

[8] Silica gel 60; ether/ethanol = 50 : 1.

[9] Determined by ^{1}H-NMR spectroscopy with Eu(tfc)$_3$ (up to 40 mol-%, shifting but no splitting of the OCH_3 signal). **11b**: oil, ^{1}H-NMR ($CDCl_3$): δ = 1.28 (d, $CH(CH_3)_2$), 1.84 (s, br, NH_2), 3.74 (s, OCH_3), 3.83 (d, OCCHCO), 3.05 (d, HC–N), 5.8 (h, $CH(CH_3)_2$); **11c**: m.p. = 63–64 °C; $[\alpha]_D^{25}$ +0.4 (*c* = 1.0, methanol); ^{1}H-NMR ($CDCl_3$): δ = 1.48 (s, $C(CH_3)_3$), 2.0 (s, br, NH_2), 3.66 (s, OCH_3), 3.75 (d, OCCHCO), 3.99 (d, HC–N). The two amino acid triesters were also isolated as Boc derivatives by allowing the mixture of **5**·HCl and **11**·HCl (obtained by hydrolysis) to react with di(*tert*-butyl) dicarbonate in dimethylformamide and separating the Boc derivatives of **5** and **11** by fractional kugelrohr distillation.

Asymmetric Addition of a Chiral Cyclic Phosphite to a Cyclic Imine—Synthesis of Phosphonic Acid Analogues of D- and L-Penicillamine**

By *Inga Hoppe,* Ulrich Schöllkopf, Martin Nieger,* and *Ernst Egert**

Dedicated to Professor Hans Musso on the occasion of his 60th birthday

α-Amino phosphonic acids,[1] the phosphonic acid analogues of α-amino carboxylic acids, are of interest owing to their potential biological activity. Only a few asymmetric syntheses for this class of compounds have been reported so far.[2] Thus, for example, only the racemate of the analogue **7** of penicillamine (obtained by addition of

[**] Asymmetric Synthesis of α-Aminophosphonic Acids, Part 2. This work was supported by the Fonds der Chemischen Industrie. We thank Mrs. *B. Lüer* for dedicated experimental assistance.—Part 1: [2b].

an achiral phosphorous acid derivative to 2,5-dihydro-2,2,5,5-tetramethylthiazole **4**) has been described.[3] We report here a procedure that makes accessible both of the enantiomers, (*R*)-**7** and (*S*)-**7**.

Reaction of the diol[4] **1a** (synthesized from diethyl (*R,R*)-2*O*,3*O*-isopropylidenetartrate) with PCl_3 and *tert*-butanol[5] affords the enantiomerically pure cyclic phosphite (−)-**3a**[6] in 90% yield, which undergoes addition to **4**[7] with BF_3 catalysis. The diastereomers (−)-**5a**[8] and (+)-**6a**[8] are thereby obtained in a ratio of 2 : 1 (yield 82%) and can be easily separated on silica gel.[9] An X-ray structure determination[10] gave the (4*R*) configuration for the diastereomer (−)-**5a**, which is present in excess (Fig. 1).

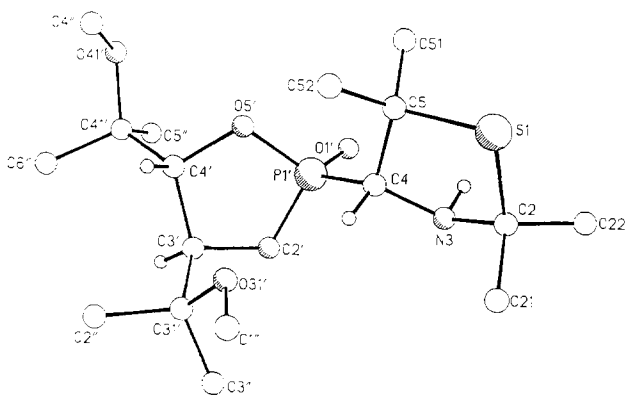

Fig. 1. Crystal structure of (−)-**5a**.

Hydrolysis of (−)-**5a** (48% HBr or conc. HCl, reflux[3b]) gives 52% (*R*)-(−)-**7**,[11] which corresponds to L-penicillamine, while 48% of the enantiomer (*S*)-(+)-**7** is obtained from (+)-**6a**.

With the phosphites **3b** (from diethyl (*R,R*)-tartrate) or **3c** (from (*R,R*)-2,3-butanediol[12]), unsatisfactory results were obtained since the adducts **5b** and **6b** as well as **5c** and **6c** undergo extensive decomposition on chromatographic separation.

The chiral phosphite (−)-**3a** is stable upon storage. It can be added to a variety of prochiral C=N or C=O groups,[13] thus opening up a general route to optically active α-amino and α-hydroxy phosphonic acids.

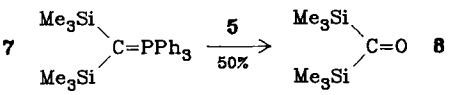
Acylsilanes via Oxidation of Phosphonium Ylides: The First Synthesis of Bis(trimethylsilyl)ketone and Its Use as a $CO^{2\ominus}$ Equivalent

By *Alfredo Ricci,* Mariella Fiorenza, Alessandro Degl'Innocenti, Giancarlo Seconi*, Pasquale Dembech, Konrad Witzgall,* and *Hans Jürgen Bestmann**

Acylsilanes, which are employed as nucleophilic acylation reagents, are a preparatively interesting class of compounds.[1,2] We have found that aromatic acylsilanes **6** can be easily synthesized from phosphonium ylides **1**.



a, Aryl = C_6H_5; **b**, Aryl = *p*–Br–C_6H_4; **c**, Aryl = *p*–CH_3O–C_6

Upon reaction of **1** with chlorotrimethylsilane **2** in a molar ratio of 2 : 1, the silylated ylides **4**,[3] along with the phosphonium salts **3**, are formed by trans-ylidation. Oxidation of **4** with the adduct **5**, formed from ozone and triphenylphosphite (5% less than the stoichiometric amount

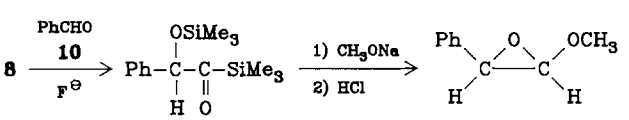
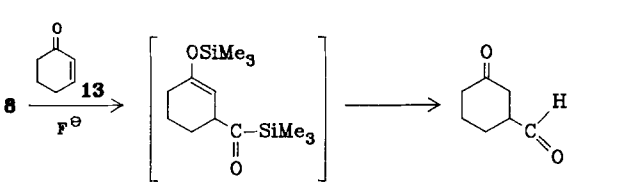
in order to avoid overoxidation) affords the compounds **6**,[4] which are purified by chromatography on silica gel with benzene (**6a**) or with ether/hexane (**6b**, **c**) as eluent and which exhibit a typical absorption for the CO group at 1615 cm^{-1} in the IR spectrum (film) [**6a**:[1] 76%; ^{1}H-NMR ($CDCl_3$): $\delta = 0.37$ (s, 9H); **6b**: 62%; $\delta = 0.37$ (s, 9H); **6c**: 53%; $\delta = 0.33$ (s, 9H), 3.82 (s, 3H)]. The same reaction with **4**, alkyl instead of aryl, leads to a complex mixture of products.



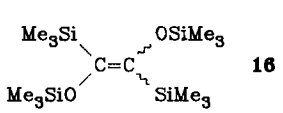
On the other hand, it was possible to prepare the bis(trimethylsilyl)ketone **8** for the first time in pure form via oxidation of the bis-silylated ylide **7**[5] with **5**. Its thio analogue was recently synthesized.[6]

$Me_3Si-CO-O-SiMe_3$ **9**



8 is a strawberry-colored oil,[7] which is extraordinarily labile toward autooxidation in air,[8] being converted into the ester **9**.[9] Its structure was established by mass, IR, ^{13}C-NMR, and ^{29}Si-NMR spectroscopy: MS (70 eV): *m/z* 174 (M^+), 159, 147, 146, 133, 131; IR (film): $\nu = 1570$, 1250, 850 cm^{-1}; ^{13}C-NMR (80 MHz, C_6D_6, TMS): $\delta = -2.9$ (CH_3), 318.8 (CO); ^{29}Si-NMR (80 MHz, C_6D_6, TMS): $\delta = -14.4$. Characteristic for a carbonyl group bonded to a silicon atom is the intense IR band at 1570 cm^{-1}. The ^{13}C-NMR and ^{29}Si-NMR signals at exceptionally low and high field, respectively, are in agreement with findings[11,10] for other acylsilanes.

It was expected that **8** would be useful as a synthetic equivalent for the dianion $CO^{2\ominus}$. Preliminary experiments confirm this to be the case. **8** undergoes $F^{\ominus}$-catalyzed (CsF) reaction under very mild conditions with typical carbon electrophiles such as benzaldehyde **10** or 2-cyclohexenone **13** (molar ratio 1 : 1). With **10**, compound



11

12

14

15

16

11 (identified by mass spectroscopy of the reaction mixture) is formed, which, after reaction with sodium methoxide and subsequent addition of acid, affords the desilylated product **12** in good yield (60% yield, b.p. = 65–67 °C/1 torr[11]).

The reaction with **13** leads to **14**, which, in the presence of traces of moisture, immediately undergoes reaction to form regioselectively 3-oxocyclohexanecarbaldehyde **15**[12] (chromatographic purification, polymerizes on attempted distillation, 55% yield, IR: $\nu = 1740$, 1710 cm^{-1} (CO)). These examples demonstrate the synthetic potential of **8** as an exceptionally effective agent for the $F^{\ominus}$-catalyzed formylation under mild conditions with complete control of regioselectivity. The reagent is expected to find a still broader range of applications.

Experimental Procedure:

8: A freshly prepared solution of **5** (4 mmol) in 20 mL of toluene was added to a solution of **7** (1.68 g, 4 mmol) in 20 mL of toluene at −78 °C. After 5 h at −78 °C, the reaction mixture was allowed to warm to room temperature and the solvent was almost completely removed by fractional distillation (30 °C/2 torr). The crude product was purified by flash chromatography on SiO_2 (Merck 60, degassed *n*-pentane, stream of argon). The residue remaining after removal of the solvent was distilled in vacuum. Yield: 0.36 g (50%) **8** as a pink oil (b.p. = 36 °C/1.5 torr); 95% purity.

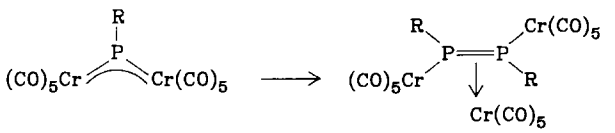
Bis(*tert*-butyl)diphosphene as Building Block of a Trichromium Cluster. A Novel Type of Coordination of Diphosphenes

By *Jutta Borm, Gottfried Huttner,** and *Laszlo Zsolnai*

Carbonylchromium complexes, in contrast to the carbonylmetal compounds of Mn, Fe, Co, and Ni, have little tendency to form clusters. Among the numerous carbonylchromium compounds reported to date only three homometallic chromium clusters have been described.[1] We have now found that triangulo-trichromium moieties can be constructed from phosphandiyl (phosphinidene) complexes.[***]



Thermal decomposition of phosphandiyl complexes[2] **1** usually leads via cleavage of a $Cr(CO)_5$ group to formation of diphosphene complexes **2** containing one side-on and two end-on coordinated $Cr(CO)_5$ moieties.[3] However,

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

[***] In accordance with the IUPAC rule D-6.12 the ligands of type RP are referred to here as phosphandiyls.

upon thermolysis of **1**, R = *t*Bu,[2] we were unable to isolate a complex of type **2**. At 100 °C, decarbonylation led to formation of the cluster **3**.[4]

1 **2**

3 is the second example of a triangulo-trichromium cluster[5] whose structure has been confirmed by X-ray analysis.[1] It contains a μ_3-PR bridge, which hitherto has only been observed in clusters containing at least two metals of the eighth subgroup.[6] **3** is the first example of a cluster containing a *Z*-diphosphene moiety $R\ddot{P}{=}\ddot{P}R$ as side-on and end-on coordinated ligand.

Whereas diphosphenes have already been observed as building blocks of complexes with metal-metal bonds in other types of coordination,[7] the type of bonding found for **3** was hitherto unknown. It corresponds to a mode of coordination of *Z*-diazenes in clusters[8] and thus substantiates the analogy between the bonding in $R\ddot{N}{=}\ddot{N}R$ and $P\ddot{P}{=}\ddot{P}R$.

Synthesis of the First α-Methylene-β-peroxylactone—Regiospecific Ene Reaction of $^1O_2$ with α,β-Unsaturated Carboxylic Acids**

By *Waldemar Adam** and *Axel Griesbeck*

Alkyl-substituted β-peroxylactones have long been known,[1-3] and their behavior upon thermolysis and upon direct or triplet-sensitized photolysis has been investigated in detail.[4] We report here on an entry to 5-methyl-4-methylene 1,2-dioxolan-3-one **4**, the first α-methylene-β-peroxylactone. The key step of the synthesis is the regiospecific photooxygenation of an α,β-unsaturated carboxylic acid (Scheme 1).

Scheme 1.

Irradiation (λ: 150-W sodium lamp, unfiltered) of a solution of tiglic acid **1** in CCl_4 (concentration: 0.25 mol/L) in the presence of traces of tetraphenylporphine at 10 °C affords the allylic hydroperoxide **2** (yield: 92%). The isomeric ene product is not formed. **2** can also be synthesized by photooxygenation of angelic acid **3**, but three- to fourfold longer reaction times are required.

This $^1O_2$-reaction is remarkable, for two reasons: a) as shown by competition experiments,[5] the addition of a carboxyl group in 2-butene does not lead to appreciable diminution in the reactivity, i.e. *trans*-2-butene reacts only ca. twice as fast as tiglic acid **1** with $^1O_2$; b) both the ene reaction of **1** as well as that of **3** proceed regiospecifically to give the β-hydroperoxy-α-methylenecarboxylic acid **2**.

Acid-catalyzed dehydration with H_2SO_4 in $CHCl_3$ at 0 °C affords the α-methylene-β-peroxylactone **4**, which can

be isolated in 61% yield by short-path distillation at 32–36°C/0.08 torr as a colorless oil having an unpleasant odor. **4** gives with potssium iodide a distinct peroxide spot on the thin-layer chromatogram ($R_f = 0.70$; SiO_2, CH_2Cl_2). The titrimetrically determined peroxide content amounted to 27.65% (calc. 28.04%), corresponding to a purity of 98.6%.

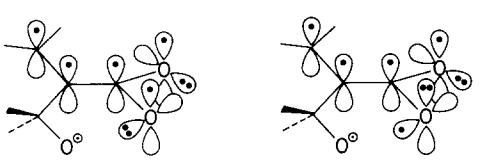

Table 1. ^{1}H- and ^{13}C-NMR data and selected IR data of **2** and **4**.

	2 [c]	**4** [c, d]
^{1}H-NMR (δ values) [a]	1.35 (d, 3H, J=6.2 Hz) 4.95 (q, 1H, J=6.2 Hz) 6.02 (s, 1H) 6.48 (s, 1H) 9.67 (br. s, 2H)	1.53 (d, 3H, J=6 Hz) 5.42 (ddd, H_c, ^3J=6 Hz, $J_{b,c}$=2.5 Hz, $J_{a,c}$=3.0 Hz) 5.77 (dd, H_b, $J_{b,a}$=0.75 Hz, $J_{b,c}$=2.5 Hz) 6.30 (dd, H_a, $J_{a,b}$=0.75 Hz, $J_{a,c}$=3.0 Hz)
^{13}C-NMR (δ values) [a]	18.34 (q) 79.13 (d) 128.32 (t) 139.91 (s) 171.90 (s)	17.76 (q) 81.27 (d) 122.11 (t) 138.66 (s) 168.48 (s)
IR [cm^{-1}] [b]	3300 (s), 2990 (m), 1700 (s), 1628 (m), 1272 (m), 1178 (m)	2990 (w), 1790 (s), 1672 (w), 1410 (s), 1246 (s), 1132 (s)

[a] 400 MHz, $CDCl_3$, δ values referred to TMS. [b] Film (NaCl plates). [c] Correct elemental analyses. [d] Molecular weight: experimental, 116 (osmometric); theoretical, 114.

A comparison of the IR and of the ^{1}H- and ^{13}C-NMR data of **2** and **4** (Table 1) lends support to the proposed structures. A striking feature of the ^{1}H-NMR spectrum of **4** is the additional $^4J_{HH}$-coupling between H_a and H_c and between H_b and H_c, which do not occur in the open-chain compound **2**. **4** can be stored without deterioration at −20°C, but on heating to 70–80°C it undergoes complete polymerization.

4 proves to be exceptionally stable upon flash photolysis: Even on passage through a quartz tube (60-cm long, 14-mm diameter, unpacked) heated to 1000°C at 0.08 torr only 15% of the substance polymerizes; 85% thereof can be recovered in the cold trap. This finding can be explained in terms of the diradical state **5**,[6] which is proposed as intermediate.

π-**5** σ-**5**

Since the relative energies of π-**5** and σ-**5** are unknown, it is impossible to make any definite statement about the electronic nature of the diradical. Decarboxylation of π-**5** should lead to a n,π*-excited CO_2-molecule—an energetically very expensive fragmentation path. The cleavage of CO_2 from σ-**5** would lead to a vinyl radical or, at least, require a concomitant 1,2-methyl shift to an olefinic C-atom, both of which are unfavorable for stereoelectronic reasons.

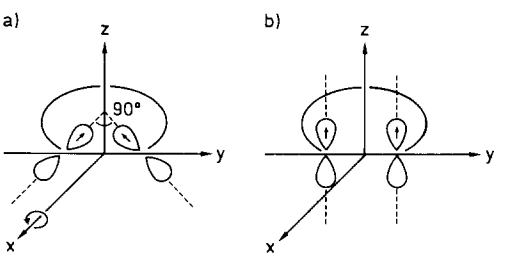
Sensitized UV/Laser Photolysis of Azoalkanes: Conformational Influences on Intersystem-Crossing and Lifetimes of Triplet Diradicals**

By *Waldemar Adam,* Klaus Hannemann,* and *R. Marshall Wilson*

Dedicated to Professor Rolf Huisgen on the occasion of his 65th birthday

The importance of diradicals in chemical reactions is reflected in the large number of studies devoted to the detection and determination of the lifetime of these short-lived intermediates.[1] Although their behavior is qualitatively well understood,[2] experimental data essential for testing theoretical models are still greatly lacking. For example, the law of conservation of total angular momentum for triplet-singlet intersystem-crossing requires a conformational arrangement of the radical orbitals in which the radical orbital axes are oriented orthogonally to one another and also to the axis about which the orbital angular momentum is generated (Fig. 1a). In contrast, a parallel arrangement (Fig. 1b) of the radical orbitals proves to be unfavorable for spin-orbital coupling.[2] To our knowledge no experimental evidence has hitherto been put forward in support of this theoretical prediction. Either the geometrical prerequisites are not given or the diradical is so strongly perturbed by substituents that no influences of the conformation on intersystem-crossing and, thus, on the lifetime of the triplet diradical, can be recognized.[1]



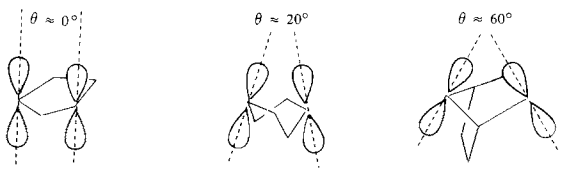


Fig. 1. Optimal orthogonal (a) and unfavorable parallel (b) arrangements of the radical orbital axes for intersystem-crossing in triplet diradicals.

Using the localized diradicals 1,3-cyclopentadiyl **1a**, 1,4-cyclohexadiyl **1b**, and 2,7-bicyclo[2.2.1]heptadiyl **1c**, which are not perturbed by substituents, as examples, we show that the arrangement of the radical orbitals considerably influences the lifetimes of these transient species—they differ by more than four orders of magnitude. The di-

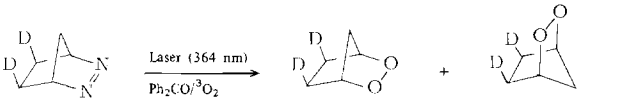
radicals **1a**–**1c** were generated by photochemical benzophenone-sensitized N_2-cleavage from the corresponding azo compounds **2a**–**2c**. The laser photolyses (Coherent supergraphite CR18 argon ion laser) were carried out in inert solvents (CCl_4, $CFCl_3$) under oxygen (10 bar) in order to trap and detect the short-lived diradicals **1a**–**1c** as peroxides. The lifetimes could be determined from the O_2-pressure-dependent product distribution between trapping product (peroxides) and cyclization product (hydrocarbon) with the aid of a Stern-Volmer plot.[3]



1a **1b** **1c**

2a **2b** **2c**

1,3-Cyclopentadiyl **1a** can readily be trapped with oxygen[4] and a quantitative evaluation of the reaction in CCl_4 at 8 °C yields a lifetime of $\tau_T = 900 \pm 40$ ns,[3] whereas 1,4-cyclohexadiyl **1b** can merely be detected by trapping with oxygen.[5] The amounts of peroxides are too small for a reliable determination of the oxygen-dependent product distribution. It can be concluded from this finding that the triplet lifetime of **1b** is very short (an estimated 0.1–1.0 ns).[5] All attempts to detect even traces of peroxides by trapping with oxygen met without success in the case of 2,7-bicyclo[2.2.1]heptadiyl **1c**. Even the very sensitive KI/HOAc test (limit of detection ca. 0.01%) gave no indication of the presence of peroxide in the concentrated photolyzate. The triplet diradical **1c** is apparently too short-lived to be intercepted by bimolecular reactions such as trapping with oxygen. Accordingly, the lifetime of this triplet diradical must be shorter than 0.1 ns.

