were bound, D-galactose and L-glucose were not. Con A therefore differentiates not only between diastereomers but also between enantiomers. Furthermore, we found that on sonication the tetraacetates **1e–1h** formed spherical aggregates similar to those obtained from lipids **1a–1d**. Electron micrographs of negatively stained specimens (pH 7; phosphotungstate) showed vesicles (diameter approx. 400 ± 100 Å) and were identical for both the glucose derivatives **1a** and **1e**. Light scattering measurements after gel chromatography (Sephadex G100) gave identical results in the dead volume for **1a** and its tetraacetate **1e**. Entrapment experiments with the water-soluble fluorescence dye pyranine, however, were only successful with **1a**. In the case of the tetraacetate aggregates, the dye dispersed equally between the dead volume and the fractions that followed. We assume that the mechanical stability of the "hydrophobic" tetraacetate membrane does not suffice for remaining impermeable during gel chromatography. Surface monolayers of **1a** on water were also more stable (collapse pressure: $\pi_c = 50 \pm 5\ mN\ m^{-1}$; molecular area: 39 ± 3 Å^2) than in the case of the tetraacetate **1e** (34 ± 3 mN m^{-1}; 54 ± 3 Å^2 per molecule).

Agglutination experiments with Con A showed that the vesicles made of the tetraacetates **1e–1h** (≥99.8% purity) were precipitated with the same binding constants and velocities as the free carbohydrates **1a–1d** (Fig. 1). This means that four acetate groups on the vesicle surfaces are bound stereoselectively by Con A in the same way as four hydroxy groups. Minute traces of non-acetylated carbohydrate head groups (≪ 0.1%) cannot possibly cause the observed precipitation, since a tenfold diluted vesicular solution shows no precipitate whatsoever under the given reaction conditions. Electron micrographs of Con A-agglutinated vesicles show a flattening of the membranes at the contact areas. We therefore assume that the Con A-covered membranes make direct contact, without a protein link between vesicle surfaces. Micrographs of unbound vesicles show exclusively monomeric spheres in the presence of Con A. At tenfold higher concentrations of Con A all stereoisomeric vesicles are precipitated.

None of the binding models of Con A given in the literature accomodate four or eight acetyl groups (assuming the binding of two carbohydrate head groups) in place of protons. We therefore propose a binding site without a "cleft" or "pocket" but consisting of planar or slightly convex β-pleated sheets, which constitute 60% of the Con A surface. Such a binding site would offer a much better explanation for the observed stereoselective binding of smooth vesicle surfaces, since there is no obvious driving force for drawing a carbohydrate pair out of the vesicle surface and into a cleft on the Con A surface. Furthermore, the low solubility of hydrophobic oligomethylene chains in the region of hydrophilic head groups would strongly oppose such movement, and in polymerized vesicles, which are also stereoselectively recognized by Con A,[2] such movement would be almost impossible.

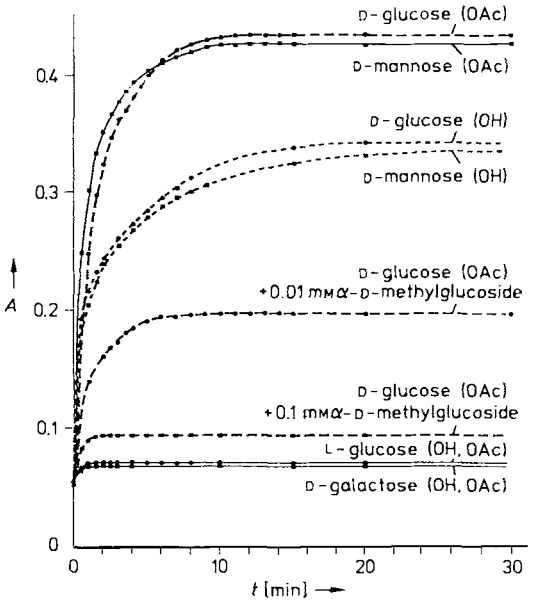

Fig. 1. Time-dependent absorption A at $\lambda = 360$ nm for the four diastereomeric and enantiomeric glycolipids **1a–1d** ("OH") and their tetraacetates ("OAc") in aqueous suspensions after addition of 10^{-4} M Con A.

We therefore propose an essentially planar binding site, whose stereospecifity is presumably caused by the arrangement of six dipoles.

The binding energy between Con A and a glycoprotein is known to be 23 kJ mol^{-1}.[9] This energy can be attributed to the dipole-dipole interactions of these six dipole pairs at an average distance of 0.45 nm.[10] Such a distance leaves ample room for the proposed acetyl groups (Fig. 2). There is even

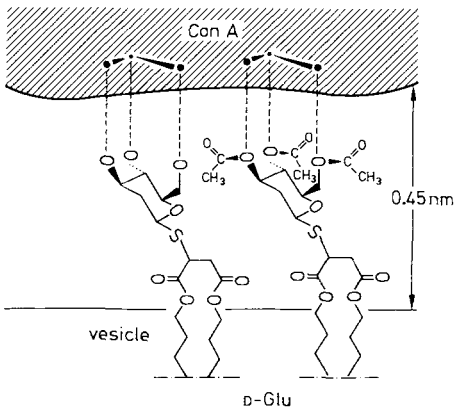

Fig. 2. Model of the stereoselective binding of D-glucose with and without acetyl groups at a smooth surface of Con A with a planar binding site distribution (hatched surface is tilted through 90°).

enough space for an additional hydration sphere between both surfaces, which would explain the observed similarities of binding constants and rates. The carbonyl dipoles of the acetyl groups obviously do not play an important role in the binding process. Formal attempts to bind the wrong enantiomers or diastereomers in the model yield at least two distances which are 20% larger. This is in agreement with the observed decrease of binding energies and equilibrium constants.

Synergic Destabilization by Geminal Ester Groups**

By *Sergej Verevkin, Barbara Dogan, Hans-Dieter Beckhaus* and *Christoph Rüchardt**

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

Stabilization by synergic interaction of geminal donor substituents on a saturated carbon atom, e.g. alkoxy groups in acetals, and its consequences, have long been known qualitatively as the "anomeric effect".[1] This anomeric stabilization and its dependence on structure was recently determined quantitatively by us.[2] In contrast, geminal nitro groups on a saturated C atom lead to destabilization.[3a] Results of ab-initio calculations and other theoretical studies,[3b–e] point to analogous effects in the case of other acceptor groups. We have now examined the synthetically important malonates **1a–c** and the methanetricarboxylates **2** in order to establish whether geminal ester groups are also synergically destabilizing.

Despite the universal use of malonates, to our knowledge no measurements of their standard enthalpies of formation have thus far been reported.[4] In the case of **1a–c**, **2**, and the reference compounds ethyl 2-methylbutyrate **3** and ethyl pivalate **4** they were now obtained from their combustion enthalpies $\Delta H_c^0(1)$ and vaporization enthalpies ΔH_v[3a] (Table 1.).

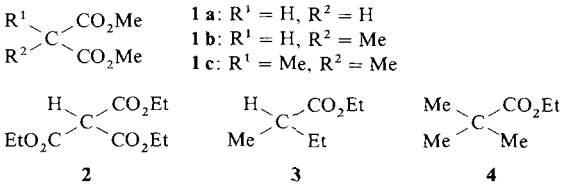

Table 1. Combustion enthalpies $\Delta H_c^0(1)$, vaporization enthalpies ΔH_v, and standard enthalpies of formation ΔH_f^0 of **1a–c** and **2–4** [kcal mol^{-1}] [a].

	$\Delta H_c^0(l)$	ΔH_v	$\Delta H_f^0(l)$	$\Delta H_f^0(g)$

[**] Geminal Substitution Effects, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, *S. V.* thanks Prof. *Alexandr M. Roznov* (Kuibyschew) for special support and the DAAD (Deutscher Akademischer Austauschdienst) for an exchange grant.–Part 2: [2].

of the isodesmic reactions which is otherwise frequently used. A possible influence of different alkyl branching on the central C atom can be tested, on the basis of the variously substituted malonic diesters **1a–c**.

Increments for the carboxy group, ΔH_f^0(g) CO_2[2C], and the O-bound carbon, ΔH_f^0(g) $CH_3^0[CO_2]$, $CH_2^0[CO_2,C]$, as well as for the ester-bearing alkyl groups, ΔH_{ester} $CH_3[CO_2]$, $CH_2[CO_2,C]$, $CH[CO_2,2C]$, $C[CO_2,3C]$ could be calculated from the known ΔH_f^0(g) values of monocarboxylates[6] with the help of already known increments for alkanes, ΔH_{alkyl}[5] (Table 2). The increments for alkyl groups with two ester groups as neighbors, $\Delta H_{diester}$, were determined from the new thermochemical data for the malonic diesters **1a–c** (see Table 1), while the increments for CH with three ester groups as neighbors, $\Delta H_{triester}$ were determined from the data for **2** (Table 2). On introducing an ester substituent instead of an alkyl group the increments hardly change; the destabilization energy ΔH_{ester}-ΔH_{alkyl} lies between 0.2 and 0.7 kcal mol^{-1} (Table 3). A second ester group, however, gives rise to a significant destabilization: the destabilization energy $\Delta H_{diester}$-ΔH_{ester} is 2.6 to 3.2 kcal mol^{-1}. The corresponding destabilization by the third ester group ($\Delta H_{triester}$-$\Delta H_{diester}$), with a value of 6.6 kcal mol^{-1}, is substantial. The extra destabilization $\Delta\Delta H_{gem} = \Delta H_{diester} - 2\Delta H_{ester} + \Delta H_{alkyl}$ and $\Delta\Delta H_{gem,gem} = \Delta H_{triester} - 2\Delta H_{diester} + \Delta H_{ester}$, i.e. the energy in excess of the additive destabilization energy is 1.9 to 2.8 kcal mol^{-1} in the case of malonic diesters and 3.5 kcal mol^{-1} in the case of tricarboxylates.

Table 2. Increments in enthalpy of formation [kcal mol^{-1}] for pure alkyl groups (ΔH_{alkyl}) and alkyl groups substituted by one (ΔH_{ester}), two ($\Delta H_{diester}$), or three ($\Delta H_{triester}$) [a] ester groups.

The classical anomeric effect is enhanced by alkyl groups on the central carbon atom.[2] The analogous dependence of the "inverse anomeric effect" on the degree of substitution is only slight in the case of the malonates.

The confirmation of the presumed inverse anomeric destabilization in the case of **1** and **2** indicates that the concept under discussion is a generally valid one. We shall next determine the extent of geminal effects and their dependence on the structure of some other substituents.

When discussing the CH-acidity of malonic esters and other geminally substituted compounds one must not only consider the stabilization of the anion but also the destabilization of the ground state as contributing to the acidity.

Some Valenes of Benzannelated Five-Membered Heteroarenes – Synthesis and NMR Spectra**

By *Manfred Christl,* Stefan Krimm* and *Arno Kraft*

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

The chemical shifts of the C-atoms common to both three-membered rings of *endo,endo'*-bridged bicyclobutanes stretch over the unusually large range of $\Delta\delta \approx 90$ (δ = − 13.4 to 75.5).[1] In the valenes of naphthalene, 1,4-disubstituted phthalazines,[1a] and quinoxaline-2,3-dicarbonitrile[2] recently investigated by us the corresponding δ-values lie between 42.4 and 48.6. We now present the first valenes of benzannelated five-membered heteroarenes and their NMR spectra.

The majority of the conventional methods for the synthesis of five-membered heteroarenes are unsuitable in the case of benzvalene-annelated derivatives. Thus, we were unable to dehydrogenate the benzvalene adducts of benzonitrile oxide and diphenyl nitrile imine.[3, 4a] We therefore carried out 1,3-dipolar cycloadditions[5] with benzvalenyl phenyl sulfone **1**.[6] This reacts with even more 1,3-dipolar compounds than does benzvalene.[3, 4] Moreover, the phenylsulfonyl

[*] Prof. Dr. M. Christl, Dipl.-Chem. S. Krimm, Dr. A. Kraft
Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

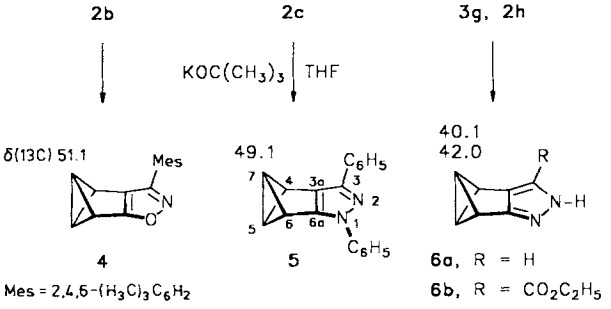
function introduced with **1** serves as leaving group in the elimination required en route to the target molecules.

Two nitrile oxides, diphenyl nitrile imine, (4-nitrophenyl)-phenyl nitrile ylide, two azides and two diazoalkanes afforded the dihydroheteroarenes **2** and **3**. Benzonitrile oxide,[5b] diphenyl nitrile imine[5b] and 4-nitrophenyl phenyl nitrile

1 2 3

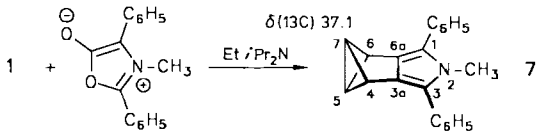
ylide[5c] were slowly generated in situ from their hydrogen chloride adducts with triethylamine, while the other 1,3-dipolar compounds were used as such. Data on the reaction conditions, yields and isomeric ratios are listed in Table 1. The regioselectivity compares with that of known 1,3-dipolar cycloadditions of vinyl sulfones.

Since the phenylsulfonyl function is only a moderately good leaving group the elimination of phenylsulfinic acid[8] from **2** and **3** did not succeed in all cases. With potassium *tert*-butoxide in tetrahydrofuran at 20 °C we obtained the isoxazole **4** (5 h, 77% yield) from **2b**, and the pyazoles **5** (5 h, 23%), **6a** (1 h, 29%) and **6b** (25 h, 68%), respectively, from **2c**, **3g** and **2h**.[7] There is no doubt about the structure of **5**, whereas in the case of **6a**, **b** tautomeric forms also have to be taken into consideration; however, on the basis of the ^{13}C-NMR spectra we prefer the structures **6**.



The success of these aromatizations seems to be dependent, inter alia, on the acidity of the protons that have to be split off. Thus, on using the mixture **2c**, **3c**, the reaction of **2c** proceeded smoothly, while **3c** remained unchanged and could then be readily isolated in isomerically pure form. In the case of **3e** the elimination reaction leading to the valene of phenylbenztriazole was not complete, and attempted separation of product and unconsumed starting material met without success.

3-Methyl-2,4-diphenyloxazolium-5-olate *N*-methyldiphenyl munchnone underwent reaction with **1** in dichloromethane, but the expected product was not obtained. In contrast, in the presence of ethyldiisopropylamine the desired pyrrole **7**[7] was immediately formed in 41% yield. Presumably, after cycloaddition and elimination of CO_2, the phenylsulfinate ion splits off at the stage of the transient azomethine ylide.[5d] The cationic precursor of **7** then transfers a proton even to the weak base ethyldiisopropylamine.



1 7

Starting from *cis*-3,4-dibenzoyltricyclo[3.1.0.0^{2,6}]hexane[1a] **8** and tricyclo[3.1.0.0^{2,6}]hexanedione **9**[2] there are several conceivable possibilities for the synthesis of the desired type of compound. However, only two reactions have thus far met with success: those to the thiophenes **10** (20% yield) and **11** (9%)[7] from **8** and Lawesson's reagent (toluene, triethylamine, 22 °C, 7 d) and from **9** and bisphenacylthioether (KOH in methanol, 20 °C, 18 h), respectively. The latter reaction provided the glycol product first, which was dehydrated with thionyl chloride in pyridine (0 °C, 1.5 h). 3,4-Diaminothiophene converted **9**, in analogy to known reactions,[2] into **12** (27%),[7] the valene of thieno[3,4-*b*]quinoxaline.

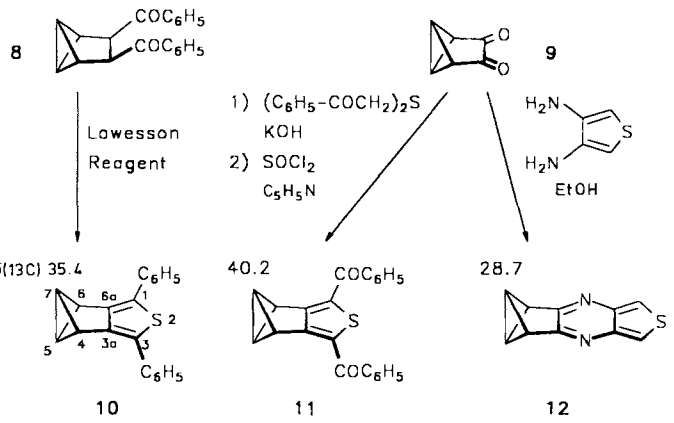


Table 1. Reactions of **1** with two nitrile oxides, diphenyl nitrile imine, 4-nitrophenyl phenyl nitrile ylide, two azides, and two diazoalkanes leading to the isomers **2** and **3**.

h	$C_2H_5O_2C$-CHN_2	CH_2Cl_2	2 d	C-$CO_2C_2H_5$	NH	46	>95:5

[a] First 4 h at 0 °C then 2 d at 20 °C. [b] **2g** was not isolated but only characterized NMR spectroscopically.

The ^{13}C-NMR chemical shifts of the bicyclobutane bridgehead atoms of the valenes are quoted alongside the formulas. They generally lie at considerably lower field than the values of the dihydro derivatives **2** and **3**. Especially noteworthy are the differences between the heteroarenes which are formally benzvalene derivatives, and those which can be derived from bismethylenetricyclo[3.1.0.0^{2,6}]hexane.[9] Thus, **4** and **5**, with $\delta = 51.1$ and 49.1, respectively, show the furthest downfield shifts of all tricyclo [3.1.0.0^{2,6}]hexane derivatives, whereas the corresponding signals of **7**, **10** and **11** with $\delta = 37.1$, 35.4 and 40.2 lie at considerably higher field. A comparison of the δ values of the pyrazoles **6** ($\delta = 40.1$, 42.0) and **5** accordingly supports the proposed structure **6**. The expansion of the aromatic system in **12** leads to a further upfield shift to $\delta = 28.7$. In comparison to the corresponding absorption of the valene in which the thiophene moiety of **12** is replaced by a benzene ring,[2] a shielding of $\Delta\delta = 6.2$ is observed in **12** which is possibly due to stronger double bond localization.

The majority of the valenes synthesized underwent isomerization under more or less energetic conditions to the benzannelated heteroarenes. In the case of **6b** and **7** this took place at 100–150 °C in C_6D_6, in the case of **10** and **11** during attempts at chromatographic purification. The isoxazole **4**, on the other hand, was converted into the acylazirine **13** (67% yield) upon heating.[7] Reactions of this type have already been reported, but thermally initiated ones generally do not terminate at the stage of the acylazirine.[10]

[**] This research was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and the Bundesministerium für Bildung und Wissenschaft within the framework of the graduate seminars "Synthesis and Structure Determination of Small Molecular Compounds" (Lecturer: *I. T.-O.*).

first isolated in 1975, have as yet been described. Nitrogen triiodide NI_3,[3] the longest-known nitrogen-halogen compound could hitherto only be prepared in the form of a donor-acceptor complex with one or three molecules of coordinated ammonia;[4] the X-ray crystal structure analysis reveals that $[NI_3 \cdot NH_3]_n$ consists of chains in which N is surrounded approximately tetrahedrally by I.[5] We recently reported the formation of $[NI_3 \cdot NH_3]_n$ from $I_3^{\oplus}AsF_6^{\ominus}$ and NH_3.[6] The aim of the present study was the synthesis of adduct-free nitrogen triiodide as the last missing member in the series of nitrogen trihalides.

The synthesis of free NI_3 can only be performed in the absence of ammonia, since $[NI_3 \cdot NH_3]_n$ cannot be transformed into NI_3 by the removal of ammonia,[4] and according to thermochemical considerations the adduct $NI_3 \cdot NH_3$ should be ca. 30 kJ mol^{-1} more stable than NH_3 and NI_3.[7] As boron nitride reacts readily with hydrogen fluoride to form ammonium tetrafluoroborate [Eq. (a)],[8] we were interested in the behavior of boron nitride towards iodine monofluoride.

$$BN + 4\,HF \longrightarrow NH_4^{\oplus}BF_4^{\ominus} \qquad (a)$$

Boron nitride reacts with IF in $CFCl_3$ according to Equation (b) to form NI_3, a red-black, highly volatile solid, very unstable at room temperature (**danger of explosion** [9]) and soluble in $CFCl_3$ giving a deep red color[10].

$$BN + 3\,IF \xrightarrow{CFCl_3} NI_3 + BF_3 \qquad (b)$$

In solution NI_3 decomposes rapidly at 0 °C and within several hours at − 60 °C. This explains the relatively small (30%) yield (see *Experimental*). In the solid state NI_3 is stable at − 196 °C, decomposes slowly at −78 °C and spontaneously at 0 °C. The driving force for the formation of the endothermic species NI_3[7] may certainly be ascribed to the large tendency for formation of BF_3 to take place.[11] After evaporation of the solvent at − 50 °C, NI_3 may be sublimed directly into a glass tube cooled to − 196 °C. In the process a small amount of decomposition takes place (iodine residue). NI_3 was characterized by Raman spectroscopy.[12]

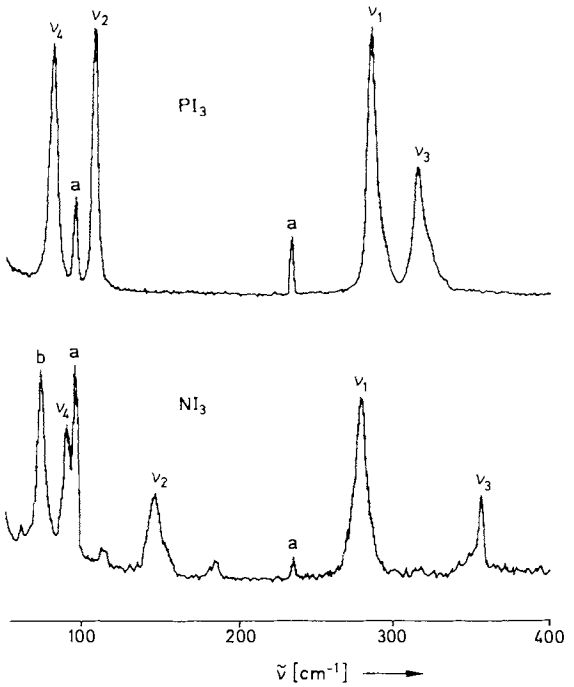

Fig. 1. Raman spectrum of NI_3[12] and PI_3 (see Table 1). ν_1–ν_4: NI_3; a: Laser lines; b: Lattice vibrations.

Table 1. Wave numbers [cm^{-1}] and relative intensities (in brackets) of the Raman active fundamental vibrations ν_1–ν_4 of the nitrogen trihalides NCl_3 and NI_3, and of PI_3.

	ν_1	ν_2	ν_3	ν_4
NCl_3[a]	535 (s)	347 (s)	637 (w)	254 (m)
NI_3[b]	279 (10)	146 (5)	354 (3)	90 (5)
PI_3[c]	285 (10)	107 (6)	315 (5)	81 (7)

[a] In CCl_4 solution, room temperature [15]. [b] Solid, − 100 °C. [c] Solid, room temperature.

The four most intense lines in the low-temperature Raman spectrum of NI_3 (Fig. 1) can be assigned to the NI_3 species with C_{3v} symmetry.[12] In Table 1 the Raman data of NI_3, of the Cl-analog NCl_3, and of PI_3 are compared. From the trend in the intensities as well as in the position of the frequencies, the four bands can be unambiguously assigned to the Raman active fundamental vibrations ν_1 to ν_4. For comparison, Figure 1 also shows the Raman spectrum of solid PI_3. The IR spectrum of $[NI_3 \cdot NH_3]_n$ contains a weak band at $\tilde{\nu} = 176\ cm^{-1}$ and a strong one at $\tilde{\nu} = 488\ cm^{-1}$, which can be assigned to the symmetric N-I stretching vibration.[13] However, as a result of the polymeric structure this assignment and the comparison with the Raman spectrum of NI_3 is problematic. On the other hand, the location of the observed N-I stretching vibration for iodine azide at 338 cm^{-1}[14] agrees well with the observed N-I stretching frequency for NI_3[12] (cf. ClN_3: $\tilde{\nu}_{N-Cl} = 719\ cm^{-1}$[14]).

When NI_3 is allowed to evaporate into the unheated ion source of a mass spectrometer (EI, 70 eV, 30 °C), it decomposes completely: the spectrum consists only of peaks of $I^{\oplus}$ (100%) and $I_2^{\oplus}$ (20%).

Freshly sublimed, deep red NI_3 reacts spontaneously with anhydrous NH_3 at − 45 °C, accompanied by a color change to green and the formation of $[NI_3 \cdot 3\,NH_3]_n$.[16] With methyl iodide, solid NI_3 reacts already below − 30 °C, losing I_2 and forming tetramethylammonium iodide,[17] as shown in Equation (c).

$$NI_3 + 4\,MeI \rightarrow NMe_4^{\oplus}I^{-} + 3\,I_2 \qquad (c)$$

Although NI_3 exists only at low temperature, the compound is more stable than one expects from the decrease in stability within the series NF_3, NCl_3, NBr_3.[4] This effect is certainly partially explained by the similar trend in the bond energies of the N–I and N-Cl bonds (E (N–Cl) = 190 kJ mol^{-1},[18] E (N–I) = 169 kJ mol^{-1}[7], which reflect the fact that I is considerably more electropositive than Cl and Br (Allred-Rochow electronegativities: Cl 2.83, Br 2.74, I 2.21).

Experimental

NI_3: All apparatus were deactivated with F_2. 20 mL of $CFCl_3$ (dried over P_4O_{10}) was condensed into a 50-mL quartz ampoule fitted with a stainless steel valve and containing a mixture of 1.00 g (3.94 mmol) of iodine and 0.065 g (2.63 mmol) of boron nitride (Aldrich). 0.157 g (4.14 mmol, i.e. 5% excess) of fluorine (Union Carbide; HF absorption by NaF) was thereafter condensed into the ampoule at − 196 °C; the reaction mixture was warmed to − 30 °C over 2 h with constant agitation. After a further 8 h at − 30 °C the mixture was irradiated for 5 minutes in an ultrasonic bath (**danger of explosion** [9]), then slowly warmed to − 10 °C, the $CFCl_3$ pumped off at − 50 °C and the NI_3 isolated as a deep-red solid from the black residue by sublimation (− 20 °C, receiving vessel − 196 °C; yield ca. 0.3 g, 30%). NI_3 already decomposes below 0 °C to iodine and nitrogen (proof via gas discharge). 0.08 g of NI_3 sets free 0.075 g I_2, corresponding to 94% I_2 (calc. 96%).

[9] **Warning**: Although pure NI_3 is stable at low temperatures in $CFCl_3$, the synthesis and isolation presents particular problems. On occasion the reaction of BN with IF does not start immediately. One of our samples cooled to $-18\,^{\circ}C$ and covered with a 10-cm thick layer of ice exploded and flying splinters caused considerable damage, for example to the full visor face protection of the experimenter.
[10] In the reaction of BN with four equivalents of IF, analogous to Equation (a), NI_3 is also formed. Byproducts: I_3BF_4 and an, as yet, not unambiguously identified yellow solid, possibly $IF_2^{\oplus}BF_4^{\ominus}$: $2\,BN + 8\,IF \rightarrow 2\,NI_3 + 2\,BF_3 + 2\,IF \rightarrow 2\,NI_3 + BF_3 + I_2F^{\oplus}BF_4^{\ominus}$; $2\,I_2F^{\oplus}BF_4^{\ominus} \rightarrow I_3^{\oplus}BF_4^{\ominus} + IF_2^{\oplus}BF_4^{\ominus}$. Up till now no indication of the existence of $NI_4^{\oplus}BF_4^{\ominus}$ could be found.
[11] A rough estimate of the enthalpy of reaction for Equation (b), neglecting the correct aggregation states, yields ΔH°_{298} (c) $= -312$ kJ mol^{-1} (ΔH°_f: BN(soln.) -254[19], IF(g) -95[18], BF_3(g) -1137[18], NI_3(g) $+287$ kJ mol^{-1} [7].
[12] Excitation wavelength: 647.09 nm, Laser energy: 15 mW, $T: -100\,^{\circ}C$. $\tilde{\nu}$ [cm^{-1}] = 72(m), 91(m), 113(vw), 146(m), 179(vw), 279(s), 354(w); Note added in proof: In the meantime it has also been possible to record a ^{15}N-NMR spectrum of NI_3 (98% ^{15}N) in $CFCl_3$ [20]. The appearance of only one singlet [$\delta = +183$ ppm, rel. to $MeNO_2$, 50.653 MHz (^{15}N), $-30\,^{\circ}C$] in the expected range points to the presence of only one species in solution. We shall report on the measurement conditions and the synthesis of $^{15}NI_3$ in a further communication..

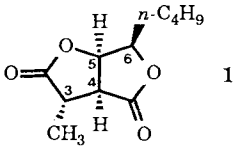
Doubly Stereodifferentiating Hiyama Addition with Mismatched Reactants; Enantio- and Diastereocontrolled Synthesis of Dihydrocanadensolide**

By *Johann Mulzer** and *Lars Kattner*

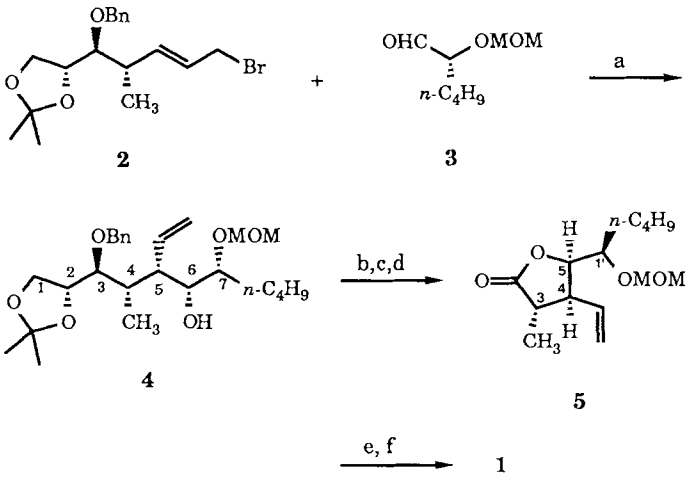
Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

Owing to its four chirality centers and the bicyclic paraconic acid lactone structure, dihydrocanadensolide **1**, a metabolite of *Penicillium canadense*,[1] is an attractive synthetic target molecule. The configuration first proposed for **1** was later revised[2,3] but is still not unequivocally elucidated.



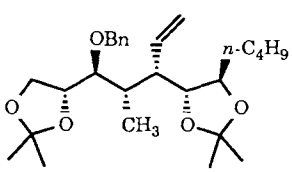
1

The physiological properties of the compound are unknown. We report here on the total synthesis of natural **1** and its enantiomer (Scheme 1).



Scheme 1. a) $CrCl_3/LiAlH_4$, THF, 0 °C, 36 h, 63%; b) Na/NH_3, THF, $-40\,^{\circ}C$, 20 min, 86%; c) pyridinium *p*-tosylate (PPTS), MeOH, 22 °C, 24 h, 64%; d) H_5IO_6, Et_2O/THF, 22 °C, 10 min; pyridinium chlorochromate (PCC), CH_2Cl_2, 22 °C, 2 h, 85%; e) HCl/MeOH/THF, 60 °C, 1 h, 98%; f) O_3/PPh_3, CH_2Cl_2, $-78\,^{\circ}C$; PCC, CH_2Cl_2, 22 °C, 2 h, 67%.

The key step is the Hiyama addition[4] of the allyl bromide derivative **2** to the aldehyde **3** (MOM = methoxymethyl). Both components are accessible in pure form in a few steps from (*R*)-2,3-isopropylideneglycerinaldehyde[5] and react highly stereoselectively (> 97% according to ^1H- and ^{13}C-NMR analysis) to give the adduct **4** (Table 1). This is the first Hiyama reaction of a chirally substituted acyclic allyl bromide derivative.[6] The configuration at the new chirality center C-6 was confirmed by conversion of **4** into the diacetal **6**, in which the *trans* position of 6-H and 7-H could be detect-



6

ed by NOE difference spectroscopy. The relative configuration at C-5/6 follows from the successful conversion of the monolactone **5** into the bislactone **1**, which is possible only in the case of *cis*-annelation[2] (Scheme 1).

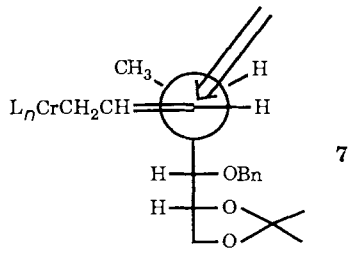
5: ^{1}H NMR: δ = 0.90 (t, 3H, J = 7 Hz, 5'-CH_3), 1.19 (d, 3H, J = 7 Hz, 3-CH_3), 1.30 (mc, 4H, 3'-CH_2, 4'-CH_2), 1.72 (mc, 2H, 2'-CH_2), 2.88 (mc, 2H, 3-H, 4-H), 3.38 (s, 3H, MOM-CH_3), 3.64 (ddd, 1H, J = 8, 6, 2 Hz, 1'-H), 4.47 (dd, 1H, J = 8, 2 Hz, 5-H), AB system: δ_A = 4.64, δ_B = 4.70 (2H, J_{AB} = 7 Hz, MOM-CH_2), 5.22 (dd, 1H, J = 16.5, 1.5 Hz, vinyl-CH_2), 5.24 (dd, 1H, J = 10, 1.5 Hz, vinyl-CH_2), 5.88 (ddd, 1H, J = 16.5, 10, 10 Hz, vinyl-CH), ^{13}C NMR: δ = 13.94, 14.20, 22.77, 27.67, 30.04, 39.44, 51.40, 56.26, 77.14, 80.26, 95.75, 119.66, 133.93, 179.51. $[\alpha]_D^{20}$ = −73 (c = 0.65, $CHCl_3$)

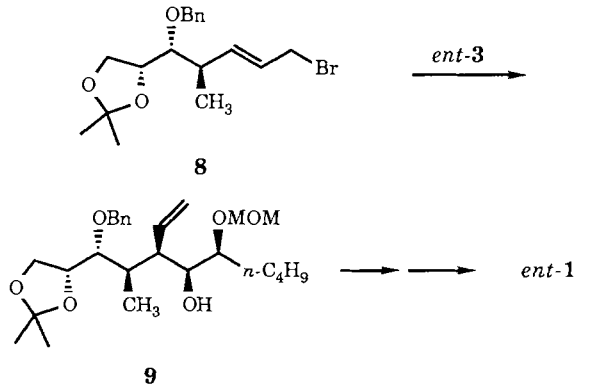
9: ^{1}H NMR (numbering as for **4**): δ = 0.86 (t, 3H, J = 7 Hz, 11-H), 0.99 (d, 3H, J = 7 Hz, 4-CH_3) 1.16–1.66 (m, 6H, 8-H, 9-H, 10-H), 1.40, 1.44 (each s, each 3H, isopropylidene-CH_3), 2.06 (m, 1H, 4-H), 2.42 (ddd, 1H, J = 10, 6.5, 4 Hz 5-H), 3.07 (s, 1H, OH), 3.40 (mc, 5H, 6-H, 7-H, MOM-CH_3), 3.62 (dd, 1H, J = 7, 4 Hz, 3-H), 3.75 (dd, 1H, J = 8.8 Hz, 1-H), 4.07 (dd, 1H, J = 8, 7 Hz, 1-H), 4.36 (ddd, 1H, J = 8, 7, 7 Hz, 2-H), AB system: δ_A = 4.59, δ_B = 4.70 (2H, J_{AB} = 7 Hz, MOM-CH_2), AB system: δ_A = 4.63, δ_B = 4.78 (2H, J_{AB} = 12 Hz, Ph-CH_2), 5.00 (dd, 1H, J = 17.5, 2 Hz, vinyl-CH_2), 5.18 (dd, 1H, J = 10, 2 Hz, vinyl-CH_2), 5.86 (ddd, 1H, J = 17.5, 10, 10 Hz, vinyl-CH), 7.33 (mc, 5H, aryl-H). ^{13}C-NMR: δ = 13.83, 15.23, 22.82, 25.64, 26.61, 27.14, 30.60, 37.12, 47.04, 55.85, 66.65, 73.70, 73.74, 78.24, 82.77, 82.84, 97.74, 108.94, 117.85, 127.32, 127.70, 128.17, 136.73, 139.24. $[\alpha]_D^{20}$ = +26 (c = 1.66, $CHCl_3$)

The all-*syn* arrangement[7] at the chirality centers C-4 to C-6 in **4** can be explained as follows. The relative configuration at C-4/5 is the result of the diastereofacial control exercised by the chirality centers of **2** which can be interpreted in terms of a Felkin-Anh-analogous transition state **7**.[8] The



7

relative configuration at C-5/6 corresponds to the normal "simple diastereoselection" of the Hiyama reaction.[9] Since C-7 is introduced into the reaction with a given configuration, the *syn*-arrangement at C-6/7 follows automatically, which is contrary to the stereochemical course of the Hiyama addition of *achiral* allyl bromides to α-alkoxyaldehydes.[10] The formation of **4** is therefore a case of double stereodifferentiation with mismatched reactants.[11] The influence of the allyl bromide surpasses by far that of the aldehyde. After debenzylation and hydrolysis of the acetal moiety the triol unit of **4** is oxidatively degraded and the compound two C-atoms shorter is converted into the lactol, which can be oxidized quantitatively to the lactone **5** (Table 1). The second



lactone ring is obtained by oxidative cleavage of the vinyl group. According to its melting point, rotation, and ^{1}H-/^{13}C-NMR data (Table 1) the product thus obtained is identical with the natural product,[12] whose structure was thus confirmed for the first time. Access to the enantiomer was accomplished by Hiyama addition of the allyl bromide derivative **8** to *ent*-**3**,[5] which affords the adduct **9** in >97% diastereomeric purity (Table 1). **9** is converted into *ent*-**1** analogously to the conversion of **4** into **1**.

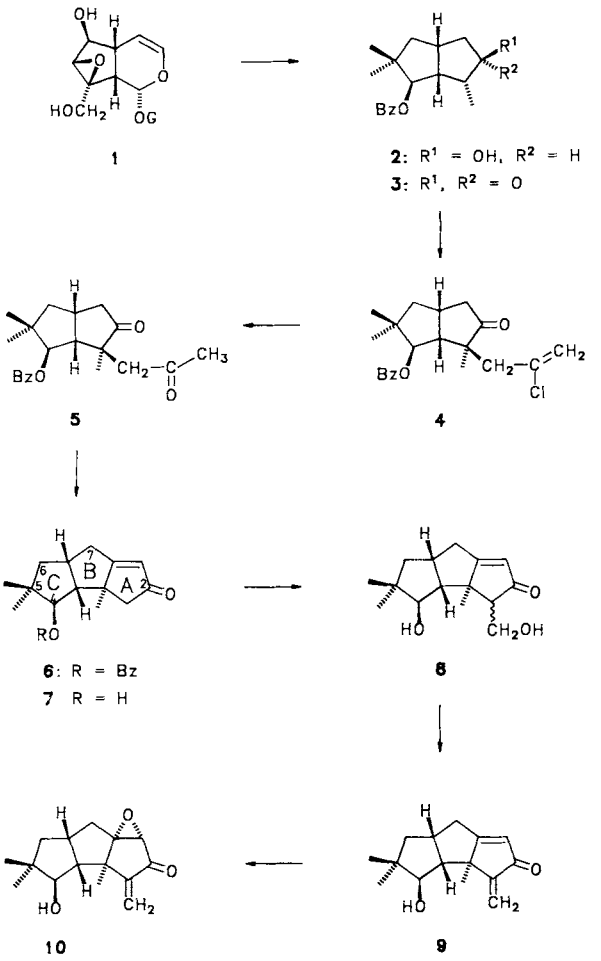
10, a sesquiterpene with triquinane structure. Two recent communications[2] concerning the synthesis of racemic **10** have motivated us to report the synthesis of enantiomerically pure **10** from catalpol **1**.

Catalpol **1** can be converted by simple reactions into all-(*R*)-**2** (Scheme 1), whose constitution and absolute configuration have been confirmed by an X-ray structure analysis.[3]



Scheme 1. **1** → **2**: [3]; **2** → **3**: pyridinium chlorochromate (PCC), $NaOCOCH_3$, CH_2Cl_2, room temperature (RT), 4 h, 85%; **3** → **4**: 2,3-dichloropropene, *t*BuOK, *t*BuOH, C_6H_6, 80 °C, 2.5 h, 60%; **4** → **5**: $Hg(CF_3CO_2)_2$, CH_2Cl_2, RT, 45 min, 80%; **5** → **6**: *t*BuOK, *t*BuOH, 35 °C, 15 min, 85%; **6** → **7**: NaOH, MeOH, 80 °C, 12 h, 78%; **7** → **8**: lithium diisopropylamide (LDA), THF, CH_2O, −78 °C bis −30 °C, 10 min, 73%; **8** → **9**: *p*-toluenesulfonchloride, pyridine, CH_2Cl_2, RT, 4 d, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), RT, 2 h, 75%; **9** → **10**: H_2O_2, K_2CO_3, CH_2Cl_2, RT, 2 d, 51%. Bz = benzoyl, G = glucosyl.

Oxidation of **2** with pyridinium chlorochromate in dichloromethane affords the crystalline ketone **3**. Alkylation of **3** with 2,3-dichloropropene leads to **4**, which is hydrolyzed with mercury(II) trifluoroacetate in dichloromethane within 45 min to the diketone **5**. This reaction has already been carried out on several α-(chlorobutenyl)cycloalkanones by *Matsumoto* et al.,[4] and proceeds in high yields. Aldol condensation of **5** affords the triquinane derivative **6**. The ester group is subsequently hydrolyzed with sodium hydroxide at 80 °C. Condensation and hydrolysis can also be carried out in one reaction step; however, the yield of **7** is then lowered. Hydroxymethylation, removal of water and epoxidation lead via **8** and **9** to enantiomerically pure (−)-hypnophilin **10**. The physical data (specific rotation, CD, and IR, ^{1}H-NMR, ^{13}C-NMR and mass spectra) of **10** are identical with those of the natural product.[1b] Hypnophilin is a colorless oil and decomposes after a few days (monitored chromatographically (TLC)). For this reason we have prepared the intermediate **9**, which is crystalline and stable, in larger amounts and epoxidized it to **10** when required.

The cyclopenta[*a*]pentalene derivative **7** (correct elemental analysis) is crystalline (m.p. 102 °C) and has a specific rotation of + 34 (c = 1 in $CHCl_3$). The IR and ^{1}H-NMR spectra are in good agreement with those for racemic **7**.[2a] The ^{13}C-NMR signals[5] are consistent with the constitution quoted for **7**. Compound **7** has already been described as intermediate in the total synthesis of enantiomerically pure (−)-coriolin; in this case, however, a specific rotation of − 115.4 (c = 0.2 in $CHCl_3$) was quoted.[6] The large difference in the values of rotation made an X-ray structure analysis necessary. Since the absolute configuration of **2** was confirmed by X-ray diffraction,[3] the absolute configurations at C3b and C6a of **7** must also be confirmed because no reaction was carried out at these C atoms. Relative to these, an *S*-configuration was found for C3a and an *R*-configuration for C4. The rings A and C are attached *anti* to each other, corresponding to the sterically most favorable conformation (Fig. 1). Ring C assumes an almost flat envelope conformation with a folding angle of 36.6° between the planes C4/C3b/C6a/C6 and C4/C5/C6. Due to the enone structure, ring A is planar within a maximum deviation of 0.08 Å, and the central ring has a slightly twisted envelope shape. The bond angles and bond lengths are, within the limits of error, as would be expected.[7]

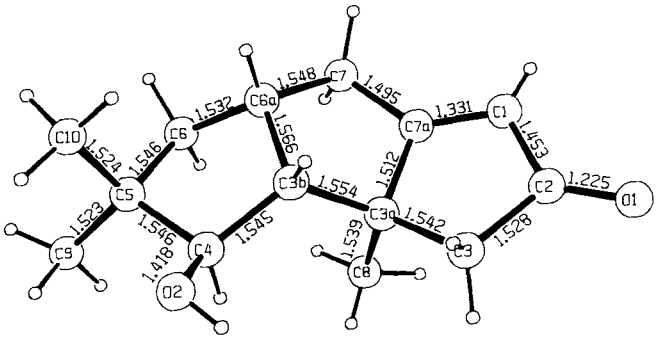


Fig. 1. Crystal structure of **7** with bond lengths [A°] (standard deviation 0.003-0.004 Å) [8].

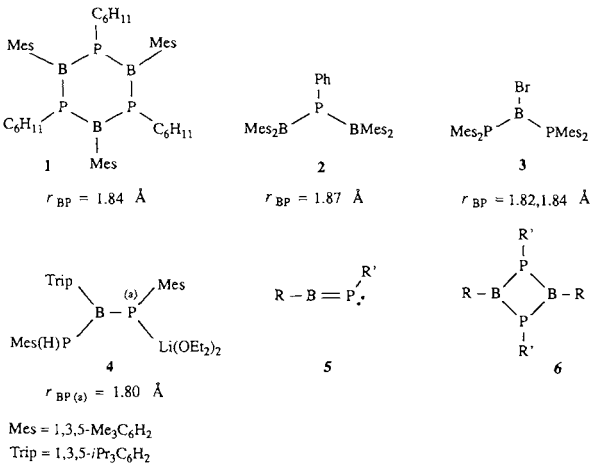
Space group $P2_12_12_1$, Z = 4, a = 7.200(1), b = 12.855(3), c = 13.440(3) Å, V = 1244.0(7) Å^3, ϱ_{calcd} = 1.176 Mgm^{-3}. CAD4 diffractometer (Enraf-Nonius), graphite monochromator, $Mo_{K\alpha}$ radiation, $\omega - 2\theta$ scan in the range to $\sin\theta/\lambda^{-1}$ = 0.661 Å^{-1}. The structure was solved with the program MULTAN 11/82 [P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J.-P. Declereq, M. M. Woolfson, York (England)] and refined in a full matrix method (C and O anisotropically, hydrogen atom positions localized by difference Fourier syntheses and subsequently refined isotropically). Lorentz and polarization corrections were carried out. R = 0.043 (R_w = 0.053). All calculations were carried out with the SDP Program packet [B A. Frenz and Ass., Inc., College Station Texas (USA) and Enraf-Nonius, Delft (Holland) 1982]. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54515, the names of the authors, and the journal citation.

scavenging reagents, except for a more recent result where the reaction of *tert*-butyllithium with tmpB(Cl)PHAryl led to the boranylphosphanide [tmp(*t*Bu)BPAryl]Li (tmp = 2,2,6,6-tetramethylpiperidino; Aryl = 2,4,6-tBu$_3$C$_6$H$_2$).[9]



An Allene-analogous Boranylidenephosphane with B=P Double Bond: 1,1-Diethylpropyl(2,2,6,6-tetramethylpiperidino)-boranylidenephosphane-*P*-pentacarbonylchromium

By *Gerald Linti, Heinrich Nöth*, Kurt Polborn*, and *R. T. Paine*

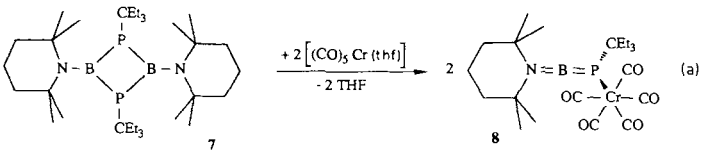
Compounds of boron with coordination number 2 are stabilized electronically by multiple bonds. However, in most cases additional sterically bulky substituents are necessary to suppress oligomerization. Examples are provided by boroxanes R–B≡O featuring a B≡O triple bond,[1] imino- and aminoiminoboranes RB≡NR'[2] and R_2N–B≡NR'[3] respectively, characterized by B≡N triple bonds, and alkylidene boranes containing a B=C double bond.[4] That elements of the third row of the periodic table such as phosphorus are also capable of forming multiple bonds to boron can be seen in formulas **1**–**4**.[5–8]

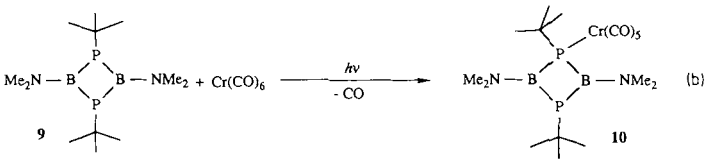
The planar triphosphatriborinane ring **1** with planar tricoordinated phosphorus atoms and relatively short B–P bonds (average: 1.84 Å) provides convincing evidence of this type of bonding. Planar coordinated phosphorus atoms are also present in the diborylphosphane **2** and in the borylated lithium phosphide **4**, while the phosphorus atoms in **3** exhibit a slightly pyramidal coordination. A common feature of these four compounds is the presence of tricoordinated boron atoms.

In spite of the introduction of very bulky substituents R and R', the preparation of boranylidene phosphanes **5** was still not possible. Their attempted synthesis led to the 1,3,2,4-diphosphadiboretane dimers **6**.[5] Also, the fleeting existence of **5** as an intermediate could not be clearly identified with

Apparently, the substituents selected up to now have been insufficient for a kinetic stabilization of a boranylidenephosphane **5**. Therefore, we tried to enhance steric shielding at the phosphorus atom in **5** by introducing an additional bulky ligand. For this purpose compounds of type **6** were treated with [(CO)$_5$Cr(thf)] at ambient temperature.[10] With **7**[11] as an example, ring cleavage results in the formation of the yellow 1,1-diethylpropyl-(2,2,6,6-tetramethylpiperidino)boranylidenephosphane **8**, complexed at P, in high yields [Eq. (a)].

In contrast, the sterically less hindered diphosphadiboretane **9**[12] reacts with $Cr(CO)_6$ under photolytic conditions to give only complex **10** [Eq. (b)]. This difference in the course of two comparable reactions is reflected in the mass spectra of **7** and **9**. The radical cation $(tmpB{=}PCEt_3)^{\oplus}$ is the base peak in **7**; i.e., the diphosphadiboretane has dissociated to a boranylidene phosphane, while no monomeric $(Me_2NB{=}PCMe_3)^{\cdot\oplus}$ is observed during the fragmentation of **9**.[12]





Compared with **7** there is little change in the shielding of the boron atom in **8** ($\Delta\delta^{11}$B = 3). δ^{31}P exhibits a more pronounced upfield shift ($\Delta\delta$ = 25). ^{1}H-NMR and ^{13}C-NMR spectra suggest that the molecule **8** is fairly symmetrical. However, a convincing prediction for the structure of **8** can-

[*] Prof. Dr. H. Nöth, Dr. G. Linti, Dr. K. Polborn

New Mexico (USA)

not be put forward solely on the basis of NMR data. If there is a true p(π)–p(π) bond between boron and phosphorus in **8**, then one must expect an allene type structure for $(tmp)=B=P(CEt_3)Cr(CO)_5$ as is found in the N-analogue $(tmp)=B=N(CMe_3)Cr(CO)_5$.[13] The X-ray structure analysis,[14] depicted in Figure 1, shows an almost linear arrangement for the NBP unit (176.1(3)°) and a nearly orthogonal arrangement for C1NC5 and CrPC10 (angle between the normals to the planes: 96.0°) (Fig. 1). The very short B–N

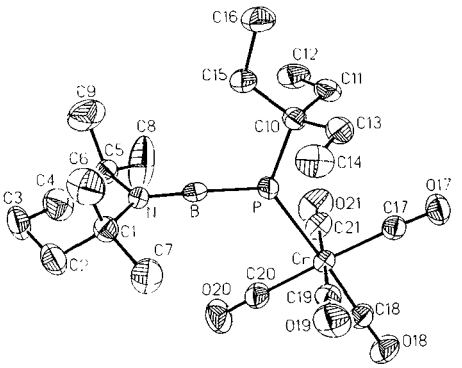

Fig. 1. Crystal structure of **8** (in ORTEP, thermal ellipsoides represent a 30% probability, hydrogen atoms are not shown). Selected bond lengths [Å] and angles [ ]: B-P 1.743(5), B–N 1.339(5), P–C10 1.885(4), P–Cr 2.420(1); N-B-P 176.1(3), B-P-C10 109.0(2), B-P-Cr 123.1(2), C10-P-Cr 127.6(1), B-N-C1 119.8(3). B-N-C5 120.0(3).

bond (1.339(5) Å) is consistent with the presence of a B=N double bond. The B–P bond length (1.743(5) Å) is 0.06 Å shorter than the shortest B–P bond length with double bond character reported for **4** (for a more recent value see Ref. [15]), and 0.18 Å shorter than the B–P bond length in **7**;[11] this corresponds with a change from a single to a double bond. Consistent with the presence of a B=P double bond, the sum of the bond angles at the phosphorus atom is, within experimental error, 360°, suggesting sp^2 hybridization. However, due to the significantly different steric requirements of the substituents at the phosphorus atom, the BPC6 bond angle deviates strongly (109.0°) from the ideal 120° expected for sp^2 hybridization. It follows that the $Cr(CO)_5$ group adds to the steric shielding of the boron atom by pushing the 1,1-diethylpropyl group toward the N=B=P system. A comparable situation to **8** exists in the isoelectronic phosphaallene complex $Ph_2C=C=P(Aryl)Ni(CO)_3$;[16] its allene skeleton remains almost unchanged compared to the free phosphaallene ligand.[17]

MNDO calculations predict for the dimerization of boranylidenephosphanes **5** (R = R′ = H, CH_3) to 1,3,2,4-diphosphadiboretanes **6** an energy barrier of only 21 kJ mol^{-1}. This barrier is more than 80 kJ mol^{-1} lower than for the dimerization of iminoboranes RN≡BR′.[18] One of the reasons for this energy difference is that the bent structure of boranylidenephosphanes in the ground state differs markedly from the linear structure of iminoboranes.[10] Nevertheless, boranylidenephosphanes carrying less bulky groups should be able to be generated in the gas phase[10] because gaseous boranylidenesulfanes of type X–B=S (X = H, F, Cl, CH_3)[19] are already well characterized. The existence of these sulfur compounds as intermediates in solution is ascertained by scavenging reactions.[20] A kinetic stabilization of boranylidenesulfanes by bulky substituents, in analogy with boranylidenephosphanes **5**, will be much more difficult. However, the present results are a promising sign that boranylidenesilanes $RB=SiR'_2$ will become accessible.[21]

Experimental

8: A solution of 1.52 g (6.9 mmol) of $Cr(CO)_6$ in 50 mL of THF was irradiated with a mercury lamp (Hanovia S 200 W). After evolution of gas ceased, a solution containing 0.67 g (1.19 mmol) of **7** in 20 mL of hexane was added. The course of the reaction was monitored by ^{31}P NMR. Five days were required for completion of the reaction. All volatile components were then removed *in vacuo* from the red-orange solution. Extraction of the residue with 50 mL of pentane furnished a yellow solution from which 0.97 g (86%) of **8** crystallized out at 20 °C as intensely yellow prisms; m.p. 95–98 °C. NMR data (C_6D_6, 25 °C, Bruker AC 200): $\delta^{11}B = 62.9$ ($h_{1/2} = 540$ Hz); $\delta^{31}P = -45.3$ ($h_{1/2} = 340$ Hz); $\delta^{13}C = 218.3$ (d, $^2J(P,C) = 14$ Hz, *cis*-CO), 211.5 (*trans*-CO), 55.9 (*d*, $^3J(P,C) = 8$ Hz, C-1,5), 37.9 (C-2,4), 33.4 (d, $^4J(P,C\text{-}6) = 3$ Hz), 32.4 (d, $^4J(P,C\text{-}9) = 2$ Hz, 16.5 (C-4), 46.6 (d, $^1J(P,C\text{-}10) = 5$ Hz, 30.3 (d, $^2J(P,C\text{-}11) = 4$ Hz, 9.3 (d, $^3J(P,C\text{-}12) = 5$ Hz); $\delta^1H = 1.32$, 1.16 (6H each, $NCCH_3$) 1.06 (6H, $NCCH_3$), 1.53 (m, 6H, $PCCH_2$ H-11), 0.89 (t, 9H, $^3J(H,H) = 7$ Hz $PCCH_2CH_3$).

10: An ice cooled suspension of 0.31 g (1.1 mmol) of **9** and 0.58 g (2.7 mmol) of $Cr(CO)_6$ in 30 mL of hexane was irradiated with a mercury lamp (Hanovia S 200 W) for one hour. CO evolution ceased after this time and 1.2 mmol of CO were collected. Addition of 5 mL of THF to the solution and additional irradiation set free another 0.8 mmol of CO. After removal of all volatiles *in vacuo* the residue was extracted with 20 mL of hexane. On cooling the extract to −78 °C the product precipitated as a sand-colored powder. Yield: 0.36 g, 70%; m.p. 120 °C (dec.). NMR data (C_6D_6, 25 °C, Bruker AC 200): $\delta^{11}B = 45.9$ ($h_{1/2} = 300$ Hz); $\delta^{31}P = -34.5$, −42.0 ($h_{1/2}$ 300 Hz each); $\delta^{13}C = 45.6$ (t, $^3J(P,C) = 8$ Hz, NMe_2), 45.3 (dd, $^3J(P_a,C) = 6$, $^3J(P_b,C) = 8$ Hz, NMe_2), 35.9 (d, $^2J(P,C) = 7$ Hz, CMe_3), 32.9 (d, $^2J(P_a,C) = 5$ Hz, CMe_3), quarternary C-atoms not observed since the DEPT sequence was used; $\delta^1H = 2.82$ (d, $^4J(P,H) = 1.5$ Hz, NMe_2), 2.68 (s, NMe_2), 1.30, 1.15 (each a dd, $^3J(P,H) = 9.5$, $^5J(P,H) = 0.5$ Hz, CMe_3).

Measuring the Optical Activity of Chiral Imprints in Insoluble Highly Cross-linked Polymers**

By *Günter Wulff** and *Günter Kirstein*

In recent years there has been increasing interest in the technique of using template molecules to produce imprints in cross-linked polymers, then applying these for molecular recognition purposes.[1, 2] To prepare these, polymerizable monomer molecules possessing suitable binding groups are first attached to template molecules. The "template monomer" is then converted into a macroporous polymer by polymerizing in the presence of a large excess of a cross-linking agent. The template can then be removed, leaving microvoids in the polymer; the shape of the voids and the configuration of the binding groups are determined by the template molecule. For example, the template monomer **1** (consisting of phenyl-α-D-mannopyranoside **2** as a template and two 4-vinylphenylboronic acid residues attached by esterification

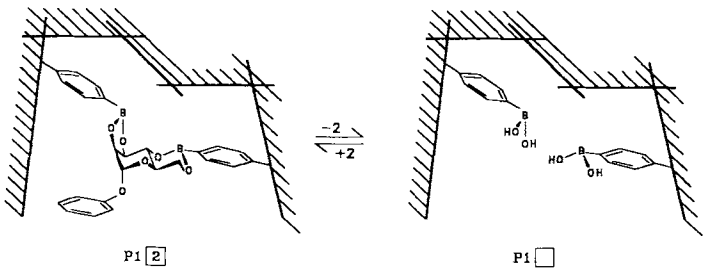

Scheme 1.

as binding groups) can be converted into the polymer **P-1-2**. After detaching the template **2** the polymer **P-1-□**, whose voids each contain two projecting free boronic acid groups, is obtained (see Scheme 1). This polymer can be used to achieve highly selective chiral separations of both the racemate of the template **2**[3] and D,L-mannose.[1c]

As these polymers are completely insoluble the chiral voids cannot be characterized by direct methods, and the usual method of investigating the racemate separation behavior only gives indirect information. If chiroptical measurements could be made on such polymers this would certainly make possible major advances. *Vogl, Pino* et al.[4] have recently described a method for measuring the optical rotation of helical atropisomeric polymers in the solid phase. We have investigated the possibility of applying this method to macroporous polymers with chiral voids, and of using it, for example, to determine the contribution of the chiral imprints to the specific rotation for the polymers **P-1-2** and **P-1-□**.

To measure the specific rotation of a solid it must be examined as a suspension in a medium whose refractive index is as close as possible to that of the substance being investigated. Where measurements are made in media with different refractive indices (Fig. 1), different values are obtained for the

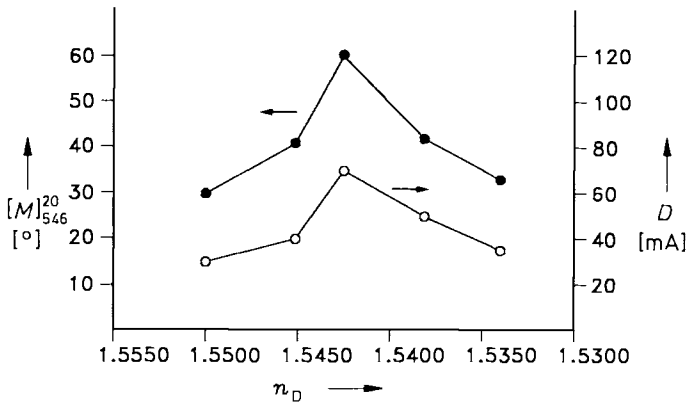

Fig. 1. Molar optical rotation $[M]^{20}_{546}$ and optical transmission D (measured in *mA* obtained from a photomultiplier) for suspensions of **P-1-2** in media with different refractive indices [5]. $c = 2.0$.

optical transmission D and the specific rotation. Only in the optimum range with 80–95% transmission does one obtain the maximum, and correct, value for the specific rotation of the substance.[4] To test the reliability of such measurements, the refractive index of the medium was adjusted to the optimum value and the molar optical rotation was measured as a function of the concentration (Fig. 2). It is also important that the density of the medium should be as similar as possible to that of the solid, so as to avoid sedimentation.[4, 5] Since birefringence effects can be mistaken for optical rota-

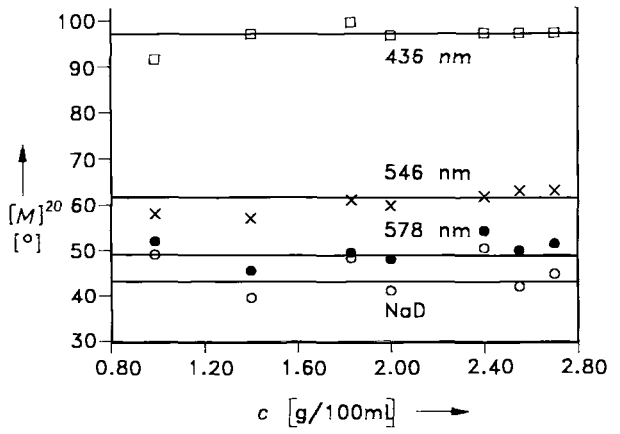

Fig. 2. Molar optical rotation of **P-1-[2]** as a function of suspension concentration c in a medium with a refractive index $n_D^{20} = 1.5424$. The average molar rotation values $\bar{x}$ and the standard deviations σ for the measurements at each wavelength are as follows: 436 nm: $\bar{x} = 97.1°$, $\sigma = 2.4°$; 546 nm: $\bar{x} = 61.7°$, $\sigma = 3.1°$; 578 nm: $\bar{x} = 48.7°$, $\sigma = 3.0°$; Na D-line: $\bar{x} = 43.3°$, $\sigma = 3.9°$.

tions,[4] an achiral macroporous polymer, which was otherwise similar to the polymers **P-1-[2]** and **P-1-□** was first prepared from the monomer **3**. From this polymer **P-3-[4]** the cyclohexanol moiety **4** was then detached to give the polymer **P-3-□**. Neither polymer showed any optical rotation under optimal measurement conditions.[5] The achiral polymer **P-3-□**, with free boronic acid groups, was then esterified by reacting in turn with an excess of (*S*)- or of (*R*)-1-phenyl-1,2-ethanediol, [(*S*)-**5** and (*R*)-**5** respectively], achieving esterification of about 96% of the boronic acid groups. Optical rotation measurements were then made on this polymer also (see Table 1). The observed molar rotation values $[M]_{546}^{20}$ for the polymers containing the (*S*) and (*R*) enantiomers were + 357° and − 366° respectively, thus giving absolute values which are identical within the limits of error, and are also of the same order of magnitude as the molar rotation value for the corresponding monomeric phenyl ester **6**. From these results one may proceed on the assumption that optical rotation values can be determined with reasonable accuracy on highly cross-linked macroporous polymers. It appears that the achiral matrix has only a small effect on the contribution of optically active side-groups to the observed rotation values.

Table 1. Optical rotation values for achiral polymers after reacting with optically active diols, and for reference samples [a].

		P-3-[5]	5	6
$[\alpha]_{546}^{20}$	(*S*)	+ 23.4 ± 1°	+ 72.0° (95.0% *ee*)	+ 159.0°
	(*R*)	− 24.0 ± 1°	− 72.6° (95.8% *ee*)	-
$[M]_{546}^{20}$	(*S*)	+ 357 ± 15°	+ 99.5°	+ 356.3°
	(*R*)	− 366 ± 15°	− 100.3°	-

[a] Macroporous polymer **P-3-[5]** prepared by removing the cyclohexanol residues from **P-3-[4]** then loading with (*S*)- or (*R*)-1-phenyl-1,2-ethandiol **5** to a level of 96.3% occupancy. Suspension medium: 6.60 g of 1,2-dichlorobenzene plus 1.00 g of a mixture of 9.00 g of dichloroethane with 2.00 g of tetrachloroethylene. $n_D^{20} = 1.5386$. Polymer concentrations: 2.748 g in 100 mL for the polymer containing (*S*)-phenylethandiol and 1.758 g in 100 mL for that with the (*R*) enantiomer. Measured rotations: + 0.643° and − 0.422° respectively.

To investigate the effects of the template and of the void structure on the optical rotation, the polymer **P-1-[2]** made from the template monomer **1** was studied in greater detail.[6] As can be seen from Figure 1 and Table 2, this gave a molar rotation value $[M]_{546}^{20}$ of − 60.6°. The measurements over a range of concentrations (Fig. 2) showed good agreement between the values, with an average $[M]_{546}^{20}$ value of − 61.7° and a mean error for the average of $m = 1.2°$. Taking into account possible systematic errors, the overall limit of error is estimated as ± 5–10%.

Table 2. Optical rotation values for various polymers with voids. The measurements were made on suspensions in a mixture of 1,2-dichlorobenzene, dichloroethane and tetrachloroethylene.[5]

	Template monomer **1**	Template **2**	P-1-[2] [a]	P-1-□ [b]	P-1-[7] [c]
α_{546}^{20}	-	-	− 0.040°	− 0.067°	+ 0.040°
$[\alpha]_{546}^{20}$	− 93.5°	+ 142.6°	− 2.0°	− 2.7°	+ 3.1°
$[M]_{546}^{20}$	− 448.9°	+ 365.3°	− 60.6°	− 76.4°	+ 110.0°
			[$\bar{x}$ = − 61.7°] [d]		

[a] $n_D^{20} = 1.5424$, $c = 2.00$, $D = 80\%$. [b] $n_D^{20} = 1.5424$, $c = 2.58$, $D = 80\%$. [c] $n_D^{20} = 1.5401$, $c = 1.28$, $D = 95\%$. [d] $\bar{x}$ was calculated from the measurements at different concentrations (see Fig. 2). D is the optical transmission of the suspension expressed as a percentage of that for the pure solvent.

If we compare the value of − 61.7° given in Table 2 for the molar rotation $[M]_{546}^{20}$ of the polymer **P-1-[2]** with the value − 448.9° for the template monomer **1**, it becomes apparent that, in contrast to the situation in **P-3-[(*R*)-5]**, the molar rotation value has decreased considerably as a result of the polymerization. It must be assumed that this has been caused by the polymer matrix. Its effect can be determined by splitting off the optically active template **2**. Since optically active boronic acid groups usually have rotation values greatly different from those of their esters,[7] it is necessary to convert **P-1-□** with ethylene glycol **7** into the ester **P-1-[7]** in order to allow a meaningful comparison. The polymer **P-1-[7]** gives a positive molar rotation $[M]_{546}^{20} = + 110.0°$. This shows that in **P-1-[7]** the imprints generated in the polymer make a positive contribution to the rotation value, and this is responsible for the low molar rotation value found for **P-1-[2]**. In this case the optical rotation is not caused by individual chiral centers, as is usual, but by the imprint as a whole. Evidently, therefore, the contribution of chiral voids to the rotation values in highly cross-linked polymers can be measured satisfactorily.

Measuring the optical rotation in the solid phase allows one to directly determine the properties of a chiral void in the polymer. For example, it is possible to recognize different binding situations of the template in the cavity. If the polymer **P-1-□** with empty voids is recharged with the template **2**, the resulting polymer, in contrast to **P-1-[2]**, has a very large positive rotation value of $[M]_{546}^{20} = + 323°$. If this loaded polymer is heated in acetonitrile in the presence of a 3 Å molecular sieve, the molar rotation $[M]_{546}^{20}$ changes to − 68°, i.e. about the same as for the original polymer **P-1-[2]**. Evidently most of the template molecules are at first bonded only by a single point of attachment (formed by esterification of only one boronic acid group in the cavity), and this

then changes to a double attachment. Results from calorimetric studies lend support to this assumption.[8]

Further interesting results can be expected from studies of the optical rotation, and of the circular dichroism where appropriate, for polymers under different swelling conditions and at different temperatures. This method could also become very important as a means of characterizing chiral stationary phases for use in separating racemates. In cases where a cross-linked polymer has been prepared with optically active side-groups there is often speculation about effects caused by an asymmetric matrix,[9] and it should now be possible to measure this directly.

[5] The measurements by *Vogl, Pino* et al. [4] were made using polymers with a particle diameter <45 μm suspended in a medium with the same refractive index contained in a 10 mm UV cuvette. The suspension was stirred to avoid sedimentation. For our measurements, in order to obtain larger rotations, we used an ordinary thermostatically controlled polarimeter cuvette with an optical path length of 100 mm. Sedimentation was prevented by aerating with a peristaltic pump or by shaking occasionally. Suspension media with different refractive indices were prepared by mixing two components, namely 1,2-dichlorobenzene ($n_D^{20} = 1.5513$) and a mixture of 1,2-dichloroethane and tetrachloroethylene (9:2 w/w, $n_D^{20} = 1.4528$). See also Figure 1.

[6] The polymer **P-1-2** used here was prepared by the usual method. [3] 24.43 g of ethylene glycol dimethacrylate, 4.60 g of **1** and 0.18 g of azo-bis-(isobutyronitrile) were polymerized in 18 g of tetrahydrofuran for 9 h at 65 °C. The polymer contained 0.33 mmol g^{-1} of the template monomer **1**. It was found possible to remove 88% of the template. In calculating the molar rotation values for **P-1-□** and **P-1-7** given in Table 2, the rotation caused by the residual 12% of the template monomer was subtracted. The molar rotation values relate to the fraction for which the given structure applies.

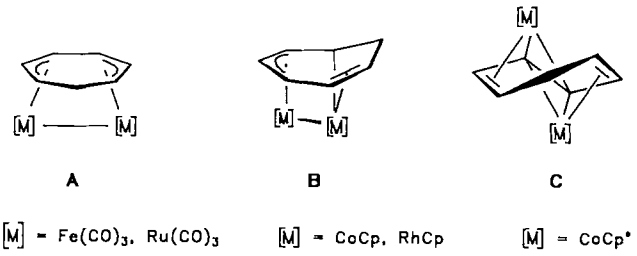
Dicobalt Complexes with *syn*- and *anti*-Coordinated μ-Cycloheptatriene Bridges**

By *Hubert Wadepohl,** *Wolfgang Galm*, and *Hans Pritzkow*

Dedicated to Professor Günter Wilke on the occasion of his 65th birthday

In binuclear complexes cycloheptatriene, as a six-electron ligand, can bind in different ways to the metal atoms. Apart from the symmetrical *syn*-coordination **A** ($\eta^3:\eta^3$; examples: $[\{(CO)_3M\}_2(\mu\text{-}C_7H_8)]$, M = Fe **1**,[1] M = Ru **2**,[2] an unsymmetrical *syn*-binding **B** of cycloheptatriene to the $(L_nM)_2$ unit is known ($\sigma^1, \eta^2:\eta^3$; example: $[(CpRh)_2(\mu\text{-}C_7H_8)]$ **3**[3]).

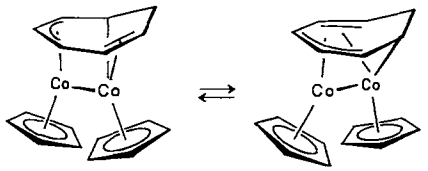
Here we report on the synthesis, structure and dynamic behavior of *syn*-$[(CpCo)_2(\mu\text{-}C_7H_8)]$ **6a** and *anti*-$[(Cp^*Co)_2(\mu\text{-}C_7H_8)]$ **6b** (Cp = η-cyclopentadienyl, Cp* = η-pentamethylcyclopentadienyl). In **6b** an *anti*-bound cycloheptatriene bridge **C** ($\eta^4:\eta^4$) has been realized for the first time.



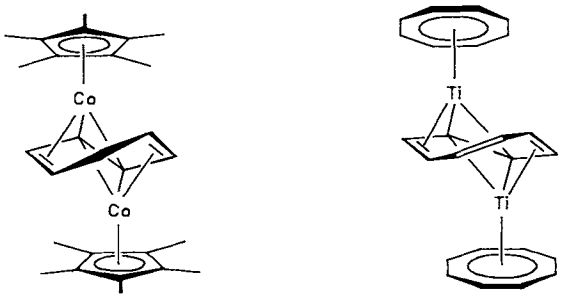
A **B** **C**

[M] = Fe(CO)$_3$, Ru(CO)$_3$ [M] = CoCp, RhCp [M] = CoCp*

Reaction of $[CpCo(1\text{-}4\text{-}\eta\text{-}C_7H_8]$ **4a**[4] with $[CpCo(C_2H_4)_2]$ **5a**[5] affords the *syn*-binuclear complex **6a** in good yields. From $[Cp^*Co(1\text{-}4\text{-}\eta\text{-}C_7H_8)]$ **4b** and $[Cp^*Co(C_2H_4)_2]$ **5b**[6] the *anti*-binuclear complex **6b** is exclusively formed. The ethene complexes **5** probably attack at the uncomplexed CC double bond of the η^4-bound cycloheptatriene ligand of **4**. The two bulky Cp*Co groups prevent the formation of a Co–Co bond, which would lead to the *syn*-binuclear complex, and force the *anti*-coordination. The high stability of **4b** prevents the formation of a "mixed" Cp*/Cp derivative of **6**. Hence, **4b** reacts neither with **5a** nor $[CpCo(C_6Me_6)]$,[5] both of which are sources of the CpCo fragment. Reaction of **4a** or $[CpRh(\eta^4\text{-}C_7H_8)]$[3, 7] with **5b** yields **4b** only, via ligand exchange.



6a



6b **7**

The *syn*-orientation of the CpCo groups in **6a** causes the bridging ligand to appear as five ^{1}H-NMR signals in the intensity ratio 2:2:1:2:1. Like **3**, **6a** is also non-ridgid in

solution. The temperature-dependent NMR spectra[8] indicate two dynamic processes with different activation energies.[9] At low temperatures the data are in accordance with a dynamic structure in which the two valence tautomers with a μ-1-σ,5-6-η:2-4-η-cycloheptatrienebridge are rapidly interconverting. The Co–C σ-bond is verified by the high field shift of the averaged ^{13}C-NMR signal of C-1 and C-6 ($\delta = 2.6$). The coalescence of the Cp proton resonances at 313 K ($\Delta G^{\neq}(313\ K) = 67.5\ kJ\ mol^{-1}$) can be explained either by a symmetrical $\eta^3:\eta^3$-binding of the cycloheptatriene to the $(CpCo)_2$ unit, or by an unhindered rotation of the cycloheptatriene ligand.

A quite different bonding situation, however, exists in the case of **6b**. The symmetrically *anti*-coordinated cycloheptatriene bridge gives rise to four multiplets (intensity ratio 2:2:2:2) in the temperature-independent ^{1}H-NMR spectrum.[10] **6b** also has C_2 molecular symmetry in the crystal (Fig. 1).[11] Each Cp*Co fragment is bound to four carbon atoms of the twisted cycloheptatriene; C1 and C1′ each have a longer and a shorter bond to both cobalt atoms. The C1–C1′ bond, which is coordinated to both metal atoms, has been elongated to 1.516(6) Å.[12]

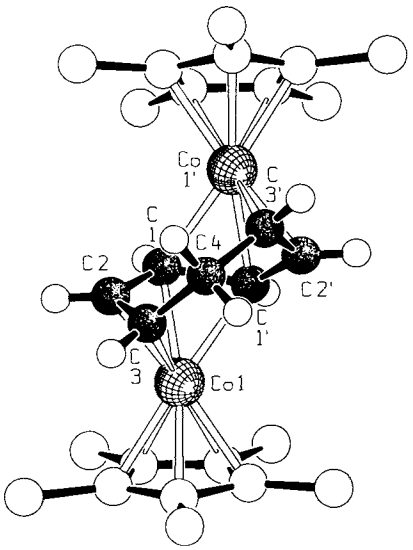

Fig. 1. Molecular structure of **6b** in the crystal (SCHAKAL [20]). Important bond lengths [Å] and angles [°] with standard deviations in parentheses: C1-C1′ 1.516(6), C1-C2 1.418(5), C2-C3 1.394(5), C3-C4 1.497(4), Co-C1 2.039(3), Co-C1′ 2.103(3), Co-C2 1.920(3), Co-C3 2.012(4), Co-C(Cp*) 1.987(8)...2.172(4), C1′-C1-C2 121.5(5), C1-C2-C3 117.3(3), C2-C3-C4 123.3(3), C3-C4-C3′ 116.7(4); torsion angles C2C1C1′C2′ −64.6°, C1′C1C2C3 15.9°.

In **6a** the bridging ligand is formally a three-electron donor to each CpCo fragment. The valence electron (VE) count of 18 per cobalt atom is attained through a metal–metal bond. In **6b** the cycloheptatriene is also a six-electron ligand. Here the large Co–Co distance (3.707 Å) precludes any direct metal-metal interaction. However, similarly to the triple-decker sandwich complexes,[13] the two metal atoms are electronically coupled via the bridging ligand, so that a closed 34 VE shell is obtained.

Among the binuclear complexes of cyclooctatetraene (cot) there are structures which are analogous to the complexes of type **B** and **C**. Here the CH_2 group of the seven-membered ring in **6** has been formally replaced by a HC=CH group which is not coordinated to the metal. However, of the 34-VE complexes $[\{(CO)_3Ru\}_2(\mu\text{-cot})]$,[14] *syn*-$[(CpRh)_2(\mu\text{-cot})]$,[15] $[(CpRh)_2(\mu\text{-cot})]^{2\oplus}$,[16] and $[(CpFe)_2(\mu\text{-cot})]$,[17] all of which are isoelectronic with **6**, only the first two have a *syn*-(μ-σ^1, $\eta^2:\eta^3$) coordination of the cot bridge (corresponding to **B**). In the latter two complexes an *anti*-(μ-$\eta^5:\eta^5$) structure is adopted. In the dititanium complex $[\{(\eta\text{-cot})\text{-Ti}\}_2(\mu\text{-cot})]$ **7**[18] (30 VE, paramagnetic[19]) the *anti*-(μ-$\eta^4:\eta^4$)cot bridge is bound similarly to **C**. However, the C–C bond lengths in the metal coordinated part of the bridging ligand exhibit a different pattern from those in **6b**.[18b]

Experimental

4b: A mixture of 0.70 g (2.8 mmol) of **5b** and 0.48 g (5.2 mmol) of cycloheptatriene in ca. 15 mL of petroleum ether (boiling range 30–60 °C) was heated under reflux for 2.5 h. After removal *in vacuo* of all volatile components at room temperature (until the mass was constant) the crude product could be used directly. For purification, the product was chromatographed on silanized silica gel (Merck RP60, ca. 3 × 2.5 cm) with petroleum ether. After reduction of the volume by evaporation, red **4b** (0.20 g, 25%) crystallized from the eluate at −80 °C. m.p. 68 °C. ^{1}H NMR (200 MHz, C_6D_6): $\delta = 5.8$ (m, 1H, H-6), 5.2 (m, 1H, H-5), 4.3 (m, 1H, H-3), 4.1 (m, 1H, H-2), 2.5 (m, 1H, H-1), 2.3 (m, 1H, H-4), 2.0 (m, 1H, CH_2), 1.69 (s, 15H, Cp*), 0.9 (m, 1H, CH_2). ^{13}C{^{1}H} NMR (50 MHz, C_6D_6): $\delta = 130.0$ (CH, C-5 or C-6), 123.6 (CH, C-6 or C-5), 89.4 (C, C_5Me_5), 88.7 (CH, C-2 od. C-3), 82.4 (CH, C-3 or C-2), 54.6 (CH, C-1 or C-4), 51.1 (CH, C-4 or C-1), 30.9 (CH_2), 9.9 (C_5Me_5). MS (EI, 70 eV): *m/z* 286 ($M^{\oplus}$, 100%), 271 ($[M-CH_3]^{\oplus}$, 54), 206 (46), 194 ($[Cp^*Co]^{\oplus}$, 48), 133 ($[Cp^*-2H]^{\oplus}$, 56), 119 (65), 91 ($[C_7H_7]^{\oplus}$, 50), 59 ($Co^{\oplus}$, 17). Correct C,H analysis.

6a: A mixture of 1 g (4.6 mmol) of **4a** and 0.9 g (5.0 mmol) of **5a** in 100 mL petroleum ether was heated at 50–60 °C for 1 h. A dark precipitate was formed. After removal of solvent *in vacuo* the residue was recrystallized from toluene. At −20 °C 0.73 g (46%) of **6a** (dark brown microcrystalline solid, sublimation at 180 °C) was obtained. MS (EI, 70 eV): *m/z* 340 ($M^{\oplus}$, 77%), 274 ($[M-C_5H_6]^{\oplus}$, 100), 216 ($[M-CpCo]^{\oplus}$, 13), 196(9), 189 ($[Cp_2Co]^{\oplus}$, 85), 124 ($[CpCo]^{\oplus}$, 22), 91 ($[C_7H_7]^{\oplus}$, 9), 59 ($Co^{\oplus}$, 9). Correct C,H analysis.

6b: A mixture of 0.81 g (2.8 mmol) of **4b** and 0.71 g (2.8 mmol) of **5b** in ca. 20 mL toluene was heated under reflux for 2.5 h. After removal of solvent *in vacuo* the residue was redissolved in ca. 10 mL petroleum ether. At −20 °C 0.76 g of (56%) **6b** was obtained as dark brown crystals (decomp. 170 °C). ^{13}C{^{1}H} NMR (50 MHz, C_6D_6): $\delta = 88.6$ (C_5Me_5), 75.5 (CH), 44.3 (CH), 38.6 (CH), 29.7 (CH_2), 9.9 (C_5Me_5). MS (EI, 70 eV): *m/z* 480 ($M^{\oplus}$, 5%), 286 ($[Cp^*Co(C_7H_8)]^{\oplus}$, 100), 271 ($[Cp^*Co(C_7H_8)-CH_3]^{\oplus}$, 54), 206 (44), 192 ($[Cp^*Co-2H]^{\oplus}$, 48), 133 ($[Cp^*-2H]^{\oplus}$, 54), 91 ($[C_7H_7]^{\oplus}$, 37), 59 ($Co^{\oplus}$, 18). Correct C,H analysis.

The Monofluorooxonium(0) Hexafluorometalate(VI)s $H_2OF^{\oplus}MF_6^{\ominus}$ (M = As,Sb)**

By *Rolf Minkwitz** and *Gabriele Nowicki*

The protonated hypofluorous acid $H_2OF^{\oplus}$ is isoelectronic with the recently prepared monofluoramine H_2NF.[1] According to ab initio calculations the cation $H_2OF^{\oplus}$ has C_s symmetry with the parameters d(OF) = 144, d(OH) = 96 pm, $\sphericalangle$(HOH) = 108, $\sphericalangle$(FOH) = 120°.[2] These values are, with exception of the FOH angle, in satisfactory agreement with the values determined by microwave spectroscopy for the corresponding parameters of H_2NF ($\sphericalangle$ FNH = 101°).[3]

An attempt to synthesize monofluorooxonium(0) salts $H_2OF^{\oplus}MF_6^{\ominus}$ in analogy to those of the hydronium salts[4] according to Equation (a) by protonation of HOF in

$$H_2O + HF + MF_5 \longrightarrow H_3O^{\oplus}MF_6^{\ominus} \quad (M = As,Sb) \qquad (a)$$

aqueous acidic media met without success.[5] On the contrary, because of the polarity $HO^{\delta\oplus}F^{\delta\ominus}$ the proton attacked at the fluorine, resulting in a decomposition into H_2O_2 and HF.[5] Also in the direct fluorination of H_2O to HOF and HF there were no indications of an $H_2OF^{\oplus}$ ion being formed.[5] The same holds true for the reaction of H_2O with XeF_2 leading to O_2, HF and Xe.[6]

$XeF^{\oplus}MF_6^{\ominus}$ salts have a high oxidation potential. Nevertheless, they are very selective fluorinating agents,[7-10] since reactions with them in anhydrous HF still proceed extremely smoothly at 195 K, and even temperature-sensitive products can thus be prepared.

Fluorination of H_2O with $XeF^{\oplus}MF_6^{\ominus}$ [Eq. (b)] leads almost quantitatively to the pale reddish salts **1**.

$$XeF^{\oplus}MF_6^{\ominus} + H_2O \xrightarrow[213\ K]{(HF)} \underset{\mathbf{1}}{H_2OF^{\oplus}MF_6^{\ominus}} + Xe \quad (M = As,Sb) \qquad (b)$$

Both salts can be stored without decomposition for a few weeks in sealed vessels at 233 K, and for up to 2 h at room temperature. In a high vacuum apparatus, however, HOF (ν(OH): 3540s; δ (HOF): 1361; ν (OF): 890 ms cm^{-1}) and HF can already be isolated in an inert gas matrix at 223 K[11] [Eq. (c)]. SbF_5 remains in the reaction vessel at this temperature.

$$\underset{\mathbf{1}}{H_2OF^{\oplus}MF_6^{\ominus}} \xrightarrow{\Delta} HOF + HF + MF_5 \qquad (c)$$

Consistent with this finding the following fragments are observed mass spectrometrically (EI, 30 eV): m/z (%) 36(2.8) $HOF^{\oplus}$, 32(32.8) $O_2^{\oplus}$, 20(10) $HF^{\oplus}$, 19(3.6) $F^{\oplus}$, 18(100) $H_2O^{\oplus}$, 17(14.3) $OH^{\oplus}$. These fragments and their intensities are characteristic for HOF.[12]

signals of the anions are observed at $\delta = -480.7$ ($AsF_6^\ominus$) and -534.9 ($SbF_6^\ominus$).

Assignment of the vibrations in the $H_2OF^\oplus$ cation in accord with Table 1 followed unambiguously by comparison with the assignment of the vibrations in the case of H_2NF, which is confirmed by calculations.[1] Only the situation $\nu_s(OH) > \nu_{as}(OH)$ is open to doubt. It is merely based on the difference in the intensities of the bands in the IR spectrum. However, because of the large half-widths of the vibration bands (Fig. 1), one can assume strong hydrogen bonding

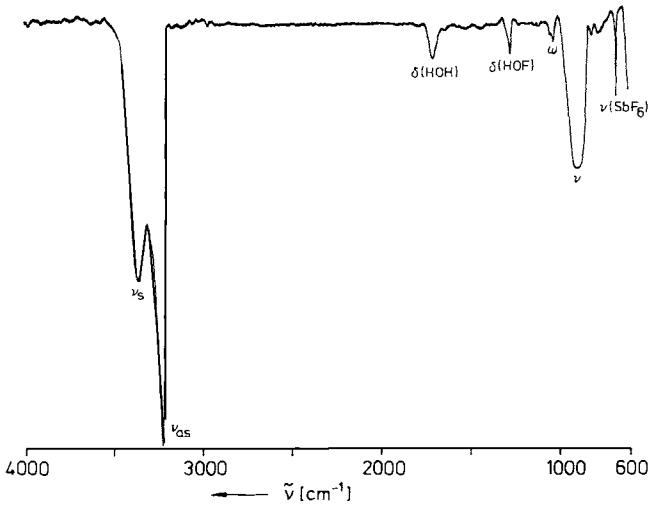

Fig. 1. IR spectrum of solid $H_2OF^\oplus SbF_6^\ominus$ at 153 K (without mull) between NaCl or polyethylene plates in an IR low-temperature cuvette.

between the ions to influence the intensities. These interactions also preclude a force field calculation, although adequate isotopic data have been measured. All frequency shifts of the isotopomers lie in the range to be expected according to the product rule.[14]

For further characterization of **1** the reactions (d)–(h) have been carried out; these afforded known compounds. They show that the cation **1** is bifunctional: depending upon

$$\mathbf{1} + SCl_2 \xrightarrow[213\ K]{} OSF_2 + 2HCl + MF_5 \quad (d)$$

$$\mathbf{1} + SF_4 \xrightarrow[213\ K]{(HF)} OSF_3^\oplus MF_6^\ominus\,[15] + 2HF \quad (e)$$

$$\mathbf{1} + ClF_3 \xrightarrow[195\ K]{(HF)} OClF_2^\oplus MF_6^\ominus\,[16] + 2HF \quad (f)$$

$$\mathbf{1} + H_2O \xrightarrow[213\ K]{(HF)} H_2OOH^\oplus MF_6^\ominus\,[17] + HF \quad (g)$$

$$\mathbf{1} + CH_3OH \xrightarrow[233\ K]{} \text{explosion} \quad (h)$$

the reaction partners it is formally either an $OF^\oplus$ or an $OH_2^\oplus$ moiety. Owing to its instability the hypofluorous acid cannot be used preparatively, whereas its protonated salts could be valuable synthetic building blocks because of the ease with which they can be handled.

Experimental

A solution of 1 mmol of $XeF^\oplus MF_6^\ominus$ (M = As,Sb) in 5 mL of XF(X = H,D) was prepared in a 30 mL KEL-F reactor fitted with a valve of the same material. An equimolar amount of $X_2^{16}O$ or $X_2^{18}O$ was then pipetted into the solution under an inert gas (N_2). After 12 hours' stirring at 213 K, Xe and the solvent XF were removed from the mixture in a high vacuum at the same temperature. The remaining pale reddish solid is only sparingly soluble in HF and immediately deliquesces on exposure to air. Contamination by iron fluorides can be ruled out as being responsible for the color. It is possibly attributable to charge-transfer transitions in the solid state.

Ring Closure and Ring Expansion Reactions in Bridged Triarylphosphanes and Triarylarsanes with *o*-Isopropenyl Substituents. Novel Candidates for Turnstile Geometry**

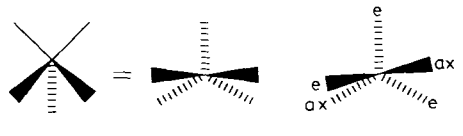
By *Dieter Hellwinkel,* Andreas Wiel, Gerhard Sattler,* and *Bernd Nuber*

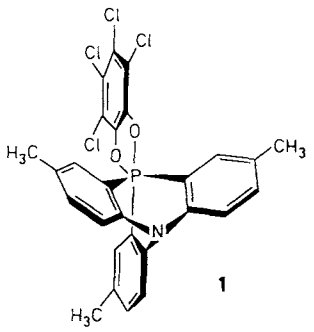
Despite optimum prerequisites – combination of a C_3-symmetric tridentate ligand with a C_2 symmetric bidentate ligand system – the phosphorane **1** does not have the ideal turnstile geometry **TS**[1] but a distorted trigonal-bipyramidal structure **TS'** ≙ **TBP**.[2] Similar deviations from the ideal type **TS** structure are also known for phosphoranes of analogous composition, with adamantane skeletal frameworks such as **2**.[3]

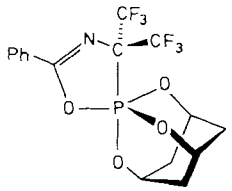
In the hope of perhaps still being able to realize the undistorted turnstile-type **TS** structure with the aid of an extremely rigid tridentate ligand we have now synthesized triphenylphosphane **5a**,[4] triply bridged by isopropylidene groups, starting from 5-phenyl-10,10-dimethyl-5,10-dihydroacrido-

[*] Prof. Dr. D. Hellwinkel, Dipl.-Chem. A. Wiel, Dr. G. Sattler, Dr. B. Nuber
Institut für Organische Chemie der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

[**] This work was supported by the Fonds der Chemischen Industrie and by BASF AG (FRG)







phosphane **3a**, which was obtained by cyclization of (2-isopropenyl)diphenylphosphane. Removal of the phenyl group in **3a** with Li in THF and reaction of the secondary phosphane **4** isolable after hydrolysis with phosgene affords the chlorophosphane **7a**, which reacts with 2,6-bis(isopropenyl)phenyllithium to give the tertiary phosphane **8a**. This can be converted in good yields into **5a** by acid-catalyzed cyclization.

The analogous arsane **5b** is accessible via essentially the same route except that the lithium arsenide obtained by Li-cleavage is converted oxidatively into the cyclic arsinic acid **6**, which is then reduced with PCl_3 to chloroarsane **7b**.[5] The doubly bridged derivatives **10a,b** can also be synthesized in a similar way. However, of the compounds **11a,b** prepared by reaction of diphenylchloroarsane and diphenylchlorophosphane, respectively, with 2,6-bis(isopropenyl)phenyllithium, only **11a** can be cyclized acid-catalytically to give **10a**.[6] **10b**, on the other hand, is obtainable by cyclization of the singly bridged arsane **9**, which in turn is accessible from 2-isopropenylphenyllithium and **7b**. The structurally relevant NMR data and melting points of the new compounds are listed in Table 1.

Table 1. Melting points, ^{31}P- and methyl-^1H-NMR signals ($CDCl_3$, δ values rel. 85% H_3PO_4 and TMS) of the compounds **3**–**10** and **12**.

[a] All the new compounds gave correct elemental analyses: ± 0.3%. [b] Coupling is observed only for the axial methyl groups [7]. [c] B.p 140–150 °C/0.1 torr. [d] B.p. 154 °C/0.1 torr. [e] Signals very broad, no ^5J(P, H) coupling.

The single-crystal X-ray structure analyses of **5a,b** showed only slight deviations from the C_{3v} structure type for the bond lengths and angles (Table 2). The element–aryl bonds are somewhat shorter than those in triphenylphosphane (182.8 pm)[8] and triphenylarsane (195.7 pm),[9] while the CPC and CAsC angles are markedly smaller than those in triphenylphosphane (103°) and triphenylarsane (100.1°), respectively, which leads to a stronger pyramidalization of the central atoms. Figure 1 shows the structure of **5b**,[10] which is virtually identical with that of **5a**.[10]

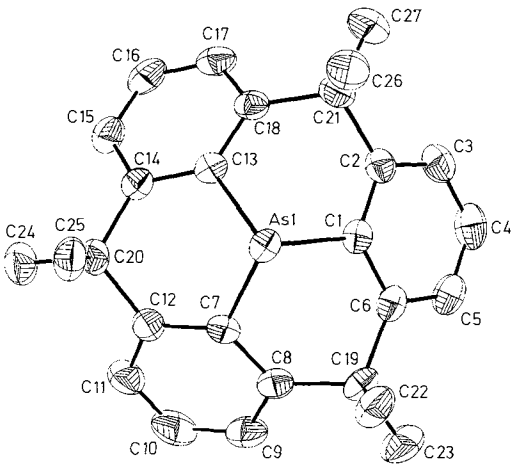

Fig. 1. Crystal structure of **5b** (without H atoms).

Reaction of **5a** with *o*-chloranil in boiling benzene leads, with concomitant decoloration of the solution, to formation of the pentacoordinated phosporane **12**, whose ^1H-NMR spectrum shows only two methyl signals of equal intensity, even at −60 °C (Table 1), which suggest a flexible structure in solution, but do not afford any further useful information. We have therefore carried out a single-crystal X-ray structure analysis of **12** too,[10] the most important informative

Table 2. Selected bond lengths [pm] and angles [°] (standard deviations in brackets) of the new compounds **5a**, **5b**, and **12**.

	5a (X = P)	**5b** (X = As)	**12** (X = P)
X1-C1	181.0(2)	194.2(3)	180.3(3)

O1-X1-O2	–	–	83.3(1)
C1-X1-O2	–	–	167.2(1)
C7-X1-O2	–	–	85.2(1)
C13-X1-O2	–	–	90.8(1)

data of which can be gleaned from Table 2 and Figure 2. Here again, the trigonal-bipyramidal structural principle has largely prevailed – albeit in a strongly distorted form – which manifests itself in a very long axial bond (192.1 pm) along with a normal length equatorial P–O bond (168.4 pm) in the symmetrical bidentate 1,2-phenylenedioxy ligand. Despite its rigidity and inherent C_3 symmetry, the tridentate ligand system also shows a clear tendency to formation of one longer axial (180.3 pm) and two shorter equatorial (175.4 and 178.6 pm, resp.) P–C bonds as well as a larger eq-eq (105.5°) and two smaller eq-ax (100.2 and 97.8°, resp.) C-P-C bond angles.

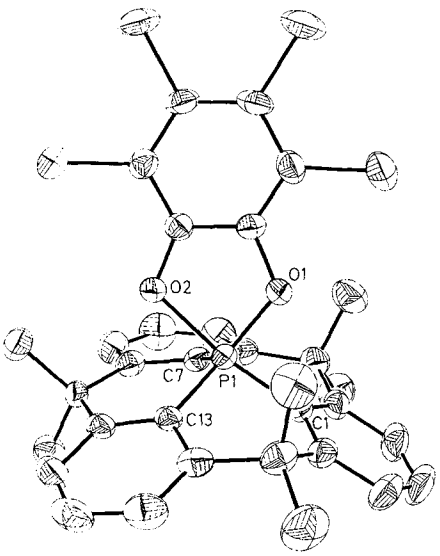

Fig. 2. Structure of **12** in the crystal (without H atoms).

On attempting to gain access, analogously to the cyclization of **8b** to **5b**, to comparable arsacycles with a zero- or one-oxygen bridge, we discovered a completely different reaction type. Reaction of **14**, which is obtainable from 5-chlorodibenzarsole **13**[11] and 2,6-bis(isopropenyl)phenyllithium, with methanesulfonic acid in glacial acetic acid affords a product whose ^{1}H-NMR spectrum shows three methyl signals and one olefinic proton signal. These data (Table 3) are only compatible with a completely unsymmetrical molecule in which, in addition, one methyl group must have been modified to an olefin function.

Table 3. Melting points and structurally relevant ^{1}H- and (in brackets) ^{13}C-NMR data (δ values rel. TMS) of the new arsacycles **16**, **18**, **19**, and **21**.

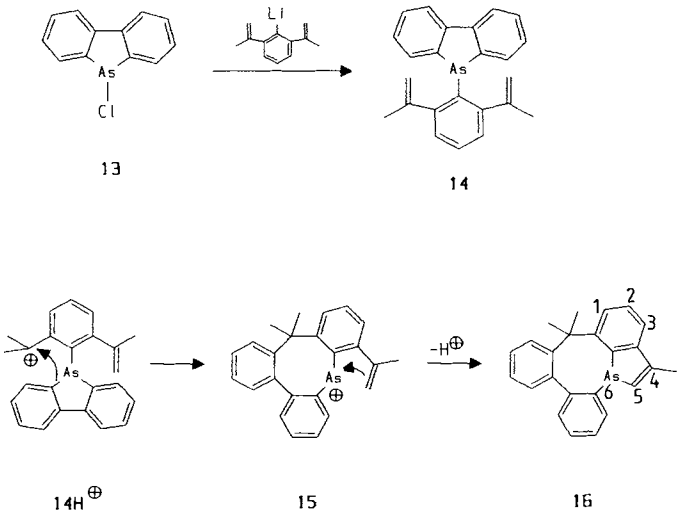
[a] All the new compounds gave correct elemental analyses ± 0.3%. [b] Accidental isochronism!

An unsymmetrical product is formed if the initial attack of the protonated isopropenyl group in **14H**$^\oplus$ does not take place, as usual, at the *ortho*- but at the *ipso*-position of the dibenzarsole unit. The resulting arsanylium center, incorporated in an eight-membered ring system **15**, can then attack the terminal C-atom of the second isopropenyl group, the reaction sequence finally ending in formation of the novel heterocycle **16**.



Definite proof of this is provided by the single-crystal X-ray structure analysis,[10] which basically reveals an almost planar arsindole moiety and a central eight-membered ring system with a highly distorted boat conformation (Fig. 3). The bond lengths and angles compare very well with those expected for a strainless molecule.[12]

An analogous *ipso*-attack of an activated isopropenyl group in the reaction of 10-(2-isopropenylphenyl)-10*H*-phenoxarsine **17** with $TiCl_4$ in cyclohexane leads to the expanded heterocycle **18**. This is also formed upon PCl_3-reduction[5] of the oxide **19**, which is obtained upon formic acid-catalyzed ring expansion of **17** (and subsequent oxidative work-up). Finally, also on treating 10-[2,6-bis(isopropenyl)-phenyl]-10*H*-phenoxarsine **20**, obtainable from 10-chloro-10*H*-phenoxarsine[13] and 2,6-bis(isopropenyl)phenyllithium, with formic acid, an isomer can be isolated whose spectroscopic data are consistent with the structure **21** (Table 3) and whose formation can be envisaged in the same

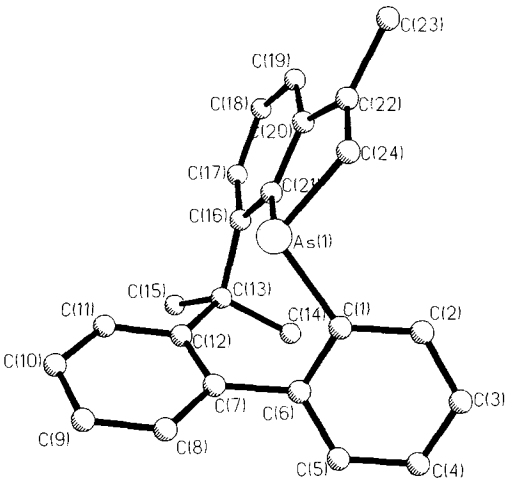


Fig. 3. Structure of **16** in the crystal (without H atoms). Selected bond lengths [pm] and angles [°] (standard deviations in brackets): As1-C1 195.2(2), As1-C21 194.6(2), As1-C24 191.8(4); C1-As1-C21 101.3(1), C1-As1-C24 105.1(1), C21-As1-C24 86.0(1).

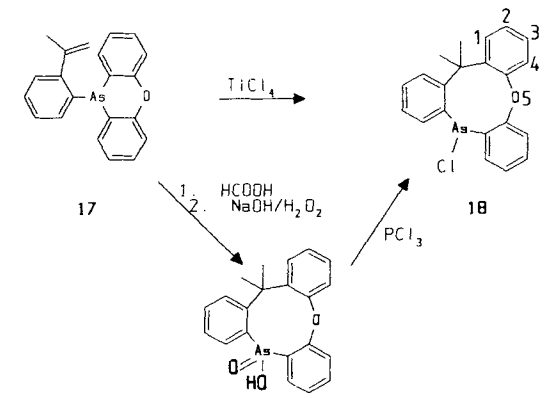
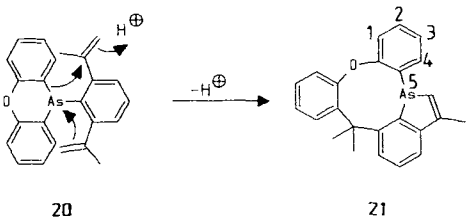
way as that of **16** as a result of a tandem ring expansion/cyclization.





We are presently investigating whether this novel ring expansion in the form of a 1,2-phenylenemethylene moiety can also be extended to analogous derivatives of other main group elements (in particular N, P, Sb, Si, C).

Electrochemical Solid-State Studies on Oligomeric *p*-Phenylenes as Model Compounds for Conductive Polymers**

By *Klaus Meerholz* and *Jürgen Heinze**

The characteristic current plateau in the cyclovoltammograms of conductive polymers has been the subject of intensive discussion for some time. On the one hand, capacitive charges in the sense of a molecular condenser are assumed as the reason for such plateaus,[1-3] while on the other there are increasing indications that capacitance effects play only a subordinate role and that the plateau current can largely be attributed to faradaic redox processes.[4-7]

Our voltammetric investigation of soluble oligomers of defined structure from the *p*-phenylenevinylene and *p*-phenylene series[8,9] has shown that the number of possible redox states increases with increasing chain length, and that the energy gap strongly increases between the lowest and highest redox states.

We have now investigated for the first time voltammetrically the redox behavior of defined oligomers of the *p*-phenylene series in the solid state. For comparison, Figure 1 a shows a typical cyclic voltammogram for the reduction of

[*] Prof. Dr. J. Heinze, Dipl.-Chem. K. Meerholz

p-quaterphenyl in solution.[9] The system is apparently reversibly reduced to the dianion in two separate redox steps at − 2.28 and − 2.45 V. Surprisingly, in the solid-state experiment (Fig. 1 b), irrespective of the chosen scan rate only one

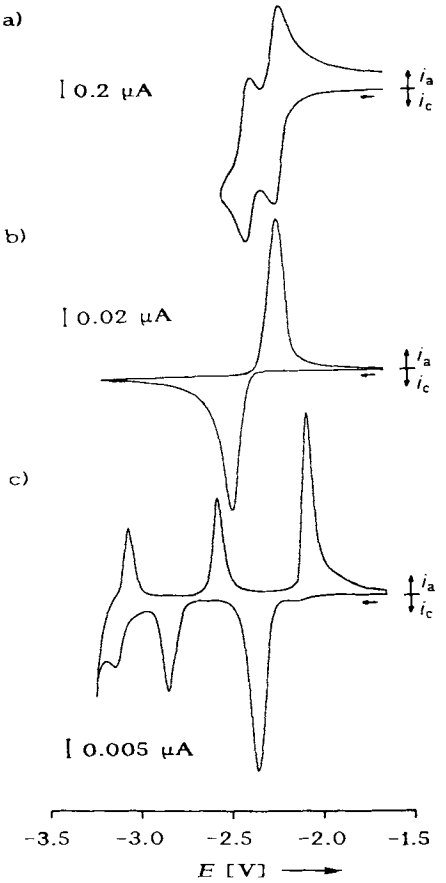

Fig. 1. Cyclovoltammograms in Me_2NH/0.1 M Bu_4NBr of a) *p*-quaterphenyl (saturated solution; $T = 10\,^{\circ}C$, $v = 100\,mV\,s^{-1}$), b) *p*-quaterphenyl (thin layer on Pt; $T = -75\,^{\circ}C$, $v = 10\,mV\,s^{-1}$), and c) *p*-sexiphenyl (thin layer on Pt; $T = -75\,^{\circ}C$, $v = 10\,mV\,s^{-1}$); potentials calibrated with $Cp_2Co^{\oplus}/Cp_2Co$ vs Ag/AgCl.

cathodic and one anodic wave are observed (at − 2.54 and − 2.25 V, resp.), both of which correspond to the transfer of two electrons per quaterphenyl molecule (see *Experimental*).

In our opinion the different redox transitions in the two voltammograms (Fig. 1 a, 1 b) are closely coupled with the structural properties of quaterphenyl in solution and in the solid state. In solution the phenyl rings can rotate freely about the linked bonds and thus also assume the conformation with the conjugation between the phenylene subunits that is optimum for the redox process. In the solid state, on the other hand, this free rotation is strongly hindered by intermolecular interactions. The molecules are present in a twisted conformation with a lesser degree of conjugation than is actually possible. Therefore, the first reduction in the solid state takes place at a more negative potential than in solution. In the monoionic state the molecules stabilize through a change in geometry from the twisted benzoid structure into a partially planar quinoid-like structure with better conjugation between the rings. Similar structural changes have been observed with substituted 5,6-dihydrobenzo[*c*]cinnolines in solution[10] and with tetrathiafulvalene in a Nafion matrix.[11, 12] As a consequence of this change in structure at the stage of the monoanion the redox potential for dianion formation shifts to more positive potentials and results in a formal two-electron transfer. At the dianion stage a further stabilizing change of structure takes place. During the reoxidation, which, because of the stabilization, takes place at more positive potentials than the reduction, a formal two-electron transfer is again observed, which is now attributable to the relaxation of the system into the initially twisted structure.

In a further solid state experiment we have investigated the electrochemical reduction of *p*-sexiphenyl voltammetrically (Fig. 1 c). In both scan directions three waves are observed, between which the current drops to almost zero. Coulometric measurements indicate transfer of two electrons for the first wave, of one electron for the second and up to one for the third (Tables 1 b–d). *p*-Sexiphenyl can accordingly be reversibly charged to the tetraanion. This finding is consistent with the rule that the number of possible redox states increases with increasing chain length of the oligomer. Particularly striking is the fact that the reoxidation waves lie at very much more positive potentials than the corresponding reduction waves.

In our opinion these effects clearly show that *p*-sexiphenyl molecules also stabilize through the transition from a benzoid into a quinoid-like structure upon uptake of electrons. This geometric stabilization still continues even after formation of the dianion. However, the extent of the additional stabilization is significantly less after the fourth electron transfer.

Table 1. Coulometric data for the reduction and oxidation of *p*-quaterphenyl and *p*-sexiphenyl. n = number of charging and discharging cycles, f = average binding number of a monomer unit, $Q_{a,c}$ = anodic and cathodic charge, respectively.

Exp.[a]	Educt	n	E_λ [V]	Q_a[b,d] [μC]	$-Q_c$[b,d] [μC]	ΔQ[b] [μC]	f
a	*p*-Quaterphenyl	1	−3.22		2.16 (2.00)	0	1.50

[a] The experiments b–d and e–j were carried out successively on the same sample. [b] Charges after subtraction of background currents. The charge equivalents transferred per mole of educt are quoted in brackets (see Experimental). [c] Solid-state polymerization. [d] $Q_a = -Q_c$ except in the case of f and h. [e] It was not possible to measure the last reduction wave entirely because the reduction of the electrolyte system starts at − 3.25 V.

In principle, similar results are obtained in the anodic oxidation of a *p*-sexiphenyl film as in the reduction. In a low-temperature experiment, reversible generation of the trication is possible. Upon further anodic charging the tetracation is formed, which, however, is not indefinitely stable and undergoes a coupled solid state reaction. The reactivity of the system increases when the temperature is raised, so that the *p*-sexiphenyl trication already reacts at room temperature.

If formation of the trication is completely excluded ($E_\lambda = 1.65$ V), *p*-sexiphenyl can be reversibly converted into the dication more than 500 times without loss of activity (Fig. 2a, Table 1e). Particularly striking are the extremely narrow waves and the large potential difference between the anodic and the cathodic peak potential of $\Delta E_p = 410$ mV, which indicates a strong energetic stabilization of the charged system.

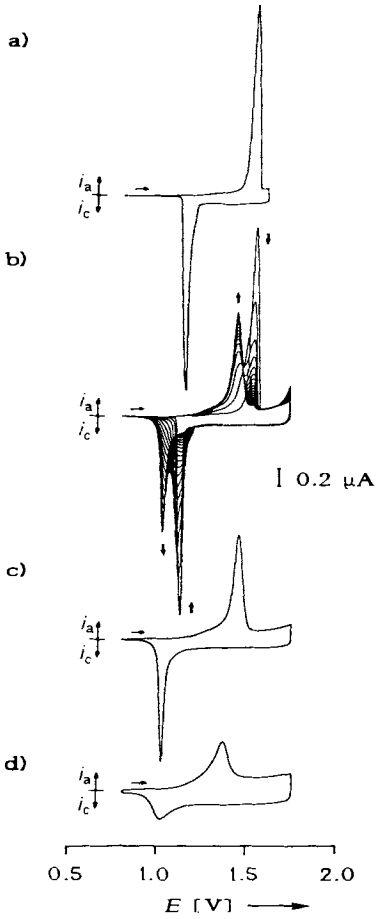

Fig. 2. Cyclovoltammograms in CH_2Cl_2/0.1 M Bu_4NPF_6 of a) *p*-sexiphenyl (thin layer on Pt), b) *p*-sexiphenyl in the multisweep experiment with $E_\lambda = 1.75$ V, c) the dodecaphenyl isomer, d) polyphenylene; potentials calibrated with $Cp_2Fe/Cp_2Fe^{\oplus}$ vs Ag/AgCl, $T = 10\,^{\circ}C$, $v = 20\ mV\,s^{-1}$.

If the switching potential in the multisweep experiment is set in the ascent of the anodic trication wave ($E_\lambda = 1.76$ V), two new, gradually increasing waves appear, whilst the original signals decrease (Fig. 2b). The resulting isopotential point confirms that *p*-sexiphenyl reacts to give a new electroactive species without side reactions. This reaction is quantitative. In addition, at high scan rates, broad waves as are typical for the reduction of protons are observed at low potentials in the cathodic reverse scan. The coulometric analysis of the voltammograms shows that one charge is lost per molecule (by proton cleavage) in the condensation reaction (Table 1f). The material formed is, in contrast to *p*-sexiphenyl, completely insoluble in all conventional solvents, and its voltammetric peak potentials lie negative to those of *p*-sexiphenyl. Furthermore, the halfwidths of the waves are still very small (Fig. 2c), and the peak-potential difference ($\Delta E_p = 430$ mV) resembles that of *p*-sexiphenyl. These are clear indications that a material of definite composition is formed. From all these observations we conclude that *p*-sexiphenyl dimerizes quantitatively in this solid state reaction to give a dodecaphenyl isomer whose redox steps each correspond to the transfer of four electrons per molecule.

If still higher electrode potentials (e.g. $E_\lambda = 2.1$ V) are applied in the multisweep experiment, further polymerization steps are induced. Depending upon the oxidation potential, 2–4 charge equivalents are thereby lost by cleavage of protons (Table 1h). The waves are once again shifted to more negative potentials, but are now also significantly broader, and the difference in peak potential decreases ($\Delta E_p = 350$ mV). An isopotential point is once again observed. The voltammogram, with its characteristic current plateau, is now typical for conductive polymers (Fig. 2d).

The amount of charge consumed in a pure charging and discharging cycle remains almost constant for all the materials investigated (Fig. 2a, c, d; Table 1e, g, j); on average, every third phenyl unit becomes charged. (The slight difference in charge of 8% between the experiments g and j can be attributed to the fact that the redox potentials in experiment j are shifted negative relative to those in g.) We can deduce from this that no material is lost or decomposed during the experiment. This is additionally supported by the appearance of isopotential points during the polymerization. The characteristic plateau region can thus be attributed unequivocally to faradaic redox processes.

Since the amount of charge that is additionally consumed for the solid-state polymerization is greater than that which is theoretically required for the complete linkage of all chains, the average binding number f of a monomeric unit must be greater than the limiting value $f = 2$ for chains of indefinite length (see Table 1i, j). A value of $f > 2$, however, signifies that coupling reactions leading to a network take place in addition to chain-lengthening steps. The chains are coupled via the *ortho* and *meta* positions of the phenyl units. Such a formation of defects has already been detected by FTIR-ATR measurements on polythiophene.[13]

The network formed exclusively by solid-state polymerization is apparently made up of numerous different structural segments. As a consequence the individual charge transitions, other than in ideal, linear chains, no longer take place in distinctly separate potential steps but are distributed over a large number of closely adjacent redox states. The typical voltammogram of conductive polymers corresponds to the superposition of all redox waves. Due to formation of the network, the mobility of the subunits formed in the polymer matrix is reduced. This might explain why a smaller peak-potential difference is observed for the polymer than for the oligomers.

Our investigations show that polyphenylene not only contains long, linear, *p*-coupled chains, as was previously assumed, but a polymer network. Since polypyrrole and polythiophene exhibit similar voltammograms, we presume that a network is partially formed also in those cases.

Experimental

For the solid state investigations, the oligomer to be investigated was deposited onto a Pt-disk electrode (∅ = 1 mm) by sublimation or by dipcoating the respective oligomer in dichloromethane. In this way, fully chargeable ($i \sim v$) homogenous layers of differing thickness could be prepared.

The amount of material employed was determined from the integral under the redox waves (= charge). In the reduction of *p*-sexiphenyl the charge numbers of the redox steps could be derived unambiguously from the observed charge ratio of 2:1 for the first two redox steps (Table 1 b,c). In the case of quaterphenyl an experiment was carried out with a large electrode and a weighable amount of material; this gave a value of 2 for the charge number. A similar experiment with sexiphenyl confirmed the above described direct method for the quantitative measurement.

By reduction and oxidation of one and the same sample of *p*-sexiphenyl it was confirmed that the integral under the first reduction wave is identical with that under the first oxidation wave ($E_\lambda = 1.65$ V), i.e., two electrons per molecule are transferred in both cases.

Zwitterions as Intermediates of the 1,3-Dipolar Cycloaddition of Electrophilic Azides to 5-Alkylidenedihydrotetrazoles – the Other Non-Concerted Limiting Case **

By *Helmut Quast,* Dieter Regnat, Eva-Maria Peters, Karl Peters* and *Hans Georg von Schnering*

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

The perturbational treatment of 1,3-dipolar cycloadditions[1] predicts for extreme HOMO-LUMO energy differences two limiting cases of a non-concerted two-step mechanism in which zwitterions occur as intermediates. *Huisgen* et al. realized one of the non-concerted limiting cases by reaction of strongly nucleophilic thiocarbonyl ylides with particularly electrophilic alkenes.[2] We report here on the first example for the other non-concerted limiting case which is to be expected in the cycloaddition of strongly electrophilic 1,3-dipoles to particularly nucleophilic alkenes. In a comparable Diels-Alder reaction with inverse electron demand a zwitterion was recently isolated and identified as intermediate.[3]

1,3-Dipolar cycloaddition of alkyl and aryl azides RN_3 to 5-alkylidenedihydrotetrazoles **2** leads to spirocycles of type **4**.[4] On the other hand, in reactions with the strongly *electrophilic* azides **1a–c** in toluene the zwitterions **3** or the 5-iminotetra-hydro-1,2,3,4-tetrazines **5** – together with molecular nitrogen – are obtained. The latter are formed from the corresponding spirocycles **4**, which, however, are not observed directly. The ring expansion of the tetrazole to the tetrahydro-1,2,3,4-tetrazine ring is an example of the rare 1,2-shift of a nitrogen atom.[5]

essentially remain unaltered in solution. The N–N distances in the triazenide moiety resemble those in uncharged triazenes[7] and suggest a considerable localization of the negative charge on N10. Particularly striking is the short distance of 258.5 pm between the centers of the opposite charges, C5 and N10. The resulting coulomb attraction is balanced by the steric repulsion between the methyl group on N4 and the *tert*-butyl group on C6, which is oriented almost orthogonally to the plane of the tetrazole ring. Thus, ring closure to the cycloadduct **4e** is sterically hindered, and the particular stability of the zwitterions of the *tert*-butyl series (**3b, d, e**) compared to the dimethyl compound **3c** apparently has steric origins.

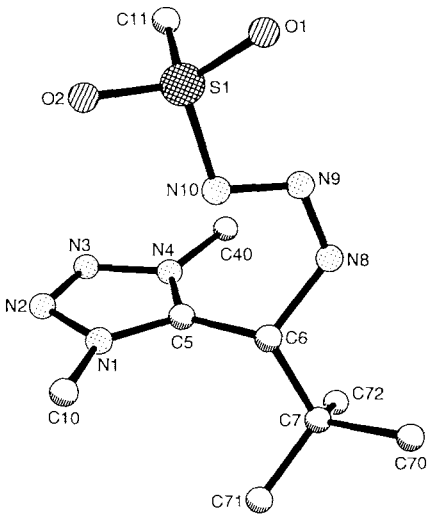

Fig. 1. Structure of the zwitterion **3e** in the crystal. Selected bond lengths [pm] and angles [°]: N1–N2 135.7(4), N1–C5 132.6(3), N2–N3 127.1(4), N3–N4 136.1(3), N4–C5 132.4(4), C5–C6 151.5(4), C6–C7 154.8(4), C6–N8 149.7(4), N8–N9 127.1(4), N9–N10 134.8(3), N10–S1 162.9(3), S1–O1 143.3(2), S1–O2 142.9(3), S1–C11 177.0(4); C5–C6–C7 115.5(2), C5–C6–N8 109.5(2), C7–C6–N8 110.5(2), C6–N8–N9 115.6(2), N8–N9–N10 116.5(2), N9–N10–S1 111.0(2).

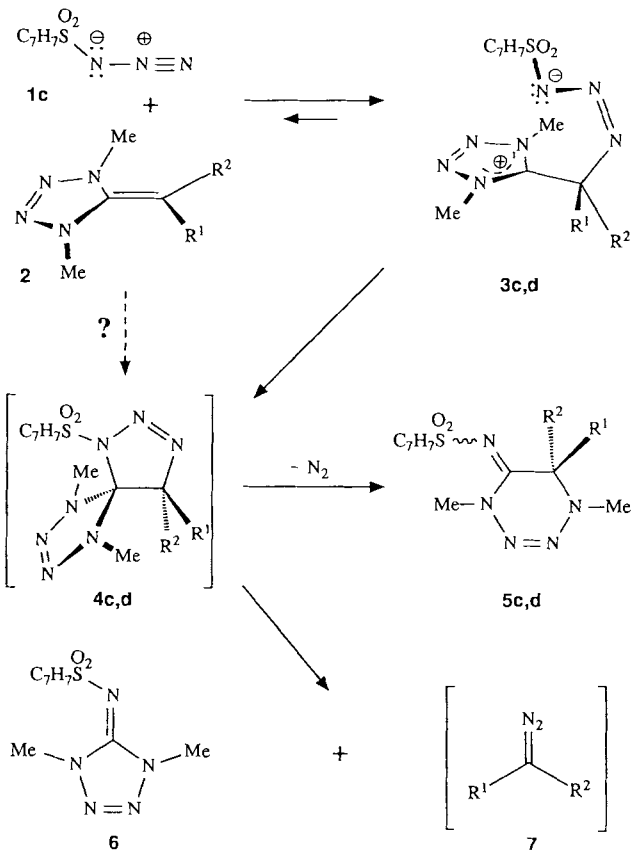
Whereas the zwitterion **3c** quantitatively affords tetrazine **5c** and iminotetrazole **6** (97:3) at temperatures as low as −10 to 0 °C (in $CDCl_3$), **3d** reacts very slowly in CD_3CN at 20–25 °C (38% conversion in 850 h) and completely only in 5 h at 80 °C. Tetrazine **5d** and iminodihydrotetrazole **6** are formed in the ratio 4:1. Numerous analogies are known for the decomposition of the intermediate cycloadducts **4c, d** into **6** and **7**.[8] The NMR spectroscopic data of some zwitterions **3** and tetrazines **5** are collected in Table 2.

Are the zwitterions **3** intermediates of a two-step 1,3-dipolar cycloaddition or do they only participate in a dead-end equilibrium alongside a concerted cycloaddition? The following observations help towards answering this question.

1. Only the zwitterions **3c, d** are formed from **2** and tosyl azide **1b** at −78 °C in CD_2Cl_2. Neither the cycloadducts **4c, d** nor the tetrazines **5c, d** could be detected by ^{1}H-NMR spectroscopy (200 MHz) at −60 °C.

2. The deuterated zwitterion [D_7] **3c** formed from deuterated tosyl azide [D_7]**1b** and **2a** at −30 °C in [D_8]toluene reacts at −10 to 0 °C in $CDCl_3$ in the presence of 20 equivalents of **1b** to give the isotopomeric tetrazines [D_7]**5c** and **5c** in the ratio (93 ± 1):(7 ∓ 1). That is, the cleavage of the zwitterion **3c** plays only a minor role compared to its cyclization.



3. Within 3 h in CD_3CN solution at 80 °C in the presence of 20 equivalents of **1b**, the zwitterion [D_7]**3d** yields 20% of the iminotetrazoles [D_7]**6**, **6** and 80% of the tetrazines [D_7]**5d**, **5d** with an isotopomeric ratio of (65 ± 3):(35 ∓ 3). Under the same conditions, **3d** in the presence of 20 equivalents of [D_7]**1b** affords ca. 35% of non-deuterated tosyl azide **1b** as well as 20% of iminotetrazoles **6**, [D_7]**6** and 80% of tetrazines **5d**, [D_7]**5d** in the ratio (65 ± 3):(35 ∓ 3). That is, the zwitterion **3d** partially decomposes into its components **1b** and **2b** at 80 °C.

Since the zwitterions **3c, d** are formed much more rapidly from tosyl azide **1b** and the alkylidene tetrazoles **2** than are the tetrazines **5c, d**, and since the zwitterions **3c, d** cyclize more rapidly to the intermediate cycloadducts **4c, d** than

Table 2. ^{1}H-NMR (200 or 250 MHz) and ^{13}C-NMR (50 or 62.5 MHz) data of the zwitterions **3a, c, d** and tetrazines **5c, d**.

they decompose into their components, *the zwitterions* **3c, d** *are intermediates of a two-step 1,3-dipolar cycloaddition. A concerted cycloaddition of* **1b** *and* **2** *cannot be detected at low temperatures*. It seems unlikely that it begins to play a role at 80 °C in the case of **1b** and **2b**, since the rate-determining step of the two-step cycloaddition, i.e. the cyclization of the zwitterion **3d** probably has a less negative activation entropy than the hypothetical concerted cycloaddition.[9]

The first step of the two-step 1,3-dipolar cycloaddition described here is influenced by the HOMO (dipolarophile)–LUMO (1,3-dipole) separation, the second step by the electronic stabilization of the zwitterion and by steric effects on its cyclization. In the case of the 1,3-dipolar cycloaddition of phenyl azide to *N*-(1-cyclohexenyl)pyrrolidine, which is regarded as concerted, the HOMO(dipolarophile)–LUMO(1,3-dipole)separation is ca. 7.3 eV.[9] The HOMO of isopropylidenedihydrotetrazole **2a** lies at −6.95 eV[10] and the LUMO of the sulfonyl azides **1b** and **1c**, according to MNDO calculations, lie at −0.14 and −0.19 eV, respectively.[11] That is, with a separation of 6.8 eV between HOMO (dipolarophile) and LUMO (1,3-dipole), a 1,3-dipolar cycloaddition can proceed in two steps. 2-Alkylidenedihydrobenzimidazoles and 2-alkylidenetetrahydroimidazoles behave like the 5-alkylidenedihydrotetrazoles **2** towards electrophilic azides. Whether this also holds true in the case of other electrophilic 1,3-dipoles remains an open question.

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Schrödinger—Life and Thought. By *W. Moore*. Cambridge University Press, Cambridge/UK 1989. xi, 513 pp., hardcover, $ 39.50.—ISBN 0-521-35434-X

The success and recognition gained by a scientist are usually measured by the frequency with which his or her publications are cited. Only a few reach a status which transcends such criteria, and these become the subjects of biographies. As a result, suddenly it is not only their already well known scientific achievements that are of interest, but also their childhood, upbringing and private lives. The theoretical physicist *Erwin Schrödinger* was virtually predestined to be the subject of a biography, being an individualist and a scientific loner whose life and achievements therefore stood out unusually clearly from those of his contemporaries. The Emeritus Professor of Physical Chemistry *Walter Moore* has meticulously gathered together information on *Schrödinger*'s private and scientific life, some of it practically unknown up to now, and assembled this into an imposing work. Even the list of names of the people in many different countries whom he has consulted in writing the book fills a whole page. As a result this biography of *Schrödinger* far exceeds all previous ones in size and comprehensiveness.

The accounts of *Schrödinger*'s youth in Vienna, of his student days, and of his early years as a professor of theoretical physics, first in Jena, then in Stuttgart and Breslau, occupy the initial third of the biography. The development of the ideas that led to *Schrödinger* taking his place in the history of physics and related disciplines begins in 1924 with *Louis de Broglie*'s prediction of the existence of particle-waves. At that time *Schrödinger* held a professorship in Zürich, and was fortunate in having the mathematician *Hermann Weyl* nearby. *Moore* has succeeded admirably in describing the development of wave mechanics with a minimum of mathe-

matical formulas. This is especially valuable, since the six lengthy original papers published by *Schrödinger* would be very laborious for the reader to tackle himself. The supreme moment in *Schrödinger*'s life was essentially the few days of the Christmas holiday of 1925. Compared with this the meetings of the Nobel committee to evaluate *Schrödinger*'s work, extending up to 1933, seem very long. It was not at first clear whether wave mechanics should be regarded as merely an extension of *de Broglie*'s particle-waves hypothesis or whether it contained ideas that were fundamentally new. The most absorbing section of the book is concerned not so much with the birth of wave mechanics as with how the theory stood up to objections by *Planck, Einstein, Born, Heisenberg, Lorentz* and others. The manner in which the Schrödinger equation was proved correct against these criticisms was a matter of surprise rather than of logic. At this point the reader is given the impression that the only problem actually solved by *Schrödinger* was that of the hydrogen atom, and in the final analysis this is true. Some of his contemporaries, such as *Paul Dirac* and *Friedrich Hund*, recognized immediately that *Schrödinger*'s equation had also laid the foundation stone for what was to become the most successful branch of theoretical chemistry, but this insight was denied to *Schrödinger* himself during his lifetime. In fact, he could not accept the interpretation of the wave function in terms of *Born*'s model. The dispute on this aspect, which *Schrödinger* pursued in a vindictive and emotional way against *Born*, is only briefly mentioned in this biography. *Schrödinger*'s later positions, such as those in Berlin (1927–1933), Graz (1936–1938) and Dublin (1939–1956), to mention only a few, appear to the reader interested in wave mechanics as no more than an epilogue.

The occasional comments of a political nature about *Schrödinger* are, as one might expect, questionable and contradictory. Nevertheless, here for the first time a biographer has ventured to reproduce *Schrödinger*'s emotional "declaration of allegiance to the Führer" of 31 March 1938 (which is the correct date), even though it is not accompanied by the no less revealing comments on this by the then rector of Graz University. I found only a few names of people and places in this biography that need to be corrected.

Schrödinger had a personality with inner conflicts. Frequent affairs at a personal level made it difficult for him to carry out his normal duties to the full. As a result of this, and the frequent changes of location which were partly connected with it, *Schrödinger*, unlike some of his other well-known colleagues, never founded institutes or produced eminent students. However, the author puts a different interpretation on the *Schrödinger* phenomenon, recognizing an essential inner connection between the rapid succession of affairs and the striving towards scientific versatility.

This biography, which is also very attractively presented and contains excellent illustrations and source references, can be recommended to every scientist.

The Conformational Analysis of Cyclohexenes, Cyclohexadienes and Related Hydroaromatic Compounds. Edited by *P. W. Rabideau*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. ix, 323 pp., hardcover, DM 154.00.—ISBN 3-527-26860-X/0-89573-702-7

This monograph belongs to the series "Methods in Stereochemical Analysis" (series editor: *A. P. Marchand*), and consists of eight chapters, an appendix and a brief subject index. The authors and short titles of the individual contributions, together with some statistical data (numbers of pages and details of literature citations) are listed in Table 1.

Table 1.

Author(s)	Short title	Number of pages	References		
			Total number	Number (and %) for 1984 onward	Number (and %) of self-citations
F. A. L. Anet	Cyclohexenes	42	137	19 (14)	4 (3)
J. B. Lambert	6-Membered rings with exocyclic double bonds	14	41	4 (10)	13 (32)
P. W. Rabideau, A. Sygula	1,3-Cyclohexadienes	21	75	3 (4)	3 (4)
P. W. Rabideau	1,4-Cyclohexadienes	35	84	17 (20)	19 (23)
F. G. Morin, D. M. Grant	^{13}C NMR Spectroscopy	38	43	6 (14)	10 (23)
S. A. Evans	Hetero-6-ring-olefins (thioxanthenes)	40	119	19 (16)	5 (4)
K. B. Lipkowitz	Applications of force field calculations	53	47	6 (13)	3 (6)
R. G. Harvey	Metabolites of carcinogenic hydrocarbons	29	97	25 (26)	44 (45)
K. B. Lipkowitz	Methodology of force field calculations (Appendix)	19	32	8 (25)	1 (3)
	Subject index	3			
Totals		294	675	107 (16)	102 (15)

The first contribution attests that virtually everything is known about the conformational behavior of cyclohexene, and that on this firm basis many of the properties of cyclohexene derivatives can be understood. The short second chapter does not really fit into the book's context, unless a rather artificial one is constructed by, for example, emphasizing the enol form of cyclohexanone as a cyclohexene derivative. The following two chapters on 1,3- and 1,4-cyclohexadienes (and their benzo derivatives) bring us back to the primary topic; these chapters include a neat analysis of the factors governing the geometry of the six-membered ring (planar or non-planar?) and of the preferred positions occupied by substituents. Chapter 5 is concerned with applications of ^{13}C NMR spectroscopy to the conformational analysis of partially hydrogenated naphthalenes, anthracenes and phenanthrenes, and includes a six-page table listing chemical shifts. The title of Chapter 6 announces an account of conformational studies on hetero-six-membered ring olefins in general, but the chapter is almost exclusively devoted to thioxanthenes of pharmacological importance. At this point one would have been pleased to find a discussion on nicotinamide adenine dinucleotide (NAD), which is so important biochemically, and whose reduced form (NADH) is of course a derivative of aza-1,4-cyclohexadiene. In contrast, Chapter 7 contains for the most part what the title promises, i.e. force field calculations on hydrocarbons with cyclohexene and cyclohexadiene units. However, 1,3-cyclohexadienes

are not included here, as they are less amenable to force field calculations, having conjugated double bonds. Apart from this omission, a remarkably wide variety of interesting strained hydrocarbons is covered, all of which indeed fit into the subject. This may help to allay doubts about the justification to publish this book as a whole, originating from its rather narrow scope. Chapter 7 is supplemented by an appendix, which gives a brief outline of force field methods. In fact, this appendix appears more or less superfluous. The material is presented very loosely and seems to stem from a casual seminar talk rather than rigorous planning; literature citations in the text are almost nil. The eighth and last chapter is on a topic that one would not expect in this book. As it concerns structure-bioactivity relationships of hydroaromatic metabolites of carcinogenic hydrocarbons, its topicality is obvious and reflected by many very recent literature citations (Table 1). A prominent feature is the discussion of NMR spectroscopic results, including many from the author's own laboratory.

As already mentioned, the book as a whole raises the question of whether the narrowly defined subject matter really justifies a monograph to itself. Further doubt is nourished by the notion that a "nugget" of the book (Chapter 8) might more appropriately have been published elsewhere. Clearly, specialization is inevitable in view of the ever increasing tide of new scientific knowledge, but is it really necessary to take this as far as has been done here? The book can be recommended to a limited number of experts; it is unlikely to reach a large readership, also in view of the frustrations ensuing from its high price.

Comprehensive Polymer Science: The Synthesis, Characterization, Reactions and Applications of Polymers. 7 volumes. Edited by *G. Allen* and *J. C. Bevington*. Pergamon Press, Oxford 1989. 5367 pp., hardcover, $ 1995.00.—ISBN 0-08-032516-5

Volume 1 of this work contains a comprehensive review of "Polymer Characterization", and Volume 2 deals with "Polymer Properties". In the latter volume a somewhat more detailed treatment of high temperature polymers and liquid crystal polymers would have been desirable. Polymer synthesis is treated in volumes 3 to 5, under "Chain Polymerization" (Volumes 3 and 4) and "Step Polymerization" (Volume 5). The contributions vary from very detailed and comprehensive to very brief, and cover all aspects, usually with the main emphasis on scientific problems.

Volume 6 is concerned with reactions involving macromolecules. The chapter on "Thermal Degradation" neglects to cover aromatic polymers. Volume 7, "Specialty Polymers and Polymer Processing", is by the nature of the subject heterogeneous. The chapter on "Polymer Blends" is very good as regards the theoretical part, but a section on methods of production and on polymer blends of technological importance would have been a welcome addition. The least satisfactory part is that on "Polymer Processing" (230 pp.).

The editors and the authors (of whom there are 250 from 20 different countries!) have set out to produce "a milestone in the literature of polymer science", covering the fields of synthesis, characterization, reactions and applications. Have they succeeded in fulfilling this ambitious self-proclaimed promise? In the opinion of the reviewers, they have only been partly successful. However, it is doubtful whether it is actually possible to cover these four aspects of such an extensive area of knowledge equally well in a single work, even in a multi-volume compendium such as this.

"Comprehensive Polymer Science" should be regarded as a valuable addition to the already existing encyclopedias and handbooks in the polymer field, and it also succeeds as a comprehensive textbook presenting the latest state of knowledge. It is recommended for readers wishing to familiarize themselves with specific areas of polymer research, including especially synthesis, characterization and reactions. In many of the chapters this objective is particularly helped by the manner of presentation, with numerous tables summarizing the information and thus making the reader's task easier. Also the bibliographies, extending partly up to 1988, give comprehensive access to the original literature.

Some defects need to be remedied in a future edition of the work. The contributions vary greatly in the amount of detail covered, and some of them only deal with selected aspects; in a few cases the format is merely that of an expanded synopsis. Also the balance between scientific and practically orientated information varies greatly. It would also be highly desirable to have a consistent nomenclature and terminology. Lastly, cross-references within the individual contributions and between them would be very useful.

Spectroelectrochemistry. Edited by *R. J. Gale*. Plenum, New York 1988. 450 pp., hardcover, $ 85.00.—ISBN 0-306-42855-5

Spectroelectrochemistry—the application of spectroscopic methods to solving electrochemical problems—is currently the fastest growing branch of electrochemistry. The numerous results that it has produced have in many cases lent further support to conclusions reached from classical electrochemical studies, and in a few cases have refuted them. Often spectroscopic methods have for the first time opened up the way to obtaining a detailed picture, on a microscopic scale, of the mechanism of an electrochemical reaction and of the structure of the electrochemical double layer. Therefore, despite the fact that in journals and monographs there are review articles covering nearly all the different methods of spectroelectrochemistry with varying degrees of depth and completeness, the idea of publishing a book which gives a comprehensive and coherent description of all the *in situ* methods is to be welcomed. The deliberate restriction to *in situ* methods, thereby avoiding the potential sources of error involved in transferring electrodes from the electrochemical sampling cell to the analytical instrument, is also sensible. However, the exclusion (which is presumably intentional) of methods whose main strength lies in identifying and quantifying species in solution as opposed to those on the electrode surfaces is incomprehensible and disappointing.

A short introductory chapter by the editor is followed by seven chapters on methods that are *in situ* in nature and essentially surface specific (although there is some doubt as to whether the second of these criteria applies to electrochemical ESR spectroscopy). The seven chapters deal with: X-ray spectroscopy, photoemission measurements, UV-VIS reflection spectroscopy, IR reflection spectroscopy, surface-

enhanced Raman spectroscopy, electron spin resonance spectroscopy and Mössbauer spectroscopy.

All the chapters are written by recognized experts, although they vary in the quality of detailed coverage, and in some cases the choice of examples and literature citations is unduly selective. Unfortunately, as in many multi-author works of this kind, it appears that each author has been unaware of what the others planned to include, and there is therefore no coordination between the contents of the chapters, especially with regard to the examples of experimental studies and results. This is all the more annoying in view of the fact that the rational use of several spectroelectrochemical methods in combination can lead to results that are considerably more accurate, reliable and complete. Examples that could have been included are studies of conducting polymers, of chemically modified electrodes, or of compounds adsorbed on electrodes. These would have provided striking illustrations of the enormous potential of using different methods in combination.

Also disappointing is the lack of completeness in the book; several methods (e.g. electrochemical mass spectrometry and the generation of surface optical waves) are missing, or are mentioned only in passing, and with outdated references. On the other hand, the treatments of Mössbauer spectroscopy and electrochemical ESR spectroscopy seem disproportionately lengthy, in view of the fact that these techniques have been relatively little used and have a limited application potential. It is true that the popularity of a technique cannot always be equated with its scientific importance, but the reader could have been helped by providing a fuller and more comprehensive introductory survey of the methods, and some justification of the choice of methods for detailed treatment.

Except for some minor errors and inaccuracies (e.g. on Raman fluorescence (p. 2), and the description of electrochemical impedance measurements as a form of absorption spectroscopy (p. 2)) the chapters seem to be clearly written and factually correct. The index is brief, and the opportunity of using it to open up the field is scarcely used.

After reading the book one is left with an overall impression that it fails to meet the expectation, from the title and publisher's blurb, that it will give the reader a comprehensive overview of the field of spectroelectrochemistry. Instead it offers a collection of competently written individual review articles that are uncoordinated with each other. In some cases (e.g. the article on IR spectroscopy) these reviews have already appeared before in a form which differs only slightly; it was therefore hardly necessary to publish them again in this book, and they were apparently included only for completeness. The book certainly contains some valuable chapters which are useful for the electrochemist seeking specific information about special techniques. However, the reader interested in finding a sound, coordinated and comprehensive review of the subject will soon put the book down in disappointment.

Rudolf Holze [NB 1011 IE]
Fachbereich Chemie
der Universität Oldenburg (FRG)

The Elements. By *J. Emsley*. Clarendon Press, Oxford 1989. 256 pp., paperback, £ 9.95.—ISBN 0-19-855237-8

Important data and properties of the chemical elements have in the past been widely scattered throughout textbooks, tabulated works of reference and other specialist literature. Attempts to provide information of this kind in a compact form for those interested in finding it have usually been limited to footnotes in tables showing the Periodic Classification of the elements. Thus *John Emsley*'s idea of preparing a convenient work of reference in book form, giving the most important properties of all the elements up to nobelium, is very much to be welcomed.

The elements are arranged alphabetically, and each is given exactly two pages. These all follow the same pattern as follows: historical information (discovery, naming), chemical and physical properties, and data on the structures and properties of the nucleus and the electron shells. Lastly there is information on natural occurrence and biological importance. The "chemical" properties given for each element include its appearance, occurrence, reactivity, uses, ionic radii, electronegativity, effective nuclear charge, standard reduction potentials and oxidation states. The information listed under physical properties includes melting and boiling points, thermodynamic data, thermal and electrical conductivities, crystal structure(s) and X-ray absorption coefficient. The nuclear properties listed include information on the main isotopes (including artificial nuclides) and NMR data. Finally, under "electronic properties", ionization energies and data on atomic spectra are given.

Owing to the way in which the work has been planned, some vagueness creeps in for elements that occur in several different modifications (e.g. B, S). Some random tests confirmed the reliability of the data. A wealth of information on sources is provided for those wishing to undertake extensive searches.

The advantage offered by this miniature encyclopedia is that it gives comprehensive and reliable information at a glance. For chemists the question arises as to whether there is a need for more information, especially with regard to history, occurrence and biological importance, matters that are given only marginal coverage here; however, the book is likely to prove an important aid, mainly for those in chemistry-related disciplines.

der Universität Regensburg (FRG)

Activation and Functionalization of Alkanes. Edited by *C. L. Hill*. Wiley, Chichester 1989. x, 372 pp., hardcover, £ 39.30.—ISBN 0-471-60016-4

Alkanes are the most abundant naturally occurring organic compounds, and are therefore a rich source of chemical feedstocks. However, their low reactivity and the problems of achieving regioselectivity in reactions limit their usefulness for manufacturing higher value products. Consequently there is growing interest among chemists in various methods for the functionalization of CH bonds. Whereas only a few papers on this topic had been published up to 1980, their number now runs into thousands. This book concentrates on studies by eminent organometallic, organic, bioorganic and inorganic chemists that are aimed at developing stable catalysts for selective functionalization of CH bonds with high yields. In each case the articles describe the principles, mechanisms and preparative potential of the reactions discussed.

In Chapter 1 (Historical Evolution of Homogeneous Alkane Activation Systems, 24 pp., 66 refs.) *A. E. Shilov* describes the oxidation of methane using platinum complexes, and the development and properties of iron porphyrins as models for monooxygenases that depend on cytochrome P-450.

Chapter 2 (Electrophilic Chemistry of Alkanes, 51 pp., 114 refs.) by *G. A. Olah, O. Farooq* and *G. K. S. Prakasch* is devoted to the oxidation of secondary and tertiary CH bonds in magic acid to carbocations and their subsequent reaction products. In this medium H_2O_2 and ozone react as electrophiles with alkanes, to give ketones; chlorine and bromine in the presence of acidic catalysts give chlorides and bromides respectively.

Chapters 3–5 deal with the activation of alkanes by three organometallic systems. Chapter 3 (Some Recent Advances in Alkane Functionalization: Metal Phosphine Catalysts and Mercury Photosensitization, 30 pp., 33 refs.) by *R. Crabtree* describes thermal or photochemical oxidative additions of CH bonds with complexes of iridium, rhodium or rhenium; this is an interesting reaction, although the catalysts are of poor stability. On the other hand, the photosensitized dehydrodimerization of alkanes, discovered more or less accidentally, uses as a catalyst elemental mercury, which is efficient, simple to use and robust, leading to interesting preparative applications.

Chapter 4 (Alkane Activation Processes by Cyclopentadienyl Complexes of Rhodium, Iridium and Related Species, 38 pp., 61 refs.) by *W. D. Jones* shows that although these complexes all react in a similar way with alkanes, the reaction rates differ widely. After photochemical activation they undergo oxidative addition at CH bonds, in some cases at temperatures as low as −20 °C. The reaction mechanisms are thoroughly discussed.

In Chapter 5 (Homogeneous Activation of Carbon-Hydrogen Bonds by High Valent Early d-Block Lanthanide and Actinide Metal Systems, 43 pp., 128 refs.) *I. P. Rothwell* discusses reactions whereby α-, β- and γ-hydrogen atoms are abstracted from alkyl, amino, mercapto and alkoxy ligands of the d°-transition metals specified in the title.

Chapters 6 and 7 and parts of Chapter 10 deal with the functionalization of alkanes by metal porphyrins. In Chapter 6 (Alkane Functionalization by Cytochrome P-450 and by Model Systems Using O_2 or H_2O_2, 20 pp., 74 refs.) by *D. Mansuy* and *P. Battioni*, the mechanism of the cytochrome P-450 hydroxylation reaction is discussed. Starting from Fe^{II} porphyrin, reactio with oxygen and reduction gives an $Fe^{IV}=O$ porphyrin radical cation, which inserts itself into the CH bond. This appears to be followed by further free radical reactions, since epimerizations and rearrangements are observed. Other iron porphyrin systems are described which are activated by H_2O_2, hydroperoxides, iodoso compounds or, in less favorable yields, by oxygen and reducing agents; in these catalysts the porphyrin ring has chlorophenyl substituents which give at least partial protection from oxidative autodecomposition. These reagents can be used for epoxidation of olefins and for hydroxylation of alkanes such as adamantane or cyclohexane.

In Chapter 7 (Shape Selective Oxidation of Hydrocarbons, 20 pp., 71 refs.) *K. Suslick* describes how the stability of porphyrins can be increased by steric shielding. The regioselectivity is improved too, as rates of oxidation for methylene groups at the outermost positions in hydrocarbons are 2–3 times greater than those for internal methylene groups. Although hydroxylations can be carried out in microheterogeneous systems (e.g. vesicles) or microporous systems (e.g. zeolites) with selectivities that are in some cases better, the isolation of the products is more difficult with these methods, and the catalyst only remains active for a small number of cycles.

In Chapter 8 (Catalytic Oxygenation of Unactivated CH-Bonds: Superior Oxo Transfer Catalysts and the Inorganic Metalloporphyrins, 30 pp., 118 refs.) *C. L. Hill* reviews this topic and shows that catalysts based on the polyoxometallate structure combine the selectivity and controllability of homogeneous catalysts with the stability of metal oxides. The transition metal substituted polyoxometallates such as $[MPW_{11}O_{39}]^{5\ominus}$ with $M = Co^{II}$ or Mn^{II} are several orders of magnitude more stable than sterically protected metalloporphyrins.

Chapter 9 (Selective Functionalization of Saturated Hydrocarbons by the "Gif" and "Gif-Orsay" Systems, 18 pp., 36 refs.) by *D. H. R. Barton* and *N. Ozbalik* gives an impressive account of the development of the Gif system, e.g. Gif IV consists of pyridine, glacial acetic acid, iron(II/III), zinc and O_2, and oxidizes adamantane preferentially at the methylene groups, with a life of up to 2000 cycles, or breaks down the side chain of cholestenone to give progesterone. The Gif-Orsay system, in which zinc is replaced by the cathode and a mediator, is superior to the Gif system, and oxidizes cyclohexane with a current efficiency of 49%. From a mechanistic standpoint the CH_2 selectivity can be explained in terms of intermediate metal carbene complexes which undergo oxidative scission.

The final chapter (Alkane Oxidation Studies in Du Pont's Central Research Department, 55 pp., 54 refs.) by *C. A. Tolman, J. D. Druliner, M. J. Nappa* and *N. Herron* describes research to elucidate the reaction steps in the industrial cyclohexane oxidation process giving cyclohexanol and cyclohexanone. By carrying out microreactor experiments and computer simulations of more than 150 reaction sequences the process conditions have been optimized. By using metalloporphyrins in zeolites it is possible to preferentially oxidize smaller hydrocarbon molecules compared with larger ones, although the catalyst life is only a small number of cycles. The iron/palladium/zeolite system which is a completely inorganic model for P-450 gives selective oxidation of octane by oxygen in the presence of cyclohexane.

The book fully achieves its aim of reporting on this rapidly developing interdisciplinary field in a concise form limited to the essential facts. Its usefulness is enhanced by the orderly arrangement of the text, the clear tables and structural formulas, and a comprehensive subject index. It can be strongly recommended to everyone working on reactions at non-activated CH bonds, or planning to do so.

The Language of Biotechnology. A Dictionary of Terms. By *J. M. Walker* and *M. Cox*. American Chemical Society, Washington, D.C. (USA) 1988. viii, 225 pp., paperback, $ 47.95 (USA & Canada: $ 39.95).—ISBN 0-8412-1490-5; hardcover, $ 59.95 (USA & Canada: $ 49.95).— ISBN 0-8412-1489-1

This little 250-page ABC of biotechnology, a work of reference which includes terms from *Abomasum* to *Zygomycotina*, gives clear and concise definitions. It should help biotechnologists to better understand the language used by colleagues in specialist fields other than their own, which is an essential prerequisite for effective team work.

The multitude of terms used in biotechnology would be enough to fill a dictionary of several volumes. The value of this little book lies in the fact that it covers a broad range of selected words and expressions used in the different specialist areas of biotechnology. To compile such a selection in an interdisciplinary field of study is no easy task. The essential

feature of the dictionary is the explanations of terms from such widely different specialist fields as microbiology, genetics, molecular biology, plant and animal cell culture, enzyme technology, fermentation technology, process control and biochemical engineering. Explanations of the more complex technological aspects are supported by diagrams and formulas.

The authors have succeeded in putting together a very useful small dictionary of biotechnology. It will help to make this wide field of research a little more comprehensible.

