NMR Microscopy— Fundamentals, Limits and Possible Applications

New Analytical Methods (39)

By Winfried Kuhn

Dedicated to Professor Karl Hermann Hausser on the occasion of his 70th birthday

Alongside the numerous applications of NMR spectroscopy to structural elucidation in analytical chemistry, and to biochemical and morphological studies by NMR tomography, NMR microscopy makes possible a whole new range of applications. These include imaging, the investigation of biological objects such as plants and small animals, and also the observation of microscopic structures and structural changes in polymers and ceramics. NMR spectroscopy can also be conducted combinationally as volume-selective spectroscopy, whereby it is possible to spatially resolve the NMR-specific parameters: spin density ϱ, chemical shifts δ, and the relaxation times T_1 and T_2. The numerous well developed methods available make it possible to study dynamic processes by fast imaging with a temporal resolution in milliseconds. This not only allows the imaging of moving objects without incurring movement artefacts but also the measurement of diffusion constants in isotropic and anisotropic diffusion—in the latter case allowing, in principle, the determination of the complete diffusion tensor. The spatially resolved measurement of the relaxation times yields information on molecular mobility and bonding, e.g. the bonding of water, or other solvents, to polymers, the mobility of fluids in polymers or ceramics, or the three-dimensional evaluation of pore size in porous materials. In biomedicine, NMR microscopy allows the observation of growth on the cellular level, the study of embryos, and the development of therapeutic methods in animal experiments. It can lead to a drastic reduction in the number of animal experiments, and in combination with volume-selective spectroscopy gives valuable information on in-vivo metabolism.

1. Introduction

The physical phenomenon of NMR was discovered in 1946 by *Felix Bloch* and *Eduard Purcell*.[1, 2] Since then it has developed into one of the most fascinating methods available to physicists, chemists, biologists and medical practitioners.

Up to the 1970s NMR was used almost exclusively for structural analysis in chemistry, and for the measurement of such parameters as magnetic shielding tensors, electrical field gradient tensors and coupling tensors in molecular physics. Since the end of the 1970s, however, NMR has become important in the investigation of biochemical processes in vivo and in vitro, as an imaging method (NMR tomography), in the observation of morphological changes in tissues, and as a diagnostic aid in clinical practice. The combination of imaging and spectroscopic techniques allows volume-selective spectroscopy.

In clinical diagnosis either resistive or superconducting magnets with horizontal bores of between 60 and 100 cm are used, whereby the magnetic field strengths lie between 0.23 T and 2.4 T. These strengths correspond to proton resonance frequencies of 9.6 to 100 MHz. Magnetic field gradients with a strength of about 10 $mT m^{-1}$ (1 $G cm^{-1}$) allow a maximum spatial resolution of 5 mm^3 for whole-body systems.

As an example of the clinical application of NMR tomography, Figure 1 shows a sagittal section through the human head. The magnetic field strength was 0.28 T, corresponding

Fig. 1. Sagittal section through a human head. Slice thickness 5 mm, pixel resolution 1 mm^2, field strength 0.28 T, spin-echo image as sum of eight echoes of a multiecho recording.

to a proton resonance frequency of 11.6 MHz. The in-plane spatial resolution, termed pixel resolution (as the smallest element of an image is called a 'pixel'), is about 1 mm^2.

When discussing spatial resolution it is important to differentiate between the in-plane resolution and the resolution perpendicular to the slice thickness. The pixel resolution is normally far higher than that through the slice. Only occasionally in NMR tomography is an isotropic resolution obtained. The reasons for this difference in resolution lie firstly in the nature of the experiment, and secondly in the attainable signal-to-noise ratio (SNR). In a two-dimensional NMR imaging experiment a slice is normally selected by applying a selective RF pulse in the presence of a constant magnetic field gradient. The RF pulse has a bandwidth dependent upon its shape and duration .The slice thickness is then determined by the bandwidth of the pulse and the strength of the gradient. Hence an isotropic spatial resolution requires a pulse with a very narrow bandwidth, or extremely strong field gradients. Both of these are difficult to realize (see Section 3.2).

In three-dimensional experiments these restrictions do not exist, as no selective pulse is required for slice selection, instead spatial information in two directions is obtained by orthogonal field gradients of varying strength that act to phase-encode the signal. An isotropic resolution is thus more easily attainable in a three-dimensional experiment. The SNR achievable for the smallest detectable volume element (the *voxel*), and the size of the object under investigation, determine the maximum attainable resolution.

In biomedical research, in which the range of applications of NMR spectroscopy embraces the in-vivo observation of metabolic processes and morphological changes in tissues in animal experiments, magnets with horizontal bore sizes between 15 and 40 cm, and magnetic field strengths between 7.05 (^1H: 300 MHz) and 4.7 T (200 MHz) are used. The best spatial resolution obtainable with these instruments, using field gradients up to 100 $mT m^{-1}$, is about 1 mm^3.

A completely new dimension is opened up by the most recent NMR application, NMR microscopy, both in the spatial resolution attainable and the access to information at a molecular level. The first example of the realization of an NMR microscope was published in *Nature* in 1986.[3] The authors studied ova from *Xenopus laevis* (African clawed toad), and obtained for the first time images with a truly microscopic resolution of $13 \times 13 \times 250$ μm^3. NMR microscopy was made possible by magnets of high field strength, and strong magnetic field gradients. The highest magnetic field strength available for NMR is currently 14.1 T (600 MHz proton resonance frequency). Typically, the magnetic field strengths used for NMR microscopy lie between 7.05 (300 MHz) and 14.1 T. Table 1 shows a comparison of typical parameters and fields of application of currently available systems.

Commercial NMR microscopes are offered as supplementary add-ons to high-resolution and solid-state NMR spectrometers. They consist of a probe head with an integrated gradient system, a control unit for the gradient system for producing gradient pulses, and a modulation unit for RF

Winfried Kuhn, born February 5, 1949, studied engineering physics at the Technical College in Aachen (1971–1976) and subsequently physics (1976–1980) at the Institute of Technology in Aachen and at the University of Heidelberg. Following his Diplomarbeit at the Max Planck Institute for Medical Research in Heidelberg under Prof. Dr. K. H. Hausser, he completed his doctorate (1980–1983) at the same institute under Prof. U. Haeberlen. From 1982 until 1986 he was scientific co-worker and leader of the Instrumental Analytical Section (Chemistry/Biology) at the University of Bremen. 1986–1989 he worked for Fa. Bruker in Rheinstetten developing the NMR microscope. Since April 1, 1989 he has been in charge of the Magnetic Resonance Research Group at the Fraunhofer Institute for Nondestructable Analytical Methods in St. Ingbert.

Table 1. Comparison of NMR imaging systems.

	^{1}H-resonance frequency [MHz]	Magnetic field strength [T]	Object size [cm]	Spatial resolution [mm^3]	Application: Imaging on
NMR tomography (clinical diagnostics)	9.6–100	0.23–2.4	< 100	ca. 5	head and extremities
Tomography and in vivo spectroscopy (biomedical research)	41–200	1.00–4.7	< 30	ca. 2	animals such as rabbits, rats or mice
Mini-imaging	300–400	7.05–9.4	< 12	ca. 5×10^{-3}	rats, mice
NMR-microscopy	200–600	4.70–14.1	< 2.5	ca. 10^{-5}	mice, insects, polymers

pulses allowing modulation of both the amplitude and the phase of the pulse. With these gradient systems gradient strengths of about 1 Tm^{-1} are achievable. The highest resolution reached so far in the author's laboratory, and probably also worldwide, is $10 \times 10 \times 100$ μm^3.[4] This corresponds to a voxel volume of 10^{-5} mm^3 (Fig. 2).

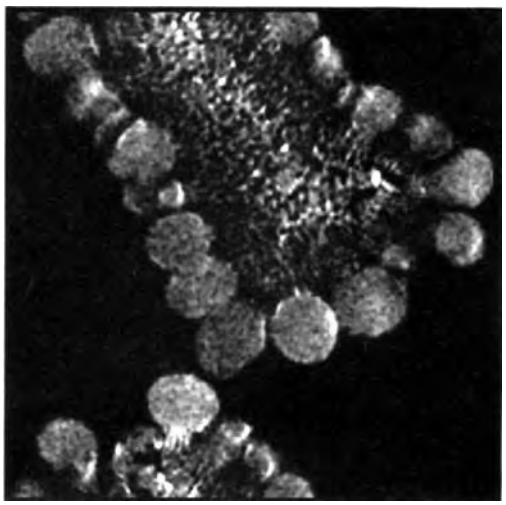

Fig. 2. Section through a leaf of the plant *Mesembryanthemum cristallinum*. The leaf of this plant is covered with oxalate crystals. Within the section the veins and some plant cells are visible. A spin-echo image is shown, recorded at a field strength of 7.05 T with a slice-thickness of 100 μm and a pixel resolution of 10^2 μm^2.

Various synonyms are used for NMR imaging. In medicine the term normally employed is "magnetic resonance imaging" (MRI), but "NMR imaging" and "spatially resolved nuclear magnetic resonance" are also used. For resolutions up to $100 \times 100 \times 1000$ μm^3 the term "mini-imaging" is common, and for superior resolutions the terms "micro-imaging" or "NMR-microscopy" are used.

2. Basic Principles of NMR Imaging

In a conventional NMR experiment, the object is placed in a static homogeneous magnetic field $\boldsymbol{B}$, which is related to the field strength $\boldsymbol{H}$ by the permeability constant μ_0 and the relative permeability μ_r [Equation (1)].

$$\boldsymbol{B} = \mu_0 \mu_r \boldsymbol{H} \tag{1}$$

In a sample with identical nuclei in an identical environment, e.g. the protons in water, all the spins experience the same magnetic field $\boldsymbol{B}$, and thus, from the resonance condition (2), have the same resonance frequency ω.

$$\omega = \gamma \boldsymbol{B} \tag{2}$$

The constant of proportionality γ is the nuclear gyromagnetic ratio, and has a value dependent upon the type of nuclei.

Nuclei in differing magnetic environments experience different magnetic fields, this being generally true of nuclei experiencing different chemical bonds. In NMR this manifests itself as discrete signals corresponding to the various chemical shifts.

This means that the resultant signal may be assigned to a given nucleus within the molecule, i.e. is localized within the molecule, but no spatial localization of the spins/molecules is possible as each nuclear species experiences a field independent of its position $\boldsymbol{r} = (x, y, z)$.

No possibility exists in such a homogeneous static magnetic field $\boldsymbol{B}_0$ of obtaining a spatial localization of the nuclei by means of their resonance frequency. The way to achieve spatially resolved NMR spectroscopy was discovered independently by *Damadian*[5] and *Lauterbur*[6] at the beginning of the 1970s. Spatially resolved magnetic resonance is made possible by superimposing a time dependent linear gradient field $\boldsymbol{G}(\boldsymbol{r}, t)$ onto the static magnetic field $\boldsymbol{B}_0$ [Eq. (3)].

$$\boldsymbol{B}(\boldsymbol{r}, t) = \boldsymbol{B}_0 + \boldsymbol{G}(\boldsymbol{r}, t) \tag{3}$$

The gradient field $\boldsymbol{G}(\boldsymbol{r}, t)$ has a linear dependence on the position, and as the nuclear resonance frequency is proportional to the magnetic field, there is then a linear relationship between the resonance frequency ω and the spatial position $\boldsymbol{r}$ [Eq. (4)].

$$\omega(\boldsymbol{r}, t) = \gamma \boldsymbol{B}(\boldsymbol{r}, t) \tag{4}$$

It should be emphasized that the gradient field has a *linear* dependence upon position, this means that the magnetic field gradients are *constant*.

The contribution made by each component of the gradient field to $\boldsymbol{B}_0 + \boldsymbol{G}(\boldsymbol{r}, t)$ is determined by the spatial derivative of the gradient field. The field gradient may be represented by a tensor having nine components [Eq. (5)].

$$\operatorname{grad} \boldsymbol{G}(\boldsymbol{r}, t) = \begin{pmatrix} \frac{\partial B_x}{\partial x} & \frac{\partial B_x}{\partial y} & \frac{\partial B_x}{\partial z} \\ \frac{\partial B_y}{\partial x} & \frac{\partial B_y}{\partial y} & \frac{\partial B_y}{\partial z} \\ \frac{\partial B_z}{\partial x} & \frac{\partial B_z}{\partial y} & \frac{\partial B_z}{\partial z} \end{pmatrix} \tag{5}$$

Usually $\boldsymbol{B}_0$ is of the order of 8 T, while the gradients are about 0.001 T. Hence the components perpendicular to the static magnetic field may be neglected, and only the components parallel to $\boldsymbol{B}_0$ lead to a spatial dependence of the resonance frequency (Fig. 3).

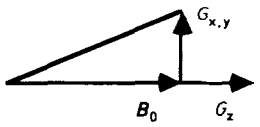

Fig. 3. Contribution of the gradient fields G_z and $G_{x,y}$ to $\boldsymbol{B}_0$. Only the components parallel to $\boldsymbol{B}_0$ make a contribution to the effective magnetic field $\boldsymbol{B}(r,t)$.

In practice the only tensor components having any influence on the resonance frequency in the sample are g_x, g_y and g_z [Eq. (6)–(8)].

$$g_x = \left(\frac{\partial B_z}{\partial x}\right) \tag{6}$$

$$g_y = \left(\frac{\partial B_z}{\partial y}\right) \tag{7}$$

$$g_z = \left(\frac{\partial B_z}{\partial z}\right) \tag{8}$$

These components may be represented as the components of a field gradient vector $\boldsymbol{g}$.

The superposition of the magnetic fields, and their effect on the nuclear resonance is shown in Figure 4. For $-x_0$,

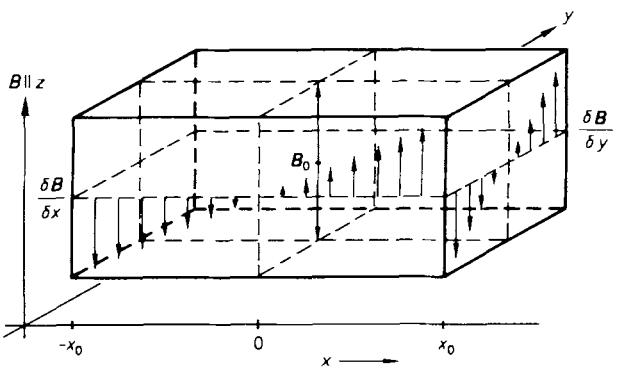

Fig. 4. Representation of the three-dimensional distribution of the gradient field $\boldsymbol{G}(\boldsymbol{r})$. The gradient fields change linearly over the sample volume. For $-x_0, -y_0, -z_0 < x,y,z < 0$, $\boldsymbol{B}(\boldsymbol{r}) < \boldsymbol{B}_0$, for $0 < x,y,z < x_0, y_0, z_0$, $\boldsymbol{B}(\boldsymbol{r}) > \boldsymbol{B}_0$ where $\boldsymbol{B}(\boldsymbol{r})$ is the resultant magnetic field.

$-y_0, -z_0 < x,y,z < 0$ the static magnetic field $\boldsymbol{B}_0$ is weakened by the influence of the gradient field $\boldsymbol{G}(x, y, z)$, and for $0 < x,y,z < x_0, y_0, z_0$ it is strengthened [Eqs. (9) and (10)].

$$\boldsymbol{B}(x,y,z) = \boldsymbol{B}_0 + \boldsymbol{G}(x,y,z) \tag{9}$$

$$\boldsymbol{B}(x,y,z) = \boldsymbol{B}_0 + \boldsymbol{gr} \tag{10}$$

From the resonance condition, the resonance frequency in the left half of the cubic volume is lower, in the right half higher, than ω_0 [Eq. (11)]. The spread of frequencies and

$$\omega(\boldsymbol{r}) = \omega_0 + \gamma \boldsymbol{gr} \tag{11}$$

hence the attainable spatial resolution is then directly proportional to the gradient strength $|\boldsymbol{g}|$ and the dimensions of the object $\Delta\boldsymbol{r} = (\Delta x, \Delta y, \Delta z)$ [Eq. (12)]. The gradient strengths

$$\Delta\omega = \gamma \boldsymbol{g} \Delta\boldsymbol{r} \tag{12}$$

determine the maximum spatial resolution attainable in an NMR imaging experiment.

3. Experimental Methods of NMR Microscopy

The excitation of nuclei within a sample is a result of irradiation with coherent electromagnetic waves. In general the RF pulse has an inexactly defined frequency spectrum from a few to several hundred kHz about the resonance frequency ω_0 of the nuclei in the static magnetic field $\boldsymbol{B}_0 = (0, 0, B_0)$, this being dependent upon the duration of the pulse. In the following discussion the simplification will be made that the static magnetic field lies parallel to the z axis of the coordinate system, and that only the z component B_0 of the field must be taken into consideration. Since nuclei subjected to a coherent irradiating RF field emit coherent RF waves, which may be detected by means of an appropriate coil, it is possible to apply a large number of different pulse experiments to the object, each yielding different characteristic information.

In the NMR spectroscopy of fluids such pulse experiments are used for the separation of coupling constants and chemical shifts, and in solid state NMR for line narrowing or for the decoupling/elimination of physical interactions, e.g. the dipolar coupling of protons or of protons and ^{13}C nuclei.

In NMR imaging a large number of different pulse sequences exist that, for example, allow very rapid imaging or images with a contrast weighted by the spin-spin or spin-lattice relaxation times. Of the numerous methods of NMR imaging available only three have proven to be of significant value.

3.1. Projection Reconstruction Techniques

These methods were used by *Lauterbur* in the early days of NMR imaging, and are now only used in special situations such as polymer imaging, or the spatially resolved measurement of spin-lattice and spin-spin relaxation times (relaxometry).[7] The reasons for this are the long measuring times and the relatively complicated data handling. These methods do however have the advantage of a very short time delay between the excitation of the nuclei and signal detection, thus allowing imaging of samples having very short spin-spin relaxation times. This also permits the detection of a large number of spin echoes in the case of relatively long spin-spin relaxation times. This is useful in relaxometry as it makes a multi-exponential fit to the relaxation curve possible, and thus enables tissue characterization.

3.2. Spin Echo Methods Based on a *Hahn*'s Spin Echo Pulse CP Sequence

The production of spin echoes by the method of *E. Hahn*,[8] uses a 90-τ-180-τ-echo sequence (Fig. 5). During the first period τ, the transverse component M_{xy} of the magnetization to a coherent state, and thus to a detectable echo. The path of the magnetization during such an experiment is shown in Figure 6.

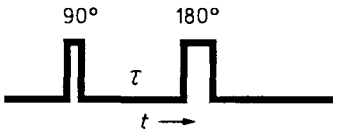

Fig. 5. Hahn spin-echo pulse-sequence. The excitation of the spin-system is achieved by a broad-band 90° pulse. The magnetization is refocussed by a 180° RF pulse. In this figure non-selective pulses are shown. This means that the pulses have a large (approx. 100 kHz) bandwidth, but this is not sharply-defined.

netization $\boldsymbol{M}$ loses phase coherence, i.e. is dephased under the influence of local inhomogeneities in the static magnetic field, and of the physical interactions with the nuclei. The 180° high-frequency pulse leads to a refocussing of the mag-

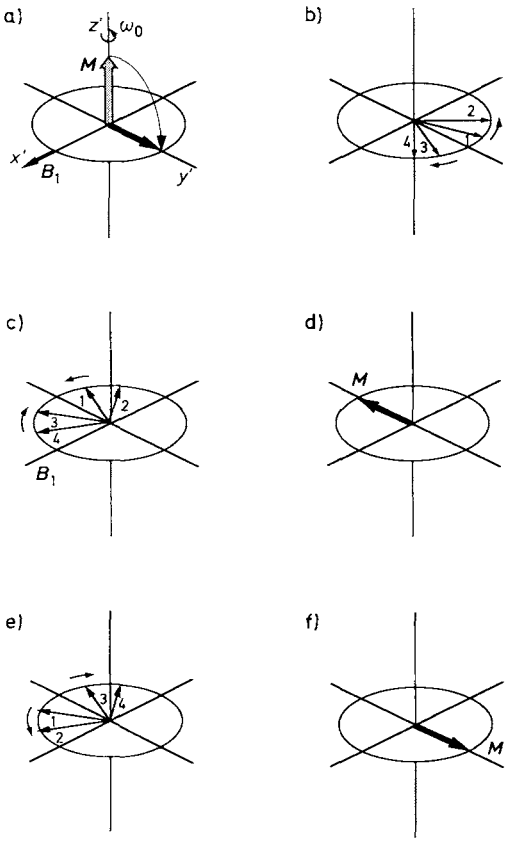

Fig. 6. Path of the magnetization during a spin-echo experiment. a) In the coordinate system rotating at the resonance frequency ω_0, the magnetization $\boldsymbol{M}$ lies parallel to the static magnetic field $\boldsymbol{B}(r) = (0,0,\boldsymbol{B}_0)$, i.e. along z'. The 90° pulse rotates the magnetization at resonance along the y'-axis, by means of an RF field $\boldsymbol{B}_1$ parallel to the x'-axis. b) The magnetization begins to dephase under the influence of local field inhomogeneities and gradients. c) The 180° pulse rotates the components of magnetization about the x'-axis, but the individual components continue to rotate in the same sense as previously. d) This leads to a coherent state after a time 2τ. This is known as a spin-echo, and is detectable. e) The magnetization starts once more to dephase, the steps (b)–(f) may be multiply repeated until the transverse magnetization M_{xy} disappears due to spin-lattice relaxation.

Spatial resolution of the nuclei is only possible by the combination of a spin-echo sequence with the appropriate magnetic field gradients. All of the following discussion of spin-echo sequences is based on the sequence shown in Figure 7.

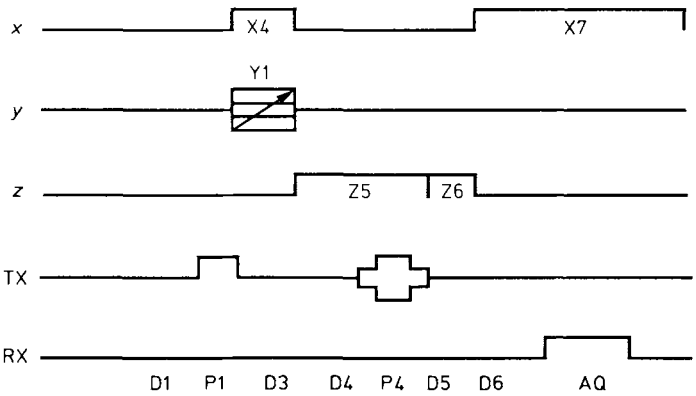

Fig. 7. The spin-echo sequence with x, y and z-gradients is shown; this is based upon the Hahn pulse sequence shown in Figure 5. Following a broad-band 90° pulse the magnetization dephases under the influence of local field inhomogeneities and the magnetic field gradients X4 and Y1 that have an exactly defined amplitude and duration. The amplitude of Y1 changes in the course of a two-dimensional imaging experiment by the increment IY1 [Eq. (13)]. X4 dephases the magnetization in the x'-y' plane of the rotating coordinate system. After the slice-selective 180° pulse P4 in the presence of gradient Z5, the magnetization is refocussed to a spin-echo by the read-gradient X7. The amplitude of the gradient Z5 and the bandwidth of the selective RF pulse determine the thickness of the selected slice. The amplitude of gradient X7 determines the in-plane resolution. TX = transmitter channel; RX = receiver channel.

In order to facilitate the description of the pulse sequence we shall consider a coordinate system rotating at the resonance frequency ω_0. After the 90° excitation pulse P1, the magnetization $\boldsymbol{M}$ at resonance is parallel to the y' axis of the rotating coordinate system, and hence only the component M_y exists. This pulse has a sufficiently large bandwidth to excite all nuclei of one species, and one isotope thereof. Under the influence of the dephasing gradient X4, and of local field inhomogeneities the transverse component of the magnetization dephases in the x'-y' plane. The incrementable phase-encoding gradient Y1 occurs simultaneously with the gradient X4. This gradient imposes on the NMR signal a phase φ characteristic of its strength I. This phase is stepped in increments $\Delta\varphi$ during the course of the experiment, as the strength I of Y1 increases or decreases by a definite increment IY1. The strength I of a gradient $g_\alpha(\alpha = x, y, z)$ is given by the time integral of the gradient [Eq. (12′)].

$$I = \int_0^{t'} g_\alpha \, dt \qquad (12')$$

For a two-dimensional image consisting, for example, of a 256 × 256 element matrix, one requires for the second image dimension 256 single experiments where the phase φ of the NMR signal at position y changes between each experiment in accord with Equation (13).

$$\Delta\varphi = \gamma \int IY1\, y\, dt \qquad (13)$$

Figure 8a shows phase-encoded spin-echoes, where the phase encoding is accomplished by gradients of varying strengths. The phase-corrected Fourier transformation of

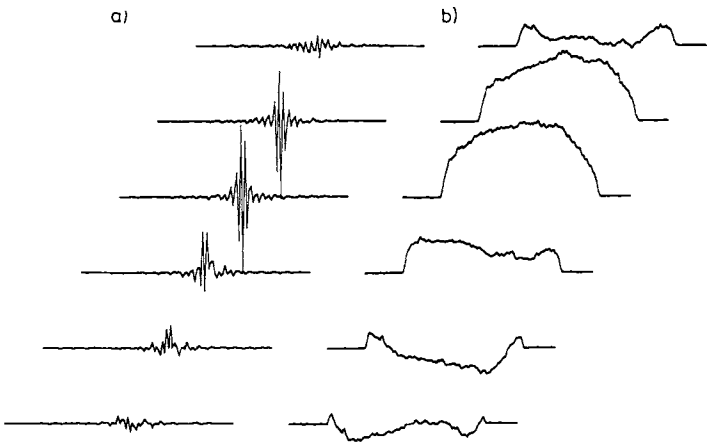

Fig. 8. a) Phase-encoded spin echoes from a two-dimensional spin echo experiment. b) Fourier transform of the spin echoes. One-dimensional phase-encoded profiles of the object in the direction of the read-gradient X7 are shown. The width of the profile is defined by the amplitude of the gradient X7.

these spin echoes is shown in Figure 8b. The spatial information in the first dimension is encoded by the application of the read-gradient X7 in the x direction. This gradient rephases the magnetization dephased by X4, and thus leads to a spin echo. The condition for complete rephasing of the signal is that the equality (14) be fulfilled, where the trans-

$$\int_0^{D3} X4\, dt = \int_0^{D6+AQ/2} X7\, dt \qquad (14)$$

verse magnetization dephased during the period D3 by the gradient X4 (see Fig. 7) is then rephased by the read gradient X7 during the period D6, which is required to stabilize the read gradient, and the acquisition time AQ. If the condition (14) is fulfilled, then a spin echo occurs with a maximum at the time AQ/2. As the echo maximum appears at the midpoint of the acquisition time, a symmetrical echo is detected, which is a condition for the ensuing Fourier transformation of the data.

In a two-dimensional imaging experiment, slice selection is achieved by a high-frequency (RF) pulse (P4) (Fig. 7) having an excitation angle of 180° and a defined bandwidth $\Delta\omega$ in the presence of a gradient Z5 perpendicular to the selected slice. RF pulses with a defined bandwidth are obtained by appropriate amplitude and phase modulation of electromagnetic waves having the carrier frequency ν_0. The Fourier theorem indicates that the duration of the pulse determines the excitation bandwidth space in the frequency range, and the carrier frequency of the pulse determines the position of the selected slice. In our example the gradient is parallel to the z axis of the coordinate system and the selected slice is perpendicular to this.

For slice selection, RF pulses with a $\sin(x)/x$ modulation or a Hermite modulation[9] are commonly used, whereby a $\sin(x)/x$ pulse of 4 ms duration gives, after Fourier transformation, an approximately square pulse with a bandwidth of 1170 Hz. For a z gradient of strength 100 $mT\,m^{-1}$ this corresponds according to Equation (15) to a slice thickness of 270 μm (Δz = slice thickness, $\Delta\omega$ = RF pulse bandwidth,

$$\Delta z = \frac{\Delta\omega}{(\gamma g)} \qquad (15)$$

γ = gyromagnetic ratio of nucleus ($\gamma_{^1H} = 42.58\ MHz\,T^{-1}$), g = strength of slice-selection gradient).

Figure 9 shows two examples of slice-selective RF pulses used in practice. These pulses are characterized by their favorable geometry for slice selection: The $\sin(x)/x$ pulse (Fig. 9a) has very steep sides and a flat plateau, corresponding to a sharply defined rectangular profile resulting from homogeneous excitation of all spins within the slice. However, at the pulse powers as are required for a 180° pulse there exists sideband modulation, which results in a partial excitation of nuclei in the vicinity of the slice. The Hermite pulse (Fig. 9c) has somewhat shallower sides, but better sideband characteristics. Figures 9b and 9d show the Fourier transformations of the RF pulses shown in Figures 9a and 9c, respectively.

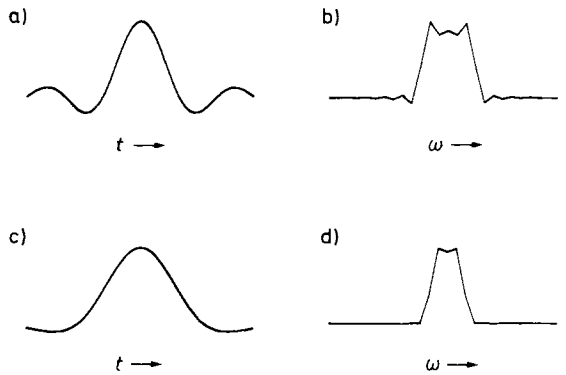

Fig. 9. RF modulation functions for slice-selective pulses. a) $\sin(x)/x$ modulation. b) Fourier transformed and phase-encoded spectrum of (a). c) Hermite function. d) Fourier transformed and phase-encoded spectrum of (b).

In principle it is possible to choose any desired slice within the object by an appropriate combination of gradients and of the carrier frequency of the slice-selective RF pulse; a mechanical alteration of the position of the object within the magnet is in general not necessary. Figure 10 illustrates effective slice selection by changing the resonance frequency in the presence of a slice-selective gradient.

The spin-echo methods include all pulse sequences having 180° refocussing pulses, and are very insensitive to inhomogeneities in the static magnetic field, thus giving images with a good signal-to-noise ratio and excellently reproducing the object profile. As a 90°–180° pulse sequence is used, the magnetization must be almost completely relaxed prior to each fresh repetition. In practice this implies a delay of at least T_1 between concluding data acquisition and the next excitation, and preferably of 3–5 T_1. These delays are in many cases of the order of seconds and lead to relatively long imaging times.

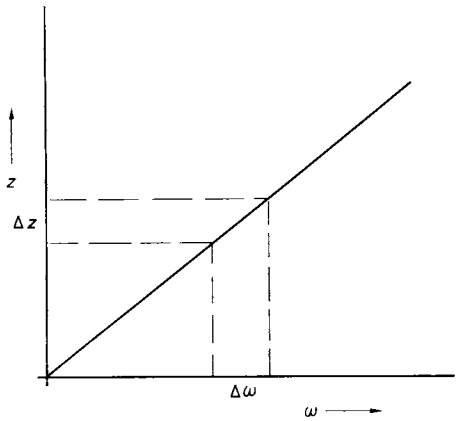

Fig. 10. Relationship of the bandwidth $\Delta\omega$ and the slice-thickness Δz in the presence of a gradient in the z-direction. The sharpness of the profile is given by the amplitude of the slice-gradient. For a given gradient strength the slice-thickness is proportional to the bandwidth of the pulse.

3.2.1. *Multi-slice Imaging*

Multi-slice imaging makes possible the imaging of a number of slices (e.g. 4, 8, 16, 32) in the same time as is necessary in a single-slice spin-echo experiment for one slice. The excitation of the spins within the sample is achieved by slice-selective 90° and 180° RF pulses. As the excitation bandwidth and profile should be the same for both pulses (both pulses affect the magnetization of the same slice), the pulses must be of differing power. As the pulses have differing profiles or even different sidebands, depending upon the pulse form, it is almost impossible to avoid some degree of overlap between neighboring slices. Effects due to overlapping may be minimized by means of a well planned excitation sequence, e.g. in an eight-slice experiment by exciting the slices in the order 1-3-5-7-2-4-6-8. The magnetization from previously excited slices relaxes following detection while the other slices are excited and detected. Thus, the relaxation delay necessary in a single slice experiment can be utilized to acquire the signals from several slices, without increasing the time required for the total experiment. Figure 11 shows the basic pulse sequence for multi-slice imaging, with two selective excitation pulses, and the corresponding gradient sequence for spatially encoding the magnetization.

The negative gradient Z3 refocusses the magnetization that is dephased by the gradient Z5 applied during the selective RF pulse P3. The duration of the latter is normally of the order of milliseconds, and for optimal rephasing the parameters are related by Equation (16).

$$Z3 = \frac{-Z5 \times P3}{(2 \times D3)} \tag{16}$$

Figure 12 shows the slice selection for a multi-slice experiment corresponding to the sequence shown in Figure 11.

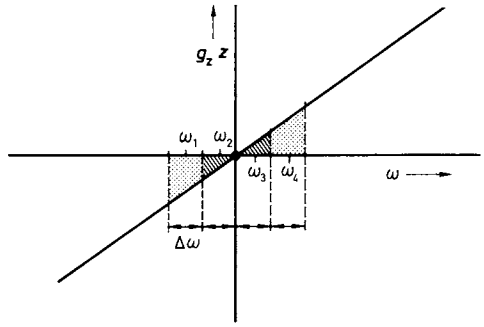

Fig. 12. A multi-slice selection is shown. The resonance frequency ω varies in the field gradient g_z, having a linear dependence with the spatial coordinate in the z-direction. The resonance frequency of the nuclei in the respective slices is ω_1 to ω_4. The bandwidth for a slice is $\Delta\omega$, determined by the duration of the selective RF pulse. The excitation of the individual slices occurs in the order slice 2 with frequency ω_2, slice 4 with frequency ω_4, slice 1 with frequency ω_1 and finally slice 3 with ω_3. This excitation sequence minimizes the effects of overlap between neighboring slices, and allows the relaxation of the spins in the slices already excited during the excitation and detection of the subsequent slices. In this experiment the repetition time is only 1/4 that of a single-slice experiment.

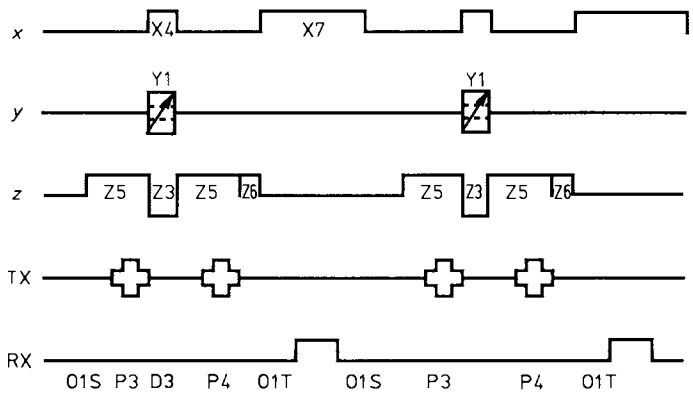

Fig. 11. Multi-slice pulse sequence with slice-selective 90° and 180° pulses. In contrast to the sequence shown in Figure 7, the spin system is excited with a defined bandwidth by the selective RF pulse P3. During this pulse the slice gradient Z5 is applied. During P3, which normally lasts several milliseconds, the magnetization is dephased by Z5. This dephasing is corrected by the negative gradient Z3, which is applied in the same direction as Z5 for a time D3. The gradient strength Z3 and Z5 are related by Equation (16). The frequency O1S defines the position of the selected slice, the frequency O1T is the receiver frequency.

3.2.2. *Multi-echo Imaging*

Multi-echo imaging is based on a Hahn echo sequence, in which, instead of a single echo, a series of echoes are generated by a sequence of slice-selective 180° RF pulses, and are detected and stored as separate data sets. Each of these echoes has the same phase encoding, and hence a complete image can be reconstructed from each echo. Figure 13 shows the multi-echo pulse sequence employed by the author, in which the phase-refocussing gradient Y2 refocusses the magnetization dephased by the phase-encoding gradient Y1.

Since the intensity of the spin echoes falls off exponentially at a rate determined by the spin-spin relaxation time T_2 [Eq. (17)], then T_2 weighted images are obtained following reconstruction.

$$M_{x,y}(t) = M_0 e^{-\frac{t}{T_2}} \tag{17}$$

According to *H. W. Spiess*[17] the spin-spin relaxation time T_2 of the nuclear spins is correlated with the mobility of the molecule via the rotation-correlation time τ_c [Eq. (18)].

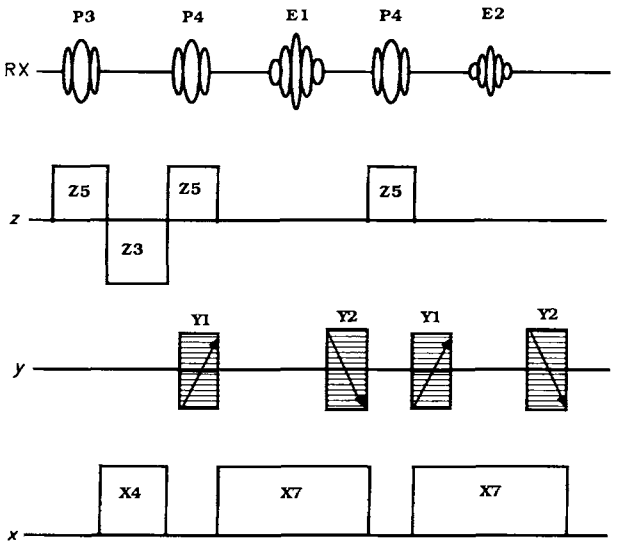

Fig. 13. Multi-echo single-slice pulse sequence. The nuclei here are excited, as in a multi-slice experiment, slice-selectively by narrow band RF pulses (P3, P4) in the presence of magnetic field gradients (Z5). Other than in the previously described methods (Fig. 7 and 12), in a multi-echo experiment a series of echoes (E1, E2, ...) are detected, not just as single echo, and the echoes are generated by repeated application of selective 180° pulses (P4) following the excitation of the system with a 90° pulse (P3). Unlike in the single-echo methods, after the detection of an echo the dephasing of the magnetization by the phase gradients Y1 is cancelled again by the gradients Y2; the strengths of the two gradients change inversely proportionally to each other from phase increment to phase increment. The advantage of this method is a prolonging of the time up to the total decay of the transversal magnetization. The amplitudes of the echoes in this experiment decrease with the relaxation time T_2. Since up to 128 echoes can be detected in the experiment, spatially resolved determination of T_2 is possible, thus enabling a parameter-selective image analysis [7].

$$\frac{1}{T_2} = \frac{1}{5}\gamma^4\left(\frac{h}{2\pi}\right)^2 I(I+1)\, r^{-6} \times \left(3\tau_c + \frac{5\tau_c}{1+\omega^2\tau_c^2} + \frac{2\tau_c}{1+4\omega^2\tau_c^2}\right) \qquad (18)$$

I is the nuclear quantum number and $r = |\boldsymbol{r}|$ the separation of the interacting nuclei, ω the resonance frequency and h the Planck constant.

Multi-echo imaging now offers the possibility of spatially resolved T_2 measurements. Hence this method gives unique access to the molecular dynamics in given regions of the sample. From the images of a multi-echo sequence it is possible to construct a "T_2-image". In a "T_2-image" the image intensity is proportional to the spin-spin relaxation time, and with this one obtains an insight into the homogeneity of the T_2 relaxation. Intensity profiles then allow the spatially resolved measurement of T_2 gradients. The summation of all the T_2 weighted images gives an image of extraordinarily rich contrast, which frequently allows the recognition of fine structures otherwise not normally seen. Possible uses of this method in polymer-research are, for example, the quantitative evaluation of the bonding of water or solvent-protons to polymer chains, and the spatial distribution of these over the complete polymer volume. Furthermore, this method offers the possibility of characterizing malignant and healthy tissue with a high spatial resolution, both in biomedical applications on humans, and in animal experiments. Multi-echo imaging is certainly one of the most valuable NMR imaging methods, both with respect to the image contrast obtained, and to the investigation of molecular dynamics.

3.2.3. *Chemical Shift Selective Imaging*

Chemical shift selective imaging is really the typical NMR imaging method. By this method images are produced only from nuclei having a given chemical shift. Hence it is possible in biomedical applications to obtain images showing the spatial distribution of water or fat in a tissue sample, an organ in vivo, or a plant. It also appears to be possible to image other metabolites, such as inorganic phosphate or phosphocreatine using ^{31}P-NMR imaging, or the metabolization of ^{13}C-labeled substances using ^{13}C-NMR imaging. The application of this method is relatively easy at high magnetic field strengths, and the spectral lines in question are well separated.

The chemical species to be detected is selectively excited by an RF pulse with a narrow bandwidth, such as a Gaussian pulse with a bandwidth of a few hundred hertz, and only this species is then detected (cf. Fig. 14). The subsequent course

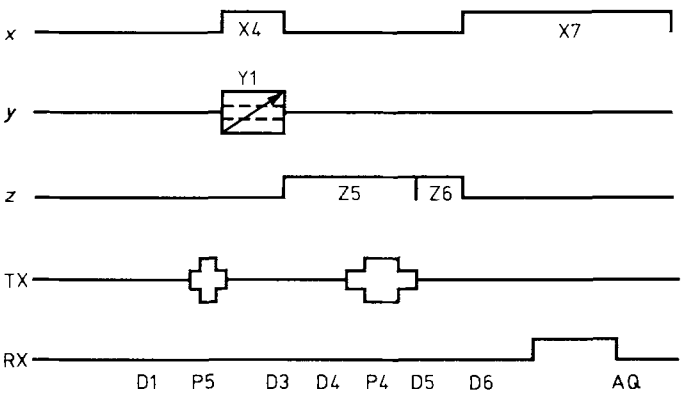

Fig. 14. Pulse sequence for the acquisition of a chemical shift selective image. The selection according to the chemical shift of a nuclear species is achieved by a gaussian 90° pulse having a narrow bandwidth. The pulse's carrier frequency corresponds to the resonance frequency of the species to be imaged. The further course of the experiment is identical to that shown in Figure 7.

of the experiment is that of a normal spin-echo experiment as described in Section 3.2, with the difference that during the experiment only magnetization excited on the basis of the chemical shift is further manipulated by the RF pulses, and then detected.

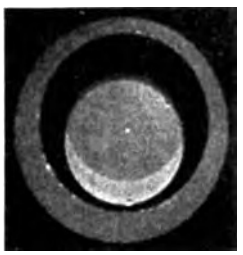

Fig. 15. Proton image of a phantom consisting of a 10-mm NMR tube filled with water, and containing a 5-mm tube filled with oil. The proton resonance frequency is 500 MHz. The chemical shift of the lipid with respect to the water protons is clearly visible.

Figures 15 and 16 demonstrate the excellent selection of chemically different species, in this case fat and water. The object consisted of a 10-mm NMR tube filled with water and containing a 5-mm tube filled with oil. This experiment was conducted at 11.74 T, corresponding to a proton resonance frequency of 500 MHz.

Fig. 16. Left: Chemical shift selective water image of the same sample as in Figure 15. Right: Chemical shift selective image of the sample's lipid protons. In both cases excitation is achieved with a gaussian pulse of approximately 600-Hz bandwidth.

3.2.4. T_1 Imaging

The return of the magnetization of thermal equilibrium following excitation by a 90° RF pulse, is described by the relaxation times T_1 and T_2. T_2 describes the loss of phase-coherence of the spin system, T_1 the relaxation of the magnetization parallel to the static magnetic field. The T_1 relaxation is given by

$$M_z(t) = \boldsymbol{M}_0(1 - e^{-\frac{t}{T_1}}) \tag{19}$$

The measurement of the spin-lattice time T_1 in NMR spectroscopy is performed using inversion-recovery[11] and saturation-recovery[12] pulse sequences. The combination of these pulse sequences with imaging methods (Fig. 17) allows the acquisition of T_1-weighted images from which spatially resolved spin-lattice relaxation times may be determined. This allows, on the one hand, inferences to be made about the molecular mobility at various positions of the sample, and, on the other, the possibility of a stronger contrast between regions with differing T_1 times.

Figure 17a shows an inversion-recovery imaging sequence. In this sequence the z-component M_z of the magnetization is inverted by the 180° pulse. After the delay VD, during which the longitudinal component of the magnetization relaxes due to spin-lattice interactions, this part of the total magnetization is detected using a spin-echo sequence. The echo amplitude is hence determined by both relaxation times [Eq. (20)].

$$M_y(t) = \boldsymbol{M}_0(1 - \beta e^{-\frac{VD}{T_1}})\,(1 - 2e^{-\frac{TR}{T_2}} e^{-\frac{TE}{2T_1}} + e^{-\frac{TE}{T_2}}) \tag{20}$$

TR is the repetition time of the experiment, TE the echo delay, β is 2 for inversion recovery, and 1 for saturation recovery experiments.

Figure 17b shows a saturation-recovery pulse-sequence. In this the magnetization is saturated by a rapid sequence of 90° pulses. The further course of the experiment is as given above.

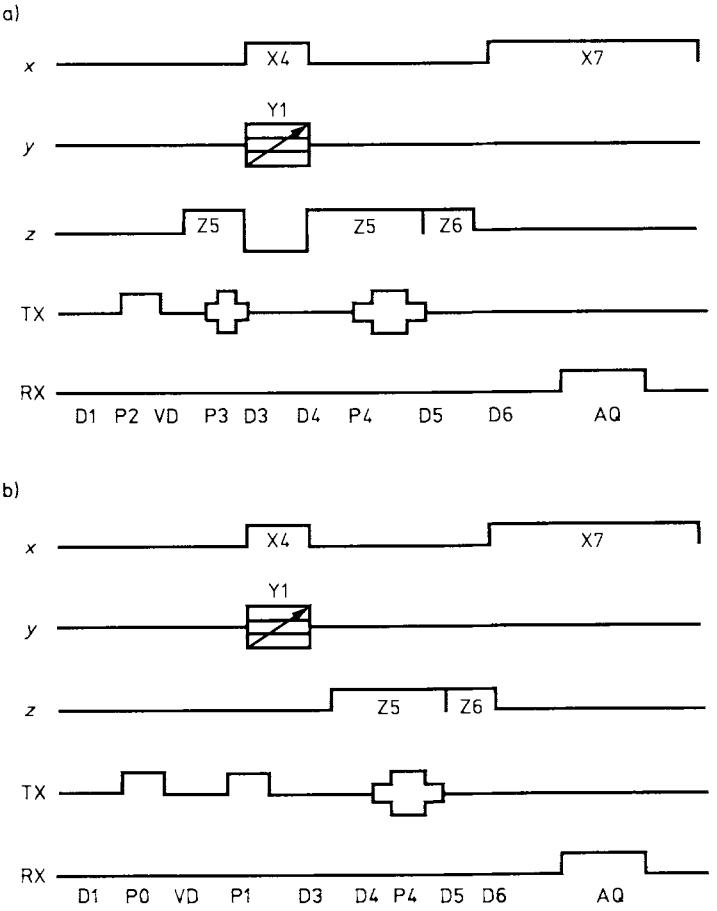

Fig. 17. a) Inversion-recovery imaging sequence. The inversion of the magnetization is achieved by a broad-band 180° pulse at the start of the pulse sequence. After a delay VD, during which the magnetization can relax along the z'-axis parallel to $\boldsymbol{B}_0$, a conventional spin-echo experiment (Fig. 7) is conducted. Depending upon the length of the delay VD, the images have a strong weighting according to the spin-lattice relaxation time. A series of inversion-recovery images with varying delays VD allows the spatially resolved measurement of T_1. b) Saturation-recovery sequence. The saturation of the magnetization is achieved by an aperiodic saturation sequence, in which the separation between consecutive pulses is reduced in geometric succession. The further course of the experiment is analogous to that of Figure 17a. The saturation-recovery sequence has the advantage over the inversion-recovery sequence that it is not necessary to wait between successive applications of the sequence, as the magnetization is saturated, and must not return to thermal equilibrium. This makes possible rapid T_1 weighted imaging.

As T_1 is correlated to molecular mobility, and also shows a clear dependence upon $1/(1 + \omega^2\tau_c^2)$, T_1 weighted images are an excellent means of visualizing molecular dynamic properties. Owing to the dependence of T_1 on the field strength, these methods are well suited to spatially resolved, field strength dependent, T_1 measurements. These measurements yield information about the physical interactions contributing to the relaxation.

3.3. Gradient Reversal Methods

Measurements with the spin-echo methods described in Sections 3.2 to 3.2.4 generally require a considerable delay between the individual experiments of at least T_1, and preferably 3–5 T_1, to allow for the relaxation of the longitudinal magnetization. In recent years, a large number of different pulse sequences have been developed in order to make rapid

imaging possible. The most popular, and for NMR microscopy the most important methods are the FLASH (*F*ast *L*ow *A*ngle *Sh*ot) methods,[13] which refocus the magnetization by gradient reversal instead of by a 180° refocussing pulse (Fig. 18).

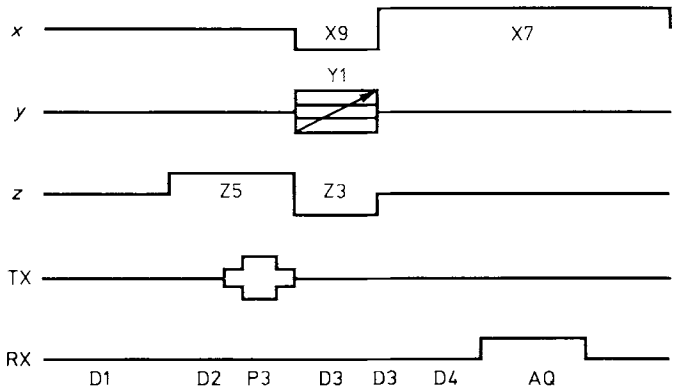

Fig. 18. Pulse sequence for rapid imaging with the FLASH sequence [13]. The magnetization is excited through a small angle from the z-axis by the RF pulse P3 in the presence of the slice-gradient Z5. The transverse components of the magnetization are then dephased by the gradients X9 and Y1 during the time D3. The Y1 gradient is turned off, and the gradient X9 reversed to give the read gradient X7. This leads to a rephasing of the transverse magnetization known as a gradient-echo.

The excitation of the spin system is accomplished in this pulse sequence by means of a slice-selective RF pulse with a small excitation angle. Under the influence of the gradient X9 the magnetization in the x'-y'-plane is dephased. The gradient Y1 simultaneously phase-encodes the second dimension of the slice. After a delay D3 the gradient X9 is reversed, this leads to a rephasing of magnetization of the observed slice, and finally once more to a coherent state that is detected as a "gradient echo". The FLASH sequence has the advantage that the short repetition time allows the acquisition of images within very short times of between 100 ms and a few seconds.

The disadvantage of this method is its sensitivity to inhomogeneities in the static magnetic field. As there is no 180° RF pulse in the FLASH sequence, only the magnetization that is dephased by the gradient X9 is refocussed. Magnetization that is dephased by main field inhomogeneities or susceptibility gradients at boundaries will not be refocussed by the gradient reversal. This magnetization makes only a small contribution to the signal, and leads to a poorer signal-to-noise ratio than in a spin-echo experiment, but may give an enhanced image contrast.

Since gradient reversal methods do not necessarily require that the magnetization is in thermal equilibrium prior to the pulse sequence, these methods are currently the only practical methods for rapid imaging. In combination with short acquisition times and very short gradient stabilization times of less than 100 μs (as are possible in a microscopy system), it is possible to acquire gradient reversed images with a matrix size of 128 × 64 in about 100 ms.

These very short imaging times allow the examination of relatively fast kinetics by NMR imaging. Figure 19 shows a glass-tube which is filled with water and contains a rectangular piece of plastic and is rotating at about 2 Hz. Despite the rotation of the sample the images are remarkably sharp.

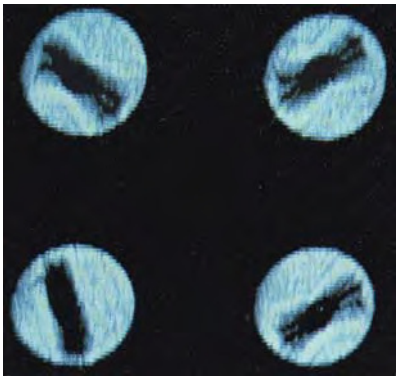

Fig. 19. Images of an NMR tube rotating at 2 Hz. The tube was filled with water and contained a submerged piece of plastic. These images were obtained with a snapshot-FLASH sequence [14] during the rotation of the tube. The imaging time was 90 ms per image for a matrix of 64 × 128 points. The gradient strengths used were 300 mTm^{-1} for the read and phase-encoding gradients and 200 mTm^{-1} for the slice gradient. The measurements were made at a field strength of 7.05 T.

4. Contrast Determining Parameters

Other than in the case of X-ray tomography, in which the contrast is determined only by the absorption of the X-rays, image contrast in NMR imaging is determined by the spin density and by the relaxation times T_1 and T_2 within the sample. By the appropriate choice of acquisition parameters it is possible to obtain an image contrast with a well defined relationship to certain physical properties of the object under investigation.

On using a spin-echo sequence for the acquisition of an image, the image contrast for a pixel is determined by the signal strength $S(\mathrm{TE,TR})$ [Eq. (21)][15] from the corresponding voxel.

$$S(\mathrm{TE,TR}) = \varrho\left(1-2e^{-\frac{TR}{T_1}}e^{-\frac{TE}{2T_1}}+e^{-\frac{TR}{T_2}}\right)e^{-\frac{TE}{T_2}} \qquad (21)$$

By appropriate choice of the parameters spin-echo time TE and repetition time TR, it is possible to weight the image contrast according to the spin density ϱ, or the relaxation times T_1 and T_2 [Eq. (21)].

For the gradient reversal method the signal strength is given by Equation (22).[16] By varying the excitation angle

$$S = \varrho\frac{\left(1-e^{-\frac{TR}{T_1}}\right)e^{-\frac{TE}{T_2}}\sin\theta}{1-e^{-\frac{TR}{T_1}}e^{-\frac{TR}{T_2}}-\left(e^{-\frac{TR}{T_1}}-e^{-\frac{TR}{T_2}}\right)\cos\theta} \qquad (22)$$

θ, spin-echo time TE and the repetition time TR it is also possible by this method to produce different image contrasts.

4.1. Spin Density

The spin density ϱ is determined by the number of nuclei of a certain species, e.g. water protons, lipid protons, in a

defined volume element. From the intensity of the signals in the spectrum, or from the integral of the image profile, it is possible to obtain the relative, or by calibration, the absolute metabolic concentration. Pure spin density images can be obtained with a spin-echo pulse sequence by choosing the parameters $TR \gg T_1$ and $TE \ll T_2$. For these parameters the signal strength $S(TE,TR)$ is only a function of the spin density ϱ, i.e. the image contrast is determined by the spin density within each voxel. In this situation the profile gives a quantitative determination of the metabolites imaged. In order to reduce the imaging time it is common to choose a shorter repetition time TR, generally $TR = T_1$. When this is the case, and when $TE \ll T_1$ and $TE \ll T_2$ are still valid, the signal intensity S of the NMR signal is, according to Equation (21), $0.63\,\varrho$, and is independent of other parameters.

4.2. Spin-Lattice Relaxation Time T_1

The spin-lattice relaxation time T_1 describes the return of the z component of the magnetization to thermal equilibrium, following the excitation of the spin system by an RF pulse.

In the case of proton imaging, the spin-lattice relaxation time is almost completely determined by the proton-proton dipolar coupling. In the case of other nuclei, such as ^{31}P in adenosine triphosphate, the contribution of the magnetic anisotropy of the phosphorus nuclei must also be considered. For the relaxation rate $1/T_1$, in the case of homonuclear dipolar coupling of nuclei I having isotropic motion one obtains Equation (23),[17] from which it can be seen that the

$$\frac{1}{T_1} = \frac{2}{5}\gamma^4\left(\frac{h}{2\pi}\right)^2 I(I+1)\,r^{-6}\left(\frac{\tau_c}{1+\omega^2\tau_c^2} + \frac{4\tau_c}{1+4\omega^2\tau_c^2}\right) \quad (23)$$

spin-lattice relaxation rate $1/T_1$ is dependent upon the correlation time τ_c of the molecule concerned. When the mobility of the molecule is restricted, as is generally the case in biological and polymeric samples, the relaxation rate $1/T_1$ is a function of the resonance frequency ω of the nuclei, and is hence dependent upon the magnetic field strength. From T_1-weighted images, or spatially resolved T_1 measurements (see Section 3.2.4), it is possible to estimate the mean intermolecular separation r if the correlation time τ_c is known, or, conversely, to determine the correlation time if r is known.

From Equation (21) one can derive the experimental conditions for T_1-weighted spin-echo images: For $TE \ll T_1 T_2$ one obtains Equation (24). An analogous condition for the

$$S(TR, T_1) = \varrho\,(1 - e^{-\frac{TR}{T_1}}) \quad (24)$$

gradient reversal method [Eq. (25)] is obtained from Equation (22) by choosing $TE \ll T_2$ and $TR \gg T_2$.

$$S(\theta) = \varrho \sin\theta \quad (25)$$

4.3. Spin-Spin Relaxation Time T_2

The spin-spin relaxation time T_2 exhibits a dependence upon the molecular correlation time of the molecule[17] in much the same way as the spin-lattice relaxation time T_1 does. Although the constant term $3\,\tau_c$ in Equation (26) [= Eq. (18)] shows that the dependence upon the magnetic field strength is significantly less. This makes the T_2 value an

$$\frac{1}{T_2} = \frac{1}{5}\gamma^4\left(\frac{h}{2\pi}\right)^2 I(I+1)\,r^{-6} \times \left(3\tau_c + \frac{5\tau_c}{1+\omega^2\tau_c^2} + \frac{2\tau_c}{1+4\omega^2\tau_c^2}\right) \quad (26)$$

ideal parameter for the characterization of molecular dynamic properties, as T_2 values measured at differing frequencies may still be compared with each other.

Pure T_2-weighted images are obtained by choosing $TR \gg T_1$. The signal intensity is hereby a function of the spin-echo time TE and the spin-spin relaxation time T_2 [Eq. (27)]. The image contrast in this case is determined only

$$S(TE, T_2) = \varrho\, e^{-\frac{TE}{T_2}} \quad (27)$$

by the spin-density ϱ and the ratio TE/T_2.

5. Limits to the Spatial Resolution of the NMR Microscope

The attainable resolution of the NMR microscope is limited by physical and technical factors.[18] Physical factors are: the line width and the chemical shift of the NMR signal, diffusion processes, and susceptibility gradients, both within the object and at its boundaries. Technical factors may be magnetic field inhomogeneity or instability, non-linearity of the magnetic field gradients, and the achievable signal-to-noise ratio.

5.1. Physical Limitations

5.1.1. Signal Line Width

The line width of the NMR signal $\Delta\nu$ is defined as the width of a Lorentzian line at half the maximum height where

$$\Delta\nu = \frac{1}{\pi T_2} \quad (28)$$

T_2 is the spin-spin relaxation time of the nuclei.

Equations (12) and (28) give the maximum obtainable spatial resolution Δx for a given spin-spin relaxation time T_2 as:

$$\Delta x = \frac{2}{\gamma g_x T_2} \quad (29)$$

In the following discussion three commonly encountered cases will be considered: NMR microscopy of a) samples similar to water, b) biological material, c) solids.

In water-like samples the T_2 times are between several hundred milliseconds and seconds. With regard to Equations (23) and (26) the situation of extreme narrowing pertains, i.e. the terms $\omega^2\tau_c^2$ are much smaller than unity, and

hence may be neglected. The relaxation rates then show no further dependence upon the field strength. For example Equation (29) shows that to obtain a pixel resolution of 10 μm for a sample having a T_2 of 1 s, a gradient strength of 0.7 mTm^{-1} (=0.07 G/cm) is necessary. In biological samples the signal line width may reach 100 Hz, depending upon the environment of the nuclei. This corresponds to a T_2 of about 3 ms. To obtain a spatial resolution of 10 μm in this situation requires a gradient strength of at least 235 mTm^{-1}.

In solids the line width may reach 50 kHz due to the dipolar coupling of protons to each other. For a resolution of only 1 mm a gradient strength of 1100 mTm^{-1} is required. For the realization of such an experiment these very strong gradients must be switched within 20 μs. This would induce enormous eddy currents in the electrically conducting parts of the magnet, which would have a strong effect on the magnetization. The experiment is also unrealizable in practice owing to the level of self-induction present.

From these considerations it is apparent that it should be possible to achieve resolution in the μm range for water-like samples and biological samples, but that, with the spin-echo and gradient-reversed methods described above, resolution of this order is impossible for solids. Possible techniques for achieving this are the combination of rotating gradients with the magic-angle spinning (MAS) frequency of the sample,[19] or of multipulse sequences with imaging methods[20–22] or RF pulse field gradients.[23] Fortunately the spin-spin relaxation times of many polymers lie in the millisecond range, and hence allow high resolution imaging by conventional methods.

5.1.2. *Chemical Shift*

The magnetic environment of a particular nuclear species can vary greatly within a sample. It is characterized by the chemical shift δ of the resonance signal in the spectrum, which is defined according to Equation (30).

$$\delta = (\omega_{signal} - \omega_{reference})/\omega_{reference} \tag{30}$$

The chemical shift δ is dependent upon the pH value, upon paramagnetic ions that may concentrate in particular regions of the sample, and upon temperature effects. This leads to a spread $\Delta\nu$ of the resonance frequencies of a molecular species over a definite range. The frequency range of the chemical shift of a nuclear species within a sample is proportional to the magnetic field strength B_0 [Eq. (31)], where the range of the chemical shift $\Delta\delta$ depends upon the magnetic environment of the nuclei

$$\Delta\nu = \gamma\,\Delta\delta\,B_0\,10^{-6} \tag{31}$$

The attainable resolution Δx for a given range of chemical shifts $\Delta\delta$ of a nuclear species, and for a given magnetic field strength B_0 is given by Equation (32). For example, to obtain

$$\Delta x = \frac{1}{g}\gamma\,\Delta\delta\,B_0\,10^{-6} \tag{32}$$

a resolution of 10 μm at a field strength of 9.4 T (400 MHz proton resonance frequency), and for a chemical shift range $\Delta\delta \approx 0.05$ for water in biological material, a gradient strength of 50 mTm^{-1} is necessary.

5.1.3. *Molecular Diffusion*

The influence of molecular diffusion on the attainable spatial resolution in NMR microscopy will be discussed under the following two aspects:

a) Molecular diffusion is certainly a resolution limiting factor if between excitation and detection the nuclei diffuse into a neighboring voxel. The maximum time allowed in a spin-echo experiment for a well defined resolution may be estimated with the help of classical thermodynamics.[24] Consider a group of particles at the center of the voxel ($x = 0$) at time $t = 0$. Under the influence of Brownian molecular motion the particles diffuse according to Fick's first law, so that at time t the expectation value of their distance from the origin is given by Equation (33). In a spin-

$$\Delta x = \sqrt{\overline{x^2}} = \sqrt{2Dt} \tag{33}$$

echo experiment the spatial resolution is only defined if, during the echo time TE, the spins do not leave the voxel in which they were excited, i.e. when the relationship (34) holds.

$$TE \leq \frac{(\Delta x)^2}{2D} \tag{34}$$

For a 10-μm voxel, and a sample consisting of pure water ($D = 2 \times 10^{-9}$ m^2/s) this implies that TE < 25 ms. In biological material and in polymers, the diffusion constant generally has a considerably lower value than that of free water. Further, in microscopy experiments TE normally lies between 1 and 20 ms, and hence, by the arguments given above, diffusion presents no limitation to the attainable resolution.

b) According to *Carr* and *Purcell*,[25] the relaxation of the transverse magnetization under the influence of T_2 in the presence of a magnetic field gradient $|\boldsymbol{G}|$ and diffusion is given by Equation (35).

$$M_{xy}(t) = \boldsymbol{M}_0\, e^{-\frac{t}{T_2}}\, e^{-\frac{1}{12}\gamma^2 G^2 D t^3} \tag{35}$$

This clearly leads to line broadening if the diffusion term M_D [Eq. (36)] reaches a similar order of magnitude to the

$$M_D = e^{-\frac{1}{12}\gamma^2 G^2 D t^3} \tag{36}$$

$$M_{T_2} = e^{-\frac{t}{T_2}} \tag{37}$$

T_2 term M_{T_2} [Eq. (37)]. For water (diffusion constant $D = 2 \times 10^{-9}$ m^2/s) it may be calculated that the gradient strength required for, e.g., a spatial resolution of 10 μm is 4 mTm^{-1}. Since the maximum gradients in an NMR microscope are always stronger than this, molecular diffusion at room temperature presents no limitation to the attainable spatial resolution.

5.2. Technical Limitations

Alongside physical considerations, technical factors must also be bourne in mind when considering the limits of spatial

resolution. Under consideration are imperfections in the apparatus, and the signal-to-noise ratio. The former may be due to magnetic field inhomogeneity, temporal instability or to nonlinearities in the gradient field.

5.2.1. Homogeneity and Stability of the Static Magnetic Field

The homogeneity of superconducting high field magnets currently in use for high resolution NMR spectroscopy, is characterized by the inhomogeneity factor f [Eq. (38)],

$$f = \frac{\Delta B}{B_0} \tag{38}$$

where f is appropriately $3 \times 10^{-8}\ h^{-1}$. In order to maintain a given resolution the inhomogeneity or instability ΔB of the static magnetic field $\boldsymbol{B}_0$ must be smaller than, or equal to, the inhomogeneity induced by the gradients during the entire experiment, i.e.

$$\Delta B = g\Delta x \tag{39}$$

By considering the inhomogeneity factor f one obtains a pixel size

$$\Delta x = f\frac{B_0}{g} \tag{40}$$

For a gradient strength of 100 $mT\,m^{-1}$ using a 10 T magnet, Equation (40) indicates that a maximum resolution of 3 μm is obtainable. If the gradient strength is 750 $mT\,m^{-1}$, then the resolution is 0.4 μm. In both instances an experimental duration not exceeding 1 h is assumed. For an "overnight" experiment having a duration of 15 h, one obtains resolutions of only 45 μm and 6 μm respectively for the two situations given above.

Hence magnetic field inhomogeneities and instabilities can have an effect on the attainable spatial resolution in NMR microscopy.

5.2.2. Magnetic Field Gradient Linearity

Unfortunately, magnetic field gradients are in general only constant in theory. In practice a coil is of finite length, and because of the limited space available, the length to diameter ratio is fixed. Hence a constant field gradient over the total length and diameter of the coil is unrealizable. Further distortion of the gradient field linearity is to be expected due to the coil construction, and to the distribution of the coil windings, which are normally multilayered.

This means that the magnetic field gradients within a gradient coil are spatially dependent, and may only be approximately described by a series expansion [Eq. 41)].

$$\boldsymbol{g} = \boldsymbol{g}(x) = a_1\boldsymbol{g}_1 x + a_2\boldsymbol{g}_2 x + a_3\boldsymbol{g}_3 x + \ldots \tag{41}$$

A consequence of gradient field nonlinearity is image distortion, and associated with this a degradation of the spatial resolution in the nonlinear regions of the field. Commercially available gradient systems give gradients that at the gradient center are linear to within 1% over a diameter of about 10 mm and 3% over 20 mm. These errors have no perceptible effect on image quality.

5.2.3. Signal-to-Noise Ratio

As in every NMR experiment, the signal-to-noise ratio determines the measuring time and attainable resolution in NMR microscopy. An improvement in the signal-to-noise ratio of the FID by a factor of 2 gives the same improvement in the image, or about a quarter of the measuring time for the same signal-to-noise ratio with the same resolution. Unfortunately however, the SNR for the acquisition of a high-resolution NMR spectrum from a sample is not identical with the SNR in an image, since in imaging the signal from a defined slice is divided between all the pixels of the image. Hence, the SNR per pixel is significantly worse than in a one-dimensional spectrum.

An improvement of the in-plane resolution by a factor of 2 in both dimensions reduces the voxel volume by a factor of 4, and necessitates about a factor of 16 more data accumulations to maintain the same SNR. Similarly, halving the slice-thickness while maintaining constant in-plane resolution requires 4 times the number of data accumulations. The volume dependence of the SNR as given by *Hoult* and *Richards*[26] [Eq. (42)] is the most significant limiting factor

$$\mathrm{S/N} \sim V \tag{42}$$

for the attainable SNR in NMR microscopy. Equation (42) implies that for an improvement in the spatial resolution of, for example, 10^3 μm^3 from 100^3 μm^3, the SNR deteriorates by a factor of 1000, and thereby the number of accumulations required for the same SNR increases by a factor of 10^6. This argument assumes that the sample volume and the diameters of the transmission and reception coils remain constant. From Equation (42) it is also possible to derive the dependence of the SNR upon the resonance frequency [Eq. (43)]. This relation is shown in Figure 20, and indicates

$$\frac{\mathrm{S}}{\mathrm{N}} \sim \sqrt[4]{\omega_0^7} \tag{43}$$

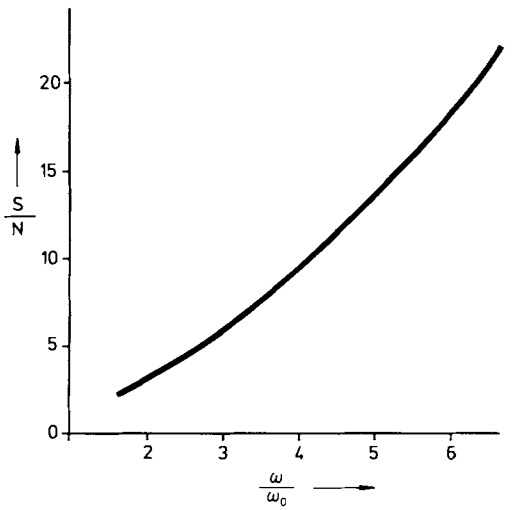

Fig. 20. Signal-to-noise ratio as a function of the resonance frequency ω and thus of the field strength of the static magnetic field [Eq. (43)] referred to $\omega_0 = 100$ MHz (S/N ≡ 1).

that on the basis of the SNR, NMR microscopy can only be usefully conducted at the highest possible field strengths.

A further interesting aspect is the dependence of the SNR upon the bandwidth $\Delta\omega$ of the receiver, or equivalently the spectral width of the image.

$$\frac{S}{N} \sim \frac{1}{\sqrt{\Delta\omega}} \tag{44}$$

Equation (44) shows that reducing the bandwidth diminishes the noise, but, however, this increases the time required for data acquisition. In spin-echo imaging the data must be symmetrically acquired, i.e. the echo maximum occurs midway through the detection period, because of data processing

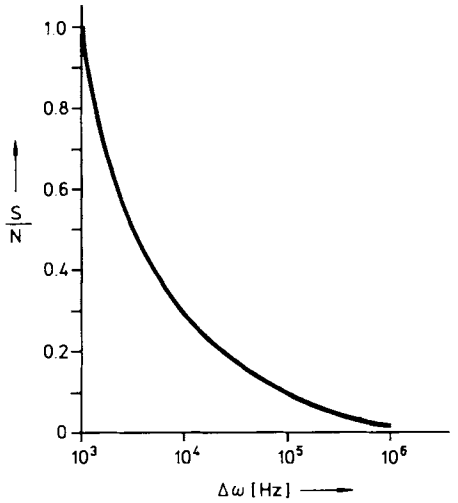

Fig. 21. Signal-to-noise ratio as a function of the detector bandwidth $\Delta\omega$ [Eq. (44)].

requirements (the FT). If the number of data points is kept constant then reducing the bandwidth leads to an increase in the spin-echo time TE. This in turn leads to losses due to T_2 in the echo intensity and so to a worsening in the SNR. Both circumstances are illustrated in Figures 21 and 22.

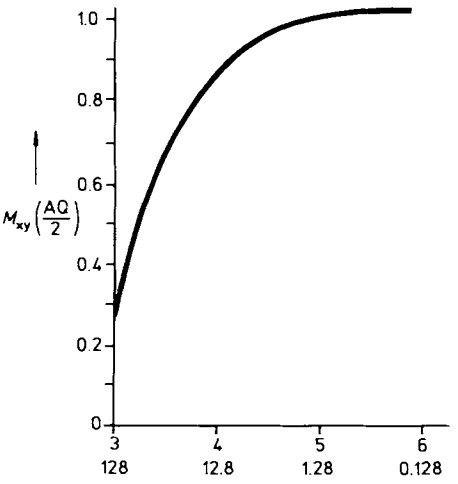

Fig. 22. Signal amplitudes $M_{xy}(t)$ after half acquisition time $T_2 = 100$ ms and data acquisition times between 128 μs and 128 ms (lower values of the abscissa: t[ms]) for 512 data points and bandwidths $\Delta\omega$ of 1–100 kHz (upper values of abscissa: $\lg(\Delta\omega)$).

Cooling of the receiver system is a further, but not very practicable, way of reducing the noise. This is because the sample, especially a biological sample, must generally be maintained at a given temperature, and thermally isolating the receiver coil from the sample would lead to the coil having a more unfavorable filling factor, and thus once more to a poorer signal-to-noise ratio.

The preceeding discussion indicates that, at least for samples such as biological samples that have relatively long spin-spin relaxation times and consequently narrow line widths, the SNR is the limiting factor for the attainable spatial resolution in NMR microscopy.

6. Applications of NMR Microscopy

As is clear from Section 5 the low sensitivity of NMR microscopy means that it will not in the forseeable future achieve resolutions comparable with those of optical microscopy (approx. 0.5 μm). So when judged by this criterion the NMR microscope presents no competition to the optical microscope, and its price is also uncompetitive. Useful applications of NMR microscopy lie only in the areas where it has special properties, such as:

a) The non-destructive investigation of samples, especially over longer time scales. These include observing the course of a disease in animal models and the slow diffusion of fluids in polymers;
b) the imaging of spin density leading to a quantitative assessment of concentrations;
c) chemical shift selective imaging for determining the spatial distribution of substances in a sample;
d) the investigation of dynamic processes by means of relaxation-time weighted images (see Sections 3.2.2 and 3.2.4);
e) the evaluation of dynamic properties by measuring the diffusion constants[27–29] of differing chemical species, or by evaluating the diagonal elements of the diffusion tensor (it may even be possible to completely determine the diffusion tensor);
f) the spectroscopy of defined partial volumes of the whole sample[30–36] or multidimensional spectroscopic imaging;[37–38]
g) the determination of flow velocities and profiles of fluids or viscous materials in capillaries or tubes.[39,40]

The above shows the incomparably broad range of applications of NMR microscopy which is not restricted by pure considerations of spatial resolution. In the following sections a few of the numerous possible applications will be discussed.

6.1. Biomedical Applications

The range of biomedical applications includes pharmaceutical research, pharmaceutical kinetics, therapeutic monitoring, and basic biomedical and biophysical research. These may be conducted on animal models for animals up to the size of a mouse or rat, on cell cultures and tissue samples in vivo and in vitro. The attainable spatial resolution with mice lies in the range from 50–130 μm, and rats at about 150 μm.

For cell cultures and tissue samples it may be better than 10 μm.

Figures 23 and 24 illustrate the use of NMR spectroscopy in arteriosclerosis research and show proton images from part of an artery. Figure 23a shows a longitudinal section;

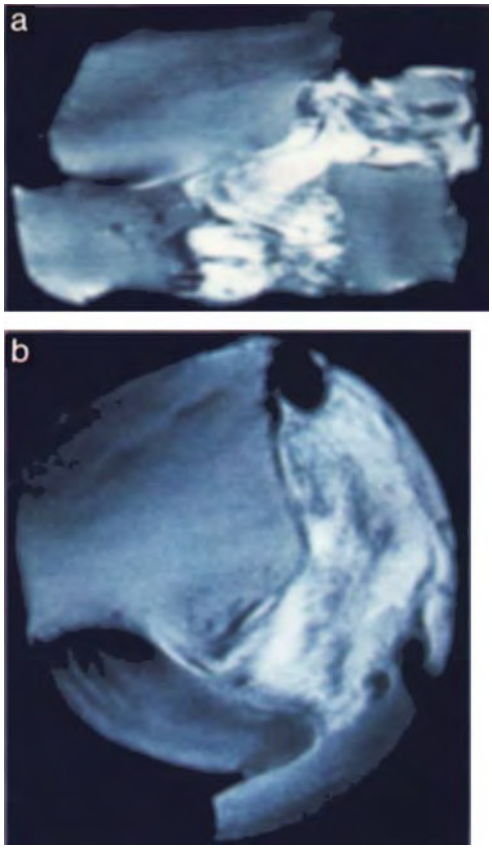

Fig. 23. Tissue sample from an artery, $B_0 = 7.05$ T. a) x-z-section, proton image. No chemical shift selection was applied. Two regions of differing intensity may be discerned. On the basis of the measuring parameters, TR = 500 ms, TE = 6.56 ms, it is to be expected that the lighter part of the image shows the lipid protons, as the spin-lattice relaxation time of these protons is several hundred milliseconds, while the T_1 of water lies in the range 1–3 s. The resolution in the x-direction is 36 μm, in the z-direction 92 μm, with a slice-thickness of 900 μm. $g_x = 100$, $g_z = 50\ \mathrm{mT\,m^{-1}}$. b) x-y-section, proton image. The in-plane resolution is now 36 μm isotropically, the slice-thickness 900 μm. Here also, the lighter part of the image shows the distribution of the lipid. $g = 100\ \mathrm{mT\,m^{-1}}$.

the region of low signal intensity represents a separation of the signals from water and lipids, that of high intensity a superposition. The high intensity of the lipid protons is a consequence of their relatively short (in comparison to water) spin-lattice (T_1) relaxation times, of several hundred milliseconds. This leads to almost complete relaxation and a strong lipid signal, whereas under the prevalent measuring conditions, water with its relatively long T_1 of about 1 s, is partially saturated. Figure 23b shows a section perpendicular to that of Figure 23a, and in this the two regions of differing intensity are clearly shown.

Figure 24 shows a chemical shift selective image (c.f. Section 3.2.3) of the lipid signal.[10] The excitation of the lipid signal is achieved with a Gaussian 90° pulse having a narrow bandwidth of about 600 Hz. The suppression of the water

Fig. 24. Chemical shift selective lipid proton image. The lipid protons were selectively excited by a narrow bandwidth 90° gaussian pulse. The short T_1 of the lipid protons allows the repetition time to be reduced to 200 ms. The other parameters are as for Figure 23b.

signal illuminates the contrast-rich structure in this part of the artery. In further studies[41] it was possible with chemical shift selective saturation-recovery imaging experiments (c.f. Section 3.2.4) to obtain spatially resolved measurements of the spin-lattice relaxation times for the water and lipid protons.

Figure 25 shows a section through the abdominal region of a healthy mouse anaesthetized with pentabarbital. In Figure 25a, the spine, spinal chord, back muscles, kidneys, stomach, spleen and liver are all clearly recognizable. Figure 25b is a zoom image of the kidney region with a pixel resolution of 60 μm × 60 μm and a slice thickness of 800 μm. For comparison Figure 25c shows an ex-vivo mouse kidney with a resolution of $36 \times 36 \times 320\ \mu m^3$.

With a mouse animal model it has been possible to follow the time course of a ceruletide-induced pancreatitis over a time period of 8 h,[42] (see Fig. 25d).

The influence of the spin-echo time is shown in Figure 26. Here, two sections through the abdominal region of a mouse are shown, obtained with TR = 3 s and a TE value of 32 ms (Fig. 26a, b) and of 12 ms, respectively (Fig. 26c, d). The regions of tissue having relatively short T_2 times make very little contribution to the signal when TE = 32 ms, but are first visible when TE = 12 ms.

Alongside the biomedical applications of NMR microscopy in animal experiments, this technique also finds numerous applications in plant research. Figures 27a and 27b each show the same sectional plane through a leaf from the plant *Bryophyllum tubiflore*. In the NMR microscopic image the vascular bundles and the cells, which have a size of ca. 40 μm in this plant, are easily recognizable. The changes in contrast in the regions of the cells are a result of the changes in the susceptibility of the cell membranes. In the light-microscopic image shown for comparison, the cells are clearly recognizable, but the dimensions of the vascular bundle are not determinable.

Figure 28 shows a spin-echo time study of a leaf from the plant *Mesembryanthemum cristallinum*.[4] The low intensity areas of the epidermis are a consequence of the very short spin-spin relaxation times of the water-protons in these areas. With decreasing TE these areas become lighter, and with a very short TE (TE = 4 ms) the intensity becomes almost uniform. This leads one to conclude that at the leaf's

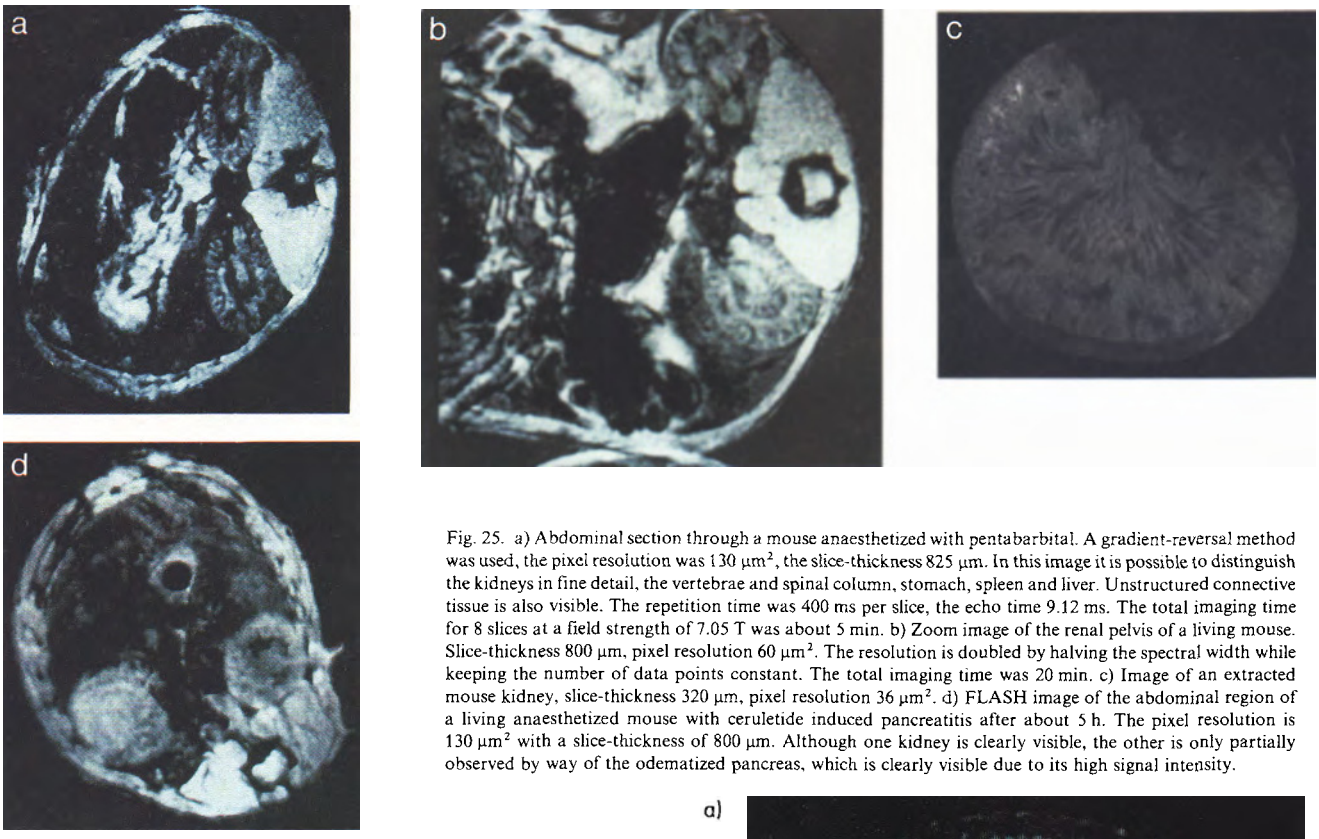

Fig. 25. a) Abdominal section through a mouse anaesthetized with pentabarbital. A gradient-reversal method was used, the pixel resolution was 130 μm^2, the slice-thickness 825 μm. In this image it is possible to distinguish the kidneys in fine detail, the vertebrae and spinal column, stomach, spleen and liver. Unstructured connective tissue is also visible. The repetition time was 400 ms per slice, the echo time 9.12 ms. The total imaging time for 8 slices at a field strength of 7.05 T was about 5 min. b) Zoom image of the renal pelvis of a living mouse. Slice-thickness 800 μm, pixel resolution 60 μm^2. The resolution is doubled by halving the spectral width while keeping the number of data points constant. The total imaging time was 20 min. c) Image of an extracted mouse kidney, slice-thickness 320 μm, pixel resolution 36 μm^2. d) FLASH image of the abdominal region of a living anaesthetized mouse with ceruletide induced pancreatitis after about 5 h. The pixel resolution is 130 μm^2 with a slice-thickness of 800 μm. Although one kidney is clearly visible, the other is only partially observed by way of the odematized pancreas, which is clearly visible due to its high signal intensity.

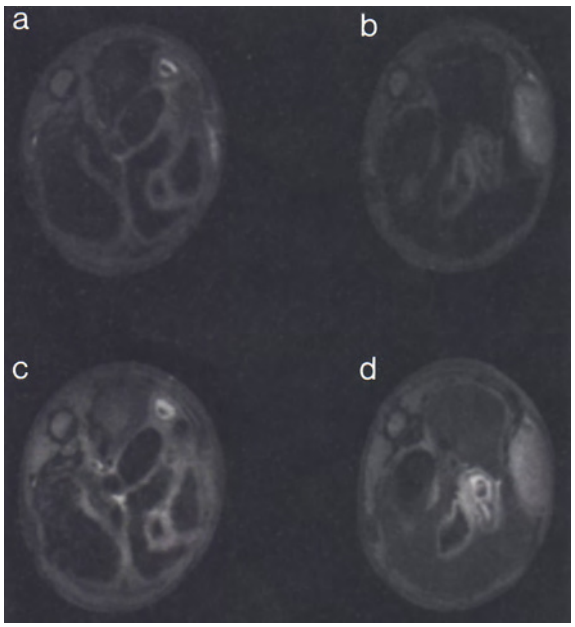

Fig. 26. Spin-echo images of the abdominal region of an anaesthetized mouse with an implanted tumour, the pixel resolution was 100^2 μm^2, the slice-thickness 500 μm. TR = 3 s, a) Slice 1, TE = 32 ms. b) Slice 2, TE = 32 ms. c) Slice 1, TE = 12 ms. d) Slice 2, TE = 12 ms. Field strength 9.4 T (by kind permission of Dr. M. Mattingly).

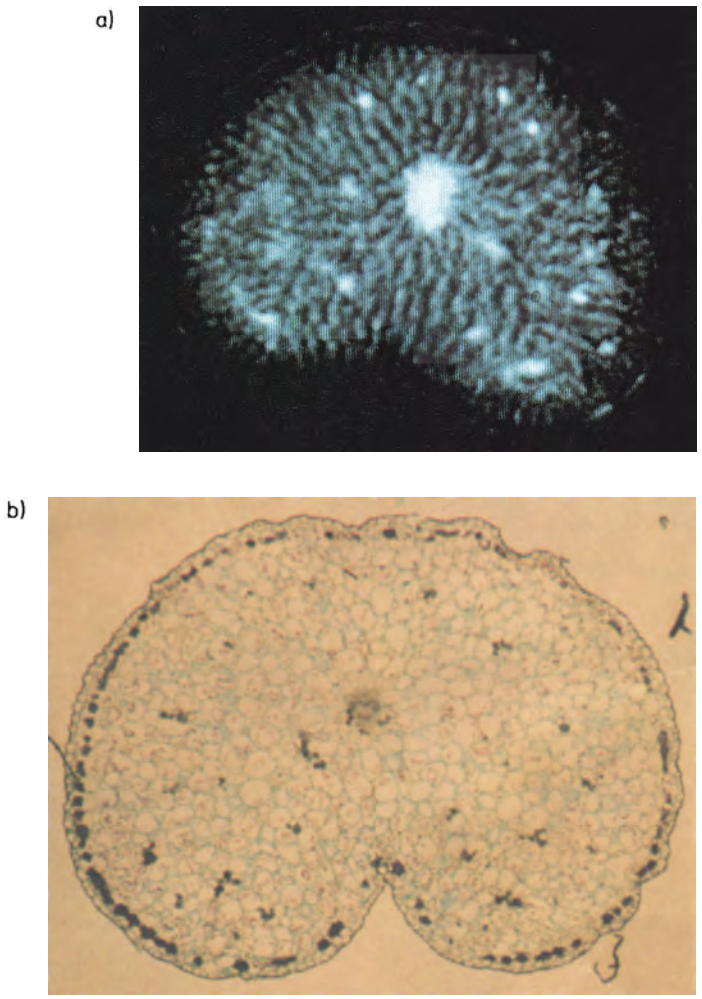

Fig. 27. Cross-section through a leaf of the plant *Bryophyllum tubiflore*. a) NMR microscopic image (7.05 T) with a resolution of $15 \times 15 \times 250$ μm^3. The vascular bundle, the individual plant cells, and the epidermis are clearly recognizable. b) Light-microscopic image. The cells have a diameter of ca. 40 μm (by kind permission of Dr. *W. Hartung*, Universität Würzburg).

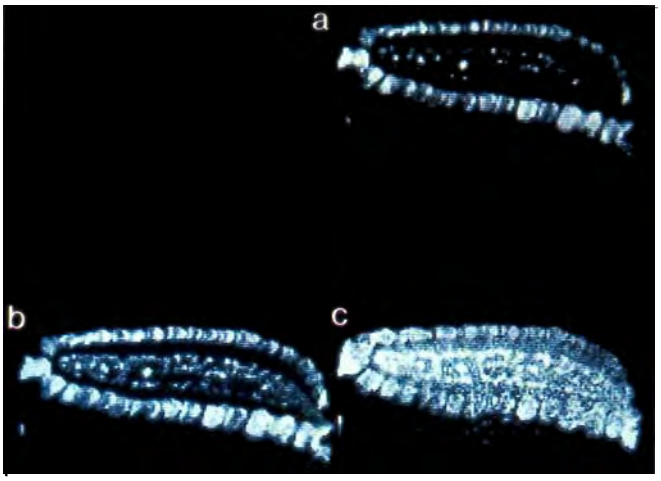

Fig. 28. Spin-echo image of *Mesambryanthenum cristallinum*. Influence of TE on the image contrast. a) TE = 18.24 ms. b) TE = 11.00 ms. c) TE = 4.40 ms.

edges the protons are relatively immobile, possibly due to the water being bound to the cellular compartments, but that the proton density throughout the leaf (except within the vein is almost constant). Further applications of NMR microscopy are the determination of the self-diffusion coefficient of water in plants,[43] changes in the water content of plant stems,[44] staging the growth of algae,[45] or, for example, studying morphology with relaxation agents.[46] The first measurements of water transport in plants by ^{17}O imaging using ^{17}O-labeled water have already been reported.[47] This, and other work[48] show that ^{17}O-labeled water is an excellent relaxation agent for biomedical applications, since its protons have a smaller T_1 than the protons of "normal water", and it is completely non-toxic. NMR microscopic investigations of intact multicellular tumor spheroids have been published in the course of the last two years.[49]

6.2. Uses of NMR Microscopy in Materials Science

NMR microscopy can be of great help in investigating the structure and dynamics of polymers, ceramics and building materials.[50, 51] Applications in the field of materials research may be classified as static or as time-dependent, depending on the nature of the experiment. *Blümich* and *Spiess*[52] give an exemplary description of the following investigations:

- The pore-distribution in unsintered ceramic.[53] The radial pore distribution was measured by proton-density images of absorbed fluids.
- The distribution of binding agent in unsintered ceramics.[54] Low molecular weight polymers and waxes are used as binding agents. With the predicted line width it should be possible to obtain images of still higher resolution.
- The distribution of pollutants in wood.[55] Pollutants in wood can change the relaxation times of the water protons. The distribution of pollutants as well as that of vaccines such as fungicides or bactericides appears to be possible.
- Fluid distributions within polymers.[56] The distribution of fluids such as water or solvents in polymers, and their diffusion in polymers or other materials is detectable.[57–60]
- Expansion-induced crystallization.[61] The proton relaxation times of the polymer protons is modified by this.
- Inhomogeneous temperature distributions,[62] e.g. in melts.
- Cross-linking of polymers as a function of various spatial, and relaxation-time-dependent values.[63]
- Diffusion processes from fluids into solids, and interfluid diffusion.

Figure 29 shows the interdiffusion of a water layer under a layer of isopropanol. The boundary between the liquids is clearly seen, owing to the difference in their susceptibilities.

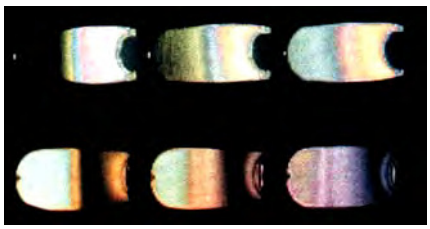

Fig. 29. Chemical shift selective spin-echo images of the interdiffusion of ethanol in water over a period of 18 h. The upper part shows the diffusion of the ethanol in water based on the protons of the methyl group; below: image of the corresponding water distribution. A gaussian RF pulse with an excitation bandwidth of ca. 700 Hz was used for the chemical shift selective excitation. The spatial resolution of the in-plane image is about 30 μm.

The difference in the susceptibilities leads to a strong local magnetic field gradient at the boundary, and hence to a dephasing of the spins. By using chemical-shift selective imaging it is possible to observe the time course of the diffusion for both fluids. The spatially resolved concentration ratio at any time may be obtained from the image profiles.

Figure 30 shows a spin-echo image with an echo-time TE = 4.5 ms of a plastic sample reinforced with fiber glass having varying water contents of between 1% and 20%. The

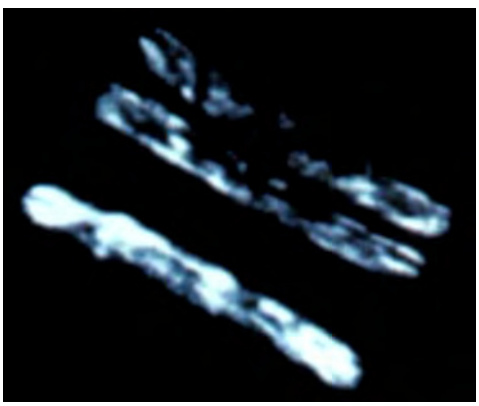

Fig. 30. Spin-echo image (20 recordings) of fiber-glass reinforced epoxy rods with water content between 1% and 20%. Pixel resolution 138 μm², slice thickness approx. 1 mm, TE = 4.5 ms, TR = 1 s.

fiber glass structures may be seen clearly. The resolution is 138 μm in the plane, with a slice thickness of about 1 mm. The images show projections of the sample in the z-direction, i.e. no slice selection was applied.

6.3. Dynamic NMR Microscopy

An interesting, novel application of NMR microscopy developed by *Callaghan* et al.[64] concerns the measurement of molecular translation. The phase shift of the NMR signal which arises when the echo being detected is preceded by a pair of intense gradient pulses separated by the phase-inverting 180° rf-pulse is used as probe. The *P*ulsed *G*radient *S*pin *E*cho[65] (PGSE) pulse sequence can be used to measure the probability $P(\boldsymbol{r}' - \boldsymbol{r}, \Delta)$, that nuclei initially at $\boldsymbol{r}$ at the first gradient pulse will move to $\boldsymbol{r}'$ at the second gradient pulse at a time Δ later. By combining PGSE and imaging methods it is possible to map $P(\boldsymbol{r}' - \boldsymbol{r}, \Delta)$ in a heterogeneous sample[64] (Fig. 31).

In the case of superposed self-diffusion and flow $P(\boldsymbol{r}' - \boldsymbol{r}, \Delta)$ is a gaussian function whose width is determined by the local molecular self-diffusion coefficient and whose center is determined by the local velocity of the particles. In the method described by *Callaghan* et al. this width and offset are computed for each pixel in the image space and thus separate maps are obtained for the molecular diffusion and the flow velocity. This dynamic imaging method has potential applications in both biological and materials science. A recent in vivo study of water transport in wheat grains has furnished valuable information about transport mechanisms and circulation pathways.[43] The diffusion constant of water was determined in vivo for various regions of the wheat grain: thus a diffusion constant D of $10^{-9}\,m^2\,s^{-1}$ was obtained for the vascular bundle and of $5 \times 10^{-10}\,m^2\,s^{-1}$ for the endosperm.

The method has also been applied to the rheological study of polymer solutions.[66] Figure 31 shows the basic Pulsed Gradient Spin Echo pulse sequence combined with an imaging sequence to obtain spatially resolved maps of diffusion processes. After slice selection the magnetization in the selected slice dephases under the influence of a very intense magnetic field gradient of a strength of several hundred Gauss/cm. Only the magnetization which is not influenced by diffusion will be completely rephased after the 180°-rf-pulse through the second intense field gradient of the same strength and duration. Spatial resolution occurs through both gradients G_x and G_y during the acquisition period. Figure 32 shows stacked profile plots for the velocity and diffusion maps of viscous polyethylene oxide solutions (PEO) flowing through a 700 μm capillary.[66] Figure 32a reproduces the behavior of a solution with low polyethylene oxide concentration (0.5%). The solution behaves as a Newtonian fluid, exhibiting the usual Poiseuille velocity profile. Figure 32b reveals that the higher concentrated polymer solution (4.5%) is non-Newtonian and behaves as a shear-thinning fluid. In the lower section of the figure there is evidence of enhanced longitudinal self diffusion in the region of higher shear rate, illustrating the ability of NMR microscopy to provide additional information at the molecular level.

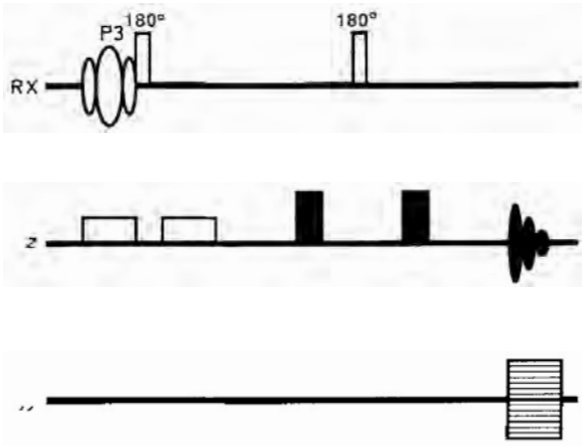

Fig. 31. Basic pulsed gradient spin-echo pulse sequence combined with an imaging sequence developed by *Callaghan* et al. [64]. After slice selection the magnetization in the selected slice dephases under the influence of a very intense magnetic field gradient (several 1000 $mT\,m^{-1}$). Only the magnetization which is not influenced by diffusion will be completely rephased after the 180° RF pulse through the second intense field gradient of the same strength and duration. Spatial resolution effected by the two orthogonal gradients G_x and G_y during the acquisition period.

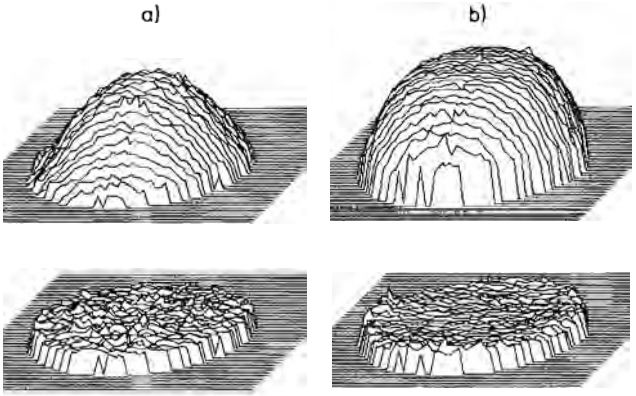

Fig. 32. Velocity map (above) and profile of the longitudinal diffusion (below) for aqueous solution of polyethylene oxide (PEO) flowing through a 700 μm I.D. teflon capillary (with kind permission of Prof. *Callaghan*). a) PEO concentration 0.5% w/v. Maximum velocity is 6.0 $mm\,s^{-1}$. The velocity profile corresponds to a power-law fluid behavior with exponent n = 1 (Newtonian fluid). b) PEO concentration 4.5%. The maximum velocity is likewise 6.0 $mm\,s^{-1}$. However, in this case, the liquid exhibits non-Newtonian behavior due to the increased shear forces at the capillary edge. The profile of the longitudinal diffusion is enlarged compared to that in Figure 32a.

7. Future Prospects

NMR microscopy is still in its early stages of development both as regards methods and apparatus. Therefore, it is not yet possible to ascertain the scope of potential applications. The use of microresonators could make possible the investigation of single cells, or of small groups of cells, enabling metabolic studies to be carried out. Resolutions of about 1 μm/pixel are conceivable. Using miniresonators it could be possible to study biopsy samples morphologically as well as biochemically, with a high spatial and spectroscopic resolution. Hence it is advantageous to work at very high field strengths: for example, 11.7 T (500 MHz)-widebore, and 14.1 T (600 MHz) magnets currently exist. In the future even stronger magnets should be available.

The use of special pulse sequences for the sensitive detection of low-concentration nuclei, such as ^{13}C in labeled substances by using polarization transfer,[67] allows the monitoring of metabolic pathways and of the distribution of metabolites by volume-selective spectroscopy. Similar information may be expected from volume-selective spectral editing as proposed by *Kimmich* et al.[68, 69]

The observation of rapid dynamic processes by application of the appropriate method (Ref. [70] and Section 3), now lies within the realm of the possible, and also allows the observation of motion without artifacts. The combination of gradients with sample rotation, as well as zero and multiquantum imaging, will make high-resolution solid-state imaging routine within the near future, allowing a new route to spatially resolved dynamic studies in solids.

For making possible the development of NMR microscopy I would like to thank Prof. G. Laukien and T. Keller (Bruker, Rheinstetten). Dr. D. Müller, Dr. Mark Mattingly and many colleagues at Bruker (Karlsruhe), Spectrospin (Zürich), and Bruker (Billerica, MA, USA) provided indispensible and encouraging assistance. I would especially like to thank Prof. Dr. K. H. Hausser and Prof. Dr. U. Haeberlen for numerous very helpful discussions and suggestions, and the following for collaborative experiments: Priv.-Doz. Dr. Dr. G. Rohr, Klinikum Mannheim der Universität Heidelberg, Dr. W. E. Hull, Deutsches Krebsforschungszentrum Heidelberg, and Prof. Dr. A. Haase, Universität Würzburg. For permission to publish the images obtained in collaborative experiments I am grateful to Prof. M. Asdente, University of Milan, Prof. U. Zimmermann, Universität Würzburg, Dr. M. Mattingly, Bruker (Billerica) and Dr. Dr. G. Rohr, Klinikum Mannheim der Universität Heidelberg.

Biologically Active Analogues of the Extracellular Matrix: Artificial Skin and Nerves

By Ioannis V. Yannas*

In memoriam Professor Piero Pino

Animal development starts as a single cell which proliferates into several new cells; these differentiate into highly specialized tissues, organs, and limbs; and the small but functioning organism eventually grows into its full scale. Throughout development the extracellular matrices, which are complex macromolecular networks, also undergo dramatic changes. Matrix transformations occasionally control the much more well-studied changes in number and type of differentiating cells. Extracellular matrix (ECM) networks are typically broken down enzymatically to oligopeptides and are then resynthesized (remodeled) to form insoluble and nondiffusible macromolecular structures which confer stability of shape to multicellular systems. Mature ECM, such as skin, tendon, cartilage, and blood vessels, provides stiffness and strength to tissues and organs. Remodeling of ECM also occurs in adult organisms, during wound healing. An understanding of the role that ECM plays during development or wound healing can be obtained by use of synthetic ECM analogues. Several simple chemical ECM analogues have been synthesized and a few have been found to possess remarkable biological activity. One of these analogues has induced the partial regeneration of skin in an adult guinea pig wound model as well as in man. Peripheral nerve has been regenerated in another animal model by use of a similar ECM analogue. In all these mammalian lesions it is well-known that regeneration does not occur spontaneously. These analogues are graft copolymers of collagen and chondroitin 6-sulfate (a glycosaminoglycan) in the state of highly hydrated and covalently cross-linked gels. Procedures are summarized for synthesis of copolymers with adjusted physicochemical properties, such as the rate at which they degrade enzymatically when implanted, the elements of their pore structure, and the degree of collagen crystallinity. ECM analogues have provided a novel window into the complexities of morphogenesis and regeneration and they have pointed towards entirely new directions in the medical treatment of serious organ dysfunction and organ loss. An ECM analogue has already become the basis of a new clinical treatment for massively burned patients. An interpretation of the results leads to a hypothesis about the nature of ECM during development. Since biological activity appears only when the physicochemical parameters fall within very narrow limits, it is intriguing to speculate that these experiments describe a single insoluble growth factor which is specific for skin synthesis. Such an insoluble growth factor appears to be just as essential to skin development as are the much more well-known soluble growth factors. A different ECM analogue appears to induce nerve regeneration, possibly because each tissue requires its own developmentally active ECM.

1. Introduction

Most tissues consist of cells and a largely insoluble, nondiffusible extracellular matrix (ECM). In multicellular systems the ECM confers stiffness, strength, and, therefore, stability of shape. Although the composition and structure of ECM varies from one tissue to the next, these matrices are typically highly hydrated macromolecular networks composed of various amounts of glycoproteins such as collagen, elastin, fibronectin, laminin, and chondronectin, as well as of glycosaminoglycans (GAG), including hyaluronic acid, chondroitin 6-sulfate, dermatan sulfate, and heparan sulfate. Glycosaminoglycans usually occur as polysaccharide chains covalently attached to a protein core (proteoglycan). Macromolecular components of the ECM are synthesized in cells and are secreted in the extracellular space where further physicochemical modification, for example, crystallization and covalent cross-linking of macromolecular chains, takes place.[1, 2]

The ECM between two cell layers of different origins is frequently referred to as a basal lamina or basement membrane, illustrated in Figure 1.[2–5] The basal lamina must play a profound role during organization of cells into functional units (morphogenesis) since its removal by selective enzymatic treatment in well-defined developmental models suppresses morphogenesis completely.[3] Throughout life, but with special urgency during development, the basal lamina is degraded, resynthesized, and degraded further as tissue remodeling occurs. Remodeling of the basal lamina is also a very active process during healing of wounds.[4] During each of these processes cells and matrix interact closely and probably iteratively. These specific interactions are being studied intensively and important advances in understanding are rapidly being made.[1, 2, 5] Nevertheless, the precise molecular mechanisms underlying critical cell–matrix or cell–cell interactions during development are not well under-

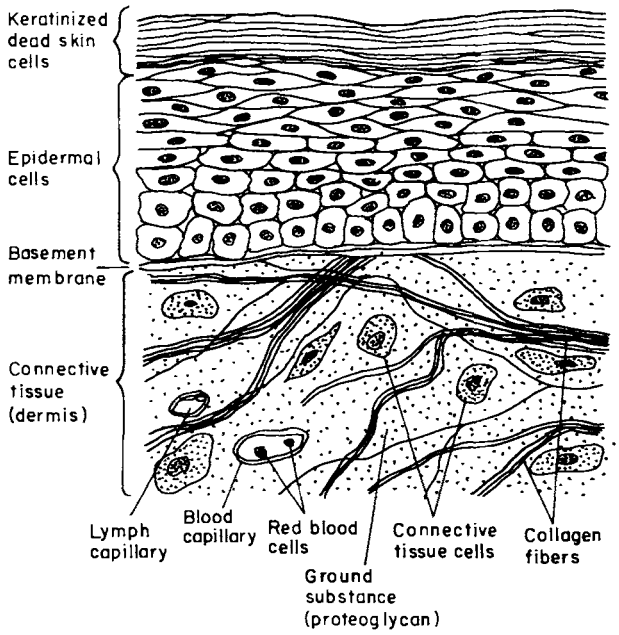

Fig. 1. A highly schematic view of skin which highlights the position of the basement membrane between the cellular epidermis and the largely noncellular dermis. The basement membrane is an extracellular matrix which typically occupies the interface between different tissues. The term basement membrane is often used interchangeably with basal lamina; however, some authors distinguish between the two terms, using each to describe a larger or smaller number of layers of interfacial matrix. (Redrawn from [97] with permission.)

stood,[3, 6] partly due to unavailability of well-defined and biologically active matrices for such investigations.[6]

Chemical analogues of the ECM provide a new probe into the complex processes of development. The analogues synthesized so far are graft copolymers of collagen and one each of several glycosaminoglycans and are, admittedly, very simple models of the chemically complex ECMs. Nevertheless, careful control of the cross-link density has yielded macromolecular networks which degrade under the action of tissue enzymes over a period that ranges from days to weeks. The essential transience of the ECM during development and wound healing can thereby be deliberately adjusted and its effect on cell–matrix and cell–cell interactions can be studied. Furthermore, control of the volume fraction of pores and of the average pore diameter has yielded gels with levels of hydration and specific surface area which extend over wide ranges. Since certain cell types interact very intimately with the surface of these ECM analogues, the opportunity presents itself to study systems in which the density of cells interacting with the matrix is varied widely.

The major constituent of these chemical ECM analogues is collagen, the fibrous protein which accounts for about one-third of the total protein in vertebrates. An unusual amino-acid composition and a characteristic wide-angle X-ray diffraction pattern distinguish collagen clearly from other tissue components.[1, 7] Various levels of structural order in collagen are illustrated in Figure 2. Collagen can be extracted from connective tissues such as cattle skin (hide) and tendon in relatively pure form and can be dispersed in aqueous acetic acid or other solvents in the form of either a solution of individual triple-helical macromolecules or a suspension of particles comprising naturally cross-linked aggregates of such macromolecules. The solid state can be recovered by either evaporation of the solvent or precipitation of the protein by use of a nonsolvent. The reconstituted collagen thereby prepared can be fashioned into membranes (films), tubes, fibers, or tape. Although collagen in the form of reconstituted membranes or sutures has been implanted surgically by several investigators since at least 1943,[8–12] the interaction between a casually reconstituted collagen and host tissue is passive and largely amounts to degradation of the triple-helical collagen molecules by collagenases secreted by cells adjacent to the implant.

By contrast with casually reconstituted collagens, the collagen analogues of the ECM described in this review interact in an active and highly specific manner with cells which migrate from adjacent tissues into the implanted analogues. The term regeneration template, or simply template, has been used to distinguish these biologically active forms of collagen.[13] Templates are recognized by their ability to induce tissue regeneration in a well-defined animal lesion (wound) for which it has been previously demonstrated that regeneration does not occur spontaneously. At least five physicochemical features distinguish templates from biologically inactive collagens, namely, the chemical composition of the macromolecular network (collagen/GAG ratio), the density of cross-links between the macromolecules, the average diameter of pores in the range 1–1000 μm, the fraction of collagen which is present in a highly crystalline (banded) form, and the volume fraction of water. The first three of these parameters have been studied rather assiduously. In addition, templates may be seeded with cells prior to implantation, a procedure which has been found to affect their

Ioannis V. Yannas studied chemistry at Harvard College, Cambridge, MA (BA, 1957). He then studied chemical engineering at the Massachusetts Institute of Technology (MIT), Cambridge (MS, 1959) and physical chemistry at Princeton University, Princeton, NJ (MS, 1965; PhD, 1966). Since 1966, he has been on the faculty of MIT and currently teaches graduate courses on deformation of polymers and on physical properties of biological polymers. His primary research activities have focused on the design of medical devices based on natural polymers, such as the design of an artificial skin for the treatment of burn patients and the design of a nerve prosthesis. Currently, he is focusing on the synthesis of physicochemical analogues of the extracellular matrix for the study of tissue regeneration in mammals. Prof. Yannas has authored or co-authored over 130 publications and has been granted 10 patents. He was elected member of the Institute of Medicine of the National Academy of Sciences (USA). He has received awards for his synthesis of an artificial skin from the American Chemical Society, Society for Biomaterials, and the Society of Plastics Engineers.

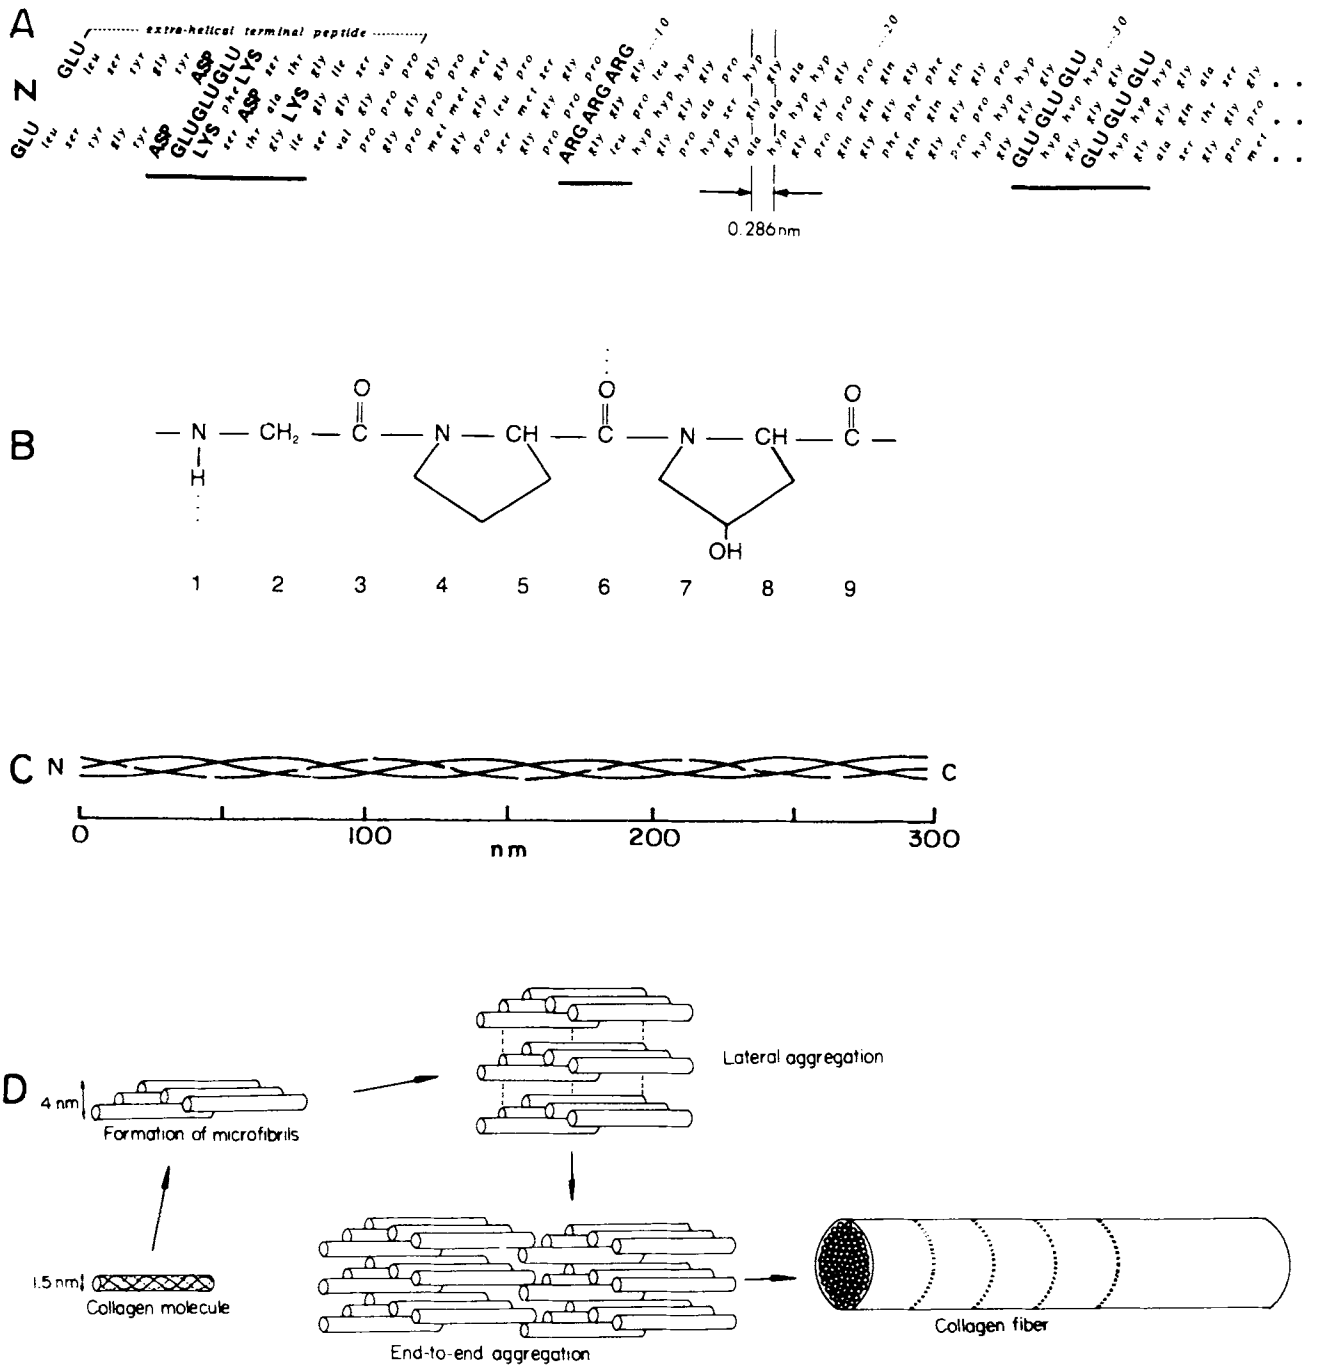

Fig. 2. Collagen, like other proteins, is distinguished by several levels of structural order. A: Primary structure—the complete sequence of amino acids along each polypeptide chain. An example is the triple chain sequence of type-I calf-skin collagen at the *N*-terminus of the molecule. Roughly 5% of a complete molecule is shown. No attempt has been made to indicate the coiling of the chains. Amino-acid residues participating in the triple helix are numbered, and the residue-to-residue spacing (0.286 nm) is shown as a constant within the triple-helical domain, but not outside it. Bold capitals indicate charged residues which occur in groups (underlined). (Reprinted from [98] with permission.) B: Secondary structure—the local configuration of a polypeptide chain. The triplet sequence Gly-Pro-Hyp illustrates elements of collagen triple-helix stabilization. The numbers identify peptide backbone atoms. The conformation is determined by *trans* peptide bonds (3 ---4, 6---7, and 9---1), fixed rotation angle of bond in proline ring (4---5), limited rotation of proline past the C=O group (bond 5---6), interchain hydrogen bonds (dots) involving the NH hydrogen at position 1 and the C=O at position 6 in adjacent chains, and the hydroxyl group of hydroxyproline, possibly through water-bridged hydrogen bonds. (Reprinted from [99] with permission.) C: Tertiary structure—the global configuration of polypeptide chains, representing the pattern according to which the secondary structures are packed together within the unit substructure. A schematic view of the type-I collagen molecule, a triple helix 300 nm long. (Reprinted from [100] with permission.) D: Quaternary structure—the unit supramolecular structure. The most widely accepted unit is one involving five collagen molecules (microfibril). Several microfibrils aggregate end to end and also laterally to form a collagen fiber, which exhibits a regular banding pattern under the electron microscope with a period of 65 nm. (Reprinted from [101] with permission.)

biological activity equally as strongly as do physicochemical manipulations.

Tissue, organ, and limb regeneration occur quite differently in various species. In amphibians, such as the salamander and the immature frog (tadpole), an entire amputated limb can be regenerated.[14] At the other extreme, spontaneous regeneration of most tissues in adult mammals is not observed.[15, 16] For example, the epidermis (the outer tissue layer of skin; cf. Fig. 1) is regenerated in adult mammals provided there is an underlying bed of dermis (the inner

layer). On the other hand, spontaneous regeneration of the dermis does not occur;[17, 18] instead, synthesis of nonphysiological connective tissue (scar) takes place. Likewise, peripheral nerves of mammals, such as the sciatic nerve in the rat, do not regenerate sufficiently well to bridge 15-mm-long gaps between the two cut stumps; a nonphysiological tissue (neuroma) is instead synthesized at the end of each stump.[19, 20]

The macromolecular matrices discussed below modify strongly the kinetics and mechanism of the wound healing process in certain adult mammalian species, including man. One of these has suppressed scar synthesis and has induced almost total synthesis of dermis in the guinea pig and in man. A similar matrix has induced synthesis of sciatic nerve in the rat over a 15-mm-long gap. Both are copolymers formed by chemically grafting chains of chondroitin 6-sulfate onto collagen fibers. Following nomenclature recommended by IUPAC,[21] these polymers have been referred to as collagen-*graft*-chondroitin 6-sulfate copolymers, or generically, as collagen-*graft*-glycosaminoglycan copolymers, or briefly, as CG copolymers. Since the biological activity is dependent on their ultrastructure, we will use the term copolymer matrix to denote the porous, hydrated, insoluble gel which results following physical processing of the copolymer. Implant refers to the sterile surgical device which is grafted at the site of the lesion.

This review surveys the coupling between the physicochemical features of CG copolymer matrices and the results of biological assays which are related, directly or indirectly, to regeneration. These connections show that very few copolymer matrices with narrowly defined structure act as if they are developmentally active ECM analogues. Several implications of such analogy in the study of development and in the experimental treatment of tissue loss are briefly discussed.

2. Synthesis of Collagen–GAG Graft Copolymers

Regeneration templates have so far been based on the family of collagen–GAG copolymers. Glycosaminoglycans that have been grafted onto collagen include chondroitin 6-sulfate, chondroitin 4-sulfate, heparan sulfate, heparin, dermatan sulfate, and keratan sulfate.[21, 22] Of these, chondroitin 6-sulfate is the member that has been studied most assiduously and the data presented in this review are based on collagen-*graft*-chondroitin 6-sulfate copolymers. There is currently no evidence in the literature which suggests that this composition is uniquely suited for biological activity; the original choice of this GAG, as well as of the predominantly type-I collagen extracted from bovine hide, was largely dictated by their availability in large enough quantity from suppliers in the early 1970s, when these copolymers were first synthesized.[22]

In fact, basal lamina, the particular ECM whose biological activity appears to be mimicked by collagen–GAG templates, has a chemically distinct composition,[23–27] consisting primarily of the following macromolecular species: collagen type IV, with a unique amino-acid composition, a highly flexible macromolecular configuration which is a collagen triple helix only in relatively small part, and an ultrastructure which does not consist of collagen-type fibrils but which rather strongly resembles a threadlike, open network or a scaffold;[24, 25, 27] three glycoproteins, namely, laminin, entactin, and fibronectin; and heparan sulfate, a GAG which is part of a proteoglycan.[24, 26] Future studies of developmental events could be profitably based on synthesis of a chemical analogue of the basement membrane which closely simulates the currently recognized composition of this specialized tissue.

The evidence obtained so far has shown clearly that significant, and apparently unprecedented, regeneration of dermis and peripheral nerve has been induced by the chemically far simpler, well-defined collagen–GAG copolymers described below. The choice of a rudimentary chemistry, although providing only a very rough model of the naturally occurring extracellular matrix, has made it possible to focus attention on the physical aspects of matrix structure. Specifically, the pore structure, the macromolecular network structure, and the fractional crystallinity have been deliberately varied and have been recognized as essential components of the observed biological activity of these templates.

Grafting of GAG chains onto collagen is conveniently carried out by first forming a coprecipitate of collagen and GAG and then treating this condensed state under conditions which favor formation of covalent bonds between the two macromolecules. Coprecipitation requires the presence of sulfate groups on the GAG and an acidic pH.[28] Hyaluronic acid, the only GAG which is nonsulfated, does not precipitate collagen out of solution.[28] Every one of the other members of this family of polysaccharides does cause precipitation; however, the precipitates formed in aqueous acetic acid readily dissolve when the pH is adjusted to neutrality.[28] The precipitate is an ionic complex probably formed by interaction between the anionic sulfate groups of the GAG and the amino groups in collagen, which are positively charged at acidic pH.[28–30]

Collagen–GAG coprecipitates can be made insoluble without use of a chemical cross-linking agent simply by drastic dehydration. This procedure is based on the discovery that removal of water below ca. 1 wt.% insolubilizes collagen; gelatin, the totally amorphous state of collagen, also requires drastic dehydration in order to become insoluble.[31, 32] The nature of cross-links formed can be inferred from results of earlier, independent studies using chemically modified gelatins. Gelatin that had been modified either by esterification of the carboxylic groups of aspartyl/glutamyl residues or by acetylation of the ε-amino groups of lysyl residues remained soluble in aqueous solvents after exposure of the solid protein to high temperature, whereas unmodified gelatins lost their solubility.[33] Insolubilization of collagen and gelatin following severe dehydration has been, accordingly, interpreted as the result of drastic removal of the aqueous product of a condensation reaction which led to formation of interchain amide links.[31] The proposed mechanism was consistent with results, obtained by titration, showing that the number of free carboxylic groups and free amino groups in collagen were both significantly decreased following high-temperature treatment.[34, 35]

Removal of water to the extent necessary to achieve a density of cross-links in excess of 10^{-5} moles of cross-links per gram of dry gelatin, corresponding to an average molec-

ular weight between cross-links, M_c, of about 70 kDa, was achieved within hours by exposure to temperatures in excess of 105 °C under atmospheric pressure.[36] The possibility that the cross-linking achieved under these conditions was caused by a pyrolytic reaction was ruled out on the basis of calorimetric data.[37] Furthermore, chromatographic data showed that the amino-acid composition of collagen remained intact after exposure to 105 °C for several days.[38,39] In fact, it was observed that the gelatin can be cross-linked by exposure to temperatures as low as 25 °C provided that a sufficiently high vacuum was present to achieve the drastic moisture removal which drives the reaction.[31]

Exposure of highly hydrated collagen to temperatures in excess of ca. 37 °C is known to cause reversible melting of the triple-helical structure.[40] The melting point increases with the collagen–diluent ratio from 37 °C, the helix–coil transition of the infinitely dilute solution, to ca. 120 °C for collagen swollen with as little as 20 wt% diluent[40] and up to ca. 210 °C, the melting point of anhydrous collagen.[32] Accordingly, it is possible to cross-link collagen using the drastic dehydration procedure described above without loss of the triple-helical structure. It is simply necessary to adjust the moisture content of collagen to a level sufficiently low to prevent melting prior to exposure to the high temperatures required for rapid dehydration. Conservation of the triple helix following prolonged exposure of solid, anhydrous collagen to 105 °C has been confirmed by wide-angle X-ray diffraction and IR spectroscopy as well as by measurement of the components of the optical activity tensor.[32,38]

The simple self-cross-linking treatment also cross-links GAG chains to collagen.[41] The reaction kinetics are outlined in Figure 3. The mechanism probably involves condensation of amino groups of collagen with carboxylic groups of glucuronic acid residues on the repeat unit of chondroitin 6-sulfate (Scheme 1), an alternating copolymer of D-glucuronic acid and an *O*-sulfate derivative of *N*-acetyl-D-galactosamine.[28]

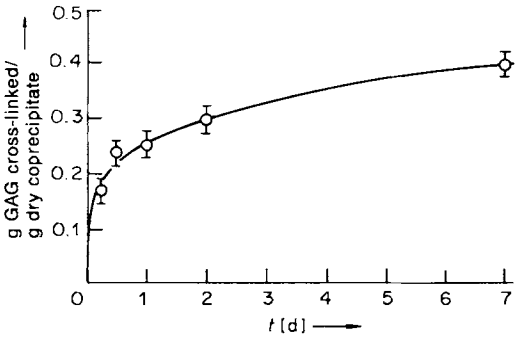

Fig. 3. Kinetics of cross-linking of chondroitin 6-sulfate, a glycosaminoglycan, to collagen following heating at 105 °C under 6.7 Pa (0.050 Torr). The mechanism of cross-linking is most probably interchain amide condensation involving ε-amino groups of lysyl residues on collagen chains with carboxylic groups on glucuronic acid residues in neighboring GAG chains. (Reprinted from [41] with permission.)

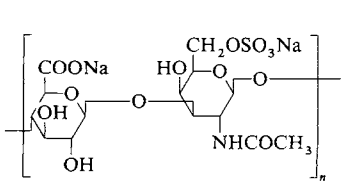
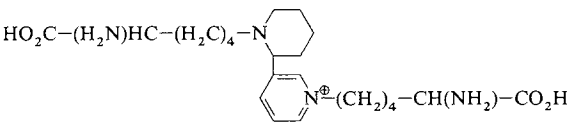


Scheme 1. Sodium chondroitin 6-sulfate.

Dehydration treatment cross-links as much as 40% of the GAG originally coprecipitated with collagen. Relative amounts of at least 10 wt% GAG (total dry copolymer basis) can be covalently bound to collagen and M_c can be varied in the range 2.5–25 kDa.[41] Proof of formation of a macroscopic network is based on inability to extract GAG from collagen under conditions of temperature and ionic strength where GAG separates readily and quantitatively from the coprecipitate.[41] Independent evidence of covalent cross-linking derives from the ability of the network to support an equilibrium tensile force under conditions where the network behaves as an ideal rubber and from the equilibrium swelling behavior (see below).[41]

Dialdehydes have been long known in the leather industry as effective tanning agents[42,43] and in histological laboratories as useful fixatives.[44] Both of these applications are based on the reaction between the dialdehyde and the ε-amino group of lysyl residues in the protein, which induces formation of interchain cross-links.[45–47] The nature of the cross-link formed has been the subject of controversy, primarily due to the complex, apparently polymeric, character of the glutaraldehyde reagent. Considerable evidence supports the proposed anabilysine structure, derived from two lysine side chains and two molecules of glutaraldehyde (Scheme 2).[47]



Scheme 2.

Evidence for other mechanisms has been presented.[48] By comparison with other aldehydes, glutaraldehyde has shown itself to be a particularly effective cross-linking agent,[42,43] as judged, for example, by its ability to decrease the average molecular weight between cross-links, M_c.[49] A wide range of M_c values provides the experimenter with a series of collagens in which the enzymatic degradation rate can be studied over a wide range, thereby affording implants which effectively disappear from the tissue between a few days and several weeks following implantation. Such experimental flexibility is indispensable in efforts to establish, by scanning over the experimental range, whether a threshold degradation rate exists below which the implant exhibits biological activity. Scanning is particularly useful in studies which involve an "unknown" animal lesion, that is, one which involves a different animal species or a wound on a different tissue site of a given species. Exposure of the collagen–GAG coprecipitate to aqueous glutaraldehyde in a neutral medium destabilizes the ionic macromolecular complex and the yield of graft copolymer is accordingly very low.[41] Destabilization of the complex and correspondingly low yields of graft copolymer also occur when the ionic strength of the aqueous medium exceeds about 0.25.[41] Up to about 3 wt% GAG (dry copolymer basis) can be incorporated at pH 3 and physiological ionic strength (0.15).[41] By controlling the source of collagen, glutaraldehyde concentration, and time of expo-

sure, networks with M_c in the range 5–40 kDa can be prepared.[41]

Although the mechanism of the reaction between glutaraldehyde and collagen at neutral pH is understood in part, the reaction in acidic media has not been studied extensively. There is little doubt that covalent cross-linking is involved, since gelatin films prepared from collagen that has been previously exposed to glutaraldehyde support an equilibrium force almost indefinitely when stretched in 1 M NaCl at 70 °C to various levels of extension;[41, 49] by contrast, gelatin prepared from untreated collagen dissolves readily in the hot medium. Likewise, little is known about the mechanism by which GAG chains attach themselves tenaciously to collagen following treatment of the coprecipitate in glutaraldehyde. What is clear is that a gelatin–GAG complex prepared from a collagen–GAG coprecipitate that was treated in aqueous acidic glutaraldehyde successfully resists elution of the attached GAG under conditions (3-h immersion in 1 M NaCl at 70 °C) where the untreated gelatin separates from the attached GAG in just seconds.[41] Additional evidence that glutaraldehyde-treated collagen–GAG coprecipitates have been converted into covalently cross-linked networks is based on the ability of their gelatinized states to support equilibrium tensile forces.[41]

Current preparation procedures for collagen–GAG copolymers make use both of drastic dehydration and glutaraldehyde treatments for reasons that are related to the requirements for a biologically active implant. Dehydration of the highly porous solid produced by freeze-drying (see below) stiffens the coprecipitate by introducing cross-links, thereby preventing pore collapse following prolonged exposure of the foam to ambient humidity. Pore collapse leads to irreversible loss of the high specific surface of the implant and results in complete loss of biological activity. In addition, both drastic dehydration and exposure to glutaraldehyde are, each in its own right and for reasons related to the protein cross-linking reaction which is promoted, efficient procedures for sterilization of the copolymer prior to implantation.[41] Both of these treatments have been used to prepare a medical device, occasionally referred to as artificial skin or artificial dermis, which has been used to treat successfully over 100 massively burned patients without clinical evidence of toxicity.[50, 51] Dehydration cross-linking, which amounts to self-cross-linking as described above, obviously does not lend toxicity to these implants. Glutaraldehyde, on the other hand, is a toxic substance and devices treated with it require thorough rinsing before use. Additional steps are occasionally followed, such as storage of the implant in media that react with residual reagent.[49]

3. Physicochemical Processing and Characterization of Copolymer Matrices

Although the chemical identity of collagen–GAG copolymers is a necessary element of their biological activity, it is not a sufficient one. In addition to chemical composition and cross-link density, biological activity also depends strongly on the degree of copolymer crystallinity and on the porous structure of these matrices. It is interesting to consider physicochemical methods for preparing and characterizing solids which are (1) primarily noncrystalline and cannot, therefore, be analyzed adequately using X-ray crystallography, (2) totally insoluble in all solvents and cannot be characterized by measurement of colligative or transport properties in states of infinite dilution, and (3) physically heterogeneous (porous) states, which are not completely defined unless detailed reference is made to the scale of heterogeneity and to the specific surface involved.

Network properties of cross-linked collagen–GAG copolymers can be analyzed structurally by methods based on the theory of rubber elasticity. If it can be demonstrated that the equilibrium force supported by a rubber is almost entirely entropic in origin and that, consequently, energetic interactions can be neglected by comparison, it is possible to compute directly the cross-link density of the network from measurements of the equilibrium modulus.[52] Collagen specimens with a high fraction of crystallinity, such as films cast at room temperature from a neutral buffer or naturally occurring tendon fibers, must be converted into gelatin before they show rubberlike elastic behavior.[53] Insoluble collagen that has been converted into gelatin by immersion in physiological saline between 65 and 80 °C for 1 h displays a resistance to uniaxial stretching (tensile modulus) which is directly proportional to the density of cross-links c (moles of cross-links per gram of dry polymer) and inversely proportional to M_c.[41, 49, 53] Collagen–GAG copolymers show similar behavior provided that the collagen is maintained in a gelatinized condition during measurement.[41, 49] These relationships demonstrate that, unlike collagen, cross-linked and swollen gelatin is a network in which the chains are random coils.[54] Below about 65 °C recrystallization of gelatin occurs, leading to development of significant energetic interactions and these relationships fail.[49] In the range of applicability of the ideal rubberlike model, the constitutive relation (1)[52, 55] describes the tensile behavior of appropriately gelatinized collagen[53] and collagen–GAG copolymers.[41, 49]

$$\sigma = (\varrho R T/M_c) V_2^{1/3} (\alpha - 1/\alpha^2) \quad (1)$$

In Equation (1), σ is the equilibrium stress (Nm^{-2}) supported by the swollen specimen; α is the stretched specimen length divided by the unstretched length (extension ratio); V_2 is the volume fraction of dry protein; and ϱ is the density of dry protein. The hypothesis that a specimen behaves as if it were an ideal rubber can be confirmed by observing a linear relation with zero intercept between σ and the strain function $(\alpha - 1/\alpha^2)$ and by establishing a direct proportionality between σ and the absolute temperature at constant value of the extension ratio, as stipulated by Equation (1).

When a sample is smaller than about 1 cm it becomes impractical to use tensile measurements to study network structure. The swelling behavior of small specimens can be used in such cases to calculate M_c. The method is based on the theory of *Flory* and *Rehner*,[55, 56] who showed that the volume fraction of a swollen polymer, V_2, depends on M_c through Equation (2).

$$\ln(1 - V_2) + V_2 + \chi V_2 - (\varrho V_{mol\,1}/M_c)(V_2^{1/3} - V_2/2) = 0 \quad (2)$$

In Equation (2) $V_{mol\,1}$ is the molar volume of the solvent, ϱ is the density of the polymer, and χ is a constant character-

istic of a specific polymer–solvent pair at a particular temperature. Although independent methods for estimating χ have been described,[55] it is possible to obtain M_c from tensile measurements for a given polymer–solvent system and use it to compute a single value of χ for a large number of network variants that can be prepared from the same polymer or copolymer. Equation (2) holds under conditions where the network behaves as an ideal rubber. The use of Equation (2) is illustrated in Figure 4. Values of M_c comput-

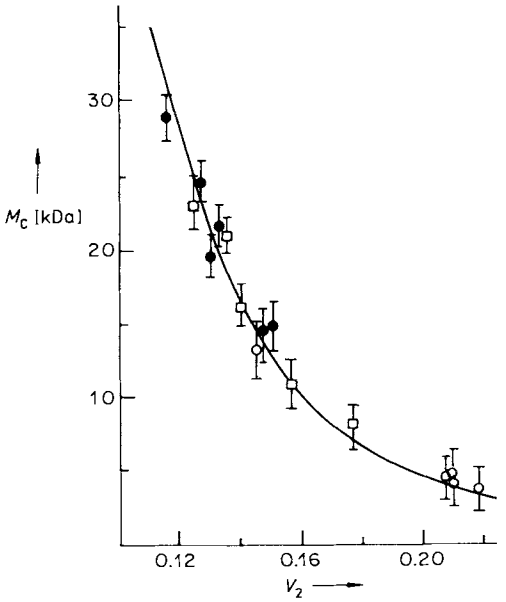


Fig. 4. Relation between the average molecular weight between cross-links, M_c, and the volume fraction of gelatinized collagen (gelatin), V_2. The swelling agent is 0.19 M citric acid/phosphate buffer solution, pH 7.4 at 80 °C. Experimental data obtained after cross-linking with various aldehydes: ●, formaldehyde; ○, glutaraldehyde; □, glyoxal. The curve is predicted by Equation (2) with $\chi = 0.52 \pm 0.04$. (Redrawn from [49] with permission.)

ed by use of Equation (1) or (2) provide insight into the structure of the network. For example, since the average molecular weight of an amino-acid residue in collagen is about 93,[57] an M_c value of 14 kDa corresponds to a not very tightly cross-linked network with an average network chain of approximately 151 amino acids. Amino-acid analysis of naturally occurring collagen from tendon yields about 27 mol% lysyl residues;[57] on the average, therefore, a lysyl residue occurs once every 37 residues. If we make the assumption, justified above, that glutaraldehyde attacks only lysyl residues, we conclude that an M_c value of 14 kDa implies that very roughly only 25% of the available ε-amino groups have reacted.

Structural order in collagen, as in other proteins, occurs at several discrete levels of the structural hierarchy. We follow below the nomenclature proposed by *Linderstrøm-Lang*[58] and *Kauzmann*[59] to describe generally structural order in proteins and we apply it to the structure of collagen[32] (Fig. 2). The *primary structure* of collagen is the complete sequence of amino acids along each of three polypeptide chains as well as the location of interchain cross-links in relation to this sequence. The *secondary structure* is the local configuration of a polypeptide chain that results from satisfaction of stereochemical angles and hydrogen-bonding potential of peptide residues. The *tertiary structure* refers to the global configuration of polypeptide chains; it represents the pattern according to which the secondary structures are packed together within the collagen molecule and it constitutes the unit substructure that can exist as a stable entity in solution (the triple-helical molecule). The fourth order or *quaternary structure* denotes the unit supermolecular structure, comprising several molecules packed in a specific lattice, which constitutes the basic element of the solid state. Higher levels of order, eventually leading to gross anatomical features which can be readily seen with the naked eye, have been proposed.[60, 61]

Crystallinity in collagen can be detected at two discrete levels of structural order: the tertiary (triple helix) (cf. Fig. 2C) and the quaternary (lattice of triple helices) (cf. Fig. 2D). Biochemists have used optical rotation, circular dichroism and viscometry as reliable methods of detecting in solution the conversion of triple-helical collagen to randomly coiled gelatin;[54] however, the use of optical methods to analyze the gelatin content of solid specimens, such as films cast from solution, has been complicated partly because of the optically anisotropic character of the solid state of this protein. Procedures for the quantitative analysis of collagen and gelatin in solid specimens that are imperfectly crystalline have been developed in order to study the substantial increase in enzymatic degradation rate which is observed when collagen is converted into gelatin.[62, 63] The presence of an intact tertiary structure (triple helix) can be detected in the

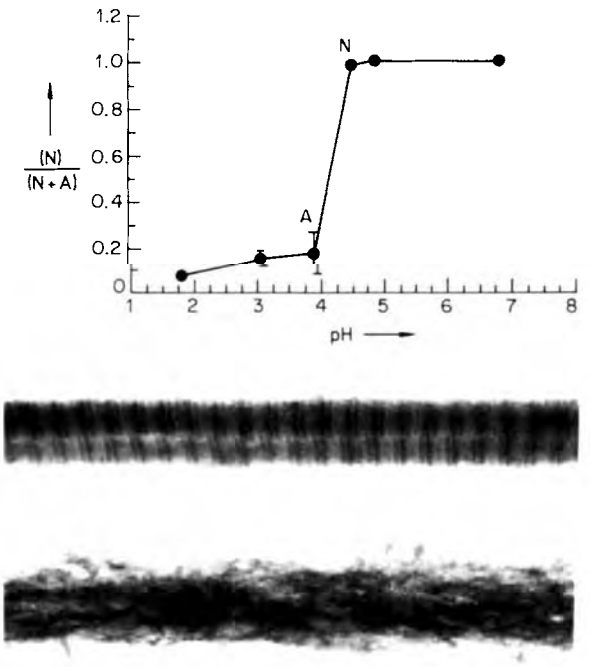

Fig. 5. The banding pattern of collagen fibers from bovine hide persists down to pH 4.25 ± 0.30 in 0.05 M acetic acid (N). The period is 65 nm. The fraction of banded fibrils $\frac{(N)}{(N+A)}$ was determined by transmission electron microscopy. Below pH 4.25 ± 0.30 the banding disappears from almost all fibers while the fiber diameter increases, indicative of swelling in the aqueous acetic acid diluent. Electron microscopy shows that a small fraction of banded fibrils, about 10% or less, persist below the transition even after long exposure to the swelling medium. The transformation abolishes the quaternary structure (packing order of helices, Fig. 2D) but leaves the tertiary structure (triple helix, Fig. 2C) intact. While banded collagen aggregates blood platelets, nonbanded collagen does not. Collagen periodicity, 65 nm. (Reprinted from [70] and [71] with permission.)

solid state by mid- and far-IR spectroscopy using "helical marker" bands which provide a quantitative measure of the extent to which a given collagen preparation has been converted into gelatin.[32, 64] Measurements of optical rotation with solid specimens also yield a quantitative analysis of gelatin in solid specimens, provided that the tensorial character of optical activity is taken into consideration and corrections are also made to account for the frequent presence of birefringence in collagen specimens.[65]

Electron microscopy has yielded the periodic banding pattern of collagen fibrils[66 - 69] and can also be used to provide a quantitative estimate of the length-average fraction of fibrils which possess discernible banding in a preparation of collagen fibrils.[70, 71] This morphological procedure can be supplemented with measurements of small-angle X-ray scattering.[72] Use of these procedures has led to the finding that the well-known loss of banding pattern that collagen fibrils undergo in aqueous acetic acid occurs relatively sharply at pH 4.25 ± 0.30 (Fig. 5).[71] Combined use of electron microscopy and IR spectroscopy showed that this transition amounts to disordering of the lattice but not to loss of the triple-helical structure.[71] Changes in pH can therefore be used to abolish selectively the quaternary structure while maintaining the tertiary structure intact. This experimental strategy has made it possible to show that the well-known phenomenon of blood platelet aggregation by collagen fibers is a specific property of the quaternary, rather than tertiary, structure.[71] Collagen has been prepared in a "thrombore-sistant" form, therefore, by selectively "melting out" the packing order of helices while preserving the helices intact.[71] Figure 6 illustrates the banding pattern observed with collagen–GAG copolymer matrices. Notice that short segments of banded collagen fibrils occasionally interrupt long segments of nonbanded fibrils (Fig. 6, inset).

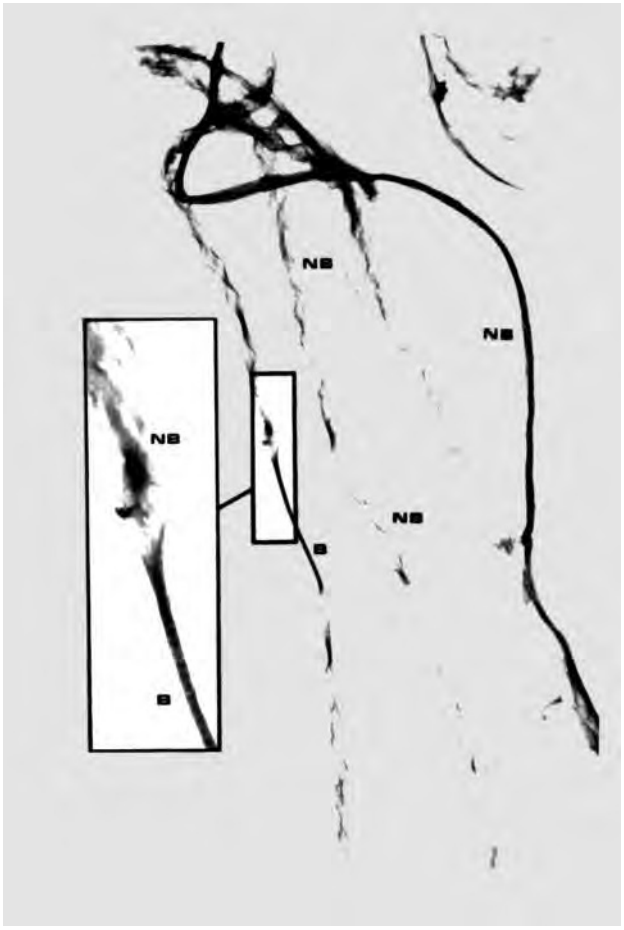

Fig. 6. Following exposure to pH below 4.25 ± 0.30, the banding pattern of type-I bovine-hide collagen practically disappears. Short lengths of banded collagen (B) do, however, persist next to very long lengths of nonbanded collagen (NB), which has tertiary but not quaternary structure. This preparation does not induce platelet aggregation provided that the fibers are prevented from recrystallizing to form banded structures when the pH is adjusted to neutral in order to perform the platelet assay. Stained with 0.5 wt% phosphotungstic acid. Banded collagen period, about 65 nm. (Reprinted from [70] with permission.)

The porosity of a collagen–GAG copolymer is an indispensable component of its biological activity.[73] Pores are incorporated by first freezing a very dilute suspension of the collagen–GAG coprecipitate and then inducing sublimation of the ice crystals by exposing the frozen suspension to vacuum at low temperatures.[74] The resulting pore structure is, therefore, a negative replica of the network of ice crystals (dendrites). It follows that control of the conditions of ice-crystal nucleation and growth can lead to a large variety of pore structures. In practice, the average pore diameter decreases with decreasing temperature of freezing, while the orientation of pore-channel axes also depends on the magnitude of the heat-flux vector during freezing. In experimental implants the mean pore diameter has ranged between about 1 and 800 μm, volume fractions have ranged up to about 0.995, the specific surface has been varied between about 10^4 and 10^8 mm^2 per gram of matrix, and the orientation of pore-channel axes in cylindrical implants has ranged from strongly uniaxial to random to highly radial. Figure 7 illustrates the range of porous structures that can be made accessible by control of the kinetics of ice nucleation and crystal growth as well as control of the heat-flux vector.

The biological activity of collagen–GAG copolymers depends generally on the structure of the porous matrix, that is, on the volume fraction, specific surface, mean pore size, and orientation of pores in the matrix. Determination of these properties is based on principles of stereology,[75, 76] the discipline which relates the quantitative statistical properties of three-dimensional structures to those of their two-dimensional sections or projections. In reverse, stereological procedures allow reconstruction of certain aspects of three-dimensional objects from a quantitative analysis of planar images.[76] Semi-automated or fully automated apparatus for quantitative image analysis has greatly facilitated stereological measurements. A plane that goes through the two-phase structure may be sampled by random points (Fig. 8A), by a regular pattern of points (Fig. 8B), by a near-total sampling using a very dense array of points (Fig. 8C), or by arranging the sampling points to form a continuous line (Fig. 8D). It can be shown[75, 76] that the volume fraction of pores, V_V, is equal to the fraction of total test points which fall inside pore regions, P_P, also equal to the total area fraction of pores, A_A (Fig. 8C), or, finally, the line fraction of pores, L_L, for a linear point array in the limit of infinitely close point spacing (Fig. 8D) [Eq. (3)].

$$V_V = P_P = A_A = L_L \tag{3}$$

The sampling methods illustrated in Figure 8 are the basis of all operations in stereology and are referred to as point counting (Fig. 8A, B), areal analysis (Fig. 8C), and lineal

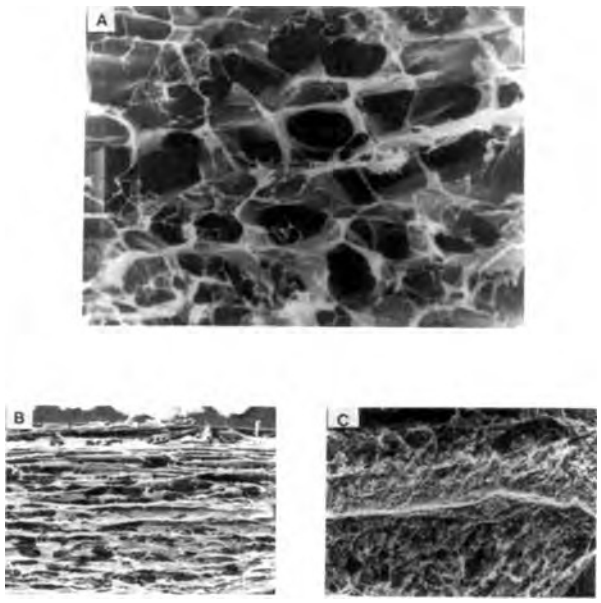

Fig. 7. Porous structures which can be obtained with collagen–GAG copolymers by adjusting the kinetics of crystallization of ice to the appropriate magnitude and direction (scanning electron microscopy). Pores form when the ice dendrites are eventually sublimed. The porous structure of collagen–GAG matrices is the negative replica of the ice-crystal structure which is formed when the dilute suspension of collagen–GAG coprecipitate particles is quenched below 0 °C. A: The orientation of pore-channel axes shown in this view is random and characterizes matrices which have induced skin regeneration. Average pore diameter, about 100 μm; pore volume fraction, about 0.99. B: Strong uniaxial orientation of pore-channel axes is shown in this cross-section of a 1.5-mm diameter cylindrical matrix which was used to induce regeneration of rat sciatic nerve across a gap. Average pore diameter, about 100 μm. C: Radial orientation of pore-channel axes yields an implant which induced synthesis of a sciatic nerve regenerate that was much less functional than when the orientation was uniaxial. Cylinder diameter: 1.5 mm. Average pore diameter, about 50 μm. (Courtesy of Massachusetts Institute of Technology.)

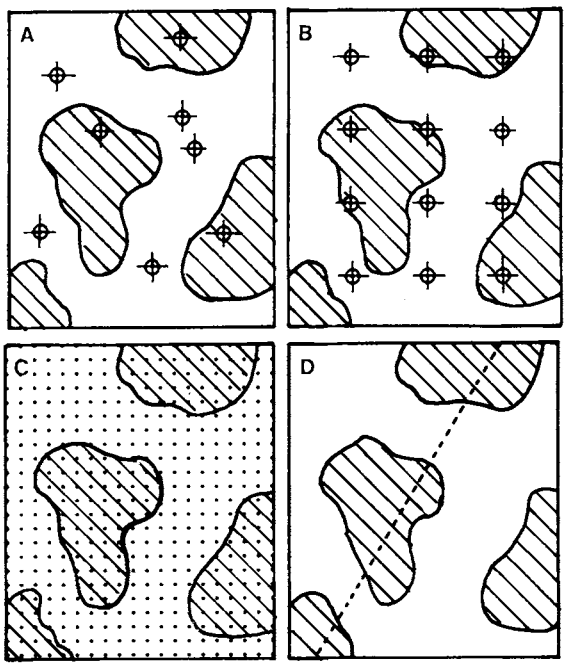

Fig. 8. Schematic representation of four procedures commonly used to sample a field in stereological analysis. These procedures have been used to study the porous structure of collagen–GAG matrices [74] and yield values for average pore diameter, pore volume fraction, and other features. In this illustration, a phase A (cross-hatched) is embedded in a continuous phase B (white background). A: Random point count. B: Systematic point count. C: Areal analysis. D: Lineal analysis. analysis (Fig. 8D). Clearly, randomness in the selection of a sampling procedure is of critical importance. Nearly complete characterization of the details of pore structure in collagen–GAG matrices has been obtained by systematic use of these procedures.[74]

4. Biological Activity and Matrix Structure

"Biological activity" is defined in a highly operational manner. Definitions are necessarily couched in terms of a highly specific assay, itself defined strictly in operational terms. Studies with collagen–GAG matrices have focused on regeneration of specific tissues which are well-known not to regenerate spontaneously. The problem, therefore, is one of constructing assays to study the effect of certain structural features of collagen–GAG matrices on the de novo synthesis of a given tissue. This problem appears on the surface to be somewhat analogous to the search for experimental strategies to study the effect of a family of heterogeneous catalysts on the yield of a macromolecular product in a well-defined reactor.

The activity of regeneration matrices has been studied in two relatively well established environments: the full-thickness, excised skin wound in the guinea pig and in man;[17, 18] and the 10-mm, as well as the 15-mm, transected gap in the sciatic nerve of the rat.[19, 20] Both of these "reactors" are wounds produced by a routine surgical procedure and in both cases the "kinetics" and the "mechanism" of the normal wound healing "reaction" have been studied rather extensively. Normal healing of a full-thickness skin wound is characterized by contraction of the wound perimeter toward the wound interior, which begins within several hours after the skin has been excised. It is considered to be over when contraction has ceased, roughly after 2 weeks, and scar tissue has been synthesized (Fig. 9A).[17, 18] Scar is distinctly different from normal skin in several ultrastructural features as well as in its optical and mechanical properties. Healing of transected sciatic nerve occurs by formation of a neuroma at each of the two cut ends (Fig. 10).[19, 20] This haphazardly growing tissue fails to reconnect with the opposite side and the result is paralysis.

The most obvious difference between a regeneration matrix and a catalyst is that the former is consumed during the course of the reaction. Implanted collagen–GAG matrices are degraded by collagenases,[77, 78] specific enzymes which attack the triple-helical molecule at one specific locus. Two characteristic products result: the *N*-terminal three-quarter fragment and the *C*-terminal one-quarter fragment, both of which are spontaneously denatured to gelatin at physiological temperatures.[77] The gelatinized fragments are then cleaved by several nonspecific proteases. Collagenases are naturally present in healing wounds and are credited with the degradation of collagen fibers at the site of trauma. At about the same time that degradation of collagen and of other ECM components proceeds in the "woundbed" these components are being synthesized by cells in the woundbed. The combined process is referred to as remodeling.[2–4] The balance between the rates of the two processes has been frequently considered to be an important feature of wound healing.[79–81]

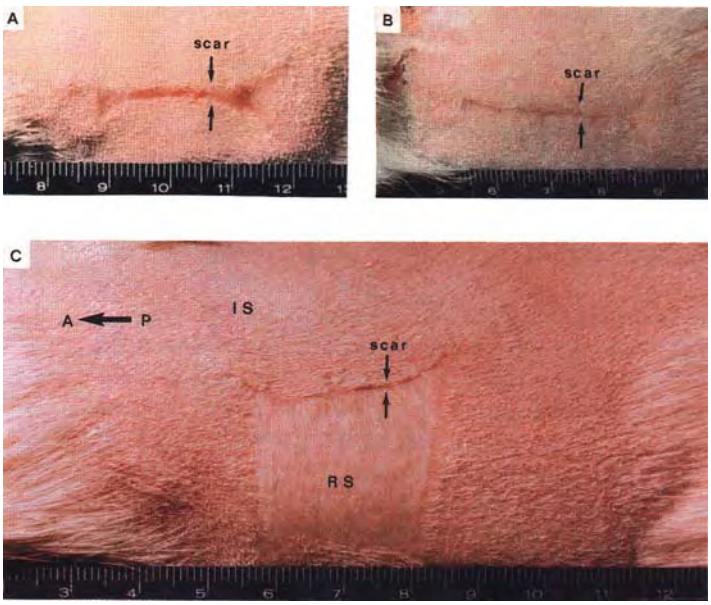

Fig. 9. The end result from healing of a full-thickness guinea pig skin wound which was treated in various ways. A: Untreated skin wound closes by contraction in about 20 days, forming a "linear scar" (arrow). Fifty percent of wound area is lost by contraction by day 8 ± 1. B: Skin wound treated with active collagen–GAG matrix, not seeded with cells, closes by strongly delayed contraction in about 40 days (arrow). Fifty percent of wound area is lost by contraction by day 27 ± 2. C: Skin wound treated with active collagen–GAG matrix seeded with skin cells does not close by contraction. Although some contraction of wound perimeter does occur, the wound closes essentially by synthesis of new skin, complete with dermis and epidermis but hairless, which forms within the wound perimeter. RS, regenerated skin. IS, intact guinea pig skin; AP, anterior-posterior axis of animal. The original wound perimeter is eventually transformed into a line of scar (arrows) which separates regenerated skin from intact skin. The scale is marked in cm. (Courtesy of Massachusetts Institute of Technology.)

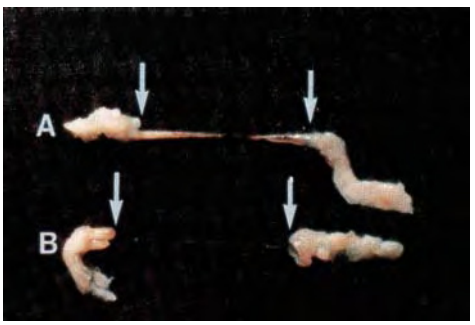

Fig. 10. Explants of rat sciatic nerve obtained six weeks after two treatments of a 15-mm gap. Silicone tubing was removed from the explants prior to photography. A: Regenerated sciatic nerve of rat spanned the entire 15-mm gap (arrows) which had been bridged with a collagen–GAG cylindrical implant; pore structure similar to the one shown in Figure 7B. The matrix was formed within a silicone rubber tube and the cut ends of the nerve were ensheathed within the ends of the tube. The new nerve totally replaced the enzymatically degradable CG matrix which occupied a 15-mm length within the silicone tube. B: A thin strand of connective tissue, but no nerve, grew across the 15-mm gap when the latter was bridged with an empty silicone tube. (Reprinted from [88] with permission.)

The availability of chemical ECM analogues that are degraded by collagenase over a relatively wide time scale makes it possible to study quantitatively the effects of ECM transience on a model wound healing process. After the ECM analogue has been brought in close physicochemical contact with the woundbed and after establishing that cells from the woundbed are migrating freely inside the pore structure of the analogue one can ask: How does a deliberate variation in the degradation rate of the ECM affect the mechanism of wound healing? Although the system of interest is a model wound, it is vitally important to establish a carefully designed in vitro experiment which can provide definitive tests of hypotheses about interactions between the matrix and specific components of the woundbed. Conclusive test results on isolated mechanistic steps frequently cannot be obtained in the complex in vivo model.

The degradation rate of collagen–GAG matrices in collagenase can be conveniently measured in vitro by at least two methods, which yield comparable results. In the first, a suspension of the finely comminuted implant is incubated in a stirred, standardized bath of collagenase. Degradation produces oligopeptides which are determined by a photometric procedure.[82, 83] The second assay is a mechanochemical method in which small strips of matrix are stretched in a standardized bath of collagenase and the kinetics of degradation are monitored by measuring the force necessary to maintain the specimen at fixed extension.[22, 49, 62] Whereas the first method measures the amount of solubilized protein, the second monitors the amount of undigested protein which persists in the form of a stress-bearing network. Additional study is necessary to correlate the information obtained by each of these two, apparently complementary, procedures. Certain interesting strategies for control of implant resistance to collagenolytic action have emerged from the use of in vitro assays. A systematic study of degradation rates of collagen specimens cross-linked with formaldehyde, glyoxal, and glutaraldehyde in the M_c range ca. 5 to 25 kDa showed an approximately 15-fold monotonous increase in the rate constant with increase in the molecular weight between cross-links.[49, 62] An approximately 10-fold increase in degradation rate with conversion to gelatin was also observed.[62] A particularly novel finding was a fivefold increase in resistance to collagenolysis as the relative amount of chondroitin 6-sulfate grafted onto collagen was increased to about 8 wt%; no further increase in resistance was observed beyond that level.[49, 81]

In vivo studies have confirmed the validity of these in vitro effects during the first 7–10 days following implantation; however, during the second week, important and revealing deviations from in vitro predictions have become evident. For example, increase in M_c led to acceleration of the rate at which subcutaneously implanted matrices were degraded[73] during the 10 days following implantation, while grafting of collagen with chondroitin 6-sulfate decreased the rate of implant degradation during that period.[22, 81] Both of these early results were expected from the in vitro studies. However, during the second week it was observed that implants in which the amount of grafted GAG exceeded about 2 wt% showed a net increase both in total dry weight and in relative collagen content; by contrast, implants in which the GAG content was lower or was zero continued to lose weight monotonously and maintained a constant relative collagen content during this period.[22, 73, 81] Histological studies showed that net increases in total dry weight followed by increases in relative collagen content were associated with synthesis of new connective tissue in very close proximity to the degrading matrix.[73, 81] These findings showed that the simple in vitro assays for degradation rate of matrices had

important predictive power which, however, was apparently limited to events occurring during the early phases of wound healing.

The effect of physicochemical manipulations of the matrix on the kinetics and mechanism of wound healing has turned out to be remarkable. One of the most obvious events that follows a total surgical removal (excision) of skin in rodents and in man is contraction of the wound perimeter. In the rodent model, where the contraction is especially vigorous, this process stops when two apposed wound edges have come in approximate contact and scar tissue has been synthesized in the narrow space separating the two edges (cf. Fig. 9A). In the human, contraction stops at an earlier stage with a greater amount of scar tissue separating the wound edges. It is now clear that skin wound contraction can be delayed so that it starts about 10 days after the wound is generated, rather than within 1–2 days after trauma, provided that the collagen–GAG matrices possess a narrowly defined constellation of properties: the resistance to degradation is higher than a critical level (Fig. 11), corresponding to

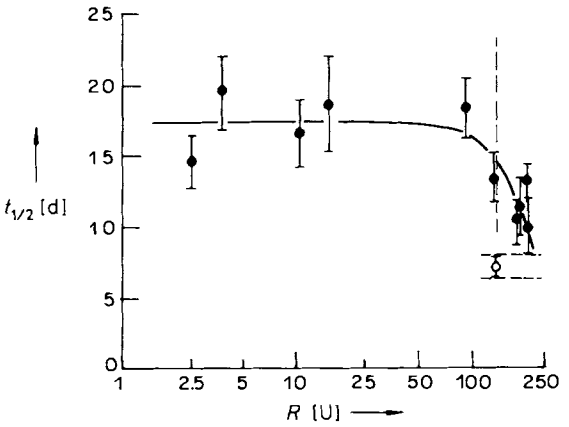

Fig. 11. Variation of the skin wound half-life with degradation rate R (in collagenase) of collagen–GAG matrix. The half-life $t_{1/2}$ is the time required for a wound to contract to 50% of the original area. The degradation is in empirical units, which are defined in terms of an in vitro assay. A somewhat arbitrary broken vertical line is drawn near $R = 140$ enzyme units. This line shows the level of degradation rate above which the half-life of matrices rapidly drops to the level of the ungrafted wound (○). The horizontal scale is logarithmic. (Reprinted from [84] with permission.)

loss of about 50% of dry implant weight within 10 days; and the average pore diameter is between 20 and 120 μm (Fig. 12), corresponding to a specific surface in the approximate range 10^6–10^7 mm^2 per gram of dry matrix.[84] Furthermore, preliminary studies have shown that collagen banding in implants must be maintained at near-zero levels (Fig. 6) while the triple-helical structure remains intact[71, 84] and that the pore volume fraction must be higher than about 0.95.[84]

When collagen–GAG matrices, which can significantly delay the onset of wound contraction, are seeded with a minimum density of easily separable skin cells (basal cells) from the same animal and the cell-seeded matrices are then grafted, wound healing is affected in an even more profound way. In this case, not only is the onset of wound contraction delayed by approximately 10 days but, a few days after it starts, contraction is arrested midway before complete clo-

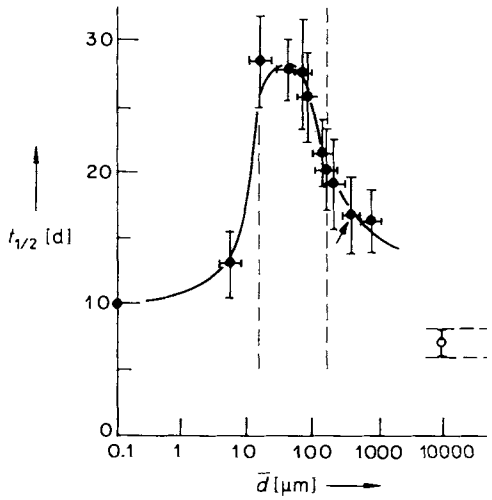

Fig. 12. Variation of half-life of skin wound with the average pore diameter of collagen–GAG matrices used as grafts for full-thickness skin wounds in the guinea pig. The vertical broken lines at about 20 and 120 μm mark the limits of matrix activity. Outside these approximate limits the wound half-life rapidly drops to the level of the ungrafted wound (○). The horizontal scale is logarithmic. (Reprinted from [84] with permission.)

sure; its direction is then reversed and the wound perimeter expands over several days until it slows down and finally stops expanding (Fig. 13). Several weeks after grafting, the area enclosed by the wound perimeter is about 65% of the original wound area and new skin, complete with a dermis and an epidermis, fills this area (cf. Fig. 9C).[85] If the matrix has not been previously seeded with skin cells, contraction is still delayed significantly, but the wound perimeter eventually closes with formation of scar (cf. Fig. 9B). The new skin synthesized with the help of cell-seeded matrices is hairless, but there is strong evidence from light scattering studies[86] as well as histological studies[84, 85, 87] that it is distinct from scar and is similar, though not identical, to normal skin. Morphological and physical (light scattering) evidence that distinguishes new skin from scar is illustrated in Figures 14

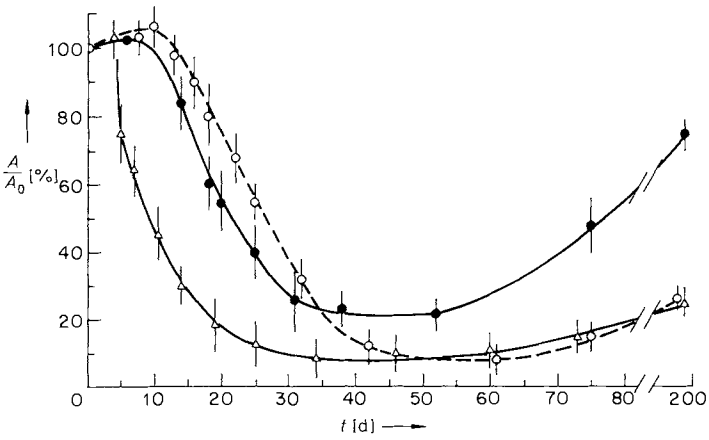

Fig. 13. Change in the original wound area, A_0, with time observed when full-thickness guinea pig skin wounds were grafted with active collagen–GAG matrices (△), active cell-free collagen–GAG matrices (○), and active cell-seeded collagen–GAG matrices (●). Active cell-free matrices delayed significantly the onset of wound contraction but did not eventually lead to arrest of contraction and skin regeneration. Active cell-seeded matrices delayed the onset of contraction, eventually arrested it, and induced skin regeneration within a woundbed which was expanding in area. and 15. The skin wound contraction kinetics are summarized in Figure 16. The kinetic data separate collagen–GAG matrices into three classes, namely, inactive matrices, active matrices which are not seeded with cells, and active matrices which are seeded with an adequate number of cells. Other collagen–GAG matrices have induced regeneration of almost intact rat sciatic nerve across a gap of 15 mm without the need for cell seeding (Fig. 10).[88]

Although the epidermis regenerates readily over an intact or partly intact dermal bed, it is well-known that de novo synthesis of the dermis does not occur spontaneously.[17, 18] Likewise, even though the rat sciatic nerve is regenerated spontaneously across a 5-mm gap or occasionally across a 10-mm gap (provided that the cut ends of the nerve are inserted in a saline-filled rubber tube), no such spontaneous regeneration is observed across a 15-mm gap.[19, 20] The appropriate use of collagen–GAG matrices leads to synthesis both of skin, complete with dermis and epidermis (cf. Fig. 15), and of new sciatic nerve (cf. Fig. 10A). It is this ability to induce de novo synthesis of nearly physiological

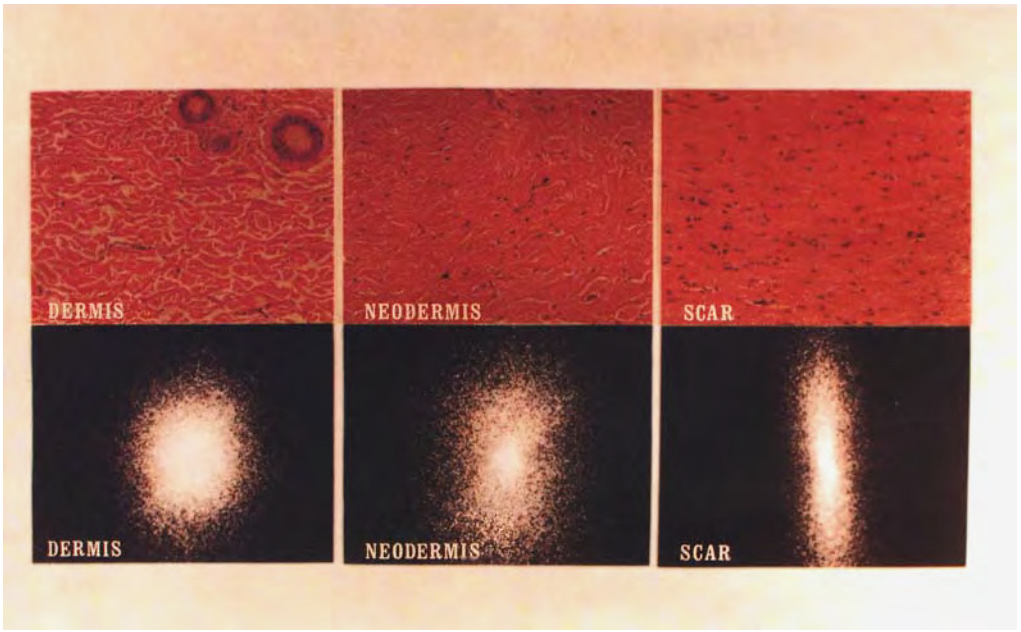

Fig. 14. Comparison of histological data obtained by light microscopy of tissue sections (top row) with small-angle patterns obtained by scattering a visible laser beam from the same tissue sections (bottom row). Tissue sections were stained with hematoxylin and eosin, but the nature of the histological stain does not appear to affect the light-scattering patterns. Left: View of normal guinea pig dermis shows a relatively random arrangement of collagen fibers and an elliptical scattering pattern. Middle: Regenerated dermis shows a less random orientation of collagen fibers and a scattering pattern which is clearly more anisometric than is true for intact dermis. Right: Dermal scar shows a highly oriented array of collagen fibers and a scattering pattern which is very highly anisometric. (Reprinted from [13] with permission.)

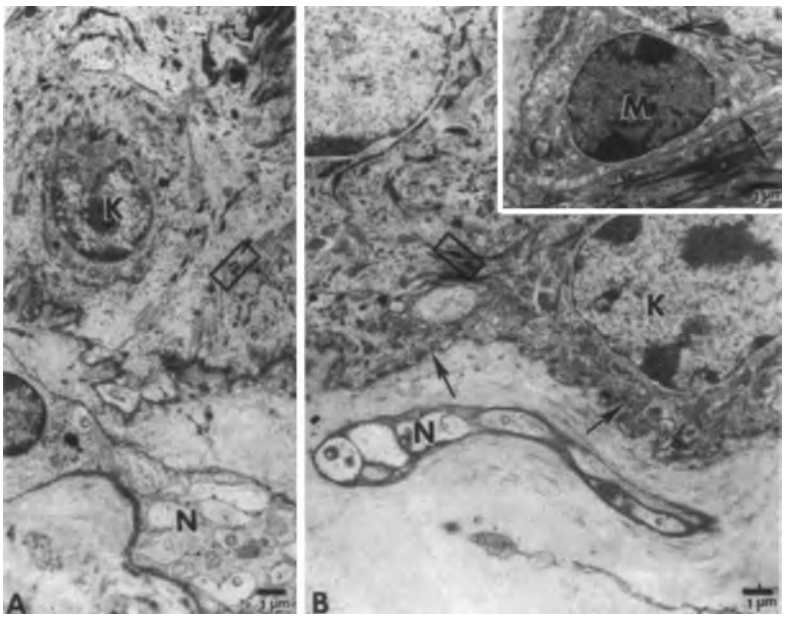

Fig. 15. A: Normal guinea pig skin viewed in the electron microscope. The epidermis is formed by keratinocytes (K) joined by junctional complexes (desmosomes enclosed). Note characteristic unmyelinated nerve fiber (N) within dermis. Bar: 1 μm. B: Regenerated skin 14 months after grafting wound with an active collagen–GAG matrix which had been seeded with skin cells. The neoepidermis is formed by keratinocytes (K) that are identical to intact skin. Desmosomes (enclosed) and basal lamina (arrows) are well-formed and normal in appearance. Melanocytes (M, inset) containing characteristic melanosomes (arrows, inset) also repopulate the neoepidermis, where they function normally in pigment production and donation. A dermal nerve fiber (N), similar to those of normal skin, is also observed. Bars in photo and in inset: 1 μm. (Reprinted from [81] with permission.)

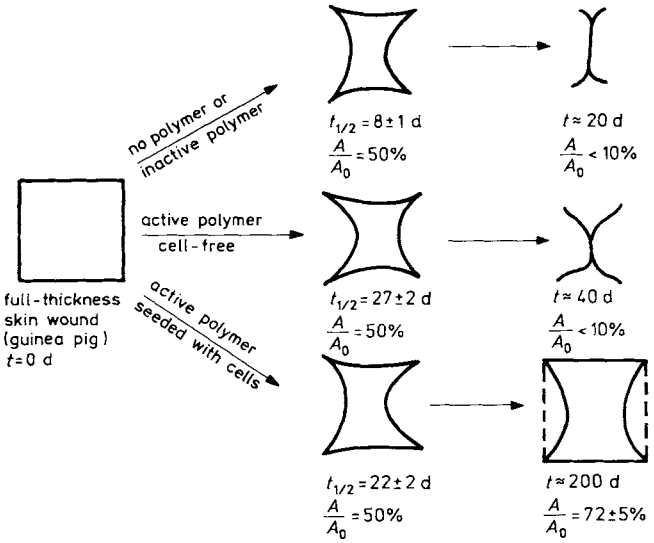

Fig. 16. The kinetics of contraction of full-thickness guinea pig skin wounds separate collagen–GAG matrices into three classes. An inactive matrix does not delay wound contraction significantly relative to the ungrafted control and eventually allows formation of "linear scar". An active, cell-free matrix delays wound contraction by about 20 days but eventually allows full contraction to occur. An active matrix, which has been seeded with a minimal number of skin cells, delays contraction significantly, later arrests it, and eventually induces synthesis of a new dermis and epidermis within an expanding wound perimeter (cf. Fig. 9). (Reprinted from [90] with permission.)

Fig. 17. A massively burned patient has been treated with autograft (left) and with a collagen–GAG matrix (right). The original clinical study of 10 patients by Dr. John F. Burke and his co-workers at Massachusetts General Hospital [50] has been expanded by a randomized clinical trial involving 106 patients [51]. Both studies concluded that a bilayer wound cover, made from a top layer of silicone rubber and a bottom layer of an active collagen–GAG matrix ("artificial dermis", "artificial skin"), performs as well as the autograft. The surgical procedure makes use of a collagen–GAG matrix which is not seeded with cells. About 15 days following grafting, the silicone layer is removed exposing a new dermal bed which is then grafted with a thin, autoepidermal graft. The conventional autograft requires removal not only of the epidermis but also of a layer of dermis, about one-half the thickness of the patient's dermis. The autografting procedure leaves a slowly healing, scarred donor site; the artificial skin procedure leaves a rapidly healing, almost unscarred donor site. (Photo of Dr. *J. F. Burke*.)

tissue under conditions where such synthesis does not occur spontaneously that characterizes regeneration matrices from the very large array of collagen or collagen–GAG matrices which are biologically inactive in this respect.

The clinical applications of ECM analogues appear to be unprecedented. Patients who have suffered massive burns and have lost a large fraction of their skin require immediate replacement of the lost skin area in order to gain back control of their dehydration rate as well as to stem large-scale infection. The best treatment currently is the skin autograft, that is, the patient's own skin, which can be obtained only after subjecting the patient to a serious operation. Clinical studies have shown that an ECM analogue virtually identical to the one which delays contraction in the guinea pig, induces synthesis of new dermis within about 15 days in patients with massive burns.[50] The new dermis forms a suitable bed on which to graft a thin layer of the patient's epidermis, which can be obtained without a serious operation, and the open wound is thereby closed permanently (Fig. 17). A recent randomized clinical trial involved 106 patients, all massively burned. This 11-hospital trial has confirmed the early finding[50] and has shown that treatment with the ECM analogue gives results which are clinically equivalent to treatment with the autograft.[51] The inability of patients to synthesize dermis spontaneously makes this clinical finding especially interesting. It is very likely that other tissues that do not regenerate spontaneously during wound healing can be induced to do so if appropriately synthesized ECM analogues are used to treat them.

It is fairly obvious that the unusual biological activity of certain collagen–GAG matrices is due to specific cell–matrix interactions which take place when these matrices are in contact with the skin woundbed or with the cut end of the nerve. What are these interactions? Electron-microscopic studies of skin wounds have shown that cells (monocytes) attach themselves particularly intimately to the collagen–GAG surface, which is itself coated with a thin layer of a fibrinlike network (Fig. 18A, B).[89] The attached cells are in close proximity on the matrix surface and most probably interact with each other. No such cell–matrix interaction is observed in a normally healing skin wound (Fig. 18C)[89] even though there are locally present, by all accounts, substantial amounts of various collagens, various GAGs, and other ECM components, all of which are undergoing remodeling, that is, degradation and synthesis. Why is contraction delayed or even arrested in the presence of active matrices? It has been hypothesized[90] that cell–matrix interactions of the type illustrated in Figures 18A and 18B may prevent differentiation of cells in the woundbed to myofibroblasts, the cells which have been credited with the contraction of wounds during normal healing.[91] This hypothesis is based on the observation that there is depletion of myofibroblasts on about day 10 following injury in woundbeds which have been treated with active matrices relative to untreated woundbeds on the same day.[89, 90]

The necessary attributes of a regeneration matrix can be most simply understood in terms of a highly specific cell–matrix interaction which diverts decisively the mechanism of wound healing away from contraction and scar synthesis to arrest of contraction and tissue regeneration in the woundbed.[84] The quantitative relations between matrix structure and wound contraction kinetics (cf. Figs. 11–13) can be used to deduce the physicochemical requirements: What seems to be necessary is the presence of a collagen–GAG surface which is (1) sufficiently extensive (upper limit of pore diameter; cf. Fig. 12), (2) sufficiently nondiffusible over a period of about 10 days (upper limit of degradation rate; cf. Fig. 11), and (3) endowed with pores which are sufficiently large to

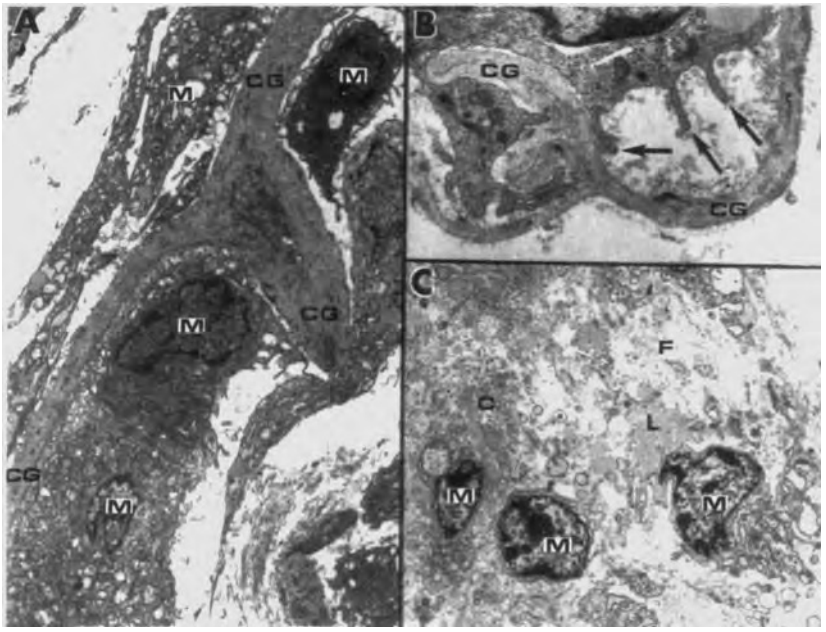

Fig. 18. Characteristic cell–matrix interactions observed when an active collagen–GAG matrix is in contact with the woundbed. The model wound is the full-thickness skin wound in the guinea pig. A, B: Seven days after grafting with a collagen–GAG matrix, mononuclear cells (M) formed an apparently continuous monolayer along the surfaces of pores in the matrix. Arrows in B indicate pseudopods extending from cells to the matrix surface. C: The ungrafted wound shows a random admixture of mononuclear cells, lipid (L), fibrin (F), and host collagen (C). Magnification: A, 3000X; B, 9500X; C, 2000X. CG = collagen-*graft*-glycosamino glycan copolymer. (Photo of Dr. *G. F. Murphy*.)

allow ready access to cells migrating into the woundbed (lower limit of pore diameter; cf. Fig. 12).[84] Additional criteria currently being studied include an apparent requirement for nearly zero crystallinity (banding) (cf. Fig. 6) and a pore volume fraction in excess of 0.95. Although skin regeneration requires that the matrix be seeded with a critical density of cells, the physicochemical structure suffices, by itself, to delay wound contraction (cf. Figs. 13 and 16) and probably sets the biological stage for regeneration to occur. In studies of nerve regeneration it has also been observed that a matrix that has not been seeded with cells can, in fact, induce synthesis of new, functional tissue over large gaps.[88, 92]

5. Conclusion

We conclude that a set of well-defined physicochemical manipulations suffices to yield insoluble but degradable, porous, cell-free macromolecular matrices which possess remarkable biological activity. Even when these matrices have not been previously seeded with cells, they modify profoundly the mechanism of healing in skin and nerve wounds. These matrices are very simple chemical analogues of the ECM. Nevertheless, deliberate changes in macromolecular network structure and in pore structure can be made and confirmed readily. These well-defined matrices can then be used to answer important questions about aspects of the mechanism of tissue remodeling which distinguish conventional wound healing from normal development or from regeneration. Such questions are currently intractable due principally to the lack of appropriately standardized preparations of biologically active ECMs.[6]

The physicochemical characteristics of collagen–GAG matrices that define the boundaries of biological activity in the skin wound model are quite narrow (cf. Figs. 11 and 12). So narrow is this description of active matrices in this animal model that the evidence probably defines a single substance. Unlike the vast majority of biologically active substances, the matrix defined in this context is insoluble and cannot be characterized by a molecular weight, as soluble macromolecules usually are; it lacks a precise three-dimensional configuration and, therefore, cannot be described by X-ray crystallography; and it is highly porous rather than forming a homogeneous phase. Nevertheless, the data define a network which maintains its nondiffusible character in the presence of collagenolytic activity and is sufficiently well endowed with surface area to enable high densities of cells to interact with it, and possibly with each other, in its presence. Accordingly, we have hypothesized that the data define a unique substance which acts as an insoluble growth factor[84] during skin development. Rather than allow the woundbed to contract and synthesize scar this matrix induces synthesis of partly physiological tissue. If it does that much the substance most probably possesses mitogenic activity and should, therefore, be considered a growth factor.

There is agreement that some kind of ECM, probably a variant or precursor of the mature basal lamina, mediates the critical interaction between epithelial and mesenchymal cells which leads to morphogenesis of several tissues during development.[4, 93] The specific matrix described by the data in Figures 11–13 must be present in order for the epithelial cells seeded into it, together with the mesenchymal cells which migrate into it from the underlying woundbed, to yield new skin. It is reasonable to hypothesize quite simply that the collagen–GAG matrix is responsible for that critical cell–cell interaction. In fact, it has been observed that if only epithelial and mesenchymal cells, but no matrix, are present in the woundbed, healing proceeds without any evidence of regeneration.[94] This line of reasoning supports the hypothesis that the regeneration matrix described here is a functional analogue of the basal lamina. This analogue mediates a critical epithelial–mesenchymal cell interaction during morphogenesis of skin and nerve before it becomes totally degraded and diffuses away from the woundbed. The final outcome of skin morphogenesis is not only a new dermis and

epidermis but also a new basal lamina (cf. Figs. 1, 15A, and 15B). In the process, the collagen–GAG matrix became completely degraded and is not visible in electron-microscopic views of newly synthesized skin (Fig. 15B). Similarly, residual fragments of collagen–GAG matrix are eventually not visible any more in sciatic nerve regenerates.

Another possibility emerges form the finding that the swollen, nonbanded type-I collagen present in the regeneration matrix (Fig. 6) does not aggregate platelets, whereas type-I banded collagen is very active.[71] It is well-known that one of the first events following tissue injury is platelet aggregation and degranulation with release of platelet-derived growth factor (PDGF), a powerful mitogen of cells of mesenchymal origin that participate in normal wound healing processes.[95, 96] Although PDGF is known to be secreted by platelets during the early phase of wound healing, other cells, principally macrophages, are also known to synthesize this growth factor in later stages of wound healing.[95, 96] Since the regeneration matrix does not aggregate platelets, PDGF is probably not secreted in woundbeds which have been treated with the matrix, and the strongly proliferative effect of this mitogen is , therefore, absent in such woundbeds, at least in the early stages of response to injury. I hypothesize that the absence of PDGF during the early phase of healing is the critical factor which diverts the kinetics and mechanism of the wound healing process away from contraction and relatively random cell proliferation towards the suspension, or even arrest, of contraction (Fig. 13) and the organization of cells into orderly arrays (Fig. 18) which synthesize new skin rather than scar (Figs. 14 and 15).

It is interesting to speculate on the structural, rather than functional, similarity between the basal lamina and the regeneration matrix. Inspection of Figure 6 opens up the intriguing possibility that type-I collagen, which is almost entirely nonbanded due to the swelling action of the diluent possesses an ultrastructure (quaternary structure) that simulates the threadlike, open network or scaffold ultrastructure[24, 25, 27] of type-IV collagen in the basal lamina. Like collagen IV in the basal lamina, but unlike collagen types I, II, and III, swollen type-I collagen (Fig. 6) does not form fibrils, except in very few locations. On the other hand, whereas the polypeptide chains in swollen, nonbanded collagen possess the triple-helical structure (tertiary structure) characteristic of type-I collagen along their entire length, the polypeptide chains of the basal lamina are partly nonhelical.[24, 25, 27] Other differences obviously extend to the amino-acid composition of the collagens, which is characteristic of collagen type IV in the basal lamina. Nevertheless, it would be extremely interesting to attempt the synthesis of collagen–GAG matrices which are based on collagen IV and which incorporate macromolecules known to be present in the basal lamina, such as heparan sulfate and laminin. There is no question that synthetic chemistry can make enormous contributions to the understanding of the role of the ECM during development.

Regeneration of rat sciatic nerve is induced by a similar, though distinct, collagen–GAG matrix. Evidence obtained so far indicates that the ECM analogue that induces sciatic nerve regeneration to occur most rapidly and completely is degraded more rapidly and has a smaller average pore diameter than does the analogue which induces skin synthesis.[81, 88, 92] It is intriguing to contemplate the possibility that morphogenesis of each type of tissue or organ requires a distinct ECM, with chemical composition and physicochemical structure that are specialized for the particular developmental task. Such hypotheses can be tested with the help of new ECM analogues.

Shape and form, the two indispensable attributes of developing systems, require not only an actively differentiating and proliferating cell population but also transient extracellular matrices which order the cells in space and probably induce transcription of genetic information. In the future I anticipate the synthesis of increasingly sophisticated but still well-defined macromolecular analogues of various ECMs which can be used to answer critical questions of development and of healing.

Replication Experiments with Nucleotide Base Analogues

By Peter Strazewski and Christoph Tamm*

The principles governing the replication fidelity of genomes are not fully understood yet. *Watson* and *Crick*'s base-pairing principle for matched deoxyribonucleotide (DNA) bases can explain why the guanine–cytosine and adenine–thymine base pairs are approximately one hundred times more stable thermodynamically than mismatched combinations. In vitro, DNA polymerases reduce the number of mismatched base pairs to about 10^{-6} per Watson-Crick base pair. Replication fidelity can further be enhanced to a mutation probability of 10^{-10} or less in vivo if optimal conditions for DNA synthesis are provided by polymerase-assisting proteins and DNA-repairing enzymes. The precise reasons for the formation of mismatched base pairs (mispairs), which are responsible for a substantial part of DNA mutations, are still in debate. Although it is agreed that a template-directed "reading" of the hydrogen-substitution pattern in the heterocyclic bases is crucial for proper base pairing during DNA synthesis, it is not clear which type of "misreading" leads to mispairs. Misreading may be due to a non-Watson–Crick base pairing as well as to a change in the hydrogen-substitution pattern, leading to Watson–Crick-like mispairs. The surprising discovery of the selective and quantitative DNA-polymerase-catalyzed formation of a pyridine–pyrimidine base pair (involving a nucleotide base analogue) indicated that rare tautomeric forms in template DNA strands can lead to Watson–Crick-like mispairings that are hardly recognized by the polymerase's proofreading activity. This reveals new pathways for substitution mutations (replication-dependent DNA point mutations) and suggests a new type of mutagen in vivo.

1. Introduction

1.1. Essential Contacts

To evolve on earth, the structures of living matter had to satisfy four basic requirements. (1) They had to be sufficiently complex and stable to store imprinted genetic (i.e., inheritable) information. (2) Their surface had to be accessible to a template-directed reading so that the information could be accurately passed on to offspring (replication). (3) They had to be able to influence their "dead" environment in such a way that it would serve their own reproduction. In other words, they must have had a biological activity which would turn their immediate surroundings into a phenotype. Such a controlled environment would have helped them to compete against a great variety of replicating structures carrying other genetic information (selection). (4) They must have consisted of metastable information units to allow their carrier to evolve under the influence of natural selection (mutability allowing adaptation).

This information carrier is deoxyribonucleic acid (DNA). It can be divided into two classes of DNA regions: DNA stretches that encode amino acid sequences in proteins (exons) and noncoding stretches. Coding DNA sequences, which probably are a minor part of most DNA, can pass on their message to the phenotype through *DNA–ribo(mono)nucleotide* contacts assisted by transcription proteins. After being transcribed into an "active form" carried by ribonucleic acid (RNA), the translation of this type of information into proteins relies on *RNA–RNA* contacts (codon–anticodon binding between the DNA transcript, messenger RNA, and the amino-acid carrier, transfer RNA) and *RNA–protein* contacts (selective, enzymatic aminoacylation of the appropriate transfer RNAs). The RNA–RNA contacts are assisted by proteins and ribosomal RNA and are governed by the universal genetic code using triplet codons. The nature of the RNA–protein contacts, recently referred to as the second genetic code,[1] is not well understood yet. Both coding and noncoding DNA sequences can influence the phenotype through direct *DNA–protein* contacts as well. These provide possibilities to regulate the expression of coding sequences, are responsible for changes in the topology of DNA (e.g., unwinding), and allow a tight packing of DNA in chromosomes. *DNA–DNA* contacts are necessary for the chemical stabilization of DNA itself through the formation of a DNA double helix. They also dominate the exchange of DNA fragments during genetic recombination, which is the basis for sexual reproduction. Finally, *DNA–deoxyribo(mono)nucleotide* contacts—with the help of replication proteins—allow all genetic information to be copied and thus serve in DNA replication.

1.2. Various Forms of Base–Base Interactions

Of all these vital contacts (Section 1.1), those between nucleotide residues are the best known, because they involve only four different information units. The information is coded by the sequence of four heterocyclic nucleotide bases; adenine, guanine, cytosine, and uracil/thymine. In spite of the relatively simple structure of these bases (compared to the 20 structures of amino-acid side chains), a variety of contacts between them are known (Fig. 1). The most common contacts are hydrogen bonds that result in base pairing.

Base pairings following the Watson–Crick rules[2] (Fig. 1a) take part in the formation of matched antiparallel double strands from DNA and/or RNA single strands. *Watson–Crick base pairs* always contain one purine base (guanine, adenine) and one pyrimidine base (cytosine, uracil/thymine); guanine pairs with cytosine and adenine with uracil (in RNA) or thymine (in DNA). Their structures, as well as the structures of *Hoogsteen pairs*, where a purine base adopts the unusual *syn* conformation around the glycosidic bond (Fig. 1b), and *wobble pairs*, where the C_2 pseudosymmetry of Watson–Crick pairs is broken (Fig. 1c), are well established thanks to X-ray crystallographic evidence. Hoogsteen and wobble pairs play an important role in alternative base-pairing modes in RNA and in DNA mutagenesis. Other types of base–base contacts are *reversed base pairs*, where two strands are assumed to be oriented parallel (Fig. 1d), and *base triplets* in DNA triple strands (Fig. 1e). These structures are constructed following the patterns of hydrogen donors and acceptors in the bases and have not yet been proven. Parallel strands are thought to exist in unusual DNA or RNA secondary structures.[3] Triple-stranded DNA sequences stabilize an unusual secondary structure that induces sharp bends in DNA double strands (H-DNA).[4] Triple-stranded DNA might also play a role in the initiation of recombination events.

All these base pairings can be formed under the instruction of the genetic information carried by DNA, either correctly or incorrectly. The "incorrect" pairs, which can lead to mutated forms of DNA, RNA, or proteins, are presently of great interest, because their formation is not as well understood as the formation of Watson–Crick pairs. Mutations are the consequence of unusual contacts, not only between nucleotide bases, but also between proteins and DNA or RNA. Yet, the most hazardous or meaningful ones (to the cell) are mutations which arise in DNA, because only they are inheritable and only they can give rise to a large amount of mutated products. Therefore, we shall focus on base pairings and mispairings formed during DNA replication.

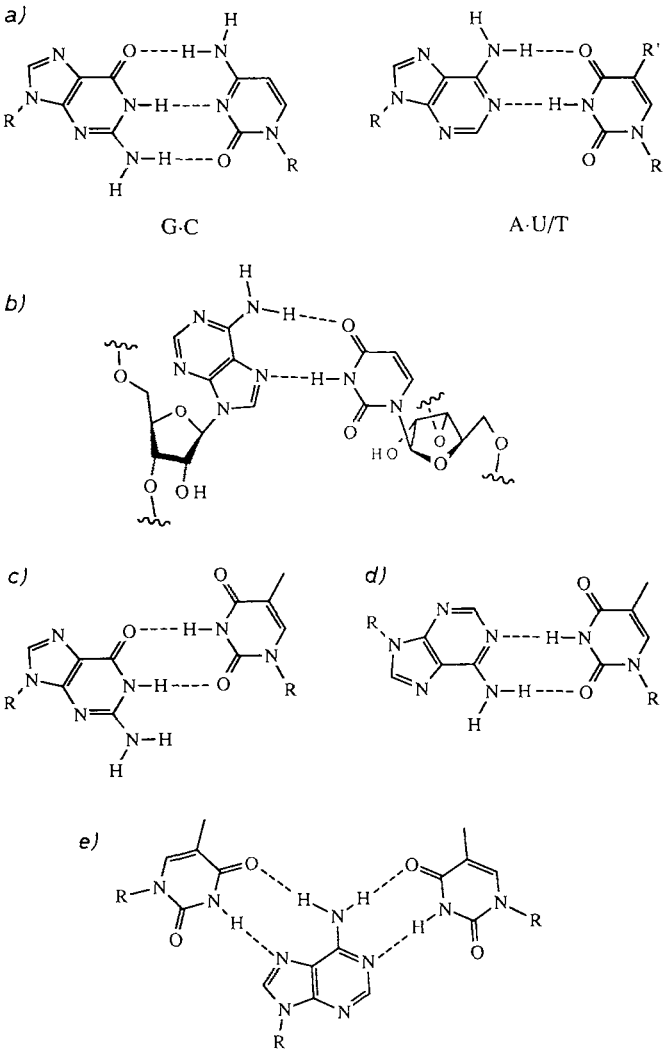

Fig. 1. Base–base interactions between nucleotides. R = β-D-ribofuranosyl or 2'-deoxy-β-D-ribofuranosyl, R' = H or CH_3. a) Watson–Crick base pairs G · C and A · U (R = ribosyl, R' = H) or A · T (R = deoxyribosyl, R' = CH_3). b) Hoogsteen pairs, e.g., A(*syn*) · U. c) Wobble pairs, e.g., G · T (wobble). d) Reversed base pairs, e.g., A · ⊥ (or ∀ · T). e) Base triplets, e.g., T · A · T.

1.3. Hydrogen-Substitution Patterns of Nucleotide Bases

Nucleotides (deoxyribonucleotides are simply referred to as nucleotides in this article) are chemically quite stable, because they are covalently bound in DNA as phosphoric acid diesters. Additionally, a quite strong secondary structure efficiently protects the bases from chemical modification and hydrolysis, because they are buried in the central core of the double helix. Nevertheless, nucleotides in DNA appear to be metastable with respect to replication (muta-

Christoph Tamm was born in 1923 in Basel. He studied at the University of Geneva and the University of Basel, where he received his Ph.D. in 1948 under Tadeus Reichstein. From 1949 to 1952, he worked as a postdoc with Oskar P. Wintersteiner, Squibb Institute for Medical Research, New Brunswick, NJ, and with Erwin Chargaff, Columbia University, New York. After his habilitation in 1953 in Basel, he worked in the Pharmaceutical Research Department at Sandoz AG, Basel (1957–1961). In 1961, he was appointed associate professor and in 1966 professor at the University of Basel. Tamm is a member of numerous research and government committees for science. His interests include the structure, synthesis, and biosynthesis of bioactive microbial metabolites, the use of enzymes in synthesis, and the synthesis of nucleosides and polynucleotides.

Peter Strazewski was born in 1958 in London. He studied at the University of Basel and received his Ph.D. in 1986 under Christoph Tamm. Since 1988, he has worked as a postdoc with Olga Kennard, University Chemical Laboratory, Cambridge (UK). His interests include the synthesis of natural products and the synthesis and X-ray analysis of oligonucleotides.

ble). The reason is the possible formation of mismatched base pairs that do not follow the Watson–Crick rules. Therefore, the base-paired nucleotides should be treated as the information-carrying units, rather than the single-stranded nucleotides.

In a strict sense, only one particular feature of the nucleotide base is crucial in governing the storage and transfer of genetic information, namely, the hydrogen-substitution pattern of the heterocycle, that is, the pattern of hydrogen acceptors and donors on the exposed side of the base. Hence, if the pattern changes before replication in such a way that the base can form normal hydrogen bonds to a different nucleotide base, the information content would be changed after replication.

How can a hydrogen-substitution pattern change in such a way? Figure 2 shows four alternative ways of changing a pattern of three donors/acceptors aligned in an anchored plane (the "information plane"), like the arrangement of H atoms and nonbonding electron pairs in a heterocyclic nucleotide base. The most trivial change is addition or removal of a proton, leaving a charged plane (Fig. 2a). This change can be neutralized by the reverse reaction or by removal or addition, respectively, of a different proton, thereby leading to a tautomer of the initial pattern (Fig. 2b). Base pairs that use these types of altered H-substitution patterns can have a Watson–Crick-like geometry but a different information content and they can therefore cause mutations. Another way of changing the pattern is to shift the reading frame out of the information plane (following the principle "no information is also information") (Fig. 2c). In nature, this is possible because the missing part of the information will be replaced by the solvent, which provides a huge reservoir of easily adjustable H donors and acceptors. Wobble pairs (cf. Fig. 1c) are base pairs with a shifted reading frame. They, too, have an altered information content and can cause mutations. Finally, we know that some natural information planes, the purine bases, carry heterocyclic H atoms and nonbonding electron pairs all around the plane. Changing the reading frame from one side of the information plane to the other can provide a different pattern. This can be achieved by simply rotating the anchored information plane by 180° (Fig. 2d). Hoogsteen pairs (cf. Fig. 1b) are arranged in such a way that another part of the purine base contains the reading frame. Some Hoogsteen pairs cause mutations as well. These basic possibilities can also be combined and offer still more ways of changing a hydrogen-substitution pattern. Examples are protonated Hoogsteen pairs and tautomeric wobble pairs.

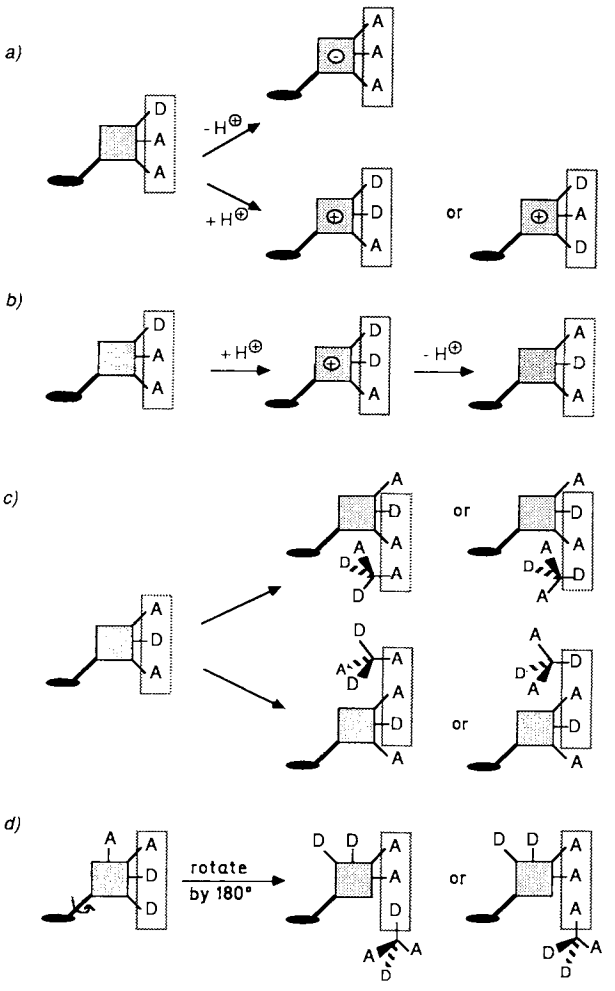

Fig. 2. Ways of changing the H-donor/acceptor substitution pattern of a nucleotide base. Shaded boxes: anchored information planes (schematic nucleotides), D = H donor, A = H acceptor, $D_2A_2 = H_2O$. Dotted lines: reading frame. a) Deprotonation or protonation. b) Tautomerization. c) Shift of the reading frame. d) Presentation of an alternative substitution pattern.

1.4. Nucleotide Base Analogues

A good way to find out which type of erroneous reading can occur in a DNA polymerase is to investigate modified nucleotide bases (analogues) with a reduced or altered capability of forming hydrogen bonds with the natural nucleotides. The behavior of such nucleoside triphosphate analogues during DNA synthesis might give an insight into what kinds of H-substitution patterns of an incoming nucleotide base are allowed by a polymerase. The use of these analogues as template nucleotides would clarify which H bonds are necessary for accurate DNA synthesis.

The modified nucleosides chosen for this purpose can all be considered to be structural analogues of deoxycytidine (Fig. 3). 1-(2′-Deoxy-β-D-ribofuranosyl)-2(1*H*)-pyridone (**1**)

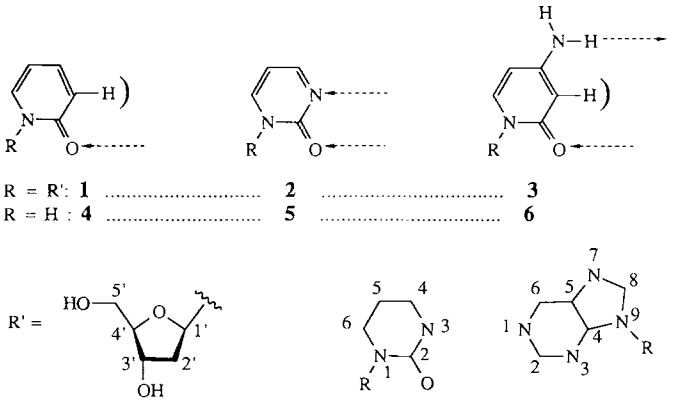

Fig. 3. Nucleoside analogues 1-(2′-deoxy-β-D-ribofuranosyl)-2(1*H*)-pyridone (**1**) and -pyrimidone (**2**) and 4-amino-1-(2′-deoxy-β-D-ribofuranosyl)-2(1*H*)-pyridone (**3**). Arrows indicate H-acceptor or -donor sites. Parentheses around H-3 in **4** and **6** mark repulsive interactions with the imino proton on N-3 of thymidine or on N-1 of deoxyguanosine upon Watson–Crick base pairing. Below: Conventional numbering of 2′-deoxy-β-D-ribofuranosyl and of pyrimidine and purine nucleoside bases.

is a nucleoside analogue that can form only one hydrogen bond (with the carbonyl oxygen of C-2). Additionally, the nucleosides deoxyguanosine (dG) and thymidine (dT), which bear an imino H atom, are prevented from base pairing with **1** because of the interactions between the protruding H-3 of the analogue and the imino protons on N-1 and N-3 of dG and dT, respectively (cf. Fig. 3 for the conventional numbering of purine and pyrimidine nucleosides). Attractive interactions between H-3 and an H acceptor like N-3 of deoxycytidine (dC) or N-1 of deoxyadenosine (dA) are expected to be present in the corresponding base pairs, but are much weaker than a normal H bond between two nitrogen atoms.

1-(2′-Deoxy-β-D-ribofuranosyl)-2(1*H*)-pyrimidone (**2**, "4-deamino-2′-deoxycytidine"; Fig. 3) is a dC base analogue lacking the 4-amino group, which is the only H donor of dC. In contrast to **1**, compound **2** could in principle form base pairs with dG (two H bonds) and dT (one H bond). Compound **2** also lacks a proton that would allow base pairing with dC or dA, but there are no constraints preventing dC or dA from base pairing with an N-3-protonated form of **2** in the polymerase.

As in **1**, H-3 in 4-amino-1-(2′-deoxy-β-D-ribofuranosyl)-2(1*H*)-pyridone (**3**, "3-deaza-2′-deoxycytidine"; Fig. 3) will prevent the analogue from base pairing with dG or dT. Pairings with dC or dA also seem rather unfavorable, because all bases have an H donor on N-4 (the rotation of aromatic amino groups out of the π conjugation is hindered) and the interactions between H-3 of **3** and N-3 of dC or N-1 of dA are expected to be very weak (as in **1**).

The expected or presumed base pairings between analogues **1**–**3** and the natural nucleosides only make sense if, during the polymerization reaction in the enzyme, both bases are uncharged and lie wholly in their predominant tautomeric form and if the positioning of both bases is Watson–Crick-like. If, nonetheless, an unexpected base pairing occurs in enzymatic in vitro experiments that allow the formation of base pairs with the analogues, one would have to consider either the formation of a protonated or rare tautomeric form in one of the bases (changes of the pattern depicted in Fig. 2a or 2b) or the dislocation of one of the bases with respect to the reading frame (Fig. 2c and 2d).

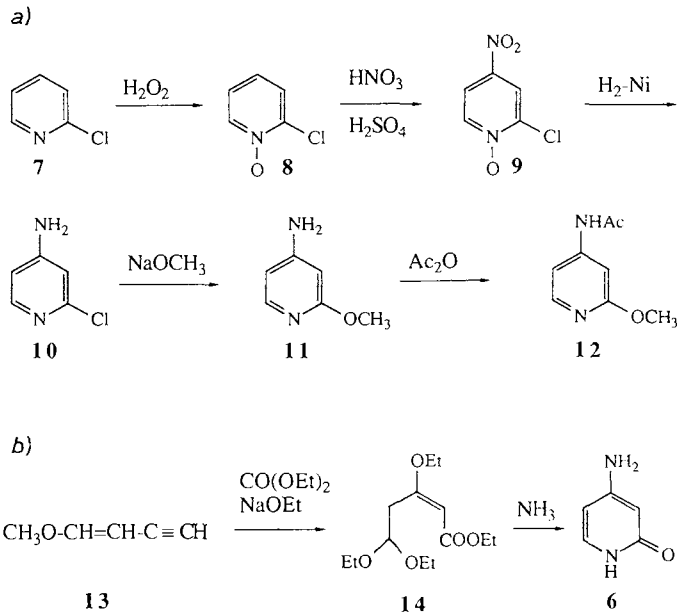
The enzymatic test reactions require synthesis of the modified bases, their stereochemically defined glycosylation, and an efficient 5′-triphosphorylation reaction. The use of the nucleoside analogues as template nucleotides in a DNA oligomer requires, besides their monophosphorylation, that the reaction conditions of a chemical DNA synthesis and of an enzymatic DNA chain elongation are compatible with these substrates, which are more sensitive than the natural compounds.

2. Synthesis of Nucleoside and Nucleotide Base Analogues

2.1. Modified Mononucleotides

2.1.1. Synthesis of Nucleoside Analogues

2-Pyridone (**4**) and 2-pyrimidone (**5**) are commercially available, but 4-amino-2-pyridone (**6**) had to be synthesized from other compounds and suitably derivatized. Our first approach (Scheme 1a) was based on published syntheses from the early 1960s and started from 2-chloropyridine (**7**), which was first oxidized to the *N*-oxide **8**, then nitrated to give the 4-nitro compound **9**. Hydrogenation of **9** gave **10**, which underwent methanolysis to yield 4-amino-2-methoxypyridine (**11**). The amino group was protected by acetylation to give **12**. Compound **12** could be used instead of **6** in the glycosylation reaction leading to **3**. Later, *Currie* et al.[5] synthesized **6** via a more straightforward route (Scheme 1b). 1-Methoxy-1-buten-3-yne (**13**) was homologized to ester **14**, which, upon aminolysis, provided compound **6**.



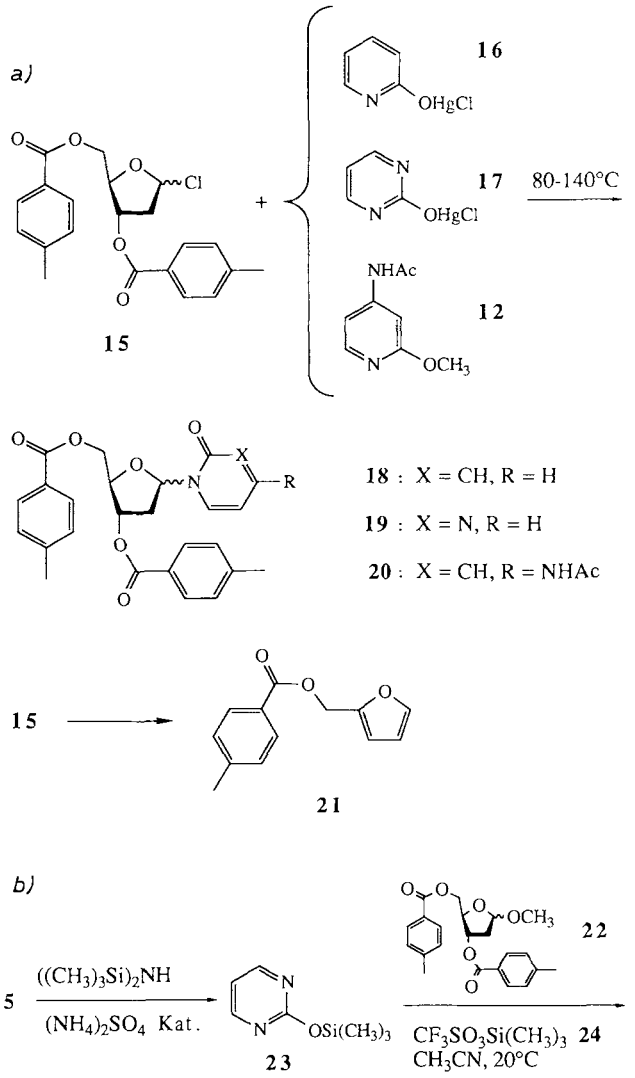
7 **8** **9** **10** **11** **12** **13** **14** **6**

Scheme 1. Syntheses of base analogues: a) **12**; b) **6**.

In all nucleoside analogues **1**–**3** the glycosylation was achieved through the well-known reaction of the 1-chloro-2-deoxyribofuranose derivative **15** with an activated form of the base heterocycle (Scheme 2a). The bases **4** and **5** were activated as mercury(II) salts **16** and **17**, respectively, whereas base **12** already represented an activated form of **6**. Condensation of **16**, **17**, and **12** with compound **15** in an inert solvent yielded **18**, **19** and **20**, respectively, as a mixture of α and β anomers in at the time satisfactory amounts.[6–10] The anomeric mixtures were separated by chromatography on silica or alumina to obtain the desired pure β anomers.

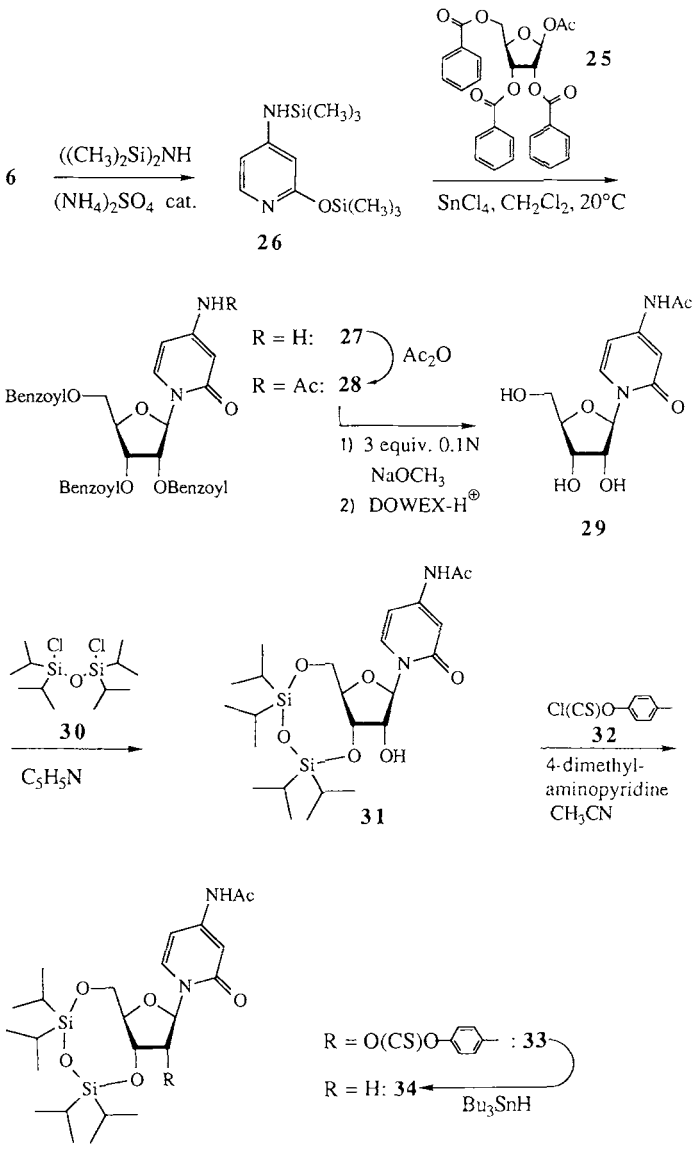
One well-known drawback of the above glycosylation procedure was the low thermal stability of **15**; under the reaction conditions, large amounts of its elimination product, **21**, are formed. This could be avoided by using the more stable methyl glycoside **22** and a more convenient base activation method (Scheme 2b). Base **5** was trimethylsilylated to give **23**, which, in the presence of trimethylsilyl trifluoromethanesulfonate (**24**) as demethoxylation agent, was glycosylated with **22** to give **19**.[11]

The yield of the desired β anomer, however, was relatively low. This problem could be solved by an alternative approach which profits from the procedure for deoxygenation of alcohols developed by *Barton* et al.[12] 2-Deoxyribofura-



Scheme 2. Glycosylation using a) **15** and b) **22**.

nose derivatives usually react unspecifically on C-1 unless special care has been taken both in the synthesis of anomerically pure 1α-chloro-2-deoxyribose derivative α-**15** and in the choice of glycosylation conditions to suppress its anomerization (cf. Refs. [13–14]). Suitably derivatized ribofuranose will yield only β anomers on glycosylation, owing to the neighboring group participation of a 2α-tosyl[15] or a 2α-benzoyl group.[5,16] Glycosylation is best performed at room temperature with commercially available and stable 1-*O*-acetyl-2,3,5-*O*-tribenzoyl-β-D-ribofuranose (**25**)[5] or 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose,[17a] pertrimethylsilylated bases, and a Lewis acid like trimethylsilyl trifluoromethanesulfonate (**24**) or tin tetrachloride to cleave the 1-acetoxy group. An example of our presently preferred synthesis of the 2'-deoxy-β-D-ribofuranoside **34** is depicted in Scheme 3. Aminopyridone (**6**) was bis-silylated to give the activated base **26**, which was glycosylated in situ with **25** in the presence of tin tetrachloride to yield the nucleoside analogue **27**.[5] The anomerically pure product was *N*-acetylated to give **28**, which was then selectively debenzoylated to yield **29**. Bis-silylation of **29** at the 3' and 5' positions with 1,3-dichloro-1,1,3,3-tetraisopropylsiloxane (**30**) afforded the ribose derivative **31**. These usually high-yield reactions must be followed by a two-step deoxygenation procedure.[18] First, a radicophilic functional group (thiocarbonate or xanthogenate) is attached to the 2'-oxygen atom. We use as a routine reagent *p*-tolyl chlorothioformate (**32**). The thiocarbonate **33** is chromatographically stable and can either be isolated in good yields or transformed in situ with tributyltin hydride to give the 2'-deoxy compound **34**.[17b]



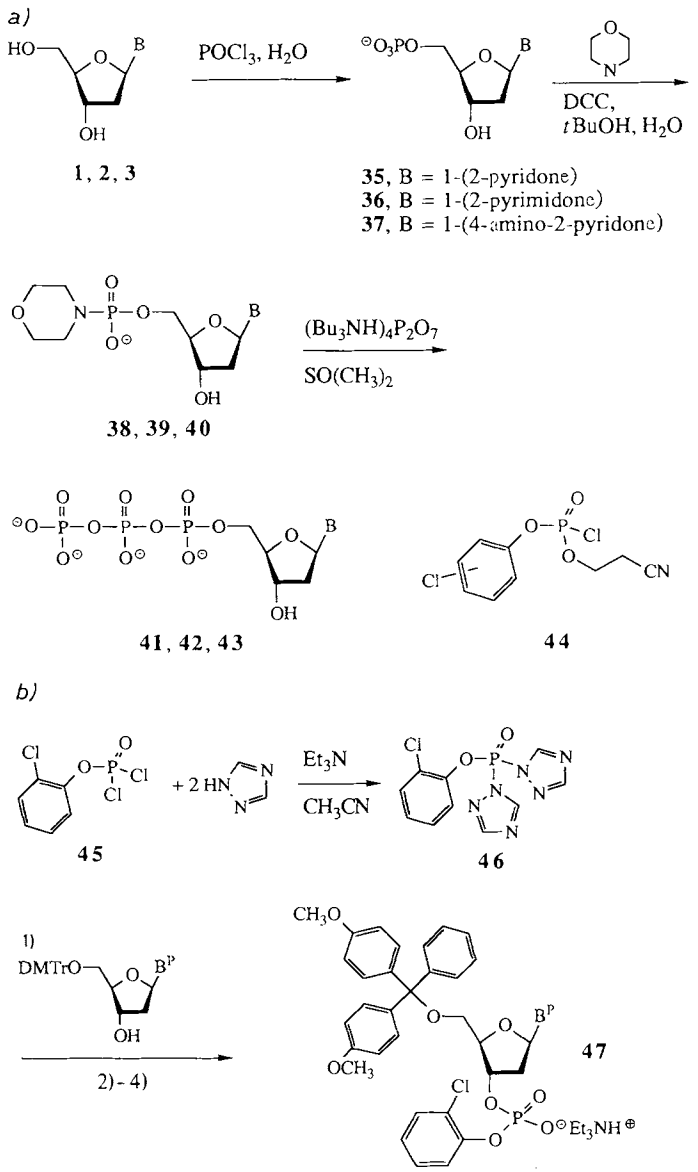
Scheme 3. Glycosylation using **25**.