The sequence of the lifetimes (τ_T(**1a**) > τ_T(**1b**) > τ_T(**1c**)) and their large differences (a factor of 10^4) cannot be explained in terms of steric or energy factors. This is only possible if the arrangement of the radical orbitals are taken into consideration. Consistent with this explanation is the result of the photolysis of the deuterated compound *exo*-[D_2]-**2a**, yielding the isomeric peroxides **3a** in a 1:1 ratio (D-NMR).[6] The 1,3-cyclopentadiyl triplet **1a** must therefore be planar on the average during the time of the oxygen trapping reaction, thus requiring the parallel arrangement of the radical orbitals ($\theta \approx 0°$); hence the long lifetime of **1a** becomes understandable on the basis of the

exo-[D_2]-**2a** *exo*-[D_2]-**3a** *endo*-[D_2]-**3a**

unfavorable intersystem crossing (Fig. 1). In contrast, the arrangement of the radical orbitals in the triplet diradical **1c** ($\theta \approx 60°$) is almost optimal for rapid intersystem-crossing as a result of the rigid bicyclo[2.2.1]heptane skeleton (Fig. 1a). A twist-boat conformation is assumed for the 1,4-cyclohexadiyl **1b**,[5] in which the radical orbital axes make an angle of 20° to each other. As expected, the lifetime of the triplet diradical **1b** lies between those of the two extreme cases **1a** and **1c**, as demonstrated by the successful trapping with oxygen; unfortunately the oxygen trapping cannot be quantified in this case.

All these results indicate that the very different lifetimes (factor of 10^4) of the triplet diradicals **1a**–**c** can be ascribed to conformational influences on the intersystem-crossing rates. Thus, the above theoretical predictions[2] have, for the first time, been confirmed experimentally.[7]

Chemistry and Technology of Water-Soluble Polymers. Edited by *C. A. Finch*. Plenum Press, New York 1984. xvi, 358 pp., bound $ 55.00.—ISBN 0-306-41251-9

According to the editor the aim of this book is to provide insight into the relationship between theoretical investigations into water-soluble polymers and the industrial application of these products and to close the gap between empirical knowledge and theoretical background. It is based on the manuscripts of the speakers at a seminar, which took place in Cambridge in 1981.

Some defects in the external form are a consequence of this. Diagrams, tables and formulas are heterogeneous in execution. A range of printing errors has crept into the text. Nor are the formulas free from errors. However, these formal defects are not so extensive that they impede the comprehension of the contents.

This book provides a diversified account in 19 chapters of the state of knowledge in the field of water-soluble polymers, whereby natural polymers are only treated peripherally. Alongside two review articles covering the chemistry and application and the preparation of the polymers, there are four contributions concerned with individual areas of application—medicine, flocculating agents, crude oil production, stabilization of dispersions. Contributions concerned with theoretical aspects are in the majority. The main emphasis is on the description of the polymers in solution, with contributions concerned with thermodynamics, rheology, interactions with solvents, with small molecules (salts, surfactants) and with polymers. A large amount of space is given to cross-linked systems which are no longer water-soluble in the true sense of the word, being merely able to swell in water. A separate chapter is devoted to their preparation by the cross-linking of soluble starting compounds, whereas unfortunately the other polymer-analogous reactions are practically ignored. There is a detailed treatment of the behavior of water-soluble polymers at the interface between water and dispersed solids and as protective colloids in emulsion and suspension polymerization.

With its copious literature citations this book stimulates to an enriching occupation with the primary literature and opens up a rapid access to the chemistry and technology of water-soluble polymers even for the non-specialist. All in all a volume worth recommending.

BASF AG, Ludwigshafen (FRG)

Solid State Chemistry and its Applications. By *A. R. West*. Wiley, Chichester 1984, 734 pp., hardback, £ 37.00.—ISBN 0-471-90377-9 (U. S.)

The author attempts to cover in around 700 pages that which is currently embraced by the concept of solid state chemistry. To define those aspects of the interdisciplinary field of solid state research which are of interest to chemists and principally dealt with by them is not an easy undertaking. In this the author succeeds remarkably well. In 21 chapters varying in length between 11 and 72 pages the following subjects are dealt with: preparative methods of solid state chemistry (reactions in the solid state, chemical transport, the use of pressure, hydrothermal synthesis, crystal growth), physical methods for characterizing materials (divided into the subsections: diffraction techniques, microscopic techniques and spectroscopic techniques—separate chapters are devoted to thermal analysis and X-ray diffraction), principles of crystallography and crystal chemistry, the defect structure of crystalline solids, state diagrams, phase transformations and, finally, selected solid state properties that are of interest for practical application. This book is indeed the first that deserves the description "Textbook of Solid State Chemistry". The textbook character is emphasized not only by the selection of material but also by the manner of its presentation. Patterns of regular behavior, methods of investigation and general perspectives of solid state chemistry are handled to a large extent by means of examples in a clear form which is also comprehensible to non-specialists. The necessary simplifications are justifiable apart from some exceptions. One such exception, for example, is the treatment of phase transformations. Even at the qualitative level, a discussion which does not take account of the concept of "other parameters" as introduced by *Landau* seems inadequate. The contents overlap considerably with monographs already available. This is inevitable, given the aims and layout of the book, but by no means problematic since the sources of information complement one another due to their different degrees of detail. At the end of each section is a compilation of carefully selected references to further literature which make it easier for the reader to investigate particular areas in more depth.

There are only a few printing errors. In some cases, however, they distort the meaning and could mislead the beginner. The typeface is clear and the diagrams are comprehensible without being used to excess.

The book may be recommended without reservation as a text for university teaching, though its high price may stand in the way of a larger readership.

Martin Jansen [NB 687 IE]

der Universität Hannover (FRG)

Amorphe und glasartige Festkörper. By *A. Feltz*. Akademie-Verlag, Berlin 1983. xix, 460 pp., bound, ca. DM 85.00.—Order No. 763 0341 (6654).

This book is a very important contribution to a field much neglected in the minds of chemists; namely the study of amorphous and glass-like substances. This can be explained by the fact that the field lies between those of molecules and crystalline solids but does not fit into either. However, the technical implications of this class of materials are most important. This book will play a key role because the author has succeeded in summarizing and critically representing the present state of practical and theoretical knowledge concerning amorphous and glass-like inorganic materials. The four main sections (the amorphous and glass-like state, material systems, properties, applications) provide a wealth of information and are clearly arranged. The lucidly formulated text is a witness to the personal experience of the author in this field. This experience has evidently provided the author with the capability of dealing with the wealth of material and the completely

different theoretical treatments without losing his way. The first section deals with the preparation, then with the thermodynamics of glasses and the kinetics of glass formation. A detailed discussion of structure and bonding then follows, which does not omit the treatment of new developments in electronic structure. The long section on material systems deals in a very detailed manner with the behavior of elements, binary systems and finally complex systems from the fields of metallic glasses, semiconductors and insulators. The relationships to crystalline structure pointed out in this section are worthy of note. The electrical and optical properties are dealt with in detail as the principal physical properties, before the final chapter on contemporary applications. The importance of structural disorders and defects for the understanding of these properties is very clearly presented. All in all a book that is worth reading, both for rapid information and also for a detailed study of amorphous materials and glasses.

Hans Georg von Schnering [NB 682 IE]
Max-Planck-Institut für
Festkörperforschung Stuttgart (FRG)

Allenes in Organic Synthesis. By *H. E. Schuster* and *G. M. Coppola*. Wiley, New York 1984. 358 pp., hardcover, $ 54.95.—ISBN 0-471-87284-9

Amongst the hydrocarbons, allenes were regarded for a long time as curiosities. Their stereochemical properties, correctly predicted by *van't Hoff*, were indeed dealt with in most textbooks but not so their reactions nor even their systematic application in organic synthesis. This monograph—the fifth comprehensive treatment of this class of compounds to appear recently—shows how fundamentally this situation has changed in the course of the last decade.

Above all, three properties of allenes make them useful to the preparative chemist as educts and intermediates: (i) their readiness to take part in additions of all kinds (amongst others ionic additions, [2+2]-, [2+4]-, 1,3-dipolar cycloadditions), (ii) their tendency to isomerize to noncumulated dienes and acetylenes, a reaction which can be brought about thermally, photochemically, catalytically or ionically, and, finally, (iii) their C–H acidity, which is particularly important for the functionalization of allenes.

Of course, the wholesale exploitation of a class of compounds in synthesis requires reliable methods for their preparation. This condition is met for allenes and, consequently, the book begins with a description of the most important syntheses of allenes, with particular reference to the parent compounds (alkyl, aryl, and cycloallenes). This is followed by extensive chapters on allene alcohols, aldehydes, ketones and carboxylic acids and their derivatives as well as their application to the synthesis of natural products and complex organic compounds. Two further chapters are allotted to heterosubstituted allenes (oxygen, sulfur, selenium, nitrogen, phosphorus, silicon and boron containing functional groups) and to halogenoallenes. Amongst the latter are found the remarkable bromoallenes which have recently been isolated as secondary metabolites of certain types of algae. The reactions of allenes are presented in three chapters. The first is concerned with addition reactions of all kinds except cycloadditions (amongst others, hydrogenation, electro- and nucleophilic additions). It makes sense to describe cycloadditions in a chapter of their own, simply on account of the amount of material to be covered. Most mechanistic investigations in allene chemistry have been concerned with this class of reactions, which is also extraordinarily useful in synthesis (4 ring syntheses by allene dimerization, allene/ketene and allene/olefin co-dimerization, allene/enone photoadditions). In a concluding "mixed" chapter, organometallic derivatives and rearrangements—mostly Claisen type—are dealt with. Even if certain individual aspects of allene chemistry are perhaps handled patchily (for example, more is known about the photochemistry, thermal isomerization reactions and organometallic complexes than would be thought after reading this book), the book offers a comprehensive survey of modern allene chemistry and complements the other recent publications particularly in the area of synthetic applications. Although the clear print and unfussy formula diagrams are pleasing, it is regrettable that this book has no author index. Since certain groups of compounds are associated chiefly with the names of those working on and with them, the absence of such an index makes literature searching unnecessarily laborious—a simple matter that is often overlooked these days, particularly in American texts.

It isn't so long ago that chemists working in this field greeted one another with the question, "are you working allene, too?" (*allene* = Berlin slang for alone!). "No longer", is the answer after the rapid and diverse development of recent years and after reading *Schuster* and *Coppola*'s book.

No part of this issue may be be reproduced in any form – by photoprint, microfilm, or any other means – nor transmitted or translated into a machine language without written permission from the publishers. Only single copies of contributions, or parts thereof, may be reproduced for personal use. Copies reproduced and used other than for private purposes in an industrial or commercial undertaking are subject to copyright and, in such cases, a copyright fee must be paid to the VG WORT, Abteilung Wissenschaft, Goethestr. 49, D-8000 München 2, from whom conditions of payment can be obtained on request.

Valid for users in the USA: The appearance of the code at the bottom of the first page of an article in this journal (serial) indicates the copyright owner's consent that copies of the article may be made for personal or internal use, or for the personal or internal use of specific clients. This consent is given on the condition, however, that the copier pay the stated per-copy fee through the Copyright Clearance Center, Inc., for copying beyond that permitted by Sections 107 or 108 of the U.S. Copyright Law. This consent does not extend to other kinds of copying, such as copying for general distribution, for advertising or promotional purposes, for creating new collective works, or for resale. For copying from back volumes of this journal see 'Permissions to Photo-Copy: Publisher's Fee List' of the CCC.

SUBJECT INDEX

(R) = Review Article (C) = Short Communication (B) = Book Review

ABSOLUTE CONFIGURATION, On the absolute configuration of (+)-tartaric acid (C) 513

ACC, Cyclopropyl-substituted aminocyclopropane carboxylic acid (cyclopropyl ACC)—an investigation of the mechanism of ethylene biosynthesis (C) 1044

Acetal reduction, Catalyzed acetal reduction with >BH boranes—1-*O*-alkyl(aryl)alditols, anhydroalditols, and 1-*O*-alditylalditols from *O*-glycopyranosides (C) 519

Acetals, Bicyclic acetals from oxacarbenes (C) 1043

Acetylene-oxo complexes of tungsten, Nitrogen monoxide as a source for oxo ligands—acetylene-oxo complexes of tungsten (C) 497

Acetylneuraminic acid, Preparation of an *N*-acetylneuraminic acid-containing trisaccharide and its use in oligosaccharide syntheses (C) 128

Acrylamides, CC Bond formation of alkenes with isocyanates on Ni^0 complexes—a new synthesis of acrylamides (C) 325

Acycloguanosine, A nucleolipid with antiviral acycloguanosine as head group—synthesis and liposome formation (C) 501

Acylsilanes via oxidation of phosphonium ylides: the first synthesis of bis(trimethylsilyl)ketone and its use as an equivalent of the dianion $CO^{2\ominus}$ (C) 1068

Addition, 1,4-Addition of dihalocarbenes to 1,3-dienes (C) 585
1,4-Additions of dihalocarbenes (C) 579
2,3-Dilithio-1,3-butadienes via addition of lithium to butatrienes (C) 571
Photochemical synthesis of an L-erythrose building block and its use in the preparation of methyl 2,3,*O*-isopropylidene-β-L-apio-L-furanoside (C) 877
Reaction of small molecules with the binuclear complex $[(\mu\text{-}C_5H_5)(\mu\text{-}Br)Pd_2(PR_3)_2]$: addition without cleavage of the metal-metal bond (C) 516
Stereoselective nucleophilic additions to a bicyclic ketone controlled by a remote tricarbonyl(diene)iron moiety (C) 787

Aggregation, On the aggregation of lithiated bicyclobutane derivatives in solution (C) 404

Alditols, Catalyzed acetal reduction with >BH boranes—1-*O*-alkyl(aryl)alditols, anhydroalditols, and 1-*O*-alditylalditols from *O*-glycopyranosides (C) 519

Aldol additions, Enantio- and *anti*-diastereoselective aldol additions of acetates and propionates via *O*-silyl ketene acetals (C) 874

Aldosterone, "Dimers" of aldosterone (C) 130

Alkali metal/aluminum oxide, Catalytic transformations of sesquiterpene hydrocarbons on alkali metal/aluminum oxide (C) 320

Alkoxy-1,6-methano[10]annulenes, Coupling of 3-diazo-3*H*-pyrazoles with 2-alkoxy-1,6-methano[10]annulenes and oxidative cyclization to pyrazolotriazines (C) 346

Alkylation, Regiospecific α-alkylation of α-haloalkylidenamines ("α-haloketimines") (C) 881
Strongly preferential alkylation and carbonyl olefination of α- and β-hydroxycarbonyl compounds by organo-transition metal reagents in competition experiments with the corresponding deoxy compounds (C) 348

Alkylbis(cyclopentadienyl)lanthanides, The cleavage of tris(cyclopentadienyl)lanthanide complexes with alkyllithium compounds—a new route to alkylbis(cyclopentadienyl)lanthanides (C) 225

Alkyl sulfides, A novel rearrangement in $(R_2S.\cdot.SR_2)^{\oplus}$-radical cations with a 3e-bond (C) 73

Alkyl transition-metal compounds, Oxidation of organometallic compounds (R) 274

Alkynylcyclopropanes, New donor-substituted vinyl- and alkynylcyclopropanes as synthetic building blocks (C) 770

Allene Claisen rearrangement with 1,4-chirality transfer (C) 700

Allene isoester, 9-Fluorenylidene-2,2,6,6-tetramethylpiperidinoborane: an allene isoester with two-coordinated boron and B=C double bond (C) 416

Allenes in organic syntheses (B) 1074
Novel retro-ene reactions of β-hydroxyacetylenes (C) 783

Allylamines, Bis[(*R*)-(+)-binap]rhodium(I) perchlorate, a highly efficient catalyst for the asymmetric isomerization of allylamines (C) 217

Allylation of aldehydes with etherification by dialkoxydichlorotitanium/allyltrimethylsilane; an asymmetric variant of the Sakurai reaction (C) 765

Allyl bridges, Dinuclear nickel complexes with bridging allyl ligands (C) 704

Allyl moieties, Cationic allylruthenium complexes via interchange of allyl moieties (C) 347

η^3-Allylpalladium compounds (R) 283

Allylruthenium complexes, Cationic allylruthenium complexes via interchange of allyl moieties (C) 347

Ambident anions (B) 234

Ambident ligands, d^6-Metal complexes of 4,4′-bipyrimidine, an ambident ligand with high π-acceptor ability (C) 430

Amino acids, Chiral copper(II) complexes for the enantioselective resolution of DL-dansyl-amino acids by HPLC (C) 336

Aminocyclopropane carboxylic acid, Cyclopropyl-substituted aminocyclopropane carboxylic acid (cyclopropyl ACC)—an investigation of the mechanism of ethylene biosynthesis (C) 1044

Amino(imino)phosphanes as face-bridging complex ligands (C) 115
Chelate ligand-controlled η^1-η^2 change of coordination in amino(imino)phosphane ligands and their conversion into a nickelaazadiphosphetidine (C) 525

α-Amino phosphonic acids, Asymmetric addition of a chiral cyclic phosphite to a cyclic imine—synthesis of a phosphonic acid analogue of D- and L-penicillamine (C) 1067

Analytical chemistry, Great fear of small amounts of elements—the significance of analytical chemistry in our modern industrialized community as exemplified by trace element analysis (R) 485

Analytical methods, Combination of chromatographic separation methods with mass spectrometry—a modern technique for studying metabolism (R) 451

Anodic oxidation, Oxidation of 2-propanol at Ti/Cr_2O_3 anodes (C) 1049
Selectivity of the anodic oxidation of CH- and CH_2-Groups; selective oxidation of steroids at C-6 (C) 1055

Anthracene dication, Electrochemical oxidation of anthracene and 9,9′-bianthryl to the respective dication and tetracation (C) 508

Anthracenides, Synthesis and structure of 1,4-dimethylanthracenemagnesium·3thf and μ-trichlorodimagnesium·6thf(1+) anthracenide (C) 960

Antibiotics, Molecular mechanism of action of the antibiotic rifampicin (R) 1009
Recent developments in the field of β-lactam antibiotics (R) 180

Antibodies, Increased production of specific antibodies by presentation of the antigen determinants with covalently coupled lipopeptide mitogens (C) 872
Monoclonal antibodies: their chemistry, functions, and possible uses (R) 139

Antibody structure, From the structure of antibodies to the diversification of the immune response (Nobel lecture) (R) 816

Anticancer target enzyme, Chemical basis of the action of glyoxalase I, an anticancer target enzyme (R) 31

Antigens, Synthesis of the immunologically essential saccharide sequence of the "enterobacterial common antigen" (C) 773

Antipyrine, Electrochemical methoxylation of antipyrine (C) 864

Arenes, Arene complexes of univalent gallium, indium, and thallium (R) 893
A three-blade propeller compound with seven bracketed benzene rings (C) 222
(Arene)thallium complex, $[\{1,3,5\text{-}(CH_3)_3H_3C_6\}_6Tl_4][GaBr_4]_4$—synthesis and structure of a mixed mono- and bis(arene)thallium complex (C) 414
Synthesis of the first linear (*o*-phenyleno)naphthalenes; a new class of benzenoid aromatics (C) 114

Arenium ions, Proton exchange between arenium ions and arenes in the gas phase (C) 693

Aromaticity, Synthesis of cyclohepta[*a*]phenalene-6,12-dione (C) 757
Synthesis of dipleiadiene by "serendipity" (C) 1046

Arsacyclopropanes, The first arsirane (C) 419

Arsanetriyl compounds, Synthesis and structure of $[(C_5H_5)_3M_3(CO)_6(\mu_3\text{-}As)]$ (M = Mo, W), transition-metal-stabilized arsanetriyl compounds (C) 66
Synthesis and structure of the spirocluster $[(\eta^5\text{-}C_5H_5)_3Mo_3As(CO)_6\{CHP(C_6H_5)_3\}]$ (C) 702

Arsenic-sulfur ligands, Synthesis of $[(C_5Me_5)_2Mo_2XS_3Co(CO)_2]$ clusters (X = P, As) and structural characterization of a μ_2,η^2-AsS ligand (C) 132

Arsirane, The first arsirane (C) 419

Arynezirconocene, Reaction of thermally generated (η^2-aryne)zirconocene with $W(CO)_6$, a novel route to carbene complexes (C) 584

Asa, Asymmetric synthesis of (*R*)-β-(Alkoxycarbonyl)aspartic diesters (derivatives of (*R*)-asa) with a chiral cationic amino acid synthon (C) 1066