Crystal Chemistry and Refractivity. By *H. W. Jaffe*. Cambridge University Press, Cambridge (UK) 1988. x, 335 pp., hardcover, £ 55.00.—ISBN 0-521-25505-8

Introduction to Crystal Chemistry. Student Edition. By *H. W. Jaffe*. Cambridge University Press, Cambridge (UK) 1988. 161 pp., paperback, £ 15.00.—ISBN 0-521-36985-1

In the last few decades chemistry has made considerable advances in the area of theory, and also in synthesis and analysis. The same also applies to crystallography, where the progress achieved includes remarkable improvements in the methods for determining crystal structures by X-ray and neutron diffraction. As a result of this a very large number of precisely determined crystal structures, including even those of very complex inorganic and organic compounds, are now known. These advances have been incorporated into a number of excellent new textbooks dealing with both chemistry and crystallography.

However, if *crystal chemistry* is understood to include not only the geometrical description of crystal structures, but also the study of the relationships between chemical composition, temperature and pressure on the one hand and, on the other hand, the structure and the factors which alter it, such as thermal expansion, compression, phase transformations and solid state reactions, then it must be said that there is a lack of good new textbooks on crystal chemistry. The textbooks by *H. Krebs* ("Anorganische Kristallchemie" (1968)) and by *R. C. Evans* ("Crystal Chemistry" (1964)) cannot be said to reflect the present state of knowledge, and the book by *A. F. Wells* ("Structural Inorganic Chemistry", 5th Edition (1984)), although an excellent work of reference, is not a student textbook. Several publishers have promised textbooks on crystal chemistry which have not yet appeared. The arrival of the book "Crystal Chemistry and Refractivity", by *H. W. Jaffe*, will therefore be greeted with much interest and curiosity.

The work consists of two parts. Part I, on the fundamentals of crystal chemistry and the refraction of light (146 pp.), contains a concise and accurate description of general principles such as atomic structure, types of chemical bonding, Pauling's rules, crystal field theory, polymorphism, diadochy and isotypes. Two separate sections are devoted to the packing density of atoms and the relationship between crystal structure and optical properties.

Although Part II (178 pp.) is entitled "Descriptive Crystal Chemistry", it is by no means restricted to the geometrical description of crystal structures. It includes a discussion, illustrated by examples, of the effects of chemical composition and temperature, and also in some cases of pressure, on the structures of crystals and the transformations which they undergo. Thus *Jaffe*'s book fulfills its claim to be a modern textbook of crystal chemistry in the sense of the definition given above, to an extent not achieved in any other book known to this reviewer. It can certainly be recommended to everyone whose work is concerned with inorganic solids.

Regrettably, it seems likely that this book by *Jaffe* will not reach as wide a readership as it deserves to, owing to the fact that, in accordance with the author's special interests, the structural examples chosen are nearly all from the minerals field. Despite this, the wide chemical and structural variety of minerals, and the fact that in a great many mineral systems the approach to thermodynamic equilibrium occurs so slowly that the progress of the reactions can be studied at leisure, means that minerals offer particularly suitable examples of crystal chemical phenomena. The book can therefore be recommended just as warmly to chemists and materials scientists as to geoscientists.

The paperback "Introduction to Crystal Chemistry" by *H. W. Jaffe*, published simultaneously with the above book, is almost completely identical to Part I of that book, and it is no doubt intended as a short textbook on crystal chemistry that students can afford. Regrettably, however, there must be some doubt as to whether the abridged version can fulfill this aim, when measured against the high standard of the total work. The fact that the description of the fundamentals in this part is so concise means that the student's appreciation of the significance and implications of these principles will probably be severely limited, if he or she is unable to draw on the carefully chosen structural examples and related discussion that are contained in Part II of the full work. The six-page appendix which is offered as a substitute, containing a few structural diagrams without the associated discussion, does not really give much help in this respect. Moreover, as the treatment of the effects of temperature and pressure on the structures of the minerals is nearly all contained in Part II of the complete work, the paperback version is lacking in some important aspects of crystal chemistry.

It appears that in deciding to publish the "Student Edition", the desire on the part of the publishers for a quick source of extra profit has taken precedence over their duty to the readers. One hopes very much that there will soon be a new paperback edition of the excellent full work, printed on cheaper paper if necessary, but at a reduced price.

Organisch-chemischer Denksport. Ein Seminar für Fortgeschrittene. By *R. Brückner*. Vieweg, Braunschweig/Wiesbaden 1989. xvii, 270 pp., paperback, DM 39.80.—ISBN 3-528-06329-7

Working through exercise problems is a necessary activity; one tests whether one has mastered the material that has been learnt and can apply it. Often, however, this task is only undertaken reluctantly, in particular by using the exercises in textbooks. In most cases one is here concerned with mature knowledge which, although of fundamental importance, is often already covered with the dust of the years. The atmosphere in the book of exercises reviewed here is quite different. There is a strong emphasis on topics taken from the most recent literature. At the outset the word "Denksport" in the title avoids creating the distance that conventionally exists between the teacher setting the exercises and the person doing them, and instead emphasizes challenge and competition.

The author also uses apt and racy quotations to break down any atmosphere of authority other than that based on facts (although for some tastes these may contain too many Americanisms). In this way the previously tiresome duty of doing exercises is transformed into a welcome activity.

In his 70 exercises, many of which are very tough nuts to crack, the author covers a remarkably wide range of topics in organic chemistry. In the answers he analyzes the basic essentials of problems that are concerned with stereochemistry, mechanisms, spectroscopy, and especially synthesis. By including many references he encourages the reader to follow up each exercise by looking into the problem in more detail with the help of the original literature, and to form his or her own opinion on the basis of the experimental facts. This is definitely to be recommended, since the author also interprets observations for which the original papers offer no explanation. In the interests of topicality he even exposes himself to the risk of being overtaken by events. This is the case, for example, in Exercise 7, which concerns an unsuccessful attempt to synthesize compound **246**. This compound has since been successfully prepared (*J. Am. Chem. Soc. 109* (1987) 2857), and the author's speculations concerning the thermal decomposition of **246** (p. 105) can now be compared with the actual behavior of **246**.

It is not unreasonable to recognize in the exercises the author's favorite hobby-horses, and also the school of chemistry from which he comes. There one often works with numerical values, in order to at least arrive at a qualitative understanding, if a quantitative treatment is not possible. This philosophy has prompted the author to include an appendix in which are tabulated bond enthalpies, stabilization energies, strain energies, the dependence of equilibrium ratios and product ratios on the difference in free enthalpies and free activation enthalpies respectively, and other quantities, all of which one often needs but never has to hand. The widespread use of kinetics, which is generally too little used in organic chemistry, and which the author therefore actively promotes, is again a feature carried over from his training. However, in accordance with his present research interests the majority of the exercises are concerned with problems of synthesis, especially natural products syntheses involving tricky stereochemical requirements. Several of these relate to natural products that have only recently been isolated, and thus the synthetic routes suggested in the answers are still awaiting experimental verification.

However, into this wine one must now pour a little water. There are a considerable number of errors, including some which alter the meaning, and some of the interpretations can be countered by alternatives that are at least equally valid. Here are some samples to illustrate these points: In Answer 3 (p. 90) formulas **3** and **205** do not match up with the problem (p. 5). In Answer 6 (p. 102) the word "Tautomerie" in the 5th line should read "Mesomerie". The suggestion for converting **248** into **12a** and **12b** (Answer 7, p. 106) seems very unlikely. In Problem 22 (p. 23) only the initiated are likely to realize that P(cyclo-C_6H_{11}) actually means HP(cyclo-C_6H_{11})$_2$. The explanations for the formation of the dibromide **75** from **403** (Answer 33, p. 165) and of the lactones **183** and **184** (Answer 7, pp. 247, 248) violate the principle of Occam's Razor. A carbon atom is missing from the precursor of **114** (Answer 44, p. 188). On p. 60 (Problem 55) reference is made to Perylen, but in the answer (p. 210) we instead find "Piperylen". In the preparation of **177** (Answer 66, p. 245) the final step requires 3,4-dihydro-2*H*-pyran, not cyclohexene. In Answer 69 (pp. 254 f.) the configurations in formulas **615**–**617** are incorrect, causing confusion. Since the book is intended primarily for advanced readers (final year undergraduates and graduate students), any compromise in the care of presentation detracts from the aims of the book as a learning aid. In the preface the author playfully lays the blame for any remaining errors onto his friend who has read the proofs. With a wink, one should compare this with the principle followed by the author's teacher, that in publications no part of the task should be left to chance, least of all to a friend. Lastly, a word of criticism to the publishers: the inadequate standard of production of the book means that the frequent leafing to and fro between the problem and answer sections soon leads to loose pages.

However, only he who never attempts anything makes no mistakes. With this motto in mind, the book's shortcomings need to be set against the gain in knowledge and pleasure afforded by this "Denksport". The result of this is a balance well on the positive side, and therefore every advanced student of organic chemistry is warmly recommended to carefully work through the book. Moreover, the price does not present a serious obstacle to buying one's personal copy.

Introduction to Inductively Coupled Plasma Atomic Emission Spectroscopy. (Series: Analytical Spectroscopy Library, Vol. 3.). By *G. L. Moore*. Elsevier, Amsterdam 1989. 340 pp., hardcover, DFl 190.00.—ISBN 0-444-43029-6

This book of 15 chapters deals with the basic principles and analytical capabilities of optical emission spectroscopy using an inductively coupled radiofrequency plasma (ICP-OES). It is practically orientated, and provides the analyst in a straightforward way with the knowledge needed for optimizing the variables, recognizing sources of systematic errors, and performing analyses. The book is therefore intended mainly for technicians in analytical laboratories. The author has successfully translated his experience in emission spectroscopy into a lively and readily understandable, but nevertheless accurate, account of the subject.

The first chapter treats atomic spectra and classical spectroscopic analysis, with special emphasis on the capabilities of all the different types of excitation sources that are now available for emission spectroscopy (electric arcs, spark discharges, glow discharges, lasers, microwave plasmas). The account of the development of the ICP source and of the excitation mechanisms is limited to that needed for optimizing the adjustment of the ICP and performing ICP analyses. The following chapter is concerned mainly with the design of optical spectrometers for both sequential and simultaneous analysis, and with their performance data. Generators for ICP spectroscopy are treated only briefly, whereas the various alternative spectrometer arrangements in commercial instruments are clearly described in detail.

In the chapter on the analytical performance characteristics of ICP-OES, the method is compared with atomic absorption spectroscopy, X-ray fluorescence spectroscopy and DCP-OES (DCP = direct current plasma). The capabilities of ICP sources with low gas throughput and working with organic solutions are also discussed. The chapter on nebulization techniques describes the use of pneumatic and ultrasonic nebulizers for producing aerosols, and techniques for working with microsamples. The reader is referred to relevant literature, including recently published work.

The chapters that follow are concerned more with matters of practical detail. The chapter on sample preparation tech-

niques is concerned with digestion and extraction methods for multielement analyses, the decomposition of organic matrices, and conventional methods such as acid digestion at both atmospheric and high pressures; also discussed are sintering techniques, fusion with fluxes and microwave digestion. Special attention is given to digestion methods for geological samples.

The chapter on alternative techniques for sample introduction describes the capabilities of the hydride method and of electrothermal vaporization, of the direct introduction of powders in a gas jet, of techniques using suspensions, of direct sample insertion and of spark ablation. In the chapter on quantitative analysis by emission spectroscopy, methods of calibration using synthetic standards, certified reference materials, and standard addition are described. The meanings of the terms detection limit, determination limit and precision are explained. In describing the various analytical applications of ICP-OES, environmental analysis receives relatively little attention, but this is compensated by the detailed discussions of development trends in on-line analysis, automation of sample handling, etc.

The discussion of random and systematic errors is clear and straightforward. The usual statistical test procedures are described, as also is the importance of the spectral background and the methods used to measure it. The use of an internal standard is not so necessary in ICP-OES as in arc and spark emission spectroscopy, with which the author is equally familiar, but nevertheless it can be useful in ICP-OES for correcting fluctuations in the rate of sample introduction, especially for high concentrations.

In the chapter on optimization of the operating variables, the several different versions of the simplex procedures are described. Here the author makes full use of the experience gained from his own work, and presents this in a clearly understandable form. A simple computer program for simplex optimization is also given.

The most complex problem encountered in the analysis of real samples is that of interferences and the choice of suitable emission lines. Nebulization interferences and matrix effects arising from the plasma are briefly described. The relationship between interferences and optimization of variables is discussed with regard to source power and height of observation. The analytical errors caused by background and interfering lines depend critically on the spectrometer resolution achieved in practice. This dependence on resolution, although understood, is often complicated, and instead of treating it in detail the reader is referred to relevant literature.

The chapter on combined techniques, in which ICP-OES is coupled to various other analytical methods, describes in particular the coupling to electrothermal vaporization and the ICP-mass spectometry technique. The power of detection, the effects of other elements on the observed signals and the spectral interferences which occur in ICP-MS for the lighter elements are critically discussed.

The book is especially suitable as an introduction and learning aid for practical ICP spectroscopy in the laboratory, and it contains an adequate number of relevant literature references for this purpose. For practical work it would perhaps also have been useful to include data on emission lines commonly used in ICP-OES. The spectroscopic fundamentals can be found in the standard works by *Boumans* and *Montaser*. This book by *Moore* is likely to be of special interest to technicians and geology students, since it contains more of relevance for these groups than for environmental analysts or users in the ultra-pure chemicals or biological fields, a fact which is not surprising in view of the author's own field of work. Thus, for example, there are no chapters on the problems of trace analysis in relation to reagent purity and purification, on working in dust-free environments, nor on blanks and their relationship to ambient concentrations. The book makes easy reading and has a pleasing format. It will undoubtedly find a lot of use in the laboratory and in the vicinity of the ICP spectrometer. For many newcomers to ICP-OES as a modern multielement analytical technique it will ease their introduction to the subject.

Photoinduced Electron Transfer. Parts A–D. Edited by *M. A. Fox* and *M. Chanon*. Elsevier, Amsterdam 1988. Part A: Conceptual Basis. xviii, 640 pp., DFl 360.00.—ISBN 0-444-87122-5; Part B: Experimental Techniques and Medium Effects. xviii, 748 pp., DFl 410.00.—ISBN 0-444-87123-3; Part C: Photoinduced Electron Transfer Reactions—Organic Substrates. xviii, 754 pp., DFl 410.00.—ISBN 0-444-87124-1; Part D: Photoinduced Electron Transfer Reactions—Inorganic Substrates and Applications. xviii, 790 pp., DFl 425.00.—ISBN 0-444-87125-X, hardcover, set: DFl 1350.00.—ISBN 0-444-87121-7

The type of elementary reaction described as photoinduced electron transfer (PIET) has been studied both theoretically and, to a now increasing extent, experimentally. One factor that has contributed to this considerable growth of interest is the rapid progress achieved in the area of ultrafast techniques such as picosecond laser spectroscopy, which provides remarkably short time resolution in studying the dynamics of molecules and thereby of fast chemical processes. For the synthetic chemist the main significance of PIET studies lies in the enticing prospect of gaining a better understanding of such reactions so as to be able to develop more efficient catalytic and energy conversion processes; this is the reason for the current attraction of this area of research.

M. A. Fox and *M. Chanon*, as editors of this very comprehensive work, have tried to bring together in four volumes as many different aspects of this interdisciplinary field as possible. The 2600-page work consists of individual chapters in the form of photographically reproduced manuscripts by 46 authors or author groups. Starting from an essentially theoretical conceptual basis (Vol. A), Vol. B deals with the experimental techniques and with medium effects, then Volumes C and D describe actual examples in organic and inorganic chemistry respectively, and some particular areas of application such as solar energy conversion and information storage.

In the excellent introductory chapter of Volume A *M. Chanon, M. D. Hawley* and *M. A. Fox* give a general overview of PIET processes and a clear account of the relevant physical quantities. This is followed by a very technically orientated chapter by *J. P. Schermann, J. P. Astruc, C. Desfrançois* and *R. Barbe* describing electron transfer between excited atoms and molecules. Some theoretical aspects based on the Marcus equation are explained and discussed in two articles by *K. F. Purcell* and *B. Blaive*, and by *M. R. Wasielewski* and *F. Wilkinson*. The clear presentation by *D. C. Mauzerall* of the problem of reverse electron transfer deserves special mention. Another well-organized chapter is that by *G. Jones II* on the photochemistry and photophysics of organic charge transfer complexes. Next come articles on

exciplexes (*Y. Haas* and *O. Anner*), on the origin of solvent effects (*D. F. Calef*), and on the photochemistry of organic free radicals, cations and anions (*J. Eriksen*). Finally, *M. Chanon* and *L. Eberson* discuss in detail the fascinating phenomenon of photoinduced chain reactions; a highlight of this is a very useful compilation of frequently used components and sensitized electron transfer reactions.

Part B begins with a status report by *J. A. Delaire* and *J. Fauré* on laser spectroscopic methods; the development of nanosecond, picosecond and even femtosecond pulsed lasers for studying transient species is described. Two articles on the application of pulse radiolysis to inorganic reactions to generate short-lived species, by *W. L. Waltz* and by *P. Neta* and *A. Harriman*, are followed by a discussion of organic systems, arranged according to classes of organic compounds, with special emphasis on porphyrins and redox catalysts. These chapters illustrate the complex character of photolysis and radiolysis as applied to understanding intra- and intermolecular electron transfer processes. *S. G. Boxer, R. A. Goldstein* and *S. Franzen* describe how reaction dynamics can be influenced by applying magnetic and electric fields. Here the reader is first introduced to the theory of CIDNP and its application to the photosynthetic reaction center and to other organic donor-acceptor systems. A comparison between photoconductivity and the processes occurring in the photosynthetic reaction center serves to illustrate the effects of electric fields on PIET reactions. Next comes a lengthy article in which *M. Julliard* surveys the various classical methods and experiments for detecting PIET reactions. A large number of studies on donor-acceptor systems are cited and tabulated according to the criteria used in the investigations. Using various experimental data as examples, the reader is made aware not only of the methods and criteria for proving the occurrence of a PIET, but also of the difficulties and possible sources of error. *L. Brus* describes studies of electron transfer reactions based on measuring inelastic scattering of photons by transient species (time-resolved resonance Raman spectroscopy). In particular, applications to studying homogeneous reactions in liquids and heterogeneous electron transfer at semiconductor–electrolyte interfaces are discussed. *L. Kevan* describes the use of conventional ESR spectroscopy as well as modern double resonance (ENDOR) and electron spin-echo modulation (ESEM) techniques for the identification of paramagnetic intermediates. The advantages of the ESEM method for characterizing heterogeneous structures (semiconductors, micelles, vesicles) are clearly pointed out. Next *J. E. Baggott, C. H. Langford* and *C. Moralejo*, and in a separate article *A. D. Kirk*, describe temperature, wavelength and pressure effects in PIET reactions from a mechanistic point of view. It appears that there are still uncertainties about some aspects, in particular the interpretation of activation volumes, where the theory is not yet well developed.

In Part 2 of Volume B, *J. Santamaria* begins with a lucid treatment of solvent and salt effects on energetics and kinetics. *S. Baral* and *J. H. Fendler* provide a link from this to PIET reactions in "organized" media, which range from mimetic vesicles and lipid bilayer membranes to biological systems. After an introduction to the preparation of organizates of this kind, they give an interesting account of some recent PIET experiments. The article also discusses the stabilization of semiconducting colloids in organizates and their potential application in redox catalysis.

S. Nakabayashi and *T. Kawai* extend this connection further to electron transfer processes at semiconductor interfaces, which are important in relation to photoelectrodes, photocatalysis and sensitization. The theory of PIET through boundary layers is described, as well as spectroscopic analysis, electron transfer dynamics and the design of such materials. *J. Rabani* provides a lucid account of how PIET processes can be influenced by polyelectrolytes. Carefully controlled tailoring of polymers by incorporating donors, acceptors or sensitizers can result in a slowing down of the reverse electron transfer process which presents a serious problem in photochemical systems for energy conversion and storage. This article is very topical, and the presentation is clear and comprehensible.

In Part C (PIET in organic and biochemical substrates), *F. D. Lewis* begins by reporting on electron transfer reactions in compounds with multiple CC bonds. He succeeds in classifying the many different ways in which olefinic radical cations and anions can react. *P. G. Gassman* gives an excellent introduction and review of PIET reactions of strained hydrocarbons. The clear presentation and logical structure give the reader an insight into what the author describes at the end of the article as a "fascinating area of photochemistry". *A. Albini* and *A. Sulpizio* classify the PIET reactions of arenes according to their reaction mechanisms, i.e. the subsequent reactions of the radical species produced. Unfortunately, the authors give hardly any information about the *photoinduced* $S_{RN}1$ reactions of arenes, justifying this by the fact that review articles already exist (although these were published in 1983 or earlier). An update on this topic would have been appropriate. Next *A. Lablache-Combier*, in a contribution of nearly 180 pages, extends the $S_{RN}1$ concept to the synthesis of heteroarenes and to their subsequent reactions. Numerous physical-chemical relationships are introduced, so that the combination of synthetic aspects with photochemical data provides the reader with a clear idea of the advantages and difficulties of such reactions. The following article, by *M. Hoshino* and *H. Shizuka*, gives a very explicit account, supported by a few examples, of the photophysics and photochemistry of aromatic carbonyl compounds. Also clearly written is the chapter by *P. S. Mariano* on photochemical reactions of iminium ions. The reader interested in synthetic aspects will certainly profit from the application of such reactions to complex systems such as alkaloids and condensed heterocycles. *N. J. Pienta* gives a general survey of the photochemistry of amines, thiols and thioethers (with 300 references). The article includes informative comparisons with other chemical and electrochemical methods for generating reactive radical cations. Well arranged tables are provided which also cover biochemical, inorganic, organometallic and polymeric systems. The chapter by *W. R. Bowman* is devoted entirely to photoinduced nucleophilic substitutions at sp^3 carbon atoms. Numerous examples, arranged according to substrates, leaving groups, nucleophiles and mechanisms, give the reader an idea of the applicability of these reactions and their limitations. *X. Ci* and *D. G. Whitten* adopt a mechanistic viewpoint in discussing photoreductions using tertiary amines as donors, and photoinduced redox fragmentations of aminoalcohols. Part C ends with two chapters by *S. Fukuzumi* and *T. Tanaka* which deal in a clear, precise and comprehensive way with the (photoinduced) redox chemistry of biological systems, which are covered rather too scantily in the work as a whole; the examples described here are the 1,4-dihydropyridines NAD(P)H and the flavines. The reader is given an excellent and informative introduction to the redox properties of these compounds in the ground and excited states, followed by a detailed discussion of their PIET reactions. In making it easier to understand complicated photocatalytic cycles in systems analogous to that of photosynthesis, this article offers much more than a mere introductory survey.

Volume D begins with a concise summary by *M. A. Fox* of O_2 activation by PIET, which again is of biological importance. The following chapter by *H. R. Mäcke* and *A. F. Williams* on transition metal complexes of O_2 is unfortunately too brief and conventional in content. In somewhat greater detail *N. Serpone* describes PIET reactions of classical hexacoordinated complexes, in particular those containing polypyridyl ligands. PIET reactions occur, often unexpectedly, in weakly interacting systems such as ion pair complexes or "supramolecular" complexes; these highly topical reactions are described by *V. Balzini* and *F. Scandola*. This is followed by a short chapter in which *A. Vogler* describes the intramolecular electron transfer between weakly coupled redox centers, e.g. in multinuclear complexes. The chapter by *C. Giannotti, S. Gaspard* and *P. Krausz* on PIET in organometallic transition metal compounds is disappointing, not just because of the poor visual impression given by the typescript, but due to the fact that essentially all that it contains is a compilation of results on cyano complexes together with a few metallocenes and carbonyl complexes. Readers interested in this topic are better served by the recent monographs by *Kochi* or by *Hennig* and *Rehorek*.

The final chapter of Volume D contains articles on the actual and potential applications of PIET. On the basis of well documented examples, *R. Pichat* and *M. A. Fox* describe photochemical "catalysis" at semiconductor surfaces. Semiconductors are also at the center of the article by *M. Grätzel* on solar energy applications. Also related to this theme, *J. S. Connolly* and *J. R. Bolton* have put together a comprehensive "historical" account of the attempts at producing artificial photosynthesis, but it is not easy reading except for insiders. The following articles, on the importance of PIET in polymerization initiation reactions (*Y. Shirota*), in the processing and storage of information (*M. V. Alfimov* and *V. A. Sazhnikov*), in modern photoresist technology, (*F. Schue, L. Giral, C. Montiginoul* and *B. Serre*), and in phototoxicity, either involving or not involving O_2 (*N. Paillous* and *M. Comtat*), each give only a brief insight into areas of application where the PIET concept has already proved its usefulness.

At the end of Volume D, in addition to a large subject index, there is a very long and comprehensive author index (137 pp.) for the collected literature citations in all the articles. It would have been equally useful to have included, along with these pages reminiscent of the Science Citation Index, a list of the most important commonly used acronyms; the lack of such a list means that many of the articles make difficult reading if one is unprepared. With such a large number of authors and a field of a very interdisciplinary nature, it is probably unavoidable that some basic concepts, some frequently used experimental techniques and some particularly relevant chemical systems are described several times. In some respects this is an advantage from the reader's standpoint, since there are inevitably variations in the quality and comprehensiveness of the articles with such a heterogeneous team of authors. Nevertheless, we must notice that, despite the claim regarding comprehensive coverage, two important topics receive rather too little attention, namely PIET processes in organometallic chemistry and in biochemistry.

And now to what is undoubtedly a negative aspect of the work: the price of the four volumes! For a work in this price range the photographic reproduction of 47 typescripts in different formats, with the poor visual impression that this gives, is quite unacceptable. Consequently one can predict, regretfully, that although this is on the whole a very useful collection of articles on a subject of high topicality, the wide readership which is desirable will not be realized in practice.

Retroviruses and Oncogenes I (Nobel Lecture)**

By Harold E. Varmus*

Introduction

The story that *Mike Bishop*[***] and I will tell in these two lectures is one in which retroviruses, oncogenes, our personal histories, and the history of tumor virology are closely interwoven. It begins with some simple questions about the origin and behavior of viral genes and takes us to a vantage point from which we can survey many aspects of retroviruses and animal cells, including some of the aberrations that lead to cancer. We now know that retroviruses capture normal cellular genes and convert them into cancer-causing genes, called oncogenes; such transductions are rare, but depend upon the normal events of an intricate virus life cycle. Retroviruses have introduced us to more than forty cellular genes with the potential to become oncogenes, some discovered as components of viral genomes, others as genetic targets for viral insertion mutations. It has been our privilege to participate in a generous share of the experiments that established these principles. But we have required the help of many talented people in our laboratories at the University of California, San Francisco (UCSF), as well as the collaboration and friendly competition of others elsewhere. (I mention as many names as the narrative can bear, but inevitably I must apologize to valued colleagues who remain anonymous here.) Several viruses also figure in our tale, but Rous sarcoma virus (RSV) again has the leading role, yet another of many tributes to the pioneering work of *Peyton Rous* and to the principle of delayed gratification in science. The product of his diligence in pursuing a single chicken tumor nearly eighty years ago,[1] *Rous*' virus remains the only retrovirus that could have satisfied the genetic and biochemical criteria for the work we accomplished in the era that preceded molecular cloning.

First Taste of Molecular Biology: Hybridizations with the *lac* Operon

My commitment to experimental science occurred, by today's standards, dangerously late in a prolonged adolescence. As an undergraduate at Amherst College, I was devoted to Dickensian novels and anti-Establishment journalism, while marginally fulfilling premedical requirements. I then indulged myself with a year of Anglo-Saxon and metaphysical poetry at Harvard graduate school, before beginning medical studies at Columbia University, with a primary interest in psychiatry. But my ambitions soon turned towards an academic career in internal medicine. So just after graduation in 1966, like many of my contemporaries, I applied for research training at the National Institutes of Health. Perhaps because his wife was a poet, *Ira Pastan* agreed to take me into his laboratory, despite my lack of scientific credentials.

At the time, *Ira* was studying the biochemical effects of thyroid stimulating hormone (TSH) on tissue slices, a subject close enough to clinical endocrinology not to be intimidating. But one day, while still an intern at Columbia-Presbyterian Hospital, I received a telephone call from *Ira*, telling me

that a lecture by *Earl Sutherland* had inspired him to begin work on the effects of cyclic AMP on regulation of the *lac* operon in *E. coli*. Late that night, alone in the house staff library, I peered for the first time into the *Journal of Molecular Biology*—it is no small tribute to Columbia that this journal was there—and attempted to read the seminal papers on the *lac* operon by *Jacob* and *Monod*.[2] I knew then that, one way or another, my life was about to change.

Science is largely the making of measurements, and I soon learned from *Ira* how much more important a new measurement could be than an old theory. He and *Bob Perlman* had just discovered that cyclic AMP reversed catabolite repression of the *lac* operon.[3] They suggested that I use the relatively new technique of molecular hybridization to ask whether regulation by cyclic AMP occurs at the transcriptional level. Apart from the pleasures of just getting results (as *Gunther Stent* has said, results are wonderful because they give us something to talk about[4]), these measurements had enormous intellectual appeal, because they very simply resolved the ambiguity of hypothesis, demonstrating unequivocal changes in synthesis of *lac* messenger RNA.[5] Furthermore, they were carried out with technical subtleties that ultimately shaped the way I later thought about the problems of detecting single genes in more complex, eukaryotic cells. We annealed radiolabeled *E. coli* RNA to filter-bound DNA from a pair of bacteriophages that differed only by the presence or absence of the *lac* operon; and we minimized irrelevant hybridization by including, as competitor, unlabeled RNA from an *E. coli* mutant from which the *lac* operon was deleted. An aesthetic merger of genetics with molecular biology, itself as pleasing as the results!

Introduction to the Provirus and the Virogene–Oncogene Hypotheses

A major feature of life at the NIH in the late 1960s was the extraordinary offering of evening courses for physicians attempting to become scientists as they neared thirty. Two classes had direct and specific effects on my subsequent work because they introduced me to important problems I believed approachable with the methods I had acquired in my brief apprenticeship.

Like many of my peers, I was excited by the prospect of applying reductionist methods to eukaryotic organisms, particularly in a way that might be informative about human disease. From some dilatory reading in the early 1960s, I knew enough about viruses and their association with tumors in animals to understand that they might provide a relatively simple entry into a problem as complex as cancer. In fact, for anyone interested in the genetic basis of cancer, viruses seemed to be the only game in town. What surprised and beckoned me were two rather simple but heretical hypotheses that described curious ways the genes of RNA tumor viruses might mingle with the chromosomes of host cells.

The more daring of these two hypotheses was the provirus hypothesis, first enunciated by *Howard Temin*.[6] (*John Bader*, one of our NIH lecturers, was among the few others to espouse it in public.[7]) The provirus hypothesis stated that the genes of RNA tumor viruses were copied into DNA, which became stably associated with the host cell; the proviral DNA then provided the information for production of new virus particles. With its existence supported principally—some said feebly—by studies with inhibitors of DNA and RNA synthesis, and its plausibility doubted in the absence of any precedent for information transfer from RNA to DNA, the provirus seemed to be a provocative target for a definitive decision with molecular hybridization.

The other hypothesis, the virogene–oncogene hypothesis, was more complex.[8] *George Todaro* and *Robert Huebner* proposed that normal cells must contain genes related to those found in RNA tumor viruses, since viral proteins could often be found in cells of apparently uninfected animals, especially chickens and mice. Such genes, known as virogenes, were believed to be transmitted vertically as components of chromosomes, expressed in response to a variety of agents, and acquired by infection of germ cells at some time in the past. Since some RNA tumor viruses were known to be highly oncogenic, it was also proposed that tumor-inducing genes of such viruses (viral oncogenes) might also be transmitted through the germ line as a consequence of ancient infection. Activation of these endogenous viral oncogenes by substances we recognize as carcinogens—chemicals, radiation, other viruses—could serve to initiate a neoplastic process.

Transition to RNA Tumor Virology in Revolutionary Times

During the summer of 1969, I combined a backpacking vacation in California with a search for a suitable place to study tumor viruses. Acting on a tip from *Harry Rubin* in Berkeley, I sought out a small group, composed of *Mike Bishop, Leon Levintow*, and *Warren Levinson*, that was beginning to work with Rous sarcoma virus at the University of California, San Francisco. (*Rubin*, it should be said, was more eager for me to meet *Peter Duesberg*, but *Duesberg* was out of town.) A brief conversation with *Mike* was sufficient to convince me of our intellectual compatibility (happily, one of the few convictions to have survived twenty years in this field), and I made plans to join the UCSF group as a postdoctoral fellow the following summer.

Before the intervening year had passed, however, two major discoveries changed the landscape of tumor virology. *Satoshi Mizutani* and *Temin*[9] and *David Baltimore*[10] found the predicted enzyme, reverse transcriptase, in virus particles, thereby erasing most of the skepticism about the provirus hypothesis by providing a means to synthesize the heretical DNA copy of an RNA genome. And *Steve Martin* isolated a crucial mutant of Rous sarcoma virus,[11] one that lost its ability to transform cells at elevated temperature and regained it when the temperature was reduced. *Martin*'s mutant offered the first clear definition of the gene we later called *src*, and it showed that the gene—and, by implication, a protein the gene encoded—was required to instigate and sustain the transformed state. Since the mutant virus grew normally at the temperature that blocked transformation, oncogenic and replicative functions could be dissociated, a facet of the story that will soon resurface.

First Forays with RSV: Seeking Proviral DNA

Reverse transcriptase was properly greeted as strong evidence for the provirus hypothesis, and defused the urgency of challenging it. Yet it still seemed important to detect the provirus directly, most obviously by molecular hybridization, and to follow the pathway of its synthesis, especially in infected cells, not just in vitro. Reverse transcriptase obligingly offered a means to simplify the job, through the synthesis of potentially powerful probes, radioactive virus-specific DNA copied from a template of viral RNA.

Some of my initial efforts to proceed with these problems look, in retrospect, frustrating, if not quixotic—though the results were published in prominent journals. We chose at first to use double-stranded products of the RSV reverse transcriptase as hybridization probes, in order to measure gene copies through the accelerating effects of cellular DNA on reassociation kinetics.[12] However, the RNA template was unevenly copied by reverse transcriptase in vitro,[13] so that the products had complicated reannealing kinetics and did not uniformly represent the viral genome (whose genetic composition was in any case still unknown). When I attempted to measure RSV-related DNA in the most obvious settings—uninfected and RSV-infected chicken cells—I found multiple copies of virus-related DNA in the normal cells, in apparent confirmation of at least some aspects of the virogene–oncogene hypothesis.[14] But I was unable to detect the anticipated increment of RSV DNA in infected chicken cells, until I switched to the use of single-stranded DNA as probes.[15] But by then *Paul Neiman* had already measured the increment by hybridization with radiolabeled RNA from virions.[16] And, in the meantime, *Hill* and *Hillova* had provided more dramatic support for the provirus hypothesis in an entirely different way, by DNA transfection: addition of DNA from RSV-infected cells to new cells allowed the recovery of the original virus.[17] So the entire viral genome must have been present in the DNA of infected cells.

Our approach to the provirus was eased when I abandoned chicken cells, the traditional hosts for RSV in culture, in favor of cells from other birds—ducks and quail—and from mammals.[18] Because we could detect little virus-related DNA in these cells prior to infection, it was relatively simple to measure new copies of RSV DNA following infection, to follow the time course of DNA synthesis, to show that reverse transcription occurred in the cytoplasm, and to define linear, circular, and integrated forms of viral DNA.[19]

Making a Probe to Test the Virogene–Oncogene Hypothesis

The varied abilities of normal avian DNAs to anneal to RSV-derived probes helped to focus our attention upon the sorts of virus-related sequences we could detect in chicken DNA. Did these sequences constitute genes for viral structural proteins? More importantly, did they include the viral transforming gene, as predicted by the oncogene–virogene hypothesis? To approach these questions, it was imperative to have more rigorously defined probes. This was not a trivial challenge in the early 1970s, before restriction mapping and molecular cloning were available to us.

But one potent reagent was available. In 1971, *Peter Vogt* reported the isolation of transformation-defective, replication-competent mutants of RSV.[20] The genomic RNA subunits of these "td" mutants were shown by *Duesberg* and his colleagues to be about 15 percent shorter than the subunits of wild-type virus.[21] The provisional interpretation was that the missing sequences (initially called "x" and later

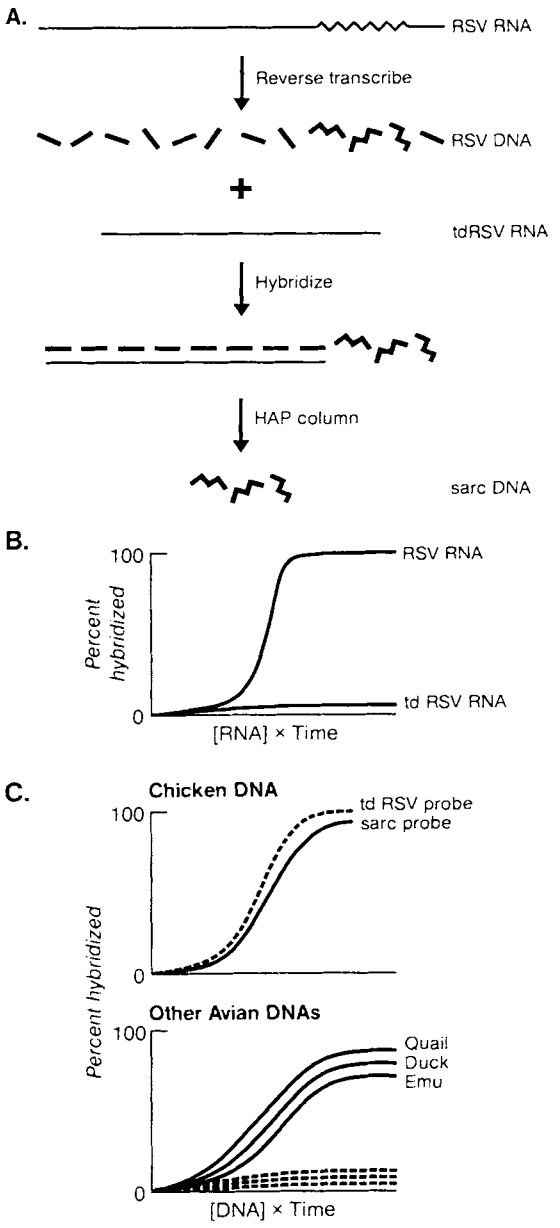

Fig. 1. Schematic summary of initial experiments with the sarc probe (see [22, 23] for primary data and further details). Panel A: Radiolabeled sarc-specific DNA was prepared by subtractive hybridization of the products of reverse transcription of RSV RNA to RNA from a transformation-defective deletion mutant of RSV (td RSV). The basis for the strategy is described in the text. Thin lines represent RNA, thick lines represent DNA, jagged portions represent sarc sequences (i.e., those present in RSV but not in td-RSV genomes). HAP, hydroxyapatite. Panel B: sarc DNA is specific for sequences that differentiate RSV and td RSV. The probe was hybridized to RSV RNA and td-RSV RNA and results monitored by HAP chromatography. Panel C: sarc probe (solid curves) anneals to DNA from many species of birds, whereas probe for other components of the RSV genome (td-RSV probe, dashed curves) anneals poorly to DNA from species other than chicken. The extent of annealing (normalized values shown here) was determined by HAP chromatography.

"sarc") included some or all of the viral transforming gene (v-*src*) earlier defined by temperature-sensitive (ts) mutants. Like *Martin*'s ts mutants, the deletion mutants retained the functions required for replication, despite the extensive loss of sequence, so it was tempting to presume that the deletion was coextensive, or nearly coextensive, with the transforming gene.

Mike and I were intimately acquainted with these conjectures through a collaborative consortium of Californian laboratories, directed by *Vogt, Duesberg*, and us, which met every six weeks or so, in Los Angeles or the Bay Area. Through these discussions, we recognized that if we could prepare radioactive DNA specific for the sequences deleted in the td-RSV mutants, we would have a reagent that would approximate a specific probe for the transforming gene of RSV.

The strategy for doing this was straightforward in principle, but difficult in practice (Fig. 1A). In essence, single-stranded, radiolabeled DNA fragments were synthesized from a template of wild-type RSV RNA, then hybridized to td-RSV RNA to remove unwanted components by hydroxyapatite chromatography, leaving the sarc-specific DNA. *Ramareddy Guntaka* first put this protocol into motion with some encouraging results. But it was ultimately the ministrations of *Dominique Stehelin* that produced a sarc probe that met rigorous standards: nearly complete annealing to RSV RNA, no significant annealing to td-RSV RNA (Fig. 1B), and representation of over 10 percent of the RSV genome, most of the sarc region, in the probe.[22]

Sarc Probe Detects Conserved Sequences in Avian DNA

When *Stehelin* incubated the sarc probe with normal chicken DNA, it annealed extensively (as, of course, did probe made from td-RSV RNA) (Fig. 1C). The results, unambiguously exciting, were still fully consistent with the original oncogene–virogene hypothesis. So we were yet more excited when the next results seemed to violate it: although the "virogene" probe from td-RSV annealed poorly to DNAs from several other avian species, the sarc probe annealed extensively, even to DNA from the Australian emu—a ratite (we learned, from our Berkeley colleague, *Allan Wilson*) at a great evolutionary distance from chickens.[23] The extent and fidelity of the hybrids formed with the sarc probe indicated that its homologues in normal cells had diverged during avian evolution at a rate similar to that of cellular genes used in the few earlier forays into molecular evolution, suggesting that the sequences had been conserved for at least 100 million years.

From these findings, we drew conclusions that seem even bolder in retrospect, knowing they are correct, than they did at the time.[23] We said that the RSV transforming gene is indeed represented in normal cellular DNA, but not in the form proposed by the virogene–oncogene hypothesis. Instead, we argued, the cellular homologue is a normal cellular gene, which was introduced into a retroviral genome in slightly altered form during the genesis of RSV. Far from being a noxious element lying in wait for a carcinogenic signal, the progenitor of the viral oncogene appeared to have a function valued by organisms, as implied by its conservation during evolution. Since the viral *src* gene allows RSV to induce tumors, we speculated that its cellular homologue normally influenced those processes gone awry in tumorigenesis, control of cell growth or development.

Firming Up the Result: Sarc Represents the c-*src* Proto-oncogene

Despite the broad claims, the first round of experiments with the sarc probe left many worrisome questions unanswered.

The most pressing question, and one foremost in the minds of our critics, seems now both essential and mundane: Was the sarc probe actually detecting a functional, protein-encoding homologue of the viral transforming gene (v-*src*)? Or were the still ill-defined genetic and physical maps of the RSV genome leading us astray? Some support came from geneticists who mapped a large number of the existing transformation mutations of RSV within the region of the viral genome lost during formation of td-RSV deletion mutants.[24] More exciting and stronger support came from protein biochemists: *Joan Brugge* and *Ray Erikson* discovered that the long-sought product of v-*src* was a protein of about 60 000 daltons,[25] one that would require about 1600 nucleotides of coding sequence and could account for most of what was missing from td-RSV. *Hermann Oppermann* and others[26] then detected a protein in normal cells that seemed virtually indistinguishable from v-*src* protein, confirming the idea that the sarc probe was measuring a gene (now called c-*src*) that resembled v-*src*. Ultimately, the molecular cloning and nucleotide sequencing of the RSV genome revealed how fortunate we had been in the design of our probe:[27] most td-RSV mutants lack all of v-*src* and little else.

The second question was more subtle: Did the conservation of c-*src* during avian speciation accurately imply that it was a cellular gene? Or might it still represent an inherited viral gene more conserved than other viral elements? Answers came from several quarters, all confirming the arguments based on evolution. Using chicken chromosomes fractioned according to size by *Elton Stubblefield* in Texas, we found that c-*src* and virogenes are unlinked; the viral genes we could detect were on one or more large chromosomes, but c-*src* was on a small chromosome.[28] *Steve Hughes* then used restriction enzymes to gauge the diversity of sequences in and around viral genes and c-*src* in many individual chickens;[29] the pattern generated with the sarc probe was monotonous, as would be expected for a conserved cellular gene (and shown to be the case for genes such as globin, ovalbumin, and others). The pattern produced with a probe for viral structural genes, however, suggested variety in number and context, as though they had been introduced into the chicken genome by recent, independent germ-line infections. When we examined the transcripts emanating from c-*src* and from virus-related genes, individual chicken embryos contained various amounts and types of viral RNAs but similar quantities of a single, differently sized species of c-*src* RNA.[30]

The most powerful evidence for the cellular nature of c-*src* required molecular cloning. For then it was possible to show that the coding sequences of c-*src* were interrupted in many places by introns,[31] in the manner recently discovered to be characteristic of cellular genes. In contrast, as described in greater detail below, endogenous virogenes have the insignia of proviruses, being composed of continuous coding domains, flanked by repeated sequences.

The third question was most informative about the mechanism by which v-*src* causes cancer: What accounted for the proposed physiological differences between a beneficial proto-oncogene and a pathogenic viral oncogene derived from it? From the first measurements of *src* gene expression, it was apparent that the viral gene, controlled by a potent viral transcriptional promoter, was expressed much more vigorously than its cellular counterpart.[32] But the levels of v-*src* protein required for transformation proved to be lower than nononcogenic amounts of c-*src* protein,[33] implying qualitative differences as well. *Mark Collett* in *Erikson*'s laboratory[34] and *Art Levinson* in ours[35] had discovered that *src* proteins are protein kinases, which *Tony Hunter* and *Bart Sefton* later showed to be specific for tyrosine residues.[36] *Hidesaburo Hanafusa*'s laboratory then defined the subtle structural and physiological differences between the viral and cellular versions of the gene:[37] at least three of several amino acid differences between $p60^{v\text{-}src}$ and $p60^{c\text{-}src}$ enhance the protein-tyrosine kinase activity of the transforming protein. Thus, quantitative and qualitative factors conspire to produce the *src* oncogene.

Finally, how well conserved is the cellular *src* gene? Early on, *Deborah Spector* showed that, under conditions of reduced stringency, most or all of the sarc probe could anneal to the genomes of all vertebrates, not just birds.[38] Since the implicated mammals included man, these findings helped to create a larger audience for our work, and they raised the possibility that retroviral proto-oncogenes might have a role in human cancer. New technologies ultimately extended the list of organisms that carry c-*src* to include virtually all metazoans—insects,[39] worms,[40] sponges,[41] and hydras[42]—reminders of our evolutionary origins that are at once exhilarating and sobering.

The *src* story remains unfinished. We cannot tell you how c-*src* benefits normal organisms or cells, although recent work implicates c-*src* both in development, especially in the central nervous system,[43] and in growth control during mitosis.[44] We do not know the physiological targets for the *src* kinase, although numerous phosphotyrosine-containing proteins have been identified.[45] And we do not know how the enzymatic activity of p60 is regulated, although phosphorylation is important.[46] Nevertheless, the *src* paradigm has stimulated our field to move in several directions: to identify many new viral oncogenes and their cellular progenitors,[47] to characterize a stunning variety of oncogenic proteins,[48] to make unexpected connections with elements of growth regulatory networks,[49] and to describe mutant proto-oncogenes in human tumors.[50] These developments are recounted in the accompanying lecture by *Mike Bishop*. It is my mission to stay with the virus—and especially the provirus.

Deciphering Proviral Structure

By the early 1970s the provirus was a well-accepted idea, but the organization of viral DNA and its position within chromosomes were still matters of conjecture. Several peculiarities of viral RNA and the viral life cycle hinted that proviral DNA must have special attributes.[19] First, the priming site for the first strand of viral DNA was near the 5′ rather than at the 3′ end of viral RNA,[51] implying that synthesis must be a complex process and that the provirus must not be a simple copy of viral RNA. Next, a short sequence (R) was found at both ends of viral RNA, and hence present in two copies, but appeared to be copied only once during synthesis of viral DNA;[52] how was the second copy of R regenerated? Finally, it was difficult to account for the efficient synthesis of viral RNA without the prospect of a strong transcriptional promoter upstream of the start site; how was that promoter provided?

These problems were solved by the unexpectedly elegant configuration of viral DNA, as worked out mainly by *Peter Shank, Steve Hughes*, and *Hsing-Jien Kung* in our group[53] and independently by *John Taylor*'s laboratory in Philadelphia.[54] Once again, RSV was the instrument of discovery, and again the results depended upon hybridization with specific probes, this time for terminal regions of the viral genome. In essence, viral genes were found to be flanked in the provirus by long terminal repeats (LTRs) derived from sequences present at both ends of viral RNA (Fig. 2). (The

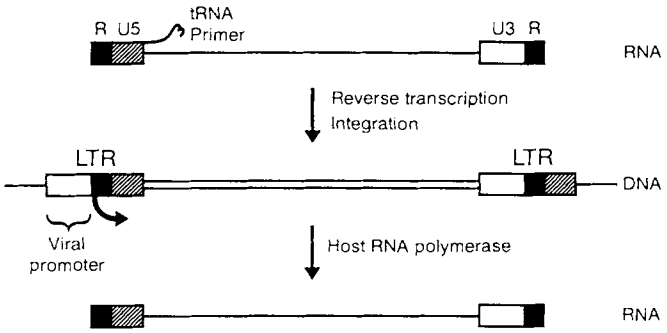

Fig. 2. The organization of proviral DNA in comparison to retroviral RNA. The top line shows one subunit of a viral dimeric genome, with host tRNA positioned near the 5′ end where it serves to prime synthesis of the first strand of viral DNA. R, short sequence present at both ends of viral RNA; U5 and U3 are sequences unique to the 5′ and 3′ regions of the RNA that are duplicated during DNA synthesis to form the long terminal repeats (LTRs). The middle line shows a provirus integrated into host-cell DNA (single line). The viral coding sequences reside between the LTRs (double line). The region encompassing the viral promoter in U3 of the upstream LTR is bracketed; the curved arrow denotes the start site and direction of transcription of the provirus by host RNA polymerase. The bottom line shows the composition of the primary viral transcript after 3′ processing; the poly(A) tract at the 3′ end is not illustrated.

ends of the LTRs correspond to the priming sites for the two DNA strands and thereby helped unravel a strategy of DNA synthesis too convoluted to review here.[19]) Because the R sequence is present once in each LTR, it can be reconstituted by transcribing parts of both LTRs. And viral sequences that contain strong transcriptional signals reside upstream of the RNA start site. Mapping of integration sites showed that many regions of the host genome could accommodate a pro-

virus; thus, transcriptional self-sufficiency of the provirus allowed it to function in varied chromosomal contexts.

Proviruses as Mobile Elements that Cause Insertion Mutations

But the structure of the provirus did more than solve some perplexities of the retrovirus life cycle. In general form and even in selected short sequences, proviruses resemble an abundant type of mobile DNA element, described by now in plants, bacteria, yeast, insects, and many other organisms (Fig. 3),[55] another arresting example of conservation throughout evolution. Their connection with retroviruses has been strengthened in recent years by discoveries that several such elements are duplicated and relocated by using reverse transcriptases to make new DNA copies from RNA transcripts,[56] although they never produce extracellular viruses. These properties also apply to endogenous proviruses, cloned from the germ lines of many vertebrates,[57] reemphasizing the profound differences between inherited virogenes and cellular proto-oncogenes.

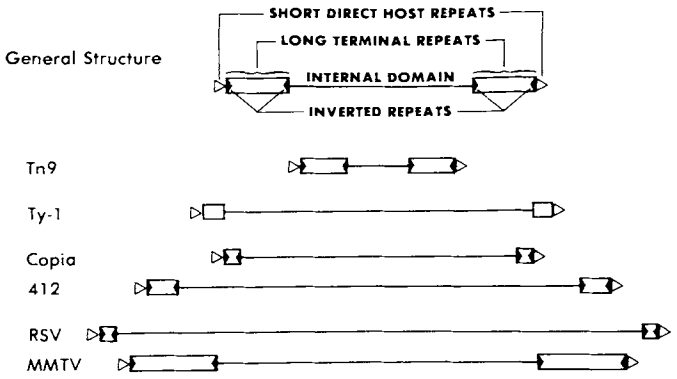

Fig. 3. Many mobile DNAs are organized like proviruses. The figure demonstrates some common features of many transposable elements, including LTRs (rectangular boxes), inverted repeats within the LTRs (closed triangles), and short duplications in host DNA generated during insertion (open triangles). The illustrated mobile elements include retroviral proviruses (RSV and mouse mammary tumor virus (MMTV)), retrotransposons of *Drosophila* (copia and 412) and budding yeast (Ty1), and a conventional transposon of *E. coli* (Tn9). (Taken from [55]).

One practical consequence of the startling similarities between retroviral proviruses and mobile elements was to consider the possibility that proviruses, like mobile DNA, might cause insertion mutations. In 1978, while on sabbatical in *Mike Fried*'s laboratory at the Imperial Cancer Research Fund, I designed an experiment to test this idea. *John Wyke* provided me with a rat cell line transformed by a single RSV provirus, which could serve as a target for insertion mutation by proviruses introduced by superinfection with mouse leukemia virus (MLV). By sifting through many clones of cells that had lost their transformed properties after infection with MLV, *Suzanne Ortiz* and I found two that contained an MLV provirus inserted at different sites within the pre-existing RSV provirus, interfering with the expression of v-*src*.[58]

This experiment established the principle that retroviruses could serve as insertional mutagens to inactivate genes. It also had the heuristic benefit of stimulating us to think about insertion mutations that acted in a dominant fashion by activating gene expression. *Greg Payne* was then attempting to explain how avian leukosis virus (ALV), a virus virtually indistinguishable from td-RSV and lacking any evidence of a viral oncogene, could nevertheless induce tumors (most commonly B-cell lymphomas) within several weeks after infection of susceptible chickens.[59] Might ALV proviruses occasionally integrate adjacent to a cellular proto-oncogene and augment expression through a viral LTR? *Greg*'s evidence for this idea,[60] however provocative, was nearly drowned out by the commotion caused by *Hayward, Neel,* and *Astrin*'s discovery[61] that ALV DNA in B-cell lymphomas was adjacent to c-*myc*—a known progenitor of a retroviral oncogene[62]—and that the viral LTR was driving c-*myc* expression.

ALV-induced tumors taught us several new principles: Retroviruses can induce neoplasia by insertionally activating proto-oncogenes;[63] proviruses and their target genes can be variously arranged with similar effects on transcription;[64] and proto-oncogenes need not be transduced to participate in oncogenesis. The last was an especially important point that presaged the later outpouring of mutant proto-oncogenes in human tumors unassociated with any virus.[50]

Using Proviruses as Transposon Tags for Novel Proto-oncogenes: The *int*-1 Story

However important, ALV has failed to introduce us to any proto-oncogenes not already known as forefathers of retroviral oncogenes. For this, we made use of another retrovirus without a viral oncogene, the mouse mammary tumor virus (MMTV). Like RSV, MMTV has a venerable history.[65] Found in the milk of inbred mice with a high incidence of mammary cancer over fifty years ago in Holland[66] and at the Jackson Laboratories in Maine,[67] MMTV was the first mammalian retrovirus to be discovered; it remains the only efficient viral agent of mammary carcinoma and thus a model for one of the most common of human cancers.

MMTV-induced mammary tumors are quasi-clonal growths of virus infected cells.[68] To ask whether the tumor cells result from insertion of viral DNA near a heretofore unknown proto-oncogene, *Roel Nusse* examined many tumors to find one with only a single new provirus; he then cloned that provirus and its flanking cellular DNA in *E. coli*. An unfamiliar gene, which we called *int*-1, was nearby, and it was expressed in that tumor and several others with nearby insertions, but not in normal mammary glands.[69]

But this was not sufficient to implicate *int*-1 as an oncogene. First, there was the circumstantial force of repetition: over three-quarters of mammary tumors in the C3H mouse strain harbor insertion mutations in the *int*-1 locus. Then, *Tony Brown* did what nature had not done, by placing the *int*-1 gene within a retroviral genome; the resulting virus alters the growth and morphology of cultured mammary cells.[70] Finally, *Ann Tsukamoto* followed a strategy pioneered by *Ralph Brinster* and *Richard Palmiter* and by *Philip*

Leder[71] and introduced the *int*-1 gene, linked to an MMTV LTR, into the mouse germ line.[72] All the transgenic mice, male or female, experience dramatic hyperplasia of the mammary epithelium, and most of the females develop mammary carcinoma within six months. This is about as close as we can come to fulfilling *Koch*'s postulates for a genetic disease: by placing the virally mutated form of the gene into the germ line--ironically, much as envisioned to occur naturally in the virogene–oncogene hypothesis—we have recreated the disease.

I cannot leave our transgenic mice without making a more general point. In California and many other places, misguided efforts to abolish the use of laboratory animals seriously threaten medical science. If *Peyton Rous* had been denied his chickens, our field would have no past; if all of us are now denied mice and other animals, it will have little future.

A Tentative Scheme for Transduction of Proto-oncogenes

The *int*-1 gene is but the first entry on a now substantial list of proto-oncogenes discovered as loci repeatedly activated by proviruses in tumors.[63] Thus, retroviruses usher in the genetic cast in the drama of cancer in two ways: by transduction and insertion mutation. Not surprisingly, the two phenomena appear to be mechanistically related: insertion mutation is probably the first step in the sequence of events that occasionally spawns a viral oncogene as its end product. What we can predict, but not yet fully substantiate by direct observation, is that two recombination events are required for transduction (Fig. 4).[73] The first occurs during proviral integration, placing viral DNA upstream from the activated cellular gene that will be acquired. The second occurs during virus replication in the tumor that results from the insertion mutation; the second step joins viral sequences to cellular sequences derived from the downstream region of the gene. We suppose that more or less in this fashion a close relative of ALV acquired a slightly mutated version of a chicken's *src* gene nearly a century ago, and set us on a path we are still traveling.

The Prospects for Retrovirology

The story thus far confirms *David Baltimore*'s statement of thanksgiving:[74] "A virologist is among the luckiest of biologists because he can see into his chosen pet down to the details of all its molecules." Because retroviruses, our chosen pets, are such remarkable agents, it has been enough to train our sights on two brief questions—how do retroviruses grow? and how do retroviruses cause cancer?—to have extended our concerns outward to the cellular host, as well as to have focused them inward upon the viruses themselves.[75] As a result, we have entered into some of the liveliest arenas in modern biology: the genetic basis of cancer, the transposition of DNA through RNA intermediates, the control of gene expression in eukaryotes, and the molecular evidence for evolution.

At this point, the study of oncogenes and proto-oncogenes

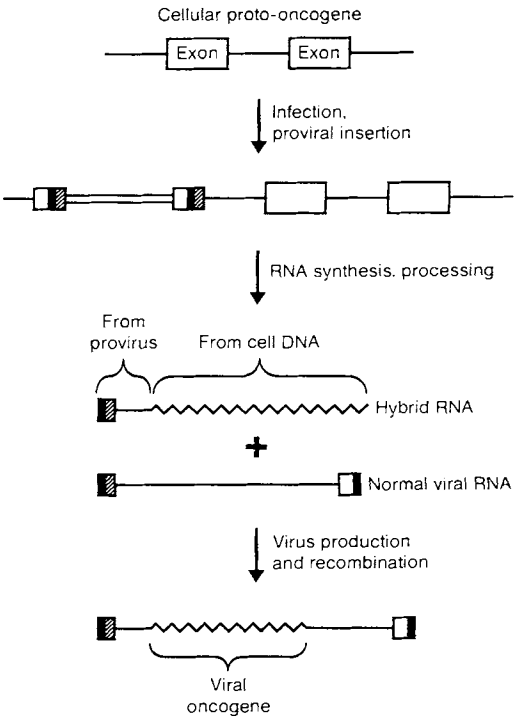

Fig. 4. Model for transduction of cellular proto-oncogenes to form retroviral oncogenes. Exons of a proto-oncogene are located downstream of a retroviral provirus recently introduced by infection and denoted as in Fig. 2. Virus-host chimeric RNA, a product of the proviral insertion mutation, recombines with normal viral RNA during virus replication to join viral sequences downstream of the cellular sequences. For further details, see [73].

has attained a degree of maturity that allows it to be conducted with astonishing little virology. Yet retroviruses remain vital tools for the isolation of important new oncogenes; witness in the past few years the discoveries of the *jun* and *crk* genes.[76] Likewise, since the discovery of reverse transcriptase nearly two decades ago, seemingly exhaustive attention has been given to the life cycle of retroviruses,[19] yet many central features are just now coming into view.[75] Cell surface receptors for viral attachment and entry have been recently identified and show a remarkable range of biochemical properties;[77] the proviral integration reaction has been recapitulated in vitro with nucleoprotein complexes,[78] allowing a description of integrative precursors and intermediates;[79] retroviruses have been recognized as pliable genetic vectors[80] that may one day be used clinically to correct gene deficiencies, in the manner used in nature to transport host-derived oncogenes; many unexpected aspects of viral gene expression have been discovered, including translational frame-shifting during the synthesis of reverse transcriptase[81] and complex viral regulatory genes that govern the behavior of two classes of human retroviruses;[82] and the principles of virus assembly are emerging through physical and genetic assaults on viral structural proteins and proteases.[83] These inherently fascinating problems have now taken on a special urgency, because we are all threatened by the worldwide dissemination of a lethal human retrovirus, the human immunodeficiency virus.[84] Thus, retroviruses continue to challenge our intellects in ways that may help us grapple with major diseases, cancer, and now AIDS, while also revealing fundamental features of the lives of our cells.

My indebtedness is large: to the many co-workers and colleagues mentioned here, and to many more unnamed, for communal labor, ideas, and criticism; to several institutions (especially the National Institutes of Health, the American Cancer Society, and the University of California, San Francisco) for nurturing my career with financial support and other resources; and to my family, for affectionate tolerance. My approach to science has been most profoundly influenced by Ira Pastan, who showed me that laboratory life was preferable to the clinic; by Peter Vogt, who taught me viral genetics when I needed it; and by Mike Bishop, who has been a generous and challenging colleague for nearly two decades. My gratitude would be incomplete if I did not especially mention the friendship and assistance of Suzanne Ortiz, Nancy Quintrell, Jean Jackson, Leon Levintow, Warren Levinson, and Don Ganem.

Retroviruses and Oncogenes II (Nobel Lecture)**

By J. Michael Bishop *

I am grateful to the family in whose embrace I formed my aspirations; the institutions modest and grand that helped me nurture those aspirations; the many colleagues with whom I have shared the pursuit of nature's secrets; the Nobel Foundation and the Karolinska Institute for glorious hospitality; and Swedish Medicine, which restored my larynx to some semblance of function.

The English critic *Cyril Connolly* once remarked that "The true index of a man's character is the health of his wife." My life in science has been rich and rewarding. I have sacrificed very little. But my partner in that life has sacrificed a great deal: *Kathryn*, my wife of thirty years. I take this moment to speak my gratitude for her forbearance, and to acknowledge that matters are not likely to improve.

If I were asked to choose a biographical theme for today, it would have to be procrastination, *Peyton Rous* withdrew from medical school for a year to spend time on a ranch in Texas, ostensibly to recover from tuberculosis.[1] Once back in medicine, he found himself "unfit to be a real doctor" (in his own words) and turned to pathology for an entry into research. *Harold Varmus* dallied with English literature before entering medical school, as you have heard.[2] And I came close to abandoning medicine entirely at an early age.

I entered Harvard Medical School knowing nothing of research. But during my first two years there, I was awakened to research by new-found friends among my classmates, particularly *John Menninger* (now at the University of Iowa) and *Howard Berg* (now at Harvard University). I sought summer work in a neurobiology laboratory at Harvard but was rebuffed because of my inexperience. My interest in practicing medicine declined. I becamed ambivalent about continuing in medical school, yet at a loss for an alternative.

Like *Peyton Rous*, I was rescued by pathologists. *Benjamin Castleman* offered me a year of independent study in his department at the Massachusetts General Hospital, and *Edgar Taft* of that department took me into his research laboratory. There was little hope that I could do any investigation of substance during that year, and I did not. But I was riotously free to read and think, which lead me to a new passion: molecular biology. I began my efforts to consummate that passion with two novitiates.

Novitiates

I served the first novitiate with *Elmer Pfefferkorn* and Sindbis virus. I had no credentials, other than my desire. Yet *Elmer* took me into his laboratory, and Harvard Medical School excused me from all but one of my fourth-year courses so that I could try research unencumbered. Both were enlightened acts, for which I remain grateful beyond measure.

I sought out *Elmer* and Sindbis virus because I had perceived that the inner sanctum of molecular biology was closed to me, that I would have to find an outer chamber in which to pursue my passion. Through *Elmer*, I found animal viruses, ripe for study with the tools of molecular biology, yet still accessible to the innocent.

I was innocent, but I was brash. I resolved to test the ability of the Sindbis RNA genome to serve as mRNA in vitro and to trace the fate of the genome following its entry into the host cell. These were novel ventures in their time (1961). They were also technically foolish. But they sired an abiding interest in how the genomes of RNA viruses commandeer the molecular machinery of the host cell, an interest that led me eventually to retroviruses.

My work with *Elmer* was sheer joy, teaching me the inebriation of research, the practice of rigor and the art of disappointment. But it produced nothing of substance. Twenty-five years later, on the occasion of my fiftieth birthday, *Elmer* recalled my first novitiate in science with a quote from *T. H. Huxley*: "There is great practical benefit in making a few failures early in life."

After two years of clinical training at the Massachusetts General Hospital, I began my second novitiate by entering the Research Associates Program at the National Institutes of Health in Bethesda, Maryland, where my mentor was *Leon Levintow*. My subject was the replication of poliovirus, which had become a test case for the view that the study of animal viruses could tease out the secrets of the vertebrate cell. In my first publishable research, I obtained evidence that the replication of polioviral RNA engendered a multistranded intermediate, although my description of that intermediate proved flawed in its details.[3]

Midway through my postdoctoral training, *Levintow* departed for the faculty at the University of California, San Francisco. In his stead came *Gebhard Koch*, who soon lured me to his home base in Hamburg, Germany, for a year. Together *Gebhard* and I explored the basis for the infectivity of multistranded RNAs.[4] I continued this work for several years to come, eventually showing that the double-stranded form of polioviral RNA is infectious because the positive strand of the duplex can be expressed in mammalian cells, as if the duplex RNA might be unraveling within the cell.[5] This finding perplexed us and seemed abstruse, but it appears to have been a harbinger of unanticipated enzymatic activities whose existence and functions are coming into view only now.[6]

Retroviruses

As my year in Germany drew to a close, I chose to join *Levintow* as a member of the faculty at the University of California, San Francisco. The decision proved providential

beyond all measure. In San Francisco, I found *Warren Levinson*, who had set up a program to study Rous sarcoma virus, an archetype for what we now call retroviruses. At the time, the replication of retroviruses was one of the great puzzles of animal virology. *Levinson, Levintow*, and I joined forces in the hope of solving that puzzle. We had hardly begun before *David Baltimore* and *Howard Temin* announced that they had solved the puzzle with the discovery of reverse transcriptase,[7, 8] work that brought them Nobel Prizes a scant five years later.

The discovery of reverse transcriptase was sobering: a momentous secret of nature, mine for the taking, had eluded me (and others, of course). But I was also exhilarated because the DNA synthesized by reverse transcriptase in vitro represented an exquisite probe for viral nucleic acids, a reagent that would give us unprecedented access to the life cycle of retroviruses. To paraphrase a memorable simile from *Arthur Kornberg*,[9] we now had a wedge with which to pry open the infected cell, and the hammer to drive that wedge would be molecular hybridization.

I had become enamored of molecular hybridization while working on poliovirus, because of the exceptional sensitivity and specificity the technique offered in the pursuit of viral nucleic acids. It was a tool made to order for the study of retroviral replication, which proceeds in concert with and is obscured by the normal metabolism of the host cell.

Improvising assays as we went, my colleagues and I soon had our first glimpse of viral RNA in cells infected with

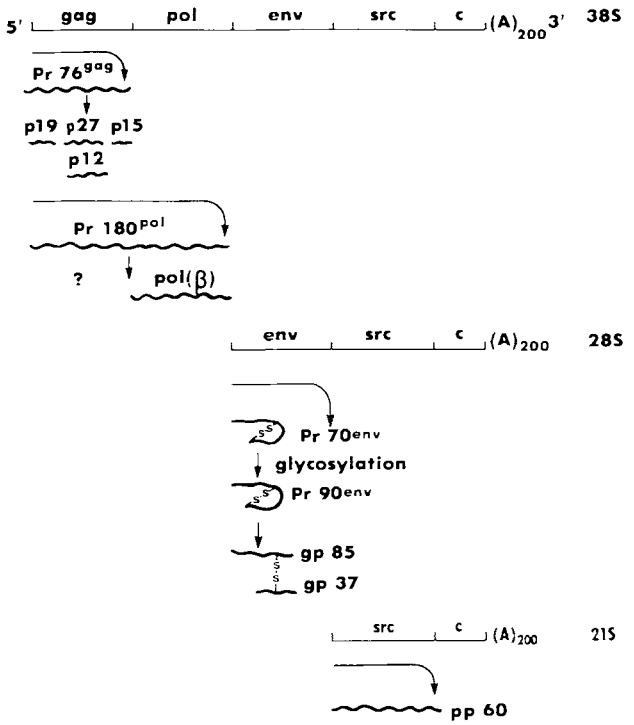

Fig. 1. Expression of the Rous sarcoma virus genes. The diagram was prepared in 1980 to portray how splicing and the processing of proteins facilitate expression of the Rous sarcoma virus genome. In the interim, we have learned that frame-shifting during translation is also required to produce the *gag-pol* polyprotein [13]. Individual genes are designated by conventional nomenclature, according to the proteins they encode: *gag*, structural proteins of the capsid and nucleocapsid; *pol*, reverse transcriptase; *env*, the glycoproteins of the viral envelope; and *src*, the oncogene of the virus. Other viral functions not illustrated include the protease that mediates maturation of several viral proteins and integrase, the enzyme that catalyzes integration of viral DNA.

retroviruses.[10] We were to pursue the character and genesis of those RNAs for years to come, laying out the manner of viral gene expression in considerable detail (Fig. 1). The work helped uncover an early example of RNA splicing[11, 12] and set the stage for the much later discovery of frame-shifting in the translation of retroviral mRNAs.[13] But our exercises with viral RNA had a larger resonance, as well, because we had constructed the technical stage on which the discovery of retroviral transduction would eventually play out.

I also picked up the study of reverse transcriptase itself, perhaps to exorcise my sense of failure at not discovering the enzyme in the first place. We began by working in vitro to explore the details of DNA synthesis by the enzyme.[14] The most notable outcome was the demonstration that the reverse transcriptase of Rous sarcoma virus uses the cellular tRNA for tryptophan as a primer to initiate transcription from the retroviral genome (Fig. 2).[14, 15] The point was soon generalized to other retroviruses and is now a feature that serves as a signature of retrotransposons at large.[16]

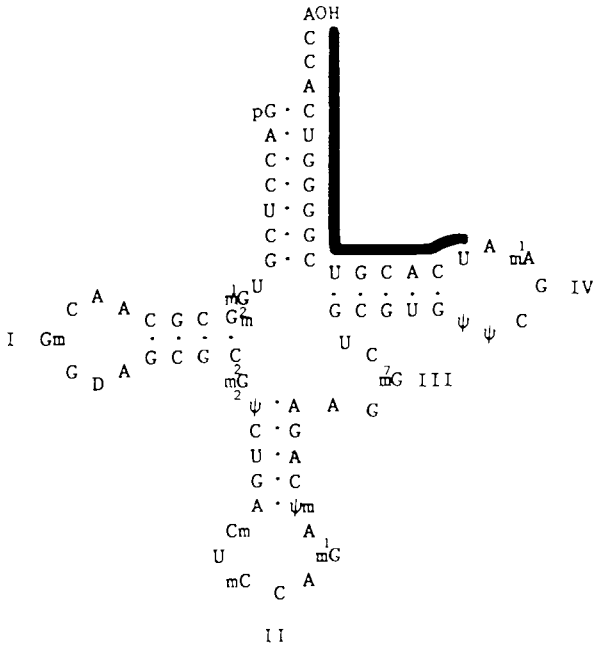

Fig. 2. The tRNA primer for reverse transcription in Rous sarcoma virus. The avian tRNA for tryptophan serves as primer for reverse transcription from the genome of Rous sarcoma virus. The RNA is displayed here in a conventional representation of secondary structure. The first sixteen nucleotides at the 3′ end of the tRNA are paired with the genome by hydrogen-bonded complementarity, as highlighted here.

But what I wanted most to know was the course of events in the infected cell. Could we find the proviral DNA first imagined by *Howard Temin* and then foretold in substance by the discovery of reverse transcriptase? Where in the cell was this DNA synthesized following infection? What form did it take before and after integration into chromosomal DNA? *Harold Varmus* arrived to provide the answers[2] and to alter my life and career irrevocably. Within the year, his name became consubstantial with expertise on the synthesis and integration of retroviral DNA. In the process, I had lost a postdoctoral fellow and gained a coequal.

Oncogenes

To this point, we had thought little of cancer. But as the virus of *Peyton Rous* first lured me away from poliovirus, now it lured us to the study of neoplastic transformation. *Peyton Rous* received his Nobel Prize two years before my initial encounter with his virus. The award dramatized the great mystery of how Rous sarcoma virus might cause cancer. It was a mystery whose solution lay in genetics.

Soon after arrival in San Francisco, a graduate student and I had conducted a search for temperature-sensitive conditional mutants of poliovirus and Rous sarcoma virus, without a particle of success. But where we had failed, others succeeded, and the study of viral tumorigenesis was transformed.[17-19] The data showed with luminous clarity that a gene within Rous sarcoma virus is responsible for cancerous growth of infected cells, that continuous action of the gene is required to sustain cancerous growth, and that the gene probably works by directing the synthesis of a protein. The oncogene *src* had been sighted.

The genetic identification of *src* was reported in the same year as the biochemical discovery of reverse transcriptase. The two became themes that intertwined and nourished one another in the daily life of our laboratory. Much as our deployment of molecular hybridization in the study of viral replication set the stage for the discovery of cellular *src*, so our ensuing success in isolating viral proteins from infected cells[20] emboldened us to seek the protein encoded by *src*.

We were in the midst of efforts to prepare antisera that would recognize the *src* protein when news of success came from Denver.[21] *Erikson* and his colleagues had obtained persuasive evidence that the oncogene encodes a 60-kilodalton protein. Once the product of *src* was a physical reality, the puzzle of its action loomed larger than ever. How could this single protein elicit the pleiotropic change in cellular phenotype that we call neoplastic transformation?

The answer came quickly. The *src* gene encodes a protein kinase,[22,23] whose amino acid substrate later proved unexpectedly to be tyrosine.[24] By phosphorylating numerous cellular proteins, the enzyme could rapidly change myriad aspects of cellular structure and function; by being the first exemplar of protein-tyrosine kinases, it gave notice of a previously unappreciated regulatory device that we now realize is second to none in the signaling pathways of the cell.[25]

The ways in which these answers emerged are illuminating. In Denver, insight came from an inspired guess, based on the pleiotropism of *src*:[22] protein phosphorylation ranks among the most versatile agents of change known to biochemists. In our laboratory, enzymological reasoning led the way:[23] Phosphorylation of the *src* protein in cellular extracts displayed properties suggestive of a unimolecular reaction, as if the protein were phosphorylating itself—which indeed it was.[26] And at the Salk Institute, the use of an erroneous buffer led to the fortuitous separation of phosphotyrosine from phosphothreonine for the first time in recorded history, the only example of productive laziness that I have ever seen acknowledged with both candor and gratitude in the biomedical literature.[25]

The sighting and subsequent characterization of *src* opened the way to a biological cornucopia. We now know of more than twenty retroviral oncogenes, whose diverse specificities in tumorigenesis provide experimental models for most forms of cancer that afflict human kind (Table 1). Each of these genes encodes a protein whose biochemical action provides distinctive purchase on the mechanisms of neoplastic growth.[27,28]

The products of oncogenes are deployed to various reaches of the cell, including the nucleus, the cytoplasm, the plasma membrane, even the exterior beyond the cell.[27,28] And they act in different ways, which for the moment are subsumed by three genre: (1) the phosphorylation of proteins, with either serine and threonine, or tyrosine as substrates—the immediate role of the oncogene product may be induction of the phosphorylation (as in the case of growth factors) or catalysis itself (as with the receptors for growth factors);[25] (2) the transmission of signals by GTP-binding proteins, as exemplified by the products of *ras* genes—whose exact position in signaling pathways remains unresolved;[29] (3) the control of transcription from DNA.[30]

Diversification of this list in the future seems likely, since the functions of many oncogenes have yet to be elucidated. But the list displays an economy of style that may survive because it reflects the need for pleiotropism: nature may have only a limited number of ways to achieve the manifold changes that create the neoplastic phenotype.

Retroviral Transduction

At first it seemed that the lessons to be learned from retroviral oncogenes might apply only to the cancers induced by viruses in animals, that the oncogenes of retroviruses might be alley cats of evolution with little importance to human kind. The discovery of cellular *src* and the inference that it gave rise to the oncogene of Rous sarcoma virus inspired hope that this narrow view might be wrong.[31] If cells contain genes capable of becoming oncogenes by transduction into retroviruses, perhaps the same genes might also become oncogenes within the cell, without ever encountering a virus. By means of accidental molecular piracy, retroviruses may have brought to view the genetic keyboard on which many different causes of cancer can play, a final common pathway to the neoplastic phenotype (Fig. 3).

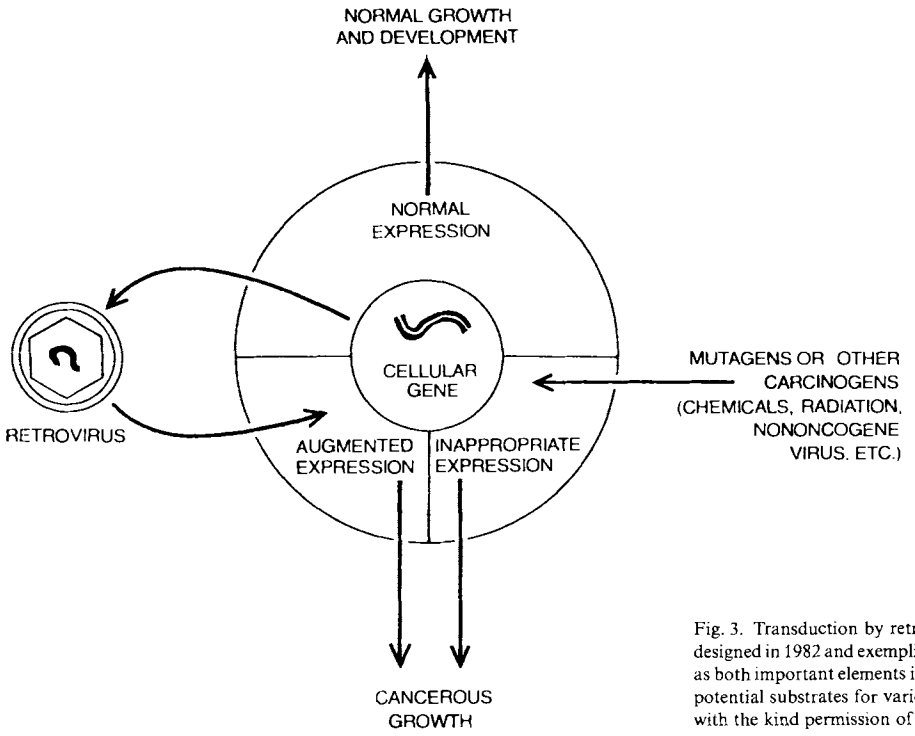

Fig. 3. Transduction by retroviruses uncovers cancer genes. The cartoon was designed in 1982 and exemplifies the now conventional view of proto-oncogenes as both important elements in the governance of normal cellular phenotype and potential substrates for various causes of cancer. (The figure is reprinted here with the kind permission of *Scientific American 246* (1982), No. 3, pp. 68–79.

The hope had its detractors.[32] Even transduction itself was challenged. But for us in San Francisco, the reality of transduction seemed inescapable. The cellular homologue of *src* had been conserved through eons of evolution, whereas the other genes of Rous sarcoma virus could be found only in chickens and a few close kin.[2] The ineluctable conclusion was that the two sorts of genes, an oncogene on the one hand and genes devoted to viral replication on the other, had separate origins.

We would eventually muster more sophisticated arguments, all of which pointed to the same conclusion: the progenitor of *src* was a conserved (and hence vital) cellular gene that found its way into Rous sarcoma virus by recombination.[2] The images of cellular and viral *src* gained eventually from molecular cloning sustained our argument in a gratifying manner,[33] but for me, they were anticlimactic.

Arguing for the cellular origins of *src* provided my first experience with the heuristic force of evolution. "Nothing in biology makes sense except in the light of evolution", to recall a famous aphorism from *Dobzhansky*.[34] The aphorism embodies a truth that has been dishonored in the United States, where religious zealots continue their efforts to hound the teaching of evolution from public schools, and men of little learning assail the truth of evolution under the fraudulent rubric of "creation science".

The genesis of retroviral oncogenes by recombination with cellular genes had been postulated by several observers. Although it may sound self-serving, I confess my ignorance of those speculations when we began our work on cellular *src*. I was motivated by a desire to test the virogene–oncogene hypothesis of *Huebner* and *Todaro*,[35] not by an interest in the origins of oncogenes. But in due course, *Howard Temin* provided a useful inspiration with his suggestion that all retroviruses arose by the cobbling together of disparate genetic elements in the cell, with intermediates that he called proto-viruses.[36] The inspiration was for taxonomy, not experiment.

As transduction by retroviruses came into common discourse, the need arose for a generic term to describe the cellular progenitors of *src* and other retroviral oncogenes. The first to find general usage was "cellular oncogene". Although I was a nominal member of the responsible committee on nomenclature, I was uncomfortable with this term because of its unwarranted implication that the native cellular genes carried intrinsic tumorigenic potential, that they need not be changed to cause trouble. So in playful homage to *Howard Temin*, I began to use the term "protosarc".[37] The generic "proto-oncogene" followed in short order.

In the interim, proto-oncogene has come into general use, as the colloquial counterpoise to oncogene. It has also become an embarrassment, because the precise connotation of the word is that of prototype rather than progenitor, not far removed from the offensive connotation of cellular oncogene. But the intent of the taxonomic invention was clear: numerous investigators (ourselves included) have spent the past decade exploring the sorts of genetic damage that can convert a harmless proto-oncogene into a pathogenic oncogene.[38]

The manuscript that announced our discovery of cellular *src* concluded with the speculation that the gene might be involved in "the normal regulation of cell growth and development or in the transformation of cell behavior by physical, chemical or viral agents".[39] These words were pure bravado, particularly because we then had no assurance that cellular *src* was in fact a full-fledged gene. The assurance accrued over the ensuing two years, first in the form of evidence that cellular *src* was transcribed in normal cells,[40,41] and then with the identification of the protein encoded by the gene.[42,43]

Expanding the Repertoire

As our confidence in the reality of cellular *src* grew, a new challenge took shape. Could we generalize the principle of transduction? Had the oncogenes of other retroviruses also originated from cellular genes? In order to pursue the generality of transduction, we turned first to a retrovirus known as MC29,[44] which attracted our attention because it offers a model for the induction of carcinomas, the most prevalent of human cancers.

During the search for an oncogene in MC29, the impatience of molecular biologists held sway, the rigor of formal genetics was cast aside. Some investigators (ourselves included) used molecular hybridization to detect nucleotide sequences unique to the genome of MC29,[45, 46] others used chemical procedures to identify the same sequences and to map their position on the viral genome.[47] Both strategies took liberties that we had not allowed ourselves with *src*. Lacking a deletion mutant that might define the oncogene, we and others made the assumption that the genomes of MC29 and its necessary helper virus were congenic except for the presence or absence of the oncogene (Fig. 4).

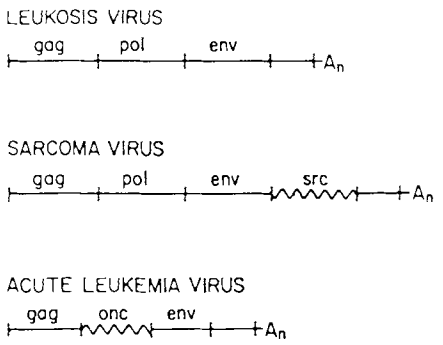

Fig. 4. The genomes of Rous sarcoma virus and related avian retroviruses. The genomes of Rous sarcoma virus, avian leukosis viruses, and acute avian leukemia viruses appear to have a common origin and, thus, are congenic with the exception of oncogenes, inserted into the genomes by transduction from host cells. The leukosis viruses have no oncogenes and induce malignancy by insertional mutagenesis [2, 38]. The viral genes are designated as in Fig. 1, except for the use of *onc*, the generic term for retroviral oncogenes.

The same assumption had been applied previously in an effort to define the oncogene of a murine sarcoma virus and had led to a molecular quagmire.[48] But now the lessons from *src* told us more precisely what we might be seeking. So we forged ahead and soon had a molecular probe that represented nucleotide sequences found in MC29 and other retroviruses with similar tumorigenicities, but not in the related helper viruses.[45]

The newly found locus was taken to be the oncogene of MC29 and eventually designated *myc*, in deference to the form of leukemogenesis (myelocytomatosis) from which the virus acquired its name. Over the next several years, the authenticity of *myc* would be ascertained by molecular cloning,[49] nucleotide sequencing,[50] and gene transfer.[51] To this day, the gene has never been defined by the strategies of classical genetics, and there is now no need to do so. The new biology is upon us.

The lessons of *src* were powerful. We and others were able to argue that the molecular probes for the oncogene of MC29 were legitimate because they also detected nucleotide sequences in the DNA of normal vertebrates,[46, 52] sequences that were transcribed into RNA in normal cells[52, 53] and that diverged among species in rough accord with phylogenetic distance.[46, 52, 53] No other portion of the MC29 genome displayed these properties. Similar findings were described in parallel for the avian retroviral oncogenes *erb* (in reality, two oncogenes) and *myb*.[46] The example of cellular *src* was not an exotic anomaly; it was an archetype.

In the years that followed, *myc* proved to be a great provider, a vehicle for several seminal discoveries that included the activation of cellular genes by insertional mutagenesis,[54] the involvement of proto-oncogenes in chromosomal translocations,[55, 56] and the amplification of proto-oncogenes in human tumors.[57] These discoveries had exceptional logical force because they involved a gene whose tumorigenic potential was already known from the study of retroviruses.

No sooner had the bounty of transduction become evident than other routes to proto-oncogenes took shape, some serendipitous, others designed:[58] the ability of retroviruses to mutate cellular genes, creating oncogenes at their place of residence within the cell; the dissection of chromosomal abnormalities in cancer cells, such as translocations and amplifications; the use of gene transfer to detect mutant proto-oncogenes by means of their biological activity; and the pursuit of phylogenetic kinships. The definition of proto-oncogene had now become more expansive, subsuming any gene with the potential for conversion to an oncogene—by the hand of nature in the cell or by the hand of the experimentalist in the test tube.

The Normal Functions of Proto-oncogenes

The tally of proto-oncogenes has now reached sixty or more. Most are genes never glimpsed before by any other means. What are these genes in their normal guise? What purposes preserved them through one billion years of evolution? Why do they harbor the potential to wreak cellular mayhem?

We formed our hypotheses from the lessons of transduction. The properties of retroviral oncogenes must echo the functions of proto-oncogenes. Three properties seemed especially telling: the stimulation of cellular proliferation; the specificity of tumorigenesis, as if each gene were designed to work in only certain cells; and the ability of many oncogenes to interrupt or sometimes reverse cellular differentiation.[59] Like father, like son: it seemed possible that the actions of viral oncogenes are merely caricatures of what proto-oncogenes are normally intended to do. Retroviruses may have revealed to us not only touchstones of tumorigenesis, but clues to the nerve center that governs the normal cell cycle and the differentiation of cellular function.

Eager to explore these thoughts in a living organism, we turned to the fruit fly, *Drosophila melanogaster*. Why the fruit fly? First, because the full collection of genes in this creature is within our scope. Second, because we have in

hand a rich catalogue of normal and mutant genes from the fruit fly, the products of more than half a century of labor. Third, because the fruit fly is for the moment the only metazoan organism in which we can manipulate genes with reasonable facility, although a soil worm on the one hand and the laboratory mouse on the other are now making strong bids for our favor. Fourth, because when reduced to essentials, the fruit fly and *Homo sapiens* are not very different. And fifth, because the fruit fly has a large complement of proto-oncogenes with counterparts in mammals.[60]

What we have learned of proto-oncogenes from *Drosophila* vindicates at least some of the bravado in our first publication on cellular *src*. Mutant alleles have been identified for the counterparts of six proto-oncogenes in the fruit fly (Table 2). In two instances, the *abl* and *myb* proto-oncogenes, the

Table 2. Mutant alleles of proto-oncogenes in *Drosophila melanogaster*.

Proto-oncogene	*Drosophila* counterpart	Biochemical function	Mutant phenotype
abl	*abl*	tyr kinase	embryonic lethal/defects in late development
int-1	*wingless*	? growth factor	segment polarity
raf	*pole hole*	ser/thr kinase	defective cellular proliferation
rel	*dorsal*	?	dorsal-ventral polarity
erbb-1	*flb/top*	tyr kinase	embryonic lethal/dorsoventral patterning
myb	*myb*	transcription factor	embryonic and pupal lethality

search for mutations was deliberate; in the remainder, mutations recognized first by their phenotypes later proved to be in *Drosophila* counterparts of mammalian proto-oncogenes. All of the mutations elicit profound disturbances of development. The work from our own hands has revealed a requirement for activity of the proto-oncogene *myb* during two distinct stages of development, embryogenesis and pupation (unpublished data of *A. Katzen* and *J. M. B.*). More precisely, a deficiency in *myb* appears to reduce the number of cell divisions that can occur in certain developmental lineages.

The actions of proto-oncogenes in development have their underpinnings in the elaborate circuitry that governs the behavior of vertebrate cells (Fig. 5). The junction boxes in this circuitry include polypeptide hormones that act on the surface of the cell, receptors for these hormones, proteins that convey signals from the receptors to the deeper recesses of the cell, and nuclear functions that orchestrate the genetic response to afferent commands (typically, by regulating transcription). Diverse lines of inquiry have brought these junction boxes to view, but the study of proto-oncogenes has been among the richest sources. Time and again, the several lines of inquiry have converged on the same junction box. We may have most of the circuitry in view. The cell is not infinitely complex; the cell can be understood.

Seeds of Cancer

But what of cancer? Are proto-oncogenes the seeds of this disease in all our cells? Are they a common keyboard for many different players in tumorigenesis? As a physician, I found these questions attractive. As a scientist, I found them intimidating. Exploration of the cancer cell is akin to archaeology: we must infer the past from its remnants in the present, and the remnants are often cryptic.

But the first remnants to emerge from the proto-oncogenes of human cancer cells told a vivid story. Molecular dissections revealed that chromosomal translocations in human and murine tumors often affect proto-oncogenes already familiar from the study of retroviruses, with the great provider *myc* prominent among them.[55,61] Emboldened by these findings, my colleagues and I mounted a belated excavation for the genetic shards of tumorigenesis. But we chose a neglected terrain in which to dig: amplified DNA.

Focal amplification of domains within chromosomes is a scheduled and purposeful event during the life cycles of diverse organisms.[62] In mammals, however, gene amplification is an unscheduled aberration that gives rise to karyotypic abnormalities known as double-minute chromosomes and homogeneously staining regions. When my colleagues and I

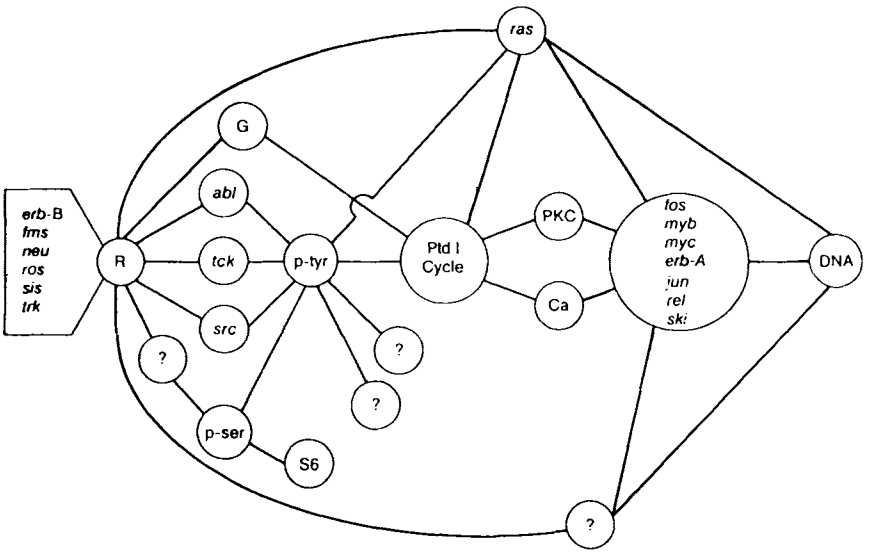

Fig. 5. The biochemical circuitry that mediates cellular phenotype. The diagram illustrates how some of the functions encoded by proto-oncogenes fit into the circuitry that regulates the phenotype of vertebrate cells. The scheme is in part hypothetical and is not intended to be comprehensive. Functions encoded by proto-oncogenes have been designated by the conventional terminology for the genes themselves. Other abbreviations include: G, GTP-binding proteins that transduce signals from cell-surface receptors; R, generic receptor; p-Ser, phosphorylation of serine in proteins; p-Tyr, phosphorylation of tyrosine in proteins; PtdI, phosphatidylinositol; S6, a ribosomal protein that is phosphorylated in response to diverse mitogenic signals; PKC, protein kinase C. (Reprinted here with the kind permission of *Science (Washington, D. C.) 235* (1987) 305–311.

began our excavations, gene amplification in cancer cells was known principally as a consequence of selection by chemotherapeutic agents. But the literature also contained occasional examples of double-minute chromosomes and homogeneously staining regions in untreated cancers. When a limited sampling of these were examined by ourselves and others, they proved to involve previously identified proto-oncogenes (yet again, *myc* was prevalent).[57] In due course, it became apparent that gene amplification is relatively common in untreated tumors and that it affects proto-oncogenes.

Intent on a more systematic study, we chose human neuroblastomas, in which gene amplification seemed exceptionally common. We resolved to ask whether the amplified DNA in neuroblastoma cells contained any of the proto-oncogenes then known. When we got to *myc*, we struck rich ore of an unexpected sort: a gene related to *myc*, sighted for the first time in the parallel work on neuroblastoma by ourselves and others, and eventually designated N-*myc*.[63-65] In due course, it became apparent that N-*myc* is an authentic proto-oncogene, a close kin of *myc* itself that apparently evolved to serve a separate purpose in the normal organism.[66-68]

As the survey of neuroblastomas broadened, a fertile correlation became apparent. Amplification of N-*myc* was found only in the more aggressive variants of the tumor, in perhaps one-quarter of all the specimens examined.[69, 70] Moreover, within single tumors, N-*myc* was expressed abundantly only in neuroblasts, the least differentiated (and presumably most malignant) cells of the tumor.[64] These correlations had two implications: first, that amplification of N-*myc* might embody a step in tumor progression, one of several events that exacerbate the malignancy of neuroblastomas; second, that we had brought to hand a prognostic tool, a device with which to supplement the conventional staging of the disease.

The passage of time has dealt kindly with these hopes. The *New England Journal of Medicine* has now provided its imprimatur by arguing that "in neuroblastoma, amplification of the N-*myc* gene is of greater prognostic value than the clinical stage of the disease".[71] Thirty years after deserting the bedside, I have found clinical relevance in my research.

The excavation that unearthed N-*myc* was a pedestrian exercise in both concept and execution. Yet in one fell swoop, it served up an important proto-oncogene without the assistance of a retrovirus, hinted at a major role for gene amplification in tumorigenesis, foreshadowed the molecular dissection of tumor progression, and gave first notice that the emerging knowledge of oncogenes would eventually prove useful at the bedside.

These themes have since found wider resonance. First, we can point to a variety of human malignancies in which damage to one or another proto-oncogene has been found with some consistency (Table 3). The damage takes diverse forms, including translocations, amplifications, and point mutations, all of which appear to have dominant effects on gene function. The list of malignancies containing these lesions is impressive: because of the diversity of tumors involved; because of their identities—several can be counted among the principal nemeses of humankind; and because the list has been assembled after only a few years of pursuit, with imperfect tools—there is doubtless more to come. Beyond this list, there lies the burgeoning repertoire of recessive lesions in human cancers, whose nature, prevalence, and unquestionable importance are just now coming into focus.[72]

Table 3. Proto-oncogenes and human tumors; some consistent incriminations.

Proto-oncogene	Neoplasm	Lesion
abl	chronic myelogenous leukemia	translocation
erbb-1	squamous cell carcinoma glioblastoma	amplification
erbb-2 (neu)	adenocarcinoma of breast and ovary	amplification
myc	Burkitt's lymphoma	translocation
	small cell carcinoma of lung	amplification
	carcinoma of the breast	
	carcinoma of the cervix	
l-myc	small cell carcinoma of lung	amplification
n-myc	neuroblastoma	amplification
	small cell carcinoma of the lung	
k-ras	carcinomas of colon, lung, and pancreas	point mutation
n-ras	acute myelogenous and acute lymphoblastic leukemia; carcinoma of thyroid	point mutation
h-ras	carcinomas of genitourinary tract and thyroid	point mutation

Second, catalogues of genetic damage within individual tumors are taking shape, showing us how the malfunction of several different genes might combine to produce the malignant phenotype:[58] for example, carcinomas of the colon contain no less than five different yet prevalent lesions—some genetically dominant, others recessive; carcinoma of the breast, at least five lesions; carcinoma of the lung, at least four; and neuroblastoma, at least three. Moreover, detection of the lesions is likely to provide information for prognosis, perhaps even for therapeutic management. Examples include neuroblastoma,[69-71] carcinoma of the breast[73, 74] and ovary,[74] and preleukemias.[75-77]

For those of us who first studied cancer more than thirty years ago in medical school, then returned to the disease decades later to find it little less a mystery, the contemporary image of the cancer cell is both thrilling and an unexcelled vindication for fundamental research. The image was forged from the vantage point of molecular genetics and with the tools of that discipline. The lines of discovery trace back to minuscule columns of hydroxyapatite from which the molecular probe for *src* first flowed; to *src* itself, which even now has not been persuasively implicated in the genesis of human cancer; and to the chickens in which *Peyton Rous* first found his tumor. From these humble roots, a great tree of knowledge has grown. And a great truth has been reiterated: we cannot prejudge the utility of scholarship, we can only ask that it be sound.

Prospects for Therapy

What of treatment? Will we acquire new antidotes for cancer from our study of oncogenes? There is little likelihood that we will be able to repair or replace damaged proto-oncogenes in the foreseeable future, particularly in the individual already burdened with countless tumor cells. There is talk of restoring functional copies of recessive oncogenes to tumors in which they are defective.[78] But realization of this objective in human subjects presently seems many years distant.

If we focus on the protein handmaidens of genes, however, we can see more cause for hope. Given sufficient information about how these proteins act, the pharmaceutical chemist or the immunotherapist may be able to invent ways to interdict their action, even to exploit the specificity of genetic damage and thus to reverse the effects of oncogenes. We are not close to implementing this strategy, but it is a reasonable hope.

I am eager not to appear naive. No single therapy against an oncogene product is likely to become a panacea. We must deal with a large variety of oncogenes, whose products are deployed to the many reaches of the cell and whose actions present great chemical and enzymological diversity; and we must be prepared to cope with evolving genetic damage within cancer cells that can bring a variety of oncogenes into play sequentially. Nevertheless, the search for genetic damage in cancer cells and the explication of how that damage affects the biochemical functions of genes have become our best hope to understand and thus to thwart the ravages of cancer.

Conclusion

At the beginning of this century, the Austrian engineer and novelist *Robert Musil* offered a description of progress in science that foreshadowed modern views of epistemology and that now exemplifies the course of contemporary cancer research.

> ... every few years, ... something that up to then was held to be error suddenly revolutionizes all views, ... an unobtrusive, despised idea becomes the ruler over a new realm. ...[79]

Harold Varmus, I, and our numerous colleagues have been privileged to assist as a despised idea became the ruler over a new realm. The notion that genetic changes are important in the genesis of cancer has met strenuous resistance over the years. But now that notion has gained ascendancy. In the event, I have learned that there is no single path to creativity: we are constrained not by the necessary discipline of rigor, but by the limits to our imaginations and our intellectual courage. In the words of an American sage: "Dare to be wrong, or you may never be right."[80]

Discovery takes two forms. The first is mundane, but nevertheless legitimate: we grope our way to reality and then recognize it for what it is. The second is legitimate, but also sublime: we imagine reality as it ought to be and then find the proof for our imaginings. I have been fortunate to know the first form of discovery and am thankful for the privilege. I have miscarried opportunities to know the second and am diminished by the failure. Redemption lies in more imaginings.

"The real truths are those that can be invented."[81]

I owe a lifelong debt to Harold Varmus, with whom I shared most of the events described here. The whole has been greater than the sum of the two parts, or so I believe. Numerous students and postdoctoral fellows have participated in the discovery and pursuit of proto-oncogenes with Harold and myself. Without their dedicated and talented efforts, I would have no story to tell. Since I could not name them all in the text, I have named none. Many of their contributions are documented in the bibliography to this manuscript. I recall the memory of Richard Parker, for his special impact. I am also grateful to colleagues in the scientific community who have helped me at crucial times in my career, including David Baltimore, Howard Berg, Peter Duesberg, Howard Goodman, Robert Huebner, Malcolm Martin, John Menninger, Aaron Shatkin, Howard Temin, and Peter Vogt. I acknowledge my many colleagues at the University of California, San Francisco, whose friendship and support have been vital, particularly Bruce Alberts, Mitzi Best, Herbert Boyer, Lois Fanshier, Julius Krevans, Jean Jackson, Marc Kirschner, Tom Kornberg, Suzanne Ortiz, Nancy Quintrell, Rudi Schmid, Lois Serxner, Holly Smith, and Karen Smith. I thank my wife and family for a gift of forbearance that cannot be repaid. My work has been supported by both the National and California Divisions of the American Cancer Society and by the National Institutes of Health. The support of biomedical research in the United States is an act of public altruism unexcelled in history. I dedicate this manuscript to the countless individuals who sustain that support, by voluntary contributions and by the payment of state and federal taxes.

Experiments with Separated Oscillatory Fields and Hydrogen Masers (Nobel Lecture)**

By Norman F. Ramsey*

I am honored to receive the Nobel Prize, which I feel is also an honor to the physicists and engineers in many countries who have done beautiful experiments using the methods I shall be discussing. In addition, I am grateful to my great teacher *I. I. Rabi*, to my friends and colleagues, to my eighty-four Ph.D. students who were close friends and collaborators and especially to *Daniel Kleppner* and *Daniel Larson*, who contributed so much to the success of our laboratory.

The Method of Successive Oscillatory Fields

In the summer of 1937, following two years at Cambridge University, I went to Columbia University to work with *I. I. Rabi*. After I had been there only a few months, *Rabi* invented[1-4] the molecular beam magnetic resonance method so I had the great good fortune to be the only graduate student to work with *Rabi* and his colleagues[1-2] on one of the first two experiments to develop and utilize magnetic resonance spectroscopy, for which *Rabi* received the 1944 Nobel Prize in Physics.

By 1949, I had moved to Harvard University and was looking for a way to make more accurate measurements than were possible with the Rabi method and in so doing I invented the method of separated oscillatory fields.[3-6] In this method the single oscillatory magnetic field in the center of the Rabi device is replaced by two oscillatory fields, one at the entrance and one at the exit of the space in which the properties of the atoms or molecules are studied. As I shall point out, the separated oscillatory fields method had many advantages over the single oscillatory field method, and in the following years it was extended to many experiments beyond those of molecular beam magnetic resonance. The device shown in Figure 1 is a molecular beam apparatus embodying successive oscillatory fields that has been used at Harvard for an extensive series of experiments.

Fig. 1. Molecular beam apparatus with separated oscillatory fields. The beam of molecules emerges from a small source aperture in the left third of the apparatus, is focussed there and passes through the middle third in an approximately parallel beam. It is focussed gain in the right third to a small detector aperture. The separated oscillatory electric fields at the beginning and end of the middle third of the apparatus produce resonance transitions that reduce the focussing and therefore weaken the detected beam intensity.

Let me now review the successive oscillatory field method, particularly in its original and easiest-to-explain application—the measurement of nuclear magnetic moments. The extension to more general cases is then straightforward.

The method was initially an improvement on *Rabi*'s resonance method for measuring nuclear magnetic moments, whose principles are illustrated schematically in Figure 2.

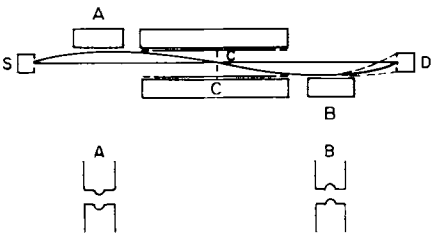

Fig. 2. Schematic diagram of a molecular beam magnetic resonance apparatus. A typical molecule which can be detected emerges from the source S, is deflected by the inhomogeneous magnetic field A, passes through the collimator C and is deflected to the detector D by the inhomogeneous magnetic field B. If, however, the oscillatory field in the C region induces a change in the molecular state, the B magnet will provide a different deflection and the beam will follow the dashed lines with a corresponding reduction in detected intensity. In the Rabi method, the oscillatory field is applied uniformly throughout the C region as indicated by the long rf lines inside the C-magnet, whereas in the separated oscillatory field method the rf is applied only in the short regions at the beginning and end of the C-magnet.

Consider a classical nucleus with spin angular momentum $\hbar \boldsymbol{J}$ and magnetic moment $\boldsymbol{\mu} = (\mu/J)\boldsymbol{J}$. Then in a static magnetic field $\boldsymbol{H}_0 = H_0 \boldsymbol{k}$, the nucleus, due to the torque on the nuclear angular momentum, will precess like a top about $\boldsymbol{H}_0$ with the Larmor frequency ν_0 and angular frequency ω_0 given by (1),

$$\omega_0 = 2\pi\nu_0 = \frac{\mu H_0}{\hbar I} \tag{1}$$

as shown in Figure 3. Consider an additional magnetic field $\boldsymbol{H}_1$ perpendicular to $\boldsymbol{H}_0$ and rotating about it with angular frequency ω. Then, if at any time $\boldsymbol{H}_1$ is perpendicular to the plane of $\boldsymbol{H}_0$ and $\boldsymbol{J}$, it will remain perpendicular to it provided $\omega = \omega_0$. In that case, in a coordinate system rotating with $\boldsymbol{H}_1$, $\boldsymbol{J}$ will precess about $\boldsymbol{H}_1$ and the angle φ will continuously change in a fashion analogous to the motion of a "sleeping top"; the change of orientation can be detected by allowing the molecular beam containing the magnetic moments to pass through inhomogeneous fields as in Figure 2. If ω is not

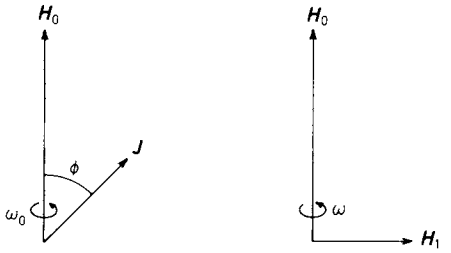

Fig. 3. Precession of the nuclear angular momentum $\boldsymbol{J}$ (left) and the rotating magnetic field $\boldsymbol{H}_1$ (right) in the Rabi method.

equal to ω_0, $\boldsymbol{H}_1$ will not remain perpendicular to $\boldsymbol{J}$; so φ will increase for a short while and then decrease, leading to no net change. In this fashion the Larmor precession frequency ω_0 can be detected by measuring the oscillator frequency ω at which there is maximum reorientation of the angular momentum and hence a maximum change in beam intensity for an apparatus as in Figure 2. This procedure is the basis of the *Rabi* molecular beam resonance method.

The separated oscillatory field method in this application is much the same except that the rotating field $\boldsymbol{H}_1$ seen by the nucleus is applied initially for a short time τ, the amplitude of $\boldsymbol{H}_1$ is then reduced to zero for a relatively long time t and then increased to $\boldsymbol{H}_1$ for a time τ, with phase coherency being preserved for the oscillating fields as shown in Figure 4. This

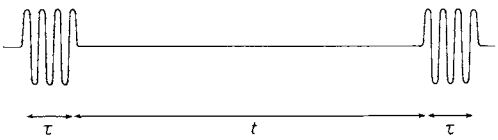

Fig. 4. Two separated oscillatory fields, each acting for a time τ, with zero amplitude oscillating field acting for time t. Phase coherency is preserved between the two oscillatory fields so it is as if the oscillation continued, but with zero amplitude for time t.

can be done, for example, in the molecular-beam apparatus of Figure 2 in which the molecules first pass through a rotating field region, then a region with no rotating field and finally a region with a second rotating field driven phase coherently by the same oscillator.

If the nuclear spin angular momentum is initially parallel to the fixed field (so that φ is equal to zero initially) it is possible to select the magnitude of the rotating field so that φ is 90° or $\pi/2$ radians at the end of the first oscillating region. While in the region with no oscillating field, the magnetic moment simply precesses with the Larmor frequency appropriate to the magnetic field in that region. When the magnetic moment enters the second oscillating field region there is again a torque acting to change φ. If the frequency of the rotating field is exactly the same as the mean Larmor frequency in the intermediate region there is no relative phase shift between the angular momentum and the rotating field.

Consequently, if the magnitude of the second rotating field and the length of time of its application are equal to those of the first region, the second rotating field has just the same effect as the first one—that is, it increases φ by another $\pi/2$, making $\varphi = \pi$, corresponding to a complete reversal of the direction of the angular momentum. On the other hand, if the field and the Larmor frequencies are slightly different, so that the relative phase angle between the rotating field vector and the precessing angular momentum is changed by π while the system is passing through the intermediate region, the second oscillating field has just the opposite effect to the first one; the result is that φ is returned to zero. If the Larmor frequency and the rotating field frequency differ by an amount such that the relative phase shift in the intermediate region is exactly an integral multiple of 2π, φ will again be left at π just as at exact resonance.

In other words: if all molecules had the same velocity, the transition probability would be periodic as in Figure 5. However, in a molecular beam resonance experiment one can easily distinguish between exact resonance and the other cases. In the case of exact resonance, the condition for no change in the relative phase of the rotating field and of the precessing angular momentum is independent of the molecular velocity. In the other cases, however, the condition for an integral multiple of 2π relative phase shift is velocity dependent, because a slower molecule is in the intermediate region longer and so experiences a greater shift than a faster molecule. Consequently, for the non-resonance peaks the reorientations of most molecules are incomplete, so the magnitudes of the non-resonance peaks are smaller than at exact reso-

Norman F. Ramsey, who was born in 1915 in Washington D.C., completed his formal studies at the Columbia University and the University of Cambridge. In 1940, under the supervision of I. Rabi, he received a PhD from Columbia University for molecular beam studies of the rotational magnetic moments of molecules. He was awarded an Sc. D. by Cambridge University in 1954 and by Oxford University in 1973, as well as honorary degrees from numerous universities. He was Executive Secretary of the group of scientists who established Brookhaven National Laboratory and was the first Chairman of its Physics Department. Since 1947 he has been at Harvard University, where he is Higgins Professor of Physics. To mention only a small selection of his various other activities, Norman Ramsey was in 1973/74 the George Eastman Professor at Oxford University, from 1966–1981 President of the Universities Research Association, and from 1980–1986 the Chairman of the Board of Governors of the American Institute of Physics. Books authored by him include "Experimental Nuclear Physics", "Nuclear Moments", "Molecular Beams", and "Quick Calculus". Of the many awards he had already received before the Nobel Prize only those of the last five years might be mentioned: Monie Ferst Award, Rabi Prize and Rumford Premium, Compton Medal and Oersted Medal, IEEE Centennial Medal, and National Medal of Science.

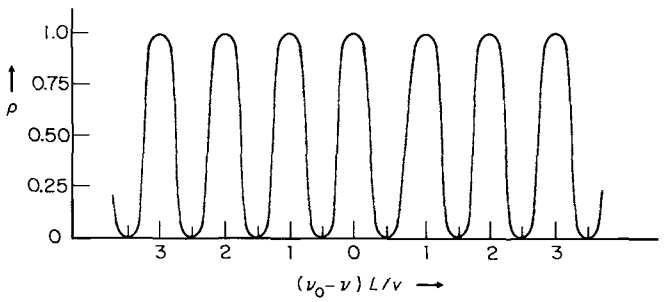

Fig. 5. Transition probability ϱ as a function of the frequency $\nu = \omega/2\pi$ that would be observed in a separated oscillatory field experiment if all the molecules in the beam had a single velocity v. L is the distance between the two separated oscillatory field regions.

nance, and one expects a resonance curve similar to that shown in Figure 6 in which the transition probability for a particle of spin 1/2 is plotted as a function of frequency.

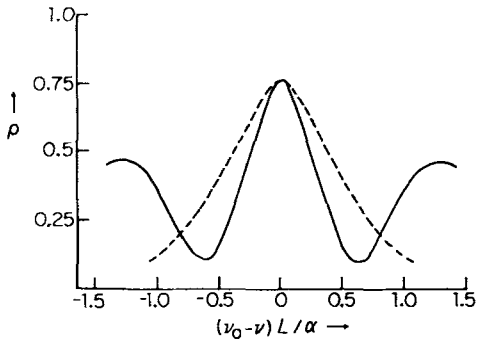

Fig. 6. When the molecules have a Maxwellian velocity distribution, the transition probability is as shown by the full line for optimum rotating field amplitude. (L is the distance between oscillating field regions, α is the most probable molecular velocity and ν is the oscillatory frequency $= \omega/2\pi$.) The dashed line represents the transition probability with the single oscillating field method when the total duration is the same as the time between separated oscillatory field pulses (Fig. 4).

Although the above description of the method is primarily in terms of classical spins and magnetic moments, the method applies to any quantum mechanical system for which a transition can be induced between two energy states W_i and W_f which are differently focussed. The resonance frequency ω_0 is then given by Equation (2) and one expects a resonance curve similar to that shown in Figure 6.

$$\omega_o = (W_i - W_f)/\hbar \qquad (2)$$

From a quantum-mechanical point of view, the oscillating character of the transition probability in Figures 5 and 6 is the result of the cross term in the calculation of the transition probability from probability amplitudes. Let C_{iif} be the probability amplitude for the nucleus to pass through the first oscillatory field region with the initial state i unchanged and for there to be a transition to state f in the final field, and let C_{iff} be the amplitude for the alternative path with the transition to the final state f being in the first field with no change in the second. Then the cross term $C_{iif}C^*_{iff}$ produces an interference pattern and gives the narrow oscillatory pattern of the transition probability shown in the curves of Figures 5 and 6. Alternatively, the pattern can in part be interpreted as resulting from the Fourier spectrum of an oscillating field which is on for a time τ, off for t and on again for τ (Fig. 4). This interpretation is however not fully valid since with finite rotations of $\boldsymbol{J}$ the problem is a non-linear one. Furthermore, the Fourier interpretation obscures some of the key advantages of the separated oscillatory field method. I have calculated the quantum mechanical transition probabilities[3, 5, 7, 8] and these calculations provide the basis for Figure 6.

The separated oscillatory field method has a number of advantages including the following:

(1) The resonance peaks are only 0.6 as broad as the corresponding ones with the single oscillatory field method. The narrowing is somewhat analogous to the peaks in a two slit optical interference pattern being narrower than the central diffraction peak of a single wide slit whose width is equal to the separation of the two slits.

(2) The sharpness of the resonance is not reduced by nonuniformities of the constant field since both from the qualitative description and from the theoretical quantum analysis, it is only the space average value of the energies along the path that enter Equation (2) and are important.

(3) The method is more effective and often essential at very high frequencies where the wavelength of the radiation used may be comparable to or smaller than the length of the region in which the energy levels are studied.

(4) Provided there is no unintended phase shift between the two oscillatory fields, first order Doppler shifts and widths are eliminated.

(5) The method can be applied to study energy levels in a region into which an oscillating field cannot be introduced; for example, the Larmor precession frequency of neutrons can be measured while they are inside a magnetized iron block.

(6) The lines can be narrowed by reducing the amplitude of the rotating field below the optimum. The narrowing is the result of the low amplitude favoring slower than average molecules.

(7) If the atomic state being studied decays spontaneously, the separated oscillatory field method permits the observation of narrower resonances than those anticipated from the lifetime and the Heisenberg uncertainty principle provided the two separated oscillatory fields are sufficiently far apart; only states that survive sufficiently long to reach the second oscillatory field can contribute to the resonance. This method, for example, has been used by *Lundeen* et al.[9] in precise studies of the Lamb shift.

The advantages of the separated oscillatory field method have led to its extensive use in molecular and atomic beam spectroscopy. One of the best known is in atomic cesium standards of frequency and time which will be discussed later.

Although in most respects, the separated oscillatory field method offers advantages over a single oscillatory field, there are sometimes disadvantages. In studying complicated overlapping spectra the subsidiary maxima (Fig. 6) can cause confusion. Furthermore, it is sometimes difficult at the required frequency to obtain sufficient oscillatory field strengths with two short oscillatory fields, whereas adequate

field strength may be achieved with a weaker, longer oscillatory field. Therefore, for most molecular beam resonance experiments it is best to have both separated oscillatory fields and a single long oscillatory field available; one can then use the most suitable method under the circumstances.

As in any high precision experiment, care must be exercised with the separated oscillatory field method to avoid obtaining misleading results. Ordinarily these potential distortions are more easily understood and eliminated with the separated oscillatory field method than are their counterparts in most other high-precision spectroscopy. I have discussed the various effects in detail elsewhere[3, 7, 8, 10] but I will briefly summarize them here.

Variations in the amplitudes of the oscillating fields from their optimum values may markedly change the shape of the resonance, including the replacement of a maximum transition probability by a minimum. However, symmetry about the exact resonance frequency is preserved, so no measurement error need be introduced by such amplitude variations.[7, 8]

Variations of the magnitude of the fixed field between, but not in, the oscillatory field regions do not ordinarily distort a molecular beam resonance provided the average transition frequency (Bohr frequency) between the two fields equals the values of the transition frequencies in each of the two oscillatory field regions alone. If this condition is not met, there can be some shift in the resonance frequency.[7, 8]

If, in addition to the two energy levels between which transitions are studied, there are other energy levels partially excited by the oscillatory field, there will be a pulling of the resonance frequency as in any spectroscopic study and as analyzed in detail in the literature.[3, 7, 8]

Even in the case when only two energy levels are involved, the application of additional rotating magnetic fields at frequencies other than the resonance frequency will produce a net shift in the observed resonance frequency.[3, 7, 8] A particularly important special case is the effect identified by *Bloch* and *Siegert*[11] which occurs when oscillatory rather than rotating magnetic fields are used. Since an oscillatory field can be decomposed into two oppositely rotating fields, the counter-rotating field component automatically acts as such an extraneous rotating field. Another example of an extraneously introduced rotating field is that which results from the motion of an atom through a field $\boldsymbol{H}_0$ whose direction varies in the region traversed. The theory of the effects of additional rotating fields at arbitrary frequencies has been developed by myself,[7, 8, 10, 12] *Winter*,[10] *Shirley*,[13] *Code*,[12] and *Greene*.[14]

Unintended relative phase shifts between the two oscillatory field regions will produce a shift in the observed resonance frequency.[13–15] This is the most common source of possible error, and care must be taken to avoid it either by eliminating such a phase shift or by determining the shift—say by measurements with the molecular beam passing through the apparatus first in one direction and then in the opposite direction.

A number of extensions to the separated oscillatory field method have been made since its original introduction:

(1) It is often convenient to introduce phase shifts deliberately to modify the resonance shape.[15] As discussed above, unintended phase shifts can cause distortions of the observed resonance, but some distortions are useful. Thus, if the change in transition probability is observed when the relative phase is shifted from $+\pi/2$ to $-\pi/2$ one sees a dispersion curve[15] (Fig. 7). A resonance of this shape provides maximum sensitivity for detecting small shifts in the resonance frequency.

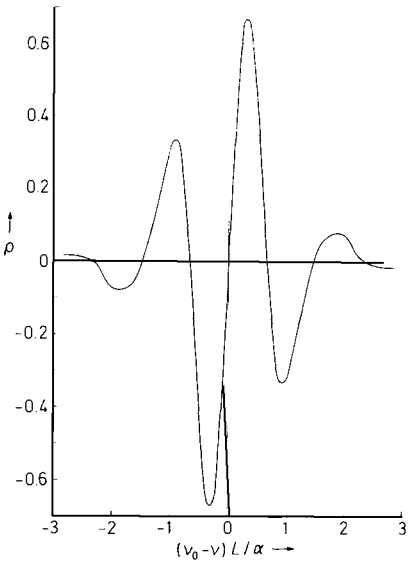

Fig. 7. Theoretical change in transition probability on reversing a $\pi/2$ phase shift. At the resonance frequency there is no change in transition probability, but the curve at resonance has the steepest slope.

(2) For most purposes the highest precision can be obtained with just two oscillatory fields separated by the maximum time, but in some cases it is better to use more than two separated oscillatory fields.[4] The theoretical resonance shapes[7] with two, three, four and infinitely many oscillatory fields are shown in Figure 8. The infinitely many oscillatory field case, of course, by definition becomes the same as the single long oscillatory field if the total length of the transition region is kept the same and the infinitely many oscillatory fields fill in the transition region continuously as we assumed

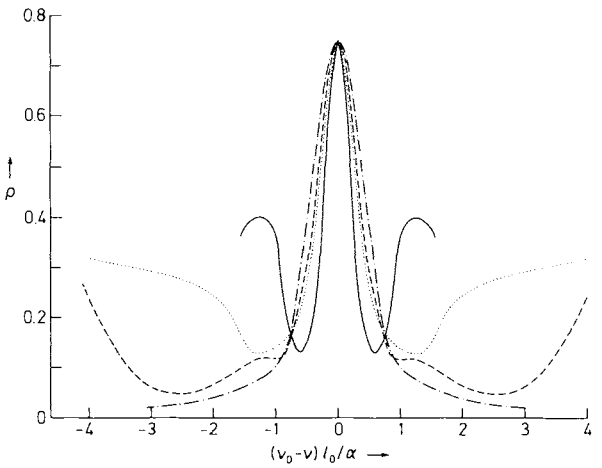

Fig. 8. Multiple oscillatory fields. The curves show molecular beam resonances with two (——), three (···), four (---) and infinitely many (–·–) successive oscillating fields. The case with an infinite number of oscillating fields is essentially the same as Rabi's single oscillatory field method (l = L).

in Figure 8. For many purposes this is the best way to think of the single oscillatory field method, and this point of view makes it apparent that the single oscillatory field method is subjected to complicated versions of all the distortions discussed in the previous section. It is noteworthy that, as the number of oscillatory field regions is increased for the same total length of apparatus, the resonance width is broadened; the narrowest resonance is obtained with just two oscillatory fields separated the maximum distance apart. Despite this advantage, there are valid circumstances for using more than two oscillatory fields. With three oscillatory fields the first and largest side lobe is suppressed, which may help in resolving two nearby resonances; for a larger number of oscillatory fields additional side lobes are suppressed, and in the limiting case of a single oscillatory field there are no side lobes. Another reason for using a large number of successive pulses can be the impossibility of obtaining sufficient power in a single pulse to induce adequate transition probability with a small number of pulses.

(3) The earlier use of the separated oscillatory field method involved two oscillatory fields separated in space, but it was soon realized that the method with modest modifications could be generalized to a method of successive oscillatory fields with the separation being in time, say by the use of coherent pulses.[16]

(4) If more than two successive oscillatory fields are utilized it is not necessary for the success of the method that they be equally spaced in time;[4] the only requirement is that the oscillating fields be coherent—as is the case if they are all derived from a single continuously running oscillator. In particular, the separation of the pulses can even be random,[16] as in the case of the large-box hydrogen maser[17] discussed later. The atoms being stimulated to emit move randomly into and out of the cavities with oscillatory fields and spend the intermediate time in the large container with no such fields.

(5) The full generalization of the successive oscillatory field method is excitation by one or more oscillatory fields that vary arbitrarily with time in both amplitude and phase.[7, 8]

(6) *V. F. Ezhov* et al.[6, 18] carried out a neutron-beam experiment, using an inhomogeneous static field in the region of each oscillatory field such that initially when the oscillatory field is applied conditions are far from resonance. Then, when the resonance condition is slowly approached, the magnetic moment that was originally aligned parallel to $\boldsymbol{H}_0$ will adiabatically follow the effective magnetic field on a coordinate system rotating with $\boldsymbol{H}_1$ until at the end of the first oscillatory field region the moment is parallel to $\boldsymbol{H}_1$. This arrangement has the theoretical advantage that the maximum transition probability can be unity even with a velocity distribution, but the method may be less well adapted to the study of complicated spectra.

(7) I emphasized earlier that one of the principal sources of error in the separated oscillatory field method is that which arises from uncertainty in the exact value of the relative phase shift in the two oscillatory fields. *Jarvis*, et al.[19] have pointed out that this problem can be overcome with a slight loss in resolution by driving the two cavities at slightly different frequencies so that there is a continual change in the relative phase. In this case the observed resonance pattern will change continuously from absorption to dispersion shape. The envelope of these patterns, however, can be observed and the position of the maximum of the envelope is unaffected by relative phase shifts. Since the envelope is about twice the width of a specific resonance there is some loss of resolution in this method, but in certain cases this loss may be outweighed by the freedom from phase-shift errors.

(8) The method has been extended to electric as well as magnetic transitions and to optical laser frequencies as well as radio- and microwave-frequencies. The application of the separated oscillatory field method to optical frequencies requires considerable modifications because of the short wavelengths, as pointed out by *Blaklanov, Dubetsky*, and *Chebotsev*.[20] Successful applications of the separated oscillatory field method to lasers have been made by *Bergquist*,[21] *Lee*,[21] *Hall*,[21] *Salour*,[22] *Cohen-Tannoudji*,[22] *Bordé*,[23] *Hänsch*,[24] *Chebotayev*[25] and many others.[25]

(9) The method has been extended to neutron beams and to neutrons stored for long times in totally reflecting bottles.

(10) In a recent beautiful experiment, *S. Chu* et al.[26] have successfully used the principle of separated oscillatory fields with a fountain of atoms that rises up slowly, passes through an oscillating field region, falls under gravity and passes again through the same oscillatory field region. This fountain experiment was attempted many years ago by *J. R. Zacharias* et al.,[3] but it was unsuccessful because of the inadequate number of very slow atoms. *Chu* et al. used laser cooling[27, 28, 29] to slow the atoms to a low velocity and obtained through the separated oscillatory fields a beautifully narrow resonance pattern.

The Atomic Hydrogen Maser

The atomic hydrogen maser grew out of my attempts to obtain even greater stability in atomic beam experiments. By the Heisenberg uncertainty principle (or by the Fourier transform), the width of a resonance in a molecular beam experiment cannot be less than approximately the reciprocal of the time the atom is in the resonance region of the apparatus. For atoms moving through a 1 m long resonance region at 100 m/s this means that the resonance width is approximately 100 Hz. To decrease this width and hence increase the precision of the measurements required an increase in this time. To increase the time by drastically lengthening the apparatus or selecting slower molecules would decrease the already marginal beam intensity or greatly increase the cost of the apparatus. I therefore decided to plan an atomic beam in which the atoms, after passing through the first oscillatory field would enter a storage box with suitably coated walls where they would bounce around for a period of time and then emerge to pass through the second oscillatory field. My Ph.D. student, *Daniel Kleppner*,[30] undertook the construction of this device as his thesis project. The original configuration required only a few wall collisions and was called a broken atomic beam resonance experiment. Initially the beam was cesium and the wall coating was teflon. The experiment[30] was a partial success in that a separated oscillatory field pattern for an atomic hyperfine transition was obtained, but it was weak and disappeared after a few wall

collisions. The results improved markedly when paraffin was used for the wall coating and a hyperfine resonance was eventually obtained after 190 collisions giving a resonance width of 100 Hz, but with the resonance frequency shifted by 150 Hz.

To do much better than this, we decided we would have to use an atom with a lower mass and a lower electric polarizability to reduce the wall interactions. Atomic hydrogen appeared ideal for this purpose, but atomic hydrogen is notoriously difficult to detect. We, therefore, calculated the possibility of detecting the transitions through their effects on the electromagnetic radiations. *Townes* et al.[31] had a few years earlier made the first successful maser (acronym for *M*icrowave *A*mplifier by *S*timulated *E*mission of *R*adiation) but no one had previously made a maser based on a magnetic dipole moment or at a frequency as low as that of an atomic hyperfine transition. We concluded, however, that if the resonance could be made narrow enough by multiple wall collisions, we should be able to obtain maser oscillations. The apparatus was designed and constructed by *Goldenberg*, *Kleppner* and myself[32] and after a few failures we obtained maser oscillations at the atomic hydrogen hyperfine frequency. Both the proton and the electron have spin angular momenta $\boldsymbol{I}$ and $\boldsymbol{J}$ as well as magnetic moments. The atomic hyperfine transitions are those for which there is a change of the relative orientation of these two magnetic moments between the initial and final states in Equation (2). We studied H atoms in the $1^2S_{1/2}$ ground electronic state and mostly observed the transitions $F = 1,\ m = 0 \rightarrow F = 0,\ m = 0$, where F is the quantum number of the total angular momentum $\boldsymbol{F} = \boldsymbol{I} + \boldsymbol{J}$ and m is the associated magnetic quantum number.

The principles of an atomic hydrogen maser are shown schematically in Figure 9. An intense electrical discharge in

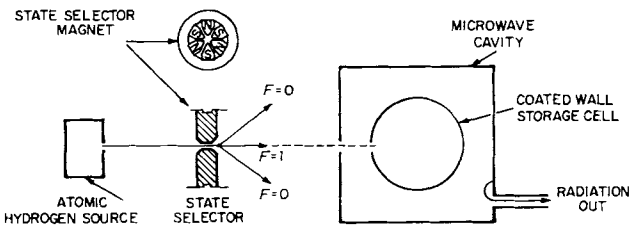

Fig. 9. Schematic diagram of atomic hydrogen maser. Only the paths of the $m = 0$ atoms are shown since the $m = 1$ atoms are not involved in the $\Delta m = 0$ transitions studied.

the source converts commercially available molecular hydrogen (H_2) into atomic hydrogen (H). The atoms emerge from the source into a region that is evacuated to 10^{-6} torr and enter a state selecting magnet which has three north poles alternating in a circle with three south poles. By symmetry, the magnetic field is zero on the axis and increases in magnitude away from the axis. Since the energy of a hydrogen atom in the $F = 1$ $m = 0$ state increases with magnetic field and since mechanical systems are accelerated toward lower potential energy, an atom in the $F = 1$ state that is slightly off axis will be accelerated toward the axis, i.e. the $F = 1$ state will be focussed onto the small aperture of the 15-cm-diameter storage cell, whereas the lower energy $F = 0$ state is defocussed. As a result, if the atomic beam flows steadily, the storage bottle in equilibrium will contain more high energy $F = 1$ atoms than low energy $F = 0$ atoms. If these atoms are exposed to microwave radiation at the hyperfine frequency, more atoms are stimulated to go from the higher energy state to the lower one than in the opposite direction. Energy is then released from the atoms and makes the microwave radiation stronger. Thus the device is an amplifier or maser. If the storage cell is placed inside a tuned cavity, an oscillation at the resonance frequency will increase in magnitude until an equilibrium value is reached. At this level the oscillation will continue indefinitely, with the energy to maintain the oscillation coming from the continuing supply of hydrogen atoms in the high energy hyperfine state. The device then becomes a free running maser oscillator at the atomic hyperfine splitting frequency.

The atomic hydrogen maser oscillator has unprecedented high stability due to a combination of favorable features. The atoms typically reside in the storage cell for 10 seconds, which is much longer than in an atomic beam resonance apparatus, so the resonance line is much narrower. The atoms are stored at low pressure, so they are relatively free and unperturbed while radiating. The first order Doppler shift is removed, since the atoms are exposed to a standing wave and since the average velocity is extremely low for atoms stored for 10 seconds. Masers have very low noise levels, especially when the amplifying elements are isolated atoms. Over periods of several hours the hydrogen maser stability is better than 1×10^{-15}.

The major disadvantage of the hydrogen maser is that the atoms collide with the walls at intervals, changing slightly the hyperfine frequency and giving rise to wall shifts of 1×10^{-11}. However, the wall shifts can be experimentally determined by measurements utilizing storage bottles of two different diameters or with a deformable bulb whose surface to volume ratio can be altered. As in all precision measurements, care must be taken in adjusting and tuning the hydrogen maser to avoid misleading results. These limitations and precautions are discussed in a series of publications by various authors.[32-34] The designs of hydrogen masers have been modified in many ways either for special purposes or for increased stability and reliability. For example, different hyperfine transitions have been used and masers have been operated in relatively strong magnetic fields. A hydrogen maser has also been operated[17] with a storage bottle that is much larger than the wavelength of the stimulating radiation by confining the microwave power to two small cavities so that it functions as a separated oscillatory field device. As shown in Figure 10 the atoms that are stimulated to emit radiation move randomly into and out of the two oscillatory field cavities and spend the intermediate time in the large container where there is no oscillatory field. Due to the larger size of the storage box the storage times are longer and wall collisions are less frequent, so the resonances are narrower and the wall shifts are smaller than for a normal hydrogen maser.

Now that I have discussed extensively the principles of the separated oscillatory field method and of the atomic maser, I shall give some illustrations as to their value. One major category of applications is to precision spectroscopy, espe-

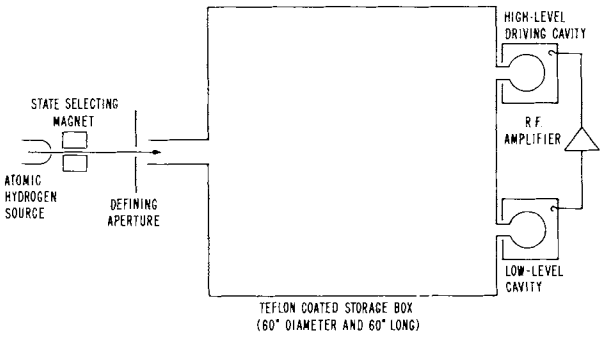

Fig. 10. Schematic diagram of a large box hydrogen maser. The two cavities on the right act as two separated oscillating fields with that of the high level cavity being obtained by amplification from the low level cavity.

cially at radio and microwave frequencies. Another category of applications is to atomic clocks and frequency standards.

Precision Spectroscopy

It is difficult to summarize the spectroscopic applications since there are so many of them. Beautiful experiments have been done by a large number of scientists in different countries. I shall, therefore use just a few illustrations from experiments in which I have been personally involved.

My graduate students have made precision measurements of the radiofrequency spectra of different molecules in various rotational states. For each of these states more than seven different molecular properties can be inferred and thus the variations of the properties with changes in the rotational and vibrational quantum numbers can be determined. These properties include nuclear and rotational magnetic moments, nuclear quadrupole interactions, nuclear spin-spin magnetic interactions, spin rotational interactions, etc. I shall illustrate the accuracy and significance of the measurements with a single example. With both D_2 and LiD we have accurately measured[35, 36] the deuteron quadrupole interaction eqQ where e is the proton electric charge, q is the gradient of the molecular electric field at the deuteron and Q is the deuteron quadrupole moment which measures the shape of the deuteron and in particular its departure from spherical symmetry. These measurements were made with the high-resolution molecular beam apparatus based on the method of separated oscillatory fields that is shown in Figure 1. We found for eqQ the value $+225\,044 \pm 20$ Hz in D_2 and $+34\,213 \pm 33$ Hz in LiD. Since q has been calculated[37, 38] for each of these quite different molecules, two independent values of Q can be calculated. The results agree to within 1.5%, which confirms the validity of the difficult calculation of q; with it we find $Q = 2.9 \times 10^{-27}$ cm^2.

In an experiment with collaborators[39] at the Institut Laue-Langevin at Grenoble, France, we have used the separated oscillatory field method with a beam of slow neutrons to make an accurate measurement of the neutron magnetic moment and found[37, 40] it to be $-1.91304275 \pm 0.00000045$ nuclear magnetons. In a somewhat different experiment with neutrons moving so slowly that they can be bottled for more than 80 s in a suitable storage vessel, we have used the method of successive oscillatory fields with the two coherent radiofrequency pulses being separated in time rather than space. In this manner and as a fundamental test of time reversal symmetry, we have recently set a very low upper limit for the neutron electric dipole moment by finding[41] its value to be $(-3 \pm 5) \times 10^{-26}$ e cm.

The atomic hydrogen maser gives very accurate data on the microwave spectrum of the ground electronic state of the hydrogen atom. The hyperfine frequency $\Delta\nu$ for atomic hydrogen has been measured in our laboratory and in a number of other laboratories. The best value[42, 43] is $\Delta\nu_H = 1\,420\,405\,751.7667 \pm 0.0009$ Hz.

This value agrees with present quantum electromagnetic theory[44] to within the accuracy of the theoretical calculation and can be used to obtain information on the proton structure. Similarly accurate values have been found for atomic deuterium and tritium and the dependence[45] of these results on the strengths of externally applied electric fields has been measured. With a modified form of the hydrogen maser designed to operate at high magnetic fields, the ratio of the magnetic moment of the electron to that of the proton is found[40, 46] to be -658.210688 ± 0.000006. Incidentally, when this result is combined with the beautiful electron measurements from Professor *Dehmelt*'s laboratory[40, 47, 48] one obtains the best values for the free proton magnetic moment in both Bohr μ_B and nuclear magnetons (μ_N).

Atomic Clocks

In the past 50 years there has been a major revolution in time keeping, with the accuracy and reproducibility of the best clocks at the end of that period being approximately a million times those at the beginning. This revolution in timekeeping and frequency control is due to atomic clocks.

Any clock or frequency standard depends on some regular periodic motion such as the pendulum of the grandfather's clock. In the case of atomic clocks the periodic motion is internal to the atoms and is usually that associated with an atomic hyperfine structure as discussed in the section on the atomic hydrogen maser.

In the most widely used atomic clocks, the atom whose internal frequency provides the periodicity is cesium and the usual method of observing it is with a separated oscillatory field magnetic resonance apparatus as in Figure 2. The first commercial cesium beam clock was developed in 1955 by a group led by *J. R. Zacharias*[4] and in the same year *L. Essen* and *V. L. Parry*[4] constructed and operated the first cesium beam apparatus that was extensively used as an actual frequency standard. Subsequently, many scientists and engineers throughout the world contributed to the development of atomic clocks, as discussed in greater detail elsewhere.[4]

Cesium atomic clocks now have an accuracy and stability of about 10^{-13} which was so far superior to all previous clocks that in 1967 the internationally adopted definition of the second was changed from one based on motion of the earth around the sun to 9 192 631 770 periods of the cesium atom.

For many purposes even greater stability is required over shorter time intervals. When such stability is needed the hy-

drogen maser is frequently used with a stability of 10^{-15} over periods of several hours.

Atomic clocks based on the above principles have for a number of years provided the greatest stability and accuracy and these are sufficiently great that further improvements might seem to be neither desirable nor feasible. But as we shall see in our final section, there are applications that already push atomic clocks to their limits and there are many current developments with great promise for the future. These include improvements to the existing devices, use of higher frequency, use of lasers, electromagnetic traps for storing both ions and atoms, laser cooling, etc.

Applications for Accurate Clocks

Accurate atomic clocks are used for so many different purposes that a list of them all is tediously long so I shall here just briefly mention a few that push clock technology to its limit.

In radio astronomy one looks with a parabolic reflector at the radio waves coming from a star just as in optical astronomy one looks with an optical telescope at the light waves coming from a star. Unfortunately, in radio astronomy the wavelength of the radiation is about a million times longer than the wavelength of light. The resolution of the normal radio telescope is therefore about a million times worse since the resolution of a telescope depends on the ratio of the wavelength to the telescope aperture. However, if there are two radio telescopes on opposite sides of the earth looking at the same star and if the radio waves entering each are matched in time, it is equivalent to a single telescope whose aperture is the distance between the two telescopes and the resolution of such a combination exceeds that of even the largest single optical telescope. However, to do such precise matching in time each of the two radio telescopes needs a highly stable clock, usually an atomic hydrogen maser.

One of the exciting discoveries in radio astronomy has been the discovery of pulsars, that emit their radiation in short periodic pulses. Precision clocks have been needed to measure the pulsar periods and the changes in the periods with time; these changes sometimes occur smoothly and sometimes abruptly. Of particular interest from the point of view of time measurements, are the millisecond pulsars which have remarkable constancy of period, rivaling the stability of the best atomic clocks.[49] Another millisecond pulsar is part of a rapidly rotating binary star that is slowly changing its period of rotation.[49] This slow change in rotation can be attributed to the loss of energy by the radiation of gravity waves—the first experimental evidence for the existence of gravity waves.

Time and frequency can now be measured so accurately that wherever possible other fundamental measurements are reduced to time or frequency measurements. Thus, the unit of length by international agreement has recently been defined as the distance light will travel in a specified time, and voltage may soon be represented in terms of frequency measurements.

Accurate clocks have provided important tests of both the special and general theories of relativity. In one experiment,[50] a hydrogen maser was shot in a rocket to a 6000 mile altitude and its periodic rate changed with speed and altitude just as expected by the special and general theories of relativity. In other experiments, observers have measured the delays predicted by relativity for radio waves passing near the sun.

Precision clocks make possible an entirely new and more accurate navigational system, the global positioning system or GPS. A number of satellites containing accurate atomic clocks transmit signals at specific times so any observer receiving and analyzing the signals from four such satellites can determine his position to within ten yards and the correct time within one hundredth of a millionth of a second (10^{-8} s).

A particularly fascinating navigational feat dependent on accurate clocks was the recent and highly successful tour of the Voyager spacecraft to Neptune. The success of this mission depended upon the ground controllers having accurate knowledge of the position of the Voyager. This was accomplished by having three large radio telescopes at different locations on the earth, each of which transmitted a coded signal to Voyager which in turn transmitted the signals back to the telescopes. The distances from each telescope to Voyager could be determined from the elapsed times and thus Voyager could be located. To achieve the required timing accuracy, two hydrogen masers were located at each telescope. Due to the rotation of the earth in the eight hours required for the electromagnetic wave to travel from the earth to Voyager and back again at the speed of light, the telescope transmitting the signal in some cases had to be different from the one receiving it; this placed an additional stringent requirement on the clocks. Thus, the spectacular success of the Voyager mission depended on the availability of highly stable clocks.

Experiments with an Isolated Subatomic Particle at Rest (Nobel Lecture)**

By Hans Dehmelt*

"You know, it would be sufficient to really understand the electron."

Albert Einstein

The 5th century B. C. philosopher *Democritus*' smallest conceivable in-divisible entity, the "a-tomon" (the un-cuttable), is a most powerful but not an immutable concept. By 1930 it had already metamorphosed twice: from something similar to a molecule, say a slippery atomon of water, to *Mendeleyev*'s chemist's atom and later to electron and to proton, both particles originally assumed to be of small but finite size. With the development of *Dirac*'s theory of the electron in the late twenties their size shrunk to mathematically zero. Everybody "knew" then that electron and proton were indivisible Dirac point particles with radius $R = 0$ and gyromagnetic ratio $g = 2.00$. The first hint of cuttability or at least compositeness of the proton came from *Otto Stern*'s 1933 measurement of proton magnetism in a Stern-Gerlach molecular beam apparatus. However, this was not realized at the time. He found for its normalized dimensionless gyromagnetic ratio not $g = 2$ but $g \approx 5$ [Eq. (1)],

$$g = (\mu/A)(2M/q) \approx 5, \tag{1}$$

where μ, A, M, q are respectively magnetic moment, angular momentum, mass and charge of the particle. For comparison the obviously composite $^4He^{\oplus}$ ion, also with spin 1/2, has according to the above formula the $|g|$ value 14 700, much larger than the Dirac value 2. Also, along with this large $|g|$ value went a very finite radius of this atomic ion of 3×10^{-11} m. And indeed, with *Hofstadter*'s high-energy electron scattering experiments in the fifties the proton radius grew again to $R = 0.86 \times 10^{-15}$ m, roughly in proportion to the excess in g of 3. Similar later work at still higher energies led to the discovery of three quarks inside the "indivisible" proton. Today, everybody "knows" that the *electron* is an indivisible atomon, a Dirac point particle with radius $R = 0$ and $g = 2.00$. ... But is it? Like the proton, it could be a composite object. History may well repeat itself once more. This puts a high premium on precise measurements of the g factor of the electron.

Geonium Spectroscopy

The metastable pseudo-atom geonium[1,2] has been expressly synthesized for studies of the electron g factor under optimal conditions. It consists of an individual electron permanently confined in an ultrahigh vacuum Penning trap at 4 K. The trap employs a homogeneous magnetic field $B_0 = 5$T and a weak electric quadrupole field. The latter is produced by hyperbolic electrodes, a positive ring and two negative caps spaced $2Z_0 = 8$ mm apart (see Fig. 1). The

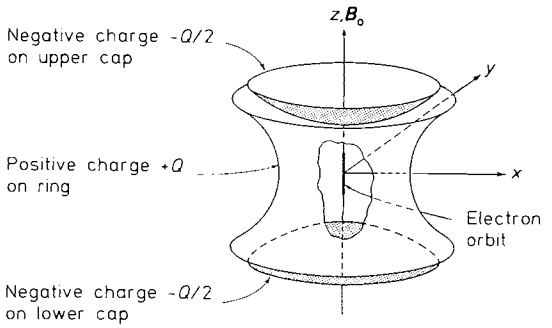

Fig. 1. Penning trap. The simplest motion of an electron in the trap is along its symmetry axis, along a magnetic field line. Each time it comes too close to one of the negatively charged caps it turns around. The resulting harmonic oscillation took place at about 60 MHz in our trap. (After [12].)

potential $\varphi(xyz)$, with A a constant, is given by Equation (2). The axial potential well depth D is 5 eV [Eq. (3)].

$$\varphi(xyz) = A(x^2 + y^2 - 2z^2) \tag{2}$$

$$D = e[\varphi(000) - \varphi(00Z_0)] = 2eAZ_0^2 = 5\,\text{eV} \tag{3}$$

The trapping of the electron is mostly magnetic. The large magnetic field dominates the motion in the geonium atom.

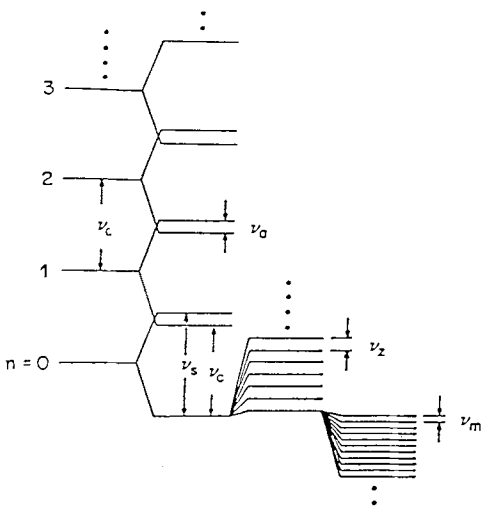

Fig. 2. Energy levels of geonium. Each of the cyclotron levels labeled n is split first by the spin–magnetic field interaction. The resulting sublevels are further split into the oscillator levels, and finally into the manifold of magnetron levels. (After [1].)

The energy levels of this atom shown in Figure 2 reflect the cyclotron motion at frequency $\nu_c = eB_0/2\pi m = 141$ GHz, the spin precession at $\nu_s \approx \nu_c$, the anomaly or $g-2$ frequency $\nu_a = \nu_s - \nu_c = 164$ MHz, the axial oscillation at $\nu_z = 60$ MHz, and the magnetron or drift motion at a frequency $\nu_m = 13$ kHz. The electron is continuously monitored by exciting the ν_z-oscillation and detecting via radio the 10^8-fold enhanced spontaneous 60 MHz emission. A corresponding signal is seen in Figure 3. Doppler side band cooling has

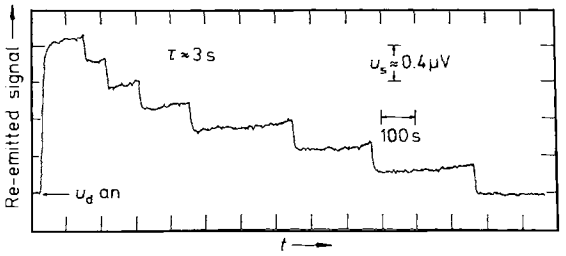

Fig. 3. Rf signal produced by trapped electron. When the electron is driven by an axial rf field, it emits a 60-MHz signal, which was picked up by a radio receiver. The signal shown was for a very strong drive and an initially injected bunch of seven electrons. One electron after the other was randomly "boiled" out of the trap until finally only a single electron was left. By reducing the drive power somewhat, this last electron could be observed indefinitely. (After [13].)

made continuous confinement of an electron in the trap center for 10 months possible.[3] This process makes the electron absorb rf photons deficient in energy and supply the balance from energy stored in the electron motion to be cooled.