2.1.2. *Phosphorylations*

Depending on the purpose of the phosphorylated products, different phosphorylation procedures were investigated. The first phosphorylation was performed on pyridone nucleoside **1**. The use of bis(2,2,2-trichloroethyl) phosphorochloridate, an attractive phosphorylating agent owing to its 5'-selectivity,[19] early revealed that **1** is more labile than the natural pyrimidone nucleosides dT and dC.[6] Pyridinium mono-2-cyanoethyl phosphate,[20] together with a

condensing agent like dicyclohexylcarbodiimide (DCC) or mesitylenesulfonyl chloride, was found to be the reagent of choice for 3'- and 5'-phosphorylations.[21-23] The 2-cyanoethyl group was removed with ammonia (via β-elimination) to give the ammonium salts of the phosphoric acid monoesters.

In order to obtain the nucleoside 5'-monophosphates directly, an alternative route has been developed (Scheme 4a).[24] Treatment of the nucleoside analogues **1**–**3** with a



Scheme 4. a) 5'-Phosphorylations. b) 3'-Phosphorylations. B^P (protected bases): 9-(N^2-isobuturylguanine), 1-(N^4-anisoylcytosine), or 1-{N^4-(1-methylpyrrolidine-2-ylidene)cytosine} [39] and 9-{N^6-(1-methylpyrrolidine-2-ylidene)adenine} [40]. No protecting group on 1-(thymine). 1) Partially protected nucleoside; 2) Et_3N/pyridine/H_2O; 3) aq. Et_3NH HCO_3, extraction into $CHCl_3$; 4) chromatography on SiO_2, precipitation.

mixture of phosphorus oxychloride and a small amount of water afforded the 5'-phosphorylated compounds **35**–**37** in high yields.[25-27] No 3'-phosphorylation and no cleavage of the bases could be detected. Of the three analogues, pyrimidone nucleoside **2** contains the most acid- and base-labile glycosidic linkage.[25] Therefore, this direct phosphorylation procedure was ideal for its 5'-phosphorylation. Compounds **35**–**37** were chemically transformed into the corresponding triphosphates **41**–**43** according to the procedure of *Moffat* and *Khorana*[28-29] through the formation of the reactive phosphoramidates **38**–**40** (Scheme 4a).[27]

Another type of phosphate of the nucleoside analogues is required in the synthesis of DNA oligomers. The building blocks needed for the phosphotriester methodology are standard fully protected nucleoside 3'-monophosphate triesters. Acid-labile di- or monomethoxytrityl groups were used as temporary 5'-protecting groups and N^6-benzoyl, N^4-anisoyl, and N^2-isobuturyl amides were chosen for permanent protecting groups for the adenylate, cytidylate, and guanylate derivatives.[30-32] The *p*-chlorophenyl (later *o*-chlorophenyl) group was used as a permanent phosphate protecting group; these groups could be selectively cleaved by the 1,1,3,3-tetramethylguanidinium salt of (*E*)-4-nitrobenzaldehyde (later (*E*)-2-nitrobenzaldehyde) oxime in the final deprotection step after the last condensation reaction.[33-34] Suitable phosphorylating agents were *p*- and *o*-chlorophenyl 2-cyanoethyl phosphorochloridate (**44**). The 2-cyanoethyl group was used as a transient phosphate protecting group in order to render the building block lipophilic and purifiable on silica gel. Before each condensation step, this group had to be removed in situ with a base like triethylamine or *tert*-butylamine.[31,32,35-37]

Recently, we found that an eluent system for the chromatography of highly polar substrates, such as amino acids (ethyl acetate/methanol/water 4:1:0.1–0.7), was ideal for the purification of the anionic, fully protected building blocks **47** as their triethylammonium salts on fine silica (40–63 μm) by "flash chromatography", without cleavage of the very acid-labile 5'-dimethoxytrityl function. This procedure not only allowed us to omit the 2-cyanoethyl phosphate protecting group (which proved thermally slightly unstable on longer storage) and its in situ deprotection, but also enabled us to use a simpler phosphorylating agent, *o*-chlorophenyl phosphorodichloridate (**45**). Scheme 4b summarizes our presently favored phosphorylation procedure adopted from *Chattopadhyaya* and *Reese*[38a]; this procedure uses in situ phosphorodiimidazolidate derivative **46** as the reactive phosphorylation species for the synthesis of triester building blocks **47**.[38b]

2.2. Condensations of Nucleotides

2.2.1. *Syntheses in Solution*

At the beginning of our studies in the early 1970s, research into oligodeoxynucleotide synthesis had not yet established a preferred approach. The mild condensation reagents needed for the couplings according to *Gilham* and *Khorana*'s phosphodiester approach,[41] in particular DCC as a coupling reagent, seemed to be appropriate for our needs, since, during the studies with nucleoside analogue **1**, it became clear that we were dealing with unstable substrates.[6-7] Nevertheless, *Falk* et al.,[21] following *Letsinger* and *Ogilvie*,[20] used the initial version of the phosphotriester approach. A comparison of these phosphotriester-coupling yields for various polythymidine nucleotides with those derived from

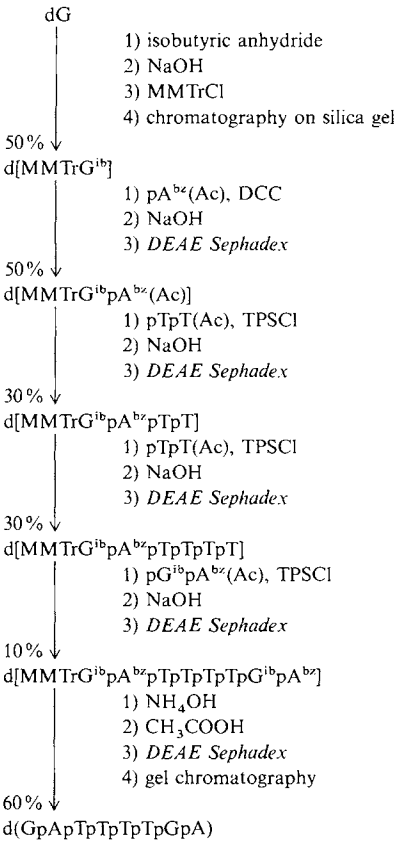
Khorana and *Vizsolyi*'s[42] diester synthesis misleadingly indicated the superiority of the latter method.

Indeed, promising results were obtained in investigations on the synthesis of di- and trinucleotides containing pyridone (**4**) and pyrimidone (**5**) with this 5′ → 3′ diester method using the easily accessible nucleoside 5′-phosphates as building blocks, where the nucleophilic attack in the condensation reaction is carried out by a secondary alcohol function.[22, 23, 25, 26, 43, 44] In contrast, *Weimann* and *Khorana*'s[45] 3′ → 5′ diester method using nucleoside 3′-phosphates as building blocks resulted interestingly in the formation of dimeric pyrophosphates (self-condensation products).[23] These results enabled us to plan a synthetic strategy for the stepwise construction of longer oligonucleotides containing modified bases.

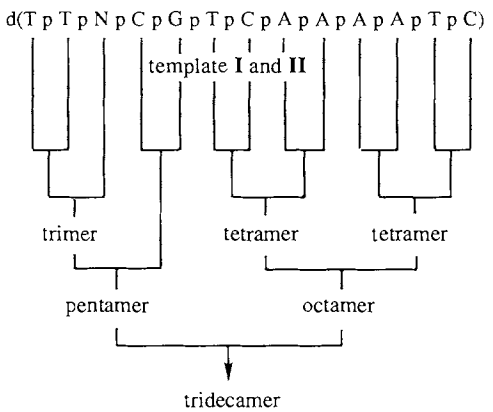
The plan for an enzymatic chain elongation involving the analogues is essentially divided into two parts, the synthesis of a wholly natural primer strand and that of three template strands bearing **1**, **2**, and **3** in defined positions.[46] The enzyme chosen for the replication experiments was the DNA-dependent *Escherichia coli* DNA polymerase I (pol I, E.C. 2.7.7.7.), which requires a DNA template and a DNA (or, in vivo, RNA) primer strand, with a minimal length of seven to nine nucleotides for both strands. The DNA should be double-stranded and for this experiment the template strand should be somewhat longer than the primer strand. The following sequences were elucidated (Scheme 8 summarizes the experimental setup and results): a tridecameric template strand, 5′-d(TpTpNpCpGpTpCpApApApApTpC)-3′, where N stands for **1**–**3** (in the following, template **I**, **II**, and **III**, respectively), and an octameric primer strand, 5′-d(GpApTpTpTpTpGpA)-3′. Note that the primer strand is complementary to the 3′ end of the template strand, leaving five nucleotides to act as the effective template with N in its center.

The primer strand was prepared by dinucleotide block synthesis (Scheme 5).[47] Since the diester method works with secondary alcohols, which, as nucleophiles, are relatively unreactive owing to steric hindrance, the formation of pyrophosphates was a common side reaction (nonactivated phosphate groups compete with 3′-OH functions). This led to low yields of the desired products (Scheme 5). The second problem was the anionic nature of reactants and products (phosphoric acid diesters), which needed to be separated on ion-exchange resins. The purification was quite tedious and the resolution of products of similar length rather difficult. Clearly, the phosphodiester method met its limits with the synthesis of an octamer.

Therefore, we reconsidered the phosphotriester approach,[35, 48] undertook two block syntheses of template **I**, and compared the diester with the triester method.[31] Although it was possible to carry out a substantial part of the synthesis, we had to abandon diester chemistry. The triester synthesis (Scheme 6) was based on standard fully protected nucleoside 3′-phosphotriesters (Section 2.1.2). The deprotected tridecamer was purified by preparative layer and ion-exchange chromatography and reversed-phase HPLC. A part of it was digested with phosphodiesterase I, and HPLC analysis of the mixture of monomers gave the expected base ratios. The preparation of template **II** was carried out essentially in the same way.[32] In addition to the HPLC analysis



Scheme 5. Total synthesis of octadeoxynucleoside heptaphosphate GATTTTGA in solution using 5′ → 3′-phosphodiester methodology. Abbreviations: ^{ib} = N^2-isobuturyl; ^{bz} = N^6-benzoyl; (Ac) = 3′-*O*-acetyl; MMTr = 5′-*O*-[diphenyl(4-methoxyphenyl)]methyl (monomethoxytrityl ether); p = phosphoric acid diester; DCC = dicyclohexylcarbodiimide; TPSCl = 2,4,6-triisopropylbenzenesulfonyl chloride; DEAE-Sephadex = strong anion-exchange resin.



Scheme 6. Block synthesis of tridecadeoxynucleoside dodecaphosphate TTNCGTCAAAATC (N = **1**, template **I**; N = **2**: template **II**) in solution using phosphotriester methodology.

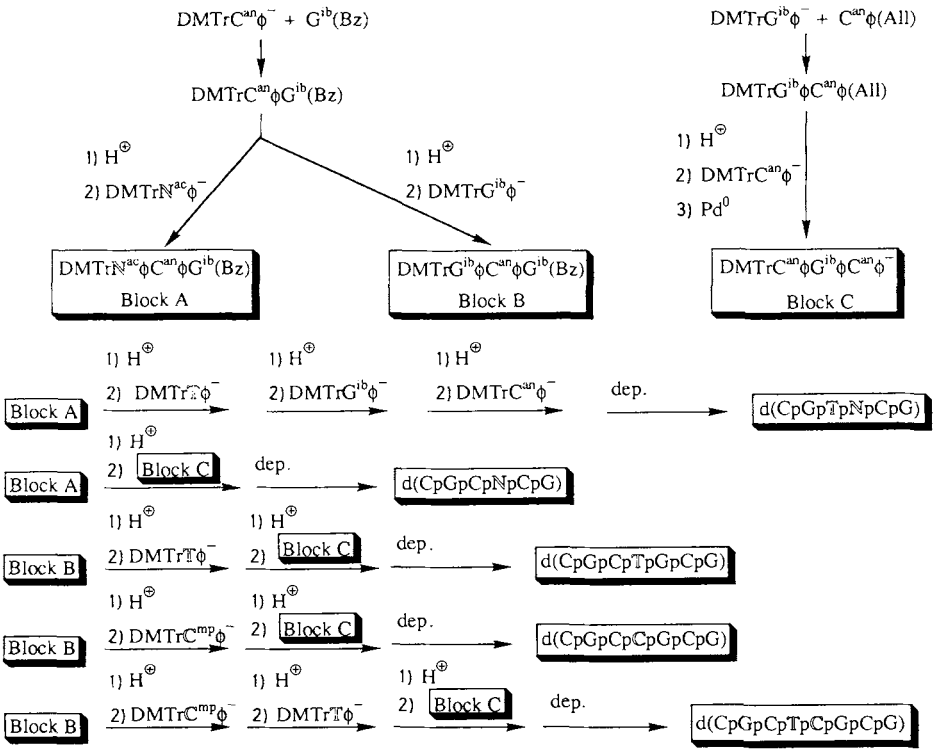
of the phosphodiesterase-I-digested oligomer, a sequence analysis according to the Maxam–Gilbert procedure[49a] showed the correct nucleotide sequence.

The results obtained from the incorporation and replication experiments (see Section 3.2) encouraged us to continue our synthetic work. The need for rather large amounts (50–100 mg per oligomer) of very pure oligomers that can be

analyzed by ^1H NMR, ^{15}N NMR, and CD spectroscopy and, if crystallizable, by X-ray diffraction again suggested the use of the block-synthesis strategy and the by now well-known triester approach in solution. We are now synthesizing as efficiently as possible five self-complementary oligomers: two hexamers (called TZ and CZ), two heptamers (called TT and CC), and one octamer (called TC). The reason for the choice of these sequences will be discussed in Section 3.3.

TZ 5′-d(CpGpTpNpCpG)-3′, dN = **3**
CZ 5′-d(CpGpCpNpCpG)-3′, dN = **3**
TT 5′-d(CpGpCpTpGpCpG)-3′
CC 5′-d(CpGpCpCpGpCpG)-3′
TC 5′-d(CpGpCpTpCpGpCpG)-3′

The trinucleotide sequences NCG, GCG, and CGC occur in several oligomers and therefore serve as blocks A, B, and C, respectively (Scheme 7). The central bases (outlined in Scheme 7) are labeled with highly enriched ^{15}N isotopes. They were synthesized from labeled urea (for labeled dT), uracil and ammonia (for labeled dC), and ammonia (for labeled **3**) according to the procedure depicted in Scheme 1b.[49b] The synthetic strategy is partly based on a modern solution procedure, the "filtration method" developed by *Chaudhuri* et al.[50] It is a triester method (5′ → 3′ chain elongation) that works with monomeric building blocks; we chose the ones already discussed in Section 2.1.2 (**47**, Scheme 4b). According to the authors, the use of a highly efficient coupling mixture results in coupling yields that are good enough to allow as many as five coupling cycles to be carried out without chromatographic purification of the intermediates (in our synthesis, three coupling cycles).



Scheme 7. Triester block synthesis of two hexamers, two heptamers, and one octamer in solution. ^{an} = N^4-anisoyl; ^{ib} = N^2-isobutyryl(Bz) = 3′-benzoyl; ϕ = 2-chlorophenyl phosphate; ϕ(All) = allyl 2-chlorophenyl phosphate; ϕ⁻ = triethylammonium 2-chlorophenyl phosphate; dN^{ac} = 4-[^{15}N]-acetamido-1-(2′-deoxy-β-D-ribofuranosyl)-[1,3-$^{15}N_2$]2(1*H*)-pyridone; T = [1,3-$^{15}N_2$]-thymidine; dC^{mp} = N^4-(1-methylpyrrolidine-2-ylidene)-[1,3-N^4-$^{15}N_3$]-2′-deoxycytidine.

2.2.2. *Syntheses on Solid Supports*

The chemical lability of **1** and **2** prevented the use of a solid-support synthesis, because the risk of obtaining a mixture of tridecamers with partly depyridinated or depyrimidinated residues after the final purification was too high. The additional 4-amino group in **3** rendered the nucleoside much more stable, presumably owing to the strong + M effect of this function in *para* position to the glycosidic linkage. Cleavage of the base was no longer a major problem, so a solid-support synthesis of template **III** was envisaged. At the time, one could choose between the rapid phosphite[51,52] and the phosphotriester methodology. The phosphoramidite method[53a] mostly used nowadays had not been established for routine work yet. Preliminary studies showed that, in the phosphite methodology, the drastic coupling conditions resulted in symmetrically coupled byproducts and lower yields than achieved with triester chemistry.[53b] Moreover, the latter and slower method had the advantage of being more flexible; for example, it allowed the use of di- or trimeric building blocks. Since our experience with the nucleotide analogues and triester chemistry in solution was good, we decided to continue with that approach.

The whole synthesis was run in a manually controlled closed system where the solutions could be added to the column containing the solid support through an eight-way valve by a slight over-pressure of dry nitrogen gas. Since the now widely used controlled-pore glass (CPG) was unknown at the beginning of this synthesis, the best solid support was found to be styrene cross-linked with 1% divinylbenzene. During the synthesis of template **III**, the reaction conditions

were optimized and tested in the synthesis of the octameric primer strand GATTTTGA.[10, 37] The building blocks for template **III** were monomers, dimers, and trimers with the same structures as used in the syntheses of templates **I** and **II** (cf. Section 2.1.2). However, GATTTTGA was synthesized using entirely monomeric building blocks.

Different coupling reagents were tested; mesitylenesulfonyl-3-nitro-1,2,4-triazol-1-ide/1-butylimidazole (minimum condensation time on solid support: 10 min) reacted fastest and afforded the best yields. The superiority of 1-butylimidazole as catalyst over the commonly used 1-methylimidazole has already been observed in phosphorylation reactions using reagent **44**.[31] It can be explained by the enhanced nucleophilicity of the butyl derivative, which is a major determinant in a rate-determining step of the coupling reaction.[10] Still more nucleophilic catalysts like 4-(dimethylamino)pyridine 1-oxide, introduced by *Efimov* et al.,[54] even enabled the triester method to compete with the coupling times of the rapid phosphoramidite method (condensation time: ca. 1 min). In consequence the average coupling yield in the optimized synthesis of the octamer was 98% and no capping of unreacted residues was necessary.

The final deprotection procedure had to be modified for template **III**, because the standard treatment with concentrated ammonia at 55 °C failed to hydrolyze the N^4-acetyl group of the base analogue. The base protection in N^4-acetyl-3-deaza-2'-deoxycytidylate, an amide derived from an enamine, proved to be more stable towards hydrolysis than an amide derived from an amidine, as in N^4-anisoyldeoxycytidylate. After cleavage of the permanent phosphate protecting groups and partial release of the product from the solid support with benzaldehyde oximate, and after total release from the solid support and cleavage of the benzoyl, anisoyl, and isobuturyl protecting groups with ammonia, a subsequent hydrolysis with 1 M NaOH for 30 min successfully deacetylated the base analogue in the tridecamer. Interestingly, the generation of a polyanion with benzaldehyde oximate afforded good enough protection for the other phosphoric acid diester bonds, which were not cleaved during final treatment with strong base.

HPLC analysis of the purified products showed apparent homogeneity; in the case of template **III**, this was confirmed by the appearance of a single band after polyacrylamide gel electrophoresis of the 5'-^{32}P-phosphorylated product. The phosphodiesterase I digestion of both the tridecamer and octamer resulted in the expected composition of mononucleotides upon HPLC analysis.[10, 37]

3. Base Pairing with Modified Nucleotides

3.1. Prokaryotic DNA Polymerases as a Model System

Escherichia coli DNA polymerase I (pol I) is the best characterized prokaryotic DNA-synthesizing enzyme.[55, 56] It has a molecular weight of 103 000 Da and consists of three domains (Fig. 4). The polymerase domain contains a template-DNA binding site, a DNA 3'-terminus binding site for the primer strand, and a nucleoside triphosphate (dNTP) binding site. The 3'-5'-exonuclease domain contains another 3'-terminus binding site, which can also bind a nucleoside

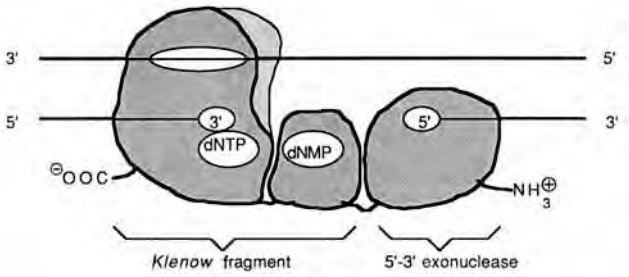


Fig. 4. Schematic drawing of DNA-bound *E. coli* DNA polymerase I (after *Joyce* and *Steitz* [57]).

monophosphate (dNMP). This domain excizes freshly polymerized 3'-terminal nucleoside 5'-monophosphates from the growing strand and therefore functions as a proofreading activity. These domains are together called the Klenow fragment or large (proteolytic) fragment having a molecular weight of 68 000 Da. Both domains require magnesium ions for proper functioning. The small fragment with a molecular weight of 35 000 Da, the 5'-3'-exonuclease domain, removes DNA ahead of the growing point of a DNA chain.[57, 58]

This enzymatic system served as a model enzyme for DNA synthesis. The aim was to determine whether our analogues would be accepted in the dNTP binding site or in the template DNA binding site of the polymerase and how they would behave in comparison to the natural substrates. Since preparations of *E. coli* DNA polymerase I were known to contain some concomitant DNA nuclease activity (possibly causing DNA digestion), an alternative, related enzyme, *Micrococcus luteus* DNA polymerase, having a much lower DNA nuclease activity, was also tested.

3.2. Enzymatic Reactions

3.2.1. In Vitro DNA Polymerase-Catalyzed Incorporations Using Modified Nucleoside Triphosphates[59]

All three triphosphate analogues, **41**, **42**, and **43** (Scheme 4a), can be considered to be dCTP structure analogues. Therefore, they were used in place of dCTP to measure the rate of incorporation into DNA. Polymerase was added to a mixture of activated calf thymus DNA ("random" sequences which act as template and primer), dATP, dGTP, TTP, [α-^{32}P]TTP, and increasing amounts of one of the analogues **41**–**43** (1 to 50 equivalents relative to natural triphosphates). After 30 min the reaction was quenched and the resulting DNA precipitated and washed. The rate of nucleotide incorporation was measured by scintillation counting of the radioactivity in the product.

The results were identical for both enzymes, pol I and *M. luteus* DNA polymerase, and did not depend on the addition of the analogues. This indicated that the polymerization continued until the first dCMP was to be incorporated and no incorporation of compounds **41**–**43** occurred. Alternatively, the analogues could have been incorporated, but the further synthesis inhibited. To test this, dCTP was added after the first incubation period and the reaction was quenched after another 30 min. The rate of incorporation increased and was practically identical to the rate measured

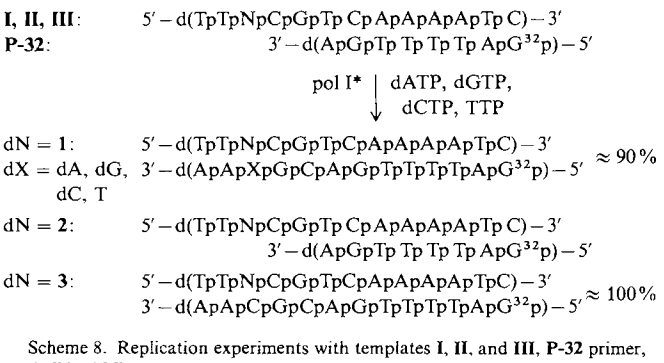
after an incubation with all four natural nucleoside triphosphates. This means that the polymerases cannot incorporate compounds **41**–**43** into DNA. When thymus DNA was replaced by synthetic poly-d(GC) and [α-^{32}P]dGTP was used at a constant concentration with increasing amounts of **41**, **42**, and **43**, essentially the same result was obtained.

Possible inhibition of the polymerase by **41**–**43** could not be ruled out. In order to measure an inhibition, a mixture of *M. luteus* DNA polymerase, thymus DNA or poly-d(GC), [α-^{32}P]TTP or [α-^{32}P]dGTP, respectively, and all the natural nucleoside triphosphates (only dGTP and dCTP for poly-d(GC)) was incubated with increasing amounts of **41**, **42**, and **43** under the same conditions as above. A very weak inhibition was observed with both templates and all three analogues. The DNA synthesis on the natural template was inhibited to 50% and on poly-d(GC) to 70% by a 50-fold excess of **41**, **42**, or **43**.

With an additional series of experiments, we intended to elucidate the type of inhibition by **41**–**43**. To a mixture of *M. luteus* DNA polymerase and thymus DNA, three natural nucleoside triphosphates were added in constant amounts and one—dATP or dCTP—in increasing amounts followed by incubation for 15 min. The dependence of DNA synthesis (i.e., reaction velocity v) on substrate concentration ([S], where S is dATP or dCTP) could be studied in this way. The dependence was measured once without and once with a 50-fold excess of one of the inhibitors **41**–**43**. In the experiments without inhibitor the rate of DNA synthesis, v, increased rapidly with increasing amounts of S to reach v_{max}. The same happened in the presence of each of the three inhibitors, but there v_{max} reached only 50% of the value without inhibitor. A Lineweaver–Burke plot[60] ($1/v$ versus $1/[S]$) for the experiments with and without inhibitor revealed that analogues **41**–**43** are uncompetitive inhibitors.

3.2.2. *In Vitro DNA Polymerase-Catalyzed Incorporations Using Modified Nucleotides in the DNA Template Strand*

As described in Section 2.2, three template strands have been constructed containing one analogue each. The primer GATTTTGA was to be elongated enzymatically (Scheme 8). First, the functioning of the primer and the templates **I**, **II**, and **III** as a DNA matrix for the Klenow fragment (pol I*) had to be tested. Only the large fragment of *E. coli* DNA polymerase I was used for all further studies, because the results derived from replication experiments with the whole enzyme would have seriously complicated the interpretations owing to the presence of the extra 5′-3′-exonuclease activity (cf. Section 3.1) and its capability of excizing mono- to decameric nucleotide fragments out of a DNA double strand after replication.[55]



Scheme 8. Replication experiments with templates **I**, **II**, and **III**, **P-32** primer, dATP, dGTP, dCTP, and TTP using the Klenow fragment of *E. coli* DNA polymerase I (pol I*).

Pol I* was added to a mixture containing the necessary coagents (buffer, $Mg^{2\oplus}$ salt, etc.), [α-^{32}P]dCTP, the first nucleotide to be incorporated, and equimolar amounts of template **I**, **II**, or **III** and primer. The solutions were incubated for 90 min. After quenching the polymerization reactions, the products were separated by HPLC and the amount of incorporated radioactivity was determined by scintillation counting. In comparison to runs without enzyme, in all experiments most of the radioactive labeling was found in a peak ascribed to the prolonged primer d(GpApTpTpTpTpGpA[^{32}p]C). Hence, the functioning of the replication system was confirmed. The primer strand was then labeled on its 5′ end with [γ-^{32}P]dATP by polynucleotide kinase and purified by HPLC to give d([^{32}p]GpApTpTpTpTpGpA) (**P-32** primer).[10]

For the replication experiments,[61] equimolar amounts of template **I**, **II**, or **III** and **P-32** primer, together with dATP, dGTP, dCTP, and TTP were dissolved in a solution of buffer salts and additives and the mixture was heated to 60 °C for 5–10 min (standard procedure for the destruction of possible undesired secondary structures). Then, it was slowly cooled to allow the formation of the primer–template double helix. Pol I* was added and the mixture was incubated for 30 min. After quenching the reaction, the replication products were, on one hand, directly analyzed by gel electrophoresis and radiography and, on the other hand, sequenced and radiographed according to the Maxam–Gilbert procedure.[49]

Our interpretations of the results from the radiograms of the sequenced (Fig. 5) and unsequenced products (not shown) are depicted in Scheme 8.[61] With template **I** the elongation of the **P-32** primer proceeded to about 90%. The nucleotides were incorporated correctly when directed by a

Fig. 5. Radiogram of sequenced **P-32** primer after elongation by pol I* (according to *Maxam* and *Gilbert* [49a]). Lanes 1–4: Replication of template **III**. Lanes 5–8: Replication of template **I**. Lanes 9–12: Replication of template **II**, here the bands beyond 3′-terminal A are inconclusive. natural template base, but the synthetic analogue led to non-specific incorporation. The replication of template **II** did not lead to any significant primer elongation. The most surprising result was obtained with template **III**. **P-32** primer was elongated to 100%. The incorporations opposite the natural bases were correct and base analogue **3** directed a specific incorporation of deoxycytidylate.

3.2.3. Mutagenicity Tests in Vivo

Bloch et al.[62] performed growth inhibition experiments and activity tests in vivo with 3-deazapyrimidine ribonucleoside analogues (e.g., 3-deazauridine and 3-deazacytidine) and found that the analogues were converted into the 5′-triphosphates but were not incorporated into either RNA or DNA. (Nucleoside 5′-triphosphates cannot be used in vivo, because ionic substrates will not penetrate cell membranes.) These results were confirmed by our own in vitro incorporation experiment using 3-deaza-2′-deoxycytidine 5′-triphosphate (**43**; cf. Section 3.2.1).

Nevertheless, *Bickle*[63] carried out in vivo mutagenicity tests with compound **3**, since the results with template **III** (Scheme 8) suggested that if deoxynucleoside analogue **3** were 5′-triphosphorylated and incorporated into DNA opposite deoxycytidylate in vivo, C → G transversions would result after a further round of replication. Specific transversion mutagens are very rare, so it would be of great help to have such a compound at hand. Unfortunately, both the standard Ames test[64] and the more sensitive "lambda-mutatest" developed by *Devoret*[65] revealed that, within a wide concentration range of compound **3**, no mutagenicity was detectable. We concluded that no incorporation into DNA occurred, although, presumably, the nucleoside analogue was 5′-triphosphorylated in the cells.

3.3. Interpretation of the Experimental Results

3.3.1. Structural Features Required for Nucleotide Incorporation

None of the experiments with the analogue triphosphates **41**–**43** led to an incorporation through a DNA polymerase. According to the information gained from successful incorporations of a variety of nucleotide analogues,[55] as well as from polymerase complexation stabilities of the natural compounds,[66] the primary binding of a nucleoside triphosphate in pol I is highly reversible, quite weak, and only moderately selective with respect to the base structure.

Therefore, it is reasonable to assume that all three compounds, being structurally closely related to the native dCTP, are able to form a complex in the triphosphate binding site of the polymerase. Yet, the reduced capability of **41**–**43** to form hydrogen bonds with any template base (Fig. 3) makes them rather weak competitors to the natural nucleoside triphosphates also present. As discussed in Section 1.4, alternative binding modes involving rare tautomers, protonated base pairs, or reading frame shifts must be ruled out for these analogue triphosphates, since no incorporation occurred at all.

3.3.2. Replication of Templates I and II

The structure of a nucleotide analogue bearing a 2-pyridone (e.g., **1**) is such that no base pairing with an imino proton of a nucleotide base (deoxyguanylate and thymidylate) can occur (cf. Section 1.4). The unspecific incorporations opposite **1** directed by template **I** included dGMP and TMP (Fig. 5). This suggests that, before polymerization, the base must have been cleaved from **1**, leaving an "abasic" site. Pol I ist capable of replicating abasic sites at a slower rate.[67]

The experiment with template **II** most probably failed owing to the exceptional instability of analogue **2** (cf. Section 2.1.2). The order of chemical stabilities of the base analogues is **3** > **1** > **2**. Yet, even the most stable template **III** showed a certain proneness towards strand cleavage, particularly between the nucleotide analogue **3** and its 5′-neighbor, thymidylate, if incubated in a buffer solution with polynucleotide kinase at room temperature for 6 h.[10] Although a reversed-phase HPLC purification of all three templates was carried out shortly before use,[10] the strands were not tested for their content of **1**–**3**. We assume that, even if template **II** was correct shortly before use, it must have been destroyed on heating to 60 °C immediately before the addition of pol I* (cf. Section 3.2.2), since the same treatment of template **I** most probably caused the even more stable analogue **1** to depyridinate.

The replication experiments with templates **I** and **II** demonstrate that the nucleotide base analogues must be sufficiently stable, not only during their chemical synthesis, but, equally important, under replication reaction conditions. Thus, the design of further analogues has to be planned very carefully.

3.3.3. Replication of Template III: The Structure of a Pyridine–Pyrimidine Pair in Polymerase-Bound DNA

To understand the specific incorporation of deoxycytidylate opposite analogue **3** in template **III**, we need to list all the theoretically possible arrangements of nucleotide base pairings in a polymerase containing the analogue in the template strand (Fig. 6). Analogue **3** in the amino-keto form cannot form a base pair with any nucleotide in the Watson–Crick arrangement, because there are always interactions between protruding hydrogen atoms that prevent the bases from coming close enough to form hydrogen bonds (Fig. 6a, first column). Theoretically, there are two alternative arrangements, the wobble position where one of the bases is shifted towards the major groove of the DNA double helix (Fig. 6a, second column) and that where the same base is shifted towards the minor groove (Fig. 6a, third column). In these positions, pairings with some purine and pyrimidine nucleotides would be sterically feasible; the most favorable pairing should be the one with deoxyguanylate. Since no deoxyguanylate was found opposite analogue **3** within the limits of accuracy of the Maxam–Gilbert procedure, we conclude that no formation of such a base pair in the wobble position is possible in the polymerase.

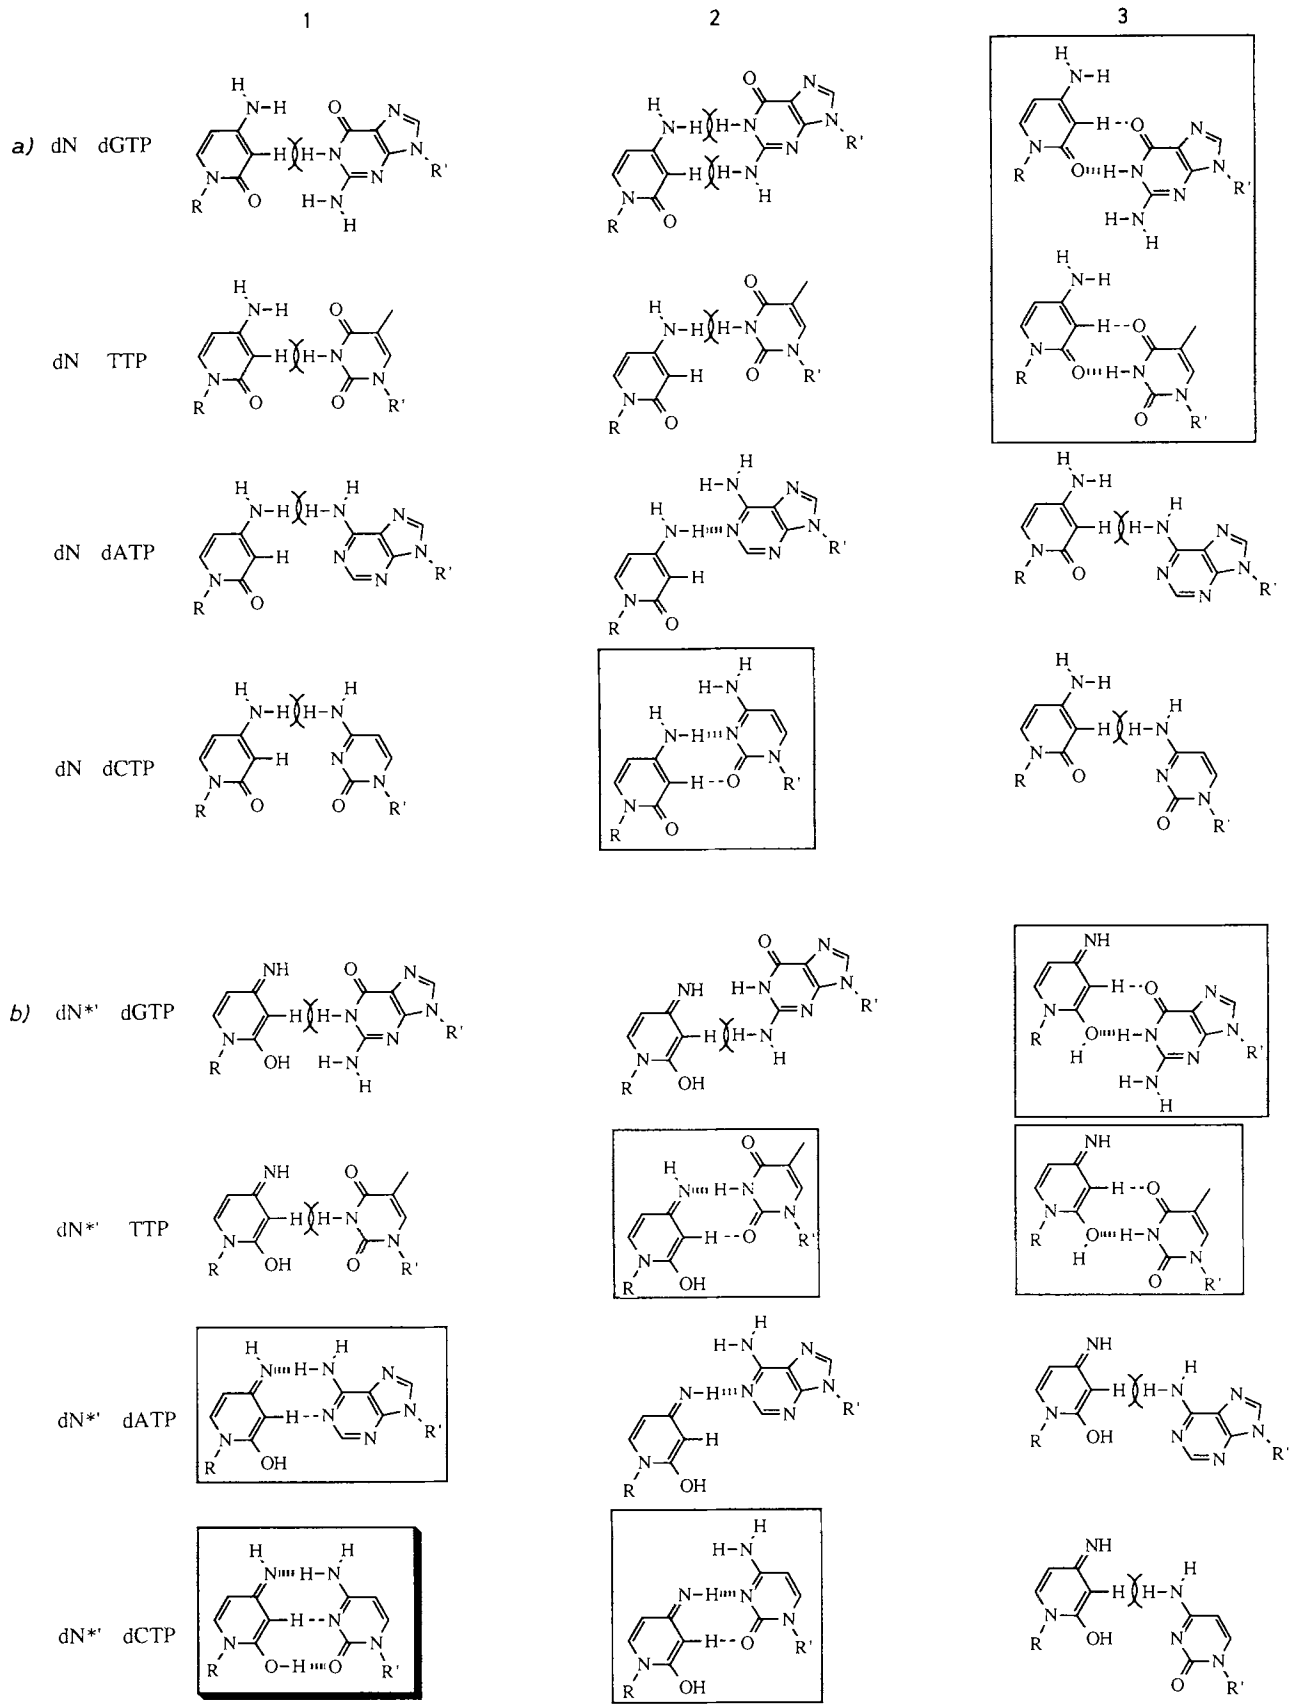

Fig. 6. Theoretically possible arrangements of nucleotide bases in a DNA polymerase between a) base analogue **3** (dN), b) tautomeric form of **3** (dN*'), and four natural deoxynucleotides in their normal tautomeric forms. First column, Watson–Crick-like arrangement; second column, wobble arrangement with incoming nucleotide shifted into major groove of DNA double helix; third column, as second, but with incoming nucleotide shifted into minor groove. R = DNA backbone; R' = 2'-deoxy-β-D-ribofuranosyl 5'-triphosphate. (III): hydrogen bonds between heteroatoms, (- - -): weak attractive interactions. Crossed bows symbolize steric hindrance (repulsion). Simple frames: more than one, but less than two H bonds per base pair. Shaded frame: two H bonds. In dN*' the position of H-N^4 (*syn* or *anti*) was chosen deliberately to provide optimal base pairing.

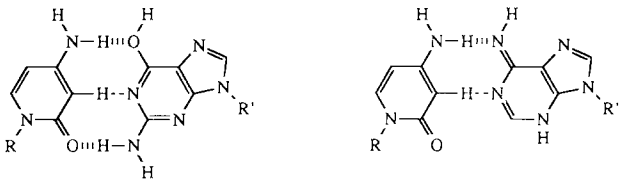
The tautomeric imino-enol form[*] of analogue **3** (dN*', Fig. 6b), in contrast, can form two hydrogen bonds with deoxycytidylate and less than two with deoxyadenylate in the Watson–Crick arrangement. In principal, base pairings with deoxyguanylate and thymidylate in a wobble position are also imaginable, but the sole incorporation of deoxycytidylate proves that, at high misincorporation frequencies, the Watson–Crick arrangement is the only accepted one in the polymerase.

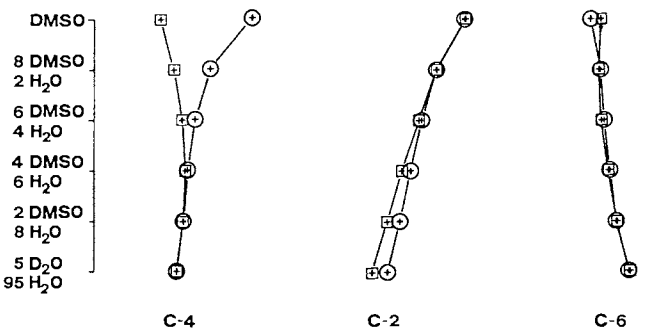
Another form of base-pair arrangement should be considered. The incoming nucleoside triphosphates could be in their alternative tautomeric forms, presenting another hydrogen-substitution pattern. In particular, the lactim form of deoxyguanylate (dG*TP) and one imino form of deoxyadenylate (3*H*-dA*TP) would match the amino-keto form of analogue **3** in the Watson–Crick arrangement (Fig. 7). Both



3 · dG*TP **3** · 3*H*-dA*TP

Fig. 7. Theoretically possible base-pair arrangements in a DNA polymerase between **3** (in the template) and rare tautomeric forms of nucleoside triphosphates dG*TP and 3*H*-dA*TP. R = DNA backbone; R' = 2'-deoxy-β-D-ribofuranosyl 5'-triphosphate.

tautomeric forms are known to be rare in the sense that their occurrence is 10^{-3} to 10^{-5} per monomeric molecule of the normal form in solution.[68] Again, since we did not observe such an incorporation, we argue that in the polymerase's binding site for nucleoside triphosphates the rare tautomeric forms are excluded. This is consistent with our finding that the tautomeric form of the triphosphate analogue **43**, dN*'TP, which was shown to be rare (see below), was not incorporated into DNA (Sections 3.2.1 and 3.3.1), as well as with other mutagenesis experiments (discussed in Ref. [69]).



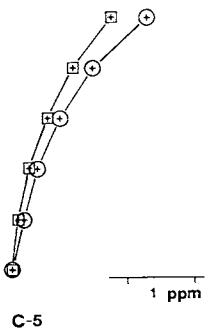


Fig. 8. Superimposition of δ(C) curves derived from the dependence of ^{13}C NMR spectra of base carbon atoms of 2'-deoxycytidine (squares) and 3-deaza-2'-deoxycytidine (circles) on solvent composition (from *Strazewski* [70]). DMSO = [D_6]dimethyl sulfoxide.

The question of the amount of the tautomeric imino-enol form of the nucleoside analogue **3** in water was answered by a comparative ^{13}C NMR study on the nucleosides **3** and deoxycytidine.[70] The tautomeric forms of deoxycytidine (dC* and dC*') are too rare in both water and dimethyl sulfoxide (DMSO) to be observable by ^{13}C NMR spectroscopy. Therefore, the differences in the chemical shifts of the carbon atoms in the sugar moiety of dC on gradually changing from DMSO to water are thought to be derived mainly from conformational changes, and the differences in the chemical shifts of the carbon atoms in the base of dC are ascribed mainly to the differences in solvation or hydration. The same holds true for the analogue. The δ(C) curves of both compounds are quite similar and differ largely in the range of $\Delta\delta_3^{dC} = 0.1-0.3$ when the "relative" δ(C) values of the corresponding carbon atoms are compared independently of the "absolute" chemical shift values (Fig. 8). The largest differences were $\Delta\delta = 0.5$ for C-5 and 1.4 for C-4 in pure DMSO, but with higher water contents the δ(C) curves become practically superimposable. This is plausible because, especially when none or only very little water is around, we expect another hydration mode in the proximity of the 4-amino group, dependent on whether an additional proton acceptor (N-3) is present or not.

A substantial, that is, spectroscopically observable shift of the tautomeric equilibrium of analogue **3**, on gradually changing from DMSO to water, should be observable as a difference in the δ(C) values for the C-4 atoms as well, but only concomitant with a difference in the δ(C) values for the C-2 atoms (dN → dN*'). In **3** the differences Δδ(C) for C-4 and C-2 between the pure DMSO and the pure water value are $\Delta\delta_{H_2O}^{DMSO} = 1.17$ and 1.16, respectively, and in dC 0.25 and 1.44, respectively. The difference derived from a change in the tautomeric form is expected to be at least $\Delta\delta_{H_2O}^{DMSO} = 2$ (when an external standard is used).[71] Since the shapes of the δ(C) curves for the C-2 atoms in the two compounds are very similar (Fig. 8), we conclude that no shift of the tautomeric equilibrium of the analogue could be observed. The ^1H NMR spectrum of compound **3** in DMSO shows two amino protons; therefore, the main tautomeric form of the analogue in aqueous solution must be the amino-keto form.

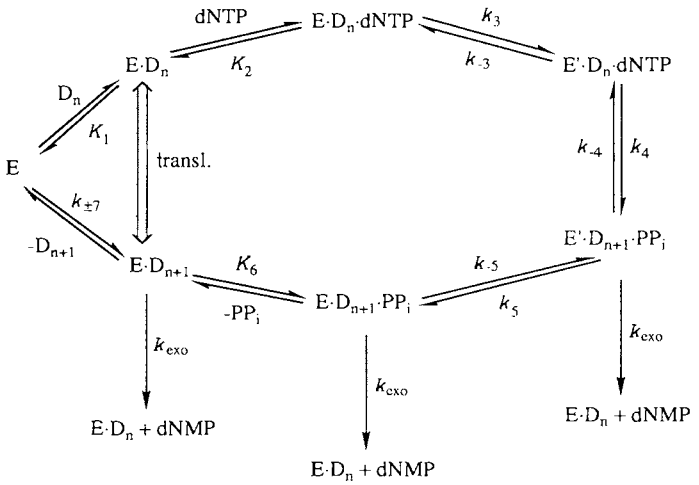
In spite of its rarity, only the imino-enol form of analogue **3** can apparently form a strong enough base pair with a nucleoside triphosphate to launch a polymerization reaction by the enzyme; the hydrogen-substitution pattern of this form is the same as in deoxyguanylate (Fig. 6b). This provides a sufficient explanation of the selective incorporation of deoxycytidylate directed by analogue **3** in template **III**.

[*] In the following, an asterisk represents the unusual tautomeric form at C-4 substituents of pyri(mi)dine and at C-6 substituents of purine nucleotides and a prime sign the unusual tautomeric form at C-2 substituents of pyri(mi)dine and purine nucleotides.

3.3.4. *A Model Mechanism of Nucleotide Base Pairing and Polymerization*

How do these interpretations compare to the so far known mechanism of nucleotide polymerization and replication fidelity? Since the present model of polymerization is mostly based on experiments with pol I*, some recent results and views shall be briefly presented.

Benkovic et al.[72–74] investigated the kinetics of DNA synthesis by pol I*. Their conclusions are summarized in Scheme 9 (taken from Ref. [74]). First, the enzyme is loaded



Scheme 9. Kinetic model for DNA synthesis and proofreading by *E. coli* DNA polymerase I (from *Kuchta* et al. [74]). E, enzyme; D_n, primer/template; PP_i, pyrophosphate; D_{n+1}, elongated primer/template.

with DNA template and primer strands (K_1). A primary complexation of a nucleoside triphosphate follows (K_2). The first rate-limiting step consists of a conformational change (E → E') of the whole complex ($k_{\pm 3}$). Then, in a quite rapid (i.e., at most only partly rate-limiting) polymerization step, the covalent bond between primer and complexed mononucleotide is formed ($k_{\pm 4}$), producing a prolonged primer and a bound pyrophosphate molecule. After these steps, the highest discrimination between correct and incorrect nucleotide is achieved (approximately $1:10^4$ to $1:10^6$). At this stage, the proofreading activity of pol I* (Fig. 4) can cleave the freshly made linkage to release a nucleoside 5'-monophosphate (k_{exo}). Another conformational change ($k_{\pm 5}$) has been proposed in order to allow a second (observed) discrimination between matched and mismatched primer termini. Owing to a decreased dissociation rate of mismatch-containing DNA, the proofreading activity is given an opportunity to remove most of the remaining mismatches (k_{exo}). Diffusion of pyrophosphate away from the complex (K_6) generates an intermediate complex that can follow three pathways: decomplexation of the template–primer ($k_{\pm 7}$), leading to an interruption of continuous (processive) DNA synthesis, cleavage of the last primer residue (k_{exo}), or a rate-limiting translocation, regenerating a free nucleoside triphosphate binding site (processive DNA synthesis).

During the first discrimination ($k_{\pm 3}$), the correct nucleoside triphosphate is thought to allow a rapid enough change from E to E', while the enzyme that binds an incorrect nucleoside triphosphate will stay long enough in its primary form E for the diffusion of dNTP away from the complex. The polymerization rate constant $k_{\pm 4}$ also varies, depending on whether a correct or an incorrect nucleotide is bound covalently. Interestingly, the proofreading activity (k_{exo}) is not only relatively inefficient in comparison to the polymerase activity, but also unselective towards the excision of nucleoside monophosphates. Correct and incorrect nucleotides can both be excized if the conditions are favorable. This particularly happens when the polymerization or its following steps slow down (i.e., become rate-limiting) owing to either the formation of a badly matched base pair or to the presence of a formerly unrecognized mispair in the position directly behind the last pair. At present, the precise (steric) reasons why mispairings cause the replication process to slow down are unclear.

Steitz et al. performed X-ray analyses on pol I* with bound TMP,[75] 5'-d(AGACCGCCCGG)-3'·5'-d(CCGGGCGG)-3', and $p(T)_4$.[76] These studies and additional structural investigations by protein engineering[57] surprisingly suggest a quite remote position of the proofreading site—about eight base pairs away from the active site of polymerization. The structure of a primer strand about to be proofread is proposed to be partly melted out, leaving the last four primer bases unpaired (Fig. 9).[76] The slowing of polymerization

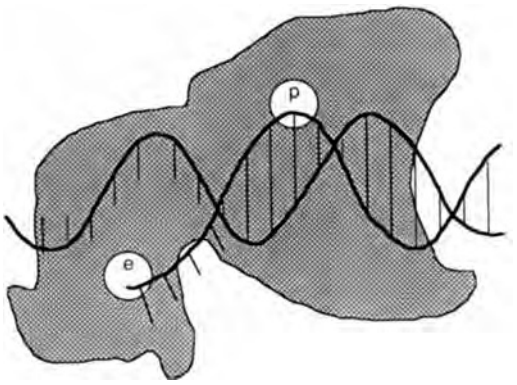


Fig. 9. Schematic drawing of pol I*/DNA with polymerase active site p. The DNA 3'-terminus is bound to exonuclease active site e (after *Freemont* et al. [76]).

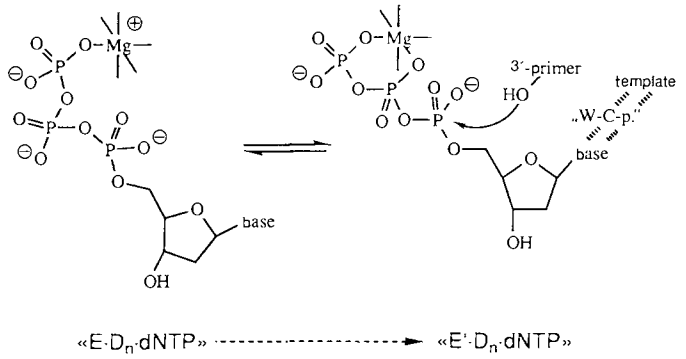
by mismatched pairs, allowing the primer strand to move to the proofreading site, was proposed to be due to a recognizing element ("reading head") located in the polymerase active site.[58] At present, this model has no experimental support, since no X-ray data showing the polymerase active site in interaction with a template strand and a nucleoside triphosphate are available yet.

Ferrin et al.[66, 77, 78] studied pol I* interactions with nucleoside triphosphates and oligoribonucleotides as templates (oligoribonucleotides were used to prevent enzymatic degradation) by NMR spectroscopy (nuclear magnetic relaxation of enzyme-bound manganese ions and nuclear Overhauser effect studies). One important conclusion of these studies was a tentative interpretation of the structural conditions involved in primary dNTP binding and the first discrimination step, corresponding to K_2 and $k_{\pm 3}$, respectively, in Scheme 9. *Ferrin* et al. proposed[66] that, in a first step, the

nucleoside triphosphate binds to the enzyme and interacts with the enzyme-bound magnesium ion only via its terminal γ-phosphoryl group (Scheme 10). Although the triphosphate



Scheme 10. Proposed interactions between $Mg^{2\oplus}$ (bound to the primer–template–pol I' complex) and dNTP prior to the actual polymerization step (after *Ferrin* et al. [77] and *Ferrin* and *Mildvan* [66]). "W-C-p." represents the formation of a Watson–Crick pair.

bases adopt, together with primer and template, a B-DNA conformation, this primary binding is not very selective with respect to the four bases of the nucleoside triphosphates and is highly reversible (K_2 in Scheme 9). In the rate-limiting step, the so-called verification step, in which a conformational change was assumed before,[72] *only if a Watson–Crick base pair, but not a wobble base pair,* can form between the substrate and the template bases does the β-phosphoryl group of the substrate also coordinate to the enzyme-bound magnesium ion ($k_{\pm 3}$). The formation of a six-membered chelate ring ($-Mg^{2\oplus}$–O–γP–O–βP–O–) decreases the distance between the α-phosphoryl group and the entering 3′-OH group of the primer strand and additionally accelerates the cleavage of the pyrophosphate leaving group. The substitution reaction $k_{\pm 4}$ follows.

This model mechanism, although speculation, rationalizes our replication experiments with analogues **41**–**43** and template **III** quite well and proves to be a useful working hypothesis. The triphosphates **41**–**43** were not incorporated, because $k_{\pm 3}$ was much too slow compared to the backward reaction of E · D_n · dNTP, owing to both the lack of H bonds and the interactions of the protruding hydrogen atoms in the pyridone analogues (Fig. 3), which prevented the formation of E′ · D_n · dNTP. More favorable protonated or tautomeric forms could not be used, because they were too rare to compete significantly with the binding of natural substrates.

However, this rarity could be used as a bottleneck passage in the case of replication of template **III**. The only way of bypassing analogue **3** in the template would be to use its rare tautomeric form as the nucleoside triphosphate base-binding (templating) residue. In our replication experiments we did not measure the polymerization velocities or turnovers from nucleoside tri- to monophosphates, so we cannot give any precise information about the kinetics of, say, the incorporation and proofreading of deoxycytidylate opposite analogue **3** in template **III**. Yet, since this reaction was complete in a time used for the replication of natural strands (cf. Section 3.2.2), it is reasonable to assume that the arrangement of the pyridine–pyrimidine pair during polymerization was Watson–Crick-like.

3.3.5. The Computed Structure of a Pyridine–Pyrimidine Pair in Enzyme-Free DNA

Basic considerations[79] and the latest crystallographic results[80] suggest that an unusual tautomeric form, although rare in the free nucleoside, can be stabilized by base pairing and base stacking.

Therefore, we carried out a preliminary computer modeling study (in collaboration with *K. Müller*, Hoffmann–La Roche, Basel, using the proprietary united-atom force field MOLOC) on a pyridine–pyrimidine pair containing the rare tautomeric form of analogue **3** and deoxycytidylate. The mispair was placed in the middle of a double-stranded B-DNA pentamer. The relaxation process of this DNA fragment, which was similar in sequence to the analogue-containing part of template **III**, resulted in an extended form of the base-pair arrangement depicted in Fig. 6b (bottom left) with an inserted, tightly hydrogen-bonded water molecule in the minor groove between the two base oxygen atoms.[69] Although this analysis did not represent a systematic comparative study of different conformational minima and therefore only showed one of perhaps several local minima, the base pair of interest resembled a normal Watson–Crick base pair astonishingly well (Fig. 10). The relaxed fragment

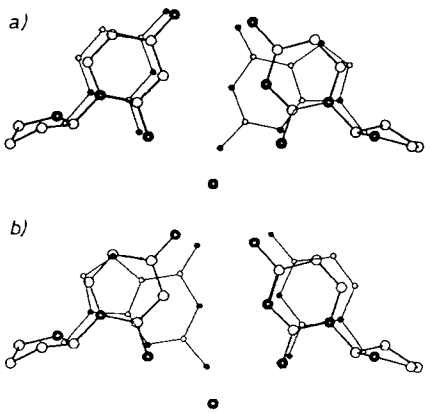


Fig. 10. Structural comparison between a modeled base pair and a standard Watson–Crick base pairs. Larger circles: 3-Deaza-2′-deoxycytidylate/2′-deoxycytidylate pair (dN*′ · dC) after relaxation of a modeled B-DNA pentamer [5′-d(pTpTpINpGpC)-3′] · [5′-pGpCpCpApA)-3′] (pdIN = 3-deaza-2′-deoxycytidylate) with an inserted water molecule in the minor groove (single circle stands for O atom of H_2O). Smaller circles: a) dC · dG base pair; b) dG · dC base pair (superimposition) from a canonical B-DNA [69].

still resembled qualitatively a normal B-DNA, indicating that pyri(mi)dine–pyrimidine, pairs can be present in DNA without greatly disrupting its overall secondary structure (Fig. 11).

There are several possibilities for the structure of our mispair. It may prefer to stay in a rare tautomeric state in solution, it could rearrange into a wobble pair with normal tautomeric forms, or it could be present in an equilibrium with both alternatives. A combined spectroscopic and crystallographic investigation of DNA double strands containing pyri(mi)dine–pyrimidine pairs is being undertaken (cf. Section 2.2.1 and Scheme 7).

In conclusion, the replication experiment with template **III** and the modeling study suggest that in the polymerase, the

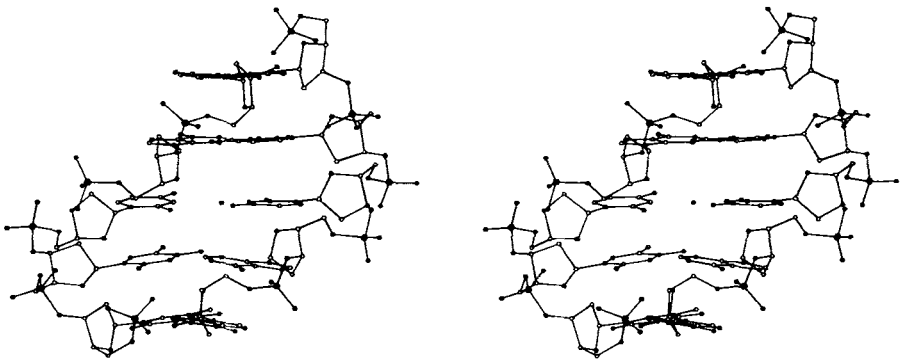

Fig. 11. Stereoview into the minor groove of the relaxed pentamer (cf. Fig. 10) including a water molecule (dot).

base-pair separation (C-1′–C-1′ distance) in the active site is not necessarily a determinant for nucleotide incorporation, whereas in a free double-helical DNA, constraints derived from the sugar–phosphate backbone and the hydration layer are likely to force the mispair to a close to normal separation. The dominant parameter for selectivity of incorporation and thus replication fidelity appears to be the hydrogen-substitution pattern of the template nucleotide base, which is read by the incoming nucleoside triphosphate base in a defined way. The position of the reading frame is strictly confined to a Watson–Crick-like arrangement of the bases (Fig. 2a, b, and d). A shifting of this position into a wobble arrangement (Fig. 2c) must be hindered by the surrounding enzyme.

3.3.6. Potential Medical Applications

What can be said about the practical applicability of nucleoside or nucleotide base analogues? One valuable use takes advantage of the potential mutagenicity of nucleoside analogues making them powerful synthetic antiviral agents.[81] Nowadays, the most prominent compound is the antiretroviral agent 3′-azido-3′-deoxythymidine (AZT, active against the AIDS virus HIV), which is a nucleoside sugar analogue. A variety of similar analogues have been prepared, among which the most interesting were shown to be the 2′,3′-dideoxy, 3′-azido-3′-deoxy, and 3′-deoxy-3′-fluoro derivatives.[82, 83] When applied in vivo, these compounds are thought to be stepwise triphosphorylated and incorporated into DNA by the retroviral RNA-dependent DNA polymerase called reverse transcriptase. This and other viral polymerases are known to replicate with a much lower fidelity[84] than, for example, bacterial polymerases such as pol I and, in fact, are therefore used by biochemists as agents for producing DNA mutations.

This larger tolerance of accepting modified nucleotides might allow the enzyme to incorporate nucleotide base analogues as well, although this has been shown not to be the case with 3-deazapyrimidine ribo- and deoxyribonucleosides (cf. Section 3.2.3) and nonviral polymerases. We think that there is a hope of finding an antiretroviral activity in combining base with sugar modifications. The first should lead to mispairings and, hence, to substitution mutations; the latter terminates the polymerization reaction due to the lack of a nucleophilic group in the 3′-position. At the very least, one could imagine a potential synergistic effect of such an analogue, when used together with AZT, which would allow a lower dosage of the still problematic anti-AIDS drug. Therefore, it will be interesting to test the dC and T analogues **48**–**53** for their toxicity and antiviral activity (Fig. 12).

3.3.7. Nucleotide Analogues Mimicking Ionized and Rare Tautomeric Forms of Natural Nucleotide Bases

The other, more indirect use for nucleotide base analogues is based on their ability to provide an unusual hydrogen-substitution pattern if used as modified template nucleotides in replication experiments. Examples for natural and synthetic variants of nucleoside bases are shown in Figure 13.

Only a few of these analogues were used to study misincorporations by polymerases. These led to various mispairings. N^4-Hydroxydeoxycytidylate is a (C · G → T · A and A · T → G · C) transition mutagen. It has a stabilized imino form, compared to deoxycytidylate and possesses an enhanced preference for the formation of base pairs with deoxyadenylate. The hydrogen-substitution pattern is the same as that in one rare tautomeric form of dC, dC*, and therefore should mimic its binding preferences (discussed in Ref. [69]) (Fig. 14a). 5-Bromo- and 5-fluorouridylate are also transition mutagens. The occasional mispairings with deoxyguanylate are due to their enhanced acidity, which allows the formation of Watson–Crick-like $^{Br}U^{\ominus}$ · G and $^{F}U^{\ominus}$ · G pairs at physiological pH.[85] Therefore, these compounds mimic the binding preferences of deprotonated thymidylate (Fig. 14b).

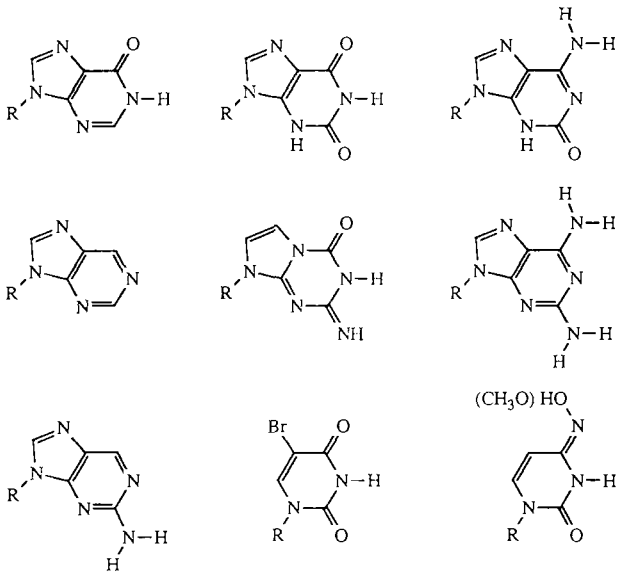

Fig. 13. Some natural and synthetic nucleoside base analogues. From left to right: 2′-deoxyinosine, -xanthosine, -isoguanosine, -nebularine, -5-aza-7-deazaguanosine, -ribosyl-2,6-diaminopurine, -ribosyl-2-aminopurine, -5-bromouridine, -N^4-methoxy-, and -N^4-hydroxycytidine. R = 1′-(2′-deoxy-β-D-ribofuranosyl).

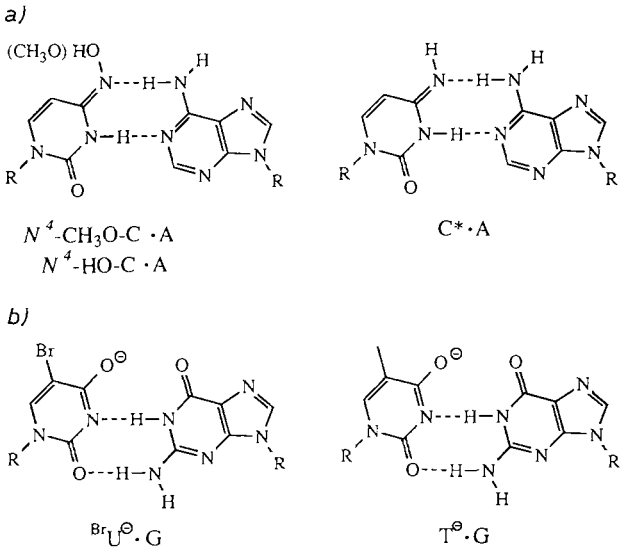

Fig. 14. Mimicry a) of a rare tautomeric form of deoxycytidine, dC*, by N^4-methoxy- or -hydroxycytidine and b) of a deprotonated form of thymidine by 5-bromodeoxyuridine in Watson–Crick-like base pairs.

2-Aminopurine (AP) as a template adenine analogue usually directs the incorporation of thymidylate, but quite often forms a base pair with deoxycytidylate, leading to A · T → G · C transitions.[86] The favored formation of a Watson–Crick-like [AP · C]$^{\oplus}$ mispair in a polymerase is responsible for the mutagenicity of AP (Fig. 15a).[87] The frequency of A · T → T · A transversions that could be derived from the formation of AP · A pairs (a wobble pair, Fig. 15b) was found to be at least an order of magnitude smaller.[88] Yet, the thermodynamic stability of a DNA duplex containing an [AP · C]$^{\oplus}$ pair was shown by *Eritja* et al.[89] to be lower than that containing an AP · A wobble pair. This led for the first time to the proposition that wobble pairs might be disfavored in polymerases, because of steric restrictions, so that a

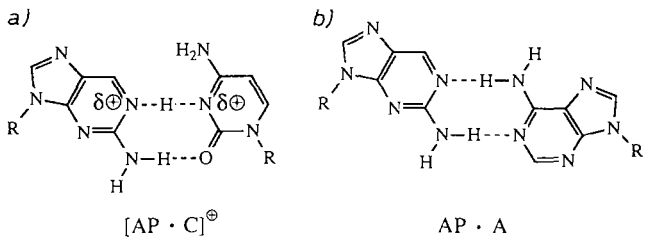

Fig. 15. a) Protonated Watson–Crick-like base pair between deoxyribosyl-2-aminopurine and deoxycytidine; b) neutral wobble base pair between deoxyribosyl-2-aminopurine and deoxyadenosine.

less stable base pair would be incorporated instead. Similar replication experiments with deoxyxanthosine (Fig. 13) as a template base revealed a still larger discrepancy between the favored incorporations by the eukaryotic DNA polymerase α and the measured thermodynamic stabilities of DNA duplexes that contain the analogue.[90] The incorporation preferences directed by deoxyxanthosine (X) were T > C ≫ A ≈ G, as opposed to the stabilities X · T > X · G > X · A ≈ X · C. This result was a first clear indication that the polymerase imposes constraints on substrate–template interactions, which can result in the more rapid formation of base mispairs having a lower stability in the final product DNA.

Naturally occurring O^6-methyldeoxyguanylate (d(O^6-meG)) and O^4-methylthymidylate (O^4-meT), derived from selective *O*-methylation by a methylating mutagen, are highly mutagenic DNA residues. Upon replication, they have a strong preference to direct the misincorporation of thymidylate and deoxyguanylate, respectively, because they bear an altered H-substitution pattern. ^{1}H NMR studies of DNA-duplex fragments bearing O^6-meG · C, O^6-meG · T, O^4-meT · A, and O^4-meT · G pairs show that the nonmutagenic O^6-meG · C and O^4-meT · A pairs form relatively stable wobble pairs (O^4-meT · A is likely to be protonated) and the mutagenic O^6-meG · T and O^4-meT · G pairs are Watson–Crick-like mispairs, apparently of relatively low thermodynamic stability in the duplex (Fig. 16).[91] Additionally,

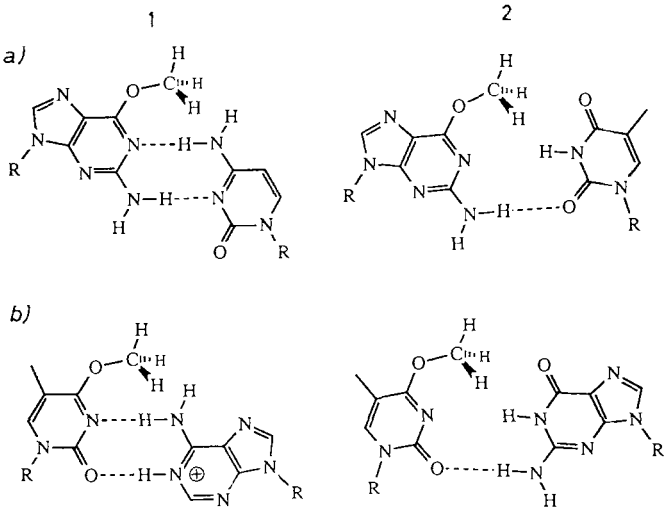

Fig. 16. Structures derived from ^{1}H NMR studies of base pairs between a) O^6-methyldeoxyguanosine and deoxycytidine (left) or thymidine (right), b) O^4-methylthymidine and deoxyadenosine (left) or deoxyguanosine (right) in B-DNA (after *Li* et al. [91]). Base pairs in left column, nonmutagenic wobble pairs; right column, mutagenic Watson–Crick-like pairs.

^{31}P NMR spectra of the d(O^6-meG)-containing compounds showed that the O^6-meG · C pair caused a much greater distortion of the sugar–phosphate backbone than did the O^6-meG · T pair, particularly in the strand opposing the alkylated base.[92] Once more, it was concluded that in a polymerase the wobble arrangement is unsuitable for polymerization.

This view is strongly supported by our experiments with template **III** that led to the formation of a pyridine–pyrimidine base pair which is presumed to be rather unstable.[93] Additionally, in this experiment the formation of a pyridine–pyrimidine base pair (and not a pyridine–purine base pair, e.g., pyridine–adenine, cf. Fig. 6b) occurred with a selectivity of 100%. This shows that the formation of a short base pair, although assumed to be unlikely because such a base pair is too unstable, can be very much favored and underlines that the stability of base pairs in a polymerase must be different from that in the free DNA.

Also, this result suggests that **3** has similar base-pairing preferences to dC*, another rare tautomer of deoxycytidylate, by mimicking its hydrogen-substitution pattern. A restriction regarding the quality of the analogy of the hydrogen-substitution pattern in compound **3** has to be noted. The real tautomer dC* does not have a hydrogen atom in the 3-position allowing, in principle, base pairing with an imino-proton-bearing nucleotide in a Watson–Crick-like arrangement. Besides the nonmutagenic binding of deoxyguanylate, there is still a chance that dC* might also direct the incorporation of thymidylate, a possible reason why C · T pairs do form in vitro.

4. Formation and Structure of Mispairs in DNA

4.1. Predicted and Evidenced Structures of Mispairs

4.1.1. Tautomeric Mispairs

Among various suggestions for the structures of mispairs responsible for the formation of substitution mutations, the first and most popular were the tautomeric transition mispairs A* = C, A = C*, G* = T, and G = T* proposed by *Watson* and *Crick*;[94] these mispairs were perfectly complementary with respect to the Watson–Crick rules. Owing to the presumed short lifetime of the rare tautomers in such mispairs in DNA, their existence could only be verified indirectly.

In 1976, 23 years later, *Topal* and *Fresco*[95] were able to lend support to the proposed structures through comparison of in vivo transition frequencies with the tautomeric equilibria of free nucleosides. Additionally, they suggested that transversions (purine–pyrimidine substitutions) could sufficiently be explained through the formation of tautomeric purine–purine pairs. These mispairs were assumed to be arranged as Hoogsteen pairs. Since two anomalies in the same base were thought to be improbable, one purine base would be a rare tautomer and the other a *syn* conformer. In the mixed G · A pair, either G*(*anti*) would form a base pair with A(*syn*) or A*(*anti*) would form a base pair with G(*syn*). The authors did not propose the straightforward and also "complementary" G(*anti*) · A(*anti*) or G(*anti*) · A(*syn*) pair without rare tautomeric forms, perhaps because tautomerization was regarded as an important reason for the formation of mispairs.

According to the authors,[95] rare tautomers could occur in the template nucleotide bases as well as in the nucleoside triphosphates and the *syn* conformers would, for steric reasons, only be allowed in the triphosphate binding site. The comparison of in vivo transversion frequencies with the tautomeric equilibria and the *syn–anti* equilibria of the purine nucleosides showed the consistency of this approach. Pyrimidine–pyrimidine pairs were thought to be unable to form base pairs within the duplex geometry. This led to the first and famous model, called "pathways for substitution mutations".[95]

This very influential paper explained for the first time, *average* mutation frequencies with simple thermodynamic parameters (equilibrium constants of *spontaneous* tautomerizations and *syn–anti* rotations) without the need of tautomerization-inducing forces. Unfortunately, from that time on, the pyrimidine–pyrimidine pairs seemed to be banned or at least denigrated by some researchers working on mismatches, polymerase mechanisms, and the like in vitro (discussed in Ref. [69]).

Later, exact measurements of the tautomerization equilibria of the free bases and the nucleosides revealed that, in fact, the mutation frequencies hardly ever correspond to these thermodynamic parameters (cf., e.g., Refs. [68, 79]). Moreover, it became clear that average mutation frequencies were by no means representative for the behavior of replicating DNA. Results accumulated showing that the probabilities of a specific substitution mutation depended strongly on the relative concentrations of the nucleoside triphosphates,[96] on the template sequence,[97–100] and on the polymerase.[101–103] The reasons for these differences, like the factors responsible for the error discrimination in polymerases (cf. Section 3.3.4), are still in dispute, though rare tautomeric forms are seldom invoked (for latest discussions see Refs. [74, 104, 105]). Thus, some researchers increasingly doubted whether rare tautomeric forms, particularly believed to occur in nucleoside triphosphates, would play a major role in mutagenesis.

On the other hand, the occurrence of pyrimidine–pyrimidine pairs could no longer be denied, since, recently, the in vitro replication of a natural template by polymerase α holoenzyme demonstrated clearly the existence of C · T and T · T pairs.[105, 106] In fact, biologists who have been performing in vivo mutagenesis experiments have never seemed to worry about the proposed inability of the polymerase to synthesize pyrimidine–pyrimidine pairs.

Therefore, the "pathways for substitution mutations" must be modernized. Obviously, all possible mispairs are involved in mutagenesis. To explain the reasons for their formation, in particular when occurring at a high frequency, we suggest that one should reconsider the formation of rare tautomeric forms not in the nucleoside triphosphate, but in the template bases. Yet, the greatest hindrance to the establishment of an important role for rare tautomeric forms in mutagenesis has still to be mentioned.

4.1.2. *Wobble Pairs*

The rapid development of useful synthetic and analytical procedures in chemistry, in particular the automated synthesis of oligodeoxynucleotides on a 10-micromolar scale, modern reversed-phase HPLC, and 2D ^{1}H NMR techniques, stimulated intensive investigations into the structure of short DNA oligomers of defined length and sequence. The combined analysis of a DNA duplex by circular dichroism and ^{1}H NMR in solution, and by X-ray crystallography in a single crystal provide the best means to ascertain the structure of a particular sequence. Of special interest are sequences bearing one or two mismatched base pairs.

As in the field of in vitro mutagenesis, the best analyzed structures are the purine–pyrimidine and the purine–purine mispairs. Oligomers containing the G · T pair were crystallized in A-, B-, and Z-DNA, the "dehydrated" right-handed, the normal right-handed, and the left-handed form, respectively. Irrespective of the overall conformation of the double helix, the bases form a wobble pair (Fig. 17a).[107–109] The A · C pair could also be crystallized in a B-DNA oligomer and proved to be very similar to the G · T pair in geometry, although it is probably protonated on N-1 of adenylate (Fig. 17b).[110–113] Both mispairs caused little disruption of

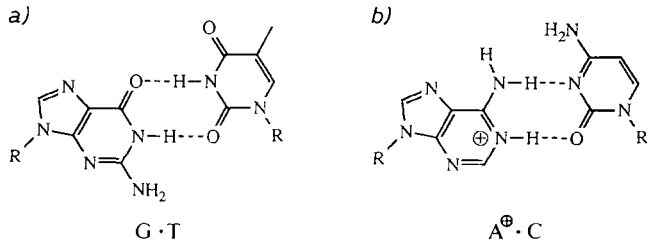

Fig. 17. a) G · T wobble pair, b) A$^{\oplus}$ · C wobble pair, schematized from X-ray data.

the DNA backbone in comparison with the native oligomer (without a mispair).

In the case of purine–purine pairs, only the G · A pair has been characterized crystallographically. It exists in several isomeric forms, dependent on the neighboring sequence. The first found was a Hoogsteen pair that induced a very slight disturbance in the DNA backbone (Fig. 18a);[114] another is

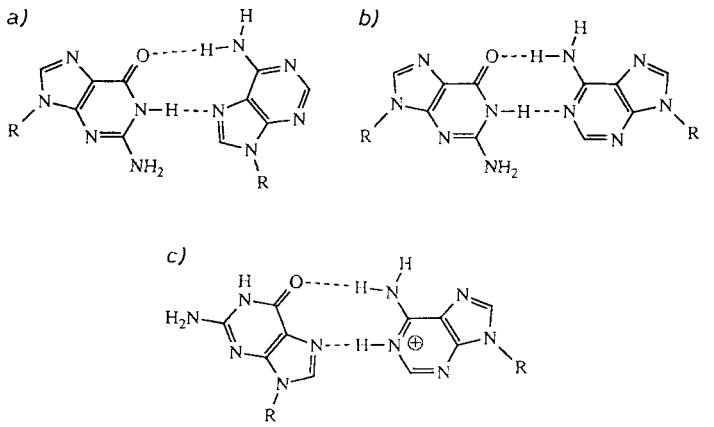

Fig. 18. a) G · A(*syn*), b) G · A, c) G(*syn*) · A$^{\oplus}$, schematized from X-ray data.

a Watson–Crick-like *anti–anti* pair, which is a little bit wider (Fig. 18b).[115] The structures of these mispairs are consistent with the ^{1}H NMR spectral data available.[116–122] *Gao* and *Patel*[123] suggested in a recent NMR study that, depending on the pH, the G · A pair could also exist in a third, protonated form, a Hoogsteen pair where G is the *syn* conformer (Fig. 18c). Very recently, this was confirmed by the crystal structure of G(*syn*) · A$^{\oplus}$.[124]

Gao and *Patel*'s work and a (mismatch repair) protein binding study on transition mispairs,[125] which showed a high sequence and pH dependence of G · T and, especially, A · C pairs, indicates that the structures of mispairs can be quite flexible and are very sensitive to their immediate surroundings.

Unfortunately, there is no crystallographic data of DNA available yet that contains a pyrimidine–pyrimidine mismatch in a duplex. Based on the ^{1}H NMR spectrum of a C · T-containing oligomer, it was proposed that this pair is an extended Watson–Crick-like type of base pair having a water molecule inserted in the gap in the minor groove, roughly similar to our computed mispair (cf. Fig. 10).[121] ^{1}H NMR spectra of oligomers containing T · T and C · C pairs suggest the wobble arrangement for the T · T pair and, although less certain, the strong pH dependence on the structure of the C · C pair is indicative for a protonated wobble pair or a variant of it.[126] Again, a high flexibility (nonrigidity) of those structures is expected, as their low thermodynamical stability suggests. In any case, it seems that none of the mismatches contain rare tautomeric forms.

4.2. Conclusions

4.2.1. *The Wobble Pair/Tautomeric Pair Conflict*

The crystallographic evidence led a substantial body of researchers to abandon the idea of rare tautomeric forms being involved in mutagenesis. The formation of wobble pairs was thought to be responsible for at least the transition mutations. The formation of purine–purine Hoogsteen pairs seems to explain adequately transversion mutations, again without the need of rare tautomeric forms.

However, various results involving experiments with a DNA polymerase contradict this point of view; some are mentioned in Sections 3.3.4 and 3.3.7, some are discussed in Ref. [69]. Therefore, we feel that the formation of Hoogsteen and wobble pairs without rare tautomeric forms cannot be responsible for all the substitution mutations found in vivo. In particular, the strong differences in substitution frequencies that usually occur at different sites (hot spots) are very badly explained by such a seemingly uninfluenced, random mode of misincorporation. Some influences that could have an effect on the sequence dependence of the probability of formation of, for instance, wobble pairs in polymerases are thought to be derived from differently stabilizing base-stacking interactions.[127a] But, considering there is a choice between only four different nearest neighbors that can stack more or less well with a wrong base at the primer end, the variability of the so stabilized mispairs is much too small to explain the enormous differences in substitution frequencies often found. Moreover, although it is known that in vivo

replication is assisted by DNA single-strand binding proteins, which are thought to destack the bases in the template strand prior to polymerization, thus enhancing the replication fidelity substantially,[127b] hot spots still occur in vivo.

Another more fundamental argument against wobble pair formation in polymerases is the function of the enzyme itself. In discussions about error discrimination mechanisms, it should always be taken into account that polymerases, prokaryotic and eukaryotic, are highly evolved proteins which presumably developed under the main constraint of not being selected unless the replication fidelity was high enough. The first restriction one can think of in order to enhance the replication fidelity, is to ensure a fixed reading frame (cf. Section 1.3, Figs. 2c and 2d), that is, to suppress or prevent the formation of wobble and Hoogsteen pairs (Fig. 1c and 1b, respectively). This can be achieved through a "clinch pocket" (or "binding cleft snugly fitting correct base pairs"[105]) provided by the protein. A much more difficult problem is to ensure a particular hydrogen-substitution pattern, that is, to prevent the bases from being (de)protonated and tautomerized (Fig. 2a and 2b), since these rapid and sterically nondemanding protolytic reactions presumably cannot be suppressed so well. It seems that the normal hydrogen-substitution patterns of the nucleotide triphosphate bases are relatively stable, whereas the template bases are more accessible to Brønsted acids and bases.

This evolutionary principle of replication fidelity strongly contrasts with the principle of another template-directed process, translation, where the proven formation of wobble pairs in the third codon position between mRNA and tRNA is not restricted, but selected by nature. There the purpose is a deliberate "infidelity of reading", in order to develop a degenerate universal code.

Hence one can assume that the formation of wobble pairs in polymerases is rather rare and will be responsible for some mutational background which can always be measured after replication and is not very site-specific. There must be some other mechanism that can lead to quite high substitution frequencies despite the replication fidelity of polymerases. The so formed mispairs should be inconspicuous; that is, they must be poorly recognized as mispairs in the polymerase.

After they have passed the crucial period in the enzyme, they will be released into solution and governed by forces inherent to hydrated, double-helical DNA. These were shown to be such that usually a most stable, normal tautomeric form is formed at the cost of a Watson–Crick-like geometry, resulting in the crystallographically observed normally tautomeric wobble and Hoogsteen pairs. At this stage, the role of wobble and Hoogsteen pairs becomes dominant in mutagenesis, because these structures can further be recognized and excized by post-replicative repairing exonucleases.

4.2.2. Rare Tautomeric Forms in the Template Strand In Vitro

It is at present difficult to prove directly the involvement of rare tautomeric forms in vitro, because of their transient appearence. Apart from our indirect evidence for a possible mutagenesis due to rare tautomeric forms in DNA template strands, there are other results which point in the same direction,[69, 128, 129] including results from X-ray crystallography. *Lippert* et al. showed that N^4-imino-1-methylcytosine (which corresponds to C^*) could be stabilized by coordination of N^4 to a platinum(IV) ion.[130] *Chattopadhyaya* et al. found a T^* residue in a Watson–Crick-like $T \cdot T^*$ pair between two non-double-helical DNA strands.[80]

Although no base pair involving a rare tautomer has been observed in an actual DNA double helix, the above results prove that forces derived from interactions present in all biological systems, such as metal coordination, base stacking, and base pairing, are able to overcome that apparent instability of rare tautomers. This means that the measured tautomeric equilibria of the free bases or even of the nucleosides represent the physico-chemical state of rare tautomeric forms neither in a protein-free DNA duplex nor in polymerase-bound DNA. The replication system seems not to be proof against kinetically labile forms in the template strand which can cause replication errors if the mispair escapes the proofreading. Such a form is a protonated or deprotonated template base or a rare tautomeric form of a template base. These forms differ from normal forms only very slightly when stacked into a DNA helix and might therefore be a "problematic" source of substitution mutations for the polymerase.

It would be very helpful, if the stability of Watson–Crick-like tautomeric or ionized mispairs within the active site of a polymerase could somehow be determined experimentally in vitro. The use of nucleotide base analogues with an altered H-substitution pattern proved to be a useful tool for the elucidation of a pathway for substitution mutations. Further investigations will be undertaken, in particular to study pol I's proofreading activity towards pyrimidine–pyrimidine base pairs.

Perhaps it would be of use to find mutagens which cause substitution mutations upon replication of their "victim" DNA, but do not cause any physical damage to it. The mode of action of such a *mild mutagen* should be a reversible reaction with DNA which is hazardous (mutagenic) when the reactant, a template nucleotide base, is replicated, but otherwise harmless owing to its kinetic lability. We suspect that there are means of tautomerizing DNA bases, particularly when they are in the easily accessible, single-stranded form. Yet, finding external mild mutagens that would produce substitution mutations in DNA upon replication in vitro (we like to call them "tauterogens") seems to be quite difficult, because it is not obvious what sort of molecules might possess the needed selectivity enabling them just to protonate or deprotonate and, hence, subsequently tautomerize DNA bases without reacting otherwise (e.g., with the polymerase).

4.2.3. Tautomerizing Mutagens in Vivo?

The most interesting possibility is the existence of tauterogens in vivo, since they would account for various kinds of mutation pressures inherent to all living cells. At present, there is no answer to the question of how an increased production of substitution mutations within a few cell genera-

tions might be achieved in vivo. The sudden production of secondary mutations in the initial stage of cancer growth and the sudden switching from an unactivated immune cell to a cell rapidly producing somatic substitution mutations in the genes that encode the antibody proteins are two examples. There must be a way of activating mutagens within a cell. These mutagens should not be dangerous in the sense that they damage the genome irreversibly (because the cell would die); they should merely cause substitution mutations in the offspring of the cell. Proteins with their immense variety of acidic and basic functional groups have deprotonating or protonating facilities. DNA-binding proteins might be candidates for this type of mild mutagen. They would act very discretely—just binding to DNA, tautomerizing a nucleotide base during replication, and diffusing off again—and therefore their biological activity could be difficult to detect.

The idea of the existence of "tauterogenic" DNA-binding proteins being responsible for a considerable amount of substitution mutations in vivo is exciting for several reasons. First, of all, if such proteins and their corresponding genes were found and identified, they might be very effective when used as, say, a cytostatic or other pharmaceutical. Moreover, a substantial part of the observed DNA sequence dependence of substitution mutations could be attributed to them, since they are expected to act very selectively. This property is known from other DNA-binding proteins, such as transcription factors and restriction enzymes. Last but not least, these mutagenic DNA-binding proteins, like all proteins, would be the almost direct products (via RNA) of DNA itself. This would enable the genome to have direct control over its own mutability; and this would answer some questions about how a given genome maintains a directional mutation pressure (e.g., a biased G + C content or a codon pressure, that is, the nonrandom use of synonymous codons) throughout many generations, in spite of the selection pressures possibly counteracting this tendency. Clearly, this is beyond the scope of this article (cf. Ref. [131]). The last part of our conclusions is at present devoid of any experimental evidence and therefore quite speculative. Still, it should encourage discussions and experimental investigations.

We should like to thank all collaborators who have significantly contributed to the project during the past years (alphabetical order): R. Altermatt, P. Bühlmayer, N. Cerletti, R. Charczuk, S. De Bernardini, W. Falk, R. Glaser, G. Graf, I. Gregor, P. Kohler, C. A. Leach, Ch. Papageorgiou, H. D. Schneider, U. Séquin, E. Volz, M. Wachtl, and F. Waldmeier. We also thank Prof. Thomas Bickle (Biocenter of the University of Basel, Department of Microbiology) and Priv.-Doz. Dr. K. Müller, F. Hoffmann–La Roche AG, Basel, for their engaged collaboration, as well as to Dr. Bill Hunter and Dr. Madeleine Moore (Chemical Laboratory, University of Cambridge, UK) for their corrections of the manuscript. The financial support from the Swiss National Science Foundation is gratefully acknowledged.

NMR Study of Nuclear Spin Polarization during Chemical Reactions with Ortho Hydrogen**

By *Joachim Bargon,** *Jörg Kandels,* and *Klaus Woelk*

Since the discovery of the CIDNP phenomenon,[1, 2] nuclear spin polarization effects in NMR spectra of chemical reactions have traditionally been ascribed to radical intermediates.[3] *Bowers* and *Weitekamp*[4, 5] showed, however, that very similar phenomena can also be observed in chemical reactions involving spin-polarized hydrogen. Thus, the cause of a nuclear spin polarization found by NMR spectroscopy is not unambiguous. Indeed, NMR polarization signals have been observed in the past during hydrogenation in the presence of organometallic catalysts[6] and often wrongly interpreted as CIDNP effects.[7] Here we describe the experimental elucidation of the cause of nuclear spin polarization by a method involving the two isomers of molecular hydrogen (i.e., ortho and para hydrogen).

So far, nuclear spin polarizations during hydrogenations have been investigated exclusively by using para hydrogen, as reflected in the acronyms PASADENA (*P*arahydrogen *A*nd *S*ynthesis *A*llows *D*ynamically *E*nhanced *N*uclear *A*lignment)[5] or PHIP (*P*ara *H*ydrogen *I*nduced *P*olarization).[8, 9] We have now studied these effects with both ortho and para hydrogen.[10]

Molecular hydrogen contains two protons having nuclear spin $I = 1/2$. These spins couple to give a total spin 1 (triplet-state nuclear spin in ortho hydrogen) or 0 (singlet-state nuclear spin in para hydrogen). At room temperature, the small energy difference between the two spin isomers can be neglected. Owing to the threefold degeneracy of the triplet state, the ratio of the two isomers at room temperature is 75% ortho to 25% para. Hydrogenation with H_2 in this ratio leads to intermediates and final products whose NMR signals are characterized by the slight difference in thermal occupation ($\Delta N/N \approx 10^{-5}$) of the nuclear spin states in the magnetic field.

If, on the other hand, only one of the two spin isomers—for example, para hydrogen—is used in the hydrogenation, then, in the intermediates and final products, the only nuclear spin states occupied are those exhibiting singlet character with respect to the protons undergoing transfer. All other states remain unoccupied. This enormous difference in occupation leads to strong emission and absorption signals in the NMR spectrum.

The mixture can be enriched in ortho hydrogen by exploiting the fact that, at low temperatures, the two spin isomers are not equally adsorbed on surfaces (theory of the hindered rotator[11]). Gas chromatography on alumina as a diamagnetic adsorber at 77 K thus affords a mixture enriched in ortho hydrogen.[12] This method yields a mixture containing about 80% ortho and 20% para hydrogen.

A mixture enriched in para hydrogen can be obtained by making use of the fact that, in the presence of a paramagnetic adsorber (active charcoal), a thermal equilibrium is established between ortho and para hydrogen. At low temperatures, therefore, para hydrogen is favored energetically.[13] In this way, we obtained a mixture of approximately 46% ortho and 54% para hydrogen at 77 K.

The isomer ratio in the mixture was determined by difference measurement with two thermal conductivity cells that exploit the differing specific heats of the two spin isomers at low temperatures (77 K).[14]

The enriched hydrogen obtained in this way was directly bubbled via a capillary into the sample tube of a ^1H NMR FT spectrometer (80 MHz) and used to hydrogenate acrylonitrile in the presence of Wilkinson catalyst, tris(triphenylphosphane)chlororhodium(I), in [D_6]benzene [Eq. (a)].

$$CH_2=CH-CN + H_2 \xrightarrow[C_6D_6]{(Ph_3P)_3RhCl} CH_3-CH_2-CN \qquad (a)$$

For kinetic reasons, the polarization signal of the reaction product propionitrile is maximal only after bubbling hydrogen into the reaction mixture at a constant rate for 30 s. Successive NMR pulses must therefore be separated by a corresponding period of time. The result of the NMR study is summarized in Figure 1.

Figure 1a shows the polarization signal of propionitrile during the hydrogenation with enriched ortho hydrogen, Figure 1b the complementary signal observed with enriched para hydrogen. Comparison of these two spectra reveals that the sequence of emission and absorption is reversed. The intensity ratio of the two spectra varies between 1:4 and 1:5.

This finding is explained as follows: During the hydrogenation, ortho and para hydrogen participate independently in the reaction. In principle, therefore, the total intensity I of the NMR signal of the reaction product should be obtainable by adding the intensities of ortho and para hydrogen weighted according to their relative amounts in the mixture. For hydrogenation with hydrogen in thermal equilibrium at room temperature (75% ortho and 25% para hydrogen), Equation (b) holds.

$$I_{thermal} = 1/4\ I_{para} + 3/4\ I_{ortho} \qquad (b)$$

The difference in occupation of the nuclear spin levels, which determines the signal intensity $I_{thermal}$, obeys the Boltzmann distribution and thus is several orders of magnitude smaller (ca. 10^{-5}) than the difference in occupation determining the signal intensities I_{para} and I_{ortho}. Therefore, it can be neglected (see Fig. 1c). Equation (c) is thereby obtained.

$$I_{ortho} = -\ 1/3\ I_{para} \qquad (c)$$

Hoberg*, Max-Planck-Institut, Mülheim a. d. Ruhr, and Prof. Dr. *M. Dosière*, Université Mons, Belgium, for valuable discussions.

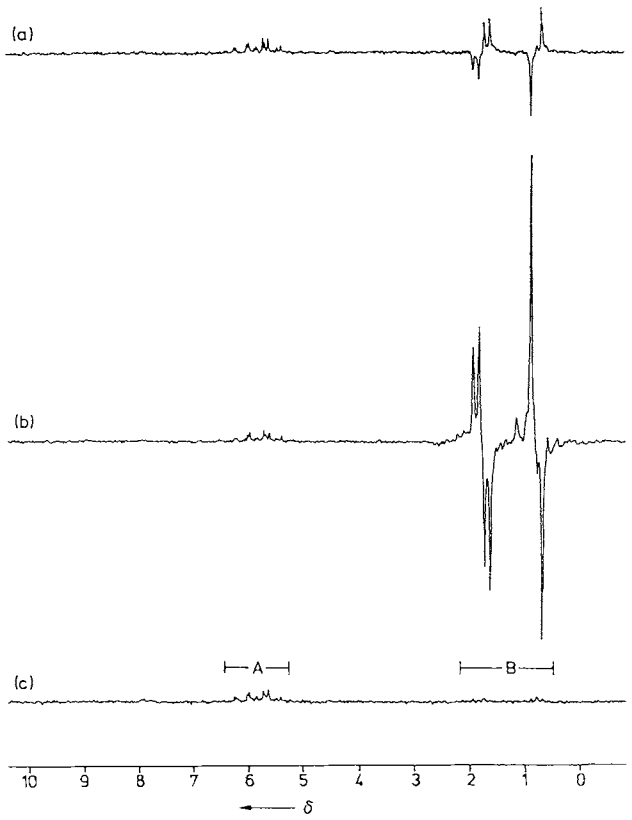

Fig. 1. Wilkinson catalyst (20 mg) and acrylonitrile (200 μL) dissolved in 1 mL of C_6D_6: NMR spectra at 80 MHz with a 45° pulse; A = acrylonitrile; B = propionitrile; NMR pulse after hydrogenation for 30 s with (a) enriched ortho hydrogen (I_{ortho}) and (b) enriched para hydrogen (I_{para}). c) NMR pulse several minutes after termination of the hydrogenation. The propionitrile nuclear spin system is relaxed; the weak thermal signal $I_{thermal}$ remains.

This equation holds only for pure ortho or pure para hydrogen. Adjustment for the experimentally accessible isomer ratios (thermal conductivity measurement) gives an intensity ratio between 1:5 and 1:6. This result agrees, within the limits of error, with the intensity ratio obtained from the experimental spectra.

According to the considerations above, the complementary behavior of the two spin isomers in hydrogenations is independent of the strength of the applied magnetic field and thus applicable to hydrogenations performed outside the NMR spectrometer, though these reactions display different polarization patterns.[15]

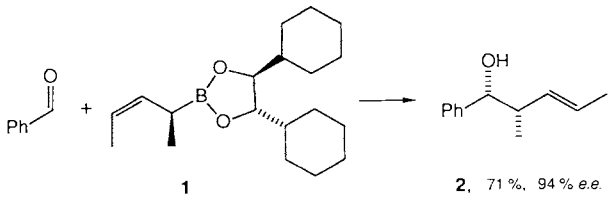
A New Route to Highly Enantiomerically Enriched (*Z*)-(1-Methyl-2-butenyl)boronic Esters**

By *Rainer Stürmer**

The (*Z*)-(1-methyl-2-butenyl)boronic ester **1** is a reliable reagent for chain lengthening of aldehydes to homoallyl alcohols **2** with full reagent control of the diastereoselectivity.[1,2]



1 **2**, 71%, 94% *e.e.*

Here we describe a new, simple route to the boronic esters **1** from the Grignard reagent **3** and the borate **4**; this approach combines, for the first time, a racemization due to 1,3-metallotropic shift[3] with a kinetic resolution of a race-

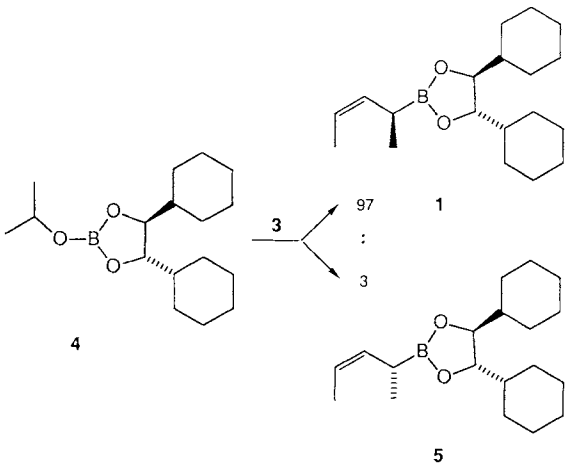
Hans-Meerwein-Strasse, D-3550 Marburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 260, partial project with Prof. Dr. *R. W. Hoffmann*) and by the "Graduiertes Kolleg Metallorganische Chemie", Universität Marburg. I thank Prof. Dr. *R. W. Hoffmann* for his friendly support of this work.

mate.[4] The Grignard reagent **3** consists of an equilibrium mixture of enantiomers, diastereomers, and conformational isomers owing to rotation around formal single bonds[5] and 1,3-metallotropic shift.[6] Borate **4** reacts preferentially with **3b, b'**[7] to afford an 89% yield of the pentenylboronic esters **1** and **5**, which have (*Z*) configurations (cf. Ref. [8]).



Furthermore, the chiral borate **4** differentiates between the enantiomers **3b, b'**, so that **1** can be obtained with a diastereomeric excess of 94% by kinetic resolution of a racemate. This was established by reaction of **1** with benzaldehyde and determination of the enantiomeric purity of alcohol **2**. The glycol from which **4** is derived and thus the reagent **1** are readily accessible in either enantiomeric form.[2, 9]

Experimental Procedure

A 0.85 M solution (6.0 mL, 5.1 mmol) of (1-methyl-2-butenyl)magnesium chloride (**3**) in THF was added dropwise over 15 min to a solution of (4*S*,5*S*)-2-isopropyloxy-4,5-dicyclohexyl-1,3,2-dioxaborolane (**4**; prepared from 1,2-dicyclohexylethane-1,2-diol and triisopropyl borate by distillative removal of the isopropanol) in 20 mL of THF at −78 °C. The solution was allowed to warm overnight to room temperature and the products were hydrolyzed by addition of a saturated solution (15 mL) of NH_4Cl. The aqueous phase was extracted with 3 × 20 mL of ether and the organic phase was dried over $MgSO_4$ and concentrated. The colorless oily residue was chromatographed with CH_2Cl_2 (column 30 × 2 cm, silica gel 60), affording 1.38 g (89%) of boronic ester **1**. For spectroscopic data and determination of the enantiomeric purity by addition to benzaldehyde, see [2].

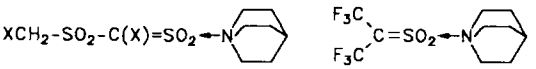
Inverse Amine-Stabilized Sulfenes $F_2C{=}SO_2$ and $FHC{=}SO_2$ **

By *Hans Pritzkow, Klaus Rall, Stefan Reimann-Andersen,* and *Wolfgang Sundermeyer**

Dedicatd to Professor Gerhard Fritz on the occasion of his 70th birthday

Over the past couple of decades several research groups have attempted the isolation of a sulfene $R_2C{=}SO_2$ (thione *S,S*-dioxide) in free form as a species analogous to SO_3,[1] but, owing to the exceptional reactivity of the C=S double bond, success has thus far only been achieved in demonstrating indirectly the existence of such a species in situ by (cyclo)additions. Double bonds between carbon and elements of the second or higher periods could, however, not only be stabilized by sterically demanding substituents but also by addition of Lewis bases to the element with the larger atomic radius. An earlier indication of the stabilization of sulfenes by tertiary amines[2] finally led to a better insight into the bonding in such adducts, in that we were able to isolate amine-stabilized sulfonylsulfenes **A** with quinuclidine as base.[3, 4]



A, X = H, Cl, Br, CF_3, CH_3 **B**

X-ray structure analyses showed that quinuclidine normally coordinates to the sulfur atom with an S–N distance which is greater than that of an S–N single bond, irrespective of the type of substituents X on the sulfene carbon atom, and that the C–S distance (1.66 Å) almost equals that of an isolated C–S double bond. This is even more evident in the case of the first symmetrically substituted sulfene **B**, which was obtained, not under the usual "sulfene forming conditions (α-H-sulfonyl halide + amine) but by aminolysis of 1,3-dithietane *S*-oxides.[5] This implies that the resonance structure $R_2\overset{\ominus}{C}-\overset{\oplus}{S}O_2$ with the sulfur atom as electrophilic center[6, 7] is essential for a description of the electron distribution in sulfenes.

We have now succeeded, however, in obtaining definite proof that sulfenes can also be stabilized via the C atom (resonance structure $R_2\overset{\oplus}{C}-\overset{\ominus}{S}O_2$; inverse amine-stabilization). A first indication of the C atom having electrophilic character was obtained on attempting to synthesize dichlorosulfene, when trichloromethane sulfinate was formed by nucleophilic addition of chloride[8] (cf. also later works[9, 10]). According to all spectroscopic data, we had already obtained an inverse amine-stabilized sulfene $Me_3\overset{\oplus}{N}-CHF-SO_2^{\ominus}$ upon reaction of fluoromethanesulfonyl chloride **1** with trimethylamine; however, we were unable to isolate any crystals suitable enough for an X-ray structure analysis.[9] Whereas quinuclidine likewise adds inversely, but the product readily decomposes,[3] in the reaction of **1** with triethylamine the isolation and crystallization of the fluorosulfene adduct **2** (m.p. 159 °C (decomp.) is possible.

1 2 3

In the 84.7-MHz ^{19}F-NMR spectrum of **2** a doublet appears at $\delta = -164.8$ ($^2J_{HF} = 46.6$ Hz), and the 200-MHz ^{1}H-NMR spectrum[11] shows the expected diastereotropism of the methylene protons of the base as evidence of the addition to the sulfene C atom. The X-ray diffraction analysis of **2**[11] finally confirms the molecular structure (Fig. 1). Both

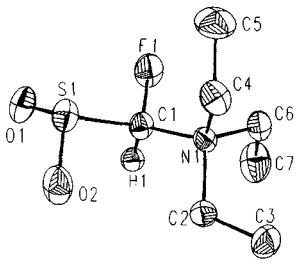

Fig. 1. Crystal structure of **2**. Important distances [Å] and angles [°]: S1–O 1.479(1), 1.485(1), S1–C1 1.904(1), C1–N1 1.515(2), C1–F1 1.370(2): O1–S1–O2 111.3(1), O1–S1–C1 96.7(1), O2–S1–C1 100.3(1), S1–C1–N1 117.9(1), S1–C1–F1 107.2(1), N1–C1–F1 107.1(1).

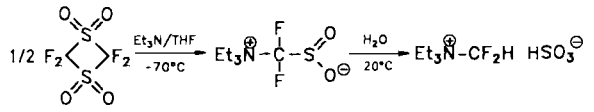
the C–N bond (1.515 Å) as well as the C–S bond (1.904 Å) are longer than the values quoted in the literature for C–N and C–S single bonds. By oxidation with peracetic acid, **2** can be converted into the corresponding sulfonate **3**,[12] which, like **2**, was characterized by its elemental analysis and mass spectrum.

The inverse amine-stabilized difluorosulfene **5** was obtained via a completely different route: by symmetrical ring cleavage of tetrafluoro-1,3-dithietane 1,1,3,3-tetroxide **4** with triethylamine.[13]



4 5 6

The 84.7-MHz ^{19}F-NMR spectrum of **5** shows a singlet at $\delta = -99.6$ ($(CD_3)_2SO$). The X-ray structure analysis reveals bond lengths comparable with those in **2** and confirms the inverse stabilization and the zwitterionic structure of the

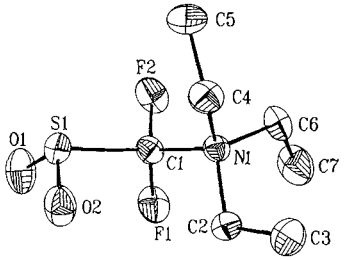


Fig. 2. Crystal structure of **5**. Important distances [Å] and angles [°]: S1–O 1.471(1), 1.470(2), S1–C1 1.949(2), C1–N1 1.521(2), C1–F 1.349(2), 1.346(2); O1–S1–O2 112.4(1), O1–S1–C1 96.7(1), O2–S1–C1 102.9(1), S1–C1–N1 120.3(1), S1–C1–F1 109.5(1), S1–C1–F2 106.5(1), N1–C1–F, 107.0(1), F1–C1–F2 105.7(1).

sulfene (Fig. 2). In contrast to **2**, **5** rapidly hydrolyzes to the (difluoromethyl)triethylammonium hydrogensulfite **6**.[14]

Thus, it could be demonstrated that sulfenes are usually coordinated by amines at the S atom, that they contain a C=S double bond in the adducts, and that they can be recovered again from the adducts. The two sulfenes $FHC{=}SO_2$ and $F_2C{=}SO_2$—the same may be expected of $H_2C{=}SO_2$, for which a structure analysis of the adduct has still to be carried out[15]—are, on the other hand, inversely amine-stabilized at the C atom. They are then present as zwitterions, have thereby lost all relation to the original sulfene, and react with cleavage of the C–S bond on attempted renewed recovery of the sulfene.

Synthesis and Structure of the Stable Tellurium Nitride $(ClTeNSN)_3N$ **

By *Herbert W. Roesky,* Jörg Münzenberg,* and *Mathias Noltemeyer*

All that is known about the tellurium nitrides that have been reported so far is that they are highly explosive.[1] Nothing

[*] Prof. Dr. H. W. Roesky, Dipl-Chem. J. Münzenberg, Dr. M. Noltemeyer

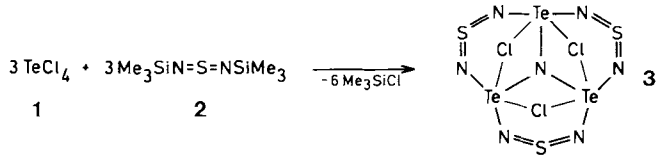
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen Foundation, and the Fonds der Chemischen Industrie.

is known about their structure or their bonding, and even their stoichiometry is still a matter of debate. In connection with our studies on metal- and nonmetal-nitrogen compounds we recently reported the synthesis of a titanium imide nitride in which the imide and nitride functions are bridged by titanium atoms. We were surprised to find that this compound first decomposes above 200 °C.[2] This prompted us to try to stabilize tellurium-nitrogen bonds in the same way by bridge functions.[3] We now report on a tellurium nitride that is stable and non-explosive at room temperature.

For the synthesis of $(ClTeNSN)_3N$ **3**, tellurium(IV) chloride **1** was allowed to react with *N,N'*-bis(trimethylsilyl)sulfur diimide **2** in the molar ratio 1:1 (with slight excess of **2**) at 0 °C in toluene. Cleavage of chlorotrimethylsilane (other byproducts could not be unequivocally characterized) resulted in formation of **3** as a yellow solid, which decomposed violently above 207 °C. An elemental analysis[4] confirmed the composition of **3** and gave no indication of a compound of the initially expected composition Cl_2TeN_2S.[5] In the FD-mass spectrum, only Te_2Cl_2NSN is observed as heaviest fragment (*m/z* 388, ^{128}Te, ^{130}Te).



Final proof of the structure of **3** followed from the X-ray structure analysis of crystals which were obtained from dimethylformamide (DMF). Three molecules of DMF are coordinated via the oxygen atoms to the tellurium atoms of **3** (Fig. 1).

The three tellurium atoms form a puckered twelve-membered ring with the three bridging NSN ligands and a six-membered ring with the three bridging chlorine atoms. In the plan view (Fig. 1, top) it is clear that the three tellurium atoms are bridged by a further nitrogen atom, N(1).[6] The side view (Fig. 1, bottom) shows the trigonal-pyramidal arrangement of the $Te_3N(1)$ unit. The Te^{IV} atoms in **3**·3 DMF have a distored octahedral environment, as has already been described for $(TeCl_4)_4$.[7] The DMF molecules bound to the free coordination sites of the Te atoms are, according to the large Te–O distance (250.5 pm), only weakly coordinatively bound. The Te–N(1) bond lengths (mean value 206.1 pm) lie in the same range as those of known compounds with covalent Te–N bonding ($PhC(NSiMe_3)_2TeCl_3$ 209.6 pm;[8] $(Ph_3PNTeCl_3)_2$ 199.6 pm[3]). Also the remaining six Te–N bonds are of comparable length (mean value 203.3 pm). The S–N (mean 152.4 pm) and Te–Cl distances (mean 284.5 pm) are consistant with those in $Me_4Si_2N_4S_2$[9] (mean value 150.7 pm) and $[Te_3Cl_{13}]^{\ominus}$[10] (mean value 284.1 pm),[11] respectively. In the titanium compound[2] mentioned at the beginning the nitridic nitrogen deviates 104 pm from the plane of the metal atoms, whereas in the case of the tellurium compound **3** the deviation is only 40 pm.

The incorporation of the nitridic nitrogen atom could proceed via an $NS^{\oplus}$ ion, in analogy to the observation made by *Martinengo* et al.,[12] that $[Co_6N(CO)_{15}]^{\ominus}$ is formed from the nitrogen-free complex dianion and nitrosyl tetrafluoroborate. Summarizing, it can be established that: compound **3** is the first structurally confirmed tellurium nitride and at the same time the first compound in which three atoms are bound via NSN ligands to give a twelve-membered ring and the first compound that contains several TeN_3 units as structural groups.

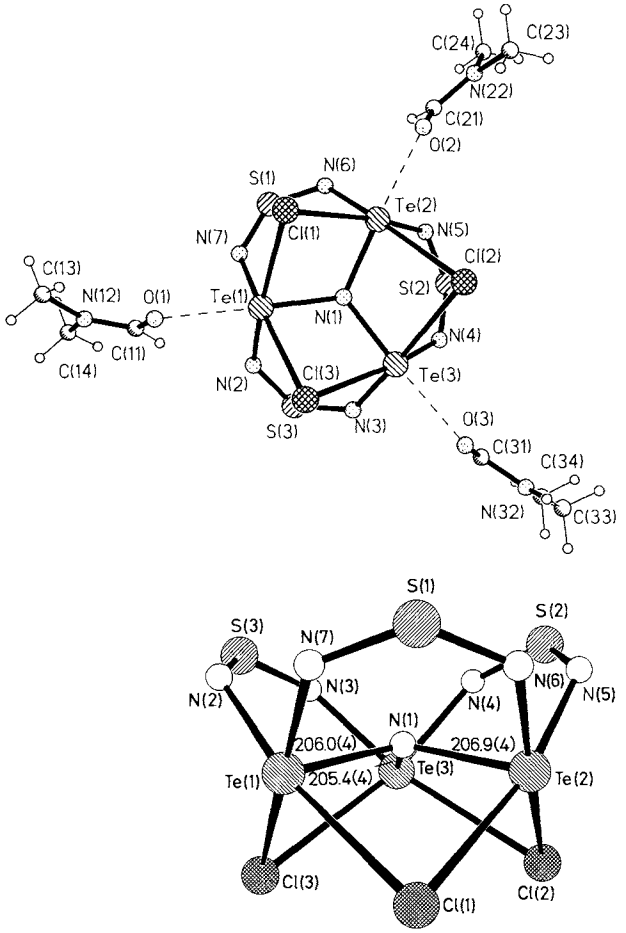


Fig. 1. Crystal structure of **3**·3 DMF. Above: top view. Below side view of the molecule without DMF molecules. Selected bond lenghts [pm] and angles [°]: Te(1)-Cl(1) 285.9(2), Te(1)-N(1) 206.0(4), Te(1)-N(7) 201.6(4), Te(1)-Cl(3) 282.6(2), Te(1)-N(2) 203.0(4), Te(2)-Cl(1) 283.7(2); Cl(1)-Te(1)-Cl(3) 99.6(1), Cl(1)-Te(1)-N(1) 80.9(1), Cl(3)-Te(1)-N(1) 82.0(1), Cl(1)-Te(1)-N(2) 169.8(1), Cl(3)-Te(1)-N(2) 85.3(1), N(1)-Te(1)-N(2) 91.0(2), Cl(1)-TeC1)-N(7) 87.3(1), N(1)-Te(1)-N(7) 91.3(2), N(2)-Te(1)-N(7) 86.7(2).

Experimental

A solution of **1** (3.50 g, 13 mmol) in toluene (120 mL) was treated dropwise at 0 °C with a solution of **2** (3.10 g, 15 mmol) in toluene (40 mL). The solution turned orange and a yellow solid precipitated. This was filtered off and washed with chloroform. 2.2 g (74%) of **3** was obtained. Recrystallization from dimethylformamide afforded, after several days storage at room temperature, yellow crystals of the composition $(ClTeNSN)_3N$·3 DMF. We cannot say with certainty whether a rearrangement takes place during the recrystallization. The solvate-free compound melts with decomposition at 207 °C.—IR: $\tilde{\nu}$[cm^{-1}] = 1120 vs sh, 1090 s, 1060 s, 1060 vs sh, 680 s, 570 s, 520 s. A ^{125}Te-NMR spectrum could not be obtained because of the sparing solubility of **3** in DMF. Nor could a suitable nitrogen-free solvent be found for ^{15}N-NMR investigations.

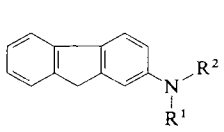
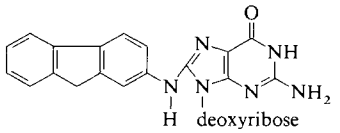
The Ultimate Carcinogen, *O*-Acetyl-*N*-(2-fluorenyl)hydroxylamine ("*N*-Acetoxy-2-aminofluorene"), and Its Reaction in vitro to Form 2-[*N*-(Deoxyguanosin-8-yl)amino]fluorene **

By *Ferdinand Bosold* and *Gernot Boche* *

After 2-acetylaminofluorene (**1a**) had been patented in 1940 as an insecticide (although it was never used), it became the most widely studied model carcinogen for aromatic amines owing to its high toxicity.[1]



1a, $R^1 = COCH_3$, $R^2 = H$
1b, $R^1 = H$, $R^2 = OCOCH_3$
1c, $R^1 = COCF_3$, $R^2 = OCOCH_3$
1d, $R^1 = H$, $R^2 = OH$



2

Not **1a** but rather the metabolite *O*-acetyl-*N*-(2-fluorenyl)hydroxylamine ("*N*-acetoxy-2-aminofluorene", **1b**) was thereby strongly implicated as an important ultimate carcinogen.[2, 3] Thus, primarily (80%) 2-[*N*-(deoxyguanosin-8-yl)amino]fluorene (**2**), that is, a DNA adduct, was isolated from rat liver (after DNA cleavage). Compound **2**, which bears no acetyl group on the fluorenylamine N atom,[4] has also been isolated from rat kidney and liver[5a] as well as from the bladder and liver of dogs.[5b] Also noteworthy is the high persistence in vivo of the DNA adduct containing **2** as a structural element.[6] Isomeric adducts in which the deoxyguanosine (dG) moiety is bonded, for example, to one of the ring C atoms of the aminofluorene moiety, have not been found. Reaction of an oligonucleotide with *O*-acetyl-*N*-(2-fluorenyl)-*N*-(trifluoroacetyl)hydroxylamine (**1c**) also afforded **2** (after DNA cleavage) as the sole adduct, thus indicating that **1b** is the active species.[7] All attempts to isolate the putative species **1b**, either formed in vivo or in vitro, or to synthesize it and study its reactivity with (bio)nucleophiles, have failed so far.[8] Here we describe the preparation of the title compound **1b** and its reaction in vitro with dG, which affords **2** as the sole adduct.[9]

1d $\xrightarrow[\text{THF, } \leq -40\,^\circ C]{CH_3CO-CN,\ Et_3N}$ **1b** $\xrightarrow[-40 \text{ to } 20\,^\circ C]{dG,\ H_2O/THF}$ **2** (14%)

Compound **1b** was prepared, in analogy to the procedure of *Prabhakar, Lobo,* and *Marques*,[10] from *N*-(2-fluorenyl)-hydroxylamine (**1d**) and acetyl cyanide in tetrahydrofuran (THF) at ≤ −40 °C. The crystalline product rapidly decomposes above −40 °C,[11] so that elemental analysis and mass-spectrometric analysis were not possible and the characterization had to be based on the ^{1}H NMR spectrum (see *Experimental Procedures*). Reaction of **1b** with dG was accomplished by adding an aqueous solution of dG to **1b** in THF at −40 °C. Noteworthy is the 14% yield of the dG adduct **2**, since the yields of the corresponding dG adducts of the *N*-acetoxyarylamines studied in Ref. [11] are at least a factor of two smaller.

In conclusion, since, in vivo and in the reaction of **1c** with an oligonucleotide, as described above, only the one non-*N*-acetylated dG adduct **2** is formed, the sole formation of **2** in the reaction of the title compound **1b** with dG is strong evidence that **1b** is indeed the ultimate carcinogen, which also leads in this case (if not generally[3]) to **2**.

Experimental Procedures

1b: A solution of acetyl cyanide (690 mg, 10.0 mmol) in 25 mL of THF was added dropwise to a vigorously stirred solution of **1d** (1.97 g, 10.0 mmol) and Et_3N (1.11 g, 11.0 mmol) in 50 mL of THF cooled to −40 to −50 °C. The temperature should not be allowed to rise above −40 °C! After 2 h, approximately 50 mL of THF was removed under vacuum and 30 mL of petroleum ether (b.p. 40–60 °C) cooled to −40 °C was added. After immediate filtration (frit at −78 °C), the filtrate was diluted with 180 mL of petroleum ether (b.p. 40–60 °C; −40 °C) and kept at −78 °C for about 1 h. The resulting colorless crystals were collected by filtration at −78 °C, washed with petroleum ether (−78 °C), dried under vacuum at −40 °C, and stored at −78 °C. Yield: 1.43 g (60%). Rapid decomposition occurs above −40 °C, the material turning black. ^{1}H NMR (400 MHz, [D$_8$]THF, 233 K): δ = 2.18 (s, 3H, CH_3), 3.84 (s, 2H, CH_2), 6.99 (d, 1H, aryl-H), 7.20 (s, 1H, aryl-H), 7.21 (d, 1H, aryl-H), 7.30 (t, 1H, aryl-H), 7.49 (d, 1H, aryl-H), 7.70 (d, 1H, aryl-H), 7.71 (t, 1H, aryl-H), 9.77 (s, broad, 1H, N-H).

2: dG (800 mg, 3.00 mmol) in 30 mL of H_2O was added to **1b** (0.72 g, 3.00 mmol) in 80 mL of THF at −40 °C. After the reaction mixture had warmed to room temperature, 100 mL of H_2O was added, the mixture was extracted with ether, and the ether phase was discarded. After addition of a further 200 mL of H_2O, the mixture was extracted eight times with ether. Compound **2** crystallized from the ether phase. The purification of **2** (and the search for other possible adducts) was carried out by chromatography with a special GC instrument (Chromatotron) ($CHCl_3$:CH_3OH = 7:3 on silica gel 60PF). Yield: 190 mg (14%). Compound **2** was characterized by comparison of its ^{1}H NMR spectrum with that of an authentic sample [4d].

Elucidation of the Structure of Hormaomycin **

By *Ellen Rössner, Axel Zeeck,** and *Wilfried A. König*

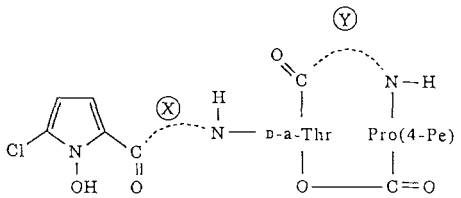
Dedicated to Professor Hans Zähner on the occasion of his 60th birthday

The novel peptide lactone hormaomycin produced by *Streptomyces griseoflavus* is selectively active against some gram-positive bacteria, and, in addition, influences both aerial mycelium formation as well as the production of secondary metabolites.[1] It thus belongs to the intercellular signal substances, of which the A factor (Khokhlov factor) is thus far the best known.[2] Hormaomycin differs fundamentally in its structure, however, from this comparably simple γ-lactone. Such signal substances are attracting increasing interest for the exploration of microbial secondary metabolism.[3] We report here on the elucidation of the structure of hormaomycin.

Hormaomycin, $C_{55}H_{69}ClN_{10}O_{14}$, contains the known amino acids *allo*-threonine (a-Thr), isoleucine (Ile) and (3-methyl)phenylalanine (Phe(3-Me)) as well as the new amino acids 4-[(*Z*)-propenyl]proline (Pro(4-Pe)) and 3-(2-nitrocyclopropyl)alanine (Ala(3-Ncp)). Phe(3-Me) and Ala(3-Ncp) each occur twice in the molecule. NMR and mass spectra point to an acylation of the N-terminal of the peptide chain by chlorine-containing *N*-hydroxypyrrole-2-carboxylic acid (Chpca).[1]

To determine the stereochemistry of the known amino acids (a-Thr, Ile, Phe(3-Me)) the acidic total hydrolyzate of hormaomycin (6N HCl/glacial acetic acid 1/1, 110 °C, 48 h), after esterification with methanol/HCl and acetylation with trifluoroacetic anhydride $(Tfa)_2O$, was analyzed chromatographically on Chirasil-Val[4] or XE-60-α-pea.[5] The amino acids known to be contained in hormaomycin could be identified as D-*allo*-threonine, L-isoleucine, and L-*threo*-(3-methyl)phenylalanine (two molecules).[1b] The stereochemistry of the new amino acids (2 × Ala(3-Ncp), Pro(4-Pe)) could not be determined by this method without the synthesis of suitable reference compounds.

The OH group of D-*allo*-threonine is esterified, as is recognizable by the downfield position of the β-CH signal of the a-Thr building block ($\delta = 5.35$) in the ^{1}H-NMR spectrum (200 MHz, $CDCl_3$) of hormaomycin. The amino acid participating with the C-terminal in the lactone bonding was determined by reduction of the ester group with $LiAlH_4$ (four mol equivalents $LiAlH_4$, THF, 0 °C, 3 h). After derivatization *N,O*-bis(trifluoroacetyl)-4-[(*Z*)-propenyl]prolinol ($m/z = 333$ ($[M]^{\oplus}$), 206 ($[M-CH_2OCOCF_3]^{\oplus}$)) could be detected in the GC/MS analysis of the hydrolyzed reaction product. The results of the structure elucidation so far indicate the partial formula **1** in which Ⓧ and Ⓨ are peptide chains of five amino acids (L-Ile, 2 × L-*threo*-Phe(3-Me), 2 × Ala(3-Ncp)).



1

The sequences in the peptide lactone ring and in the side chain could be clarified by combining the results of several mass spectrometric and NMR spectroscopic investigations. Partial hydrolyzates of hormaomycin (e.g. 12 N HCl/glacial acetic acid 1/1, room temperature, 48 h) contained two tripeptides, which were identified as the trifluoroacetylated methyl esters by GC/MS coupling (Table 1).

Table 1. Peptides contained in the partial hydrolyzates of hormaomycin (derivatized to trifluoroacetylated methyl esters).

Peptide	Characteristic ions in the EI-mass spectrum (*m/z*)
N-Tfa-Phe(3-Me) · Ile-OCH_3	402 $[M]^{\oplus}$, 230 $[M-(OC\text{-}Ile\text{-}OCH_3)]^{\oplus}$
N,O-Bis(Tfa)-a-Thr · Phe(3-Me)-OCH_3	427 $[M-COOCH_3]^{\oplus}$, 266 $[M-OC\text{-}Phe(3\text{-}Me)\text{-}OCH_3)]^{\oplus}$, 192 $[Phe(3\text{-}Me)\text{-}OCH_3]^{\oplus}$
N-Tfa-Phe(3-Me) · Ile · Pro(4-Pe)-OCH_3	539 $[M]^{\oplus}$, 371 $[M-(Pro(4\text{-}Pe)\text{-}OCH_3)]^{\oplus}$, 230 $[M-(OC\text{-}Ile\cdot Pro(4\text{-}Pe)\text{-}OCH_3)]^{\oplus}$, 168 $[Pro(4\text{-}Pe)\text{-}OCH_3]^{\oplus}$

The open-chain hormaomycin methyl ester **2** (see Scheme 1), which no longer exhibits a biological activity comparable with hormaomycin,[1c] proved to be an important derivative for the mass spectrometric investigation. **2** is readily accessible from hormaomycin (methanol, catalytic amounts of K_2CO_3, room temperature, 12 h).[1a] Its FAB mass spectrum shows a sequence of ions, all of which can be characterized (Scheme 1). The successive cleavage of Pro(4-Pe)-OCH_3, Ile, and Phe(3-Me) starting from the esterified C-terminal of the peptide chain confirms the sequence of the tripeptide Phe(3-Me) · Ile · Pro(4-Pe) detected in the partial hydrolyzate. All the quoted fragment ions excluding the fragment *m/z* 418 show the typical isotopic

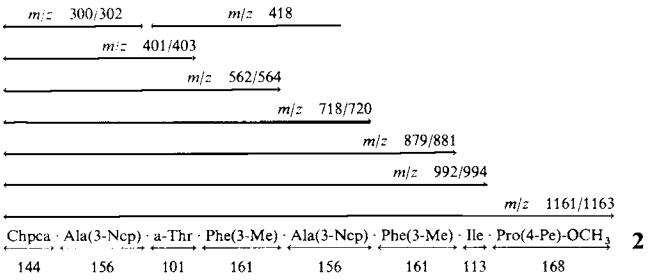
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Ze 120/14-1). We thank Priv.-Doz. Dr. *H. Wolf*, Stuttgart, and Dr. *N. Andres*, Tübingen, for supplying the crude hormaomycin and Herrn Dipl.-Chem. *R. Machinek* for recording the ROESY spectra.



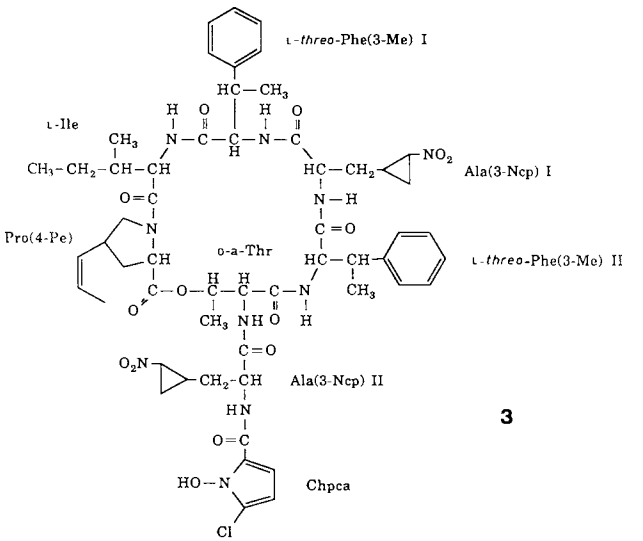
Scheme 1. Sequence ions of hormaomycin methyl ester **2** in the FAB-mass spectrum (*m*-nitrobenzyl alcohol as matrix, positive ions). Ion pairs with $\Delta(m/z) = 2$ confirm the presence of a Cl atom (m/z 1161, $[M + H]^{\oplus}$ for ^{35}Cl). The molecular weights of the individual building blocks are given below.

distribution for a Cl atom. As can be deduced from Scheme 1, the fragment m/z 418 is formed by cleavage of the amide bonds at the two Ala(3-Ncp) building blocks. The FAB-mass spectrum also shows a fragment ion of high intensity at m/z 144/146. It arises from the Cl-containing Chpca building block, which hitherto could not be detected in the total and partial hydrolyzates of hormaomycin. The sequence thus derived for the open-chain methyl ester **2** can be assumed for the natural product. The partial formula **1** can thus be extended as follows: Ⓧ = Ala(3-Ncp), Ⓨ = Phe(3-Me) · Ala(3-Ncp) · Phe(3-Me) · Ile.

ROESY(rotating-frame Overhauser enhancement spectroscopy)-NMR experiments[6] on the intact natural product could independently confirm parts of the sequence. Most of the numerous NOE effects[1b] are of no significance for the sequence analysis, but can be helpful for the (still outstanding) conformational analysis of the lactone ring. The NOE effects from the ROESY spectrum of hormaomycin that are of significance for a sequence analysis are collected in Table 2; however, the complete sequence could not be derived in this way.

Table 2. NOE effects between neighboring amino acids in the ^{1}H-ROESY-NMR spectrum (200 MHz, $CDCl_3$) of hormaomycin.

Amino acid	δ_H	Amino acid	δ_H
Ala(3-Ncp) I	3.49 (H_α)	Phe(3-Me) I	6.80 NH)
Phe(3-Me) II	4.37 (H_α)	Ala(3-Ncp) I	6.58 (NH)
Ala(3-Ncp) II	5.15 (H_α)	a-Thr	9.08 (NH)
Ile	4.62 (H_α)	Pro(4-Pe)	3.98 (5-H_b)



3

The combined data quoted here yielded the constitution **3** for hormaomycin. Peptide lactones of this structural type have hitherto not been described as microbial secondary metabolites.

$[BP_2]^{3\ominus}$ and $[BAs_2]^{3\ominus}$, Zintl Anions with Propadiene Structure

By *Hans-Georg von Schnering,* Mehmet Somer, Martin Hartweg,* and *Karl Peters*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Depending on the elements involved and on the state of aggregation, triatomic 16-electron systems display all conceivable forms of coupling and bond orders, be it in monomers such as $BeCl_2(g)$, CO_2, ClCN and N_2O, in oligomers such as $(BOCl_3)_3$, or in the various polymers with different coordination, e.g. compounds of the structure type SiO_2, SiS_2, AlOCl, SnO_2, CaF_2 etc. Such variations can also be realized as partial structures in salt-like compounds, if a formal transfer of electrons from electropositive cations to an anion $[MX_2]^{n\ominus}$ is assumed as described by *Zintl*[1]. The expression $(e_M + 2e_X + ne) = 16$ holds true for the electron balance, and interatomic linkages as are found in the above mentioned compounds are expected for the partial structure of $[MX_2]^{n\ominus}$. In the case of heteroaromatic polyanions this treatment naturally contains a certain arbitrariness, which becomes apparent with big differences between M and X (M also "cation", formation of isolated $X^{m\ominus}$ anions); nevertheless, it is extremely valuable for systematic considerations and for the planning of syntheses. *Juza* et al.[2] have already detected polymeric partial structures $^3_\infty[MX_{4/2}]^{3\ominus}$ with tetra-

hedral coordination of M for Li_3AlN_2 and Li_3GaN_2 as well as for Li_3AlP_2 and Li_3AlAs_2. Topological variants of these three-dimensional network structures are known with $^3_\infty[MX_{4/2}]^{2\ominus}$ (M = Si, Ge, Sn; X = P, As)[3] and with $^3_\infty[MX_{4/2}]^{1\ominus}$ ($M^{\oplus}$, $X^{2\ominus}$).[4] Tetrahedral chains of the SiS_2-type structure characterize the partial structures $^1_\infty[MX_{4/2}]^{n\ominus}$ of K_2SiP_2,[5] Rb_2SiAs_2,[6] and Na_3AlAs_2.[7] Especially interesting, however, are the isolated linear propadienes such as $[CN_2]^{2\ominus}$ and $[BN_2]^{3\ominus}$, because of their properties as synthetic building blocks (synthons), even though units like $[NiO_2]^{2\ominus}$[8] and $[ZnP_2]^{4\ominus}$[9] differ only slightly from them.

Ternary boron phosphides and arenides were hitherto unknown. They are formed from the elements or even from BP and/or BAs respectively at 1000–1100 K.[10] We obtained K_3BP_2 **1** and K_3BAs_2 **2** as bright yellow crystals and yellow-red crystals, respectively. X-ray structure analyses [11] and vibrational spectra confirm the presence of propadiene systems. The bond lengths $d_{B-P} = 176.7$ and $d_{B-As} = 186.8$ pm, have a Pauling bond order PBO = 1.9, and compare very well with those expected for double bonds, based on the bond distances in BP and BAs taken as single bonds ($d_1 = 196.5$ and 206.9 pm). As expected, the bonds are somewhat weaker than in $[BN_2]^{3\ominus}$[12] ($d_{B-N} = 133.6$ pm; $d_1 = 156.5$ pm; PBO = 2.1), whose propadiene structure was already established spectroscopically by *Goubeau* and *Anselment*[13] in 1961. The bond length and bond order in the anion $[BP_2]^{3\ominus}$ complement the corresponding values in the phosphorus analogues of borazine $R_3R'_3(BP)_3$[14] ($d_{B-P} = 184$ pm, PBO = 1.5) quite well.

The crystal structure (Fig. 1) of the isotypic compounds **1** and **2** is a model example for illustrating Nature's economy in matching widely different local building blocks to simple, optimum ensembles. A molecular 1,2,3-tripotassium diphosphaboracyclopropane could, e.g., satisfy the classical valences of all atoms in **1**, but not the striving for a higher coordination of the peripheral K atoms. For stoichiometric reasons this can only be achieved when the P atoms as minority component show an even higher coordination. Should potassium be on average fourfold or sixfold coordinated then phosphorus must have the coordination numbers (CN) 8 and 12, respectively, because K_3BP_2 ($\triangleq M_3M'X_2 \triangleq M''_2X$) is, in principle, a 2:1 compound. Accordingly, the structure of **1** in fact is a variant of the AlB_2 type, whereby the P atoms form the corners of trigonal prisms whose centers are 3/4 occupied by K atoms. $P_2(K_3\square)$. The B atom could occupy the hole $\square$ (CN 6), the center of the P_3-triangle adjacent thereto (CN 3), or one of the prism edges (CN 2). The latter is the case, and the formation of the propadiene structure $[P=B=P]^{3\ominus}$ apparently is not enforced by the composition of **1** and **2**, respectively. The defect 6^3 networks of K atoms are reorganized to pentagon ribbons (Fig. 1), whereby short K–K distances are avoided ($d_{K-K} \geq 331.5$ pm instead of 269 pm in AlB_2). Five K atoms surround each $[BP_2]^{3\ominus}$ unit (pentagonal bipyramids K_5P_2 surround the B atom with $d_{B-K} = 307.2-331.5$ pm). The six d_{K-P} distances in each case are for K1 330.2–399.3 pm ($\bar{d} = 355.2$ pm) and for K2 338.0–378.9 pm ($\bar{d} = 354.0$ pm). The P atoms are bound to one B atom and are coordinated by nine K atoms (instead of twelve).

Three internal vibrations can be expected for the anion $[BX_2]^{3\ominus}$ with $D_{\infty h}$ symmetry: $\Gamma_{vib} = \Sigma_g^+(RE, \nu_1) + \Sigma_u^+(IR, \nu_2) + \Pi_u(IR, \nu_3)$, with an isotope splitting (^{11}B, ^{10}B) in the IR active modes ν_2 and ν_3. In each case, a doublet of very high frequency (ν_2) and a low-lying triplet (site-symmetry-splitting; ν_3)—besides the lattice modes with $\tilde{\nu} < 200\ cm^{-1}$ are also observed in the IR spectra (Fig. 2). As expected $\tilde{\nu}(^{11}B)/\tilde{\nu}(^{10}B)$ is in each case 0.95/1,[14] and the force constants f, f', d [$N \cdot cm^{-1}$] determined according to *Siebert*[15] are 3.78, 0.60, 0.20 for **1** and 3.00, 0.30, 0.18 for **2**. These values give bond orders of 1.8 and 1.9, respectively,

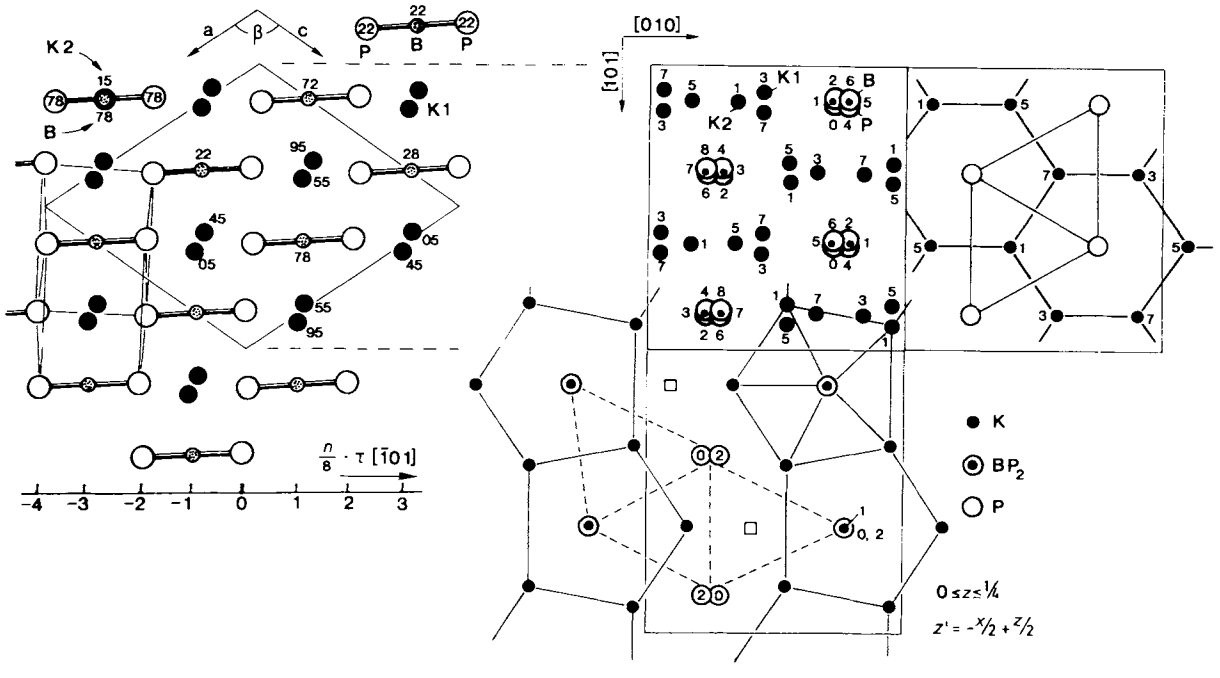

Fig. 1. Left: Projection of the structure of **1** along [010] with y in $n/100$; [101] corresponds to the hexagonal a-axis of an AlB_2 structure, [$\bar{1}$01] its fourfold c-axis (direction of the axes of the trigonal prisms). Right: Projection along [$\bar{1}$01] $\triangleq c'$ with the real atom positions (z' approximation in $n/8$). The idealized AlB_2-type structure is also shown. The connecting lines merely delineate the AlB_2 unit cells and the 6^3 network, the heights z' only the position of the defects $\square$. Along c' there are sequences of four P atoms with two alternatingly inserted B atoms (··· P–B–P ··· P–B–P), whereas only 3/4 of the M positions are occupied (MMM $\square$). Below: Section of the real structure parallel to [$\bar{1}$01]. The defects $\square$ break the 6^3 graphite network into bent chains, and the M partial structure becomes reformed to chains of condensed five-membered rings (increase in $d_{M\ M}$). One of the pentagonal bipyramids made up of 5 K + 2 P around the B atoms is indicated.

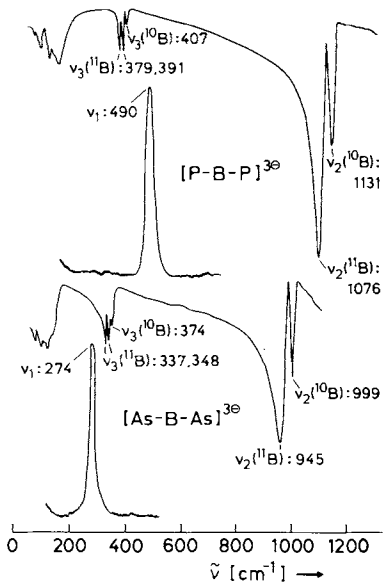

Fig. 2. IR and Raman spectra of **1** and **2**.

which are in excellent agreement with the above PBO's derived from the bond lengths.

K_3BP_2 reacts vigorously with water, alkalis and acids. It also reacts with NH_3 and chloroalkanes in THF, but in each case to give heterogeneous products which have not as yet been identified.

According to the most recent theoretical studies by *Pyykkö* and *Zhao*[16] a bond length of 183 pm is expected in the anion of **1**. The respective calculated vibrational wave numbers are 451 (ν_1) 1003 (ν_2) and 389 cm^{-1} (ν_3). On average, the calculated wave numbers are 5% smaller than the observed wave numbers, while the calculated bond length (6 pm) is 3% greater than the observed bond length. This discrepancy could be associated with shortcomings in the calculations; on the other hand, the deviations fit quite well to *Badger*'s rule, according to which $\tilde{\nu} \sim f^{1/2} \sim d^{-3/2}$.[17] In the K_3BP_2 crystal the effective charges in the $[BP_2]^{3\ominus}$ anion are certainly smaller, through interactions with the cations, than in the gaseous group. The shortening of d_{B-P} compared to that calculated is thus understandable. This effect, however, is possibly also an indication of considerable asymmetry in the electron density of the strongly polarized P atoms. Therefore we are planning to determine the nuclear distances by neutron diffraction.

Synthesis of (+)-Terrein from L-Tartaric Acid

By *Hans-Josef Altenbach** and *Winfried Holzapfel*

(+)-Terrein is a metabolic product of several types of fungi.[1] It was first isolated as long ago as 1935, but it was not until 1955 before its correct structure could be elucidated.[1b,2] Compound **1**, which is readily obtainable fermentatively but does not exhibit any noticeable biologically activity, has found interest as an enantiomerically pure, highly functionalized cyclopentanoid building block, for example, for prostaglandin precursors.[3] The synthesis of terrein proved to be problematical because of its high sensitivity towards acids and bases, but in the meantime three routes to *rac*-**1** have been reported.[4]

We planned to synthesize optically active terrein **1** from the suitably protected L-tartaric acid derivative **2**, for the absolute configuration of **1** had been derived by *Barton* et al. by degradation down to the natural tartaric acid.[2] This idea was all the more attractive, as a simple retrosynthetic strategy to form both double bonds in **1** by Wittig-Horner olefinations leads to a C_2 symmetrical bisketophosphonate **3** as key compound, which appeared to be easily accessible from the tartrate **2**[5] (Scheme 1).

As protection for the alcohol functions of the tartaric acid, we chose the *tert*-butyldimethylsilyl group since it can be cleaved under such mild conditions that an isomerization (and racemization) to the isoterrein with *cis* arrangement of the hydroxy groups is avoided.

Compound **2** was obtained in 95% yield under standard conditions[6] by reaction of L-diethyl tartrate with *tert*-butyl(dimethyl)silyl chloride and imidazole in dimethylformamide. Surprisingly, upon reaction of **2** with four equivalents of diethyl lithiomethylphosphonate analogously to a synthetic method described by *Corey* et al.[7] for β-ketophosphonates (two equivalents are needed for the deprotonation of the bisketophosphonate **3** that is formed), mainly the Knoevenagel product **5** derived from **3** was isolated; in addition, small amounts of **4**, the desired product of an intramolecular Wittig-Horner reaction of **3**, was formed. Apparently, a cyclic intermediate is immediately formed, since the open-chain diadduct **3** could not be trapped, not even by quenching with acetic acid at −78 °C. The highest yields of the olefination product **4** required for the further step of the synthesis were obtained when two equivalents of acetic acid were first added after addition of the lithiomethylphospho-

nate and warming of the reaction solution to $-20\,^{\circ}C$, and then stirring continued for 20 h at room temperature before the reaction was worked-up in aqueous solution. Under these conditions the product ratio **4**:**5** is 4:1. Owing to the large difference in their polarity **4** and **5** can be readily separated chromatographically and **4** [m.p. 54 °C (ether); $[\alpha]_D^{20} = +42.1^{\circ}$ ($c = 1.07$ in $CHCl_3$)] is obtained in 61% yield based on **2**. Introduction of the side chain in the required *E*-configuration was achieved smoothly via Wittig-Horner olefination of **4** with acetaldehyde. The product, which was obtained as a colorless oil, and whose spectral properties were consistent with those of the compound obtained by silylation of (+)-terrein,[8] is very labile and was allowed to react directly with Et_4NF—generated in situ from Et_4NCl and $KF \cdot H_2O$[9]—for cleavage of the alcohol protecting group. **1** was obtained in 42% yield based on **4**; its melting point, ^1H- and ^{13}C-NMR spectroscopic data, and rotation [m.p. 122 °C (CH_2Cl_2); $[\alpha]_D^{20} = 164^{\circ}$ ($c = 0.37$ in H_2O)] were identical with those of natural terrein.[1]

Remarkably, with this simple reaction sequence it appears that not only the synthesis of the optically active terrein is shorter and more effective than all the previously described routes to the racemate, but also that, with the intermediates, readily accessible enantiomerically pure five-membered ring building blocks are available which should be useful for the synthesis of other target materials, for example carbocyclic nucleoside analogues.

Structure–Magnetism Relationship in $[Ti^{III}\text{-}O\text{-}Ti^{III}]^{4\oplus}$ Complexes**

By *Axel Bodner, Stefan Drueke, Karl Wieghardt,* Bernhard Nuber,* and *Johannes Weiss*

Structure-magnetism relationships in homobinuclear transition metal complexes containing two paramagnetic metal ions joined by an oxo bridge with octahedrally arranged ligands are currently the subject of intensive study.[1] Depending upon a) the electronic configuration of the two metal ions and b) the geometry of the $[M\text{–}O\text{–}M]^{n\oplus}$ moiety, which is puckered or linear, the intramolecular interaction of the spins can be antiferromagnetically or ferromagnetically coupled or even uncoupled. In complexes of type **A** containing a di-μ-carboxylato-μ-oxodimetal(III) structural unit, a strong antiferromagnetic behavior was observed for the iron(III) complex [d^5, high spin(hs)],[2] a strong ferromagnetic behavior for the analogous vanadium(III) complex (d^2),[3] and, finally, a weak ferromagnetic or weak antiferromagnetic, or even a decoupled behavior for the manganese(III) complex (d^4, hs). Compounds with a linear $[M\text{–}O\text{–}M]^{n+}$ unit (type **B**) show, e.g., strong antiferromagnetic coupling for Fe^{III} (d^5, hs),[5] ferromagnetic coupling for V^{III},[3] and antiferromagnetic coupling for Cr^{III}.[6]

Surprisingly, nothing has thus far been reported in the literature about the magnetic properties of the electronically simplest complexes **A** and **B** containing two titanium(III) ions (d^1). We have therefore synthesized the complexes **1** and **2** and studied their magnetic properties.

$[L_2Ti_2(\mu\text{-}O)(\mu\text{-benzoato})_2](PF_6)_2$ **1**
$[L_2Ti_2Cl_4(\mu\text{-}O)]$ **2**
(L = *N*,*N*′,*N*″-trimethyl-1,4,7-triazacyclononane)

Figure 1 shows the structure of the cation **1**.[7] Two distorted octahedrally coordinated Ti^{III} ions are coupled with each other via a μ-oxo group as well as two symmetrical benzoato-

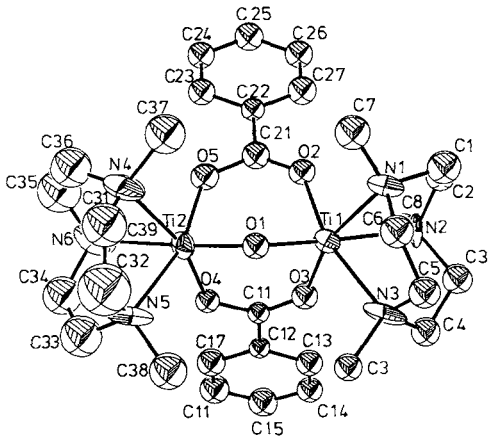

Fig. 1. Structure of the binuclear dication in crystals of **1**. Important bond lengths [Å] and angles [°] in **1**: Ti1-O1 1.81(2), Ti1-O2 2.03(2), Ti1-O3 2.06(2), Ti1-N1 2.24(2), Ti1-N2 2.34(2), Ti1-N3 2.20(2), Ti2-O1 1.84(2), Ti2-O4 2.05(2), Ti1-O5 2.04(2), Ti2-N4 2.23(2), Ti2-N5 2.21(2), Ti2-N6 2.30(2), Ti1···Ti2 3.198(4); Ti1-O1-Ti2 122.7(8), N-Ti-N 77.4(8) (average), O4-Ti2-O5 91.9(6), O2-Ti1-O3 92.7(6).

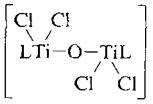
groups. The $[Ti\text{–}O\text{–}Ti]^{4\oplus}$ unit is bent [122.7(8)°]; the mean $Ti\text{–}O_\mu$ distance (1.82(2) Å) is very short. The $Ti\text{–}O_\mu$ bonds have a strong *trans* influence on the *trans* Ti–N bonds, which are about 0.10 Å longer than the corresponding *cis* Ti–N bonds. The Ti···Ti distance is 3.198(4) Å; it rules out a direct Ti–Ti bonding.[8] As follows from a comparison of the dimensions in analogous complexes of type **A**,[2–4] the distances and angles within the μ-oxo-bis-di-μ-carboxylato-μ-oxo-dimetal(III) unit are very similar.

The structure of **2** has not been determined, but it is highly probable that it contains a linear $[Ti^{III}\text{–}O\text{–}Ti^{III}]^{4\oplus}$ unit.



2

The magnetic properties of **1** and **2** differ drastically: crystals of **1** are *diamagnetic* at 298 K,[9] whereas **2** shows a temperature independent magnetic moment (90–298 K) of 1.72 μ_B per Ti^{III} center, which corresponds exactly to the spin-only value of one unpaired electron per Ti atom.

Thus, in **1** a very strong intramolecular spin-spin coupling of the two d^1 electrons is observed ($\boldsymbol{H} = -2JS_1 \cdot S_2$; $S_1 = S_2 = 1/2$; $-J > 400\ cm^{-1}$), whereas in **2** these electrons are uncoupled.

Figure 2 shows the X-band ESR spectrum of a powdered sample of **1** at 20 °C.[10] ESR spectroscopy is substantially more sensitive for the detection of unpaired electrons than measurements of the susceptibility on solid samples by the Faraday method. Three signals are observed. The two outer signals are strongly temperature dependent, and below 130 K they are no longer detectable. The signal at $g \approx 2.0$ is temperature independent; it can be ascribed to a paramagnetic impurity with $S = 1/2$ ground state ($LTiCl_3$ or $L_2Ti_2(\mu\text{-}O)(\mu\text{-benzato})_2]^{3\oplus}$).[11] The two temperature dependent signals are ascribed to an excited state of **1** with $S = 1$ which is no longer populated at low temperatures ($S = 0$ ground state).[12]

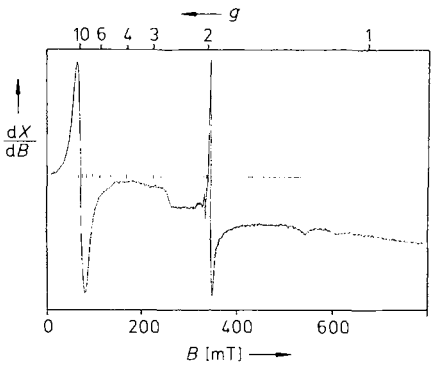


Fig. 2. ESR spectrum (X-band) of a solid sample of **1** at 246 K (20.0 mW/10 dB; 9.4232 GHz).

The bonds between the Ti atoms and the bridging O-atoms are the shortest bonds in **1** and **2**. It is therefore practicable for the following discussion to choose coordinates in which this bonding vector coincides with the *z*-axis; the d_{z^2} orbital in both complexes is then the energetically highest lying d-orbital and the d_{xy} orbital the energetically lowest lying (occupied) d-orbital. Since the d_{z^2} orbitals in **1** and **2** are unoccupied, a classical magnetic superexchange via the oxo bridges in **2** *cannot* explain the strong coupling. As shown in Figure 3 (left), however, it can be due to a

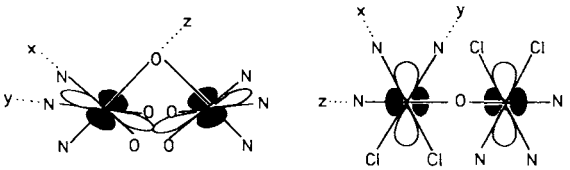

Fig. 3. Schematic representation of the overlap of the $d^1_{x^2-y^2}$ orbitals in **1** (left) and of the parallel $d^1_{x^2-y^2}$ orbitals in **2** (right).

symmetry allowed through-space overlapping of the two d_{xy} orbitals. In **1**, such an interaction leads to an $S = 0$ ground state (diamagnetism).[13] In the case of a linear $Ti^{III}\text{–}O\text{–}Ti^{III}$ group with longer Ti···Ti distance the d_{xy}-d_{xy} overlap would have δ symmetry and would be very weak (Fig. 3, right). The assumption of such a bridging geometry is consistent with the observed paramagnetism of **2**.

1 and **2** are good examples for demonstrating that the analysis of the possible magnetic orbitals in a given structure type of a binuclear complex can qualitatively correctly describe the observed coupling.[1b]

Experimental

1: A suspension of 1 g of $TiCl_3$ in 15 mL of dry CH_3CN was heated under reflux in an inert atmosphere (Ar) until a deep-blue solution was obtained. This was then treated dropwise with a solution of 1.2 g of *N,N',N''*-trimethyl-1,4,7-triazacyclononane (L) in 10 mL of CH_3CN. After 30 minutes' stirring at 20 °C a turquoise colored precipitate of $LTiCl_3$ was recovered by filtration (yield: 92%). UV/VIS (CH_3CN): $\lambda_{max} = 690$ nm ($\varepsilon = 30$); μ_{eff} (293 K) = 1.7 μ_B. 20 mL of a methanolic solution of 0.5 g of $LTiCl_3$ and 1 g of sodium benzoate was heated under reflux in an inert atmosphere (Ar) for 30 min. The resulting black-violet solution was treated with 1 g of $NaPF_6$. After 12 h at 5 °C, black-violet crystals of **1** were formed in 80% yield. IR (KBr): $\tilde{\nu} = 1541$ [$\tilde{\nu}_{as}$(C–O)], 1397 [ν_s(C–O)], 685 cm^{-1} [ν_{as}(Ti–O–Ti)]; UV/VIS (CH_3CN): $\lambda_{max} = 450$ ($\varepsilon = 2100$), 595 (sh) nm.—**2**: a solution of 0.8 g of L in 20 mL of dimethylformamide which contained about 1% H_2O was purged with argon and treated with 0.5 g of $TiCl_3$. The resulting suspension was heated under reflux for 30 min. After cooling to 5 °C a bright blue, microcrystalline precipitate of **2** was recovered by filtration (yield 45%). IR(KBr): $\tilde{\nu} = 745$ cm^{-1} [ν_a (Ti–O–Ti)]; UV/VIS (CH_3CN): $\lambda_{max} = 570$ nm ($\varepsilon = 520$ mol^{-1} cm^{-1}), 750 nm (sh). Magnetic moment: $\mu = 1.7$ μ_B per Ti atom (90–298 K). All the complexes gave correct elemental analyses (C,H,N,Cl).

Coordination Chemistry of Polyoxomolybdates: The Structure of a Dodecanuclear Molybdate Cage Incorporating Hydrogen Squarate Ligands, $[(C_4H_9)_4N]_4[Mo_{12}O_{36}(C_4O_4H)_4] \cdot 10Et_2O$ **

By *Qin Chen, Shuncheng Liu,* and *Jon Zubieta**

The coordination chemistry of polyoxometalate clusters with organic substrate molecules has received considerable attention in recent years by virtue of the structural relationship of polyoxoanions to solid oxides.[1] The reaction chemistry of polyoxomolybdates with organic compounds containing carbonyl or enolic oxygens has proved particularly fruitful,[2] and we recently demonstrated that rhodizonic acid **1** reacts with octamolybdate **2** to yield **3**, an unusual cyclic octanuclear polyoxomolybdate with an oxalate-occupied cavity,[3] while *Haushalter* und *Lai* have described the aggregate $[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}]$, a hollow cluster filled with an H_3PO_4 molecule.[4] This result suggested that the chemistry of other "oxocarbons",[5] compounds in which all of the carbon atoms are bonded to carbonyl or

enolic oxygens, with polyoxomolybdate anions would provide further insight into polyoxomolybdate-carbonyl chemistry and into ligand-oxometalate aggregation chemistry. Consequently, we initiated investigations of the chemistry of squaric acid **4** with dimolybdate **5** under a variety of reaction conditions. We have already reported on the struc-

8.[13] The IR spectrum of **8** shows a band at 1630 cm^{-1} associated with C=O stretching vibrations and intense bands at 949 and 919 cm^{-1} attributed to $\nu_s(Mo=O_t)$ and $\nu_{as}(Mo=O_t)$ stretching vibrations (O_t = terminal oxygen), respectively. The band at 812 cm^{-1} establishes the presence of bridging oxo groups (Mo–O_b–Mo). Furthermore, a broad feature at 3440 cm^{-1} may be ascribed to ν(O–H), while the bands at 1382 and 1080 cm^{-1} are assigned to O–H and C–OH bending respectively.

The complex anion of compound **8** (Fig. 1)[8] consists of a dodecanuclear cage of Mo atoms, bridged by oxo groups, producing a cyclic $[Mo_{12}O_{12}]$ framework. Each of the hydrogen squarate ligands bridges six Mo sites, such that two of the oxygen donors adopt bridging modes and two oxygen

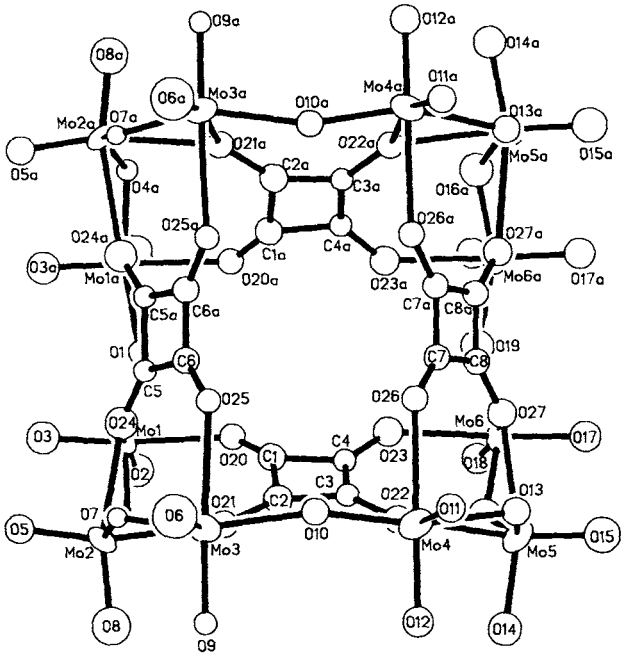

Fig. 1. Structure of the anion of **8**. Selected average bond lengths [Å] and angles [°]: Mo–O_t 1.68(3), Mo–O_b 1.92(3), Mo–O_t (ligand) 2.24(2); Mo–O_s (ligand) 2.37(3), O_t–Mo–O_t 104.9(15), O_b–Mo–O_b 146.8(17). Abbreviations: O_t = terminal oxo-group; O_b = bridging oxo-group; O_s(ligand) = terminally ligated squarate oxygen donor; O_b(ligand) = bridging squarate oxygen donor.

donors assume terminal coordination. In this fashion, each Mo center exhibits distorted octahedral geometry via coordination to two terminal oxo groups, two bridging oxo groups,

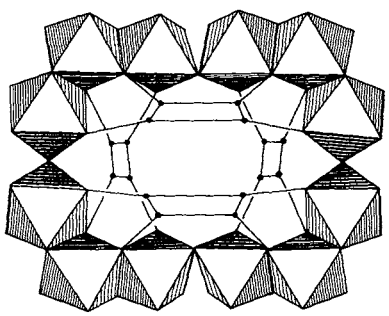

Fig. 2. The structure of the anion of **8** viewed as edge- and corner-sharing $[MoO_6]$ octahedra, with the hydrogen squarate C_4 backbones represented by the tetragons.

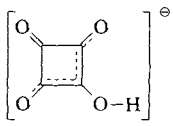
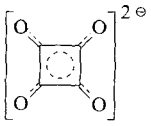
and two oxygen donors from the hydrogen squarate ligands. The anion exhibits approximate four-fold inversion symmetry about an axis normal to and passing through the center of the molecule, as illustrated in Figure 1.

Although polyoxomolybdate structures are generally constructed exclusively from edge-shared octahedra,[9] **8** presents both edge- and corner-sharing in the framework, as illustrated in Figure 2. Another unusual feature of the structure is the presence of the organic ligand as the singly deprotonated hydrogen squarate moiety **9**, rather than the commonly observed pseudoaromatic squarate form **10**.[10] The

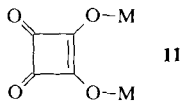


9



10

protonated ligand form **9** is consistent with the relatively long Mo–O(ligand) distances (2.24(2) Å, average terminal squarate O atom; 2.37(2) Å, average bridging squarate O atom), compared to distances in the 1.95 Å to 2.12 Å range for Mo–O(squarate) bonds with 1,2 bridging structures **11**.[6, 7] A similar trend in bond lengths has been estab-



11

lished for structures exhibiting coordinated alcohol moieties [Mo(HOR)] as opposed to coordinated alkoxide [Mo(OR)] where ranges of 1.81 to 1.98 Å[11] and 2.24 to 2.28 Å[3, 12], respectively, have been observed. The quality of the data precluded assignment of the protonation sites, nor did ^{1}H-NMR studies provide resonances attributable to the alkoxy protons, presumably as a consequence of rapid exchange. The observation of a broad O–H stretching band at 3440 cm^{-1} in the IR spectrum of **8** is consistent with some degree of intramolecular H-bonding.

Experimental

A solution of **5** (2.0 g, 2.5 mmol) in CH_2Cl_2 (10 mL) was added to a solution of **4** (0.43 g, 3.8 mmol) in 2-chloroethanol/CH_2Cl_2 (30 mL, 1:1 by volume). After stirring at room temperature for 10 h, the resulting orange-brown solution was filtered and concentrated to 15 mL on a rotary evaporator. After layering this solution with diethyl ether (25 mL) and allowing it to stand for 2 weeks at 4 °C, small greenish crystals were isolated. Recrystallization of these from 2-chloroethanol/diethyl ether afforded colorless transparent crystals of **8** in 70% yield. Upon standing at room temperature, crystals of **8** became waxy and opaque. Removal from the mother liquor likewise resulted in opacity and loss of crystallinity. The analytical data corresponds to a sample which has lost two diethyl ether molecules of crystallization, i.e. $[(n\text{-}C_4H_9)_4N]_4[Mo_{12}O_{36}(C_4O_4H)_4] \cdot 8(C_2H_5)_2O$: calcd. C 35.9, H 6.10, N 1.49; found: C 35.3, H 6.23, N 1.29.

[8] Crystal data at 233 K: orthorhombic, space group *Cmc*2 (alternative setting of No. 40, *Ama*2), $a = 25.391(5)$ Å, $b = 28.071(5)$ Å, $c = 26.335(5)$ Å, $V = 18.769.4(19)$ Å^3, $Z = 4$. Structure solution and refinement based on 3973 reflections with $F_0 \geq 4\sigma(F_0)$ ($Mo_{K\alpha}$, $\lambda = 0.71073$ Å); final discrepancy factor, 0.0757. The sample was mounted in a quartz capillary tube in the presence of the mother liquor to prevent loss of diethyl ether and consequent loss of crystallinity. The $[(n\text{-}C_4H_9)_4N]^{\oplus}$ ions and the diethyl ether molecules of crystallization displayed varying degrees of disorder, giving rise to several unreasonable bonding parameters and to large temperature factors. No completely satisfactory disorder model could be deduced, and this was not pursued as the anion was well-ordered. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für Wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD 54171, the names of the authors, and the journal citation.

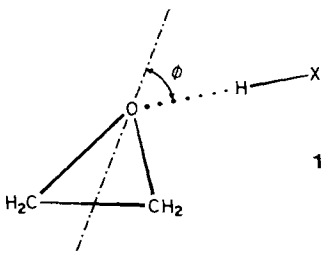
Characterization by Microwave Spectroscopy of a Transient Hydrogen-Bonded Complex of Oxirane and Hydrogen Chloride Isolated in a Pulsed Jet**

By *Anthony C. Legon** and *Christopher A. Rego*

From the experimental standpoint little is known about the mechanism of the reaction in which an oxirane ring is opened by a hydrogen halide HX to give the 2-halogenoethanol. When X = Cl the gas-phase reaction at room temperature has been reported[1] to produce instantaneously a fog of 2-chloroethanol, even when conducted with anhydrous components in a polypropylene vessel to minimize surface effects. An ab initio investigation[2] of the reaction pathway



1

for X = F suggests that the first step is the formation of the hydrogen-bonded complex **1** followed by concerted cleavage of the HF bond and an OC bond with synchronous formation of OH and CF bonds. The interaction of HF with the oxygen atom of oxirane in **1** (X = F) was found to lower substantially the energy necessary to break the HF bond. While such a mechanism does not appear to predominate in the relatively slow reaction of oxirane and HF (2-fluoroethanol is a minor product[11]), it might be appropriate for X = Cl when the reaction occurs in aprotic nonpolar solvents (where no evidence for the presence of ions has been adduced[12]) or in the gas phase when surface effects are rigorously excluded. Of course, the ab initio calculation[2] refers to a pair of interacting molecules that are otherwise isolated. Is it possible to investigate experimentally the interaction of an oxirane molecule and a hydrogen chloride molecule under conditions appropriate to the ab initio calculation? In particular, can **1** (X = Cl) be observed and characterized as a stable but reactive species prior to any rapid ring opening reaction?

We report here the first observation and characterization of the hydrogen-bonded complex **1** (X = Cl) in isolation in the gas phase. The rotational spectrum of **1** (X = Cl) has been observed with a pulsed-nozzle, Fourier-transform microwave spectrometer[3] (frequency range 4–18 GHz) which incorporates a mixing nozzle of the type described by *Gutowsky* et al.[4] The essential feature of this nozzle is that the two reactive components do not mix until the point at which they independently expand into the Fabry-Pérot cavity. A gas mixture of ca. 1% oxirane in argon is pulsed through a 0.7 mm orifice in a solenoid valve into a tube which vents into the cavity. This supersonically expanded gas then meets a mixture of ca. 5% hydrogen chloride in helium that issues continously from a concentric, narrow bore (0.3 mm) tube. The time between mixing and the subsequent collisionless expansion of the species thereby formed is thus kept very short ($\lesssim$ a few μs) and hence the complex **1** (X = Cl) is frozen before any rapid ring opening reaction can occur. According to the microwave spectrum no 2-chloroethanol was formed after the mixing process in our experiments.[5] However, a careful search revealed a rotational spectrum that required the presence of both oxirane and hydrogen chloride and that could be attributed to the ground state of **1** (X = Cl).

The observed spectrum was characteristically that of a nearly prolate asymmetric rotor ($\kappa = -0.993$) containing a single Cl($S = 3/2$) nucleus. Quadrupole hyperfine structure arising from the presence of this nucleus allowed the unambiguous assignment of rotational transitions. Analysis of 33 hyperfine components of nine μ_a-transitions in the observed spectrum of the ^{35}Cl-isotopomer of **1** by standard methods yielded the rotational constants A_0, B_0, C_0, the centrifugal distortion constants Δ_J, Δ_{JK}, and δ_J and the ^{35}Cl-nuclear quadrupole coupling constants χ_{aa}, χ_{bb} and χ_{ac} shown in Table 1. Also included in Table 1 is the quantity $P_b = 1/2\,(I_a + I_c - I_b)$ where $I_b = h/(8\pi^2)B_0$, etc.

Table 1. Spectroscopic constants for the ground state of **1** (X = Cl).

$A_0 = 15286(20)$ MHz	$B_0 = 2077.3620(9)$ MHz	$C_0 = 2030.4161(9)$ MHz
$\Delta_J = 4.663(9)$ kHz	$\Delta_{JK} = 11.52(8)$ kHz	$\delta_J = 0.35(1)$ kHz
$\chi_{aa} = -38.518(5)$ MHz	$\chi_{bb} = 25.97(2)$ MHz	$\chi_{ac} = 31.6(4)$ MHz
$P_b = 19.34(2)$ amu Å^2		

The spectroscopic constants in Table 1 allow a preliminary description of the species responsible for the spectrum. Since $P_b = \sum_i m_i b_i^2$ is unchanged from the corresponding quantitiy $P_a = 1/2\,(I_b + I_c - I_a) = \sum_i m_i a_i^2 = 19.432$ amu Å^2 of free

oxirane,[6] there is strong evidence that the inertial plane *ac* of the complex coincides with a vertical symmetry plane (*bc*) of oxirane, that the HCl subunit lies in this plane, and that the geometry of oxirane is not significantly changed on complex formation. Conversely, the other symmetry plane (*ab*) of oxirane has not been preserved, for otherwise A_0 for the complex would be essentially identical with $B_0 =$ 22120.77 MHz for free oxirane.[6] The most likely arrangement of the two subunits consistent with these conclusions is as illustrated in **1** (X = Cl), with HCl forming a hydrogen bond to O in oxirane. Detailed isotopic substitution is necessary to establish this conclusion rigorously and is in progress.

Assuming a linear hydrogen bond O···H–Cl, an unchanged r_s-geometry of oxirane[6] and an unchanged r_0-distance in hydrogen chloride,[7] the geometry of **1** (X = Cl) is defined by the angle ϕ and the distance $r(O\cdots Cl)$. A least squares fit of A_0, B_0 and C_0 then leads to $\phi = 77.08(2)°$ and $r(O\cdots Cl) = 3.112(3)$ Å. We note that ϕ is consistent with some simple rules recently proposed[8] for the rationalization of angular geometries of hydrogen-bonded complexes. These suggest that at equilibrium the HCl subunit should lie along the axis of a nonbonding electron pair on the acceptor atom. Given that the angle between the nonbonding pairs, as conventionally pictured, on oxygen in dimethyl ether is $2 \times 54.5°$, we expect the corresponding angle in oxirane to increase as the angle COC decreases. Hence, the rules predict that ϕ should be greater than 54.5°, as observed.

A property of **1** (X = Cl) of importance in connection with the mechanism of the gas-phase ring opening reaction is the position of the H atom in the HCl subunit. Is **1** (X = Cl) a reactive intermediate in the sense that there is already incipient proton transfer to O and a concomitant weakening of the HCl bond? Qualitatively, a contribution $>\overset{\oplus}{O}H\cdots\overset{\ominus}{Cl}$ to the valence bond description of **1** can be detected from the magnitude of the ^{35}Cl-nuclear quadrupole coupling constant along the direction *z* of the HCl subunit in the complex. For this structure, χ_{zz} is expected to be similar in magnitude to the value $-5.643(4)$ MHz observed[9] for the vapor-phase ion pair $\overset{\oplus}{Na}\overset{\ominus}{Cl}$. In the free $Cl^{\ominus}$ ion, χ is necessarily zero.

The zero-point average value $\chi_{zz} = -53.6$ MHz is readily obtained by diagonalization of the complete Cl-nuclear quadrupole coupling tensor in the principal inertial axis system given in Table 1. Although χ_{zz} is greatly reduced in magnitude from $\chi_0 = -67.62$ MHz in the free HCl molecule,[10] the reduction does *not* arise from a significant ionic contribution. The *z*-component of the electric field gradient at the Cl nucleus due to the oxirane subunit and the zero-point oscillation of the HCl subunit both also act to reduce χ_{zz}. In the related, effectively planar complex $H_2O\cdots H^{35}Cl$, for which there is no evidence of ionic character,[11] these two factors decrease the value of χ_{zz} from -67.62 MHz to -53.4 MHz.[12] If we assume that the two factors have a broadly similar effect in **1** (X = Cl) to that in $H_2O\cdots HCl$, we thus find it unnecessary to invoke an ionic contribution $>\overset{\oplus}{O}H\cdots\overset{\ominus}{Cl}$. A larger ionic contribution might be expected in **1** when X = Br, because of the weaker HBr bond, or when the oxirane is replaced by the stronger base aziridine. We are examining both of these systems experimentally.

Coupling of an Iridium Vinylidene Complex with Aluminum Alkyls; Carbon-Carbon Bond Formation via Migratory Insertion of a Vinylidene Unit

By *Michael D. Fryzuk,* Neil T. McManus, Steven J. Rettig,* and *Graham S. White*

Very reactive organic fragments can be stabilized by coordination to metal complexes.[1] These include, inter alia, carbenes,[2] benzynes,[3] cyclobutadienes,[4] and thiocarbonyls.[5] Vinylidenes (:C=CHR) are tautomers of terminal acetylenes and have only short lifetimes at normal temperatures;[6] however, they can also be stabilized by coordination to a metal complex. Indeed, much has been reported on the formation of vinylidene-metal complexes and the reactivity of the coordinated vinylidene unit.[7] Depending on the L_nM fragment the α–C atom can be attacked either nucleophilically or electrophilically (cf. **A**, **B**).[8]

Herein we document a new mode of reactivity for a vinylidene ligand that involves carbon–carbon bond formation via coupling with an organoaluminum reagent. The key feature in this type of reactivity is that the metal center is coordinatively unsaturated and this promotes migratory insertions with electrophiles.

The red-orange vinylideneiridium complex **3** was prepared by addition of acetylene to the cyclooctene derivative **1**[9] by way of the transient η^2-acetylene adduct **2**. Although this adduct was only spectroscopically characterized, its identity is unmistakable.[10] The transformation of **2** into the vinylidene complex **3** occurs without observation of any intermediates (by ^{1}H-NMR spectroscopy) over a period of 24 h in benzene or toluene. Diagnostic of the vinylidene complex is the presence of an upfield triplet at $\delta = -3.53$

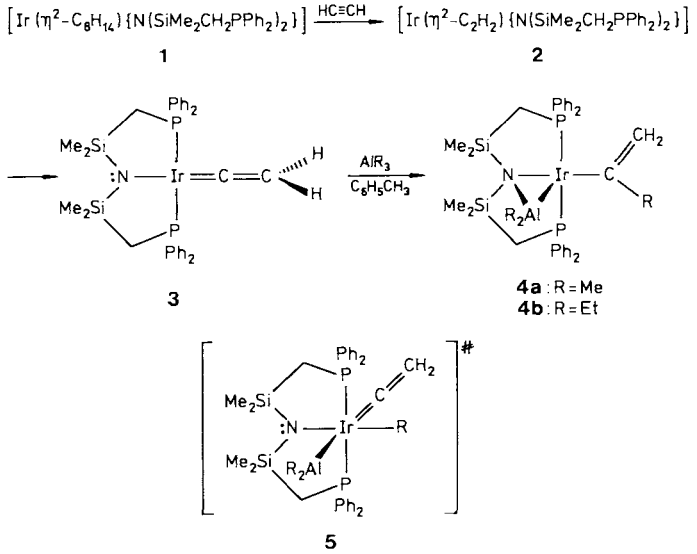
($^4J_{PH}$ = 3.5 Hz),[11] in accord with other related vinylidene-iridium complexes.[12]

Addition of trimethyl- or triethylaluminum to a solution of **3** in toluene results in the loss of the red color and formation of yellow-orange solutions containing a single product ($^{31}P\{^1H\}$-NMR spectroscopy); crystallization from toluene/hexane affords the new complexes **4a**, **b**[13] in 70–80% yield (Scheme 1).



Scheme 1.

The ^{1}H-NMR spectrum of **4a** is very straightforward but structurally ambiguous; resonances are observed that indicate that the $AlMe_3$ reagent has transferred a methyl group to the vinylidene moiety to generate an isopropenyl ligand and that the $AlMe_2$ unit is still bound in some way to the complex. Similar results were obtained with $AlEt_3$, leading to **4b**.[13] To ascertain the mode of binding of the $AlMe_2$ unit to iridium, we carried out an X-ray crystal structure analysis of **4a** (Figure 1).[14]

The aluminum-iridium complex **4a** has a distored square-pyramidal geometry with the isopropenyl ligand in the equatorial plane and an $AlMe_2$ group apical but bent, bridging over to the nitrogen atom of the iridium amide. The Ir–Al bond length of 2.411(2) Å is slightly shorter than the Rh–Al distance of 2.4581(8) Å in $[CpRh(PMe_3)_2(Al_2Me_4Cl_2)]$.[15] The distances in the Ir–N–Al triangle are informative; the Ir–N bond length is 2.373(5) Å and the Al–N distance is 1.970(5) Å, indicative of metal-amine[16] lengths typical for an amide ligand bridging two metals. The nitrogen has a distorted tetrahedral geometry. Also of interest in the solid state structure is the presence of an agostic C–H ··· Ir interaction from an *ortho* hydrogen of one of the phenyl rings to the open site of the square-based pyramid; the Ir–H(32) bond length is 2.68 Å.

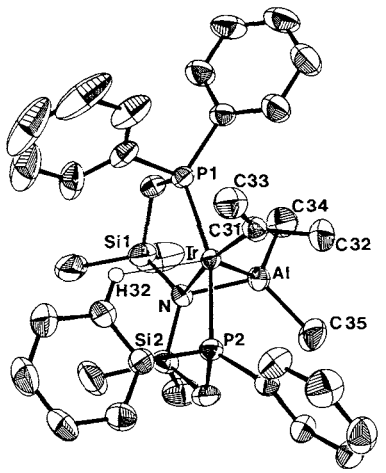


Fig. 1. Crystal structure of **4a**. Important bond lengths [Å] and bond angles [°]: Ir–P1, 2.272(2); Ir–P2, 2.294(2); Ir–N, 2.373(5); Ir–Al, 2.411(2); Ir–C31, 2.014(6); C31–C33, 1.348(9); C31–32, 1.505(8); Al–N, 1.970(5); Al–C34, 1.961(7); Al–C35, 1.979(8); Ir ··· H32, 2.68; P1–Ir–P2, 161.86(5); Ir–C31–C32, 115.8(4); Ir–C31–C33, 125.8(5); C32–C31–C33, 118.4(6); Ir–Al–N, 64.7(1); N–Ir–Al, 48.6(1); Ir–N–Al, 66.7(1); Si1–N–Si2, 119.8(3); C31–Ir–N, 168.8(2).

The formation of the complexes **4a**, **b** probably involves oxidative addition[17] of the AlR_3 monomer to the 16-electron Ir^I-complex **3** to generate a transient species **5** having an AlR_2 ligand, an alkyl ligand and the vinylidene ligand (cf. Scheme 1). Migration of the vinylidene ligand to the Me–Ir bond generates the isopropenyl unit; the proximity of the amide N-atom to the Al-atom undoubtedly facilitates formation of the amide bridge.

For the most part, the reactivity of the coordinated vinylidene fragment has been investigated on systems that are coordinatively saturated at the metal center. While this has allowed a number of new reactivity patterns to be unveiled, systems having unsaturation at the metal site should allow new reaction types to be found. An especially good example of this involves protonation via the metal center to convert a vinylidene unit into a carbyne ligand.[18]

Our particular tridentate ligand combination has allowed for the isolation of an iridium-aluminum adduct with carbon–carbon bond formation. Further work is underway in our laboratory to exploit the migratory insertion capability of both a vinylidene fragment and a methylidene unit[19] coordinated to an unsaturated metal center.

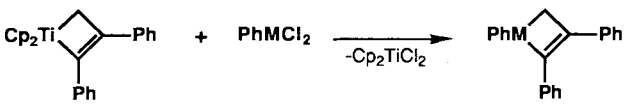
Application of Titanacycles to Heterocycle Synthesis: Phospha- and Arsacyclobutenes**

By *William Tumas,* Joseph A. Suriano,* and *Richard L. Harlow*

Dedicated to Dr. George Parshall on the occasion of his 60th birthday.

The propensity of early transition metal alkyls to undergo transmetalation reactions with main group halides[1] coupled with the wealth of metallacyclic complexes now available[2] should provide access to novel heterocycles that heretofore have been difficult to prepare. Except for the widely studied phosphetanes,[3] examples of four-membered carbocycles containing a group 15 (5th main group) element are rare.[4, 5] In the course of our search for organometallic routes to main group heterocycles, we have discovered that the bis(cyclopentadienyl)titanacyclobutene **1** reacts rapidly and cleanly with group 15 aryl dichlorides to yield the corresponding heterocyclobutenes, **2** and **3**. Herein, we report the synthesis, and characterization of **2** the first arsacyclobutene (1,2-dihydroarsete); comparisons with the P analog **3** will be drawn.



1 **2**: M = As; **3**: M = P

The addition of one equivalent of $PhAsCl_2$ or $PhPCl_2$ to bis(cyclopentadienyl)titanacyclobutene **1**[6] in hydrocarbon solvents results in the immediate precipitation of titanocene dichloride and formation of **2** or **3**,[7] respectively (essentially quantitative by NMR spectroscopy).[8] **2** and **3** were isolated in greater than 50% yield as colorless crystals by filtration of the titanocene dichloride byproduct, removal of solvent, and recrystallization from cold (−20 °C) ether or pentane. NMR[9] and high resolution mass spectral data[10] are consistent with a four-membered ring structure for **2** and **3**. The diastereotopic α-methylene hydrogens appear as doublets (J = 13.3 Hz) at δ = 2.75 and 2.35 in the ^{1}H-NMR spectrum of **2**. The $^1J_{PC}$ of 33.9 Hz for the *ipso* phenyl carbon of **3** (^{13}C NMR) is consistent with reported values for phosphetanes. $^1J_{CH}$ at the α positions of 140–146 Hz (^{13}C NMR) of **2** and **3** are also indicative of a cyclic structure.[11]

The proposed arsacyclobutene structure **2** was confirmed by X-ray crystallography (Fig. 1).[12] The four-membered

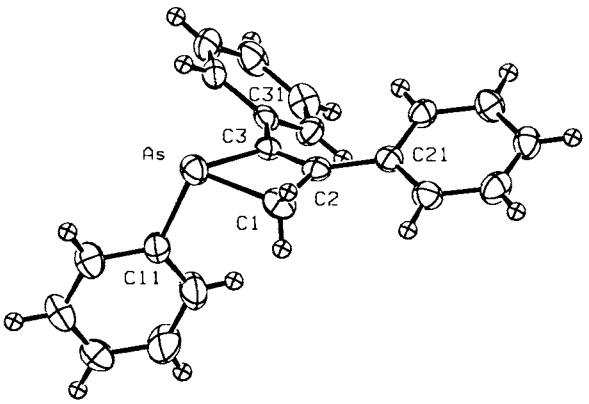


Fig. 1. Structure of **2** in the crystal. For bond lengths and angles see Table 1.

ring is essentially planar with only a slight enveloping; the atoms of the ring deviate from a mean plane by only 0.039, −0.052, 0.073, and −0.059 Å, for As, C1, C2, and C3, respectively. Moreover, the As atom is clearly pyramidal with C–As–C angles of 69.9, 102.3 and 101.7°. For the sake of comparison we also prepared and structurally characterized the isostructural phosphacyclobutene **3**.[7, 13] Pertinent bond lengths and angles for **2** and **3** as well as two previously reported metallacyclobutenes[14] are listed in Table 1. The

[a] [14b]; this structure is for *p*-tolyl rather than phenyl substituents.

four-membered ring in all these compounds is essentially planar.[15] The X–C bond lengths also reflect the hybridization of the carbon atoms in the ring. As expected, the C1–C2 single bond is considerably longer than the C2–C3 double bond. The double bond in the four-membered ring is, however, slightly longer in the P and As compounds than in the transition metal complexes. It is possible that this difference may be indicative of more delocalization in the main group compounds or may be due to less strain in the transition metal complexes due to bonding through d orbitals.

Both the arsa- and phosphacyclobutenes are surprisingly robust; no appreciable decomposition was observed upon heating toluene solutions in sealed tubes at 100 °C for up to 20 h. Preliminary studies reveal that **2** and **3** are, however, photochemically reactive. We are also investigating a number of other heterocycles prepared by transmetalation reactions of titanacycles.

[15] The atoms in the four-membered ring of **3** deviate from a mean plane by 0.039, −0.071, 0.071, and −0.061 Å for P, C1, C2, and C3, respectively.

Structure of a 1:1 Adduct of Silyl Chloride and Dimethyl Ether at 100 K

By *Alexander J. Blake,* Stephen Cradock, E. A. V. Ebsworth,* and *Keith C. Franklin*

In the course of an investigation of the Raman and IR spectra of mixtures of dimethyl ether with silyl and germyl halides at low temperatures,[1] we found evidence for the existence of discrete adducts. As there are very few reports of simple adducts involving silyl halides as acceptors,[2,3] and no structural data have been reported except for (chlorosilyl)dimethylamine,[4] (where we have shown that a dimer forms in the crystal, with nitrogen acting as a donor to a five coordinate silicon), we sought more direct evidence for the precise nature of the interactions in the dimethyl ether sys-

[*] Dr. A. J. Blake, Dr. S. Cradock, Prof. E. A. V. Ebsworth, K. C. Franklin
Department of Chemistry, University of Edinburgh,
West Mains Road, GB-Edinburgh EH9 3JJ (Scotland)

tems by diffraction experiments. Noting that an equimolar mixture of silyl chloride and dimethyl ether formed a mass of crystals very readily on cooling or sublimation at low temperatures, this mixture was solidified by cooling on a Stoë STADI-4 four-circle diffractometer equipped with an Oxford Cryosystems low temperature device.[5] The bulk of the solid was melted, leaving only a seed crystal from which a single crystal ($0.5 \times 0.5 \times 0.6$ mm) suitable for X-ray diffraction was grown by cooling at the rate of 1 K min^{-1} to 100 ± 0.1 K, at which temperature data collection was undertaken.[6]

The individual adduct molecules lie on crystallographic mirror planes, with Cl, Si, H(1S) and O all lying in the plane and with the remaining silyl H atoms and the two methyl groups related by it (Fig. 1). The coordination at oxygen is

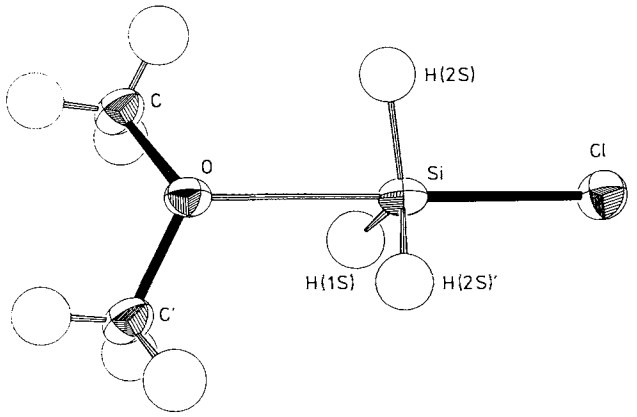

Fig 1. ORTEP plot of the 1:1 adduct of silyl chloride and dimethyl ether, with atom labeling scheme. Some pertinent bond lengths [Å] and angles [°] are: Si-Cl 2.1422(6), Si-O 2.2724(12), C-O 1.4331(20); O-Si-Cl 178.56(4), Cl-Si-H(1S) 101.7(12), Cl-Si-H(2S) 98.3(9), H(1S)-Si-H(2S) 115.4(15), H(2S)-SiH(2S)' 121.3(13), Si-O-C 115.53(9), C-O-C' 111.02(12).

pyramidal, the sum of the bond angles being only 342°. Cl, Si and O are almost colinear, which is consistent with trigonal bipyramidal coordination at Si, where Cl and O are axial. The silyl hydrogens are apparently pushed apart by the donor oxygen, giving HSiH and HSiCl angles which are respectively greater than and less than the tetrahedral value. Fully trigonal bipyramidal coordination at Si is not achieved in this structure, in contrast to the situation in the pentamer of silyldimethylamine,[9] where two equivalent bonds to nitrogen are axial, and the three bonds to hydrogen on each silicon equatorial.

The Si–Cl bond has lengthened over that found in the isolated SiH_3Cl molecule (2.05076(6) Å; gas phase, r_0).[10] This increase is less than that found in the dimer of (chlorosilyl)dimethylamine,[4] where the Si–Cl bond length is 2.231(6) Å, compared with 2.070(1) Å in the monomer (gas phase, r_a). The increase (0.09 Å) is comparable with that between solid and gaseous germyl chloride (0.07 Å).[11] In solid germyl chloride the germanium is essentially five coordinate, with two chlorine atoms in axial positions. Although it is clear from powder diffraction patterns that solid silyl chloride is isostructural with GeH_3Cl, difficulties in obtaining single crystals[12] mean that no Si–Cl bond length in solid SiH_3Cl is available.

The Si–O distance is far too short to be a van der Waals contact (the sum of the van der Waals radii is 3.5 Å), but long for a single bond. The sum of the covalent radii is 1.91 Å, and Si–O bonds are normally shorter than this (1.63–1.70 Å), because of the effects of bond polarity and d-orbital participation on Si. We may therefore compare the distance with other "secondary bonding" contacts in crystals of silyl compounds where we have shown that significant interactions occur between Si and donor atoms in other molecules (Table 1). The Si–O distance in Me_2O–SiH_3Cl is much short-

Table 1. Intermolecular contact distances between Si and first-row atoms in crystals.

Substance	Atom Pair	Distance [Å]	Ref.
$(ClH_2SiNMe_2)_2$	Si–N'	2.054(13)	[4]
Me_2O–SiH_3Cl	Si–O	2.2724(12)	this work

Silyl isocyanate	Si···O	3.303(3)	[d]

[a] M. J. Barrow, S. Cradock, E. A. V. Ebsworth, D. W. H. Rankin, *J. Chem. Soc. Dalton Trans. 1981*, 1988. [b] A. J. Blake, E. A. V. Ebsworth, S. G. D. Henderson, M. Dyrbusch, *Acta Crystallogr. Sect. C44* (1988) 1. [c] M. J. Barrow, E. A. V. Ebsworth, M. M. Harding, ibid. *Sect. B35* (1979) 2093. [d] M. J. Barrow, E. A. V. Ebsworth, M. M. Harding, *J. Chem. Soc. Dalton Trans. 1980*, 1838.

er than any other Si ··· O contact yet characterized; it is also shorter than the Si ··· F contact in solid silyl fluoride[13] or the Si ··· N contact in solid silyl cyanide,[14] both of which form well-defined chains. It is much more like the longer Si–N bond in the dimer of (chlorosilyl)dimethylamine[4] (like the present adduct, formed only in the solid), which at 2.054(13) Å is only 10% shorter.

We may relate these differences crudely to the differing basicities of the donor atoms; it is well known[15] that oxygen bound to Si is much less basic than oxygen in normal alkyl ethers, while nitrogen is intrinsically more basic than oxygen. The weak acceptor power of a silyl group thus allows the formation of distinctly stronger, and shorter, secondary bonds with dimethyl ether than between molecules of disiloxane, and even stronger, shorter bonds to the nitrogen of (chlorosilyl)dimethylamine, even though all these interactions are so weak that they give rise to discrete bonded species only in crystalline solids.

[6] Orthorhombic, space group $Pn2_1m$, $a = 4.5395(5)$, $b = 7.7207(10)$, $c = 8.6532(10)$ Å, $V = 303.28$ Å^3 [from 2θ values of 36 reflections measured at $\pm\omega$ ($2\theta = 30-32°$, $\lambda = 0.71073$ Å)], $M = 112.63$, $Z = 2$ (implying that each adduct molecule lies on a crystallographic mirror plane), m.p. 190 K, $\varrho_{calc} = 1.233$ g cm^{-3}, $T = 100$ K, $\mu(Mo_{K\alpha}) = 0.691$ mm^{-1}. Data collection using $Mo_{K\alpha}$ radiation yielded 1493 data to $2\theta_{max} = 60°$, 768 unique ($R_{merg} = 0.034$), of which 741 with $F > 6\sigma(F)$ were used in all calculations. Automatic direct methods [7] located the non-H atoms, and a difference Fourier synthesis located all H atoms: these were subsequently refined [8] with anisotropic and isotropic thermal parameters respectively. Refinement converged to $R = 0.0203$, $R_w = 0.0264$, $S = 1.173$ for 46 refined parameters and the final ΔF synthesis showed no peak above

0.40 eÅ^{-3}. (In contrast, the alternative polarity gave higher residuals of 0.0307 and 0.0428 respectively and higher uncertainties in all refined parameters.) Atomic coordinates may be obtained from The Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW. Ambident Behavior of the "New Vitamin" Methoxatin (Cofactor PQQ) towards Metals: Coordinative Stabilization of the Pyrrolide Form and the Semiquinone Form**

By *Brigitte Schwederski, Volker Kasack, Wolfgang Kaim,* Eberhard Roth,* and *Jeanne Jordanov*

Following the discovery and characterization of the novel oxidoreductase-coenzyme methoxatin (cofactor PQQ, 4,5-dioxo-4,5-dihydro-1*H*-pyrrolo[2,3-*f*]quinoline-2,7,9-tricarboxylic acid) in methanogenic and other microorganisms,[1] this system was recently established by several research groups as amineoxidase cofactor in bovine serum[2] and even designated as a potential "new vitamin".[3] Biochemical studies have afforded evidence pointing to an important function of the $1e^{\ominus}$-reduced (= *o*-semiquinone) form of methoxatin;[4] also the possibility of the redox behavior being influenced by coordination has been deduced from investigations conducted in the presence of metal ions.[5] On the basis of an ESR spectroscopically detectable ^{14}N-hyperfine structure, complexes of methoxatin[6] with $[Cu^{II}(bpy)]^{2\oplus}$ or $[Cu^{II}(terpy)]^{2\oplus}$[6b] have been described as *N,O*-coordinated; we report here that an O^4,O^5-coordination[7a] with resulting stabilization of the *o*-semiquinone intermediate[7] and of the pyrrole-deprotonated form favored by resonance takes place with the π-back-bonding metal center in $[Ru(bpy)_2]^{2\oplus}$.[7]

Reaction of PQQ with *cis*-$[Ru(bpy)_2Cl_2]$ in ethanol/water (1:5) under reflux affords after 1 h the green *o*-quinone complex **1** with intensive metal-to-ligand charge transfer (MLCT) transitions[7] from occupied d-levels of ruthenium(II) (low spin d^6) to the π* orbitals of the *o*-quinone PQQ and of the 2,2'-bipyridine ligands (Table 1). The comparability of these data with those of *o*-quinone model complexes such as for example of the 4,7-phenanthroline-5,6-dione **2** or of the 9,10-phenanthrenequinone **3**[7a] as well as the absence of the quinonecarbonyl stretching vibration at 1700 cm^{-1} in the IR spectrum confirm the O^4,O^5-coordination.[7] An elemental analysis and a pH titration indicated the neutral form of the isolated complex with double deprotonation of the very acidic[1c, 3a] COOH groups in the 7- and 9-position.

Reduction to the brown *o*-semiquinone complex $\mathbf{1}^{\bullet\ominus}$ takes place in a physiologically easily accessible range at a more positive potential than in the case of free PQQ[3a] (Table 1); the radical shows a low-temperature ESR signal (Fig. 1a), which is identical to that of the reduced model complex $\mathbf{2}^{\bullet\ominus}$ (Fig. 1b) and is also hardly distinguishable from that of the phenanthrene-9,10-semiquinone complex $\mathbf{3}^{\bullet\ominus}$[7a] (Table 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Deutsche Akademische Austauschdienst (Program PROCOPE). We thank Degussa AG and Ciba AG for generous gifts of chemicals.

As expected, the ESR spectrum of $\mathbf{1}^{\bullet\ominus}$ at room temperature (Fig. 1c) shows no resolution of the ^{1}H-and ^{14}N-hyperfine splitting.[1c] Therefore the particular line shape of the signal could not be reproduced. Nevertheless, the outer lines of the ^{99,101}Ru isotopic coupling (sextet) of 0.5 mT are clearly observable ($I = 5/2$, 30% natural abundance),[8] and can be reproduced by computer simulation (Fig. 1d): satellite lines and main lines appear in a ratio of (30%:6)/70% = 7.14%. From the absence of a strong ^{14}N-superhyperfine coupling in the ESR spectrum,[6b] O^4,O^5-coordination is also concluded at this stage; the basicity of the *o*-quinone oxygen centers should increase to a particularly large extent upon reduction, as also shown by the increase of the d(Ru)→π* excitation energy[7] (Table 1). A second reduction to the diamagnetic catecholate complex takes place at 0.26 V.

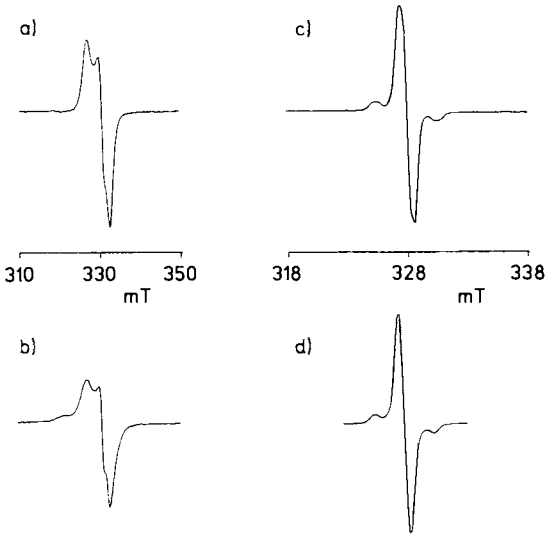

Fig. 1. ESR spectra (X band, measuring frequency $\nu = 9.22$ GHz) of a) complex $\mathbf{1}^{\bullet\ominus}$, adsorbed on Al_2O_3, 300 K; b) complex $\mathbf{2}^{\bullet\ominus}$ in acetone, 4 K; c) complex $\mathbf{1}^{\bullet\ominus}$ in acetonitrile, 300 K. d) Simulation of c) with $a(^{99,101}Ru) = 0.5$ mT, line width = 0.5 mT, gaussian line shape.

The quinone complex can not only be deprotonated at the carboxylic acid groups ($pK_a \leq 2.7$), but, with $pK_a = 8.5$, that is in a physiologically interesting region, at the pyrrole ring of the chromophore. The protonated green form of the complex **1** shows absorption maxima at 722 nm ($d_{Ru} \rightarrow \pi^*_{methoxatin}$) and 375 nm ($d_{Ru} \rightarrow \pi^*_{bpy}$) (Table 1), whereas these values are shifted upon deprotonation to 465 nm and 332 nm. This can

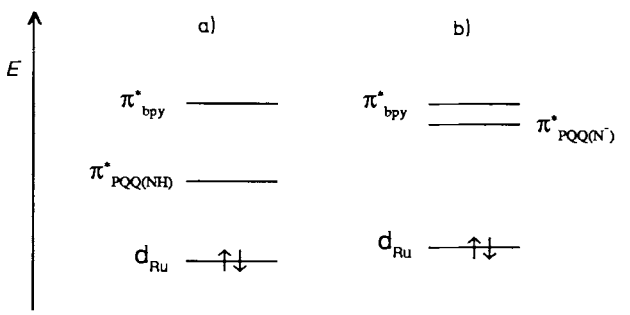

Fig. 2. Orbital energy diagrams of the complex **1** in a) protonated (pH < 7) and b) deprotenated form (pH > 10).

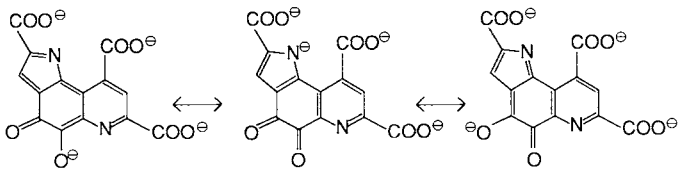
be interpreted in terms of a destabilization of the ruthenium d orbitals with concomitant larger destabilization of the methoxatin π* orbitals, as depicted in Figure 2.

The marked ease of pyrrolide formation (free PQQ has $pK_a \approx 10$)[1c] can be explained in terms of an electron delocalization corresponding to the three resonance forms of the deprotonated chromophore PQQ – $4H^{\oplus}$, whereby, as also in the semiquinone step,[1c, 7b, 9] a substantial part of the negative charge reaches to the metal-coordinating oxygen centers.



PQQ is thus an "isoambialterdentate" ligand,[10] which can not only coordinate differently to metal clusters with different "hardness", but, in addition, is also strongly influenced in its acid-base and redox behavior.

Experimental

A solution of methoxatin (50 mg, 0.15 mmol) and *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$(80 mg, 0.15 mmol) in 30 mL of water/ethanol (5:1) was heated under reflux for 1 h. After cooling, the solution was treated with 50 mg of NH_4PF_6; the resulting precipitate was filtered off, washed with ethanol/water, and dried in a vacuum. Recrystallization from acetonitrile/diethyl ether (4:1) afforded the complex **1** in 65% yield (73 mg).

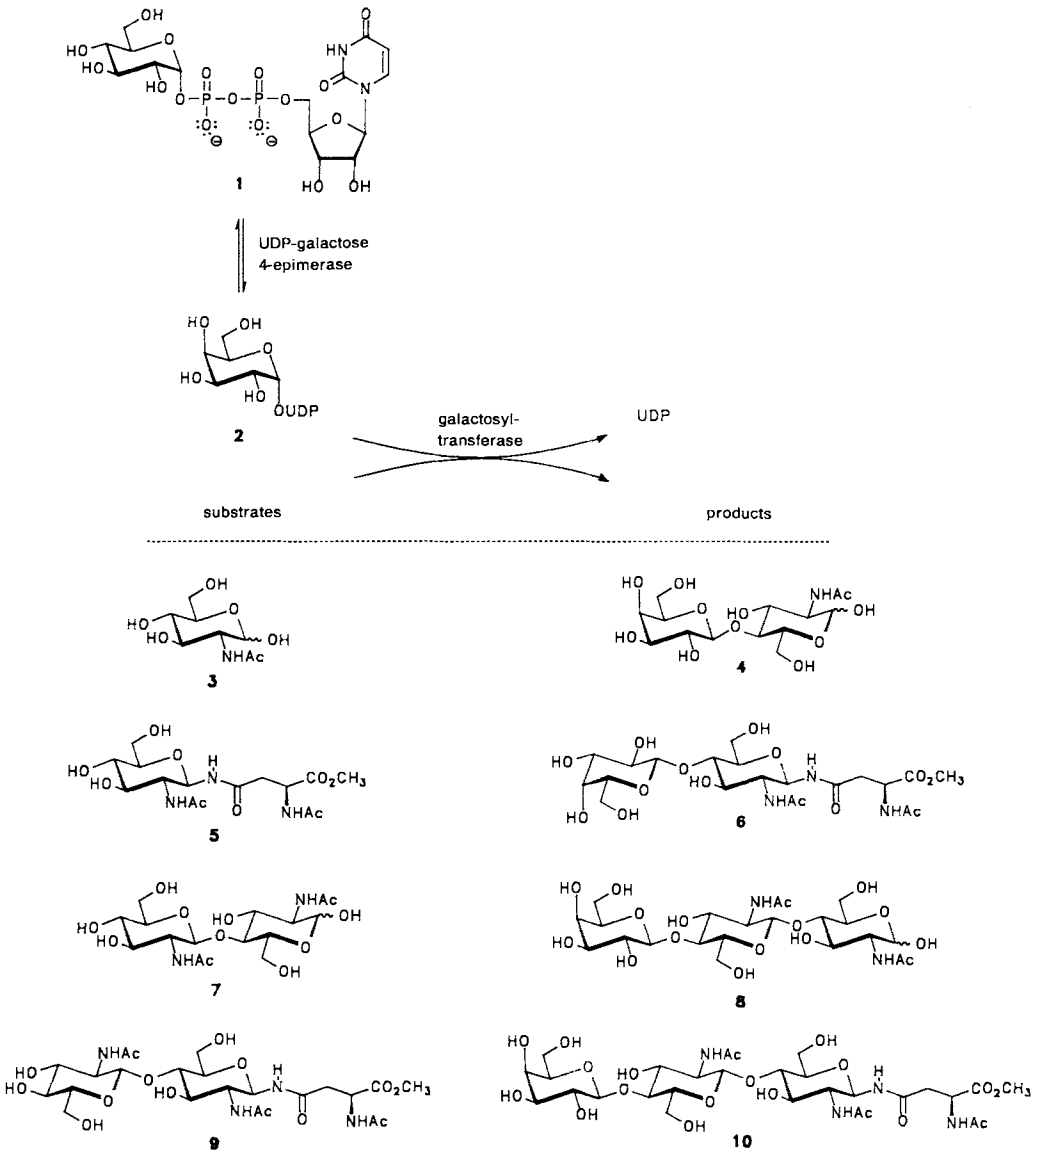
Combined Chemoenzymatic Synthesis of *N*-Glycoprotein Building Blocks**

By *Joachim Thiem** and *Torsten Wiemann*

N-Glycoproteins play a central role in processes of biological recognition[1a, b] such as oncogenesis,[1c] bacterial and viral infection,[1d] and uptake of various macromolecular substances. Furthermore, they govern blood-group type[1e] and are responsible for cell–cell recognition, cell growth, and cell differentiation.[1f]

ical synthesis of unprotected heterooligosaccharides is laborious and affords only low yields. Despite several modern and efficient glycosylation procedures, a practical alternative is often the use of enzymes.

With the goal of synthesizing partial structures of *N*-glycoproteins, we have used galactosyltransferase to form the Gal-β(1→4)-GlcNAc bond in the asparagine-linked oligosaccharides **6** and **10** (Scheme 1). The substrates for this enzymatic reaction (**5** and **9**, respectively) were synthesized via a chemical route (Scheme 2). The oligosaccharides **4** and **8**,



Scheme 1. Galactosylation catalyzed by galactosyltransferase.

The ready availability of reference substances for investigations of these highly specific phenomena is therefore of great importance. The molecular basis of such recognition processes derives from the extremely diverse ways of coupling monosaccharides; however, this also means that chemical synthesis of unprotected heterooligosaccharides is laborious and affords only low yields. Despite several modern and efficient glycosylation procedures, a practical alternative is often the use of enzymes.

With the goal of synthesizing partial structures of *N*-glycoproteins, we have used galactosyltransferase to form the Gal-β(1→4)-GlcNAc bond in the asparagine-linked oligosaccharides **6** and **10** (Scheme 1). The substrates for this enzymatic reaction (**5** and **9**, respectively) were synthesized via a chemical route (Scheme 2). The oligosaccharides **4** and **8**, which are not linked to an amino acid, were also synthesized enzymatically.

The galactosylation was accomplished by a standard procedure. The activated form of galactose required for the transferase reaction, namely, uridine-5′-diphosphate galactose (UDP-Gal, **2**) is very expensive and was therefore generated in situ from UDP-glucose (**1**) in a reaction catalyzed by UDP-galactose 4-epimerase. The galactose transfer from UDP-galactose to the respective acceptor thus occurs with release of UDP.

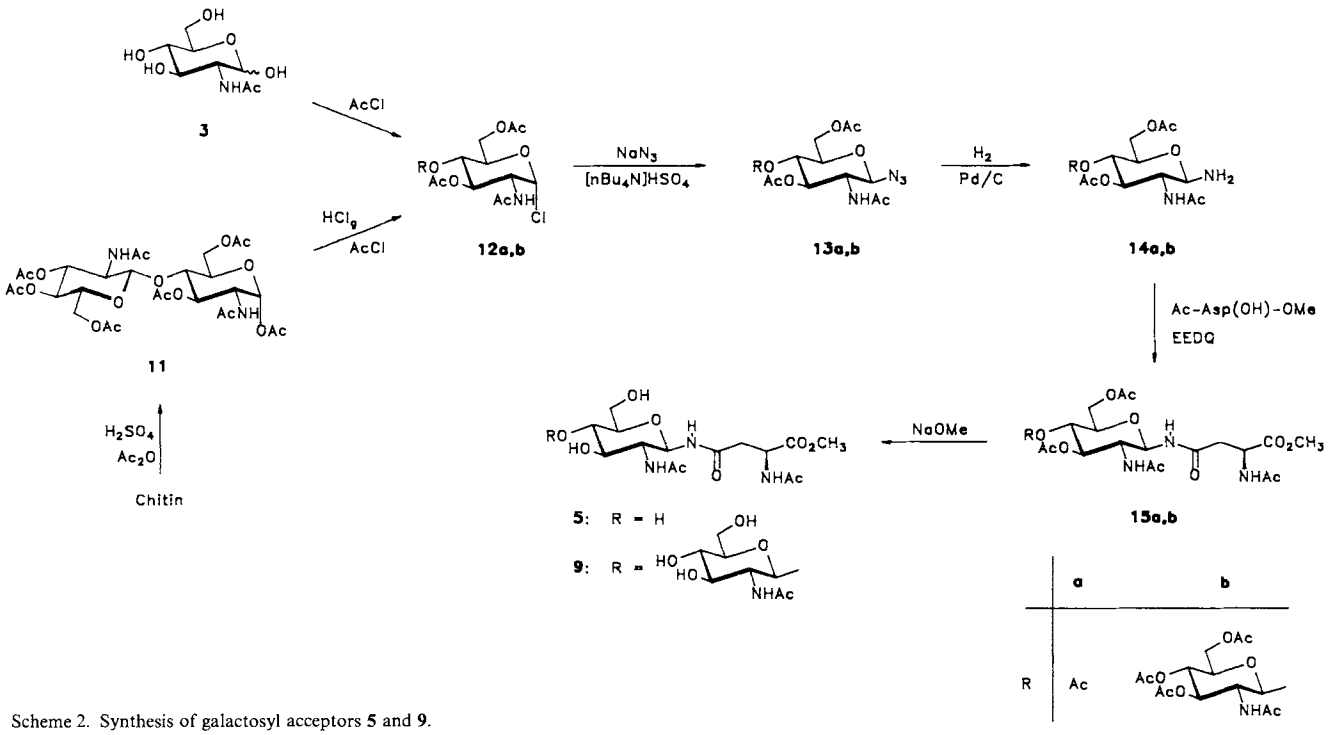

Scheme 2. Synthesis of galactosyl acceptors **5** and **9**.

This two-step galactosylation has also been carried out with immobilized enzymes and applied to other substrates in a synthetic cycle involving cofactor regeneration.[2] The combination of transferase and epimerase in soluble form offers a good compromise between cost on the one hand and preparation time and experimental facility on the other.

Galactosylation of *N*-acetylglucosamine (GlcNAc, **3**; 280 mg, 0.43 mmol) and of *N,N'*-diacetylchitobiose (**7**; 10 mg, 24 μmol) according to the procedure described here affords *N*-acetyllactosamine (**4**; 46 mg, 28%),[3a] the central disaccharide unit of numerous glycoproteins, and trisaccharide **8** (8 mg, 60%),[3b] respectively. Both substances may also be synthesized starting from UDP-Gal;[4] in the case of *N*-acetyllactosamine (**4**), a synthetic cycle involving cofactor regeneration[2] is also possible. The older chemical synthesis of **4** is much more laborious in our opinion, because of the large number of steps.[5]

The glycoconjugate β-D-galactopyranosyl-(1→4)-2-acetamido-1-[(*N*-acetyl-1-methyl-4-L-aspartyl)amino]-2-deoxy-β-D-glucopyranose (**6**) is present in the urine of patients suffering from aspartylglucosaminyluria.[6] The acceptor **5** required for the enzymatic galactosylation step was synthesized chemically by a procedure similar to that of *Hough* et al.[7] (Scheme 2). First, GlcNAc (**3**, 25 g, 113 mmol) was allowed to react with acetyl chloride to give the peracetylated α-chloride **12a**. Its substitution to afford β-azide **13a** was accomplished under phase-transfer catalysis in chloroform/water. Compound **13a** was then reduced to β-amine **14a**, which was coupled with α-methyl *N*-acetyl-L-aspartate in a reaction promoted by ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ). The de-*O*-acetylation with sodium methoxide affords the aspartylglucosamine **5** (20% yield over five steps, based on **3**). Before the galactosylation step, **5** has to be chromatographically purified on Bio-Gel P2. The standard method was again used in the enzymatic galactosylation to **6**, which was obtained in 35% yield (0.1-mmol scale). The expected β(1→4) linkage in **6** was confirmed by ^{1}H NMR spectroscopy.[3c] An earlier chemical synthesis of the completely deprotected form of **6** was accomplished by *Jeanloz* et al. in sixteen steps.[8]

Glycopeptide **10** is probably the receptor site for Robinia lectin on the surface of erythrocytes.[9] The synthesis of the asparagine-linked trisaccharide requires, once again, an initial chemical synthesis; galactosyl acceptor **9** was prepared in analogy to the work of *Jeanloz* et al.[10] and *Kunz* et al.[11] Acetolysis of chitin affords a mixture of oligomers, from which α-octaacetylchitobiose (**11**, 10%) can be isolated by flash chromatography. Octaacetate **11** (4.5 g, 6.7 mmol) was converted into α-chloride **12b**, which, in analogy to the synthesis of **5**, was transformed into β-azide **13b**. Compound **13b** was reduced to **14b**, which, in turn, was coupled with α-methyl *N*-acetyl-L-aspartate in an EEDQ-promoted reaction to give **15b**. After de-*O*-acetylation, the free disaccharide **9** (295 mg, 18% over five steps, based on **11**) was purified on Bio-Gel P2 and then used in the enzymatic galactosylation. The synthesis of the asparagine-linked trisaccharide **10** was accomplished in 28% yield (50-μmol scale).[3d]

Experimental Procedure

Enzymatic galactosylation of **3**, **5**, **7**, and **9**: The reaction was carried out in sodium cacodylate buffer (25 mM, pH 7.7) in the presence of manganese chloride (5 mM). After addition of UDP-glucose (**2**, 13 mM), acceptor (13 mM), and bovine serum albumin (1 mg mL^{-1}), the solution was degassed with nitrogen. Galactosyltransferase (EC 2.4.1.22, 1 U) and UDP-galactose 4-epimerase (EC 5.1.3.2, 10 U) were then added. After two days at 37 °C, the reaction mixture was worked up by anion exchange and the products **4**, **6**, **8**, and **10** were purified by gel chromatography (Bio-Gel P2).

Direct Electrical Communication between Graphite Electrodes and Surface Adsorbed Glucose Oxidase/Redox Polymer Complexes

By *Michael V. Pishko, Ioanis Katakis, Sten-Eric Lindquist, Ling Ye, Brian A. Gregg,* and *Adam Heller**

The redox centers of glucose oxidase, like those of most oxidoreductases, are electrically insulated by a protein (glycoprotein) shell. Because of this shell, the enzyme cannot be oxidized or reduced at an electrode at any potential. In an earlier communication it was shown that in homogeneous solutions, water-soluble polycationic poly(vinylpyridine) complexes of $[Os(bpy)_2Cl]^{2\oplus}$ bind to and accept electrons from reduced glucose oxidase, a polyanion.[1] Here we show that the same polycationic redox polymers are strongly adsorbed on graphite; that these modified surfaces adsorb strongly the enzyme; and that the surface adsorbed enzyme/polymer complexes communicate electrically with the electrodes. Electrodes containing these adsorbed complexes are faster and easier to construct than commercially available glucose electrodes.

Poly(4-vinylpyridine) (PVP), as well as *N*-methylated PVP, were shown earlier to be strongly adsorbed on pyrolytic graphite and to yield, with diffusing redox species, long-lived reproducible electrodes.[2, 3] Their electrochemistry is consistent with the physisorption of segments of the macromolecules providing a three-dimensional network into and out of which ions diffuse. Earlier studies of the electrochemistry of small redox proteins that do not have thick insulating shells around their redox centers, (such as cytochrome c, myoglobin, ferredoxin and phycocyanin) have also shown that, even though these proteins are directly electrooxidized/reduced on electrodes, their rates of electron transfer can be enhanced by adsorbed "promoters" (e.g. bipyridine, methyl viologen) that bind and orient the proteins, but do not participate in the redox processes.[4] We now find that pyrolytic carbon and graphite electrode surfaces can be modified with adsorbed polycationic redox polymers that complex glucose oxidase. In these structures, electrons are vectorially transferred from enzyme-bound glucose to the electrode via the redox centers of the enzyme and those of the redox polymer.