Aspartic diesters, Asymmetric synthesis of (*R*)-β-(Alkoxycarbonyl)aspartic diesters (derivatives of (*R*)-asa) with a chiral cationic amino acid synthon (C) 1066

Aspicilin, The structure of the lichen macrolide (+)-aspicilin (C) 987

Association, Crystal and solution structures of $[t\text{Bu}_2\text{C}=\text{NLi}\cdot\text{O}=\text{P}(\text{NMe}_2)_3]_n$ (C) 328
Pentamethyldiethylenetriamine(phenyl)lithium, a monomeric organolithium compound (C) 215

Asymmetric addition of a chiral cyclic phosphite to a cyclic imine—synthesis of a phosphonic acid analogue of D- and L-penicillamine (C) 1067
Asymmetric Diels-Alder reaction, Concerning the mechanism of the asymmetric Diels-Alder reaction: first crystal structure analysis of a Lewis acid complex of a chiral dienophile (C) 112
Asymmetric isomerization, Bis[(*R*)-(+)-binap]rhodium(I) perchlorate, a highly efficient catalyst for the asymmetric isomerization of allylamines (C) 217
Asymmetric synthesis, Double asymmetric synthesis and a new strategy for stereochemical control in organic synthesis (R) 1
Asymmetric synthesis of (*R*)-β-(Alkoxycarbonyl)aspartic diesters (derivatives of (*R*)-asa) with a chiral cationic amino acid synthon (C) 1066
Atomic absorption spectroscopy, Atomabsorptionsspektrometrie (B) 137
Azaallenium salts, A new, facile route to 2-azaallenium salts—bis(2-adamantylidene)-ammonium hexachloroantimonate (C) 340
Azaallenylidene complexes, Cationic 2-azaallenylidene complexes, novel compounds with unusual photochemical properties (C) 121
Azaallylmolybdenum complexes, Synthesis, structure, and reactivity of η^3-1-azaallylmolybdenum complexes (C) 422
Azaborolyl compounds, Bis(dihydro-1,2-azaborolyl)tin—a novel boron-nitrogen stannocene (C) 602
Azahexamethineneutrocyanines from a *N*-(tetramethylformamidinio)pyridinium salt (C) 511
Azido-3-methyl-1,2-butadiene, Synthesis and reactions of 4-azido-3-methyl-1,2-butadiene (C) 216
Azoalkanes, Sensitized UV/laser photolysis of azoalkanes: conformational influences on intersystem-crossing and lifetimes of triplet diradicals (C) 1071
Azo ligands, Extremely long-wavelength charge-transfer absorptions of binuclear complexes with azo-modified 2,2′-bipyridyl ligands (C) 684
Azulene derivatives, A novel transformation of a calicene to an azulenofulvene (C) 60

BARBARALANES, Reaction of homobenzvalene with tetracyanoethylene; formation of a tetracyanodihydrobarbaralane derivative and a tetracyanocyclopropane derivative (C) 611
Beckmann rearrangement, Selective reactions using organoaluminum reagents (R) 668
Beilstein handbook of organic chemistry (B) 890
Benzene dimers, *o,p′*-Dibenzene (C) 1059
Benzo[*bc*]naphtho[2,1,8-*ghi*]oxecine, The first [2.1]phane: a new helical molecular skeleton (C) 885
Benzosemibullvalene, Intramolecular [4+3]-cycloaddition to 5-diazomethyl-5*H*-benzocycloheptenes—a step in a new benzosemibullvalene synthesis (C) 597
Bergmeyer, Methods of enzymatic analysis. Vol. 2. Samples, reagents, assessment of results (B) 797
Methods of enzymatic analysis. Vol. 3: Enzymes 1. Oxidoreductases, transferases (B) 888
Bianthryl tetracation, Electrochemical oxidation of anthracene and 9,9′-bianthryl to the respective dication and tetracation (C) 508
Bicyclobutane derivatives, On the aggregation of lithiated bicyclobutane derivatives in solution (C) 404
Bicyclo[3.2.0]heptaphosphane, P_7tBu_5—the first bicyclo[3.2.0]heptaphosphane (C) 504
Bicyclotetraphosphane, Bis(2,4,6-tri-*tert*-butylphenyl)bicyclotetraphosphane (C) 1056
Binuclear complexes, Reaction of small molecules with the binuclear complex [(μ-C_5H_5)(μ-Br)$Pd_2(PR_3)_2$]: addition without cleavage of the metal-metal bond (C) 516
Biotechnology. A comprehensive treatise in 8 volumes. Vol. 5: Food and feed production with microorganisms (B) 436
Chiral compounds synthesized by biocatalytic reductions (R) 539
Bipyridyl ligands, Extremely long-wavelength charge-transfer absorptions of binuclear complexes with azo-modified 2,2′-bipyridyl ligands (C) 684
4,4′-Bipyrimidine, d^6-Metal complexes of 4,4′-bipyrimidine, an ambident ligand with high π-acceptor ability (C) 430
Bis(2-adamantylidene)ammonium hexachloroantimonate, A new, facile route to 2-azaallenium salts—bis(2-adamantylidene)ammonium hexachloroantimonate (C) 340
Bis(*tert*-butyl)diphosphene as building block of a trichromium cluster. A novel type of coordination of diphosphenes (C) 1069
Biscarbyne cluster, Nonacarbonylbis(μ_3-fluoromethylidyne)triiron: formation of a biscarbyne cluster from carbonyliron and tribromofluoromethane (C) 119
Bis-2,3-diazabicyclo[2.2.1]hept-2-ene, Laser photolysis of the bisazoalkane 7-*syn*,7′-*anti*-bis-2,3-diazabicyclo[2.2.1]hept-2-ene (C) 421
Bis(diisopropylamino)-1,2-dihydro-1,2-diborete, 1,2-Bis(diisopropylamino)-1,2-dihydro-1,2-diborete (C) 759
Bishomoperylene, *syn*- and *anti*-bishomoperylene (C) 590
Bis-lactonization, Pd^{II}-catalyzed stereoselective bis-lactonization (C) 1045
Bis(pyridine)iodine(I) tetrafluoroborate, I(py)$_2BF_4$, a new reagent in organic synthesis: general method for the 1,2-iodofunctionalization of olefins (C) 319
Bis(tricarbonyliron)-*para*-quinodimethanes: preparation and molecular structure (C) 521
Bis(trimethylsilyl)ketone, Acylsilanes via oxidation of phosphonium ylides: the first synthesis of bis(trimethylsilyl)ketone and its use as an equivalent of the dianion $CO^{2\ominus}$ (C) 1068
Bis(trimethylsilyl) telluride, Novel reactions of acyl halides with bis(trimethylsilyl) telluride: C,Te and C,C bond formation (C) 1041
Bituminous coal, Reductive alkylation of bituminous coal: coal-propanesulfonic acids having remarkable solubilities (C) 342
Bond cleavage, Cleavage of a C—C bond in the catalytic hydrosilylation of camphor oxime (C) 703
Methyl migration and transannular 1,5-hydride shift on oxidative cleavage of C—Pd bonds with $CuCl_2$ (C) 207
Bond shift, Synthesis and dynamic properties of chiral heptalenes (C) 212
Bonellin dimethyl ester, Total synthesis of (±)-bonellin dimethyl ester (C) 775
Boraethenes, Simply substituted boraethenes (C) 1065
Boranes, Catalyzed acetal reduction with >BH boranes—1-*O*-alkyl(aryl)alditols, anhydroalditols, and 1-*O*-alditylalditols from *O*-glycopyranosides (C) 519
Boron compounds, An organoboron model system for the Fischer-Tropsch synthesis (C) 572
9-Fluorenylidene-2,2,6,6-tetramethylpiperidinoborane: an allene isoester with two-coordinated boron and B=C double bond (C) 416
Simple synthesis of stable iminoboranes (C) 324
Boron heterocycles, 1,2-Bis(diisopropylamino)-1,2-dihydro-1,2-diborete (C) 759
2,3-Dihydro-1,3-diborole-metal complexes with activated C—H bonds: building blocks for multilayered sandwich compounds (R) 943
Boron-nitrogen double bond, Hydroboration and hydrozirconation of *tert*-butylimino-2,2,6,6-tetramethylpiperidinoborane (C) 998
Boron-nitrogen stannocene, Bis(dihydro-1,2-azaborolyl)tin—a novel boron-nitrogen stannocene (C) 602
Branched-chain sugars, Synthesis of 3′-*C*-methyl-2′-deoxyribonucleoside with methylmagnesium iodide (C) 52
Bridge-formation, First sixfold bridge-formation in one step (C) 794
Bridge ligands, Amino(imino)phosphanes as face-bridging complex ligands (C) 115
Cyanogen as a bridging ligand—preparation and crystal structure of polymeric $[Ag\{(CN)_2\}_2]_n[AsF_6]_n$ with an undulating square cationic network (C) 417
Dinuclear nickel complexes with bridging allyl ligands (C) 704
Pentacarbonylolefin- and pentacarbonyldiolefinrhenium complex cations; synthesis and structure of the 2-butene-1,4-diyl-bridged carbonyldirhenium complex *trans*-[$(OC)_5ReCH_2CH=CHCH_2Re(CO)_5$] (C) 505
Preparation, magnetism, and crystal structures of the tautomers [LCu(μ-OH)$_2$CuL](ClO$_4$)$_2$ (blue) and [LCu(μ-OH$_2$)(μ$_2$-O)CuL](ClO$_4$)$_2$ (green): μ-aqua-μ-oxo vs. di-μ-hydroxo linkage (C) 57
Stepwise formation of a dinuclear μ-aminocarbyne- and a μ-formimidoyl-metal complex by insertion of methyl isocyanide into an MHM bridge (C) 577
Sulfur monoxide as 4-electron bridge-ligand in the complex [{(η^5-C_5H_5)-$(CO)_2Mn$}$_2$SO] (C) 228
Synthesis and structure of [$Pt_2(\mu$-H)(μ-$CHCH_2Ph)(diphos)_2$][BF_4] (C) 120
Synthesis, structure, and ligand motion of [$Cr(CO)_2\{P(OCH_3)_3\}(\eta^4$-2,4-dimethyl-1,3-pentadiene)], a complex with a C—H—Cr bridge (C) 502
Butatrienecarboxylic acid derivatives, On the thermal behavior of butatrienecarboxylic acid derivatives: crystal and molecular structure of a [4]radialene tetracarboxylic ester (C) 852
Butatrienecarboxylic acids, Synthesis of 1,2,3-butatrienecarboxylic acids (C) 851
Butterfly molecule, (i-$C_3H_7SGaI_2)_2$, the first "butterfly" molecule with tetracoordinated gallium (C) 970
tert-Butylimino-2,2,6,6-tetramethylpiperidinoborane, Hydroboration and hydrozirconation of *tert*-butylimino-2,2,6,6-tetramethylpiperidinoborane(C) 998
Butyrolactones, Synthesis and biological activity of α-methylene-γ-butyrolactones (R) 94

CALICENE, A novel transformation of a calicene to an azulenofulvene (C) 60
Camphor oxime, Cleavage of a C—C bond in the catalytic hydrosilylation of camphor oxime (C) 703
Captodative substituent effects, 1,4-Photocycloaddition of α-morpholinoacrylonitrile to 1-acylnaphthalenes (C) 1048
Carbaboranes, Dimerization of a C_2B_3-*closo*-carbaborane(5) to the C_4B_6-adamantane and its 2z/3z valence isomerization to the C_4B_6-*nido*-carbaborane(10) (C) 326
σ-Carbamoylnickel complex, The first isolated carbonylation-active σ-carbamoylnickel complex (C) 325
Carbanions, New bicyclic ketones and the stereochemistry of their reaction with carbanions (C) 972
Synthesis of a novel stable carbanion: 1,1,2-tricyano-2-(3,4-dicyano-5-imino-2,5-dihydro-1*H*-pyrrol-2-ylidene)ethanide by reduction of tetracyanoethylene with tris(2,2′-bipyridine)titanium (C) 426
X-ray structure determination of [α-

(phenylsulfonyl)benzyllithium-tetramethylethylenediamine]$_2$: chirality of an α-sulfonyl "carbanion" (C) 573
Carbene complexes, Reaction of thermally generated (η^2-aryne)zirconocene with $W(CO)_6$, a novel route to carbene complexes (C) 584
Transition metal carbene complexes (B) 137
Carbene (carbenoid) insertion reaction, Spiroacetal formation by carbene (carbenoid) insertion reaction: synthesis of the major constituent of the sex attractant of the olive fly *(Dacus oleae)* (C) 230
Carbon disulfide, Fragmentation and recombination of CS_2 and CSSe in the coordination sphere of platinum metals (C) 518
Carbon monoxide coupling, Monomeric, mononuclear enediolate complexes of zirconium: molecular geometry and electronic structure of the products of reductive CO coupling on the metal (C) 712
Carbon selenide sulfide, Fragmentation and recombination of CS_2 and CSSe in the coordination sphere of platinum metals (C) 518
Carbon tetrachloride, $Cl_2C-Cl-Cl^{\ominus\oplus}$, $Cl_2C-Cl-Br^{\ominus\oplus}$, and $Br_2C-Br-Cl^{\ominus\oplus}$ by gas-phase decarbonylation of $CX_3COY^{\ominus\oplus}$ (C) 869
Carbonylation, Reductive carbonylation of *o*-nitrophenol with a Fe-Pd cluster-derived heterogeneous catalyst; CO migration in $[FePdPt(CO)_4(Ph_2PCH_2PPh_2)_2]$ (C) 768
Carbonylcyclopropane dimers, Novel carbonylcyclopropane dimers and trimers—free ketenes or organometallic intermediates? (C) 605
Carbonylcyclopropane trimers, Novel carbonylcyclopropane dimers and trimers—free ketenes or organometallic intermediates? (C) 605
Trispiro[2.1.2.1.2.1]dodecane-4,8,12-trione (C) 607
Carbonyl olefination, Strongly preferential alkylation and carbonyl olefination of α- and β-hydroxycarbonyl compounds by organo-transition metal reagents in competition experiments with the corresponding deoxy compounds (C) 348
Carbyne cluster, Nonacarbonylbis(μ_3-fluoromethylidyne)triiron: formation of a biscarbyne cluster from carbonyliron and tribromofluoromethane (C) 119
Carbynemetal complex, Synthesis of $[Et_2N-C\equiv W(CO)_2(\mu\text{-}PPh_2)_2Mo(CO)_4]^{\ominus}$, the first anionic carbynemetal complex; addition of CO_2 to the W≡C bond (C) 203
Carcinogens, Environmental carcinogens: polycyclic aromatic hydrocarbons (B) 235
Catalysis, 3-Aminoindoles, imidazolidines, and oxazolidines from isocyanides and carbene complexes by metal-induced [4+2]- and [3+2]-cycloadditions (C) 978
An intermediate and its secondary products in a nickel-catalyzed synthesis of [4]-radialenes (C) 496
Carbonyliron-assisted coupling of cyclopolyenes with methyl acrylate (C) 353
Catalytic hydroboration with rhodium complexes (C) 878
Catalyzed acetal reduction with >BH boranes—1-*O*-alkyl(aryl)alditols, anhydroalditols, and 1-*O*-alditylalditols from *O*-glycopyranosides (C) 519
CC Bond formation of alkenes with isocyanates on Ni^0 complexes—a new synthesis of acrylamides (C) 325
Cleavage of a C—C bond in the catalytic hydrosilylation of camphor oxime (C) 703
Ethynebis(triphenylphosphane)nickel(0) (C) 323
Nickel-catalyzed cyclodimerization of 2-*tert*-butyl- and 2-trimethylsilyl-1,3-butadiene (C) 313
Nickel(0)-catalyzed synthesis of sorbanilide from 1,3-pentadiene and phenyl isocyanate (C) 961
Novel polymerization of α-olefins with the catalyst system nickel/aminobis(imino)phosphorane (C) 1001
Organocobalt compounds in the synthesis of pyridines—an example of structure-effectivity relationships in homogeneous catalysis (R) 248
Pd^{II}-catalyzed stereoselective bis-lactonization (C) 1045
Selectivity and mechanism of diene cyclodimerization on iron(0) complexes (C) 781
The first isolated carbonylation-active σ-carbamoylnickel complex (C) 325
Catalysts, η^3-Allylpalladium compounds (R) 283
Bis[(*R*)-(+)-binap]rhodium(I) perchlorate, a highly efficient catalyst for the asymmetric isomerization of allylamines (C) 217
Catalytic transformations of sesquiterpene hydrocarbons on alkali metal/aluminum oxide (C) 320
Cationic allylruthenium complexes via interchange of allyl moieties (C) 347
Highly active ylide-nickel catalysts for the polymerization of ethylene (C) 599
Novel trimerization of cyclopentadiene with a homogeneous, bifunctional palladium-acid catalyst system (C) 314
Polymerization of propene and butene with a chiral zirconocene and methylalumoxane as cocatalyst (C) 507
Reductive carbonylation of *o*-nitrophenol with a Fe-Pd cluster-derived heterogeneous catalyst; CO migration in $[FePdPt(CO)_4(Ph_2PCH_2PPh_2)_2]$ (C) 768
Cation effect, Reduction of ketones by alkali metals in tertiary alcohols: unexpected cation effect on the stereochemistry (C) 499
Cations, Electrochemical oxidation of anthracene and 9,9′-bianthryl to the respective dication and tetracation (C) 508
CC Bond formation of alkenes with isocyanates on Ni^0 complexes—a new synthesis of acrylamides (C) 325
Carbonyliron-assisted coupling of cyclopolyenes with methyl acrylate (C) 353
Novel reactions of acyl halides with bis(trimethylsilyl) telluride: C,Te and C,C bond formation (C) 1041
Syntheses with radicals—C-C bond formation via organotin and organomercury compounds (R) 553
The first isolated carbonylation-active σ-carbamoylnickel complex (C) 325
CC bonding, Misinterpretation of CC bonding through unusually large $^2J_{CC}$ values—a caveat for the use of INADEQUATE-^{13}C-NMR spectroscopy (C) 854
Ceramic, Radwaste immobilization by structural modification—the crystallochemical properties of SYNROC, a titanate ceramic (R) 357
Cerebrosides, Short synthesis of cerebrosides (C) 65
Chain-lengthening difunctionalization of Grignard compounds by reaction with ketenylidenetriphenylphosphorane (C) 405
Chaksine, The revised structure and absolute configuration of chaksine (C) 959
Charge distribution, Calculation of the charge distribution in conjugated systems by a quantification of the resonance concept (C) 687
Charge-transfer absorptions, Extremely long-wavelength charge-transfer absorptions of binuclear complexes with azo-modified 2,2′-bipyridyl ligands (C) 684
Charge-transfer interaction, The synthesis of porphyrins doubly linked to quinones by hydrocarbon chains (C) 1003
Chelate ligands, Chelate ligand-controlled η^1-η^2 change of coordination in amino(imino)phosphane ligands and their conversion into a nickelaazadiphosphetidine (C) 525
Chelate-stabilized diphosphene and diphosphorus complexes of nickel (C) 522
Transition metal polysulfides: coordination compounds with purely inorganic chelate ligands (R) 742
Chelation control, Chelation-controlled stereoselective synthesis of cyanohydrins (C) 989
Chemical bonds, High-resolution X-ray crystallography—an experimental method for the description of chemical bonds (R) 237
Cherry crystallites, Synthesis and structure of the $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$ (n=5, 4) ions: Ni-Pt clusters as models for "cherry" crystallites (C) 697
Chiral compounds synthesized by biocatalytic reductions (R) 539
Chiral heptalenes, Synthesis and dynamic properties of chiral heptalenes (C) 212
Chiral homoallylic ethers, Allylation of aldehydes with etherification by dialkoxydichlorotitanium/allyltrimethylsilane; an asymmetric variant of the Sakurai reaction (C) 765
Chirality, Axial chirality can lead to chiral smectic and cholesteric liquid crystals (C) 64
Chirality Transfer, Allene Claisen rearrangement with 1,4-chirality transfer (C) 700
Chlorophilic attack, Reactions of per(chloro,fluoro)ethanes with aryloxide and alkoxide ions—evidence for chlorophilic attack on C—Cl bonds (C) 871
Chromatography, Combination of chromatographic separation methods with mass spectrometry—a modern technique for studying metabolism (R) 451
The analysis of gases by chromatography (B) 136
Chromium cluster, Bis(*tert*-butyl)diphosphene as building block of a trichromium cluster. A novel type of coordination of diphosphenes (C) 1069
Chromium(V) compounds, $[(\eta^5\text{-}C_5Me_5)\text{-}CrO_2]_2$—a dinuclear oxo-complex of chromium(V) (C) 601
Chrysanthemic acid methyl esters, Stereo- and enantioselective synthesis of both *cis*-chrysanthemic acid methyl esters in high optical purity (C) 996
Claisen rearrangement, Allene Claisen rearrangement with 1,4-chirality transfer (C) 700
Clathrates, Host/guest chemistry of organic onium compounds—clathrates, crystalline complexes, and molecular inclusion compounds in aqueous solution (R) 727
Clusters, Cluster expansion with Cp(CO)Rh fragments (C) 424
closo-Clusters, Synthesis and structure of a thallium complex with an anionic sandwich complex ligand (C) 71
Nonacarbonylbis(μ_3-fluoromethylidyne)triiron: formation of a biscarbyne cluster from carbonyliron and tribromofluoromethane (C) 119
Novel MoFeS clusters from $[(C_5Me_5)_2Mo_2S_4]$ and $Fe(CO)_5$ or $Fe_2(CO)_9$ (C) 133
Skeletal isomerization of the $[Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2]$ cluster by recrystallization in various solvents (C) 861
Synthesis and structure of $[(C_5H_5)_3M_3(CO)_6(\mu_3\text{-}As)]$ (M = Mo, W), transition-metal-stabilized arsanetriyl compounds (C) 66
Synthesis and structure of the spirocluster $[(\eta^5\text{-}C_5H_5)_3Mo_3As(CO)_6\{CHP(C_6H_5)_3\}]$ (C) 702
Synthesis of $[(C_5Me_5)_2Mo_2XS_3Co(CO)_2]$ clusters (X = P, As) and structural characterization of a μ_2,η^2-AsS ligand (C) 132
C-Methyl-2′-deoxyribonucleoside, 3′-*C*-Methyl-2′-deoxyribonucleoside, Synthesis of 3′-*C*-methyl-2′-deoxyribonucleoside with methylmagnesium iodide (C) 52