The corresponding shrinking of the radius of the magnetron motion is displayed in Figure 4. Extended into the optical region, the cooling scheme is most convincingly demonstrated in Figure 5. The transitions of primary interest at ν_c, ν_a, ν_m are much more difficult to detect than the ν_z oscillation. Nevertheless, the task may be accomplished by means of the continuous Stern-Gerlach effect,[4] whereby the geonium atom itself is made to work as a 10^8-fold amplifier. In the scheme a single ν_a-photon of only about 1 μeV energy gates the absorption of approximately 100 eV of rf power at ν_z. The continuous effect uses an inhomogeneous magnetic field in a similar way as the classic one. However, the field now takes the form of a very weak Lawrence cyclotron trap or magnetic "bottle" (cf. Fig. 6a). The "bottle" adds only a minute monitoring well D_m to the axial potential well of large electrostatic depth $D = 5$ eV [Eq. (4)], where m and n respec-

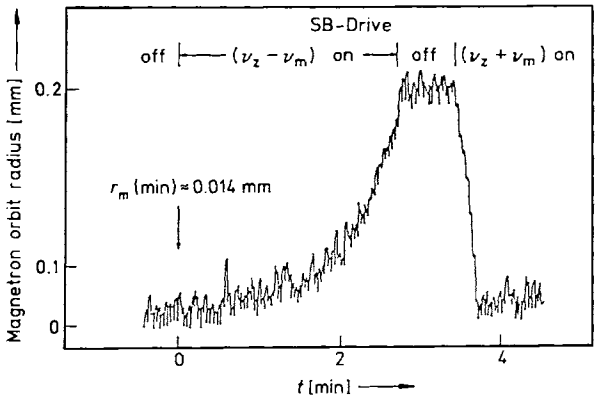

Fig. 4. Side-band "cooling" of the magnetron motion at ν_m. By driving the axial motion not on resonance at ν_z but on the lower Doppler side-band at $\nu_z - \nu_m$, it is possible to force the metastable magnetron motion to provide the energy balance $h\nu_m$, and thereby expand the magnetron orbit radius. Conversely, an axial drive at $\nu_z + \nu_m$ shrinks the radius. The roles of upper and lower side bands are reversed here from the case of a particle in a well, where the energy increases with amplitude because the magnetron motion is metastable and the total energy of this motion *decreases* with radius. (After [1].)

$$D_m = (m + n + 1/2)\,0.1\ \mu\text{eV} \tag{4}$$

tively denote the spin and cyclotron quantum numbers. Thus, jumps in m or n show up as jumps in ν_z [Eq. (5)].

$$\nu_z = \nu_{z0} + (m + n + 1/2)\,\delta \tag{5}$$

In our experiments $\delta = 1.2$ Hz, and ν_{z0} corresponds to the axial frequency of a hypothetical electron without magnetic moment. Random jumps in m and n occur when spin or cyclotron resonances are excited. Figure 6b shows an early example of a series of such jumps in m (spin flips). For the spin, spontaneous transitions are totally negligible. Standard text books discuss transitions between two sharp levels induced by a broad electromagnetic spectrum $\varrho(\nu)$: The transition rate from either level is the same and is proportional to the spectral power density $\varrho(\nu_s)$ of the radiation field at the transition frequency ν_s. Ergo, the average dwell times in either level are the same, (cf. Fig. 6a). In the geonium experiments the frequency of the weak rf field is sharp, but the spin resonance is broadened and has a shape $G_s(\nu)$. One may convince oneself that moving the sharp frequency of the rf field upwards over the broad spin resonance should produce the same results as moving a broad rf field of spectral shape $\varrho(\nu) \propto G_s(\nu)$ downwards over a sharp spin resonance: The

Hans Georg Dehmelt was born on September 9, 1922 in Görlitz (GDR). He studied physics at the Universities of Breslau and Göttingen. As a student of H. Kopfermann he also met up with Wolfgang Paul in Göttingen, where he was awarded his Dr. rer. nat. in 1950 for his Studies on Nuclear Quadrupole Resonance (title of his Dissertation) under the supervision of H. Krüger. His studies on and co-discovery of nuclear quadrupole resonance were of great importance for the study of chemical bonding. In 1952 he joined Walther Gordy's laboratory at Duke University in Durham, NC, USA, as a postdoctoral associate. Since 1955 he has been a faculty member of the University of Washington in Seattle, USA. He has been a naturalized American citizen for more than 30 years.

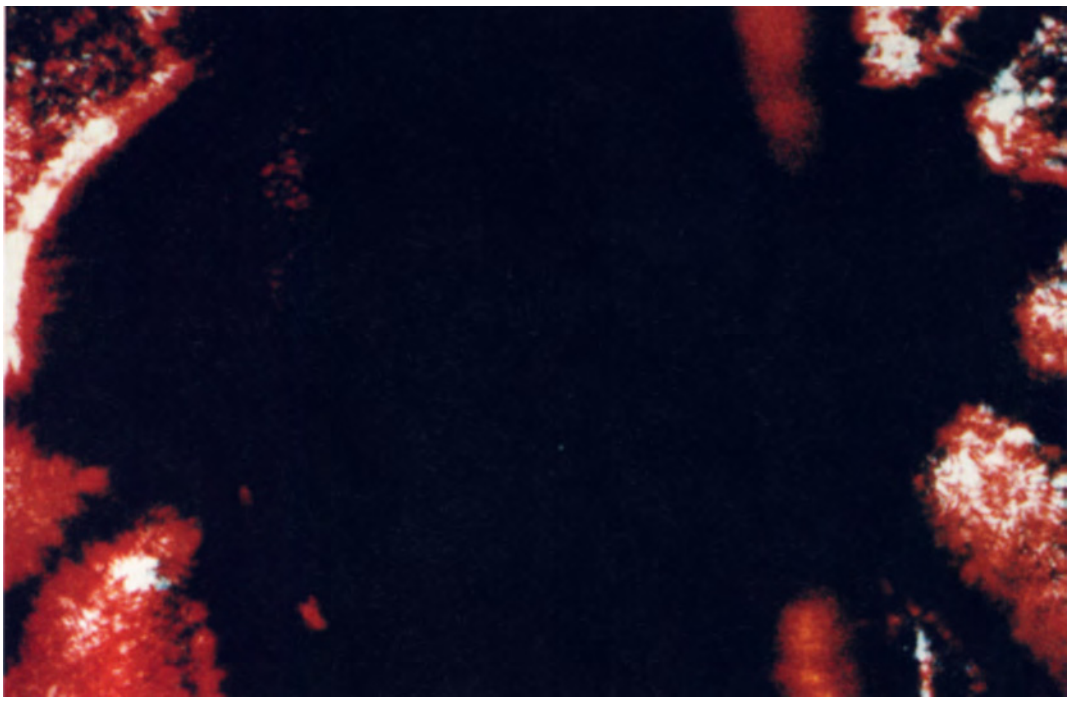

Fig. 5. Visible blue (charged) barium atom "Astrid" at rest in the center of a Paul trap photographed in natural color. The photograph strikingly demonstrates the close localization ($\ll 1$ μm) attainable with geonium cooling techniques. Stray light from the lasers focussed on the ion also illuminates the ring electrode of the tiny rf trap of about 1 mm internal diameter. (After [4].)

rate of all spin flips or jumps in m in either direction counted in the experiment is proportional to $G_s(\nu)$. To obtain the plot of $G_s(\nu)$ in Figure 7 the frequency of the rf field was increased in small steps, and at each step spin flips were counted for a fixed period of about half an hour. From our ν_s, ν_c data for electron and positron[5] we have determined the value shown

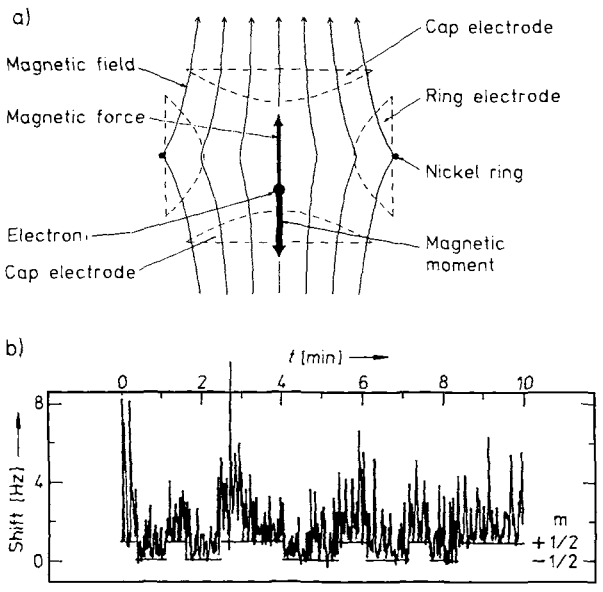

Fig. 6. a) Weak magnetic bottle for continuous Stern-Gerlach effect. When in the lowest cyclotron and magnetron level the electron forms a 1-μm long wave packet, 30 nm in diameter, which may oscillate undistorted in the axial electric potential well. The inhomogeneous field of the auxiliary magnetic bottle produces a minute spin-dependent restoring force that causes the axial frequency ν_z for spin ↑ and ↓ to differ by a small but detectable value. (After [14].) b) Spin flips recorded by means of the continuous Stern-Gerlach effect. The random jumps in the base line indicate jumps in m at a rate of about 1 per minute when the spin resonance is excited. The upwards spikes or "cyclotron grass" are explained by expected rapid random thermal excitation and spontaneous decay of cyclotron levels with an average value $\langle n \rangle \approx 1.2$. (After [15].)

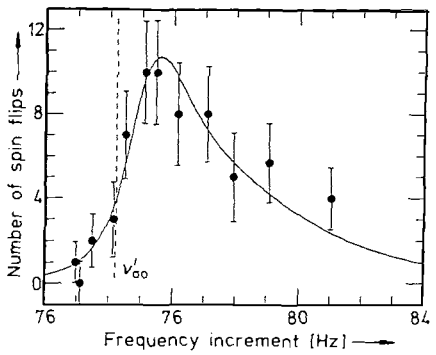

Fig. 7. Plot of electron spin resonance in a geonium atom near 141 GHz. A magnetic radiofrequency field causes random jumps in the spin quantum number. As the frequency of the exciting field is stepped through the resonance in small increments, the number of spin flips occurring in a fixed observation period of about 1/2 hour are counted and then plotted vs frequency. (Actually the 141 GHz field flipping the spin is produced by the cyclotron motion of the electron through an inhomogeneous magnetic rf field at $\nu_s - \nu_c = 164$ MHz.) (After [5].)

in (6), both for the particle and for the anti-particle. The

$$\tfrac{1}{2} g^{exp} = \nu_s/\nu_c = 1.001\ 159\ 652\ 188(4) \qquad (6)$$

error in the difference of their g factors is only half as large. Heroic quantum electrodynamical calculations by *Kinoshita*[6] have yielded for the shift of the g factor of a point

electron associated with turning on the interaction with the electromagnetic radiation field the expression (7).

$$\tfrac{1}{2}(g^{\text{point}} - 2) = \tfrac{1}{2}\Delta g^{\text{Kinoshita}} = 0.001\ 159\ 652\ 133(29) \quad (7)$$

In the calculations $\Delta g^{\text{Kinoshita}}$ is expressed as a power series in α/π. *Kinoshita* has critically evaluated the experimental α input data on which he must rely. He warns that the error in his result, which is dominated by the error in α, may be underestimated. Muonic, hadronic and other small contributions to g amount to less than about 4×10^{-12} and have been included in the shift. *Kinoshita*'s result may be used to correct the experimental g value, and leads to (8).

$$g = g^{\text{exp}} - \Delta g^{\text{Kinoshita}} = 2 + 11(6) \times 10^{-11} \quad (8)$$

Electron Radius R?

Extrapolation from known to unknown phenomena is a time-honored approach in all the sciences. Thus, from known g and R values of other "near-Dirac particles" and our *measured* g value of the electron I attempt to extrapolate a value for its radius. Stimulated by the theoretical works of *Brodsky* and *Drell* in the year 1980,[7] I have plotted $g - 2$ vs $R/\lambda\!\!\!^{-}_{C}$ in Figure 8 for the helium-3 nucleus, triton, proton, and electron.[8] Here, $\lambda\!\!\!^{-}_{C}$ is the Compton wavelength of the respective particle. The plausible relation [Eq. (9), (10)], given by *Brodsky* and *Drell* for the simplest composite theoretical model of the electron,[7] fits the admittedly sparse data surprisingly well. Even for such a very different spin ½ structure as the atomic ion $^4He^{\oplus}$ composed of an α-particle and an electron the data point does not fall too far off the full line. Intersection in Figure 8 of this line with the line

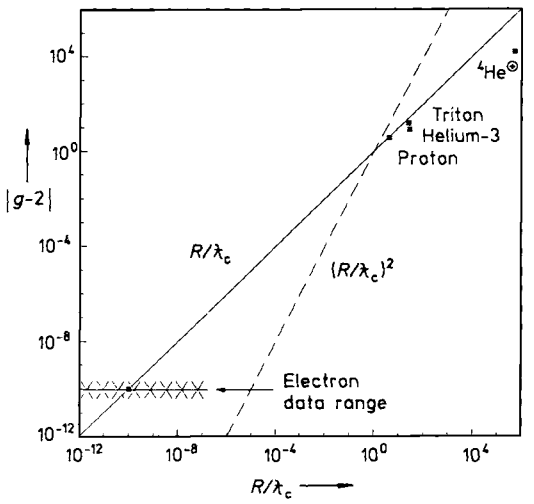

Fig. 8. Plot of $|g - 2|$ values, with radiative shifts removed, vs reduced rms radius $R/\lambda\!\!\!^{-}_{C}$ for near-Dirac particles. The full line $|g - 2| = R/\lambda\!\!\!^{-}_{C}$ predicted by the simplest theoretical model provides a surprisingly good fit to the data points for proton, triton and helium-3 nucleus. It may be used to obtain a new radius value for the *physical* electron from its intersection with the line $|g - 2| = 1.1 \times 10^{-10}$ representing the Seattle electron g data. The data are much less well fitted by the relation $|g - 2| = (R/\lambda\!\!\!^{-}_{C})^2$, which is shown for comparison in the dashed line. The atomic ion $^4He^{\oplus}$ is definitely *not* a near-Dirac particle, but even its data point does not fall too far off the full line.

$g - 2 = 1.1 \times 10^{-10}$ for our g value yields for the electron the extrapolated point shown and gives with $\lambda\!\!\!^{-}_{C} = 0.39 \times 10^{-10}$ cm an electron radius of $R \approx 10^{-20}$ cm.

$$|g - 2| = R/\lambda\!\!\!^{-}_{C} \quad (9)$$

$$|g - g_{\text{Dirac}}| = (R - R_{\text{Dirac}})/\lambda\!\!\!^{-}_{C} \quad (10)$$

The row of X's in Figure 8 reflects the data range defined by the uncertainty in our g data and the upper limit $R < 10^{-17}$ cm determined in high energy collision experiments. It appears that this combination of current data is not in harmony with electron structure models assuming special symmetries that predict the quadratic relation $|g - 2| \approx (R/\lambda\!\!\!^{-}_{C})^2$ (shown by the dashed line in Fig. 8). This favors the linear relation used in the above extrapolation of R for the electron. Thus, the electron may have *size* and *structure*!

If one feels that the excess g value $11(6) \times 10^{-11}$ measured is not significant because of its large relative error, then the value $R \approx 10^{-20}$ cm given here still constitutes an important new upper limit. Changing the point of view the close agreement of g^{point} with g^{exp} provides the most stringent experimental test of the fundamental theory of quantum electrodynamics in which $R = 0$ is assumed. Furthermore, the near-identity of the g values measured by us for electron and positron constitutes the most severe test of the CPT theorem (CPT = *C*harge-*P*arity-*T*ime reversal theory) or mirror symmetry of a *charged* particle-antiparticle pair.

Lemaître's "L'Atome Primitif" Revisited—A Speculation

From 1974 on *Salam* and others have proposed composite electron and quark models.[9] On the strength of these proposals and with an eye on Figure 8, I view the electron as the third approximation of a Dirac particle, d_3 particle for short, and as composed of three fourth-approximation Dirac or d_4 particles. The situation is taken to be quite similar to that previously encountered in the triton and proton subatomic particles, respectively assumed to be of type d_1 and d_2. In more detail, three d_4 subquarks of huge mass $m' \approx 10^{10}\, m_e$ in a deep square well make up the electron in this working hypothesis. However, their mass $3m_4$ is almost completely compensated by strong binding to yield a total relativistic mass equal to the observed mass m_e of the electron. Figure 8 may even suggest a more speculative extrapolation: The constituents of the electron in the infinite regression $N \rightarrow \infty$ proposed in Figure 9 have ever more massive, ever smaller sub-sub-..... constituents d_N. However, these higher order subquarks are realized only up to the "cosmon" with $N = C$, the most massive particle ever to appear in this universe. At the beginning of the universe, a lone bound cosmon-anticosmon pair or lifetime-broadened cosmonium atomic state of near-zero total relativistic mass/energy was created from *Vilenkin*'s metastable "nothing" state of zero relativistic energy[10] in a spontaneous quantum jump of cosmic rarity. Similar, though much more frequent, quantum jumps that have recently been observed in a trapped $Ba^{\oplus}$ ion are shown in Figure 10. In this case the system also jumps spontaneous-

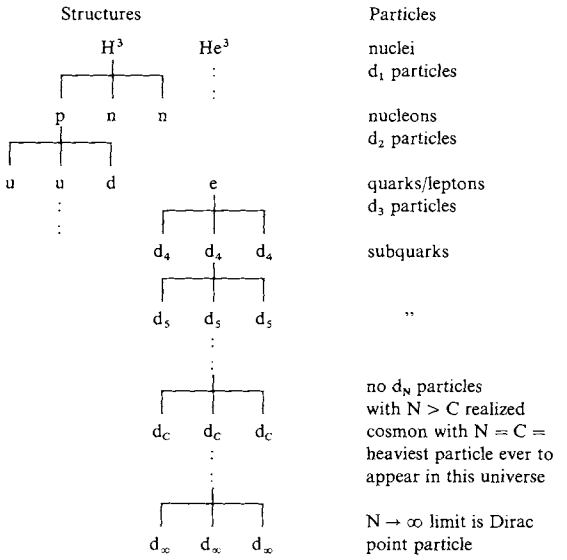

Fig. 9. Triton model of "near-Dirac particles". (After [17].)

ly from one state (ion in metastable $D_{5/2}$ level plus no photon) to a new state (ion in $S_{1/2}$ ground level plus photon) of the same total energy. The "cosmonium atom" introduced here is merely a modernized version[19] of Lemaître's "l'atome primitif"[11] or world-atom whose explosive radioactive decay created the universe. At the beginning of the world the short-lived cosmonium atom decayed into an early gravitation-dominated standard big bang state that eventually developed into a state, in which again rest mass energy, kinetic, and Newtonian gravitational potential energy add up to zero (see formula 8 in Ref. [20]). The electron is a much more complex particle than the cosmon. It is composed of 3^{C-3} cosmon-like d_C particles, but only two particles of this type formed the cosmonium world-atom from which sprang the universe. In closing, I should like to cite a line from *William Blake*: *"To see a world in a grain of sand ---"*, and allude to a conceivable parallel: to see worlds in an electron —.

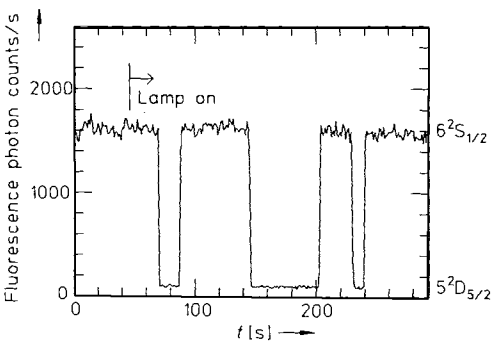

Fig. 10. Spontaneous decay of $Ba^{\oplus}$ ion in metastable $D_{5/2}$-level. Illuminating the ion with a laser tuned close to its resonance line produces strong resonance fluorescence and an easily detectable photon count of 1600 photons per second. Later, when an auxiliary, weak $Ba^{\oplus}$ spectral lamp is turned on, the ion is randomly transported into the metastable $D_{5/2}$ level of 30 s lifetime and becomes invisible. After dwelling in this shelving level for 30 s on the average, it drops down to the $S_{1/2}$ ground state *spontaneously* and becomes visible again. This cycle then repeats. (After [18].)

Electromagnetic Traps for Charged and Neutral Particles (Nobel Lecture)**

By Wolfgang Paul*

Introduction

Experimental physics is the art of observing the structure of matter and of detecting the dynamic processes within it. But in order to understand the extremely complicated behavior of natural processes as an interplay of a few constituents governed by as few as possible fundamental forces and laws, one has to measure the properties of the relevant constituents and their interaction as precisely as possible. And as all processes in nature are interwoven one must separate and study them individually. It is the skill of the experimentalist to carry out clear experiments in order to get answers to his questions undisturbed by undesired effects and it is his ingenuity to improve the art of measuring to ever higher precision. There are many examples in physics showing that higher precision revealed new phenomena, inspired new ideas, or confirmed or dethroned well established theories. On the other hand, new experimental techniques conceived to answer special questions in one field of physics became very fruitful in other fields too, be it in chemistry, biology, or engineering. In awarding the Nobel prize to my colleagues *Norman Ramsey, Hans Dehmelt* and me for new experimental methods the Swedish Academy indicates its appreciation for the aphorism the Göttingen physicist *Georg Christoph Lichtenberg* wrote two hundred years ago in his notebook "one has to do something new in order to see something new". On the same page *Lichtenberg* said: "I think it is a sad situation in all our chemistry that we are unable to suspend the constituents of matter free".

Today, the subject of my lecture will be the suspension of such constituents of matter or in other words, traps for free charged and neutral particles without material walls. Such traps permit the observation of isolated particles, even of a single one, over a long period of time and therefore according to Heisenberg's uncertainty principle enable us to measure their properties with extremely high accuracy.

In particular, the possibility to observe individual trapped particles opens up a new dimension in atomic measurements. Until a few years ago all measurements were performed on an ensemble of particles. Therefore, the measured value—for example, the transition probability between two eigenstates of an atom—is a value averaged over many particles. Tacitly one assumes that all atoms show exactly the same statistical behavior if one attributes the result to the single atom. On a trapped single atom, however, one can observe its interaction with a radiation field and its own statistical behavior alone.

The idea of building traps grew out of the molecular beam physics, mass spectrometry and particle accelerator physics I was involved in during the first decade of my career as a physicist more than 30 years ago. In these years (1950–55) we had learned that plane electric and magnetic multipole fields are able to focus particles with a magnetic or electric dipole moment in two dimensions. Lenses for atomic and molecular beams[1, 2, 3] were conceived and realized, improving considerably the molecular beam method for spectroscopy or for state selection. These lenses facilitated the development of both the ammonia as well as the hydrogen maser.[4]

The question "What happens if one injects charged particles, ions or electrons, into such multipole fields" led to the development of the linear quadrupole mass spectrometer. It employs not only the focusing and defocusing forces of a high-frequency electric quadrupole field acting on ions but also exploits the stability properties of their equations of motion in analogy to the principle of "strong focusing" for accelerators which had just been conceived in the same year.

If one extends the rules of two-dimensional focusing to three dimensions one possesses all ingredients for particle traps.

As already mentioned the physics or the particle dynamics in such focusing devices is very closely related to that in accelerators or storage rings for nuclear or particle physics. In fact, multipole fields were used in molecular beam physics first. But the two areas have complementary goals: the storage of particles, even of a single one, of extremely low energy down to the micro electron volt region on the one side, and of as many particles as possible of extremely high energy on the other. Today we will limit ourselves to the low energy region.

At first I will deal with the physics of dynamic stabilization of ions in two- and three-dimensional radio frequency quadrupole fields, the quadrupole mass spectrometer, and the ion trap. I shall then report on the trapping of neutral particles with emphasis on an experiment with magnetically stored neutrons.

As in most cases in physics, especially in experimental physics, the achievements are not the achievements of a single person, even if he contributed in posing the problems and some basic ideas in solving them. All the experiments I am awarded for were done together with research students or young colleagues in mutual inspiration. In particular, I have to mention in the very early days *H. Friedburg* and *H. G. Bennewitz, C. H. Schlier* and *P. Toschek* in the field of molecular beam physics, and in conceiving and realizing the linear quadrupole spectrometer and the r.f. ion trap *H. Steinwedel, O. Osberghaus* and especially the late *Erhard Fischer*. Later *H. P. Reinhard, U. v. Zahn* and *F. v. Busch* played an important role in developing this field.

Focusing and Trapping of Particles

What are the principles of focusing and trapping particles? Particles are elastically bound to an axis or a coordinate in

Physikalisches Institut der Universität
Nussallee 12, D-5300 Bonn (FRG)

[**] Copyright © The Nobel Foundation 1990. – We thank the Nobel Foundation, Stockholm, for permission to print this lecture.

space if a binding force acts on them which increases linearly with their distance r [Eq. (1)],

$$F = -cr \tag{1}$$

in other words if they move in a parabolic potential (2).

$$\Phi \sim (\alpha x^2 + \beta y^2 + \gamma z^2) \tag{2}$$

The tools appropriate for generating such fields of force to bind charged or neutral particles with a dipole moment are electric or magnetic multipole fields. In such configurations the field strength and the potential increases according to a power law and shows the desired symmetry. Generally, if m is the number of "poles" or the order of symmetry the potential is given by

$$\Phi \sim r^{m/2} \cos(m/2\,\varphi) \tag{3}$$

For a quadrupole $m = 4$ it gives $\Phi \sim r^2 \cos 2\varphi$, and for a sextupole $m = 6$ one gets $\Phi \sim r^3 \cos 3\varphi$ corresponding to a field strength increasing with r and r^2 respectively.

Trapping of Charged Particles in Two- and Three-Dimensional Quadrupole Fields

In the electric quadrupole field the potential is quadratic in the cartesian coordinates.

$$\Phi = \frac{\Phi_0}{2r_0^2}(\alpha x^2 + \beta y^2 + \gamma z^2) \tag{4}$$

The Laplace equation $\Delta\Phi = 0$ imposes the condition $\alpha + \beta + \gamma = 0$. There are two simple ways to satisfy this condition.

a) $\alpha = 1 = -\gamma$, $\beta = 0$ results in the two-dimensional field

$$\Phi = \frac{\Phi_0}{2r_0^2}(x^2 - z^2) \tag{5}$$

b) $\alpha = \beta = 1$, $\gamma = -2$ generates the three-dimensional configuration, in cylindrical coordinates

$$\Phi = \frac{\Phi^0(r^2 - 2z^2)}{r_0^2 + 2z_0^2} \quad \text{with} \quad 2z_0^2 = r_0^2. \tag{6}$$

The Two-Dimensional Quadrupole or the Mass Filter [5, 6]

The configuration a) is generated by four hyperbolically shaped electrodes linearly extended in the y-direction as shown in Figure 1. The potential on the electrodes is $\pm\Phi_0/2$

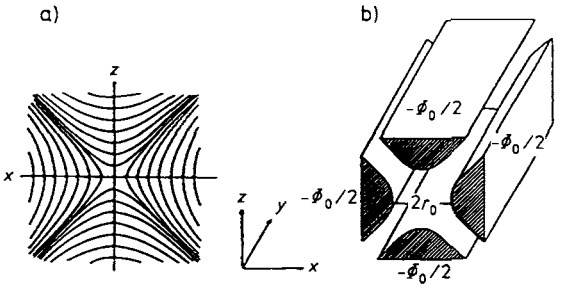

Fig. 1. a) Equipotential lines for a plane quadrupole field. b) the electrodes structure for the mass filter.

if one applies the voltage Φ_0 between the electrode pairs. The field strength is given by (7).

$$E_x = -\Phi_0 x/r_0^2, \quad E_z = \Phi_0 z/r_0^2, \quad E_y = 0 \tag{7}$$

If one injects ions in the y-direction it is obvious that for a constant voltage Φ_0 the ions will perform harmonic oscillations in the x–y plane but due to the opposite sign in the field E_z their amplitude in the z-direction will increase exponentially. The particles are defocused and will be lost by hitting the electrodes.

This behavior can be avoided if the applied voltage is periodic. Due to the periodic change of the sign of the electric force one gets focusing and defocusing in both the x- and z-directions alternating in time. If the applied voltage is given by a dc voltage U plus an r.f. voltage V with the driving frequency ω [Eq. (8)] the equations of motion are as given in (9) and (10).

$$\Phi_0 = U + V\cos\omega t \tag{8}$$

$$\ddot{x} + \frac{e}{mr_0^2}(U + V\cos\omega t)\,x = 0 \tag{9}$$

$$\ddot{z} - \frac{e}{mr_0^2}(U + V\cos\omega t)\,z = 0 \tag{10}$$

Wolfgang Paul, one of the most outstanding physicists of our time was born in 1913. He obtained his doctorate at the Technische Hochschule Berlin in 1939 and his habilitation at the University of Göttingen in 1944. Since 1952 he has been Professor for Experimental Physics at the University of Bonn. In the years 1958 and 1959 he was visiting professor at CERN in Geneva. 1960–1962 he was director of the KFA Jülich, 1964–1967 of the physics department at CERN, and from 1970–1973 of DESY in Hamburg. In 1970 he was Loeb Lecturer at Harvard University and in 1977 he was awarded an honorary doctorate by the University of Uppsala and by the Technische Hochschule Aachen. He is a member of the Akademie der Wissenschaften zu Düsseldorf und Leopoldina zu Halle. Since 1979 he has been the President of the Alexander-von-Humbold Stiftung. In 1989 he was awarded the Robert-Wichard-Pohl prize of the German Physical Society. Of his numerous discoveries and inventions, the Quadrupole Mass Spectrometer is of outstanding importance to the chemist.

At first sight one expects that the time-dependent term of the force cancels out in the time average. But this would be true only in a homogenous field. In a periodic inhomogenous field, like the quadrupole field there is a small average force left, which is always in the direction of the lower field, in our case toward the center. Therefore, certain conditions exists that enable the ions to traverse the quadrupole field without hitting the electrodes, i.e. their motion around the y-axis is stable with limited amplitudes in the x- and z-directions. We have learned these rules from the theory of the Mathieu equations, as this type of differential equation is called.

In dimensionless parameters these equations are written as in (11) and (12). By comparison with equations (9, 10) one obtains (13).

$$\frac{d^2x}{d\tau^2} + (a_x + 2q_x \cos 2\tau)\, x = 0 \tag{11}$$

$$\frac{d^2z}{d\tau^2} + (a_z + 2q_z \cos 2\tau)\, z = 0 \tag{12}$$

$$a_x = -a_z = \frac{4eU}{mr_0^2\omega^2}, \quad q_x = -q_z = \frac{2eV}{mr_0^2\omega^2}, \quad \tau = \frac{\omega t}{2} \tag{13}$$

The Mathieu equation has two types of solution:

1. Stable motion: the particles oscillate in the x–z-plane with limited amplitudes. They pass the quadrupole field in the y-direction without hitting the electrodes.

2. Unstable motion: the amplitudes grow exponentially in the x or z direction, or in both directions. The particles will be lost.

Whether stability exists depends only on the parameters a and q and not on the initial parameters of the ion motion, e.g. their velocity. Therefore, in an a,q-map there are regions of stability and instability (Fig. 2). Only the overlapping region for x and z stability is of interest for our problem. The most relevant region $0 < a,q < 1$ is plotted in Figure 3. The motion is stable in the x and z directions only within the triangle.

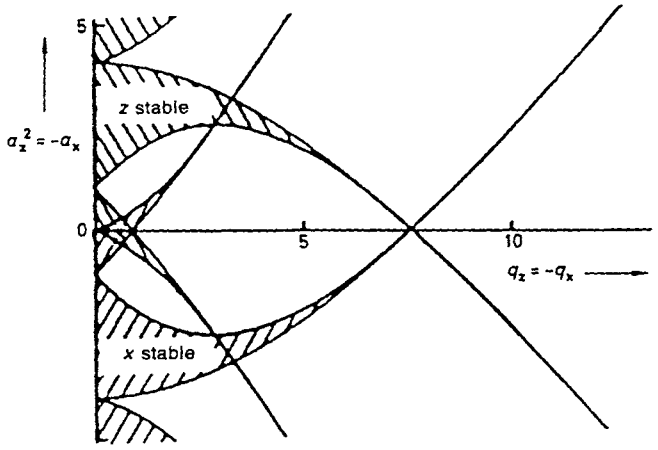

Fig. 2. The overall stability diagram for the two-dimensional quadrupole field.

For fixed values r_0, ω, U and V all ions with the same m/e have the same operating point in the stability diagram. Since

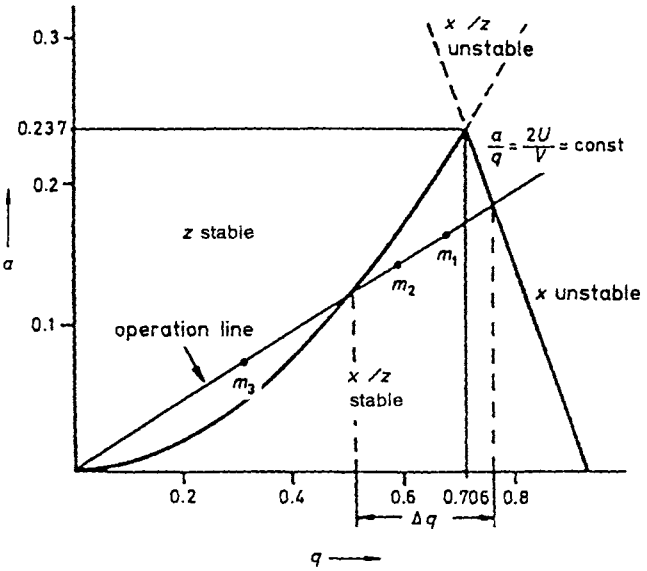

Fig. 3. The lowest region for simultaneous stability in x- and z-direction. All ion masses lie on the operation line. $m_2 > m_1$.

a/q is equal to $2U/V$ and does not depend on m, all masses lie along the operating line a/q = const. On the q axis ($a = 0$, no d.c. voltage) one has stability for $0 < q < q_{max} = 0.92$ with the consequence that all masses between $\infty > m > m_{min}$ have stable orbits. In this case the quadrupole field works as a high-pass mass filter. The mass range Δm becomes narrower with increasing dc voltage U, i.e. with a steeper operating line, and approaches $\Delta m = 0$ if the line goes through the tip of the stability region. The bandwidth in this case is given only by the fluctuation of the field parameters. If one changes U and V simultaneously and proportionally in such a way that a/q remains constant, one brings the ions of the various masses successively into the stability region, thus scanning through the whole mass spectrum in this way. That is the quadrupole acts as a mass spectrometer. A schematic representation of a quadrupole mass spectrometer is given in Figure 4.

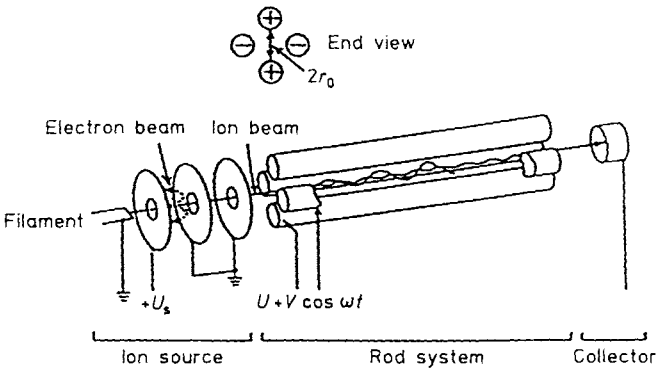

Fig. 4. Schematic view of the quadrupole mass spectrometer or mass filter.

Figures 5a and 5b show the first mass spectra obtained in 1954.[6] One can clearly see the influence of the d.c. voltage U on the resolving power.

The performance and application of such instruments were the subject of a number of theses at Bonn Universi-

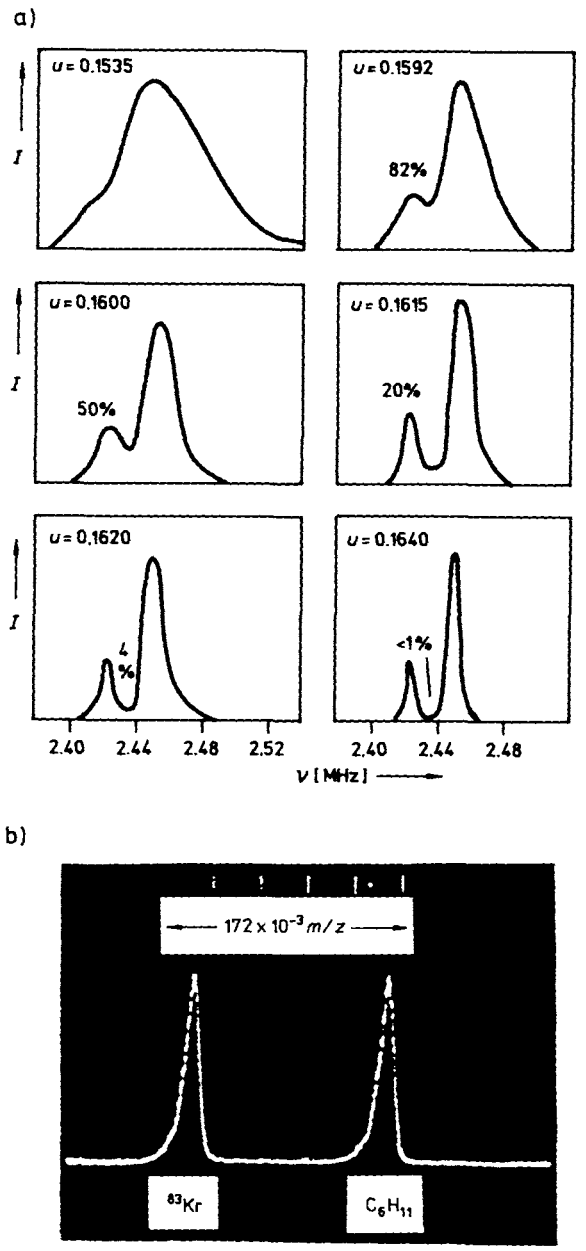

Fig. 5. a) First mass spectrum of rubidium. Mass scanning was achieved by periodic variation of the driving frequency ν. Parameter: $u = U/V$, at $u = 0.164$ ^{85}Rb and ^{87}Rb are fully resolved. I = ion current. b) Mass doublet ^{83}Kr—C_6H_{11}. Resolving power $m/\Delta m = 6500$ [9].

ty.[7–9] Thus, we studied the influence of geometrical and electrical imperfections giving rise to higher multipole terms in the field. A very long instrument ($l = 6$ m) for high precision mass measurements was built achieving an accuracy of 2×10^{-7} in determining mass ratios at a resolving power of $m/\Delta m = 16\,000$. On the other hand, very small instruments have been used in rockets to measure atomic abundances in the upper atmosphere. In another experiment we succeeded in separating isotopes in amounts of milligrams using a resonance method to shake single masses out of an intense ion beam guided into the quadrupole.

In the past years the r.f. quadrupole, whether as mass spectrometer or beam guide, has, owing to its versatility and technical simplicity, found broad applications in many fields of science and technology. It became a kind of standard instrument and its properties have been reported extensively in the literature.[10]

The Ion Trap

Already at the very beginning of our thinking about the dynamic stabilization of ions we were aware of the possibility of using it for trapping ions in a three-dimensional field. We called such a device an "Ionenkäfig" (ion cage).[11–13] Nowadays the word "ion trap" is preferred.

The potential configuration in the ion trap is given by Equation (6). This configuration is generated by an hyperbolically shaped ring and two hyperbolic rotationally symmetric caps as is shown schematically in Figure 6a. Figure 6b shows a section through the first realized trap in 1955.

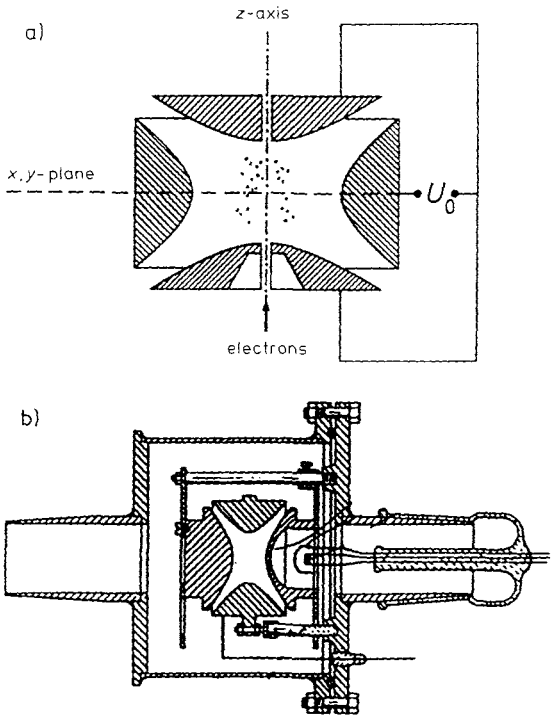

Fig. 6. a) Schematic view of the ion trap. b) Cross section of the first trap (1955).

If one brings ions into the trap, which is easily achieved by ionizing a low-pressure gas inside by electrons passing through the volume, they perform the same forced motions as in the two-dimensional case. The only difference is that the field in the z-direction is stronger by a factor 2. Again a periodic field is needed for the stabilization of the orbits. If the voltage $\Phi_0 = U + V \cos \omega t$ is applied between the caps and the ring electrode the equations of motion are represented by the same Mathieu functions [Eq. (11), (12)]. The relevant parameters for the r motion correspond to those in the x-direction in the two-dimensional case. Only the z parameters are changed by a factor 2.

Accordingly, the region of stability in the a, q-map for the trap (Fig. 7) has a different shape. Again the mass range of

the storable ions (i.e. ions in the stable region) can be chosen by the slope of the operation line $a/q = 2U/V$. Starting with operating parameters in the tip of the stable region one can trap ions of a single mass number. By lowering the d.c. voltage one brings the ions near the q-axis where their motions are much more stable.

For many applications it is necessary to know the frequency spectrum of the oscillating ions. From mathematics we learn that the motion of the ions can be described as a slow (secular) oscillation with the fundamental frequencies $\omega_{r,z} = \beta_{r,z}\omega/2$ modulated by a micromotion, a much faster oscillation of the driving frequency ω if one neglects higher harmonics. The frequency determining factor β is a function only of the Mathieu parameters a and q and therefore mass dependent. its value varies between 0 and 1; lines of equal β are drawn in Figure 7.

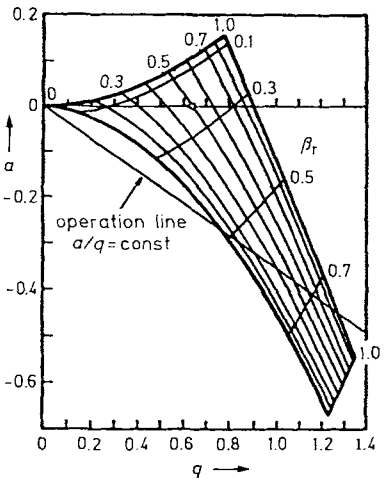

Fig. 7. The lowest region for stability in the ion trap. On the lines inside the stability region β_z and β_r respectively are constant.

Due to the stronger field, the frequency ω_z of the secular motion becomes twice ω_r. The ratio ω/ω_z is a criterion for the stability. Ratios of 10:1 are easily achieved and therefore the displacement by the micromotion averages out over a period of the secular motion.

The dynamic stabilization in the trap can easily be demonstrated in a mechanical analogue device. In the trap the equipotential lines form a saddle surface as is shown in Figure 8. We have machined such a surface on a round disc. If one puts a small steel ball on it, then it will roll down: its position is unstable. But if one let the disk rotate with the right frequency appropriate to the potential parameters and the mass of the ball (in our case a few turns/s) the ball becomes stable, makes small oscillations and can be kept in position over a long time. Even if one adds a second or a third ball they stay near the center of the disk. The only condition is that the related Mathieu parameter q be in the permitted range.[*]

This behavior gives us a hint of the physics of dynamic stabilization. The ions oscillating in the r- and z-directions

[*] I brought the device with me. It is made out of plexiglass, permitting the demonstration of the particle motions with the overhead projector.

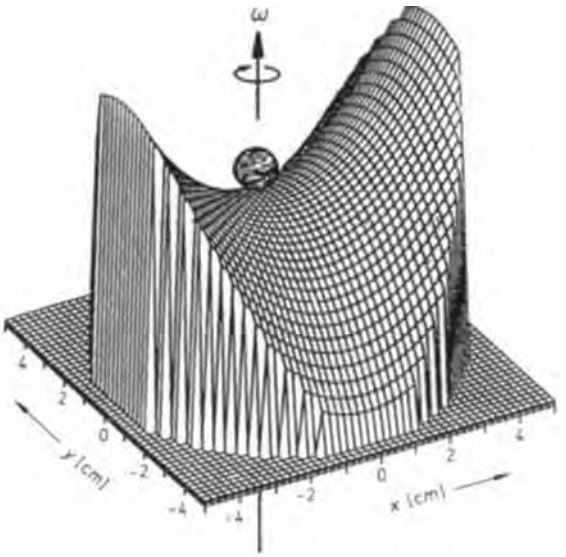

Fig. 8. Mechanical analogue model for the ion trap with steelball as "particle".

behave, to a first approximation, harmonically, as if they are moving in a pseudo potential well which increases quadratically in all coordinates. From their frequencies ω_r and ω_z we can calculate the depth of this well for both directions. It is related to the amplitude V of the driving voltage and to the parameters a and q. Without any d.c. voltage the depth is given by $D_z = (q/8)V$; in the r-direction it is half of this value. As in practice, V amounts to a few hundred volts, the potential depth is of the order of 10 volts. The width of the well is given by the geometric dimensions. The resulting configuration of the pseudo potential[14] is therefore given by Equation (14).

$$\Phi = D\frac{(r^2 + 4z^2)}{r_0^2 + 2z_0^2} \tag{14}$$

Cooling Process

As already mentioned, the depth of the relevant pseudo potential in the trap is of the order of a few volts. Accordingly the permitted kinetic energy of the stored ions is of the same magnitude and the amplitude of the oscillations can reach the geometrical dimensions of the trap. But for many applications one needs particles of much lower energy and well concentrated in the center of the trap. For precise spectroscopic measurements, in particular, it is desirable to have extremely low velocities to get rid of the Doppler effect and an eventual Stark effect, caused by the electric field. It becomes necessary to cool the ions. Relatively crude methods of cooling are the use of a cold buffer gas, or the damping of the oscillations by an external electric circuit. The most effective method is the laser-induced side-band fluorescence developed by *Wineland* and *Dehmelt*.[5]

In 1959 *Wuerker* et al.[16] performed an experiment trapping small charged aluminum particles ($\Phi \sim \mu$m) in the quadrupole trap. The necessary driving frequency was around 100 Hz. They studied all the eigenfrequencies and took photographs of the particle orbits (Figs. 9a, b). After

they had damped the motion with a buffer gas they observed that the randomly moving particles arranged themselves in a regular pattern. They formed a crystal.

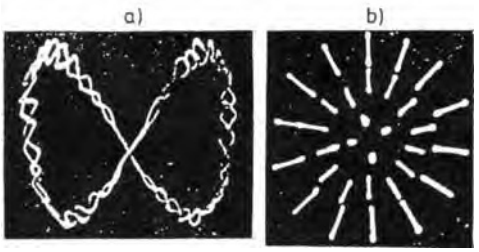

Fig. 9. a) Photomicrograph of a Lissajous orbit in the r–z-plane of a single charged particle of aluminum. The micro motion is visible. b) Pattern of "condensed" Al particles [16].

In recent years one has succeeded in observing optically single trapped ions by laser resonance fluorescence.[17] Using a high resolution image intensifier *Walther* et al. observed the pseudo crystallization of ions in the trap after cooling them with laser light. The ions move to such positions where the repulsive Coulomb force is compensated by the focusing forces in the trap and the energy of the ensemble has a minimum. Figures 10a, b show such a pattern with seven ions.

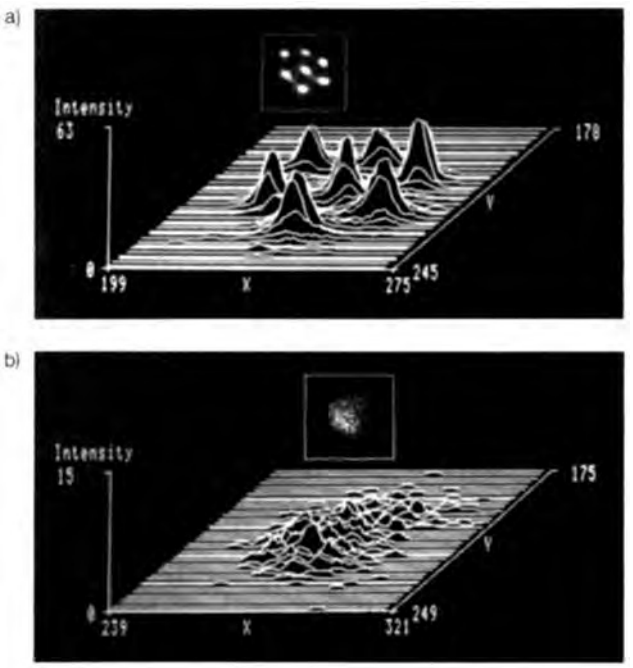

Fig. 10. a) Pseudo crystal of seven magnesium ions. Particle distance 23 μm. b) The same trapped particles at "higher temperature"; The crystal has melted [18].

Their separation distance is of the order of a few micrometers. These observations opened a new field of research.[18]

The Ion Trap as Mass Spectrometer

As mentioned earlier the ions perform oscillations in the trap with frequencies ω_r and ω_z which at fixed field parameters are determined by the mass of the ion. This enables a mass selective detection of the stored ions. If one connects the cap electrodes with an active r.f. circuit of eigenfrequency Ω, in the case of resonance $\Omega = \omega_z$ the amplitude of the oscillations increases linearly with time. The ions hit the cap or leave the field through a borehole and can easily be detected by an electron multiplier device. By modulating the voltage V determining the ion frequency in a sawtooth mode one brings the ions of the various masses one after the other into resonance, thus scanning the mass spectrum. Figure 11

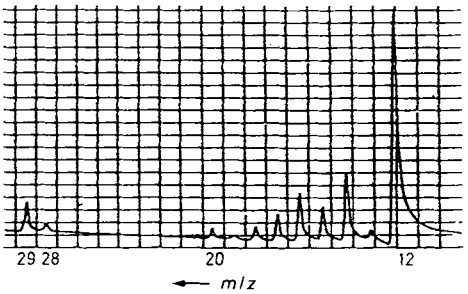

Fig. 11. First mass spectrum achieved with the ion trap. Gas: air at 2×10^{-9} torr [19].

shows the first spectrum of this kind achieved by *Rettinghaus*[19].

The same effect with a faster increase of the amplitude is achieved if one inserts a small band of instability into the stability diagram. It can be generated by superimposing on the driving voltage $V \cos \omega t$ a small additional rf voltage, e.g., with frequency $\omega/2$, or by adding a higher multipole term to the potential configuration.[5b, 20]

In summary the ion trap works as ion source and mass spectrometer at the same time. It became the most sensitive mass analyzer available, as only a few ions are necessary for detection. The underlying theoretical principles and applications are reviewed in detail in a monograph by *R. E. March* and *R. J. Hughes*.[21]

The Penning Trap

If one applies to the quadrupole trap only a d.c. voltage in such a polarity that the ions perform stable oscillations in the z-direction with the frequency $\omega_z^2 = \dfrac{2eU}{mr_0^2}$ the ions are unstable in the x–y-plane, since the field is directed outwards. Applying a magnetic field in the axial direction, the z-motion remains unchanged but the ions perform a cyclotron motion ω in the x–y-plane. It is generated by the Lorentz force F_L directed towards the center. This force is partially compensated by the radial electric force $F_r = eUr/r_0^2$. As long as the magnetic force is much larger than the electric force, we also have stability in the radial direction. No r.f. field is needed. The resulting rotational frequency is given by Equation (15).

$$\omega = \omega_c - \frac{\omega_z^2}{2\omega} \tag{15}$$

It is slightly smaller than the undisturbed cyclotron frequency $\omega_c = eB/m$. The difference is due to the magnetron frequency ω_m [Eq. (16)], which is independent of the particle mass.

$$\omega_M = \frac{\omega_z^2}{2\omega} \tag{16}$$

The Penning trap,[22] as this device is called, is of advantage if the magnetic properties of particles have to be measured, as for example Zeeman transitions in spectroscopic experiments, or cyclotron frequencies for a very precise comparison of masses, as have been performed, e.g., by *G. Werth*. The most spectacular application the trap has found is in the experiments of *G. Gräff*[23] and *H. Dehmelt* for measuring the anomalous magnetic moment of the electron. This method was brought by *H. Dehmelt*[24] to an admirable precision by observing only a single electron stored for many months.

Traps for Neutral Particles

In the last examination I had to pass as a young man I was asked if it would be possible to confine neutrons in a bottle in order to prove if they are radioactive. This question, at that time only to be answered with "no", pursued me for many years until I could have had replied: Yes, by means of a magnetic bottle. It took 30 years until by the development of superconducting magnets its realization became feasible.

Using the example of such a bottle I would like to demonstrate the principle of confining neutral particles. Once again this goes back to our early work on focusing neutral atoms and molecules having a dipole moment by means of multipole fields, making use of their Zeeman or Stark effect to first and second order.[1-3] Both effects can be used for trapping. Until now only magnetic traps have been realized for atoms and neutrons. In particular, *B. Martin, U. Trinks* and *K. J. Kügler* contributed to their development with great enthusiasm.

The Principle of Magnetic Bottles

The potential energy U of a particle with a permanent magnetic moment $\boldsymbol{\mu}$ in a magnetic field is given by $U = -\mu B$. If the field is inhomogenous it corresponds to a force $F = \text{grad}(\boldsymbol{\mu B})$. In the case of the neutron, with its spin $\hbar/2$, only two spin directions relative to the field are permitted. Therefore, its magnetic moment can be oriented only parallel or antiparallel to $\boldsymbol{B}$. In the parallel position the particles are drawn into the field and in the opposite orientation they are repelled. This permits their confinement to a volume with magnetic walls.

The appropriate field configuration to bind the particles harmonically is in this case a magnetic sextupole field. As I have pointed out such a field $\boldsymbol{B}$ increases with r^2, $\boldsymbol{B} = \boldsymbol{B}_0\, r^2/r_0^2$ and the gradient $\partial B/\partial r$ with r, respectively.

In such a field, neutrons with orientation $\mu \uparrow\uparrow \boldsymbol{B}$ satisfy the confining condition, as their potential energy $U = +\mu B \sim r^2$ and the restoring force $\mu \,\text{grad}\, \boldsymbol{B} = -cr$ is always oriented towards the center. They oscillate in the field with the frequency $\omega^2 = \frac{2\mu B_0}{m r_0^2}$. Particles with $\mu \uparrow\downarrow \boldsymbol{B}$ are defocused and leave the field. This is valid only as long as the spin orientation is conserved. In the sextupole, of course, the direction of the magnetic field changes with the azimuth, but as long as the particle motion is not too fast the spin follows the field direction adiabatically, conserving the magnetic quantum state. This behavior permits the use of a magnetic field constant in time, in contrast to the charged particle in an ion trap.

An ideal linear sextupole in the x–z-plane is generated by six hyperbolically shaped magnetic poles of alternating polarity extended in the y-direction (Fig. 12a). It might be approximated by six straight current leads with alternating current directions arranged in a hexagon (Fig. 12b). Such a configuration works as a lens for particles moving along the y-axis.

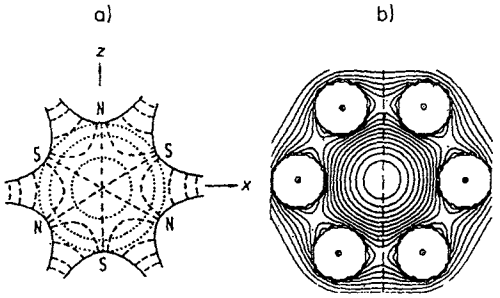

Fig. 12. a) Ideal sextupole field. Dashed: magnetic field lines, dotted: lines of equal magnetic potential (B = const.). b) Linear sextupole made of six straight current leads with alternating current direction.

There are two possible ways of achieving a *closed storage volume:* a sextupole sphere and a sextupole torus. We have realized and studied both. In particular *B. Martin, U. Trinks* and *K. J. Kügler* have participated enthusiastically in this development.

The spherically symmetric field is generated by three ring-currents in an arrangement shown in Figure 13. The field B

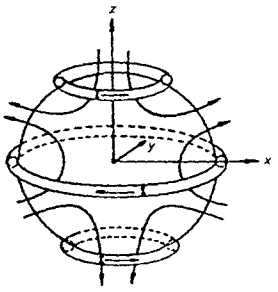

Fig. 13. Sextupole sphere.

increases in all directions with r^2 and has its maximum value B_0 at the radius r_0 of the sphere. Using superconducting current leads we achieved $B_0 = 3$T in a sphere with a radius of 5 cm. But due to the low magnetic moment of the neutron

$\mu = 6 \times 10^{-8}$ eV/T the potential depth μB_0 is only 1.8×10^{-7} eV, and hence the highest velocity of storable neutrons is only 6m/s. Due to their stronger moment, in the case of Na atoms these values are 2.2×10^{-4} eV and 37 m/s, respectively.

The main problem with such a closed configuration is the filling process, especially the cooling inside in order to avoid that the particles injected from outside are again leaving the storage volume. However, in 1975 in a test experiment we succeeded in observing a storage time of three seconds for sodium atoms evaporated inside a bottle with helium cooled walls.[25] But the break through in confining atoms was achieved by *W. D. Phillip* and *H. J. Metcalf* using the modern technique of laser cooling.[26]

The problem of storing neutrons becomes easier if one uses a linear sextupole field bent to a closed torus with a radius R (Fig. 14). The magnetic field in the torus volume is

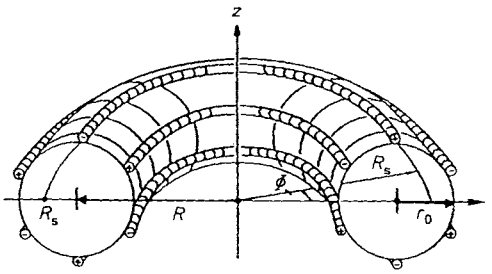

Fig. 14. Sextupole torus. R_s orbit of circulating neutrons.

unchanged $\boldsymbol{B} = \mathbf{B}_0\, r^2/r_0^2$ and has no component in the azimuthal direction. The neutrons move in a circular orbit with Radius R_s if the centrifugal force is compensated by the magnetic force [Eq. (17)].

$$F_c = \frac{m v_\varphi^2}{R_s} = \mu \left.\frac{\partial B}{\partial r}\right|_{R_s} \tag{17}$$

In such a ring the permitted neutron energy is limited by

$$E_{max} = \mu B_0 \left(\frac{R}{r_0} + 1\right) \tag{18}$$

It is increased by a factor $(R/r_0 + 1)$ compared to the case of the sextupole sphere. As the neutrons have not only an azimuthal velocity but also components in the r and z directions they are oscillating around the circular orbit.

But this toroidal configuration has not only the advantage of accepting higher neutron velocities, it also permits an easy injection of the neutrons in the ring from the inside. The neutrons are not only moving in the magnetic potential well but they also experience the centrifugal barrier. Accordingly, one can lower the magnetic wall on the inside by omitting the two inward current leads. The resulting superposition of the magnetic and the centrifugal potential still provides a potential well with its minimum at the beam orbit. But there is no barrier for the inflected neutrons.

It is obvious, that the toroidal trap in principle works analogous to the storage rings for high energy charged particles. In many respects the same problems of instabilities of the particle orbits by resonance phenomena exist, causing loss of the particles. But also new problems arise like, e.g., undesired spin flips or the influence of the gravitational force.

In accelerator physics one has learned to overcome such problems by shaping the magnetic field by employing the proper multipole components.

This technique is also appropriate in the case of the neutron storage ring. The use of the magnetic force $\mu \cdot \mathrm{grad}\boldsymbol{B}$ instead of the Lorentz force, which is proportional to B, just requires multipole terms of one order higher. Quadrupoles for focusing have to be replaced by sextupoles and, e.g., octupoles for stabilization of the orbits by decapoles.

In the seventies we designed and constructed such a magnetic storage ring with orbits of a diameter of 1 m. The achieved usable field of 3.5 T permits the confinement of neutrons in the velocity range of 5–20 ms^{-1}, corresponding to a kinetic energy up to 2×10^{-6} eV. The neutrons are injected tangentially into the ring by a neutron guide with totally reflecting walls. The inflector can be moved mechanically into the storage volume and shortly afterwards be withdrawn.

The experimental set up is shown in Figure 15. A detailed description of the storage ring and the underlying theoretical principles is given in Ref. [27].

In 1978 in a first experiment we tested the instrument at the Grenoble high flux reactor. We could observe neutrons stored up to 20 min after injection by moving a neutron counter through the confined beam after a preset time. As in the detection process the neutrons are lost, one has to refill the ring, starting a new measurement. But due to the relative-

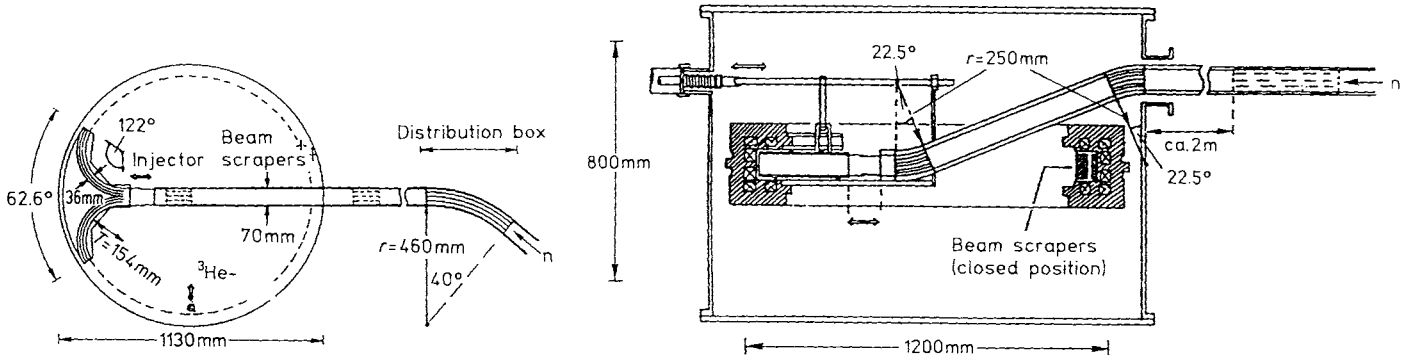

Fig. 15. Schematic top view and side view of the neutron storage ring experiment.

ly low flux of neutrons in the acceptable velocity range, their number was too low to make relevant measurements.

In a more recent experiment,[28] using a new neutron beam with a flux improved by a factor 40 we could observe neutrons up to 90 min, i.e. roughly six times the radioactive decay time of the neutron. Figure 16 shows the measured

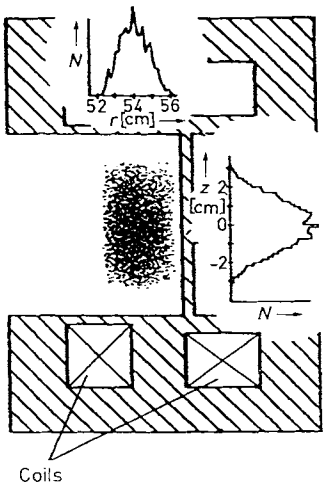

Fig. 16. Beam profile of the stored neutrons inside the magnet gap 400 s after injection.

profile of the neutron beam circulating inside the magnetic gap. Measuring carefully the number of stored neutrons as a function of time we could determine the lifetime as $\tau = 877 \pm 10$ s (Fig. 17).

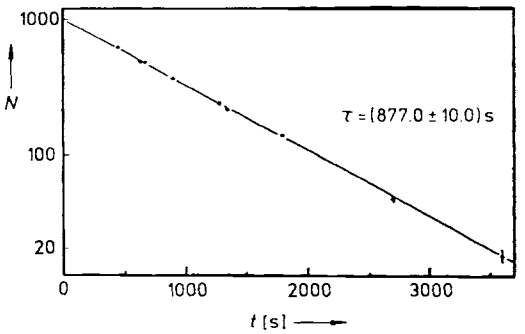

Fig. 17. Logarithmic decrease of the number of stored neutrons with time (τ = half-time).

The analysis of our measurements let us conclude that the intrinsic storage time of the ring for neutrons is at least about one day. It shows that we had understood the relevant problems in its design.

The Storage Ring as a Balance

This very reproducible performance permitted another interesting experiment. As I have already explained, neutrons are elastically bound to the symmetry plane of the magnetic field. Due to their low magnetic moment the restoring force is of the order of the gravitational force. Hence it follows that the weight of the neutron stretches the magnetic spring that the particle is hanging on; the equilibrium center of the oscillating neutrons is shifted downwards.

The shift z_0 is given by the balance $mg = \mu \operatorname{grad} \boldsymbol{B}$. One needs a gradient $\partial B/\partial z = 173\ \mathrm{Gcm}^{-1}$ for compensating the weight. As the gradient in the ring increases with z and is proportional to the magnetic current I one can calculate the shift z_0 according to Equation (19).

$$z_0 = \text{const.}\ mg/I. \tag{19}$$

It amounts in our case to $z_0 = 1.2$ mm at the highest magnet current $I = 200$ A and 4.8 mm at 50 A accordingly.

By moving a thin neutron counter through the storage volume we could measure the profile of the circulating neutron beam and its position in the magnet. Driving the counter alternately downwards and upwards in many measuring runs we determined z_0 as a function of the magnetic current.

The result is shown in Figure 18. The measured data taken with different experimental parameters follow the predicted line. A detailed analysis gives for the gravitational mass of the neutron the value $m_g = (1.63 \pm 0.06) \times 10^{-24}$ g. It agrees within 4% with the well known inertial mass.

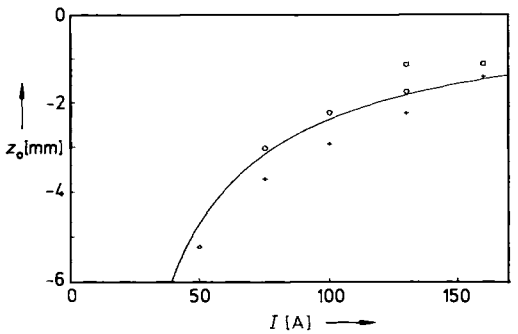

Fig. 18. Downward shift of the equilibrium center of the neutron orbits due to the weight of the neutron as function of the magnetic current I. Size of injection aperture: ±35.3(+), ±21.3(○), ±18.8 mm. (◇), ±14.5 mm □. The curve gives the theoretical shift.

Thus the magnetic storage ring represents a balance with a sensitivity of 10^{-25} g. It is only achieved because the much higher electric forces play no role at all.

I am convinced that the magnetic bottles developed in our laboratory and described here are potentially very useful instruments for many other experiments in the future, as the ion trap has already proven in the past.

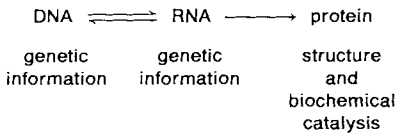
Enzymatic Cleavage of RNA by RNA (Nobel Lecture)**

By Sidney Altman*

Introduction

The transfer of genetic information from nucleic acid to protein inside cells can be represented as shown in Scheme 1. This simple scheme reflects accurately the fact that the information contained in the linear arrangement of the nucleotides in DNA is copied accurately into the linear arrangement of nucleotides in RNA, which, in turn, is translated by machinery inside the cell into proteins, the macromolecules responsible for governing many of the important biochemical processes in vivo. The straightforward transfer of information from DNA to protein is carried out by a class of molecules called messenger RNAs (mRNAs). The diagram shown does not elaborate on the properties of other RNA molecules that are transcribed from DNA, namely, transfer RNA (tRNA) and ribosomal RNA (rRNA) and many other minor species of RNA found in vivo that had no identifiable function prior to 1976, nor does it indicate that the information in DNA and RNA can be replicated as daughter DNA and RNA molecules, respectively.[1]



Scheme 1. A representation of the flow of information inside cells from DNA to protein. This diagram is not a complete representation of the central dogma (see [1]).

Ribosomes are complexes which, in *Escherichia coli*, are made of about 50 proteins and three RNA molecules. It is on these particles that mRNA directs the synthesis of protein from free amino acids. tRNA molecules (Fig. 1) perform an adaptor function in the sense that they match particular amino acids to groups of three specific nucleotides on the mRNA to be translated and ensure that the growing polypeptide (protein) chain contains the right linear sequence of amino acid subunits. Thus, rRNA and tRNA participate in the process of information transfer inside cells, but they clearly do so in a comparatively complex manner.

My work on RNA began as a study of certain mutants that disrupt the ability of tRNA molecules to function normally during translation.[2] This research, in turn, led to the identification of another RNA molecule that had, unexpectedly, all the properties of an enzyme.[3] Aside from its intrinsic interest to students of catalysis and enzymology, our finding of an enzymatic activity associated with RNA has stimulated reconsideration of the role of RNA in biochemical systems today (Scheme 1; see *Cech*[4] and *Altman*[5] for reviews) and of the nature of complex biochemical systems eons ago.[6-11]

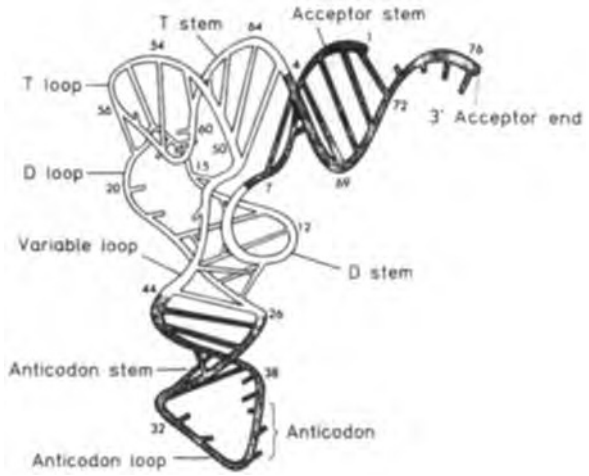


Fig. 1. A diagram illustrating the folding of the yeast $tRNA^{Phe}$ molecule. The ribose–phosphate backbone is drawn as a continuous ribbon and internal hydrogen bonding is indicated by crossbars. Positions of single bases are indicated by bars that are intentionally shortened. The anticodon and acceptor arms are shaded. (Reprinted with permission from [63].)

As was first pointed out over twenty years ago by *Woese*,[12] *Crick*,[13] and Orgel,[14] if RNA can act as a catalyst then the origin of the genetic code plays a much less critical role in the early stages of the evolution of the first biochemical systems that were capable of replicating themselves. The variety of biochemical reactions now known to be governed by RNA (Table 1)[5] allows one to consider the possibility that a large number of different enzymatic reactions might indeed occur in the absence of protein. To add further substance to these ideas about life on our planet over a billion years ago, it is important to expand our understanding of how modern catalytic RNAs work and of the roles they play in vivo today. This discussion deals primarily with the discovery and characterization of the catalytic RNA subunit of the enzyme ribonuclease P from *Escherichia coli*.

Table 1. Some properties of catalytic RNAs.

RNA	End groups [a]	Cofactor	Mechanism
1. Group I introns	5'-P, 3'-OH	Yes	Transesterification
2. Group II introns	5'-P, 3'-OH	No	Transesterification
3. M1 RNA	5'-P, 3'-OH	No	Hydrolysis
4. Viroid/satellite	5'-OH, 2',3'-cyclic phosphate	No	Transesterification
5. Lead ion/tRNA	5'-OH, 2',3'-cyclic phosphate	No	Similar to RNase A

[a] The end groups are those produced during the initial cleavage step of self-splicing reactions or during the usual cleavage reactions of other RNA species.

A Brief Account of Studies of Ribonuclease P

Finding the Substrate

In October 1969, I arrived at the Medical Research Council Laboratory of Molecular Biology in Cambridge, England, ostensibly to study the three-dimensional structure of tRNA through the use of physical-chemical methods. On my arrival, *Sydney Brenner* and *Francis Crick* informed me that the crystal structure of yeast $tRNA^{Phe}$ had just been solved,[15,16] and that there was no need to engage in the studies originally outlined for me. I was further instructed to get settled, to think about a new problem for a week or two, and then to return for another discussion. Although some of my colleagues remember me as being disappointed after that conversation with *Brenner* and *Crick*, the feeling must have passed quickly because I only recall being presented with a marvelous opportunity to follow my own ideas.

I proposed to make acridine-induced mutants of $tRNA^{Tyr}$ from *E. coli* to determine whether altering spatial relationships in tRNA, by deleting or adding a nucleotide to its sequence, would drastically alter the function of the molecule. Since *Brenner* and *John D. Smith* and their colleagues[17–19] had just completed a classic series of studies of base-substitution mutants of $tRNA^{Tyr}$, they were not overly excited by the prospect of someone simply producing more mutants. Nevertheless, *Brenner* and *Crick* did not prevent me from pushing ahead and *John Smith*, in time, provided valuable advice about the genetics of the system in use in the laboratory.

The mutants I made lacked the usual function of suppressor tRNAs and made no mature tRNA in vivo, but they reverted at a very high rate (about 1%) to wild type. These properties indicated that there might be an unstable duplication or partial duplication of the gene for tRNA in the DNA that contained the information for the tRNA. Furthermore, it seemed likely that RNA would be transcribed from this mutant gene. I reasoned that if I could isolate the RNA transcript, which had to be unstable since no mature tRNA was made, I might be able to understand the nature of the duplication event.

The simple expedient of quickly pouring an equal volume of phenol into a growing culture of *E. coli* labeled with $^{32}PO_4^{3\ominus}$ enabled me to isolate and characterize not only the transcript of the gene for $tRNA^{Tyr}$ mutated by acridines, but also transcripts of the gene for $tRNA^{Tyr}$ (Fig. 2),[2] which had been previously mutated by other means by *Brenner*, *Smith*, and their colleagues. These gene transcripts contained sequences in addition to the mature tRNA sequences at both ends of the molecules (Fig. 3)[20a] and were, therefore, tRNA precursor molecules. The ability to isolate the precursors depended on the rapid phenol extraction technique and the fact that the mutated molecules, by virtue of having altered conformations in comparison to the wild type, were less susceptible to attack by intracellular ribonucleases than the transcripts of the wild-type gene. The "extra" sequences, themselves, though of interest because such segments of gene transcripts had not been characterized at that time, proved not to be particularly revealing.

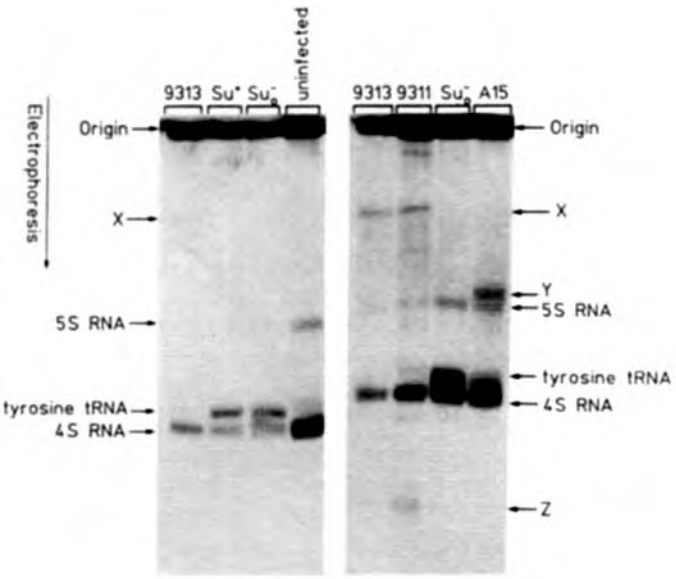

Fig. 2. Separation by electrophoresis of labeled RNA from *E. coli* infected with derivatives of bacteriophage $\phi 80$ that carried various genes for $tRNA^{Tyr}$. The figure shows an autoradiogram of polyacrylamide gels. Experimental details are given in and the figure is taken from [2]. Each column in the gel patterns is titled according to the $tRNA^{Tyr}$ gene carried by the infecting phage. 9313 and 9311 are acridine-induced mutants of the suppressor $tRNA^{Tyr}su_3^+$. A15 is a mutant derivative carrying the G15–A15 mutation and su_0^- is the wild-type $tRNA^{Tyr}$ gene. (Reprinted with permission from [2].)

Although the earlier work of *Darnell*[21a] and *Burdon*[21b,c] and their co-workers had shown that tRNAs were probably made from precursor molecules in eukaryotic cells, further characterization of the enzymes involved in the biosynthesis of tRNA, or tRNA-processing events, could not proceed without a radiochemically pure, homogeneous substrate of the kind that I had isolated.

Sidney Altman, born in 1939 in Montreal, received his undergraduate education in physics at the Massachusetts Institute of Technology. He began graduate studies in physics at Columbia University, but switched to biophysics at the University of Colorado Medical Center (with Leonard Lerman) and then molecular biology at Harvard University (with Mathew Meselson). His work with Sydney Brenner and Francis Crick at the Medical Research Council Laboratory of Molecular Biology in Cambridge, England, led to the discovery of RNase P and the enzymatic properties of the RNA subunit of that enzyme. In 1971 he began work as an assistant professor at Yale University and became a professor in 1980. In 1989 he received, together with Thomas R. Cech, the Nobel Prize in chemistry.

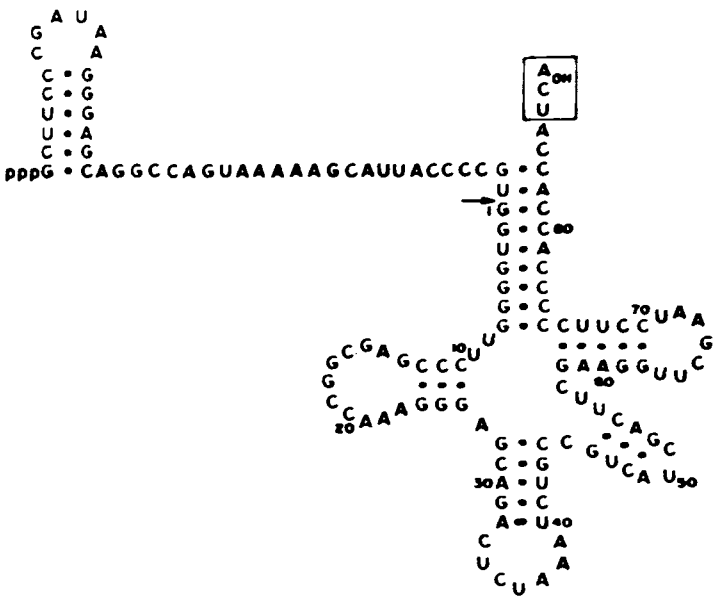

Fig. 3. Nucleotide sequence of the precursor to $tRNA^{Tyr}su_3^+$. The arrow pointing toward the sequence indicates the site of cleavage by RNase P on the 5′ side of nucleotide 1 of the mature tRNA sequence. The boxed nucleotides are extra nucleotides at the 3′ terminus (after [20a]).

When the precursor to one of the mutant $tRNA^{Tyr}$ molecules was mixed with an extract of *E. coli*, it was immediately apparent that enzymatic activities were present in the cell extract that could remove the "extra" nucleotides from both the 5′ and 3′ ends of the mature tRNA sequence (Fig. 4).[20a,b] The activity that processed the 5′ end of the tRNA precursor, which we named Ribonuclease P, did so by a single endonucleolytic cleavage event, in contrast to what appeared to be nonspecific exonucleolytic degradation at the 3′ end of the molecule. In fact, no ribonucleases with such high specificity with respect to site of cleavage as that exhibited by RNase P were known at that time, so the novelty of this reaction assured our continuing interest. Some characterization of the reaction was immediately carried out in collaboration with *Hugh Robertson* and *John Smith*.[20b]

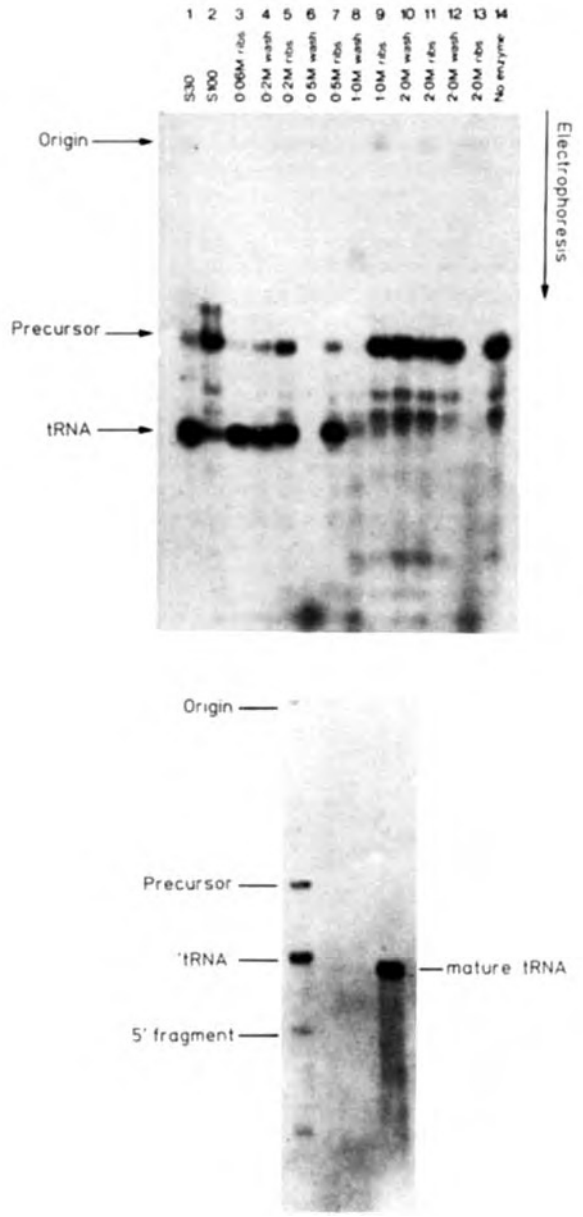

Fig. 4. Top: RNase P activity in extracts of *E. coli*. Extracts of *E. coli*, partial purification of RNase P, and cleavage reactions were carried out as generally described in [20b]. The substrate used was the precursor to *E. coli* $tRNA^{Tyr}$. The column titles in the figure refer to fractions from crude cell extracts of *E. coli* and washes, with buffers that contained increasing concentrations of NH_4Cl, of ribosomes prepared by centrifugation of the S100 fraction. About 100 μg of protein was added to the reaction in lane 1 and lesser amounts to each of the other reactions. There are spontaneous breakdown products of the substrate visible between the "precursor" and "tRNA" bands in the gels. Bottom: Separation by gel electrophoresis of the products of cleavage in vitro of the precursor to $tRNA^{Tyr}A25$ by a partially purified preparation (DEAE-Sephadex fraction) of RNase P. The 3′ end fragment ("tRNA") includes the additional nucleotides of the precursor. (Reprinted with permission from [20b].)

Characterization of Ribonuclease P from *Escherichia coli*

At the MRC laboratory, we showed that RNase P produced 5′-phosphate and 3′-hydroxyl groups at its site of cleavage,[20b] unlike most nonspecific nucleases which produce 5′-hydroxyl and 3′-phosphate groups. This observation fitted with the fact that mature tRNAs have a 5′ phosphate at their 5′ termini. While some progress was made in terms of chromatographic purification of the enzyme, in retrospect the most striking observation made in the early studies was that "it is possible that the active form of RNase P, which must have a strong negative charge, could be associated with some nucleic acid." The next important step was taken a few years later by *Benjamin Stark*, a graduate student in my laboratory at Yale, who showed that an RNA of high molecular weight copurified with the enzymatic activity and, in a classic experiment, demonstrated that this RNA molecule was essential for enzymatic activity.[22] The RNA was named M1 RNA and had a fingerprint that was similar to that of a stable RNA species (band IX) of unknown function that had been described by *Ikemura* and *Dahlberg*[23] as one of a series of minor RNA species found in *E. coli*; the protein subunit of RNase P from *E. coli* was named C5 protein.

The essential role of the RNA component was established by first treating RNase P with micrococcal nuclease, an enzyme that destroys RNA, and subsequently assaying the treated enzyme for RNase P activity: there was none after

treatment with micrococcal nuclease (Fig. 5) or, for that matter, after treatment with various proteinases. Thus, under the conditions we were then using (that is, buffers that contained 5 mM $MgCl_2$), both protein and RNA components were shown to be essential for enzymatic activity. Concurrently we showed that the enzyme had a buoyant density in CsCl of 1.72 g mL^{-1},[22] characteristic of an RNA–protein complex that consists predominantly of RNA. Velocity sedimentation experiments had previously determined the sedimentation coefficient to be about 11.5 S.[20b]

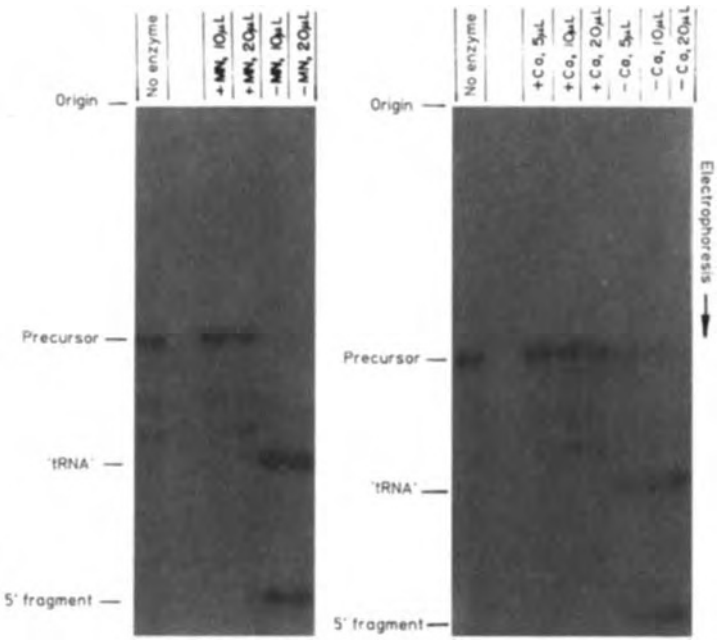

Fig. 5. Inactivation of RNase P by pretreatment with ribonuclease. Control reactions were performed without micrococcal nuclease (MN) in the pretreatment mixture (left) or without $CaCl_2$ (right). RNase P pretreated with MN had less than 5% of the activity of the control reaction RNase P. The extent of inactivation can be varied by changing the reaction conditions as shown. (Reprinted with permission from [22].)

While the biochemical purification was proceeding, studies of temperature-sensitive mutants of *E. coli* made by *Schedl* and *Primakoff* et al.[24,25] and *Shimura, Ozeki,* and their co-workers[26,27] showed that RNase P is essential in *E. coli* for the biosynthesis of all tRNAs and that both RNA and protein subunits are required in vivo. Furthermore, work from the laboratories of *William McClain*[28,65] and *John Carbon*[29] added to the evidence that RNase P is responsible for the processing of many different tRNA precursor molecules. Although appropriate genetic analyses could not be performed, we also showed that RNase P-like activities exist in the extracts of cells from many other organisms, including humans.[30,31] These early studies showed that RNase P was capable of cleaving many different tRNA precursor molecules and that there was no identifiable similarity in terms of nucleotide sequence around the sites of cleavage. The manner in which the enzyme recognized its sites of cleavage in different substrates with such selectivity seemed worthy of study, and recognition of some feature of the structure in solution, common to all tRNA precursor molecules, was suspected.

When *Stark*'s experiments were published we did not have the temerity to suggest, nor did we suspect, that the RNA component alone of RNase P could be responsible for its catalytic activity. The fact that a simple enzyme had an essential RNA subunit, in itself, seemed heretical enough. Shortly thereafter, however, when *Ryszard Kole* demonstrated that the enzyme consisted of an RNA (M1 RNA) and a protein subunit (C5 protein; $M_r \approx 14000$), which were not covalently linked and which could be separated into inactive subunits and then reconstituted to form an active enzyme,[32] the similarities in chemical composition and properties of assembly of this system to those of the ribosome were sufficiently striking that we could not escape thinking about the possibility that the RNA, at the very least, participated in the formation of the active site of the enzyme. Indeed, making the comparison with ribosomes proved to be important in overcoming some resistance to the idea that an enzyme could have an RNA subunit.[33] From a purely chemical point of view, there was no reason why RNA could not participate in formation of the active site or even in catalysis itself.

The advent of recombinant-DNA technology and powerful systems for the transcription in vitro of isolated pieces of DNA enabled us to characterize in some detail the RNA subunit of RNase P (377 nucleotides in length)[34] and to prepare large quantities for biochemical experiments. Concurrent progress in our purification of the protein subunit prepared us for a series of experiments, conducted in collaboration with *Norman Pace*'s group at Indiana University, in which we made hybrid enzymes with subunits from *E. coli* (prepared in our laboratory) and from *B. subtilis* (prepared in *Pace*'s laboratory). As an offshoot of these experiments, *Cecilia Guerrier-Takada* in my laboratory assayed reconstituted RNase P from *E. coli* under ionic conditions optimal for the activity of the holoenzyme from *B. subtilis* and different from the ones we had previously employed. She found, in control experiments in which she tested the RNA and protein subunits separately, that the RNA subunit from *E. coli,* exhibited catalytic activity of its own in buffers that contained 60 mM $MgCl_2$. (An example of such reactions is shown in Figure 6.) In fact, the catalytic activity of M1 RNA is evident when the concentration of $Mg^{2\oplus}$ is greater than 20 mM.[3] The protein subunit of the enzyme increased the k_{cat} by a factor of 10–20 but had little effect on the K_m. We quickly determined that M1 RNA had all the properties of a true enzyme as defined in biochemistry textbooks:[35] it was unchanged (in size) during the course of the reaction; it had a true turnover number as measured by Michaelis–Menten analysis of the kinetics (Fig. 7) and, therefore, it was a catalyst; it was needed in only small amounts and it was stable. These observations were possible because of the purity of our preparations of M1 RNA and the use of a natural substrate, the precursor to $tRNA^{Tyr}$ from *E. coli*.

We soon proposed a model of the secondary structure of M1 RNA based on its susceptibility to nucleases in solution and some simple notions of the stability of RNA structures. We also outlined the general ionic requirements of the reaction (Table 2).[36] The curve of the dependence of the rate of the reaction on the pH is flat between 5 and 9 and is suggestive of the involvement of more than one group with a pK_a not characteristic of those found on nucleotides alone in solution. It is reasonable to expect, therefore, that the active

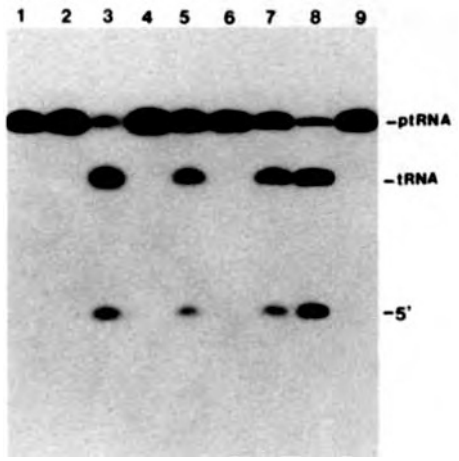

Fig. 6. Dependence of the catalytic activity of M1 RNA on the concentration of $Mg^{2\oplus}$. The precursor to $tRNA^{Tyr}$, abbreviated as pTyr, is the substrate. Reactions and reconstitution of RNase P were carried out as described in [3]. Lane 1: No enzyme added; 10 mM $MgCl_2$. Lane 2: M1 RNA (2×10^{-8} M); 10 mM $MgCl_2$. Lane 3: M1 RNA (0.1×10^{-8} M) plus C5 protein (2×10^{-8} M); 10 mM $MgCl_2$. Lane 4: No enzyme added; 100 mM $MgCl_2$. Lane 5: M1 RNA (2×10^{-8} M); 100 mM $MgCl_2$. Lane 6: M1 RNA (0.1×10^{-8} M) plus C5 protein (2×10^{-8} M); 100 mM $MgCl_2$. Lane 7: M1 RNA (2×10^{-8} M); 100 mM $MgCl_2$ and 4% polyethylene glycol. Lane 8: M1 RNA (2×10^{-8} M) plus C5 protein (4×10^{-7} M); 100 mM $MgCl_2$. Lane 9: C5 protein (4×10^{-7} M); 10 mM $MgCl_2$.

site of M1 RNA is embedded in a folded structure and that the local environment of the active site is not precisely identical to that of the aqueous buffer in which the whole molecule is dissolved.

Table 2. Catalytic activity of M1 RNA.

M1 RNA active [a]:	
	≥ 20 mM $MgCl_2$
	10 mM $MgCl_2$ plus C5 protein
	10 mM $MgCl_2$ plus 5 mM polyamine
M1 RNA not active:	
	10 mM $MgCl_2$

[a] The table summarizes data of *Guerrier-Takada* et al. [3]. The complete composition of reaction mixtures is given in the reference.

These findings complemented those of *Thomas Cech*'s group[37,38] on self-splicing RNA and started intense speculation about the role RNA may have played in the origin of life. However, our immediate interest was in determining precisely how the enzyme works, what its role is in vivo, and how it manages to recognize 60 or so different substrates in *E. coli* that have no apparent sequence similarity around their sites of cleavage.

Recent Work

Structure

The original model[64] of the secondary structure of M1 RNA has been extensively refined by phylogenetic analysis (Fig. 8) carried out primarily by *Pace* et al.[39] This analysis has not yet yielded a satisfactory correlation between the phenotypes of mutants[40] and features of the secondary structure of M1 RNA or its analogues from other bacteria (see below). However, it does provide the basis for hypotheses about the regions of M1 RNA that are essential for function,[41] as indicated by evolutionary conservation, and it highlights the necessity of determining the three-dimensional features of the structure. To this end, both additional phylogenetic comparisons, utilizing data concerning the homologue of M1 RNA from several eukaryotic species,[42-45] and crystallographic studies are in progress. One observation of continuing interest from these studies is that the evolutionary clock for both the RNA and protein subunits of RNase P seems to be very fast in comparison with that for rRNAs.[46,47] Although the function of RNase P, as judged by the antigenic properties of the protein[48a,b] and its ability to cleave various substrates and to reconstitute active enzyme with subunits from different organisms[3,46,49] has been highly conserved, the nucleotide sequences of the genes for the subunits of the enzyme have drifted extremely rapidly.[45,47]

Mechanism

The detailed mechanism of the reaction catalyzed by RNase P is not known, but two proposals have been made. In one case,[36] a variation of the S_N2 in-line displacement mechanism has been suggested in which a complex between one magnesium ion and six water molecules facilitates the nucleophilic action of a water molecule in solution (Fig. 9).

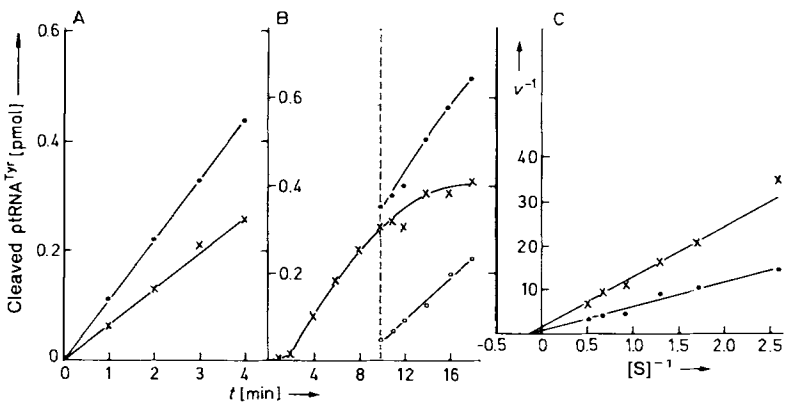

Fig. 7. Kinetic analysis of the reactions of M1 RNA and RNase P with the precursor to $tRNA^{Tyr}$ (pTyr) as substrate. A) Comparison of the kinetics of reconstituted (by dialysis) *E.coli* RNase P in buffer that contained 5 mM $MgCl_2$ with those of M1 RNA in buffer that contained 60 mM $MgCl_2$ that had been treated in the same way. •, RNase P activity; x, M1 RNA activity. B) Kinetics of the reaction catalyzed by M1 RNA in buffer that contained 60 mM $MgCl_2$. M1 RNA was incubated with a fivefold excess of pTyr. Ten minutes after the start of incubation a further threefold excess of pTyr, or buffer alone, was added to the reaction mixture. •, pTyr added after 10 min; x, buffer alone added after 10 min; o, net added pTyr cleaved after 10 min (all in pmol). C) Determination of K_m and V_{max} for the reactions shown in A. A Lineweaver–Burk double-reciprocal plot was constructed from the appropriate kinetic data. •, RNase P in buffer that contained 5 mM $MgCl_2$; x, M1 RNA in buffer that contained 60 mM $MgCl_2$. Units: $[S]^{-1}$ (pmol $\times 5 \times 10^{-4})^{-1}$; v^{-1} [(pmol substrate cleaved per min)$^{-1}$]. (Reprinted with permission from [3].)

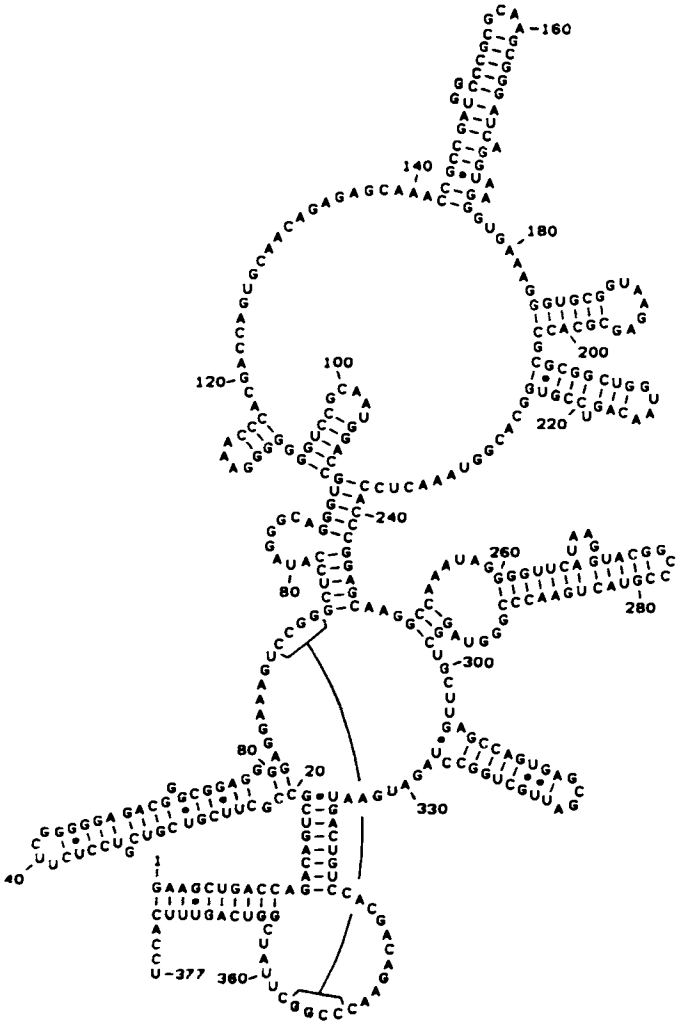

Fig. 8. A model for the secondary structure of M1 RNA based on extensive phylogenetic analysis of the nucleotide sequence of the RNA subunit of RNase P from several eubacteria. (Reprinted with permission from [39].)

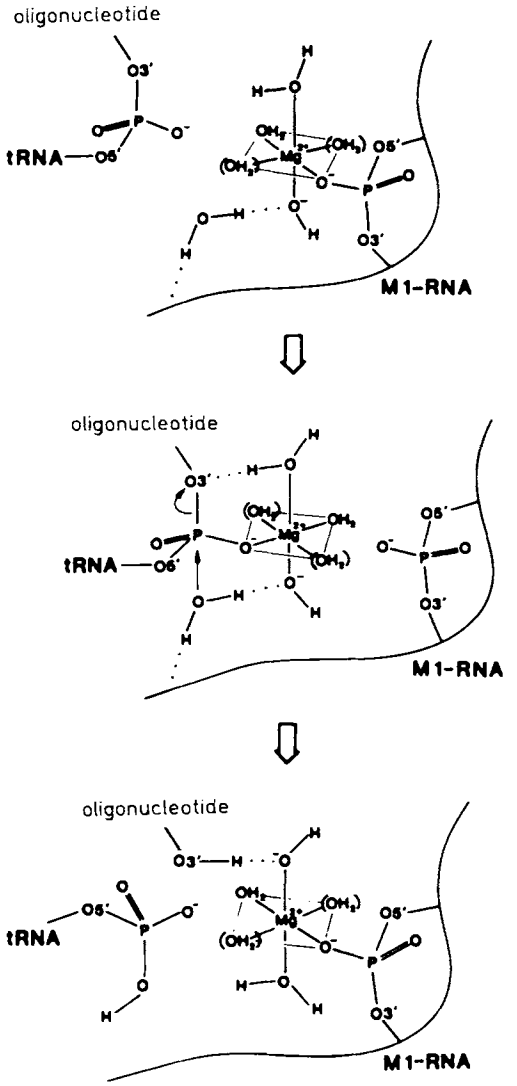

Fig. 9. Hypothetical electronic mechanism of tRNA precursor hydrolysis by M1 RNA of RNase P. The reaction is catalyzed by an Mg–H_2O complex that is initially bound to a phosphate of M1 RNA. $Mg^{2\oplus}$ is formally shown as hexacoordinated, but it may well be tetracoordinated as indicated by the parentheses around the two equatorial water ligands. Top: A water molecule form the solvent that will participate in hydrolysis is positioned by a hydrogen bond to an O or N atom in M1 RNA. Middle and bottom: The tRNA precursor substrate is bound by the water molecule attached to M1 RNA and passes through a transition state prior to cleavage of the "extra" oligonucleotide and prior to the addition of OH to its O5′ terminal phosphate. After the reaction steps shown here, a solvent water chain between the axial ligands of $Mg^{2\oplus}$ recocks the enzyme for the next cycle. (Reprinted with permission from [36].)

Investigations of the rRNA self-splicing reaction in *Tetrahymena* in *Thomas Cech*'s laboratory indicate that the S_N2 mechanism proposed for the RNase P reaction may also be relevant in the self-splicing reaction.[4, 50] In the other proposal for the mechanism of the RNase P reaction,[51] the nucleophile is derived from groups on the surface of the enzyme and the role of the magnesium ion is not as clearly specified. Attempts are underway in our laboratory to test the first model, by the insertion of a phosphothioate bond at the cleavage site and analysis of the stereochemistry of the cleaved product.

While many aspects of the RNase P reaction may be revealed if the crystal structure of the enzyme becomes available, the determination of a crystal structure may prove to be elusive. We have, therefore, embarked on an attempt to identify regions of M1 RNA that are critical for the reaction by cross-linking the substrate to the enzyme by irradiation with ultraviolet light. Such experiments have revealed that a cross-link is formed between a nucleotide close to the site of cleavage in the substrate (C-3; see Fig. 3) and residue C92 in M1 RNA.[52] If C92 is deleted from M1 RNA, the kinetics of the enzymatic reaction and the site of cleavage of particular substrates are significantly altered. Furthermore, the region of secondary structure around C92 in M1 RNA resembles that of the tRNA E site in 23 S rRNA (Fig. 10). Additional studies have shown that this site is important in the binding of the aminoacyl stem of a tRNA precursor to the enzyme and that, as in the binding of tRNA to the E site of 23 S rRNA,[53] the 3′-terminal CCA sequence plays a critical role in the interaction of the enzyme with the substrate. These results, in addition to allowing the identification of domains with similar structural and functional properties in RNA molecules with very different cellular functions, delineate a region of importance for function in M1 RNA and suggest further experiments aimed at a more

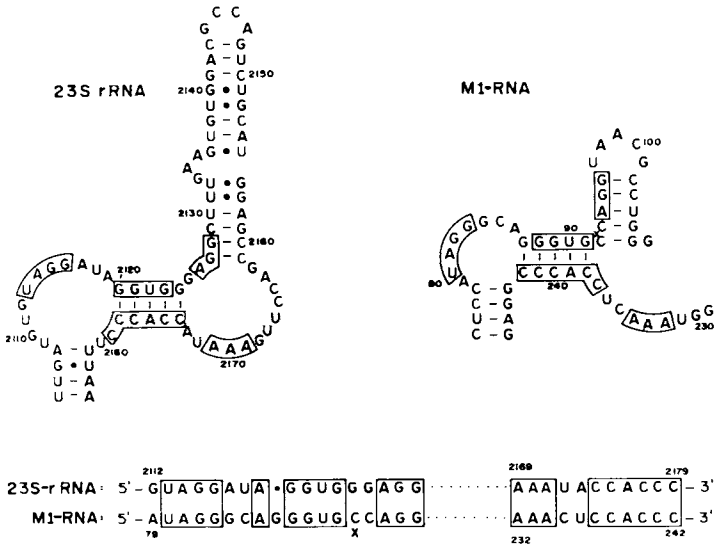

Fig. 10. Comparison of part of the E site of 23 S rRNA with a region in M1 RNA that surrounds the cross-link with the substrate. The secondary structures are taken from [53] and [39]. The "x" marks C92, the nucleotide in M1 RNA that is cross-linked to the substrate. Nucleotides shown in boxes are found in approximately the same relative positions in the structures shown (see [52].)

detailed definition of the interactions between enzyme and substrate and of the particular steps in the enzymatic reaction that involve this region.

Recognition of the Substrate

Early notions of the features important for the recognition by RNase P of its substrate focused either on the possibility of Watson–Crick pairing of nucleotide sequences common to all tRNAs (e.g., CCA and GUUCG) with sequences in M1 RNA[54] or some other, incompletely specified, measuring mechanism that recognizes the three-dimensional structure of the tRNA moiety of the precursor.[55] Results of several experiments indicated that extensive base-pairing between enzyme and substrate was not essential for the enzymatic reaction[54, 56] and attention was focused on the conformation of the substrate in solution. It had been demonstrated early on that RNase P from any one source can cleave tRNA precursors from any other source. Thus, when an unusual tRNA that lacked the D stem and loop was found, namely, $tRNA^{Ser}$ from bovine mitochondria,[57] we examined whether M1 RNA could cleave an analogue of a precursor to that tRNA.

In collaboration with *William McClain*,[58] we showed not only that the D stem and loop were not essential for recognition, but also that the anticodon stem and loop were dispensable, too (Fig. 11). A substrate that consisted merely of a single-stranded region at the 5′ end of a mini-tRNA, containing only the T stem and loop stacked on the aminoacyl acceptor stem, was cleaved almost as efficiently as the parent tRNA precursor from which it was derived. This minimal substrate contains an RNA helix that is analogous to the part of the intact three-dimensional structure of a normal tRNA that contains the T stem stacked on the acceptor stem (Fig. 1). Recently, we have also shown that cleavage by M1 RNA requires neither the loop segment of the structure nor more than six base pairs in the helical region and (in separate experiments) that no more than one "extra" nucleotide at the 5′ terminus is required. While substrates with these features are not cleaved as efficiently as either a normal precursor tRNA or pAT1 (the substrate shown in Fig. 11 that resembles a hairpin), they must, nevertheless, contain sufficient recognition elements to allow the reaction to proceed. All these model substrates have the 3′-terminal CCA sequence and none are cleaved efficiently when the CCA sequence is altered. Therefore, it appears that the CCA sequence, as we had recognized earlier with normal tRNA precursors,[59]

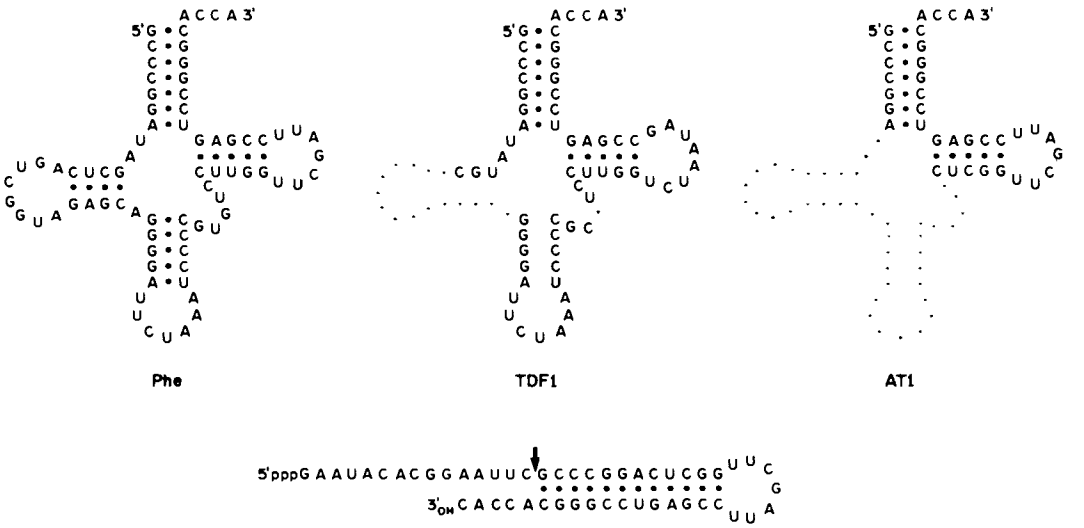

Fig. 11. Structure of mature $tRNA^{Phe}$ and derivatives of it, encoded by synthetic genes. Top: The sequences are shown without the modified nucleotides characteristic of mature $tRNA^{Phe}$ because they are not present in the transcripts made in vitro. The transcripts contain "extra" nucleotides at both ends of the molecules (after [58]). Bottom: Structure of the AT-1 precursor drawn in a stem and loop structure similar to the corresponding region in $tRNA^{Phe}$. The arrows mark the site of cleavage by RNase P or M1 RNA. The sequence of mature AT-1 is shown in the upper part of the figure. (Reprinted with permission from [58].)

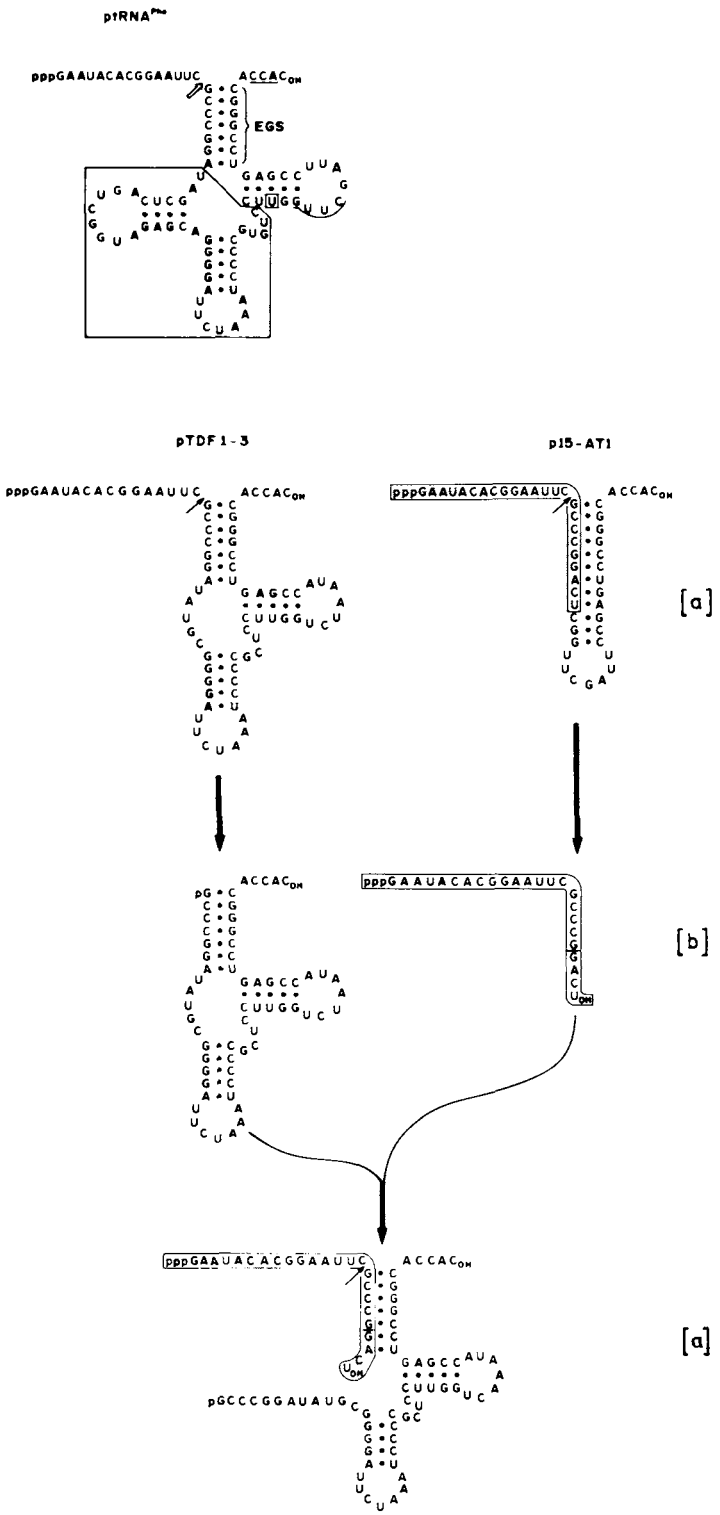

Fig. 12. Scheme for the formation of substrates for RNase P by hybridization of two oligoribonucleotides. TDF-1 (see Fig. 11) was prepared by cleavage by RNase P in vitro of its precursor molecule that had been transcribed in vitro [58]. A portion (boxed sequence) of the precursor to AT-1 (Fig. 11) was prepared by transcription in vitro of a restriction fragment of the DNA that encoded the AT-1 synthetic gene (A.C. Forster and S. Altman, *Science (Washington, D.C.)* (1990), in press). [a], cleaved; [b] uncleaved.

and at least one half turn of a RNA helix play an essential role in recognition of small substrates.

Conclusions from experiments with model substrates have to be tempered by the knowledge that some recognition elements, which appear to play a prominent role in these examples, may not play as important a role and/or may be supplemented by other elements in the normal tRNA precursors found in cells. It is certainly the case that a change in the D stem or anticodon stem of a normal tRNA precursor can have a dramatic effect on the rate of cleavage by RNase P even though these regions of the substrate are entirely absent from the model substrates.

Through the hybridization of two oligoribonucleotides, as shown in Figure 12, we can create and manipulate novel substrates. An "external guide sequence" which can guide RNase P to its target, can be hybridized in theory to any other RNA of known sequence and will form the 3′ or downstream part of the substrate. RNase P should then cleave the hybrid target at the junction between the single- and double-stranded region at the 5′ side of the double-stranded region. This new method presents opportunities to investigate more precisely the details of the recognition mechanism and it also provides, in principle, a means to inactivate any RNA of known sequence in vivo (Fig. 13). Aside from the problem

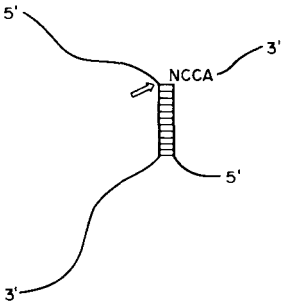

Fig. 13. Targeting of RNA for cleavage by RNase P. An external guide sequence (EGS) is shown by the shorter line ending in NCCA. N is most frequently found to be A in tRNA molecules. The region of the EGS shown as hydrogen-bonded is designed to be complementary to a region of known sequence in the RNA to be targeted.

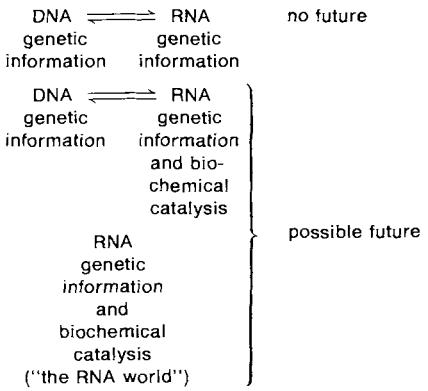
of the expression of the external guide sequence in vivo, the method does have the advantage that RNase P is already present in cells of all types. Providing that the hybrid can be designed to be compatible with the cleavage-site specificity of the enzyme in the particular host organism of choice, the target RNA should be inactivated.

In this example of the use of one oligoribonucleotide to target another RNA that is to be cleaved by RNase P, substrate recognition by the enzyme resembles, in a formal sense, selection of the site of cleavage by some of the other known RNA catalysts. Group I introns and the satellite and similar RNAs use guide sequences[4,5] in the selection of cleavage sites or to form structures in which a cleavage site becomes defined. In virtually all other respects, these reactions are quite distinct from that carried out by RNase P.

The Past, Present, and Future of RNase P

The discovery of RNA catalysis has led to new hypotheses about the origin of the earliest self-replicating biochemical systems. Models of these early systems rely entirely on RNA

as the genetic material and as the source of catalytic activity (Scheme 2).[6, 7, 10, 11] All this speculation clearly presupposes that what we see in present-day systems reflects, in some manner, the properties of RNA over a billion years ago. Should that indeed be the case, the richness of biochemical mechanisms exhibited by RNA (see Table 1) is impressive and can allow for the development of rather complex systems in the absence of protein and DNA. In this context, we shall allow ourselves to consider very briefly some aspects of the reactions governed by RNase P in vitro.



Scheme 2. A representation of three possible schemes of information transfer before proteins were part of the scheme. The mechanisms, nonenzymatic or enzymatic, of information transfer between DNA and RNA are unspecified. The phrase "the RNA world" was coined by *Gilbert* [7].

Although M1 RNA can cleave very simple substrates, it is apparent that these particular cleavage reactions cannot occur in vivo today because such cleavages would occur too frequently in the population of RNA in any cell: that is, the entire population of RNA molecules would be too susceptible to degradation by RNase P. However, one can imagine that in an RNA world, there was considerable advantage to having an RNA molecule that could identify many sites in very long molecules generated by enzymatic or nonenzymatic mechanisms. The proliferation of many smaller molecules from larger ones would give rise to the possibility of a great variety of conformations of RNA in solution, some of which may have endowed RNA with catalytic activity or other useful functions that very long transcripts did not have.

Setting aside for the moment the details of the origin of the genetic code and the appearance of proteins, one can ask why a protein subunit became associated with M1 RNA? We recently showed that the protein subunit of RNase P can alter the site of cleavage and affect the rate of the reaction in a manner sensitive to the nature of the particular substrate being used.[52, 60] Thus, it is possible that proteins may have fine-tuned the site specificity of RNA enzymes by enhancing the rates of reaction at particular sites and with particular substrates. What we see today as the "normal" cleavage sites of RNA enzymes may have been selected for over the eons, in conjunction with the appearance of protein cofactors, as physiological conditions changed during evolutionary time. The "unselected" reactions—for example, those with very small hairpin substrates—became in consequence second- or lower-order reactions and are no longer relevant to events in vivo.

Finally, why do RNA enzymes only cleave phosphodiester bonds? Three answers come readily to mind. First and most trivially, RNA enzymes may cleave or form other classes of bonds and we just have not yet made the critical observations or found the right reaction conditions (the last part of the answer is a generic response to questions about the lack of success in performing any reaction in vitro). Second, it is possible that, in the RNA world, RNA molecules could only cleave or form phosphodiester bonds: it was a primitive world and no other reactions were governed by enzymes. Once proteins appeared on the scene there was no further need to diversify RNA enzymes. Lastly, and most important, the chemistry of RNA enzymes and enzymes with RNA subunits,[61,62] when sufficiently well-understood, may indicate to us that there is a compelling reason why RNA molecules cleave only phosphodiester bonds. The validity, or lack of it, of this last answer can be tested by direct experimentation, and therein lies the work of the next several years.

My indebtedness to so many people makes it impractical to list them all here. Nevertheless, I wish to express my gratitude to my parents, my family, my teachers (especially Leonard Lerman, Mathew Meselson, Sydney Brenner, John D. Smith, and Lee Grodzins), my professional colleagues and collaborators (especially Hugh Robertson and William H. McClain) and my students and co-workers (especially Cecilia Guerrier-Takada) in my laboratory. The taxpayers of the United States, through the agencies of the National Institutes of Health and the National Science Foundation, have generously supported my work.

Self-splicing and Enzymatic Activity of an Intervening Sequence RNA from *Tetrahymena* (Nobel Lecture)**

By Thomas R. Cech*

Introduction

A living cell requires thousands of different chemical reactions to utilize energy, move, grow, respond to external stimuli, and reproduce itself. While these reactions take place spontaneously, they rarely proceed at a rate fast enough for life. Enzymes, biological catalysts found in all cells, greatly accelerate the rates of these chemical reactions and impart to them extraordinary specificity. In 1926, *James B. Sumner* crystallized the enzyme urease and found that it was a protein. Skeptics argued that the enzymatic activity might reside in a trace component of the preparation rather than in the protein,[1] and it took another decade for the generality of *Sumner*'s finding to be established. As more and more examples of protein enzymes were found, it began to appear that biological catalysis would be exclusively the realm of proteins. In 1981 and 1982, my research group and I found a case in which RNA, a form of genetic material, was able to cleave and rejoin its own nucleotide linkages. This self-splicing RNA provided the first example of a catalytic active site formed of ribonucleic acid. This lecture gives a personal view of the events that led to our realization of RNA self-splicing and the catalytic potential of RNA. It provides yet another illustration of the circuitous path by which scientific inquiry often proceeds. The decision to expend so many words describing the early experiments means that much of our current knowledge about the system will not be mentioned. For a more comprehensive view of the mechanism and structure of the *Tetrahymena* self-splicing RNA and RNA catalysis in general, the reader is directed to a number of recent reviews.[2-7] Possible medical and pharmaceutical implications of RNA catalysis have also been described recently.[8]

Why *Tetrahymena*?

In the pre-recombinant DNA era of the early 1970s, much of the research on the structure and function of eukaryotic chromosomes utilized entire genomes as experimental systems. My own research with *John Hearst* in Berkeley and with *Mary Lou Pardue* at the Massachusetts Institute of Technology (MIT) concerned the organization of DNA sequences and chromosomal proteins in the mouse genome. During my stay at MIT, I began to be dissatisfied with this global approach and became interested in the prospect of being able to dissect the structure and expression of some particular gene. Thus, when I set up my own laboratory in Boulder in 1978, I turned my attention entirely to the rDNA (gene for the large ribosomal RNAs) of the ciliated protozoan *Tetrahymena* (Fig. 1).

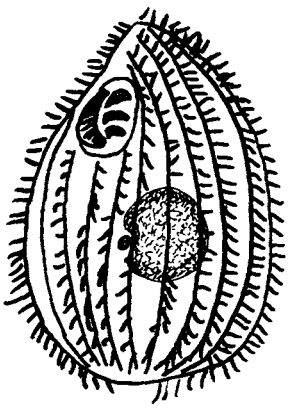

Fig. 1. *Tetrahymena thermophila*, showing the transcriptionally active macronucleus and the germ-line micronucleus.

Unlike most nuclear genes, which are embedded in giant chromosomes, the genes for rRNA in *Tetrahymena* are located on small DNA molecules in the nucleoli; they are extrachromosomal.[9, 10] Furthermore, in the transcriptionally active macronucleus the gene is amplified to a level of approximately 10000 copies.[11] These properties made it possible to purify a significant amount of the rDNA. The ability to purify the gene was not in itself a major attraction, because by this time the availability of recombinant DNA techniques ensured that no gene would long escape isolation and sequence analysis. Rather, the attractive feature was the prospect of being able to isolate the gene complete with its associated structural proteins and proteins that regulated transcription (the synthesis of an RNA copy by RNA polymerase).

One feature of the *Tetrahymena* rDNA that was of only peripheral interest to me at that time was the presence of an intervening sequence (IVS) or intron, which interrupted the rRNA-coding sequences of the rDNA of some strains of *Tetrahymena pigmentosa*.[12] In the course of mapping the RNA-coding regions of the rDNA of *Tetrahymena thermophila, Don Rio* and I found that this species also harbored an IVS in its rDNA (Fig. 2;[13] independently described by *Din* et al.[14]). Although intervening sequences had been discovered only two years before by *Phil Sharp*'s lab at MIT and a group from Cold Spring Harbor Laboratory, there were already a large number of examples. Thus, the finding of another IVS was hardly cause for us to be distracted from our plan to investigate the proteins that regulated rDNA transcription.

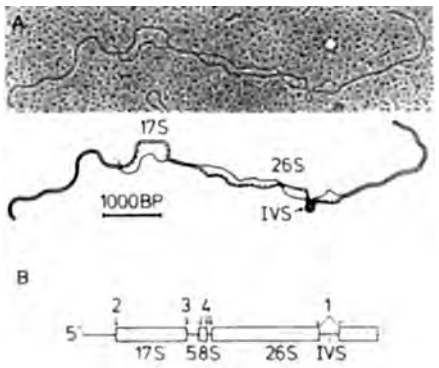

Fig. 2. A) Visualization of the RNA-coding portions of the *T. thermophila* rDNA by electron microscopy. The mature, processed rRNA was hybridized to the DNA under R-loop conditions. In the interpretation, each solid line indicates a single strand of DNA and each dashed line a strand of RNA. (Reproduced from [13].) BP = base pair. B) The pre-rRNA, thin lines representing portions that are removed during processing and open boxes representing the mature rRNA sequences. Numbered arrows indicate the usual order of RNA processing events: 1, splicing; 2–4, endonucleolytic cleavages.

RNA Splicing in Vitro

The first step towards biochemical dissection of the transcriptional process was to see if rRNA synthesis would proceed in a crude cell-free system. We isolated nuclei from *T. thermophila* (the nuclei provided both the RNA polymerase and the ribosomal chromatin templates) and incubated them with the nucleoside triphosphates and salts necessary for transcription. We also included α-amanitin, a mushroom toxin known to inhibit the polymerases that transcribe mRNA, tRNA, and other small RNAs, which enabled us to focus on synthesis of the large rRNA.

When the products of these in vitro transcription reactions were separated by gel electrophoresis, they were found to consist of a somewhat heterogeneous distribution of high-molecular-weight RNA (≥ 26 S), the size expected for full-length pre-rRNA (Fig. 3). In addition, there was a discrete low-molecular-weight product (ca. 9 S). The small RNA accumulated post-transcriptionally.[15] Thus, it seemed likely to be one of several short regions of the pre-rRNA that was cut out and ultimately discarded during the maturation process. These candidate regions included an external transcribed spacer at the 5′ end, the internal transcribed spacers flanking the 5.8 S rRNA, and the IVS (cf. Fig. 2B).

Driven more by curiosity than by any conviction that the results would be of central importance to our research goals, I encouraged *Art Zaug* to identify the sequences encoding the small RNA. He confirmed that the small RNA was encoded by the rRNA gene, and then mapped it to the intervening sequence.[15, 16]

Fig. 3. Transcription and splicing of pre-rRNA in vitro in isolated *T. thermophila* nuclei. Lanes 1–4: RNA produced by incubation of nuclei at 30 °C for times ranging from 5 to 60 min. The 0.4-kilobase species is the excised IVS RNA. Lanes 5 and 6: Purified *Tetrahymena* 26 S and 17 S rRNAs, serving as molecular weight standards. RNA was analyzed by polyacrylamide gel electrophoresis. (Reproduced from [15].)

This was a finding of considerable excitement: the intervening sequence, synthesized as part of the pre-rRNA in our in vitro transcription reactions, was also being cleanly excised from the pre-rRNA in vitro. Despite a great deal of interest in the mechanism of RNA splicing,[17–20] in only one other case—pre-tRNA in yeast—had RNA splicing been confirmed to occur in vitro.[21, 22] It seemed reasonable that rRNA splicing in *Tetrahymena* might follow a quite different path than tRNA splicing in yeast, so that detailed study of both systems would be justified.

Furthermore, in each *Tetrahymena* cell there were 10 000 identical genes, each pumping out unspliced pre-rRNA at the rate of one copy per gene per second. I reasoned that the nuclei might contain an unusually high concentration of the splicing enzyme to accomplish so much reaction, which could facilitate isolation of the first splicing enzyme. Little did we guess that the splicing "enzyme" would not exist in the traditional sense, but that something much more interesting lay in wait for us.

Thomas R. Cech, born on December 8, 1947, studied chemistry at Grinnell College, Iowa (B. A., 1970) and at the University of California, Berkeley (Ph. D., 1975). Following postdoctoral research in the Department of Biology at MIT, he joined the faculty of the University of Colorado, Boulder, in 1978. His finding of self-splicing RNA and subsequent analysis of the mechanisms of RNA catalysis have led to many national and international awards and prizes, culminating in the Nobel Prize in Chemistry in 1989. In 1987, Dr. Cech was elected to the National Academy of Sciences (USA). He remains at the University of Colorado, where he is American Cancer Society Professor and Investigator, Howard Hughes Medical Institute.

Self-splicing Unrecognized

Our strategy for purifying the splicing enzyme was conventional. We would find conditions in which pre-rRNA transcription occurred but splicing was inhibited, and purify the accumulated pre-rRNA to use as a substrate. We would then treat the pre-rRNA with extracts of *Tetrahymena* nuclei, which we already knew contained splicing activity, and would use gel electrophoresis to monitor the splicing reaction. Finally, we would obtain ever-purer subfractions of the nuclear extract that retained activity, eventually isolating the splicing enzyme.

Isolation of unspliced pre-rRNA substrate proved to be straightforward.[23] *Art Zaug* purified this RNA by standard SDS-phenol (SDS = sodium dodecyl sulfate) extraction and used it in a series of RNA splicing reactions. One set of test tubes contained substrate RNA and nuclear extract dissolved in the same solution of simple salts and nucleotides that had been conducive to RNA transcription and splicing in our earlier experiments with intact nuclei. Another tube, containing the same components except with the nuclear extract omitted, was to serve as the "splicing minus" control.

The very first attempt was successful. The RNA in the tubes containing the nuclear extract gave rise to the small band of RNA characteristic of the IVS. Surprisingly, however, the control RNA incubated only in salts and nucleotides produced the same amount of IVS. "Well, Art, this looks very encouraging, except you must have made some mistake making up the control sample." Yet several careful repetitions of the experiment gave the same result: release of the IVS occurred independently of the addition of nuclear extract and therefore apparently independently of any enzyme. I became concerned that we weren't observing RNA splicing at all; perhaps the RNA we had been calling "precursor" had already been spliced in vivo, and what we were observing in vitro was some disaggregation or release of the IVS from already-spliced RNA. Clearly, the reaction would be worthy of further pursuit only if we could show that a chemical transformation was occurring in vitro, and that it was the same cutting and rejoining that occurred in the living cell. We would have to teach ourselves some RNA chemistry.

The Mystery of the Extra G

To verify the accuracy of RNA splicing in nuclei, we decided to determine the nucleotide sequence of the IVS RNA product. (It was not obvious that this would be particularly illuminating, since we had already shown that the IVS product came from the IVS region of the rDNA and that, within the error limits of our measurements, it was the correct size to account for the entire IVS.) When *Art Zaug* labeled the RNA on its 5′ end with ^{32}P and subjected it to sequencing reactions, he determined a sequence 5′-GAAAUAGNAA ... (where N represents an unidentified nucleotide). The DNA sequence across the exon–IVS junction had been reported earlier for *T. pigmentosa* by *Wild* and *Sommer*[24] and was being determined for *T. thermophila* by *Nancy Kan* in *Joe Gall*'s laboratory. The *T. thermophila* DNA sequence predicted that the IVS RNA would begin with 5′-AAAUAGCAA ...

Thus, our RNA sequence was a perfect match to the DNA sequence except for the extra G residue on its 5′ end. *Art Zaug* meticulously checked and rechecked the identity of this terminal nucleotide using a variety of enzyme treatments and chromatography systems until there was no doubt: the IVS RNA began with an ordinary guanosine residue, linked to the next nucleotide by a standard 3′–5′ phosphodiester bond such as that produced by RNA polymerase. Clearly the *Gall* lab, known for the high quality of their science, must have made an error. We telephoned them, advising them that they had determined most of the sequence correctly but had apparently missed one G right at the 5′ end of the IVS. Much to our surprise, they defended every nucleotide of their sequence: no ambiguity in the DNA sequence, at least in that region, and no chance of a G at the 5′ splice site.

At about the same time, I was working to define the minimum components necessary for the release of the IVS from pre-rRNA. The original experiments had been done in a "transcription cocktail" that included the four nucleoside triphosphates, building blocks for RNA synthesis. I found that removal of three of the NTPs had no effect on the reaction, but the fourth, GTP, was required in micromolar concentration. In addition, IVS release required $MgCl_2$ and was stimulated by certain salts such as $(NH_4)_2SO_4$.

Was it a coincidence that GTP, the nucleotide required for IVS release in our simple in vitro system, was also the nucleotide that was found unexpectedly at the 5′ end of the excised IVS? Or might there be a causal relationship between the two observations? The obvious hypothesis was that GTP was required so that it could be added to the 5′ end of the IVS during splicing. The test was simple: mix ^{32}P-labeled GTP with unlabeled pre-rRNA, and look for labeling of the IVS RNA concomitant with its excision. The experiment was the strangest I had ever performed. On the one hand, its success was a straightforward prediction from our existing knowledge of the system. On the other hand, it seemed incredibly naive and unrealistic to expect that simple mixing of a nucleotide with phenol-extracted, proteinase-treated RNA could possibly result in formation of a covalent bond. I certainly didn't want to be embarrassed in front of my graduate students and colleagues by the failure of such an experiment, so I did it very quietly.

The next day I ran the gel, exposed it for autoradiography, and developed the X-ray film. In the sample containing ^{32}P-GTP plus $MgCl_2$ there was a bright signal of radioactivity at the position of the IVS RNA. In a sample containing ^{32}P-GTP but no $MgCl_2$, and in a sample in which ^{32}P-ATP had been substituted for the ^{32}P-GTP, there was no labeled IVS.

Over the next weeks, we confirmed several major features of the reaction. GTP addition was stoichiometric, one GTP per IVS RNA. The GTP was added precisely to the 5′ end of the IVS by a normal 3′–5′ phosphodiester bond. Finally, the triphosphate was unnecessary; GMP and even guanosine were active. The last of these observations eliminated one otherwise very reasonable hypothesis, that the GTP was providing an energy source for ligation much as ATP is used by phage T4 RNA ligase. Had that been the case, forms such as guanosine and GMP, which are missing the phosphoanhydride moiety, would have been inactive.

It took only a few moments of thought to devise a simple splicing pathway that integrated our new information about

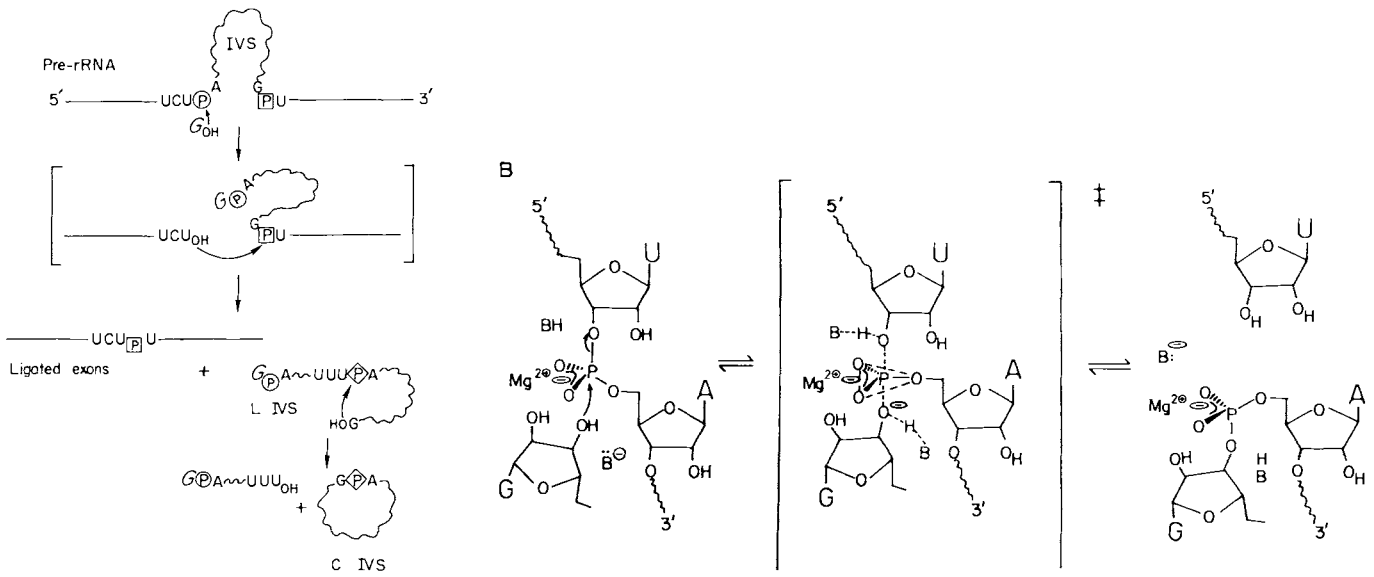

Fig. 4. A) Self-splicing of the *Tetrahymena* pre-rRNA by consecutive transesterification reactions. Straight lines, exons (mature rRNA sequences); wavy line, IVS; circle, 5′ splice-site phosphate; square, 3′ splice-site phosphate; diamond, cyclization site phosphate. B) Model for the initial step involving nucleophilic attack by the 3′-hydroxyl group of guanosine on the phosphorus atom at the 5′ splice site. The hypothesis of an in-line, S_N2 (P) reaction with inversion of configuration around phosphorus was subsequently confirmed [31]. The hypotheses of acid-base catalysis and coordination of $Mg^{2\oplus}$ to the phosphate, enhancing the electrophilicity of the phosphorus atom and stabilizing the trigonal-bipyramid transition state, are untested. (Reproduced from [3].)

the reaction. Addition of guanosine to the phosphorus atom at the 5′ splice site must be occurring by a transfer of phosphate esters, or transesterification reaction (Fig. 4A). Such a reaction would free the 5′ exon, leaving a new 3′-hydroxyl group at its 3′ end. The simplest way to proceed from such proposed intermediates to the final observed products was to invoke a second transesterification reaction: attack of the 3′ hydroxyl of the 5′ exon at the 3′ splice site. Thus, a single active site capable of promoting transesterification could be responsible for the entire splicing reaction.

The model shown in Figure 4A has undergone little change since we first described it in 1981 and drew a more explicit version in 1982.[23, 25] It has been a good predictor of a great many other IVS-catalyzed reactions since then.[26, 27] Furthermore, the model has been strongly bolstered by the isolation and characterization of the proposed intermediates,[28] by the demonstration of the reversibility of the reactions,[29, 30] and by determination of the stereochemical course.[31, 32] An atomic-level model of transesterification occurring by an S_N2 (P) mechanism is presented in Figure 4B.

Self-splicing Recognized

The guanosine-addition reaction provided us with the proof we needed: specific RNA bond breakage and formation were occurring in our simple in vitro splicing reaction. Such a chemically difficult reaction between very unreactive molecules certainly had to be catalyzed. But what was the catalyst?

Our first hypothesis was that the splicing activity was a protein tightly bound (perhaps even covalently bonded) to the pre-rRNA isolated from *Tetrahymena* nuclei. This would have to be a very unusual protein–RNA complex to survive the multiple forms of abuse to which we had subjected it: boiling in the presence of the detergent SDS, SDS-phenol extraction at temperatures as high as 65 °C, and extensive treatment with several nonspecific proteases (Fig. 5). That we took this hypothesis seriously provides an indication of how deeply we were steeped in the prevailing wisdom that only proteins were capable of highly efficient and specific biological catalysis.

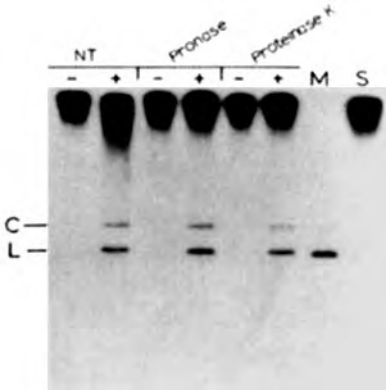

Fig. 5. IVS RNA excision and cyclization activities are resistant to protease treatment. Lane S: Pre-rRNA, purified by SDS-phenol extraction. This RNA was then treated exhaustively with proteases or not treated (NT). Incubation with GTP was performed, in the absence of $MgCl_2$ (lanes −) or with 10 mM $MgCl_2$ (lanes +). Excision of the IVS RNA as a linear molecule (L) and subsequent conversion to a circular form (C) were undiminished by protease treatment. Lane M: Isolated linear and circular IVS RNAs. (Reproduced from [96].)

In the same paper, we described an alternative hypothesis:[23]

The resistance of the splicing activity to phenol extraction, SDS and proteases can also be interpreted in a

more straightforward manner. The rRNA precursor might be able to undergo splicing without the participation of a protein enzyme. A portion of the RNA chain could be folded in such a way that it formed an active site or sites that bound the guanosine cofactor and catalyzed the various bond-cleavage and ligation events. If one of the RNA molecules produced in the reaction (for example, the free IVS) retained its activity and catalyzed additional splicing events, then it would be an example of an RNA enzyme.

As we accumulated negative result upon negative result trying to identify a protein stuck to the pre-rRNA, the alternative "RNA only" hypothesis began to appear more and more attractive. But how could we obtain a positive result to prove it?

The best strategy we could devise was to synthesize the RNA in as artificial a manner as possible, so that it was never in contact with the *Tetrahymena* cells that up to now had been our sole source of the RNA. Complete chemical synthesis of an RNA the size of the pre-rRNA (or even the size of the IVS) was and still is beyond the scope of available technology. The next best approach was to synthesize RNA from a recombinant DNA template using purified RNA polymerase.

A bacterial plasmid (Fig. 6) encoding the IVS and a portion of the flanking rRNA sequences, situated so as to allow

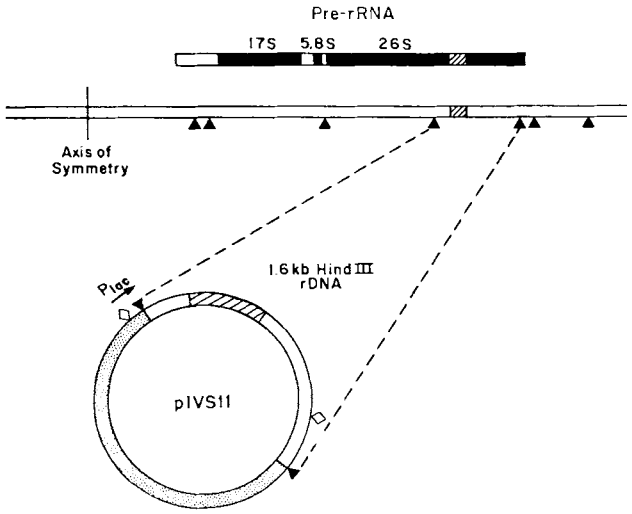

Fig. 6. Plasmid constructed to enable synthesis of an artificial, shortened version of the pre-rRNA. Top: Diagram of the natural pre-rRNA, with transcribed spacers shown as open boxes, mature rRNA sequences as solid boxes, and the IVS as a hatched box. Middle: The *T. thermophila* rDNA. One half of a palindromic rDNA molecule is shown. Bottom: Plasmid pIVS11 containing the 1.6-kilobase Hind III fragment of the rDNA inserted adjacent to P_{lac}, a promotor for transcription by *E. coli* RNA polymerase. Restriction endonuclease sites are Hind III (▲) and *Eco* RI (◇). (Adapted from [34].)

transcription by *Escherichia coli* RNA polymerase, was already being constructed in the lab by *Kelly Kruger*. The original purpose was to facilitate synthesis of large quantities of pre-rRNA substrate for isolation of the splicing enzyme. The cloning took longer than any of us had anticipated, such that by the time it was accomplished early in 1982 we were desperate to have the plasmid for a different purpose: to produce synthetic pre-rRNA for the self-splicing test.

The plasmid was grown up in *E. coli*, carefully deproteinized, and incubated with purified *E. coli* RNA polymerase under conditions that we already knew were inhibitory for splicing. The polymerase was then destroyed and the RNA purified by gel electrophoresis under denaturing conditions. Upon addition of GTP, $MgCl_2$, and salt, the IVS RNA was released from this artificial, shortened pre-rRNA. The site at which GTP broke the RNA chain was exactly the position that served as the 5′ splice site in vivo, providing some confidence that self-splicing was relevant to splicing as it occurred in the living cell.

We held a relatively subdued celebration in the lab. Between sips of champagne we compiled a list of possible general names for RNA molecules able to lower the activation energy for specific biochemical reactions. It was then that we coined the term "ribozyme" for a ribonucleic acid with enzymelike properties.

RNA in Circles

Concurrent with our studies of pre-rRNA splicing in isolated nuclei, we were pursuing a post-splicing phenomenon: the conversion of the excised intervening-sequence RNA into a circular RNA molecule in isolated *Tetrahymena* nuclei.[33] The circular form survived treatment with protease and various denaturants, which suggested that it was a covalently closed circle of RNA. As *Paula Grabowski*, then a graduate student in the laboratory, characterized the cyclization reaction, she found that it occurred with extensively deproteinized RNA in a simple buffered $MgCl_2$ solution. I dismissed her original observation of protein-free cyclization as being an artifact of incomplete denaturation of the linear RNA. Yet, as the experiments proved reproducible, I began to derive some solace in the knowledge that two researchers, *Zaug* and *Grabowski*, studying two different reactions, splicing and cyclization, were both finding activity in the absence of added protein. Having two strange results somehow made me more comfortable than having just a single strange result. The two sets of observations came together when we found that the plasmid transcripts that underwent self-splicing produced IVS RNA that underwent self-cyclization.[34]

The circular IVS RNA was not formed by end-to-end joining of the linear form. Instead, the 3′ end of the linear IVS attacked an internal phosphorus atom near the 5′ end of the molecule, clipping off a short oligonucleotide in the process (Fig. 4A). Thus cyclization, like RNA splicing, occurred by transesterification.[26]

How Does the RNA Do It?

At first glance, RNA seemed ill-suited to be a catalyst. With its four rather similar bases, RNA would appear greatly limited in its ability to form a specific substrate-binding pocket. In contrast, the 20 amino acids found in proteins explore a wide range of sizes and shapes, hydrophilicity and hydrophobicity. In terms of promoting chemistry, RNA has a dearth of functional groups that are ionizable near neutral

pH, whereas proteins have histidine and cysteine (pK_a's in the range of 6–8). How, then, was the *Tetrahymena* IVS able to catalyze transesterification?

The first glimpse of the catalytic mechanism came from detailed studies of the guanosine requirement. *Brenda Bass* tested every available guanosine analogue and found great variation in their activity.[35, 36] Derivatives carrying bulky substituents on the 7 or 8 position of the guanine base or on the 5′ position of the ribose sugar were as active as guanosine, indicating that these positions did not interact with the IVS RNA. Other derivatives were fully active but only at high concentration, or were inactive as substrates but acted as competitive inhibitors of the reaction of guanosine. Using the K_m or K_i of these guanosine analogues, we could assign free energy contributions to individual functional groups of guanosine. All the data pointed to the IVS containing a well-behaved binding site for guanosine. The site has recently been located within the IVS in elegant work by *Michel* et al.[37]

The existence of a G-binding site explained the high specificity for guanosine. In addition, by orienting the nucleophile with respect to the 5′-splice-site phosphate, the G site would contribute substantially to rate acceleration. RNA catalysis was suddenly in a familiar context; the loss of entropy and orientation of reacting groups achieved by formation of a specific enzyme–substrate complex is central to catalysis by protein enzymes.[38, 39]

The other reactant in the first transesterification step, the phosphorus atom at the 5′ splice site, is also held in place by a binding interaction. As first proposed by *Davies* et al.[40] and also apparent in models of *Michel* et al.,[41] a 5′ exon-binding site within the IVS base-pairs to the last few nucleotides of the 5′ exon. This pairing interaction specifies the site of guanosine addition and also holds the 5′ exon in place for the second step of splicing, exon ligation.[42–45]

The IVS does much more than simply hold the reacting groups in place. In the absence of guanosine, hydrolysis occurs specifically at the splice-site phosphodiester bonds, producing 5′-phosphate/3′-hydroxyl termini.[28, 46] A 3′ hydroxyl is the same as the product of self-splicing but opposite to the product of random alkaline hydrolysis of RNA. This site-specific hydrolysis reaction reflects the ability of the catalytic center of the IVS to activate the splice-site phosphates (or perhaps activate the nucleophile, in which case it must be able to activate $OH^{\ominus}$ as well as the hydroxyl of guanosine). While the structural basis of this activation is unknown, reasonable hypotheses include stabilization of the pentacoordinate transition-state structure of the phosphate and specific coordination of a $Mg^{2\oplus}$ ion.[3, 46–49] Once again, in a general sense the RNA catalyst is recapitulating a major catalytic strategy of protein enzymes, or vice versa.

Tetrahymena Is Not Alone

While we were intently characterizing splicing of the *Tetrahymena* IVS, we were also wondering when (and perhaps if) related intervening sequences would be found in other organisms. The differences in nucleotide sequences near the splice sites made it seem unlikely that *Tetrahymena* rRNA splicing would be related to nuclear tRNA or mRNA splicing. The related intervening sequences came from an unexpected direction: yeast mitochondria. This was unanticipated because mitochondria, thought to have arisen from symbiotic prokaryotes, do not usually have genes or modes of gene expression similar to those of eukaryotes. Furthermore, yeast is evolutionarily extremely distant from *Tetrahymena*.

In 1982, several groups identified short sequence elements that were conserved among a group of fungal mitochondrial intervening sequences.[40, 41, 50] Furthermore, both the Michel group[41] and the Davies group[40] had proposed that the conserved sequence blocks interacted to form a common set of short base-paired regions, serving to fold the intervening sequences into the same fundamental secondary structure (Fig. 7, top). *Michel* called these the group I in-

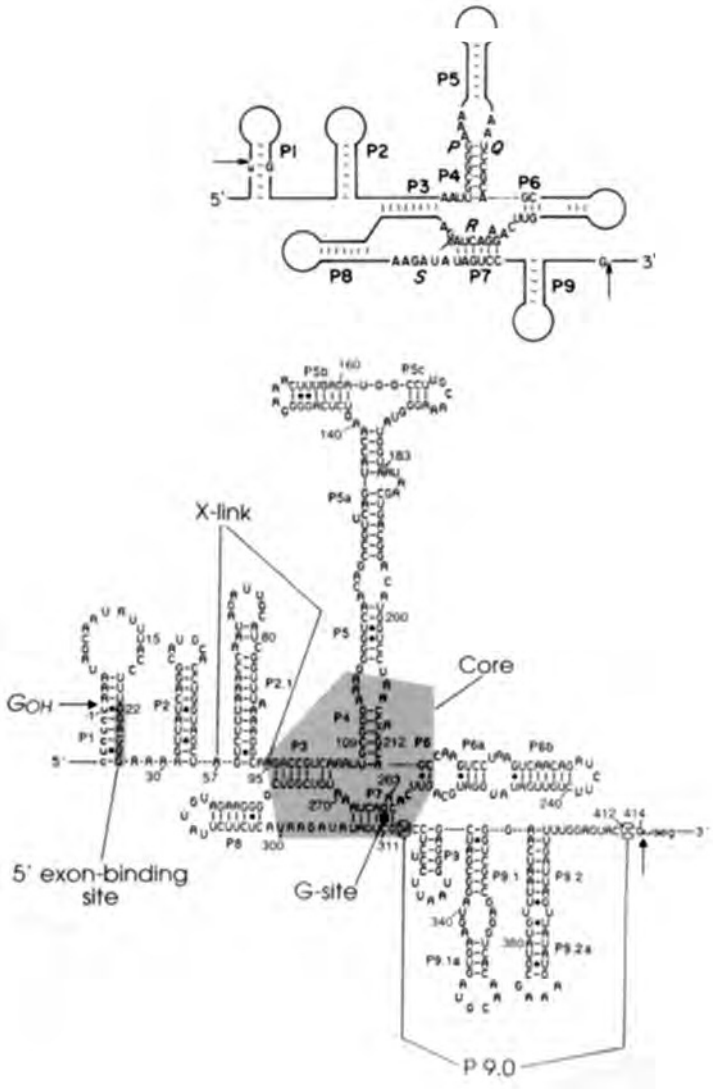

Fig. 7. Secondary structure of group I intervening sequences determined by *Michel* et al. [41] and Davies et al. [49] by the method of comparative sequence analysis [97, 98]. A) Generalized structure indicating conserved base-paired elements P1–P9. Conserved sequence elements, P, Q, R, and S are represented by their most common nucleotide sequences. Filled arrows, 5′ and 3′ splice sites. Open arrow, site of insertion of extra stem loop(s) in group IA structures. B) Secondary structure of the *T. thermophila* rRNA IVS, with the 5′ exon-binding site and the core structure most conserved in group I IVSs shaded. Guanosine-binding site (G site) was located by *Michel* et al. [37]. UV-induced cross-link (X-link) identifies a tertiary structure interaction [99]. Lowercase letters, exons; uppercase letters, IVS. (Adapted from [4].)

trons, to distinguish them from a second group of mitochondrial introns that shared a different structure.[51]

The *Tetrahymena* rRNA IVS contained the conserved sequence elements and secondary structures characteristic of the mitochondrial group I.[51,52] Furthermore, a very similar structure model of the *Tetrahymena* IVS was independently derived by another method, free-energy minimization as constrained by experimentally determined sites of cleavage of the folded RNA by various nucleases.[53] A current version of the secondary structure is shown in Figure 7, bottom.