Strong adsorption of the redox polymer **1** on graphite is seen in the cyclic voltammetry of the terpolymer of poly(*N*-methyl-4-vinyl pyridinium chloride), 4-aminostyrene, and the PVP complex of $[Os(bpy)_2Cl_2]$ (see Scheme 1); at scan rates from 2 to 200 mV s^{-1}, the peak separation is 30 mV or less. Integration of the cyclic voltammograms at low scan rates (2–5 mV s^{-1}) shows that approximately 1.0×10^{-9} moles cm^{-2} of **1** are electroactive. The polymer does not desorb from rotating disk electrodes even at high angular velocities (2000 rpm), and coulometry shows that less than 10% of the polymer is desorbed from the electrodes after 30 days of storage in a stirred water bath. The polycationic adsorbed polymer **1** strongly binds glucose oxidase. Cyclic voltammograms for the oxidation of glucose by the enzyme–polymer complex are shown in Figure 1. The current response at a constant potential of 0.45 V (vs. SCE) persists for more than 10 hours when electrodes are rotated at 20 rpm in physiological salt solutions that do not contain

[**] We wish to thank *Yinon Degani* for his valuable advice on the synthesis of the polymers and *Goran Svensk* for the molar mass determination of the Osmium-containing redox-polymer **1**. This work was supported in part by the Office of Naval Research and the Robert A. Welch Foundation.

any enzyme or polymer, declining approximately 10% over the first hour and 70% after 10 hours. The electrodes were stored in air at room temperature for 30 days with negligible loss in activity. Chronoamperometric measurements in a flow cell show that the current responds to an increase in glucose concentration in less than 1 s (Fig. 2). Response

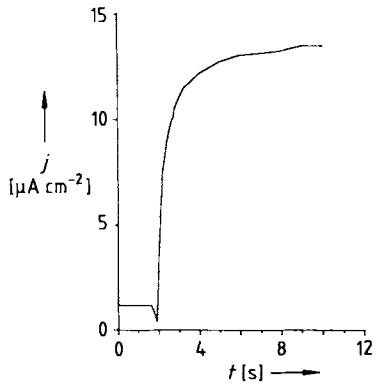

Fig. 2. Electrode response to a change in glucose concentration from 0 to 50 mM glucose in 0.15 M NaHEPES at pH 7.9.9 units catalase mL^{-1}. Flow rate: 193 $cm\,s^{-1}$. Glucose oxidase/**1**/graphite electrode.

times for different flow rates vary from 0.4 s at a linear flow rate of 42 $cm\,s^{-1}$ to 0.2 s at a flow rate of 210 $cm\,s^{-1}$. The glucose concentration dependence of the current at 0.45 V (SCE) is shown in Figure 3. A background current persists at zero glucose concentration. Because the electrodes are simple to construct and the materials cost little, they are likely to be appropriate for use in fast, disposable glucose sensing tips.

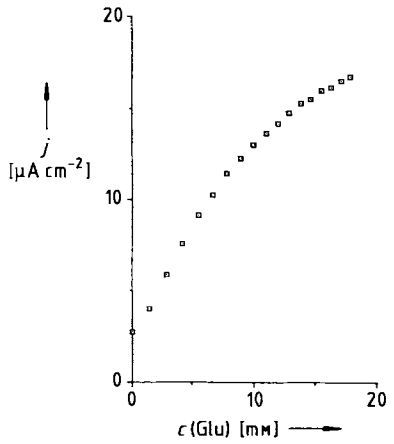

Fig. 3. Glucose concentration dependence of the current density at 0.45 V for the glucose oxidase/**1**/graphite electrode system in 0.15 M NaHEPES at pH 7 and 9.9 units catalase mL^{-1}.

The rate of glucose oxidase adsorption on redox-polymer **1** modified graphite electrode was studied by chronoamperometry. Electrodes were placed in 4 mL solutions of 60 mM glucose and 0.15 M NaHEPES at pH 7 and kept under N_2. 0.9 μg of catalase (44 000 units per mg protein) was added to prevent the deactivation of glucose oxidase by evolved H_2O_2. Approximately 10 μL of a 4 $mg\,mL^{-1}$ solution of glucose oxidase was slowly injected into the electrochemical cell to yield a final glucose oxidase concentration of 10 $\mu g\,mL^{-1}$. The potential was then stepped from 0 V to 0.45 V (SCE). The rise in current upon enzyme-complexing by the redox polymer coating of the electrode is shown in Figure 4.

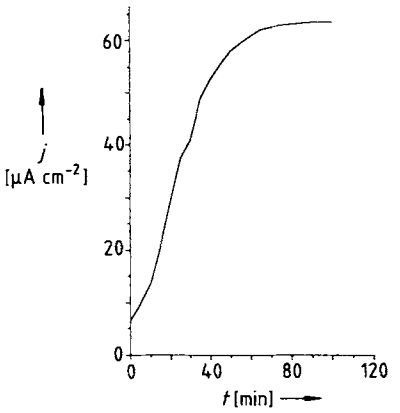

Fig. 4. Chronoamperometric response of a **1**/graphite electrode in 10 $\mu g\,mL^{-1}$ glucose oxidase, 60 mM glucose, 0.15 M NaHEPES at pH 7 with no catalase present.

Investigation of the effect of increasing salt concentration shows that electron transfer ceases at high (> 0.5 M) salt concentration in solutions containing only NaCl and buffer (no enzyme) but recovers upon dilution (to 0.15 M). This indicates that appropriate electrostatic bonding is critical for electron transfer not only in solution,[1] but also in adsorbed layers. The recovery of the current when the ionic strength is decreased shows that even at increased ionic strength, the complex does not dissociate. The loss in current response to glucose at high ionic strength is apparently caused by coiling of the polycationic redox polymer **1**.[1, 5] The coiled polymer no longer penetrates the protein, wherefore electron transfer cannot take place. At physiological ionic strength, the complex of polyanionic glucose oxidase and polycationic redox polymer **1** is, however, an effective electron relay between the enzyme bound substrate and the conductor.

Experimental Procedure

Glucose oxidase (E.C. 1.1.3.4) type X, catalase (E.C. 1.11.1.6) and NaHEPES were purchased from Sigma. $[Os(bpy)_2Cl_2]$ was prepared from K_2OsCl_6 (Aldrich) following a reported procedure. [6] 4-aminostyrene was purchased from Polysciences. Azobisisobutyronitrile (AIBN) and 4-vinylpyridine were purchased from Aldrich. Synthesis of the redox terpolymer **1** was prepared as reported [1]. Graphite (HB pencil leads 0.5 or 0.9 mm diameter) and pyrolytic carbon disks (4 mm diameter) were used as electrodes.

A Pine Instruments AFMSRX Rotator and an MSRX Speed Control were used for the rotating disk electrode (RDE) experiments. The flow cell was similar in design to a reported wall jet system [7].

The electrodes were insulated with a heat-shrinkable polypropylene sleeve. Their tips were then polished with 0.3 μm alumina, sonicated in deionized water for 20 s and blown dry with a stream of N_2. A drop (4 μL) of a solution of **1** (2.6 $mg\,mL^{-1}$ solvent) was applied to the electrode tip, allowed to stand for 4 min and then washed off with deionized water. The enzyme was adsorbed on the terpolymer coated surfaces by placing a 4 μL droplet of glucose oxidase solution (4.5 $mg\,mL^{-1}$) on the electrode surface, contacting for 10 min and rinsing. No containment membrane was used. Electrodes for the RDE experiments were polished and modified with a redox polymer in a similar manner.

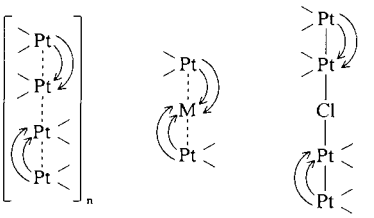
Platinum in the Unusual Oxidation State + 2.75: A Linear Tetranuclear Complex with the Model Nucleobase 1-Methylthymine**

By *Oliver Renn, Alberto Albinati,** and *Bernhard Lippert**

Besides the numerous mixed valence compounds of platinum with polymeric structure, which are stabilized via direct (Pt···Pt) stacking contacts[1] or via axial halogeno bridges,[2, 3] also smaller aggregates have been known for some time. In these tetra- and octanuclear complexes **I** and **II**, which, without exception, can be obtained from *cis*-$[(NH_3)_2Pt^{II}]$ and deprotonated cyclic[4–6] or open chain amides,[7] there are stacked dinuclear units with head-to-head bridging amidate ligands and direct (Pt···Pt) contacts; the average oxidation state is + 2.25[4, 6b, 7] and + 2.5,[5] respectively. A further type (**III**), which so far has only been isolated with M = Pd,[8] has a trinuclear structure with an average oxidation state of + 2.33 for the three metal atoms.

We report here on a new type of chloro-bridged tetranuclear complex (**IV**), in which platinum is present in the formal oxidation state + 2.75.

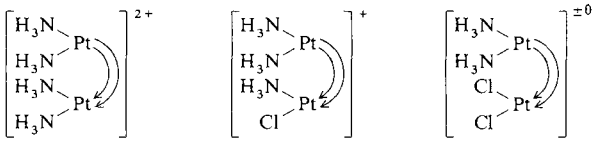
Mixed valence platinum compounds with the nucleobases uracil, thymine and cytosine ("platinum-pyrimidine blue



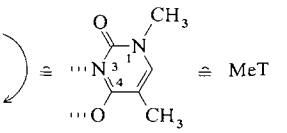
I, n = 1
II, n = 2 **III** **IV**

compounds") are of interest, inter alia, in view of their cancerostatic properties.[9]

In connection with studies on the characterization of such species we have also concerned ourselves with the oxidation behavior of diplatinum complexes which contain two 1-methylthymine anions in head-to-head arrangement as well as ammine- and choro-ligands. We found that diplatinum(II) complexes of type **1** (4 NH_3 ligands) exhibit a different oxidation behavior than **2** (3 NH_3, 1 Cl^-) and **3** (2 NH_3,



1 **2** **3**



≙ MeT

2 Cl^-). Thus, in the absence of Cl^-, **1** is oxidized by cerium(IV), first to the tetranuclear platinum (2.25) complex **1a** and then to the diplatinum(III) complex **1b**;[10] in the case of **2** and **3**, on the other hand, not only the Pt(2.25) step is inter-

$$2\,[Pt(2.0)]_2 \xrightarrow{-e^\ominus} [Pt(2.25)]_4 \xrightarrow{-3e^\ominus} 2\,Pt(3.0)]_2$$
1 **1a** **1b**

mediary but also further mixed valence complexes, which are also characterized by their intense colors. For example, the $[Pt(2.25)]_4$-compound **2a** ($E^0_{Pt(2.0)/Pt(2.25)}$ = 450 mV, λ_{max} = 740 nm, ε = 16300 $M^{-1}cm^{-1}$) initially formed from **2** is first oxidized with cerium(IV) to one (or two[11]) further compound(s) (**2b**(?), **2c**) which absorbs (absorb) at 480 nm and after further addition of cerium(IV) is (are) finally converted into an orange-yellow diplatinum(III) compound **2d**.

$$2[Pt(2.0)]_2 \xrightarrow{-e^\ominus} [Pt(2.25)]_4 \xrightarrow{-e^\ominus} [Pt(2.5)]_4 \xrightarrow{-e^\ominus} [Pt(2.75)]_4 \xrightarrow{-e^\ominus} 2\,[Pt(3.0)]_2$$
2 **2a** **2b** **2c** **2d**

The preparative synthesis of the cations **2c** and **2d** in the form of the compounds **4** and **5**, respectively, was achieved by oxidation of **[2]**Cl[12] with H_2PtCl_6 in acid (pH 0.3). The structures are confirmed by the elemental and crystal structure analyses.[13] The average oxidation states of the platinum in the cations **2c** and **2d** are 2.75 and 3.0, respectively. With inclusion of all Pt atoms, i.e. also those of the anions,

Viale Abruzzi, 42, I-20131 Milano (Italy)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the average oxidation numbers are 3.0 and 3.2 for **4** and **5** respectively.

cis-{[$(NH_3)_2Pt(MeT)_2PtCl_2]_2Cl$}$[PtCl_6] \cdot 6\,H_2O$
4 with cation **2c**

cis-$[(H_2O)(NH_3)_2Pt(MeT)_2PtCl_3][PtCl_6]_{0.5} \cdot 3\,H_2O \cdot 0.4\,HCl$ **5**
5 with cation **2d**

In both oxidation products, the NH_3-ligand *cis* to the Cl-ligand of the starting compound **2** has been replaced by a $Cl^{\ominus}$. A similar situation has already been found in a related diplatinum(III) complex of 1-methyluracil (MeU).[14] In **5** the geometry of the cation **2d** closely resembles that of the related MeU complex;[6c] however, a disorder of axial ligands (Cl, H_2O) and Cl^- from HCl is observed. This is the subject of further refinements. The Pt–Pt distance is 2.556(1) Å.

The centrosymmetric $[Pt(2.75)]_4$ cation **2c** consists of two diplatinum units of the composition *cis*-$(NH_3)_2Pt(MeT)_2$-$PtCl_2$ (Fig. 1) bound via a chloro bridge (Fig. 1). The geometry of these units is, in principle, similar to that of the corresponding diplatinum(II) compound **3**,[12] yet they both differ significantly in their Pt–Pt distances: 2.699(1) Å in **2c**, 2.861(1) Å in **3**. The Pt–Cl bonds in the linear chloro bridge (Pt1–Cl1–Pt* 180°) are markedly longer than the equatorial Pt–Cl bonds. The geometry of the $[PtCl_6]^{2\ominus}$ anion is normal. Aside from the hydrogen bonding there are no interactions with the cation. It may be assumed that the linearity of the chloro bridge is crucial for the electronic delocalization along the Pt_4 chain. It is reflected in the golden luster of the compound and in the ESR spectrum, which is typical for axially symmetric, mixed valence Pt-chains ($g_\perp = 2.411$, $g_\parallel = 1.987$).

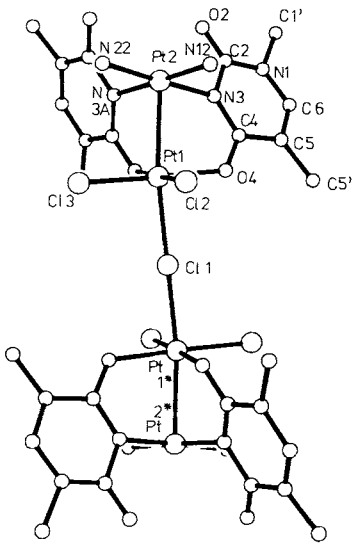

Fig. 1. Structure of the cation **2c** in compound **4**. Selected bond lengths [Å] and angles [°]: Pt1-Pt2 2.699(1), Pt1-Cl1 2.542(3), Pt1-Cl2 2.288(3), Pt1-Cl3 2.283(3), Pt1-O4 2.051(7), Pt1-O4A 2.034(7), Pt2-N3 2.027(8), Pt2-N3A 2.033(7), Pt2-N12 2.057(9), Pt2-N22 2.046(8); Pt2-Pt1-Cl1 167.00(2). Numbering of ring A corresponds to that of the ring shown here.

In contrast to [**2**]Cl and **5** (with the cation **2d**), **4** (with the cation **2c**) is relatively sparingly soluble in water. The cation **2c** ($\lambda_{max} = 430-480$ nm) is unstable in water and exhibits time-dependent changes in the visible spectral region. Reduction of **2d** with $Na_2S_2O_3$ leads to an intense absorption at 463 nm, whose maximum is reached after addition of exactly 0.25 equivalents of $S_2O_3^{2-}$ per Pt and which disappears again upon addition of further $Na_2S_2O_3$.[15] In terms of **2c** an extinction coefficient $\varepsilon \approx 21\,000\ M^{-1}\,cm^{-1}$ is obtained for this absorption.

The title compound **4** with the cation **2c** described here represents the first linear Pt_4-complex in which formally three platinum(III) and one platinum(II) are present.

Experimental

4 with cation **2c**: A solution of [**2**]Cl (44 mg) in 1 N HCl (7.5 mL) was treated dropwise with 0.1 mL of a 25% solution of H_2PtCl_6 in H_2O. After crystallinization at 4 °C in an open dish the supernatant orange solution was pipetted off; the shiny golden cubic crystals were washed with H_2O and acetone. Yield: 20%.

5 with cation **2d**: A solution of [**2**]Cl (44 mg) in 1 N HCl (7.5 mL) was treated with 0.3 mL of a 25% solution of H_2PtCl_6 in H_2O. After crystallization at 4 °C in an open dish, the supernatant orange solution was pipetted off; the red needlelike crystals were washed with H_2O and acetone. Yield 40%. Alternatively, **5** is obtained in comparable yield by reaction of a suspension of **3** in 1 N HCl with H_2PtCl_6.

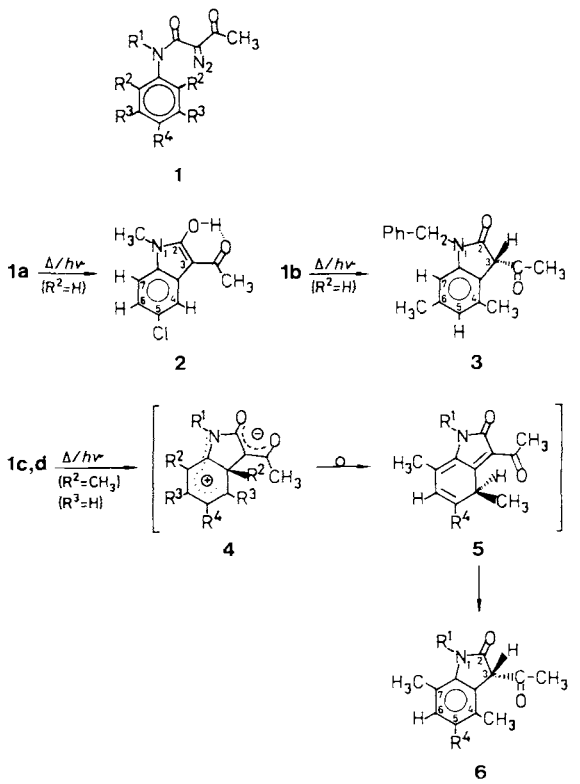
[15] For comparison: Na_2PtCl_6 is not reduced under the given reaction conditions (pH 3).

A Wagner–Meerwein Rearrangement as Intermediate Step in the Formation of Dihydroindolones from 2-Diazoacetoacetanilides **

By *Gerhard Himbert** and *Martin Ruppmich*

For an intended study of the intramolecular reactivity of arylcarbamoylketenes, we synthesized the *N*-aryl-2-diazoacetoacetamides **1**[1] and attempted to induce them to undergo Wolff rearrangement. Our plan to achieve this by metal-catalyzed decomposition—an unfavorable route in view of our goal—was abandoned when, shortly after the start of our work, *Doyle* et al.[2] reported that this approach[3] (for example, addition of $[Rh_2(OAc)_4]$) could be used to transform 2-diazoacetoacetanilides **1** into 2-hydroxyindoles (type **2**) or the tautomeric dihydroindolones (type **3**).

We found, however, that simple heating of toluene or xylene solutions of **1** without the addition of a metal catalyst also led to the corresponding indole derivatives. Thus, thermolysis of *N*-(4-chlorophenyl)-2-diazo-*N*-methylacetoacetamide (**1a**) and of *N*-benzyl-2-diazo-*N*-(3,5-dimethylphenyl)acetoacetamide (**1b**) gave the 2-hydroxyindole derivative **2** and the tautomeric dihydroindolone derivative **3**, respectively (see Table 1). The formation of these derivatives



1	R^1	R^2	R^3	R^4	⟶	product
a	CH_3	H	H	Cl	⟶	**2**
b	$CH_2C_6H_5$	H	CH_3	H	⟶	**3**
c	CH_3	CH_3	H	H	⟶	**6a**
d	$CH_2C_6H_5$	CH_3	H	CH_3	⟶	**6b**

[**] We thank *T. Grub* for his assistence as part of an advanced laboratory course.

can be explained as formally occurring by insertion of the carbene C atom into the *ortho* C–H bonds of aniline.[4]

We were very surprised, therefore, when thermolysis of the diazoacetoacetanilides **1c** and **1d** afforded the dihydroindolones **6a** and **6b**, respectively, as the sole characterizable products.[5] Since both *ortho* positions in the aniline moieties of **1c** and **1d** were blocked by methyl groups, Wolff rearrangement was expected to lead to carbamoylketenes.

The structure of the dihydroindolones **6a** and **6b** is supported by the spectroscopic data, in particular the ^1H NMR evidence that the methine H atom (3-H) is derived from the aryl H atom of **1c,d** (see Table 1). Both **6a** and **6b**, like **3**,

2: Colorless needles with m.p., 120–121 °C in 79% yield after 24 h of heating in xylene. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1650, 1630 (C=O/C=C); ^1H NMR (60 MHz, $CDCl_3$): δ = 2.40 (s, 3H, $COCH_3$), 3.30 (s, 3H, NCH_3), 6.78 (d, J_{AB} = 10 Hz, 1H, 7-H), 7.0–7.3 (m, 2H, 4-H, 6-H), 12.5 (s, 1H, OH); ^{13}C NMR (50.28 MHz, $CDCl_3$): δ = 20.57 (q, CH_3), 25.92 (q, NCH_3), 101.28 (s, C-3), 109.77, 119.77, 124.95 (3d, C-7, C-6, C-4), 123.73, 127.66, 137.31, 170.89, 174.47 (5s, C-5, C-7a, C-3a, C-2, C=O)

3: Colorless needles with m.p., 105–107 °C in 32% yield after 12 h of heating in toluene. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1720, 1685, 1615 (C=O); ^1H NMR (60 MHz, $CDCl_3$): δ = 2.10, 2.23 (2s, 3H and 6H, 3 CH_3), 4.50 (s, 1H, 3-H), 4.85 (d, AB character, 2H, NCH_2), 6.40, 6.64 (2s, each 1H, 7-H and 5-H), 7.25 (m, 5H, Ph)

6a: Colorless crystals with m.p., 95–96 °C in 30% yield after 12 h of heating in toluene. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1690 (C=O); ^1H NMR (90 MHz, $CDCl_3$): δ = 2.11, 2.26, 2.55 (3s, each 3H, 3 CCH_3), 3.50 (s, 3H, NCH_3), 4.43 (s, 1H, 3-H), 6.79, 7.02 (AB signal, J_{AB} = 8 Hz, each 1H, 5-H, 6-H); ^{13}C NMR (50.28 MHz, $CDCl_3$): δ = 18.33, 18.73, 28.28, 29.92 (4q, 4 CH_3), 60.63 (d, ^1J = 136.9 Hz, C-3), 117.69, 123.19, 124.72, 133.05, 133.24, 142.52 (total of 4s, 2d, 6 aryl C), 171.57, 200.17 (2s, 2 C=O)

6b: Colorless crystals with m.p., 122–124 °C in 40% yield after 12 h of heating in toluene. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1690–1720 (C=O); ^1H NMR (90 MHz, $CDCl_3$): δ = 2.08, 2.21, 2.34 (3s, 3H, 6H and 3H, 4 CH_3), 4.60 (s, 1H, 3H), 5.18 (s, broad, 2H, NCH_2), 6.80 (s, 1H, 6-H), 7.1–7.4 (m, 5H, Ph)

exist in the keto form. Owing to its steric interaction with the acetyl methyl group, the methyl group in the 4 position prevents formation of the lower energy 2-hydroxyindole form, which has an intramolecular hydrogen bond (cf. **2**; the H atom in the 4 position leaves the acetyl group just enough room to form the planar enol system).

The formation of **6** more or less compells the intermediacy of zwitterion **4**, which arises by electrophilic attack of the carbene center on the *ortho* C atom[6] and whose charges can be optimally delocalized into, on the one hand, an aminosubstituted benzenium system, and, on the other, a bisacyl anion.[7] Since only indole formation occurs (see **2**, **3**, **6**), we are convinced that this electrophilic substitution of an arene does not involve free carbene. Instead, nitrogen elimination is induced by anchimeric participation of the electron-rich arene. In **4**, all prerequisites are present for the 1,2 shift of the "perturbing" methyl group in the neighboring (formerly, *meta*) position; the negative charge of the anionic moiety further promotes this rearrangement. The fully conjugated trienone **5** thereby obtained undergoes rearomatization to the benzene system, perhaps by 1,5-sigmatropic shift of the H atom to the O atom of the acetyl group. The final products, after tautomeric hydrogen shift, are the 3-acetyl-1,3-dihydro-2-indolones **6**.

Experimental Procedure

A solution of diazoacetamide **1a–d** [1] (10 mmol) in 30 mL of toluene or xylene (see Table 1) was refluxed for several hours. The solvent was removed under vacuum and the residue was dissolved in diethyl ether. Cooling of the resulting

solution and scratching of the glass to induce crystallization afforded the crystalline indole derivatives **2**, **3**, **6a**, and **6b** (solvent, reaction times and yields, see examples in Table 1).

[5] Also, photolysis of **1c** (10 mmol in 150 mL of benzene, 2.5 h at room temperature; Heraeus TQ 150 laboratory immersion lamp) gives **6a** (22%) as the sole product.

[6] The formation of zwitterion **4** might be preceded by an intramolecular cyclopropanation by the carbene center at the π system between *ipso* and *ortho* C atoms. The resulting norcaradiene, containing a fused β-lactam moiety, should then, for steric reasons, undergo heterolytic bond cleavage at the central σ bond affording **4**.

[7] Zwitterion **4** may also be involved as an intermediate in the formation of indole derivatives **2** and **3**.

Anions Isosteric with CO_3^{2-} in Cs_5SiP_3, Cs_5SiAs_3, Cs_5GeP_3, and Cs_5GeAs_3**

By *Brigitte Eisenmann*,* *Jürgen Klein*, and *Mehmet Somer*

The oxygen ligands in the orthosilicate ion SiO_4^{4-} and in the germanate ion Ge_4^{4-} can be completely replaced by the 5B elements phosphorus and arsenic. The charges of the resulting isosteric Zintl anions SiP_4^{8-} and $SiAs_4^{8-}$ and GeP_4^{8-} and $GeAs_4^{8-}$, respectively, can be compensated by doubly positive cations (E^{II} = Ca,Sr,Ba)[1–3] or by singly (Na) and doubly positive cations (E^{II} = Ca,Sr,Eu)[4] in the ratio 4:2. In contrast to the colorless oxosilicates and oxogermanates, these phosphido- and arsenido-silicates and -germanates are deep-red to black and are highly reflecting.

All attempts to replace the doubly positive cations completely by Na^+ ions have thus far failed. They led instead to the compounds Na_5SiX_3 and Na_5GeX_3 (X = P,As), respectively. These compounds contain oligomeric, binuclear units $[Si_2X_6]^{10-}$ and $[Ge_2X_6]^{10-}$, respectively,[5,6] which are formed from two edge-sharing tetrahedra.

We have now replaced the sodium by the significantly larger cesium and obtained the analogous compounds Cs_5SiX_3 and Gs_5GeX_3 (X = P,As) in the form of metallic, dark colored, extremely air-sensitive crystals. The compounds form an isotypic series: According to complete X-ray structure determinations[7] their crystal structures contain isolated SiP_3^{5-}, $SiAs_3^{5-}$ and GeP_3^{5-}, $GeAs_3^{5-}$ units respectively, in which the central atom is still only threefold coordinated by P and As atoms, respectively. The anions are strictly planar, but not exactly trigonal. The variation in the bond lengths is small; in all four compounds the maximum difference in the bond angles is about 6° (Table 1). The mean bond lengths are significantly shorter than the sum of the single bond radii corrected with regard to the difference in electronegativity.[8] Values between 1.28 ($SiAs_3^{5-}$) and 1.12 (GeP_3^{5-}) are calculated for the bond order according to *Pauling*.[8]

Table 1. Bond lengths d (E^{IV}-E^{III}) and bond angles ∢ (E^{III}-E^{IV}-E^{III}) in the anions [a].

Cpd.	d [pm]	∢ [°]	d_m [pm]	d_1 [pm]	d_2 [pm]	n

Cs_5GeP_3	226.8	115.7	227.3	230.8	210.8	1.12
	227.0	121.8				
	228.2	122.1				
Cs_5GeAs_3	235.6	116.1	236.7	243.8	223.8	1.26
	235.9	121.8				
	238.5	122.1				

[a] d_m = mean bond length; d_1 = single bond lengths corrected with respect to difference in electronegativity according to *Pauling*; d_2 = double bond lengths corrected with respect to difference in electronegativity according to *Pauling*; n = bond order according to *Pauling*.

In the crystal, all atoms lie in the (010) plane at $y = 1/4$ and $y = 3/4$; the SiX_3^{5-} or GeX_3^{5-} groups in these planes are translated relatively to one another referred to the direction of projection [010] of Figure 1. The charge balancing Cs ions encapsule the anions in the form of large distorted trigonal prisms in which the centers of the basal plane edges are each occupied by a further Cs atom. The large prisms can thus also be described as an assemblage of four smaller trigonal prisms coupled face-to-face, each of which form the coordination polyhedron around each atom of the anionic groups. The coupling of the larger prisms via their basal planes leads to the formation of triangular columns parallel to [010], which in turn are each further bonded via two common edges to give puckered layers. Adjacent layers, displaced by 1/2 in b with regard to the anion planes, are so arranged that "free" prism edges of one and coupling edges of the other layer are adjoining.

With regard to their structure the SiX_3^{5-} and GeX_3^{5-} ions fit in the series of 24-valence-electron units BO_3^{3-}, CO_3^{2-} and NO_3^-, that is oxoanions of the first short period. They are the first examples of planar YX_3 anions in the solid state in which central atoms and ligands belong to higher periods. In the case of the PS_3^- ion, a trigonal-planar structure had actu-

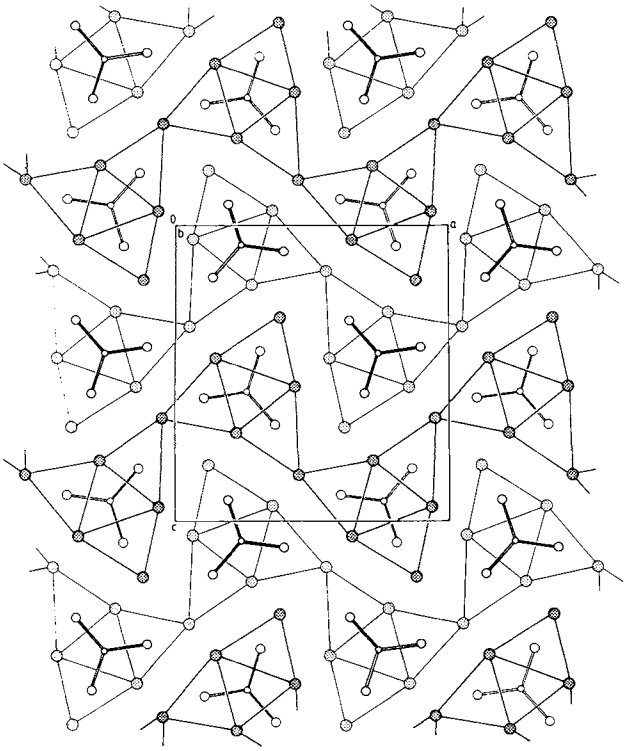

Fig. 1. Projection of the crystal structure of the compounds Cs_5SiP_3, Cs_5SiAs_3, Cs_5GeP_3 and Gs_5GeAs_3 on (010). The Cs atoms are shown as hatched circles, the Si and Ge atoms as small open circles, and the P and As atoms as large open circles; the boldness of the lines indicate the heights of the displacements 1/2 in *b*. The connecting lines between the Cs atoms do not represent bonds but merely serve to outline the polyhedra.

ally been deduced for the gaseous state, but this could not be unequivocally detected in the solid state.[9] Homonuclear trigonal-planar Si_4 clusters are present in $Li_{12}Si_7$.[10] Here, band structure calculations[11] show that largely covalent Li–Si interactions contribute to the stabilization of the clusters.

Experimental

The elements (Cs; Si or Ge; P or As) were weighed out in the ratio 7:1:3 under argon in tantalum ampoules and heated within 4 h to 675 °C, kept at this temperature for 6–8 h, and then cooled to room temperature in 40 h. For the preparation of the phosphorus compounds the elemental phosphorus was replaced by equivalent amounts of Cs_4P_6. The excess Cs was removed by distillation in a high vacuum at 150 °C. According to X-ray powder photographs, the compounds are formed in pure phases. They form dark, shiny metallic, prismatic crystals, which decompose spontaneously to still unidentified products on exposure to moist air.

$[H_6As_{10}Mo_{24}O_{90}]^{8\ominus}$, a Heteropolyanion Comprising Two Linked Spherical Fragments, and Reduced Keggin Anions as Its Degradation Products**

By *Achim Müller,* Erich Krickemeyer, Michael Penk, Volker Wittneben,* and *Joachim Döring*

Dedicated to Professor Gerhard Fritz on the occasion of his 70th birthday

We have been interested in V^{IV}/V^V, $As^{III}/V^{IV}/V^V$, $As^{III}/Mo^V/Mo^{VI}$, and $Bi^{III}/Mo^V/Mo^{VI}$ oxygen clusters and polyanions because of their interesting structural chemistry and their importance for catalysis.[1] Examples include a bismuth-molybdate catalyst[1c] for selective oxidations in petrochemistry and the "V_2O_5" catalyst, which contains V^{IV} centers.[1a] Both catalysts are poisoned by As. Of particular interest, for example in analytical chemistry, are reduced heteropolyanions of the Keggin type (cf. Ref. [2]). Very little is known about the corresponding crystalline mixed-valence species, especially about their electronic structures, which are of general importance for understanding the electron-storage function of metal clusters.[2]

We have now synthesized the blue title compound **1**, whose anion may be formally described as $[H_6As^{III}_{10}Mo^V_8Mo^{VI}_{16}O_{90}]^{8\ominus}$. Oxidation of **1** by exposure to air affords the likewise blue salts **2** and **3** containing mixed-valence Keggin-type heteropolyanions (a well-known Keggin anion is $[PMo_{12}O_{40}]^{3\ominus}$),[2] which may be formally regarded as $[H_4As^VMo^V_4Mo^{VI}_8O_{40}]^{3\ominus}$ and $[H_2As^VMo^V_2Mo^{VI}_{10}O_{40}]^{3\ominus}$.

$(HNMe_3)_8[H_6As_{10}Mo_{24}O_{90}] \cdot 9\,H_2O$ **1**
$(HNMe_3)_3[H_4AsMo_{12}O_{40}]$ **2**
$(HNMe_3)_3[H_2AsMo_{12}O_{40}]$ **3**

These species provide textbook examples for structural chemistry; however, their isolation and characterization has been difficult so far.[2] The compounds **1**–**3** were characterized by elemental analysis (including manganometric titration of Mo^V), electrochemical studies (for **1**), thermoanalysis (to determine the amount of crystal water in **1**), IR and

[**] We thank Professor *M. T. Pope*, Washington, D.C., for important suggestions.

electronic absorption spectroscopy, and single-crystal X-ray structure analysis.[3]

The novel 34-nuclear mixed-valence discrete anion of **1** occupies a center of inversion in the crystal lattice and consists of MoO_6 octahedra and AsO_3 pyramids (Fig. 1). For-

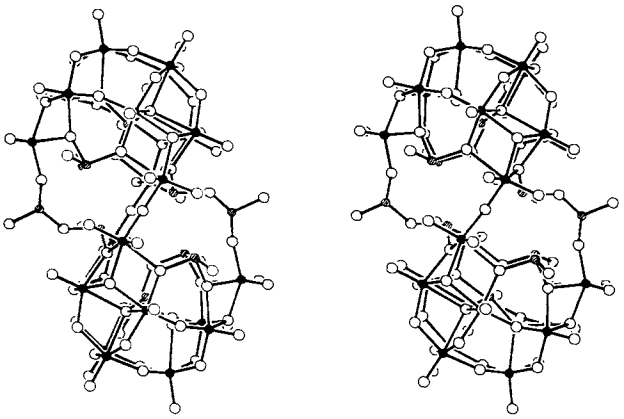

Fig. 1. Stereoview of the structure of the anion in **1** (H atoms omitted; Mo = black, As = hatched, O = white). Interatomic distances [pm] and angles [°]: Mo···Mo (edge-linked 327.6–348.0, Mo···Mo (corner-linked) 363.3–369.1, Mo-O_{term} 165.6–173.1, Mo-(μ-O) 182.4–237.8, As-O_{term} 173.2–181.1, As-(μ-O) 174.9–180.8; O_{term}-Mo-(μ-O) 87.5–104.4, 162.5–170.3, (μ-O)-Mo-(μ-O) 69.5–97.4, 148.1–159.1, O-As-O 93.2–102.5.

mally, it is composed of two $As_4Mo_{12}O_{42}$ spherical fragments of approximate C_{3v} symmetry with a central AsO_3 group. The two units are linked by four bridges in such a way that the openings of the spheres do not lie directly opposite each other. Both halves contain an $AsMo_9$ Keggin fragment (cf. Fig. 1) capped by a ring built up of three AsO_3 and three $Mo^{VI}O_6$ polyhedra (the oxidation states of these three Mo atoms are derived from the significantly higher value of the valence sum[4] and are also supported by the fact that, in polyanions, reduced Mo centers with two terminal O atoms are unknown). This means that, in both halves, four electrons are delocalized over the remaining Mo atoms.

Cluster **1** displays a number of interesting structural features, such as the novel connection of two spherical fragments[5] and the As_2O_5 groups linking the two halves.

The anions of **2** and **3**, formed from **1** by mild oxidative degradation, are both of the Keggin type and each contains one As^V center (Fig. 2; the anions are viewed from a similar perspective as in Fig. 1 in order to highlight the partial structural similarity of the anions). $[H_4AsMo_{12}O_{40}]^{3\ominus}$ (**2**) is a four-electron-reduced β-Keggin anion;[2] disregarding the H atoms, it is isostructural to $[H_6PMo_{12}O_{40}]^{\ominus}$,[2a] the only previously structurally characterized reduced Mo Keggin anion, whose protonated O atoms could not be completely identified. The anion of the further oxidation product **3** formally contains two Mo^V centers and has an α-Keggin structure. (To the best of our knowledge, a twofold reduced Keggin anion has not yet been structurally characterized.) The β isomer of the Keggin anion can formally be formed from the α isomer by rotating one of the four Mo_3O_{13} units by 60° (similar structural changes presumably occur within the bismuth-molybdate catalyst; cf. Ref. [1c]). It is interesting in this connection that the Mo_{12} partial framework of **1** rearranges to the Keggin-type framework of **2** and **3** with retention of the structure of the $AsMo_9$ spherical fragment (cf. Figs. 1 and 2) and that, on going from **1** to **2**, merely As^{III} is oxidized to As^V.

The Mo–Mo distances in the anions are, on average, 335.9 pm in **1** and 347.2 pm in **2** for the edge-linked octahedra and 366.0 pm in **1** and 368.7 pm in **2** for the corner-linked octahedra. An average Mo–Mo distance of 358.2 pm (influenced by the disorder[3]) is found in the anion of **3**. The slight changes in the Mo–Mo distances in comparison to those in nonreduced polymolybdates[2] indicate only weak metal–metal interactions (cf. below).

The number of protons in **1**, **2**, and **3** was derived from a titrimetric determination of the number of Mo^V centers and the charge of the anion. The six terminal O atoms bonded to As in **1** are probably protonated, because the As–O_{term} and As–(μ-O) bonds are of roughly equal length (cf. Fig. 1). In **2**, the positions (cf. Fig. 2a) of the four protonated O atoms can be identified unambiguously owing to the markedly longer Mo–O bonds (210.0 instead of 191.1 pm) and smaller Mo–O–Mo angles (115.9 instead of 126.6°).

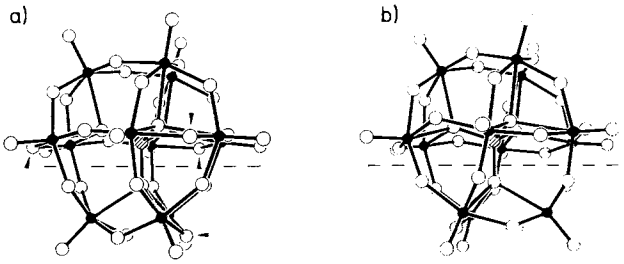

Fig. 2. Comparison of the two Keggin anions (H atoms omitted) of **2** and **3**, which may be transformed into each other by rotating an Mo_3O_{13} group (below the broken line) [3]. The structural moiety above the broken line corresponds to the $AsMo_9$ spherical fragment of **1**. Mo = black, As = hatched, O = white. a) Structure of the β-Keggin anion of **2** (protonated O atoms marked with arrows). Interatomic distances [pm] and angles [°]: Mo···Mo (edge-linked) 341.0–361.3, Mo···Mo (corner-linked) 364.7–371.1, Mo-O_{term} 165.5–171.1, Mo-(μ-O) 187.5–243.0, As-O 165.3–169.1; O_{term}-Mo-(μ-O) 96.9–105.1, 164.8–171.5, (μ-O)-Mo-(μ-O) 69.8–94.2, 149.7–163.2, O-As-O 108.2–111.7. b) Structure of the α-Keggin anion of **3**. The central AsO_4 tetrahedron is shown in only one of the disordered positions (bond lengths and angles are not accurate owing to disorder). Interatomic distances [pm] and angles [°]: Mo···Mo 350.5–379.6, Mo-O_{term} 161.1–167.5, Mo-(μ-O) 176.6–248.0, As-O 165.9–170.7; O_{term}-Mo-(μ-O) 98.9–104.3, 151.6–161.6, (μ-O)-Mo-(μ-O) 56.8–101.8, 154.9–158.9, O-As-O 105.4–112.2.

The electronic spectra of **1**–**3** (measured in H_2O) show characteristic intervalence charge-transfer transitions at ca. 8850 (**1**), 9000 (**2**), and 9100 (**3**) cm^{-1}. In basic solvents (e.g., dimethylformamide (DMF)) deprotonations of the anions lead to marked changes in the electronic spectra, especially for the more intense and complex near-IR bands (presumably also intervalence charge-transfer bands) with a maximum at ca. 12000 cm^{-1}. Magnetic measurements on **1**–**3** indicate very strong spin–spin interactions. Detailed investigations are in progress.

Mixed-valence metal clusters[9] that exist with different electron populations, such as those described here,[10] are also of importance for understanding electron-transfer and electron-storage systems in nature (e.g., ferredoxins, which are very important and ubiquitous in the biosphere) and in catalysis. In the catalysts described at the beginning of this communication, the "turn-over process" results in the delocalization of electrons in the lattice or the metal cluster, whereby HOMO and LUMO have to satisfy certain conditions. Of particular importance is the kind of interaction of the nd valence electrons of the metal atoms, which should not be involved in strong covalent metal–metal bonds. Weak metal–metal interactions have been observed, for example,

in Fe/S clusters (nitrogenases, ferredoxins), in V/O clusters,[1b] and, as described here, in Mo/O clusters (cf. Refs. [6, 7]). For 5d metal centers, for example, tungsten, very strong 5d–5d overlap results in more facile formation of markedly covalent metal–metal bonds (cf. the significant shortening of certain W–W distances in sixfold-reduced $[H_2W_{12}O_{40}]^{12\ominus}$[8] with Keggin-like structure).

Experimental Procedure

Some characteristic main IR absorption bands in the region of framework stretching vibrations (solid, CsI pellet; 1000 to 600 cm^{-1}) are given.

1: All operations were carried out with degassed H_2O under argon atmosphere. $(NH_4)_6[Mo_7O_{24}] \cdot 4\,H_2O$ (2.1 g, 1.7 mmol), As_2O_3 (1.5 g, 7.6 mmol), and NH_4SCN (5.0 g, 66 mmol) were dissolved in 60 mL of H_2O at 95 °C. The solution was allowed to cool to 80 °C and hydrazinium sulfate (0.8 g, 6.1 mmol) was then added, resulting in a sudden change in color from pale yellow to green to dark blue. The resulting mixture was stirred for 3 min at 80 °C and cooled rapidly to 20 °C, and the unreacted As_2O_3 was removed by filtration. The filtrate was treated immediately with a solution of $(HNMe_3)Cl$ (6.0 g, 63 mmol) in 140 mL of H_2O and allowed to stand in a closed vessel for 24 h at 20 °C. The deep blue crystals of **1** that formed were collected by filtration and dried on the filter paper. Yield 1.85 g (73%). IR: $\tilde{\nu}[cm^{-1}] = 964/955$(vs) ($Mo\text{-}O_{term}$); 760(m), 660(m) (As-O; As-O-As, Mo-O-Mo). Potentials [V] versus SCE (solvent DMF; electrolyte $(NBu_4)BF_4$; three-electrode arrangement, Pt, Pt, SCE; scan rate 150 $mV s^{-1}$); −0.06, +0.04, +0.43, +0.54 (cf. [10]).

2: **1** (5.0 g, 1.0 mmol) in 200 mL of H_2O in a 300-mL Erlenmeyer flask (wide-necked, covered with a watch glass (d = 6 cm)) was allowed to stand on a hot plate at 70–75 °C for 20 h without stirring. After separation of the blue precipitate, the filtrate was allowed to stand for 2–3 d without stirring at 70–75 °C. The deep blue crystals of **2** that formed were collected by filtering the hot solution and dried on the filter paper. Yield 1.1 g (28%). IR: $\tilde{\nu}[cm^{-1}] = 968/955$(vs) ($Mo\text{-}O_{term}$), 890(m) (As-O), 854(s), 740(m), 675/660(s) (Mo-O-Mo).

3: **1** (0.5 g, 0.1 mmol) was dissolved in 27.5 mL of H_2O at 70–75 °C and the resulting solution in a 100-mL Erlenmeyer flask (as described for **2**) was allowed to stand on a hot plate at 70–75 °C without stirring. The deep blue crystals of **3** that had formed after 5–6 d were collected by filtering the hot solution and dried on the filter paper. Yield 0.11 g (28%) (clearly, **3** can also be prepared from **2**). IR: $\tilde{\nu}[cm^{-1}] = 968$(vs) ($Mo\text{-}O_{term}$), 884(vs) (As-O), 770(vs) (Mo-O-Mo).

Rogers, *Acta Crystallogr. Sect. A 37* (1981) 734. **3**: *Pnma*; a = 1605.6(4), b = 1897.7(6), c = 1419.9(4) pm, $V = 4326.6 \times 10^6$ pm^3; μ = 41.2 cm^{-1}; Z = 4, ϱ_{calcd} = 3.08 $g\,cm^{-3}$; R = 0.089 for 3701 reflections ($F_o > 4\,\sigma(F_o)$). Syntex $P2_1$ diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator. The protons of the anions of **1** and **3** could not be localized. In the crystals of **1**, **2**, and **3**, one cation per formula unit and in **1** a part of the crystal water is disordered. The anion of **3** is disordered over two positions, resulting in approximate apparent O_h symmetry. The disorder could only be solved for the O atoms of the central $AsO_4^{3\ominus}$ group, since the positions of the remaining atoms were only slightly changed by the disorder. The powder diffraction diagrams calculated from the single-crystal data agree with the measured diagrams. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54186, the names of the authors, and the journal citation.

[4] The average valence sum is 6.1 for Mo atoms in the As_3Mo_3 ring and 5.5 for the other Mo atoms; it was calculated as described by I. D. Brown, Kang Kun Wu, *Acta Crystallogr. Sect. B32* (1976) 1957.

[5] In addition to **1**, we were also able to synthesize and characterize preliminarily $[H_xAs_8Mo_{24}O_{88}]^{y\ominus}$ as its ammonium salt containing crystal water. **4**. **4** also contains Mo^V centers and, like **1**, consists of two $As_4Mo_{12}O_{42}$ units. The only difference is the absence of two As-O groups in the bridges of **4**. Two Mo atoms are thereby coordinated by three terminal O atoms in a fashion unusual for heteropolyanions.

[6] A. Müller, V. Wittneben, *J. Mol. Struct. (THEOCHEM)*, in press. In contrast to 3d clusters with classical ligands, in most cases strong metal–metal interactions occur in 4d clusters, for example, Mo_xS_y species (cf. A. Müller, R. Jostes, W. Eltzner, Chong-Shi Nie, E. Diemann, H. Bögge, M. Zimmermann, M. Dartmann, U. Reinsch-Vogell, Shun Che, S. J. Cyvin, B. N. Cyvin, *Inorg. Chem. 24* (1985) 2872).

[7] Relevant in this connection are the results of X_α calculations on model substances ($[Fe_4S_4(SH)_4]^{2\ominus}$, $[VFe_3S_4(SH)_6]^{4\ominus}$, and $[MoFe_3S_4(SH)_6]^{3\ominus}$) for the catalytic centers or cofactors (FeMS cluster, M = Fe, V, Mo) of nitrogenases and of alternative forms in which only weak interactions are present [6].

[8] Y. Jeannin, J. P. Launay, M. A. Seid Sedjadi, *Inorg. Chem. 19* (1980) 2933.

[9] The term is used generally here to refer to species in which metal–metal interactions are present, even if they are weak, as is the case for the ferredoxins (with no covalent metal–metal bonds).

[10] Cluster **1**, which, in DMF, undergoes four quasi-reversible two-electron oxidations in a cyclovoltammetric study, as well as the Keggin anions of **2** and **3** and the corresponding, known $[AsMo_{12}O_{40}]^{3\ominus}$ nonreduced anion.

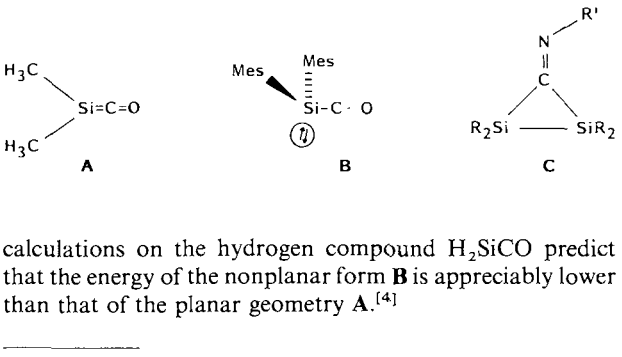
A Cyclodimeric Silaketenimine**

By *Manfred Weidenbruch,* Brigitte Brand-Roth, Siegfried Pohl,* and *Wolfgang Saak*

Dedicated to Professor Gerhard Fritz on the occasion of his 70th birthday

Despite the great progress made in recent years in the area of unsaturated silicon compounds,[1] compounds containing silicon as part of a cumulated double-bond system have not yet been reported.

Recently, *Arrington* et al.[2] as well as *Pearsell* and *West*[3] investigated the reactions of silanediyls (silylenes) with carbon monoxide in matrices. Whereas reaction of dimethylsilanediyl supposedly forms silaketene **A**,[2] in the case of the dimesitylsilanediyl addition product, for example, both the electronic spectra and the formation of disilenes on thawing of the matrix indicate that Lewis acid–base adducts of type **B** are formed between the silanediyl and CO. Theoretical



calculations on the hydrogen compound H_2SiCO predict that the energy of the nonplanar form **B** is appreciably lower than that of the planar geometry **A**.[4]

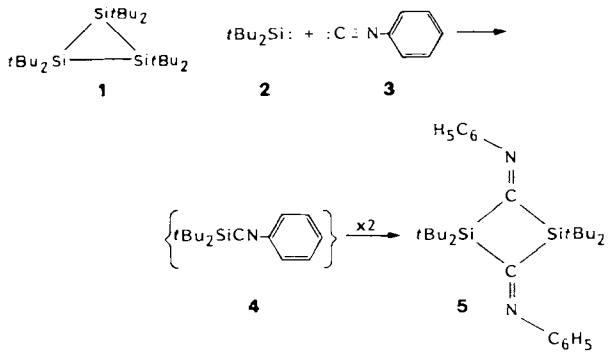
[**] Silicon Compounds with Strong Intramolecular Steric Interactions, Part 38. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 37: M. Weidenbruch, B. Brand-Roth, S. Pohl, W. Saak, *J. Organomet. Chem.*, in press.

We found that the reaction of di-*tert*-butylsilanediyl (**2**) with phosphaalkynes[5] and with nitriles[6] begins with [2 + 1] cycloaddition, resulting in the formation of three- and six-membered rings, respectively. On the other hand, reactions of **2** with isocyanides, which are isolectronic to CO, should lead to compounds of type **A** or **B** or to products derived therefrom.

Indeed, reaction of **2**, generated photolytically from hexa-*tert*-butylcyclotrisilane (**1**),[7] with phenyl isocyanide (**3**) gives a compound, **5**,[8] whose mass spectra and NMR data



support a cyclodimeric silaketenimine. The X-ray structure analysis[9] (Fig. 1) confirms its structure and clearly reveals that the two phenyl rings are exclusively *trans* to each other in the crystal. The ring atoms, as well as the exocyclic N atoms, lie almost exactly in one plane. Within the ring, the smaller angles are found at the Si atoms, the larger angles at the carbon atoms.

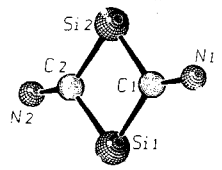


Fig. 1. Molecular structure of **5** (H atoms omitted). Selected bond lengths [pm] and angles [°] (standard deviations): C1-Si1 195.0(3), C2-Si1 192.8(3), C1-Si2 192.9(3), C2-Si2 194.8(3), C1-N1 127.7(3), C2-N2 128.3(3); C1-Si1-C2 = C1-Si2-C2 83.0(1), Si1-C1-Si2 = Si1-C2-Si2 97.0(1).

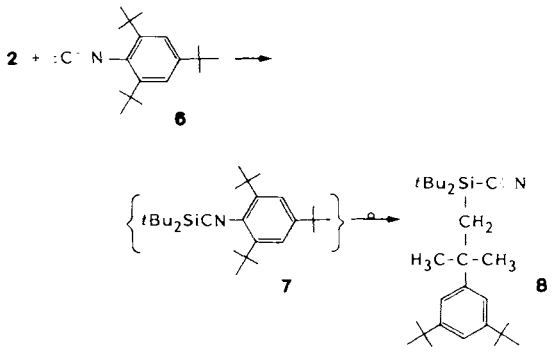
The most striking feature of **5** is its ruby red color, which is reflected in the absorption at $\lambda_{max} = 520$ nm. This shift of the longest-wavelength band, which is extreme for silyl imines, has only been observed previously for a disilacyclopropanimine (**C**) with $\lambda = 510$ nm, obtained by addition of an isocyanide to a disilene.[10] The rationalization given there for the color of the compound—the effect of ring strain on the transition energy or on an intramolecular Si–Si $\sigma \rightarrow \pi$ charge transfer—should be reconsidered, since the less strained compound **5** exhibits the same phenomenon. Simple MO considerations indicate that the lowering of the excitation energy is more likely due to an adiabatic shift of the excited state in the direction of the ground-state minimum.[11]

To verify that **5** indeed results from dimerization of the silaketenimine of type **4** and not from twofold addition of **3** to tetra-*tert*-butyldisilene formed simultaneously in the photolysis of **1**, we allowed **2** to react with isocyanide **6**,[12] whose bulky ortho-*tert*-butyl groups should disfavor both cyclodimerization and insertion into the Si–Si bond of a possible intermediate of type **C**.



In fact, a monomeric compound, consisting of **2** and **6** in a ratio of 1:1, was isolated. The spectroscopic data indicate, however, that the expected intermediate **7** rearranged to the trialkylsilyl cyanide **8**.[13] Several examples of such aryl–alkyl isomerizations of the 2,4,6-tri-*tert*-butylphenyl group have meanwhile been observed.[14] Their mechanism is still not understood.

To determine whether **8** might result from a precursor of type **5** via a CH activation of the peripheral *tert*-butyl groups, we have also carried out the photolysis of **1** in the presence of 2,4,6-trimethylphenyl isocyanide (mesityl isocyanide). This compound also contains methyl groups capable of undergoing isomerization reactions, but it cannot compete with the steric overloading of **6**. In this case, we isolated a derivative of **5** with mesityl instead of phenyl groups. Although other routes of formation for **5** cannot be definitively ruled out, these reactions support the formation of cyclodimer **5** from **2** and **3** via the monomeric compound **4**.

Experimental Procedures

5: A solution of **1** (0.42 g, 1.0 mmol) and **3** (0.31 g, 3.0 mmol) in 40 mL of petroleum ether (40–60 °C) was irradiated with a medium-pressure Hg lamp for 2 h at 20 °C. Fractional crystallization (*n*-pentane) of the residue remaining after removal of the solvent by distillation gave 0.16 g (65% yield, based on **1**) of **5** as ruby red crystals.

8: Analogously to the synthesis of **5**, reaction of **1** (0.42 g, 1.0 mmol) and **6** (0.82 g, 3.0 mmol) in 70 mL of petroleum ether (40–60 °C) for 6 h at 20 °C gave 0.29 g (70%) of crystalline **8**.

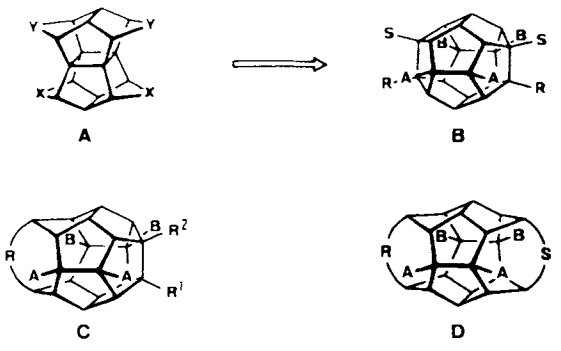
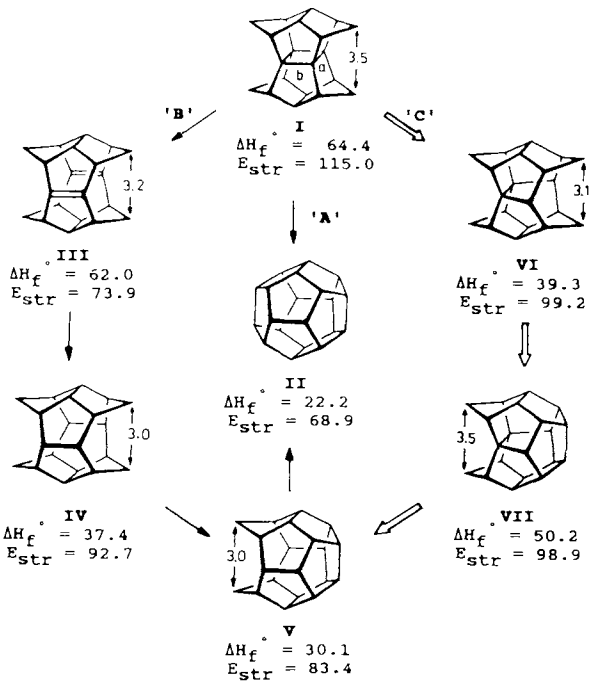
The Pagodane Route to Dodecahedranes: An Efficient Variant—New Substitution Patterns**

By *Rolf Pinkos, Johann-Peter Melder,* and *Horst Prinzbach**

Our efficient syntheses of 4,9,14,19-tetrasubstituted pagodanes **A**[1] have opened a broad route to dodecahedranes **B** and homologous dodecahedranes **C**, **D**.[2, 3] Beyond an intrinsic aesthetic appeal, the value of this class of carbo- and heterocyclic compounds is determined not least by the possibility of specifically varying the substitution pattern.[4] For the dodecahedranes **B**, the aldol route (starting from **A**, X = $CHCO_2R$, CHCN; Y = C=O) allows the directed functionalization of up to eight framework positions.[1–3]

The S_N2 variant described here (starting from **A**, X = CHA; Y = CHL; cf. "d" in the caption to Scheme 1 in Ref. [2]) permits a significant extension of this synthetic concept[5]—preparatively in the realization of additional substitution patterns (cf. **16, 21**) and thermodynamically unfavorable C–C coupling reactions (cf. **25**),[6] methodologically in that the reaction sequence **I** → **VI** → **VII** → **V** → **II** (Scheme 1) corresponds to the third (C) variant of the originally formulated pagodane → dodecahedrane routes[7] (A,[8] B[9]). For the parent hydrocarbons, the corresponding reaction sequence of hydrogenative C–C bond cleavages and dehydrogenative C–C bond formations had earlier failed at the stage of the kinetically unusually stable species **VI**. A noteworthy feature of this C route is the occurrence of "isododecahedranes"[10, 11] derived from **VII**. In the S_N2 route, however, leaving (L) and acceptor (A) groups have to be incorporated at the pagodane stage (**A**, X = CHA; Y = CHL), and the lateral C–C coupling reactions (X,Y) are only possible after the pagodane four-membered ring (**I**, a) has been opened.[2, 3] Thus, it was necessary to study the effect of the electronegative functionalities on the conditions of four-membered ring opening, that is, on the photochemical addition and elimination of bromine, as well as to determine what kinds of leaving groups are compatible with the drastic reaction conditions required in these reactions.





Scheme 1. Alternative pagodane → dodecahedrane routes (A, B, C). MM2-calculated ΔH_f° and E_{str} (strain energy) values [kcal mol^{-1}].

The starting materials for the S_N2 route are pagodanes **4** (cf. **A**) with leaving groups on C-14(19) in *anti* position and acceptor groups on C-4(9) in *syn* position (Scheme 2). After the yield of bislactone **2** obtained from biscarboxamide **1** (R = NH_2), readily accessible via the pagodane synthesis,

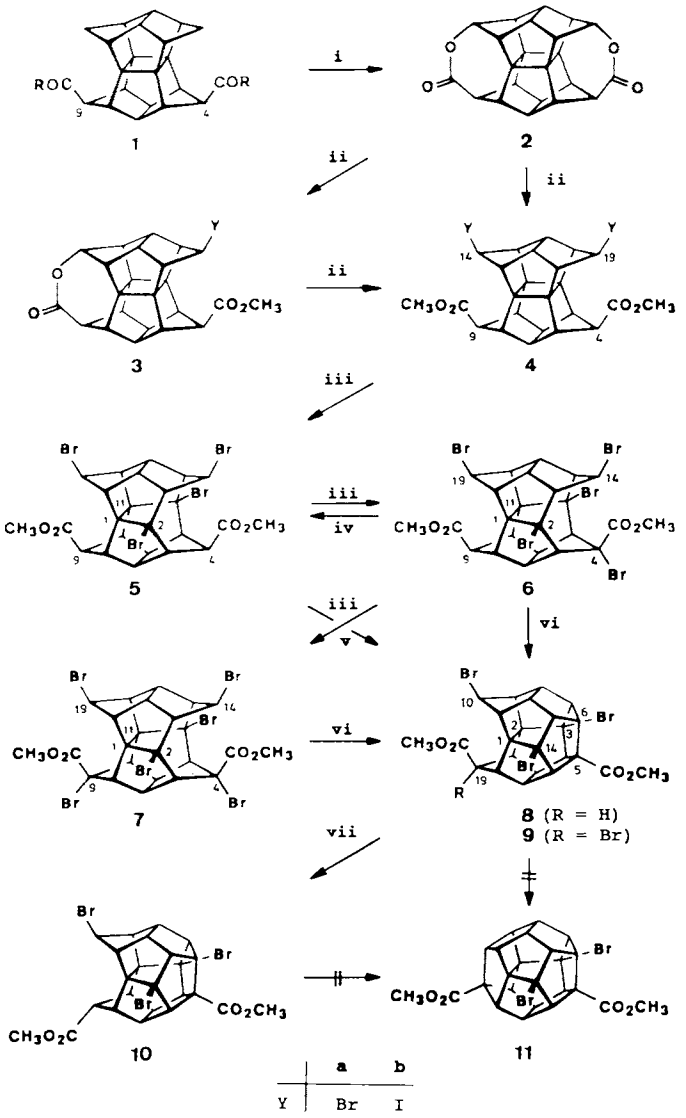
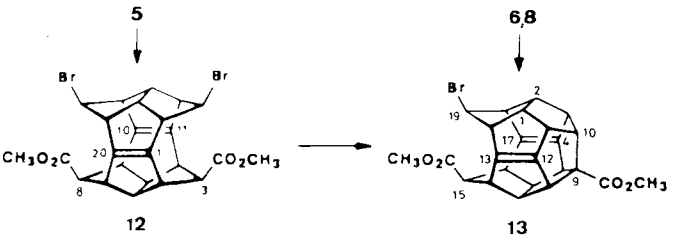
could be increased from originally 35% to 70%,[3] **2** became the intermediate of choice for the regiospecific introduction of *anti*-Y leaving groups.[1,2] Reaction of **2** with Me_3SiY (Y = Br, I) afforded dibromide **4a** and diiodide **4b**[1,3] in nearly quantitative yield (10-mmol scale). The first (**2** → **3**) and second (**3** → **4**) substitutions are kinetically so different that intermediates **3a, b**, which are useful in other transformations (see below), can be isolated selectively. The four-membered ring opening **4** → **5**, which we planned to accomplish by proven procedures,[3] presented difficulties—as was found for the aldol route[2]—since the photochemical addition of bromine was considerably slowed by the four electronegative substituents. Under the more drastic conditions therefore required, diiodide **4b** underwent halogen exchange to give dibromide **4a**; total conversion unavoidably results in subsequent bromination of **4a** to pentabromide **6** and (to a lesser extent) hexabromide **7** (at room temperature (RT) in $CDCl_3$, rotamers are present according to NMR). Fortunately, the mixture of bromides could largely be transformed into **6** (92% together with **7** (5%), 2-mmol scale); moreover, treatment of **6** with Pt/H_2 led to selective replacement of the bromine substituent at C4 with hydrogen (100% **5**, no cyclization to **8**[6]). The ring closure, which, in the parent framework (**VI** → **VII**), is considerably endothermic and could not be achieved, could be effected by deprotonation in **5** as well as reductively in **6** (**7**). As expected, only the "open" side (d(C4-C14) ca. 3.1 Å) participates in each case. The yields of tri- and tetrabromoisododecahedranedicarboxylic esters **8** and **9**, respectively, were reproducibly better than 85%. Attempts to achieve, via **8** or **9**, C–C bond formation on the "closed" side (d(C10–C19) ca. 3.5 Å) to give the extremely strained dehydrododecahedrane derivative **11** were unsuccessful. The use of various bases or reducing agents led to epimerization of **8** to give **10** and to the formation of a complex mixture of products from **9** (no **11**).



Scheme 2. i: 1. I_2, $Pb(OAc)_4$, CH_2Cl_2, reflux, *hv*; 2. HOAc, HCl, reflux; 3. EtOH, $NaBH_4$; 4. benzene, DMF, $(COCl)_2$. ii: 1. $CHCl_3$, Me_3SiBr (Me_3SiI), reflux; 2. MeOH; 3. CH_2N_2. iii: CH_2Cl_2, Br_2, reflux, *hv*. iv: CH_2Cl_2, PtO_2, H_2. v: THF, NaH (1 equiv.). vi: DMF, Zn, NaI, 100 °C. vii: THF, NaH (5 equiv.).

The preparation of bissecododecahedradiene **12** by 1,4-bromine elimination from **5**—competing reductive recyclization to **4** necessitates high reaction temperatures—was also expected to be problematic owing to the additional bromine substituents. The 58–62% yield of **12** (2% **3a**), obtained after very short treatment (10 s) with $Zn/NaI/Na_2SO_3$ (DMF, 153 °C; ca. 90% conversion), is relatively small, but may be amenable to further improvement. Presumably, the modest yield primarily reflects the instability of this diene; moreover, 1,4-bromine elimination involving the bromine substituent at C19 is a probable side reaction (cf. the high yield with **4** (**5**)[6]). The conversion of pentabromide **6** to seco-diene **13** was carried out in a one-pot reaction at 130 °C under otherwise identical conditions and, after quantitative conversion and chromatography of the reaction mixture, has so far afforded only a ca. 60% yield of **13** together with **8** (ca. 10%). Compound **13** is presumably formed preferentially via the zinc enolate (C3) of **12**; in control experiments, 1,4-bromine elimination from **8** is much slower and much less selective than that from **6**.

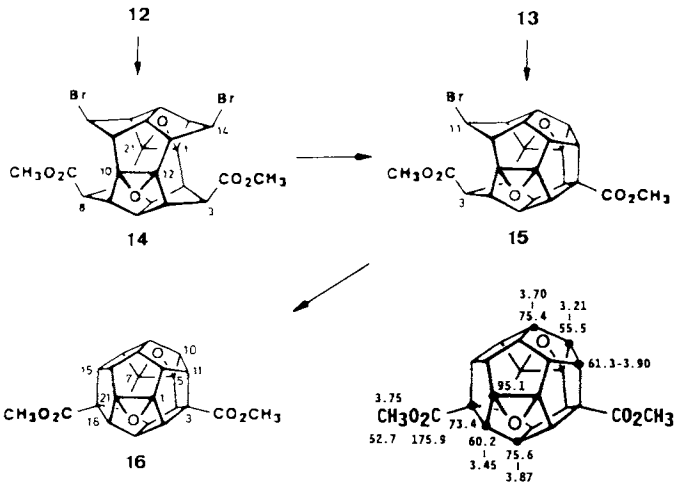


The bisseco-diene **12** (d(C1-C11) ca. 2.7 Å, δ_{C1} = 155.7 ($CDCl_3$)) exhibits the transannular reactivity known for this framework (*Z,Z*- or *E,E*-cyclodeca-1,6-diene subunits): clean [$\pi_2 + \pi_2$] cycloaddition to give **4a** on excitation in the presence of a sensitizer (acetone); clean homo-1,4-addition of bromine to give **5**. The secododecahedradiene framework, isolated here in the form of **13** for the first time, is useful as a "hermaphroditic" model consisting of bissecododecahedradiene (**12**, $d_{\pi\text{-}\pi}$ ca. 2.7 Å) and dodecahedra-1,16-diene ($d_{\pi\text{-}\pi}$ ca. 3.5 Å; cf. **10** in Ref. [6]) skeletal moieties. Transannular interactions in **13** between the CC double bonds, which are coplanar but not parallel (d(C13-C17) = 2.849 Å and d(C4-C12) = 3.195 Å according to X-ray structure analysis[6,14]), are manifested in the UV spectrum (CH_3CN) by a maximum at 263 nm (ε = 25) and by strongly differing pyramidalization of the sp^2 C atoms, as revealed by the ^{13}C NMR shifts of the olefinic carbon atoms (δ = 149.8 (C-13,-17), 172.2 (C-4,-12)). The transannular reactivity of the "hermaphrodite" **13** has not been elucidated in every detail. As in **12**, bromine adds rapidly and regiospecifically in a homo-1,4

fashion, with re-formation of **8**; addition at C13(17) would be much more unfavorable energetically. However, irradiation in acetone does not lead to the $[\pi_2 + \pi_2]$ cycloadduct, a dehydropagodane derivative.

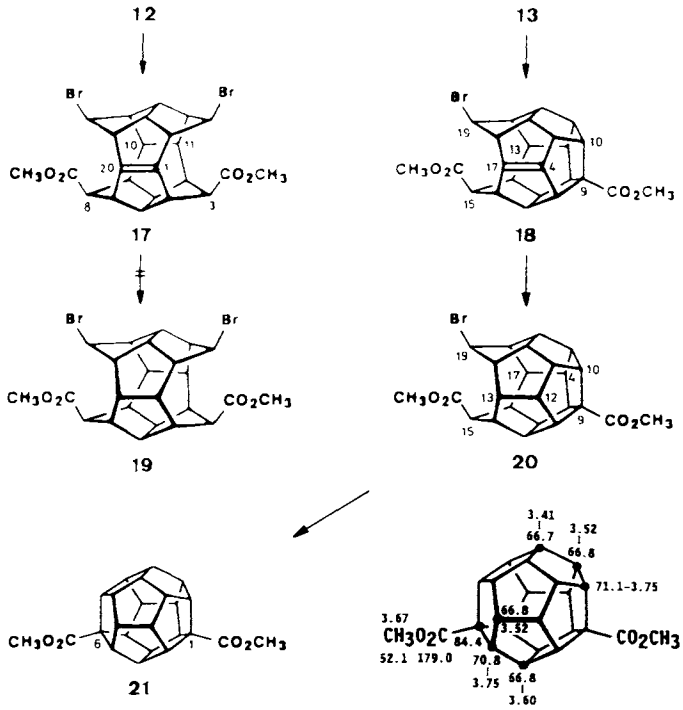
The further modifications of the dodecahedrane sphere made possible by the synthesis of **12** and **13** are closely connected with a stepwise transformation of the CC double bonds and with the reactivity of the corresponding singly unsaturated frameworks ("hyperstable" versus "non-hyperstable"). Clearly, the procedure exemplified here for the saturated dodecahedranes **16** and **21** can be extended to a wide variety of other derivatives. Examples not mentioned in the following communication[6] include the preparation of singly unsaturated analogues of **16** and **21**, which are accessible by single epoxidation or hydrogenation of **12** or **13**.

Dienes **12** and **13** are oxidized quantitatively to the diepoxides **14** and **15**, respectively, by treatment with excess benzoylperoxycarbamic acid (4 equiv., CH_2Cl_2, RT). Ring closure of **14** (d(C3-C14) ca. 3.2 Å)[1] to give **15** and of **15** (d(C3-C11) ca. 3.3 Å) to give **16** (cf. **7** → **14** → **15** in Ref. [2]), a considerably exothermic reaction in each case, occurs quantitatively (ca. 40% based on **1**) by transannular substitution using NaH as base (2 equiv., THF, RT). C_{2v} symmetry of the diepoxydodecahedranedicarboxylic ester **16** (m.p. 280–283 °C) is revealed by five ^{1}H NMR ($J_{10,11}$ = 11.2 Hz) and seven ^{13}C NMR skeletal signals of corresponding intensity (assignment confirmed by COSY, NOE, and selective decoupling experiments). In the mass spectrum of **16** (m/z [%] 404 ($M^{\oplus}$, 100), 344 (40), 285 (21)), loss of the two ester groups gives rise to a remarkably intense signal at m/z 285 (protonated diepoxydodecahedradiene).[6]



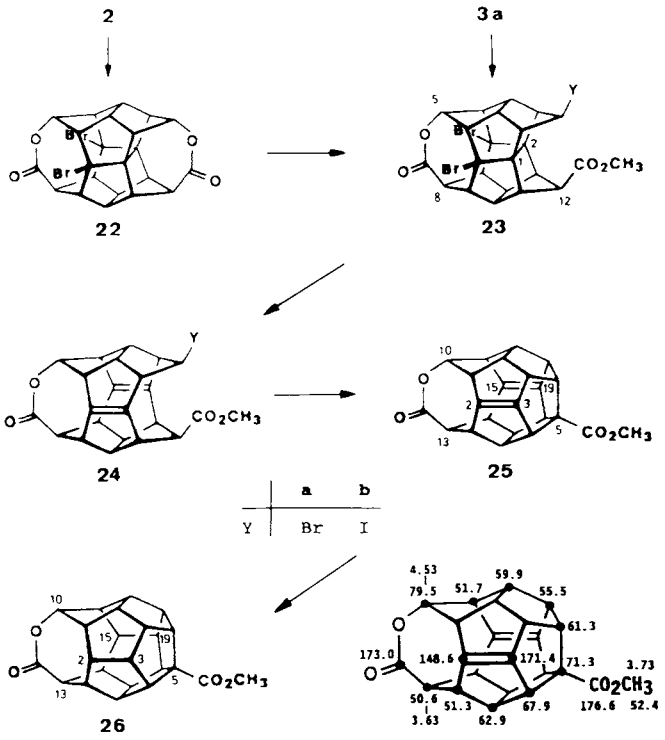
The hydrogenations of **12** and **13** with diimide ($(KOOCN)_2$, HOAc; 26 equiv., CH_2Cl_2/CH_3OH, RT) proceed, as expected, differently (cf. **2** → **3** → **4** in Fig. 1 of Ref. [9] as well as **A** → **B** → **C** and **G** → **H** → **I** in Scheme 1 of Ref. [2]). Bisseco-ene **17** proved to be hyperstable (no **19**); seco-ene **18** rapidly reacts further to give **20**. Compound **20** (d(C15-C19) ca. 3.0 Å) undergoes quantitative cyclization (ca. 45% based on **1**) in the presence of NaH (THF, RT) to the C_{2v} dodecahedrane-1,6-dicarboxylic ester **21** (m.p. 190–192 °C), which was fully characterized by NMR spectroscopy. Its mass spectrum (m/z [%] 376 ($M^{\oplus}$, 14), 344 (10), 316 (100), 257 (58), 256 (34)) also displays relatively intense signals for (protonated) dodecahedradiene (m/z 257, 256).[6]

The value of the S_N2 variant for endothermic transformations is impressively demonstrated by the direct cyclization of dienes **12** and **13** to dodecahedradienes[6] as well as by the cyclization of the homologous seco-diene **24b** to the homologous dodecahedradiene **25** (cf. **A** → **I** ($\Delta\Delta H_f^\circ$ = + 13.5, ΔE_{str} = + 23.3 kcal mol^{-1}) in Scheme 1 of Ref. [3]) and the absence of the corresponding aldol cyclization.[3] Two synthetic routes were used for the precursors **24a, b**: In the dibromobislactone **22**, prepared from **2**, the more highly strained lactone ring on the "closed" side is selectively opened by nucleophiles, for example, by reaction with Me_3SiI (20 equiv., CH_2Cl_2, RT, 12 h). After O–Si cleavage (CH_3OH) and esterification (CH_2N_2), the yield of **23b** was over 95%. The 1,4-bromine elimination in iodide **23b** under conditions that take account of the iodine substituent (NaI, Na_2SO_3, DMF, 153 °C, 30 min) affords diene **24b**, isolated by chromatography, in a relatively low yield of 45% (together with ca. 10% of the known[3] dienebislactone). The alternative offered by the availability of monobromide **3a** might be more economical, since the photochemical addition of bromine to **23a**, which is energetically more favorable, occurs exclusively on its lactone side. Under the conditions used for **14**/**16** and **20**/**21** (NaH, THF, RT), compound **24b** is cleanly converted into **25** (ca. 25% based on **1**). Compound **25** (m.p. 280–283 °C, $\tilde{\nu}_{CO}$ = 1720 cm^{-1}) can be chromatographed, crystallized, and stored as a solid (0 °C); however, it is rapidly attacked by oxygen, particularly in solution.



The relative arrangement of the CC double bonds in **25**,[6] a dodecahedradiene enlarged on one side (π–π transannular distances 2.9 and 3.1 Å[3]) and flattened, largely corresponds to that in seco-diene **13**.[14] Characteristic of this structure are the comparatively small vicinal H,H coupling constants (e.g., $J_{1,13}$ = 6.8, $J_{9,10}$ = 7.1 Hz) as well as the strongly, differing ^{13}C NMR shifts of the olefinic centers. Electron impact leads to CH_3CO_2H elimination and formation of an intense (protonated) trienelactone fragment (m/z [%] 358 ($M^{\oplus}$, 100), 298 (64)). As in **13**, bromine adds regiospecifically to the "dodecahedradiene side" (C-3(19)); the hydrogenation with diimide (excess) leads cleanly to the homododecahedrane **26**.

In summary, based on efficient syntheses of the correspondingly substituted starting materials, the S_N2 variant significantly extends the scope of the pagodane → dodecahedrane route. There is good evidence that the efforts re-



quired to prepare the key intermediates **12** and **13** can be dramatically decreased: Extensive photochemical bromination of the pagodane-*syn,syn*-dicarboxylic ester **1** (R = OCH_3) (2,12-di- → 2,4,12-tri- → 2,4,9,12-tetra- → 2,4,9,12,14-pentabromide, subsequent brominations nonselective), followed by bromination (at C-19) with *N*-bromosuccinimide), at low conversions (25–41%), affords hexabromide **7** with high selectivity and with low material loss. However, conversion of **7** to **12** (**13**) has so far given unsatisfactory results.[15]

[10] The difficulty in the nomenclature of these complex, in part highly symmetrical polycyclic compounds according to the von Baeyer system lies in the selection of main bridge from the large number of zero bridges. In this communication, the systematic names and numberings were determined by use of the POLCYC program (*G. Rücker* and *C. Rücker*, unpublished; computer version of IUPAC rule A-32 as well as its proposed improvement by CAS). Several earlier names [1–3] were corrected with this computer program: **13**: dimethyl 19-*anti*-bromo-decacyclo[9.9.0.0^{2,18}.0^{3,10}.0^{4,17}.0^{5,9}.0^{6,16}.0^{7,14}.0^{8,12}.0^{8,12}.0^{13,20}]icosa-4(17),12-diene-9,15-*syn*-dicarboxylate. **16**: dimethyl 6,22-dioxatridecacyclo-[10.10.0.0^{1,21}.0^{2,19}.0^{3,11}.0^{4,18}.0^{5,7}.0^{5,10}.0^{7,17}.0^{8,15}.0^{9,13}.0^{14,21}.0^{16,20}]docosane-3,16-dicarboxylate. **25**: methyl 12-oxo-11-oxaundecacyclo-[11.9.0.0^{2,9}.0^{3,7}.0^{4,22}.0^{5,20}.0^{6,18}.0^{8,17}.0^{10,16}.0^{14,21}.0^{15,19}]decosa-2,15-(19)diene-5-carboxylate.

The Pagodane Route to Dodecahedranes: Dodecahedradienes—Unusually "Pyramidalized", Isolable Olefins**

By *Johann-Peter Melder, Rolf Pinkos, Hans Fritz,* and *Horst Prinzbach**

Carbon–carbon double bonds on the surface of regular pentagonal dodecahedrane[1,2] are particularly attractive functionalities[3] (Scheme 1). On the one hand, the rigid[4] spherical framework enforces an unusually strong pyramidalization of the sp^2 centers, that is, *syn* bending of the CC double bonds;[3,5,6] on the other hand, advantageously

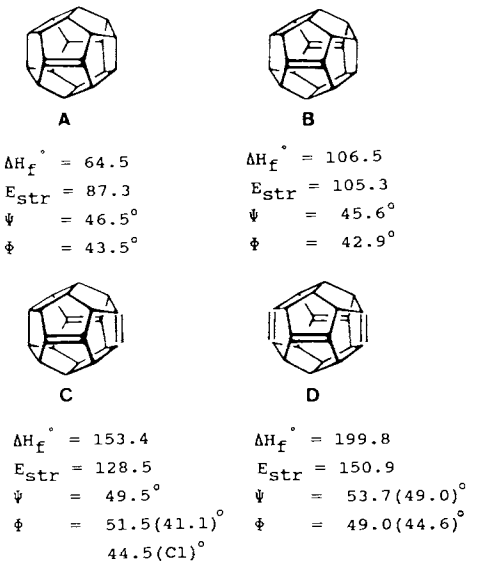
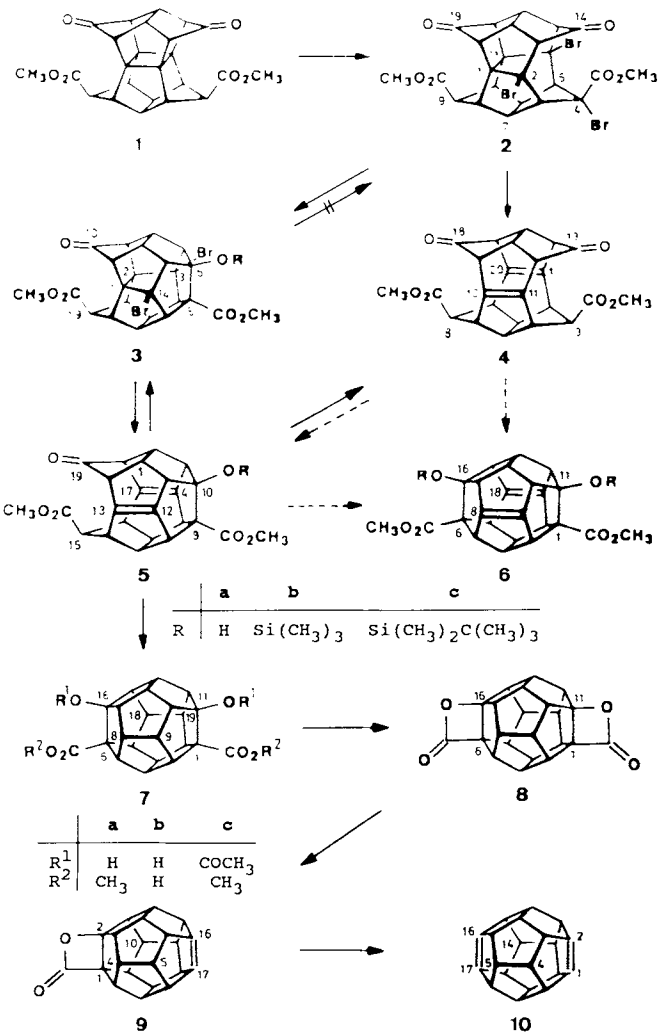
Keller* for NMR analyses, Dr. *J. Wörth* for MS analyses, *M. Lutterbeck, G.* and *J. Leonhardt*, and *M. Froom* for starting materials, *G. Fehrenbach* for graphical work, and Dr. *W.-D. Fessner*, Dr. *C. Rücker*, and Dr. *L. Knothe* for helpful discussions.

placed H atoms should provide an effective steric shielding of these very reactive double bonds against dimerization/polymerization. Indeed, a fourfold substituted pentagonal dodecahedrene (cf. parent compound **A**) proved to be isolable in crystalline form,[7] and the existence of multiply unsaturated dodecahedranes has been inferred from intense signals in mass spectra.[1, 7, 8] Doubly and multiply unsaturated dodecahedranes such as the D_{2h} diene **B**, the C_{2v} triene **C**, and the D_{2h} tetraene **D**, which are per se a challenge because of their structural and energetic particularities, are also of special interest with respect to transannular electron interactions ("σ-homoaromaticity") in the bissecododecahedradiene radical cation[9] and dication.[10] The first results in our quest for diene **B** (≡ **10**) as well as for two- and fourfold substituted derivatives (**12** and **6**, respectively) are presented in this communication.[11]

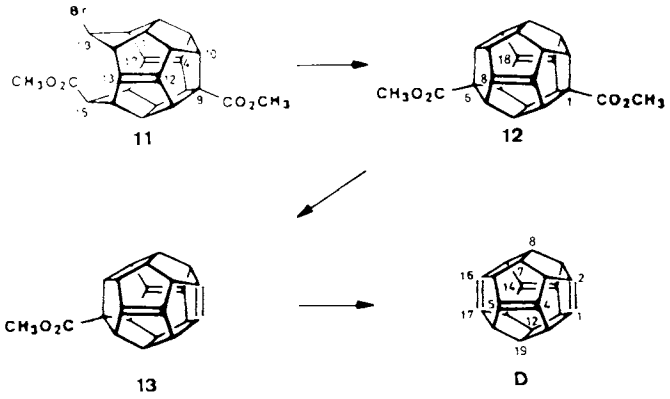


Scheme 1. Dodecahedranes **A**–**D** with double bonds. MM2-calculated ΔH_f^0 and E_{str} (strain energy) values [kcal mol^{-1}]. Ψ, Φ see [6].

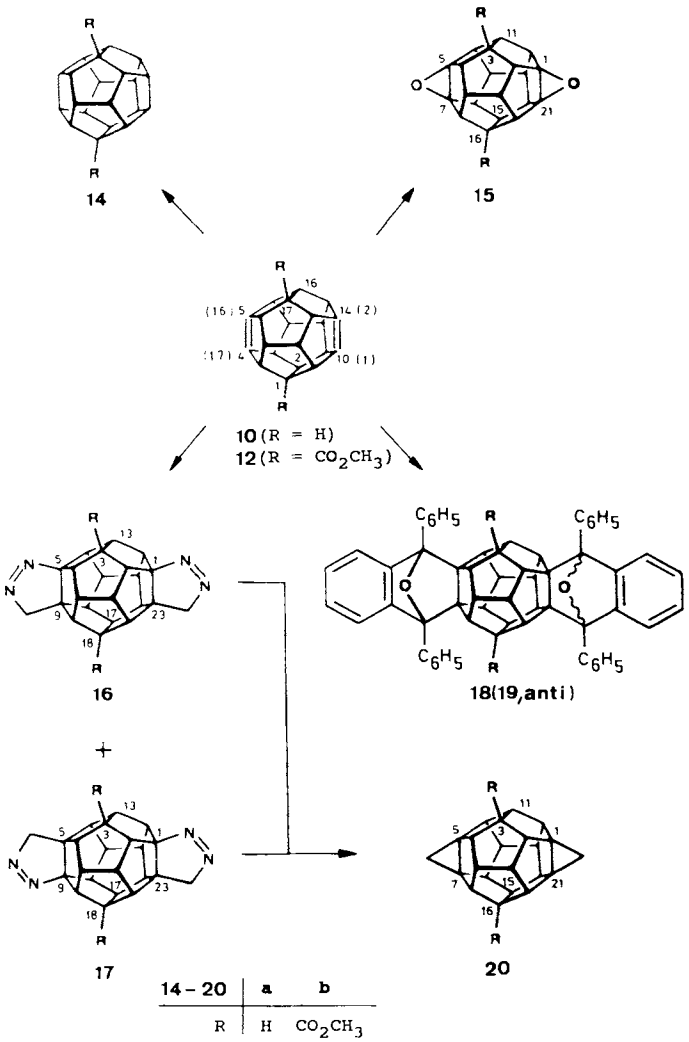
Potential routes to the unsubstituted dodecahedradiene **B** (≡ **10**) are twofold β-elimination or Grob fragmentation in 1,6,11,16-tetrasubstituted dodecahedranes **7**[7] and twofold CO_2 elimination from bis-β-lactone **8**. Because of the presumably high sensitivity of **10** toward oxygen and electrophiles/nucleophiles, we first studied the gas-phase thermolysis of **8**, especially since the aldol route (cf. Ref. [1]) provides an efficient access to **8**. Tribromide **2**,[7] prepared selectively from the dioxopagodanedicarboxylic ester **1**, undergoes clean catalytic cleavage of the C4–Br bond (5-mmol scale, >95%), although as a mixture of seco-diene **5a** and bisseco-diene **4**. Reaction of this crude mixture with diimide decahedrane derivative **3** (95%).[15, 16] Of the several methods of 1,4-bromine elimination tested on **3**,[7, 8] the Zn/DMF variant at 120 °C (1–2 h) gave an excellent yield (2-mmol scale, >95%), although as a mixture of seco-diene **5a** and bisseco-diene **4**. Reaction of this crude mixture with diimide ($(KOOCN)_2$, HOAc; 50 equiv., CH_2Cl_2/CH_3OH, **4** → hyperstable dihydro-**4**; **5a** → tetrahydro-**5a**), with CH_3ONa/CH_3OH (2 equiv., dihydro-**4** → dihydro-**5a** → dihydro-**6a**, tetrahydro-**5a** → **7a**), with $Pd/C/H_2$ (50 mg mmol^{-1}, dihydro-**6a** → **7a**), with KOH/CH_3OH (**7a** → **7b**), and with phenylsulfonyl chloride/pyridine (2.25 equiv., RT, 24 h)[18] gave bislactone **8** ($\tilde{\nu}_{C=O}$ = 1820 cm^{-1}; *m/z* (CI, NH_3) 362 ($M^{\oplus}$ + 18), 318 (100, **9** + 18), 274 (48, **10** + 18), 256 (20, **10**)).[19] Compound **8**, isolated from the CH_2Cl_2/pyridine extraction phase, is sufficiently pure for use in subsequent reactions; it can be crystallized (68% based on **1**) from CH_2Cl_2/ethyl acetate (a small amount of pyridine should be added for stabilization) and remains unchanged in the solid state and in degassed solution (toluene) to ca. 220 °C, but decomposes with gas evolution at higher temperatures. Thermolysis of **8** in the gas phase (500 °C, 10^{-2} Torr) and condensation of the product on a cold finger affords up to 70% of the crystalline diene **10** (together with traces of **9** in some cases). The NMR spectra (Fig. 1) reveal D_{2h} symmetry; the mass spectrum (*m/z* [%] 256 ($M^{\oplus}$, 60), 141 (34)) shows the stability of the molecular ion. In degassed, ca. 10^{-2} M solutions and in the solid state (inert atmosphere), **10** is stable at room temperature for hours, but reacts rapidly and unspecifically (no **15a**) with oxygen. After evaporation of degassed THF solutions to dryness, up to ca. 70% of the colorless, crystalline residue is soluble as monomeric **10**.



In the course of these investigations, the limits of the aldol variant once more became obvious. Our attempts to prepare the 1,6,11,16-fourfold substituted dodecahedradienes **6** (presumably less reactive than **10**), which, among other things, are of interest as potential intermediates along the route to tetraene **D**, starting from **1** and using the aldol variant via bisseco-diene **4**, had already met with failure (the C–C



coupling reactions **4a** → **5a** → **6a** are considerably endothermic; cf. **A** → **G** ($\Delta\Delta H_f^\circ = +12.4$ kcal mol^{-1}) and **G** → **N** ($\Delta\Delta H_f^\circ = +5.9$ kcal mol^{-1}) in Scheme 1 of Ref. [7]). The availability of the seco intermediates **5a–c** provides no breakthrough; even under potentially irreversible conditions, no cyclization **5** → **6** could be realized.



Encouragingly unproblematic, on the other hand, is the preparation of the dodecahedra-8,18-diene-1,6-dicarboxylic ester **12** by the S_N2 variant via the *anti*-bromo seco-diene diester **11** (d(C15-C19) = 3.281 Å) described in the preceding communication.[1] Stirring the degassed THF solution of **11** over NaH (2 equiv., 2 h, RT), followed by filtration and concentration, afforded pure, colorless, crystalline **12**. Compound **12**, like **10**, is very sensitive toward oxygen, readily soluble in benzene, THF, and CH_2Cl_2 (ca. 20 mg in 0.3 mL), and thermally stable (in ca. 10^{-2} M solutions or in the crystalline state, **12** remains unchanged for days in the absence of oxygen). In the qualitatively recorded UV spectrum (CH_3CN), there is no pronounced maximum (no shoulder) along an absorption band that steadily decreases to ca. 260 nm—in contrast to the spectra of **11** or **4/5**. The NMR data of **12** (Fig. 1) are characterized, in particular, by the similarity of the shifts of the olefinic ^{13}C NMR signals with those of C-4(12) in seco-diene **11** and those of C-1(16) in diene **10**. The most striking feature of the mass spectrum (m/z [%] 372 ($M^\oplus$, 56), 312 (100, e.g., **13**), 253 (72), 252 (58, e.g., **D**)) is the intensity of the signals ascribable to multiply unsaturated dodecahedranes.

Common to dienes **10** and **12** is the ease of hydrogenation (Pt, H_2, diimide) of both double bonds (formation of dodecahedranes **14a, b**[11]), their rapid oxidation by benzoylperoxycarbamic acid (5 equiv., CH_2Cl_2, RT, 5 min) to give diepoxides **15a, b**,[1] and the addition of diazomethane (10 equiv., CH_2Cl_2, 10 min) to give ca. 1:1 mixtures of *syn*/*anti*-bis(dihydropyrazoles) **16a, b**/**17a, b** and of diphenylisobenzofuran (5 equiv., RT, immediate reaction) to give ca. 1:1 mixtures of *syn*/*anti*-bisadducts **18a, b**/**19a, b**. Compound **18a** was isolated in pure form by chromatography. Photolysis of dihydropyrazoles **16a**/**17a** ($\lambda_{max} = 310$ nm, benzene, Pyrex photoreactor, high-pressure Hg lamp) gave dicyclopropadodecahedrane **20a** (m/z [%] 284 ($M^\oplus$, 77), 97 (26), 71 (54), 57 (100)). The assignment of the cyclopropane-ring ^{13}C NMR signals (Fig. 1), which differs from that of cyclopropadodecahedrane,[2, 20] was confirmed by DEPT experiments. Addition of bromine to **10** or **12** at room temperature leads to the spontaneous formation of complex mixtures of products, in contrast to the corresponding reactions with bisseco-dienes

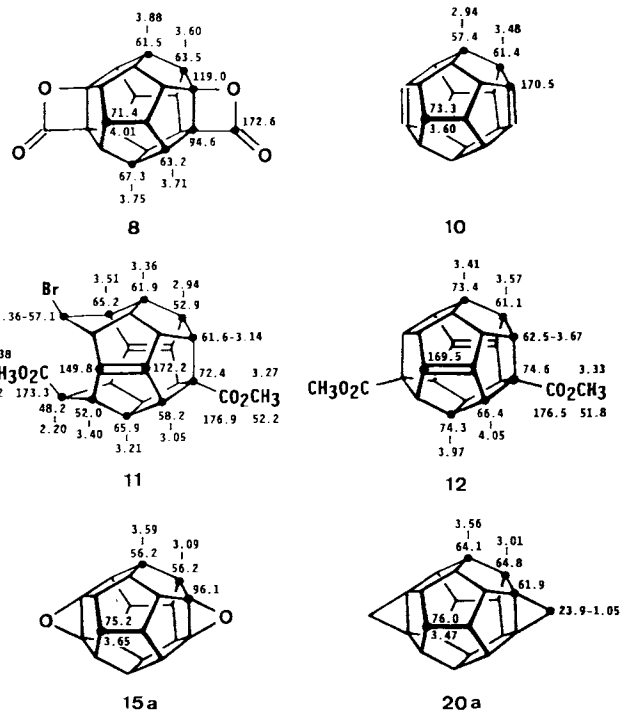


Fig. 1. ^1H and ^{13}C NMR spectroscopic data ($CDCl_3$) of **8**, **10** (C_6D_6), **11**, **12** (C_6D_6), **15a**, and **20a**.

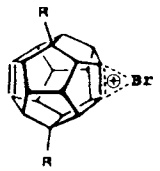
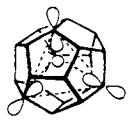
(e.g., **4**) and seco-dienes (e.g., **11**); the homo-1,4 adducts derived analogously from **21a,b** (cf. **11** in Ref. [1]) are extremely unfavorable thermodynamically.

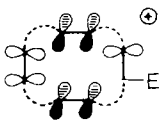
Prospects: The pagodane route provides the prerequisites for the preparation and isolation of singly and doubly unsaturated, variously substituted (stabilized) dodecahedranes. Thus, it becomes possible to test experimentally[21] diverse and in part contradictory thermodynamic predictions (heats of hydrogenation and heats of formation) and to investigate the homoconjugative interactions in dienes **B** and cations of type **21**.[10, 22] Trienes (**C**) and tetraenes (**D**) are important in this context. There is mass spectrometric evidence that they are possibly isolable compounds. The "inner life" of such multiply unsaturated dodecahedranes, for example, homoconjugative/homoaromatic interactions in the potentially "three-dimensionally homoaromatic"[23] dication **22** or in cations/dications such as **23/24** derived from tetraene **D**, is



21

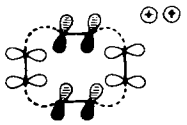


22



23

a, R = H



24

just one exciting aspect. The respective transannular p–π and π–π distances clearly touch the limits of such interactions, all the more since decreases in distances due to bonding interactions are severely counteracted by the rigidity of the molecular frameworks.[24] For the same reason, the MM2-calculated structural parameters, in particular the relevant transannular distances and Ψ (Φ) values,[6] should be subject to relatively small error,[25] usually due to underestimate of repulsive π–π interactions.[26] Particularly informative in this respect are the X-ray structure data[27] of seco-diene **11** and diepoxide **25** (Fig. 2). Compound **25** is the best model so far available for the diene framework **B** (**10, 12**); cf. the transannular distances [Å] of the bonds in **25** (Fig. 2), **10** [MM2, 3.52 (1(2)-17(16)), 4.12 (4(5)-10(14)), 4.05 (7(8)-19(12))], and **D** [MM2, 3.59 (1(2)-17(16)), 3.79 (4(5)-10(14)), 4.12(7(8)-19(12))]. Undoubtedly, the unsaturated dodecahedranes will open a further fascinating chapter in the chemistry of this class of compounds.[28]

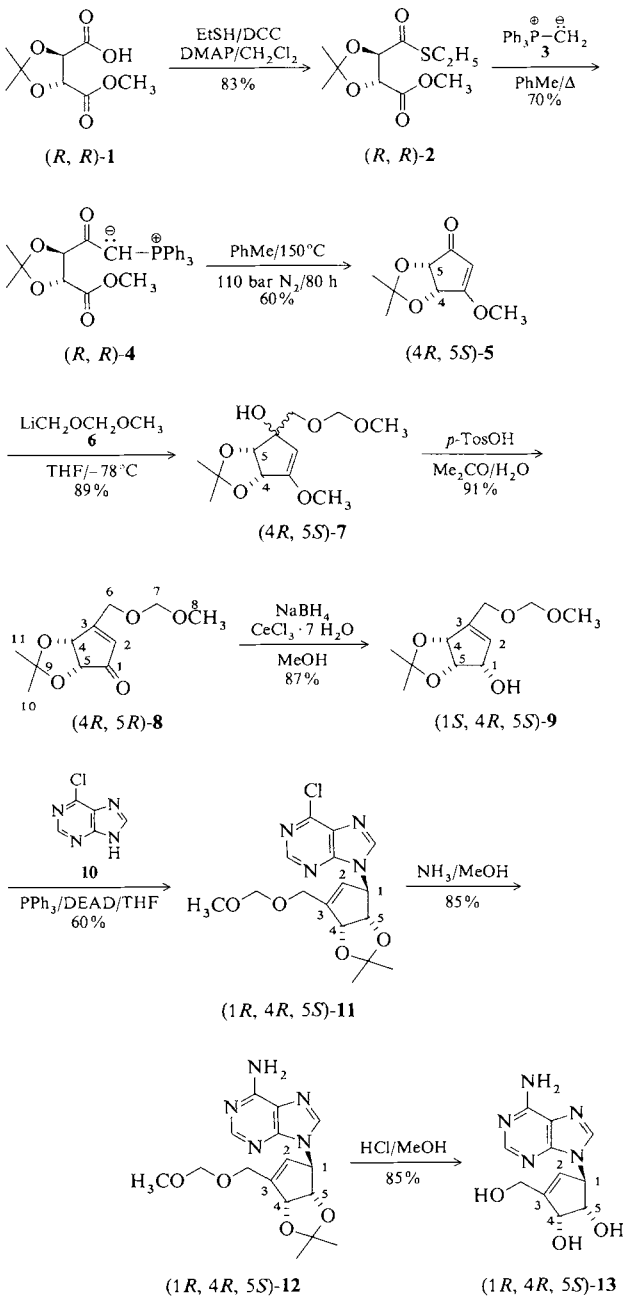
[28] The existence of dodecahedrene was recently concluded indirectly from gas-phase ion-molecule reactions, although the molecule was not directly observed: a strain energy (heat of hydrogenation) of 63 ± 3 kcal mol^{-1} was estimated for the CC double bond: J. Kiplinger, F. R. Tollens, A. G. Marshall, T. Kobayashi, D. R. Lagerwall, L. A. Paquette, J. E. Bertmess, *J. Am. Chem. Soc. 111* (1989) 6914.

Synthesis of (−)-Neplanocin A from (*R*,*R*)-Tartaric Acid**

By *Hans Jürgen Bestmann** and *Dieter Roth*

Recently, we reported on the possibility of transforming tartaric acid into optically active cyclopentanediol synthetic building blocks such as **5**.[1] Here we describe the use of **5** to synthesize the naturally occurring carbocyclic nucleoside analogue (−)-neplanocin A (**13**), which exhibits antiviral and antitumor activity.[2]

The synthesis of **5** has meanwhile been improved as shown in Scheme 1. The protected monomethyl tartrate (*R*,*R*)-**1**



(*R*, *R*)-**1** (*R*, *R*)-**2** (*R*, *R*)-**4** (4*R*, 5*S*)-**5** (4*R*, 5*S*)-**7** (4*R*, 5*R*)-**8** (1*S*, 4*R*, 5*S*)-**9** **10** (1*R*, 4*R*, 5*S*)-**11** (1*R*, 4*R*, 5*S*)-**12** (1*R*, 4*R*, 5*S*)-**13**

Scheme 1. Synthesis of (−)-neplanocin A (**13**).

[**] We thank Hoechst AG for carrying out studies of the biological activity of **13**.

was converted into the *S*-ester **2** by treatment with ethanethiol and dicyclohexylcarbodiimide (DCC) in the presence of dimethylaminopyridine (DMAP).[3] Compound **2** reacts with methylenetriphenylphosphorane (**3**) to give ylide **4**.[4] We found that the subsequent intramolecular Wittig reaction at the ester carbonyl group[5] proceeded much more smoothly under increased pressure. As described earlier, epimerization occurs during the reaction. Originally, we assumed by analogy that *ent*-**5** of absolute configuration (4*S*,5*R*) had been formed.[1] Using the new procedure of triplet phase measurement, however, we were able to show that the absolute configuration of **5** is, in fact, (4*R*,5*S*);[6] that is, the epimerization takes place at the C atom bearing the C=O ylide group.

Addition of (methoxymethoxy)methyllithium (**6**), generated in situ from *n*-butyllithium and (methoxymethoxy)-methyltributyltin,[7] gives a mixture of the diastereoisomeric α,β-unsaturated alcohols **7**, which, without further purification, were converted into cyclopentenone **8** by acid-catalyzed elimination of methanol accompanied by allylic rearrangement. Diastereoselective reduction[8] of the carbonyl function of **8** affords the optically pure α,β-unsaturated alcohol **9**. The base component of the nucleoside structure was introduced by reaction of **9** with 6-chloropurine (**10**) according to the Mitsunobu procedure (triphenylphosphane/diethyl azodicarboxylate (DEAD)[9]) with inversion at C1 to give **11**. Transformation of the chloropurine ring to the adenine ring (**11** → **12**) was accomplished by a known method[2c] using a methanolic solution of ammonia in a sealed reaction vessel. The subsequent, simultaneous cleavage of both protecting groups in **12** with dilute HCl affords **13**; its physical constants, spectroscopic data (Table 1), and antiviral activity are identical with those of natural neplanocin A. Thus, this natural product is accessible in 11 steps from inexpensive, natural tartaric acid.

If, instead of **6**, other organolithium compounds (**14**) are used in the synthetic route shown in Scheme 1, neplanocin derivatives (**15**) with different side chains R may be prepared.

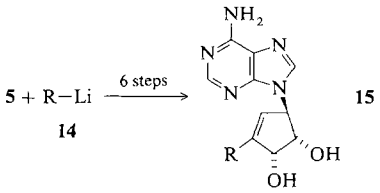

Table 1. Selected physical data for **8**, **9**, and **11**–**13**:

8: b.p. 77–78 °C/0.01 Torr, $[\alpha]_D^{20} = -13.1$ ($c = 1.1$, $CHCl_3$); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 1.36$, 1.37 (each s, 10-, 11-H, each 3H), 3.36 (s, 8-H, 3H), 4.38 (dd, $J_a = 17.7$, $J_b = 1.83$ Hz, 6-H, 1H), 4.47 (d, $J = 5.49$ Hz, 5-H, 1H), 4.52 (dd, $J_a = 17.7$, $J_b = 1.83$ Hz, 6-H, 1H), 4.68 (s, 7-H, 2H), 5.08 (d, $J = 5.49$ Hz, 4-H, 1H), 6.12 (t, $J = 1.83$ Hz, 2-H, 1H)

9: b.p. 74–76 °C/0.02 Torr, $[\alpha]_D^{20} = +36.8$ ($c = 0.8$, $CHCl_3$) (>97:3 after GC, ^1H- and ^{13}C NMR); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 1.22$, 1.26 (each s, 10-, 11-H, each 3H), 2.73 (d, $J = 10.1$ Hz, 1-OH, 1H), 3.38 (s, 8-H, 3H), 4.17 (d, $J = 13.6$ Hz, 6-H, 1H), 4.24 (d, $J = 13.6$ Hz, 6-H, 1H), 4.57 (m, 1-H, 1H), 4.66 (s, 7-H, 2H), 4.77 (t, $J = 5.5$ Hz, 5-H, 1H), 4.97 (d, $J = 5.5$ Hz, 4-H, 1H), 5.78 (br. s, 2-H, 1H)

11: m.p. 56–57 °C, $[\alpha]_D^{20} = -68.8$ ($c = 1.0$, $CHCl_3$) (>99:1 after ^1H- und ^{13}C NMR); ^1H NMR (400 MHz, $CDCl_3$): $\delta = 1.39$, 1.51 (each s, 10-, 11-H, each 3H), 3.42 (s, 8-H, 3H), 4.38 (m, 6-H, 2H), 4.74 (s, 7-H, 2H), 4.78 (d, $J = 5.8$ Hz, 4-H, 1H), 5.46 (d, $J = 5.8$ Hz, 5-H, 1H), 5.70 (br.s, 1-H, 1H), 5.87 (br.s, 2-H, 1H), 8.10, 8.77 (each s, arene-H, each 1H)

12: m.p. 134–135 °C, $[\alpha]_D^{20} = -74.2$ ($c = 0.8$, $CHCl_3$) [according to [2c]: m.p. = 134–136 °C, $[\alpha]_D^{20} = -69.8$ ($c = 1.1$, $CHCl_3$)]; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 1.37$, 1.49 (each s, 10-, 11-H, each 3H), 3.42 (s, 8-H, 3H), 4.35 (m, 6-H, 2H), 4.72 (d, $J = 5.5$ Hz, 4-H, 1H), 4.73 (s, 7-H, 2H), 5.40 (d, $J = 5.5$ Hz, 5-H, 1H), 5.70 (br.s, 1-H, 1H), 5.84 (br.s, 2-H, 1H), 6.20 (br.s, NH_2, 2H), 7.71 8.38 (each s, arene-H, each 1H)

13: m.p. 218–220 °C (dec.), $[\alpha]_D^{20} = -154.5$ ($c = 0.3$, H_2O) [according to [2a]: m.p. = 220–222 °C (dec.), $[\alpha]_D^{23} = -157.0$ ($c = 0.5$, H_2O)]; ^1H NMR (400 MHz, $(D_3C)_2SO$): $\delta = 4.16$ (m, 6-H, 2H), 4.32 (dd, $J_a = 6.7$, $J_b = 5.5$ Hz, 5-H, 1H), 4.44 (t, $J = 5.5$ Hz, 4-H, 1H), 4.93 (t, $J = 5.5$ Hz, 6-OH, 1H), 4.98 (d, $J = 6.1$ Hz, 4-OH, 1H), 5.16 (d, $J = 6.7$ Hz, 5-OH, 1H), 5.35 (br.s, 1-H, 1H), 5.71 (d, $J = 1.8$ Hz, 2-H, 1H), 7.22 (br.s, NH_2, 2H), 8.13, 8.21 (each s, arene-H, each 1H)

About the $Li^{\oplus}$ Gegenion Effect on α-Sulfonyl Carbanions**

By *Hans-Joachim Gais,** *Gunther Hellmann*, and *Hans Jörg Lindner*

Characteristic for lithium salts of α-sulfonyl carbanions are monomeric (in THF solution)[1, 2] and dimeric (in the crystal)[1, 3–5] O–Li contact ion pairs (cf. Scheme 1 and

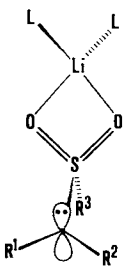

Scheme 1.

Fig. 1) as well as an anion conformation in which the C_α electron pair is *gauche* with respect to both O atoms. This conformation brings about the chirality for an α-sulfonyl carbanion whose anionic C atom bears different groups. The finding that the racemization barrier of lithio*trifluoromethyl*-sulfones (lithiotriflones) is appreciably larger than that of lithio*phenyl*sulfones recently made possible the enantioselective synthesis of a lithiosulfone that was optically stable at low temperatures.[1] It then became of interest to determine how the O-associated $Li^\oplus$ ion (+ ligands) influences the structure and dynamic behavior of an α-sulfonyl carbanion and what importance torsional effects have for the C_α–S rotational barrier of lithiotriflones. Ab initio calculations on the structural aspect of the $Li^\oplus$ gegenion effect, which is still of current interest in carbanion chemistry,[6] have already been performed.[7]

$[PhCH_2C(Ph)\text{–}SO_2R]^\ominus$
$\mathbf{1}^\ominus$, R = CF_3; $\mathbf{2}^\ominus$, R = *t*Bu; $\mathbf{3}^\ominus$, R = Ph

To answer the questions posed above, we have prepared the tetraalkylammonium salt $\mathbf{1}^\ominus/NBu_4^\oplus$, elucidated its crystal structure, and determined the enantiomerization barriers of the salts $\mathbf{1}^\ominus/NBu_4^\oplus$, $\mathbf{1}^\ominus/K^\oplus$, and $\mathbf{2}^\ominus/Li^\oplus$. In addition, we have measured the ^1H NMR and ^{13}C NMR chemical shifts for the *para* position of the α-phenyl ring in $\mathbf{1}^\ominus/NBu_4^\oplus$and $\mathbf{1}^\ominus/Li^\oplus$ as probes for the charge distribution[8] of the anion $\mathbf{1}^\ominus$. A tetraalkylammonium salt of $\mathbf{1}^\ominus$ was chosen because the large $NBu_4^\oplus$ ion, the positive charge of which is distributed over the H atoms,[9] should have a smaller and less specific effect on $\mathbf{1}^\ominus$ than the small, O-associated $Li^\oplus$ ion, which has a high charge density. Tetraalkylammonium salts of other carbanions have long been known,[10] but their crystal structure, apart from a few exceptions,[10e–g] is unknown. The crystal structure of the lithium salt ($\mathbf{1}^\ominus/Li^\oplus \cdot TMEDA)_2$ served as a reference structure;[11] in order to know exactly how the TMEDA ligands structurally influence the anion $\mathbf{1}^\ominus$, however, we determined, in addition, the crystal structure of $(\mathbf{1}^\ominus/Li^\oplus \cdot 2\ THF)_2$—the first of a THF-coordinated monolithiosulfone.[11]

Although, according to cryoscopy, $\mathbf{1}^\ominus/Li^\oplus$ is monomeric in THF solution,[1] it crystallizes as an achiral dimer ($\mathbf{1}^\ominus/Li^\oplus \cdot 2\ THF)_2$[12a] (Fig. 1) with O-associated $Li^\oplus$ ions, similarly to a lithiosulfone containing *chelate* ligands.[1,3,4] The anionic C atoms (sum of bond angles 360 °C) of the anions, which have (*M*) and (*P*) configuration, are coordinated in a planar fashion. There are no fundamental differences in the crystal structures of $(\mathbf{1}^\ominus/Li^\oplus \cdot 2\ THF)_2$ and ($\mathbf{1}^\ominus/Li^\oplus \cdot TMEDA)_2$. The exchange of the ligands has only a small effect on the conformational parameters of $\mathbf{1}^\ominus$ and practically none on its bonding parameters.

Single crystals of the ammonium salt $\mathbf{1}^\ominus/NBu_4^\oplus$ were obtained by deprotonation of (α-benzyl)benzyltriflone with Bu_4NOH and crystallization from *n*-hexane/THF. $\mathbf{1}^\ominus/NBu_4^\oplus$ is less sensitive to moisture than $\mathbf{1}^\ominus/Li^\oplus$ and melts without decomposition. In the crystal of $\mathbf{1}^\ominus/NBu_4^\oplus$[12b] there exist discrete cations and anions (Fig. 2), which are possibly joined through weak C-H···O hydrogen bonds[9,14] between the *n*-butyl and the sulfonyl groups: The distances O1-H281′ and O2-H241 (2.27 and 2.46 Å, respectively) are smaller than the sum of the van der Waals radii of O and H

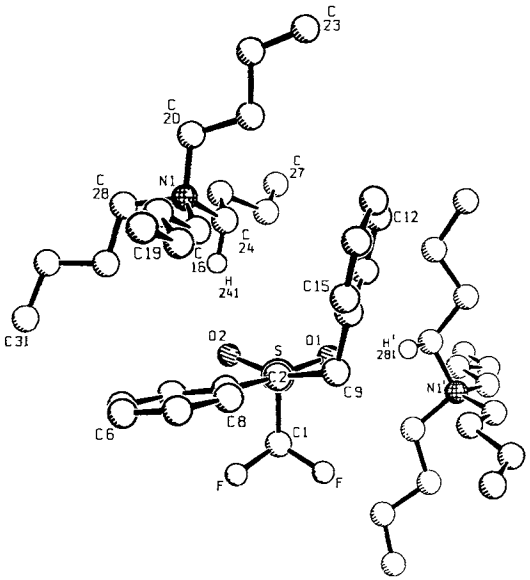

Fig. 2. Molecular structure of $\mathbf{1}^\ominus/NBu_4^\oplus$ including a $NBu_4^\oplus$ ion (symmetry operation $1-x, y-1/2, 1/2-z$) in the crystal [13]. Selected distances [Å] and angles [°]: S-C2 1.638(4), S-C1 1.826(6), S-O1 1.449(3), S-O2 1.443(3), C2-C3 1.468(5), Ni-C16 1.519(4), N1-C20 1.516(4), N1-C24 1.521(5), N1-C28 1.528(5), N1-O1 5.590, N1-O2 4.493, N1-C2 4.813, N1′-O2 6.302, N1′-C2 6.378, N1′-O1 4.124; C3-C2-S 122.7(3), C9-C2-S 116.5(3), C9-C2-C3 120.3(3), O1-S-O2 118.2(2), C1-S-C2 110.6(2), C1-S-C2-C9 − 95.2, C1-S-C2-C3 77.1, S-C2-C3-C4 − 8.5.

(2.70);[15] the angles C28′-H281′ ··· O1 and C24-H241 ··· O2 are 152° and 160°, respectively, and the H atoms of $NBu_4^{\oplus}$ involved are those with the highest positive partial charge.[9] With respect to the partial negative centers of $1^{\ominus}$, the $NBu_4^{\oplus}$ ion (Fig. 2) is positioned more symmetrically than the $Li^{\oplus}$ ions in $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$ (Fig. 1). The packing diagram of $1^{\ominus}/NBu_4^{\oplus}$ shows a quasi ionic lattice consisting of layers of parallel anion–cation helices (Fig. 3). The (mutually repulsive) CF_3 groups face one another (shortest F–F distance 4.056 Å) within a double layer of $1^{\ominus}$. The anion $1^{\ominus}$ displays

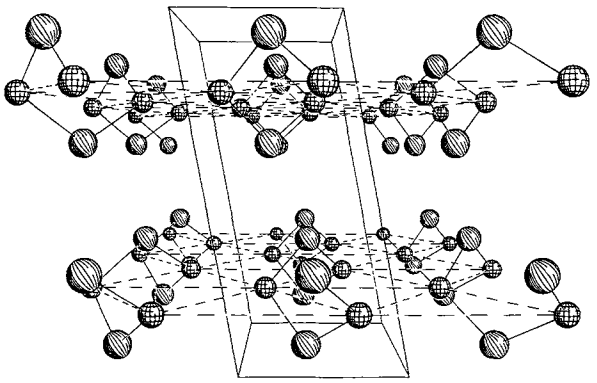

Fig. 3. Crystal packing diagram of $1^{\ominus}/NBu_4^{\oplus}$ [13]. Perspective view along the crystallographic *c* axis. Only the S (large spheres) and N (small spheres) atoms are shown.

the typical chiral conformation of the $Li^{\oplus}$-associated anions of $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$ as well as a practically planar coordinated α-C atom (sum of bond angles 359°). The α-phenyl ring in $1^{\ominus}/NBu_4^{\oplus}$ (Fig. 2) is somewhat better placed for benzyl resonance than that in $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$ (Fig. 1). Presumably owing to the thereby resulting repulsion between H4 and O2 (distance 2.162 Å) in $1^{\ominus}/NBu_4^{\oplus}$, the deviation from the ideal *gauche* position of the C_α electron pair (with respect to both O atoms) is slightly larger that in $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$. Whereas the S–O bonds of $1^{\ominus}/NBu_4^{\oplus}$ and $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$ are nearly identical in length, the C1–S bond in $1^{\ominus}/NBu_4^{\oplus}$ is 0.033 Å shorter and the C2–S bond 0.018 Å longer than those in $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$. The lengthening of the C2–S bond can be explained as resulting from the loss of a stronger n_C–$\sigma^*_{SCF_3}$ conjugation and Coulomb interaction due to the O-association of the $Li^{\oplus}$ ion. Ab initio calculations on $[MeSO_2CH_2]^{\ominus}$ and $[MeSO_2CH_2]^{\ominus}Li^{\oplus}$ (with a structure of the type shown in Scheme 1)[7] also revealed that, as a result of the O-association of the $Li^{\oplus}$ ion, the C_α–S bond is shortened (by 0.029 Å); in addition, however, a lengthening (not realized for $1^{\ominus}/NBu_4^{\oplus}$) of the S–O bond by 0.040 Å was found. The effect of the $Li^{\oplus}$ ion on the charge distribution of $1^{\ominus}$ can be probed by NMR spectroscopy in THF solution: In $1^{\ominus}/Li^{\oplus}$, the charge density in the *para* position of the α-phenyl ring is smaller than in $1^{\ominus}/NBu_4^{\oplus}$ (deshielding of the *para* H and *para* C atoms by $\Delta\delta = 0.18$ and 1.1, respectively). If the lack of lengthening of the C1–S bond on going from (α-benzyl)benzyltriflone (1.859 Å) to $(1^{\ominus}/Li^{\oplus} \cdot TMEDA)_2$ (1.853 Å)[1] and also to $(1^{\ominus}/Li^{\oplus} \cdot 2\,THF)_2$ (1.859 Å) was already somewhat surprising in view of the n_C–$\sigma^*_{SCF_3}$ stabilization,[7] even more surprising is the shortening of this bond in $1^{\ominus}/NBu_4^{\oplus}$ (1.826 Å). Whether and to what extent this is due to the repulsion between the CF_3 groups remains to be answered.

The relatively small effect of the O-associated $Li^{\oplus}$ ion (+ ligands) on $1^{\ominus}$ found so far is also reflected in its dynamic properties. The C_α–S rotational barrier of $1^{\ominus}/Li^{\oplus}$ (cf. Scheme 1, L = THF) in THF amounts to $\Delta G^{\ddagger}_{333} = 16.0$ kcal mol^{-1}.[1] For $1^{\ominus}/NBu_4^{\oplus}$ in DMSO *or* THF solution ($c = 10^{-2}$ mol L^{-1}) as well as for $1^{\ominus}/K^{\oplus}$ in DMSO solution ($c = 2 \times 10^{-2}$ to 2×10^{-1} mol L^{-1}), $\Delta G^{\ddagger}_{327}$ values of 15.7 ± 0.2 kcal mol^{-1} were determined by ^{1}H NMR spectroscopy on the basis of the exchange of the nonequivalent methylene protons.[16, 17] This value corresponds to the C_α–S rotational barrier of the gegenion-free anion $1^{\ominus}$, since, in DMSO solution with $K^{\oplus}$[18] and presumably also with $NBu_4^{\oplus}$ as gegenion,[19] ion pairing plays only a minor role. This is supported, for example, by the observation that the ^{1}H and ^{13}C NMR chemical shifts for the *para* position of the α-phenyl ring of $1^{\ominus}/K^{\oplus}$ ($\delta = 6.42$ and 116.3, respectively) in DMSO solution ($c = 2 \times 10^{-1}$ mol L^{-1}) do not change either upon dilution by a factor of 100 or upon addition of one equivalent of [2.2.2]cryptand. The ^{1}H and ^{13}C NMR chemical shifts of $1^{\ominus}$ in DMSO solutions of the salts $1^{\ominus}/K^{\oplus}$ and $1^{\ominus}/NBu_4^{\oplus}$ are practically identical.

The C_α–S rotational barrier of the lithiotriflone $1^{\ominus}/Li^{\oplus}$ is appreciably greater than that of the lithiophenylsulfone $3^{\ominus}/Li^{\oplus}$ ($\Delta G^{\ddagger}_{215} = 9.6$ kcal mol^{-1}, THF).[1] We conclude from the following results that this finding is due *primarily* to the stronger n_C–$\sigma^*_{CF_3}$ conjugation and Coulomb interaction and not to the larger torsional effects:[21] As determined by NMR spectroscopy, the $\Delta G^{\ddagger}_{283}$ value for the enantiomerization of the lithio-*tert*-butylsulfone $2^{\ominus}/Li^{\oplus}$ in THF is "only" 13.5 ± 0.2 kcal mol^{-1} ($c = 2.8 \times 10^{-1}$ mol L^{-1}),[16] despite the still increased steric hindrance to C_α–S rotation, and, as shown by the ^{1}H and ^{13}C NMR spectra, the charge density in the *para* position of the α-phenyl ring is appreciably smaller for $1^{\ominus}/Li^{\oplus}$ than for $2^{\ominus}/Li^{\oplus}$ and $3^{\ominus}/Li^{\oplus}$ [deshielding of the *para* H(C) atoms by $\Delta\delta = 0.33$ (4.5) and 0.21 (3.5), respectively, all in THF]. According to cryoscopic measurements in THF (8.7×10^{-2} mol L^{-1}) at −108 °C, the salt $2^{\ominus}/Li^{\oplus}$ is also monomeric[22] and most likely contains two coordinated THF molecules.

Experimental Procedure

$1^{\ominus}/NBu_4^{\oplus}$: (±)-(α-Benzyl)benzyltriflone (314 mg, 1.0 mmol) was dissolved in 5 mL of Et_2O and the resulting solution was treated dropwise at 0 °C with 10 mL of a 0.1 M solution of Bu_4NOH in *i*PrOH. The reaction mixture was allowed to warm to 25 °C and the volatile components were then removed at 25 °C/10^{-3} Torr. The solid residue, obtained by drying at 40 °C/10^{-3} Torr, was dissolved in 15 mL of *n*-hexane/THF (4:3) by warming to 60 °C under argon. Cooling the solution to 0 °C afforded light yellow needles of $1^{\ominus}/NBu_4^{\oplus}$ within 12 h. The crystals were collected by filtration under argon, washed with *n*-hexane, and dried (25 °C/10^{-3} Torr). Yield 466 mg (84%), m.p. 118–120 °C; correct elemental analysis.

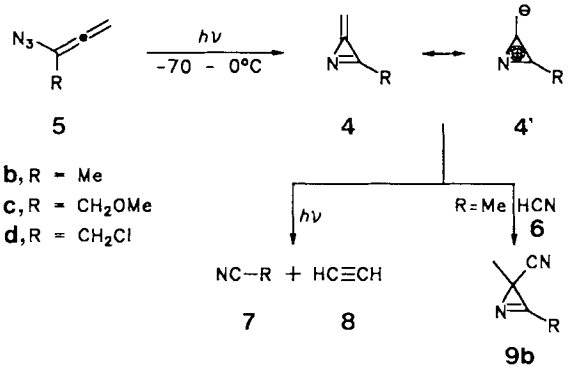
2-Methylene-2*H*-azirines by Photolysis of 1-Azidoallenes**

By *Klaus Banert** and *Manfred Hagedorn*

Although cyclopropenone **1**[1] has been known for several decades, and the first synthesis of the methylenecyclopropene **2**[2] was reported a few years ago, only plausible indications but no unequivocal proof could be found for derivatives of the aza compounds **3**[3] and **4a**.[4, 5] We report here on the first trapping reactions which confirm the existence of 2-methylene-2*H*-azirine **4a** as well as on the methyleneazirine derivatives **4b–d** and their spectroscopic data.

1 **2** **3** **4a**

The recently accessible 1-azidoallenes **5**[6] have proven to be ideal precursors for methyleneazirines. The photolyses[7] of **5b–d** generate **4b** (yield $\le 54\%$), **4c** ($\le 59\%$) and **4d** ($\le 60\%$), respectively. The yield of methyleneazirine is limited by a photochemical secondary reaction leading to the fragments **7** and **8**.[7] Prolonged radiation leads to complete degradation of **4b–d**, with almost quantitative formation of **7b**, **7c** and **7d**, respectively (yields referred to **5**), without any further products being detectable. At room temperature, solutions of **4b** are stable at most for 1 h, while concentrated solutions of **4c** or **4d** are stable for only a few minutes.



Although the methyleneazirines **4b–d** already polymerize rapidly in solution,[8] their structure can nevertheless be confirmed by spectroscopic data (Table 1). In the region of double-bond stretching vibrations, the IR spectrum of **4b** resembles the spectra of substituted methylenecyclopropenes,[9] whereas the frequency of the C=N stretching vibration is shifted considerably compared to that of simple 2*H*-azirines.[10] A participation of the dipolar mesomer **4'**, which contains an aromatic azirinylium ion[11] as partial structure,

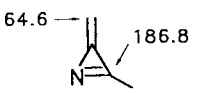
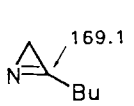
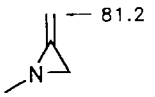
[a] IR and NMR spectra in $CDCl_3$ (if not otherwise stated); ^{1}H NMR at 80 and 400 MHz, ^{13}C NMR at 100.6 MHz; GC-MS at 70 eV; $\tilde{\nu}$ in cm^{-1}, J in Hz.

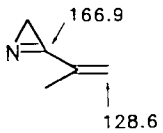
is manifested in the ^{13}C-NMR data of the 2-methylene-2*H*-azirines: the signal for C-3 lies extremely downfield, while a relatively small δ value is measured for the sp^2-hybridized methylene carbon. This is demonstrated by a comparison with simple 2*H*-azirines[10] and the heterocycles **10**,[12] **11**,[13] and **12**[14] (Fig. 1). Analogous, but more marked shifts are found for the ^{13}C-NMR signals of **2**[2a] upon comparison with the data for cyclopropene[15] and methylenecyclopropane.[16]



4b







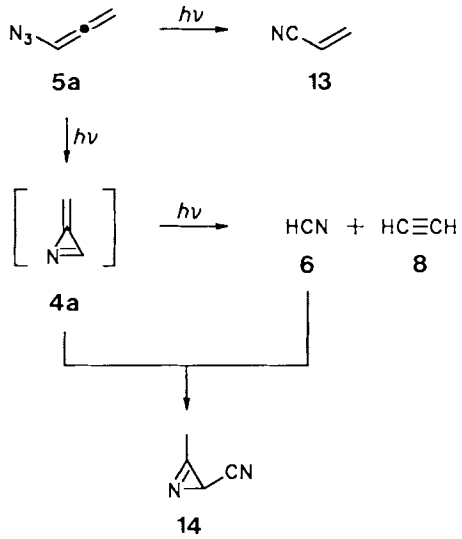
10 **11** **12**

Fig. 1. Selected ^{13}C-NMR data (δ values) of **4b** and of **10**, **11** [13], and **12** (for comparison).

4b reacts with hydrogen cyanide **6** in chloroform to give the azirine **9b** in 84% yield. The same product (**9b**) is obtained upon photolysis of **5b** in the presence of an excess of **6** (74%, based on **5b**). In this case the irradiation must be conducted at 0 °C, because the addition of **6** to **4b** cannot compete with the photochemical decomposition to **7b** and **8** at low temperatures.

Photolysis of the azidoallene **5a** yields the products **6**, **8**, **13** and **14** whose compositions strongly depend upon the temperature (0 to −70 °C) and the concentration of **5a**.[7] Whereas the yield of **8** decreases with increasing temperature (−70 °C 35%, −30 °C ca. 9%, 0 °C 7%), that of **13** (24–30%) remains almost constant. Hydrogen cyanide **6** can be detected only after irradiation at low temperature (ca. 40% at −70 °C). In contrast **14** is rather formed at higher temperatures (2–4% at 0 to −30 °C, traces at −70 °C).

We consider **6**, **8** and **14** as secondary products of the parent compound **4a** ("1-azatriafulvene"). This seems plausible when one compares this reaction with the reactions of **4b–d**. How effectively the formation of **14** from **4a** and **6** can compete with the photoreaction **4a** → **6** + **8** is apparently dependent upon the temperature and the concentration of hydrogen cyanide **6**. When **5a** is photolyzed at 0 to −70 °C in the presence of an excess of added **6** the yield of **14** increases to 54–57%, whereas it hardly changes in the case of **13**, and decreases in the case of **8**. Since a good yield of **14** can also be obtained at −70 °C, the addition **4a** + **6** → **14** presumably proceeds much more rapidly than the analogous reaction **4b** + **6** → **9b**. Acrylonitrile **13** is most likely generated not from **4a**, but via another route from **5a**. This is the reason why the yield of **13** proves to be almost independent of the temperature and of the concentration of **6**.



We are presently trying to characterize the, presumably very unstable,[17] compound **4a** spectroscopically at still lower temperatures.

[2.2](4,4')Azobenzenophane

By *Nobuyuki Tamaoki,* Kenichi Koseki,* and *Tsuguo Yamaoka*

In macrocyclic compounds containing two azobenzene units in the skeletal framework the rate of isomerization of the azobenzene unit on one side is dependent on the conformation (*trans* or *cis*) of the other azobenzene unit. According to *Rau* et al. the *cis-trans* isomerization of an azobenzene unit on one side of the [3.3]azobenzenophane **5** occurs 1000 times faster at 25 °C when the other azobenzene unit is *trans* configurated instead of *cis* configurated.[1] The shorter the bridges between the two azobenzene units are, the more significant is the effect of the one azobenzene unit on the rate of isomerization of the other. In the extreme case (direct bonding between the two azobenzenes), a *trans, cis(tc)*-conformation may not exist because of too large a strain.

In this communication we report on a simple synthesis of [2.2](4,4')azobenzenophane **1**, on spectroscopic data which suggest deformed azo linkages in **1** in solution, and on the extremely rapid thermal isomerization of the *tc* form to the *tt* form.

Several azobenzenophanes whose bridges contain more than two atoms each have been synthesized.[1,2] Many [2.2]- and [2.2.2]cyclophanes have also been synthesized, but usually by a method in which the cyclization process is accomplished by "bridge-building".[3] The reaction conditions for "bridge-building", however, seem to be too harsh for azo linkages. We describe here a synthetic route in which the azobenzene chromophores are first formed in the final step, so that the exposure of azo linkages to harsh synthetic conditions can be circumvented.[4,5] A dilute solution of 1,2-bis(4'-nitrophenyl)ethane in dry THF was reduced with

$LiAlH_4$. From this reaction mixture the macrocyclic compounds **1**–**3** were isolated by column chromatography.

The spectroscopic data of the compounds **1**–**3** and of the model compound 4,4'-dimethylazobenzene **4** are summarized in Table 1. The ^{1}H-NMR signals of the aromatic protons shift to higher magnetic field as the number of azobenzene units is decreased. This finding is understandable if one assumes that the azobenzene units are arranged triangularly and quadrilaterally in compounds **2** and **3**, respectively, and face-to-face in **1**. In the macrocycles **1**–**3** the angle between the benzene rings, which are linked by ethylene bridges, grows and the mutual effect of the magnetic anisotropy between benzene units decreases.[6] In the UV/VIS spectra the molecular extinction coefficient (ε) from the $\pi \rightarrow \pi^*$ transition per azobenzene unit becomes smaller as the number of azobenzene units is decreased, while ε for the $n \rightarrow \pi^*$ transition of an azobenzene unit in **1** is exceptionally large. On the basis of CPK models this spectral behavior is most reasonably explained in terms of the bent conformation shown in Figure 1. In this conformation the n orbital of an azo linkage could have better overlap with the π orbital.[7,8]

Table 1. Spectroscopic data of the compounds **1**–**4**.

	$\pi\pi^*$ [a]		$n\pi^*$ [a]		^{1}H NMR [b]	
	$\varepsilon(\lambda_{max}$ [nm])	ε/unit	$\varepsilon(\lambda_{max}$ [nm])	ε/unit	CH_2	arene
1	41300(328)	20700	2400(462)	1200	3.07	6.79, 7.24
2	74600(329)	24900	2200(442)	750	3.08	6.98, 7.53
3	116000(333)	29000	3000(440)	750	3.06	7.03, 7.70
4	24900(339)	24900	880(442)	880	2.38	7.24, 7.76

[a] In benzene. [b] δ value in $CDCl_3$.

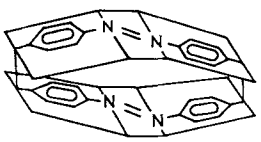

Fig. 1. Bent structure of the azobenzene units of **1**

Upon exposure to 366-nm light, **1** isomerizes like azobenzene to the photostationary state, whereby 88% of the initial absorbance at 328 nm (λ_{max} of the $\pi \rightarrow \pi^*$ transition band) disappears and the absorbance around 440 nm ($n \rightarrow \pi^*$ tran-

sition band) increases. This means that more than 88% of compound **1** in *tt*-form is photochemically isomerized to the *cc*-form. The photostationary state can be reversed by slow thermal reaction or 436-nm irradiation. If the photoisomerization by 366-nm light is arbitrarily interrupted, a small amount of rapid thermal recovery of **1** in the spectrum is also observed. A similar phenomenon observed in the case of **5** was attributed to the thermal isomerization of the *tc*-form to the *tt*-form (*tc* → *tt*).[1] UV/VIS spectroscopically determined thermal isomerization data for *tc* → *tt* and *cc* → *tc* in the case of **1**, and for *c* → *t* in the case of **4** are listed in Table 2. The thermal isomerization *tc* → *tt* in the case of **1** is

Table 2. Rate constants and activation parameters for the thermal isomerization of **1** and **4** in benzene.

	Type of isomerization	k_{298} [s^{-1}]	E_a [kcal mol^{-1}]	$\Delta S^{\neq}_{298}$ [cal K^{-1}]
1	*tc* → *tt*	4.54×10^{-2}	14.0	− 19.8
	cc → *tc*	4.53×10^{-6}	22.2	− 10.5
4	*c* → *t*	4.53×10^{-6} [9]	21.7 [9]	− 12.0 [9]

10000 times faster than *cc* → *tc* for **1** or *c* → *t* for **4** at 25 °C. This difference is 10 times larger than in the case of the [3.3]azobenzenophane **5**. This is mainly due to the extremely low activation energy E_a of the *tc* → *tt* isomerization in **1**. Thus, the shorter the chains which connect the two azobenzene units, the less stable is the *tc* form.

Experimental

A solution of 9.6 g (35 mmol) of 1,2-bis(4′-nitrophenyl)ethane in 240 mL of dry THF was added dropwise in 3 h to a suspension of 6.7 g (180 mmol) of $LiAlH_4$ in 400 mL of dry THF under a nitrogen atmosphere. After 21 hours' stirring, 200 mL of water was carefully added to the reaction mixture. The precipitate was filtered off and the THF was removed from the water/THF mixture by distillation. A further orange solid that precipitated in the water was separated by filtration, and then the solid was extracted by dichloromethane. The dichloromethane solution was washed with water and evaporated down. The residue was purified by column chromatography (silica gel and dichloromethane/chloroform (1:1 v/v)). The fractions with R_f values of 0.90, 0.86 and 0.81 were evaporated down, recrystallized by slow evaporation of dichloromethane solution and identified as **3**, **2** and **1**, respectively, by ^1H NMR, FD-MS and satisfactory elemental analyses [10]. **1**: 22 mg (0.30%); m.p. above 305 °C, $m/z = 416 (M^{\oplus})$. **2**: 38 mg (0.52%); m.p. 286–288 °C, $m/z = 624 (M^{\oplus})$. **3**: 17 mg (0.23%); m.p. above 305 °C, $m/z = 832 (M^{\oplus})$.

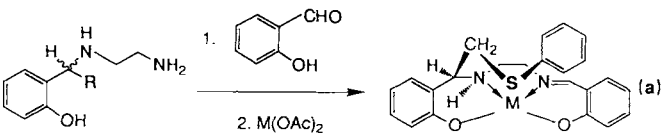
Oxygen Activation with Transition Metal Complexes: Nickel-Catalyzed Oxidation of a Pentacoordinated Substrate **

By *Albrecht Berkessel,* Jan. W. Bats, and Christine Schwarz*

Selective oxidations, e.g. the epoxidation[1] and dihydroxylation[2] described by *Sharpless* et al. count among the important methods of modern organic synthesis. The ultimate aim in the development of methods for selective oxidation can be seen as the stereoselective functionalization of non-activated substrates with the readiest available oxidant, namely molecular oxygen.

Hydroxylations with microorganisms[3] or with isolated monooxygenases such as cytochrome P-450[4] fulfill the aforementioned requirements, but, on the other hand, are subject to the side effects of enzymatic reactions, e.g. undesired substrate selectivity. An alternative approach is the development of low molecular weight catalysts, which in the ideal case are supposed to make selective reactions possible on any desired substrate ("enzyme models"). Molecular oxygen has already been successfully used as selective oxidizing agent, both with some monooxygenase models[5–7] as well as with model compounds for dioxygenases such as the catechol dioxygenase.[8a–c] We have now extended the principle used by dioxygenases and their models to initiate or steer the oxygen transfer by *coordination of oxygen and substrate to a suitable transition metal ion*,[8,9] to an oxidation reaction without natural precedent and with a metal center ($Ni^{2\oplus}$) as yet unknown for oxygenases.

By reaction of the diamine **1a** with salicylaldehyde and the acetate of $Co^{2\oplus}$, $Ni^{2\oplus}$ or $Cu^{2\oplus}$ the chelate complexes *rac*-**2a–c** were obtained [Eq. (a)], of which *rac*-**2b** and *rac*-**2c** were characterized by X-ray structure analyses.[10]



1a: R = CH_2-S-Ph

rac-**2a,b,c** 90–95 %

2a: M = Co
2b: M = Ni
2c: M = Cu

Figure 1 shows the result of an X-ray structure analysis of *rac*-**2b**. The nickel ion is coordinated equatorially to the O and N atoms of the ligand, while the S atom of the thioether side chain occupies an axial position. In the crystal the octahedral coordination of the metal ion is completed by a phenolate O-atom of a second (enantiomeric to the first) molecule (Fig. 1).

In *solution* this sixth coordination site can either be occupied by a solvent molecule or it could coordinate molecular oxygen. Indeed, the complex *rac*-**2b**, which is stable in the crystalline state, reacts rapidly with oxygen in solution (ca. 2–3 h at room temperature, a few minutes in EtOH under reflux) according to Scheme 1 to give the Ni(salen) complex

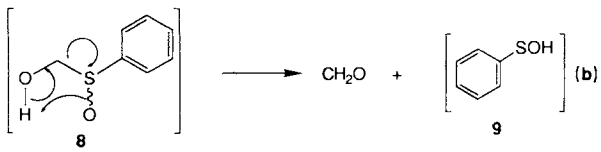
4 (H_2salen = bis(salicylidene)ethylenediamine). The thioether side chain of *rac*-**2b** undergoes degradation thereby, to formaldehyde and diphenyl disulfide.

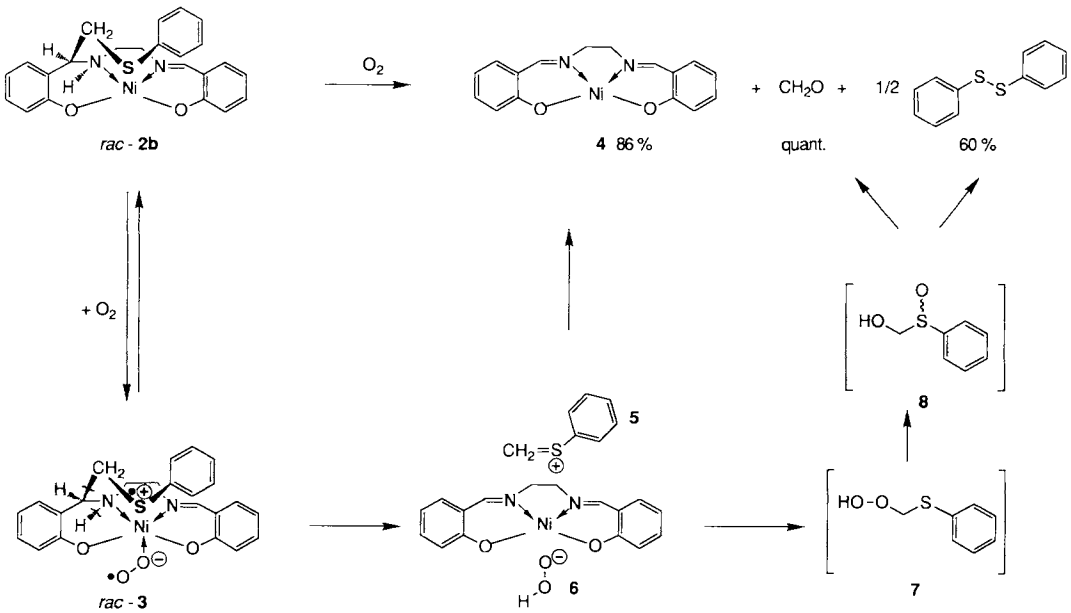
Scheme 1 also contains a mechanistic interpretation of the oxidation beginning with the binding of oxygen to the free axial coordination site at the Ni atom of *rac*-**2b**. *Reversible* binding of molecular oxygen is well documented for a plethora of $Co^{2\oplus}$ chelate complexes,[6,11,12] and the analogous adduct formation of a specific group of macrocyclic $Ni^{2\oplus}$ complexes has also been reported.[13] As follows from ESR and structural data,[6,9,11,12] O_2-adducts such as *rac*-**3** (Scheme 1) can be described as complexes of the superoxide anion with the metal ion in the $(n+1)$ oxidation state. In the case of *rac*-**3** the electron deficit at the metal center can be balanced out by the axially coordinated S-ligand. Radical abstraction of the amine H atom and subsequent homolytic β-cleavage[14] lead to the salen-complex **4** and the ionic fragments **5** and **6**. Their combination to give (phenylthio)methyl hydroperoxide **7** and subsequent intramolecular oxygen transfer afford **8**, the precursor of formaldehyde and diphenyl disulfide. Loss of formaldehyde from **8** leads to formation of benzenesulfenic acid **9** [Eq. (b)].[15] This is not isolable and like numerous other unstable arenesulfenic acids



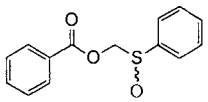
reacts further to give the corresponding diaryl disulfide—along with other disproportionation products.[16,17] Only in exceptional cases can the sulfenic acids be isolated.[16,17]

By deuteration of the methylene group adjacent to the S atom in *rac*-**2b** (Scheme 1) and ^{2}H- and ^{1}H-NMR spectroscopic monitoring of the atmospheric oxidation it could be shown that this CH_2 group is converted *exclusively* into formaldehyde, and that it is the *only* source of formaldehyde.

The assumption that formation of the labile (hydroxymethyl)phenyl sulfoxide **8** occurs in the oxidation of *rac*-**2b** could be substantiated by a control experiment with the stable benzoyl-protected derivative **10**:[18] hydrolysis of **10** with



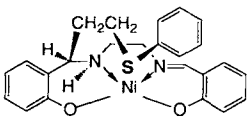
Scheme 1. Mechanistic interpretation of the oxidation of *rac*-**2b**. The yields of diphenyl disulfide and **4** refer to isolated, analytically pure material; the yield of formaldehyde was determined by ^{1}H- and ^{2}H-NMR spectroscopy.



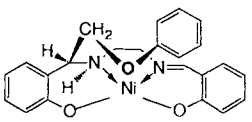
10

potassium hydroxide in methanol afforded formaldehyde (^{1}H-NMR spectroscopically quantitative as $DO-CH_2-OCD_3$ in CD_3OD) and diphenyl sulfide (61%) as the only chromatographically isolable product.[19] The yields of formaldehyde and diphenyl disulfide were thus comparable with those obtained in the atmosheric oxidation of *rac*-**2b** (Scheme 1).

For further examination of the mechanism of oxidation of *rac*-**2b** (Scheme 1) the $Ni^{2\oplus}$ complexes *rac*-**11** and *rac*-**12** were prepared from the corresponding diamines **1b**



rac-**11**



rac-**12**

($R = CH_2CH_2-S-Ph$) and **1c** ($R = -CH_2-O-Ph$) according to Equation (a). Both complexes are stable towards oxygen. In the case of *rac*-**11** the structural requirements for the formation of the sulfonium ion **5** by homolytic β-cleavage[14] (as in the O_2-adduct *rac*-**3**, Scheme 1) are lacking; in the oxygen analogue *rac*-**12**, oxidation of the axially coordinated heteroatom cannot take place.

The Co-complex *rac*-**2a** proved to be oxidizable, as shown by the rapid formation of diphenyl disulfide. In contrast, the Cu-complex *rac*-**2c**, as also the metal-free ligand, was found to be inert towards oxygen. The crystal structure of *rac*-**2c** is essentially the same as that of the Ni-complex *rac*-**2b** (Fig. 1); the distances between the central ion and the axially coordinated heteroatoms, however, are—as to be expected for a d^9 ion—significantly longer (Ni–S: 2.575(2); Cu–S: 2.896(2) Å; Ni–O_{ax}: 2.109(4), Cu–O_{ax}: 2.543(4) Å). These differences, in particular the different M–S distances possibly explain the difference in reactivity. Also, for the same ligand a higher half-wave potential $M^{2\oplus}/M^{3\oplus}$ is found for copper chelate complexes than for the corresponding nickel complexes.[13,20] This property is likewise detrimental to the oxygen coordination[6,11-13] and thus to the overall reaction according to Scheme 1.

Experimental

Preparation of the complexes *rac*-**2a–c, 11, 12**: A solution of 0.50 mmol of the diamine **1** [21] in 5 mL of ethanol was treated with 61.0 mg (0.50 mmol) of salicylaldehyde. The resulting yellow solution was added dropwise with stirring into a solution of 0.50 mmol of the metal acetate in 3 mL of distilled water at ca. 50 °C. The incipient precipitation was completed by addition of 30 mL of H_2O. After filtration and drying over P_2O_5 in vacuo the complexes *rac*-**2, 11, 12** were obtained as microcrystalline powders in 90–95% yield. C,H,N analyses: Δ% < 0.3.

Crystals of *rac*-**2b** and *rac*-**2c** suitable for an X-ray structure analysis were obtained by slow cooling of their solutions in MeOH in the absence of O_2.

Atmospheric oxidation of *rac*-**2b**: The complex (100 mg, 0.223 mmol) was dissolved with stirring in warm ethanol (5 mL); upon contact with oxygen the color of the solution became darker (reddish brown). When no further darkening was observed, the solution was partially evaporated, cooled, and filtered under suction. The Ni(salen) complex was obtained in the form of reddish-brown crystals (62 mg, 86%). Chromatographic separation of the mother liquor on silica gel (elution with dichloromethane/hexane 1/1) furnished 29 mg (60%) of diphenyl disulfide.

For the qualitative detection of formaldehyde, air can be bubbled through a solution of *rac*-**2b** in $CHCl_2$–$CHCl_2$ and fed into a solution of 2,4-dinitrophenylhydrazine or 5,5-dimethyl-1,3-cyclohexanedione (dimedone). For the quantitative NMR spectroscopic determination of formaldehyde (as hemiacetal) the atmospheric oxidation of *rac*-**2b** was carried out in $CDCl_3$ (2% EtOH) (^{1}H-NMR) and that of deuterated *rac*-**2b** in $CHCl_3$ (2% EtOH) (^{2}H-NMR). The yields of formaldehyde determined in this way were quantitative. The 1:1 stoichiometry of the reaction of *rac*-**2b** with oxygen was determined by measured addition of air with concomitant monitoring of the reaction by UV/VIS.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Beilstein Handbook of Organic Chemistry. 4th Edition. 5th Supplementary Series. Volumes 17, 18, and 19. Edited by *R. Luckenbach*. Springer, Berlin 1984–1988. 30572 pp., hardcover, DM 90440.00

With the appearance of sub-volume 17/1, the first in the 5th Supplementary Series of the 4th Edition, in 1984 and sub-volume 19/12 in 1988 all the chalcogen-containing heterocycles reported in the period 1960–1979 have now been fully described in "Beilstein".

This is an overwhelming work considering that in 35 sub-volumes and more than 30000 pages 200307 individual compounds have been described. In the accompanying Subject Index to the sub-volumes some 219296 names are listed; however, several compounds are cited more than once under different names. Cumulative Subject Indexes covering the contents of Volumes 17–19 will soon appear and should be completed by 1990.

The contents of Volumes 17–19 cover the oxygen heterocycles. Volumes 17 (11 sub-volumes) and 19 (12 sub-volumes) deal with oxygen heterocycles with one oxygen atom in the ring while Volume 19 (12 sub-volumes) is devoted to the oxygen heterocycles with two or more ring oxygens. Following the traditional Beilstein system, the heterocycles containing higher chalcogens in the ring are dealt with as derivatives of the corresponding oxygen compounds and follow them accordingly. A very useful feature is the inclusion, in each sub-volume, of a short introduction to the Beilstein system. With this even the unpractised user can soon locate the compound sought for. Additional help is available in the form of the booklet "How To Use Beilstein" published by the Beilstein Institute in German, English, and Japanese, and a "German-English Dictionary" containing the most important formulations used in Beilstein. These are both available free of charge. For those who wish to have electronic access to Beilstein the search program "SANDRA" is available. In this respect Beilstein has also managed a smooth transition into modern developments and so fulfilled the needs of all those users to whom date processing is a daily routine.

Use of the sub-volume Subject Index is facilitated by the inclusion of a short introduction to the nomenclature used by Beilstein. In addition, in sub-volumes 17/1, 18/1 and 19/1, a comprehensive list of the prefixes used and a dual language explanation of the stereochemical descriptors has also been included. These are all valuable aids, enabling one, on the one hand, to find compounds easily in Beilstein and, on the other, to name new compounds correctly. It would be a great advantage if the names thus generated were accepted by the primary publications.

On taking a closer look at Volumes 17–19 one finds that industrially important compounds, e.g. ethylene oxide (sub-volume 17/1), ecologically relevant substances, e.g. chlorinated dibenzodioxins (sub-volume 19/2), and natural products, e.g. steroids (sub-volume 19/3) are all represented. The foregoing is only an indication of the wide selection of compounds which are dealt with. Precisely in the case of the dibenzodioxins one becomes aware of the advantages of the Beilstein system. One finds chlorinated compounds containing the dibenzodioxin skeleton, with the chlorine atoms in all possible positions, are dealt with one after the other following the parent compound. This gives the user an overview of related compounds which in practice allows him or her to make a substructure search in a printed medium. In addition, Beilstein enables the user to see the relationships between stereoisomers as they so often occur in natural products. In sub-volume 19/3, for example, there are entries for seven stereoisomeric spirostan-2,3-diols which have been described and assigned their correct stereodescriptors.

The layout of the individual entries follows a well established pattern. Details about the constitution and configuration of a compound, which have often been clarified and corrected by the Beilstein team after taking into consideration the latest available literature, are followed by an account of the natural occurrence, extraction from natural products, preparation, synthesis, and purification. It is worth mentioning that biochemical methods are also dealt with here if they have been used on a preparative scale.

There then comes the factual part, which is the largest and, certainly for the user looking for data, the most important part of the entry. Here the structure and energy parameters as well as the physical properties, including spectroscopic data, are presented. Special mention should be made of the plethora of numerical data in Beilstein, which makes it one of the largest factual databases in the world. It still has not dawned on many chemists that a wealth of information is tucked away in Beilstein. This should be emphasized more strongly in future. As a result of this data collection, Beilstein has become a link between the spectroscopic databases dealing with relatively few compounds and the bibliographic databases of Chemical Abstracts Services (CAS). Due to the method of indexing it is difficult to make a directed search for data in Chemical Abstracts.

The entry continues with a description of the chemical behavior and addition compounds and concludes with an account of the derivatives.

Changing the language in which Beilstein is published from German to English has made further compression in the text of the entries possible. This is particularly noticeable in the descriptions of preparative methods and chemical behavior, which are presented in telegraphic style. For the chemist who is exclusively interested in preparative work this compression – relative to that in the earlier Supplementary Series – may be painful. In exchange, however, he gets an enormous increase in the amount of physico-chemical data: this is to be welcomed. In this area especially, functions have been assumed from which the "classic" Beilstein user can only profit.

The "Beilstein Online Database" must also be viewed in this light. The first part of this database (at the time of writing) contains the heterocycles reported in the period 1830–1959 which were described in Volumes 17–27 of the Main Series and Supplementary Series I–IV. The volumes reviewed here form an extension to the database. Together

the two constitute a valuable supplement to the CAS databases.

In this connection it would be useful if the CAS Registry Numbers were available in the text as well as in the indexes so that one could move more easily from one reference work to the other.

The overall impression of the volumes reviewed is excellent, and how could it be otherwise for this standard work on organic chemistry with its new, up-to-date format? Both the publisher and the Institute have done everything possible to make "Beilstein" attractive to the synthetic chemist. He should make the most of what is offered.

Non-Metal Rings, Cages and Clusters. By *J. D. Woollins*, Wiley, Chichester 1988. ix, 124 pp., hardcover, £ 25.95. – ISBN 0-471-91592-0

The rapid progress made during the last 25 years in the chemistry of cyclic nonmetal compounds is still not reflected in the contents of most textbooks. This very area, however, is particularly well suited to making students clearly aware, at an early stage, that the chemistry of all nonmetal elements (including carbon) forms a unified whole. Therefore, this introductory book, which originated as the text of a lecture, unquestionably fulfills a real need by serving as an appetizer to this area of chemistry.

After a short presentation of the most important fundamental concepts and synthetic strategies, the following three chapters discuss a series of exemplary nonmetal ring systems, from electron-deficient compounds and classical ("electron-precise") compounds to electron-rich compounds. Understandably, the limited coverage of the book necessitates a somewhat arbitrary selection of compounds or, as the author puts it, the selection "should be regarded as my choice from a very large box of chocolates". However, the limited number of compounds makes it possible to indicate numerous relationships and structural similarities between different classes of compounds. This feature is especially valuable for students, who, all too often, organize their chemical knowledge in separate boxes according to element symbols. In this respect, however, it would have been useful to have included at least some examples of cyclic hydrocarbons.

The chapter on electron-deficient compounds contains a good overview on structures, bonding, syntheses, and properties of boron–hydrogen compounds and metallaboranes. The importance of ^{1}H and ^{11}B NMR spectroscopy for structural elucidation is made clear through several representative spectra. However, the section on polyhedral boron subchlorides is much too short, while the fragmentary treatment of transition-metal clusters could have been omitted in view of the book's title.

The chapter on normal ("electron-precise") compounds covers the most important homo- and heterocyclic ring systems of sulfur, phosphorus, and silicon. The cyclic silicates and metaphosphates are not mentioned, since this would have exceeded the intended coverage of the book. Lacking in the discussion of homocyclic silicon compounds is mention of the three-membered ring as well as of the existence of fused ring systems; this also holds true for the large number of corresponding silazanes. Similarly, the discussion of phosphorus omits mention of the interesting cyclic acid anions with P–P bonds.

The last chapter on electron-rich compounds presents a concise discussion, illustrated by numerous formula schemes, of what is currently known about borazenes, phosphazanes, phosphazenes, sulfur–nitrogen rings and cages, and polychalcogen cations.

The book is directed at undergraduates with the goal of awakening their interest in this area of molecular chemistry. Helpful in this respect is the list of references, in particular key review articles, at the end of each chapter. Furthermore, the two-volume work of *Haiduc-Sowerby* is recommended as a source of additional information.

Not surprisingly, the treatment of such a huge amount of information and the attempt to systematize it leads to some errors. Apart from obvious typographical errors (like the name *Gillespie* on page 5), these can sometimes lead to confusion, especially for students. For example, on page 7, the formation of P_3H_5 from P_2H_4 is not a polymerization. On page 15 (sixth line from the bottom), electron pairs would be correct; on page 49, dichlorodisulphane; on page 54, P_4H_6 and P_7H_3; on page 55 in Fig. 3.11, Li_2P_{16}; and on page 67 in Fig. 3.18, $P_3O_9^{3\ominus}$. The "equation" for the synthesis of P_5H_5 (page 54) is incomprehensible and the formation of P_9Me_3 (page 55) is not a redox reaction with evolution of elemental chlorine. In addition, several references to the literature contain errors.

Despite these privisos, this highly readable book offers an initial, informative overview of the heterogeneous area of cyclic nonmetal compounds and is also suitable as an introduction to those wanting to study nonmetal rings and cages. Moreover, chemists interested in preparative and structural chemistry will find the book highly interesting. The book is excellent in appearance, although somewhat overpriced.

Marianne Baudler [NB 1039 IE]
Institut für Anorganische Chemie
der Universität Köln (FRG)

Industrial Inorganic Chemistry. By *W. Büchner, R. Schliebs, G. Winter* and *K. H. Büchel*. Translated by *D. R. Terrell*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. 614 pp., hardcover, DM 145.00. – ISBN 3-527-26629-1/0-89573-610-1

This English translation of a 1984 German edition has been updated and supplemented with data from the U.S. industrial inorganic chemicals market. The original authors were all with Bayer AG in 1984, and have produced a book which includes a broad range of "technical chemistry". It is organized into "primary inorganic materials" (H_2, H_2O, peroxides, N-compounds, P-compounds, S-compounds, halogen compounds, metals and their compounds), then into product classes (mineral fertilizers, silicones, zeolites, inorganic fibers, construction materials, ceramics, wear-resistant materials, pigments) as well as nuclear fuel principles and production. The organization by element makes it ideal for lecturers wishing to illustrate an inorganic chemistry course with applications (e.g., video cassettes, optical fibers, microelectronic devices).

The advertising claims that economic aspects, process energy balance and ecological consequences are treated, and that the intended use is not only the classroom (abundant marginal notes repeat central points of the text), but also in business and law. Indeed, there is an abundance of tables of workable terrestrial reserves, of production, and of consumption (e.g., annual asbestos production, by country, to six significant digits!). Ecological matters are treated only

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0101-0110 $ 02.50/0

superficially, however, (e.g., one sentence about asbestos "toxicity"). Since any single topic is treated very briefly, references are crucial for effective non-classroom utilization of such a book. While the book is liberally referenced, these are frequently limited to standard reference encyclopedias of chemical technology and to statistical yearbooks. There are too few references to more current and specialized review articles, especially those describing scientific (or ecological) rather than technological points. Likewise, certain topics are referenced with only older literature (e.g., silicones); a topic as modern as magnetic coatings is only thinly referenced.

It goes without saying that I learned a great deal from this book: the molecular mechanism of chrome tanning of leather, that Norway exceeds the U.S. in production of ferrosilicon, that South Africa possesses the predominant world reserve of chromite ores, "... and the world's dependence thereon can therefore not be overlooked". The book even encourages self-development: I was forced to consult my dictionary to learn the meaning of nacreous.

In addition to all of the above applications, this book will also be useful to the inorganic researcher seeking a bridge into new research areas with problems worthy of his/her attack.

Kenneth G. Caulton [NB 997 IE]
Department of Chemistry, Indiana University
Bloomington, IN (USA)

Bromine Compounds. Chemistry and Applications. Edited by *D. Price, B. Iddon* and *B. J. Wakefield.* Elsevier, Amsterdam 1988. xii, 422 pp., hardcover, HFl 285.00. – ISBN 0-444-42982-4

This volume contains the edited contributions to the First International Conference on the Chemistry and Applications of Bromine and its Compounds, held in September 1986 at the University of Salford, Great Britain. The contents are arranged in 14 chapters. Of the 39 authors 17 are from Great Britain, 17 from Israel, four from the USA and one from Switzerland. Since the majority of them work in industrial laboratories (The Associated Octel Co. Ltd., Bromine Compounds Ltd., Great Lakes Chemical Corporation, and Dow Chemical Europe), the papers deal mainly with problems related to industrial applications.

World production of bromine, which is usually obtained by oxidation of bromides by chlorine, is currently in the region of 4×10^5 t/year. However, the relative shares of the different bromine compounds of technological importance have altered greatly; since 1975, 1,2-dibromoethane, which for the previous 50 years was by far the most important product (being used mainly as a fuel additive in combination with lead tetraethyl, to scavenge the lead that is released by forming the more volatile lead bromide) has come increasingly into disrepute. An alternative market for organobromine compounds which has come into prominence is in fire retardants for polymers (e.g. brominated diphenyl ethers, polypentabromobenzylacrylate, or tetrabromobisphenol-A). In the area of inorganic bromine compounds a market which has become increasingly important is in transporting oil and natural gas, where solutions of bromine salts (calcium and zinc bromides) are used as components of "packer fluid". The book reviewed here provides up-to-date surveys and reports on research relevant to these new applications. Moreover, the chapter on the up and down history of the bromine industry ("Bromine Chemical Industry—Retrospect and Prospect", by *W. R. Merriman* and *H. E. Arkens,* 24 pp., 21 refs.) is an interesting and stimulating account of an important part of the industrial history of the twentieth century.

Now that the standard monograph on bromine chemistry ("Bromine and its Compounds", edited by *Z. E. Jolles,* 1966) is getting on in years, new review articles on bromine compounds are especially welcome. The "Introductory Review" of the present book (120 pp., 459 refs.), written by eight authors from Associated Octel, provides a very good review of recent developments, including the applications of bromine compounds. Other reviews deal with "Brominated Marine Natural Products" (*D. J. Faulkner,* 24 pp., 103 refs.), "Polybromoalkanes—Aspects of Chemistry and Reaction Mechanisms" (*R. Bolton,* 36 pp., 132 refs.), "Brominated Aromatic and Heteroaromatic Compounds" (*B. Iddon* and *B. J. Wakefield,* 71 pp., 323 refs.) and "The Use of Bromine Compounds as Flame Retardants" (*C. F. Cullis,* 31 pp., 66 refs.). The remaining eight chapters deal with special topics and report new research results.

Altogether the book offers a great deal of information. Since it contains review articles as well as research reports from a conference, it has, of course, not been possible to completely avoid some imbalances in emphasis; for example, the numbers of literature references in the individual chapters vary between 459 and 2. Half of the articles include in their references the titles of the original papers, which is very useful in view of the fact that the secondary literature is widely scattered. The inorganic side of bromine chemistry tends to be treated here as subordinate to the organic; for example, silver halide photography, which is still very important, is only touched on briefly, and there is no mention of perbromates or bromine cations, which have stimulated much scientific discussion about the higher oxidation states of bromine. In contrast the organic chemistry and marine biological chemistry of bromine are comprehensively treated. The particular value of this book probably lies in the detailed and up-to-date account of the present and potential future uses of bromine and its compounds in science and technology. The book can be thoroughly recommended; it will be indispensable to all bromine chemists, and useful as a source of information for many others, including chemistry teachers. It is a pity that it is so expensive.

Max Herberhold [NB 1001 IE]
Anorganisch-chemisches Laboratorium
der Universität Bayreuth (FRG)

Copper Oxide Superconductors. By *C. P. Poole, T. Datta* and *H. A. Farach.* Wiley, Chichester 1988. xii, 289 pp., hardcover, £ 22.40. – ISBN 0-471-62342-3

To write a monograph on this subject now is a bold and welcome initiative. It is scarcely possible to review the whole of the flood of published work in this field (about 10000 papers have appeared in three years of research!). Nevertheless the authors have competently surveyed and evaluated the most recent work up to the book's manuscript deadline of July 1988.

Basic concepts, standard techniques and the many different physical and chemical aspects of these materials are covered. Starting from what is known about conventional superconductors, the authors extend the discussion to the various phenomena found with the new oxide type materials. A concise description of the currently accepted basic theories is followed by an experimentally-orientated review of the chemical methods for preparation, including essential advice

regarding the quite considerable toxicity of thallium compounds. Next there comes a detailed account of the structural features of the most important compounds, and of the unique physical and chemical properties which result. In this context the authors also deal with the chemical characterization of the materials. The magnetic behavior, which is of crucial importance in superconductors, is discussed in detail, taking into consideration both the fundamental macroscopic magnetic effects which are important in superconductivity, and phenomena of microscopic origin such as paramagnetism and antiferromagnetism. The magnetic resonance methods which are routinely used to investigate such phenomena are described, with special emphasis on their applications to superconductors. Other features of the solid state such as energy gaps, densities of states, electron-phonon coupling, and the experimental methods used to investigate them, are also covered, and a selection of typical data is included, which is useful for the experimentalist. The concluding chapters are devoted to transport properties and tunneling phenomena, especially in relation to electrical and thermal effects.

It would have been useful to include more detail on real structures, e.g. by discussing results from electron microscopy studies. Also it is surprising that the ionic radii according to *Shannon*, which are nowadays most generally used, have not been applied here. The few small errors which have crept into the work as a consequence of the vast amount of literature to be covered do not significantly diminish the value of the monograph. The book is aimed particularly at readers who are already working in this field, but it also provides a valuable introduction to the very large and complex body of published work for newcomers to the topic.

Vitamins. By *W. Friedrich*. Walter de Gruyter, Berlin/New York 1988. xii, 1058 pp., hardcover, DM 380.00.—ISBN 3-11-010244-7/0-89925-273-7

This comprehensive monograph is a very welcome revised and translated edition of a recently published book in German by the same author (W. Friedrich: *Handbuch der Vitamine*, Urban & Schwarzenberg, Munich 1987, 657 pp.). This book provides a lucid and authoritative summary of the present state of knowledge in biochemical and medical research on vitamins, and is a rich source of information, especially for readers interested in the medical, pharmaceutical and biochemical aspects. As in the German version, this convenient and attractive book contains a separate comprehensive chapter (thirteen altogether) on each of the vitamins and their derivatives.

The introduction examines in a general way the topic of vitamins. Historical aspects are discussed, and an overview is presented of where vitamins are found, the need for them, and their biological functions. This chapter is enhanced by clear illustrations in color relating to the individual vitamins.

Next come a series of chapters devoted to the individual vitamins and vitamin derivatives. In accordance with the usual sub-division of the topic, the first four chapters deal with the fat-soluble vitamins (1. Vitamin A and its Provitamins; 2. Vitamin D; 3. Vitamin E; 4. Vitamin K). These are followed by nine chapters on the water-soluble vitamins (5. Thiamine, Vitamin B_1, Aneurine; 6. Vitamin B_2: Riboflavin and its Bioactive Variants; 7. Niacin: Nicotinic Acid, Nicotinamide; 8. Vitamin B_6; 9. Folic Acid and Unconjugated Pteridines; 10. Biotin; 11. Pantothenic Acid; 12. Vitamin B_{12}; 13. Vitamin C). These thirteen comprehensive and information-packed chapters on the individual vitamins (each with about 60 to 80 pages of text) all follow a similar construction. Each chapter treats (mainly from a medical and biochemical standpoint) the following aspects: history, nomenclature, stereochemistry and structure, synthesis and chemical reactions, vitamin analogs and antagonists, biosynthesis, stability, physical properties, separation and purification, analysis and standardization, biochemical functions, metabolization, transport and storage in the human body, pathological symptoms of vitamin deficiency, etc. A comprehensive bibliography is provided at the end of each chapter. The clarity of presentation of the information is helped by a well-balanced choice of clearly arranged tables and by carefully prepared figures and chemical formula schemes.

The work is rounded off by a supplement giving references to the more recent literature (1984 to 1986), mainly on medical topics, and a lengthy but clearly arranged subject index.

Like the original German version, this lucidly written book is an excellent and comprehensive source of up-to-date information on the biochemical and physiological aspects of vitamins; it is mainly suitable for use by medical scientists, biologists, biochemists, pharmaceutical chemists, and all chemists with medical or biochemical interests. It also shows that, contrary to what many people think, the subject of vitamins is a highly productive field of research. From the chemist's point of view the work would be even more valuable if it included a more detailed treatment of the chemical aspects of vitamins research (chemical structure, reactivity, synthetic methods); nevertheless the book is highly recommended.

Fractals and Related Hierarchical Models in Polymer Science

By Alexander Blumen* and Horst Schnörer

Polymer science, an interdisciplinary science well-rooted in organic chemistry and in materials science, encompasses an inordinate number and diversity of substance classes and thus has far-reaching applications. Interestingly, polymers also represent a great challenge to the theoreticians, since their theoretical treatment often necessitates appropriate extensions of the classical methods from solid state physics and from statistical physics. Thus, new concepts often have to be invoked when considering the special properties of polymers. In this review we concentrate on one of the modern concepts in the theory of polymers, namely on scaling. Scaling is closely associated with new developments in the field of fractals and of hierarchical structures. Such concepts are invaluable for the modeling of complex geometries and for describing dynamical processes in polymeric materials. Here, we focus on a presentation of these ideas and we outline examples of recent research in which these concepts have been successfully applied.

1. Introduction

One of the most fascinating aspects of today's polymer science lies in the highly interesting combination of new materials' properties on the one hand and of recent theoretical developments on the other. That polymers are substances with enormous potential in the applied sciences is self-evident; that the same polymers display features making them one of the favorite testing-grounds for new theoretical concepts is not so well known. In the authors' opinion, this underscores the fact that progress in natural sciences occurs historically, by which we mean that formerly, apparently unrelated fields are suddenly perceived as related, and thereafter develop in parallel. Thus, in polymer science theoretical modeling and chemical synthesis are, in fact, much more intimately linked than what one might naively expect. In fact, as we shall now demonstrate, most of the *mathematical* apparatus required for modeling macromolecules as objects sui generis was already available for quite some time; the *need* to use such mathematical techniques, however, increased dramatically with the advent of highly sophisticated devices for monitoring substances usually regarded as complex and irregular (i.e. not fitting simple model concepts of the day).

The basic idea underlying the new theoretical models is that of scaling, which, in its geometrical form is exemplified by the concepts of percolation[1] and of fractals.[2–5] In Sections 2 and 3 we shall remind our readers of these ideas, which, in view of the large number of recent publications,[2–14] may by now be quite familiar (a fact which for some time made us hesitate to write this article). Geometric scaling (self-similarity) is, however, only one part of the story—scaling involves also the dynamical properties of polymers, an aspect often ignored in most of the recent reviews. We will therefore also address questions related to the dynamics of excitation and charge carrier transport in polymeric materials,[10,15–17] topics which require modeling through time fractals[18–21] and through hierarchical energy distributions.[22] First, however, let us discuss the basic ideas.

2. Polymers and Scaling Concepts

In 1979 *de Gennes*[23] published one of the seminal works in the field, underscoring the importance of scaling ideas in deriving the properties of numerous diverse materials. In this brilliant work *de Gennes* demonstrates how scaling, combined with a feeling for the problems at hand, leads to a seemingly effortless derivation of many polymeric features. Of course, many of the foundations underlying *de Gennes*' book were laid in the classical works of *Flory, Rouse, Zimm,* and *Stockmayer*.[24–27]

As perhaps simplest example for scaling let us consider a polymer chain and focus on its mean squared end-to-end distance $<\boldsymbol{R}^2>$. For a chain consisting of N monomers and in the absence of any hindering interactions it is a simple matter to show that $<\boldsymbol{R}^2>$ is proportional to N [Eq. (a)], where L is a (model-dependent) constant.

$$<\boldsymbol{R}^2> = NL^2 \qquad \text{(a)}$$

The result (a) is very general, since it can be traced back to one of the basic theorems of probability theory, the central-limit theorem. In fact many textbooks[24, 28–30] use models based on random walk (Fig. 1a) ideas (the random flight chain, the freely rotating chain, the Gaussian chain) and show that Equation (a) holds true in all these (special) cases. Interestingly, one also learns from these derivations that *local* hindrances (such as fixed bond lengths, limitations of the rotations around the bonds, or *short-ranged* correlations in orientation) do not change the character of Equation (a). Thus, different models only lead to differences in the constant L (L is practically *Kuhn*'s persistence length[31]).

It should also be pointed out, of course, that Equation (a)—as distinct from many of the expressions which we will encounter in the following—does *not* depend on the dimension d of the Euclidean space in which the random walk takes place; Equation (a) is truly very general.

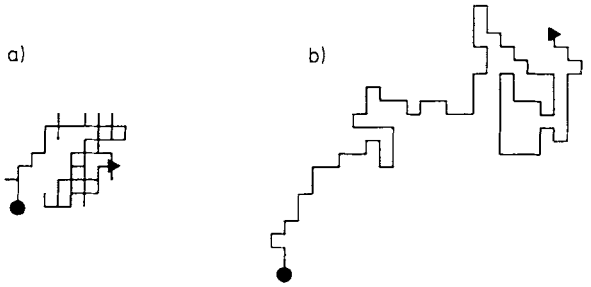

Fig. 1. Random walk (a) and self-avoiding walk (b) with 100 steps each on a square lattice, using the same sequence of random numbers. Starting points and end points are marked with filled circles or triangles, respectively. In case (b) the walker cannot visit occupied sites again ("excluded volume"), which leads to an increase of the spatial extension of the walk.

It is thus very remarkable that the introduction of an excluded volume,[31] i.e. of steric hindrances between the monomers (this results in so-called self-avoiding walks, SAW) leads to a vastly different behavior for $<\boldsymbol{R}^2>$. One has the relationship (b), where ν (the Flory-parameter[32]) is

$$<\boldsymbol{R}^2> \sim N^{2\nu} \qquad \text{(b)}$$

in general a non-integral, dimension-dependent constant. The physical reason for steric hindrances is the short-range repulsion between different monomers, as occurs, for instance, in good solvents. Now we already know that interactions between neighboring monomers *along the chain* do not cause departures from Equation (a). What happens here is that some monomers, which along the chain are quite distant, may come into close contact due to a loop in the chain. The repulsion between such monomers creates (mathematically speaking) *long-range* correlations. As forcefully stressed by *Flory*, this leads to swelling of the polymer in good solvents (see Fig. 1b). A straightforward approximate

Alexander Blumen, born 1948 in Bucharest/Rumania, studied physics at the University of Munich 1966–71. He gained his PhD in theoretical chemistry in 1976 from the Technical University Munich under the guidance of G. L. Hofacker. After a post-doc period in the chemistry department of the Massachusetts Institute of Technology with R. Silbey and J. Ross he obtained his Habilitation in 1982 at the T.U. Munich, where he was appointed Privatdozent in 1983. A Heisenberg stipend was awarded to him by the Deutsche Forschungsgemeinschaft in 1984. He spent a year, starting in 1985, at the Max-Planck-Institute of Polymer Science in Mainz with E. W. Fischer. Since 1986 he has been a member of the Physical Institute of the University of Bayreuth, where he has a C3-Fiebiger professorship. His special interests are the theory of disordered media (glasses, polymers), the dynamics of complex systems, and stochastic processes.

Horst Schnörer, born 1962 in Nankendorf (Bavaria), studied physics at the University of Bayreuth from 1982 to 1987. After an experimental diploma thesis dealing with photoconductivity in polymers, he now aims at his PhD in theoretical physics under the guidance of Alexander Blumen. Central topics of his research are the theory of transport processes on irregular structures and the kinetics of diffusion-limited reactions.

calculation of the free energy for the polymer chains leads to Equation (c).[32] The values obtained from Equation (c) are

$$\nu = 3/(d+2) \tag{c}$$

in remarkable agreement with today's best estimates for SAWs[30] ($\nu = 0.588$ for $d = 3$ and $\nu = 0.750$ for $d = 2$). Furthermore, Equation (c) displays two limiting behaviors: In $d = 1$ a SAW is trivial (being a straight segment of length LN) so that $<\boldsymbol{R}^2> = L^2N^2$, i.e. $\nu = 1$. Moreover, in $d \geq 4$ $\nu = 1/2$, i.e. the SAW behaves as a simple random walk; for this reason the dimension $d = 4$ is marginal.

The expression (b) provides a classical example for a scaling law. First, it relates the mean end-to-end SAW distance $R = \sqrt{<\boldsymbol{R}^2>}$ to the number of monomers N in a highly nontrivial way (d). The exponent $1/\nu$ in (d) is dimension-

$$N \sim R^{1/\nu} \tag{d}$$

dependent [Eq. (c)], and we thus have *qualitatively* different behaviors for different d, while the details of the local interactions are unimportant: the problem displays distinct *universality* classes. Secondly, introduction of the innocuously-looking but fundamental condition of monomer-monomer repulsion causes departures from the central-limit theorem. In later sections we will show that the first point [Eq. (d)] is directly related to (geometric) fractals, whereas the ideas behind the second aspect are echoed in non-Gaussian (Lévy) stable laws and in time fractals.

The linear chain in a good solvent is only one of the many examples for scaling, and we refer the reader to the books by *de Gennes*,[23] by *Doi* and *Edwards*[29] and by *des Cloizeaux* and *Jannink*[30] for an extensive list of scaling relations. To present just a few spectacular examples, we consider the semidilute regime, in which there is a relatively small concentration of chains in a good solvent; the concentration c is, however, high enough, so that chains can mutually interpenetrate. In this regime the osmotic pressure π behaves as in Equation (e)[23, 29] (using $\nu = 3/5$), whereas the averaged

$$\pi \sim c^{3\nu/(3\nu-1)} \sim c^{9/4} \tag{e}$$

end-to-end distance R follows the law (f), i.e. the chains

$$R \sim c^{(2\nu-1)/(2-6\nu)} \sim c^{-1/8} \tag{f}$$

shrink therefore with increasing concentration, a result confirmed by neutron scattering.[33]

A much-discussed scaling relation concerns the viscosity η. At a constant content of polymeric material in concentrated solutions and in melts the viscosity scales with the degree of polymerization N in accord with Equation (g), where the

$$\eta \sim N^{\varepsilon} \tag{g}$$

exponent ε is about 3.4. This behavior is quite universal, independent of temperature and molecular species, and requires only linear, flexible polymers in dense, entangled fluids.[29] Remarkably, the reptation theory by *de Gennes* predicts $\varepsilon = 3$.[23] In recent years, however, several improvements have been proposed for the determination of ε; thus the very recent theories of *Scher, Shlesinger, Weiss* and *Bendler* give $\varepsilon = 10/3$ as exact solution to their models.[34, 35]

3. Theories of Scaling

A fundamental aspect of scaling-laws such as (b) or (d)–(g) is their self-similarity. Take for instance Equation (d), which relates a mesoscopic, i.e. in general fairly large (ca. 1000 Å) length R to the (microscopically determined) degree of polymerization N (average number of monomers per chain). Equation (d) also holds if we group our monomers in pairs (dimers) and relate R to the number $(N/2)$ of dimers. The same is, of course, true if we group λ monomers together, and view R as a function of (N/λ); as long as λ stays much less than N we have $R \sim (N/\lambda)^{1/\nu}$. On the mesoscopic level we are unable to distinguish the microscopic details and a scale change (within reasonable bounds) leads to the same physicochemical situation. Pictorially speaking, we cannot differentiate between the whole system and a (fairly substantial) rescaled part of it—on the mesoscopic scale both look the same.

This idea is the basis of the renormalization group (RG) theory, a very powerful method developed in conjunction with the analysis of phase transitions.[36–38] Here the main observation is that near a critical point the correlation length of the order parameter diverges. We may exemplify the situation by considering a percolation cluster—probably the best means for visualizing a phase transition geometrically. In (site-)percolation, sites on a regular lattice are occupied at random by conducting and insulating elements. Now an electrical current can pass a bond only if both its ends are occupied by conducting elements. The question is: when does a current cross the entire sample? It is evident that for a small concentration of conducting elements no current will be transferred, whereas in the opposite case a current will flow. Interestingly now, such a transition is not very gradual. A detailed analysis shows that (for an infinite sample) below a critical concentration p_c no current will flow at all: the resistivity is infinite. Above p_c there is always a macroscopic current I, whose magnitude scales around p_c. One has for the conductance σ above p_c:

$$\sigma \sim I \sim (p - p_c)^{\bar{t}} \tag{h}$$

where $\bar{t}$ is a universal constant ($\bar{t} \simeq 1.3$ in $d = 2$ and $\bar{t} \approx 2.0$ in $d = 3$ for lattice percolation[11]). This behavior is thus very reminiscent of a second-order phase transition; here the conductance plays the role of an order parameter. These are in fact detailed works which stress the close correspondence between typical features encountered in percolation and the behavior of the thermodynamic parameters in second-order phase transitions.[39, 40]

Furthermore, at p_c the incipient infinite cluster (that set of connected conducting elements which spans the system from one side to the other) scales. Figure 2 illustrates the realization of such a cluster on a square lattice, for which $p_c \approx 0.593$. Note the appearance of voids of all sizes and that one cannot distinguish the random pattern of this cluster from that of a similar enlarged section of another incipient

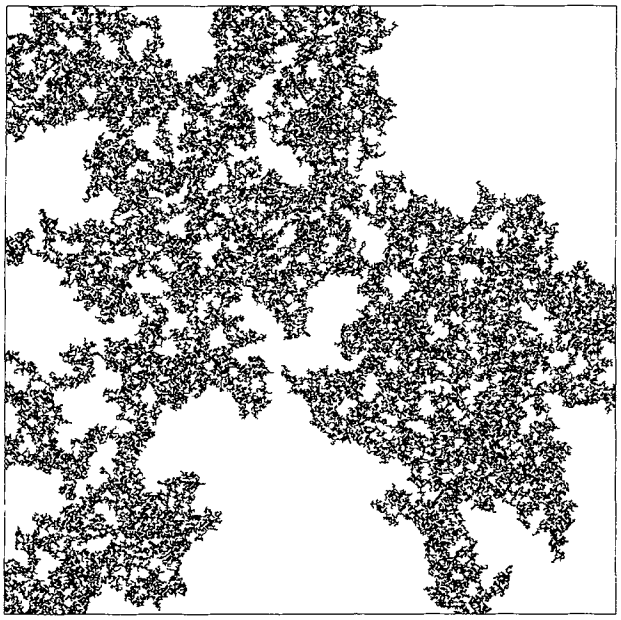

Fig. 2. Percolation cluster on a two-dimensional square lattice at the critical concentration $p_c = 0.593$.

infinite cluster. That such a cluster (barely) conducts current is due to the divergence of its connectivity at p_c, i.e. to a singularity in the correlation length.

Now the renormalization group theory makes use of this observation through judicious use of scaling: Imagine that we were to repeatedly enlarge (renormalize) our scale (or, equivalently, shrink our sample) by a fixed factor. Obviously, finite clusters will then become smaller and smaller at each step, whereas a self-similar infinite cluster would practically stay the same. Hence, the iterated renormalization procedure allows us to get rid of the uninteresting features (finite clusters), while keeping that part of the problem which stays invariant under the transformation. In mathematical terms, the critical variables at the transition show up as fixed-points of the corresponding hamiltonian function under the RG.[36-38]

An early implementation of the RG was suggested by *Kadanoff*:[37,41] it consisted in systematically deleting (decimating) lattice points from a hamiltonian formulated in the site representation and in recalculating the effective interactions between the remaining sites (renormalization of the interactions). For regular lattices (but not for some simple fractals!) this real-space renormalization (RSR) scheme runs into difficulties,[42] because it often alters the structure of the hamiltonian (e.g. it may lead to long-range interactions). Hence, a more successful way to implement the RG procedure is to renormalize in momentum space,[43] also splendidly demonstrated by *Wilson*, who was awarded the Nobel Prize for Physics in 1982 for his work in this field.

The real-space renormalization (RSR) could have been the starting point for fractals. Indeed, one of *Wilson*'s students, the Indian scientist *Dhar*, proceeded along these lines and asked himself what simple lattice-type structures stay invariant under RSR. In this way he created a structure[44,45] which is similar to the Sierpinski-gaskets, which we will discuss in the following section. The historical development followed, however, another course.

3.1. Fractals

The notion of fractals was introduced by *Mandelbrot* in a book in 1975;[46] he stressed that many structures in Nature are self-similar.[2,46] Starting point for a mathematical self-similar description were the works of *Cantor, Sierpinski, Julia,* and *Fatou,* who provided us with classes of patterns which display scale-invariance.[47]

In this section we present several ways of obtaining geometrical patterns which scale with distance. Common to all objects is their underlying self-similarity, which is most easily visualized in terms of dilation. We start thus by discussing the fundamental features in terms of Sierpinski gaskets and continue by describing the general stochastic and deterministic means of creating fractal shapes.

Perhaps the simplest fractal is the Sierpinski gasket[2,48] embedded in the two-dimensional space, as displayed in Figure 3. The structure can be generated by a procedure which

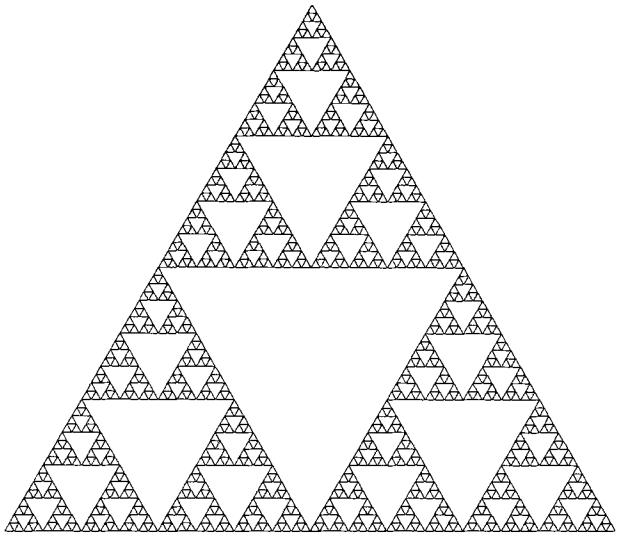

Fig. 3. Sierpinski gasket in $d = 2$ at the sixth stage of iteration.

renders clear the underlying symmetry. One starts with a triangle of side length 2, which includes three smaller, upwards-pointing triangles of side length 1. In the nomenclature introduced by *Mandelbrot*[2] this basic pattern is called a generator. A dilation by a factor of 2 from the upper corner transforms the upper small triangle into the large one, and creates two additional, larger triangles. One may also view the operation as attaching two copies (left and right) below the original pattern. The procedure is then iterated n times, and leads to the structure at its nth stage. As an example, the portion of the Sierpinski gasket depicted in Figure 3 corresponds to the 6th stage of iteration.

Sierpinski gaskets can be generated in embedding spaces of arbitrary dimension d, by starting with the corresponding

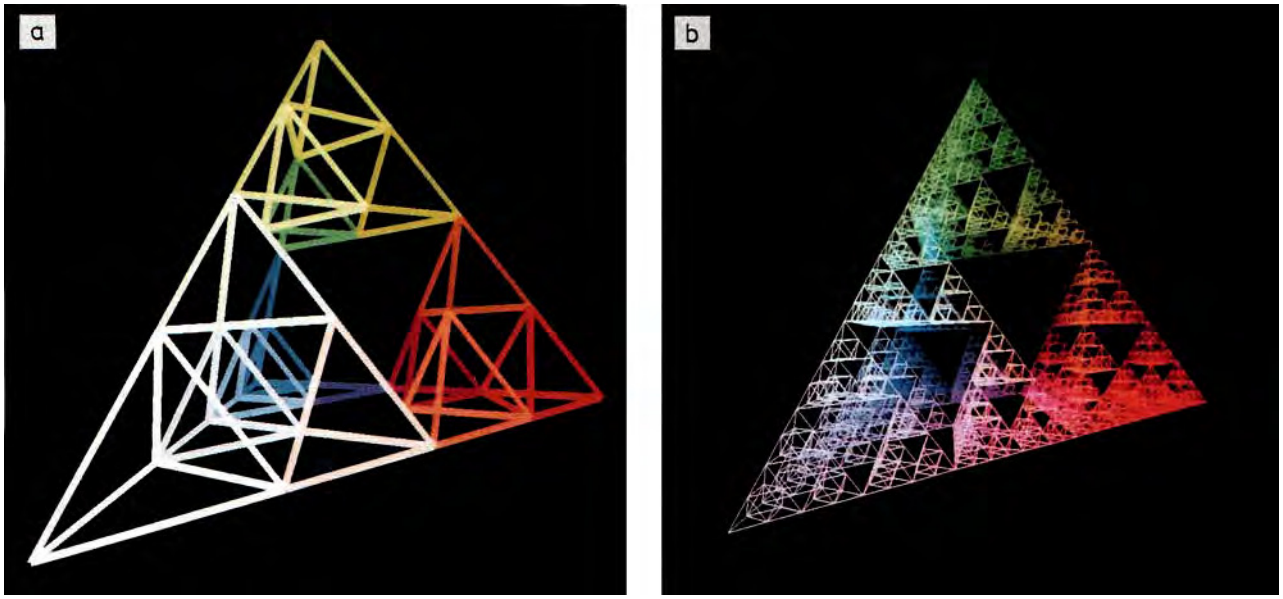

Fig. 4. Sierpinski gasket in $d = 3$ at the second (a) and the fifth (b) stage of iteration.

hypertetrahedrons.[49, 50] Figure 4 shows a Sierpinski gasket in three dimensions at the 2nd and 5th stage of iteration. Also more general patterns can be constructed along the same lines of reasoning.

Properties of fractal objects related to physical quantities (such as mass distribution, density of vibrational states, conductivity and elasticity) are describable by several, not necessarily integral parameters. These parameters play roles similar to that of the spatial dimension. Here we focus on the fractal (Hausdorff) dimension $\bar{d}$ which characterizes the distribution of mass. Denoting by N the number of lattice points inside a sphere of radius R, one has the proportionality (i), where $\bar{d}$ is defined by $\bar{d} = \lim_{R \to \infty} \ln N / \ln R$. Hence,

$$N \sim R^{\bar{d}} \tag{i}$$

for a Sierpinski gasket embedded in the d-dimensional Euclidean space one obtains Equation (j).[2, 51]

$$\bar{d}_s = \frac{\ln (d+1)}{\ln (2)} \tag{j}$$

A comparison of the expressions (i) and (d) shows that a polymer chain in a good solvent has a fractal dimension $\bar{d}$ of $1/\nu$.

Another important parameter which plays a role in connection with the dynamical properties of or on fractals (such as diffusion-controlled reactions and heat conduction) is the spectral (fracton) dimension $\tilde{d}$. Using a scaling argument, *Alexander* and *Orbach*[51] have found that Equation (k) holds for Sierpinski gaskets in d dimensions.

$$\tilde{d}_s = 2 \frac{\ln (d+1)}{\ln (d+3)} \tag{k}$$

As example, for the Sierpinski gasket of Figure 3, (where $d = 2$) one has $\bar{d}_s = 1.584$ and $\tilde{d}_s = 1.365$. In many cases the relation $\tilde{d} < \bar{d} < d$ holds; furthermore, for Sierpinski gaskets $1 < \tilde{d}_s < 2$, as may be seen from Equation (k). It should be emphasized that $\bar{d}$ and $\tilde{d}$ are amenable to experimental observation.[10, 51, 52] For modeling purposes it is therefore desirable to construct deterministic fractals with prescribed $\bar{d}$ and $\tilde{d}$ values.

Based on the systematic construction of the Sierpinski gaskets one can consider modified Sierpinski-type structures. The spectral dimensions $\tilde{d}$ for these structures lie between that of a 2d-Sierpinski gasket, $\tilde{d}_s = 1.36$, and the value 2. In References [49, 50] one took as generators d-dimensional tetrahedrons of side length b filled with N smaller tetrahedrons of unit side length. For such generators the fractal pattern follows by iteration, and one has the relationship (l).

$$\bar{d} = \ln N / \ln b \tag{l}$$

On the other hand, $\tilde{d}$ can be obtained from the long-time behavior of the probability of being at the origin (see References [49, 50] for details) and lies between 1 and 2. Hence such symmetric fractals represent a wide class of lattices which generalize the Sierpinski gaskets.

Not all fractal systems display the strong symmetry of the Sierpinski gaskets, which are 'deterministic' fractals, designated as such since for each point in space it is unambiguously clear whether it belongs to the structure or not. The distribution of points in a fractal pattern may be random, as exemplified through the previously discussed percolation clusters. A related model is that of photopolymerization of multifunctional monomers. Here the procedure is to pick at random at each step a monomer adjacent to the boundary of the growing cluster, and to attach it to the cluster. This so-called Eden model is a special case of epidemic growth, where, in a more general version, a fresh cell at the boundary of an infected cluster either gets infected with probability p (and hence joins the cluster) or becomes immune. The general version is identical to percolation;[1] for p smaller than the

critical concentration p_c the growth of the cluster always terminates, while for $p \geq p_c$ infinite clusters may be formed. Models similar to epidemic growth have also been developed in conjunction with the spread of forest fires.[1, 53, 54]

A wide variety of fractal patterns is encountered in the investigation of kinetic growth models. Here (see reviews [6] and [12]) it is customary to distinguish the models according to the mass transport and to accretion. Mass transport describes the way in which the reactants come in close contact: in solvents the reactants diffuse towards each other, so that one has Brownian motion; more rarely also ballistic aggregation may occur, in which case the reactants approach each other along linear trajectories. Accretion may occur at first encounter (the growth is then motion-limited) or several encounters of the reactants may happen before a bond is created (the growth is then reaction-limited). Furthermore, one may allow only monomers to attach themselves to the already existing polymer cluster (monomer-cluster aggregation, MC) or the clusters may also combine (cluster-cluster aggregation, CC). An example for a MC diffusion-limited aggregate (DLA) is given in Figure 5. As a rule, CC leads to more ramified clusters than MC, and the density of clusters increases from diffusion-limited to ballistic to reaction-limited. Model calculations[112] lead to the following fractal dimensions $\bar{d}$ for clusters grown in $d = 3$: a) MC: diffusion-limited $\bar{d} = 2.50$, ballistic $\bar{d} = 3.00$, reaction-limited (Eden model) $\bar{d} = 3.00$; b) CC: diffusion-limited: $\bar{d} = 1.80$, ballistic $\bar{d} = 1.95$, reaction limited $\bar{d} = 2.09$. All these patterns are encountered in polymeric systems, and examples will be provided in Section 4, where we will discuss the experimental techniques used to monitor the fractal dimensions. First, however, let us turn to scaling aspects in dynamical processes.

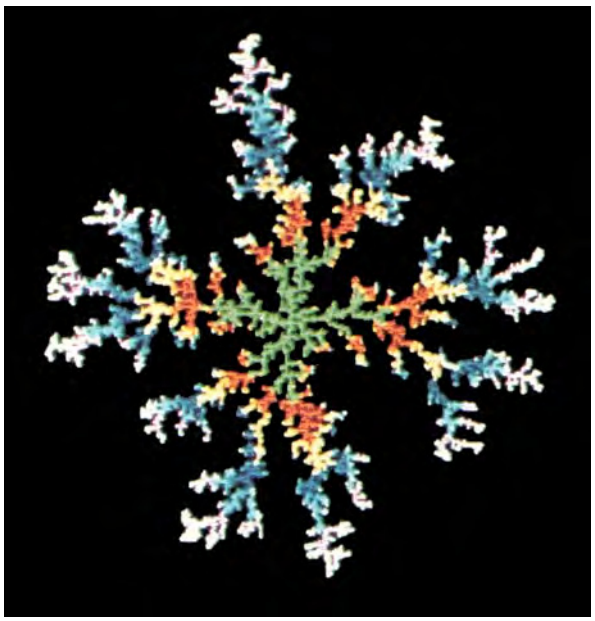

Fig. 5. Cluster of monomers grown by diffusion-limited monomer–cluster aggregation on a square lattice. The different colors show different stages of evolution.

3.2. Time-Fractals and Ultrametric Spaces

A major field of application of scaling ideas in the time domain is photoconductivity.[115, 116] As pointed out in a recent review article[117] the use of polymeric photoconductors in printing and copying techniques represents one of the most sophisticated applications for organic materials. In fact organic photoconductors have been improved in the last two decades to the extent that they are nowadays at least equivalent (if not even superior) to their inorganic counterparts.

From the theoretical viewpoint, the issue at stake in amorphous photoconductors is the dispersive transport, as contrasted to the familiar diffusive, Gaussian behavior. Diffusive motion, in its many facets, ranging from the transfer of heat (macroscopic) to Brownian motion (microscopic) is a well-understood phenomenon and may be modeled using the mathematical theory of Markov processes, in which the system keeps no memory of past events. Typical discrete examples are random walks on regular lattices—first introduced by *Bachelier* at the turn of the century for monitoring the fluctuations of the stock market[55]—which nowadays comprise a vast mathematical literature.[56] Simple random walks on regular lattices for arbitrary dimensions lead to a time-independent diffusion coefficient, or, expressed differently, in the absence of a biasing field, to a linear increase in the mean squared displacement as a function of time.

In amorphous photoconductors the situation is different, since one encounters dispersive transport: the motion of the carriers through a sample becomes slower and slower with the passage of time, so that no diffusion constant in the usual sense can be defined. Here the diffusion coefficient D displays an algebraic dependence on time [(m) with $\gamma < 1$];

$$D(t) \sim t^{\gamma - 1} \qquad \text{(m)}$$

with a similar finding for the current $I(t)$ flowing in a biasing field. Such behavior is incompatible with the usual diffusion equation. Note, however, the nontrivial scaling behavior of D with respect to t.

Progress in the advancement of theoretical models for dispersive transport was slow, due to the Gaussian character of most of the probability distribution functions put forward. Here again the central-limit theorem of probability theory plays an important role. One should recall that under very general conditions, a sum of random variables will tend to form a normal (Gaussian) distribution when the number of elements in the sum increases. The position vector of a particle may be viewed as a sum of distance increments due to past events, say collisions. If energies, directions etc., are randomized after such events, most distributions will lead to regular diffusion. Hence, for a successful modeling of dispersive transport in such a framework one has to look for the (relatively rare) distributions for which the central-limit theorem does not hold.

The basic theoretical problem in modeling the transport of light-generated charge carriers through an amorphous medium is to take care of the broad distribution of stepping times. One models the motion of individual carriers which move under the influence of an external electric field through hopping. Here it is important that the probability for performing a step per unit time is not exponential, but decays much more

slowly. Physically this may be pictured as arising from the fact that an amorphous material has rather irregular lattice spacings (geometrical disorder), which lead to large variations in stepping times (temporal disorder).

Mathematically, the most important parameter characterizing the transport is the distribution of waiting-times between subsequent carrier jumps. A theoretical breakthrough occurred here through the works of *Scher, Lax,* and *Montroll,* who showed that long tails in the waiting-time distribution $\psi(t)$ between the microscopic events can qualitatively describe the dispersive transport,[57, 58] when one assumes the relationship (n) with $0 < \gamma < 1$,

$$\psi(t) \sim t^{-1-\gamma} \tag{n}$$

so that the zeroth but not the first moment of the distribution $\psi(t)$ exists. Such distributions lead to Lévy processes, a field which was long considered to be a domain of mathematical curiosities only.[2, 59] The main technical point in investigating random walks in continuous time (CTRW) with such distributions, was the realization that the basic CTRW framework (as formulated ten years earlier by *Montroll* and *Weiss,*[60] could readily incorporate these, less usual, $\psi(t)$-forms. However, although the theory developed in References [57, 58] was successful in providing a scheme for the qualitative understanding of dispersive transport, one could at the time only speculate on the nature of the microscopic parameters leading to $\psi(t)$.

Today we know that this approach is only one of the possible was of obtaining algebraic time dependences for $D(t)$, and that the key ingredient in the CTRW framework is the idea of temporal scaling, or of time fractals, as formulated by *Shlesinger.*[18-21, 61]

As pointed out in Reference [21], scaling has a long history in probability theory. As early as 1713 the work of *N. Bernoulli* was reported, who analyzed a game of chance with infinite average winning (the Petersburg paradox). Furthermore, scaling also shows up in a function introduced by *Weierstrass* [Eq. (o)]. $W(k)$ is everywhere continuous but

$$W(k) = (1-a)\sum_{n=0}^{\infty} a^n \cos(b^n k) \tag{o}$$

$(a < 1,\ b > a^{-1})$

nowhere differentiable. For our purposes, an expression related to Equation (o) provides an excellent means to obtain the asymptotic behavior given by Equation (n).[10, 21]

$$\psi(t) = \frac{1-a}{a}\sum_{n=1}^{\infty} a^n b^n \exp(-b^n t) \tag{p}$$

It is a rather straightforward matter to verify that at large values for t Equation (p) scales: From (p) one has $ab\psi(bt) = \psi(t) - (1-a)\mathrm{b}\exp(-\mathrm{b}t)$, so that for slowly decaying (slower than exponential) $\psi(t)$ one finds at longer times: $\psi(t) \approx ab\psi(bt)$, i.e. scaling behavior. From the last expression one obtains γ of Equation (n) to be equal to $\ln a/\ln b$. Expression (p) is very valuable, since it allows one to investigate the behavior of several dynamical quantities near their marginal dimensions; notice that we can, through a judicious choice of a and b, get any preassigned value of γ. Some examples concerning photocurrents and excitation depolarization in polymeric materials will be presented in Sections 5 and 6.

One physical reason for such broad distributions of waiting times is energy disorder. The motion of particles through an amorphous solid as well as relaxation in glassy materials can be described in terms of dynamical processes in multidimensional random potentials with valleys and barriers of different heights.[10, 62] The microscopic motion over the barriers is in many ways similar to *Eyring*'s ideas of the activated complex in chemical reactions.[63]

There are several models which are simplified variants of the random potential, e.g. the random valley and random barrier models[64] (see Fig. 6). Random valley models consider a random distribution of valley depths with barriers at equal top level. A similar model, in which charge carriers in the conduction band get captured by and released from traps of various depth (multiple trapping) was formulated by *Schmidlin.*[65] The multiple trapping model was shown to correspond to the CTRW-theory.[16, 66]

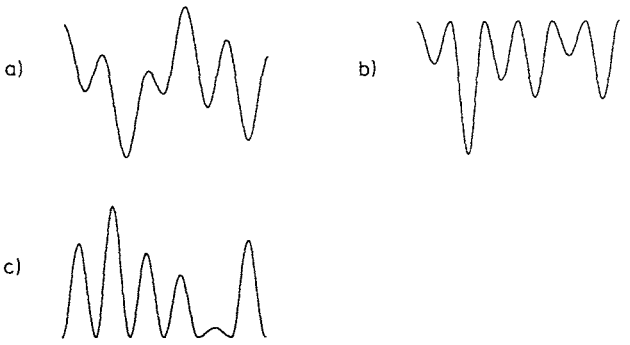

Fig. 6. (a) Random potential, (b) random valley, and (c) random barrier models.

In random barrier models the valleys are at equal level. These structures are amenable to hierarchical modeling through so-called ultrametric spaces.[10, 22] In these models sites are separated by energy barriers with random heights. Thus, a particle positioned on a certain site needs thermal energy to surmount the surrounding barriers. A given activation energy lets the particle visit only a subset (cluster) of sites around the starting point. One may then classify the sites through the energy required to reach them:[67] To such a classification corresponds an ultrametric space (UMS).

As examples, Figure 7 shows the regularly multifurcating ultrametric spaces Z_2 and Z_3. Note that only the points on the baseline belong to the UMS and that the structure above the baseline documents barrier heights and intersite connections. The height $d(x,y)$ of the barrier between sites x and y may be used as a generalized 'distance': It may be easily verified that Equation (q) holds for all UMS sites. Equation

$$d(x,y) \leq \max(d(x,w),\ d(y,w)) \tag{q}$$

(q) is the 'strong' triangle inequality which leads to the name 'ultra'metric. Z_2 and Z_3 have branching ratios $z = 2$ and

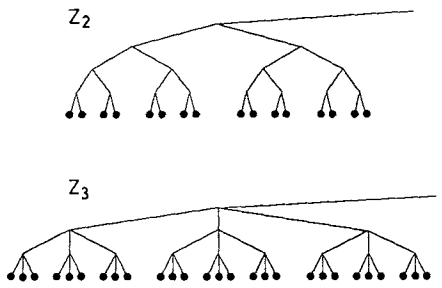

Fig. 7. The ultrametric spaces Z_2 and Z_3.

$z = 3$, respectively, and, for simplicity, we have taken the barrier heights to be hierarchically arranged, so that all consecutive energy levels differ by Δ. Now, it may be shown that several dynamical parameters scale with $\delta = kT \ln z/\Delta$. We refrain, however, from continuing with this topic and we refer the interested reader to References [10, 22, 68] and works cited therein for further details.

4. Geometrical Aspects of Disordered Systems

In this section we focus on the determination of the geometric scaling aspect for aggregates. The basic quantity here is the fractal dimension $\bar{d}$, which was defined in Equation (i). Since the total mass M of the aggregate is directly proportional to N, the number of monomers involved, the expression (i) may be replaced by (r).

$$M \sim R^{\bar{d}} \tag{r}$$

Objects that obey Equation (r) are named "mass-fractals".[12] Distinct from these, one also encounters "surface fractals", i.e. aggregates which are uniformly dense ($d = 3$), while having a rough surface S, for which the relationship (s) holds, where $\bar{d}_f$ is the surface fractal dimension.

$$S \sim R^{\bar{d}_f} \tag{s}$$

The methods of choice for investigating fractal objects include, in particular, scattering techniques. The intensity profile I of a scattered beam (light, neutrons, X-rays) is in such cases algebraically dependent upon the scattering wave vector $\boldsymbol{k}$ in accordance with (t),[12] where $-2\bar{d} + \bar{d}_f$ is the

$$I \sim k^{-2\bar{d}+\bar{d}_f} \tag{t}$$

so-called Porod slope. *Schaefer* et al. have investigated whole classes of substances and have demonstrated that, in general, many structures can be distinguished by their Porod slopes; they find that aggregates formed by polymer precursors give rise to scattering curves whose slopes lie between -1 and -3, whereas rough colloids yield slopes between -3 and -4 and smooth colloids slopes of -4. The methods even allow one to differentiate between substances grown by monomer-cluster (MC) and cluster-cluster (CC) aggregation; we refer the reader to Reference [12] for a summary of recent results.

Another method of choice in measuring the fractal dimension, advocated by *Avnir* et al.,[13] makes extensive use of adsorption techniques. It consists in determining the monolayer capacity $N(\sigma)$ of adsorbed molecules of cross section σ required to cover the surface to be investigated. For a fractal surface one expects as a function of the cross section the relationship (u).[69]

$$N(\sigma) \sim \sigma^{-\bar{d}_f/2} . \tag{u}$$

Such behavior was reported by *Avnir, Pfeifer* et al.[69-72] in their study of crushed glass, carbon black, charcoal, and of porous silica gels. The adsorbates that they use include N_2, alkanes and polycyclic arenes and alcohols.

This approach, however, has its problems: adsorption is an intricate process, in which the local interactions of the molecules with the surface are complex and may mask the geometric details.[73] It appears that both the measurements of the monolayer capacity and the calculations of the molecular cross sections are quite delicate. Recent molecular-size-dependent experiments on porous silica gels[74] led to values of $\bar{d}_f$ even larger than 3, a clearly very problematic result.

Another method which provides morphological information (including the fractal dimension of self-similar objects) centers on the direct transfer of electronic excitations. This method, which monitors the *fractal* dimension and which was proposed by us,[75] is now of widespread use. Furthermore, the *spectral* dimension can be monitored through reaction-diffusion processes as propagated by us[75] and by *Kopelman*.[76] For newer developments on the spectral dimension see References [77, 78].

Let us now consider the direct energy transfer (ET), which takes place from donor molecules to acceptor molecules, and assume that donors and acceptors occupy substitutionally sites on a regular lattice. In this classical problem[79, 80] one considers an excited donor molecule surrounded by acceptors which occupy some of the sites of the structure. The transfer rates $w(\boldsymbol{r})$ depend on the mutual distance r between each donor-acceptor pair. An often encountered form for $w(\boldsymbol{r})$ which holds for isotropic multipolar interactions is Equation (v).[79] The parameter s equals 6 for dipole-dipole,

$$w(\boldsymbol{r}) = ar^{-s} \tag{v}$$

8 for dipole-quadrupole and 10 for quadrupole-quadrupole interactions. For regular, d-dimensional lattices one obtains the decay function $\Phi(t)$ according to (w), where A is a constant and B is the reciprocal intrinsic lifetime of the donor in the absence of acceptors.

$$\Phi(t) = \exp(-At^{d/s} - Bt) \tag{w}$$

Let us now focus on optical properties related to fractals. From Equation (w) we see that the Förster-type decays are determined by the spatial dimension d of the region accessible to acceptors. Thus, the extension of Equation (w) to fractal objects gives (x) (see Ref. [10] for a detailed derivation).

$$\Phi(t) = \exp(-At^{\bar{d}/s} - Bt) \tag{x}$$

Since $\bar{d} < s$, the long-time decay is governed by intramolecular processes. This, on the other hand, also limits the

spatial range in which the ET method can probe the structure of the underlying material. Typically, this range is of the order of 100 Å, which is also the region amenable to the small angle X-ray scattering technique. Hence, in this region these two methods give complementary information.

The ET method, as proposed in Reference [75], was first used by *Even* et al.[81] for the investigation of the pore structure of Vycor glass. They studied the kinetics of the ET between rhodamine B and malachite green in solution inside the glass. Using Equation (x), *Even* et al. found $\bar{d} = 1.74$. This result has recently been questioned with regard to its compatibility with light and X-ray scattering data.[82, 83] Similar experiments have been conducted by *Rojanski* et al.[84] on a porous silica gel; they obtained $\bar{d}_f = 3$ for the silica gel surface, a result also corroborated by adsorption and by X-ray scattering. These findings were later questioned by *Levitz* and *Drake*[85] and by *Levitz* et al.[86] who asserted that this type of silica gel is characterized by a smooth surface on the molecular scale ($\bar{d}_f = 2$). As shown by *Levitz* et al.[86] it is problematic to claim that a structure is fractal based only on results compatible with Equation (x).

Yang et al. performed computer simulations;[87] they considered the ET among particles located on pores of spherical or cylindrical shape, whose radii are of the order of the typical transfer distance; the calculated kinetics show fractal-like decays. Similar geometrical restrictions for ET have been studied by *Baumann* and *Fayer*[88] and by ourselves.[89, 90]

ET processes have been studied for polymeric systems. Singlet ET mechanisms in anthracene-loaded copolymers of vinylnaphthalene show complicated temporal behaviors, which are thought to be partly due to fractal-like distributions of naphthalene and anthracene molecules.[91] Triplet ET kinetics in doped polymer films has been investigated by *Lin, Nelson,* and *Hanson*.[92] Their data fit their model better when fractal structures are taken into account. Further discussions of polymeric systems in terms of fractals are given in References [93 and 94].

We close this section by mentioning that the ET model has also initiated new ideas; thus, fractals have been considered in the discussion of the energy migration and trapping among cationic porphyrins adsorbed on anionic vesicle surfaces.[85] Furthermore, a stretched exponential modulation model has been proposed for simulating vibrational dephasing in locally amorphous media.[96] Finally, hierarchical and fractal concepts have been used in the analysis of time-resolved spectra of mixed crystals of dichlorobenzene and dibromobenzene.[97]

5. Dynamical Aspects of Disordered Systems

We will now turn our attention to dynamical aspects for which the ideas of scaling in time play an important role. The dominant feature, distinct from the topics of the previous section, is that here we focus on changes in dynamics brought about by irregular objects, rather than on the geometrical aspects. Important problems in this field are (macroscopically) liquid flows through porous systems and (microscopically) charge and excitation transfer through polymeric samples.

A flow through a porous system, as any motion through a fractal space, may show dispersion, i.e. the diffusion is in general governed by Equation (m). This field has recently been well reviewed by *Po-Zen Wong*,[98] so we shall contend ourselves here with a summary of the results. The ionic conductivity of rocks σ_r scales with their porosity φ, following *Archie*'s law,[99] $\sigma_r \sim \varphi^{-m}$, where m is around 2. This result corresponds to the 'shrinking tube' model, which is analogous to percolation,[1] see for instance Equation (h), with $p_c = 0$.[99] An extension of the model leads to the 'grain consolidation' model, obtained from random sphere packing.[100] This model again leads to *Archie*'s law over much of the range of practical interest.[100]

Special topics of attention in flows in random systems involve problems which arise when two (or more) liquids are present at the same time, e.g. the question of how oil and water displace each other. Here one encounters 'viscous fingering' aspects, and 'invasion percolation'.[101] The latter model ensures that the invader flows along a continuous path while the defender may form trapped clusters. For details on these models we refer the reader to the literature.[98]

Another field of research in which temporal scaling and the CTRW scheme play an important role is charge carrier transport in amorphous materials, especially in polymeric photoconductors. A technique which is often applied for investigating the properties of amorphous photoconductors is the time-of-flight method. Charge carriers, generated by a short light pulse near the top surface of a thin film of the photoconductive material, drift under the influence of an external electric field through the sample and give rise to a transient photocurrent in the external circuit. In many inorganic and organic amorphous materials the shapes of the photocurrents $I(t)$ show dispersive behavior, i.e. the current decreases monotonically without exhibiting a regime with constant current, which one would expect if all charge carriers moved with the same mean velocity through the sample.

As also noted in Section 4, *Scher* and *Montroll*[58] applied the CTRW-theory to this problem and using the algebraic waiting-time distribution of the form (n) derived expressions for the asymptotic decay of the current. Two regimes have to be distinguished. In the time regime before the so-called transit time t_T (the time when the fastest carriers passed through the sample) the current decays according to (y),

$$I \sim t^{-1+\gamma} \tag{y}$$

whereas in the time range $t > t_T$ the current decays according to (z).

$$I \sim t^{-1-\gamma} \tag{z}$$

The results (y) and (z) mean that here the temporal aspect dominates the dynamics. As an example for which Equations (y) and (z) provide the right description for experimental data we present in Figure 8 the transient photocurrent in polysiloxanes with pendant carbazole groups.[102] Note that both axes are logarithmic, leading to an algebraic decay of the form $t^{-\beta}$ appearing as a straight line with slope $-\beta$. The experimental curve (1) and the theoretical curve (2), calculated with $\gamma = 0.58$, coincide over a period of four decades in

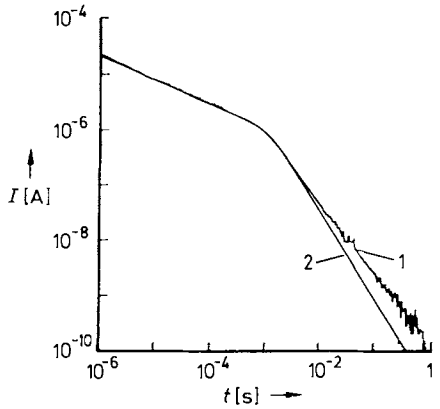

Fig. 8. Transient photocurrent in polysiloxane (1) and theoretical curve, calculated from an algebraic $\psi(t)$ with $\gamma = 0.58$ (2), double logarithmic plot.

time. Therefore, also in photoconductivity we obtain in many instances scaling behavior (see Ref. [15]).

However, the behavior of the photocurrents in polymeric systems is manifold. In the next section we will show some limitations of the idea of temporal scaling and we will also present crossover effects.

Let us now turn to percolative aspects in photoconductivity, an aspect more akin to geometric scaling. Percolation is important, if the substrate consists of impurity centers embedded in an inert matrix. In a recent investigation[1103] a benzotriazole derivative embedded in a polycarbonate matrix was used. In such a situation, especially at relatively low impurity concentrations, the fluctuations in the intersite distances become very drastic. As a result, the influence of the geometric disorder becomes dominant, and percolation, as described in Section 3, prevails. As discussed there, one has a critical concentration p_c, below which no current can flow. Slightly above p_c the current depends on the impurity concentration p, according to the expression (h), where p_c is nonuniversal while t is a universal constant (which depends mainly on the dimension). Figure 9 shows the carrier mobilities μ_T found for the benzotriazole–polycarbonate system. The experimental data appear to agree fairly well with the percolation picture.

To close this section let us consider the problem of electronic energy transfer in substitutionally disordered molecular and ionic crystals. Here the general interest has focused on the diffusion coefficient, which is related to the mean-squared distance traveled by the excitation, or on the decay of the excitation, due to trapping and annihilation.[10, 104–106] In the case of dipolar interactions, a less direct but experimentally very versatile method to test the transport consists in performing depolarization measurements.[107, 108] For randomly oriented molecules already a single-step transfer depolarizes very efficiently, so that in the long run the memory of the original polarization is lost, *except* for those excitations which are (still or again) on the originally excited sites. Thus depolarization measurements probe $P_0(t)$, the probability that an originally excited site is excited at time t. As we will show, $P_0(t)$ scales with time.

We have treated this problem in the framework of the previously described CTRW theory,[57, 58, 109] incorporating the local disorder in the waiting-time distribution $\psi(t)$, for which we used the time fractal Weierstrass-form Equation (p). Now for a simple random walk in $d = 3$ the relationship (A) holds true, and for general dimension d the relationship (B). Here the geometry of the lattice plays an important role.

$$P_0(t) \sim t^{-3/2} \quad \text{(A)}$$
$$P_0(t) \sim t^{-d/2} \quad \text{(B)}$$

On the other hand, when we perform a continuous-time random walk with an algebraic $\psi(t) \sim t^{-1-\gamma}$ we find that the long-time $P_0(t)$ expression is a direct reflection of the waiting-time distribution $\psi(t)$, as long as this distribution is broad, while for sufficiently narrow waiting-time distributions the classical random-walk behavior [Eq. (B)] for $P_0(t)$ is recovered. The decay behavior follows Equation (C)

$$P_0(t) \sim \begin{cases} t^{-\gamma} & \text{for } 0 < \gamma < 3/2 \\ t^{-3/2} & \text{for } \gamma \geq 3/2 \end{cases}, \quad \text{(C)}$$

(see also Fig. 10). Equation (C) is an example for the interplay between temporal and spatial aspects of excitation transport, the temporal aspect being dominant for small γ (high dispersion, wide distribution of jump times).

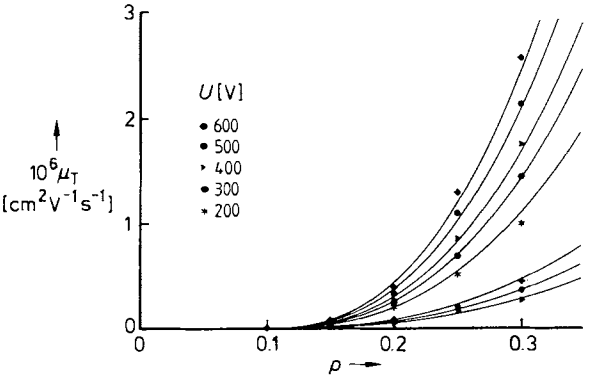

Fig. 9. Effective charge carrier mobilities μ_T of polycarbonate matrices containing different concentrations p of benzotriazole. The μ_T data were measured at the U-values given in the inset (sample thickness ca. 10 μm) at two different temperatures (293 K and 333 K). All curves are fitted to the percolation model [(h), with $p_c = 0.1$ and $\bar{t} = 2.5$].