C-NMR Spectroscopy, ^{13}C-NMR Spectroscopy of mixed dialkylzinc compounds with prochiral alkyl residues (C) 335
Coal-propanesulfonic acids, Reductive alkylation of bituminous coal: coal-propanesulfonic acids having remarkable solubilities (C) 342
Cobalt clusters, New Co and Ni clusters with Se and PPh_3 as ligands: $[Co_4(\mu_3\text{-}Se)_4(PPh_3)_4]$, $[Co_6(\mu_3\text{-}Se)_8(PPh_3)_6]$, $[Co_9(\mu_4\text{-}Se)_3(\mu_3\text{-}Se)_8(PPh_3)_6]$, and $(Ni_{34}(\mu_5\text{-}Se)_2(\mu_4\text{-}Se)_{20}(PPh_3)_{10}]$ (C) 993
Cobalt compounds, Cofacial dimer of a diiminosuccinonitrile complex containing a Co^{II}—Co^{II} bond and its reduction to the monomeric Co^{I} complex (C) 210
Cobalt-rhodium compounds, Tridentate oxygen ligands as cyclopentadienyl equivalents: structure and properties of $[LRh(\mu\text{-}CO)_3RhL]$, $L^- = [(C_5H_5)Co\{P(O)R_2\}_3]^-$ (C) 683
Cobalt-sulfur clusters, Novel cobalt- and nickel-clusters with S and PPh_3 as ligands; crystal structures of $[Co_7S_6(PPh_3)_5Cl_2]$, $[Co_6S_8(PPh_3)_6]^+[CoCl_3(THF)]^-$, and of $[Ni_8S_6Cl_2(PPh_3)_6]$, and $[Ni_8S_5(PPh_3)_7]$ (C) 706
CO bond formation, Novel C—O bond formation via [3+2] cycloaddition of diphenylketene to a dioxo metal moiety (C) 860
Cobyrinic acid derivatives, The first chemical partial synthesis of the nickel complex of a cobyrinic acid derivative (C) 867
Competition experiments, Strongly preferential alkylation and carbonyl olefination of α- and β-hydroxycarbonyl compounds by organo-transition metal reagents in competition experiments with the corresponding deoxy compounds (C) 348
Complexation, A photochemically "switched-on" crown ether containing an intraannular 4-methoxyphenylazo substituent (C) 866
Computer-controlled precipitation of metal hydroxides and hydrous oxides—preparation of manganese dioxide having uniform particle sizes (C) 1057
Conformation, Consequences of strain for the structure of aliphatic molecules (R) 529
Coordination, A dithioester as allylic-type 4e ligand (C) 971
Bis(*tert*-butyl)diphosphene as building block of a trichromium cluster. A novel type of coordination of diphosphenes (C) 1069
Chelate ligand-controlled η^1-η^2 change of coordination in amino(imino)phosphane ligands and their conversion into a nickelaazadiphosphetidine (C) 525
$[CuCo(CO)_4]_n$—crystal structure of a polymer with a one-dimensional, infinite copper-cobalt bonding system (C) 70
Cyclodextrins as second sphere ligands for transition metal complexes—the X-ray crystal structure of $[Rh(cod)(NH_3)_2\cdot$α-cyclodextrin$][PF_6]\cdot 6\,H_2O$ (C) 786
Diamminebis(1,5-cyclooctadiene)(μ-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-N^7,N^{16})dirhodiumbis(hexafluorophosphate): an example of simultaneous first and second sphere coordination (C) 135
$[Mn(S_2C_6H_3Me)_2]^{n-}$: mononuclear manganese complexes with square-planar (n=1) and distorted tetrahedral (n=2) sulfur coordination (C) 117
Novel aspects of the coordination chemistry of phosphane (C) 68
Phosphorus, arsenic, antimony, and bismuth multiply bonded systems with low coordination number—their role as complex ligands (R) 924
Synthesis and structure of *trans*-$[MCl(=C=CHR)(P\mathit{i}Pr_3)_2]$ (M=Rh, Ir): the first square-planar vinylidenemetal complexes (C) 406
X-ray structure determination of [α-(phenylsulfonyl)benzyllithium-tetramethylethylenediamine]$_2$: chirality of an α-sulfonyl "carbanion" (C) 573
Coordination tautomerism, Preparation, magnetism, and crystal structures of the tautomers $[LCu(\mu_2\text{-}OH)_2CuL](ClO_4)_2$ (blue) and $[LCu(\mu_2\text{-}OH_2)(\mu_2\text{-}O)CuL](ClO_4)_2$ (green): μ-aqua-μ-oxo versus di-μ-hydroxo linkage (C) 57
Corrinoids, Complete signal assignment of the ^{13}C-NMR spectra and structure determination of corrinoids by 2D-INADEQUATE and 2D ^{13}C,^{1}H-NMR chemical shift correlation using ^nJ(C,H) (C) 333
The first chemical partial synthesis of the nickel complex of a cobyrinic acid derivative (C) 867
Coupling constants, Complete signal assignment of the ^{13}C-NMR spectra and structure determination of corrinoids by 2D-INADEQUATE and 2D ^{13}C,^{1}H-NMR chemical shift correlation using ^nJ(C,H) (C) 333
Misinterpretation of CC bonding through unusually large $^2J_{CC}$ values—a caveat for the use of INADEQUATE-^{13}C-NMR spectroscopy (C) 854
^{15}N-^{29}Si coupling constants and ^{15}N isotope effect on ^{29}Si chemical shifts in compounds with natural isotopic abundance (C) 568
Simplification of spectra for the determination of coupling constants from homonuclear correlated 2D NMR spectra (C) 690
Crinipellins, the first natural products with a tetraquinane skeleton (C) 709
Crown ethers, A photochemically "switched-on" crown ether containing an intraannular 4-methoxyphenylazo substituent (C) 866
Chiral poly(9,9′-spirobifluorene) crown ethers (C) 792
Reactions in the ligand sphere of iron(II): synthesis of crown ethers (C) 858
Crystal morphology, Growth and dissolution of organic crystals with "tailor-made" inhibitors—implications in stereochemistry and materials science (R) 466
Crystal structures, Distortional isomers of $[LWOCl_2]^+$ in the solid state and in solution; crystal structures of the blue and green forms of $[LWOCl_2]PF_6$ (C) 777
NaGe—high-pressure formation of the NaPb-type structure (C) 500
Preparation, magnetism, and crystal structures of the tautomers $[LCu(\mu_2\text{-}OH)_2CuL](ClO_4)_2$ (blue) and $[LCu(\mu_2\text{-}OH_2)(\mu_2\text{-}O)CuL](ClO_4)_2$ (green): μ-aqua-μ-oxo vs. di-μ-hydroxo linkage (C) 57
C,Te bond formation, Novel reactions of acyl halides with bis(trimethylsilyl) telluride: C,Te and C,C bond formation (C) 1041
Cumulenes, Synthesis of 1,2,3-butatrienecarboxylic acids (C) 851
Cyanogen as a bridging ligand—preparation and crystal structure of polymeric $[Ag\{(CN)_2\}_2]_n[AsF_6]_n$ with an undulating square cationic network (C) 417
Cyanohydrins, Chelation-controlled stereoselective synthesis of cyanohydrins (C) 989
Cyclization, Non-induced, highly diastereoselective intramolecular ene reactions of 1,7-dienes to *trans*-1,2-disubstituted cyclohexanes (C) 1042
Cycloadditions, 3-Aminoindoles, imidazolidines, and oxazolidines from isocyanides and carbene complexes by metal-induced [4+2]- and [3+2]-cycloadditions (C) 978
Intramolecular [4+3]-cycloaddition to 5-diazomethyl-5*H*-benzocycloheptenes—a step in a new benzosemibullvalene synthesis (C) 597
Light-induced [2+2] cycloaddition reactions of nonconjugated dienes—the effect of through-bond interaction (C) 566
4-Methylene-1-cyclopentenes from methylenecyclopropanes and alkynyltrimethylsilanes (C) 316
Novel C—O bond formation via [3+2] cycloaddition of diphenylketene to a dioxo metal moiety (C) 860
On the role of radical ion pairs in [4+2] cycloadditions (C) 337
On the thermal behavior of butatrienecarboxylic acid derivatives: crystal and molecular structure of a [4]radialene tetracarboxylic ester (C) 852
Synthesis of 1,4-dihydropyridine nucleosides by photochemical cycloaddition (C) 127
Synthesis of seven-membered rings by $[(\sigma 2+\pi 2)+\pi 2]$ cycloaddition to homodienes (C) 594
Cycloalkylation, 1,1- and 1,*o*-dilithioallyl phenyl sulfone: synthesis, geminal cycloalkylation, and lithium-titanium exchange (C) 610
Cycloalkynes, New silacycloalkynes with up to four 1,4-disila-2-alkyne units in the ring (C) 565
Cycloarsanes, $As_{12}\mathit{t}Bu_8$—a tricyclo[6.4.0.0^{2,6}]-dodecaarsane (C) 991
Cyclodextrins as second sphere ligands for transition metal complexes—the X-ray crystal structure of $[Rh(cod)(NH_3)_2\cdot$α-cyclodextrin$][PF_6]\cdot 6\,H_2O$ (C) 786
Cyclodimerization, Nickel-catalyzed cyclodimerization of 2-*tert*-butyl- and 2-trimethylsilyl-1,3-butadiene (C) 313
Selectivity and mechanism of diene cyclodimerization on iron(0) complexes (C) 781
Cyclohepta[*a*]phenalene-6,12-dione, Synthesis of cyclohepta[*a*]phenalene-6,12-dione (C) 757
Cycloheptenes, Synthesis of seven-membered rings by $[(\sigma 2+\pi 2)+\pi 2]$ cycloaddition to homodienes (C) 594
Cyclohexastibane, $(C_6H_5Sb)_6\cdot$(1,4-dioxane), the first cyclohexastibane (C) 72
Cyclohexene derivatives, Nickel-catalyzed cyclodimerization of 2-*tert*-butyl- and 2-trimethylsilyl-1,3-butadiene (C) 313
Cyclooligomerization, Ethynebis(triphenylphosphane)nickel(0) (C) 323
New silacycloalkynes with up to four 1,4-disila-2-alkyne units in the ring (C) 565
Reaction of ethylene oxide with sulfur dioxide in the presence of cesium ions: synthesis of 1,3,6,9,2λ^4-tetraoxathia-2-cycloundecanone (C) 695
Cyclopentadienide ions, Donor-acceptor substituted anions and cations in the cyclopentadienyl system (C) 982
Cyclopentadienyl equivalents, Tridentate oxygen ligands as cyclopentadienyl equivalents: structure and properties of $[LRh(\mu\text{-}CO)_3RhL]$, where the ligand $L^- = [(C_5H_5)Co\{P(O)R_2\}_3]^-$ (C) 683
Cyclopentadienylium ions, Donor-acceptor substituted anions and cations in the cyclopentadienyl system (C) 982
Cyclopeptides, Total synthesis of ulicyclamide (C) 569
Cyclophanes, Vols. 1 and 2 (B) 435
Cyclophosphanes, A novel type of cyclotriphosphane complex: synthesis and structure of $[Ni_2(\mu\text{-}P_3\mathit{i}Pr_3)_2(CO)_4]$ (C) 415
Bis(2,4,6-tri-*tert*-butylphenyl)bicyclotetraphosphane (C) 1056
$P_7\mathit{t}Bu_5$—the first bicyclo[3.2.0]heptaphosphane (C) 504
Cyclopolyenes, Carbonyliron-assisted coupling of cyclopolyenes with methyl acrylate (C) 353
Cyclopropanecarboxylates, Thiophene derivatives by novel rearrangements of siloxy-substituted cyclopropanecarboxylates (C) 588
Cyclopropane cleavage, Photochemistry of 1-methoxybicyclo[2.2.2]octenones; photolytic cyclopropane cleavage of the initially formed tricyclo[3.3.0.0^{2,8}]octan-3-ones (C) 763
Cyclopropenyl complexes, Dicarbonyl-η^5-cy-

clopentadienyl(1-cyclopropenyl)iron complexes—a new class of σ-cyclopropenyl complexes (C) 209
Cycloreversion, Intramolecular [4+2]-cycloreversion of the two symmetrical homobasketenes (C) 331
Cyclosporine, Synthesis of cyclosporine and analogues: structural requirements for immunosuppressive activity (R) 77
Cyclotriphosphane complex, A novel type of cyclotriphosphane complex: synthesis and structure of $[Ni_2(\mu\text{-}P_3iPr_3)_2(CO)_4]$ (C) 415

DAMAGE TO FORESTS, Photosignal II as an indicator for damage to forests - EPR spectroscopic investigation of spruce needles (C) 425
DL-Dansyl-amino acids, Chiral copper(II) complexes for the enantioselective resolution of DL-dansyl-amino acids by HPLC (C) 336
Decabenzylgermanocene: synthesis and structure of a monomeric, air-stable germanocene (C) 773
Decamethyl-7-thiahexasilanorbornane $(CH_3)_{10}Si_6S$ (C) 992
Deformation, Consequences of strain for the structure of aliphatic molecules (R) 529
Deformation densities, Comparison of theoretical and experimental deformation densities in S—O bonds (C) 509
Delocalized ground states, Cofacial dimer of a diiminosuccinonitrile complex containing a Co^{II}—Co^{II} bond and its reduction to the monomeric Co^{I} complex (C) 210
Deoxyhemerythrin, $[L_2Fe^{II}_2(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2](ClO_4)\cdot H_2O$, a model compound for the diiron centers in deoxyhemerythrin (C) 778
Dialkylzinc compounds, ^{13}C-NMR Spectroscopy of mixed dialkylzinc compounds with prochiral alkyl residues (C) 335
Diastereoselectivity, Non-induced, highly diastereoselective intramolecular ene reactions of 1,7-dienes to *trans*-1,2-disubstituted cyclohexanes (C) 1042
anti-Diastereoselective aldol additions, Enantio- and *anti*-diastereoselective aldol additions of acetates and propionates via *O*-silyl ketene acetals (C) 874
Diazadiphospholes, 1,2,3,5-Diazadiphospholes—the first 1,3-diphospha-1,3-diene system (C) 124
Diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane, Synthesis and structure of a diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane (C) 999
Diaza-1,3-dienes, Selectivity and mechanism of diene cyclodimerization on iron(0) complexes (C) 781
Diazecine derivatives, A triphenylamine double-decker (C) 596
Diazene complexes, The first diazene complex with sulfur-coordinated transition metal centers, $[\mu\text{-}N_2H_2\{Ru(PPh_3)dttd\}_2]$, (dttd^{2-} = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(−2) (C) 981
Diazepines, Photoreactions of *N*-(1-pyridinio)amidates in monolayers and liposomes (C) 882
Diazocines, 1,5-Diazocines (C) 576
Diazo-3*H*-pyrazoles, Coupling of 3-diazo-3*H*-pyrazoles with 2-alkoxy-1,6-methano[10]annulenes and oxidative cyclization to pyrazolotriazines (C) 346
o,p'-Dibenzene (C) 1059
Diboraallyl system, Diboriranides and a 1,3-diboraallyl system with *B*-H-*B* bridge (C) 788
Diboroles, Synthesis and structure of a thallium complex with an anionic sandwich complex ligand (C) 71
Dichlorosilanediyl, $SiCl_2$: photoelectron spectroscopic optimization of various syntheses (C) 205
Diels-Alder reactions, Chemoselective multicomponent synthesis of α,β-unsaturated esters and lactones and of their Diels-Alder adducts (C) 790
Concerning the mechanism of the asymmetric Diels-Alder reaction: first crystal structure analysis of a Lewis acid complex of a chiral dienophile (C) 112
Highly enantioselective intramolecular hetero Diels-Alder reactions for the synthesis of enantiomerically pure tricyclic lactones (C) 784
Photochemically initiated, electron-transfer-catalyzed Diels-Alder reactions of electron-rich dienophiles (C) 412
Primary adduct, γ-ketoketene, and some subsequent products of the reaction of methyl 6-oxo-5-phenyl-1,3,4-oxadiazinecarboxylate with norbornene (C) 886
Diethyl thioxomalonate *S*-oxide; a sulfine as reactive intermediate (C) 855
Dihalocarbenes, 1,4-Addition of dihalocarbenes to 1,3-dienes (C) 585
1,4-Additions of dihalocarbenes (C) 579
Dihydro-1,3-diborole-metal complexes, 2,3-Dihydro-1,3-diborole-metal complexes with activated C—H bonds: building blocks for multilayered sandwich compounds (R) 943
Dihydropyridine nucleosides, 1,4-Dihydropyridine nucleosides, Synthesis of 1,4-dihydropyridine nucleosides by photochemical cycloaddition (C) 127
Diiminosuccinonitrile complex, Cofacial dimer of a diiminosuccinonitrile complex containing a Co^{II}—Co^{II} bond and its reduction to the monomeric Co^{I} complex (C) 210
Diiron compounds, The compound $[L_2Fe^{II}_2(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2](ClO_4)\cdot H_2O$, a model compound for the diiron centers in deoxyhemerythrin (C) 778
Dilithioalkyl sulfones, Dilithio(phenylsulfonyl)trimethylsilylmethane: synthesis, $^{13}C/^{1}H$-NMR characterization, and lithium-titanium exchange (C) 696
Dilithioallyl phenyl sulfone, 1,1- and 1,*o*-dilithioallyl phenyl sulfone: synthesis, geminal cycloalkylation, and lithium-titanium exchange (C) 610
Dilithio-1,3-butadienes, 2,3-Dilithio-1,3-butadienes via addition of lithium to butatrienes (C) 571
Dilithio(phenylsulfonyl)trimethylsilylmethane: synthesis, $^{13}C/^{1}H$-NMR characterization, and lithium-titanium exchange (C) 696
Dimerization, "Dimers" of aldosterone (C) 130
Dimethylanthracenemagnesium·3thf, Synthesis and structure of 1,4-dimethylanthracenemagnesium·3thf and μ-trichlorodimagnesium·6thf(1+) anthracenide (C) 960
2D-INADEQUATE ^{13}C-NMR spectrum, Complete signal assignment of the ^{13}C-NMR spectra and structure determination of corrinoids by 2D-INADEQUATE and 2D $^{13}C,^{1}H$-NMR chemical shift correlation using $^{n}J(C,H)$ (C) 333
Dinickel compounds, Dinuclear nickel complexes with bridging allyl ligands (C) 704
Dinuclear complexes with predictable magnetic properties (R) 834
Diphenylketene, Novel C—O bond formation via [3+2] cycloaddition of diphenylketene to a dioxo metal moiety (C) 860
Diphosphaallylcobalt, Tricarbonyl(1,3-diphosphaallyl)cobalt, a phosphorus analogue of (η^3-allyl)tricarbonylcobalt (C) 420
Diphosphene, Bis(*tert*-butyl)diphosphene as building block of a trichromium cluster. A novel type of coordination of diphosphenes (C) 1069
E→*Z*-Photoisomerization of a diphosphene on carbonylmetal complexes (M=Cr, Mo, W) (C) 211
Diphosphene complexes, Chelate-stabilized diphosphene and diphosphorus complexes of nickel (C) 522
Diphosphenyl complexes, $[(\eta^5\text{-}C_5Me_5)(CO)_2M\text{—}P\text{=}P(2,4,6\text{-}tBu_3C_6H_2)]$ (M = Fe, Ru), the first diphosphenyl complexes (C) 865
Diphosphorus complexes, Chelate-stabilized diphosphene and diphosphorus complexes of nickel (C) 522
Diphosphorus dications, Preparation and structure of a diphosphorus compound with positive charges on the two directly bonded phosphorus atoms (C) 975
Dipleiadiene, Synthesis of dipleiadiene by "serendipity" (C) 1046
Dipolar cycloadditions, 1,4-Dipolar cycloadditions, First 1,4-dipolar cycloadditions of 6-oxo-3,6-dihydro-1-pyrimidinium 4-olates to ketenes and other carbonyl compounds (C) 608
Di(*p*-tolyl)-1,4-pentaazadien-3-ide, 1,5-Di(*p*-tolyl)-1,4-pentaazadien-3-ide, Complexes of 1,5-di(*p*-tolyl)-1,4-pentaazadien-3-ide, crystal structures of [Cu(tolylNNNNNtolyl)]$_3$ and [Ni(tolylNNNNNtolyl)$_2$]$_2$ (C) 409
Diquat dication, A macrobicyclic receptor molecule for the diquat dication (C) 581
Distortional isomerism, Distortional isomers of $[LWOCl_2]^+$ in the solid state and in solution; crystal structures of the blue and green forms of $[LWOCl_2]PF_6$ (C) 777
Disulfido ligands, $(\eta^5\text{-}C_5Me_5)_2Fe_2S_4$ and $(\eta^5\text{-}C_5Me_5)_2Co_2S_4$, two novel bis(pentamethylcyclopentadienylmetal) complexes rich in sulfur (C) 1060
Disulfur monoxide as complex ligand—preparation and molecular structure of $[(\eta^5\text{-}C_5Me_5)Mn(CO)_2(S_2O)]$ (C) 515
Ditellurium, On the transformation of $[\{(CO)_5W\}_3Sn]$ into $[\{(CO)_5W\}_3Te_2]$, a compound containing unusually bonded ditellurium (C) 428
Dithioesters, A dithioester as allylic-type 4e ligand (C) 971
Dithiolanes, Photoreaction of thiones with bromoketene acetals (C) 976
D-NMR spectroscopy, 2D-NMR spectroscopy, Simplification of spectra for the determination of coupling constants from homonuclear correlated 2D NMR spectra (C) 690
2D-NMR-spectroscopy, The first application of 2D-NMR to the spectral analysis of a paramagnetic complex. Example: bis[*R*-(+)-*P,P*-diethylthiophosphinic acid-*N*-α-methylbenzylamido]nickel(II) (C) 231
Donor-acceptor substitution, Donor-acceptor substituted anions and cations in the cyclopentadienyl system (C) 982
Double asymmetric synthesis and a new strategy for stereochemical control in organic synthesis (R) 1
Double bond, Isolation and structure of a stable molecule containing a silicon-carbon double bond (C) 229
9-Fluorenylidene-2,2,6,6-tetramethylpiperidinoborane: an allene isoester with two-coordinated boron and B=C double bond (C) 416
Phosphaalkenylrhenium complexes—a novel class of substances with P=C bonding (C) 53
Phosphorus, arsenic, antimony, and bismuth multiply bonded systems with low coordination number—their role as complex ligands (R) 924
Dyestuffs, Organic chemistry in colour (B) 75