This convergence of two previously noninteracting sets of ideas was important in several respects. In terms of splicing mechanisms, it was now unlikely that the *Tetrahymena* intron would be unique; we could extend our knowledge of its mechanism by comparing and contrasting splicing of different members of the group. Second, a believable model of the secondary structure of the *Tetrahymena* IVS was now in hand, and one could begin to formulate structure–function relationships. Finally, the similarity between the *Tetrahymena* rRNA and fungal mitochondrial introns might be revealing their origin; perhaps they were transposable elements able to enter both nuclear and mitochondrial compartments.[53]

Waiting for Number Two

If RNA catalysis were of any general significance to biology, there would be additional examples. Throughout 1982 and most of 1983, none came forth. Yet there seemed to be some reasonable candidates. In the fall of 1983, we wrote an article in which we speculated:[35]

> Several enzymes, such as RNase P, 1,4-α-glucan branching enzyme and potato *o*-diphenol oxidase, have RNA components essential for their catalytic activities. The peptidyl transferase activity of ribosomes also requires an RNA-protein complex. It remains to be seen whether the RNA is directly involved in the active site of any of these ribonucleoprotein enzymes.

The speculation about RNase P was already outdated when our paper was published in 1984, because by that time *Guerrier-Takada* et al.[54] had announced that the RNA component was the catalytic subunit of that ribonucleoprotein enzyme. This was followed by the report early in 1984 that a synthetic *E. coli* RNase P RNA, transcribed in vitro from a recombinant DNA template, also had intrinsic catalytic activity; the possibility that catalysis was due to protein contamination was thereby eliminated.[55] Similarly, the RNA subunit of *Bacillus subtilis* RNase P acted as an enzyme in vitro.[54,56] The RNase P discovery was very exciting to us. Not only did it provide a second example of an RNA molecule that lowered the activation energy for a specific biochemical reaction, but it was the first proven case of an RNA molecule that catalyzed a reaction without itself undergoing any net change. RNA catalysis was not restricted to the realm of intramolecular catalysis.

Within the next year, self-splicing of additional group I intervening sequences was reported. *Garriga* and *Lambowitz*[57] found that the first IVS of the cytochrome *b* pre-mRNA from *Neurospora* mitochondria underwent self-splicing in vitro. Several self-splicing group I RNAs from yeast mitochondria were characterized by *van der Horst* and *Tabak*.[58] Most unexpectedly, self-splicing group I IVSs were found in three bacteriophage T4 mRNAs;[59–61] RNA splicing took place in a prokaryote. In all cases, splicing occurred by the same G-addition pathway as splicing of the *Tetrahymena* nuclear rRNA IVS.

The mitochondrial group II intervening sequences have conserved sequences and secondary structures distinct from those of group I.[51] *Peebles* et al.[62] and *Van der Veen* et al.[63] discovered that pre-mRNA containing a group II intervening sequence was self-splicing in vitro. The reaction did not require guanosine and occurred by formation of a branched "lariat" RNA. The proposed mechanism is shown in Figure 8.

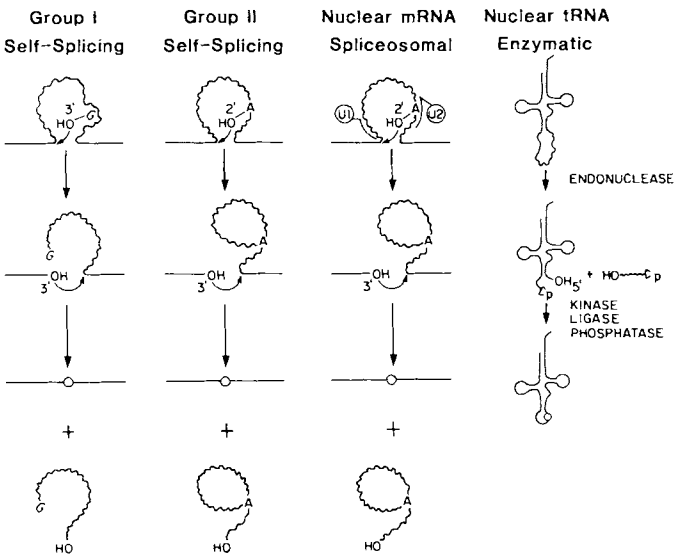

Fig. 8. Mechanism of splicing of the four major groups of precursor RNAs. Wavy lines indicate IVSs, smooth lines indicate flanking exons. For nuclear mRNA splicing, many components assemble with the pre-mRNA to form the spliceosome; only the U1 and U2 small nuclear ribonucleoproteins are shown here. (Adapted from [102].)

The fundamental chemistry of group II RNA splicing appears to be the same as that of nuclear pre-mRNAs, which do not self-splice. Instead, nuclear mRNA splicing requires assembly of the substrate with a large complex of proteins and small nuclear ribonucleoproteins to form the spliceosome.[64–67] The mechanistic similarities have led to the speculation that nuclear mRNA splicing may also be RNA catalyzed, with much of the catalysis being provided in the form of the small nuclear RNAs.[34,67]

Enzymologists Outraged

Although our description of RNA self-splicing was shocking to many, it was quickly accepted by the scientific community. In contrast, our use of the words "catalysis" and

"enzymelike" to describe the phenomenon provoked some much more heated reactions.

Our reasons for emphasizing the relationship between RNA self-splicing and biological catalysis might be better appreciated in the context of the definition given in Table 1. First, biological catalysts achieve rate accelerations of the order of 10^6 to 10^{13}, bringing the reactions into a time scale that is useful for living systems. Self-splicing clearly meets

Table 1. Defining characteristics of biological catalysis (from [95]).

Characteristic	Self-splicing	L – 19 IVS RNA
1. Rate acceleration	+	+
2. Specificity	+	+
3. Catalyst regenerated	[a]	+

[a] No, although the active site is preserved through the reactions.

this criterion; although the quantitation of rate acceleration can be done only for the site-specific hydrolysis reaction promoted by the RNA active site, even the rate of this relatively slow side-reaction is 10^{10}-fold higher than the estimated uncatalyzed rate (Fig. 9). Second, the extraordinary

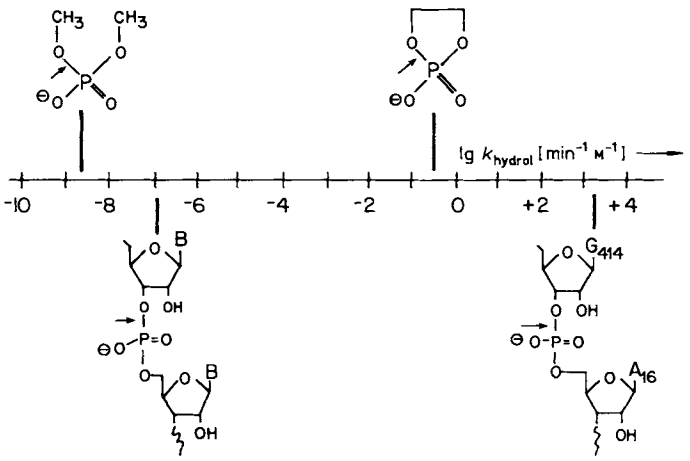

Fig. 9. The IVS RNA has an extremely efficient catalytic center. Second-order rate constants (42 °C) for the alkaline hydrolysis of phosphate diesters are displayed on a logarithmic scale. Arrows designate the P–O bond that undergoes cleavage. Above line: Data for dimethyl phosphate and ethylene phosphate from *Kumamoto* et al. [100] and *Haake* and *Westheimer* [101]. Below line: Hydrolysis of RNA uncatalyzed (left) and catalyzed (right) by the catalytic center of the *Tetrahymena* IVS. (Reproduced from [3].)

specificity of biological catalysts is evident in the self-splicing reaction; the molecule selects GTP as the attacking group for the first step of the reaction and is able to choose 2 of the 6000 nucleotides in the pre-rRNA as splice sites. On the other hand, the IVS RNA is clearly not regenerated in exactly the same form as it entered the reaction; after all, the purpose of self-splicing is to convert pre-rRNA into ligated exons plus excised IVS. Nevertheless, enzymologists do speak of intramolecular catalysis,[38, 39, 68] and we thought that such a descriptor was particularly appropriate for self-splicing.

The enzymologists who reviewed our article (*Bass* and *Cech*[35]) were far from convinced. All three referees wrote thoughtful reviews, expressing considerable interest in the data but chastising us for our naivete about enzymes. For example:

> Enzymes are true catalysts: they speed the rate of a reaction, but are themselves unchanged by the reaction. In the present instance, the ribozyme acts in a "one-shot" reaction and is permanently changed so that it can no longer cycle as does a true catalyst. The authors are well aware of this, but appear to ignore this key feature in making their comparisons.

How fundamental was this distinction between self-splicing and catalysis? Opinions would probably vary as much today as they did six years ago. Instead of engaging in a protracted argument, we decided to test experimentally whether the self-splicing RNA could be converted into a multiple-turnover catalyst. *Arthur Zaug* made a slight alteration of the self-splicing IVS, removing its first 19 nucleotides. The resulting L – 19 IVS RNA met all three criteria of a biological catalyst[69] (Table 1).

Shortened forms of the *Tetrahymena* IVS have multiple enzymatic activities. Depending on the substrates with which they are presented, these RNA enzymes can catalyze nucleotidyl-transfer, phosphotransfer, and hydrolysis reactions; nucleotidyl transfer can result in either endonucleolytic cleavage or polymerization of RNA.[43, 69–74]

As an example, consider the reaction diagramed in Figure 10. A form of the IVS RNA missing both its splice sites catalyzes the cleavage of other RNA molecules after sequences resembling that of the normal 5′ exon, CUCU. The reaction is an intermolecular version of the first step of RNA self-splicing, in which RNA cleavage is accompanied by covalent joining of guanosine to the 5′ end of the 3′ cleavage product. Because the IVS RNA is unaltered by the reaction, it can sequentially bind and process a large number of substrate RNA molecules. The k_{cat}/K_m for cleavage of an oligoribonucleotide substrate containing a CCCUCU recognition sequence is 10^8 M^{-1} min^{-1},[75] well within the range of protein enzymes.

Site-directed mutagenesis of the 5′ exon-binding site of the IVS redirects substrate specificity as predicted by the rules of Watson–Crick base-pairing.[71, 76] Thus, it has been possible to create a whole set of "RNA restriction endonucleases" that may be of use for the sequence-specific cleavage of RNA.

Converting a self-processing RNA into an RNA enzyme by physically separating its internal substrate from its catalytic center has been generally successful. The "hammerhead" and "hairpin" ribozymes, both found in plant infectious agents (viroids or viral satellite RNAs), undergo self-cleavage leaving 2′,3′-cyclic phosphate termini.[77, 78] Both have been converted into RNA enzymes.[79–81] A group II IVS can cleave RNA containing a 5′ splice site or ligated exon RNA in an intermolecular reaction,[82, 83] although in these cases multiple turnover was not demonstrated. Even the intramolecular lead-cleavage reaction of tRNA can be converted into an enzymatic system.[84] The ability of pieces of a structured RNA molecule to self-assemble, recreating an active unit, therefore appears to be a general property of the RNA biopolymer. In addition, if the fragment that undergoes reaction is secured to the rest of the molecule by a

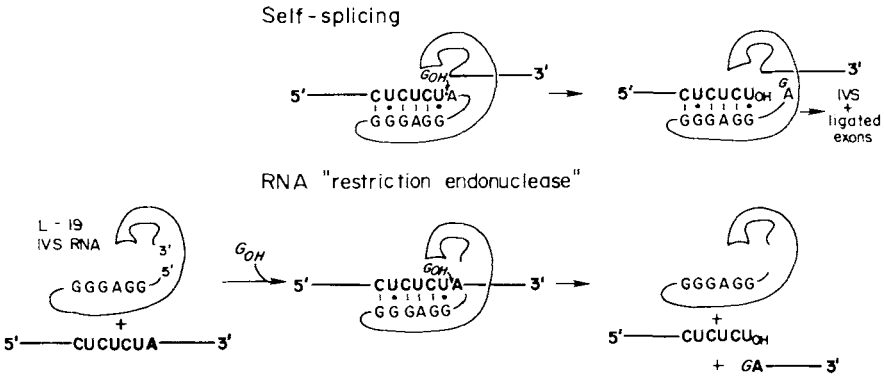

Fig. 10. A shortened version of the *Tetrahymena* IVS RNA has enzymatic activity as an endonuclease. The mechanism is an intermolecular version of the first step of pre-rRNA self-splicing. Thin letters and lines, IVS sequences; bold letters and thick lines, exon sequences (top) or substrate RNA sequences (bottom); G in italics, free guanosine or GTP. (Reproduced from [71].)

relatively weak interaction such as a few base pairs, it will dissociate quickly enough to permit multiple turnovers.

Origin of Life Fantasies

The discoveries of RNA self-splicing and the enzymatic activity of RNase P RNA rekindled earlier speculation concerning the possible role of RNA in the origin of life.[85-87] Contemporary cells depend on a complex interplay of nucleic acids and proteins, the former serving as informational molecules and the latter as the catalysts that replicate and express the information. Certainly the first self-reproducing biochemical system also had an absolute need for both informational and catalytic molecules. The dilemma was therefore, *Which came first, the nucleic acid or the protein, the information or the function?* One solution would be the coevolution of nucleic acids and proteins.[88] The finding that RNA can be a catalyst as well as an information carrier lent plausibility to an alternative scenario: the first self-reproducing system could have consisted of RNA alone.[87, 89, 90]

Perhaps coincidentally or perhaps because of its ancestry, one of the reactions catalyzed by the *Tetrahymena* IVS RNA enzyme is a nucleotidyl-transfer reaction with fundamental similarity to the reaction catalyzed by RNA replicases.[69, 73] A specific model for RNA self-replication based on the properties of the catalytic center of the *Tetrahymena* IVS RNA is given in Figure 11. The RNA enzyme (ribozyme*) differs from the L-19 IVS RNA in that it utilizes an external rather than an internal template.[91] Separation of the template region from the rest of the catalytic center of the RNA with retention of activity has recently been achieved by *Doudna* and *Szostak*.[74]

Now that we have examples of catalytic RNAs, it has been entertaining to look back at earlier speculations about the catalytic potential of RNA. As a representative example, consider the following:[92]

> ... in the evolutionary scheme, folded nucleic acid structures were abandoned by nature in favour of proteins. Although nucleic acids may have performed many enzymatic tasks in primitive cells, this is much more efficiently done by proteins....With nucleic acids the four bases are all of one structural type, though the existence of many modified bases points to an evolutionary proliferation giving much greater possibilities in forming structures. Nevertheless, the use of bases cannot match the enormous flexibility provided by having twenty amino acids which fall into three or four different structural types.

One implication is that nucleic acids, if they could have any such activity, would by nature be inferior catalysts. At one time I had a similar bias, but it was gradually dispelled as we quantitated the rate acceleration and specificity inherent to the catalytic center of the *Tetrahymena* ribozyme. The

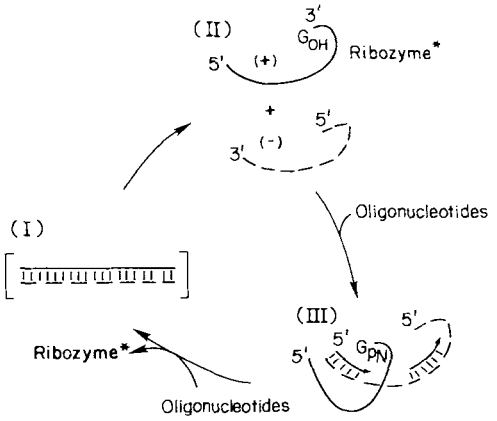

Fig. 11. Hypothetical model for RNA self-replication involving an RNA catalyst (ribozyme*). Double-stranded RNA (I) undergoes strand separation to give ribozyme* ((+) strand) and the complementary (-) strand (II). The ribozyme* catalyzes synthesis of a new (+) strand, using the (-) strand as a template (III). The detailed mechanism is described in [91]. Completion of synthesis re-forms the double-stranded RNA (I). A second cycle is needed to achieve replication of the starting material.

second conclusion, regarding the limited versatility of RNA catalysts, still strikes me as being correct. In all well-established examples, the substrate for an RNA catalyst or ribonucleoprotein enzyme is RNA or DNA or, in the case of protein synthesis on ribosomes, the closely related aminoacyl-tRNA. To its credit, RNA can form a specific binding site for at least one amino acid,[93] and there is evidence that covalent linkage of the terminal protein to poliovirus RNA is at least in part RNA-catalyzed.[94] Nevertheless, it seems unlikely that RNA can match the enormous variety of binding sites that can be formed from amino-acid side chains. The list of RNA catalysts is still growing quite rapidly. Yet it seems likely that if an entire list of biological catalysts is ever complete, it will include more proteins than RNA molecules.

I dedicate this lecture to my wife Carol and to my parents, Robert and Annette. I am indebted to my co-workers over the past decade, who performed the experiments and contributed many of the ideas about RNA catalysis described here. In addition to those whose work I have described, there are many who made important contributions that have gone unmentioned here but not at all unappreciated. Funding for our research has been provided principally by the National Institutes of Health and the American Cancer Society, and more recently by the Howard Hughes Medical Institute; I thank them for their uninterrupted and enthusiastic support. Finally, I have enjoyed the comradeship and helpful criticism of the RNA research community, both in Boulder and worldwide.

A Spacious Cyclophane Host for Inclusion Complexation of Steroids and [m.n]Paracyclophanes**

By *Daniel R. Carcanague* and *François Diederich**

Over the past years, we have investigated the binding properties of tetraoxa[n.1.n.1]paracyclophanes such as **1**.[1, 2] The two diphenylmethane units in these water-soluble hosts shape cavities with pronounced apolar character suitably sized for inclusion of flat aromatic and, to some extent, also alicyclic guests.[1-4] Here we describe the synthesis and complexation properties of the new host **2**. Contrary to **1**, compound **2** possesses a wider apolar binding site for the inclusion of larger, more spherical guests.[5, 6] In **1**, the distance between the two oxygens of one diphenylmethane unit, which defines the cavity width, is 8.41 Å (X-ray analysis).[2] At about 10.6–11.2 Å, depending on the host conformers (MMX force-field calculations),[7] the O···O distance at the naphthylphenylmethane units in **2** is considerably larger.

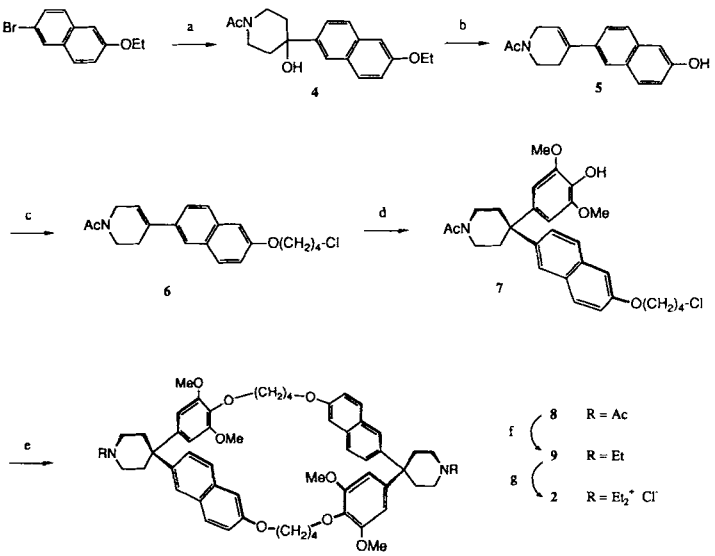
3

The selective complexation of cholesterol from aqueous solution and the complexation-induced dissolution of solid cholesterol deposits represent worthwhile targets in molecular recognition. Therefore, exploring the binding of steroids was of interest in our first studies with **2**.[5, 6, 8] Furthermore, by forming inclusion complexes of [m.n]paracyclophanes, we intended to show unambiguously that the dimensions of the binding site of **2** are suitable for incorporation of two π systems in a sandwich-type orientation. Such a demonstration would be followed by investigations of the supramolecular catalysis of reactions between two included guests (e.g., the Diels–Alder reaction).[9, 10]

The synthesis of cyclophane **2** is shown in Scheme 1.[11] Steroid complexation by **2** was investigated by ^{1}H NMR spectroscopy in D_2O/CD_3OD (1:1 v/v) at 293 K. Table 1 shows the results of binding titrations, performed at concentration ranges below the critical aggregation concentration of the host (cac ≈ 5 mM). The complexation-induced shifts of the isolated signals of the steroid methyl groups were best monitored and evaluated in these titrations. Cholic acid derivatives, corticoids, and androgenic steroids form stable complexes with **2**. According to CPK model examinations, the steroids are included in an axial geometry as depicted in Figure 1. Axial rotation is maintained in the complex. This geometry allows the highly solvated polar functional groups of the steroids at C-3 in ring A and at ring D to orient into the solution. In agreement with an axial inclusion geometry, the ^{1}H NMR resonances of the steroid methyl groups show characteristic upfield complexation shifts.



Scheme 1. a) Mg, THF, 1-acetyl-4-piperidone; 50–60% yield; **4**, m.p. 169–171 °C. b) 3.5 equiv. BBr_3, CH_2Cl_2, 40 °C, 3 h; **5**, m.p. 193 °C (dec.). c) NaH, DMF, 10 equiv. 1,4-dichlorobutane; 65% yield (from **4**); **6**, m.p. 89 °C. d) 7 equiv. $BF_3 \cdot Et_2O$, CH_2Cl_2, 6 equiv. 2,6-dimethoxyphenol, 20 °C, 6 d; 80% yield; **7**, m.p. 139–141 °C. e) 3 equiv. Fig. 1. Schematic representation of the axial inclusion of lithocholic acid (**10e**).

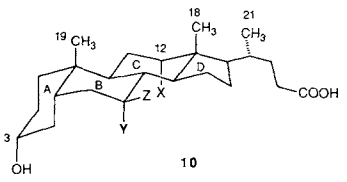
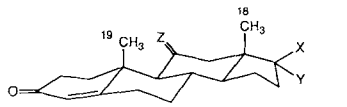
High binding selectivity is observed in the series of structurally related bile acid derivatives **10a–e**. The complex formed by deoxycholic acid (**10b**) (K_a = 250 L mol^{-1}) is approximately 2 kcal mol^{-1} less stable than the complex of lithocholic acid (**10e**) (K_a = 7075 L mol^{-1}) due to the presence in **10b** of only one additional hydroxyl group at C-12α. In the complex of lithocholic acid (**10e**), the apolar surfaces of rings B, C, and D interact favorably with the cavity walls of complementary polarity. In contrast, complexes of the other cholic acid derivatives **10a–d** are destabilized by unfavorable interactions between the strongly solvated hydroxyl groups at their rings B and C and the apolar cavity walls. Similarly, in the series **11a–c**, testosterone (**11c**) forms a more stable complex than the two corticoids **11a**, **b** having polar functional groups at ring C.



10

Steroid	X	Y	Z
a cholic acid	OH	OH	H
b deoxycholic acid	OH	H	H
c chenodeoxycholic acid	H	OH	H
d ursodeoxycholic acid	H	H	OH
e lithocholic acid	H	H	H



11

a hydrocortisone	$COCH_2OH$	OH	αH, βOH
b cortisone	$COCH_2OH$	OH	O
c testosterone	OH	H	H_2

The presence of polar, highly solvated groups at the central rings B and C of the steroid skeleton also affects the geometry of the complexes. Characteristic upfield shifts of the steroid methyl resonances in the ^{1}H NMR spectra indicate that ring B of **10a** and **10b** is preferentially encapsulated (Table 1). The derivatives **10c–e** are preferentially included at rings C and D, whereas the corticoids **11a**, **b** and testosterone (**11c**) are incorporated at rings A and B.

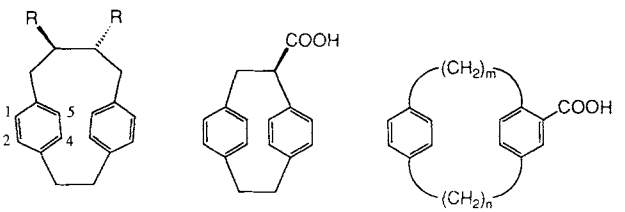
Cyclophane **2** shows high selectivity for apolar steroids. Other alicyclic systems, such as the sodium salt of 1-adamantylacetic acid (K_a = 115 L mol^{-1}, ΔG° = − 2.77 kcal mol^{-1}) or camphor (K_a = 145 L mol^{-1}, ΔG° = − 2.90 kcal mol^{-1}) are more weakly bound. These guests[12] are unable to fill the large cavity of **2**. The nonmacrocyclic comparison compound **3** and cyclophane **1** do not undergo complexation with steroids under the above-mentioned conditions.

Table 1. Association constants K_a and free binding energies $-\Delta G^0$ for the steroid complexes of cyclophane **2** [a] and upfield complexation shifts $\Delta\delta$, calculated for saturation binding, of the ^{1}H NMR resonances of the steroid methyl groups in positions 18, 19, and 21 in the complexes of **2**; D_2O/CD_3OD (1:1 v/v), T = 293 K.

Steroid	K_a [L mol^{-1}]	$-\Delta G^0$ [kcal mol^{-1}]	$\Delta\delta$ CH_3 (19)	CH_3 (18)	CH_3 (21)
10a[b]	145	2.90	0.73	0.56	0.25
10b[b]	250	3.21	0.76	0.66	0.39
10c[b]	810	3.91	0.47	1.40	0.89
10d[b]	1750	4.35	0.30	1.49	1.23
10e[b]	7075	5.18	0.55	1.49	0.90
11a	1095	4.08	1.44	0.22	
11b	1510	4.26	1.48	0.30	
11c	3545	4.76	1.48	0.43	

[a] All values obtained by nonlinear least-squares curve fitting of 500-MHz ^{1}H NMR binding titrations. Concentration ranges during titrations were chosen to provide approximately 20–90% complexation of the steroid present at constant total concentration. Accuracy of the K_a values: ± 10%. [b] Solutions contain 0.01 M Na_2CO_3.

The formation of structurally defined inclusion complexes by [m.n.]paracyclophanes as guests[13] was observed for the first time with cyclophane **2** as the host (Table 2). Cavity inclusion of compounds **12–18** is supported by strong upfield shifts of the aromatic guest resonances and characteristic up- and downfield shifts of the host resonances in ^{1}H NMR spectra of solutions of their complexes. For example, the upfield shifts of the aromatic guest resonances at saturation binding of **12** are $\Delta\delta$ = 0.86 and 0.63 (1-H and 5-H, respectively) and $\Delta\delta$ = 1.82 and 2.03 (2-H and 4-H, respectively). In the ^{1}H NMR spectrum of a solution of **2** (1 mM) and **12** (4 mM), the signals of the bridges in the host are shifted upfield ($\Delta\delta$ = 0.04 to 0.15) and those of the phenyl protons weakly downfield ($\Delta\delta$ = − 0.04). For the naphthyl resonances of the host, characteristic downfield complexation shifts are observed [$\Delta\delta$ = − 0.14 (1-H), − 0.21 (3-H), − 0.18 (4-H), − 0.13 (5-H), − 0.14 (7−H), − 0.15 (8-H)]. These shifts indicate a preference for an inclusion geometry in which the four benzene rings of host and guest are aligned in a fourfold π–π stacking array (Fig. 2).[14]



12 R = COOH
13 R = OH

14

15 m = n = 2
16 m = n = 3
17 m = 3, n = 4
18 m = n = 4

The binding strength is strongly dependent on the site of attachment of carboxylate residues to the paracyclophane skeleton. The complexes of **12** and **14** with carboxyl residues attached to the paracyclophane bridges are the most stable. In contrast, a [4.4]paracyclophanedicarboxylic acid bearing one carboxyl function at each benzene ring no longer forms a complex with **2**. Upon inclusion, the two carboxylates of this guest would be positioned deeply inside the apolar cavity. Apparently, the costs for desolvation of two carboxyl residues are too large for such a process to take place.

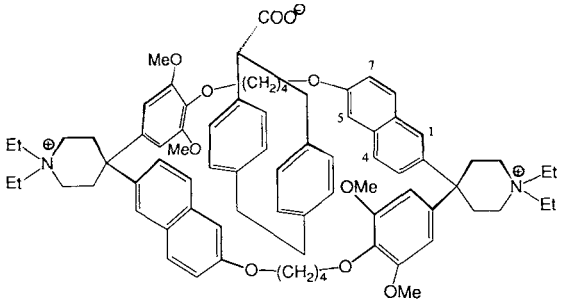


Fig. 2. Schematic representation of the geometry of the [m.n]paracyclophane complexes which, according to ^{1}H NMR analysis, is favored in solution.

Apolar interactions and desolvation rather than ion pairing provide the major driving force for efficient steroid or cyclophane complexation by **2**. This is demonstrated by the favorable binding of the neutral guests **11a–c** and **13**. The stability of all complexes formed in the solvent mixture D_2O/CD_3OD (1:1 v/v) is remarkably high. Based on previous experience, association constants for the complexes in pure water should be about two magnitudes higher than those shown in Tables 1 and 2 for the binary mixture.[15]

Table 2. Association constants K_a and free binding energies $-\Delta G^0$ for the complexes formed between [m.n]paracyclophanes **12–18** and host **2** in D_2O/CD_3OD (1:1 v/v) containing 0.01 M Na_2CO_3, $T = 293$ K [a].

[m.n]Paracyclophane	K_a[L mol^{-1}]	$-\Delta G^0$[kcal mol^{-1}]
12	840	3.92
13[b]	460	3.57
14	530	3.64
15	200	3.07
16	375	3.43
17	440	3.54
18	425	3.54

[a] For the method, see Table 1. [b] No Na_2CO_3 added.

With compound **2**, we have prepared a host which widens considerably the spectrum of guests to be complexed. The cholesterol complex of **2** is insoluble, and its stability could not be determined. The development of modified derivatives of **2** which form water-soluble cholesterol complexes and investigations of supramolecular reactivity in 1:2 host–guest complexes of **2** are currently being pursued in our laboratory.

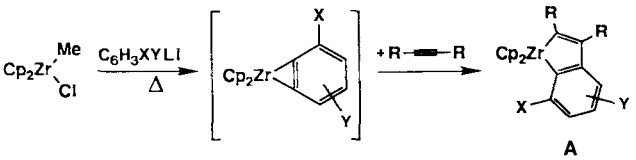
The Synthesis and Structure of Stibaindoles**

By *Stephen L. Buchwald,* Richard A. Fisher,* and *Bruce M. Foxman*

Heterocyclic compounds are ubiquitous in organic chemistry and have, consequently, been a popular synthetic target. The vast majority of these efforts have focused on naturally occurring heterocyclic skeletons containing second- and third-row elements with significantly less attention directed to their heavier main-group analogues.[1] As a consequence, an impressive array of useful reactions is available to the chemist wishing to construct heterocycles of N, O, P, and S, while methods for the synthesis of their heavier analogues are limited.[2] Here we report the synthesis and characterization of a series of new metalloid heterocycles, benzo[*b*]stiboles.[3]

In the course of developing new zirconocene-based methodology for organic synthesis, we,[4i–k] and others,[4a–h] have established that sequential treatment of zirconocene(methyl) chloride with an aryllithium and an alkyne, followed by heating, affords the metallacycle **A**.



The generality of this reductive coupling reaction is documented elsewhere.[4] Treatment of benzene solutions of the zirconacycles **1–3** with one equivalent of $XSbCl_2$ (**a**, X = Cl; **b**, X = Ph) produces the benzo[*b*]stiboles **4–6**.[5] The only byproduct of the reaction, Cp_2ZrCl_2, is removed by flash chromatography on alumina III (**4b–6b**) or anhydrous $MgSO_4$ (**4a–6a**).

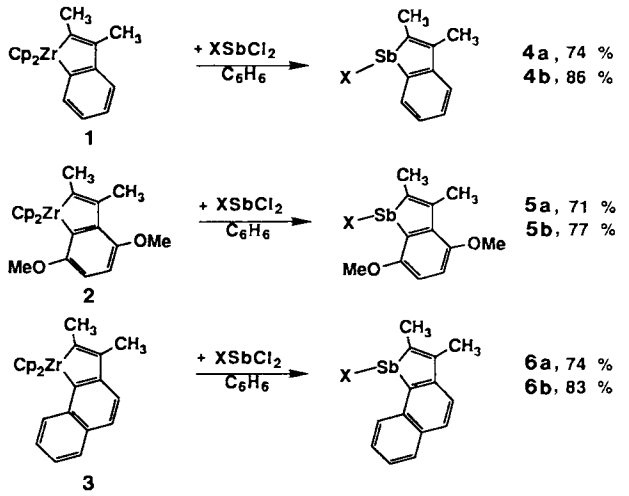
[**] This work was supported, in part, by the Office of Naval Research and by Union Carbide,whom we gratefully acknowledge.

The antimony metallacycles **4**–**6** are moderately air stable, crystalline solids. The 1-chloro derivatives slowly decompose, when stored for prolonged periods in air, to give as yet uncharacterized species. They may be stored indefinitely in a dry nitrogen atmosphere. The 1-phenyl derivatives are substantially more robust and may be stored in the laboratory atmosphere without detectable decomposition. Complexes **4**–**6** are all considerably more prone to decomposition in



solution than in the solid state. All the compounds were characterized by ^{1}H NMR, ^{13}C NMR, IR, and combustion analysis or high-resolution mass spectrometry. Solution molecular-weight determinations indicate that the stibaindoles are monomeric in benzene solution.[6]

An X-ray crystal structure determination was carried out on compound **5b**,[7] and the structure is shown in Figure 1.

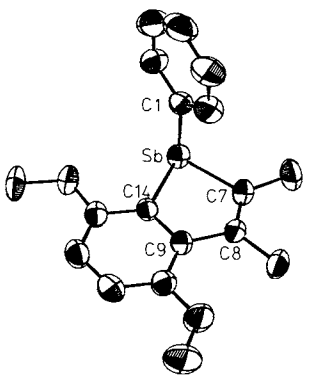


Fig. 1. Molecular structure of **5b**. Bond distances [Å] and angles [°]: Sb-C1 2.164(4), Sb-C7 2.131(3), Sb-C14 2.119(3), C7-C8 1.334(4), C8-C9 1.504(3), C9-C14 1.387(4); C1-Sb-C7 96.5(1), C1-Sb-C14 95.5(1), C7-Sb-C14 79.9(1).

The stibaindole ring is planar, as anticipated (no deviations greater than 0.03 Å), and orthogonal to the plane of the phenyl ring. The shortest intermolecular Sb–Sb distance is 4.75 Å. The highly pyramidalized geometry about the antimony atom, the bond distances, and bond angles are all in good agreement with other structurally characterized stibole derivatives.[7]

Continued interest in heterocyclic compounds coupled with recent applications of main-group organometallics in materials science provides a powerful incentive for the development of new and more selective synthetic routes to main-group metallacycles. Results from this laboratory, and elsewhere, indicate that early-transition-metal complexes may play an important role in the discovery of new and valuable classes of main-group compounds.

Experimental Procedure

General procedure for the preparation of stibaindoles: The zirconacycle (1.00 mmol) was dissolved in 20 mL of benzene in a nitrogen-filled dry box. Either antimony trichloride (0.228 g, 1.00 mmol) or phenylantimony dichloride (0.270 g, 1.00 mmol), was added, all at once, as a solid. After 5 min, the flask was sealed with a septum, brought out of the dry box, and the solvent removed, in vacuo, on a Schlenk line. Zirconocene dichloride and the desired stibaindoles were the only species detectable in the crude reaction mixture as determined by ^{1}H NMR. The zirconocene dichloride was separated from the product by extraction with 10/1 hexanes/ether followed by rapid chromatography on either anhydrous $MgSO_4$ (**4a**, **5a**, **6a**) or alumina II (**4b**, **5b**, **6b**).

Cp*Ru(acac)—A Coordinatively Unsaturated, Stable 16-Valence-Electron Complex**

By *Ulrich Kölle,** *Janusz Kossakowski*, and *Gerhard Raabe*

According to extended Hückel MO calculations of *P. Hofmann*,[1] the MLL plane in d^6 complexes of the $CpML_2$ type should be tilted with respect to the MCp normal (C_s symmetry). This prediction is of importance for the retention of configuration on substitution at the central atom of "chiral metal" complexes CpMLL'L''. In many cases, such substitutions proceed stereospecifically with retention.[2] For example, the "pyramidal" cation $[CpRe(NO)PPh_3]^{\oplus}$ [3] generated from optically active $[CpRe(NO)PPh_3Me]$ not only undergoes stereospecific substitution reactions,[4] but also adds olefins enantioselectively.[5] Furthermore, the inversion of the pyramidal cation $[CpCo(PR_3)Et]^{\oplus}$ results in equilibration of the protons of the ethyl group.[6]

In $[Cp^*RuP(cyclo\text{-}C_6H_{11})_3Cl]$[7] the coordination gap at Ru is filled by the bulky phosphane ligand; accordingly, the P-Ru-Cl plane is orthogonal to the Cp* plane. The title compound represents the first structurally characterized, coordinatively unsaturated, fivefold coordinated d^6 complex with a pyramidal structure in the ground state.

The discovery of the alkoxo complex ["Cp"RuOR]$_2$ (**1**, "Cp" = η^5-C_5Me_5 (Cp*), η^5-C_5Me_4Et),[8] which is formed surprisingly readily [Eq. (a)] and, for **1a** (R = Me, "Cp" = Cp*), practically quantitatively from the halides ["Cp"$RuCl_2]_2$, provided an entry to a series of valuable starting materials, which allowed the preparative chemistry of the "Cp"Ru fragment to be extensively explored.[9, 10]

$$[\text{"Cp"}Ru^{III}Cl_2]_2 + 2ROH \xrightarrow[-2KCl,\ -R'CHO]{K_2CO_3} \underset{\mathbf{1}}{[\text{"Cp"}Ru^{II}OR]_2} \qquad (a)$$

Reaction of **1a** with acetylacetone in a molar ratio of 1:2 at room temperature in ether [Eq. (b)] affords, within a few minutes, the acac derivative **2**.[11] Compound **2**, like complexes **1**, is air-sensitive and displays a similar intense red color (λ_{max} = 520 nm); it crystallizes from pentane as red needles.

$$\underset{\mathbf{1a}}{1/2[Cp^*RuOMe]_2} + acacH \xrightarrow{-MeOH} \underset{\mathbf{2}}{Cp^*Ru(acac)} \qquad (b)$$

In accordance with its coordinatively unsaturated character, **2** (like **1**) readily adds two-electron ligands to give compounds **3**[12] [Eq. (c)].

$$\underset{\mathbf{2}}{Cp^*Ru(acac)} + L \xrightarrow[\text{pentane}]{} \underset{\mathbf{3}}{Cp^*Ru(acac)L} \qquad (c)$$

L	CO	PMe_3	$P(OMe)_3$	PPh_3
3	**a**	**b**	**c**	**d**

The carbonyl compound **3a**, like **1a**,[10a] is not very stable; on the other hand, more stable complexes are formed with phosphane and phosphite ligands. Reaction (c) is a rare example of simple addition to a coordinatively unsaturated system and therefore proceeds very fast.[13]

Of preparative interest is the reaction of **2** with hard Lewis acids such as $Zn^{2\oplus}$ or $Mg^{2\oplus}$, which, similar to the reaction of **1** with protonic acids,[9a, 10a] results in degradation to the cationic $Cp'Ru^{\oplus}$ fragment. This fragment is thus accessible without the use of protonic or strong Lewis acids and can therefore be widely used in complexation reactions such as (d).[14, 15]

$$\underset{\mathbf{2}}{Cp^*Ru(acac)} + 1/2\ Zn(BF_4)_2 \begin{cases} \xrightarrow[MeOH]{C_4H_4S} \underset{\mathbf{4}}{[Cp^*Ru(\eta^5\text{-}C_4H_4S)]BF_4} \\ \xrightarrow[MeOH]{C_7H_8} \underset{\mathbf{5}}{[Cp^*Ru(\eta^6\text{-}C_7H_8)]BF_4} \end{cases} \qquad (d)$$

The crystal structure of complex **2**[17] (Fig. 1) exhibits two independent molecules in the asymmetric unit and does not show the intermolecular metal–acac interactions[18] often observed for acac complexes (shortest intermolecular distance, Ru···C13, > 5 Å). Unlike the ligand in most other acac complexes, the ligand here is not coplanar with the metal–O–O plane, but rather tilted along the O1–O2 vector by the angle α (Fig. 3), "inward" by 9° in **2** and "outward" by 16° in **3c**. The average Ru–O distances (2.114(4) Å) are short, but longer than in **1a** (Table 1). The most striking feature in **2** is the tilting of the Ru–O1–O2 plane with respect

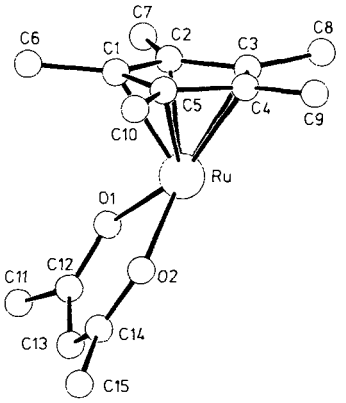

Fig. 1. Molecular structure of **2**.

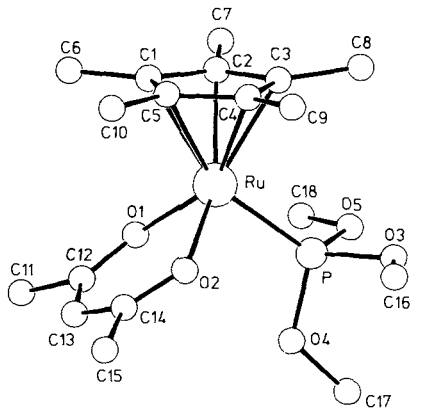

Fig. 2. Molecular structure of **3c**.

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Johnson-Matthey (donation of $RuCl_{3aq}$). We thank Prof. Dr. *C. Krüger*, Max-Planck-Institut für Kohlenforschung, Mülheim a. d. Ruhr, for the opportunity to carry out the structure determination in his laboratory and Prof. Dr. *P. Hofmann*, Technische Universität München, for valuable suggestions.

to the Ru–Cp* normal by $\beta = 37.5°$; that is, the Ru atom has a free, easily accessible coordination site.

On addition of $P(OMe)_3$ to **3c**[19] this tilting increases by only 3° and the Ru–O distances are increased by about 0.02 Å; that is, the structure changes only slightly (Figs. 2 and 3).

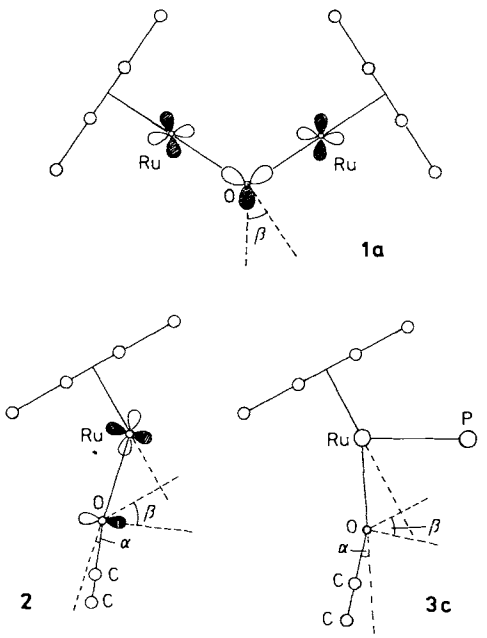

Fig. 3. Schematic drawing of the bonding in **1a**, **2**, and **3c**. The angle β is the angle between the O pz (hybrid) orbitals and the Ru–Cp* normals.

In the methoxo complex **1a**,[10, 16] the Ru–Cp* normals deviate by only 2° from the respective Ru–O–O planes; however, since the two Ru–O–O planes form an angle of 115°, the oxygen p orbitals, as in **2**, are tilted with respect to the RuCp* normals (ca. 34°). Thus, the Cp*–Ru–O orbital arrangement is similar for **1**, resulting here in an opening of the Ru-O-Ru-O rectangle against the van der Waals repulsion of the Cp* methyl groups.

The structural features of **1a**, **2**, and the phosphite complex **3c** are summarized in Table 1.

Table 1. Characteristic bonding parameters in $[Cp^*RuOMe]_2$ (**1a**), Cp*Ru(acac) (**2**), and [Cp*Ru(acac) $(P(OMe)_3]$ (**3c**). Bond lengths in Å, angles in °; see also Fig. 3.

	1a	**2**	**3c**
Ru-O	2.055 (5)	2.114 (4)	2.131 (3)
Ru-C(Cp*)	2.125 (8)	2.132 (6)	2.167 (5)
O-Ru-O	70.9 (2)	85.3 (2)	86.8 (2)
α	-	9.0	16.3
β	33.8	37.5	40.5

Preliminary EHT (EHT = extended Hückel type) calculations indicate that, in comparison to isolobal 16-electron complexes containing acceptor ligands (e.g., $CpMn(CO)_2$[11]), the increased stability of **2** is due, at least in part, to a larger HOMO–LUMO separation.

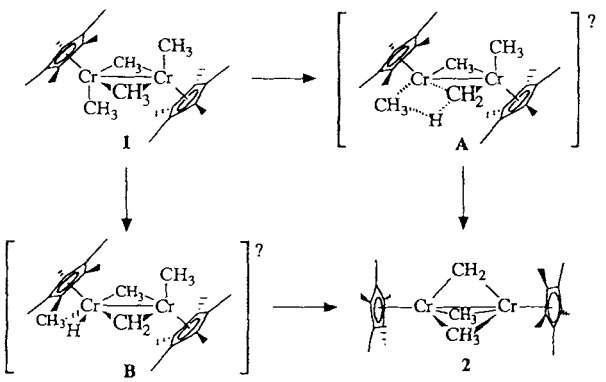
A Paramagnetic μ-Methylene Complex with a Short Cr^{III}–Cr^{III} Bond**

By *Seok Kyun Noh, Robert A. Heintz, Christoph Janiak, Shawn C. Sendlinger*, and *Klaus H. Theopold**

Despite the intensive study of μ-methylene complexes,[1] representatives of this class of organometallic compounds with unpaired electrons are rare,[2] and μ-CH_2 complexes of chromium are unknown. Our ongoing study of the reactivity of paramagnetic chromium(III) alkyls[3] has now produced an unusual molecule with one bridging methylene group and two bridging methyl ligands spanning a Cr–Cr bond. From an inorganic viewpoint this complex represents an unprecedented example of metal–metal bonding between two Cr^{III} ions of a face-sharing bioctahedron.[4]

We have recently reported the synthesis of the methyl-bridged dimer $[Cp^*(CH_3)Cr(\mu\text{-}CH_3)]_2$ (**1**) (Cp^* = pentamethylcyclopentadienyl).[3g] In solution this electron-deficient compound decomposed with a half-life of ca. 4.5 hours at room temperature. Toepler pump experiments and gas-chromatographic analysis showed that 0.92 equivalents of methane were produced in this reaction. In the ^1H NMR spectrum the Cp^* resonance of **1** ($\delta = 0.56$ in C_6D_6) was cleanly replaced with a new signal at $\delta = 3.0$. Recrystallization of the organometallic product from hexanes at $-30\,^\circ C$ yielded analytically pure $[\{Cp^*Cr(\mu\text{-}CH_3)\}_2(\mu\text{-}CH_2)]$ (**2**) in 45% yield (Scheme 1).[5] The mechanism of this intramolecular C–H activation may involve either a concerted "σ-bond metathesis" (transition structure **A**) or an oxidative addition yielding the *cis*-(alkyl)hydride **B** as an intermediate. While the former reaction pathway is well precedented only for d^0 alkyls,[6] the intermediacy of **B** is made plausible by the existence of alkyls and hydrides of Cr^{IV}.[7]



Scheme 1.

The crystal structure of **2** was determined by X-ray diffraction at $-65\,^\circ C$ (Fig. 1).[8] Complex **2** is a binuclear chromium complex and possesses no crystallographic symmetry.

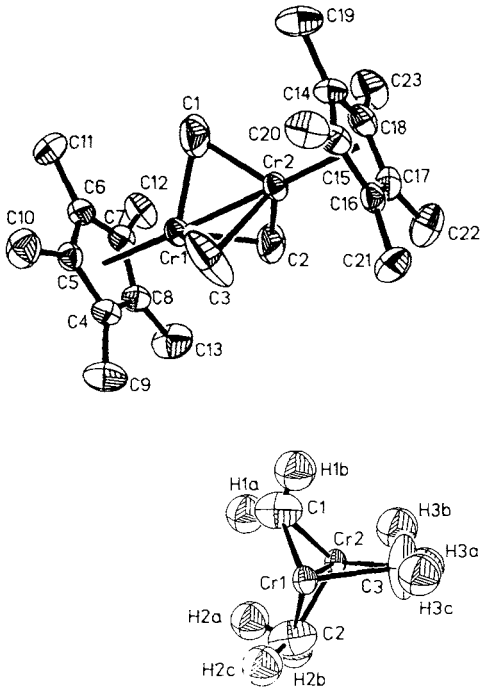


Fig. 1. The molecular structure of $[\{Cp^*Cr(\mu\text{-}CH_3)\}_2(\mu\text{-}CH_2)]$ (**2**). Selected bond distances [Å] and angles [°]: Cr1-Cr2 2.394(1), Cr1-C1 2.033(7), Cr2-C1 2.050(8), Cr1-C2 2.119(8), Cr2-C2 2.103(6), Cr1-C3 2.177(6), Cr2-C3 2.197(7), C1-H1a 0.905, C1-H1b 0.981, C2-H2a 1.064, C2-H2b 0.936, C2-H2c 1.086, C3-H3a 1.007, C3-H3b 0.868, C3-H3c 0.826; Cr1-C1-Cr2 71.8(3), Cr1-C2-Cr2 69.1(2), Cr1-C3-Cr2 66.3(2), C1-Cr1-C2 90.4(3), C1-Cr1-C3 92.0(3), C2-Cr1-C3 91.2(3), C1-Cr2-C2 90.4(3), C1-Cr2-C3 91.0(3), C2-Cr2-C3 91.1(3).

Each chromium is bonded to an η^5-Cp^* ligand, one bridging methylene group, and two bridging methyl ligands, thus placing the metal atom in the pseudooctahedral coordination environment of a three-legged piano stool. The two individual octahedra are joined via a trigonal face, resulting in a very close interaction between the two chromium atoms. Indeed, the Cr–Cr distance of 2.394(1) Å falls squarely within the range found in binuclear Cr^{II} carboxylates (2.28–2.54 Å), which are generally assigned quadruple bonds.[9] Thus **2**, which exhibits the shortest Cr^{III}–Cr^{III} distance found to date, certainly contains a metal–metal bond (see below). All hydrogen atoms of the bridging ligands were located in a difference map, and their positions were refined. Considering the limitations of an X-ray diffraction experiment, the C–H distances and H–C–H angles are reasonable, adding some credibility to the structural results overall. The Cr–C bonds to the methylene group (2.033(7) and 2.050(8) Å) are somewhat shorter than comparable σ bonds to terminal alkyl groups (ca. 2.09 Å).[3] Unexpectedly, the two methyl groups exhibit significantly different Cr–C bond lengths. While the bonds to C3 (2.177(6) and 2.197(7) Å) are similar to those found in **1** (2.170(5) and 2.206(4) Å), C2 features much shorter Cr–C distances (2.103(6) and 2.119(8) Å).

The extremely short Cr–Cr distance of **2** might be expected to lead to pairing of the d electrons in bonding molecular orbitals and thus we were surprised to find that the effective magnetic moment of **2** at room temperature substantially exceeds that of **1** (2.1 μ_B at room temperature), which exhibits a longer Cr–Cr distance (2.606(4) Å). The magnetic susceptibility of solid **2** in the temperature interval 60–280 K was measured with a Faraday balance; μ_{eff} increased with temperature and reached a value of 3.3 μ_B at room temperature. This behavior is consistent with merely antiferromagnetic coupling[10] of the two chromium centers (note that

$[Cp^*Cr(\mu\text{-}Cl)CH_3]_2$ has no Cr–Cr bond (d_{Cr-Cr}: 3.278 Å)[11] and $\mu_{eff} = 3.5\ \mu_B$ at 280 K[3e]).

To address the extent of metal–metal bonding in **2** and to reconcile the structural data with the magnetic measurements, we have performed an EHMO calculation on the model compound $[\{\eta^5\text{-}Cp)Cr(\mu\text{-}CH_3)\}_2(\mu\text{-}CH_2)]$ (**2a**).[12] It is important to realize that one does not have to invoke metal–metal bonding to explain the short metal–metal contact found in **2**. A simple geometric calculation—assuming average $Cr\text{–}C_{bridge}$ bond distances of 2.11 Å and ideal octahedral geometry (all C–Cr–C angles 90°)—yields a Cr–Cr distance of 2.44 Å for a confacial bioctahedral structure. Thus, a strong metal–metal interaction may be a consequence rather than the cause of the observed structure. Figure 2 shows a partial interaction diagram of the fragment orbitals of two CpCr moieties and the hybrid orbitals of the bridging

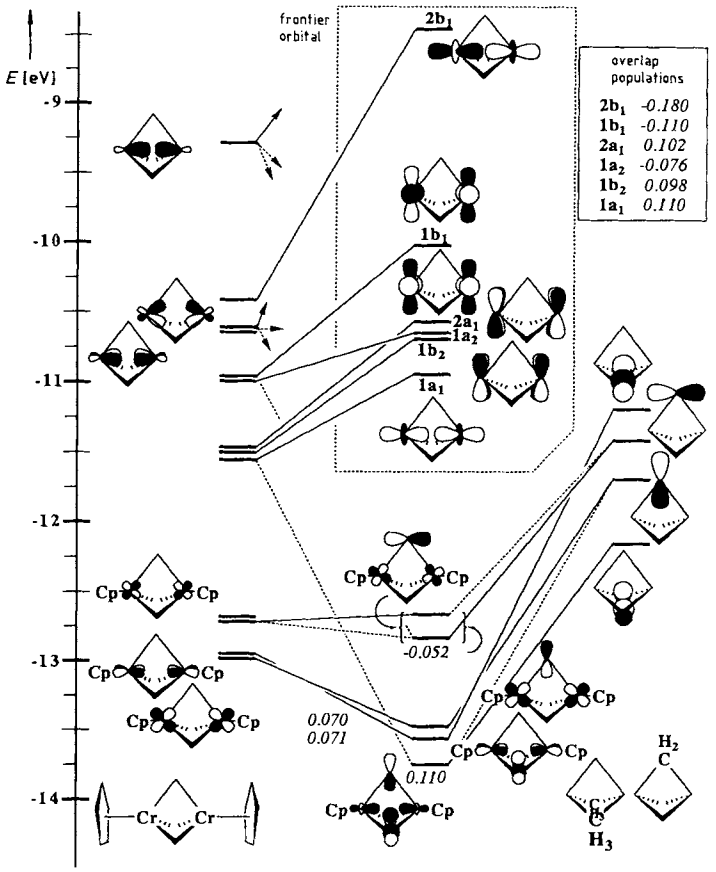

Fig. 2. Partial interaction diagram for $[\{CpCr(\mu\text{-}CH_3)\}_2(\mu\text{-}CH_2)]$ (**2a**). Numbers in italics are overlap populations; symmetry labels were assigned assuming C_{2v} symmetry. The overlap populations for the frontier d orbitals (inner box) were calculated for doubly occupied levels. Cp denotes substantial charge density on the cyclopentadienyl ligand.

ligands. As in the theoretical analysis of **1**,[3g] we find that the two three-center two-electron methyl bridges provide for substantial M–M overlap population (0.206) due to core orbitals. The three-center four-electron methylene bridge, on the other hand, makes only a minor contribution, as its filled Cr–C bonding combinations also give rise to metal–metal antibonding core levels.

Concerning the frontier d orbitals, Figure 2 shows the lower six levels (the two "t_{2g} sets" of the local octahedra) of the general 4-over-6 pattern expected for a confacial bioctahedron.[13] In idealized D_{3h} symmetry these are split into a_1' (σ), e′ (δ), e″ (δ^*), and a_2'' (σ^*) levels, the details of the pattern and energy gaps depending strongly on the metal and the M–X–M bridge angles. In the present case the σ^* level ($2b_1$ in C_{2v} symmetry) is too high in energy (1.5 eV above $1b_1$) to be populated in the electronic ground state. The remaining five levels lie within 1.0 eV and are available for filling with a total of six electrons. The extended Hückel method[14] does not take into account electron–electron interactions and thus cannot reliably predict the ground state of **2a**. However, the calculations are entirely consistent with a spin equilibrium between singlet, triplet, and pentet configurations. Herein lies the explanation for the higher magnetic moment of **2** when compared with **1**. Complex **1** features both σ and π bonding between the metals; both σ^* and π^* levels are thus destabilized beyond possible occupation, leaving only four MOs for six electrons (possible spin multiplicities $S = 0,1$). However, **2** exhibits σ and δ overlap and only the σ^* orbital is destabilized sufficiently to prevent occupation by electrons, thus leaving five MOs to be filled with six electrons (possible spin multiplicities $S = 0, 1, 2$).

We believe **2** is best described as having a chromium–chromium single bond. One aim of further experiments in our laboratory is the preparation of molecules with even shorter Cr^{III}–Cr^{III} distances. The "supershort" Cr^{II}–Cr^{II} quadrupole bonds (down to 1.828(2) Å)[9] provide a challenge, and the discovery of further examples of metal–metal bonding involving trivalent chromium is anticipated.

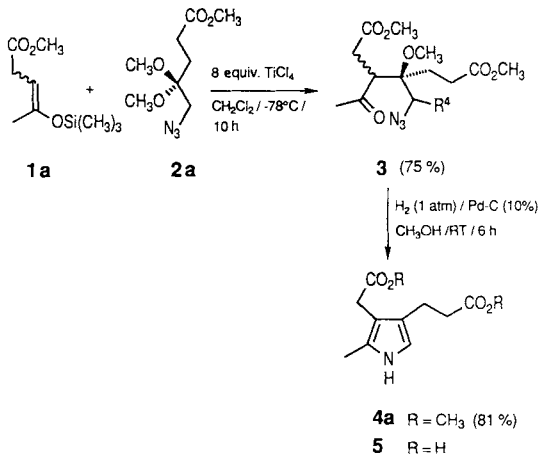

Scheme 1. Synthesis of the pyrrole **4a** via crossed aldol reaction (RT = room temperature).

A Novel Pyrrole Synthesis**

By *Hugo Bertschy, Anne Meunier*, and *Reinhard Neier**

The importance of pyrroles as natural products can be traced to the many functions which are fulfilled by tetrapyrrolic ligands.[1] The most important example of a natural alkyl-substituted pyrrole is porphobilinogen, the precursor for all tetrapyrrolic ligands. Biosynthetically, porphobilinogen is formed with the help of δ-aminolevulinic acid dehydratase (EC 4.2.1.24) in a condensation reaction starting from two molecules of δ-aminolevulinic acid.[2] Formally, this transformation corresponds to a Knorr pyrrole synthesis. Up to now, however, this synthetic path could not be imitated in vitro.

Two mechanisms have been postulated for the enzyme-catalyzed synthesis of porphobilinogen, but no unequivocal proof for either of them has been put forward.[3] The mechanism proposed by *Shemin* is especially attractive for chemists, because the reaction sequence starts with the key step, the formation of the C–C bond. The problem of regioselectivity is solved right at the beginning and all the successive steps follow from the natural reactivity of the intermediates. This is in contrast to the proposed mechanism for the Knorr pyrrole synthesis,[4] where the C–N bond is formed first. In the Knorr synthesis the C–C bond formation occurs regioselectively only if the intermediate enamine is stabilized by conjugation. It is therefore difficult to synthesize alkyl-substituted pyrroles using a Knorr reaction.

We report here the regioselective synthesis of alkyl-substituted pyrroles, which follows *Shemin*'s proposal for the biosynthesis of porphobilinogen. Regioselectively formed silyl enol ethers are used in a crossed aldol reaction[5] (Scheme 1). The aldol products are transformed into mono-, di-, tri-, and tetraalkyl-substituted pyrroles (Table 1). Annelated and aryl-substituted pyrroles can also be synthesized via this sequence. The substitution pattern is determined by the aldol reaction. This sequence allows the synthesis of pyrroles starting with aldol products under very mild conditions.

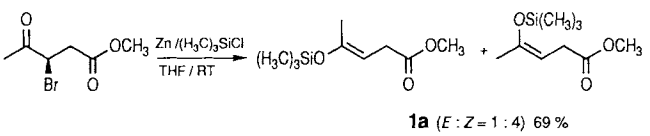
In order to use *Mukaiyama*'s crossed aldol reaction for the synthesis of pyrroles, adequate derivatives of α-amino ketones had to used. The azido group has been used successfully as a synthetic equivalent for amino groups. The acetal of α-azido ketones can be easily synthesized in two steps starting from α-halo ketones.[6] The synthesis of the second component, the silyl enol ethers, has been described already.[7]

Table 1. Synthesis of alkylpyrroles using the regioselective aldol reaction followed by cyclization.

No.	Silyl enol ether [a]	Acetal [b]	Reaction conditions [c]	Product (yield [%]) [d]
1	 **1a**	 **2a**	1. A, 75 % 2. B, 81 %	 **4a** (61 %)
2	 **1a**	**2b**	1. A, 84 % 2. B, 52 %	**4b** (44 %)
3	 **1a**	**2c**	1. A, 80 % 2. B, 63 %	**4c** (50 %)
4	 **1b**	**2c**	1. A, 98 % 2. B, 26 %	 **4d** (25%)
5	 **6**	**2b**	1. A, 85 % 2. C, 89 %	 **4e** (76%)

[a] Acetal:silyl enol ether = 1:1.1. [b] Acetals **2a** and **2b** were synthesized starting from the azido ketones [6]. Compound **2c** was synthesized starting from commercially available 2-bromo-1,1-dimethoxyethane (1.5 equiv. NaN_3/DMSO/KI (cat.)/90 °C/5 d). [c] A: 6 equiv. $TiCl_4/CH_2Cl_2/-78$ °C/6–8 h (trial 1:8 equiv. $TiCl_4$), yield calculated starting from the acetal; B: H_2/Pd-C 10%/CH_3OH/room temperature 6 h–2 d; C: PBu_3/C_6H_6/room temperature/5 d. yield relative to the unpurified aldol product; after crystallization (trial 1), after flash chromatography (hexane/EtOAc) (trials 4, 5), after kugelrohr distillation (80–120 °C/10^{-3} Torr) (trials 2, 3). [d] Total yield.

However, only the synthesis of the mixture of the two regioisomers **1a** and **1b** has been reported. We succeeded in synthesizing **1a** and **1b** regioselectively starting from the corresponding bromides (Scheme 2). The α-bromo ketones could be transformed reductively with zinc and trimethylchlorosilane into the pure silyl enol ethers **1a** and **1b** (69% and 76% yield, respectively). The addition of tetramethylethylenediamine after the reduction but before workup is crucial for the success of the reductive silylation.[8]



1a ($E:Z = 1:4$) 69%

Scheme 2. Regioselective synthesis of the silyl enol ether **1a** under reductive conditions (RT = room temperature).

The key step of our synthetic plan, the aldol reaction between a silyl enol ether and an α-azido acetal generally gave product in good yield (75%–98%, compare Table 1). A great excess of $TiCl_4$ was used to accelerate the aldol reaction. The separation of the mixture of diastereoisomers formed in the aldol reaction was not necessary for the synthesis of pyrroles. The aldol product could be directly treated with phosphanes in a Staudinger reaction or reduced with hydrogen[9] to give pyrroles in good yields (26%–89%, compare Table 1). Only the corresponding pyrrole could be isolated. The purification of the sensitive alkyl-substituted pyrroles was the most difficult task in this reaction sequence. The products are very unstable in the presence of tiny amounts of acids. Therefore, the workup for each product had to be optimized. The catalytic reduction has been successful in most cases. Removal of the catalyst by filtration followed by evaporation of the solvent often furnished a product of good spectroscopic purity.

This novel pyrrole synthesis allows the formation of unstablized alkylpyrroles in a regioselective manner. The synthetic strategy follows the proposal of *Shemin* for the biosynthesis of porphobilinogen. The enzymatic synthesis of the pyrrole **5** starting from one molecule of levulinic acid and one molecule of δ-aminolevulinic acid has been described.[10] Therefore, the synthesis of the pyrrole **4a** mimics formally the biosynthetic process by which the pyrrole **5** is formed.

Typical Experimental Procedure

Aldol product **3**: To a solution of azido acetal **2a** (2.17 g, 0.01 mol) in 50 mL of CH_2Cl_2, 8.8 mL (0.08 mol) of $TiCl_4$ was added in two portions at −78 °C under nitrogen atmosphere. Silyl enol ether **1a** (2.43 g, 0.012 mol) in 50 mL of CH_2Cl_2 was slowly added in such a manner that the temperature did not rise above −70 °C. The red-brown suspension was stirred for 10 h at −78 °C. The reaction was then quenched by adding 100 mL of ice water. After the separation of the two phases, the water phase was extracted with 3 × 50 mL of CH_2Cl_2. The organic phases were washed with 2 × 50 mL of saturated NaCl and dried with $MgSO_4$ and the solvent was removed. Removing methyl levulinate by distillation (40 °C, 10^{-3} Torr) gave 2.58 g of a raw material with the following composition: aldol product **3** as a mixture of diastereoisomers (71%); two products of elimination (4%); methyl 5-azidolevulinate (9%, yields are calculated relative to **2a**).

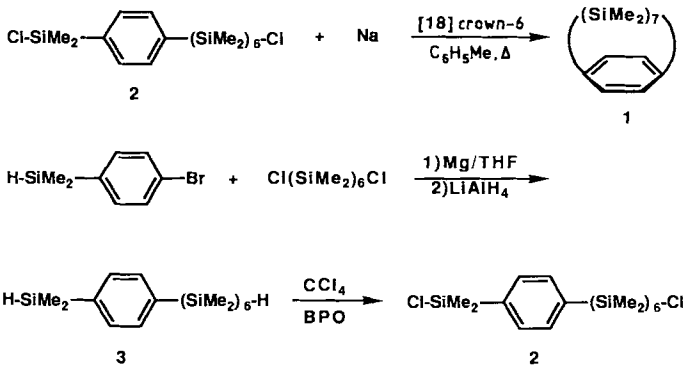
Heptasila[7]paracyclophane

By *Wataru Ando,* Takeshi Tsumuraya*, and *Yoshio Kabe*

In recent years [n]paracyclophanes having a short bridge have attracted considerable interest because of the unique properties resulting from bending of the benzene ring.[1–4] The smallest [n]paracyclophane so far isolated is the [6] isomer, first prepared by *Jones* et al. in 1974.[2] Recently, *Bickelhaupt* succeeded in spectroscopic characterization of [5]paracyclophane, which is stable at low temperature in solution, but not isolable,[3] and, more recently, a [4]paracyclophane system has been proposed as a reactive intermediate.[4] In contrast to rather extensive studies of [n]paracyclophane bridged by methylenes, there is no report of preparation of [n]paracyclophanes bridged by heteroatom chains. We report here successful synthesis of the first type of these compounds, heptasila[7]paracyclophane **1**, including the crystal structure of **1**.



Reductive coupling of 1-chloro-6-[4-(chlorodimethylsilyl)-phenyl]-1,1,2,2,3,3,4,4,5,5,6,6-dodecamethylhexasilane (**2**)[5] by treatment with sodium in refluxing toluene in the presence of [18]crown-6 produced heptasila[7]paracyclophane **1** in 1.2% yield.

Compound **1**, obtained as colorless crystals [UV(hexane): $\lambda_{max} = 248$ nm ($\log\varepsilon = 4.63$)], is stable toward atmospheric oxygen and moisture and does not decompose even when heated to its melting point of 88–88.5 °C. The presence

[*] Prof. W. Ando, Dr. T. Tsumuraya, Dr. Y. Kabe
Department of Chemistry, The University of Tsukuba
Tsukuba, Ibaraki 305 (Japan)

of [18]crown-6 is essential for the formation of **1**; only polymeric substances were obtained in the absence of [18]crown-6.[6] The spectral data are consistent with the proposed structure. The high-resolution mass spectrum and the isotopic ratios of the molecular ion [*m/z* (relative intensity in %) 482 (100), 483 (57), 484 (38), 485 (16), 486 (6), 487 (2)] show that the molecule has composition $C_{20}H_{46}Si_7$. The ^1H, ^{13}C, and ^{29}Si NMR spectra show the presence of a twofold symmetry axis in the molecule [^1H NMR (500 MHz, $CDCl_3$): $\delta = -0.16$ (s, 6H), 0.02 (s, 12H), 0.13 (s, 12H), 0.41 (s, 12H), 7.45 (s, 4H). ^{13}C NMR (125 MHz, $CDCl_3$): $\delta = -5.13$(q), -4.42(q), -3.31(q), -1.80(q), 133.10(d), 140.18(s); ^{29}Si NMR (18 MHz, $CDCl_3$): $\delta = -39.2$, -38.7, -37.1, -18.0.

X-ray structural determination established unequivocally the molecular structure of **1** as shown in Figure 1.[7] Owing to

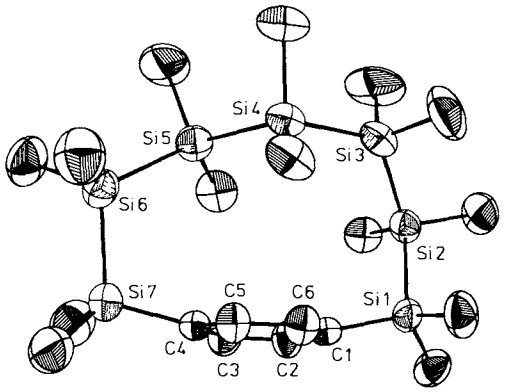


Fig. 1. Molecular structure of **1** (ORTEP) Selected bond lengths [Å] and angles [°]: Si1-Si2 2.376(4), Si2-Si3 2.350(5), Si3-Si4 2.336(5), Si4-Si5 2.350(5), Si5-Si6 2.371(4), Si6-Si7 2.338(5), C1-C2 1.40(1), C1-C6 1.41(1), C2-C3 1.41(1), C3-C4 1.39(1), C4-C5 1.40(1), C5-C6 1.40(1); C2-C1-C6 119.4(9), C1-C2-C3 119.7(9), C2-C3-C4 120.8(9), C3-C4-C5 118.8(9), C4-C5-C6 120.8(9), C1-C6-C5 119.9(9); for further data see text.

the unsymmetrical orientation of the central Si atom (Si4), the molecule has no crystallographic symmetry. Although the Si–Si bond lengths are normal and range between 2.336(5) and 2.371(4) Å, there is interestingly an alternation in the bond angles around the polysilane chain; the bond angles of C1-Si1-Si2 (105.5(3)°) and C4-Si7-Si6 (107.4(3)°) are contracted while those of Si1-Si2-Si3 (117.7(2)°), Si2-Si3-Si4 (126.5(2)°), Si3-Si4-Si5 (116.2(2)°), Si4-Si5-Si6 (115.6(2)°), and Si5-Si6-Si7 (113.7(2)°) are considerably expanded from the normal bond angles.

The most interesting feature in the structure of **1** is the deformation of the benzene ring from planarity, which is represented by the deviation angles θ_1 and θ_2. The deformation angles θ_1 of compound **1** are 6.6 and 4.5° and θ_2 are 6.5 and 9.0°, which are comparable with those observed in octamethyltetrasila[2,2]paracyclophane (**4**) ($\theta_1 = 4.3°$, $\theta_2 = 15.0°$)[8] and its chromium complex **5** ($\theta_1 = 2.5$, 2.2°, $\theta_2 = 10.1$, 10.9°).[9] These θ values are smaller than those of the [7]paracyclophane derivative **6** ($\theta_1 = 17°$, $\theta_2 = 24°$)[10a] and those of the [8]paracyclophane derivative **7** ($\theta_1 = 9°$, $\theta_2 = 15°$).[10b] The deformation in the benzene ring is less in **1** than in the analogue **6**, but an increase in the deformation in the polysilane chain of **1** is definitely noticeable. These observations are best explained by high flexibility of the conformation in the polysilane chain compared to the methylene chain, involving expansion of the Si–Si–Si angles.

The structure of **1** reveals two new aspects of paracyclophane chemistry: (1) polysilane chains could stabilize [n]paracyclophanes and (2) thermal or photochemical silylene extrusion might give lower homologous [n]paracyclophanes.

Experimental Procedure

To a mixture of molten sodium (101 mg, 4.4 mmol) and [18]crown-6 (618 mg, 2.3 mmol) in refluxing toluene (20 mL) was added dropwise a toluene (20 mL) solution of **2** (1.11 g, 2.0 mmol) under dry argon. The mixture was chromatographed on a silica gel with hexane; subsequent separation by preparative HPLC (Japan Analytical Ind. Co., Ltd. LC-08 with JAIGEL-1H column) gave **1** in 1.2% yield as colorless crystals.

[7] A single crystal with dimensions of $0.5\times0.2\times0.2$ mm, obtained from ethanol was used for the X-ray analysis. Lattice constants were determined by the least-squares method with an angular setting of 25 reflections within the range $11<\theta<13°$. Intensity data were obtained on a Enraf-Nonius CAD4 diffractometer equipped with graphite monochromatized $Mo_{K\alpha}$ radiation and using the $\omega-2\theta$ scan technique ($2\theta<50°$). During data collection three standards, measured every 120 min, indicated a total loss in intensity of 18.4%. A linear decay correction was applied. Of 3158 independent reflections measured, only 2298 were considered as observed on the basis of the criterion $I>3.0\ \sigma(I)$. All intensities were corrected for Lorentz and polarization effects but not for absorption. Crystal data for **1**: $M_r=483.19$; orthorhombic; P_{na21}; $a=15.037(3)$, $b=9.029(3)$, $c=23.231(5)$ Å; $V=3154.3$ Å^3; $Z=4$; $\varrho_{calcd}=1.02$ g cm^{-3}; μ ($Mo_{K\alpha}$) = 3.0 cm^{-1}. The structure of **1** was solved by direct methods and refined by full-matrix least-squares methods. The final refinements with anisotropic temperature factors for the non-hydrogen atoms lowered R and R_w values to 0.059 and 0.072, respectively.

Base-Free Cationic 14-Electron Titanium and Zirconium Alkyls: In situ Generation, Solution Structures, and Olefin Polymerization Activity**

By *Manfred Bochmann,* Andrew J. Jaggar,* and *Julian C.Nicholls*

Various lines of evidence suggest that cationic group IV metal alkyl complexes of the type $[Cp_2M-R]^{\oplus}$ (M = Ti, Zr, Hf) are the catalytically active species in homogeneous metallocene-based Ziegler–Natta polymerization systems.[1] We have earlier reported the synthesis of a number of ligand-stabilized cationic titanium complexes[2] and, with the aid of model compounds, have demonstrated the mechanistic pathway which is available to unsaturated substrates capable of insertion into the Ti–C σ bond.[3] In independent work it was shown that cationic alkyl complexes that contain weakly coordinating ligands such as THF[4] and base-free zwitterionic compounds such as $[Cp_2^*Zr\text{-}C_6H_4BPh_3]$[5] polymerize ethylene in the absence of aluminum alkyl activators, sometimes requiring elevated temperatures and pressures.[5] While these findings are highly suggestive of the catalytic role played by cationic metal alkyls, no information has as yet been available about the structure of such species under the conditions of polymerization catalysis. We now report the generation in solution of some cationic titanium and zirconium alkyls and the observation of multiple ethylene insertion into the $Ti-CH_3$ bond.

Treatment of a dichloromethane solution of bis(indenyl)dimethyltitanium (**1a**) with one equivalent of dimethylanilinium tetraphenylborate (**2a**) gives methane and the deep brown cation of **3a**, $[Ind_2TiMe]^{\oplus}$ (Scheme 1). The reaction can be conveniently followed by high-field NMR spectroscopy (see *Experimental Procedure*). The methyl signal of the starting material **1a** ($\delta=-0.94$) is replaced by a singlet at $\delta=-0.15$; the ^{13}C NMR signal for the methyl group of **3a** at $\delta=70.8$ lies within the range expected for cationic titanium alkyl complexes.[2b]

$$[R_2MMe_2] + [R'_3NH]BPh_4 \xrightarrow[CH_2Cl_2]{-CH_4/-NR'_3} [R_2M-Me]BPh_4$$

1a, R = Ind, M = Ti; **1b**, R = Cp, M = Ti; **1c**, R = Cp, M = Zr

2a, R'_3N = $PhNMe_2$; **2b**, R'_3N = nBu_3N

3a/3a', R = Ind, M = Ti; **3b**, R = Cp, M = Ti; **3c/3c'**, R = Cp, M = Zr

$$\left[Ind_2Ti\begin{matrix}Me\\OEt_2\end{matrix}\right]BPh_4 \quad (\mathbf{4}) \xleftarrow{Et_2O} \mathbf{3a} \xrightarrow{C_2H_4} [Ind_2Ti(CH_2CH_2)_nMe]^{\oplus}$$

Scheme 1. Ind = indenyl, Cp = cyclopentadienyl.

By an analogous procedure, deep orange $[Cp_2TiMe]BPh_4$ (**3b**) and pale yellow $[Cp_2ZrMe]BPh_4$ (**3c**) are synthesized in dichloromethane solution by allowing **1b** and **1c**, respectively, to react with $[PhNMe_2H]BPh_4$ (**2a**). The reaction of **1a**, or **1c** with $[nBu_3NH]BPh_4$ (**2b**) proceeds equally facilely to give **3a** and **3c**, respectively. The addition of diethyl ether to solutions of **3a** results in the formation of $[Ind_2TiMe(Et_2O)]BPh_4$ (**4**) as poorly soluble black microcrystals, while the addition of acetonitrile to **3b** produces the known[2b] adduct $[Cp_2TiMe(NCMe)]BPh_4$.

Various structural possibilities (**A**–**E**; Scheme 2) can be envisaged for the complex cations. A trigonal-planar geometry (**A**) is ruled out by the observed inequivalence of H-1 and H-3 of the indenyl five-membered ring in **3a**; the signal pattern resembles that of isolated pseudo-tetrahedral complexes of the type $[Ind_2TiMe(L)]^{\oplus}$.[2b] Although not necessarily conclusive, a comparison of the C-H coupling constants of the methyl groups of **3a** ($J=128.7$ Hz) and of the nonagostic $[Ind_2TiMe_2]$ ($J=125.2$ hz) makes an agostic structure (**B**) appear unlikely; neutral scandium complexes isoelectronic to **3b** have also failed to provide conclusive evidence for an agostic methyl ligand.[6]

It could be expected that Lewis-acidic cationic metal centers such as those present in **3a–3c** would have a tendency to interact with $BPh_4^{\ominus}$. Solutions of **3a–3c**, prepared using $[PhNMe_2H]BPh_4$ (**2a**), show a complex ^1H NMR pattern in the aromatic region. In $[PhNMe_2H]BPh_4$ (**2a**) the chemical shifts of the phenyl groups of the anion are strongly influenced by the presence of the anilinium cation, presumably due to ion pairing, while solvent-separated $BPh_4^{\ominus}$ ions as in $[nBu_3NH]BPh_4$ (**2b**) gives rise to three well-separated ^1H NMR signals for the *para, meta,* and *ortho* protons.[7] Solutions of **3a–3c** at $-40\,^{\circ}C$ show the presence of both ion-paired and solvated $BPh_4^{\ominus}$ ions in ratios varying from 3:1 to 3:2. In addition, the signals of free dimethylaniline are identified; an adduct of type **C** is not found. There is also no evidence that one phenyl ring of a $BPh_4^{\ominus}$ ion is coordinated to a metal center or subject to an environment different from the other three (cf. structure **D**), even at low temperature. This finding contrasts with our recent isolation of an η^6-$BPh_4^{\ominus}$ complex of a trialkylzirconium cation, $[Zr(CH_2Ph)_3(\eta^6\text{-}C_6H_5BPh_3)]$.[8] The observations suggest that base-free bis(cyclopentadienyl)metal alkyl cations have a pseudo-tetrahedral solvated structure of type **E**.[9]

By contrast, titanium and zirconium cations prepared from $[nBu_3NH]BPh_4$ (**2b**) and **1** show only solvated $BPh_4^{\ominus}$; there is no indication of an association between anions and cations. Because of the basicity of nBu_3N, the formation of labile amine complexes as indicated in **C** is likely in these cases. In agreement with this assumption, the ethylene polymerization activity of **3a′** and **3c′**, prepared with **2b**, is reduced to ca. 20% of the activity of **3a** and **3c**.

Exposure of a solution of **3a** in CD_2Cl_2 at $-40\,^{\circ}C$ to ca. 5 equivalents of ethylene leads to a reduction in intensity of the Ti-CH_3 signal at $\delta = -0.15$ and the appearance of new signals in the alkyl region at $\delta = 0.7$, 0.9, and 1,2, indicating the insertion of ethylene into the titanium–carbon bond. These signals grow further on prolonged exposure to an excess of ethylene, until the precipitation of polyethylene is seen.[12] The Ti-Me signal does not disappear completely during the initial stages of the chain-growth reaction; this observation suggests that subsequent C_2H_4 insertions proceed more readily than the first.[13]

Solutions of **3a** polymerize ethylene at 1 bar over a temperature interval of $+10$ to $-60\,^{\circ}C$; the activity shows a maximum at ca. $-20\,^{\circ}C$ and decreases rapidly above ca. $+15\,^{\circ}C$. The polymerization rate is fast for the first 10 to 15 minutes before it decays to a more steady lower level. The polydispersity of the resulting polyethylene decreases with the polymerization temperature from $\bar{M}_w/\bar{M}_n = 2.5$ at $+10\,^{\circ}C$ to 2.0 at $-40\,^{\circ}C$; such a narrow distribution is typical of chemically homogeneous active sites. The IR spectra of hot-pressed films showed the absence of pendent-methylene and terminal unsaturation.[14] The catalytic activities of **3b** and **3c** under identical conditions are lower than that of **3a**. Of the three catalysts, the zirconium complex is the thermally most stable and, although operating at a lower initial activity than **3a**, appears less susceptible to catalyst deactivation. Propylene is polymerized by **3a** at $0\,^{\circ}C$ at a slower rate. In agreement with earlier observations on non-stereorigid catalysts operating at comparable temperatures,[15] the resulting polypropylene is atactic.

Experimental Procedure

All reactions were performed under purified argon. Reactions with $[PhNMe_2H]BPh_4$ (**2a**): For NMR experiments, **2a** (37 mg, 0.084 mmol) was suspended in 0.3 mL of CD_2Cl_2 and cooled to $-80\,^{\circ}C$. A solution of $[Ind_2TiMe_2]$ (**1a**) (26.5 mg, 0.086 mmol) in 0.3 mL of CD_2Cl_2 was injected, the tube was sealed, and the sample allowed to warm to $0\,^{\circ}C$. The solution began to darken at $-60\,^{\circ}C$, and the reaction was complete after 10–15 min at $0\,^{\circ}C$ to give **3a**. Samples of **3b** and **3c** were prepared on a similar way. In all cases the formation of methane was observed ($\delta = 0.22$).

3a: ^1H NMR (400 MHz, CD_2Cl_2, $-40\,^{\circ}C$): $\delta = -0.15$ (s, 3 H, Ti-Me), 5.98 (dd, poorly resolved, 1 H, indenyl H-1), 5.78 (t, 1 H, indenyl H-2, $J = 3.3$ Hz), 6.21 (dd, poorly resolved, 1 H, indenyl H-3), 7.2–7.8 (indenyl H-4 to H-7), unresolved); associated $BPh_4^{\ominus}$: 7.63 ("d", *ortho*-H), 7.51 ("t", *meta*-H), 7.56 ("t", *para*-H); solvent-separated $BPh_4^{\ominus}$: 7.21 (unresolved, *ortho*-H), 7.07 ("t", *meta*-H), 6.93 ("t", *para*-H); free dimethylaniline: 2.92 (s, N-Me), 6.71 ("d", *ortho*-H), 7.22 ("t", *meta*-H), 6.68 ("t", *para*-H). ^{13}C NMR: $\delta = 70.8$ (Ti-Me, J(C-H) 128.7 Hz). In some samples, a second, as yet unidentified titanium species is also formed, characterized by ^1H NMR signals at $\delta = -0.19$ (Ti-Me), 5.94, 6.01, and 6.35 (indenyl); this species does not participate in polymerization reactions. **3b**: ^1H NMR (400 MHz, CD_2Cl_2, $-40\,^{\circ}C$): $\delta = 1.26$ (s, 3 H, Ti-Me), 6.28 (s, 10 H, Cp). **3c**: ^1H NMR (400 MHz, CD_2Cl_2, $-40\,^{\circ}C$): $\delta = 0.27$ (s, 3 H, Zr-Me), 6.25 (s, 10 H, Cp). The values for solvent-separated and associated $BPh_4^{\ominus}$ and for dimethylaniline present in solutions of **3b** and **3c** closely correspond to those given for **3a**. **4**: A solution of $[Ind_2TiMe_2]$ (**1a**) (0.37 g, 1.2 mmol) in 5 mL of toluene was added to a suspension of 0.441 g of $[PhNMe_2H]BPh_4$ **2a** in 20 mL of dichloromethane–diethyl ether 1:1 at $-70\,^{\circ}C$. On warming to room temperature, black microcrystalline **4** separated and was filtered off, washed with CH_2Cl_2–Et_2O, and dried (0.2 g, 0.29 mmol, 29%). Satisfactory elemental analysis. ^1H NMR (60 MHz, C_5D_5N): $\delta = 0.23$ (s, 3 H, Ti-Me), 1.09 (t, 6H, OCH_2CH_3), 3.36 (q, 4 H, OCH_2CH_3), 6.38 (m, 2 H, indenyl), 6.51 (m, 4H, indenyl), 7.2 (m, 20 H, indenyl, $BPh_4^{\ominus}$, 8.08 (m, broad, 8 H, $BPh_4^{\ominus}$).

Reactions with $[nBu_3NH]BPh_4$ (**2b**): Procedure as described for $[PhNMe_2H]BPh_4$ (**2a**). **3a′** ^1H NMR (400 MHz, CD_2Cl_2, $-40\,^{\circ}C$): $\delta = -0.15$ (Ti-Me), 5.99 (dd, poorly resolved, 1 H, indenyl H-1), 5.79 (t, 1 H, indenyl H-2, $J = 3.3$ Hz), 6.22 (dd, poorly resolved, 1 H, indenyl H-3), 7.3–7.7 (m, indenyl H-4 to H-7); $BPh_4^{\ominus}$: 7.41 (unresolved, *ortho*-H), 7.08 ("t", *meta*-H), 6.93 ("t", *para*-H); nBu_3N: $\delta = 0.89$, 0.94, 1.18, 2.11, 2.43. **3c′**: ^1H NMR (400 MHz, CD_2Cl_2, $-40\,^{\circ}C$): $\delta = 0.27$ (s, 3 H, Zr-Me), 6.24 (s, 10 H, Cp); the values for $BPh_4^{\ominus}$ and nBu_3N closely correspond to those given for **3a′**.

General procedure for polymerization reactions: $[PhNMe_2H]BPh_4$ (**2a**) (0.240 g, 0.544 mmol) was suspended in 30 mL of dichloromethane and cooled to $-40\,^{\circ}C$. 3.05 mL of a 0.18 M solution of $[Ind_2TiMe_2]$ (**1a**) in toluene (0.549 mmol) was injected with rapid stirring and purified ethylene was admitted. After two hours the reaction was quenched by the injection of 10 mL of methanol and polyethylene (3.25 g) was isolated ($\bar{M}_w$ relative to NBS1475 standard: 16000; $\bar{M}_w/\bar{M}_n = 2.0$).

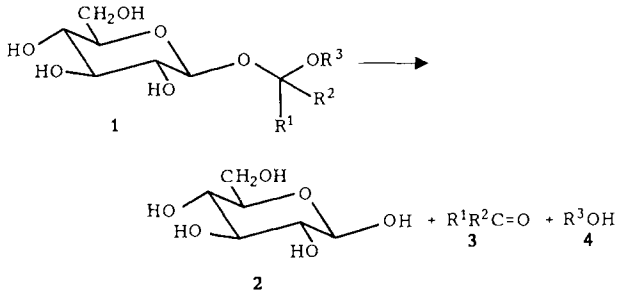
Development of Tailor-Made Cytostatics Activable by Acid-Catalyzed Hydrolysis for Selective Tumor Therapy**

By *Lutz F. Tietze,* Matthias Beller, Roland Fischer, Michael Lögers, Eckhard Jähde, Karl-Heinz Glüsenkamp,* and *Manfred F. Rajewsky*

The chemotherapy of malignant tumors is extremely problematic because of the narrow therapeutic range of the cytostatics currently available and the resulting side effects.[1] The goal of our work[2] is to exploit phenotypic differences between malignant and normal cells for the development of tumor-selective cytostatic drugs. Several groups have independently shown that, owing to an increase in the blood-sugar level of a tumor-bearing host, the rate of glycolysis in malignant cells is increased relative to that in the normal cell population.[3] The resulting increase in the amount of lactic acid results in a lowering of the pH value in the tumor tissue to 6.2 on the average, whereas the pH value of normal tissue remains nearly constant (pH 7.2). We use this pH difference to release selectively within the tumor tissue a cytostatic drug generated from a nontoxic precursor by acid-catalyzed hydrolysis. A crucial problem here is the development of functional groups that, on the one hand, guarantee the detoxification of the cytocidal component and, on the other, ensure sufficient acid lability that, at pH 6.2, the active species is released fast enough. To this end, we have developed the acetal glycosides[4] of general formula **1**, which can release a cytotoxic aldehyde or ketone, **3**, together with an alcohol, **4** and a sugar, **2**. Although the compounds



we have so far synthesized exhibited increased selectivity in vitro, their rate of hydrolysis was too low.[5] Here we describe the preparation of the glucoside **10c**, which satisfies the above requirements very well.

Reaction of trimethylsilyl-2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranoside (**5**) with three equivalents of 4-(*tert*-butyldiphenylsiloxy)butan-2-one (**6**) and one equivalent of the corresponding acetal **7** in the presence of a catalytic amount of trimethylsilyl trifluoromethanesulfonate (TMSOTf) in dichloromethane at −70 °C gave exclusively the acetal-β-glucoside **8a** (β:α >99:1) in 39% yield. Owing to the minimal difference between the substituents at the carbonyl group, however, a nearly 1:1 mixture of C-2′ epimers was obtained. The lower yield, compared with the formation of acetal glucosides from aldehydes, is due to the lower reactivity of ketones.[4] Trehaloses were formed as side products in the reaction. Cleavage of the trialkylsilyl group with tetrabutylammonium fluoride (TBAF) led to a 94% yield of an epimeric mixture of alcohols **8b**, which, upon treatment with [(bis(2-chloroethyl)amido]phosphoric acid dichloride (**9**)[6] in the presence of triethylamine (CH_2Cl_2, 36 h, 20 °C) followed by reaction with NH_3 (CH_2Cl_2, 1.5 h, 20 °C), afforded the diamidophosphate **10b** in 74% yield via **10a**. Cleavage of the acetyl groups to give **10c** was accomplished by solvolysis

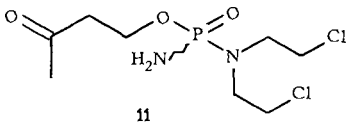
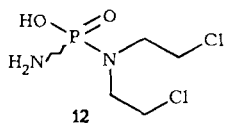
with potassium carbonate in methanol. Compound **10c**[7] was obtained as a mixture of four stereoisomers, since the phosphorus atom is also a stereogenic center and the phosphorylation with **9** proceeded, as expected, in a nonstereoselective fashion. All the compounds reported here are very acid labile, so that chromatography is only possible in the presence of triethylamine.

The stereochemistry of **10c** at the anomeric center is revealed by the doublet for 1-H at $\delta = 4.53$ ($J = 8$ Hz) in the ^{1}H NMR spectrum.[8] The configuration at C-2′ is assigned on the basis of the ^{13}C NMR signals for C-1′ and C-3′. We assume that, by analogy to the NMR data[4] for the acetal glycosides of aldehydes, the signals in the spectrum of the (2′*R*) epimer lie at lower field for C-1′ and higher field for C-3′, compared to the corresponding signals of the (2′*S*) isomer.

The kinetics of the acid-catalyzed hydrolysis[9] of **10c** was determined using NMR spectroscopy. The first-order rate constant for deuterolysis at pD = 6.10 in phosphate buffer at 35 °C (0.10 M, $I = 0.5$ M) is $k = 2.45 \times 10^{-5}$ s^{-1}. Assuming a $k_{D^\oplus}/k_{H^\oplus}$ value of 1.5,[10] **10c** has a half-time for hydrolysis of 15 h at pH = 6.2 and 35 °C. This value roughly corresponds to the desired value. Cleavage of **10c** yields besides glucose and methanol, the diamidophosphate **11** (ketophosphamide),[11] which, via either elimination or hydrolysis, is converted into the cytotoxic phosphoramide mustard **12** in the cell. This compound is also the active metabolite of the clinically used cytostatic drug cyclophosphamide.[12]



11



12

The dependence of the cytostatic activity of **10c** on pH was determined in vitro by treating mammary carcinoma cells (M1R) of Marshall rats for 24 h. At physiological extracellular pH ($pH_e = 7.4$) and a concentration of 10 μg mL^{-1}, nearly no toxicity was observed; at $pH_e = 6.2$, however, under otherwise indentical conditions, the survival rate of the cancer cells decreased by a factor of 5×10^4. We are currently using transplanted tumors to investigate whether this surprisingly high selectivity is also exhibited in vivo.

Heteronuclear Complexes Containing $CuCo(CO)_4$ Structural Units and Nitrogen Ligands**

By *Matthias Achternbosch, Heinrich Braun, Ralf Fuchs, Peter Klüfers,* Alexandra Selle*, and *Ulf Wilhelm*

Dedicated to Professor Hans-Uwe Schuster on the occasion of his 60th birthday

Bonds between different metal atoms can form according to Equation (a) if M′L′$_m$ is a Lewis acidic metal complex fragment containing ligands capable of being substituted

$$M'L'_m + ML_n \rightarrow L'_iM'\text{-}ML_n + (m-1)\,L' \qquad (a)$$

(e.g., $[CuCl_2]^\ominus$) and ML$_n$ is a nucleophilic metalate ion such as $[Co(CO)_4]^\ominus$, $[(C_5H_5)Mo(CO)_3]^\ominus$, or $[Fe(CO)_4]^{2\ominus}$.[1, 2] Heteronuclear clusters (M′M)$_x$ are formed when the metalate ion bridges M′L′ fragments with displacement of several ligands L′.

The compounds $[\{CuCo(CO)_4\}_4]$ (**1a**) and $[\{CuCo(CO)_4\}_\infty]$ (**1b**), made up of Cu atoms and μ_2-bridging $Co(CO)_4$ fragments, are formed upon reaction of chlorocuprate(I) and tetracarbonylcobaltate(−I) in such a cluster-forming reaction.[1a, b] μ_3-ML$_n$ groups are present in the anions $[Cu_5Fe_4(CO)_{16}]^{3\ominus}$ and $[Cu_6Fe_4(CO)_{16}]^{2\ominus}$, in which the $Fe(CO)_4$ fragments are each coordinated to three copper atoms of the cluster.[2] Here we report new compounds con-

[**] Heteronuclear Complexes with Metal–Metal Bonds, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 3: [1a].

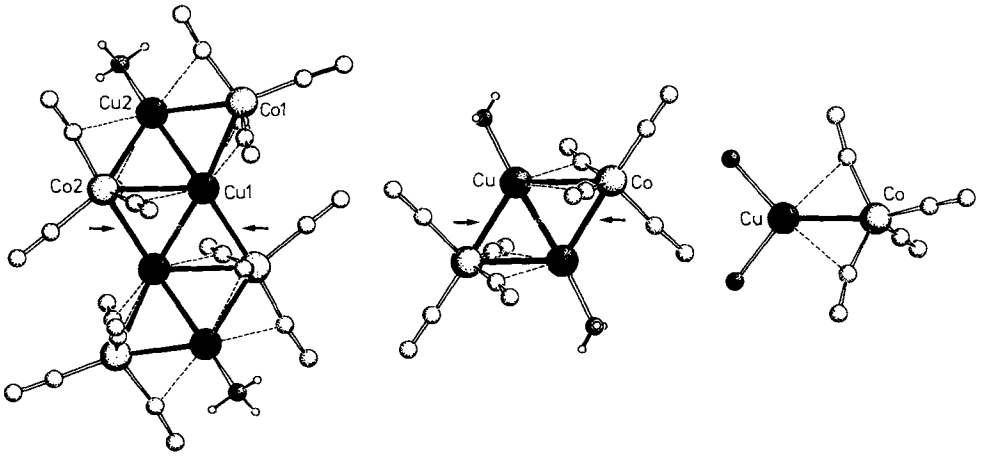

Fig. 1. Left: Structure of **2a** in the crystal. Selected distances [pm]: Cu1-Co1 253.0(1), Cu1-Co2 268.2(2), Cu1-Co2^z 258.2(1), Cu-Co1 252.3(1), Cu2-Co2 257.1(1); Cu1-Cu2 253.1(1), Cu1-Cu1^z 254.8(1). Atoms marked with a superscript z are generated by the symmetry center shown. Maximal deviation of the metal atoms from the best plane: 45 pm. The Cu–Co bond is formally cleaved by NH_3 at the positions marked with an arrow (→**2b**). Broken lines: Semibridging CO groups. Middle: Structure of **2b** in the crystal. Selected distances [pm]: Cu-Co 258.9(1), Cu-Co^z 255.6(1), Cu-Cu^z 249.4(1). Arrows: Formal bond cleavage converting **2b** into **2c**. Right: Structure of **2c** in the crystal. The Cu–Co distance is 242.9(2) pm.

taining $CuCo(CO)_4$ structural units, in which stronger ligands L′ compete with the metalate for the Lewis acidic copper(I) and thus oppose cluster formation. The more donor atoms are bonded to copper, the fewer $Co(CO)_4$ bridges are formed. Eventually, after formation of a heteronuclear binuclear complex, the M′–M bond is cleaved.

$CuCo(CO)_4$–NH_3 adducts are formed in the reaction of CuCl in aqueous ammonia with $Na[Co(CO)_4]$. Recrystallization from dichloromethane or toluene affords, depending on the experimental conditions, the crystalline compounds $(NH_3)_x CuCo(CO)_4$ (**2**) with x = 0.5 (**2a**), 1 (**2b**), and 2 (**2c**). As the concentration of NH_3 is increased, the tendency of the $Co(CO)_4$ groups to bridge the copper atoms and thus the degree of oligomerization of the $CuCo(CO)_4$ units decreases. In the crystal, **2a** is present as a tetramer, $[(NH_3)_2\{CuCo(CO)_4\}_4]$ (Fig. 1, left). Two μ_3-$Co(CO)_4$ and two μ_2-$Co(CO)_4$ groups together with four copper atoms form a nearly planar Cu_4Co_4 cluster. Since the Cu–Co and Cu–Cu distances differ only slightly, the arrangement of the metal atoms corresponds to a section of a closest-packed layer of spheres. Crystals of **2b** consist of the dimer $[\{(NH_3)CuCo(CO)_4\}_2]$ (Fig. 1, middle). The two additional ammine ligands (based on one molecule of **2a**) each formally cleave one of the Cu–Co bonds to the μ_3-$Co(CO)_4$ moieties of **2a**, so that, in **2b**, only μ_2-$Co(CO)_4$ groups are present. Finally, in **2c**, a further ammine ligand per copper displaces the $Co(CO)_4$ fragment from a bridging to a terminal position. Complex **2c** is therefore monomeric in accordance with the formula $[(NH_3)_2CuCo(CO)_4]$ (Fig. 1, right). The Cu–Co distance in **2c** (242.9 pm) is somewhat longer than those in **1a** and **1b** (236.5 and 237.4 pm, respectively); the values for the Cu–Co bond order based on the isolobal relationship between $Co(CO)_4$ and CH_3 (1 for **2c** and 0.5 for **1**) thus do not show the expected pattern based on the simple model. In **2a** and **2b**, the distances between copper and μ_2-$Co(CO)_4$ are increased by almost 20 pm compared to that of **1** for *steric* reasons. The Cu_2 units in **1** are each bridged by only one $Co(CO)_4$ group, whereas in **2a** and **2b** two such opposite-lying groups are present; any further approach to the Cu_2 unit is opposed, however, by the mutual repulsion of the carbonyl groups (estimated by use of the van der Waals shape of a CO group in $[Co(CO)_4]^{\ominus}$ [4]).

No evidence has so far been found for a homologous compound containing *three* ammine ligands per $CuCo(CO)_4$ unit. High NH_3 concentrations seem instead to lead directly to a compound with x = 4. Pale yellow **2c** dissolves in liquid ammonia with formation of a colorless solution, the conductivity of which indicates that the Cu–Co bond is cleaved with formation of $[Cu(NH_3)_4]^{\oplus}$ and $[Co(CO)_4]^{\ominus}$ ions.[5] Coordination of three nitrogen donor centers is achieved, however, when **2c** is allowed to react with the tridentate chelate ligand diethylenetriamine (dien), which results in loss of NH_3 and formation of $[(dien)CuCo(CO)_4]$ (**3**). Reaction of **2c** with other amines also results in loss of NH_3 and formation of further adducts with $CuCo(CO)_4$. Thus, reaction of **2c** with equimolar amounts of the chelate ligands ethylenediamine (en) and 1,10-phenanthroline (phen) leads to $[(en)CuCo(CO)_4]$ (**4a**) and $[(phen)CuCo(CO)_4]$ (**4b**); reaction with twice the molar amount of morpholine results in $[(C_4H_9ON)_2CuCo(CO)_4]$ (**5**). In the crystal,[3] all these amine adducts, like **2c**, are monomeric; morpholine is present in chair conformation and is coordinated only through nitrogen. The Cu–N distances become somewhat larger in the series N_2-chelate < 2 N < N_3-chelate (average values [pm]: 204.9 (**4a**) ≈ 205.3 (**4b**) < 208.2 (**2c** and **5**) < 212.7(3)). Independent of the number of nitrogen donor atoms, all complexes in the crystal contain semibridging CO ligands in which the C atoms of the Co-C-O unit concerned are directed toward a copper atom (e.g., **4b**, $(Cu\text{-}C)_{min}$ = 212.9(4) pm for Co-C = 176.2(3) pm and Co-C-O = 164.4(3)°). According to the classification of *Crabtree* and *Lavin*,[6] the semi-μ-CO groups found here belong to the common class of bent semibridging carbonyls. For the present class of substances, a limiting Cu–C distance of 260 pm is found, below which the semibridging bonding mode begins. All carbonyl ligands that, according to this rule, are semibridging are indicated in Figure 1. For higher-nuclear compounds, semi-μ_2-CO but not semi-μ_3-CO ligands are found.

Experimental Procedure

2c: NaOH (5 g, 125 mmol) and $Co_2(CO)_8$ (10.2 g, 30 mmol) were allowed to react in 100 mL of THF to give $Na[Co(CO)_4]$. The filtered solution was evaporated almost to dryness, the residue redissolved in water, the resulting solution evaporated once again, and the resulting residue diluted with water and added to a stirred solution of CuCl (4 g, 40 mmol) in 100 mL of concentrated NH_3. Cooling of the reaction mixture to −5 °C resulted in formation of a bright precipitate of **2**, which, after filtration under N_2, was dissolved in CH_2Cl_2. The resulting solution, after drying over Na_2SO_4, was saturated with NH_3 gas and, after addition of pentane until the onset of turbidity, cooled to −40 °C. Compound **2c** was obtained as pale yellow, needle-shaped crystals. Yield 65% (based on $Co_2(CO)_8$), m.p. 64 °C. IR (KBr): $\tilde{\nu}$(CO) = 2050(m), 2025(s), 1985(m), 1965(s), 1930(vs), 1895(vs) cm^{-1}. ^1H NMR (300 MHz, TMS, CH_2Cl_2): δ = 2.10 (s, NH_3).

2b: N_2 was bubbled through a solution of **2c** (1 g) in 30 mL of CH_2Cl_2 at −5 °C. After 6 h, any precipitate formed was redissolved by addition of a small amount of CH_2Cl_2 and a layer of pentane was added. Yellow crystals formed after about one week at −2 °C. Yield 80%, m.p. 77 °C. IR (KBr): $\tilde{\nu}$(CO) = 2088(w), 2045(sh), 2025(m), 1926(s; half-width, 71 cm^{-1}) cm^{-1}. ^1H NMR (CH_2Cl_2, −70 °C): δ = 2.43 (s, NH_3).

2a: Red crystals of **2a** formed upon an (unsuccessful) attempt to convert **2c** into **1** by reaction with a strongly acidic ion exchanger ($H^{\oplus}$ form) in CH_2Cl_2 solution. An efficient synthesis has not yet been developed; m.p. 79–80 °C. Replacement of NH_3 by an amine: A solution of **2c** in CH_2Cl_2 or toluene was treated with the calculated amount of dien or morpholine; NH_3 was removed by brief application of a vacuum. After addition of pentane, **3**, **4a**, or **5** were obtained as bright yellow crystals. Addition of phen to a solution of **2c** resulted in immediate formation of an orange precipitate; after recrystallization from hot acetone, **4b** was obtained as orange crystalline needles. **4a**: IR (CH_2Cl_2): $\tilde{\nu}$ (CO) = 2010(m), 1940(s), 1900(m), 1850(m) cm^{-1}. **4b**: IR (KBr): $\tilde{\nu}$ (CO) = 2017(st), 1938(st), 1900(st), 1840(s) cm^{-1}. **5**: IR (CH_2Cl_2): $\tilde{\nu}$ (CO) = 2010(s), 1900(s) cm^{-1}.

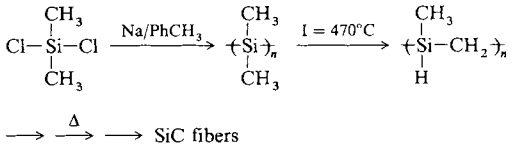
A New Way to SiC Ceramic Precursors by Catalytic Preparation of Preceramic Polymers**

By *Bruno Boury, Leslie Carpenter,* and *Robert J. P. Corriu**

The preparation of ceramic materials by organometallic processes has opened a new chapter in chemical research. In order to show the importance of the nature of the starting organometallic polymer, we have prepared a new ceramic precursor of the polycarbosilane type containing bifunctional silicon atoms. After characterization of the nature and the structure of the units along the chains, we obtained SiC ceramic via direct pyrolysis.

The discoveries of *Yajima* et al.[1] and *Verbeek*[2] opened very interesting perspectives for the chemist, since it was the first time that a ceramic material was prepared in a very useful form as fibers by a set of chemical transformations starting from organosilicon monomers.

Yajima obtained SiC fibers by a process which starts from dichlorodimethylsilane and involves first the synthesis of a polysilane and then, via Kumada rearrangement,[3] a polycarbosilane (Scheme 1). However, in spite of the great novelty of this discovery, the process has some disadvantages:



Scheme 1. Preparation of SiC fibers by the Yajima procedure.

1. It does not provide a general route to preceramic polymers, since it is limited to the preparation of polysilanes. This preparation requires a stoichiometric amount of sodium and it is only possible to modify the nature of the substituents at silicon.

2. The preceramic polymer formed in the thermolysis at 470 °C has a structure which is not well-defined, since it is the result of thermal rearrangement of the original polysilane polymer. It was demonstrated by *Dunoguès* et al.[4] and *Interrante* et al.[5] that the linear structure $-(SiHMe-CH_2)_n-$ without further reticulation does not give a high yield of ceramic.

In fact, the structure of *Yajima*'s preceramic polymer has been shown to be more complex as a result of some cross-linking.[6] This feature renders it difficult to study pyrolysis processes and mechanisms, since the chemical structure of the preceramic polymer is not precisely known.

Our approach to this problem is to try to achieve the following targets:

1. The preparation of preceramic polymer by a direct route avoiding polysilane synthesis.

2. The elaboration of the polymer by a catalytic process able to provide well-defined structures.

3. The development of a process as general as possible.

The hydrosilylation reaction is a very promising one for these purposes since it is a catalytic and very flexible reaction.[7] In this process we can choose both the nature of the substituents at silicon and the nature of the group between two silicon atoms. We can thus obtain well-defined polymers allowing studies of the pyrolysis process.

As starting monomer, we chose vinyldichlorosilane (**1**), produced by redistribution. The polymerization was performed using platinum on charcoal (Pt/C). The resulting chlorine-containing oligomer **2** was reduced by $LiAlH_4$ to **3**, an oligomer containing SiH_2 groups (Scheme 2).

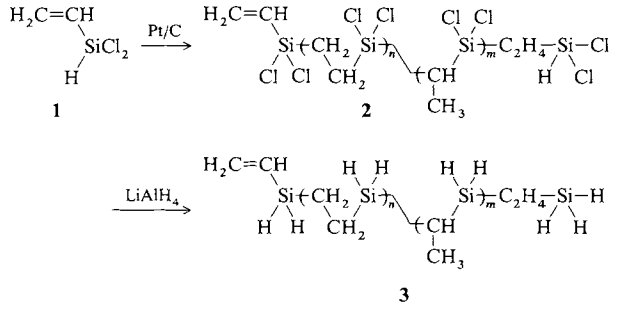


Scheme 2. Synthesis of oligomers containing SiC_x units from dichlorovinylsilane (**1**).

The ^1H, ^{13}C and ^{29}Si NMR spectra of **3** (Table 1) showed that hydrosilylation occurred mainly at the β carbon giving SiH_2-CH_2-CH_2 linear units rather than, as expected, at the α carbon, which would have produced SiH_2-CHMe units. Thus, the ^{29}Si NMR spectrum shows two main signals in the ratio 4/1 and a strong proton signal of the methylene group is observed in the ^1H NMR spectrum. The number-average molecular weight, M_n, was determined by both gel permeation chromatography and vapor-phase osmometry. From this we can determine that the oligomer **3** exhibits a DP_n value in the range of 15 to 20 units. In all polymerization experiments the formation of dimeric and trimeric species as an isomeric mixture of six- and five-membered rings was observed. The end groups of **3** are (vinyl)H_2Si and -H_3Si units.

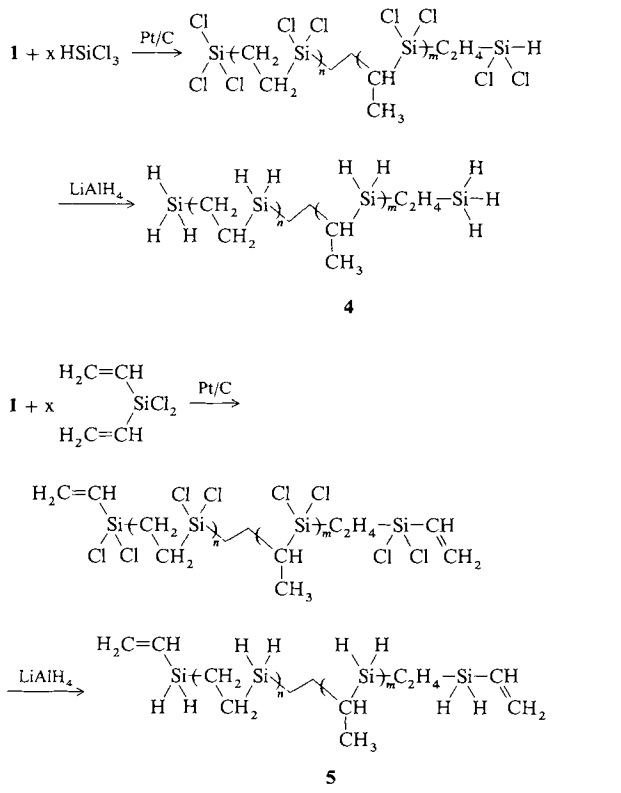
Table 1. NMR assignments for oligomers of type **3** (200-MHz ^{29}Si NMR and 250-MHz ^1H NMR spectra).

Oligomer	δ(^{29}Si)[a]	δ(^{1}H)
$H_2C{=}CH{-}\overset{2}{Si}H_2{-}(CH_2{-}CH_2{-}\overset{1}{Si}H_2{-}CH_2{-}CH_2)_p{-}\overset{3}{Si}H_3$	Si1 −21.9	Ha 3.9
a b c	Si2 −31.8	Hb 3.75
	Si3 −55.0	Hc 3.5
$H_2C{=}CH{-}\overset{2}{Si}H_2{-}(CH_2{-}CH_2{-}\overset{1}{Si}H_2{-}\underset{CH_3}{\overset{e}{CH}})_q{-}\overset{3}{Si}H_3$	Si1 −19.8	Hd 0.75 / 0.77
	Si2 −28.9	
d f	Si3 −51.9	He 0.35
		Hf 1.25

[a] The assignments have been confirmed by spin echo experiments and comparison with the spectra of oligomers **4** and **5**

In the same way we have prepared oligomers **4** and **5** having the same groups at each end by polymerization in the presence of terminating agents (Scheme 3). These oligomers allow confirmation of the assignments for the end groups of **3**.

Thermogravimetric analysis (TGA) was performed by constant heating (5 K per min) up to 1300 °C. A very large loss of weight occurred in the case of **4** and only 12% of ceramic residue was obtained instead of the 69% expected from the theoretical conversion $SiC_2H_6 \rightarrow SiC$. Interestingly, **4** does not exhibit at 180 °C any exothermicity as observed in the differential thermal analysis (DTA) curves for the other two oligomers **3** and **5** (Fig. 1). Furthermore, the TGA curve of **4** corresponds to a regular loss of weight. Apparently the ceramization process follows a different course for **4** than in the cases of **3** and **5**. This observation can be related to the



Scheme 3. Synthesis of oligomers having the same groups at each end. x = 0.1, 0.2.

presence of vinyl groups: **5** exibits a high ceramic yield (52%), much better than the 32% observed for **3**, which contains only one vinyl group.

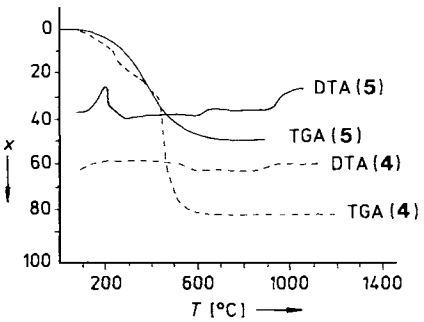


Fig. 1. DTA and TGA curves for the oligomers **4** (---) and **5** (—). x = weight loss in %.

The simplest explanation is that hydrosilylation is occurring between the vinyl groups and the Si-H functions. This hydrosilylation corresponds to the exothermic reaction observed in the DTA curves and gives a more reticulated polymer. It avoids the elimination of volatile compounds (by distillation). The efficiency of the cross-linking for increasing the yield of ceramic residues has been well demonstrated in the case of silicon nitride[8] and silicon carbide.[9]

The SiC obtained from **3** and **5** remained amorphous up to 1000–1100 °C. Crystallization occurred above 1100 °C: β-SiC was identified by X-ray diffraction. The microanalysis of

a sample prepared at 950 °C corresponds precisely to the stoichiometry Si/C = 1. The oxygen content (0.3 to 3%) is highly dependent on the experimental conditions both in the preparation of the oligomer and during ceramization. Careful control of the experimental conditions minimizes the oxygen content. The residue obtained appears as a compact solid with a density 2.1 $g\,cm^{-3}$ lower than that of β-SiC (3.12) and a specific surface between 0.5 and 2 m^2g^{-1} depending on the thermal treatment.

In agreement with the initial aims, we have demonstrated a catalytic procedure leading to the direct synthesis of preceramic oligomers which are precursors of SiC ceramics. This route may hopefully open possibilities for the preparation of new precursors of SiC given the wide chemical variation possible in the hydrosilylation reaction. In fact, as our results show, it is not necessary to use high-molecular-weight polymers since we obtained a good ceramic yield of SiC from oligomeric carbosilanes. The key point is the cross-linking of chains by chemical means (hydrosilylation in our case).

Finally, a comparison of the behavior during the direct pyrolysis of our oligomer containing SiH_2-CH_2-CH_2 units with that of the isomeric polymer having SiHMe-CH_2 units, which contains the alternating Si-C-Si-C arrangement of SiC, shows that the latter is not necessary for a high ceramic yield.[4,5] The good ceramic yields we have obtained can perhaps be explained by the bifunctionality of H_2Si groups.

The β elimination reaction,[10] which could lead to complete depolymerization, does not significantly compete with the mineralization process in the case of cross-linked polymers. Since our linear system does not undergo depolymerization either, we assume that the linear chain can undergo appropriate rearrangements during ceramization.

Experimental Procedure

Preparation of **3**: **1** (4.48 g, 35 mmol), 1,2-dichloroethane (4 mL), and Pt(5%)/C (0.2 g) were heated at reflux for 10 h. A white precipitate formed and was separated by filtration. This solid (5.25 g), as a suspension in Et_2O (150 mL), was reduced by $LiAlH_4$ (1.8 g, 47.3 mmol) in Et_2O (50 mL) at 0 °C. The mixture is allowed to warm to room temperature and then refluxed for 2 h. After acid hydrolysis, evaporation of solvent yielded 1.74 g (72.8%) of a clear, colorless oil (elemental analysis: calcd, C 41.4, H 10.3, Si 48.3; found, C 39.4, H 9.6, Si 43.2; Cl 0.04%).

The Re–Re Bond in Binuclear Di-μ-oxorhenium Complexes Containing the 1,4,7-Triazacyclononane Ligand**

By *Georg Böhm, Karl Wieghardt,* Bernhard Nuber,* and *Johannes Weiss*

Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

Rhenium compounds have played a central role in the development of our understanding of metal–metal multiple bonds in binuclear complexes.[1] Thus, the $[Re_2Cl_8]^{2\ominus}$ ion provides the classic example of a nonbridged M–M quadruple bond (Re-Re 2.24 Å).[2] In binuclear complexes containing bridging ligands, however, the identification of an M–M bond is problematical—particularly if the formal bond order is small. M–M double bonds have been characterized for only a small number of molecules.[1] Rhenium(v) possesses a d^2 electron configuration and is therefore ideally suited for the formation of M–M double bonds. In recent years, *Herrmann* and his co-workers have synthesized and structurally characterized a series of binuclear Re^V compounds.[3] They have observed an unusually wide range of Re–Re distances in complexes containing the $[Re_2(\mu\text{-}O)_2]^{6\oplus}$ structural element: **1**[3a] has a planar Re_2O_2 framework and *no* Re–Re bond, whereas **2**, **3**, and **4** exhibit a puckered Re_2O_2 framework with a Re–Re double bond[3] (Scheme 1). The crystal

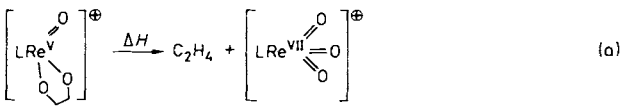
structures of $Nd_4Re_2O_{11}$[4a] and $La_6Re_4O_{18}$[4b] display edge-sharing dimeric units, **5**, having a $Re^{V}_2O_2$ framework, and show the shortest Re^{V}–Re^{V} distances so far found (2.42 and 2.46 Å, respectively). Binuclear coordination compounds of the Werner type, **5**, were previously unknown.

In recent years, we have repeatedly pointed out the structural and chemical relationship of the organometallic fragments CpM and Cp*M ($Cp = C_5H_5^{\ominus}$; $Cp^* = C_5Me_5^{\ominus}$) to the classic, isoelectronic fragment LM, where L is the cyclic triamine 1,4,7-triazacyclononane (or its *N*-trimethylated derivative). For example, the cation $[LReO_3]^{\oplus}$[5] can be prepared by oxidative decarbonylation of the corresponding carbonyl complex (here, $[LRe(CO)_3]^{\oplus}$[6]) with H_2O_2, in full analogy to the preparation of $[Cp^*ReO_3]$[7]. We have now synthesized two binuclear analogues of *Herrmann*'s compounds **1**–**4** and characterized them by X-ray analysis.

Reaction of ethylene glycol, L, and $[ReOCl_3(PPh_3)_2]$[8] in THF leads to formation of a pale violet precipitate, **6**Cl,

$[LReO(C_2H_4O_2)]Cl$ **6**Cl

which can be transformed in aqueous solution into the violet bromide or iodide by addition of NaBr or NaI, respectively. Compound **6** is analogous to $[Cp^*ReO(C_2H_4O_2)]$[9] and, like that compound, **6**I loses ethylene quantitatively upon heating, resulting in formation of colorless $[LRe^{VII}O_3]I$ [Eq. (a)]. Differential thermal analysis of $\mathbf{6}I \cdot H_2O$ gives a



(a)

6

peak at 144 °C (loss of C_2H_4 and H_2O). Figure 1 shows the structure of the cation[10] in crystals of $\mathbf{6}Br \cdot H_2O$; the $[ReO(C_2H_4O_2)]^{\oplus}$ fragment is very similar to that in $[Cp^*ReO(C_2H_4O_2)]$.[9]

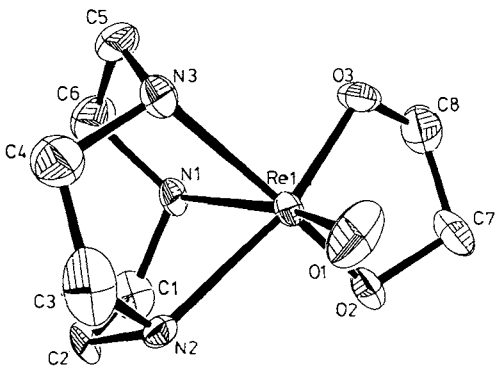


Fig. 1. Structure of the cation in $\mathbf{6}Br \cdot H_2O$. Important distances [Å]: Re1-N1 2.27(1), Re1-N2 2.175(11), Re1-N3 2.18(1), Re1-O1 1.702(15), Re1-O2 1.93(1), Re1-O3 1.939(9), C7-C8 1.51(2), C8-O3 1.42(2), C7-O2 1.45(2).

Reduction of $\mathbf{6}I \cdot H_2O$ with zinc amalgam in aqueous solution under argon at 40 °C results in formation of a green-brown solution, which, after separation of Zn/Hg, air oxidation, and addition of NaI, affords violet crystals of **7**. When an aqueous solution of $ZnCl_2$ and NaCl (1:2) is treated with CH_3SO_3H until the solution is no longer turbid and then **7** is added, dark brown crystals of **8** crystallize from the clear, green-brown solution within 2 d.

$[L_2Re_2(OZnCl_3)_2(\mu\text{-}O)_2]$ **8**

Figure 2 shows the structure of the dication in **7** and Figure 3 that of the neutral complex **8**.[10] In **7**, two Re^{V} ions are joined through two oxo bridges; the Re_2O_2 ring is planar.

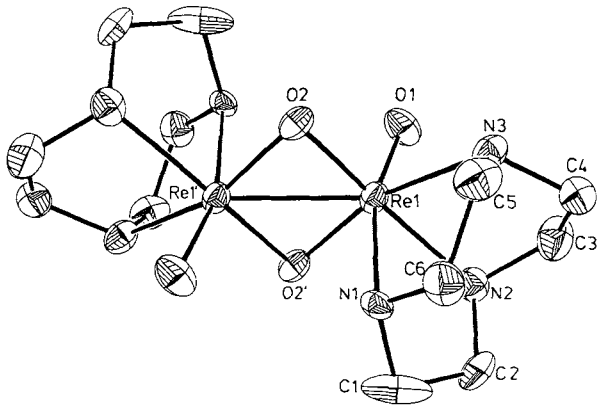

Fig. 2. Structure of the dication in **7**. Important distances [Å] and angles [°]: Re1-Re1' 2.405(1), Re1-O1 1.779(8), Re1-O2 1.933(10), Re1-N1 2.215(9), Re1-N2 2.16(1), Re1-N3 2.17(1), Re1-O2' 1.96(1), O2···O2' 3.07(1); Re1-O2-Re1' 76.2(4), O2-Re1-O2' 103.8(4).

Each Re^{V} ion possesses a terminal oxo group and a tridentate, facially coordinated amine ligand. The Re–Re distance (2.405(1) Å) is very short. Interestingly, the structure of **8** is very similar. However, the presence of a $ZnCl_3^{\ominus}$ fragment on each of the two terminal oxo ligands leads to a dramatic increase in the terminal Re=O distance in **8** and to a decrease in the Re–Re distance to 2.358(1) Å.

The cause is presumably the lower π-donor ability of the Cl_3Zn-substituted O atom. The occupied p orbitals of the oxo ligand can overlap with the unoccupied σ* and π* or-

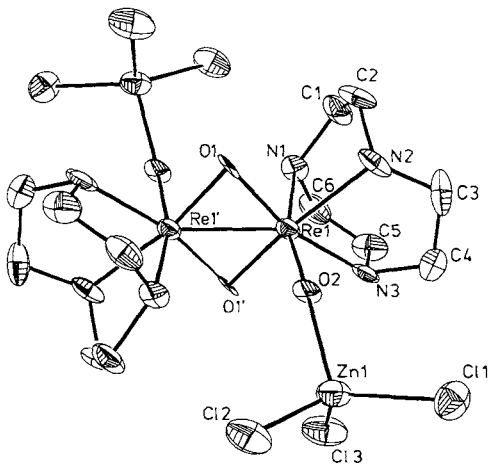

Fig. 3. Structure of the neutral complex **8**. Important distances [Å] and angles [°]: Re1-Re1' 2.358(1), Re1-O1 1.910(9), Re1-O1' 1.926(9), Re1-O2 2.075(8), Re1-N1 2.14(1), Re1-N2 2.19(1), Re1-N3 2.14(1), Zn1-Cl1 2.270(4), Zn1-Cl2 2.257(5), Zn1-Cl3 2.219(5), Zn1-O2 1.994(8); Re1-O1-Re1' 75.9(3), O1-Re1-O1' 104.1(3), Re1-O2-Zn1 137.1(5).

bitals of the Re–Re bond more strongly in **7** than in **8**.[11] The Re_2O_2 ring in **8** is also planar; the Re–μ-O distances of 1.933(10) Å in **7** and 1.910(9) Å in **8** are identical within experimental error. The corresponding distances in **1–5** are in the same range.

Refluxing of a solution of **6I** · H_2O in 0.5 M HCl for 3 h followed by cooling and treatment with NaI results in the formation of black crystals of **9** within 2 d, together with colorless $[LReO_3]I$.

$[L_2Re_2Cl_2(\mu\text{-}O)_2]I_2 \cdot 2H_2O$ **9**

Compound **9** is a dimeric Re^{IV} (d^3) compound. Figure 4 shows the structure of the cation in **9**;[10] a planar Re_2O_2 framework is again observed; each Re^{IV} ion is bonded to a

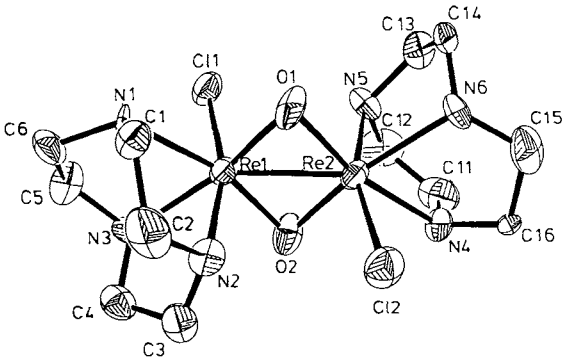

Fig. 4. Structure of the dication in **9**. Important distances [Å] and angles [°]: Re1-Re2 2.376(2), Re1-Cl1 2.385(7), Re1-O1 1.94(2), Re1-O2 2.00(2), Re1-N1 2.24(2), Re1-N2 2.12(2), Re1-N3 2.21(2), Re2-Cl2 2.391(8), Re2-O1 1.99(2), Re2-O2 1.95(2), Re2-N4 2.22(2), Re2-N5 2.13(2), Re2-N6 2.22(2); Re1-O1-Re2 74.2(6), Re1-O2-Re2 73.9(7), O1-Re1-O2 105.9(7), O1-Re2-O2 106.0(7).

terminal $Cl^{\ominus}$ ligand. The Re^{IV}–Re^{IV} distance (2.376(2) Å) is nearly as short as that in the anion of **10** (2.362(1) Å).[12] In

$K_4[Re_2^{IV}(\mu\text{-}O)_2(C_2O_4)_4] \cdot 3H_2O$ **10**

octahedral, edge-sharing complexes, a σ, a π, and a δ metal–metal bond can form between the metal ions.[11, 13] A formal Re–Re double bond ($\sigma^2\pi^2$) results for **7** and **8** and a triple bond ($\sigma^2\pi^2\delta^2$) for **9**.[18] We described earlier the complexes *anti*-$[L_2MO_2(\mu\text{-}O)_2]^{2\oplus}$ (M = Mo^V,[14a] W^V[14b]), which have an M–M single bond (2.56 Å) and a *planar* $M_2(\mu\text{-}O)_2$ ring; in the *syn* isomers, with a *puckered* M_2O_2 ring, the M–M distance is just as large. $[L_2Mo_2^{III}(\mu\text{-}OH)_2Cl_2]^{2\oplus}$[15] is isoelectronic to **9**; the Mo–Mo distance is 2.501(3) Å and corresponds to a triple bond. In the electron-rich organometallic complexes **2–4**, the Re–Re distance is up to approximately 2.7 Å long, though still in the range of Re–Re double bonds.

The reason for the absence of a Re–Re bond in **1** is therefore still unclear. The fact that the oxo bridges are involved in strong hydrogen bonding to H_2O molecules cannot explain the enormous increase in the Re–Re distance, since even $M_2(\mu\text{-}OH)_2$ complexes can exhibit strong M–M bonds. The theoretical analysis of *Bursten* et al.[16] on the relative stability of planar versus puckered M_2O_2 rings in $[Cp_2^*M_2O_4]$ complexes is not relevant to complexes **7–9**, since a *short* Mo–Mo single bond is observed in the classical compound *syn*-$[L_2Mo_2^VO_2(\mu\text{-}O)_2]^{2\oplus}$ *and* in its organometallic counterpart *syn*-$[Cp_2^*Mo_2^VO_2(\mu\text{-}O)_2]$[17] (Mo-Mo 2.555(1) and 2.587(1) Å, respectively). Both complexes have a puckered M_2O_2 ring. Furthermore, the M–M distance is just as large in the complex *anti*-$[L_2M_2O_2(\mu\text{-}O)_2]^{2\oplus}$ (M = Mo^V, W^V), which has a planar M_2O_2 ring.

Experimental Procedure

6X · H_2O (X = Br, I): $[ReOCl_3(PPh_3)_2]$[8] (1.57 g, 1.88 mmol) was added under argon to a solution (60 mL) of dry THF, L (0.52 g, 4.02 mmol), and ethylene glycol (0.19 g, 3.06 mmol), which had been dried over molecular sieves. After stirring for 3 h at 20 °C, the solution was filtered to collect the pale violet precipitate of **6**Cl. Compound **6** was then crystallized from water as the bromide or iodide by addition of NaBr or NaI (yield ca. 75%). IR (KBr): $\tilde{\nu}$ = 961 (Re=O), 654 and 615 cm^{-1} (Re-OC). UV/VIS (H_2O): λ_{max} [nm] (ε[L mol^{-1} cm^{-1}]) = 546(29).

7: **6I** · H_2O (0.27 g, 0.55 mmol) was dissolved in 25 mL of water and the resulting solution was stirred under argon over Zn/Hg at 40 °C for 3 h. The green-brown solution was then separated from Zn/Hg and stirred under air at 20 °C for 24 h, whereby the solution turned intense violet. Addition of 5 mL of a saturated aqueous NaI solution resulted in formation of a violet, microcrystalline precipitate of **7**. Single crystals suitable for X-ray structure analysis were grown by slow cooling of an aqueous solution, saturated at 50 °C (yield 60%). IR (KBr): $\tilde{\nu}$ = 818 and 794 (Re=O), 729 cm^{-1} (Re_2O_2). UV/VIS (H_2O): λ_{max} [nm] (ε[L mol^{-1} cm^{-1} per binuclear unit]) = 556 (1560), 730 (300).

8: 0.1 M CH_3SO_3H was added to 20 mL of an aqueous solution of $ZnCl_2$ (0.82 g, 6.01 mmol) and NaCl (0.70 g, 11.98 mmol) until a clear solution resulted. After addition of **7** (0.47 g, 0.50 mmol), the solution was stirred for 3 h at 30 °C. Dark brown crystals of **8** crystallized from the clear green-brown solution within 2 d (yield 0.21 g, 40%). IR (KBr): $\tilde{\nu}$ = 712 (Re_2O_2), 555, 535 cm^{-1} (Zn-O or Re-OZn).

9: A solution of **6I** · H_2O (0.27 g, 0.55 mmol) in 20 mL of 0.5 M HCl was refluxed for 3 h and then cooled to 20 °C. Addition of NaI (1.5 g, 10.01 mmol) resulted in the crystallization within 2 d of black crystals of **9** together with colorless crystals of $[LReO_3]I$. The black crystals were sorted manually and recrystallized from a small amount of 0.5 M HCl (yield 0.15 g, 30%). IR (KBr): $\tilde{\nu}$ = 694 cm^{-1} (Re_2O_2). UV/VIS (1 M NaCl): λ_{max} [nm] (ε[L mol^{-1} cm^{-1}]) = 461 (4500), 520 (sh), 621 (272), 757 (217).

Compounds **7**, **8**, and **9** are diamagnetic (Faraday method). All compounds gave correct elemental analyses (C, H, N, halogen).

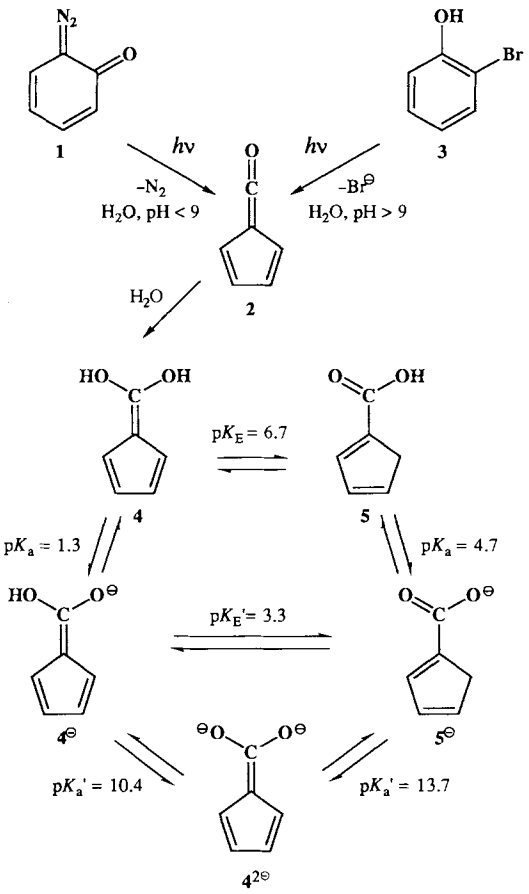
The Tautomeric Equilibrium between Cyclopentadienyl-1-carboxylic Acid and Fulvene-6,6-diol in Aqueous Solution**

By *Bernhard Urwyler* and *Jakob Wirz**

The light-induced decomposition of diazoketones has been studied since the origins of organic photochemistry.[1] Quinone diazides find commercial application as positive photoresists in microlithography.[2] *Süs* first described the mechanism of the photochemical ring contraction of *o*-quinone diazides and identified cyclopentadienyl carboxylic acids as the final products of photolysis in aqueous solution.[3] Recent kinetic studies of this photoreaction have, however, led to contradictory interpretations.[4]

The primary photoproduct of the parent compound 1,2-benzoquinone diazide (**1**) in a nitrogen matrix has been identified as 6-fulvenone **2** by IR spectroscopy.[5] We generated the ketene **2** by laser flash photolysis of **1**[6] as well as of 2-bromophenol (**3**)[7] and report here its reaction kinetics in aqueous solution (Scheme 1). The hydrolysis of **2** proceeds via the metastable intermediate 6,6-fulvenediol (**4**) to give 1,3-cyclopentadienyl-1-carboxylic acid (**5**). Combination of the two dissociation constants of the OH- and CH-acid **5** with the kinetic data of the decay of **4** provides the first complete characterization of the equilibrium and kinetics of the enolization of a carboxylic acid.[8]

The quantum yield of photohydrolysis of 2-bromophenol (**3**) drops to almost zero[7] in acidic solutions [pH < pK_a (**3**) = 8.45].[9] On the other hand, 1,2-benzoquinone diazide (**1**) is unstable in basic aqueous solutions. Therefore, we used the diazide **1** in acidic solutions and the phenol **3** in basic solutions (both ca. 0.5×10^{-4} M, 24 ± 2 °C) as precursors to the ketene **2** in the flash photolysis experiments (excimer laser, 248 or 308 nm, ca. 100 mJ per pulse, pulse width ca. 25 ns). Control experiments with weakly basic aqueous solutions confirmed that both **1** and **3** give the same transient intermediates upon photolysis. In the proton concentration range from 10^{-1} to 10^{-13} M all solutions were adjusted to an ionic strength of $I = 0.1$ M by the addition of NaCl. The reaction was not affected by oxygen except for the oxidation of $\mathbf{4}^{2\ominus}$ in strongly basic solutions (vide infra). Thus, in most cases air saturated solutions were used. Experiments with basic buffers such as tris(hydroxymethyl)methylamine, phosphate, and borax showed that the ketene **2** reacted with the basic buffer components, whereby the formation of **4** was suppressed. Therefore, only dilute NaOH could be used to prepare weakly basic solutions. These solutions were prepared under argon and controlled by a glass electrode.



Scheme 1. All equilibrium constants are concentration quotients in aqueous solution (I = 0.1 M, 24 ± 2 °C).

A mixture of dimers of **5** is readily accessible by reaction of the cyclopentadienyl anion with CO_2.[10] The monomeric acid **5**[11] was isolated by fractional vacuum sublimation of the dimers (3×10^{-2} torr, 180 °C). The acid may be stored at −70 °C in crystalline form and is stable for hours in dilute aqueous solution at ambient temperature. Twofold deprotonation in aqueous base gave the conjugate dianion $\mathbf{4}^{2\ominus}$ reversibly, which, however, was stable only when air was strictly excluded. The oxygen and carbon dissociation constants (concentration quotients at I = 0.1 M) of **5** were measured by spectrophotometric titration,[12] pK_a = 4.71 ± 0.02, pK_a' = 13.71 ± 0.04. The second titration required NaOH concentrations of up to 1.2 M. The H_{2-} acidity function defined by *Yagil*[13] was used to calculate the concentration quotient for I = 0.1 M. A possible systematic error arising from this procedure should be less than ±0.1 pK units.

Upon flash excitation of basic solutions of **3** we observed the formation and subsequent decay of a transient intermediate absorbing in the range 280 to 320 nm (see insert in Fig. 1). Both reactions obeyed a first-order rate law (τ_1 = 1 μs, τ_2 = 7 μs at pH ≈ 10). Below 280 nm, the first reaction appeared as a decay of transient absorbance. The

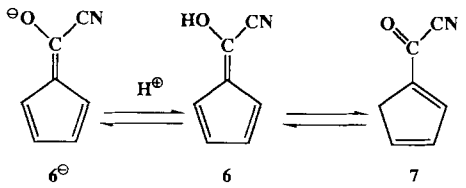
absorption maximum of the ketene **2** is at 260 nm.[5] The first reaction is thus attributed to hydrolysis of the ketene **2** yielding the enediol **4**. This assumption is fully corroborated by the following observations.

The rate of hydrolysis of **2** remained constant in aqueous solution from pH = 2 to 11, $k_0 = (9.0 \pm 0.4) \times 10^5\ s^{-1}$. In basic solutions (pH > 11) it increased with the concentration of hydroxyl ions. Linear regression of the rates measured in the range $[OH^\ominus] = 10^{-3}$ to 10^{-1} M gave the intercept $k_0 = (9.5 \pm 0.1) \times 10^5\ s^{-1}$ and the slope $k_{OH^\ominus} = (4.8 \pm 0.1) \times 10^7\ M^{-1}\ s^{-1}$. Similar rate profiles were reported by *Tidwell, Kresge* et al. for the hydrolysis of alkyl and aryl ketenes.[14]

Upon addition of KCN to a solution of **3** in aqueous NaOH (3×10^{-4} M), the decay rate of **2** increased linearly with the concentration of cyanide, $k_{KCN} = (1.6 \pm 0.2) \times 10^8\ M^{-1}\ s^{-1}$, and the intensity of the subsequent decay of **4** was reduced accordingly. The formation of a new photoproduct ($\lambda_{max} = 340$ nm) in the presence of KCN was confirmed by 400-MHz ^{1}H-NMR spectroscopy: irradiation ($\lambda > 300$ nm) of $\mathbf{3}^\ominus$ (10 mg) in 10 ml D_2O/KCN (1 M) gave rise to new signals of equal intensity at $\delta(J[Hz]) = 6.81$(d, 4), 6.79(d, 4), 6.57 (dd, 4 and 2) and 6.46 (dd, 4 and 2) which we attribute to 6-cyanofulven-6-olate ($\mathbf{6}^\ominus$). Attempts to isolate the enol **6** failed. Presumably, **6** tautomerizes to the cyclopentadiene **7**, which in turn yields a complex product mixture.



$\mathbf{6}^\ominus$ **6** **7**

The ketonization of the enediol **4** to the carboxylic acid **5** was monitored at 315 nm. The V-shaped rate profile approaches maximum values of ca. $10^6\ s^{-1}$ at both the acidic and the basic ends of the scale (Fig. 1, curve b). This is clear evidence that two acid-base equilibria are established prior to the decay of **4**: In the pH range from 2 to 10, the predominant species is $\mathbf{4}^\ominus$. Its rate profile has the same shape as that of simple enols.[15] The maximum lifetime of $\mathbf{4}^\ominus$ is about 20 ms at pH 6. Due to preequilibration with the more reactive dianion $\mathbf{4}^{2\ominus}$, the reaction rate increases with increasing concentration of $OH^\ominus$ and approaches its maximum value when the equilibrium shifts to the dianion. With increasing $H^\oplus$ concentration, the rate increases again due to protonation of $\mathbf{4}^\ominus$ at carbon; the plateau is reached in strong acid as the equilibrium shifts to the less reactive, neutral enediol **4**. Since, as usual,[15] the protonation of the enediol and its anions at carbon is rate determining, the rate law[16] for the ketonization reaction of the enol **4** is given by Equation (a).

$$\log(k_{obs}) = \log\left\{k + \frac{k' K_a}{[H^\oplus]} + \frac{k'' K_a K'_a}{[H^\oplus]^2}\right\} - \log\left\{1 + \frac{K_a}{[H^\oplus]} + \frac{K_a K'_a}{[H^\oplus]^2}\right\} \quad (a)$$

Least squares fitting of Equation (a) to the measured rate constants k_{obs} gave the first-order rate constant of the ketonization of the enediol **4**, $k = (1.08 \pm 0.08) \times 10^6\ s^{-1}$, and of the dianion $\mathbf{4}^{2\ominus}$, $k'' = (9.6 \pm 0.9) \times 10^5\ s^{-1}$, as well as the two dissociation constants of the enediol **4**, $pK_a = 1.31 \pm 0.05$ and $pK'_a = 10.4 \pm 0.1$. Due to poor buffering of the solutions at the second inflection we need to consider an additional systematic error of at most ± 0.1 pK units. As expected, the "uncatalyzed" reaction of the anion $\mathbf{4}^\ominus$ did not contribute significantly to the observed rate ($k' < 40\ s^{-1}$).

Flash photolysis ($\lambda = 308$ nm) of 2-bromophenol (**3**) in 1 M NaOH gave the dianion $\mathbf{4}^{2\ominus}$ within 100 ns after excitation. Its oxidation in air-saturated solution could thus be monitored directly; it occurs at a nearly diffusion-controlled rate, $k_{O_2} = (4.70 \pm 0.05) \times 10^9\ M^{-1}\ s^{-1}$. Indeed, the oxidation potentials of -0.62 V and -0.67 V (vs. SCE),[17] measured for the dilithium salts of phenyl- and diphenylacetic acid in THF/HMPA, are close to the first reduction potential of oxygen in aqueous solution (1 M NaOH, -0.563 V).[18]

The equilibrium constant for the enolization of the carboxylic acid **5** may be calculated through the thermodynamic cycle of Scheme 1: $pK_E = pK_a(\mathbf{5}) + pK'_a(\mathbf{5}) - pK_a(\mathbf{4}) - pK'_a(\mathbf{4}) = 6.71 \pm 0.2$. The quoted error range includes, by the law of error propagation, the conservative estimates given above for possible systematic errors in $pK'_a(\mathbf{5})$ and $pK'_a(\mathbf{4})$. The enolization constant of the carboxylic acid anion $\mathbf{5}^\ominus$ is obtained similarly as $pK'_E = pK'_a(\mathbf{5}) - pK'_a(\mathbf{4}) = 3.3 \pm 0.2$. The enol content of the carboxylic acid **5** is thus nearly nine orders of magnitude higher than that of mandelic acid.[8] It is also interesting to compare the pK_a values of **4** with those of the structurally related carbonic acid, $CO(OH)_2$: $pK_a = 3.9$ and $pK'_a = 10.3$.[19] The high enol content of **5** and the high acidity of the enediol **4** reflect the stabilization of the electron-rich dioxy function by charge transfer to the five-membered ring.

Figure 1 summarizes the rate profiles for the hydrolysis of the ketene **2**, the ketonization of the enediol **4**, and the enolization of **4**, calculated from the latter via the equilibrium constants. Note that the enolization reaction is catalyzed by base, but hardly by acid. The readily accessible dianion $\mathbf{4}^{2\ominus}$ might be useful as a reactive, electron-rich diene component for synthetic purposes.

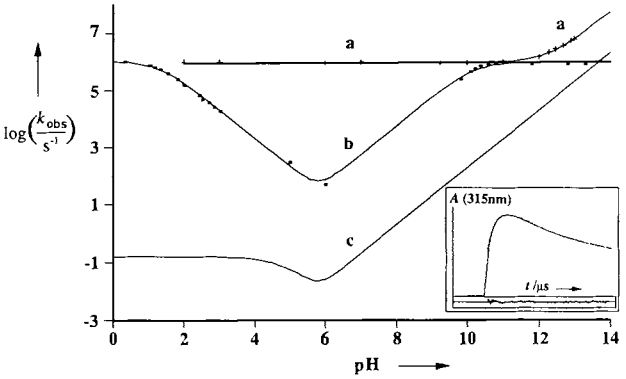


Fig. 1. Rate profiles for a) the hydrolysis of **2**, b) the ketonization of **4**, and c) the enolization of **5**. All pH values reported in this work refer to proton *concentrations* rather than activities. They were adjusted by HCl in the range pH = 1 to 3, by dilution series with acetic acid buffer at 5 and 6 and with NaOH above 9.8; $I = 0.1$ M. The inset shows the formation and subsequent decay of the transient intermediate **4** at pH = 10.

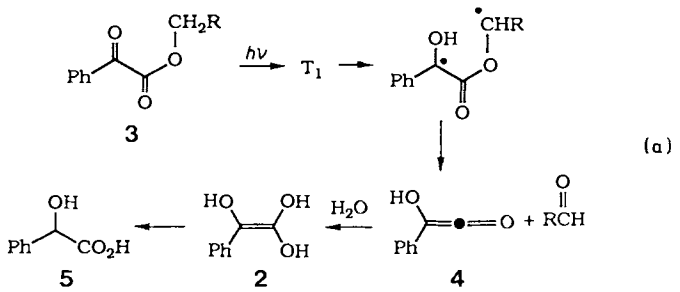
The Enol of Mandelic Acid, Detection, Acidity in Aqueous Solution, and Estimation of the Keto-Enol Equilibrium Constant and Carbon Acidity of Mandelic Acid**

By *Y. Chiang, Alexander J. Kresge,* P. Pruszynski, N. P. Schepp,** and *Jakob Wirz*.

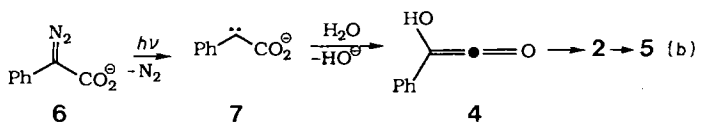
The current renaissance of interest in the chemistry of enols is providing a wealth of new information about enol isomers of simple aldehydes and ketones.[1] Little, however, is as yet known about enols of other carbonyl compounds, such as carboxylic acids and esters: we are aware of only two previous observations of carboxylic acid enols in solution.[2] One of these[2a] was of the enol of bis(pentamethylphenyl)-acetic acid **1** (Ar = Me_5C_6), whose bulky aryl groups give it remarkable stability, reminiscent of the unusually stable hindered enols of aldehydes and ketones prepared by *Fuson* some 40 years ago[3] and currently being reinvestigated by *Rappoport* et al.[1b] We wish to report that we have now generated an unhindered and very much more reactive carboxylic acid enol **2**, namely the enol of mandelic acid in aqueous solution, and have begun investigating its chemistry in this medium.

1 **2**

We prepared this enol by two different flash photolytic methods: Norrish type II photoelimination of methyl or isobutyl benzoylformate **3** [Eq. (a), R = H, *i*Pr], and photo-Wolff reaction of diazophenylacetate **6** [Eq. (b)].