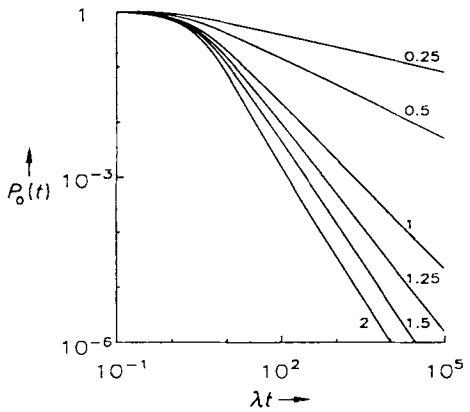

Fig. 10. Decay behavior of $P_0(t)$ for a bcc lattice under CTRW with $0.25 \leq \gamma \leq 2$, plotted on log–log scales. The γ-values are as indicated. λ is a scaling factor with the dimension s^{-1}.

In summary, in this section we have shown that the ideas of temporal and geometrical scaling (exemplified by the CTRW and by the percolation scheme) are fruitful methods for describing transport phenomena in disordered systems like polymers. In the next section we will outline some limitations of these methods.

6. Concluding Remarks

In a real physical system one cannot expect to have an infinite hierarchy of temporal or spatial scales. There always exist maximal and minimal cut-offs, like the size of the system or the distances between atoms, where the hierarchy of scales ends. Therefore, it depends on the range of the experimental parameters, whether the idea of scaling is fully applicable. Moreover, a more subtle limitation for scaling occurs when one works in the marginal regime for the critical parameters; in this regime one must be careful, since crossover effects (which may lead to a transition to normal behavior) may have to be taken into account. In such transition regions scaling is attainable only at exceedingly long times, possibly far outside the experimentally interesting range.

In order to illustrate this comment let us consider a very transparent model: we focus on a particle (charge carrier) diffusing under the influence of an external bias (electric field) on a linear chain and take the sites (traps) to have different energy levels ε with a distribution $\varrho(\varepsilon)$ (Fig. 11).

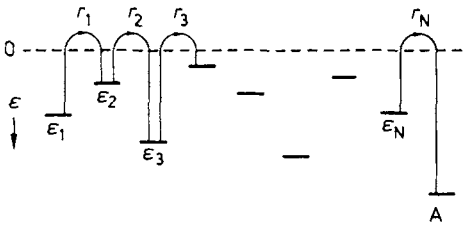

Fig. 11. Charge carrier hopping on a linear chain of equidistant sites with different trap energies ε_i and transition rates r_i. The ε_i are randomly chosen for a distribution $\varrho(\varepsilon)$. A = absorber.

Assuming thermal activation, we readily calculate the transition rates and, after averaging over the distribution $\varrho(\varepsilon)$, we get the corresponding waiting-time distribution $\psi(t)$.[110] This leads, like in the CTRW theory, to the current $I(t)$. The analysis shows that for a finite mean waiting-time $\tau = <t> = \int_0^\infty t\psi(t)\,dt$, a crossover from dispersive behavior for $t < \tau$ to nondispersive behavior for $t \gg \tau$ occurs. This is illustrated in Figure 12, which shows the current I for a Gaussian distribution of energy levels. Depending on the length N of the chain, the regime of normal transport (constant I) is more or less pronounced.

The situation is quite different for exponential energy distributions of the form (D). These lead to $\psi(t) \sim t^{-1-\gamma}$, just as considered in Section 3.

$$\varrho(\varepsilon) = \gamma e^{-\gamma\varepsilon} \qquad \text{(D)}$$

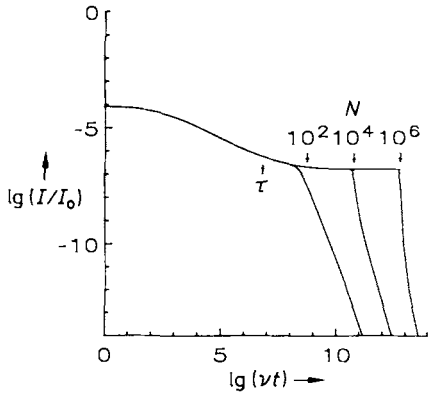

Fig. 12. Current curves for a Gaussian distribution $\varrho(\varepsilon)$ with $\varepsilon_0 = 12.5$ and $\sigma = 2.5$ for different chain lengths N. The arrows mark τ and $N\tau$, respectively. ν is a scaling factor.

For $\gamma > 1$ there exists a mean waiting-time $\tau = \gamma/(\gamma-1)$ and thus in the long-time limit the transport behavior is nondispersive. As long as γ is less than unity, the resulting current decays asymptotically as $I(t) \sim t^{-1+\gamma}$. These findings are illustrated in Figure 13. Now we have a crossover from dispersive to nondispersive behavior depending on the parameter γ. Note, however, and this is the important point here, that the time to reach the asymptotic regime diverges as γ approaches the marginal value 1. Thus, if γ is around unity, the asymptotic behavior may well be of no experimental significance.

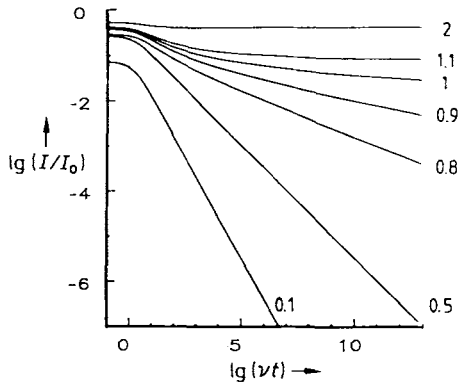

Fig. 13. Current curves for an infinite chain with an exponential distribution $\varrho(\varepsilon)$. The parameters γ are as indicated.

This example shows that the ideas of scaling are quite useful if one is well inside the range of validity of the critical parameters. However, in a marginal regime one has to be aware that a simple asymptotic scaling analysis may not be sufficient and that crossover effects have to be taken into account.

In conclusion, there is no doubt that ideas based on scaling, such as fractals and related hierarchical models have entered into almost all scientific disciplines. Scaling concepts are becoming increasingly standard for physicists and chemists, and such concepts are ideally suited for the analysis of polymers. Nevertheless, on a note of caution, it must be emphasized that not all irregular structures are ultimately

fractals; furthermore, switching now to the time scale, it must be pointed out that not all irregular time evolutions are indicative of scaling. In applications one has to be aware of crossover effects and of the fact that self-similarity is generally bounded by lower and upper cut-offs, a feature that renders the interpretation of experimental data delicate and which requires care in order to attain a sound physicochemical understanding.

The support of this work by the Deutsche Forschungsgemeinschaft (SFB 213), by the Fonds der Chemischen Industrie (grant of an IRIS-workstation) and by grants of computer time from the Hochschulrechenzentrum Bayreuth is gratefully acknowledged. We have greatly benefited from discussions with our friends and colleagues, Professors D. Haarer, J. Friedrich, J. Klafter and G. Zumofen, who have callaborated with us on many of the here-mentioned articles. Many thanks are also due to Dr. G. Zumofen for providing us with Figures 1 to 3 and 5.

Highly Reactive Intermediates from the Cocondensation Reactions of Iron, Cobalt and Nickel Vapor with Arenes**

New Synthetic Methods (80)

By Ulrich Zenneck*

In 1969, *P. L. Timms* reported the first preparative cocondensation reactions of metal vapors with organic and inorganic substrates. The use of this technique in preparative chemistry soon spread rapidly, but in recent years there has been less activity in this sector. If metal atom reactions are not utilized primarily for the formation of new products, but for the synthesis of highly reactive intermediates, a new synthetic strategy may be developed. Our aims are reaction sequences which, based on an effective cocondensation reaction, lead gradually and selectively to new substance classes. This principle can be illustrated by the example of the cocondensation products of arenes and iron, cobalt, or nickel vapor, which decompose between −70 and −50 °C. The classes of products accessible by this method extend from clusters, through π-complexes, organophosphorus and organoboron cage compounds to pure organic cycloaddition products.

1. Introduction

Many chemical reactions require an activation process. In the case of a transition metal complex, this can mean that a coordination site is opened up in a preceding reaction. The substrate molecule can then directly attack at the center. On the other hand, thermal or photochemical excitation of the central particle gives rise to a highly energetic state, which is particularly reactive. A special type of excitation is the production of free atoms by the vaporization of nonvolatile elements. These exhibit enhanced reactivity since:

- They are free of ligands, which could kinetically hinder any reaction; substrate molecules encounter atoms with each collison.
- The atoms possess a high potential energy, so that reactions are mostly exothermic.

The combination of both of these factors suggests that the reaction of free atoms with ligands should be carried out at low temperature, and this is generally the case. In practice, the region between −100 and −196 °C has proved to be the best for preparative work.

The first work of this kind was carried out in 1963 by *Skell* et al. on the vaporization products of graphite.[1] In 1969, *Timms* cocondensed transition metal vapors with organic substrates for the first time.[2] This initiated a rapid increase in the amount of work being carried out in this field, which appeared in several reviews[3] and monographs.[4, 5]

Neglecting the certain, gradual coupling of ligands to a free metal atom, the simplified energetic course of a metal atom reaction can be represented by Figure 1.

The vaporization of metals requires a relatively high vaporization enthalpy. In the case of transition metals, this energy is, on the whole, higher than for the C–C bond.[6] If an atom is introduced into a cooled matrix or solution of substrate molecules, there are two reaction pathways available to it. Either the desired reaction with the ligand results, with formation of the monomeric complex ML_n, or the metal atoms react with each other to give clusters M_xL_y, which often then aggregate to a metallic state.[7] Cluster formation is generally the kinetically and thermodynamically favored process.[3e] Thus, to obtain noticeable yields of the monomeric complex, it is necessary to use large excesses of the ligand molecules (at least 10:1, better 50:1). Therefore, this method is limited to ligands which are readily available and easily vaporized or highly soluble at low temperature. The complex forming reactions are mostly strongly exothermic, due to the high potential energies of the metal atoms. A clear tendency to give side reaction results, as can be seen in the example of transition metal atom/alkyne reactions.[8] This is not such a problem if, first of all, a highly reactive intermediate complex is generated in a metal atom reaction, and then allowed to react in situ to give the desired complex. This simultaneously results in an increase in the usefulness of metal atom reactions which can be worked with on a stoi-

chiometric basis at the second stage. The simplified energy diagram of this reaction pathway is shown in Figure 2.

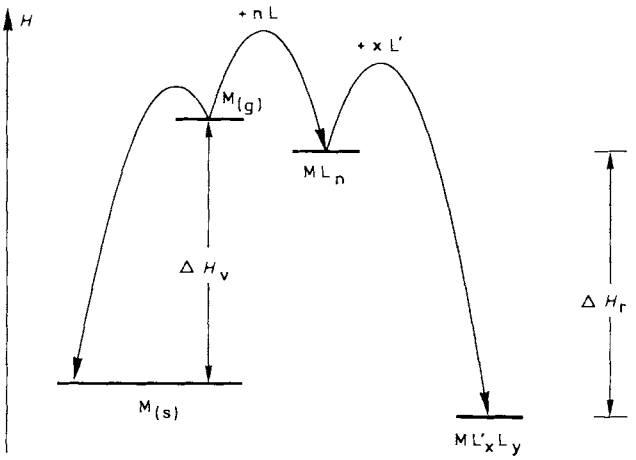

Fig. 2. Energy diagram of a two step synthesis involving a metal atom reaction and a highly reactive intermediate (arbitrary units) ΔH_r = reaction enthalpy of the second step.

The first examples of this type again came from the research groups of *Skell* and *Timms*, who allowed bis(arene)-iron[2] to react at about $-60\,^{\circ}C$ with PF_3. The result was the simple substitution of an arene ligand with formation of $[(\eta^6\text{-arene})Fe(PF_3)_2]$.[9, 10]

A systematic exploitation of the high energy available in the intermediate step is only possible, however, if the pathway outlined in Figure 2 is broadened. The aim of the resultant reaction of the cocondensation product ML_n (ML_n = reactive intermediate step **A**) should preferably not be a thermodynamically stable product, but another reactive particle which thermally decomposes below room temperature. Thus, from the partially extremely unstable cocondensation products **A**, one can obtain new, reactive, isolable intermediates **B** which can be optimized to the requirements of the desired synthetic aim. This step may be repeated, such that further reactive but more easily handled complexes **C** are synthesized from the isolable intermediates **B**. In the end, a cascade **A** → **B** → **C** → **D** etc. of slightly exothermic reactions results from metal atom product **A**. Thereby emerged the following hypotheses:

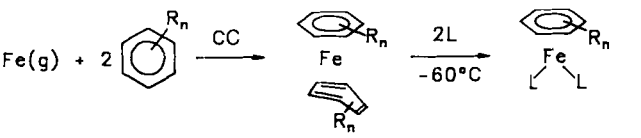
- If the energy changes between the single steps are small, then the reactions can be carried out selectively.
- The more intermediate steps, **A, B, C, D** etc. that can be carried out, the greater is the variability of the resulting chemistry.

In principle, this concept contains no limitations with respect to the metal or substrate which can be used.

The present review is intended to show some of the possibilities, for instance, of cocondensation products of iron, cobalt and nickel vapor with arenes. We are particularly interested in the cyclization reactions of unsaturated organic molecules in the coordination sphere of reactive metal complexes. By using new intermediates, we are looking for novel aspects of this reaction type, as compared with the known systems.

2. Areneiron Complexes

The first reaction of iron atoms with an arene was reported in the very first communication on metal atom chemistry by *Timms* in 1969.[2] The resulting bis(benzene)iron **1a** exploded at about $-50\,^{\circ}C$. As has already been described in Sec-



1a-e

1a: R_n = H **1b**: R_n = Me **1c**: R_n = 1,4-Me_2
1d: R_n = CF_3 **1e**: R_n = 1,4-F_2

tion 1, the thermally labile arene/iron cocondensation products can react with ligands at ca. $-60\,^{\circ}C$ to give stable complexes of the type $[(\eta^6\text{-arene})FeL_2]$. Ligands which have been added by this route are: PF_3,[9, 10] $P(OR)_3$, PR_3, diolefins, cycloheptatriene, 1,3,5,7-cyclooctatetraene[11] and 2,2'-bipyridyl (CC = metal-ligand cocondensation).[12]

The structures of the cocondensation products of iron atoms with arenes were disputed for a long time, for the results of the investigations are dependent on the concentra-

Ulrich Zenneck was born in 1946 in Clausthal-Zellerfeld/West Germany. After professional training as a dairyman and four years service in the federal border police, he studied chemistry at the Universities of Clausthal und Marburg. In 1980 he received his Ph.D. from the University of Marburg, under the supervision of Christoph Elschenbroich. He left Marburg for postdoctoral studies with P. L. Timms in Bristol (UK) (1980/81) and moved to the University of Heidelberg thereafter, where he finished his habilitation in 1988. He is now teaching there. His scientific interests are centered on preparative organometallic chemistry, starting with metal vapors, and redox reactions of transition metal complexes. His investigations of redox processes involve the utilization of electrochemical and ESR and NMR spectroscopical characterization of paramagnetic redox products.

tions of the species involved, as well as on the reaction temperature. In principle, 1:1 and 2:1 complexes, as well as clusters can be postulated. In the case of the 2:1 complexes η^6:η^6-, η^6:η^4- and η^4:η^4-structures have been discussed.[13-18] The requirements of preparative metal atom chemistry clearly favor the η^6:η^4-structure type for benzene and toluene.[16,17] In contrast to this, the stable bis(hexamethylbenzene)iron has an η^6:η^6-structure, and can be prepared by classical methods.[19]

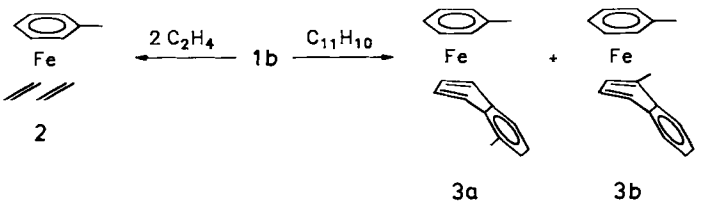
In a number of cases, a three component reaction of Fe(g) with arenes and ligands L has proved to be an alternative for the formation of [(arene)FeL_2] complexes.[11] This is particularly true for benzene, since **1a** usually gives only low yields in substitution reactions with ligands.

2.1. Synthesis of Novel, Highly Reactive Areneiron Complexes

Olefinic ligands can be rapidly substituted well below room temperature in the case of cyclopentadienylbis(olefin)cobalt and tricarbonylbis(olefin)iron complexes, which are isoelectronic with areneiron complexes.[20,21] Thus, (η^6-arene)bis(alkene)iron complexes seemed to be promising candidates for novel reactive intermediates. On the other hand, there was the opportunity to replace the (η^4-arene)-ligands of bis(arene)iron by naphthalene derivatives. This can offer additional bonding energy via better π-conjugation of the uncoordinated naphthalene ring. Accordingly an (η^6-arene)(η^4-naphthalene)iron complex of type **3** should be more stable than an (η^6-arene)(η^4-arene)iron complex of type **1**. But it can still be assumed that the η^4-bonded naphthalene may be substituted by other ligands as also (η^6-naphthalene)-ligands can easily be exchanged.[22] Until now, structurally confirmed (η^4-naphthalene)metal complexes have been confined to only two examples with one 4d- and one 5d-metal respectively.[23,24,25] Naphthaleneiron complexes have thus far only been obtained by matrix isolation in spectroscopic quantities.[17] Earlier reports of a [(naphthalene)$Fe(CO)_3$] complex[26] were soon questioned.[27]

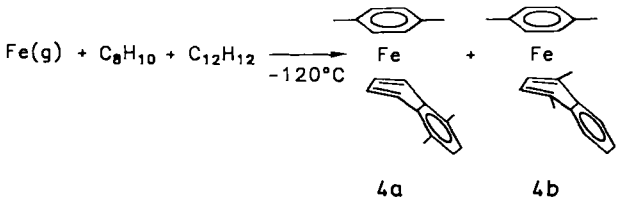
Bis(toluene)iron **1b**, freshly prepared by cocondensation, is stirred in the temperature range −80 to −40 °C under an atmosphere of ethene. A 56% yield of bis(ethene)-tolueneiron **2** is obtained, calculated from the amount of iron which is vaporized.[28] Since it is impossible to direct all of the metal vapor produced into the cocondensation zone,[5] only about two-thirds of the metal atoms can react with the toluene. The remainder form a metal layer on exposed surfaces of the apparatus. Thus, the chemical yield of the reaction is in excess of 80%. We usually vaporize 5–10 g of iron, or other 3d-metals, over a period of 1–2 hours in our "home-made" apparatus, thus obtaining 10–20 g of **2** in less than a day.[28] Other complexes described herein are also attainable in similar quantities. Cocondensation apparatus of comparable efficiency are also commercially available. **2** decomposes in solution above −20 °C, and as crystals at 0 °C. Long term stability can be obtained by storage at −78 °C under ethene. Decomposition products are the ligands and metallic iron. Despite its instability, **2** could be characterized spectroscopically and by crystal structure analysis.[28]

Reaction of 1-methylnaphthalene and **1b** in the temperature range −80 to −40 °C, furnishes orange-brown (η^4-1-methylnaphthalene)(η^6-toluene)iron as a mixture of two isomers, **3a** and **3b**, in the ratio 5:3.[29]

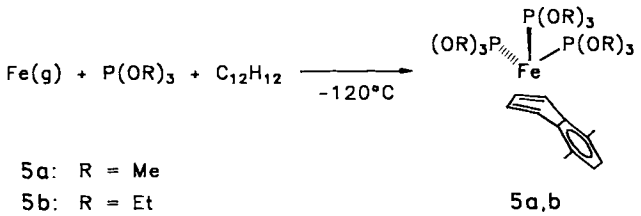


3a and **3b** can be subjected to work-up by normal chromatographic techniques at −30 °C. However, a successful separation cannot be achieved by column chromatography. Apart from their NMR spectra, there are no noticeable differences between **3a** and **3b**. They both decompose at ca. 0 °C, to the ligands toluene and 1-methylnaphthalene, and metallic iron.

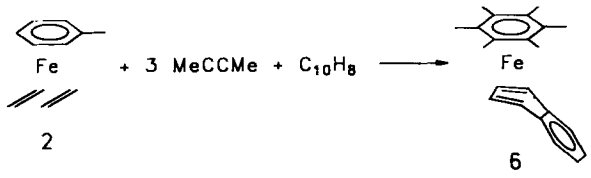
The (1,4-dimethylnaphthalene)(*p*-xylene)iron derivatives **4a** and **4b** are analogous to **3**, and also have very similar properties. They are most conveniently synthesized in a three component reaction between iron atoms and the ligands. Again, the 5–8-η-isomer **4a** is predominant over the 1-4-η-



complex **4b**, but, in this case, the two isomers can be partially separated by chromatography. (5–8-η-1,4-Dimethylnaphthalene)tris(trialkylphosphite)iron **5** (orange) is obtained from 1,4-dimethylnaphthalene, the relevant trialkylphosphites and iron vapor. Neither in **5a** nor in **5b** have the 1–4-η-derivatives been observed. Unlike **3** and **4**, both **5a** and **5b** are stable up to almost 150 °C, although they are far more sensitive to oxidation.



Reaction of **2** with 2-butyne and naphthalene affords the brown complex (η^6-hexamethylbenzene)(η^4-naphthalene)iron **6**, which is stable up to room temperature.[30]



As with the other η^4-naphthalene complexes,[24, 25, 29] the bicyclic moiety in **6** is bent along the C1–C4 axis (Fig. 3). The properties of this class of substances can best be understood if one accepts that there is a very extensive decoupling of the

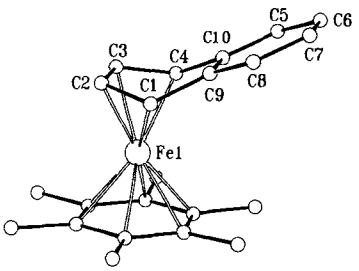


Fig. 3. Molecular structure of hexamethylbenzene(naphthalene)iron **6** in the crystalline state.

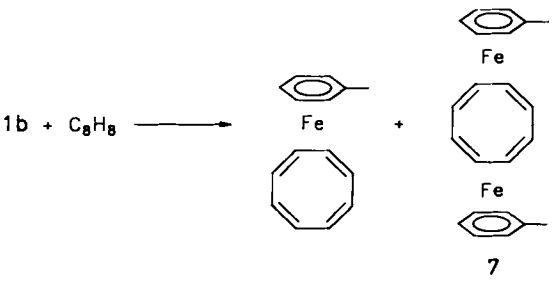
complexed π^4-system from the free π^6-system. The substances behave, both NMR-spectroscopically and in structural terms, about the same as would be expected for benzoannelated 1,3-cyclohexadiene complexes. Thus, the dihedral angle in the partly coordinated six-membered ring is $40 \pm 2°$ in the naphthalene complexes **5a** and **6**, as well as in the cyclohexadiene complex **31b** (see Section 2.3). Also, the ^{1}H- and ^{13}C-NMR shifts for the corresponding nuclei of the ligands of both substance types lie close to one another,[11, 29] and the free rings of the bicyclic moieties are influenced little by the metal.

Upon stirring a mixture of **1b** and 1,3,5,7-cyclooctatetraene (COT) variable amounts of the known complex cyclooctatetraene(η^6-toluene)iron[11] and the dinuclear complex μ-cyclooctatetraenebis[(η^6-toluene)iron] **7** are formed, depending on the concentration ratios used. **7** is obtained as a mixture of different structural isomers.[31]

Using an excess of **1b** gives **7** as the major product. Red solutions of **7** stored at $-78\,°C$ in aliphatic solvents, quantitatively decompose overnight to give cyclooctatetraene(η^6-toluene)iron and metallic iron. Solutions in toluene or benzene are stable up to 20 °C, and then slowly form metallic mirrors. Crystals of **7** are stable up to 70 °C, and then decompose in the same way as in solution.

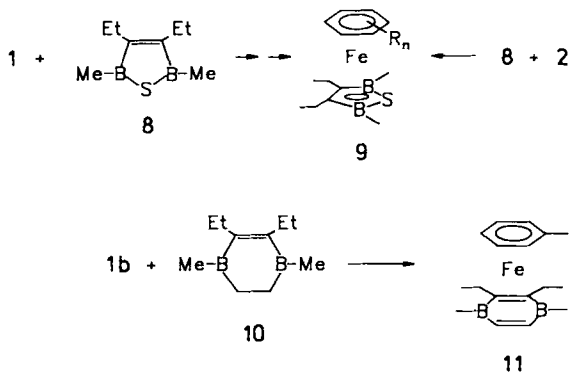


2.2. Substitution Reactions with Unsaturated Boron-Containing Heterocycles

As with **1**, the initial product of the cocondensation of arenes with iron, the novel reactive areneiron complexes **2, 3, 4, 6** and **7** also give substitution reactions at temperatures below room temperature with ligands such as phosphanes, phosphites, diphosphanes, dienes and CO. These always form complexes of the type [(arene)FeL_2] in the first step.[28–31] If one disregards the more easily handleable complexes which have been used here as educts, the reactions do not, in principle, differ from the well-known analogous reactions of derivatives of **1**.[9–12]

Since boron heterocycles possess a number of interesting ligand properties,[32] we decided to check whether the reactive complexes accessible from cocondensation reactions would allow, should the situation arise, a route to areneiron sandwich complexes with unsaturated boron-containing heterocycles as second ligand.

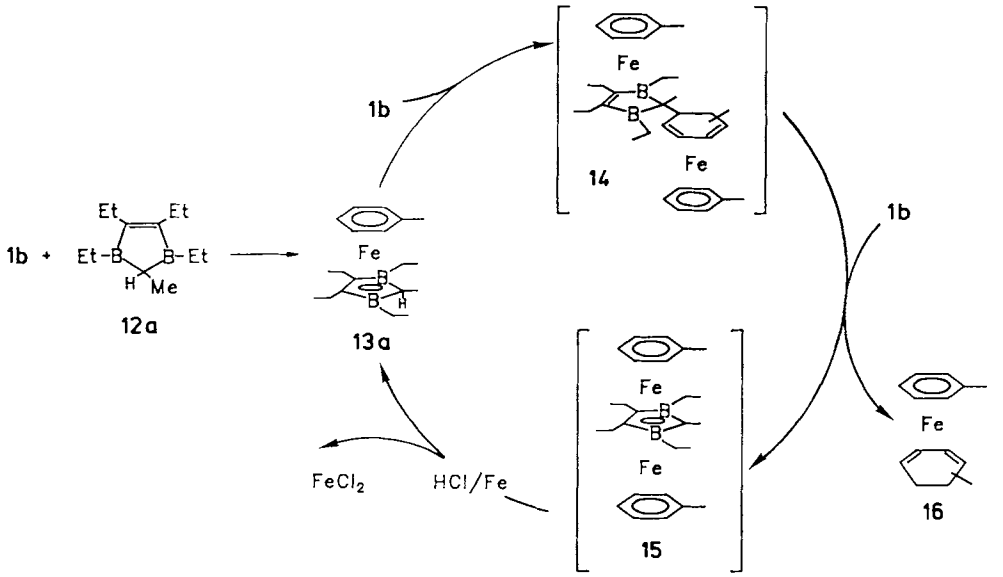
On allowing 3,4-diethyl-2,5-dihydro-2,5-dimethyl-1,2,5-thiadiborole **8** to react with **1a–1e** or **2**, the red compounds (η^6-arene)(η^5-dihydrothiadiborole)iron **9a–9e** are obtained as substitution products,[33] while 2,3-diethyl-1,4-dimethyl-1,4-diboracyclohex-2-ene **10**[34] and **1b** form the orange-red sandwich complex **11** containing an (η^6-diboracyclohexadiene) ligand by dehydrogenative complexation.[35]



The reaction of the tetraethyl(methyl) derivative **12a** of 2,3-dihydro-1*H*-1,3-diborole with **1b** follows a complex pathway.[36] The desired substitution product, (η^5-tetraethyl(methyl)dihydrodiborole)(η^6-toluene)iron **13a** (orange-red), can actually be obtained. What is particularly interesting is the reaction of the thermally labile intermediate **15** with concentrated HCl, which is unusual in organometallic chemistry. Without this reaction, the only stable iron complex isolated from **1b** and **12a** is the hydrogenation product **16**. X-ray and neutron diffraction experiments carried out on single crystals of **13a**[32, 36] show that in this complex, a pentacoordinated carbon atom (C-2) exists which has enhanced reactivity—similarly to the electronically isovalent cyclopentadienyl cobalt complex of **12a**.[37] Thus, **13a** can be deprotonated at C-2, quantitatively forming the corresponding complex anion.

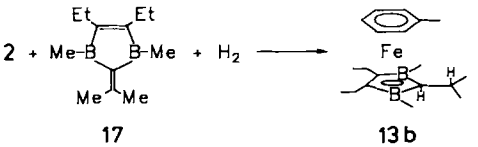
The reactivity of the C2–H bond of complex **13a** allows a rapid and effective reaction with **1b** at low temperatures which is much faster than the reaction of **1b** with **12a**, but

leads to the same result. The combination of electrochemical[38] and ESR-spectroscopical measurements on the reaction mixtures of **1b** with **12a** or **1b** with **13a**, furnishes results from which a reaction hypothesis might be derived.



From the measurements it emerges that the end product **13a** is concomitantly the first intermediate of the reaction sequence. A large number of oligodecker sandwich complexes containing the (μ,η^5-dihydrodiborolyl)(η^6-toluene)iron unit can be synthesized from **13a** and its deprotonated product,[32,39] thus confirming the structures proposed for **14** and **15** on the basis of spectroscopic data.

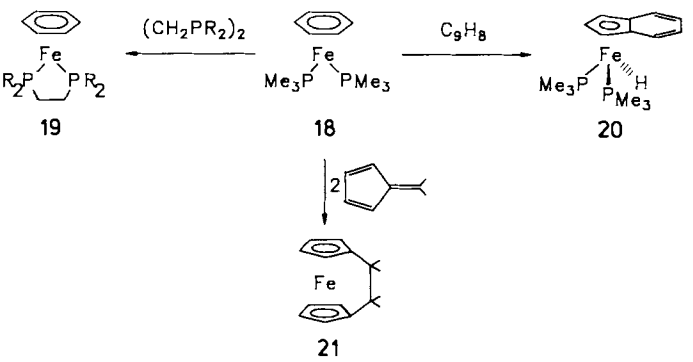
Unlike **1b**, **3** does not react with **12a**, while reaction of **2** with **12a** gives only small amounts of the substitution product **13a**, along with the (η^6-toluene)iron complex of a product formed by ethene insertion into **12a**. An alternative route to derivatives of **13** is the reaction of **2** with the diborafulvene **17**[41] under an atmosphere of hydrogen. In this reaction, a molecule of hydrogen is added across the exocyclic double bond, whereupon the diborafulvene is transformed into a 2-isopropyldihydrodiborole derivative, and forms the sandwich complex **13b**.[42]



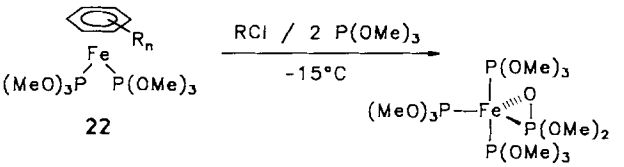
2.3. Substitution of Arene Ligands

In benzenebis(trimethylphosphane)iron **18**,[11] either the arene, the phosphane, or the entire ligand sphere can be substituted at room temperature, depending on the choice of substrate. This is contrary to the reactions described in Section 2.2. Typical examples of the numerous products accessible from **18** are complexes of the type [(benzene)FeL_2] **19**, [(indenyl)FeL_2H] **20** (or analogous cyclopentadienyliron complexes), as well as CC-coupling products such as the bridged ferrocene derivative **21**.[43]

18 has proved to be a versatile reagent for these reactions, and is rapidly accessible on a 20 g-scale, like **2** and **3**, in a three component reaction of iron vapor with the ligands.[43]



Arenebis(trimethyl phosphite)iron **22** is obtained almost quantitatively from **1**,[11] **2** or **3**[29] by ligand exchange with trimethyl phosphite. If it is allowed to react with additional trimethyl phosphite and organic chloro compounds, it will also lose its arene ligand.[44]



RCl = $CHCl_3$, $CDCl_3$, $MeCCl_3$, $PhCH_2Cl$

R_n = H, Me, 1,4-Me_2, 1,3,5-Me_3

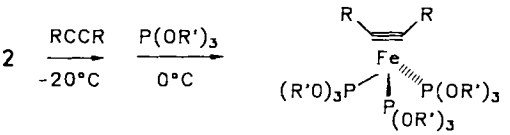
The formation of the dark green, paramagnetic iron complex **23** requires a Michaelis-Arbusov reaction, in which a methyl group is removed, as well as an exchange of the arene for additional phosphite ligands. According to the ^{31}P-hyperfine structure observed in the ESR spectrum ($a_1 = 2.69$, $a_2 = 3.06$, $a_3 = a_4 = 3.63$ mT; $<g> = 2.063$), the dimethylphosphonate ligand cannot be σ-bonded;[45] rather, it suggests an η^2-coordination, which otherwise is only known in thiophosphonate ligands.[46] It shows good correlation with the ESR data of 17-valence electron (VE) complexes of the type $[(\eta^3\text{-allyl})[P(OMe)_3]_3Fe]$.[47]

2.4. Reactions with Alkynes

Alkynes belong to the most important group of substances for cycloaddition reactions in the coordination sphere of transition metals. The opportunity presented itself to investigate their reactivity with areneiron complexes.

A number of alkynes have been cyclotrimerized by the complexes described in Section 2.1, in some cases at temperatures lower than room temperature.[31] These catalytic reactions can be of use as an effective source of further, reactive areneiron complexes, which can be converted into new alkyne complexes.[48]

Reaction of **2** with alkynes at −20 °C, followed by addition of trialkyl phosphite to the reaction mixture at less than 0 °C, leads to the the intensely blue-violet alkynetris(trialkyl phosphite)iron complexes **24a**–**24f** in fairly good yields.



24a-f

	R	R'
24a:	Ph	Me
24b:	Ph	Et
24c:	COOMe	Me
24d:	COOMe	Et
24e:	$SiMe_3$	Me
24f:	$SiMe_3$	Et

Hitherto, **24a** and **24b** were only available in small amounts by another route.[49] Both the ^{13}C-NMR signals for this series of complexes ($\delta(^{13}C)$ for the sp carbons lies between 178 and 206, cf. Ref. [50]) as well as the results of the crystal structure analysis of **24a** (Fig. 4) indicate that the alkynes in these compounds use all four π-electrons in their bonding to the metal.[44] Thus, they can be viewed as 18VE complexes, which is reflected in their thermal stability.

Reaction of bis(trimethylsilyl)acetylene with **2** affords the two bis(μ-alkyne)Fe_2 clusters tetrakis[bis(trimethylsilyl)acetylene]diiron(*Fe=Fe*) **25** (dark brown)[51] and tris[bis(trimethylsilyl)acetylene]bis(trimethyl phosphite)diiron **26** (deep violet).[31] While diamagnetic **25** can be synthesized just as well from **3**, paramagnetic **26** (two unpaired electrons) is

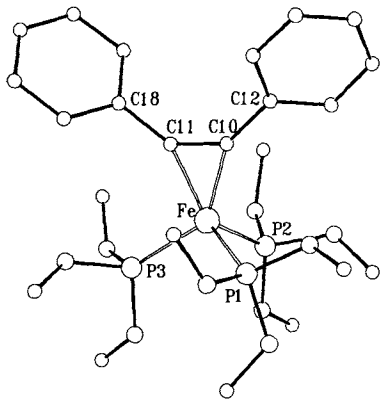


Fig. 4. Molecular structure of tolantris(trimethyl phosphite)iron **24a** in the crystal. Selected bond lengths [Å]: Fe–C10 1.896(5); Fe–C11 1.850(6).

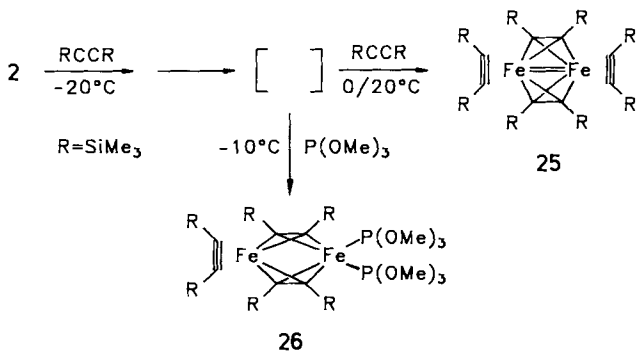
only accessible via the route using **2**, since the trimethyl phosphite must be added at between −20 and 0 °C.



26

Since both dinuclear complexes are electronically isovalent (the terminal alkyne ligands of **25** and **26** function as π^4 ligands as in **24**), the structural (Fe–Fe distance: **25**, 2.46 Å;[51] **26**, 3.08 Å[52]) and magnetic[53] differences between them are noteworthy.

25 is the first, structurally characterized, homoleptic alkyne metal cluster. The practically quantitative route from **2** or **3**, directly illustrates the great advantage of a "roundabout" approach to the synthesis using reactive intermediates. The product formed by the direct cocondensation of iron atoms with bis(trimethylsilyl)acetylene has been de-

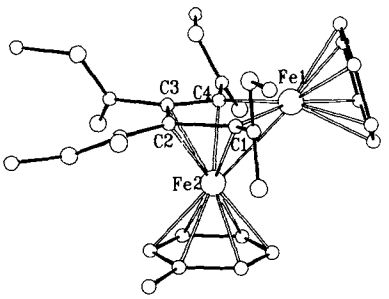


Fig. 5. Molecular structure of {(η^6-toluene)[η^5-1-(η^6-toluene)-2,3,4,5-tetrakis(methoxycarbonyl)ferrole]}iron **28b** in the crystal. The toluene ligand of Fe1 is rotationally disordered.

scribed as a non-stoichiometric substance,[54] which also obviously contains some of **25**.

The C–C linkage of two alkynes in the catalytic cyclotrimerization by areneiron complexes leads presumably first of all to ferrole complexes of the type **27**. The likely existence of these can be demonstrated by allowing an excess of **1b** to react with an alkyne. Dark green, complex-stabilized ferroles **28** are formed (Fig. 5). Tetraphenylcyclobutadiene(toluene)iron **29** (Fig. 6), which is a σ-π rearrangement

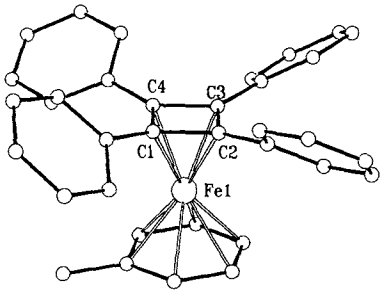

Fig. 6. Molecular structure of (η^4-tetraphenylcyclobutadiene)(η^6-toluene)iron **29** in the crystal. Selected bond lengths [Å]: Fe–C(C_4R_4) 2.002–2.050; Fe–C-(toluene) 2.036–2.138.

product of the ferrole, and the hydrogen addition product tetraphenylbutadiene(toluene)iron (**30**, Fig. 7) are formed together from **1b** and tolan.[48] The origin of the hydrogen for the formation of **30** has not been explained in this instance. Hydrogen addition reactions have also been observed with other derivatives of **1**.[55]

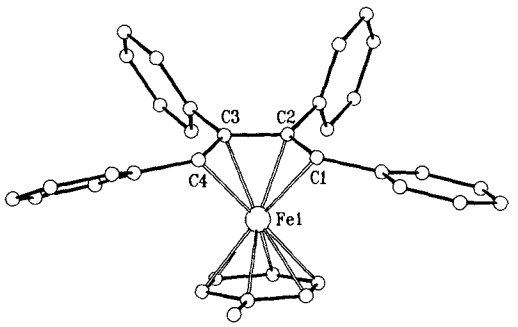

Fig. 7. Molecular structure of (η^4-tetraphenylbutadiene)(η^6-toluene)iron **30** in the crystal. Selected bond lengths [Å]: Fe–C($C_4R_4H_2$) 2.060–2.113; Fe–C-(toluene) 2.007–2.115.

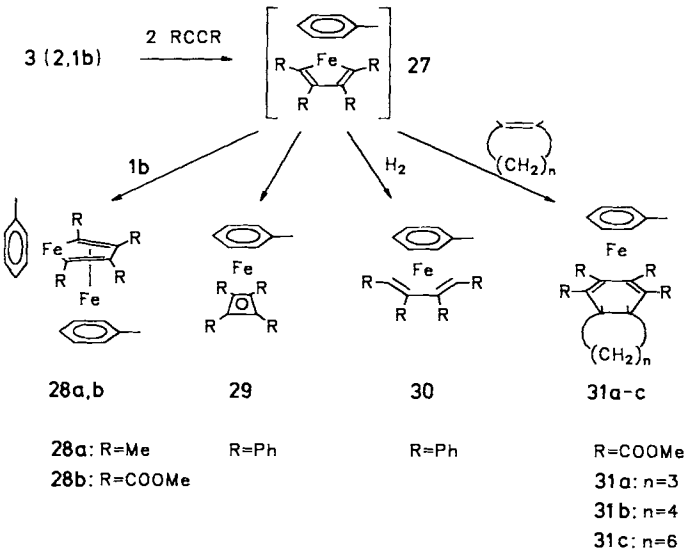
29 and **30** form a pair of electronically isovalent complexes. The Fe–C distances differ only very little, while other properties are markedly different. Thus, for example, **29** can be reversibly oxidized and reduced, which is very unusual for a mononuclear areneiron complex, and it only starts to thermally decompose at about 500 °C.[44] **30**, however, like most other (arene)FeL_2 complexes, is air sensitive and decomposes at 210 °C.

The important synthetic value of reactions of reactive areneiron complexes with alkynes is shown by the [2+2+2]-cycloaddition of two alkynes with one olefin. Here, 1,3-cy-



clohexadienes are formed in the coordination sphere of the metal, and bound as ligands, as in the analogous reactions of cyclopentadienylcobalt complexes.[56] However, contrary to the cobalt system, the reaction of the iron complexes (**3** is most suitable in this case) is strictly stereoselective. For example, upon addition of cyclic mono- or diolefins, the olefinic ring inserted into complexes of the type arene(cyclohexadiene)iron **31** are always found in the *exo*-position.[48] The *endo*-isomers cannot be detected NMR spectroscopically. A reason for the higher stereoselectivity of the iron complexes could primarily be the low reaction temperatures used—maximally room temperature—while for the cobalt complexes more than 70 °C is required.[56] Decomplexation of the ring bound to the metal in **31** and other related complexes is simple. After addition of $Fe^{3\oplus}$-salts to solutions of the complexes, the ligands can be almost quantitatively isolated.

The cyclotrimerization products of alkynes have also been fixed directly as complex ligands, and the reaction using 1,5-cyclooctadiene (COD) affords arene(cyclooctadiene)-iron derivatives **32** in high yield.[44]

	R	R'
32a:	H	H
32b:	Me	Me
32c:	Et	Et
32d:	H	*t*Bu

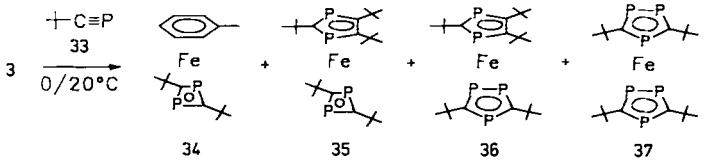
In this case, the entire ligand sphere of the iron has been exchanged. Hence, for formation of benzene-, 1,3,5-trialkylbenzene- or hexaalkylbenzene-complexes, one can also start with tolueneiron complexes **2** or **3**, both of which are readily accessible. Hexamethylbenzene(naphthalene)iron **6** (see Section 2.1) offers the additional possibility of carrying out such a synthesis stepwise. Firstly, the areneiron fragment is formed from **2** and the alkyne between −20 and +20 °C,

and then the naphthalene is slowly replaced at room temperature by the desired ligands.

2.5. Reactions with *tert*-Butyl Phosphaacetylene

tert-Butylphosphaacetylene **33**[57] was first used in metal-catalyzed cycloaddition reactions in 1986.[58] Since then its chemistry has developed exceedingly quickly.[59, 60] Since the ligand sphere of the reactive areneiron complexes can be completely exchanged for alkynes, we hoped that addition of phosphaalkyne **33** would lead to formation of larger oligomers at the iron center.

The reaction of **3** with **33** in molar ratios from 1:2 to 1:5 between 0 and 20 °C yields the cyclodimer of **33**, which is bound as a ligand in 1,3-diphosphete(toluene)iron **34** (orange) and the sandwich complexes **35** (olive), **36** (green), and **37** (green)[61, 62] containing 1,3-diphospholyl- and 1,2,4-triphospholyl ligands. The formation of these ligands must also involve cleavage of the P–C triple bond in **33**.

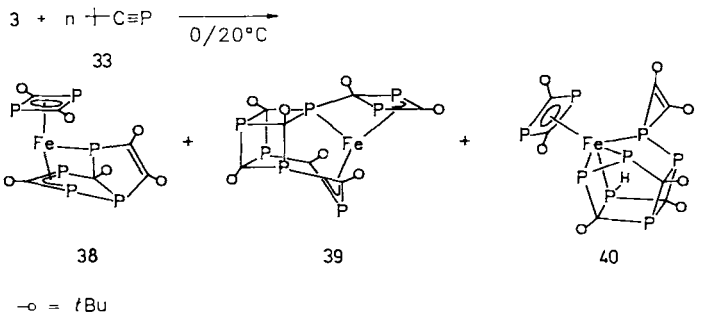


34 is a diphosphorus analogue of the cyclobutadiene complex **29**; the properties of the two complexes manifest their close relationship. **36** and **37** can be regarded as penta- and hexaphosphaferrocene derivatives respectively. However one should distinguish **36** from the similarly green pentaphosphaferrocene derivative containing a *cyclo*-P_5 ligand, which has recently been described by *Scherer* et al.[63]

Although one must accept that **36** is formed via an exceedingly complex reaction pathway, nevertheless five complete molecules of **33** react with one molecule of **3** in the formation of both five-membered rings. For **35** and **37**, things are more complicated. In these compounds, the ratio of the P/C units of the phosphaalkyne is not 1:1. In **35**, there are four phosphorus atoms and five C–R fragments, while for **36** the ratio is 6:4. This has to be interpreted in terms of an intermolecular exchange of these groups, at least in the early stages of the isolated complexes.

By using a very large excess of phosphaalkyne in the reaction of **3** with **33** (which offers no problems, due to its improved accessibility[64]), the consumption of about 9 moles of **33** per mole of **3** is observed in less than a day at room temperature.[65]

Aside from **34** to **37**, which are present in lower proportions than when using smaller amounts of **33**, a product mixture is now obtained which was shown by medium pressure chromatography to contain at least ten other iron-containing fractions. After repeated MPLC of this mixture, the complexes $(PCCMe_3)_6Fe$ **38** (dark brown, paramagnetic), $(PCCMe_3)_7Fe$ **39** (olive brown, paramagnetic), and $P_8(CCMe_3)_7HFe$ **40** (red, diamagnetic) were isolated in small quantities and characterized.[65, 66]



38[66] and **39** are thermally stable 16VE complexes, which are clearly distinguishable in this respect from other 16VE complexes of iron.[67] In **38** (Fig. 8), as in **34** and **35**, there is

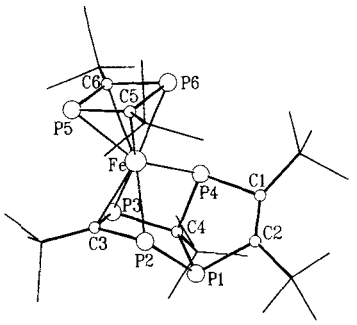


Fig. 8. Molecular structure of $(PCCMe_3)_6Fe$ **38** in the crystal.

a diphospheteiron fragment which is bound to a bicyclic tetramer of **33** in a complex. The interaction of the tetramer with iron takes place via a 1,3-diphosphaallyl grouping and a P–Fe σ bond. In **39** (Fig. 9), the ligand is formed by a

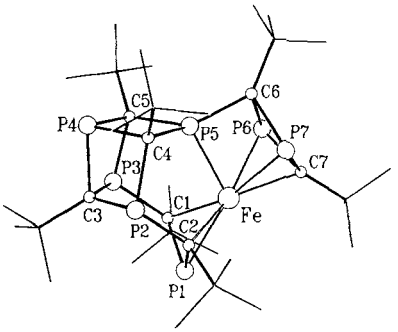

Fig. 9. Molecular structure of $(PCCMe_3)_7Fe$ **39** in the crystal.

polycyclic heptamer of **33**. Again, there is a coordinating $P_2(CCMe_3)_2$ ring, but this is joined to a $(PCCMe_3)_5$ cage via a σ-bond between C6 and P5, and is bound as a 1,3-diphosphaallyl ligand. The cage is bound to the metal by a 2-phosphaallyl on the one side, and on the other side a coordination site is occupied by the free electron pair of the phosphorus atom P5. The skeletal framework of **40** can be described as a ferrahexaphosphapentaprismane derivative (Fig. 10),[66] in which the $P_6(CCMe_3)_5H$ moiety behaves as a tetradentate

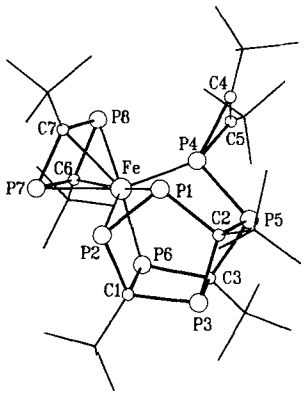

Fig. 10. Molecular structure of $P_8(CCMe_3)_7HFe$ **40** in the crystal.

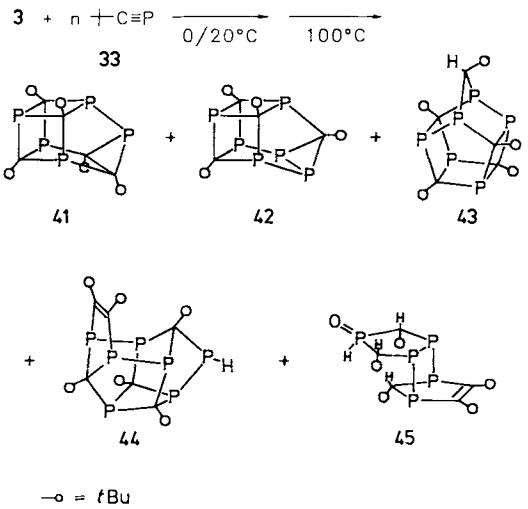
P_4 ligand. In contrast to **38** and **39**, **40** has a closed shell, 18VE structure. The phosphirene ring[68] P4C4C5, which juts out of the molecule, is only bound via P4 to the framework and the metal. Thus, reaction of a larger excess of **33** with the iron complex **3** can lead to up to seven units of the phosphaalkyne being coupled around the metal to give novel types of cage structures. All attemps at the direct removal of the organophosphorus skeletal frameworks from the complexes have thus far proved unsuccessful. However, heating of the reaction mixture under vacuum at 100 °C, on completion of the above-mentioned reaction met with some success. Thus, aside from the iron complexes 38 to 40, small amounts of metal-free organophosphorus skeletal compounds can also be obtained.



$(PCCMe_3)_5$ **41** is a polycyclic pentamer of **33**,[65] the structure of which can be derived from that of the tetraphosphacubane[69] by replacing one corner by a three-membered ring, formed by insertion of a $PCCMe_3$ unit. A structurally analogous hydrocarbon is known,[70] but not an organophosphorus compound or a polyphosphide. $P_6(CCMe_3)_4$ **42** (Fig. 11) belongs to the same structural group.[66] $P_6(CCMe_3)_5H$ **43**[65] is a heteroanalogue of homopentaprismane.[71] Like **40**, which also has a pentaprismane structure, **43** contains an additional hydrogen atom. $P_7(CCMe_3)_6H$ **44**

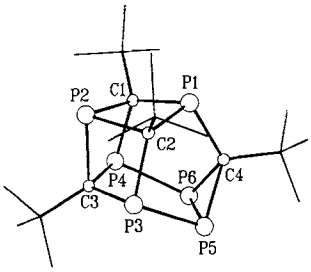


Fig. 11. Molecular structure of $P_6(CCMe_3)_4$ **42** in the crystal.

is formally derived from **43**, which has been enlarged by an additional unit of **33**. The structural form of **44** is, to our knowledge, new. Parts of the framework have similarities with organopolyphosphanes of the type P_7R_3.[72]

Tricyclic $(PCCMe_3)_5H_4O$ **45** (Fig. 12)[66] has far less internal bonding than the compounds **41**–**44**. Here, we are dealing with an oxidation product, which has, in addition, incorporated four hydrogen atoms. The pentaphosphaferrocene derivative **36**, in particular, could be considered to be an educt of **45**. Not only is the number of $PCCMe_3$ units the same in each, but also the relative orientation of the two five-membered rings. Similar correlations can be drawn between **39** and **41**, as well as **40** and **43**. In both cases, only one diphosphete-iron fragment has to be removed from the complexes, such that on formation of the new structures, the remaining frameworks can be stabilized in their most saturated and closed conformations. An explanation to this problem has been sought just as intensively as the principal question, of how these systems organize themselves around the metal center.

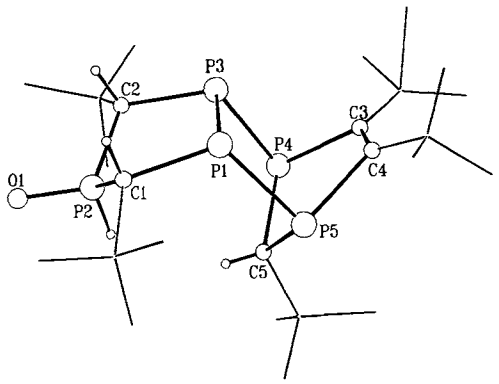

Fig. 12. Molecular structure of $(PCCMe_3)_5H_4O$ **45** in the crystal.

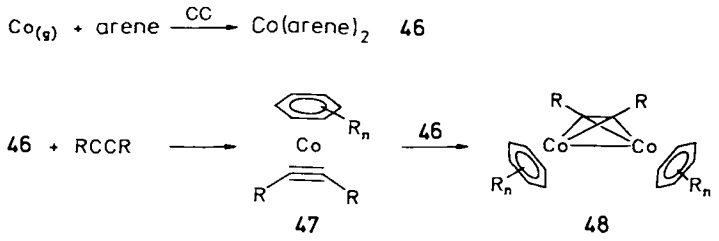
3. Arenecobalt Complexes

Arene/cobalt condensates have already proved useful in the formation of bis(2,2'-bipyridyl)cobalt,[73] of reactive organometallic slurries[74] and of catalytically active solutions.[75] However, up till now, it has not proved possible to attach the arenes as π-ligands to the cobalt atoms, to form cobalt complexes.

Reaction of the cocondensates **46a** to **46e** (arene = benzene, toluene, *p*-xylene, trifluoromethylbenzene 1,4difluorobenzene) in the temperature range −100 to −20 °C with alkynes [2-butyne, bis(trimethylsilyl)acetylene] yields both alkyne(arene)cobalt **47** (green, paramagnetic) and μ-alkynebis(arenecobalt) **48** (red, diamagnetic) in variable ratios, dependent on the type and concentration of the educts used.[76]



47, 48	R	R_n
a	Me	H
b	Me	Me
c	Me	1,4-Me_2
d	Me	CF_3
e	Me	1,4-F_2
f	$SiMe_3$	Me

The benzene complex **46a** reacts with 2-butyne to give **47a**. For the toluene/butyne system, the formation of **48b** is strongly favored. Addition of excess butyne to **46b** increases the amount of **47b**, so that the reaction path outlined in the scheme is assumed. In the case of toluene/$C_2(SiMe_3)_2$, the formation of **47f** is favored, and **48f** is formed in trace amounts only. As in the toluene system, the dinuclear complex **48d** is again favored in the trifluoromethylbenzene/butyne system, and the corresponding mononuclear complex **47d** can only be identified spectroscopically. In the reactions of butyne with *p*-xylene and with 1,4-difluorobenzene, the respective derivatives of **47c** and **47e**, respectively, can be observed by ESR spectroscopy. Separation of the reaction products is achieved by fractional vacuum sublimation. It must be accepted that certain losses arise during this process (**47a**–**47f** slowly decompose above room temperature).

While the dinuclear complexes **48** are analogous to $[CO_2(CO)_6(\mu\text{-alkyne})]$ clusters,[77] there was, at first, no other example comparable to complex **47**.[78] The crystal structure analysis of **47a** (Fig. 13), and interpretation of the ESR data for the series of compounds,[76] afforded unequivocable proof of the alkynes using all four π-electrons in their bonding with the metal.

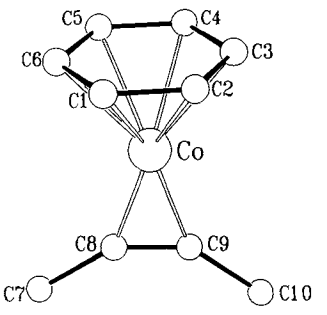


Fig. 13. Molecular structure of (η^6-benzene)(2-butyne)cobalt **47a**. Selected bond lengths [Å]: Co–C8 1.885(4); Co–C9 1.901(5).

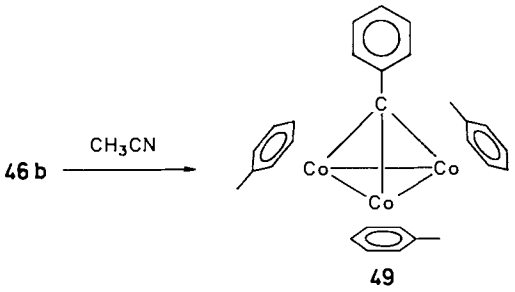
Chemical and electrochemical oxidation experiments on **47a** and **47f**, to form **47a**$^{\oplus}$ and **47f**$^{\oplus}$, have, up till now, been unsuccessful. The lifetime of the predicted 18 VE cationic complex **47**$^{\oplus}$ is so short, even at −60 °C, that only clean, irreversible oxidations are observed.

Thermal decomposition of the mononuclear butyne complexes affords hexamethylbenzene, together with small amounts of the corresponding dinuclear complexes. These also yield the cyclotrimer of 2-butyne at higher temperatures.

Reaction of **46b**, not with alkynes, but with the N–C triple bond of acetonitrile, leads to formation of small amounts of the dark red trimetallatetrahedrane (μ_3-benzylidyne)tris(toluenecobalt) **49**,[76] and much metallic cobalt. **49** is not observed in the thermal decomposition of **46b**.

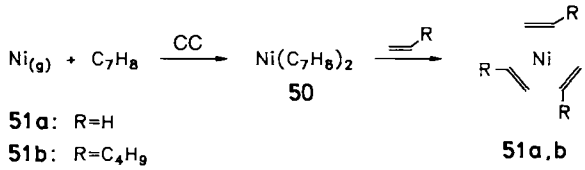


49 is closely related to **48**, and results from the formal replacement of a C–R fragment by an isolobal arenecobalt unit.

4. Arenenickel Complexes

Arene/nickel cocondensates also behave similarly to the corresponding iron and cobalt compounds **1** and **46**, respectively.[3e, 4, 5] Upon thermal decomposition of (toluene)$_2$Ni **50**[79] at about −50 °C, very finely divided nickel with a hydrocarbon coated surface is obtained, which can be used for a number of reactions.[80]

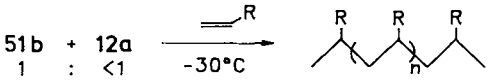
When the decomposition of **50** is allowed to take place in the presence of phosphites, $[P(OR)_3]_4Ni$ is formed.[79] In the presence of ethene, $(C_2H_4)_3Ni$ **51a**[81] is obtained, which is also accessible via classical routes.[82] Owing to the small amount of time required, and the use of very simple chemicals, together with the availability of a cocondensation apparatus, the route to derivatives of **51** via **50** is an interesting alternative to the synthesis of **51a** from cyclododecatrienenickel.



The synthesis of **51a** from **50** is complete in less than one working day, analogously to the synthesis of **2** from **1b**. Even

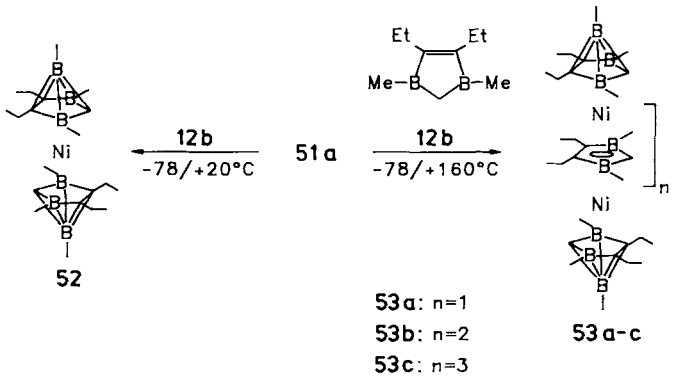
the yields and amounts synthesized correlate very well (10–20 g per run). Reaction of **50** with hex-1-ene instead of ethene furnishes tris(hexene)nickel **51b**, which thermally decomposes above −30 °C. The characterization of **51b** has not yet been completed.

Reaction of **51b** with the dihydrodiborole derivative **12a** (cf. Section 2.2) in a ratio of greater than 1:1 in the presence



of free hexene led to rapid polymerization of the hexene above −30 °C. Ethene polymerization can also be observed in reactions of the ethene complex **51a** with **12a** or **12b** in a molar ratio greater than 1:1 below room temperature. However, the yields of polymers are clearly lower than with hexene.[83] This may be caused by the olefin concentration, since the reaction was conducted at normal pressure.

Reaction of **51a** and **12b** in a ratio of 1:1.5 at room temperature for several hours leads to formation of the novel green compound bis(diethyltrimethyl-2,3,5-tricarbahexaboranyl)nickel **52**,[84] the parent compound of a series of oligodecker sandwich complexes **53a** to **53c**, which are obtained in only small amounts via this reaction route.



The same reaction can be optimized with regard to the yield of the known tripledecker **53a**.[85] The educts, in a ratio of 1:3, are heated to over 160 °C, without solvent, at which point, a little air is introduced to initiate partial oxidation.[86] The higher oligodeckers **53b** and **53c** can be detected, although their amounts are still small. Qualitative MO considerations show that the η^5-1,3,5-tricarbahexaboranyl ligands can be regarded as being isolobal with cyclopentadienyl ligands. **52** would then be a nickelocene analogue. In fact, all of the properties which are related to the electronic structure of the molecule can easily be understood in terms of this hypothesis.[84] This holds true, for instance, for the magnetism—which shows Curie-Weiss behavior of two unpaired electrons for both compounds and for the electrochemistry.[88] However the ESR data for the reversibly formed 19 VE-cation $\mathbf{52}^{\oplus}$ are clearly different from that for the nickelocenium ion.[89] The reason for this lies in the Jahn-Teller activity of the nickelocenium, which does not appear in **52** for reasons of symmetry.

5. Conclusion

The areneiron system, in particular, has proved its versatility in the results which have been presented and summed up in this review. The initially formulated aim to convert a few highly reactive cocondensation products gradually and selectively via further reactive, but isolable intermediates into a number of novel compound classes, could, in some cases, be achieved. For example, in the reaction sequence $Fe_{(met)} \rightarrow Fe_{(g)} \rightarrow \mathbf{1b} \rightarrow \mathbf{2} \rightarrow \mathbf{25}$, a total yield of 50% can be obtained (calculated from the amount of iron vaporized); 20 g of **25** can be prepared in two days from elemental iron. Pieces of nail or waste sheet steel have proved to be a far better source of iron for metal vaporization than pure metal powder, which tends to liberate too much gas when heated under vacuum.

The intermediates are so reactive that in several cases the entire coordination sphere of the metal complex is exchanged, even under mild conditions. Thus, novel types of structures with an organoelement framework can be built around a metal, using the appropriately reactive educts.

On searching through the literature of metal atom reactions conducted on a preparative scale and the corresponding matrix spectroscopy, it would seem that stable primary products are in the minority. Thus, we feel confident that we have revealed a much broader scope of application for highly reactive cocondensation products in systematic syntheses, than was hitherto ever thought possible.

I would like to thank my co-workers Dr. A. Funhoff, D. Hu, Dr. H. Schäufele, C. Tolxdorff, and Dr. L. Vasquez for their care, commitment and enthusiasm shown in carrying out this work. The assignment of particular projects was as indicated in the literature. Dr. H. Pritzkow performed all of the crystal structure analyses which appear in this review. Reactions involving boron heterocycles were the result of strong collaboration with Professor Dr. W. Siebert, Heidelberg, and his co-workers Dr. G. Brodt, Dr. D. Büchner, Dr. L. Suber, Dr. J.-K. Uhm, and Dr. J. Zwecker. I would like to thank them all for their outstanding cooperation, and in particular Prof. Dr. W. Siebert for giving me all the necessary support for such a project. Finally, I am most grateful to the Stiftung Volkswagenwerk, the Land Baden-Württemberg, and the Deutsche Forschungsgemeinschaft (SFB 247) for their generous financial support of this work.

Starburst Dendrimers: Molecular-Level Control of Size, Shape, Surface Chemistry, Topology, and Flexibility from Atoms to Macroscopic Matter**

By Donald A. Tomalia,* Adel M. Naylor, and William A. Goddard III

In memoriam Piero Pino

Starburst dendrimers are three-dimensional, highly ordered oligomeric and polymeric compounds formed by reiterative reaction sequences starting from smaller molecules—"initiator cores" such as ammonia or pentaerythritol. Protecting group strategies are crucial in these syntheses, which proceed via discrete "Aufbau" stages referred to as generations. Critical molecular design parameters (CMDPs) such as size, shape, and surface chemistry may be controlled by the reactions and synthetic building blocks used. Starburst dendrimers can mimic certain properties of micelles and liposomes and even those of biomolecules and the still more complicated, but highly organized, building blocks of biological systems. Numerous applications of these compounds are conceivable, particularly in mimicking the functions of large biomolecules as drug carriers and immunogens. This new branch of "supramolecular chemistry" should spark new developments in both organic and macromolecular chemistry.

1. Introduction

Over 300 years ago, the notion of "a universe within a universe" became a well documented and vivid concept in the work of *Jonathan Swift*.[1] A more contemporary version of this concept may be seen in the fractal geometry of *Mandelbrot*[80, 81] (Fig. 1). Each of these analogies serves well in dimensionally relating atoms to "pointlike" covalent molecules and to biomacromolecules, which are so quintessential of life (cf. Fig. 3). Although the first Lilliputian organic molecules were discovered some 150 years ago, molecular biologists and synthetic chemists are just now beginning to understand how nature bridges this dimensional gap.[2] Recent results[3] indicate that a dimensional hierarchy can also exist in abiotic systems. Within metals or partitioned water, for example, clusters of specific "mesoscopic" dimensions exhibit unique properties which differentiate them from single atoms or molecules or from higher-dimensioned macroscopic matter.

Are there abiotic synthetic strategies which allow covalent entry to such mesoscopic systems? More specifically, are there viable synthetic schemes which allow a systematic molecular morphogenesis from atoms to (microscopic) pointlike organic molecules and ultimately to (mesoscopic) biomorphic/receptor-like molecules and assemblies (cf. Fig. 3)? The latter question has been asked from a multitude of perspectives.[4]

This article offers partial answers to these questions and describes our efforts to develop, characterize, and predict three-dimensional organizations of ordered, covalent connectivity around various microscopic reference points (i.e., pointlike organic molecules referred to as initiator cores). The resulting covalent architecture can be systematically controlled by stepwise reiterative reaction sequences (generations). This process (cf. Fig. 2) involves the following steps:

1. Start with an initiator core ① possessing N_c reactive sites (e.g., $N_c = 3$ for ammonia).

Fig. 1. Computer-generated enlargement of a boundary site in a Mandelbrot set (generated in a Graphiklabor "Dynamische Systeme" by *Heinz-Otto Peitgen, P. H. Richter*, and *D. Saupe*, Universität Bremen).

2. Choose a reaction sequence so that each of the N_c reactive sites adds a reactant B_1 possessing N_b ($N_b > 1$) new reactive sites, which introduce multiplicity, to obtain dendrimer[70] D_0 of generation 0. With ammonia as initiator core, a β-alanine derivative ($N_b = 2$) might be chosen as reactant.
3. Use protection/deprotection strategies to ensure that B_1 reacts with all reactive sites of ①, but that no reactions occur at the new reactive sites on B_1 of dendrimer D_0.
4. Define an iterative sequence involving addition of new reactants B_{i+2} to the molecule D_i of generation i to form a new dendrimer D_{i+1} of generation i + 1.

In this fashion, it is possible to control size, shape, topology, flexibility, and surface chemistry, referred to as critical molecular design parameters (CMDPs), at the molecular level. Such space-filling, terminally functionalized molecular organizations have been coined starburst dendrimers.[70] One can grow predictable, stoichiometric structures up to a self-limited dimension (generation), which is determined by N_c and N_b as well as by the dimensions of the structural components.

The branching implicit in $N_b > 1$ leads to geometric growth in the number of atoms for each generation. For example, the number of β-alanine monomers for starburst polyamidoamines (PAMAMs) with ammonia as initiator core is 3, 9, 21, 45, 93, 189, 381, 765, and 1533 for generations 0–8, respectively. Since the overall size can only grow linearly because of the constraints of the covalent bonds, these systems eventually become congested and change from an open, starfish-shaped molecule to a ball-shaped structure. This is illustrated in Figure 2 (generations 0–7) for PAMAM (molecular dynamics simulations).

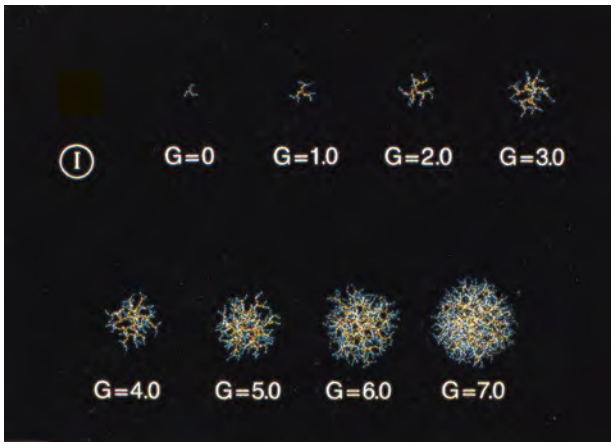

Fig. 2. Computer-simulated molecular graphics (wireframe) using POLYGRAF [97b] for starburst polyamidoamines (PAMAMs) as a function of generation. Initiator core ① (ammonia), red; interior, yellow; surface units, blue. Here, the dendrimer core is generation 0.

2. Dimensional Hierarchy in the Evolution of Organic Matter and Life

In order to comprehend the complex architectures obtainable by controlling a few critical molecular design parameters, we will consider some aspects of life processes from the perspective of these parameters.

2.1. Critical Molecular Design Parameters Involved in Life Processes

The most plausible current models for the origin and evolution of life revolve around self-assembling molecular systems: "Order begot order from chaos."[5, 6] These models have the following features:[5, 6c]

1. Small pointlike molecules were assembled into more complex, "intelligent" biomacromolecules and assemblies possessing ordered, retrievable molecular information for specialized functions.
2. Successful molecular evolution required very faithful transfer of molecular information. This was possible only by exquisite molecular-level control of size, shape, topology, flexibility, and surface chemistry. In this context, these five parameters are referred to as critical molecular design parameters (CMDPs).
3. Control of these CMDPs allowed the development of features and functions inherent in all living systems; namely, their ability to reproduce, to pass on genetic information (i.e., a prototype blueprint) to their progeny, to perform various specialized functions, and finally to grow to prespecified limited dimensions, usually with some characteristic morphology.

These very simple principles, together with natural selection processes, have led to an incredibly rich array of life forms. Figure 3 illustrates a hierarchy which describes the

Donald Tomalia was born in Owosso, Michigan, in 1938. He received a B.A. in chemistry from the University of Michigan (Flint College) in 1961 and joined the Dow Chemical Company as a research chemist in 1962. He progressed to the level of research manager while receiving a Ph.D. from Michigan State University in physical-organic chemistry (1968). His major activities from 1965 to 1975 were in the area of synthetic polymer chemistry; his discovery of the cationic polymerization of 2-oxazolines led to the receipt of two national industrial research awards (IR-100 Awards) for creative research in 1978 and 1986. Presently, he holds the positions of Research Scientist at The Dow Chemical Company (Agricultural Discovery Synthesis) and Adjunct Professor at the Michigan Molecular Institute. D. A. Tomalia holds 78 U.S. patents and has published extensively in the areas of carbonium ion chemistry, reactive heterocyclic monomers, and new polymer architectures. His main research interests include molecular recognition, enzyme inhibition, molecular self-organization, controlled delivery systems, and precision design of macromolecules.

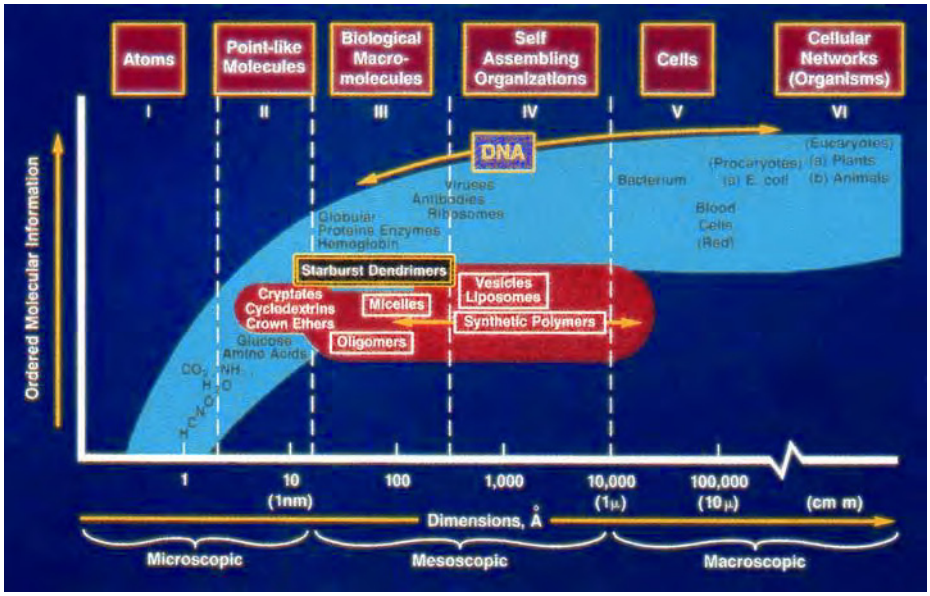

Fig. 3. Dimensional hierarchy of atoms, covalent matter, assemblies, and biological cells as a function of ordered molecular information.

advancement of atomic- and molecular-level entities (I, II) along various biological pathways to biomacromolecules (III) and higher-ordered molecules and assemblies such as IV–VI. Advancement from atoms (I) to pointlike molecules and subsequently to biocellular networks (VI) can generally be related to the amount of ordered molecular information possessed by the entities II–VI as well as to their relative dimensions. Superseding and in fact directing the assembly and function of many members of categories III–VI is the fundamental template of life, deoxyribonucleic acid (DNA). Because of its relatively high aspect ratio, one may think of DNA as a one-dimensional template which transmits molecular information through a cascade of intermediates (m-, t-, and rRNAs, ribosomes, etc.). Ultimately, this genetic (molecular) information becomes translated into one-dimensional protein sequences. The size of these proteins is determined by the length of the polypeptide chain, whereas the shape, interior topology, and surfaces result from foldings and convolutions determined by the sequence and the side chains of the amino acids.[7] Thus, the initial one-dimensional molecular information is ultimately translated into a three-dimensional message. Precise control of the CMDPs is the foundation upon which evolution chemistry has advanced and reached its present state of development.

2.2. Comparison of Synthetic with Evolutionary Strategies for Controlling Critical Molecular Design Parameters

Over the last 150 years, organic chemists have learned how to synthesize highly complex compounds as they have explored the options for precisely controlling the CMDPs of pointlike organic molecules (category II, Fig. 3). More recent attention has been directed toward the synthesis of larger, yet structurally defined macromolecules. For example, such molecules have been the subject of intense interest over the past 20 years as "endo-receptors" for the examination of guest–host relationships. Their design has been derived largely from macrocyclic[8] or macropolycyclic[9] structures as well as from acyclic architecture (podands).[10] The selectivity achieved by such endo-supramolecular chemistry[9c, 11–13] has been compared with that of binding substrates in the cavities (active sites) of larger proteins (enzymes).[14] Currently, these synthetic constructions depend largely on low-aspect-ratio, three-dimensional architecture for their endo-receptor design. Most notable are the cavitands and carcerands, whose interiors are large enough to enclose covalent guest molecules. They have been referred to recently by *Cram* in his Nobel lecture[12c] as synthetic molecular cells.

In contrast, biological protein synthesis involving one-dimensional sequences of amino acids is the fundamental theme of evolution chemistry in the construction of biomacromolecules (category III, Fig. 3). This one-dimensional polymerization strategy, which involves specific sequences of just 20 naturally occurring amino acids, leads to proteins with an enormous variety of possible shapes and sizes. The control of their chemical reactivity, provided by the juxtaposition of electrostatic and hydrogen-bonding "scenarios" at their surfaces, governs the CMDPs of living systems. By this means, very "intelligent", information-laden protein structures (i.e. bio-morphic/receptor molecules) have evolved to fulfill intricate molecule-recognition roles in biological membranes. In other instances, these CMDPs have been used to create microdomains (cavities) suitable for the amazingly selective substrate binding and catalytic chemical transformation carried out by enzymes. The cavity and cleft dimensions required for these important life processes generally seem to necessitate globular proteins with around 300 amino-acid units and molecular dimensions of the order of 25–200 Å in order to provide adequate scaffolding and tertiary-structure development.[15]

On the other hand, a completely different strategy is used for constructing biological compartments and assemblies such as micelles, liposomes, viruses, protein coats, and biological cells. Here, the game plan is *organization* and *aggregation* of either pointlike molecules or biomacromolecules,

whereby *self-assembly* processes are involved. Very precise control of size, shape, topology, flexibility, and surface chemistry (CMDPs) is the primary function and role these entities display in various life processes. These self-assembling systems use weaker interactions such as van der Waals forces and hydrophobic associations to produce precise three-dimensional structures.

Since the days of *Staudinger*[16] and the birth of polymer science early in this century, vast arrays of oligomers and high-molar-mass synthetic polymers have been produced with coil dimensions well over 10 Å.[17] Although many advances have been made in defining classical polymerizations as a function of types, mechanisms, and processes, substantial progress will be necessary to approach the control of CMDPs that Mother Nature has mastered in the production of biomacromolecules and assemblies (categories III und IV, Fig. 3). Considering only size, for example, most globular proteins are obtained as monodispersed products with $M_w/M_n = 1.00$, whereas classical random coil polymers are usually polydispersed with $M_w/M_n \gg 1.00$. Only recently has significant progress been made in producing such monodispersed synthetic polymer systems[18,19] without the use of protection/deprotection strategies. At best these methods offer reproducible control of one-dimensional lengths without necessarily controlling ultimate three-dimensional features such as shape, surface chemistry, or topology.

Without a doubt, the solid-phase peptide synthesis (Merrifield method) remains a preferred method for controlling all five critical molecular design parameters (size, shape, topology, flexibility, and surface chemistry) by precisely producing amino-acid sequences in a stepwise fashion. The scope and limitations of this approach have been reviewed[20a] and widely recognized.[20b] These solid-phase syntheses with protection/deprotection procedures are used routinely to produce numerous polypeptides and polynucleotides which were previously unattainable.[20c,d] Perhaps one of the ultimate synthetic efforts in the control of CMDPs was the total synthesis by *Khorana* et al.[21] of a DNA molecule in the 1960s.

In spite of these accomplishments, no synthetic strategy has successfully matched the diversity or the precise molecular morphogenesis which Mother Nature has mastered in the successful evolutionary development from simple pointlike organic molecules to more complex biomacromolecules and assemblies. It is in this quest that we sought not necessarily total solutions but at least new synthetic strategies for producing such *bio-morphic/receptor mimetics*.[22] This adventure has led us not only to new insights into the molecular-level control of size, shape, topology, flexibility, and surface chemistry, but has also demonstrated some remarkable parallels between higher-ordered biocellular networks (organisms) and information transfer in abiotic molecular-level networks (cf. Section 10).

2.3. Mimicking Macroscopic Ordered Branching Networks at the Molecular Level—A New Strategy

The belief that molecular-level prototypes can be constructed to imitate familiar macroscopic objects has been the inspiration for many intensive and successful synthetic efforts.[23–29] Molecular-level construction of Platonic solids such as the tetrahedron,[26] the cube,[27] and the dodecahedron,[28] as well as non-Euclidian objects such as molecular knots,[29a] Möbius strips,[29b] and even molecular machinery[29d] exemplifies such efforts. Synthetic organic chemists have developed a rich legacy in this area as described in more detail by *Nickon* and *Silversmith*.[29c]

Inspired by the beauty and efficiency with which nature "controls" macroscopic three-dimensional space by use of branching networks in trees,[30] coral,[83] and physiological structures,[31,32] one of us (*D.A.T.*) sought to mimic such branched assemblies at the molecular level. Analysis of parameters involved in synthetically mimicking such branching included the following hypothetical steps (see Fig. 4):

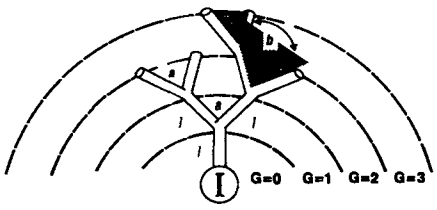

Fig. 4. Illustration of construction parameters involved in controlling macroscopic or microscopic space. l = branch-segment length; a = branching angle, b = rotational angle.

1. Construction and control of branch-segment lengths l.
2. Control and development of branch multiplicities m.
3. Development of a reiterative growth process which would allow concentric construction of branches upon branches around an initiator core ⓘ, which specifies the direction of growth.

The branching angles a are determined by the chemical nature (geometry) of the branch juncture, whereas the rotational angles b are influenced by secondary-structure parameters such as steric effects and hydrogen bonding. These parameters contribute significantly to the development of excluded volume around the branch juncture. Reiteration of these branching patterns in an ideal, tiered manner (G = 0,1,2,3...) should lead to highly ordered macromolecular domains ("microdomains"). The ultimate interplay of all the above parameters would be expected to produce near total control of size, shape, and disposition of chemical moieties, both in the interior and on the exterior surface of these microdomains.

This hypothesis for producing a low-aspect-ratio, three-dimensional molecular prototype can be contrasted with nature's one-dimensional protein synthesis strategy for molecular morphogenesis. Beginning with a reference carbon (Fig. 5), one can use its tetravalency to construct a wide variety of pointlike molecules. In this molecular category, one can find molecules which may function as initiators as well as monomers. Mother Nature elected to use α-amino acids with various side chains (R) for this function. In this case, polymerization involves unidirectional accumulation of α-amino-acid units in a one-dimensional mode. The ultimate size of this one-dimensional protein is controlled by the degree of polymerization n. Its shape, however, is deter-

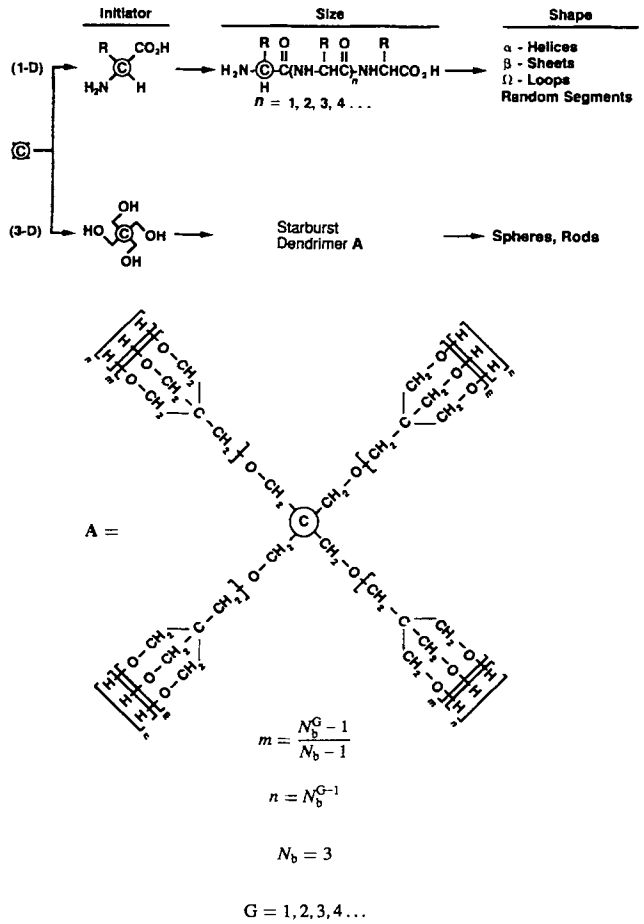

Fig. 5. Molecular morphogenesis: one-dimensional versus three-dimensional strategy for controlled construction of macromolecules.

mined by the sequence of the R groups, which, of course, produces a variety of secondary shapes connected by random sequences; these secondary structures include α-helices, β-sheets, and Ω-loops. These domains then self-assemble into three-dimensional shapes, the tertiary protein structures. Our three-dimensional approach, in contrast, involves the use of a multifunctional initiator (e.g., pentaerythritol) which can accumulate monomer units as branch cells (see Section 3, Fig. 7) in a radial, exponential fashion by forming branches upon branches to produce a starburst topology. This results in the development of entities with low aspect ratios, wherein the degree of branch-cell polymerization m, and hence the size, is defined by the following relation:

$$m = \left[\frac{N_b^G - 1}{N_b - 1}\right]$$

N_b is the branch-juncture multiplicity ($N_b = 3$ for pentaerythritol) and G the generation. The size and shape are clearly influenced by the nature of the initiator core. In addition, the degree of surface congestion caused by the summation of the excluded volumes for the branched monomer units might affect both the shape and the packing density of the surface. Should this be true, this morphogenesis strategy differentiates itself from that used by nature to control CMDPs. Although clearly different molecular arrangements are involved, the CMDPs of these highly branched synthetic macromolecules might be controlled and designed to mimic the CMDPs of naturally occurring biomacromolecules and assemblies. Success in this quest would give rise to a new molecular realm of mesoscopic building blocks, which we refer to as *bio-morphic/receptor mimetics*.[22]

2.4. Why Should We Want to Mimic Bio-Morphic/Receptor Structures and Assemblies Found in Nature?

Human fascination with the mysteries of biological processes has been going on since the origins of man. Molecular-level examination and probing of these processes is a relatively recent development. Led by intense efforts in molecular biology, biophysics, and biochemistry, a rudimentary understanding of these phenomena is beginning to evolve. More recently, however, this understanding has been used in the development of molecular-level, synthetic prototypes to mimic these entities and phenomena. Most notable are the efforts of *Lehn*,[9] *Cram*,[12] and *Pedersen*,[8] whose studies on molecular recognition in guest–host systems involving organic and inorganic compounds are viewed as initial steps toward mimicking highly specific recognition reactions commonly found in biological systems.[9c, 10, 33–36] In a similar manner, extensive efforts by *Ringsdorf*,[37] *Fendler*,[38] *Kunitake*,[39] *Fuhrhop*,[40] and others[41, 153] have been directed toward the use of liposomes as a means for mimicking the organization, surface recognition, and dynamics of biological membranes (cells). Although these efforts were initially

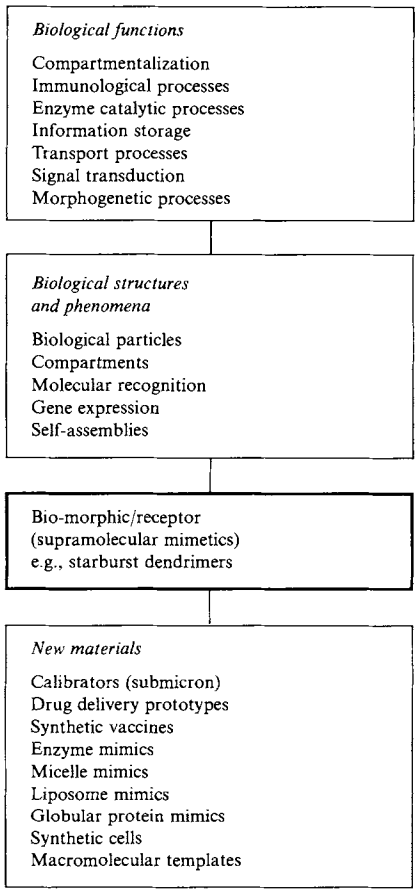

Fig. 6. Potential new materials resulting from bio-morphic/receptor supramolecular mimicking of biological structures and phenomena.

driven by sheer intellectual curiosity, it is becoming apparent that they will ultimately lead to the development of many new prototypes and materials which will constitute a new field of materials science for which *Fendler* has coined the term membrane mimetics.[42] By our own approach, we hope to discover new and useful materials which will contribute not only to materials science but also to a better understanding of biological structure and phenomena.[163] Figure 6 (left side) describes just a few of the potential new materials that may arise in the efforts to develop such biomorphic and bioreceptor mimetics (see also Section 14).

3. Historical Background

The origins of the present three-dimensional molecular-level branching concepts can be traced back to the initial introduction of infinite network theory by *Flory*[43-46] and *Stockmayer*.[47,48] In 1943, *Flory* introduced the term network cell, which he defined as the most fundamental unit in a molecular network structure.[49] To paraphrase the original definition, it is the recurring branch juncture in a network system as well as the excluded volume associated with this branch juncture. *Graessley*[50,51] took the notion one step further by describing ensembles of these network cells as micronetworks. Taken out of the context of *Flory*'s and *Graessley*'s statistical treatment of Gaussian-coil networks, analogous species that are part of an open, branched organization have been coined branch cells and branch-cell assemblies, respectively (Fig. 7).

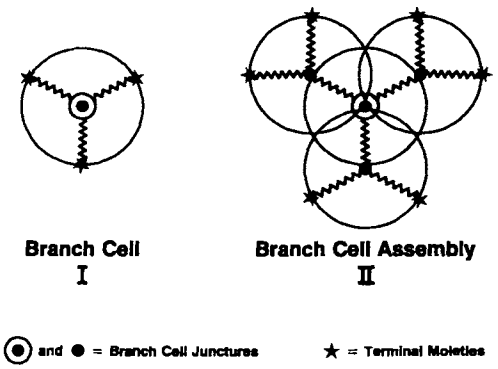

Fig. 7. Two-dimensional projections of branch cells (I) and a branch-cell assembly (II).

Subsequent statistical modeling by *Gordon* et al.[52a-e] and others[52d,e] reduced such branched species to graph theory designed to mimic the morphological branching of trees (Fig. 8). These dendritic models were combined with "cascade theory"[53a,b] mathematics to give a reasonable statistical treatment for network-forming events at that time.

Since these species were conceptual, there were no well-characterized synthetic examples of such regular architecture. Although *Meyer*[56] proposed such symmetrical, ordered architecture for amylopectin, subsequent work by *Erlander* and *French*,[57] as well as by *Burchard* et al.,[58] showed that amylopectin and glycogen are not so regular; instead, they are random f-functional polycondensates possessing a large, highly branched dextrin core as shown in Figure 9.

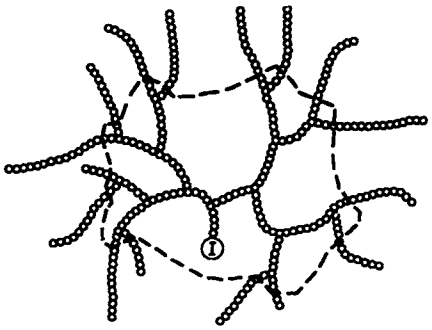

Fig. 9. Dendritic branching topology of amylopectin.

It was not until 1978 that *Vögtle* et al.[59] reported a single, isolated example of a protection/deprotection scheme involving the idea of assembling branches upon branches. The scheme consisted of a sequence of reactions involving Michael addition of an amine to acrylonitrile, followed by reduction of the nitrile group to an amino group. Perhaps due to the difficulties and disappointing yields in the reduction step, no subsequent reports on this work could be found. In any case, the idea of "cascade synthesis" was first introduced to the literature at this time. Essentially concurrent with these activities, we began our work at the Dow Laboratories in Midland, Michigan (USA), on the synthesis of starburst dendrimers.[70] In 1979, we discovered that a variety of amines could be added to methyl acrylate and the products subsequently amidated with α,ω-diaminoalkanes to give "cascade products" (Section 5). With this chemistry, controlled concentric "starburst growth" could be produced around various initiator cores. This growth could be dramatically influenced by both the geometry and multiplicity of the initiator core, as well as by the reiterative chemistry. Subsequent synthetic effort at Dow (1981–1984) showed that, much as anticipated from the macroscopic tree and coral branching analogies, these starburst systems offered a wide range of synthetic options for controlling size, shape, interior topology, flexibility, and surface chemistry at the molecular level.[60-67]

In 1983, mathematical predictions by *de Gennes* et al.[68] showed that a starburst dendrimer series should reach a so-

called starburst limited generation beyond which branching can no longer occur in an ideal fashion. More recent studies have shown that advancement to higher-generation dendrimers ultimately leads to a new critical branching state which is referred to as starburst dense packing.[67-69] At this critically branched generation, an apparent surface association occurs to yield solvent-filled spheroids[69, 101] which are reminiscent of "unimolecular cells".[12b, 69, 71] Such morphologies were suggested in a theoretical paper by *Maciejewski*[72] in 1982, where he referred to them as "shell topologies".

At that time, an isolated, yet related, dendrimer example appeared in the patent literature. *Denkewalter* et al.[73] reported that highly monodispersed macromolecular products were produced by a stepwise linking of α,ω-protected diamino acids (e.g., lysine). Using protection/deprotection methods of polypeptide chemistry, these workers synthesized a series of dendrimers possessing unsymmetrical branch lengths. Although the precise nature of the branch cells and the chemical structures has not been established, subsequent work by *Aharoni* et al.[74] and us[67] showed that they differed dramatically from the present symmetrical starburst dendrimers in certain important physical properties. Unlike starburst dendrimers, they were found to be constant density, nonhollow macromolecules with "nondraining" character and may constitute a subclass to the present dendritic series.

Since 1985, *Newkome* and co-workers[75-77] have reported the synthesis of related symmetrically branched macromolecules which they refer to as "arborols". These macromolecules are highly branched dendrimers which are not amenable to size control as a function of generation in that reiterative chemistry for advancing concentric growth has not been reported. These prototypes have been used successfully for controlling molecular shape and, in some cases, surface moieties. To date, examples of uni-, di- and tridirectional arborols have been reported[75-77] (see Section 5).

4. Starburst Topology and Branching Concept

4.1. Mathematical and Geometrical Precedence

Mathematicians such as *Cantor* and *Koch*[78, 79] and, more recently, *Mandelbrot*[80] have partitioned dimensionality in a variety of ways. *Cantor* started with a simple line, removed the middle third of the line segment, repeated this process on the two remaining segments, and so on to produce increasingly more segments (Fig. 10a). Connecting the midpoints of the segments produces a branching pattern which remains confined in width to the original length of the line. Hence, the connectivity pattern becomes more congested as a function of generation. Subsequently, the Swedish mathematician *Helge von Koch* (1904) partitioned two-dimensional triangles in an analogous fashion to produce the well-known Koch snowflakes (Fig. 10b). This reiterative process produces triangular-edged Koch curves, whose shapes depend on the generation. These curves enclose areas which are less than but approach the limiting area of the circumscribed circle around the curve.[82] In a similar manner, one may envision the partitioning of three-dimensional space by conceptualizing a "spherical universe within a universe" as a series of nesting spheres[31a] (Fig. 10c).

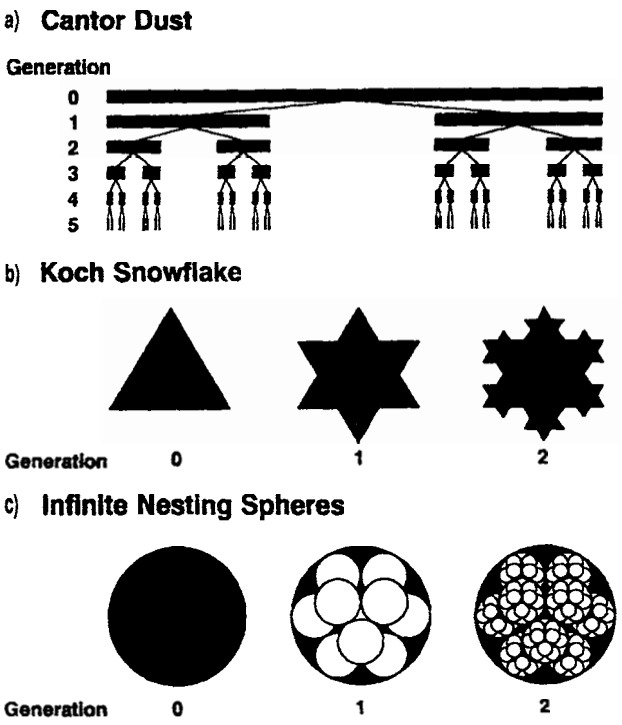

Fig. 10. a) Bifurcation of a line segment with connectivity paths to define Cantor dust. b) Bifurcation of a triangle (two-dimensions) to define Koch snowflakes. c) Fitting of a sphere (three-dimensions) to define a series of infinite nesting spheres (see also Fig. 56).

These three cases are classical examples of fractal curves and dimensions as pioneered by *Mandelbrot*[80, 81] for macroscopic objects. They suggested to us possible extensions for the creation and analysis of unique spatial organizations of atoms within monomer repeat units within branch cells within dendrons within a dendrimer to give molecular-level surfaces in three dimensions.

4.2. Molecular-Level Perspective of Cubic Space

The present dendritic branching concept uses these mathematical/geometrical notions in the context of partitioning or occupying three-dimensional molecular-level space around a reference point, with atoms, chemical bonds, repeating chemical units, and branch cells as the construction parameters. The dendritic branching of coral,[32] Bryozoan colonies,[83] trees,[30] and physiological networks[31] provided prototypes to mimic at the molecular level. The resulting branch-cell assemblies were referred to as possessing starburst topology, and the molecular entities, constructed by reiterative synthetic steps, were coined starburst dendrimers.[70a] Two-dimensional projections of these dendrimers (A–E, Fig. 11) illustrate the concentric assembly of branches upon branches to produce radial arrays of branch

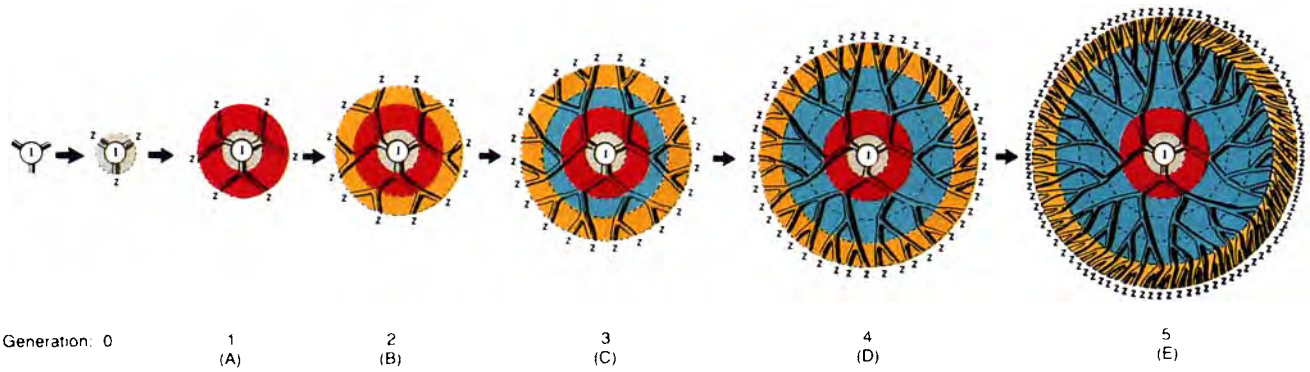

Fig. 11. Two-dimensional projections of an initiator core ($N_c = 3$), a core cell, and tridendron dendrimers ($N_b = 2$).

junctures and terminal functionality (Z) around a reference point or initiator core, ①.[70b]

In a geometrical context, the treelike structures A–E are recognized by physicists and mathematicians as Bethe lattices or Cayley trees. According to graph theory,[70c] dendrimers in this series may be viewed as triads of symmetrical trees rooted to a common initiator core ①. Each of these trees is referred to as an ideal dendron. Such a dendron consists of a root, ①, with connectivity to vertices (branch junctures) through edges (branch segments) which expand symmetrically according to a geometric progression to produce generations containing predictable numbers of vertices and edges.

4.2.1. Effect of Core and Branch-Juncture Multiplicity on Molecular Structure

Both the initiator-core multiplicity N_c and the branch-juncture multiplicity N_b directly affect the number of terminal groups, the number of repeating units (branch segments), and the molar mass of the dendrimers as a function of generation. These values can be predicted mathematically for ideal systems according to the following expressions:

Number of dendrimer terminal groups $z = N_c N_b^G$

Number of dendrimer repeat units (degree of polymerization) $N_{RU} = N_c\left(\dfrac{N_b^{G+1} - 1}{N_b - 1}\right)$

Number of dendrimer branch cells $N_{BC} = N_c\left(\dfrac{N_b^{G} - 1}{N_b - 1}\right)$

Theoretical molar mass of dendrimer $M = M_c + N_c\left[M_{RU}\left(\dfrac{N_b^{G+1} - 1}{N_b - 1}\right) + M_t N_b^{G+1}\right]$

$$M = M_c + N_c\left[M_{BC}\left(\frac{N_b^{G} - 1}{N_b - 1}\right) + M_t N_b^{G}\right]$$

M_c, M_{RU} or M_{BC}, and M_t are the molar masses of the initiator core, repeat units or branch cells, and terminal units, respectively. A general structural notation for a homogeneous dendrimer with core multiplicity N_c and branch-juncture multiplicity N_b may be represented in empirical form as follows:

$$[\text{core}]\left[\text{repeating unit}_{\left[\frac{N_b^{G+1} - 1}{N_b - 1}\right]}\text{terminal unit}_{[N_b^{G+1}]}\right]_{N_c}$$

From a molecular perspective, dendrimers are simply assemblies of dendrons attached to a common initiator core, ①, or a variety of initiator cores in the same molecule. Beginning with ①, these branched assemblies are developed by growing dendrons in a stepwise, radial manner according to multiplicity rules. Figure 11 shows an example of dendrimer growth for $N_c = 3$ and a branch-juncture multiplicity of $N_b = 2$. A wide range of multiplicities N_c are possible, varying from mono- to polydendron assemblies. The size, shape, and initiator-core multiplicity dramatically influence the ultimate CMDPs of the dendrimer.

4.3. Structural Aspects

4.3.1. Dendrimer Branch-Cell Hierarchy

Dendrimers possess three distinguishing architectural features: (1) an initiator-core region, (2) interior zones containing cascading tiers of branch cells with radial connectivity to the initiator core, and (3) an exterior or surface region of terminal moieties attached to the outermost generation. Even in an ideal, homologous dendrimer series there exists a hierarchy of branch cells that are differentiated not only by their topological positions, but also by structural features. This is illustrated in Figure 12, where a fully developed dendrimer is grown in four stages from an initiator core, ①, with $N_c = 3$.

The initiator core ① may be as small as an atom or as large as a molecule. It may be homogeneous with the other dendrimer components or it may contain special design features (e.g., metal atoms, chromophores, etc.) which make it heterogeneous.

Synthetic elaboration to create the first tier of terminal functionality or branch junctures defines a microdomain referred to as the *core cell* (gray-green in Fig. 12). In situ construction of branch junctures or coupling partially masked, branch-cell reagents ($N_b \geqq 2$) gives the first three surface cells (orange-yellow), each of which possesses two reactive surface groups (Z). On progressing from dendrimer A to B, the three surface cells become initiator cells (red) and six new

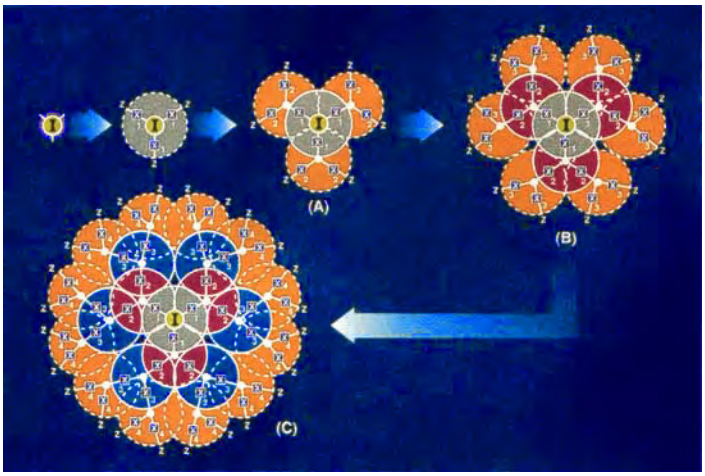

Fig. 12. Construction of a dendrimer of generation 3 (the numbers 1 to 4 in the circles should be replaced by 0 to 3) and its dendrimer branch-cell hierarchy. Color coding: green-gray, core cell (G = 0) red, initiator cells (G = 1); blue, interior cells (G = 2); yellow-orange, surface cells (G = 3).

surface cells are added. Advancement from B to dendrimer C leads to complete development of the cell hierarchy, which consists of one initiator core cell, three initiator cells, six interior cells (blue), and twelve surface cells with a total surface stoichiometry of twenty-four Z groups. Owing to these surface groups, the dendrimer should function as an exo-receptor.[9c]

If the branch junctures or the coupling junctures are heteroatoms or contain designed moieties amenable to reaction or chelation, the dendrimer should exhibit endo-receptor characteristics.[9c] Each of these bonding features has been observed experimentally (for experimental examples, see Section 9).

4.3.2. *Dendrimer Branch-Cell Symmetry Properties*

The symmetry properties of the interior branch cells can dramatically affect the physical and perhaps chemical properties of a dendrimer. For example, symmetrical interior and surface cells, such as those in Figures 11 and 12, exhibit identical connectivity paths from the initiator core to the termini. The equal radii place the terminal groups on a sphere or a segment of a sphere, thus making these dendrimers ideal models of functionalized submicron spheres.

In contrast, the polylysine dendrimers described by *Denkewalter* et al.[73] have unsymmetrical branch cells with either three or seven bonds between branch points. If one considers the paths of connectivity from initiator core to termini of a single dendritic branch, it can be seen that no two paths are identical. In fact, every possible permutation of the sequences of the two given linear segments is present in the branch. If the two segment lengths are given values of s and l, and the number of tiers in the branch is N, the number of different paths, X, is given by the relation $X = 2^N$. Since the paths are constructed from all possible combinations of the two given segment lengths, the number of paths of a given length follows a binominal distribution. Thus, the number of paths composed of a short segments and b long segments (in a molecule consisting of $a + b$ tiers) is given by the following relation:

$$X_{a+b} = (a + b)!/(a!\, b!)$$

For example, a molecule with three tiers of branching has eight terminal groups. There is one path consisting of three short segments, three paths consisting of two short and one long segment, three paths consisting of one short and two long segments, and one path consisting of three long segments (see Fig. 13).

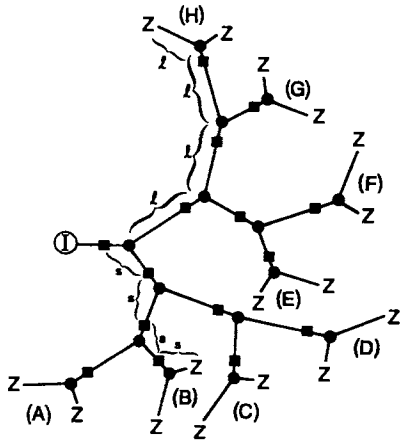

Fig. 13. Two-dimensional projection of a monodendron with unsymmetrical branch junctures (Denkewalter topology) and surface branch cells (A–H). s and l are the lengths of the short and long segments, respectively.

The different lengths of these paths mandate that some terminal groups will be tethered closer to the center of the branched assembly than others and be subject to more steric interactions. This suggests that this dendrimer class has surfaces with higher fractal dimensions[80–82, 84] and interior branching zones which are less ordered than those of the starburst dendrimers (Fig. 14).

These two classes differ substantially in certain physical properties.[67] Although it has not been demonstrated, one might expect the various terminal groups in the Denkewalter dendrimers to show a range of chemical reactivities based on different steric environments. These clefted, highly fractal

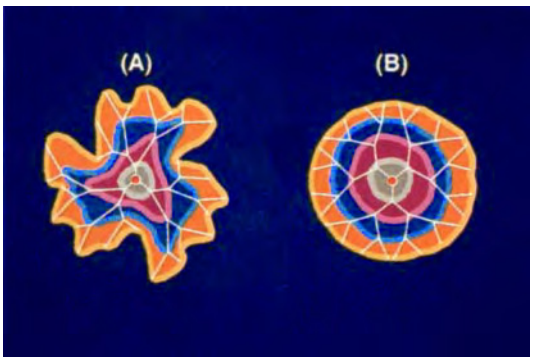

Fig. 14. Two-dimensional projection of a tridendron dendrimer ($N_c = 3$; $N_b = 2$) with unsymmetrical branch junctures (A) compared with one possessing symmetrical branch junctures (B).

surfaces are not unlike microenvironments usually associated with enzymes. This issue as well as other topological questions will, no doubt, provide ample reason for wanting to characterize and gain a deeper understanding of dendrimer infrastructure and surfaces.

5. Dendrimer Syntheses

Classical, random coil, functional macromolecules are substrates upon which it is often difficult to perform high-yield, efficient reactions. Their coiled configurations frequently lead to inaccessible buried functionality that can frustrate even the most patient synthetic chemist. Unlike these situations, the radial orientation of starburst topology presents the terminal functionality in a very favorable fashion, accessible to incoming reagents and media. For this reason, essentially any reaction that proceeds well on a pointlike organic molecule can be expected to occur equally well on a dendrimer surface, at least in the earlier generations. As surface congestion develops, however, reaction kinetics and stoichiometry would be expected to change dramatically (cf. Section 9).

Considering the intricacies of the dendrimer assembly steps, one can conceive of a variety of defects that could lead to divergence from ideality. Broadly speaking, they are of two types: those involving intra-dendrimer events and those leading to inter-dendrimer bridging or looping. The former defects decrease branching ideality, whereas the inter-dendrimer bridging events lead to more polydispersed systems. These defects have been minimized or eliminated by both process optimization and synthetic strategy optimization. Figure 15 illustrates some flawed structures.[85]

Defects such as **1** and **2** lead to abnormal cell development within the dendrimers and can dramatically affect the surface stoichiometry if they become extensive. Branch defects

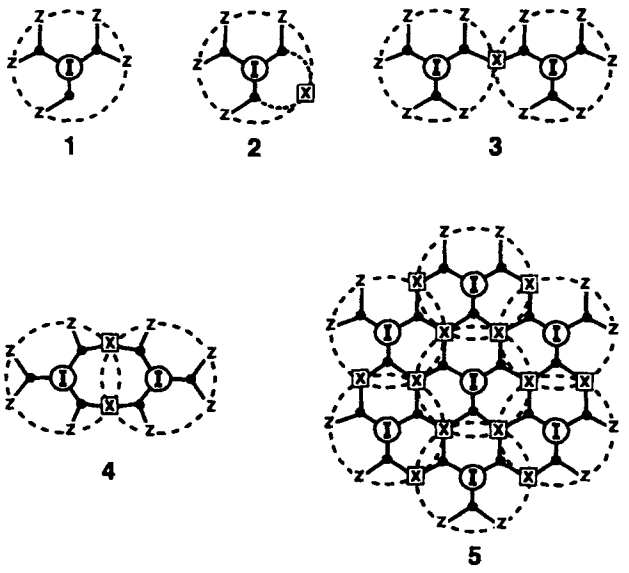

Fig. 15. Two-dimensional projections of various branch-cell defects which may lead to divergence from ideal dendrimer development. Branch defective dendrimer, **1**; intra-dendrimer looping, **2**; inter-dendrimer bridging, **3**; inter-dendrimer looping, **4**; dendrimer cluster (bridged/looped), **5**.

such as **1** may be due to (1) incomplete reactions resulting from surface-group deactivation or inappropriate reaction conditions, (2) branch-juncture fragmentation, (3) abnormal branch-juncture development, or (4) sterically induced stoichiometry (SIS, see Section 9). Both this type of defect and intramolecular cyclization lead to reduced surface stoichiometry and may affect ultimate symmetry properties of the dendrimer.

Intermolecular events leading to bridged or looped structures such as **3**, **4**, and **5** are the chief contributors to increased polydispersity. Other factors that can cause polydispersity include (1) incomplete removal of reagents (which may function as initiator cores) and (2) dendrimer fragmentation (to produce molecular entities which may subsequently become initiator species).

In general, successful synthetic strategies allowing the assembly of branch cells into ideal open-branched assemblies (i.e., dendrons, dendrimers) have involved the following steps:

1. Selection of a suitable initiator that can be converted in high yield into a reactive initiator core cell.
2. Definition of an iterative reaction sequence that allows presentation of the reactive initiator core cell to appropriate reagents or other reactive branch cells (partially protected), resulting in high-yield conversions to a branched assembly with specific molecular surfaces.
3. Reiteration of these step-growth or chain-growth sequences to produce dendrimers possessing concentric generations of repeating units and branch junctures. These parameters define the number of branch cells which accumulate exponentially within these generation zones. A geometric consequence of this reiterative step-growth propagation is that the covalent connectivity paths (i.e., the radial summation of branch-cell diameters) from the initiator core to the dendrimer surface increases linearly, whereas the microvolumes occupied by the dendrimer surface cells accumulate exponentially as a function of generation. Because of the "tethering effect" on these exponentially greater numbers of surface cells, one eventually reaches a "starburst limited generation" as predicted by *de Gennes* et al.[68] This defines a self-limiting size (generation) for any given dendrimer series, which is based on its branch-segment lengths, core/juncture multiplicities, and surface-group dimensions. Penultimate to this generation, certain reaction rate digressions and stoichiometry aberrations are observed.

Specific synthetic approaches may be divided into two major categories: Controlled step-growth propagation and uncontrolled chain-growth propagation.

5.1. Initiator Cores and Dendrimer Profiles

The selection or synthesis of the initiator core is of great importance. It is the fundamental unit to which the dendrons are tethered; thus, its size, shape, multiplicity, and specialized function will clearly influence the dendrimer throughout its construction. Core-cell design may range from simple attachment of one dendron to the use of "starbranched", multiarmed functionalized entities,[86] or even multifunc-

tionalized, polymeric substrates. Synthetic design of these core cells may include introduction of chromophores, chelating groups, metals, molecular recognition moieties, or hydrophilic/hydrophobic domains for desired guest–host properties. Enclosure or molecular encapsulation of these core cells is initiated in the next step of the dendrimer construction. Introduction of branch junctures (see Figs. 11, 12) may involve either "in situ" construction, coupling of preformed branch cells, or chain propagation of functionally differentiated branched monomers to produce the first tier of branch cells.

Considering the present starburst polyamidoamine family derived from an ammonia core and $-CH_2CH_2CONHCH_2CH_2N$ units, such dendrimer compositions may be expressed in the following way:

$$N[(-CH_2CH_2CONHCH_2CH_2N<)_x(H)_y]_{N_c}$$

$$x = \left(\frac{N_b^{G+1} - 1}{N_b - 1}\right), \quad y = N_b^{G+1},$$

In this case, $N_c = 3$ and $N_b = 2$.

The first three generations have the following compositions:

$$G = 0: N(CH_2CH_2CONHCH_2CH_2NH_2)_3$$

$$G = 1: N[CH_2CH_2CONHCH_2CH_2N(CH_2CH_2CONHCH_2CH_2NH_2)_2]_3$$

$$G = 2: N[CH_2CH_2CONHCH_2CH_2N(CH_2CH_2CONHCH_2CH_2N[CH_2CH_2CONHCH_2CH_2NH_2]_2)_2]_3$$

$$G = 3: N[CH_2CH_2CONHCH_2CH_2N(CH_2CH_2CONHCH_2CH_2N[CH_2CH_2CONHCH_2CH_2N(CH_2CH_2CONHCH_2CH_2NH_2)_2]_2)_2]_3$$

Since one has the option of continuing homogeneous dendrimer development or changing chemistry to produce differentiated generations, it is important to define a dendrimer profile for describing a branched assembly composition. We propose the use of cross-sectional descriptions, as illustrated here for a hypothetical heterogeneous starburst polyamidoamine dendrimer. This second-generation polyamidoamine dendrimer derived from an ammonia initiator core, with a 50% hexamethylenediamine component in the first generation and hydroxyl terminal groups, may be expressed as follows:

$$N[CH_2CH_2CONHCH_2CH_2\text{-}N\begin{pmatrix}CH_2CH_2CONH[CH_2]_6\text{-}N[CH_2CH_2CONHCH_2CH_2OH]_2\\ CH_2CH_2CONHCH_2CH_2\text{-}N[CH_2CH_2CONHCH_2CH_2OH]_2\end{pmatrix}_2]_3$$

Examination of such dendrimer profiles allows one to identify the initiator core, core cells, initiator cells, interior cells, and surface cells as illustrated in Figures 11, 12, and 16.

5.2. Controlled Step-Growth Propagation

5.2.1. *In Situ Construction of Branch Cells*

Dendrimer construction with this synthetic strategy requires very high yield/conversion syntheses as well as efficient workup procedures for separation of the dendrimers from the reagents. A variety of polypeptide synthesis methods were used successfully for this approach. They included (1) protection/deprotection methods, (2) solid-phase synthesis and (3) excess reagent methods. Either ultrafiltration or preparative HPLC techniques were used for workup and purification. A major advantage offered by this approach is that the steric bulk of the reagents is usually much lower than that of branched-reagent coupling synthons.

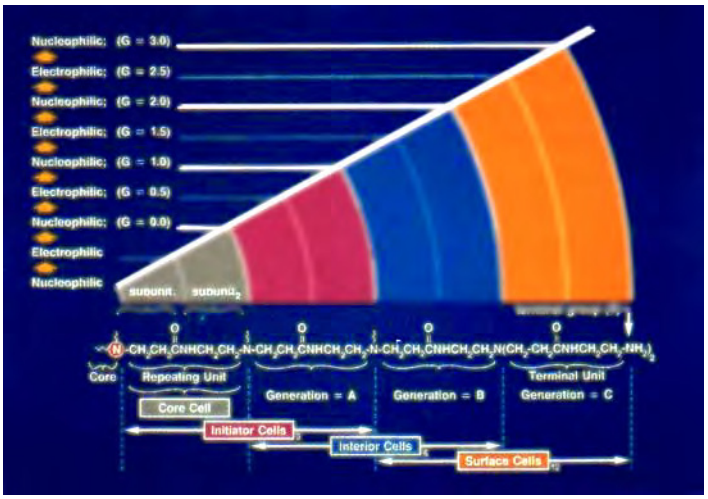

Fig. 16. Cross-sectional view of PAMAM dendron (generation 3) illustrating repeating branch segments, branch-cell hierarchy (for color coding see Fig. 12) and surface electron density features as a function of generation.

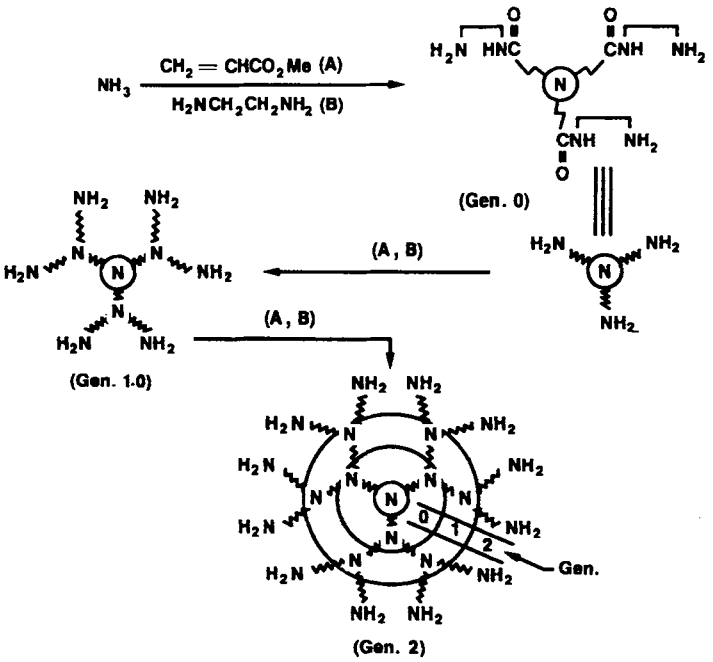
Starburst Polyamidoamine (PAMAM) Dendrimers

Starburst polyamidoamine (PAMAM) synthesis may begin with either a nucleophilic or an electrophilic core. In the case of a nucleophilic core such as ammonia or amine, step A in Scheme 1 involves exhaustive Michael addition to methyl acrylate. This addition occurs very rapidly and in high yield with essentially complete selectivity and no amidation at room temperature. Step B requires addition of this triester intermediate to a large excess of ethylenediamine at room temperature (formation of "subunit$_2$", Fig. 16) to produce the terminal triamine core cell shown in Scheme 1. Repeating the sequence of steps A and B leads, via a hexaester (generation = 0.5), to a hexaamine (generation = 1.0). Continuing the sequence of steps A and B (Scheme 1) produces increasingly higher generations. Dendrimer growth beyond generation 3 simply introduces more concentric tiers of interior cells which provide scaffolding for surface cells whose number follows a geometric progression. Ideal branching



Scheme 1. Synthetic scheme for starburst PAMAM dendrimers.

growth would produce dimensionally precise surfaces with a defined number of surface groups (see Table 1).

Table 1. Relative molar mass M_r, number of monomer units, number of terminal amino groups, predicted diameters (CPK models), and hydrodynamic diameter (determined by size exclusion chromatography) for starburst (PAMAM dendrimers as a function of generation).

10	700091	6141	3072	123.0 (143.0)	124.0

[a] CPK = Corey–Pauling–Koltun; the first value refers to a three-dimensional contracted model, the value in parentheses to a three-dimensional extended model.

The present tridendron PAMAM dendrimer series increases its diameter by approximately 10 Å per generation, evolving from a disklike shape (generations 0–2) to an oblate spheroid (generations 3, 4) to a nearly symmetrical spheroid at generations 5 and higher[111] (cf. also Section 10). A Corey–Pauling–Koltun (CPK) model of generation 5 is shown in Figure 17. Successful syntheses of ideal highly branched PAMAM dendrimers through generation 9 have been completed.

Alternatively, initiator cores have been tethered to solid supports (Merrifield resins). Using protein synthesis procedures that avoid the workup difficulties involved in handling large excesses of reagents, one can readily control dendrimer growth. Unfortunately, only noncleavable linkers have been examined to date for these PAMAM dendrimers. The use of initiator cores possessing cleavable linkers should make dendrimer synthesis and isolation very facile. This was demonstrated for starburst polylysines by *Tam* et al.[129–131] (see Section 9.2.6).

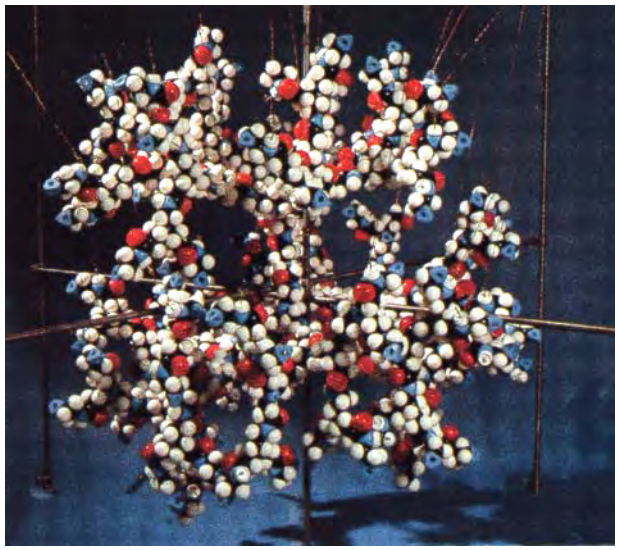

Fig. 17. CPK model of a starburst PAMAM dendrimer of generation 5.

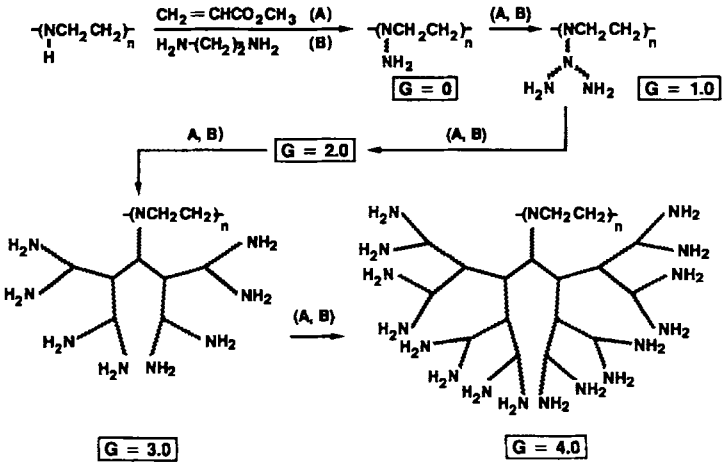
A variety of mono-, di-, tri-, tetra-, and polydendron PAMAMs have been synthesied from simple amines as well as linear polyamine cores.[62–67] Linear polyethylenimines with core multiplicities N_c of ca. 300–400) have been shown to produce high-aspect-ratio, rodlike dendrimers at generation 3 or 4.[87] Their length is determined by the degree of polymerization (n) of the initiator core and their diameter is derived from the number of generations (see Scheme 2).

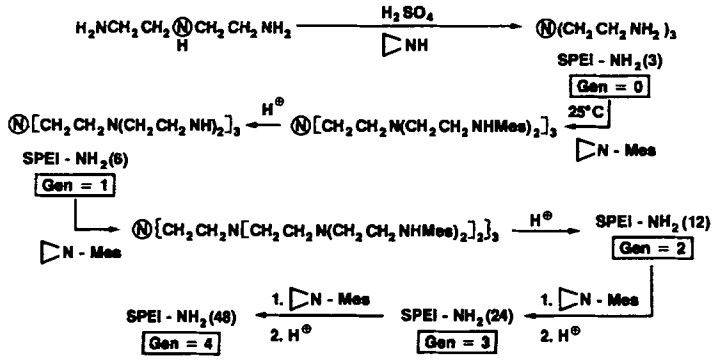


Scheme 2. Synthetic scheme for starburst PAMAM rodlike dendrimers.

Starburst Polyethylenimine (PEI) Dendrimers

Polyethylenimine (PEI) has been examined extensively both in its classical random branched topology[88] and in its

linear form.[89] Here we describe the first example of this polymer system as an ideal highly branched molecular assembly. Synthesis of a tridendron polyethylenimine dendrimer derived from an ammonia core involved first the selective alkylation of diethylenetriamine (DETA) with aziridine to produce a symmetrical core cell, namely, tris-(2-aminoethyl)amine. Subsequent exhaustive alkylations of the terminal amino moieties with activated aziridines,[88] such as *N*-tosyl- or *N*-mesylaziridine gave very good conversions to the first-generation protected starburst PEI (SPEI) dendrimer (see Scheme 3). Deprotection by acid hydrolysis



Scheme 3. Synthetic scheme for starburst polyethylenimine (SPEI) dendrimers.

yielded the demasked first-generation dendrimer. The higher generations were obtained by simply repeating these sequences. These SPEIs are described by the following general notation:

$$N[(CH_2CH_2N<)_x(H)_y]_{N_c}$$

$$x = \left(\frac{N_b^{G+1} - 1}{N_b - 1}\right),\ y = N_b^{G+1},\ N_c = 3,\ N_b = 2$$

The defect levels become progressively higher and divergence from branch ideality becomes substantial as one approaches generations 3 and 4 and especially generation 5.[90]

These dendrimers have branch-segment lengths which are approximately one-half that of the PAMAM series (5 Å versus 10 Å) and possess chemical linkages which have much greater chemical and physical stability. A comparison of theoretical molar masses, number of terminal groups, CPK-predicted diameters, and measured diameters (size exclusion chromatography, SEC) as a function of generation is shown in Table 2.

Table 2. Relative molar mass M_r, number of terminal amino groups, predicted diameter (CPK models), and hydrodynamic diameter (SEC) for starburst dendrimers as a function of generation.

Generation	M_r	Terminal groups	Diameter [Å] CPK [a]	SEC
0	146	3	7.2 (8.8)	7.9
1	398	6	11.2 (15.6)	15.1
2	917	12	13.6 (19.2)	20.0
3	1949	24	18.2 (24.8)	–
4	3968	48	23.0 (29.0)	–
5 [b]	–	–	–	–

[a] The first value refers to a three-dimensional contracted model, the value in parentheses to a three-dimensional extended model. [b] Forbidden molecular structure.

CPK models of generations 0–5 (Fig. 18) show that these SPEIs are much more congested and compact than the starburst PAMAMs. These models indicate that ideally branched generation 5 is forbidden due to starburst dense packing as described and predicted by *de Gennes* and others.[64, 68, 69]

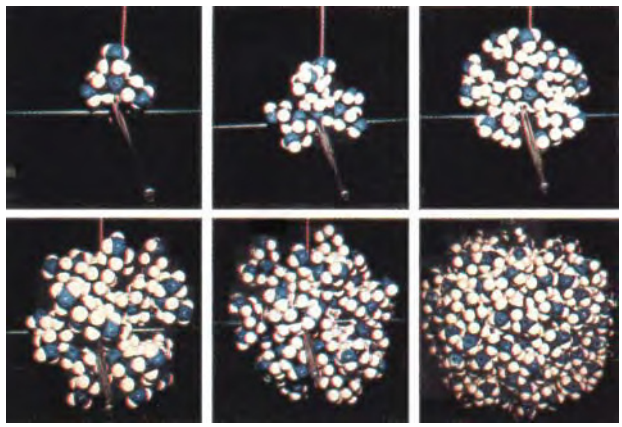


Fig. 18. CPK models of starburst PEI dendrimers of generations 0–5.

Hydrocarbon Dendrimers (Iptycenes)

A unique class of structures referred to as iptycenes has recently been reported by *Hart* et al.[91, 92] These architectures may represent the first examples of all-hydrocarbon dendrimer prototypes. Starting with either benzene or triptycene as the initiator core, branch junctures were constructed in situ by Diels–Alder adduct formation to give the heptaiptycene and the nonaiptycene (tritriptycene) **7**, respectively (Fig. 19). The tritriptycene derivative possesses molecular

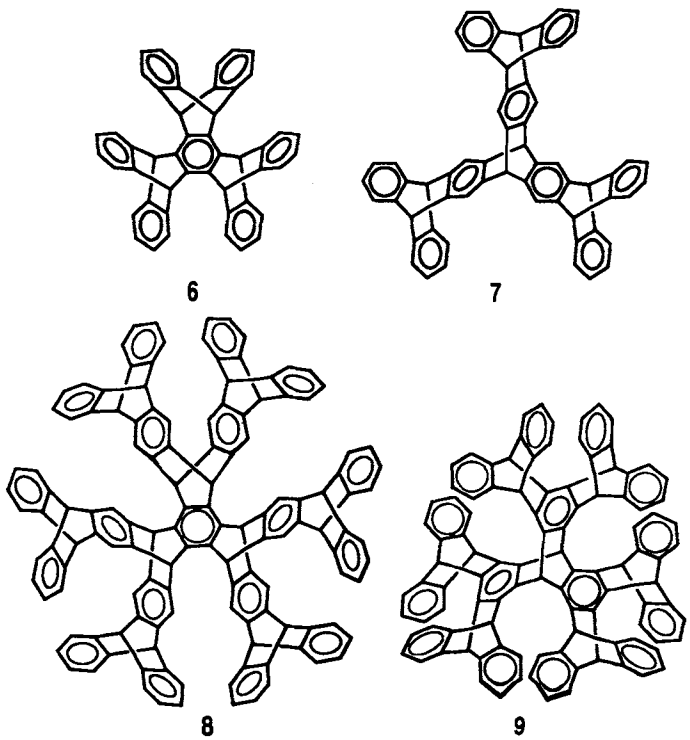

Fig. 19. Hydrocarbon dendrimers (iptycenes): heptaiptycene, **6**; nonaiptycene, **7**; nonadecaiptycene, **8**; supertriptycene, **9**.

clefts defined by parallel benzene moieties ca. 9 Å apart. These U-shaped cavities defined by the arene planes accommodate acetone to form a 1:1 crystalline complex which was verified by X-ray structure studies. More recently, *Hart* et al.[93] have successfully added six more 9,10-dihydroanthracene moieties to **6** to give the $C_{132}H_{78}$ hydrocarbon **8** (nonadecaiptycene). Similar reactions led to **9** (supertriptycene).

5.2.2. *Coupling of Partially Masked or Differentiated Branch-Cell Reagents*

The use of protection/deprotection methods or highly differentiated, branched reagents allows selective coupling without bridging or looping side reactions. Table 3 summarizes the branched reagents used successfully so far.

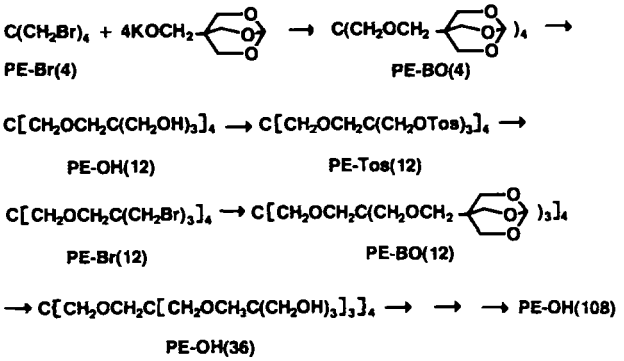
Starburst Polyether Dendrimers

This dendritic series includes examples of the most highly branched, as well as the shortest-branch, segmented dendrimers produced to date.[65] The high initiator core multiplicity ($N_c = 4$), combined with high branch multiplicity ($N_b = 3$), produces very compact, highly congested microdomains which possess, at most, only very small internal voids. This homologous series has the following general notation:

$$[C(CH_2O)_4][([CH_2C(CH_2O)_3]_x[CH_2C(CH_2OH)_3]_y)_{N_c}$$

$$x = \left(\frac{N_b^G - 1}{N_b - 1}\right),\ y = N_b^G,\ N_c = 4,\ N_b = 3$$

Standard synthetic methods are used to couple partially protected pentaerythritol to the core cell and subsequent dendrimer surfaces.[65] Synthesis of the first generation involves displacement of bromide from $C(CH_2Br)_4$ with a masked pentaerythritol (bicyclic orthoester). One obtains



Scheme 4. Synthetic scheme for starburst polyether (PE) dendrimers.

three hydroxyl groups per terminal group after deprotection (Scheme 4; see also Fig. 5, bottom). Therefore, a series that triples both its surface hydroxyl groups and its molar mass is obtained (see Table 4).

Table 4. Relative molar mass M_r, number of terminal hydroxyl groups, predicted diameters (CPK models), and hydrodynamic diameter (SEC) for starburst polyether dendrimers as a function of generation.

Generation	M_r	Terminal groups	Diameter [Å] CPK [a]	SEC
0	136	4	– –	–
1	606	12	10.4 (12.0)	9.8
2	2024	36	16.2 (18.4)	18.6
3	–	108	22.4 (24.0)	25.0
4 [b]	–	–	–	–

[a] The first value refers to a three-dimensional contracted model, the value in parentheses to an extended model. [b] Forbidden molecular structure owing to surface congestion.

Molecular dynamics simulations (Section 6) clearly demonstrate that these tetradendron prototypes assume spheroidal shapes early in their development. Synthetic efforts revealed that branching defects became progressively higher as one advanced from generation 2 to generation 3. The simulations indicate that the fourth-generation dendrimer possessing 324 hydroxyl surface groups is a highly constrained, rigid system with essentially no internal voids or channels (see Figs. 20, 24 and 25). Starburst dense packing appears to occur between generations 3 and 4.

Starburst Polythioether Dendrimers

This series was synthesized according to Scheme 4 as described for the polyethers, with the exception that a mercapto-functionalized, bicyclic orthoester was used for the coupling step.[94] This produced a dendrimer series containing thioether linkages in the interior with hydroxyl surface groups as described by the following general notation:

$$[C(CH_2O)_4][([CH_2C(CH_2O)_3]_x[CH_2C(CH_2OH)_3]_y)_{N_c}$$

$$x = \left(\frac{N_b^G - 1}{N_b - 1}\right),\ y = N_b^G,\ N_c = 4,\ N_b = 3$$

In contrast to the polyether series, the number of hydroxyl surface groups in the thioether series did not triple upon

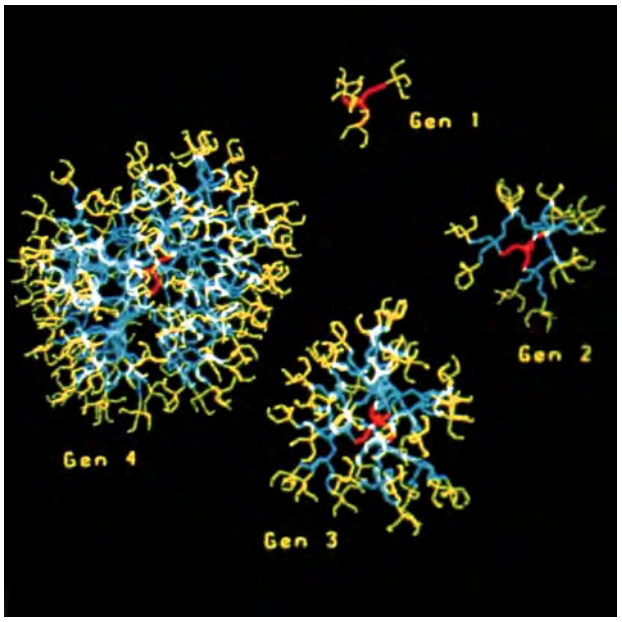


Fig. 20. Computer-simulated molecular graphics (wireframe) using POLYGRAF [97b] for starburst polyether dendrimers of generations 1–4.

attempted advancement from generation 2 to generation 3. This suggests that sterically induced stoichiometry effects are occurring one generation earlier than in the polyether series.

Polyamide Dendrimers (Denkewalter Dendrimers)

Denkewalter et al.[73] reported the synthesis of monodendron polyamides through generation 10. The scheme involved protection/deprotection methods commonly used by polypeptide chemists. Dendrimer construction started with benzhydrylamine as the initiator core and an activated ester of amino-protected L-lysine as the branching reagent (Scheme 5).

N,N'-Bis(*tert*-butoxycarbonyl)-L-lysine nitrophenyl ester was the branching monomer used in the stepwise propagation. The dendrimer surfaces initially possessed hydrophobic Boc units and then, after deblocking, hydrophilic amine moieties. Although the dendrimer structures were not rigorously verified, subsequent work by *Aharoni* et al.[74] showed that they were quite monodispersed and behaved as "nondraining" spheres. *Tam* and co-workers[129–131] produced these dendrimers on a Merrifield resin followed by surface functionalization with various antigenic polypeptide sequences (see Section 9.2.6). A comparison of molar mass, number of terminal groups, and dimensions as a function of generation for the Denkewalter dendrimer is shown in Table 5. Unlike all the other dendrimer examples reported, the branch junctures in this system are constructed from unequal branch-segment lengths.

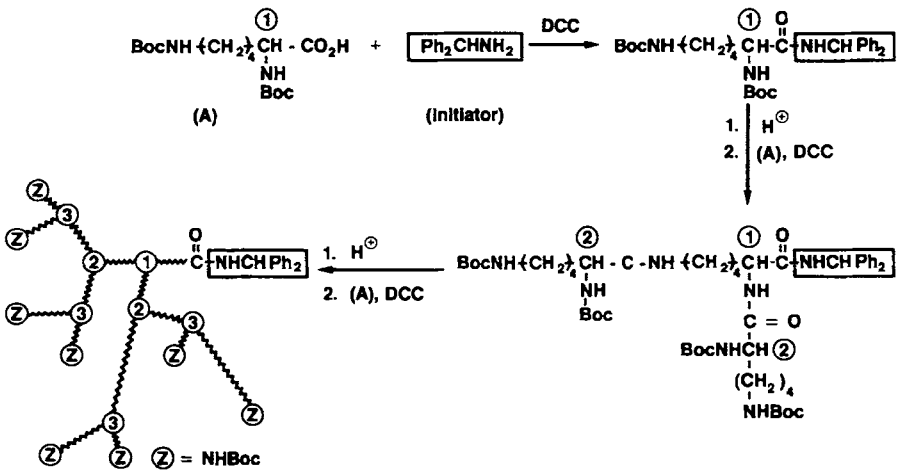
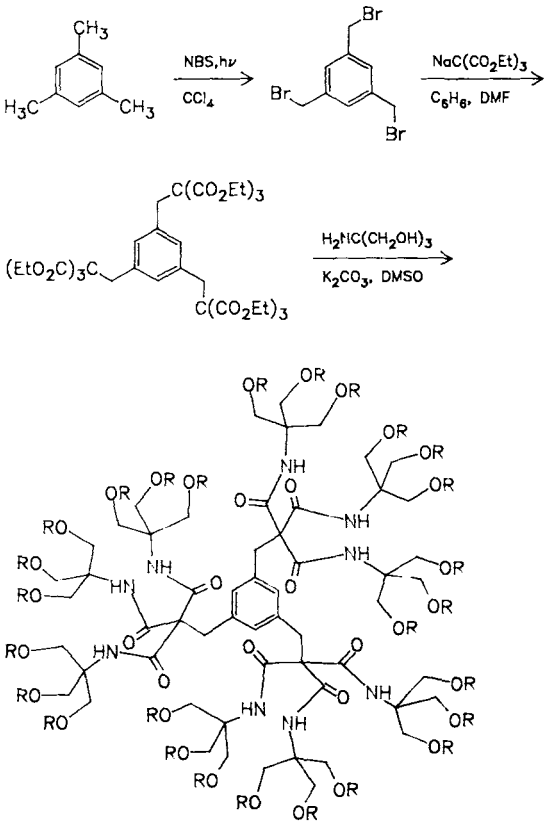
Polyamido Alcohol Dendrimers (Arborols)

This dendrimer class is a special example of a heterogeneous series. It possesses branch cells derived from the branched reagents triethyl methanetricarboxylate and aminotris(hydroxymethyl)methane. In the present case, a tridendron dendrimer with $N_c = 3$ and $N_b = 3$ is obtained by advancement through an alkylation stage and an amidation step (Scheme 6). The resulting hydroxyl-functionalized dendrimers from these "cascade" syntheses have been coined "arborols" by *Newkome* and co-workers.[75–77] They described the synthesis of mono-, di-, and tridendron proto-

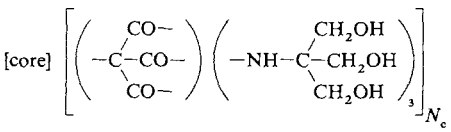


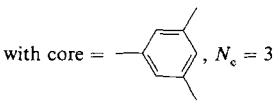
Scheme 5. Synthetic scheme for Denkewalter dendrimers.



Scheme 6. Synthetic scheme for arborols [75–77]. NBS = *N*-Bromosuccinimide, DMSO = dimethyl sulfoxide; R = H, COC_6H_5.

types, with the following general structural notation ($N_b = 3$);





with core = , $N_c = 3$

with core = , $N_c = 2$
with core = C_nH_{2n+1} ($n = 1-9$), $N_c = 1$

Certain didendron prototypes that possess hydrocarbon interiors having "barbell-like" architecture self-assemble into rod-type nanostructures (see Section 13).[77]

This method leads to very compact, highly branched dendrimers possessing as many as 27 surface groups. Reiterative chemistry, which would allow advancement to higher generations, has not been reported yet.

Polyarylamine Dendrimers

Hall et al.[54] produced a low-molar-mass series of polyarylamine dendrimers by using a protection/deprotection scheme involving the protected, branched reagent 2,4-dinitrofluorobenzene. Using various anilines as initiator cores, the reiteration scheme involved fluoride displacement by the anilines, reduction of nitro groups to amino groups, and subsequent reaction with 2,4-dinitrofluorobenzene.

5.3. Uncontrolled Chain-Growth Propagation

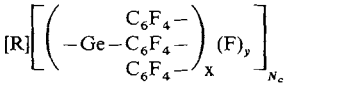
Flory[46] first suggested the possibility of forming highly branched, treelike networks by polymerization of a differentiated monomer such as A-R-B_n, where n is greater than one and functional group A can react with B. Very early reports on these systems described them as polycondensates, consisting of broad molar-mass distributions with randomly branched topologies. The methods of synthesis included Friedel–Crafts coupling of benzyl alcohols[55a] and the polymerization of 2,5,6-tribromophenol by aryl ether formation.[55b] In addition, natural carbohydrate polymers, such as amylopectin, dextrin, and glycogen have been extensively studied.[56–58]

Very recently, Russian workers[95] have reported studies on organometallic analogues of these systems. Their work describes the formation of spheroidal, treelike topologies, which appear to approach a self-limiting molecular-mass range, by uncontrolled, anionic chain polymerizations.

Similarly, *Webster* and *Kim*[96] have reported the synthesis of "hyperbranched" polyphenylenes by aryl–aryl coupling reaction of differentiated, branched aryl monomers.

5.3.1. Chain Propagation of Differentiated, Branched Monomers

Bochkarev et al.[95] have recently described the anionic polymerization of $HM(C_6F_5)_3$, M = Ge, Si, or Sn ($N_c = 1$, $N_b = 3$). Most noteworthy is the germanium system, where they have obtained self-limiting molecular-mass ranges of approximately 100000–170000, in spite of the mode of preparation. These workers hypothesize that deprotonation at germanium produces anions that nucleophilically displace fluorine atoms in *para* positions to produce a dendrimer structure of the following general formula:



$$x = \left(\frac{N_b^G - 1}{N_b - 1}\right), \quad y = N_b^G; \quad N_c = 1, \quad N_b = 3$$

Structural verification is based on viscosity data (indicating Einstein spheroid characteristics), elemental analyses, light-scattering experiments, and direct observation of individual dendrimers by electron microscopy.

The self-limiting molar-mass ranges correspond to approximately 38 branch-cell propagations (three tiers) around a germanium initiator core. Furthermore, analysis of molecular models indicates that further propagation is precluded owing to "steric screening". This appears to be the first example of a self-limiting *polymerization* to form a densely packed starburst polymer.

6. Molecular Structure of Dendrimers

Although the same types of dendrimer have the same composition and topology for a given generation, they can exhibit an enormous number of possible configurations. In the condensed phase, therefore, each dendrimer is expected to

have a configuration different from the next, so that there is no long-range order. Thus, X-ray diffraction may not be the most effective method for obtaining the molecular-level structure of dendrimers. Consequently, we have resorted to the methods of molecular dynamics to provide these data.

The parameters (force constants, bond distances, etc.) used in these calculations are those of the AMBER force field (optimized for proteins).[97a] The atoms of the dendrimer and solvent (water or methanol) are treated explicitly and used to evaluate the forces on *all* the atoms. Using these forces, we have solved Newton's equations to predict the dynamics of motion for the dendrimer at room temperature. Such calculations, referred to as molecular dynamics, were carried out with the program POLYGRAF.[97b] The polymer-building facilities of POLYGRAF were also used to simulate the dendrimers, generation by generation. At each generation the structures were equilibrated and sampled periodically to obtain average properties.

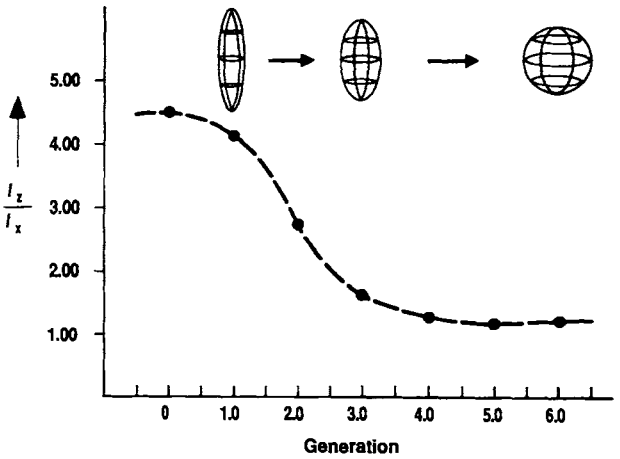


Fig. 22. Comparison of change in starburst PAMAM dendrimer morphology (aspect ratios, I_z/I_y) as a function of generation.

6.1. Starburst Polyamidoamine (PAMAM) Dendrimers

Figure 2 shows wireframe structures of generations 0 through 7 for PAMAM. Through generation 3 the dendrimer resembles a starfish. However, by generation 5 it is already a tangled mass. Better definition of the structure is presented in Figure 21, where dots at the van der Waals

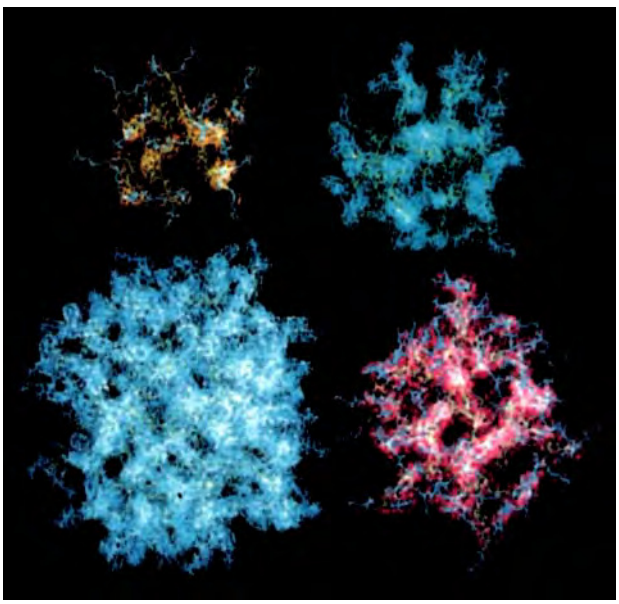

Fig. 21. Computer-simulated molecular graphics (POLYGRAF) for PAMAM dendrimers of generations 3–6 (clockwise). Dots represent van der Waals radii of dendrimer atoms.

radius of each atom define the outside of the molecule. The early generations are somewhat amorphous in shape, but the latter ones are clearly spherical. This transition to a spheroidal form is clearly illustrated by the aspect ratio of the largest to smallest principal moment (I_z/I_x) for various generations (Fig. 22). The aspect ratio decreases from 4.5 for generation 0 to 1.3 for generations 5 and 6.

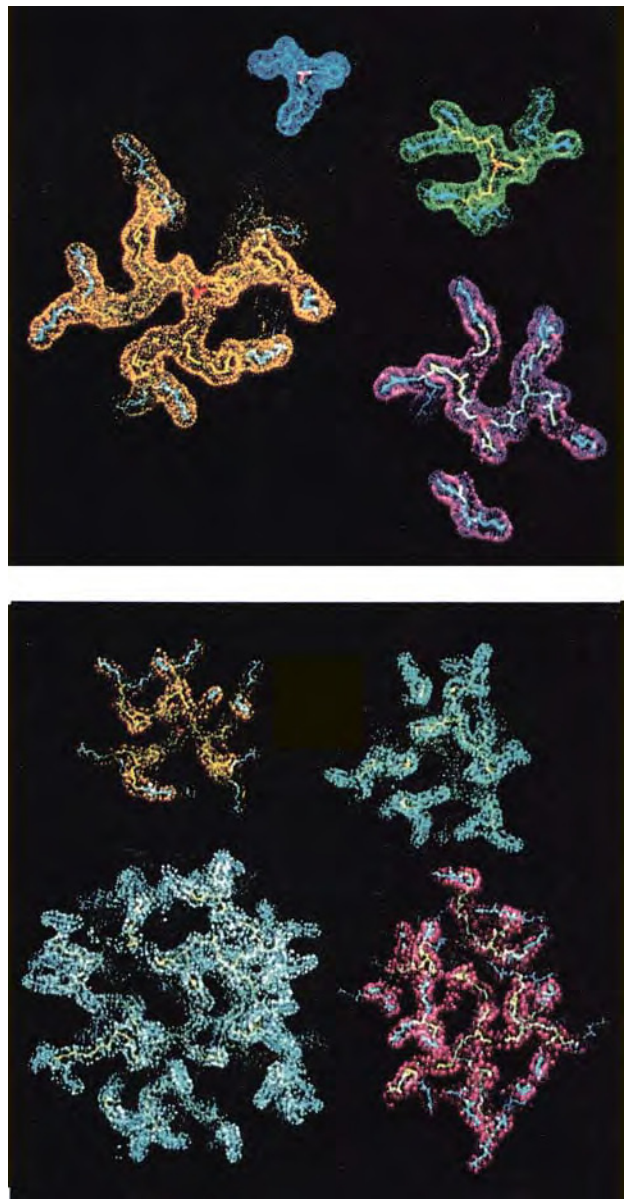

Fig. 23. Computer-simulated molecular graphics (POLYGRAF) of infrastructure of starburst PAMAM dendrimers by graphical slabbing. Top half: generations 0–3. Bottom half: generations 3–6 (clockwise in each case).

These views from the dendrimer exterior give little clue as to the internal character of these systems. This internal structure is illustrated in Figure 23, where graphical "slabbing" is used to display only a section from the middle portion of the macromolecule. Already by generation 4, there are substantial nooks and crannies, which, by generation 6, have evolved into a labyrinth of channels and cavities. These later generations clearly display well-defined internal structures.

6.2. Starburst Polyether Dendrimers

Since the initiator-core and branch-juncture multiplicities in the polyether system ($N_c = 4$, $N_b = 3$) are higher than in the PAMAM system, the polyether system quickly becomes congested and has little in the way of internal cavities (see Figs. 20, 24 and 25).

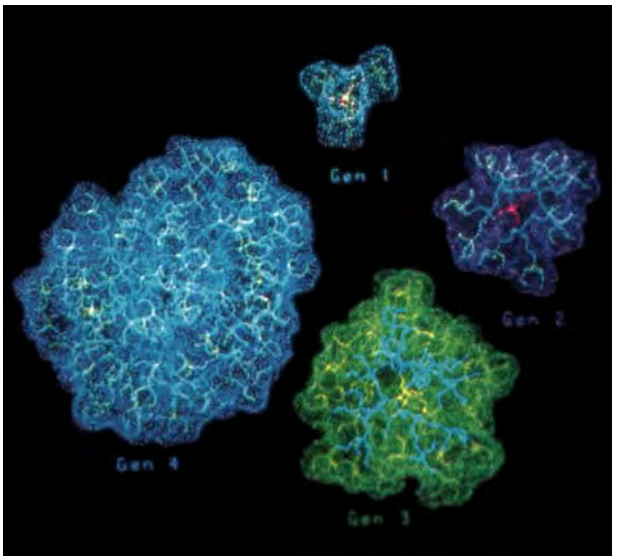

Fig. 24. Computer-simulated molecular graphics (POLYGRAF) of starburst polyether dendrimers of generations 1–4. Dots represent van der Waals radii of dendrimer atoms.

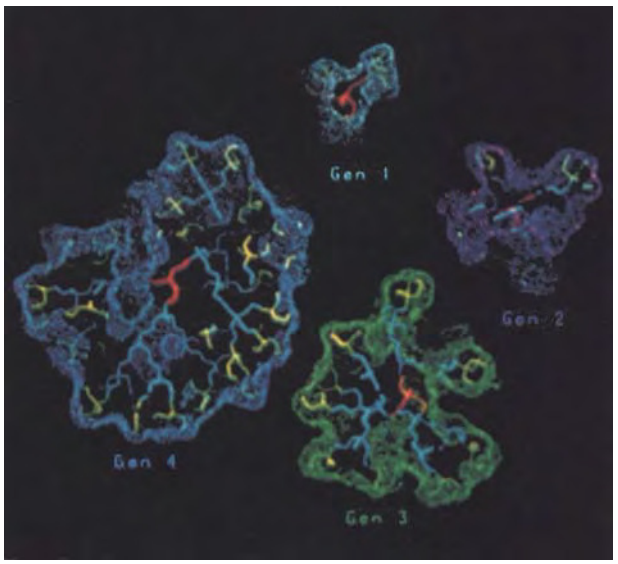

Fig. 25. Computer-simulated molecular graphics (POLYGRAF) of starburst polyether dendrimers of generations 1–4, exposing infrastructure by graphical slabbing.

6.3. Internal Surfaces and Volumes

The PAMAM dendrimers have a great deal of internal surface area and solvent-filled volume (see Fig. 23), whereas the polyether dendrimers have very little. A quantitative comparison can be made by using the concept of solvent-accessible surface (SAS).[98] The SAS is obtained by "rolling" a sphere of radius p (the probe radius) around the van der Waals surface of the molecule, where p represents the effective radius of the solvent (e.g., $p = 1.4$ Å for H_2O). The SAS is then composed of the locus of the probe-sphere midpoints. The program GEPOL87[99] has been used to calculate the SAS and its associated volume as a function of probe radius (see Fig. 26).

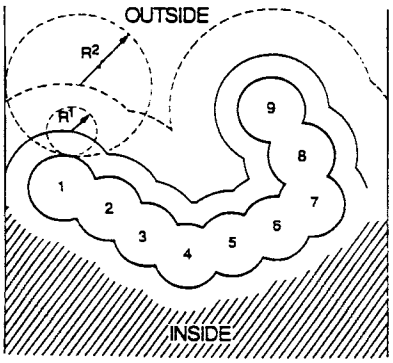

Fig. 26. Schematic representation of the solvent accessible surface (SAS) concept. A section through part of the van der Waals envelope of a dendrimer is shown with the atomic centers numbered 1–9. The SAS is mapped out by the center of various-sized probe spheres.

Consider, for example, the surface of an ideal, spherical body containing no internal voids. For such a system, the surface area is defined as follows:

$$A_{SAS} = 4\pi(R + p)^2$$

R is the radius of the spherical body and p is the radius of the probe. For spherical macromolecules, a plot of $\sqrt{A_{SAS}}$ versus p would be linear with a slope of $2\sqrt{\pi}$ and intercept proportional to the radius R.

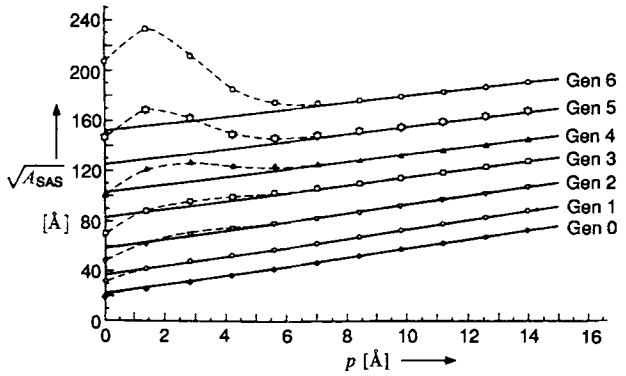

Fig. 27. Plots of $\sqrt{A_{SAS}}$ as a function of probe radius p for PAMAM dendrimers of generations 0–6. Solid lines represent linear regression fits ($p \geq 7.0$ Å); dashed lines connect the calculated values from GEPOL 87 analysis.

The PAMAM and polyether dendrimers are not ideally spheroidal, but they can, to a first approximation, be treated as such. Figures 27 and 28 contain plots of $\sqrt{A_{SAS}}$ as a function of probe radius p for the various PAMAM and polyether dendrimers simulated. Indeed, for large values of

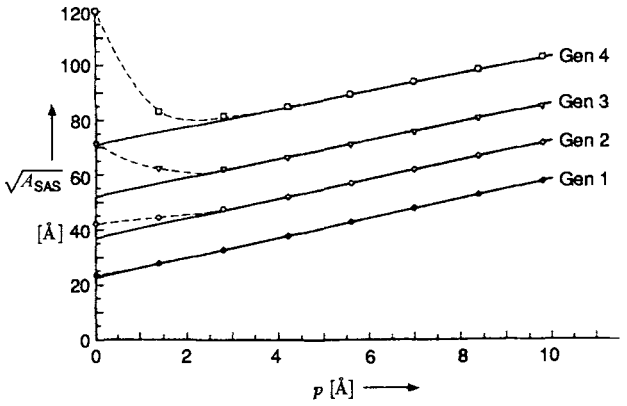

Fig. 28. Plots of $\sqrt{A_{SAS}}$ as a function of probe radius p for polyether dendrimers of generations 1–4. Solid lines represent linear regression fits ($p \geq 4.2$ Å); dashed lines connect the calculated values from GEPOL 87 analysis.

the probe radius, a linear curve is obtained with a slope approximating $2\sqrt{\pi}$. However, for small probe radii, a deviation from linearity is observed owing to the extra surface area associated with the interior regions of the polymer. Linear regression analysis of these SAS areas indicates both the amount of any internal surface area and the size of the macromolecule (see Table 6). For the PAMAM series, the fraction of internal surface is only 1.4% at generation 3 but rises to 29% by generation 4, 69% by generation 5, and 124% by generation 6. Thus, at generation 6, there is more internal surface area than external surface area! In contrast, for the polyether dendrimers, the internal surface area peaks at approximately 20% for generations 3 and 4.

A measure of the volume associated with the internal cavities of the PAMAM dendrimers is achieved by analysis of the volume contained within the calculated SASs (as a function of probe radius). Returning to the example of an ideal sphere devoid of internal cavities, the volume contained within the sphere's SAS is given by the following relation:

$$V_{SAS} = 4/3\,\pi(R + p)^3$$

A plot of $\sqrt[3]{V_{SAS}}$ versus p should be linear with a slope of $\sqrt[3]{4/3\,\pi}$ and an intercept proportional to the radius R. Indeed, this relationship is satisfied for large probe radii (see Figs. 29 and 30), but there is a deficit of volume for small

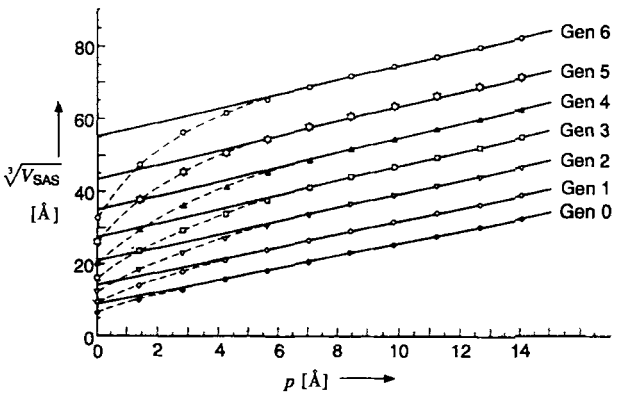

Fig. 29. Plots of $\sqrt[3]{V_{SAS}}$ as a function of probe radius p for PAMAM dendrimers.

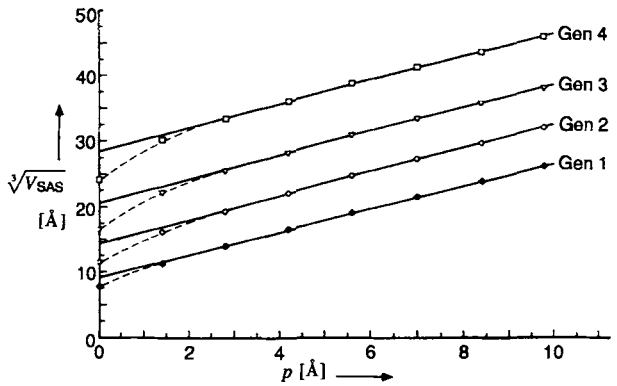

Fig. 30. Plots of $\sqrt[3]{V_{SAS}}$ as a function of probe radius p for polyether dendrimers.

probes owing to the presence of the internal cavities and channels (see Table 6). The dramatic difference between the PAMAM and polyether series is once again quite evident.

6.4. Diameters

Molecular simulations were used to estimate sizes (diameter d) of both the polyamidoamine and polyether dendrimer families as a function of generation (see Table 6 as well as Figs. 31 and 32). The following four simulation procedures were used.

1. d_{max}, the maximal end-to-end distance between terminal heteroatoms (nitrogens for the PAMAM series and oxy-

gens for the polyethers), was determined periodically and averaged over the entire set of trajectories. This value should provide an upper bound since it emphasizes any dangling arms protruding out of the dendrimer.

2. d_{R_g} is an equivalent diameter determined from the radius of gyration of the polymer, with mass weighting for all atoms.
3. $d_{A_{SAS}}$ is the diameter determined from the linear regression fits of the probe radius versus $\sqrt{A_{SAS}}$, assuming an ideal sphere.
4. $d_{V_{SAS}}$ is the diameter determined from the linear regression fits of the probe radius versus $\sqrt[3]{V_{SAS}}$ assuming an ideal sphere.

All four of these values, plus those obtained from size exclusion chromatography (SEC) studies (d_{exp}, see Section 7), are plotted in Figures 31 and 32 for the PAMAM and

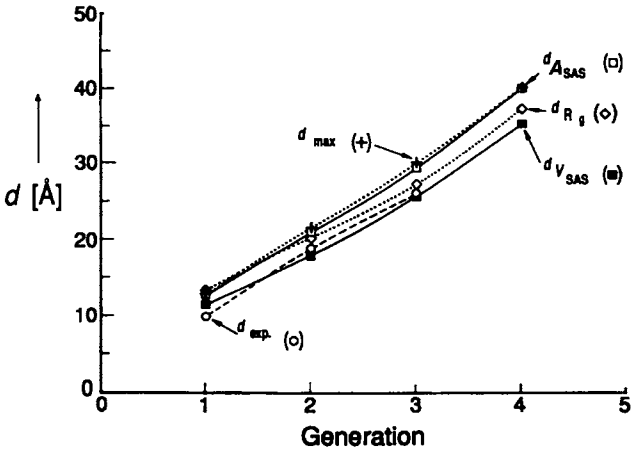

Fig. 31. Plot of calculated and experimental diameters d of PAMAM dendrimers as a function of generation (see text).

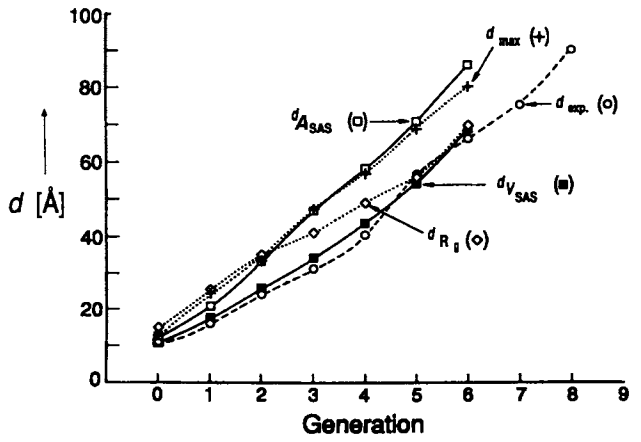

Fig. 32. Plot of calculated and experimental diameters d of polyether dendrimers as a function of generation (see text).

PE dendrimers, respectively. Generally speaking, there is very good agreement between the calculated diameters and those deduced from the experiments. The d_{max} values do indeed provide an upper bracket to the experimental and the other calculated diameters.

7. Characterization of Dendrimers

The structural subtleties represented in these dendrimer topologies require a variety of analytical methods for unequivocal characterization. The following dendrimer features were studied by these methods:

1. *Elemental composition:* C, H, N analyses; mass spectrometric fragmentation patterns.
2. *Molar mass versus generation:* low-angle laser light scattering (LALLS), CI and FAB mass spectrometry; vapor-phase osmometry.
3. *Homogeneity:* size exclusion chromatography (SEC) coupled with low-angle laser light scattering (SEC-LALLS); electron microscopy.
4. *Interior and end groups:* IR spectroscopy; ^{15}N, ^{13}C, and ^{1}H NMR spectroscopy; titration.
5. *Structures:* ^{13}C and ^{1}H NMR spectroscopy (T_1 relaxation times, signal intensity ratio versus generation); rheology studies; electron microscopy; computer-assisted molecular simulations, comparison to CPK models.
6. *Dimensions:* Electron microscopy; intrinsic viscosity measurements; size exclusion chromatography; computer-assisted molecular simulations; comparison with CPK models.

These methods were used extensively for structure verification of starburst PAMAM,[62-66,85] polyether,[65] and polyethylenimine dendrimers.[100] In many cases, small-molecule model systems were used for process optimization, defect identification, and stoichiometry studies.

In the case of PAMAMs, dendrimer bridging and branching defects were identified and minimized by process optimization and/or special purification techniques. Initial work indicated that it would be difficult to prepare dendrimers beyond generations 4 and 5 without bridging.[85] More recent work[101,102] has shown that generations 0–9 can be obtained in very monodispersed form with branching "idealities" of 95 mol% or greater.

7.1. Branching Ideality

^{13}C NMR spectroscopy has served as the best method for appraising branch defects. The symmetry of ideally branched dendrimers produces discrete resonances which are well separated from branch-defect signals (Fig. 33). The branch defects occur when acrylate alkylations are incomplete. The result of such a defect is to give lower molar-mass and surface-group values than theoretically expected. Secondary amine groups resulting from branch defects may become alkylated during advancement to the next generation. The consequence of such an event is that the progeny of such defects are one generation retarded in branch-cell development compared to the rest of the molecule.

7.2. Polydispersity

Very precise appraisals of polydispersities due to branch defects can be made by HPLC fractionation and mass-spectral analyses of the components. The molecular-mass and

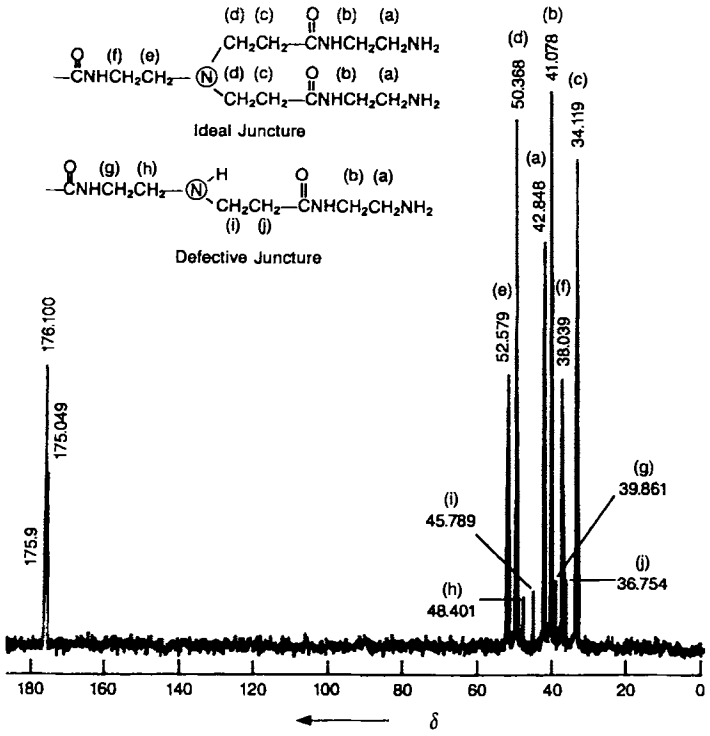

Fig. 33. ^{13}C NMR spectrum of starburst PAMAM dendrimers of generation 7 with assignments for ideal and defective branches (defective branch level ca. 5 mol%).

polydispersity values thus obtained corroborate branch-defect ranges determined by high-field ^{13}C NMR spectroscopy.

Although branch defects may contribute in a minor way to dendrimer polydispersities, inter-dendrimer bridging/looping and extraneous starburst growth derived from unremoved propagating reagents are the major contributors. PAMAM dendrimers may be obtained as very monodispersed samples, if propagating reagents and bridged forms can be removed at each stage. This is accomplished by ultrafiltration with appropriate pore-size membranes. With this technique, polydispersities of 1.01–1.08 were obtained for generations 0–9. Molecular masses, polydispersities, and hydrodynamic diameters are routinely determined by use of size exclusion chromatography (SEC), low-angle laser light scattering (LALLS), and intrinsic viscosity measurements ([η]).

Figure 34 shows an LALLS-monitored SEC chromatogram of a ninth-generation PAMAM dendrimer. In such an experiment, the polymer is injected onto a chromatographic column which separates the sample on the basis of size. Elution of the sample is monitored by two detectors in series. One detector monitors concentration and the other monitors light scattered from the sample. Response from the latter detector depends on the product of concentration and molar mass. By combining the data from both detectors, the molar mass of that portion of the distribution eluting at any instant in time can be determined. In this way, the molar-mass distribution of the entire polymer sample can be determined. For a typical polydisperse sample, the peak profiles for the detector responses will be dramatically different. Since higher-molar-mass components elute first, the LALLS detector will exhibit a larger response at early elution times (and a smaller response at later times) than the concentration detector. On the other hand, for a truly monodisperse sample, the two peaks will coincide since every molecule in the sample has the same molar mass. Figure 34 shows the latter to be essentially

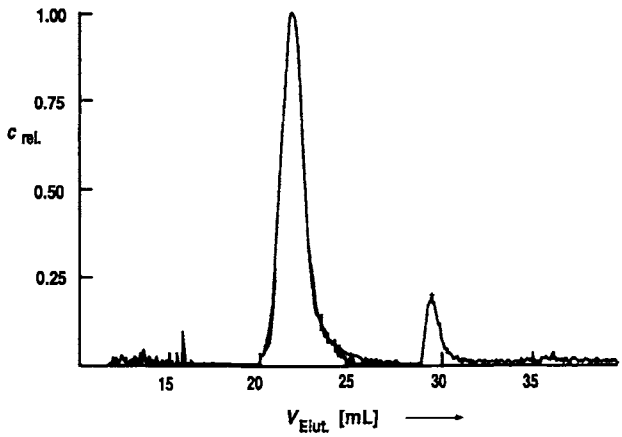

Fig. 34. SEC/LALLS curve for starburst PAMAM dendrimers of generation 9 (* = salt peak). M_w = 351000, M_r = 345000, M_{calcd} = 350338; polydispersity = 1.02. $c_{rel.}$ = relative concentration, $V_{elut.}$ = elution volumes.

the case for this ninth-generation material. Only a small amount of bridged material is present as evidenced by the slight difference between the two profiles of the rising and falling edges. The polydispersity index was determined to be 1.02 for this sample. The absolute molar masses at the peak of the distributions for generations 3–8 are given in Table 7 and compared with the theoretical values. The agreement is well within the experimental error of the light-scattering technique.

Table 7. Comparison of experimental molar masses determined by low-angle laser light scattering (LALLS), theoretical calculations, and hydrodynamic diameters d_{SI} and d_{SEC} (intrinsic viscosity and calibrated SEC) for starburst polyamidoamine dendrimers as a function of generation.

Gen.	M_r (theor.)	M_r (exp.)	d_{SI} [Å]	d_{SEC} [Å]
0	360	– [a]	11	11
1	1044	– [a]	17	16
2	2070	– [a]	22	24
3	5154	5200	31	31
4	10633	10700	40	40
5	21591	21600	53	56
6	43503	44000	67	66
7	87341	88000	76	75
8	175006	174000	90	90

[a] The relative molar mass is too low to be determined by this method.

The hydrodynamic diameter of the dendrimers has been determined by two methods. Both involve application of an equation developed by *Hester* and *Mitchell*.[103] This equation relates the molar mass, the intrinsic viscosity, and the molecular (hydrodynamic) diameter.

$$d = (240/\pi N_A)^{1/3} (M[\eta])^{1/3}$$

d = hydrodynamic diameter (in cm)
N_A = Avogadro number
M = molar mass
$[\eta]$ = intrinsic viscosity (in dL g^{-1})

As mentioned, the factor that determines the elution volume of a polymer from an SEC column is its size. Chemical composition, molar mass, etc. are relevant only to the extent that they determine the hydrodynamic diameter of the polymer in the chromatographic eluent. With this in mind, the SEC columns were calibrated using polyethyleneoxide standards of known molecular mass and intrinsic viscosity. Hydrodynamic diameters of the dendrimers were then determined from their elution volumes by comparison to these standards. They were also determined by measuring intrinsic viscosities. These values and the measured molar masses were used in the Hester–Mitchell equation. The two methods yield diameters which are in very close agreement (see Table 7).

The increase in hydrodynamic diameters as a function of generation in this series may be analyzed by comparing with values obtained from molecular simulations (see Figs. 31 and 32 as well as Table 6). The agreement is excellent. When the surfaces of these dendrimers are charged (e.g., $Z = -CO_2^{\ominus}Na^{\oplus}$), they exhibit hydrodynamic diameters that are dramatically expanded and approach the upper limit. This is no doubt due to Coulombic repulsion on the surface of the dendrimers as well as to an increased solvent cage associated with the charged system.

8. Critical Features and Physical Properties of Dendrimers

8.1. Dendrimer Genealogy

Starburst dendrimers possess three major architectural components: an initiator core/core cell, an interior, and an exterior (see Fig. 35). By definition or construction, these three components are interdependent and reflect a unique molecular genealogy. As one progresses from the initiator-core stage to an advanced dendrimer stage (e.g., generation 3.0), this molecular genealogy manifests itself in a variety of ways (see Figs. 12 and 16).

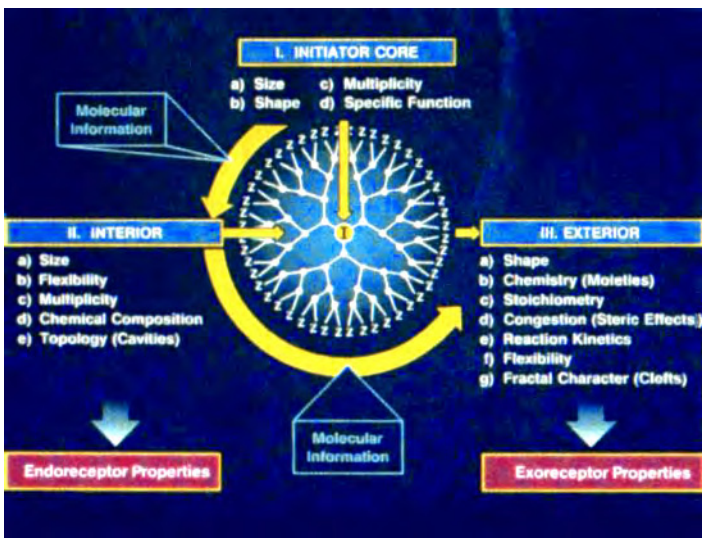

Fig. 35. Dendrimer architectural components with molecular genealogy associated with CMDPs that contribute to endo- and exo-receptor properties.

Just as one can trace ancestry and lineage in higher organisms, so can one observe a molecular-level parallel by thinking of these transformations in the context of (1) stored molecular information at each dendrimer stage and (2) molecular information transferred (transcribed) to the progeny dendrimer surface at each transformation. For example, the initiator core may be thought of as a primitive abiotic gene.[132–134] Beginning with the initiator core, molecular details are sequentially transcribed and stored to produce interior and ultimately exterior (surface) features which are characteristic of that dendrimer family (phenotype). In this fashion, interior features such as size, chemical composition, flexibility, and topology (cavities) are developed and manifested as stored molecular information, which may exhibit convergent recognition[12] or endo-receptor properties.[9c] Important biological analogies to these microenvironments may be found in the active binding sites of enzymes. The interior of a dendrimer consists of a scaffolding upon which surface properties such as shape, reactivity (functionality), stoichiometry, congestion, special kinetic features, flexibility, and "fractal" character (clefts) can be generated and controlled. These surface features govern divergent recognition and as such may be expected to exhibit exo-receptor properties.[9c] Significant biological analogies include antibody–antigen interfaces involved in immunological recognition processes[104–106] as well as most protein–protein interactions and exo-recognition at membranes or cell walls[38, 107, 108] (see also Section 11).

8.2. Topology, Branch-Cell Differentiation, and Surfaces

8.2.1. Initiator-Core and Core-Cell Effects

As mentioned earlier (see also Fig. 35), the initiator core/core cell is the primary template. As such, very important molecular information such as size, shape, multiplicity (N_c), and specific function can be introduced. For example, introduction of a specific function such as a chromophore or metal chelator in the initiator core represents stored information which will become buried by subsequent generations. In contrast, parameters such as size, shape, and multiplicity will be transcribed and displayed (translated) throughout the dendrimer development. These variables can have dramatic effects on the ultimate shape, the interior topology, and the exterior surface properties (congestion) of the developing dendrimer.

8.2.2. Interior Development

In addition to size, chemical composition, multiplicity, and flexibility, the interior of a dendrimer may be characterized by branch-cell differentiation, topology, and the evolution of a branch-cell hierarchy. Branch-cell differentiation, in particular, can dramatically change not only the interior topology but also the gross exterior surface of a dendrimer. Symmetrical branch junctures appear to favor "shell topology" formation if they have adequate branch-segment lengths l and the N_c and N_b values are not too high. Asymmetrical

branch junctures, as represented by Denkewalter dendrimers (Figs. 13 and 14) exhibit a more classical relationship between density and molecular mass[67] (Fig. 36). Presumably, this is due to more effective interior packing of the asymmetrical branch cells.

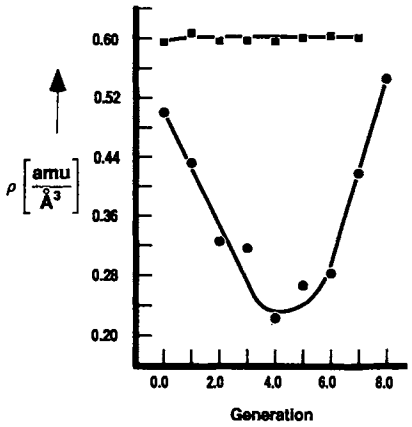

Fig. 36. Dependence of density ϱ on generation for symmetrically branched and asymmetrically branched dendrimers. amu = atomic mass unit. ■, Denkewalter dendrimers (unsymmetrical branch cells); ●, starburst PAMAM dendrimers (symmetrical branch cells).

Such subtleties are difficult to analyze in most homogeneous, classically branched, random-coil macromolecules in that these systems generally lack suitable internal reference points. An exception to this is the generic class referred to as starbranched macromolecules.

8.2.3. Comparison of Starburst Dendrimers to Starbranched Systems

The topology of starbranched macromolecules has certain similarities to that of starburst dendrimers, such as an initiator core, radial branches, and, in some cases, even telechelic functionality.[150] Beyond these comparisons and according to the Daoud–Cotton model,[109, 110] there are dramatic differences between the two systems. In the starbranched model, there are radial cell-like differentiations referred to as blobs. Most notable, however, is the fact that the branch-segment densities of many-armed starbranched polymers are inverse to those of symmetrically branched starburst dendrimers. As found in the two-dimensional projections of the Daoud–Cotton model (Fig. 37) and in computer-simulated models of many-armed starbranched systems (Fig. 38), the branch-segment densities are greatest near the initiator core and decrease in a concentric, radial fashion. In contrast, starburst dendrimer models possessing symmetrical branch cells and shell topologies predict increased branch-segment densities (congestion) as one advances to higher generations (cf. Fig. 11). By contrast, asymmetrically branched starburst dendrimers (cf. Figs. 14 and 36) exhibit constant branch-segment densities as a function of generation.[67]

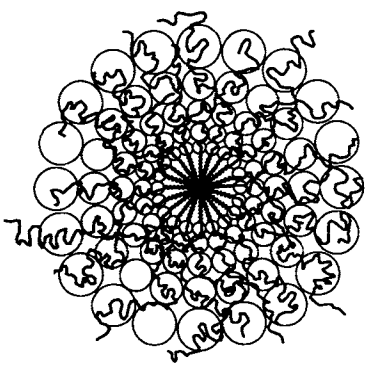

Fig. 37. A two-dimensional projection of a Daoud–Cotton model for starbranched polymers.

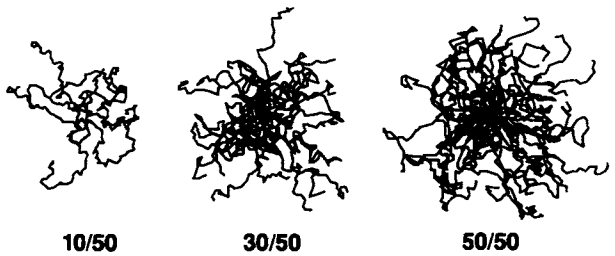

Fig. 38. Computer-simulated models of starbranched systems with 10, 30, and 50 arms. Each arm consists of 50 monomer units.

8.2.4. Starburst Dense Packing—A Critical Branched State?

Mathematically, one can appraise dendrimer surface congestion, as a function of generation, from the following relation:

$$A_Z = \frac{A_D}{N_z} \propto \frac{r^2}{N_c N_b^G}$$

A_Z is the surface area per terminal group Z, A_D the dendrimer surface area, and N_Z the number of surface groups Z per generation. From this relation, it can be seen that at higher generations G, the surface area per Z group should become increasingly smaller and experimentally approach the cross-sectional area or van der Waals dimensions of the surface groups Z. The generation G thus reached is referred to as the starburst dense-packed generation. As predicted by *de Gennes* and *Hervet*,[68] ideal starburst growth without branch defects is possible only for those generations preceding this dense-packed state. This critical dendrimer property gives rise to self-limiting starburst dimensions, which are a function of the branch-segment length l, the core multiplicity N_c, the branch-juncture multiplicity N_b, and the steric dimensions of the terminal group Z. Since the dendrimer radius r in the expression above is dependent on the branch-segment lengths l, larger l values will delay this congestion, whereas larger N_c and N_b values and larger Z dimensions will dramatically hasten it.

As early as 1983, *de Gennes* et al.[68] derived a simple equation from fundamental principles, which was proposed to predict the starburst limited or dense-packed generation m_l for PAMAM dendrimers. Based on ideal starburst growth, with tertiary amine branch junctures connected by

linear, flexible branch segments P, this equation relates m_1 to the branch-segment length l or P:

$$m_1 \approx 2.88\ (\ln P + 1.5)$$

With this equation and based on branch-segment lengths described for PAMAMs (see Section 5), the dense-packed generation m_1 was predicted to occur between generations 9 and 10. This appears to have been experimentally verified.

Clearly, this proposed congestion at the critical branched state M_1 should exhibit (1) sterically inhibited reaction rates, (2) sterically induced stoichiometry, and, quite possibly, (3) a critical phase change due to surface cooperativity (association). These phenomena have been observed experimentally for the starburst PAMAM dendrimers and may prove to be diagnostic probes for this critical branched state in other dendrimer families.

Computer-assisted molecular modeling has shown that starburst PAMAM dendrimers progress through a continuum of morphologies ranging from open hemispherical domes to closed spheroids (see Fig. 22).[111] The simulations indicate that the closed spheroids possess well-developed internal hollows and channels beyond generations 4 and 5. These morphological changes are paralleled by monotonic decreases in the spin–lattice relaxation times T_1 when various guest molecules (e.g. acetylsalicylic acid or 2,4-dichlorophenoxyacetic acid) are present. Presumably, this finding indicates a multiple guest–host relationship. Guest:host stoichiometries as high as 4:1 (by weight) and 3:1 (based on molar comparison of the interior tertiary amino groups of the dendrimer to the carboxylic acid moieties of the guest) were observed for generations 1.5 to 4.5.

Calculation of dendrimer exterior surface areas, assuming spherical geometry, allows the determination of surface area per Z group, A_Z, as a function of generation (Fig. 39). The

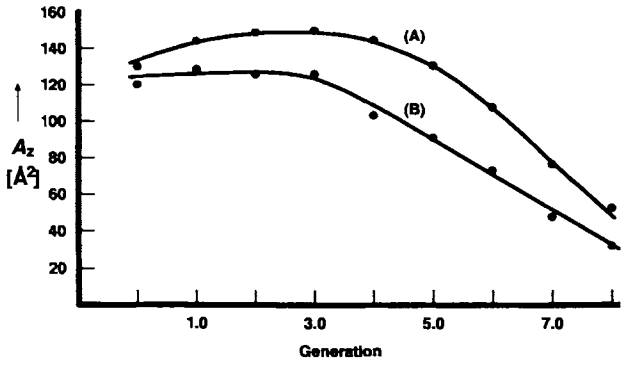

Fig. 39. Plot of surface area per terminal Z group, A_z, as a function of generation for starburst PAMAM dendrimers. Curves A and B assume 95% and 100%, respectively of the theoretical number of surface groups.

curves show that A_Z values remain relatively constant (ca. 100–120 Å^2 per Z group) for generations 0–3 and then decline to a minimum value of ca. 33 Å^2 per Z group at generation 8. These experimental data are supported by computer-assisted simulations and surface areas derived from these calculations.

These effects all contribute to the differentiation of dendrimer branch cells as one advances to higher generations (Fig. 40). A comparison of T_1 values for dendrimer interior carbons and surface carbons shows that although the T_1 values for interior carbons remain relatively constant with increasing generation, the T_1 values for the surface carbons decrease dramatically.[102]

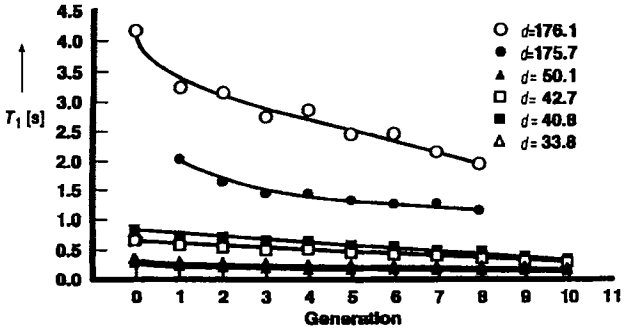

Fig. 40. Plot of spin–lattice relaxation times T_1 for interior and surface carbons versus generation.

Additional physical evidence that supports the anticipated development of congestion as a function of generation is shown in the composite comparison in Figure 41. The plots of intrinsic viscosity [η], density ϱ, surface area per Z group (A_Z), and refractive index n as a function of generation clear-

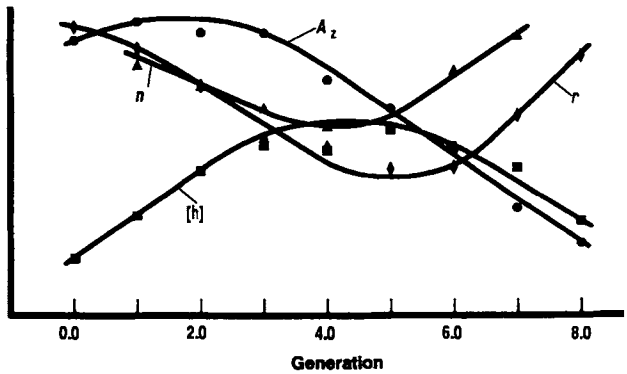

Fig. 41. Variation of surface area per terminal group (A_z), refractive index n, density ϱ, and intrinsic viscosity [η] for starburst PAMAM dendrimers as a function of generation. The units along the ordinate are arbitrary.

ly show maxima or minima at generations 3–5 which parallel computer-assisted molecular-simulation predictions. The intrinsic viscosities [η] increase in a very classical fashion as a function of molar mass (generation) and then decline beyond generation 4, presumably owing to surface congestion, which would reduce optimum surface–solvent interactions. In effect, the dendrimer is beginning to act more like an Einstein spheroid beyond generation 4. The dendrimer density ϱ (atomic mass units per unit volume) clearly minimizes between generations 4 and 5 and then begins to increase owing to the increasingly larger exponential accumulation of surface groups as a function of generation. Since refractive indices are directly related to density parameters,[112] their

values should minimize and parallel the above density relationship.

Less certain, however, is the necessary inducement of a critical phase change. Penultimate induction of branch defects would be expected to lead to unordered, heterogeneous surfaces which would not likely exhibit any special surface cooperativity or association. For this reason, it was surprising to observe physical change, which suggested a critical phase change for starburst PAMAM dendrimers at generation 8.0. Upon attempted removal of solvent from this generation, it was found that the dendrimer assembled into colorless sheets which precipitated from the solution. These sheets were separated, frozen (liquid N_2), thin-sliced, and stained with OsO_4 to produce a reverse-contrast electron micrograph (Fig. 42, left). The electron micrograph is self-consistent, if one compares an apparent isolated dendrimer at the sample edge to the ordered rows in the sample interior. A possible explanation invokes desolvation of the surface amino groups, thus leading to both intramolecular two-dimensional surface association and inter-dendrimer association to produce the assembly shown in Figure 42.[116]

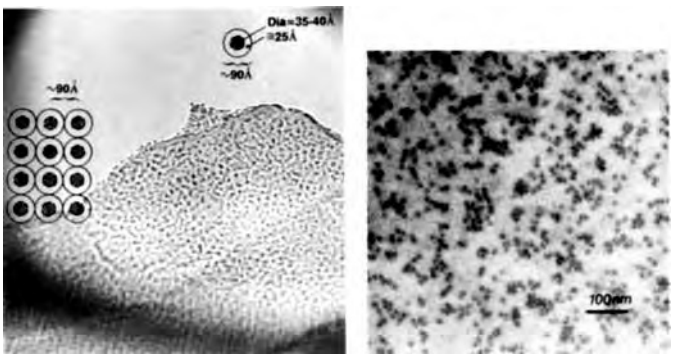

Fig. 42. a) Electron micrograph of thin-sliced films of starburst PAMAM dendrimers of generation 8. Stain: osmium tetraoxide (reverse contrast). b) Electron micrograph of individual starburst PAMAM dendrimers: core = NH_3; surface = $NH_3^{\oplus}{}^{\ominus}O_2C$-polystyrene; generation = 9; diameter = 107–110 Å; stained with RuO_4 vapor, normal contrast. (Courtesy of Prof. D. Meier and Y. Zou, Michigan Molecular Institute.)

Stain was taken in the outer congested dendrimer cells to give the observed reverse-contrast effect. This should be compared to Figure 42b, where starburst PAMAM dendrimers (generation = 9.0) have been treated with carboxylated polystyrene to give hydrocarbon-soluble dendrimers. Individual, dispersed dendrimers are observed by staining with RuO_4 (normal contrast) to produce hollow spheroids approximately 107 Å in diameter.

In either case, it is apparent that physical differentiation of the dendrimer branch cells has occurred to give what appears to be a unique example of *unimolecular encapsulation.*

9. Dendrimer Surface Reactions

In biological systems, the size and shape of smaller components is often controlled (morphogenesis) to produce self-assemblies, such as cellular vesicles, viruses, and phages. As noted by *Stryer*[113] and others,[114] many of these biological assemblies are either spheres, rods, or combinations of these shapes. Analogous molecular-level morphogenesis from pointlike organic molecules to well-defined covalent macromolecular entities has rarely been observed until the present.[9c] The ability to construct starburst dendrimers with similar shapes, sizes, and well-defined surfaces is no doubt of considerable importance in the effort to mimic the CMDPs and biomorphic features of these fundamental biological entities.

It is well known that small viruses possess many identical protein subunits symmetrically arranged around their RNA, which both provide protection and fulfill targeting functions. Similarly, the self-assembling polyhedral clathrin surfaces on cellular vesicles have recently been shown[115] to play important roles in mediating uptake of biological cell-surface receptors. Topologically, dendrimers may be viewed as analogues of the surfaces of these biological particles. The dendrimer surface cells would be expected not only to provide steric protection to its interior, but also function in primary molecular recognition of external reagents and solvents. This has indeed been observed in dendrimer protonation modes[62] as well as in the solubility characteristics of well-developed dendrimers. Solubilities are determined by the hydrophilic–hydrophobic characteristics of the surface cells (groups) of dendrimers. For example, dendrimers with very hydrophobic interiors and hydrophilic surfaces are water-soluble (e.g., starburst polyethers), whereas dendrimers such as starburst PAMAMs with hydrophilic interiors and hydrophobic surfaces are hydrocarbon-soluble.

Starburst dendrimers may be functionalized with either reactive or passive surface cells. It is implicit that all dendrimers involved in reiterative starburst growth schemes possess reactive surface groups; however, there are occasions where reactivity needs to be reduced or suppressed altogether.

In either case, the homogeneity of symmetrical, branch-junctured dendrimer surfaces provides unique opportunities to study the effect of congestion on surface stoichiometry, reaction kinetics, surface cooperativity,[164] and surface charge repulsion. Physical evidence for surface congestion was noted in Section 8.2.4. A constriction in the surface area per Z group due to the dendrimer tethering effect does not occur until approximately generation 4.0. This congestion is manifested in the higher generations by dramatically decreased surface reactivity as one approaches the starburst dense-packed generation.

9.1. Sterically Induced Aberrations due to Dendrimer Tethering Effect

9.1.1. Sterically Induced Stoichiometry and Reaction Rates

Examination of Figure 39 shows that, at generation 8, the surface area per Z group in PAMAM dendrimers approaches the cross-sectional area of the amine-terminated branch segment (ca. 33 $Å^2$) of the surface cell. Curve B assumes quantitative reactions and 100% branching ideality at each stage. Since our present analytical methods assure branching-ideality detection limits of no more than 95%, curve A may more nearly approximate experimental congestion levels.

Thus, sterically induced stoichiometry (SIS) is manifested whenever the summation of dendrimer surface-group volumes ® and incoming reagent volumes ® approaches available exterior volume surrounding the reactive dendrimer surface groups Z. This concept is illustrated in Figure 43. As

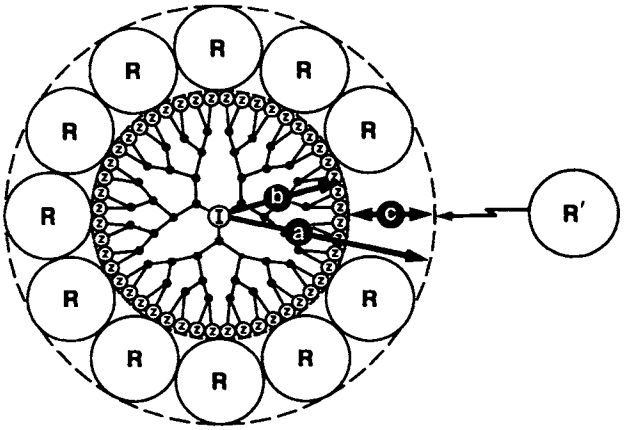

Fig. 43. Sterically induced stoichiometry (SIS).

long as the summation of the volumes ® and ® involved in bond formation with Z remains much less than $4/3\,\pi(r_a^3-r_b^3)$, ideal starburst surface stoichiometry should be expected. Large increases in the volume ® relative to the surface groups Z can be used as a means for controlling or, in fact, dramatically reducing surface stoichiometry at a particular generation. Preliminary evidence for this phenomenon was observed when advanced-generation starburst PAMAM dendrimers (where $Z = CO_2CH_3$) were combined with a large excess of a dendrimer with volume ® and NH_2 surface functionality. As much as 70% of the CO_2CH_3 groups remained unreacted in the bridged dendrimer adducts, although less sterically hindered model systems indicated the amidation was nearly quantitative under the same conditions.

Similarly, in the starburst polythioether system,[94] the surface stoichiometry was approximately one-third of the anticipated amount when attempting to advance from generation 2.0 (PTE-OH(36)) to generation 3.0 (PTE-OH(108)). This is one generation earlier than in the starburst polyether series.

9.2. Surface Chemistry

Dendrimer surface chemistry has been used to introduce both reactive and passive chemical moieties for a wide variety of interior or exterior design functions, which include:

1. chelation
2. dendrimer stratification (heterogeneous generations)
3. optically active groups
4. molecular-level templating (antigenic surfaces)
5. modification of dendrimer stoichiometry
6. modification of dendrimer solubility

In view of the ordered, nonrandom proximities of functional groups either inside or on the dendrimer surfaces, one should expect to observe time-dependent reaction rate "constants" referred to as fractal kinetics by *Kopelman*.[117] This area is still unexplored.

9.2.1. Protonation

Analyses of NH_2-terminated PAMAM dendrimers by titration and concurrent ^{13}C NMR monitoring of carbons attached to primary and tertiary amino groups were very interesting. Usually, it is assumed that tertiary amines are more basic than primary amines. With the present prototypes, the opposite was true. Titrations with hydrochloric acid showed that neutralizations occurred to give rather sharp breaks at pH ≈ 6.85 and pH ≈ 3.86 (Fig. 44), which

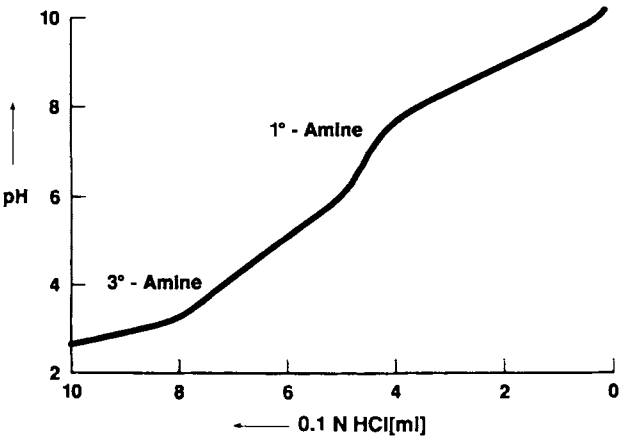

Fig. 44. Titration curve for starburst PAMAM dendrimers of generation 1 with endpoints observed for tertiary and primary amino groups.

were in very close agreement with theoretical values for terminal primary amino groups and interior tertiary amino groups, respectively.[62] The distinctive endpoints exhibited by these dendrimers are quite different from those observed for classical amino macromolecules, such as polyethylenimine.[88,89]

A wide variety of crystalline derivatives have been prepared by allowing various NH_2-terminated dendrimers to react with either inorganic or organic acids. One such intermediate was implicated in the development of lyotropic phases[118] when octanoic acid was combined with starburst polyethylenimine (generation 3).

9.2.2. Chelation to Endo- and Exo-Receptor Sites

The construction of starburst dendrimers can be controlled by appropriate choices of N_c, N_b, and branch-segment lengths l, as well as the flexibilities and shapes of the branch segments. A qualitative overview of how N_c and N_b may affect interior topology is provided by the two-dimensional projections shown in Figure 45. Because of the variety of possible heteroatoms or functional groups, it is easy to conceptualize many new endo-receptor microenvironments, which would resemble multiarmed entities described by *Vögtle* and *Weber*,[119] *Suckling*,[120] and *Menger*[121] or pseudo-macrocyclic (cryptate-like) prototypes.[9,13,34-36]

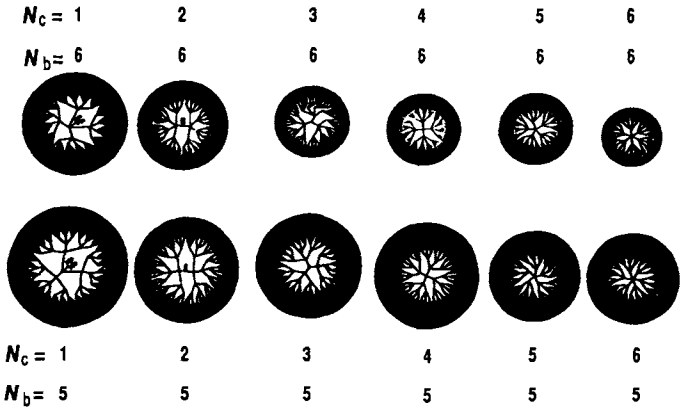

Fig. 45. Two-dimensional projections of various starburst dendrimers (symmetrical branch junctures) as a function of N_c and N_b.

Very little is known about these dendrimer properties, although it has been noted that ester-terminated PAMAM dendrimers form deep blue complexes with $CuSO_4$ solutions, whereas NH_2-terminated homologues produce deep purple solutions.[62] The well-known coordination properties of the amide bond, which lead to the formation of metal-ion complexes,[122] should make this a very rich area for further investigation.

PAMAM dendrimers develop molecular clefts[111] on their surfaces. This may be visualized from *de Gennes'* starburst dendrimer model (Fig. 46).[68] *de Gennes*[68] hypothesizes

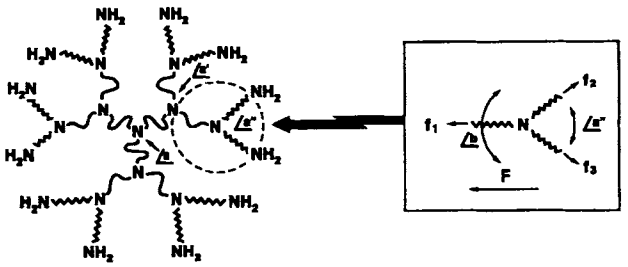

Fig. 46. The de Gennes model for self-consistent force field operating on a dendrimer branch cell.

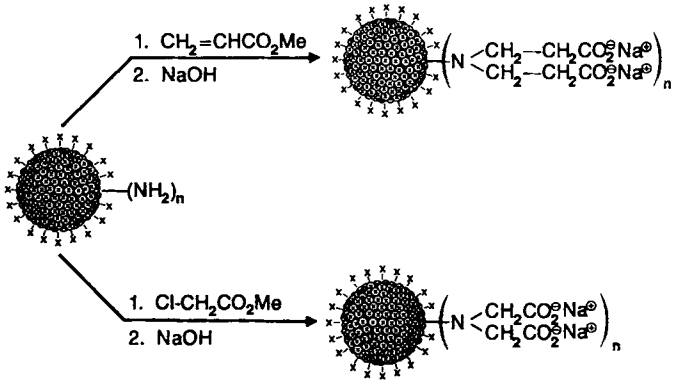
that the starburst structures should be quite flexible in the early generations, whereas the surface branch cells should become substantially more rigid and constrained as one approaches the starburst dense-packed limit. This would be expected to affect the branching angles $\measuredangle a$ of the branch cells or dendrons as well as their rotational angles $\measuredangle b$. Suppressed spin–lattice relaxation times for dendrimer surface cells in advanced generations appear to support this notion, as do apparent enhanced complexation constants for advanced generations.

The most facile entry into surface complexation involved hydrolysis of ester-terminated dendrimers, derived from Michael additions of surface NH_2 groups to methyl acrylate, with stoichiometric amounts of alkali-metal hydroxides. In this manner, salts of $Na^{\oplus}$, $K^{\oplus}$, $Cs^{\oplus}$, or $Rb^{\oplus}$ were readily obtained (Scheme 7) as white hygroscopic powders. Dilute solutions of the sodium salts allowed direct observation of the individual dendrimer molecules by scanning transmission electron microscopy without the use of staining techniques.[62–64] Elemental analyses showed that essentially stoichiometric exchanges with divalent cations such as $Ca^{2\oplus}$ could be performed.[123]

Alternatively, $N(CH_2CO_2^{\ominus})_2$ salts were prepared by the reaction of starburst PAMAM or PEI NH_2-terminated dendrimers with methyl bromoacetate, followed by hydrolysis. Each of the above dendrimer carboxylate families readily formed complexes with such metals as $Fe^{3\oplus}$, $Gd^{3\oplus}$, $Mn^{2\oplus}$, $Pr^{3\oplus}$, and $Y^{3\oplus}$. In general, the $N(CH_2CO_2^{\ominus})_2$ complexes were more stable than the $N(CH_2CH_2CO_2^{\ominus})_2$ complexes. Within the latter series, it was found that the complexes were considerably more stable (e.g., toward $OH^{\ominus}$ attack) for the higher generations (6, 7) than for the lower generations (2, 3). For example, a multimetal chelate with the empirical formu-



Scheme 7. Synthetic scheme for surface complexation of dendrimers.

la $[Na_5H_{127}Fe_{20}][C_{1521}H_{2469}N_{379}O_{573}]$ was readily formed from $FeCl_3$ and a starburst PAMAM dendrimer (96 $N(CH_2CH_2CO_2^{\ominus})_2$ groups).[124,128] An orange complex containing approximately 60 iron atoms was obtained from the next-generation dendrimer possessing 192 $N(CH_2–CH_2–CO_2^{\ominus})_2$ groups. These two complexes were stable up to pH 9–10, whereas ferric hydroxide precipitated from lower-generation homologues at pH 5.

Sub-stoichiometric yttrium complexes of starburst PAMAMs with $N(CH_2CH_2CO_2^{\ominus})_2$ surface groups displayed intramolecular exchange reactions as determined by ^{13}C NMR spectroscopy and ^{90}Y tracer experiments.[125] These and other complexation properties may serve as useful probes for the systematic characterization of dendrimer surfaces.

9.2.3. *Reactions with Electrophilic and Nucleophilic Reagents*

Table 8 lists a small sampling of surface reactions which have been successfully carried out. Reactions 1–3, 8, 9, 13–17, and 19–22 have been used in reiterative starburst propagation schemes. They are generally very high yield, quantitative processes, unless one is close enough to the starburst limited generation. Reactions 1–3 and 14–17 have been used in various combinations to create stratified dendrimers with differentiated generations possessing different segment lengths, different branch-juncture multiplicities, and varied hydrophobicity. Reaction 17 is of special interest in combi-

nation with reactions 1–3 in that it can be used to produce linear nonbranched dendrimer segments which possess interior OH groups. Since the OH groups do not participate in Michael addition reactions, these hydroxylated segments can be subsequently functionalized.

Reactions 1–3 produce intermediates which can be hydrolyzed to give dendrimers with anionic surfaces. Intermediates derived from reaction 11 yield cationic surfaces after quaternization. Dendrimers possessing chiral surfaces were readily prepared from optically active epoxides, as in reaction 4.

Hydrophobic surfaces result from reactions 4–10, 11, and 20–22. Thus, the resulting dendrimers are soluble in organic solvents, although their interiors might be quite hydrophilic. Conversely, water-soluble dendrimers are obtained from reactions 1–3 (after hydrolysis), 4 (R = H), 14, and 16–19.

9.2.4. Comparison of Dendrimers to Regular and Inverse Micelles

Very recently, both starbranched macromolecules[151a–c] and starburst[64] dendrimers have been compared to micelle systems both as synthetic models and for theoretical purposes. Theoretically, a micelle may be viewed as two concentric spherical regions: an inner core consisting of close-packed, solvent-incompatible, amphiphilic components and an outer corona of solvent-compatible (swollen) moieties. In the starburst case, the analogy is good for a number of critical parameters. First, the dendrimer dimensions (10–200 Å) are of the right order, the spherical shape is appropriate, and the number of head groups as a function of generation can be compared to well-known, discrete aggregation numbers.[126,127] A closer examination reveals that the surface area per head group can vary from about 100 $Å^2$ to 33 $Å^2$ (cf. Fig. 39), thus simulating surface-group proximity effects ranging from those in spherical micelles to those noted for liposomes or bilayers.[126] For these reasons, certain star-

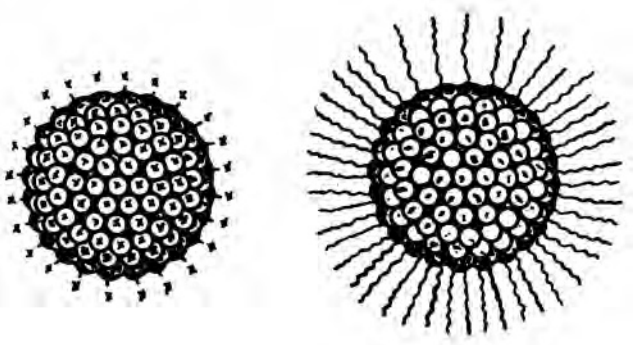

Fig. 47. Hydrophilic (left) and hydrophobic (right) surface-functionalized dendrimers viewed as mimics of reverse and inverse micelles.

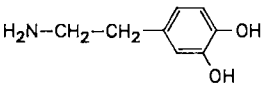
burst dendrimer families may be thought of as covalently fixed microdomains, which mimic either regular or inverse micelles, depending on the compatibility of the dendrimer surface with water[164] (Fig. 47).

Appropriate dendrimer surface and interior design offers many possibilities for unimolecular mimicry of micelles. With this approach, the head-group multiplicity is determined by synthesis, in contrast to the self-adjusting micelle systems, where aggregation numbers (head groups) are determined by free-energy minimization[126] and/or head-to-tail packing ratios.[127]

9.2.5. *Starburst Dendrimers as Models for Liposomes*

The sequestering of small molecules such as dopamine in the channels of PAMAM dendrimers (cf. Section 6.1) has been studied by use of molecular dynamics calculations.

Dopamine, which is important pharmacologically, possesses both the hydrogen-bond donor and acceptor sites necessary for favorable binding interactions with the dendrimer's interior carbonyl, amide, and amino groups. Potentially advantageous in various areas of cardiovascular therapy are the ability to selectively deliver dopamine to peripheral kidney receptors without eliciting complications due to the existence of dopamine receptors in the central nervous system and the ability to maintain a supply of non-metabolized dopamine.



Dopamine

A dendrimer of generation 6 should have a hosting capacity for 10–20 molecules of dopamine. Molecular simulations were carried out with ten dopamine guest molecules sequestered in the channels of a PAMAM host dendrimer of generation 6. Initially, the dendrimer matrix was treated as a rigid entity while the small molecules optimized their positions within the interior regions. Subsequent calculations then allowed both polymeric host and dopamine guest to relax and equilibrate. After 1.5 and 3.0 ps of simulation time, the environment of the heteroatom units of the ten encapsulated dopamine molecules was examined (Fig. 48). Of the dopamine amino groups, 75% were involved in hydrogen bonding to dendrimer interior components while the remaining 25% occupied sites distant enough from these moieties to be accessible to the solvent. For the hydroxyl groups, 90% were involved in hydrogen bonds with the dendrimer interior while only 10% were free from dendrimer interaction to hydrogen bond with solvent.

The dimensions of the higher-generation β-alanine dendrimers (Fig. 49) are such that these dopamine–dendrimer complexes should not readily cross the blood–brain barrier.

A potential advantage of this strategy is the modification of the dendrimer surface to allow targeted delivery to a desired site. Thus, adding catechol units to the terminal amino groups leads effectively to dopamine-like surface features on the dendrimer. These modified surfaces should recognize

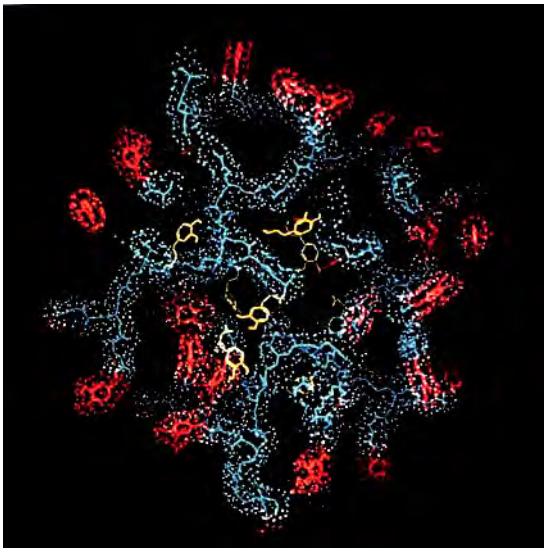


Fig. 48. Computer simulation (POLYGRAF) of a complex formed from a dendrimer (interior, light blue) containing catechol units (red) on its surface and dopamine (yellow).

dopamine receptor sites and bind sufficiently well to help increase the concentration of ligand near these sites. However, this composite dendrimer should be displaceable by dopamine as it diffuses out of the dendrimer. This concept has not yet been verified experimentally.

9.2.6. *Dendrimers with Antigenic Surfaces*

The ability to conjugate starburst dendrimers to monoclonal antibodies and subsequently deliver these antibodies to desired sites is of special interest for both therapeutic and diagnostic purposes.[128]

Recently, *Tam* and co-workers[129–131] have demonstrated the unique properties of polylysine dendrimers as scaffolding for the presentation of certain antigen structures. This approach, which could lead to new synthetic vaccine strategies, involves growing appropriate polypeptide sequences upon a dendrimer scaffold. These prototypes have been referred to as multiple antigen peptide (MAP) systems. Dendrimer matrices used to date include those shown in

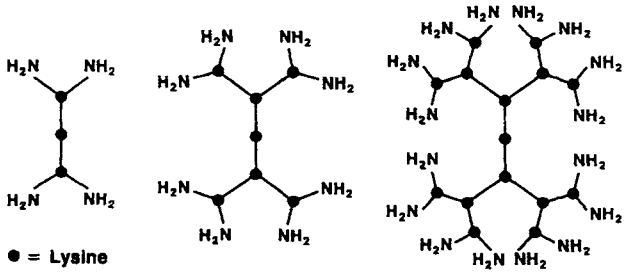

Fig. 50. Two-dimensional projections of dendrimer matrices (scaffolding) used for multiple antigen peptide (MAP) systems.

Figure 50. The octameric MAP (Fig. 51) was highly immunogenic in mice and rabbits, thus allowing production of both polyclonal and monoclonal antibodies. Most significant was the fact that no antibodies were raised against the

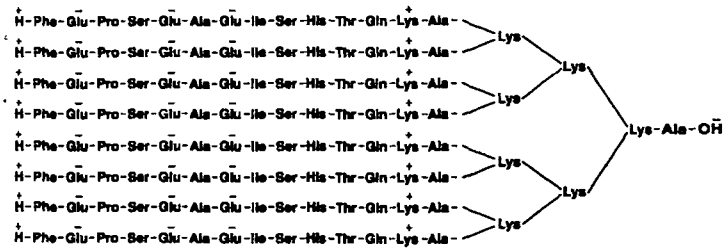

Fig. 51. An octameric multiple antigen peptide (MAP) system.

lysine dendrimer core. This indicates that the dendrimer matrix (core) is effectively and uniformly covered by the antigenic surface. Such behavior is dramatically different from conventional peptide-carrier conjugates composed of large protein substrates and low-density peptide antigen structures randomly distributed along the support matrix. It will be of considerable interest to determine the type of dendrimer and the dendrimer generation levels most effective in supporting antigen structures.

10. Biological Analogies

10.1. Dendrimers as Templates

As early as 1926, the American geneticist *H. J. Muller* and others proposed that the first organisms were simply naked genes. At least 25 years before the role of DNA was defined, Muller described genetic material as "any substance which, in given surroundings—protoplasmic or otherwise—is capable of causing the reproduction of its own specific composition, but which can nevertheless change repeatedly—'mutate'— and yet retain the property of reproducing itself in its various forms."[133] Subsequently, *Cairns-Smith*[132] proposed inorganic genes based on clays as the earliest templates, predating nucleic acids and proteins.

More recently, *Dawkins*[134] has shown that computer simulations involving reiterations of branched structures, which are actually two-dimensional projections of our dendrimer prototypes, can be used to demonstrate a variety of evolutionary principles. For example, such notions as gene expression, selection, and mutations were introduced to produce a rich array of structural entities which he referred to as biomorphs.

This suggests that there may be very primitive, abiotic, molecular examples of gene expression, transcription, translation, and self-replication which may mimic the more elaborated and ubiquitous biological examples. For comparison to our system, a generalized, conceptual overview of eukaryotic biocellular network development[168] is shown in Figure 52.

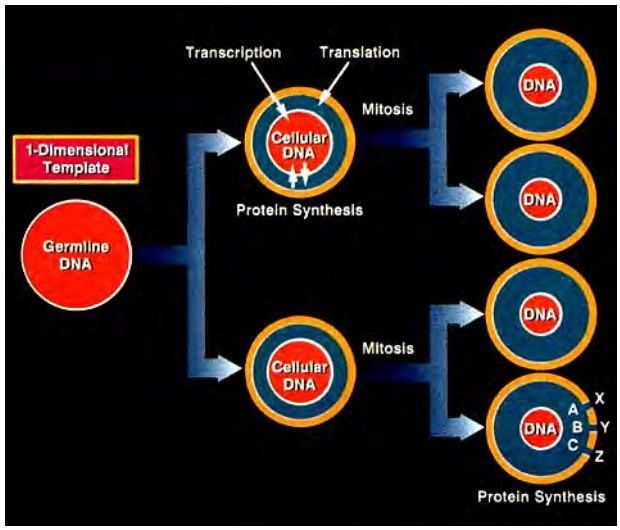

Fig. 52. Biocellular network development involving genetic transcription, translation, and protein synthesis.

Molecular information from the germ-line DNA is transferred to somatic DNA, where it is subsequently transcribed and translated into proteins. It is estimated that an average cell synthesizes 10^3-10^4 different proteins,[135] thus allowing transfer of both intra- und intercellular information, designated as A–C and X–Z, respectively, in Figure 52. This molecular information determines cellular size, shape, and surface features. No doubt this information is also involved in intercellular communication for defining the ultimate architecture, morphology, development, and growth of the biocellular network (organism).