ELECTROCHEMISTRY, Electrochemical methoxylation of antipyrine (C) 864
Electrochemical oxidation of anthracene and 9,9'-bianthryl to the respective dication and tetracation (C) 508
Heterogeneous redox catalysis on Ti/TiO_2 cathodes—reduction of nitrobenzene (C) 771

Oxidation of 2-propanol at Ti/Cr_2O_3 anodes (C) 1049
Electron impact ionization, $Cl_2C-Cl-Cl^{\odot\oplus}$, $Cl_2C-Cl-Br^{\odot\oplus}$, and $Br_2C-Br-Cl^{\odot\oplus}$ by gas-phase decarbonylation of $CX_3COY^{\odot\oplus}$ (C) 869
Electron microscopy, Practical analytical electron microscopy in materials science (B) 890
Electron-transfer catalysis, Photochemically initiated, electron-transfer-catalyzed Diels-Alder reactions of electron-rich dienophiles (C) 412
Elimination, Cleavage of an ether bond via β-elimination of ethanol from $[(H_2O)_5CrCH_2CH_2OC_2H_5]^{2+}$ in aqueous solutions; a pulse radiolysis study (C) 779
Enantiomeric excess, A new method for determining enantiomeric excess, where the sample serves as its own reference (C) 315
Enantiomer resolution, Direct enantiomer resolution of hydroxy and carbonyl compounds by gas chromatography on Chirasil-Val (C) 48
Enantioselective aldol additions, Enantio- and *anti*-diastereoselective aldol additions of acetates and propionates via *O*-silyl ketene acetals (C) 874
Enantioselective hydrosilylation of prochiral 3,4-dihydro-2*H*-pyrrole derivatives (C) 995
Enantioselective resolution, Chiral copper(II) complexes for the enantioselective resolution of DL-dansyl-amino acids by HPLC (C) 336
Enediolate Complexes, Monomeric, mononuclear enediolate complexes of zirconium: molecular geometry and electronic structure of the products of reductive CO coupling on the metal (C) 712
Ene reaction, First α-methylene-β-peroxylactone—regiospecific ene reaction of $^1O_2$ with α,β-unsaturated carboxylic acids (C) 1070
Non-induced, highly diastereoselective intramolecular ene reactions of 1,7-dienes to *trans*-1,2-disubstituted cyclohexanes (C) 1042
(*E*)-Enols, Isolation of the (*E*)-enols of β-ketocarboxylic acid derivatives (C) 350
Enterobacterial common antigen, Synthesis of the immunologically essential saccharide sequence of the "enterobacterial common antigen" (C) 773
Environmental chemistry, Photosignal II as an indicator for damage to forests - EPR spectroscopic investigation of spruce needles (C) 425
Enzymatic analysis, Methods of enzymatic analysis. Vol. 2. Samples, reagents, assessment of results (B) 797
Methods of enzymatic analysis. Vol. 3: Enzymes 1. Oxidoreductases, transferases (B) 888
Enzymes as catalysts in synthetic organic chemistry (R) 617
Chemical basis of the action of glyoxalase I, an anticancer target enzyme (R) 31
Enzymes hosted in reverse micelles in hydrocarbon solution (R) 439
The construction of new proteins and enzymes—a prospect for the future? (R) 639
Epidermin, Elucidation of the structure of epidermin, a ribosomally synthesized, tetracyclic heterodetic polypeptide antibiotic (C) 1051
EPR spectroscopy, Photosignal II as an indicator for damage to forests - EPR spectroscopic investigation of spruce needles (C) 425
Error rates of the replication and expression of genetic information (R) 1015
Esters, Chemoselective multicomponent synthesis of α,β-unsaturated esters and lactones and of their Diels-Alder adducts (C) 790
Oxidation of α,β-unsaturated esters and lactones with selenium dioxide to γ-oxo or γ-hydroxy derivatives; synthesis of (±)-A 26771 B and norpyrenophorin (C) 791
Ethylene, Highly active ylide-nickel catalysts for the polymerization of ethylene (C) 599
Ethylene biosynthesis, Cyclopropyl-substituted aminocyclopropane carboxylic acid (cyclopropyl ACC)—an investigation of the mechanism of ethylene biosynthesis (C) 1044
Ethynebis(triphenylphosphane)nickel(0) (C) 323

FAB MASS SPECTROMETRY, Sequencing of short peptides using FAB mass spectrometry—increased information via derivatization (C) 408
Fischer-Tropsch synthesis, An organoboron model system for the Fischer-Tropsch synthesis (C) 572
Fluctuating structure, 2,5,7,10-Tetrakis(trimethylsilyl)-1,6-methano[10]annulene, a fluxional valence tautomer with cyclopolyolefin structure (C) 587
9-Fluorenylidene-2,2,6,6-tetramethylpiperidinoborane: an allene isoester with two-coordinated boron and B=C double bond (C) 416
Fluorine chemistry, Hexafluoropropene oxide—a key compound in organofluorine chemistry (R) 161
Folding, The construction of new proteins and enzymes—a prospect for the future? (R) 639
Formaldehyde complex, Synthesis of $[(\eta^5-C_5H_5)_2Mo(\eta^2-CH_2O)]$: a formaldehyde complex of molybdenum (C) 402
Fulvene, A novel transformation of a calicene to an azulenofulvene (C) 60

GALLIUM COMPOUNDS, Arene complexes of univalent gallium, indium, and thallium (R) 893
$(i\text{-}C_3H_7SGaI_2)_2$, the first "butterfly" molecule with tetracoordinated gallium (C) 970
Gas chromatography, Direct enantiomer resolution of hydroxy and carbonyl compounds by gas chromatography on Chirasil-Val (C) 48
Gas-phase reactions of organic compounds on Raney nickel (C) 418
Gene technology, Gene und Klone. Eine Einführung in die Gentechnologie (B) 1006
Genetic information, Error rates of the replication and expression of genetic information (R) 1015
Germanocene, Decabenzylgermanocene: synthesis and structure of a monomeric, air-stable germanocene (C) 773
Glycine receptor, The glycine receptor of rat spinal cord: exploring the site of action of the plant alkaloid strychnine (R) 365
Glycopeptides, Construction of disaccharide *N*-glycopeptides—synthesis of the linkage region of the transmembrane-neuraminidase of an influenza virus (C) 883
Glycopyranosides, Catalyzed acetal reduction with >BH boranes—1-*O*-alkyl-(aryl)alditols, anhydroalditols, and 1-*O*-alditylalditols from *O*-glycopyranosides (C) 519
Glycosphingolipids, Short synthesis of cerebrosides (C) 65
Glyoxalase I, Chemical basis of the action of glyoxalase I, an anticancer target enzyme (R) 31
Gold compounds, Synthesis and structure of new potassium-gold-tellurium polyanions: $[KAu_9Te_7]^{4\ominus}$, $[K_2Au_4Te_4(en)_4]^{2\ominus}$, and $[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]^{2\ominus}$ (C) 432
Grammar, The generative grammar of the immune system (Nobel lecture) (R) 810
Grignard compounds, Chain-lengthening difunctionalization of Grignard compounds by reaction with ketenylidenetriphenylphosphorane (C) 405
Guanosine, A nucleolipid with antiviral acycloguanosine as head group—synthesis and liposome formation (C) 501
Guest selectivity, "In-out"-isomeric large cavities and their differing guest selectivity (C) 219

HALF-SANDWICH COMPLEX, Reductive trimerization of the trioxo half-sandwich complex $[(\eta^5-C_5Me_5)ReO_3]$ with deoxygenation: the electron-deficient cluster ion $[(\eta^5-C_5Me_5)_3Re_3(\mu\text{-}O)_6]^{2+}$ (C) 50
Haloalkylidenamines, Regiospecific α-alkylation of α-haloalkylidenamines ("α-haloketimines") (C) 881
Haloketimines, Regiospecific α-alkylation of α-haloalkylidenamines ("α-haloketimines") (C) 881
H-Azepine synthesis, 1*H*-Azepine synthesis, A previously unrecognized 1*H*-azepine synthesis (C) 875
Helical molecules, The first [2.1]phane: a new helical molecular skeleton (C) 885
Hemoglobin: structure, function, evolution and pathology (B) 717
Heptalenes, Synthesis and dynamic properties of chiral heptalenes (C) 212
Heteroallenes, Diethyl thioxomalonate *S*-oxide; a sulfine as reactive intermediate (C) 855
Heterocycles, 3-Aminoindoles, imidazolidines, and oxazolidines from isocyanides and carbene complexes by metal-induced [4+2]- and [3+2]-cycloadditions (C) 978
Comprehensive heterocyclic chemistry. The structure, reactions, synthesis and uses of heterocyclic compounds (B) 1005
Synthesis and structure of a diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane (C) 999
Hetero Diels-Alder reaction, Highly enantioselective intramolecular hetero Diels-Alder reactions for the synthesis of enantiomerically pure tricyclic lactones (C) 784
Hexacyanocobaltate(III), Polymeric tris[trimethyltin(IV)]hexacyanocobaltate(III), a compound non-analogous to "super prussian blue", and its tris[tricyclopentadienyluranium(IV)] homologue (C) 879
Hexafluoropropene oxide—a key compound in organofluorine chemistry (R) 161
Hexahydroindane derivatives, Stereospecific synthesis of 3-substituted hexahydroindane derivatives (C) 131
Hexaphosphabenzene as complex ligand (C) 351
History of science, Theoriewandel in der Wissenschaftsgeschichte. Chemie im 18. Jahrhundert (B) 234
Homoallylic ethers, Allylation of aldehydes with etherification by dialkoxydichlorotitanium/allyltrimethylsilane; an asymmetric variant of the Sakurai reaction (C) 765
Homobasketenes, Intramolecular [4+2]-cycloreversion of the two symmetrical homobasketenes (C) 331
Homobenzvalene, Reaction of homobenzvalene with tetracyanoethylene; formation of a tetracyanodihydrobarbaralane derivative and a tetracyanocyclopropane derivative (C) 611
Homoisoquinoline, 3,8-Methanoaza[10]annulene (homoisoquinoline) (C) 592
Homothiopyrylium ion, The homothiopyrylium ion; generation and characterization (C) 214
Host/guest chemistry of organic onium compounds—clathrates, crystalline complexes, and molecular inclusion compounds in aqueous solution (R) 727

HPLC analysis, Quantitative HPLC analysis and thermodynamics of sulfur melts (C) 59
Hydrazine and its derivatives. Preparation, properties, applications (B) 1006
Hydride shift, Methyl migration and transannular 1,5-hydride shift on oxidative cleavage of C—Pd bonds with $CuCl_2$ (C) 207
Hydrido bridges, Diboriranides and a 1,3-diboraallyl system with *B*-H-*B* bridge (C) 788
Stepwise formation of a dinuclear μ-aminocarbyne- and a μ-formimidoyl-metal complex by insertion of methyl isocyanide into an MHM bridge (C) 577
Synthesis, structure, and ligand motion of $[Cr(CO)_2\{P(OCH_3)_3\}(\eta^4$-2,4-dimethyl-1,3-pentadiene)], a complex with a C—H—Cr bridge (C) 502
Hydroboration, Catalytic hydroboration with rhodium complexes (C) 878
Hydrogenobyrinic acid and vitamin B_{12} (C) 46
Hydrogen storage, Catalytic synthesis of organolithium and organomagnesium compounds and of lithium and magnesium hydrides—applications in organic synthesis and hydrogen storage (R) 262
Hydroperoxide, Photooxidation of chloroform: isolation and characterization of trichloromethyl hydroperoxide (C) 50
Hydrosilylation, Cleavage of a C—C bond in the catalytic hydrosilylation of camphor oxime (C) 703
Enantioselective hydrosilylation of prochiral 3,4-dihydro-2*H*-pyrrole derivatives (C) 995
Hydrothermal synthesis, The role of hydrothermal synthesis in preparative chemistry (R) 1026
Hydroxyacetylenes, Novel retro-ene reactions of β-hydroxyacetylenes (C) 783
Hydroxybenzo[*a*]pyrene 4,5-oxide, Reactive metabolites of carcinogenic polycyclic hydrocarbons: synthesis and trapping reaction of 9-hydroxybenzo(*a*)pyrene 4,5-oxide (C) 699
Hyperconjugation, Hyperfine coupling to ^{13}C nuclei in alkyl substituents—a Contribution to the problem of C—C and C—H hyperconjugation (C) 495
Hyperfine coupling to ^{13}C nuclei in alkyl substituents—a contribution to the problem of C—C and C—H hyperconjugation (C) 495
$^1H,^{13}C$-NOE difference spectroscopy, Selective $^1H,^{13}C$-NOE difference spectroscopy for the elucidation of structures (C) 705

IMINOBORANES, Hydroboration and hydrozirconation of *tert*-butylimino-2,2,6,6-tetramethylpiperidinoborane(C) 998
Simple synthesis of stable iminoboranes (C) 324
Immune response, From the structure of antibodies to the diversification of the immune response (Nobel lecture) (R) 816
Immune system, The generative grammar of the immune system (Nobel lecture) (R) 810
Immuno enzyme techniques in cytochemistry (B) 614
Immunosuppressive drugs, Synthesis of cyclosporine and analogues: structural requirements for immunosuppressive activity (R) 77
INADEQUATE-^{13}C-NMR spectroscopy, Misinterpretation of CC bonding through unusually large $^2J_{CC}$ values—a caveat for the use of INADEQUATE-^{13}C-NMR spectroscopy (C) 854
Inclusion compounds, Host/guest chemistry of organic onium compounds—clathrates, crystalline complexes, and molecular inclusion compounds in aqueous solution (R) 727
Indane derivatives, Stereospecific synthesis of 3-substituted hexahydroindane derivatives (C) 131
Indium compounds, Arene complexes of univalent gallium, indium, and thallium (R) 893
Inorganic polymers, $[CuCo(CO)_4]_n$—crystal structure of a polymer with a one-dimensional, infinite copper-cobalt bonding system (C) 70
Cyanogen as a bridging ligand—preparation and crystal structure of polymeric $[Ag\{(CN)_2\}_2]_n[AsF_6]_n$ with an undulating square cationic network (C) 417
Synthesis and structure of new Hg—Te polyanions: $[Hg_4Te_{12}]^{4\ominus}$, a cluster containing $Te^{2\ominus}$, $Te_2^{2\ominus}$, and $Te_3^{2\ominus}$ ligands and $[Hg_2Te_5]^{2\ominus}$, a new one-dimensional inorganic polymer (C) 433
Insertion, Monomeric, mononuclear enediolate complexes of zirconium: molecular geometry and electronic structure of the products of reductive CO coupling on the metal (C) 712
Spiroacetal formation by carbene (carbenoid) insertion reaction: synthesis of the major constituent of the sex attractant of the olive fly *(Dacus oleae)* (C) 230
Stepwise formation of a dinuclear μ-aminocarbyne- and a μ-formimidoyl-metal complex by insertion of methyl isocyanide into an MHM bridge (C) 577
Intercalation compound, $(Te_2)_2(I_2)$—an unusual intercalation compound (C) 393
Iodofunctionalization, $I(py)_2BF_4$, a new reagent in organic synthesis: general method for the 1,2-iodofunctionalization of olefins (C) 319
Ion transport, Mechanisms of biological ion transport—carriers, channels, and pumps in artificial lipid membranes (R) 905
Iron clusters, Nonacarbonylbis(μ_3-fluoromethylidyne)triiron: formation of a biscarbyne cluster from carbonyliron and tribromofluoromethane (C) 119
Iron compounds, Dicarbonyl-η^5-cyclopentadienyl(1-cyclopropenyl)iron complexes—a new class of σ-cyclopropenyl complexes (C) 209
Reactions of tricarbonyl(sorbaldehyde)-iron with carbanions: a repeatable organometallic reaction with $Fe(CO)_3$-migration (C) 126
Iron-palladium clusters, Reductive carbonylation of *o*-nitrophenol with a Fe-Pd cluster-derived heterogeneous catalyst; CO migration in the iron-palladium cluster $[FePdPt(CO)_4(Ph_2PCH_2PPh_2)_2]$ (C) 768
Isocyanomethylenetriphenylphosphorane (C) 979
Isomerization, A photochemically "switched-on" crown ether containing an intraannular 4-methoxyphenylazo substituent (C) 866
Skeletal isomerization of the $[Pt_3(\mu$-$PPh_2)_3Ph(PPh_3)_2]$ cluster by recrystallization in various solvents (C) 861
Isotope Effect, ^{15}N-^{29}Si coupling constants and ^{15}N isotope effect on ^{29}Si chemical shifts in compounds with natural isotopic abundance (C) 568

KETENES, First 1,4-dipolar cycloadditions of 6-oxo-3,6-dihydro-1-pyrimidinium 4-olates to ketenes and other carbonyl compounds (C) 608
Novel carbonylcyclopropane dimers and trimers—free ketenes or organometallic intermediates? (C) 605
Ketenylidenetriphenylphosphorane, Chain-lengthening difunctionalization of Grignard compounds by reaction with ketenylidenetriphenylphosphorane (C) 405
Ketocarboxylic acid derivatives, Isolation of the (*E*)-enols of β-ketocarboxylic acid derivatives (C) 350
Ketoketene, Primary adduct, γ-ketoketene, and some subsequent products of the reaction of methyl 6-oxo-5-phenyl-1,3,4-oxadiazinecarboxylate with norbornene (C) 886
Ketones, New bicyclic ketones and the stereochemistry of their reaction with carbanions (C) 972
Kinetics, Solvent exchange on magnesium([15]crown-5) complexes—a first- and second-order reaction (C) 575