(a)



(b)

Reports in the literature[4] suggest that the first of these processes involves generation of a triplet excited state of **3** (T_1), followed by diradical formation and cleavage to hydroxyphenylketene **4**, which may then combine with water to give mandelic acid **5** via its enol **2**. Consistent with this we find that flash photolysis of methyl or isobutyl benzoylformate gives rise to triphasic UV spectral changes (Fig. 1),

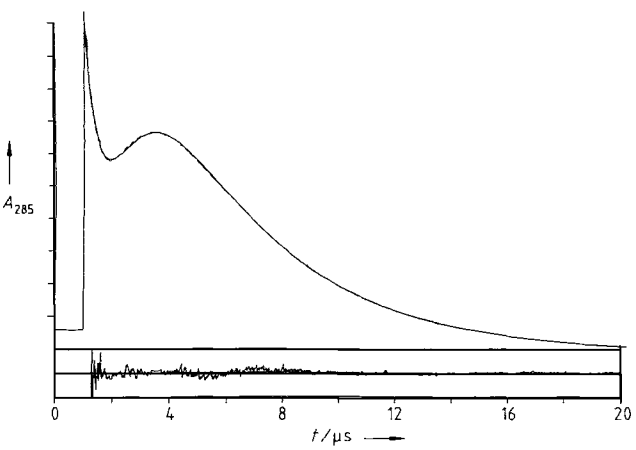


Fig. 1. Absorbance changes at λ = 285 nm upon flash photolysis of methyl benzoylformate in aqueous biphosphate buffer solution ($[H_2PO_4^{\ominus}]$ = 0.002 M, $[HOP_4^{2\ominus}]$ = 0.006 M, I = 0.10 M) at 25 ° using an excitation pulse from a KrF eximer laser. λ_{exc} = 248 nm, 20 ns pulse width, 200 mJ per pulse; the bottom trace shows residuals from a least squares fit of the data to a triple exponential expression.

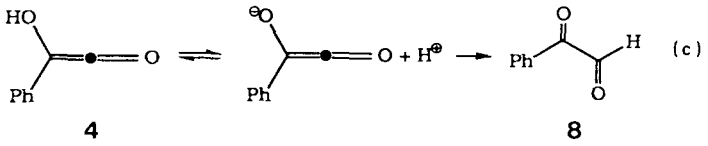
implying the production of three successively formed transient species. Flash photolysis of **6** also gives the second and third of these transients, as expected from rearrangement of a carbene intermediate to **4** followed by hydration of the ketene to mandelic acid enol **2**. Both reactions also produce mandelic acid **5** as a major product.

Decay of the shortest-lived transient formed by flash photolysis of **3** is not catalyzed by acids or bases over the pH range investigated (2–8), and the lifetime of the transient, $\tau \approx 300$ ns, is similar to that reported for the triplet excited states of benzoylformate esters in water ($\tau = 300$ ns)[5] and other solvents ($\tau = 400$–700 ns).[4] This, plus the fact that its lifetime increases to $\tau = 450$ ns in degassed aqueous solution, as well as its broad UV spectrum extending from $\lambda = 300$ to 500 nm, serves to identify this species as the triplet.

Decay of the transient attributed to **4** is also not catalyzed by $H^{\oplus}$ or $HO^{\ominus}$ over the pH range investigated (2–8), and only weakly if at all by phosphate or tris(hydroxymethyl)-methylamine (TRIS) buffers. Its rate of reaction with water is $6.7 \times 10^5\ s^{-1}$ and it exhibits a solvent isotope effect $k_{H_2O}/k_{D_2O} = 1.3$. This is the behavior expected for hydration of a phenyl-substituted ketene; for example, hydration of phenylketene itself shows no acid catalysis and catalysis by hydroxide ion becomes significant only above pH = 12, and the reaction exhibits a solvent isotope effect $k_{H_2O}/k_{D_2O} = 1.4$.[6]

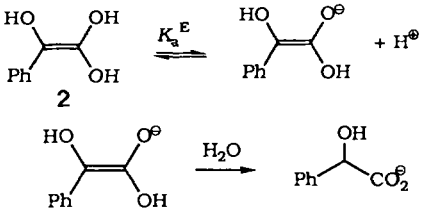
Since **4** also contains an enol functional group, it could, at least in principle, undergo a formally uncatalyzed ketonization reaction [Eq. (c)] by ionization of the enol followed by



4 8 (c)

rate-determining protonation of the enolate ion on carbon. This process, however, would by expected to give a solvent isotope effect much greater than the $k_{H_2O}/k_{D_2O} = 1.3$ observed: the acid ionization step of Equation (c) would contribute a factor of $K_{H_2O}/K_{D_2O} = 3$–4, and the rate-determining step another factor of $k_H^{\oplus}/k_D^{\oplus} = 2$–$3$, for an overall prediction of $k_{H_2O}/k_{D_2O} = 6$–12. This reaction, moreover, produces benzoylformaldehyde **8**, but no **8** was found in the reaction product. Reaction by this route would also give rise to one transient less than the number observed.

The absorbance of the transient attributed to mandelic acid enol shifts to longer wavelength in basic solution, as expected for conversion of an enol into its enolate ion.[7] The decay of **2** is catalyzed by both $H^{\oplus}$ and $HO^{\ominus}$, and it also shows strong catalysis by phosphate and TRIS buffers. This is characteristic of the ketonization of enols. Decay of this transient also gives a rate profile (Fig. 2) which is typical of such a process.[1c] In particular, the apparent hydroxide ion catalysis that becomes saturated above pH = 7 can be attributed to ionization of the enol [Eq. (d)], followed by rate-determining protonation of the much more reactive enolate ion on carbon by water [Eq. (e)]. Standard treatment of rate data

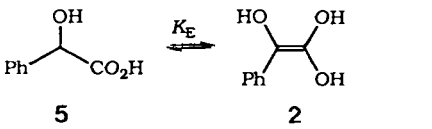


(d)

(e)

obtained in the region of transition from catalysis to saturation gives the equilibrium constant for the ionization step, which is the acidity constant of the enol. The present data produce the result, $pK_a^E = 6.62 \pm 0.07$.[8,10]

We also attempted to measure the rate of enolization of mandelic acid **5** in order to provide an estimate of the keto-enol equilibrium constant as the ratio of enolization to ketonization rate constants, $K_E = k_E/k_K$. Since **5** contains an asymmetric carbon atom which will lose its chirality upon enolization [Eq. (f)], we chose to do this by monitoring the



(f)

racemization of optically active mandelic acid by polarimetry. The rates of racemization proved to be very slow, and we were forced to make measurements at elevated temperatures (138–155 °C) in concentrated acid solutions (1.1–4.5 M HCl). Acid-catalyzed enolization is a classic example of a reaction whose rate is proportional to acid concentration rather than some steeper acidity function,[11] and we found this to be the case for the present racemization in the range [HCl] = 1–2 M. Above this region, however, rates increased more rapidly than in direct proportion to acid concentration, suggesting that some process in addition to enolization – perhaps nucleophilic substitution – was intervening. We plan to investigate this matter, but in the meantime, working on the assumption that the component of the racemization reaction whose rate is proportional to acid concentration is in

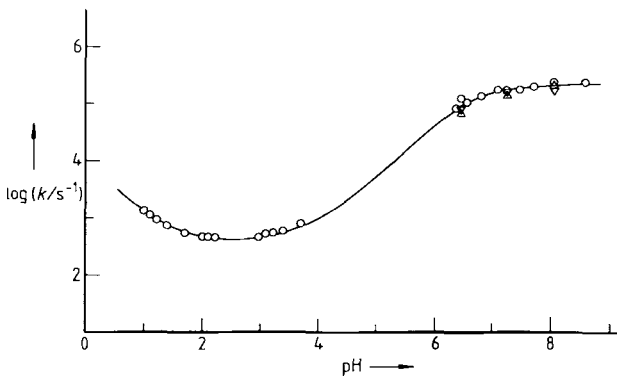


Fig. 2. Rate profile for the ketonization of **2** in aqueous solution at 25 °C; ○: enol generated from **3**, R = H; △: enol generated from **3**, R = *i*Pr; ▽: enol generated from **6**. The data for the pH range ≈6–9 were obtained from measurements in $H_2PO_4^{\ominus}$ and TRIS buffers extrapolated to zero buffer concentration. All pH data in this work refer to proton *concentrations* and not to proton activities.

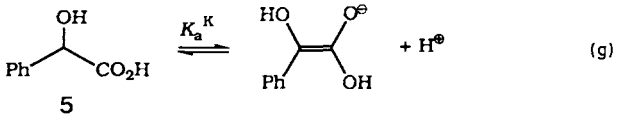
fact enolization, we can estimate a hydronium-ion catalytic coefficient of $k^{E}_{H\oplus} = 4 \times 10^{-12}\ M^{-1}\ s^{-1}$ for the enolization reaction at 25 °C. Combination of this with the hydronium-ion catalytic coefficient for ketonization measured at 25 °C, $k^{E}_{H\oplus} = 9.3 \times 10^{3}\ M^{-1}\ s^{-1}$,[12] then leads to the keto-enol equilibrium constant $pK_E = 15.4$.

This keto-enol equilibrium [Eq. (f)] and the acid ionization of the enol, [Eq. (d)] form two branches of a thermodynamic cycle whose third member is the deprotonation of mandelic acid **5** as a carbon acid [Eq. (g)]. The equilibrium constant for this reaction may therefore be calculated from the other two: $pK^{K}_{a} = pK_E + pK^{E}_{a} = 22.0$.



(g)

These three equilibrium constants, pK_E, pK^{E}_{a}, and pK^{K}_{a}, are the first ever measured for a simple carboxylic acid keto-enol system in aqueous solution.[13] They show the enol content to be very low—orders of magnitude less than of simple aldehydes and ketones—as expected from stabilization of the keto tautomer of the carboxylic acid system through conjugative interaction of its carbonyl and hydroxyl groups. The carboxylic acid enol, on the other hand, is more acidic than those of simple aldehydes and ketones, and that makes the carbon acidity of this carboxylic acid greater than it would otherwise be.

[8] This pK_a probably refers to ionization of the hydroxy group *trans* to phenyl [Eq. (d)] rather than the *cis* hydroxyl, inasmuch as the *trans* enol of phenylacetaldehyde has been found to be a stronger acid than its *cis* isomer [9]. Ionization of the hydroxy group geminal to phenyl can be ruled out because this would produce phenylglyoxal, which is not found in the reaction product.

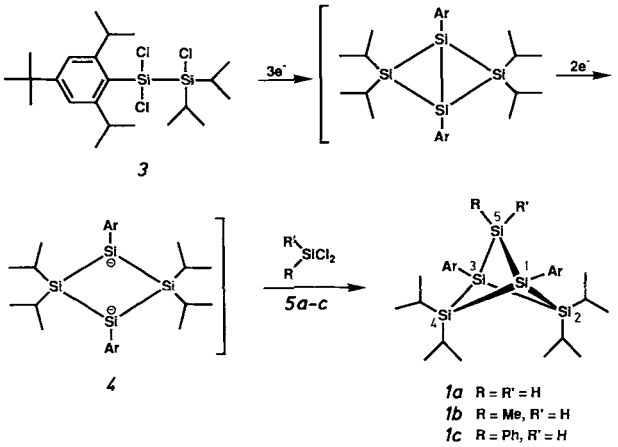
A Bicyclo[1.1.1]pentasilane Derivative. Synthesis, Molecular Structure, and Comments on Structural Homology**

By *Yoshio Kabe, Takeshi Kawase, Joji Okada, Osamu Yamashita, Midori Goto*, and *Satoru Masamune**

In recent years we have witnessed a surge of activities in constructing strained polycyclic systems with the Group 14 elements, Si, Ge, and Sn. Those systems whose members have yielded to synthesis and are now adequately characterized include bicyclo[1.1.0]tetrasilane,[1a] bicyclo[2.2.0]-hexasilane,[1b] octasilacubane,[1c] hexagermaprismane,[1d] bicyclo[2.2.0]hexastannane,[1e] pentastanna[1.1.1]propellane,[1f] tricyclo[2.2.0.$0^{2,5}$]hexasilane,[1g] and tetracyclo-[3.3.0.$0^{2,7}$.$0^{3,6}$]octasilane,[1g] and octagermane.[1h,i] We wish to add to this list the bicyclo[1.1.1]pentasilane system **1**, which has been an object of recent theoretical investigation.[2a,b]. Comparison of the molecular structure of 1,3-bis(4-*tert*-butyl-2,6-diisopropylphenyl)-2,2,4,4-tetraisopropylbicyclo[1.1.1]pentasilane (**1a**), with the corresponding carbon analog **2** (Scheme 2) reveals a high degree of structural homology. This *approximate* homology applies also to other Si ring systems and can provide useful information on the unique Si,Si non-bonding distance in unknown compounds.

Treatment of the trichlorodisilane **3** with five equivalents of naphthalenelithium in THF at −78 °C led to the formation of the dianion **4**[3] (Scheme 1) which was quenched with



Scheme 1. Synthesis of **1a–c** (Ar = aryl).

excess dichlorosilane (**5a–c**) to provide **1a** in 31%, **1b** in 12%, and **1c** in 15% yield, respectively. The spectral data of these compounds (Table 1) are consistent with the proposed structures. Particularly revealing are the ^{29}Si-NMR spectra,

whose analysis, based on the molecular symmetry of **1a–c**, readily permits signal assignments without recourse to 2D ^{29}Si NMR.[4] The assignments are indicated in Table 1.

An X-ray analysis of **1a** discloses several interesting structural features (Fig. 1).[5] As expected, the three cyclotetrasilane rings making up **1a** are highly puckered with an average dihedral angle of 60°, which contrasts with the 0–37° angles normally found in the monocyclic system. The Si–Si–Si bond angles at the bridge head atoms Si(1) and Si(3) approximate to 84° and those at the bridging silicon atoms Si(2), Si(4), and Si(5) are 78°. These values are in accord with the X-ray[6a] and electron diffraction[6b,c] (gas phase) data recorded for the carbon analogues, bicyclo[1.1.1]pentanes (**2**) showing that **1a** and **2** are homologous.

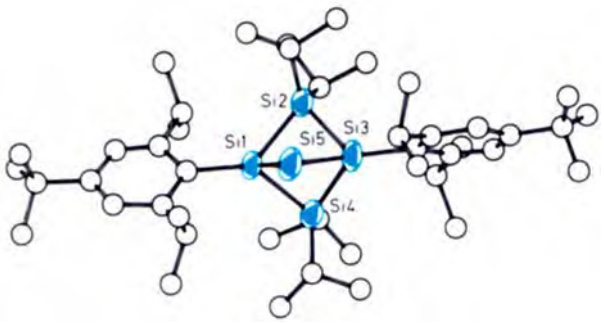

Fig. 1. Molecular structure of **1a**. Since two independent molecules in the asymmetric unit contain almost the same geometry, bond lengths [Å] and angles [°] of only one molecule are given below: Si1–Si2 2.38(1), Si1–Si4 2.34(1), Si1–Si5 2.32(1), Si2–Si3 2.34(1), Si3–Si4 2.36(1), Si3–Si5 2.35(1); Si2–Si1–Si4 87.4(3), Si2–Si1–Si5 82.6(4), Si4–Si1–Si5 83.2(4), Si1–Si2–Si3 78.0(4), Si2–Si3–Si4 87.6(5), Si2–Si3–Si5 82.2(4), Si4–Si3–Si5 82.1(4), Si1–Si4–Si3 78.5(3), Si1–Si5–Si3 79.1(5).

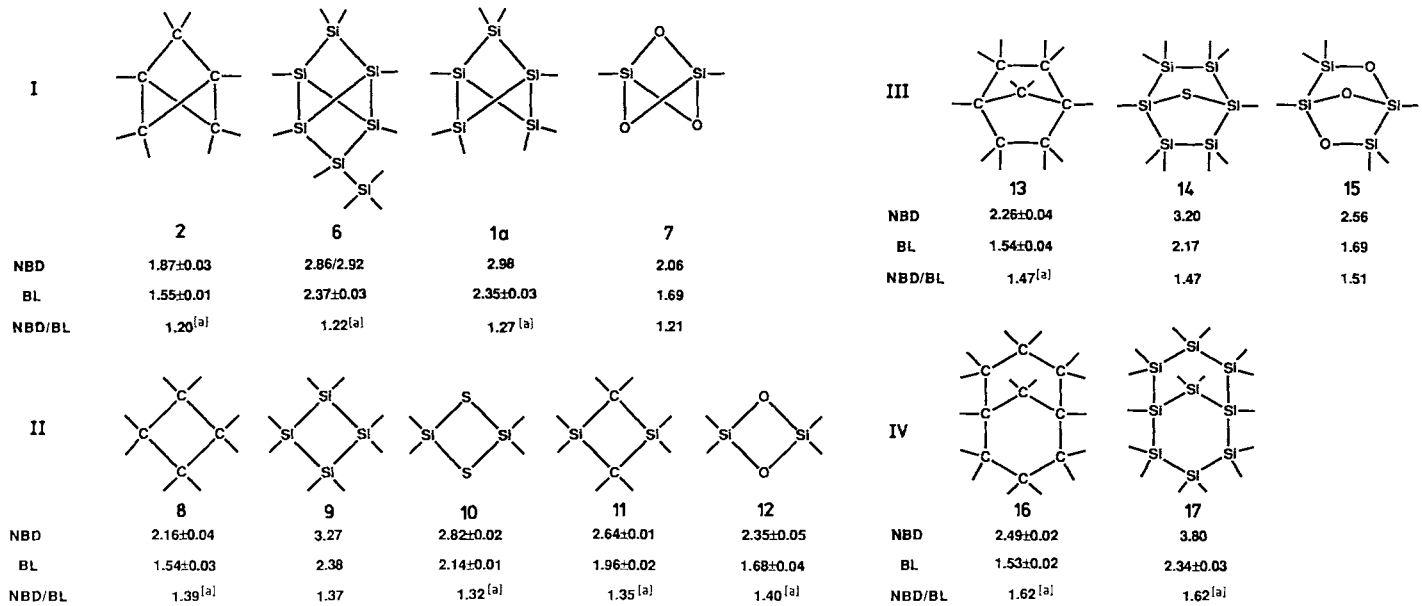
In **1a** the ratio of the "non-bonding distance" (NBD, Si1···Si3 2.98 Å) to the averaged length of the single bond (BL, Si–Si 2.35 Å) is 1.26 and, as a result of the homology discussed above, this ratio should be and indeed is close to that (1.22) calculated for NBD (1.89 Å)/BL (1.54) in **2**. Two other examples having the same ring framework as **1a** and **2** are the known tricyclo[2.2.0.0^{2,5}]hexasilane derivative **6**[1g] and the unknown trioxo analog **7**[2b,c] whose geometry was computed recently. Remarkably, both **6** and **7** exhibit an NBD/BL ratio of 1.21 and the latter has an Si···Si NBD of 2.06 Å, a distance well below the normal Si–Si BL. Even this unusual, predicated NBD conforms with the *approximate* homology rule.

The validity of the rule is not confined to the compounds of the above series I (Scheme 2) but also applies to those of three other series. Thus, a nearly constant NBD/BL ratio obtains for each of series II (cyclobutane[8a,9–13]), III (bicyclo[2.2.1]heptane[8b,14,15]), and IV (bicyclo[3.3.1]nonane.[8c,16] Of particular interest is **12** in series II. The finding that the Si···Si distance in this compound falls within the



Scheme 2. The ratio NBD/BL (NBD: distance between non-bonding Si atoms; BL: bond lengths Si–X) in bi- and monocycles, data in [Å]. The analogous carbacyclic systems are also shown for comparison. [a] NBD/BL from averaged distances.

normal Si–Si bond length has aroused much discussion as to the nature of the bonding between those Si atoms.[7, 9] The remarkable consistency observed for series II implies that: 1) the shortening of the Si···Si distance in **12** is due mainly to the short Si–O (1.66 Å) BL compared to other BD's in other compounds of this series and 2) the "effective" van der Waals radius of the Si atom along the direction toward the other Si atom is smaller than that normally estimated for this atom. This inference is admittedly simplistic, but the *approximate* homology rule appears to provide an instant, good estimate on the NBD of unknown silicon compounds.

[5] Crystals suitable for X-ray crystallography were obtained by recrystallization from EtOH. Monoclinic, $a = 32.228(13)$, $b = 16.373(6)$, $c = 20.689(5)$, $\beta = 114.49(2)$, $V = 9934$ Å^3, space group Cc, $Z = 8$, $\varrho_{calcd} = 1.00$ g/cm^3. The 5722 independent observed reflections [$2\theta \leq 126°$; $|F_o| > 3\sigma|F_o|$] were measured on a Rigaku four-circle diffractometer using $Cu_{K\alpha}$ radiation and ω-2θ scan. The structure was solved by direct methods and all non-hydrogen atoms were refined anisotropically to $R = 0.071$ ($w = 1.0$). Further details of the crystal structure investigation are available on request from the Director of the Cambrigde Crystallographic Data Centre, University Chemical Laboratory, Lensfied Road, Cambridge CB2 1EW (UK), on quoting the full journal citation.

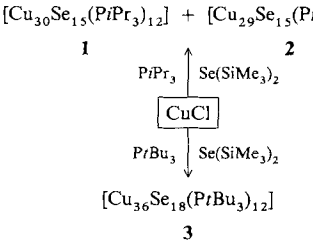
Synthesis and Structure of Novel Cu-Clusters: $[Cu_{30-x}Se_{15}(PiPr_3)_{12}]$ (x = 0,1) and $[Cu_{36}Se_{18}(PtBu_3)_{12}]$**

By *Dieter Fenske,* Harald Krautscheid,* and *Silke Balter*

Silyl derivatives of the elements P,As,S,Se and Te react with complexes of transition metal halides containing cyclopentadienyl, allyl or phosphane ligands to form cluster complexes. In our investigations to date we have found a large number of examples justifying this synthetic principle both in the case of electron-deficient (Ti,V) as well as in the case of electron-rich (Ni,Pd) transition metals.[1] We have also checked whether phosphane complexes of the elements Cu, Ag and Au react with $E(SiMe_3)_2$ (E = S,Se) to give metal-rich complexes.

When, for example, $[AgCl(PPh_3)_3]$ is allowed to react with $E(SiMe_3)_2$ in organic solvents, one observes the formation of binary sulfides and selenides of Ag. In contrast, in the analogous reaction of $[CuCl(PPh_3)]_4$, $[Cu_2Cl_2(PPh_3)_3]$, and $[CuCl(PPh_3)_3]$ with $Se(SiMe_3)_2$ in THF, deep-colored solutions are formed, from which black crystals precipitate; they are, however, X-ray amorphous. According to elemental analyses, the amorphous products are metal-rich compounds.

When carried out with ether as solvent, the reaction with CuCl, $PiPr_3$ and $Se(SiMe_3)_2$ now led to rapid formation of a dark colored solution, from which a mixture of **1** and **2** crystallized out within a few hours, whereas under the same conditions reaction of CuCl, $PtBu_3$ and $Se(SiMe_3)_2$ led to formation of **3**.[2]



Normally, microcrystalline products which are sparingly soluble in organic solvents are formed in these reactions. However, crystals suitable for a structure analysis are obtained if the reaction temperature is allowed to increase from -30 °C to room temperature over the course of several days. **1** and **2** form black (in thin layers brown) crystals, whereas crystals of **3** are brown. As expected, **1** and **3** are diamagnetic, whereas **2** is paramagnetic.

The IR spectra are not very informative, since they only contain characteristic vibrations for the $PiPr_3$ and $PtBu_3$ ligands. X-ray structure analyses were carried out, in order to clarify the molecular structures of **1**, **2**, and **3**.[3] It was found that the structures of **1** and **2** are almost identical. In contrast to **2**, **1** contains a further Cu atom in the center of the molecule. An exact determination of the structure, however, is rendered difficult by a disordering of the *i*Pr groups.

Like **1**, in the crystalline state **2** contains (Fig. 1) five parallel layers of Cu atoms and μ_4- to μ_7-bridging Se ligands;

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa AG.

consequently the Cu–Se bonds are of various lengths. In the case of the μ_4-Se ligands, Se4–Se6 and Se10–Se12, which bridge the Cu atoms of the 2nd and 3rd and 3rd and 4th layers, respectively, one finds in each case two short (**1**: 236–241(1); **2**: 236.3–238.8.8(6) pm and two longer Cu–Se bonds (**1**: 243–252(1); **2**: 244.4–249.8(6) pm).

The μ_5-Se ligands Se1–Se3 and Se13–Se15 bridge the Cu atoms of the 1st and 2nd and 4th and 5th layers, respectively. In each case there are three long bonds to the outer layers (**1**: 250–256(1); **2**: 247.7–256.1(6) pm) and two short bonds to the Cu atoms of the 2nd and 4th layers, respectively (**1**: 235–241(1); **2**: 238.7–241.0(6) pm).

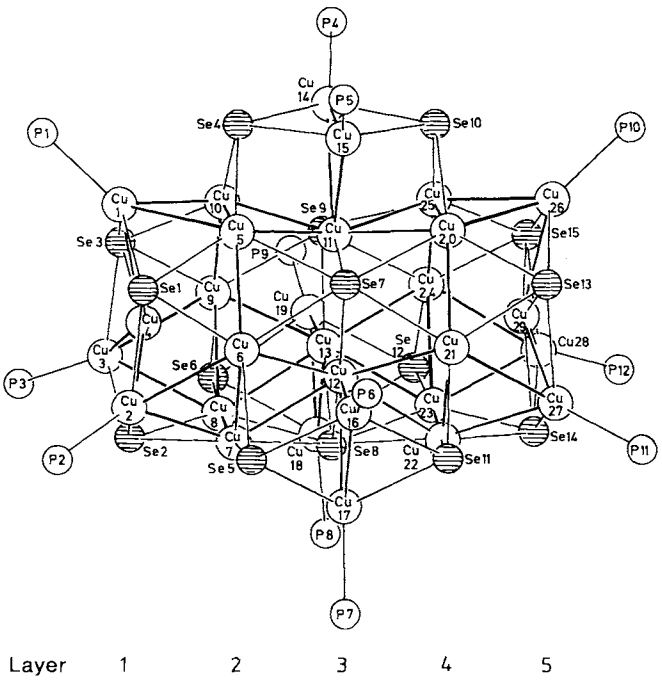

Fig. 1. Structure of **2** in the crystal (*i*Pr groups omitted, Cu–Cu distances up to 290 pm are shown). Important bond lengths [pm] and angles [°] (error ± 0.6 pm and ± 0.2°): 1st layer: Cu1-Cu4 260.6 Cu2-Se2 252.0 Se1-Cu4 247.7–252.3 Cu1-Se1-Cu2 122.1 Se1-Cu4-Se2 119.2 Se1-Cu4-Cu2 60.1. 2nd layer: Cu9-Cu10 255.5 Cu8-Cu9 267.1 Cu9-Se6 236.5 Cu5-Cu6-Cu7 120.0 Se5-Cu6-Cu5 175.4 Cu6-Se5-Cu7 68.4 3rd layer: Cu12-Se8 238.1 Cu12-Cu16 283.2 Cu16-Cu17 271.8. Se7-Cu12-Se8 161.1 Cu11-Se7-Cu12 82.2 Cu16-Cu12-Cu17 57.0 Cu12-Cu16-P6 153.7. Cu-P 223(1) pm. Cu-Cu (between layers): Cu1-Cu5 263.8 Cu2-Cu6 264.1 Cu3-Cu8 266.7 Cu5-Cu11 261.9 Cu9-Cu13 259.7.

The μ_6-Se ligands in **2** and μ_7-Se ligands in **1** (Se7–Se9) function as bridges between the inner layers, in each case with two short (**1**: 242–252(1); **2**: 235.5–240.0(7) pm) and four long Cu–Se distances (**1**: 252–261(1); **2**: 255.7–261.0(6) pm). Differently coordinated chalcogen ligands also occur in other compounds;[1, 4] overall, the Cu–Se bond lengths in **1** and **2** are comparable with those in binary copper selenides and in the few copper complexes with Se-ligands which have already been structurally characterized such as $[Cu_3Cl_4MoOSe_3]^{3\ominus}$, $[Cu_3ClMoSe_4(PPh_3)_3]$, and $[Cu_4(Se_4)_{2.4}(Se_5)_{0.6}]^{2\ominus}$.[5, 6]

The structures of the layers in **1** and **2** are shown in Figure 2. The 3rd layer is approximately a mirror plane, i.e. the 1st and 5th and 2nd and 4th layers are almost identical. **2** can accordingly be described as a sequence of Cu_3Se_3 six-membered rings (Fig. 2a), Cu_6Se_3 planes and Cu_9Se_3 planes (Fig. 2b, 2c). The deviations from the best fitting planes are never greater than 13 pm. In contrast the deviation of Cu4

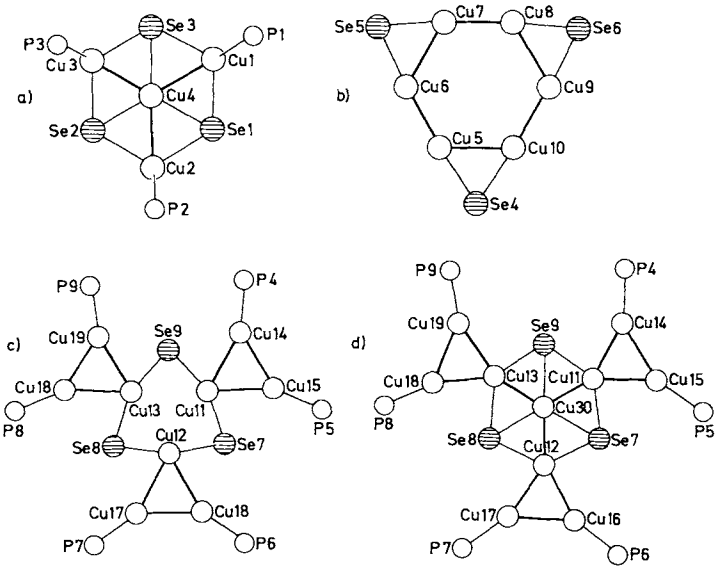

Fig. 2. Structures of the Cu,Se,P layers in **1** and **2**. a) 1st and 5th layers; respectively b) 2nd and 4 layers respectively; c) 3rd layer in **2**, d) 3rd layer in **1**.

and Cu29 from the plane of the Cu_3Se_3 rings is 41 pm in **2** and 50 pm in **1**. Of the 29 Cu atoms in **2** and 30 Cu atoms in **1**, 12 Cu atoms of the cluster periphery are in each case bound to $PiPr_3$ groups.

Unlike **2**, **1** contains a further Cu atom (Cu30) in the cluster center (Fig. 2d), and as a result the Cu-Cu contacts in the central Cu_3Se_3 ring (Cu11–C13, Se7–Se9) are noticeably expanded. In **2** they are 310–322 (0.6) pm and in **1** 402–414(1) pm,[7] while the distances between Cu30 and Cu11–Cu13 (238–244(1) pm) are remarkably short. Although Se and Cu are not clearly distinguishable by means of X-ray diffraction, we are certain that the atom in the cluster center of **1** is a Cu atom, as indicated by elemental analysis and diamagnetic behavior. The structures of **1** and **2** consist of a cluster core of 24 and 23 Cu atoms, respectively. In addition, Cu pairs (Cu14, Cu15; Cu16, Cu17; Cu18, Cu19) are bound via Se bridges to this core. The distances of these Cu pairs from the core are 252–260(1) pm (**1**) and 271.4–284.4(5) pm (**2**). All other Cu–Cu contacts lie in the range of distances that has already been found in metallic copper (256 pm) and in copper selenides.[5]

Figure 3 shows the crystal structure of **3**. The complex **3** contains a twofold axis and consists of a cluster of 36 Cu atoms having no structural relationship with **1** or **2**.

As in **1** and **2**, μ_3- (Se7), μ_4- (Se1,Se9), μ_5- (Se2–Se6,Se8) and a μ_6-Se ligands (Se10) are also found in **3**. The Cu–Se distances lie in a similar range to those in **1** and **2** (Cu–(μ_3-Se): 237.5(6); Cu–(μ_4-Se): 235.8–245.3(6); Cu–(μ_5-Se): 240.0–261.3(6) pm). The μ_3-, μ_4- and μ_5-Se ligands cover the surface of the Cu cluster. In contrast, Se10 resides in the cluster center and is surrounded by six Cu atoms and is trigonal-prismatically coordinated (Cu–Se: 243.2(6) pm). Alternatively, the central unit of the cluster can be described as two Cu_6Se_2 cubes bridged by Se10 (Fig. 4).

As shown in Figure 3 this structural unit (Cu atoms dotted) is bound by twelve Cu atoms (striped: Cu5–Cu8, Cu5′–Cu8′, Cu14, C15, C14′, C15′) which are coupled via the μ_5-Se ligands with three Cu_4 units (checkered: Cu1–Cu4, Cu1–Cu4′, Cu16, Cu17, Cu16′, Cu17′). The twelve phosphane ligands are bound to Cu atoms of the cluster periphery and effect complete shielding of the $C_{36}Se_{18}$ cluster. The Cu atoms bound to P (Cu1, Cu4, Cu6, Cu7, Cu15, Cu16) are all

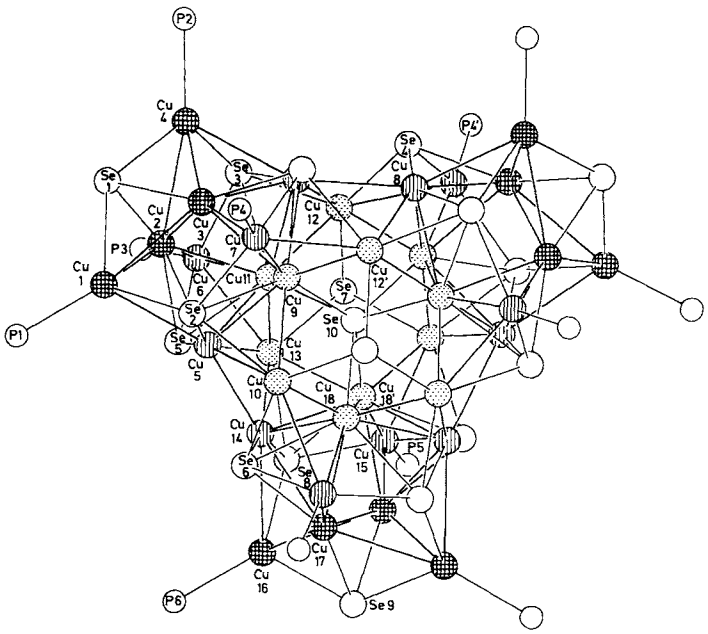

Fig. 3. Structure of **3** in the crystal (*t*Bu groups omitted, Cu–Cu distances up to 290 pm shown). Important bond lengths [pm] and angles [°] (error ± 0.5 pm and ± 0.2°): Cu1-Cu2 266.4 Cu1-Cu3 288.9 Cu1-Cu5 282.9 Cu2-Cu3 269.1 Cu2-Cu4 286.7 Cu2-Cu5 280.2 Cu2-Cu6 273.3 Cu6-Cu11 264.1 Cu6-Cu13 271.6 Cu9-Cu10 262.2 Cu9-Cu11 281.5 Cu9-Cu12 250.3 Cu9-Cu3 257.5 Cu9-Cu5 252.3 Cu9-Cu7 264.5 Cu9-Cu8 275.6 Cu10-Cu15 271.8 Cu10-Cu18 250.8 Cu10-Cu9 262.2 Cu9-Cu5 266.4 Cu-P 226–230(1) Cu9-Cu10 244.5 Cu11-Se10 243.0 Cu18-Se10 242.4 Cu-Se7-Cu 99.4-100.8 Cu-(μ_4-Se)-Cu 67.1–73.8, 130.9–131.6 Cu-(μ_5-Se)-Cu 57.3–69.8, 82.1–89.3, 106.1–137.7 Cu18-Se10-Cu9' 142.5 Cu18-Se10-Cu9 91.2 Cu11-Se10-Cu9 91.1 Cu18-Se10-Cu11 90.8.

bound to two Se atoms and three Cu atoms (Cu–Cu: 264–287(1) pm).

In contrast, higher coordination numbers are found for other Cu atoms (Cu2, Cu3, Cu5, Cu8: 2 Se and 6 Cu, Cu–Cu: 252.3–288.9(5) pm; Cu9, Cu11, Cu18: 3 Se and 7 Cu, Cu–Cu: 250.2–281.5(5) pm; Cu10, Cu12, Cu13: 3 Se and 4 Cu, Cu–Cu: 250.2–278.1(6) pm).

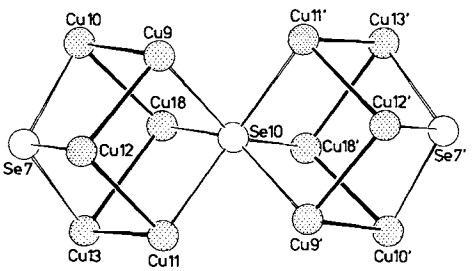

Fig. 4. Central $Cu_{12}Se_3$ unit in **3**.

The shortest Cu–Cu distances are observed in the central $Cu_{12}Se_3$ skeleton. They are comparable with those that have been found in other multinuclear Cu-complexes, for example in [Cu(tolyl)NNNNN(toly)]$_3$ (235 pm), [CuMes]$_5$ (245 pm), [Me_3SiCH_2Cu]$_4$ (242 pm), $[Cu_3I_7]^{2\ominus}$ (258 pm), $[Cu_6(S_4)_3S_5]^{2\ominus}$ (270 pm), $[Cu_{12}S_8]^{4\ominus}$ (277–295 pm), $[Cu_4(SPh)_6]^{2\ominus}$ (275 pm), [$Cu(SC_6H_4SiMe_3)$]$_{12}$ (274–317 pm).[8]

If one assumes that $Se^{2\ominus}$ ligands are present, then the clusters in **1**, **2** and **3** have the formal charge $Cu_{30}^{30\oplus}$, $Cu_{29}^{30\oplus}$ and $Cu_{36}^{36\oplus}$.[7] Accordingly, the clusters in **1** and **3** should contain copper in the formal oxidation state + 1 (d^{10} configuration). Although the contribution of d^{10}–d^{10} interactions to the metal–metal bonding is controversial, examples are known which show that this can be significant.[9] The Cu–Cu distances found in **1**, **2**, and **3**, however, clearly indicate only weak interactions.

The formation of these large clusters is surprising; however, so far we have not found any evidence of the formation of smaller multinuclear complexes. Examples of metal clusters of similar size are known for other transition elements. Examples include compounds such as: $[Au_{18}Ag_{19}Br_{11}(P\text{-}p\text{-}Tol_3)_{12}]^{2\oplus}$, $[Ni_{38}Pt_6(CO)_{48}H_{6-n}]^{n\ominus}$, $[Pd_{38}(CO)_{28}(PEt_3)_{12}]$, and $[Au_{55}(PPh_3)_{12}Cl_6]$.[10]

Steigerwald et al. recently reported on the reaction of [$(COD)_2$Ni] with Et_3PTe.[11] Depending on the reaction conditions $[Ni_9Te_6(PEt_3)_8]$ and $[Ni_{20}Te_{18}(PEt_3)_{12}]$ or $NiTe_x$ is formed. Consistent with this observation we find that **1**–**3** are formed in good yields (60%) at temperatures below 20 °C. In contrast, a binary copper selenide of unknown structure is formed at temperatures above 100 °C.

[2] Procedures: **1** and **2**: 0.4 g (4 mmol) of CuCl was suspended in 50 mL of ether. On addition of 1.5 mL (8 mmol) of P*i*Pr$_3$ the CuCl dissolved. Upon subsequent treatment with 0.5 mL (2 mmol) of Se(SiMe$_3$)$_2$ the solution turned dark brown, and within 2 d a mixture of **1** and **2** precipitated in the form of black crystals. These could be separated from each other by virtue of their different habits (yield 60%).
3: A suspension of CuCl (0.4 g, 4 mmol) in THF (50 mL) was treated with 1 mL (4 mmol) of P*t*Bu$_3$. After addition of 0.5 mL (2 mmol) of Se(SiMe$_3$)$_2$ at − 30 °C, the mixture was allowed to warm to room temperature over the course of several days. Brown crystals of **3** precipitated from the brown solution (yield 30%).

[3] X-ray structure analyses: Stoe Stadi IV, $Mo_{K\alpha}$, empirical absorption correction; data collection and refinement: ω scan; Cu, Se, P anisotropic, C isotropic. **1** (from diethyl ether): lattice constants (200 K): a = 1998.6(8), b = 1898.2(7), c = 2367.7(10) pm, α = 89.80(3), β = 93.86(4), γ = 92.05(4)°, $V = 8956 \times 10^6$ pm^3; space group, $P\bar{1}$, Z = 2, $\mu(Mo_{K\alpha})$ = 64.9 cm^{-1}. Profile analysis, $2\theta_{max}$ = 45°, 25400 reflections, 10895 with $I > 2\sigma(I)$, 854 parameters, R_1 = 0.12; R_2 = 0.10. The poor R value arises as the result of a disorder of the *i*Pr groups. **2** (from diethyl ether): lattice constants (190 K): a = 2396.6(13), b = 2624.9(12), c = 2831.4(12), β = 91.80(4), $V = 17804 \times 10^6$ pm^3. Space group $P2_1/c$, Z = 4, $\mu(Mo_{K\alpha})$ = 65.2 cm^{-1}. Profile analysis, $2\theta_{max}$ = 45°, 23251 reflections, 11875 with $I > 2\sigma(I)$, 937 parameters, R_1 = 0.081, R_2 = 0.073. **3** (from THF): **3** crystallizes with six molecules THF/formula unit. Lattice constants (200 K): a = 2117.4(12), b = 3593.2(13), c = 3059.2(6) pm, β = 89.22(2)°, $V = 23273 \times 10^6$ pm^3. Space group $C2/c$, Z = 4, $\mu(Mo_{K\alpha})$ = 59.7 cm^{-1}. Profile analysis, $2\theta_{max}$ = 48°, 19243 reflections, 11430 with $I > 2\sigma(I)$, 631 parameters, R_1 = 0.063, R_2 = 0.060. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54560, the names of the authors, and the journal citation.

[7] The refinement of the structure of **2** yielded a residual electron density of 6–8 electrons in the cluster center. We cannot as yet make any statements about the nature of the atom that has been encapsulated.

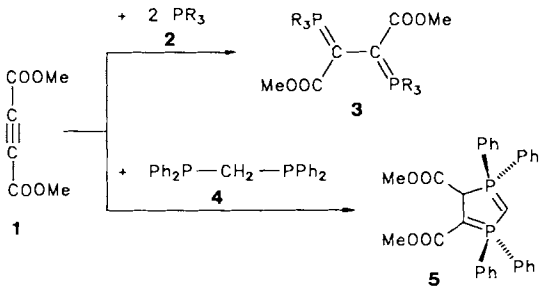
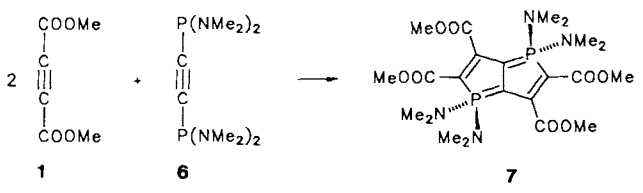
Synthesis and Structure of a $1\lambda^5,4\lambda^5$-Diphosphapentalene

By *Jürgen Silberzahn, Hans Pritzkow*, and *Hans Peter Latscha**

Molecules containing activated C-C multiple bonds react with trivalent phosphorus compounds with formation of P-C double bonds to give phosphoranes. Thus, alkynes such as dimethyl acetylenedicarboxylate **1** react with tertiary phosphanes **2** in the molecular ratio 1:2 to give stable 1,2-bis(triorganophosphoranylidene)alkanes such as **3**. Reaction with diphosphanoalkanes **4** leads to cyclic diphosphoranes **5**.[1]



We now wish to report the isolation of brilliant orange-red crystals of $1\lambda^5,4\lambda^5$-diphosphapentalene **7** upon reaction of **1** with acetylenebis(phosphonousbis(dimethylamide)) **6** in the ratio 2:1.[2]



[*] Prof. Dr. H. P. Latscha, Dipl.-Chem. J. Silberzahn, Dr. H. Pritzkow
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

Compound **7**, the first analogue of pentalene with a phosphorus atom in each ring, has a high melting point (194 °C) and is stable towards air and hydrolysis. Its extraordinary stability compared to that of carbocyclic pentalenes[3] leads to the molecular peak (*m/z* 546) in the mass spectrum being simultaneously the base peak. The stability is apparently due to the formation of ylidic structures. Figure 1 shows the crystal structure[4] of the planar ring system with a symmetry center on the C1–C1′ axis.

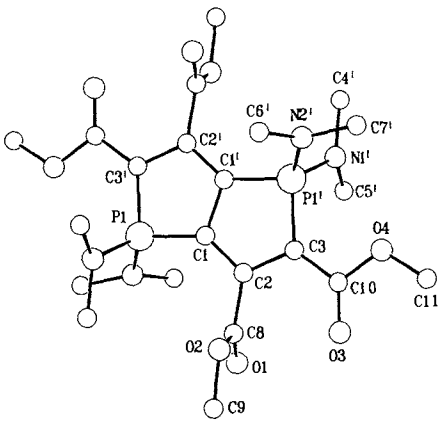


Fig. 1. Structure of **7** in the crystal. Important bond lengths [Å] and angles [°]: C1-C2 1.379(2), C2-C3 1.423(2), C3-P1′ 1.759(1), P1′-C1′ 1.758(1), C1′-C1 1.466; C1-C2-C3 115.1(1), C2-C3-P1′ 109.4(1), C3-P1′-C1′ 93.5(1), P1-C1-C1′ 108.7(1), C1′-C1-C2 111.8(1).

Cyclovoltammetric measurements indicate that the 8π-electron system of **7** can be both oxidized to the 6π-electron system as well as reduced to the 10π-electron system, in each case in two reversible steps.

Experimental

A solution of **1** (5.8 g, 41 mmol) in benzene (25 mL) was treated dropwise at 10 °C with a solution of **6** (5.3 g, 20.3 mmol) in benzene (25 mL). The resulting dark orange-brown reaction mixture was then heated under reflux for 1h. The reaction product **7**, which precipitated upon cooling the mixture, was filtered off and recrystallized from benzene or ethyl acetate (brilliant orange-red crystals). Yield: 7.9 g (71 %); Fp = 194 °C; ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.52, 3.48, 3.71; ^{13}C NMR (50 MHz, $CDCl_3$): δ = 36.7, 49.9, 51.9, 74.6, 96.2, 144.6, 164.8, 168.3; ^{31}P NMR (80 MHz, $CDCl_3$): δ = 51.7; MS: *m/z* 546 ($M^{\oplus}$); correct elemental analysis (C,H,N,P).

$Na_{10}\{Li_2[MnO_4]_4\}$, a Compound in Which LiO_4 and MnO_4 Tetrahedra Form Chains Consisting of Six- and Eight-Membered Rings**

By *Dieter Fischer* and *Rudolf Hoppe**

Little is known about the structure of oxides of the type $A_3[MO_4]$ with A = K, Rb, Cs and M = P^V, As^V, V^V, Cr^V, Mn^V. In all single crystals so far obtained, the $[MO_4]$ structural unit exhibits disorder. This situation abruptly changes when derivatives such as $K_2\{Li[VO_4]\}$[1] and $Cs_2\{Li[VO_4]\}$[2] are synthesized. In these "lithovanadates", the linkage of $[MO_4]$ and $[LiO_4]$ groups ensures an ordered structure. An especially important example of this kind is $K_{11}\{Li[OMnO_3]_4\}$,[3] which contains an anion not found so far for pentaphosphates, for example. Upon attempting to prepare $Na_2\{Li[MnO_4]\}$,[4] we surprisingly obtained $Na_{10}\{Li_2[MnO_4]_4\}$, which has an unexpected structure.

The structure determination[5] afforded the motifs of mutual adjunction[7] and distances given in Table 1. Included are the "naive" coordination numbers (C. N.) and the effective coordination numbers (ECoN).[7-9]

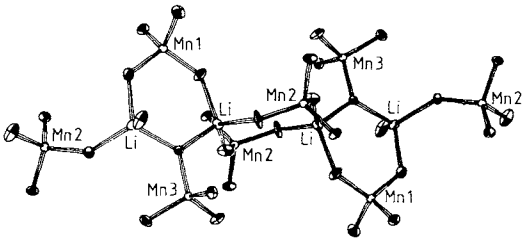

Fig. 1. Section of the Li-Mn-O chains along [010] in $Na_{10}\{Li_2[MnO_4]_4\}$; the oxygen atoms are drawn as thermal ellipsoids (ORTEP at 50% probability).

consist of alternating six- and eight-membered rings. The eight-membered rings, $\{Li[O_{1/2}Mn(O_{2/1})O_{1/2}]_2Li\}$, lie roughly parallel to (001). The six-membered rings, $\{Li[O_{1/2}Mn(O_{2/1})O_{1/2}][O_{1/2}(MnO_{3/1})]Li\}$, are oriented parallel to (100). The chains are linked through Na^+ ions.

The structure of the chainlike anion $\{Li_2[MnO_4]_4\}^{10-}$, formed from two kinds of rings, is even more bizarre than

Table 1. $Na_{10}\{Li_2[MnO_4]_4\}$: motifs of mutual adjunction, distances [pm], naive coordination numbers (C. N.), and effective coordination numbers (ECoN).

[a] Cations/ΣO. [b] O/Σ cations. [c] Starting values for the ionic radii: ionic radii with $r(O^{2\ominus})$ = 140 pm were derived from the averaged distances weighted according to the ECoN concept.

Primary structure: Lithium and manganese are surrounded in a tetrahedral fashion by O (distances: Li-O, 191.0–195.6 pm; Mn-O, 168.4–172.2 pm). The coordination spheres of the Na^+ ions are irregular; the naive coordination numbers are 5–7.

Secondary and tertiary structure: The structure is characterized by unusual chains along [010] (Fig. 1). The chains

those of the many other intriguing anions we have so far obtained during the synthesis of new oxides of alkali metals.

We have found mono- and multinuclear anions such as those in $K_2[O\text{-}Ni\text{-}O]$[10] (analogous to XeF_2[11]), in $K_4[ZnO_3]$,[12] and in $Na_4[FeO_3]$,[13] with structural units analogous to $CO_3^{2\ominus}$. Furthermore, we have found compounds containing two-tetrahedra units, for example, $K_6[O_2FeO_2FeO_2]$,[14] three-octahedra units, for example, $K_2Li_{14}[M_3O_{14}]$ with M = Pb,[15] Zr,[16] Tb,[17] and four-triangle units ($Na_{10}[Co_4O_9]$).[18] Ring-shaped anions are present in oxides such as $K_4[Cu_4O_4]$, $Na_4[Ag_4O_4]$,[19] and $Cs_4[Au_4O_4]$,[20] zigzag chains in $Cs[CuO_{2/2}]$,[21] "Zweier-Einfach-Tetraederketten", for example in $K_2Na_4[(FeO_3)_2]$,[22] "Vierer-Einfachketten" of this kind in

$Cs_2Na_{10}[(GaO_3)_4]$,[23] and mixed chains consisting of tetrahedra and squares in $Rb_5[O_{2/2}SiO_2LiO_2SiO_2NiO_{2/2}]$.[24] A unique kind of chain is present in $K_4Be_3O_5$, in which planar triple coordination and tetrahedral coordination alternate according to the formula $^1_\infty[O_{4/2}Be^{[3]}OBe^{[3]}O_{4/2}Be^{[3]}]$;[25] that is, the "butterfly motif" of oxides such as $K_2Na_4[O_2MOMO_2]$ with M = Be,[26] Co,[27] and Fe[28] (in $Cs_2K_4[Fe_2O_5]$) is combined with BeO_4 tetrahedra. In addition, there are layer structures ($Na_4[Fe_2O_5]$[29]) and framework structures such as $KGaO_2$.[23]

However, chains consisting of rings are rare for such oxides. So far, we have found only one other example, $Na_{14}[Fe_6O_{16}]$, in which twelve- and eight-membered rings made up of Fe and O alternate.[30] $\{Li_2[MnO_4]_4\}^{10-}$, consisting of alternating cyclohexane- and cyclooctane-like rings, is much more complicated, since $[MnO_4]^{3-}$ groups are involved in the structure.

The Madelung Part of Lattice Energy (MAPLE)[31] was calculated and a value of MAPLE(Mn_2O_5) = 9694 kcal mol^{-1} was obtained. This value is in good agreement (−0.2%) with the MAPLE values for Mn_2O_5 from the $K_{11}\{Li[OMnO_3]_4\}$ structure determination[3] and for V_2O_5 from the orthovanadates(v) (A_2LiVO_4 with A = K, Rb, Cs[1,2] and $Rb_4V_2O_7$[32]).

[4] The preparation was carried out by annealing thoroughly mixed amounts of Na_2O_2 and $LiMnO_4$ (Na:Mn = 2.8:1) in Ag bombs (580 °C, 30 d). Both the starting materials and the product were handled under dry argon.
[5] Crystal data: $Na_{10}\{Li_2[MnO_4]_4\}$ crystallizes orthorhombically, space group *Pnma* (No. 62) with $a = 1048.1(7)$, $b = 1518.4(9)$, $c = 1044.4(6)$ pm (diffractometer data), $Z = 16$, $\mu(Mo_{K\alpha}) = 31.4\ cm^{-1}$. 2469 unique reflections ($3° \le \Theta \le 30°$) were measured (Siemens AED 2 four-circle diffractometer with $Mo_{K\alpha}$ radiation, graphite monochromator); absorption correction. The structure was solved by the use of direct methods in conjunction with difference Fourier syntheses (SHELX-76 and -86)[6]. The subsequent refinement of the parameters, carried out with "anisotropic" temperature factors (least-squares method), gave $R = 8.6\%$, $R_w = 3.6\%$ ($w = 0.5451\ \sigma^{-2}(F_o)$ for 2450 reflections; goodness of fit = $[\Sigma w(F_o - F_c)^2/(N_{observns} - N_{parameters})]^{1/2} = 1.138$. Highly Selective Synthesis of (*E*)-Alkene Isosteric Dipeptides With High Optical Purity via $RCu(CN)Li \cdot BF_3$ Mediated Reaction**

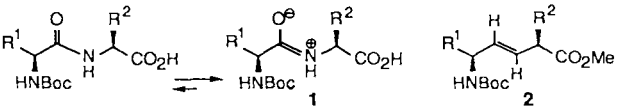
By *Toshiro Ibuka,* Hiromu Habashita, Susumu Funakoshi, Nobutaka Fujii,* Yusaku Oguchi, Tadao Uyehara,* and *Yoshinori Yamamoto**

The concept of replacing the scissile C-N unit of a peptide bond in enzyme substrates by suitable isosteric units that could provide potential protease inhibitors has drawn a lot of attention in recent years.[1] Thus, it has been suggested that replacement of the amide bond (-CO-NH-) of a peptide **1** by an (*E*)-double bond might provide "(*E*)-CH=CH isosteres" **2** possessing high lipophilicity as well as enhanced resistance to biodegradation.[2]



The (*E*)-CH=CH- bonding in **2** closely resembles the three-dimensional shape (rigidity, bond angle, and bond length) of the parent amide **1**.[3] Except in a few cases,[4] however, published synthetic routes to such peptide mimics give unsatisfactory results with regard to double bond geometry and/or stereochemistry at the α-position.[5] For example, the reaction of α,β-unsaturated esters with lithium diisopropylamide (LDA) followed by alkyl halides gave, as one might expect, both α-alkylation isomers and a dialkylated by-product.[6] Clearly, development of an efficient synthetic route to compounds of type **2** would be extremely valuable.

We now report another solution, based on the 1,3-chirality transfer reaction of γ-mesyloxy-α,β-enoates, to the problem of controlling the double bond geometry at the β,γ-position and the stereochemistry of the chiral carbon center at the α-position. The requisite γ-mesyloxy-(*E*)-α,β-enoates (**3**, **5**,

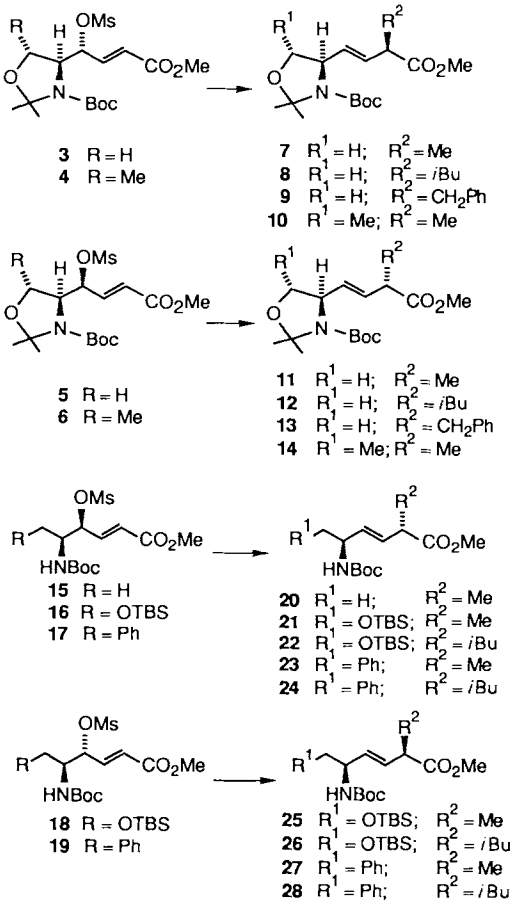
[**] We thank Dr. G. J. Hanson, Department of Medicinal Chemistry, G. D. Searle & Co., Skokie, Ill, USA., for sending us the ^{1}H-NMR spectra of authentic *tert*-butyl *N*-[(1*S*, 2*S*)-1-benzyl-2-hydroxy-3-butenylcarbonate and its (1*S*, 2*R*)-isomer. We also thank Dr. *P. Herold*, Ciba-Geigy AG, Zentrale Forschungslaboratorien, Basel, Switzerland, for providing us with the ^{1}H-NMR spectra of authentic *tert*-butyl (4*S*, 1′*S*)-4-(1-hydroxy-2-propenyl-2,2-dimethyl-1,3-oxazolidine-3-carboxylate and its isomer. This work was supported by the Sound Technology Promotion Foundation.

16, and **18**), (**4** and **6**), (**15**), and (**17** and **19**) for the present isosteric dipeptide synthesis were readily prepared in acceptable yields from (*S*)-serine, (*S*)-threonine, (*S*)-alanine, and (*S*)-phenylalanine, respectively, according to the usual method.[7] Reaction of the mesylate (**3**) with $MeCu(CN)Li \cdot BF_3$ (LiBr) in THF/Et_2O (ca. 15/1), iso-$BuCu(CN)Li \cdot BF_3$ in THF, and $PhCH_2Cu(CN)Li \cdot BF_3$ in THF/cyclohexane (ca. 5/1) at −78 °C for 30 min gave the regio-, (*E*)-stereo-, and diastereoselective 1,3-chirality transfer products **7** (98% yield), **8** (97% yield), and **9** (97% yield), respectively, after flash chromatography over silica gel (Table 1, entries 1, 2, and 3). In a similar manner, other substrates **4**–**6** and **15**–**19**) gave the desired products in acceptable chemical and optical yields by treatment with organocyanocopper as shown in



Scheme 1. Abbreviations: OMs = methanesulfonyloxy; OTBS = *tert*-butyldimethylsilyloxy; Boc = *tert*-butoxycarbonyl.

Scheme 1 and Table 1. The diastereoselectivities shown in Table 1 were determined by ^1H NMR in $CDCl_3$ for isolated compounds; >99:1 indicates that the other diastereomer was not detectable. Additionally, in some cases (Table 1, entries 1, 4, 11, 14), diastereoselectivities were determined by capillary gas-chromatography (50 m × 0.2 mm).

To achieve very high chemical and optical yields, it should be noted that a γ-mesyloxy group in the substrate, organocyanocopper · BF_3 reagent, and THF or a mixed solvent involving THF are essential.[8] Addition of $BF_3 \cdot Et_2O$ is essential for the clean 1,3-chirality transfer.[8] The reactions with organocyanocopper · BF_3 reagents in a solvent involving THF were very fast at −78 °C and went to completion within a few minutes, although the reaction mixture was stirred for 30 min. Furthermore, the geometry of the β,γ-double bond of the products (**7**–**14** and **20**–**28**) is exclusively the desired geometry (*E*) and the diastereoselectivity is in the range of 97:3 to >99:1—except in the case of entries 4, 7, and 8. The presence of an HNBoc group at the δ-position in the substrates (**15**–**19**) does not exert any influence on the course of the *anti*-S_N2' reaction.

Table 1. Synthesis of protected (*E*)-CH = CH isosteres by reaction of δ-*N*-Boc-amino-γ-mesyloxy-(*E*)-α,β-enoates with organocyanocopper-boron trifluoride reagents.[a]

Entry	Substrate	Reagent[b]	Product	Isolated yield [%] (Diastereoselectivity at C-2)[c]
1	**3**	$MeCu(CN)Li \cdot BF_3(LiBr)$	**7**	98% (>99:1)
2	**3**	iso-$BuCu(CN)Li \cdot BF_3$	**8**	97% (>99:1)
3	**3**	$PhCH_2Cu(CN)Li \cdot BF_3$	**9**	97% (>99:1)

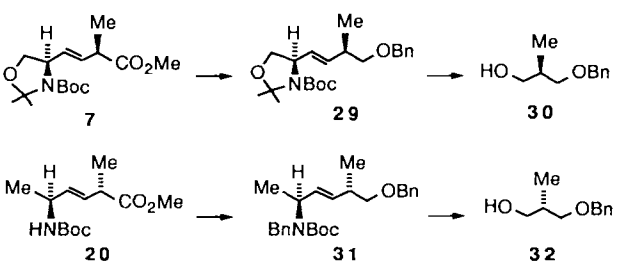
16	**19**	$MeCu(CN)Li \cdot BF_3(LiBr)$	**27**	98% (>99:1)
17	**19**	iso-$BuCu(CN)Li \cdot BF_3$	**28**	96% (>99:1)

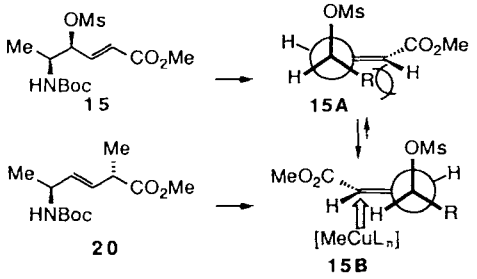
[a] All reactions were carried out at −78 °C for 30 min with 3–4 molar equiv. of reagents. [b] The notation $MeCu(CN)Li \cdot BF_3(LiBr)$ is intended to indicate that the reagent has been prepared from ethereal MeLi as the LiBr complex (see, Ref. [8c] and [8d]). Substrates **4** and **6** gave comparable results on treatment with $MeCu(CN)Li \cdot BF_3(LiI)$ as for the entries 4 and 8. [c] All the new compounds have been fully characterized spectrally [IR($CHCl_3$), ^1H-NMR ($CDCl_3$) and CD (isooctane)] and their elemental compositions have been determined by high-resolution mass spectroscopy and/or combustion analysis. Diastereoselectivities were determined by ^1H NMR (200, 270, 300, and/or 400 MHz).

The absolute configuration of the alkyl-bearing carbon center, although apparent from the reaction course of the *anti*-S_N2' attack of the organocopper reagents[8–10, 11a, b] and from the *E*-geometry of the β,γ-double bond of the products, could be established by chemical degradation. For example, ozonolysis of benzyl ether **29** and **31**, derived from **7** and **20** by a two-step reaction (1. diisobutylaluminum hydride, room temperature (DIBAL) in CH_2Cl_2, −78 °C; 2. NaH/BnBr in DMF, 0 °C ~ room temperature), followed by reduction with DIBAL, gave the known alcohols **30**,



$[\alpha]_D^{22} = +17.2$ ($CHCl_3$), and **32**, $[\alpha]_D^{20} = -17.2°$ ($CHCl_3$). The optical rotations of **30** and **32** exactly match the reported values.[8d, 8e, 11]

Although all of the controlling factors in the present organocyanocopper·BF_3-mediated reaction of δ-*tert*-butoxycarbonylamino-γ-mesyloxy-α,β-enoates are not clear, the following explanation concerning the *anti*-S_N2' reaction could be drawn. Conformer **15A**, which would lead to the (*Z*)-olefin, would be destabilized in comparison with **15B** owing to unfavorable interaction between the bulky R group and the hydrogen. Consequently, elimination of the leaving group (OMs group) will take place only when the attacking copper reagent and the leaving group are in a mutual antiperiplanar disposition.



It is apparent from these preliminary data that by judicious selection of organocopper-Lewis acid reagents, the described method offers facile entry to stereochemically pure isosteric dipeptides.

Experimental

Synthesis of (*E*)-CH=CH isosteric dipeptides, for example **23**: To a stirred slurry of CuCN (72 mg, 0.8 mmol) in 5 mL of dry THF at −78 °C was added by syringe 0.533 mL (0.8 mmol) of 1.5 M MeLi/LiBr in Et_2O; the mixture was allowed to warm to −20 °C and was stirred at this temperature for 10 min. $BF_3 \cdot Et_2O$ (0.1 mL, 0.8 mmol) was added to the above mixture at −78 °C and the mixture was stirred for 5 min. A solution of γ-mesyloxy-α,β-enoate (**17**)(85 mg, 0.2 mmol) in dry THF (4 mL) was added dropwise to the above reagent at −78 °C with stirring, and stirring was continued for 30 min followed by quenching with 3 mL of a 2:1 saturated NH_4Cl–28% NH_4OH solution. The mixture was then extracted with Et_2O and the extract was washed successively with 5% citric acid, 5% $NaHCO_3$, and water, and dried over $MgSO_4$. Concentration under reduced pressure gave a crystalline residue, which was purified by flash chromatography over silica gel (*n*-hexane/EtOAc (4/1)) followed by recrystallization from *n*-hexane/Et_2O (4/1) gave the title compound **23** (66 mg, 96% yield) as colorless crystals.—m.p. 74 °C; $[\alpha]_D^{20} = +36.36$ ($c = 0.902$, $CHCl_3$); IR ($CHCl_3$) cm^{-1} = 3460, 3010, 2960, 1727 (shoulder), 1713, 1498, 1459, 1440, 1372, 1174, 974; ^{1}H-NMR (300 MHz, $CDCl_3$): $\delta = 1.19$ (d, $J = 7.08$ Hz, 3H), 1.40 (s, 9H), 1.63 (broad s, 1H), 2.75–2.89 (m, 2H), 3.11 (m, 1H), 3.66 (s, 3H), 4.30–4.50 (m, 2H), 5.49 (dd, $J = 15.22$, 4.42 Hz, 1H), 5.57 (dd, $J = 15.22$, 6.83 Hz, 1H), 7.14–7.30 (m, 5H); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 17.21$, 28.35, 41.76, 42.45, 51.85, 126.46, 128.28, 129.55, 129.66, 131.43, 137.34, 155.11, 174.89. Satisfactory elemental analysis (C, H, N).

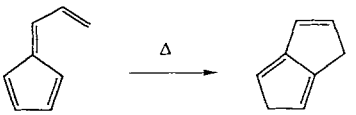
Gas-Phase Thermolysis of 6-Cyclopropyl- and 6-Oxiranylpentafulvenes: Novel Routes to Dihydroindenes and Vinylcyclopentadienes**

By *Axel G. Griesbeck,* Karl Peters, Eva-Maria Peters,* and *Hans Georg von Schnering*

The electrocyclic ring closure of 6-vinylpentafulvenes **1**[1] via gas-phase thermolysis is an efficient and flexible route to 1,5-dihydropentalenes **2**.[2] We have now investigated the $[\pi^6 + \sigma^2]$ variant, which should open up a route to the homologous dihydroindenes and oxa analogues thereof.



1 2

Both series of compounds are of importance for the synthesis of terpenoid natural products.[3] The employment of 6-oxiranylfulvenes in the synthesis of natural products has already been reported: *Fallis* et al.[4] were able to prepare a

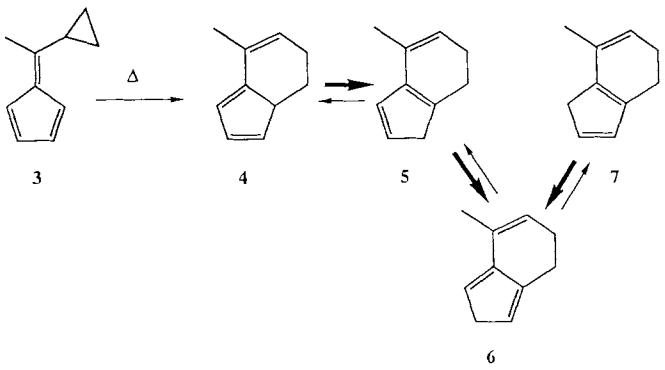
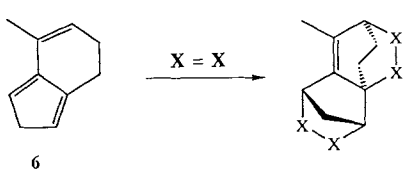
series of spiroannelated cyclopentadienes by reaction of these compounds with alkyllithium. Gas-phase thermolysis with 6-oxiranyl- and 6-cyclopropylpentafulvenes, on the other hand, were not investigated.

6-Cyclopropyl-6-methylpentafulvene **3**[5] is accessible in good yields by a standard method.[6] Upon gas-phase thermolysis (580–620 °C/0.08 torr, unpacked quartz tube, 30-cm thermolysis zone) a mixture of three isomeric dihydroindenes is formed in a total yield of 90–94%. **6** is formed as main component (62%) together with the isomers **7** (ca. 20%) and **5** (ca. 10%).[7]

It cannot be ruled out that this reaction proceeds via a corresponding spiro [4.4]nonatriene[8] as a primary product (as a result of a vinylcyclopropane-cyclopentene rearrangement). However, no intermediate product was observed even at significantly lower thermolysis temperatures (520–550 °C, ca. 20% conversion), i.e. the opening of the cyclopropane ring could lead directly to the indene derivative **4**, which then spontaneously undergoes 1,5-hydrogen shifts with formation of **5**–**7**. When this mixture of isomers was allowed to react with dienophiles such as tetracyanoethylene (TCNE), 4-methyl-1,2,4-triazole-3,5(4*H*)-dione (MTAD) and benzoquinone (BQ) only a 2:1 adduct of the dienophile and isomer **6** could be isolated in each case. The crystal structure analysis[9] of the MTAD adduct **9**[10] confirmed the *anti* arrangement of the two triazolidine rings (Fig. 1).



This high stereoselectivity upon attack of the second dienophile can doubtles be attributed to the shielding effect of the first triazolidine ring[11] and shows that the primary adduct of **6** and the first MTAD molecule has to be regarded as a norbornene derivative (which are usually attacked *exo*-selectively[12]) rather than as an isodicyclopentadiene derivative (which exhibit opposite activity[12]). The NMR data of the compound **9** are analogous to those of the adducts **8** and **10**, thus suggesting the same stereochemistry for these derivatives. In the adduct **10** the benzoquinone rings can be arranged *exo* as well as *endo* to the norbornane skeleton. The attack of the first benzoquinone molecule results in formation of the *endo* primary adduct, which in a subsequent step adds a second dienophile *anti* and *exo* to the newly formed diene system. No photocycloaddition (which is to be expected in the case of the *endo,endo* isomer) could be observed upon irradiation of **10**.



X=X :
TCNE **8** (52%)
MTAD **9** (58%)
BQ **10** (62%)

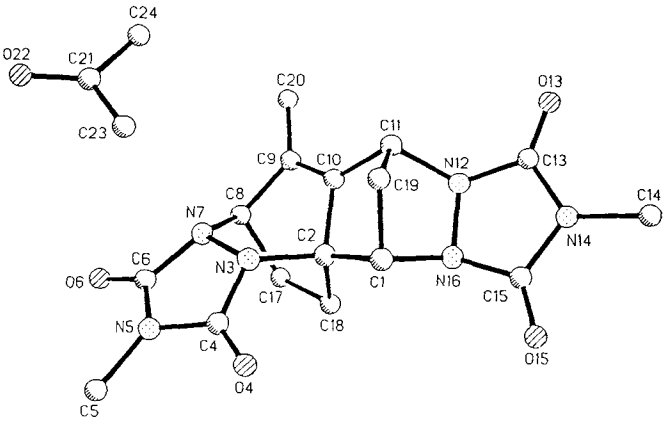


Fig. 1. Crystal structure of **9**.

The formation of the isomers **5**–**7** in a ratio which cannot be significantly altered even by distillation or prolonged heating of the thermolyzate, corresponds with the results of the dihydropentalene formation in the thermolysis of vinylpentafulvene **1**[1,2] or cyclooctatetraene.[13] The results of the MNDO calculation[14] on five different dihydroindene species are listed together with those on the dihydropentalenes[16] in Table 1. A striking result is that the annelation of a six-membered ring to cyclopentadiene strongly reduces the energy difference between the isomers **A**, **B**, and **C** unsaturated at the bridgeheads. The triene **A**, $n = 2$, remains as in the dihydropentalene series, the stabilomer.[17,18]

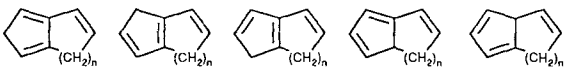

Table 1. Heats of formation ΔH_f [kcal mol^{-1}] of the isomers **A**–**E** (n = 1,2) according to MNDO.

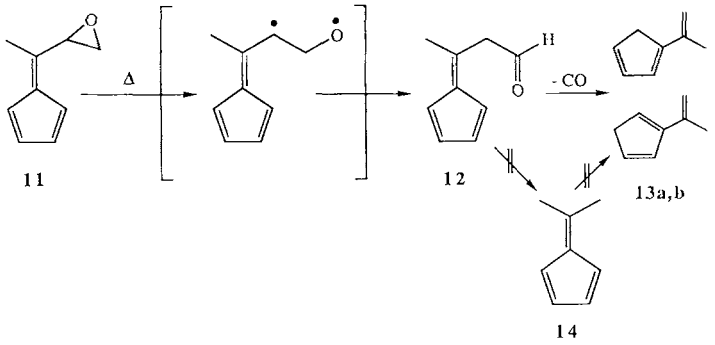
	A	B	C	D	E
n = 1 [16]	50.7	54.9	55.4	59.0	60.0
n = 2 [14]	32.2	32.5	33.0	39.0	40.0

The epoxy compound **11** analogous to **3**[4] yielded no ring-annelation products upon gas-phase thermolysis. When the thermolysis was carried out at temperatures above 600 °C (0.08 torr), the two vinylcyclopentadienes **13a** and **13b**[19] could be isolated quantitatively. Under milder conditions (460–580 °C/0.01 torr) the aldehyde **12** could be detected to an extent of 10–15% in the thermolyzate. 6,6-Dimethylpentafulvene **14** is not formed as intermediate (formally via 1,2-H-migration) upon cleavage of carbon monoxide from **12**.

We were able to show that **14** undergoes isomerization to **13a**, **b** only to a small extent under the aforementioned conditions, as had already been established by *Zimmermann* et

al.[20] The isomeric ratio **13a**:**13b** was identical with the equilibrium ratio (64:36 ± 4%) in all experiments. In particular, in none of the cases could the 5-alkylated cyclopentadiene isomer be detected, so it must be assumed that the dienes **13** already completely equilibrate under the thermolysis conditions.



Thus, whereas an electrocyclic $[\pi^6 + \sigma^2]$-reaction had to be noted with the cyclopropylfulvene **3**, the rapid formation of the carbonyl group hinders a corresponding reaction in the case of the oxiranylfulvene **11**. We are presently trying to force a ring closure reaction also in the thermolysis of 6-oxiranylpentafulvenes by blocking the oxirane positions, and thus to facilitate an entry to iridoid compounds (oxa-analogous dihydroindenes).

A Surface Organometallic Approach for Controlling the Pore Opening Size of Zeolites: the Case of Mordenite Modified via Grafting of Dineopentylmagnesium **

By *Albert Théolier, Emmanuel Custodero, Agnès Choplin, Jean-Marie Basset** and *Francis Raatz*

Shape selectivity is one of the most important properties of zeolites in their application in the field of adsorption and catalysis.[1] For a given zeolite, this property is related, inter-alia, to the pore size and/or to the size of the pore openings. For a number of applications in the fields of adsorption and the synthesis of fine chemicals, a certain cut-off pore diameter is often desired; this cannot be achieved, however, via direct synthesis. One way to circumvent this problem is to modify, post synthesis, the pore opening of a given zeolite. This has recently been attempted by way of the chemical vapor deposition (CVD) of alkoxysilanes.[2–9] Subsequent calcination then led to a coating of silica on the external surface of the zeolite. However, although a layer by layer build up of such a coating seems to be achieved, the deposit is sometimes heterogeneous, some pores being fully blocked whereas others are not modified.[10, 11]

Another way of adjusting the shape selectivity could be to chemically graft a bulky organometallic complex at the external surface of a given zeolite and more specifically and efficiently at the pore entrance. The steric hindrance of the organometallic fragment could then be easily modulated via the bulkiness of the organic moiety. We wish to report here, to our knowledge, the first example illustrating the feasibility of such an approach; we have modified the adsorptive properties of a mordenite via the reaction of dineopentylmagnesium [$MgNp_2$] with its external OH groups.[12]

Two methods have been used for this surface reaction: a sublimation method (method A)[13] and a liquid phase method (method B).[14] In order to characterize the surface reaction between $MgNp_2$ and mordenite, preliminary experiments were carried out on a silica ($SiO_{2(400)}$) previously

data,[15] volumetric measurements,[16] elemental analysis,[17] and ^{13}C-MAS-NMR data. The neopentyl group exhibits two distinct ^{13}C-NMR signals at $\delta = 31.82$ (CH_3) and 28.51 (CH_2), respectively. This surface species is thermally[18] stable, as is to be expected for compounds of the type Mg(R)(OR).[19] Total disappearance of the ν(CH) bands occurs only above 300 °C.

The reaction of $MgNp_2$ with the mordenite has been followed by in situ IR spectroscopy. Sublimation of $MgNp_2$ on a mordenite causes the disappearance of the band at 3745 cm^{-1}, characteristic of surface silanol groups and the appearance of weak bands at 2955 and 2869 cm^{-1}, typical of $\nu(CH_3)$ vibrations. This behavior is similar to that observed under comparable conditions with silica. The amount of magnesium which can be grafted by both methods (A or B) never exceeds 0.2 wt.-%. As in the case of silica, the grafted organometallic fragment is stable up to ca. 200 °C, a temperature above which it starts to decompose into neopentane and an unidentified magnesium species.

Although we have no direct evidence that dineopentylmagnesium is grafted exclusively on the external surface of the mordenite, a number of observations support this hypothesis. The amount of grafted magnesium never exceeds 0.2 wt-%, in good agreement with the number of available external surface OH groups.[20] The Van der Waals radius of solvated $MgNp_2$ ($MgNp_2 \cdot 2Et_2O$) is greater than that of the pore entrance of the mordenite (6.7 × 7.0 Å). Consequently, the method of impregnation in solution (Method B) should not allow easy access of the complex into the pore system. For the unsolvated gas phase $MgNp_2$, the Van der Waals radius is close to that of the pore entrance. Nevertheless, the fact that both methods lead to similar results (e.g. Mg content and adsorption data) suggests that the solvated $MgNp_2$ mainly reacts with the external surface of the zeolite.

The adsorptive properties of these MgNp-modified mordenites have been measured by a pulse-chromatographic method.[21] The adsorption capacities thus determined for *n*-hexane (kinetic diameter $\sigma = 4.2$ Å) and isooctane ($\sigma = 6.3$ Å) are shown in Figure 1 as a function of the temperature of treatment of the Mg-mordenite. Two points should be emphasized: (i) the grafting of the organometallic moiety -Mg-Np reduces the adsorption capacity of the mordenite for *n*-hexane by a factor of 2 and nearly suppresses the adsorption of isooctane; (ii) as the temperature of treatment of the modified mordenite increases, this selectivity toward *n*-hexane is reduced and finally suppressed above 400 °C. This phenomenon is correlated to the thermal stability of the grafted organometallic fragment.

The above results indicate that the grafting of an organometallic species on the external surface of mordenite is indeed a way of controlling the shape selectivity of zeolites.

Computer modeling[22] of the interaction of $MgNp_2$ with the silanol groups available on the external surface of mordenite indicates that on the (001) face, two types of sites are available: the first type allows grafting of an MgNp moiety via one surface O atom [giving (≡Si–O-)MgNp]; the second type would allow the grafting via two O atoms: a 1e-donor (≡Si–O) and a 2e-donor (adjacent ≡Si–OH, able to coordinate to the Mg atom) [giving (≡Si–O)(≡Si–OH)MgNp] (Fig. 2). On the (010) and (100) faces, only 1e-donor O atoms are available, leading to (≡Si–O)MgNp. Once a MgNp fragment is grafted, the reaction of a second molecule of $MgNp_2$ in the close vincinity may be difficult for steric reasons. In any case, no more than 2 MgNp moieties can be grafted in the vicinity of a pore aperture. (Fig. 2) Computer modeling also suggests that only a minor fraction of the surface-grafted MgNp fragments efficiently controls the pore entrance

aperture and thus the selectivity of the adsorptive properties. When one MgNp is grafted per pore aperture, the discrimination capacity between *n*-hexane and isooctane by MgNp-modified mordenite can be easily visualized (Fig. 2): numerous short contact distances seem to exist between the organic molecule and the organometallic fragment in the case of isooctane, but none or very few in the case of *n*-hexane. When two MgNp fragments are grafted per pore aperture no hydrocarbon can enter the pore system (Fig. 2), as is consistent with the lowering of the *n*-hexane adsorption capacity.

This preliminary study indicates that it should be possible to design a shape selective system for a given application, starting from a readily available zeolite, modified by an organometallic complex, whose steric bulk can be accurately tuned. Studies are now in progress to fully characterize these new solids (precise localization of the organometallic entity) and to extend this new method to different couples of zeolites and complexes. The solid obtained by this approach suggests applications in the field of adsorption or catalysis at low temperature. One can nevertheless imagine that successive reactions (such as hydrolysis, complex grafting ...) should lead to the build-up in a layer by layer fashion of an oxide coating on the zeolite. Such solids may find more applications in catalytic reactions occurring at higher temperatures.

[12] $MgNp_2$ was synthesized from NpBr and Mg following published procedures (R. R. Schrock, G. D. Feldmann, *J. Am. Chem. Soc. 100* (1978) 3360. The mordenites (large pore, from Norton, Si/Al = 6.5 and Toyosoda Si/Al = 10.2) were used in their Na or H forms; they were pretreated under vacuum (400 °C, 16 h) to remove any trace amount of water. Diethyl ether was distilled prior to use. All experiments were performed with strict exclusion of air and water by standard Schlenk tubes or break and seal techniques.
[13] Method A. $MgNp_2$ was sublimed (150 °C, 10^{-4} mm Hg) on the zeolite at 150 °C; excess of complex, physisorbed on the surface of the zeolite, was removed by evacuation at the same temperature for 4 h.
[14] Method B. The zeolite (1 g) was placed in contact with a solution of the complex (50 mg) in ether (10 mL), at room temperature. After ca. ½ h, the solution was removed via a syringe and the solid was washed two times with 10 mL aliquots of ether, then evacuated at room temperature for 6 hours.
[15] Reaction of $MgNp_2$ with a silica dehydroxylated at 400 °C led to total consumption of the silanol groups (disappearance of the band at 3745 cm^{-1}) and to the appearance of ν(C–H) bands at $\tilde{\nu}$ = 2955 and 2869 cm^{-1} corresponding to the grafted neopentyl moiety.
[16] Reaction of $MgNp_2$ with a $silica_{(400)}$ led to the evolution of 1 mole of NpH per mole of Mg.
[17] The Mg/C ratio after grafting was equal to 1/5, as expected for surface MgNp.
[18] The grafted organometallic began to decompose above 200 °C to give mostly neopentane and traces of methane.
[19] E. C. Ashby, G. F. Willard, A. B. Goel, *J. Org. Chem. 44* (1979) 1221.
[20] The number of surface $\equiv$Si–OH groups available for MgNp grafting on the [100] and [010] faces is approximately 2 per unit cell per plane. These two planes are those which contribute the most to the external surface, which is 27 m^2/g. A maximum amount of ca. 0.15 wt-% Mg is thus suggested.
[21] The modified zeolite was synthesized in situ or transferred in a chromatographic type column. Its adsorption capacity for a given hydrocarbon was related to the number of pulses which have to be injected on the column in order to obtain a constant signal at the outlet. Under our conditions, the pressure of the hydrocarbon, controlled by a stream of argon bubbling through it, was such that $p/p_s \approx 1$.
[22] Computer modeling has been performed using ALCHEMY (TRIPOS Assoc.). The crystallographic parameters of mordenite are those determined by Meier (*Zeit. Fur Krist. 115* (1961) 439). The bond distances and angles of the MgNp moiety are those from the electron diffraction study of $MgNp_2$ (E. C. Ashby, L. Fernholt, A. Haaland, R. Seip, R. S. Smith, *Acta Chem. Scand. A 34* (1980) 213). The chosen Mg–O distance was 1.98 Å (an average value).

^{13}C-MAS-NMR Spectra of Technical Calcium Carbide and Barium Carbide — Are the $C_2^{2\ominus}$ Ions in Ionic Carbides Surrounded Symmetrically?**

By *Bernd Wrackmeyer,* Klaus Horchler, Angelika Sebald, Lawrence H. Merwin*, and *Charles Ross II*

The $C_2^{2\ominus}$ ion is a central link in the 14-electron family of diatomic molecules[1] and a building block of fascinating structures with C_2 units.[2] The salt-like carbides MC_2 (M = Ca,Sr,Ba) provide an opportunity of obtaining ^{13}C-NMR parameters of $C_2^{2\ominus}$ ions in the solid state. In all textbooks one finds that these carbides are said to have a tetragonal structure[3] in which each metal atom is surrounded by six $C_2^{2\ominus}$ ions. Each $C_2^{2\ominus}$ ion has six metal atoms as neighbors, namely two terminal and four side-on (space group *I4/mm*): an exactly axially-symmetric environment results for the carbon atoms. In the case of CaC_2[4] at least four phases are discussed, of which three could be stable or metastable at room temperature. The preparation of single crystals for an X-ray structure analysis has so far met with little success, so that the available crystallographic data is inadequate. Tetragonal symmetry was assumed in the determination of $r_{C\equiv C}$ = 120 pm by neutron diffraction measurements on technical CaC_2.[5]

In order to help towards the structural elucidation and to investigate the question of the ionic character of the alkaline earth metal carbides we have now recorded ^{13}C-MAS-NMR spectra of technical CaC_2 and BaC_2 (Fig. 1)[6] and analyzed them concerning the tensor components σ_{11}, σ_{22} and σ_{33} (Table 1).[7] ^{13}C-NMR spectra of static samples of CaC_2[8, 9] as well as of SrC_2 and BaC_2[9] are already available; however, these are either completely uninformative[8] or their quality is not satisfactory enough for an exact analysis with regard to the uniformity of the samples, the isotropic δ^{13}C values, and the tensor components of the ^{13}C shielding constants.[9]

Table 1. Isotropic $\delta^{13}C$ values [a] and tensor components of the ^{13}C shielding constants $\sigma^i(^{13}C)$ [b] for CaC_2 (cf. Fig. 1) and BaC_2.

	$\delta^{13}C$	σ_{11}	σ_{22}	σ_{33}	$\Delta\sigma$	η
CaC_2	206.2 [c]	−350	−283	14	331	0.31 ± 0.1
BaC_2	232.1	−354	−288	−55	265	0.38 ± 0.1

[a] Relative to external Me_4Si for one of the ^{13}C resonances ($\delta^{13}C = 38.5$) of solid adamantane. [b] σ-values are likewise referred to Me_4Si but have opposite signs to the δ values; the convention is: $\sigma^i = 1/3\ (\sigma_{11} + \sigma_{22} + \sigma_{33})$ and $|\sigma_{33} - \sigma^i| \geq |\sigma_{11} - \sigma^i| \geq |\sigma_{22} - \sigma^i|$; the anisotropy of the chemical shift $\Delta\sigma = \sigma_{33} - 1/2\ (\sigma_{11} + \sigma_{22})$; the asymmetry parameter $\eta = 3/2\ (\sigma_{22} - \sigma_{11})\ (\Delta\sigma)$. [c] $\delta^{13}C$ of the second species (ca. 5–10%): 200.3 (as far as the spinning side bands are recognizable, their relative intensities compare with those of the main component.

The simulation of the ^{13}C-MAS-NMR spectra[7] shows, that in the case of CaC_2 and BaC_2, the deviation from axial symmetry for the carbon atoms is so marked that a highly symmetric structure of MC_2 is out of the question. One way in which to reconcile the widely differing information provided by the powder X-ray diffraction data and the ^{13}C-MAS-NMR spectra is to assume that the C≡C axis only statistically coincides with the *c* axis of the lattice, i.e. the orientation of the individual C_2 units deviates from this axis.[10] Numerous phases with orientational disorder are characterized by molecular units with high external symmetry and strong internal bonding which are coordinated via many weak bonds to other large atoms.[11]

Consistent with the data provided by powder X-ray diffraction diagrams[6] one finds, in the case of CaC_2 (Fig. 1),

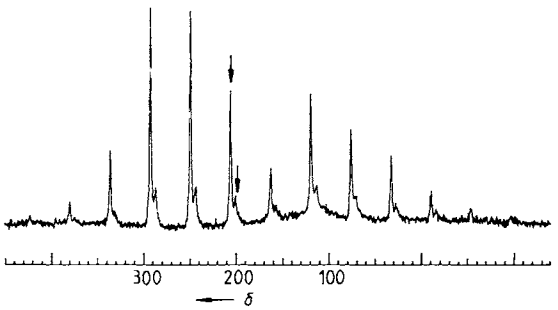

Fig. 1. 75.5 MHz ^{13}C-MAS-NMR spectrum (Bruker MSL 300) of technical calcium carbide; the isotropic $\delta^{13}C$ values are indicated with arrows and were identified by measurements at different rates of rotation. Measuring conditions: 25 °C, rotation rate 3272 Hz, pulse angle ca. 72° (4.0 μs), 800 scans, relaxation delay 300 s.

that a second modification is present to the extent of ca. 5–10%, with almost the same $\delta^{13}C$ value as the main component. In the case of the smaller component of the mixture it is impossible to glean any information about the symmetry of the environment of the $C_2^{2\ominus}$ units, since the signal-to-noise ratio is not large enough for a spectral simulation.

The $\delta^{13}C$ values depend markedly on the cation,[9] whereby the deshielding of the ^{13}C nucleus increases with increasing size of the cation. This dependence indicates that there are covalent interactions between the $C_2^{2\ominus}$ ions and the $M^{2\oplus}$ ions.[12] So far, there are scarcely any NMR data available about ionic species in solution and in the solid state. In the case of $NH_4^{\oplus}$ $NCS^{\ominus}$, however, good agreement was found between the $\delta^{15}N$ and $\delta^{13}C$ values in both states of aggregation,[13] so that this compound is the example resorted to for largely ionic bonding. The correlations with the ionization energy of M or the terminal M–C distance based on less exact $\delta^{13}C$ values for MC_2[9] are questionable and—on using our more accurate data—do not under any circumstances permit extrapolations to H–C≡C–H.

The $\delta^{13}C$ values are unusual for alkyne carbon atoms.[14] A correlation between $\delta^{13}C$ and $\delta^{15}N$ of isoelectronic and isostructural linear compounds[15] [Eq. (a)] predicts a $\delta^{13}C$ of ca. 140 for a "free" $C_2^{2\ominus}$ ion on using the $\delta^{15}N$ value for the cyanide ion ($\delta^{15}N = -106.1$).[15b]

$$\delta^{13}C = 0.536\ \delta^{15}N_{(MeNO_2 \equiv 0)} + 196.5 \qquad (a)$$

The following considerations support this $\delta^{13}C$ value for a "free" $C_2^{2\ominus}$ ion: In analogous structures the δ values should behave like the anisotropy of the chemical shift $\Delta\sigma_{(^{13}C)}$ and $\Delta\sigma_{(^{15}N)}$. With $\delta^{13}C = 140$ for the $C_2^{2\ominus}$ ion, $\Delta\sigma_{(^{13}C)} = \sigma_{\parallel} - \sigma_{\perp} = 345$, when $\sigma_{\parallel(^{13}C)} = 90$ (as reference value for linear undisturbed systems[16]). Experimentally, $\Delta\sigma_{(^{15}N)} = 654$ was determined for the N_2 molecule corresponding to the $C_2^{2\ominus}$ ion;[17] the quotient of the two $\Delta\sigma$ values is almost identical with the slope of the straight line plotted according to Equation (a).

Together with the finding that the environment of the carbon atoms in MC_2 is not axially symmetric, the large difference between the $\delta^{13}C$ value (ca. 140) expected according to Equation (a) and the experimental values (206.1 ppm for CaC_2 and 232.1 ppm for BaC_2) merely allows the conclusion that the $C_2^{2\ominus}$ unit in "ionic" carbides and the C≡C triple bond in alkynes are not comparable.

[10] a) Room temperature powder X-ray diffraction data ($20° \leq 2\theta \leq 100°$, $Cu_{K\alpha}$ radiation) of BaC_2 (space group *I4/mmm*; $a = 4.3991(5)$ Å, $c = 7.1024(10)$ Å) were collected out by us in order to find evidence of orientationally-disordered C_2 units. The data were refined [10b] using different models for the distribution of the carbon atoms. For the assumption of a perfect structure these converged after absorption corrections to $R_p = 3.98$, $R_{wp} = 4.56$ and $R_{Bragg} = 23.9$. The last value (R_{Bragg}) and the extremely large isotropic thermal parameter for the carbon atoms [10.0(1) Å^2 compared with 4.1(2) Å^2 for Ba] indicate that this model does not fit (even on applying anisotropic temperature factors), obviously as a result of the orientationally-disordered C_2 units. Unfortunately, no reliable value can be quoted for $d_{C\equiv C}$ (span from 1.1 to 1.5 Å) so we can only solve this problem with the help of a neutron diffraction experiment. b) D. B. Wiles, R. A. Semisynthetic Rhodomycins: Novel Glycosylation Methods for the Synthesis of Anthracycline Oligosaccharides

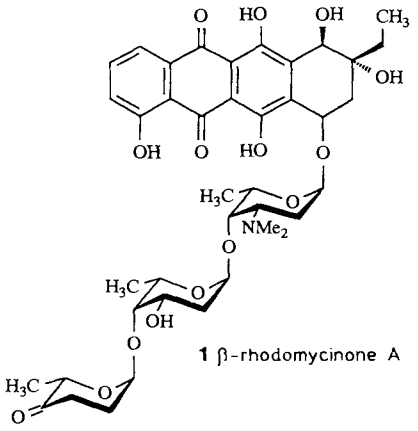
By *Cenek Kolar** and *Günther Kneissl*

β-Rhodomycinone A **1**[1] as well as other microbial anthracyclines of the aclacinomycin-type contain one or two oligosaccharide chains consisting of α(1 → 4)-linked oligodeoxy sugars.[1,2] The most frequently occurring partial sequences are 2-deoxy-α-L-fucosyl-(1 → 4)-L-rhodosamine, contained in **1**, and α-L-rhodosaminyl-(1 → 4)-L-rhodosamine.

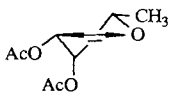


1 β-rhodomycinone A

The synthesis of these disaccharides is difficult, since only a poorly reactive axial 4-hydroxy group of a daunosamine moiety must be glycosylated.[3,4] The established procedures such as the Koenigs-Knorr method[5] or the *N*-iodosuccinimide (NIS) glycosylation technique[6] have proven unsuitable for this purpose. The recently introduced $(Bu_3Sn)_2O$/NIS method indeed affords α(1 → 4)-disaccharides in good yields (74–82%), but the iodine on C-2′ of the product must then be removed in a reductive step.[7]

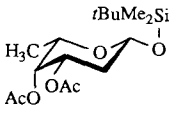
We have now found that the 1-*O*-*t*$BuMe_2Si$-2,6-dideoxy-β-*lyxo*-hexopyranoses[8a] **4** and **12** as well as the 3-trifluoroacetylamino-*lyxo*- and 3-trifluoroacetylamino-*arabino*-glycals **14** and **15**, respectively, are suitable as glycosyl donors for the preparation of anthracycline oligosaccharides. In the case of the glycosyloxysilanes, so far only the 1-*O*-trimethylsilylated derivatives have been used [9–11] in combination with trimethylsilyl triflate (TMSOTf) or other catalysts, in particular for the synthesis of acetal-glycosides.[8b] In the case of the glycals **14** and **15**, reactions with anthracyclinones in the presence of *p*-toluenesulfonic acid as promoter have thus far been described.[12,13]

For the preparation of the 2-deoxy-L-fucosyl donor **4**, fucal **2**[14] was converted by hydrolysis[14] (30% CF_3COOH) into the diacetate **3**, which, in turn can be converted selectively with *t*$BuMe_2SiCl$/imidazole in 1,2-dichloromethane into the β-L-anomer **4** ($[\alpha]_D^{24} = 17.2°$ ($c = 1.02$, $CHCl_3$): 200-MHz ^{1}H-NMR (C_6D_6, TMS): $\delta = 5.08$ (4-H), 4.74 (3-H), 4.41 (1-H). Under standard conditions (DMF as medium)[15] the silylation furnishes a mixture of both α- and β-anomers (α:β = 1:4).



2

3



4

The 3-azido-*arabino*-hexopyranose **5**,[16] which is readily accessible from L-rhamnal and must be epimerized in the 4-position,[17] was chosen as starting compound for the synthesis of the daunosaminyl donor **12**. For the regioselective silylation, **5**, like **3**, was allowed to react with *t*$BuMe_2SiCl$/imidazole in CH_2Cl_2. The β-anomer **6** ($[\alpha]_D^{24} = +2°$ ($c = 1.0$, $CHCl_3$)) obtained in 92% yield was deacetylated under Zemplén conditions to **7**, which was converted under previously tested conditions[17] (trifluoromethanesulfonic anhydride, pyridine/dichloromethane at −30 °C) into the triflate **8**. Epimerization[18] of the *arabino*-compound **8** with a mixture of cesium and sodium acetates adjusted to pH 8 afforded the *lyxo*-acetate **9** in 72% yield ($[\alpha]_D^{24} = +5.6°$ ($c = 1.0$, $CHCl_3$)). After deacetylation of **9** to **10**, the azido group in **10** was reduced (10% Pd/C, ammonia/ethanol, pH 9), and the resulting amino group converted into a trifluoroacetamido group. Introduction of the acetyl group into **11** finally furnished the glycosyl donor **12**[19] ($[\alpha]_D^{24} = -24.4°$ ($c = 1.0$, $CHCl_3$); 200-MHz ^{1}H-NMR ($CDCl_3$ TMS): $\delta = 6.44$ (NH), 5.02 (4-H), 4.84 (1-H).

To check the linkability of the glycosyl donors **4** and **12** we chose the benzyldaunosaminide **13**[4] as glycosyl acceptor

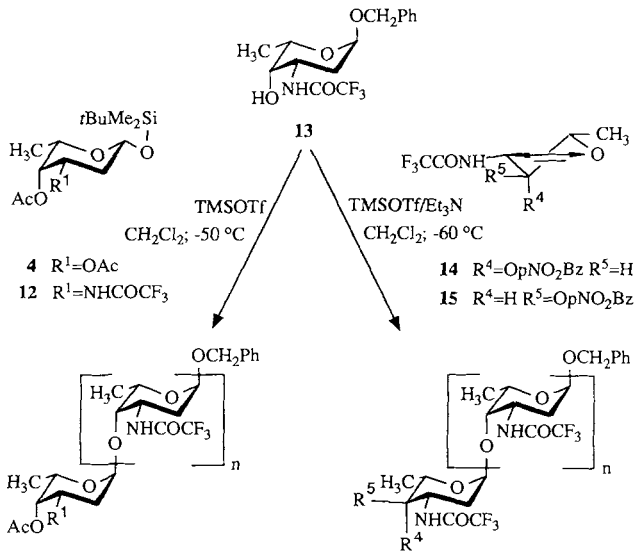
and TMSOTf as promotor,[20, 21] and employed equimolar amounts of the glycosylation components.[22] In the presence of 0.3 equivalents of TMSOTf and 4 Å molecular sieve (CH_2Cl_2), **4** reacts at $-50\,^{\circ}C$ with **13** to give the disaccharide **16**[4] ($[\alpha]_D^{24} = -170^{\circ}$ ($c = 1.0$, $CHCl_3$); 400-MHz ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 7.99$ (N-H), 5.26 (3′-H), 5.14 (4′-H), 4.91 (1-H, 1′-H)) in 73% yield. With an excess of the promoter (0.6 equiv) the terminal glycoside bond in **16** is attacked, leading to formation of the benzylglycoside **18** (ca. 8%)[23a] and the trisaccharide **20** (ca. 5%).[24a] **12** reacts in the same way (0.4 equiv. TMSOTf) with 13 to give the disaccharide **17** in 75% yield ($[\alpha_D^{24} = 127.9^{\circ}$ ($c = 0.99$, $CHCl_3$); 200-MHz ^{1}H-NMR ($CDCl_3$, TMS): $\delta = 8.02$ (3-NH), 6.58 (3′-NH), 5.15 (4′-H), 5.05 (1-H, 1′H), 3.55 (4-H); with an excess of the promoter, the mono- and the trisaccharide **19**[23b] and **21**,[24b] respectively, are then formed besides **17**.

The 3-trifluoroacetylamino-*lyxo*- and 3-trifluoroacetylamino-*arabino*-glycals **14**[12] and **15**[13] were also used for the glycosylation of **13** (pNO_2Bz = *para*-nitrobenzoyl), but TMSOTf was used instead of *p*-toluenesulfonic acid as promoter. In the presence of TMSOTf and 4 Å molecular sieve (CH_2Cl_2) **13** reacts with **14** or **15** at $-40\,^{\circ}C$ to give the disaccharides **22**[25a] and **23**,[25b] respectively, in 60–70% yield, and, as in the reaction of **12** with **13**, the benzylglycosides **24**[23c, 26] and **25**[23d] and the trisaccharides **26**[24c]



and **27**,[24d] respectively, are also formed. When, however, the glycoside syntheses are carried out in the presence of TMSOTf/triethylamine (5:1) at $-60\,^{\circ}C$ the glycals are activated by the triethylammonium triflate formed in situ, and the disaccharides **22** and **23**, respectively, are formed in over 90% yield.[27] The mono- and trisaccharides are formed in only trace amounts.

The route via the disaccharide **28**, which is obtained after cleavage (0.1M, NaOH) of the acyl groups in **17** or **22**, is more suitable for the preparation of the trisaccharides, even though transglycosylations also occur. The glycosylation of **28** with **4**, **12**, **14** or **15** under the above-mentioned conditions affords the trisaccharides **20**, **21**, **26** and **27**, respectively, in 40–65% yield.

As these glycoside syntheses demonstrate, the β-glycosyloxysilanes as well as the 3-trifluoroacetylaminoglycals are very reactive readily linkable glycosyl donors. Since α-*O*-glycosidally-linked 2-deoxy sugars are present as building blocks in natural products of microbial and plant origin these glycosylation techniques can contribute immensely to their preparation. The β-glycosyloxysilanes could find wide application in glycoside syntheses.

[22] General procedure: A mixture of **13** (0.75 g, 2.25 mmol), glycosyloxysilane (2.25 mmol), 3.5 g of molecular sieve 4 Å and 100 mL of CH_2Cl_2 was treated at $-50\,^{\circ}C$ under N_2 with 0.3 equiv. TMSOTf. After seven hours' stirring at $-50\,^{\circ}C$ a further 0.1 equiv TMSOTf was added if necessary, and the mixture was stirred for a further 6 h, then treated at $-50\,^{\circ}C$ with 0.75 mL of Et_3N and 100 mL of CH_2Cl_2, and finally filtered. The filtrate was washed with 0.1M citrate buffer (adjusted to pH 5 with NaOH) and then with water, dried (Na_2SO_4), and evaporated to dryness in vacuo. Column chromatographic separation of the residue (200 g silica gel; eluent: petroleum ether/CH_2Cl_2/acetone 8:5:1) furnished an α(1 → 4)-linked disaccharide. The course of the glycoside syntheses can be controlled by the addition of a polar solvent (acetone, THF). The reactions conducted in CH_2Cl_2/acetone (20:1) proceed slower, but require increased concentration of the promotor.

[27] General procedure: A mixture of **13** (0.75 g, 2.25 mmol), glycal (2.25 mmol), 3.5 g of molecular sieve 4 Å and 100 mL CH_2Cl_2 was treated at -60 °C under N_2, firstly with triethylamine (0.18 mmol, 0.024 mL) and then with TMSOTf (0.67 mmol, 0.12 mL). After 1.5 hours' stirring at -60 °C the mixture was treated with 0.75 mL of Et_3N and 100 mL of CH_2Cl_2 and worked up as described above.

μ-Hydroxobis(μ-formato)hexaaquadichromium(III), an Intermediate in the Formation of Basic Chromium Carboxylates**

By *Petra N. Turowski, Avi Bino*, and *Stephen J. Lippard**

A century ago, violet compounds, variously formulated as $[Cr_3(O_2CR)_5(OH)_2](OH)_2 \cdot 2H_2O$ and $[Cr_2(OH)_3(O_2CR)_3]$, were obtained during formation of the now classical dark green basic chromium carboxylates, $[Cr_3O(O_2CR)_6L_3]^{\oplus}$ **1**. We here report the identification of this elusive violet species, isolated and structurally characterized as the formate derivative [μ-hydroxobis(μ-formato)hexaaquadichromium(III)], **1**. Its preparation and reaction to form basic chromium for-

$$Cr_2(OH)(O_2CH)_2(H_2O)_6]^{3\oplus} \quad \mathbf{1}$$

mate closely parallel results obtained for the violet complexes observed by *Weinland* and others.[1d, e]

1 was isolated, after reduction of chromium(VI) oxide in formic acid or reaction of Cr^{III} salts in aqueous formic acid at 50 °C, in the form of the salt **1**, $[p\text{-}CH_3C_6H_4SO_3]_3 \cdot 2H_2O$.[2] The complex consists of two octahedrally coordinated chromium atoms bridged by an hydroxo ligand and two bidentate formato ligands (Fig. 1). The remaining, terminal coordination sites are occupied solely by aqua ligands, a unique feature in complexes of this class. The structural parameters of the bridging unit of **1** are compared with those of selected hydroxo-bridged species in Table 1. Note that the Cr–OH distances in **1** (1.920 Å) are rather short. The core geometry is very similar to that of an analogous diiron(III) complex, $[Fe_2(OH)(O_2CCH_3)_2(HBpz_3)_2](ClO_4)$,[3] and it is intermediate between the structures of more nearly linear $\{Cr_2(OH)\}^{5\oplus}$ complexes and those of di- and trihydroxo-bridged dichromium(III) species.[4] The complex is extensively hydrogen-bonded in the crystal, mostly to the *p*-toluenesulfonate ions. The bridging ligands provide a pathway for antiferromagnetic

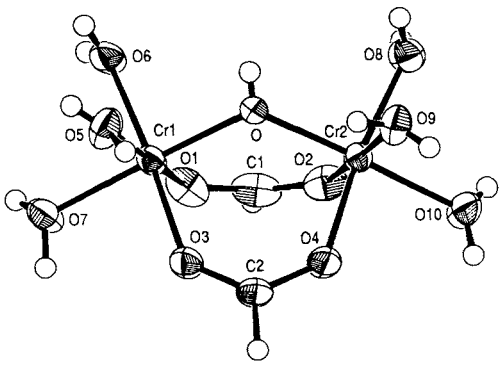

Fig. 1. Structure of **1** in the crystal (ORTEP, showing 50% probability thermal ellipsoids and atom labeling schemes for non-hydrogen atoms of the cation. Hydrogen atoms are included as arbitrary isotropic spheres). Selected interatomic distances [Å] and angles [°]: Cr1-O, 1.923(3); Cr1-O1, 1.957(4); Cr1-O3, 1.956(3); Cr1-O5, 1.983(4); Cr1-O6, 1.965(4); Cr1-O7, 2.008(4); Cr2-O, 1.916(4); Cr2-O2, 1.963(3); Cr2-O4, 1.958(3); Cr2-O8, 1.983(4); Cr2-O9, 1.974(4); Cr2-O10, 1.983(5); Cr1···Cr2, 3.381(1); Cr1-O-Cr2, 123.4(2); O-Cr1-O1, 91.6(2); O-Cr1-O3, 91.9(1); O1-Cr1-O3, 94.1(2); O-Cr2-O2, 92.4(2); O-Cr2-O4, 92.4(1); O2-Cr2-O4, 93.8(2).

exchange coupling between the Cr^{III} centers in **1** ($J = -11.2(2)$ cm^{-1}).[5] The metal atoms in the other complexes listed in Table 1 are also antiferromagnetically coupled to one another, as indicated.[3, 4]

Table 1. Comparison of structural and magnetic features of hydroxo-bridged dichromium(III) and diiron(III) complexes.

Compound	M-OH [Å]	M···M [Å]	M-OH-M [°]	$-J$ [cm^{-1}]
1 $[p\text{-}CH_3C_6H_4SO_3]_3 \cdot 2H_2O$	1.920(4)	3.381(1)	123.4(2)	11.2(2)
$[Fe_2(OH)(O_2CCH_3)_2(HBpz_3)_2](ClO_4)$ [3]	1.956(4)	3.439(1)	123.1(2)	17(1)
$[Cr_2(OH)(NH_3)_{10}]Cl_5 \cdot H_2O$ [4]	1.97	3.852(9)	165.6(9)	16
Δ,Λ-$[Cr_2(OH)(en)_2(OH)_2](ClO_4)_3$ [4]	1.99	3.677(2)	135.4(2)	–
$[Cr_2(OH)_2(NH_3)_8](S_2O_6)_2$ [4]	1.97	3.045(1)	101.5	14
$\Delta,\Delta/\Lambda,\Lambda$-$[Cr_2(OH)_2(phen)_4]I_4$ [4]	1.92	2.986(4)	102.1(3)	6.5
$[Cr_2(OH)_3(metacn)_2]I_3$ [4a, c]	1.97	2.642(2)	84.1(3)	64

We noticed in the preparation of **1** that, if the temperature of the exothermic reaction exceeds 50 °C, a green material gradually forms. The product was characterized by visible spectroscopy as the basic chromium formate, $[Cr_3O(O_2CH)_6(H_2O)_3]^{\oplus}$. This result suggested that **1** and its analogues might be intermediates in the formation of basic chromium carboxylates. This hypothesis was confirmed by heating a solution of pale green "$CrCl_3 \cdot 6H_2O$" in formic acid and water to 70 °C and monitoring its visible spectrum. Formation of the blue dichromium(III) complex **1** was observed in the first 20 min, after which the characteristic dark green color of basic chromium formate appeared over a period of 5 h. The spectral changes observed after 30 min were identical to those of **1** in aqueous formic acid at 70 °C. A similar series of reactions was observed upon heating chromium (III) chloride in aqueous acetic acid. The conversion of the dinuclear into the trinuclear complex could be reversed by adding water and driving off carboxylic acid from the basic chromium carboxylate.

These studies have thus provided structural characterization of a new kind of dichromium(III) complex which contains one hydroxide and two formate bridging ligands. Previously, structures of oxo- or hydroxo-bridged compounds

containing two additional carboxylate bridges were obtained for transition metal systems such as Fe_2^{III}, Fe_2^{II}, Mn_2^{III}, Mn_2^{II}, V_2^{III}, Os_2^{IV}, and Ru_2^{III},[3, 6] but not for Cr_2^{III}, although many other types of dichromium(III) complexes are known.[4] Such carboxylate-bridged units with iron and with manganese are important in biology, in proteins such as hemerythrin and manganese catalases.[6a, b, 7] Recently, *Wieghardt* et al. reported the synthesis of the red complex, $[Cr_2(OH)(O_2CCH_3)_2(metacn)_2](ClO_4)_3$,[4c] which, although not structurally characterized, most likely has the same μ-hydroxobis(μ-acetato)dichromium(III) core as **1**.[8] Significantly, we have demonstrated that **1** is an intermediate in reactions leading to the well-known basic chromium formate. It is possible that similar complexes of other transition metals are also intermediates in the formation of their trinuclear basic carboxylates. Mechanistic studies are in progress.

[2] Experimental procedure for **1**: A solution of 0.60 g (10.0 mmol) of chromium(VI) oxide in 5 mL of water was added dropwise to 50 mL of formic acid (88%). The resulting blue solution was diluted with 50 mL of water and adsorbed on a 1.5 × 7 cm column of Dowex 50X2-200 cation exchange resin. After washing the column with water, the blue ion was removed with 0.5 M aqueous *p*-toluenesulfonic acid solution. Upon slow evaporation, violet crystals of **1** $[p\text{-}CH_3C_6H_4SO_3]_3 \cdot 2H_2O$ were obtained, which were separated from solid *p*-toluenesulfonic acid by extensively washing with acetone. These crystals (0.53 g, 20%) were suitable for X-ray diffraction studies. Correct elemental analysis (C,H,S). ^1H NMR (300 MHz, CD_3OD): $\delta = 7.7$ (br, 6H), 7.24 (s, 6H), 4.88 (s, 17H + HOD), 2.36 (s, 6H); FT-IR (KBr): $\tilde{\nu}[cm^{-1}] = 3337, 3141, 2471, 1604, 1497, 1457, 1409, 1390, 1376, 1214, 1203, 1155, 1127, 1036, 1011, 813, 761, 729, 718, 686, 619, 565$; UV/VIS ($H_2O$): $\lambda[nm] = 254(\varepsilon = 1180\ mol^{-1}\ cm^{-1}/Cr)$, 410(44), 572(46), 632(sh); magnetic susceptibility: $\mu_{eff}/Cr = 3.54$ (290 K, solid state), 3.5 μ_B (293 K, CD_3OD solution); crystal data at 295 K: monoclinic, space group $C2/c$ (No. 15), $a = 15.920(3)$ Å, $b = 17.381(3)$ Å, $c = 26.517(4)$ Å, $\beta = 91.77(1)°$, $V = 7334(4)$ Å^3, $M_r = 868.73\ g\ mol^{-1}$, $\varrho_{obsd} = 1.57(1)\ g\ cm^{-3}$, $\varrho_{calcd} = 1.573\ g\ cm^{-3}$, $Z = 8$. For 4552 unique, observed reflections with $F^2 > 3\sigma(F^2)$ and 526 variable parameters, the current discrepancy indices are $R = 0.051$ and $R_w = 0.067$. Further details of the crystal structure determination may be obtained from the Fachinformationszentrum Karlsruhe Gesellschaft für Wissenschaftlich-technische Information mbH, D 7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-54568, the names of the authors, and the journal citation.

Synthesis and Characterization of the Linear Trinuclear Complexes $[M_3^{II}(O_2CCH_3)_6(biphme)_2]$, M = Mn, Fe**

By *R. Lynn Rardin, Avi Bino, Peter Poganiuch, William B. Tolman, Shuncheng Liu,* and *Stephen J. Lippard**

Recent interest in polynuclear complexes of iron and manganese with oxygen donor and nitrogen donor ligands has been motivated by the occurrence of a growing class of metalloproteins known or believed to contain such polymetallic units as their functional cores.[1-3] The hydrolytic polymerization of iron or manganese in the presence of carboxylate and varying amounts of nitrogen donor ligands has led to the formation of dinuclear, trinuclear and higher nuclearity complexes.[1, 2, 4] Some of these species accurately mimic the spectroscopic and physical properties of the metal centers in hemerythrin, ribonucleotide reductases[1, 2] or the oxygen evolving complex of Photosystem II.[2, 4b] Our recent studies in this area have focused on complexes of first row transition metals with biomimetic carboxylate and imidazole containing ligands.[5-7] Here we report the synthesis and characterization of the divalent linear, trinuclear complexes

$[M_3^{II}(O_2CCH_3)_6(biphme)_2]$ **1**: M = Mn; **2**: M = Fe

biphme = 
1 and **2**, the central structural unit of which is a striking departure from the triangular $\{M_3O(O_2CR)_6\}$ core that has dominated the chemistry of trivalent manganese and iron carboxylates for decades.[8]

Compounds **1** and **2** were synthesized by reaction of $M(O_2CCH_3)_2 \cdot x\ H_2O$ (M = Mn, x = 4 for **1**; M = Fe, x = 0 for **2**) with biphme in methanol.[9-11] Two geometric isomers of **1** have been structurally characterized, which we designate as *syn*-**1** and *anti*-**1**[9, 10] depending on the disposition of biphme imidazole groups with respect to the best plane passing through the three metal atoms and two monodentate oxygen atom bridges (Fig. 1). Only the *anti* isomer of **2** has been structurally characterized to date.[11]

Complexes **1** and **2** are comprised of a linear array of three M^{II} ions in which a central, hexacoordinate metal, that resides on a crystallographic inversion center in the *anti* isomers, is flanked by two metal ions that are essentially pentacoordinate. The metals are bridged by four bidentate and two relatively rare monodentate μ-acetato ligands.[12-14] Bidentate biphme ligands cap the $\{M_3(O_2CCH_3)_6\}$ core. The

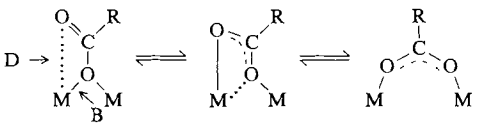
geometry of the terminal metal ions is trigonal bipyramidal with the pseudo-C_3 axes defined by N21-Mn2-O4 and N61-Mn3-O46 for *syn*-**1** and N21-M2-O4 for *anti*-**1**/**2**. Distortions arise from weak interactions of the terminal metal with the dangling oxygen from the monodentate μ-acetate ligand. In particular, the O-M-N angle in the trigonal plane, where O refers to the bridging oxygen atom from the monodentate carboxylate, e.g. O1, is correlated with the degree of interaction between the metal and the dangling oxygen atom. Thus, e.g., the angle O1-Mn2-N11 is widened by about 29° compared to the expected angle of 120°. This M···O interaction inhibits ligation at the potential sixth coordination site on the terminal metal ions, possibly limiting the formation of higher order oligomers.

The Mössbauer spectrum of **2**[11] consists of two quadrupole doublets arising from Fe^{II}, judging by the isomer shifts, with an intensity ratio of 2:1. The large quadrupole splitting for the more intense of the two doublets is consistent with the more distorted trigonal bipyramidal environment of the terminal Fe^{II} ions. Moreover, the relative quadrupole splitting of the pentacoordinate Fe^{II} ions in **2** and the recently reported $[Fe_2(O_2CH)_4(biphme)_2]$, **3**,[5] correlates nicely with the extent of the distortion of the coordination from trigonal bipyramidal geometry discussed above, varying from $\Delta E_Q = 3.30$ mm s^{-1} for Fe2 in **3**[5] to 3.60 mm s^{-1} for Fe2 in **2**.

A noteworthy feature of the two structures of **1** is the variation in the intramolecular Mn···Mn distances, from 3.370 (3) Å to 3.635 (1) Å. Although the observed values fall within the range reported for doubly and triply bridged dinuclear Mn^{II} complexes,[2a, 15] a difference of 0.27 Å in M···M distance within a single structural motif is extraordinary. This variability in Mn···Mn distances observed for **1** underscores the need for caution in interpreting EXAFS data for metalloproteins, in which details of the metal core geometry, especially M···M distances, are frequently used in postulating a specific structural model.[16]

The linear M^{II}_3-core geometry in **1** and **2** is unique among carboxylato-bridged trimanganese und triiron complexes, most of which have basic metal carboxylate[2c, 8] or other triangular structural motifs.[17] Aspects of the core geometries of **1** and **2** are known in related compounds, however. The $\{M_2(O_2CCH_3)_3(biphme)\}^{\oplus}$ unit comprising half the trinuclear complexes **1** and **2** is similar in structure to that reported for **3**.[5] The $\{M_3(O_2CCH_3)_6\}$ structure also appears in polymeric $Mn(O_2CCH_3)_2 \cdot 4\ H_2O$.[18] Here, however, all Mn^{II} ions are hexacoordinate and, instead of interacting weakly with terminal Mn^{II} ions as in the $\{M_3(O_2CCH_3)_6\}$ unit of **1** and **2**, the second oxygen atom from the monodentate bridging acetate binds to a Mn^{II} center that is part of another $\{Mn_3(O_2CCH_3)_6\}$ unit. A complex that appears to be very similar to **1**, $[Mn_3(O_2CPh)_6(bipy)_2]$ (bpy = 2,2'-bipyridine), has been mentioned recently, but detailed structural information is not yet available.[2c] Several linear homo- and heterotrinuclear complexes have been reported[14, 19] that contain a $\{M_2M'(O_2CR)_6\}$ core (M = M' = Co, Zn; M = Zn, M' = Mg, Ca, Sr, Co, Ni, Mn, Cd) similar to that found for **1** and **2**. Finally, a linear trinuclear complex, $[Mn_3(O_2CCH_3)_4(Saladhp)_2(CH_3OH)_2]$ [Saladhp = 2-methyl-2-(salicylideneamino)-propane-1,3-diol], was recently synthesized.[20] No linear carboxylatotriiron complexes are known.

Analysis of the structural parameters of the monodentate bridging carboxylate ligands in the present and a few related complexes[5, 21] reveals an interesting trend. In particular, a linear relationship exists between the bridging (B) and dangling (D) metal-to-oxygen distances as the carboxylate ligand moves from monodentate bridging toward bidentate bridging (Scheme 1). This movement, which we term the



Scheme 1. Transition from monodentate to bidentate μ-carboxylato ligand ("carboxylate shift").

"carboxylate shift", may be of general importance in the active site structures of metalloproteins. In particular, concanavalin A is known to contain a monodentate bridging carboxylate[22] and a similar unit may well occur in the reduced form(s) of ribonucleotide reductase.[23]

[9] a) Experimental procedure for *syn*-**1**: A slurry of $Mn(O_2CCH_3)_2 \cdot 4\,H_2O$ (0.13 g, 0.53 mmol) and biphme (0.10 g, 0.35 mmol) in methanol (2 mL) was allowed to stir in air for 15 min, affording a clear, nearly colorless solution. Complex **1** was precipitated as a beige solid (0.154 g, 81% yield) by addition of diethyl ether. Correct elemental analysis (C, H, N). FT-IR (KBr): ν [cm^{-1}] = 3130, 3047, 3030, 3004, 2962, 2930, 2831, 1597 (ν_{asym} CO_2), 1497, 1448, 1416 (ν_{sym} CO_2), 1338, 1281, 1174, 1155, 1138, 1089, 1068, 1018, 988, 895, 757, 721, 704, 672, 646. X-ray quality crystals of *syn*-**1** were obtained by vapor diffusion of diethyl ether into a methylene chloride solution of **1** in air. Crystal data for *syn*-**1** $\cdot$ 3 CH_2Cl_2 at $-75\,^{\circ}C$: monoclinic, space group $P2_1/c$ (No. 14), $a = 12.672(11)$ Å, $b = 21.422(16)$ Å, $c = 22.279(21)$ Å, $\beta = 100.36(4)^{\circ}$, $V = 5949(9)$ Å^3, $Z = 4$, $M_r = 1338.57$ g mol^{-1}, $\varrho_{calcd} = 1.494$ g cm^{-3}. For 4771 unique, observed reflections with $F^2 > 3\sigma(F^2)$ and 703 variable parameters, the current discrepancy indices are $R = 0.058$ and $R_w = 0.080$. b) Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54570, the names of the authors, and the journal citation.

[10] Experimental procedure for *anti*-**1**: the preparation, analytical data and FTIR spectrum of **1** are reported in Ref. [9a]. X-ray quality crystals of *anti*-**1** were obtained by slow evaporation of a methylene chloride solution in air. Crystal data for *anti*-**1** $\cdot$ 2 CH_2Cl_2 at $-45\,^{\circ}C$: monoclinic, space group $P2_1/c$ (No. 14), $a = 10.754(2)$ Å, $b = 19.466(2)$ Å, $c = 13.724(2)$ Å, $\beta = 100.74(1)^{\circ}$, $V = 2823(1)$ Å^3, $Z = 2$, $M_r = 1253.64$ g mol^{-1}, $\varrho_{calcd} = 1.475$ g cm^{-3}. For 2501 unique, observed reflections with $F^2 > 3\sigma(F^2)$ and 358 variable parameters, the current discrepancy indices are $R = 0.064$ and $R_w = 0.076$; for further details see Ref. [9b].

[11] Experimental procedure for *anti*-**2**: A slurry of $Fe(O_2CCH_3)_2$ (1.85 g, 10.64 mmol) and biphme (2.00 g, 7.08 mmol) in methanol (22 mL) was allowed to stir under argon at 50 °C for 1 hr, affording a clear, pale green solution. The volume of the solution was reduced by 50% *in vacuo*, then tetrahydrofuran was vapor-diffused into the solution, affording X-ray quality crystals of **2** $\cdot$ 2 THF (2.77 g, 71% yield) in 1 week. Correct elemental analysis (C, H, N). FT-IR (KBr): ν [cm^{-1}] = 3126, 3107, 2974, 2967, 2871, 1597 (ν_{asym} CO_2), 1500, 1448, 1417 (ν_{sym} CO_2), 1372, 1306, 1285, 1142, 1068, 989, 895, 798, 762, 723, 704, 656, 645. Mössbauer (zero field, 4.2 K) δ_1 [mm s^{-1}, versus iron metal] = 1.36, ΔE_{Q1} [mm s^{-1}] = 2.64, intensity = 34%; $\delta_2 = 1.14$, $\Delta E_{Q2} = 3.60$, intensity = 66%. Crystal data for **2** $\cdot$ 2 THF at $-75\,^{\circ}C$: monoclinic, space group $P2_1/c$ (No. 14), $a = 10.3105(8)$ Å, $b = 19.924(3)$ Å, $c = 14.009(1)$ Å, $\beta = 102.563(6)^{\circ}$, $V = 2809(1)$ Å^3, $Z = 2$, $M_r = 1230.71$ g mol^{-1}, $\varrho_{calcd} = 1.455$ g cm^{-3}. For 2590 unique, observed reflections with $F^2 > 3\sigma(F^2)$ and 358 variable parameters, the current discrepancy indices are $R = 0.043$ and $R_w = 0.056$; for further details see Ref. [9b].

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Conformational Analysis of Medium-Sized Heterocycles. Edited by *R. S. Glass*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1988. 274 pp., DM 126.00.—ISBN 3-527-26789-1/0-89573-283-1

Is there a justification for a book which, in the form of a collection of review articles, treats heterocycles with seven to twelve atoms in the ring?

In a total of six chapters some well-known authors have here attempted to give as complete as possible an overview of this topic. Chapters 2–5 deal with heterocycles having O, N, S and P atoms in the ring, and in addition there is a chapter on small cyclopeptides. The main emphases within the chapters reflect the interests of their authors, but it is apparent throughout that an effort has been made to give as complete a survey as possible, at least through the literature references.

Medium-sized aliphatic cyclic hydrocarbons can adopt many different stable conformations, and consequently several conformers are present in equilibrium in solution or in the gas phase. Nevertheless, the book makes it clear that in heterocycles, and especially in partially unsaturated compounds, there are conformational restrictions which greatly reduce the number of stable conformations.

In Chapter 1, *D. A. Case* gives a concise review (30 pages) of computational methods for determining conformations. Quantum mechanical methods are still seldom applied to medium-sized rings, partly due to the long computing times involved (for *ab initio* calculations), and partly because of the uncertainty of the results obtained (for semiempirical methods). More space is given to force field calculations, where *D. A. Case* describes, in summary at least, the most important force field computer programs, and tests their effectiveness using cyclooctane as an example. The data given on the force fields in peptides are useful; however, the treatment of Ramachandran diagrams as applied to alanine model dipeptides seems rather too detailed (even though it was of considerable interest to this reviewer), in view of the fact that on other topics the reader is only given a few references to the original papers (e.g. in the case of the "anomeric effect"). In contrast the sections on the problem of multiple energy minima are well furnished with references, although here molecular dynamics calculations are treated rather too briefly.

In Chapter 2 *F. A. L. Anet* first sets out definitions and the conformational nomenclature for medium-sized rings, then discusses cyclic hydrocarbons, followed by the additional geometrical restrictions that are imposed on the rings by oxygen atoms, sometimes combined with (partial) double bonds. He then gives a survey of O-heterocycles, arranged according to ring size, which is as complete as existing knowledge allows. The general part of the chapter is systematically set out and makes easy reading; it provides a useful introduction, not only to this chapter but also to the other parts of the book.

In Chapter 3 *R. W. Alder* and *J. M. White* deal with N-heterocycles, using a similar sequence. Especially noteworthy are the sections on transannular interactions and bicyclic N-heterocycles, which are the author's special fields of interest. The conformations of sulfur-containing cyclic compounds, including studies using photoelectron spectroscopy, are discussed by *W. N. Setzer* and *R. S. Glass* in Chapter 4. In general, however, spectroscopic methods are mentioned only briefly in the rest of the chapters, without any detailed discussion (Chapter 6 is an exception). Medium-sized rings containing phosphorus (Chapter 5 by *L. D. Quin*) are found less frequently, and could offer a large field of research in the future. In particular few medium-sized rings containing CPC units have so far been synthesized.

In Chapter 6 *V. J. Hruby* and *P. S. Hill* present a survey of cyclic tri- and tetrapeptides, peptide antibiotics and disulfide peptides. The chapter begins with a section on analytical methods (NMR, CD, IR), describing the basic features of these techniques as applied to the conformational analysis of peptides. The exclusion of larger cyclopeptides seems rather arbitrary, since these show the same conformational features, apart from the more frequent occurrence of *cis*-amide bonds and cyclol formation in the small rings.

Thus the publishers are offering here a book which brings together a heterogeneous area of knowledge from the viewpoint of ring size; this is done in such a way that, despite having different authors, a consistent picture of conformations in medium-sized rings emerges. The book draws together, from many different areas of chemistry, a wealth of information which it would not be easy to find by searching the literature directly. It is recommended for use as a work of reference by every chemist who seeks to control conformations in reactions, complexations or rearrangements, and therefore needs to be concerned with medium-sized rings.

Bioorganic Chemistry. A Chemical Approach to Enzyme Action. 2nd Edition. By *H. Dugas*. Springer, Berlin 1989. xv, 651 pp., hard cover, DM 98.00.—ISBN 3-540-96795-8

Bioorganic chemistry reached a high point in the fifties and sixties, mainly through the use of isotopes for elucidating biosynthetic pathways and enzyme mechanisms, but also through chemical synthetic work mimicking biogenesis; in the last few years it has been undergoing a powerful renaissance. The reason for this is a shift in research objectives, with a greater emphasis now on investigating the factors which influence biological processes, instead of merely aiming to describe the sequence of events, e.g. in terms of an enzymic mechanism. Recently, there have been efforts to gain a better understanding of the non-covalent interactions which play the key role in all biological processes. A whole new area of bioorganic chemistry that reaches far beyond the original concept of enzyme chemistry has been opened up by the magic phrase "molecular recognition". During the last

few years various monographs, some of them quite excellent, have appeared dealing with different aspects of this topic from a variety of viewpoints. With the publication of this second edition of "Bioorganic Chemistry" we now have a work which aims to treat the whole area in textbook style.

The same division of the material into seven chapters, as in the first edition, has been retained. However, this is a very coarse structure for the wide range of topics now covered, and leads to some unexpected classifications, such as the inclusion of the "suicide" deactivators in the chapter on coenzymes.

Chapter 1 provides a good introduction outlining some basic principles, although it includes the misleading comment that bioorganic chemistry began only in the 1950s with the work of *F. H. Westheimer* (on this side of the Atlantic the biomimetic syntheses carried out by *Clemens Schöpf* and *Sir Robert Robinson* in the twenties are still well remembered). However, this discussion has been kept very short (22 pp.) and consequently it is unavoidably superficial. The following chapters on amino acids and peptides (86 pp.) and on phosphate esters and polynucleotides (60 pp.) not only treat these topics comprehensively, from the basic features of peptide and phosphate ester chemistry through to the biosynthesis of the corresponding polymers, but also include interesting sections on newer and very recent developments such as catalytic antibodies, semisynthetic enzymes and DNA-intercalating compounds. Chapter 4 (enzyme chemistry, 91 pp.) and Chapter 5 (enzyme models, 136 pp.) form the core of the book. In Chapter 4 the author first defines and explains the use in this context of terms such as "catalysis" (although even in this latest textbook we find the frequently used expression "intramolecular catalysis", which is incompatible with the definition of catalysis given earlier), "prochirality" and "specificity". Examples of actual enzyme reactions are then discussed, followed by short sections on enzyme technology (including immobilization) and the increasingly important use of enzymes in organic synthesis.

The sections that are also included here on enzyme-analog-built polymers and on the construction of non-macrocyclic molecular clefts could more appropriately have been added to the next chapter on enzyme models. These describe all the important strategies and design approaches whose common denominator is the mimicking of biological host-guest relationships. As well as recent developments based on the now already classic cyclodextrin and crown ether parent structures, the discussion also includes systems without a precisely defined structure (functionalized polymers and micelle-forming species). Also noteworthy is the treatment in this chapter of biomimetic reactions which, although they are models for biological specificity, do not need a molecular host; these include polyene cyclizations and functionalizations at non-activated steroid sites.

Chapter 6 is concerned with models that mimic the role of metal ions in biological processes. The ions of the transition metals Zn, Fe, Cu and Co are treated in turn; for these artificial systems, some of which seem very contrived, the ions are mainly introduced using porphyrin ligands. The simulation, using cobalt complexes, of enzymic reactions that depend on vitamin B_{12} links up with Chapter 7, which is devoted to the chemistry of coenzymes. This classic field of bioorganic chemistry is here subdivided according to the functions and structures of the coenzymes (redox enzymes: NAD, flavine etc.), and the most recent findings concerning reaction mechanisms and model reactions are described by means of well chosen examples. However, no reference is made to the wide variety of new coenzymes obtained from methanogenic bacteria (methanofuran, methoxatin, factor F_{430} etc.), for which details of the reaction mechanisms as well as some model reactions are already known.

These omissions are not very serious when one considers the wealth of information that is here very well presented, in both textual and diagrammatic form. Nevertheless, it is clear that the limitation of bioorganic chemistry to the chemistry of enzymes, and therefore also the book's subtitle, is obsolete and does not adequately describe the subject.

"Bioorganic Chemistry" is certainly not a textbook in the popular sense, as the emphasis is less on general principles and "proven" knowledge than on illustration by examples. This is no doubt intentional, and as a result the book makes stimulating reading. However, one would have preferred the author of such a textbook—especially one on an interdisciplinary topic like this—to be bolder in critically evaluating the material and expressing his opinions. This applies especially to situations where there is controversy between alternative approaches, which are here simply not mentioned. The reductionistic approximation for bioorganic systems, although it is currently by far the most successful approach to understanding the action of enzymes, is by no means the only one, or even the only useful one.

Despite this criticism, *H. Dugas* has succeeded in producing a book which clearly describes the beauty and subtlety of both living and abiotic molecular architecture. As well as the readership for whom the book is mainly intended (i.e. advanced students), I can warmly recommend it to everyone who seeks a comprehensive account, at a moderate price, of current front-line developments in this highly topical field of research.

Fundamentals of Molecular Spectroscopy. By *W. S. Struve*. Wiley, Chichester 1989. 379 pp., hard cover, £ 31.95.—ISBN 0-471-85424-7

A good training in the fundamentals of molecular spectroscopy is important for all chemists and for many physicists and biologists. Several generations of young scientists have grown up with *Herzberg*'s three-volume classic work "Molecular Spectra and Molecular Structure", Volume 1 of which was originally published in German in 1939 (*Molekülspektren und Molekülstruktur*, Steinkopff Verlag). *Herzberg*'s books are still unsurpassed in scientific thoroughness and depth of treatment. Moreover, it is pedagogic masterpiece because of the many well chosen examples and the clear, usually simple, manner of presentation. However, the third and last volume was published as long ago as 1966, and since then the books have not been revised (except for the publication of a supplementary volume of tables, K. P. Huber and G. Herzberg: *Constants of Diatomic Molecules*, van Nostrand, 1979). Since 1966 great developments have taken place in molecular spectroscopy. On the experimental side Fourier transform spectroscopy and laser spectroscopy have become well established, while on the theoretical side quantitative quantum chemical calculations have become possible, developments which one could at best only have guessed at in 1966. Thus, there has for some time been an urgent need for up-to-date textbooks on molecular spectroscopy. This has now been partly covered, e.g. by the textbooks of Kroto: *Molecular Rotation Spectra*, Wiley, 1975, and Hollas: *High Resolution Spectroscopy*, Butterworth, 1982, both of which can be recommended in this context.

The book by *W. S. Struve* is based on lectures to American graduate students between 1974 and 1987; in Germany this level corresponds approximately to the final semesters of the diploma course and to special lecture courses for Doktoranden (post-graduate students), although the latter courses are now often neglected, unfortunately. Radiative transitions are treated first in an elementary way, followed by atomic spectra (40 pp.), diatomic molecules (90 pp.), polyatomic molecules (100 pp.) and, in the concluding chapters, line shapes and intensities, lasers, two-photon processes and non-linear optics. The treatment is generally competent and appropriate for teaching purposes. The book as a whole is comparable with the corresponding chapters of typical physical chemistry textbooks, but goes a little further. However, it is disappointing to find some quite outdated material, and the coverage of recent developments is very incomplete. Thus, there are examples of IR spectra of HCl from around 1960, and the information that the student will gain from this book concerning the development of techniques such as FT-IR spectroscopy is hardly adequate. Furthermore, in discussing the theory of molecular spectra there is no mention of such an important aspect as the development of the concept of molecular symmetry groups by *Longuet-Higgins, Hougen* and *Watson*, which was already mentioned as a new development in 1966 in Volume 3 of "Herzberg", and about which a textbook (by *P. R. Bunker*) has been in existence for ten years. Also some other developments belonging to the "post-*Herzberg*" era, such as *Watson*'s theory of the spectra of asymmetric rotor molecules and many other topics, are only mentioned in passing. On the other hand, some new special techniques (CARS and others) are treated in Chapter 11.

In summary one may say that this book by *W. Struve* is suitable for the bookshelves of a university teacher preparing a lecture course on this subject, and it should also be available as a rule in departmental libraries.

Electrochemical Reactors, Their Science and Technology. Part A: Fundamentals, Electrolysers, Batteries and Fuel Cells. Edited by *M. I. Ismail*. Elsevier, Amsterdam 1989. xviii, 548 pp., hard cover, HFl 265.00.—ISBN 0-444-87139-X

This book is the first of three volumes with the general title "Electrochemical Reactors". As the series editor explains in the preface, Volume A deals with the basic principles of electrochemical reactors and with batteries and fuel cells, Volume B will deal with special types of reactors, and Volume C with production techniques for commercial reactors and mathematical modeling of the processes occurring in electrochemical reactors. The series is intended for both specialists and students.

The first volume contains a short general introduction to the field, followed by 14 longer articles in which recognized experts report on the current state of knowledge in individual areas. These deal with fundamental aspects (thermodynamics, electrode kinetics, transport of heat and matter, flow mechanics), with more general considerations (concepts used in describing electrochemical processes, general technical problems, regulating systems) and with special aspects (electrodes, electrolytes, diaphragms, materials of construction, process control systems). Batteries and fuel cells are treated in separate articles.

The quality of the individual contributions strikes the reviewer as being just as heterogeneous as the impression given by the overall visual appearance of the book. They range from very good review articles (e.g. those on thermodynamics and electrode kinetics) to tabulated compilations of equations with virtually no discussion (as in the article on transport of heat and matter). Also the SI system is not employed universally.

The articles on fundamentals can be recommended as an introduction for newcomers to the extensive field of electrochemical processes, and experts will value the comprehensive bibliography provided. The book will be hindered from reaching a wider readership by the weaknesses mentioned above, and more especially by its high price, which the poor visual appearance (with typography and figures which are sometimes difficult to read) does nothing to counteract.

Thomas Hahn [NB 1044 IE]
Institut für chemische Verfahrenstechnik
der Universität Karlsruhe (FRG)

The Chemistry of Soils. By *G. Sposito*. Oxford University Press, Oxford 1989. 277 pp., hardcover, £ 25.00.—ISBN 0-19-504615-3

The declared aim of this book is to develop soil chemistry from the level of purely qualitative description into an exact science which makes use of all available techniques, ranging from spectrometers to computer modeling. This means that it should not only meet the needs of modern agriculture, but should also provide a basis for understanding and solving many environmental problems. The reader who already has the necessary basic knowledge of soil science, mineralogy and chemistry will find here an interesting textbook, which deals in the first few chapters with the chemical composition of soils, then goes on to describe soil chemical processes, and finally discusses questions of acidity, salt excess and fertility.

Starting from the elemental composition of soils, the mineral constituents and trace elements are discussed. The three-phase system consisting of soil solids, soil air and soil water leads on to the stages in weathering. In discussing the inorganic constituents those which mainly feature are, of course, ionic solids, primary silicates and clay minerals, oxides and hydroxides, carbonates and sulfates. Coming to the organic soil constituents, the account of humus-related problems is concise but very instructive. However, the interactions with organic trace impurities are not treated in sufficient detail; for example, pesticide-related problems are an important topic which could usefully have been included. The topic of soil solvation begins with a brief discussion of sampling methods, then continues with the most important equilibria and calculations on these. Solubility calculations are given for several minerals, and the corresponding activity-partition diagrams are developed. Under electrochemical properties the pE concept (including pE–pH diagrams), redox reactions, relevant measurement techniques and conditions in water-saturated soils are included. The characteristics of the particle surface are discussed in terms of the functional groups present, the adsorption equilibria, surface charges, the points of zero charge and the adsorbed water. The treatment of the effects of adsorbed cations, anions and molecules is extended to include descriptions of batch and column experiments, together with thermodynamic and kinetic modeling of the processes. The range of functionalities that occur

in soils is completed by discussions of ion exchange mechanisms and their quantitative treatment, together with colloid chemistry aspects and models related thereto. The chapters concerned with applications include the acidification of soils, with the main emphasis here on proton cycles, dissolved aluminum compounds, redox effects and methods for neutralizing soils. Next salt excess is discussed, including definitions, ion exchange processes, boron chemistry and irrigation problems, followed by soil fertility, including investigations on both essential and toxic elements, with sections on bioavailability, the kinetics of nutrient uptake by plants, and the effects of the pH and pE values.

The value of this comprehensive work from a learning standpoint lies in the clear diagrams and formula schemes, the comprehensive literature references (up to 1987), and the numerous exercises included in the individual chapters. The emphasis placed on calculations and modeling throughout the range of topics covered is extremely valuable. However, in cases where insufficient basic data are available for this purpose, the reader is unfortunately not helped to determine these by experiment.

A useful appendix lists units and physical constants used in soil chemistry. Regrettably there is no list of the numerous symbols and abbreviations that appear in the text. The provision of a comprehensive index and seven blank pages for notes reinforce the impression of a typical American style student textbook. The book can be recommended for everyone with an interest in soil science. For university teachers it will provide valuable additional class material, and it will enable students to rapidly become familiar with modern methods of treating problems in soil science. The style and presentation of the book are exemplary.

Fritz H. Frimmel [NB 1038 IE]
Lehrstuhl für Wasserchemie
der Universität Karlsruhe (FRG)

The Chemistry of Antitumor Antibiotics. Vol. 2. By *W. A. Remers*. Wiley, New York 1988. 290 pp., hard cover, £ 31.95.—ISBN 0-471-08180-9

This series, which was begun in 1979 by the same author, is now continued with the publication of Volume 2. It consists of seven chapters, each dealing with a further antitumor antibiotic isolated from microorganisms. This volume does not contain any extension or updating of the material covered in Volume 1, which reported on actinomycins, anthracyclines, the aureolic acid group of antibiotics, bleomycins and phleomycins, together with mitomycins and porphyromycins. This is not a serious omission, since there are enough up-to-date review articles and proceedings of symposia.

The antibiotics covered in this second volume are: streptozocin; pyrrolo-1,4-benzodiazepines; saframycins, renieramycins and safracins; naphthyridomycins, cyanocyclins and quinocarcin, CC-1065, nogalamycin and related compounds, and lastly streptonigrin and lavendomycin.

Each chapter is divided into six sections: discovery, isolation and characterization, structure determination and chemical transformations, mechanism of action, synthesis, biosynthesis, and structure-activity relationships. The efforts involved in the development of cytostatic agents, often extending over long periods, and all the problems associated with indications in view of the narrow dividing line that exists between high antitumor activity and unacceptable toxicity, are vividly described.

The author notes critically that biological data from different laboratories are often not comparable. He also emphasizes that difficulties often arise in transfering results from animal tests into the clinical situation, owing to the highly species-specific nature of tumor diseases. Regrettably, though, there is no explicit mention of the changes that have been introduced into preclinical testing methods in the last decade, mainly in the pharmaceutical industry, and recently also at the US National Cancer Institute (NCI); these involve using human tumors at a very early stage instead of animal tumors, both in cell cultures and as implants in experimental animals.

Current ideas regarding molecular activity mechanisms and structure-activity relationships in antitumor antibiotics are thoroughly discussed, and experimental models and results are clearly described. The only exception is Figure 5.2 (p. 155), showing a stereopair for a CC-1065-DNA adduct, which can only be understood with difficulty. The chemical synthetic work is illustrated by reaction schemes which are very clear and well drawn. In addition, the history of the discovery of each antibiotic, the problems arising in fermentation, the process of isolating it and the determination of the structure (including many figures showing spectra), the question of side effects, and last but not least, analytical aspects, are very well described.

The index is comprehensive and clear; a particularly good feature is the ability to search using group and generic names. Unfortunately, though, adriamycin, which is widely used as a standard compound and mentioned as such in the text, is not in the index. One does not expect to find an exhaustive list of all the many names that are used in the literature for a given antibiotic, due to the fact that in many cases it was independently discovered and named in several different places; however, for such an important compound as CC-1065 the alternative name "Rachelmycin" which occurs in the literature ought to have been mentioned. The text makes easy reading, and the incidence of printing errors, most of which do not alter the meaning, is in accordance with modern standards.

The treatment of the various topics is balanced, and the information given is sufficiently comprehensive to benefit even specialist readers. The coverage of the original literature which the book provides is considerable, the most recent references being to work published in 1988. If it appears that the bibliography is predominantly weighted towards American and Japanese research groups, this is, regrettably, a true reflection of the present distribution of research activity on the chemotherapy of tumor diseases. Some random checks indicated that the author has carefully surveyed and evaluated the literature.

Readers with a chemical background will probably find the accounts of synthetic research of most interest; such work has in many cases led to wide departures from the natural product originally discovered, as is convincingly demonstrated by the example of CC-1065. As the quantities of material that need to be produced, even for clinical applications of antitumor agents, are usually only in the region of a few kilogrammes, it is quite appropriate to use relatively expensive modern synthetic methods; the quantities needed for preclinical testing and for characterization are often surprisingly small.

Although the likely source of the next generation of clinically usable antitumor agents is still an open question, it seems highly probable that natural products will play an important role. Books such as that reviewed here can exert a beneficial influence on progress in this respect. Unfortunately, the reviewer has no information on how wide a readership

has been achieved by the first volume in this series; however, by reason of their content and presentation both volumes deserve to be widely read, especially as the price seems reasonable. As the present book treats all aspects of the subject equally thoroughly, it can be recommended both as an introduction and as more advanced reading for those engaged in the research areas covered.

Hans Gerd Berscheid [NB 1023 IE]
Frankfurt/Main (FRG)

Flow Injection Atomic Spectroscopy. (Series: Practical Spectroscopy, Vol. 7). Edited by *J. L. Burguera*. Marcel Dekker, New York 1989. 353 pp., hard cover, $125.00.— ISBN 0-8247-8059-0

In this book, the 7th volume in the "Practical Spectroscopy" series, the editor and the authors have succeeded in producing a concise, comprehensive work on the principles and applications of flow injection analysis (FIA) in atomic spectroscopy. The experimental aspects and practical hints occupy more space in the book than the theory, an emphasis which is opportune and appropriate at this time, but nevertheless the theory is not neglected.

The quality of printing and presentation is excellent, and the many clear figures and tables make for easy understanding of the main text. Although there are considerable variations in the style of the contributions by different authors, a consistently high quality is maintained throughout.

Chapters 1–3 deal with general and theoretical aspects of the method (including the introduction of the physical quantities used to describe the technique) and instrumental considerations, whereas Chapters 4 and 5 are devoted to the main areas of application of FIA in atomic spectroscopy. Chapters 6 and 7 provide those using the technique in the special fields of environmental and clinical analysis with advice on many aspects and methods for solving practical problems. Lastly Chapter 8 offers a critical appraisal of FIA, together with many stimulating ideas for the further development of instruments and techniques.

However, at this point one must mention the one drawback of this otherwise commendable book. Chapter 1, "General Introduction", fails to do full justice to its subject. The author, instead of aiming his article at beginners in the FIA technique, has chosen to discuss at some length the everyday problems encountered in using the FIA method. Only readers already familiar with FIA are likely to understand this chapter; the spectroscopist who wishes to begin using the method and needs an introduction to it is badly served by the article.

The rest of the articles are all good, and I especially recommend those interested to read Chapter 3, "Basic Components and Automation" by *J. F. van Staden*, Chapter 4, "Analytical Methods and Techniques" by *Z. Fang*, and Chapter 5, "Separation Techniques" by *M. Valcarel* and *M. Gallego*. The book is worth buying for these three fundamental chapters alone, which are recommended not only for advanced readers but also for beginners in the FIA-AS method. They enable one to quickly become familiar with the many different valve systems, instrumental arrangements, sample preparation methods and other options which make the FIA method so useful to the spectroscopist.

Chapters 6 and 7 offer the experienced FIA user much advice regarding the special problems encountered in environmental and clinical analysis, and these two chapters alone contain over 140 literature references. Despite its apparent brevity, the character of the book is in fact more that of a work of reference than of a collection of review articles, as the treatment of the subject is so masterly and concise. It contains altogether more than 700 literature references, covering publications up to 1987 in all but a few cases.

Because of its clear structure and the high quality of the individual articles, the book will be an excellent aid to becoming familiar with the subject and for work planning, both for newcomers to this interesting area of application of flow injection analysis and for those already experienced in the method. One can therefore do no more than advise potential readers not to be deterred from buying this very interesting and informative book by the rather high price of $ 125.00 ($ 150.00 in Europe). It is definitely worth it!

Lehrstuhl für Analytische Chemie
der Universität Münster (FRG)

Modern Synthetic Methods. Volume 5. Edited by *R. Scheffold*. Springer, Berlin 1989. 304 pp., paperback, DM 78.00.— ISBN 3-540-51060-5

Following the established sequence of triennial meetings, the 5th International Seminar on Modern Synthetic Methods took place in Interlaken on 27–28 April 1989. It was held under the auspices of the Schweizerischer Chemiker-Verband, and was organized by Prof. *R. Scheffold*. This seminar-type conference can always be relied on to turn out successfully. The form is based on presentations of topical themes by a few leading researchers, each reporting comprehensively on his or her special subject, including the most recent developments, from as practical a standpoint as possible.