With this as a conceptual reference, let us examine the degree of mimicry offered by the more simplistic starburst dendrimer systems. First, dendrimer branch-cell growth (for $N_b = 2$) may be viewed as an abiotic molecular-level analogue of biological cell division, where the growth numbers in each case follow a geometric progression (2^{gen}).[149]

Second, the dendrimer initiator core (i.e., NH_3) may be regarded as an abiotic analogue of the germ-line gene. The sequence of transcription, translation, and ultimately, somatic branch-cell self-replication results in the construction of a starburst polyamidoamine dendrimer (Fig. 53).

Below each of these stages is listed the molecular information which is transcribed to the dendrimer surface at that particular stage. As observed in biological systems, abiotic

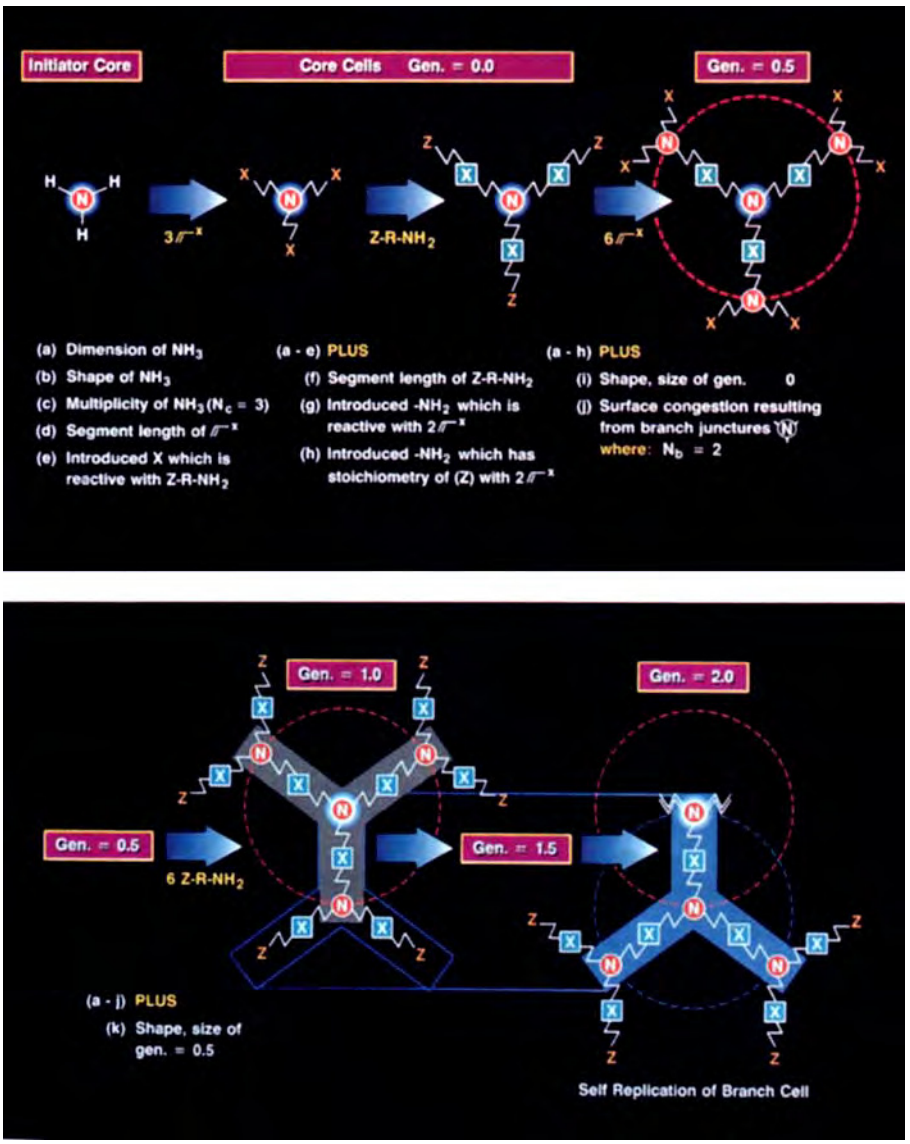

Fig. 53. Molecular information transferred from the initiator core NH_3 to the surface of starburst PAMAM dendrimers as a function of generation.

growth defects may be induced by introducing non-reiterative X or Z groups. A branch defect (missing arm) may manifest itself as an abnormal branch cell. Similar events are observed in biological systems during embryonic development and may account for many of the morphological variations in both the plant[136] and animal[137] kingdoms.

We have shown that fragments of a dendrimer that possess X or Z groups may function as "genetic" material to produce new dendrimer species which are compositionally altered ("mutated") relative to the original idealized dendrimer series.[85, 138] Preliminary work has shown that "cross-breeding" various dendrimer morphologies (e.g., spheres with rods or various-sized spherical dendrimers) yields new molecular organizations (templates) which may function as "abiotic molecular genes".[138]

Of course, it is very risky to compare such primitive abiotic prototypes to the highly elaborated, sophisticated examples nature has produced over billions of years of evolution. Hopefully, deeper insights into these issues will shed additional light upon our evolutionary origins.

10.2. In Quest of the Unimolecular Synthetic Cell

Nature teaches us that compartmentalization and self-organization of lipids into bilayers is quintessential of life. For that reason, considerable effort has been expended in the past several decades to mimic these organizations and their functions. The polymolecular assembly approach, referred to as membrane mimetics,[38] has been the central theme in this strategy.

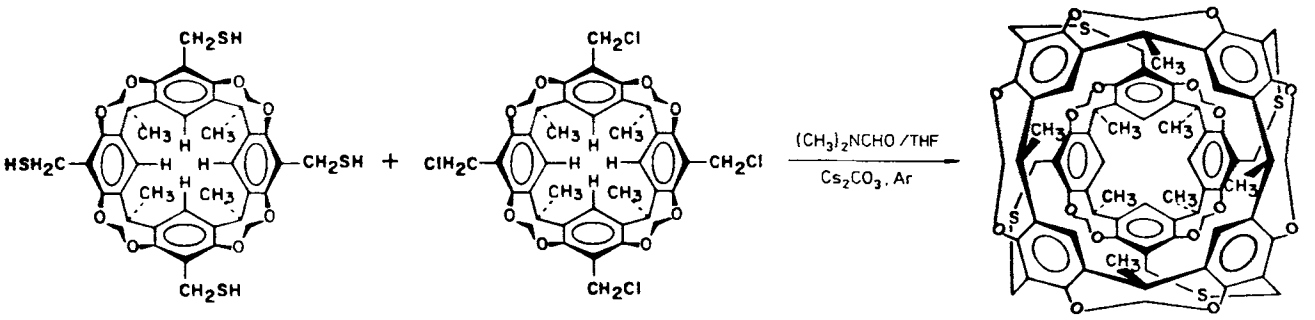
More recently, *Cram*[139] posed a very interesting synthetic challenge, directed at unimolecular synthetic cells, by raising the following questions:

"Can cavitands be prepared with 'pores' in their 'skins' that allow the entrance and departure of certain guests from their interior, but forbid passage to others?"

"In other words, can cavitands be made that resemble cells?"

"What types of synthetic strategies are required to bring such cavitands to hand and to make their solubility properties manipulable?"

Within five years, *Cram*'s group had synthesized the first unimolecular synthetic cell (Scheme 8), which he refers to as a cacerand.[12c] Their approach involved the covalent coupling of two cavitand molecules, rim to rim, much like two soup bowls in a kettle of stew, in an effort to capture guest species in the kettle. Although these prototypes satisfy many of the criteria initially raised, *Cram* concedes that their physical and chemical usefulness will become apparent only after their design renders them soluble and separable.



Scheme 8. Synthetic scheme for cacerands (unimolecular synthetic cells).

Although our objectives are much the same, our approach to producing unimolecular synthetic cells involves a closer mimicry of biological cells by systematically developing a substructure (cytoskeleton). It was anticipated that, upon approaching the starburst limiting generation, a tridendron dendrimer (see Fig. 12) with appropriate dimensions and flexibility would force a geometric and steric closure of the surface. One would visualize a variety of surface modifications for further biological cell mimicry. These might include templating groups for organizing lipid layers[164] or bilayers as well as the introduction of channels or pores for controlling entry and exit of guest molecules. Designing appropriate interiors to encourage guest entry may already have been accomplished.[111]

The cytoskeletal organizations and substructures, which are currently the object of extensive investigations in biological cells,[140] provide a clearer vision and offer further incentives for continuing the above dendrimer approach toward construction of new unimolecular synthetic cells.

11. Dendrimers as Bio-Morphic/Receptor (Supramolecular) Mimetics

As stated by *Lehn*,[9c] "Molecular chemistry, the chemistry of the covalent bond, is concerned with uncovering and mastering the rules that govern the structures, properties, and transformations of molecular species." According to him, "Supramolecular chemistry may be defined as 'chemistry beyond the molecule', bearing on the organized entities of higher complexity that result from the association of two or more chemical species held together by intermolecular forces ... to form supermolecules possessing features as well defined as those of molecules themselves." He aptly states that "supermolecules are to molecules and the intermolecular bond what molecules are to atoms and the covalent bond." This latter analogy makes dimensionality an explicit component in the definition of supramolecular chemistry and supermolecules. Driven by evolution, biological systems manifest a very efficient use of molecular space in the supramolecular domain for molecular recognition, transformation, and translocation, thus allowing one to make qualitative correlations between stored molecular information and dimensionality (see Fig. 3 in Section 2).

Recent articles by *Lehn*[9c] and *Ringsdorf*[37] have described synthetic supramolecular chemistry as being divided into two broad, overlapping categories: (1) well-defined *oligo*molecular species resulting from intermolecular association of a receptor (usually an endo-receptor) with a substrate, giving rise to supermolecules; (2) polymolecular assemblies resulting from spontaneous association of amphiphilic molecules into a specific phase having well-defined microscopic organization and macroscopic behavior (e.g., micelles, vesicles, membranes, layers). Certain of these latter prototypes may possess both exterior and interior surfaces (e.g., liposomes).

To place starburst dendrimers in an appropriate supramolecular perspective, we would like to enlarge and build upon these earlier definitions. Examination of the biological hierarchy of supramolecular chemistry reveals a broad category of macromolecular bio-morphic/receptors (e.g., enzymes, globular proteins, antibodies) which exhibit colloidlike dimensionality in addition to well-defined endo- and exo-receptor sites; however, their structures are governed by specific sequences as well as noncovalent forces (e.g. electrostatic forces, hydrogen bonding, van der Waals forces), which are not unlike those involved in the polymolecular, supramolecular assemblies (category 2) described above. Starburst dendrimers may be viewed as synthetic models for this third, broad category of bio-morphic/receptors. They also possess the supramolecular features of category 1 (i.e., endo-receptor properties) and category 2 (i.e., morphogenetic-type exo-receptor properties).

The demonstrated mimicry of gross properties such as dimensionality, surface area, morphology, and topology is readily apparent. For example, the diameter (ca. 58 Å) and spherical shape of a fifth-generation starburst polyamidoamine dendrimer are almost identical to the diameter (ca. 55 Å) and shape of hemoglobin[113] (Fig. 54, top).

Starburst polyethers, polyethylenimines, and early-generation polyamidoamines exhibit exterior surface areas similar to those involved in antigen–antibody complexes. *Amit* et al.[106] have shown that surface areas of 600–1000 Å^2 are

involved in these supramolecular complexes (cf. Fig. 54, bottom). Perhaps this similarity plays an important role in the successful use of dendrimers for the presentation of antigen moieties as reported by *Tam* et al.[129–131]

Fig. 54. Top: Structural model of hemoglobin (taken from [113]). Bottom: Structural model of antigen–antibody complexes. The H and L chains of the Fab D1.3 antibody are shown in blue and yellow, respectively; lysozyme (antigen) is shown in green and the L-glutamate moieties crucial for binding in red (taken from [106]).

One can envision many surface modifications which would allow the design of dendrimers having shapes, sizes, and cleft/concavity features similar to those of biological exo-receptors as well as of substrates, inhibitors, and cofactor mimetics.

Histones are ubiquitous DNA-binding proteins in plants and animals. The structures of histones are reminiscent of those of dendrimers, whose shapes (spheres, cylinders), dimensions (40–125 Å), and charge-modifiable surfaces suggest their use as templates for presenting DNA in a variety of replication and transcription experiments. A review of these possibilities has recently been published.[141]

The topology and dimensions of IgM antibodies[142] are remarkably similar to those of starburst dendrimers (Fig. 55, top). These biological assemblies are pentamers of the basic four-chain antibody structural units (e.g., IgG type). A high multiplicity and radial distribution of their variable regions (binding sites) no doubt accounts for their very high binding affinity to microorganisms (e.g., viruses). Their ability to activate macrophages suggests the possible design and use of starburst dendrimers for this purpose.

Finally, recent work on the topology of central neurons in mammals[143] reveals the involvement of distal dendritic tree configurations, which are reminiscent of a monodendron dendrimer (Fig. 55, bottom). Although this biological example is orders of magnitude larger than the dendrimer molecular assemblies, it suggests that these connectivity patterns may be mimicked by molecular-level computer prototypes.

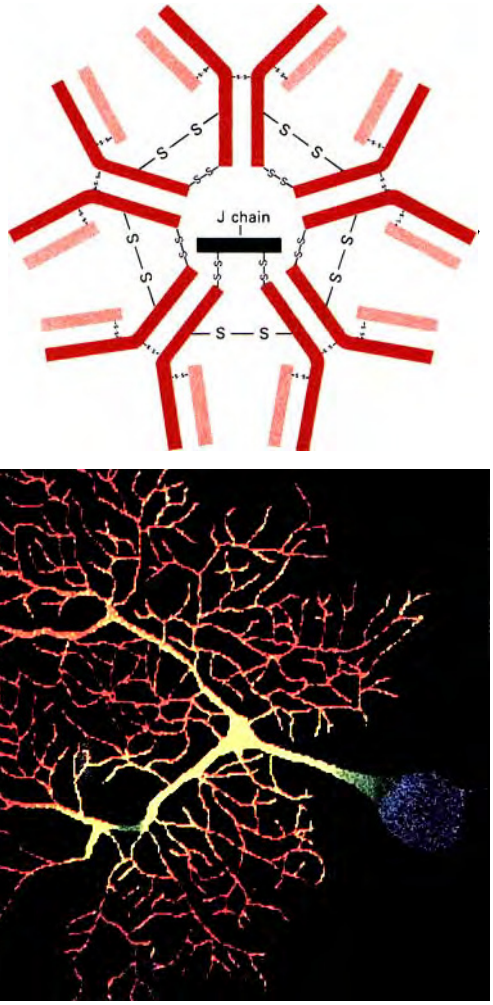


Fig. 55. Top: Pentameric structure of an IgM antibody (taken from [137a]). Bottom: Neuronal network (taken from [143].

Hopefully, these comparisons and the suggested potentials of dendrimers for developing systems based on molecular recognition will stimulate and encourage further investigations.

12. Nanostructures, Nanotechnology, and Supramolecular Devices

The biological world is replete with examples of self-organizing supramolecular assemblies: the double helix of DNA, the assembly of protein coat to form viruses, the self-organization of lipids to produce cellular membranes and vesicles, and the aggregation of α- and β-tubulin to form biological nanostructures[152] exhibiting specialized functions. These nanostructures may function as molecular receptors, catalysts, or carriers/transporters.

In the past, substantial effort has been expended to mimic these functions. Such terms as membrane mimetics or supramolecular devices have been coined to describe this synthetic mimicry. Successful pioneering efforts by *Ringsdorf*,[37] *Fendler*,[38] *Kunitake*,[39] and others[40, 155] have led to a better understanding of how lipids assemble to form membranes and how transport through membranes occurs. Investigators such as *Lehn, Cram, Vögtle, Breslow, Tabushi, Diederich, Rebek, Stoddart*, and others[154] have established sound foundations for the comprehension of molecular recognition, receptors, and catalysts.

The statement by *Pauling*[155] that "the elaboration of macromolecular structure may be necessary to stabilize transition states" is indeed prophetic[14b] in view of recent successes by *Lerner* et al.[144] and *Schultz* et al.[145] with "abzymes". Macromolecular architecture may provide further guidance for other efforts to develop not only synthetic models of biological structures, but also self-assembling synthetic organizations not found in nature.

Such assemblies include macromolecular dendrimer species shaped like "barbells", which have been reported by *Newkome* et al.[77] to exhibit unusual micellar- and gelation-type properties. Slight changes in the microscopic architecture of these prototypes can dramatically alter their macroscopic (gelation) properties. Perhaps the relationship of head group to hydrophilic tail dimensions (morphology) as described by *H. Hoffmann* et al.[156] and others[126, 127] may play an important role in this behavior.

Other self-assembling nanostructures referred to as helicates have recently been reported by *Lehn* et al.[148] These oligomeric bipyridine ligands develop rodlike configurations with metal ions, giving lengths that appear to be limited only by the molecular mass (length) of the organic ligand.

Lubensky and *Piscus*[146] have noted that colloid-sized particles up to 1000 Å act like atoms or molecules as they assemble to form supramolecular chains, periodic lattices, and entities with fractal geometries. These mesoscopic systems, which possess properties between those of single atoms or molecules and bulk materials, may assemble into macroscopic systems. Such mesoscopic behavior has been noted for metal clusters,[147] various microclusters,[170] and microdomains of water held between lipid bilayers, wherein they act as binary systems in association with macroscopic matter.[3]

We propose that this analogy might be made for our covalent dendrimer assemblies. One need only examine dendrimers and their architectural components as part of a self-similar assembly hierarchy or unimolecular fractal organized around an initiator core. For simplicity, one may visualize these scaled, self-similar organizations as a series of nesting spheres (Fig. 56), starting with atoms and proceeding dimensionally upward to macroscopic matter. *Mazur* has organized atoms (elements of the periodic table) in a similar fashion with period cones stretched in a vertical display.[157] Preliminary results[158] show that dendrimers can be dimensionally advanced from the mesoscopic range to the macroscopic region (infinite networks) as shown in Figure 42 as well as by use of other covalent bridging schemes. These bridged dendrimers are referred to as starburst polymers.

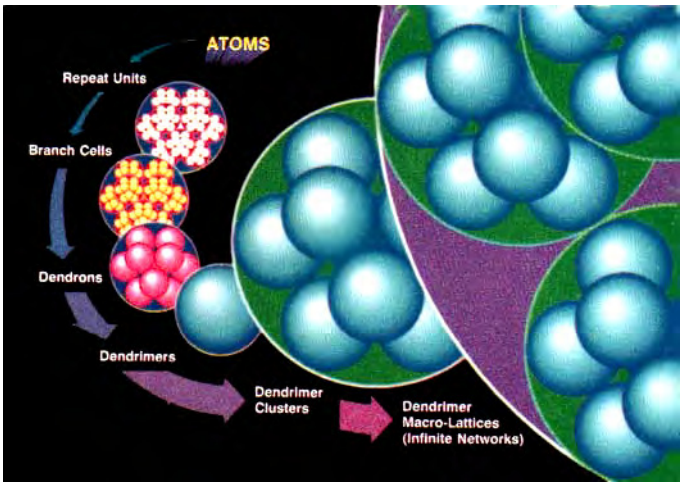

Fig. 56. Finite series of nesting spheres representing atoms, repeat units, branch cells, dendrons, dendrimers, dendrimer clusters, and dendrimer macrolattices (ordered infinite networks).

13. Starburst Dendrimers and Polymers in Relation to Classical Polymer Science

In the 1930s, *Staudinger* launched the present polymer science era by demonstrating that monomers (X–Z) can be covalently organized to produce Gaussian distributions of one-dimensional macromolecules referred to as random-coil polymers. Their well-known molar mass distributions ($M_w/M_n \gg 1$) result from largely uncontrolled processes, which produce molecular species spanning the entire continuum from microscopic to macroscopic sizes. Those species found in the mesoscopic region are often referred to as oligomers. This entire area is commercially recognized as the basis for thermoplastics technology (cf. Fig. 57).

Nearly a decade later, *Flory* and *Stockmayer* demonstrated that copolymerization of monomers containing several reactive groups with normal X–Z monomers produces three-dimensional macromolecules. Once again, the uncontrolled nature of these processes generally leads to broad molar-mass distributions. The vast array of species found in the mesoscopic range are referred to as pre-gel sols, reactive colloids, microgels, etc. This area has been the subject of intensive investigation for the past five decades.[159] The commercial importance of these infinite network systems is well recognized as the basis for thermoset/elastomer technologies (Fig. 57).

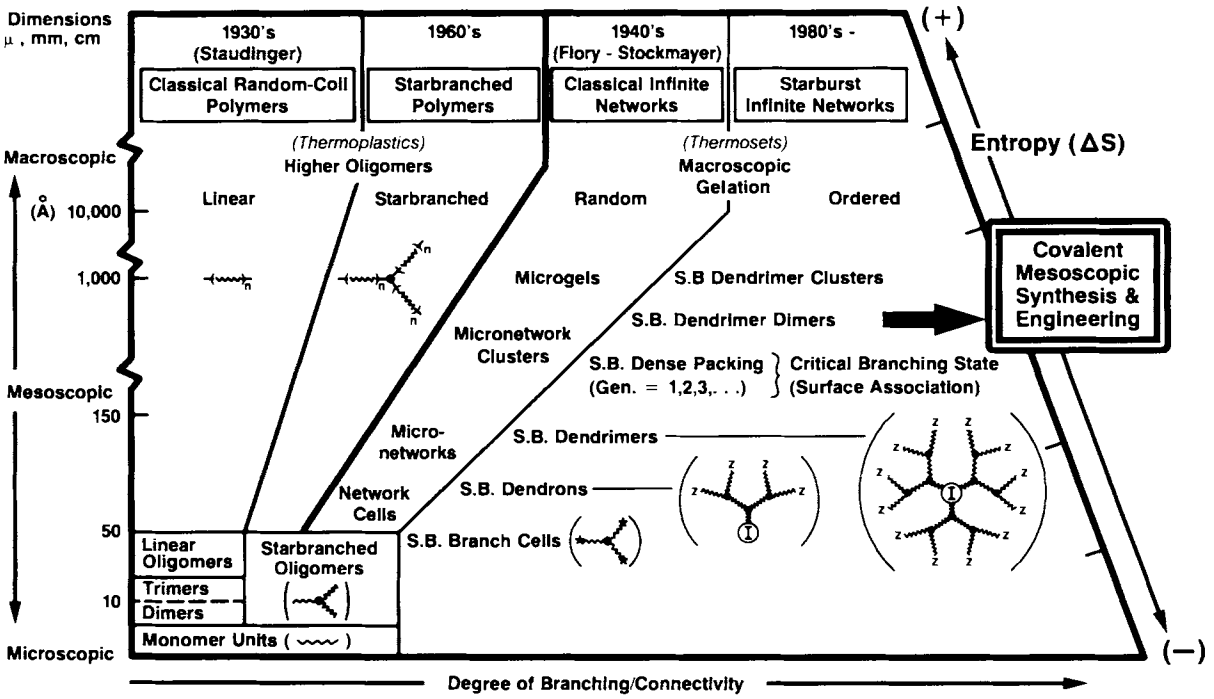

Fig. 57. Developments in polymer science

The present starburst dendrimer chemistry differs from either of these classical areas in that it teaches the systematic construction of three-dimensional, ordered, covalent organizations (dendrimers), which permit complete control of CMDPs as one progresses from microscopic to mesoscopic molecular species. This synthetic control (monomer repeat units → branch cells → dendrons → dendrimers) produces very unique mesoscopic building blocks, which have many of the attributes of atomic species and should allow the creation of new, higher-ordered covalent systems.

Figure 57 shows a comparison of the infinite network of starburst dendrimers to classical random-coil (thermoplastic) and infinite-network (thermoset) systems as a function of dimensions, degree of branching and covalent connectivity, and relative entropy. Without a doubt, the more highly organized dendrimer assemblies would be expected to be higher-energy, lower-entropy systems compared to their less-ordered classical counterparts.

14. Synthesis, Engineering, and Applications of Covalent Mesoscopic Compounds

During the past 150 years, history has witnessed a steady and sometimes dramatic progress in covalent microscopic synthesis. The field has been generally referred to as classical organic chemistry. Since the days of *Staudinger*,[16] *Flory*,[43] and *Stockmayer*,[47] macromolecular chemistry has also evolved into a flourishing area of chemical research and commerce.[160] We refer to this field as covalent macroscopic synthesis. Between these two extremes lies the more or less neglected area of covalent mesoscopic synthesis, which in a classical sense deals with reactive oligomers, teleomers, colloids, microgels, latexes etc.[169] Systematic development of covalent order and structure in this region has been hampered by the absence of reactive entities which possess controllable CMDPs (size, shape, topology, surface chemistry, and flexibility).[166] Starburst dendrimers set the stage for such progress. However, there are still technical hurdles to be dealt with, if one wishes to use dendrimers as building blocks for ordered, mesoscopic systems. One might consider dividing a dendrimer sphere into quadrants with different functionalities and reactivities (in analogy to tetrahedral sp^3 C atoms; cf. Fig. 58a). Such strategies may involve classical protection/deprotection schemes and/or SIS-type (see Section 9.1.1) protection. Such an approach has allowed us to produce a number of monodendrons possessing various masked functionalities on the initiator core. Subsequent coupling of these differentiated monodendrons to external tetradirectional anchoring reagents possessing differentiated or partially protected functionality is expected to give dendrimers with differentiated quadrants or hemispheres.

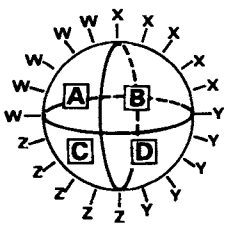

Fig. 58. a) Differentiation of dendrimer quadrants with various dendron surface moieties (A, B, C, D); b) Differentiated initiator core I–(A, B, C, D).

Perhaps a more simple demonstration might involve hemispherical functionalization.[167] Such differentiation could involve dendrimer growth on a polymeric support.[161] Linear coupling of such dendrimers would be expected to lead to

rod-type assemblies. Such condensations may mimic the polymerization of G actin to F actin.[162]

Combining various dendrimer morphologies (e.g., spheres and rods) would give rise to a wide variety of construction components and combinations. Reaction of dendrimers with classical telechelic polymers or oligomers[150] would produce novel networks with dendrimer branch junctures, whereas hydrophobic functionalization of dendrimer rods might be expected to yield unique self-assembling rod clusters with applications as artificial channels. Covalent linking of dendrimers to important bioactive entities should allow targeted delivery of therapeutic or diagnostic amounts of metals or radionuclides[125, 128]

Mesoscopic engineering offers diverse applications, such as producing submicron calibrators, abiotic templates, catalytic/chromatographic supports, synthetic membranes, molecular encapsulation devices, synthetic enzymes, biosensors, molecular electronic devices, chemical amplifiers, and photographic imagery. Clearly, mesoscopic systems have broad implications in such fields as materials research, biophysics, and microelectronics, as well as medical diagnostics and therapy.

15. Conclusion

A living organism has the astonishing gift of concentrating a stream of order on itself and thus escaping decay into atomic chaos.

Erwin Schrödinger, 1947

Just as nature has derived "order out of chaos" by evolving and using biotemplates (RNA and DNA),[79, 165] so may there be similar promise in the synthetic materials science area. Abiotic templates as simple as "initiator cores" and a branching strategy based on starburst dendrimers may provide the appropriate covalent synthetic organizations necessary for deriving ordered complexity and covalent control from atoms to macroscopic matter.

I ascribe to nature neither beauty, deformity, order nor confusion. It is only from the viewpoint of our imagination that we say that things are beautiful or unsightly, orderly or chaotic.

Baruch Spinoza, 1665

We wish to express sincere thanks to numerous colleagues both past and present who have contributed so much to the work cited in this paper. We are especially grateful for useful discussions with Professors P. de Gennes (Collège de France), G. Newkome (University of South Florida), N. Turro (Columbia University), H. Hall (University of Arizona), D. Tirrell (University of Massachusetts), and D. Meier (Michigan Molecular Institute), as well as Dr. D. M. Hedstrand and Dr. L. R. Wilson (Dow Chemical Company). Generous support for one of us (D.A.T.) from the Michigan Molecular Institute and the New Energy and Technology Development Organization (NEDO) of the Ministry of International Trade and Industry of Japan (MITI) assisted significantly in certain critical synthetic and theoretical efforts. The computer simulations were funded by a contract from Energy Conversion and Utilization Technologies Program of the Department of Energy (USA). The computer equipment used was funded by a contract (No. N00014-86-K-0735) from Defense Advanced Research Projects Agency, Office of Naval Research, and by a grant (No. DMR-94-21119) from the Division of Materials Research of the National Science Foundation, Materials Research Groups (USA).

[70] a) This term was coined in deference to their branched (dendritic = treelike) as well as their oligomeric nature. b) The dendrimer generation numbering system used in earlier work [62–64, 67, 111] designated the first starbranched species derived from the initiator core as generation 1. The present system is preferred wherein that starbranched intermediate is designated generation 0, thus making it consistent with the geometric progression (cf. Section 4.2.1). c) R. E. Scheme 1. **a**, R = CH_3; **b**, R = C_2H_5; **c**, R = $SiMe_3$

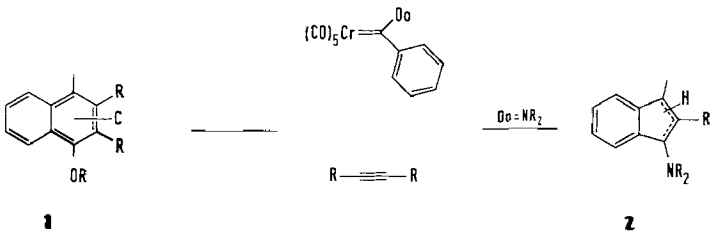
Synthesis of Nitrogen Heterocycles by Diastereoselective Intramolecular Aminocarbene Annelation**

By *Karl Heinz Dötz,* Thomas Schäfer*, and *Klaus Harms*

Reaction of alkoxycarbene-carbonyl complexes of chromium with alkynes results in regioselective alkyne/carbene/CO coupling to give $Cr(CO)_3$-coordinated 4-alkoxyphenols **1**.[1] By contrast, the corresponding aminocarbene complexes undergo five-membered ring annelation to give **2**;[2] however, the higher temperatures required often lead to loss of the metal complex fragment, so that the planar chirality is no longer present as an important stereogenic element in the product. Since the $Cr(CO)_3$ fragment in either the arene ligand or the aryl side chain should offer an effective means of stereocontrol in subsequent reactions,[3] we have attempted to suppress decomplexation of the annelation product by using milder reaction conditions. A possible approach—besides the use of carbene chelate complexes[4]—is an *intra*molecular annelation.



1 **2**

To examine this concept, we have investigated the alkynylaminocarbene complexes **5a–c** (Scheme 1). They are accessible from **3** and the amine hydrochlorides **4a–c** in the presence of a base in yields of 85–95% by modification of the known aminolysis reaction. On heating these complexes in refluxing toluene, annelation of the aryl substituents occurs to give the tetrahydroindeno[1,2-*b*]pyrrole complexes **6a–c**, which have three new stereogenic elements. The cyclization proceeds with high diastereoselectivity: ^1H and ^{13}C NMR spectroscopy reveal only a single diastereomer. The relative configuration of the two neighboring stereocenters in the central five-membered ring (3a-C, 4-C) was determined for **6a** by an ^1H NOE experiment. Irradiation of the 3a-H absorption resulted in an increase in intensity by 5.2% for 4-H and by 5.9% and 8.3% for the two 3-H atoms; these latter increases in intensity serve as internal standard for the interaction with vicinal *trans* and *cis* H atoms, respectively. Accordingly, 3a-H and 4-H are arranged *trans* to each other. On the other hand, only the X-ray structure analysis[5] of **6a** (Fig. 1) showed unambiguously that the $Cr(CO)_3$ fragment and the substituent R, originally the alkyne substituent, are *cis* to each other and thus bonded to the same side of the ring system as 3a-H. The resulting steric interaction in **6c** between the trimethylsilyl group and the metal fragment explains the ready decomplexation of this tricyclic compound.

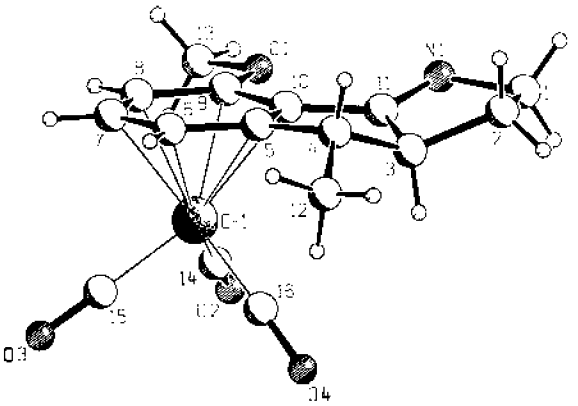


Fig. 1. Molecular structure of **6a** (the C atoms are only labeled with numbers). Selected bond lengths [Å] and angles [°]: C5-C10 1.429(7), C10-C11 1.452(7), **C3-C11 1.497(7), C3-C4 1.526(7), C4-C5 1.510(8), C11-N1 1.281(6), C1-N1** 1.491(7); C10-C11-C3 108.5(4), C3-C11-N1 118.1(5), N1-C11-C10 132.8(5), C3-C4-C5 102.7(4), C1-N1-C11 105.2(4); Torsional angle [°]: C3-C4-C5-C10 − 20.3(6), C3-C11-N1-C1 0.8(7), C11-C3-C4-C5 27.2(5), C1-C2-C3-C11 − 25.4(5), C5-C10-C11-N1 − 156.6(6).

The diastereoselective carbene annelation may be explained as follows (Scheme 2): After thermally induced decarbonylation, the alkyne is coordinated intramolecularly and then inserted into the metal–carbene bond by alkyne/carbene coupling.[6] Electrophilic addition of the metal complex fragment (16-electron species) to the arene followed by reductive elimination leads to formation of the central five-membered ring, with the complex fragment and the C_{sp^3} H atom lying on opposite sides of the ring. The six-membered ring can undergo rearomatization by a suprafacial sigma-

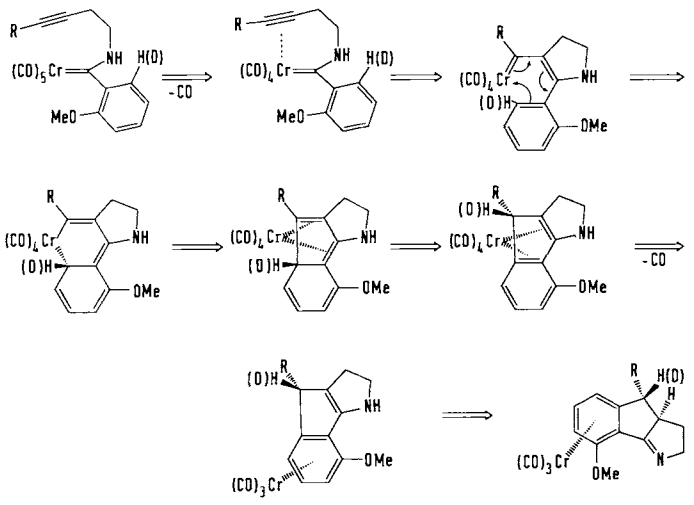

Scheme 2. Proposed mechanism for the transformation of **5** to **6**.

tropic 1,5-H shift in the five-membered ring and then coordinate the metal carbonyl fragment. This step also establishes the *cis* configuration of R and the complex fragment. Thus, whereas the chiral center 4-C and the planar chirality arise during the diastereoselective, metal-induced carbene annelation, the configuration of the stereocenter 3a-C presumably results from a thermodynamically controlled enamine/imine tautomerization.[7] The mechanism proposed in Scheme 2 is supported by a labeling study, which showed that deuterium introduced at the 3-position of the aryl substituent of **5a** is incorporated exclusively as *trans* 4-D in **6a**.

Metal-induced aminocarbene annelation thus offers a novel diastereoselective entry to arene–$Cr(CO)_3$ complexes, which may be further functionalized in a controlled fashion by metalation and nucleophilic addition.[8]

Experimental Procedures

Typical aminolysis: 5-Amino-2-pentyne hydrochloride, **4a** (0.70 g, 5.85 mmol), was added to a solution of pentacarbonyl[methoxy(1-methoxy-2-phenyl)carbene]chromium, **3** (1.65 g, 4.82 mmol), and 4 mL of triethylamine in 10 mL of dichloromethane at −78 °C. After 30 min, the solvent was removed under high vacuum. Column-chromatographic workup (0 °C, petroleum ether/dichloromethane 2/1) afforded **5a** as a yellow-brown oil (1.63 g, 86%. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.43 (s, br, 1H, NH), 7.21 (m, 1H, 5-H_{aryl}), 7.00 (m, 1H, 4-H_{aryl}), 6.89 (d, J = 8.3 Hz, 1H, 6-H_{aryl}), 6.74 (m, 1H, 3-H_{aryl}), 3.82 (s, 3H, OCH_3), 3.25 (m, 2H, NCH_2), 2.39 (m, 2H, $\equiv CCH_2$), 1.86 (t, J = 2.5 Hz, 3H, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 280.2 (Cr=C), 223.6 (CO_{cis}), 217.3 (CO_{trans}), 148.7 (1-C_{aryl}), 138.0 (2-C_{aryl}), 128.2 (C_{aryl}), 120.9 (3-C_{aryl}), 120.8, 110.8 (2 C_{aryl}), 80.6 ($C\equiv C$-CH_3), 73.7 ($\equiv C$-CH_3), 55.3 (OCH_3), 48.5 (NCH_2), 19.3 ($\equiv CCH_2$), 3.3 (CH_3). IR (CH_2Cl_2): $\tilde{\nu}$ = 2060, 1975, 1930 cm^{-1} [$Cr(CO)_5$]. EI-MS: m/z 393 ($M^{\oplus}$, 4%).

Typical carbene annelation: A solution of **5a** (0.26 g, 0.65 mmol) in 20 mL of toluene was heated at 110 °C for 2 h. After removal of the solvent under high vacuum and chromatography on silica gel (− 30 °C, dichloromethane containing 2% methanol), **6a** was obtained as a yellow powder (0.11 g, 50%). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 5.69 (t, J = 6.5 Hz, 1H, H_{aryl}), 5.05 (d, J = 6.7 Hz, 1H, H_{aryl}), 4.96 (d, J = 6.2 Hz, 1H, H_{aryl}), 4.38 (m, 1H, 2-H), 4.18 (m, 1H, 2-H), 3.89 (s, 3H, OCH_3), 3.18 (m, 1H, 3a-H), 2.86 (m, 1H, 4-H), 2.30 (m, 1H, 3-H), 1.62 (m, 1H, 3-H), 1.48 (d, J = 6.8 Hz, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 232.1 [$Cr(CO)_3$], 180.4 (C=N), 140.4 (8-C), 129.9 (C_{aryl}), 94.3 (C_{aryl}), 86.6 (C_{aryl}), 81.0 (C_{aryl}), 73.0 (C_{aryl}), 67.5 (2-C), 58.5 (OCH_3), 56.4 (3a-C), 40.7 (4-C), 30.5 (3-C), 15.6 (CH_3). EI-MS: m/z 337 ($M^{\oplus}$, 5%). IR (CH_2Cl_2): $\tilde{\nu}$ = 1961, 1897 [$Cr(CO)_3$], 1654 cm^{-1} (C=N).

Starting from 6-deutero-2-methoxybenzoic acid [9], the alkoxycarbene complex [D]**3** was accessible via the acid chloride [10]. Aminolysis of [D]**3** gave [D]**5**, which was cyclized to [D]**6a**. [D]**5a**: δ = 9.43 (s, br, 1H, NH), 7.21 (m, 1H, 5-H_{aryl}), 7.00 (m, 1H, 4-H_{aryl}), 6.89 (d, J = 8.3 Hz, 1H, 6-H_{aryl}), 6.74 (m, 90% D, 3-H_{aryl}), 3.82 (s, 3H, OCH_3), 3.25 (m, 2H, NCH_2), 2.39 (m, 2H, $\equiv CCH_2$), 1.86 (t, J = 2.5 Hz, 3H, CH_3). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 280.1 (Cr=C), 223.5 (CO_{cis}), 217.2 (CO_{trans}), 148.6 (1-C_{aryl}), 137.9 (2-C_{aryl}), 128.2 (C_{aryl}), 120.8 (3-C_{aryl}, decreased intensity), 120.7, 110.7 (2 C_{aryl}), 80.5 ($C\equiv C$-CH_3), 73.6 ($\equiv C$-CH_3), 55.2 (OCH_3), 48.4 (NCH_2), 19.2 ($\equiv CCH_2$), 3.2 (CH_3). [D]**6a**: influenced signals δ (^{1}H) = 3.18 (m, 1H, 3a-H), 2.86 (m, 90% D, 4-H), 1.48 (s, 3H, CH_3); δ (^{13}C) = 40.7 (4-C, decreased intensity).

Hexaalkynyltriphenylene: A New Type of Nematic-Discotic Hydrocarbon**

By *Klaus Praefcke,** *Bernd Kohne*, and *Dirk Singer*

Hydrocarbons are rarely found in the group of non-calamitic, disc-shaped liquid crystals.[1–4] Large, highly unsaturated, centrosymmetric hydrocarbons, as well as analogous heteroatom-containing compounds, with unusual liquid crystalline properties, have now become available for the first time by a simple one-pot reaction involving repeated

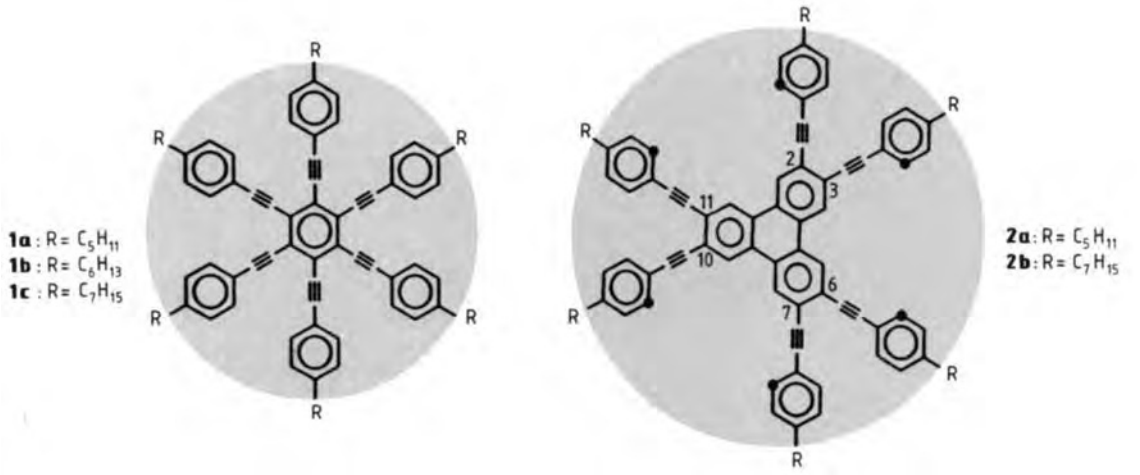
[**] Liquid Crystalline Compounds, Part 52. This work was supported by the Deutsche Forschungsgemeinschaft (Sfb 335, Teilprojekt C3), E. Merck (Darmstadt), and the Technische Universität Berlin (UP, K, and PA 1). We thank *S. Völzke* for technical assistance. Part 51: [12a].

Pd-catalyzed alkynylation of brominated arenes with variously substituted arylacetylenes.[1-4]

Particularly noteworthy are the favorable nematodiscogenic properties of these novel mesogens.[1-4] Of great interest, furthermore, are the electrooptic field effects[3-5] recently found in the surprisingly low-viscosity N_D phases of some representatives of this class of compounds. Similar results are also expected for structurally varied multi(phenylethynyl)arenes, such as hydrocarbons of the series **1** and **2**, and potential applications are conceivable.

We synthesized the seven new hydrocarbons presented here, **1a–c, 2a, b,** and two only hexaalkynyl-substituted triphenylene derivatives (see *Experimental Procedure*), by C–C coupling[1-4] reaction of (4-alkylphenyl)acetylenes and 1-alkynes with hexabromobenzene and the relatively recently prepared 2,3,6,7,10,11-hexabromotriphenylene,[6] respectively. Whereas the alkylethynyl derivatives of triphenylene, unlike hexaalkynylbenzenes,[1] do not exhibit liquid crystalline phases, the yellow hydrocarbons **1a–c** and **2a, b,** which emit blue fluorescence in solution (e.g., in $CHCl_3$), are monothermomesomorphic and, in fact, nematic-discotic, with the phase transition data given in the *Experimental Procedure*.



When the mesogens **1a–c** and **2a, b** are heated above their melting points and examined under a polarization microscope, one observes in each case only an N_D phase displaying the typical fluidity, strong thermal fluctuations, and schlieren or marbled texture;[2,4,7] such a phase has been very seldom found for noncalamitic mesogens.[1,2] This characterization is corroborated by the fact that these N_D phases are miscible with those of two hexa(phenylethynyl)benzene derivatives, which were shown to be nematic-discotic by X-ray structure investigations.[4] On slow cooling of the isotropic melts of mesogens **1** and **2** below the clearing temperatures or after annealing their N_D phases, nonbirefringent, pseudoisotropic regions are formed as a result of homeotropic orientation of the large molecules parallel to the surfaces of the glass slides.

Like other multi(phenylethynyl)arenes with N_D phases,[1-4] the new nematic-discotic compounds **1a–c** and **2a, b** exhibit strikingly small transition enthalpies $\Delta H_{N_D \rightarrow I}$ (approximately 0.2 kJ mol^{-1}) for the clearing processes ($N_D \rightarrow I$), as determined by differential scanning calorimetry (DSC).[8]

The stable mesophase regions (ΔT_{N_D}) observed for **2a, b** (80 and 54 K, respectively) are appreciably broader than those found (16 and 32 K, respectively) for the hexakis(phenylethynyl)benzenes **1a, c** with the same R groups. In contrast to **1a–c**, compounds **2** display three "bays", each roughly 8.5 Å[9] wide, between the carbon atoms marked with solid circles in the formula and assumed to lie in the same plane. If this difference in the surface features of the "core" region is ignored, the width of the N_D phases of the two classes of liquid crystals can be regarded as a function of the diameter of their superdisc-like[10] mesogen cores (gray background). Whereas the core diameter of **1a–c** is about 19.5 Å, the mesogen core[11] of **2a, b** has a diameter of about 24 Å.[9]

The significance of the core size and geometry for the liquid crystalline behavior of noncalamitic mesogens is made still clearer by comparison of the N_D-phase-forming monomesomorphic hexaynes **1a, c** and of **2a, b**, which contain benzene and triphenylene, respectively, as centers of the mesogen cores, with analogous naphthalenes containing alkyne substituents at positions 1–3 and 5–7.[2] The latter mesogens are ellipsoidal in structure and therefore biaxial with "superdisc core" diameters of about 19.5 and 21.7 Å, respectively.[2,9] These naphthalene derivatives are multimesomorphic with inverse phase sequence $K \rightarrow N_D \rightarrow D_r \rightarrow D_h \rightarrow I$; the D phases vanish when the alkyl groups are lengthened.[2]

Like the naphthalene derivatives, the triphenylene derivatives **2a, b** also readily form complexes with numerous functionalized carbocyclic compounds (e.g., cyclohexyl chloride, chloro- and nitrobenzene), whereby the type of mesophase changes (transformation of N_D phases into columnar mesophases!).[3] Further doping effects with typical acceptor molecules (e.g., 2,4,7-trinitrofluoren-9-one) on both low-molecular-weight and polymeric liquid crystals have been reported recently.[12]

Because of their enantiotropic N_D phases and their strongly unsaturated character, hydrocarbons **1a–c** and, even more (owing to their larger core diameters), those of type **2** are potential model substances[1,13] for the study of the "carbonaceous" mesophases described as occurring in pitches and pyrolysis products.[14]

Experimental Procedure

The seven new hexaalkynylarene derivatives were prepared on a 2-mmol scale from hexabromobenzene and 2,3,6,7,10,11-hexabromotriphenylene [6], respectively, and an excess (e.g., 20 mmol for **1a, b** and 36 mmol for **2a, b**) of monosubstituted ethynes following a proven C–C coupling principle [1–4]. Reaction conditions: 100–120 °C bath temperature, 25–180 h, argon atmosphere (e.g.,

for **2a, b**, 38 h at 100 °C in 30 mL of NEt_3 with 250 mg of $(Ph_3P)_2PdCl_2$, 250 mg of CuI, and 500 mg of Ph_3P; for **1a, c**, 180 and 43 h, respectively, in 20 mL of NEt_3 with 100 mg of $(Ph_3P)_2PdCl_2$, 100 mg of CuI, and 250 mg of Ph_3P). Workup was performed by treating the reaction mixture with petroleum ether (PE, b.p. 30–70 °C) or ether, followed by filtration. The filtrate was washed with 2 M hydrochloric acid as well as with saturated aqueous sodium chloride solution, dried over magnesium sulfate, filtered, and evaporated to dryness under vacuum. Products **1a–c** were purified by flash chromatography on 100 mL of silica gel 60 (E. Merck, 230–400 mesh; eluent PE/ethyl acetate (EE) 100/1) and repeated crystallization from acetone and heptane. The triphenylenehexaynes **2a, b** were each purified by column chromatography on 400 mL of silica gel 60 (E. Merck, 70–230 mesh; eluent PE/EE 100/1) and subsequent recrystallization (**2a**, 2 × from acetone, 1 × from heptane, 3 × from acetone containing 30% 1,2-dichlorobenzene, and 6 × from acetone; **2b**, 1 × from acetone containing 30% 1,2-dichlorobenzene and 20 × from acetone). The phase transition data were obtained by polarizing microscopy (PM, Leitz Laborlux 12 Pol with a Mettler FP 82 hot stage, usual rate of heating 1 K min^{-1}) and by DSC (Mettler TA 3000/DSC 30 S and GraphWare TA 72, usual heating rate 5 K min^{-1}).

The hexaynes **1** and **2** described here are multimorphic in the solid phase with reproducible solid/solid transitions and/or form—depending on the thermal history of the sample—metastable modifications. The value given as the melting point refers in each case to the highest-melting crystal modification; if necessary, this modification was obtained by suitable thermal pretreatment of the samples (e.g., annealing or a second heating). K = crystalline, N_D = nematic-discotic, I = isotropic phase.

Hexakis[(4-pentylphenyl)ethynyl]benzene **1a** ($C_{84}H_{90}$, M_r = 1099.7): Yield 46%, yellow crystals from heptane, m.p. (K → N_D) = 169.5 °C (PM), 170.4 °C (DSC, ΔH = 44.1 kJ mol^{-1}), clearing point (N_D → I) ≈ 187 °C (PM, owing to the strong tendency of this compound to decompose, only an approximate transition temperature could be measured; after determining the rough transition temperature, a fresh sample was placed in the hot stage at a temperature just below this value and the sample was heated at 10 K min^{-1}), 184.9 °C (DSC, ΔH = 0.2 kJ mol^{-1}, heating rate 10 K min^{-1}). IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 2220 (C≡C). UV/VIS (Cary 118, hexane): λ_{max} [nm] (lg ε) = 373 (sh, 4.946), 350 (5.199). ^1H NMR partial spectrum (Bruker WH 400, $CDCl_3$): δ = 7.6 and 7.2 (2 d, $^3J(H,H) \approx 8$ Hz each; phenyl H *ortho* and *meta* to C≡C); 2.6 (t, $^3J(H,H) \approx 7.5$ Hz; α-CH_2), 1.7 (tt, $^3J(H,H) \approx 7.5$ Hz each; β-CH_2). ^{13}C NMR (Bruker AM 270, off resonance, $CDCl_3$): δ = 143.89 (s; phenyl *C*-CH_2), 131.83 and 128.48 (2 d; 2 × phenyl CH each), 127.37 and 120.66 (2 s; 2 × phenyl *C*-C≡C), 99.42 and 87.20 (2 s; C≡C), 35.99, 31.50, 30.88, 22.52, and 13.98 (4 t, 1 q; pentyl C). **1b, c** were obtained analogously; their spectra are in good agreement with those of **1a**.

Hexakis[(4-hexylphenyl)ethynyl]benzene **1b** ($C_{90}H_{102}$, M_r = 1183.8): Yield 57%, yellow crystals from acetone, m.p. (K → N_D) = 123.7 °C (PM), 124.4 °C (DSC, ΔH = 38.9 kJ mol^{-1}), clearing point (N_D → I) = 142.0 °C (PM), 142.9 °C (DSC, ΔH = 0.2 kJ mol^{-1}).

Hexakis[(4-heptylphenyl)ethynyl]benzene **1c** ($C_{96}H_{114}$, M_r = 1268.0): Yield 52%, yellow crystals from acetone, m.p. (K → N_D) = 98.2 °C (PM), 99.0 °C (DSC, ΔH = 44.4 kJ mol^{-1}), clearing point (N_D → I) = 131.2 °C (PM), 132.6 °C (DSC, ΔH = 0.4 kJ mol^{-1}).

2,3,6,7,10,11-Hexakis[(4-pentylphenyl)ethynyl]triphenylene **2a** ($C_{96}H_{96}$, M_r = 1249.7): Yield 35%, bright yellow crystals from acetone, m.p. (K → N_D) = 156.2 °C (PM), 156.8 °C (DSC, ΔH = 36.7 kJ mol^{-1}), clearing point (N_D → I) = 236.6 °C (PM, owing to the strong tendency of this compound to decompose, only an approximate transition temperature could be measured; after determining the rough transition temperature, a fresh sample was placed in the hot stage at a temperature just below this value and the sample was heated at 10 K min^{-1}), 237.1 °C (DSC, ΔH = 0.1 kJ mol^{-1}). IR(CCl_4): $\tilde{\nu}$ [cm^{-1}] = 2220 (C≡C). UV/VIS (heptane): λ_{max} [nm] (lg ε) = 367 (sh, 5.176), 345.0 (5.370), 314.0 (sh, 5.001). ^1H NMR partial spectrum: δ = 8.6 (s; triphenylene H), 7.6 and 7.2 (2 d, $^3J(H,H) \approx 8$ Hz each; phenyl H *ortho* and *meta* to C≡C), 2.6 (t, $^3J(H,H) \approx 7.8$ Hz; α-CH_2), 1.7 (tt, $^3J(H,H) \approx 7.5$ Hz each; β-CH_2). ^{13}C NMR: δ = 143.18 (s; phenyl *C*-CH_2), 131.99 and 128.30 (2 d; 2 × phenyl CH each), 127.97 and 124.77 (2 s; inner and outer triphenylene C without assignment, 126.67 (d; triphenylene CH), 120.79 (s; phenyl *C*–C≡C), 94.62 and 88.41 (2 s; C≡C), 36.04, 31.68, 30.99, 22.64, and 14.13 (4 t, 1 q; pentyl C). Compound **2b** was obtained analogously; its spectra are in good agreement with those of **2a**.

2,3,6,7,10,11-Hexakis[(4-heptylphenyl)ethynyl]triphenylene **2b** ($C_{108}H_{120}$, M_r = 1418.2): Yield 23%, bright yellow needles from acetone, m.p. (K → N_D) = 121.3 °C (PM), 122.0 °C (DSC, ΔH = 41.1 kJ mol^{-1}), clearing point (N_D → I) = 174.8 °C (PM), 176.6 °C (DSC, ΔH = 0.1 kJ mol^{-1}).

2,3,6,7,10,11-Hexakis(1-heptynyl)triphenylene ($C_{60}H_{72}$, M_r = 793.2): Yield 14–20%, bright yellow, partly crystalline oil. IR (CCl_4): $\tilde{\nu}$ [cm^{-1}] = 2235 (C≡C). ^1H NMR partial spectrum: δ = 8.5 (s; triphenylene H), 2.5 (t, $^3J(H,H) \approx 7$ Hz; C≡C-CH_2) 1.7 (tt, $^3J(H,H) \approx 7$ Hz each; β-CH_2). ^{13}C NMR: δ = 127.96 and 125.35 (2 s; inner and outer triphenylene C without assignment), 126.99 (d; triphenylene CH), 95.12 and 79.65 (2 s; C≡C), 31.19, 28.55, 22.31, 19.77, and 14.01 (4 t, 1 q; pentyl C).

2,3,6,7,10,11-Hexakis(1-decynyl)triphenylene ($C_{78}H_{108}$, M_r = 1045.7): Yield 13%, bright yellow crystals after flash column chromatography (silica gel 60, heptane/ethyl acetate 150/1), m.p. (K → I) ≈ 37 °C (PM), 41.0 °C (DSC, ΔH = 63.0 kJ mol^{-1}). IR ($CHCl_3$): $\tilde{\nu}$ [cm^{-1}] = 2235 (C≡C). ^1H NMR partial spectrum: δ = 8.5 (s; triphenylene H), 2.5 (t, $^3J(H,H) \approx 7$ Hz; C≡C-CH_2), 1.7 (tt, $^3J(H,H) \approx 7$ Hz each; β-CH_2). ^{13}C NMR: δ = 127.96 and 125.37 (2 s; inner and outer triphenylene C without assignment) 126.96 (d; triphenylene CH), 95.12 and 79.66 (2 s; C≡C), 31.91, 29.25, 29.07, 28.69, 22.68, 19.82, and 14.09 (6 t, 1 q, aliphatic CH_2 and CH_3).

Asymmetric Nucleophilic Acylation via Metalated Chiral Amino Cyanides: Enantioselective Synthesis of 3-Substituted 4-Oxoesters by Asymmetric Michael Addition**

By *Dieter Enders,** *Peter Gerdes,* and *Helmut Kipphardt*

Since the pioneering work of *Hauser* et al.[1] in the early 1960s, metalated amino cyanides **A**[2] have been used as d^1 synthons[3] for umpolung of the classical a^1 reactivity of carbonyl compounds[4] and amines.[5] Examples include the syntheses of α-hydroxy ketones,[6] amino alcohols,[7] and α-amino ketones.[8] Compounds **A** are of particular synthetic value as equivalents of acyl carbanions **B**, especially since conjugate additions of **A** to 1,4-unsaturated ketones,[1b, 9] cyanides,[10, 11a, b] and esters[1b, 9c, 11] have been developed

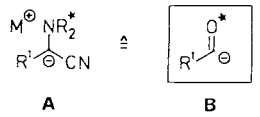
to prepare 1,4-dicarbonyl compounds.[12] Numerous applications of optically active amino cyanides have been published in recent years.[13–23] Surprisingly, however, their synthetic potential for asymmetric nucleophilic acylation has



A B

hardly been exploited so far. Here we report an efficient enantioselective synthesis of 3-substituted 4-oxoesters by asymmetric Michael addition of lithiated chiral amino cyanides to α,β-unsaturated esters (Scheme 1).

In this approach, aldeydes **1** are first allowed to react with the enantiomerically pure secondary amine (*S,S*)-**3**[24] [(*S,S*)-**3** · HCl, KCN, H_2O, 0 °C; 1.3 equivalents R^1CHO, 0 °C → room temperature, 3–14 h, 90–98 %] to give the epimeric amino cyanides (*S,S,R/S*)-**4**, which are then metalated with lithium diisopropylamide in ether. Addition of the α,β-unsaturated ester (*E*)-**2** at −100 °C results in formation of the partially crystalline, highly diastereomerically pure Michael adducts (*S,S,R,R*)-**5**, which, as crude products, are hydrolyzed without racemization by addition of saturated copper sulfate solution and tetrahydrofuran as cosolvent. Distillative or chromatographic workup affords the 3-substituted 4-oxoesters (*R*)-**6** in good overall yields (47–71 %) and with high enantiomeric excesses (*ee* = 90 to ≥ 96 %; Table 1). Up to 91 % of the chiral auxiliary reagent (*S,S*)-**3** may be recovered from the aqueous phase, after basification, by extraction with ether.

Table 1. Oxoesters (*R*)-**6** of high enantiomeric purity prepared by conjugate nucleophilic acylation.

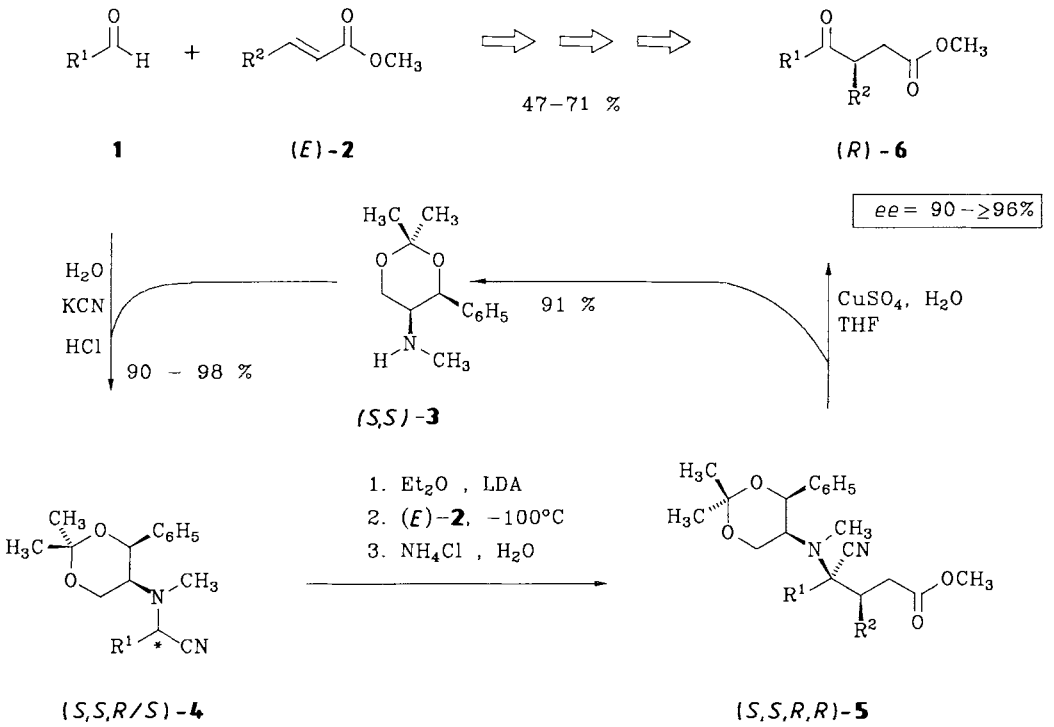
6	R^1	R^2	Overall yield [%]	α_D^{23} [°] (neat)	*ee* [%] [a]	Configuration [b]
a	CH_3	CH_3	69	+ 57.2	93	(*R*)
a	CH_3	CH_3	65	− 56.6	92	(*S*) [c]
b	C_2H_5	n-C_4H_9	47	+ 51.9	≥ 95	(*R*)
c	n-C_3H_7	C_2H_5	51	+ 47.2	≥ 95	(*R*)
d	p-C_6H_4Cl	CH_3	66	+ 28.7	≥ 95	(*R*)
e	2-furyl	n-C_4H_9	61	+ 62.6	90	(*R*)
f	p-C_6H_4F	CH_3	71	+ 18.25	≥ 96	(*R*)

[a] Determined by ^1H NMR shift experiments with $Eu(hfbc)_3$. [b] The absolute configurations are based on an X-ray structure analysis of a crystalline adduct, **5**, as well as on polarimetric measurement after chemical correlation with compounds of known configuration [25]. [c] (*R,R*)-**3** was used as chiral auxiliary.

As exemplified for **6f** ($R^1 = p$-C_6H_4F, $R^2 = CH_3$), the enantiomeric excesses may be determined in a facile and relatively exact fashion from the ^1H NMR shift of the sharp methoxy singlet of the ester function (Fig. 1). The racemic oxoester *rac*-**6**, required as a reference compound, was prepared in each case by a route analogous to that in Scheme 1 with achiral pyrrolidine instead of (*S,S*)-**3**. The optical antipodes (*S*)-**6** are correspondingly obtained by using the enantiomeric auxiliary (*R,R*)-**3** [for example, (*R*)-**6a**/(*S*)-**6a**].

The absolute configurations given here are supported by an X-ray structure analysis of a crystalline adduct, **5g** ($R^1 = p$-$H_3COC_6H_4$, $R^2 = CH_3$), and by polarimetric measurement after chemical correlation with known compounds as well as by the assumption of a uniform reaction mechanism.[25]

This new procedure of conjugate nucleophilic acylation of enoates with metalated amino cyanides, which occurs with



Scheme 1.

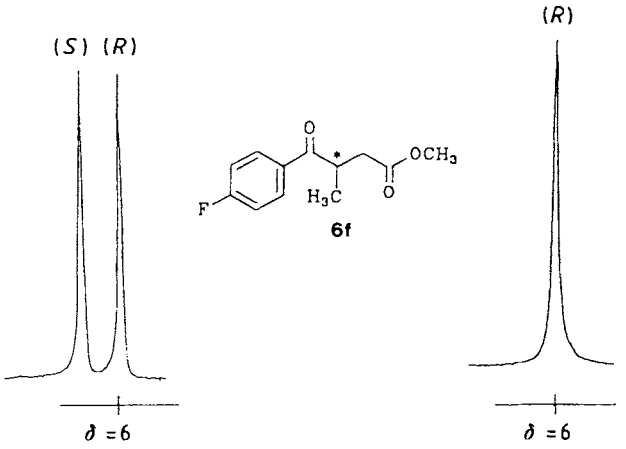


Fig. 1. Determination of the enantiomeric excess by ^{1}H NMR shift experiments (methoxy singlet). Samples: 50 mg **6f** + 200 mg Eu(hfbc)$_3$ in 1 mL $CDCl_3$. Left: *rac*-**6f**, *ee* = 0%. Right: (*R*)-**6f**, *ee* ≥ 96%.

high asymmetric induction, opens a simple route to 3-substituted 4-oxoesters **6**[26, 27] of high enantiomeric purity. Preliminary investigations with other Michael acceptors, such as α,β-unsaturated phosphonates and sulfones, show that the new method has a wide scope of application.[25b]

Experimental Procedure

6: A solution of (*S,S,R/S*)-**4** (10 mmol) in 75 mL of ether was added dropwise to a stirred solution at −78 °C of lithium diisopropylamide (11.0 mmol; prepared from 6.9 mL of a 1.6 N solution of butyllithium in *n*-hexane and 1.1 g of diisopropylamine in 25 mL of ether at 0 °C). The reaction mixture was allowed to warm over 0.5 h to 0 °C and then cooled to − 100 °C. (*E*)-**2** (10 mmol) was slowly added to the vigorously stirred solution, which was then stirred for an additional 1 h, allowed to warm over 2–3 h to − 20 °C, and worked up with 20 mL of saturated NH_4Cl solution and 30 mL of ether. The organic phase was separated, washed with 2 × 10 mL of saturated NaCl solution, dried over Na_2SO_4, and evaporated under vacuum. The crude Michael adducts **5** were hydrolyzed with 20 mL of saturated $CuSO_4$ solution and 40 mL of THF as cosolvent by stirring at room temperature (2–16 h, TLC monitoring; **5d–f**, 3 h, reflux). Ether (150 mL) was then added and the aqueous phase was separated and extracted with 2 × 50 mL of ether. The combined organic phases were washed with 2 × 10 mL of saturated NaCl solution and dried over Na_2SO_4. After removal of the solvent, the oxoesters (*R*)-**6** were purified by kugelrohr distillation or flash chromatography (petroleum ether:ether 1:1). The chiral auxiliary (*S,S*)-**3** can be recovered (2.0 g, 91%) by addition of 3 g of K_2CO_3 to the aqueous phase followed by extraction with 3 × 50 mL of ether.

Synthesis of Tetrachloroammonium Hexafluoroarsenate, $NCl_4^{\oplus}AsF_6^{\ominus}$ **

By *Rolf Minkwitz,* Dirk Bernstein,* and *Wolfgang Sawodny*

The chemistry of binary haloamines[1, 2] is characterized by striking contrasts. Only NF_3 is thermodynamically stable ($\Delta H^\circ = -31.44$ kcal mol^{-1} [3]); even with elemental fluorine, it reacts in the presence of Lewis acids only when energy is supplied[4] to give $NF_4^{\oplus}$ salts. Pure NCl_3 ($\Delta H^\circ = +54.7$ kcal mol^{-1} [5]), on the other hand, violently explodes

upon warming or during phase transitions. This behavior is so pronounced for NBr_3 that it has so far eluded spectroscopic identification.[6] Finally, NI_3 can be stabilized in the solid state in the presence of diverse nitrogen bases; these substances are mostly nonexplosive and consist of a polymeric network of chains composed of NI_4 tetrahedra.[7] This coordination is presumably responsible for the kinetic stability of NI_3 derivatives. This observation motivated us to attempt the synthesis of $NCl_4^{\oplus}AsF_6^{\ominus}$ (**1**).

In order to determine whether the $NCl_4^{\oplus}$ ion can indeed exist, an ab initio calculation, using the force-field method[8, 9] and a basis set already employed for other NCl compounds,[10] was carried out for the isolated species. An energy minimum was found for a tetrahedral configuration with an N–Cl distance of 176.4 pm, only slightly longer than known N–Cl distances.[13]

Since it was expected that $NCl_4^{\oplus}$ salts would be stable only at low temperatures, we chose the oxidative chlorination of NCl_3 with Cl_2/AsF_5 in SO_2 as the route of synthesis [Eq. (a)].

$$2\,NCl_3 + Cl_2 + 3\,AsF_5 \xrightarrow{SO_2} \underset{\mathbf{1}}{2\,NCl_4^{\oplus}AsF_6^{\ominus}} + AsF_3 \qquad (a)$$

The reaction was carried out at −78 °C, usually in a Raman cuvette, and is dependent on the solvent. All components except for **1** were then removed at this temperature under dynamic high vacuum. This procedure avoids the necessity of working directly with the potentially explosive substance in subsequent reactions.

$NCl_4^{\oplus}AsF_6^{\ominus}$ is a colorless, moisture-sensitive solid, which is stable at −40 °C for ca. 14 days and at −78 °C indefinitely. In contrast to NCl_3, the salt is not explosive. Subsequent explosions that sometimes occurred were clearly due to residual NCl_3. Compound **1** decomposes in melting H_2O to short-lived NCl_3, which can be observed by Raman spectroscopy. The identity of **1** is also established by the reactions given in Equations (b) to (f). The $NH_4^{\oplus}AsF_6^{\ominus}/Cl_2$ ratio in Equation (b) is 1:4.12. The amount of $NH_4^{\oplus}AsF_6^{\ominus}$ was determined gravimetrically and that of Cl_2 iodometrically.

$$\mathbf{1} + 4\,HCl \longrightarrow NH_4^{\oplus}AsF_6^{\ominus} + 4\,Cl_2 \qquad (b)$$

$$\mathbf{1} + 4\,CH_3Cl \not\longrightarrow \qquad (c)$$

$$\mathbf{1} + 4\,CH_3Br \longrightarrow N(CH_3)_4^{\oplus}AsF_6^{\ominus} + 4\,BrCl \qquad (d)$$

$$2\,\mathbf{1} + CF_3SCl \longrightarrow SCl_3^{\oplus}AsF_6^{\ominus} + CF_4 + 2\,NCl_3 + AsF_5 \qquad (e)$$

$$\mathbf{1} \xrightarrow{\Delta} NCl_3 + AsF_5 + SiF_4 \text{ (from ClF + glass)}$$
$$\text{(isolated in an } N_2 \text{ matrix)} \qquad (f)$$

The vibrational absorption spectra in Figure 1 show, besides the signals of the cation, those of the anion (O_h) [IR: $\tilde{\nu}$ = 690 s, 399 m cm^{-1}; Raman: $\tilde{\nu}$ = 681(100), 573(32), 377(62) cm^{-1}]. From the isotope data for the cation (Table 1), a force field having the following values was calculated for $NCl_4^{\oplus}$: A_1: $F_{11} = 3.812 \times 10^2$ Nm^{-1}; E: $F_{22} = 1.154$ aJrad^{-2}; F_2: $F_{33} = 2.544 \times 10^2$ Nm^{-1}, $F_{34} = 0.803 \times 10^{-8}$ $Nrad^{-1}$, $F_{44} = 1.107$ aJrad^{-2}. These values give an NCl valence force constant of 2.86×10^2 Nm^{-1}, which is somewhat larger than that of NCl_3.[10] Compared with CCl_4, the $NCl_4^{\oplus}$ ion exhibits lower frequencies with the exception of the deformation vibration of type E and, accordingly, a smaller valence force constant (3.35×10^2 Nm^{-1} for CCl_4[11]). The valence force constants of $NF_4^{\oplus}$ are also smaller, by about 15%,[12] than those of CF_4.[13] This is certainly due to increased ligand repulsion in the arrangement around the small N atom.

Table 1. Raman wavenumbers $\tilde{\nu}$ of $NCl_4^{\oplus}$ in **1** [cm^{-1}].

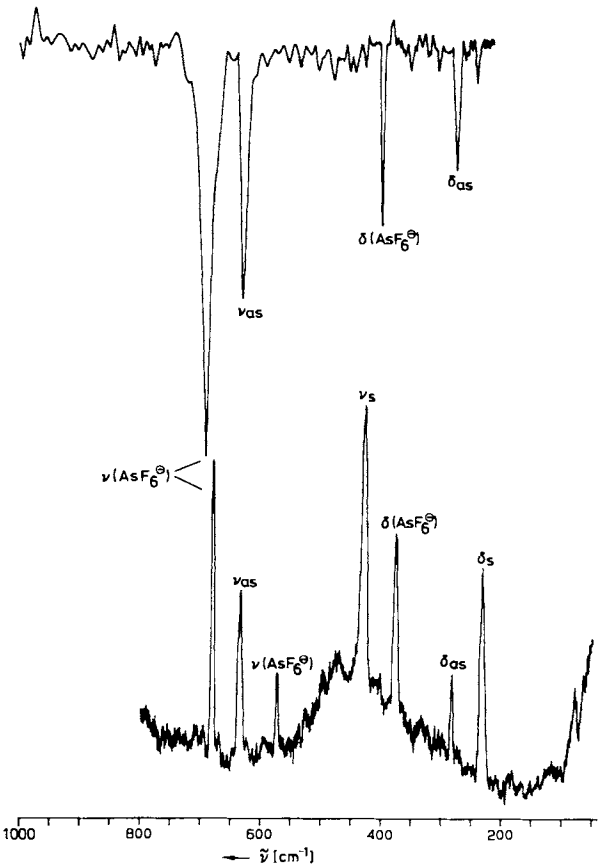

Fig. 1. IR and Raman spectrum of $^{14}NCl_4^{\oplus}AsF_6^{\ominus}$, measured at −78 °C for pure solid in each case.

Experimental Procedure

NCl_3 was prepared by bubbling Cl_2 gas through 4 mL of a 2 M NH_4Cl solution. The NCl_3/Cl_2 gas mixture leaving the solution was passed through a $CaCl_2$ drying tower, pretreated with this mixture, and then bubbled over 3 h into a solution of AsF_5 (375 mg, 2.1 mmol) in 1.5 mL of SO_2 at −78 °C. The reaction vessel was then sealed and kept for 14 h at this temperature. The solution turned dark red to brown during this period. The solvent and starting materials were removed within 48 to 60 h under dynamic vacuum. This time is required in order to quantitatively remove simultaneously formed $AsF_5 \cdot SO_2$ adduct (the presence of the adduct is revealed by an intense Raman line at 721 cm^{-1}). Colorless **1** (ca. 150 mg) remains as residue.

Experimental and Theoretical IR Spectra of the 2-Norbornyl Cation**

By *Wolfram Koch,* Bowen Liu, Douglas J. DeFrees, Dionis E. Sunko,** and *Hrvoj Vančik*

Koch et al.[1] were recently able to conduct a systematic, high-level quantum-chemical investigation of the vibrational spectrum of the 2-norbornyl cation, which unequivocally showed that the 2-norbornyl cation assumes a nonclassical geometry in the gas phase,[2] in line with earlier theoretical studies.[3,4] Not included in that paper was the complete set of harmonic frequencies and IR intensities which were obtained at high levels of ab initio theory, including electron correlation effects. At the same time, *Sunko* and *Vančik*[5] developed a new experimental technique, which allows the study of short-lived reactive intermediates like carbocations and carbocation-like species in cryogenic SbF_5 matrices by IR spectroscopy.[6] In this communication we wish to present a comparison of the experimental IR spectrum of the matrix-generated 2-norbornyl cation with the theoretically predicted spectrum.

2-Chloronorbornane and SbF_5 were codeposited on the CsI window according to the previously described technique[5] and the IR spectrum recorded (Figs. 1a, 2a). On allowing the temperature to rise to 150 K, the IR bands of the chloride start to decrease with the appearance of new signals corresponding to the 2-norbornyl cation. This spectrum remains unchanged up to 200 K. The final spectrum of the matrix-generated carbocation (Figs. 1b, 2b, Table 1) is significantly different from the spectrum of the precursor chloride. The deformation region below 1500 cm^{-1} clearly shows bands not present in the chloride. Particularly eye-catching is the region between 1440 and 1340 cm^{-1}. Here the 2-chloronorbornane spectrum shows hardly any peak while the IR spectrum of the cation exhibits bands of strong intensity.[7] Subsequent quenching of the deposited material afforded *exo*-2-norborneol.

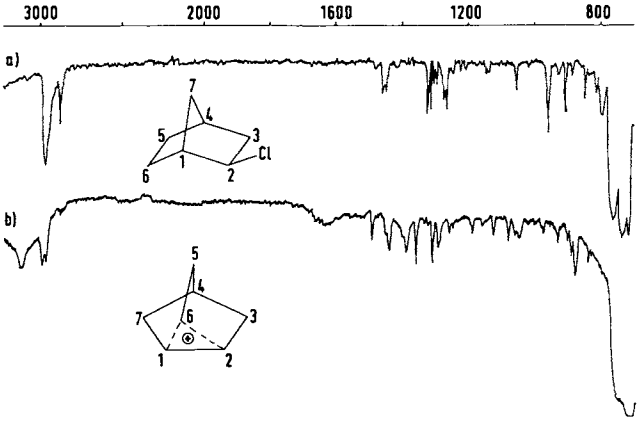

Fig. 1. IR spectra of (a) 2-chloronorbornane and (b) the cation generated from 2-chloronorbornane.

The structure of the nonclassical 2-norbornyl cation was optimized in C_s symmetry by using analytical gradient techniques. A standard 6-31G* basis set was used.[8] The effects of dynamical electron correlation were included through second-order Moller–Plesset perturbation theory (MP2).[8] The vibrational frequencies at this MP2/6-31G* level were then obtained by numerical differentiation of analytical gradients, which consisted of more than 60 MP2/6-31G* analytical gradient computations, possibly one of the largest calculations ever done for a molecule of this size. All calculations were performed using the vectorized IBM version of the Gaussian 86 program[9] installed on an IBM 3090 with Vector Facility computer at the IBM Science and Engineering National Support Center in Dallas, Texas. The results of the calculations are presented in Table 1.

It is well documented in the recent literature that harmonic frequencies computed at the MP2/6-31G* level of approximation in general tend to overestimate the experimental, anharmonic frequencies by 4–7%.[10–13] This is due to the combined effect of the neglect of anharmonicity and the insufficiency of the theoretical method. Therefore, a uniform scaling factor was applied to the theoretical frequencies to achieve better agreement with the experimental spectrum (Table 1). However, it should be noted that this uniform scaling of all frequencies with only a single scaling factor may even worsen the agreement with the experimental frequencies for some modes. Known examples are multiple bond stretching and out-of-plane deformation modes for which the computed, unscaled frequencies are sometimes even *smaller* than the experimental frequencies.[10,12] The same pertains for high-frequency in-plane stretching modes, which typically have a larger anharmonicity.[12] The recent review by *Hess* et al.[14] describes many examples where the comparison of theoretically determined harmonic frequencies with the experimental IR spectra has been successfully applied to aid structure identification and to decide between structural possibilities.[15] The assignment of the experimental to the computed frequencies in Table 1 is based on the best numerical match of the two sets of frequencies and intensities. Figure 2 shows a graphical representation on the

[a] The assignment of the experimental frequencies to the computed ones is based purely on the best numerical match. [b] w, weak; m, medium; s, strong; vs, very strong.

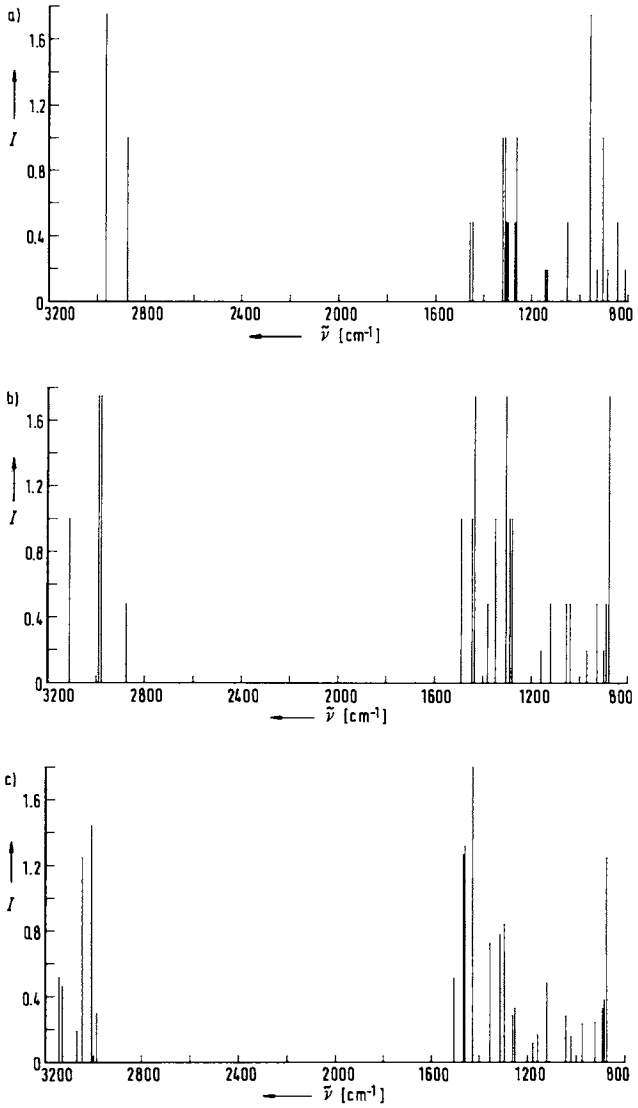

Fig. 2. Bar representation of (a) the IR spectrum of 2-chloronorbornane, (b) the experimentally observed IR spectrum of the 2-norbornyl cation, and (c) the calculated IR spectrum of the 2-norbornyl cation, computed at the MP2/6-31G* level for the nonclassical, bridged structure (scaled by a factor of 0.96).

same scale of the experimental spectrum and the scaled, computed spectrum to allow an easy comparison of the two spectra. The overall agreement of the two spectra (Fig. 2b, c) is reasonably good if one bears in mind that experimentally we are not dealing with an isolated cation in the gas phase but with ion pairs which obviously may have a slightly different spectrum.

In the CH stretching region we experimentally observe four bands at 3110(s), 2990(vs), 2980(vs), and 2875(m) cm^{-1}. The corresponding computed bands, after scaling, are at 3145 and 3131(s), 3047(vs), 3009(vs), and 2988(m) cm^{-1}, respectively. Before scaling, the computed frequencies in this region differ from the experimental ones by 5.2–8.2% (average 6.2%), which is very similar to the 6.5% average difference reported for CH and NH stretches in heterocyclic arenes by *Simandiras* et al. using a comparable level of approximation.[12] However, more significant than the CH stretching region, which can be expected to show similar frequencies for most carbocations, is the lower-frequency region of the spectrum. Here, below 1600 cm^{-1}, the agreement is even more satisfactory, in particular when bands with strong and very strong intensity are considered. The very strong bands in the experimental spectrum occur at 1435, 1305, and 878 cm^{-1}, while their computed counterparts (after scaling) are at 1428, 1296, and 875 cm^{-1}, respectively.

The agreement of the computed and experimental spectra supports all previously reported evidence that antimony pentahalide complexes of the 2-norbornyl cation have a bridged, nonclassical structure. This was inferred by *Yannoni* et al.[16] from the ^{13}C cross-polarization magic-angle-spinning (CP-MAS) spectra of a fluoroantimonate of the 2-norbonyl cation as well as by *Laube*[17] and by *Montgomery* et al.[18] from the X-ray structure of a fluoroantimonate of the 1,2,4,7-tetramethylnorborn-2-yl cation and of 2-methoxy-1,7,7-trimethylbicyclo[2.2.1]hept-2-ylium fluoroborate, respectively. Similar conclusions were reached by *Saunders*

and *Kates*[19] based on the deuterium isotopic perturbation effect. An additional factor that supports this conclusion can be found by analyzing further the CH stretching region. In the hypothetical classical 2-norbornyl cation, the hyperconjugative interaction of the C(3)–H bonds with the formally empty p orbital at C(2) should exert a significant stabilizing effect. This would lead to a weakening of the C(3)–H bonds, which should be reflected in a sizeable decrease in the frequencies of the corresponding CH stretching modes. Such a shift was recently demonstrated for the 1-methylcyclopentyl cation,[5] where strong hyperconjugative interaction of the C(2)–H bonds with the cationic center at C(1) caused a decrease in the frequency of the C(2)H stretch of about 220 cm^{-1} to 2775 cm^{-1}, in perfect agreement with accurate calculations for the parent cyclopentyl cation.[20] In a delocalized, bridged structure ascribed to the 2-norbornyl cation, such an interaction should be small and the only bonds that could contribute to a hyperconjugative stabilization are C(3)–H and C(7)–H. The normal mode analysis of the computed spectrum shows that the modes corresponding to the two lowest CH stretching modes, computed at 2991 and 2987 cm^{-1}, indeed involve hydrogens at C(3) and C(7). The absence of a significant hyperconjugative decrease in the stretching frequencies is additional, albeit negative, evidence for the bridged structure of the cation. The same conclusion was reached some twenty years ago[21] on the basis of secondary kinetic isotope effect measurements in solvolysis of 2-norbornyl brosylates.[22]

Peptides as Conformational Switch: Medium-Induced Conformational Transitions of Designed Peptides **

By *Manfred Mutter** and *René Hersperger*

The design of peptides adopting predetermined secondary and tertiary conformations is of utmost interest in structure–function studies as well as in protein de novo design.[1, 2] Empirical predictive schemes[3] and experimental studies on synthetic model peptides[4] have allowed the delineation of design principles for the construction of peptides which exhibit tailor-made conformational properties.[5] More recently, the amphiphilicity of secondary structures has been used as a powerful design principle for the stabilization of helical and β-sheet conformations in solution and for the design of self-associating peptides in the de novo design of tertiary structures.[2, 6, 7]

We have now used these design principles to construct peptides which exhibit solvent-induced conformational transitions. Most notably, this type of peptide may serve as a "conformational switch", the predetermined change in the configurational properties being intimately related to changes in the physicochemical and biological properties. To this end, three different primary sequences of the same overall composition (4 A, 4 L, 3 E, 3 K) were designed (Fig. 1).

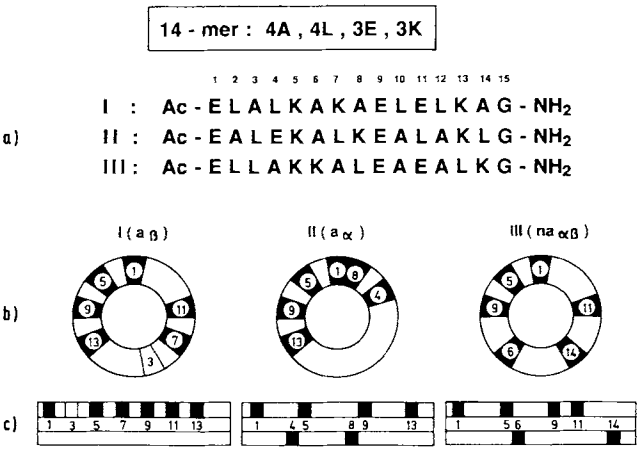

Fig. 1. Design of three tetradecapeptides (with an additional C-terminal glycine). a) Primary sequences of peptides **I**–**III** (A = alanine, L = leucine, E = glutamic acid, K = lysine). In the "helical wheel" [9] and β-sheet representation, the hydrophilic residues (E, K) are indicated by the sequence number and a black square.

Rue de la Barre 2, CH-1005 Lausanne (Switzerland)

[**] This work was supported by the Swiss National Science Foundation.

Residues with high potential for secondary-structure formation were chosen;[3, 4a] in order to achieve maximum flexibility in the design of amphiphilic structures, we used L as hydrophobic residue, E and K as hydrophilic residues, and A as a "neutral" building block. The chain length of 14 residues (the C-terminal G was attached for synthetic reasons) corresponds to the critical size for helix formation in solution.[4b] The periodicity of hydrophilic and hydrophobic residues was chosen so as to obtain one of the following conformations:

1. an amphiphilic β-sheet[8] (a_β = peptide **I**)
2. an amphiphilic α-helix[9] (a_α = peptide **II**)
3. a peptide sequence which is nonamphiphilic with respect to α-helix or β-sheet formation ($na_{\alpha,\beta}$ = peptide **III**)

The CD spectra of **I**–**III** (Fig. 2a) show that the three peptides adopt a helical conformation in the helix-supporting solvent 2,2,2-trifluoroethanol (TFE), as expected from the high potential for helix formation of the individual residues. The values of $<P_\alpha>$ and $<P_\beta>$ for the three peptides according to the Chou–Fasman predictive algorithm[3] are 1.31 and 0.87, respectively; that is, all three peptides are much more likely to occur in an α-helical than in a β-sheet conformation. It is very interesting that despite the difference in their amino acid sequences and their Coulombic interactions along the helical cylinder,[10] all three peptides exhibit a comparable degree of helix formation in TFE (Fig. 2a). On going from TFE to H_2O, the CD spectra reveal dramatic differences in the preferred conformation of peptides **I**–**III** (Fig. 2b). The CD spectrum of peptide **I** is consistent with the adoption of a fully established β-sheet conformation.[11a] The solvent-induced conformational transition (Fig. 2c) of the type $\alpha \rightleftharpoons \beta$ occurs for a mixture of 55% H_2O and 45% TFE. On the other hand, peptides **II** and **III** show only partially helical structures. Interestingly, the amphiphilic peptide **II** exhibits a substantially higher helix content than the nonamphiphilic peptide **III** in H_2O.

As shown schematically in Figure 3, the self-association of amphiphilic peptide blocks provides the major free energy contribution ("hydrophobic interaction") for the formation of a specific secondary structure. For example, despite the low intrinsic β-sheet potential of peptide **I**, the formation of an energetically favorable bilayer structure, in which two pleated sheets assemble to form a hydrophobic pocket and a hydrophilic surface, will increase the tendency of this peptide to form an amphiphilic β-sheet in H_2O. Similarly, the amphiphilic helical cylinder of peptide **II** shows a high tendency to self-associate to a multimeric bundle structure[6a] (as verified by gel permeation chromatography (GPC) studies[11b]); the helical conformation is thereby stabilized. The different conformational features of peptides **I**–**III** in aqueous solution are also preserved in the solid state as indicated by IR data (Fig. 4): the amide I absorptions[12] are observed at 1655 cm^{-1} for peptides **II** and **III** (α-helix or random coil) and at 1630 cm^{-1} for peptide **I** (β-sheet). The observed conformational features of peptides **I**–**III** are also reflected in their membrane activity.[13]

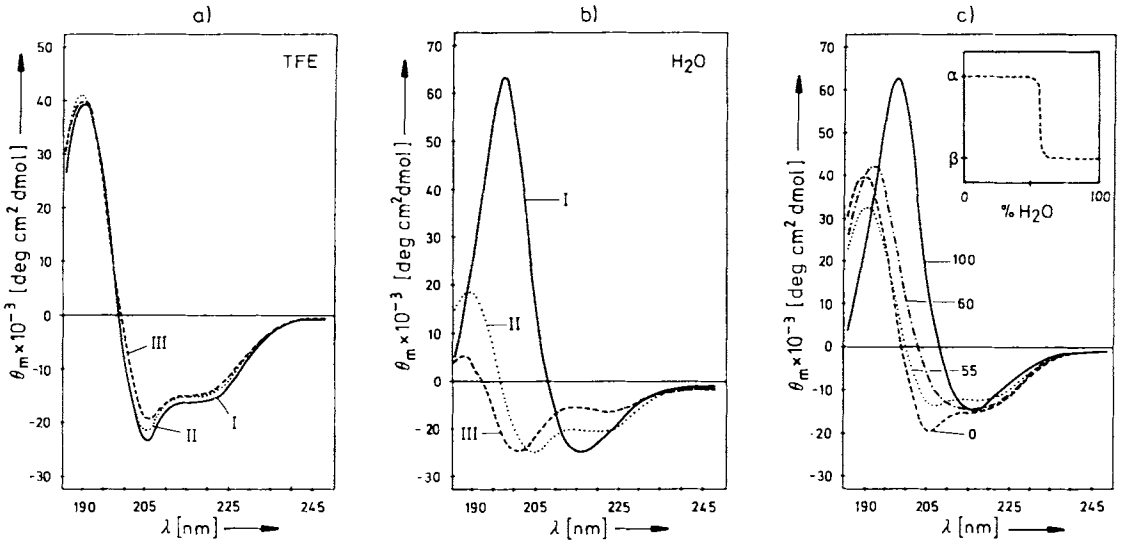

Fig. 2. Circular dichroism (CD) spectra of peptides **I**–**III** (1 mg mL^{-1}) in (a) 2,2,2-trifluoroethanol (TFE) and in (b) H_2O, pH 7; (c) CD spectra of peptide **I** (1 mg mL^{-1}) in H_2O/TFE systems. The numbers indicate the percentage of H_2O in TFE (vol%). The insert shows the cooperative transition from a α-helix (TFE) to a β-sheet (H_2O) conformation at 55% H_2O.

The question of the preferred conformation of peptides containing the same amino acids but different amino acid sequences has been addressed in earlier studies.[4b, 6d] For example, *Brack* and *Spach* have demonstrated that alternating copolymers of K and L are capable of adopting a β-sheet conformation in salt-containing aqueous solutions, whereas

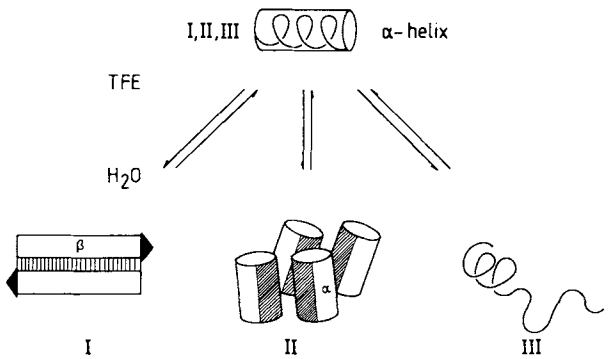

Fig. 3. Schematic representation of the conformational states of peptides **I**–**III** in TFE (α-helix) and in H_2O. **I**, bilayer; **II**, helix bundle; **III**, unordered conformation (see text).

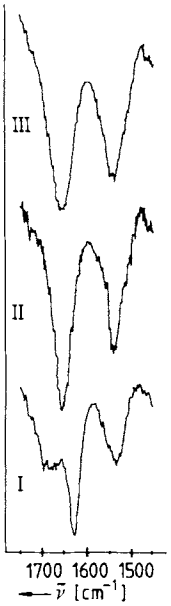

Fig. 4. IR absorption spectra in the amide I region of peptides **I**–**III** (KBr pellets).

statistical copolymers of the same composition favor a helical conformation under the same experimental conditions. In contrast to the peptides investigated in the present study, these copolymers contain only two different amino acids and have molecular weights greater than 5000; moreover, owing to the statistical distribution of the hydrophilic and hydrophobic residues, the nonalternating homologues are not able to adopt a helical conformation with well-defined amphiphilic character. In contrast, *DeGrado* and *Lear*[6d] studied the conformational properties of smaller peptides with the sequences $(LKKLLKL)_2$ and LKLKLKL. In analogy to the results of *Brack* and *Spach*, they found that the peptide with the alternating sequence of K and L residues formed a β-structure in aqueous solution; at low peptide concentration, $(LKKLLKL)_2$ did not exhibit any ordered conformation, but high peptide or salt concentrations resulted in the formation of an amphiphilic helical structure. It is important to note that these α-helix- and β-structure-forming peptides are of different chain length; thus, the conformational behavior of these isocompositional peptides is substantially different from the reversible $\alpha \rightleftharpoons \beta$ transition observed for peptide **I** in this study.

In summary, the data presented here clearly show that the self-association of peptide blocks (releasing solvation entropy) represents a major driving force for secondary structure formation. Whenever the sequence of a peptide allows the adoption of an ordered conformation which is amphiphilic with respect to the spatial orientation of hydrophobic and hydrophilic residues, this particular conformation will be the preferred state in aqueous solution. This finding can be used for the design of peptides that exhibit reversible conformational transitions, thus acting as "conformational switch". For example, a pronounced relationship between conformation and physicochemical properties of the peptides **I**–**III** was found;[14] whereas the three peptides show excellent solubility in TFE (helical conformation), the transition of peptide **I** to a β-sheet structure in H_2O results in a considerable decrease in its solubility. On the other hand, the postulated helical-bundle structure of peptide **II** and the predominantly unordered (monomeric) structure of peptide **III** guarantee good solubility of these peptides in H_2O. The design principles emerging from these observations are presently being used in the construction of template-assembled synthetic proteins (TASP).[7]

Experimental Procedures

The peptides were synthesized by the solid-phase method [15] on a trialkoxybenzhydrylamine resin [16] (1% cross-linked polystyrene); the 9-fluorenylmethoxycarbonyl (Fmoc) group was used for temporary protection of the α-amino function and the *tert*-butyl and *tert*-butoxycarbonyl (Boc) groups for side-chain protection of glutamic acid and lysine, respectively. Reaction with a 3.5-fold excess of the symmetrical anhydride of the corresponding Fmoc-amino acid in DMF for 1 h in each case gave complete reaction as monitored by the quantitative ninhydrin test. Removal of the Fmoc group was achieved by double treatment of the peptide resin (3 and 15 min) with 20% piperidine in DMF. After the last deprotection step, the terminal amino group was blocked by treatment with an excess of a 1:1 mixture of acetic anhydride and pyridine in DMF (30 min). After cleavage from the resin with 2% trifluoroacetic acid (TFA) in dichloromethane (1 h, room temperature) and subsequent final deprotection with TFA/*m*-cresol (9:1; 1 h, 0 °C), the crude peptides were desalted and purified by gel filtration chromatography (Sephadex LH 20, methanol/80% acetic acid (1:1)) and HPLC (C_{18} reversed-phase column, 0.05% aqueous TFA and 0.05% TFA in acetonitrile). The peptides proved to be pure according to TLC, HPLC, and amino acid analysis.

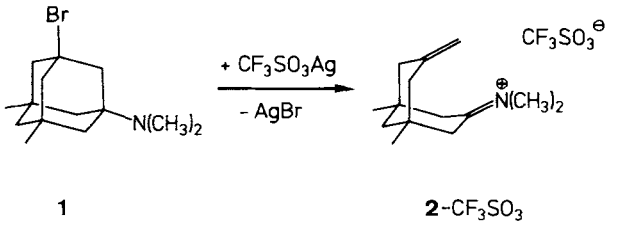
X-Ray Structure Analysis of an Iminium Ion Generated by Grob Fragmentation**

By *Sandro Hollenstein* and *Thomas Laube**

Grob fragmentation,[1] which is generally carried out under solvolytic conditions, can lead to formation of carbocations as intermediates, which, depending on their subsequent reactions, afford various solvolysis products. Heterolysis of the well-investigated γ-haloalkylamines gives unfragmented γ-aminoalkyl cations or, for synchronous fragmentation, iminium ions and olefins. To investigate the electronic interaction of the iminium C=N bond with the olefin C=C bond (which, in the extreme case, may be regarded as a hyperconjugation), we have determined the structure of the iminium ion **2**, formed as an intermediate upon solvolysis of 1-bromo-3-dimethylamino-5,7-dimethyladamantane (**1**),[2] by carrying out an X-ray structure analysis[3] of the corresponding triflate (prepared by reaction of **1** with silver triflate).[4] The asymmetric unit consists of three ion pairs (Fig. 1), for which



1 **2**-CF_3SO_3

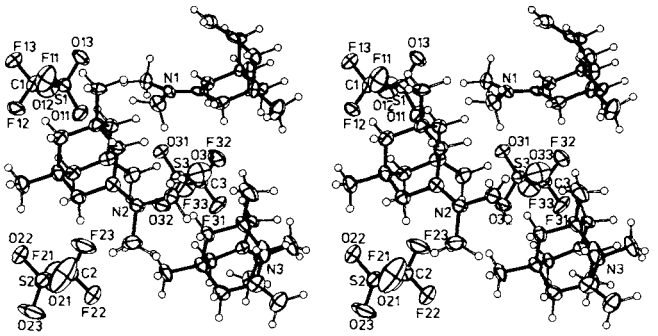


Fig. 1. Stereoplot (ORTEP) of the asymmetric unit of **2**-CF_3SO_3 (three ion pairs). The ellipsoids are drawn at the 50% probability level; the hydrogen atoms are represented by spheres with a radius of 0.1 Å (complete numbering of the atoms in the cation is given in Fig. 2).

there is no evidence of covalent bonding between cations and anions.[5, 6] All cations belong approximately to point group C_s (cations 1 and 3 display a slight torsion of ca. 3° around the Cx03=Nx bonds) and have similar conformations[7] (see Table 1).

Equally oriented rotations of the C=C and C=N systems around the Cx06–Cx08 and Cx04–Cx02 axes, respectively, reveal a certain degree of flexibility for ion **2** (Fig. 2). The mean distance Cx03···Cx10 (ca. 3.26 Å) is only slightly smaller than the sum of the van der Waals radii of the two C atoms (3.40 Å). Thus, the iminium ion structure **2** provides a largely accurate description of the structure of the cation in the crystal; that is, the contribution of the adamantyl cation resonance formula **2'** is small[8, 9] (the experimentally determined structure of **2** is similar to the calculated structure[10] of ketone **3**[6]). Nonetheless, the pyramidalizations at Cx03 and Cx07 in all three ions are in the direction expected for **2'**.[11] Furthermore, the fact that force-field calculations[10] on ketone **3** reveal no pyramidalization for the olefinic bond and only very weak pyramidalization in the expected direction ($\Delta C_{C=O}$ = 0.015 Å) for the carbonyl double bond indicates the existence of an electronic interaction. The weak correlation of the lengthening of the two double bonds with the conformational change (represented as a change in the angle between the planes: see Table 1; x, 3 → 2 → 1), the

Table 1. Selected structural data for cation **2** (distances in Å, angles and torsional angles in °). *P*(n,···) is the best plane through the atoms Cx0n, ...; Mx is the midpoint of the axis through Cx07 and Cx10; *p*A is a point on that part of the symmetry axis of the p-like orbital on atom A that passes through the larger lobe of the orbital; ΔA is the distance of atom A from the plane defined by its three bonding partners.

shortening of the distance Cx03···Cx10, and the increase in the angle Nx–Cx03···Cx10 indicate an increasing interaction in the sense of a nucleophilic attack of the C=C on the C=N$^{\oplus}$ bond (which would lead to **2'**).[12]

CAS Registry numbers:
1, 124686-11-9; **2**·$CF_3SO_3^{\ominus}$, 124686-13-1.

[1] C. A. Grob, *Angew. Chem. 88* (1976) 621–627; *Angew. Chem. Int. Ed. Engl. 15* (1976) 569–575; *ibid. 81* (1969) 543–555 and *8* (1969) 535–546.

[2] The adamantane derivative **1** was synthesized starting from commercially available 3,5-dimethyladamantan-1-ol as follows: bromination with HBr/glacial acetic acid (W. Fischer, C. A. Grob, H. Katayama, *Helv. Chim. Acta 59* (1976) 1953–1962) and Koch–Haaf reaction and bromination with $Br_2/AlBr_3$ (F. N. Stepanov, Yu. I. Srebrodol'skii, *Zh. Org. Khim. 2* (1966) 1612–1615; *J. Org. Chem. USSR Engl. Transl. 2* (1966) 1590–1592) to give 3-bromo-5,7-dimethyladamantane-1-carboxylic acid, followed by conversion to the amide, Hofmann degradation to a urethane (from which ketone **3** is obtainable by refluxing in aqueous sodium hydroxide) in analogy to H. Stetter, P. Tacke, *Chem. Ber. 96* (1963) 694–698, and, finally, hydrolysis and *N*-methylation (formalin and catalytic hydrogenation) in analogy to C. A. Grob, W. Schwarz, *Helv. Chim. Acta 47* (1964) 1870–1878.

[3] Enraf–Nonius CAD4 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, measurement temperature −80 °C, space group $Pna2_1$, a = 14.98(1), b = 14.76(1), c = 23.678(9) Å, V = 5237(6) Å^3, ϱ_{calcd} = 1.352 g cm^{-3}, Z = 12, 4721 measured reflections (Θ < 25°), 3640 with $I > 3\sigma_I$. The structure was solved by direct methods (SHELXS 86; G. Sheldrick, Universität Göttingen); the non-hydrogen atoms were refined isotropically with SHELX 76 and anisotropically (first unweighted, then with $w = 1/\sigma_F^2$) with the UCLA version (Nov. 1985) of SHELX 76. Most of the H atoms were refined at calculated positions by using the riding model; for 15 H atoms, U_{iso} = 0.08 Å^2 was fixed and not varied (a total of 708 optimized parameters); R = 0.052, R_w = 0.047. (The structure could not be solved in the space group *Pnma*, which also fits the systematic absences.) Further details of the crystal structure investigation are available from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, GB-Cambridge CB2 1EW (UK), on quoting the names of the authors and the full journal citation.

[4] **2**-SbF_6 was synthesized by reaction of **1** with $AgSbF_6$; however, the crystal studied showed orientational disorder of the cations and anions. The analogously prepared tosylate of **2** crystallized only after the solution had been allowed to stand for weeks; the perchlorate of **2** formed no crystals.

[5] In principle, a trifluoromethanesulfonate ester might also have been formed. For the structure of a bromobenzenesulfonate ester of a tertiary alcohol, see B. L. Barnett, J. D. Yordy, *J. Cryst. Mol. Struct. 5* (1975) 113–119.

[6] ^1H and ^{13}C NMR measurements in solution confirm that **1** is a covalent compound, whereas the data for **2** (largely independent of the counterion (triflate, tosylate, $SbF_6^{\ominus}$) and the solvent (CD_2Cl_2, CD_3NO_2)) are similar to those obtained for ketone **3** and are therefore only in agreement with an iminium ion (see also G. A. Olah, P. Kreienbühl, *J. Am. Chem. Soc. 89* (1967) 4756–4759).

[7] The mean bond lengths of the C=N fragment in **2** do not deviate significantly from those of known iminium ions substituted with four sp^3 C atoms (Cambridge Structural Database: F. H. Allen, O. Kennard, R. Taylor, *Acc. Chem. Res. 16* (1983) 146–153).

[8] Formulas **2** and **2'** may be regarded as resonance formulas in the sense of a hyperconjugation (see also T. Laube, *Angew. Chem. 98* (1986) 368–369; *Angew. Chem. Int. Ed. Engl. 25* (1986) 349–350).

[9] The slight shortening of the Cx03–Cx02 and Cx03–Cx04 bonds (mean value: 1.494(4) Å) compared with the C_{sp^3}–C_{sp^3} bonds of ketones (1.511 Å; F. H. Allen, O. Kennard, D. G. Watson, L. Brammer, A. G. Orpen, R. Taylor, *J. Chem. Soc. Perkin Trans. 2* (1987) S1–S19) might be due to an increased hyperconjugative interaction of the cationic center with the α-CH_2 groups.

[10] MM2(85) in the program MacroModel, version 1.5 (W. C. Still, Columbia University, New York, USA).

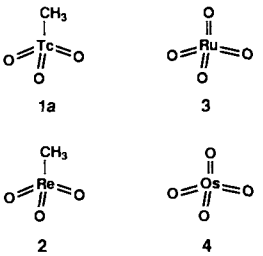
[11] Similar pyramidalizations are found for the carbonyl groups of ketones that have a C=C bond lying above the C=O bond; see, e.g., W. B. Schweizer, J. D. Dunitz, R. A. Pfund, G. M. Ramos Tombo, C. Ganter, *Helv. Chim. Acta 64* (1981) 2738–2740; M. A. Gómez-Rodríguez, M. Martínez-Ripoll, S. García-Blanco, *Acta Crystallogr. Sect. C42* (1986) 894–896.

[12] All effects observed here are similar to those found for structures that can be interpreted in the sense of an attack of O or N nucleophiles on carbonyl groups; e.g., H. B. Bürgi, J. D. Dunitz, E. Shefter, *Acta Crystallogr. Sect. B30* (1974) 1517–1527; M. Kaftory, J. D. Dunitz, *ibid. B32* (1976) 1–4.

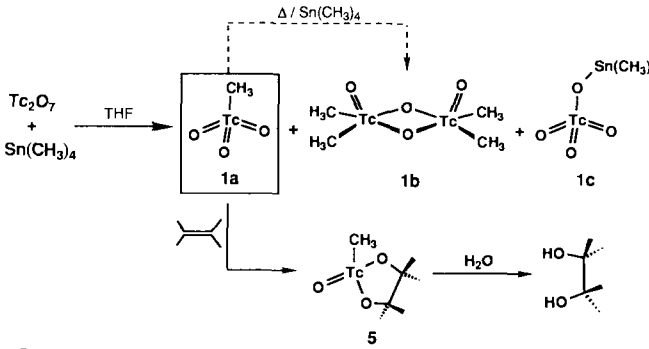
Alkyltechnetium Oxides: First Examples and Reactions**

By *Wolfgang A. Herrmann,* Roger Alberto, Paul Kiprof,* and *Franz Baumgärtner*

Methyltrioxorhenium(VII) (**2**) is an excellent catalyst for the epoxidation of even nonactivated olefins with hydrogen peroxide.[1] Still not understood, however, was why the valence-isoelectronic analogue osmium tetraoxide (**4**), in view of the parallels in its structural and coordination chemistry,[2] does not react with olefins to give epoxides, but instead directly affords so-called osmate esters (e.g., $O_2Os(-OCH_2CH_2O)$) and is therefore the only catalyst widely used so far for the *cis* hydroxylation of olefins.[3] A better understanding of the difference in reactivity of CH_3ReO_3 (**2**) and OsO_4 (**4**) was expected from the investigation of hitherto unknown alkyltechnetium oxides.



Treatment of Tc_2O_7 with tetramethyltin at approximately 10 °C (Scheme 1) yields methyltrioxotechnetium(VII) (**1a**) together with the stannyl ester **1c** of pertechnetium acid. Heating to temperatures above 20 °C leads to formation of larger amounts of reduced products, especially the likewise new,



Scheme 1.

paramagnetic, sublimable Tc^{VI} complex **1b**, whose molecular and crystal structure[4] we determined by X-ray diffraction analysis (Fig. 1). Separation of the mixture of compounds proved to be very simple, since **1a** can be rapidly distilled

A.*), the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie. We thank the Paul-Scherrer-Institut in Würenlingen (Switzerland) for supplying ^{99}Tc. Part 74: J. Takacs, P. Kiprof, J. Riede, W. A. Herrmann, *Organometallics*, in press.

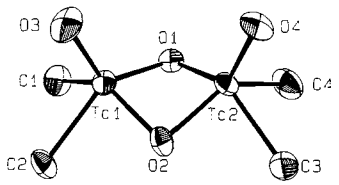

Fig. 1. Structure of bis[dimethyl(μ-oxo)oxotechnetium(VI)] (**1b**) in the crystal (ORTEP plot, hydrogen atoms omitted). The thermal ellipsoids are drawn at the 50% level. The coordination sphere of the Tc atom is best described as distorted square-pyramidal (Tc=O unit apical). The TcTc distance of 256.17(3) pm appears to support the assumption of a (single) bond, but the paramagnetism of the compound (no ^{99}Tc NMR signal) indicates that there is no bonding. Further distances [pm] and angles [°]: Tc1-C1 213.3(2), Tc1-C2 212.9(3), Tc1-O1 190.6(2), Tc1-O2 192.5(2), Tc1-O3 166.6(2), Tc2-C4 212.8(3), Tc2-C3 208.6(3), Tc2-O1 191.2(2), Tc2-O2 190.0(2), Tc2-O4 164.7(2); O1-Tc1-O2 88.77(8), C1-Tc1-C2 79.5(2), Tc1-O1-Tc2 84.28(6), O1-Tc2-O2 89.37(8), C3-Tc2-C4 79.9(1), Tc1-O2-Tc2 84.06(7). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54298, the names of the authors, and the journal citation.

from the mixture at 0 °C under oil-pump vacuum; **1b** (yellow) can be extracted with nonpolar solvents (e.g., *n*-pentane) and **1c** (colorless), the most polar and least volatile component, with tetrahydrofuran. The titanium(IV) reagent $CH_3Ti(O\text{-}i\text{-}C_3H_7)_3$, which is suitable for the methylation of metal oxides,[5] may be used instead of tetramethyltin.

Although methyltrioxotechnetium(VII) (**1a**) is obtainable as yellowish, centimeter-long, fine crystalline needles and is stable when stored at ca. 0 °C, it decomposes above ca. 20 °C to form primarily **1b**. In addition, **1a** is sensitive to moisture. By contrast, the rhenium analogue **2** is stable even at temperatures up to 200 °C and also, to a certain extent, in aqueous solution; in alkaline solution, however, it decomposes quantitatively according to Equation (a).[6a]

$$CH_3ReO_3 + OH^{\ominus} \longrightarrow CH_4 + [ReO_4]^{\ominus} \qquad (a)$$

Presumably, CH_3TcO_3 is a much stronger Lewis acid than CH_3ReO_3 ($pK_a \approx 6.9$ for **2**[7]), since it reacts even with water to give pertechnetium acid. Unlike **2**,[6b] moreover, **1a** does not form stable adducts with amines, not even with 2,2'-bipyridine or quinuclidine.

Taking into consideration the large difference in atomic masses (^{99}Tc versus ^{186}Re), the IR investigations indicate that the title compound **1a** has appreciably weaker metal–oxygen bonds (νTcO 1002 m, 948 cm^{-1} vs; CS_2) than the rhenium analogue **2** (ν ReO 1002 m, 967 cm^{-1} vs; CS_2).

In other reactions, the two alkylmetal oxides differ not only in degree but fundamentally. Thus, olefins such as cyclohexene add to **1a** as shown in Scheme 1 to form glycolate complexes **5** (Tc^V), which, in the presence of water and acids, decompose with liberation of the 1,2-diol and disproportionation to $TcO_2 \cdot xH_2O$ and $[TcO_4]^{\ominus}$; as observed for osmium tetraoxide, this reaction sequence occurs catalytically and leads, in the case of cyclohexene, to formation of *cis*-1,2-cyclohexanediol in a stereospecific fashion. The complex $[TcO_3Cl(2,2'\text{-bpy})]$ also adds olefins, which may then be functionalized and released (although noncatalytically) as *cis* diols;[8a] the analogous rhenium(VII) complex does not react with olefins.[8b]

Apart from the finding that alkyltechnetium oxides are in principle isolable compounds,[9–12] the results described here show that the oxidizing strength and apparently the Lewis acidity of Tc^{VII} derivatives are far greater than those of the Re^{VII} analogues. The importance of the "double-bond structure" **A** in describing the ground state of CH_3TcO_3 (**1a**)

$$M{=}\ddot{O} \leftrightarrow \overset{\ominus}{M}{\equiv}\overset{\oplus}{O}$$
A **B**

appears to be responsible for its ability to add to olefins to give 1,2-glycolate complexes. We draw particular attention to this relationship between technetium and osmium. Accordingly, the still more powerful, olefin-cleaving oxidizing agent RuO_4 (**3**) should correspond to "CH_3MnO_3", which has so far eluded all synthetic efforts. CH_3MnO_3 should be unstable, in agreement with theoretical studies,[13] so long as the strong decrease in thermal stability on going from CH_3ReO_3 to CH_3TcO_3 is continuous.

Experimental Procedure

Important Notice: The isotope ^{99}Tc used in the synthesis is a low-energy β emitter ($E_{max} \approx 0.29$ MeV) with a very long half-life (2.1×10^5 a) and without nuclide-specific γ radiation. Owing to the high volatility of **1a**, special precautions were necessary to avoid contamination.

All preparative procedures were carried out in a glove box. The total radioactivity used was at most 370 MBq. The whole-body exposure outside the glove box was 2 μSv/h, the hand exposure < 25 μSv/h.

1a: The reaction vessel should be equipped with an acetone/dry ice cold finger. Particular care must be taken to exclude moisture. Tc_2O_7 (127 mg, 0.41 mmol) was treated with a solution of $Sn(CH_3)_4$ (81 mg, 0.45 mmol) in 7 mL of precooled THF and the reaction solution was stirred for 2 h at 0 °C; it turned initially green then yellow. After warming to room temperature, the mixture was stirred until the color had vanished (ca. 10 h). A dark precipitate contained only 5–7% of the radioactivity. THF was removed under oil-pump vacuum. Once the residue was free of solvent, it was cooled *immediately* to − 50 °C and sublimed onto the cold finger. Despite these precautions, losses of up to 25% occurred on sublimation. Compound **1a** can also be extracted from the residue with *n*-pentane. If the extraction residue is then sublimed (see above), the losses can be kept smaller. Yield in solution > 90%, after sublimation 46 mg (68%). Colorless crystals, ^{99}Tc content: 60.70% (calcd 61.10%). EI-MS: *m/z* 162 (molecular ion). IR (CS_2): $\tilde{\nu}$ = 1002 m, 948 vs cm^{-1} (νTcO); 2922 w, 2850 w cm^{-1} (νCH). ^{1}H NMR (C_6D_6, 28 °C): δCH_3 = 1.55 [s]. ^{99}Tc NMR ([D$_8$]THF/C_6D_6, 28 °C): δTc = 433 (vs. $[TcO_4]^{\ominus}$).

1c: The extraction residue (see above) was dissolved in 7 mL of THF. After filtration and evaporation of the filtrate under oil-pump vacuum at − 50 °C, 119 mg of **1c** was obtained as a colorless, microcrystalline substance (89%), ^{99}Tc content: 30.90% (calcd 30.28%). EI-MS: *m/z* 313 (35%, $[M-CH_3]^{\oplus}$), 283 (20%; $[M-3\ CH_3]^{\oplus}$), 165 (100%; $[Sn(CH_3)_3]^{\oplus}$). IR (KBr): $\tilde{\nu}$ = 920 vs 908 vs cm^{-1} (νTc=O). ^{1}H NMR ([D$_8$]THF, 28 °C): $\delta(CH_3) = 0.66$ [s; $^2J(^1H,^{117}Sn) = 64.6$ Hz; $^2J(^1H,^{119}Sn) = 67.2$ Hz]. ^{99}Tc NMR ([D$_8$]THF/C_6D_6, 28 °C): δTc = − 1.16 (vs. $[TcO_4]^{\ominus}$).

1b: Same amounts as for **1a**, but 2 h at reflux temperature. After evaporation of the black-brown solution under oil-pump vacuum (− 50 °C), **1b** was sublimed at 65 °C, affording orange crystals. ^{99}Tc content: 59.94% (calcd 61.46%). EI-MS: *m/z* 322 (molecular ion). IR (KBr): $\tilde{\nu}$ = 1006 s, 986 cm^{-1} vs (νTcO). ^{1}H NMR (C_6D_6, 28 °C): $\delta(CH_3) = 2.40$ [broad].

[9] A polymeric ^{99}Tc complex, $[(\eta^5\text{-}C_5Me_5)Tc_2O_3]_n$, was recently reported [10]. The argumentation used in that communication is not convincing in our opinion: (1) The position of the ν(TcO) bands (909, 880 cm^{-1}) is characteristic of terminal oxo ligands for *all* known Re and Tc complexes. (2) The TcTc distance (186.7 pm) is surprisingly short, about 27 pm shorter than the quadruple bond in $[Tc_2Cl_8]^{2\ominus}$ [11]! For "$Tc(\mu\text{-}O)_2Tc$" systems with formal TcTc triple bonds, on the other hand, distances of 235 pm have been found [12]. (3) The still unsatisfactorily solved crystal structure of $(\eta^5\text{-}C_5Me_5)ReO_3$ shows comparable cell constants to those of "$[(\eta^5\text{-}C_5Me_5)Tc_2O_3]_n$": 594.6/869.7/1063.0 and 592.6/865.1/1059.1 pm. The isomorphism of the analogous Tc and Re complexes, as observed here for **1b**, indicates that compound described in [10] is in fact $(\eta^5\text{-}C_5Me_5)TcO_3$.

Catalytic Cyclophanes: A Porphyrin-Bridged Cyclophane as a Model for Cytochrome P-450 Enzymes**

By *David R. Benson, Robert Valentekovich,* and *François Diederich**

Cytochrome P-450 enzymes represent an extraordinarily versatile class of biological oxidation catalysts.[2] In their function as monooxygenases, they are responsible for the metabolism of endogenous as well as exogenous lipophilic substrates. Prominent examples for the mode of action of P-450 enzymes are the hydroxylation of steroids and the epoxidation of unsaturated fatty acids, the first steps in the metabolism of these compounds. The hydroxylation of alkanes and arenes represents the predominant mechanism for enzymatic detoxification of these materials in humans. Substrates include disease-targeted drugs and environmental pollutants. However, with some polycyclic aromatic hydrocarbons, such as benzo[*a*]pyrene, the same transformation can also lead to the formation of extremely potent carcinogens.[3]

A large body of biochemical studies[2] and recent X-ray crystal structure analyses[4] have made enormous contributions to the understanding of the structure and mode of action of the P-450 cytochromes. Three structural features are highly characteristic for these enzymes: (1) An iron porphyrin forms one side of the oxygen and substrate binding site, which is deeply buried in the protein and, therefore, of pronounced hydrophobic character. (2) No additional catalytically active groups can be found at this hydrophobic active site. (3) A cysteinyl ligand, located on the porphyrin side opposite to the binding site, acts as a sixth axial ligand of the heme-bound iron.[5] For monooxygenase activity, molecular oxygen is bound by the heme iron(II). In a sequence of redox processes, the bound oxygen is cleaved with formation of water and a high-valent iron oxo complex ("oxenoid") believed to be $Porph^{\bullet\oplus}Fe^{IV}=O$. This iron oxo complex subsequently transfers its oxygen atom to the complexed substrate.

In many elegant studies in recent years, the mechanism and the synthetic potential of olefin epoxidations and alkane hydroxylations catalyzed by simple cytochrome P-450 model systems have been explored.[6] High catalytic turnovers and remarkable regio- and stereoselectivity have been reported. In the majority of these studies, the natural process of oxygen activation has been circumvented, and the catalytically active iron oxo intermediate has been generated by direct reaction of iron(III) porphyrinates with oxygen-transfer agents like iodosobenzene.[7]

Interestingly, the hydroxylation of aromatic hydrocarbons has not been at the center of interest in studies with P-450 model compounds. Therefore, we planned the synthesis of the porphyrin-bridged cyclophane **1**, having an efficient apolar binding site for arene complexation in close proximity to a porphyrin ring.[8, 9] Detailed studies of arene hydroxylation in complexes of the iron-containing host **3** were intended to focus specifically on the dependence of the redox potential and the spin state of **3** on substrate binding.[4b, 10, 11] Furthermore, the possibility of developing new homogeneous catalysts for synthetically useful arene hydroxylations added additional interest to the projected studies with **3**. Here, we describe the synthesis and complexation properties of **1** and **3** as well as first studies of the catalytic properties of the iron complex **3**.

For the synthesis of **1**, the activated ester **4**[12] was prepared in three steps starting from salicylaldehyde. Alkyl-

1: quantitative yield; m.p. 220 °C, dec. ^{1}H NMR (500 MHz, [D$_{10}$]*p*-xylene, T = 393 K): $\delta = -1.56$ (br, s, 2H), 0.5–0.6 (m, 4H), 1.05 (*t*, J = 7.1 Hz, 6H), 1.4–1.5 (m, 2H), 1.55–1.65 (m, 10H), 1.76 (br. s, 24H), 2.1–2.25 (m, 8H), 2.28 (q, J = 7.1 Hz, 4H), 2.3–2.6 (m, 16H), 2.77 (s, 12H), 3.54 (s, 12H), 4.04 (t, J = 6.4 Hz, 4H), 6.76 (s, 8H), 7.23 (ddd, J = 7.5, 7.5 and 1.2 Hz, 2H), 7.36 (dd, J = 8.3 and 1.2 Hz, 2H), 7.55 (dd, J = 7.5 and 1.6 Hz, 2H), 7.67 (ddd, J = 8.3, 7.5 and 1.6 Hz, 2H), 10.21 (s, 2H) UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 628 (3.10), 576 (3.78), 541 (3.69), 507 (4.16), 409 (5.25), 338 (sh, 4.20), 277 (sh, 4.04), 271 (4.05) [14a]. MS (FAB, *m*-nitrobenzyl alcohol): *m/z* 1589 ($M^{\oplus}$ + 2H, 38%), 1588 ($M^{\oplus}$ + H, 82%), 1587 ($M^{\oplus}$, 100%)

2: 7–10% yield; m.p. 247 °C, dec. UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 575 (3.95), 539 (4.20), 502 (3.49), 411 (5.47) [14a]. MS (FAB, *m*-nitrobenzyl alcohol): *m/z* 1651 ($M^{\oplus}$ + 2H, 97%), 1650 ($M^{\oplus}$ + H, 100%), 1649 ($M^{\oplus}$, 32%)

3: M.p. 277 °C, dec. UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 652 (3.45), 589 (sh, 3.40), 540 (sh, 3.81), 507 (3.94) 394 (4.97) [14a]. MS (FAB, *m*-nitrobenzyl alcohol): *m/z* 1644 ($M^{\oplus}$ – HBr – 2Br, 54%), 1643 ($M^{\oplus}$ – 2HBr – Br, 100%), 1642 ($M^{\oplus}$ – 3HBr, 75%)

4: 87% yield; m.p. 119–121 °C

5: 93% yield; colorless oil

6: 85% yield; m.p. 91–92.5 °C

8: 75% yield; colorless foam

9: 75% yield; pale-yellow foam

10: 78% yield; m.p. 68–69 °C

four equivalents of **4** in dioxane at 80 °C afforded the dialdehyde **8**.[12] For the construction of the porphyrin according to the procedure of *Baldwin* et al.,[14] the β-(trimethylsilyl)ethyl ester **10**[12] was prepared by allowing ethyl 3,4-dimethylpyrrole-2-carboxylate[15] to react with 2-trimethylsilylethanol in the presence of sodium methoxide. The tetrapyrrole derivative **9**[12] was obtained by heating **8** with four equivalents of **10** in absolute ethanol in the presence of 2.1 equivalents of methanesulfonic acid. Fourfold β-elimination with tetra-*n*-butylammonium fluoride in THF led to formation of ethylene, trimethylsilyl fluoride, and the free tetra(2-pyrrolecarboxylic acid) derived from **9**. This was treated in situ in dichloromethane with trimethyl orthoformate and trichloroacetic acid in the presence of zinc acetate dihydrate (48 h, 20 °C) to give the zinc-containing porphyrin.[14] Two atropisomers are formed, interconvertible by rotation about the bond from the porphyrin to the *meso*-phenyl ring, and these could be separated by flash chromatography. The desired atropisomer **2**[12] with an open, preorganized cavity was isolated in 7–10% yield and spectroscopically unambiguously identified as a zinc-containing octamethyl-*meso*-diphenylporphyrin derivative. Upon short stirring of **2** in methanol/conc. HCl (1:1), the free porphyrin cyclophane **1**[12] was obtained. At the free porphyrin stage, heating of the atropisomer mixture in toluene led to the quantitative conversion of the undesired into the desired atropisomer **1**. According to examination of CPK models, the atropisomer with the bridges to the cyclophane on opposite sides of the porphyrin is sterically disfavored. The iron(III) porphyrinate **3**[12] was prepared by treating **1** with anhydrous $FeBr_2$ at reflux in THF, washing with 2% HBr, and subsequent crystallization from CH_2Cl_2/EtOAc.

^{1}H NMR binding studies (500 MHz, 293 K) demonstrated the formation of inclusion complexes between **1** and aromatic hydrocarbons in [D$_4$]methanol/D_2O/[D$_4$]acetic acid (95:4.85:0.15 v/v). The ^{1}H NMR binding titrations were evaluated by nonlinear least-squares curve fitting. Table 2 gives the association constants and the free energies of formation for the 1:1 arene complexes. Figure 1 shows the remarkably large upfield shifts calculated for saturation binding for those guest proton resonances which could be evaluated in the binding titrations.[16] The upfield complexation shifts of the guest resonances in complexes of **1** are considerably larger than in the complexes of similar cyclophanes[9] that are not bridged by a porphyrin. In the complexes of **1**, the aromatic substrates are exposed not only to the shielding cyclophane cavity but also to the strongly shielding region of the porphyrin ring. According to computer modeling studies using the MM2 force field in the Macromodel program,[17] acenaphthylene and phenanthrene come

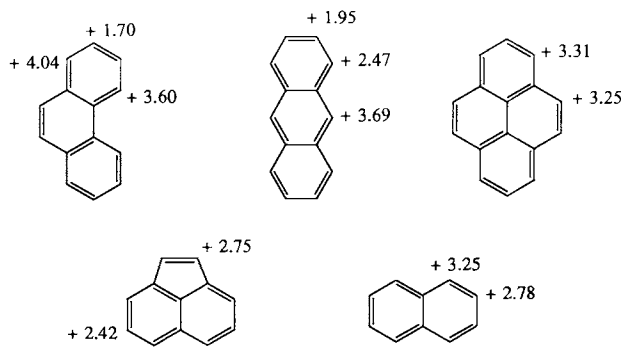

Figure 1. Calculated upfield complexation shifts ($\Delta\delta$ values) of observable guest proton resonances in complexes of **1** at saturation binding; for experimental details, see Table 2.

within van der Waals distance of the porphyrin ring upon energetically favorable incorporation deep into the cyclophane cavity of **1**.

Preliminary investigations of the catalytic properties of the iron(III) porphyrinate **3** were undertaken in homogeneous solution in 2,2,2-trifluoroethanol with the strongly binding acenaphthylene as substrate (Table 2) and iodosobenzene as the oxygen-transfer reagent.[18] The GC-MS and ^{1}H NMR spectroscopic analysis showed that acenaphthylene is exclusively attacked at the C1–C2 bond, which is intermediate between an aromatic and an olefinic C=C bond in its reactivity towards epoxidizing agents.[19] In all runs, acenaphthen-1-one was the major isolable product. Thus, stirring a mixture of **3** (0.48 mM), acenaphthylene (10.5 mM), and iodosobenzene (11 mM) for four hours with rigorous exclusion of oxygen afforded a 65% yield of acenaphthen-1-one, isolated by column chromatography. This yield corresponds to a turnover number (moles of substrate converted per mole of catalyst) of ca. 14. The initial reaction is extremely fast as evidenced by thin layer chromatograms recorded directly after the reaction had started. The reaction of iodosobenzene with acenaphthylene in the absence of catalyst leads to less than one percent conversion. 2,2,2-Trifluoroethanol was chosen as solvent since it provides homogeneous reaction conditions and represents an extraordinarily good solvent for promoting apolar complexation processes, second only to water.[20] Furthermore, this solvent, in contrast to methanol, is not subject to oxidation by the catalytically active, high-valent iron oxo intermediate.[21] The evaluation of UV/VIS titrations, in which the decrease in intensity of the Soret band was monitored as a function of increasing guest concentration, gave an association constant of $K_a = 39\,500\ \mathrm{L\,mol^{-1}}$ for the high-spin **3**–phenanthrene complex in 2,2,2-trifluoroethanol at 293 K. Support for supramolecular catalysis is provided by the inhibition of the acenaphthen-1-one formation by phenanthrene, an arene of low reactivity, presumably as a result of strong but unproductive binding. Upon addition of phenanthrene (9.9 mM) to the catalytic run described above, the isolated yield of acenaphthen-1-one is reduced to 55%. According to computer modeling, phenanthrene highly prefers an axial inclusion geometry which orients the reactive C9–C10 double bond away from the catalytic center and, under the above-mentioned conditions, phenanthrene shows very low reactivity (conversion to products: ca. 1%). The elucidation of the structure of the catalytically active complex and of the mechanism of the **3**-mediated oxidation of acenaphthylene to acenaphthen-1-one are currently the subject of intensive investigations.

Table 2. Association constants K_a and free binding energies $-\Delta G^\circ$ for the arene complexes of the porphyrin cyclophane **1** in [D$_4$]methanol/D$_2$O/[D$_4$]acetic acid (95:4.85:0.15 v/v), $T = 293$ K.

Guest	K_a[L mol^{-1}] [a]	$-\Delta G^\circ$[kcal mol^{-1}]
Phenanthrene	1330	4.19
Acenaphthylene	1050	4.05
Anthracene [b]	460	3.57
Naphthalene	330	3.38
Pyrene	160	2.95

[a] Accuracy of the K_a values: ± 10%. [b] In [D$_4$]methanol/[D$_6$]Me$_2$SO/D$_2$O/[D$_4$]acetic acid (90:5:4.85:0.15 v/v).

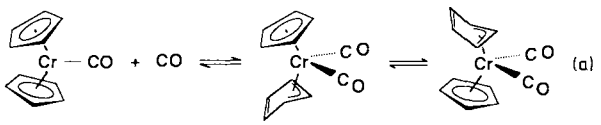
High-Pressure NMR Studies of $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)Cr(CO)_2]$. Evidence for Concerted Ring Interchange

By *John M. Millar, Rodney V. Kastrup, Suzanne Harris,** and *István T. Horváth**

Dedicated to Professor György Bor on the occasion of his 65th birthday

Reversible ring slippage of coordinatively saturated sandwich and half-sandwich complexes is a possible path to accommodate ligand activation in homogeneous catalytic reactions.[1] The reversible reaction of $[(\eta^5\text{-}C_5H_5)_2Cr(CO)]$ (**1**) with CO at elevated pressure has recently been studied [Eq. (a)].[2] On the basis of high-pressure IR spectral data, the formation of the ring-slipped species $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)Cr(CO)_2]$ (**2**), analogous to the structurally characterized complex $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)W(CO)_2]$,[3] was suggested. We now wish to report that **2** undergoes concerted ring interchange, with an activation barrier of 13.5 ± 1.0 kcal mol^{-1}, which does not involve CO-elimination-induced $\eta^3 \rightarrow \eta^5$ ring slippage or CO-addition-induced $\eta^5 \rightarrow \eta^3$ ring slippage.



1 **2**

Reaction of $[(\eta^5\text{-}C_5H_5)_2Cr]$ with CO at 1.5 atm resulted in the formation of **1**.[4] The ^{13}C NMR spectrum of **1** at room temperature shows a resonance at $\delta = 75.9$ for the C_5H_5 ligands and another at $\delta = 263.1$ for the carbonyl ligand (Fig. 1, top), while the ^1H NMR spectrum shows a singlet at $\delta = 4$ for the C_5H_5 ligands. When the CO pressure was increased to 130 atm, the intensity of the peak at $\delta = 75.9$ in the ^{13}C NMR spectrum decreased and a new singlet appeared at $\delta = 96.9$ (Fig. 1, middle). Similarly, the ^1H NMR spectrum showed a new singlet at $\delta = 5.2$, while the intensity of the peak at $\delta = 4$ decreased. The new resonances are due to the formation of **2**, which at room temperature undergoes ring interchange. Surprisingly, there was only one resonance in the carbonyl region at $\delta = 259.4$, slightly shifted from the value observed for **1**. The ratio of its intensity to the combined intensity of the signals for the C_5H_5 ligands in **1** and **2**, however, clearly indicates that the former resonance is due to the carbonyls of both **1** and **2**.

On cooling to 0 °C, the peak at $\delta = 75.9$ disappeared, as expected from the temperature dependence of equilibrium (a),[2] and only **2** is present in the solution. Upon further cooling, the peak at $\delta = 96.9$ broadened and coalesced at -15 °C. Two singlets of equal intensity at $\delta = 89.0$ and 102.7 were resolved on cooling to -70 °C (Fig. 1, bottom). Although this proves the presence of two different C_5H_5 ligands in **2**, rotation of the η^3- and η^5-C_5H_5 ligands renders the ring carbon atoms equivalent even at -140 °C in a 1:1 mixture of $[D_8]$toluene and CD_2Cl_2. Simulations of the ^{13}C NMR spectrum at various temperatures give 76000 s^{-1} as the rate of exchange of the two C_5H_5 ligands at

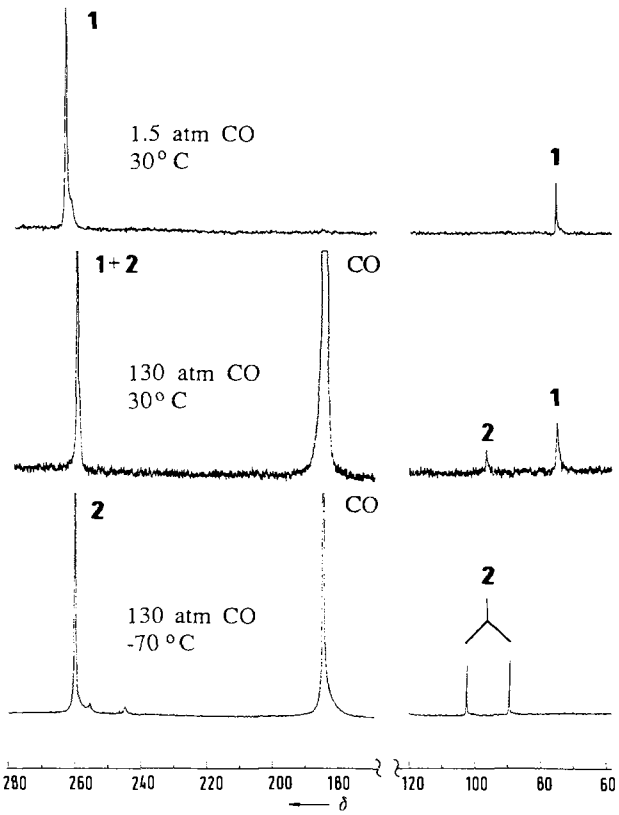

Fig. 1. ^{13}C NMR spectra of $[(C_5H_5)_2Cr]$ under 1.5 atm of ^{13}CO at 30 °C and under 130 atm of ^{13}CO at 30 °C and -70 °C. The extremely weak signals at $\delta = 256$ and 245 are due to $[(\eta^5\text{-}C_5H_5)_2Cr_2(CO)_6]$, which is formed above 0 °C under CO pressure [2].

room temperature and an energy of activation of 13.5 ± 1 kcal mol^{-1} (Fig. 2). As expected from the variable-temperature ^{13}C NMR results, two different rings are resolved in the low-temperature ^1H NMR spectrum as well.

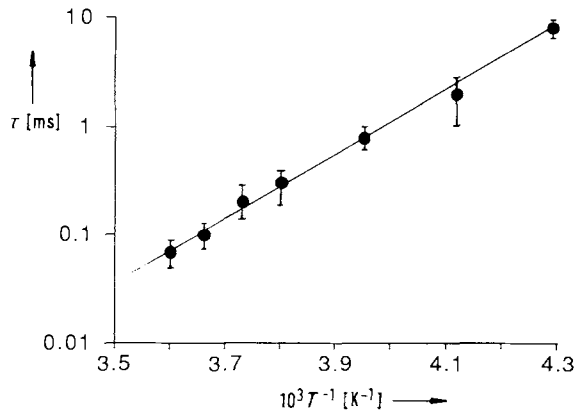

Fig. 2. Arrhenius plot for the concerted η^3/η^5 ring interchange in $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)Cr(CO)_2]$ (**2**).

Saturation-transfer experiments do not show any evidence for exchange between the coordinated CO ligands in **2** and free CO. Our measurements indicate an upper limit of 10 s^{-1} for this process at room temperature. Mechanistically, it is clear that **2** undergoes concerted ring interchange, which does not involve CO-elimination-induced $\eta^3 \rightarrow \eta^5$ ring slip-

page followed by CO-addition-induced $\eta^5 \rightarrow \eta^3$ ring slippage. An examination and comparison of the electronic structures of $[(\eta^5\text{-}C_5H_5)_2M(CO)_2]$ and $[(\eta^3\text{-}C_5H_5(\eta^5\text{-}C_5H_5)M(CO)_2]$ complexes suggest why and how a ring interconversion not requiring loss of a CO ligand occurs in **2**. Strong M-to-CO π back-donation is generally observed in 18-electron $[(\eta^5\text{-}C_5H_5)_2M(CO)_x]$ complexes,[6, 7] and we find that this π back-donation becomes even more important in a complex such as **2**.

Recent calculations for $[(C_5H_5)_2M(CO)_2]$, M = Ti, Zr, show that the ordering of the lower-energy metal-based orbitals is as shown in Figure 3a.[7] The HOMO in the 18-electron (d^2) Ti and Zr complexes is an a_1 orbital which facilitates back-donation from the metal to the CO π^* orbitals lying in the plane of the CO ligands. The two lowest-energy unoccupied orbitals are the b_1 and a_2 orbitals. These orbitals are antibonding between the metal and C_5H_5 orbitals (this interaction is not shown in Fig. 3), but are stabilized by bonding interactions with the CO π^* orbitals which are perpendicular to the plane of the two CO ligands. The addition of two more electrons in $[(C_5H_5)_2M(CO)_2]$, M = Cr, Mo, W, leads to a formally 20-electron complex, and the unusual bent, rather than merely slipped, η^3-C_5H_5 configuration observed for one of the C_5H_5 rings in $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)W(CO)_2]$ is usually associated with the attainment of a formally 18-electron complex. In order to better understand the effects of this bent C_5H_5 ring, Fenske–Hall[8] MO calculations were carried out for $[(\eta^3\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)W(CO)_2]$. The results of these calculations show that the bending of the C_5H_5 ring and the resulting C_s symmetry lead to a loss of most of the M–C_5H_5 antibonding character in the b_1 (now a') orbital (Fig. 3b). As a result, this orbital is

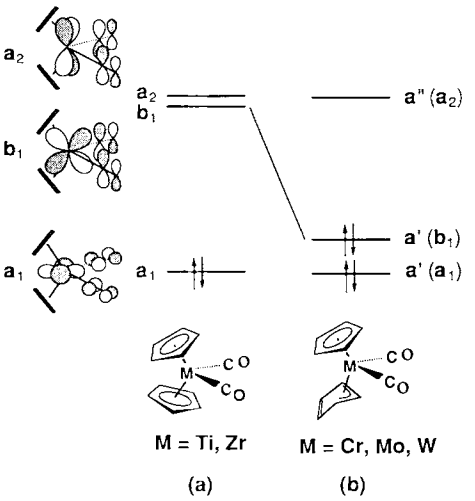

Fig. 3. Lowest-energy metal-based orbitals for $[(C_5H_5)_2M(CO)_2]$ complexes in which (a) both C_5H_5 rings are bound to the metal via a normal η^5-coordination mode and (b) one of the C_5H_5 rings binds to the metal via the unusual bent η^3-coordination mode.

significantly stabilized in the W complex (and presumably in the Mo and Cr complexes) and becomes the HOMO. The occupation of this orbital in the W, Mo, or Cr complex leads to increased back-donation to the CO π^* orbitals, which in turn stabilizes the complex. Both sets of CO π^* orbitals now accept charge from the metal. The significant degree of back donation is consistent both with the CO vibrational frequencies in **2** (the average of the two CO stretching frequencies in **2** is close to the single CO stretching frequency in **1**)[2] and with the similar ^{13}C NMR chemical shifts for the carbonyl ligands in **1** and **2**.

In light of the strong M–CO back-donation observed in the dicarbonyl complex **2**, it is perhaps not surprising that the concerted ring interchange does not involve elimination or addition of a CO ligand. Interconversion of the two rings (the bent η^3 and the flat η^5 rings) presumably occurs through a simultaneous straightening and bending of the two rings. The intermediates involved in such a conversion would continue to be stabilized by π back-donation, since even though the a' (b_1) orbital would be somewhat destabilized during the process, this orbital would remain occupied and serve to remove charge from the metal throughout the whole process.

Mixed Kolbe Electrolyses with Sugar Carboxylic Acids**

By *Andreas Weiper* and *Hans J. Schäfer**

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Carboxylic acids can be decarboxylated to give radicals and/or carbocations by anodic oxidation. Dimers or the products of addition to double bonds are accessible via the radical pathway (Kolbe electrolysis).[1] The cationic pathway (non-Kolbe electrolysis) can give esters, ethers, acetals, and olefins as well as fragmentation and rearrangement products.[1c, 2] The pathway taken is determined not only by the reaction conditions (pH of the electrolyte, kind of electrode material, added salts, current density) but also, to a large extent, by the structure of the carboxylic acid. For example, carboxylic acids bearing hydrogen atoms or electron-withdrawing substituents on the α-carbon atom preferentially afford dimers, whereas carboxylic acids bearing alkyl or aryl groups or electron-donating substituents on the α-carbon atom give primarily or exclusively products arising from

Table 1. Coelectrolysis of sugar carboxylic acids with substituted and unsubstituted alkanoic acids.

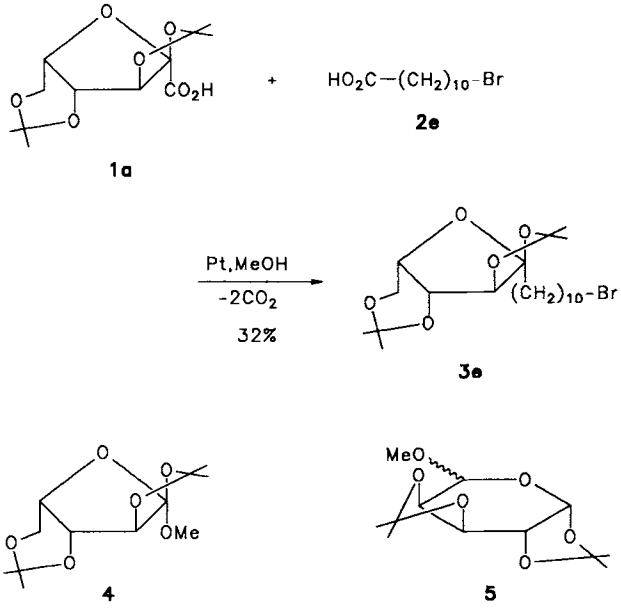
Sugar carboxylic acid **1**	Coacid **2** [a]	Product **3** [b] (Yield)
 **a**	$HO_2C-(CH_2)_3-OAc$ **a**	 **a** (30%)
a	$HO_2C-(CH_2)_2-CO_2Me$ **b**	 **b** (28%)
a	$HO_2C-C_7H_{15}$ **c**	 **c** (31%)
a	$HO_2C-C_{11}H_{23}$ **d**	 **d** (33%)
a	$HO_2C-(CH_2)_{10}-Br$ **e**	 **e** (32%)
 **b**	$HO_2C-C_7H_{15}$ **c**	 **f** (32%)
 **c**	$HO_2C-C_7H_{15}$ **c**	 **g** (24%)
 **d**	$HO_2C-C_7H_{15}$ **c**	 **h** (20%)
 **e**	$HO_2C-C_7H_{15}$ **c**	 **i** (40% [c])  **j** (29%)

[a] Electrolysis: ratio sugar carboxylic acid/coacid = 1/10. [b] Compounds **3a–j** were characterized unequivocally by elemental analysis, ^1H NMR spectroscopy, and mass spectrometry. [c] Isomeric mixture: 1/2.04.

cations. Thus, in the anodic decarboxylation of sugar carboxylic acids and of tetrahydropyran-2-carboxylic acids, acetals were isolated but no coupling products.[3]

We have now found that, in the presence of coacids (ratio 1:10), sugar carboxylic acids can be coupled to give satisfactory yields of unsymmetrical coupling products (Table 1).

In addition, the reaction gives products in which the carboxyl group is replaced by a methoxy group and which presumably are formed from cationic intermediates. Coupling of **1a** in the absence of coacid to give a symmetrical dimer has only been accomplished in yields of less than 5%. Electrolysis of **1a** at a graphite anode affords **4** in 85% yield. By contrast, electrolysis of **1c** in the presence of octanoic acid as coacid gives, in addition to **3g** and **3h**, two further products in 43% and 9% yield, respectively, which were shown to be probably **5** and the dimer of **1c**, respectively.



The occurrence of radical coupling despite the favorable conditions for a cationic pathway appears to be due, at least in part, to the simultaneous decarboxylation of the coacids. The alkyl radicals thereby formed apparently couple with part of the α-alkoxymethylene radicals, before these can be further oxidized to cations. In the absence of coacids, radical reactions play only a minor role.

The sugar carboxylic acids are accessible in a one-step reaction from the corresponding protected sugars by oxidation at a nickel hydroxide electrode.[4] The reaction described here offers a simple route for CC coupling of substituted alkyl moieties with carbohydrates.

Experimental Procedure

Preparation of 1,2:3,4-di-*O*-isopropylidene-6-deoxy-6-*n*-hexyl-D-galactopyranose (**3g**) and 1,2:3,4-di-*O*-isopropylidene-6-deoxy-6-*n*-hexyl-L-altropyranose (**3h**): Octanoic acid (2.88 g, 20 mmol) and **1c** (548 mg, 2 mmol) were dissolved in 30 mL of methanol, neutralized to 10% with potassium methoxide, and electrolyzed in a glass-beaker cell [5] at Pt electrodes with a current density of 200 mA cm^{-2} at 40 °C (current consumption: 1.2 F mol^{-1}). The electrolyte was concentrated to about 10 mL and added to 100 mL of saturated $NaHCO_3$ solution. The resulting solution was saturated with NaCl and then extracted with ether (5 × 30 mL). The organic phases were combined and dried ($MgSO_4$), and the solvent was evaporated. The remaining mixture of products was separated by flash chromatography (eluent: petroleum ether/ether, 20/1 and 10/1) to give 128 mg (20%) of **3h** and 153 mg (24%) of **3g**. GC-MS indicated that compound **5** (ca. 43% based on **1c**) and the dimer of **1c** (ca. 9% based on **1c**) were also present. **3g**: ^1H NMR (300 MHz, $CDCl_3$): δ = 0.8 (t, ^3J = 6.7 Hz, 3H; 12-H), 1.16–1.70 (m, 24H), 3.64 (m, 1H; 5-H), 4.06 (dd, $J_{3,4}$ = 7.9, $J_{4,5}$ = 1.7 Hz, 1H; 4-H), 4.22 (dd, $J_{1,2}$ = 5.1, $J_{2,3}$ = 2.3 Hz, 1H; 2-H), 4.51 (dd,

1H; 3-H), 5.47 (d, 1H; 1-H). GC-MS (70 eV): m/z 328 ($M^{\oplus}$, 0.5%), 313 (M-CH_3, 22), 282(3), 255(4), 195(12), 167(10), 113(60), 100(100). $[\alpha]_D^{20} = -77.8$ ($c = 1.24$ in $CHCl_3$). **3h**: ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 0.8$ (t, $^3J = 6.6$ Hz, 3H; 12-H), 1.19–1.70 (m, 24H), 3.07 (m, 1H; 5-H), 3.81 (dd, $J_{3,4} = 5.4$, $J_{4,5} = 9.6$ Hz, 1H; 4-H), 4.14 (d, $J_{1,2} = 2.5$ Hz, 1H; 2-H), 4.43 (d, 1H; 3-H), 5.14 (d, 1H; 1-H). GC-MS (70 eV) as for **3g**. $[\alpha]_D^{20} = -50.2$ ($c = 0.96$ in $CHCl_3$).

Bis(1,4,7-trithiacyclononane)gold Dication: A Paramagnetic, Mononuclear Au^{II} Complex**

By *Alexander J. Blake, John A. Greig, Alan J. Holder, Timothy I. Hyde, Anne Taylor,* and *Martin Schröder**

We have shown previously that the potentially six-electron donor macrocycle [9]aneS$_3$ (1,4,7-trithiacyclononane), which prefers to bind metal ions facially,[1,2] is capable of modifying its coordination to accommodate a range of transition-metal stereochemistries.[3] As part of a study of third-row transition-metal complexes of [9]aneS$_3$,[3b] we report herein the preparation of $[Au([9]aneS_3)_2]^{2\oplus}$, the first structurally characterized mononuclear Au^{II} complex.

Reaction of $KAuCl_4$ with two molar equivalents of [9]aneS$_3$ in refluxing aqueous HBF_4(40%)/MeOH affords a reddish brown solution, which was extracted with CH_3NO_2 after addition of water. The CH_3NO_2 solution was filtered, the solvent removed in vacuo, and the residue taken up in CH_3CN. Vapor diffusion with diethyl ether afforded the complex $[Au([9]aneS_3)_2](BF_4)_2$ in 50% yield. $[Au([9]aneS_3)_2]^{2\oplus}$ shows characteristic UV/VIS absorption bands at $\lambda_{max} = 398$ ($\varepsilon = 7990$), 234 nm ($\varepsilon = 15000\ M^{-1}\ cm^{-1}$) and a strong signal in the ESR spectrum at $g_{av} = 2.010$ (77 K). Hyperfine coupling to ^{197}Au ($I = 3/2$, 100%) is observed clearly with $A_{av} = 57.3$ G (Fig. 1).

Crystals of $[Au([9]aneS_3)_2](BF_4)_2 \cdot 2CH_3CN$ suitable for X-ray diffraction were grown from CH_3CN/Et_2O. The single-crystal X-ray structure[4] of the complex (Fig. 2) confirms unequivocally its assignment as a genuine, mononuclear d^9 Au^{II} species: in the centrosymmetric cation, Au^{II} is bound to six thioether donors in a tetragonally elongated stereochemistry (Au-S1 2.839(5), Au-S4 2.462(5), Au-S7 2.452(5) Å). The two [9]aneS$_3$ macrocycles therefore encapsulate the d^9 Au^{II} center to give a Jahn–Teller-distorted octahedral stereochemistry. Interestingly, the related d^9 complex cation $[Cu([9]aneS_3)_2]^{2\oplus}$ also shows an octahedral stereochemistry, although in this case the tetragonal elongation is less than in the Au^{II} analogue (Cu-S1 2.419(3), Cu-S4 2.426(3), Cu-S7 2.459(3) Å[1]).

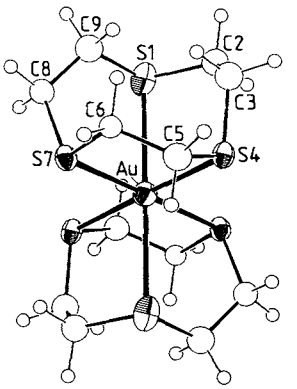

Fig. 2. Structure of the cation $[Au([9]aneS_3)_2]^{2\oplus}$.

$[Au([9]aneS_3)_2]^{2\oplus}$ is air-stable in the solid state. It can be reduced in MeOH or more slowly in CH_3CN to a colorless d^{10} Au^{I} species, $[Au([9]aneS_3)_2]^{\oplus}$ ($E_{pc} = +0.10$ V vs $Fc^{\oplus}$/Fc, Fc = ferrocene), and can be oxidized to the corresponding d^8 Au^{III} complex $[Au([9]aneS_3)_2]^{3\oplus}$ ($E_{\frac{1}{2}} = +0.46$ V vs $Fc^{\oplus}$/Fc).[3b] When the oxidation of Au^{II} to Au^{III} ($\lambda_{max} = 334$ ($\varepsilon = 19765$), 246 nm ($\varepsilon = 20265\ M^{-1}\ cm^{-1}$)) is monitored by UV/VIS spectroscopy, isosbestic points ($\lambda_{iso} = 372$, 208 nm) are observed. The chemical synthesis of $[Au([9]aneS_3)_2]^{2\oplus}$ depends on control of these redox reactions. Isolation of the Au^{II} species from electrosynthesis experiments is hampered by problems associated with removing the base electrolyte and purifying the complex.

Very few examples of mononuclear Au^{II} species have been reported in the literature. Most of these examples are transient or intermediate species or involve significant charge delocalization onto the ligands (e.g., $[Au(mnt)_2]^{2\ominus}$, mnt = 2,3-dimercapto-2-butanedinitrile[5]). The ligand [9]aneS$_3$ is redox-inactive up to +0.99 V (vs $Fc^{\oplus}$/Fc),[2] suggesting that delocalization of the positive charge in $[Au([9]aneS_3)_2]^{2\oplus}$ onto the thioether donors will be limited. The coordination about the Au center in $[Au([9]aneS_3)_2]^{2\oplus}$ is fully consistent with that of a d^9 transition-metal center and reflects the ability of [9]aneS$_3$ to encapsulate and stabilize an otherwise highly reactive metal radical center. Interestingly, we have found that the hexathia ligand [18]aneS$_6$ is also capable

[4] Structure determination of $[Au([9]aneS_3)_2]^{2\oplus} \cdot 2BF_4^{\ominus} \cdot 2CH_3CN$: An orange-red column-shaped crystal ($0.55 \times 0.3 \times 0.2$ mm), bathed in mother liquor, was sealed in a Lindemann capillary tube and cooled to 173 ± 0.1 K on a Stoe STADI-4 four-circle diffractometer equipped with an Oxford Cryosystems low-temperature device [6]. $M_r = 813.28$, orthorhombic, space group *Pcab*, $a = 8.6921(13)$, $b = 14.823(3)$, $c = 21.5687(23)$ Å, $V = 2779.0$ Å^3 [from 2Θ values of 42 reflections measured at $\pm\omega(2\Theta = 24 \rightarrow 26°$, $\lambda = 0.71073$ Å)], $T = 173$ K, $\varrho_{calcd} = 1.944$ g cm^{-3}, $Z = 4$, $\mu(Mo_{K\alpha}) = 5.781$ mm^{-1}, $T = 173$ K, $\omega - 2\Theta$ scans, 2715 reflections measured ($2\Theta_{max} = 45°$), 1586 unique ($R_{int} = 0.022$), initial correction for absorption by means of ψ scans, giving 1146 data with $F \geq 4\sigma(F)$. Intensity statistics indicated the position of the Au atom on an inversion center and, using this information, DIRDIF [7] located the S atoms. Iterative rounds of least-squares refinement and difference Fourier synthesis [8] then located all other non-H atoms. At isotropic convergence, final corrections for absorption were made using DIFABS [9]. Some disorder in the $BF_4^{\ominus}$ anion required modeling. H atoms were included in fixed, calculated positions [8]. At final convergence, $R, R_w = 0.0663$ and 0.0859, respectively, for 123 parameters, $S = 1.209$. The maximum and minimum residues in the final ΔF syntheses were $+1.50$ and -1.21 eÅ^{-3} respectively. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the full journal citation.

$[H_2Ru_6(CO)_{16}(\mu\text{-}C_6H_4O)]$: Binding of Five Metal Atoms to a Phenol Molecule**

By *D. Scott Bohle*, and *Heinrich Vahrenkamp**

Alcohols, esters and similar compounds belong to the important products of metal-catalyzed CO hydrogenation, e.g. in the Fischer-Tropsch reaction or the synthesis of methanol.[1] Since, as end products of such reactions they form only moderately stable carbonylmetal complexes, they are seldom investigated as ligands.[2] With the aim of also testing the soundness of the cluster-surface analogy[3] on them with regard to structure and reactivity we turned our attention to the cluster chemistry of organic OH-compounds. Here, some important bond types are known,[4] but also the observation that one synthesizes $Os_3(CO)_{12}$ in alcohol,[5] and the comment about $Ru_3(CO)_{12}$, "the corresponding reactions with alcohols are complex and will be reported later".[6]

Twenty years and one publication[7] later we now find that the complexation of organic oxo compounds with carbonylruthenium compounds can be controlled on a preparative scale. To demonstrate this, we present the title complex $[H_2Ru_6(CO)_{16}(\mu\text{-}C_6H_4O)]$, which is formed in almost 30% yield upon heating $Ru_3(CO)_{12}$ and an excess of phenol in boiling cyclohexane.[8]

The structure analysis (cf. Fig. 1[9]) gives a good indication of the course of the reaction: In the first step the oxidative addition of the phenol could lead to a complex $[Ru_3(CO)_{10}(\mu\text{-H})(\mu\text{-OR})]$,[7] which is still recognizable here in the form of the Ru1–Ru2–Ru3–O unit. The second Ru_3-unit could then be attacked in the sense of an *ortho*-metalation at the β-C atom of the phenol,[4b] opened by η^6-coordination of the phenol ring to Ru4, and condensed to the first Ru_3 unit via four new metal–metal bonds (Ru1–Ru4, Ru1–Ru5, Ru2–Ru5, Ru2–Ru6). This results in a highly puckered "raft" arrangement[10] of the ruthenium atoms, of which only Ru3 is not coupled to the phen-yl-olate ligand. Alternatively, the C_6H_4O–Ru_5 fragment can be regarded as a doubly *C*-metalated derivative of cyclohexadienone, even though the uniformity of the C–C bond lengths in the ring [139–144(1) pm] and the C–O distance of 136(1) pm, which corresponds to that in the free phenol, do not support this. The bridging Ru–O and Ru–C bonds (Ru1–O 217(1), Ru2–O 213(1), Ru5–C 234(1), Ru6–C 221(1) pm) of the phen-yl-olate ligand lie in the known range;[2,4] however, the asymmetry of the Ru5–C–Ru6 bridge and the very long Ru5–C distance are striking. The two hydride ligands are presumably over the two longest edges least shielded by CO groups, namely Ru2–Ru3 (308 pm) and Ru2–Ru5 (311 pm); the remaining Ru–Ru bonds have lengths of 277–304 pm.

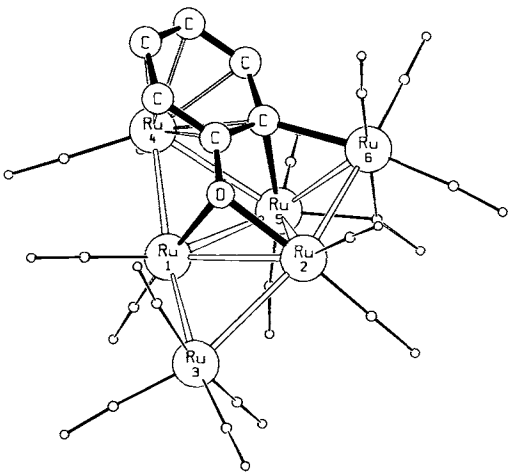

Fig. 1. Structure of $[H_2Ru_6(CO)_{16}(\mu\text{-}C_6H_4O)]$ in the crystal (schematic).

The C_6H_4O ligand counts as a 10-electron donor (6 e from the aromatic π-system, 1 e from the *ortho* metalation and 3 e

from the μ-OR unit). Together with the electrons of the 2 H- and 16 CO-ligands, the raft-shaped R_6-unit has 44 ligand electrons, two more than would be required to fulfill the 18-electron rule for all ruthenium ions. An electron excess of this kind has already been observed and theoretically justified in earlier works for structures of this type.[11]

The three bonding modes of the C_6H_4O fragment (η^6 of the arene, M–C–M three-center bonding, and μ-OR coordination) are each in themselves not unusual in Ru- and Os-complexes.[2] However, they are found together for the first time in the title complex. They demonstrate, on the one hand, how far the "loading" of such a simple molecule as phenol with metal atoms can go, and on the other, how multiple coordination can stabilize the very open metal atom arrangement. In the context of the cluster-surface analogy they draw attention to the possibility of multiple functionalization of the substrate (here of the phenol) and the deformability of the surface by attachment of the substrate.

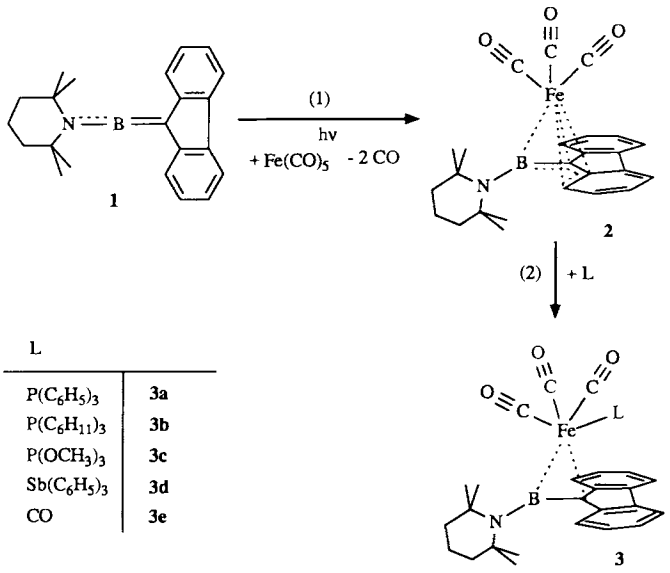
A Carbonyliron Complex of an Amino-9-fluorenylideneborane with Coordination at a Borabutadiene Unit

By *Sreelatha Channareddy, Gerald Linti,* and *Heinrich Nöth**

Alkylideneboranes, compounds of two-coordinate boron containing a B=C double bond, are kinetically stabilized by sterically demanding substituents.[1] In alkylidene(amino)-boranes an electronic component also contributes to the stability.[2] Nevertheless, 9-fluorenylidene(tetramethylpiperidino)borane **1**,[2a, b] is highly reactive due to the presence of a dicoordinated boron atom. Thus, **1** adds covalent metal and nonmetal halides, forming B–C metal/nonmetal bonds, and boron-containing heterocycles result from [2+2]- and [2+3]-cycloadditions.[2a, 3, 4] **1** can also function as an η^5- or η^2-ligand. Typical examples are $[(\eta^5\text{-tmpBClCR}_2)TiCl_3]$ and $[(\eta^2\text{-tmpBCR}_2)Fe(CO)_4]$[3a, 5] (tmp = 2,2,6,6-tetramethylpiperidino, CR_2 = 9-fluorenylidene). We have now observed an unusual behavior of **1** towards pentacarbonyliron.

Prolonged UV-irradiation of **1** in the presence of $Fe(CO)_5$ does not afford $[(\eta^2\text{-tmpBCR}_2)Fe(CO)_4]$ but the tricarbonyliron complex **2** [Reaction (1)]. Its carbonyl groups are equivalent on the NMR time scale at room temperature.[6] At 210 K, however, the ^{13}C-NMR spectrum shows three signals in a 1:1:1 ratio. In addition, there are four ^{1}H- and four ^{13}C-NMR signals for the methyl groups of the tetramethylpiperidino substituent as well as twelve ^{13}C-NMR signals for the fluorenylidene group. The fluorenylidene C-atom bound to boron is not observed due to quadrupolar broadening. These findings and the presence of three ν(CO) stretching bands in the IR spectrum are consistent with an asymmetric coordination of the $Fe(CO)_3$ unit to the ligand **1**.



L	
$P(C_6H_5)_3$	**3a**
$P(C_6H_{11})_3$	**3b**
$P(OCH_3)_3$	**3c**
$Sb(C_6H_5)_3$	**3d**
CO	**3e**

This conclusion is further supported by the X-ray structure of **2**[7] (cf. Fig. 1). It demonstrates that the $Fe(CO)_3$ group is coordinated to a "borabutadiene" unit, B=C–C=C,[8] of the fluorenylideneborane moiety of **1**. This occupies two basal sites in the slightly distorted tetragonal pyramid, as is well established in other conjugated diene-metal complexes.[9] The B–C1 and C2–C3 bonds are 0.08 and 0.10 Å longer, while the C1–C2 bond is 0.04 Å shorter than in uncomplexed **1**;[4] this is indicative of a delocalization of electron density in the borabutadiene moiety. Such a bonding would imply the loss of aromaticity in the benzene ring to which the coordinated C=C-bond belongs. This is indeed reflected in the rest of the C–C bond lengths of this ring. On the other hand, the bond lengths in the uncoordinated benzene ring of **2** are normal.[10] Significant is also the fact that the Fe–C bond lengths vary considerably. The distances of

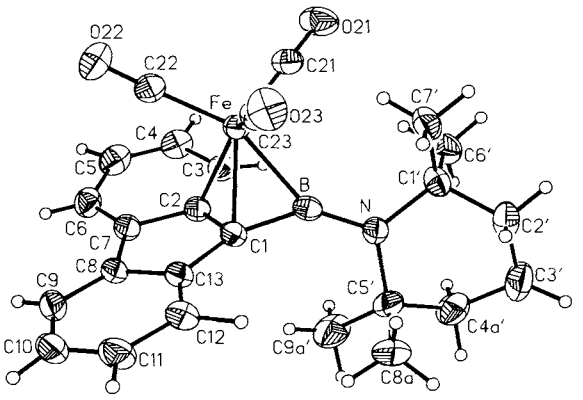

Fig. 1. ORTEP-Plot of **2**. Thermal ellipsoids are shown at the 30% probability level. Selected bond lengths [Å] and angles [°]: B-Fe 2.080(4), Fe-C1 2.072(4), Fe-C2 2.138(4), Fe-C3 2.330(4), B-C1 1.504(7), C1-C2 1.432(6), C2-C3 1.393(6), C1-C3 1.484(6), C11-C12 1.381(7), C10-C11 1.375(9), C9-C10 1.367(7), C8-C9 1.307(7), C8-C13 1.415(7), C2-C3 1.393(6), C3-C4 1.427(7), C4-C5 1.345(8), C5-C6 1.413(7), C6-C7 1.354(7), C2-C7 1.434(6), C7-C8 1.458(6), Fe-C21 1.774(5), Fe-C22 1.808(5), Fe-C23 1.735(5), B-N 1.370(6); Fe-B-N 149.3(3), C21-Fe-C22 104.4(2), C21-Fe-C22 100.7(2), C22-Fe-C23 92.3(2), B-Fe-C21 153.1(2), C3-Fe-C23 165.0(2), C3-Fe-C22 96.6(2). B-Fe-C21 102.5(2), B-Fe-C21 83.0(2), C2-Fe-C22 91.9(2), C1-Fe-C21 138.9(2), C2-Fe-C21 124.4(2).

2.072(4) and 2.138(4) Å compare favorably with the literature values,[11] and although the Fe–C3 bond (2.330(4) Å) is longer it has still to be considered as a bonding distance. The Fe–B bond length is almost equal to the Fe–C1 bond distance, despite the fact that the atomic radius of boron exceeds that of carbon. This may be explained by the π-acceptor character of the boron atom.[12] The electron demand of the boron atom is also satisfied by BN-π-bonding, as evidenced by the short B–N bond. Consistent with this conclusion, the C1′/C5′/N/B plane is almost parallel to the Fe/B/C1 plane, the angle between the normals being only 11.2°.[13]

2 is thus one of the few organometallic complexes in which η^4-complexation is achieved at the expense of the aromaticity of a ligand.[14] It was, therefore, to be expected that **2** would react with donor molecules to produce η^2-complexes of the ligand **1**. Triphenylphosphane, tricyclohexylphosphane, trimethylphosphite and triphenylstibane, indeed, readily form complexes of type **3** [Reaction (2)]; CO reacts in the same way to give the known **3e**.[5] **3a–d** are also obtained by the addition of the ligands to the complex **2** prepared in situ. The ^{13}C-NMR spectra of the complexes **3 a–d** reveal symmetrical bonding of the $Fe(CO)_3L$ group in **1**, since only six signals are observed for the fluorenylidene unit. The CO groups are equivalent on the NMR time scale at ambient temperature. However, at 210 K two signals appear in a 1:2 ratio as doublets in the phosphite complex **3c** and as singlets in **3d**. The IR spectra show three bands for the carbonyl groups shifted to lower wave numbers as compared to those in **2**. Moreover, the 1718 cm^{-1} band of **1** is missing in all complexes of type **3**, indicative of an η^2-complex.[5]

This binding of ligand **1** is confirmed by the X-ray structure of **3c** (see Figure 2).[15] The stereochemistry of this compound can be described either as distorted trigonal bipyramidal or as distorted tetragonal pyramidal.[12, 16] However, due to the low symmetry of **3c**, neither of the two is unambiguous. Assuming the latter alternative, both the σ-donor and the B=C-ligand would occupy a basal position.[17] Due to the presence of the bulky phosphite ligand as well as the steric requirements of **1** the angle between the apical CO and the basal CO group reduces from 151.2° in $[(CO)_4Fe(\eta^2\text{-}\mathbf{1})]$ to 141.3° in **3c**. The BC bond length in **3c** is increased by 0.11 Å relative to **1**. The C1′/N/C5′ plane of the tetramethylpiperidino group is almost coplanar with the Fe/B/C1 plane (angle between the normals of these planes: 7.2°). In consonance with **3e**[5], the Fe–B bond distance in **3c**

Table 1. Spectroscopic data of **2** and **3a–d**. 90-MHz ^{1}H-, 64.186-MHz ^{11}B-, 50.323-MHz ^{13}C-, and 81.015-MHz ^{31}P-NMR spectra in $CDCl_3$, toluene, $CDCl_3$ (except in the case of **3d**) and toluene/$CDCl_3$, respectively; 70 eV mass spectra.

is considerably shorter than the Fe–C1 bond length, indicating that the boron atom plays a dominant role in accepting π-electron density from the metal atom,[12] as is the case in many other metal π-complexes of unsaturated organoboranes.[18]

Experimental

2: A mixture of **1** (2.17 g, 6.9 mmol) and $Fe(CO)_5$ (0.96 g, 6.9 mmol) in toluene (100 mL) was irradiated for 3 h using a Hg-lamp, Hanau Q150. In this period ca. 13 mmol of CO gas was liberated. The resulting dark red-brown solution was filtered, concentrated in vacuo to about 10 mL and layered with 20 ml of pentane. On cooling to −20 °C for one week, dark red microcrystalline **2** separated. When the reaction was carried out in hexane solution, the product separated from the solution at −20 °C within 24 h as well formed crystals. Yield: 60–65%, m.p. 160–165 °C (decomp.).

3a: A solution of **2** (1.1 g, 2.4 mmol) in toluene (5 ml) was stirred with an equimolar amount of $P(C_6H_5)_3$ (0.63 g, 2.4 mmol) for 2 h at ambient temperature. **3a** separated as a yellow powder; this was recrystallized from a hot toluene/hexane mixture (1:2). Yield: 53%, m.p. 200–205 °C.

3b: Addition of $P(C_6H_{11})_3$ (0.90 g, 3.2 mmol) to an irradiated mixture of 1.02 g (3.2 mmol) of **1** and 0.4 g (3.2 mmol) of $Fe(CO)_5$ in 40 mL of toluene yielded a yellow orange powder after 3 h. Recrystallization from a mixture (1:2) of hot toluene and hexane. Yield: 57%, m.p. 185 °C (decomp.).

3c: Analogously to **3b**, from 0.6 ml (5 mmol) of $P(OCH_3)_3$, 1.6 g (5 mmol) of **1** and 0.86 mL (6 mmol) of $Fe(CO)_5$. Yield: 66%, orange crystals, m.p. 175 °C (decomp.).

3d: Analogously to **3a**, from 1.62 g (4.6 mmol) of $Sb(C_6H_5)_3$ and 2.0 g (4.6 mmol) of **2**. Yellow orange crystals from toluene/hexane. Yield: 52%, m.p. 169–172 °C.

3e: Dry CO gas was bubbled through a solution of 1.5 g of **2** dissolved in 20 mL of toluene. The color of the solution changed from red to brown. Removal of the solvent, dissolution of the residue in a minimum amount of toluene, and layering with 10 mL of hexane afforded light-brown crystals of **3e**. The yield was not determined; m.p. 137 °C (dec.). Identity checked by comparison with an authentic sample[5].

Tetrasilylmethane, $C(SiH_3)_4$, the Si/C-Inverse of Tetramethylsilane, $Si(CH_3)_4$**

By *Rudolf Hager, Oliver Steigelmann, Gerhard Müller, Hubert Schmidbaur,* Heather E. Robertson,* and *David W. H. Rankin*

Hydrogen-containing amorphous silicon (a-Si:H) is of great interest as a semiconductor material, particularly because the inclusion of other elements allows desired variations in photoelectric properties to be achieved in a simple manner. Besides the elements of the third and fifth main groups the group IV elements carbon and germanium in particular can also be used for doping; the band gap of the amorphous semiconductor (a-Si:H) can be increased by carbon, whereas with germanium (a-SiGe:H) the band gap is decreased. These layers are usually prepared by Plasma

Enhanced Chemical Vapor Deposition (PE-CVD) of mixtures of SiH_4 and CH_4 or GeH_4, respectively. In contrast to the a-SiGe:H and pure a-Si:H films, the a-SiC:H films obtained in this way show much poorer optoelectrical properties, especially if the carbon content is high.[1]

Numerous investigations in recent years have shown that, because of the relatively high stability of the CH bond, the use of methane results in the inclusion of carbon predominantly in the form of CH_3 groups, so that carbon itself makes hardly any contribution to the formation of the amorphous network; indeed it tends to loosen it.[2] In order to prepare a-Si:H films with larger band gaps—an "optical gap" of at least 2 eV is of special interest for applications in the area of solar cells[3]—which nevertheless have satisfactory electronic properties, the carbon atoms must be included in the Si network in an efficient manner, preferably substituent-free. One possible method for doing this is to use as sources of carbon (feedstock gases) those organosilanes which possess few or no CH functions, such as the last members of the series of silylmethanes $(H_3Si)_xCH_{4-x}$ (x = 1, 2, 3 or 4). Only modest success was achieved at first with methylsilane, H_3SiCH_3,[4] but the deposition of a-SiC:H films with the desired high photoconductivity, with a large "optical gap", was achieved soon afterwards in several laboratories with disilylmethane, $(H_3Si)_2CH_2$.[5] The properties are apparently also determined by the abundance of quasi-crystalline domains.[6] Investigations with trisilylmethane, $(H_3Si)_3CH$, are in progress.[7]

Tetrasilylmethane, $(H_3Si)_4C$, was hitherto unknown even though its use has already been patented.[5b] We now report the first synthesis of tetrasilylmethane. Several convenient methods for the preparation of disilylmethane[8] have been reported recently.[9] However, in the case of trisilylmethane[9a,10] there are already considerable preparative difficulties, and it has only recently been possible to develop a really efficient method for the synthesis of this compound.[11] As pointed out in the cited work, a similar route should be suitable for the preparation of tetrasilylmethane.

Chlorophenylsilane, an easily accessible, stable compound[11,12] can, with the use of magnesium metal and tetrahalogenomethanes under conditions described earlier by *Merker* and *Scott* for similar systems,[13] be converted into tetrakis(phenylsilyl)methane **1** in ca. 50% yield [Eq. (a)].

$$CBr_4 + 4\,PhSiH_2Cl + 4\,Mg \rightarrow \underset{\mathbf{1}}{C(SiH_2Ph)_4} + 4\,MgClBr \qquad (a)$$

$$HCBr_3 + 3\,PhSiH_2Cl + 3\,Mg \rightarrow \underset{\mathbf{2}}{HC(SiH_2Ph)_3} + 3\,MgClBr \qquad (b)$$

$$H_2CBr_2 + 2\,PhSiH_2Cl + 2\,Mg \rightarrow \underset{\mathbf{3}}{H_2C(SiH_2Ph)_2} + 2\,MgClBr \qquad (c)$$

As well as the desired precursor **1** the less silyl-rich homologues tris(phenylsilyl)methane **2** and bis(phenylsilyl)methane **3**, are also obtained in not inconsiderable yields (20% and 10% respectively) [Eq. (b), (c)]; presumably transmetalation reactions are responsible for this. **2** and **3** can be separated from the reaction mixture by distillation and can be usefully converted into tri- or disilylmethanes.[11] Colorless crystals (m.p. = 46 °C) separate at − 78 °C from hexane solutions of the residue from the distillation, the ^{1}H-NMR spectrum of which shows almost exclusively the signals expected for **1**. The structure of this product has been established by, inter alia, single crystal X-ray structure analysis.[14] As shown in Figure 1 the central carbon atom is surrounded tetrahedrally by four silicon atoms.

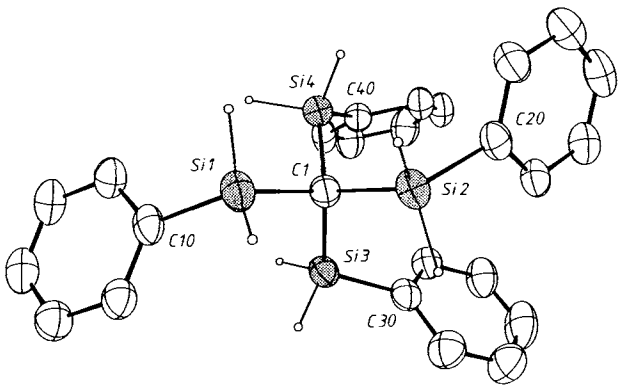

Fig. 1. Molecular structure of compound **1** in the crystal (ORTEP 50%). Important distances [Å] and angles [°]: C1–Si1 1.889(2), C1–Si2 1.892(2), C1–Si3 1.876(2), C1–Si4 1.884(2); Si1–C10 1.876(2), Si2–C20 1.873(2), Si3–C30 1.872(2), Si4–C40 1.865(2); Si1–C1–Si2 103.1(1), Si1–C1–Si3 109.3(1), Si1–C1–Si4 105.9(1); Si2–C1–Si3 11.5(1), Si2–C1–Si4 105.9(1), Si3–C1–Si4 113.5(1); C1–Si1–C10 117.6(1), C1–Si2–C20 115.0(1), C1–Si3–C30 115.5(1), C1–Si4–C40 117.2(1).

The phenyl groups in **1** can be removed as benzene by treatment with liquid hydrogen bromide at − 78 °C[15] [Eq. (d)].

$$\underset{\mathbf{1}}{C(SiH_2Ph)_4} + 4\,HBr \rightarrow \underset{\mathbf{4}}{C(SiH_2Br)_4} + 4\,C_6H_6 \qquad (d)$$

In contrast to the phenylsilylmethanes **2** and **3**, where the reaction to the corresponding bromosilylmethanes proceeds in nearly quantitative yield in a relatively short time (3 h and 10 h respectively), the removal of the phenyl groups in **1** is not complete even after several days. The ^{1}H-NMR spectrum of the product mixture clearly shows in the HSi region the singlet ($\delta = 4.52$) with ^{29}Si satellites ($^1J(H, Si) = 253.6$ Hz) which is expected for tetrakis(bromosilyl)-methane **4**. In addition, however, there are several other groups of signals. Presumably the long reaction times lead to isomerization and to bromination of the SiH functions. Nevertheless the whole reaction mixture can be converted with $LiAlH_4$ into the title compound **5** without prior purification [Eq. (e)].

$$\underset{\mathbf{4}}{C(SiH_2Br)_4} \xrightarrow{LiAlH_4} \underset{\mathbf{5}}{H_3Si-\overset{\displaystyle SiH_3}{\overset{|}{\underset{|}{C}}}-SiH_3} \qquad (e)$$
$$\qquad\qquad\qquad

86.5 °C and freezes at 5 °C; the yield is 15% based on the amount of **1** used. The spectroscopic data for **5** are as expected. For example, in the high resolution ^{1}H-NMR spectrum a singlet is observed at 3.84 ppm, which, because of the magnetic inequivalence of the protons on the ^{29}Si and ^{28}Si nuclei, shows satellites at a larger distance with decet fine structure (^1J(H, Si) = 205.7 Hz, ^4J(H, H) = 0.6 Hz; 5% intensity relative to the central singlet) and at a smaller distance satellites with quartet structure (^3J(H, Si) = 4.6 Hz; 15%).

The structure of compound **5** has been determined by electron diffraction.[18] In principle, the molecule adopts the expected tetrahedral structure, but the idealized T_d symmetry is reduced to point group T through a silyl twist (dihedral angle Si–C–Si–H = 20.04°).[19, 20] All other dimensions are in the expected range (Fig. 2). The structure of tetramethylsilane has been determined previously.[21]

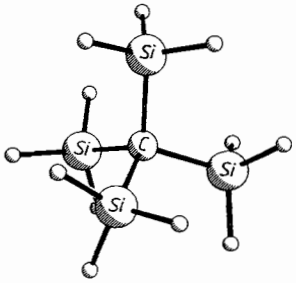

Fig. 2. Molecular structure of **5** in the gas phase. Important distances [Å] and angles [°]: Si–C 1.8751(7), Si–H 1.486(4), Si–C–Si 109.47 (fix.), C–Si–H 108.5(6), Si–C–Si–H 20.0(10), SiH_3(tilt) 0.00(fix.).

Details of photoelectron spectroscopic studies,[22] and CVD experiments will be reported later.

Experimental

1: A mixture of 56.7 g (0.40 mol) of $PhSiH_2Cl$ and 10.6 g (0.44 mol) of Mg turnings in 200 mL of THF was first treated at 60 °C with a solution of 33.2 g (0.10 mol) of CBr_4 in 200 mL of THF over a period of 6 h and then heated to boiling for a further 4 h. The whole reaction mixture was poured onto ice and neutralized with $NaHCO_3$. The organic phase was separated and, after addition of 100 mL of *n*-hexane, washed three times with 100-mL portions of water, and dried over $MgSO_4$. After removal of the hexane, the bright yellow crude oil was fractionally distilled at a pressure of 0.1 torr through a short Vigreux column at a temperature of 220 °C to achieve the separation and isolation of **2** (b.p. 96 °C/0.2 torr) and **3** (b.p. 190 °C/0.2 torr). The residue from the distillation (21.7 g, containing at least 20 g of **1**, corresponding to a crude product yield of 45%) was dissolved in 75 mL of *n*-hexane and stored for 4 weeks over dry ice. The majority of the material separated again as an oil, but in addition 0.6 g of **1** was obtained as a colorless crystalline solid (m.p. 46 °C).—^{1}H NMR (400 MHz, C_6D_6, 25 °C, TMS int.): δ = 4.90 (s, 8 H; SiH_2), 7.19 (m, 20 H; C_6H_5); ^{13}C NMR (100.4 MHz, C_6D_6, TMS): δ = − 19.78 (non, ^2J(C, H) = 6.7 Hz, ^1J(C, Si) = 30.5 Hz; CSi_4), 128.07 (dd; C2/6), 130.29 (dt; C4), 131.13 (m; C1), 136.91 (dm; C3/5), $^1J(C_{ar}, H)$ ca. 159 Hz, $^2J(C_{ar}, H)$ ca. 7 Hz; ^{29}Si NMR (79.4 MHz, C_6D_6, TMS): δ = − 29.84 (tm, ^1J(Si, H) = 202.6 Hz); IR (Nujol, [cm^{-1}]): 2132 (*v* SiH); MS (70 eV): *m/z* 440 ($M^{\oplus}$, 3%), 282 ($Ph_2CSi_4H_4$, 100).

4: 19.0 g (0.043 mol) of **1** (oily fraction) was transferred to a Schlenk tube and covered with an excess of anhydrous HBr (31 g, 0.383 mol) by condensation at − 196 °C. After warming to − 78 °C, the mixture, which was largely homogeneous after a few hours, was stirred for three days at this temperature. The excess HBr was evaporated off by warming to room temperature and the resulting benzene (9.5 g, 71%) was removed at a pressure of 1 torr.—^{1}H NMR: δ = 4.52 (s, ^1J(Si, H) = 253.6 Hz; SiH_2), together with other signals.

5: A solution of 18.3 g of the oily product mixture **4** (obtained from the reaction with HBr) in 50 mL of tetrahydronaphthalene (THN) was added dropwise to a suspension of 9.2 g (0.24 mol) $LiAlH_4$ and 1.9 g (8.3 mmol) of benzyltriethylammonium chloride in 200 mL of THN. The reaction mixture was first stirred for 3 days at room temperature and then for a further 5 h at 60 °C. The volatile products were then condensed at this temperature at a pressure of 10^{-1} torr into a nitrogen cold trap through a gas cooler (helix length ca. 2.5 m) which was connected to the reaction flask. *Caution*: on thawing the cold trap, a not inconsiderable amount of SiH_4 undergoes spontaneous combustion at the exit of the Hg vent connected to the apparatus! The remaining colorless liquid (1.9 g) contains **5**, **6**, THN and $PhSiH_3$ as the main components. By further HBr treatment of the reaction residue (after filtration and removal of the solvent by distillation), followed by hydrogenation in an analogous manner to above, a further 2 g of crude product was obtained. From the combined product mixture 0.85 g of **5** (14.5% based on **1**) can be isolated as a colorless liquid by repeated trap-to-trap condensation and fractional distillation (b.p. 86.5 °C, m.p. ca. 5 °C).—^{1}H NMR: δ = 3.84 (s, ^1J(H, Si) = 205.7 Hz, ^3J(H, Si) = 4.6 Hz, ^4J(H, H) = 0.6 Hz; SiH_3); ^{13}C NMR (pure, C_6D_6 ext.): δ = − 38.99 (tredecet, ^1J(C, Si) = 31.3 Hz, ^2J(C, H) = 5.5 Hz); ^{29}Si NMR (pure, TMS ext.): δ = − 47.78 (qdec); IR (Film [cm^{-1}]): 2155 s (*v* SiH), 916 s, 883 m (δ SiH_3), 798 vw (vSiC); MS (70 eV): *m/z* 136–124 [CSi_4H_x], 106–96 [CSi_3H_x], 74–69 [CSi_2H_x], 32–28 [SiH_x].

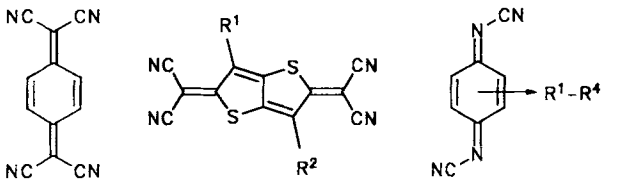
Novel S-Heteroquinoid Electron Acceptors. Synthesis of 2,5-Bis(cyanoimino)-2,5-dihydrothieno-[3,2-*b*]thiophenes (DCNTTs) and Conductive Charge Transfer Complexes**

By *Erhard Günther, Siegfried Hünig,* Karl Peters, Harald Rieder, Hans Georg von Schnering, Jost-Ulrich von Schütz, Svante Söderholm, Hans-Peter Werner,* and *Hans C. Wolf*

The discovery of highly conductive charge transfer (CT) complexes of tetracyanoquinodimethane (TCNQ) **1** and tetrathiafulvalene (TTF)[1] initiated an intensive search for further CT complexes with high conductivity. The skeletal framework in the donor TTF was kept intact, while the substitution pattern and the heteroatoms (S, Se, Te) were varied extensively.[2] In the case of TCNQ on the other hand, so far the $=C(CN)_2$ terminal groups have been kept intact and only a few variations of the quinoid skeleton have been examined. Some good conducting CT complexes were recently synthesized with the thieno[3,2-*b*]thiophene system **2**.[3]

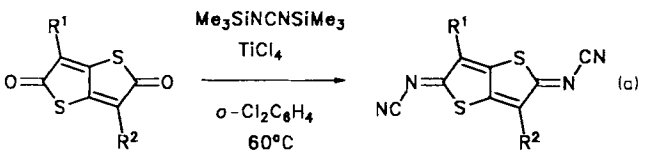
In the meantime the *N,N'*-dicyanoquinone diimines (DCNQIs) **3** have been described as novel acceptors, accessible



1 **2**: R = H, Br **3**

with widely different substituents from the corresponding quinones, bis(trimethylsilyl)carbodiimide and $TiCl_4$ in dichloromethane at 0–25 °C.[4, 5] These DCNQIs act as efficient acceptors in CT complexes[6] and especially in highly conductive radical anion salts.[7]

The question now arose as to how far these properties are retained when the =N–CN groups bracket a heteroquinoid system. As first examples of such compounds we describe the DCNTTs **4** mentioned in the title, which were obtained from the corresponding quinones **5** via the route previously developed for **3**.[8, 9] However, the standard conditions which have proven satisfactory for DCNQIs do not apply in this instance. Conversion of the largely unreactive **5** into **4** [Eq. (a)] was first achieved in 1,2-dichlorobenzene at 60 °C; the small yields of **4b, c** and **f** (cf. Table 1) are due to the sensitivity towards $TiCl_4$.



5 **4** (a)

The compounds **4a–g** (Table 1) behave as two-step, reversible redox systems; the radical anions are, according to the lgK_{SEM} values, thermodynamically equally as stable as those of the DCNQIs. The redox potentials can be varied within wide limits by suitable substituents R^1 and R^2.

Table 1. Yields, melting points, and electrochemical data of the 2,5-bis(cyanoimino)-2,5-dihydrothieno[3,2-*b*]thiophenes **4a–g**.

The compounds **4e, g** react with various donors to form complexes exhibiting considerable conductivity (Table 2). **4g** · TMTSeF is one of the best conducting CT complexes with TMTSeF as donor.

The crystal structure of **4g** · TTF[10] suggests the presence of a two-stack conductor array: Figure 1 shows separated,

Table 2. CT complexes from **4e** and **4g** with TTF derivatives (TM = tetramethyl, TSeF = tetraselenafulvalene, TTT = tetrathiatetracene, BEDT = bisethylenedithio).

Complex [a]	M.p. [°C] [b]	Conductivity [Scm^{-1}] σ_p [c]	σ_s
4g · TTF	200	7×10^{-2}	25 [d]
4g · TMTSeF	200	2×10^{-2}	200 [e]
4g · TMTTF	164	1.2	–
4g · TTT (5:2)	208	5×10^{-2}	–
4g · BEDT-TTF	184	2×10^{-5}	–
4e · TMTTF	182	2.0	–

straight stacks of planar donor and acceptor units which are almost equidistant at room temperature (stack separation 348 pm).

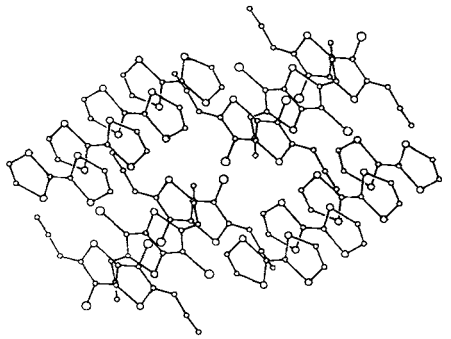

Fig. 2. Perspective view of the unit cell of **4g** · TTF.

According to Figure 3c the conductivity of the complex **4g** · TFF increases slightly with decreasing temperature down to a phase transition temperature of $T_c = 160$ K and then decreases down to 77 K, corresponding to a transition from metal to semiconductor.

The complex shows a broad ESR signal ($\Delta B_{pp} = 4.5$–8.5 mT) and a spin concentration of ca. 9×10^{22} s mol^{-1} (Fig. 3b) above room temperature. Also these values, as well as the susceptibility (Fig. 3a), first change below ca. 160 K.

According to the above results it can be expected that also other heteroquinoid systems containing =N–CN terminal groups as acceptors will be suitable for the production of conductive materials. The radical anion salts of the DCNTTs will be reported on elsewhere.

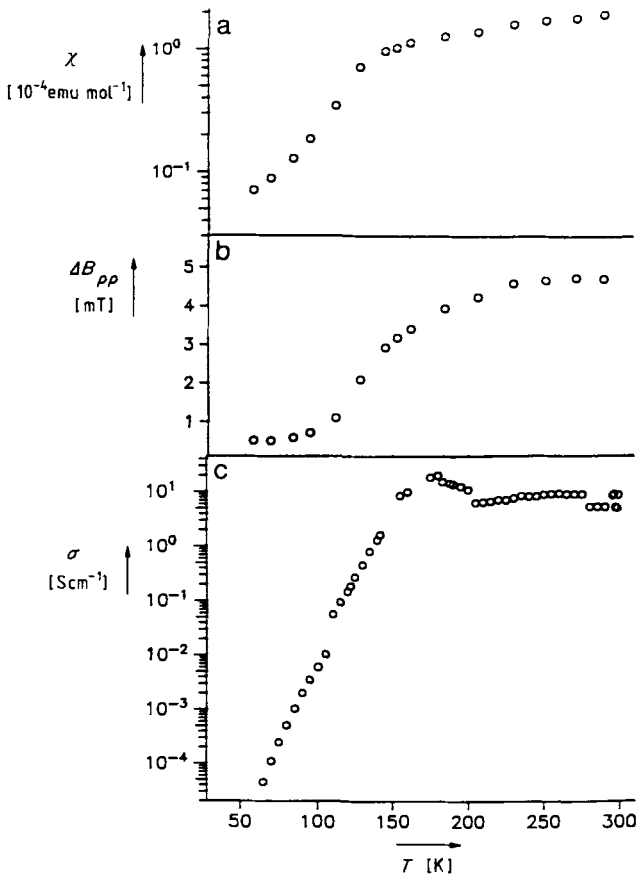

Fig. 3. Temperature dependence a) of the susceptibility, b) of the ESR line width, and c) of the conductivity of the CT complex **4g** · TFF. The steps in the curve (c) are due to cracks (jogs) in the crystal upon cooling.

[8] The procedure given in the literature for **5a–c** [G. F. Pedulli, P. Zanirato, A. Alberti, M. Guerra, M. Tiecco, *J. Chem. Soc. Perkin Trans. 2* (1976) 946–952] has been modified somewhat. **5d–f** were obtained by halogenation of **5b** and **5c** with SO_2Cl_2 in chlorobenzene and Br_2 in acetic acid, respectively. **5c** was recently synthesized via another route (K. Kobayashi, ISNA Conference, Osaka, August 1989).

[9] a) Preparation of the 2,5-bis(cyanoimino)-2,5-dihydrothieno[3,2-*b*]thiophenes, as for example **4a**: A solution of $TiCl_4$ and bis(trimethylsilyl)carbodiimide in 1,2-dichlorobenzene was treated with a solution of 3,6-dimethyl-2,5-dihydrothieno[3,2-*b*]thiophene-2,5-dione **5a** in anhydrous 1,2-dichlorobenzene (10 equivalents of $TiCl_4$ and bis(trimethylsilyl)carbodiimide per equivalent of **5a**). After 48 hours' stirring at 60 °C the mixture was poured onto ice, extracted with CH_2Cl_2, and the organic phase dried over $MgSO_4$. After removal of CH_2Cl_2 by distillation the mixture was treated with pentane. The resulting precipitate was filtered off (suction) and chromatographed on silica gel (CH_2Cl_2, Kieselgel Woehm, 0.063–0.200). The product was then recrystallized from CH_3CN. b) Preparation of the CT complex: donor and acceptor components were combined in the ratio 1:1 in acetonitrile at the boiling point. On cooling, black needles or a microcrystalline powder separated out.

[10] **4g** · TFF: orthorhombic, *Pccn*, $a = 1382.4(8)$, $b = 1918.8(11)$, $c = 697.0(3)$ pm, $V = 1849(2) \times 10^6$ pm^3, $Z = 4$, $\varrho_{calcd} = 2.085$ gm cm^{-3}, $Mo_{K\alpha}$ radiation (graphite monochromator), 1931 reflections, 1176 measured with $F > 3\sigma(F)$, $R = 0.052$, $R_w = 0.038$. tioselective catalysis with transition metal complexes.[1] The use of this homogeneous catalysis is, however, limited in that the frequently strongly reducing reaction conditions (e.g. in hydrogenations or hydroformylations) can lead to rupture of the phosphorus-carbon bond and thus to destruction of the catalyst.[2] Optically active chelate-forming nitrogen compounds are therefore finding increasing interest in preparative chemistry[3, 4] and increasing use as ligands of transition metals in asymmetric catalysis.[4, 5] Although the complex forming properties of bipyridine and phenanthroline derivatives have been well investigated,[6] only a few optically active compounds of this class of substances have thus far been described.[4]

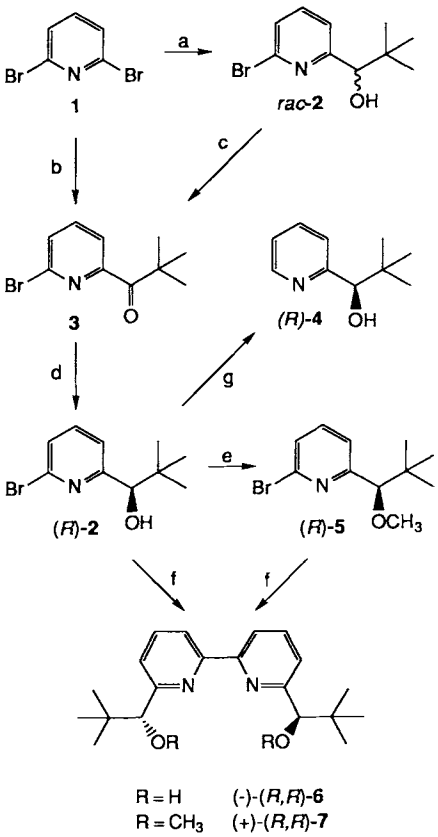
Herein we report the enantioselective synthesis of the homochiral C_2-symmetric bipyridines **6** and **7**, the X-ray structure analysis of a complex of (*R*,*R*)-**7** and cobalt(II) chloride, and the first investigations of the use of these optically active bipyridines in enantioselective catalysis.

For the synthesis of the enantiomerically pure bipyridine (−)-(*R*,*R*)-**6** (Scheme 1) we used the optically active alcohol



Scheme 1. a) BuLi, *t*BuCHO, THF, −78 °C to room temperature (RT), 3 h (79%). b) BuLi, $tBuCO_2CH_3$, THF, −78 °C to RT, 3.5 h (80%). c) Pyridinium chlorochromate, CH_2Cl_2, RT, 16 h (74%). d) 1) (−)-*B*-chlorodiisopinocampheylborane (1.2 equiv.) neat, RT, 2 d; 2) iminodiethanol (3.6 equiv.), ether, 3 h (59%): (*R*)-**2**:(*S*)-**2** = 95:5. e) NaH, CH_3I, THF, 0 °C to RT, 1.5 h (85%). f) $NiCl_2 \cdot 6H_2O$ (1.2 equiv.), Zn (1.3 equiv.), PPh_3 (4.8 equiv.), DMF, 72 °C, 3.5 h (**6**: 55%, **7**: 65%). g) Bu_3SnH, AIBN, toluene, 90 °C, 3 h (72%).

(*R*)-**2**, which is accessible in a two-step reaction from 2,6-dibromopyridine (**1**); two molecules of (*R*)-**2** were coupled by a nickel(0)/triphenylphosphane-mediated reaction.[7, 8] (*R*)-**2** and (*S*)-**2** were obtained in the ratio 95:5 by asymmetric reduction of the ketone **3** with (−)-*B*-chlorodiisopino-campheylborane.[9] The enantiomeric excess can be determined NMR spectroscopically on the camphanates; the absolute configuration is found by correlation with the known alcohol (*R*)-**4**.[10]

It could be shown via the camphanic acid diester of **6**, whose methine protons in the α-position to the *tert*-butyl group give rise to separate signals in the ^{1}H-NMR spectrum (400 MHz), that the chromatographically purified sample of the optically active bipyridine (*R*,*R*)-**6** was an *enantiomerically* pure compound.

Two molecules of the optically active methyl ether (*R*)-**5** can be coupled with nickel(0)/triphenylphosphane to give the bipyridine (*R*,*R*)-**7**. *rac*-**2** and *rac*-**5** each form two diastereomers (*rac*-**6**/*meso*-**6** and *rac*-**7**/*meso*-**7**, respectively) in the ratio 1:1, which can be separated by column chromatography.[11]

From the characteristic downfield shift of the NMR signals of the 3,3′-protons ($\delta = 8.31$ for (*R*,*R*)-**6**, $\delta = 8.26$ for (*R*,*R*)-**7**, a *transoid* arrangement must be assumed for the nitrogen atoms in solution.[12] Complexation with a metal converts the molecule into the *cisoid* form.

Deep-blue crystals of the composition (*R*,*R*)-**7** · $CoCl_2$ could be obtained from a solution of (*R*,*R*)-**7** and $CoCl_2 \cdot 6H_2O$ in the molar ratio 1:1 in acetonitrile/methanol. The X-ray structure analysis (Fig. 1) confirms the C_2 symmetry

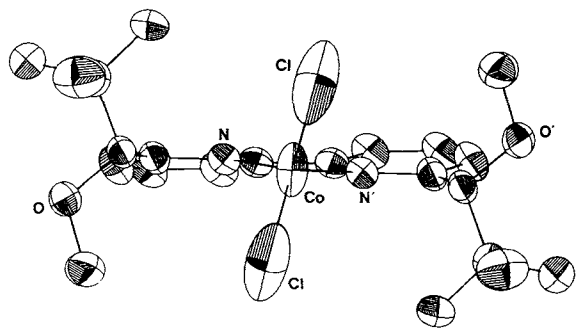


Fig. 1. Structure of (*R*,*R*)-**7** · $CoCl_2$ in the crystal (hydrogen atoms not shown).

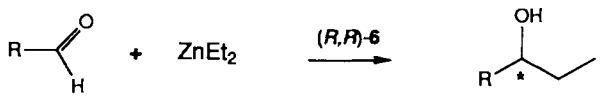
of the metal complex; the cobalt is surrounded tetrahedrally by the two nitrogen atoms of the bipyridine ligand and the two chlorine atoms.[13] Coordinative bonding of an ether oxygen atom to the metal center, as observed in $CoCl_2$ complexes with bipyridine crown ethers,[14] does not take place.

High asymmetric induction has been achieved in additions of diethylzinc to aldehydes in the presence of catalytic amounts of optically active amino alcohols.[15] (*R*,*R*)-**6** has



also proven to be an efficient enantioselective catalyst for this reaction. With only 5 mol-% of this optically active bipyridine, alcohols are formed in good yields and with high enantiomeric excess (up to 97%) (Table 1).

A lowering of the reaction temperature leads to an increase of asymmetric induction in the reaction with benzaldehyde (No. 1–3); however, the product is still obtained with high enantiomeric excess even at room temperature (Table 1). A doubling of the amount of catalyst from 5 to 10 mol-% has only little effect on the enantioselectivity (No. 2, 93 and 94% *ee*, respectively). Both the reactivity as

Table 1. Enantioselective addition of diethylzinc to aldehydes, catalyzed by 5 mol-% (*R,R*)-**6**.

No.	R	Solvent	*T* [°C]	*t* [h]	Yield [%] [a]	$[\alpha]_D$ [°] [b]	*ee* [%] [c]

8	*n*-C_6H_{13}	toluene	0	3	≈75 [e]	≈ − 5.2 [e]	≈54 [e] (70)

[a] By column chromatography. [b] All products are of *R*-configuration. [c] According to rotation value [15b]; in brackets: determined ^{1}H- (No. 1–7) or ^{13}C-NMR spectroscopically (No. 8) after esterification with (−)-3,3,3-trifluoro-2-methoxy-2-phenylacetyl chloride ((−)-MPTA chloride). [d] 0 °C/9.5 h, then RT/37 h. [e] The product was not analytically pure.

well as the asymmetric induction is lower in acetonitrile than in toluene or hexane (No. 1–5). The methylated compound (*R,R*)-**7** and the cobalt complex (*R,R*)-**7** · $CoCl_2$ show only slight catalytic activity and lead to products with lower enantiomeric excesses.[16]

Further investigations should prove whether the optically active bipyridines presented here can also act as enantioselective catalysts in other reactions.

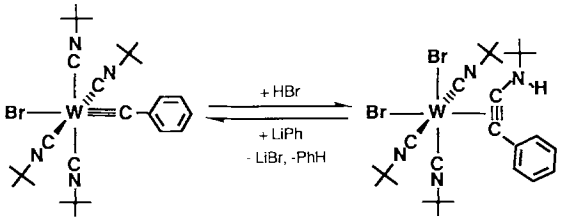
Alkyne Cleavage as a Novel Route to Low-Valent Carbyne-Metal Complexes**

By *Alexander C. Filippou,* Christian Völkl, Walter Grünleitner,* and *Paul Kiprof*

The compounds *trans*-$X(CO)_4M{\equiv}CR$ (X = halogen; M = Cr, Mo, W; R = alkyl, aryl) containing a metal–carbon triple bond were first reported on in 1973 by *E. O. Fischer*.[1] Such complexes and their carbonyl-containing substitution products obtainable by successive CO exchange exhibit a versatile reaction behavior which has been well documented in numerous works.[2] In contrast, the reactivity of low-valent, carbonyl-free carbyne complexes has been the subject of very few studies.[2a, 2b, 3]

We recently reported on a novel acid-induced carbyne–isocyanide coupling reaction, the reaction of the carbyne complex **1** with HBr to give the aminoalkyne complex **2** (Scheme 1).[4] This type of reaction was previously postul-



1 **2**

Scheme 1. Acid-induced CC coupling in **1**—base-induced CC cleavage in **2**.

ated as the elementary step of CC bond formation in the reductive coupling of two isocyanide ligands in sevenfold coordinated complexes of Mo^{II} and W^{II}, but could not be experimentally verified.[5] We have now successfully carried out the converse of this carbyne–isocyanide coupling: reaction of the *alkyne* complex **2** with LiPh affords the *carbyne* complex **1** (Scheme 1). This base-induced reaction is to our knowledge the only hitherto known example for the cleavage

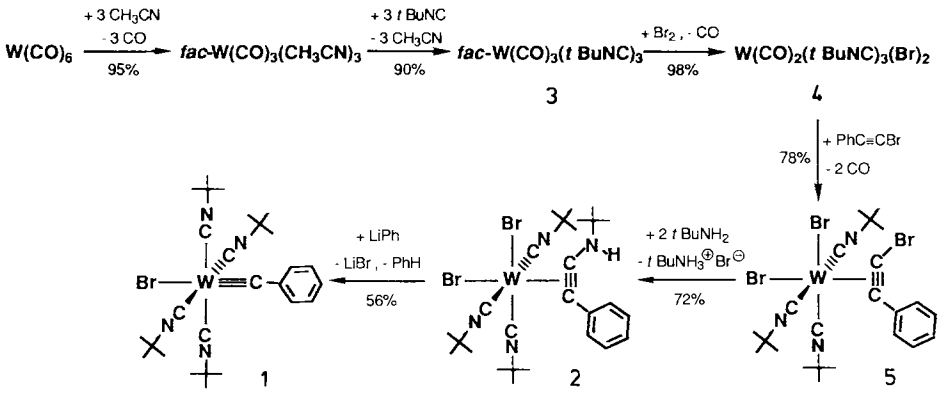

Scheme 2. New synthetic route to **1** from $W(CO)_6$ via alkyne complexes.

of an alkyne to C_1 fragments at a transition metal center.[6] On the basis of this reaction we have developed a new synthetic route to low-valent carbyne complexes starting from $(W(CO)_6$; the strategy is presented here, outlining the synthesis of **1** as example (Scheme 2).

$W(CO)_6$ is converted in two steps via *fac*-$W(CO)_3(CH_3CN)_3$[7a] into the triisocyanide-substituted complex **3**,[7b] which is oxidatively decarbonylated with Br_2 to the sevenfold coordinated W^{II} complex **4**. Thermal substitution of the two remaining CO ligands by $PhC\equiv CBr$ then leads to the bromoalkyne complex **5**,[8] which is finally converted with tBuNH$_2$ into the structurally related aminoalkyne complex **2**. This can then be converted by reaction with phenyllithium into **1**. Some data for the complexes **1**–**5** are collected in Table 1.

Table 1. Spectroscopic data of the complexes **1**–**5** [a, b].

[a] Correct elemental analyses and isotopically correct mass spectra for all compounds. [b] IR spectrum: ν(C≡N*t*Bu), ν(C≡O) and ν(C=N) in CH_2Cl_2, ν(NH) of **2** in KBR (Nicolet FT-5 DX spectrometer); NMR spectra in CD_2Cl_2 at 20 °C, values referred to the solvent (Jeol FT-GX-400 spectrometer).

The positions of the signals of the alkyne C atoms in the ^{13}C-NMR spectra ($\delta \approx 200$) of **2** and **5** are consistent with the presence of a 4e-donor alkyne ligand.[9a] The tungsten(II) center thus achieves noble gas configuration, like other d^4 metals in alkyne complexes.[9a] In agreement with earlier findings, no C≡C stretching vibration is observed for the 4e-donor alkyne ligands in **2** and **5**.[4a, 9a] In the series of carbyne complexes $Br(CO)_{4-n}(t$BuNC$)_n$W≡CPh (n = 0–4) the carbyne-C signal in the ^{13}C-NMR spectrum is shifted upfield with increasing n.[3b, 4a, 9b]

The assignment of the structure of the carbyne complex **1** was confirmed for the solid state by a single crystal X-ray structure analysis (Fig. 1).[10] For low-valent carbyne-tungsten complexes, striking features of the structure of **1** are the remarkably short W≡C (176.4(6) pm) distance and the long W–Br distance (275.62(6) pm.[11] The atomic sequence Br–W≡C–C is almost linear. Four equatorial *tert*-butyl isocyanide ligands complete the distorted octahedron (Fig. 1).

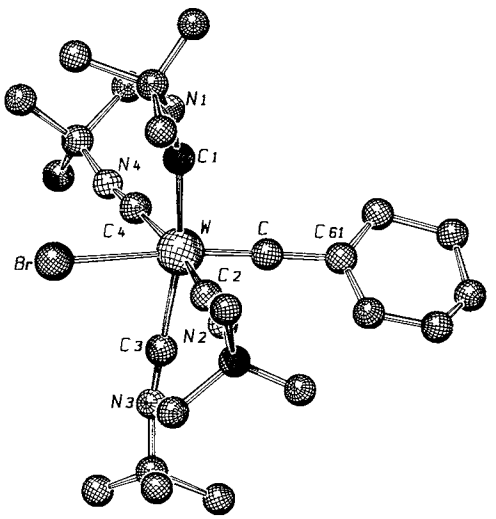

Fig. 1. Molecular structure (SCHAKAL) of the carbyne complex **1** in the crystal. Selected bond lengths [pm] and angles [°]: W–C 176.4(6), W–Br 275.62(6) W–C1 211.4(7), W–C2 209.1(6), W–C3 204.8(7), W–C4 210.9(5); W–C–C61 172.9(4), Br–W–C 171.0(1), Br–W–C1 80.5(1), Br–W–C2 82.1(1), Br–W–C3 85.5(2), Br–W–C4 88.4(1).

The newly developed synthetic route to the low-valent carbyne complex **1** from $W(CO)_6$ is not only an equally good alternative to the hitherto only known route via carbonyl-containing carbyne complexes,[3b, 4a] but, owing to its adaptability to alkyne complexes of other metals isoelectronic with W^{II}, (e.g. Ta^{I}), it opens up new perspectives in the chemistry of the low-valent carbon–metal multiple-bond systems. The key step of this new route, the base-induced CC-cleavage in

2 to give **1** is directly connected with the catalytic activity of carbyne-metal complexes in alkyne metathesis.[2c]

Experimental

All experiments were carried out in the absence of air and moisture. **4**: A solution of **3** (0.34 g, 0.66 mmol) in CH_2Cl_2 (20 mL) was treated at $-80\,^{\circ}C$ with a solution of Br_2 (0.105 g, 0.034 mL, 0.66 mmol) in CH_2Cl_2 (20 mL). The color of the reaction solution turned from pale to intense yellow. Finally, the solution was allowed to warm to room temperature, the solvent removed by evaporation, and the resulting residue reprecipitated from Et_2O/pentane; yield 0.42 g (98%), yellow solid, m.p. 115 °C (decomp.).

5: A solution of **4** (0.30 g, 0.46 mmol) in toluene (40 mL) was treated with PhC≡CBr (0.142 g, 0.097 mL, 0.78 mmol) and heated at 70 °C for 1 h. The color of the solution changed from yellow to green. After cooling to room temperature, the solvent was removed by distillation, and the resulting residue chromatographed on Al_2O_3 silica gel at 0 °C. **5** was eluted with CH_2Cl_2/Et_2O (1/5); yield 0.28 g (78%), green solid after reprecipitation from Et_2O/pentane, m.p. 66 °C.

2: A solution of **5** (0.48 g, 0.62 mmol) in THF (50 mL) was treated with tBuNH$_2$ (0.223 g, 0.32 mL, 3.05 mmol) and heated under reflux for 1.5 h. The color of the solution changed from green to blue. After removal of the solvent the residue was chromatographed on silica gel at 0 °C. **2** was eluted with Et_2O; yield 0.34 g (72%), blue, microcrystalline solid after reprecipitation from Et_2O/pentane, m.p. 144 °C.

1: A solution of **2** (0.32 g, 0.42 mmol) in THF (40 mL) was treated at $-80\,^{\circ}C$ with 1.10 mL of a 0.49 M solution of LiPh in Et_2O (0.54 mmol LiPh), warmed to room temperature, and stirred for 1.5 h. The color of the reaction solution changed from blue to brown-red. After removal of solvent, the residue was chromatographed on Al_2O_3 at 0 °C, and **1** was eluted with Et_2O/CH_2Cl_2 (2/1); yield 160 mg (56%), red, microcrystalline solid after reprecipitation from Et_2O/pentane, m.p. 122 °C (decomp.).

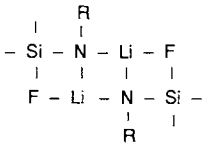
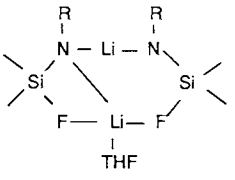
Lithium Bis(di-*tert*-butylfluorosilyl)amide as Contact Ion Pair with Linear Si–N$^{\ominus}$–Si Unit and as Ion Pair without Li$^{\oplus}$-Anion Contact**

By *Ursula Pieper, Simone Walter, Uwe Klingebiel,** and *Dietmar Stalke*

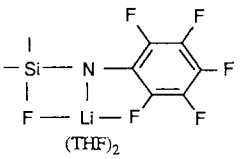
Structure investigations on lithium organo(fluorosilyl)-amides have repeatedly furnished astonishing results: the structural types found so far include tri-(**I**),[1] bi- (**IIa, IIb**),[2, 3] and monocyclic (**III**)[4] compounds containing an LiF contact, as well as LiF adducts (**IV**) of iminosilanes.[5]



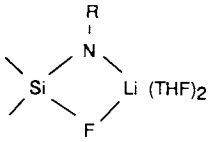
I[1]



IIa[2]



IIb[3]



III[4]

IV[5]

Essentially three factors determine the structural make up of the lithium derivatives:

1) A common feature of all compounds is that the Lewis acid strives to bind lithium, while the Lewis base strives to bind fluorine.
2) The LiF contact is influenced by bases which coordinate lithium.

[*] Prof. Dr. U. Klingebiel, U. Pieper, S. Walter, Dr. D. Stalke
Institut für Anorganische Chemie der Universität
Tammannstrasse 4, D-3400 Göttingen (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. *P. von R. Schleyer* and Dr. *M. Bremer* for their help with the ab initio calculations.

3) The decreasing basicity of the nitrogen in the series of lithium derivatives with R = alkyl, silyl, aryl finally leads to rupture of the Li–N bond.

In the present communication we describe the syntheses and crystal structures of the first lithium bis(fluorosilyl) amide in various donor solvents.

Starting from $t\mathrm{Bu_2SiFNH_2}$ and $t\mathrm{Bu_2SiF_2}$ we isolated bis-(tri-*tert*-butylfluorosilyl)amine **1** [6] (Table 1). **1** was lithiated with BuLi, and, after treatment with the donor reagent THF, TMEDA, or [12]crown-4, the amides **2, 3** and **4**, respectively, were isolated and characterized (Table 1). **4** is also formed on using only one equivalent of the crown ether.

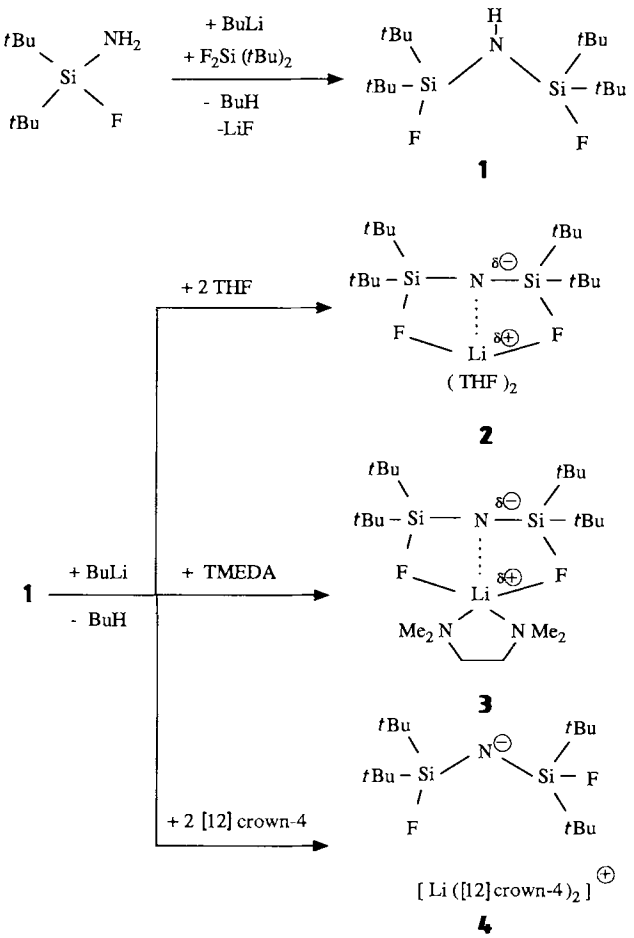


Table 1. NMR data of the compounds **1**–**4**. All measurements at 25 °C with a 250-MHz spectrometer (except ^{19}F: 80-MHz apparatus). Standard for ^{1}H, ^{13}C and ^{29}Si NMR: TMS int., for ^{19}F NMR C_6F_6 ext., for ^{7}Li NMR: LiCl ext.