β-LACTAM antibiotics, Recent developments in the field of β-lactam antibiotics (R) 180
Lactones, Chemoselective multicomponent synthesis of α,β-unsaturated esters and lactones and of their Diels-Alder adducts (C) 790
First α-methylene-β-peroxylactone—regiospecific ene reaction of $^1O_2$ with α,β-unsaturated carboxylic acids (C) 1070
Highly enantioselective intramolecular hetero Diels-Alder reactions for the synthesis of enantiomerically pure tricyclic lactones (C) 784
Oxidation of α,β-unsaturated esters and lactones with selenium dioxide to γ-oxo or γ-hydroxy derivatives; synthesis of (±)-A 26771 B and norpyrenophorin (C) 791
Pd^{II}-catalyzed stereoselective bis-lactonization (C) 1045
Lanthanide compounds, Cleavage of tris-(cyclopentadienyl)lanthanide complexes with alkyllithium compounds—a new route to alkylbis(cyclopentadienyl)lanthanides (C) 225
Lanthanum compounds, *cis*-Triaza-tris-σ-homobenzene as tridentate ligand $[La(C_6H_9N_3)_4 \cdot CH_3CN \cdot (ClO_4)_3]$: LaN_{12} complex with icosahedral coordination (C) 318
Large cavities, "In-out"-isomeric large cavities and their differing guest selectivity (C) 219
Large carbocyclic cavities for the selective inclusion of organic guest molecules in aqueous solution (C) 221
Laser photolysis, Sensitized UV/laser photolysis of azoalkanes: conformational influences on intersystem-crossing and lifetimes of triplet diradicals (C) 1071
Layer structure, $(Te_2)_2(I_2)$—an unusual intercalation compound (C) 393
Lead compounds, Multiple bonds between "naked" lead and transition metals—the first example (C) 1062
Lead-manganese double bond, Multiple bonds between "naked" lead and transition metals—the first example (C) 1062
Ligands, A dithioester as allylic-type 4e ligand (C) 971
Cyclodextrins as second sphere ligands for transition metal complexes—the X-ray crystal structure of $[Rh(cod)(NH_3)_2 \cdot$ α-cyclodextrin$][PF_6] \cdot 6\,H_2O$ (C) 786
Disulfur monoxide as complex ligand—preparation and molecular structure of $[(\eta^5$-$C_5Me_5)Mn(CO)_2(S_2O)]$ (C) 515
Fragmentation and recombination of CS_2 and CSSe in the coordination sphere of platinum metals (C) 518
Hexaphosphabenzene as complex ligand (C) 351
$[La(C_6H_9N_3)_4 \cdot CH_3CN \cdot (ClO_4)_3]$: LaN_{12} complex with icosahedral coordination (C)318
d^6-Metal complexes of 4,4′-bipyrimidine, an ambident ligand with high π-acceptor ability (C) 430
Phosphorus, arsenic, antimony, and bismuth multiply bonded systems with low coordination number—their role as complex ligands (R) 924
Synthesis, structure, and reactivity of η^3-1-azaallylmolybdenum complexes (C) 422
Transformation of $[\{(CO)_5W\}_3Sn]$ into $[\{(CO)_5W\}_3Te_2]$, a compound containing unusually bonded ditellurium (C) 428

cis-Triaza-tris-σ-homobenzene as tridentate ligand Tricarbonyl(1,3-diphosphaallyl)cobalt, a phosphorus analogue of (η^3-allyl)tricarbonylcobalt (C) 420
Tridentate oxygen ligands as cyclopentadienyl equivalents: structure and properties of $[LRh(\mu\text{-}CO)_3RhL]$, $L^- = [(C_5H_5)Co\{P(O)R_2\}_3]^-$ (C) 683
Ligand sphere, Reactions in the ligand sphere of iron(II): synthesis of crown ethers (C) 858
Lipid membranes, Mechanisms of biological ion transport—carriers, channels, and pumps in artificial lipid membranes (R) 905
Lipopeptide mitogens, Increased production of specific antibodies by presentation of the antigen determinants with covalently coupled lipopeptide mitogens (C) 872
Liposomes, Photoreactions of *N*-(1-pyridinio)amidates in monolayers and liposomes (C) 882
Liposome formation, A nucleolipid with antiviral acycloguanosine as head group—synthesis and liposome formation (C) 501
Liquid crystals, Axial chirality can lead to chiral smectic and cholesteric liquid crystals (C) 64
Smectic liquid crystals, textures and structures (B) 891
Lithium alkylsulfones, Lithium-coordinated α-sulfonyl carbanions: synthesis and X-ray structure determination of $[\{CH_2(SO_2C_6H_5)\}Li(tmeda)]_2$ (C) 859
Lithium compounds, Pentamethyldiethylenetriamine(phenyl)lithium, a monomeric organolithium compound (C) 215
Lithium hydride, Catalytic synthesis of organolithium and organomagnesium compounds and of lithium and magnesium hydrides—applications in organic synthesis and hydrogen storage (R) 262
Lithium methyleneamides, The crystal and solution structures of the complexes $[tBu_2C{=}NLi\cdot O{=}P(NMe_2)_3]_n$ (C) 328
Lithium silicate glass, Probing the structure and crystallinity of a lithium silicate glass by ^{29}Si magic-angle-spinning NMR spectroscopy (C) 61
Lithium-titanium exchange, Dilithio(phenylsulfonyl)trimethylsilylmethane: synthesis, $^{13}C/^1H$-NMR characterization, and lithium-titanium exchange (C) 696
1,1- and 1,*o*-dilithioallyl phenyl sulfone: synthesis, geminal cycloalkylation, and lithium-titanium exchange (C) 610
Lone pair of electrons, "Stereochemical activity" of a lone pair of electrons on low valent elements of the 4th main group: $(GeNtBu)_4\cdot 2AlCl_3$ and $(SnNtBu)_4\cdot 2AlCl_3$ (C) 223
Lutetium compounds, A novel route to pentamethylcyclopentadienyllutetium alkoxides and thiolates (C) 985

MACROCYCLES, A macrobicyclic receptor molecule for the diquat dication (C) 581
Cyclodextrins as second sphere ligands for transition metal complexes—the X-ray crystal structure of $[Rh(cod)(NH_3)_2\cdot\alpha\text{-cyclodextrin}][PF_6]\cdot 6\,H_2O$ (C) 786
Diamminebis(1,5-cyclooctadiene)(μ-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane-N^7,N^{16})dirhodiumbis(hexafluorophosphate): an example of simultaneous first and second sphere coordination (C) 135
First sixfold bridge-formation in one step (C) 794
Host/guest chemistry of organic onium compounds—clathrates, crystalline complexes, and molecular inclusion compounds in aqueous solution (R) 727
"In-out"-isomeric large cavities and their differing guest selectivity (C) 219
Large carbocyclic cavities for the selective inclusion of organic guest molecules in aqueous solution (C) 221
Macrolide antibiotics, Oxidation of α,β-unsaturated esters and lactones with selenium dioxide to γ-oxo or γ-hydroxy derivatives; synthesis of (±)-A 26771 B and norpyrenophorin (C) 791
Macrolides, The structure of the lichen macrolide (+)-aspicilin (C) 987
Magic-angle-spinning NMR spectroscopy, Probing the structure and crystallinity of a lithium silicate glass by ^{29}Si magic-angle-spinning NMR spectroscopy (C) 61
Magnesium-anthracene systems, Synthesis and structure of 1,4-dimethylanthracene-magnesium·3 thf and μ-trichlorodimagnesium·6 thf(1+) anthracenide (C) 960
Magnesium hydride, Catalytic synthesis of organolithium and organomagnesium compounds and of lithium and magnesium hydrides—applications in organic synthesis and hydrogen storage (R) 262
Magnesium([15]crown-5) complexes, Solvent exchange on magnesium([15]crown-5) complexes—a first- and second-order reaction (C) 575
Magnetic properties, Dinuclear complexes with predictable magnetic properties (R) 834
Manganese dioxide, Computer-controlled precipitation of metal hydroxides and hydrous oxides—preparation of manganese dioxide having uniform particle sizes (C) 1057
Manganese-sulfur compounds, The species $[Mn(S_2C_6H_3Me)_2]^{n-}$: mononuclear manganese complexes with square-planar (n = 1) and distorted tetrahedral (n = 2) sulfur coordination (C) 117
MAS NMR spectroscopy, Phosphorus-substituted thioformamides and thioformimidates: molecular structure and solid state ^{13}C-NMR spectra (C) 715
Probing the structure and crystallinity of a lithium silicate glass by ^{29}Si magic-angle-spinning NMR spectroscopy (C) 61
Mass spectrometry, $Cl_2C{-}Cl{-}Cl^{\odot\oplus}$, $Cl_2C{-}Cl{-}Br^{\odot\oplus}$, and $Br_2C{-}Br{-}Cl^{\odot\oplus}$ by gas-phase decarbonylation of $CX_3COY^{\odot\oplus}$ (C) 869
Combination of chromatographic separation methods with mass spectrometry—a modern technique for studying metabolism (R) 451
Materials science, Growth and dissolution of organic crystals with "tailor-made" inhibitors—implications in stereochemistry and materials sciene (R) 466
Membrane electrodes, Bioelektrochemische Membranelektroden (B) 355
Membranes, Mechanisms of biological ion transport—carriers, channels, and pumps in artificial lipid membranes (R) 905
Sealing and opening porous monolayer vesicle membranes (C) 339
Mercury compounds, Synthesis and structure of new Hg—Te polyanions: $[Hg_4Te_{12}]^{4\ominus}$, a cluster containing $Te^{2\ominus}$, $Te_2^{2\ominus}$, and $Te_3^{2\ominus}$ ligands and $[Hg_2Te_5]^{2\ominus}$, a new one-dimensional inorganic polymer (C) 433
Merrifield synthesis, Solid phase synthesis (Nobel lecture) (R) 799
Metabolism, Combination of chromatographic separation methods with mass spectrometry—a modern technique for studying metabolism (R) 451
Metabolites, Reactive metabolites of carcinogenic polycyclic hydrocarbons: synthesis and trapping reaction of 9-hydroxybenzo(*a*)pyrene 4,5-oxide (C) 699
Metallocenes, Reactive organometallic compounds obtained from metallocenes and related compounds and their synthetic applications (R) 295
Torsional isomerism in metallocenes: hindered Cp-rotation in (*s-cis*-η-butadiene)-bis(η-*tert*-butylcyclopentadienyl)zirconium (C) 321
Metal-metal bond, $(NEt_4)_2[Cl_3Mo(\mu\text{-}S_2)(\mu\text{-}Cl)_2MoCl_3]$, a paramagnetic molybdenum(IV) compound with a metal-metal bond (C) 689
Reaction of small molecules with the binuclear complex $[(\mu\text{-}C_5H_5)(\mu\text{-}Br)Pd_2(PR_3)_2]$: addition without cleavage of the metal-metal bond (C) 516
Methanoaza[10]annulene, 3,8-Methanoaza-[10]annulene (homoisoquinoline) (C) 592
Methemerythrin model compounds, Reactivity of the $[Fe_2(\mu_2\text{-}O)(\mu\text{-acetato})_2]$ unit in methemerythrin model compounds towards $N_3^\ominus$ and $NCS^\ominus$ (C) 392
Methoxybicyclo[2.2.2]octenones, Photochemistry of 1-methoxybicyclo[2.2.2]octenones; photolytic cyclopropane cleavage of the initially formed tricyclo[3.3.0.$0^{2,8}$]octan-3-ones (C) 763
Methoxylation, Electrochemical methoxylation of antipyrine (C) 864
Methyl acrylate, Carbonyliron-assisted coupling of cyclopolyenes with methyl acrylate (C) 353
Methylalumoxane, Polymerization of propene and butene with a chiral zirconocene and methylalumoxane as cocatalyst (C) 507
α-Methylene-γ-butyrolactones, Synthesis and biological activity of α-methylene-γ-butyrolactones (R) 94
Methylene-1-cyclopentenes, 4-Methylene-1-cyclopentenes from methylenecyclopropanes and alkynyltrimethylsilanes (C) 316
α-Methylene-β-peroxylactone, First α-methylene-β-peroxylactone—regiospecific ene reaction of $^1O_2$ with α,β-unsaturated carboxylic acids (C) 1070
Methyl migration and transannular 1,5-hydride shift on oxidative cleavage of C—Pd bonds with $CuCl_2$ (C) 207
Methyl 2,3,*O*-isopropylidene-β-L-apio-L-furanoside, Photochemical synthesis of an L-erythrose building block and its use in the preparation of methyl 2,3,*O*-isopropylidene-β-L-apio-L-furanoside (C) 877
Micelles, Enzymes hosted in reverse micelles in hydrocarbon solution (R) 439
Microemulsions, Phase behavior of ternary systems of the type H_2O—oil—nonionic amphiphile (microemulsions) (R) 654
Minisci reaction, Marked increase in the regioselectivity of radical substitution: Minisci reaction in a two-phase system (C) 692
Model systems, An organoboron model system for the Fischer-Tropsch synthesis (C) 572
Modern synthetic methods 1983. Vol. 3: Transition metals in organic synthesis (B) 233
Modification, c-TiS_2, a new modification of titanium disulfide with cubic structure (C) 67
Molybdenum compounds, Synthesis of $[(\eta^5\text{-}C_5H_5)_2Mo(\eta^2\text{-}CH_2O)]$: a formaldehyde complex of molybdenum (C) 402
Molybdenum(IV) compounds, The complex $(NEt_4)_2[Cl_3Mo(\mu\text{-}S_2)(\mu\text{-}Cl)_2MoCl_3]$, a paramagnetic molybdenum (IV) compound with a metal-metal bond (C) 689
Molybdenum-sulfur compounds, Novel MoFeS clusters from $[(C_5Me_5)_2Mo_2S_4]$ and $Fe(CO)_5$ or $Fe_2(CO)_9$ (C) 133
Synthesis of $[(C_5Me_5)_2Mo_2XS_3Co(CO)_2]$ clusters (X = P, As) and structural characterization of a μ_2,η^2-AsS ligand (C) 132
Monoclonal antibodies, Derivation and diversification of monoclonal antibodies (Nobel lecture) (R) 827
Monoclonal antibodies, their chemistry, functions, and possible uses (R) 139
Monolayer vesicle membranes, Sealing and opening porous monolayer vesicle membranes (C) 339
Multicomponent synthesis, Chemoselective multicomponent synthesis of α,β-unsatu-

rated esters and lactones and of their Diels-Alder adducts (C) 790
Multicomponent systems, Phase behavior of ternary systems of the type H_2O—oil—nonionic amphiphile (microemulsions) (R) 654
Multiple bonds between "naked" lead and transition metals—the first example (C) 1062

NATURAL PRODUCTS, A simple approach to the naphtho[1,8-*bc*]pyrandione system (C) 711
Crinipellins, the first natural products with a tetraquinane skeleton (C) 709
Synthesis and biological activity of α-methylene-γ-butyrolactones (R) 94
The chemistry and antibiotic activity of the toadstool *Agaricus xanthoderma* (agaricales) (C) 1063
Neutrocyanines, Azahexamethineneutrocyanines from a *N*-(tetramethylformamidinio)pyridinium salt (C) 511
Nickelaazadiphosphetidine, Chelate ligand-controlled η^1-η^2 change of coordination in amino(imino)phosphane ligands and their conversion into a nickelaazadiphosphetidine (C) 525
Nickel clusters, Amino(imino)phosphanes as face-bridging complex ligands (C) 115
New Co and Ni clusters with Se and PPh_3 as ligands: $[Co_4(\mu_3\text{-}Se)_4(PPh_3)_4]$, $[Co_6(\mu_3\text{-}Se)_8(PPh_3)_6]$, $[Co_9(\mu_4\text{-}Se)_3(\mu_3\text{-}Se)_8(PPh_3)_6]$, and $(Ni_{34}(\mu_5\text{-}Se)_2(\mu_4\text{-}Se)_{20}(PPh_3)_{10}]$ (C) 993
Novel cobalt- and nickel-clusters with S and PPh_3 as ligands; crystal structures of $[Ni_8S_6Cl_2(PPh_3)_6]$ and $[Ni_8S_5(PPh_3)_7]$ and of $[Co_6S_8(PPh_3)_6]^+[CoCl_3(THF)]^-$ and $[Co_7S_6(PPh_3)_5Cl_2]$, (C) 706
Synthesis and structure of the $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n-}$ (n = 5, 4) ions: Ni-Pt clusters as models for "cherry" crystallites (C) 697
Nitrile imines: thermal generation, direct observation, and subsequent trapping (C) 56
Nitrogen fixation, $[\mu\text{-}N_2H_2\{Ru(PPh_3)dttd\}_2]$, the first diazene complex with sulfur-coordinated transition metal centers ($dttd^{2-}$ = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(−2) (C) 981
Nitrogen homocycles, Direct structural proof for the pentazole ring system in solution by ^{15}N-NMR spectroscopy (C) 513
Stable triaziridines (C) 341
Nitrogen monoxide as a source for oxo ligands—acetylene-oxo complexes of tungsten (C) 497
Nitrogen silicon double bond, Isolation of the stable silaketimine $tBu_2Si{=}N{-}SitBu_3$ (C) 1053
Nitrosyl complexes, Cationic thionitrosyl and nitrosyl complexes (C) 202
NMR Spectroscopy, A new method for determining enantiomeric excess, where the sample serves as its own reference (C) 315
Complete signal assignment of the ^{13}C-NMR spectra and structure determination of corrinoids by 2D-INADEQUATE and 2D ^{13}C,^{1}H-NMR chemical shift correlation using ^nJ(C,H) (C) 333
NMR and chemistry. An introduction to the Fourier transform-multinuclear era (B) 355
^{15}N-^{29}Si coupling constants and ^{15}N isotope effect on ^{29}Si chemical shifts in compounds with natural isotopic abundance (C) 568
Selective ^{1}H,^{13}C-NOE difference spectroscopy for the elucidation of structures (C) 705
^{15}N-NMR spectroscopy, Direct structural proof for the pentazole ring system in solution by ^{15}N-NMR spectroscopy (C) 513
Nobel lectures, Derivation and diversification of monoclonal antibodies (R) 827
From the structure of antibodies to the diversification of the immune response (R) 816
Solid phase synthesis (R) 799
The generative grammar of the immune system (R) 810
Nomenclature, A simple notation system for transition-metal clusters (C) 45
Non-benzenoid conjugated carbocyclic compounds (B) 1007
Nonclassical cations, Destabilized 2-norbornyl cations (C) 55
Norbornyl cations, Destabilized 2-norbornyl cations (C) 55
Norpyrenophorin, Oxidation of α,β-unsaturated esters and lactones with selenium dioxide to γ-oxo or γ-hydroxy derivatives; synthesis of (±)-A 26771 B and norpyrenophorin (C) 791
Nucleolipids, A nucleolipid with antiviral acycloguanosine as head group—synthesis and liposome formation (C) 501
Nucleophilic addition, Stereoselective nucleophilic additions to a bicyclic ketone controlled by a remote tricarbonyl(diene)iron moiety (C) 787
Nucleophilic reactions, Reactions of per(chloro,fluoro)ethanes with aryloxide and alkoxide ions—evidence for chlorophilic attack on C—Cl bonds (C) 871
Nucleosides, Synthesis of 1,4-dihydropyridine nucleosides by photochemical cycloaddition (C) 127
Synthesis of 3′-*C*-methyl-2′-deoxyribonucleoside with methylmagnesium iodide (C) 52

OCTABISVALENE derivatives, an octabisvalene derivative, (*Z*)-3,7-Bis(phenylsulfonyl)pentacyclo[5.1.0.0^{2,4}.0^{3,5}.0^{6,8}]octane (C) 411
Octaphenyldiazahexaphosphocine, Octaphenyl-1,5,2λ^5,3,4λ^5,6λ^5,7,8λ^5-diazahexaphosphocine (C) 580
α-Olefins, Novel polymerization of α-olefins with the catalyst system nickel/amino-bis(imino)phosphorane (C) 1001
Oligonucleotides, Three-phase synthesis of oligonucleotides (C) 685
Oligosaccharide syntheses, Preparation of an *N*-acetylneuraminic acid-containing trisaccharide and its use in oligosaccharide syntheses (C) 128
Olive fly, Spiroacetal formation by carbene (carbenoid) insertion reaction: synthesis of the major constituent of the sex attractant of the olive fly *(Dacus oleae)* (C) 230
Onium compounds, Host/guest chemistry of organic onium compounds—clathrates, crystalline complexes, and molecular inclusion compounds in aqueous solution (R) 727
Optimization of syntheses, $SiCl_2$: photoelectron spectroscopic optimization of various syntheses (C) 205
Organic synthesis, Enzymes as catalysts in synthetic organic chemistry (R) 617
New pathways for organic synthesis. Practical applications of transition metals (B) 613
Selectivity—a goal for synthetic efficiency. Workshop conferences Hoechst. Vol. 14 (B) 614
Organoaluminum compounds, Formation of organoaluminum compounds in the mixture $AlCl_3$—$TiCl_4$—Al—C_2H_4 (C) 311
Organoaluminum reagents, Selective reactions using organoaluminum reagents (R) 668
Organolithium compounds, On the aggregation of lithiated bicyclobutane derivatives in solution (C) 404
Pentamethyldiethylenetriamine(phenyl)lithium, a monomeric organolithium compound (C) 215
Polymorphism of an organolithium compound: dilithium 1,2-diphenylbenzocyclobutadienediide · 2tetramethylethylenediamine (C) 863
Organomercury hydrides, Syntheses with radicals—C-C bond formation via organotin and organomercury compounds (R) 553
Organometallic compounds, Oxidation of organometallic compounds (R) 274
Reactive organometallic compounds obtained from metallocenes and related compounds and their synthetic applications (R) 295
The chemistry of the metal-carbon bond. Vol. 1: The structure, preparation, thermochemistry and characterization of organometallic compounds (B) 75
Organostibanes, $(C_6H_5Sb)_6$ · (1,4-dioxane), the first cyclohexastibane (C) 72
Organotin hydrides, Syntheses with radicals—C-C bond formation via organotin and organomercury compounds (R) 553
Oxacarbenes, Bicyclic acetals from oxacarbenes (C) 1043
Oxadiazole, Can 1,2,3-oxadiazole be stable? (C) 713
Oxidation of α,β-unsaturated esters and lactones with selenium dioxide to γ-oxo or γ-hydroxy derivatives; synthesis of (±)-A 26771 B and norpyrenophorin (C) 791
Oxidation of organometallic compounds (R) 274
Oxo bridges, $[(\eta^5\text{-}C_5Me_5)CrO_2]_2$—a dinuclear oxo-complex of chromium(V) (C) 601
Oxo ligands, Nitrogen monoxide as a source for oxo ligands—acetylene-oxo complexes of tungsten (C) 497
Oxygen ligands, Tridentate oxygen ligands as cyclopentadienyl equivalents: structure and properties of $[LRh(\mu\text{-}CO)_3RhL]$, $L^- = [(C_5H_5)Co\{P(O)R_2\}_3]^-$ (C) 683
Oxygen-sulfur anions, Reactivity of bis(η^6-benzene)chromium(0) toward sulfur dioxide: formation and structure of $[(\eta^6\text{-}C_6H_6)_2Cr]_2S_4O_{10}$, a salt containing the anion $[S_2O_6 \cdot 2SO_2]^{2\ominus}$ (C) 967
Ozonides, Crystal structures of potassium ozonide and rubidium ozonide (C) 54