To enable others as well as the participants to benefit from the seminar, the papers presented are here collected together, as for the previous meetings, in a book with the ambitious title "Modern Synthetic Methods"; this is the fifth such publication since 1976. The general theme of this meeting was catalysis; a wide range of topics was covered under this heading, as is evident from the titles of the contributions: "Biotransformations in Organic Synthesis" by *D. H. G. Crout* and *M. Christen*; "Enantioselective Catalysis with Metal Complexes: An Overview" by *R. Noyori* and *M. Kitamura*; "Enantioselective Catalysis with Chiral Cobalt and Copper Complexes" by *A. Pfaltz*; "Clays, Zeolites and Other Microporous Solids for Organic Synthesis" by *J. M. Thomas* and *C. R. Theocharis*. All the papers include typical laboratory recipes and detailed lists of literature references. It can be seen that the range of topics extends from tailored inorganic catalysts through organometallic compounds to biocatalysts.

Within the broad field of biotransformations the authors have confined their discussion to well established methods with general applicability. Reactions that can be carried out using esterases, lipases and proteases are described in detail, as are those using redox enzymes, especially baker's yeast. Particular enzyme-catalyzed syntheses that are described are those of amino acids, amides, peptides, glycosides and oligosaccharides. Important applications of enzymes for the formation or scission of C-C bonds are also discussed.

Coming now to the contributions on enantioselective catalysis with metal complexes, *Noyori* and *Kitamura* give an excellent review of this rapidly growing field and the recent fascinating developments that have occurred, while *Pfaltz*, taking as an example his highly promising semicorrin com-

plexes with C_2 symmetry, offers an interesting detailed insight into the development work needed to achieve spectacular successes of this kind.

The last contribution in the book describes the structures of zeolites and ways of modifying them for specific purposes, then indicates how they can be used for organic syntheses; up to now these have been used mainly on an industrial scale for producing basic chemicals.

Altogether the book is a very useful guide to the subject of catalysts in organic synthesis, which has a promising future; in particular it offers beginners a straightforward introduction to this field. All the articles are competently written and thorough, and are therefore likely to be frequently cited. It would be difficult at present to find other reviews presenting the current state of knowledge in such a concentrated form. One can only hope that the price, which has increased further to DM 78.00—too much for a paperback in my view—will not prevent this interesting book from reaching a wide readership that will include students.

Nucleotide Analogues as Antiviral Agents. (ACS Symposium Series, Vol. 401). Edited by *J. C. Martin*. American Chemical Society, Washington, DC (USA) 1989. viii, 190 pp., hard cover, $ 53.95.—ISBN 0-8412-1659-2

This book is a collection of papers presented at a symposium held on the occasion of the 196th meeting of the American Chemical Society in September 1988. As the editor notes in his introduction, efforts to develop antiviral nucleoside and nucleotide analogues as an answer to the AIDS epidemic have been greatly increased in the last few years. The majority of the nucleoside analogues used up to now, of which 3′-azidothymidine and 9-(hydroxyethoxymethyl)guanine (Acyclovir) are the two most important, are effective in the form of 5′-triphosphates. The phosphorylation proceeds via three steps, one of which is often a bottleneck—for example, in the case of azidothymidine this is the phosphorylation of the 5′-monophosphate to the diphosphate. Thus it already became apparent some time ago that, instead of nucleoside analogues, one might try to introduce nucleotide analogues with potential antiviral activity into the cells. Since one of the obstacles to the uptake of nucleotides is that they can be broken down by enzymes in the plasma membrane, phosphate analogues that cannot be broken down in this way seem to offer especially good chances for successful uptake. Consequently several chapters of the book are mainly concerned with results obtained using the stable phosphonate derivatives. In addition, however, there are separate chapters dealing with other derivatives, e.g. with nucleoside-5′-amines and -acetamides (Chapter 7), nucleoside-5′-sulfamates (Chapter 9), nucleotide dimers (Chapter 11) and oligonucleotides (Chapter 12).

As the book is a collection of articles by different authors, the quality of the contributions varies. For example, some contain unnecessarily extensive tables (pp. 10, 57, 60, 61 and 67) which make it difficult for the reader to distinguish essentials from non-essentials. Also very often the absence of compound names under their structural formulas—where these are given—is confusing, as it makes it difficult to quickly relate them to the text. The book is evidently intended for experts, for whom the meanings of the many abbreviations are obvious, and who will know, for example, that DHPG, which incidentally does not appear in the index, is identical to Ganciclovir. As is often the case in symposium proceedings, every article stands alone and no account is taken of other articles with which there is an overlap of subject matter or an amplification of a topic, as, for example, in contributions 4 and 5 which deal with the compounds 9-(2-phosphonylmethoxy)ethyladenine (PMEA) and 9-(2-phosphonylmethoxy)ethylguanine (PMEG). No doubt in order to produce this symposium volume as cheaply as possible, the text is very closely printed throughout, and this has not exactly made the book user-friendly. Also it seems a little strange that in the index entries referring to azidothymidine are found not only under this abbreviated name but also under "3′-azido-2′,3′-dideoxythymidine".

In addition to the more general discussions the book contains a few items of information which I found especially interesting, not least because they could provide a stimulus for future experiments. For example, it is remarked on pages 80 and 85 that phosphonate derivatives often show higher *in vivo* than *in vitro* activity. Unfortunately no further commentary on this is given. Another interesting result reported but not explained further is that some phosphonate alkyl esters also show antiviral activity (p. 32).

This book is the first of its kind on antiviral nucleotide analogues. Although none of the compounds discussed here has yet been cleared for clinical use, it becomes evident from reading the book that this is a class of compounds with great potential, and that further systematic research on these is justified. Despite the shortcomings mentioned, the book provides a good basis of material for the specialist.

Nitration. Methods and Mechanisms (Organic Nitro Chemistry Series). By *G. A. Olah, R. Malhotra*, and *S. C. Narang*. VCH Verlagsgesellschaft, Weinheim, VCH Publishers, New York 1989. xii, 330 pp., hard cover, DM 145.00.—ISBN 3-527-26698-4/0-89573-144-4

The third volume to appear in the Organic Nitro Chemistry Series, this book deals exclusively with aspects of nitration in organic chemistry. In keeping with the preceding two volumes (*Nitrazoles* and *Nitrile Oxides, Nitrones and Nitronates in Organic Synthesis*), it provides a broad survey of the subject, encompassing in four chapters many of the methods and mechanisms for the nitration of aromatic and aliphatic compounds.

After a brief introduction in Chapter 1 (8 pages, 21 literature citations), the authors go on in Chapter 2 (108 pages, 264 literature citations) to describe preparative methods for aromatic nitration. Numerous examples of the great many reagents used for nitrating arenes appear mainly in tabular form, accompanied in the text by the corresponding methods.

The authors have devoted a great deal of space in one section of Chapter 2 to nitration with nitronium ions; unfortunately, the examples in this section are not as complete as those from the section on nitration with nitric-sulfuric acid (isomer-distribution data). Although this format does not allow for comparison of aromatic nitration methods by way of example, it gives the reader a good, comprehensive overview. Some neglect is also apparent in the cursory treatment of homolytic (i.e., free-radical) and, more importantly, nucleophilic nitration, considering the significance of these

topics. One other disturbing feature of this chapter is the citation of patents in the reference section with no reference to the appropriate Chem. Abstr. Citation.

Chapter 3 (101 pages, 160 literature citations) is divided into three sections, covering mechanisms for electrophilic, free radical, and nucleophilic nitration of arenes. These fully detailed sections provide insight into the current level of understanding of nitration mechanisms. As in Chapter 2, however, the discussion of nucleophilic nitration is somewhat short (2 pages) compared to the coverage of electrophilic nitration.

In Chapter 4 (92 pages, 269 literature citations) the nitration of aliphatic compounds is surveyed. Here again, well-arranged examples accompany the text. The book ends with author and subject indexes that leave no stone unturned.

At this high price, one would have expected better-quality structural formulas. Nevertheless, this third volume of the series on nitro compounds, like its predecessors, merits recommendation.

Symmetrien der Natur. Ein Handbuch der Natur- und Wissenschaftsphilosophie. By *K. Mainzer*. De Gruyter, Berlin 1988. 739 pp., hard cover, DM 365.00.—ISBN 3-11-011507-7

Most important are those areas of pure science in which there is no longer a mention of practical applications, but where pure thought investigates the hidden harmonies of the universe. This inner circle, where one can hardly distinguish between science and art, is perhaps the only place where humanity today is confronted with pure truth, that is no longer veiled by human ideology and desires.

W. Heisenberg

Among his contemporaries in the development of the "new physics" during the early decades of this century, it was particularly *W. Heisenberg* who pointed out the fundamental importance to physics of abstract symmetry (i.e. symmetry in a general sense, not only geometrical). This importance is now universally accepted, and is part of the common knowledge of every young physicist and chemist. Furthermore, we now regard symmetry as providing a fascinating link between very different fields of human thought and knowledge. There have thus been many minor and major attempts to treat this subject in book form.

This book by *Klaus Mainzer* occupies a special position in view of its comprehensiveness, exemplary depth, and thoroughness. In the words of the subtitle, it is in fact a "handbook on natural philosophy and science". In over 700 pages it treats, or at least touches on, almost every aspect of this theme. Its five chapters are arranged as follows: 1. The early history of symmetry; 2. Symmetry properties in modern mathematics; 3. Symmetry properties in classical physics and natural philosophy; 4. Symmetry properties in modern physics and science; 5. Symmetry and philosophy (also art and architecture). The book also includes a comprehensive bibliography and index, which serve as an encyclopedic guide to specific topics, specific facts, people, and historical aspects. It would be useful to enlarge the index in future editions so as to increase still further the value of the book as an "encyclopedia of symmetry".

It would not be appropriate in this short review to try to summarize the contents of this comprehensive work. The book combines many functions, being at the same time an encyclopedia, a textbook and an intellectually stimulating entertainment. There is scarcely a single aspect of the subject on which one fails to find a chapter, or at least a brief comment with literature references. Whole chapters of the book can be used by the student who needs an "introduction to symmetry for chemists" (or for physicists, mathematicians etc.). Perhaps the most remarkable comment I can offer is that, in avoiding the effort of "textbook-reading" I have read many of the book's 700 pages for pleasure and relaxation and was never bored. This is literary writing for scientists in the best possible sense.

Let us cite two sentences from the introduction to *Mainzer*'s book: "In the end, therefore, there remains the need to achieve an understanding of nature which will enable Man to act in harmony with nature, even more so because of his scientific knowledge and technological capabilities. For this reason the traditional approach of the philosophy of nature, which views research as part of human history and nature, is becoming again an important component of a scientific education".

"Symmetrien der Natur" could and should be used as a textbook of general scientific education by all science students, and is also basically suitable for students of the philosophically orientated humanities. Regrettably, the very high price, which is only partly justified by the excellent quality of production and presentation, is likely to prove an obstacle to this readership. One can therefore only hope that "Symmetrien der Natur" will achieve enough sales to persuade the publishers soon to bring out a second edition at a lower price. Meanwhile, I recommend to all who can afford it to buy the book. They will not regret it.

Patai's Guide to the Chemistry of Functional Groups. By *S. Patai*. Wiley, Chichester 1989. 455 pp., hard cover, £ 24.95.—ISBN 0-471-91256-2

In the well-known series "The Chemistry of Functional Groups", 40 titles were published up to the end of 1988, comprising 59 volumes with over 700 chapters and more than 43 000 closely printed pages. In the book reviewed here the series editor *S. Patai* has set out to provide an overall picture of this impressive amount of material, to accompany the immense stack of volumes that he has edited. So as to make the information contained in this monumental series more readily accessible, *Patai* has taken up a suggestion by *H. C. Brown*, providing a 455-page summary of the entire work with a detailed description of what the volumes contain.

The contents of the individual chapters are here described, including important information such as the number of pages, number of literature citations and the period that they cover, and the nature of the tables, formula schemes etc. that are included. This goes far beyond a mere summary of the list of contents for each volume; *Patai* also summarizes the most important chemical results, supported by many formulas. As well as the author and subject indexes he also includes two very useful sorts of cross-references: "complementary" cross-references, which refer to descriptions of *the same*

functional group in other volumes, and "relevant", referring to similar types of reactions for *other* functional groups.

The need for such a summary arises from the structure of "Patai": some overlapping of the material is unavoidable in view of the self-contained and monographic character of the chapters. This book is an effective guide to the series.

der Technischen Universität Braunschweig (FRG)

The Elements—Their Origin, Abundance and Distribution. By *P. A. Cox*. Oxford University Press, Oxford 1989. viii, 207 pp., paperback, £ 9.95.—ISBN 0-19-855298-X

The reader interested in buying this book should not allow him- or herself to be irritated by the symbols used for the elements and compounds, which seem reminiscent of alchemy. Notwithstanding the historical references in the book, *P. A. Cox*, a senior lecturer in inorganic chemistry, is concerned here not with the history of chemistry, but instead gives an interdisciplinary account of the origin, abundance and distribution of the elements and of their physical and chemical properties. The special feature of this book of six chapters is the interdisciplinary treatment of the various topics, which range from the chemistry of the sun and the universe (Chapter 4) and geochemistry (Chapter 5) to isotopic distributions (Chapter 6) and the chemical and physical properties of nuclei and atoms (Chapter 2).

Chapter 3 deals with the origin of the elements, beginning with a description of the universe in early times and the formation of the stars. This is followed by detailed accounts of the fusion of hydrogen and of helium. Excellent summaries and references to more advanced literature (with brief descriptions indicating what these books contain) are given at the end of each chapter. Chapter 1 contains a short introduction to the Periodic System, and to the elements of the earth, solar system and universe, and discusses the factors that determine the occurence and distribution of the elements.

The book is intended for first and second year students and for those teaching these groups. In the preface *P. A. Cox* states that the main aim in this book is to trace the history of the elements from their origin in the cosmos to their occurrence as minerals. In the course of this he also brings in knowledge from nuclear physics, astronomy and geology. The introductory character of the book, which is based on the author's lecture courses, is maintained by the easily comprehensible style and by a suitable form of presentation, which includes an orderly arrangement of topics and appropriate historical aspects (e.g. the historic experiment of *Geiger* and *Marsden* as described on p. 27), theories, figures and tables, with important terms emphasized by bold type.

The student is familiarized with the relationships and terminology that are important for a basic course, without going into excessive detail. Nevertheless, the topics are not treated too briefly, as can be seen by comparing the chapter on "The Origin of the Elements. Isotopes and Atomic Masses" in "Greenwood and Earnshaw", which consists of 25 pages of text, with the 36 pages devoted to the same topic in "Cox", even though the latter has about 20% fewer characters per page. The appendix contains tables giving isotope distributions and data on the occurrence of the elements (in the earth, sun, meteorites, earth's crust, the oceans and the human body), information which could otherwise only be obtained by searching through several other books. In summary this book seems to me well worth reading and recommending to students, especially when one considers that it is written in easily comprehensible English and has an interdisciplinary character which is becoming increasingly important.

Syntheses, Conformations and X-Ray Structure Analyses of the Saccharide Chains from the Core Regions of Glycoproteins

By Hans Paulsen*

The covalently bound carbohydrate moiety in glycoproteins can stabilize the protein molecule intramolecularly, or it may have an intermolecular function as receptor in biological recognition. The discovery of these biological phenomena has led to a renaissance of the chemistry and biochemistry of carbohydrates. Both *N*-glycoproteins as well as *O*-glycoproteins contain special, invariant oligosaccharide chains in the protein-binding region, which occur again in all glycoproteins, and are described as the "core regions." This review describes the various methods of oligosaccharide synthesis that may be used to arrive at the basic core structures by chemical means. Methods of oligosaccharide synthesis have improved so much that it is possible to synthesize complex lactosamine-type structures, and "bisected"-type structures up to nona- and undecasaccharides respectively. Oligosaccharide chains are considerably less flexible than peptide chains. Using modern methods of NMR spectroscopy, their preferred solution conformation can readily be determined. In the case of one branched octasaccharide, a comparison of the conformations in solution and in the crystal is possible. Oligosaccharides may be linked to the amide group of an asparagine, or to the hydroxyl groups of serine or threonine. By using suitable protecting groups, the glycosyl amino acids obtained can be extended with further amino acids at the *N*- or *C*-terminus, thus arriving at the desired glycopeptide sequences. In the linkage region, glycopeptides prefer certain conformations. Future research into glycoprotein functions may involve the synthesis and biochemical study of modified glycoprotein segments.

1. Introduction

The enormous growth in interest in glycoproteins over the past decade is not without reason. Glycoproteins contain highly variable amounts of saccharide (up to $> 85\%$).[1, 2] Thanks to improved analytical techniques, carbohydrate residues have now also been found in compounds which were earlier considered to be pure proteins. Carbohydrate residues can influence the stability, conformation, protease lability, thermal properties, and solubility of proteins. Glycoproteins are found in soluble form in blood and in numerous secretions, and in a fixed state in the bilayer of the membrane,[3, 4] where the carbohydrate residue is extracellularly directed. In both cases the carbohydrate moiety performs important functions. This is especially true for the specific receptor interaction with functional proteins. Glycoproteins are active in the binding and transport of enzymes, hormones and antibodies, and in cell-cell interactions.[7, 8] The carbohydrate moiety can bind hormones, enzymes, antibodies and lectins, but also toxins, viruses, and bacteria. In this connection the reader is referred to the relevant review articles.[1–8]

The most important chemical forms of the linkage between the protein and oligo- or polysaccharide chains are of two types,[1] which also differ in their biosynthesis. In *N*-glycoproteins, one finds a β-*N*-glycosidic linkage between 2-acetamido-2-deoxy-D-glucose (GlcNAc) and the amide group of an asparagine side chain. Because of its amide na-

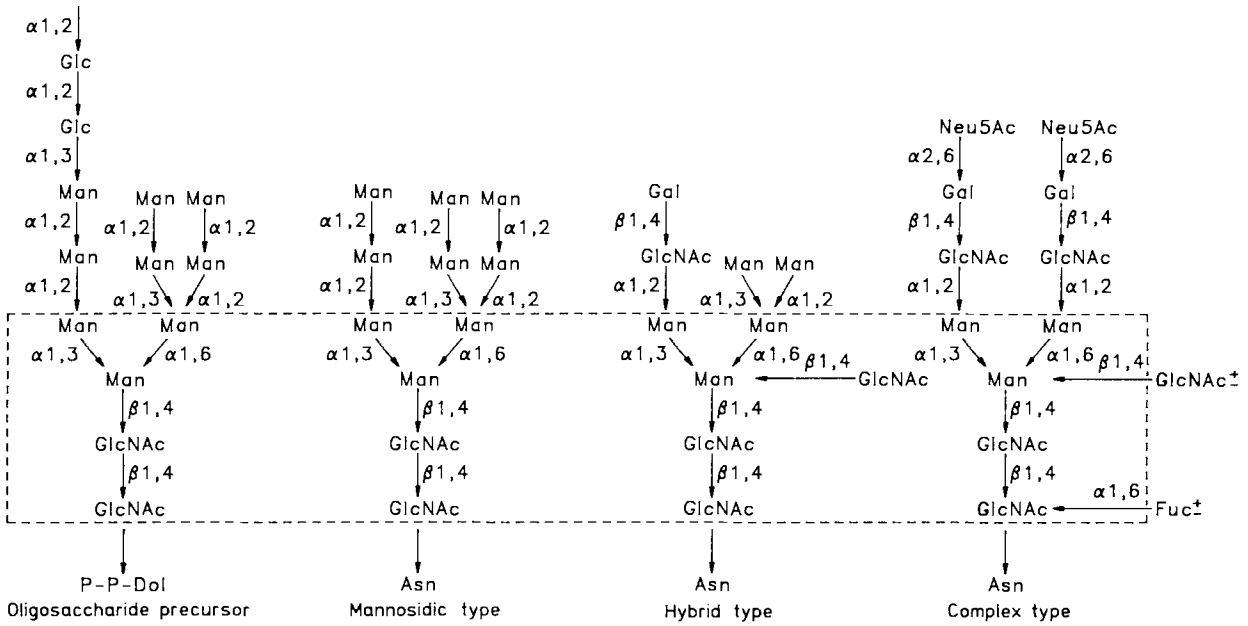

Fig. 1. Basic structures of *N*-glycoproteins. Glc = glucose, Man = mannose, P-P-Dol = dolicholpyrophosphate, Asn = asparagine, Neu5Ac = *N*-acetylneuraminic acid, Fuc = fucose.

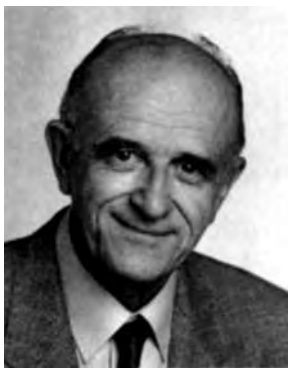
ture, the basicity of the nitrogen atom is so reduced that the otherwise labile glycosylamine group is well stabilized. In the second type, the *O*-glycoproteins, there is either an α-*O*-glycosidic linkage of 2-acetamido-2-deoxy-D-galactose (GalNAc) or a β-*O*-glycosidic linkage of D-xylose (Xyl) to a serine or threonine hydroxy group. It is interesting that, despite the great variety of glycoproteins, the saccharide in the binding region retains a very similar, indeed partially identical sequence. This constant sequence, bound directly to the protein, is described as the "core structure."[1, 2] The appearance of a core structure characteristic for either *N*- or *O*-glycoproteins is determined by the biosynthesis of the respective glycoproteins.[9, 10]

The chemical synthesis of segments of this binding region is of interest for structure determination, for studies of glycoprotein function, and for determination of the specificity of biosynthetic addition and removal of sugar residues. Oligosaccharide segments bound to larger molecules via a spacer act as suitable antigens for the production of monoclonal antibodies. After binding oligosaccharides to a solid phase column, the column may be used for affinity chromatography of enzymes and antibodies. This review describes the chemical synthesis and molecular arrangement of such binding regions of glycoproteins.

2. *N*-Glycoproteins: Asparagine-bound Oligosaccharides

2.1. Basic Structures and Biosynthesis

The most important types of *N*-glycoprotein basic structures are summarized in Figure 1.[1, 10] Apart from the oligosaccharide precursor, they include the mannosidic structure, the hybrid structure, and the complex structure, of which the last is the most common. As can be seen, all these structural types contain a similar core pattern, consisting of two GlcNAc residues and a branching element of three mannose units (Man). This pentasaccharide structure occurs in all the formulas (circled structure). Variations in the structure of glycoproteins arise outside this core structure by fur-



Hans Paulsen was born in 1922 in Hamburg, where he gained his PhD in 1955 in the research group headed by Professor Kurt Heyns. In 1962 he received his habilitation from the Faculty of Mathematics and Natural Sciences of the University of Hamburg, and, in 1972 he accepted a newly founded position as Professor for the Chemistry of Natural Products at the same University. His studies embraced the whole field of saccharide chemistry; however, in the last fifteen years his interests have centered on oligosaccharide syntheses. In addition he has concerned himself with biologically active compounds such as blood-group substances, glycolipids and glycoproteins, whose great importance is becoming more and more evident. His activities have found international recognition; all the honors carbohydrate chemistry has to offer have been bestowed on him. In 1980 the German Chemical Society awarded him the Emil Fischer Medal, in 1983 the Royal Society of Chemistry honored him with the Haworth Memorial Medal, and in 1985 the American Chemical Society presented him with the Claude S. Hudson award. In 1989 he received the J. Heyrovsky Medal from the Czechoslovakian academy of Sciences.

ther extension and branchings of the chains at the top of the diagram.

In order to understand the uniformity of the core structures in all *N*-glycoproteins, the principle of their biosynthesis should be explained.[10] The oligosaccharide precursor (Fig. 1) is synthesized from dolichol phosphate by specific glycosyl transferases in the rough endoplasmic reticulum. Within the dolichol phosphate cycle, the entire oligosaccharide of fourteen saccharide units is transferred to the asparagine of a polypeptide chain, wherever the signal sequence of Asn-X-Ser/Thr is found. Here, X can be any amino acid, but the presence of the adjacent hydroxy amino acid serine or threonine is essential for the transfer process.

The *N*-glycoprotein now passes through the cisternae of the Golgi apparatus, where the trimming process begins.[10] The desired structure is obtained by the action of glycosidases and glycosyl transferases removing and adding residues, respectively. However, the core pentasaccharide structure on the asparagine is not touched in this process, and it therefore appears unchanged in all products. In the mannosidic structure one sees merely degradation of one of the chains. In the hybrid type, lactosamine is coupled to one chain. This type of structure usually contains an additional GlcNAc unit, linked to the branch-point mannose. The complex type contains several lactosamine units and can be greatly branched and extended at the chain ends. An additional fucose (Fuc) is sometimes also bound to the GlcNAc linked to the asparagine. In addition, both the complex and hybrid types of structure may have an additional GlcNAc unit bound to the branch residue. This gives rise to the so-called "bisected" type, which is of great importance in biosynthesis and will be dealt with separately later.

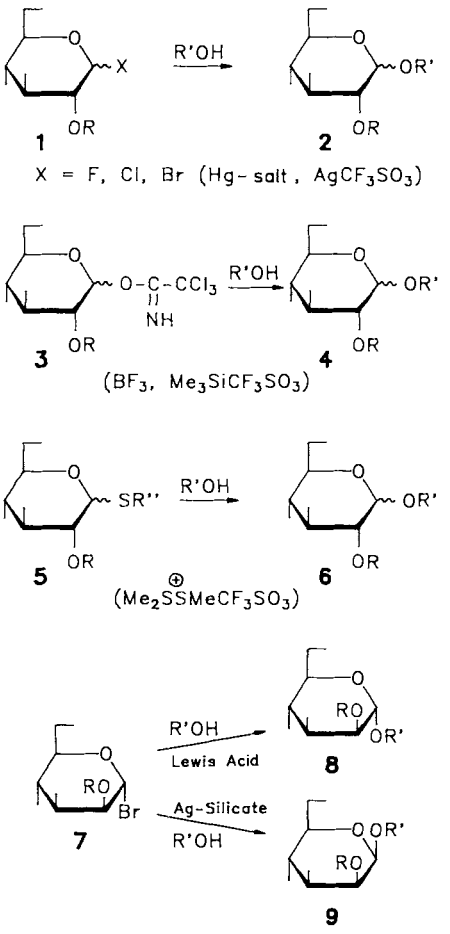
2.2. Chemical Synthesis

2.2.1. *Reliable Glycoside Coupling Methods*

In constructing large oligosaccharides, three methods have proved themselves in glycosidic linkage: the halogenide, imidate and thioglycoside methods. The fluorides, chlorides or bromides **1** may be used as halogenide donors, while mercury or silver salts are good catalysts.[11] The imidate procedure uses donor **3** with addition of Lewis acid catalysts.[12] In the thioglycoside method, activation of the sulfur in donor **5** is necessary; by conversion into a sulfonium form it becomes a good leaving group. $Me_2SS^{\oplus}Me$ triflate and a series of other reagents have been used as catalysts.[13a]

In all three methods, neighboring group interactions lead stereoselectively to the *trans*-glycosidation product, which means that in the D-*gluco* and the D-*galacto* series only the β-glycoside of **2**, **4**, or **6** can be formed. In the absence of neighboring group participation, all three procedures yield preferentially the α-glycoside, but varying amounts of the anomeric β-glycosides are produced simultaneously. The proportion of α-glycoside is strongly dependent on conditions such as solvent, catalyst, and structure of the reaction partners. Optimization of the process is always required here. It is not simple to carry out an S_N2-type reaction on a normally labile β-anomeric donor to obtain an α-glycoside. Experience so far suggests that the most suitable donor here is a β-glycosyl chloride. With β-glycosyl fluorides a preferred α-glycosidation was observed in the presence of the catalyst $Cp_2ZrCl_2 \cdot AgClO_4$.[13b]

With D-mannose, the situation is somewhat different, since the configuration at C2 is reversed. The methods all yield the α-glycoside **8**, with Lewis acid catalysis with or without neighboring group participation. The β-glycoside **9**



is not obtainable by these routes. Its synthesis can only be achieved by the method we have developed, which uses a heterogeneous catalyst such as silver silicate.[14] By this means donor **7** may be converted into the β-glycoside **9** in the absence of Lewis acid.

2.2.2. *Synthesis of the Basic Core Structure*

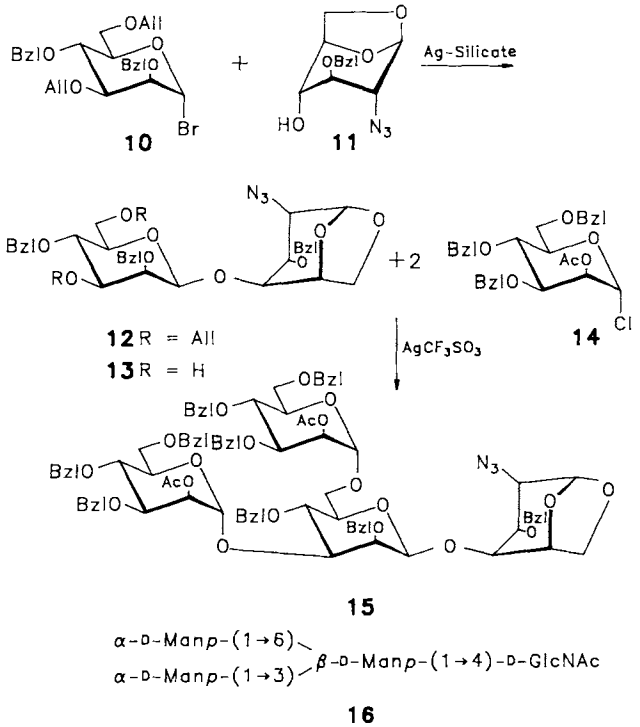
Early studies of the synthesis of the basic core structure (cf. Fig. 1) were carried out by *Jeanloz* et al.[15] The main difficulty to be encountered was the formation of the (1 → 4)-β-glycosidic linkage between the branch-point mannose and the adjacent GlcNAc unit. This bond could not be formed at the time. For that reason, a suitably protected β-D-Glc-(1 → 4)-D-GlcNAc disaccharide was first synthesized, since the β-glycosidic linkage to glucose is much easier to produce with neighboring group participation. The 2-OH group of the Glc unit then had to be selectively deprotected and oxidized to a keto group. Finally, selective reduction converted

this unit into the *manno* configuration, yielding the key disaccharide β-D-Man-(1 → 4)-D-GlcNAc.[15] This route requires several steps, and was also used for the synthesis of the tetrasaccharide β-D-Man-(1 → 4)-β-D-GlcNAc-(1 → 4)-D-GlcNAc.[16]

A new variation of this method has recently been reported by *Kunz*.[17] The starting material is the same disaccharide β-D-Glc-(1 → 4)-D-GlcNAc. With neighboring group participation from a vicinal phenylurethane residue, intramolecular nucleophilic substitution led to inversion of a 2-*O*-triflate group on the Glc unit. The same key disaccharide is hence obtained, without an oxidation reaction.

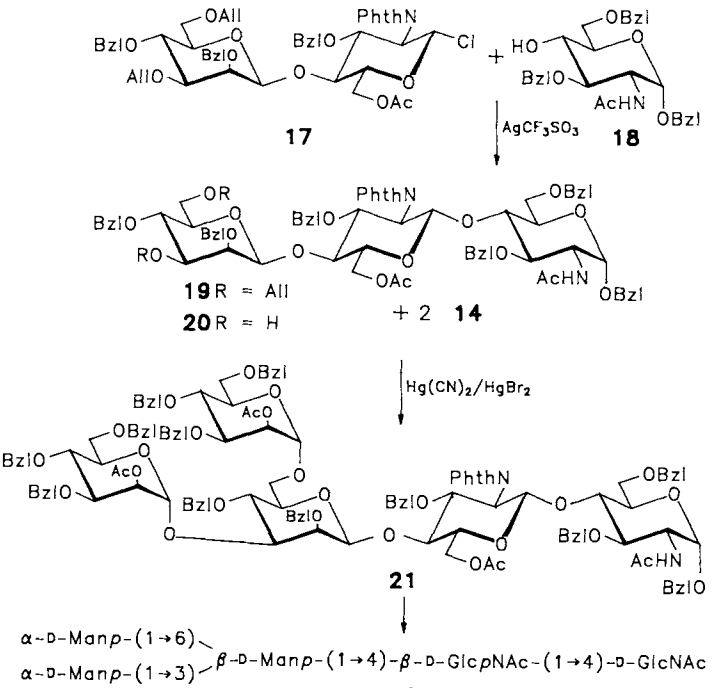
Direct synthesis of the desired β-mannosidic linkage is only possible by heterogeneous catalysis with silver silicate.[18] A reactive donor and acceptor are needed here. Donor **10** is activated at the anomeric center by the presence of ether substituents,[11] while in acceptor **11**, the 4-OH group is made more reactive by conversion of the *gluco* configuration into the 1,6-anhydro form, since it is now in the axial position. Reaction of **10** and **11** in the presence of silver silicate affords the desired β-linked disaccharide **12** in about 70% yield.[19]

After cleavage of the allyl groups in **12** to give **13**, reaction with mannose donor **14** is possible, with neighboring group participation, leading stereoselectively to the α-glycosidic bond. This reaction is considerably simpler than that described previously. Two moles of **14** can react smoothly with **13** to give the branched tetrasaccharide in 82% yield. By deprotection of **15**, the important branched sequence of the basic core structure **16** can thus be obtained.[19]

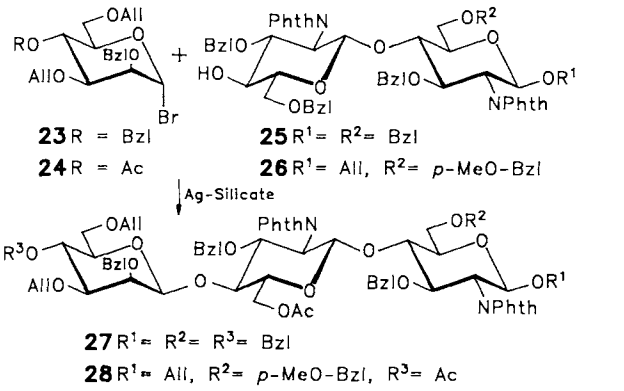


16

The tetrasaccharide **16** was also extended by a further GlcNAc unit at the reducing end to give the complete core structure. In addition, disaccharide **12** was converted into the glycosyl donor **17** and treated with **18**, yielding stereoselectively the β-linked trisaccharide **19**. After cleavage of the allyl groups to give **20**, this again reacts smoothly with two moles of the mannose derivative **14**, to give pentasaccharide



22



21 in one step.[20] Deprotection then leads to the complete branched core pentasaccharide **22**, which is directly bound to asparagine.

Ogawa et al.[21] followed a different route to arrive at the trisaccharide chain corresponding to **19**. On reaction of mannose donor **23** with disaccharide **25** by the silver silicate method, they isolated the β-linked trisaccharide **27** in 40% yield, as well as significant amounts of the α-linked product. This is remarkable, since the 4'-OH group in **25** is only very poorly reactive. The trisaccharide **27** was used as an intermediate for further reactions.

Van Boeckel et al.[22] have carried out systematic studies on β-mannoside synthesis by the silver silicate procedure, and conclude that the substitution pattern in the glycosyl donor is crucial. C3 and C6 should, if possible, carry electron-donating substituents, while C4 should have an electron-withdrawing group to promote β-glycosidation. Donor **24**, with its 4-OAc group, is therefore optimally substituted.

Reaction of **24** with **26** by the silver silicate method indeed yields the desired β-linked trisaccharide **28** in an increased yield of 48%, while only 19% of the α-glycoside is produced.[23] The trisaccharide **28** thus synthesized was also used for further reactions.

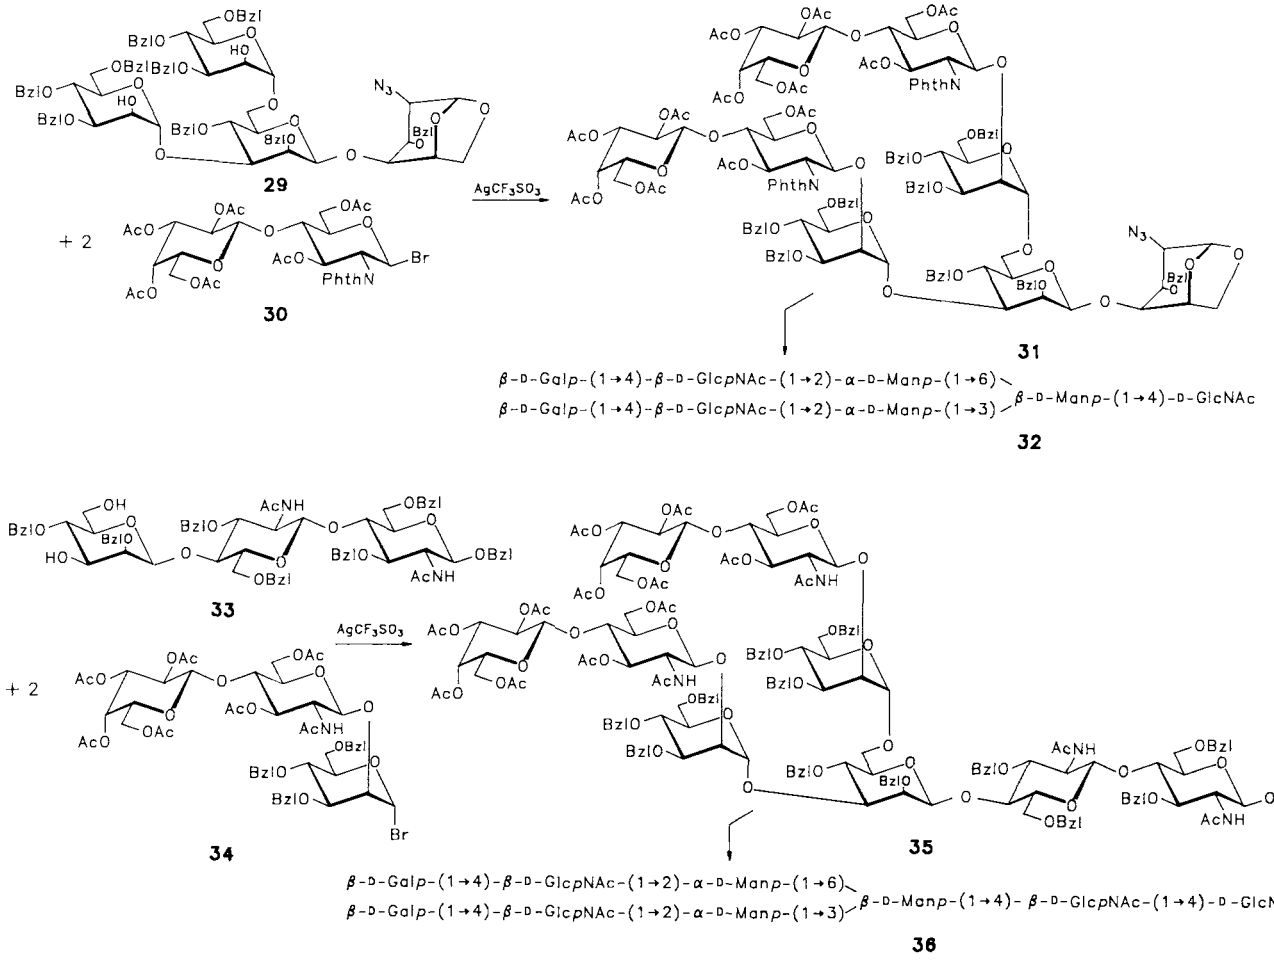
2.2.3. *Synthesis of Lactosamine-type Structures (Complex Type)*

The most important of the structures shown in Figure 1 is the complex type, and it is the commonest found in glycoproteins. Here, lactosamine residues, also called lactosamine antennae, are linked to the inner core structure. Depending on the number of lactosamine residues bound, these compounds are described as di-, tri- or tetra-antennary structures. The external residues may show further variations, such as additional residues or branchings.[1, 2] 5-*N*-Acetylneuraminic acid (Neu5Ac) and L-fucose (Fuc) occur frequently as the terminal residues. Most of the syntheses that have been carried out have been of compounds of this important lactosamine type, or of the so-called "bisected" type (also a complex type in Fig. 1). This review will therefore consider these syntheses closely.

Selective deprotection of the simple tetrasaccharide **15** at the 2-OH group of the terminal mannose residues leads to acceptor **29**. Disaccharide **30** is available as an excellent lactosamine donor,[24] and in one step two residues of **30** may be stereoselectively linked by β-glycosidic bonds to afford octasaccharide **31** in over 70% yield. A series of deprotection steps then leads to **32**. This route enabled us to synthesize a "bi-antennary" lactosamine type structure for the first time.[25, 26]

Ogawa et al.[27, 28] have synthesized a structure in which an additional GlcNAc unit is present at the reducing end. In the *N*-glycoprotein this is bound directly to the asparagine. They used trisaccharide **33** as acceptor, which is available by a few modifications from **27**. The glycosyl donor **34** is a most interesting trisaccharide of lactosamine and mannose. Reaction of **33** with two equivalents of bromide **34** in the presence of silver triflate leads to nonasaccharide **35** in 59% yield.[27] This reaction is remarkable in that it is a reaction of an α-D-mannosyl bromide without neighboring group participation. In the presence of the Lewis-acid-type catalyst silver triflate, the reaction leads stereoselectively to the product with α-linked mannose residues. This peculiarity of mannose has already been remarked upon in Section 2.2.1. Stepwise deprotection of **35** yields **36**, which contains the complete core structure with two lactosamine residues.[27]

Since 5-*N*-acetylneuraminic acid is very often bound to lactosamine in a terminal position, experiments have also been carried out to construct intermediates containing Neu5Ac that could then couple to other residues as such. There are two fundamental difficulties in glycoside synthesis with 5-*N*-acetylneuraminic acid.[29] One observes a competing β-elimination reaction, brought about by the adjacent

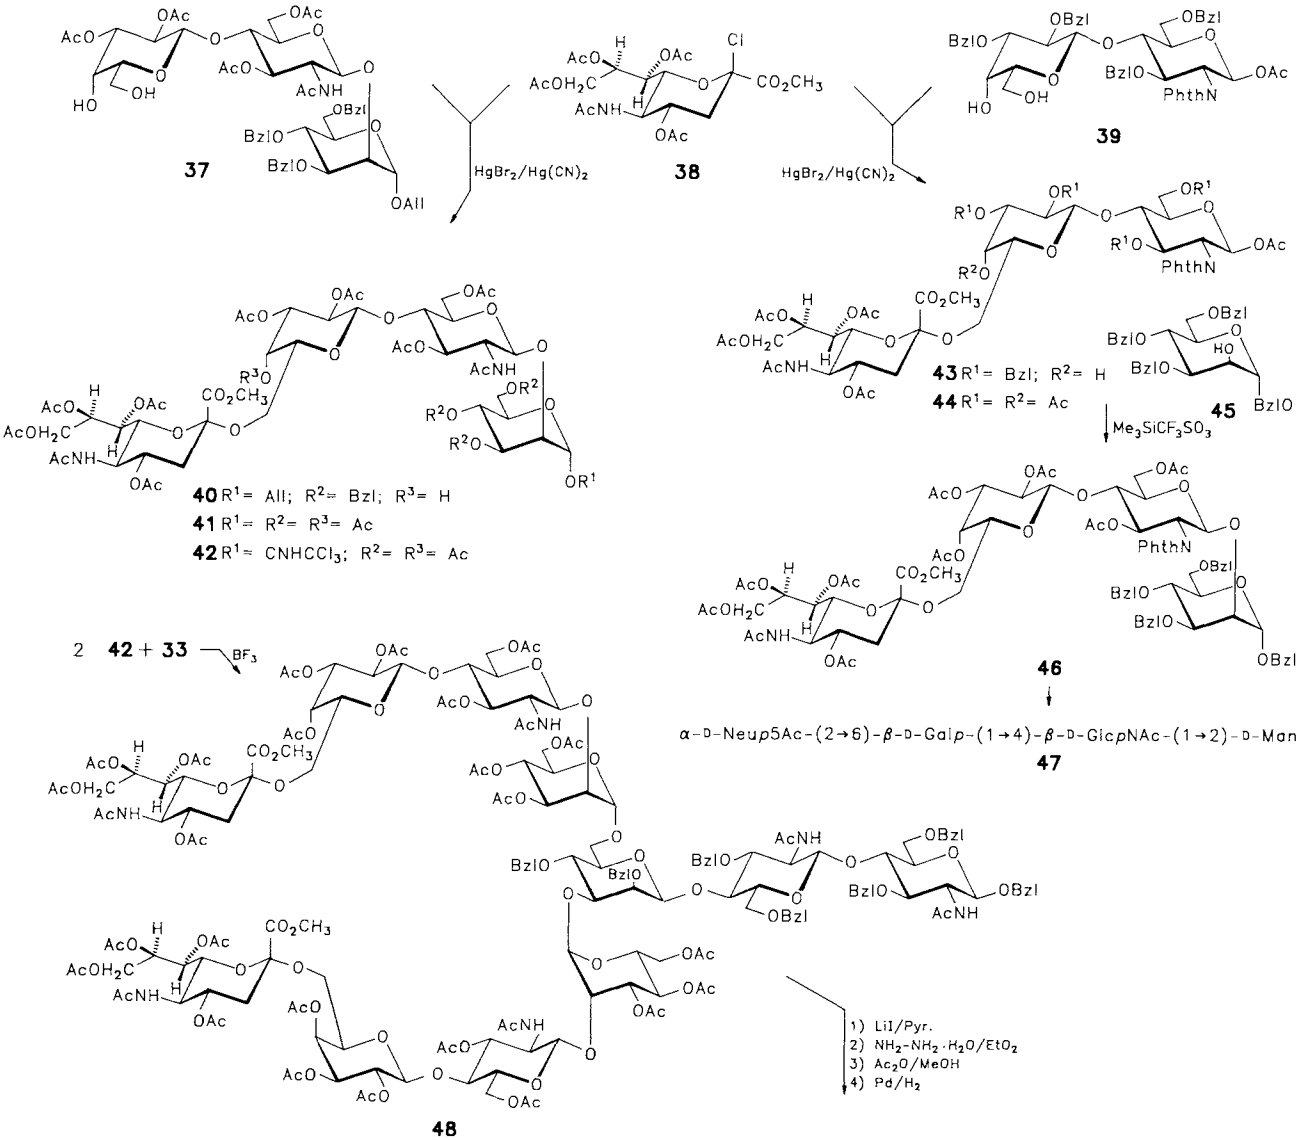


carboxylate group, which gives rise to a 2,3-unsaturated derivative that cannot take part in glycoside synthesis. Furthermore, glycoside synthesis with 5-*N*-acetylneuraminic acid proceeds non-stereoselectively, and α and β products are obtained in varying amounts depending on the reaction conditions. A purification step is required to remove the undesired anomers. Despite these serious obstacles to glycoside synthesis, a number of interesting synthetic intermediates have been synthesized.

Reaction of neuraminic acid donor **38** with lactosamine acceptor **39** gives trisaccharide **43** in 25% yield. If **43** is then converted into the acetate **44**, one has a very useful neuraminic acid-containing glycosyl donor. An example of this is the glycosidation of the mannose derivative **45**. In this case, trimethylsilyl triflate is used as a catalyst, and the 1-*O*-acetyl group acts as a leaving group, with neighboring group participation. The product, obtained in 47% yield, is the β-linked tetrasaccharide **46**. Deprotection leads to the free tetrasaccharide chain **47**.[30]

A different synthetic block was synthesized by *Ogawa* et al.[31] They chose trisaccharide **37** as the glycosyl acceptor for the neuraminic acid donor **38**. In all cases, the most favorable catalyst for the reaction was $HgBr_2/Hg(CN)_2$. After optimization of the reaction conditions, the reaction of **37** with **38** gave the tetrasaccharide **40** in 48% yield.[31] This product **40** could be stabilized by conversion into the fully acetylated **41**. After selective hydrolysis of the 1-*O*-acetyl group the imidate **42** was obtained, which proved to be a useful synthetic intermediate.

The trisaccharide acceptor **33** mentioned above can undergo a double reaction with **42** in the presence of boron trifluoride, though the reaction must be carried out in two steps. First, the chain of **42** is coupled to the reactive 6″-OH group of the mannose. This yields the monoglycosylated product in 48% yield, which must be purified for the second step. The 3″-OH group of the mannose is then glycosylated with **42**, and one obtains oligosaccharide **48** in 56% yield.[32] Stepwise deprotection of this product then yields the free un-



decasaccharide **49**. This synthesis can be said to mark the limits of chemical oligosaccharide synthesis at this time.

It should be mentioned that numerous attempts have been made to improve glycoside synthesis with neuraminic acid. Halogen,[33] sulfur, or selenium[34] groups can be introduced at C3, to avoid the competing elimination reaction. The deoxy form is then regenerated in the end product by reduction at C3. However, these routes require a number of additional steps, and one needs to calculate the yield over the entire pathway in order to assess which route is more favorable. Selectivity in the direction of the α-glycoside has been improved by use of the thioglycosidation method[35] (see Section 2.2.1.). This is also true for the glycosidation of secondary hydroxy groups, which are by nature even more difficult to glycosylate with neuraminic acid donors. In a more recent investigation a larger proportion of α-product was obtained in the presence of a heterogeneous catalyst.[35a]

2.2.4. *Synthesis of "Bisected" Structures*

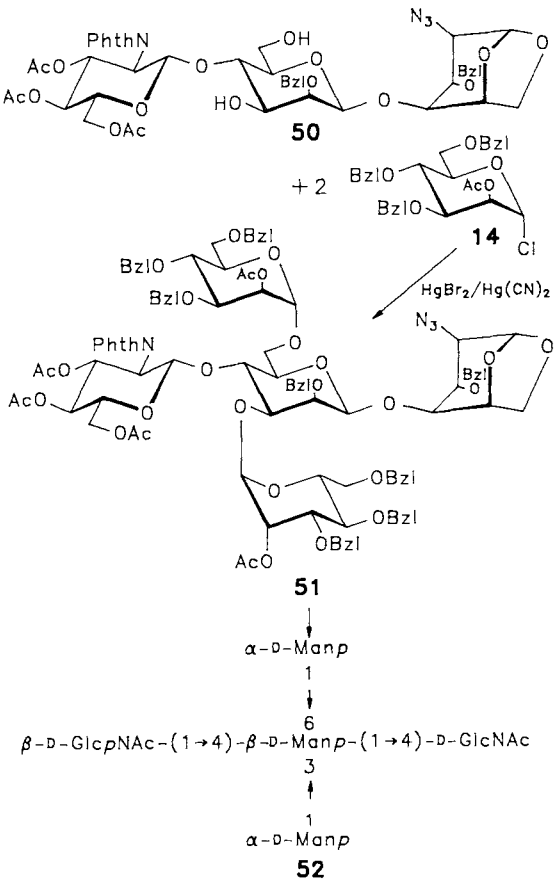
The so-called "bisected" structures of the complex type in Figure 1 are also interesting, and are important in the biosynthetic pathway as well.[9] In the "bisected" structure, the mannose which forms the branch point bears an additional GlcNAc unit on its 4-OH group. This gives rise to an extremely branched structure, whose construction poses some interesting chemical problems.

We have constructed the trisaccharide acceptor **50**, in which the central mannose unit is intended to form the branch point. The reaction of glycosyl donor **14** with **50** is much more sluggish than that of **14** with **13**. However, by using a large excess of **14** under controlled conditions, **50** can also be coupled to two mannose residues to give **51** in 68% yield.[36] Stepwise deprotection of **51** then yields the extremely branched pentasaccharide **52**.

A number of attempts have been made to deprotect the 2-OH groups on both side-mannose residues in **51** and to link lactosamine chains to them to obtain larger units (as in the lactosamine-type synthesis).[37] However, the reaction with lactosamine donor **30**, which is so successful in the conversion of **29** into **31**, is impossible with derivatives of **51**. Pentasaccharides such as **51** have proved completely resistant to all methods of chain extension.[37] A different strategy therefore had to be adopted.

To construct the required intermediate, it was planned to couple two moles of a trisaccharide donor of lactosamine and mannose, such as **53**, with the trisaccharide diol **50**. Of the various possibilities for activating the trisaccharide donor, only imidate **53** proved sufficiently reactive. It was expected to yield the α-glycoside selectively (cf. Section 2.2.1), in a non-neighboring group active reaction. However, reaction of **50** with **53** led only to the monosubstituted product **54**, in 53% yield. Only the reactive primary hydroxy group of **50** reacts. Even with an excess of **53**, the less reactive secondary 3′-OH group of **54** could not be induced to react.[37]

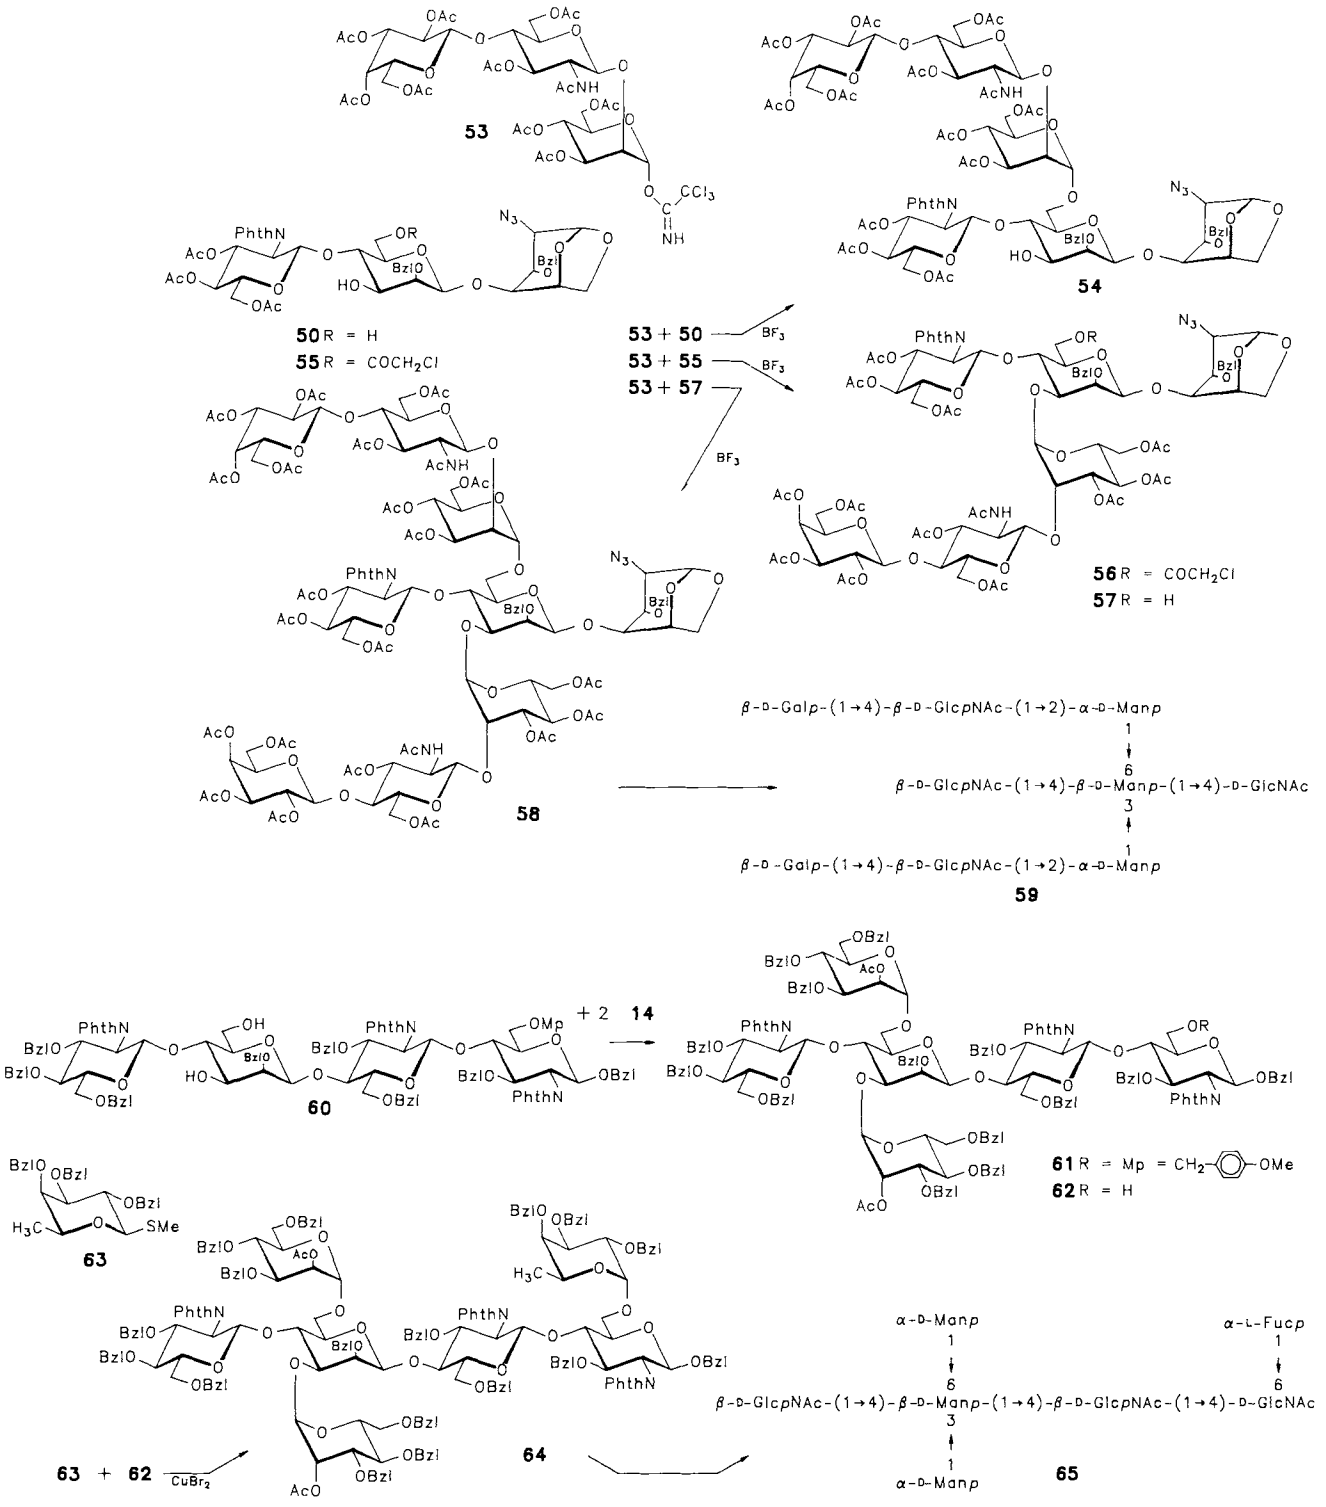
A detour proved successful, however. If the reactive 6′-OH group in **50** is first protected by a chloroacetyl group



(**50** → **55**), then the reaction of **55** with **53** can be carried out. Use of excess **53** gives a 19% yield of the reversed-substituted hexasaccharide **56**. After selective cleavage of the chloroacetyl group to give **57**, the second side chain can be introduced with **53**, in 58% yield, leading to the desired nonasaccharide **58**.[37] The free "bisected" unit **59** can then be obtained by a series of deprotection steps. This series of reactions makes up an oligosaccharide synthesis of the greatest complexity.

Ogawa et al.[38] have synthesized another "bisected" structure, in which the chain is extended at the reducing end by a GlcNAc unit. As starting material they used the tetrasaccharide diol **60**, which can be obtained from a compound analogous to **33**. Like **50**, this diol can now react with a large excess of mannose donor **14** in the presence of silver triflate in a neighboring group-assisted manner. One obtains the hexasaccharide **61** in 37% yield, along with 34% of the monosubstituted product in which only the reactive, primary 6″-OH group of **60** has undergone reaction. The monoproduct can also be transformed into **61**, in 36% yield.

The 6-OH group of the reducing GlcNAc unit in **61** contains a *p*-methoxybenzyl ether residue which can be selectively cleaved with $[(NH_4)_2Ce(NO_3)_6]$ to give **62**. **62** can then react further with the thioglycoside donor of fucose **63**, in a thioglycosidation reaction in the presence of $CuBr_2 \cdot n Bu_4NBr$. Selective formation of an α-glycosidic linkage to fucose then leads to heptasaccharide **64**. From **64** one can obtain the deprotected compound **65**, which represents a complete core structure of the "bisected" type.[38]



2.2.5. *Synthesis of Other Core Structures*

Of the other basic structures in Figure 1, such large structures as for the complex type have not yet been synthesized, though studies have been made on the synthesis of their side-chains. Thus, *Ogawa* et al.[39] have synthesized hexasaccharide **66** with three glucose units. This makes up one chain of the oligosaccharide precursor that is transferred to the peptide in the dolichol phosphate cycle. The chain is broken down again during the trimming process. The synthesis of these α-linked glucose residues generally gives variable amounts of the β-anomer as a side product.

In addition, *Ogawa* et al.[40] have synthesized derivatives of the branched hexasaccharide **67**, which contains only mannose residues. This chain represents one arm of the mannosidic type. The structure shortened by one mannose unit at each reducing end was also synthesized.[40] This tetrasaccharide is found in both the mannosidic and hybrid types (see Fig. 1).

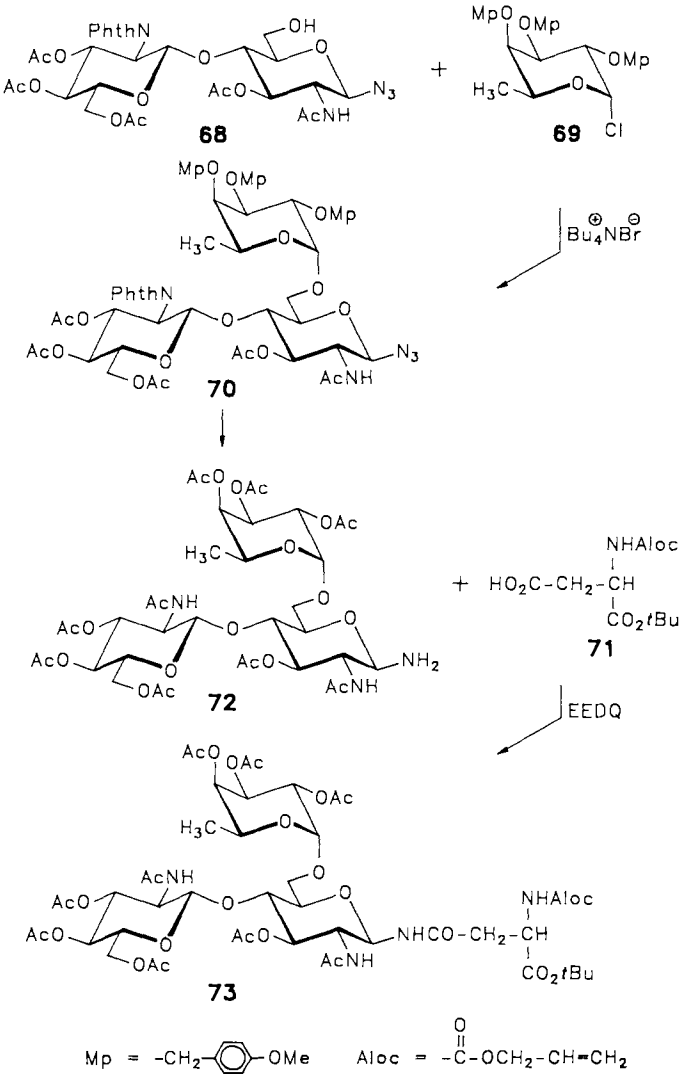
2.2.6. *Synthesis of N-Glycopeptides*

Syntheses of *N*-glycopeptides have been carried out from quite an early date, especially by *Jeanloz* et al.[41] GlcNAc[42] and chitobiose[43] were coupled *N*-glycosidically to the amide group of asparagine, which was then extended with further amino acids. The coupling reaction of the saccharide residues with the amino acid was performed by first making the β-glycosyl azide of the amino sugar. This was reduced to the β-glycosylamine, which was then reacted directly with the carboxyl group of the side chain of aspartic acid, using peptide coupling reagents (DDC, EEDQ).[41] This reaction is a critical one, since glycosylamines are relatively labile and tend to dimerize.



This reaction has been taken up and improved upon by *Kunz*.[44] He was able to couple the key trisaccharide of chitobiose and fucose with asparagine.[45] First the β-glycosylazide **68** was coupled with the fucose donor **69**. Under "in situ" anomerization conditions,[11] one obtains the α-linked trisaccharide **70** selectively. "In situ" anomerization reactions always proceed especially smoothly with fucose derivatives without neighboring group participation.

The *p*-methoxybenzyl substituents in **69** were chosen in order to be able to selectively remove the *O*-*p*-methoxybenzyl groups in the fucose moiety of **70** oxidatively and replace them with *O*-acetyl groups. In the fucose protected with benzyl ether groups, the glycosidic bond is so labile that it cannot tolerate the trifluoroacetic acid required later for release of the *C*-terminus of the amino acid moiety. In contrast, the acetate-protected fucose has a much stabler glycosidic bond, as would be expected. After reduction of the azide group to give glycosylamine **72**, coupling with the aspartate derivative **71** affords *N*-glycosyl amino acid **73**. The amino acid moiety contains the differentiable protecting groups Aloc/*t*Bu, allowing release of either the *C*- or the *N*-terminus. This permits chain extension with any desired amino acids, using peptide coupling methodology.[45] Details may be found in the appropriate review papers.[41,44]

2.3. Conformation of *N*-Glycoprotein Oligosaccharides

2.3.1. *Conformation of the Core Structure and of the "Bisected" Form*

Conformational analysis of the oligosaccharide chains is of great interest, since biological function is frequently correlated to the conformation. In the case of oligosaccharide chains, the number of possible conformations is severely restricted. If, as here, the residues are of *manno*, *gluco* or *galacto* configuration, then the pyranose rings adopt the $^4C_1$-chair conformation almost exclusively (e.g. C4 is above and C1 below the plane of the ring). The size of the glycosidic bond angle τ does not, therefore, vary much at all. Variations in conformation can hence only occur by twisting of the torsion angles ϕ and ψ between the glycosidic bonds (see Fig. 2). The dihedral angle ψ is severely restricted by the

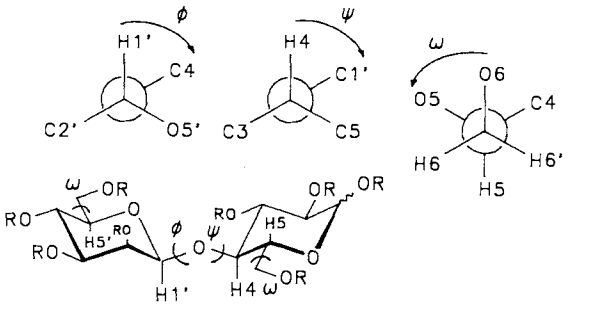


Fig. 2. Definition of the dihedral angles ϕ, ψ and ω in saccharides.

exo-anomeric effect, which predicts a preference for the *gauche* configuration of the ring oxygen with respect to the O–R bond of the aglycone. Model studies and energy calculations show that with two saccharide units that are linked by

a secondary hydroxyl group, the minimum energy form occurs when both protons in the anomeric bond (e.g. H1′- and H4 in Fig. 2) are pointing in approximately the same direction. Conformations in which one ring is reversed possess such a high energy, due to steric interactions, that they virtually do not occur. If there is a bond to a primary 6-OH group, then rotation around the C5–C6 bond constitutes a further variable, described by torsion angle ω. Where branching occurs at the 6-OH group, some variation in conformation is therefore to be expected. A new review of the conformation analysis of oligosaccharides is given by *B. Meyer*.[45a]

Conformational analysis in solution is performed by NMR spectroscopy. To do this, the chemical shift of as many protons as possible needs to be determined. Since the ring protons of the various pyranose rings show very similar chemical shifts, a great deal of overlap is observed, and it is necessary to make intensive use of modern, two-dimensional methods with various correlations.[46] NOE, NOESY or ROESY experiments afford information about NOE-effects within the molecule. ROESY experiments are needed especially when unfavorable molecule correlation times lead to a disappearance of the cross-correlation rate and the NOE-effect passes through zero. With molecules of the size described, this occurs quite often. Interglycosidic NOE-effects are currently of interest. Thus, as shown in Figure 2, one always observes strong NOE-effects over the glycosidic bond when the linkage is to a secondary hydroxyl group, e.g. between protons H1′ and H4. This gives valuable information about the conformation at the glycosidic bonds. Some quantitative evaluation of the NOE-effects is also possible.

The NMR measurements can be complemented by energy calculations using detailed semi-empirical programs such as PCILO[47] or force-field programs such as modified MM2,[48] AMBER,[49] or CHARMM.[50] A simple procedure that has been specially developed for carbohydrate sequences is the force-field program GESA.[45a, 51] This operates by the HSEA method, and is an empirical procedure in which the molecule is calculated iteratively using parametrized potential functions. The energy terms taken into consideration are van-der-Waals interactions in the form of the Kitaigorodsky expression[52] and the *exo*-anomeric effect. Pyranose rings are treated as rigid units whose coordinates are derived from X-ray structures and neutron diffraction studies. When their positions in the crystal structure are not well defined, the protons on the skeleton are not usually adopted, but are generated subsequently by a subprogram. Hydrogen atoms on the OH-groups are not considered. For suitable initial conformations, the ϕ, ψ and ω dihedral angles are optimized simultaneously, using the Fletscher-Powell algorithm.[53] Careful comparative studies by *Carver* et al.[54] have shown that the less complex GESA or HESA procedure gives very similar or identical results to the force-field programs named above. However, in assessing the variable 6-OH side-chain bond it is important to take the population distribution of the conformations into account.[55, 56]

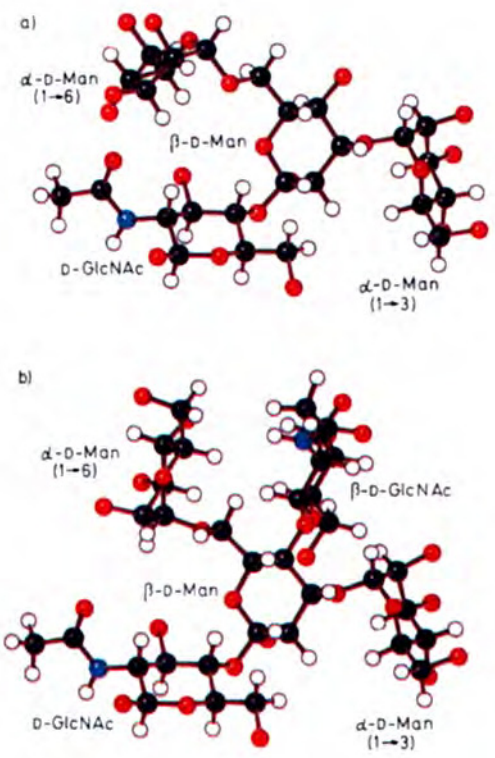

Fig. 3. Conformational minima from NMR data and GESA calculations for: a) tetrasaccharide **16**; b) "bisected" pentasaccharide **52**.

The results of one conformational analysis are given in Figure 3, where the minimum conformations of the branched, central tetrasaccharide **16**[57] and the "bisected" structure **52**[58] are presented. It is important that in both structures the part of the molecule with bonds from secondary hydroxyl groups to the (1 → 3)-arm of the mannose adopts the expected favored conformation. This agrees very well with the NMR data.[57] The flexible (1 → 6)-arm of the mannose in **16** is inclined towards the GlcNAc residue. It is interesting to compare **16** with the "bisected" form **52**. The lower part, with the (1 → 3)-arm, is virtually unchanged. The variable (1 → 6)-arm, however, now prefers a different conformation. This is supported by interglycosidic NOE-effects between the (1 → 6)-Man unit and the "bisected" (1 → 4)-GlcNAc unit.[58] As far as the (1 → 6)-arm is concerned, Figure 3 shows the forms with the highest proportions of the population distribution.

Table 1 presents the torsion angles ϕ and ψ for the individual glycosidic bonds of **16** and **52**. If one compares **16** and **52** it is clear that the values for the lower trisaccharide chain of the (1 → 3)-arm are virtually identical. The variation in the (1 → 6)-arm of the mannose, which prefers a different position in **52**, stands out clearly. The lower trisaccharide α-D-Man-(1 → 3)-β-D-Man-(1 → 4)-D-GlcNAc is the only oligosaccharide for which the X-ray structure is known.[59] For this part of both **16** and **52**, the ϕ and ψ values from the crystal structure are also included in Table 1. These values

Table 1. Torsion angles [°] of the preferred configurations of **16** and **52** determined by NMR measurements and GESA calculations, and in the crystal structure.

also do not differ greatly from those calculated for **16** and **52**, showing that the (1 → 3)-arm adopts very similar conformations in solution and in the crystal.

2.3.2. *Reaction of Modified Core Oligosaccharides with GlcNAc Transferase I*

Compounds **16** and **52**, whose conformations have been discussed here, are of great interest because of the difference in their behavior with GlcNAc transferase I. GlcNAc transferase I is the first enzyme to begin construction of new chains on the invariant core structure **22** during the trimming process.[9] It selectively adds the initial GlcNAc unit onto the (1 → 3)-arm of the mannose. Structure **74** (Fig. 4) corresponds to the substrate of this process, and reacts most actively (100%) with the enzyme. The two additional mannose residues on the (1 → 6)-arm in **74** are removed later by mannosidases.[9]

Tetrasaccharide **16** is also a very active substrate for this enzyme (65%). The "bisected" structure **52**, however, is not glycosylated;[60] the "bisected" arrangement is hence a stop signal for GlcNAc transferase I. It seemed reasonable to suggest that this inactivity is due to the great difference in conformation between **16** and **52** observed above, and brought about by the additional GlcNAc group on the 4′-OH in **52**.

In order to test this assumption, the modified tetrasaccharide **75** was synthesized, bearing a 4′-deoxy functionality at the branch unit.[61] **75** is not a substrate for GlcNAc transferase I either.[62] Further, **75** was also found to prefer the same conformation as **16**,[63] showing that the change in conformation in **52** is not important for the enzyme reaction. For activity, GlcNAc transferase I requires the 4′-OH group of the central mannose. Interestingly, the modified tetrasaccharide **76**,[61] which contains D-talose at the branch point, is not a substrate either.[63] If one methylates the 4′-OH group in **16** to the 4′-*O*-methyl ether, the resulting compound also does not react with GlcNAc transferase I.

From these findings, one may conclude that GlcNAc transferase I has an absolute requirement in substrate binding for an equatorial 4′-OH group (key polar group). Possibly the enzyme forms a hydrogen bond here, since the corresponding 4′-*O*-methyl ether does not react. This example shows most impressively how the synthesis of modified oligosaccharide substrates can lead to very subtle information about an enzyme binding site. However, it also shows how careful one must be in interpreting the significance of conformational changes.

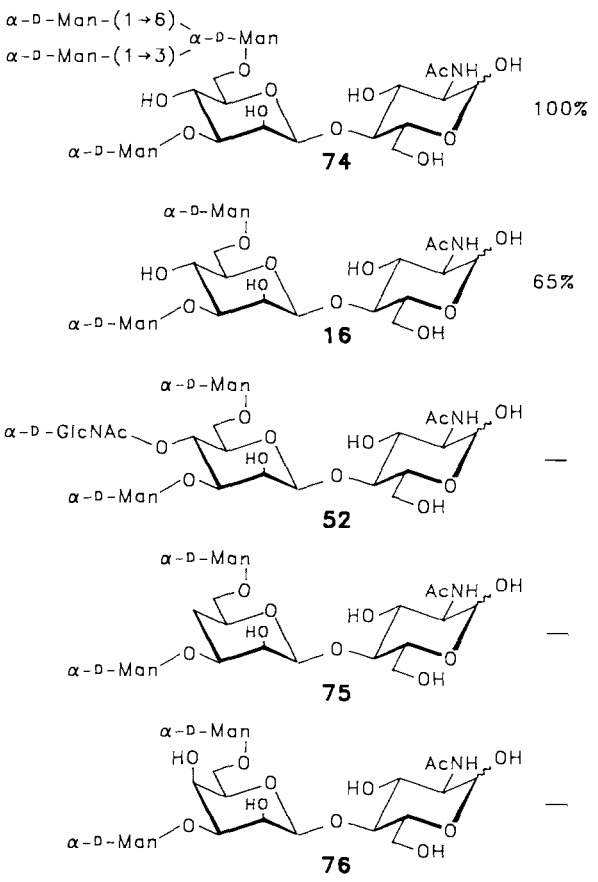

Fig. 4. GlcNAc transferase I activity with natural and modified oligosaccharide substrates.

2.3.3. *Conformation of the Lactosamine-type Structure and Comparison with the X-Ray Structure of the Saccharide Chain in Immunoglobulin*

Conformational analysis by the NMR and GESA methods described above was also carried out on the available octasaccharide **32**.[64, 65] The result is presented in Figure 6a.[64] The pentasaccharide chain with linkages to the secondary hydroxy groups of the (1 → 3)-arm shows the expected preferred conformation. The side chain of the (1 → 6)-arm is also inclined towards the reducing GlcNAc unit, as in **16**. Selective deshielding of the protons in the reducing GlcNAc unit confirm that this form indeed makes up a distinct proportion of the population.

With **32** it is now possible to make a comparison with a corresponding crystalline structure. **32** naturally does not crystallize. However, this octasaccharide is contained in an immunoglobulin which has been crystallized by *Huber*[66] and *Deisenhofer*,[67] and of which the X-ray structure has been determined. Figure 5 shows a schematic diagram of the IgG_1 immunoglobulin molecule. The upper portion contains the light chains, the lower F_c portion consists of the heavy

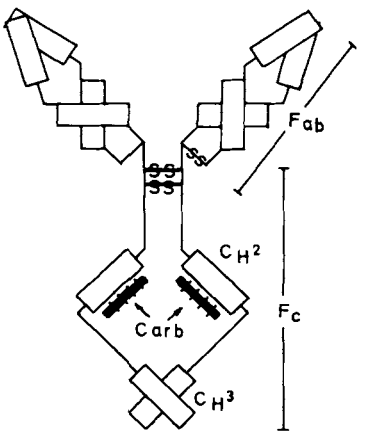

Fig. 5. Schematic model of IgG_1. Carb = oligosaccharide chain.

chains, and includes two identical carbohydrate chains facing each other in the interior of the molecule. These two chains are *N*-glycosidically linked to Asn297 and Asn597, and possess a complex lactosamine-type structure. They therefore also contain the base structure of **32**, and occur twice in the F_c-fragment.

Huber and *Deisenhofer* were able to crystallize the separated F_c-fragment, determine the protein chain structure, and also resolve the carbohydrate chain to 2.8 Å.[66–68] This resolution is remarkable. They were assisted in this by the fact that the carbohydrate chain inside the molecule is largely fixed. In other glycoprotein crystal structures, the carbohydrate moiety is usually flexible and can only be localized with difficulty. The sample studied by *Huber* and *Deisenhofer* contained no 5-*N*-acetylneuraminic acid and no "bisected" unit. The GlcNAc group bound to asparagine carried fucose at its 6-OH as a branch unit. All saccharide units were localized, except the terminal galactose on the (1 → 3)-arm. This unit has been added for completeness in Figures 6 and 7. It should be mentioned that the carbohydrate moiety in different types of immunoglobulin can vary, and deviations from the structure described here may be found.[69]

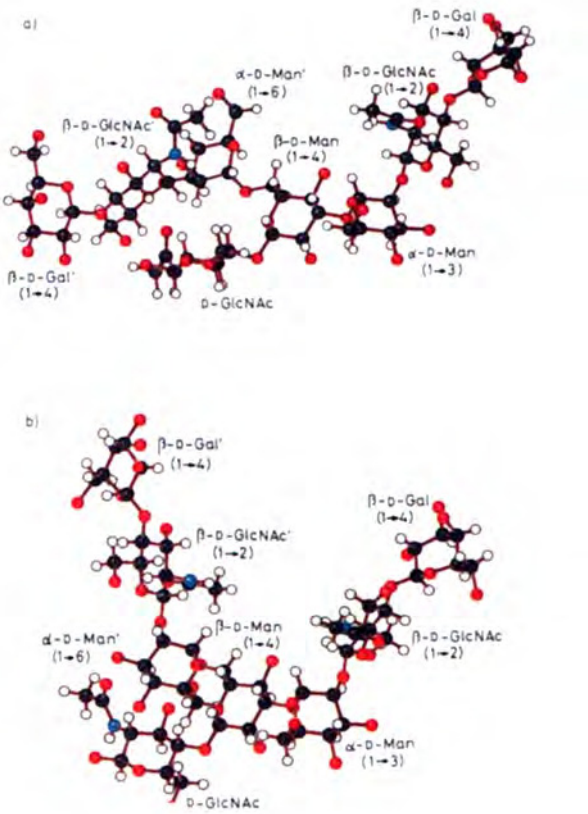

Fig. 6. Conformation of octasaccharide **32**: a) from NMR data and GESA calculations; b) in the crystal of the F_c fragment of IgG_1 immunoglobulin molecule.

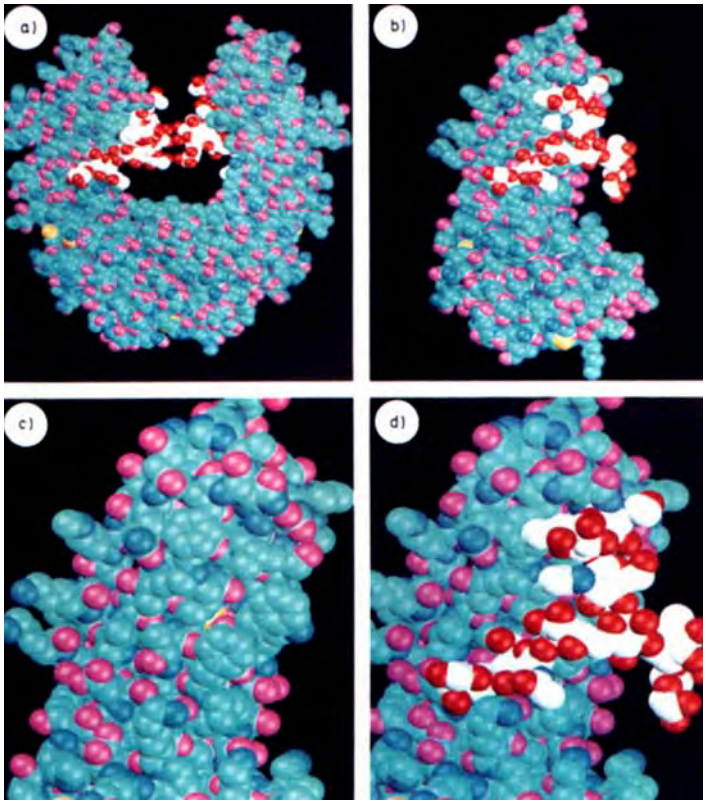

Fig. 7. a) X-ray crystal structure of the IgG_1 molecule F_c-fragment. b) One half of the F_c-fragment. c) Enlarged section of the region of the protein chain where the carbohydrate moiety is bound. The carbohydrate moiety has been omitted. d) The same section as in 7(c), with the carbohydrate chain replaced. Carbohydrate chain: C white, O red, N dark blue; protein chain: C light blue, O pink, N dark blue, S yellow.

The conformation of octasaccharide **32** in the crystal is reproduced in Figure 6b. It can be seen that the pentasaccharide chain with linkages through secondary hydroxy groups in the (1 → 3)-arm is very similar in solution and in the crystal. The flexible (1 → 6)-arm, however, is completely changed, and in the crystal points upwards. Table 2 compares the torsion angles ϕ and ψ for the two conformations. The crucial difference appears in the ψ-value for the (1 → 6)-bond (171 ° in the crystal, 79 ° in solution). The other values for bonds through secondary hydroxy groups are remarkably similar. In these portions of the molecule, quite similar conformations must be preferred both in solution and in the crystal. The deviation at the reducing GlcNAc unit is understandable, since in the crystal this is linked to a further GlcNAc residue. The variation in the (1 → 6)-arm occurs largely because this chain of the molecule lies on a protein

structure. This prompted us to examine the conformation of the entire F_c-fragment more closely.

Figure 7a shows the entire F_c-fragment in the structure derived from the X-ray analysis.[45a, 68] The two carbohydrate chains can clearly be discerned in the center, surrounded by the heavy protein chains. In the left half of the molecule one part of the carbohydrate chain is directed forward. In the right-hand portion of the molecule, the corresponding carbohydrate strand points backwards.

In order to make the structure clearer, Figure 7b shows only one half of the molecule. The coupling of the carbohydrate chain to the asparagine occurs quite high up in the molecule, where the attached fucose residue can also be identified. The mannose that functions as the crucial branching unit lies in the center of the star-like carbohydrate chain. It is most interesting that the two lactosamine arms which arise from the branching point display quite different arrangements. The flexible (1 → 6)-arm lies to the left, directly on a protein chain. The less flexible (1 → 3)-arm, in contrast, is oriented to the right and points exactly into the center of the entire molecule. This arm is not in contact with any part of the protein chain.

For clarity, Figures 7c and 7d show the carbohydrate binding region in Figure 7b, further enlarged. Figure 7c shows the regions of the protein without the carbohydrate, in the upper part of the molecule where the carbohydrate chain is eventually inserted. Phenyl rings can be clearly identified in this region, assignable to phenylalanine and tyrosine. In this section lie Phe 241, Phe 243, Val 262, Val 264 and, in the upper part, Tyr 296. The flexible (1 → 6)-arm therefore lies on a hydrophobic region of the protein chain.

This becomes particularly clear in Figure 7d: The flexible (1 → 6)-arm, at the lower left, lies on a hydrophobic section of the protein chain, and possibly acquires more hydrophobic characteristics. The (1 → 3)-arm at the lower right is unaffected, and points into the center of the molecule. It can presumably be assigned more hydrophilic properties. It should be pointed out that this arm has no contact with the other (1 → 3)-arm which is directed towards the inside from the other half of the molecule. In the upper part lies the chitobiose and the fucose that adjoins it. The arrangement is therefore an interesting one, in which lactosamine arms clearly have different functions. It can be assumed that this arrangement contributes to the special stabilization of the F_c-fragment that is required for reactions of the immunoglobulin as an antibody.

3. *O*-Glycoproteins

3.1. Basic Structures

In the *O*-glycoproteins, too, constantly recurring sequences are found as the basic core structures. The most important of these sequences are brought together in **77**–**81**. In types **77** to **80**, the key element is a galactosamine unit bound α-glycosidically to the hydroxy group of a serine or a threonine, to which galactose or glucosamine groups are then linked. Types **77** to **80** are denoted Core-I to Core-IV. The most important is the Core-I structure **77**, which is extraordinarily widespread and occurs in the most diverse glycoproteins. The Core-II, Core-III and Core-IV structures are found particularly in mucins and in a number of slimy secretions. In structure **81**, by contrast, a xylose residue is bound

β-D-Gal-(1→3)-α-D-GalNAc-L-Ser/Thr **77**
Core I

β-D-GlcNAc-(1→6)
β-D-Gal-(1→3) → α-D-GalNAc-L-Ser/Thr **78**
Core II

β-D-GlcNAc-(1→3)-α-D-GalNAc-L-Ser/Thr **79**
Core III

β-D-GlcNAc-(1→6)
β-D-GlcNAc-(1→3) → α-D-GalNAc-L-Ser/Thr **80**
Core IV

β-D-Gal-(1→3)-β-D-Gal-(1→4)-β-D-Xyl-L-Ser **81**

to the hydroxy group of the serine, with galactose residues then linked to the xylose. Sequence **81** occurs primarily as a linker element between the carbohydrate and protein chains in proteoglycans and hyaluronic acids.

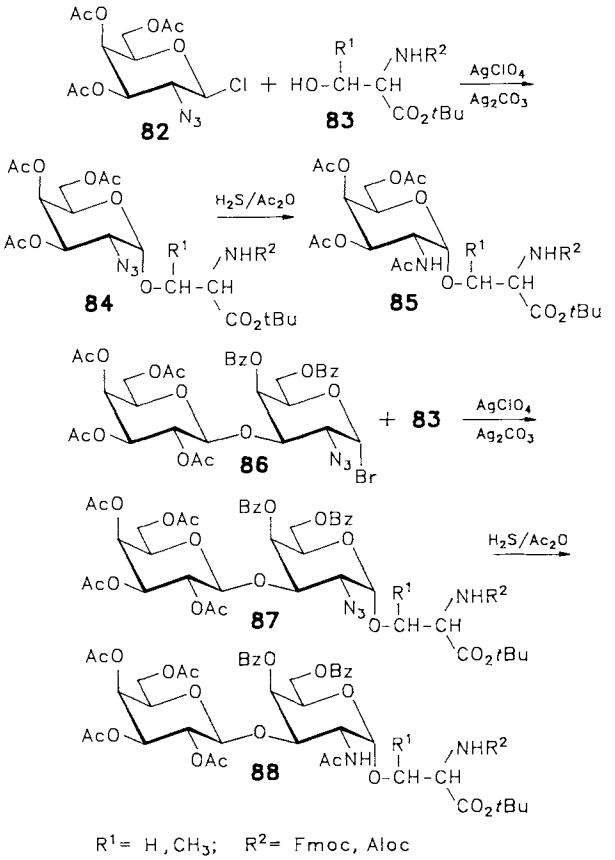
The biosynthesis of the *O*-glycoproteins is, however, fundamentally different from that of the *N*-glycoproteins described above.[9] In *O*-glycoproteins, the primary step involves the transfer of an activated GalNAc residue onto the hydroxy group of serine or threonine by a specific GalNAc transferase. It is not yet known how this process is controlled, and whether there are signal sequences for it. Presumably a proline unit plays a role in the transfer. The other carbohydrate residues are then added stepwise to the GalNAc unit by the corresponding specific glycosyl transferases. Here, then, unlike in the *N*-glycoproteins, large oligosaccharide residues are not transferred onto the peptide chain, but the synthesis proceeds stepwise at the peptide chain.

3.2. Synthesis of *O*-Glycopeptides

Many studies have been made of the synthesis, in particular, of glycopeptides of the most important Core-I structural type.[44, 70] The problem is that an α-glycosidic linkage to the hydroxy amino acid has to be synthesized, without neighboring group participation. With derivatives of galactosamine, this is not possible. Halogenides of 2-azido-2-deoxy-D-galactose are excellent glycosyl donors in this reaction.[72–75]

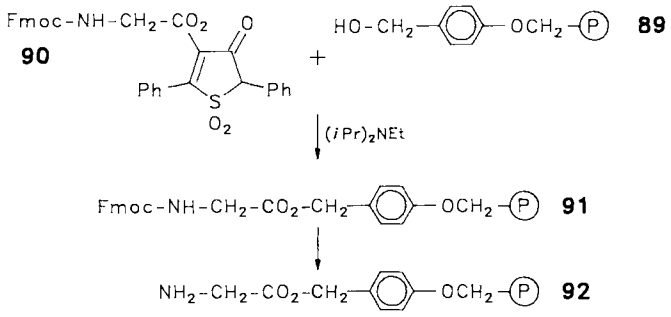
Thus, donor **82**[71] reacts with the amino acid derivative **83** with good stereoselectivity and in good yield to afford the glycosyl amino acid **84**.[76, 77] Reduction of the azide group and subsequent acetylation then leads to the desired product **85**. Similarly, disaccharide **86**[72] can be converted into **87** with the amino acid **83**, and from **87** the synthetic intermediate **88** can then be obtained.[76, 77]

In the amino acid moiety of the compounds, protecting groups must be chosen which allow selective deprotection. Of the numerous protection possibilities that have been studied,[44, 70] the Fmoc/*t*Bu and Aloc/*t*Bu combinations have proven the most successful. Both pairs allow the selective deprotection of either the *N*-terminal or the *C*-terminal position. Using normal peptide coupling methods, further amino acids or glycosyl amino acids may then be added to either the *C*- or *N*-termini. Intermediates **85** and **88** can hence be insert-



ed at any desired position in a peptide chain, wherever a glycosylated serine or threonine is required. After removal of the peptide protecting group, the acyl groups of the sugar moiety are then cleaved under carefully controlled conditions, such that β-elimination or racemization of the peptide does not occur.

O-Glycopeptide synthesis can also be carried out as a solid-phase process.[78, 79] Amongst others, Wang resin is suitable for this.[79] Wang resin contains the anchoring group shown in **89**. The initial amino acid coupled to the resin is the TDO ester **90**, to give **91**.[80] After release of the amino group as **92**,



the partially deprotected amino acid building blocks of **85** or **88** can be added, as can any other amino acid required to build up the peptide chain. An example of such an *O*-glycopeptide synthesis is shown in the reaction scheme of Figure 8.[81] The completed glycopeptide can be cleaved from the solid support with trifluoroacetic acid to give **93**, without endangering the carbohydrate moiety. Deprotection of the peptide and of the sugar moiety then yields the free glycopeptide **94**. This example illustrates that even glycopeptides with complex amino acids such as arginine can be synthesized on a solid support.

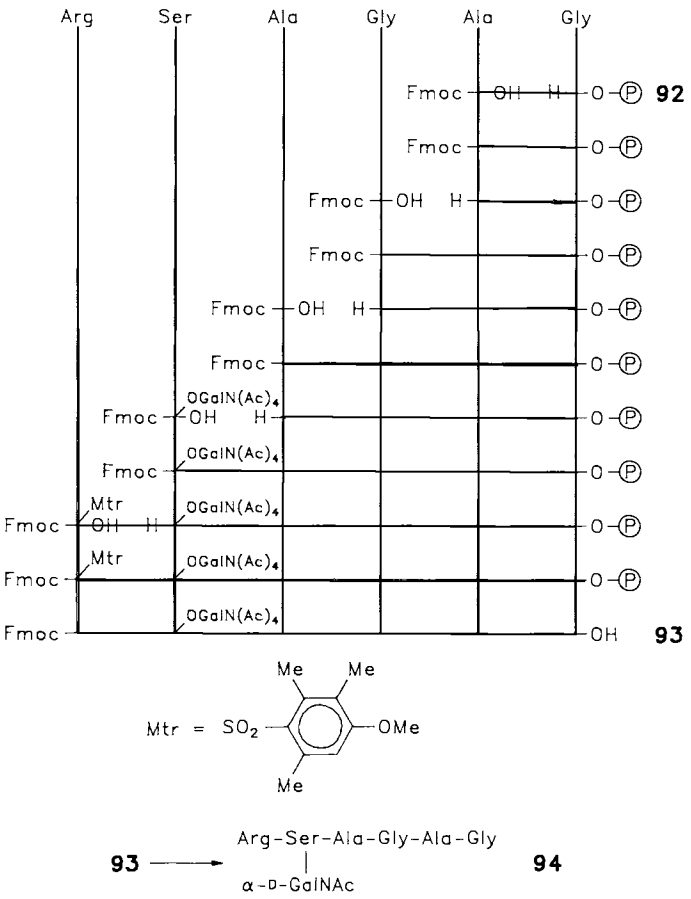


Fig. 8. Example of a solid-phase glycoprotein synthesis (Wang resin). Synthesis of Arg-Ser[α-D-GalNAc]-Ala-Gly-Ala-Gly **94**.

As well as a series of *O*-glycoproteins of the Core-I type, compound **78**, of the Core-II type, has also been synthesized.[82, 83] The xylose-containing compound **81** has been synthesized as the fragment β-D-Gal-(1 → 4)-β-D-Xyl-L-Ser[84] and also as the entire chain of **81**,[85] (for review articles see Refs.[44, 70]).

3.3. Conformational Analysis of *O*-Glycopeptides

Studies of the conformation of *O*-glycopeptides have concentrated especially on the molecular arrangement in the coupling region of the carbohydrate residue with the peptide chain. Though the peptide chain is always extremely flexible, in the carbohydrate-binding region preferred conformations are nonetheless to be expected. The question also arises of whether the peptide chain is significantly affected by the linked carbohydrate molecule.

The series of glycopeptides **95** to **98** have been studied particularly intensively.[86] These compounds make up seg-

ments of the *N*-terminus of interleukin-2. In interleukin-2, Ala is located at the *N*-terminus. Thr3 carries a carbohydrate chain of the Core-I type, which contains additional 5-*N*-acetylneuraminic acid residues. The entire molecule consists of 133 amino acids. The *N*-terminal structures **95** to **98** were synthesized by the above methods, with the peptide being extended by one or more units successively at the *C*-terminus.[76] This was done to examine whether extension of the peptide chain influenced the conformation of the sugar moiety at the link.

Ala-Pro-Thr-Ser
α-D-GalNAc **95**

Ala-Pro-Thr-Ser-Ser
α-D-GalNAc **96**

Ala-Pro-Thr-Ser-Ser-Ser
α-D-GalNAc **97**

Ala-Pro-Thr-$(Ser)_3$-Thr-$(Lys)_2$-Thr
α-D-GalNAc **98**

Ala-Ser-Gly-Ile
β-D-Xyl **99**

Conformational analysis was carried out by means of modern NMR spectroscopy, as described above. After assignment of all the protons with the aid of various correlation methods, coupling constants and NOE effects were determined using NOE, NOESY and ROESY experiments.[46] Hydrogen bonding was measured by the temperature dependence of the chemical shifts. Relaxation times afforded information about the mobility of the atoms. Evaluation of all the data yields a consistent picture which shows that there are significant amounts of preferred conformation around the coupling site.[86]

In addition, energy calculations for the molecules were carried out using the program AMBER,[49] after this had been tested for its applicability. It turned out that AMBER is suitable for calculations on peptide chains with one saccharide unit. Calculations for compound **95** led to the minimum conformation depicted in Figure 9a. This conformation turned out to be in very good agreement with the NMR data, especially with the coupling constants and NOE-effects observed. The protons between which NOE-effects were found are indicated with arrows in Figure 9a. The numbers given are the distances in Å derived from the AMBER calculation. At the distances given, it can be seen that NOE-effects are to be expected.

The arrangement between GalNAc and threonine is largely determined by the *exo*-anomeric effect of the glycosidic bond. The relationship between the peptide chain and the sugar residue, however, is probably dictated by steric influences. The conformation can be demonstrated by coupling constants and NOE-effects, e.g. between the methyl acetyl group of GalNAc and the serine. Here, one finds clearly preferred arrangements of the peptide chain and the sugar residue. It is interesting, now, to compare this with compounds **96**, **97** and **98**. It turns out that the basic arrangement for **95** given in Figure 9a appears almost completely unchanged on chain extension to **96**, **97** and **98**. Extension of the peptide chain at the *C*-terminus therefore has no significant influence on the preferred conformation around the linkage between saccharide residue and peptide chain.[86]

It should be mentioned that *Bush* et al.[87] have carried out a conformational analysis of the antifreeze-protein that is present as an anti-freezing agent in the blood of antarctic deep sea fish. The antifreeze-protein is a homopolymer of the peptide unit (L-Ala-L-Thr-L-Ala)$_n$, in which a hydroxy group of each threonine is glycosylated with a disaccharide of the Core-I structure. The preferred conformation determined by *Bush* et al. agrees well with that found for **95**. So far, there is only one X-ray analysis of a glycosyl amino acid, the rare structure α-D-Man(1 → *O*)-L-Thr, which occurs in bacteria.[88] The configuration in this X-ray structure is also in good agreement with the conformational minimum of **95** (Fig. 9a) calculated with AMBER.[86]

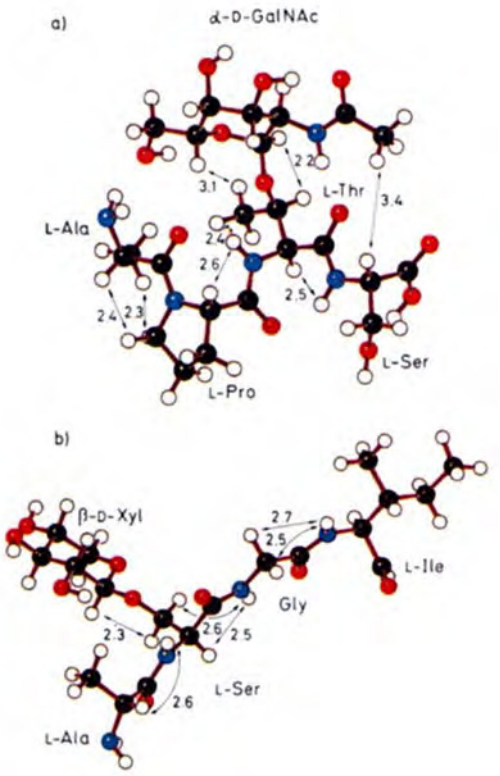

Fig. 9. Preferred conformation of *O*-glycopeptides, from NMR data and AMBER calculations. The arrows show the protons where NOE-effects were found which are important in determining the conformation. The numbers are distances in Å, from the calculations. a) Preferred conformation of Ala-Pro-Thr[α-D-GalNAc]-Ser **95**. b) Preferred conformation of Ala-Ser[β-D-Xyl]-Gly-Ile **99**.

Conformational analyses have also been carried out on *O*-glycopeptides with xylose and serine as the link.[89] This arrangement is more flexible, as shown by the NMR data of the simple compound β-D-Xyl(1 → *O*)-L-Ser. An example is the tetra-*O*-peptide **99**, which represents a sequence from proteodermatan sulfate in bovine skin. This was synthesized by direct glycosylation of the end-group-protected tetrapeptide with β-D-xylose tetraacetate, using the trimethylsilyl triflate procedure.[90] A conformational analysis was performed as for **95**, by evaluation of all available NMR data, and with an energy calculation using the program AMBER.

The result is presented in Figure 9b.[89] Here again, the arrows indicate the protons between which NOE-effects

were found, and the numbers are the distances in Å. The *exo*-anomeric effect is decisive here, too. Further, steric interactions are probably also important. The NMR measurements and energy calculations clearly show that there are also preferred conformations with structures like **99**, in which, as is shown in Figure 9b, the peptide chain adopts a particular arrangement with respect to the saccharide residue.

This review contains primarily the results of our research group. I am indebted to a large number of capable co-workers for their tireless commitment and stamina. The synthetic work was performed largely by K. Adermann, M. Heume, R. Lebuhn, G. Merz, H. Nürnberger, T. Peters, M. Raatz, H. Tietz. The conformational analyses of the N-protein structures were all carried out by Dr. T. Peters and Dr. V. Sinnwell, those of the O-protein structures by Dr. A. Pollex-Krüger. My special thanks are due to Dr. B. Meyer (Athens) for the GESA program, and for further calculations. I am also grateful to him for the diagrams of the F_c-fragment crystal structure, which were made at the University of Georgia (Complex Carbohydrate Research Center, Prof. P. Albersheim). I thank Professor R. Huber (Munich) for the data for the F_c-fragment crystal structure. Professor J. Deisenhofer (Dallas) kindly provided the corrected and refined data for the carbohydrate part of the crystal structure, which he had determined together with Dr. B. Meyer. For the programs MACROMODEL and AMBER, I thank Professor C. W. Still (New York) and Professor P. Kollman (San Francisco). The Deutsche Forschungsgemeinschaft has generously supported our work over many years.

Nonmolecular Metal Chalcogenide/Halide Solids and Their Molecular Cluster Analogues

By Sonny C. Lee and Richard H. Holm*

A variety of transition-metal cluster structures are found within the extended arrays of solid-state materials. Although molecular analogues of some of these clusters have been synthesized—either by the self-assembly of smaller components in solution or by the excision of intact cluster units directly from the solid-state phase—molecular chemists are often unaware of the rich structural variety expressed in solid-state clusters. This article presents these diverse structural types as potential targets for synthetic molecular chemistry by describing fundamental solid-state cluster topologies in transition-metal chalcogenide/halide phases and detailing cases where molecular counterparts have been prepared. Particular emphasis is placed on cluster excision as a method of molecular cluster synthesis.

1. Introduction

In a broad structural sense, crystalline nonmolecular compounds of the transition elements are of three types: (I) infinite polymers with no localized organizations of metal atoms recognizable as clusters, (II) extended arrays containing recognizable but condensed clusters that are polymeric by means of apex-, edge-, or face-sharing between repeating cluster motifs, and (III) extended arrays containing discrete, recognizable clusters, independent except for the bridging interactions between them. All three types are extensively represented.

Examples of noncluster solids (type I) include binary metal sulfides with the nickel arsenide (TiS, FeS, CoS), pyrite (FeS_2), and zinc-blende structures (BeS, ZnS).[1] While coordination units such as tetrahedral ZnS_4 and octahedral FeS_6 are readily apparent in such structures, no subset of metal and sulfur atoms is locally integrated into a cluster. Polymeric condensed cluster solids (type II) have been reviewed, with many examples, by *Simon*.[2] One prominent case is $M^I_2Mo_6Se_6$,[3] in which uncapped faces of the Mo_6 octahedron within the $[Mo_6Se_6]^{2\ominus}$ repeat unit are linked by metal–metal bonds to afford infinite chains. Nonmolecular solids with discrete clusters (type III) include Re_3Cl_9,[4] NbSeBr,[5] and $PbMo_6S_8$,[6] which contain discrete triangular $[Re_3(\mu_2\text{-}Cl)_3]$, cubane-type $[Nb_4(\mu_3\text{-}Se)_4]$, and face-capped octahedral $[Mo_6(\mu_3\text{-}S)_8]$ clusters, respectively, that are connected by metal–halide or metal–chalcogenide bridges. Also included in this category are finite condensed clusters such as the $[Mo_{12}Se_{14}]$ unit in $Cs_2Mo_{12}Se_{14}$,[7] which is composed of face-sharing Mo_6 octahedra and bridging selenide ligands. Pertinent to the considerations that follow is that the $[Re_3Cl_3]$ unit has been obtained in a variety of soluble molecular forms (e.g., $[Re_3Cl_{12}]^{3\ominus}$[8]) and $[Mo_6S_8]$ has been synthesized as $Mo_6S_8(PEt_3)_6$.[9] In these cases, the cluster structure in the solid state is retained in the molecule but with small dimensional changes.

Our interest in type III solids arose most recently while examining the reactions of the cage complex $[Co_4(SPh)_{10}]^{2\ominus}$ with NaSH. We synthesized the clusters $[Co_8S_6(SPh)_6]^{4\ominus/5\ominus}$[10] and came to recognize that their nearly cubic $[Co_8(\mu_4\text{-}S)_6]$ core topology is identical with that of the rigorously cubic clusters in cobalt pentlandite (Co_9S_8).[11] The availability of these clusters provided the initial opportunity to examine the structural, electronic, and reactivity properties of *molecular* Co_8S_6 species, albeit not at the same oxidation level as the pentlandite cluster. At about the same time, *Pohl* and *Saak*[12] prepared and structurally characterized $[Fe_8S_6I_8]^{3\ominus}$, a cluster topologically equivalent to the cobalt clusters and closely related to cluster structures in certain iron–sulfur minerals and synthetic phases.[13,14]

These observations raise the intriguing question of the accessibility of molecular analogues to the impressively wide array of clusters in type III solids synthesized in the laboratory by high-temperature methods or found naturally in minerals. Such analogues are available by only two approaches. One is the synthesis of soluble molecular solids, usually by low-temperature methods. This is the usual pursuit of the cluster chemist, and it remains a largely empirical approach. The second is the removal of an intact cluster from an extended array by reactions that rupture bridge bonds and stabilize and solubilize emergent clusters by substitution of appropriate ligands at metal sites.

While the recognition of clusters in solids is quite apparent in solid-state chemistry,[2,15–19] it is not always evident that this is the case for the molecular chemist working with clusters, particularly with respect to the wide range of cluster topologies found in type III solids. We anticipate that cognizance of clusters in solids will contribute to the development of reaction chemistry directed toward their isolation in molecular form. In this way, small fragments of solids—ideally, their structural motifs—will become available for study. A conspicuous step in this direction is the preparation, by a fragment coupling reaction, of $Mo_6S_8(PEt_3)_6$,[9] whose $[Mo_6S_8]$ core is the building block of the Chevrel phases.[6]

The compounds of primary interest are nonmolecular solids with discrete clusters containing chalcogenide and/or halide ligands. Coverage of these materials and the reactions by which clusters can be removed from certain of them is extensive, and deals with many representative cluster structures, but it is not exhaustive. Metal oxides are beyond the purview of this treatment, but an analogous structural classification applies to them.

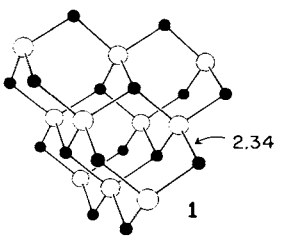
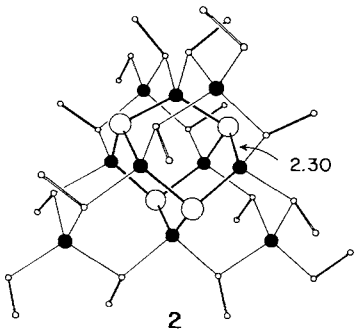
2. Noncluster Solids and Molecular Fragments

While type I solids are of only subordinate interest here, we note that fragments of their structures have been obtained in molecular form. In this and subsequent sections, the term "fragment" does not necessarily imply a strict isoelectronic or a metrically equivalent relationship with the bulk solid, but does mean core compositional identity and a structural similarity sufficient to justify a relationship to the solid. Three examples are considered. In them and others that follow, distances [Å] and angles [°] are mean values where appropriate.

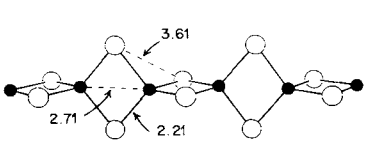


1

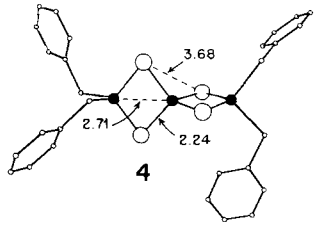


2

The mineral sphalerite (α-ZnS)[20] (**1**) exhibits one of the fundamental cubic lattices of solid-state chemistry. The molecular complex $[Zn_{10}S_4(SPh)_{16}]^{4\ominus}$[21] (**2**) can be viewed as a molecular fragment of the sphalerite lattice (the relevant Zn_6S_4 fragment is emphasized in the formula, with only the first carbon of each ligand included). The adamantanoid Zn_6S_4 center is only slightly distorted from the strict T_d symmetry found in the mineral, and Zn–S distances are comparable. A similar congruence can be observed in the case of $RbFeS_2$[22] (**3**) and the trinuclear Fe^{III} complex $[Fe_3S_4(SPh)_4]^{3\ominus}$[23] (**4**), both of which contain edge-sharing FeS_4 tetrahedra. Their Fe–S, Fe–Fe, and S···S distances are only slightly different, and both fragment **4** and polymer **3**

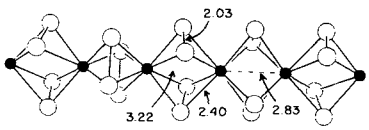


3

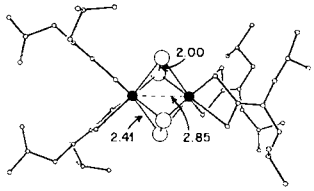


4

are antiferromagnetic. The structure **5** of the mineral patronite[24] (VS_2) consists of V^{IV} atoms bridged by η^2,η^2,μ_2-disulfide ligands with alternating short and long V–V distances. On the basis of the bond distances of its $[V_2S_4]$ core, $V_2(S_2)_2(S_2CN\mathit{i}Bu_2)_4$[25] (**6**) is a very close, solubilized version of the tight $V_2(S_2)_2$ fragment in the polymeric chain of the mineral. Note that clusters **2**, **4**, and **6** were not prepared by fragmentation of the corresponding solids.



5



6

Patronite is included here to illustrate a compound on the edge of type I and III solids. It is an infinite polymer with $V(S_2)_2$ repeat units. However, these units are not identical owing to the large (0.39 Å) difference in alternate V–V distances. We view the $V_2(S_2)_2$ chain fragment with the shorter

Richard H. Holm was born in Boston, Massachusetts, USA, and is a graduate of the University of Massachusetts (B.S., 1955) and the Massachusetts Institute of Technology (Ph. D., 1959). He has served on the faculties of the University of Wisconsin, M.I.T., and Stanford University. Since 1980 he has been at Harvard University, where he has been department chairman and is currently Higgins Professor of Chemistry. His research interests are in the area of inorganic and bioinorganic chemistry, with particular reference to synthesis, reactions, and structures pertinent to cluster chemistry and to biological processes.

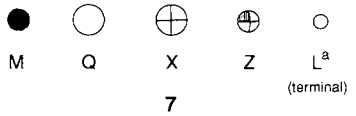
Sonny C. Lee was born in 1966 in Ping-Tung, Taiwan. He attended the California Institute of Technology as an undergraduate (B.S., 1987), where he performed research under the direction of Professor Terrence J. Collins. Currently, he is a National Science Foundation Predoctoral Fellow and Ph.D. candidate at Harvard University, where he is investigating metal–chalcogenide chemistry with Professor Holm.

V–V distance as a discrete cluster bridged to another by two disulfides. Further, the distance of 2.83 Å is short enough for there to be direct orbital interactions between the two metal atoms. Consequently, patronite and other compounds with alternating long and short distances between pairs of metal atoms are classified as type III solids. In general, the requirement for cluster designation is an organized collection of atoms with metal sites close enough for metal–metal interaction. Such interactions generally lead to spin-pairing and, in the limit, to strong metal–metal bonds.

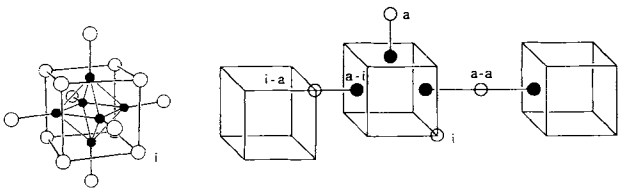
3. Nonmolecular Solids with Discrete Clusters

3.1. Nomenclature[*]

In the tabulations of compounds that follow, X is halide, Q a chalcogenide, and Z an atom interstitial to a cluster. When for a given compound type X = Cl, Br, or I and Q = S, Se, or Te, X and Q are not further specified in the formula. Metal (M), X, Q, Z, and terminal ligand atoms are symbolized as in **7**. In describing solid-state structures, the i/a notation of *Schäfer* and *von Schnering*[15] is employed and is illustrated with the diagrams **8** adapted from *Perrin* et



7



8

al.[18] The cubes represent an M_6L_8 core such as occurs in Mo_6Cl_{12}. Ligand L^i (inner) bridges metal atoms in the core of a cluster, while ligand L^a (apical) is a terminal or bridging ligand, always external to the core. These atoms can function in bridging modes L^{a-a}, L^{i-a}, and L^{a-i} between clusters, which in turn generate the connectivity of the extended solid-state array. Several examples are considered. The cluster connectivity of $Li_4Re_6S_{11}$[26] is $[Re_6S_i^i]S_{6/2}^{a-a}$; that is, the cluster contains a $[Re_6S_8]$ core (a Re_6 octahedron concentric with a S_8 cube) and a terminal sulfide at each Re site that forms a Re–S–Re bridge to another cluster. In Ta_6I_{14},[27] a more complicated connectivity pattern, $[Ta_6I_{10}^iI_{2/2}^{i-a}]I_{2/2}^{a-i}I_{4/2}^{a-a}$, is encountered. Ten iodine atoms of the $[Ta_6I_{12}]$ core (an edge-bridged Ta_6 octahedron) are unshared and two serve as apical ligands in other clusters. Two of the apical iodine atoms are part of the cores of, and four participate in Ta–I–Ta bridges to, other clusters. Illustrations of connectivity patterns appear in the following sections. Ligands involved in L^{i-i} interactions are found exclusively in type II solids. These solids are not further considered.

3.2. Clusters

Some seventeen cluster structural types have been identified in type III solids, all of which were prepared by high-temperature methods. These are collected in Tables 1–5, which are arranged in order of increasing cluster nuclearity. The great majority of these materials contain second- and third-row early transition elements in their lower oxidation states, familiar cases for the formation of metal–metal bonds. In this and subsequent sections, the emphasis is on structural patterns, synthesis, and reactivity of clusters. Electronic structural aspects of the clusters, many of which have been treated in the literature, are not included. Here, cluster structural types are briefly described.

Included in Table 1 are the bi-, tri-, and tetranuclear clusters **9**–**18**. Binuclear clusters **9** (excluding $MoCl_3$) and **11**–**13** contain metal–metal d^1–d^1 single bonds. While their connectivities are quite different, $NbCl_4$ and α-NbI_4 (**9**), NbS_3 (**11**), and VS_2 (**13**) share the characteristic of being linear polymers with alternating long and short metal–metal separations. In the other cases, the binuclear cluster units are well separated by halide bridges. In $Nb_3Se_5X_7$ (**13**), the additional niobium atom occurs in the $[Nb^{V}SeX_4]^{\ominus}$ ion, which interacts with $Nb_2^{IV}Cl_3$ bridges between clusters; this ion is not included in the connectivity description. The two d^3–d^3 cases, $MoCl_3$ (**9**) and β-$ReCl_4$ (**10**), form clusters by octahedral edge- and face-sharing, respectively. These clusters contain metal–metal triple bonds of length 2.76 Å in $MoCl_3$ and 2.73 Å in β-$ReCl_4$. Trinuclear clusters are of three structural types. The triangular planar clusters **14** are found only with the Re^{III} halides. Clusters **15** and **16** are related to **14** in possessing bonded M_3 triangles. The central triply bridging atom is displaced from the M_3 plane. Cluster **15** has the appearance of a cubane-type cluster but with one metal site vacant. In the case of **16**, the displacement of the central bridge atom is on the side of the plane opposite to that occupied by the exterior sulfur atoms of the disulfide ligands. Tetranuclear cluster **17** can be considered a derivative of **15** in which two M_3 triangles are edge-fused to form a centrosymmetric unit with a planar M_4 rhomb. The other tetranuclear cluster is the cubane-type **18**, which incorporates chalcogenides in the core. Each metal site has three halide or remaining chalcogenide terminal ligands that bridge to other clusters.

Hexanuclear clusters contain metal–metal-bonded octahedra with eight ligands capping triangular faces (**19**, **20**) or twelve ligands bridging edges (**21**, **22**). These structures are illustrated in Table 2. Structure **19** is most frequently encountered with Mo^{II} and W^{II} halides, but is also found with two Nb–I compounds. Its occurrence here is due to the size of the iodide ion, inasmuch as other Nb halides, which are also more oxidized, adopt structure **21**. At temperatures above 300 °C, Nb_6I_{11} absorbs dihydrogen at atmospheric pressure to form Nb_6HI_{11} (**20**). The interstitial atom has been located

by a neutron diffraction investigation of Nb_6DI_{11}.[55] Similarly, $CsNb_6I_{11}$ reacts with dihydrogen at 400 °C to afford an analogous cluster in which the interstitial atom causes small changes in cell parameters.[49] Under similar conditions, dihydrogen does not react with Ta_6Cl_{15} (**21**) and Mo_6Cl_{12} (**19**).[49]

A remarkable array of interstitial clusters **22**, principally containing Zr and with at least four connectivities, has recently been prepared by *Corbett* and co-workers.[19] All previously reported Zr_6X_{12}-type compounds are now recognized to contain interstitially substituted clusters. Size restrictions on the included atoms are not yet apparent; interstitial atoms currently range from H to first-row transition elements. Other types of interstitial cluster materials are summarized elsewhere.[2]

Hexanuclear chalcogenide and mixed chalcogenide/halide clusters are set out in Table 3. All have the face-capped octahedral motif **23**. The first two entries in the table are Chevrel phases, an extensive series of molybdenum-containing materials that also include clusters of nuclearities exceeding 6 (see below). Over 40 metals have been incorporated in the $M_xMo_6Q_8$ series. These atoms are not part of the clusters, but reside in channels in the crystal structures where they can sometimes be introduced by intercalation or removed by chemical or electrochemical reactions. Chevrel phases have been described at length.[6, 67, 68] The remaining compounds contain primarily the cubic $Re_6Q_{8-n}X_n$ units (n = 0–3). In the cases of mixed ligands, chalcogenide is always maximally incorporated within a cluster. Summaries of structural properties and further examples of these clus-

ters and of Mo chalcogenide/halide compounds are available.[16, 18, 80, 84, 85]

The few compounds containing the discrete octanuclear clusters **24** are listed in Table 4. The cluster consists of a cube of metal atoms concentric with an octahedron of sulfur atoms. It has been found naturally in three minerals, bartonite, djerfisherite, and pentlandite. The first compound listed, while synthetic in origin, is closely related to the mineral djerfisherite. Pentlandites usually contain mixed-metal Fe/Ni clusters, with traces of Co; however, several pentlandites have been identified in which Co is the principal metal.[87] The compound Co_9S_8 is synthetic in origin but has the pentlandite crystal structure. The additional Co atom, and a corresponding Fe, Co, or Ni atom in other compounds, is located in an S_6^i octahedral site and is not included in the connectivity formula.

Lastly, clusters of nuclearity higher than six occur in the various Chevrel phases that are listed in Table 5. Cluster **25** consists of two Mo_6S_7 units bridged by four sulfur atoms, one of which is of the rare μ_6 type. Clusters **26** and **27** are composed of linear arrays of face-sharing Mo_6 octahedra indicated by the brackets. The repeat unit is $Mo_6S_6^i$. In this manner, large condensed clusters of nuclearities as high as 30 have been achieved. Compounds of this sort terminate with $M_2^IMo_6Q_6$, which are pseudo-one-dimensional solids containing $^1_\infty[Mo_3Q_3]$ chains.

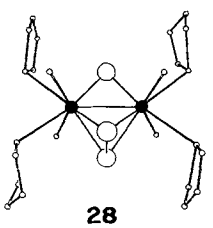
4. Synthetic Clusters Related to Those in Nonmolecular Solids

Many of the clusters present in type III solids have been prepared in molecular form by either low-temperature solution methods or removal from these solids by chemical reactions. In Table 6, clusters of crystallographically established structures whose cores are topologically (but not necessarily isoelectronically) related to those in nonmolecular solids are collected. The L^i notation is retained to designate ligands in the cluster cores. Preparations and structures of selected clusters are summarized.

4.1. Binuclear Clusters

Among the five types of binuclear clusters **9**–**13** in solids (Table 1), solubilized versions of all but **12** have been prepared. Cluster **11** has been produced in the form of $Nb_2S_3X_4(tht)_4$ (**28**) in the complex redox reaction (1) involving the reductive abstraction of sulfur from tetrahydrothiophene or solvent and the reduction of Nb^{V}.[144] The core portion of molecule **28** and cluster **11** in an extended lattice present the not uncommon situation of isoelectronic, topologically similar but metrically dissimilar structures. The latter feature is most evident in the Nb–Nb distances, which are 2.83–2.84 Å in **28** (X = Cl, Br), significantly shorter than the closest Nb–Nb separation of 3.04 Å in the NbS_3 linear polymer. Evidently, there are constraints specific to the extended structure that are relaxed upon passing to a molecular species. In this case a shorter, stronger metal–metal single bond occurs in the molecule.

$$NbSBr_3 + 5tht \xrightarrow[CS_2]{} \quad (1)$$



28

A molecular form of **13** as complex **6** is prepared from a mononuclear precursor in redox reaction (2).[125] Here sulfide functions as a reductant for V^{V} and the thiuram disulfide,

$$[VS_4]^{3\ominus} + 2(i\mathrm{Bu}_2\mathrm{NCSS})_2 \xrightarrow[\text{toluene}]{} V_2S_4(i\mathrm{Bu}_2\mathrm{NCS}_2)_4 + S_x^{2\ominus} \quad (2)$$

and appears as disulfide in the cluster product. The reaction of $[MoO_4]^{2\ominus}$ in aqueous polysulfide affords $[Mo_2S_{12}]^{2\ominus}$, al-

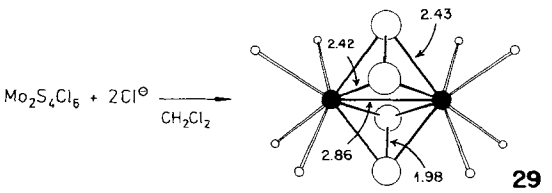
so containing **13**, and $[Mo_3S_{13}]^{2\ominus}$ as well, which apparently exists in equilibrium under the preparative conditions.[146]

In contrast to the foregoing processes, in which small clusters are assembled from soluble mononuclear species, heterogeneous reaction (3) in dichloromethane affords $[Mo_2S_4Cl_8]^{2\ominus}$ (**29**) in high yield.[101] This species contains

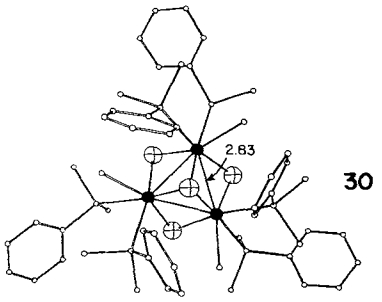


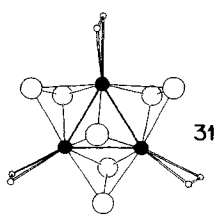
(3)

cluster unit **13** with bond distances that are within 0.03 Å of those in $Mo_2S_4Cl_6$; that is, the molecular cluster and that in the solid state are nearly identical. The reaction ostensibly removes the $Mo_2(S_2)_2$ cluster from the solid state by cleavage of the four chloride bridges linking clusters (Table 1). The reactant chloride is incorporated into the molecular product. We will hereafter term such a process a *cluster excision* reaction. We acknowledge that in no case has it been shown that a cluster remains intact in passing from the solid to the solution state; given the general structural stability of clusters with multiple bridging and metal–metal bonding, however, it is probable that most or all excision reactions result in the solubilization of intact cluster units. Reaction (3), while seemingly simple, exemplifies a large body of reactions that liberate clusters from solids in suitably ligated forms. Such reactions, which are not always recognized or described as ones of cluster excision, are considered more fully in Section 5. A second example of the apparent excision of a binuclear cluster is the isolation of $[Re_2Cl_9]^{2\ominus}$, containing **10**, by treatment of β-$ReCl_4$ with 12 N HCl followed by precipitation of the $Ph_4As^{\oplus}$ salt.[147] This species is oxidizable to the Re^{IV} complex $[Re_2Cl_9]^{\ominus}$, of known confacial bioctahedral structure.

4.2. Trinuclear Clusters

Clusters **14**–**16** (Table 1) are known in molecular form. Species containing the triangular unit **14** are generally derived from Re^{III} halides by excision reactions. The cuboidal unit **15** has been established in two Nb clusters, both prepared by the sodium amalgam reduction of $NbCl_4(thf)_2$ in toluene in the presence of a tertiary phosphane.[104] These clusters bracket by one electron the oxidation state of Nb_3Cl_8, whose Nb–Nb distance in **15** is 2.81 Å. The more reduced of these, $Nb_3Cl_7(PMe_2Ph)_6$ (**30**) with a metal–metal distance of 2.83 Å, bears the stronger resemblance to Nb_3Cl_8; the equivalent distance in the more oxidized cluster is 2.98 Å. In many respects, $[Mo_3S_{13}]^{2\ominus}$ (**31**), which we have already noted to be formed from molybdate and polysulfide, is prototypic of soluble forms of **16**. It is virtually isostructural with the cluster in $Mo_3S_7Cl_4$. Other clusters contain combinations of bidentate chelate ligands, tertiary phosphanes, and solvate ligands in place of the terminal disulfides. In addition, the pyridinium salt of $[Mo_3S_7Cl_7]^{3\ominus}$ carries six terminal chloride ligands and a seventh chloride which approaches the terminal sulfur atoms of the disulfide along a threefold axis at a distance of 2.97 Å.





4.3. Tetranuclear Clusters

Cluster **17** (Table 1) is unknown in any molecular form. However, the cubane-type unit **18**, composed of concentric Q_4 and metal–metal-bonded M_4 tetrahedra, is a familiar structural entity in molecular clusters. No such clusters containing the Nb_4Q_4, Mo_4Se_4, or $Mo_2Re_2S_4$ cores have been prepared. However, within the last eight years, a set of Mo_4S_4 clusters in several different oxidation states has been obtained. The first of these, $[Mo_4S_4(CN)_{12}]^{8\ominus}$, was isolated as its potassium salt from the reaction of MoS_3 and aqueous cyanide.[115] Subsequently, other methods of preparation have been developed, including the reaction of $Mo(CO)_6$ and Na_2S in acetic anhydride followed by hydrolysis and workup by ion exchange[114] and by chemical[113] and electrochemical[148,149] reduction of Mo^V. The latter method is illustrated in reaction scheme (4).

Reductive electrolysis of the μ-oxo Mo^V cysteinate complex at a mercury-pool electrode followed by ion-exchange separation affords a trinuclear and a tretranuclear aquo ion [Eq. (4)]. The latter is readily converted into the edta derivative, whose oxidation and reduction affords $Mo^{IV,III}$ di- and

$$Na_2[Mo_2O_2S_2(Cys)_2] \xrightarrow[2)\ \text{cation exchange}]{1)\ \text{electrolysis}} [Mo_4S_4(OH_2)_{12}]^{5\oplus} + [Mo_3S_4(OH_2)_9]^{4\oplus} \quad (4)$$

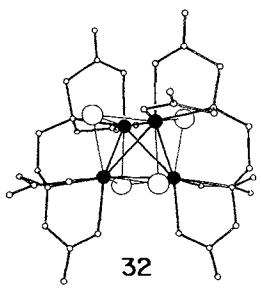
leaf-green; dark green

$[Mo_3S_4(OH_2)_9]^{4\oplus}$ $\xrightarrow{NCS^{\ominus}}$ $[Mo_3S_4(NCS)_9]^{5\ominus}$

$[Mo_4S_4(OH_2)_{12}]^{5\oplus}$ $\xrightarrow{Na_2(edta)}$ $[Mo_4S_4(edta)_2]^{3\ominus}$

$$[Mo_4S_4(edta)_2]^{2\ominus} \xleftarrow{Br_2} [Mo_4S_4(edta)_2]^{3\ominus} \xrightarrow{NaBH_4} [Mo_4S_4(edta)_2]^{4\ominus} \quad (5)$$

tetraanions [Eq. (5)]. This series and related redox series of other Mo_4S_4 clusters can also be traversed electrochemically. The cubane core is apparent in the structure of $[Mo_4S_4(edta)_2]^{3\ominus}$ (**32**). Successive oxidation increases the



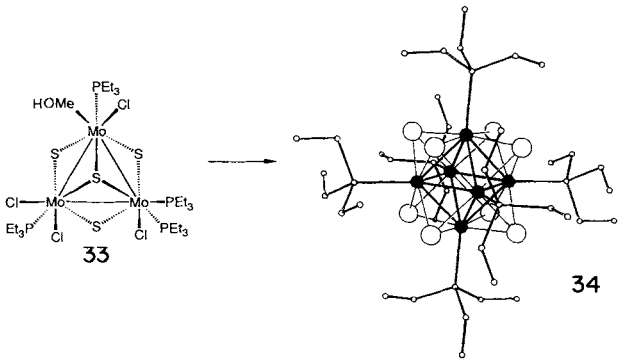
volumes of the Mo_4 tetrahedron and Mo_4S_4 core,[145] indicating that removal of electrons from electron-precise $[Mo_4S_4(edta)_2]^{4\ominus}$ (12 electrons) depopulates the six bonding Mo_4 orbitals ($a_1 + e + t_2$) in T_d symmetry. Consequently, the mean Mo–Mo distances increase by ca. 0.05 Å across the series, while the Mo–S distances are indistinguishable. The tri- and tetraanions are isoelectronic with the clusters **18** in $M^{III}Mo_4S_8$ and MoSX, respectively. Further, the molecular and solid-state clusters[43,44] are congruent in structure, inasmuch as Mo–Mo and Mo–S distances are the same to within ca. 0.02 Å. The other product of reaction (4), $[Mo_3S_4(OH_2)_9]^{4\oplus}$,[148,150] is conveniently isolated as its thiocyanate derivative. In this form and all others,[151] the $[Mo_3S_4]^{4\oplus}$ core has the cuboidal topology of **15**. However, no M_3Q_4 core has yet been detected in a type III solid.

4.4. Hexanuclear Clusters

With the exception of **20**, the solid-state halide clusters **19**–**22** (Table 2) have been isolated in molecular forms. A number of these, including the familiar ions $[M_6X_{14}]^{2\ominus}$ (M = Mo, W) and $[M_6X_{18}]^{2\ominus}$ (M = Nb, Ta), readily visualized by addition of a terminal halide at each metal site in **19** and **21**, respectively, are usually obtained by excision from solids. These reactions are illustrated in Section 5. Certain molecular clusters are also obtainable by high-temperature solid-state reactions. Examples include $LuNb_6Cl_{18}$ and $M^ILuNb_6Cl_{18}$, whose structures contain isolated $[Nb_6Cl_{18}]^{3\ominus/4\ominus}$ clusters.[152,153] The solubility properties of these solids have not been reported. Among halide clusters, a special case is W_6Cl_{18}, obtained by the reaction of W_6Cl_{12} with liquid chlorine.[137] This compound contains the core **21**. It is the only hexanuclear Mo or W cluster that is *not* based on the core **19** and thus has no solid-state analogue. Clusters of types **19** and **21** undergo terminal halide substitution, affording entry to a large group of substituted species. Examples include the reaction of $[Mo_6Cl_4]^{2\ominus}$ with NaOMe in methanol to give $[Mo_6Cl_8(OMe)_6]^{2\ominus}$[154] and the formation of the alkyl-substituted clusters $Mo_6Cl_8Cl_2R'_2(PR_3)_2$ from $Mo_6Cl_8Cl_4(PR_3)_2$ and R'_3Al in toluene.[134]

Heating a solution of $Zr_2Cl_6(PMe_2Ph)_4$ under undefined conditions gave $Zr_6Cl_{12}(PMe_2Ph)_6$ in unspecified yield.[119] This cluster is based on **21**, but it is not known if the actual core is **22** with a conceivable interstitial hydrogen atom. An "empty" cluster would be quite surprising in view of the experience of *Corbett* and co-workers with solid-state structures.[19] In those cases, an interstitial atom Z appears to be obligatory in order to achieve a cluster-based electron count at (or near) 14, which from MO arguments affords stability. A clear example of an isolated interstitially substituted cluster **22** is found in the solid phase $Rb_5Zr_6BCl_{18}$, prepared from elemental Zr and B, RbCl, and $ZrCl_4$ in a sealed Ta container at 850 °C.[120] The crystal structure consists of independent $[Zr_6BCl_{18}]^{5\ominus}$ clusters immersed in an environment of rubidium cations. Whether or not this compound is a *soluble* source of its cluster remains to be seen.

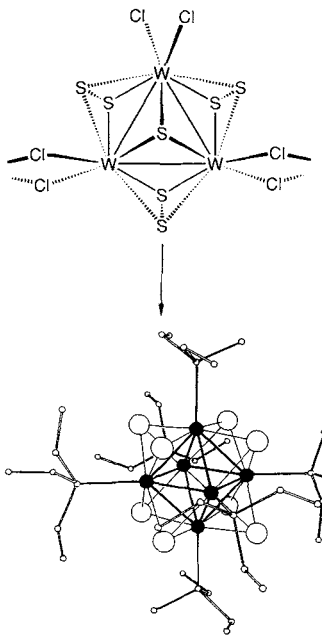
There is a much smaller set of molecular chalcogenide/halide clusters **23** (Table 3). A major advance in this area was achieved by *Saito* et al.[9] in the form of reaction (6). In this attractive conception, fragment condensation of two cuboidal Mo_3S_4 clusters **33** is employed to generate the product cluster **34**, obtained in 30% yield as dark purple crystals. The W analogue **36** has been synthesized by the related reaction (7) and isolated in 10% yield as light brown crystals.[155] In this case, the fragments are the clusters **35** present in $W_3S_7Cl_4$. Clusters **34** and **36** are mixed-valence species with 20 core electrons and essentially identical structures; **36** is the first example of a W_6Q_8 cluster in either a molecular or solid-state condition. The structures are consistent with electronically delocalized descriptions. For reasons presently unclear, the Mo–Mo distance of 2.66 Å in **34** is closer to that of Chevrel phase clusters with 24 rather than 20 electrons.[9] Both clusters can be oxidized and reduced to $[M_6S_8(PEt_3)_6]^{\oplus/\ominus}$ at potentials that, as expected, are more



33 34

$$2[Mo_3S_4Cl_4(PEt_3)_4(MeOH)] + 2Mg \xrightarrow[THF]{} Mo_6S_8(PEt_3)_6 + 2MgCl_2 + 2Et_3PCl_2 + 2MeOH \quad (6)$$

$$2[W_3S_7Cl_4] + 10PEt_3 \xrightarrow[toluene]{} W_6S_8(PEt_3)_6 + 6Et_3PS + 4Et_3PCl_2 \quad (7)$$



35 36

negative for **36** than for **34**. Our proposed reaction stoichiometries are consistent with the required eight-electron reductions in passing from fragments to cluster, but are not

experimentally established. If they are correct, an interesting feature is the use of Et_3P as a reducing agent for M^{IV} in both reactions and for disulfide in reaction (7) in addition to serving as a stabilizing terminal ligand in the product clusters. Most important, however, is the outcome of reaction (6), which provides the first access to a Chevrel phase cluster in *molecular* form. Prior to this work, one sulfur atom had been introduced to form the $[Mo_6SCl_7]^{3\oplus}$ core of $[Mo_6SCl_{13}]^{3\ominus}$ by the reaction of Mo_6Cl_{12} and NaSH in refluxing pyridine followed by treatment with HCl.[139] The cluster was isolated as a soluble pyridinium salt; X-ray diffraction could not distinguish sulfide from chloride in the core.

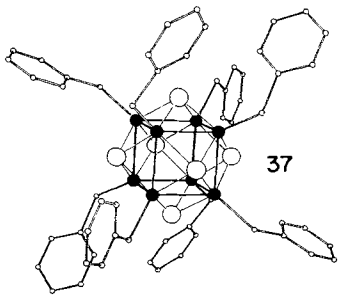
A series of compounds (see Table 6) with the $[Re_6Q_nX_{8-n}]$ core **23** have been prepared by high-temperature methods. These solids contain isolated clusters, and several are sources of solubilized clusters. The compounds $Re_6Q_4X_{10}$ (Q = Se, Te; X = Cl, Br) are claimed to be insoluble in organic solvents but dissolve upon heating in Me_2SO solution in the presence of N-donor ligands L, including Et_3N.[158] If the initial compounds all contain **23**, as is the case for $Re_6Se_4Cl_{10}$ (Table 6), the corresponding product formulations are $Re_6Q_4X_{10} \cdot 2L \cdot 2Me_2SO$; there is no structural characterization of these species. $KRe_6Se_5Cl_9$ is described as slightly soluble in ethanol, and recrystallization from aqueous ethanol gives $K[Re_6Se_5Cl(OH)_2Cl_6]$, where hydroxide has displaced chloride form the core.[19] Further, metathesis of the former compound with Bu_4NCl in absolute ethanol affords $(Bu_4N)[Re_6Se_5Cl_9]$,[142] which is soluble in organic solvents. The synthesis and properties of octahedral Re_6 clusters have been summarized.[19, 85] The availability of serveral soluble species provides an entry to the molecular chemistry of these clusters.

4.5. Octanuclear Clusters

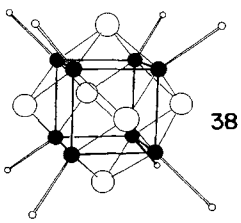
The face-capped cubic cluster **24** has been achieved in two synthetic species. Reaction (8) affords the product cluster **37** as a black solid, which is isolated in 50% yield as the $Pr_4N^{\oplus}$ salt.[10] The cluster can be reduced to the pentaanion, in

$$2[Co_4(SPh)_{10}]^{2\ominus} + 6HS^{\ominus} \xrightarrow[Me_2CO]{} \underset{\mathbf{37}}{[Co_8S_6(SPh)_8]^{4\ominus}} + 6PhS^{\ominus} + 6PhSH \quad (8)$$

which the $[Co_8S_6]^{3\oplus}$ core is one electron more oxidized than **24** in cobalt pentlandite. The cluster in Co_9S_8 is topologically similar to **37** but is substantially smaller, with Co–Co and S^i–S^i distances that are 0.15 and 0.23 Å shorter, respectively. The black cluster $[Fe_8S_6I_8]^{3\ominus}$ (**38**) was mechanically separated in 40% yield as its $Et_4N^{\oplus}$ salt from a complicated reaction mixture initially containing Fe metal, iodine, iodide, and the prismane cluster $[Fe_6S_6I_6]^{2\ominus}$.[112] The only property of the compound that has been determined is its crystal structure. The cluster contains a nearly perfect Fe_8 cube whose range of Fe–Fe distances (2.70–2.73 Å) includes the corresponding distances in bartonite (2.73 Å) and synthetic djerfisherite (2.72 Å). Thus, in this case, the molecular cluster is topologically and dimensionally equivalent to the solid-state compounds. Investigation of the chemistry of this unique Fe–S cluster awaits the development of an efficient synthesis.



37



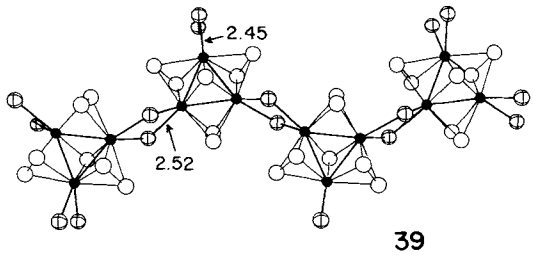
38

5. Clusters from Solids: Excision Reactions

Solubilization of discrete clusters in type III solids has been introduced by reaction (3), in which a binuclear cluster is removed from the solid phase in the form of its chloride derivative. Cluster excision is a reaction that can be recognized to occur in a range of solids where clusters are bridged by halide in a variety of connectivity patterns. Inasmuch as there are few clearcut cases of binuclear cluster excision, and such clusters are usually obtainable by low-temperature solution synthesis, we concentrate on the excision of higher nuclearity clusters. Those which have been removed from solids are of the trinuclear and hexanuclear types, and the conditions of excision are summarized in Tables 7 and 8, respectively. In recognizing these reactions, we assume that the cluster $[M_nL^i_m]$ remains intact upon its liberation from the solid phase in the form of the molecular cluster $[M_nL^i_m]L^a_x$, or if not, converts into a structurally related cluster of equal nuclearity. In nearly all cases, x is the same as the total of L^a, L^{a-a}, and L^{a-i} ligands in the solid phase. When describing the connectivities specified in Tables 1 and 2, we quote mean metal–ligand bond distances.

5.1. Trinuclear Clusters

Two types of intact clusters have been excised by the reactions in Table 7, $[Mo_3(S_2)_3S]$ (**16**) in $Mo_3S_7X_4$ and triangular Re_3X_3 (**14**) in Re_3X_9. Considering first the Mo clusters, the connectivity **39** of $Mo_3S_7X_4$ shows that the clusters are



39

arranged in a zigzag chain through four chloride bridges per cluster.[37] The terminal Mo–Cl bond distance is 2.45 Å and the bridging distances range from 2.47 to 2.56 Å and average to 2.52 Å. In 1980, *Müller* et al.[183] reported the conversion of $Mo_3S_7Cl_4$ to $[Mo_3S_{13}]^{2\ominus}$ (**31**) with aqueous polysulfide (but without supporting detail). Later, this reaction was car-

Table 7. Excision of clusters from nonmolecular solids with discrete trinuclear clusters.

Re_3Cl_9 ("aged")	RMgX; THF, Et_2O	$Re_3Cl_3^iR_6$ (R = Me, CH_2Ph, CH_2CMe_3, CH_2SiMe_3)	[165, 166, 182]

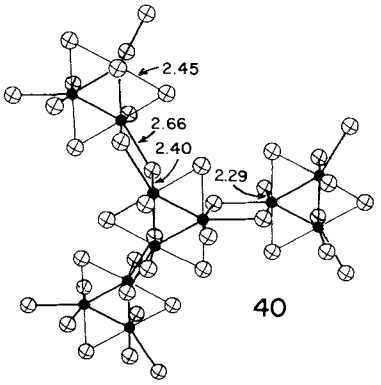
ried out in boiling aqueous polysulfide to give the same product. Reaction with Ph_3P in refluxing acetonitrile affords $Mo_3S_7X_4(PPh_3)_2$. Identification of the latter compounds, obtained in 40–48% yield, was claimed on the basis of mass spectrometry and partial elemental analysis; their structures have not been proven by X-ray analysis. The lack of firm characterization and the forcing conditions of both reactions perhaps render these two cases among the least certain of intact cluster excision.

When allowed to react with excess tertiary phosphane at room temperature over periods of hours to days, cluster **16** of $Mo_3S_7Cl_4$ was partially desulfurized to the cuboidal Mo_3S_4 core, which was solubilized as a chloro-phosphane cluster. Illustrative reaction (9) accounts for the formation of

$$Mo_3S_7Cl_4 + 6\,Et_3P \xrightarrow[MeOH]{} Mo_3S_4Cl_3(PEt_3)_3(MeOH)_2 + 3\,Et_3PS \quad (9)$$

one of the two clusters obtained in the reaction with Et_3P. It and the related transformations in Table 7 are further examples of the reduction of coordinated disulfide to sulfide with nucleophiles.[184] A related example is the conversion of $[Mo_3S_{13}]^{2\ominus}$ to $[Mo_3S_4(CN)_9]^{5\ominus}$ with cyanide.[185] Reaction of $Mo_3S_7Cl_4$ with five equivalents of Ph_3P in hot acetonitrile is reported to give three equivalents of Ph_3PS and $Mo_3S_4Cl_4(PPh_3)_2$. The terminal ligand formulation of the cluster product is subject to reexamination in view of the compositions of the four Mo_3S_4 clusters in Table 7, whose structures have been crystallographically established.[41,156] These are the only evident reactions in which clusters are removed from the solid state with modification in the bridge modality at constant nuclearity.

The Re^{III} halides are readily solubilized by a variety of means, a behavior that is readily understandable in terms of the connectivity pattern **40** of Re_3Cl_9.[5] The triangular clusters **14** are bridged to each other through one of the two Cl atoms at each Re site that are out of the Re_3 plane. The result

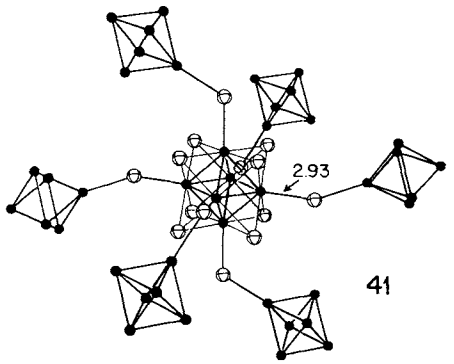


is a layer structure with four Re–Cl distances: Re–Cl^a, Re–Cl^i, and two types of Re–Cl^{a-a} distances involving Cl atoms in and out of the Re_3 plane. The three bridging interactions in the plane are ca. 0.2 Å longer than any other bond length in the crystal structure, which approaches the limit of a molecular solid. The structure of Re_3Br_9 has not been determined. That of Re_3I_9 has a different connectivity (Table 1), in which two Re atoms in a given cluster are linked through iodide bridges to adjacent clusters, leading to chains of cluster units rather than a lamellar network. Again, the longest bonds (also by ca. 0.2 Å) are the bridge bonds in the Re_3 plane. It would appear that facile cleavage of these bonds by even weak nucleophiles permits the ready excision of Re_3X_9 units from the solid. Many of these reactions are listed in Table 7.

Rhenium^{III} chloride is soluble in solvents such as acetone, acetonitrile, and DMF to afford the species $Re_3Cl_9(solv)_3$, which are readily susceptible to substitution reactions. Various observations support the lability order Cl^a (in plane) > Cl^a (out of plane) > Cl^i.[147] Because it is not known that solubilization of Re_3X_9 in the presence of added ligands occurs exclusively by solvation, reactions in the presence of such ligands are taken to fall under the excision description and are included in Table 7. In such systems, a large variety of derivatives of Re_3X_9 have been obtained including the classic ions $[Re_3X_{12}]^{3\ominus}$. These are among the simpler solubilized forms of **14** and support an extensive substitution chemistry. Substituted derivatives may be obtained directly under excision conditions, and then further modified. For example, Re_3Cl_9 has been excised as $[Re_3Cl_9(N_3)_3]^{3\ominus}$ by reaction with azide in acetone at $-10\,^{\circ}C$, and converted into $[Re_3Cl_6(N_3)_6]^{3\ominus}$ and $[Re_3Cl_3(N_3)_9]^{3\ominus}$ in subsequent reactions.[160] The substitution reactions of clusters with core **14** are beyond the scope of this review, but have been described by *Cotton* and *Walton*.[147]

5.2. Hexanuclear Clusters

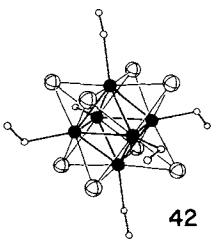
Clusters of types **19**, **21**, and **22** have been excised from solids by the reactions in Table 8. A particularly interesting example of the solubilization of a face-capped cluster **19** occurs with Nb_6I_{11}, which has the connectivity pattern **41**. Each Nb atom of a given cluster is bridged by a single iodide to another Nb atom, each of these belonging to a different cluster. (In the interest of clarity, we retain only the metal



41

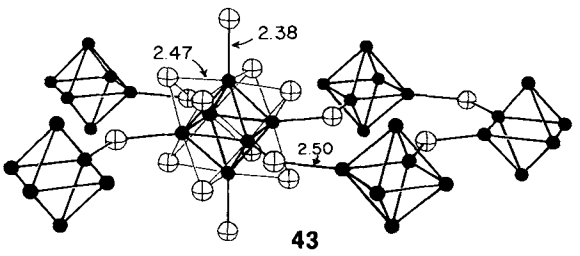
atoms of some clusters in this and several subsequent depictions of connectivity.) Treatment of Nb_6I_{11} with methylamine [Eq. (10)], or with *n*-propylamine under similar conditions, results in the slow dissolution of the solid-state cluster phase to afford $Nb_6I_8(RNH_2)_6$. The structure of the diamagnetic cluster **42** reveals that the I^{a-a} atoms in the solid state have been replaced by methylamine in the molecular cluster. Certain spectroscopic features of these clusters have been examined.[121,186] However, their reactivity properties have not been investigated.

$$Nb_6I_{11} \xrightarrow[\text{in EtOH}]{20\%\ MeNH_2} \quad (10)$$



42

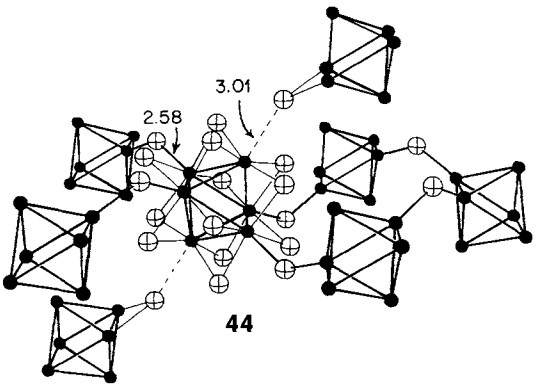
Replacement of two X^{a-a} atoms in a structure such as **41** by two X^a atoms produces the composition M_6X_{12} of the Mo^{II} and W^{II} halides. These compounds show the connectivity pattern **43**. The X^a atoms are *trans*, resulting in a layer



43

structure; the terminal and bridging distances given are for Mo_6Cl_{12}.[30] Bridge bonds are cleaved in the presence of polar solvents to give $Mo_6Cl_{12}(solv)_2$. Addition of other ligands to the excision system provides a simple route to clusters with a variety of terminal ligands. Depending on conditions, up to four halides may be substituted. The situation is similar to that of Re_3Cl_9, where a two-dimensional bridging network is interrupted by reaction with solvent and/or added nucleophiles.