1 (all measurements in CH_2Cl_2/C_6D_6: ^{1}H NMR: $\delta = 1.08$ (d, ^4J(H,F) = 0.6 Hz, 36H; *t*Bu); ^{13}C NMR: $\delta = 20.6$ (d, ^2J(C,F) = 15.8 Hz, 4C; CC_3), 27.7 (d, ^3J(C,F) = 0.9 Hz, 12C; CC_3); ^{19}F NMR: $\delta = 1.58$ (d, ^3J(H,F) = 8.61 Hz); ^{29}Si NMR: $\delta = 2.60$ (d, ^1J(Si,F) = 305.8 Hz, 2 Si)

2: ^{1}H NMR (C_6D_6): $\delta = 1.32$ (36H; *t*Bu), 1.3 (8H; $O(CH_2CH_2)_2$), 3.5 (8H; $O(CH_2CH_2)_2$); ^{13}C NMR (C_6D_6): $\delta = 22.5$ (d, ^2J(C,F) = 21.7 Hz, 4C; CC_3), 29.7(12C; CC_3), 68.2 (4C; $O(C_2C_2)$); ^{19}F NMR (C_6D_6): $\delta = 11.7$; ^{29}Si NMR (hexane/THF: $\delta = -12.3$ (d, ^1J(Si,F) = 272.5 Hz); ^{7}Li NMR (toluene/THF: $\delta = 0.17$ (t, ^1J(Li, F) = 15.0 Hz)

3 (all measurements in C_6D_6): ^{1}H NMR: $\delta = 1.36$ (36H; tBu), 1.9 (12H; TMEDA); ^{13}C NMR: $\delta = 22.07$ (d, ^2J(C,F) = 22.7 Hz; 4C; CC_3), 29.72 (12C; CC_3), 46.2 (4C; TMEDA); ^{19}F NMR: $\delta = 13.1$; ^{29}Si NMR: $\delta = -12.0$ (d, ^1J(Si,F) = 271.4 Hz)

4 (all measurements in C_6D_6/THF): ^{1}H NMR: $\delta = 1.02$ (36H; *t*Bu); 3.5 (32H; [12]crown-4); ^{13}C NMR: $\delta = 22.0$ (d, ^2J(C,F) = 23.7 Hz; d, ^4J(C,F) = 2.3 Hz, 4C; CC_3), 29.93 (12C; CC_3), 68.93 (16C, [12]crown-4); ^{19}F NMR: $\delta = -22.5$ (d, ^1J(Si,F) = 295.2 Hz); ^{7}Li NMR: $\delta = -1.34$

Lithiated bis(di-*tert*-butylfluorosilyl)amine crystallizes from THF as the monomeric amide **2** (Fig. 1). According to the results of an X-ray structure analysis [7] the coordination sphere of the lithium is made up of the two fluorine atoms, the nitrogen atom, and two THF molecules. The lithium thus brackets the Si_2NF_2 skeleton to form a planar six-membered ring. This geometry enforces the *tert*-butyl groups into an eclipsed position. Despite this steric compression the nitrogen atom is shifted, as a result of electrostatic interaction, towards the lithium atom. The six-membered ring contains an almost linear Si–N$^{\ominus}$–Si unit (Si–N–Si = 176.7°), the first time that this has been observed. Alkali-metal compounds of bis(trimethylsilyl)amine have Si–N–Si angles of 125 to 136°.[8] The amide **2** is thus structurally analogous to the isoelectronic siloxane (Ph_3Si–O–$SiPh_3$).[9] The widening of the Si–N–C angle in **II b** to 140.1° continues towards linearity in **2**. The Si–N distances in **2** (163.6 pm) lie in the range typical for Si–N double bonds. The ^{7}Li-NMR spectrum already shows a triplet at $\delta = 0.17$ with $J_{LiF} = 15$ Hz at room temperature, i.e. the lithium atom is also coordinated to fluorine in solution. From the similarity of their NMR data it can be concluded that **2** and **3** have analogous molecular structures.

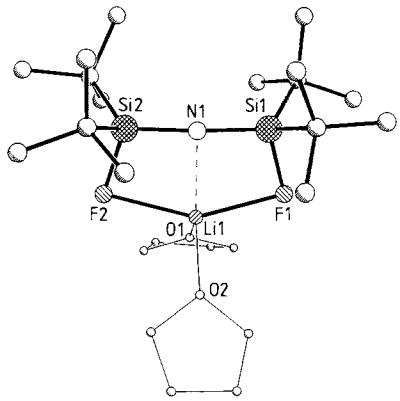

Fig. 1. Molecular structure of **2** in the crystal. Selected bond lengths [pm] and angles [°]: Si1–N1 163.6(6), Si–N1 163.6(6), Si1–F1 165.9(4), Si2–F2 165.3(4), Li1–F1 212.3(15), Li1–F2 220.5(13), Li1–N1 211.5(13), mean Li–O 193.9; Si1–N1–Si2 176.7(4), F1–Li1–F2 149.5(6), N1–Si1–F1 104.2(2), N1–Si2–F2 104.3(2).

If, however, the stronger donor [12]crown-4 is used for coordination saturation of the Lewis acid lithium, free ions are formed instead of a contact pair like **2** (Fig. 2). It follows

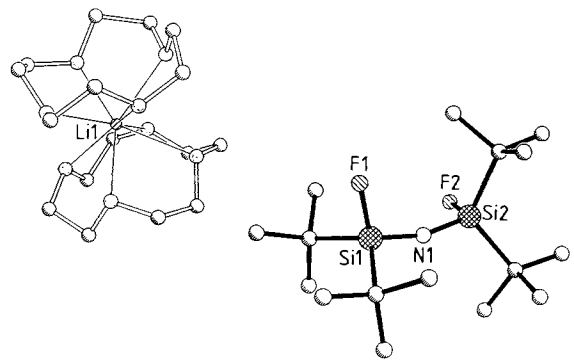

Fig. 2. Molecular structure of the amide **4** in the crystal. Selected bond lengths [pm] and angles [°]: Si1–N1 160.6(7), Si2–N1 163.0(6), Si1–F1 164.4(5), Si2–F2 163.7(5), mean Li–O 236.5; Si1–N1–Si2 162.6(5).

from the crystal structure analysis of **4**[10, 11] that interaction between the ions ceases upon coordination of two crown ether molecules to the lithium ion. Lithium is formally eightfold coordinated. Since the lithium atom no longer brackets the two fluorine atoms of the anion, the *tert*-butyl groups become staggered, and steric compression thus minimized. The Si–N–Si angle in **4** is reduced by 14.1° compared to that in **2** to 162.6°, and is thus ca. 8° larger than in the $[Ph_3SiNSiPh_3]^{\ominus}$ system.[12]

The model system $(H_3Si)_2N^{\ominus}$ was computed with GAUSSIAN 88[13] using the basis set 6–31 + G*.[14] The starting value for the Si–N–Si angle was optimized from 120° to 180°. The calculated Si–N bond length is 162.4 pm. The experimental data of the structure analysis of **2** and **4** are thus in good agreement with the ab initio calculated data.[13–15] The $Si–N^{\ominus}–Si$ system bent at an angle of 120° at the nitrogen atom is only 25 kJ mol^{-1} more energetic than the system with optimized geometry.

Experimental

1: A solution of 0.01 mol (1.77 g) of tBu_2SiFNH_2 in 50 mL of hexane was treated with 0.01 mol of BuLi (15% in hexane). The lithium salt that was formed was brought into solution by addition of ca. 50 mL of THF. After subsequent addition of 0.01 mol of tBu_2SiF_2, the reaction mixture was heated under reflux for ca. one week. The reaction was monitored ^{19}F-NMR spectroscopically. **1** was purified by distillation. Yield 3.0 g (90%).

2 and **3**: A solution of 0.01 mol (3.37 g) of **1** in 25 mL of hexane was treated with 0.01 mol of BuLi (15% in hexane). The resulting slurry was brought into solution by addition of THF. The solvent was then removed in vacuo and the crude product was crystallized from hexane (**2**) or TMEDA (**3**). Yield: 95% of **2** and 95% of **3**, respectively.

4: A solution of 0.01 mol (3.37) of **1** in 50 mL of THF was treated with 0.01 mol of BuLi (15% in hexane). After addition of 0.02 mol (1.76 g) of [12]crown-4, the crude product was recrystallized from THF. Yield: 85%.

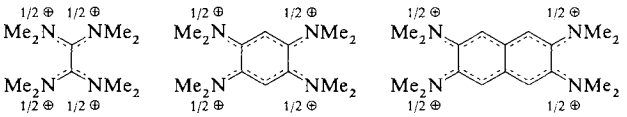
Vinylogous Cyanine-like Dications of Tetrakis(dimethylamino) Compounds**

By *Karin Elbl-Weiser, Claus Krieger,* and *Heinz A. Staab**

The dications **1**–**3** can be regarded as a vinylogous series in which two cyanine-like mesomeric π-bond systems are coupled by one, two and three single bonds, respectively. The dication **1** derived from tetrakis(dimethylamino)ethene was already studied in detail by *Wiberg* and *Buchler*[1] in the sixties; its spatial structure, however, was still unknown.[2] An X-ray structure analysis of **1** $(PF_6^{\ominus})_2$[3] confirmed the above formulation: the two cyanine-like substructures show a hitherto unexpected[1b] strong twisting of ca. 72° about the central C–C bond, which, according to its length of 151.1(5) pm, is a single bond. We already reported in 1986 on the synthesis of 1,2,4,5-tetrakis(dimethylamino)benzene and on the formation and structure of the dication **2** derived therefrom.[4] The two mesomeric substructures in **2** are also twisted (≮ 49°) against each other, leading to a correspondingly distinct twist form of the six-membered ring; on the basis of their lengths the C(1), C(2) and C(4)–C(5) bonds can be regarded as single bonds, whereas the C–N bonds at C(1), C(2), C(4), and C(5) have double bond character corresponding to the formulation **2**. In continuation of this series, the species **3**, whose π-subsystems are to be formally seen as vinylogous to **2**, was of special interest.[5]



For the synthesis of 2,3,6,7-tetrakis(dimethylamino)naphthalene **4** the diaminonaphthalene **5**[6] was converted by reaction with *N*-bromosuccinimide (1,4-dioxane, 3 h, 20 °C, under argon) and subsequent treatment with tin in the pres-

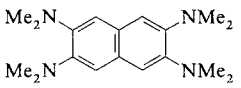
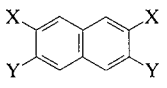
ence of glacial acetic acid (18 h reflux)[7] into **6** (76% yield; m.p. 229–230 °C).[8] Reductive *N*-methylation of **6** (formaldehyde, sodium cyanotrihydroborate, acetonitrile/glacial acetic acid)[9] afforded **7** (93% yield; m.p. 51–52 °C).[8] Subsequent halogen-metal exchange (*n*-butyllithium, tetrahydrofuran/*n*-hexane, 20 min, −78 °C), reaction with diphenyl azidophosphate (tetrahydrofuran, −78 °C), and immediate reduction with sodium bis(2-methoxyethoxydihydridoaluminate (toluene, −78 °C to 0 °C)[10] furnished **8**, which was converted by reductive methylation (see above) into **4** (13% yield; m.p. 170–171 °C)[8] [^{1}H NMR (360 MHz, CD_2Cl_2):



4



5: X = NH_2, Y = H

δ = 2.83 (s, 24H), 7.02 (s, 4H); MS: *m/z* 300 ($M^{\oplus}$, base peak)]. Figure 1 shows (above) the molecular structure of **4**[11] viewed onto the naphthalene plane and (below) a side view perpendicular to the C(2)–C(3) bond.

Despite the steric interaction between the two pairs of vicinal dimethylamino groups (N···N distances between neighboring dimethylamino groups: 285.2 pm) the C–N bonds at C(2), C(3), C(2i) and C(3i) do not deviate out of the naphthalene plane; striking, however, is the lengthening of the bond between the substituted ring atoms C(2)–C(3) and C(2i)–C(3i), resp., to 143.8 pm.

Compound **4** differs markedly from its benzene analogue in its much weaker electron donor strength. Whereas the first two oxidation steps in the latter, which lead to the formation of **2**, cannot be separated cyclovoltammetrically (E_{ox} = −0.266 V),[4] in the case of **4** one finds, under the same conditions, a first oxidation step corresponding to donation of *one* electron with E_{ox} = +0.08 V, followed by a second oxidation step, which likewise corresponds to a *one*-electron transfer with E_{ox} = +0.16 V (the potentials of higher oxidation steps were not determinable, owing to irreversible processes under the conditions employed).[12] Consistent with these results is the finding that **4** forms a more stable radical cation than 1,2,4,5-tetrakis(dimethylamino)benzene, the ESR and ENDOR investigations of which will be reported elsewhere.[13] With oxidizing agents

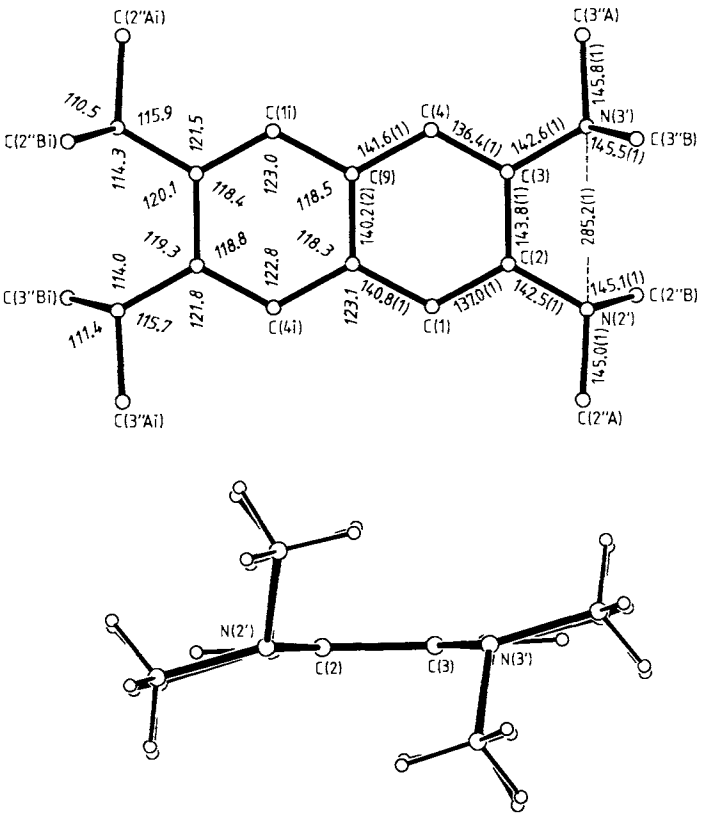

Fig. 1. Molecular structure of **4**; above: view onto the naphthalene plane with bond lengths [pm] and bond angles [°]; below: side view in the direction of the longitudinal axis of the naphthalene plane [11].

such as iodine or 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), **4** forms green to black products which we have so far been unable to fully characterize; with tetracyanoquinodimethane (TCNQ) a crystalline complex [black prisms, m.p. 207 °C (decomp.)] was actually isolable, but its analytical data provided no confirmatory evidence for the presence of the dication **3**. Also an attempt to detect **3** spectroscopically in a dilute solution of **4** in dichloromethane after addition of two equivalents of bromine did not lead to an unequivocally informative result. We attribute the striking difference in the stability of the vinylogous dications **2** and **3** to the following steric factors: whereas in the case of **2** a high degree of planarity is possible within the two cyanine subunits including the terminal Me_2N groups by the above-

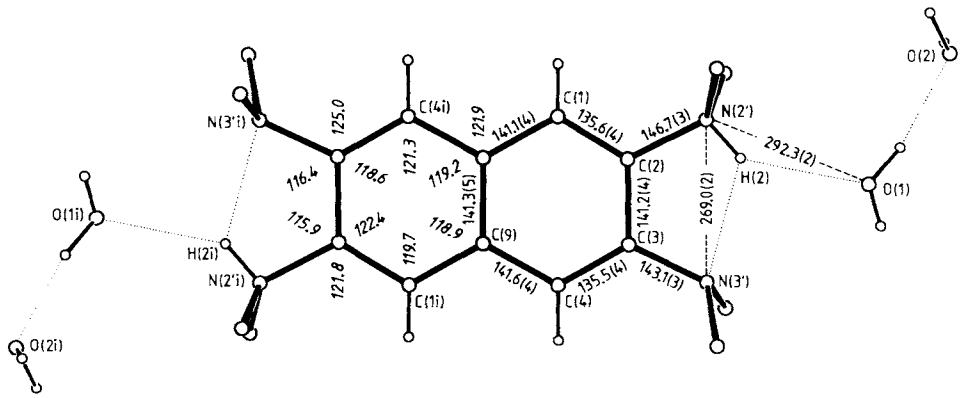

Fig. 2. Partial structure of **4** · dihydrobromide tetrahydrate viewed onto the naphthalene plane, with bond lengths [pm] and bond angles [°] [16].

mentioned twist arrangement of the six-membered ring, in the case of **3** the bicyclic framework is so strongly planarized by threefold coupling that steric interaction between the neighboring Me_2N groups hinders a planar arrangement of the mesomeric cyanine systems.

Although the N···N distance between the neighboring dimethylamino groups in **4** is only a few pm greater than in typical "proton sponges",[14] **4** does not display the special properties of these compounds. In **4**, both the destabilization of the base by repulsive interaction of the dimethylamino groups as well as the stabilization of the protonated form are less, since the lone pairs of the nitrogen atoms are not directed towards each other due to steric factors, and strong linear N···H···N hydrogen bonds cannot be formed. However, in analogy to the "proton sponges", **4** is not protonated fourfold but only twofold in the presence of excess acid. Reaction with aqueous hydrobromic acid affords the dihydrobromide of 4, which crystallizes as the tetrahydrate.[8] Figure 2 shows the structure of diprotonated **4** with incorporated molecules of water of crystallization. It is immediately apparent that in each case the subunits of two neighboring dimethylamino groups are singly protonated and that unsymmetric strongly bent N–H···N hydrogen bonds are present which are "bifurcated" due to interaction with the molecules of water of crystallization. This structure resembles that of the dihydrobromide dihydrate of 1,2,4,5,-tetrakis(dimethylamino)benzene.[15]

Structure and Color of Substituted Pentaphenylbismuth **

By *Arno Schmuck, Pekka Pyykkö,* and *Konrad Seppelt* *

The deep violet complex $Bi(C_6H_5)_5$, first described by Wittig in 1952, has an almost regular square pyramidal structure[1] quite like that of solvate-free $Sb(C_6H_5)_5$,[2] but in complete contrast to that of $P(C_6H_5)_5$ and $As(C_6H_5)_5$, both of which have trigonal-bipyramidal stereochemistry.[3] In the solid state $Bi(C_6H_5)_5$ is dichroic. The aim of this investigation was to establish, by experimental and theoretical work, how the structure of the molecule and its derivatives affects their chromophoric properties.

$Bi(C_6H_5)_3(2\text{-}F\text{-}C_6H_4)_2$ **1** $Bi(4\text{-}H_3C\text{-}C_6H_4)_3(2\text{-}F\text{-}C_6H_4)_2$ **2**

All previously investigated pentaphenylbismuth derivatives are colored and have a square-pyramidal structure,[4, 5] an unusual feature in main group chemistry. The fluoro-derivative **1** is violet and dichroic in the solid state also, and has a square-pyramidal structure (Fig. 1a). In solution, however, it has a reddish color (see Fig. 2), but again forms purple crystals. The very similar methylfluoro-derivative **2** has the same color in solution (see Fig. 2), but forms *orange* crystals. Its structure is the first in which five (substituted) phenyl groups surround bismuth in a trigonal-bipyramidal array (Fig. 1b).

It is clear from the colors in solution that both structures involved in the Berry pseudorotation mechanism are present. The ratio of the absorption intensities does not change, even with large variations in temperature. It follows, therefore, that the difference between the energies of the trigonal-bipyramidal and square-pyramidal arrangements must be close to zero and that the solid state structure is determined by lattice forces. Ligand exchange cannot be frozen-out even at the lowest achievable temperature (^{19}F NMR); this result also points to a low energy barrier between the two structures ($\Delta G < 20$ kJ mol^{-1}).

[4], $\Delta = 60°$ for ideal trigonal bipyramids.—Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54259, the names of the authors, and the journal citation.

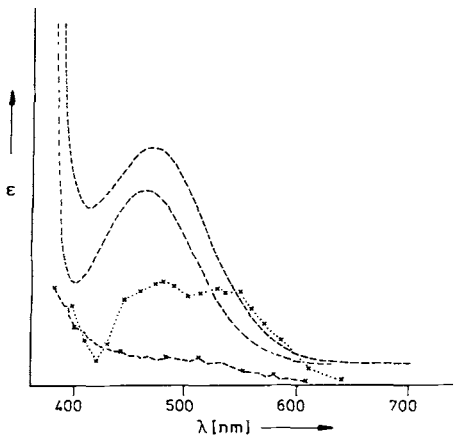

Fig. 2. UV/VIS spectra for **1** and **2**. (——) above: **1** in THF solution −40 °C; (——), below: **2** in THF solution, −40 °C. The two curves are almost identical, but the absorption of **2** is weaker (solubility!). (x···x): **1**, crystalline, +25 °C; (x–––x): **2**, crystalline, +25 °C. Solid state UV measurements: Carl Zeiss UMSP-80 microphotometer. Because of the intense light the substances have only a short lifetime; this explains the poor quality of the spectra. The eye is the better spectrometer in this instance.

Extended Hückel calculations with relativistic corrections show a very different MO diagram for the hypothetical molecule BiH_5 in the case of ideal D_{3h} and C_{4v} symmetry.[6] The reduced HOMO-LUMO separation in the latter is very striking. The HOMO is predominantly a (non-bonding) ligand orbital in the basal plane, while the LUMO has mainly Bi-6p$_z$ character, i.e. it points into the vacant coordination site (Fig. 3). Such a qualitative difference between the MO diagrams for the two geometries has already been calculated for the hypothetical PH_5,[7] which, even if it existed, however, should be trigonal-bipyramidal. The optical transition in the bismuth compounds corresponds to charge transfer from the basal ligand to bismuth. This electronic excitation is actually forbidden; and the ε values of the absorption are correspondingly small.

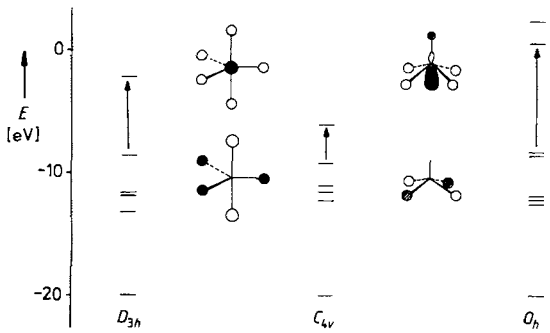

Fig. 3. MO diagram for BiH_5 with trigonal-bipyramidal geometry (D_{3h}) and square-planar (C_{4v}) geometry, and for $BiH_6^{\ominus}$ (O_h), corrected for relativistic effects. The HOMO–LUMO excitation is symbolized by an arrow. Alongside: presentation of HOMO and LUMO by population analyses. Since the HOMO has practically no Bi-orbital participation, whereas the LUMO has a large one, only the LUMO is drastically lowered by lanthanoids and relativistic contraction. The occupation of the sixth coordination site in the C_{4v} model leads to an octahedral $BiH_6^{\ominus}$ with particularly large HOMO–LUMO splitting (right). The unstable anion $Bi(C_6H_5)_6^{\ominus}$ is pale yellow [11].

The bonding in the excited molecule is comparable to that of a trivalent square-pyramidal bismuth compound, e.g. $BiCl_5^{2\ominus}$. Because of the poor shielding by the 4f electrons and through the relativistic contraction, s-orbitals participate less in bonding than in the lighter homologues; hence the preference for the square-pyramidal structure. Moreover, the highly bismuth-centered LUMO in particular is considerably lowered by the above mentioned effects, so that the absorption is centered in the visible region of the spectrum. To our knowledge this is the first demonstration of the influence of the relativistic effect on an excited state. Extended Hückel calculations without relativistic correction for BiH_5 in both geometries give a qualitatively similar diagram with smaller HOMO-LUMO splitting for the C_{4v} model. The HOMO-LUMO splitting changes by about 27%, however, on applying the relativistic correction for C_{4v}, but only by about 14% for D_{3h}. That is, "non-relativistic" pentaphenylbismuth would not be violet.

It is possibly worthwhile pointing out that bismuth behaves similarly in oxidic superconductors: a Bi^{III}-Bi^{IV} redox process coupled with a square-pyramidal/octahedral vibrational transition can be assumed.[8] In addition, common to both phenomena is that they are only observed within a narrow set of boundary conditions.

Since the intensity of color of the pentaphenylbismuth derivatives correlates with the weakness and ease of excitation of the basal Bi–C bonds, compounds with even weaker Bi–C bonds, which would be expected to be more deeply

colored, may no longer be stable at room temperature. In the case of the pentaphenylantimony derivatives, corresponding phenomena should be observable in the UV, except that the weak absorption will be masked by strong phenyl ring π-π^* transitions.

Experimental

A solution of 6 mmol of 2-F-C_6H_4Li (freshly prepared from 1-bromo-2-fluorobenzene and *n*BuLi at $-78\,^{\circ}C$) in anhydrous Et_2O was fed through a small Teflon tube into a stirred suspension of 3 mmol of triarylbismuth dichloride [9, 10] in 20 mL of anhydrous Et_2O cooled to $-78\,^{\circ}C$. The colored suspension was then warmed with stirring to room temperature. After decanting from deposited LiCl, the clear red-violet solution was carefully evaporated. Crystallization at $0\,^{\circ}C$ and $-25\,^{\circ}C$, respectively, afforded the substituted pentaarylbismuth compounds **1** and **2**, which are readily soluble in diethyl ether, insoluble in pentane, and sensitive to hydrolysis.

1: 45%, violet dichroic crystals, m.p. 103 °C (decomp.); ^{19}F NMR (84.25 MHz, THF, $CFCl_3$ ext.): $\delta = -94.1$; FIR (Nujol): $\tilde{\nu} = 530, 452, 444, 434, 282, 231, 195, 175, 126, 109\ cm^{-1}$; UV (THF): $\lambda_{max} = 487$ nm.

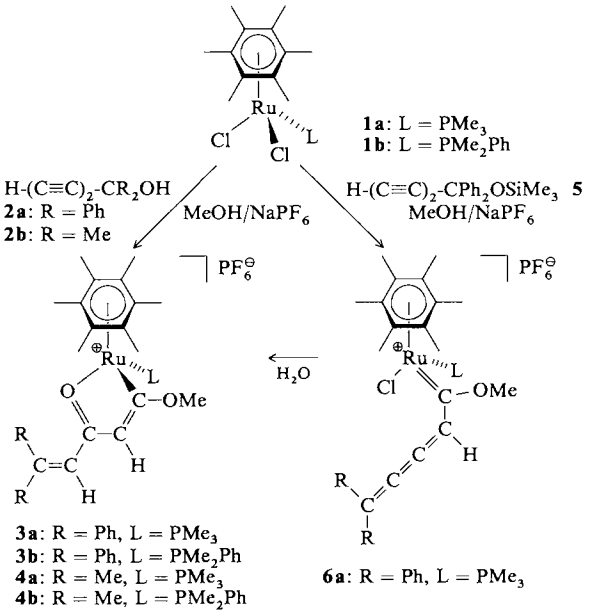
unusual physical or catalytic properties[1, 2] and as building blocks for new polymers.[3, 4] The metallacumulene species $M=(C=)_4CR_2$ is still a hypothetical transient species, although a few examples of allenylidene-metal complexes $M=(C=)_2CR_2$ have been described,[5, 6] (arene)-$Ru=(C=)_2CR_2$ intermediates were obtained from propargyl alcohol derivatives, and they readily underwent further reaction to give 2-propenylidene ruthenium complexes,[6]; we have therefore considered the possibility of generating metallacumulenes (arene)$Ru=(C=)_4CR_2$ by reaction of H-$(C\equiv C)_2CR_2OY$ derivatives with ruthenium(II) complexes to give highly unsaturated complexes. We now describe the first example of a 2,3,4-pentatrienylidene-metal complex and its transformation into a novel 3-oxo-1,4-pentadienyl-ruthenium derivative.[7]

Reaction of the Ru-complex **1a** with $NaPF_6$ and 1,1-diphenylpenta-2,4-diyn-1-ol **2a** in methanol led, via a violet intermediate, to formation of orange crystals (48%) of **3a**. Similarly, the complex **1a** and the diynol derivative **2b** afforded 56% of **4a**. Analogous complexes **3b** and **4b** were obtained by reaction of **1b** with **2a** and **2b**, respectively (Scheme 1).



Scheme 1.

Ruthenium-containing Cumulenes: Generation of 2,3,4-Pentatrienylidene- and 3-Oxo-1,4-pentadienyl-Complexes**

By *Antonio Romero, Angel Vegas,* and *Pierre H. Dixneuf**

Polyunsaturated organometallic complexes are scarce, in spite of their interest for access to novel compounds with unusual physical or catalytic properties[1, 2] and as building blocks for new polymers.[3, 4] The metallacumulene species $M=(C=)_4CR_2$ is still a hypothetical transient species, although a few examples of allenylidene-metal complexes $M=(C=)_2CR_2$ have been described,[5, 6] (arene)-$Ru=(C=)_2CR_2$ intermediates were obtained from propargyl alcohol derivatives, and they readily underwent further reaction to give 2-propenylidene ruthenium complexes,[6]; we have therefore considered the possibility of generating metallacumulenes (arene)$Ru=(C=)_4CR_2$ by reaction of H-$(C\equiv C)_2CR_2OY$ derivatives with ruthenium(II) complexes to give highly unsaturated complexes. We now describe the first example of a 2,3,4-pentatrienylidene-metal complex and its transformation into a novel 3-oxo-1,4-pentadienyl-ruthenium derivative.[7]

Reaction of the Ru-complex **1a** with $NaPF_6$ and 1,1-diphenylpenta-2,4-diyn-1-ol **2a** in methanol led, via a violet intermediate, to formation of orange crystals (48%) of **3a**. Similarly, the complex **1a** and the diynol derivative **2b** afforded 56% of **4a**. Analogous complexes **3b** and **4b** were obtained by reaction of **1b** with **2a** and **2b**, respectively (Scheme 1).

A single-crystal X-ray structural analysis of **3a**[8] (Fig. 1) confirms that the activation of the diynol **2a** by **1a** results in the unprecedented formation of a novel 3-oxo-1,4-pentadienyl-ruthenium derivative.[9] The structure of the product **3a**, and the fact that (arene)RuC_2CPh_2 moieties exist,[6] suggest formation of an "RuC_4CPh_2" intermediate followed by addition of methanol at C1 and of the released water at C3 of the ligand. To gain an insight into the formation of complexes **3** and **4** an attempt to isolate the violet intermediate was undertaken. The complex **1a** was allowed to react with one equivalent of the silyloxypentadiyne **5** in dry methanol. A violet product was isolated in 40% yield and was identified as complex **6a**. This compound shows one strong absorption in the IR spectrum at $2080\ cm^{-1}$, which can be assigned to the [C=C=C=C] group.[1] In the ^{13}C-NMR spectra, a signal is observed at $\delta = 295.13$, characteristic for a ruthenium-bound carbene carbon atom,[6]; a signal at

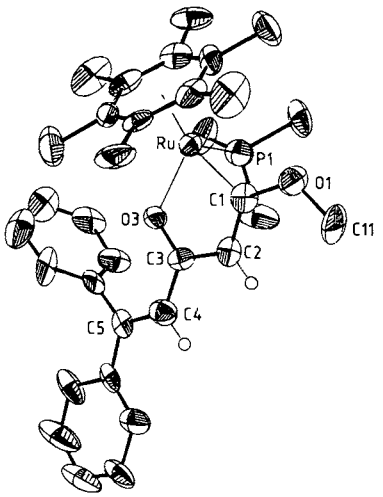

Fig. 1. Molecular structure of **3a** (ORTEP, 50% probability thermal motion ellipsoids). Selected bond lengths [Å] and angles [°]: Ru-C1 1.99(2), C1-C2 1.36(3), C2-C3 1.38(2), C3-O3 1.30(2), Ru-O3 2.09(1), Ru-P 2.32(1), C3-C4 (1.49(2), C4-C5 1.35(2); Ru-C1-C2 116(1), C2-C3-O3 119(2), C3-O3-Ru 112(1), O3-Ru-C1 78.0(6).

109.79 ($^1J_{C,H}$ = 172 Hz) can be assigned to the HC=C= group, and three singlets at δ = 166.88, 148.83 and 148.42 stem from the $(C=)_3$ skeleton.

Compound **6a** reacts with water at room temperature to give **3a** quantatively after 3 h. This demonstrates that complexes of type **3** and **4** are formed on addition of water to the C(3) carbon of the butatrienyl group of intermediate **6**.

Since the addition of methanol to the $Ru=(C=)_2CR_2$ moieties leads to 2-propenylidene-ruthenium complexes,[6] the metallacumulene $Ru=(C=)_4CPh_2$ is likely to be the key intermediate in the reaction of the diynes **2** or **5** with the complexes **1** to afford complex **6** by addition of methanol.

Experimental

3a: **2a** (0.24 g, 1 mmol) was added to a solution of **1a** (0.41 g, 1 mmol) and $NaPF_6$ (0.18 g, 1 mmol) in 20 mL of dry methanol. The solution turned violet after a few minutes and then progressively dark red. The mixture was stirred for 20 h at room temperature. The solvent was removed in vacuo and the red solid was dissolved in 20 mL of THF. The solution was filtered, and crystallization from a THF/*n*-hexane (2/1) solution afforded 0.36 g (48%) of **3a** as orange crystals.

3a: IR (KBr): $\tilde{\nu}$ = 1615 [s, ν(C=O)], 855 [s, ν(P-F)] cm^{-1}; ^{1}H NMR (300.13 MHz, $CDCl_3$): δ = 6.77 (s, 1H; *HC*=C), 5.57 (d, 1H, ^4J(P, H) = 0.8 Hz; *HC*=C), 3.76 (s, 3H; OMe), 1.99 (s, 18H; C_6Me_6), 1.15 (d, 9H, ^2J(P, H)) = 10.1 Hz; PMe_3). ^{31}P NMR: δ = 3.55 (s, PMe_3), −144.39 (sept; $PF_6^{\ominus}$). ^{13}C NMR: δ = 254.82 (d, ^2J(P, C) = 20.4 Hz; RuCOMe), 199.60 (s; C=O), 153.48 (s; =*C*Ph$_2$), 121.92 (^1J(C, H) = 156.6 Hz, H*C*=CPh$_2$), 111.09 (^1J(C, H) = 162.4 Hz; *HC*=C(OMe). Correct elemental analysis (C, H).

3b and **4a, b** were prepared analogously to **3a** and isolated in 52%, 56% and 58%, respectively. ^{13}C-NMR data for Ru-*C*OMe (75.469 MHz, $CDCl_3$): δ = (^2J(C, P) = 255.29/18.9 Hz (**3b**), 253.11/20.2 Hz (**4a**), 253.76/20.3 Hz (**4b**): δ = ^1J(C, H) = 112.25/162.4 Hz (**3b**), 110.79/161 Hz (**4a**), 111.38/161 Hz (**4b**).

6a: **1a** (0.30 g, 0.73 mmol) and $NaPF_6$ (0.13 g, 0.77 mmol) were dissolved in 20 mL of dry methanol and treated with 0.225 g, 0.73 mmol of 5,5-diphenyl-5-(trimethylsiloxy)penta-1,3-diyne **5**. The mixture was stirred at room temperature for 1 h. Half of the solvent was removed in vacuo. The red-violet product was filtered and crystallized from dichloromethane/ether (20 mL/10 mL); Yield: 0.22 g (40%) of a violet powder of **6a**. Correct elemental analysis (C, H).

6a: IR (KBr): $\tilde{\nu}$ = 2080 [s, ν(C=C=C=C)]; 855 [vs, ν(P-F)] cm^{-1}, ^{31}P NMR (121.49 MHz, CD_2Cl_2): δ = 10.54 (s; PMe_3), −143.45 (sept., $PF_6^{\ominus}$); ^{1}H NMR (300.13 MHz, CD_2Cl_2), δ = 7.69–7.47 (m, 10H; Ph), 7.29 (s, 1H; =C=*CH*), 4.51 (s, 3H; OMe); 2.06 (d, 18H; ^4J(P, H) = 0.7 Hz; C_6-*Me*$_6$), 1.40 (d, 9H; ^2J(P, H) = 10.6 Hz; PMe_3). ^{13}C NMR (75.469 MHz, CD_2Cl_2): δ = 295.13 (^2J (C, P) = 21.2 Hz; Ru=*C*-OMe), 166.88, 148.83 and 148.42 (=*C*=*C*=*C*Ph$_2$), 109.79 (^1J(C, H) = 172 Hz; H*C*=C=), 106.47 (C_6Me$_6$), 67.43 (OMe), 16.41 (C_6*Me*$_6$), 16.05 (^1J(C, P) = 34.6 Hz; PMe_3). The conformation of the carbene ligand is based on an NOE experiment.

[8] Crystals for X-ray analysis were obtained from a THF/ether (1/2) solution. **3a** crystallizes in the space group $P2_1/n$ with a = 13.788(5), b = 13.328(5), c = 18.457(6) Å, β = 100.21(3)°, Z = 4, V = 3338 Å^3, ϱ_{calcd} = 1.488 g cm^{-3}, crystal dimensions 0.50 × 0.20 × 0.10 mm. The diffraction data were collected with a single-crystal diffractometer CAD-4 (graphite monochromator, $Mo_{K\alpha}$-radiation, (θ – 2θ scan) at 293 K. 5855 reflections were obtained in the range 3° < 2θ < 50°, 1831 with $I > 3\sigma(I)$ considered as observed. The structure was solved by the heavy atom method and refined by full-matrix least-squares calculations and unit weights, using absorption correction data; all calculations were carried out with the program system 'X RAY-70'. The fluorides of the hexafluorophosphate ion showed extremely high temperature factors and some unresolved disorder and they were fixed at the position of the maxima in the Fourier map. Anisotropic treatment of the non-hydrogen atoms, except the $[PF_6]^{\ominus}$ ion, gave R = 0.064 for the observed reflections. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54350, the names of the authors, and the journal citation.

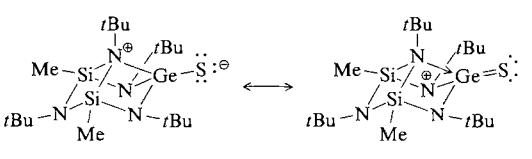
An Intramolecularly Lewis-Base-Stabilized Ge=N-Compound and a Related Ge-Fe Complex

By *Michael Veith,* Sabine Becker,* and *Volker Huch*

We have recently demonstrated that a germanium–sulfur double bond can be stabilized by intramolecular addition of bases to the germanium atom. The bonds in the polycyclic azasilagermane **1** can be formally described in terms of the resonance structures **1a** and **1b**.[1]

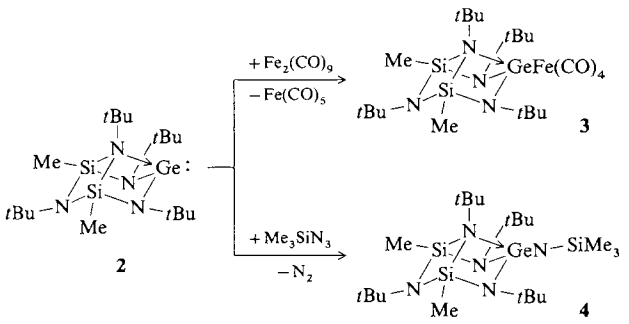


1a **1b**

[*] Prof. Dr. M. Veith, Dipl.-Chem. S. Becker, Dr. V. Huch
Institut für Anorganische Chemie der Universität
D-6600 Saarbrücken 11 (FRG)

We have now considered the question of whether germanediylamines (germanimines) and germanediyl-transition-metal complexes analogous to **1** can also be prepared, i.e. whether the sulfur in **1** can be replaced by a nitrene, e.g. $Me_3Si-\ddot{N}$, or an isolobal complex fragment such as $Fe(CO)_4$. Stable germanediylamines have only recently been isolated and spectroscopically characterized,[2] while germanediyl complexes of the transition metals have been known for some time.[3] Some X-ray structure analyses of silanediylamines (silanimines) and base-stabilized silanediylamines have been carried out independently by others.[4]

The target compounds **3** and **4** are obtained in high yields upon reaction of the germanediyl **2** with nonacarbonyldiiron and trimethylsilylazide respectively at room temperature. The reactions proceed in accord with Scheme 1, with elimination of pentacarbonyliron and dinitrogen, respectively.



Scheme 1. Synthesis of **3** and **4**.

The ^{1}H-NMR spectra of **3** and **4** in solution[5] differ primarily in that three signals are observed for the *tert*-butyl groups in the case of **3**, whereas only two signals are observed in the case of **4**. Thus, in **3** the donor bond from the nitrogen to the germanium atom is closed on the ^{1}H-NMR time scale, whereas in the case of **4** (like in **1**[1]) a bond fluctuation occurs (see also the ^{13}C-NMR spectrum of **4**[5]). The $\Delta G^{\ddagger}$ value of **4** derived from the temperature dependence of the ^{1}H-NMR spectra is 56(9) kJ mol^{-1} at 298 K and is thus 8 kJ mol^{-1} smaller than that of **1**. The marked difference in the activation entropies of **1** and **4** ($\Delta S^{\ddagger}$(**1**) = − 51(5), $\Delta S^{\ddagger}$(**4**) = − 95(9) J mol^{-1} K^{-1}) is apparently associated with the additional trimethylsilyl groups in **4**.

The results of the X-ray structure analyses of **3** and **4** are collected in Figure 1.[6] In the solid state, both compounds are present as isolated molecules with only van-der-Waals contacts. **3** contains a crystallographic mirror plane, whereas **4** loses its point symmetry C_s(m) in the crystal. In both molecules the germanium atom is incorporated in a seconor-cubane-like Si_2N_4Ge cage by bonding to three nitrogen atoms. The fourth coordination site of the germanium atom is taken up in an $Fe(CO)_4$ and $N(SiMe_3)$ group, respectively. The nitrogen atom N5 in **4** is only twofold coordinated; the Ge–N5–Si3 angle is 151.2(7)°.

The germanium atoms in **3** and **4** are *not* in a tetrahedral environment but lie almost in a plane together with the bond partners N1,N1′ and Fe or N2,N3 and N5 (sum of angles at Ge in **3**: 354.7°, in **4**: 357.7°). The fourth bond to a further nitrogen atom of the polycycle forms an angle of 49 and 57°, respectively, to this plane. From a comparison of the Ge–N bond lengths it follows that this fourth interaction is the weakest (**3**: Δ(N3–Ge/N1–Ge) = 0.144 Å; **4**: Δ(N1–Ge/N(2,3)–Ge = 0.156 Å).

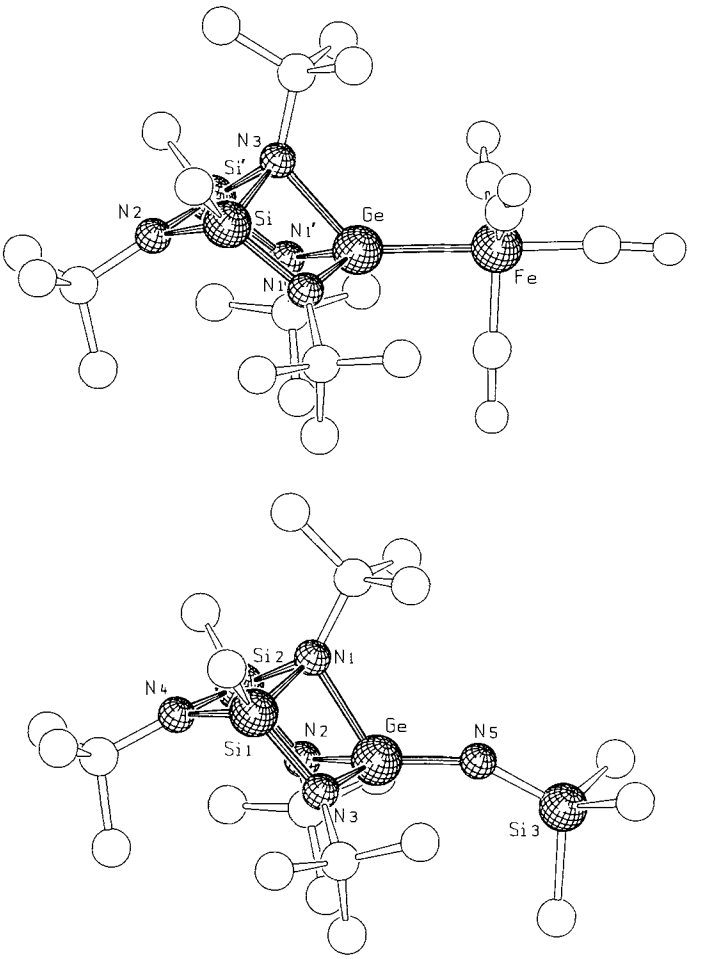


Fig. 1. The crystal structures of **3** (top) and **4** (bottom) (Schakal drawings, the carbon atoms are not shown). Some important bond lengths [Å] and angles [°]: **3**: Ge–Fe 2.348(1), Ge-N1 1.916(3), Ge-N3 2.060(4), Si-N1 1.718(3), Si-N2 1.735(3), Si-N3 1.821(3); N3-Ge-Fe 130.6(1), N1-Ge-Fe 122.8(1), N1-Ge-N1′ 109.1(1), N1-Ge-N3 78.8(1). **4**: Ge-N1 2.045(7), Ge-N2 1.896(7), Ge-N3 1.882(7), Ge-N5 1.688(9), Si1-N1 1.819(7), Si1-N3 1.710(7), Si2-N1 1.803(7), Si2-N2 1.697(8), Si3-N5 1.648(9); N1-Ge-N5 122.6(4), N2-Ge-N3 108.3(3), N2-Ge-N5 125.8(4), N3-Ge-N5 123.6(4), N2-Ge-N1 78.5(3), N3-Ge-N1 79.5(3), Ge-N5-Si3 151.2(7).

The Ge–N bond lengths for the three different nitrogen atoms in **4** (N1 quadruply, N2 and N3 each triply, and N5 only doubly coordinated) correlate as usual with the coordination numbers.

Of special interest are the Ge–Fe and the Ge–λ^2-N bond lengths. They have to be assessed differently! The value found for Ge–Fe corresponds approximately to the sum of the single bond radii of the two elements (2.39 Å,[7a] 2.37 Å[7b]). The Ge–N5 distance is very much smaller than expected for a single bond (1.86 Å[7b]) and on taking into account the larger atomic radius of germanium is comparable with the Si–λ^2-N distances (1.57–1.60 Å) in free and base-stabilized silanedylamines.[4] The bond shortening relative to the standard single bond is 9% in the case of Ge–λ^2-N in **4**, whereas it is noticeably smaller (7%) in the case of Ge–S in **1** (Ge–λ^1-S = 2.063(3),[1] Ge–λ^2-S = 2.21[7b]). The Si3–N5 bond length and the Ge–N5–Si3 angle in **4** resemble the corresponding bond length and bond angle in (thf) $Me_2Si{=}N{-}SitBu_3$ (N–Si 1.66 Å, Si = N–Si 161.3°[4]).

As quintessence for the description of the bonding in **3** and **4**, it follows from the experimental data that:

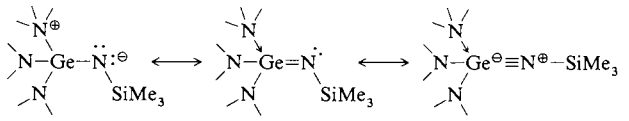
1) The germanium–iron bond in **3** is analogous to the bonding of a classical two-electron donor to a transition

metal. A back-bonding of the metal to the germanium cannot be ruled out, but if present does not lead to a drastic bond shortening. The addition of the $Fe(CO)_4$ fragment to **2** leads to a strengthening of the donor bond N3 → Ge, as can be deduced from the different ^{1}H-NMR spectra[1] (in the case of **3** no coalescence of the nonequivalent *tert*-butyl groups is observed up to 90 °C).

2) In **4**, the plane in which the N2,N3 and N5 atoms lie and the plane through the atoms Ge, N5 and Si3 are orthogonal. Hence, a p_π–p_π bond between Ge and N5 can be ruled out on geometric grounds, independently of the coordination number of Ge.

3) The donor bond N1 → Ge in **4** competes, similarly as in the case of **1**[1] in solution, with the N4 → Ge bond. This bond fluctuation has a highly negative activation entropy (ca. -96 J mol^{-1} K^{-1}), which could be explained in terms of a threefold and symmetrically coordinated germanium atom in the transition state.

4) Of the resonance structures **A**–**C**, **A** best reproduces the polar portions. Thus seen, **4** can in the broadest sense be



A **B** **C**

referred to as a neutral pendant to a germylsilylamide or disilylamide ion.[8] The stabilization of negative partial charges on N by electropositive Si has already been pointed out on a number of occasions.[9] However, the coordination geometry found at the germanium atom is not satisfactorily explained in terms of the resonance structure **A**.

The resonance structure **B** takes into account possible d_π–p_π bonds between Ge and N5 and must, by all means, also be taken into consideration besides the structure **A**. The observed Ge–N–Si angle suggests a resonance between **B** and **C**, but details of the structure would indicate that the widening of the angle is largely of steric origin.

Experimental

A solution of **2** (217 mg, 0.49 mmol) **1** in benzene (5 mL) was treated at room temperature, either dropwise with a solution of trimethylsilylazide (59 mg, 0.49 mmol) in benzene (2 mL) or with 178.2 mg (0.49 mmol) of $Fe_2(CO)_9$. The resulting solution, or suspension, was stirred for 12 h and the solvent removed by distillation. Subsequent sublimation at 80 °C/0.001 torr or crystallization from toluene, afforded 185 mg (71%) of **4** and 291 mg (97%) of **3** (yellow crystals), respectively.

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Vom Radiothor zur Uranspaltung. Eine wissenschaftliche Selbstbiographie. (Reprint of the 1st Edition). By *O. Hahn*. F. Vieweg & Sohn, Braunschweig/Wiesbaden 1988. xvi, 160 pp., hard cover, DM 78.00.—ISBN 3-528-08413-8

Of the many books on the life and work of *Otto Hahn* this one, published in 1962 in his 84th year, was the first, and it is probably the only one written entirely by him. The re-publication of the book on the fiftieth anniversary of the discovery of nuclear fission is therefore greatly to be welcomed. The description of it as a "reprint" is to be interpreted literally, as *Otto Hahn*'s text has remained completely unaltered. Even the few printing errors have not been corrected. Also unaltered are the three appendices, which are facsimiles of papers on nuclear fission: *Otto Hahn* and *Fritz Strassmann*'s "second" paper in the 1939 volume of Naturwissenschaften reporting the famous radioactive indicator experiments, and two review articles from the Abhandlungen der Preußischen Akademie der Wissenschaften for 1941 and 1944. The illustrations section has, however, been revised; the editor *Dietrich Hahn*, grandson of the author, has approximately doubled their number to 40. Also new are a preface by the editor and an introduction by *Kurt Starke*, who worked with *Hahn* from 1935 to 1940 as a graduate student and scientific collaborator.

The book is first and foremost a *scientific* autobiography; personal details are only included in special circumstances. However, it is not written in a scientific style with the customary self-effacement on the part of the author. On the contrary, *Hahn*'s temperament and his style of working become clearly apparent after only a few pages. In a relaxed and unpretentious way he describes his early youth, student days and teaching days with much anecdotal background—his famous "cock tales"—even when the point of the story is at his expense. A lucky accident—and in this book luck is often mentioned—had the effect of diverting him from a planned career as an industrial organic chemist towards radioactivity instead. Having gone to London in order to learn English, he achieved his first scientific success in 1904 in *William Ramsey*'s laboratory, in a way that was typical of him: while separating radium from barium salts by fractional crystallization the mother liquor was unexpectedly found to be still weakly radioactive afterwards. This "residue effect" led him to discover a new member of the natural radioactive decay series, radiothorium (thorium-228). This earned him a place in *Ernest Rutherford*'s laboratory in Montreal, and eventually, in 1906, in that of *Emil Fischer* in the chemistry department of Berlin University. There he made his next important discovery, that of mesothorium-1 (radium-228), which was soon greatly in demand for radiotherapy as an alternative to the considerably more expensive radium. However, the greatest discovery escaped him: despite the fact that he had made more unsuccessful attempts than *Frederick Soddy* at separating closely similar "radioelements" (p. 46), it was *Soddy* rather than *Hahn* who arrived at the concept of isotopes which was the key to this problem.

In 1907 he gained his Habilitation under *Fischer*. In the same year there began the collaboration with the physicist *Lise Meitner*, which was excellent both scientifically and from a personal standpoint. *Hahn* had access to nearly all the known radioelements, and they now undertook a systematic study of all their radiations. While once more investigating a "residue effect", they discovered radioactive recoil. *Lise Meitner* gradually made a reputation for herself in this environment, in which the attitude towards women was one of disapproval. In 1912 the two moved to the new Kaiser-Wilhelm-Institut für Chemie, which was another stroke of luck, since *Otto Hahn* had scarcely any prospects for a university career in his field of work; he was regarded by chemists as a physicist, whereas to physicists he was a chemist. He turned his attention to the radioactivity of the elements potassium and rubidium; out of this work was developed, twenty years later, the rubidium-strontium method for determining the age of geological samples. The laborious studies of radioactive decay series, interrupted by *Hahn*'s and *Meitner*'s war service, reached their high point in 1918 with the discovery of element 91, protactinium. Once again it was a "residue effect" in protactinium-234 which led to *Hahn*'s discovery in 1922 of the first example of nuclear isomerism, although it was not fully understood until many years later.

The paths of *Otto Hahn* and *Lise Meitner* now diverge. Although *Hahn* continued to provide support for *Lise Meitner*'s detailed studies of radioactive emissions, which eventually led *Wolfgang Pauli* to the discovery of the neutrino, *Hahn* himself now turned, with the help of his now numerous collaborators, to applied radiochemistry. He used radioactive isotopes to investigate chemical problems such as the chemistry of substances in extremely small quantities, or—by using his "emanation method"—the modification of surfaces, the structures of solids, and solid-state chemical reactions. In 1933 he gave a series of lectures at Cornell University, Ithaca, which subsequently appeared in the form of a book. Worried about political developments and about the fate of Jewish friends and colleagues, he cut short his stay there. In January 1935 he courageously gave the keynote address at the remarkable memorial service for *Fritz Haber*. From a scientific point of view this was the least productive period in *Hahn*'s life. At that time, as *Kurt Starke* describes it, the younger research collaborators felt that nothing more remained to be discovered in radiochemistry.

However, that verdict was premature. In the spring of 1934 *Enrico Fermi* and his collaborators reported the discovery of the first transuranic element, number 93, resulting from the irradiation of uranium with neutrons. Nevertheless there were objections to this: might not the element be protactinium instead? *Lise Meitner* and *Otto Hahn*, acknowledged authorities on matters related to protactinium, resumed their work together, and were soon joined by the young *Fritz Strassmann*. The results became more and more complex; it emerged that there were two decay series of transuranic elements which extended as far as element 96. For thorium too several isomeric decay series were found, but in this case they corresponded to known elements, begin-

ning with radium. In the summer of 1938 events took a dramatic turn: *Lise Meitner* was forced to flee the country, while *Irène Curie* and *Paul Savitch* in Paris discovered a transuranic element whose chemical properties certainly did not fit into the scheme of the Berlin team. *Hahn* and *Strassmann* at first identified this activity as due to radium, but after further work aimed at rigorously verifying this surprising result they revised their verdict and identified barium—thus uranium fission was discovered. A hesitant first communication was followed soon by the second paper which is reprinted here, providing certain confirmation through a whole series of brilliant radiochemical indicator experiments. In the fractional crystallization of barium salts the activity obtained from uranium became uniformly distributed through all the fractions, whereas natural radium added at the same time became selectively concentrated in the top fractions. These fractionations were the same as those which *Hahn* had performed in his student days in *Ramsey*'s laboratory, and the most important indicator for radium was mesothorium-1, *Hahn*'s own discovery. In this remarkable way the nearly sixty-year-old scientist had thus returned to the starting-point of his researches.

Otto Hahn does not discuss the further developments leading to the atomic bomb, since the team at the Kaiser-Wilhelm-Institut was not involved in this aspect. Nor do we learn anything about the German "uranium club". The political tensions in the Institute receive equally little attention. The fact that *Hahn* was under extraordinary pressure at that time can be best only be inferred between the lines: the anecdotal detail no longer appears, the tone becomes more serious. He summarizes the work of chemically unravelling the complex mixture of fission products, and the results thus obtained. He relates with satisfaction how, using primitive resources, they identified 100 products, and speculates about which of the fission products might have been mistaken for "transuranics". From the pre-war research only uranium-239 remains as having been unambiguously identified as such by *Hahn, Meitner* and *Strassmann*. However, its decay product, element 93, proved very difficult to find in Berlin. The final chapter is brief: a few sentences about *Hahn*'s internment in England, the Nobel Prize for Chemistry in 1944, the presidency of the Max-Planck-Gesellschaft.

The illustrations section has grown in size compared with the first edition, as *Dietrich Hahn* has chosen to include some photographs relevant to the period. Some of these are of great interest, such as the "Sofabild" of 1920 (p. 88), showing *Lise Meitner* and *Otto Hahn* with their circle of friends—*Herta Sponer, Einstein, Grotrian, Westphal,* the *Francks, Otto von Baeyer, Peter Pringsheim, Haber, Hertz*. What a remarkable élite was gathered there!—and what happened to them? However, some changes in the selection of photographs will be a cause of regret. For example, Kaiser *Wilhelm* the second arriving in uniform at the formal opening of the Chemie-Institut, followed by *Adolf von Harnack* and *Emil Fischer* wearing top-hats, is so typical of the period that one would have liked to see this photograph (1st Edition, p. 61) still included.

Kurt Starke evokes the atmosphere in *Hahn*'s research institute from the viewpoint of a young member of the team. One gains an impression of the rather simple way in which the laboratory was furnished, and of the strict safety precautions against radioactive contamination; one senses the cordial atmosphere, but also the clear division between the leader's immediate team and the younger members. For the latter, the first news of the successful experiments carried out around the turn of the year in 1938/39 came when the work was published.

Otto Hahn's book ends with a backward look, in which he represents his scientific career as a succession of lucky events. This probably has something to do with his Rhineland-Hessen temperament, which always looks at the positive side of a situation. The fact that there were also low points, such as the propagation over several years of the transuranic elements, which eventually faded away, is not apparent from the book, but only from the correspondence between *Hahn* and *Meitner*. Nevertheless, *Hahn* and *Strassmann* were able to correct their error by making a discovery of even greater importance. Of course there are many questions that remain unanswered: what prompted *Hahn* and *Strassmann* to carry out the apparently superfluous radioactive indicator experiments?—how were tasks distributed, and what was the nature of the interactions, in the *Hahn-Meitner-Strassmann* team?—and many more. However, one can learn a great deal from this book without necessarily wishing to go into radioactive phenomena in greater depth: concerning, for example, how science advances not by logical steps in an orderly sequence, but by circuitous and often strange routes; how the most experienced research groups can continue for years with experiments and theories which miss the point; how, on the other hand, they can be set on the right track by a lucky stroke of intuition; and how a scientist may return, decades later, to something which he worked on as a novice. One therefore hopes that this book will be read especially by young scientists. Some will look here for some comments on nuclear energy by the man who has often been called the "father of the atomic era". *Otto Hahn* devotes only half a sentence in the foreword to this topic—it seems that he did not see himself in that role.

Nitrosamines. Toxicology and Microbiology. (Ellis Horwood Series in Food Science and Technology). Edited by *M. J. Hill*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York/Ellis Horwood, Chichester 1988. 169 pp., hardcover, DM 180.00—ISBN 3-527-26708-5/0-89573-605-0; ISSN 0930-3332

Many nitrosamines are highly toxic, carcinogenic and genetically harmful. Owing to their organ-specific carcinogenic properties and their occurrence in foodstuffs, cosmetics and tobacco smoke, and in work-places, together with the fact that they can be formed endogenously in the human body, there has been widespread interest in this class of compounds in experimental cancer research and in environmental health studies.

The main emphasis in this book is on the importance of nitrosamines in relation to human health. The eight chapters by various authors cover methods for detecting *N*-nitroso compounds in biological samples, the chemistry of *N*-nitrosylation reactions, mechanisms of endogenous *N*-nitrosylation, the occurrence of *N*-nitroso compounds in the human environment, the toxicology of *N*-nitroso compounds, and the role of these compounds in inducing human cancers. A further chapter suggests ways in which the risks of nitrosamine-induced cancers can be minimized.

Impressive characteristics of the book are the systematic and well-disciplined structure of the individual chapters, and the detailed references to original publications (extending up to 1988 in some parts). The book deals with all important aspects of the topics treated, and the reader is enabled to

quickly locate the relevant original papers. Another feature likely to be useful to the non-specialist is that gaps in current knowledge are clearly pointed out.

To summarize, the book is a sound introduction to and overview of this subject for all chemists with an interest in nitrosamines, and for foodstuff and pharmaceutical chemists, biologists and medical scientists; it can be unreservedly recommended.

The Chemistry of Organic Silicon Compounds. Parts 1 and 2. Edited by *S. Patai* and *Z. Rappoport*. Wiley, Chichester 1989. Part 1: pp. 1–892; Part 2: pp. 893–1668, hardcover, £ 350.00.—ISBN 0-471-91441-X (Pt. 1)/0-471-91992-6 (Pt. 2)/0-471-91993-4 (set)

In the preface to the two latest volumes in the series "The Chemistry of Functional Groups" the editors write: "The chemistry of organic silicon compounds is one of the fastest growing fields in organic chemistry". In 25 chapters the 32 authors of these volumes, most of whom are very eminent, offer proof of this statement. Such a comprehensive treatment of organosilicon chemistry was long overdue; as well as the classic works in this field, such as *C. Eaborn*'s "Organosilicon Compounds" of 1960, the 1968 article by *C. Eaborn* and *R. W. Bott* in "Organometallic Compounds of the Group IV Elements" (edited by *A. G. McDiarmid*), and the seven-volume "Handbook of Organosilicon Compounds" (edited by *V. Bažant, V. Chvalovský* and *J. Rathouský*, published in 1965 and 1973, and mainly arranged under individual compounds), there are also numerous annual reviews and monographs on particular compound classes, but no comprehensive and up-to-date treatment of the whole field.

The recent blossoming of organosilicon chemistry owes much to the unsaturated compounds, most of which were isolated or proved to exist only in the last few years, and which keep reappearing under different topics like a red thread running through many of the articles. The editors have nevertheless managed to avoid too much overlapping of subject matter, resulting in a well-integrated and up-to-date treatment of this aspect.

The introductory chapter, in which carbon and silicon are compared (*J. Y. Corey*, 56 pp.), reads in some parts like a summary of the articles which follow. Next there is a brilliant account of the theoretical treatment of organosilicon compounds (*Y. Apeloig*, 170 pp.). Embedded in two useful reviews dealing with structural chemistry (*W. S. Sheldrick*, 38 pp.) and thermochemistry (*R. Walsh*, 21 pp.) is a description of the dynamic stereochemistry of silicon compounds (*R. J. P. Corriu, C. Guerin* and *J. J. E. Moreau*, 66 pp.). Although a similar article by the same authors appeared not long ago in another series (*Top. Stereochem. 15* (1984) 43), a definitive article of this sort is worth reading for a second time, especially as it has been updated and expanded. Regrettably, the same does not apply to the article on the analysis of organosilicon compounds (*T. R. Crompton*, 52 pp.), which has been repeated virtually unaltered from Volume 2 of the series "Chemical Analysis of Organometallic Compounds", published in 1974 (!). Nowadays it seems strange that only gas chromatography and IR spectroscopy are discussed in detail as modern instrumental methods.

In the exemplary way expected of these authors, *H. Schwarz* deals with the gas phase ionic chemistry of organosilicon compounds (64 pp.), while *H. Bock* and *B. Solouki* describe their photoelectron spectra (98 pp.). The latter article is a pleasure to read because of the many clear illustrations and the critical comments that are interspersed. Between these two articles there is a short contribution on ^{1}H, ^{13}C and ^{29}Si NMR spectroscopy (*E. A. Williams*, 44 pp.).

The central item in previous monographs on organosilicon compounds, namely a discussion of methods for forming Si–C bonds, here reappears in a less obvious form as Chapter 10 (106 pp.), in which *L. Birkofer* and *O. Stuhl* collect together methods for the preparation of organosilanes, including compounds which contain SiN, SiO, SiS, SiSe and SiTe functional groups. After a digression into synthetic applications of various organosilanes (*G. L. Larson*, 46 pp.), *A. R. Bassindale* and *P. G. Taylor* deal with the acid-base and complex-forming properties of organosilanes (30 pp.). The same authors have also written the chapter on the mechanisms of nucleophilic attack at silicon atoms (54 pp.), and that on activating and directing effects of silicon (71 pp.), which is perhaps of particular interest to the preparative organic chemist.

The contributions by *A. G. Brook* on photochemistry (42 pp.), *R. Tacke* and *H. Linoh* on organosilicon compounds in biochemistry (64 pp.), and *R. West* on polysilanes (34 pp.) are, as one expects from these authors, competently written and highly topical. The chapter by *G. Raabe* and *J. Michl* on multiple bonding to silicon (128 pp.) was awaited with some anticipation, since at the end of 1985 the same authors published an article on the same subject in *Chemical Reviews*, which was not merely long but of high quality. By leaving out aspects which have been treated in other chapters of this book, thus shortening it (!), and by updating it, the authors have again produced an excellent critical evaluation of the literature on this topic.

Although the notion of "hypervalence" is not universally accepted, *R. J. P. Corriu* and *J. C. Young* give, under this title, a review of penta- and hexacoordinated silicon compounds (48 pp.) which is well worth reading. In the short chapter (8 pp.) by *J. B. Lambert* and *W. J. Schulz* on trivalent silyl ions, the opportunity to explain the reasons for the considerable error and confusion which has arisen regarding the evidence for $R_3Si^{\oplus}$ ions in solution is unfortunately allowed to slip by; this would have provided an understanding of the definite proof now emerging for the existence of such ions.

Silicones, whose annual production in the western world has now reached a value of around $ 3 billion, receive a due amount of attention in the contribution by *T. C. Kendrick, P. Parbhoo* and *J. W. White* on siloxane polymers and copolymers (80 pp.); this includes the manufacture of silicones and their present and potential applications, and also those of the organofunctional polysiloxanes which are still relatively new.

After two short articles by *D. A. Armitage* on phosphorus, arsenic, antimony and bismuth derivatives (32 pp.), and on SiS, SiSe and SiTe compounds, there is a more extensive review of transition metal-silyl derivatives by *T. D. Tilley* (63 pp.). The text part of the book then ends with an informative chapter on hydrosilylation reactions (*I. Ojima*, 48 pp.).

At the end of the second volume are a name index of cited authors and an index of compounds. Difficulties can sometimes arise when using the compounds index, due to the fact that the nomenclature is not always consistent, but the name

index is pleasingly free of errors. However, this reviewer was surprised to find that a well-known Munich chemist seemed to have acquired an aristocratic title.

The two volumes are well produced, and the structural formulas are clear and easy to read. Some occasional instances where an R has been omitted from a formula or silicon has apparently become sulfur are almost unavoidable. Errors that one notices instantly are few. Examples of such are on page 1343, where the hydrosilylation mechanism has been incorrectly taken from the original paper, and on pages 659–660, where a synthetic route is given for tetracyclohexylsilane which was refuted as long ago as 1966.

The literature coverage is claimed to extend to mid-1987, and sometimes to the beginning of 1988. This has been achieved in most, though not all, cases.

The editors indicate in the preface that the originally intended chapters on "Silyl radicals, silylenes and rearrangements" and on "Silicon-nitrogen bonds" could not be included. This is regrettable, since considerable advances have been made in these areas especially in the last few years. Thus, for example, it has proved possible to isolate a large number of silanediyls (silylenes) in matrices. Trapping reactions of these intermediates have yielded various novel cyclic and open-chain compounds.

These two volumes are definitely a must for all university libraries. There is some confusion regarding the price information given by the publishers, since a large international book supplier in West Germany quoted a price of more than DM 1700 for the two volumes!

Manfred Weidenbruch [NB 991 IE]
Fachbereich Chemie
der Universität Oldenburg (FRG)

Application of Pattern Recognition to Catalytic Research. By *I. I. Ioffe*. Research Studies Press, Letchworth/Wiley, Chichester 1988. viii, 188 pp., hard cover, £ 30.50. – ISBN 0-86380-069-6/0-471-91907-1

In this monograph the author presents a survey of quantitative methods for the optimization of heterogeneous catalysts. The methods described, which belong to the category called "pattern recognition", are based on searching for correlations between the activity and selectivity of catalysts and their chemical composition and properties. Properties such as the specific surface area and density of the catalyst, and the electron affinities, lowest ionization potentials and ionic radii of the elements present, together with many other variables, have a major role in determining the catalytic activity. Since in many cases there is not a simple linear relationship between these properties and the activity and selectivity of the catalyst, statistical methods are used to analyze the data. The required data must either be taken from the literature or determined by experiment. It is important to base the analysis on a large number of catalysts for the reaction being investigated.

The first stage is to classify the catalysts into three groups with high, medium and low selectivities, and to correlate these with the properties of the catalysts concerned. On the basis of the properties that show the best correlations, one can now allocate new catalysts, which have not yet been investigated, between these three groups. Finally, experiments must be carried out to test whether or not the method of classification is appropriate. The purpose of such a study is to reduce, by appropriate preselection, the number of experiments that are needed to evaluate new catalysts. The questions of how reliable this classification is, and whether it is likely to result in an active catalyst being rejected too soon because of wrong classification, is determined, among other factors, by the quality of the data used and of the computer model. Accordingly, the greater part of the book is devoted to a discussion of the various models for heterogeneous catalysts with one or more components. The capabilities and limitations of the method are illustrated by examples such as the aromatization of dodecane, the oxidation of arenes, and the synthesis of isoprene from formaldehyde.

The monograph makes easy reading, and gives an insight into the relationships between the molecular properties of catalysts and their activities. However, those wishing to learn about the technique in greater depth so as to apply it in their own research will need to consult the original papers. Most of these are only available in Russian, as can be seen from the references listed. Consequently the book is of only limited value to the experimentalist in his day-to-day work. It is aimed more especially at readers who are involved in the theoretical aspects of catalysts, or who are engaged in long-term development work on large-scale chemical processes and need to evaluate large amounts of data.

Active MgH_2–Mg Systems for Reversible Chemical Energy Storage

By Borislav Bogdanović,* Alfred Ritter, and Bernd Spliethoff

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

An overview of the importance of and methods available for heat storage in the form of sensible and latent heat is followed by a discussion of the advantages and disadvantages of reversible thermochemical energy storage compared to conventional energy sources such as fuels, i.e. irreversible chemical energy carriers. Of the reversible metal-hydride–metal systems, the MgH_2–Mg system is particularly attractive as a hydrogen and a high-temperature heat storage material because of its high hydrogen content and the high energy content of the Mg–H bond. The advances made in this area over the past few years, namely in catalytic hydrogenation and the doping of magnesium powders, have led to the development of "active MgH_2–Mg systems" for energy storage. The first experimental results on high-temperature heat storage (also with cooling) by coupling a MgH_2–Mg storage system with a low-temperature metal hydride storage system are presented.

1. Introduction

For thousands of years—ever since the discovery of fire—mankind has conveniently satisfied its energy needs by burning wood or fossil fuels, thus liberating, in the form of high grade heat, solar energy which had been stored chemically for years (or millions of years) by photosynthesis. The energy problem currently facing us primarily arises from an incorrigible disparity between the storage of solar energy in nature and our energy consumption, which will lead, on the one hand, to a serious shortage of fossil fuels and, on the other, most probably to a climatic change through a build-up of carbon dioxide in the atmosphere ("greenhouse-effect"). This problem may be resolved, however, by: 1) reduction of the use of fossil fuels in favor of other energy sources, such as nuclear power, water power and wind power; 2) intelligent, more economical energy consumption;[1] 3) the search for, and use of energy storage systems which obtain their energy from a primary energy source, e.g. from the sun, and whose energy transformations occur in a closed cycle and hence are environmentally unobjectionable.[2] The following review article describes, inter alia, an experimental chemical contribution to the last of these three possibilities.

2. The Importance of Energy and Heat Storage, especially of High-Temperature Heat Storage[3]

The necessity of energy storage in general, and of heat storage in particular, arises from the fact that there is a temporal and intensity mismatch and also a spatial separation between the energy supply from an available energy source and our need or consumption of energy. Energy storage can offset this incongruity, improve the efficiency of an

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0303-0223 $ 02.50/0

energy supply system and hence reduce the energy costs. Consequently, energy storage is a major factor in energy saving and conservation. The storage of energy from a periodic or intermittent energy source, such as the sun, is of prime importance.

The type and magnitude of the mismatch between energy supply and need are exemplified in Figure 1.[4] Figure 1 (a) shows the case of constant energy supply with, however, a brief peak load which must be covered by energy storage. In case (b), the energy supply is periodic (solar energy), while the energy requirement remains constant; a significant part of the energy must, therefore, be stored during daytime in order to cover the needs at any time. Finally, when energy supply and demand are out of phase, as in (c), the total energy requirement must be stored (e.g., nocturnal indoor heating via solar heat).

The potential significance of heat storage, is impressively demonstrated by the fact that sufficient solar energy could be collected on the roof of a building during the summer for covering the heating requirements of the building during the winter (Fig. 2). In the case of a typical one-family house *in Germany* with a roof surface of 100 m^2—either facing south or oriented horizontally (flat roof)—an average incident solar radiation of 10^5 kWh[5] could be collected per year. This energy is sufficient to produce an amount of warm water equivalent to that requiring approximately 10000 L of heating oil, i.e., an amount which is more than adequate for heating a household during the winter. If one could make use of this energy in all of the households in the FRG, then up to ca. 40% of the currently consumed primary energy could be saved.

The amount of warm water whose energy content on cooling from, e.g., 90° to 40 °C corresponds to that of 10000 L of heating oil has however, in the ideal case, i.e. without heat storage loss, a volume of 1724 m^3. This is far larger than the volume of an average one-family house. Because of the unavoidable heat losses which constantly occur due to insulation problems, the volume of the warm-water storage tank would have to be substantially larger. Thus, it is immediately apparent that the, as yet, unsolved problem of *seasonal heat storage* is the main reason why solar radiation can presently play only an insignificant role as a source of energy, particularly in more northerly latitudes.[5,6]

An important aspect in connection with the amount of stored heat, namely the quality of the energy, or the so-called "exergy", should not be overlooked. Heat energy can be converted into other forms of energy with good Carnot efficiency, e.g. mechanical or electrical energy, but only above

Borislav Bogdanović was born in 1934 in Novi Sad, Yugoslavia and studied chemistry at the University of Belgrade. He gained his doctorate in 1962 under the supervision of G. Wilke at the Technische Hochschule Aachen. Since 1960 he has been working at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr, where he is now head of a catalysis department. Bogdanović habilitated in 1974 at the Universität Bochum where he was awarded a professorship in 1976. His research interests center on organometallic chemistry and catalysis and its applications in organic and inorganic synthesis; in 1986 he was awarded the Ruhrpreis für Kunst und Wissenschaft der Stadt Mülheim an der Ruhr for his more recent works on the storage of energy with the MgH_2–Mg system.

Alfred Ritter was born in 1928 in Rottweil am Neckar and studied chemistry at the Technische Hochschule Stuttgart (where he gained his doctorate under L. Birkofer). Thereafter he worked as a scientific assistant at the Universität Köln and was engaged in research on organosilicon reactions in organic synthesis. In 1963 he was awarded a fellowship grant by the Dow Corning Corporation (Midland, Michigan) for research with L. H. Sommer at the Pennsylvania State University. Since 1964 he has been in charge of a research group at the Max-Planck-Institut für Strahlenchemie in Mülheim an der Ruhr. His current interests center on the radiation chemistry of organosilicon compounds and reversible chemical reactions for the storage of solar energy.

Bernd Spliethoff was born in 1953 in Oberhausen and completed his training as a laboratory technician at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr. In 1971 he won the Bundeskanzler's Prize for young scientists in the open competition "Jugend forscht". Since completing his studies in engineering science at the Gesamthochschule Essen in 1975 he has been working at the Max-Planck-Institut für Kohlenforschung. He has participated right from the beginning in the development of active MgH_2–Mg systems as energy storers; he has developed measuring instruments and measuring techniques for the characterization of their storage properties.

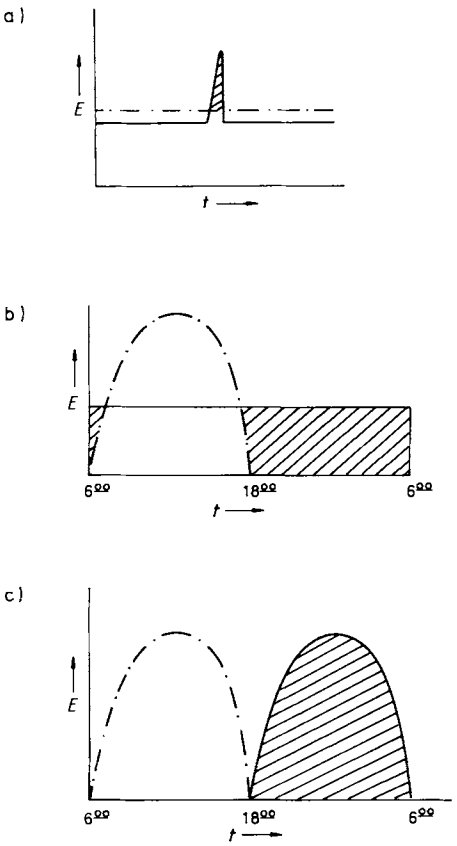

Fig. 1. Energy available from store ▨, which balances out the mismatch between energy supply (· – ·) and need (—): a) constant energy supply, short peak period; b) constant energy requirement, variable (periodic) energy supply during a half-day cycle; c) phase shift between energy supply and need; the entire energy need is covered by stored energy [3a] (reproduced by kind permission of Kluwer Academic Publishers).

300–400 °C. Consequently, energy storage systems must be developed, not only for low-temperature heat (LT) but also for high-temperature heat (HT).

An example of the *spatial* separation between energy supply and need, is provided by electrical power plants, which produce large amounts of low-grade waste heat, but owing to the distances between supply and consumer, often only part of this heat can be economically used for domestic heating ("power-heat-coupling").

3. Methods of Heat Storage

The oldest and simplest method used in everday life, as in industry, is to store heat in the form of sensible (perceptible) heat using materials having a high specific heat c. The materials most commonly used, and their heat capacities, are listed in Table 1.

Table 1. Frequently used liquid and solid materials for the storage of sensible heat [3a, b].

	M.p. [°C]	Temperature range [°C]	ϱ [g/cm³]	c [kJ kg⁻¹ K⁻¹]
Water	0	0–100	0.98 [a]	4.19
Thermo-oils	−70/−10	up to 350 [b]	0.87 [a]	2.1
53 KNO_3/40 $NaNO_2$/ 7 $NaNO_3$ [c]	142	up to 450	1.85 [a]	1.3
Na	98	– –	0.84	1.26
Cast iron	1150–1300	– –	7.2 [d]	0.54

Concrete	–	– –	–	0.9

[a] Average density in the temperature range given. [b] Some thermo-oils can be used up to 390 °C. [c] Wt.%. [d] At room temperature.

A further basic method for reversible heat storage consists in storing the heat evolved in a solid–liquid phase transition process in the form of latent heat. The advantage over the storage of sensible heat is the higher energy density and that the temperature remains constant during the heat storage and heat recovery processes. In contrast to the systems for the storage of sensible heat, those for the storage of latent heat are still at an early stage of development. A list of possible materials for this purpose is given in Table 2.

Table 2. Data for several potential latent heat stores [3a, b].

	M.p. [°C]	Heat of fusion [kJ kg⁻¹]

[a] Wt.%.

The demand for high energy content per unit weight and volume especially in the case of mobile energy carriers,[7] as well as high exergetic quality and constant temperature, together with an unlimited storability of the stored energy, usually can only be satisfied by chemically stored energy, i.e., by fuels and not by sensible heat. An advantage of chemically stored energy is its direct transformability not only into heat, but also into other forms of energy with high efficiency (e.g., into electrical energy via fuel cells). The basic proce-

dures for transforming heat energy into chemical energy are dealt with in the following section.

4. Energy Storage from the Chemist's Viewpoint; Reversible and Irreversible Chemical Energy and Heat Storage

A list of the best-known fuels and their energy densities is given in Table 3. In general, the energy densities of the conventional energy carriers are much higher than those of the potential reversible chemical energy storage systems (Table 4). One should, however, take into consideration that these high energy densities arise from the fact that the combustion process generally occurs in an open system in the presence of oxygen from the environment, and this oxygen is not taken into account in the energy density calculation.[8] If the combustion were to take place in a closed system and if the amount of the consumed oxygen were to be considered in the calculation of the energy density, then, e.g., in the case of hydrogen as a rocket propellant the energy density would drop to 14×10^3 kJkg^{-1} and in the case of gasoline to 10×10^3 kJkg^{-1}.

Table 3. Most common fuels and their energy densities.

Fuel	Energy density [kJ kg^{-1}]
Hydrogen	125×10^3
Methane	48×10^3
Petrol	44.5×10^3
Heating oil	39.6×10^3
Coal	29.9×10^3
Wood	15.1×10^3
Ethanol	28.8×10^3
Methanol	21.6×10^3

A major disadvantage, both in the case of conventional energy sources and of hydrogen[9] (Table 3) is the practical irreversibility of the combustion reaction. The combustion processes occur at temperatures much lower than those at which the combustion products CO_2 and H_2O are in thermodynamic equilibrium with fuels and oxygen. This means that the regeneration of the combustion products CO_2 and/or water in fuels and O_2 by direct thermochemical pathways is not feasible because of the extremely high temperatures which would be required. The indirect thermochemical[10] procedures for achieving this for water are presently being intensively investigated, while the photochemical methods[11] are still at an early stage of development.

In the following, we will concentrate on the problems of heat storage. Its importance becomes immediately apparent through the fact that, apart from the fossil energy sources, the major remaining primary energy sources—nuclear energy and solar energy—deliver their energy in the form of high-quality heat or in the form of electromagnetic radiation which can immediately be converted into high-quality heat.

Independent of the fact, whether nuclear or solar energy is the primary energy source, it is necessary to search for new, reversible (i.e., closed), ecologically compatible cycles for heat storage. These should preferentially be reversible chemical systems, as mentioned in the previous section. This poses the question: How can heat be reversibly transformed into chemical energy?

In the reversible thermochemical[12] storage of energy the heat of a reversible chemical reaction is stored in the form of chemical energy. Thus, a compound of, e.g., type A–B can, by take up of heat (positive ΔH, endothermic process, heat storage), dissociate reversibly into the components A and B (molecules or atoms) and hence transform the heat energy ΔH into the chemical energy of the system A + B [Eq. (a)]. If the reverse reaction of A + B to A–B is prevented by

$$\text{A–B} + \Delta H \underset{\text{heat recovery}}{\overset{\text{heat storage}}{\rightleftharpoons}} \text{A} + \text{B} \qquad \text{(a)}$$

separating A from B, or by the absence of a catalyst in the case of a catalytic reaction, then the amount of heat ΔH stored in chemical form can be stored without any loss. On combining A and B or on catalysis, the reaction proceeds in the opposite sense liberating the amount of heat ΔH[13] (exothermic process, heat recovery). If A–B and A + B are in chemical equilibrium, then displacement of the equilibrium in favor of A + B or A–B will depend on the amount of heat added to or withdrawn from the system ("self-regulating systems", "chemical heat buffer").

Two thermodynamically based criteria must be fulfilled by potential chemical reactions for heat storage: for high energy density a high heat of reaction ΔH is required; for technical reasons the reaction must be reversible in a temperature region adjusted to that of the heat source. The temperatures should not be too high (for instance, above 1000 °C), because of material and heat insulation problems.[14] As will be shown in the following, high energy densities can generally only be achieved in reactions which have high turning temperatures T^*.[15] In other words: The reversibility of a chemical reaction at an acceptably low temperature can only be achieved by loss of energy density, i.e. compared to the case of irreversible heat storage (fuels), compromises concerning the energy densities must be accepted.

For a chemical reaction at equilibrium, Equation (b) holds true.

$$\Delta F = \Delta H - T\Delta S = 0 \qquad \text{(b)}$$

According to this the turning temperature is, to a first approximation,[15] given by Equation (c).

$$T^* = \frac{\Delta H}{\Delta S} \qquad \text{(c)}$$

It therefore follows that the turning temperature T^* does not exceed a certain value, and high energy densities (cf. ΔH) can only be achieved if the reaction proceeds with large entropy changes (ΔS).[8, 16] The highest entropy changes occur in dissociation reactions with gaseous reaction products and with large differences in the number of moles of starting materials and reaction products [see, e.g., Eq. (d)].[16]

$$NH_4HSO_4\ (\text{liq.}) \rightleftharpoons NH_3\ (g) + H_2O\ (g) + SO_3\ (g) \qquad \text{(d)}$$

According to *Alefeld*,[17] the so-called heterogeneous vaporization reactions (i.e. reactions of type (e)) are especially suitable for heat storage.

$$\text{A–B (solid or liquid)} + \Delta H \underset{\text{heat recovery}}{\overset{\text{heat storage}}{\rightleftharpoons}} \text{A (solid or liquid)} + \text{B (gaseous)} \qquad \text{(e)}$$

In these reactions the turning temperature T^* is relatively low and in addition the different aggregation states allow simple separation of A from B. The thermodynamical and technical advantages of heterogeneous vaporization are counterbalanced by the disadvantage of the considerable increase in volume, which lowers the volumetric energy density of the total system (for a solution of this problem in the case of the MgH_2–Mg system, see Section 6).

The energetic and thermodynamic factors are not the sole factors which are important for the choice of reactions for reversible heat(energy)storage. Other criteria such as the following may also be important or even decisive:

- complete reversibility of the reaction over a large number of cycles, i.e., no side reactions and hence no loss of storage capacity;
- excellent kinetics of the heat storage and recovery processes; long stability and activity of the catalyst in the case of catalytic reactions;
- possibility of stopping or controlling the heat producing process by separation of the components from each other or from the catalyst;
- minimal heat loss by thermal radiation;
- heat storage and recovery in desired temperature ranges;
- as constant and controllable as possible a temperature during the heat recovery process;
- simple realization and low processing costs;
- no (or only minor) hysteresis effects; low temperature differences between storage and recovery, i.e., minimal exergy loss;
- excellent heat transport to and from the reaction bed;
- availability of the storage material in large amounts and at low costs;
- no environmental or fire risks on handling the storage material and carrying out the storage reaction; low toxicity or corrosiveness of the materials used.

In view of the many criteria, it is obvious that the choice of the reactions must involve compromises.

Some examples of the best-known types of reactions which have been suggested for reversible thermochemical heat storage or which are presently being investigated are given in Table 4. Of the catalytic gas dissociation reactions, the dissociation of SO_3 to SO_2 and O_2 (Solchem process) and the dissociation of NH_3 to give N_2 and H_2 have been particularly well investigated or considered as reversible reactions for the storage of solar energy. The technically mature NH_3 dissociation (catalysis of forward and reverse reaction, separation of the reactants, corrosiveness and toxicity) is considered to be less problematic than that of SO_3 dissociation.[18] The thermal dissociation of NH_4HSO_4 is a potential candidate for energy storage because of the high energy density and relatively low reaction temperature. The Eva-Adam process now being operated on a pilot-plant scale at the nuclear research center Jülich (West Germany) is based on the known steam reforming of methane to CO and H_2. This process was developed for the transportation of nuclear reactor heat to distant users according to the principle of the chemical heat pipe.[19]

Because of the necessity of complete reversibility, i.e., absence of side reactions, the organic chemical reactions that were considered, apart from the methane reforming reaction, included only the reversible catalytic dehydrogenations of cyclohexane, methyl cyclohexane, and ethane to benzene, toluene, and ethene, respectively.[20]

All of the remaining reactions in Table 4 belong to the category of heterogeneous vaporization reactions. Of the

Table 4. Several potential reversible reactions for the thermochemical energy storage [3a, b].

Type of reaction	Examples	Temperature range [°C]	Energy density [kJ kg^{-1}]
Catalytic or thermal dissociation	$SO_3 \overset{Cat.}{\rightleftharpoons} SO_2 + 1/2\ O_2$ [a]	520–960	1235

[a] Solchem process.

dehydration reactions, slaked lime, $Ca(OH)_2$, has been particularly well investigated for the storage of solar heat, as have also the salt hydrates (e.g., $MgCl_2 \cdot 6\,H_2O$) and H_2SO_4, in addition to the reversible *adsorption* of water on zeolites.[21] In contrast, the thermal dissociation of metal carbonates and the reversible thermal dissociation of several metal oxides and peroxides ("reversible oxidation") have hardly been investigated for heat storage purposes. Apart from the advantage of easy separation of the gaseous reaction products from the solids, positive aspects in the dehydration and in the thermal dissociation of ammoniates and carbonates include the easy condensation of water vapor, NH_3 and CO_2, which means that large spaces for interim gas storage are not required. A particular advantage of "reversible oxidation" compared to other reversible reactions would be the possibility of storing heat in an open system.[8]

Apart from very few exceptions (Eva–Adam process,[19] the $Na_2S \cdot H_2O$ system[22]) the reactions mentioned have thus far only been investigated on a laboratory scale. In many cases, the suitability of the proposed reactions was only estimated on the basis of available physicochemical data, while chemical investigations of the systems under conditions relevant for heat storage and recovery or tests during various cycles have not been carried out. It is thus obvious why all of the present large-scale solar thermal storage systems are based only on sensible heat.[23]

5. Metal Hydrides as Reversible Chemical Energy Stores

Numerous metal-hydride–metal systems fulfill many of the criteria required for reversible thermochemical heat storage.[24] A special feature of the reversible metal-hydride–metal reactions compared to other heterogeneous vaporization reactions (cf. Table 4) is that the hydrogen liberated during the thermal loading is the chemical fuel having the highest energy density (cf. Table 3), and it is considered as the possible future clean secondary energy source.[9]

$$MH_n + \Delta H \underset{\text{heat recovery}}{\overset{\text{heat storage}}{\rightleftharpoons}} M + n/2\,H_2 \qquad \text{(f)}$$

M = metal, metal alloy, intermetallic compound

Since the reversible reaction of many metals, metal alloys and intermetallic compounds with hydrogen [Eq. (f), right to left] is being intensively investigated, inter alia, as a method for the safe *storage of hydrogen* with a high hydrogen density per unit weight and volume (Table 5) for the transport of hydrogen and as a fuel for motor vehicles, fuel cells etc.,[24,25] the metal-hydride–metal systems should be regarded as reversible energy stores in a double sense, namely as hydrogen stores *and* as heat stores. A fundamental difference between the use of metal hydrides as heat stores and hydrogen stores is that, in the former case, the heat of reaction of the hydride formation can be used as heat while retaining the hydrogen in a closed system during many heat storage cycles, whereas in the latter case the hydrogen is liberated from the hydride in an open system and is burned irreversibly to give water. The reversibly stored chemical energy in the case of the metal hydrides used as heat storage systems is naturally smaller than that of hydrogen as irreversible energy carrier, but it can be up to one third of the energy of the hydrogen bound in the hydride, as in the case of the MgH_2–Mg system.

The properties of many metal-hydride–metal systems as reversible hydrogen storage materials are well-known and have been thoroughly tested through many hydrogen charging and discharging cycles; such systems have already been used commercially for preparing high purity hydrogen[25] and are used technically as inherently safe hydrogen stores.[25] Their use as materials for thermochemical heat pumps and for air conditioners, has already been tested on a large scale but has not yet been commercialized.[26]

On the basis of the temperature T_d, at which the decomposition pressure reaches values of $P_{H_2} \geq 1$ bar, *Buchner*[24a] subdivided metal hydrides into low ($50 \geq T_d \geq -30\,^\circ C$ or lower) middle ($200 \geq T_d \geq 100\,^\circ C$) and high temperature hydrides ($T_d \geq 200\,^\circ C$). A list of some typical metal-hydride–metal systems used for hydrogen storage together with characteristic data is given in Table 5. The low-temperature hydrides are characterized by relatively low hydrogen contents (1.3–2.0 wt%) and low heats of hydrogenation; they thus have low energy densities as hydrogen and heat storage materials. Liberation of hydrogen from these hydrides is already achieved with small amounts of low-temperature heat (environmental heat). The low-temperature hydrides are therefore suitable, e.g., for heat pumps, air conditioners, and refrigerators (see Section 6). Disadvantageous, however, are the relatively high costs of the alloys. In the case of high-temperature hydrides, hydrogen contents of 3.8 (Mg_2NiH_4) to 7.6 wt.-% (MgH_2) are achieved. Because of the high stability of their metal–hydrogen bonds, they have high heats of hydrogenation. All of these hydrides have in common a high hydrogen storage density per unit volume of the storage material; in all cases it exceeds that in liquid hydrogen (0.075 g/cm³ at 20 K).

Table 5. Data for several energy stores used as reversible metal hydride–metal systems.

Metal hydride–Metal system	H_2 content [wt.%]	g H_2 per cm³ hydride [a]	H_2-dissociation pressure of the hydride/T	ΔH [kJ per mol H_2]	Energy density as heat store [kJ kg^{-1}]	Energy density as H_2 store [kJ kg^{-1}]
$FeTiH_{1.93}$–FeTi	1.8	0.1	3.5 bar/20 °C	28 [b]	~ 300	2200

6. Magnesium Hydride as an Energy Store; Generation and Possible Applications of Active MgH_2–Mg Systems as Hydrogen and High-Temperature Heat Stores

Since magnesium is the lightest of the metals or metal alloys which can be considered for hydrogen storage, MgH_2 has the highest hydrogen content[27] and hence the highest energy density (9 MJ/kg Mg) of all the hydrides used for this purpose. Further principle advantages of MgH_2 as an energy storage material are the low costs of magnesium metal, the wide distribution of magnesium in nature[28] and its environmental compatibility. Furthermore, hydrogen storage in the form of MgH_2 is much safer than the conventional storage technology using containers under pressure.

The disadvantage of magnesium hydride as a *hydrogen* store, is that a relatively large amount of energy [75 kJ mol^{-1}, Eq. (g)] at a high temperature level is needed

$$MgH_2 + 75\ kJmol^{-1} \rightleftharpoons Mg + H_2 \qquad (g)$$

capacity for heat storage: 0.9 kWh (3 MJ) per kg Mg

to displace the hydrogen, but this is advantageous for the MgH_2–Mg system when used as a *heat* store because, in principle, 75 kJ per mol of heat or 0.9 kWh per kg Mg can be stored at a hydrogen pressure (1 to >100 bar) dependent temperature level between 300 and about 500 °C (Table 6,

Table 6. Temperature-dependent hydrogen dissociation pressure of magnesium hydride p_{H_2}.

[a] Own measurements. [b] Extrapolated values based on own measurements.

Fig. 3). Hence, an extremely interesting temperature range is made available for possible technical uses of heat storage. Heat energy at this temperature level can be efficiently transformed into other forms of energy, in particular into mechanical energy (steam turbines, Stirling motors) and electrical energy or via thermovoltaic cells directly into electrical energy. There are no equally suitable thermochemical systems in this temperature region. Therefore, heat stores based on sensible or latent heat (Tables 1 and 2) are currently used to store high-temperature heat between 300–500 °C. In comparison with conventional heat storage materials in the same temperature range, magnesium hydride has the advantages of an energy density which is an order of magnitude higher (c.f., Table 1), and the chemically stored heat is free from losses for any length of time. In contrast to sensible heat

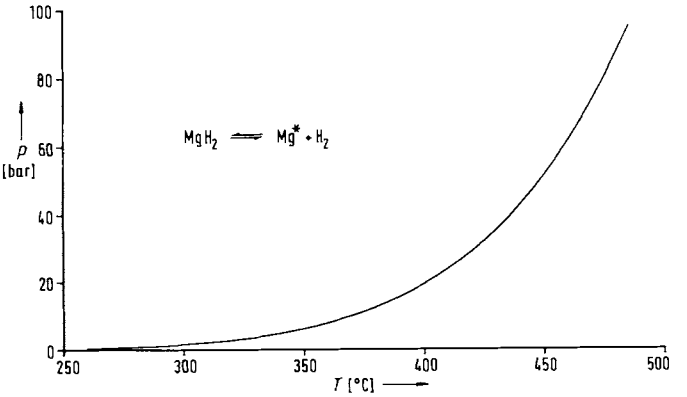

Fig. 3. Temperature dependence of the hydrogen dissociation pressure of magnesium hydride.

stores in which the temperature and hence the exergetic quality of the stored energy continually decreases during the heat discharge process (see Section 3), in the case of the MgH_2–Mg systems the exergetic quality remains constant because of the horizontal plateau of the concentration–pressure isotherm (Fig. 4) during the hydrogenation as long as the

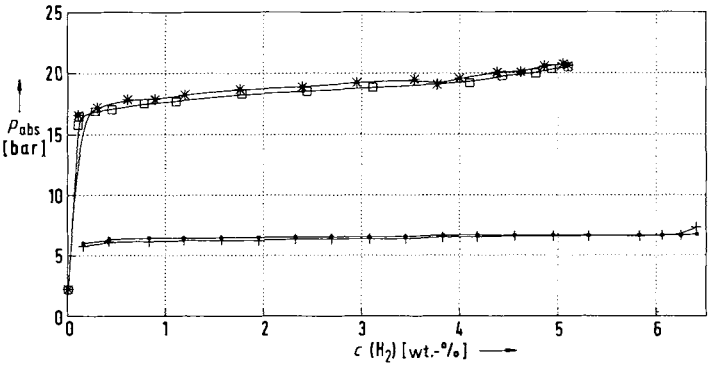

Fig. 4. Concentration-pressure isotherm for the MgH_2–Mg system (nickel-doped, 270 mesh Mg powder) at 352° (■ absorption, + desorption) and 402 °C (• absorption, □ desorption).

hydrogen pressure above the magnesium remains constant. By regulating the H_2-pressure the desired temperature level of heat generation can be maintained because each hydrogen pressure corresponds to a precisely fixed equilibrium temperature (cf. Table 6). Furthermore, the steep gradient of the hydrogen pressure in the range of 300–500 °C (Fig. 3) makes it suitable for heat transformations (raising heat to a higher temperature level) and for hydrogen compression.[26d]

The disadvantages of the hydride heat stores in comparison to heat stores based on sensible heat, are their cost, which cannot be estimated at present (no plant of this type is in operation, as yet), and the necessity of interim storage of the hydrogen liberated from the hydride. The heat conductivities are comparable with those of conventional heat storage systems or, in certain cases, even better. The intermediate storage of the liberated hydrogen in another metal–metal-hydride system which has different thermodynamic properties can be very advantageous, since the coupling of two metal hydride storage systems represents a chemical heat

pump and hence can be used for heat transformation and for cooling (see below).[26, 29]

The synthesis of MgH_2[30] from the elements was first described in 1951 by *Wiberg* and *Bauer*.[31] Ever since *Alefeld*[17] first proposed the MgH_2–Mg system as a possible candidate for heat storage because of its favorable thermodynamic properties, its use has been the subject of continued discussion. A technical evaluation concluded that there were no economic benefits over heat stores based on sensible heat,[32] mainly because of the estimated low heat conductivity of the MgH_2–Mg reaction bed and inadequate reaction kinetics. The reason for the lack of experiments in this direction is probably due to the known poor chemical reactivity of the pure MgH_2–Mg system.[33] Our own experiments have shown that the above-mentioned shortcomings do not apply to the active MgH_2–Mg systems.

Reilly and *Wiswall*[34] showed that the intermetallic compound Mg_2Ni and also magnesium that is alloyed with metallic nickel exhibit a higher hydrogenation-dehydrogenation rate than pure magnesium. This finding led to numerous experiments involving the formation of alloys of magnesium with other metals[33, 35] in order to improve the kinetics of the hydrogen charging and discharging processes. A magnesium/nickel alloy with ca. 10 wt.-% Ni[35, 36] has been considered as a hydrogen storage material for hydrogen-powered vehicles, but it could only be used in combination with a low-temperature metal hydride store or an additional heat source, since the energy content of the exhaust gases did not suffice in order to obtain the necessary high-temperature heat for displacing hydrogen gas from the store.[37]

Our chemical research on energy storage is mainly concerned with improving the kinetics of the dehydrogenation and hydrogenation steps of the active MgH_2–Mg systems. The work began with the so-called homogeneous catalytic[38] synthesis of magnesium hydride.[39] The superior kinetics of the dehydrogenation of magnesium hydride which had been prepared by homogeneous catalysis (referred to as MgH_2^* from here on), and the hydrogenation of the active magnesium (Mg*)[33, 40] obtained from it, prompted our investigations on their use as energy stores. Furthermore, MgH_2^* and Mg* found useage as reagents in organic and inorganic syntheses because of their high reactivity.[41] They have also been employed for the preparation of intermetallic compounds and their hydrides and carbides via non-metallurgic routes.[42] In the following, we shall review more recent developments in the area of energy storage (for earlier work, see Ref. [33]).

The high chemical reactivity of MgH_2^* is considered to be due to its generation in an inert atmosphere in the form of microcrystals (0.05 μm) with an oxide-free and high specific surface area (70–180 $m^2 g^{-1}$).[41] Other possible reasons for the superior dehydrogenation–rehydrogenation kinetics of MgH_2^* include the defects in the crystal lattice caused by impurities such as MgO and $MgCl_2$ and the catalytic effect of the transition metals (Ti, Cr)[43] resulting from the tetrahydrofuran-soluble hydrogenation catalysts which remain in the solid. In order to test this effect, the influence of doping MgH_2^* with small amounts of transition metals was studied using the transition metals in the form of soluble organometallic complexes or compounds and assessing the effect on the dehydrogenation–rehydrogenation. It was found that both the rate and the degree of the dehydrogenation–rehydrogenation could be improved considerably by adding small amounts (0.5–3 wt.-%) of transitional metal complexes, especially nickel complexes, to the MgH_2^*.[44]

MgH_2^*, as an energy storage material, has the disadvantages of being highly pyrophoric and of being relatively difficult to prepare. It therefore seemed obvious to use the above-described method of catalytic doping to improve the properties of the commercially available magnesium powders. This led to the development of various, relatively simple methods for the preparation of storage materials based on magnesium powders.[44]

The doping generally consists of treating finely ground magnesium powders (preferentially 270 mesh or finer) or magnesium hydride with a solution of a suitable transition metal complex, if necessary in the presence of hydrogen. In this way, the transition metal is deposited in an extremely finely divided form on the surface of the Mg or MgH_2 particles and it assumes the role of the catalyst in the hydrogenation and dehydrogenation processes. The advantages of this method are that small amounts of the deposited transition metal already have a strong catalytic effect and that the so *doped* magnesium powders become air-stable. A typical procedure consists of doping the Mg powder with a solution of bis(1,5-cyclooctadiene)nickel (cod_2Ni)[45] in toluene by passing hydrogen into the solution at room temperature under normal pressure. The nickel complex is autocatalytically hydrogenated to cyclooctane and nickel which is deposited in very fine distribution on the surface of the Mg particles [Eq. (h)].

$$\text{Mg powder (excess)} + cod_2Ni + 4\,H_2 \xrightarrow[-2c\text{-}C_8H_{16}]{20\,^\circ C} Mg(Ni) \qquad \text{(h)}$$

The Mg powder (270 mesh) doped with 2 wt.-% of nickel and obtained in this way proved to be suitable as a hydrogen and heat storage material in numerous tests and it is used at the present time as a standard material in our experiments described below. The standard material has the following properties:

- reversible hydrogen contents of 6–6.5 wt.-%,
- satisfactory and complete display of the kinetics after the first hydrogenation,
- stability over a long period, demonstrated by extended testing in a closed system through 1800 cycles,
- very little absorption–desorption hysteresis[46] and an almost horizontal plateau in the concentration-pressure isotherm (cf. Fig. 4),
- relatively good heat conductivity of the solid MgH_2–Mg storage bed during the hydrogenation and dehydrogenation (Fig. 5).[47]

A further improvement of the H_2-storage capacity and of the long term stability as well as the economic optimization of the storage material production are currently being attempted.[48]

Our present research in the area of energy storage is focused on the use of active MgH_2–Mg systems as high temperature heat stores.[8, 29] A heat store based on MgH_2, operating on the principle shown in Equation (g), consists essentially of a pressure-proof container interconnected with a second container for the intermediate storage of the de-

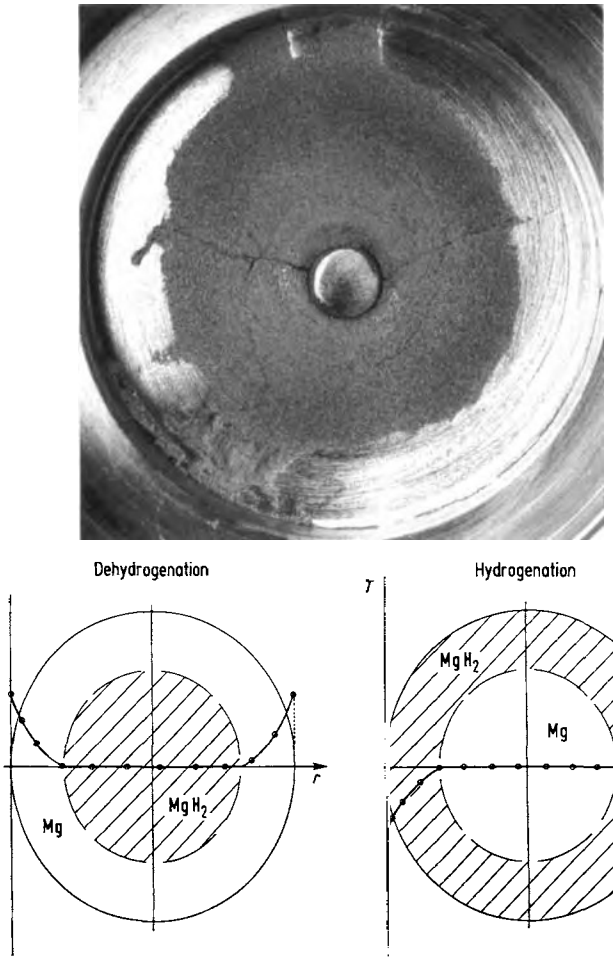

Fig. 5. Top: opened cylindrical MgH_2–Mg experimental heat store with an internal diameter of 70 mm which can be heated or cooled externally. During the dehydrogenation, which proceeds from the outside to the inside, as does the heat flow, the reaction was stopped, so that two cylindrical zones were present in the store. The slightly abraded material clearly shows an outside metallic shining ring made of magnesium, and an inner ring consisting of MgH_2. The middle of the store has a sinter metal pipe for delivering and withdrawing hydrogen. The irregularities within the outer ring are due to the difficulties encountered while abrading the brittle material. By measuring the dynamic temperature curves during the hydrogenation and dehydrogenation at various depths in the hydride bed, the "average effective total heat conductivity" of the MgH_2–Mg system during the chemical reaction can be determined when using an empirical formula. This is characterized by the various single conductivities of the MgH_2–Mg material combinations which are formed from the initially pure educts MgH_2 or Mg, respectively, and which are separated by the reaction zone which always moves from the outside to the inside. Bottom: From the narrow width of the reaction zone and the temperature jump which occurs there, it can be concluded that the chemical reaction rate must be greater than the rate of the heat transportation. In the inverse case, the reaction zone should be spread over the entire width of the tube filling [47].

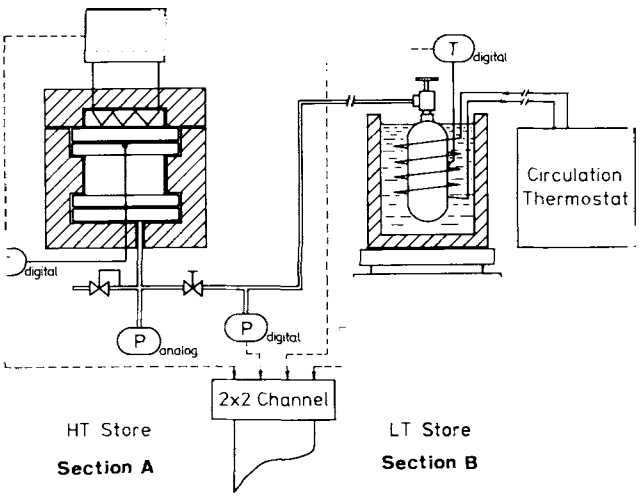
sorbed hydrogen. A valve regulates the flow of hydrogen between the two containers. The intermediate storage of the desorbed hydrogen can be achieved in three ways: 1) storage in a gas container under normal pressure; 2) storage under the decomposition pressure of the magnesium hydride in a pressure-proof container; 3) storage in the form of a low-temperature metal hydride. The latter two possiblities have been realized and tested by us on a laboratory scale.[29]

The third possibility of intermediate storage of hydrogen is based on the use of a suitable metal alloy, which on taking up hydrogen yields a low-temperature hydride by delivering heat to the environment. This hydride must be able to release the chemically bound hydrogen by taking up environmental heat to cover the reaction enthalpy. This approach is of particular interest for the following reasons:

- The absorption of hydrogen yielding the low-temperature metal hydride releases low-temperature heat, which constitutes 30–40% of the high-temperature heat of reaction and can be used, for example, for chemical heat pump processes.
- The desorption of hydrogen from the low-temperature metal hydride results in cooling, which can be used to produce ice or for air-conditioning purposes.
- The large temperature difference, which occurs in the combined metal hydride systems during the reverse reaction of magnesium to magnesium hydride can be used advantageously for improving the efficiency of thermodynamic machines such as Stirling motors or thermovoltaic cells.
- By supplying low-temperature heat, e.g., waste heat from industrial processes, into the low-temperature part of a combined metal hydride system, the hydrogen pressure can be increased, hence leading to a temperature increase in the high-temperature section (heat transformation).
- The volume of the intermediate hydrogen storage tank is much smaller than that of either of the alternative storage variants.

The apparatus shown in Figure 6 was used in order to study the processes mentioned. Section A (HT heat store)



includes a thermally insulated cylindrical stainless steel container which is filled with 1054 g of nickel-doped magnesium powder (standard material).[44] Heat was transferred via the upper horizontal plate of this container to the magnesium hydride bed using an electrically heated hot plate.

Section B (LT heat store) shows the commercially available[49] low-temperature metal hydride container (hydrogen storage capacity 1 m^3), which contains the alloy Code 5800 ($Ti_{0.98}$ $Zr_{0.02}$ $V_{0.43}$ $Fe_{0.09}$ $Cr_{0.05}$ $Mn_{1.2}$). This is immersed in a water or water/glycol bath which is kept at the desired

constant temperature using a thermostat. The two containers are interconnected via a copper tube in order to allow hydrogen exchange in both directions. A high precision digital balance serves for the gravimetric determination of the absorbed/desorbed hydrogen in and from the low-temperature metal hydride container.

The experimental set up shown in Figure 6 was used to carry out the following experiments, the results of which are summarized in Table 7. In all of the experiments, the rate of heating (405 $K\,h^{-1}$) of the magnesium hydride container from room temperature to the final temperature of 425 °C

Table 7. Experimental results during high-temperature heat storage and recovery (for experimental setup see Fig. 6).

Temp. of the LT-metal hydride [°C]	Amount of H_2 desorbed from MgH_2 [g]	Max. rate of H_2-desorption [gh^{-1}]	Amount of H_2 resorbed by Mg [g]	Heat performance of the MgH_2 container [kW]	Heat capacity of the MgH_2 container [kWh]
+10	69	40.4	69(6.0 h)	0.26(2.5 h)	0.71
+20	69.4	33.6	69(6.0 h) [a]	0.3(2.5 h)	0.71

[a] 60 g after 2.5 h.

was constant. This temperature was maintained for an additional 5 h. The temperature at which the liberated hydrogen was absorbed by the low-temperature alloy was varied at 10 °C intervals between 10 and 40 °C.

The amount of absorbed hydrogen in the low-temperature metal alloy, i.e. the amount of hydrogen desorbed from MgH_2, was determined by weighing the relevant container on a high-precision balance (columns 2 and 3 of Table 7). During the heat recovery, the heating plate is removed so that the heat can be delivered to the surroundings via the upper plate of the autoclave. The amounts of hydrogen desorbed from the low-temperature metal hydride (which become reabsorbed by Mg) are listed in column 4 of Table 7. The plot of the experiment carried out at 20 °C (Fig. 7) shows

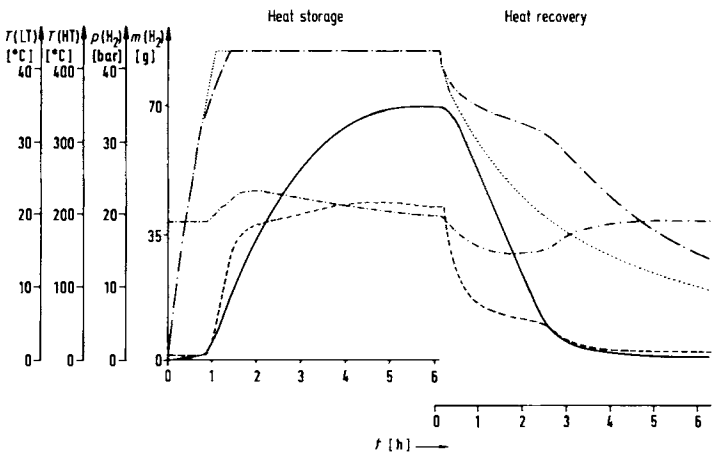

Fig. 7. Plot of the heat storage and recovery cycle using the setup shown in Figure 6: —— weight increase or decrease of the low-temperature hydride store, - - - temperature of the high-temperature heat store, – · – · – temperature of the low-temperature heat store, – – – H_2-pressure, · · · heating and cooling curves of the high-temperature heat store with closed valve.

that the hydrogen displacement from the MgH_2 store was complete after about 4 h, and that the resorption required approximately 3 h at a practically constant rate. The values in column 4 of Table 7 apply only to the case where the heat of hydrogen sorption in the magnesium container is vented to the atmosphere by thermal radiation and natural convection via its thermally uninsulated upper horizontal plate. A remarkable increase of hydrogen sorption is recorded when this plate is covered with a pot containing cold water, which after a short time starts boiling.

Also the data in Table 7, column 5 for the heat output during regeneration of the magnesium hydride only apply when the high-temperature reaction heat is given off under the conditions described above. In an experiment carried out at 10 °C on the low-temperature side of the system, the heat output could be doubled by using cold water for the heat transfer.

The used heat capacity of the magnesium hydride container (Table 7, column 6), like the maximum amount of H_2 desorbed and reabsorbed by Mg per hour, decreases with increasing temperature of the low-temperature metal hydride container (Table 7, column 3).

In order to realize the heat recovery during a reaction cycle, one must know the lowest preheating temperature in the magnesium container at which the hydrogen resorption begins. On the basis of two experiments, during which the low-temperature metal hydride container was kept at 10 and 20 °C, respectively, it could be demonstrated that the magnesium container had to be heated to 150 °C in order to initiate the heat recovery process.

The most interesting application of the storage unit shown in Figure 6 is the simultaneous production of ice with the low-temperature metal hydride container and of high-temperature heat by resorption of hydrogen in the magnesium container with reformation of magnesium hydride.

To demonstrate this double effect, the container with the low-temperature metal alloy was cooled to 0 °C and kept at this temperature level using a water/ice bath until the hydrogen transfer from the magnesium hydride container was completed. Under these conditions, 67.2 g of hydrogen gas are taken up within 3 h at a maximum delivery rate of 46.0 $g\,h^{-1}$ by the low-temperature metal alloy, leading to formation of the corresponding metal hydride.

After completion of this step, the low-temperature metal hydride container was immersed in a water-bath at 0 °C and the magnesium container was heated to the preheat temperature, as mentioned above. After 3 h, 59.0 g of the hydrogen is resorbed by the magnesium bed and 2.5 g more after a further two hours. This corresponds to a heat capacity of 0.64 kWh for the magnesium container. The heat performance is almost constant over a period of 2.3 h and amounts to 0.23 kW. At the end of the reaction, 1.9 kg of ice had formed around the low-temperature metal hydride container. This is equivalent to a cooling capacity of 0.18 kWh (28 % of the high-temperature heat capacity) and a cooling performance of 0.076 kW. The temperature at the hot plate of the magnesium container was 315 °C during this period of ice production (Table 8).

The system shown in Figure 6 can also be used as a heat transformer, as can be verified by the following experiment: The magnesium hydride in the container is thermally decom-

Table 8. Simultaneous production of ice and high-temperature heat (for experimental setup, see Fig. 6).

Cooling capacity of the LT-metal hydride container:	0.18 kWh (28% of the high-temperature heat capacity)
Cooling performance of the LT-metal hydride container:	0.076 kW
Operation temperature of the HT-heat store during the cooling process:	315 °C
Amount of ice produced at the end of the experiment:	1.9 kg

posed by heating from 20 to 349 °C within 45 min, and the desorbed hydrogen (76 g) is absorbed in the container with the low-temperature metal alloy, which is kept at −20 °C, corresponding to a final hydrogen pressure in the system of 4.3 bar.

The reverse reaction is allowed to take place at 29 °C in the low-temperature metal hydride container. The hydrogen pressure in the system rose from the initial 4.3 bar to 24.3 bar.

The temperature in the insulated magnesium container, from which heat can only be emitted in accord with the degree of insulation, rapidly rises from the initial 350 °C to 373 °C, and remains at this temperature for two hours. After a further 2 h, the temperature drops to 340 °C. The result of this experiment shows that the initial temperature increase of 49 K in the low-temperature metal hydride container leads to an upgrading of high-temperature heat in the magnesium container of 23 K, whereby the considerable hysteresis of the low-temperature hydride has an adverse influence.

7. Summary and Outlook

The experimental results presented in Section 6 demonstrated, for the first time, the use of a high-temperature metal hydride based on a pure metal and not an alloy, for the storage of high-temperature heat. Further development work on active MgH_2–Mg systems as high-temperature heat stores is currently being carried out at the two Max-Planck-Institutes in Mülheim an der Ruhr (FRG) in cooperation with BOMIN-SOLAR, Lörrach (FRG) (project leader: Dipl.-Phys. *J. Kleinwächter*) and the Institut für Kernenergetik und Energiesysteme (IKE) der Universität Stuttgart (FRG) (project leader: Prof. Dr.-Ing. *M. Groll*) with financial support of the German Federal Ministry for Research and Technology, (BMFT). A major aim of this project is to build and test the first thermochemical energy store with about 100 kg MgH_2 for solar and other energy supply systems on the basis of MgH_2–Mg.[50]

From a chemist's point of view, it is still an urgent and rewarding task to develop new and inexpensive reversible metal hydrides with high energy densities on both the high and low temperature sides, and also to search for other reversible thermochemical energy storage systems.

We would like to thank Professor Dr. G. Wilke for his generous support of the work described above. One of us, (B.B.), would like to thank his co-workers, mentioned in the references, for their valuable contributions to this work. We are grateful to the Federal Ministry for Research and Technology, for financial support.

Nickel: An Element with Wide Application in Industrial Homogeneous Catalysis

By Wilhelm Keim*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

The efficiency and future development of the chemical industry are closely linked to catalysis. It has been estimated, for example, that 60 to 70% of all industrial chemicals have involved the use of a catalyst at some point during their manufacture. In the past two decades the share of the market credited to homogeneous transition metal catalysis increasead to 10–15%. Besides cobalt, which is used mainly in hydroformylation reactions, nickel is the most frequently used metal. Many carbon–carbon bond formation reactions can be carried out with high selectivity if catalyzed by organonickel complexes. Such reactions include, inter alia, carbonylation reactions, cyclic and linear oligomerization and polymerization reactions of monoenes and dienes, and hydrocyanation reactions. It was *Reppe* and *Wilke* who pioneered and shaped the field of homogeneous nickel catalysis. Great impetus was also given to the development of organonickel chemistry by *Wilke* and his students. Research in this area has contributed immensely towards an understanding of the reactions involved in catalysis.—This review is primarily concerned with nickel-catalyzed reactions which are of interest both preparatively and industrially; some mechanistic aspects are also dealt with.

1. Introduction

In the 16th century, miners working in the neighborhood of Annaberg in Sachsen tried to recover copper from a reddish ore which in fact contained only nickel and arsenic. They never suspected that this "enchanted copper", copper-nickel, contained a new element that would later play a significant role in industrial catalysis. Nickel, meaning "bad partner (boy)" in the German language, was later isolated in pure form from this "enchanted rock" by *Cronstedt* in 1754. More than a further hundred years were to pass before Mond, in 1888, discovered the first carbonylnickel complex, $Ni(CO)_4$. This discovery initiated a vigorous development of organonickel chemistry. A metal, which existed in the gas phase and which could be isolated in pure form in this way fascinated Mond's contemporaries, one of whom even wrote: "Mond gave wings to a metal".

In 1906, *Sabatier* reported the nickel-catalyzed hydrogenation of carbon monoxide to methane, a reaction which is still used today on an industrial scale to remove carbon monoxide from a stream of hydrogen gas, as, e.g., in the production of ammonia. The reverse reaction, the cleavage of methane (steam reforming), also proceeds via nickel-based catalysis. *Sabatier*'s biggest contribution to chemistry was the recognition of these hydrogenation properties, thus paving the way for catalysis. One of the oldest hydrogenation catalysts is Raney-nickel, which was first used industrially in 1925, and which subsequently became one of the most important catalysts. In more recent times, however, dissatisfaction with the pyrophoric properties of Raney-nickel led to the development of Ziegler systems,[1] in which, for instance, nickel salts are reduced with alkylaluminum compounds. The nature of these catalysts has not been studied in great detail, and the "solutions" obtained after the reduction appear to be homogeneous to the eye. A process developed by Rhône Poulenc for the hydrogenation of benzene to cyclohexane using this catalyst is used on a large scale by many companies.

Many inherent drawbacks of highly dispersed nickel catalysts can be avoided by supporting nickel salts on various carriers. In this connection, particular mention must be made of the nickel catalysts used for hydrogenating fats and those used, in the form of $Ni \cdot Mo/Al_2O_3$ and Ni/Al_2O_3, in crude oil conversions and hydrogenations. Among the industrial applications, the processes for the hydrogenation of carbon-carbon double bonds are the most widely used, followed by those for the hydrogenation of carbonyl groups, with those for the hydrogenation of nitrogen-containing compounds third.

The development of homogeneous nickel catalysis began over fifty years ago with the pioneering work of *Reppe*.

2. Nickel in Reppe Chemistry

On searching for possible applications of carbon monoxide, produced as a byproduct in the manufacture of acetylene, *Reppe* discovered a series of homogeneous catalytic reactions called carbonylations [Eq. (a)–(c)].[2–5] Reaction (a)

$$HC{\equiv}CH + CO + HY \xrightarrow{[Ni]} H_2C{=}CH{-}\overset{\overset{O}{\|}}{C}{-}Y \qquad (a)$$

$$H_2C{=}CH_2 + CO + HY \xrightarrow{[Ni]} H_3C{-}CH_2{-}\overset{\overset{O}{\|}}{C}{-}Y \qquad (b)$$

$$R{-}CH_2OH + CO \xrightarrow{[Ni]} R{-}CH_2{-}\overset{\overset{O}{\|}}{C}{-}OH \qquad (c)$$

$Y = OH, OR, NR_2, RS, O_2CR$

represented the most important route used for acrylic acid production until the end of the 1960's. Depending upon the amount of $Ni(CO)_4$ used in the reaction, distinction was made between a stoichiometric, a modified, and a catalytic variant, the latter of which is still used today by BASF. New methods of acrylic acid synthesis, however, favor a route via propene oxidation.

The use of ethylene [Eq. (b)] leads to propionic acid, a process employed by BASF which produces about 50,000 tons per year.

The carbonylation of alcohols [Eq. (c)], especially that of methanol in the synthesis of acetic acid, has developed into one of the most important industrial processes. Originally, nickel was used as catalyst; in the first industrial plant at BASF, however, cobalt complexes were used as catalyst. Later the Monsanto Process, using rhodium catalysts, proved superior, and it is currently the preferred process for acetic acid synthesis.

The carbonylation of esters yields acid anhydrides, a reaction which is used by Tennessee Eastman for the synthesis of acetic acid anhydride.[7, 8] Rhodium catalysts are also used in this homogeneous process. Numerous efforts are being made in industry, however, to replace rhodium by the more economical nickel, and these efforts appear very promising in the case of the latter process. The variety of potential applications of Equations (a)–(c) is immense, the fundamental "building blocks" are inexpensive, and the process technology is well worked out. It can be anticipated that many further uses of carbonylation reactions may evolve in the future, especially if the raw materials derived from crude oil should be replaced by coal, natural gas, or biomass in the manufacture of synthesis gas. For instance, processes for the manufacture of ethylene from acetic acid, which in the final analysis originates from synthesis gas, are already known; two steps are involved, namely hydrogenation, yielding ethanol, followed by dehydration.

One of the most impressive reactions discovered by *Reppe* is perhaps the tetramerization of acetylene to cyclooctatetraene.[10] Although this reaction has not, as yet, found commercial application, it has nevertheless played a decisive role in the development of theoretical chemistry. The planar $C_8H_8^{2\ominus}$ dianion with its 10 π-electrons and its numerous complexes have stimulated a plethora of fundamental theoretical investigations.[11]

The element nickel, especially $Ni(CO)_4$, heralded the beginning of homogeneous transition metal based catalysis. *Reppe* himself wrote: "It became evident throughout these investigations that it was a lucky choice using nickel carbonyl as a starting material from the beginning of this work."[84]

3. Nickel in Wilke Chemistry[12–16]

Up to now, one of the most important discoveries in chemistry in our century has been that of *Holzkamp*, who, in 1952, observed that nickel salts can alter the AlR_3-catalyzed "growth reaction" of ethylene to α-olefins in such a way that only dimers (butenes) are formed, a phenomenon referred to in the literature as the "nickel effect".[16] This observation consequentially led to the discovery of "Ziegler catalysis", a reaction which is of utmost importance, both in industry and in academic research for the production of a variety of polymers.

In 1959, *Wilke* studied the possibility of using Ziegler catalysts prepared from nickel acetylacetonate and $AlEt_2OEt$ for the polymerization of butadiene. A mixture of products was obtained: (*E,E*)-1,5-cyclooctadiene (COD) (25%), 4-vinylcyclohexene (VCH) (10%), and (*E,E,E*)-1,5,9-cyclododecatriene (CDT) (65%). Had *Wilke* tried only the Ziegler system $NiCl_2/Et_2AlCl$, which produces polybutadiene, an exciting area of organonickel chemistry might have been overlooked. Cyclic compounds containing large ring systems were in great demand by preparative chemists, and the synthesis, especially of eight- and twelve-membered ring derivatives, was an exceptional challenge. Following *Wilke*'s discovery, various ring systems could be produced economically and quite elegantly. Not long after, *Wilke* observed that the ratio of COD:CDT:VCH could be altered by addition of R_3P-ligands (see Table 1).[16] One of *Wilke*'s greatest accomplishments was to have recognized for the first time the route to controlling the distribution of oligomers by ligand varia-

Table 1. Reaction of butadiene with nickel acetylacetonate and $AlEt_2OEt$; control of oligomerization using R_3P ligands. Conditions: 30 °C, 5 bar.

Product	$(c\text{-}C_6H_{11})_3P$ [%]	$(o\text{-}Ph\text{-}C_6H_4O)_3P$ [%]	without [%]
4-Vinylcyclohexene (VCH)	39.6	3.1	10

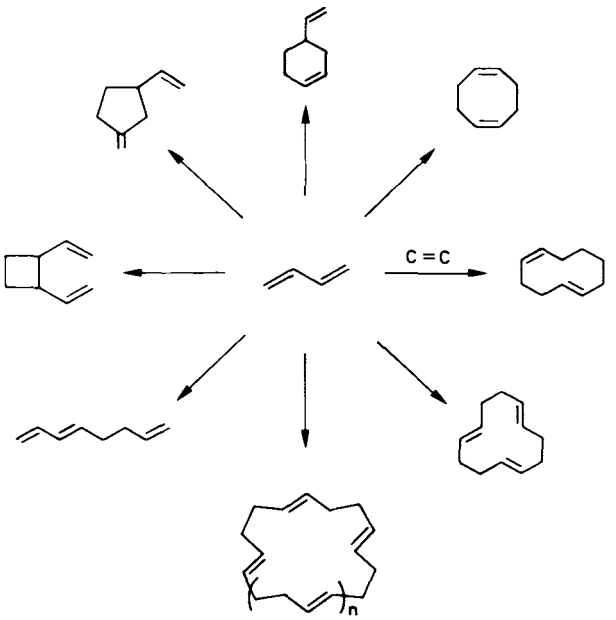
1,5,9-Cyclododecatriene (CDT)	14.4	0.2	65
Higher oligomers	4.8	0.2	–

Wilhelm Keim was born in Oberhausen in 1934. He studied chemistry at the Universities of Münster and Saarbrücken before moving to the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr, where he obtained his doctorate under the supervision of Professor G. Wilke. After one year as a postdoc with Professor T. Katz at the Columbia University, New York, he joined the Shell Development Company in Emeryville, CA. In 1967 he was promoted to leader of the petrochemistry research group, in 1969 to leader of the Department of Petrochemistry, and, finally, in 1972 to leader of Basic Research. In 1973 he accepted an appointment as Professor and Director of the Institut für Technische Chemie und Petrolchemie der RWTH Aachen. Wilhelm Keim is, among other things, a member of the board of the Deutsche Gesellschaft für Mineralölwissenschaften und Kohlechemie, Gesellschaft Deutscher Chemiker, and the Deutsche Gesellschaft für Chemisches Apparatewesen, Chemie Technik und Biotechnologie. He also is a member of the supervisory board of Degussa AG.

tion. This so-called "ligand tailoring" is of considerable importance to all scientists working in this area of chemistry. The ligands are often precisely "tailored" to the process envisaged. Two noteworthy examples of industrial uses are: Shell's hydroformylation reaction for converting olefins into linear alcohols,[18] and Du Pont's hydrocyanation of butadiene to adipodinitrile (see Section 4.5).

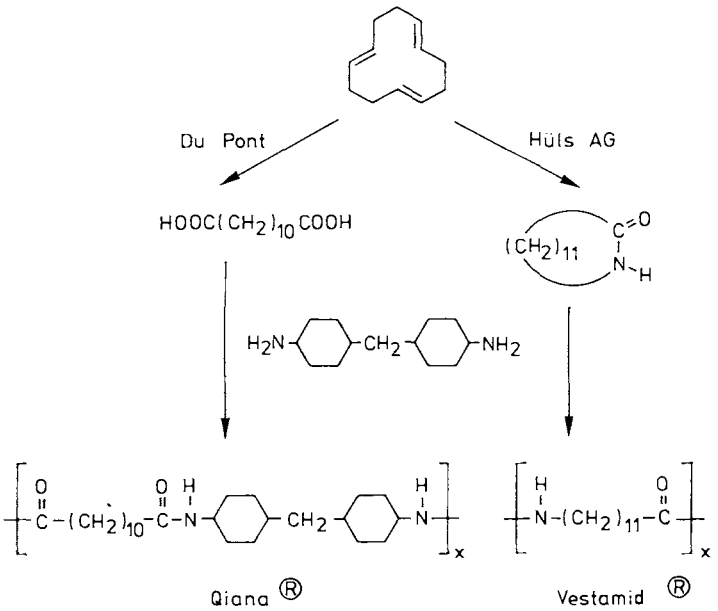
Over the years, *Wilke* and his co-workers have studied the syntheses of the above ring systems quite extensively. Scheme 1 shows examples of the various possibilities. De-



Scheme 1. Ring syntheses from butadiene.

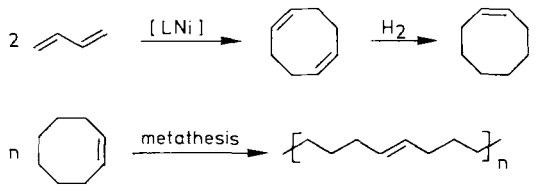
pending on the reaction conditions, linear and/or cyclic compounds are obtainable, whereby cyclooctadiene and cyclododecatriene are of special industrial importance. Fundamental investigations leading to an understanding of the impact of various ligands on controlling product selectivity go back to the work of *Heimbach*.[17]

Cyclododecatriene is used for the preparation of Nylon-12. Scheme 2 outlines this synthesis as practiced by Hüls AG (18,000 tons per year) and Du Pont.[19] Valuable textiles are produced from Du Pont's Qiana®. Owing to its stability of shape, corrosive resistance, and low-temperature properties, Vestamid®, manufactured by Hüls AG, has numerous applications in compression cylinders for brakes in automobiles, in fuel pressure lines, in the soles of sports shoes, in cable coverings, in anti-corrosive coatings (coatings for wires, steel pipe construction units) and in the linings of jackets and coats. Hüls AG also manufactures the special rubber Vestenamer® from cyclooctadiene, [Eq. (d)]. Characteristic features of Vestenamer are its partial crystallinity and its relatively low molecular weight. The crystallinity is dependent on the number of *trans* double bonds present. In blends with other rubbers, Vestenamer improves the viscosity and is thus of great help in complicated production procedures, such as those of brake hoses from EPDM (ethylene-propene-diene elastomer), corrugated bellows from polychloroprene, tooth

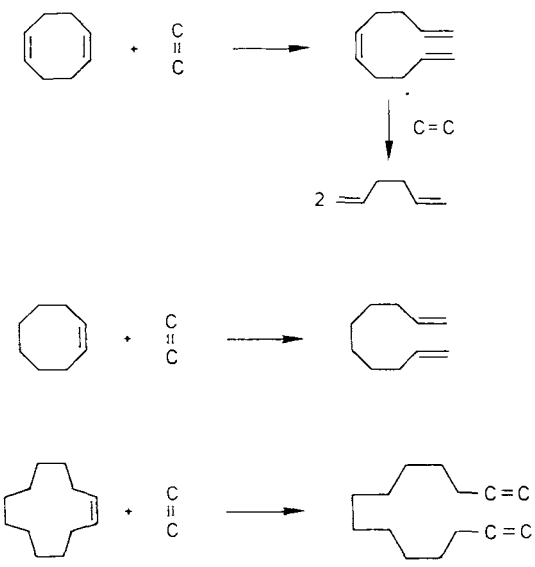


Scheme 2. Nylon-12 derivatives from cyclododecatriene.

crowns from hard plastics, and printing molds from nitrile rubber.



Shell produces a selection of industrially interesting olefins based on cyclooctadiene and cyclododecatriene by the Feast Process, [Eqs. (e)–(g)].[20]



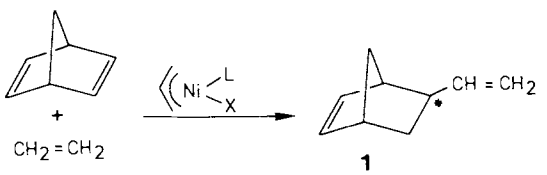
The successful reactions of organonickel complexes with dienes automatically led to an extension of their range of

application by including reactions with monoenes. One of the most impressive examples of ligand-nickel-control, the dimerization of propene, was first reported by *Bogdanović* and *Wilke* et al.[16, 21, 23] With trialkyl- or arylphosphane-modified nickel systems, hexenes, 2-methylpentenes, or 2,3-dimethylbutenes can be produced depending upon the substituent on the phosphorus (see Table 2). The catalytic activity is exceptionally high, and even at low temperatures good turnover numbers can be obtained. It should be noted, however, that the selectivity leading to 2,3-dimethylbutene in the case of *tert*-butyldiisopropylphosphane can be increased to 96.4% at −70 °C. A mixture rich in branched dimers has proven useful for increasing the octane number in gasoline, and is used in the Dimersol process (see Section 4.4.1). 2,3-Dimethylbutene has also attracted some industrial attention since it can be dehydrogenated to 2,3-dimethylbutadiene, a potential monomer for polymerization. The oxidation of 2,3-dimethylbutenes could provide a route to pinacol.

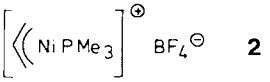
Table 2. Dimerization of propene with $C_3H_5NiCl/AlClEt_2$. Influence of the ligand R_3P on the selectivity. Conditions: 25 °C, 10 bar.

R_3P	Hexenes [%]	2-Methylpentenes [%]	2,3-Dimethylbutenes [%]
Ph_3P	21.6	73.9	4.5
Me_3P	9.9	80.3	9.8
iPr_2tBuP	0.1	19.0	80.9
$iPrtBu_2P$	1.0	81.5	17.5

It is not surprising that the possibilities for controlling carbon-carbon linkages via nickel-phosphane ligand systems have also led to the investigation of enantioselective syntheses with organonickel complexes.[22] The catalysts consist of 1:1 adducts of η^3-allylnickel halides and optically active phosphanes. For instance, as depicted in Equation (h), *ee* values of 80% could be achieved for **1**. Racemic **1** is of interest as third component ("diene") in EPDM. A noteworthy example of "ligand tailoring" is displayed by the enantioselective dimerization of styrene with ethylene; (*R*)-(−)-3-phenyl-1-butene is formed with *ee* values greater than 95%.[16] In this context, also *Pino*'s work on the asymmetric oligomerization of propylene is of interest.[23]

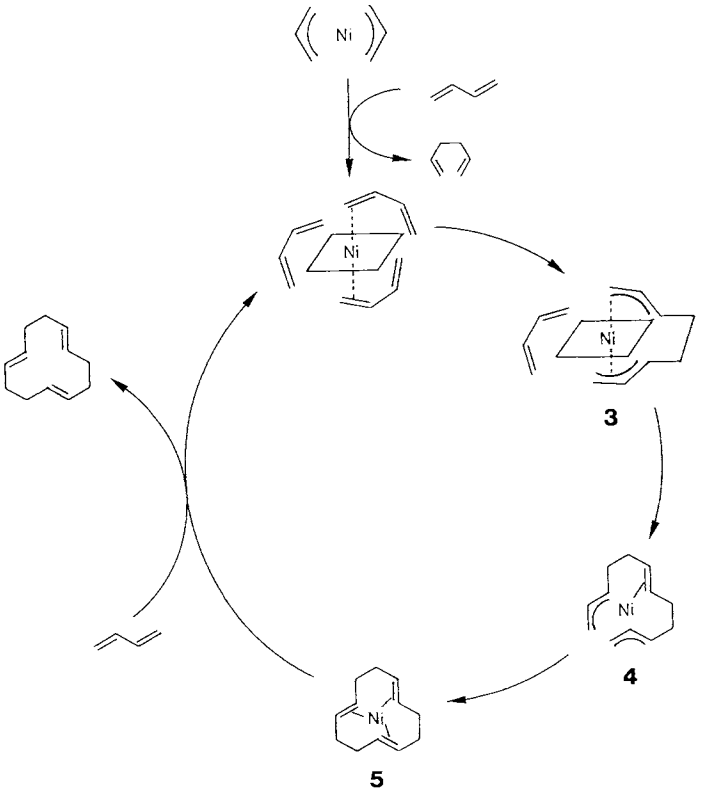


Almost exclusively monoenes and dienes are used in the aforementioned C–C linkage reactions. The inclusion of functionalized olefins would considerably expand the scope of application of homogeneous nickel catalysis. *Wilke* and co-workers have also attempted to include functionalized olefins in their catalytic investigations. In this connection, the linear dimerization of acrylic acid, which leads to starting materials for the production of nylon, is worth mentioning. Acrylic acid methyl ester dimerizes smoothly with complex **2** to yield monounsaturated esters of adipic acid.[16] In general, such a dimerization of functionalized olefins with Ziegler catalysts is difficult because in most cases the catalysts will react with the functionalizing group. Unfortunately, the turnover numbers achieved so far using complexes of type **2** are too low for this synthesis to be applied industrially.



2

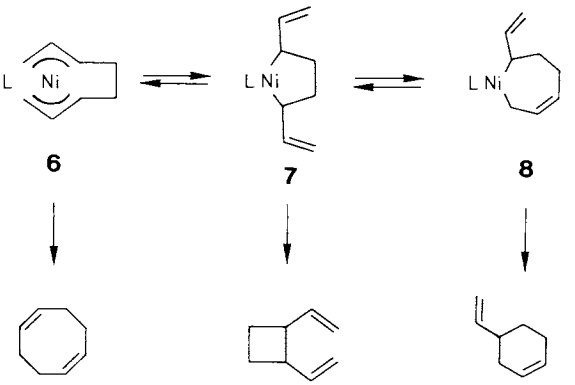
Other pioneering contributions by *Wilke* and his co-workers include their mechanistic investigations related to organonickel chemistry, which have greatly improved our understanding of the reactions involved in the catalysis. A large variety of complexes could be isolated which are considered to be reactive intermediates. For the mechanism of the cyclotrimerization of butadiene, it could be shown that π-complexes and $\eta^1\eta^3$-allyl systems play a crucial role in the reaction pathways. Scheme 3 illustrates this for cyclododecatriene synthesis. Using bis(η^3-allyl)nickel as starting complex, three molecules of butadiene orient themselves coordinatively around a "naked" nickel atom with displacement of 1,5-hexadiene. The nickel atom with its six possible coordination sites can coordinate up to three molecules of butadiene, bound either as η^4- or η^2-coordinated ligands. Two butadiene molecules combine via a carbon–carbon linkage to yield complex **3**, in which a C_8-chain with two η^3-allyl



Scheme 3. Mechanism of cyclododecatriene synthesis.

ligands is bonded to the nickel atom. Formation of an additional C–C linkage leads to complex **4**, in which a C_{12}-chain is arranged around the nickel atom. In this stepwise mechanism the intermediate **5** is formed via a third C–C linkage. Butadiene displaces the nickel atom from **5**; cyclododecatriene is formed and "naked" nickel is liberated and reacts again with butadiene, thus completing the catalytic cycle. The complexes **4** and **5** could be isolated, and their structures have been determined by X-ray crystallography.[22]

If phosphane ligands are added to the system (see Table 1), coordination sites for butadiene are blocked and the intermediates **6**–**8** are formed, in which the nickel atom is so modified that only two butadiene molecules fit into the coordination sphere of the nickel (see Scheme 4). Cyclooctadiene, divinylcyclobutane, and vinylcyclohexene are easily derived from complexes **6**–**8**.



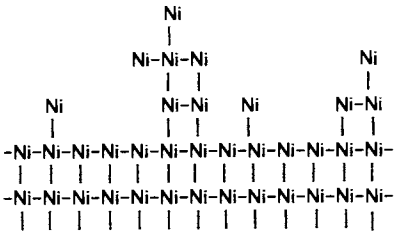
Scheme 4. Product distribution in the dimerization of butadiene in dependence of phosphane addition $L = R_3P$ (see Table 1).

Several important criteria, first recognized and postulated by *Wilke*, emerge from the catalytic cycles described in Schemes 3 and 4:

- η^1- and η^3-allyl complexes are reactive intermediates from which C–C linkages can be derived. A continual change in the formal oxidation state occurs through oxidative addition and reductive elimination.
- "naked" metal atoms or ligand-metal systems facilitate a "pre-orientation" of the reactants, thus influencing the stereochemistry (selectivity) and consequently the type of product formed. The necessary free coordination sites are created as a result of ligand dissociation via η^1- and η^3-allyl equilibria.
- isolated, well characterized organometallic complexes can be used as precursor complexes leading to the "true" catalyst.

The complex chemistry of η^1- and η^3-allyl systems as we know it today goes back to the fundamental work carried out at the Max-Planck-Institut für Kohlenforschung. Numerous allyl complexes were synthesized, and their reaction behavior monitored in detail in a series of systematic investigations.[24–26] In this connection, the numerous X-ray structure analyses performed by *Krüger* deserve special mention, for they impressively support formation of the various reaction intermediates proposed for the catalytic cycles.

The expression "naked" nickel was introduced by *Wilke* in order to describe one of the most important principles of catalysis, namely that of the necessity of free coordination sites. There is a very close relationship here to heterogeneous catalysis which requires free sites for chemisorption—a phenomenon which had already been postulated by *Taylor* and is illustrated in **9**[27]. Some 60 years ago *Taylor* put forward the theory that single nickel atoms stick out randomly from the metal surface, and thus form the "free" sites for the chemisorption (coordination) of molecules.



9

The ongoing studies of *Wilke*'s η^1,η^3-allyl systems led to numerous "one component catalysts", which are far less complex than Ziegler catalysts. These studies opened up a new area of research, mainly focused on the use of organometallic compounds as precursor complexes in homogeneous catalysis, and thus leading to new reactions which provide a better understanding of catalysis.

4. Further Examples of Homogeneous Nickel Catalysts Used in Industrial Processes

4.1. Dimerization and Oligomerization of Monoolefins[28]

With *Wilke*'s discoveries, a new era of chemistry developed based on organometallic chemistry applied to homogeneous transition metal catalysis. There are first of all the students of *Wilke* who provided a rapid transfer of technological knowhow to industry. But there are also other research groups who—inspired by *Wilke*'s publications—have developed their own ideas and concepts.

4.1.1. Dimersol Technology

One of the earliest works on propene dimerization, and following the *Wilke* tradition, goes back to *Ewers*.[29] Also *Chauvin* from the Institut Français du Pétrole (IFP) developed nickel catalysts ($Ni^{2\oplus}/AlEtCl_2$) that dimerize propene and/or *n*-butene.[30–32] These systems are highly active, hence the recycling of catalyst can be dispensed with. The propene dimers are used extensively, especially in the USA, for improving the octane number in gasoline and to provide heptenes and octenes for plasticizers. Since the first plant was established in the USA in 1977, IFP have given about 45 licences, which include the following variants: in the Dimersol G process, propene, produced by catalytic cracking, is dimerized to yield C_6-olefins useful in octane-number improvements (about 20 plants). The Dimersol X variant has found application in the dimerization of butene or codimer-

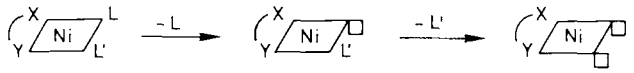
ization of propylene/butene for the preparation of plasticizers. In the Dimersol E process, high-octane gasoline is prepared form FCC-based olefins (FCC = fluid catalytic cracking process for the processing of crude oil).

In this context, the Hüls Octol process must be mentioned.[33] 1-Butene is first separated off from the corresponding C_4-fraction, and the remaining 2-butene/*n*-butane mixture is converted into (remarkably linear) octenes on a supported nickel catalyst. Two commercial processes underline the importance of this new technology, which is in direct competition with the homogeneous Dimersol route.

Other recent examples include the replacement of oxygen by sulfur in acetylacetonate ligands to give dithio-β-diketonate species. Nickel complexes of the dithio ligand give rise to extremely active olefin oligomerization catalysts.[34]

4.1.2. Shell Higher Olefin Process (SHOP)

While employed at the Shell Oil Company in 1965, the author was given the task of converting ethylene into value added chemicals such as α-olefins. As a former student of *Wilke* familiar with the background of ligand tailoring the author used the model shown in Scheme 5 for tackling the



Scheme 5. Proposed model for the formation of free coordination sites □.

problem. Chelates $\widehat{XY}$ were chosen since they favor square-planar structures with potentially free coordination sites for formation of an octahedral system.[35] The atoms X and Y should behave as an electron donor and acceptor, respectively. Finally, it should be possible to exchange the ligands L and L′ for ethylene. In the course of the investigations, this concept led to the Shell Higher Olefin Process (SHOP),[36–39] which, with approximately a one million ton capacity in 1990, is one of the largest applications of homogeneous catalysis by a transition metal, especially nickel.

Figure 1 shows the X-ray structure of complex **10**, which fulfills all of the requirements in Scheme 5.[40] Indeed, when

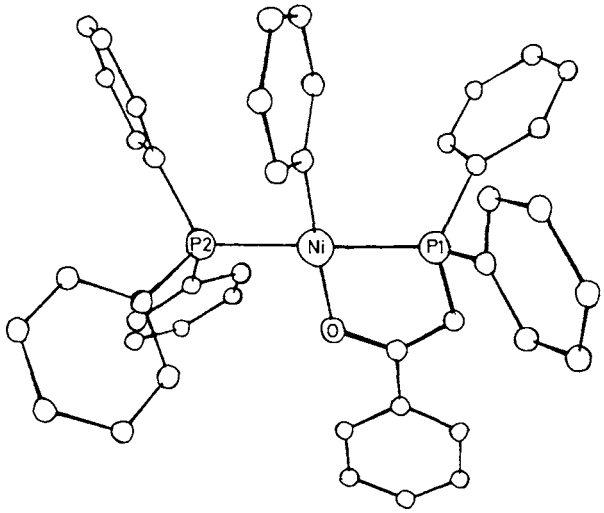


Fig. 1. Molecular structure of complex **10** in the crystal [see Eq. (k)].

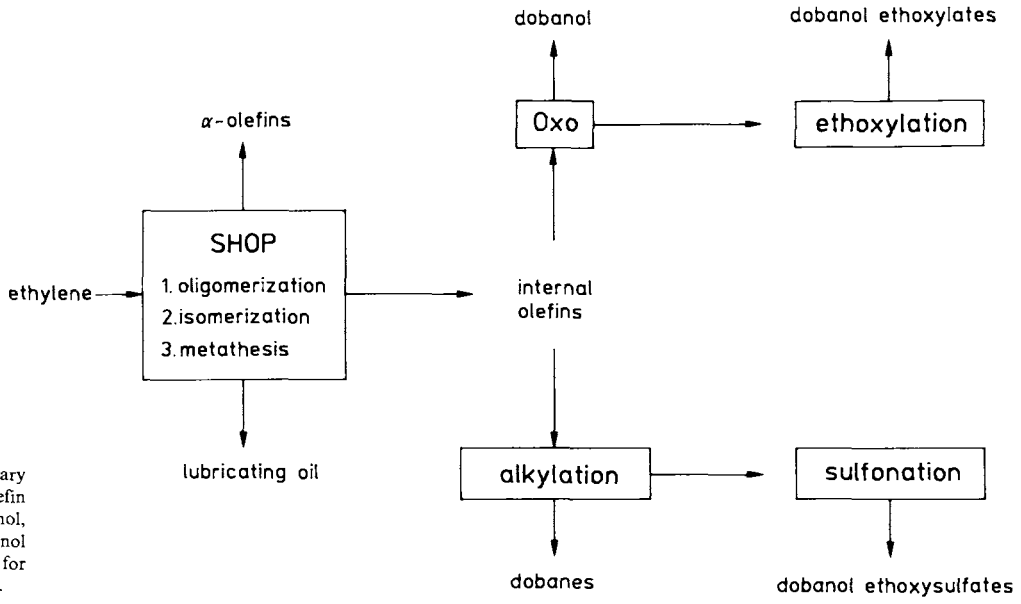
10 is dissolved in toluene and allowed to react with ethylene, oligomers are produced which are up to 99% linear, of which about 98% are formed as α-olefins. The olefins up to C_{30}, and present in geometric distribution, were isolated by gas chromatography. Activities of 6000 moles of ethylene per mole of complex **10** have been observed. If, however, the reactions are carried out with complex **10** suspended in *n*-hexane, linear polyethylene is produced. The directly marketable α-olefins produced in the oligomerization part of Shell's SHOP-process are separated by distillation. The remaining, unmarketable α-olefins are isomerized and converted in a third step by metathesis reactions into linear olefins with internal double bonds. An overview of the products manufactured by Shell is given in Scheme 6. By com-



Scheme 6. Products and secondary products of the Shell Higher Olefin Synthesis (SHOP). Dobane, dobanol, dobanol ethoxylate and dobanol ethoxysulfate are Shell tradenames for surface active products (detergents).

bining oligomerization, isomerization, and metathesis, a high degree of flexibility in producing linear olefins of any carbon chain length is possible.

To gain a better insight into the reaction mechanism of the SHOP-process, our research group at Aachen synthesized a number of $\widehat{PO}$ nickel chelate complexes and tested them as catalytic precursors.[41] In general, it may be stated that: all complexes active in the SHOP-process consist of a chelate moiety and an organyl ligand part, as in Figure 2. The organo part only stabilizes the complex, while the chelate ligand controls the catalytic activity and selectivity.[42, 43]

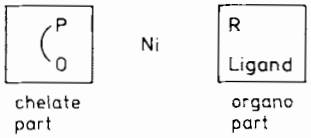


Fig. 2. General form of precursor complexes leading to catalysts.

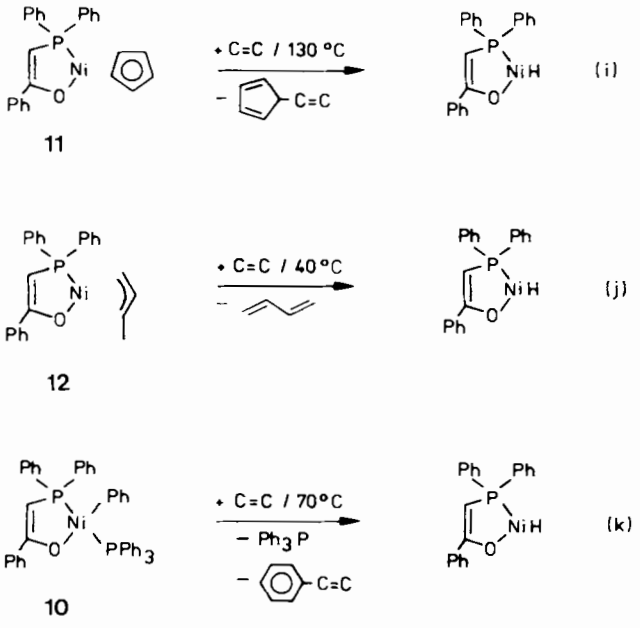
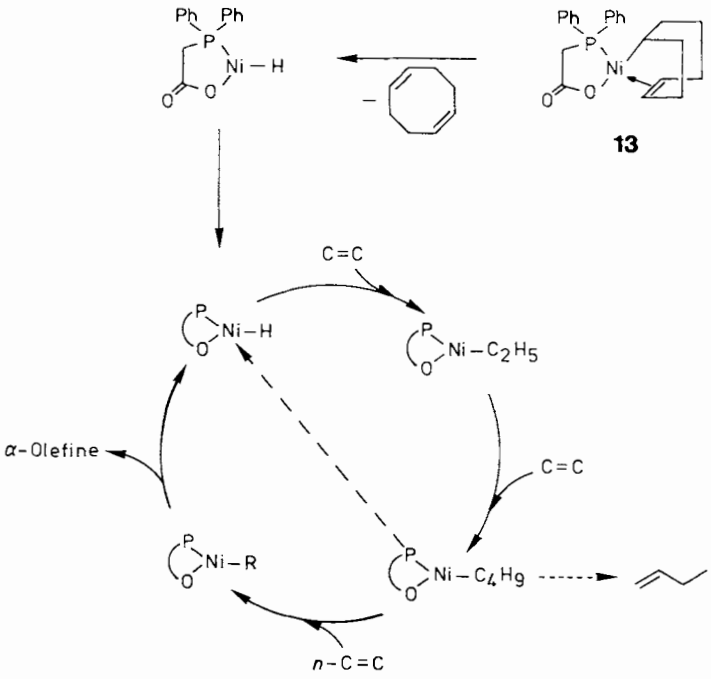
Assuming that nickel hydride complexes are the active catalysts, the reactions (i)–(k) offer a plausible explanation for Ni–H formation, starting from various complexes as catalyst precursors. In reaction (i) temperatures of 130 °C are needed for the insertion of ethylene into the cyclopentadienyl group and formation of a nickel hydride, whereas the nickel-crotyl complex in reaction (j) readily yields a nickel hydride through butadiene elimination at 40 °C, and, finally, in reaction (k) ethylene inserts into the nickel-phenyl group followed by elimination of styrene. All the reactions (i)–(k) outlined could be verified chemically. As predicted, the complexes **10**–**12** only become active for ethylene oligomerization at the temperatures needed for nickel hydride formation as depicted in (i)–(k).



Scheme 7 presents a postulated mechanism for ethylene oligomerization, using complex **13** as a catalyst precursor



Scheme 7. Postulated mechanism of ethylene oligomerization.

complex. In the case of complex **13**, only in situ NMR studies indicated that a nickel hydride is produced,[44] while the nickel hydride **14** (Fig. 3) could be trapped by using

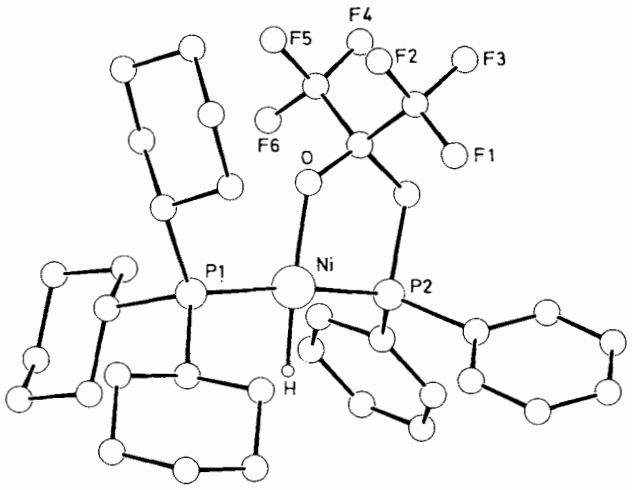


Fig. 3. Molecular structure of the Ni-H complex **14** in the crystal.

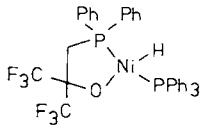
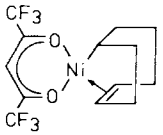
$Ph_2PCH_2C(CF_3)_2OH$ as a ligand.[45] It was also possible to isolate the corresponding ethyl complex of **14**, formed by an ethylene insertion into the nickel hydride bond. On heating, the nickel-ethyl complex splits off ethylene to give complex **14** again. A variety of nickel hydrides are reported in the literature that can be considered as additional support for the postulated mechanism.[15, 16, 46]

The success with $\widehat{PO}$ chelate ligands suggested the use of other ligands of this type to be included in a systematic study. The chelate complex **15** catalyzes the linear oligomerization

of α-olefins.[35,47] To our knowledge, this is the only complex (catalyst) that produces highly linear dimers (> 80%), but unfortunately, until now, the turn over numbers are too low for an industrial application.[48] In this context, also the work of *Cavell* and *Masters* concerning olefin oligomerization deserves mentioning.[34]



14



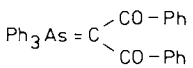
15

4.2. Monoolefin Polymerization

The formation of polyethylene using nickel catalysts was already reported in a patent in 1953.[49] Also, *Bogdanović* and *Wilke* reported the formation of polyethylene on using the catalyst η^3-$C_3H_5NiX/AlX_3/P(tC_4H_9)_3$.[16] In our investigations with various chelate ligands, e.g. derivatives of 1,3-diphosphapropene[50] or $(C_6H_{11})_2PCH_2COOH$,[51] we frequently observed polyethylene formation, especially when a solvent was used in which the complex was insoluble.[40] Until now, no general predictions can be made as to what ligand properties are needed to synthesize either oligomeric olefins or polyethylene, respectively. Generally, it can be said that starting from a nickel hydride, growth occurs via ethylene insertion and β-elimination leading to the α-olefins as shown in Scheme 7, thus giving rise to a geometric distribution (Schulz-Flory distribution) of products.[28] In agreement with this, and under the assumption that no chain transfer occurs, the product pattern can consist predominantly of dimers, higher oligomers or even polymers.

Following our work, and in an attempt to react functionalized monoolefins such as acrylic esters, *Klabunde* also employed complexes of the type shown in Figure 2 in polymerization and copolymerization reactions.[52,53]

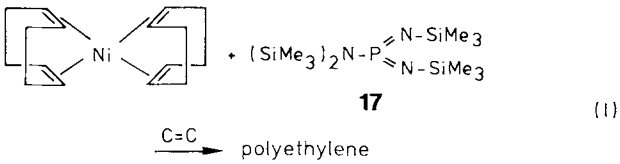
Of *Klabunde*'s investigations, the formation of polyketones from ethylene and carbon monoxide using complex **10** should be emphasized.[54] We were able to demonstrate that the ligand **16** in combination with $(cod)_2Ni$ also yielded



16

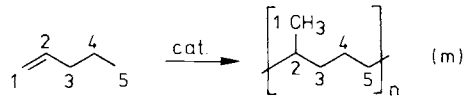
polyketones from ethylene and carbon monoxide. Such polyketones have potential application as novel industrial polymers. Also worth noting in this connection are the works of *Sen*[57], *Nozaki*[58] and *Drent*[59] of Shell, who have used palladium instead of nickel in their catalytic studies aimed at the production of polyketones from ethylene and carbon monoxide.

By reacting amino-bis(imino)phosphorane **17**, $(cod)_2Ni$ and ethylene acording to Equation (l), a system results which catalyzes a novel ethylene polymerization (2,ω-polymerization).[60] According to *Fink*, who has thoroughly investigat-



17

(l)



(m)

ed and interpreted this system,[61] polymers with methyl-branches arranged at regular intervals are formed [Eq. (m)]. The methyl groups of the polymer chain are formed from the C(1)-atom of the α-olefins. This can be explained in terms of a 1,2-hydride shift with concommitant migration of the catalytically active nickel atom along the carbon chain. It should be emphasized that this type of polymerization—in contrast to that with Ziegler catalysts—is carried out with aluminum-free systems.

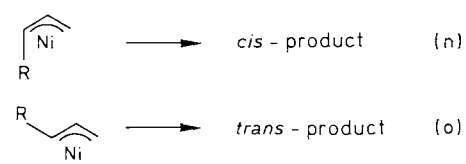
4.3. Dimerization and Oligomerization of Dienes

The success of the trimerization of butadiene to cyclododecatriene led a number of research groups to further investigations with other 1,3-dienes such as, for example, isoprene.[4,13,28] Until now, however, poor selectivities have precluded larger industrial applications. An example of an industrial use is the trimerization of isoprene to 1,5,9-trimethyl-1,5,9-cyclododecatriene reported by the Takasago Perfumery Company.[62]

The nickel-catalyzed codimerization of butadiene with ethylene leading to 1,4-hexadiene, which is useful for the manufacture of EPDM, has been thoroughly investigated.[28,63] Here, rhodium catalysts proved to be superior for industrial production.[64]

4.4. Polymerization of Dienes

A large variety of nickel complexes used for the polymerization of butadienes has been reported.[17,64,65] Depending on the nature of the nickel starting salt, *cis*-1,4-, *trans*-1,4- or 1,2-polybutadienes and/or mixtures are formed. An explanation for the stereoselectivity may rest on the *syn* and *anti* forms of the η^3-allyl system [Eqs. (n, o)]. The choice of anion



(n)

(o)

also plays a crucial role; e.g. with η^3-C_3H_5NiI, 1,4-*trans*-polybutadiene is obtained. *Teyssié* et al.[65] contributed to a better understanding of the observed selectivities, by show-

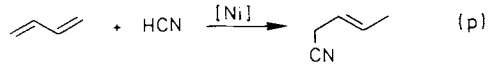
ing that variation of X in η^3-allylnickel-X leads to a dramatic change in activity in the series $X = CH_3COO^{\ominus} < CCl_3COO^{\ominus} < CF_3COO^{\ominus}$.[66]

The Goodyear Tire and Rubber Company introduced a nickel-BF_3 system for the synthesis of 1,4-*cis*-polybutadiene.[67]

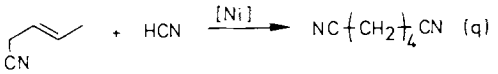
Bunawerke Hüls markets, "Polyöl Hüls", a low molecular weight 1,4-*cis*-butadiene polymer. This oligomer is prepared by a nickel-catalyzed reaction and is used as an anticorrosion agent and as an adhesive material.[68]

4.5. Hydrocyanation

The nickel-catalyzed addition of hydrocyanic acid to mono- and di-olefins is an elegant method for the synthesis of alkyl nitriles, which are important starting materials for the production of amides, amines, and acids. Hydrocyanation, first reported by *Taylor*,[69] was used by *Drinkard* of Du Pont for the reaction with butadiene according to Equations (p) and (q).[70, 71] This reaction is currently used at three

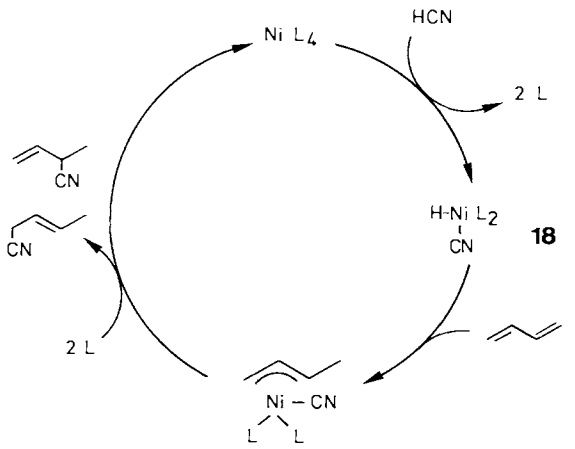


(p)



(q)

plants by Du Pont for producing the starting materials for nylon. It may be assumed that the primary amines supplied by Du Pont are produced likewise via α-olefin hydrocyanation. Complexes such as NiL_4 (L = aryl phosphite) are employed as catalysts for the hydrocyanation. An explanation of the reaction mechanism goes back to the work of *Tolman*, who thoroughly investigated this process.[72–74] The proposed mechanism is shown in Scheme 8. HCN reacts with



Scheme 8. Proposed mechanism of butadiene hydrocyanation. L = $P(OC_6H_5)_3$.

NiL_4 with dissociation of two phosphite ligands to yield **18**, which can be isolated.[73] Reaction of **18** with butadiene yields an η^3-nickel complex, from which butene carbonitriles are released through reductive elimination with re-initiation of the catalytic cycle. This reaction is another example of ligand control. By using Ph_3P instead of $(PhO)_3P$, the reaction path changes [Eq. (r)], and no nickel hydride is formed; $(Ph_3P)_2Ni(CN)_2$ precipitates, and leads to "catalyst death".[75]

$$(Ph_3P)_4Ni + 2HCN \xrightarrow{-2\,Ph_3P} (Ph_3P)_2Ni(CN)_2 + H_2 \qquad (r)$$

4.6. Telomerization[6, 13, 28, 76]

A reaction studied in great detail is that of 1,3-dienes with nucleophiles HY, as shown for butadiene in Equation (s). The telomer **19** or octatriene is formed. Although these reactions lead to a wide range of products, their use on an industrial scale has not yet been reported.

$$2C=C-C=C + HY \xrightarrow{[Ni]} \underset{\mathbf{19}}{Y-C-C=C-C-C-C-C=C}$$

$$\xrightarrow{[Ni]} HY + C=C-C=C-C-C-C=C \qquad (s)$$

5. Outlook

Aside from cobalt, which is used mainly in hydroformylation reactions, nickel is probably the most frequently used metal in homogeneous transition metal catalysis. This is undoubtedly due, on the one hand, to its economical price,[77] and, on the other, to the abundant and diverse reaction possibilities and selectivities. In the present article, primarily only industrial processes have been considered. About 15% of the established catalytic processes used in the chemical industry can be ascribed to homogeneous transition metal catalysis, and many products can be obtained only by these processes. Nickel plays an important role in this area which may even increase in the future. Generally, one can expect that homogeneous transition metal catalysis will attract increasing interest as value added chemicals grow in importance in the chemical industry.[78, 79] Considering the potential in the area of specialty chemicals, many uses of nickel catalysts may be foreseen. Organonickel complex chemistry is progressing at a considerable rate, and this could provide the nutrient for many future applications. Of course, the question may be raised: "Is the current importance of the element nickel in catalysis due to its nature or due to the amount of work which has been undertaken in organonickel complex chemistry?"

Homogeneous catalysis by nickel began with the work of *Reppe*, and it is to *Wilke*'s great merit to have introduced organonickel chemistry and its application into catalysis. By isolating model compounds, he was able to gain insights into the mechanistic pathways of homogeneous catalysis and catalytic cycles. The areas of homogeneous transition metal catalysis and organonickel chemistry are greatly indebted to both *Reppe* and *Wilke*. In conclusion it would not be amiss to quote Max Planck:[83]

"During the stormy development of all branches of science, it has become apparent that the progress of science rests first of all upon the success of the individual scientist".

Molecular Recognition with Model Systems

By Julius Rebek, Jr.*

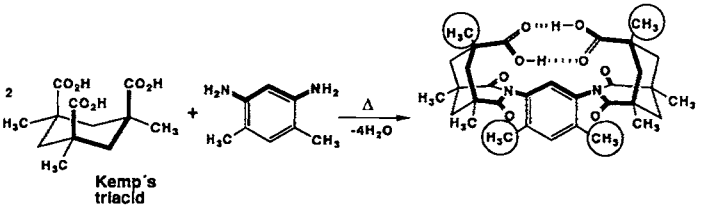
How structures fit together is the principal domain of molecular recognition, and current studies are evolving from the host–guest chemistry of ions to interactions between two molecules. Recent advances in the synthesis of sizable concave molecules, especially those featuring convergent functional groups, make it possible to bind smaller convex structures with considerable selectivity. One result is that hydrogen bonding can be addressed in model systems. The present review emphasizes the use of cleftlike structures as a means of probing the forces involved in nucleic acid recognition. The application of such molecules to the catalysis of chemical reactions, particularly those involved in self-replicating systems, is also described. Some implications for future pharmaceutical agents are suggested as a result of access to synthetic receptors for biologically relevant targets.

1. Introduction

The study of intermolecular forces is one of the paradigms of current bioorganic chemistry. With good reason. The biochemical phenomena that inspire much of the work in the area all owe their origins to such forces. Regulation, recognition, transport, and catalysis are some of the specific phenomena and they have captured the attention of model builders during the 1980s. These terms have added charms for the adventuresome; they have no structural content. It is up to the investigator to guess which structural features are required to express the given behavior. Our own work has followed the path from regulation[1] to recognition, and in the present review we relate efforts to bridge the gap between recognition and catalysis, that is, bring these two events *closer together in space and time.*

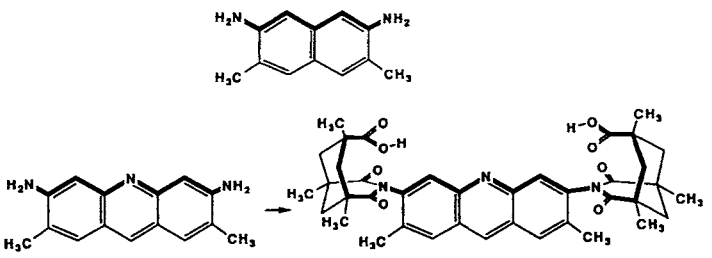
In 1984 we introduced molecules of a cleftlike shape to bioorganic chemistry.[2] This was, and may still be regarded as, heresy in a field so dominated by macrocyclic structures, but the peculiar advantages of such structures justified the apostasy. One significant advantage was the convergence of useful functional groups, particularly carboxylic acids. It permitted the use of hydrogen-bonding interactions rather than the ion–dipole interactions that are the principal forces offered by crown ethers[3] or the hydrophobic interactions of cyclodextrins[4] and cyclophanes.[5] Directionality in binding was the result, and structures bearing basic sites could be considered targets for recognition studies.

The unique shapes of the molecules arise from the use of Kemp's triacid,[6] a molecule in which the triaxial conformation of three carboxyls forces a U-shaped relationship between any two of them. Its condensation with diamines (Scheme 1) leads to molecules which fold back upon themselves, structures in which the carboxylic acid can be oriented with respect to other parts of the molecule. The concave shape of the overall structure is due to the passive effects of the methyl groups. Those α to the carboxyls prevent epimerizations, while those *ortho* to the imides prevent rotations to divergent conformations. In macrocyclic structures, the concavity of the interior is due to the existence of the ring itself. The new structures, particularly those involving the convergence of carboxylic acids, have been useful in exploring stereoelectronic effects at carboxyl oxygen (see Section 2).



Scheme 1.

Another advantage that accelerated our explorations was the facile, modular assembly of cleftlike molecules of different sizes and shapes. For example, using the inexpensive dye acridine yellow and a technique resembling a mixed melting point determination, excellent yields of a new dicarboxylic acid could be obtained[7] (Scheme 2). Such structures are capable of binding molecules of the size of small biological targets, for example, amino acids,[8] heterocyclic amines,[9] and diketopiperazines.[10] These structures, with their relatively few degrees of rotational freedom, make attractive frameworks for computational chemistry. Recent calculations by *Jorgensen* et al.[11] and by *Lipkowitz* et al.[12] have elaborated the dynamics and multipoint contacts available



Scheme 2.

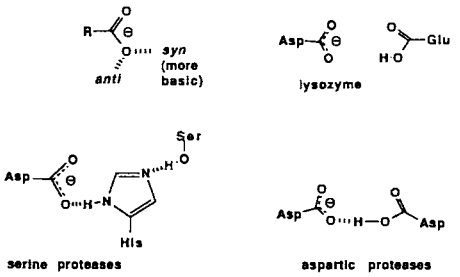
in complexations involving the clefts. Kemp's triacid is commercially available and it is conveniently prepared on an 80-gram scale in the laboratory.[9]

2. Stereoelectronic Effects at Carboxyl Oxygen

Because we had a franchise on molecules featuring convergent carboxyl functions, we felt obliged to examine the consequences. Nearly a decade has passed since *Gandour*[13] drew attention to the consistent orientation of carboxyl groups at enzyme active sites. It had been known that the basicities of the in-plane lone pairs of a carboxylate were different, so much so that approximately 5 kcal mol^{-1} separate the two forms of a carboxylic acid.[4] Recent calculations[15] indicate that the energy difference can be even greater. What *Gandour* pointed out was that, in enzyme active sites, the more basic *syn* lone pair is invariably directed toward the substrate (Scheme 3). For example, in aspartic

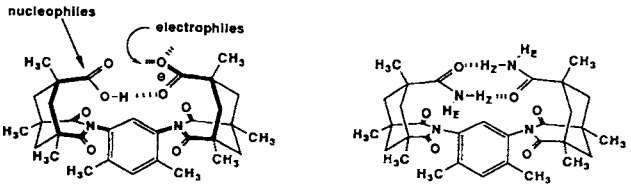


Scheme 3.

proteases or lysozyme, it is the convergence of two carboxyl functions that creates the active site. In zinc proteases,[16] a carboxyl is likewise directed toward the substrate, and, even in serine proteases, the more basic *syn* lone pair of the aspartate is directed toward the proton relay apparatus of the catalytic triad. Since Nature incorporates this feature of carboxyl groups, it was inevitable that we would attempt some experimental measures of these effects with our model systems.

Our first qualitative evidence on these effects was the rather unusual behavior of the dicarboxylic acid in Scheme 1, which reacted *slowly* with diazomethane. With other alkylating agents (e.g., Meerwein salts) slow and clean monoalkylation occurred.[7] Remarkably, the peracid derivatives showed selective epoxidation of *cis* versus *trans* olefins.[17] In acyl transfer reactions, however, the diacids showed normal behavior. For example, they could be converted into their acid chlorides, from which methyl esters or amides could be made without event. This behavior can be understood from the point of view of reaction trajectories; in acyl transfer reactions, nucleophiles enter and depart along a line (Scheme 4) where there is not much of an opportunity for them to interact with the distal carboxyl group. In electrophilic reactions, particularly when the more basic *syn* lone pairs are involved, the electrophile must wedge between the two carboxyl functions. The slow reactions with electrophilic reagents were one of the first expressions of this effect.

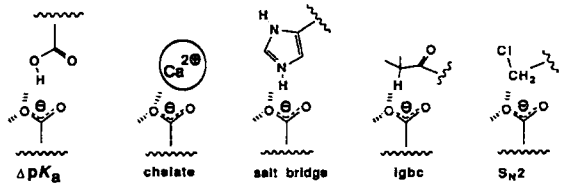
Another result has been the observation of direct proton exchange within hydrogen-bonded amides.[18] These studies involved the detection of different rates for exchange in the diamide of Scheme 4. H_Z exchanges with solvent some 30 times slower than H_E under basic conditions.



Scheme 4.

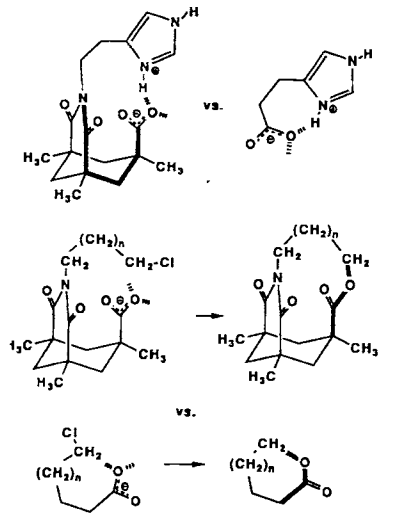
We have attempted to evaluate this effect in a number of settings (Scheme 5) but are on the verge of despair concerning a quantitative measure of it. The problem is merely staging a fair comparison between a system involving the *syn* lone pair and a corresponding one with the *anti* lone pair. It has been nearly impossible for us to obtain two molecules that differ in that respect, yet have the same degrees of rotational freedom as well as the same rigidity, distance, etc. To be sure, unfair comparisons are quite easy to arrange, but as we have pointed out,[7] one of the problems of physical organic chemistry is that there are no continuities of structure. Even the insertion of a single methylene into a system changes not only the distance, but the conformation as well. Some of the settings that we have studied are shown in Scheme 5.

Julius Rebek, Jr., was born in Hungary in 1944 and lived in Austria from 1945 to 1949. He and his family then settled in the USA in Kansas. He completed his undergraduate education at the University of Kansas in 1966 and obtained the Ph.D. degree from the Massachusetts Institute of Technology in 1970 for studies in peptide chemistry with Professor D. S. Kemp. As an Assistant Professor at the University of California at Los Angeles (1970–1976), he developed the "three-phase test" for reactive intermediates. In 1976 he moved to the University of Pittsburgh, where he rose to the rank of Professor of Chemistry and Chairman of the Organic Division. In 1989 he returned to the Massachusetts Institute of Technology as Professor of Chemistry. He has been awarded NSF, Alfred P. Sloan, J. S. Guggenheim, and Alexander von Humboldt Fellowships. His current research interests are in mechanistic organic chemistry, enzyme models, oxidation reagents, and molecular recognition.



Scheme 5. igbc = intramolecular general base catalysis.

The extraordinary difference in the first and second pK_a of the dicarboxylic acids, namely, six units, is probably the most dramatic observation,[19] and the very high affinity of these new chelating agents to divalent metals[20] must also reflect these stereoelectronic effects. Perhaps one of the best comparisons we have staged is in the carboxylate–imidazolium salt bridge.[21] The difference in pK_a's of our model system and dihydrourocanic acid indicate that most of the requirements of distance, flexibility, lack of strain, etc. are met (Scheme 6). Here, we see that the *syn* lone pair is approximately one order of magnitude more basic than the *anti* lone pair.[22] However, many of these situations are dominated by electrostatic components, where distance rather than orientation is the greatest consideration and stereoelectronics can be whelmed. Accordingly, we have looked at a system involving intramolecular general base catalysis. In enolization reactions,[23] about an order of magnitude (relative to the reference) is observed. Even in such a system, it was not possible to avoid strains in trying to arrange the perfect transition structure. *Houk* et al.[24] have computed that these strains can mask the effects to some yet unknown extent.



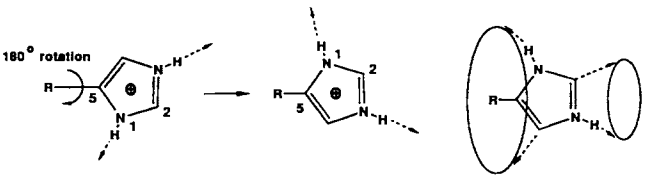
Scheme 6.

Most recently, we have studied a lactonization reaction in which some larger, directional (covalent) component could be expected. In direct comparisons between the cyclization to the *Z* ester (Scheme 6) and that involved in valerolactone, the rates are found to be quite comparable; that is, no effect is apparent.[25] Is this the bottom line, then? Who knows? Again, there may exist subtle strains or torsional effects in our molecule worth a few kilocalories per mole that could confuse the issue. Moreover, it has been suggested[26] that the *syn* lone pairs are more heavily solvated than the *anti* lone pairs. If so, their intrinsic reactivity in protic solvents is inevitably at a disadvantage. Only in proton transfers from solvent (i.e., basicity) or in enzyme interiors, where water has been squeezed out, will this effect be of any magnitude. Whether it is from misplaced optimism or sheer stubbornness, we intend to continue these studies with our model systems.

3. Other Stereoelectronic Effects

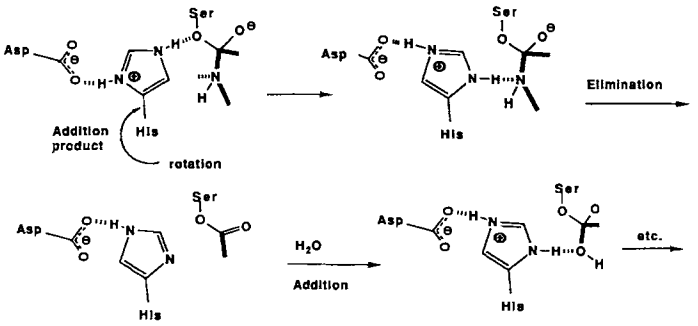
One spin-off of these investigations concerns the active sites of enzymes and the stereoelectronics of proton transfer reactions. We begin with the assumption that *every structural detail is important*. For example, phenomena such as the leucine zipper[27] have recently emerged and the subtle difference between aspartate and glutamate in enzyme active sites[28] also underscores the importance of details; every side chain of every amino acid is laden with this information, whether or not it has been brought to light.

Consider the side chain of histidine, which is frequently found at active sites. The pK_a of the imidazolium ion, ca. 7, permits significant concentrations of both acidic and basic forms to exist near neutrality. There is another attribute of the structure, namely, its ability to transfer protons in a variety of directions.[29] By anchoring the imidazole at C-5, the acidity (or basicity) can be reoriented by rotations about the C5–Cβ bond. These are represented by the circles of Scheme 7. The significance of this motion may be expressed in the action of the serine proteases.



Scheme 7.

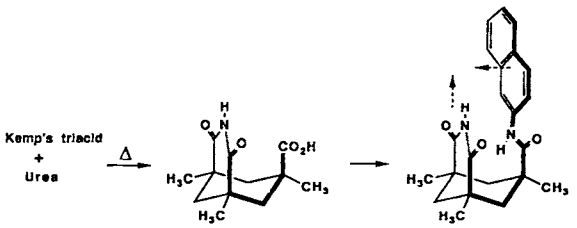
The generally accepted sequence of events for this type of enzyme (Scheme 8) involves the formation of a tetrahedral intermediate.[30] The departing nitrogen must become protonated before breakdown of the tetrahedral intermediate can occur. This could be accomplished by rotation around the single bond indicated. The hydrogen-bonding network is temporarily disrupted during the rotation but is recovered as the system is poised for the breakdown of the intermediate. A reversal of the sequence, with water entering as a nucleophile on the serine ester, leads ultimately to deacylation. There is some evidence that the protease and esterase activities of chymotrypsin involve different nitrogen atoms of the imidazole ring.[31] This would support the mechanism of proton transfers described above. At any rate, we suggest that the shape of histidine may be as important as its pK_a for its function at the active sites of enzymes.



Scheme 8.

4. Base-Pairing and Stacking Interactions

Among the more attractive recent targets of molecular recognition have been the heterocyclic bases of nucleic acids. They are small and rigid and they present a wealth of basic sites that are unattractive to receptors with more conventional linings. The hydrogen-bonding aspects have been well-established[32] using the relatively noncompeting solvent $CHCl_3$. In water, stacking associations dominate the interactions.[33] The U-turn inherent in derivatives of Kemp's triacid permitted us to construct molecules in which hydrogen-bonding and aryl-stacking interactions (Scheme 9) could

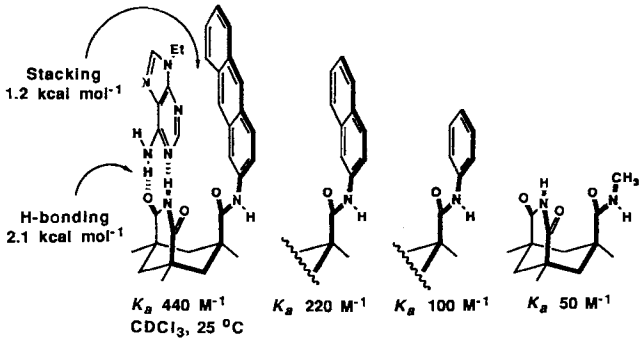


Scheme 9.

be evaluated simultaneously.[34] Organic solvents, which have a polarity between the fierce competitions in aqueous media and the calculational simplicity of the gas phase, provide a magnifying glass with which to observe these principal forces that stabilize double-stranded nucleic acids.

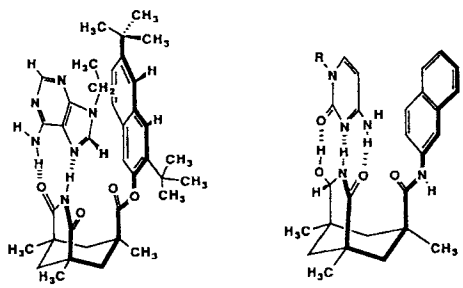
Merely heating Kemp's triacid with urea gives the imide, which presents a hydrogen-bonding surface similar to that of thymine. We were able to attach a number of molecular surfaces, including a series from methyl to anthracyl, and measure the association constants by NMR titration methods.[35] These gave the results shown (Scheme 10) in which it can be seen that about 400 cal mol^{-1} separate adjacent pairs of the series. The overall effect of a large polarizable aryl surface is worth about 1.2 kcal mol^{-1}, corresponding to nearly an order of magnitude in binding affinity at room temperature. These are not hydrophobic effects; rather, they represent the polarizability that an anthracyl surface experiences when the dipole of adenine is brought up against it. In other systems, progress has been made in understanding ion–dipole effects[36] and the intrinsic nature of hydrophobic effects.[37] Both of these advances have been made using macrocyclic structures in aqueous media.

Geometric considerations lead to the conclusion that the aryl–aryl interactions in these systems are of the face-to-face sort rather than the edge-to-face sort observed in protein interiors by *Petsko* et al.[38] There may even be the possibility that the stacking directly enhances the hydrogen bonding in such systems.[39] Even so, we were surprised to find that the aromatic surface not only increased overall binding, but could contribute to the *orientation* of the components. Experiments involving nuclear Overhauser enhancement (NOE) measurements established that, with small surfaces, roughly equal amounts of Watson–Crick and Hoogsteen base pairing (and their reverse counterparts) were involved in the complexation. Heteronuclear NOE experiments revealed that even bifurcated hydrogen bonding was present in these systems.[40] But the Hoogsteen/Watson–Crick ratio was affected by the length and shape of the aromatic surface. For example, with the extended anthracyl surface, the Watson–Crick base-pair mode, involving extensive overlap between the π systems, is favored (Scheme 10). On the other



Scheme 10.

hand, it was possible to use remote steric effects to enforce Hoogsteen base pairing.[41] Specifically, the *tert*-butyl derivative of the naphthyl ester (Scheme 11) can accommodate the aryl-stacking interaction best in the Hoogsteen mode; the Watson–Crick mode causes destabilizing steric interactions between the side chains of the receptor and adenine components.

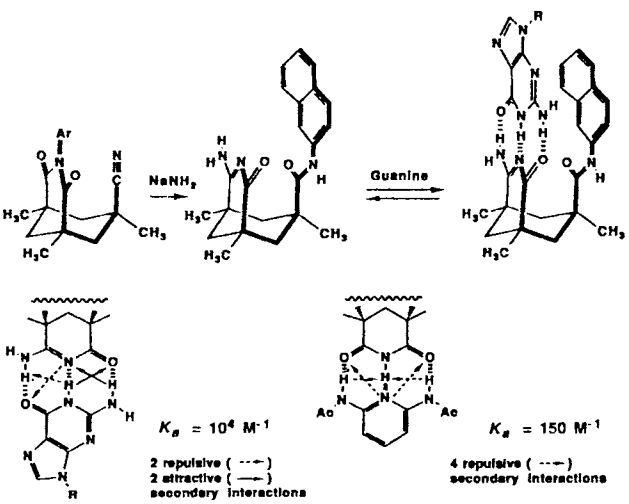


Scheme 11.

The pattern of hydrogen bonds and their significance in recognition could be explored by tailoring the edges of such structures. For example, the imides bind adenines over cy-

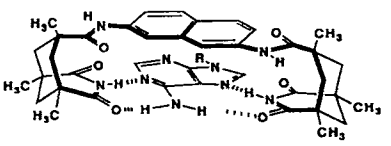
tosines by a factor of >20. Merely reducing the imide to the hydroxy lactam (Scheme 11) alters the acid–base patterns; cytosine is bound >10 times better than adenine.[42] At first glance, an *apparently* singular change alters the recognition pattern. However, because these forces act over such short distances, an isolated change is not possible. This reflects a frequently encountered problem in physical organic chemistry: *changes can rarely be made one at a time*. The influence of the change extends beyond the immediate atom or functional group and causes disruptions elsewhere. Interpretations become, accordingly, ambiguous.

We have recently been successful in preparing acylated amidine derivatives for the recognition of guanines.[43] These are prepared by treating the imide nitriles with amides such as $NaNH_2$ (Scheme 12, top). Association constants for the binding of guanines to such surfaces are greater than $10^4\ M^{-1}$. These again parallel earlier observations and bear out the more recent predictions of *Jorgensen* et al.[44] concerning the secondary interactions involved in hydrogen-bonding patterns. In parallel studies with macrocyclic frameworks, *Hamilton*'s group has been able to observe hydrogen-bonding and aryl-stacking interactions in the complexation of such nucleic acid components.[45]



Scheme 12. Ar = aryl.

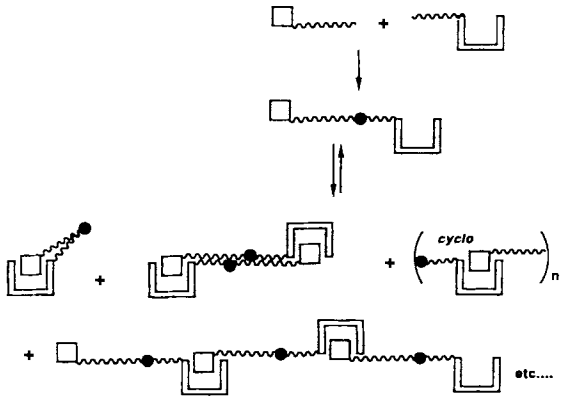
The triple helices that have been recently developed for sequence-specific DNA recognition[46] could also be modeled by these simple structures. By merely combining two imides with proper orientation on a single naphthyl surface, structures with extraordinary affinity for adenines resulted (Scheme 13). Adenine and even carbohydrate derivatives—adenosine and deoxyadenosine—could be extracted from aqueous solution and transported across organic liquid membranes by such materials.[47] We are currently developing systems for similar recognition and transport of nucleotides, using the guanidinium functions developed by *de Mendoza* et al.[48] and *Schmidtchen* et al.[49] (see also Section 9).



Scheme 13.

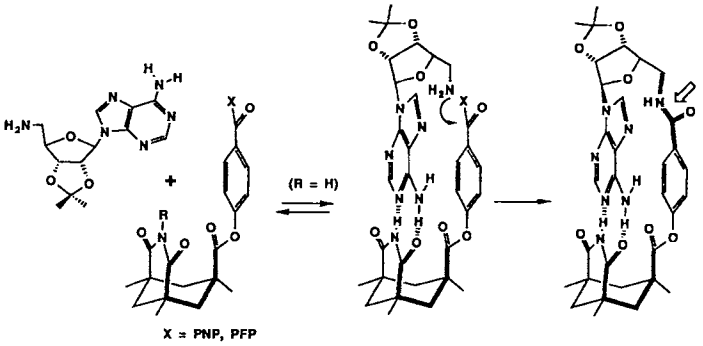
5. Recognition and Replication

Another dividend, perhaps even a distraction, resulting from our research in nucleic acid recognition has been the development of self-replicating systems. The premise was quite simple, even tautological; covalent attachment of an adenine to a receptor for adenine must lead to a molecule that can recognize itself. Provided that the orientation, flexibility, and spacing of the binding surfaces are appropriate, the molecule might collapse through intramolecular folding, it might dimerize, or even higher molecular assemblies might be organized (Scheme 14). In any event, such a molecule is self-complementary.



Scheme 14.

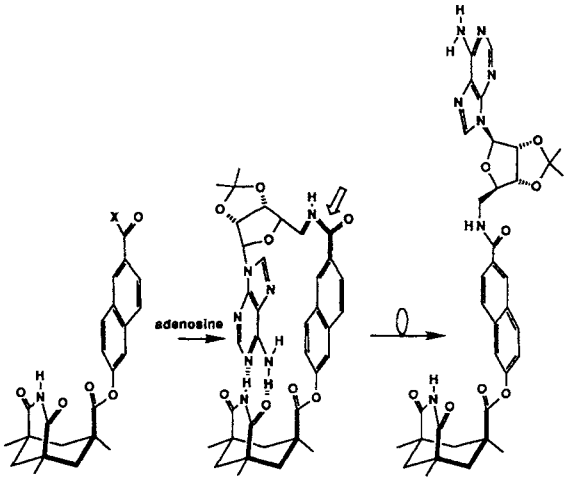
This simple notion has led us into swampy terrain or even the prebiotic soup. The simple aminolysis of the adenosine derivative with the imide bearing a phenyl spacer shows template-assisted behavior. That is, base-pairing precedes acyl transfer (Scheme 15). This is easily demonstrated; merely placing an *N*-methyl group on the imide reduces the coupling rate sixfold, a factor that can hardly be attributed to steric effects at a site so remote from the acyl-transfer reaction. The product with the phenyl spacer is self-complementary in an



Scheme 15. PNP = *p*-nitrophenyl; PFP = *p*-fluorophenyl.

intramolecular sense and it remains "folded shut". This is because a short phenyl spacer can accommodate a perfectly stable *trans* amide bond in the coupled product.

We next examined the consequences of using a longer naphthalene spacer. Again, template effects are operating and simple inhibition experiments can be used to demonstrate this. For example, other imides, as well as diacylamino pyridine, compete for the reaction surfaces and slow the coupling reaction. But now, when intramolecular acyl transfer does take place, the initial product is a *cis* amide. Once this material is formed, it can relax to the *trans* amide by a "jackknife" motion (Scheme 16). This exposes the complementary hydrogen-bonding surfaces and leads to dimerization (Fig. 1). The association constant observed for dimerization is somewhat less than would be expected for four reasonable hydrogen bonds and suggests that some steric effects are operating at the bulges in the middle of the dimer.



Scheme 16.

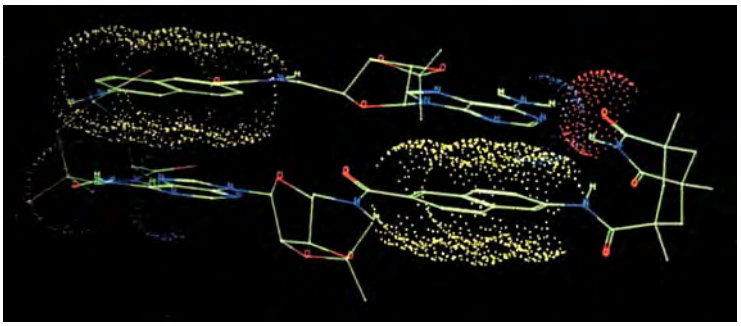


Fig. 1. Hydrogen-bonding (red/blue) and aryl-stacking interactions (yellow) stabilize a self-complementary and self-replicating system.

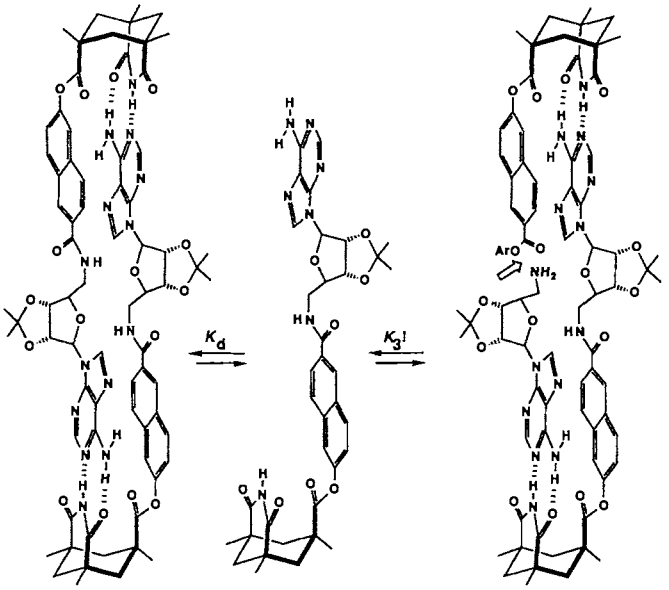
This system, however, shows a very astonishing feature of catalysis. *The product catalyzes its own formation,* and this is a primitive sign of a living system.[50] Addition of various amounts of product to coupling mixtures is observed to increase the initial coupling rates. One interpretation (yet unproven) is that in this case a third type of reaction leads to



Scheme 17. Ar = aryl.

coupled product. The likely process involves a termolecular complex (Scheme 17 and Fig. 2) in which electrophile and nucleophile are brought together on the product's surface acting as a template.[51] This reaction must be quite efficient, since it can be calculated from the known association constants that the termolecular species represents only a few

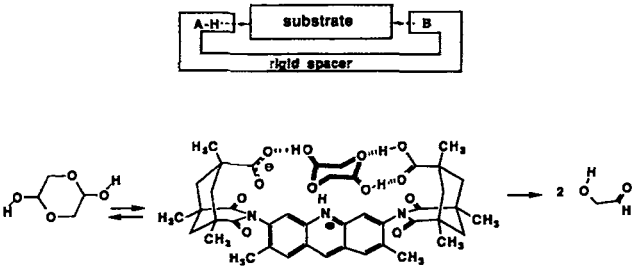
Fig. 2. Electrophile and nucleophile are brought together on a template through hydrogen-bonding (red, blue) and aryl-stacking (yellow) forces. Autocatalysis is observed in this self-replicating system.

percent of the reaction mixture. We are now refining the system to reduce the number of nonproductive complexes and thereby further increase the efficiency of autocatalysis. In the meantime, we draw attention to an exceptionally beautiful template-catalyzed system devised by *Kelly* et al.[52] for a substitution reaction.

6. Catalysis

Using base pairing to enhance acyl-transfer reactions is an example of bringing recognition and catalysis closer together in time. The ultimate goal in model systems would be to recognize transition states as is defined by the Pauling princi-

ple.[53] Many groups have been concerned with the development of such synthetic catalysts and a number of excellent examples exist in the chemistry of cyclophanes,[54] cyclodextrins,[55] and crown ethers.[56] In most bioorganic model systems, the general endeavor involves fitting a substrate into the host species, then placing catalytically useful functional groups nearby. The advantage of cleftlike molecules having rigid spacers is that both acidic and basic components can coexist without collapsing upon one another (Scheme 18). Convergence again is the key. Functional groups arranged in

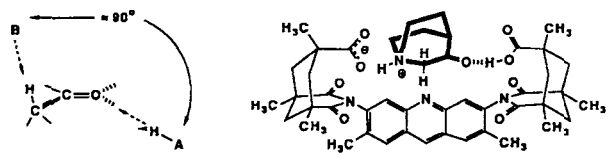


Scheme 18.

a divergent sense could annihilate one another in intermolecular interactions, but arrangement in a convergent sense, that is, on concave surfaces[57] with rigid spacers, allows the two groups to communicate only through solvent. Accordingly, concerted or general acid-base catalysis[58] is ideally suited for study with such molecular scaffolds.

Our first success with these was in the cleavage of a hemiacetal (Scheme 18).[59] This molecule just fits within the cleft and, once bound, a constellation of acids and bases can focus on the reacting centers. At the present time, the identity of the participating acid and base components is unknown. The carboxylic acid itself could act in the manner of a conventional mutarotation catalyst. Alternatively, the protonated acridine nitrogen and the carboxylate could act on the substrate from perpendicular directions.

We have permissive evidence for the latter sort of catalysis in the enolization of ketones. Stereoelectronic considerations indicate that the ideal arrangement for acid and base components in a concerted or "push-pull" mechanism involves the approach of such components from perpendicular directions (Scheme 19). This follows from the early observations of



Scheme 19.

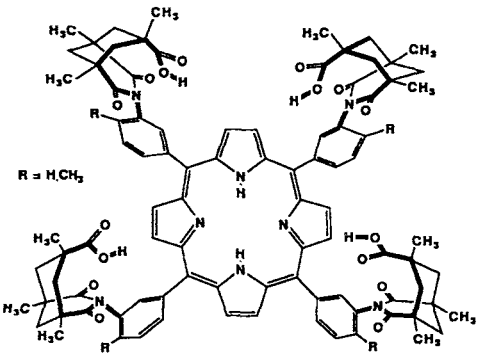
Corey and *Sneen*[60] and the recent NMR characterization[61] of simple enols in solution. The quinuclidinone shown fits within the cleft, and, in the complex, acids and bases are poised in the proper geometry. Catalysis of α-hydrogen exchange occurs.[62]

In the two previous examples, a substrate can be tailored to fit within the cleft, but it is a much more difficult proposition to design a catalyst for a given substrate or even type of reaction. Nonetheless, we cannot help but think that the efficient synthesis of cleftlike molecules and the richness of shapes, sizes, and functionality that they provide will offer solutions. In this we are responding to the message provided by naturally occurring molecules. They generally present *concave* surfaces: clefts, pockets, folds, and even grooves that are lined with a variety of chemical functions.

It may also be important to bring the recognition and the catalysis events closer in *space* as well as in time. The significance of this point stems from the difficulty in controlling conformations over considerable distances. Systems that fold back upon themselves can reduce the distance between functional groups and enhance their efficacy. The remarkable progress made recently with catalytic antibodies presents an urgent challenge. The combining sites of antibodies are unrivaled in selectivity and versatility. If catalytically useful functionality can be introduced, as has been achieved in some cases by *Lerner* et al.[63] and *Schultz* et al.,[64] model systems such as ours may become the dinosaurs of the 1990s.

7. New Sizes and Shapes

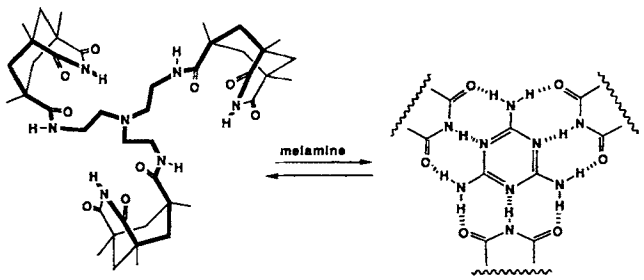
We have already reported on the uses and limitations of rigid aromatic spacers represented by the series benzene, naphthalene, and acridine.[9] We report now on progress with some newer spacers. Tetraarylporphyrins provide very large aromatic surfaces and a tetracarboxylic acid was readily synthesized (Scheme 20) by the procedure recently devel-



Scheme 20.

oped by *Lindsey* et al.[65] In this molecule, the space is appropriate for the complexation of 4,4′-bipyridine derivatives. A 2:1 complex is formed, since one bipyridine can be held above the porphyrin plane by two carboxylic acids while a second is held beneath, perpendicular to the first.[66] It should be possible to develop metal-ion derivatives of these molecules in which the reactive metal center is brought to the middle of an α,ω-diamine grasped at both ends by the carboxyls. Within macrocyclic frameworks, this notion is being explored by *Lehn*'s group[67] and *Sutherland*'s group.[68]

Spacers with three arms have also been obtained. For example, the *tris* imide in Scheme 21 shows an extraordinary



Scheme 21.

affinity for melamine.[66] This material forms 1:1 complexes (Fig. 3) and features slow exchange at room temperature. Dilution studies put the lower limit on the dissociation constant in the micromolar range.

Rigid spacers with three arms are also available. Condensation of acetophenone derivatives leads to triarylbenzenes (Scheme 22). These have been used in molecular recognition

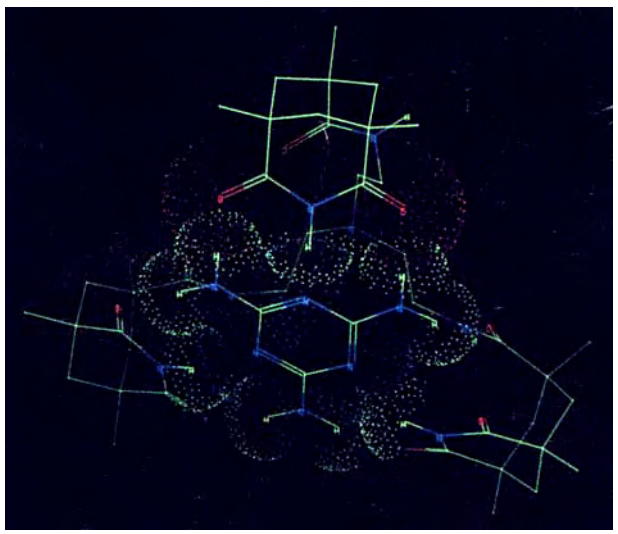


Fig. 3. Three imide functions converge to provide a complementary hydrogen-bonding surface to melamine. Convergent functional groups tailored for small, biorelevant targets are a key feature of model systems for molecular recognition.

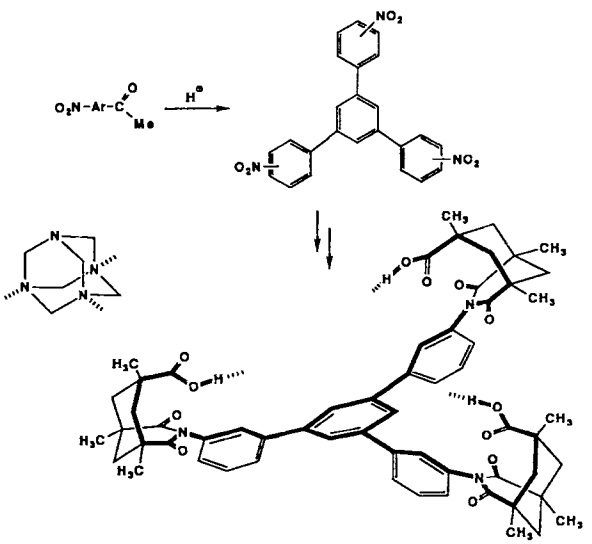
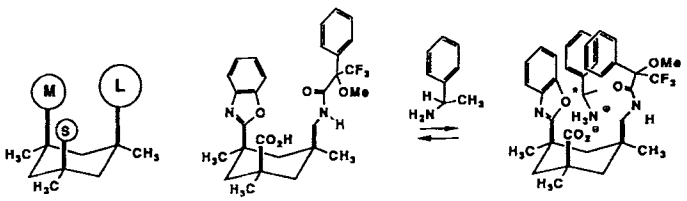


Scheme 22. Ar = C_6H_4.

studies by *Vögtle* et al.[69] We have also prepared the Kemp triacid derivatives of these systems. For example, the *meta*-substituted compound binds hexamethylenetetramine quite nicely; at low temperature, the exchange process can be frozen out. A larger cleft, represented by the *para*-substituted compound, is also easily prepared.[70] Macrocyclic compounds have also been devised recently by *Still*'s group for complexation of heterocycles.[71] These studies have led to the discovery of the effects of solvent size on complexation phenomena.[72]

8. Asymmetry and Auxiliaries

Asymmetric recognition has been a long-standing endeavor in complexation chemistry, and, for reasons that are not at all clear, most synthetic receptors, both macrocyclic and cleft-shaped,[73] feature C_2 symmetry. As we have pointed out, there is no advantage of this shape for recognition of a single asymmetric center.[74] Rather, as in *Pirkle*'s systems,[75] three contact points appear to be the minimal requirement. Whether such points of contact are attractive or steric in nature, they are much better suited in shape for recognizing a single asymmetric center than are more symmetrical shapes. The Kemp triacid may be regarded as a tripod on which three groups—large, medium, and small—can be placed on a single face of the molecule (Scheme 23), and we have found such structures useful for asymmetric recognition.

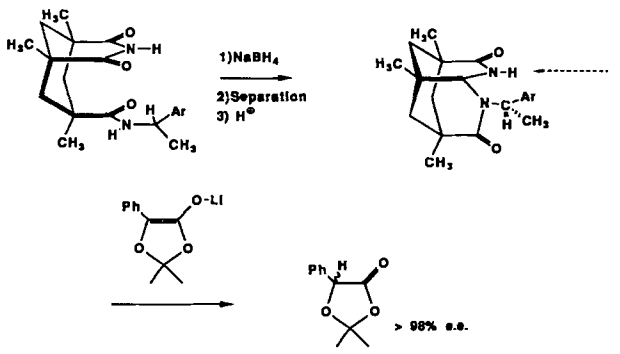


Scheme 23.

More recently, we have developed sandwiching (Scheme 23). Aromatic amines are bound initially by the acid–base interaction; then the two aryl surfaces of the receptor surround the amine as shown.[76] In these systems as well as others we have explored, acidity is directed toward an asymmetric microenvironment. This can be contrasted with conventional carboxylic acids in which acidity is directed *away* from the nearest asymmetry (usually at the α-carbon).

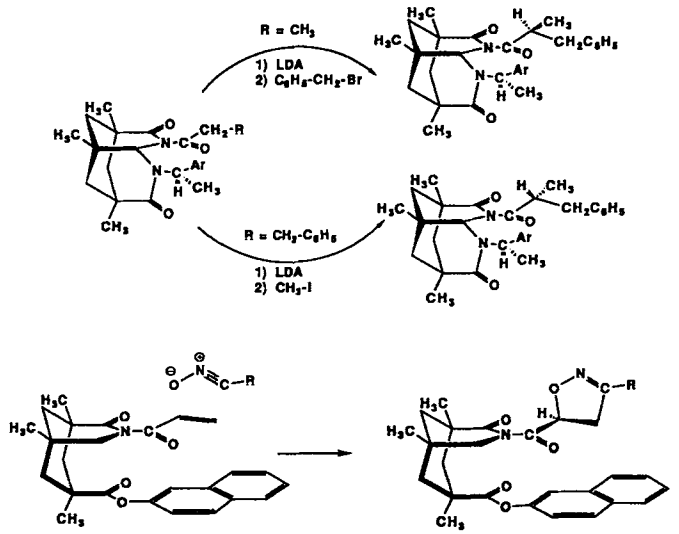
We have now developed these findings into some chiral proton sources. The tricyclic lactam shown in Scheme 24 is quite efficient in this regard. It is prepared in simple steps and it protonates the test system developed by *Hünig* et al.[77] in $\geq 98\%$ enantiomeric excess. From studies of other diastereomers it is clear that both the asymmetric center and the sense of molecular asymmetry of the cyclohexane ring are involved.[78]

Derivatives of this structure are also quite effective as chiral auxiliaries. For example, acyl derivatives can be prepared as shown in Scheme 25 and their enolates show high diastereofacial selectivity in complementary alkylation reac-



Scheme 24. Ar = aryl.

tions.[79] The selectivity extends to other types of reactions as well. *Curran* et al.[80] have shown that acryl derivatives, as well as other derivatives, feature high selectivities in cycloadditions with nitrile oxides. The extended shelf beneath the



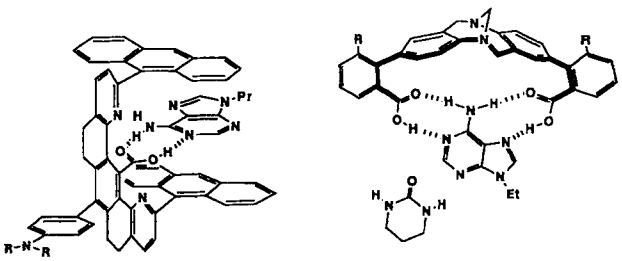
Scheme 25. Ar = 2-naphthyl. LDA = lithium diisopropylamide.

structure prevents approach of the notoriously unselective nitrile oxide from the bottom. Removal of the auxiliary can be accomplished by, among other methods, selectride reduction.

9. Newer Cleft Systems

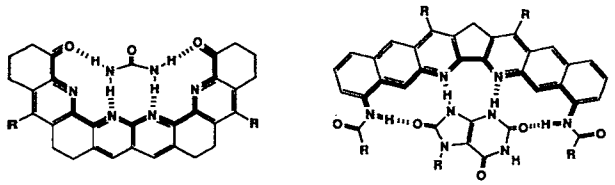
It would be negligent of me to overlook the rapid progress being made elsewhere in the area of molecular recognition, particularly as many of the new systems involve cleftlike structures. A large number of these feature acidic sites that converge: NH bonds, OH bonds, and even metal-ion empty orbitals.[81] The slow development of these systems reflects the greater difficulty in arranging convergent Lewis acidic sites versus Lewis basic sites; that is, it has always been easier to complex cations than anions.

Two new cleftlike systems have appeared for complexation of adenine derivatives (Scheme 26). Remote steric barriers enforce the concave shapes of these structures, and they show unprecedented affinity for adenine derivatives. *Zimmerman* et al.[82] report a system that features a carboxyl group deep within the cleft with low accessibility to solvents. *Wilcox* et al.[83] have a system that features convergent carboxylic acid at a distance appropriate for simultaneous Watson–Crick and Hoogsteen binding. This latter structure has added versatility; rotation about the carboxyl group leads to hydrogen-bonding patterns complementary to, for example, trimethylene urea.



Scheme 26.

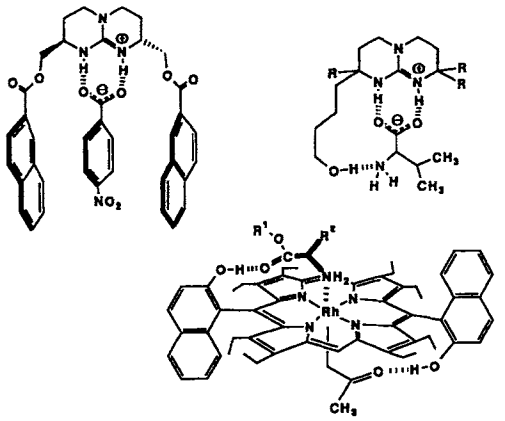
Another recent development is the synthesis of "two-dimensional" systems for the complexation of flat substrates (Scheme 27, left). *Bell* et al.[84] have developed a naphthyridine-derived system which binds urea. It should be possible to enhance binding by incorporating acidic sites for the carbonyl oxygen. *Kelly* et al.[85] have prepared complexing agents for uric acid derivatives (Scheme 27, right). The gentle curvature imparted by the central five-membered ring provides the complementary functions for the convex shape of the substrate. The inflexibility of such systems places a high premium on arranging an exact match between host and guest. Systems with a little adjustability (and corresponding "promiscuity") are usually easier to synthesize. The ideal design for artificial receptors is still a matter of some debate.



Scheme 27.

Systems for the binding of carboxylates have also been developed, and a cleftlike strategy has been useful to arrange additional contacts between host and guest. Since initial encounter of the carboxylate is with its *syn* lone pairs, a U-turn must be built into the receptor to arrange contacts beyond the α-carbon of the acid. One system, prepared by *de Mendoza* et al.[48] involves a guanadinium derivative (Scheme 28) in which aryl-stacking interactions provide the additional contact. The second system, due to *Schmidtchen* et al.,[49] also uses the guanadinium function and a well-placed hydroxyl group to provide an additional hydrogen bond. By using highly lipophilic derivatives of this receptor, valine can

be extracted as the anion from aqueous solution into $CHCl_3$. Both of these systems have excellent potential for asymmetric recognition.



Scheme 28.

Finally, a porphyrin derivative has been developed by *Aoyama* et al.[86] for the recognition and extraction of amino acids and their derivatives. The metal ion in the porphyrin complexes the amine, and hydroxyl groups on the periphery stabilize the carboxyl by hydrogen bonding.

Excitement continues in macrocyclic host–guest chemistry as well. Molecular belts and collars[87] and molecules within molecules[88] define the leading edge of this field. Self-assembling structures are also emerging,[89] but are beyond the scope of the present review.

10. Perspective

As the discussion above indicates, most of the activity in model systems for molecular recognition is concerned with the design of host species for small, convex, biorelevant targets. In addition to the amino acid and nucleic acid components, carbohydrates[90] and dicarboxylates[91] have become accessible targets and synthetic drugs such as barbiturates[92] can also be complexed. The sequestration of small endogenous intermediates is the first step in what may become a new pharmaceutical tactic. Biochemical cycles could be interrupted by either removing these intermediates, or processes could be enhanced by delivering them to the requisite sites more effectively. Their sequestration requires access to medium-sized molecules with concave surfaces such as described in this review.

Why has Nature not availed itself of this type of intervention? One reason may be stoichiometry. When the targets are biological macromolecules such as receptors, enzymes, or nucleic acids, the low concentrations of such molecules require only small "doses". But in at least in one case, Nature has availed itself of concave agents. The vancomycin antibiotics are of the size of structures discussed here and involve a concave surface lined with hydrogen-bonding arrays complementary to a dipeptide terminus. With access to molecules of intermediate size, such as antibody-combining sites, synthetic peptides, and synthetic nucleotides, the tactic offered by the concave medicinal agent may become an attractive one in the future.

I am grateful to the outstanding group of young men and women who have been associated with this project; their names appear on the publications cited. The National Institutes of Health and the National Science Foundation provided financial support of this research.

On the Conformation and Structure of Organometal Complexes in the Solid State: Two Studies Relevant to Chemical Synthesis

By Soroosh Shambayati, William E. Crowe, and Stuart L. Schreiber *

Dedicated to Professor Jack Dunitz

Conformational preferences of two classes of organometal complexes have been surveyed by inspecting the Cambridge Structural Database (CSD). Lewis acid carbonyl complexes demonstrate a variety of coordination geometries, depending on the electronic and steric requirements of the carbonyl ligands and the nature of the Lewis acid. Similarly, the solid-state conformation of various π-bonding ligands in metal acyl, metal nitrosyl, metal acetylene, and metal imido complexes is revealed. These insights have stimulated the development of a conformational model that is based on considerations of π-bond hybridization and frontier molecular orbital theory. The analyses are relevant to the mechanism and transition structures of many synthetically important transformations. A deeper understanding of the conformational properties of organometal complexes, based on accurate structural information, will likely expedite the design and improvement of metal-mediated processes.

1. Introduction

Soon after the advent of X-ray crystallography, it became clear that crystal structures can uncover more than just a simple picture of the covalent connectivity of molecular entities.[1] The realization of the potential of X-ray crystallography in providing information regarding two central questions in chemistry—namely, reactivity and the three-dimensional conformation of molecules—rapidly led to the foundation of the powerful field of structural chemistry.[2] In organic chemistry, perceptions of bonding and reactivity have benefited from this structural approach enormously. Although many of the important questions remain unanswered, many of the ground-state physicochemical properties of molecules can be predicted fairly reliably by the structural theory of organic chemistry. At first, it seemed implausible that static, crystalline species could reveal any information regarding the dynamics of transition states. However, the pioneering work of *Dunitz, Bürgi,* and coworkers in the early 1970s showed that, in certain instances, even these parameters can be derived from the inspection of a family of crystal structures.[3] Hence, this approach came to be known as the "structure–reactivity correlation" method.[4]

Today, largely due to the efforts of the Cambridge Crystallographic Data Centre[5] and partly due to the ready availability of powerful and efficient computing machines, thorough searches of more than 70000 crystal structures of organic, inorganic, and organometallic compounds can be achieved with reasonable ease and speed. Attracted by the wealth and accuracy of the information provided by crystal structure analyses, an ever-growing number of organic chemists now utilize this powerful tool to infer mechanistic and conformational hypotheses based on structural data.[6] This approach has been particularly fruitful in the study of weak interactions such as hydrogen bonding[7] and donor–acceptor interactions of Lewis acid–Lewis base pairs.[8]

In this review we shall describe how analyses of crystal structures led to the formulation of principles and hypotheses regarding the conformational preferences of two classes of organometal complexes. First, we report on recent insights into carbonyl–Lewis acid complexation. Next, the influence of π bonding on the conformation of a variety of ligands attached to transition metals will be addressed. In both instances the original search of the Cambridge Structural Database (CSD) was prompted by a simple question regarding the conformation of a complex or an intuitive hunch about the origins of an unusual observation. Unfortunately, even after careful inspection of numerous crystal structures, the answers to the original questions were not altogether transparent. However, during this exercise many important lessons were learned and some of the missing links in the context of the more general problem were pinpointed. It is hoped that these observations will not only lead to a better understanding of the conformational properties of organometal complexes, but also guide future efforts in related areas of research.