PARAMAGNETIC transition-metal complexes, The first application of 2D-NMR to the spectral analysis of a paramagnetic complex. Example: bis[*R*-(+)-*P*,*P*-diethylthiophosphinic acid-*N*-α-methylbenzylamido]nickel(II) (C) 231
Paterno-Büchi reaction, Photochemical synthesis of an L-erythrose building block and its use in the preparation of methyl 2,3,*O*-isopropylidene-β-L-apio-L-furanoside (C) 877
Pentaaqua(β-hydroxyalkyl)chromium(III) complexes, Cleavage of an ether bond via β-elimination of ethanol from $[(H_2O)_5CrCH_2CH_2OC_2H_5]^{2+}$ in aqueous solutions; a pulse radiolysis study (C) 779
Pentaazadiene, Complexes of 1,5-di(*p*-tolyl)-1,4-pentaazadien-3-ide, crystal structures of [Cu(tolylNNNNNtolyl)]$_3$ and [Ni(tolylNNNNNtolyl)$_2$]$_2$ (C) 409
Pentacoordination, $(CH_3)_2NSF_4^{\oplus}AsF_6^{\ominus}$ — the synthesis and stability of a simple pentacoordinated sulfur(VI) cation (C) 344
Pentamethylcyclopentadienyllutetium alkoxides, A novel route to pentamethylcyclopentadienyllutetium alkoxides and thiolates (C) 985
Pentamethylcyclopentadienylmetal complexes, $(\eta^5\text{-}C_5Me_5)_2Fe_2S_4$ and $(\eta^5\text{-}C_5Me_5)_2\text{-}Co_2S_4$, two novel bis(pentamethylcyclopentadienylmetal) complexes rich in sulfur (C) 1060
Pentazole ring system, Direct structural proof for the pentazole ring system in solution by ^{15}N-NMR spectroscopy (C) 513
Peptide analysis, Sequencing of short peptides using FAB mass spectrometry—increased information via derivatization (C) 408

Peptides, Applications of synthetic peptides (R) 719
Exhaustive *tert*-butoxycarbonylation of peptide nitrogens (C) 510
Peptide synthesis, Basic principles of protease-catalyzed peptide bond formation (R) 85
Principles of peptide synthesis (B) 527
Solid phase synthesis (Nobel lecture) (R) 799
Per(chloro,fluoro)ethanes, Reactions of per(chloro,fluoro)ethanes with aryloxide and alkoxide ions—evidence for chlorophilic attack on C—Cl bonds (C) 871
Peroxylactone, First α-methylene-β-peroxylactone—regiospecific ene reaction of $^1O_2$ with α,β-unsaturated carboxylic acids (C) 1070
PE Spectroscopy, $SiCl_2$: photoelectron spectroscopic optimization of various syntheses (C) 205
Phanes, First sixfold bridge-formation in one step (C) 794
The first [2.1] phane: a new helical molecular skeleton (C) 885
Pharmaceutical chemistry, Einführung in die Pharmazeutische Chemie (B) 797
Phase behavior of ternary systems of the type H_2O—oil—nonionic amphiphile (microemulsions) (R) 654
Phenylcarbene, Reaction of phenylcarbene with oxygen (C) 988
(*o*-Phenyleno)naphthalenes, Synthesis of the first linear (*o*-phenyleno)naphthalenes; a new class of benzenoid aromatics (C) 114
Phenyl silaisocyanide: the first organosilicon compound with a formal Si≡N triple bond (C) 111
Pheromones, Spiroacetal formation by carbene (carbenoid) insertion reaction: synthesis of the major constituent of the sex attractant of the olive fly *(Dacus oleae)* (C) 230
Phosphaalkene ligands, Tricarbonyl(1,3-diphosphaallyl)cobalt, a phosphorus analogue of (η^3-allyl)tricarbonylcobalt (C) 420
Phosphaalkenyl complexes, The species *Z*-[(η^5-C_5H_5)(CO)$_2$Fe—P=C(OSiMe$_3$)(*t*Bu)], a phosphaalkenyl-complex with FeP single bond (C) 604
Phosphaalkenylrhenium complexes—a novel class of substances with P=C bonding (C) 53
Phosphaallyl cations, 2-Phosphaallyl cations, How is phosphorus bound in 2-phospha- and 2-"phosphoniaallyl" cations? (C) 764
Phosphane, Novel aspects of the coordination chemistry of phosphane (C) 68
2-"Phosphoniaallyl" cations, How is phosphorus bound in 2-phospha- and 2-"phosphoniaallyl" cations? (C) 764
Phosphonic acids, Asymmetric addition of a chiral cyclic phosphite to a cyclic imine—synthesis of a phosphonic acid analogue of D- and L-penicillamine (C) 1067
Phosphorus cations, Symmetrical and unsymmetrical triphosphenium ions (C) 226
Phosphorus compounds, Preparation and structure of a diphosphorus compound with positive charges on the two directly bonded phosphorus atoms (C) 975
Phosphorus-nitrogen heterocycles, Octaphenyl-1,5,2λ^5,3,4λ^5,6λ^5,7,8λ^5-diazahexaphosphocine (C) 580
Phosphorus ylides, Isocyanomethylenetriphenylphosphorane (C) 979
Photochemical initiation, Photochemically initiated, electron-transfer-catalyzed Diels-Alder reactions of electron-rich dienophiles (C) 412
Photochemistry, A photochemically "switched-on" crown ether containing an intraannular 4-methoxyphenylazo substituent (C) 866
Cationic 2-azaallenylidene complexes, novel compounds with unusual photochemical properties (C) 121
Photocycloaddition, 1,4-Photocycloaddition of α-morpholinoacrylonitrile to 1-acylnaphthalenes (C) 1048
Photoisomerization, *E*→*Z*-Photoisomerization of a diphosphene on carbonylmetal complexes (M=Cr, Mo, W) (C) 211
Photolysis, Laser photolysis of the bisazoalkane 7-*syn*,7′-*anti*-bis-2,3-diazabicyclo-[2.2.1]hept-2-ene (C) 421
Sensitized UV/laser photolysis of azoalkanes: conformational influences on intersystem-crossing and lifetimes of triplet diradicals (C) 1071
Photooxidation of chloroform: isolation and characterization of trichloromethyl hydroperoxide (C) 50
Photooxygenolysis of vitamin B_{12} (C) 62
Photopolymerization, Sources and applications of ultraviolet radiation (B) 796
Photoreaction of thiones with bromoketene acetals (C) 976
Physical chemistry, Moleküle und Molekülanhäufungen. Eine Einführung in die physikalische Chemie (B) 235
Platinum hydrides, Synthesis and structure of [Pt$_2$(μ-H)(μ-CHCH$_2$Ph)(diphos)$_2$][BF$_4$] (C) 120
Polyanions, Synthesis and structure of new Hg—Te polyanions: $[Hg_4Te_{12}]^{4\ominus}$, a cluster containing $Te^{2\ominus}$, $Te_2^{2\ominus}$, and $Te_3^{2\ominus}$ ligands and $[Hg_2Te_5]^{2\ominus}$, a new one-dimensional inorganic polymer (C) 433
Synthesis and structure of new potassium-gold-tellurium polyanions: $[KAu_9Te_7]^{4\ominus}$, $[K_2Au_4Te_4(en)_4]^{2\ominus}$, and $[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]^{2\ominus}$ (C) 432
Polycycles, Laser photolysis of the bisazoalkane 7-*syn*,7′-*anti*-bis-2,3-diazabicyclo-[2.2.1]hept-2-ene (C) 421
New bicyclic ketones and the stereochemistry of their reaction with carbanions (C) 972
Polycyclic hydrocarbons, A three-blade propeller compound with seven bracketed benzene rings (C) 222
Reactive metabolites of carcinogenic polycyclic hydrocarbons: synthesis and trapping reaction of 9-hydroxybenzo[*a*]pyrene 4,5-oxide (C) 699
Polycyclic quinones, Synthesis of cyclohepta[*a*]phenalene-6,12-dione (C) 757
Polymerization, Highly active ylide-nickel catalysts for the polymerization of ethylene (C) 599
Novel polymerization of α-olefins with the catalyst system nickel/aminobis(imino)phosphorane (C) 1001
Polymerization of propene and butene with a chiral zirconocene and methylalumoxane as cocatalyst (C) 507
Polymers, Chemistry and technology of water-soluble polymers (B) 1073
Properties and applications. Vol. 8: Polymer degradation and stabilization (B) 889
4-[Tri(*n*-butyl)]phosphinio-2,5-diselenoxo-1,3-diselenacyclopentanide (C) 1058
Polymer spectroscopy, Polymers. Properties and applications. Vol. 7: Introduction to polymer spectroscopy (B) 717
Polymorphism of an organolithium compound: dilithium 1,2-diphenylbenzocyclobutadienediide · 2 tetramethylethylenediamine (C) 863
Polypeptide antibiotic, Elucidation of the structure of epidermin, a ribosomally synthesized, tetracyclic heterodetic polypeptide antibiotic (C) 1051
Polypeptides, Applications of synthetic peptides (R) 719
Polysulfides, Transition metal polysulfides: coordination compounds with purely inorganic chelate ligands (R) 742
Poly(9,9′-spirobifluorene) crown ethers, Chiral poly(9,9′-spirobifluorene) crown ethers (C) 792
Porphyrins, The synthesis of porphyrins doubly linked to quinones by hydrocarbon chains (C) 1003
Total synthesis of (±)-bonellin dimethyl ester (C) 775
Potassium ozonide, Crystal structures of potassium ozonide and rubidium ozonide (C) 54
Precipitation, Computer-controlled precipitation of metal hydroxides and hydrous oxides—preparation of manganese dioxide having uniform particle sizes (C) 1057
Primary adduct, γ-ketoketene, and some subsequent products of the reaction of methyl 6-oxo-5-phenyl-1,3,4-oxadiazinecarboxylate with norbornene (C) 886
Proteases, Basic principles of protease-catalyzed peptide bond formation (R) 85
Protecting groups, Exhaustive *tert*-butoxycarbonylation of peptide nitrogens (C) 510
Protein biosynthesis, The 3′-end of *t*RNA and its role in protein biosynthesis (R) 371
Proteins, The construction of new proteins and enzymes—a prospect for the future? (R) 639
Proton exchange between arenium ions and arenes in the gas phase (C) 693
Prussian blue, Polymeric tris[trimethyltin(IV)]hexacyanocobaltate(III), a compound non-analogous to "super prussian blue", and its tris[tricyclopentadienyluranium(IV)] homologue (C) 879
Pulse radiolysis study, Cleavage of an ether bond via β-elimination of ethanol from [(H$_2$O)$_5$CrCH$_2$CH$_2$OC$_2$H$_5$]$^{2+}$ in aqueous solutions; a pulse radiolysis study (C) 779
Purines, Synthesis of 6-substituted purines and ribonucleosides with *N*-(6-purinyl)-pyridinium salts (C) 1054
Purinylpyridinium salts, Synthesis of 6-substituted purines and ribonucleosides with *N*-(6-purinyl)pyridinium salts (C) 1054
Purpurogallin formation, Mechanism of purpurogallin formation: an adduct from 3-hydroxy-*o*-benzoquinone and 4,5-dimethyl-*o*-benzoquinone (C) 224
Pyrazolotriazines, Coupling of 3-diazo-3*H*-pyrazoles with 2-alkoxy-1,6-methano[10]-annulenes and oxidative cyclization to pyrazolotriazines (C) 346
Pyrazolylium salts, (Bis)dimethylamino-pyrazoles and pyrazolylium salts (C) 984
Pyrethroids, Stereo- and enantioselective synthesis of both *cis*-chrysanthemic acid methyl esters in high optical purity (C) 996
Pyridine synthesis, Organocobalt compounds in the synthesis of pyridines—an example of structure-effectivity relationships in homogeneous catalysis (R) 248
Pyridinioamidates, Photoreactions of *N*-(1-pyridinio)amidates in monolayers and liposomes (C) 882
Pyrrole derivatives, Enantioselective hydrosilylation of prochiral 3,4-dihydro-2*H*-pyrrole derivatives (C) 995
Pyrrolylidene ethanide, Synthesis of a novel stable carbanion: 1,1,2-tricyano-2-(3,4-dicyano-5-imino-2,5-dihydro-1*H*-pyrrol-2-ylidene)ethanide by reduction of tetracyanoethylene with tris(2,2′-bipyridine)titanium (C) 426

QUINONES, *para*-Quinodimethanes, Bis(tricarbonyliron)-*para*-quinodimethanes: preparation and molecular structure (C) 521
Synthesis of cyclohepta[*a*]phenalene-6,12-dione (C) 757
The synthesis of porphyrins doubly linked to quinones by hydrocarbon chains (C) 1003

RACEMIZATION, Activation energy of the racemization of optically active tricarbonyl(tropone)iron complexes (C) 329

Radialenes, [4]-Radialenes, An intermediate and its secondary products in a nickel-catalyzed synthesis of [4]-radialenes (C) 496
Radialene tetracarboxylic ester, [4]Radialene tetracarboxylic ester, On the thermal behavior of butatrienecarboxylic acid derivatives: crystal and molecular structure of a [4]radialene tetracarboxylic ester (C) 852
Radical cations, A novel rearrangement in $(R_2S.\cdot.SR_2)^{\oplus}$-radical cations with a 3e-bond (C) 73
$Cl_2C-Cl-Cl^{\odot\oplus}$, $Cl_2C-Cl-Br^{\odot\oplus}$, and $Br_2C-Br-Cl^{\odot\oplus}$ by gas-phase decarbonylation of $CX_3COY^{\odot\oplus}$ (C) 869
Radical ion pairs, On the role of radical ion pairs in [4+2] cycloadditions (C) 337
Radical ions, Hyperfine coupling to ^{13}C nuclei in alkyl substituents—a contribution to the problem of C—C and C—H hyperconjugation (C) 495
Radicals, Do $Cp(CO)_2Mn$ fragments stabilize radicals? (C) 856
Sensitized UV/laser photolysis of azoalkanes: conformational influences on intersystem-crossing and lifetimes of triplet diradicals (C) 1071
Syntheses with radicals—C-C bond formation via organotin and organomercury compounds (R) 553
Radical substitution, Marked increase in the regioselectivity of radical substitution: Minisci reaction in a two-phase system (C) 692
Radwaste immobilization by structural modification—the crystallochemical properties of SYNROC, a titanate ceramic (R) 357
Raney nickel, Gas-phase reactions of organic compounds on Raney nickel (C) 418
Reaction control, Stereoselective nucleophilic additions to a bicyclic ketone controlled by a remote tricarbonyl(diene)-iron moiety (C) 787
Reaction dynamics, Chemical dynamics via molecular beam and laser techniques (B) 435
Reaction mechanisms, Concerning the mechanism of the asymmetric Diels-Alder reaction: first crystal structure analysis of a Lewis acid complex of a chiral dienophile (C) 112
Determination of organic reaction mechanisms (B) 795
Novel carbonylcyclopropane dimers and trimers—free ketenes or organometallic intermediates? (C) 605
Novel polymerization of α-olefins with the catalyst system nickel/aminobis(imino)phosphorane (C) 1001
Reaction of phenylcarbene with oxygen (C) 988
Rearrangements, A novel rearrangement in $(R_2S.\cdot.SR_2)^{\oplus}$-radical cations with a 3e-bond (C) 73
Dimerization of a C_2B_3-*closo*-carbaborane(5) to the C_4B_6-adamantane and its 2z/3z valence isomerization to the C_4B_6-*nido*-carbaborane(10) (C) 326
Reactions of tricarbonyl(sorbaldehyde)-iron with carbanions: a repeatable organometallic reaction with $Fe(CO)_3$-migration (C) 126
Synthesis and reactions of 4-azido-3-methyl-1,2-butadiene (C) 216
Thiophene derivatives by novel rearrangements of siloxy-substituted cyclopropanecarboxylates (C) 588
Walk rearrangement in the 1,2,3,4-tetra-*tert*-butylhydroxycyclobutenylium ion (C) 429
Redox catalysis, Heterogeneous redox catalysis on Ti/TiO_2 cathodes—reduction of nitrobenzene (C) 771
Reduction, Chiral compounds synthesized by biocatalytic reductions (R) 539
Reduction of ketones by alkali metals in tertiary alcohols: unexpected cation effect on the stereochemistry (C) 499
Reductive carbonylation of *o*-nitrophenol with a Fe-Pd cluster-derived heterogeneous catalyst; CO migration in $[FePdPt(CO)_4(Ph_2PCH_2PPh_2)_2]$ (C) 768
Regioselectivity, Marked increase in the regioselectivity of radical substitution: Minisci reaction in a two-phase system (C) 692
Repeatable organometallic reaction, Reactions of tricarbonyl(sorbaldehyde)iron with carbanions: a repeatable organometallic reaction with $Fe(CO)_3$-migration (C) 126
Resolution, Chiral copper(II) complexes for the enantioselective resolution of DL-dansyl-amino acids by HPLC (C) 336
Direct enantiomer resolution of hydroxy and carbonyl compounds by gas chromatography on Chirasil-Val (C) 48
Resonance concept, Calculation of the charge distribution in conjugated systems by a quantification of the resonance concept (C) 687
Retinal Schiff base, UV and CD spectroscopic evidence of the self-association of a Schiff base of all-*trans*-retinal (C) 761
Retro-ene reactions, Novel retro-ene reactions of β-hydroxyacetylenes (C) 783
Reverse micelles, Enzymes hosted in reverse micelles in hydrocarbon solution (R) 439
Rhenium compounds, Novel C—O bond formation via [3+2] cycloaddition of diphenylketene to a dioxo metal moiety (C) 860
Pentacarbonylolefin- and pentacarbonyldiolefinrhenium complex cations; synthesis and structure of the 2-butene-1,4-diyl-bridged carbonyldirhenium complex *trans*-$[(OC)_5ReCH_2CH=CHCH_2Re(CO)_5]$ (C) 505
Reductive trimerization of the trioxo half-sandwich complex $[(\eta^5\text{-}C_5Me_5)ReO_3]$ with deoxygenation: the electron-deficient cluster ion $[(\eta^5\text{-}C_5Me_5)_3Re_3(\mu\text{-}O)_6]^{2+}$ (C) 50
Rhodium complexes, Catalytic hydroboration with rhodium complexes (C) 878
Rhodium compounds, Cluster expansion with Cp(CO)Rh fragments (C) 424
Ribonucleosides, Synthesis of 6-substituted purines and ribonucleosides with *N*-(6-purinyl)pyridinium salts (C) 1054
Rifampicin, Molecular mechanism of action of the antibiotic rifampicin (R) 1009
Ring expansion, Bicyclic acetals from oxacarbenes (C) 1043
4-Methylene-1-cyclopentenes from methylenecyclopropanes and alkynyltrimethylsilanes (C) 316
Ring inversion, Synthesis and dynamic properties of chiral heptalenes (C) 212
Ring opening, Azahexamethineneutrocyanines from a *N*-(tetramethylformamidinio)pyridinium salt (C) 511
RNA synthesis, Molecular mechanism of action of the antibiotic rifampicin (R) 1009
Rubidium ozonide, Crystal structures of potassium ozonide and rubidium ozonide (C) 54
Ruthenium-sulfur-diazene complexes, $[\mu\text{-}N_2H_2\{Ru(PPh_3)dttd\}_2]$, the first diazene complex with sulfur-coordinated transition metal centers ($dttd^{2-}$ = 2,3,8,9-dibenzo-1,4,7,10-tetrathiadecane(−2) (C) 981