With edge-bridged clusters **21**, four bridging interactions in the same plane result in the composition M_6X_{14} and the connectivity scheme **44**. A typical example is Nb_6Cl_{14}, whose clusters are arranged in a layer structure and connected by Nb–Cl^{a-a} bonds of 2.58 Å. The layers weakly interact through long Nb–$Cl^{i-a/a-i}$ bridge bonds of 3.01 Å. If all



44

bridging interactions are of the M–X^{a-a} type, the composition is M_6X_{15}, as with Ta_6Cl_{15}, and the compound assumes a three-dimensional network structure similar to **41**. When anhydrous, these compounds dissolve with some difficulty in certain polar solvents in the absence of halide, but appear to be more readily soluble in the presence of halide (Table 8).

W_6I_{12} (**43**)	EtOH	$W_6I_8^iI_4(EtOH)_2$	[176]
W_6X_{12} (**43**)	aqueous HL; EtOH (L = Cl, Br, I)	$[W_6X_8^iL_6]^{2\ominus}$	[173, 176]
M_6X_{14} (**44**) (M = Nb, Ta; X = Cl, Br)	H_2O; aqueous HCl; MeOH; EtOH	"$[M_6X_{12}^i]^{2\oplus}$"	[177–180]
Ta_6X_{14} (**44**) (X = Cl, Br)	HX, X_2; MeOH (Δ)	$[Ta_6X_{12}^iX_6]^{2\ominus}$	[177]
Ta_6Cl_{15}	H_2O	"$[Ta_6X_{12}^i]^{2\oplus}$"	[180]
KZr_6CCl_{15}	18-crown-6, Et_4NBr; MeCN	$[Zr_6CCl_{12}^iCl_6]^{4\ominus}$	[181]
KZr_6FeCl_{15}	[2.2.2]cryptand, Et_4NBr; MeCN	$[Zr_6FeCl_{12}^iCl_3Br_3]^{4\ominus}$	[181]
$Na_4Zr_6BeCl_{16}$	[2.2.2]cryptand (PPN)Cl, MeCN	$[Zr_6BeCl_{12}^iCl_6]^{4\ominus}$	[181]

The species produced range from $[M_6X_{12}(solv)_6]^{2\oplus}$ to $[M_6X_{18}]^{2\ominus}$ or their redox products, depending on reagents used. Species written as "$[M_6X_{12}]^{2\oplus}$" are possible mixtures of solvated and solvated/halide species. Dissolution of hydrated compounds such as $M_6X_{14} \cdot nH_2O$ (M = Nb, Ta; X = Cl, Br)[178, 179, 187] is unlikely to be a reaction of cluster excision inasmuch as $Ta_6Cl_{14} \cdot 7H_2O$ contains the unbridged cluster $Ta_6Cl_{14}(OH_2)_4$ (Table 6). Lastly, we observe that, in work currently at an early stage, at least three edge-bridged interstitial clusters **22** have been excised; all possess connectivities through halide bridges. Molecular clusters have been obtained by the addition of halide and crown ether or cryptand to solubilize $Na^{\oplus}$ or $K^{\oplus}$ in the acetonitrile reaction solvent. It remains to be seen if other types of halide-bridged interstitial clusters,[188] such as Y_6RuI_{10} and those of the type M^{III} (M_6ZI_{12}), containing a six-coordinate non-cluster metal ion, can be solubilized. Their structures present $Y\text{–}I^{i-i}$ and $Y\text{–}I^{i-a}$ interactions on the one hand and $M\text{–}I^{i-i}$ and $I\text{–}M^{III}\text{-}I$ bridges on the other.

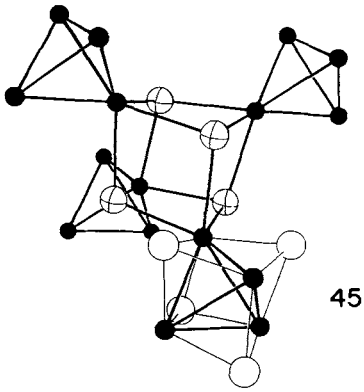
6. New Molecular Clusters from Old Solids: Some Prospects

Of cluster structural *types* having nuclearities of three or higher (**14**–**27**), clusters **14**–**16**, **18**, **19**, possibly **21** or **22**, **23**, and **24** have been prepared by low-temperature solution methods. The accessibility of **21** or **22** currently rests with $Zr_6Cl_{12}(PMe_2Ph)_6$, whose cavity occupancy is unclear as is the method of preparation and the yield. For **23**, there are just two examples, $Mo_6S_8(PEt_3)_6$ (**34**) and $W_6S_6(PEt_3)_6$ (**36**). However, a number of specific examples of these structural types have been prepared only at high temperature. Although such clusters, as well as those (**17**, **20**, **25**–**27**) thus far accessible only by high-temperature reactions, might well be assembled at low temperature, some of them may first be obtained in molecular form by excision from the solid state. A case in point is the Nb_6I_8 core **19**, acquired in the amine-derivatized form **42** by excision reaction (*10*). The starting material Nb_6I_{11} can be obtained by thermal decomposition or reduction of Nb_3I_8 with Nb at temperatures of 800 °C or higher.[51] No Nb_6I_8 species has been prepared by a low-temperature reaction. We call attention to several possibilities for cluster solubilization.

6.1. Halide-Bridged Clusters

Given that all successful reactions of cluster excision have been performed with type III solids having only *halide* bridges (Tables 7 and 8), we note several clusters that may be solubilized on this basis. Thus, the W_3S_7 core **16**, unknown in molecular form, is potentially accessible from $W_3S_7X_4$ (X = Cl, Br; Table 1). Further, from an appropriate molecular form of **16** the unknown cuboidal W_3S_4 core should be attainable by reduction of disulfide with cyanide or tertiary phosphanes in a process analogous to reaction (9).

A particularly intriguing problem is posed by the compounds containing cubane-type cluster **18** (Table 1). The compounds NbQX are prepared from the elements at ca. 700–900 °C.[5] Their crystal structure is cubic and isomorphous with MoSX. These structures have the connectivity pattern **45**. Each metal atom forms three $M\text{–}X^{a-a}$ bonds to different clusters, as part of its octahedral MQ_3X_3 coordination sphere. Consequently, the bridges are of the type



45

$M(\mu_2\text{-}Cl)_3M$. In NbSeI the Nb–I distance of 3.02 Å is longer than the bridge bond in Nb_6I_{11} (2.93 Å), which was broken in cluster excision. The phases MoSX potentially could yield the $[Mo_4S_4]^{4\oplus}$ core, although it is obtained more conveniently by low-temperature processes such as reactions (4) and (5). However, the Nb_4Q_4 core in any oxidation state has never been achieved in molecular form, or indeed in any solid phase other than NbQX. Consequently, its electronic and reactivity properties are completely unknown. Excision systems with halide to afford $[Nb_4Q_4X_{12}]^{8\ominus}$, or, better, with a halide/tertiary phosphane mixture to afford the species $[Nb_4Q_4X_{12-n}(PR_3)_n]^{(8-n)\ominus}$, appear to be reasonable possibilities. Examination of Tables 1–3 reveals other halide-bridged clusters potentially subject to solubilization. Reactions involving halide and/or phosphane might be employed to solubilize the $[Nb_4X_6]^{4\oplus}$ core **17** of $M^{I}Nb_4X_{11}$. Similarly, certain $[ReQ_nX_{8-n}]$ clusters **23** (n = 5–7) are potentially obtainable by excision. However, as already noted, the n = 4–6 species have been prepared in molecular form in high-temperature reactions (Table 6). The synthesis of interstitial clusters **22** with Z larger than a hydrogen atom by other than high-temperature methods is difficult to conceive. While several such clusters have been prepared in molecular form by high-temperature processes, the great majority of compounds containing **22** are halide-bridged in several different connectivities. Excision reactions are a promising route to these fascinating molecules, as borne out by the experiments of *Corbett* and co-workers (Table 8).

6.2. Chalcogenide-Bridged Clusters

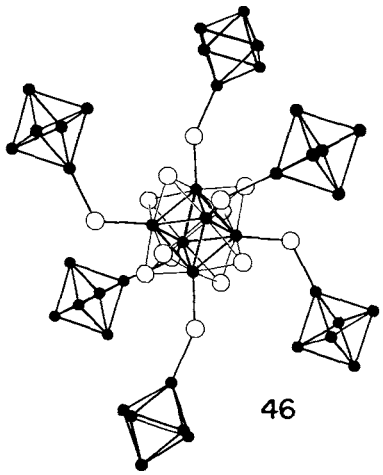
The characteristic structural motif of Mo and Re binary and ternary chalcogenides is the face-capped octahedral cluster **23**; it has not been found in other metal chalcogenide phases. In molecular form the Mo_6Q_8 core is known only in sulfide cluster **34**. No molecular species containing any Re_6Q_8 core has been prepared; consequently, the chemistry of clusters with the core is completely unexplored. Hence, considerable interest attends solid phases containing these two units, many of which are listed in Table 3. This tabula-

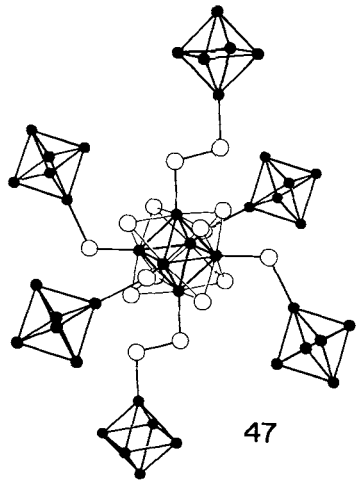
tion does not include Mo_6Q_8 cluster phases with Q^{i-i} interactions (type II solids), which presumably could not be broken without substantial or complete cluster degradation. The most promising cases for cluster excision are materials in which chalcogenide bridges are of the Q^{a-a} type only. In this event all bridges are external to the cluster, a situation in common with all metal halide clusters that have been solubilized.

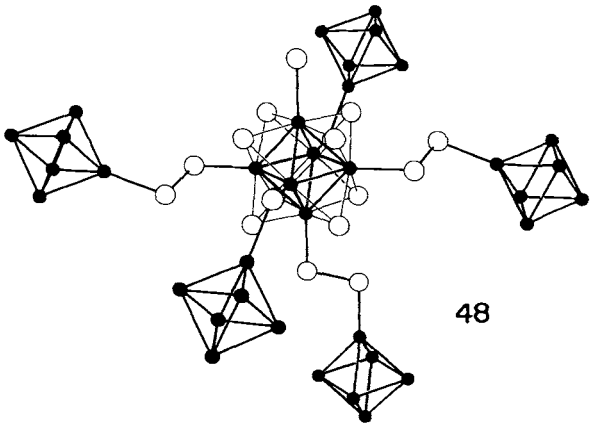
The connectivities of four Re–S phases are illustrated in $Li_4Re_6S_{11}$ (**46**), $K_2Re_3S_6$ (**47**), $Cs_4Re_6S_{13}$ (**48**), and $Rb_4Re_6S_{13}$ (**49**). These compounds are prepared from Re metal, the appropriate metal carbonate, and H_2S at temperatures in the 800–1350 °C range.[26, 74–79] Cluster **46** has sulfide bridges at each Re site, whereas **47**–**49** exhibit mixed sulfide/disulfide bridges. Cluster **48** presents an uncommon case of a terminal sulfide ligand. Although there is no existing measure, Re–S–Re and Re–S–S–Re bridges are expected to be more stable than metal–halide bridges. However, the bridge units, with their electrophilic and nucleophilic sites, may be subject to cleavage with retention of cluster structure. Because there is no precedent for cluster excision that does not involve cleavage of a M–X–M bridge, excision reactions of metal–chalcogenide phases necessitate development of appropriate reactions. Possibilities include the reaction of a Re–S–Re bridge with $R_3PH^{\oplus}/R_3P$ to afford terminal Re-PR_3 and $HS^{\ominus}$, and of a Re–S–S–Re bridge with R_3P/R_3PX_2 to give terminal Re-X and R_3PS. Additionally, the latter bridge might be reducible to the Re-S terminal group, which upon immediate alkylation with RX should produce terminal Re-SR and $X^{\ominus}$. These simply conceived reactions would potentially yield products such as $[Re_6S_8(PR_3)_6]^{2\oplus/3\oplus}$, $[Re_6S_8X_6]^{4\ominus/3\ominus}$, and/or mixed-ligand species. Cluster excision may be significantly assisted by the presence of a crown ether or cryptand to complex alkali-metal cations on reaction surfaces. The selection of these reagents can be guided by their kinetic and thermodynamic properties for complexation of the cation in question.[189] Other matters such as solvent, temperature, and particle size for these heterogeneous reactions must await experimentation.

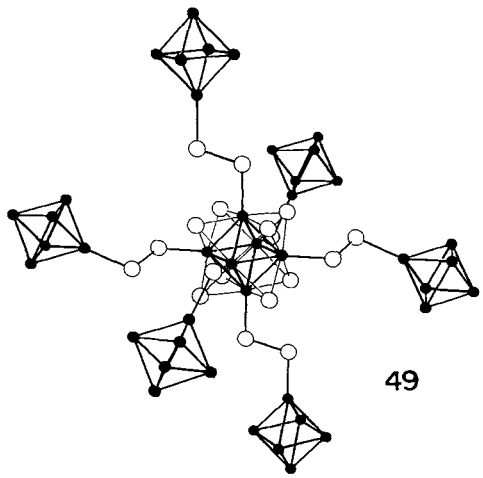
Certain Re_6Se_8 cluster phases have connectivities that are analogous to those of the sulfides (Table 3) and may yield to the same reagents. A unique connectivity is found with Re_2Te_5 (**50**), which is the only proven Re–Te binary phase. It has been prepared by high-temperature reaction of the elements or by an iodine transport reaction.[82,83] Cluster **50** contains a unique planar Te_7 unit, of which each atom except the central atom acts as a Te^a ligand to a Re atom in a different Re_6Te_6 cluster. No two Re atoms in the same cluster are bonded to the same ring.

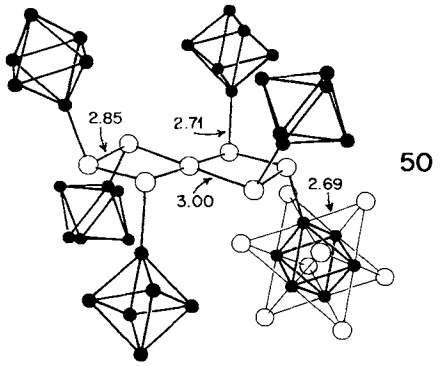
Other compounds with chalcogenide bridges solely of the Q^{a-a} type are those containing M_8S_6 clusters **24** in Table 4. However, the bridging multiplicity of the Q^a atom exceeds that in the foregoing cases. Synthetic djerfisherite has been





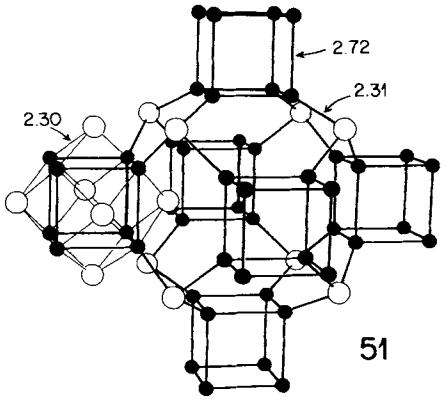






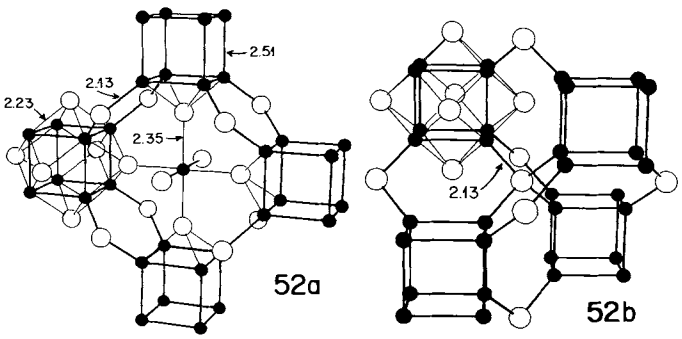
50

prepared by an electrochemical method and also from Fe metal and Li_2FeS_2 in a molten LiCl–KCl eutectic mixture at 400–450 °C.[114] The connectivity pattern **51** (exclusive of



51

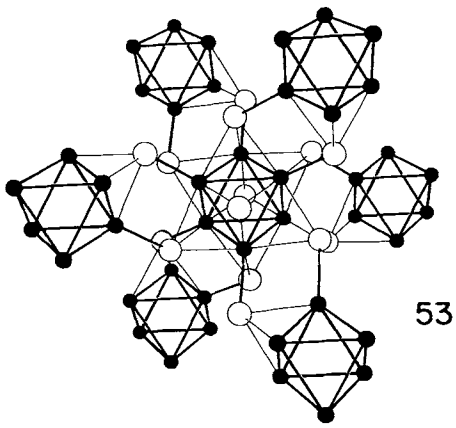
$K^{\oplus}$, $Li^{\oplus}$, and $Cl^{\ominus}$) is such that each Fe atom in a given cluster carries an apical sulfide ligand. It bridges to two other clusters and thus has a μ_3-S function. If the formulation is exact, the mean metal oxidation state is $Fe^{1.92\oplus}$ and the clusters are on average more reduced than **38**, the only molecular example of a Fe_8S_6 cluster. In natural and synthetic pentlandites, the clusters are linked by means of octahedral MS_6^i coordination units (**52a**) and by μ_4-S bridges between clusters (**52b**). Both djerfisherite and pentlandite



52a 52b

form tightly connected structures. Excision of clusters from these structures, especially the pentlandites in which the μ_4-S atoms have no nucleophilic character, should prove extremely difficult.

Lastly, we observe that the clusters **23** in Chevrel phases, typified by $M_xMo_6Q_8$ (Table 3), are held together tightly by twelve $Q^{i-a/a-i}$ bridges in connectivity pattern **53**. These



53

bonds should prove very difficult to cleave with retention of cluster structure. Unsuccessful attempts to solubilize ternary Mo chalcogenides have been noted.[190] Fortunately, with the advent of **34**, the properties of a least one individual Mo_6S_8 cluster can be examined. With the face-shared condensed clusters **26** and **27**, prospects of solubilization improve with increasing number n of repeat units $M_3Q_3^i$. Whatever the value of n, only six bridge bonds, involving the three Mo atoms at the ends of the cluster, need be cleaved. At the limit of no bridge bonds are the materials Mo_6Q_6 and $M_2^IMo_6Q_6$,[191,192] which contain the chains $^1_\infty[M_3Q_3]$ separated by the ternary element (if present). Interchain separations in these compounds are about 6.4 Å compared to intercluster Mo–Mo distances of 3.1–3.6 Å in $M_xMo_6Q_8$ and related compounds. As a consequence, the compounds $M_2^IMo_6Q_6$ (M^I = Li, Na) are soluble in highly polar solvents such as Me_2SO and *N*-methylformamide. The chain structure has been shown to be retained; these are the first soluble metal–chalcogenide polymers. In the sense of this review, the process of dissolution is not one of cluster excision inasmuch as the solid lacks intercluster bridge bonds. It remains to be seen if the larger condensed clusters **26** and **27** (n = 9–30) can be solubilized.

7. Concluding Remarks

To the molecular chemist, the existence of broad families of cluster structures in the solid state might be at first sight surprising. The dominance of thermodynamics in high-temperature synthesis would seem to preclude the formation of complex, often highly symmetric, local organizations in the lattice. That the clusters do form under these conditions is a testament to the extraordinary stability of the structural types. This stability in turn implies that, first, all structures listed in this account should be stable in molecular form (with appropriate ligation) and, second, they are probably accessible by solution syntheses. Both anecdotal and axiomatic in cluster research is the statement that all clusters are thermodynamically downhill from some combination of

starting materials; as a corollary, the units presented in Tables 1–5 must indeed lie at the bottom of the slope!

Given the vagaries of finding an auspicious starting point that leads to a given cluster, it must be said that cluster self-assembly in solution is much like a designed synthesis in the solid state: a hit-or-miss affair, with only limited rational planning. As our work on Fe–S clusters has shown,[193] the results can usually be rationalized after the fact; beforehand, however, the outcome is unpredictable. Notable advances in the rational solution syntheses of clusters have come of late with the concept of fragment condensation. Although self-assembly is arguably a process of fragment condensation (using very small fragments), the successes in truly rational syntheses have come about by employing larger, more organized starting blocks, themselves clusters, with one clearly defined condensation step. This concept is well exemplified by the fusion of two $[Mo_3S_4]$ clusters to form the $[Mo_6S_8]$ cluster **34** in reaction (6). However, this method, too, is subject to limitations, particularly in regard to accessible starting fragments.[194]

Thus, we are left with another thought unexpected to the molecular chemist: cluster excision as a rational method for accessing solid-state structures in molecular form. The clusters are clearly present in the solid state; the only question is one of a method for their excision, a question whose answer, if it exists, can be determined by rational lines of inquiry. It must also be emphasized that molecular analogues of the higher nuclearity clusters (such as **21** and **23**) have, in large part, been achieved via excision and not self-assembly. In light of the size and high symmetry of the desired products, rational synthetic routes to such clusters have proven quite difficult to formulate.

By whatever the means, the preparation of molecular analogues to the varied structural types in solid-state materials presents a worthy challenge for the molecular inorganic chemist and others interested in the synthesis of new organized assemblies.

Research on clusters in the authors' laboratory is supported by the U.S. National Institutes of Health and the National Science Foundation. [194] A procedure analogous to reaction (7) for the preparation of $Mo_6Q_8(PEt_3)_6$ has recently been reported: T. Saito, N. Yamamoto, T. Nagase, T. Tsuboi, K. Kobayashi, T. Yamagata, H. Imoto, K. Unaura, *Inorg. Chem. 29* (1990) 764. Direct reaction of $Mo_3Q_7Cl_4$ with excess PEt_3 in toluene afforded the Q = S (32%) and Se (21%) clusters in the indicated yields. In the event that a trinuclear species such as that in reaction (6) is first generated, as seems probable on the basis of reaction (9), the process involves cluster excision, partial desulfurization, and fragment reductive condensation.

Interfaces between Molecular and Polymeric "Metals": Electrically Conductive, Structure-Enforced Assemblies of Metallomacrocycles

By Tobin J. Marks*

The design, synthesis, characterization, and understanding of new molecular and macromolecular substances with "metal-like" electrical properties represents an active research area at the interface of chemistry, physics, and materials science. An important, long-range goal in this field of "materials by design" is to construct supermolecular assemblies which exhibit preordained collective phenomena by virtue of "engineered" interactions between molecular building blocks. In this review, such a class of designed materials is discussed which, in addition, bridges the gap between molecular and polymeric conductors: assemblies of electrically conductive metallomacrocycles. It is seen that efforts to rationally construct stacked metal-like molecular arrays lead logically to structure-enforced macromolecular assemblies of covalently linked molecular subunits. Typical building blocks are robust, chemically versatile metallophthalocyanines. The electrical, optical, and magnetic properties of these metallomacrocyclic assemblies and the fragments thereof, provide fundamental information on the connections between local atomic-scale architecture, electronic structure, and the macroscopic collective properties of the bulk solid.

1. Introduction

Until only a few years ago, the idea that an organic or metal-organic solid could exhibit the electrical, magnetic, and optical characteristics normally associated with bulk metals would have seemed far-fetched indeed. Among other factors, simple band-theoretical concepts tell us that such substances inherently lack the partially occupied, spatially delocalized manifolds of electronic energy levels (bands) characteristic of metals.[1] In molecular and polymeric solids, such bands are built up of contributing, molecular-level atomic and molecular orbitals, and, as in metals, only the energetically close proximity of filled and empty levels can give rise to electronic (charge) mobility and metallic character. However, typical electron-occupancy patterns found in organic and metal-organic solids lead to wide gaps between filled and unoccupied bands. Such traditional materials, as exemplified by solid benzene, polyethylene, and poly(tetrafluoroethylene), are electrical insulators. These concepts are illustrated schematically in Figure 1.

The past several years have seen a dramatic reassessment of the aforementioned historical picture. As a result of both serendipity and rational chemical synthesis, whole new classes of molecular and polymeric materials have emerged with macroscopic characteristics that are in many ways reminiscent of metals.[2] These include molecular solids which become superconducting at low temperatures[2c, 3] and flexible polymers with electrical conductivities approaching that of copper metal.[4] However, while many macroscopic properties may be similar to metals, the building blocks which compose these new substances and the synthetic chemistry necessary to prepare them are radically different. Indeed, the new "synthetic metals", "molecular metals", and "organic metals" are infinitely richer in their architectural diversity and tailorability. Furthermore, a host of fundamentally new concepts such as "soliton conductor", "bipolaron conductor", and "Mott–Hubbard insulator" have emerged to challenge and enrich our understanding of the condensed state. Equally important has been the close collaboration between chemists, physicists, materials scientists, and engineers that this new interdisciplinary area has spawned. Intellectual bridges have been built which never before existed and which allow condensed matter problems of unparalleled complexity to be attacked.

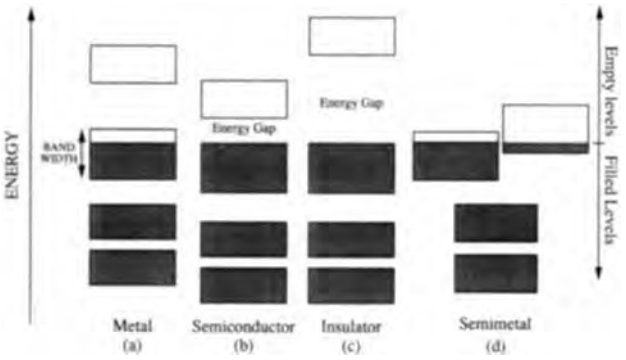

Fig. 1. Schematic depiction of electron occupancy of allowed energy bands for a classical metal, a semiconductor, an insulator, and a semimetal. The energy of the highest occupied level is called the Fermi energy. The unoccupied energy levels are white, the occupied energy levels gray.

In addition to importance in fundamental solid-state chemical and physical research, it is also apparent today that conductive, processable, functionalizable, and light-weight organic materials offer the possibility of new technologies.[2a, 4a] Applications as diverse as energy storage devices,[5] sensors,[6] switching devices,[7, 8] chemoselective electrodes,[8, 9] static charge-dissipating materials and electromagnetic shielding materials,[10] nonlinear optical materials,[11] transparent microphones,[12] "smart" windows,[12] solar energy devices,[7] and electrochromic devices[13, 14] have been proposed. Many of these concepts are in various

stages of development and, in some cases, commercialization.

Despite the major advances that have been achieved in the areas of electrically conductive molecular and polymeric substances, we must also concede that our current level of synthetic chemical control over, ability to effectively process, and physical understanding of such materials is at a very rudimentary level. Chemically, it is apparent that while the art of synthesizing individual molecules is at a very sophisticated level, the technology for constructing lattices of molecules with precise control over molecular packing and intermolecular interactions is embarrassingly primitive. This problem of course transcends the subject of molecular metals and is fundamental to many areas of condensed matter molecular chemistry (e.g., nonlinear optics, molecular ferromagnets). Likewise, the methodology for turning the latest generations of conductive organic substances into useful films, fibers, monoliths, etc., is only now beginning to develop. For conductive polymers, it is apparent that presently achievable mechanical and electrical properties are far below the theoretical maxima that optimum processing may afford. Finally, our fundamental understanding of how macroscopic physical properties connect with microscopic details of molecular structure, crystal packing, counterion interactions, degree of band filling, disorder, interchain communication, defects, etc., is far from the level where the ab initio design of new substances can be confidently pursued.

The purpose of this review is to summarize and to analyze recent results in a research area that in many respects is at the crossroads of molecular metals and conductive polymers: electrically conductive assemblies of metallomacrocycles. The long-range goal of this effort has been to develop rational and versatile synthetic approaches to low-dimensional molecule-based conductors and, via closely connected physical and theoretical investigations, to better understand their properties. The strategies to be discussed here have progressed logically from simple systems composed of aggregates of single molecules to more elaborate, structure-enforced polymeric assemblies of linked molecular constituents. It will be seen that the design, synthesis, and properties of these assemblies impinge upon issues common to both molecular and macromolecular conductors and provide new insights of relevance to both. Due to space limitations, it is only through these regions of common overlap that it will be possible to mention the excellent work of numerous other groups now studying molecular and macromolecular conductors.

2. Design Considerations for Molecular Metals

In Figure 2 are shown some of the common building blocks of molecular conductors. It is generally recognized that two overriding features are essential for converting an unorganized collection of organic or metal-organic molecules into an electrically conductive, multimolecular array.

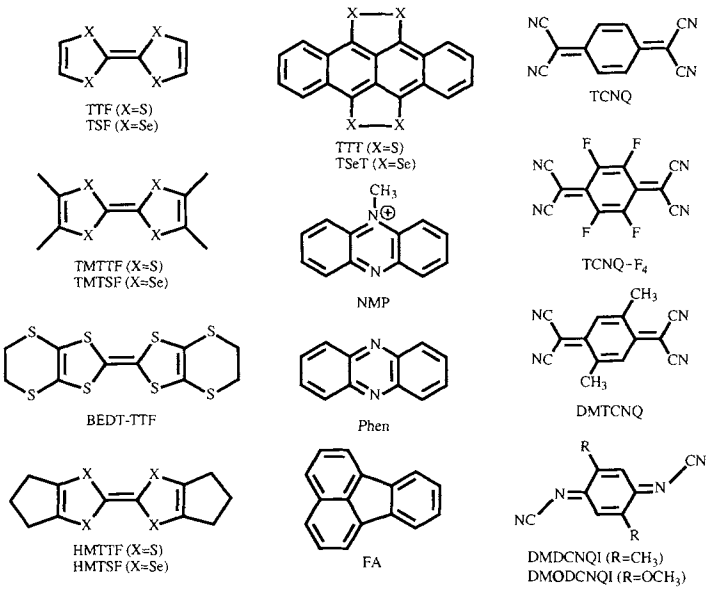

Fig. 2. Common building blocks for nonmetallomacrocylic molecular conductors. The two leftmost columns contain electron donors while the rightmost contains electron acceptors. TTF = tetrathiafulvalene, TSF = tetraselenafulvalene, TMTTF = tetramethyltetrathiafulvalene, TMTSF = tetramethyltetraselenafulvalene, BEDT-TTF = bisethylenedithiotetrathiafulvalene, HMTTF = hexamethylenetetrathiafulvalene, HMTSF = hexamethylenetetraselenafulvalene, TTT = tetrathiatetracene, TSeT = tetraselenatetracene, NMP = *N*-methylphenazinium, Phen = phenazine, FA = fluoranthene, TCNQ = tetracyanoquinodimethane, TCNQ-F_4 = tetrafluorotetracyanoquinodimethane, DMTCNQ = dimethyltetracyanoquinodimethane, DMDCNQI = dimethyl-*N*,*N*'-dicyanoquinodiimine, DMODCNQI = dimethoxydicyanoquinodiimine

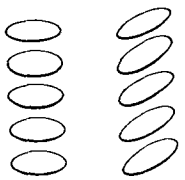
First, the molecules must be located in close spatial proximity and in similar crystallographic and electronic/Coulombic environments so that an energetically uniform (i.e., devoid of

Tobin J. Marks was born in Washington, D.C., in 1944. He received a B.S. degree from the University of Maryland in 1966 and a Ph.D. from M.I.T. in 1970, working under F. A. Cotton. He moved to Northwestern University as an assistant professor in 1970. Tobin Marks is currently Charles E. and Emma H. Morrison Professor of Chemistry and Professor of Materials Science and Engineering at Northwestern. He serves on a number of editorial boards and advisory panels, has won several awards, including the American Chemical Society Award in Organometallic Chemistry, and is currently Associate Editor of Organometallics. His present research interests include polymer and solid-state chemistry, f-element organometallic chemistry, homogeneous and heterogeneous catalysis, nonlinear optical materials, metal-organic chemical vapor deposition, and carcinostatic metal complexes.

carrier-trapping hills and valleys), extended pathway exists for electronic charge diffusion. This is equivalent to saying that a band structure having sizeable bandwidths ($\gtrsim 0.5$ eV) must exist. Such a situation is commonly realized when flat, conjugated molecules crystallize in various types of stacking motifs which allow extensive overlap of the π-electron systems (e.g., **1** or **2**). The way in which a band structure is built



1 **2**

up from highest occupied molecular orbitals (HOMOs) as increasing numbers of molecules are added to a cofacial molecular stack is illustrated in Figure 3. In an simplistic

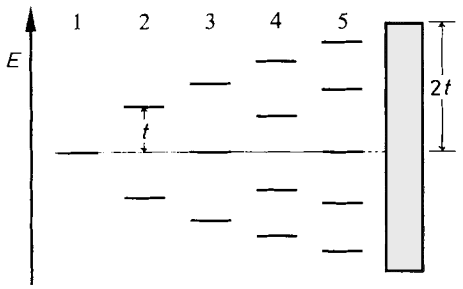


Fig. 3. Schematic illustration of how a band structure is built up by arraying increasing numbers of molecular subunit HOMOs in a molecular stack. The parameter t is the tight-binding transfer integral, analogous to the Hückel β integral. The tight-binding bandwidth is $4t$.

Hückel-like tight-binding band-structure description,[1a, b] the measure of how strongly neighboring HOMOs interact is given by the transfer integral t, which is directly analogous to the Hückel resonance integral, β. In an extended stack consisting of a very large number of molecular constituents, the bandwidth is given by $4t$ (4β). This important condensed state parameter is directly connectable to molecular properties and as such is an important quantity to accurately measure and understand.

The second key requirement for metallic characteristics in a molecular stack is that the highest energy band be incompletely filled. This characteristic has already been discussed in reference to Figure 1 for classical metals; for molecular systems, however, several important caveats must be added. In all of the molecular metals prepared to date, the substances are actually salts and the molecular subunits are in formal *fractional* oxidation states ("partial oxidation" (or reduction), "incomplete charge transfer", "mixed valence"). That is, the molecules have valence shells which, formally, are fractionally occupied as in $(TMTSF^{0.5\oplus})_2X^{\ominus}$, $TTF^{0.59\oplus}$-$TCNQ^{0.59\ominus}$, and $[H_2(Pc)^{0.33\oplus}](I_3^{\ominus})_{0.33}$; the symbol ϱ is normally used to designate the subunit oxidation state. Since each of the simple bands of the type shown in Figures 1 and 3 can accommodate two electrons per constituent molecular subunit (the occupancy of the HOMO), the quantities $(2-\varrho)/2$ and $|\varrho|/2$ give the band occupancy (e.g., 2/3-filled, 1/3-filled) for $\varrho > 0$ and $\varrho < 0$, respectively. Equally important is the observation that materials with $\varrho = 1$ (half-filled bands for classical metals) are never found to be molecular metals and are usually insulators.

The above complexities are due to a number of factors. As was first noted for certain transition-metal oxides by *Mott*, situations may occur in which the Coulombic repulsion (denoted by the parameter U) of having two charge carriers on a single site [Eq. (1)] is comparable to or exceeds the band-

(1)

width. In the extreme case where $U \gg 4t$, a material with a half-filled band can actually be a magnetic insulator.[1, 2] That is, all carriers are confined to their individual molecules. A valence-bond picture of how mixed valency affects charge mobility in molecular conductors is shown schematically in Figure 4. Currently, the degree to which U can be

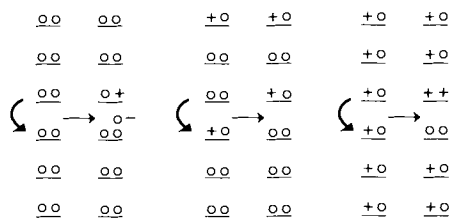

Fig. 4. Schematic depiction of how the degree of oxidation affects charge mobility in a typical molecular stack. Left: no oxidation. Middle: partial oxidation. Right: complete oxidation (one electron per subunit).

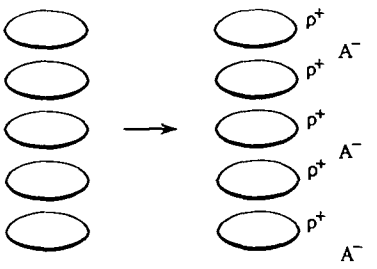
manipulated by alterations in molecular architecture, crystal packing, neighboring counterions, and level of band filling has been the subject of much speculation. Such relationships are presently obscure, large U effects may be entangled with other structural features, and accurate measurements of U are not without ambiguity. It is generally agreed that enhanced mangnetic susceptibilities are, in most molecular conductors, an indication of large U effects ("Coulomb enhancement"), as are certain types of band-filling-dependent structural distortions ($4k_F$ instabilities, where k_F refers to the electronic wave vector at the Fermi level).[1b, 15]

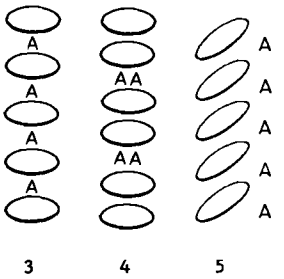
In addition to Coulombic effects, the properties of a molecular metal can be exceedingly sensitive to the coupling of the electronic system to certain phonons (lattice vibrations). Such an instability is analogous to a Jahn–Teller distortion and is predicted theoretically for a low-dimensional metal. The net consequence can be a periodic structural distortion and charge buildup in the stack (a charge density wave, Peierls distortion, or $2k_F$ instability), the periodicity of which reflects the filling of the highest occupied band.[1a–c, 15] In the extreme case (especially for half-filled bands or at low temperatures) the distortion "locks in" and an opening of a gap in the conduction band can induce a metal-to-insulator transition. Since other structural effects such as interactions with counterions in the crystal lattice can also induce periodic structural distortions in the stacking

geometry, identification of the origin of charge-density-wave phenomena is not always unambiguous. Qalitatively, such phenomena become less important as the molecular chain deviates strongly from unidimensionality (i.e., interchain interactions become very large). Electron–phonon interactions are also believed to play a crucial role in a variety of charge-transport mechanisms, including organic superconductivity[2c, 3, 16] and the $\sigma \sim T^{-2}$ behavior frequently observed in molecular metals.[17]

From a synthetic chemical perspective, the most obvious way to clarify many of the above phenomena would be to prepare and study molecular conductors in which there was sequential variation of one crucial parameter (e.g., molecule–molecule interplanar spacing, off-axis counterion, band filling) while all other parameters were held fixed. Unfortunately, current routes to molecular metals are not subject to such high degrees of control. Thus, conventional syntheses usually rely on crystallization combined with a chemical or electrochemical oxidation or reduction process as in Equation (2). The success of such a self-assembly process in forming segregated stacks of closely arrayed radical cations (or anions) and evenly distributed, complementary arrays of off-axis counterions is by no means guaranteed. The structural outcome hinges upon a complex and largely uncontrollable collection of Madelung, exchange, polarization, bandwidth, van der Waals, core repulsion, crystal-growth kinetic, and ionization potential/electron affinity factors, which determine, in poorly understood ways, the level of partial oxidation (ϱ) and the crystallization architecture. Thus, charge transfer may not occur, and if it does, numerous other packing modes are possible (e.g., **3**–**5**).

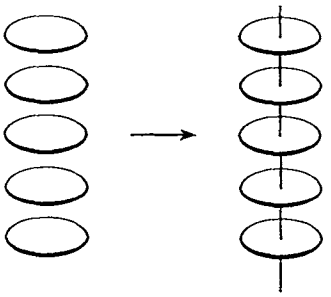


(2)



3 4 5

Most embodiments of motifs **3** and **4** lack an obvious conduction band structure and, to date, such materials have been found to be insulators.[2, 3] In addition, simple changes in the molecular building block or off-axis counterion in these syntheses typically induce major changes in stacking architecture, hence in a myriad of correlated physical properties. It is therefore apparent that any rational synthetic strategy for disentangling the numerous molecular-metal architectural/electronic structural variables must possess a means of rigorously controlling the subunit stacking rather than relying upon capricious packing forces. The principal focus of the present article, then, is upon the chemical and physical consequences of effecting, via the introduction of strong, covalent intrastack bonds, the connectivity modification shown in Equation (3).[18]



(3)

6

It should also be appreciated that structure **6** is a macromolecule. The field of electrically conductive polymers has developed in parallel to that of molecular metals, and representative structures are illustrated in Figure 5.[4] In common with stacked molecular systems, oxidation or reduction (commonly called "doping" as for conventional inorganic semiconductors) is necessary to mobilize charge carriers. However, the bandwidths of most highly conductive polymers are greater, and charge-transport mechanisms may be different. Furthermore, structural regularity is not as great as in molecular conductors, and a number of classes of conductive polymers are poorly crystalline or amorphous. This factor and the accompanying structural uncertainties severely complicate the interpretation of chemical and physical data.

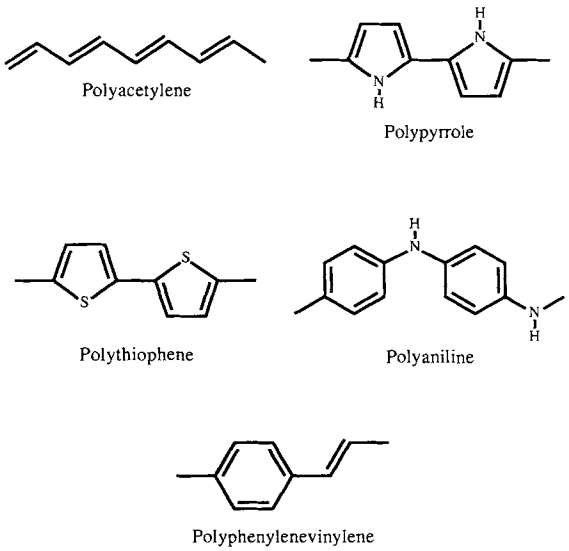


Fig. 5. Precursors of common electrically conductive polymers.

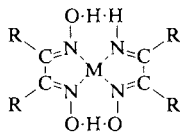
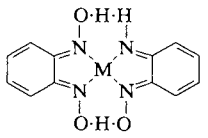
3. Building Blocks and Model Materials

Reference to target structure **6** indicates that a suitable molecular subunit must have chemical functionality perpendicular to the molecular plane. An ideal synthon for such a strategy is a metallomacrocycle in which the central metal atom has the possibility of bond formation perpendicular to the square coordination plane. Early work in this laboratory established that partial oxidation of glyoximates (**7**, **8**),[19] dibenzotetraazaannulenes (**9**),[20] hemiporphyrazines (**10**),[21] and phthalocyanines (**11**)[22] with halogens afforded new



7



8

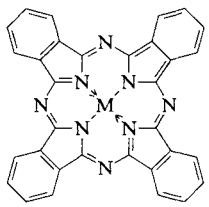
10



11

families of low-dimensional molecular conductors. In all cases, spectroscopic analysis of the form of the halogen present in the crystal structure showed unambiguously that the metallomacrocyclic subunits were in formal fractional oxidation states.[18b, 23]

Metallophthalocyanines, M(Pc), are robust, highly functionalizable commodity chemicals that are widely used as pigments and oxidation catalysts.[24] More importantly for the present purposes, they form the basis for a class of molecular metals in those cases where the tactic of Equation (2) is successful. A particularly informative example is $H_2(Pc)(I_3)_{0.33}$[25] (**11**, where M = two H atoms), which exhibits many of the physical properties typical of a molecular metal. As can be seen in Figure 6, the tetragonal crystal structure consists of $H_2(Pc)^{0.33\oplus}$ cations, arrayed at 3.251(2)-Å intervals and staggered by 40.0° with respect to neighboring subunits. Chains of disordered $I_3^{\ominus}$ counterions extend parallel to the stacking direction. This particular structural pattern will be seen to be ubiquitous for phthalocyanine metals. The electrical conductivity of these exceedingly thin crystals (0.07 × 0.07 × 0.65 mm) in the stacking direction ($\sigma_{\parallel}$) is ca. 700 $\Omega^{-1}cm^{-1}$ at room temperature. When normalized for the large $H_2(Pc)$ cross-sectional area, this room temperature conductivity is one of the highest yet reported for a molecular metal. The high unidimensionality of the charge transport is demonstrated by the result $\sigma_{\parallel}/\sigma_{\perp} \gtrsim 500$. As the temperature of $H_2(Pc)(I_3)_{0.33}$ crystals is slowly lowered, the stacking-axis conductivity becomes metal-like (Fig. 7, top, $d\sigma/dT < 0$), reaches a maximum at ca. 15 K, and exceeds 3500 $\Omega^{-1}cm^{-1}$ even at 1.5 K. Also shown in Figure 7, top, is the thermoelectric power (TEP) of

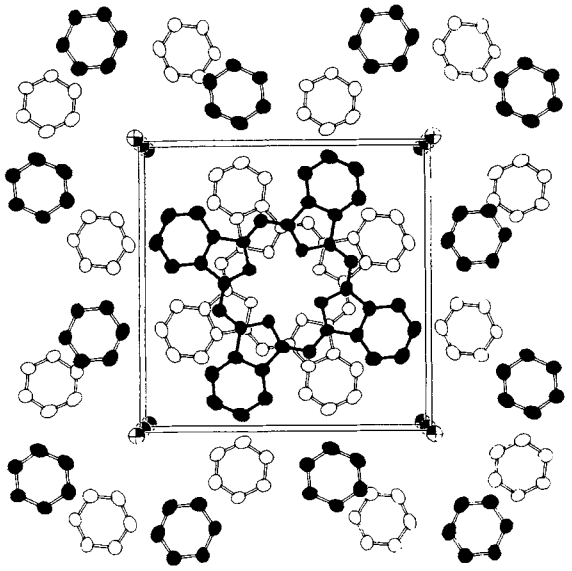


Fig. 6. The crystal structure of the macrocyclic molecular metal $H_2(Pc)(I_3)_{0.33}$ viewed parallel to the molecular stacking direction (crystallographic c axis).

an $H_2(Pc)(I_3)_{0.33}$ crystal measured in the stacking direction. The positive sign of the Seebeck coefficient (S) indicates that this material is a radical-cation conductor (the major conduction pathway is through the $[H_2(Pc)^{0.33\oplus}]_{\infty}$ chain), while the relatively small magnitude and linear dependence on temperature are classic signatures of metallic behavior.[26–28] Note the change in the thermoelectric power toward semiconducting behavior at the temperature (ca. 15 K) where $\sigma_{\parallel}(T)$ passes through a maximum. In a one-dimensional tight-binding picture, the temperature dependence of S can be related to the bandwidth ($4t$, Fig. 3) via Equation (4).[26–28, 29] Here, k_B is the Boltzmann constant. Analysis

$$S = \frac{2\pi^2 k_B^2 T \cos(\pi\varrho/2)}{3e(4t)\sin^2(\pi\varrho/2)} \tag{4}$$

of the $S(T)$ data for $H_2(Pc)(I_3)_{0.33}$ yields a tight-binding bandwidth of 1.0(1) eV. In agreement with this ligand radical-cation-based picture of charge transport, fully assigned solid-state ^{13}C CPMAS NMR data[30] evidence large, locally resolved Knight shifts (due to nuclear-conduction electron interactions) consistent with a phthalocyanine radical cation. ESR spectra are characterized by nearly free-electron g values and narrow line widths. These are signatures of a radical-cation conductor with the narrow line width indicating a high degree of unidimensional character (in accord with charge transport and optical data) and only minor interaction of the carrier spins with the $I_3^{\ominus}$ counterions (i.e., only small contributions to electron-spin relaxation by phonon-modulated spin–orbit interactions).[31, 32]

The optical and magnetic properties of $H_2(Pc)(I_3)_{0.33}$ crystals also provide classic signatures of metal-like character. In Figure 7, middle, is shown the reflectance spectrum of an $H_2(Pc)(I_3)_{0.33}$ crystal polarized parallel to and perpendicular to the macrocycle stacking direction. The small size of the crystals necessitated the development of specialized microspectrophotometry techniques.[25] The most striking feature of the spectrum is the parallel-polarized edge[33, 34] observed at ca. 3100 cm^{-1} ($\lg \nu \approx 3.49$). This feature is analogous to

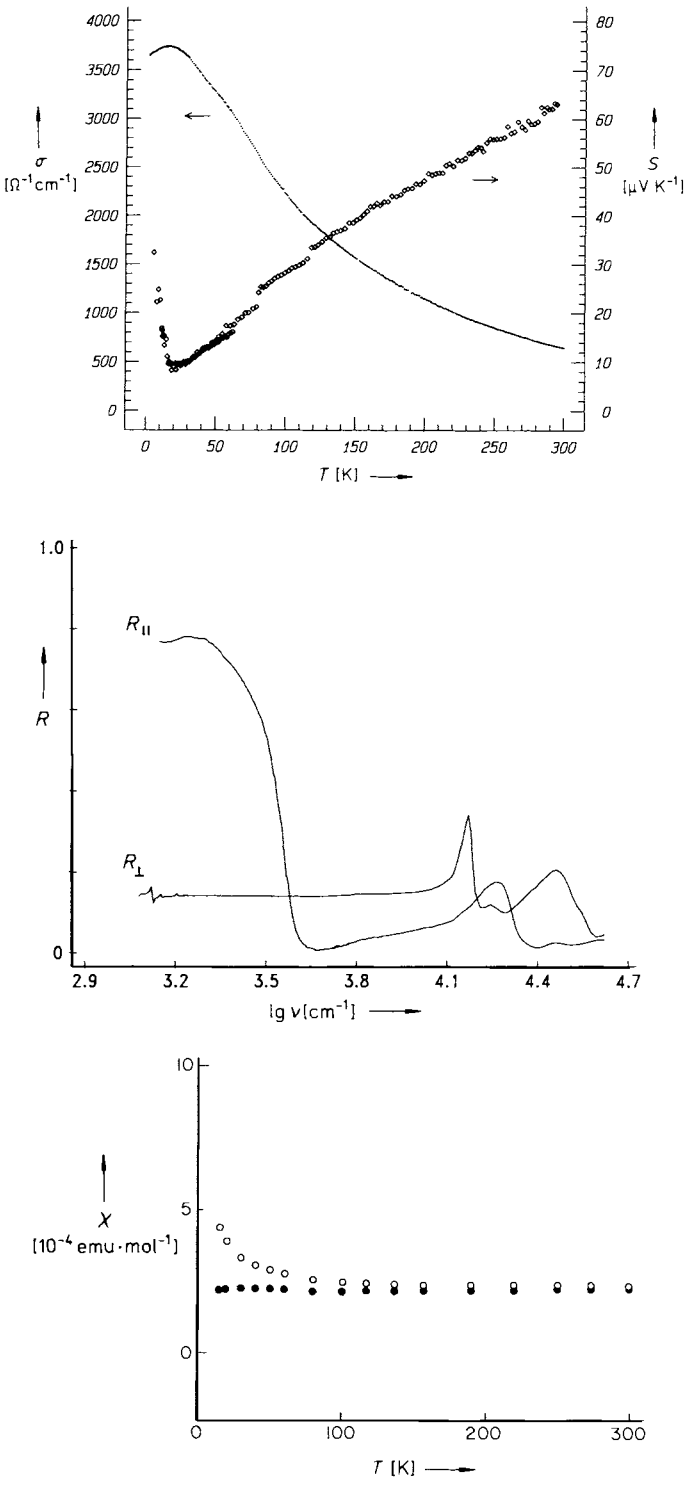

Fig. 7. Physical properties of the macrocyclic molecular metal $H_2(Pc)(I_3)_{0.33}$. Top: Variable-temperature electrical conductivity and thermoelectric power measured parallel to the molecular stacking direction. Middle: Reflectance spectrum of an $H_2(Pc)(I_3)_{0.33}$ single crystal; $R_\parallel$ and $R_\perp$ denote reflectance parallel to and perpendicular to the molecular stacking direction. The perpendicularly polarized features at 14 800 (lg $\nu = 4.17$) and 29 000 cm^{-1} (lg $\nu = 4.46$) are assigned to Pc-centered π–π^* transitions, while the parallel-polarized feature at 18 200 cm^{-1} (lg $\nu = 4.26$) is assigned to an $I_3^{\ominus}$-centered excitation. Bottom: Variable-temperature magnetic susceptibility (χ) data for a polycrystalline $H_2(Pc)(I_3)_{0.33}$ sample. The filled circles denote the Pauli-like component, the open circles the paramagnetic Curie-like component.

the plasma edge observed in the reflectivity of metals[1e] and can be associated with carrier excitation in the partially filled conduction band. The marked polarization indicates that $H_2(Pc)(I_3)_{0.33}$ is only metallic (there is a significant bandwidth) in the stacking direction. Analysis of the optical data yields the carrier relaxation time and mass, the plasma frequency (ω_p), and, via the tight-binding expression of Equation (5),[33,34] the bandwidth. Here, N_c is the carrier density. Analysis of the $H_2(Pc)(I_3)_{0.33}$ reflectivity data yields

$$4t = \frac{\varrho(\hbar\omega_p)^2}{4N_c e^2 c^2 \sin(\pi\rho/2)} \tag{5}$$

$4t = 1.3(1)$ eV, in excellent agreement with the thermopower data. Static magnetic susceptibility data for $H_2(Pc)(I_3)_{0.33}$ crystals are shown in Figure 7, bottom. When a small Curie-like component of the type normally associated with defects and impurities[35,36] is subtracted, the remaining susceptibility is only weakly paramagnetic and virtually independent of temperature. This behavior is reminiscent of the Pauli susceptibility of bulk metals,[1d,e] which is a consequence of the partially filled character of the conduction band. Assuming a one-dimensional tight-binding band and noninteracting electrons ($U = 0$), a tight-binding bandwidth can be derived from Equation (6).[37] The result for $H_2(Pc)(I_3)_{0.33}$ is that $4t = 0.37(3)$ eV, in clear disagreement with the afore-

$$\chi_{Pauli} = \frac{N\mu_B^2}{t\pi \sin(\pi\varrho/2)} \tag{6}$$

mentioned TEP and optical data. The implication of this finding is that the magnetic susceptibility is "enhanced", that is, that U and therefore Coulombic repulsions are not insignificant.[38,39] In summary, $H_2(Pc)(I_3)_{0.33}$ exhibits many of the classic features of a molecular metal, to which we will make reference in later discussion: (1) metal-like conductivity in the stacking direction; (2) thermoelectric power which is small in magnitude and the absolute value of which is linearly proportional to temperature; (3) a plasma-like edge in the reflectivity; (4) Pauli-like paramagnetism. These results also clearly demonstrate that a metal-ion substituent is not required in the core of the macrocycle for metal-like character. How reliable the formalisms are that allow extraction of $4t$ from condensed-phase TEP and optical data is an important, unanswered question which will be taken up in Section 5.

Although the molecular self-assembly tactic of Equation (2) was a useful first-generation approach, subsequent studies have shown it to have limited scope. Several additional salts have recently been prepared by high-temperature electrocrystallization procedures developed in this laboratory, such as $Ni(Pc)(BF_4)_y$[40] and $Ni(Pc)(ClO_4)_y$.[41] The crystal structure of the latter material ($y \approx 0.42$) is shown in Figure 8 and is similar to that of $H_2(Pc)(I_3)_{0.33}$, as are those of $Ni(Pc)(I_3)_{0.33}$[22c] and $Ni(Pc)(BF_4)_{0.33}$.[40]

Electrical, optical, and magnetic studies of these materials indicate metallic character in the macrocycle stacking direction and further show that the presence of the Ni ion has a relatively minor influence on the charge-transport characteristics.[40–42] Comparative charge-transport data are presented in Figure 9. $Ni(Pc)(ClO_4)_y$ also displays the interesting characteristic that y values for different crystals can vary slightly (0.39–0.47) as a function of electrocrystallization conditions,[41] presumably reflecting different occupancy levels of the anion channels. Such modest variations in

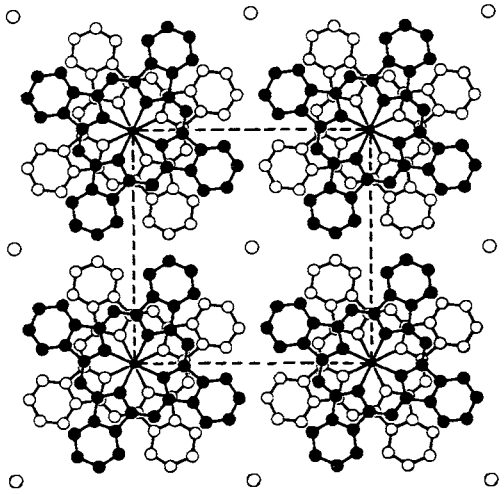

Fig. 8. The crystal structure of $Ni(Pc)(ClO_4)_{0.42}$ viewed parallel to the macrocycle stacking direction. The $ClO_4^{\ominus}$ ions are drawn as open circles for clarity.

molecular-metal band-filling/stoichiometry level are unusual but not completely unprecedented[43] and, in this case, are evident in TEP and optical measurements (cf. the ϱ dependence in Eqs. (4) and (5)). Perhaps more interestingly, the $ClO_4^{\ominus}$ ions are rotationally disordered (and likely tumbling) at room temperature in these crystals, but lock into ordered positions at lower temperatures.[44] The effects of this counterion ordering on the collective properties of $Ni(Pc)(ClO_4)_y$ are rather small compared to the effects on $(TMTSF)_2ClO_4$, where cooling-rate-dependent anion-ordering phenomena have a dramatic effect on superconducting behavior.[4, 45]

Beyond the above small anions, attempts via self-assembly to probe phthalocyanine band-structure–counterion interactions are frustrated in that electrocrystallization experiments with larger anions (e.g., $AsF_6^{\ominus}$, $SbF_6^{\ominus}$) lead to materials with different packing arrangements and ϱ values.[42f] Likewise, the use of organic oxidants such as high-potential quinones (e.g., TCNQ) fails to produce molecular metals, yielding instead insulators which are presumed to have integrated stacking as in **3** or **4**.[46] Clearly, the forces retaining the stacking architecture in these ligand-based conductors are rather delicate and unreliable. Comparative physical data on phthalocyanine molecular conductors are compiled in Tables 1 and 2.

4. Cofacial Condensation Assembly as an Approach to Enforced Molecular Stacking

A particularly attractive approach to target structure **6** employs the solid-state condensation polymerization of dihydroxy group 4 phthalocyaninato complexes (Fig. 10).[18, 47–49] These robust, highly crystalline rigid-rod polymers have been characterized by various end-group analyses (radiochemical, FT-IR),[47a] solid-state NMR spectroscopy,[30] electron microscopy,[50] and powder X-ray diffraction[47a] (aided by computer simulation techniques and single-crystal diffraction studies of model oligomers[51]), and solution diffraction techniques (for more soluble, ring-functionalized derivatives).[52] Together, these data provide a detailed picture of $[M(Pc)O]_n$ architecture and crystal

Fig. 9. M = Si; 3.53(2)Å, M = Ge; 3.82(2)Å, M = Sn. Combined with the data base of model molecular conductors discussed above, these stacking-enforced arrays of ligand-based conductive building blocks offer a unique opportunity to probe many of the poorly understood features of molecular metals as well as conductive polymers. We begin with a discussion of chemical and electrochemical redox phenomenology and the physical properties of the resulting materials.

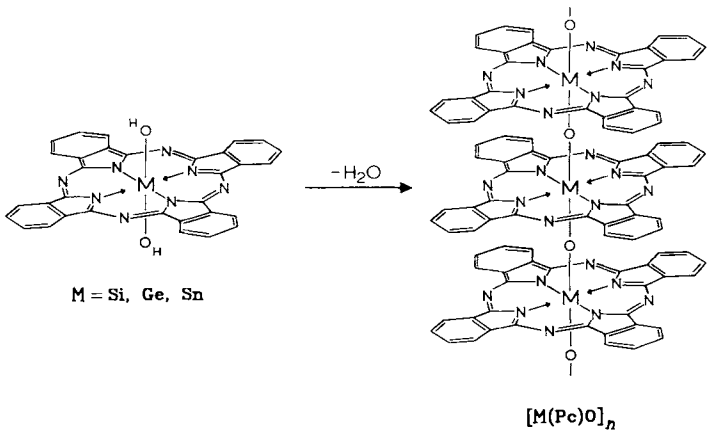

Fig. 10. Strategy for the cofacial assembly of structure-enforced group 4 metallophthalocyanine assemblies.

4.1. Chemical Doping of $[M(Pc)O]_n$ Materials: Interplanar Spacing and Counterion Effects on Collective Properties

Partial oxidation of the $[M(Pc)O]_n$ polymers with halogen[53] and nitrosyl salts[54] proceeds as shown in Equations (7) and (8). X-ray diffraction studies reveal that the doping

$$[M(Pc)O]_n + 0.53n\ X_2 \longrightarrow \{[M(Pc)O](X_3)_y\}_n \quad (7)$$
M = Si, Ge; X = Br, I; $y \approx 0.35$

$$[M(Pc)O]_n + 0.35n\ NO^{\oplus}Z^{\ominus} \longrightarrow \{[M(Pc)O]Z_{0.35}\}_n + 0.35n\ NO \quad (8)$$
M = Si; $Z^{\ominus} = BF_4^{\ominus}, PF_6^{\ominus}, SbF_6^{\ominus}$

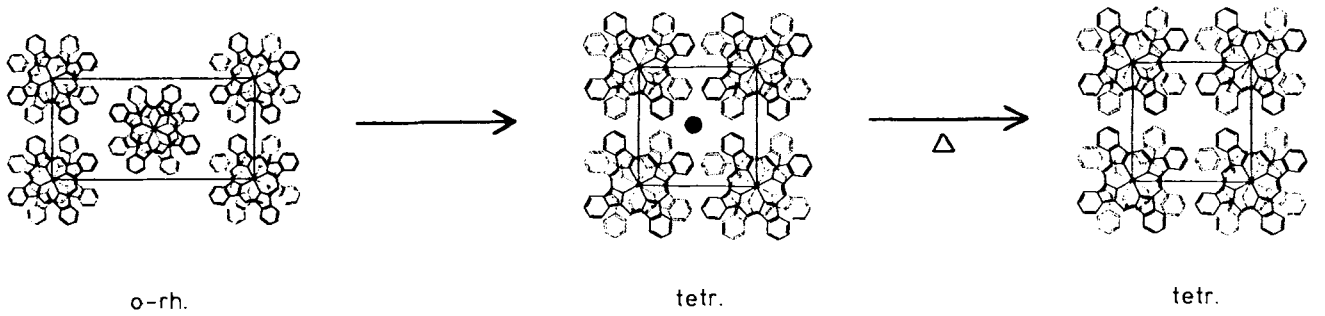

Fig. 11. Structural model of the changes accompanying chemical doping of as-polymerized $[Si(Pc)O]_n$ with I_2, followed by thermal undoping. The view is parallel to the phthalocyanine stacking direction. o-rh = orthorhombic, tetr. = tetragonal.

processes are largely inhomogeneous. That is, incremental addition of oxidant produces progressively larger amounts of the fully doped phase, having a discrete stoichiometry (fixed ϱ) and a different crystal structure. This process is illustrated schematically for $[Si(Pc)O]_n$ in Figure 11. Until full uptake of oxidant is achieved, the material is a heterogeneous mixture of starting material and product. This inhomogeneity has been verified by transmission electron microscopy.[50] X-ray diffraction studies also indicate that the tetragonal doped phases are essentially isostructural with the molecular phthalocyanine analogues (cf. $H_2(Pc)(I_3)_{0.33}$ in Fig. 6 and $Ni(Pc)(ClO_4)_{0.42}$ in Fig. 8), differing principally in interplanar spacing. Relevant structural data are compiled in Table 1. It can also be seen in Equations (7) and (8) that the ultimate degree of partial oxidation (band depletion, ϱ) is ca. $+0.35$ for all oxidants. Born–Haber cycles using proper $\Delta H_{subl.}$ and ionization potential data for molecular phthalocyanines show that this is not an unexpected result.[54] Drastic modifications in ϱ and off-axis counterions are best achieved using electrochemical techniques (see Section 4.2). Interestingly, the products of Equation (7) can be "undoped" by heating under vacuum to yield a new $[Si(Pc)O]_n$ phase which is best modeled by a tetragonal crystal structure (Fig. 11).

The series $Ni(Pc)(I_3)_{0.33}$ (**I**); $\{[Si(Pc)O](I_3)_{0.35}\}_n$ (**II**), and $\{[Ge(Pc)O](I_3)_{0.35}\}_n$ (**III**) provides an extremely informative picture of how an expansion in interplanar spacing from 3.24 to 3.30 to 3.48 Å modifies the properties of a molecular metal. Comparative variable-temperature electrical conductivity data are shown in Figure 12. In viewing these data, it should be noted that measurements on polycrystalline samples (high-quality single crystals of the doped polymers are not available) are influenced by the isotropy of the macroscopic specimen and interparticle contact effects.[55, 56] Hence, while full "metal-like" character is partially masked (cf. the $Ni(Pc)(I_3)_{0.33}$ data), an empirical rule of thumb[55, 57] suggests that polycrystalline conductivity values can be multiplied by a factor of ca. 500 to estimate single-crystal conductivity in the stacking direction ($\sigma_{\parallel}$). This approximate relationship has been verified for a number of molecular conductors and, in the present case, allows meaningful, although not strictly quantitative, comparisons to be drawn. Most importantly, the data evidence a dramatic diminution in the efficiency of charge transport as overlap decreases between the adjacent macrocycle π systems. In accord with the inhomogeneous character of the doping processes, the doping-level dependence of the conductivity is not monotonic, but exhibits an abrupt discontinuity which can be associated with a percolation threshold, as found in many composite materials.[58] Such discontinuous behavior is observed in mixtures of conductive and nonconductive particles when the volume fraction of the former reaches a certain critical threshold beyond which there is a continuous network of contacting conductive particles. At this point—the percolation threshold—the material becomes highly conductive. The temperature dependence of $\{[Si(Pc)O]X_y\}_n$ conductivity can best be fit to a fluctuation-induced carrier tunneling model[59] in which relatively large conductive regions are separated by insulating barriers having a parabolic potential. At low temperatures, transport is dominated by temperature-independent elastic tunneling, while it is thermally activated at higher temperatures. Importantly, the $\sigma(T)$ data cannot be convincingly fit to conventional carrier hopping models which apply to many conductive polymers.[4]

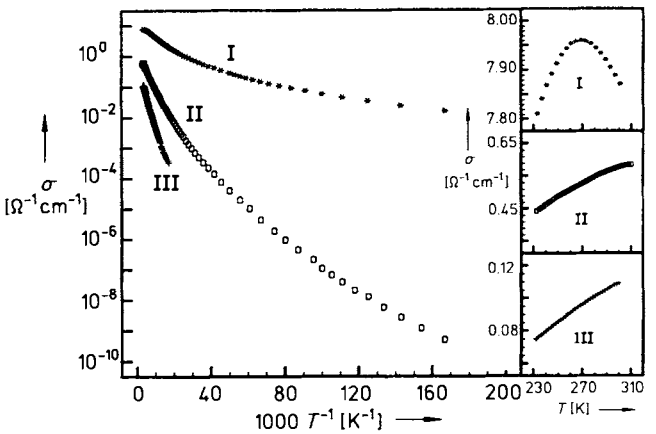

Fig. 12. Variable-temperature electrical conductivity data for compressed polycrystalline samples of $Ni(Pc)(I_3)_{0.33}$ (**I**), $\{[Si(Pc)O](I_3)_{0.35}\}_n$ (**II**), and $\{[Ge(Pc)O](I_3)_{0.35}\}_n$ (**III**). Note that metal-like behavior observed in $Ni(Pc)(I_3)_{0.33}$ single crystals (Fig. 9, top) is modified by the polycrystalline nature of the samples.

The sensitivity of band-structure-related properties to Pc–Pc interplanar separation is also evident in comparative optical reflectivity data, where a progressive shift of the plasma edge to lower energy is observed with increasing interplanar spacing (Fig. 13). This behavior is in excellent agreement with the simple tight-binding band-theoretical picture [Eq. (5)]. Finally, while the magnetic susceptibilities of **I**–**III** are all essentially Pauli-like (cf. Fig. 7), the susceptibility increases incrementally with increasing interplanar spacing, again in accord with simple theoretical notions [Eq. (6)].

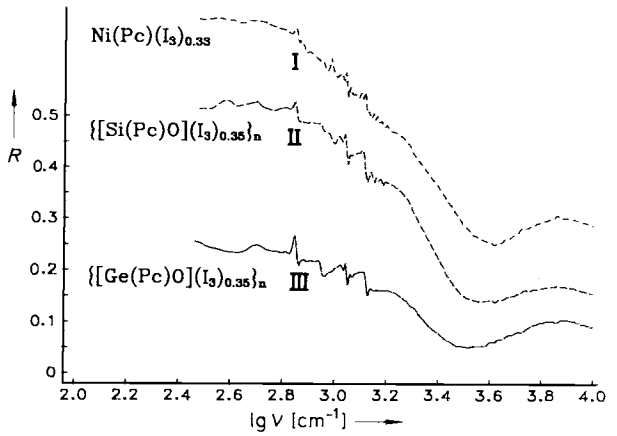

Fig. 13. Optical reflectance spectra of compressed polycrystalline samples of $Ni(Pc)(I_3)_{0.33}$ (I), $\{[Si(Pc)O](I_3)_{0.35}\}_n$ (II), and $\{[Ge(Pc)O](I_3)_{0.35}\}_n$ (III). Spectra are offset vertically by 0.2 reflectance units for ease of viewing.

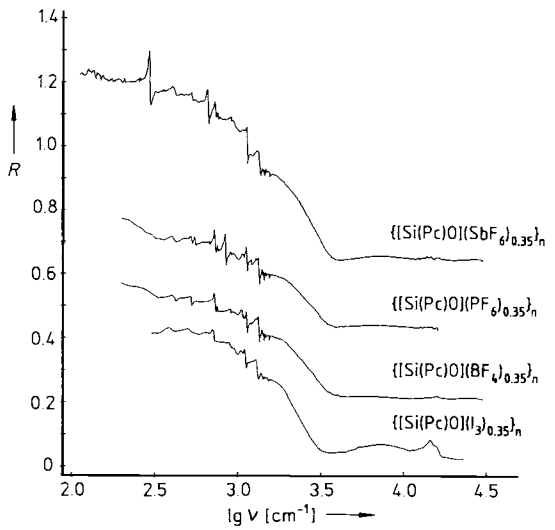

Fig. 14. Optical reflectance spectra of compressed polycrystalline samples of $\{[Si(Pc)O(SbF_6)_{0.35}\}_n$, $\{[Si(Pc)O](PF_6)_{0.35}\}_n$, $\{[Si(Pc)O](BF_4)_{0.35}\}_n$ and $\{[Si(Pc)O](I_3)_{0.35}\}_n$. Spectra are offset vertically by 0.2 reflectance units for ease of viewing.

Relevant physical data and derived $4t$ values are set out in Tables 1 and 2. It can be seen that reflectivity-derived (and susceptibility-derived) $4t$ values fall with increasing interplanar spacing. All of the susceptibility-derived bandwidths evidence some degree of Coulombic enhancement. At this stage, a completely independent measure of $4t$, for example, not tied to the many approximations inherent in the condensed-state derivation, would be highly desirable. This subject will be taken up in Section 5.

The intriguing question next arises as to the nature and magnitude of band-structure–counterion interactions. If the $[Si(Pc)^{\varrho\oplus})O]_n$ stacking is essentially frozen in these materials, to what degree are the charge carriers influenced by whether off-axis anions are large and highly polarizable (e.g., $I_3^{\ominus}$) or small and hard (e.g., $BF_4^{\ominus}$)? This question was addressed via magnetic, optical, charge-transport, and ESR measurements. Magnetic susceptibility data are one means to probe the electronic structure and population of the highest occupied band, and the result is that all of the $[Si(Pc)^{0.35\oplus}O]_n$ materials that have been studied exhibit Pauli-like paramagnetism that is virtually identical in magnitude and temperature dependence (Table 1). Any effects of the counterion on the Coulombic enhancement ("screening" effects of this type have frequently been invoked for other molecular conductors) are undetectable by this technique. Optical reflectivity studies of these materials reveal essentially identical, plasma-like edges (Fig. 14), with derived ω_p and $4t$ parameters virtually independent of counterion (Tables 1 and 2). Likewise, variable-temperature conductivity data for the partially oxidized $[Si(Pc)^{0.35\oplus}O]_n$ series evidence only slight differences of the type that can be associated with slightly different interparticle resistances and different chain-packing densities in the respective crystal structures. Data are set out in Table 1. Studies of ESR data for polycrystalline $\{[Si(Pc)^{0.35\oplus}O]X_y\}_n$ reveal nearly isotropic free-electron g values, which are consistent with ligand-based oxidation, and relatively narrow line widths that increase in the progression $BF_4^{\ominus} < PF_6^{\ominus} < SbF_6^{\ominus} < I_3^{\ominus}$ (0.36 to 2.9 G at 300 K). As noted in Section 3 for the molecular phthalocyanine conductors, narrow line widths can in general be associated with the absence of heavy atoms in extensive communication with the carriers as well as with the highly unidimensional crystal and electronic structure ($t_\perp$ is small, in agreement with the other physical measurements). The anion-dependent line width effects likely reflect minor interactions with the off-axis anions and resulting electronic relaxation via phonon-modulated spin–orbit interactions.[31]

The present results stand in sharp contrast to those for most organo-chalcogen-based molecular conductors and superconductors.[2, 3, 45] In these cases, small changes in counterion effect significant changes in crystal packing, hence major changes in charge-transport, optical, and magnetic properties; differences in resulting properties are sometimes as large as those expected for a superconductor rather than an insulator. For the present $[Si(Pc)^{0.35\oplus}O]_n$ materials, the insensitivity appears to arise from two major factors. The first and probably most important factor is the essentially frozen character of the stacking architecture, so that band-structure–counterion interactions must be Coulombic or involve subtle static or dynamic modifications in Pc–Pc staggering angles. The second factor is likely connected with the unique M(Pc) π electronic structure and will be discussed in Section 5.

4.2. Electrochemical Doping of $[M(Pc)O]_n$ Materials: Structure, Counterion, and Band-Filling Effects—Tunable ϱ

Electrochemical techniques have been employed extensively to effect the "doping" of electrically conductive polymers.[4] In general, those structural changes which accompany oxidation and reduction cycles are not well-understood. For the $[M(Pc)O]_n$ polymers, electrochemical studies offer an opportunity to address these issues as well as to vary anions and modify ϱ to an extent not readily possible with chemical reagents.

Electrochemical studies of $[Si(Pc)O]_n$ oxidative (reductive) doping have been carried out under rigorously anhydrous and anaerobic conditions in several experimental configurations in which the polymer solid is in direct contact with a

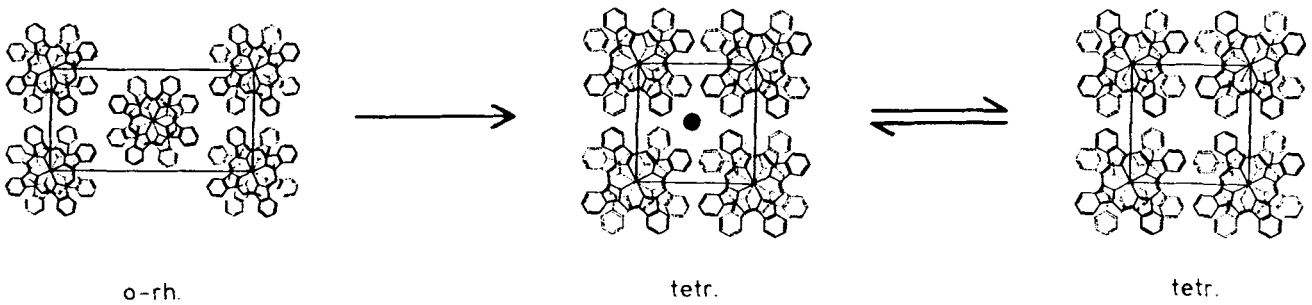

Fig. 15. Structural model of the changes accompanying initial electrochemical oxidation of as-polymerized $[Si(Pc)O]_n$. Initial "break-in" is accompanied by a transformation to a more open structure which allows more facile redox cycling. The view is parallel to the phthalocyanine stacking direction.

liquid electrolyte containing the anion (cation) of interest.[60, 61] Most studies involve an automated electrochemical potential spectroscopy (ECPS) experiment in which the applied potential is changed in steps, and at each step Coulombs of charge passed in the doping/undoping process are measured. The result is a map of applied potential versus doping stoichiometry, with the precise shape of the curve indicating where transformations between phases occur. Preparative-scale experiments are used to provide macroscopic samples for elemental analysis and diffractometric, magnetic, optical, and charge-transport characterization.

Perhaps the most interesting feature in the oxidative electrochemistry of "as-polymerized" $[Si(Pc)O]_n$ (orthorhombic; cf. Fig. 11) in common electrolytes such as $n\mathrm{Bu_4N^{\oplus}BF_4^{\ominus}}$/acetonitrile is the observation of a large overpotential/kinetic barrier upon initial oxidation.[60] The oxidation product is a tetragonal $\{[Si(Pc)O](BF_4)_y\}_n$ material, structurally similar to that prepared with $NO^{\oplus}BF_4^{\ominus}$ [Eq. (8)] except that $y \approx 0.50$ rather than 0.35. Importantly, subsequent electrochemical undoping and doping cycles for this material no longer exhibit the large overpotential, and the shape of the ECPS curve indicates that $\varrho(y)$ can be tuned smoothly between 0.00 and 0.50. The reason for the initially difficult oxidation (commonly referred to as "break-in" behavior[4, 62] but poorly understood) followed by facile cyclability can be directly correlated with the structural information. The break-in doping involves an orthorhombic to tetragonal phase transformation (Fig. 15) in which considerable reorganization of the $[Si(Pc)O]_n$ chains and expansion of the crystal lattice is required. In contrast, subsequent cycling involves interconversions between structurally similar doped and undoped tetragonal phases, requiring only anion migration through "tunnels" parallel to the stacking direction and minimal reorganization of the $[Si(Pc)O]_n$ chains (Fig. 15). The undoped phase produced in the electrochemical cycling is spectroscopically, electrochemically, and diffractometrically indistinguishable from that afforded by thermally undoping $\{[Si(Pc)O](I_3)_{0.35}\}_n$ (Fig. 11). This electrochemical behavior is unaffected by the degree to which the solid polymer sample has been finely ground, the number of redox cycles performed, or the addition of electrochemical mediators such as $[Os(bpy)]^{2\oplus}$. Further confirmation that the doping level in $\{[Si(Pc)O]BF_4)_y\}_n$ can be homogeneously tuned is provided by the observation that the tetragonal a lattice parameter varies monotonically with doping level (Fig. 16). This is the first example where the band-filling level in a molecular metal could be homogeneously tuned over a broad range

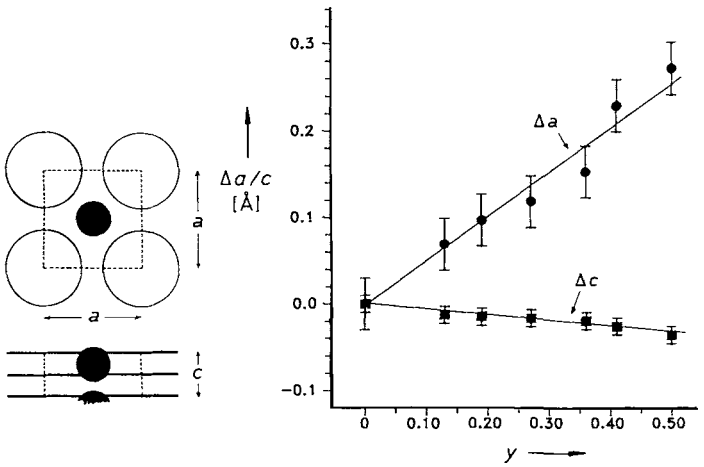

Fig. 16. Change in unit-cell parameters a and c as a function of degree of partial oxidation for $\{[Si(Pc)O](BF_4)_y\}_n$.

without a major change in crystal structure. In the closest previous example, ϱ in the system of "alloys" $(NMP)_x(Phen)_{1-x}(TCNQ)$ (NMP = *N*-methylphenazinium; Phen = phenazine) has been tuned from ca. -0.50 to -0.66 in the TCNQ band.[63, 64]

Detailed studies of $[Si(Pc)O]_n$ electrochemistry have been carried out with a wide variety of anions of differing size, shape, polarizability, and charge.[60] Representative ECPS plots are shown in Figures 17 and 18. Excepting cases where the electrochemical window of the electrolyte is exceeded, the general pattern governing the maximum stoichiometry of doping, hence the degree of band depletion that can be achieved, appears to be largely determined by the anion size. Simple packing calculations employing anion van der Waals radii show that in most cases there is good agreement between maximum possible occupancy of the anion tunnels and the doping level achieved. In the case of $n\mathrm{Bu_4N^{\oplus}BF_4^{\ominus}}$, no further oxidation of $\{[Si(Pc)O](BF_4)_{0.50}\}_n$ is observed at potentials as high as $+3.5$ V vs. the saturated calomel electrode with NaCl instead of KCl (SSCE) in liquid SO_2 at $-30\,^{\circ}C$.[65] At this point, irreversible oxidation of the polymer begins. It can also be seen in Figure 17 that the present electrochemical/synthetic results include the first case in which the charge-compensating counterion in a molecular conductor is a dianion ($SO_4^{2\ominus}$).

In the case of anions having very large dimensions, the behavior upon doping is somewhat different. For $n\mathrm{Bu_4N^{\oplus}}$ pyrenesulfonate in acetonitrile (Fig. 17), the threshold po-

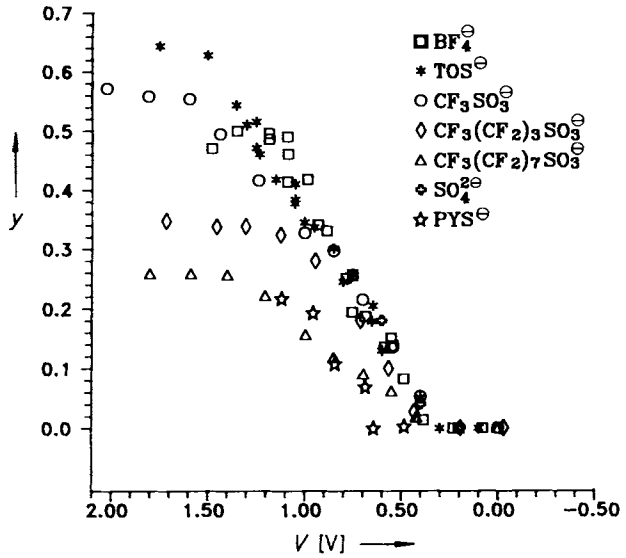

Fig. 17. Electrochemical potential spectroscopy plots for electrochemical oxidation of tetragonal $[Si(Pc)O]_n$ slurries in electrolytes composed of $nR_4N^{\oplus}$ salts (R = alkyl group) of various counterions in acetonitrile. Legend identifies the counterions. TOS = *p*-toluenesulfonate; PYS = 1-pyrenesulfonate. Potential is given vs. SSCE.

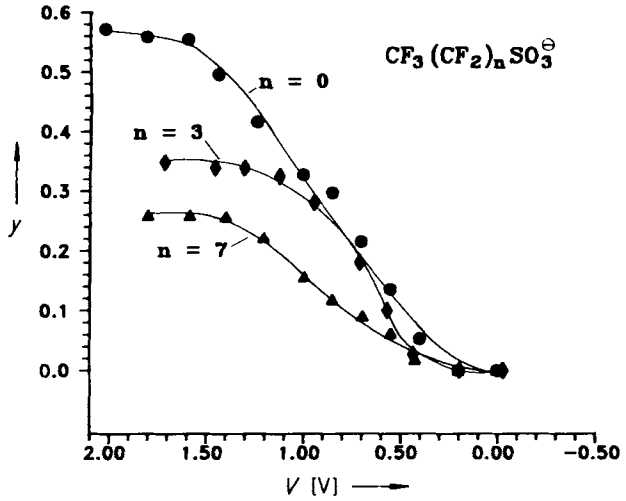

Fig. 18. Electrochemical potential spectroscopy curves for electrochemical oxidation of tetragonal $[Si(Pc)O]_n$ slurries in $nR_4N^{\oplus}CF_3(CF_2)nSO_3^{\ominus}$ (n = 0, 3, 7)/acetonitrile (R = alkyl group). Potential is given vs. SSCE.

tential for oxidative doping of tetragonal $[Si(Pc)O]_n$ is higher than for other anions studied and the ultimate doping level is rather low. In the case of $[nBu_4N^{\oplus}]_4[Mo_8O_{26}]^{4\ominus}$ in acetonitrile, an even higher threshold is observed (ca. + 0.9 V vs. SSCE) and an even lower ultimate doping level, $y \approx 0.06$, is achieved.[65] These results demonstrate the marked structure sensitivity of the $[Si(Pc)O]_n$ electrochemical doping process.

In addition to the present $[Si(Pc)O]_n$ materials, electrochemical/structural relationships have been extensively investigated for *trans*-polyacetylene.[6, 66, 67] Considerably more information is presently available for reductive doping (alkali-metal insertion) than for oxidative doping. In both cases, however, the picture is quite different than for $[Si(Pc)O]_n$ oxidative doping. Initial doping of polyacetylene is invariably found to be inhomogeneous, with the coexistence of undoped (or lightly doped) and doped $(CHX_y)_n$, $y \approx 0.06$) phases. Then, depending on the counterion, transformations are observed upon further doping to different polymer-chain/counterion packing arrangements and/or there is a modest tunability in band filling for a given crystal structure. However, in no case is the overall limiting degree of charge storage per monomer subunit as great as in the phthalocyanine polymer, nor is comparable tunability in the band filling possible. These differences no doubt reflect the far larger dimensions of the delocalized phthalocyanine π system and the attendant demonstrated capacity to store positive or negative charge, as well as the spatially closer polyacetylene-counterion interactions. The latter is understandable in terms of the higher concentration of charge per polyacetylene subunit and a polymer structure which is more favorable for close π-system–counterion interactions. The magnitudes of these interactions doubtless favor different polyacetylene packing arrangements for different stoichiometries and/or counterions, while we have shown that direct π-system–counterion interactions are small for structure-enforced phthalocyanine conductors. The factors mentioned above also suggest that doped polyacetylene crystal structures will collapse upon undoping and that well-ordered broken-in crystal structures, which are more amenable to facile doping/undoping cycles, will not be as accessible. Presently available polyacetylene data appear to confirm this.[66]

How important is the structure-enforced character of the $[Si(Pc)O]_n$ chains in the aforementioned electrochemistry? This intriguing question can be addressed via solid-state electrochemical investigations of Ni(Pc), which lacks covalent Pc–Pc structural connectivity.[60] As-sublimed Ni(Pc) has a monoclinic, slipped-stack ("β" phase) packing arrangement as shown in Figure 19. Not surprisingly, initial electrochemical oxidation is accompanied by a substantial overpotential, and the product is the tetragonal doped phase (Fig. 19). At this point, however, the behavior diverges from that of $[Si(Pc)O]_n$ in that subsequent undoping also occurs with a large overpotential, and the product is *not* an undoped tetragonal phase, but rather a second (known) monoclinic Ni(Pc) ("γ" phase). It is evident that an undoped tetragonal Ni(Pc) phase must be unstable with respect to a slipped-stack structure and that further electrochemical cycling is necessarily accompanied by $D_n \rightleftarrows$ slipped-stack structural reorganiza-

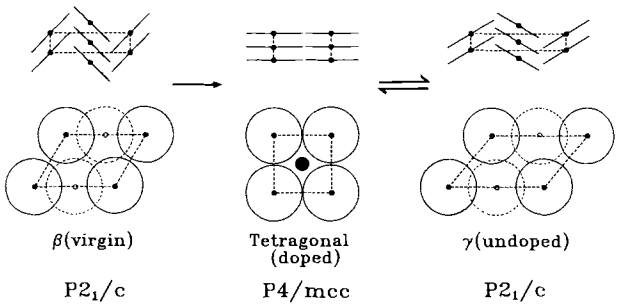

Fig. 19. Crystal structure relationships in the electrochemical oxidation of Ni(Pc) (left) to $Ni(Pc)(BF_4)_y$ where y = 0.00–0.48 (middle), followed by reduction ("undoping") (right).

tions and accompanying overpotentials. Tunability of y in the tetragonal $Ni(Pc)(BF_4)_y$ phase is rather modest.[60a]

Electrochemical experiments also answer the question of whether reductive doping of the $[Si(Pc)O]_n$ framework is possible. Partial occupancy of a band constructed from the lowest unoccupied molecular orbitals (LUMOs) of $[Si(Pc)O]_n$ might also yield a metal-like substance according to theoretical calculations.[51,68] Figure 20 shows an electrochemical

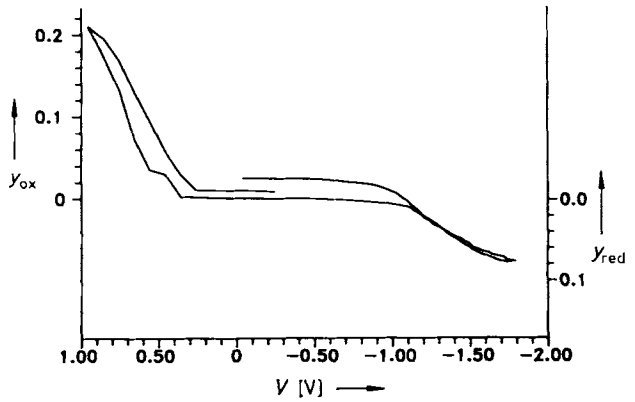

Fig. 20. ECPS data for a tetragonal $[Si(Pc)O]_n$ microcompaction in $n Bu_4N^{\oplus}BF_4^{\ominus}$/THF showing reversible reductive and oxidative doping. The anodic process is limited by the oxidation potential of THF. Potential is given vs. SSCE.

cycling experiment with solid tetragonal $[Si(Pc)O]_n$ in $Bu_4N^{\oplus}BF_4^{\ominus}$/THF. It can be seen that the polymer can be reversibly reduced with a limiting reduction stoichiometry of $y \approx 0.09$, that is, to form $\{(nBu_4N)_{0.09}[Si(Pc)O]\}_n$. Furthermore, the polymer can be cycled a number of times between the oxidized and reduced states with minor, if any, decomposition. The difference in threshold potentials measured for tetragonal $[Si(Pc)O]_n$ oxidation and reduction is ca. 1.5 V, which compares favorably with the HOMO–LUMO band gap estimated from optical spectroscopy: 1.65 eV (750 nm).[47a] Initial measurements indicate that the reductively doped $[Si(Pc)O]_n$ polymers are electrically conductive.[69]

As noted above, the electrochemically doped $\{[Si(Pc)O]X_y\}_n$ macromolecules not only incorporate a great diversity of off-axis anions (and a dianion), but also represent the first class of molecular metals in which band filling is widely tunable. Detailed charge-transport, optical, and magnetic measurements have been carried out as a function of anion and y.[60,70] Intriguing questions include whether the additional Coulombic perturbation of an off-axis dianion might cause "pinning" of the carriers and whether metal-like characteristics are tunable over the entire range of mixed valency, as suggested by simple band-theoretical considerations (Fig. 1), or whether there is a certain threshold doping level beyond which they "switch on".

In Figure 21 are shown room-temperature conductivity data for a series of polycrystalline $\{[Si(Pc)O](BF_4)_y\}_n$, $\{[Si(Pc)O](tosylate)_y\}_n$, and $\{[Si(Pc)O](SO_4)_y\}_n$ samples as a function of y. It can be seen that the $\sigma(y)$ behavior is rather insensitive to the identity of the anion and that an abrupt increase in conductivity at low doping levels is followed by a leveling off at $y \approx 0.20-0.30$. Beyond this point, the conduc-

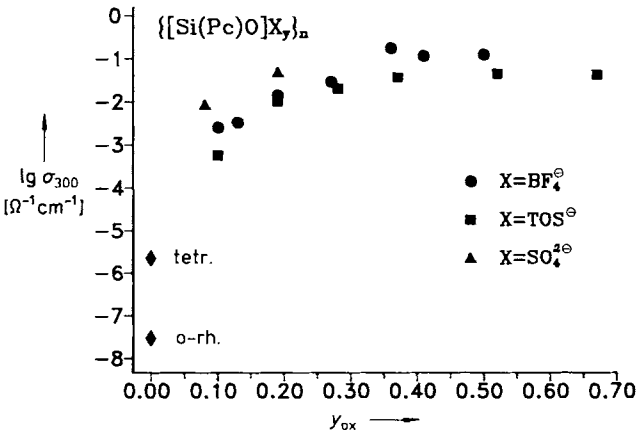

Fig. 21. Electrical conductivity (lg σ) at room temperature for polycrystalline $\{[Si(Pc)O]X_y\}_n$ samples as a function of the degree of oxidation per Si(Pc) unit (y_{ox}). The y values for $\{[Si(Pc)O](SO_4)_y\}_n$ have been multiplied by 2.0 to correct for the dinegative charge of $SO_4^{2\ominus}$.

tivity is virtually independent of y as far as $y \approx 0.67$. Variable-temperature studies indicate that, for $y \lesssim 0.20$, the $\sigma(T)$ data can be best fit to a model appropriate for a highly disordered material or one in which there is carrier hopping between localized states.[4,71-74] For $y \gtrsim 0.20$, the best fit is to the previously mentioned fluctuation-induced tunneling model.

Because the thermoelectric power measurement is a zero-current experiment and because temperature drops at grain boundaries are expected to be less important than voltage drops, this technique should be far less susceptible to polycrystalline sample effects than dc conductivity measurements.[26-28] Indeed, we find that, in contrast to conductivity measurements (cf. Figs. 9, top, and 12), variable-temperature TEP data for single crystal and polycrystalline samples of the same molecular metal are rather similar.[55] Figure 22 shows room-temperature TEP data for polycrystalline $\{[Si(Pc)O](BF_4)_y\}_n$, $\{[Si(Pc)O](tosylate)_y\}_n$, and $\{[Si(Pc)O](SO_4)_y\}_n$ samples as a function of y. With increasing y, the Seebeck coefficient (S) drops steeply from large, positive values characteristic of p-type semiconductors to small, positive values typical of p-type molecular metals (Fig. 22) and then levels off at $y \gtrsim 0.35$. Variable-temperature studies as a

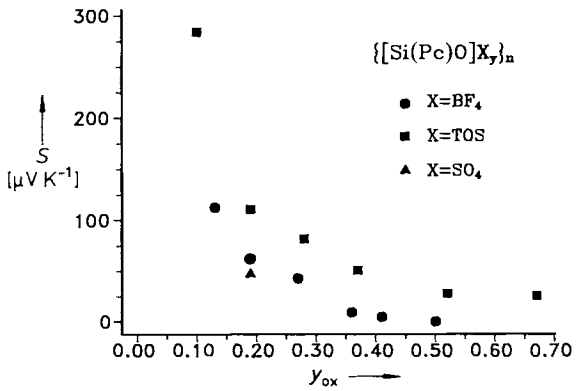

Fig. 22. Room-temperature thermoelectric power (S) data as a function of doping level for polycrystalline $\{[Si(Pc)O](BF_4)_y\}_n$, $\{[Si(Pc)O](tosylate)_y\}_n$, and $\{[Si(Pc)O](SO_4)_{0.095}\}_n$ conductive polymer samples. The y value shown for $\{[Si(Pc)O](SO_4)_{0.095}\}_n$ has been corrected for the dinegative charge of $SO_4^{2\ominus}$.

function of y have also been carried out. Although the data for the above three classes of doped polymers differ in small details, all evidence a smooth, continuous transition from behavior characteristic of a p-type semiconductor (large, positive S with $S \sim 1/T$) to a radical-cation molecular metal (small, positive S with $S \sim T$). An example is shown in Figure 23. Importantly, the transition from a semiconductor to

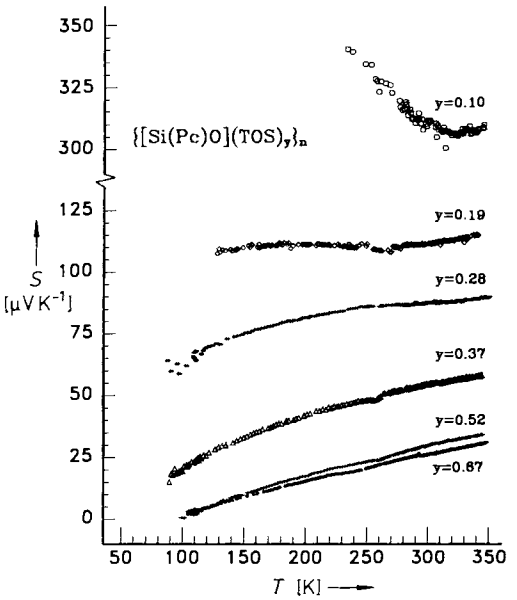

Fig. 23. Variable-temperature thermoelectric power (S) data for polycrystalline {[Si(Pc)O](tosylate)$_y$}$_n$ samples.

a metal occurs for all three series in the region $y \approx 0.20$. How do these experimental $S(y,T)$ results compare with the predictions of simple tight-binding band theory? Using Equation (4) and assuming U is negligible and $4t \approx 0.60$ eV (cf. Table 2), the curves in Figure 24 are generated. While the agreement between experiment and theory for $S(y)$ at fixed T appears reasonable (Fig. 24, top), the theory predicts continuous metallic behavior ($S \sim T$) for all doping levels (Fig. 24, bottom). In contrast, the experimental TEP data evidence a "switching on" of metallic character in the neighborhood of $y \approx 0.20$. That the thermopower of the present {[Si(Pc)O]X$_y$}$_n$ materials with $y = 0.50$ does not exhibit temperature-independent $|S| \approx 60\ \mu V\ K^{-1}$ behavior stands in marked contrast to the great majority of low-dimensional $|\varrho| = 0.50$ systems having very large $U/4t$ ratios.[26, 27]

Detailed reflectivity, magnetic susceptibility, and ESR studies have also been carried out for the {[Si(Pc)O](BF$_4$)$_y$}$_n$, {[Si(Pc)O](tosylate)$_y$}$_n$, and {[Si(Pc)O](SO$_4$)$_y$}$_n$ materials as a function of y.[70] We have shown elsewhere that single-crystal and polycrystalline optical reflectivity data for low-dimensional conductors are readily interconvertible.[33c, 53, 54] As exemplified by the optical data for the series of $BF_4^{\ominus}$ salts (Fig. 25), initial doping yields reflectance spectra characteristic of a molecular semiconductor. A well-defined plasma edge is not evident until $y \gtrsim 0.20$, beyond which doping level the energy of the edge shifts monotonically to higher energy. Indeed, for y values within the metallic regime, the adherence to Equation (5), derived for tight-binding, is quite good (Fig. 26).

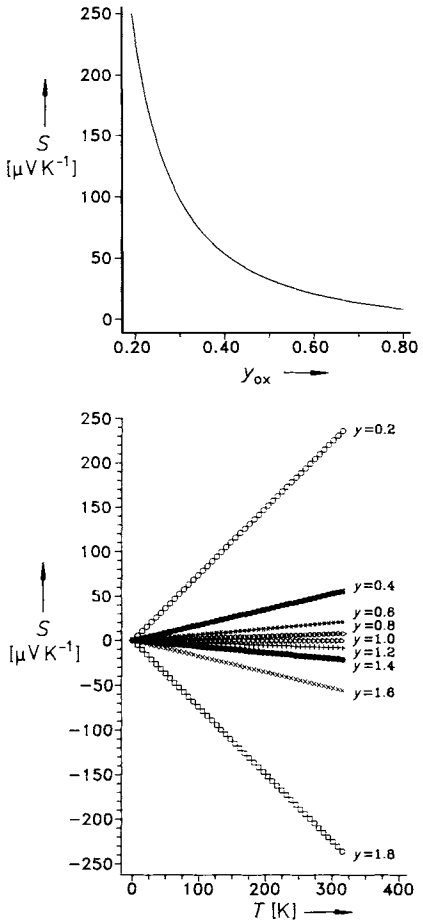

Fig. 24. Top: Band-filling dependence of thermoelectric power for a simple low-dimensional tight-binding band structure with energy-independent scattering, negligible U, $T = 300$ K, and $4t = 0.60$ eV calculated with Eq. (4). Bottom: Temperature dependence of thermoelectric power as a function of degree of oxidation ϱ calculated using Eq. (4) for a simple tight-binding band structure with energy-independent scattering, negligible U, and $4t = 0.60$ eV.

Magnetic susceptibility studies of the {[Si(Pc)O](BF$_4$)$_y$}$_n$ materials as a function of increasing y reveal a large Curie component typical of localized radical-cation states for low values of y (Fig. 27). This component of the susceptibility peaks at $y \approx 0.20$ and then falls abruptly with increasing y. Over this same y range, a Pauli component grows in and remains essentially constant beyond $y \gtrsim 0.25$. As also shown in Figure 27, this $\chi(y)$ behavior is distinctly different from that found for the chemically (inhomogeneously) doped {[Si(Pc)O](I$_3$)$_y$}$_n$ materials.[53] Because the chemical doping process is largely inhomogeneous, the Pauli contribution is linearly dependent upon the doping level (because the fraction of doped phase is linearly dependent upon the doping level). The $\chi(y)$ dependence of the homogeneously doped {[Si(Pc)O](BF$_4$)$_y$}$_n$ polymers can now be compared with the predictions of simple tight-binding band theory [Eq. (6)] in Figure 28. As for the thermopower and reflectivity data, the agreement with theory is poorest at low doping levels where, in the magnetic data, the $BF_4^{\ominus}$ salt exhibits the large, y-dependent Curie component. However, some aspects of the predicted flattening-out in $\chi(y)$ are observed at higher doping levels. Magnetic susceptibility measurements on {[Si(Pc)O](tosylate)$_{0.67}$}$_n$ and {[Si(Pc)O](SO$_4$)$_{0.095}$}$_n$ (in or near the metallic regime) also reveal large Pauli-like compo-

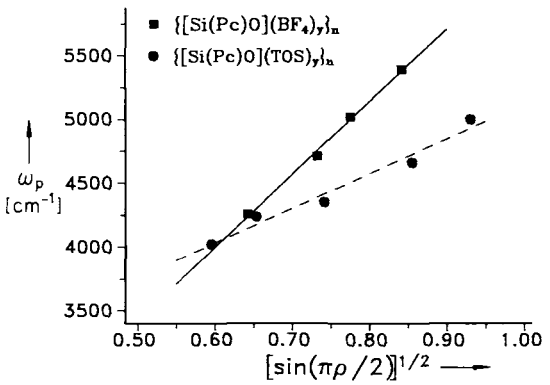

Fig. 26. Plot of $\{[Si(Pc)O](BF_4)_y\}_n$ and $\{[Si(Pc)O](tosylate)_y\}_n$ plasma frequencies ω_p (from reflectance data) as a function of degree of partial oxidation $\varrho(y)$ according to the tight-binding band theoretical expression of Eq. (5).

nents and, in the case of the latter material, no evidence of carrier localization by the dinegative counterion. Magnetic data are compiled in Table 1 and magnetically derived bandwidths in Table 2. It is found that susceptibilities are again enhanced, but also that the degree of enhancement depends upon ϱ.[70a] This is the first experimental verification of the important theoretical prediction[38a,d] that U can be ϱ (band filling) dependent.

ESR data for the above polycrystalline $\{[Si(Pc)O]X_y\}_n$ materials as a function of y are in substantial agreement with the aforementioned characterization results.[70,75] Incremental doping is accompanied by an invariance in the essentially free-electron g value (indicative of ligand-centered carriers) and by a general decrease in line width. The magnitudes and

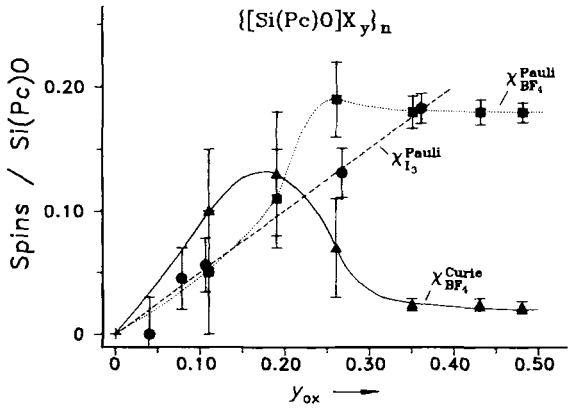

Fig. 27. Stoichiometry (y) dependence of the Pauli-like (■) and Curie-like (▲) spin susceptibilities of electrochemically (homogeneously) doped $\{[Si(Pc)O](BF_4)_y\}_n$ polymers. The dashed line indicates the Pauli-like term (●) for the chemically (inhomogeneously with I_2) doped polymer.

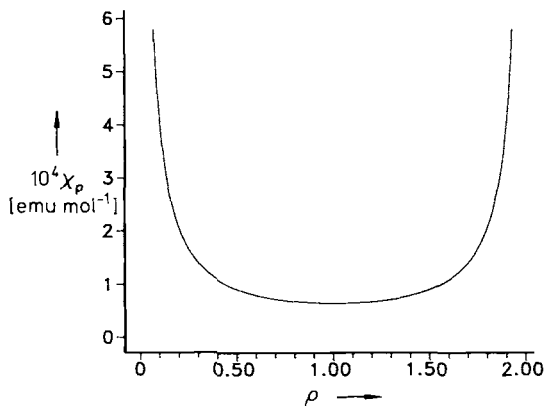

Fig. 28. Band filling dependence of the Pauli magnetic susceptibility (χ_p) calculated according to the one-dimensional tight-binding model of Eq. (6) for $4t = 0.60$ eV and $U = 0$.

y dependence of the line widths are in general accord with increasingly mobile (delocalized) conduction electrons upon doping and with a relatively unidimensional band structure (small interstack interactions). The only surprise in these data is the observation that the ESR line widths of $\{[Si(Pc)O](SO_4)_y\}_n$ are slightly larger than those of the $BF_4^{\ominus}$ and tosylate salts (ca. 1.5 G vs. 0.5–1.0 G). It is not clear at this point whether the enhanced broadening reflects decreased carrier mobility and/or greater two-dimensionality for Coulombic reasons, or whether greater carrier density on the $SO_4^{2\ominus}$ counterion induces more efficient electronic relaxation via phonon-modulated spin–orbit interactions as in the $I_3^{\ominus}$ and $SbF_6^{\ominus}$ salts discussed in Section 4.1.

4.3. Origin of the $\{[Si(Pc)O]X_y\}_n$ Insulator/Semiconductor Metal Transition

The dramatic changes in $\{[Si(Pc)O]X_y\}_n$ properties that occur in the vicinity of $y \approx 0.20$ indicate that a major change in electronic structure and carrier mobility occurs. The diffraction and electrochemical data give no indication of equally drastic structural changes, but rather evidence a fairly smooth evolution in structure as a function of y. As will be discussed below, the nature of the $y \approx 0.20$ transition is from a localized-carrier, insulating or semiconducting material to

a delocalized, metal-like material, the properties of which continue to evolve in an instructive manner as y approaches the maximum doping stoichiometry. The electronic structural model that best fits these y-dependent changes focuses on the effects of disorder and defects on the properties of a quasi-one-dimensional band structure. To do so, we make use of another band-structural concept which indicates the number of energy levels per unit energy in the band: the density of states.[1] In a classical description, many of the properties of metal-like substances (e.g., conductivity, magnetic susceptibility) are extremely sensitive to the density of states near the highest occupied band level (the Fermi level). Figure 29 A illustrates a density of states versus energy diagram for a classical, one-dimensional tight-binding band.[1] This is the idealized model from which the thermoelectric power, optical spectroscopic, and magnetic models of Equations (5) (Fig. 24), (6), and (7) (Fig. 28), respectively, are derived. The effects on this picture of disorder and defects will be to alter the density of states as shown schematically in Figure 29 B and to introduce a mobility edge (E_C) between

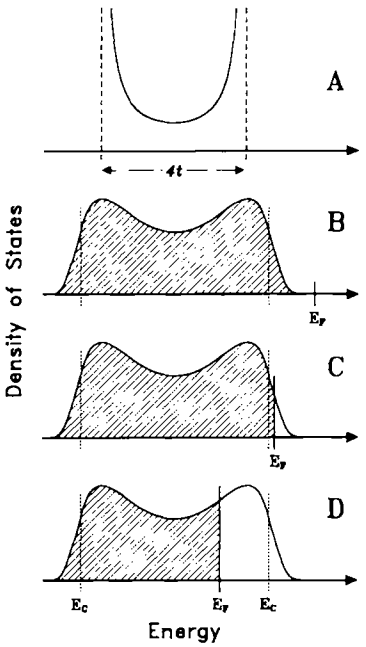

Fig. 29. Schematic density of states model of the electronic structural consequences of incrementally oxidizing $[Si(Pc)O]_n$. A: Undoped. Classical quasi-one-dimensional tight-binding description. B: Part A in the presence of disorder and defects. C: Lightly doped. D: Heavily doped. E_F represents the Fermi energy and E_C the energy of a mobility edge.

localized states at the tails of the band and the more central, delocalized (metal-like) states.[76, 77] A transition of the Fermi level (E_F) across such an edge as a function of composition or some other property is classically known as an Anderson transition.[76] In the commonly accepted description, the localized Anderson state possesses a "Fermi glass" electronic structure having a relatively continuous density of localized states.[76, 77] Whether such a situation has been truly realized in the present materials is currently under further investigation.

At low oxidation levels of $\{[Si(Pc)O]X_y\}_n$, it is reasonable that the doped polymer is significantly disordered, presumably as a consequence of varying $[Si(Pc)O]_n$ chain lengths and/or crystallographic positions as well as possibly other types of defects (including in anion locations). The effect of these perturbations will be localization of conduction band states at the tails of the band. In this regime, the carriers (holes) will therefore have low mobilities. The charge-transport data are in good accord with this model: the dc conductivity is low, exhibits high apparent activation energies, and can be fit to a transport model applicable to disordered systems or carrier hopping between localized states. At this same doping level, the magnitude and temperature dependence of the thermoelectric power is also typical of a p-type semiconductor (Figs. 22 and 23). Additional evidence for carrier localization in this regime is noted in the optical reflectivity, which is in accord with a semiconducting or insulating electronic structure (Fig. 25), and the magnetic susceptibility, which evidences a large concentration of localized Curie-like spins and little, if any, Pauli-like behavior (Fig. 27).

In the region of $y \approx 0.20$, major changes are detected. Both the magnitude and temperature dependence of the thermoelectric power evidence a transition to a metal-like substance (Figs. 22 and 23). Although interparticle contact effects are likely to obscure the sharpness of the transition, the electrical conductivity begins to level off in the vicinity of $y \approx 0.20$, while the apparent activation energies (slopes in lg σ vs. $1/T$) fall.[70a] For $y \gtrsim 0.20$, the temperature dependence of $\{[Si(Pc)O]X_y\}_n$ conductivity can be better fit to a fluctuation-induced tunneling-transport model appropriate for a more metal-like material. Also at $y \approx 0.20$, a metal-like plasma edge is first observed in the optical reflectivity, while magnetic measurements indicate that the concentration of Curie-like spins drops precipitously and the concentration of Pauli-like spins rises sharply. ESR line widths exhibit a decrease to values characteristic of more mobile spins. In terms of the model shown in Figure 29, the $y \approx 0.20$ doping region represents the region at which the Fermi level is crossing the mobility edge. This picture stands in contrast to the classical model (Fig. 29), which would predict a "turn-on" of metallic characteristics at the lowest doping levels. To our knowledge, such a doping level-dependent turn-on has not previously been observed in a molecular metal.

Depleting the band structure beyond $y \approx 0.25$ evokes a number of interesting responses. The room-temperature electrical conductivity remains remarkably constant over a very broad range, while the decrease in apparent activation energy is smaller than in the $y \approx 0.20$ region. Beyond $y \approx 0.35$, the Pauli-like component of the magnetic susceptibility remains nearly constant while the Curie-like component declines to a low, constant level. Meanwhile, the ESR line widths fall to levels typical of unidimensional phthalocyanine molecular metals not having heavy-atom counterions. For y increasing beyond ca. 0.25, the optical plasma edge shifts continuously to higher energy, in good accord with simple tight-binding band theory (Fig. 26). These observations generally agree with the picture of Figure 29 D in which the Fermi level is in the metallic portion of the conduction band and in which the density of states varies only modestly as a function of y. The latter contention is supported by the weak sensitivity of the conductivity and Pauli-like susceptibility to y. As noted elsewhere, agreement between

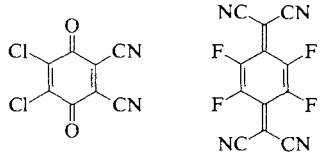
experimental parameters, such as bandwidths derived from a tight-binding analysis of optical reflectivity and thermopower data and those measured by other methods, is always poor at low doping levels, but more satisfactory at higher doping levels.[51, 68] Comparison of Figure 29A to Figures 29B–26D shows that one reason derives mainly from how the density of states responds to disorder and defects. The deviation of the density of states from the idealized formalism (Fig. 29A), upon which Equations (5)–(7) are based, is greatest near the tails of the band, that is, at very low and very high doping levels.

4.4. Tunable Approach to a Mott–Hubbard Insulator: Quinone Doping of $[Si(Pc)O]_n$

The maximum $\{[Si(Pc)O]X_y\}_n$ doping levels achieved via electrochemical techniques are on the order of + 0.70, corresponding to a 65%-filled classical band. With reference to Figure 4 and earlier discussion, the fascinating question next arises as to whether it is possible to incrementally tune y to even higher levels, perhaps to the half-filled band (integral oxidation state) level. Will the products be metals, semiconductors, or insulators? Doping of $[Si(Pc)O]_n$ with the strongly oxidizing reagents 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) or 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane ($TCNQF_4$) proceeds as shown in Equation (9).[42b, 46a, b, 78] Heating the doped polymers under vacuum

$$[Si(Pc)O]_n + yn\,Q \rightleftharpoons \{[Si(Pc)O]Q_y\}_n \qquad (9)$$

Q =



DDQ

$TCNQ\text{-}F_4$

removes the quinones and regenerates undoped $[Si(Pc)O]_n$. IR, Raman, and optical spectral data indicate that most, if not all, of the quinone molecules are present as radical anions ($Q^{\bullet\ominus}$). Hence, oxidation of the phthalocyanine subunits has occurred. X-ray diffraction data indicate that the quinone doping process is at least partially inhomogeneous and that the doped polymer crystal structures are significantly disordered/poorly crystalline.

The electrical and optical properties of the $\{[Si(Pc)O]Q_y\}_n$ materials are markedly different from those of quinone-doped *molecular* phthalocyanines. While the latter materials were found to be insulators, in agreement with the proposed integrated stacking crystal structures (**3**, **4**), the quinone-doped stacking-enforced polymers exhibit electrical and optical properties reminiscent of the halogen- and nitrosyl-doped $[Si(Pc)O]_n$ materials discussed in Section 4.1.[53, 54] Thus, a steep rise in conductivity is observed upon initial oxidation (Fig. 30) along with a drop in the thermoelectric power from that characteristic of a semiconductor to that of a π-radical-cation-based $[Si(Pc)^{e\oplus})O]_n$ molecular metal (Fig. 31). The optical reflectivity at $y \approx 0.40$ exhibits a characteristic molecular-metal plasma edge virtually identical to

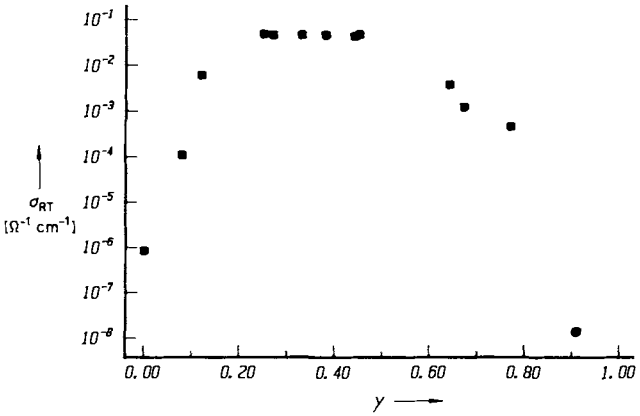


Fig. 30. Room-temperature electrical conductivity (σ_{RT}) data of compressed polycrystalline $\{[Si(Pc)O](DDQ)_Y\}_n$ samples as a function of y.

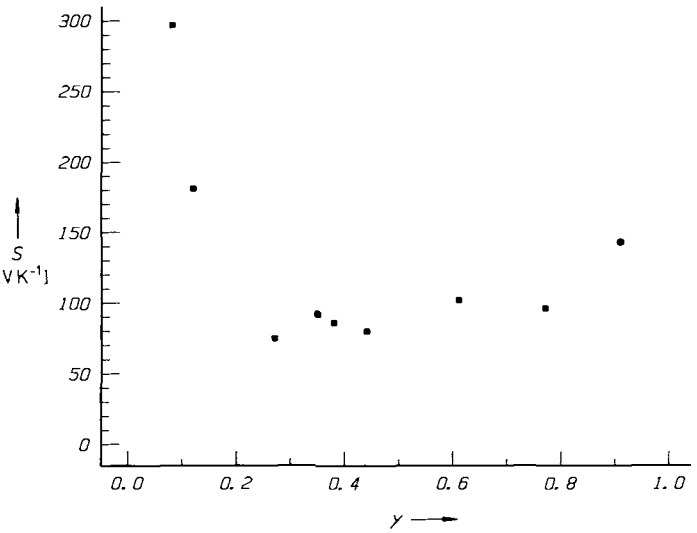

Fig. 31. Room-temperature thermoelectric power (S) data for compressed polycrystalline $\{[Si(Pc)O](DDQ)_y\}_n$ samples as a function of y.

that of the corresponding $I_3^{\ominus}$, $BF_4^{\ominus}$, and $PF_6^{\ominus}$ salts (Fig. 14).[53, 54, 78] As the $\{[Si(Pc)O]DDQ_y\}_n$ doping level is increased beyond $y \approx 0.20$, the room-temperature conductivity and thermoelectric power remain nearly constant, as observed for other $\{[Si(Pc)O]X_y\}_n$ materials (Figs. 21 and 22). In addition, the $\sigma(T)$ data can be fit to the aforementioned fluctuation-induced carrier tunneling model, while the $S(T)$ data are reminiscent of the $X^{\ominus} = BF_4^{\ominus}$ and tosylate analogues (Fig. 23).

As y is increased beyond ca. 0.50–0.60, dramatic changes occur in the $\{[Si(Pc)O]DDQ_y\}_n$ physical properties. The electrical conductivity begins to fall and, by $y \approx 0.90$, the material has become an insulator with a ca. 10^7 decrease in electrical conductivity versus that at $y \approx 0.40$ (Fig. 30). Indeed, the conductivity at $y \approx 0.90$ is lower than for $y \approx 0.00$. In this high-doping-level regime, a plasma edge is no longer discernible in the $\{[Si(Pc)O]DDQ_y\}_n$ optical reflectivity, and the strong carrier absorption commonly observed in the transmission infrared spectra of phthalocyanine molecular metals[53] is no longer apparent. As y increases beyond ca. 0.50, the room-temperature thermoelectric power of

$\{[Si(Pc)O]DDQ_y\}_n$ rises and becomes semiconducting by $y \approx 0.90$ (Fig. 31). Interpretation of magnetic susceptibility data is presently complicated by unknown and potentially varying contributions of the paramagnetic $Q^{\bullet\ominus}$ counterions.

It is evident from the above discussion that $\{[Si(Pc)O]DDQ_y\}_n$ undergoes a dramatic metal to insulator transition as y is tuned toward ca. + 1.0 (a half-filled classical band). As noted above, the admittedly simplistic model of Figure 4 implies that, all other factors being equal, electron–electron Coulombic interactions will adversely affect carrier mobility most at the integral oxidation levels of $\varrho = 0$ and 1. The latter situation would correspond to a molecular/macromolecular Mott–Hubbard insulator, and the result is effectively a gap at the center of the highest filled band. Several isolated examples are known where such a regime is believed to obtain;[2, 38a, d, 79] however, data interpretation is complicated by the crystal-structure and building-block alterations needed to produce the $\varrho = 1$ material. The present $\{[Si(Pc)O]DDQ_y\}_n$ system is the first example where the Mott–Hubbard insulator state can be incrementally tuned into a low-dimensional material. That the onset of insulating character is somewhat in advance of the $\varrho = 1.0$ oxidation level supports the not unexpected presence of localized states at the low-energy tail of the conduction band (cf. Fig. 29). If the admittedly simplistic model of Figure 4 is correct, oxidation beyond $y \approx 1.0$ should give rise to a second regime of metal-like characteristics. Preliminary results with the more strongly oxidizing dopant $TCNQF_4$ support this picture.[78] Thus, while the sharpness of the effect is likely convoluted to some degree with artifacts arising from doping inhomogeneity and disorder, it is evident that an oxidative increase of y in $\{[Si(Pc)O](TCNQF_4)_y\}_n$ materials leads (Fig. 32) initially to a

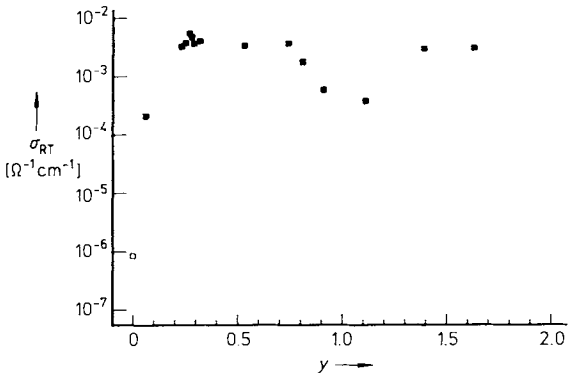

Fig. 32. Room-temperature conductivity data for compressed polycrystalline $\{[Si(Pc)O](TCNQF_4)_y\}_n$ samples as a function of y.

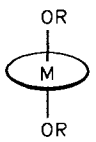
steep rise in conductivity followed by a leveling off by $y \approx 0.20$ as seen for DDQ (Fig. 30). At this point, a plasma edge is evident in the reflectance spectrum. As in the case of $\{[Si(Pc)O]DDQ_y\}_n$, the conductivity begins to decline by $y \approx 0.50$ and reaches a minimum near $y \approx 1.0$. However, it is possible to dope $\{[Si(Pc)O](TCNQF_4)_y\}_n$ beyond the integral oxidation state, and this chemistry effects a return in conductivity to the levels observed in the metal-like, $0.20 \lesssim 0.70$ stoichiometry region! This remarkable result suggests that oxidation beyond the $y \approx 1.0$ state involves electronic depletion of the lower Mott–Hubbard band. In terms of Figure 4, charge mobility is again increased by the creation of additional site vacancies.

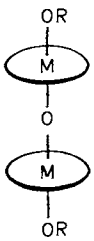
5. Electronic Structure Considerations: Connections between the Microscopic and the Macroscopic

The dicussion to this point has focused upon how deliberate, chemically induced changes in metallomacrocycle stacking architecture, counterion environment, and band filling influence band structure, hence macroscopic electrical, optical, and magnetic properties. We now consider these observations in light of what is known about the composition and nature of the band structure. We also inquire as to the validity of the tight-binding formalism[1] employed here and elsewhere to extract band structure information from macroscopic, condensed-phase thermopower and optical reflectivity measurements. In particular, we ask whether small-molecule theoretical and experimental means exist to calibrate this formalism.

As depicted in Figure 3, the $[Si(Pc)O]_n$ band structure is built up by suitable combinations of Si(Pc) molecular orbitals. The highest-energy filled band, the depletion of which gives rise to metallic character, will be composed of Si(Pc) HOMOs, while the lowest-energy unfilled band, which is populated upon reductive doping, is composed of Si(Pc) LUMOs. Electronic structure calculations have been carried out at the first-principles discrete-variational local exchange (DV-Xα) level[80] on the molecules $Si(Pc)(OH)_2$ (**12**; M = Si, R = H) and the cofacial dimer HOSi(Pc)OSi(Pc)OH (**13**; M = Si, R = H).[51, 68] Species **13** is a prototype for known molecules of the type $Me_2(tBu)SiOSi(Pc)OSi(Pc)OSi(tBu)Me_2$, which have been characterized by single-crystal diffractometry[51] (structural results are in good agreement with those deduced for $[Si(Pc)O]_n$[47a]). It will be seen that the availability of cofacial dimers that model the simplest aspect of the macrocycle π–π band-forming interaction is a particularly important dividend of the $[Si(Pc)O]_n$ architectural connectivity.



12



13

The DV-Xα calculations on **12** and **13** give results in excellent agreement with experimental optical and orbital ionization energy data.[51] In Figure 33 are shown graphic representations of the HOMO and LUMO of $Si(Pc)(OH)_2$. The most significant conclusion about the HOMO is that the greatest orbital amplitudes are near the core of the macrocycle with a lesser contribution from the fused benzo ring orbitals and almost negligible contribution (forbidden by symmetry) from the orbitals of the $(Si\text{-}O)_n$ chain. These ob-

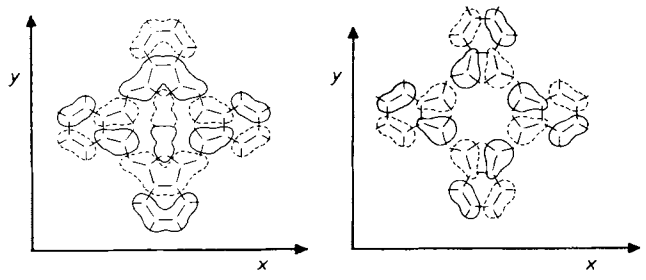


Fig. 33. Graphic representations of DV-Xα-derived molecular orbitals of $Si(Pc)(OH)_2$ viewed perpendicular to the macrocyclic plane. Left: $7e_g$(LUMO). Right: $2a_{1u}$(HOMO).

servations help to understand the largely ring-centered, π-radical-cation character of the conduction process. Furthermore, the spatial remoteness of the band-structure-forming orbitals from off-axis counterions (cf. also Figs. 6 and 8) helps to explain the observed insensitivity of the collective properties of $\{[Si(Pc)O]X_y\}_n$ to the identity of X. The DV-Xα results for the $Si(Pc)(OH)_2$ LUMO (Fig. 33) indicate that the band structure populated upon reductive doping will be of significantly different orbital composition. For example, it will have a non-negligible contribution from Si orbitals.

Calculations on dimeric structure **13** and related dimers have included an examination of how π–π interactions as expressed by 4*t* (Fig. 3) vary with interplanar eclipsing/twist angle and ring–ring interplanar spacing (Fig. 34). The DV-Xα formalism is known to be accurate in situations where relatively small π–π orbital overlap obtains.[151, 68, 81] From the upper part of Figure 34, it can be seen that the bandwidth of an infinite $[Si(Pc)O]_n$ stack is sensitive to the ring–ring eclipsing angle (with fixed interplanar spacing). It can also be seen that the experimentally observed angles on the order of 40° only approach one of two possible overlap maxima at 0° and 45°. The former may be disfavored due to nonbonded repulsions. These calculations also reveal a zero bandwidth minimum near 20°. Clearly, all synthetic strategies for a phthalocyanine molecular metal must avoid approaching this eclipsing angle. The lower part of Figure 34 shows the calculated effect on the bandwidth of varying the Pc–Pc interplanar spacing (with a fixed eclipsing angle). It can be seen that the calculated 4*t* value falls off rapidly as the stacking repeat distance increases. In Table 2, these results are compared with experimental thermopower- and reflectivity-derived tight-binding bandwidth estimates at the three experimentally accessible interplanar spacings of 3.25, 3.30, and 3.48 Å. It can be seen that the agreement between the condensed-phase measurements, interpreted within the framework of a Hückel-like formalism, and the DV-Xα theoretical calculations is quite good. However, an independent experimental calibration of the solid-state measurement would be highly desirable.

As can be appreciated from Figure 3, the electronic structure of dimers such as **13** should be directly extrapolable to the bandwidth of the corresponding polymer. That is, the HOMO–HOMO splitting of 2*t* should be one-half the tight-binding bandwidth. Molecules of structure **13** provide a

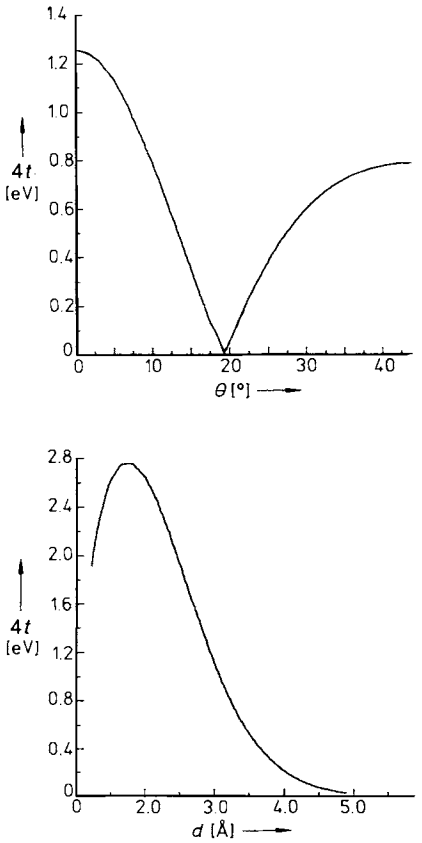

Fig. 34. Top: Calculated variation of the HOSi(Pc)OSi(Pc)OH conduction (HOMO) bandwidth as a function of Pc–Pc eclipsing (twist) angle at an interplanar separation of 3.32 Å (0° = completely eclipsed, D_{nh} Si(Pc)OSi(Pc) geometry). Bottom: Pc–Pc interplanar separation with an eclipsing angle of 37°.

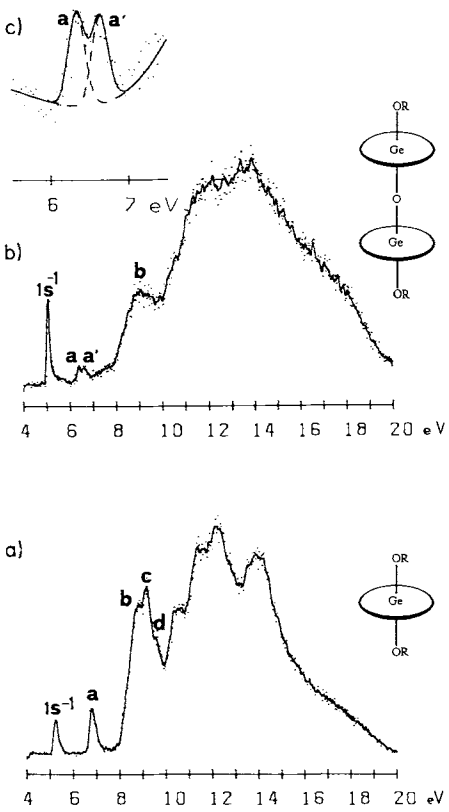

Fig. 35. Gas-phase He(I) photoelectron spectra of a) $PcGe(OSiMe_2tBu)_2$, b) $(tBu)Me_2SiOGe(Pc)OGe(Pc)OSiMe_2(tBu)$, and c) expanded-scale presentation of the aa' doublet in b.

unique ex situ measure of $4t$ since the HOMO–HOMO splitting energy can be measured in the gas phase by photoelectron spectroscopy.[51, 68d] As exemplified by Figure 35, the HOMO–HOMO interaction energy in the gaseous M = Ge compound is clearly visible in the splitting of the lowest-energy Pc π ionization (aa′ band). The measured splitting in the M = Ge dimer is 0.19(3) eV, while that in the M = Si dimer is 0.29(3) eV. Assuming molecular geometies are similar and monomer/dimer relaxation effects upon ionization are approximately constant, multiplication of these splittings by a factor of two should provide an independent measure of the tight-binding bandwidth. In Table 2 are compared $4t$ values measured in the solid state (TEP, reflectivity, magnetic), measured in the gas phase (PES), and calculated using the DV-Xα formalism. With the exception of the bandwidths derived from magnetic measurements, which are susceptible to Coulomb enhancement (see above), the agreement is quite good. Clearly, $4t$ values derived from properly analyzed condensed-phase measurements are reliable in these kinds of materials. Moreover, the era is fast approaching when first-principles quantum chemistry will play a major predictive role in guiding the design and synthesis of new electronic materials.

6. Comparison of $\{[M(Pc)O]X_y\}_n$ Materials to Other Molecular and Polymeric Conductors

The initial goal at the outset of this research was to devise a system of molecular conductors in which a number of key parameters could be perturbed while retaining control of the stacking architecture. No other system of molecular metals has allowed wide uniaxial variation of interplanar spacing or wide variation of off-axis counterions without major changes in the stacking architecture. In regard to broad excursions in the partial oxidation level, only $(NMP)_x(Phen)_{1-x}TCNQ$[63] merits comparison and contrasting. The band filling in this low-dimensional molecular conductor can be tuned from $\varrho \approx -0.50$ to -0.66 in the TCNQ stack by substitution of neutral Phen for $NMP^{\oplus}$. Electron–phonon coupling is very large, giving rise to a Peierls distortion in the stacking architecture and gap-related semiconducting charge-transport behavior even at room temperature. As x is tuned from 1.0 to 0.5, the material changes (at $x \approx 0.65$) from a two-chain conductor with a relatively small U (due to interchain screening) to a large-U single-chain (TCNQ) conductor. In the narrow region where $x \approx 0.50-0.56$, excess charge is accommodated by maintaining a commensurate (dimerized) TCNQ stacking architecture and forming pairs of charged defects (bipolarons).[63] This behavior is to be contrasted with the present phthalocyanine conductors, where the molecular $M(Pc)X_y$ systems exhibit metallic characteristics over a broad temperature range, where there is minimal to no evidence for a Peierls instability down to low temperatures, and where the lattice-stiffening of the $\{[Si(Pc)O]X_y\}_n$ backbone and the lower bandwidth are likely to further oppose electron–phonon coupling-based structural distortions. In addition to these contrasts, off-axis counterion screening effects appear to be far larger in $(NMP)_x(Phen)_{1-x}(TCNQ)$.[63]

As macromolecules, the large family of $\{[M(Pc)O]X_y\}_n$ conductors differs from the great majority of electrically conductive polymers in that the conjugation pathway does not coincide with the putative charge transport pathway and electron–phonon coupling is much smaller. Thus, initial doping of Peierls-distorted *trans*-polyacetylene results in a decrease in the magnetic susceptibility and semiconducting transport via spinless charged soliton (π free radical) defect states in the band gap.[4, 66] At the doping level of ca. $[(CH)X_{0.06}]_n$, there is an abrupt transition to a metallic state with Pauli-like magnetic susceptibility. At this point, the material has been described as having a disorder-induced metallic density of states in the band gap,[82] or as a polaron metal.[83] Polyacetylene can be prepared in highly crystalline microstructures, considerable crystal-structure-doping information is accumulating, and off-axis counterion effects are presently being explored.[4, 66, 67]

There is far less structural information on polypyrrole, polyaniline, and polyphenylenevinylene (Fig. 5). The former two materials have nondegenerate ground states and very strong electron–phonon coupling. Incremental doping of polypyrrole gives rise initially to polarons (radical-cation sites bound strongly to lattice distortions), then predominantly to spinless bipolarons in the band gap.[84] Thus, the magnetic susceptibility initially increases, goes through a broad maximum, and then drops to very low levels as partial oxidation progresses (0.0 to 0.33 holes per monomer unit). The magnitude and temperature dependence of the magnetic susceptibility is never Pauli-like. The conductivity peaks near the maximum in the susceptibility and then remains approximately constant. The temperature dependence of the conductivity at all doping levels is suggestive of carrier hopping between localized states. To our knowledge, the homogeneity and crystal-structural aspects of polypyrrole doping remain obscure. Doping (via protonation) of polyaniline[85] appears to be largely inhomogeneous using the type of $\chi(y)$ arguments presented in Section 4.2 for $\{[Si(Pc)O]I_y\}_n$ (Fig. 27). The fully doped material has been described both as a granular polaronic metal above the percolation threshold[85] and as a nonmetallic "Fermi glass".[86] A number of aspects of the undoped and doped polyaniline macromolecular structures are presently unclear.

Polyphenylenevinylene and its 1,4-dimethoxy derivative undergo chemical and electrochemical oxidation to yield conductive polymers.[87] Although doping/structural relationships are not yet fully resolved, it appears that two doped phases are present in the electrochemistry of the dimethoxy derivative. For this material, y can be brought as high as $+0.32$. Charge transport has been discussed in terms of polaron and bipolaron states in the band gap with a temperature dependence characteristic of hopping between relatively localized states.[87]

7. Conclusions

It is hoped that this review has conveyed some sense of the rich and illuminating cornucopia of solid-state chemical and physical phenomena exhibited by the $\{[M(Pc)O]X_y\}_n$ family of electrically conductive, multimolecular assemblies. Such substances clearly stand at the frontier between molecular

conductors and conductive polymers. As such, they shed new light upon each area and contribute to our better understanding of both classes of materials.

It is a sincere pleasure to acknowledge the outstanding contributions and stimulating collaboration of a host of talented colleagues. Their names can be found in the references. The author thanks the National Science Foundation through the Northwestern Materials Research Center (Grants DMR 8520280 and DMR 8821571) and the Office of Naval Research for generous financial support of this research. He thanks the Technical University of Berlin and the Free University of Berlin for a Graduiertenkolleg Lectureship, during which much of this account was written.

[56] Single-crystal conductivity measurements are by no means immune to experimental artifacts and can be severely affected by disorder, defects, and impurities, as well as other factors related to the purity of the starting materials and the crystallization methodology [40, 56a–d]. In addition, even in cases of optimum electrical contact alignment [56e], measurement-dependent phenomena such as contact strain [41, 55] and cooling rate effects [56f] can have major and frequently unappreciated effects on the observed $\sigma(T)$. Phthalocyanine conductors are particularly treacherous in this regard. a) K. Khanna, W. W. Fuller, G. Grüner, P. M. Chaikin, *Phys. Rev. B. 24* (1981) 2958, and references cited therein; b) A. J. Novel Platinum Complexes Enable Selective C-H and C-Si Activation of Tetramethylsilane at Room Temperature **

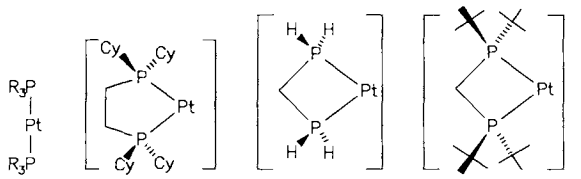
By *Peter Hofmann*,* *Helmut Heiss, Peter Neiteler, Gerhard Müller*, and *Joachim Lachmann*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The *inter*molecular activation of C–H and C–X bonds at saturated carbon [Eq. (a)] is one of the topical fields of research in organometallic chemistry.[1] Since 1982, a series of transition metal complex fragments ML_n have been reported, which can be generated in solution, and which are capable of *inter*molecular homogeneous C–H activation even at saturated (sp^3) C atoms.

Although the prerequisites for such reactions are, in principle, known, both from experiment[1] as well as from theory,[2] a directed control of reactivity patterns is still far from realizable, since the ability of ML_n to coordinate and oxidatively add even C–H bonds[3] generally implies small activation barriers, and thus low selectivities.[4] In all known systems the activation of aromatic C–H bonds is, in addition, thermodynamically[5] or kinetically favored by pre-coordination and formation of π-complexes,[6] compared to the activation of aliphatic C–H bonds. We report here an electronically and structurally unusual, two-coordinate Pt^0-intermediate, which enables the activation of C–Si bonds of tetramethylsilane (TMS) and of homologous molecules at room temperature—via prior C-H activation of a CH_3 group—but does not activate benzene.

MO model calculations showed[7] that bending of Pt^0 complexes $Pt(PR_3)_2$ **1**, which are linear in their ground states, by phosphane chelate ligands must lead to highly reactive d^{10}-ML_2 fragments (14-electron species, isolobal with CH_2).

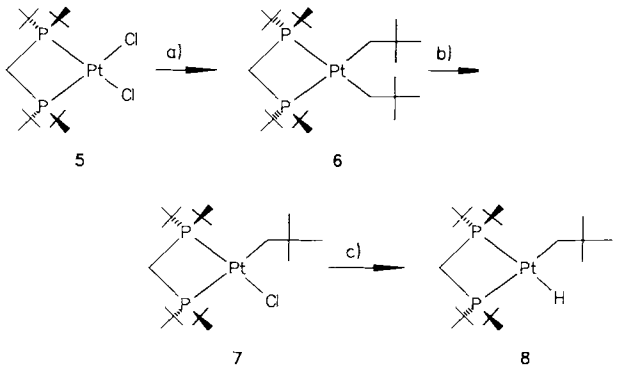


1 2 (Cy = *cyclo*-C_6H_{11}) 3 4 = [(dtbpm)Pt]

The smaller the P–Pt–P angle the higher the reactivity towards C–H and C–X bonds, since not only the total energy increases, but also the frontier orbitals change accordingly.[2c, 7] *Whitesides* et al. were able to confirm this experimentally in the case of the five-membered ring complex fragment **2**, which activates preferably aromatic, but also aliphatic, C–H bonds.[9]

On the basis of MO studies[7] of the parent system **3**, Pt^0 intermediates with four-membered ring structures, i.e. with "minimum" P–Pt–P angles were our synthetic targets. For a number of reasons,[10a] bis(di-*tert*-butylphosphino)methane (dtbpm)[11] appeared especially suitable for favoring highly strained, monomeric four-membered rings over the bridged arrangements[10b] often preferred in the case of diphosphinomethane complexes, and for suppressing side reactions.

Starting from the dichloro complex **5**[7] we were able to synthesize the *cis*-hydridoneopentyl complex **8** according to Scheme 1; complex **8**, which is stable at room temperature,



Scheme 1. Synthesis of **8**. a) $LiCH_2tBu$ in Et_2O, room temperature; b) CH_2Cl_2/CH_3OH, CH_3COCl in *n*-heptane, room temperature; c) $Na[B(OMe)_3H]$, THF, 0 °C; (synthesis of **11**, **12**: LiC_6H_5 or $LiCH_2SiMe_3$, following reaction steps as in (a).

is an ideal precursor of the 14-electron species [(dtbpm)Pt] **4**.[12] The crystal structure of **8**[13] is shown in Figure 1.[14]

The Pt atom displays planar coordination geometry (sum of angles at Pt 360.3°), the relevant P–Pt–P angle is 74.7(1)°. The Pt–P, Pt–C and Pt–H bond lengths are in the usual range. The displacement parameters of the *tert*-butyl groups, which are interlocked and sterically completely shield the four-membered ring side of complex **8**, are surprisingly small.[15]

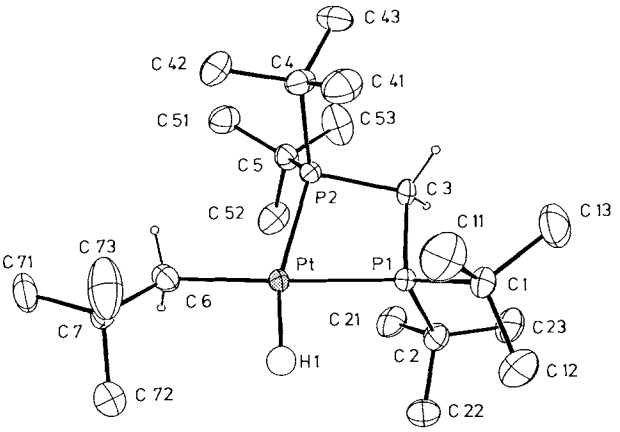

Fig. 1. Crystal structure of **8** (ORTEP, thermal ellipsoids at the 50% probability level, H atoms of the *tert*-butyl groups omitted). Selected bond lengths [Å] and angles [°]: Pt-P1 2.300(1), Pt-P2 2.338(1), Pt-H1 1.58(5), Pt-C6 2.117(5), P1-C3 1.869(5), P2-C3 1.895(5), P1-Pt-P2 74.7(1), C6-Pt-H1 96(2), P1-Pt-H1 89(2), P2-Pt-C6 100.8(1), Pt-P1-C3 93.1(2), P1-C3-P2 97.7(2).

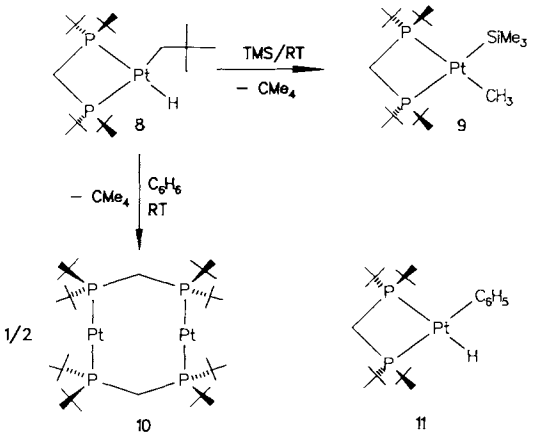
The sought after complex fragment [(dtbpm)Pt] **4**, which, with suitable substrates L (2-butyne, 2,3-dimethyl-2-butene, acrylonitrile), can be identified as intermediate in the form of very stable alkyne or olefin complexes [(dtbpm)Pt(L)], is formed from **8** in solution already at room temperature by elimination of neopentane.

More interesting, however, are the following findings:

1) the methyltrimethylsilyl complex **9**[16a] is formed in quantitative yield from **8** in neat TMS, i.e. exclusively *C–Si activation of TMS* is observed. **9** is stable at room temperature. Reactions interrupted prior to completion show only the presence of **8** and **9**. Compound **8** also reacts smoothly with C–Si cleavage and formation of the stable products $[(dtbpm)Pt(CH_3)(SiMe_2OSiMe_3)]$[16c] and $[(dtbpm)Pt(CH_3)(SiMe_2SiMe_3)]$ analogous to **9** in pure $Me_3Si–O–SiMe_3$ and $Me_3Si–SiMe_3$ (no Si–Si cleavage as with other Pt^0 species[16b]!).

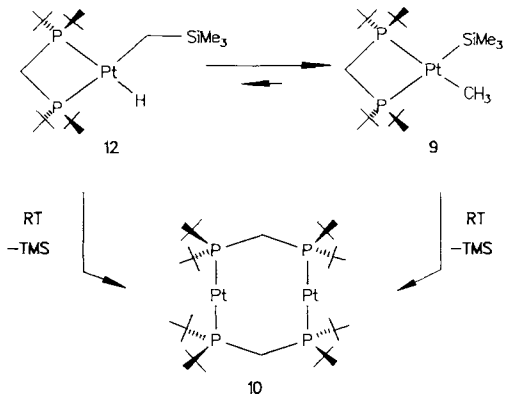


2) Decomposition of **8** at room temperature in neat benzene leads to formation of a deep-red dimer of **4**, to which we assign structure **10**, novel for Pt^0.[17] *C–H activation of benzene does not take place.*

3) Even in benzene solution with only 5 mol-% TMS, the reaction leads, with C–Si activation, to formation of **9** besides **10**; however, no hydridophenyl complex **11** is formed.

4) Complex **11**, the potential C–H activation product of benzene, synthesized according to Scheme 1, is considerably more stable than **8** and would therefore be detectable spectroscopically if it should occur in 2) and 3).

Thus, complex fragment **4** is not only capable of cleaving C–Si bonds, but of even doing so in the presence of benzene, without activating the C–H bonds of the arene. This surprising fact gains further significance in that the observed C–Si activations can only be explained consistently in terms of a prior activation of sp^3 C–H bonds. Namely, if **12**, the direct C–H activation product of TMS, is likewise prepared independently according to Scheme 1, then this alkylhydrido complex rearranges at room temperature in accordance with Scheme 2 to give the C–Si activation product **9**.



Scheme 2. RT = room temperature.

In neat TMS the rearrangement leads to **9** quantitatively, in benzene it is accompanied by the formation of dimer **10**, which according to preliminary kinetic measurements is formed by reductive elimination of TMS, both from **9** as well as from **12**. The kinetic relationships between **12**, **9** and **10** become complicated by the fact, that **9** also generates a small equilibrium concentration of **12** in benzene solution. If the, apparently, thermodynamically favored rearrangement of **12** to **9** is carried out in $[D_{12}]$TMS or in a mixture of C_6D_6/$[D_{12}]$TMS, only deuterium-free **9** is formed, thus indicating a strictly *intra*molecular reaction and ruling out intermediate reductive elimination of TMS.[18] With specifically labeled $[D_1]$**12** (Pt–D instead of Pt–H), $[D_1]$ **9** with a CH_2D group on Pt is formed, thus also clarifying the topology of this rearrangement, a topic which will be reported in more detail elsewhere (kinetics, MO model calculations, modeling studies).

Consequently, mild, quantitative C–Si activation is possible even in the case of the extremely stable and inert molecule TMS with the "hot" but readily accessible 14-electron complex fragment [(dtbpm)Pt] **4**. Not only the rearrangement of the hydrido complex **12** to **9** but also the lack of any H/D isotope effects and the purely random C–Si activation, respectively, in *inter*molecular competition experiments, where **4** is generated in TMS/$[D_{12}]$TMS, $Me_3Si–O–SiMe_3$/TMS and $Me_3Si–O–SiMe_3/Me_3Si–SiMe_3$ mixtures, suggests sp^3-C–H activation as the step prior to C–Si cleavage. A direct and selective C–Si activation by **4** seems, in contrast, much less likely, especially on steric grounds,[10a] according to the results of MO model calculations and modeling studies carried out so far. Hence, **4** would be the first ML_n fragment which activates sp^3-C–H bonds, but not the C–H bonds of benzene. Further experimental and theoretical studies are presently being carried out to gain better understanding of the anomalous reactivity of intermediate **4**, especially compared to that of **2**[19] with its essentially "more open" Pt

center and with regard to the interplay of electronic and steric effects in C–H and C–X activation processes. We also point out the importance of **9** in connection with *cis*-alkylsilyl complexes of Pt as postulated intermediates of catalytic cycles of hydrosilylation,[20] and the synthetic potential of the observed C–Si activations via subsequent insertion and elimination reactions (carbosilylation of C–C multiple bonds?).