2. Carbonyl–Lewis Acid Complexation

A Lewis basic carbonyl group can be activated through coordination to a metal-centered Lewis acid, with profound reactivity and stereochemical consequences. In the context of asymmetric synthesis, many of the Lewis acid–mediated reactions are known to proceed with improved stereoselectivities as compared to their non-catalyzed counterparts, and, most recently, a variety of chiral Lewis acids have been used as remarkably efficient catalysts for carbonyl addition processes.[9] Although the origins of many of the effects brought about by Lewis acids are still poorly understood, it is clear that the conformational preferences of the Lewis acid carbonyl complex are ultimately responsible for determining the stereochemical course of Lewis acid–mediated reactions. In

Sections 2.1–2.3, some of the crystallographic studies on the complexes of Lewis acids with organic carbonyl ligands will be discussed. The relevance of the crystallographic data to the general conformational biases of such complexes will be the focus of this discussion.

2.1. Conformational Issues

Factors that may influence the reactivity and conformation of Lewis acid carbonyl complexes can be classified broadly into three categories. The primary question in analyzing a Lewis acid carbonyl complex concerns the mode of coordination. Both η^1 (σ) bonding and η^2 (π) bonding of Lewis acids to carbonyl ligands are observed (Fig. 1), and, as will be seen, crystallographic studies seem to provide fairly straightforward rules for the prediction of each mode of coordination.

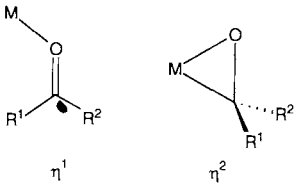

Fig. 1. σ (left) vs. π (right) bonding in Lewis acid carbonyl complexes.

Second, the exact location of the Lewis acid with respect to its carbonyl ligand is of interest. Specifically, knowledge of the range and limits of several parameters, such as the Lewis acid–oxygen distance r and the angles θ and ϕ in Figure 2, is an obvious requirement for the prediction of the structure of these complexes.

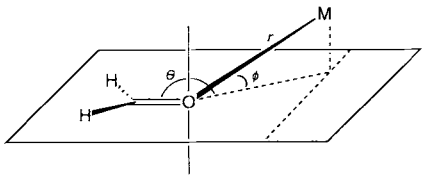

Fig. 2. Definition of the parameters r, θ and ϕ.

Third, the effect of Lewis acid coordination on the inherent conformational preferences adjacent to the carbonyl group should be considered. In particular, how is the s-*cis*–s-*trans* equilibrium of α,β-unsaturated carbonyls or the energy

Stuart Lee Schreiber was born in 1956 and raised in Virginia. His undergraduate studies were at the University of Virginia in Charlottsville from 1973 to 1977. It was at Virginia, in the laboratory of Professor Richard J. Sundberg, that he first discovered the excitement of organic chemical research. He spent the following years (1977–81) at Harvard University in the Chemistry Department, where he received his doctorate with Professors R. B. Woodward and Yoshito Kishi. His first appointment, as Assistant Professor, was at Yale University (1981), where he was promoted to Associate Professor (1984) and then Professor (1986) of Chemistry. In 1988, he returned to Harvard to accept a position in the Chemistry Department as Professor of Chemistry. His research interests include the synthesis and conformational analysis of complex systems, including complexes of ligands and their biological receptors.

Soroosh Shambayati was born in Tehran, Iran, on December 8, 1964. After receiving his secondary education in Sweden, he moved to the United States in 1982. He studied chemistry at Occidental College under the direction of Professor Donald Deardorff, before joining Professor Schreiber's research group at Yale University in 1986. In 1987 he followed Professor Schreiber to Harvard University, where he is now a fourth-year graduate student.

William E. Crowe was born in Salem, Massachusetts, on May 31, 1960. He received a B.S. degree from the California Institute of Technology and earned his Ph.D. under Professor Stuart Schreiber at Yale University. Currently, Dr. Crowe is an NIH postdoctoral fellow at the Massachusetts Institute of Technology under the direction of Professor Richard Schrock.

profile for the rotation about the CO–C_α bond of nonconjugated carbonyls affected by Lewis acid complexation (Fig. 3)?

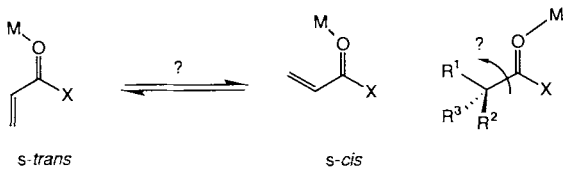

Fig. 3. How is rotation about the CO–C_α bond of carbonyls influenced by Lewis acid coordination?

2.2. Crystal Structures of Lewis Acid Carbonyl Complexes

2.2.1. *Cationic Alkali-Metal Lewis Acids*

Some of the earliest inquiries into such questions were performed by *Dunitz, Seebach,* and co-workers. In their report of the crystal structure of the LiBr–acetone complex, these researchers discussed the conformational biases of alkali–metal carbonyl complexes.[10] In particular, the LiBr–acetone complex assumes a dimeric form in the solid state, in which each lithium ion is coordinated by two molecules of acetone through the carbonyl lone-pair electrons with a bent, planar geometry in a tetrahedral environment (Fig. 4). The

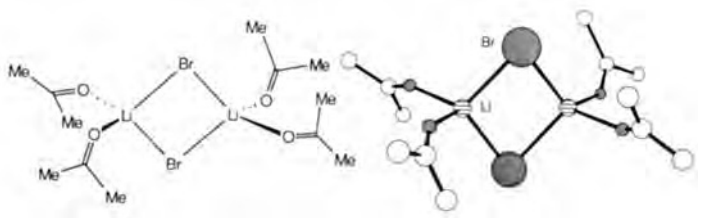

Fig. 4. Crystal structure of LiBr–acetone complex [10].

Li–O bond length is 2.0 Å, the Li–O–C angle 145°. In order to determine the generality of these observations in other alkali-metal carbonyl complexes, the researchers also conducted a general search of the Cambridge Structural Database. Of the nine crystal structures that were analyzed in this study, six contained $Li^\oplus$, two $Na^\oplus$, and one $K^\oplus$ as the Lewis acid bound to the carbonyl ligands. The coordination angle θ for $Li^\oplus$ (cf. Fig. 2) was consistently found to be less than 180° (120–156.3°), but large distortions from planarity ($\phi \neq 0°$) seemed to occur randomly. Furthermore, the Li–O bond distance showed no linear dependence on the Li–O–C–X dihedral angle.

The crystal structures of $Na^\oplus$ complexes, however, showed that linear and bent geometries are equally accessible and bending out of the plane of the carbonyl was once again observed (Fig. 5).[11]

The researchers concluded that the potential energy surface for carbonyl coordination to alkali metals is likely to be fairly flat with respect to changes in the M–O–C angle and the M–O–C–X dihedral angle.

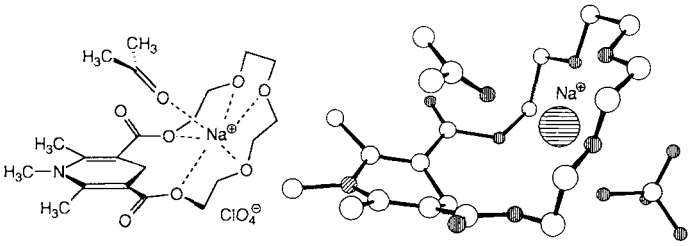

Fig. 5. Linear complexation of a $Na^\oplus$–acetone complex [11].

A more recent search of the CSD for crystal structures of alkali-metal carbonyl complexes also confirmed these results.[12] The average Li–O bond length and the Li–O–C bond angle were found to be 1.99 ± 0.07 Å and 139 ± 3°, respectively. Of the 23 examples found, 9 exhibited coordination by more than 10° out of the plane of the carbonyl group.

Thus, cationic alkali-metal Lewis acids do not exhibit any strong directional preferences upon coordination to carbonyls. In particular, bending toward the π cloud of the carbonyl ($\phi \neq 0$) with no significant lengthening of the M–O bond is commonly observed. Coordination seems to occur from the direction that best satisfies the cation's electron demand and minimizes steric interactions. These, in turn, depend on the coordination number of the cation, the relative size and electronic properties of the ligands, and, in the solid state, on crystal packing forces.

Two remarkable examples of the diversity of $Li^\oplus$–carbonyl coordination can be found in the crystal structures of $Li^\oplus$ bound to the cyclic decapeptides antamanide and perhydroantamanide, reported by *Karle*.[13,14] In the $Li^\oplus$–antamanide complex (Fig. 6), for instance, lithium was found to

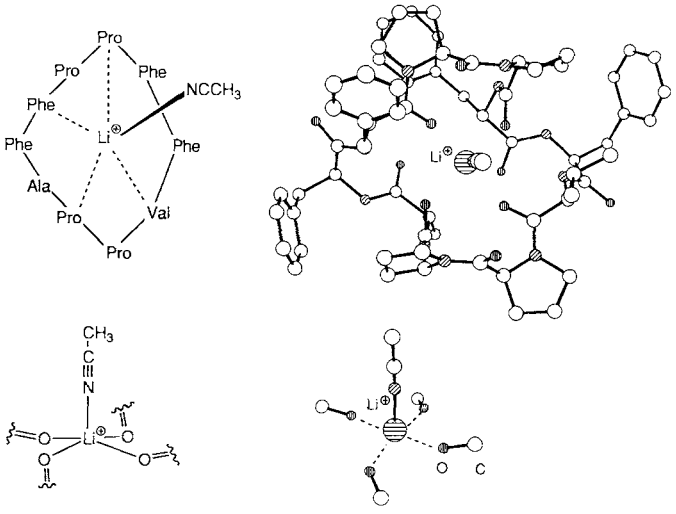

Fig. 6. Crystal structure of $Li^\oplus$–antamanide complex [13].

be pentacoordinated to four carbonyl oxygens and the nitrogen atom of an acetonitrile solvent molecule in a pseudo-square-pyramidal arrangement. In this structure, the Li–O bond lengths and Li–O–C bond angles are similar to the values discussed previously and are consistent with the principles of the foregoing discussion.

It is interesting to note that ab initio, gas-phase calculations on the $Li^{\oplus}$–carbonyl complexes predict a strong preference for the linear, planar geometry ($\theta = \phi = 0°$), wherein the main source of metal–carbonyl interaction is electrostatic ion–dipole attraction.[15, 16] This discrepancy with the experimental observations may be an artifact of either the assumption of in vacuo conditions or the restriction of 1:1 stoichiometry. Thus, bent geometries may have been predicted had solvent molecules or additional carbonyl ligands been included in these calculations.

2.2.2. *Main-Group and Early-Transition-Metal Lewis Acids*

Relative to alkali-metal cations, neutral Lewis acids seem to perform much more consistently. The crystal structure of the BF_3–benzaldehyde complex may serve as a representative example (Fig. 7).[17] Here the Lewis acid is placed 1.59 Å

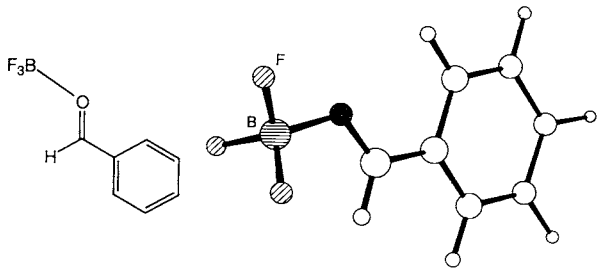

Fig. 7. Crystal structure of BF_3–benzaldehyde complex [17].

from the carbonyl oxygen, along the direction of the oxygen lone pair and *anti* to the larger phenyl substituent.[18]

Although crystal structures of other bimolecular complexes of carbonyls with boronic Lewis acids have not been reported, a number of intramolecular chelates have been detected in the solid state.[19–21] In all these cases boron is found to lie in the direction of the carbonyl lone pair with no more than an 11° distortion (ϕ) away from the best plane of the carbonyl group. The average B–O bond length (r) is 1.581 ± 0.019 Å and the B–O–C angle lies between 112 and 119°.

A search of the CSD files for the Al–O=C substructure revealed thirty such interactions with Lewis acidic aluminum atoms from 23 crystal structures.[13] Mean values for the Al–O distances (r) and Al–O–C bond angles were found to be 1.88 ± 0.09 Å and 136 ± 4°, respectively, and aluminum was found to lie within 18° (ϕ) of the carbonyl plane.

The crystal structure of the $AlCl_3$–tetramethylurea (TMU) complex shows a 1:1 adduct (Fig. 8) in which aluminum binds to the carbonyl lone-pair electrons at an angle of 132.5° and at a distance of 1.78 Å.[22] The C–O bond length (1.239 Å) is approximately 0.06 Å longer than that of unbound TMU and 0.03 Å longer than in the corresponding Me_2SnCl_2–TMU complex. The Lewis acid is slightly out of the plane of the carbonyl, although the dimethylamino group *syn* to aluminum is completely twisted out of conjugation to avoid steric interactions.

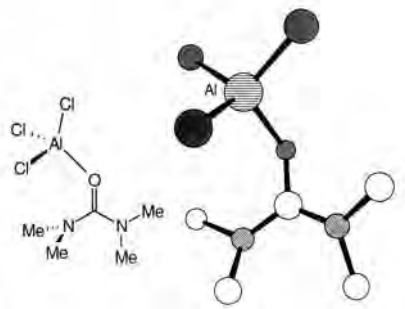

Fig. 8. Crystal structure of $AlCl_3$–TMU complex [22].

Based on the average values revealed in the CSD searches (see above), it may be reasonable to propose that the structure in Figure 8 reflects the "idealized" or low-energy mode of coordination to carbonyls for aluminum-centered Lewis acids. It would be interesting to see how distortions away from such an arrangement may come about. Imposition of steric congestion through bulky substituents is one way to address this question. The crystal structure of the complex formed between (2,6-di-*tert*-butyl-4-methyl)phenoxydiethylaluminum and methyl *p*-toluate was recently reported by *Ittel* et al. (Fig. 9).[23] In this structure a pseudo-tetrahedrally

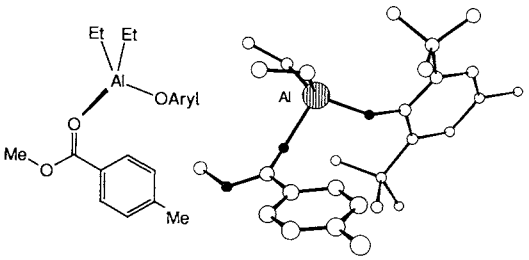

Fig. 9. Crystal structure of $Et_2Al(OAryl)$–methyl *p*-toluate complex [23]. Aryl = 2,6-tBu$_2$-4-Me-C_6H_2.

coordinated aluminum is positioned 1.89 Å from the carbonyl ligand. The Al–O–C angle of 145.6° is on the more linear end of the Al–O–C angle spectrum, but, more interestingly, the Al–O–C–C torsion angle (49.9°) shows considerable bending toward the π plane. Clearly, this distortion from the idealized structure is a result of the unusually bulky di-*tert*-butylphenoxide ligand on the Lewis acid, coupled with the fact that in *Z* aromatic esters both sp^2 lone pairs are fairly hindered. Notice that other available mechanisms for relief of steric strain were not employed. Either twisting of the phenyl substituent or alteration of an idealized *Z*-ester conformation could have accommodated a more planar Lewis acid complex, but neither occurs to any considerable extent (τ(O-C-C-C) = 12.1°, τ(O-C-O-C) = 4.1°). Furthermore, a linear Lewis acid complex would also avoid steric interactions with the carbonyl substituents, but this mode of coordination seems to be excluded as well. These results suggest that the energetic barrier for out-of-plane bending of the Lewis acid is less steep and probably lower than the barrier for either *E*/*Z* ester isomerization, rotation about the phenyl–carbonyl C–C bond, or *in-plane distortion to a linear structure*. The latter proposition is in sharp contrast to theoretical predictions.[24]

Ittel's crystal structure (Fig. 9) also supports a model proposed by *H. Yamamoto* et al. for the complexation of bulky aluminum Lewis acids to carbonyls.[25] These researchers have attributed the preponderance of axial attack of nucleophiles on cyclohexanones such as **1** (formation of **3**), in the

presence of the Lewis acid MAD, to out-of-plane complexation (**2**), as depicted in Figure 10.

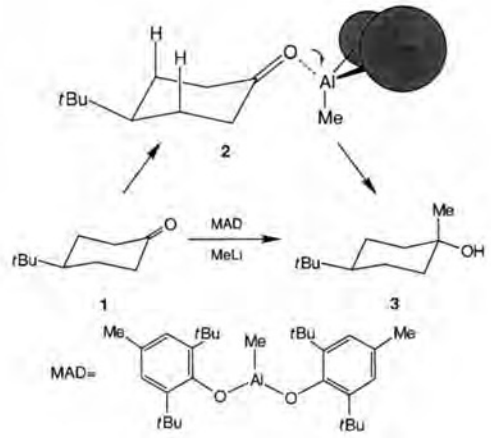

Fig. 10. Out-of-plane complexation of MAD to carbonyls leads to axial attack of nucleophiles on cyclohexanones such as **1** [25].

When a Lewis acid possesses two empty coordination sites, another degree of complexity is added to the structural issues discussed above. Titanium(IV) Lewis acids, for example, show a strong preference for a six-coordinate, octahedral arrangement. Thus, the acid:carbonyl stoichiometry for these complexes is often 1:2 or, when only a single equivalent of the carbonyl base is present, dimeric structures with bridging ligands are observed. The crystalline 1:1 adduct of $TiCl_4$ and ethyl acetate, for example, contains dimeric units of two octahedrally coordinated titaniums with bridging chlorine atoms (Fig. 11).[26] The 2.03-Å-long Ti–O bond is almost

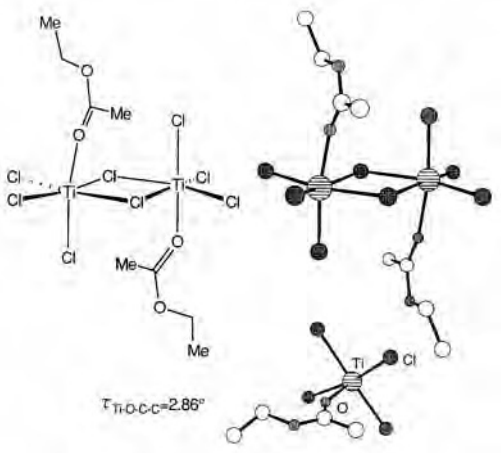

Fig. 11. Crystal structure of $TiCl_4$–ethyl acetate complex [26]. Bottom right: Side view of in-plane titanium coordination.

coplanar with the carbonyl group (τ(Ti-O-C-C) = 2.86°) and the Ti–O–C angle is 152°.

These values agree well with the average Ti–O bond lengths and Ti–O–C bond angles derived from searches of the CSD files (mean Ti-O = 2.14 ± 0.07 Å), though the Ti–O–C angle is on the wider side of the observed range (mean Ti-O-C = 125 ± 12°).[12] The *Z* conformation of the ester is retained (τ(O-C-O-C) = 2.6°) due to *syn* coordination of the Lewis acid to the methyl substituent.

In line with the behavior of aluminum-centered Lewis acids, deviations from the idealized conformation are observed when steric congestion is imposed on the structure. This point is illustrated in the crystal structure of the $TiCl_4$–ethyl anisate complex (Fig. 12).[27] Although at first glance

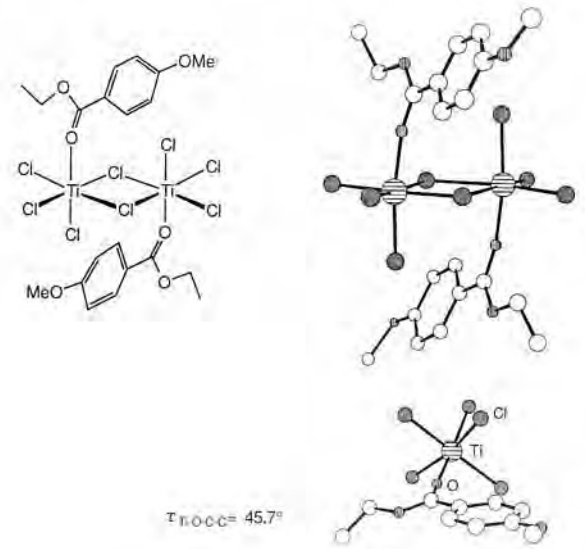

Fig. 12. Crystal structure of $TiCl_4$-ethyl anisate complex [27]. Bottom right: Side view of out-of-plane titanium coordination.

the main features of this complex (dimeric complex, octahedral titanium, etc.) are very similar to those of the $TiCl_4$–ethyl acetate structure, out-of-plane bonding to the carbonyl clearly distinguishes the two structures. The Ti–O–C–C dihedral angle is 45.7° and the Ti–O–C angle has now opened up to 168.7°. The *Z* conformation of the ester is still intact (τ(O-C-O-C) = 1.4°), and the Lewis acid is bound more or less *syn* to the phenyl substituent, which, in turn, is twisted out of conjugation and away from the Lewis acid by 13.0°. These structural features are very similar to those of the bulky aluminum Lewis acid complex (Fig. 9) and one may expect them to be quite general in similar systems. Interestingly, distortions from the idealized structures are more prominent for the titanium complex, which may suggest that, in the dimeric form, $TiCl_4$ is in fact even larger than the aryloxyaluminum reagent or that π distortion occurs more readily for Ti than for Al.

Extreme out-of-plane bonding is observed in the crystalline complex of $TiCl_4$ and acryloylmethyl lactate (Fig. 13).[28] In this structure Ti is bound by two ester car-

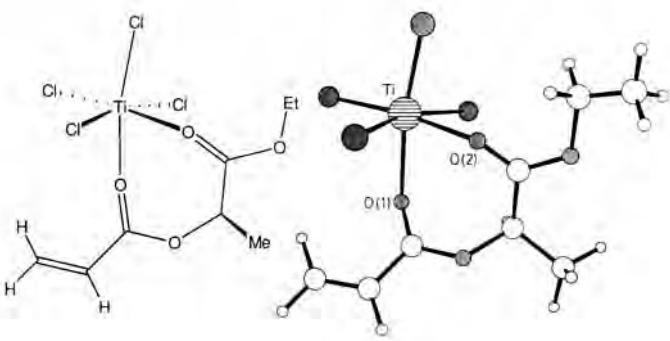

Fig. 13. Crystal structure of $TiCl_4$–acryloylmethyl lactate complex [28].

bonyls in a seven-membered ring chelate. Both carbonyls are bound out-of-plane with τ(Ti-O(1)-C-C) = 63.6° and τ(Ti-O(2)-C-C) = − 132.2°. Both esters, however, remain very close to planarity (τ_1 = 8.8°, τ_2 = 4.1°) and in the preferred *Z* conformation. Furthermore, due to the presence of a chelate ring, the Lewis acid is *anti* to the acrylate double bond and the enoate adopts an s-*cis* geometry. It is difficult to rationalize out-of-plane bonding in this case since direct steric interactions appear to be unimportant. Moreover, out-of-plane bonding cannot be the result of chelation, since crystal structures of $TiCl_4$ chelated by acetic anhydride (Fig. 14, left)[29] or 3,3-dimethyl-2,4-pentanedione[30] show no evidence for π bonding. Even the seven-membered ring

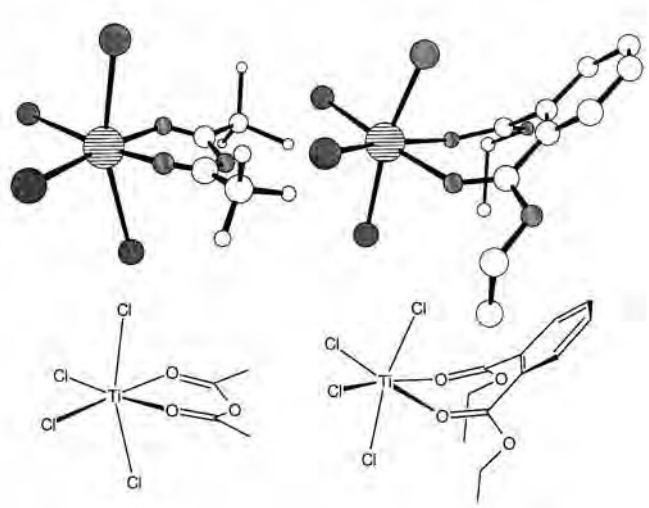

Fig. 14. Crystal structure of two $TiCl_4$ chelates [29, 31].

diester chelate of $TiCl_4$ with diethyl phthalate (Fig. 14, right) has the Lewis acid coplanar with the carbonyl ligands.[31] Another noticeable feature of the chelated structures is that they are all monomeric, probably due to the ability of the bidentate ligands to satisfy titanium's desire for hexacoordination and octahedral geometry.

The crystal structures of titanocene cations containing coordinated dimethylformamide (DMF) also support the idea of loose angle dependence of carbonyl coordination to titanium Lewis acids. For example, the $[Cp^*_2TiCl]^{\oplus}$–DMF complex displays a near-linear Ti–O–C angle of 167.0° and a Ti–O–C–N dihedral angle of − 140.2° (Fig. 15).[32] Similar semilinear η^1 bonding is also observed for the $[Cp^*_2Ti]^{2\oplus}$–$(DMF)_2$ complex.[32] In this structure the two Ti–O–C angles are 148.1° and 158.2° and the respective dihedral angles 163.6° and 174.2°.

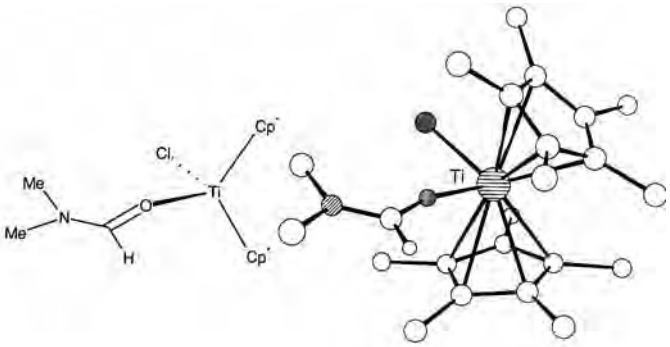

Fig. 15. Crystal structure of $[Cp^*_2TiCl]^{\oplus}$–DMF complex [32].

Zirconocene complexes with ketone and aldehyde ligands show yet another interesting variety of coordination chemistry. In the solid state, carbonyl-bound zirconocenes are often found η^2-coordinated and in dimeric units. The structure of the zirconocene–benzophenone complex is illustrative (Fig. 16).[33] In this structure the observed Zr–O–C geometry, the benzophenone C–O bond lengths (1.425 and 1.419 Å), and the Zr–C distances (2.346 and 2.35 Å) indicate a π-bonded metallaoxirane conformation. The fundamentally different modes of coordination for the related zirconocene and titanocene structures are doubtless a result of the electronic requirements of the Lewis acid. Thus, η^2 bonding seems to be the preferred mode of coordination for the more electron-rich zirconium complexes, while η^1 complexation is observed with the more highly oxidized titanocene cations (also see Section 2.2.3).

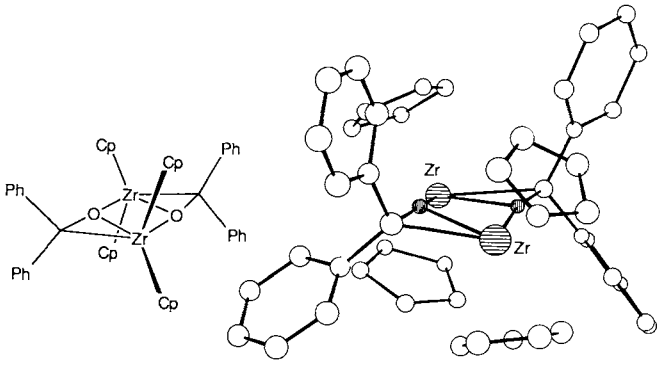

Fig. 16. Crystal structure of the Cp_2Zr–benzophenone dimer [33].

NMR spectroscopic studies indicate that in solution tin-derived Lewis acids, like titanium, prefer to form 1:2 acid:carbonyl or 1:1 chelated adducts.[34] Consistent with these findings, the crystal structure of $SnCl_4$–4-*tert*-butylbenzaldehyde shows a 1:2 stoichiometry with two nonequivalent aromatic aldehydes *cis* to one another around the octahedrally coordinated tin atom (Fig. 17).[34]

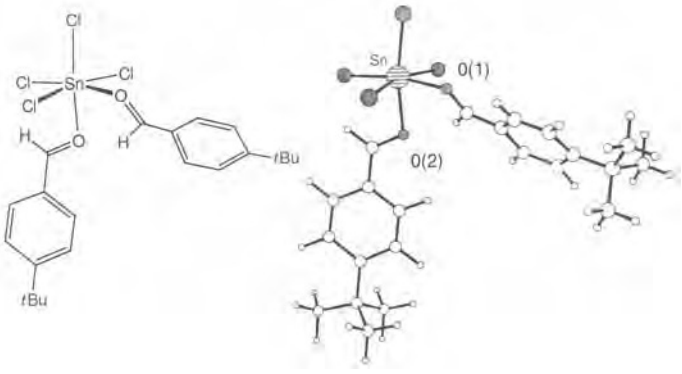

Fig. 17. Crystal structure of the $SnCl_4$–4-*tert*-butylbenzaldehyde complex [34].

Similar to the BF_3–benzaldehyde complex (Fig. 7), tin lies within the carbonyl plane with respect to both aldehydes (τ_1 = 2°, τ_2 = 4°), in the direction of sp^2-hybridized lone

pairs (Sn-O(1)-C = 128°, Sn-O(2)-C = 126.2°) and *anti* to the aromatic ring.

These measurements and the Sn–O bond lengths (2.23 Å) are close to the average values of Sn–carbonyl bond angles and bond lengths found in the CSD files (Sn-O = 2.3 ± 0.1 Å; Sn-O-C = 127 ± 10°).[12] However, the 1:2 stoichiometry and the *cis* relationship of the carbonyl ligands are not universal. Only slight alterations in the nature of the Lewis acid or its ligands are necessary to alter this arrangement. For example, an X-ray analysis of the Ph_2SnCl_2–*p*-dimethylaminobenzaldehyde complex shows a monomeric 1:1 complex with a trigonal-bipyramidally pentacoordinated tin atom (Fig. 18).[35] Although neither the Sn–O bond

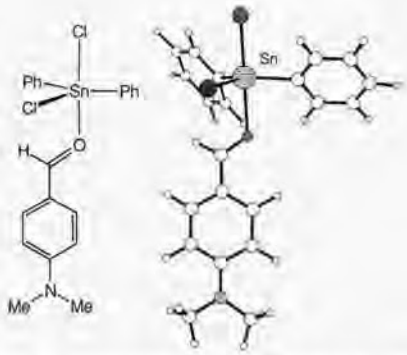

Fig. 18. Crystal structure of Ph_2SnCl_2–*p*-NMe_2-C_6H_4-CHO complex [35]

length (2.3 Å), nor the bond angles (Sn-O-C = 121°, τ(Sn-O-C-C) = 4°), nor the *anti* geometry of coordination have changed significantly, compared to the $SnCl_4$ complex (Fig. 17), the environment about the Sn atom is clearly different. It is likely that these changes are caused by the substitution of chlorines for aryl groups on the Lewis acid. Thus, crystal structures of Ph_3SnCl–TMU,[36] Me_2SnCl_2–TMU,[37] Me_3SnCl–diacetonetriphenylphosphorane,[38] and Me_2SnCl_2–salicaldehyde[39] all feature pentacoordinated, trigonal-bipyramidal 1:1 adducts, while $SnX_4 \cdot 2\,L$ (X = Cl, Br, I; L = urea or thiourea) complexes contain *cis*-octahedrally coordinated tin centers.[40] The *cis* and *trans* stereochemistry of the octahedral complexes seems to depend on the size and the basicity of the base, as well as on the nature of the Lewis acid. Me_2SnCl_2–DMU[37] and $SnCl_4$–ethyl cinnamate[41] are both *trans*-octahedral 1:2 complexes. The latter complex is particularly relevant to the discussion of the conformational preferences of α,β-unsaturated carbonyl complexes (Fig. 19). Here the ligand adopts a *Z*-s-*trans* conformation with tin coordinated *syn* to the double bond. The Sn–O–C–C dihedral angle of 21° indicates some out-of-plane bonding although not as much as in the titanium complexes.

Crystal structures of chelated tin Lewis acids have also been obtained. Recently, X-ray analysis of two five-membered chelates of $SnCl_4$ were reported by *Reetz* et al.[42] $SnCl_4$ complexes of 2-benzyloxy-3-pentanone and methoxyacetophenone are both 1:1 monomeric chelates with distorted octahedral geometry (Fig. 20). In the former complex (Fig. 20, left), tin is apparently coplanar with the carbonyl plane (10° puckering of the stannacycle) at a distance of

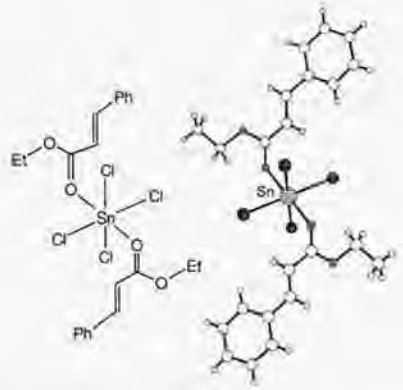

Fig. 19. Crystal structure of $SnCl_4$–ethyl cinnamate complex [41].

2.184(3) Å away from the carbonyl oxygen. More importantly, the ether group is planar and the ether oxygen seems to coordinate to the Lewis acid through an sp^2-like lone pair. This observation lends credence to the proposal of *Keck* et al. for $A^{1,3}$-like interactions between the oxygen protecting group and a second β-substituent in chelation of β-alkoxy aldehydes.[43] Methoxyacetophenone chelates $SnCl_4$ in much the same way (Fig. 20, right).[42] There are, however,

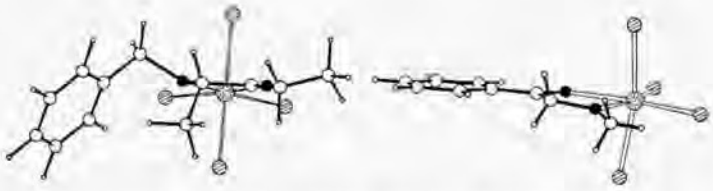

Fig. 20. Crystal structures of two $SnCl_4$ chelates [42]. Left: With 2-benzyloxy-3-pentanone. Right: With methoxyacetophenone. ◎ = Sn, ◍ = Cl, ● = O.

two distinct conformations about the ether oxygen in these crystals. In one conformer, the ether group is planar with sp^2-like donation to the Lewis acid, while in the second conformer (not shown) the ether oxygen is better described as sp^3-hybridized and pseudo-tetrahedral.

2.2.3. Late-Transition-Metal Lewis Acids

Despite the focus of the previous section on the most commonly utilized Lewis acids in organic synthesis, a much larger body of data regarding the structure of donor–acceptor complexes of late transition metals with carbonyls exists. Although a comprehensive treatment of this subject is beyond the scope of the present discussion, it is nonetheless worthwhile to consider the structural features of some of these complexes briefly, since many demonstrate novel and unusual interactions with the carbonyl group.[44]

To begin with, one can consider those high-valent transition metals that seem to behave analogously to the Lewis acids discussed thus far. The crystal structure of a cationic iridium complex, $[IrH_2(Me_2CO)_2PPh_3]BF_4$, shows *cis* coordination of two acetone ligands to an octahedrally coordinated iridium atom (Fig. 21).[45] Iridium is coordinated to the lone pairs of the acetone ligands and is coplanar with the

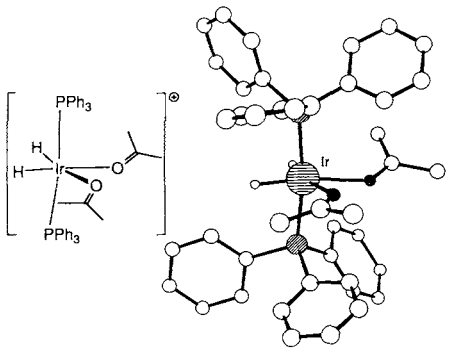

Fig. 21. Crystal structure of $[IrH_2(Me_2CO)_2PPh_3]BF_4$ [45] (anion omitted).

carbonyl groups at an Ir–O–C angle of 133.1° for one acetone ligand and 134.9° for the other. Aside from the interest in this complex due to its role as an active dehydrogenation catalyst,[46] one can also regard it as an effective Lewis acid towards acetone, since it seems to possess all the necessary structural characteristics.

Dicarbonylcyclopentadienyliron cation, $[CpFe(CO)_2]^{\oplus}$ ($\{Fp\}^{\oplus}$), is another reactive Lewis acid. This 16-electron complex is known to coordinate ethers, nitriles, and various carbonyl-containing compounds quite effectively and with 1:1 stoichiometry. The resulting 18-electron complexes are often stable, crystalline compounds and the crystal structures of a few of them have been solved.[12, 47, 48]

X-ray analysis of $[\{Fp\}(cyclohexenone)]PF_6$, for instance, shows iron σ-bonded in the plane of the carbonyl ligand (τ(Fe-O-C-C) = 3.7(9)°) with an Fe–O–C angle of 132.81(4)° (Fig. 22).[12, 47] Interestingly, iron is coordinated

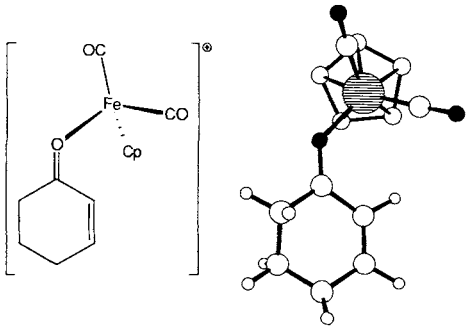

Fig. 22. Crystal structure of $[\{Fp\}(cyclohexenone)]PF_6$ [12, 47] (anion omitted).

syn to the C–C double bond, which could be explained by steric or electronic arguments. Sterically, coordination next to the smaller methine, as opposed to the methylene, α to the carbonyl should be favored. A similar preference may be expected if the enone moiety is envisioned in an enol ether resonance structure (cf. Fig. 23). Thus, the known preference of enol ethers to adopt a *Z* conformation may be extended to this case to explain the observed result. The latter, electronic argument, however, does not appear to override steric factors in an aldehyde complex. Preliminary results from a crystal structure of $[\{Fp\}(cinnamaldehyde)]PF_6$ indicate metal coordination *cis* to the aldehydic hydrogen and *trans* to the enal double bond.[12]

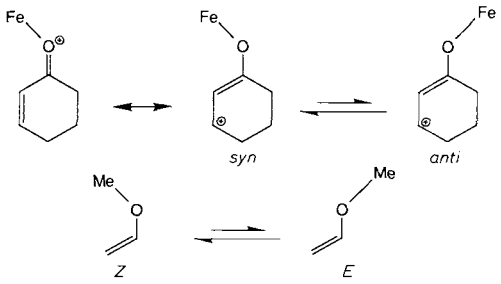

Fig. 23. Is there an analogy between *E*/*Z* enol ethers and *syn*/*anti* Lewis acid complexes with α,β-unsaturated carbonyl compounds?

It is also noteworthy that the observed conformation of the Lewis acid–bound cyclohexenone is fully consistent with the transition structure **5** (Fig. 24) of *Corey, Hannon* et al. for the asymmetric 1,4-addition of alkyl cuprates to cyclohexenone (**4**).[49]

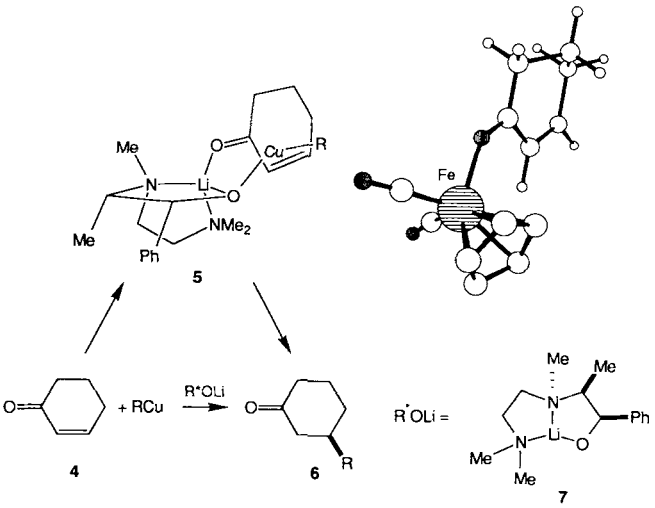

Fig. 24. The Corey–Hannon model for the asymmetric Michael reaction of alkylcopper reagents with cyclohexenone (**4**) in the presence of chiral Li salts such as **7** to give cyclohexanones (**6**). [49].

$[\{Fp\}(4\text{-methoxy-3-butenone})]BF_4$ also shows coordination *syn* to the C–C double bond, s-*trans* geometry, and no evidence for π bonding (Fig. 25, τ(Fe-O-C-C) = 0(1)°).[12] $[\{Fp\}(tropone)]BF_4$ is yet another complex whose crystal structure has been solved.[48] In this case, the complex is particularly stable due to the high basicity of the tropone ligand and the crystal shows very similar structural features to other $\{Fp\}^{\oplus}$ complexes of carbonyl compounds.

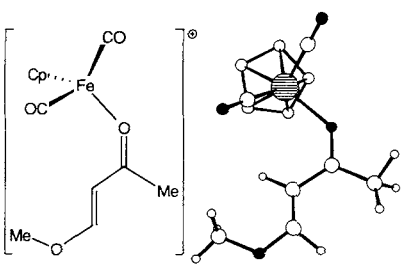

Fig. 25. Crystal structure of $[\{Fp\}(4\text{-methoxy-3-butenone})]BF_4$ [12] (anion omitted).

A tungsten Lewis acid, $[(Me_3P)(CO)_3(NO)W]SbF_6$, was recently reported to catalyze diene polymerization and Diels–Alder reactions.[50] A crystal structure of the acrolein-bound complex (Fig. 26) shows tungsten σ-coordinated

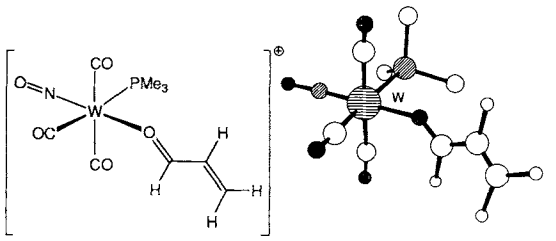

Fig. 26. Crystal structure of $[(Me_3P)(CO)_3(NO)W]SbF_6$–acrolein complex [50] (anion omitted).

(τ(W-O-C-C) = 180°), *syn* to hydrogen, at an angle of 137.1°. In line with ab initio predictions,[51] acrolein adopts an s-*trans* conformation, despite the absence of any obvious steric interactions in the s-*cis* conformer. It is apparent from this crystal structure that the tungsten complex behaves similarly to classical Lewis acids, and its structure can be predicted based on the same principles.

Gladysz's cationic complex $[(\eta^5\text{-}C_5H_5)(PPh_3)(NO)Re]^{\oplus}$ (**A**) is capable of binding carbonyls either η^2, through the π system, or η^1 through the lone-pair electrons.[52, 53] Crystal structures of **A**–phenylacetaldehyde (Fig. 27, right) and **A**–acetophenone (Fig. 27, left) clearly show the two different

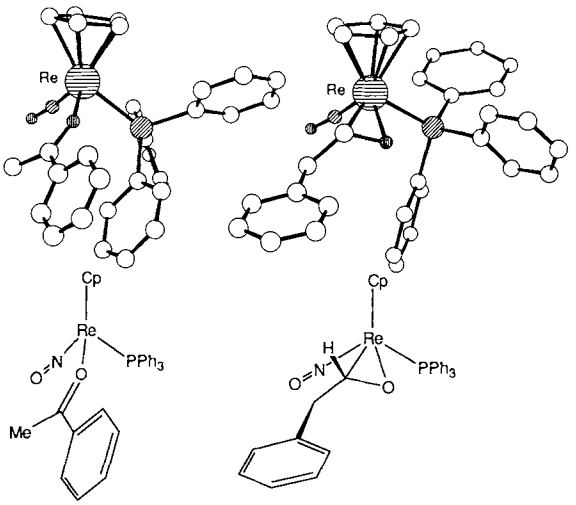

Fig. 27. η^1 (left) and η^2 (right) bonding for $[Cp(Ph_3P)(NO)Re]^{\oplus}$ (**A**) [52, 53].

modes of complexation. The authors attributed the difference in binding to increased steric bulk and lower π acidity of ketones as compared to aldehydes. No crystal structures of $\{Fp\}^{\oplus}$–aldehyde complexes are available in order to determine whether $\{Fp\}^{\oplus}$ has a similar "amphichelic" binding property, but $[(Ph_3P)(CO)_2Fe^0]$ binds cinnamaldehyde in an η^4 fashion.[54, 55] Additionally, it is worth noting that both of the rhenium complexes shown here are chiral and it has been shown that in the enantiomerically pure form, they undergo nucleophilic additions to the carbonyls with high enantioselectivities.[52, 53] Finally, the significance of the phenylacetaldehyde crystal structure should not escape attention. This is the first crystal structure of a nonchelated, α-substituted complex formed between a Lewis acid and an aldehyde. Despite the unusual, η^2 bonding in this complex there may be direct implications for the conformational preferences of complexes formed between Lewis acids and α-chiral aldehydes. Remarkably, the phenyl ring lies nearly perpendicular to the plane of the carbonyl at a dihedral angle of τ(C-C-C-O) = 94°, which is reminiscent of the Felkin–Anh proposal for the reactive conformation of α-substituted carbonyl systems.[56] However, it also seems reasonable to argue that the phenyl group occupies the sterically least congested area of space, and that the observed conformation is merely an artifact of the steric requirements of this particular complex, rather than a general, electronic phenomenon.

η^2 Bonding appears to occur with electron-rich metals and electron-deficient carbonyls. This combination allows for better back-bonding from the metal to the carbonyl π* orbital and disfavors competitive η^1 coordination by lowering the carbonyl lone-pair basicity. Hexafluoroacetone, for example, is η^2-bound to $[Ir(Ph_3P)_2(CO)Cl]$[57] (cf. also Ref. [45]), and electron-rich Ni^0 complexes show π bonding to both aldehydes[58] and ketones.[59] The crystal structure of $[(tmeda)Ni(C_2H_4)(H_2CO)]$, for example, shows formaldehyde bound in a metallaoxirane structure in which the C–O bond has lengthened to 1.311 Å (Fig. 28).[60] Similarly, a

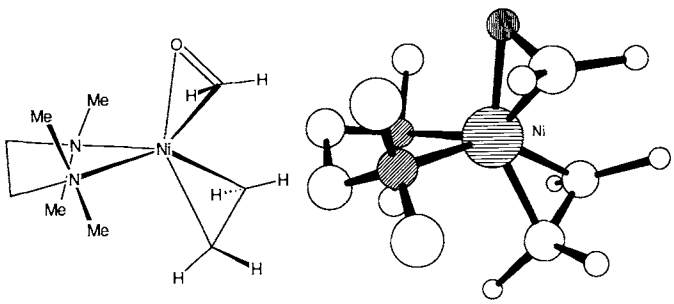

Fig. 28. Crystal structure of $[(tmeda)Ni(C_2H_4)]$–formaldehyde complex [60].

molybdenum Lewis acid bound to benzaldehyde shows η^2 bonding and a C–O bond length of 1.333 Å.[61] Acetone bound to pentaammineosmium(II) (C-O = 1.322 Å) has also been detected in the solid state, and π bonding is observed in this case as well.[62]

The structure of these η^2-bound carbonyl–Lewis acid complexes, especially those of Ni, may be relevant to the Au^I-catalyzed aldol reaction of isocyanoacetates with aldehydes to give the heterocycles **9**, discovered by *Ito, Sawamura,* and *Hayashi*.[63] It is reasonable to expect that the isoelectronic Ni^0–aldehyde complexes and the presumed Au^I–aldehyde intermediate in this reaction would exhibit similar structural features. Thus, **8** can be proposed as a transition-state model (Fig. 29), although the presence of other potential ligands in the reaction mixture (i.e., isocyanates, tertiary amines) may lead to other, structurally distinct, Au^I complexes as well.

Finally, carbonyls can bind two metals at once. The crystal structure of a complex containing bridging μ-η^2-bound acetaldehyde, for example, shows the carbonyl coordinated

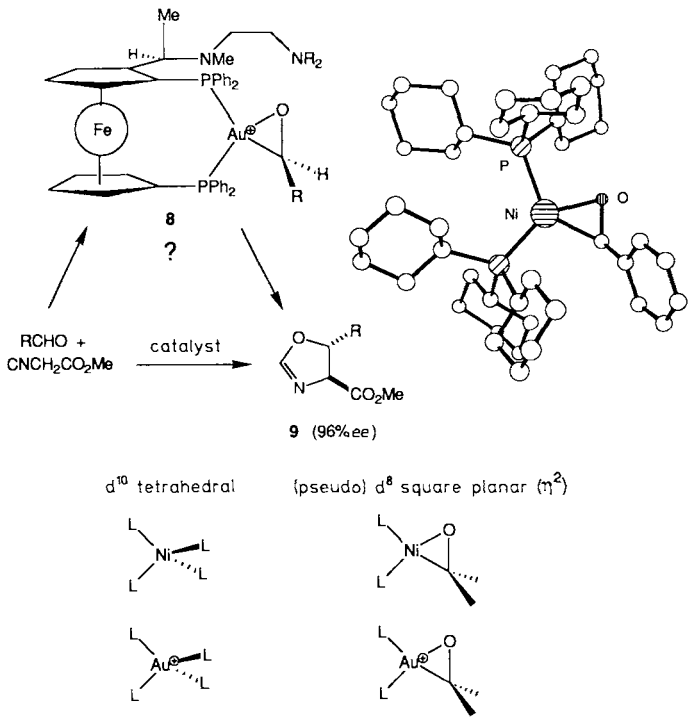

Fig. 29. A Ni^0–aldehyde complex as model for the transition state of Au^I-catalyzed aldol reaction of cyanoacetoacetates and aldehydes [58, 63].

to two molybdenum atoms (Fig. 30).[64] It appears that in this structure the carbonyl utilizes its π as well as its lone-pair electrons to bond to the two metal centers. Conceptually, one can think of this molybdenum complex as a bidentate Lewis acid that chelates the carbonyl group.

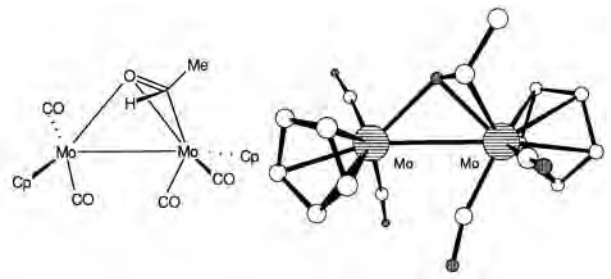

Fig. 30. Crystal structure of $[(\eta^2\text{-}\mu\text{-}CH_3CHO)Cp_2(CO)_4Mo_2]$ [64].

2.3. Discussion

It is now appropriate to summarize a few general points that can be made, based on the structural information in Sections 2.2.1–2.2.3, regarding the complexation of the carbonyl group to various Lewis acids. It is fairly clear that alkali-metal cations do not show a strong directional preference for binding to carbonyls and, for these complexes, coordination numbers and coordination geometries vary greatly. Boron, aluminum, titanium, and tin Lewis acids all accept electron density from sp^2 lone pairs of a carbonyl ligand at an angle of ca. 130–140°, but, in the presence of steric interactions, they easily distort from their optimal geometry. For aluminum, titanium, and tin complexes there is fairly strong evidence that, contrary to theoretical predictions, these distortions are invariably out of plane, toward the π cloud of the carbonyl group rather than the linear, in-plane geometry. This may also suggest a mechanism for *syn–anti* isomerization of the Lewis acid, although this point is less clear. Electron-rich metals and electron-deficient carbonyls prefer η^2 bonding. Thus, many of the late transition metals bind carbonyls through the π cloud.[65]

The stoichiometry of complexation is ordinarily 1:1 (acid:carbonyl) for boron- and aluminum-centered Lewis acids, which give pseudo-tetrahedral complexes, and 1:2 for octahedral Ti^{IV} complexes. Sn^{IV} Lewis acids can form either 1:2 octahedral or 1:1 trigonal-bipyramidal complexes, depending on the nature of their ligands and on the carbonyl base. For late transition metals the stoichiometry is often predicted by the 18-electron rule.

η^1-Bound Lewis acids prefer to lie *syn* to the smaller substituent of the carbonyl: for example, *syn* to H for aldehydes, *anti* to -OR for simple alkyl esters. In α,β-unsaturated systems, Lewis acid coordination *syn* to the C–C double bond favors the s-*trans* conformation, but in two crystal structures, where coordination *anti* to the olefin occurs, s-*cis* complexes are observed.[28, 66] Finally, chelation with titanium and tin occurs readily and yields stable, crystalline complexes.

Some of the difficulties encountered in obtaining structural data on Lewis acid carbonyl complexes should also be noted here. One of the most common challenges in X-ray crystallographic analyses is the task of obtaining suitable, X-ray-diffracting crystals. This task is made even more formidable for the highly reactive and often unstable Lewis acid carbonyl complexes. Most of the crystal structures discussed in Sections 2.2.1 and 2.2.2 were obtained by crystal growth and data collection at low temperatures, under inert atmospheres. Some of the late-transition-metal complexes, however, seem to be exceptional in this respect. Many of the systems discussed in Section 2.2.3 exhibit exceptional robustness, stability, and a propensity to form crystalline complexes. This would facilitate the task of crystallization and structural analysis, and one can imagine that transition-metal complexes could be used as structural probes of carbonyl–Lewis acid interactions.

3. π-Bond Hybridization in Transition-Metal Complexes[67]

Numerous theoretical[68] and structural[69] studies point to the fact that π bonding plays an important role in determining the geometry of transition-metal complexes. Conformational preferences of π-bonding ligands are often rationalized by simple consideration of the relative energies of the metal d orbitals which can overlap with the ligand in question. In d^8 trigonal-bipyramidal complexes, for example, π-acid ligands favor equatorial positions and adopt geometries which allow π overlap with the $d_{x^2-y^2}$ or d_{xy} orbitals (metal-centered HOMOs) lying in the equatorial plane. Likewise, d^6 octahedral and pseudo-octahedral complexes possessing a single carbonyl (or nitrosyl) ligand have a well-defined metal-centered HOMO lying in the plane perpendicular to the carbonyl (or nitrosyl) ligand (Fig. 31, left). *Gladysz* et al.

have shown that stereoelectronic interactions involving the metal-centered HOMO in [CpRe(NO)(PPh_3)R] complexes dramatically influence the structure and reactivity in a wide variety of these chiral molecules (Fig. 31, middle and right).[70] Thus, electronic interactions involving ligand π

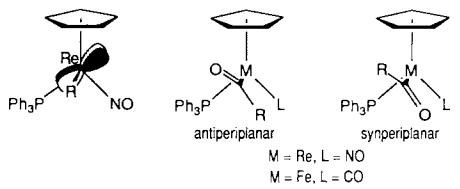

Fig. 31. Alternative acyl ligand conformations that maximize primary stereoelectronic interactions in d^6 complexes containing a single carbonyl (or nitrosyl) ligand. Left: Metal-centered HOMO.

orbitals and metal-centered HOMOs and LUMOs, which we will term primary stereoelectronic interactions, are often reliable predictors of ligand conformation.[71]

Ordinarily, assessment of primary stereoelectronic interactions plays a key role in the conformational analysis of transition-metal complexes. Nevertheless, ligand alignment is seldom uniquely determined by primary stereoelectronic interactions since there are often two ligand alignments that maximize π bonding or primary stereoelectronic interaction (see Fig. 31). Considering the chiral metal acyl complexes studied by *Gladysz* et al.,[72] *Davies* et al.[73] and *Liebeskind* et al.,[74] we note that the observed alignment of the acyl carbonyl antiperiplanar to the π-bonding CO (or NO) ligand maximizes π back-bonding to the acyl ligand from the metal-centered HOMO. However, alignment of this acyl carbonyl *syn* to the CO (or NO) ligand also maximizes π back-bonding. This raises the question: What forces govern the preferred antiperiplanar orientation of the acyl carbonyl?

The influence of steric interactions on the *syn–anti* isomerism of acyl ligands in [CpFe(CO)(PPh_3)(RC=O)] and [CpRe(NO)(PPh_3)(RC=O)] complexes (see Fig. 31) has been argued persuasively by *Davies*.[75] While steric interactions are certainly important in these systems, there are some trends which indicate that *syn–anti* isomerism in these complexes is not adequately rationalized by consideration of steric interactions alone. Notably, formyl complexes (R = H) show the same antiperiplanar conformational preference as acyl complexes possessing bulky alkyl (e.g., R = *sec*-butyl) substituents (see Section 3.1.2).

Since a number of metal acyl complexes with *cis* π-bonding ligands show a preference for alignment of the acyl oxygen antiperiplanar to the π-bonding ligand, and since evaluation of steric interactions does not adequately explain this alignment in all of the cases, we sought another explanation for the phenomenon. In Section 3.1 we discuss how examination of crystallographic data led to the proposal that *syn–anti* isomerism in transition-metal acyl complexes possessing *cis* π-bonding ligands is influenced by *secondary* stereoelectronic interactions. Secondary stereoelectronic interactions result from the mixing of metal-centered d and p orbitals, which occurs during π bonding. This dp mixing leads to hybridization of π-bonding molecular orbitals toward the π-bonding ligand. Interaction of the C–O σ* orbital of the acyl ligand with the π-bonding orbitals of the *cis* CO (or NO) ligand leads to a stereoelectronically preferred antiperiplanar orientation of the acyl ligand.

Secondary stereoelectronic interactions may also influence the alignment of *cis* π-bonding ligands in systems other than the acyl complexes mentioned above. Based on the presence of orbital interactions similar to those found for acyl complexes, we also propose that ligand orientations that place a ligand acceptor orbital (e.g., σ*) *syn* or a ligand donor orbital (e.g., heteroatom lone pair) *anti* to a *cis* π-bonding ligand are stereoelectronically favored (Fig. 32).

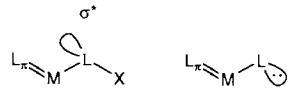

Fig. 32. Ligand conformation favored by secondary stereoelectronic interactions in complexes containing a *cis* π-bonding ligand. Left: Ligand acceptor, orbital (σ*) *syn* to L_π. Right: Lone-pair donor orbital *anti* to L_π. See sections 3.2.1–3.2.3.

The theoretical basis for the conformational model depicted in Figure 32 has been presented elsewhere.[67] Here, we consider the structural data which lend credence to this model.

3.1. *Syn–Anti* Isomerism in Metal Acyl Complexes

3.1.1. Steric Interactions in Metal Acyl Complexes: The Seeman–Davies Model

Certain reactions of organic ligands attached to stereogenic transition-metal centers in complexes of the type $CpML_3$ have been shown to proceed with a remarkable degree of asymmetric induction. Prompted by this observation, *Seeman* and *Davies* recently published conformational models for alkyl and acyl complexes containing the organometallic fragment [CpFe(CO)(PPh_3)].[76] Their models were based on the results of extended Hückel and ab initio calculations on model systems where PPh_3 was replaced with simpler ligands. Their principal conclusions were that iron serves primarily as a template for the ligands and that alkyl or acyl ligand conformation is governed by steric interactions with the PPh_3 ligand.

3.1.2. Acyl Ligand Conformations Not Explained by the Seeman–Davies Model

If Seeman–Davies-type steric interactions are the only forces responsible for the observed conformational preferences for metal acyl complexes, then formyl complexes should—due to the smaller size of H versus O on the formyl ligand—show a preference for alignment of the acyl oxygen *syn* to the M–CO bond. *This is not the case.*

The solid-state structure of [CpRe(NO)(PPh_3)(CHO)] (**10**) has been determined by *Gladysz* et al.[77] and this formyl complex has the formyl oxygen oriented antiperiplanar ($N–Re–C_{acyl}–O_{acyl}$ torsional angle = 176°) to the M–NO bond (Fig. 33). This conformation is not predicted by the Seeman–Davies model. *Gladysz* has noted that the observed conformation allows for a stabilizing electronic interaction between the highest occupied d orbital on the rhenium and the π^*_{CO} orbital on the acyl ligand. Complex **10** also shows a very short $Re–C_{formyl}$ bond (2.06 Å) and a low formyl car-

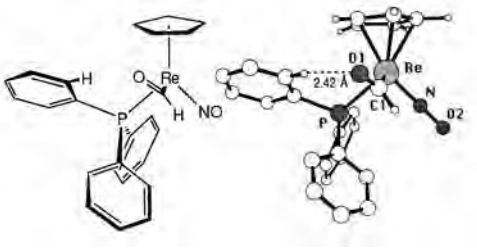

Fig. 33. Structure of **10** [77].

bonyl stretching frequency (ν_{CO} = 1558 cm^{-1}); both of these observations are in accord with a substantial amount of Re-to-formyl electron donation. However, synperiplanar orientation of the formyl ligand would allow for the same electronic stabilization. There are no obvious intramolecular steric interactions between the other ligands and the formyl ligand; in fact, the triphenylphosphane conformation is as observed by *Davies* and *Seeman* in iron acyl complexes. Intermolecular steric interactions (crystal packing forces) are unlikely to play a major role in determining the formyl ligand conformation due to the smallness of this ligand relative to other ligands on the complex. Clearly, some other force must be acting to align the formyl ligand in the observed antiperiplanar orientation.

Based on the examination of some other metal acyl complexes with *cis* CO ligands that do not possess Seeman–Davies-type steric interactions (Figs. 34–36), it is tempting to speculate that there is an intrinsic electronic preference for alignment of the acyl oxygen *anti* to the CO ligand. In *Herndon*'s iron acetyl complex **11** (Fig. 34)[78] the bulky

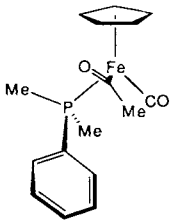

Fig. 34. Solid-state geometry of [CpFe(CO)(PMe_2Ph)COMe] (**11**) [78].

triphenylphosphane ligand central to the Seeman–Davies model is replaced by the smaller dimethylphenylphosphane ligand. Although there is no steric interaction between the acyl ligand and the *ortho* C–H bond of a phenyl group, the acetyl ligand adopts an antiperiplanar alignment (C_{CO}–Fe–C_{acyl}–O_{acyl} torsional angle = − 163°). The methoxycarbonyl ligand in *Albano*'s octahedral iridium complex **12** (Fig. 35)[79] certainly is in a very different steric environment

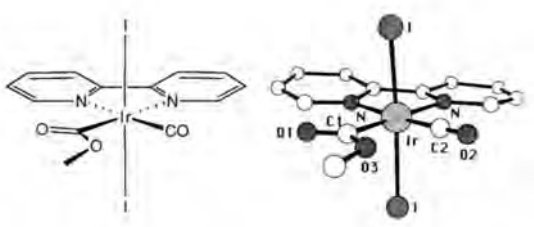

Fig. 35. Structure of [Ir(bpy)I_2(CO)CO_2Me] (**12**) [74].

than that found in pseudo-octahedral complexes of the type [CpFe(CO)(PPh_3)(COR)], yet the carbonyl oxygen is aligned antiperiplanar to the CO ligands (C_{CO}–Ir–C_{acyl}–O_{acyl} torsional angle = 176°).

Berke's octahedral rhenium complex **13**[80] (Fig. 36) is another example of a rhenium formyl complex where the formyl oxygen is aligned *anti* to the *cis* π-bonding ligand (cf. *Gladysz*'s complex, Fig. 33) despite steric interactions which should favor the *syn* alignment.

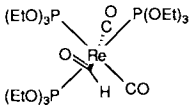

Fig. 36. Solid-state geometry of [$Re(CO)_2${$P(OEt)_3$}$_3$CHO] (**13**) [80].

Electronic interactions that lead to preferential stabilization of the antiperiplanar rotational isomer of the metal acyl complexes discussed above are depicted in Figure 37. Primary stereoelectronic interaction is optimized when the acyl ligand is coplanar with the M–CO bond, since this allows for maximum overlap of the π^*_{CO} orbital of the acyl ligand with the metal-centered HOMO (cf. Fig. 31). Secondary stereoelectronic interactions are optimized when the acyl ligand is antiperiplanar to the M–CO bond, since this allows for max-

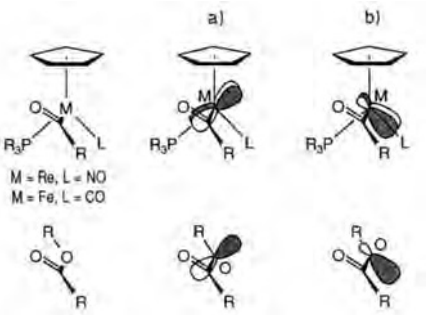

Fig. 37. Stereoelectronic interactions in metal acyl complexes and carboxylic esters. a) Primary stereoelectronic effect; b) secondary stereoelectronic effect.

imum overlap of the σ^*_{CO} orbital of the acyl ligand with the M–CO π-bonding orbital, which is metal-centered *and hybridized toward the CO ligand.* Similar electronic effects have been invoked to explain the stability of the *Z* conformation of carboxylic esters (Fig. 37, bottom).[81, 82] In this description of π bonding, the polarized metal-centered d orbitals are similar to the lone pair of the oxygen heteroatom.

Despite the plausibility of these arguments in a qualitative sense, it is extremely difficult to assess the exact energetic worth of secondary stereoelectronic interactions. However, a general sense of the energetic contributions of secondary stereoelectronic effects may be derived from the consideration of factors that can override these preferences. We close this section with a discussion of some metal acyl complexes with *cis* CO ligands where the acyl ligands are not oriented antiperiplanar to CO ligands.

Ruthenium formyl complex **14** (Fig. 38), prepared by *Nelson* et al.,[83] has a C_{CO}–Ru–C_{formyl}–O_{formyl} torsional angle of − 28°. However, this complex possesses several unusual structural features, including an exceptionally short C–O

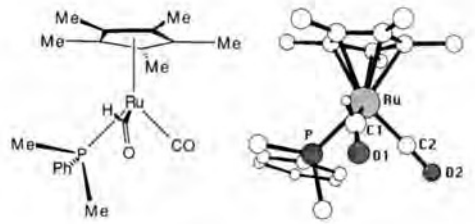

Fig. 38. Structure of [Cp*Ru(CO)(PMe_2Ph)CHO] (**14**) [83].

bond length (1.106 Å) and a large Ru–C–O bond angle (140°) for the formyl ligand—the C–O bond of the formyl ligand is shorter than that of the carbonyl ligand present in the same complex (C-O = 1.134 Å for the carbonyl ligand). The reasons for the unusual structural features present in **14** are unclear. However, a comparison between *Nelson*'s ruthenium formyl complex **14** ($C\text{-}O_{formyl}$ = 1.11 Å, $\tilde{\nu}_{CO}$ = 1601 cm^{-1}) and *Gladysz*'s rhenium formyl complex **10** ($C\text{-}O_{formyl}$ = 1.22 Å, $\tilde{\nu}_{CO}$ = 1554 cm^{-1}) indicates that there is substantially less back-bonding to and hence less electronic stabilization of the formyl ligand in the ruthenium complex **14**. In *Nelson*'s complex, the stereoelectronic preference for antiperiplanar alignment of the formyl ligand is presumably overridden by the steric demand of the bulky pentamethylcyclopentadienyl ligand.

Polar groups such as the CO group in metal acyl complexes are often involved in electrostatic interactions. Figure 39

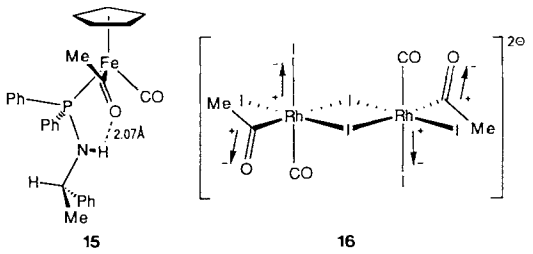

Fig. 39. Structures of [CpFe(CO)($PPh_2NHCHMePh$)COMe] (**15**) [84] and $[RhI_3(CO)COMe]_2^{2\ominus}$ (**16**) [85], where electrostatic interactions determine acyl ligand conformation.

shows two acyl complexes whose solid-state structures may be influenced by electrostatic interactions. The orientation of the acetyl ligand in iron complex **15** is controlled by a strong hydrogen bond to the NH group attached to the phosphane ligand.[84] The orientation of acetyl ligands in the binuclear rhodium complex **16**[85] may be determined by dipole–dipole interactions, since the observed conformation leads to the most favorable alignment of $Rh^{\delta\oplus}$–$I^{\delta\ominus}$ and $(C^{\delta\oplus}\text{–}O^{\delta\ominus})_{acyl}$ dipoles.

3.2. *Syn–Anti* Isomerism of Ligands other than η^1-Acyl

3.2.1. *Bent Nitrosyl Ligands*

X-ray crystal structures of the bent nitrosyl complexes **17**[86] and **18**[87] are shown in Figures 40 and 41. In both cases the bent nitrosyl ligand adopts the stereoelectronically preferred conformation (Scheme 1) that places its lone pair antiperiplanar to the *cis* π-bonding ligand.

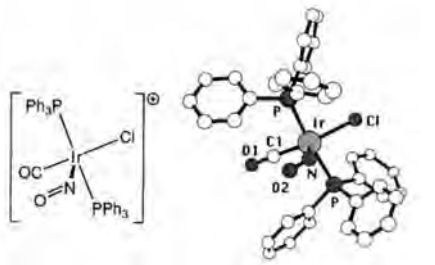

Fig. 40. Structure of $[Ir(PPh_3)_2(CO)(NO)Cl]BF_4$ (**17**) (anion omitted). The C–Ir–N–O torsional angle is − 5° [86].

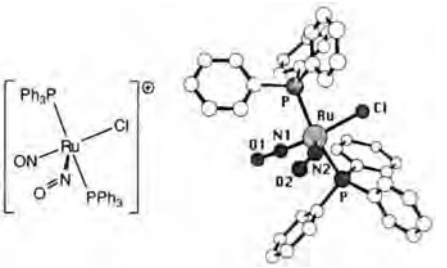

Fig. 41. Structure of $[Ru(PPh_3)_2(NO)_2Cl]PF_6$ (**18**) (anion omitted). The N_{linear}–Ir–N_{bent}–O torsional angle is 2° [87].

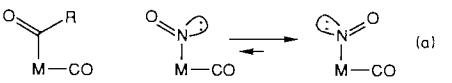
Scheme 1. Conformations of the nitrosyl ligand (cf. Fig. 32).

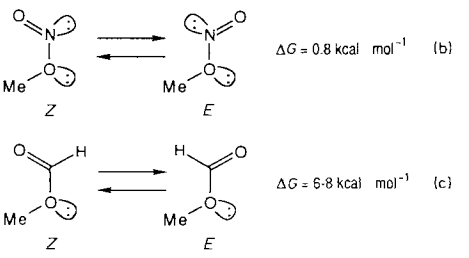
Bent nitrosyl complexes are related to acyl complexes by the isoelectronic substitution of N for CR. As this substitution replaces the C–R bond with a nitrogen lone pair, the stereoelectronically preferred alignment of the nitrosyl N=O bond is different from that of the acyl C=O bond [Eq. (a)]. Since the metal-centered M–CO π cloud ("lone



(a)

pair") is concentrated along the M–C bond, the lone pair of the bent nitrosyl can minimize "lone pair–lone pair" repulsion in the *syn* conformation.

It is interesting to compare bent nitrosyl and acyl complexes to their organic analogues: nitrite and carboxylic esters. Since nitrite esters are related to carboxylic esters by the same isoelectronic substitution (N for CR), the stereoelectronically preferred alignment of the nitrite N=O bond should be different from that of the carboxylic C=O bond. In fact, this appears to be the case: In both methyl nitrite[88] and methyl formate[89] the *Z* conformer is preferred, but to a very different extent [Eqs. (b) and (c)].



ΔG = 0.8 kcal mol^{-1} (b)

ΔG = 6.8 kcal mol^{-1} (c)

This difference is understood if the forces governing these conformational preferences are viewed as a superposition of electrostatic (dipolar) and stereoelectronic interactions (Fig. 42). Electrostatic forces favor the *Z* conformation for

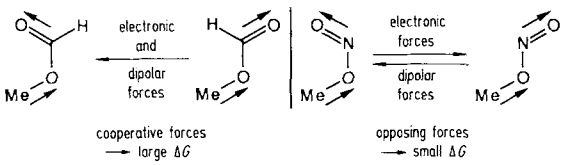


Fig. 42. The influence of electronic and dipolar forces on the preferred conformations of carboxylic esters (left) and nitrite esters (right).

both nitrite and carboxylic esters. Stereoelectronic forces, however, favor the *Z* conformation for carboxylic esters and the *E* conformation for nitrite esters. In the case of methyl formate stereoelectronic and electrostatic forces act in unison to produce an energetically substantial conformational preference, whereas in the case of methyl nitrite these forces largely cancel out to produce a small conformational preference.

3.2.2. *Acetylene Ligands*

Figures 43–45 show some ynolate and ynol ether complexes of tungsten (**19**–**21**) which are derived from carbyne–

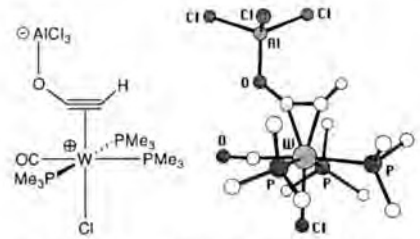

Fig. 43. Structure of [W(HC≡COAlCl$_3$)(CO)(PMe$_3$)$_3$Cl] (**19**) [90a].

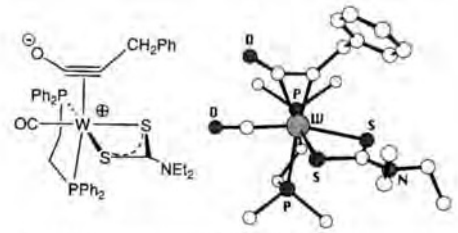

Fig. 44. Structure of [W(PhCH$_2$C≡CO)(CO)(Ph$_2$PCH$_2$CH$_2$PPh$_2$)(S$_2$CNEt$_2$)] (**20**) [90b].

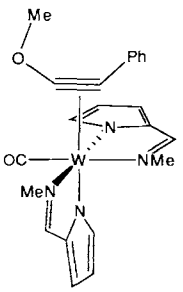

Fig. 45. Solid-state structure of [W(PhC≡COMe)(CO)(2-MeNCH-pyrrole)$_2$] (**21**) [90c].

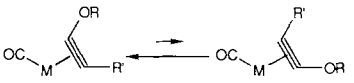

Scheme 2. Conformations of alkyne ligands (see also Fig. 46).

ic interactions that cause the alkyne ligands to be parallel to the carbonyl ligand have been discussed at length by *Templeton* et al.[91] The alkyne is thus aligned so that it may receive electron density from a filled tungsten-centered orbital and donate electron density to an empty one. The *syn* orientation of the oxygen substituent, however, is not explained by these interactions. The π^*_{CC} orbital of an ynolate or ynol ether is hybridized toward the carbon bearing the oxygen substituent and the filled metal-centered orbital with which it interacts is polarized toward the carbonyl ligand (Fig. 46).[92] Thus, the observed conformation of the alkynes is that which maximizes the overlap between these two orbitals.

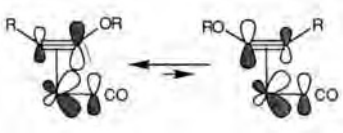

Fig. 46. Preferred alkyne alignment for maximum π back-bonding in complexes **19**–**21**.

3.2.3. *Bent Imido Ligands*

X-ray crystal structures of the bis-imido complexes **22**[93] and **23**[94] are shown in Figures 47 and 48. In both cases the bent imido ligand adopts the stereoelectronically preferred conformation that places its lone pair antiperiplanar to the

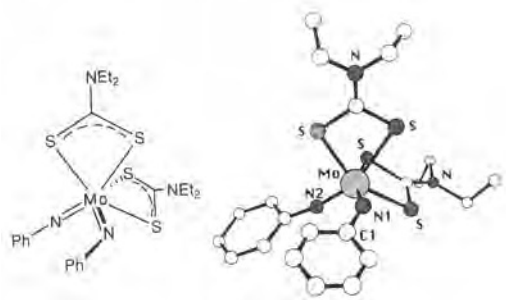

Fig. 47. Structure of [Mo(S$_2$CNEt$_2$)$_2$(NPh)$_2$] (**22**). The N_{linear}–Mo–N_{bent}–C torsional angle is −5° [93].

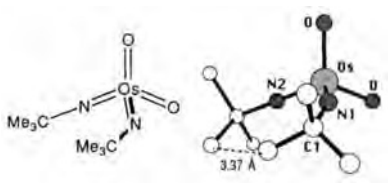

Fig. 48. Structure of [OsO$_2$(N-*t*Bu)$_2$] (**23**). The N_{linear}–Os–N_{bent}–C torsional angle is 0° [94].

metal–nitrogen triple bond of the linear imido ligand (Scheme 3). Here, the stereoelectronic preference is probably governed by donation of the lone pair of the bent amido

Scheme 3. Conformations of imido ligands (cf. Fig. 32).

ligand into a metal-centered non-bonding orbital.[82c] Of course, avoidance of "lone-pair"–π interactions in the antiperiplanar arrangement may also contribute to a bias for the observed conformation.

Interestingly, both **22** and **23** adopt conformations which place the imido substituent in a sterically more hindered environment. Thus, in these cases secondary stereoelectronic effects seem to override steric preferences.

4. Summary and Outlook

The examples presented in this article demonstrate a few of the many ways that useful conformational conjectures can be made using the Cambridge Structural Database. Synthetic and design applications aside, the development of further mechanistic studies that would verify the validity of these conjectures should be emphasized. In particular, systematic structural analyses of a family of related complexes—where only a few parameters change in going from one complex to another—would be highly informative. In the absence of systematic studies, care should be taken to avoid overinterpretation of single structures and invalid generalizations. Generally, statistical analyses of a larger number of crystal structures can be used to distinguish the ordinary from the unusual. In unusual systems, crystal packing forces may be the cause of deviations from the norm, and it is always important to take this factor into consideration.

In the complexation of Lewis acids to carbonyls—a process of great interest in organic synthesis—definite structural trends were observed. The more unexpected observations included the widespread occurrence of out-of-plane bonding and the diversity of coordination geometries for very similar Lewis acids (e.g., $L_nX_{4-n}Sn$ Lewis acids). Of the unanswered questions, the conformational preferences of Lewis acid–bound, α-chiral carbonyls seem to attract the most immediate attention.

In organometal complexes with π-bonding ligands, the presence of secondary stereoelectronic interactions is strongly implicated by the structural data. Considerations of molecular orbital theory also support this notion. Notably, the cases where stereoelectronic *syn–anti* preferences override clear steric preferences (complexes **10, 13, 22,** and **23**) occur for metals (Re, Mo, and Os) that have been noted to show a predilection for forming metal–ligand multiple bonds. It may be that stereoelectronic interactions (primary and secondary) are more important for these metals than for metals, such as Fe, which do not show a tendency to form multiple bonds. A more definitive answer, however, is likely to come from future X-ray analyses and the test of our ability to predict the conformation of these complexes.

Another way to gain insights from the structure of molecules is through the structure–reactivity correlation method.[1, 3, 4] Recently, for example, the question of the structure and basicity of silyl ethers was probed using the CSD.[95] A search for the $Si–O–C_{sp^3}$ fragment revealed an unusually wide average Si–O–C angle (134.2°) and a negative correlation between the Si–O bond length and the Si–O–C bond angle (Fig. 49; correlation factor − 0.68). The latter observation contradicts the steric arguments previously presented for the occurrence of wide Si–O–C angles.

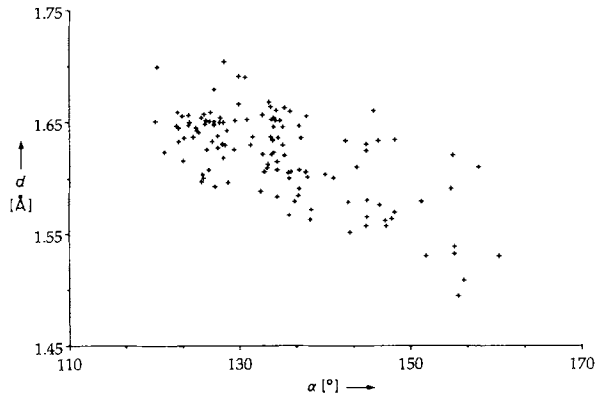

Fig. 49. Correlation of the Si–O bond length and the Si–O–C angle in acyclic silyl ethers [95].

An alternative explanation, based on Si–O π interactions, on the other hand, is consistent with the observed results.[96] Subsequently, calculations of *Jorgensen* et al.[95] at the 6-31G* level reproduced the same contrasteric trend and presented a theoretical basis for these observations. Although these findings do not yield any direct information on the features of a transition structure, they can account for the relatively low basicity of silyl ethers and also for the inability of α- and β-siloxy carbonyls to chelate Lewis acids.[96]

Finally, it should be recalled that "chemical reactivity depends on many factors besides purely conformational ones; an exclusive preoccupation with the geometric aspects of molecular structure can sometimes prevent us from recognizing other factors that might be important or even decisive in influencing the rate of a reaction."[97] Future work in this area will focus not only on the refinement of the conformational models, but also on the uncovering of the "other factors" that influence the reactivity of organometal complexes.

We are grateful to Kurtis MacFerrin for the implementation of CSD on a VAXstation 3500 computer. Financial support for this project was provided by NIH, NSF, and Pfizer Inc., to whom we express our deep appreciation.

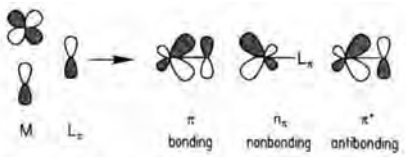
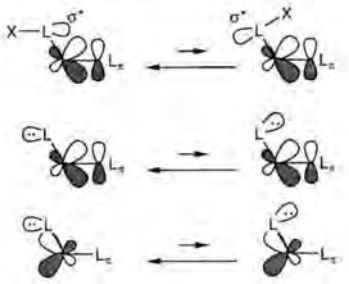
[82] Evaluation of the orbital mixing that occurs when a π-bonding ligand interacts with a transition-metal center requires the assessment of second-order mixing which takes place when two or more orbitals on the same fragment (i.e., metal d and p orbitals) overlap with the same orbital of an interacting ligand (i.e., ligand p orbital). The result of this second-order mixing is that bonding and antibonding orbitals are hybridized toward the ligand involved in the bonding interaction, and nonbonding orbitals are hybridized away from the ligand. This is illustrated in Scheme 4 for the



Scheme 4. Orbital mixing leading to π-bond hybridization.



Scheme 5. Possible stereoelectronic interactions in complexes consisting of a σ-bound ligand L and a complex fragment M-L_n, where L and L_n are *cis*. The X–L–M–L_n dihedral angle is 180° on the left and 0° on the right.

interaction of a π-bonding ligand with a transition-metal center. There are three types of stereoelectronic interactions that could influence the *syn–anti* isomerism of a ligand bound *cis* to a π-bonding ligand: (1) π↔acceptor (e.g., σ*)—a stabilizing two-center two-electron interaction (Scheme 5, top); (2) π↔π′ donor (e.g., lone pair)—a destabilizing two-center four-electron interaction (Scheme 5, middle); (3) n_π↔donor (e.g., lone pair)—a stabilizing two-center two-electron interaction (Scheme 5, bottom). The relative importance of the three types of stereoelectronic interactions depicted above will, of course, depend on the nature of the metal–L_n bonding interaction [70]. In all cases, however, ligand conformations that place a ligand acceptor orbital *syn* or a donor obital *anti* to a metal ligand π bond are stereoelectronically favored. For a complete discussion of the theoretical basis of second-order mixing see ref. [67].

The Preparation of Finely Divided Metal and Alloy Powders

By *Helmut Bönnemann,* Werner Brijoux,* and *Thomas Joussen*

Dedicated to Prof. Günther Wilke on the occasion of his 65th birthday

Finely divided powders of metals and alloys are of great interest in industrial powder technology[1] and as catalysts.[2] Newer methods for the preparation of metals in the form of very fine powders are metal evaporation,[3] electrolytic processes,[4] and the reduction of metal salts, either with naphthalene-activated alkali metals[5] or with anthracene-activated magnesium.[6] We report here a process for preparing finely divided powders of metals and alloys by reducing metal salts in organic phases. The salts are kept in solution using organoboron complexing agents BR_3 or $BR_n(OR')_{3-n}$ (R,R' = alkyl or aryl; $n = 0, 1, 2$) in the form of hydroorganoborates[7] of the general formula $M'H_v \cdot (BR_3)_v$ or $M'H_v[BR_n(OR')_{3-n}]_v$ (M' = alkali or alkaline earth metal, $v = 1, 2$).

Elements of groups 6–12 and 14 of the periodic table can be prepared as pure powders by treating their metal salts with hydroorganoborates in THF or hydrocarbons at temperatures between −20 °C and 67 °C. Since the ate complexes formed by reaction of hydroxides, alkoxides, cyanides, cyanates and thiocyanates with the organoboron complexing agents are highly soluble in organic solvents, the metal powders can be isolated according to Equation (a) ($u = 1, 2$) by simple filtration (Table 1). The organoboron complexing agent can be regenerated by treatment with acid. Thus, HCl/THF liberates 98% of the triethylborane from $Na(BEt_3)OH$.

$$uMX_v + vM'(BR_3H)_u \xrightarrow{THF} uM\downarrow + vM'(BR_3X)_u + uv/2\ H_2\uparrow \quad (a)$$

M = metal powder,

M' = alkali or alkaline earth metal,

R = C_1-C_6-alkyl;

X = OH, OR, CN, OCN, SCN

M' halides do not generally form stable ate complexes, but, in many cases, remain with the BR_3 in solution in the organic solvent [Eq. (b)]. This is true in particular in the case of LiCl, LiBr, LiI, and NaI in THF. To simplify the regeneration, the cation in the hydride is chosen so that the corresponding halide is soluble in organic solvents. If the M' halide (e.g., NaCl) precipitates, it must be separated from the metal powder by washing with water.

$$uMX_v + vM'(BR_3H)_u \xrightarrow{THF} uM\downarrow + vM'X_u + vBR_3 + uv/2\ H_2\uparrow \quad (b)$$

X = halogen

The reduction of metal halides can also be achieved using a "catalytic amount" of BR_3, since the organoboron complexing agents liberated according to Equation (b) react in situ with further $M'H_v$ [Eq. (c), Table 2, Nos. 5 and 23).

$$uMX_v + vM'H_u \xrightarrow{BR_3,\ THF} uM\downarrow + vM'X_u + uv/2\ H_2\uparrow \quad (c)$$

X = halogen

The line widths in the X-ray diffractograms reveal that the metal powders prepared in this way are microcrystalline to amorphous. The line widths of the strongest reflection ($Co_{K\alpha}$ radiation, Fe filter)[8] allowed an initial rough estimate of ca. 5 nm for the grain size of the base metals Fe, Co and Ni. According to scanning electron microscope studies,[8] the particle size lies between 10 and 100 nm.

In analogy to Equations (a) and (b), the simple co-reduction of salts of different metals affords alloys of two and more metals. This method corresponds to a "cold powder technology". The alloy powders, which are shown by X-ray diffraction measurements to be practically amorphous, can be generated on support materials; this is of particular interest in catalytic applications. Co-reduction of $FeCl_3$ and $CoCl_2$ according to Equation (b) yields a boron-free Fe/Co powder with a particle size of ca. 100 nm (Table 3, No. 3). In the diffractogram,[8] only the diffuse strongest reflection at a scattering angle 2θ of 52.5° and a reciprocal lattice distance D of 2.02 Å can be discerned (Fig. 1a, bottom). The line

width reveals that weakly crystalline to amorphous phases are present in the Fe/Co powder. After the sample has been heat treated (2 h, 400 °C), one observes that the line becomes sharper (Fig. 1 a, top). Since scanning electron microscopy[8] shows that the particle size is unchanged by the heat treatment, the sharpening of the peak indicates that the grain size has increased.

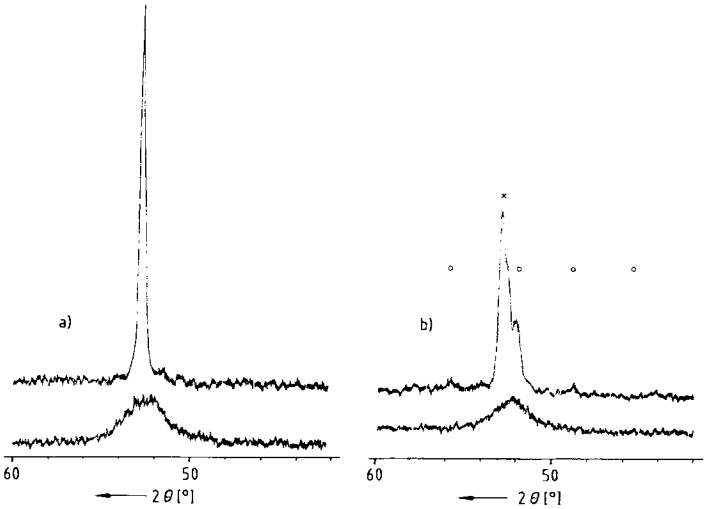

Fig. 1 a) Strongest reflection in the diffractogram of the Fe/Co alloy (Table 3, No. 3); bottom: untreated original sample; top: after 2 h at 400 °C ($Co_{K\alpha}$-radiation with Fe filter). b) Strongest reflection in the diffractogram of an Fe/Co mixture; bottom: untreated original sample; top: after 2 h at 400 °C. x = Fe, o = Co ($Co_{K\alpha}$ radiation with Fe filter).

A comparison of the diffractograms of the alloys with that of a mixture of amorphous iron and cobalt powders (Fig. 1 b, bottom) demonstrates that the Fe/Co alloy is formed at the stage of the co-reduction (under thermodynamic control[9]) and not as a result of the subsequent heat treatment: after the tempering, the diffractogram of the Fe/Co mixture (Fig. 1 b, top) is, in contrast to that of the alloy, a superimposition of two sets of lines for Fe and Co.

The fact that an alloy had been prepared as a result of the co-reduction was finally proved by recording a Mössbauer spectrum (source: $^{57}Co/Pt$, 27 °C)[10] of the sample before heat treatment. The spectrum shows the characteristic six resonance lines for metallic iron. The total splitting (i.e., the distance between the outer lines) is 36 T, a value which has been found for comparable alloys formed by melting but which is 3 T larger than for pure iron.

Therefore the co-reduction of metal salts in organic solvents with hydroorganoborates provides a method of preparing single-phase, almost amorphous alloys of two or more components (Table 3).

The redox potential of sodium hydrotriethylborate in THF (supporting electrolyte: NBu_4PF_6) was determined electrochemically to be -0.77 V, corresponding to -0.62 V in H_2O.[11] Thus, the reaction between the metal salt and the hydride proceeds either as a reduction or as a metathesis depending on the particular metal involved. The findings described above can be rationalized on the basis of the HSAB concept.[12] The metal ions $M^{\oplus}$ act as soft acids and compete with the moderately hard acid BR_3[13] for the soft basic hydride ion to form **1**. If $M^{\oplus}$ is a softer acid than BR_3, the hydride is transferred to $M^{\oplus}$, the resulting MH then decomposes spontaneously to metal and hydrogen [Eq. (d)].

$$MX + M'(BR_3H) \xrightarrow{-M'X} \underset{\mathbf{1}}{(M\cdots H\cdots BR_3]} \longrightarrow [MH] + BR_3 \xrightarrow{-BR_3} M\downarrow + 1/2\ H_2\uparrow \qquad \text{(d)}$$

Experimental

Preparation of an iron/cobalt alloy from $FeCl_3$, $CoCl_2$ and $LiBEt_3H$ in THF: A solution of 9.1 g (56 mmol) of $FeCl_3$ and 3.1 g (24 mmol) of $CoCl_2$ in 2.5 L of THF was added dropwise to a stirred 1.7 M (255 mmol) solution of $LiBEt_3H$ in THF over 5 h at 23 °C. After stirring overnight, the iron/cobalt alloy was separated from the clear reaction solution and washed twice with 200 mL portions of THF. The product was then stirred with 300 mL of ethanol and subsequently with a mixture of 200 mL of ethanol and 200 mL of THF until the evolution of gas ceased. Finally, the product was washed again with 2×200 mL of THF. The yield of alloy powder after drying in a high vacuum (10^{-3} mbar) was 5.0 g (Table 3, No. 3); Particle size according to scanning electron microscopy: 10–100 nm.

Ketenimine Complexes from Metal Isocyanides and Diazoalkanes**

By *Beate Strecker* and *Helmut Werner**

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

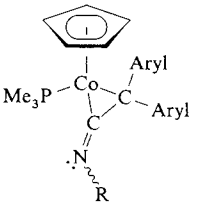
Carbene-metal complexes react with isocyanides under mild conditions to give ketenimine–metal compounds which are useful building blocks for the synthesis of four-, five-, and six-membered carbo- and N-heterocycles.[1] With regard to the converse reaction, namely addition of a free carbene to a metal isocyanide, so far the only example has been the synthesis of the nickel complex $Ni[\eta^2\text{-}N,C\text{-}(t\mathrm{Bu})N{=}C{=}C(CN)_2](CN t\mathrm{Bu})_2$.[2]

As part of a study of [2+2]- and [2+3]-cycloadditions of cobalt isocyanide complexes $[(C_5H_5)Co(CNR)(PMe_3)]$,[3] we have found that their reactions with carbene sources, as for instance diaryldiazomethanes, opens up a facile entry to ketenimine complexes. This formal [2+1]-cycloaddition of a carbene to a M=C=NR moiety reinforces our recently developed method of adding a nitrene to an M=C=CHR unit, which leads to an N,C-bound ketenimine ligand.[4]

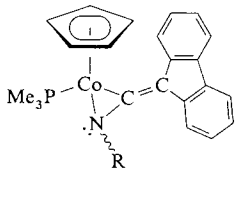
The cobalt compounds **1** and **2** react with Ph_2CN_2, $(p\text{-Tol})_2CN_2$, and 9-diazofluorene in acetone at -78 to 20 °C to give the dark-colored, slightly air- and moisture-sensitive complexes **3**–**6**.[5] The "side-on" coordination (π-bond) of the ketenimine ligand which is expected for electron-rich ligand–metal fragments[1] is clearly demonstrated by the IR and NMR spectroscopic data.[6] Moreover, these data confirm that in **3** and **4** the ketenimine is coordinated via the C=C bond, whereas in complexes **5** and **6** it is bound via the C=N bond. Supporting evidence for the two types of bonding is provided by: 1) the difference in the NCC stretching frequencies in the IR (ca. 1695 cm^{-1} for **3** and **4** in contrast to ca. 1625 cm^{-1} for **5** and **6**); 2) the different chemical shift and coupling constants of the signal of the NCH_3 protons in the ^{1}H-NMR spectra; and 3) the considerable difference in the chemical shift of the signals of the C_α and C_β atoms in the ^{13}C-NMR spectra of **3**, **4** and **5**, **6**.[6]

$$[(C_5H_5)Co(CNR)(PMe_3)] + R'_2CN_2 \xrightarrow[-N_2]{} [(C_5H_5)Co(RN{=}C{=}CR'_2)(PMe_3)]$$

1, R = Me
2, R = (*S*)-CHMePh



3, **4**



5, **6**

3, R = Me, $CR'_2 = CPh_2$
4, R = Me, $CR'_2 = C(p\text{-Tol})_2$
5, R = Me, $CR'_2 = C(C_{12}H_8)$
6, R = CHMePh, $CR'_2 = C(C_{12}H_8)$

The proposed structure of **3** and **4** is further supported by a comparison of the ^{13}C-NMR data with those of the rhodium complexes $[(C_5H_5)Rh(\eta^2\text{-}C,C\text{-}RN{=}C{=}CHPh)(PiPr_3)]$ ($R = p\text{-}SO_2C_6H_4Me$, $o\text{-}C_6H_4NO_2$)[4b] and $[(C_5H_5)Rh(\eta^2\text{-}CH_2{=}C{=}CHR)(PiPr_3)]$ (R = H, Me, Ph),[7] in which the respective heteroallene and allene ligands are also coordinated via a C=C bond. The reaction of **2** with 9-diazofluorene affords, as expected, two diastereomers, which can be easily discerned by the duplicate sets of signals in both the ^{1}H- and ^{13}C-NMR spectra of **6**.[6]

By adding an equimolar amount of iodine to toluene solutions of complexes **3**–**6**, the corresponding ketenimines **7**–**10** are formed. $C_5H_5Co(PMe_3)I_2$ is obtained as by-product.[8] Compounds **7**–**10** are soluble in most organic solvents and can be isolated in good yields as yellow, partially oily materials. Compound **7** had previously been described and was spectroscopically characterized;[9] **8**–**10** are, to our knowledge, new compounds not yet reported in the literature. In the IR spectra, very intense bands are found at ca. 2020 to 2030 cm^{-1}, which are characteristic for ketenimines;[10] this is also the range expected for IR bands typical of cumulenes.[11]

R/CR'$_2$ see **3**–**6** (above)

Since both cobalt complexes of the type $[(C_5H_5)Co(L)(CNR)]$[12] as well as diaryldiazoalkanes are easily accessible, we assume that other novel ketenimines, similar to **8**–**10**, can also be prepared in two steps in this way. It is predicted that isocyanide complexes, like carbene complexes,[1, 13] will establish themselves as useful building blocks for the synthesis of various heterocyclic compounds.

Cycloaddition Reactions of CpCo-Stabilized Cyclobutadiene Derivatives**

By *Rolf Gleiter** and *Detlef Kratz*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The reaction of alkynes to form arenes using homogenous transition metal catalysts is described in the literature in terms of catalytic loops as depicted in scheme 1.[1, 2] The formation of cobalt-stabilized cyclobutadiene derivatives **B** is usually considered as an unwanted side reaction and as a pathway constituting a dead end of [2+2+2]-cyclotrimerization reactions to arenes **D** with catalysts of the type $CpCoL_2$.

These complexes **B** withdraw the catalytically active species, the CpCo-fragment, from the trimerization cycle and

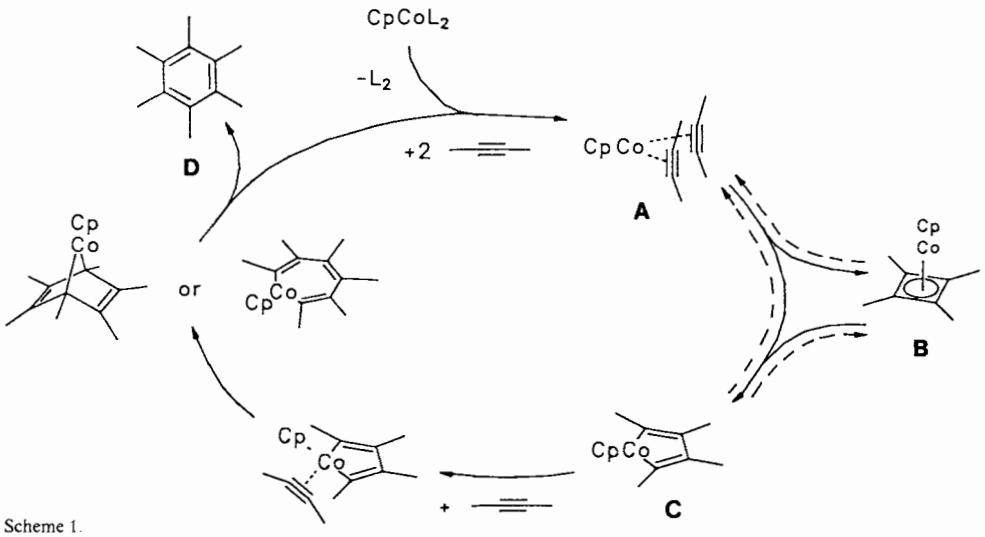
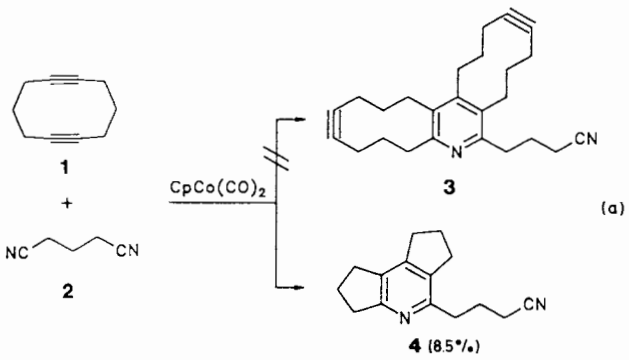


Scheme 1.

are excluded as possible intermediates on the following grounds: firstly, the formation of **B** requires a higher activation energy than the formation of a cobaltacyclopentadiene **C** (cobaltole);[3, 4] secondly, they are considered to be inert and to show resistance to further cycloaddition reactions; and thirdly, an equilibrium between the primary dialkyne complex **A**, the CpCo-cyclobutadiene complex **B** and the cobaltacyclopentadiene **C** has not, as yet, been unequivocally substantiated.[5, 6] In the present communication we show that complexes of type **B** are by no means entirely inert and may react with triple bonded species X≡Y to yield arenes.

Our research focussing on the reactivity of the cobalt complexes **5** and **10** was initiated by the following observations: To our surprise the reaction (a) of cyclodeca-1,6-diyne **1** with



glutaronitrile **2** in xylene in presence of catalytic amounts of $CpCo(CO)_2$ did not afford the "intermolecular" 2:1 pyridine derivative **3**, that we had hoped for; apart from the already known CpCo-cyclobutadiene complexes,[7] only the "intramolecular" 1:1 pyridine derivative **4** was detected. When the reaction of **1** was carried out in the absence of a nitrile it was also possible to isolate, inter alia, the CpCo-cyclopentadienone derivative **13** (Table 1). In both products a formal cleavage of one of the triple bonds in **1** has occurred. Furthermore, the results of X-ray investigations[8] on tricylic CpCo-cyclobutadiene complexes such as **5** clearly indicate bond alternance,[8] whereas the bonds in the four-membered ring of CpCo-cyclobutadiene complexes are normally equalized out.[9]

It seemed reasonable to conclude that **5** could behave as a diene towards further species with triple bonds. In fact we were able to transform **5** into the 6π-systems **4**, **8** and **9** (Table 1).

Table 1. Some spectral data of the compounds **4, 8, 9, 11,** and **13**.

4: ^{1}H NMR ([D$_6$]-acetone, 300 MHz): δ = 2.7–2.9 (m, 10H), 2.41 (t, 2H), 1.99–2.13 (m, 6H); ^{13}C NMR ([D$_6$]-acetone, 75.46 MHz): δ = 17.0, 23.8, 25.2, 25.3, 29.6, 30.9, 31.8, 34.4, 34.6, 120.7, 131.3, 135.9, 150.0, 153.8, 163.6; UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 225 nm (4.51), 275 nm (4.67); MS (EI): *m/z* (%) = 226(13), 225(11), 186(25), 173(100), 172(34), 85(26), 71(42), 57(74), 43(68), 41(40).

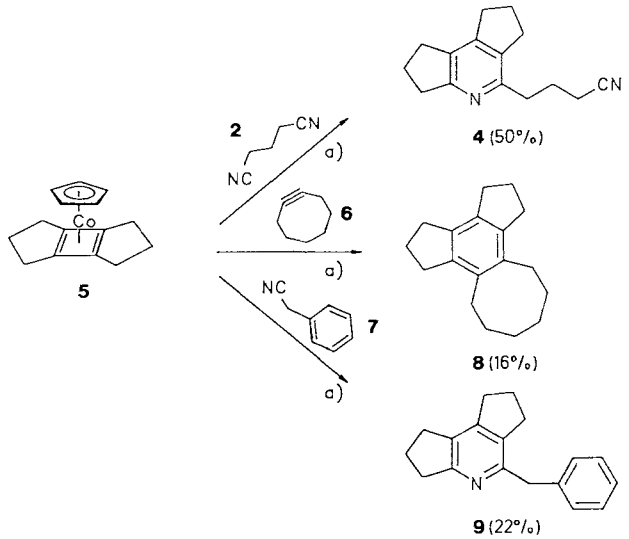
8: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 2.69–2.86(m), 1.96–2.11(q), 1.62(br.), 1.34(broad), 1.23(s) (integration is not clear-cut as trimeric cyclooctyne is present); ^{13}C NMR ($CDCl_3$, 50.32 MHz): δ = 24.95, 26.34, 28.5, 29.69, 31.49, 31.5, 134.45, 136.9, 140.4; GC-MS (EI): *m/z* [%] = 240(82), 211(41), 197(100), 185(40), 171(43), 155(27), 128(20), 115(17), 77(9), 41(15).

9: ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 7.16 (m, 5H), 4.01 (s, 2H), 2.73–2.93 (m, 8H), 1.94–2.14 (m, 4H); ^{13}C NMR (CD_2Cl_2, 50.32 MHz): δ = 23.49, 24.96, 29.5, 30.9, 31.5, 34.2, 42.5, 126.2, 128.5, 129.1, 131.2, 135.8, 140.5, 150.1, 153.6, 163.2; UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 212 nm (4.03), 277 nm (3.82); GC-MS (EI): *m/z* [%] = 249(50), 248(100), 221(6), 172(2), 170(3), 115(3), 91(4), 65(2).

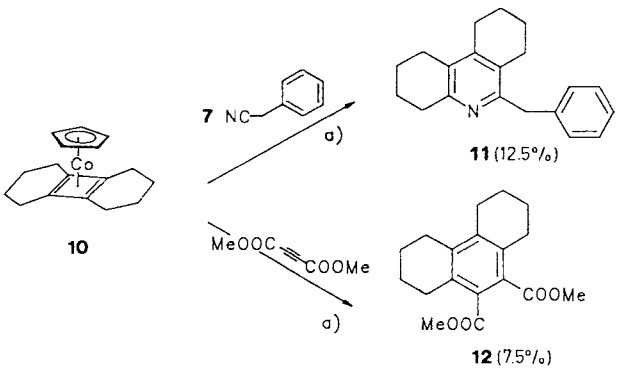
11: ^{1}H NMR (CD_2Cl_2, 300 MHz): δ = 7.12–7.26 (m, 5H), 4.05 (s, 2H), 2.83 (br. 2H), 2.54 (q, 6H), 1.83 (q, 4H), 1.7 (m, 4H); ^{13}C NMR (CD_2Cl_2, 75.46 MHz): δ = 22.8, 23.0, 23.5 (2×), 25.7, 26.5, 26.6, 33.4, 41.9, 126.2, 128.3, 128.6, 128.7, 129.1, 140.6, 145.2, 153.1, 155.3; UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 212 nm (4.09), 272 nm (3.60); GC-MS (EI): *m/z* [%] = 277(72), 276(100), 262(14), 248(5), 218(2), 186(8), 115(3), 91(5), 65(2).

13: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 4.74 (s, 5H), 2.84 (br. 2H, H_2O), 1.83–2.42 (m, 12H), ^{13}C NMR (DEPT spectrum) ($CDCl_3$, 50.32 MHz): δ = 25.39 (CH_2), 25.86 (CH_2), 28.8 (CH_2), 83.11 (CH), 92.97 (C), 94.5 (C), 149.0 (CO); UV/VIS (CH_2Cl_2): λ_{max} (lg ε) = 212 nm (4.09), 283 nm (4.29), 358 nm (3.43), 420 nm (2.93); MS (EI): *m/z* [%] = 284(57), 255(68), 189(100), 187(23), 129(46), 128(35), 124(73), 115(22), 91(27), 59(76), 40(38); IR ($CDCl_3$): $\tilde{\nu}$ = 3684(m), 3150(w), 2952(m), 2846(w), 2254(m), 2208(m), 1599(s), 1548(s), 1261(vs), 804(vs).

In choosing **10** as a diene component we wanted to test a cyclobutadiene complex containing bonds of almost equal length in its four-membered ring (cf. Scheme 3). This compound also led to cycloaddition reactions under more vigorous conditions[10] to afford the aromatic compounds **11** (Table 1) and **12**.[11]



Scheme 2. a) In xylene under reflux.

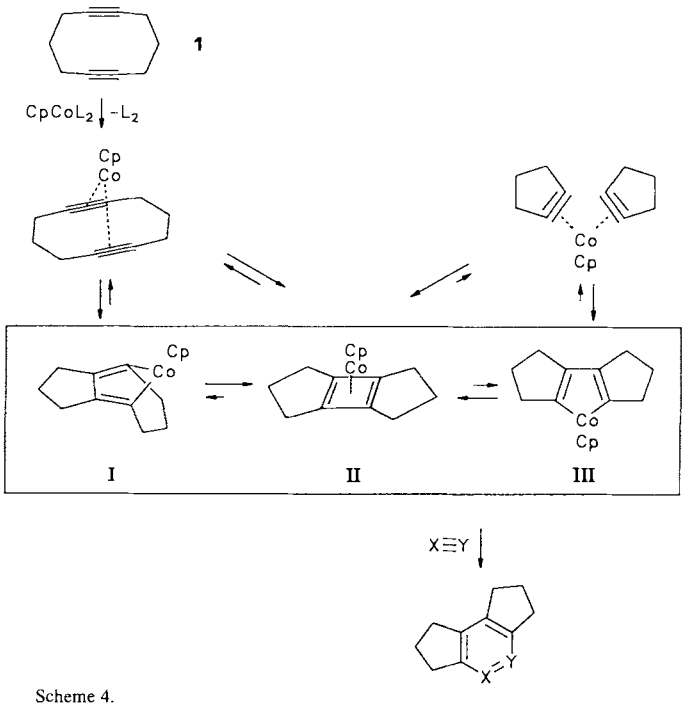


Scheme 3. a) 200 °C, without solvent.

These results suggest that certain (steric) restrictions may influence the reaction in a manner such that the "cyclobutadiene path" in cobalt-catalyzed [2+2+2]-cyclotrimerizations cannot be excluded from the start. To explain the formal cleavage of the triple bond of **1** in reaction (a) we postulate a mechanism that includes the cyclobutadiene derivative **II** as a plausible intermediate (Scheme 4).

Thus, the cobaltacyclopentadiene **I** is in equilibrium with its isomer cobaltacyclopentadiene **III** via the CpCo-cyclobutadiene complex **II**. This isomerization is the decisive step in order to explain the course of the reaction. The equilibrium **I** $\rightleftharpoons$ **II** $\rightleftharpoons$ **III** corresponds to an alkyne metathesis reaction, for which cyclobutadienes stabilized by transition metal fragments have been invoked as potential intermediates.[12] The "cycloaddition" of a further triple bond X$\equiv$Y may then proceed directly on **II** or by primary coordination of the 16e-species **III** and subsequent cyclization. A Dewar-benzene derivative may occur as an intermediate that is formed with concomitant liberation of the CpCo-fragment. However, under the reaction conditions this intermediate is unstable and will rearrange to the corresponding 6π-system. An analogous reaction of **I** would lead to the highly strained [3]paracyclophane skeleton and does not seem feasible on energetic grounds; the extremely labile [4]paracyclophane has been observed to undergo Wagner-Meerwein rearrangement to yield an *ortho*-substituted benzene under acid catalyzed conditions.[13]

The simultaneously released 14e-transition metal fragment (CpCo) may now become catalytically active as in reaction (a), and either induce further formation of **4** from the cyclic dialkyne **1** and dinitrile **2**, or react with the "dienophile" component and thus lead to numerous side reactions. Therefore, depending on the X$\equiv$Y-component present we observe the formation of cyclooctyne-trimer,[14] dimeric or trimeric products of benzyl cyanide, or mellitic acid hexamethyl ester in varying amounts. The catalyst is, however, prone to reduction and may decompose to form a cobalt mirror in the reaction flask.



Scheme 4.

If the same mechanism is presumed to operate in the formation of **13** (a mechanism via CpCo(CO)-dimers or -clusters is also conceivable), the final cleavage of the triple bond is caused by "end-on" addition of carbon monoxide. This may be preceded by a "side-on" coordination, as this mode of reaction has already been observed in reactions of CpCo complexes with ketones and aldehydes.[15]

Stereo- and Regioselectivity of Chiral, Alkyl-substituted *ansa*-Zirconocene Catalysts in Methylalumoxane-activated Propene Polymerization**

By *Werner Röll, Hans-Herbert Brintzinger,* Bernhard Rieger,* and *Ralf Zolk*

Dedicated to Professor Dr. Günther Wilke on the occasion of his 65th birthday

The isotactic polymerization of α-olefins by methylalumoxane-activated, chiral *ansa*-zirconocene catalysts has recently been studied in considerable detail. With very few exceptions,[1, 2] however, studies on the stereochemical course of these reactions have been limited to ring-bridged bis(indenyl)- and bis(tetrahydroindenyl)zirconium complexes (see, e.g., Refs. [3–6, 10–14]). Since further insights into the factors governing the stereoselectivity of these reactions[3–5] can only be gained from a more widely varying range of complexes, we have studied the course of methylalumoxane-activated propene polymerization by a series of differently substituted, axially symmetric *ansa*-zirconocenes, **1**–**4**.[7]

2, R^1 = *t*Bu, R^2 = H, μ-X = Me_2Si
3, R^1 = *t*Bu, R^2 = Me, μ-X = Me_2Si
4, R^1 = *i*Pr, R^2 = Me, μ-X = Me_2Si

Polymerization reactions with the tetramethylethano-bridged zirconocene complex **1**, with the dimethylsilano-bridged zirconocene complexes **2**–**4**, and, for comparison, with the ethano-bridged bis(tetrahydroindenyl)zirconium complex **5**[6] were studied at 50 °C, a propene pressure of 2 bar and an Al/Zr ratio of 300:1. The yields and properties of the polymers thus obtained are collected in Table 1.

Table 1. Yields and properties of the polypropylene (PP) polymers obtained with the complexes **1**–**5** after activation with methylalumoxane (Al/Zr = 300/1) at 50 °C under 2 bar of propene.

Catalyst	**1**	**2**	**3**	**4**	**5**
Reaction time [min]	120	120	185	45	50
Polymer yield [g]	9	36	79	114	95
Productivity [kg(PP)/(h mol(Zr) p)]	85	355	505	3000	2250
Melting point [°C]	103	128	149	107	85
M_w [a]	775	1981	9190	4958	3153
M_w/M_n	1.8	2.4	2.5	3.0	2.9
Isotacticity [% mmmm Pentads]	62	77	94	73	49
n-Propyl- ends [b]	3.5	2	0.6	1.5	1.5
2-Propenyl ends [b]	1.5	2	0.5	0.8	1.5
1-3-Misinsertions [b]	1.5	1.5	0.4	–	1.5

[a] Absolute values with uncertainties of ±20%. [b] Intensities of the ^{13}C-NMR signals in percent of main signals; besides the signals for 2-propenyl end groups, another set of signals with varying intensity occurs at δ = 17.9, 25.7, 129.1, and 132.2.

Under the reaction conditions employed, the catalysts **1**–**4** all yield more highly isotactic polymers than the "classical" catalyst **5**. Of the *t*Bu-substituted zirconocenes, the Si-bridged complex **2** is distinctly superior to its C_2-bridged analogue **1** in terms of stereoselectivity, probably due to its higher stereorigidity.[8] An even higher degree of isotacticity, with an mmmm pentad intensity of greater than 90%, is obtained with the Si-bridged complex **3**, which contains at each ring ligand, in addition to the *t*Bu group in the 4(β) position, a methyl group in the 2(α) position. The decreased stereoselectivity of the catalyst **4** with *i*Pr instead of β-*t*Bu substituents demonstrates the importance of steric bulk in the β position of both rings for a stereochemically uniform olefin insertion.

A remarkable effect of α-methyl substituents is the suppression of 1–3 misinsertions, which arise from a tail-to-tail (2–1) insertion of the α-olefin into the metal–polymer bond and subsequent isomerization of the ensuing species with a secondary alkyl ligand.[9] These misinsertions occur in the polymers obtained with **1** and **2** with a frequency of ca. 1.5%, i.e. about as often as in polymers obtained with the catalyst **5**.[10–13] In polymers produced with the α-methyl-substituted complexes **3** and **4**, however, these regio-irregularities are suppressed to levels close to or below the detec-

tion limit. In this respect, the performance of the α-methyl substituted catalysts approaches that of heterogeneous Ziegler catalysts, in which these regio-irregularities are not observed.

The molecular weights of the polymers obtained with the catalysts **1**–**4** show a surprising correlation with the respective stereo- and regio-regularities of the catalysts: Complex **3** produces by far the longest and most isotactic, complex **1** the shortest and least isotactic polymer chains. This unexpected observation can be explained based on structural models for the reactive zirconocene alkyl olefin cation[15]: The β-agostic binding required for chain termination by β-H transfer places the polymer chain (Pl) of a stereoregular unit into that ligand sector (Fig. 1a) which is occupied by the ring substituent R^1. If R^1 is sufficiently large, chain termination will therefore be largely suppressed except in those cases where the positions of the polymer and CH_3 substituents at the β-carbon are inverted, i.e. in a stereo-irregular unit, or where the β-carbon carries two H atoms, as in a regio-irregular unit.

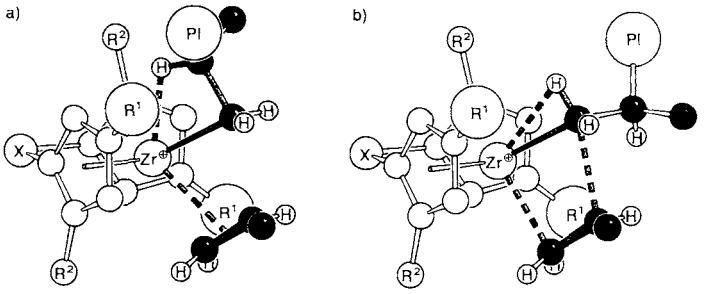

Fig. 1. a) β-agostic Zr-H interaction as prerequisite for the β-H transfer and thus chain termination; b) α-agnostic Zr-H interaction leads to stereoregular olefin insertion.

Stereoregular olefin insertion on the other hand might proceed via agostic binding of that one of the two α-H atoms[16] which places the polymer chain in an open sector of the ligand framework (Fig. 1b): The entering olefin will then be steered into the correct enantiofacial orientation both by repulsive interaction with the ring substituent R^1 and by the preferred *trans* configuration of the CH_3 and $CH(CH_3)Pl$ groups in the four-center transition state. Simple models of this kind might prove useful for the development of working hypotheses for more far-reaching, rational modifications of these metallocene polymerization catalysts.

Experimental

The propene polymerizations were carried out under N_2 in solutions of methylalumoxane (0.45 g, 7.6 mmol CH_3AlO) (Schering AG, mean molecular weight 1300 g/mol) in 400 mL of dry toluene containing 2.5×10^{-2} mmol (10–12 mg) of the respective racemic *ansa*-zirconocene dichloride, under 2 bar of propene (BASF AG). After draining the reaction mixture into CH_3OH/HCl, the precipitated polymer was filtered, washed with CH_3OH, and dried in vacuo. The molecular weights were determined by gel permeation chromatography, the melting points by differential scanning calorimetry. ^{13}C-NMR spectra were measured at 120 °C in solutions containing 120–150 mg of polymer in 0.4 mL of $C_2D_2Cl_4$, on a Bruker AC-250 FT spectrometer and analyzed by known methods [10–14].

A New Type of Double Calix[4]arenes by Linkage via the Phenolic Hydroxy Groups

By *M. Anthony McKervey,* Michael Owens, Hans-Rolf Schulten, Walter Vogt,* and *Volker Böhmer**

Calixarenes are macrocyclic molecules in which phenolic units (normally four, six or eight) are linked via methylene bridges.[1] In addition to their easy accessibility,[2] these compounds have the great advantage that they can be chemically modified in various ways.[3] We and others have demonstrated that calix[4]arene esters, amides, and ketones are very efficient and selective receptors for alkali metal cations. The potential importance of these ligands ranges from purely analytical applications (ion-selective electrodes, ion-selective field effect transistors) via medical problems (complexes with a long lifetime) to applications in the decontamination of industrial waste water, including nuclear wastes.

We recently reported the first examples of double calixarenes in which the two calix[4]arene moieties are linked via their *para* positions by one, two or four aliphatic chains.[4] An alternative way of combining calixarenes into larger molecular assemblies having potentially new receptor properties consists in linking two or more units via the phenolic positions. The tetraethyl ester **1** can be very selectively hy-

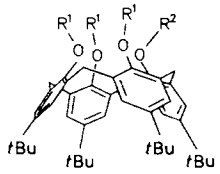
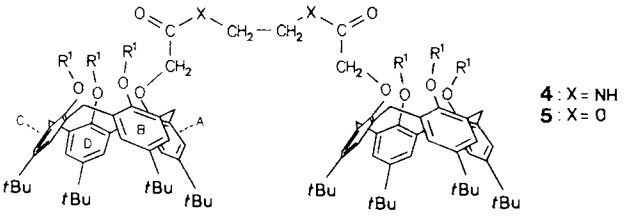
drolyzed by trifluoroacetic acid in chloroform to give the triester monoacid **2**.[5] Thus, a subsequent coupling of two molecules of **2** via amide or ester links is possible. We describe here the first examples of this new type of double calix[4]arenes.[6]



1: $R^2 = CH_2-COOEt$
2: $R^2 = CH_2-COOH$
3: $R^2 = CH_2-COCl$



4: X = NH
5: X = O

$R^1 = CH_2-COOEt$

Treatment of the acid **2** with thionyl chloride afforded the acid chloride **3**, which, without further purification, was treated with 1,2-diaminoethane in benzene in the presence of triethylamine. The product thus obtained in 41% yield was unequivocally identified from its ^{1}H-NMR spectrum as the double calix[4]arene **4**[7]. The signals for NH- ($\delta = 8.687$) and N-$(CH_2)_2$-N ($\delta = 3.638$) have the correct intensity ratio to those of the other protons. For the aromatic protons as well as for the *tert*-butyl groups, three signals are observed (ratio 1:2:1), corresponding to the different phenolic units A, B/D and C. Also in the case of the ethyl groups the correct ratio 1:2 is observed in the region for CH_2-protons. Two quartets superimpose to give a multiplet with intensities in the ratio 2:6:7:5:3:1. Characteristic for the molecular structure are the O–CH_2–CO protons. Two singlets (units A and C), and especially the two doublets of the AB-system of the diastereotopic protons at the phenolic units B and D, provide convincing evidence in support of structure **4**. Two superimposed AX-systems for the two different types of Ar-CH_2-Ar protons (A/B, D/A and B/C, C/D) show that the two calix[4]arene moieties are still fixed in the cone conformation.

The structure of **4** was further confirmed by mass spectrometry. The molecular peak $M^{\oplus}$, $m/z = 1953$, can already be detected with a relative abundance of ca. 8% in the electron impact spectrum. With the field ionization technique[8] (FIMS) the molecular peak is obtained as the base peak under optimum conditions. Peaks at 976.5 (for $M^{2\oplus}$, and 1867 (for $M^{\oplus} - 86$) are in agreement with the postulated structure. The distribution of isotopes found for the molecular ion corresponds to that expected theoretically.

In the field desorption mass spectrum[8] (FDMS) intense signals for the ions $M^{\oplus}$ ($m/z = 1953$) and $M^{\oplus}$ + Na ($m/z = 1976$) provide unequivocal proof of the molecular weight. In addition, peaks are observed at $m/z = 1867$ and 1890 at higher emitter temperature, which again indicate the loss of one CH_3COOEt group. Interestingly, no signal is observed for the ion $M^{2\oplus}$ + 2 Na, although such a complex is formed in solution (see below).

When a solution of NaSCN in CD_3OD is added portionwise to a solution of **4** in $CDCl_3$, initially additional signals for the $Na^{\oplus}$-complex are observed in the ^{1}H-NMR spectrum. This spectrum becomes simpler again after a total amount of 2 moles of NaSCN has been added per mol of **4**, and then does not change further. The same spectrum is obtained after a solution of **4** is shaken with solid NaSCN. The spectral changes are similar to those observed earlier with the tetraester **1** and NaSCN.[9] Particularly striking is the downfield shift of the aromatic protons ($\delta = 7.04-7.07$) and the upfield shift of the O–CH_2–CO protons and the A part of the Ar–CH_2–Ar protons ($\delta \approx 4.5$). In contrast, the B part is shifted to lower field (3.31 and 3.29, respectively). These results show that, under these conditions, kinetically stable complexes are formed in which obviously both calix[4]arene moieties independently take up a $Na^{\oplus}$ ion.[9]

Similarly to **4**, the double calixarene **5** with a diester bridge was formed upon reaction of **3** with ethylene glycol. Extended bridging with three or four calixarene subunits in a linear arrangement should also be possible using the recently described *1,3*-derivatives of calix[4]arenes.[10] Furthermore, the synthesis of double calixarenes, in which two calix[4]arene units are linked by more than one ester and/or amide bridge, is presently under investigation. The latter type of bridged calixarene should be highly preorganized for cation reception. Thus, new host molecules with higher affinity and improved selectivity for metal ions could be obtained on the basis of the readily available calix[4]arenes.

Experimental:

2: A solution of **1** (5.01 g, 5.05 mmol) in chloroform (100 mL) was treated with trifluoracetic acid (0.2 mL), and the mixture stirred at room temperature for 24 h. The solution was washed with water, dried, and evaporated to dryness. The white, solid residue was recrystallized from ethanol/water, furnishing 4.3 g (88%) of **2** as colourless crystals, m.p. 166–169 °C. Correct elemental analysis.

3: A solution of **2** (3.86 g, 4 mmol) was treated with 25 mL of thionyl chloride and the mixture heated under reflux in a nitrogen atmosphere for 2.5 h. Subsequent removal of excess thionyl chloride at reduced pressure furnished a yellow solid, which was used without further purification.

4: To a stirred solution of 3 g (3 mmol) of the acid chloride **3** in 100 mL of dry benzene under nitrogen was added dropwise at room temperature a solution of 0.1 mL (0.09 g, 1.5 mmol) of ethylenediamine and 1 mL (0.72 g, 7.0 mmol) of triethylamine in 200 mL of dry benzene. The mixture was stirred for 24 h and then was filtered to remove triethylammonium chloride. Concentration of the filtrate at reduced pressure furnished a white solid, which was purified by column chromatography over silica gel with methanol/ethyl acetate (2:3) followed by recrystallization from acetone to yield 1.21 g (41%) of **4** as white crystals, m.p. 250–253 °C. Correct elemental analysis.

[2] Procedures for the synthesis of calix[4]-, calix[6]-, and calix[8]arenes have been submitted for publication: C. D. Gutsche, *Org. Synth.*, in press.

[3] The *tert*-butyl group in the readily available *tert*-butylcalixarenes may be replaced by different substituents such as SO_3H (S. Shinkai, S. Mori, H. Koreishi, T. Tsubaki, O. Manabe, *J. Am. Chem. Soc. 108* (1986) 2409), NO_2 (S. Shinkai, K. Araki, T. Tsubaki, T. Arimura, O. Manabe, *J. Chem. Soc. Perkin Trans. 1, 1987*, 2297), N=N-C_6H_4-R (S. Shinkai, K. Araki, J. Shibata, O. Manabe, *ibid. 1989*, 195), CH_2-CH_2-NH_2 (C. D. Gutsche, K. C. Nam, *J. Am. Chem. Soc. 110* (1988) 6153), and CH_2-CH_2-COOH (C. D. Gutsche, I. Alam, *Tetrahedron 44* (1988) 4689). Reactions at the phenolic hydroxy groups lead, e.g., to esters (F. Arnaud-Neu, E. M. Collins, M. Deasy, G. Ferguson, S. J. Harris, B. Kaitner, A. J. Lough, M. A. McKervey, E. Marques, B. H. Ruhl, M.-J. Schwing, E. M. Seward, *J. Am. Chem. Soc. 111* (1989) 8681), ketones (G. Ferguson, B. Kaitner, M. A. McKervey, E. M. Seward, *J. Chem. Soc. Chem. Commun. 1987*, 587), and amides (A. Arduini, E. Ghidini, A. Pochini, R. Ungaro, G. D. Andreetti, G. Calestani, F. Ugozzoli, *J. Inclusion Phenom. 6* (1988) 119) with complexation selectivities toward certain alkali cations. Macrobicyclic derivatives like calixcrowns (C. Alfieri, E. Dradi, A. Pochini, R. Ungaro, G. D. Andreetti, *J. Chem. Soc. Chem. Commun. 1983* 1075) or

calixspherands (D. N. Reinhoudt, D. J. Dijkstra, P. J. A. in't Veld, K. E. Bugge, S. Harkema, R. Ungaro, E. Ghidini, *J. Am. Chem. Soc. 109* (1987) 4761) should be mentioned too. Finally, the methylene groups may also be converted, e.g., into keto groups by oxidation (G. Görmar, K. Seiffarth, M. Schulz, J. Zimmermann, G. Flämig, *Makromol. Chem.*, in press). These few examples demonstrate the wide variety of possibilities.

Carbonylation of Doubly Lithiated *N*-Pivaloylanilines. A Novel Approach to Dioxindoles via Intramolecular Trapping of Aromatic Acyllithiums**

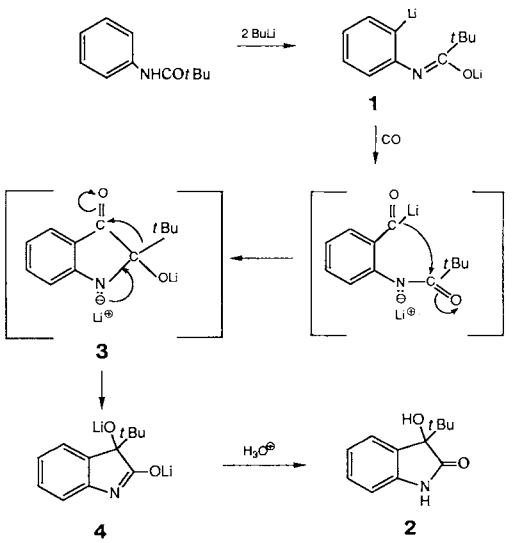
By *Keith Smith** and *Gareth J. Pritchard*

Doubly lithiated *N*-pivaloylanilines react smoothly with carbon monoxide at 0 °C and atmospheric pressure to give, following protonation during workup, good yields of 3-*tert*-butyldioxindoles. The reactions were undertaken in order to investigate whether intramolecular trapping of intermediate acyllithiums might lead to more convenient and more generally useful synthetic procedures than those currently available for acyllithiums. The results bear out the validity of the hypothesis and the reactions provide an interesting new access to indole derivatives.

Whereas reactions of organolithium compounds with carbon dioxide are widely used for the synthesis of carboxylic acids, reactions with carbon monoxide are almost never used in synthetic organic chemistry. This latter fact presumably results from the instability and high reactivity of acyllithiums, which can decompose, dimerize, take up further carbon monoxide, or in other ways lead to products other than those derived by simple electrophilic trapping.[1] To circumvent this problem, organic chemists have devised a range of acyl carbanion equivalents with which to effect nucleophilic acylation reactions.[2] Useful though these reagents are, however, they necessitate the use of additional steps to unmask the carbonyl functionality, lack the appeal of genuine acyllithiums, and preclude the use of isotopically substituted carbon monoxide for introduction of an isotopic label. Thus, there is still much to be gained by direct carbonylation of organolithium reagents.

Seyferth et al. have shown that it is possible to trap acyllithiums formed via carbonylation of alkyllithium reagents provided that the temperature is kept very low (preferably ca. −130 °C) and the trapping electrophile can be used in situ.[3] These conditions are extremely restrictive, however, and in any case are reported generally to be unsuccessful in the case of aryllithiums.[4]

Against this background we wondered if intramolecular trapping of intermediate acyllithiums might provide a more generally applicable synthetic approach for carbonylation reactions of organolithium reagents. As a first attempt to investigate this idea, we undertook the direct carbonylation of doubly lithiated *N*-pivaloylaniline (**1**)[5] and were extremely gratified to discover that carbon monoxide was smoothly taken up, even at room temperature (Scheme 1). Protonation and workup of the reaction mixture gave a substantial yield of a crystalline product, identified as 3-*tert*-butyldioxindole (**2**).[6] The yield was even better (77% after purification) when the carbonylation was carried out at 0 °C.



Scheme 1.

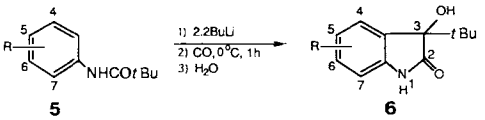
[**] We thank the University College of Swansea for providing the studentship to *G. J. P.* which enabled this work to be carried out.

In order to test the generality of the method for the synthesis of substituted 3-*tert*-butyldioxindoles **6**, a range of ring-substituted *N*-pivaloylanilines **5** was subjected to identical reaction conditions without optimization of individual cases. The yields of isolated products were good (Table 1). It is known that dioxindoles such as **2** and **6** can be reduced to the corresponding indoles.[9, 11]

Table 1. Synthesis of 3-*tert*-butyldioxindoles **5** from *N*-pivaloylanilines **6**.



5 **6**

5/6	R	M.p. of **6** [°C]	Yield of **6** [%] [a]
a	7-CF_3	149	80
b	5-Cl	280–285 (dec.)	82
c	5-Me	263 [b]	61
d [c]	4-OMe	194–195	78

[a] Yield of isolated, purified product based on **5**. [b] Ref. [8] 260–261 °C. [c] The structure of **6d** has been verified by X-ray crystallography [12].

We have not investigated the mechanism of the reaction leading to **2**, but Scheme 1 shows a plausible pathway. There is literature precedent for the rearrangement of 2-*tert*-butyldioxindole **2** under basic conditions,[7, 8, 13] which adds credence to the intermediacy of species **3** and **4**. Furthermore, when the reaction of **5b** was carried out with ^{13}CO, the product **6b** had the label at position 3, as evidenced by ^{13}C NMR.

This reaction appears to be the first generally applicable carbonylation reaction of aryllithiums which allows trapping of the acyllithium intermediate without incorporating a second aryl group from the original reagent. It also demonstrates the value of intramolecular trapping of intermediate acyllithiums even when the trapping center is a weakly electrophilic amide anion. The ease of incorporation of carbon monoxide into the indole nucleus holds out the prospect that such reactions might be applicable to reactions of ^{11}C carbon monoxide ($t_{1/2}$ = 20 min), which could present opportunities for use in positron emission tomography (PET).[14] The method also nicely complements *Wender*'s recent method for the regiocontrolled synthesis of indoles.[15] Finally, it appears likely that other ring systems can be synthesized via carbonylation of appropriately substituted organolithium reagents.

Typical Experimental Procedure

A solution of **5b** (1.00 g, 4.7 mmol) in THF (20 mL) was stirred at 0 °C under nitrogen for 2 h with *n*BuLi (6.5 mL, 1.6 M, 10.4 mmol). A balloon filled with carbon monoxide (ca. 500 mL) was fitted to a needle and CO was allowed to bleed into the reaction mixture. After 1 h the solution was poured into saturated NH_4Cl solution (40 mL) and extracted with ethyl acetate (60 mL). The organic layer was washed with water, dried ($MgSO_4$), and evaporated. The solid obtained was recrystallized from ethyl acetate to give **6b** (0.92 g, 82%), as a white solid. ^1H NMR ([D$_6$]DMSO, 250 MHz): δ = 0.94 (s, 9H, *t*Bu), 5.82 (s, 1H, OH), 6.76 (d, J = 8 Hz, 1H, H-7), 7.18 (d, J = 2 Hz, 1H, H-4), 7.22 (dd, J = 2, 8 Hz, 1H, H-6), 10.26 (br. s, 1H, NH). ^{13}C NMR ([D$_6$]DMSO, 62.9 MHz): δ = 179.05, (s, C-2), 141.2 (s, C-7a), 133.5 (s, C-3a), 128.3 (d, C-6), 125.5 (d, C-4), 124.8 (s, C-5), 110.4 (d, C-7), 80.0 (s, C-3, enriched in reactions utilizing ^{13}CO), 36.7 (s, $C(CH_3)_3$), 23.8 (q, $C(CH_3)_3$). MS (ammonia CI, % intensity): m/z 259 (33), 257 (100, $M + NH_4^{\oplus}$), 242 (23), 240 (84, $M + H^{\oplus}$); accurate mass of $M + H^{\oplus}$ ion 240.0791 (calcd for $C_{12}H_{15}{}^{35}ClNO_2$ = 240.0791).

Mesolytic Cleavage of C–C Bonds. Comparison with Homolytic and Heterolytic Processes in the Same Substrate**

By *Przemyslaw Maslak** and *Javier N. Narvaez*

Mechanistic information on cleavage of C–C bonds leading to formation of two fragments containing three-valent carbon atoms has been limited for a long time to homolytic reactions.[1] Only recently have examples of heterolytic scission[2] been found and investigated in detail. Carbon–carbon bond cleavage may also be induced by one-electron reduction[3, 4] or oxidation[5–7] of molecules. In such cases, unimolecular fragmentation of the resulting radical ions leads to radicals and ions in a process that may be viewed as homolytic or heterolytic depending on electron apportionment to the fragments.[8] To reflect this mechanistic duality we propose to call such processes mesolytic. Here we provide the first kinetic and thermodynamic comparison of four different C–C bond cleavage modes in the same molecule. The study illustrates the tremendous accelerations obtainable in mesolytic processes. We show that this acceleration is due to thermodynamic factors, and, most importantly, that almost all of the thermodynamic advantage is expressed in the lowering of the transition-state energy, even for weakly endergonic processes.

When **1** was heated to 110–140 °C in perdeuterio-*o*-xylene in the presence of thiophenol (Scheme 1), a first-or-

[**] This work was supported by a grant from the National Science Foundation and by the New Faculty Award from the Camille and Henry Dreyfus Foundation.

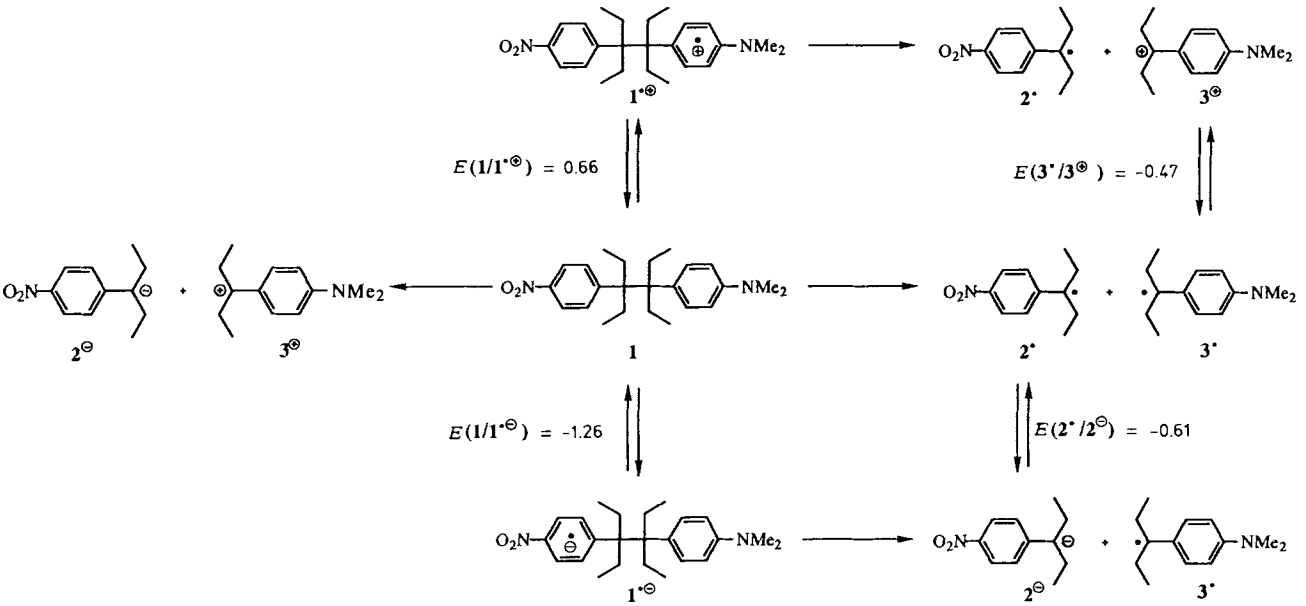
der reaction was observed, resulting in the formation of 3-(4′-nitrophenyl)pentane (87%) and 3-(4′-dimethylaminophenyl)pentane (91%) as the major products. The half-life for disappearance of **1** at 130 °C was 11 min. The observed products and kinetic parameters are consistent with the homolytic cleavage of the central C–C bond. The kinetic data for the homolysis of **1** (Table 1) are almost identical to those reported by *Rüchardt* et al. for homolysis[9] of the hydrocarbon analogue of **1**. The characteristically large entropy of activation is due largely to release of rotational degrees of freedom in the side chains. Based on the studies of *Rüchardt* et al.,[9] it might be assumed that, even in these sterically crowded molecules, radical recombination has only a small barrier, mostly due to entropic effects. Thus, the activation energy measured for this process may serve as a good estimate of the free energy change in this process ($\Delta G^{\neq}(\mathbf{1}) \approx \Delta G(\mathbf{1})$).

In a polar solvent ($(CD_3)_2SO$, 80–110 °C), **1** underwent a clean unimolecular heterolysis of the C–C bond with $t_{1/2} = 7$ min at 100 °C. The major products were 3-(4′-nitrophenyl)pentane (78%) and 3-(4′-dimethylaminophenyl)-pent-2-ene (93%), apparently formed via proton transfer from $\mathbf{3}^{\oplus}$ to $\mathbf{2}^{\ominus}$ (Scheme 1). The dramatically different activation parameters—as compared to those observed in the nonpolar solvent—attest to the change of cleavage mechanism. When this reaction was run in the presence of sodium azide, the rate was unchanged. In addition to 3-(4′-dimethylaminophenyl)pent-2-ene (48%), 3-azido-3-(4′-dimethylaminophenyl)pentane (47%) was observed, indicating involvement of the corresponding benzylic cation ($\mathbf{3}^{\oplus}$).

The radical anion of **1** decayed in a clean first-order fashion[4] with a half-life of 21 min at 20 °C in Me_2SO. The rate constant was independent of the counterion ($Li^{\oplus}$, $Na^{\oplus}$, $K^{\oplus}$). One of the products, anion $\mathbf{2}^{\ominus}$, could be observed directly by NMR. After quenching the reaction mixture with O_2/MeOH/H_2O, the major products of this *aniomesolytic* fragmentation of the C–C bond included 3-(4′-nitrophenyl)-pentan-3-ol (60%), 3-(4′-nitrophenyl)pentane (25%), 3,4-diethyl-3,4-bis(4′-dimethylaminophenyl)hexane (30%), and 4′-dimethylaminophenyl)pentan-3-ol (50%).

The *catiomesolytic* cleavage of $\mathbf{1}^{\bullet\oplus}$ was very rapid even at −95 °C ($t_{1/2} = 3.0$ min, CH_2Cl_2/MeOH (10%), $SbCl_6^{\ominus}$ counterion).[7] The isolated products included 3-(4′-nitrophenyl)-3-methoxypentane (30%), 3-(4′-nitrophenyl)pent-3-ene (65%), 3-(4′-dimethylaminophenyl)-3-methoxypentane (20%), and 3-(4′-dimethylaminophenyl)pent-3-ene (24%). Apparently, $\mathbf{2}^{\bullet}$ is oxidized by $\mathbf{1}^{\bullet\oplus}$ to the corresponding cation, and both cations ($\mathbf{2}^{\oplus}$ and $\mathbf{3}^{\oplus}$) are trapped by methanol. The styrenes are products of thermal decomposition of the ethers.[7]

The data in Table 1 illustrate the dramatic acceleration of C–C bond scission obtainable by addition or removal of an electron. The difference between the homolytic and catiomesolytic fragmentations spans nearly twenty powers of ten when expressed in half-lives of the species undergoing cleavage, or more than 24 kcal mol^{-1} in activation energy. The aniomesolytic process is 10^8 times faster than homolysis. Of course, to fully evaluate these cleavage processes, thermodynamic data must also be considered. The primary products of the other three modes of cleavage are derived from $\mathbf{2}^{\bullet}$ and $\mathbf{3}^{\bullet}$ by one-electron redox processes. Therefore, the knowledge of redox potentials of these radicals and **1** would make thermodynamic comparison of all these processes possible via appropriate thermodynamic cycles[10] (Scheme 1). The required reversible redox potentials for $\mathbf{2}^{\ominus}/\mathbf{2}^{\bullet}$, $\mathbf{3}^{\oplus}/\mathbf{3}^{\bullet}$, and $\mathbf{1}/\mathbf{1}^{\bullet\oplus}$ or $\mathbf{1}/\mathbf{1}^{\bullet\ominus}$ may be obtained using cyclic voltammetry (CV)[11] or second-harmonic ac voltammetry (SHAC)[12] (Scheme 1).



Scheme 1. Fragments derived from **1** and its radical ions as well as the corresponding redox potentials in V vs. SCE.

Interestingly, the estimated free-energy change in heterolysis ($\Delta G(\mathbf{1}\pm)$) is 11 kcal mol^{-1} higher than the activation energy measured for this process. This discrepancy can be accounted for if ion pairs, and not free ions, are the primary products. There is evidence[13] that Coulombic attraction may stabilize such ion pairs by as much as 27 kcal mol^{-1}. A plausible description of the products may involve an ion sandwich solvated on the outside, but with no solvent

Table 1. Kinetic data of four alternative modes of C–C bond cleavage in **1** ($T = 300$ K) [a].

Mode of cleavage	$t_{1/2}$ [b] [min]	$\Delta H^{\neq}$ [kcal mol^{-1}]	$\Delta S^{\neq}$ [cal K^{-1} mol^{-1}]	$\Delta G^{\neq}_{300}$ [kcal mol^{-1}]	ΔG_{300} [c] [kcal mol^{-1}]
Homolytic	1.7×10^{9}	45.6	38	34.2	34
Heterolytic	8.2×10^{3}	22.5	−13	26.4	37
Aniomesolytic	2.0×10^{1}	22.2	2	21.6	20
Catiomesolytic	2.0×10^{-11}	7.0	−10	10.0	8

[a] The estimated errors of enthalpies and entropies of activation for homolysis and heterolysis are ± 2 kcal mol^{-1} and ± 5 cal K^{-1} mol^{-1}. The corresponding estimates for mesolyses are ± 1 kcal mol^{-1} and ± 3 cal K^{-1} mol^{-1}. [b] Estimated. The actual values measured in the experimentally accessible range are reported in the text. [c] Estimated from redox data (± 2 kcal mol^{-1}).

molecules between the aromatic rings. The transition state very likely resembles such an ion pair. Therefore, the observed highly negative $\Delta S^{\neq}$ of heterolysis might be due in part to the compactness of the transition structure. It has to be stressed that **1** is biased by substitution to favor a heterolytic process. A rate increase such as that observed in this case (in comparison to homolysis) is not expected to be a universal phenomenon.

In contrast, the thermodynamically driven acceleration of mesolytic processes is general since radicals undergo oxidation or reduction easier than the corresponding neutral precursors.[14] As our data indicate, all the scission reactions have activation energies that are only slightly higher than the free-energy changes accompanying the reactions. This is not surprising for the highly endergonic homolysis, but quite remarkable for mesolytic cleavages. In the latter cases, almost all of the thermodynamic advantage gained by electron removal or addition is exhibited in the transition state, even for the very weakly endergonic reaction of $\mathbf{1}^{\bullet\oplus}$. This observation is of particular significance for designing low-activation-energy processes for fragmentation of C–C bonds. Not only can the cleavage be carried out in a selective manner[15] under mild conditions, but the energy supplied to the system in order to generate the reactive radical ions is likely to result in the largest possible lowering of the activation energy.

[14] This statement applies to removal of bonding electrons or addition of electrons to antibonding orbitals of the precursor molecules.
[15] The increased selectivity (as compared to homolysis) is due to the fact that substitution and solvent influence ion stability more strongly than radical stability.

The Ammonium Salt Route to Oligomeric Lanthanum Salt Complexes: Synthesis and X-Ray Crystal Structure of $La(NCS)_3 \cdot 4\,HMPA$**

By *Donald Barr, Alan T. Brooker, Michael J. Doyle, Simon R. Drake, Paul R. Raithby,* Ronald Snaith,* and *Dominic S. Wright*

Donor complexes of alkali and alkaline-earth metal salts, $(MX \cdot xL)_n$ and $(MX_2 \cdot xL)_n$, respectively (e.g., M = Li, Na, K, Ca, Sr, Ba; X = Cl, Br, I, SCN; L = HMPA, TMEDA; x = 1–4), can be obtained by reactions of solid ammonium salts with metal sources (*n*BuLi solution, MH or MH_2, the metals themselves) in toluene containing stoichiometric amounts (x) of Lewis bases (L) ("ammonium salt route").[1, 2] Here we report extensions of this synthetic method (but using the metal only, not its hydride or an organometallic compound) to complexes of salts of similarly electropositive non-main-group metals, namely lanthanum (in particular), yttrium, europium, and manganese; the crystal structure of one product so obtained, $La(NCS)_3 \cdot 4$ HMPA (**1**), is also described. In related previous work,[3a, b] ammonium salts have been employed in the syntheses of (uncomplexed) organolanthanoid and -actinoid salts by reacting them with cyclopentadienyl organometallic compounds. For example, NH_4X salts (X = F, Cl, NO_3, BPh_4) react with $(C_5H_5)_4U$ in benzene or tetrahydrofuran to give $(C_5H_5)_3UX$ salts,[3a] and $(C_5Me_5)_2ThMe_2$ reacts with $[R_3NH][BPh_4]$ (R = Me or Et) in toluene to give $[(C_5Me_5)_2Th(Me)][BPh_4]$.[3b]

$La(NCS)_3 \cdot 4$ HMPA **1**

In a typical procedure, a mixture of La metal, solid NH_4NCS, and HMPA (1:3:3 molar ratios) in toluene was treated with ultrasound and heated at 90 °C for up to 1 day (see *Experimental Procedure*). Such conditions caused gas

[**] This work was supported by the Associated Octel Co. Ltd., ICI, the UK Science and Engineering Research Council, and St. John's College, Cambridge. HMPA = hexamethylphosphoramide; TMEDA = *N,N,N′,N′*-tetramethylethylenediamine.

evolution and dissolution of most of the solids. After filtration, chilling of the colorless solution afforded colorless crystals of **1**. The complex has a relatively low melting point and moderate solubility in benzene or toluene, properties indicative of a monomeric or oligomeric (ionically bonded) structure rather than of a continuously latticed one. Reaction of La metal with NH_4Br, under similar conditions, affords the complex $LaBr_3 \cdot 4$ HMPA.[4] All such processes can best be rationalized in terms of $NH_4^{\oplus}$ behaving as a protic acid (pK_a of $NH_4^{\oplus}$: 9.24) towards the metal, so leading to its oxidation (compare reactions of electropositive metals with organic acids such as PhOH, pK_a 10.0).[5]

This ammonium salt route to such complexes has several advantageous features. First, the parent (uncomplexed) lanthanum salts themselves are not too easy to make; for example, the halides LaX_3 are all formed from high-temperature reactions of La metal with HX or X_2 vapors,[6] and the rare-earth trichlorides, in particular, have been obtained (8–97% yields) by allowing the metal oxides to react with $AlCl_3$ at temperatures of 310–500 °C.[7] In contrast, the ammonium salt route assembles LaX_3 species under mild, solution or suspension conditions. Second, although some lanthanoid (Ln) salts will dissolve directly in donor solvents (e.g. $PrCl_3$ dissolves on heating in ethanolic HMPA to give $PrCl_3 \cdot 4$ HMPA[8]), such dissolution is often incomplete; in some cases, of course, where lattice energy factors outweigh complexation energy ones, it does not occur at all. Again in contrast, an infinite lattice $(LnX_3)_\infty$ is not necessarily allowed to form in the ammonium salt route since association of initially generated LnX_3 monomers can be prevented (or at least limited) by the small donor molecules (L) present. Finally, even when direct dissolution works, the parent $(LnX_3)_\infty$ salts are extremely hygroscopic (even deliquescent);[6] it is difficult to obtain these salts as fully anhydrous materials, so that H_2O often appears as a coligand (with L) in complexes. This difficulty is avoided in the ammonium salt route since the precursors are not generally hygroscopic.

The solid-state structure of **1** (Fig. 1)[9] has been solved by X-ray diffraction. As its physical properties indicated, **1** is monomeric. The La atom has a geometry in which the three $NCS^{\ominus}$ ligands occupy positions which are pseudo-*trans* to O atoms of three of the four HMPA ligands. The three La–N distances average 2.581(14) Å; the three La–O distances pseudo-*trans* to the La–N bonds average 2.436(10) Å, the fourth La–O distance being slightly shorter, 2.385(9) Å. The La center thus has a relatively unusual (low) coordination number, seven; eight-coordination seems most common for lanthanoid species, though much higher coordination numbers are well documented for these highly ionic systems.[6]

Similar reactions of NH_4X salts (X = SCN, Br) with the lanthanoid and transition elements Eu, Y, and Mn in toluene containing various donors (TMEDA, HMPA, and DMPU (DMPU = $MeN\overline{C(=O)NMe(CH_2)_2CH_2}$) have afforded, in yields of up to 80%, complexes such as $Eu(NCS)_3 \cdot 2$ TMEDA, $Y(NCS)_3 \cdot 3$ HMPA, and $MnBr_3 \cdot 3$ DMPU.[10] All such low-melting, oligomeric complexes (and others derived from NH_4NO_3, such as $La(NO_3)_3 \cdot 3$ HMPA[10, 11]) are being examined as possible precursors for vapor-phase deposition of metal oxide films, while the reactions of the halide complexes (which are soluble in organic solvents) in solution with RLi and ROLi reagents are being studied as possible routes to organometallic and metal alkoxide complexes.

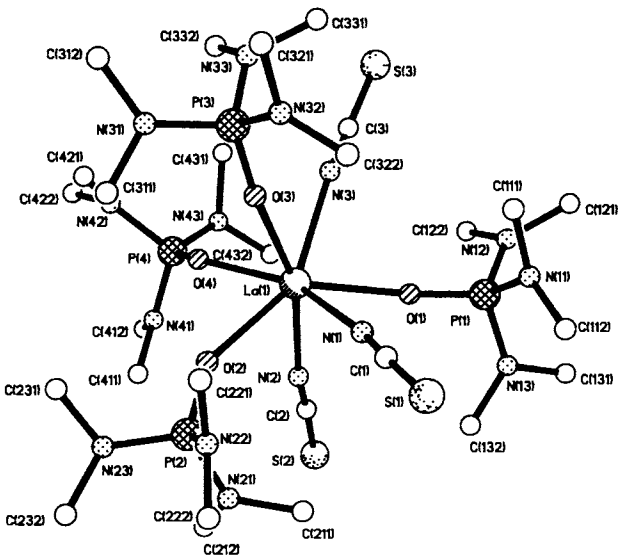

Fig. 1. The molecular structure of **1**. Hydrogen atoms have been omitted for clarity. Key bond lengths [Å]: La(1)-O(1) 2.385(9), La(1)-O(2) 2.450(8), La(1)-O(3) 2.418(8), La(1)-O(4) 2.441(8), La(1)-N(1) 2.581(12), La(1)-N(2) 2.576(12), La(1)-N(3) 2.587(11).

Experimental Procedure

1: A mixture of powdered La metal (0.32 g, 2.3 mmol), solid NH_4SCN (0.52 g, 6.9 mmol), and HMPA (1.24 g, 6.9 mmol) in toluene (10 mL) was first treated with ultrasound for 1 h. No reaction was apparent at this stage, but, on heating to 90 °C, gas evolution (H_2 and NH_3, confirmed by gas chromatography) was observed. Such evolution continued over 24 h, most of the solids dissolving. Extra toluene (10 ml) was added and the mixture filtered hot; cooling of the resulting colorless solution afforded colorless crystals characterized, after filtration and drying in vacuo, as **1** (first-batch yield, 0.84 g, 49%, m.p. 183–185 °C; correct C, H, N, P analysis. ^1H NMR (C_6D_6, 80 MHz, 20 °C): $\delta = 2.51/2.63$ (HMPA doublet).

Single crystals of **1** suitable for X-ray crystallography were sealed under N_2 in Lindemann capillary tubes prior to data collection.

[9] 1. Crystal data: $C_{27}H_{72}LaN_{15}O_4P_4S_3 \cdot 0.5\ (C_6H_5CH_3)$, $M_r = 1069$, monoclinic, space group $P2_1/n$, $a = 11.179(3)$, $b = 21.922(7)$, $c = 22.432(7)$ Å,

$\beta = 91.40(2)^\circ$, $V = 5496(3)$ Å^3, $Z = 4$, $\varrho_{calcd} = 1.29$ g cm^{-3}, $F(000) = 2228$, $Mo_{K\alpha}$ radiation, $\lambda = 0.71073$ Å, $\mu = 1.05$ mm^{-1}. The structure was determined by Patterson and Fourier difference techniques and refined from 5070 unique observed reflections measured at room temperature with a Nicolet R3mV diffractometer ($2\Theta_{max} = 45.0^\circ$), with anisotropic thermal parameters, and with isotropic H atoms in calculated positions; $R = 0.082$, $R_w = 0.099$, $S = 1.71$ for 512 parameters. The crystals examined (sealed in tubes without prior vacuum drying) contained disordered toluene solvate molecules, hence the high-weighted R factor; attempts to grow crystals without solvent failed. Further details of the crystal structure investigation can be obtained from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW (England) on quoting the full journal citation.

[10] The four complexes mentioned were obtained in a similar way to **1**. Typically, the mixture of metal and NH_4X salt in L/toluene was first ultrasonicated for 1 h, then heated at 80–110 °C for 12 h. Most of all of the solids dissolved over this period to give, after filtration, colorless (for Eu, Y, La) or green (Mn) solutions. Refrigeration then afforded the crystalline products: $Eu(NCS)_3 \cdot 2$ TMEDA, yield 64%, m.p. 127–131 °C; $Y(NCS)_3 \cdot 3$ HMPA, yield 80%, m.p. 177–179 °C; $MnBr_3 \cdot 3$ DMPU, yield 44%, m.p. 125–127 °C; $La(NO_3)_3 \cdot 3$ HMPA, yield 76%, m.p. 213–214 °C. Product identities were established by satisfactory elemental analyses (C, H, N; P and Br in the appropriate cases). No evidence (from analyses, IR spectra) was found for the presence of coordinated NH_3 in the products. For the europium complex, the presence of $Eu^{3\oplus}$ was confirmed by cyclic voltammetry.

[11] X-ray crystallography shows $La(NO_3)_3 \cdot 3$ HMPA to be monomeric, with bidentate $NO_3^{\ominus}$ ligands and thus nine-coordinate lanthanum.

Ethynyl(phenyl)iodonium Triflate, $[HC\equiv ClPh][OSO_2CF_3]$: Preparation, Spectral Properties, Mechanism of Formation and X-Ray Molecular Structure**

By *Peter J. Stang,* Atta M. Arif,* and *Charles M. Crittell*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The newest members of the family of polycoordinated iodine species, alkynyl(phenyl) iodonium salts **1**, have rapidly become valuable reagents in organic chemistry.[1] They serve as precursors to novel alkynyl esters such as alkynyl sulfonates,[2] alkynyl carboxylates,[3] and alkynyl phosphates,[4] as well as to microbicides.[5] Vinylcopper reagents stereoselectively couple with **1** to give conjugated enynes with stereodefined double-bond geometries.[6] Alkynyliodonium salts **1** undergo efficient cyclopentene annulations[7] and serve as a progenitor of a unique vinyliodinane species.[8]

$R{-}C{\equiv}C{-}\overset{\oplus}{I}{-}PhX^{\ominus}$ (**1**) $H{-}C{\equiv}C{-}\overset{\oplus}{I}{-}Ph\ \ CF_3SO_3^{\ominus}$ (**2**)

In spite of the surging interest in alkynyl(phenyl)iodonium salts **1**, the parent member of the family, **2**, remains unknown and little is known about the mechanism of formation of these species. Current methods of preparation of **1** employ either terminal alkynes[2, 9] or silylalkynes,[10, 11] neither of which are applicable for the formation of the parent, unsubstituted, ethynyl(phenyl)iodonium salt. In this communication we wish to report the preparation, spectral properties, X-ray structure, and mechanism of formation of **2**, the simplest member of the family of alkynyliodonium salts **1**.

[**] This work was supported by the National Cancer Institute of the NIH (ROCA16903).

Reaction of Zefirov's reagent,[12] **5**, readily prepared[13] in situ by the reaction of iodosobenzene (**3**) with triflic anhydride (**4**), with tri-*n*-butylstannylacetylene gave, upon workup, the desired species **2** in 56% isolated yield (Scheme 1). Compound **2** is a stable, off-white, microcrystalline solid.

$$2\,PhIO\ (\mathbf{3}) + (CF_3SO_2)_2O\ (\mathbf{4}) \xrightarrow[0\,^\circ C]{CH_2Cl_2} PhI(OTf)-O-IPh(OTf)\ (\mathbf{5})$$

$$2\,nBu_3SnC{\equiv}CH + \mathbf{5} \xrightarrow[0\,^\circ C,\ 30\ min]{CH_2Cl_2} 2\,HC{\equiv}\overset{\oplus}{C}IPh\ \overset{\ominus}{O}Tf\ (\mathbf{2}) + (nBu_3Sn)_2O$$

Scheme 1. Tf = CF_3SO_2.

Its IR spectrum shows absorptions at 3285 cm^{-1} and at 2047 cm^{-1} characteristic of the terminal acetylenic C–H stretch and the C–C triple bond, respectively, as well as at 1174, 1232, 1251, 1276, and 634 cm^{-1} due to ionic triflate absorptions.[14] The ^{1}H NMR spectrum of **2** displays a singlet at $\delta = 3.75$ due to the acetylenic hydrogen and aromatic signals at $\delta = 7.65$, 7.83, and 8.24. The relatively low-field position of these signals is in accord with the strong electron-withdrawing effect and concomitant deshielding by the $PhI^{\oplus}$ moiety. Likewise, the ^{13}C NMR spectrum has signals at $\delta = 27.3$ and 98.3 due to the α and β acetylenic carbons, respectively, at $\delta = 117.6$, 134.2, 134.8, and 136.4 for the four different aromatic carbons, and at $\delta = 121.6$ (q, $J_{FC} = 319.1$ Hz) due to the triflate carbon. The very low field absorption of the β carbon ($\delta = 98.3$ vs. 71.9 for acetylene[15] itself) is indicative of a considerable amount of positive charge on this carbon, due to the importance of the resonance structures $HC{\equiv}C{-}\overset{\oplus}{I}Ph$ and $H\overset{\oplus}{C}{=}C{=}IPh$. Analogous low-field ^{13}C absorptions have been observed in the case of alkynyl phosphonium salts.[16] The ^{19}F NMR signal of the triflate is at $\delta = -77.6$.

A suitable single crystal of **2**, grown from $CHCl_3$, was subjected to standard X-ray analysis (Fig. 1). The data indicate a distorted pseudo-trigonal-bipyramidal or T-shaped geometry for **2** in accord with the 10–I–3 nature[17] of **2**. Particularly noteworthy are the I–O1 and I–O2 distances of 2.620 and 2.915 Å, well outside the computed covalent I–O single-bond length of 1.99 Å, along with the three nearly identical S---O bond lengths of 1.424 ± 0.023 Å, which are indicative of the strongly ionic nature of this salt. The unusually short C≡C bond (1.145 ± 0.006 Å) is also interesting. It represents one of the shortest acetylenic bonds known; the average C≡C bond length[18] is 1.181–1.183 Å for 350 acetylenes for which structures have been determined[17] and only a few C≡C bonds are shorter than 1.167 Å.[17] In contrast, the gross features of **2** are in accord with the known[2, 19] structural features of other tricoordinate iodine species such as $PhICl_2$ and $PhI(OAc)_2$.

The mechanism of formation of **2** is deserving of attention. In general, the preparation[2, 9–11] of alkynyliodonium salts **1** must involve the electrophilic addition of an iodonium species to an alkyne and initial formation of a vinyl cation.[20] The high energy[20] of the parent vinyl cation accounts for the lack of reactivity of acetylene itself and hence the fact that the parent species **2** was previously unknown. It is well established[21, 22] that Si substitution destabilizes α-cations but stabilizes β-cations ($Me_3SiC\text{-}\overset{\oplus}{C}$). Yet, we found $Me_3SiC{\equiv}CH$ still too unreactive to give **2**. However,

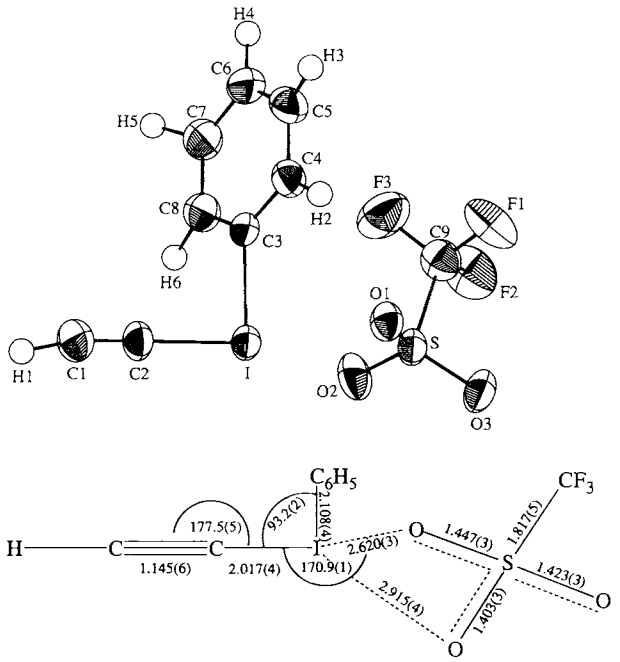

Fig. 1. Top: Molecular structure (ORTEP) of **2**. Bottom: Relevant structural data such as bond lengths [Å] and angles [°]. Crystallographic data: space group $P2_1/n$ (No. 1014); monoclinic, $a = 12.744(4)$, $b = 6.993(2)$, $c = 14.164(6)$ Å, $\beta = 101.79(3)°$, $V = 1235.58$, $Z = 4$; crystal dimensions $0.29 \times 0.25 \times 0.15$ mm^3, $\varrho_{calcd} = 2.032$ g cm^{-3}, $Mo_{K\alpha}$ radiation (0.71073 Å), 2234 measured reflections, 2054 unique; $2.50 < 2\Theta < 48°$, $\Theta/2\Theta$ scan. $I < 3.00\sigma(I)$, 1602 observed reflections, 154 variables; $R = 0.0214$, $R_w = 0.0238$. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK), on quoting the full journal citation.

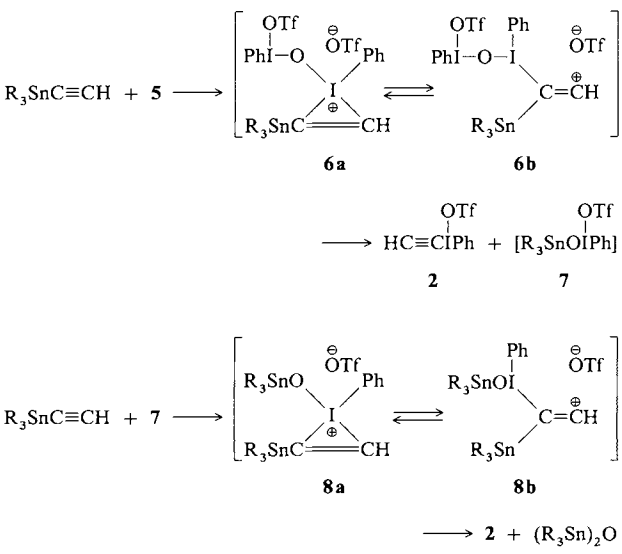
recently *Lambert* and co-workers[23] demonstrated that a β-stannyl substituent stabilizes a cation some $10^{20}-10^{35}$ times better than a β-silyl group. Hence, our use of nBu$_3$SnC≡CH and the highly ionic (therefore strongly electrophilic) Zefirov reagent results in the formation of **2** (Scheme 2).



Scheme 2. R = nBu.

Electrophilic addition of Zefirov's reagent, **5**, to nBu$_3$SnC≡CH results in the β-tin-stabilized vinyl-cation ion pair **6**, which forms **2** upon loss of the iodonium compound **7**. Species **7** adds to a second molecule of nBu$_3$SnC≡CH to form the β-tin-stabilized vinyl-cation ion pair **8**, which gives a second mole of the desired salt **2** and one mole of the stannyl ether **9** (Scheme 2). This mechanism nicely accounts for the overall stoichiometry of the reaction, the observed formation of **9**, and, most importantly, why only the stannylacetylene yields the desired parent ethynyliodonium salt **2**. The ions **6a** and **6b** need the powerful stabilizing effect of the β-stannyl group to be readily accessible.

Owing to the powerful electron-withdrawing iodonium group, the acetylene derivative **2** should be among the strongest known carbon acids. *Kresge* et al.[24] recently determined the pK_a of HC≡CCN to be 8. Based upon this value, the pK_a for **2** should be in the range of 2–5 or comparable to carboxylic acids and approaching that of HF with a pK_a of 3.2.[25]

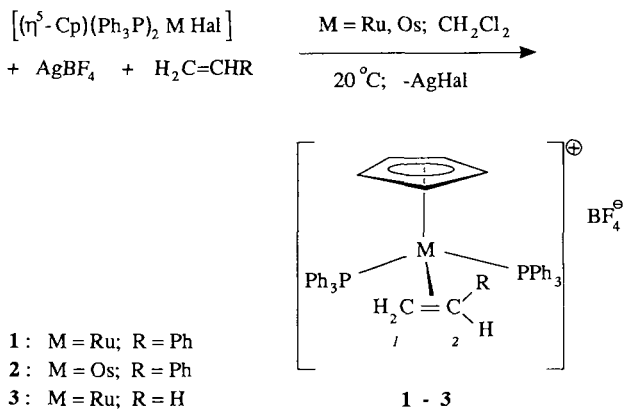
Restricted Rotation of an Unsubstituted η^5-Cyclopentadienyl Group in Solution Demonstrated by ^{13}C NMR Spectroscopy

By *Richard Mynott,* Herbert Lehmkuhl, Eva-Maria Kreuzer,* and *Eckhard Joussen*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

The barrier to rotation of η^5-cyclopentadienyl groups about the ring–transition-metal axis, which has been studied both in solution and the solid by a number of methods,[1–7] is generally considered to be very low. The activation energy $\Delta G^{\ddagger}_{300}$ in solution for rotation of the unsubstituted cyclopentadienyl ring in $[(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4R)Fe]$ (R = CMe_2Et, *n*Bu) has been determined from ^{13}C NMR T_1 measurements to be 8.3 and 8.6 kJ mol^{-1}, respectively.[2] Low-temperature solid-state NMR studies on substituted ferrocenes using the temperature dependence of the second moments of the ^1H lines[3] and ^{13}C spin–lattice relaxation times in $CpTiCl_3$, $[CpMo(CO)_3]_2$, and Cp_2TiS_5[4] have demonstrated similarly low barriers. Despite many attempts to observe restricted rotation of unsubstituted η^5-cyclopentadienyl groups in the NMR spectra of transition-metal complexes in solution at low temperature, to our knowledge no such case has been reported.[1] Indeed, examples are rare even where the Cp ring carries bulky substituents such as *tert*-butyl groups.[7] We have now found that in cationic $[Cp(Ph_3P)_2(\eta^2\text{-olefin})M]^{\oplus}$ (M = Ru, Os) complexes with sterically demanding olefin ligands, the barrier to rotation of an unsubstituted η^5-Cp group can be high enough to give rise to splitting of the Cp signal in the ^{13}C and ^1H NMR spectra in solution at low temperature.

The cationic $[(\eta^5\text{-Cp})(R_3P)_2(\eta^2\text{-olefin})M]^{\oplus}$ complexes **1–3** were prepared from the corresponding $[(\eta^5\text{-Cp})(R_3P)_2MHal]$ compounds according to Scheme 1 by methods based upon known syntheses.



1: M = Ru; R = Ph
2: M = Os; R = Ph
3: M = Ru; R = H

Scheme 1. Synthesis of the cationic complexes **1–3** as $BF_4^{\ominus}$ salts.

At 40 °C the signals in the ^{31}P and ^{13}C NMR spectra of **1** dissolved in CD_2Cl_2 are broadened by dissociation and exchange of the phosphane ligands. The sample was therefore examined at lower temperature in order to obtain well-resolved spectra. In the 75.5-MHz ^{13}C NMR spectrum at −30 °C the cyclopentadienyl resonance ($\delta_C = 90.0$) was sharp. However, while all the other resonances had become narrow at −80 °C, the line width of the Cp signal had increased to 400 Hz. On cooling the sample to −100 °C, this line then split into four signals in the intensity ratio 1:2:1:1 (Fig. 1). Their weighted average chemical shift ($\delta_C = 89.4$) is

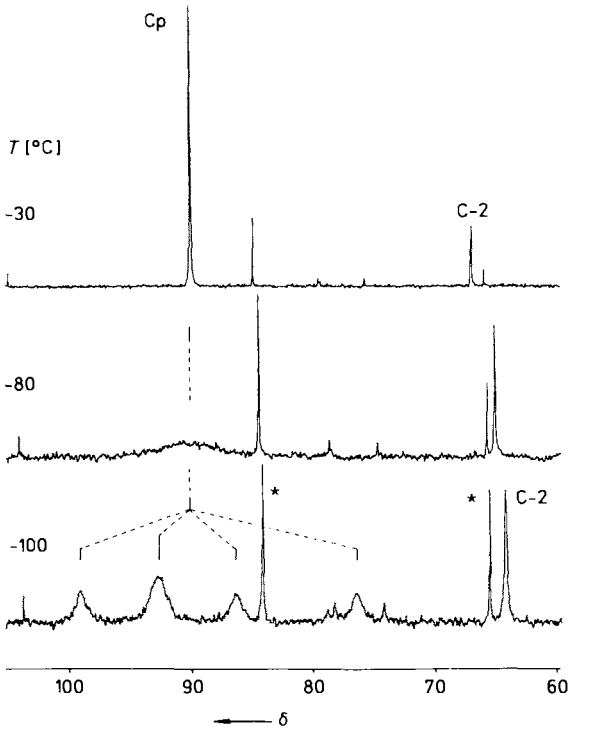


Fig. 1. The η^5-C_5H_5 region of the 75.5-MHz ^{13}C NMR spectrum of **1** in CD_2Cl_2 at −30 °C, −80 °C, and −100 °C. The signal intensities at −100 °C are 1:2:1:1; two of the Cp resonances are unresolved. The corresponding spectrum of **2** is very similar, except that all five Cp signals are resolved. The impurity (*) in the spectrum of **1** is $[Cp(Ph_3P)_2RuCH_2CH_2Ph]$ [8]. The two unresolved ^{13}C NMR resonances of the Cp group in **1** can just be separated in $CD_2Cl_2/CFCl_3$ at −110 °C.

the same within experimental error as that of Cp at higher temperatures (see Table 1). Analogous behavior was observed in the 400-MHz ^1H NMR spectrum. The Cp resonances of **1** dissolved in $CD_2Cl_2/CFCl_3$ ($\delta_H = 4.37$ at −80 °C) split into five signals of equal intensity at −120 °C.

Since the ^{31}P NMR spectrum and the single resonances for the olefinic carbon atoms of the coordinated styrene in the ^{13}C NMR spectrum indicate that (with the exception of a small amount of $[(\eta^5\text{-Cp})(Ph_3P)_2RuCH_2CH_2Ph]$[8] as an impurity) the sample contained just one compound, it can be ruled out that these observations are due to the presence of different compounds, isomers, or rotamers.

The NMR spectra of **2** show similar behavior, except that all five cyclopentadienyl signals of equal intensity were resolved in the ^{13}C NMR spectrum at −110 °C.

The NMR spectra of **1** and **2** are consistent with the rotation of the η^5-Cp ring about the Cp–metal axis becoming slow on the NMR time scale at −100 °C. The molecules possess no elements of symmetry (C-2 in the styrene ligand is a chiral center). Therefore, the η^5-Cp group should give rise to five NMR signals in the limit of slow exchange. The

2	− 30	−1.3, − 11.1	18.1	33.9	46.9	87.2	
	−110			32.6	44.6	97.1, 90.4, 89.8, 81.6, 73.2 [d]	5.83, 4.83, 4.69, 4.08, 3.65 [c]
3	− 95	42.8		42.0		87.0	

[a] Intensity = 2. [b] Weighted average of the η-C_5H_5 signals: δ = 89.4. [c] In $CD_2Cl_2/CFCl_3$ at −120 °C. [d] Weighted average of the η^5-C_5H_5 signals: δ = 86.4.

barrier to rotation $\Delta G^{\neq}_{183}$ of the Cp group in **1** was estimated from the ^{13}C NMR spectra by line-shape analysis to be 34.2 ± 1.5 kJ mol^{-1}.[9] This unusually large value apparently results largely from steric crowding: when the styrene ligand in **1** is replaced by ethylene to give **3**, no significant broadening of the Cp resonance in the ^{13}C NMR spectrum is observed at temperatures down to −95 °C, even though the appearance of three sets of phenyl resonances shows that the phenyl groups on each phosphorus become inequivalent as a result of the slowing of the rotation of the phosphane ligands about the Ru–P bonds.

Complexes **1** and **2** are probably pseudo-tetrahedral with the axis of the C–C double bond parallel to the plane of the Cp ring and with the phenyl group of the styrene on the same side as the Cp ring (see Scheme 1), similar to the X-ray structure of **4**, which has less bulky phosphorus ligands.[10]

$[(\eta^5\text{-Cp})\{P(OMe)_3\}_2(CH_2{=}CHPh)Fe]BF_4$ **4**

It appears that the crowding in **1** and **2** forces the Cp group and the phenyl substituent in the stryrene ligand close to one another and that the phenyl groups on phosphorus and in the styrene mesh well with the cyclopentadienyl ligand.[6]

The Cp resonances of these compounds at low temperature cover unexpectedly large ranges (**1**, ^{13}C 22.5, ^1H 2.47; **2**, ^{13}C 23.9, ^1H 2.18 ppm; see Table 1). While this suggests that the bonding between the metal and the individual carbon atoms of the cyclopentadienyl ring varies considerably (e.g., by ring tilting[11]), the ^{13}C NMR chemical shifts show that all the ring carbons must be complexed. Thus, while we attribute the high rotational barrier mainly to steric factors, it cannot be ruled out that electronic factors may also contribute to the barrier in **1** and **2**. We are examining compounds related to **1** to establish more about the nature of the barrier.

Experimental Procedure[12]

The ^{13}C and ^{31}P NMR spectra were measured on a Bruker WM-300 NMR spectrometer at 75.5 and 121.4 MHz, respectively (δ_P relative to 85% aqueous phosphoric acid). The ^1H NMR spectra were recorded on Bruker AM-200 and WH-400 spectrometers.

1: A solution of $[Cp(Ph_3P)_2RuCl]$ (3.99 g, 5.49 mmol), $AgBF_4$ (1.07 g, 5.49 mmol), and styrene (0.63 mL, 5.49 mmol) in 50 mL of CH_2Cl_2 was kept at 20 °C for 15 min. After filtration, the solution was evaporated to 20 mL and, on addition of 200 mL of ether, 4.62 g (5.24 mmol; 95%) of **1** was precipitated as a yellow solid. ^1H NMR (200 MHz, CD_2Cl_2, 27 °C): δ = 7.8–6.8 (Ph), 4.42 (s, Cp), 4.37 (m, partly obscured by Cp signal, H-2 (styrene)), 3.65 (m, H-1(*Z*)), 2.36 (m, H-1(*E*)). For ^{13}C and ^{31}P NMR data, see Table 1.

2: A solution of $[Cp(Ph_3P)_2OsBr]$ (1.0 g, 1.16 mmol) in 20 mL of CH_2Cl_2 was added dropwise to $AgBF_4$ (0.23 g, 1.16 mmol) and styrene (1 mL, 8.73 mmol) in 10 mL of CH_2Cl_2. Immediately afterwards, the AgBr that had precipitated was filtered off, the filtrate was evaporated to ca. 5 mL, and 50 mL of Et_2O was added. The light yellow precipitate that had formed was filtered off, washed with Et_2O, and dried in vacuo to yield 1.1 g (1.13 mmol; 97%) of **2**. ^1H NMR (200 MHz, $CDCl_3$, 27 °C): δ = 7.8–7.0 (m, Ph), 4.66 (s, Cp), 3.77 (m, H-2 (styrene)), ^3J(H-2,H-1(*Z*)) = 10.7, ^3J(H-2,H-1(*E*)) = 8.4, J(P,H) = 10.1 Hz), 3.21 (m, H-1(*Z*), ^2J(H-1(*E*),H-1(*Z*)) = 1.8, J(P,H) = 7.1, 4.5 Hz), 2.74 (m, H-1(*E*), J(P,H) = 13.0, ca. 1 Hz). For ^{13}C and ^{31}P NMR data see Table 1.

3: Prepared similarly to **1** and **2**, except that ethylene was passed through the solution. From 2.05 g (2.82 mmol) of $[Cp(Ph_3P)_2RuCl]$ and 0.55 g (2.83 mmol) of $AgBF_4$ in 150 mL of CH_2Cl_2, 1.94 g (2.41 mmol; 85%) of **3** was obtained as a yellow solid. ^1H NMR (200 MHz, CD_2Cl_2, 27 °C): δ = 7.48 (*o*-H (Ph)), 7.33 (m, *p*-H (Ph)), 6.89 (m, *m*-H (Ph)), 4.85 (s, Cp), 3.12 (t, $H_2C{=}CH_2$). For ^{13}C and ^{31}P NMR data, see Table 1.

Solid-Phase Synthesis of Glycopeptide Amides under Mild Conditions: Morphiceptin Analogues**

By *Eduard Bardají, Josep L. Torres,* Pere Clapés, Fernando Albericio, George Barany,* and *Gregorio Valencia*

The crucial role of membrane glycoproteins in many biological processes has stimulated the efforts of peptide chemists to develop methods for the synthesis of glycopeptides.[1] This is an especially difficult task due to the sensitivity of the glycosidic bond to acids and bases.[2] Under basic conditions, *O*-glycosyl-β-hydroxycarboxylic acid derivatives (e.g., glycosylserine or -threonine) undergo β-elimination.[3] The sugar moiety of glycopeptides may also be cleaved[4] or anomerized[5] by acids.

Many synthetic opioid derivatives are *C*-terminal amides.[6] One of our laboratories has recently shown that incorporation of sugar moieties into the fifth position of an enkephalinamide results in very active antinociceptive analogues,[7] and we have described a versatile solution-phase route to prepare large amounts of such glycopeptides.[8] These promising results make it important to find a facile procedure for the rapid preparation under mild conditions of a series of glycopeptide amide analogues for pharmacological testing; a solid-phase approach[9] would have obvious advantages in this regard.

The standard Boc/MBHA strategy[9] for synthesis of *C*-terminal amides relies on final cleavage with anhydrous hydrogen fluoride and is therefore unsuitable for solid-phase synthesis of glycopeptide amides. An attractive alternative procedure may use N^{α}-9-fluorenylmethoxycarbonyl (Fmoc) protection[10] in conjunction with appropriate resin-linkage agents.[11] Unfortunately, a literature procedure[12] involving cleavage of a 4-hydroxymethylbenzoic acid linker with ammonia–methanol is liable to result in β-elimination of the glycosyl moiety.

The recent result from one of our laboratories[13, 14] that *C*-terminal peptide amides can be successfully prepared by Fmoc chemistry, with final acidolytic cleavage, suggested an answer to our synthetic problem. Here we describe the incorporation of 5-[4-(Fmoc-aminomethyl)-3,5-dimethoxyphenoxy]valeric acid (PAL, **1**) onto aminomethyl-polystyrene and subsequent synthesis of the glycosyl derivatives $O^{1,4}$-(β-D-galactopyranosyl) [Hyp^4]-morphiceptin (**2**) and $O^{1,4}$-(β-D-glucopyranosyl) [Hyp^4]-morphiceptin (**3**).

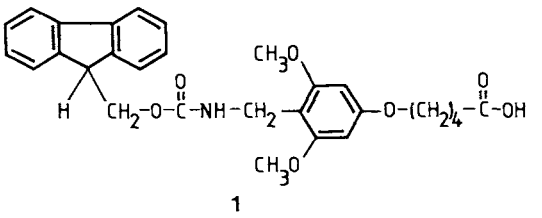
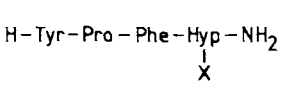
We thank *E. Crusi* (University of Barcelona) for the NMR data and Dr. *J. Rivera* and *M. Guerra* (Laboratory of Mass Spectrometry, C.I.D.-C.S.I.C., Barcelona) for the FAB-MS analyses. Abbreviations: Boc, *tert*-butoxycarbonyl; DCC, *N,N'*-dicyclohexylcarbodiimide; DMF, *N,N*-dimethylformamide; FAB-MS, fast atom bombardment mass spectrometry; Fmoc, 9-fluorenylmethoxycarbonyl; galac, galactopyranosyl; glcp, glucopyranosyl; HOBt, 1-hydroxybenzotriazole; HPLC, high-performance liquid chromatography; Hyp, hydroxyproline; MBHA, *p*-methylbenzhydrylamine; PAL, 5-[4-(9-fluorenylmethoxycarbonyl-aminomethyl)-3,5-dimethoxyphenoxy]valeric acid; Su, *N*-hydroxysuccinimidyl; TFA, trifluoroacetic acid.

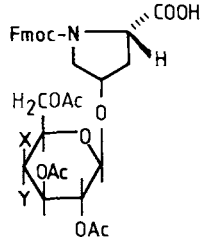
For the synthesis of glycosylmorphiceptins, the linker **1** (2 equiv.) was attached to an aminomethyl-polystyrene (1% cross-linked, 200–400 mesh, 0.65 m equiv. aminomethyl groups per gram resin) by DCC/HOBt coupling in DMF. After removal of the Fmoc group from **1** with piperidine-DMF (1:4), the syntheses of tetrapeptides **2** and **3** proceeded smoothly using the corresponding building blocks **4** and



1



2, X = Galac
3, X = Glcp



4, X = OAc, Y = H (Galac)
5, X = H, Y = OAc (Glcp)

5[15] via their HOBt esters, performed in situ with DCC in CH_2Cl_2. The remaining Fmoc-amino acids were incorporated by the same procedure.[16] Upon completion of chain assembly, the Fmoc group was removed with piperidine–DMF (1:4), and the acetyl protecting groups for the sugar moiety were best removed with hydrazine–methanol *while the peptide remained anchored to the resin.* Thus, excess hydrazine was simply eliminated by washings with methanol and CH_2Cl_2. Deacetylation with hydrazine–methanol (4:1) was complete after 2 h at 25 °C.[17–19] Acidolytic cleavage from the support was achieved by treatment with TFA–CH_2Cl_2 (7:3) for 2.5 h at 25 °C with concomitant formation of the *C*-terminal amide and deprotection of the *tert*-butyl side chain on tyrosine. This procedure provided glycopeptide amide analogues **2** and **3** in nearly quantitative yields for the cleavage[20] and initial purities of 90% and 75%, respectively. Both compounds were purified by reversed-phase semipreparative HPLC to obtain, in 85 and 70% recovery, final products of >99% purity as shown by analytical HPLC. The FAB MS was correct.[21, 22]

In conclusion, we have successfully applied the recently described PAL handle **1**[13] to the synthesis of glycopeptide amides. The cleavage conditions do not cause damage to the glycosidic bond, and *C*-terminal amides are smoothly obtained in good yields. Moreover, the described solid-phase synthesis allows deprotection of the sugar moiety to be carried out on the resin. These results provide the first examples for the synthesis of glycopeptide amides by the solid-phase procedure.

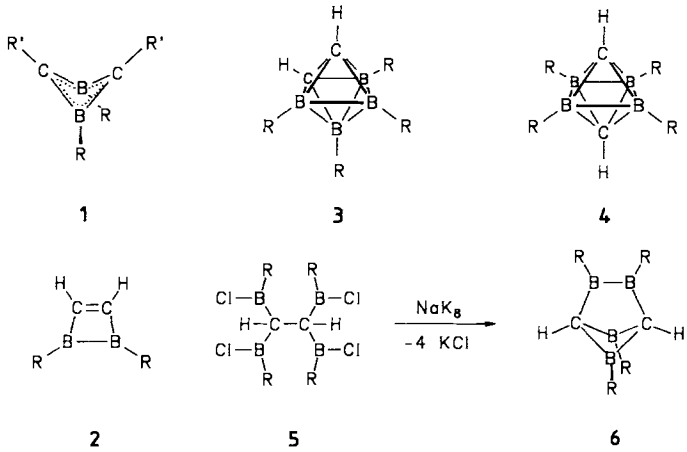
[18] The absence of peptide in the filtrates from hydrazine–methanol treatments was proved by HPLC.
[19] Despite the fact that glycosylhydroxyproline does not undergo β-elimination under basic conditions, we opted for a mild treatment so that it could be generalized in the future to the solid-phase synthesis of more labile glycopeptide amides.
[20] After cleavage, no peptide was detected on the resin by amino-acid analysis.
[21] Analytical HPLC of **2** and **3**: $t_R = 11.6$ min, $k = 3.5$. Conditions: 4.6 × 250-mm C_{18} column, 10 μm, elution with 0.1% aqueous TFA – 0.1% TFA in a CH_3CN gradient from 10% to 100% organic solvent over 30 min (flow rate 0.9 mL min^{-1}, $\lambda = 215$ nm). FAB MS of **2** and **3**: *m/z* 700 ($M + 1$), 722 ($M + Na$).
[22] No destruction of the glycosydic bond occurred as proved by the absence of nonglycosylated peptides. These compounds were prepared by the same procedure and used as HPLC standard ($t_R = 12.9$ min, $k = 3.9$, under the same conditions stated in [21]). This test was performed before cleavage of the glycopeptide from the resin.

A Bicyclic Isomer of the *closo*-Carbaborane $(CH)_2(BR)_4$**

By *Albrecht Krämer, Hans Pritzkow*, and *Walter Siebert**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The prediction of *Schleyer* et al.[1] that the puckered 1,3-dihydro-1,3-diborete **1** should be more stable than the planar 1,2-dihydro-1,2-diborete **2** (R = R′ = H) was followed by the successful synthesis of substituted derivatives of **1**[2–4] and of a derivative of **2**.[5] A comparison of the calculated structure of **1** for R′ = H and R = H, NH_2[1,6] with the results of the X-ray structure analyses[2] showed remarkably good agreement. Compounds **1** can be reduced to dianions $\mathbf{1}^{2\ominus}$,[7,8] which could in principle react with diborane(4) derivatives XRB–BRX (X = Cl) to give 2,3,5,6-tetraborabicyclo[2.1.1]hexane derivatives **6**; however, this has not yet been achieved. Here we report on the synthesis and structure of the boron-rich organoborane **6** (R = N*i*Pr$_2$), the predicted classical isomer of *closo*-carbaboranes **3** and **4**. Compound **6** (R = H) was postulated by *Lipscomb* et al.[9] as an intermediate in the rearrangement of **3** to **4**; our results corroborate the PRDDO calculations, which indicated that electron-donor substituents on boron should stabilize the organoborane structure. In the case of the fluorine-substituted derivative, **6** (R = F) is 130 and 134 kcal mol^{-1} more stable than **3** and **4**, respectively.[9] This is also supported by an example of destabilization of a *nido*-C_4B_2 carbaborane by amino substituents on boron, resulting in formation of the bicyclic organoborane.[10]



Starting from 1,1,2,2-tetrakis(dichloroboryl)ethane (**5**, R = Cl),[11] partial amination with HN*i*Pr$_2$ gives 1,1,2,2-tetrakis[chloro(diisopropylamino)boryl]ethane (**5**, R = N*i*Pr$_2$) in 83% yield. Its dehalogenation with Na/K in refluxing benzene affords **6** (R = N*i*Pr$_2$) in 73% yield.

The X-ray structure analysis[12] of **6** (R = N*i*Pr$_2$) confirms the presence of a 1,3-diboretane derivative bridged at the 2,4-positions with a 1,2-diborane(4)diyl unit (Fig. 1a). The bicyclic compound does not have the expected C_{2v} symmetry in the crystal, but rather approximate C_2 symmetry. The

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.

B2B3 bridge does not lie symmetrically over the diboretane, but instead has a zigzag structure (Fig. 1 b). This deviation is clearly revealed in the different angles B2C2B1/B2C2B4 and B3C1B1/B3C1B4 as well as, to a lesser extent, in the B–C distances in the 1,3-diboretane.

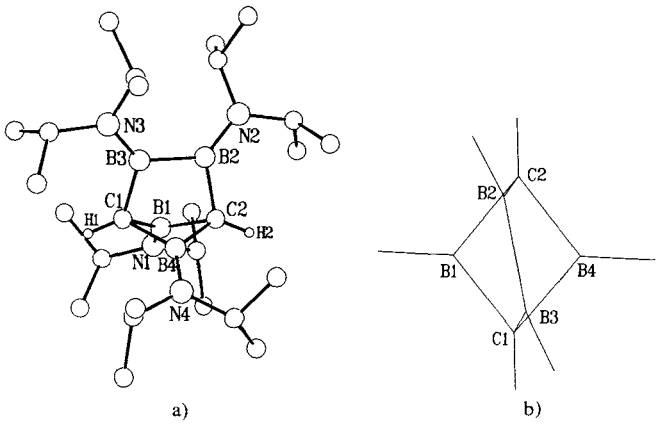

Fig. 1. a) Molecular structure of **6** (R = N*i*Pr$_2$) in the crystal. Selected distances [Å] and angles [°] (±0.007 Å and ±0.3°; values for the two independent molecules): C1-B1 1.561/1.566, C2-B4 1.589/1.576, C1-B4 1.605/1.594, C2-B1 1.611/1.612, C1-B3 1.562/1.563, C2-B2 1.566/1.557, B2-B3 1.749/1.738, B1-B4 1.934/1.918, B1-N1 1.396/1.391, B4-N4 1.376/1.387, B2-N2 1.413/1.416, B3-N3 1.413/1.411; B1-C1-B4 75.3/74.7, B1-C2-B4 74.4/74.0, C1-B1-C2 95.3/94.6, C1-B4-C2 94.5/94.9, B3-C1-B1 101.8/102.3, B2-C2-B4 103.1/104.0, B3-C1-B4 94.0/94.8, B2-C2-B1 93.3/92.5. b) Framework of **6** (R = N*i*Pr$_2$). Projection along the (approximate) twofold axis of the molecule.

Noteworthy is the very short transannular B1–B4 distance (1.93 Å), which likewise confirms the weak, nonbonding boron–boron interaction predicted by the MO calculations.[9b] In **6** (R = N*i*Pr$_2$) the 1,3-diboretane ring is more strongly puckered (angle E1(C1,B1,C2)/E2(C1,B4,C2) 53°, E3(B1,C1,B4)/E4(B1,C2,B4) 44°) than in the nonbridged 1,3-diboretane derivative[8] $(CH_2)_2(BN{i}Pr)_2$ (E1/E2 39°, E3/E4 34°) (R = N*i*Pr$_2$).

Compound **6** displays temperature-dependent ^{1}H NMR spectra. At 293 K, the diisopropyl groups give rise to three septets in the ratio 1:2:1, two doublets, and two broad signals; at 183 K, four septets and eight, partly overlapping doublets are observed. At 363 K, however, two overlapping septets and two doublets are found. A singlet is observed for the ring protons. The splitting of the signal pattern into four septets and eight doublets is in agreement with the crystal structure. At room temperature, vibration of the B2–B3 bridge results in averaging of the signals at N1 and N4; at increased temperature, we expect a rotation around the B–N bond, so that the diisopropylamino groups only give rise to two septets and two doublets. A broad ^{11}B NMR signal is found at $\delta = 46$ ($T = 298$ K) with a half-width of 1.2 kHz; this signal is in agreement with the presence of a diborane(4) derivative with alkyl and dialkylamino substituents or of a dialkylamino(organo)borane. In the mass spectrum, the molecular-ion peak appears at $m/z = 470$ (81.8%) with the isotope distribution expected for four boron atoms.

Experimental Procedure

5 (R = N*i*Pr$_2$): HN*i*Pr$_2$ (15.9 mL, 114.4 mmol) was slowly added dropwise to a solution of **5** (R = Cl; 5.0 g, 14.3 mmol) [11] in 120 mL of petroleum ether 60/70. The reaction mixture was then refluxed for 2 h, filtered, and washed three times with petroleum ether 60/70. The solvent was removed from the combined filtrates under high vacuum and the residue was recrystallized from *n*-pentane. Yield: 7.24 g (11.9 mmol, 83%), m.p. 213.5 °C. ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 1.12$(d$_a$, 24H), 1.34(d$_b$, 12H), 1.36(d$_b$, 12H), 1.92(s, 2H), 3.31(sept$_b$, 4H), 4.13(sept$_a$, 4H), $^3J_a = 7.0$ Hz, $^3J_b = 6.6$ Hz. ^{11}B NMR (28.75 MHz, $CDCl_3$): $\delta = 40$. ^{13}C NMR ($CDCl_3$, 50 MHz): $\delta = 20.83$(q, NCH*C*H$_3$), 21.64(q, NCH*C*H$_3$), 23.2(q, NCH*C*H$_3$), 23.31(q, NCH*C*H$_3$), 29(br, B*C*), 45.97(d, N*C*HCH$_3$), 50.51(d, N*C*HCH$_3$). MS (EI): m/z 610 ($M^{\oplus}$, 1%), 595 ([M–Me]$^{\oplus}$, 23), 510 ([M – N*i*Pr$_2$]$^{\oplus}$, 5.9), 429 ([M – BClN*i*Pr$_2$ – Cl]$^{\oplus}$, 60), 386 ([M – BClN*i*Pr$_2$ – *i*Pr – Cl]$^{\oplus}$, 100).

6 (R = N*i*Pr$_2$): **5** (R = N*i*Pr$_2$) (2.3 g, 3.75 mmol) and NaK$_8$ (640 mg, 1.91 mmol) were allowed to react in 60 mL of refluxing benzene for 24 h. The reaction mixture was then filtered, the solvent was removed under high vacuum, and the residue was recrystallized from *n*-pentane. Yield 1.29 g (2.74 mmol, 73%); m.p. 136.5 °C (dec.). ^{1}H NMR (293 K, [D$_8$]toluene): $\delta = 1.05$(br, 12H), 1.10(d, 12H), 1.20(d, 12H), 1.39(br, 12H), 2.83(s, 2H), 3.20(m, 2H), 3.50(sept, 4H), 3.82(m, 2H); 193 K: $\delta = 1.0$–1.25[br, m, (5d)], 1.33(d, 6H), 1.42(d, 6H), 1.44(d, 6H), 2.90(sept, 2H), 2.95(s, 2H), 3.14(sept, 2H), 3.93(sept, 2H), 4.08(sept, 2H); 363 K: $\delta = 1.11$(d, 24H), 1.20(d, 24H), 2.81(s, 2H), 3.51(m, 8H). ^{11}B NMR ([D$_8$]toluene): $\delta = 46$(br, half-width = 1.2 kHz). ^{13}C NMR(C_6D_6, 293 K): $\delta = 22.9$(br, NCH*C*H$_3$), 23.91(NCH*C*H$_3$), 23.97(NCH*C*H$_3$), 25.7(br,NCH*C*H$_3$), 44.7(br,N*C*HCH$_3$), 48.9(br,N*C*HCH$_3$), 55.2(br,N*C*HCH$_3$), 62(br, B*C*). MS (EI): m/z 470($M^{\oplus}$, 81.8%), 455([M-Me]$^{\oplus}$, 100), 427([M-*i*Pr]$^{\oplus}$, 93.2), 369([M-HN*i*Pr$_2$]$^{\oplus}$, 37.2).

$Te_8^{2\oplus}$, a New Tellurium Polycation

By *Johannes Beck* *

The elements sulfur, selenium, and tellurium are capable of forming homo- and heteronuclear polycations. Of the tellurium-containing cations, $Te_4^{2\oplus}$ [1] and $Te_6^{4\oplus}$,[2] as well as

[*] Dr. J. Beck
Institut für Anorganische Chemie der Universität
Engesserstrasse, D-7500 Karlsruhe (FRG)

$[Te_2Se_2]^{2\oplus}$,[3] $[Te_3Se]^{2\oplus}$,[3], $[Te_2Se_4]2^{\oplus}$[4], $[Te_3S_3]^{2\oplus}$,[4] $[Te_2Se_6]^{2\oplus}$,[5] and $[Te_2Se_8]^{2\oplus}$,[5] have so far been structurally characterized. These ions are obtained from the elements by oxidation with oleum, AsF_5, or SbF_5 or in $AlCl_3$ melts with $TeCl_4$ as oxidizing agent. The species $Te_8^{2\oplus}$, analogous to the known homonuclear cations of sulfur and selenium, $S_8^{2\oplus}$[6] and $Se_8^{2\oplus}$,[7] has not yet been reported.

During attempts to synthesize the first ternary compounds in the system W-Te-halogen, I found that WCl_6 is also a suitable oxidizing agent for the synthesis of tellurium polycations. WCl_6 is reduced by tellurium to the hexachlorotungstate(v). Reaction of WCl_6 and two equivalents of tellurium in an evacuated, sealed glass ampoule at 170–200 °C gives $Te_4[WCl_6]_2$, a compound containing the square-planar $Te_4^{2\oplus}$ cation.[8] Even the use of an excess of tellurium does not reduce WCl_6 beyond oxidation state +5. Reaction of WCl_6 with four equivalents of tellurium results in formation of $Te_8[WCl_6]_2$ (**1**). This reaction is carried out in an evacuated, sealed glass ampoule at 150 °C and the yield, after three weeks, is quantitative.[9] Compound **1** is obtained as blue-black crystals, which are transported to the coolest side of the ampoule. In the presence of moist air, the crystals slowly hydrolyze. Above 280 °C, **1** decomposes to the starting materials, elemental tellurium and liquid WCl_6, the latter of which can be removed by distillation. When the temperature is lowered again to 150 °C, **1** is re-formed.

The structure determination[10] shows that **1** consists of $Te_8^{2\oplus}$ cations and $[WCl_6]^{\ominus}$ anions. The $Te_8^{2\oplus}$ ion can be described as a bicyclic framework made up of two five-membered rings in envelope conformation (Fig. 1). A crystallographic twofold axis passes through the cation, resulting in point-group symmetry C_2. The Te–Te distances in the eight-membered ring range from 270.4 to 278.3 pm. These values correspond to twice the covalent radius of tellurium (274 pm)[11] and are found in compounds with Te–Te single bonds. For example, the Te–Te distances in diphenyl telluride are 271.2 pm[12] and the Te–Te distance in the $Te_2^{\ominus}$ anion of $MgTe_2$ is 274.0 pm.[13] In addition, there is a transannular interaction between Te1 and Te1^{I} in $Te_8^{2\oplus}$. The Te1–Te1^{I} distance (299.3 pm) is longer than a single bond, but still markedly shorter than the Te–Te bonds (312 pm) in the trigonal-prismatic $Te_6^{4\oplus}$ cation along the edges of the prism.[2] All angles in $Te_8^{2\oplus}$ lie between 84.3° and 100.0°, smaller than the angle of 103.1° in the helical tellurium chain in the structure of the element.[14] Such an angle contraction relative to the element has so far been observed for all chalcogen cations. The structure of $Te_8^{2\oplus}$ thus displays clear differences with those of its homologues $S_8^{2\oplus}$ and $Se_8^{2\oplus}$, which exhibit approximate mirror symmetry (C_s) and only weak transannular interactions.

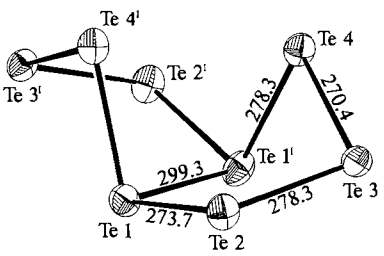

Fig. 1. Structure of the $Te_8^{2\oplus}$ ion in the crystal of $Te_8[WCl_6]_2$ (**1**). The thermal elipsoids are drawn at the 70% probability level. The bond lengths are given in pm (standard deviation: 0.1 pm). Bond angles [°]: Te2-Te1-Te4^{I} 97.7(1), Te2-Te1-Te1^{I} 98.3(1), Te1^{I}-Te1-Te4^{I} 90.7(1), Te1-Te2-Te3 99.8(1), Te2-Te3-Te4 100.0(1), Te3-Te4-Te1^{I} 84.3(1).

An association of the $Te_8^{2\oplus}$ ions occurs in **1**, as shown more clearly in Figure 2 by a larger section of the structure. The

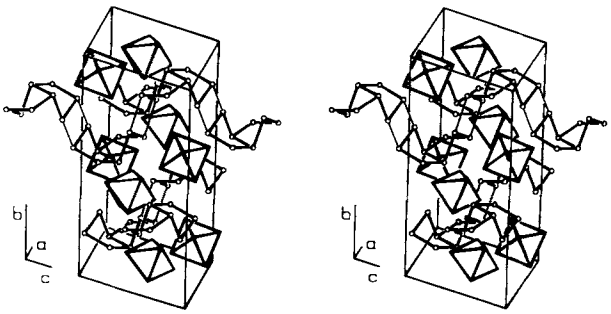

Fig. 2. Stereoscopic drawing of the unit cell of **1**. The $WCl_6^{\ominus}$ ions are drawn as octahedra. Bond lengths [pm] and angles [°]: W-Cl 226.7(2) to 235.8(2), Cl-W-Cl 88.1(1) to 92.1(1) and 176.4(2) bis 179.3(2).

edges Te3-Te4 and Te3^{I}-Te4^{I} of each $Te_8^{2\oplus}$ ion form a rectangular, planar Te_4 ring with the corresponding edges of the neighboring ion. The Te–Te distances to the neighboring cation (342.4 pm) lie in the range of weak bonding; they are much shorter than the sum of the van der Waals radii (440 pm[11]) and also shorter than the Te–Te bond of bond order 2 in the element (349.1 pm[14]). The tellurium partial structure in **1** can therefore be regarded as a one-dimensional, undulating, band-shaped tellurium polycation $[Te_n]^{n/4\oplus}$. No association of the ions has been observed in tellurium cations so far investigated; the homologous ions $S_8^{2\oplus}$ and $Se_8^{2\oplus}$ in $S_8[AsF_6]_2$[6] and $Se_8[AlCl_4]_2$[7] are also isolated. In the structure of $Se_8[AlCl_4]_2$, however, one interionic Se–Se contact less than the van der Waals distance has been found and may point to the increasing tendency of the heavy main-group elements to assume higher coordination numbers.

The $WCl_6^{\ominus}$ ions in **1** form distorted octahedra, whose W–Cl bond lengths (226.7 to 235.7 pm) differ significantly. The average W–Cl distance of 232.1 pm, however, is in good agreement with that in $Te_4[WCl_6]_2$ (232.2 pm[8]) and that in $CsWCl_6$ (232.5 pm[15]).

The distortion of the $WCl_6^{\ominus}$ ion is due to strong interactions of the chlorine atoms with the $Te_8^{2\oplus}$ ions. The shortest Te–Cl distances are 316.5 and 331.4 pm; overall, the atoms Te1 to Te4 display distances to 15 Cl atoms that are shorter than the sum of the van der Waals radii (400 pm[11]). Short chalcogen–halogen distances are typical of halometalates of chalcogen cations and are regarded as the cause for the generally observed distortion of the ions.[1–3, 7, 16]

[9] *Experimental Procedure:* $WOCl_4$-free WCl_6 (2 g) and finely powdered tellurium (2.57 g) were placed in a glass ampoule of 20-cm length and 1.5-cm diameter. The ampoule was sealed under vacuum and heated for two days at 180 °C with as little temperature gradient as possible. The temperature was then reduced to 150 °C. At the start of the reaction, it is advantageous to make the contents of the ampoule homogeneous by strongly tapping it several times. The tellurium reacts completely within several weeks and **1** is formed as blue-black crystals up to 5 mm in size.

$Si[(Me_2P)_2C(SiMe_3)]_2$, a Stable σ-Bonded Compound Containing Divalent Silicon**

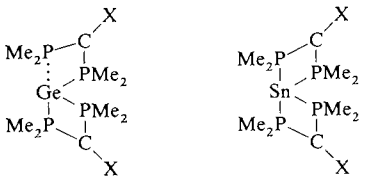
By *Hans H. Karsch,* Ursula Keller, Siegfried Gamper,* and *Gerhard Müller*

Divalent silicon compounds should lead to novel silicon chemistry because of their high synthetic potential. Only one such compound,[1] $(C_5Me_5)_2Si$, which contains π-bonded ligands (silicocene),[2] has so far proven stable under normal conditions. Upon derivatization, however, its monomeric Si^{II} structure is lost.[3] Stable silicon(II) compounds containing σ-bonded ligands have not yet been reported.

Although silanediyls, SiR_2, which are isoelectronic to carbenes, have been intensively investigated as short-lived species,[4] no stable monomers, even those containing bulky substituents, have been isolated so far. Dimesitylsilanediyl, for example, dimerizes even at low temperatures to give disilenes.[5]

Donor ligands increase the stability only slightly: the adducts decompose even at temperatures < -70 °C.[6] Only when the lone pair on silicon is deactivated by complex formation are such "Si^{II}" compounds ("donor-stabilized silanediyl complexes") stable.[7] However, in these complexes the oxidation state is hardly more than a mere formalism.

The most promising route to unstable silicon(II) compounds appeared to be via *intramolecular* donor stabilization exploiting the chelate effect. Earlier results with the corresponding germanium(II) and tin(II) compounds (cf. **1**, **2**) indicated that diphosphinomethanides should be particularly suitable as ligands.[8, 9]



1 **2**

a, X = PMe_2; **b**, X = $SiMe_3$

Because the coordinated phosphane donors shield the negative charge of the carbanion from electron-rich, low-valent coordination centers, a high ionic bonding component and thus the attainment of higher coordination numbers is ensured and the compounds are thereby stabilized. Simultaneously, this carbanion nature leads to increased chemical reactivity, which can be exploited to carry out ligand exchange reactions without changing the oxidation state. Moreover, unlike many other monoanionic chelate ligands, phosphinomethanides are stable toward reduction. Accordingly, it should also be possible to stabilize silicon(II) with phosphinomethanide ligands. Indeed, in the presence of $Li[C(PMe_2)_2(SiMe_3)]$, Si_2Cl_6 is smoothly reduced to **3** [Eq. (a)].

$$Si_2Cl_6 + 4\,Li[C(PMe_2)_2(SiMe_3)] \xrightarrow{a,\,b} \underset{\mathbf{3}}{2\,Si[(Me_2P)_2\,C(SiMe_3)]_2} \qquad (a)$$

a, Mg/THF; b, Li-naphthalide/THF.

The bright yellow, air-sensitive crystals of **3**, like those of **1a,b** and **2a,b**, are readily soluble in hydrocarbons. An X-ray structure analysis[10] shows that, in the crystal, **3**, like **1a** and **2a**, has a (distorted) pseudo-trigonal-bipyramidal (ψ-tbp) structure in which silicon, as a spiro center, is surrounded by four phosphorus atoms[12] (Fig. 1). A common

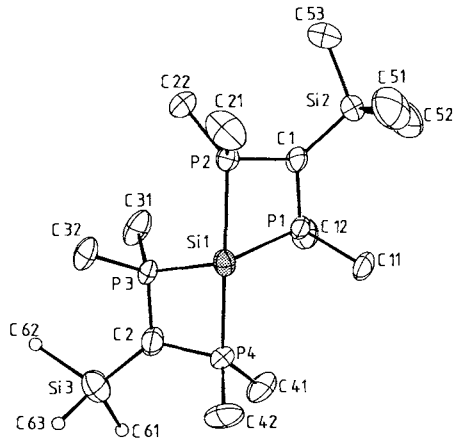


Fig. 1. Molecular structure of **3** (ORTEP, displacement ellipsoids 50%; H atoms omitted; only one alternative is shown for the disordered methyl C atoms at Si3). Important distances [Å] and angles [°]: Si1-P1 2.271(4), Si1-P2 2.514(4), Si1-P3 2.269(4), Si1-P4 2.609(4), C1-P1 1.72(1), C1-P2 1.76(1), C1-Si2 1.82(1), C2-P3 1.73(1), C2-P4 1.67(1), C2-Si3 1.89(1); P1-Si1-P2 68.4(1), P3-Si1-P4 67.3(1), P1-Si1-P3 111.6(1), P2-Si1-P4 154.2(1), P2-Si1-P3 98.0(1), P1-Si1-P4 96.3(1), P1-C1-P2 101.8(5), P3-C2-P4 106.1(6); sum of angles at C1, 359.8; at C2, 359.9.

feature of the three compounds is also the marked difference between axial and equatorial element–phosphorus bond lengths. For **3**, the latter agree with the expected value for

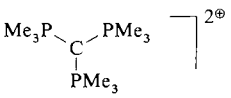
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. *H. Schmidbaur* for institutional support, Prof. *F. R. Kreissl* for recording the mass spectrum, and Prof. *B. Wrackmeyer* for recording the complicated NMR spectra.

Si–P single bonds (although no data is available for Si^{II}). A bond shortening, which would be expected for an ylide formalism, is not observed. On the other hand, the relatively short P–C1/2 bonds are evidence supporting such an ylide component.[13]

One equatorial position within the tbp structure remains unoccupied and can formally be assigned to the lone pair on silicon. Thus, **3** is the first silicon(II) compound containing σ-bonded ligands and the first with a formal electron "decet".

Interestingly, the structure of the silicon compound **3** more strongly resembles that of the tin compound **2a** than that of the germanium derivative **1a**.[14] Compounds **2a** and **3** are tetracoordinated; the two axial M–P bond lengths in each molecule differ only slightly (**2a**, 0.04 Å; **3**, 0.1 Å). By contrast, these bond lengths differ markedly in **1a** (0.38 Å), thus indicating a transition from tetracoordination to tricoordination, as is also typically observed for carbon (see below). Since the values for **3** are subject to large errors due to the poor quality of the crystal, more detailed structural comparison must await a new measurement.

Compounds **3** and **2b** behave similarly in solution. Whereas the pseudorotation of the germanium compound **1b**, that is, the equilibration of axial and equatorial PMe_2 groups, can be frozen out at low temperature, this is not possible for either **2b** or **3**; between 50 and −100 °C, only a singlet is observed in the ^{31}P NMR spectrum of **3**.[15] In principle, the structural units $R_3P \rightarrow E$:, such as those in **1–3**, may be regarded as phosphorus ylides and are thus comparable to phosphane-donor-stabilized carbenes, R_3P–CX_2. Accordingly, they may be compared structurally with, for example, **4**,[16] whose planar carbanion is stabilized by three phosphonium centers (alternatively, **4** may be viewed as a triphosphane adduct of $:C^{2\oplus}$).



4

However, the high tendency to expand their coordination and the low tendency to undergo hybridization clearly distinguishes the higher homologues from the phosphorus ylides.

Experimental Procedure

3: All operations were performed under nitrogen. First $Li[C(PMe_2)_2(SiMe_3)]$ (1.6 g, 7.47 mmol) [13] and then Si_2Cl_6 (0.32 mL, 1.86 mmol) was added to a solution of naphthalene (0.57 g, 4.48 mmol) and lithium (0.03 g, 4.48 mmol) in 40 mL of THF at −78 °C. The reaction solution was allowed to warm to 0 °C, the solvent was removed under vacuum, and the residue was dissolved in 60 mL of pentane. After filtration, the pentane was removed under vacuum and the naphthalene was removed by sublimation (40 °C, 10^{-2} Torr, 8 h). Recrystallization of the residue from pentane afforded bright yellow needles, 1.27 g (77%).

M.p. 95–98 °C; MS(EI, 70 eV, 20 °C): m/z = 442 ($M^{\oplus}$, 5.6%), 235 ($M^{\oplus}$ − $C(PMe_2)_2(SiMe_3)$, 23), 147 ($CH(PMe_2)(SiMe_3)$, 7), 73 ($SiMe_3$, 100); NMR (C_6D_6, 20 °C, TMS or H_3PO_4 ext.): δ (^1H) = 1.33 (pseudo-quint; PCH_3), 0.28 (s; $SiCH_3$); δ (^{13}C) = 21.5 (s; PCH_3), 4.4 (s; $SiCH_3$); δ (^{31}P) = −5.2(s).