SAKURAI REACTION, Allylation of aldehydes with etherification by dialkoxydichlorotitanium/allyltrimethylsilane; an asymmetric variant of the Sakurai reaction (C) 765
Sandwich complexes, A new type of sandwich complex formed by Ag^I and $[Pt_3(\mu_2\text{-}CO)_3(PiPr_3)_3]$ (C) 766
Novel high-nuclearity HgCoRu and HgCoFe sandwich complexes. Synthesis and structure of $[Hg\{RuCo_3(\mu\text{-}CO)_3(CO)_9\}_2]$ (C) 767
Synthesis and structure of a thallium complex with an anionic sandwich complex ligand (C) 71
Sandwich compounds, 2,3-Dihydro-1,3-diborole-metal complexes with activated C—H bonds: building blocks for multilayered sandwich compounds (R) 943
Reactions in the ligand sphere of iron(II): synthesis of crown ethers (C) 858
Selectivity—a goal for synthetic efficiency. Workshop conferences Hoechst. Vol. 14 (B) 614
Selenium compounds, 4-[Tri(*n*-butyl)]phosphinio-2,5-diselenoxo-1,3-diselenacyclopentanide (C) 1058
Self-association, UV and CD spectroscopic evidence of the self-association of a Schiff base of all-*trans*-retinal (C) 761
Sesquiterpene hydrocarbons, Catalytic transformations of sesquiterpene hydrocarbons on alkali metal/aluminum oxide (C) 320
Side chains, Carbonyliron-assisted coupling of cyclopolyenes with methyl acrylate (C) 353
Silacycloalkynes, New silacycloalkynes with up to four 1,4-disila-2-alkyne units in the ring (C) 565
Silaketimine, Isolation of the stable silaketimine $tBu_2Si=N-SitBu_3$ (C) 1053
Silicon-carbon double bond, Isolation and structure of a stable molecule containing a silicon-carbon double bond (C) 229
Silver oxide, Ag_2O_3, a novel binary silver oxide (C) 118
Silyl ketene acetals, Enantio- and *anti*-diastereoselective aldol additions of acetates and propionates via *O*-silyl ketene acetals (C) 874
Single bond, *Z*-$[(\eta^5\text{-}C_5H_5)(CO)_2Fe-P=C(OSiMe_3)(tBu)]$, a phosphaalkenyl-complex with FeP single bond (C) 604
Skeletal isomerization of the $[Pt_3(\mu\text{-}PPh_2)_3Ph(PPh_3)_2]$ cluster by recrystallization in various solvents (C) 861
Sodium germanide, NaGe—high-pressure formation of the NaPb-type structure (C) 500
Solid phase synthesis (Nobel lecture) (R) 799
Solid state chemistry, Amorphe und glasartige Festkörper (B) 1073
Solid state chemistry and its applications (B) 1073
Solid-state NMR spectroscopy, Phosphorus-substituted thioformamides and thioformimidates: molecular structure and solid state ^{13}C-NMR spectra (C) 715
Solvates, Reactivity of bis(η^6-benzene)chromium(0) toward sulfur dioxide: formation and structure of $[(\eta^6\text{-}C_6H_6)_2Cr]_2S_4O_{10}$, a salt containing the anion $[S_2O_6\cdot 2SO_2]^{2\ominus}$ (C) 967
Solvent exchange on magnesium([15]crown-5) complexes—a first- and second-order reaction (C) 575
Sorbanilide, Nickel(0)-catalyzed synthesis of sorbanilide from 1,3-pentadiene and phenyl isocyanate (C) 961
Spectral analysis, The first application of 2D-NMR to the spectral analysis of a paramagnetic complex. Example: bis[*R*-(+)-*P*,*P*-diethylthiophosphinic acid-*N*-α-methylbenzylamido]nickel(II) (C) 231
Spiroacetal formation by carbene (carbenoid) insertion reaction: synthesis of the major constituent of the sex attractant of the olive fly *(Dacus oleae)* (C) 230
Spirobifluorene, Chiral poly(9,9′-spirobifluorene) crown ethers (C) 792
Spiroclusters, Synthesis and structure of the spirocluster $[(\eta^5\text{-}C_5H_5)_3Mo_3As(CO)_6\{CHP(C_6H_5)_3\}]$ (C) 702
Stabilization of radicals, Do $Cp(CO)_2Mn$ fragments stabilize radicals? (C) 856
Stannocene analogs, Bis(dihydro-1,2-azaborolyl)tin—a novel boron-nitrogen stannocene (C) 602
Stereochemical activity, "Stereochemical ac-

tivity" of a lone pair of electrons on low valent elements of the 4th main group: $(GeNtBu)_4 \cdot 2AlCl_3$ and $(SnNtBu)_4 \cdot 2AlCl_3$ (C) 223
Stereochemical control, Double asymmetric synthesis and a new strategy for stereochemical control in organic synthesis (R) 1
Stereochemistry, Growth and dissolution of organic crystals with "tailor-made" inhibitors—implications in stereochemistry and materials sciene (R) 466
Reduction of ketones by alkali metals in tertiary alcohols: unexpected cation effect on the stereochemistry (C) 499
Stereoselective nucleophilic additions to a bicyclic ketone controlled by a remote tricarbonyl(diene)iron moiety (C) 787
Stereoselective synthesis, Chelation-controlled stereoselective synthesis of cyanohydrins (C) 989
Stereospecific synthesis of 3-substituted hexahydroindane derivatives (C) 131
Steroids, Selectivity of the anodic oxidation of CH- and CH_2-Groups; selective oxidation of steroids at C-6 (C) 1055
Stibanes, $(C_6H_5Sb)_6 \cdot$(1,4-dioxane), the first cyclohexastibane (C) 72
Strain, Consequences of strain for the structure of aliphatic molecules (R) 529
Structure-effectivity relationships, Organocobalt compounds in the synthesis of pyridines—an example of structure-effectivity relationships in homogeneous catalysis (R) 248
Structure revision, The revised structure and absolute configuration of chaksine (C) 959
Strychnine, The glycine receptor of rat spinal cord: exploring the site of action of the plant alkaloid strychnine (R) 365
Sulfine, Diethyl thioxomalonate *S*-oxide; a sulfine as reactive intermediate (C) 855
α-Sulfonyl carbanions, Lithium-coordinated α-sulfonyl carbanions: synthesis and X-ray structure determination of $[\{CH_2(SO_2C_6H_5)\}Li(tmeda)]_2$ (C) 859
X-ray structure determination of [α-(phenylsulfonyl)benzyllithium-tetramethylethylenediamine]$_2$: chirality of an α-sulfonyl "carbanion" (C) 573
Sulfur melts, Quantitative HPLC analysis and thermodynamics of sulfur melts (C) 59
Sulfur monoxide as 4-electron bridge-ligand in the complex $[(\eta^5\text{-}C_5H_5)(CO)_2Mn]_2SO$ (C) 228
Sulfur-nitrogen rings, The X-ray crystal structures of two 1,2,4,5-tetrathia-3,6-diazacyclohexanes (C) 760
Sulfur-oxygen bonds, Comparison of theoretical and experimental deformation densities in S—O bonds (C) 509
Sulfur-silicon heterocycles, Decamethyl-7-thiahexasilanorbornane $(CH_3)_{10}Si_6S$ (C) 992
Sulfur(VI) cation, $(CH_3)_2NSF_4^{\oplus}ASF_6^{\ominus}$—synthesis and stability of a simple pentacoordinated sulfur(VI) cation (C) 344
Superconduction, β-$(ET)_2AuI_2$: an organic volume superconductor with $T_c = 3.2$ K at ambient pressure (C) 968
Surface antigens, Synthesis of the immunologically essential saccharide sequence of the "enterobacterial common antigen" (C) 773
SYNROC, Radwaste immobilization by structural modification—the crystallochemical properties of SYNROC, a titanate ceramic (R) 357
Synthetic methods, Chiral compounds synthesized by biocatalytic reductions (R) 539
Enzymes as catalysts in synthetic organic chemistry (R) 617
Modern synthetic methods 1983. Vol. 3: Transition metals in organic synthesis (B) 233
Selective reactions using organoaluminum reagents (R) 668
Selenium in natural products synthesis (B) 1007
Syntheses with radicals—C-C bond formation via organotin and organomercury compounds (R) 553

TARTARIC ACID, On the absolute configuration of (+)-tartaric acid (C) 513
Tellurides, Novel reactions of acyl halides with bis(trimethylsilyl) telluride: C,Te and C,C bond formation (C) 1041
Tellurium compounds, Synthesis and structure of new Hg—Te polyanions: $[Hg_4Te_{12}]^{4\ominus}$, a cluster containing $Te^{2\ominus}$, $Te_2^{2\ominus}$, and $Te_3^{2\ominus}$ ligands and $[Hg_2Te_5]^{2\ominus}$, a new one-dimensional inorganic polymer (C) 433
Synthesis and structure of new potassium-gold-tellurium polyanions: $[KAu_6Te_7]^{4\ominus}$, $[K_2Au_4Te_4(en)_4]^{2\ominus}$, and $[K_2Au_4Te_4(dmf)_2(CH_3OH)_2]^{2\ominus}$ (C) 432
$(Te_2)_2(I_2)$—an unusual intercalation compound (C) 393
Tellurium-tungsten compounds, Transformation of $[\{(CO)_5W\}_3Sn]$ into $[\{(CO)_5W\}_3Te_2]$, a compound containing unusually bonded ditellurium (C) 428
Terpenes, Catalytic transformations of sesquiterpene hydrocarbons on alkali metal/aluminum oxide (C) 320
Tetra-*tert*-butylhydroxycyclobutenylium ion, Walk rearrangement in the 1,2,3,4-tetra-*tert*-butylhydroxycyclobutenylium ion (C) 429
Tetracyanocyclopropane derivative, Reaction of homobenzvalene with tetracyanoethylene; formation of a tetracyanodihydrobarbaralane derivative and a tetracyanocyclopropane derivative (C) 611
Tetracyanodihydrobarbaralane derivative, Reaction of homobenzvalene with tetracyanoethylene; formation of a tetracyanodihydrobarbaralane derivative and a tetracyanocyclopropane derivative (C) 611
Tetracyanoethylene, Synthesis of a novel stable carbanion: 1,1,2-tricyano-2-(3,4-dicyano-5-imino-2,5-dihydro-1*H*-pyrrol-2-ylidene)ethanide by reduction of tetracyanoethylene with tris(2,2′-bipyridine)titanium (C) 426
Tetrakis(trimethylsilyl)-1,6-methano[10]annulene, 2,5,7,10-Tetrakis(trimethylsilyl)-1,6-methano[10]annulene, a fluxional valence tautomer with cyclopolyolefin structure (C) 587
Tetraoxathia-2-cycloundecanone, Reaction of ethylene oxide with sulfur dioxide in the presence of cesium ions: synthesis of 1,3,6,9,2λ^4-tetraoxathia-2-cycloundecanone (C) 695
Tetraphosphanetin(II) complex, Synthesis, dynamic behavior, and structure of $[Sn\{C(PMe_2)_3\}_2]$—a homoleptic tetraphosphanetin(II) complex with pseudo trigonal bipyramidal structure (C) 402
Tetraquinanes, Crinipellins, the first natural products with a tetraquinane skeleton (C) 709
Tetrathia-3,6-diazacyclohexanes, The X-ray crystal structures of two 1,2,4,5-tetrathia-3,6-diazacyclohexanes (C) 760
Thallium complexes, Synthesis and structure of a thallium complex with an anionic sandwich complex ligand (C) 71
Arene complexes of univalent gallium, indium, and thallium (R) 893
$[\{1,3,5\text{-}(CH_3)_3H_3C_6H_4\}][GaBr_4]_4$—synthesis and structure of a mixed mono- and bis(arene)thallium complex (C) 414
Thiahexasilanorbornane, Decamethyl-7-thiahexasilanorbornane $(CH_3)_{10}Si_6S$ (C) 992
Thiazaphospholes, 1,3,4-Thiazaphospholes (C) 123
Thiepinium ion, The homothiopyrylium ion; generation and characterization (C) 214
Thiolate complexes, A new class of tantalum(V) dithiolate complexes: synthesis and characterization of $[Ta(\eta^5\text{-}C_5Me_4R)(SCH{=}CHS)_2]$ (R = Me, Et) and $[Ta(\eta^5\text{-}C_5Me_5)(SCH_2CH_2S)_2]$ (C) 332
Thionitrosyl complexes, Cationic thionitrosyl and nitrosyl complexes (C) 202
Thiophene derivatives by novel rearrangements of siloxy-substituted cyclopropanecarboxylates (C) 588
Photoreaction of thiones with bromoketene acetals (C) 976
Three-phase synthesis of oligonucleotides (C) 685
Through-bond interaction, Light-induced [2+2] cycloaddition reactions of nonconjugated dienes—the effect of through-bond interaction (C) 566
Tin compounds, Synthesis, dynamic behavior, and structure of $[Sn\{C(PMe_2)_3\}_2]$—a homoleptic tetraphosphanetin(II) complex with pseudo trigonal bipyramidal structure (C) 402
Titanate ceramic, Radwaste immobilization by structural modification—the crystallochemical properties of SYNROC, a titanate ceramic (R) 357
Titanium cathodes, Heterogeneous redox catalysis on Ti/TiO_2 cathodes—reduction of nitrobenzene (C) 771
Titanium disulfide, c-TiS_2, a new modification of titanium disulfide with cubic structure (C) 67
Titanocene derivatives, $[Cp_2Ti(PMe_3)_2]$—a versatile source of titanocene derivatives (C) 394
Toadstool, The chemistry and antibiotic activity of the toadstool *Agaricus xanthoderma* (agaricales) (C) 1063
Torsional isomerism in metallocenes: hindered Cp-rotation in (*s-cis*-η-butadiene)-bis(η-*tert*-butylcyclopentadienyl)zirconium (C) 321
Toxicology, Die Bleibelastung des Menschen (B) 614
Trace analysis, Great fear of small amounts of elements—the significance of analytical chemistry in our modern industrialized community as exemplified by trace element analysis (R) 485
Transition metal polysulfides: coordination compounds with purely inorganic chelate ligands (R) 742
Transmembrane-neuraminidase, Construction of disaccharide *N*-glycopeptides—synthesis of the linkage region of the transmembrane-neuraminidase of an influenza virus (C) 883
Triaza-tris-σ-homobenzene, *cis*-Triaza-tris-σ-homobenzene as tridentate ligand $[La(C_6H_9N_3)_4 \cdot CH_3CN \cdot (ClO_4)_3]$: LaN_{12} complex with icosahedral coordination (C) 318
Triaziridines, Stable triaziridines (C) 341
Tricarbonyl(sorbaldehyde)iron, Reactions of tricarbonyl(sorbaldehyde)iron with carbanions: a repeatable organometallic reaction with $Fe(CO)_3$-migration (C) 126
Tricarbonyltroponeiron complexes, Activation energy of the racemization of optically active tricarbonyl(tropone)iron complexes (C) 329
Trichlorodimagnesium·6thf(1+) anthracenide, Synthesis and structure of 1,4-dimethylanthracenemagnesium·3thf and μ-trichlorodimagnesium·6thf(1+) anthracenide (C) 960
Trichloromethyl hydroperoxide, Photooxidation of chloroform: isolation and characterization of trichloromethyl hydroperoxide (C) 50
Tricobalt ligands, Novel high-nuclearity HgCoRu and HgCoFe sandwich complexes. Synthesis and structure of $[Hg\{RuCo_3(\mu\text{-}CO)_3(CO)_9\}_2]$ (C) 767

Tricyclo[6.4.0.0^{2,6}]dodecaarsane, $As_{12}tBu_8$—a tricyclo[6.4.0.0^{2,6}]dodecaarsane (C) 991
Tricyclooctanone concept, Extensions of the tricyclooctanone concept. A general principle for the synthesis of linearly and angularly annelated triquinanes (C) 973
Tricyclo[3.3.0.0^{2,8}]octan-3-ones, Photochemistry of 1-methoxybicyclo[2.2.2]octenones; photolytic cyclopropane cleavage of the initially formed tricyclo[3.3.0.0^{2,8}]-octan-3-ones (C) 763
Trimerization, Novel trimerization of cyclopentadiene with a homogeneous, bifunctional palladium-acid catalyst system (C) 314
Trioxo half-sandwich complex, Reductive trimerization of the trioxo half-sandwich complex [(η^5-C_5Me_5)ReO_3] with deoxygenation: the electron-deficient cluster ion [(η^5-C_5Me_5)$_3Re_3(\mu$-O)$_6]^{2+}$ (C) 50
Triphenylamine double-decker, A triphenylamine double-decker (C) 596
Triphosphenium ions, Symmetrical and unsymmetrical triphosphenium ions (C) 226
Triplatinum ligands, A new type of sandwich complex formed by Ag^I and [$Pt_3(\mu_2$-CO)$_3$($PiPr_3$)$_3$] (C) 766
Triple bond, Phenyl silaisocyanide: the first organosilicon compound with a formal Si≡N triple bond (C) 111
Phosphorus, arsenic, antimony, and bismuth multiply bonded systems with low coordination number—their role as complex ligands (R) 924
Triplet diradicals, Sensitized UV/laser photolysis of azoalkanes: conformational influences on intersystem-crossing and lifetimes of triplet radicals (C) 1071
Triquinanes, Extensions of the tricyclooctanone concept. A general principle for the synthesis of linearly and angularly annelated triquinanes (C) 973
New donor-substituted vinyl- and alkynylcyclopropanes as synthetic building blocks (C) 770
Trisaccharides, Preparation of an *N*-acetylneuraminic acid-containing trisaccharide and its use in oligosaccharide syntheses (C) 128
Synthesis of the immunologically essential saccharide sequence of the "enterobacterial common antigen" (C) 773
Tris(cyclopentadienyl)lanthanide complexes, Cleavage of tris(cyclopentadienyl)-lanthanide complexes with alkyllithium compounds—a new route to alkylbis(cyclopentadienyl)lanthanides (C) 225
Tris(methylene)phosphate ion, The first tris(methylene)phosphate ion [P(=C<)$_3$]$^-$ (C) 589
Trispiro[2.1.2.1.2.1]dodecane-4,8,12-trione (C) 607
tRNA, The 3'-end of tRNA and its role in protein biosynthesis (R) 371
Troponeiron complexes, Activation energy of the racemization of optically active tricarbonyl(tropone)iron complexes (C) 329
Tungsten compounds, Synthesis of [Et_2N—C≡W(CO)$_2$(μ-PPh_2)$_2$Mo(CO)$_4]^{\ominus}$, the first anionic carbynemetal complex; addition of CO_2 to the W≡C bond (C) 203

ULICYCLAMIDE, Total synthesis of ulicyclamide (C) 569
Uranium compounds, Polymeric tris[trimethyltin(IV)]hexacyanocobaltate(III), a compound non-analogous to "super prussian blue", and its tris[tricyclopentadienyluranium(IV)] homologue (C) 879

VALENCE TAUTOMER, 2,5,7,10-Tetrakis(trimethylsilyl)-16-methano[10]annulene, a fluxional valence tautomer with cyclopolyolefin structure (C) 587
Vesicle membranes, Sealing and opening porous monolayer vesicle membranes (C) 339
Vinyl azides, Synthesis and reactions of 4-azido-3-methyl-1,2-butadiene (C) 216
Vinylcyclopropanes, New donor-substituted vinyl- and alkynylcyclopropanes as synthetic building blocks (C) 770
1,4-Addition of dihalocarbenes to 1,3-dienes (C) 585
1,4-Additions of dihalocarbenes (C) 579
Vinylidenemetal complexes, Synthesis and structure of *trans*-[MCl(=C=CHR)($PiPr_3$)$_2$] (M=Rh, Ir): the first square-planar vinylidenemetal complexes (C) 406
Vitamin B_{12}, Hydrogenobyrinic acid and vitamin B_{12} (C) 46
Photooxygenolysis of vitamin B_{12} (C) 62
Volume superconductor, β-$(ET)_2AuI_2$: an organic volume superconductor with T_c=3.2 K at ambient pressure (C) 968

WALK REARRANGEMENT in the 1,2,3,4-tetra-*tert*-butylhydroxycyclobutenylium ion (C) 429
Wood chemistry, ultrastructure, reactions (B) 527

X-RAY CRYSTALLOGRAPHY, High-resolution X-ray crystallography—an experimental method for the description of chemical bonds (R) 237

YLIDE-NICKEL catalysts, Highly active ylide-nickel catalysts for the polymerization of ethylene (C) 599
Ylides, Acylsilanes via oxidation of phosphonium ylides: the first synthesis of bis(trimethylsilyl)ketone and its use as an equivalent of the dianion $CO^{2\ominus}$ (C) 1068
4-[Tri(*n*-butyl)]phosphinio-2,5-diselenoxo-1,3-diselenacyclopentanide (C) 1058

ZIEGLER CATALYSTS, Formation of organoaluminum compounds in the mixture $AlCl_3$—$TiCl_4$—Al—C_2H_4 (C) 311
Zirconocene, Polymerization of propene and butene with a chiral zirconocene and methylalumoxane as cocatalyst (C) 507
Zirconocene derivatives, Monomeric, mononuclear enediolate complexes of zirconium: molecular geometry and electronic structure of the products of reductive CO coupling on the metal (C) 712
Torsional isomerism in metallocenes: hindered Cp-rotation in (*s-cis*-η-butadiene)-bis(η-*tert*-butylcyclopentadienyl)zirconium (C) 321
Zwitter ions, First 1,4-dipolar cycloadditions of 6-oxo-3,6-dihydro-1-pyrimidinium 4-olates to ketenes and other carbonyl compounds (C) 608
Synthesis and structure of a diaza-λ^2-phosphanylia-λ^5-stannatacyclobutane (C) 999