Preparation of an Enantiomerically Enriched Allyllithium Derivative by Deprotonation with Kinetic Resolution of Enantiomers**

By *Oliver Zschage, Jan-Robert Schwark*, and *Dieter Hoppe**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

Chiral allylmetal derivatives with a uniformly configurated metal-bearing carbon atom—for example, boronates **1**,[1] stannanes **2**,[2] silanes,[3] or titanates **3**[4]—have proven useful in the enantioselective and diastereoselective synthesis of homoallyl alcohols **6**; they add to aldehydes with nearly complete transfer of chirality from C-1 to C-3 and with high enantiofacial differentiation at the carbonyl group. The corresponding secondary (1-lithio-2-alkenyl)carbamates **5a** have so far been the only alkali-metal allyl derivatives found to be configurationally stable to a preparatively useful de-

[*] Prof. Dr. D. Hoppe, Dipl.-Chem. O. Zschage, Dipl.-Chem. J.-R. Schwark

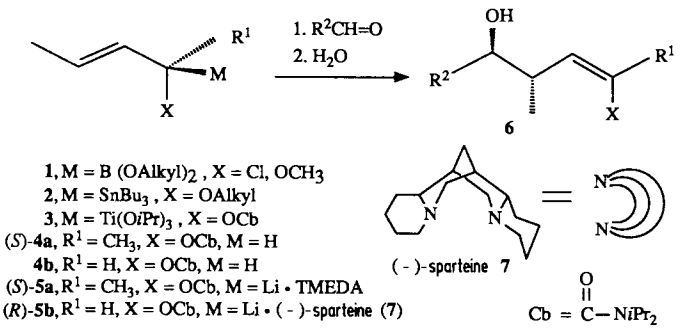
Olshausenstrasse 40–60, D-2300 Kiel 1 (FRG)

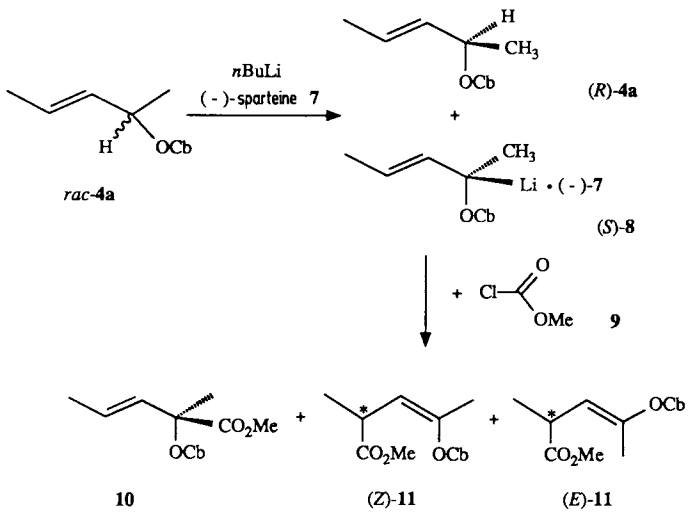
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

gree.[4] They are obtained by "stereoretentive" deprotonation of optically active carbamates such as **4a**.[4] The lithium compound (*R*)-**5b** was obtained from the prochiral precursor **4b** by asymmetric lithiation in the presence of the diamine (−)-sparteine (**7**); here, the stereochemical course is governed by a second-order asymmetric transformation.[5]



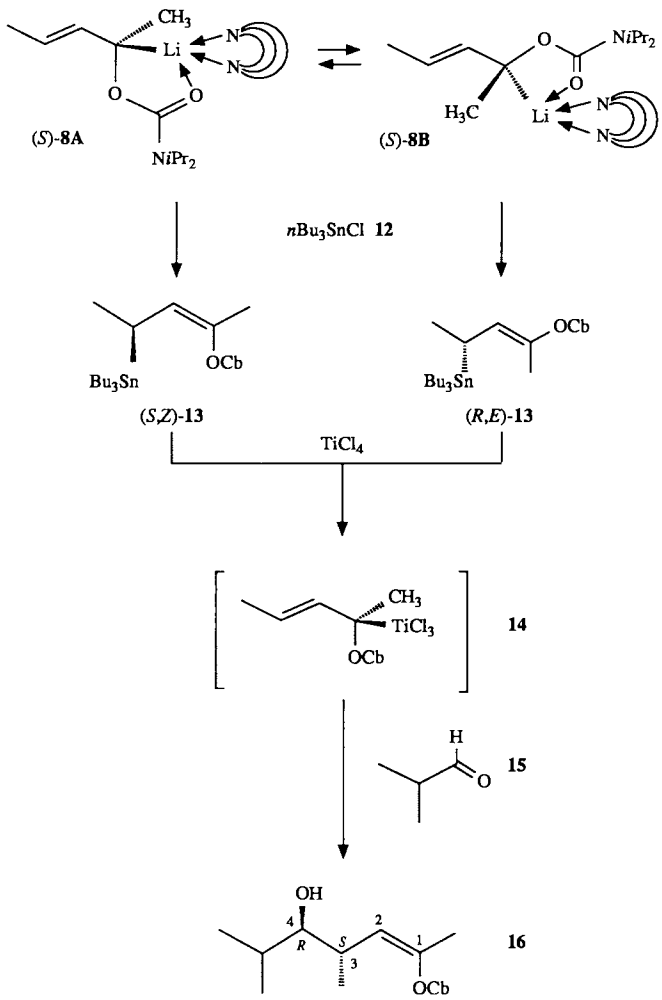
1, M = B (OAlkyl)$_2$, X = Cl, OCH_3
2, M = $SnBu_3$, X = OAlkyl
3, M = $Ti(OiPr)_3$, X = OCb
(*S*)-**4a**, R^1 = CH_3, X = OCb, M = H
4b, R^1 = H, X = OCb, M = H
(*S*)-**5a**, R^1 = CH_3, X = OCb, M = Li • TMEDA
(*R*)-**5b**, R^1 = H, X = OCb, M = Li • (-)-sparteine (7)

Here we report on the first generation of nonracemic, chiral lithium derivatives by enantiomer-differentiating deprotonation. A solution of *rac*-**4a**[6] and 0.5 equiv. of (−)-sparteine (**7**) in pentane was treated with 0.5 equiv. of *n*-butyllithium at −78 °C and, after 10 h, with methoxycarbonyl chloride (**9**). Ester **10** was obtained in 36% yield with 82% *ee*[7] together with the γ-adducts (*E*)- and (*Z*)-**11** (13%)[8] and a 46% yield of (*R*)-**4a** with 80% *ee*.[4] The



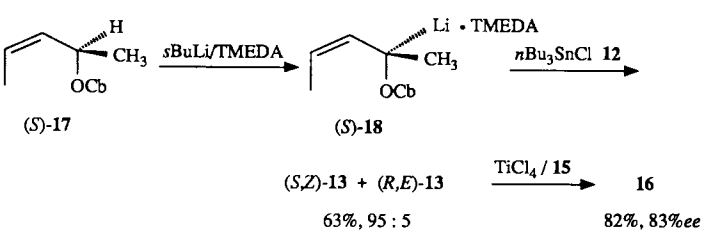
yields are based on *rac*-**4a**. Even the use of 1.1 equiv. of *n*-butyllithium and 1.1 equiv. of (−)-**7** (4 h at −78 °C)—that is, an amount of base that should be sufficient for complete deprotonation of (*R*)-**4a** as well—gave the same result.[9] Under the reaction conditions, therefore, (*S*)-**4a** is rapidly deprotonated to give (*S*)-**8**, but (*R*)-**4a** reacts only very slowly.

Reaction of a solution enriched in (*S*)-**8** with tri-*n*-butyltin chloride (**12**) leads to a mixture of stannanes[10,11] (*S*,*Z*)- and (*R*,*E*)-**13** in an 87:13 ratio (96% yield based on **7**); this configuration, as well as the enantiomeric purity of >80% *ee*, was determined by a recently developed reaction sequence:[4c] reaction of **13** with 2-methylpropanal (**15**) and



$TiCl_4$ gave the homoaldol adduct (1*Z*,3*S*,4*R*)-**16** in 74% yield and with 80% *ee*.[10,12]

Thus, the trichlorotitanium intermediate **14** has (*R*) configuration and, since the tin–titantium exchange proceeds via a *syn*-S_E2' mechanism,[4c] the two stannanes **13** have the configuration shown. The stereodivergence of their formation from conformers (*S*)-**8A** and (*S*)-**8B** is "neutralized" by the stereoconvergent transformation to (*R*)-**14** and is therefore unimportant in preparative applications. In a control experiment, the enantiomerically pure (*Z*)-carbamate (*S*)-**17**[13] was lithiated with *n*-butyllithium/TMEDA[4c] and converted, by reaction with **12**, into the stannanes (*S*,*Z*)- and (*R*,*E*)-**13**, which were then allowed to react with **15**/$TiCl_4$. The homoaldol adduct thereby obtained in 82% yield exhibits 83% *ee*.



Overall, the kinetic resolution of enantiomers with chiral allyllithium complexes offers a novel route to nonracemic

allylmetal derivatives, the efficiency of which extends to the deprotonation of enantiomerically pure precursors.

Experimental Procedure

A ca. 1.6 M solution of *n*-butyllithium (2.2 mmol) was added to a solution of 4 mmol of (*E*)-1-methyl-2-butenyl-*N*,*N*-diisopropylcarbamidate (*rac*-**4a**)[6] and 2 mmol of (−)-sparteine (**7**) in 10 mL of pentane cooled in a dry ice–acetone bath. After 10 h, 15 mmol of methoxycarbonyl chloride (**9**) or 2.4 mmol of tributyltin chloride (**12**), both precooled, were added dropwise. After 10 min, the solution was allowed to warm to room temperature and then treated with 2 N hydrochloric acid and ether (20 mL each) and worked up as usual. Purification was accomplished by flash chromatography on silica gel with ether/pentane (1:8 or 1:10).

On a (1,4-Diazabutadiene)bis(ethene)nickel(0) Complex and Related Compounds**

By *Werner Bonrath, Klaus R. Pörschke,** and *Stephan Michaelis*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

Tetracoordinated 18-electron Ni^0 complexes containing ethene as ligand have so far been isolated only in the form of $[(Me_2PC_2H_4PMe_2)(R_3P)Ni(C_2H_4)]$ (R = Me, *cyclo*-C_6H_{11}, Ph; dec. −20 °C)[1] and $[(Me_2NC_2H_4NMe_2)Ni(C_2H_4)(H_2C=O)]$ (dec. −10 °C).[2] Apparently, their formation strongly depends on the coordination of the bidentate chelate ligand to nickel(0) to give a five-membered ring ("five-membered ring effect"). Although they readily decompose, the complexes have been characterized by, among other methods, crystal structure analysis. A "$[(Ph_3P)_2Ni(C_2H_4)_2]$" complex, however, has remained speculative.[3] Here we report on the synthesis and reactivity of the first 18-electron Ni^0 complex containing two ethene ligands and on related compounds.

Deep violet, fine cubes of **1** (81%) crystallized from a solution of tris(ethene)nickel(0)[4] and an equimolar amount of 1,4-bis(2,6-diisopropylphenyl)-1,4-diazabutadiene (iPr$_2$Ph)$_2$-dad[5] in pentane at −78 °C.[6] Under argon, **1** is only stable to −5 °C, but under ethene atmosphere it is stable to 20 °C. The complex is readily soluble in cold pentane as well as in other solvents. It shows an extremely high reactivity starting at −100 °C. In the ^{1}H NMR spectrum (400 MHz) recorded at −80 °C, the ethene protons of **1** give rise to two signals ($\delta_H = 2.62$, 2.22; AA'BB') and, in the ^{13}C NMR spectrum (75.5 MHz), the ethene C atoms to one signal ($\delta_C = 64.9$; sharp to −105 °C). Assuming that the Ni^0 atoms are tetrahedrally coordinated by the dad N atoms and the ethene ligands, the NMR spectra are consistent with an idealized parallel orientation of the C=C bonds with respect to the N–N axis, resulting in magnetically equivalent ethene C atoms and magnetically different geminal ethene protons. Upon raising the temperature, the signals of the ethene protons coalesce owing to rotation of the ligands around the bond axis to the Ni^0 atom ($\Delta G^{\ddagger}_{200K} \approx 40$ kJ mol^{-1}). The phenyl rings of the 2,6-diisopropylphenyl substituents are either perpendicular to the plane of the dad-Ni five-membered ring or they are able to rotate freely around their bond to the N atom, even at low temperature.

A solution of Ni(cdt)[7] (cdt = all-*trans*-1,5,9-cyclododecatriene) in 1,5-hexadiene at 20 °C affords the yellow complex Ni(η-C_6H_{10})$_2$.[8a] Addition of an equimolar amount of

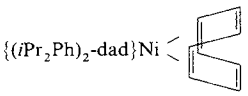
[**] We thank *Barbara Gabor, Gerhard Schroth,* and *Richard Mynott* for the NMR studies.

(iPr$_2$Ph)$_2$-dad dissolved in pentane results in the formation of a deep red reaction solution, which yields dark crystals of **2** (91%) at −78 °C. This method allows the preparation of numerous, in part thermally labile $L_nNi(\eta\text{-}C_6N_{10})$ complexes (n = 1,2; L,L$_2$ = phosphanes, phosphites, 2,2′-bipyridyl, 1,4-diazabutadienes).[8] Complex **2**, like **1**, shows good solubility; it is stable at room temperature (m.p. 142 °C) and exhibits its reactivity above about −30 °C. Presumably, the complex geometry of **2** is similar to that of **1**; owing to the C_2H_4 bridging of the two vinyl groups, however, the C_2 axis is no longer present. In the low-temperature ^{1}H NMR (400 MHz, −30 °C) and ^{13}C NMR spectra (75.5 MHz, −30 °C), therefore, **2** shows one set of signals for the hexadiene ligand and two sets of signals for the nonequivalent halves of the (iPr$_2$Ph)$_2$-dad ligands. The mass spectrum of **2** displays the molecular ion peak at m/z 516 (for ^{58}Ni); the molecular ion undergoes fragmentation with loss of hexadiene.

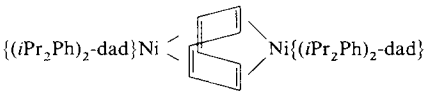
Complexes **1** and **2** are appreciably more reactive than **3**, preparable from Ni(cod)$_2$[7] (cod = 1,5-cyclooctadiene) and (iPr$_2$Ph)$_2$-dad (36%),[5] in which the macrocyclic effect[9] of the cod ligand contributes to the stabilization of the complex. The order of stability is also reflected in the increasing thermodynamic reactivity of the compounds. Thus, reaction of **1** with 1,5-hexadiene affords **2** and reaction of **1** or **2** with cod affords **3** (60%); the backward reactions are not observed (e.g., **3** dissolved in 1,5-hexadiene does not reconvert into **2**). Complexes **1** and **2** react with one equivalent of (iPr$_2$Ph)$_2$-dad to give the reddish-brown complex **4** (X-ray structure analysis), which is not accessible from **3**[5] and which we will describe elsewhere.[10]

[{(iPr$_2$Ph)$_2$-dad}Ni(cod)] **3** [{(iPr$_2$Ph)$_2$-dad}$_2$Ni] **4**

Compounds **1** and **2** in pentane, on addition of cyclooctatetraene (cot) at −78 to −30 °C, afford red reaction solutions and, at −78 °C, cubes of **5a** slowly crystallize (94%). Complex **5a** has been synthesized via a different route before, but could not be isolated in pure form.[11] Crystalline **5a** may be kept at 20 °C for several days without noticeable decomposition. The substance is readily soluble in THF, but less soluble in ether and pentane; in solution at 20 °C, **5a** slowly dimerizes with loss of a cot ligand to form **5b**.



5a



5b

The IR spectrum of **5a** contains stretching bands for free and for complexed C=C bonds ($\tilde{\nu}$ = 1620 and 1512 cm^{-1}). NMR spectroscopy revealed a dynamic process for **5a**. In the 200-MHz ^{1}H NMR spectrum at −30 °C, signals of equal intensity were observed at δ_H = 5.38 and 3.79 for the protons of the free and coordinated double bonds, respectively; at 27 °C, a coalescence signal, due to rapid exchange, was observed at δ_H = 4.59. As in [(Me$_3$P)$_2$Ni(1:2,5:6-η-cot)] (X-ray structure analysis),[12] a cod-like coordination of the cot at nickel is presumed for **5a**. Reaction of **1**–**3** with cot at 20 °C in pentane affords a violet solution, from which needles of the dinuclear complex **5b** (58%) crystallize (cot, δ_H = 3.81). In the mass spectrum, the molecular ion of **5a** ($M^{\oplus}$ 538) fragments by loss of cot and that of **5b** ($M^{\oplus}$ 972) by loss of [(iPr$_2$Ph)$_2$-dad]Ni (transformation to **5a**$^{\oplus}$).

Complex **1** reacts with ethyne at −100 °C (!) immediately and **2** at −30 °C within only a few minutes to give a blue solution (**3**: several hours at 20 °C), from which dark crystals of the dinuclear complex **6** slowly crystallize in up to 70% yield. Extensive spectroscopic investigations and an X-ray crystal structure analysis of **6** revealed the presence of a butadienediyl group, formed by coupling of two ethyne molecules.[13] The (iPr$_2$Ph)$_2$-dad complexes **1**–**3** thus differ in their reactivity from the analogous bipyridyl complexes (e.g., [bipyNi(C$_2$H$_4$)$_2$][14] at −78 °C), which decompose on addition of ethyne.

[{[(iPr$_2$Ph)$_2$-dad]Ni}$_2$(μ-C$_4$H$_4$)] **6**

On thermal decomposition of **1**, the ethene ligands do not couple with nickel(0) to form a nickelacyclopentane complex, as reported for the system PPh$_3$/Ni(0)/C$_2$H$_4$;[3b] instead, **4** is formed. In the presence of **1**, ethene under pressure (60 bar) at 40 °C reacts to form polyethylene.[8b,16]

Experimental Procedure

1: A yellow solution of Ni(C$_2$H$_4$)$_3$ in 30 mL of pentane was prepared from Ni(cdt) (1.17 g, 5.0 mmol; 95%, some cocrystallized cdt) and ethene and then treated at −30 °C with a solution of (iPr$_2$Ph)$_2$-dad (1.88 g, 5.0 mmol) in 20 mL of pentane. The reaction solution immediately turned violet and, on cooling to −78 °C, afforded fine, violet, crystalline cubes. These were freed of mother liquor with a capillary, washed twice with cold pentane, and dried under oil-pump vacuum at −30 °C. Yield 1.99 g (81%); correct elemental analysis.
MS: The compound cannot be vaporized without decomposition. ^{1}H NMR (400 MHz, [D$_8$]THF, −100 °C): δ = 8.08 (2H; CH=N), 7.28 (6H; Ph), 2.96 (4H; CHMe$_2$), 1.30, 1.06 (each 12H; CH$_3$, dad), 2.62, 2.22 (each 4H; C$_2$H$_4$). ^{13}C NMR (75.5 MHz, [D$_8$]THF, −80 °C): δ = 152.2 (s, 2C), 140.3 (s, 4C), 126.0 (d, 2C), 123.7 (d, 4C; each Ph), 144.8 (dd, 2C, ^1J(CH) = 174 Hz; CH=N), 28.2 (d, 4C; CHMe$_2$), 26.4, 23.5 (each q, 4C; CH$_3$, dad), 64.9 (t, 4C; C$_2$H$_4$).

2: A yellow solution of Ni(cdt) (1.17 g, 5.0 mmol) in 5 mL of 1,5-hexadiene (nonisolable Ni(η^2,η^2-C$_6$H$_{10}$)$_2$ is presumably present) was treated with a solution of (iPr$_2$Ph)$_2$-dad (1.88 g, 5.0 mmol) in 30 mL of pentane, whereby the color turned deep red. On cooling the reaction solution from −30 to −78 °C, red crystals formed; these were isolated as described above and dried at 20 °C. Yield 2.35 g (91%); correct elemental analyses; m.p. 142 °C. The substance tends to retain small amounts of solvent.
MS (70 eV, 110 °C): m/z 516 ($M^{\oplus}$, 8%), 434 ($M^{\oplus}$ − C$_6$H$_{10}$, 100). UV/VIS (benzene): λ_{max} = 495 nm (ε_{max} = 9212 Lmol^{-1}cm^{-1}). ^{1}H NMR (400 MHz, [D$_8$]THF, −30 °C): δ = 8.04, 8.03 (each s, 1H; CH=N and CH′=N), 7.25, 7.20 (each 3H; Ph and Ph′), 3.15 (4H; CHMe$_2$ and CH′Me$_2$), 1.35, 1.32, 1.10, 1.00 (each d, 6H; CH$_3$, dad), 4.06 (2H; C=CH–), 2.44, 2.34 (each 2H; H$_2$C=), 2.16, 1.21 (each 2H, partially overlapped; CHH′, alkene; at 27 °C, the signals are broadened. ^{13}C NMR (75.5 MHz, [D$_8$]THF, −30 °C): δ = 154.25 (s, 1C), 153.5 (s, 1C), 140.1 (s, 2C), 139.9 (s, 2C), 125.9 (d, 1C), 125.7 (d, 1C), 123.55 (d, 2C), 123.5 (d, 2C; each Ph), 143.3, 142.1 (each dd, 1C, ^1J(CH) = 171 Hz; CH=N), 28.3, 28.25 (each d, 2C; CHMe$_2$), 26.5–23.0 (4 signals q, 2C; CH$_3$, dad), 89.8 (d, 2C; C=CH–), 67.3 (t, 2C; H$_2$C=), 32.3 (t, 2C; CH$_2$, each alkene).

3: Synthesis from Ni(cod)$_2$ and (iPr$_2$Ph)$_2$-dad [5] or from **1** (or **2**) and cod in pentane; from brown reaction solution (20 °C), dark brown crystals obtained at −78 °C; m.p. 131 °C.
MS: The substance cannot be vaporized without decomposition. UV/VIS (benzene): λ_{max} = 476 nm (ε_{max} = 8223 Lmol^{-1}cm^{-1}) [5]. ^{1}H NMR (200 MHz, [D$_8$]THF, 27 °C): δ = 7.97 (s, 2H; CH=N), 7.22 (m, 6H; Ph), 3.21 (sept, 4H; CHMe$_2$), 1.33, 1.04 (each d, 12H; CH$_3$, dad); 3.70 (4H; –CH=), 2.39, 1.49 (each m, 4H; –CH$_2$–, cod); see also [5]. ^{13}C NMR (75.5 MHz, [D$_8$]THF, 38 °C): δ = 154.8 (s, 2C), 140.2 (s, 4C), 125.7 (d, 2C), 123.4 (d, 4C; each Ph), 142.3 (dd, 2C, ^1J(CH) = 170 Hz; CH=N), 28.4 (d, 4C; CHMe$_2$), 26.5, 23.1 (each q, 4C; CH$_3$, dad), 89.3 (d, 4C; –CH=), 30.9 (t, 4C; –CH$_2$–, cod).

5a: Reaction of **2** and cot in pentane at $-30\,^{\circ}C$ afforded a red solution, from which red cubes (94%) crystallized at $-78\,^{\circ}C$; correct elemental analysis; m.p. 261 °C.
MS (70 eV, 90 °C): *m/z* 538 ($M^{\oplus}$, 20%), 434 ($M^{\oplus}-C_8H_8$, 100). UV/VIS (benzene): $\lambda_{max} = 498$ nm ($\varepsilon_{max} = 5280\ Lmol^{-1}cm^{-1}$). ^1H NMR (200 MHz, [D$_8$]THF, $-30\,^{\circ}C$): $\delta = 8.19$ (s, 2H; CH=N), 7.23 (m, 6H; Ph), 3.32 (sept., 4H; $CHMe_2$), 1.30, 1.08 (each d, 12H; CH_3, dad), 5.38 (4H; $-CH=_{free}$), 3.79 (4H; $-CH=_{compl.}$, cot). ^{13}C NMR (75.5 MHz, [D$_8$]THF, $-80\,^{\circ}C$): $\delta = 153.3$ (s, 2C), 140.1 (s, 4C), 125.9 (d, 2C), 123.6 (d, 4C; each Ph), 143.3 (dd, 2C, $^1J(CH) = 173$ Hz; CH=N), 28.3 (d, 4C; $CHMe_2$), 26.3, 23.3 (each q, 4C; CH_3, dad), 134.1 (d, 4C; $-CH=_{free}$), 94.4 (d, 4C; $-CH=_{compl.}$, cot).

5b: Reaction of **2** and cot at 20 °C gave a violet solution, from which dark violet needles formed at $-30\,^{\circ}C$; correct elemental analyses; m.p. 266 °C.
IR (KBr, Nujol): no bands from 1700 to 1480 cm^{-1}. MS (70 eV, 200 °C): *m/z* 972 ($M^{\oplus}$, 45%), 538 (**5a**$^{\oplus}$, 10). UV/VIS (benzene): $\lambda_{max} = 525$ nm ($\varepsilon_{max} = 17872\ Lmol^{-1}cm^{-1}$). ^1H NMR (200 MHz, [D$_8$]THF, 27 °C): $\delta = 7.94$ (s, 4H; CH=N), 7.10 (m, 12H; Ph), 3.17 (sept., 8H; $CHMe_2$), 1.15, 0.97 (each d, 24H; CH_3, dad), 3.81 (s, 8H; $-CH=$, cot). ^{13}C NMR (75.5 MHz, [D$_8$]THF, 38 °C): $\delta = 154.1$ (s, 4C), 140.3 (s, 8C), 125.8 (d, 4C), 123.5 (d, 8C; each Ph), 141.8 (dd, 4C, $^1J(CH) = 170$ Hz; CH=N), 28.2 (d, 8C; $CHMe_2$), 25.7, 23.5 (each q, 8C; CH_3, dad), 98.2 (d, 8C; $-CH=$, cot).

[16] In the condensate of the reaction solutions, no cyclobutane and only traces of 1- and 2-butene were found by gas chromatography.

Synthesis and Structure of a Dimeric Lithium Diphenylcuprate: $[\{Li(OEt)_2\}(CuPh_2)]_2$**

By *Nis Peter Lorenzen* and *Erwin Weiss**

Dedicated to Professor Alfred Schmidpeter on the occasion of his 60th birthday

Lithium organocuprates, particularly lithium diorganocuprates (Gilman reagents) find many applications in organic syntheses, e.g. in the Corey-Posner reaction[1] and in the stereospecific 1,4-addition of alkyl, alkenyl or aryl groups to α,β-unsaturated carbonyl compounds.[2] In many cases they are superior to the traditional Grignard and organolithium reagents in such reactions. Since they are thermolabile, however, very little information is available concerning their structure.[3]

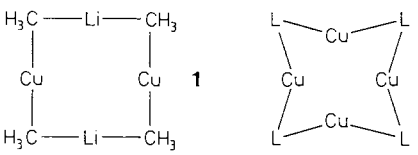
Lithium di*alkyl*cuprates are particularly unstable. They are generated at low temperatures according to the overall equation (a) by reaction of organolithium compounds with

$$2\ LiR + CuX \xrightarrow[\text{or THF}]{Et_2O} LiCuR_2 + LiX \qquad (a)$$

suspensions of Cu^I-halides or better with soluble Cu^I compounds, and are used in situ for the reactions.

So far it has still not been possible to isolate even any of the simpler lithium di*alkyl*cuprates in a form suitable enough for an X-ray crystallographic characterization. Consequently, structural investigations have been limited, inter alia, to those performed in solution (NMR methods[4] and molecular weight determinations). Depending on the molar ratio LiR/CuX, not only different species were detected (e.g. $LiCuMe_2$, $LiCu_2Me_3$, Li_2CuMe_3[4a–c]), but also complicated equilibria, e.g. $Li_2CuMe_4 \rightleftharpoons LiMe + LiCu_2Me_3$.[5]

Dimers of the type $Li_2Cu_2R_4$ had already been discussed more than a decade ago.[6] According to EXAFS investigations on the dissolved methyl compound $Li_2Cu_2Me_4$ **1**,[6] a cyclic structure as in $[Cu(CH_2SiMe_3)]_4$ **2a**[7] or $[Cu(OCMe_3)]_4$ **2b**[8] (planar eight-membered ring) appeared more likely than a tetrahedral structure resembling that of $(LiCH_3)_4$.[9]



2a, L = CH_2SiMe_3
2b, L = $OCMe_3$

In this connection, we should also mention recent investigations in which salts with *isolated* diorganocuprate ions have been prepared and X-ray crystallographically characterized for the first time. Such salts are obtained either by using sterically bulky residues such as in $[Cu(dppe)_2][Cu(C_6H_2Me_3\text{-}2,4,6)_2]$[10] (dppe = bis(diphenylphosphino)ethane) and $[Li(thf)_4][Cu\{C(SiMe_3)_3\}_2]$[11] or by complexation of the Li ions with crown ethers, e.g. as in the compounds obtained from $[Li([12]crown\text{-}4)_2]^{\oplus}$ and the monomeric linear anions $[CuMe_2]^{\ominus}$, $[CuPh_2]^{\ominus}$, and $[Cu(Br)CH(SiMe_3)_2]^{\ominus}$.[12]

The thermally somewhat more stable lithium *aryl*cuprates have likewise been insufficiently studied regarding their structure. Since 1966, lithium phenylcuprates of various stochiometries have been obtained from the reaction of CuBr with LiPh.[13] Later NMR spectroscopic[14] and especially X-ray crystallographic investigations revealed, inter alia, the formation of polynuclear (lithium-)cuprate ions such as $[Cu_5Ph_6]^{\ominus}$,[15a] $[LiCu_4Ph_6]^{\ominus}$,[15b] and $[Li_2Cu_3Ph_6]^{\ominus}$.[16a] The latter can be described as trigonal-bipyramidal metal clusters in which the equatorial positions are always occupied by the Cu, the axial by Li and Cu; the Ph groups form bridges between axial and equatorial metal atoms. Noteworthy, is the recently determined structure of $[Li_3Cu_2Ph_5(SMe_2)_4]$;[16b] the $[Cu_2Ph_5]^{3\ominus}$ anion contained

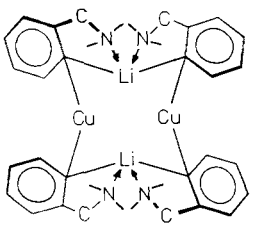
[**] Metal-Alkyl and Metal-Aryl Compounds, Part 42. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 41: K. Gregory, M. Bremer, W. Bauer, P. von R. Schleyer, N. P. Lorenzen, J. Kopf, E. Weiss, *Organometallics*, in press.

herein can be imagined as consisting of $[CuPh_2]^{\ominus}$ and $[CuPh_3]^{2\ominus}$ units.

On using aromatic ligands with chelating amino groups in the *o*-position, e.g. [2-(dimethylamino)methyl]phenyl, *dimers* with a cyclic structure, $[(Li_2Cu_2(C_6H_4CH_2NMe_2\text{-}2)_4]$ **3** and related compounds, could already be unequivocally characterized earlier, at first NMR spectroscopically,[17] and later also X-ray crystallographically.[18] By way of analogy, such a structure has also been proposed for $[Li_2Cu_2(4\text{-tolyl})_4(Et_2O)_2]$.[19]



3

Undoubtedly the N-donor substituents play an important role in determining the structure of the cuprates containing amino-substituted phenyl groups. Hence, a direct structural comparison with simple methyl- or unsubstituted phenyl cuprates, as are present in the preparatively interesting compounds remains an open question.

Lithium phenylcuprates are usually obtained by reaction of a phenyllithium-solution with a suspension or solution of the Cu^{I} starting compound in Et_2O, THF, or *n*-hexane at lower temperatures. Instead of using the pure copper(I) halides, it is far more advantageous to use their soluble solvates. In our attempts to synthesize lithium phenylcuprates[20] it emerged that not only the reaction temperature but also the solvent composition is an important reaction parameter. With CuI · P*n*Bu$_3$ as starting compound and ether/hexane mixtures as reaction medium we were able to isolate the title compound **4** in crystalline form according to Equation (b).

$$2\,CuI \cdot PnBu_3 + 4\,LiPh \xrightarrow[-2\,PnBu_3]{\substack{n\text{-Hexan/}Et_2O\\ -78\,^{\circ}C}} \underset{\mathbf{4}\,(38\,\%)}{[\{Li(OEt_2)\}(CuPh_2)]_2} + \frac{2}{n}[LiI(Et_2O)]_n \quad (b)$$

4 is also formed in smaller yield from CuBr · SMe_2 (0.05 M in pure Et_2O) under otherwise similar reaction conditions. When the reaction (b) was carried out with CuI · P*n*Bu$_3$ and LiPh in a ratio other than 2:4, other products were obtained.

The structure analysis of **4** revealed the following:[21a] the unit cell contains four dimers, two of which form the asymmetric unit (molecules 1 and 2). Only one of these (molecule 1) is shown in Figure 1. The molecules 1 and 2 are virtually mirror images of each other, but their atomic distances and angles are significantly different. The differences are best explained in terms of a packing effect.

Each dimer consists of two almost linear $CuPh_2$ units (C–Cu–C 163.3 to 168.0°), which are bound by solvated Li ions to give a distorted eight-membered ring. To our knowledge, **4** is the first example of an X-ray crystallographically characterized lithium cuprate dimer as have been suggested to exist in ether solutions. The two diphenylcuprate moieties in the ring are strongly bent towards each other, but only very weak Cu–Cu interactions have been reported (Cu–Cu 286.5 and 307.5 pm; cf. **2a** (241.7 pm), **2b** (264.6(2)–277.1(3) pm), **3** (266.60(8) pm), and Ref. [23]. The four-membered ring formed by the Cu and Li atoms is also not planar, but noticeably folded at the Cu atoms (154.3° in molecule 1, 140.6° in molecule 2). The Cu–C_{ipso} distances (av. 191.8 pm) are similar to those also found in other phenylcuprates, and similar-

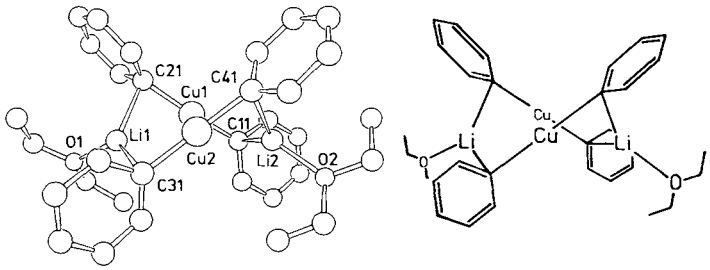


Fig. 1. SCHAKAL plot and line drawing of **4** (molecule 1). Important bond lengths [pm] and angles [°] (the values in square brackets refer to molecule 2): Cu1-Cu2 286.5(2) [307.5(3)], Cu1-C11 192.2(7) [192.8(7)], Cu1-C21 190.6(5) [191.5(7)], Cu2-C31 192.8(7) [192.3(7)], Cu2-C41 191.4(6) [191.2(6)], Li1-C21 221.6(11) [227.8(11)], Li1-C31 226.4(10) [224.9(11)], Li2-C11 225.4(10) [228.2(13)], Li2-C41 221.3(12) [221.1(12)], Li1-O1 192.6(9) [192.6(10)], Li2-O2 191.5(10) [188.9(11)]; C11-Cu1-C21 167.7(3) [165.2(3)], C31-Cu2-C41 168.0(2) [163.3(3)], C21-Li1-C31 123.6(4) [118.0(5)], C11-Li2-C41 121.9(5) [126.4(5)].

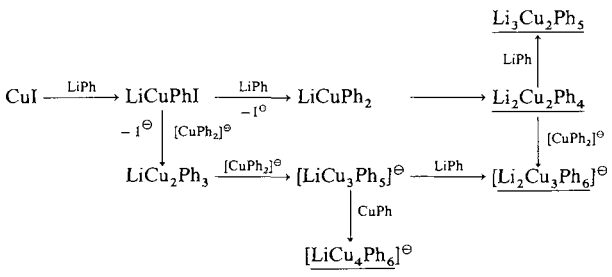
ly, the Li–C_{ipso} distances (av. 225.2 pm) are comparable with those in $[PhLi(tmeda)]_2$ (av. 224.3 pm)[24] and other organolithium compounds. The planes of the two phenyl groups in each $CuPh_2$ moiety are twisted through about 88° with respect to each other as a result of Li–C interactions. The additional solvation by ether molecules leads to a trigonal-planar coordination with bond angles deviating only slightly from 120°, a rare coordination geometry for Li.

A comparison of **4** with the above mentioned homo- and heteronuclear (lithium-)phenylcuprate clusters shows close structural relationships. Thus, the skeletal framework of **4** can be derived from that of $Li_2Cu_3Ph_6$ by removal of $[CuPh_2]^{\ominus}$; the resulting vacant coordination sites are occupied by two ether molecules. Since $[Li_2Cu_3Ph_6]^{\ominus}$ (and similarly also $[LiCu_4Ph_6]^{\ominus}$) consists of three $CuPh_2$ units, which are held together by Li (and Cu) ions, all the phenylcuprates known so far contain, in end effect, the $CuPh_2$ unit as building block.

In the synthesis of lithium phenylcuprates, equilibria can be assumed from which various products can be isolated depending on the reaction conditions (concentrations, solvent, temperature). Almost all previously characterized lithium phenylcuprates are consequently built up from the basic units CuPh, $CuPh_2$, and LiPh. From these, a model for the formation of the various products can be developed (Scheme 1).



Scheme 1. Model for the formation of lithium phenylcuprates; products characterized by X-ray structure analysis are underlined; solvate ligands are not shown.

Experimental

4: A cooled (CO_2, −78 °C) solution of phenyllithium (1.4 g, 16.8 mmol) [25] in 30 mL of diethyl ether was treated dropwise with stirring and continuous cool-

ing within 90 min with a solution of CuI · $PnBu_3$ [26] (3.3 g, 8.4 mmol) in 90 mL of *n*-hexane. The temperature of the reaction mixture must not in any case exceed − 60 °C. After completion of the addition the mixture was stirred for a further 3 h at − 75 °C, and the finely crystalline pale yellow percipitate was filtered off (max. temp. − 30 °C), washed portionwise with a total of 90 mL *n*-hexane (− 30 °C), and dried at − 30 °C. Yield 0.94 g (38%); golden yellow, extremely air-sensitive rhombs, stable in the dry state at room temperature but not in solution (decomposition with separation of Cu). Readily soluble in hexane and benzene. Correct analytical values for Cu, Li, C, H, O. Crystals suitable for an X-ray structure analysis were obtained from the yellow filtrate after prolonged storage at − 30 °C.

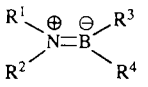
The First Monomeric Diorgano(pyrazolyl)borane: A Nonclassical Boronium Ion in Solution?**

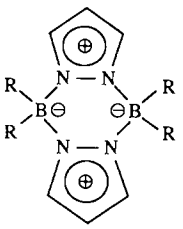
By *Mohamed Yalpani,* Roland Köster, Roland Boese,** and *Waldemar A. Brett*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

Aminoboranes **I** exhibit a tendency toward self-association.[1] The tetrasubstituted members generally occur as monomers.[2] The diorgano(pyrazolyl)boranes, however, exist exclusively in the form of the unusually stable dimers **II**.[3,4] Here we report the synthesis and structure of a number of these donor–acceptor molecules which remain monomeric even in the solid state.

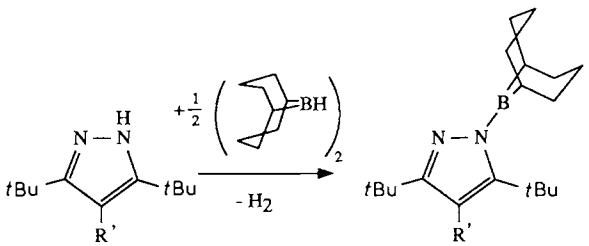


I



II

Reaction of the sterically very demanding 3,5-di- and 3,4,5-trisubstituted pyrazoles **1a–c** with the similarly bulky and rigid bis(9*H*-9-borabicyclo[3.3.1]nonane), $(9H\text{-9-BBN})_2$, in a 2:1 ratio in refluxing toluene for 18–24 h gave the diorgano(pyrazolyl)boranes **2a–c**, respectively, in nearly quantitative yields.



1a-c **2a-c**

a, R' = H ; **b**, R' = CH_3 ; **c**, R' = C_2H_5

Compounds **2a–c** were obtained as crystalline low-melting solids. The low-field ^{11}B NMR signals at $\delta = 63.0$ for **2a**, $\delta = 64.2$ for **2b**,[5] and $\delta = 65.3$ for **2c** strongly suggest the presence of monomeric species in solution. Both the room-temperature 200.1-MHz ^{1}H NMR and 50.3-MHz ^{13}C NMR spectra show only one set of signals for the two *t*Bu groups

in **2a–c** and for each of the sets of α, β, and γ carbon atoms of the 9-BBN skeleton.[6] The ^{13}C NMR spectra of **2a–c** obtained at −50 °C show no significant changes, suggesting a continued rapid exchange of the boryl group between the two nitrogen atoms of the pyrazolyl groups. Further cooling of the probe of **2a** to −80 °C resulted in partial line broadening and, at −100 °C, the ^{13}C NMR spectrum (75.5 MHz) shows resolved sharp peaks for the two *t*Bu groups and for the C 3,5 atoms of the pyrazolyl group. For the carbon atoms (2α, 4β, 2γ) of the 9-BBN skeleton only three broadened peaks are observed. This shows that, while the fluctuation of the 9-BBN group has become relatively slow, its rotation about the N–B bond remains fast. In the limiting structures shown, two separate signals for each of the two α and four β carbon atoms of the 9-BBN group should be expected.

In the ^{13}C NMR spectrum of **2b** obtained at −110 °C, the sharp lines for only one type of *t*Bu group and for the other relevant carbon atoms are retained. This suggests either the continued rapid fluctuation of the 9-BBN group or the presence of the unique intermediate structure **4**, in which the boron atom is partially and simultaneously bonded to both nitrogen atoms of the pyrazolyl group. Such a structure, as deduced from the solid-state structure of **2a** and **2c** (see below), could be stabilized by the severe spatial interactions of the 9-BBN skeleton with the neighboring *t*Bu groups.

The X-ray structure analysis of **2c**[7] (Fig. 1) shows, as inferred from its low-temperature ^{13}C NMR spectrum, that

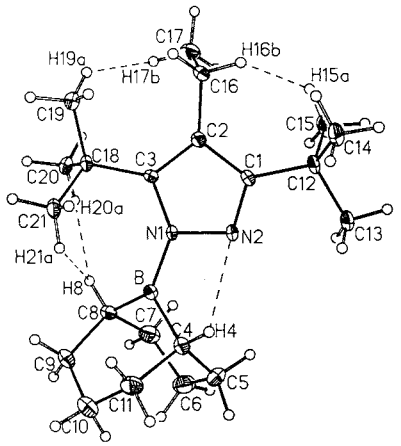

Fig. 1. Molecular structure of **2c**. Selected bond lengths [Å] and angles [°]: B-N1 1.466(4), N2-C1 1.314(3), C1-C2 1.431(4), C2-C3 1.384(3), C3-N1 1.387(4); B-N1-N2 110.3(2), N1-B-C4 119.4, N1-B-C8 128.2(2), B-N1-C3 139.4(2). Broken lines: very short intramolecular nonbonded distances.

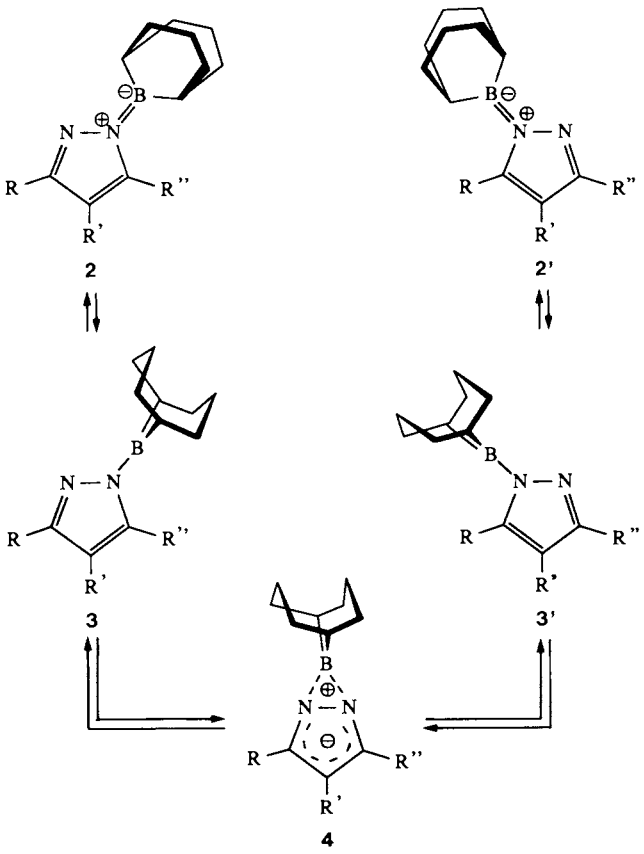
the boron atom is bonded to only one of the nitrogen atoms of the pyrazole. The presence of severe steric interactions is clearly revealed by the extremely short H8···H20a, H8···H21a, H15a···H16b, and H17b···H19a distances (Fig. 1, broken lines). A consequence of these interactions is the distortion of the interplanar angle between the planes C1-C2-C3-N1-N2 and C4-B-C8 by 15.6° in **2a**[8] and by 44.3° in **2c** (torsion angle C8-B-N1-C3 = −19.8° in **2a** and 44.1° in **2c**), causing a severe decrease of optimal π overlap between the boron and the nitrogen atoms. As a result, the B–N bond (1.466 Å) is significantly longer than that calculated[9] and commonly found in amino(diorgano)boranes.[10]

Molecular models show that these strains can significantly decrease when the 9-BBN group is rotated by 90°, placing the vacant p_z orbital of boron orthogonal to the nonbonded electron pair of the adjacent nitrogen atoms [stucture **3** (**3'**)]. In this conformation a pendular motion of the 9-BBN group between the two equivalent structures, with partially developed B–N single bonds, is largely unhindered. This interconversion presumably proceeds via species **4** involving a nonclassical boronium ion.



Conversion of **2** to an intermediate of type **3** should not only reduce the intramolecular steric interactions, but also decrease the dipolar character of the molecule and shift its electronic absorption maximum to lower wavelengths. Conversely, the conversion of **2** to the symmetrical intermediate **4** should increase the dipole character and shift the absorption maximum to higher wavelengths. The observed ultraviolet spectra do in fact show a progressive shift of the main absorption band to higher wavelengths as the bulkiness of the substituents increases.[11]

To estimate the viability of **4** as a relatively stable intermediate, we carried out extensive MNDO calculations[12, 13] on the limiting acyclic and the proposed intermediate cyclic structures for **2a–c**[14] and for **2d**, the analogue of **2a** with Me instead of *t*Bu groups, in order of increasing bulkiness of their substituents. The result of introducing such substituents is a progressive decrease in the calculated differences of the enthalpies of formation between the acyclic and the cyclic structures (Fig. 2). The corresponding energy barriers between the two structures increase: for **2c**, $\Delta H_f^{SCF}(\max) - \Delta H_f^{SCF}(\text{cyclic}) = 14.4\ \text{kJ mol}^{-1}$.

Even if the most crowded pyrazolylborane presently available, **2c**, should, on further experimental scrutiny, prove to possess an acyclic structure in solution, the considerations presented above suggest an enhancement in both the kinetic

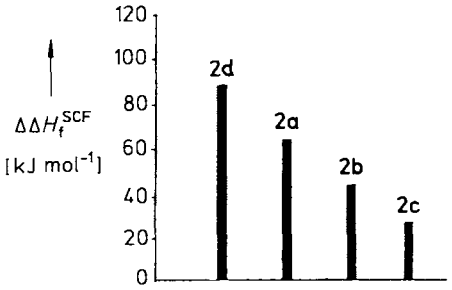


Fig. 2. Dependence of the differences in the enthalpy of formation $\Delta\Delta H_f^{SCF}$ (ΔH_f^{SCF}(cyclic) − ΔH_f^{SCF}(acyclic)) on the substituents of the pyrazolyl groups of boranes **2a–d**.

and thermodynamic stability of species **4** relative to the corresponding acyclic structure (**3**/**3'**) upon further increase in the internal crowding of the molecule. Hitherto, all attempts to introduce a substituent substantially larger than a methyl or ethyl group have failed at the β-diketone, starting material stage.

Experimental Procedure

2a: A solution of **1a** (1.5 g, 8.3 mmol) and (9*H*-9-BBN)$_2$ (1.0 g, 4.15 mmol) dissolved in 10 mL of toluene was heated to reflux for 18 h, during which time 200 mL of H_2 gas evolved. The solvent was removed in vacuo and the solid residue recrystallized from hexane by slow cooling to −78 °C. Crystalline **2a**: 2.4 g (96%). m.p. 89–90 °C. MS: *m/z* 300 ($M^{\oplus}$, B_1, 90%), 285 (45), 271 (45), 257 (65), 243 (100). ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 63.1 ($h_{1/2}$ = 350 Hz). ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 6.09 (s, 1H), 2.33 (br, 2H), 1.88 (m, 12H), 1.26 (s, 18H). ^{13}C NMR (50.3 MHz, $CDCl_3$, *T* = 311 K): δ = 162.8 (s, 2C), 106.5 (d, 1C), 33.6 (t, 4C), 30.5 (q, 6C), 30.0 (s, 2C), 28.5 (br., d, 2C), 22.8 (t, 2C). ^{13}C NMR (75.5 MHz, C_7D_8, *T* = 173 K): δ = 165.1 (s, 1C), 161.9 (s, 1C), 108.0 (d, 1C), 33.9 (t, 4C), 32.8 (s, 1C), 32.5 (s, 1C), 31.4 (q, 3C), 29.9 (q, 3C), 28.4 (br., d, 2C), 23.5 (t, 2C).

2b: (9*H*-9-BBN)$_2$ (0.53 g, 2.2 mmol) and **1b** (0.84 g, 4.3 mmol) were allowed to react as above for 24 h to give 1.3 g (94%) of a colorless solid. Purified by sublimation in vacuum; m.p. 70–71 °C. MS: *m/z* = 314 ($M^{\oplus}$, B_1, 80%), 299 (20), 285 (40), 257 (100). ^{11}B NMR (64.2 MHz, $CDCl_3$). δ = 64.2 ($h_{1/2}$ = 500 Hz). ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 1.95 (s, br., 12H); 1.27 (s, 3H); 1.39 (s, 20H). ^{13}C NMR (50.3 MHz, CD_2Cl_2, *T* = 311 K): δ = 157.4 (s, 2C), 115.8 (s, 1C), 33.8 (t, 4C), 32.9 (s, 2C), 30.1 (br., d, 2C), 29.9 (q, 6C), 22.8 (t, 2C), 12.7 (q, 1C). ^{13}C NMR (75.5 MHz, C_4D_8O, *T* = 163 K): δ = 158.5 (s, 2C), 117.3 (s, 1C), 34.7 (t, 4C), 33.9 (s, 2C), 31.2 (d, 2C), 30.3 (q, 6C), 24.0 (t, 2C), 13.6 (q, 1C).

2c: (9-H-9-BBN)$_2$ (0.84 g, 3.4 mmol) and **1c** (1.36 g, 6.5 mmol) were allowed to react as above for 24 h to give 1.9 g (88%) of a colorless solid. Purified by sublimation in vacuum; m.p. 82–83 °C. MS: *m/z* = 328 ($M^{\oplus}$, B_1, 100%), 285 (65), 271 (85), 245 (85), 232 (90). ^{11}B NMR (64.2 MHz, $CDCl_3$): δ = 65.3 ($h_{1/2}$ = 550 Hz). ^{1}H NMR (200.1 MHz, $CDCl_3$): δ = 2.67 (q, 2H), 1.95 (br., 2H), 1.88 (m, 12H), 1.36 (s, 18H), 1.14 (t, 3H). ^{13}C NMR (50.3 MHz, $CDCl_3$, *T* = 311 K): δ = 157.9 (s, 2C), 122.3 (s, 1C), 33.8 (t, 4C), 33.2 (s, 2C), 30.8 (q, 6C), 30.0 (br., d, 2C), 22.8 (t, 2C), 17.8 (t, 1C), 16.5 (q, 1C).

[13] The version of this manuscript submitted on October 10, 1989 also included an MNDO calculation for the hypothetical unsubstituted parent compound of **4**. The results led to an intermediate (activated complex) structure with C_s geometry (interplanar N_2B/N_2C_3 angle 37.1°) with bond lengths and energies of similar magnitudes as are reported by *Schleyer* et al. [15] using ab initio methods. Since our results evoked the criticism of one of the referees, who insisted on a C_{2v} geometry, we omitted their discussion in the present version of this communication. Finally, since the IGLO NMR calculations in [15] do not take account of the severe intermolecular interactions present in the real molecules **2a–c**, their relevance to the values actually found is open to question.
[14] The calculated structural data (bond distances and angles) are in good agreement with the experimental values found by X-ray diffraction.

On the Nature of Pyrazolylborane. An Ab Initio/IGLO/NMR Study**

By *Paul von Ragué Schleyer** and *Michael Bühl*

Dedicated to Professor Dr. Günther Wilke on the occasion of his 65th birthday

As described in the preceding communication by *Yalpani* et al., diorgano(pyrazolyl)boranes substituted with bulky groups undergo degenerate fluxional isomerization in solution.[1] Although the available crystal structures show the BR_2 group to be classically bonded to a single nitrogen (but with varying degrees of twist), the possibility was considered that a symmetrical structure might be present in solution. This species would involve simultaneous bonding between the boron and both nitrogens. We were intrigued by this novel system, and also by the possibility of using the combined ab initio/IGLO/NMR chemical shift method[2, 3] to probe the nature of the highly substituted species in solution. This new combination of methods, which involves comparison of chemical shifts calculated for several structural models with experimental data, is quite successful for the elucidation of structural problems.[3]

We calculated the structural parameters of **1–3**, three basic forms of the parent pyrazolylborane, at reasonably sophisticated ab initio levels.[4] The geometries were optimized with the polarized split valence 6-31G* basis set; key parameters are included in Figure 1. One set of single point

We thank the Kernforschungsanstalt Jülich for a grant of computer time, and are indebted to Prof. *W. Kutzelnigg* and his group for the development of the IGLO program. *M. Schindler* for the Convex version, and *U. Fleischer* for discussions. We thank Prof. *Yalpani* and his associates for discussions and for additional experimental information.

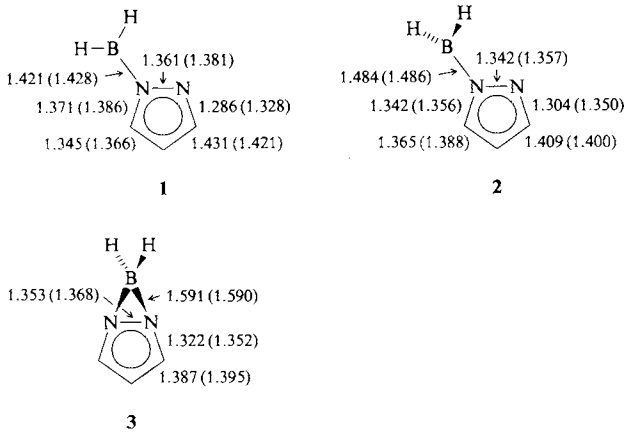

Fig. 1. The 6-31G* optimized geometries of **1**–**3** (C_s symmetry). The MP2(FU)/6-31G* parameters are given in parentheses.

energies were obtained with a larger basis set, 6-31+G*, which adds a set of diffuse s and p functions on the non-hydrogen atoms, and includes electron correlation at the second order Møller-Plesset (MP2) level using the frozen core (FC) approximation. Electron correlation favors the bridged structure (**3**) preferentially and lowers its relative energy below that of **2** (Table 1). The effect of correlation results from the more delocalized character of the bonding in **3** with its three-membered ring. Consequently, **1**–**3** were reoptimized at the MP2(FU)/6-31G* correlated level (FU = full). This changed the geometries only slightly (see Fig. 1, MP2 values are given in parentheses). Our final relative energies (Table 1) include the zero point (ZPE) corrections, calculated at 6-31G*. At MP2(FU)/6-31G*//MP2(FU)/6-31G*+ZPE(6-31G*), **3** lies 12.4 kcal mol^{-1} above **1** and the energy of **2** is a little higher (18.1 kcal mol^{-1}).

Frequency calculations at 6-31G* indicate both **1** and **3** to be minima. Transition state **2** is involved in BH_2 rotation, while **3** is an intermediate in the interconversion between **1** and its degenerate counterpart. The barrier we calculate for the parent species (our best value is at least 12.4 kcal/mol) is in line with the experimental observations on the more crowded derivatives in solution.[1] The bulky substituents lower the barrier and, as indicated from the crystal structures, twist the borane moieties from the preferred coplanar arrangement (**1**) to intermediate conformations tending towards **2**. The geometries shown in **1** and **2** are in reasonable agreement with the X-ray data,[1] when one takes the expected repulsions due to the substituents into account.

Table 1. Absolute [a] and relative [b] energies for **1**–**3**.

Level of theory	**1** (C_s, planar)	**2** (C_s, perpend.)	**3** (C_s, bridged)
6-31G*//6-31G*	250.08825 (0.0)	250.05479 (21.0)	250.04713 (25.8)
6-31+G*//6-31G*	250.09526 (0.0)	250.06238 (20.6)	250.05336 (26.3)
MP2(FC)/6-31+G*//6-31G*	250.87806 (0.0)	250.84647 (19.8)	250.85594 (13.9)
MP2(FU)/6-31G*//6-31G*	250.89061 (0.0)	250.85815 (20.4)	250.87280 (13.0)
MP2(FU)/6-31G*//MP2(FU)/6-31G*	250.89375 (0.0)	250.86200 (19.9)	250.87280 (13.1)
ZPE(6-31G*) [c]	49.8	48.0	49.1
Final [d]	0.0	18.1	12.4

[a] In a.u. [b] In parentheses, kcal mol^{-1}. [c] Zero point energy, kcal mol^{-1}, scaled by 0.89 as recommended in reference [4]. [d] Relative energies in kcal mol^{-1} at MP2(FU)/6-31G*+ZPE.

We now address the two principal questions which were posed by the experimental results, but remained unanswered. Even though **3** is inherently less stable than **1**, could it be possible that the bulky substituents result in a preference for the symmetrical form in solution? If this symmetrical form be present, what is its electronic structure? This second question can be answered by examining an ab initio wave function, but the calculated geometry (see **3**) also is revealing. Since the C–C and C–N bond lengths in the pyrazole ring in **3** have about the averaged values of those in **1** and **2**, there is no indication of any significant change in the basic 6π aromatic character of the pyrazole ring. The B–N bond lengths in **3**, 1.590 Å at 6-31G* (the MP2/6-31G* lengths are nearly the same), are about 0.2 Å longer than the single B–N distance in **2**, but are ca. 0.1 Å shorter than the dative[5] N → B bond length, 1.690 Å, calculated at the same level for H_3NBH_3.[4] Hence, the geometry of **3** indicates a classical three-membered ring arrangement. When the B–N–N angle is decreased, the nitrogen lone pair electrons in **2** interact with the vacant p-orbital on boron and a three-membered ring structure for **3** results.

Natural population analysis[6] confirms this picture. As expected, B–N bond order (0.88) is highest in **1**, because of the double bond character. The partial ionic nature of the bonding reduces the bond order, as calculated using *Wiberg*'s definition.[7] The B–N bond order of 0.71 in **2** represents the value for a single B–N bond given by this method of analysis. The B–N bond order of 0.54 in **3** is only slightly smaller despite the three-membered ring structure and partial dative character. The natural charge[6] on boron is largest in **2** (+0.81); the lower value +0.64 in **1** results from the π back donation from the ring nitrogen to boron. The boron charge (+0.49) in **3** is lowest of all. Note that the sign is positive, despite the formal negative charge which one would write classically for a tetravalent borate ion. This is general behavior. When the atoms involved differ in electronegativity (as do B and N in the present case), the formal charges which satisfy Lewis octet requirements are not consistent with charges derived from quantum mechanics wave functions.[8] (See below for an example.)

The IGLO ^{11}B-NMR chemical shifts, calculated for **1**–**3** using the MP2/6-31G* geometries, showed large variations with structure. These IGLO calculations employed a double zeta (DZ) basis set for most of the atoms,[2] but a more sophisticated triple zeta + polarization basis for boron. This better description of the nucleus in question employing "locally dense basis sets" has been proposed by *Chestnut*.[9] While perfect agreement with the experimental values obtained on substituted derivatives cannot be expected, the general accord is pleasing. Thus, $\delta(^{11}B)$ (vs. $BF_3 \cdot OEt_2$) for planar **1** (47.6) and for perpendicular **2** (62.0) may be compared with the values (63.1, 64.2) found experimentally for twisted structures.

The IGLO ^{11}B-NMR chemical shift calculated for **3**, $\delta = 19.3$, effectively rules out symmetrically bridged structures as candidates for the species present in solution. None of the experimentally observed ^{11}B-NMR chemical shifts[1] approach this IGLO value. However, there is good agreement between the IGLO result for **3** and that for numerous other tetracoordinated boron analogues which involve the simultaneous attachment of two nitrogen substituents to boron.[10] A simple experimental example, $[(CH_3)_2B(NH_3)_2]Br$ with $\delta(^{11}B) = 13.9$,[10, 11] is representative. The IGLO $\delta(^{11}B)$ value is 11.5 for $[(CH_3)_2B(NH_3)_2]^{\oplus}$ using the 6-31G*-optimized geometry. The computed B–N length is 1.657 Å

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0303-0305 $ 02.50/0

and the Wiberg bond order is 0.67. The natural charges are +0.87 on B and −1.00 on N (vide supra, note signs).

We conclude that the diorgano(pyrazolyl)boranes have similar geometries in solution and in the solid phase. Although symmetrical structures like **3** are involved in the degenerate rearrangement, they are not present in significant concentration in solution. Both the electronic structure and the ^{11}B-NMR chemical shift of **3** are normal.[12] That is, the pyrazole ring in the hypothetical **3** retains its 6π aromatic character and the B–N bonding is intermediate between single B–N and dative N → B arrangements.

[12] We also examined two planar symmetrially-bridged C_{2v} structures like **3**, with perpendicular and with coplanar BH_2 groups. The latter was 85 kcal mol^{-1} higher in energy than **1** at 6-31G*//6-31G* and possessed three imaginary frequencies. The perpendicular form was a transition state for the degenerate interconversion of **3**, and was 2.4 kcal mol higher in energy than the latter at our final level.

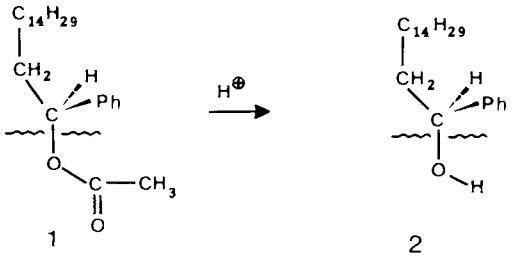
Switching Reaction Mechanism by Monolayer Compression: An Ester Hydrolysis

By *Jamil Ahmad** and *Kenneth Brian Astin**

Monolayers provide a novel opportunity to examine the reactivity of molecules constrained to a plane, where the geometrical requirements of transition states may be inferred from the reactivity of films at varying surface pressures (or areas per molecule). The method is suitable for the investigation of neighboring group and proximity effects.[1–3]

[*] Prof. Dr. J. Ahmad, Prof. Dr. K. B. Astin,
Department of Chemistry, University of Bahrain
P.O. Box 32038, Isa Town (Bahrain)

For example, the rates of the acid-catalyzed cyclization of nerol[1] and the acid-catalyzed dehydration of 1,1-diphenyl-1-octadecanol[2] are strongly affected by surface pressure changes, since these reactions require the involvement of remote functionalities, i.e. the remote double bond in nerol and the β-hydrogens in the 1,1-diphenyl-1-octadecanol, for reaction. High surface pressures disfavor this participation and the rate is correspondingly lowered. By contrast, reactions taking place at a single center, e.g. the chromic acid oxidation of 1-phenyl-1-hexadecanol[3] and the base-catalyzed hydrolysis of an octadecyl ester,[4] are not significantly affected by surface pressure changes. We report here the effect of surface pressure on the mechanism of the acid-catalyzed hydrolysis of 1-phenylhexadecyl ethanoate **1** to 1-phenyl-1-hexadecanol **2** in monolayers at an air/sulfuric acid interface.



1 2

The investigation of reactions in monolayers requires that the substrate forms films stable within the time scale of the experiment. The monolayer film of 1-phenylhexadecyl ethanoate amply satisfies this requirement. Compressed films ($\pi > 15.0$ mN m^{-1}) over water produce negligible reduction in π (< 5%) over a 30 min period. The surface pressure-area (π-A) isotherm (Fig. 1) is characteristic of amphipatic systems; the limiting area (obtained by extrapolating the π-A isotherm to $\pi = 0$) of 0.85 nm^2 is larger than for simple alkyl chains such as octadecanoic acid, where the limiting area is 0.21 nm^2,[5] because of the phenyl group inhibiting further compression. 1,1-Diphenyl-1-octadecanol has a limiting area of 0.72 nm^2.[2] Interestingly, the surface pressure-area isotherm in Figure 1 exhibits a just discernible plateau region

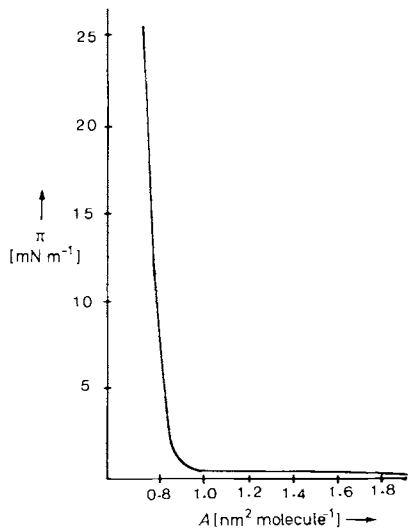


Fig. 1. π-A isotherm of 1-phenylhexadecyl acetate at 25 °C over water, using a Wilhelmy balance (initial film area 300 cm^2, final area 70 cm^2, compression rate 24 cm^2 min^{-1}).

suggesting a liquid type film between ca. 0.9 nm^2 and ca. 1.6 nm^2. In this film type the hydrophobic chains are believed to be interacting and orientated away from the surface, but are less ordered than in the solid type film observed at higher π. The gaseous type film at larger area/molecule consists of molecules which are essentially independent.[5]

The experiments were performed on a modified Langmuir trough, consisting of a thermostated multicompartment PTFE trough with Wilhelmy plate balance.[2, 6] The films were formed by spreading a calculated volume (ca. 2–20 μL) of a hexane solution of the ester onto a trough area to give the desired area/molecule. After a given time at constant area (surface pressure in the compressed films also remained essentially constant since the major product of the reaction 1-phenyl-1-hexadecanol is also surface active with a limiting area of ca. 0.55 nm^2[3]), the monolayer was swept into a reservoir containing hexane, where the reaction mixture dissolved. Typical recoveries exceeded 90%, even at the longest reaction times studied.

Despite the low qualities of material in the monolayer film the reaction mixture could be readily analyzed by HPLC using a Supercosil LC-8 5 μm column. Both ester and products were detected in the UV at 210 nm at 0.02 absorbance units full scale (AUFS): the peaks were integrated electronically and the concentrations determined using molar response factors calculated from standard solutions. The kinetics of hydrolysis were pseudo-first-order and a plot of the rate constant k against concentration of H_2SO_4 is shown in Figure 2.

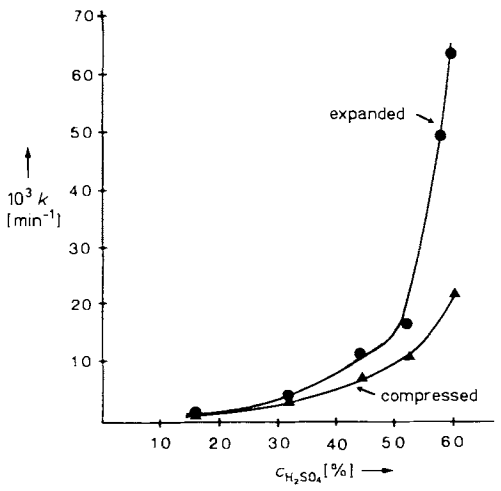

Fig. 2. Plot of the pseudo-first-order rate constant versus sulfuric acid concentration [%] for compressed (0.8 nm^2 $molecule^{-1}$) and expanded (3.8 nm^2 $molecule^{-1}$) film types at 25.0 ± 0.1 °C.

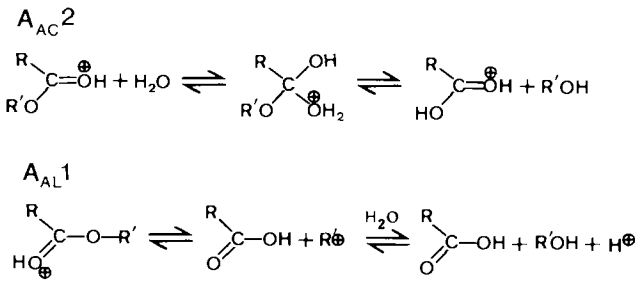
The dramatic difference in behavior between compressed (0.8 nm^2 $molecule^{-1}$) and expanded (3.8 nm^2 $molecule^{-1}$) films is apparent from the plot. At low acid concentrations the rates of hydrolysis are essentially independent of film type. This behavior is typical for reactions taking place at a single center, i.e. one not involving proximate or neighboring functionalities.[3, 4] Increasing the acid concentration produces enhanced reaction rates in the expanded films; this is strongly suggestive of the incursion of a new mechanistic pathway.[7] If the increased reactivity of the expanded film had been due to a neighboring group effect,[1, 2] parallel curves would have been expected in Figure 2 since the enhanced reactivity of the expanded film would then be evident at all acid concentrations.

The two most probable acid-catalyzed mechanisms[8] are outlined in Scheme 1. The bimolecular $A_{AC}2$ mechanism is the one generally observed in dilute acid solution and we suggest the major pathway in the compressed film. At higher acid concentration the unimolecular $A_{AL}1$ mechanism involving alkyl-oxygen fission and the formation of the secondary 1-phenylhexadecyl cation becomes competitive. The increased curvature of the compressed film rate profile could reflect imperfection in the film, allowing a component of the $A_{AL}1$ mechanism to take place even in the compressed film. An alternative unimolecular mechanism $A_{AC}1$ involving acyl-oxygen fission is considered highly unlikely since it would involve the formation of an acylium ion and is only observed at high acid concentrations (> 90% H_2SO_4).[9]



Scheme 1.

This analysis is supported by the elegant work of *Yates*[9] on bulk phase ethanoate ester hydrolysis in aqueous sulfuric acid. With Type II ethanoates (i.e. those with secondary alkyl, benzyl or allyl residues), increasing acid concentration affords an initial rate increase followed by a drop, reflecting the $A_{AC}2$ mechanism, catalyzed by acid but requiring the less available free H_2O as a nucleophile. This is followed by a further dramatic rate increase as the $A_{AL}1$ mechanism takes over; this mechanism does not require the nucleophilic participation of water.

The observation of small quantities (maximally 8% at 60% H_2SO_4 usually 3–6%) of the alkene product[10] 1-phenyl-1-hexadecene, from the reaction of expanded films at higher acid concentrations is, unfortunately, not unequivocal support for the $A_{AL}1$ mechanism, since the alkene can also be formed from the dehydration of the alcohol product **1**.[10] Control experiments with the expanded alcohol over sulfuric acid gave similar, although slightly lower, amounts of alkene than the corresponding ester films.

To obtain further insight into the mechanism, the reactivity of the ester film over 58% H_2SO_4 was studied as a function of area/molecule, (Fig. 3). The sigmoid nature of the curve is reminiscent of that obtained for the acid-catalyzed dehydration of 1,1-diphenyl-1-octadecanol;[2] however, in the present study the rate increase is less dramatic and occurs at a smaller area/molecule (1.5 instead of 2.5 nm^2).[2]

This suggests that a gaseous film type is not required for the ester hydrolysis and that the $A_{AL}1$ mechanism can occur at relatively small areas/molecule. It is clear that neighboring group effects are inoperative here and that the absence of the $A_{AL}1$ mechanism in the compressed film can be traced to a simpler geometric factor, namely, that the alkyl group is forced out of the subphase at high surface pressures and the alkyl–oxygen fission and concomitant cation ion formation thereby disfavored. Only a modest reduction in surface pres-

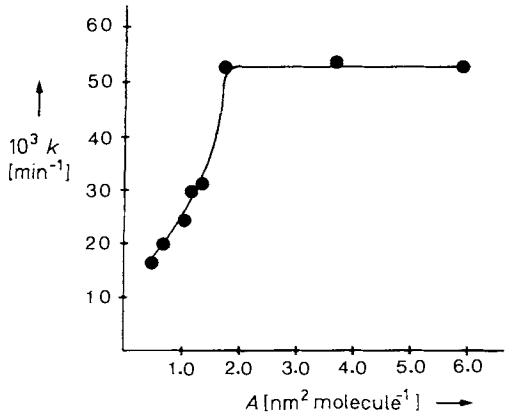


Fig. 3. Plot of the pseudo-first-order rate constant versus area/molecule over 58% sulfuric acid at 25.0 ± 0.1 °C.

sure is required to allow the alkyl–oxygen bond into the subphase where fission and solvation of the cation can take place.

[*n*BuLi · LiO*t*Bu]$_4$, Solid-State Structure of an *n*-Butyllithium–Lithium *tert*-Butoxide Complex **

By *Michael Marsch, Klaus Harms, Lubomir Lochmann,* and *Gernot Boche* *

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

Complexes [RLi · LiOR] formed from organolithium compounds RLi and lithium alkoxides LiOR, which are expected to be formed, for example, during addition of RLi to an aldehyde or ketone, have long been known.[1–4] The properties of the starting materials change upon complex formation, as exemplified in the addition of *n*BuLi to a C=O[5] or C=C[6] bond. Anionic polymerization is also affected by LiOR,[7–9] and, in the presence of LiOR, organolithium compounds are less thermally stable.[10, 11]

During NMR spectroscopic investigations of *n*BuLi in the presence of lithium *n*-butoxide or lithium *tert*-butoxide in THF, complexes of structure $n\mathrm{Bu}_x\mathrm{Li}_4(\mathrm{OBu})_{4-x}$ ($x = 1-4$) were observed, whereby one or two LiOR ligands acted to stabilize the structure.[4] The complex *n*BuLi · LiO*t*Bu[2] forms a tetramer, **1**, in benzene (degree of aggregation $\alpha = 3.7$).[12]

$[CH_3(CH_2)_3Li \cdot LiOC(CH_3)_3]_4$

1

A Weissenberg photograph (of little informative value)[13] has been recorded for *n*BuLi · LiO*t*Bu.[2] Here we report on the X-ray structure analysis of this compound, which crystallizes from hexane as tetramer **1** (Fig. 1). The elucidation of its structure interested us because solid-state structures are unknown either for a complex of the type [RM · MOR'] (M = Li, Na, K) or for *n*BuLi and LiO*t*Bu.

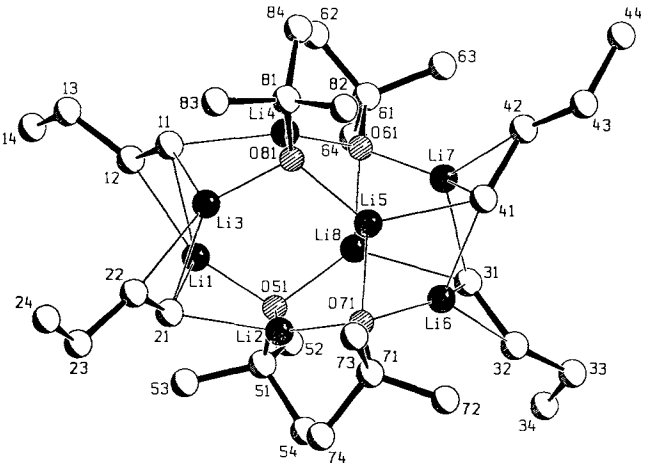

Fig. 1. Molecular structure [14] of **1** (hydrogen atoms omitted). Important bond lengths and distances [pm]: Li1-C11 215(1), Li1-C12 236(1), Li1-C21 219(1), Li1-O51 185(1), Li1-H121 197(5), Li1-H122 280(5), Li3-C21 215(1), Li3-C22 234(1), Li3-C11 222(1), Li3-O81 185(1), Li3-H221 264(5), Li3-H222 213(5), Li6-C31 217(1), Li6-C32 234(1), Li6-C41 225(1), Li6-O71 182(1), Li6-H321 252(5), Li6-H322 203(6), Li7-C41 215(1), Li7-C42 236(1), Li7-C31 226(1), Li7-O61 184(1), Li7-H421 208(5), Li7-H422 256(5), Li2-C21 218(1), Li2-O51 190(1), Li2-O71 186(1), Li4-C11 221(1), Li4-O61 187(1), Li4-O81 192(1), Li5-C41 225(1), Li5-O71 189(1), Li5-O81 186(1), Li8-C31 222(1), Li8-O51 186(1), Li8-O61 192(1).

As revealed by Figure 1, two kinds of differently bonded Li atoms are present. Li1, Li3, Li6, and Li7 are each bonded to two *n*Bu α-C atoms (e.g., for Li3: Li3-C11 222(1) pm; Li3-C21 215(1) pm) and one O atom (Li3-O81 185(1) pm). Unusual are the short distances to the *n*Bu β-C atoms (Li3-C22 234(1) pm) as well as to one of the two β-hydrogen atoms (Li3-H222 213(5) pm; Li3-H221 264(5) pm). Figure 2 shows the typical structure of the *n*-butyl groups.

The β-H atoms H222 and H221, which are tilted toward Li3, are reminiscent of agostic hydrogen atoms.[20] The $^6Li^1H$ HOESY NMR spectrum of $(n\mathrm{BuLi})_4$ in THF reveals

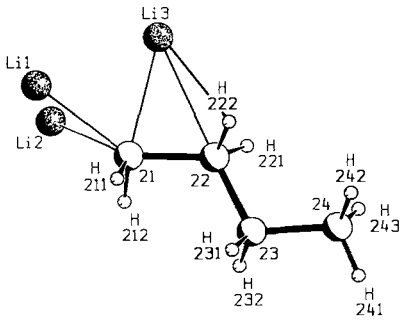

Fig. 2. Section of the crystal structure of **1**, showing the bonding of a typical *n*Bu group; bond lengths [pm]: Li1-C21 219(1), Li2-C21 218(1), Li3-C21 215(1), Li3-C22 234(1), Li3-H211 272(5), Li3-H212 300(5), Li3-H222 213(5), Li3-H221 264(5), C21-C22 151.4(9) [24].

an interaction between Li and the β-H atoms.[21] At the same time, the *n*-butyl groups were assumed to have a conformation largely corresponding to that found for **1**.[21] However, whereas the cross peaks to the β-H atoms are smaller than those to the α-H atoms in the $^6Li^1H$ HOESY spectrum of $(n\text{BuLi})_4$,[21] the Li–H distances in **1** are always smaller for the β-H atoms than for the α-H atoms (see caption to Fig. 2).

The second kind of Li, namely, Li2, Li4, Li5, and Li8, has two Li–O contacts (e.g., Li2-O71 186(1) pm and Li2-O51 190(1) pm) and only one Li–α–C contact (Li2-C21 218(1) pm), whereas the fourth coordination site of Li remains unoccupied, presumably owing to steric hindrance by the O*t*Bu groups (Fig. 1).

When RLi is mixed with Na(K,Rb,Cs)OR, superbases such as *n*BuLi + KO*t*Bu are obtained; the formation of these species, which are extremely useful synthetically, is also assumed to proceed via complexes.[22, 23] Since nothing is known about the structure of these complexes, the structure of **1** offers possible clues (although any conclusions drawn therefrom can only be speculative owing to the different sizes of Li and, e.g., K). The fourfold coordination of Li1, Li3, Li6, and Li7 might resemble the bonding of the K atoms, while the more strongly O-bonded threefold coordinated atoms Li2, Li4, Li5, and Li8 should instead correspond to the Li atoms. The formation of *n*BuK and LiO*t*Bu as well as the reaction with RH to give RK could involve such a complex.[22, 23]

Note added in proof (February 28, 1990): In a theoretical work (J. P. Ritchie, S. M. Bachrach, *J. Am. Chem. Soc. 109* (1987) 5909), which has only recently come to our attention the authors agreed, in the case of 1,3-dilithiocyclobutane, upon a "bond path connecting a methylenic carbon to lithium, in addition to the bond paths connecting lithium to the anionic carbons." This unexpected bond path appears to have been demonstrated experimentally for the first time in structure **1**.

Lewis-Acid-Induced Transformation of a Terminal Carbonyl Ligand: Synthesis and Structure of the Alkyne-Cluster-Analogue $[(\mu\text{-H})_3Os_3(CO)_9\{\mu_3,\eta^2\text{-}C(OBC_8H_{14})B(Cl)\}]$**

By *David P. Workman, Hai-Bin Deng,* and *Sheldon C. Shore**

Lewis acids have been shown to activate the BCO fragment of the boron-triosmium cluster $[(\mu\text{-H})_3Os_3(CO)_9(\mu_3\text{-BCO})]$ **1**[1] by electrophilic addition at its oxygen atom.[2] Reaction of **1** with $BH_3 \cdot THF$ leads to reduction of the unique carbonyl to a methylene group with formation of the vinylidene analogue $[(\mu\text{-H})_3Os_3(CO)_9(\mu_3,\eta^2\text{-}BCH_2)]$ **2**.[4] In contrast, reaction of **1** with BCl_3 leads to formation of **3**, a structurally different type of vinylidene comlex analogue[5]

[**] This work was supported by the National Science Foundation (Grants CHE 88-00515 and CHE 84-11630). The spectroscopic data were recorded at The Ohio State University Campus Chemical Instrument Center (funded in part by NSF Grant 79-10019 and NIH Grant 1 S10 PRO145128-O1A).

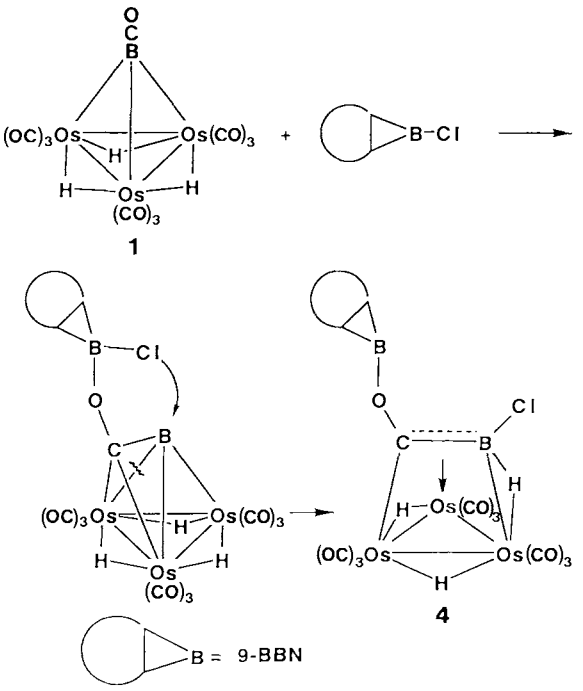
$[(\mu\text{-}H)_3Os_3(CO)_9(\mu_3\text{-}CBCl_2)]$ **3**

in which the transformation is believed to occur via an intramolecular rearrangement of the boron and carbon atom positions. Such a mechanistic scheme requires halogen atom transfer from the BCl_3 to the cluster boron. We report here the first structurally characterized product formed by the electrophilically induced shift of a terminal carbonyl in a neutral carbonyl cluster.[6]

The reaction of **1** with the electrophilic reagent 9-chloro-9-borabicyclo[3.3.1]nonane (9-Cl-9-BBN),[7] provides direct evidence for such a halogen atom transfer. Electrophilic activation of the BCO unit of **1** results in a shift of the carbonyl group from a terminal position to a face capping site, leading to formation of **4** [Eq. (a)]

$$\underset{\mathbf{1}}{[(\mu\text{-}H)_3Os_3(CO)_9(\mu_3\text{-}BCO)]} + \text{9-Cl-9-BBN} \rightarrow \underset{\mathbf{4}}{[(\mu\text{-}H)_3Os_3(CO)_9\{\mu_3,\eta^2\text{-}C(OBC_8H_{14})B(Cl)\}]} \quad (a)$$

The initial step in the formation of **4** (Scheme 1) involves addition of the boron of 9-Cl-9-BBN to the oxygen of the



Scheme 1. Proposed mechanism for Reaction (a).

boron-bound carbonyl group in **1**.[2] The resulting reduction of the CO bond order induces a shift of the carbonyl carbon to a μ_3 position,[8] thereby exposing the boron vertex which allows the chlorine atom to transfer to it.

The molecular structure of **4** (Fig. 1) was determined by a single crystal X-ray diffraction study.[10] It consists of a triangle of osmium atoms bound to the boron and carbon atoms of a triply bridging ligand derived from the BCO unit of **1**. The carbonyl has been shifted to occupy a bridge site between two osmiums and the boron atom. The 9-BBN group is bound to the oxygen atom of the carbonyl group

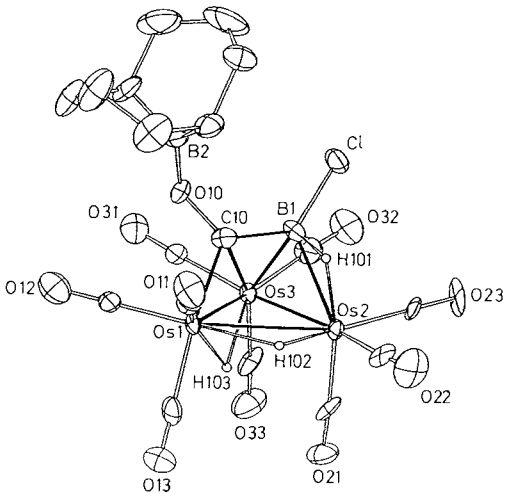


Fig. 1. Structure of **4** in the crystal (ORTEP plot with 50% probability ellipsoids). Selected distances [Å]: Os1-Os2 3.0454(6), Os1-Os3 2.8532(6), Os2-Os3 2.7974(5), Os1-C10 2.13(1), Os3-C10 2.24(2), Os2-B1 2.38(1), Os3-B1 2.36(1), B1-Cl 1.81(1), B1-C10 1.46(2), C10-O10 1.40(1), B2-O10 1.36(1).

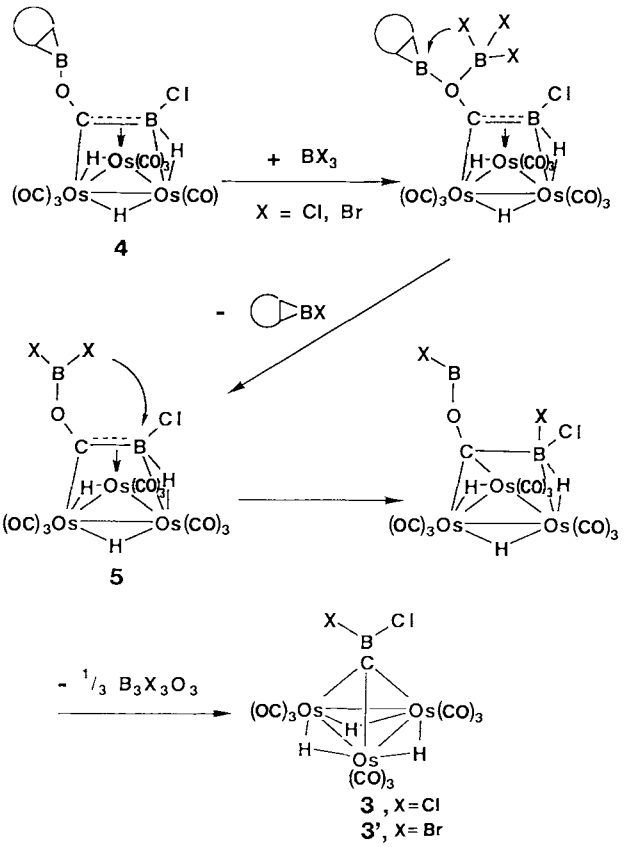
[B2-O10 1.36(2) Å], while the chlorine atom from the 9-Cl-9-BBN unit now resides on the boron vertex, [B1-Cl 1.82(1) Å]. The C10-O10 distance of 1.40(1) Å, (single bond[12]) is larger than the corresponding distance in **1** (1.145(15) Å). The B1-C10 distance of 1.46(2) Å is comparable with the corresponding B-C distances in **1**,[1,3] **3**,[5] and in the ditungstenalkyne complex analogue $[W_2(\mu\text{-MeCB(H)Et})(CO)_4(\eta^5\text{-}C_5H_5)_2]$[11] (1.469(15) Å, 1.47(2) Å, and



Scheme 2. **4** as model for the postulated intermediate **5** in the synthesis of **3** from **1**.

1.46(2) Å, respectively). These bonds are considered to have boron–carbon partial double bond character. They are longer than the boron–carbon double bond distance of 1.361(4) Å reported by *Paetzold* et al.,[13] but shorter than B–C single bonds (ca. 1.6 Å[14]). The "short" B–C distances found in **1**, **2**, and **3** suggest that a strong boron–carbon interaction is maintained throughout the transformation of **1** into **3**, supporting an intramolecular process.

Compound **4** is a model compound for the proposed intermediate in the transformation of **1** into **3**. The availability of only one chlorine atom in Reaction (a) halts the conversion of **1** into **3** and allows isolation of **4**. The intermediacy of **4** is revealed by treating it with BX_3 to produce **3** (X = Cl) or the mixed halo derivative **3'** (X = Br) and the boroxine $B_3X_3O_3$, (Scheme 2). This completes the conversion of **1** into **3**. Scheme 2 is based on ^{11}B-NMR studies which indicate initial formation of the 9-BBN halide, which would produce the intermediate **5** proposed for the reaction of **1** with BCl_3 when X = Cl.

Compound **4** can also be considered to be an alkyne complex analogue. The B–C fragment adopts a μ_3,η^2 bonding mode and is oriented nearly parallel to the Os1–Os2 bond. The B–C unit along with the hydrogen atom bridging Os2–B1, donate four electrons to the cluster.[15] Two electrons are donated to Os3 through a π-interaction and the two remaining electrons are distributed between a σ-bond to Os1 and a hydrogen bridged bond to Os2.

Experimental

A CH_2Cl-solution (6 ml) of 9-Cl-9-BBN (74.3 mg, 0.474 mmol) was transferred to a flask containing 82.1 mg, 0.095 mmol of **1**. The reaction mixture was stirred at room temperature for one hour, and the volatile components were then removed leaving an oily yellow residue, which, on washing with pentane, furnished pale yellow **4**: yield 72.5 mg (0.071 mmol, 75%). IR (ν_{CO}, CH_2Cl_2): $\tilde{\nu}$[cm^{-1}] = 2010 m(sh), 2035s, 2075s, 2095s, 2117w cm^{-1}. Satisfactory H,C-analysis. MS (EI): *m/z* 1027 ($M^{\oplus}-1$). 250.1-MHz ^{1}H-NMR (CD_2Cl_2, 30 °C): δ = 1.90(m), 1.82(m), 1.39(m), −11.75 (br. s), −16.18(s), −21.87(s), −21.87(s). 80.3-MHz ^{11}B NMR (CD_2Cl_2, 30 °C): δ = 58.8 (br. s), 18.5(s). 69.9 MHz ^{13}C{^{1}H}NMR (CD_2Cl_2, 30 °C): δ = 138.0 (br.s, C-B), 175.03, 174.42, 172.75, 169.06, 168.26, 167.95, 166.06, 165.93, 162.51 (each CO), 33.79, 33.57, 24.96 (br. s), 23.42 (9-BBN C-atoms).

Formation of Tetranuclear Chelate(4-) Ions of Divalent Metals (Mn, Co, Ni) with Idealized *T* Symmetry by Spontaneous Self-assembly

By *Rolf W. Saalfrank,* Armin Stark, Matthias Bremer,* and *Hans-Ulrich Hummel*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The structures of enolates and their reactivity are currently of great interest.[1] The same holds true for polynuclear metal complexes.[2] Since a tetranuclear manganese cluster constitutes the active center in photosystem II, which carries out photooxidation of water in green plants and algae, tetranuclear manganese chelate complexes might serve as models for the elucidation of this fundamental biological process.

Earlier we obtained the tetranuclear magnesium chelate complex **3b** in 85% yield by reaction of diethyl malonate (**1b**), methylmagnesium iodide, and oxalyl chloride (**2**) in a molar ratio of 1:1:0.25 at −78 °C in tetrahydrofuran followed by workup in aqueous ammonium chloride solution.[3] We were convinced that, in addition to magnesium, other divalent metals would also undergo such "*spontaneous self-assembly*"[4] to form similar "adamantanoid" chelate complexes. However, the alkylmetal chlorides of manganese, cobalt, and nickel are less readily available.[6] We have therefore modified our synthetic procedure for **3b** and now use methyllithium/magnesium chloride instead of methylmagnesium iodide. The advantage of this approach lies not only in the slight improvement in yield of **3b** from 85% to 90% but also in the simpler experimental procedure. Much more important than the more facile preparation of **3b** is the fact that mere replacement of magnesium chloride by the chlorides of manganese, cobalt, and nickel allows the

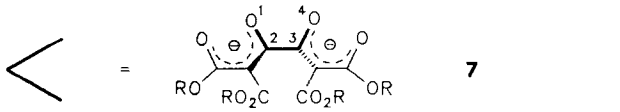
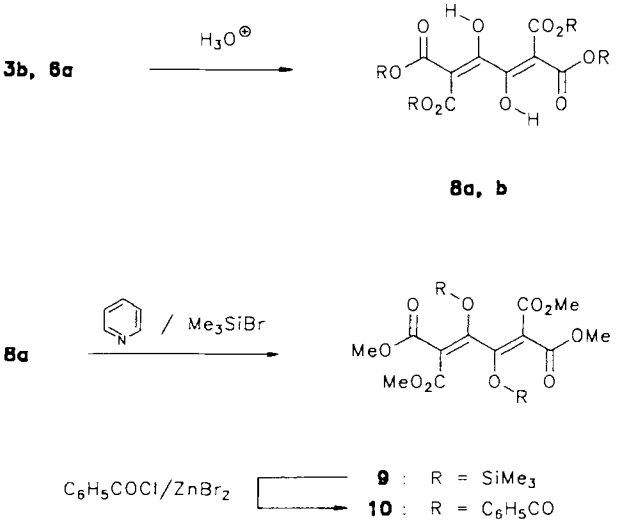
	$Mg^{2\oplus}$	$Mn^{2\oplus}$	$Co^{2\oplus}$	$Ni^{2\oplus}$



corresponding tetranuclear complexes **4**, **5**, and **6**, respectively, to be easily synthesized in good yields (80 to 87%).[7] The doubly bidentate bridging ligand **7** is formally obtained by *template coupling* of two malonate ester monoanions with oxalyl chloride (**2**) to give the tetraalkyl 2,3-dihydroxy-1,3-butadiene-1,1,4,4-tetracarboxylate **8** followed by spontaneous double deprotonation of **8**.

Under appropriate conditions, the 2,3-dihydroxy-1,3-butadienes **8** may be isolated. Hydrolysis of **6a** under mild conditions (pH ≈ 5, 20 °C, 2 min ultrasonication) affords **8a** (keto–enol equilibrium; yield 46%, m.p. 77 °C). Compound **8a** reacts with bromotrimethylsilane/pyridine to give tetramethyl 2,3-bis(trimethylsiloxy)-1,3-butadiene-1,1,4,4-tetracarboxylate (**9**; oil, yield 82%, dec. ≈50 °C). Reaction of **9** with benzoyl chloride in the presence of a catalytic amount



of zinc bromide results in formation of tetramethyl 2,3-bis(benzoyloxy)-1,3-butadiene-1,1,4,4-tetracarboxylate (**10**; yield 44%, m.p. 139 °C).

The ^1H and ^{13}C NMR spectra of **4**, **5**, and **6** (electron configurations: $Mn^{2\oplus}$, d^5; $Co^{2\oplus}$, d^7; $Ni^{2\oplus}$, d^8; paramagnetism) do not unambiguously establish the structure of these compounds. Therefore, we chose[8] to carry out X-ray structure analyses of **4a** and **5a**.[9] The two compounds are present as tetraammonium salts in the crystal. The counterions are the fourfold negatively charged, "adamantanoid",[10] complex tetramanganate(4-) $\mathbf{4a}^{4\ominus}$ and tetracobaltate(4-) $\mathbf{5a}^{4\ominus}$, respectively. Complexes **4a** and **5a** are the first of this type.[11] Complex **5a** was chosen for graphical presentation (Figs. 1–3). The core of the complex tetra-

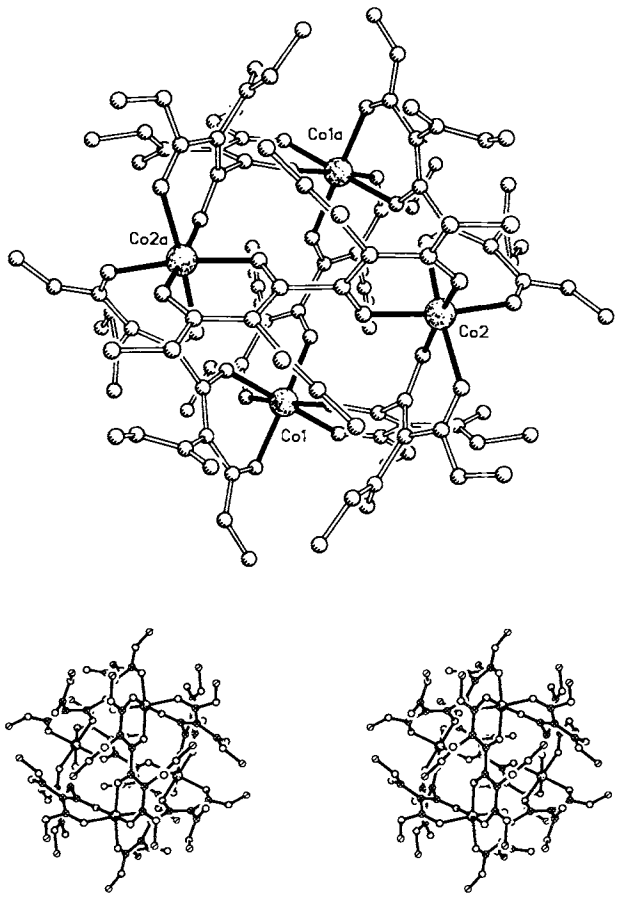


Fig. 1. Top: Structure of the tetracobaltate(4-) chelate ion $\mathbf{5a}^{4\ominus}$ in the crystal along the crystallographic C_2 axis. Bottom: Stereoview of $\mathbf{5a}^{4\ominus}$ along the crystallographic C_2 axis. ○ = O, ⊗ = C, ∅ = CH_3.

cobaltate(4-) ion $\mathbf{5a}^{4\ominus}$ is a distorted tetrahedron composed of four cobalt(II) ions [Co–Co distances: Co1-Co1a 660.6, Co1-Co2a and Co2-Co1a 660.9, Co1-Co2 and Co1a-Co2a 669.6, Co2-Co2a 675.6 pm]; these ions are linked along each of the six edges of the tetrahedron by a doubly bidentate tetramethyl 2,3-dioxobutane-1,1,4,4-tetracarboxylato(2-) bridge (**7a**), so that each of the four cobalt(II) ions is octahedrally coordinated by six oxygen atoms[12] [the torsional angles O1-C2-C3-O4 are 65.1, 73.9, 93.2, and 101.5°].

The tetracobaltate(4-) chelate ion $\mathbf{5a}^{4\ominus}$ has exact C_2 symmetry in the crystal. Viewed ideally (the Co–Co distances differ by less than 2.3%); however, the anion can be regarded as having nearly T symmetry (characterized by three C_2

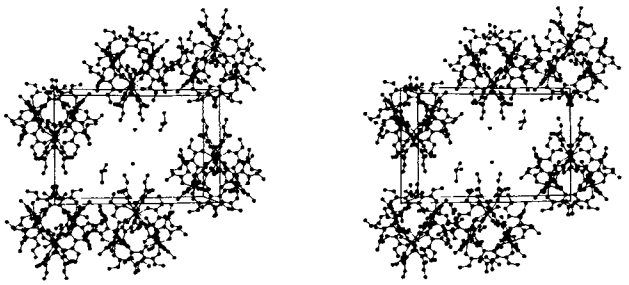

Fig. 2. Stereoview of the crystal packing of **5a**. For clarity, the hydrogen atoms, the crystal water, and the $\mathbf{5a}^{4\ominus}$ ions lying at the center in front of and behind the plane of the figure are not shown. The ammonium ions are shown as points, the chloroform molecules as three-pointed stars.

Fig. 3. Space-filling model of **5a** (cocrystallized chloroform and water are also shown) as viewed along the crystallographic C_2 axis. White, H atoms; black, C atoms; violet, N atoms outside the "adamantanoid" chelate anion; red, O atoms; green, Cl atoms; blue, Co atoms inside the "adamantanoid" chelate anion.

and four C_3 axes).[13] Accordingly, the tetracobaltate(4-) ion $\mathbf{5a}^{4\ominus}$ should be dissymmetric and thus chiral. The dissymmetry of this tetranuclear anion results from the atropisomerism[14] of ligands **7a**. The six chelate bridges **7a** linking the four $Co^{2\oplus}$ centers are twisted in the same sense and have nearly C_2 symmetry. The chiral subgroups of the point symmetry groups of the regular tetrahedron T_d are C_2, C_3, D_2, and T. Whereas numerous examples of molecules with C_2 symmetry are known, there are only a few organic molecules having the higher point-group symmetries (C_3,[15] D_2,[16] T[17]). Only relatively complicated molecules can have T symmetry. One of the reasons for the rarity of the higher-symmetry chiral compounds is that the required geometric prerequisites, all of which have to be simultaneously fulfilled, make a non-directed formation improbable. All the more surprising, therefore, is the high degree of symmetry obtained by "*spontaneous self-assembly*".

Experimental Procedure

4a, 5a, 6a: 30 mmol of a 1.6 M solution of methyllithium in diethyl ether was added to a solution of **1a** (4.0 g, 30 mmol) in 50 mL of dry THF (under N_2, $-78\,^\circ C$). The reaction mixture was stirred for 1 h at $-78\,^\circ C$ followed by addition of 30 mmol of previously dried MCl_2 (**4a**, $MnCl_2$; **5a**, $CoCl_2$; **6a**, $NiCl_2$). After stirring for 1 h, the mixture was treated dropwise with oxalyl chloride (**2**; 0.9 g, 7.5 mmol) in 20 mL of THF over 30 min, then allowed to warm over 18 h to 20 °C, and finally worked up with aqueous ammonium chloride solution.

4a: yield 2.2 g (80%), colorless prisms from $CHCl_3$/hexane, dec. $\approx 185\,^\circ C$. IR (KBr): $\tilde{\nu} = 1685$ (C=O), 1625 cm^{-1} (C=C).

5a: yield 2.4 g (87%), violet prisms from $CHCl_3$/hexane, dec. $\approx 193\,^\circ C$. IR (KBr): $\tilde{\nu} = 1690$ (C=O), 1625 cm^{-1} (C=C).

6a: yield 2.4 g (87%), green prisms from $CHCl_3$/hexane, dec. $\approx 160\,^\circ C$. IR (KBr): $\tilde{\nu} = 1685$ (C=O), 1620 cm^{-1} (C=C).

8a: **6a** (1.1 g, 0.5 mmol) was suspended in 100 mL of water and treated with a solution of 15 g of aluminum sulfate in 50 mL of water. After ultrasonication of the reaction mixture for 2 min, the aqueous phase was extracted with 3×100 mL of dichloromethane. The extracts were dried over sodium sulfate and the solvent was removed. The remaining yellow oil was crystallized from chloroform/diethyl ether. Yield: 0.4 g (46%), colorless crystals, m.p. 77 °C. IR (KBr): $\tilde{\nu} = 1725$ (C=O), 1650 cm^{-1} (C=C). The ^1H and ^{13}C NMR spectra contained many signals (keto–enol equilibrium). MS (70 eV): m/z 318 ($M^{\oplus}$).

9: **8a** (1.0 g, 3 mmol) was dissolved in 40 mL of dry THF (under N_2) and treated with pyridine (0.5 g, 6 mmol) and bromotrimethylsilane (1.9 g, 13 mmol). The reaction mixture was stirred for 1 h at 20 °C and then filtered. The solvent was removed and all volatiles were removed from the silyl enol ether at 20 °C under high vacuum. Yield: 1.2 g (82%). Dec. $\approx 50\,^\circ C$. IR (neat): $\tilde{\nu} = 1730$ (C=O), 1635 cm^{-1} (C=C). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.16$ (s, 18H; $2Si(CH_3)_3$), 3.58 and 3.67 (each s, 12H; $4CH_3$). ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 0.15$ ($2Si(CH_3)_3$), 51.83 ($4CH_3$, two coincidentally overlapping signals), 112.37 (2 =C), 157.46, 163.95 and 164.28 (2 =C–O and 4 O–C=O). MS (70 eV): m/z 434 ($M^{\oplus} - 28$).

10: **9** (1.0 g, 2 mmol) was dissolved in 20 mL of dry dichloromethane (under N_2) and treated with benzoyl chloride (0.6 g, 4 mmol) and previously dried $ZnBr_2$ (0.1 g). After 18 h, the mixture was worked up with 20 mL of a saturated aqueous solution of sodium hydrogen carbonate. The organic layer was dried over sodium sulfate and the solvent removed. The remaining oil was crystallized from diethyl ether. Yield: 0.5 g (44%), colorless crystals, m.p. 139 °C. IR (KBr): $\tilde{\nu} = 1750$ and 1720 (C=O), 1640 cm^{-1} (C=C). ^1H NMR (400 MHz, $CDCl_3$): $\delta = 3.56$ and 3.71 (each s, 12H; $4CH_3$), 7.49, 7.64 and 8.08 (each m_c, 10H; $2C_6H_5$). ^{13}C NMR (100.5 MHz, $CDCl_3$): $\delta = 52.77$ and 52.90 ($4CH_3$), 120.81 (2 =C), 127.71 ($2\,C_{ipso}$), 128.70, 130.49 ($4\,C_{ortho}$ and $4\,C_{meta}$, respectively), 134.33 ($2\,C_{para}$), 149.77 (2 =C–O), 162.03, 162.15, and 162.84 (6 O–C=O). MS (70 eV): m/z 526 ($M^{\oplus}$).

Correct elemental analyses for **4a**, **5a**, **6a**, **8a**, and **10**.

[7] The use of sodium hydride/metal chloride has so far given ca. 15% lower yields. The multistep process used, for example, in the synthesis of the corresponding zinc chelate complex [3] cannot compete with these one-pot procedures. In this process, hydrolysis of the magnesium chelate complex **3b** initially yields the tetraethyl ester **8b**. Reaction of **8b** with sodium hydride/zinc bromide proceeds via the free doubly bidentate chelate anion **7b** to afford, after workup with aqueous ammonium chloride solution, the "adamantanoid" zinc chelate complex, but only in yields of ca. 66% (based on **3b**).

[8] In addition to **4a,b**, **5a,b**, and **6a,b**, the corresponding complexes with R = *tert*-butyl or benzyl were also synthesized. In all cases, beautiful crystalline compounds were obtained, although only the methyl-substituted derivatives (**a** series) were suitable for X-ray analysis.

[9] **4a**: $C_{72}H_{72}O_{60}Mn_4\,(NH_4)_4$, colorless prisms from chloroform/hexane. The compound crystallizes with two equivalents of chloroform and water. [4+2]-Cycloadditions of Phosphinodiazoalkanes: Synthesis of 1,2,4-λ^5-Diazaphosphinines**

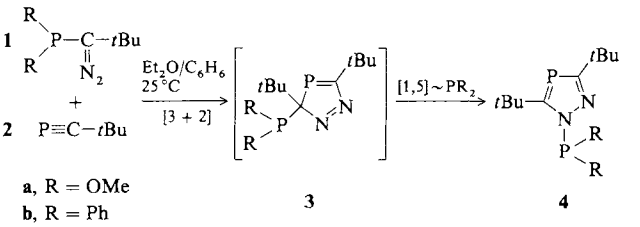
By *Thomas Facklam, Oliver Wagner, Heinrich Heydt,* and *Manfred Regitz**

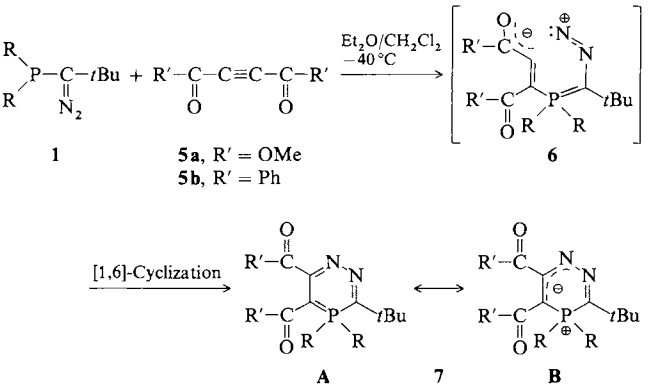
Dedicated to Professor Alfred Schmidpeter on the occasion of his 60th birthday

There is no reaction which so compellingly characterizes aliphatic diazo compounds as 1,3-dipolar cycloaddition. This behavior has been documented in numerous reactions with double- and triple-bonded systems, and has been used for the synthesis of heterocycles.[1] It is all the more surprising that the phosphinodiazoalkanes first reported a few years ago[2] undergo either [3+2]- or even, as presented here, [4+2]-cycloadditions, depending on the cycloaddition partners.

As model substances, we have used the phosphinodiazoalkanes **1a** and **1b**,[3] which are readily accessible by electrophilic diazoalkane substitution[4] of lithium 1-diazo-2,2-dimethylpropane with the corresponding chlorophosphane. Their reaction with the phosphaalkyne **2**,[5] which possesses an electron-rich triple bond, still proceeds "normally": the regiospecific [3+2]-cycloaddition step leading to the 3*H*-1,2,4-diazaphospholes **3a, b** is followed by spontaneous sigmatropic [1,5]-shift of the R_2P residue to give the isomers **4a, b**.[6] Since $^1J_{PP}$ couplings are absent in the ^{31}P-NMR spectra, and since the ^{13}C-NMR spectrum of **4a** shows only sp^2 ring carbon atoms with comparably large phosphorus couplings (δ = 189.2, 199.2, $^1J_{PC}$ = 59.1 and 63.0 Hz), the phosphino substituent must be bound to one of the nitrogen atoms.[7]



In contrast **1a, b** react quite differently, and in the sense of a [4+2]-cycloaddition, with the electron-deficient alkynes **5a, b**: the previously unknown 1,2,4-λ^5-diazaphosphinines **7a–d** are formed in good yields. The special role played by the phosphino residue in this reaction is best expressed in terms of a nucleophilic attack at the alkyne carbon atom (→ **6**), followed by a 1,6-ring closure leading to **7**.



In general, the transition **1** → **7** is characterized by an upfield shift of the ^{31}P-NMR resonance signal, which is especially striking upon methoxy substitution at the phosphorus (cf. Ref. [3] and Table 1). In the ^{13}C-NMR spectra of **7a–d**, the ylidic character of C-5 is indicated by the high-field resonances at δ = 65.1–104.0 ($^1J_{PC}$ = 95.6–131.8 Hz) (**7A** ↔ **7B**);[8] C-3 is clearly identifiable by the unmistakable broadening of its signal in the ^{1}H-decoupled ^{13}C-NMR spectrum (small ^3J(H,C)-coupling). That the six-membered ring is no longer planar is immediately evident from the presence of two magnetically different P-methoxy groups for **7a** and **7b**, only one of which, however, shows a distinct ^3J(P,H) coupling in the ^{1}H-NMR spectrum (see Table 1).

The crystal structure analysis carried out on **7c** shows that the heterocycle has a distorted boat conformation[9] (Fig. 1); λ^5-phosphinines without further heteroatoms, on the other hand, are planar.[10]

The deviations from the least squares plane for the atoms N2, C3, C5, C6 are −0.038, 0.040, 0.044 and −0.047 Å, respectively. The angles between this plane and the P–C3–C5 and N1–N2–C6 planes are 22.67 and 10.77°, respectively.

7d: 61%, m.p. = 176 °C (decomp. yellow). ^{1}H NMR: δ = 1.16 (s, *t*Bu), 7.0–8.1 (m, arene-H); ^{13}C NMR: δ = 29.9 [q, ^1J(C,H) = 127.6 Hz, C(CH_3)$_3$], 41.7 [d, ^2J(P,C) = 17.9 Hz, C(CH_3)$_3$], 74.8 (d, ^1J(P,C) = 95.6 Hz, C-5), 121.5–139.8 (m, arene-C, C-3), 154.3 (s, C-6), 192.8, 192.9 (each s, CO); ^{31}P NMR: δ = −32.0

[a] 90-MHz ^{1}H-, 50.32-MHz ^{13}C-, and 80.8-MHz ^{31}P-NMR spectra in CD-Cl_3 TMS (int.) or 85% H_3PO_4 (ext.). [b] Note that only one P–OMe residue shows the expected $^3J_{PH}$ coupling.

The ylidic character of **7c** is immediately recognizable from the distances between the phosphorus atom and its neighboring carbon atoms P–C3 1.811(4), P–C5 1.744(4) Å; The P–C5 distance corresponds almost exactly to the P–C distance

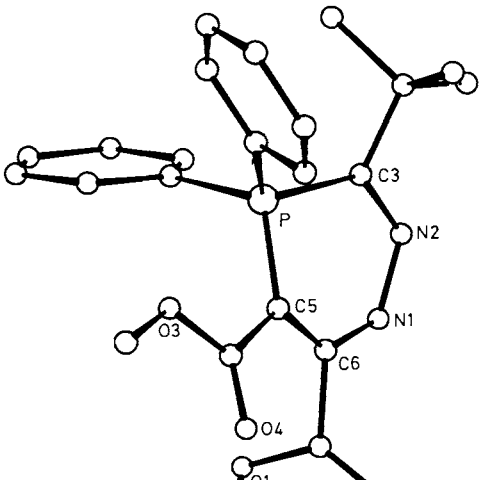

Fig. 1. Structure of **7c** in the crystal [11]. Selected bond lengths [Å] and angles [°]: P-C3 1.811(4), P-C5 1.744(4), N1-N2 1.373(5), N1-C6 1.321(5), N2-C3 1.284(5), C5-C6 1.373(5); C3-P-C5 99.3(2), N2-N1-C6 118.9(3), N1-N2-C3 126.5(3), P-C3-N2 120.9(3), P-C5-C6 116.3(3), N1-C6-C5 129.6(4).

in acceptor-substituted 1λ^5,3λ^5-diphosphetes.[2b] Shortening of the C5-C6 bond [1.373(5) Å] and lengthening of the N1–C6 distance are consistent with an electron distribution as in **7B**. In comparison to the case in λ^5-phosphinines,[10] the internal angle at the phosphorus atom is compressed, while the internal angles at N2 and N6 are markedly widened.

Experimental

7a–d: a solution of **1a** and **1b** (2.5 mmol) in diethylether/dichloromethane 1/1 (100 mL) was treated with stirring at −40 °C with 2.5 mmol of **5a** or **5b**, and the respective mixture allowed to thaw, prior to evaporating down at 25 °C/10^{-1} mbar. Subsequent chromatography on 40 g of silica gel with the same solvent mixture furnished, after evaporation to dryness and cooling to −30 °C, **7b** or **7d**; in the case of **7a** and **7c**, chromatographic purification was unnecessary.

trans-1,2-Difluoro-1,2-bis[(tetracarbonyl)cobaltio]-ethene, a Difluoroethyne Complex with μ_2-η^1-η^1-Coordination**

By *Dieter Lentz** and *Dagmar Preugschat*

So far, only a few complexes containing dihaloethyne ligands have been described in the literature.[1,2] We recently reported the synthesis of the first difluoroethyne complex $[Cp^*CoFe_3(CO)_9(\mu_4\text{-}\eta^2\text{-}FC{\equiv}CF)]$[2] by C–C linkage of two fluoromethylidine ligands. Since free difluoroethyne is extremely unstable[3] and thus inaccessible for direct reactions, we searched for further possibilities of synthesizing difluoroethyne complexes via an indirect route.

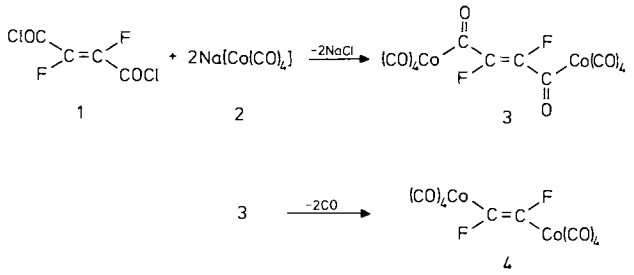
[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. *J. Fuchs* for his help with the crystal structure investigations.

Reaction of difluorofumaric dichloride **1** or difluoromaleic dichloride with the tetracarbonylcobaltate **2** seemed a promising strategy. First of all, reactions of difluoromalonic dichloride with $[Co(CO)_4]^{\ominus}$ and $[Mn(CO)_5]^{\ominus}$ enabled a systematic synthesis of difluoromethylene-bridged metal complexes,[4] and secondly the alkynecobalt complexes $[Co_2(CO)_6(\mu_2\text{-}\eta^2\text{-}RC{\equiv}CR)]$ are very stable.[5]

By reaction of **2** with difluorofumaric dichloride **1**, we have now been able to synthesize the difluoroethyne complex **4**,[6] in which the difluoroethyne ligand bridges two tetracarbonylcobalt fragments in the very unusual μ_2-η^1-η^1 coordination. The formation of **4** presumably proceeds via the bis(acyl)-complex **3**.



The structure of **4** is confirmed by its spectroscopic data[6] and a crystal structure analysis (Fig. 1).[7] Each of the two cobalt atoms is trigonal-bipyramidally coordinated by four carbonyl ligands and the μ_2-η^1-η^1-difluoroethyne ligand, which occupies the axial position. The distance from the

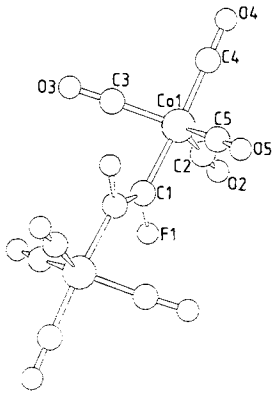


Fig. 1. Structure of **4** in the crystal. Selected bond lengths [pm] and angles [°]: Co1-C1 197.3(3), C1-F1 138.3(3), Co1-C2 181.8(3), Co1-C3 179.1(3), Co1-C4 181.4(3), Co1-C5 180.6(3), C1-C1 132.3(5), C-O 112.4(4)–113.2(4); C1-Co1-C2 91.3(1), C3-Co1-C5 125.9(2), C1-Co1-C3 82.6(1), C4-Co1-C5 93.7(1), C1-Co1-C4 173.5(1), C1-Co1-C5 83.7(1), C2-Co1-C3 116.3(2), C2-Co1-C4 95.2(1), C2-Co1-C5 116.1(1), C3-Co1-C4 94.3(1), Co1-C1-F1 115.5(2).

cobalt atom to the carbon atom C1 of the difluoroethyne ligand corresponds to a cobalt–carbon σ-bond. The bond angle (F–C1–Co) at the carbon atom is 115.5(2)°, so that the carbon atom is largely sp^2 hybridized. The atoms of the difluoroethene ligand and the two cobalt atoms lie in a plane (max. deviation 0.3 pm) and the C–C distance (132.3(5) pm) corresponds to that of a C=C double bond. Consequently, **4** is best described as 1,2-difluoro-1,2-dicobaltio-ethene. There are very few examples for such a μ_2-η^1-η^1-coordination of an ethyne to transition metals. Thus, *Wilkinson* et al. obtained a compound of the composition $K_6[Co_2(CN)_{10}C_2H_2]\cdot 4\,H_2O$, for which they formulated a *trans*-dimetallioethene structure on the basis of IR spectroscopic data.[8] A crystal structure analysis of the derivative $K_6[Co_2(CN)_{10}(H_3COOC\text{-}C{\equiv}C\text{-}COOCH_3)]\cdot 6\,H_2O$ has already been reported,[9] which confirms the μ_2-η^1-η^1-*trans*-configuration. $[(CH_3)_3PAu(CF_3)C{=}C(CF_3)Au(CF_3)_2\text{-}P(CH_3)_3]$[10] is likewise *trans*-configurated. However, in further structurally characterized examples such as $[(C_6H_5)_3PAu(F_3C)C{=}C(CF_3)AuP(C_6H_5)_3]$[11], $[\{(C_6H_5)_3P\}_2(NO)_2Ir_2(\mu_2\text{-}\eta^1\text{-}\eta^1\text{-}F_3C\text{-}C{\equiv}C\text{-}CF_3)_2]$[12], $[(\eta\text{-}C_5H_5)_2Rh_2(CO)_2(\mu_2\text{-}\eta^1\text{-}\eta^1\text{-}F_3C{\equiv}C\text{-}CF_3)]$[13], $[(\eta\text{-}C_5H_5)_2Rh_2(CO)(C_9H_9N)(\mu_2\text{-}\eta^1\text{-}\eta^1\text{-}F_3C{\equiv}C\text{-}CF_3)]$[14] and $[Re_2(CO)_{10}(\mu_2\text{-}\eta^1\text{-}\eta^1\text{-}C_4O_2)]$[15] a *cis*-configuration is observed.

The synthesis via difluoromaleic dichloride has thus far failed. On attempting to prepare the difluoromaleic dichloride, only difluoromaleic anhydride was obtained. This is not particularly surprising in view of the extremely questionable existence of maleic dichloride.[16] A substance described on several occasions as dichloromaleic dichloride has proven to be a γ-lactone of tetrachloro-4-hydroxybut-2-enic acid.[17]

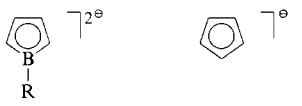
Borole Dianions: Metalation of 1-(Dialkylamino)-2,5-dihydro-1*H*-boroles and the Structure of $Li_2(C_4H_4BNEt_2) \cdot TMEDA$ **

By *Gerhard E. Herberich,* Martin Hostalek, Ralf Laven,* and *Roland Boese*

Borole dianions (dihydroborolediides) are,[1] as boracarbocyclic 6π-electron systems, isoelectronic with the cyclopentadienide ion (Scheme 1). We report here on the synthesis of some dilithium 1-(dialkylamino)dihydroborolediides and on the structure of one of their TMEDA adducts.



Scheme 1.

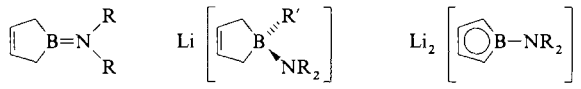
[**] Derivatives of Borole, Part 15. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 14: G. E. Herberich, I. Hausmann, B. Hessner, M. Negele, *J. Organomet. Chem. 362* (1989) 259.

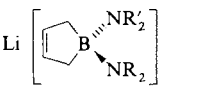
As a rule 1-(Dialkylamino)-2,5-dihydro-1*H*-boroles **1**[2] are quaternized by organolithium compounds LiR′ to borates **2**.[2] Borate formation can be suppressed only by steric hindrance at the boron atom and at the basic center of LiR′: **1c** reacts with Li*t*Bu to give the lithiation product **3c**.[1b]



1 **2** **3**

a, R = Me; **b**, R = Et; **c**, R = *i*Pr

Quaternization usually also occurs with lithium amides: from **1a**/$LiNMe_2$, **1b**/$LiNEt_2$ and from **1a**/$LiNiPr_2$ or **1c**/$LiNMe_2$ the corresponding bis(dialkylamido)borates **4a, b, d** are formed, recognizable in the NMR experiment by



4a, R = R′ = Me
4b, R = R′ = Et
4c, R = R′ = *i*Pr
4d, R = Me, R′ = *i*Pr

a shift of the ^{11}B signal from $\delta \approx 51$[2] to $\delta \approx 5$.[3] The oily borate **4a** was converted with tetramethylethylenediamine (TMEDA) into a crystalline adduct **5**.[4] At 60 °C, borate formation is reversible; metalation (25 h) of **1a, b** leads to formation of the dihydroborolediides **3a, b** with $\delta(^{11}B) = 25-27$.[3] In the case of **1c**/$LiNiPr_2$ the formation of the borate **4c** is blocked because of double steric hindrance, and at 60 °C **1c** isomerizes very slowly (7 d)[3] to the known 1-(diisopropylamino)-4,5-dihydro-1*H*-borole.[2]

With the sterically demanding lithium 2,2,6,6-tetramethylpiperidide (LiTMP), borate formation does not take place. Here, the metalation of **1a, b** to **3a, b** already occurs at room temperature, and the troublesome problems of ether cleavage do not arise. In contrast, **1c** does not react with LiTMP at 20 °C.

$Li_2(C_4H_4BNR_2) \cdot TMEDA$
6a, R = Me
6b, R = Et
6c, R = *i*Pr

The lithium derivates **3a–c** are powdery solids which form well crystallized derivatives **6a–c** with TMEDA. The determination of the structure of a dihydroborolediide was possible for the first time with the diethylamino compound **6** (Fig. 1).[5, 6]

6b is a centrosymmetric dimer containing a phane-like $(C_4H_4BNEt_2 \cdot Li)_2$ ring and two external Li(TMEDA) groups. Both Li atoms of a dihydroborolediide unit are pentahapto bound, and the higher coordinated Li1 atom of the Li(TMEDA) group is expectedly weaker than the Li2 atom of the Li–NEt_2 group. The π-coordination of the Li atom and the formation of a dimer with the help of N-donor atoms of the metalated ring are known structural patterns in the case of organolithium compounds.[7]

The C_4B ring is planar (maximum deviation 0.5 pm for the B atom). The bond pattern in the ring is that of a delocalized 6π-electron system and impressively reflects the occupation of the borole LUMO (B–C1, B–C4 and C2–C3 shortened,

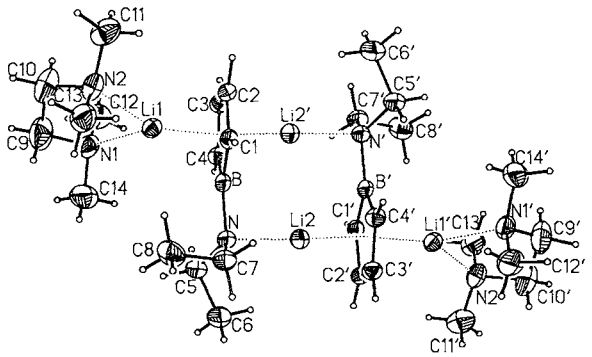


Fig. 1. Structure of **6** in the crystal. Selected bond lengths [pm]: Li1-C1 227.2(4), Li1-C2 218.4(4), Li1-C3 217.1(4), Li1-C4 226.9(3), Li1-B 234.1(3), Li1-C_4B-ring 186.9, Li2'-C1 220.2(4), Li2'-C2 212.3(3), Li2'-C3 213.2(4), Li2'-C4 219.5(4), Li2'-B 227.5(4), Li2'-C_4B-ring 179.5, Li1-N1 215.0(4), Li1-N2 216.9(3), Li2-N 202.8(3); in the C_4B-ring: B-C1 152.2(3), C1-C2 143.4(3), C2-C3 139.9(3), C3-C4 144.0(3), C4-B 152.0(3); B-N 151.5(3).

C1–C2 and C3–C4 lengthened). The π-interaction with the exocyclic amino group is also greatly weakened: the B–N bond (151.5 pm) is about 10 pm longer than that typically found in (dialkylamino)boranes (141–142 pm[8]), and the amino group is no longer planar (sum of angles at the N atom 344.7° vs. 328.5° in the case of the regular tetrahedron).

Dihydroborolediides are interesting synthetic building blocks, as has already been demonstrated in the case of the diisopropylamino compound **3c**.[9] However, in the numerous transition metal complexes of **3c**, substitution at the B atom has thus far proven impossible.[9b] We shall shortly show elsewhere that this limitation does not arise in the case of complexes of **3a, b**:[3b, 10] borole complexes with quite different substituents at the B atom can be prepared via the 1-(dimethylamino)- and 1-(diethylamino)borole complexes by substitution reactions.

Experimental

3a: a solution of LiTMP [11] (18.0 g, 122 mmol) in THF (60 mL) was treated at −78 °C with 6.4 g (59 mmol) of **1a** [2] and the mixture stirred for 12 h at 20 °C. Concentration of the solution, addition of 200 mL of pentane and double crystallization at −78 °C furnished colorless needles of **3a** · THF, which on drying in vacuo (10^{-6} bar) yielded 5.0 g (70%) of powdery **3a**. M.p. >250 °C, extremely sensitive towards air and moisture [12]. ^{1}H NMR (80 MHz, [D$_8$]THF, int. TMS): δ = 5.35 (m; H-3,4), 4.03 (m; H-2,5), $N = {}^3J_{2,3} + {}^4J_{2,4}$ = 7.4 Hz, 2.27 (s; NMe_2); ^{11}B NMR (32.08 MHz, [D$_8$]THF, ext. $BF_3 \cdot Et_2O$): δ = 27 (halfwidth 280 Hz); ^{13}C NMR (67.88 MHz, 213 K, [D$_8$]THF, int. TMS): δ = 98.9 (d, J = 151 Hz; C3,4), 82.8 (d, J = 140 Hz; C2,5), 44.5 (q, J = 129 Hz; NMe_2).

3b: synthesis as in the case of **3a** afforded a colorless powder of **3b** (71%). M.p. 126 °C, no decomposition up to 250 °C, extremely sensitive towards air and water [12].—^{1}H NMR (80 MHz, [D$_8$]THF, int. TMS): δ = 5.37 (m; H-3,4), 3.95 (m; H-2,5), $N = {}^3J_{2,3} + {}^4J_{2,4}$ = 7.3 Hz, 2.70 (q, J = 7.1 Hz; 2 CH_2), 0.96 (t, J = 7.1 Hz; 2 Me); ^{11}B NMR (32.08 MHz, [D$_8$]THF, ext. $BF_3 \cdot Et_2O$): δ = 25 (halfwidth, 400 Hz).

4a: $LiNMe_2$ (1.0 g, 20 mmol) was treated at 0 °C with 2.1 g (19.3 mmol) of **1a** [2] and the mixture stirred for 3 h at 20 °C. Removal of the solvent in vacuo (10^{-2} bar) furnished **4a** as a highly viscous oil (97%), which could not be brought to crystallization from, e.g., Et_2O/pentane at −70 °C; soluble in THF, insoluble in pentane.—NMR data: [3b]; see also **5** [13].

5: a solution of **4a** (1.5 g, 9.4 mmol) in THF (20 mL) was treated with 1.2 g (10 mmol) of TMEDA. Concentration of the solution, layering with pentane, and cooling to −78 °C furnished 2.4 g (93%) of white crystals of **5**. M.p. 53 °C, decomp. 110 °C, sensitive towards air and moisture [12]. ^{1}H NMR (80 MHz, [D$_8$]THF, int. TMS): δ = 5.55 (m, H-3,4), 0.92 (s br; H-2,5), 2.33 (s, 2 NCH_2), 2.18 (s; 2 + 2 NMe_2); ^{11}B NMR (32.08 Mhz, [D$_8$]THF, ext. $BF_3 \cdot Et_2O$): δ = 5.0 (halfwidth, 49 Hz); ^{13}C NMR (67.88 MHz, 300 K, [D$_8$]THF, int. TMS): δ = 134.0 (d, J = 153 Hz; C3,4), 26.3 (t, J = 132 Hz; C2,5), 44.5 (q, J = 133 Hz; 2 NMe_2); TMEDA: 58.3 (t, J = 129 Hz; 2 NCH_2), 46.1 (q, J = 134 Hz; 2 NMe_2).

6a: a solution of **3a** (1.0 g, 8.3 mmol) in THF (30 mL) was treated with 1.2 g (10 mmol) of TMEDA. Evaporation of the reaction solution to a half of its volume and crystallization at −78 °C furnished 1.9 g (97%) of clustered crystals of **6a**. M.p. >250 °C, extremely sensitive towards air and moisture [12].—NMR data: [3b, 13].

6b: synthesis as in the case of **6a** yielded colorless rectangular crystals of **6b** (94%). M.p. 166 °C, decomp. 210 °C (black coloration), extremely sensitive towards air and moisture [12].—NMR data: [3b, 13].

6c: synthesis from **3c** [1b] as in the case of **6a** afforded colorless rectangular crystals of **6c** (97%). M.p. 193 °C, no decomposition up to 250 °C, extremely sensitive towards air and moisture [12].—NMR data: [3b, 13].

[**] Hydrocarbon-Bridged Complexes, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Professor Dr. *W. Herrmann* and Dr. *E. Herdtweck*, Technische Universität München, for valuable discussions.—Part 15: [18].

metal atoms,[1] dinuclear complexes with a single carbon atom between two metal atoms appear especially interesting. To our knowledge the dimetalla-allenes **1** (L = tetraphenylporphyrinate,[2] phthalocyaninate[3]) and the C-metalated carbyne complex **2**[4] have thus far been isolated and structurally characterized.

$[LFe=C=FeL]$ **1** $[(Me_3CO)_3W\equiv C\text{-}Ru(CO)_2Cp]$ **2**

$[L_2Pt\{\text{-}C\equiv W(OR)_3\}_2]$ **3** $[(OC)_4Fe=Si=Fe(CO)_4]\cdot 2\,HMPT$ **4**

$[L(OC)_2Mn=E=Mn(CO)_2L]$ **5**

Pt–C≡W compounds, e.g. **3**, have been mentioned as intermediates.[5] μ-Carbido complexes are of interest as model systems for surface carbides.[1,4] Of the compounds of the homologues of carbon, **4**[6] and **5** (E = Ge,[7] Sn,[8] Pb[9]; L = C_5H_5 or C_5Me_5) are known. In the course of our studies on the directed synthesis of hydrocarbon-bridged complexes using carbonylmetalates[10] we found a simple entry to heterometallic μ_2-carbido complexes. Reaction of the dichlorocarbene complex **6**[11] with pentacarbonylrhenate(-*I*) affords the trinuclear compound **7** with 1,3-dimetalla-allene system[12] (TPP = tetraphenylporphyrinate).

$$[(TPP)Fe=CCl_2] \xrightarrow[CO,\ 2\,Cl^{\ominus}]{2\,Re(CO)_5^{\ominus}} [(TPP)Fe=C=Re(CO)_4Re(CO)_5]$$

6 **7**

Compound **7**, which is moderately soluble in dichloromethane and stable in the solid state, is extremely thermostable (decomposition above 260 °C). In the ^{13}C-NMR spectrum of **7**, the "carbide" C-atom is shifted upfield by about $\Delta\delta = 13$ compared to that of **6**.

Upon adding *n*-hexane to a CH_2Cl_2 solution of **7**, shiny deep-violet crystals suitable for an X-ray structure analysis were obtained. The structure of **7** in the crystal (Fig. 1) shows an almost linear Fe–C–Re grouping (172.8(4)°). The Fe–C distance (1.605(13) Å) is very short; it is shorter than in **1**, L = tetraphenylporphyrinate (1.67 Å),[2b] and also shorter than in carbynemetal complexes.[13] The Re–C(carbide) bond in **7** (1.957(12) Å) is somewhat longer than the axial Re–C(carbene) bond of the carbene complex **8** (1.85(3) Å)[14] and of about the same length as found in an allylidene-rhenium complex.[15] In **9**, Ru–C and C≡W distances of 2.09(2) and 1.75(2) Å, respectively, have been established.[4] The Re–Re bond in **7** is of a similar length to that found in the Fischer carbene complexes **10**[14] (3.052(1) Å) and **11**[14] (3.091(2) Å) and in $Re_2(CO)_{10}$ (3.041(1) Å).[16]

$[\{Ph_3Si(EtO)C=\}(OC)_4Re\text{-}Re(CO)_4\{=C(OEt)SiPh_3\}]$ **8**

$[Cp(OC)_2Ru\text{-}C\equiv W(OCMe_3)_3]$ **9** $[Re_2(CO)_9\{C(OR)SiPh_3\}]$ **10**

$[Re_2(CO)_8\{C(OEt)SiPh_3\}_2]$ **11**

Figure 1b shows quite impressively the twisting of the porphyrin ligand in **7**.

The equatorial CO ligands of the two $Re(CO)_4$ groups are staggered and as in $Re_2(CO)_{10}$,[16] **12**,[17] and **13**,[18] are bent towards each other.

$[(OC)_5Re\text{–}CH_2CH_2\text{–}Re(CO)_5]$ **12**

$[(OC)_5Re\text{–}C\equiv C\text{–}Re(CO)_5]$ **13**

Experimental

All operations were carried out in anhydrous solvent under nitrogen.

7: A clear orange-colored solution (20 °C) of $Na[Re(CO)_5]$ (prepared from 185 mg (0.285 mmol) of $Re_2(CO)_{10}$ and sodium amalgam in 5 mL of THF) was added with stirring to the violet suspension of **6** [11] (150.3 mg, 0.2 mmol) in 10 mL of THF (−78 °C). After 1 h at −78 °C, the mixture was warmed to 30 °C, stirred for a further 60 min, and the solvent removed in vacuo. The residue was taken up in CH_2Cl_2, centrifuged, and the solvent again removed in vacuo. Subsequent washing of the residue with hexane (three times) and cold MeOH (once) followed by drying in vacuo furnished **7** as a reddish-brown powder. *Yield*: 135 mg (51%). Crystals from CH_2Cl_2/hexane.

[12] Compound **6** was also allowed to react with the carbonylmetalates $Mn(CO)_5^{\ominus}$, $Fe(CO)_4^{2\ominus}$ and $Cr(CO)_5^{2\ominus}$. The manganese compound can, according to the IR spectrum [νCO [cm^{-1}] (CH_2Cl_2): 2095(m), 2033(s), 2004(s), 1970(m)], be assigned a structure analogous to **7**. Analytical and IR data of the products obtained from **6** and $Fe(CO)_4^{2\ominus}$ and $Cr(CO)_5^{2\ominus}$ are consistent with the formation of (TPP)Fe=C=$Fe(CO)_4$ and (TPP)Fe=C=$Cr(CO)_5$, respectively.

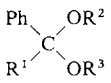
Dependence of Anomeric Stabilization on Structure in Acetals**

By *Hans-Dieter Beckhaus, Barbara Dogan, Sergej Verevkin, Johannes Hädrich*, and *Christoph Rüchardt**

Dedicated to Paul von Ragué Schleyer on the occasion of his 60th birthday

The anomeric effect[1] is a well known example of a synergetic interaction of geminal substituents on a saturated carbon atom. According to this concept the two alkoxy groups in acetals **1** contribute more to the stabilization of the molecule than would correspond to a purely additive effect.[1c] Although this extra stabilization is thought to be responsible for a number of phenomena, e.g. the conformational preference and reactivity of glucosides,[1e] very few quantitative experimental data are available[2, 3] on the extent of anomeric stabilization and its variation by substituents on the anomeric carbon atom. The generally accepted model[1d] of "negative hyperconjugation" suggests that alkyl and aryl residues on the central C-atom could alter the anomeric stabilization.



1a: R^1 = H, R^2 = R^3 = Me
1b: R^1 = R^2 = R^3 = Me
1c: R^1 = H, R^2, R^3 = $-CH_2CH_2-$
1d: R^1 = Me, R^2, R^3 = $-CH_2CH_2-$
1e: R^1 = H, R^2, R^3 = $-CH_2CMe_2CH_2-$
1f: R^1 = Me, R^2, R^3 = $-CH_2CMe_2CH_2-$

We report here on thermochemical measurements with the aromatic acetals **1a–f**. The standard enthalpies of formation ΔH_f^0 (g) were obtained from the enthalpies of combustion ΔH_c (l) and vaporization ΔH_v[4] (Table 1). The results of earlier measurements on aliphatic acetals[3] were used in the calculations.

We determined the extra, anomeric stabilization by comparison of the increments in enthalpy of formation of alkyl and alkoxy groups with acetal groups. That is, we did not use the enthalpy of formation of an individual compound in the otherwise usual process of the isodesmic reaction,[5] but group increments,[2] which were calculated from several homologous structures. The result then has a broader experimental basis. We used the known increments ΔH_{alkyl} for alkanes[6a] and alkylbenzenes[6b] (Table 2) and determined the remaining increments according to the least squares method. Firstly, the increments for the alkoxy groups ΔH_{oxy} were calculated from the ΔH_f^0 (g) values of dialkyl ethers.[7] The division into the ether group O[2C] and the groups with C as key atom and an O atom as neighbor CH_2[O,C], CH[O,2C], and C[O,3C] was done by defining the methyl group: ΔH_f^0 (g) of CH_3[O] = ΔH_f^0 (g) of CH_3[C] = −10.05 kcal mol^{-1}. Finally, the increments for the alkyl groups with two

[a] Group increments, see Table 2. [b] Ring strain (7.5 kcal mol^{-1} in the case of dioxacyclopentane, 2.5 in the case of all other oxacycles) and repulsion of geminal methyl groups at the quaternary C-atom (2.0 kcal mol^{-1}) were taken into consideration as additive terms. [c] $\Delta\Delta H = \Delta H_{f,calcd} - \Delta H_f^0(g)$. [d] $\Delta H_m = 4.44$.

O-atoms as neighbors (ΔH_{dioxy}) were calculated from the enthalpies of formation of the acetals (Table 1).[8] The goodness of fit is seen from the small differences $\Delta\Delta H$ (see Table 1) between the calculated value $\Delta H_{f,calcd}^0$, i.e. the sum of the increments including the strain enthalpy, and $\Delta H_f^0(g)$.

The increments ΔH_{oxy} for α-CH_2, α-CH and α-C atoms in ethers are clearly smaller than the corresponding ΔH_{alkyl} values in alkanes (Table 2). Since we have allotted the same

Table 2. Increments in enthalpy of formation [kcal mol^{-1}] for alkyl (ΔH_{alkyl}), alkoxy (ΔH_{oxy}) and acetal groups (ΔH_{dioxy}) [8].

	ΔH_{alkyl} [6]	ΔH_{oxy} [7]	ΔH_{dioxy} aliphatic [8]		ΔH_{dioxy} aromatic [b]
CH_3	[C] −10.05	[O] ≡ −10.05		–	–
CH_2	[2C] −5.13	[O,C] −8.0	[2O] −14.1	–	
CH	[3C] −2.16	[O,2C] −6.3	[2O, C] −15.6	[2O, C_{Ph}]	−18.9
C	[4C] −0.30	[O,3C] −4.7	[2O, 2C] −17.9	[2O, C, C_{Ph}]	−21.2

values to the methyl groups CH_3[O] as to the CH_3[C] groups, it follows that C atoms are more strongly stabilized by a neighboring C-atom. The extent of this stabilization corresponds to the differences $\Delta H_{oxy} - \Delta H_{alkyl}$ and $\Delta H_{dioxy} - \Delta H_{oxy}$ (Table 3). In ethers, this oxygen effect is similar for all groups ($\Delta H_{oxy} - \Delta H_{alkyl} = -2.8$ to -4.4 kcal mol^{-1}). The stabilization on going from the ether to the acetal, on the other hand, strongly depends on the degree of substitution of the C-atom; $\Delta H_{dioxy} - \Delta H_{oxy}$ varies from -6.1 to -16.5 kcal mol^{-1}.

The extra, anomeric stabilization $\Delta\Delta H_{anomer}$, i.e. the additional energy gained on introduction of the second oxygen atom in comparison to the first is given by the difference $(\Delta H_{dioxy} - \Delta H_{oxy}) - (\Delta H_{oxy} - \Delta H_{alkyl})$ (Table 3). Aliphatic acetals containing the C[2O,2C] group are stabilized by $\Delta\Delta H_{anomer} = -8.8$, aliphatic acetals containing the CH[2O,C] group by -5.1, and formaldehyde acetals by only -3.3 kcal mol^{-1}. The anomeric effect increases by 2–4 kcal mol^{-1} on substitution of the anomeric carbon atom by an alkyl. On replacing an alkyl group by a phenyl group with the ability to undergo π conjugation the molecule is stabilized by a further 3.3 kcal mol^{-1}. The acetal of an alkyl phenyl ketone containing the C[2O,C,C_{ph}] group exhibits

[e] To differentiate the pure aliphatic acetals with $CH_y[2O,C_{2-y}]$ groups from aromatic compounds with $CH_y[2O,C_{1-y}C_{Ph}]$ groups.

the highest anomeric stabilization (-12.1 kcal mol^{-1}) detected so far. Current investigations should show whether a further phenyl group (in benzophenone acetals) would increase the anomeric effect further, and whether an analogous phenyl effect is effective in benzyl ethers.[9]

[7] The $\Delta H_f^0(g)$ values [3] of the following alkyl ethers enter into the calculation of the group increments ΔH_{oxy} (Table 2): methoxymethane, 1-methoxyethane, 1-methoxypropane, 1-methoxybutane, 2-methoxypropane, 2-methoxy-2-methylpropane (1.4 kcal mol^{-1}), 1-ethoxyethane, 1-ethoxypropane, di-*n*-propyl ether, diisopropyl ether (0.5), di-*n*-butyl ether, diisobutylether (0.5) and di-*tert*-butyl ether (6.6). The respective steric strains taken into account in the calculations are quoted in brackets. They were determined from the structurally analogous alkanes, obtained by replacing O by CH_2. O[2C] = −23.8 kcal mol^{-1}.

[8] The group increments for aliphatic acetals in Table 2 were derived from 1,3-dioxolane ($\Delta H_f^0(g) = -71.10$ kcal mol^{-1}), 1,3-dioxane (−80.86), 1,3,5-trioxacyclohexane (−111.32), 1,3,5,7-tetraoxacyclooctane (−148.24), 1,3,5,7,9-pentaoxacyclodecane (−186.38), 2-methoxytetrahydropyran (−95.50), dimethoxymethane (−83.27), 1,1-dimethoxyethane (−93.26), 2,2-dimethoxypropane (−101.89), diethoxymethane (−99.14), 1,1-diethoxyethane (−108.39), 2,2-diethoxypropane (−121.08), and dibutoxymethane (−119.81) [3].

[9] $\Delta H_f^0(g)$ values for alkyl benzyl and dibenzyl ethers have not yet been listed [3].

First Coupling of a Metal Atom with Four Ethene Molecules to give a Metallaspiroalkane**

By *Klaus Jonas,** *Günter Burkart, Christian Häselhoff, Peter Betz,* and *Carl Krüger*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

Up to now, only a few examples of transition metal complexes with more than two ethene ligands are known. Tris(ethene)nickel(0),[1] the first homoleptic transition-metal-ethene-complex, was reported in 1973, and two years later *Stone* et al. described the analogous platinum compound **2**.[2] There are only the iridium compound **3**[3] and the alkali metal-transition metal complexes **4** and **5** containing one more ethene ligand. **4** and **5** are accessible from cobaltocene and ferrocene, respectively, by reductive five-membered ring ligand removal[4].

$Ni(C_2H_4)_3$ $Pt(C_2H_4)_3$ $ClIr(C_2H_4)_4$

1 **2** **3**

$M_A[Co(C_2H_4)_4]$, $Li_2[Fe(C_2H_4)_4]$

4, M_A = Li,K **5**

First findings on the reactivity of ethene towards low-valent manganese have already been briefly reported in a review article.[4] In the case of the reaction of manganese(II) cyclopentadienide (Cp_2Mn) with naphthalenepotassium (molecular ratio 1:3) in ethene-saturated tetrahydrofuran (THF) mentioned therein, we have now found that exactly 3 moles of C_2H_4 are taken up per mole of Mn at $-65\,^{\circ}C$. All the Cp precipitates as KCp, and the markedly thermolabile manganese compound **6**, which must contain potassium and manganese in the molar ratio 1:1, remains in solution [Eq. (a)]. As yet we have been unable to isolate and fully characterize **6**. Consequently, it is also still an open question whether the manganese in **6** is present as manganese(-I) (with three π-bound ethene molecules) or whether the oxidation state of the manganese increases with uptake of the ethene (**6** as a metallacyclopentane[4, 5] or as a hydridovinyl compound[6]).

$$Cp_2Mn + 3\,K[C_{10}H_8] + 3\,C_2H_4 \xrightarrow[-65\,^{\circ}C]{THF} 2\,KCp\downarrow + x\,C_{10}H_8 + K[C_6H_{12}Mn(C_{10}H_8)_{3-x}] \quad (a)$$

6

When Cp_2Mn is reduced with naphthalenelithium (again in the ratio 1:3) and the ethene is replaced by trimethylphosphane [Eq. (b)], then, after substitution of the tetrahydrofuran bound to lithium by tetramethylethylenediamine (TMEDA), the novel manganese(-I) compound **7**, which is stable at room temperature, can be isolated (yield: 65%).

According to an X-ray structure analysis of the diamagnetic complex **7**,[7] three coordination sites of the pentacoordinated manganese are occupied by PMe_3 ligands, while the other two are occupied by an η^4-coordinated naphthalene molecule.

$$Cp_2Mn + 3\,Li[C_{10}H_8] + 3\,PMe_3 \xrightarrow[78\,^{\circ}C\ldots+20\,^{\circ}C]{THF}$$

$$2\,LiCp + 2\,C_{10}H_8 + [Li(thf)_x][Mn(\eta^4\text{-}C_{10}H_8)(PMe_3)_3]$$

$$\downarrow TMEDA \quad THF \quad (b)$$

$$[Li(tmeda)_2][Mn(\eta^4\text{-}C_{10}H_8)(PMe_3)_3]$$

7

We intended to convert complex **6**, which is obtained in THF solution according to equation (a), to a more thermally stable manganate. Decisive for the success of the synthesis of the novel potassium manganese compound **8** from **6**, ethene and pyridine [Eq. (c)] was the observation that the color of the ethene-saturated THF solution of **6** changes from red to brownish-yellow on warming to $-35\,^{\circ}C$. Orange **8** is isolated if pyridine is added and the solution subsequently warmed to room temperature (yield: 68%).

$$\mathbf{6}\text{ in THF (ethene)} \xrightarrow[-65\,^{\circ}C\ldots-35\,^{\circ}C]{} \text{brownish-yellow solution} \xrightarrow[-35\,^{\circ}C\ldots+20\,^{\circ}C]{pyridine} [K(py)_2][(py)Mn(C_4H_8)_2] \quad (c)$$

8

In the solid state, **8** contains two crystallographically independent ion pairs. Figure 1 shows both pairs in comparable orientation. With almost identical bond lengths they differ in the orientation of the pyridine ligands, both at the distorted square-pyramidally coordinated manganese atom as well as at the potassium. In the unit cell the latter forms ion pair contacts of unequal length to the butanediyl ligands of adjacent anions (K-C_α 3.09–3.33 Å). Correspondingly, the arrangements of the pyridine ligands bound to potassium (N–K (av) 2.787(3) Å) are not linear; the N–K–N angle is 139.0(1) and 147.0(1)°, respectively. The C–C bond lengths and the angles of the C_4H_8 ligands correspond within the limits of error to the values expected for $C(sp^3)$–$C(sp^3)$ bonds. The average Mn–N distance is 2.354(2) Å, while the average Mn–$C(sp^3)$ distance is 2.128(10) Å.

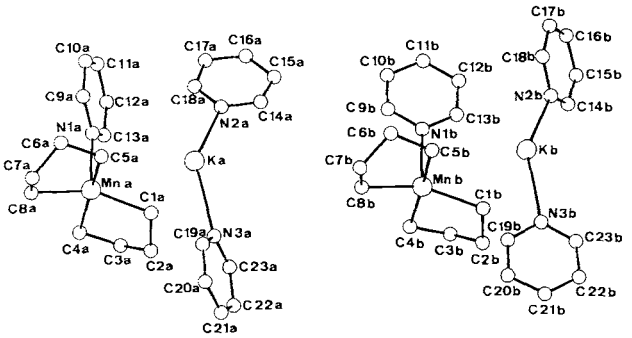

Fig. 1. Structure of **8** in the crystal (two crystallographically independent ion pairs, see text). $P2_1/a$, $a = 17.092(8)$, $b = 15.482(6)$, $c = 17.959(6)$ Å, $\beta = 108.32(3)°$, $V = 4511.4$ Å^3, $T = -173\,^{\circ}C$, $Z = 8$, $\varrho_{calcd} = 1.31$ g cm^{-3}, $\lambda = 0.71069$ Å, $\mu = 7.59$ cm^{-1}, $R = 0.052$, $R_w = 0.045$. 13127 independent reflections, 8538 observed ($I > 2\sigma(I)$), 505 refined parameters, residual electron density 0.51 eÅ^{-3}. Hydrogen atoms localized, but not refined [13].

[+] Crystal structure analysis.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (stipendium for *P.B.*).

The synthesis and elucidation of the structure of **8** confirm once again that ring closure reactions of metal atoms with ethene to give metallacyclopentanes are to be expected, especially of the transition elements on the left of the 8th subgroup in the periodic system.[4, 8] That butanediyl ligands formed by the coupling of two ethene molecules can also occupy bridge positions was first demonstrated with the dinuclear complex $CpV(\mu\text{-}C_4H_8)_2VCp$.[9] Here we report on the new finding in metallacyclic chemistry[10, 11] that the ring closure with ethene leading to formation of a five-membered ring can also take place twice at a metal atom. The result is a metallaspirononane in which the transition metal functions as spiroatom.

Experimental

A THF-solution of naphthalenelithium (prepared from lithium (0.6 g, 86.5 mmol), naphthalene (10.98 g, 85.7 mmol) and THF (150 mL) at −15 °C) was treated with 10 mL (ca. 100 mmol) of PMe_3 at −78 °C and then with 5.28 g (28.5 mmol) of solid Cp_2Mn. After 1.5 hours' stirring at −78 °C, the mixture was allowed to warm to room temperature, and the resulting deep-red solution was evaporated to dryness; uncomplexed naphthalene was then removed by sublimation (20 °C, high vacuum). The residue remaining was taken up in 250 mL of Et_2O, filtered to remove LiCp, and the filtrate treated with 20 mL of TMEDA. On cooling to −30 °C, dark-red crystals of **7** separated out; these were washed with a little ether at −78 °C and dried in vacuo (oil-pump) at 20 °C (yield 12.10 g, 65%). Correct elemental analysis.

8: A solution of naphthalene (18.25 g, 142.4 mmol) in THF (400 mL) was treated with 5.63 g (144.0 mmol) of potassium pellets [12] and the mixture stirred for 1.5 h at −15 °C. Following subsequent cooling to −65 °C, saturation with ethene, and addition of solid Cp_2Mn (8.87 g, 47.9 mmol) the mixture was stirred under an atmosphere of ethene for a further 16 h and allowed to warm to −35 °C within 8 h. After a further 16 h at −78 °C, the KCp that separated out was removed by filtration, the filtrate treated with 15 mL (186.2 mmol) of pyridine and the mixture warmed to 20 °C. After evaporation to dryness, the naphthalene was removed at 20 °C by sublimation in vacuo. The residue was then taken up in 400 mL of ether, filtered, and the filtrate evaporated down in vacuo until **8** began to separate. By warming to 30 °C, **8** was brought into complete solution again and the solution stored at −30 °C. **8** separated as brownish-orange crystals. The crystals were washed with pentane and dried at 20 °C in vacuo (oil-pump). Yield: 14.45 g, 68%; correct elemental analysis.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Supramolekulare Chemie. By *F. Vögtle*. Teubner, Stuttgart 1989. 447 pp., paperback, DM 42.00. – ISBN 3-519-03502-2

This book meets a need arising from the growth of interest in supramolecular chemistry, especially since the award of a Nobel Prize to *Pedersen, Lehn* and *Cram* for their work in the area. The twelve chapters (whose lengths vary from six to 135 pages) describe both older and more recent aspects of supramolecular chemistry. Molecular recognition mechanisms of a purely biochemical nature are not included, nor are membrane and polymer chemistry. Instead the book concentrates mainly on the now almost classical chemistry of the complexation of charged and uncharged guest molecules by host molecules of widely differing structures. In addition, however, it contains separate chapters on liquid crystals and inclusion complexes in the solid state. These are followed by chapters on organic switches, organic conductors, molecular electronics and the light-induced decomposition of water, which indicate future perspectives in supramolecular chemistry.

Following an introductory chapter, host molecules for cations and anions are described (Chapter 2). Here, after a thorough treatment of bipyridyl-containing molecules, Section 2.2 discusses in detail the differences and common features of various open-chain podands, macrocyclic coronands and macrobicyclic cryptands, and describes the wide variety of molecules and applications (e.g., in phase transfer catalysis or in analysis). In the chapter on podands, however, it is surprising that the EDTA molecule is not included. After a detailed treatment of iron-complexing siderophores and descriptions of some cyclophane complexes (metal ion complexes; the neutral complexes of cyclophanes are treated in Chapter 4), this chapter concludes with the catenanes.

The separation of Chapters 3 and 4, on bioinorganic and bioorganic model compounds, from Chapter 2 seems rather arbitrary. In these two chapters host–guest complexes are

grouped together from a different viewpoint (keyword: model enzymes). Beginning with the chemistry of the cyclodextrins, the discussion is concerned mainly with the bonding of neutral guest molecules in host systems such as cyclophanes and cryptophanes, though some ionic guest molecules are also discussed. Chapter 4 ends with an account of the host–guest chemistry of non-macrocyclic molecular pincers.

Chapters 5 and 6 are devoted to inclusion complexes in the solid state and their applications. Chapter 7 describes systems that can function as molecular switches, beginning with those based on azobenzenes. Chapter 8 gives a very detailed treatment of liquid crystal systems, from the physico-chemical fundamentals through LCDs to the latest applications in polymer chemistry. The book concludes with short chapters on surface-active agents, micelles and vesicles (Chapter 9), organic conductors (Chapter 10), molecular electronics (Chapter 11), and light-induced decomposition of water (Chapter 12); these describe new developments, mainly those based on supramolecular chemistry.

The division of such a new field as supramolecular chemistry into separate sub-areas is very difficult, and the author addresses this problem in the preface. Thus, for example, the photoactive cryptands (Chapter 2, Section 2.2.2.6) seem rather out of place in the section on multinuclear host–guest complexes (2.2.2), as also do the catenanes (Section 2.5) in Chapter 2, which is on host–guest chemistry involving cations and anions.

Excellent and detailed descriptions of synthetic methods are given for some host molecules and supramolecular structures, e.g. *Collet*'s synthesis for cryptophanes, *Corey*'s total synthesis of enterobactin, *Schill*'s method for catenanes, and *Sauvage*'s for catenands. Unfortunately the policy of making each chapter self-contained results in some repetition, e.g. the separation of the enantiomers of cyclotriveratrylene derivatives appears on pages 173 and 217.

Last but not least, thanks to the 48 pages of literature references (up to 1988) the book provides a good guide to published work in many different areas of supramolecular chemistry, especially in the author's own fields of research. However, the provision of references varies greatly between individual topics. In Section 2.2 the introduction alone has 94 references, whereas there is only one reference for the whole of Chapter 6. The collecting together of all the references at the end of the book is a good feature. However, it does not entirely eliminate repeated searching, since in each chapter the references begin again with [1].

Whereas most of the sections are written in such a way that a knowledge at undergraduate level is enough to understand them, Section 2.3 goes into great depth, and Table 1 contains many abbreviations which are incomprehensible without a familiarity with the original literature. The book contains few spelling mistakes, although there are some which occur repeatedly (e.g. *Allcook* instead of *Allcock*). On page 191 the impression is given that *Whitlock* did not begin his researches until after 1985. The modern German names Benzen and Toluen are used; on the other hand, the pressure unit atm (atmosphere) still finds its way into this book (p. 271). The structural diagrams are clear and consistent, which is a considerable achievement in view of the fact that some of the three-dimensional structures are very complicated.

It has, of course, not been possible to include in this book all that is known about supramolecular chemistry. For example, a few readers may notice the absence of some particularly effective host structures such as molecular boxes, collars or belts. Syntheses also could have been given a further section, as the "dilution principle" and the "template effect" have received insufficient attention. The coverage of historical aspects could also have been extended: the first macrocyclic polyethers were reported by *Lüttringhaus* 30 years earlier than *Pedersen*, and even the chemistry of the cyclam macrocycles has been known for many years.

Reactions, including those of a catalytic nature, that can be carried out using supramolecular systems are treated rather too briefly. Perhaps it will be possible in a future edition to devote a separate chapter to these applications. The desirability of publishing an English translation of the work has already been mentioned at the 1989 Conference on Macrocyclic Chemistry.

In summary, this is a very interesting book on the many different aspects of supramolecular chemistry, which provides both a good introduction to the topic, through the comprehensive introductory sections included in each of the chapters, and a good starting point for reading the original literature (with 48 pages of references). It is also a valuable source of new ideas, especially in the last few chapters. However, two facts in particular stand out: the book is written in the *German* language, and each page costs less than ten pfennigs!

Ulrich Lüning [NB 1009 IE]
Institut für Organische Chemie und Biochemie
der Universität Freiburg (FRG)

Pesticide Chemistry. (Series: Studies in Environmental Science, Vol. 32). Edited by *Gy. Matolcsy, M. Nádasy* and *V. Andriska*. Elsevier, Amsterdam 1988. 800 pp., hardcover, HFl 495.00. – ISBN 0-444-98903-X

The last comprehensive review of the chemistry of plant protection chemicals appeared about ten years ago. On the other hand there are numerous excellent and up-to-date monographs on individual topics which have been well cataloged. It is to be welcomed, therefore, that *Gy. Matolcsy, M. Nádasy* and *V. Andriska*, as they indicate in the preface to this new review of the field, have set out to devote particular attention to the most recent developments in plant protection chemistry, and on products which exemplify interesting new trends. The expert will immediately think in this context of keywords such as pyrethroids, azoles, sterol biosynthesis inhibitors, sulfonylureas, imidazolinones, ALS inhibitors, chlorotics and photosynthesis inhibitors, and will be glad to learn that at last a compact treatment of these topics, which has long been needed, has arrived. However, the expectation will be dampened to some extent on glancing through the contents list of this bulky volume. The reader will find only nine pages on pyrethroids, as a sub-section in a chapter on "Insecticides of Natural Origin", whereas a little later on, no less than 43 pages are allocated to the older chlorinated hydrocarbons. The triazoles, which are now probably the most important and intensively studied single class of fungicides, are dealt with in eight pages, and the sulfonylureas, which have set new standards in the area of herbicides, are given only three pages. This apparent lack of topical emphasis can perhaps be explained by the book having been a long time in preparation. From an analysis of the literature citations, which are very numerous in all the chapters, one can conclude that the manuscript deadline was in 1984. The delay in publication is regrettable, expecially as the authors have been exceptionally thorough and careful in summarizing the published material up to that date; the coverage is considerably wider than in the earlier reviews, especially as regards mechanisms of action, metabolism and the effects of

residues, aspects which have been given more space for every class of compounds where the information was available.

Within each of the six large chapters on insecticides, acaricides, nematicides, rodenticides, fungicides and herbicides, the material is arranged strictly according to chemical classes. Of course this is reasonable, but it makes it more difficult to recognize the characteristic behaviour of each of the various classes of compounds, which in practical use as well as in research are determined by their common mechanisms of action or activity spectra. The clarity of presentation within the individual chapters would have benefited greatly from a consistent and more visibly obvious division into the recurring sections dealing with chemistry, spectrum of biological activity, mechanism of action, metabolism and toxicology, together with a greater use of tables to summarize the information.

The chapter on insecticides is clearly dominated by the conventional classes of compounds. The pyrethroids, for example, are definitely under-represented. Compared with the space devoted to other compound classes one notices the absence here not only of some of the newer products such as Cyfluthrin and Fenpropathrin, but, more importantly, of any impression of the considerable chemical research activity in this field that was already under way in the late 1970s. For example, although there is a description of one of the enantiospecific, but commercially quite insignificant, syntheses of chrysanthemum dicarboxylic acid, one searches in vain for one of the more commercially important permethrin acid syntheses, which was the subject of a brilliant research project. Again under phosphoric acid esters some important, and even quite old, products such as Azodrin® (Monocrotophos), Counter® (Terbufos), Miral® (Isazofos) and Nemacur® (Fenamifos) are not included. The last two are also missing from the appropriate part of the chapter on nematicides.

In contrast the section on insect growth regulators is excellent. On the basis of the literature up to 1984, the theoretical studies that have been carried out in this area with the aim of developing highly specific insecticides with favorable toxicological properties are reviewed. The chemistry and synthesis of these compounds and the insect physiological aspects are discussed in detail. Research along these lines has so far failed to yield products of wide applicability, despite some limited successes in narrow areas, and the accurate assessment given here still remains appropriate now.

On the other hand, the chapter of acaricides, the section on triazoles, and some parts of the chapter on herbicides are considerably diminished in value by the rapid further developments in these areas during the long time that it has taken to complete the book. For example, it has not been possible to include the new standards in acaricides that were introduced into the market between 1983 and 1985, namely Hexythiazox (Nissorun®), and Clofentezine (Apollo®), nor to convey an impression of the wide-ranging developments and many new products in the triazoles area. The mechanism whereby these act as sterol biosynthesis inhibitors is only briefly mentioned as a literature reference.

However, the chapter on herbicides, which is the longest in the book (300 pp.), is a very detailed and comprehensive account of these classes of compounds. Particularly noteworthy are the sections on phenoxyalkanecarboxylic acids, phenoxyethanols and dinitroanilines. The chapter includes a detailed review of structure-activity relationships and of the biodecomposition of phenoxyacetic acids, a discussion of the TCDD problem, and a comprehensive account of the research on 2,4-dichlorophenoxyethanol (DCPE) and on Buvinol® (pp. 533–541). Here, as also in many other parts of the book, one gains an interesting impression of plant protection research in Eastern Europe and of the products developed from it; this does not emerge to the same extent from books published in the West. The photochemical decomposition of Trifluralin is described in detail, and alternative routes are given in the two schemes on pages 608 and 609; however, the difference between these is only one of emphasis, and this illustrates that there are many points where the material could be tightened up and presented more concisely. In the case of the sulfonylureas there is regrettably no mention of the results published in 1984 on the mechanism of action of this group of compounds as acetolactate-synthase inhibitors, nor of the intensive worldwide chemical research, leading to a flood of patents, that has occurred since the appearance of the first examples of these compounds.

From today's standpoint the book definitely does not justify the claim to present current trends and synthetic methods of modern plant protection chemistry; furthermore, some of the obsolete plant protection chemicals that are discussed in detail here, such as the organomercury fungicides and the chlorinated hydrocarbon insecticides, need to be differently evaluated nowadays. Nevertheless, despite the fact that other more up-to-date books exist, the considerable amount of material which this book contains, and the special attention that is given to biochemical, toxicological and ecological aspects, make it a valuable addition to the existing review literature. It will therefore be a useful source book for those engaged in research or applications who need rapid access to comprehensive information, and a guide to the original publications on particular classes of compounds that are or have been important in plant protection. The high price means that it will not be easy for individuals to commit themselves to buying it, but the book will find a place in well-equipped departmental libraries.

Joachim Weißmüller [NB 999 IE]

PF-Zentrum Monheim (FRG)

Modern Supercritical Fluid Chromatography. Edited by *C. M. White*. Dr. Alfred Hüthig Verlag, Heidelberg 1988. xii, 239 pp., hardcover, DM 98.00. – ISBN 3-7785-1569-1

Supercritical fluid chromatography (SFC), in which a supercritical gas is used as the mobile phase, has established a place as a third technique intermediate between gas chromatography and liquid chromatography. Rapid strides are being made in the development of this method and of commercially available instruments. In the book reviewed here *Curt M. White* provides an up-to-date account of the development of SFC.

The editor has been successful in enlisting a number of eminent authors as collaborators. The eleven chapters, dealing with such varied and topical themes as an introduction to the mechanisms producing gradients in SFC, the advantages and disadvantages of packed columns in SFC, the solubility of modifiers in CO_2, interfacing SFC to mass spectrometry and FTIR, applications of SFC in petrochemicals analysis, and restrictor properties, are all written by scientists with many years of experience in these fields.

The individual contributions are self-contained rather than forming a sequence of interdependent chapters. A few of the authors preface their contributions by short introductions to the essentials of SFC, but the inclusion of a general introductory overview would have given the book a better defined structure, and would undoubtedly have made it useful to a wider readership.

The contributions are written in the style of review articles, giving both an insight into the authors' own research and an up-to-date survey of the current state of knowledge. The literature references, varying from 20 to 59 in number for the individual contributions, enable the reader to find more detailed information on the topics covered. Scientists who already follow the current literature on SFC will gain little new knowledge from the book. However, for readers who are only familiar with the basics of SFC the book offers an opportunity to rapidly absorb a thorough knowledge of current developments. The chapters on column techniques and on SFC-MS interfacing are especially valuable in that respect. The numerous examples of separations of oligomers, polymers and polymer additives, pesticides, dyestuffs, detergents and petroleum fractions provide readers with a good survey of the many varied areas to which SFC can be applied. From this point of view the book well fulfills the promise of its title. However, it is less suitable for complete novices and for students, as some of the chapters require quite a sound knowledge of the fundamentals of SFC in order to understand them.

The numerous, and often very detailed, figures are an excellent feature of the book; this applies especially to the chapter on SFC-MS interfacing. Equally impressive are the typography and the quality of production. The text and the many tables are easy and convenient to read; good quality paper, stitched binding and a substantial cover combine to make this a serviceable book.

Wolfgang Kleiböhmer [NB 1000 IE]
Anorganisch-chemisches Institut
der Universität Münster (FRG)

Strategies and Tactics in Organic Synthesis. Vol. 2. Edited by *T. Lindberg*, Academic Press, San Diego 1989. 469 pp., hardcover, \$ 75.00. – ISBN 0-12-450-281-4

The book describes various case histories of organic syntheses, originating from 13 prominent academic laboratories of the United States. Unlike Volume 1, which also featured the synthesis of two unnatural products (dodecahedrane and superphane), changing views on research funding probably dictate that the present volume deals with the synthesis of natural products, which are of intrinsic structural and also of special medicinal interest. Ideas and false starts, spin-offs and setbacks, changes of direction and key experimental problems are often chronicled, and this makes the recorded efforts human and the book interesting to read.

Cycloaddition methodology plays an important role in at least five chapters. In Chapter 1 (*D. L. Boger*: synthetic quinoline-5,8-quinones, antitumor antibiotics of the streptonigrin and lavendamycin types) the intramolecular, inverse-electron demand Diels–Alder addition of azadienes is developed and utilized, and one may gather that the synthetic endeavors had something to do with the appearance of a recent useful book in this general area.[1] In Chapter 7 *M. E. Jung* describes a concise synthesis of the bottom half of ivermectin. The combination of the electron-rich 3,4-dibenzoxyfuran (as 2π component) and an electron-deficient coumalic ester (α-pyrone as 4π component) turns out to be a key reaction. In Chapter 9 *S. F. Martin* deals with the synthesis of indole alkaloids of the yohimbine and corynanthe family, including reserpine: intramolecular Diels–Alder additions of nitrogen-linked trienes and heterotrienes are used to build up the D/E ring fragments. Chapter 12 by *D. D. Sternbach* describes the synthesis of a linearly fused triquinane ($\Delta^{9(12)}$-capnellene) and of an angularly fused triquinane (silphinene). Again, intramolecular Diels–Alder reactions of substituted cyclopentadienes are used to approach the triquinanes.

Retigeranic acid, a member of the comparatively rare class of sesterpenes (C_{25}) has a tricyclic fragment resembling silphinene, with a trans-perhydroindane fused to it. *E. J. Corey* and *T. A. Engler* (Ch. 3) develop an intramolecular cycloaddition of a ketene to an olefin to assemble an advanced pentacyclic intermediate. As a beginner in synthesis one is often given the advice: "Don't use known chemistry. Choose the target so that you have to invent new chemistry. Otherwise you only reinvent the wheel". At its best, science is, of course, often iconoclastic. The crossed cycloaddition of ketenes to electron-rich olefins is a very old reaction which, in its intermolecular form, goes back to *Staudinger* and the turn of the century. Who could have foreseen – or why did it take so long to realize – that given the optimum three-atom tether, the intramolecular variant can be so spectacularly successful, even with simple unactivated olefins, for building up a variety of four-membered rings within complex polycyclic frameworks?[2, 3]

S. D. Burke (Chapter 2) describes the synthesis of (+)-phyllantocin, which is the sesquiterpene aglycone of biologically active phyllantoside, and also the synthesis of (±)-quadrone, a compact tetracyclic ketolactone. Quadrone has also been a target of *P. Helquist* (Chapter 5), who shows clearly that the development of new chemistry can often become more important and probably have greater impact than the synthesis of the target itself. In fact, quadrone appears to have been synthesized by at least 15 groups up to now,[4] yet this does not detract from the work accomplished.

In Chapter 4 *Fraser-Reid* and *Tsang* continue to demonstrate that carbohydrate chemistry has become an active part of mainstream organic chemistry. Further strategies for preparing carbocycles from carbohydrates are introduced, where the carbocycle is built "around" the sugar and advantage is elegantly taken of the natural stereochemistry of the sugar.

Saxitoxin (Chapter 6 by *P. A. Jacobi*), one of the most toxic of the non-protein poisons known, is a non-crystalline diiminium salt. Plenty of heteroatoms dictate the synthetic strategy (or is it tactics?), which features electrophilic activations with, e.g. Meerwein salt, and intramolecular 1,3-dipolar cycloadditions. The route developed is remarkably efficient, giving the key saxitoxin precursor on a 0.5–1.0 g scale without any chromatographic separation. In Chapter 8 *A. P. Kozikowski* and *M. N. Greco* tackle the mycotoxic cyclopiazonic acids which belong to the category of substituted tetramic/tetronic acids. In the course of this work a novel C-glycoside synthesis is developed, using *O,S*-acetals and dimethylzinc.

Olivomycin A (Chapter 10) was originally chosen by *W. R. Roush* as a target to learn about two important areas of contemporary research, i.e. (i) acyclic diastereoselective techniques and (ii) carbohydrate chemistry. Both premises turned out to be entirely correct. With respect to (i), allylboronate chemistry proved to be most useful. (−)-Casbene and (−)-bertyadionol are two diterpenes that have yielded to total synthesis by the group of *A. B. Smith* (Chapter 11), who, like *E. J. Corey*, had also contributed a chapter to Volume 1. Finally, the synthesis of pseudomonic acid C (*D. R. Williams*, Chapter 13) provides an exercise of stereocontrol in tetrahydropyran chemistry and also requires attachment of two appendages, one of which is chiral.

If the case for organic synthesis needs to be restated,[5, 6] the present volume, like Volume 1, helps to focus that case.

There is a great deal in this book that the attentive reader and student may learn, also by reading between lines. Organic chemistry without synthesis is hard to imagine. Conversely and even more cogently, organic synthesis remains the essence of organic chemistry.

H. Martin R. Hoffmann [NB 1002 IE]

Metalloproteins, Chemical Properties and Biological Effects. (Series: Bioactive Molecules, Vol. 8). Edited by *C. I. Otsuka* and *T. Yamanaka*. Elsevier, Amsterdam 1988. xiv, 572 pp., hardcover, HFl 450.00. – ISBN 0-444-98887-4

This book is the result of the combined efforts of 54 authors. As one expects from the title, it contains chapters on metalloproteins and metalloenzymes containing one or more of the metals magnesium, calcium, vanadium, manganese, iron, cobalt, nickel, copper, zinc, molybdenum, tungsten and selenium; in addition there are chapters on flavines and metal ions, complexes formed by nucleosides and nucleotides with metal ions, carcinogenicity of metal ion, and antitumor activity of metal compounds. Finally, there is a chapter on affinity fractionation using metal chelates.

The book is mainly suitable as a work of reference, since much of the information which it contains is presented in the form of useful tables. However, this only applies to the older literature; results from the last four years receive little coverage or are treated only superficially, sometimes only by a "note added in proof". The individual chapters are very varied in quality. For example, the sections on molybdoenzymes and nickel enzymes are hardly up to the standard of a good textbook treatment. Nowhere is there a critical discussion of the historical significance of particular topics, e.g. of the discovery of nickel in urease. These failings detract appreciably from the value of this otherwise interesting book.

Rudolf Kurth Thauer [NB 1003 IE]
Fachbereich Biologie
der Universität Marburg (FRG)

Houben-Weyl. Methoden der Organischen Chemie. Band E13, Teil 1 und 2: Organische Peroxo-Verbindungen. 4th Edition. Edited by *H. Kropf*. Thieme, Stuttgart 1988. Part 1: xliv, pp. 1–990, hardcover, ISBN 3-13-218304-0; Part 2: xx, pp. 991–1768, hardcover, ISBN 3-13-218304-0; price for Parts 1 and 2: DM 2200.— (subscription and pre-ordered price: DM 1980.—)

The fourth edition of "Houben-Weyl" began to appear in 1952 with Volume VIII and the article "Herstellung und Umwandlung von Peroxyden", by *R. Criegee*. The topic which could then be reviewed in 74 pages by one author has now grown to a two-volume work whose contents list alone consists of 57 pages. In this connection it is interesting to read in the preface which *E. Müller* wrote for Volume VIII: "It is planned to complete the new work, consisting of about 14 volumes of 700 pages each, over a four-year period." Evidently it was not then foreseen that in 34 years time there would be 67 volumes, together with indexes and supplementary volumes.

Despite the large number of contributors to Volume E13 (30 authors), the editor *H. Kropf* has managed to achieve a very uniform style of presentation which is in keeping with the high quality of this standard work. The new volumes are also commendably up-to-date: the literature up to 1987 has been covered, and even some 1988 references are included (the volumes appeared on 1 December 1988). The nomenclature is mainly in accordance with the IUPAC rules. Alongside the physical data in SI units the values in older units have also been included in some cases; this unnecessarily increases the size of the tables, for example where all the energy data are given both in kJ and (in parentheses) in kcal. However, listing distillation pressures in kPa could lead to mistakes in converting to more familiar units, resulting in delayed boiling or other accidents, and in this case, therefore, all the values have been given in torr (with the SI units, kPa, in parentheses in this case).

The arrangement of the subject matter essentially follows the usual pattern adopted in "Houben-Weyl". The first volume, which is the larger of the two, contains an introductory chapter and preparative methods (Part A). The second volume contains transformations of peroxides into other compounds (Part B), peroxy compounds as reagents (Part C), and analysis (Part D). The whole work is rounded off by a general section (classification, structure, thermochemical data, naturally occurring substances, safety aspects and toxicology), which precedes Part A, and a comprehensive index at the end of Volume 2.

The classification of peroxy compounds given in the introductory chapter contains a degree of arbitrariness. According to this, peroxy compounds contain the characteristic group -O-O-, which, in organic peroxides, is attached through at least one carbon atom (or through a heteroatom X bonded to a carbon atom). As a result of this definition, carbonyl oxides are not counted as peroxides, and they are not covered. However, organo-heteroelement peroxides are included only in cases where the carbon is σ-bonded. Consequently the important metalla-dioxiranes are not covered (p. 956). On the other hand, the dioxiranes which are analogous to metallacycles are included, even though these are isomeric with the carbonyl oxides (and related to them in chemical properties). A somewhat more pragmatic definition of peroxides would definitely have helped here.

In the first, introductory, chapter the newer methods of "experimental computer chemistry" are treated too briefly, even for a work in which the emphasis is on preparative methods. A sentence such as "Theoretical calculations gave values ranging from 80 to 180°, depending on the method of calculation (CNDO, INDO, MINDO, MNDO, ab initio, 4–31 G)..." certainly does not do justice to the enormous power of modern theoretical methods. In the area of peroxides especially, there are many instances where structures first arrived at by calculation have later been confirmed in an impressive way by experimental results.

Notable features of the general section are the newly revised thermochemical tables, and the chapter on safety aspects. This short and lucidly written chapter should be on display in every laboratory where peroxides are used.

Part A which follows, dealing with methods of preparation, is the core of the whole work. In the familiar style of

"Houben-Weyl" it details a wealth of general and specialized preparative methods, including yields, melting or boiling points, and information about the properties of the compounds. This section is a mine of information, and in looking up a particular compound or experimental recipe one is continually tempted to browse on adjacent pages. Part A is arranged according to compound classes, starting with alkylhydroperoxides and continuing through to organotrioxides and -tetroxides. A detailed index enables one to easily find individual compounds, and the arrangement under compound classes also makes it possible to quickly locate functional groups, in cases where one is concerned with variations in the peroxide group. In a work as large as "Houben-Weyl", however, it would be useful to have an index in the form of a computer data base (as in Beilstein), which would allow one to search for particular structural units. The general section of the subject index is quite pathetic. Under heading F, "General terms, named reactions, compound classes, trivial names", we find a more or less arbitrary selection of terms, consisting of only eight pages of the lengthy 176-page subject index. Important reactions such as the Criegee rearrangement and the Sharpless epoxidation are not included in this section, for example.

Part B deals with reactions whereby peroxides are converted into non-peroxide containing products. The topic is treated under nine reaction type headings: thermal reactions, catalytic reactions (catalysis by metals, bases and acids), photolytic and radiolytic reactions, rearrangements, reductions, oxidations and lastly a short separate chapter on organohydrotrioxides in the ozonolysis of C—H sp^3 bonds. After discussing the general mechanisms, specific examples are given, often in the form of tables. The treatment of rearrangements in a separate chapter leads to some overlapping with material in other chapters of Part B, but in view of the importance of many of these reactions (e.g. the Hock and Criegee rearrangements) this is justified. However, one searches in vain here for the Baeyer-Villiger reaction; instead this has been banished to a half-page paragraph on page 862.

The many different methods whereby peroxy compounds are used as reagents in organic chemistry are described in Part C. This part is a continuation of Section 1a (Peroxy Compounds as Oxidizing Agents) in Volume IV of the Handbook, published in 1981, and it therefore covers only the more recent literature. However, as the arrangement of the topics is identical to that in the 1981 treatment, it is easy to refer back to the earlier literature. The reactions described here range from the use of "exotic" peroxides such as the dioxiranes for the hydroxylation of unactivated CH bonds to some very detailed chapters on the use of transition metal catalysts. In particular the enantioselective Sharpless epoxidations have been given a considerable amount of space in view of their importance.

Volume E13 concludes with the excellent Part D, which has the simple title "Analysis". Everyone who has ever searched through the literature for spectroscopic data on a group of compounds will appreciate the value of the tables and the large compilation of data given here. All the analytical methods that are important for elucidating the structures of peroxides are represented, from IR spectroscopy through NMR spectroscopy (^1H, ^{13}C, ^{17}O) to mass spectrometry. Wet chemical methods for quantitative analysis and chromatographic methods are also described.

Volume E13 of Houben-Weyl will have a place in every well-equipped chemistry library. Critical reviews of the literature on specialist topics such as this make an important contribution towards maintaining a perspective over the tide of publications which continues to grow exponentially. Good workmanship has its price, and when one considers how often Houben-Weyl is referred to, there can be no doubt that it is a worthwhile purchase for every library.

The Quartz Microbalance: A Novel Approach to the In-Situ Investigation of Interfacial Phenomena at the Solid/Liquid Junction

New Analytical Methods (40)

By Rolf Schumacher*

When *Archimedes* was asked by King Hiero of Syracuse to prove whether a handcrafted crown really consisted of pure gold and not of gold with a proportion silver, he immersed the crown and an equal weight of pure gold, both attached to a beam balance, into a vessel of water. We all know that according to Archimedes's principle the scale beam rose on the side the crown was attached proving that the goldsmith had intermingled some silver. In spite of the simplicity of this experiment, the result convincingly demonstrates the physical integrity of this classical approach which is based on a weighing procedure. The mass sensitive technique we shall report on in this article is based on the principle that a shift in the resonance frequency of an oscillating AT-cut quartz disk can be correlated quantitatively with a change in mass in the nanogram range. One side of the quartz disk is in contact with a liquid, while the other side remains exposed to the atmosphere. The changes in weight involved in testing Hiero's crown were probably several hundred grams which corresponds to about 10^{25} water molecules. By applying the quartz microbalance, e.g., to solvent migration through thin films, one can sense entrapment of water with a resolution down to 10^{14} molecules per unit surface area. If adsorbate layers are in question, fractional coverages down to 0.02 monolayers can be monitored, which only goes to prove the capability of this instrument for investigating interfacial processes on a microscopic level. The option of recording charge flux and interfacial capacitance along with the mass change makes this instrument a powerful in-situ tool for scientific and technological applications in many fields.

1. Introduction

In the past few years, some novel techniques have been developed which enable the in-situ detection and monitoring of interfacial phenomena on a microscopic level.[1] One such approach involves the use of quartz crystals, which can be made to oscillate in a liquid environment.[2–8] The quartz microbalance has demonstrated its extraordinary sensitivity for monitoring accurately mass changes of several nanograms even when applied in-situ for the investigation of interfacial phenomena at a solid/liquid junction.[3–8]

The monitoring of a surface process on the basis of a change in weight is a classical but not very specific approach. However, a coupling of the in-situ microbalance with the recording of the differential capacity and charge flux enables an assignment of the measured data to specific processes in the region of the phase boundary. Furthermore, the three measurements can, in part, be carried out concomitantly. This decisive extension determines the character and uniqueness of the information which can be obtained with this methodological approach.

Since their introduction to in-situ interfacial research about half a decade ago, quartz oscillators have gained immense importance and broad acceptance as highly informative measuring devices. In this article, we present an overview

of the characteristic features and broad applicability of this technique with special emphasis on the uniqueness of the information that can be drawn from such measurements. It also outlines some concepts developed for describing the changes in frequency observed upon contact of a resonator surface with a liquid. These concepts are related to the physical and chemical nature of the interfacial environment. The article focuses on the state of the art of this area of research with the in-situ microbalance and reflects a currently fast changing situation.

In Figure 1 some fundamental principles associated with oscillating quartz resonators brought into contact with a

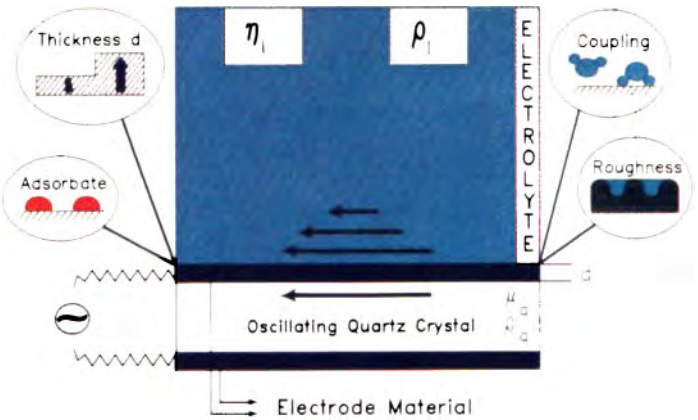

Fig. 1. Schematic presentation of the principles of a quartz microbalance which operates in solution. The arrow size and direction indicates the shear wave oscillations at the solid/liquid junction sustained by an electronic driver (~). Some interfacial phenomena which affect the resonant frequency of the quartz resonator are indicated in the insets. The bulk properties of the electrolyte such as viscosity and density are denoted as η_l and ϱ_l, respectively; μ_q and ϱ_q are the shear modulus and the density of quartz.

fluid are illustrated along with some typical interfacial processes. The damped propagation of shear oscillations[2] perpendicular to the resonator surface is symbolized by the decreasing arrow length on the liquid side of the junction. It is obvious that not only the viscosity η_l and density ϱ_l of the liquid but also the degree of coupling between the two phases will determine the extent to which these viscous oscillations penetrate into the liquid before they are damped out. The penetration represents the thickness of the liquid layer which is dragged along while the oscillator vibrates; this layer behaves like a rigidly attached liquid deposit and gives rise to a characteristic lowering of the resonant frequency f_0. Other processes of importance on the solid side of the junction, e.g., growth,[3, 5-7, 9-10] decay,[5, 7-8, 17-19] and content[11-16, 20-21] of solid thin films, adsorbate formation[5, 22-27] on a submonolayer range, passivity[4, 6, 7, 28-30] and roughness effects[4, 7, 28-30] etc., are presented in supermagnified images inside the circled areas of Figure 1. As illustrated in the lower right circled area, some water is confined in valleys of the roughened surface and is dragged along while the oscillator vibrates, thus giving rise to significant changes in weight which are related to the roughness pattern.[4, 30]

The present article deals firstly with some requirements of importance for designing an operating system, and then with frequency changes which can be ascribed to physical effects such as solid and liquid deposition, surface roughness and stress etc. Finally, the influence of chemically induced interfacial processes on the resonance frequency of quartz oscillators is discussed.

2. Some Experimental Requirements and Setups to Sustain Stable Shear Wave Oscillations of Quartz Resonators in Liquids

Figure 2 gives a schematic presentation of an experimental setup for recording in-situ changes of frequency of shear wave oscillations on quartz resonators immersed with one face in a liquid. Several groups have independently developed their own technical approaches and instrumentation, details of which are given elsewhere.[5-8, 28] Here are some useful principal requirements: The quartz oscillators used were AT-cuts which operate in the shear mode (the abbreviation AT signifies the lines of the quartz cut relative to the crystal axis). Both oscillator faces are covered with conducting layers (thickness d typically 1000 Å), which are electrically connected to an electronic driver device to sustain stable oscillating shear motions. To affix various noble and less noble metals onto the quartz surface, standard surface cleaning procedures such as sputtering with argon and/or seeding with chromium or silicon were used. The face exposed to the liquid serves as working electrode if this setup is used as an electrochemical device. The function generator of the potentiostatic control unit allows repetetive potential scanning at various rates and provides a fast potential step technique, which, inter alia, is essential for recording complex plane impedance spectra in conjunction with the Fourier transform method.[30, 31] For experiments which are carried out

Rolf Schumacher, born 1943, studied chemistry from 1968 to 1973 at Bonn University, where he also gained his doctorate under the supervision of R. N. Schindler for physicochemical work, the experimental part of which was performed at the KFA Jülich. From 1978 to 1979 (Research Fellowship) and 1984 to 1985 (Visiting Scientist) he worked as postdoc in the USA at the Research Centers of General Electric, Schenectady (L. A. Harris, R. N. Wilson) and IBM, San Jose (J. G. Gordon, K. K. Kanazawa). Following his research activities at KFA Jülich and the Universities of Essen and Kiel in 1987 he joined the GT Research Staff of the Schering AG in Berlin. In 1989 he habilitated as a Faculty Member for Physical Chemistry at the University of Kiel. His research activities are focused on the kinetics of gas phase reactions and interfacial electrochemical phenomena at the solid/liquid junction.

under potentiostatic/galvanostatic control, commercial systems can be used if these instruments operate with a grounded working electrode. This instrumental arrangement is needed to match the design of the driver electronics, the requirement of which is that the grounded resonator face is exposed to the liquid while its opposite hot face is free from the electrolyte. In case the electrochemical arrangement is operated without any external potential/current control, the potential of the working electrode can adjust dynamically to the electrolyte conditions.

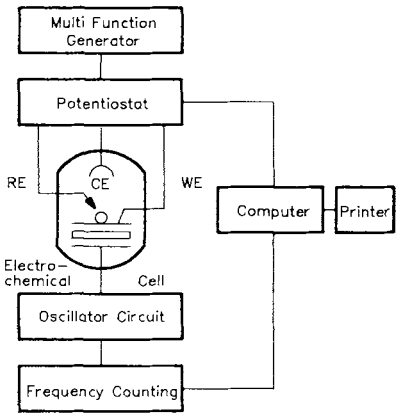

Fig. 2. Experimental setup for sustaining and recording frequency changes of a quartz resonator immersed in a fluid [8]. RE, CE, WE = reference electrode, counter electrode and working electrode, respectively.

Recently, a dynamic technique was suggested in which a galvanostatically controlled deposition process is perturbed with a small sinusoidal current oscillation. The analysis of the frequency data is performed with a transfer function analyzer which allows a simultaneous registration of impedance data. The observed mass-voltage transfer function is expected to reveal information on, e.g., the nature and kinetics of intermediary processes of the electrochemical surface process.[32]

Two different experimental concepts were put forward for the exploitation of the extraordinary sensitivity of shear wave oscillations toward a mass load. The first concept is based on the stationary arrangement;[3-8] the immersed quartz housing is kept at a fixed position and does not make any movement in the cell. This is the most common technique and is used in the meantime in many laboratories around the globe. Recently, an elegant variant was developed in which the resonator disk rotates and still operates effectively as a mass-sensitive tool.[20] This type of device provides defined hydrodynamic conditions suitable for the suppression of polarization, e.g., in experiments with dilute solutions.

The design of a quartz housing which allows a quick and easy oscillator change presents its own problems. On the one hand, the resonator plates have to be mounted without incurring any strain, which, of course, would affect the resonance conditions, and, on the other, the liquid must be prevented from penetrating into the housing, which requires a certain amount of stress to be applied to effectively seal the crucial contacts. Suggestions, which meet these opposing needs are based on a sandwich model.[7, 8] One of the historical proposals for solving this problem is given in Figure 3. A bent glass tube houses the electronic driver circuit. The quartz resonator is pressed against the tube opening and sealed with silicone adhesive.[3, 4]

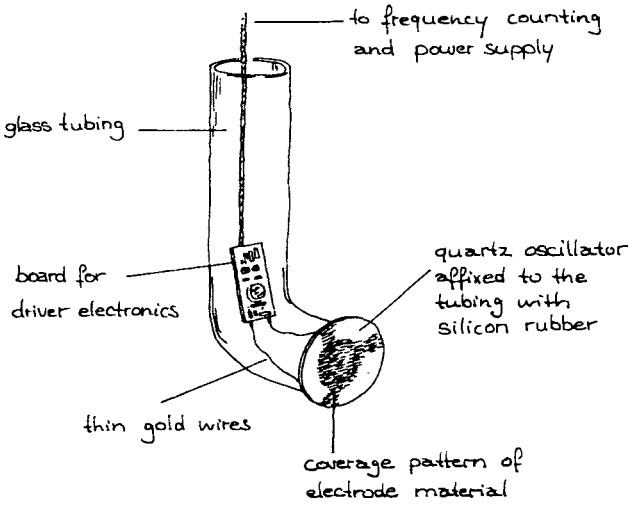

Fig. 3. Early assemblage of a quartz microbalance for operation in solution.

The layout of the electronic driver circuits to sustain stable oscillating shear motions on resonators with one face in contact with a liquid is based on the conventional type of driver devices such as those proposed by *Pierce-Miller, Colpitz* etc.[33] But devices which are operated with a differential video type amplifier,[3, 4, 8, 28, 29, 34] have also been used. The electronic modifications suggested account for the viscous damping at the liquid/solid junction. The resulting losses can be compensated, e.g., with a positive feedback which enhances the amplification characteristic of the driver.

3. Shear Stress Oscillations at the Solid/Liquid Interface

3.1. Influence of Solid Deposits on the Resonance Frequency of Quartz Oscillators

The relationship which quantitatively correlates a change in frequency Δf with a change in mass Δm [Eq. (a)] was first derived by *Sauerbrey*.[35] In this relationship, with μ_Q the

$$\Delta f = -[2 f_0^2 (A \sqrt{\mu_Q \varrho_Q})^{-1} \Delta m] \qquad \text{(a)}$$

shear module of quartz, ϱ_Q its density and A the geometric surface area of the deposits, Δf is linearly related to Δm; this has been verified experimentally for thin rigid overlayers exposed to vacuum or to ambient pressure conditions. In these cases, the physical properties of the deposits such as mechanical stress and damping[36] do not affect the material constants of the quartz μ_Q and ϱ_Q significantly, so that Δf changes linearly with Δm. When the overlayers are thick, this relationship becomes nonlinear, a behavior for which corrections have been developed. Today, this technique is used

routinely in vacuum systems, e.g., in thin film technology.[36]

The evaluation of Equation (a) for reduced and ambient pressure conditions was achieved by varying the amount and nature of the foreign mass deposited. The results reveal that the relationship between Δf and Δm is no longer linear when the coverages exceed a value of roughly 0.5% with respect to the weight of the uncovered quartz resonator. Thus, for a 5-MHz resonator weighing about 100 mg, the linearity of Equation (a) ranges up to a point corresponding to a deposit of about 0.5 mg of foreign material.[36]

The negative sign on the right hand side of Equation (a) indicates that a loss in mass causes an increase in frequency and vice versa.

The interesting question whether this linear mass-frequency relationship holds also for resonators with one face exposed to a fluid was explored on 5-MHz, 6-MHz and 10-MHz crystals operated in their fundamental oscillation modes.[5-9] The experimental procedure used was based on the electrochemical dissolution of copper and silver from various thick deposits to determine the relevant quotient $(\Delta f/\Delta m)$ A. By recording Δf and the corresponding charge flux Δq in-situ and simulataneously, this quotient can be calculated with the help of Equation (a) and Faraday's law. A comparison of the experimental data obtained with theoretical expectations according to Equation (a) are shown in Figure 4 for the resonators used. In this figure both

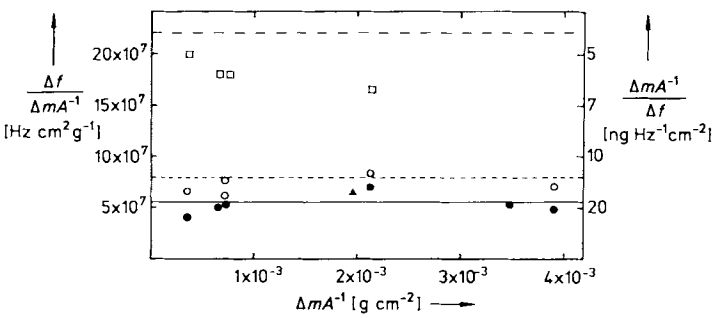

Fig. 4. Sensitivity of a quartz microbalance in a liquid environment. Dependence of the integrated sensitivity $(\Delta f/\Delta m)A$ and its reciprocal $(\Delta m/\Delta f A)$ on the amount and nature of foreign deposits $\Delta m/A$. 5 MHz: Cu(●), Ag(▲); 6 MHz: Cu(○); 10 MHz; Cu(□). The data points represent experimentally determined values, while the predicted sensitivities for 5 MHz (—), 6 MHz (....) and 10 MHz (---) resonators according to Equation (f) are given as horizontal lines [8].

$(\Delta f/\Delta m)$ A and its reciprocal $(\Delta m/\Delta f$A) are given as a function of the amount of metal deposited $\Delta m A^{-1}$. According to these data, there is a satisfactory agreement between experiment and theory; the deviation from theory does not exceed 20% in the range of investigations, regardless of whether one face is attached to a liquid. Thus, for a 5-MHz crystal a change in frequency of 1 Hz corresponds to a mass change of about 18 ng, which corresponds to a fractual coverage of about 0.06 monolayers of copper. The same frequency change on a 10-MHz crystal corresponds to 4.5 ng or about 0.02 monolayers of copper. These data are related to a unit surface area and correspond to investigations which were carried out under reduced pressure.[36]

3.2. Influence of a Total Immersion of One Resonator Face in a Liquid on the Resonance Frequency

The change in resonant frequency that occurs upon coupling one face of a resonator to a liquid has been ascribed to the liquid density,[37] to combinations of density/conductivity,[38] density/viscosity,[39] and to the mass of a solid deposit as outlined in the previous chapter. The response of shear wave oscillations to a liquid-like deposit,[40-42] as treated in recent papers, does not describe the case where one face of the resonator plate is totally immersed in a viscous environment. As outlined by *Kanazawa* et al.,[2] the case at hand can be analyzed in terms of a simple physical model which treats the quartz resonator as a lossless elastic solid and the liquid as a purely viscous medium. The resulting change in frequency upon immersion arises from the coupling of the standing shear wave of the oscillating resonator to the liquid. The result is a damped propagating shear wave that travels normal to the surface in the viscous medium. According to the definition of the coordinates[2] the fluid velocity v_x describes the movement of the liquid parallel to the surface and can be described with the differential Equation (b), in which ϱ_l and

$$\frac{\partial^2 v_x(z,t)}{\partial z^2} = \frac{\varrho_l}{\eta_l}\frac{\partial v_x(z,t)}{\partial t} \tag{b}$$

η_l are the density and viscosity of the bulk liquid, respectively. Equation (b) is based on the assumption that the first layer of fluid is rigidly attached to the oscillator surface and that η_s, the interfacial viscosity, is identical with η_l, the bulk viscosity. The explicit solution of this equation in terms of v_x yields Equation (c), where z is the coordinate normal to the surface, L the thickness of the oscillator, v_0 the velocity of the quartz surface, ω the fundamental frequency, and k_l the propagation constant.

$$v_x(z-L,t) = v_0 e^{-k_l(z-L)} e^{j[k_l(z-L)-\omega t]} \tag{c}$$

The latter quantity is given by Equation (d) and describes

$$k_l = \sqrt{\frac{\omega \varrho_l}{2\eta_l}} \tag{d}$$

shear waves traveling normal to the surface with extremely heavy damping. Their velocity profiles $\bar{v}$ normal to the surface are shown in Figure 5. These snapshots represent three different times, corresponding to: a) peak surface velocity, b) intermediate surface velocity, and c) zero surface velocity.[2]

The reciprocal of k_l is the characteristic decay length σ of the envelope function which indicates that the oscillating crystal resonator does not drive the entire bulk of liquid. The decay length σ represents the effective thickness of a rigidly bound liquid deposit, which in the case of water is ca. 2500 Å. Since σ increases with increasing viscosity, the added mass Δm_σ of this liquid deposit increases as well [Eq. (e)].

$$\Delta m_\sigma = A\sqrt{\frac{2\varrho_l\eta_l}{\omega}} \tag{e}$$

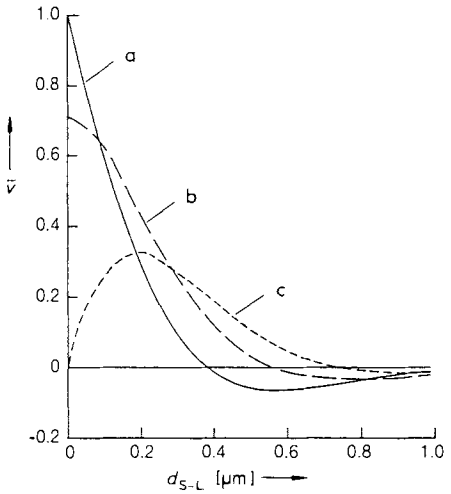

Fig. 5. Distribution profiles of the fluid velocity $\bar{v}$ normal to the surface d_{S-L}. The profiles (a–c) for pure water represent three different times: a) time of peak velocity at the surface; b) intermediate time; c) time of zero velocity at the surface [2].

The change in frequency Δf due to the total contact of one resonator face[2] with a viscous fluid can, under the assumption that the transverse velocity of the quartz surface is identical to that of the adjacent fluid layer, also be evaluated from Equation (b).[2] The solution is expressed in terms of Equation (f).

$$\Delta f = -f_0^{3/2}\sqrt{\frac{\eta_l \varrho_l}{\pi \mu_Q \varrho_Q}} \qquad \text{(f)}$$

Several attempts have been made at the verification of Equation (f). The results are not consistent and, in the following, are subjected to a critical evaluation: *Kanazawa* et al.[2] have tested several systems such as glucose–water and ethanol–water mixtures and found a satisfactory agreement between theory [Eq. (f)] and experiment. Figure 6

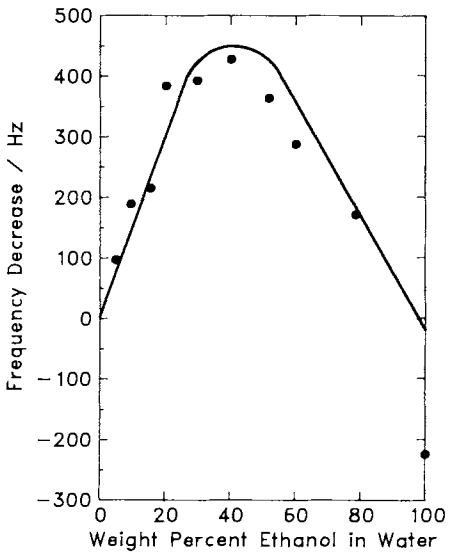

Fig. 6. Influence of water:ethanol ratio in a water/ethanol mixture on the resonance frequency of an immersed quartz oscillator. The solid line represents predictions according to Equation (f), while the data points correspond to a relative frequency shift with respect to pure water [2].

shows the frequency response of various mixtures with respect to pure water. A good agreement between theory and experiment was also found for a saccharose–water mixture.[38] Equation (f) does not apply, however, in the case of some organic fluids,[43] as can be seen from Figure 7, in which the comparison of calculated and experimentally ob-

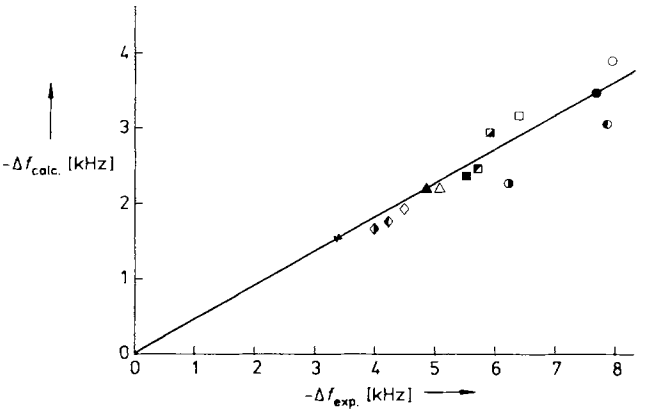

Fig. 7. Observed decrease in frequency upon immersion of one resonator face in various organic fluids [43] versus the predicted frequency decrease according to Equation (f): (×): hexane; (◪): cyclohexane; (◆): acetonitrile; (◑): acetone; (□): ethanol; (▲): methanol; (△): 4-methyl-2-pentanone; (◇): 2-butanone; (■): toluene; (◩): benzene; (○): dioxane; (●): 1,2-dichloroethane; (◑): carbon disulfide; (◐): chloroform.

served data fits to a straight line which passes through the origin of the coordinate system. The slope is about 0.45, indicating that the predicted data are generally smaller by roughly a factor of 2 than the experimentally determined data. This observation is in accord with an early study by *Haardt*:[44] on using a 5-MHz oscillator he obtained, from the observed changes in frequency, viscosity data which are clearly higher than the calculated data. In his explanation, he adopted a model which claims that the viscosity of water close to the surface, η_s, is much higher, than of the bulk, η_l. Using the relation η_s/η_l he calculated a value of 4.2, which is in excellent agreement with *Pechel*'s experimental results. To investigate the interfacial viscosity of liquids[45,46], these authors used thin, fused silica disks, which were allowed to approach each other along their common central axis under the influence of a given force.

In a more recent paper, *Pittermann* and *Weil* et al.[47] likewise observed deviations between data calculated with *Kanazawa*'s formula and their experimental results obtained in various concentrated LiCl solutions. Their results reveal, that these deviations might be related to the electronic circuits used to drive the crystal. Upon immersion, the measured decrease in frequency Δf with a 4.9-MHz resonator connected to a Pierce-Miller circuit is roughly a factor of 3 larger than that predicted according to Equation (f). A lowering of Δf by a factor of roughly 1.5 compared to the theoretical value was found for a 9.4-MHz resonator with integrated circuit (IC). Both crystals were operated in their fundamental modes. On the other hand, a good agreement between theory and experiment was found for the 3rd harmonic of a 5-MHz crystal driven with a Pierce-Miller circuit. Finally, a good agreement was found for all three types of

circuits provided the frequency was determined with reference to the real impedance. This was demonstrated on a 5-MHz crystal operated in its fundamental and 3rd harmonic modes as well as for a driver circuit based on an IC. To explain this finding the authors pointed out that the readout of the frequency counter must not be necessarily identical with the resonance frequency of the quartz oscillator calculated from the maximum of the real impedance. Coincidence of both frequencies might occur, however, for a driver circuit which uses a video type amplifier with a positive feedback to ensure that the oscillation occurs near the zero-phase condition.

3.3. Influence of Surface Roughness on the Resonance Frequency

As shown by *Schumacher* et al.,[4, 28–30] surface roughness can also drastically affect the resonant frequency f_0. As outlined schematically in Figure 8, liquid confined in surface cavities is dragged along while the crystal surface oscillates. This leads to a frequency shift, which correlates with the mass of the liquid confined. This amount of liquid can be determined and related to the mean cavity size ε which makes up the roughness pattern.

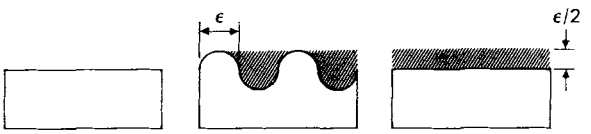

Fig. 8. Electrode cross section to illustrate liquid enclosures in an ideally roughened surface. Left: smooth surface; center: roughened surface made up from hemicylinders with liquid entrapments (hatched area); right: equivalent rigidly attached liquid layer on the smooth surface [4].

To illustrate this procedure, we refer to the electrochemical oxidation/reduction of polycrystalline gold electrodes in neutral and alkaline solutions. Figure 9 shows the cyclovoltammogram and potentiodynamic recording of the frequency at a gold electrode in an alkaline environment. It can be seen that the onset potentials for charge flux and frequency change coincide, indicating the formation and decay of an oxide adlayer. The change in surface roughness is clearly shown by SEM micrographs taken before and after the oxidative/reductive cycle and on samples emersed and examined after their electrochemical oxidation (cf. Fig. 10A, B). These pictures definitely show that the oxidized surface is rougher. The metallic surface remaining after the reduction process is comparable in roughness with an untreated surface (Fig. 10C). Interestingly, the surface layers deposited in alkine medium (Fig. 10B) are visibly rougher than those which are formed in a neutral environment (Fig. 10A).

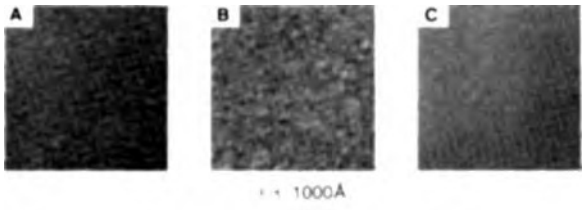

Fig. 10. Scanning electron micrographs on gold surfaces. Micrograph C: surface structure before and after the redox cycle. A and B: surface structure after electrochemical oxidation in neutral and basic media, respectively [4].

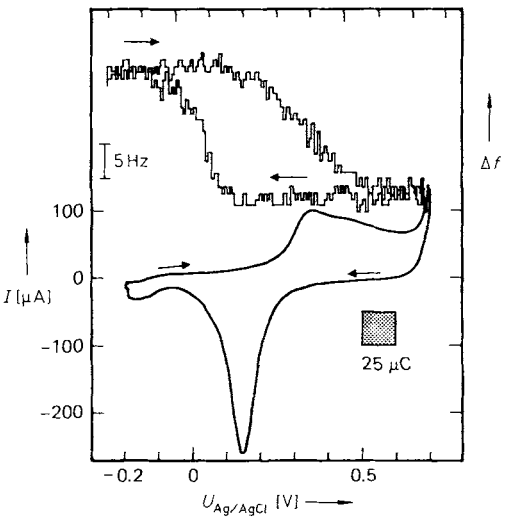

Fig. 9. Potentiodynamic recordings of current and frequency for a freshly prepared gold sample in an alkaline environment [4].

The mass, Δm_1, of liquid confined in cavities of the roughened, oxidized gold electrode can be determined by substracting, Δm_q, the weight gain due to oxide formation, from Δm_f, the total apparent weight gain as measured with the microbalance. Δm_q is determined from Δq, the total charge measured during oxidation, by applying Faraday's law. In order to estimate the degree of surface roughness, the surface was assumed to be corrugated, as illustrated in Figure 8, with a hemicylindrical corrugation of diameter ε.

The amount of liquid carried along in the valleys according to this simplified model is equal to that in uniform layer of thickness $\varepsilon/2$ rigidly attached to a smooth surface. By modification of Equation (a) the mean diameter ε can be estimated from Δm_1 and the density ϱ_1 of the liquid [Eqs. (g) and (h)]. The value obtained for sample A (Fig. 10A) is ca.

$$\Delta f = -[2f_0^2(A\sqrt{\mu_Q \varrho_Q})^{-1}\,\Delta m_1] \qquad \text{(g)}$$

$$\Delta m_1 = \varrho_1 A\,\varepsilon/2 \qquad \text{(h)}$$

30 Å, that for sample B (Fig. 10B) ca. 62 Å. Estimations based on the respective SEM micrographs however give ε-values of 250 ± 100 Å. This difference is not surprising, since it is unlikely that the water confined in surface pockets will behave completely rigidly at this frequency. On the other hand, one cannot determine the depth accurately from SEM; it is possible that the real roughness pattern of samples A, B in Figure 10 can be described only approximately by a hemispherical model and that the observed features are flattened spheroids with a depth shallower than their width. It is interesting to note, that the surface roughness generated in an alkaline environment (cf. Fig. 10B) due to oxidation is approximately twice as large as that created in a neutral environment (cf. Fig. 10A). This is also indicated by the Δm_1 values which were found to be 140 ng for sample A and

310 ng for sample B. Thus, roughly 80% of the observed frequency shifts are caused by roughness effects, while the remainder are due to oxide formation. This analysis definitely demonstrates the uniqueness of information which can be gained from these measurements and underlines the formation of a distinctly different roughness pattern upon oxidation of gold in various electrolytes.

3.4. Influence of Surface Stress on the Resonance Frequency

When one face of a quartz resonator is immersed in a liquid while the opposite face remains exposed to the atmosphere internal strains arise due to the hydrostatic pressure. The magnitude of this pressure depends on how deep the crystal is immersed into the liquid. As outlined by *Heusler* et al.[48] these strains cause a frequency shift that depends on the hydrostatic pressure and on the mass rigidly deposited on the quartz faces. This effect is not to be confused with the change in resonance frequency that occurs if both faces of the resonator are in contact with the liquid. Such frequency changes are found to depend linearly on the hydrostatic pressure, but occur at much higher pressure values.[44]

In Figure 11, the effects described by *Heusler* et al. are schematically presented in a frequency/pressure diagramm.

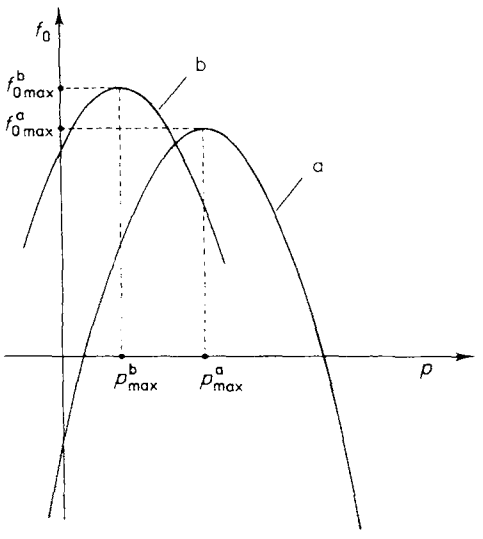

Fig. 11. Parabolic dependence of the resonant frequency f_0 on the pressure p between the *im*mersed and the *e*mersed oscillator face. The superscript *max* refers to the maximum of the parabolic curves with mass loads a and b (a > b) [48].

The curves a and b describe the situation for different mass loads. Contrary to the postulate of *EerNisse*,[49] who claims a linear frequency/pressure behavior, the curves are parabolic and can be expressed by the relationship (i).

$$f_0 - f_{0max} = A(p - p_{max})^2 \qquad \text{(i)}$$

The absolute values $|f^a_{0max} - f^b_{0max}|$ and $|p^b_{max} - p^a_{max}|$ are related to the increase in mass Δm and to the increase in compressive surface stress γ. For the quantitative determination of $\Delta\gamma$ one measures the pressure difference, Δp_{max}, at f^b_{0max} and f^a_{0max}. With the help of equation (j), which was worked out by *Heusler* et al.[48] one can determine $\Delta\gamma$ for that face

$$\frac{\Delta\gamma}{\Delta p_{max}} = \frac{R^3}{4 r_e d}\,[(7 + \nu)(1 - \nu)]^{1/2} \qquad \text{(j)}$$

which encounters stress changes. In this equation, ν is Poisson's number; R and r_e describe the overall radius and effective radius of the electrode surface, respectively.

The first in-situ investigations on the measurement of surface stress $\Delta\gamma$ were carried out on a polycrystalline gold substrate covered with a monolayer of lead.[48] For this type of measurement a special apparatus was designed which allows compensation of the hydrostatic pressure to determine Δp_{max}. From these data the surface stress change was estimated to be $3(\pm 2)$ N m^{-1}, indicating that this type of measurement is, in principle, possible and valuable, but the reproducibility of the measured results leaves much to be desired.

The important question of whether the strains caused by the hydrostatic pressure and their consequent effects lead to a falsification of the results measured by the quartz microbalance can be unequivocally ruled out, since the resonators are typically kept just below the liquid surface, where the hydrostatic pressure effect is negligible. However, strain effects which occur as a result of an increase in film thickness etc. can seriously affect the mass–frequency relation discussed above.[8, 36]

4. Usage of Oscillating Quartz Resonators to Investigate Interfacial Processes on the Solid/Liquid Junction

4.1. Growth and Decay of Solid Thin Films

4.1.1. Metallic Layers

So far, most of the investigations performed with oscillating quartz crystals have been concerned with the dissolution and deposition of various metallic films. In some cases it could be demonstrated that the dissolution and deposition rate, which is proportional to $\Delta\dot{f}$, is constant with time, as expected under galvanostatic control.[7, 9] By combining *Sauerbrey*'s equation [Eq. (a)] with Faraday's law, it has also been shown that, under certain conditions, the current efficiency ξ is close to 1, while in other cases values of $\xi < 1$ were determined. As described above, the former conditions were usually applied to calibrate frequency and mass changes (see Fig. 4). The change in ξ was observed to occur as a function of the applied current density or could be related to a simultaneously occurring competitive reaction which uses up additional charge.[9]

Dissolution experiments under potentiostatic control were performed on nickel[7] and nickel-phosphorus[18] films fixed to polycrystalline gold substrates. As shown in Figure 12, a plot of the anodic dissolution of electrochemically deposited nickel films as a function of the applied voltage exhibits two distinct current maxima at roughly -250 mV and -120 mV (reference potential: saturated calomel electrode, SCE). Since the observed current flux represents the mass

change associated with it, the dissolution rate, $> \Delta\mathring{f}$, is expected to follow this current pattern as well. The occurrence of two maxima correlates with *Fleischmann*'s[50] postulated concept that the nickel films consist of two different nickel

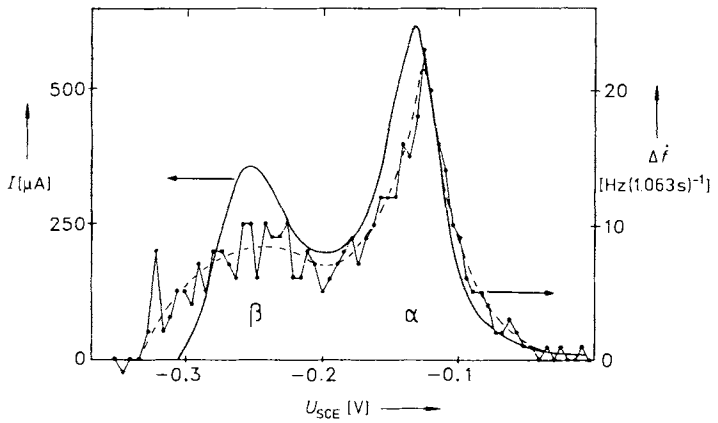

Fig. 12. Anodic dissolution of a nickel film presented in terms of current I and $\Delta\mathring{f}$ as function of the applied voltage U [7].

hydrogen NiH_x phases α and β which dissolve anodically in different potential regions in accord with Equation (k).

$$NiH_x \rightarrow Ni^{2\oplus} + 2e^{\ominus} + \tfrac{x}{2}H_2 \qquad (k)$$

By comparing the observables frequency response and current flux upon anodic dissolution, informative results could also be gained on the composition of nickel-phosphorus films. Here again, two distinctly separate anodic processes were identified. In order to avoid an atmospheric contact of galvanically deposited Ni–P films (composition $Ni_{100-x}P_x$; $8 \leq x \leq 30$) an apparatus was developed which enabled a rapid electrolyte exchange. Using the resulting data in conjunction with Equation (l) the compositional vari-

$$Ni_{100-x}P_x \rightarrow (100-x)\ Ni^{2\oplus} + x P^{z\oplus} + [2(100-x) + xz]\ e^{\ominus} \qquad (l)$$

able x can now be calculated. If one takes $z = 5$ as a basis, it can be concluded from the mass to charge ratio that two Ni–P structures with different composition are present. This result is consistent with the Ni–P phase diagram and electron diffraction experiments on the Ni–P system. The phosphorus content of the electrochemically more noble phase is higher than that of the electrochemically less noble phase. The less noble phase corresponds to supersaturated cubic face centered nickel, while the more noble phase corresponds to a nickel-phosphorus glass.

Investigations on the corrosion[17] and electroless deposition[3] of copper with the in-situ quartz microbalance likewise furnished interesting information. These investigations were carried out without potentiostatic/galvanostatic control, so that the potential of the working electrode could adjust itself according to the electrolytic conditions. In both cases the change in mass was monitored as a function of time. The data were analyzed according to formal kinetic rules. The results underscore the importance of surface reactions that occur on the submonolayer range for the dissolution and deposition of copper films.

Figure 13 shows that the frequency of resonators with copper films[17] in a sulfuric acid electrolyte enriched with various amounts of dissolved oxygen increases with time and is determined by corrosion. The data measured suggest that surface reactions with $Cu^{\oplus}$, O_2, $H^{\oplus}$ with formation of $HO_2^{\ominus}$ and $Cu^{2\oplus}$ are important steps in the dissolution of metallic

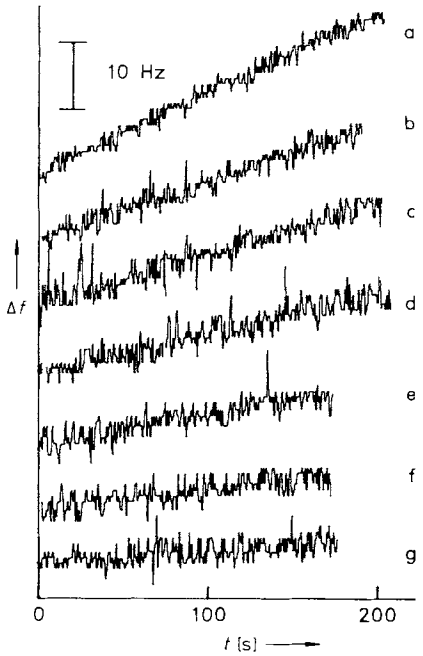

Fig. 13. Dissolution of a copper film presented as a frequency increase vs time plot in oxygenated sulfuric acid solution for various oxygen contents [μg/cm³]. a: 1.6; b: 6.5; c: 5.5; d: 4.3; e: 3.2; f: 2.2; g: 1.6 [17].

copper in oxygenated sulfuric acid according to the overall reaction given in Equation (m).

$$Cu + O_2 + 2H^{\oplus} \rightarrow Cu^{2\oplus} + H_2O_2 \qquad (m)$$

The observation, that the H_2O_2 concentration in an electrolyte does not exceed the millimole range under these conditions suggests that a simultaneous decomposition of dissolved H_2O_2 which may be catalyzed either homogeneously with cupric solution ions or heterogeneously on the copper surface.[51]

As shown by *Schumacher* et al.[3] the electroless deposition of copper with formaldehyde as reducing agent occurs via participation of adsorbed methanediol anions (MDA). The proportionality between $\Delta\mathring{f}$ and the concentration for formaldehyde in the electrolyte is consistent with a formal first order reaction. It also demonstrates that the degree of coverage of the copper surface with the active surface species MDA is proportional to the concentration of the formaldehyde under stead-state conditions and thus reflects a general principle that, at low adsorbent concentrations, the adsorption isotherm increases practically linearly with the concentration of the adsorbent. In the case of electroless deposition of copper the degree of surface coverage with MDA under steady-state conditions was estimated from measurements with the quartz microbalance to be 0.07. As proven in experiments with deuterated formaldehyde, the rate-determining

step for the deposition of copper is the cleavage of the carbon–hydrogen bond of the adsorbed MDA species to give formate.[3]