[12] An alternative route, from $(COD)PtCl_2$ via $(COD)Pt(CH_2tBu)_2$ and $(COD)Pt(Cl)(CH_2tBu)$ to **7** (analogous to that in [9]) is possible, but less efficient.

[13] Crystal structure analysis of **8**: Syntex $P2_1$ diffractometer, $Mo_{K\alpha}$ radiation, $\lambda = 0.71069$ Å, $T = -50$ °C, crystal dimensions $0.25 \times 0.4 \times 0.5$ mm. $C_{22}H_{50}P_2Pt$, $M_r = 571.681$, monoclinic, space group $P2_1/n$, $a = 10.450(1)$, $b = 16.391(2)$, $c = 15.166(2)$ Å, $\beta = 99.92(1)°$, $V = 2558.9$ Å^3, $d_{calc} = 1.484$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 56.7$ cm^{-1}, $Z = 4$, $F(000) = 1160$. 5021 unique reflections, 4531 "observed" with $F_o \leq 2\sigma^2(F_o)$ (ω scan, $\Delta\omega = 0.7°$, $(\sin\theta/\lambda)_{max} = 0.617$ Å^{-1}). $R(R_w) = 0.036\ (0.034)$, $w = 1/\sigma^2(F_o)$(anisotropic), H1 (observed) isotropic, CH_3 as rigid groups, 275 parameters, SHELX-76). Residual electron density $+2.89/-1.83$ Å^{-3}, maximum distance from Pt 0.82 Å. Further details of the crystal structure analysis are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54656, the names of the authors, and the journal citation.

[14] To our knowledge **8** is only the third X-ray crystallographically characterized *cis*-hydridoalkyl complex of a transition metal besides $Cp^*Ir(PMe_3)(H)(C_6H_{11})$ [4b] and (dcpe)Pt(H)(CH_2tBu) [9a].

[15] Practically identical orientation of the *t*Bu groups is found also in the structures of **5** [7] and of $[(dtbpm)PdCl_2]$, $[(dtbpm)NiCl_2]$ and $[(dtbpm)Pt(Cl)(CH_2SiMe_3)]$: P. Hofmann, M. E. Krause, H. Heiss, G. Müller, G. Reber, J. Lachmann, unpublished. In constrast, considerable distortions on steric grounds occur in $[(dtbpm)Ni(\eta^2\text{-}trans\text{-}PhCH{=}CHPh)]$: P. Hofmann, L. A. Perez-Moya, M.-E. Krause, O. Kumberger, G. Müller, *Z. Naturforsch. B45* (1990) 897.

[16] a) Procedure for **9**: 30 mL (220 mmol) of dried TMS (over Na dust) were distilled onto 528 mg (0.923 mmol) of finely powdered **8**. After 7 days' stirring at room temperature under N_2 the white solid was filtered off and washed with 2×15 mL of TMS. After drying in high vacuum, 561 mg (0.785 mmol, 85.0%) of analytically pure, colorless **9** was obtained. When excess TMS was completely removed after completion of the reaction in a separate run formation of **9** was found to be quantitative (NMR spectroscopy). M.p. 216–217 °C (decomp.), correct elemental analysis; ^{1}H NMR (270 MHz, C_6D_6, 20 °C; C_6D_5H, int.): $\delta = 3.09$ (dd + sat, $^2J(P_A, H) = 6.4$ Hz, $^2J(P_B, H) = 7.3$, $^3J(Pt, H) = 6.8$, 2H; PCH_2P), 1.43 (dd + sat, $^3J(P_{cis}, H) = 6.8$, $^3J(P_{trans}, H) = 11.2$, $^2J(Pt, H) = 66.9$, 3H; $PtCH_3$), 1.22 (d, $^3J(P, H) = 12.2$, 18H; *t*Bu), 1.15 (d, $^3J(P, H) = 12.2$, 18H; *t*Bu), 0.73 (d + sat, $^4J(P, H) = 2.9$, $^3J(Pt, H) = 27.9$, 9H; $PtSi(CH_3)_3$); ^{13}C-NMR (67.9 MHz, C_6D_6, 20 °C; C_6D_6, int.): $\delta = 35.09$ (vt + sat, $N(P, C) = |^1J(P, C) + {}^3J(P, C)| = 13.2$ Hz, $^2J(Pt, C) = 6.4$; $P_AC(CH_3)_3$), 33.76 (dd + sat, $^3J(P, C) = 7.1$, $^1J(P, C) = 14.9$, $^2J(Pt, C)$ not resolved; $P_BC(CH_3)_3$), 33.64 (dd + sat, $^1J(P_A, C) = 4.9$; $^1J(P_B, C) = 7.3$, $^2J(Pt, C) = 31.1$; PCH_2P), 30.79 (d, $^2J(P, C) = 6.4$; $PC(CH_3)_3$), 6.91 (dd + sat, $^3J(P_{trans}, C) = 8.6$, $^3J(P_{cis}, C) = 2.7$, $^2J(Pt, C) = 82.2$, $^1J(Si, C) = 39.1$; $PtSi(CH_3)_3$), -4.59 (dd + sat, $^2J(P_{trans}, C) = 83.6$, $^2J(P_{cis}, C) = 5.9$, $^1J(Pt, C) = 594.7$; $PtCH_3$); ^{31}P-NMR (109.4 MHz, C_6D_6, 20 °C; 85% H_3PO_4, ext.): $\delta = 9.55$ (d + sat, $^2J(P_A, P_B) = 21$ Hz, $^1J(Pt, P) = 1608$; P(*trans* to CH_3)), -1.08 (d + sat, $^2J(P_A, P_B) = 21$, $^1J(Pt, P) = 656$, $^2J(Si, P) = 194$; P(*trans* to $SiMe_3$)); MS (EI, 70 eV): no $M^{\oplus}$, *m/z* 572 ($M^{\oplus} - CH_3$, 4%), 499 ($M^{\oplus} - SiMe_4$, 18), 73 ($SiMe_3^{\oplus}$, 100); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 825, 839 (C–Si), 345 (Pt–Si); b) T. Hayashi, T. Kobayashi, A. M. Kawamoto, H. Yamashita, M. Tanaka, *Organometallics 9* (1990) 280; c) an X-ray structure analysis of the C–Si activation product of hexamethyldisiloxane, $[(dtbpm)Pt(CH_3)(SiMe_2O\text{–}SiMe_3)]$ has been performed: P. Hofmann, H. Heiss, O. Kumberger, P. Bissier, unpublished.

[17] The alternative structure of a dimer of two intact, Pt^c–Pt^o bound four-membered ring fragments corresponding to the system containing 1,3-bis-(di-*tert*-butylphoshino)propane described by *Otsuka* et al. (Y. Yoshida, Y. Yamagata, T. H. Tulip, J. A. Ibers, S. Otsuka, *J. Am. Chem. Soc. 100* (1978) 2063) is ruled out on the basis of the MS, ^{1}H-, ^{13}C-, ^{31}P-, and ^{195}Pt-NMR data of **10** and a comparison of the data with the data of *Otsukas* compound and all other (dtbpm)Pt four-membered ring systems characterized by us, and also on the basis of the chemical behavior. The novel compound **10** and the corresponding palladium system (P. Hofmann, M. E. Krause, unpublished) will be reported on in a separate communication.

[18] a) A second experiment confirms the intramolecular course of the reaction: in $Me_3SiOSiMe_3$, which is itself C–Si activated by **8**, **12** also rearranges only to **9**. b) An Si–Si cleavage, which appears to be related to the rearrangement of **12** to **9** has been reported recently: L. S. Chang, M. P. Johnson, M. J. Fink, *Organometallics 8* (1989) 1639.

[19] In the meantime, the four-membered ring system $[(dcpm)Pt(H)(CH_2tBu)]$ directly corresponding to **2** has also been synthesized: P. Hofmann, J. U. Notheis, unpublished.

Heteronuclear "X-Y" Decoupling in the MAS-NMR Spectroscopy of Inorganic Solids**

By *Robert Maxwell, David Lathrop, Deanna Franke,* and *Hellmut Eckert**

It has been widely established that magic angle spinning (MAS) NMR spectroscopy can be tremendously successful in the structural elucidation of solids. Nevertheless, the spec-

tra of many crystalline inorganic materials, ceramics and glasses are often found rather non-descript, poorly resolved, and bear little chemical information. We have found this to be the case in a variety of rare-spin resonances in crystalline and glassy metal phosphide and phosphorus chalcogenide materials, which are currently of great interest for applications in infrared optics and semiconductor technology.

In the past, much of the power of solid-state magic angle spinning (MAS)-NMR experiments has come from the ability to exploit dipolar or scalar coupling between high-γ nuclei (^{1}H or, in a few cases, ^{19}F) and lower-γ nuclei (^{13}C, ^{29}Si, ^{15}N) to facilitate detection via cross polarization or to provide spectral editing by double resonance experiments.[1] Although the application of such techniques to inorganic materials that are devoid of protons would be highly desirable, experiments of this kind are extremely scarce and have been mostly limited to spin-echo double resonance (SEDOR) experiments on non-spinning samples.[2-5]

In this communication, we wish to demonstrate that the informational content of MAS-NMR spectra can be dramatically enhanced if the standard rare-spin MAS-NMR experiment is combined with heteronuclear decoupling. Figure 1 shows the ^{113}Cd-NMR spectra of the chalcopyrite-

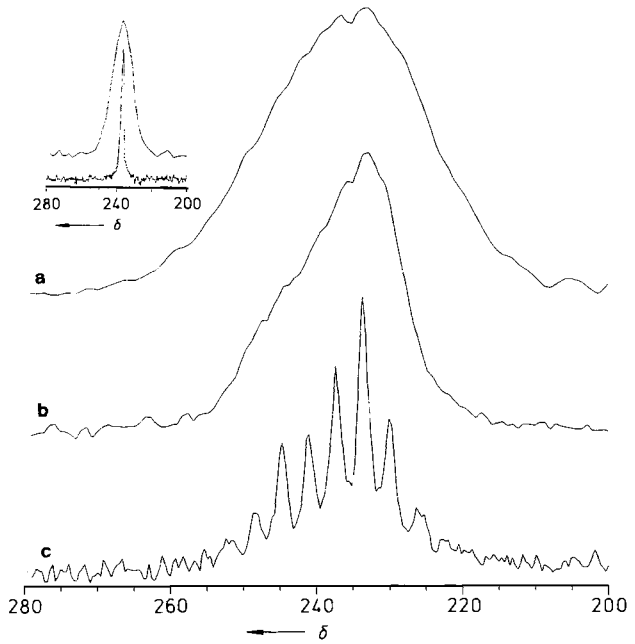

Fig. 1. 66.70-MHz ^{113}Cd-NMR spectra of crystalline $CdGeP_2$, obtained with 7-μs 90° pulses and 15-min recycle delay. a) ^{113}Cd-single-resonance MAS-NMR spectrum (rotation frequency 0.25 kHz). This spectrum is identical with the single-resonance NMR spectrum (stationary); b) {^{31}P}-^{113}Cd double-resonance NMR spectrum (stationary); c) {^{31}P}-^{113}Cd double-resonance MAS-NMR spectrum (spinning speed 0.25 kHz). The inset shows a comparison of single- and double-resonance ^{113}Cd-NMR spectra (top and bottom respectively) at a spinning speed of 5 kHz.

structured semiconductor $CdGeP_2$ with and without ^{31}P decoupling. The resolution of the single-resonance spectra is severely hampered by the sizeable dipolar coupling between ^{31}P and ^{113}Cd in this compound (Fig. 1a). As previously discussed by *Maricq* and *Waugh* for the ^{1}H-^{13}C case,[6] the ^{31}P-^{113}Cd dipolar interaction functions as a source of homogeneous line-broadening due to the magnitude of ^{31}P-^{31}P dipole couplings present in this sample. The resulting line-narrowing by MAS-NMR is only moderate even at a spinning speed of 5 kHz and non-existent at low speeds, because averaging of homonuclear interactions by MAS requires fast spinning speeds compared to the strength of the dipole coupling (in Hz). In contrast, note the superb resolution improvement obtained on combination of MAS with ^{31}P decoupling (Fig. 1c). From the distinct spinning side-band patterns observed, it is now possible to measure the chemical shift anisotropies. Using the method of *Herzfeld* and *Berger*[7] we determine $\delta_{11} = 225 \pm 2$, $\delta_{22} = 236 \pm 1$ and $\delta_{33} = 250 \pm 1$ ppm (vs. dimethylcadmium).

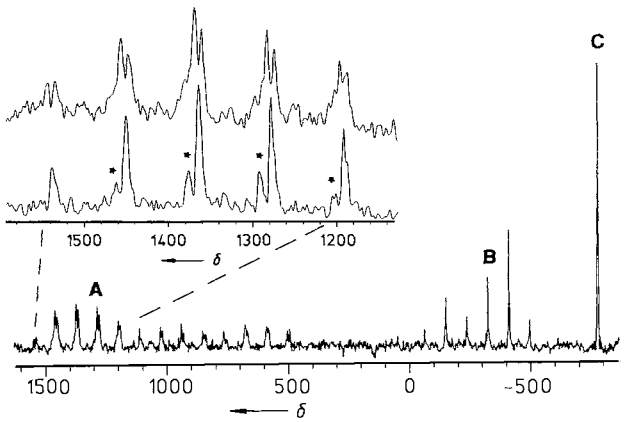

Fig. 2. 57.31-MHz ^{77}Se-NMR spectra of Ag_7PSe_6 (spinning speed 5.0 kHz). The overall spectrum shows the single-resonance case; distinct peak patterns **A**, **B**, and **C** are indicated. The inset shows the most intense part of the MAS-NMR side-band pattern with and without ^{31}P decoupling. Note the two distinct Se sites, the less intense one of which is labeled by an asterisk. Both spectra are averages of 48 scans obtained with 90°-pulses of 7-μs duration and recycle delays of 15 min.

Figure 2 shows an application to the fast ionic conductor Ag_7PSe_6. Although the X-ray powder pattern of this compound has been indexed in the cubic space group $F\bar{4}3m$ with a lattice constant of 10.768 Å,[8] its crystal structure is unknown. Differential scanning calorimetry shows that Ag_7PSe_6 undergoes a first-order phase-transition at 188 °C; presumably for this reason, we have been unable to grow single crystals of the low-temperature phase. The ^{77}Se-MAS-NMR spectrum reveals three chemically distinct species: a signal cluster **A** centered at $\delta = 1104$, a signal cluster **B** centered at $\delta = -326$, and a signal **C** at $\delta = -779$ (all shifts refered to solid CdSe at 0 ppm.[9] Signal cluster **A** and resonance **B** give rise to spinning side-band patterns due to the large ^{77}Se chemical shift anisotropy. ^{31}P decoupling leaves resonances **B** and **C** unaffected, and simplifies the spectrum of species **A** considerably: the multiplet collapses and two distinct resonances, in a ratio of approximately 3:1, become visible. Thus, the ^{77}Se{^{31}P}- double-resonance MAS-NMR experiment not only serves to differentiate between phosphorus-bound and non-phosphorus bound Se atoms, but also shows that there are two different types of phosphorus-bound Se atoms in the asymmetric unit. This result is nicely compatible with the ^{31}P-MAS-NMR spectrum of Ag_7PSe_6 shown in Figure 3. This spectrum shows a central resonance at $\delta = -51.2$ (vs 85% H_3PO_4) and two distinct pairs of ^{77}Se-^{31}P spin-spin-coupling satellites, with coupling constants of 524 ± 1.0 Hz and 430.4 ± 3.0 Hz, respectively. The intensity ratio of these satellites compares well with that observed for the respective ^{77}Se-NMR spectra of the two distinct P-bound selenium atoms. The total integrated intensity of the spin-spin-coupling pattern relative to the center band indicates, in conjunction with the natural abundance of the ^{77}Se isotope (7.0%), that P is bonded to four Se atoms.

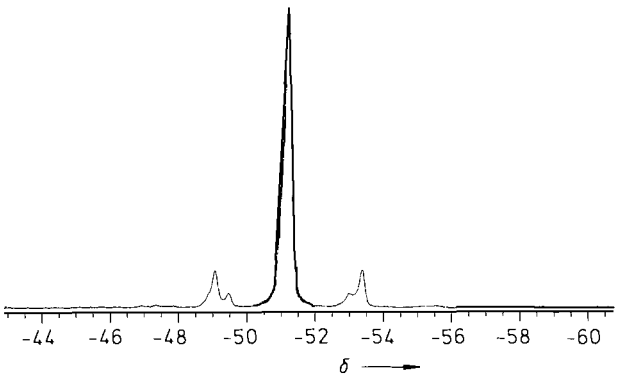

Fig. 3. 121.65-MHz ^{31}P-MAS-NMR spectrum of Ag_7PSe_6 (spinning speed 2.3 kHz), 56 scans obtained with a 45° pulse of 4-μs duration and a 1-min recycle delay.

From this NMR evidence we can conclude that the P atoms are located on sites with three-fold symmetry. Furthermore, there are two additional, nonequivalent Se atoms in the structure, which are only coordinated to Ag atoms. Thus, the ^{31}P-^{77}Se double-resonance experiment described here provides important structural insights which are crucial for our current attempt to solve the crystal structure of Ag_7PSe_6 by Rietveld X-ray analysis.

In summary, the results reported in the present communication show that heteronuclear decoupling provides an important new tool of resolution improvement and spectral editing in the MAS-NMR spectroscopy of rare nuclei in inorganic materials devoid of hydrogen. Limitations could arise if the chemical shift anisotropy of the irradiated nuclei (here ^{31}P) is very large compared to the spinning frequency. In this case only a fraction of observed nuclei would be decoupled efficiently at any given phase of the rotor cycle and hence decoupling would be incomplete. On the other hand, the sensitivity of decoupling efficiency to resonance offset effects can also be turned into an advantage for establishing connectivities by selective decoupling experiments. Other promising prospects for future applications include two-dimensional correlated spectroscopy, and measurements of heteronuclear distances by spin-echo double-resonance NMR. The development of such techniques and applications to ceramics and glasses is currently in progress.

Experimental

$CdGeP_2$ was prepared from the elements heated in stoichiometric proportions in a flame-sealed quartz container at 800 °C and 10^{-3} torr, followed by slow cooling (20 Kh^{-1}). Ag_7PSe_6 was prepared in an analogous fashion, via solid-state reaction at 500 °C. The purity of these compounds was ascertained by X-ray powder diffraction. All NMR experiments were carried out on a General Electric GN-300 NMR spectrometer using a specially designed double broadband tuned MAS-NMR probe constructed by Doty Scientific. One of the channels is tunable from 70–175 MHz (X), whereas the other one covers the frequency range 20–80 MHz (Y). The probe contains extra tuning capacitors to reject the decoupling frequency in the observe channel; additional rejection (40 dB) is provided by an external 87 MHz low-pass filter. The heteronuclear decoupling pulse is generated from the pulsed 300-MHz ^{1}H-decoupler output by mixing with a local oscillator (PTS 250) frequency, low-pass filter and two-stage amplification (up to 200 W), using Amplifier Research 50L and Henry Radio amplifiers. In all cases, the decoupling field *was applied exactly on* resonance.

[9] The experimental area ratio **A**/(**B** + **C**) is ca. 1.7:1; in reasonable agreement with the ratio 2:1 expected for the P-bound/non-P-bound ratio. The deviation is probably due to partial saturation of resonances **A** and **C**, which were found to have substantially longer spin-lattice relaxation times than **B**.

Hydrogenobyrinic Acid: Isolation, Biosynthesis, and Function **

By *Francis Blanche,* Denis Thibaut, Denise Frechet, Marc Vuilhorgne, Joel Crouzet, Béatrice Cameron, Kersten Hlineny, Ute Traub-Eberhard, Maureen Zboron,* and *Gerhard Müller**

Hydrogenobyrinic acid **1**, the cobalt-free analogue of the tetrapyrrolic vitamin B_{12} parent substance cobyrinic acid **2**, has been discovered for the first time in a bacterium, the B_{12}-producing *Pseudomonas denitrificans SC 510.*[1] We have now developed a biosynthetic method for its isolation, which we report herein. Surprisingly, **1** occurs a) in a non-photosynthesizing bacterium,[2] b) in both cobalt-containing as well as cobalt-free cultivation, and c) intracellularly bound to a protein *bP* specific for it. The biosynthetic entry to **1** opens up new perspectives for studies on the biosynthesis of **1** and **2** and concerning the question whether and how the biosynthetic pathways of these two compounds differ; the first relevant experiments will be reported.

The protein **1**-*bP* leading to **1** was isolated and purified.[3] **1**-*bP* is reddish-orange, in the SDS-polyacrylamide electrophoretogram the only band, corresponding to 23 kD, and the first 15 amino acids at the NH_2 terminal can be cleanly sequenced. Since **1** is set free from **1**-*bP* by heat treatment (70 °C, 10 min) there is a non-covalent protein/pigment bond present. For the isolation of **1**, **1**-*bP* or the crude extract obtained from 100 g of wet bacterium[3a] was heat-treated, centrifuged, and the **1** present in the supernate was fixed on DEAE-Sephadex A-25 (0.5 × 1 cm, 0.1 M phosphate buffer, pH 7.0). After washing with 20 mL of 0.3 M phosphate buffer, pH 7.0, **1** was eluted with 10 mL of aqueous 1 M KH_2PO_4 and transferred onto LiChroprep RP-18 (0.5 × 2 cm), washed with 10 mL of 0.25 M KH_2PO_4, and eluted with H_2O/*t*BuOH (9:1, v/v); lyophilized **1** was stored dry and protected from light at −20 °C. Yield 100 μg of **1** per 100 g of wet bacterium. For the isolation of the heptamethyl ester **1a**, **1** was treated with MeOH/H_2SO_4 (100:5, v/v) and the mixture allowed to stand for 48 h; **1a** was then isolated as described.[5]

[a] The NMR spectra were recorded in D_2O with a Bruker AM-400; ^1H: 400 MHz, ^{13}C: 100.6 MHz. The HDO resonance was suppressed by gated decoupling. [b] Assignment by heteronuclear correlation experiments [10, 11], optimized for normal (130 Hz) and remote coupling (10 Hz). [c] Derived from homonuclear COSY [12] and RELAY 2D experiments [13].

known to date,[4, 7, 8] and is suitable for labeling and biosynthetic studies of **1**. The methylation process starting from uroporphyrinogen III and proceeding via the precorrins **1**–**3**[7] shows the same methylation sequence at the tetrapyrrolic ligand in the formation of **1** as in the formation of **2**: [7, 6b] C2, C7, C20, C17, C12, C1, C5/15. Figure 1A

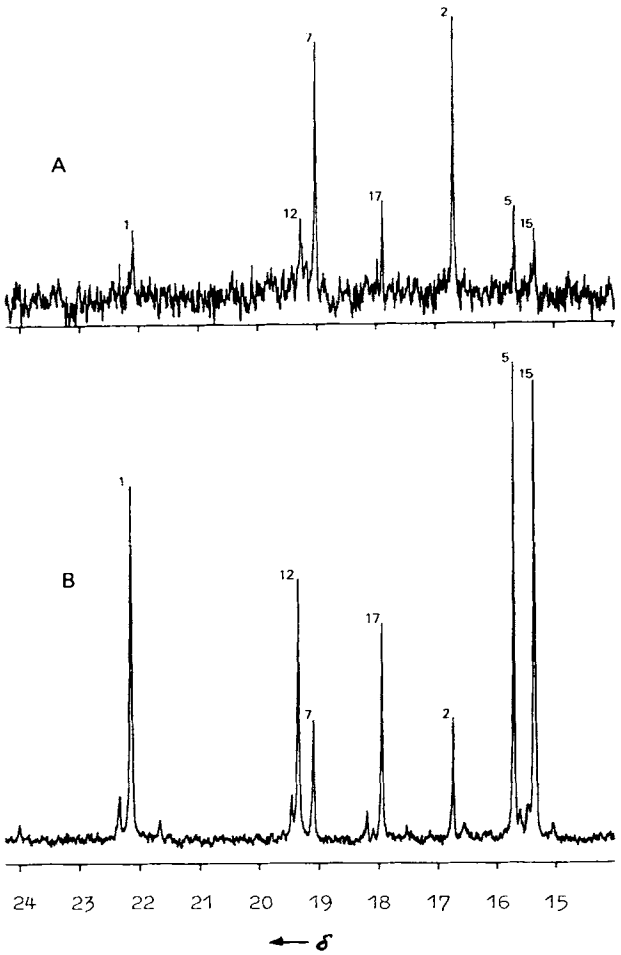

Fig. 1. ^1H broad-band decoupled 100.6-MHz ^{13}C-NMR spectra (64000 scans in [D_6]benzene) of **2a**, prepared from biosynthesized **1** [5]. *Biosynthesis:* A: crude extract from 100 g of cells [3a] + 1 μmol [C2, C7, C20-methyl-$^{13}C_3$] factor III [4c] (90 atom-% ^{13}C) + 20 μmol *S*-adenosyl-L-methionine (SAM), incubated 18 h at 30 °C. For the isolation, 3 mg of unlabeled **1** added, then heat treatment; isolation of **1** and synthesis of **2a** [5]: 2 mg. B: crude extract from 100 g of cells + 20 μmol of 5-aminolevulinic acid + 20 μmol [$^{12}CH_3$]SAM incubated 5 h at 30 °C, then 100 μmol [$^{13}CH_3$]SAM (90 atom-% ^{13}C) added, 6 h further incubation and **1** isolated; **1a**: ca. 500 μg, **2a**: 400 μg.

provides supporting evidence for the conversion of the precorrin **3** (last known precursor of **2**) into **1**: its ^{13}C-labeled didehydro-isolate and trimethylisobacteriochlorin [C2, C7, C20-methyl-$^{13}C_3$] factor III[4c, 7, 8a] was incubated with the crude extract synthesizing **1**; finally, **1** was isolated and converted by known methods[4, 5] into the dicyanoheptamethyl ester **2a** (Cobester), whose ^{13}C-NMR spectrum showed $^{13}CH_3$ signals typical for **2a** in the methyl-group region,[7] with the signals of the methyl groups C1, C12, C17, C5 and C15 corresponding to the natural ^{13}C-content of the sample. The two most intense signals arise from the $^{13}CH_3$ groups on C2 and C7 of precorrin **3**; as expected, the $^{13}CH_3$ group on C20 is not recorded and should—as in the formation of **2**—be eliminated, together with C20, as acetic acid.[8] The further methylation sequence followed—as in studies on the biosynthesis of **2**—from a ^{13}C-pulse labeling experiment.[7]

S-Adenosyl-L-[methyl-^{13}C]methionine was added to the cell extract forming **1** and preincubated for the accumulation of precursors; after further incubation **1** was isolated. Figure 1 B shows the ^{13}C-NMR of **2a**, prepared from **1**; the increase in intensity of the signals allows conclusions to be drawn about the methylation sequence.

The in-vitro transformation of radioactive **1** or **1**-*pP* into **2** could not be accomplished with *Pseudomonas dentrificans* or with *Propionibacterium shermanii*, even though the mechanism of the biosynthesis of **2** is, as far as is known, also realized in the formation of **1**. Thus, the manner and time of the cobalt incorporation leading to **2** remain unclear. The results listed in Table 2 are unequivocal and confirm conclusions drawn from experiments with unlabeled semisynthetic **1**.[5] **1** and **1**-*bP* are not utilized by the enzyme preparations synthesizing **2**, rather these are inhibitors in the formation of **2**, whereby the steps leading to the precorrin **3** are not inhibited. Additional experiments showed that the C38 mono- and C27,C38-diamide of **1** as well as the Ni^{II} analogue of **2**[9] do not inhibit formation of **2**. This finding provides a first insight into the molecular events of the inhibition, the interpretation of which is expected to provide valuable information concerning the biosynthesis of **2**. One would especially like to know whether the protein *bP* binding **1** plays a role in the formation of **2**, and if so what sort of role.

Table 2. Formation of cobyrinic acid **2** with enzyme preparations from *P. shermanii* [4, 5] and the radioactively labeled substrates hydrogenobyrinic acid **1** and protein-bound hydrogenobyrinic acid **1**-*bP* [a].

Experiment	Substrate [nmol] [f]	Cobyrinic acid **2** isolated as Cobester **2a** [nmol] [g]	[nmol] [h]
1 [i]	235 [b]		0.44
2	--	60	
3	235 [b]	10	0.17
4	450 [b]	13	0.33
5	500 [c]	5	0.10
6	700 [d]	165	102.00
7	700 [e] + 500 [c]	27	0.10

[a] In each case the same enzyme preparation from 100 g of wet bacterium per experiment [5] + 2.5 μmol $Co^{2\oplus}$ + 50 μmol *S*-adenosyl-L-methionine + substrate (specific radioactivities in brackets). [b] [Methyl-^{3}H]-**1** (762 Bq/nmol). [c] [Methyl-^{3}H]-**1**-*bP* (162 Bq/nmol, 10 mg protein). [d] [Methyl-^{3}H]-factor III [4c] (303 Bq/nmol) [e] = unlabeled [d]. [f] By in-vitro biosynthesis from 5-aminolevulinate + *S*-adenosyl-L-[methyl-$^3H_3$] methionine. [g] In all incubations **2** is formed from endogenous precursors of the enzyme preparation. [h] Based on radiochemical yields of the substrate/product conversion. [i] Incubated without enzyme, demonstrates chemical cobalt incorporation in **1**; "carried" with **2** for isolation.

Application of the Combined ab initio/IGLO/NMR Method to Resolve the B_6H_{12} Structural Question**

By *Michael Bühl* and *Paul von Ragué Schleyer**

Although B_6H_{12} was first prepared as early as 1960,[1] its accurate structure is still in doubt. On the basis of NMR spectra, a general 4212 structure (*styx* notation) was proposed.[2] As the crystals of hexaborane(12) are not suitable for X-ray structure analysis, *Beaudet* concluded in his review, "only microwave spectroscopy holds any promise for solving this structural problem".[3] Nevertheless, in the same year a gas-phase electron diffraction (GED) structure was published by *Greatrex* et al.[4] This study confirmed that the molecule possesses C_2 symmetry; the proposed structure is shown in Figure 1 a. However, the detailed dimensions differ substantially from the ones just reported by *McKee*[5] from theoretical calculations at the 3-21G and 6-31G* ab initio levels. We now decide between the two structures.

We have been employing the combined ab initio/IGLO/NMR method for the solution of structural problems.[6] In this approach, various structures derived from experiment and from ab initio geometry optimizations, are assessed by means of IGLO (individual gauge for localized orbitals)[7]

[a] False minimum at HF-levels, see text. [b] Ref. [5]. [c] Ref. [4].

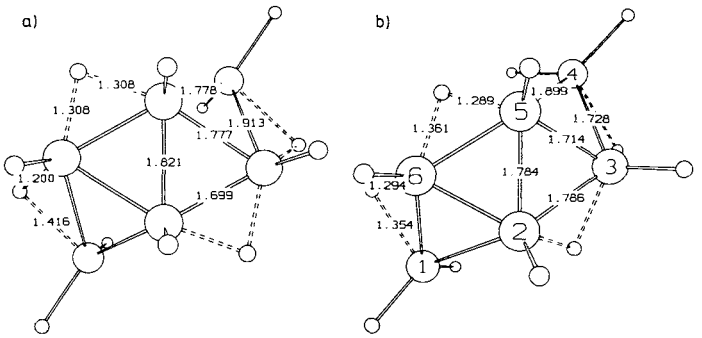

Fig. 1. Comparison of the GED (a) and MP2/6-31G* (b) structures of B_6H_{12}. Bond distances in Å, see Table 1.

NMR calculations. The chemical shifts obtained by this method for various geometries are compared with the experimental chemical shifts. Figure 2 shows the quality of the

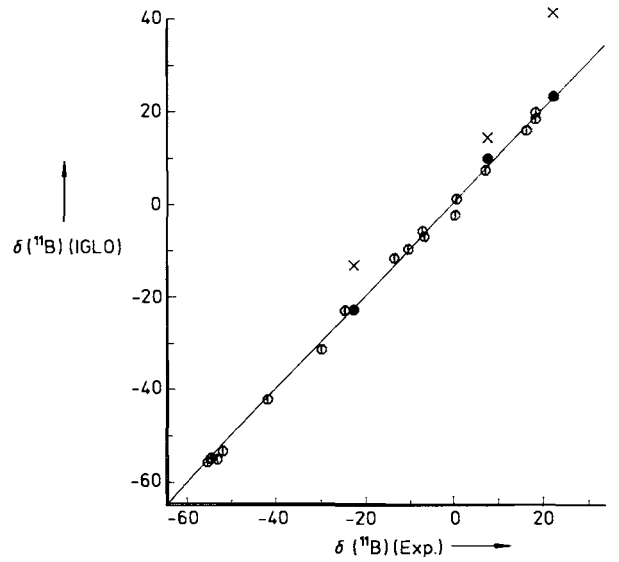

Fig. 2. Theoretical (IGLO) vs. experimental ^{11}B-NMR chemical shifts for boron hydrides. The IGLO DZ basis was used employing MP2/6-31G* optimized geometries. The ideal line with slope = 1.00 is shown. The IGLO B_6H_{12} boron chemical shifts obtained for the MP2/6–31G* structure (●) agree much better than those derived from the experimental geometry (x). Φ: B_2H_6, B_4H_{10}, B_5H_9, B_5H_{11}, B_6H_{10}, $B_2H_7^{\ominus}$, $B_3H_8^{\ominus}$, $B_4H_9^{\ominus}$ (IGLO DZ//MP2/6-31G*).

results for a collection of 9 boranes and borane anions. The geometries were calculated[8] at the MP2/6-31G* level, i.e. with a polarized basis set including electron correlation (Fig. 1b). Using these geometries, the agreement between experimental and IGLO chemical shifts is remarkably good[9] (the correlation coefficient is 0.999, the slope, 1.01, is nearly equal to the ideal value, and the standard deviation is only 1.4 ppm). In contrast, the experimental structures recommended by *Beaudet*[3] perform somewhat more poorly (correlation coefficient 0.990, slope 1.02, average deviation 4.2 ppm). We have now applied this combined ab initio/IGLO/NMR method to the B_6H_{12} structure problem.

At the time our geometry optimizations began, we were not aware of the GED structure. An assumed geometry was employed as the starting point and an optimization carried out using the small, split valence 3-21G basis set, with further refined reoptimization at the 6-31G* level (**3a**, key geometrical parameters in Table 1). As indicated by the IGLO results in Table 2, agreement of the chemical shifts using these geometries (which were shown to be minima by frequency analysis), did not give good agreement with experiment. Consequently, the structure was reoptimized at the MP2/6-31G* level. This gave somewhat different geometrical parameters (Fig. 1b, Table 1) and an excellent fit, IGLO vs. experiment (Table 2.).

Table 2. IGLO ^{11}B chemical shifts[a] (rel. $BF_3 \cdot OEt_2$) for B_6H_{12}.

Structure	Geometry	$\delta(^{11}B)$ [ppm] $B_{1,4}$		$B_{3,6}$		$B_{2,5}$	
B_6H_{12}	Exp. [b]	14.1		41.1		−13.3	
3a	3-21G	21.6		16.2		−10.9	
	6-31G*	15.5		17.2		−11.8	
3b	3-21G	14.5		22.5		−22.1	
	6-31G*	12.9		21.6		−22.4	
	MP2/6-31G*	9.6	[10.1]	22.9	[23.5]	−23.0	[−22.8]
	Exp.[c]	7.9		22.6		−22.6	

[a] In the IGLO calculations a Double Zeta (DZ) basis set was used, the values in brackets refer to calculations using a larger basis set of Triple Zeta + polarization quality, denoted as II', cf. Ref. [7]. [b] IGLO calculation carried out using the experimental geometry given in Ref. [4]. [c] Experimental chemical shifts, from I. S. Jaworiwsky, J. R. Long, L. Barton, S. G. Shore, *Inorg. Chem. 18* (1979) 56.

Puzzled by these discrepancies, we reran the 3-21G and 6-31G* optimizations using the MP2/6-31G* geometry as starting point. Indeed, new minima were obtained (**3b**) which were considerably lower in energy (ca. 27 kcal/mol^{-1}) than those obtained earlier. These lower energy minima are identical with those just reported by *McKee*.[5] The **3a** structure is a "false minimum", since it is only present at Hartree-Fock levels but disappears at a correlated level. To have two quite similar minimum energy structures (with the same symmetry), even at lower levels of theory, is unprecedented in our experience.

However, the geometrical parameters for our best theoretical structure, **3b** optimized at the MP2/6-31G* level (which was the only minimum found at that level) still differ appreciably from the GED data (Table 1). In the following, the

theoretical (MP2/6-31G*) and experimental (GED) structures are compared more critically.

The authors of the GED study pointed out an interesting structural relationship between the *arachno*-boranes B_4H_{10} **1**, B_5H_{11} **2**, and B_6H_{12} **3**.[4] The higher homologues can be thought of as arising from **1** by successive replacement of two bridging hydrogens by BH_2 groups. Figure 3 illustrates the

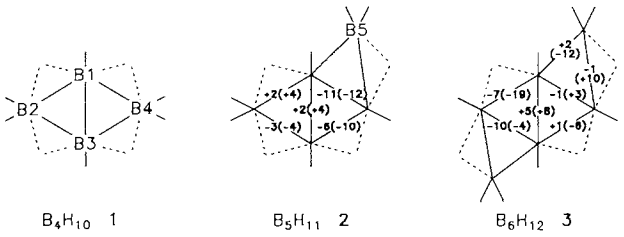

Fig. 3. The structural relationship between B_4H_{10} **1**, B_5H_{11} **2** and B_6H_{12} **3**. The changes in bond lengths (in pm) in going from **1** to **2** and from **2** to **3** are given for the MP2/6-31G* geometries (and in parentheses for the GED geometries). Notice the greater consistency of the calculated versus the experimental trends for **2** and **3**; see text.

changes in bond lengths (in pm) induced by each replacement, comparing the MP2/6-31G* and GED[4, 10] structures. Going from **1** to **2**, the replacement of one B-H-B bridge by a three-center B-B-B bond shortens the B1–B4 bond by ca. 11 pm, the adjacent B3–B4 bond by ca. 6–10 pm. Going from **2** to **3**, nearly the same "increments" are found for the corresponding bonds in the MP2 structures. In the GED structures, no analogous trend is apparent: changing the bridge between B2 and B3 in **2** from H to BH_2 mostly affects the B1–B2 distance (19 pm decrease); also, the position of the "bridging boron" B5 is considerably changed in the GED, but not in the MP2 structures. In summary, the structural relationship between **1**, **2** and **3** is more clearly visible and more consistent with the MP2 geometries.

A single point calculation at the MP2/6-31G* level on the experimental geometry shows this to be 59 kcal mol^{-1} less stable than the minimum! This enormous energetic difference strongly disfavors the GED geometry, and is in line with *McKee*'s calculations (the MP2/6-31G* energies of the GED and 3-21G structures differ by 56 kcal mol^{-1}). *McKee* also estimated the "energy loss" in the GED structure due to poor hydrogen placements to be about 37 kcal mol^{-1}.[5]

Finally, the δ values in the ^{11}B-NMR spectrum calculated for the GED structure show large deviations from the experimental chemical shifts (up to 18 ppm). For the GED structure of, e.g., B_5H_{11}, the agreement between IGLO and experiment was significantly better (maximum deviation ca. 4 ppm).[6f] The IGLO values for the false minimum **3a** also accord rather poorly with experiment (Table 2). The best agreement with the measured values, however, is found for the MP2/6-31G* geometry **3b**.

In summary, judging from structural, energetic, and NMR criteria, we conclude that the structural parameters of B_6H_{12} as derived from gas phase electron diffraction are not accurate, and that the MP2/6-31G* geometry most closely resembles the actual dimensions of B_6H_{12} both in the gas phase and in solution. Not only microwave spectroscopy, but also theoretical computations can be relied upon to provide accurate structures.

Surprising Basicity of Low Valent Transition Metal Carbonyl Fluorides; Crystallographic Characterization of an sp^2-CH···F Hydrogen Bond**

By *Carolyn E. Osterberg, Margaret A. King, Atta M. Arif,* and *Thomas G. Richmond**

Although the chemistry of organic receptors for organic[1] and inorganic[2] guests is quite sophisticated, transition metal based reagents for molecular recognition have received little attention despite possibilities for diverse chemistry compared to wholly organic materials[3].

Hydrogen bonding is one important type of noncovalent interaction used in the design of molecular receptors. Although hydrogen bonding is frequently noted in crystallographic investigations of inorganic solids, only recently have solution equilibrium measurements demonstrated the high basicity of alkoxide ligands in low-valent transition-metal complexes.[4] In this work we report two synthetic routes to unusual carbonyl(fluoro)tungsten(II) complexes and demonstrate that the fluoro ligand rivals pyridine in its ability to hydrogen bond to phenols. A low temperature X-ray diffraction study provides evidence for an sp^2-CH···F hydrogen bond in the solid-state structure of **2**.

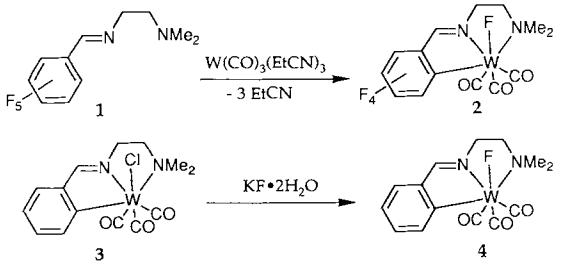
[**] This research was supported by the National Science Foundation through a Presidential Young Investigator Award to *T.G.R.* (CHEM-895845), by the Enraf-Nonius Corporation (USA) (CHE-8811363), by the National Institutes of Health (NIH-BRSG), by the American Cancer Society (IN-178), and by the Camille & Henry Dreyfus Foundation (New Faculty Fellowship for *T.G.R.*).

As anticipated from our previous studies,[5] chelate assisted insertion of tungsten into an *ortho*-C–F bond of the unsymmetrical Schiff base ligand[6] **1** proceeds readily to afford the tungsten(II) complex **2** in 66% yield. Treatment of the chloride **3** with excess potassium fluoride affords **4** in 94%



yield. The chelating monoanionic C,N,N′ ligand provides a relatively hard ligand environment for the W^{II} center.[7] This may be responsible for the high stability of these carbonyl(fluoro)metal complexes in contrast to tricarbonyl(cylopentadienyl)tungsten complexes which are unknown.[8]

Low-temperature (−140 °C) crystallographic characterization of **2** afforded a high-quality structure in which the imine hydrogen atom H1 bound to C10 was located and its position successfully refined as an isotropic contribution.[9] Examination of a unit cell of **2** (Fig. 1) revealed infinite chains by C10′–H1′···F–W interactions characterized by C10′–H = 0.98(9) Å, C10′···F = 3.099(5) Å, C10′–H1′···F = 172(7)° and H1′···F = 2.13(9) Å. This distance is significantly shorter than that defined by the H···F von der Waals[10] separation of 2.6 Å. We attribute the solid-state packing of this material to the ability of the coordinated fluoride to form an intermolecular hydrogen bond even to the weakly acidic proton on the imine carbon.[11] Of all the carbon–hydrogen bonds that have been postulated to participate in hydrogen bonding, those involving sp^2-CH groups have proved to be the most controversial.[12] However, weak interactions such as CH···X hydrogen bonds are frequently crucial in the three dimensional solid state packing of materials.[13] This result suggests that the coordinated fluoride remains a significantly basic site in this complex.[5, 6]

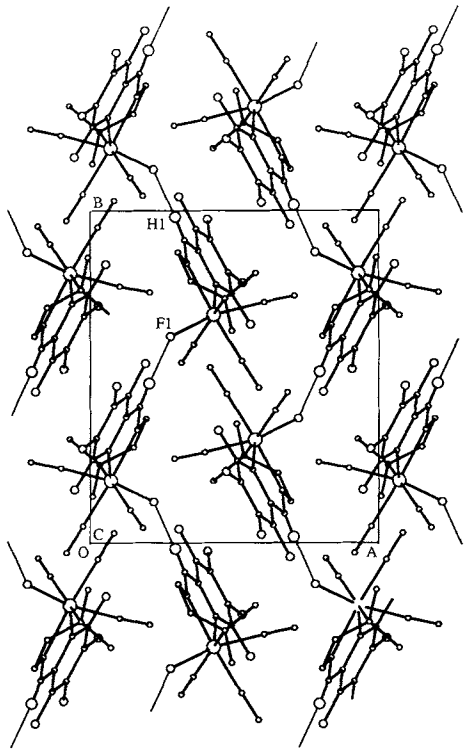


Fig. 1. PLUTO unit cell representation of **2** viewed down the *c*-axis. The intermolecular CH···F hydrogen bonds which link the molecules into chains are indicated by thin lines.

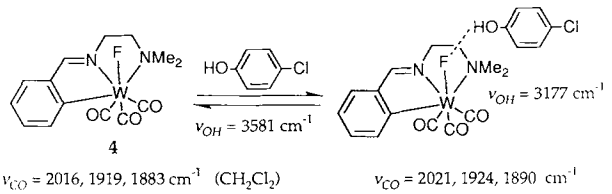
Accordingly, we have determined the equilibrium association of **2** and **4** with 4-chlorophenol in several solvents by observing the upfield shift of the ^{19}F-NMR signal assigned to the tungsten-bound fluorine as a function of phenol concentration. For the adduct **2**·4-chlorophenol in $(CD_3)_2CO$ an association constant of $K = 1\,M^{-1}$ was determined, but it increases to $K = 15\,M^{-1}$ in CH_2Cl_2, as derived from a Scatchard analysis of the titration data for 1:1 complexation.[14] Complex **4** is an even stronger base, with $K = 32\,M^{-1}$ in CH_2Cl_2 and $K = 330\,M^{-1}$ in toluene. Interaction of 4-chlorophenol with **4** is also signaled by appearance of a broad new ν_{OH} absorbance at 3177 cm^{-1} and increased terminal ν_{CO} bands for **4** in the infrared spectrum (Scheme 1).



Scheme 1.

These results indicate that the tungsten(II) complexes **2** and **4** are surprisingly strong Lewis bases capable of forming strong hydrogen bonds.[15] Remarkably, the equilibrium constants reported above are in the same range as observed for pyridine/4-chlorophenol association in CCl_4.[16] We attribute the significant basicity of these low-valent metal fluorides to their electronically saturated 18-electron configuration and the lack of suitable vacant orbitals on the metal to accept π-electron density from the fluoride.[17] The propensity of the fluoride to engage in hydrogen bonding is one manifestation of the ionic character of the W^{II}–F bond. Thus, low-valent metal fluorides should be useful for the design of molecular receptors utilizing hydrogen bonding as a mode of recognition.

Experimental

2: Dissolution of 1.10 g (2.54 mmol) of $W(CO)_3(EtCN)_3$ and 0.676 g (2.54 mmol) of **1** in 25 mL of THF under a N_2 atmosphere gave a deep-red solution. After 0.5 h, the solution was evaporated to dryness to remove released EtCN and then 45 mL of THF was added. After stirring for 2 h, the solution was filtered in air and 0.896 g (1.67 mmol, 66.4%) of orange-gold crystals were obtained by addition of hexane and cooling to −10 °C. Selected characterization data: IR (THF) [cm^{-1}]: $\tilde{\nu}$ = 2020(s), 1934(vs), 1900(s); ^{19}F NMR (282 MHz) $(CD_3)_2CO$,CCl_3F): δ = −114.27 (dd,1F), −141.12 (dd, 1F), −154.12(dd, 1F), −164.46 (dd, 1F), −214.6 (br.s, 1F). C,H,N analysis.

4: A solution of **3** (3.42 g, 7.15 mmol) in 50 mL of THF was treated with excess KF · $2H_2O$ (1.35 g, 14.3 mmol). The mixture was stirred overnight, filtered in air and the filtrate concentrated by evaporation. The solid thus obtained was isolated on a glass frit and washed with 20 mL of water followed by 20 mL of Et_2O. Recrystallization from THF afforded 3.10 g (6.70 mmol) of **4** in 93.7% yield. Selected characterization data: ^{19}F NMR: δ = −229.2 (br, s). C,H,N analysis.

O-Atom Insertion into Si–H Bonds by Dioxiranes: A Stereospecific and Direct Conversion of Silanes into Silanols**

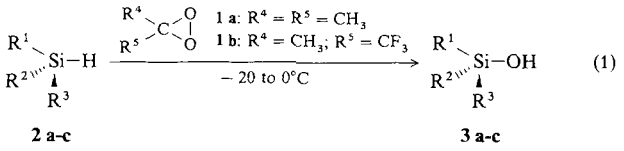
By *Waldemar Adam*,* *Rossella Mello*, and *Ruggero Curci**

Dedicated to Professor Christoph Rückardt on the occasion of his 60th birthday

Dioxiranes **1** constitute a new class of reactive organic peroxides that possess great potential as oxidants.[1] Recently, we reported[2] on the efficient, highly stereoselective oxyfunctionalization of a variety of acyclic, cyclic, and polycyclic saturated hydrocarbons under extraordinary mild conditions, using solutions of methyl(trifluoromethyl)dioxirane.

Silanols serve as key intermediates in the preparation of useful "building blocks" in organosilicon chemistry.[3] Furthermore, in recent years there has been an increasing interest in optically active silanols, because they figure as useful drugs in experimental pharmacology,[4] e.g. optically active antimuscarinic agents of the sila-procyclidine type. Since the usual synthetic methodologies are encumbered by side products such as disiloxanes $R_3SiOSiR_3$,[5] there seems to be much need and interest in developing preparative methods to achieve the direct, stereoselective conversion of silanes into silanols.

For instance, by using peroxybenzoic acid, the conversion of **2c** into **3c** could be accomplished in only 49% yield;[6] ozonization of trialkylsilanes[7] afforded the corresponding silanols only as major products, by a pathway involving hydrotrioxides $R_3SiOOOH$ as intermediates.[8] We now report that silanes **2a–c**[9, 10] are quantitatively and stereospecifically converted into the corresponding silanols **3a–c**[10, 11] upon treatment with solutions of dioxirane **1a, b** at subambient temperatures [Eq. (1)]. Salient data are summarized in Table 1.



(1)

2 a-c **3 a-c**

a: $R^1 = R^2 = R^3 = Et$; **b**: $R^1 = Ph$, $R^2 = R^3 = Me$;
c: $R^1 = \alpha$-Naph, $R^2 = Ph$, $R^3 = Me$

To carry out the reaction a cold (−20 °C for **1b** and 0 °C for **1a**) standardized solution of the dioxirane **1**[2] (ca. 4 mmol) was quickly added to a cold solution of the silane **2** (ca. 4 mmol) in dry CH_2Cl_2. Capillary GC monitoring revealed ca. 100% conversion immediately on mixing of the partners (Table 1). Product isolation involved simply the removal of the volatile solvents at 10–20 °C/80–100 torr on a rotary evaporator. The IR and ^{1}H-NMR spectra[11] revealed that the isolated silanols were of high purity, obviating the necessity of further purification.

Kinetic runs (under second order reaction conditions) were performed at 0 °C by monitoring the disappearance of

Table 1. Reaction of the silanes **2a–c** with the dioxiranes **1a, b** leading to the silanols **3a–c**.

Substrate	Dioxirane	Solvent	*t* [min][a]	Yield [%][a]
Et_3SiH **2a**	**1b** [b]	CH_2Cl_2/TFP [c]	<1	≥98 **3a**
$PhMe_2SiH$ **2b**	**1b** [b]	CH_2Cl_2/TFP [c]	<1	≥98 **3b**
(+)α-Naph(Ph)(Me)SiH **2c** [e]	**1b** [b]	CH_2Cl_2/TFP [c]	<1	≥98 **3c** [d]
	1a [f]	CH_2Cl_2/acetone	18	≥98 **3c**

[a] Data refer to >98% conversion of the silane substrate (determined by GC, SE 54 capillary column, 30 m long and 0.25 mm i.d.). [b] The initial concentration of the dioxirane ranged from 0.6 to 0.7 M, the dioxirane to substrate ratio was ca. 1.0, ca. 4 mmol were used. [c] TFP = 1,1,1-trifluoropropanone, CH_2Cl_2:TFP = 4:1. [d] Viscous oil $[\alpha]_D = +20.0$ ($c = 7.0$, ether); Ref. [10]: $[\alpha]_D = +20.5$ ($c = 6.7$, ether). [e] 96.5% optical purity, $[\alpha]_D = +32.5$ ($c = 4.0$, cyclohexane), Ref. [10]: $[\alpha]_D = +33.7$ ($c = 4.0$, cyclohexane). [f] Initial dioxirane concentration was 0.03–0.04 M, dioxirane to substrate ratio ca. 1.2, ca. 4 mmol were used.

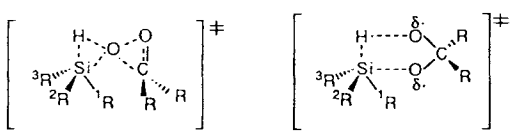
the silane **2c** (initial concentration 0.02 to 0.04 M) via capillary GC analysis, after eliminating the dioxirane **1a,b** with PhSMe as already described.[2] Satisfactory second-order rate plots (log[(a − x)/(b − x)] versus t) were obtained, from which the rate constant ($k_2 = 0.78\ M^{-1}\ s^{-1}$) for the oxidation of **2c** with **1a** was determined. Under the same conditions, dioxirane **1b** afforded $k_2 = 450\ M^{-1}\ s^{-1}$, i.e. over 550 times more reactive than dioxirane **1a** towards **2c**.

In competition experiments,[2] the dioxirane oxidations of Et_3SiH **2a** and adamantane were investigated. It was found that **2a** was ca. 200-fold more easily hydroxylated by dioxirane **1a** than the adamantane C–H bridgehead positions, while dioxirane **1b**, a more powerful oxidant, reacted ca. 56-fold faster with **2a** than with adamantane. Since Si–H bonds are considerably weaker than C–H bonds (bond energies ca. 77. kcal mol^{-1} and 99 kcal mol^{-1}), it is understable that oxyfunctionalization by dioxiranes is remarkably easier with silanes than hydrocarbons. Employing the same competition technique, a kinetic isotope effect of $k_H/k_D = 2.6$ (at 0 °C) was determined for the oxyfunctionalization of Et_3SiH versus Et_3SiD[15] by dioxirane **1a**.

Concerning mechanistic implications, the modest size of the H/D kinetic isotope effect and the fact that oxyfunctionalization of Si–H bonds by dioxiranes occurs with complete retention of configuration suggest that free silyl radicals ($R_3Si^{\bullet}$) do not intervene in this oxygen transfer process. Although silyl radicals possess considerable configurational stability, complete retention of configuration is unlikely in radical processes;[12] for example, the photolysis of (−)-α-NaphPhMeSiOCOCH$_3$ in CCl_4 affords α-NaphPhMeSiCl in 64% optical purity[12]. On the other hand, it is known that the insertion of dichloro- or dibromocarbenes into the Si–H bond of (+)-**2c** proceeds with more than 95% retention of configuration.[13] Moreover, the isotope effect observed presently for the oxygen atom insertion into Et_3SiH by dioxirane **1a** ($k_H/k_D = 2.6$) is quite similar to that reported for the insertion of dichlorocarbene[14] into nBu$_3$SiH ($k_H/k_D = 1.23$), but quite distinct from that found in the electrophilic attack of ozone on nBu$_3$SiH ($k_H/k_D = 6.9$)[15] to give silyl hydrotrioxides. Therefore, as for the carbene insertions, an oxene mechanism is proposed for the hydroxylation of silanes by dioxiranes, which is analogous to the "butterfly" three-centered transition state **4** suggested for the oxyfunctionalization of hydrocarbons by dioxiranes.[2] The alternative five-centered transition state **4'** is consistent with all the presently acquired experimental facts on this novel oxygen insertion process, in which the attacking species is the dioxy diradical derived from peroxide bond cleavage of the dioxirane.[16] For this to apply, however, a prerequisite is that the peroxide bond homolysis is not rate determining, otherwise, the observed second-order rate law (i.e. first-order in both dioxirane and silane) would not be consistent with the proposed **4'**.



4 **4'**

We conclude that the oxene mechanism is most consistent with the present experimental facts for the oxyfunctionalization of silanes. More significant from the preparative point of view is that a convenient, efficient, and stereospecific direct conversion of silanes **2** into silanols **3** has been made available for synthetic chemistry.

Synthesis and Molecular Structure of *cis*-[Pd(C$_6$F$_5$)$_2$(C$_6$H$_5$CH$_2$NMe$_2$)], an Intramolecular Coordination Compound Containing an Unusual η^1-Arene Ligand

By *Larry R. Falvello, Juan Forniés,* Rafael Navarro, Violeta Sicilia,* and *Milagros Tomás*

Several arene bonding modes to transition-metal centers have been described. A wide range of η^6-arene complexes are known, and well-defined species with η^3- and η^1-arene bonding have also been prepared.[1] However, the η^3- and η^1-arene coordination types are very scarce. In fact, the platinum phenalenyl complex **A** (Scheme 1) is, as far as we know, the only example in which an η^3-arene coordination mode has been confirmed by X-ray structure determination.[2]

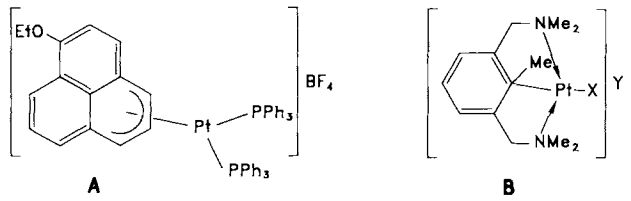

Scheme 1. **B**, X = I, Y = BF_4; X = *o*-tolyl, Y = I.

Concerning the very scarce η^1-arene coordination, two different types of structures have been reported. One contains a boat-type aryl ring which can be considered as a σ-metal-substituted arenium ion and in which a rehybridization of some of the sp^2 C centers has taken place; for example, compounds of type **B**.[3] The other contains planar aryl rings in which all the C atoms are sp^2-hydridized; for example, $AgB_{11}CH_{12} \cdot 2C_6H_6$[4] and $[Cr\{NMes(BMes_2)\}_2]$[5] (Mes = mesityl).

In the course of our research into the chemistry of *C,N*-cyclopalladated derivatives,[6] we have studied the reaction of *cis*-$[Pd(C_6F_5)_2(thf)_2]$[7] with $C_6H_5CH_2NMe_2$ (benzyldimethylamine is a typical starting material for the synthesis of the *ortho*-palladated structural unit $H_4\overline{C_6\text{-}CH_2\text{-}Me_2N}\text{-}Pd$). This process [Eq. (a)] leads to **1**, which, as established by an X-ray study, is an unprecedented palladium complex displaying η^1-arene coordination.

$$cis\text{-}[Pd(C_6F_5)_2(thf)_2] + C_6H_5CH_2NMe_2 \xrightarrow{CHCl_3} cis\text{-}[Pd(C_6F_5)_2(C_6H_5CH_2NMe_2)] + 2THF \quad (a)$$

The IR spectrum of **1** shows two bands (795, 784 cm^{-1}) assignable to the X-sensitive mode of the C_6F_5 groups,[8] which retain their *cis* positions through reaction (a). The ^{19}F NMR spectrum of **1** indicates that the two C_6F_5 groups are inequivalent.

The structure of **1**, established by a single-crystal X-ray diffraction analysis,[9] is shown in Figure 1. The palladium atom has a distorted square-planar environment formed by C1 and C1′, the *ipso*-C atoms of *cis*-C_6F_5 groups, and the N and C7 (*ipso*-C) atoms of the amine ligand. One effect of the unexpected *C,N*-chelating nature of benzyldimethylamine is to provide an acute N–Pd–C7 angle of 64.4(3)°. The Pd–C_6F_5 distances and the C1–Pd–C1′ angle are similar to those observed in *cis*-$[Pd(C_6F_5)_2\{S_2CP(C_6H_{11})_3\}]$.[10]

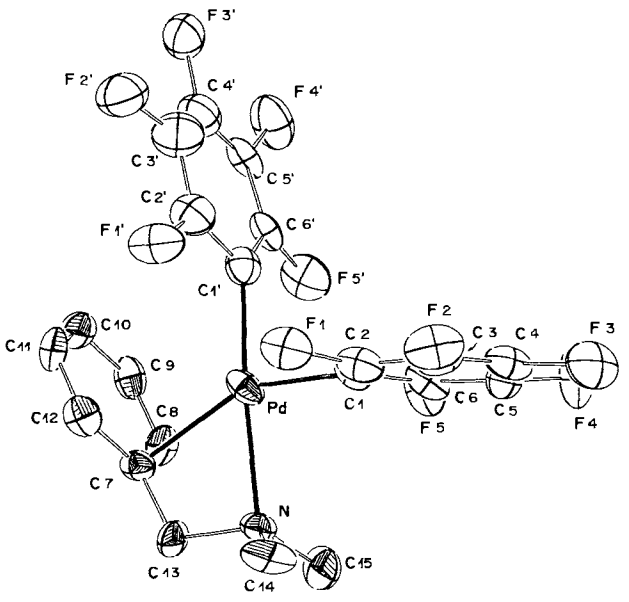

Fig. 1. Molecular structure of complex **1**. Selected bond lengths [Å] and bond angles [°]: Pd-C1 1.957(8), Pd-C1′ 2.022(11), Pd-N 2.314(6), Pd-C7 2.335(7); C1-Pd-C1′ 88.6(2), C1-Pd-N 88.0(3), C7-Pd-N 64.4(3), C13-C7-Pd 88.9(5), C12-C7-Pd 86.2(5), C8-C7-Pd 90.4(5).

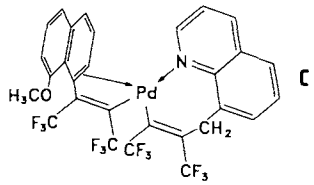
The coordination mode of the phenyl ring to the palladium atom is noteworthy. The shortest Pd–C(phenyl) distance is that corresponding to Pd-C7 (2.335(7) Å). This value is higher than that corresponding to a σ Pd bond (1.9–2.1 Å) and lower than the Pd–C distances observed in the η^2-arene complex **C** (2.571(4) and 2.433(3) Å).[11] The long Pd–C8 (2.706(8) Å) and Pd–C12 (2.663(9) Å) distances exclude an η^3-coordination to the palladium center.[2] The dihedral angle between the C_6H_5 plane and the best least-squares plane through Pd-N-C1-C1′ (plane A) is 92.75(28)°. Atom C7 lies essentially on plane A, its mean position being 0.028 Å form the plane.[12]



C

Moreover, the C_6H_5 ring is planar and all C–C bond lengths and C–C–C bond angles are the same within experimental error. That is an unexpected structural feature for an η^x (x ≠ 6) arene group bonded to a transition-metal center. Because of the coordination we should expect a deformation of the ring. As can be seen from the structural data, the arene ring is η^1-coordinated to the palladium atom in a similar way to that previously observed for $AgB_{11}CH_{12} \cdot 2C_6H_6$ (Ag–η^1-C distance = 2.400(7) Å)[4] and $[Cr\{NMes(BMes_2)\}_2]$ (Cr–η^1-C distances = 2.391(15) and 2.383(15) Å).[5] This structure differs significantly from the structures shown by the platinum η^1-arene complexes **B**,[3] which display a small but noticeable "boat" type puckering of the ring, and the Pt–C distances (2.183(7) and 2.293(9) Å) are shorter than the Pd–C7 distance in **1**.[13]

Concerning the bonding mode between the ring and the Pd center, several points are to be noted. (1) The values of the angles C13–C7-C12 (118.9(7)°), C8-C7-C12 (117.7(8)°), and C13-C7-C8 (123.1(8)°) indicate that the C7 atom is sp^2 hybridized. (2) C7 is basically in the plane A. (3) The Pd–C7 bond is almost perpendicular to the aryl ring plane (the deviation from the perpendicularity being only 3.72(29)°).[11] Consequently, the p(π) orbital of C7, which is perpendicular to the plane of the aryl ring, must be responsible for the interaction with the palladium center.

The study of the reactivity of **1**, including its role as a potential intermediate in an *ortho*-metalation process is in progress.

Experimental Procedure

To a solution of *cis*-$[Pd(C_6F_5)_2(thf)_2]$ (0.30 g, 0.51 mmol) in $CHCl_3$ (20 mL) at room temperature was added $C_6H_5CH_2NMe_2$ (77 μL, 0.51 mmol), and the mixture was stirred at room temperature for 30 min. After evaporation to dryness and addition of *n*-hexane (30 mL) a pale yellow solid was isolated and identified as **1**; 74% yield. Correct C, H, N elemental analysis. IR (Nujol): $\tilde{\nu}$ [cm^{-1}]: C_6F_5: 1495 vs, 1054 vs, 795 s, 784 s; $C_6H_5CH_2NMe_2$: 1374 s, 1352 s, 840 s, 746 vs, 700 s. NMR spectra in $CDCl_3$. ^1H m (200 MHz): δ = 7.79 (d, 2H, *o*-phenyl-H) 7.42 (t, 2H, *m*-phenyl-H), 7.18 (t, 1H, *p*-phenyl-H), 4.04 (s, 2H, $-CH_2-$), 2.61 (s,6H, NMe_2). ^{19}F NMR (188 MHz, standard $CFCl_3$): δ = −117.2 (*o*-F); −160.5, −161.2 (*p*-F); −163.8, −164.7 (*m*-F). Complex **1** is nonconducting in an acetone solution ($c \approx 5 \times 10^{-4}$ M).

[9] Suitable crystals for X-ray study were obtained by slow diffusion at 5 °C of *n*-hexane into a solution of **1** in CH_2Cl_2. Crystal data: monoxlinix, $a = 21.0836(23)$, $b = 8.0959(10)$, $c = 13.6030(20)$ Å, $\beta = 114.690(8)°$, $V = 2109.65$ Å^3. Size: $0.25 \times 0.75 \times 0.35$ mm, $\mu(Mo_{K\alpha}) = 9.12$ cm^{-1}. Data reduction included an absorption correction (maximum and minimum transmission factors, 0.7211 and 0.5471, respectively). Siemens/STOE AED2 four-circle diffractometer. $\omega-2\theta$ scan technique at room temperature; scan range, $4 \le 2\theta \le 50°$. Total number of reflections, 4000; 2660 unique reflections with $F_o \ge 6\sigma(F_o)$ used for all calculations; $Z = 4$. Systematic absences: (*hkl*): $h + k \neq 2n$ and (*h* 0*l*): $1 \neq 2n$, consistent with either of the space groups *C*2/*c* and *Cc*. Successful refinement and detailed analysis of the structure established the space group as *Cc*. The positions of the central Pd atom and the immediately ligated atoms were found by direct methods [14] under the assumption of space group *C*2/*c*. Further development was possible only in the acentric group *Cc*. The structure has pseudosymmetry with one C_6F_5 ligand related to the other by approximate local twofold symmetry. The $C_6H_5CH_2NMe_2$ ligand, however, is clearly and unambiguously inconsistent with the presence of overall twofold symmetry. Since the bisector of the R–Pd–R angle is roughly parallel to the crystallographic *b* axis, we expected and observed a modest degree of correlation between some pairs of corresponding parameters of the two C_6F_5 groups in the final least-squares refinement of the structure. We thus applied loose observational restraints [15] on interatomic distances in the C_6F_5 groups. The correlation was not so serious as to preclude full anisotropic refinement of the structure, with 296 variables in full-matrix least-squares analysis. The final residuals for the correct enantiomorph are $R = 0.0590$. Further details of the crystal structure investigation are available form the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (England), on quoting the full journal citation.

Bis(pentamethylcyclopentadienyl)silylene as Ligand in Gold(I) Chloride Complexes**

By *Peter Jutzi** and *Andreas Möhrke*

Dedicated to Professor Edwin Hengge on the occasion of his 60th birthday

After the discovery of complexes containing terminal carbene ligands,[1] there was no lack of efforts to prepare complexes in which divalent homologues of carbon were bonded as ligands to transition metals. The first germylene,[2] stannylene,[3] and plumbylene complexes[4] were followed by further representatives. Thus, these complexes now constitute a well-investigated and well-established class of compounds (type **A**).[5]

$R_2E \rightarrow ML_n$ **A**, E = C, Ge, Sn, Pb

So far, however, all attempts to prepare silylene (silanediyl) complexes analogous to carbene complexes have failed.[6] In the course of our investigations concerning the chemistry of decamethylsilicocene (**1**),[7] we have now succeeded in synthesizing the first such compound.

Reaction of **1** with carbonylgold(I) chloride in toluene at about -90 °C results in loss of CO and formation of [bis(pentamethylcyclopentadienyl)silanediyl]gold chloride (**2**) [Eq. (1)] in good yield. The silylene complex **2**, obtained as a

$$\underset{\mathbf{1}}{(\pi\text{-}Me_5C_5)_2Si} + (CO)AuCl \xrightarrow[-CO]{} \underset{\mathbf{2}}{[(\sigma\text{-}Me_5C_5)(\pi\text{-}Me_5C_5)SiAuCl]} \quad (1)$$

very dark red powder, is extremely sensitive to air and moisture and readily soluble in aprotic organic solvents such as toluene, benzene, and chloroform. The structure of **2** was established unambiguously by NMR spectroscopy, mass spectrometry and elemental analysis.

The chemical shifts in the ^{29}Si NMR spectra of **1** and **2** differ markedly. Whereas a resonance at unusually high field ($\delta = -398$) is found for **1**,[7] the ^{29}Si NMR signal for **2** lies at $\delta = +82.8$, in a region characteristic for unsaturated, low-coordinated silicon compounds (silaethenes and disilenes).[8]

Interestingly, the two pentamethylcyclopentadienyl (Cp*) ligands are differently coordinated to the silicon atom in the silylene complex **2**. This is revealed by the temperature-dependent ^{1}H NMR spectra, which indicate the presence of a σ- and a π-bonded Cp* ligand. The σ-bonded ligand gives rise to three broadened signals in a 2:2:1 ratio; at lower temperature (-60 °C) these signals clearly show fine structure. This is characteristic for σ-Cp* systems that undergo a slow sigmatropic rearrangement.[9] The π-bonded Cp* ligand gives rise, as expected, to only one signal for all methyl groups, even at low temperature. The ^{13}C NMR data for **2** are also in accord with the Cp* bonding described here (see *Experimental Procedure*). The exact hapticity of π-bonded Cp* ligands cannot generally be determined from NMR spectra. However, X-ray analysis of the structurally comparable germylene complexes $[(\pi\text{-}Me_5C_5)(Cl)GeW(CO)_5]$ and $[(\pi\text{-}Me_5C_5)\{(Me_3Si)_2CH\}GeW(CO)_5]$ has shown a dihapto coordination.[10] Examination of models supports such a mode of coordination for the π-Cp* ligand in **2** as well.

The bonding in **2** corresponds qualitatively to that in carbene complexes of the Fischer type. In the latter, the electron deficit of the carbene carbon is reduced primarily by transfer of electron density from nonbonding orbitals of heteroatoms in the α position. In the silylene complex **2**, a π ligand acts as the electron donor.

The π-bonding components in the Cp^*_2Si unit of **2** are overall significantly less than those in **1**. Presumably, the resulting electron deficit at the Si atom is at least partly compensated by electron withdrawal from the Au atom through (d–p) π back-bonding.

In the compounds of carbon homologues, the tendency for irreversible coordination of a donor molecule is very pro-

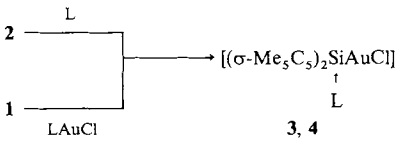
Universitätsstrasse, D-4800 Bielefeld (FRG)

[**] According to IUPAC rules, carbene (CH_2) homologues should have the suffix -diyl (i.e., silanediyl, stannanediyl, etc.). However, the names silylene, stannylene, etc., in analogy to methylene, are still commonly used in the chemical literature.

nounced and results in formation of donor-stabilized complexes of type **B** (ylide complexes).[5] This class of compounds now also includes examples with silicon; numerous interesting and readily accessible complexes have been reported, especially in recent years.[11]

$R_2E \rightarrow ML_n$ **B** E = C, Si, Ge, Sn, Pb
↑
donor

The silylene complex **2** can be very easily converted into the corresponding complex of type **B**. Thus, reaction of **2** with *tert*-butyl cyanide and with pyridine affords compounds **3** and **4**, respectively. These complexes can also be prepared directly from decamethylsilicocene (**1**), as shown by the reactions of **1** with (*tert*-butyl cyanide)- and pyridinegold(I) chloride [Eq. (2)].



(2)

3, L = *t*-C_4H_9NC; **4**; L = C_5H_5N

The compounds, obtained as colorless (**3**) or brown (**4**) crystals, were characterized unambiguously by spectroscopy and elemental analysis. The ^1H NMR spectra reveal that, in both cases, the two Cp* ligands are σ-bonded and the fluxional process is more rapid than in **1**. The additional coordination of a σ-donor ligand apparently obviates the necessity of π coordination of Cp* ligands. In comparison to **2**, the ^{29}Si NMR signals of **3** and **4** are shifted slightly to higher field and lie in the expected range.[12] In the ^{13}C NMR spectrum of **3**, the electrophilic character of the Si atom is reflected in a significant downfield shift of the signal of the cyanide C atom.[13]

Complexes **2**, **3**, and **4**, described here for the first time, clearly exemplify that the Cp* ligand can be used as required in compounds of low-valent main-group elements by change in hapticity ($\eta^5 \rightarrow \eta^1$). In addition, the bulky σ-bonded Cp* ligand also provides for kinetic stabilization.[14]

Experimental Procedure

2: A solution of **1** (1.47 g, 4.92 mmol) in toluene (20 mL) was added to a stirred suspension of carbonylgold(I) chloride (1.28 g, 4.92 mmol) in toluene (15 mL) at − 90 °C, and the reaction mixture was stirred for 1 h. The resulting deep red solution was allowed to warm to about − 20 °C, reduced in volume to ca. 15 mL, and treated slowly with 15 mL of *n*-pentane. Compound **2**, thereby obtained as a deep red powder, was washed with *n*-pentane and dried under vaccum. Yield 2.01 g (77%), m. p. 88–90 °C (dec.). ^1H NMR (300.1 MHz, $CDCl_3$, TMS): δ = 1.25, 1.74, 1.79 (s, broad, 3H:6H:6H, σ-C_5Me_5), 1.98 (s, 15H, π-C_5Me_5). ^{13}C NMR (75.4 MHz, $CDCl_3$, TMS): δ = 11.6, 14.6, 21.1 (broad, σ-C_5Me_5), 59.2 (broad, "allyl"(σ-C_5Me_5)), 135.0, 136.5, (broad, "vinyl"(σ-C_5Me_5)) 13.7 (s, π-C_5Me_5), 127.4 (s, π-C_5Me_5). ^{29}Si NMR (59.6 MHz, $CDCl_3$, TMS): δ = + 82.8. MS (70 eV): *m/z* 530 [$M^{\oplus}$, 1%], 395 [$M^{\oplus}$ − C_5Me_5, 1], 233 [$AuCl^{\oplus}$, 7], 163 [C_5Me_5Si, 100]. Correct C, H, Cl elemental analysis.

3, **4**: a) From **2**: A stirred solution of **2** (594 mg, 1.12 mmol) in toluene (7 mL) at 0 °C was treated with an equimolar amount of *tert*-butyl cyanide or pyridine. After a few seconds (**4**) or within several hours (**3**), the deep red solution changed color. Removal of the solvent, extraction into *n*-hexane, filtration, and crystallization led to colorless **3** (80%) or brown **4** (36%). b) From **1**: A solution of (*tert*-butyl cyanide)gold(I) chloride (1.70 g, 5.4 mmol) or pyridinegold(I) chloride (1.68 g, 5.4 mmol) in toluene (10 mL) was added to a solution of **1** (1.62 g, 5.4 mmol) in toluene (10 mL) at 0 °C. After stirring for several hours, the reaction mixture was allowed to warm to room temperature, and the volatile components were removed under vacuum; the residue was then redissolved in toluene and the solution filtered. Recrystallization at about − 60 °C afforded **3** (78%) or **4** (62%). Recrystallization from *n*-hexane/toluene (4/1) led to analytically pure products. **3**: m. p. 110 °C (dec.). ^1H NMR ($CDCl_3$): δ = 1.54 (s, 9H, CMe_3), 1.68 (broad, 30H, C_5Me_5). 1H NMR ([D_8]toluene, − 60 °C): δ = 0.31 (s, 9H, CMe_3), 1.87, 1.92, 1.96, 2.32, 2.54 (s, 6H:6H:6H.6H:6H, C_5Me_5). 1H NMR ([D_8]toluene, + 60 °C): δ = 0.65 (s, 9H, CMe_3), 1.93 (s, 30H, C_5Me_5). ^{13}C NMR ($CDCl_3$):δ = 13.5 (broad, C_5Me_5), 29.7 (CMe_3), 57.8 (CMe_3), 134.5 (very broad, CMe_5), 165.0 (CN-CMe_3). ^{29}Si NMR ($CDCl_3$):δ = + 71.2. IR (CsI): $\tilde{\nu}$[cm^{-1}] = 2231, 2208 (N≡C). Correct C, H, N elemental analysis. Molecular mass (cryoscopic in benzene): 621 g mol^{-1} (calcd 614.1 g mol^{-1}) **4**: m. p. 72–74 °C ^1H NMR ($CDCl_3$): δ = 1.74 (s, broad, 30H, CMe_5), 7.56, 7.90, 8.49 (m, 2H:2H:1H, C_5H_5N). ^{13}C NMR ($CDCl_3$): δ = 13.6 (broad C_5Me_5), 65.7 (allyl-C_5Me_5), 125.9 (C_5H_5N), 135.8 (broad, vinyl-C_5Me_5), 139.2, 150.0 (C_5H_5N). ^{29}Si NMR ($CDCl_3$): δ = + 54.3. Correct C, H, N elemental analysis.

Ytterbium(II) Benzamidinates, a New Class of Highly Reactive Lanthanoid(II) Complexes**

By *Michael Wedler, Mathias Noltemeyer, Ursula Pieper, Hans-Georg Schmidt, Dietmar Stalke* and *Frank T. Edelmann**

The discovery of a simple synthesis of samarium diiodide by *Kagan* et al. marked the beginning of an impressive development of organolanthanoid(II) chemistry.[1] However, in view of the enormous increase in their importance in preparative organic chemistry,[2] the number of soluble, fully characterized divalent lanthanoid derivatives is still surprisingly small.[3, 4] The well-investigated compounds include primarily the decamethylmetallocenes $(C_5Me_5)_2M$ (M = Sm, Eu, Yb), the bis(trimethylsilyl)amides $M[N(SiMe_3)_2]_2(thf)_2$ (M = Sm, Eu, Yb), and $(C_6F_5)_2Yb(thf)_4$.[4]

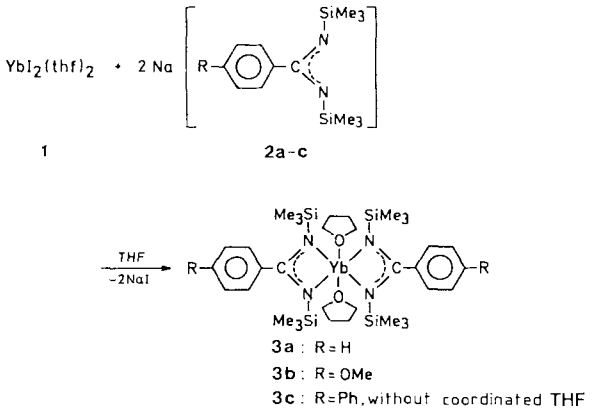
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

We describe here the synthesis, structure, and reactivity of silylated ytterbium(II) benzamidinates. These compounds represent a new class of soluble, highly reactive lanthanoid(II) complexes.

Ytterbium diiodide **1**[1] reacts with sodium *N,N'*-bis(trimethylsilyl)benzamidinates **2**[5, 6] in THF to give deep red solutions. The ytterbium(II)benzamidinates **3** formed in these reactions are obtained, after recrystallization from *n*-hexane, as black-red solids in high yield.



As expected, the ytterbium(II) benzamidinates **3a–c** are very sensitive to oxidation. The homoleptic ytterbium(III) benzamidinates $[RC_6H_4C(NSiMe_3)_2]_3Yb$ can be identified as oxidation products.[7] The $SiMe_3$ substituents are responsible for the excellent solubility of complexes **3** in nonpolar solvents such as toluene, cyclohexane, and *n*-hexane. In contrast, the lanthanoid(II) acetates $Sm(OAc)_2$ and $Yb(OAc)_2$ have been reported to be insoluble.[1b]

Both **3a** and **3b** are present as bis-THF adducts according to ^1H NMR spectroscopy and elemental analysis, whereas crystalline **3c** is unsolvated. Single crystals of **3a** suitable for an X-ray structure analysis (Fig. 1)[8] were obtained by cooling a saturated solution of **3a** in *n*-hexane. The ytterbium atom is coordinated in a very distorted octahedral fashion and, together with the oxygen atoms of the two *trans* THF molecules, lies on a crystallographic twofold axis. The Si-N-C-N-Si units of the benzamidinato ligands are planar. However, owing to the bulky $SiMe_3$ substituents, they are rotated by 26.3° with respect to each other. The Yb–N bond lengths (average value 248 pm) are comparable to those in $Na[Yb^{II}\{N(SiMe_3)_2\}_3]$ (Yb-N: 238, 244, 247 pm).[9] Conjugation of the π systems of the phenyl rings of the chelate ligands with the amidinato units can be ruled out by the large dihedral angle (77.3°).

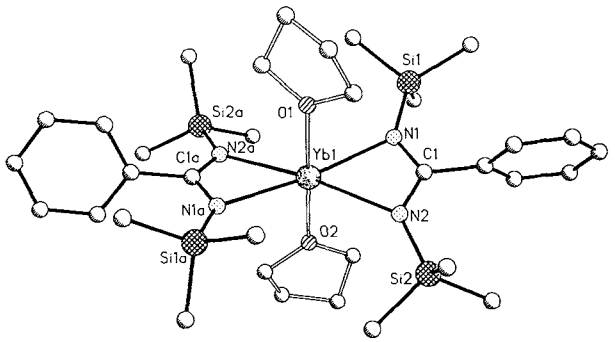


Fig. 1. Molecular structure of **3a**. Selected bond lengths [pm] and angles [°]: Yb1-N1 246.8(2), Yb1-N2 247.8(2), Yb1-O1 242.4(3), Yb1-O2 240.6(3); N1-C1-N2 120.4(2), N1-Yb1-N2 55.6(1), N1-Yb1-N1a 169.0(1), N2-Yb1-N2a 170.1(1).

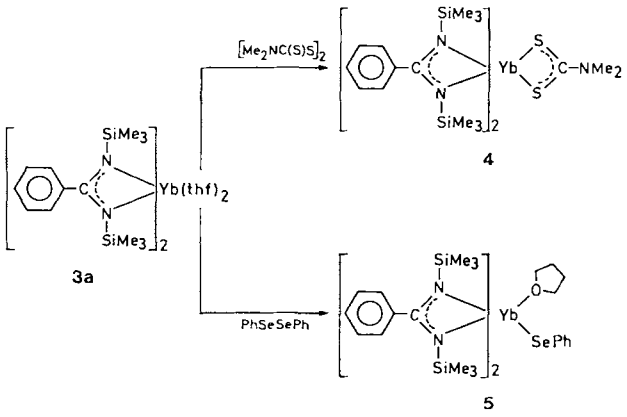
Ytterbium(II) compounds are strong reducing agents ($E^\circ(Yb^{3\oplus}/Yb^{2\oplus}) = -1.15$ V).[4] The high reactivity of benzamidinates **3** can be exploited for the synthesis of novel ytterbium(III) complexes. S–S and Se–Se bonds are readily and quantitatively cleaved by **3a**. For example, the reaction of **3a** with tetramethylthiuram disulfide affords colorless **4**. Reaction with PhSeSePh yields yellow, crystalline **5** in good yield.



The transition from diamagnetic ytterbium(II) to paramagnetic ytterbium(III) complexes is demonstrated impressively by the strongly temperature-dependent ^1H NMR spectra of **4** and **5**. According to the X-ray structure (Figs. 2 and 3),[8] both are hexacoordinated complexes. In **4** the chelating dithiocarbamato ligand has displaced both THF molecules from the starting material. The distances and angles in the YbS_2CNMe_2 part of the molecule are largely comparable to those in $(C_5Me_5)_2Yb(S_2CNEt_2)$.[10] A monomeric ytterbium(III) selenolate with a terminal PhSe ligand is present in compound **5**. The chelating amidinate ligands, originally *trans* in **3**, are tilted with respect to each other in **4** and **5**. This feature strikingly shows the structural analogy between the Cp* complexes $(C_5Me_5)_2Yb(S_2CNEt_2)$[9] and $(C_5Me_5)_2Yb(NH_3)TePh$[10] on the one hand and the benzamidinates **4** and **5** on the other.

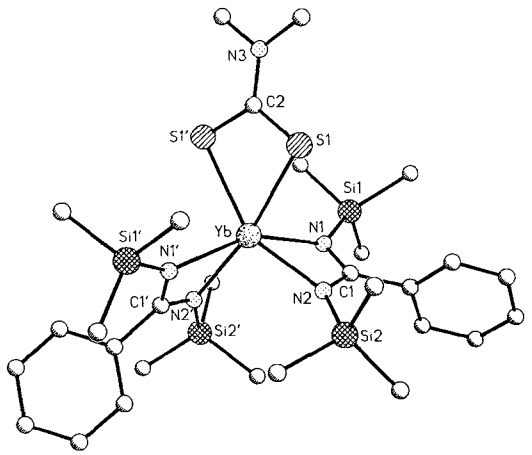


Fig. 2. Molecular structure of **4**. Selected bond lengths [pm] and angles [°]: Yb-N1 231.9(8), Yb-N2 229.8(6), Yb-N1' 230.5(8),Yb-N2' 232.3(7), Yb-S1 274.5(3), Yb-S1' 273.0(3); N1-C1-N2 119.0(8), N1-Yb-N2 59.6(2), N1'-C1'-N2' 118.2(7), N1'-Yb-N2' 59.3(3), S1-C2-S2' 120.1(5), S1-Yb-S1' 65.6(1).

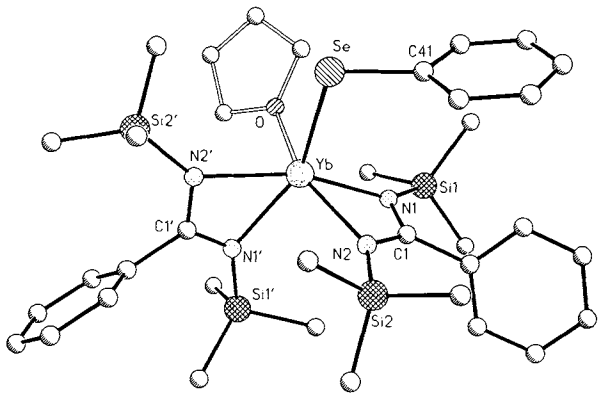

Fig. 3. Molecular structure of **5**. Selected bond lengths [pm] and angles [°]: Yb-Se 280.5(1), Yb-N1 230.5(8), Yb-N2 226.5(7), Yb-N1′ 236.6(7), Yb-N2′ 233.4(8), Yb-O 233.6(6); Yb-Se-C(41) 105.3(3), N1-C1-N2 117.8(8), N1′-C1′-N2′ 118.7(8), N1-Yb-N2 59.8(3), N1′-Yb-N2′ 58.5(3).

Experimental Procedure

All operations were performed in degassed solvents under N_2. Correct elemental analyses were obtained.

1: A solution of 1,2-diiodoethane (1.41 g, 5.00 mmol) in 150 mL of THF was added dropwise to Yb powder (1.08 g, 6.25 mmol) and the reaction mixture was stirred for 24 h at room temperature. The pale yellow solution of YbI_2 thereby obtained can be used directly in the subsequent reactions.

3a–c: Compound **2** (10 mmol), dissolved in 30 mL of THF, was added dropwise to **1** (5 mmol) in 150 mL of THF. The reaction mixture was stirred for 12 h at room temperature and the THF was then completely removed under vacuum. The residue was extracted with 150 mL of *n*-hexane (**3c**: toluene) and the resulting solution was filtered through Celite and then concentrated to ca. 30 mL. Cooling to − 25 °C afforded black-red crystals. **3a**: yield 2.30 g (55%); m.p. 150–155 °C. ^{1}H NMR (80 MHz, C_6D_6): $\delta = 7.03-7.32$ (m, 10H, Ph), 4.43 (m, 8H, THF), 2.00 (m, 8H, THF), 0.14 (s, 36H, $SiMe_3$). EI-MS (70 eV): *m/z* 844 ($M^{\oplus}$, 1%), 700 ($M^{\oplus}$ − 2 THF, 15), 263 ($PhC(NSiMe_3)_2$, 37), 146 (Si_2Me_6, 100), 73 ($SiMe_3$, 56). **3b**: Yield 1.65 g (37%); m.p. 117 °C. ^{1}H NMR (80 MHz, C_6D_6): $\delta = 7.16$ (m, 4H, C_6H_4), 6.70 (m, 4H, C_6H_4), 3.84 (m, 8H, THF), 3.26 (s, 6H, OMe), 1.57 (m, 8H, THF), 0.12 (s, 36H, $SiMe_3$). EI-MS (70 eV): *m/z* 760 ($M^{\oplus}$ − 2 THF, 5%), 133 ($MeOC_6H_4CN$, 100). **3c**: Yield 4.15 g (97%), dec. above ca. 200 °C. ^{1}H NMR (80 MHz, C_6D_6): $\delta = 7.63-7.88$ (m, 18H, PhC_6H_4), 0.22 (s, 36H, $SiMe_3$). EI-MS: *m/z* 853 ($M^{\oplus}$, 100%), 513 ($PhC_6H_4C(NSiMe_3)_2Yb$, 16).

4: $[Me_2NC(S)S]_2$ (0.29 g, 1.2 mmol) was added to a solution of **3a** (2.03 g, 2.4 mmol) in 60 mL of *n*-hexane. The reaction mixture was stirred for 12 h at room temperature and then filtered through Celite. The filtrate was concentrated to 30 mL and cooled to 0 °C. Colorless crystals formed within 2–3 days. Yield 0.64 g (33%); m.p. 147 °C. ^{1}H NMR (80 MHz, C_6D_6, 32 °C): $\delta = 7.00$ ($\nu_{1/2} = 19$ Hz, 36H, $SiMe_3$), 2.42 (s, 6H, NMe_2), − 1.94 (t, 2H, *p*-Ph), − 3.80 ($\nu_{1/2} = 16$ Hz, 4H, *m*-Ph), − 21.48 ($\nu_{1/2} = 16$ Hz, 4H, *o*-Ph). EI-MS: *m/z* 820 ($M^{\oplus}$, 24%), 700 ($M^{\oplus} - Me_2NCS_2$, 100).

5: A solution of PhSeSePh (0.26 g, 0.83 mmol) in 30 mL of *n*-hexane was added to a solution of **3a** (1.40 g, 1.66 mmol) in 70 mL of *n*-hexane. The reaction mixture was stirred for 12 h at room temperature, turning from deep red to yellow. It was then filtered through Celite and the filtrate was concentrated to 20 mL. Cooling to − 25 °C afforded 1.02 g (66%) of bright yellow crystals. M.p. 205 °C. ^{1}H NMR (80 MHz, C_6D_6, 32 °C): $\delta = 50.5$ (m, 4H, THF), 18.3 (m, 4H, THF), 13.5 ($\nu_{1/2} = 36$ Hz, 4H, SePh), 7.7 ($\nu_{1/2} = 16$ Hz, 1H, SePh), 3.5 ($\nu_{1/2} = 169$ Hz, 36H, $SiMe_3$), − 0.5 ($\nu_{1/2} = 8$ Hz, 2H, *p*-Ph), − 1.9 ($\nu_{1/2} = 17$ Hz, 4H, *m*-Ph), − 15.6 ($\nu_{1/2} = 46$ Hz, 4H, *o*-Ph). EI-MS: *m/z* 700 ($[PhC(NSiMe_3)_2]_2Yb$, 26%), 437 ($PhC(NSiMe_3)_2Yb$, 9), 73 ($SiMe_3$, 100).

Oxidative Addition of Phosphorus Ylides to $Ru_3(CO)_{12}$ **

By *D. Scott Bohle, Daniel Heineke, Antonio Tiripicchio, Marisa Tiripicchio Camellini*, and *Heinrich Vahrenkamp**

The versatile reactivity of phosphorus ylides has made them important reagents in organic chemistry.[1] In inorganic chemistry their strong basicity has been the basis of a rich coordination chemistry.[2] The way has thereby been paved "for an understanding of some of the complicated reactions in the system metal/phosphane/C_1 building block".[2] This should also open a fertile area of metal-assisted organic reactions of phosphorus ylides. With this in mind we have begun to investigate the reactivity of phosphorus ylides towards organometallic cluster compounds. After observing a new type of C–C bond formation between a cluster-bound vinylidene (CCH_2) unit and the ylides $R_3P{=}CHX$,[3] we have now found a new kind of oxidative addition in which a

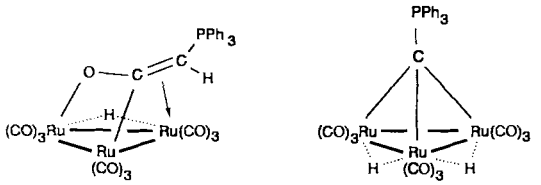
phosphorus ylide and $Ru_3(CO)_{12}$ react to give a phosphoniomethylidyne ligand linked to three ruthenium atoms.

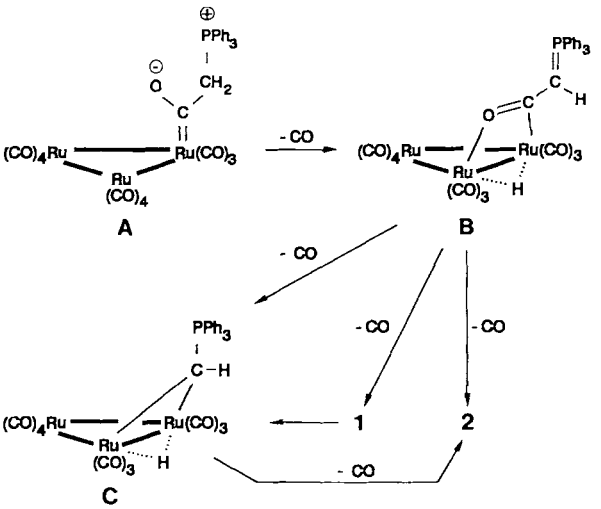
Reaction of $Ru_3(CO)_{12}$ with $Ph_3P{=}CH_2$ at $-20\,^{\circ}C$ in THF results in formation of a deep red intermediate, which, after workup, affords a 23% yield of **1**.[4] Upon heating in cyclohexane, **1** is converted into **2** in 31% yield.[5] A mixture of **1** (38%) and **2** (24%) is also obtained when $Ru_3(CO)_{12}$ is



1 **2**

treated with an excess of $Ph_3P{=}CHCHO$ in refluxing cyclohexane. Our findings have coincided with those of *Deeming* et al.,[6] who isolated five products from the reaction of $[Os_3(CO)_{10}(MeCN)_2]$ with $Ph_3P{=}CHCHO$. One product is similar, but not completely analogous, to those identified here.

Both **1** and **2** are products of an oxidative addition of $Ph_3P{=}CH_2$ to $Ru_3(CO)_{12}$. Although this is immediately obvious for **2**, the formation of **1** requires an intermediate CO insertion. We believe this to occur according to Scheme 1. As observed in the reactions of $R_3P{=}CH_2$ with simple metal carbonyls[2] and based on the immediate color change, the primary product is presumably **A**, which then rearranges to **B**. Like in the reactions of electron-rich aldehydes with $Ru_3(CO)_{12}$,[7] **B** is also the product of oxidative addition of $Ph_3P{=}CHCHO$ to $Ru_3(CO)_{12}$ and has been isolated as such for the Os_3 cluster by *Deeming* et al.[6] Compound **B** has two alternatives for decarbonylation, one of which leads to **1**, the other to **C**, the initially formed, but not yet observed, intermediate in the oxidative addition of $Ph_3P{=}CH_2$ to $Ru_3(CO)_{12}$. Both **1** and **C** can further decarbonylate in the second step of oxidative addition to form the final product **2**.



Scheme 1.

The structures of **1** and **2** have been determined by X-ray crystallography.[8] Figures 1 and 2 show that they both represent unusual bonding patterns. In **1** the ligand Ph_3PCHCO is linked via a π-bonding interaction of the C–C unit to one ruthenium atom, while the central C atom and the terminal O atom are σ-bonded to the second and third ruthenium atoms. The μ_3-bridging ligand can be called a phosphonium enolate with the P–C2 bond (181 pm) having a single-bond distance and both the C–C and the C–O bonds having between single- and double-bond distances. The C–C bond length (144 pm) is also longer than in the vinyl-bridged cluster $[HOs_3(CO)_{10}(\mu\text{-}CH{=}CH_2)]$ (140 pm).[9] Likewise, the C–O bond length (131 pm) is longer than in the acyl-bridged cluster $[HOs_3(CO)_{10}(\mu\text{-}PhCH_2C{=}O]$ (126 pm).[10] The comparatively simple structure of **2** contains a μ_3-bridging carbon atom with three normal Ru–C bond distances around 210 pm.[11] Unusual, however, is the fact that the carbon atom is ligated by the phosphane and can thus be called a cluster constituent like a metal atom. That this view is not unrealistic has been demonstrated recently by *Shriver* et al.[12a] for the substitution of CO by phosphane in the cluster $[Fe_2Co(CO)_9(\mu_3\text{-}C \cdot CO)]^{\ominus}$. *Schmidbaur*'s compound $[(Ph_3PAu)_3(\mu_3\text{-}C \cdot PMe_3]Cl$ similarly contains a phosphane-substituted μ_3-C ligand.[12b]

The formation of **2** completes the utilization of all four hydrogen atoms of methane in the sequence $CH_4 \rightarrow CH_3I \rightarrow CH_2{=}PPh_3 \rightarrow$ **2**. The resulting cluster unit should now be a useful starting point for subsequent organic reactions.[13] What this may mean has indirectly been shown by us in making the cluster compounds **3**[14] and **4**.[3] In **3** and **4** the M_3C units are isoelectronic to the one in **2**, while on top

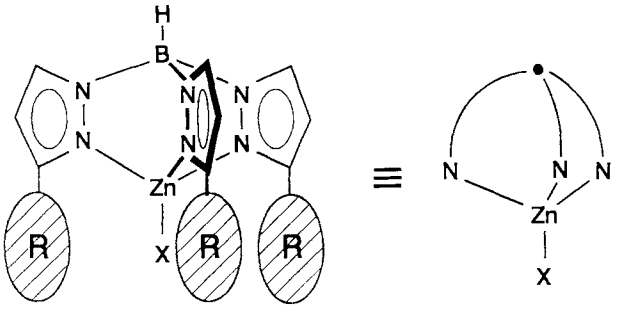
Functional Tetrahedral Zinc Complexes**

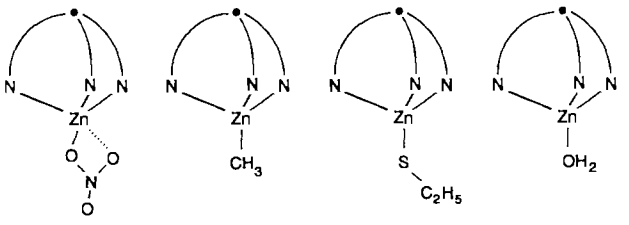
By *Ralf Alsfasser, Anne K. Powell,* and *Heinrich Vahrenkamp**

In the numerous zinc-containing enzymes, the zinc ion is almost always coordinated in a tetrahedral fashion.[1] Three of the four coordination sites are occupied by peptide donor groups, while the fourth, the "functional" site, is occupied by the substrate of the enzyme (or, in the "resting state", by a water molecule). Because of the lability of zinc complexes and the diverse coordination possibilities for zinc, it is unexpectedly difficult to obtain this simple coordination pattern, L_3ZnX, in model complexes.[2] Thus, typical chelating L_3 ligands such as triazacyclononane,[3a] tris(aminomethyl)-methane,[3b] *cis*-triaminocyclohexane,[3c] and even hydrotris(pyrazolyl)borate[3d] usually also afford octahedral 1:2 complexes. Only a complicated and bulky L_3 ligand such as tris(4,5-diisopropylimidazolyl)phosphane leads to a complex, $[L_3ZnCl]^{\oplus}$, that models the structure and function of the enzyme carbonic anhydrase.[4]

To obtain novel L_3ZnX complexes **1**, we have now exploited the fact that the well-studied hydrotris(pyrazolyl)borate ligands as their 3-phenyl or 3-*tert*-butyl-substituted derivatives form stable tetrahedral complexes L_3MX, M = Co,Ni,Cu,Zn.[5] In complexes **1**, the hydrophobic pocket formed around the fourth coordination site of the zinc by the substituents of the pyrazole can accommodate a variety of groups X. The utility of this concept is demonstrated by the four compounds **1a**–**1c** and **2**, all of which have been characterized by X-ray structure analyses.[6]



1, R = Ph, *t*Bu



1a **1b** **1c** **1d** (?)

Hydrotris(phenylpyrazolyl)boratozinc nitrate (**1a**) precipitates when methanolic solutions of $Zn(NO_3)_2 \cdot 6H_2O$ and the potassium salt of the ligand are combined (56% yield after recrystallization from benzene). Complex **1a** is first and foremost a further example of the well-investigated class of hydrotris(pyrazolyl)boratozinc salts.[5] Its structure analysis clearly shows, however, that the coordination of the nitrato ligand, as shown in the formula, is somewhere between monodentate and bidentate (Zn-O 195 and 247 pm). Complex **1a** is thus a primitive analogue of the enzyme carbonic anhydrase in two respects: first, the pocket at zinc in L_3ZnX has room for both a monodentate X and a second, small ligand (the substrate); second, the nitrato ligand is coordinated in just the way discussed for the isoelectronic hydrogen carbonate in carbonic anhydrase.[4]

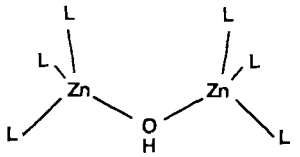
Hydrotris(phenylpyrazolyl)boratozinciomethane (**1b**) is formed in 90% yield as a practically analytically pure product when methyllithium (ca. 2 M, in ether, 10% excess) is added dropwise to a solution of L_3ZnCl in benzene. After concentration of the reaction solution to dryness, the product is separated from the lithium compounds by extraction with toluene. Further such organozinc compounds are synthesized analogously. Together with the organozinc compounds of hydrotris(*tert*-butylpyrazolyl)borate recently synthesized by *Parkin* et al.,[7] they are the first monomeric representatives of the class of compounds RZnX.[8] Although their bonding alone is intriguing (the Zn–C distance in **1b** is 197 pm), their primary importance presumably lies in their reactivity toward protic reagents HX. Treatment with these reagents results in alkane elimination and formation of the corresponding Zn–X compounds. In the simplest case—for example, reaction with HCl or RCOOH—the resulting compounds may be more easily obtained by other routes (cf. also Ref. [7]). As shown for **1c** in the following discussion, however, this reaction can also lead to novel compounds, not accessible via other routes.

Hydrotris(phenylpyrazolyl)boratozinc ethanethiolate (**1c**) is obtained practically analytically pure in 85% yield when the *t*BuZn compound analogous to **1b** is allowed to react for one week in a stirred solution containing a stoichiometric amount of ethanethiol, followed by filtration of the reaction solution and concentration of the filtrate to dryness. The easy preparation and manipulation of **1c** demonstrate especially clearly the advantages of the L_3 coligand chosen here, since monomeric complexes of the type L_3ZnSR were previously unknown. Zinc thiolates are usually oligomeric,[2] and only a few monomers of the type $[Zn(SR)_4]^{2\ominus}$[9a] and $L_2Zn(SR)_2$[9b] have been described. The importance of **1c** (Zn–S distance 221 pm) lies in its structural relationship to the numerous enzymes in which zinc is surrounded in a tetrahedral fashion by histidine-imidazole and cysteine-thiolate coordination partners.[1]

[μ-Hydroxobis{tris(*tert*-butylpyrazole)zinc}] trisperchlorate (**2**) is formed within a few minutes when the potassium salt of the *tert*-butylpyrazolylborato ligand is allowed to react with $Zn(ClO_4)_2 \cdot 6H_2O$ in methanol; after recrystallization from toluene, **2** can be isolated in 42% yield. The expected product was the cationic complex **1d**. Complex **1d** may in fact be the precursor of **2** if the zinc increases the hydrolytic activity of the coordinated water molecule in **1d**, as it does in the enzymes containing the unit $L_3Zn\text{-}OH_2$ in the active site. If this zinc-catalyzed hydrolysis is directed toward the complex itself in **1d**, the BH unit can be released from the otherwise hydrolysis-stable pyrazolylborate as H_3BO_3 and a tris(pyrazole)zinc complex such as **2** can be formed. Complex **2**, more easily prepared from *tert*-butylpyrazole, KOH, and $Zn(ClO_4)_2$ in methanol, shows Zn–O distances of 190 and 192 pm and a Zn–O–Zn angle of 137°. It is the first isolable compound in which an $L_3Zn\text{-}OH$ unit is present; such a unit has been discussed for the hydrolytic function of carbonic anhydrase and carboxypeptidase.[1, 10]

Two typical hard ligands are bound to zinc in complexes **1a** and **2** and two typical soft ligands in **1b** and **1c**. The extreme cases are the coordination of an $OH^{\ominus}$ ion and a methyl group in comparable ligand environments. The fact that all four complexes are soluble in nonpolar media such as toluene supports the assumption that, even in **1a** and **2**, the very polar Zn–X units are buried within a hydrophobic ligand environment. This should result in an unusual reactivity of these Zn–X units.



cation of **2**, L = *tert*-butylpyrazole

A 1,2:2,1-Bis(2-silapropane-1,3-diyl)diborane(6): Stabilization Product of Bis(trisyl)diborane(2)?

By *Theo Mennekes, Peter Paetzold,** and *Roland Boese**

Dedicated to Professor Edwin Hengge on the occasion of his 60th birthday

In the course of our investigations of two-coordinate boron,[1] we wanted to gain 1,2-bis(trisyl)diborane(2) (**2**) by a kind of Wurtz synthesis from the known dichloro(trisyl)borane (**1**)[2] and Na/K alloy. We hoped that the bulky "trisyl" group, $(Me_3Si)_3C$, would kinetically stabilize **2**. Instead, however, the title compound **3** was obtained. Its constitution was established from the NMR, MS, and IR spectra[3] and was confirmed by an X-ray structure examination (Fig. 1).[4]

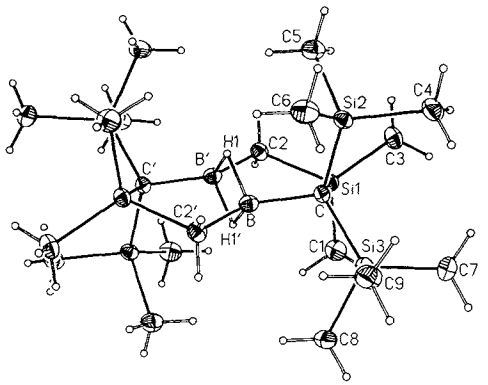

Fig. 1. Centrosymmetric molecular structure of **3**. Selected distances, angles, and torsion angles ([Å] and [°], standard deviations in parentheses): B···B' 1.856(3), B-H1 1.266(15), B'-H1 1.280(14), B-C 1.605(2), C-Si1 1.918(2), Si1-C2 1.896(2), C2-B' 1.586(3); B-H1-B' 93.6(9), H1-B-H1' 86.4(9), C-B···B 112.7(2), C-B-C2' 137.5(1), B-C-Si1 101.0(1), C-Si1-C2 104.3(1), Si1-C2-B' 103.9(1), Si1-C-Si2 110.6(1), Si1-C-Si3 113.9(1), Si2-C-Si3 112.7(1), C1-Si1-C3 106.7(1); B-C-Si1-C2 27.0, C-Si1-C2-B' −27.6, Si1-C2-B'···B 17.5, Si1-C-B···B' −17.7, C2-B'···B-C 0.4.

Compound **3** has C_i symmetry. The atoms B, B', C, C', C2, and C2' are arranged in a nearly coplanar fashion in two nonplanar five-membered rings sharing a common B–B' edge. The parallelogram B-H1-B'-H1' lies nearly perpendicular to the planes of those atoms. The distance B···B' (1.856 Å) is comparable to the B···B distance in *trans*-1,2-bis(trisyl)diborane(6), $[(Me_3Si)_3C]_2B_2H_4$[5] (1.839 Å), and markedly longer than the B···B distance in B_2H_6 (1.76 Å).[6] The 1,5-disila-3,7-diboracyclooctane structure of **3**, with a double 3,7-transannular H bridge, resembles the established structure of a likewise transannularly bridged 1,6-diboracyclodecane.[7]

Obviously, intermediates in the reaction of **1** with Na/K might be either trisylboranediyl, $(Me_3Si)_3CB$:, or dichlorobis(trisyl)diborane(4), $(Me_3Si)_3C(Cl)B\text{-}B(Cl)C(SiMe_3)_3$, which could undergo dimerization or a second dechlorination step, respectively, to give **2**. Intramolecular additions of C–H bonds to unsaturated systems, as presumed to occur in the stabilization of **2** to give the isolated product **3**, are well known. Examples in boron chemistry include the stabilization of RB≡O (R = 2,4,6-tri-*tert*-butylphenyl), $C_6F_5B{\equiv}NR$ (R = mesityl), and $R_2NB{\equiv}NNR_2$ (NR_2 = 2,6-dimethylpiperidino).[8]

Experimental Procedure

1,2:2,1-Bis[2,2-dimethyl-1,1-bis(trimethylsilyl)-2-silapropane-1,3,diyl]diborane(6), **3**: A solution of **1** (3.0 g) in 25 mL of hexane was treated at room temperature with 0.90 g of Na/K alloy (1:3). The reaction mixture was refluxed for 4 d and then filtered. The filtrate was concentrated until the crude product started to crystallize. Recrystallization once from hexane and twice from diethyl ether afforded 0.36 g of colorless **3** (15%; m.p. 250 °C). The product can be handled under air without decomposition.

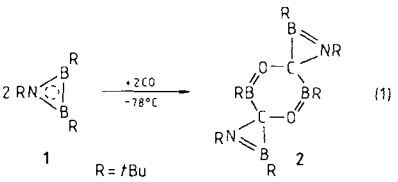
Boroboration of CO with Tri-*tert*-butylazadiboriridine

By *Peter Paetzold,* Burkhard Redenz-Stormanns* and *Roland Boese**

Tri-*tert*-butylazadiboriridine (**1**)[1] reacts at −78 °C with CO according to Equation (1) to form the tricyclic product **2**; NMR monitoring of the reaction indicates that it is complete. We have isolated colorless, crystalline **2** in 71% yield.



The constitution of **2** was established from the NMR and mass spectra,[2] and the unexpected structure was confirmed by X-ray structure analysis (Fig. 1).[3] In the centrosymmetric molecule **2**, two CBN three-membered rings are joined in a spirocyclic fashion to the central, planar six-membered ring, and the planes of neighboring rings are nearly perpendicular to each other. The *t*Bu groups at B3 and B3' are displaced toward the ring O atoms by the neighboring three-membered rings, as shown by the angles C1'-B3-C30 and O-B3-C30 (128 and 113°, respectively). The B–O distance of 1.36 Å supports the assumption of appreciable π contributions to the B–O bonding. Especially striking is the B–N distance of 1.33 Å, the shortest B–N double bond so far found.[4]

The surprising formation of **2** according to Equation (1) may be explained as follows: First, the carbene-like C atom of CO inserts into the B–B bond of **1** with formation of a four-membered ring; that is, the C atom is "boroborated". The four-membered ring then undergoes cyclodimerization

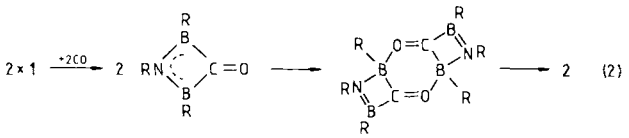
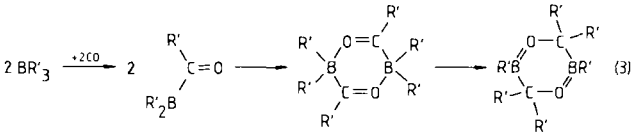
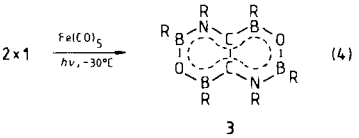
along a BCO unit to form the corresponding six-membered ring. Finally, sigmatropic migration of the amino groups from the B atoms to the C atoms results in rearrangement to **2** [Eq. (2)]. This proposal is supported by the "alkyloboration" of CO with BR'_3, which occurs according to Equation (3) in a fully analogous fashion.[5]





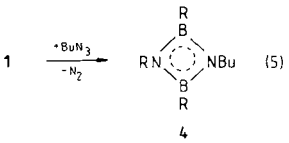
Irradiation of $Fe(CO)_5$ in the presence of **1** at −30 °C results in a product completely different from **2** but also corresponding to a 1:1 reaction of **1** and CO. The colorless, crystalline compound **3** is formed in 34% yield [Eq. (4)].



3

NMR and mass spectra[6] are in agreement with structure **3**, which was confirmed by an X-ray structure analysis (Fig. 2).[7] In the centrosymmetric molecule **3**, which is similar to naphthalene, the central ring atoms C1, C1', B1, B1', N, and N' are arranged in a planar fashion, but the trapeziform outer parts of the ring, B1-O-B2-N and B1'-O'-B2'-N', form an angle of 37.4° with the plane defined by the central ring atoms. The distances between neighboring ring atoms lie between those of typical single and double bonds involving the respective elements. This indicates a naphthalene-like cyclic delocalization of the π-electron systems despite the nonplanarity of the framework. The *t*Bu groups at B1, N and at B',N' project "below" and "above", respectively, the ring framework. The pyramidal distortion at these four ring atoms caused by the nonplanarity of the ring framework is thereby largely compensated. In the formation of **3**, the C–O triple bond is opened at −30 °C. Presumably, the Fe atom of an unknown intermediate is involved catalytically in this process.

The smooth reaction of the carbene-like molecule CO indicates that nitrenes or their precursors should react similarly. We therefore carried out the reaction of **1** with butyl azide, which resulted in loss of N_2 and formation of diazadiboretidine **4** in 65% yield [Eq. (5)]. The constitution of **4** was



4

established unambiguously from the NMR and mass spectra.[8] The diazadiboretidines $(t\mathrm{BuBN}t\mathrm{Bu})_2$ and $(\mathrm{BuBN}t\mathrm{Bu})_2$ related to **4** have been well investigated structurally.[9] In the formation of **4**, the nitrene BuN: formally undergoes boroboration. First, one of the B atoms of **1** must attack the N1 atom of the N_3 group. The second step could involve either 1,1 boroboration or 1,3 boroboration of the N_3 group to give a six-membered ring, followed by loss of N_2. Product **4** corresponds to the hypothetical intermediate in Equation (2).

CO or BuN_3 do not react with the open-chain diborane(4) $t\mathrm{Bu}(\mathrm{Me_2N})\mathrm{B}\text{-}\mathrm{B}(\mathrm{NMe_2})t\mathrm{Bu}$, which is comparable to **1**. The boroboration tendency of **1** thus depends on its three-membered ring structure.

Experimental Procedure

1,2,5,7,8,10-Hexa-*tert*-butyl-4,9-dioxa-1,7-diaza-2,5,8,10-tetraboradispiro-[2.2.2.2]decane, **2**: CO was bubbled through a solution of **1** (0.62 g) in 50 mL of pentane at −78 °C for 30 min. Compound **2** (0.50 g, 71%) crystallized from the reaction solution.

1,3,4,5,7,8-Hexa-*tert*-butyl-2,6-dioxa-4,8-diaza-1,3,5,7-tetraboranaphthalene, **3**: A solution of **1** (1.04 g) and $Fe(CO)_5$ (0.98 g) in 60 mL of hexane was irradiated (254 nm) at −30 °C for 24 h. All volatiles were then removed under vacuum at room temperature. Compound **3** (0.40 g, 34%) was crystallized from ether.

1-Butyl-2,3,4-tri-*tert*-butyl-1,3,2,4-diazadiboretidine, **4**: Compound **1** (0.80 g) and butyl azide (0.39 g) were combined in 10 mL of pentane at 0 °C and the resulting solution was stirred for 30 min at room temperature. Distillative workup gave **4** (0.70 g, 65%) as a colorless liquid at 70 °C/0.01 Torr.

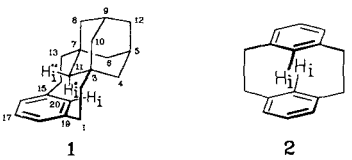
The First Clamped and Strongly Deformed Adamantane**

By *Fritz Vögtle,* Joachim Dohm,* and *Kari Rissanen*

Can benzene rings in strained macrocycles be replaced by adamantane building blocks? If so, this would offer a general approach to varying the lipophilicity, ring strain, and cavity size and shape of cyclophanes and host compounds. Comparison of the angles in adamantane and benzene (Scheme 1) shows that the bridgehead bonds in 1,3-position, like the *m*-phenylene bonds, form an angle of ca. 120°.

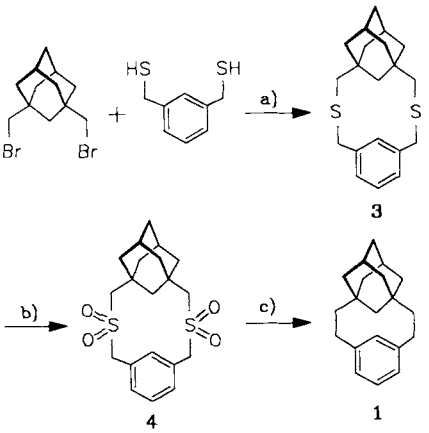
Scheme 1.

The stereochemistry of the new hydrocarbon phane **1**, which we designed with this consideration in mind, was expected to be fundamentally different from that of the known [2.2]metacyclophane **2**, since *three* intraannular H_i hydrogen atoms project into the interior of the ten-membered ring.



1 **2**

The synthesis of **1** (m.p. 78–79.5°) was accomplished via the dithia[3.3]cyclophane route, starting from 1,3-bis(mercaptomethyl)benzene and 1,3-bis(bromomethyl)adamantane,[1] to give dithia[3.3]phane **3** (40% yield),[2] followed by sulfone pyrolysis (50% yield)[3] (Scheme 2).



Scheme 2. a) High-dilution technique, 2 equiv. NaOH, EtOH/C_6H_6 (4:1), 78 h reflux, 12 h room temperature, 40%; b) HOAc, H_2O_2 (30%), 5 h reflux, 65%; c) 10^{-4} Torr, 550 °C, 50%.

The "[2.2](1,3)adamantanometacyclophane" **1**[4] exhibits an intense molecular peak in the mass spectrum (*m/z* 266) and characteristic ^1H and ^{13}C NMR spectra. The signals of H_i' and H_i'' are strongly shifted upfield ($\delta = -0.10$ and $+0.06$),[5] whereas H_i of the benzene ring absorbs at $\delta = 7.75$. The signals of dithiaphane **3** and disulfone **4** are even more strongly shifted upfield (up to $\delta = -2.18$; cf. Table 1).

[a] 200 MHz. [b] 90 MHz. [c] Cf. [2]. [d] 100 MHz, cf. [6]. [e] 60 MHz, cf. [6].

The ^{1}H NMR spectrum of **1** remains largely unchanged even at 116 °C (90 MHz, [D_8]toluene) and 126 °C (90 MHz, $C_2D_2Cl_4$); the AB splitting pattern of the signals of H_i' and H_i'' is merely transformed into an AM pattern, whereby the signal of the more strongly shielded H_i' is shifted to higher field, that of the less shielded H_i'' to lower field (cf. Table 1). The increase in temperature apparently affects the interaction of the solvent with the aromatic system and thus influences the ring-current effect, which causes the opposite shifts of the H_i' and H_i'' signals. From these observations we conclude that **1** is conformationally rigid and is present in the *anti* conformation.

Comparison of these findings with the ^{1}H NMR results for the corresponding [7]metacyclophane **5**,[6] for which a ring inversion has a barrier of only $\Delta G^{\ddagger} = 48$ kJ mol^{-1}, reveals that the conformational rigidity of adamantanophane **1** is remarkable. In contrast to **5**, compound **1** has a stiffened aliphatic "chain". The two aliphatic bridges in **1** and **5** therefore differ strongly in their steric demands and, in particular, in their interaction with the aromatic H_i proton.

The X-ray structure analysis reveals that, despite the "spherical" adamantane moiety, **1** adopts the *anti* conformation (Fig. 1), as observed for the [2.2]metacyclophane **2**.[7, 8]

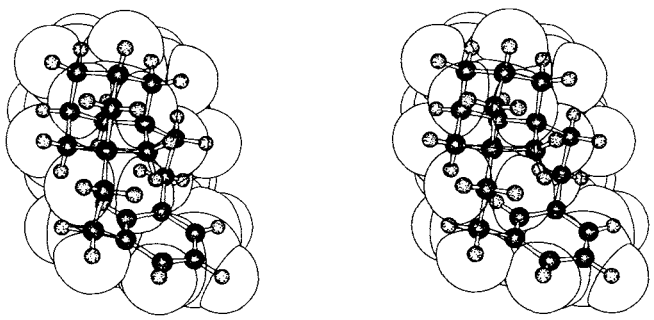

Fig. 1. Molecular structure of **1** (stereoview).

Especially striking is the strong distortion of the adamantane framework in **1**. In order to reduce the steric interactions in the interior of the macrocycle, C11 is bent away from the aromatic ring (distance C11-C20 278.6 pm, cf. Fig. 2), resulting in a flattening of the cyclohexane chair of the adamantane moiety and a decrease in the angles C10-C3-C11 and C8-C7-C11 to unusually small values (100.6° and 100.3°, respectively) for sp^3 carbon atoms (normal value: 109.5°). At the same time, the adamantane bonds C7-C8 and C3-C10 are lengthened to 154.8 and 154.5 pm, respectively, whereas the bonds C5-C6 and C4-C5 are shortened to 150.8 and 150.5, respectively. This is all the more remarkable, since known adamantane compounds encumbered sterically with substituents (e.g., biadamantane and biadamantylidene) are much less deformed.[9]

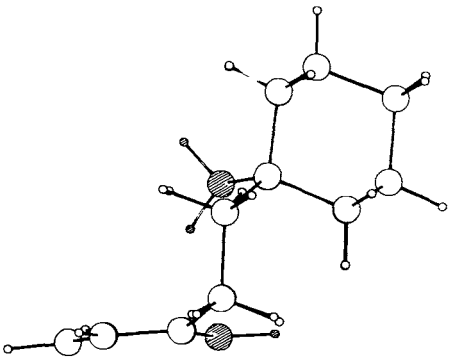

Fig. 2. Molecular structure of **1** (side view); the parts of the molecule in the "back" are exactly covered by those in the front, since this allows the intraannular atoms (hatched) and the deformations to be optimally shown.

The bond lengths and angles in the benzene ring of **1** are more strongly distorted than in the [2.2]metacyclophane **2** (values in parentheses): for example, C18-C19 141.6 pm (138.2 pm), C17-C18 136.0 pm (138.7 pm), and C18-C19-C20 116.4° (117.3°). Furthermore, the boat-shaped deformation of the benzene ring characteristic of the [2.2]metacyclophane is even more pronounced in **1**: C20 is displaced by 16.7 pm (14.3 pm) and C17 by 7.4 pm (4.2 pm) from the ring plane and the corresponding angles are 14.3° for C20 and 6.5° for C17 (11.9° and 3.5°, respectively, in **2**)! Finally, the CH_2-CH_2 bridges (157.0 and 157.8 pm) are longer in **1** than in [2.2]metacyclophane (155.9 pm).

The increased strain in **1** (compared with **2**) caused by the adamantane moiety is thus compensated by deformation of both the rigid adamantane and the benzene ring. According to MM2(85) calculations, the strain energy of **1** is nearly a factor of 2.5 higher than that of [2.2]metayclophane (**2**).[10]

The investigation shows that the rigid adamantane framework can be significantly distorted by bridging; such distortion was previously not achieved by substitution with bulky substituents. In addition, the study shows that it is possible to replace benzene rings, even in strained ring compounds, by adamantane units serving as "rigid" building blocks. These findings open up new possibilities, especially within phane chemistry, where arene units (benzene, naphthalene, pyridine, thiophene, etc.) might be replaced by adamantane and related hydrocarbons and heteropolycycles.[11, 12] Furthermore, transannular chemical reactions should be possible in these new "aliphanes"[4] and might lead—as usual for [2.2]phanes—to new polycyclic hydrocarbons hardly accessible via other routes.

[4] In a strict sense, the name "adamantanophane" is not in accord with phane nomenclature, since, according to this name, the aliphatic adamantane is treated as an "aromatic" unit. Although in violation of the rules, this name is nonetheless useful because it is short and descriptive. For comparison:

pentacyclo[9.3.3.1.1^{4,8}.1^{13,16}]eicosa-4,6,8(20)-triene (IUPAC name), pentacyclo[0.16.1^{1,5}.1^{1,7}.1^{3,7}.1^{3,7}.1^{10,14}]eicosane-10,12,14(20)-triene(nodal nomenclature[13]), [1^{3,7}.1^{3,9}.1^{5,7}][11]metacyclophane (usual phane nomenclature[14]), [2.2](1,3)adamantanometacyclophane ("araliphane" name). For this reason, corresponding names of compounds (e.g., triquinacenophane[15], cyclooctatetraenophane[16]) have already been coined in the literature. It seems reasonable to classify *arali*phatic compounds such as **1**, **3**, and **4** as "*arali*phanes" and completely *ali*phatic phane analogues as "*ali*phanes" (from *ali*phatic).

[5] Spectroscopic data for **1** (numbering shown in formula: ^{1}H NMR (200 MHz, CD_2Cl_2, TMS): $\delta = 7.75$ (s, 1H; 20-H); 7.20 (t, $^3J = 7.4$ Hz, 1H; 17-H); 6.96 (d, $^3J = 7.4$ Hz, 2H; 16,18-H); 3.14, 2.65 (AB, $^2J = 13.6$ Hz, $^3J = 12.1/3.6$ Hz, 4H; 1-H$_{ax/eq}$, 14-H$_{ax/eq}$); 2.53, 1.29 (AB, $^2J = 12.0$ Hz, 4H; 4,6-H$_{ax}$, 4,6-H$_{eq}$); 2.23 (m, 1H; 5-H); 1.98 (m, 1H;9-H); 1.65 (tt, $^3J = 3.2$ Hz, $^4J = 1.0$ Hz, 2H; 12-H); 1.41, 0.87 (AB, $^2J = 12.6$ Hz, $^3J = 12.0/3.6$ Hz, 4H; 2-H$_{ax/eq}$, 13-H$_{ax/eq}$); 1.36 (m, 4H; 8-H, 10-H); 0.06 (dt, $^2J = 16.6$ Hz, $^4J = 3.0$ Hz, 1H; 11-H$_{eq}$); -0.10 (d, $^2J = 16.6$ Hz, 1H; 11-H$_{ax}$). ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 145.7$ (C-15, C-19); 140.5 (C$-$20); 130.0 (C-17); 127.4 (C-18, C-16); 50.6 (C-8, C-10); 42.6 (C-2, C-13); 41.1 (C-11); 39.2 (C-12); 37.3 (C-6, C-4); 32.3 (C-1, C-14); 32.2 (C-9); 31.4 (C-3, C-7); 29.0 (C-5). The assignment was made by H,H- and C,H-COSY, spin-echo, and ^{1}H{^{1}H} NOE difference NMR spectroscopy. MS (70 eV): *m/z* 266.2027 ($M^{\oplus}$, 100%) (calcd 266.2028).

$CsNa_2(OH)_3 \cdot 6H_2O$: Structural Differentiation in the Hydrate of a Ternary Alkali-Metal Hydroxide**

By *Dietrich Mootz** and *Heinz Rütter*

Dedicated to Professor Dietrich Babel on the occasion of his 60th birthday

The structures of most hydrates of the lighter alkali-metal hydroxides were determined some time ago.[1, 2] More recently, structural characterizations have also been carried out for such compounds of the heavy alkali metals[3] as well as for anhydrous ternary alkali hydroxides.[4] *Hydrates*, however, of ternary alkali hydroxides, to our knowledge, have so far not been subjected to crystal structure analysis. Only one phase of this kind, to which the composition $CsOH \cdot 2\,NaOH \cdot 4H_2O$ has been assigned, can be found in the literature.[5] Our structure determination[6] unmistakably shows that the compound in question, melting congruently at 46.5 °C, is a *hexa*hydrate dominated in a characteristic way by differentiation between the cations of unequal size as well as between the H_2O molecules and the $OH^{\ominus}$ ions.[7]

In the crystal structure of $CsNa_2(OH)_3 \cdot 6H_2O$ the $Na^{\oplus}$ ions are coordinated by the six H_2O molecules to form distorted octahedra (Na–O distances between 2.275(3) and 2.688(3) Å). The octahedra are linked by common faces to form columns parallel to the crystallographic *b* axis. These are arranged according to the pattern of closest packing of cylindrical rods[8] and connected with each other by a complex system of hydrogen bonds with the H_2O molecules as twofold proton donors and the $OH^{\ominus}$ ions as fourfold proton acceptors (O···O distances between 2.633(4) and 2.798(4) Å). Thus, each $OH^{\ominus}$ ion bridges two octahedron edges in adjacent columns. Each column, together with two further ones and the associated $OH^{\ominus}$ ions, encloses in a

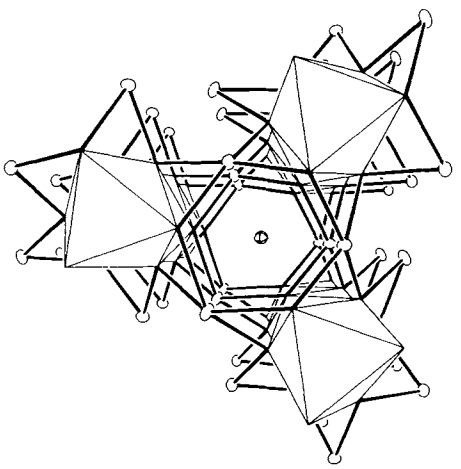

Fig. 1. Perspective drawing of the structure of $CsNa_2(OH)_3 \cdot 6H_2O$, projected down the *b* axis (atomic thermal-vibration ellipsoids at the 25% probability level, ORTEP plot[10]). Ellipsoids without equators, $OH^{\ominus}$ ions; ellipsoid with equator, $Cs^{\oplus}$ ion; bold lines, hydrogen bonds. One sees the pseudotrigonal arrangement of three columns of the face-linked $Na(H_2O)_6$ octahedra and, between them and the bridging $OH^{\ominus}$ ions, the large cavities containing the $Cs^{\oplus}$ ions. For completion of the three small cavities another column each (not shown in the figure) has to be added.

[*] Prof. Dr. D. Mootz, Dipl.-Chem. H. Rütter
Institut für Anorganische Chemie und Strukturchemie der Universität
Universitätsstrasse 1, D-4000 Düsseldorf (FRG)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, the Fonds der Chemischen Industrie, and the Dr. Jost Henkel-Stiftung. It is part of the doctoral dissertation in progress of *H. Rütter*, Universität Düsseldorf.

pseudotrigonal arrangement a total of three small and three large cavities, of which the latter type is highlighted in Figure 1. The H atoms of the $OH^{\ominus}$ ions probably project into the small cavities. In agreement with the generally low proton-donor strength of the $OH^{\ominus}$ion, they do *not* participarte in hydrogen bonds.[9] The large cavities enclose the $Cs^{\oplus}$ ions and may be considered as cuboctahedra consisting of nine H_2O molecules and the three $OH^{\ominus}$ groups, compressed along the pseudo-threefold axis (Fig. 2). The corresponding

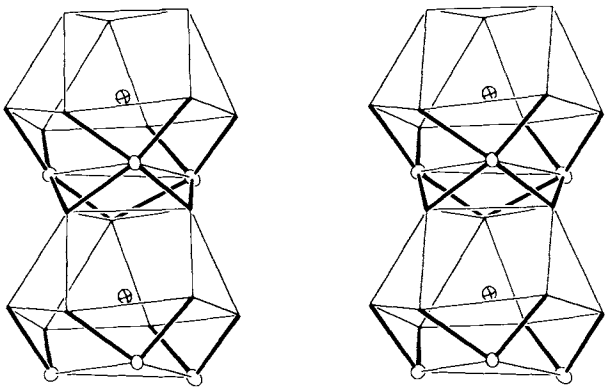

Fig. 2. Stereoscopic drawing of two cuboctahedra containing the $Cs^{\oplus}$ ions, succeeding each other along the pseudo-threefold axis, and their connection by hydrogen bonds; same way of representation as in Figure 1.

twelve Cs–O distances of 3.287(3) to 3.981(3) Å are the shortest ones; the next shortest distance, however, is already 4.113(3) Å.

In the higher hydrates of NaOH the $OH^{\ominus}$ ions are also not coordinated to the small, hard $Na^{\oplus}$ ions.[2] This generally has to do with the lowered charge density of the $OH^{\ominus}$ ions due to multiple proton-acceptor function in hydrogen bonds. Conversely, in the title compound the coordination of two of the $OH^{\ominus}$ ions to the large, softer $Cs^{\oplus}$ ion is reflected in the shortest Cs–O distances (3.287(3) and 3.296(3) Å), and also the third $OH^{\ominus}$ ion, following after five H_2O molecules, is still rather tightly bound at 3.542(3) Å.

[6] Large, colorless columns of the title compound were obtained by slow evaporation of the solvent water; space group $Pca2_1$ (No. 29), a = 13.951(3), b = 6.089(1), c = 12.508(3) Å, V = 1062.6 Å^3, Z = 4, Siemens-Stoe AED2, $Mo_{K\alpha}$ radiation, graphite monochromator, measuring range $3° < 2\theta < 70°$, 2430 measured symmetry-independent reflections, of which 2202 with $F > 4\sigma(F)$, absorption correction with ψ-scan, R = 0.026, R_w = 0.040. Due to the strongly scattering Cs atoms the H atoms could not be localized unambiguously; a neutron diffraction study is planned. Further details of the crystal structure determination can be obtained on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54521, the names of the authors, and the journal citation.

[7] Even without definitely determined H-atom positions the assignment of H_2O and $OH^{\ominus}$ as made for the subsequent description of the structure is practically inevitable.

[8] M. O'Keeffe, S. Andersson, *Acta. Crystallogr. Sect. A 33* (1977) 914.

[9] Due to difficulties in the preparation of samples an IR spectrum of the substance suitable for a check of this result could so far not be obtained. However, apart from the O···O distances already assigned as hydrogen bonds (see text), there are no further distances with $OH^{\ominus}$ ions smaller than 3.385(5) Å in the structure.

C_4O_2 (1,2,3-Butatriene-1,4-dione), the First Dioxide of Carbon with an Even Number of C Atoms

By *Günther Maier,* Hans Peter Reisenauer, Heinz Balli, Willy Brandt*, and *Rudolf Janoschek*

Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

The long known dioxides of carbon, CO_2 **1** and C_3O_2 **3**, as well as that recently prepared by us, C_5O_2 **5**,[1] have an odd number of carbon atoms. Analogues with an even number of carbon atoms—C_2O_2 **2** or C_4O_2 **4**—have so far defied experimental detection.[2, 3]

O=C=O **1** O=C=C=O **2** O=C=C=C=O **3**

O=C=C=C=C=O **4** O=C=C=C=C=C=O **5**

Theoretically, the compounds **2** and **4** should—in contrast to **1**, **3** and **5**—have a triplet ground state,[4] as also indicated by simple MO considerations: the electronic situation compares with that in the O_2 molecule. The π-molecular orbitals of **1**–**5**, with a linear geometry ($D_{\infty h}$), are pairwise degenerate (x and y directions indistinguishable). This leads, with an even number of C atoms, to two electrons being available for the highest occupied pair of molecular orbitals instead of the four electrons required for a closed shell. According to *Hund*'s rule this situation should lead to a triplet ground state.

Motivated by the simple synthetic entry to **5** by photolytic or thermal decomposition of trisdiazocyclohexanetrione[1] we have prepared the structurally similar cyclic diazoketones **6**[5]–**8** by diazo-group transfer in the hope of finding an entry to **2** or **4**.

The three precursors were subjected both to a high-vacuum flash pyrolysis with subsequent isolation of the products in an argon matrix, as well as to direct irradiation in the matrix. In the thermolysis of **6** and its photolysis with a Hg low-pressure lamp (254 nm) only **3** could be detected IR spectroscopically. In contrast, the gas-phase thermolysis of the diazoketones **7** and **8** afforded the already known C_3O **9**,[6] which could be identified by its characteristic bands in the IR spectrum of the matrix-isolated products. More interesting is the photolysis of the matrix-isolated precursors **7** and **8**, which crucially depends on the wavelength of the irradiating light. With wavelengths >300 nm (Hg high-pressure lamp/long pass filter or monochromator) **9** is smoothly formed again in both cases. If, on the other hand, a Hg low-pressure lamp (254 nm) is used as light source only a small amount of **9** is formed initially. The main product is now C_4O_2 **4**, the IR spectrum of which is shown in Figure 1.

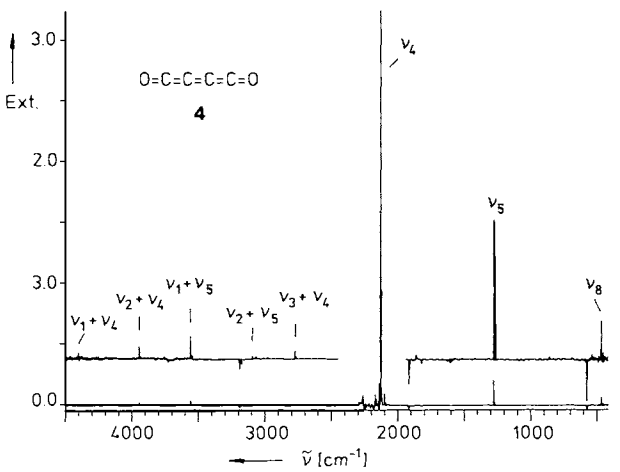

Fig. 1. Photolysis of 7 in an argon matrix: difference spectrum (5 min 254 nm – 10 min 335 nm; the bands pointing downwards belong to C_3O; numbering referred to $D_{\infty h}$ symmetry). Ext. = absorbance.

This assignment is supported by the observation that **4** rapidly dissociates into CO and **9** upon continuation of the photolysis with wavelengths > 300 nm.

To corroborate the analysis of the IR spectrum we have calculated the geometry of C_4O_2 (triplet and singlet state) by semiempirical methods (PM3 and MNDO) [optimized geometries: linear ($D_{\infty h}$) and bent (C_{2h}), resp.]. The calculated vibrational spectra are listed together with the experimental data in Table 1. The band patterns obtained for both geometries compare equally well with the experimental spectrum, so that a decision between a linear and slightly bent structure on the basis of the IR spectrum is not possible. The bands observed at 2130 and 1277 cm^{-1}, however, can be assigned to the two IR-active stretching vibrations Σ_u or B_u respectively, and the weak band at 467 cm^{-1} to the higher of the two IR-active bending vibrations Π_u or A_u respectively. The positions of the three IR-inactive stretching vibrations Σ_g and A_g can be calculated indirectly from the six observable combination bands ($\Sigma_g + \Sigma_n$ or $A_g + B_u$). They should be observable at about 2277, 1816 and 642 cm^{-1} in the Raman spectrum.

Table 1. Observed IR absorptions (argon matrix, 12 K) and calculated vibrations of **4** ($^3\Sigma_g^-$, ^1A_g) [cm^{-1}], relative IR intensities [%] in brackets.

[a] Numbering referred to $D_{\infty h}$ symmetry. [b] Average value determined from combination bands. [c] The values for this vibration vary between 50 i and 50 cm^{-1} with very small changes in geometry. The associated differences in energy are <0.01 kcal mol^{-1}. This suggests presence of a quasilinear molecule.

The dependence of the photolysis of **7** and **8** on the wavelength of the incident light is clearly demonstrated in Figure 2. C_4O_2 absorbs at λ = 340, 334 and 212 nm; its absorption at 250 nm, on the other hand, is negligible. Consequently, the secondary cleavage into C_3O and CO proceeds decisively slower with light from a mercury low-pressure lamp (λ = 254 nm) than with light of longer wavelength. More-

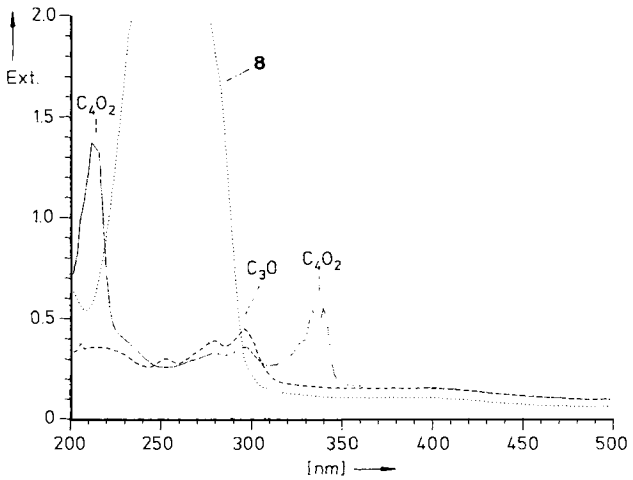

Fig. 2. Photolysis of **8** in an argon matrix: (···) unirradiated, (—) 5 min 254 nm, (---) 10 min 335 ± 10 nm.

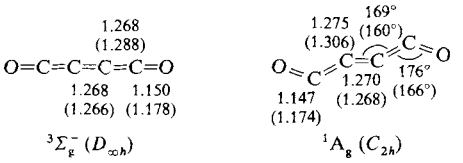
 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0808-0906 $ 3.50+.25/0 Angew. Chem. Int. Ed. Engl. 29 (1990) No. 8

over, C_4O_2 must also weakly absorb above 400 nm (not recognizable in the spectrum), since it also dissociates into C_3O and CO on irradiation with monochromatic light of wavelength 436 ± 10 nm.

The equilibrium structure of C_4O_2 in the triplet state was calculated both at the ab-initio UHF/3-21G(d) level as well as by the semiempirical UHF-PM3 method (Scheme 1, left). In both cases a linear structure ($D_{\infty h}$) results. The orbital situation also requires, despite *Hund*'s rule, the investigation of the lowest singlet state in order to determine the nature of the ground state of **4**, for the singlet state could, other than in the case of the O_2 molecule, be stabilized by bending and thus compete energetically with the triplet state. Both ab-initio SCF as well as PM3 calculations indicate a non-linear singlet structure with C_{2h} symmetry (Scheme 1, right).



Scheme 1. Left: equilibrium structure of **4** in the lowest triplet state, calculated at the ab initio UHF/3-21G(d) level (UHF-PM3 values in brackets). The bond lengths are given in Å. Right: equilibrium structure of **4** in the lowest singlet state, calculated at the ab initio SCF/3-21G (d) level (PM3 values in brackets).

Four different sets of calculations consistently indicate a triplet ground state. The small term splittings (Table 2), however, do not permit unequivocal conclusions to be drawn about the ground state.

Table 2. Calculated relative energy [kcal mol^{-1}] of the lowest singlet and triplet states of **4** [^1A_g(C_{2h}) correlates with $^1\Delta_g$ ($D_{\infty h}$)].

	PM3-CI[7]	MCSCF[a] 3-21+G	UMP2[9] 3-21G(d)	6-31G(d)
^1A_g (C_{2h})	8.8	8.5	4.8	4.0
$^3\Sigma_g^-$ ($D_{\infty h}$)	0.0	0.0	0.0	0.0

[a] 2-Electron-4-orbital-(π_g, π_u)-MCSCF[8].

The electronically excited states and vertical excitation energies of C_4O_2 were calculated by the MCSCF method.[8] The results are listed in Table 3. There are symmetry allowed excitations at ca. 180 and 400 nm in both the triplet as well as the singlet term scheme, whereas transitions, at 330 nm are only possible from the ^1A_g state. The data for the observed absorptions of C_4O_2 (Fig. 2) are, in good agreement with the calculated singlet transitions, at 212, 334, 340 and above 400 nm. For the photolysis product C_3O we have calculated 317 and 288 nm respectively for the symmetry allowed transitions $^1\Sigma^+ \rightarrow {}^1\Pi$ and $^1\Sigma^+ \rightarrow {}^1\Sigma^+$. These values are in good agreement with measured values 295 and 280 nm.

Table 3. Calculated (2-configuration-MCSCF) vertical electronic transitions λ [nm] from $^3\Sigma_g^-$ ($D_{\infty h}$) and ^{1}Ag (C_{2h}).*: symmetry allowed transitions.

$^3\Sigma_g^-$	λ	^1A_g	λ
$^3\Delta_u$	433	$^{*1}A_u$	510
$^3\Sigma_u^+$	421	$^{*1}B_u$	435
$^{*3}\Sigma_u^-$	400	$^{*1}B_u$	412
$^3\Delta_u$	299	$^{*1}A_u$	339
$^3\Sigma_u^+$	295	$^{*1}A_u$	324
$^{*3}\Sigma_u^-$	176	$^{*1}B_u$	186

The photolysis of C_4O_2 at wavelengths of over 400 nm can be correlated with the calculated transition $^1A_g \rightarrow {}^1B_u$ at 412 nm (Fig. 3). If the photolysis starting from the C_{2h} symmetry terminates in the C_s symmetry, ^1A_g (C_4O_2 with eight π electrons) correlates with the doubly excited state $^1\Sigma^+$ (C_3O with six π electrons) + $^1\Sigma^+$ (CO with two π electrons). ^1B_u (C_4O_2 with six π electrons) correlates with the ground state $^1\Sigma^+$ C_3O with four π electrons) + $^1\Sigma^+$(CO). As a result of the avoided crossing C_4O_2 (^1B_u) can dissociate non-adiabatically to C_3O + CO in the ground states. The height of the barrier to kinetic stabilization of C_4O_2 (^1A_g) must, according to Figure 3, lie below the point of intersection of the correlation lines, i.e. below 60 kcal mol^{-1}. Literature values of 200 kcal mol^{-1} [4f] are based on unsuitable methods of calculation (SCF), which cannot describe an avoided crossing.

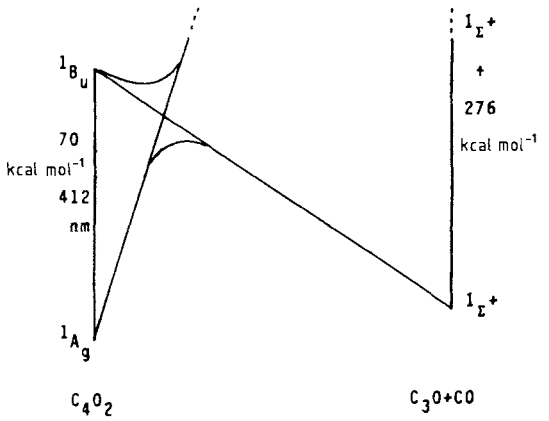


Fig. 3. State correlation diagram for the mechanism of photolysis of C_4O_2.

In the hope of obtaining direct evidence for the triplet character of C_4O_2 we have investigated the irradiated (λ = 254 nm) samples of **7** and **8** (argon matrix) ESR spectroscopically. However, up to the maximum magnetic field strength of 7000 Gauss (measuring frequency: 9.38 GHz) of the spectrometer available, no triplet signal could be recorded. On the assumption that C_4O_2 does in fact have a triplet ground state, the zero-field splitting parameter D must be greater than 1.0 cm^{-1}.[10] Such a value is not unreasonable, since very high D values have been measured for structurally similar, linear cumulenes (ground state $^3\Sigma$) such as C_nO (n even),[11] C_n (n > 2, even),[12] CNN,[13] SiCO,[14] and SiNN.[14] Hence, the negative ESR results do not in any way rule out a triplet ground state for C_4O_2.

Summarizing: C_4O_2 is a stable molecule under matrix conditions. It can be readily split photochemically into C_3O and CO. The question whether the molecule has a singlet or triplet ground state is open.

Experimental

7: A mixture of 1,2,4-cyclopentanetrione [15] (0.50 g, 4.5 mmol) and 2-azido-3-ethylbenzothiazolium tetrafluoroborate [16] (5.00 g, 17.1 mmol) in water

(200 mL) was acidified with 3 drops of 32% HCl and stirred for 15 min at 50 °C (exclusion of light). After extraction with CH_2Cl_2, the organic phase was dried (Na_2SO_4) and purified on silica gel (20 g). After removal of the solvent there remained 0.53 g (72%) of a crystalline product. For further purification the substance was recrystallized from CH_2Cl_2/Et_2O; yield 0.42 g (57%), colorless platelets. M.p. 135–137 °C (decomp.), noticeable decomposition above 120 °C. UV (CH_2Cl_2): λ_{max} (lgε) = 256 nm (4.37), 288 (4.01), 311 (3.51), 340 (3.55). IR (KBr): $\tilde{\nu}$ = 2160 cm^{-1}, 2135, 1755, 1685, 1355, 1355, 1310, 712. MS (70 eV): *m/z* (%) = 164 (9, $M^{\oplus}$), 136(7), 80(86), 68(69), 52(100). Correct elemental analysis.

8: A mixture of dihydropyran-2,4,6-trione [17] (0.60 g, 4.7 mmol) and 2-azido-3-ethylbenzothiazolium tetrafluoroborate [16] (3.00 g, 10.3 mmol) in 150 mL of 100% glacial acetic acid was stirred for 2 h at 60 °C. The crude desired product was precipitated by addition of 180 mL of Et_2O. After filtration the crystalline residue almost completely dissolved in CH_2Cl_2/CH_3CN (4:1) and was purified chromatographically on silica gel with CH_2Cl_2 as eluent. Evaporation of the liquid phase to dryness furnished a crystalline residue, which was dissolved in 60 mL of CH_2Cl_2 and 20 mL of CH_3CN. Subsequent dropwise addition of 250 mL of Et_2O and filtration afforded 0.31 g (36%) of colorless platelets. Noticeable decomposition above 150 °C. UV (CH_2Cl_2): λ_{max} (lg ε) = 244 nm (4.23, 258 (4.28), 268 (4.27), 280 (4.24). IR (KBr): $\tilde{\nu}$ = 2170 cm^{-1}, 2100, 1750, 1740, 1715, 1640, 1355, 740, 735. MS (70 eV): *m/z* (%) = 180 (30, $M^{\oplus}$), 80(10), 68(39), 52(100). Correct elemental analysis.

Identification of Butatrienedione, Its Radical Anion, and Its Radical Cation in the Gas Phase**

By *Detlev Sülzle* and *Helmut Schwarz**

Dedicated to Professor Wolfgang Kirmse on the occasion of his 60th birthday

There are several reasons for the exceptional interest[1] in linear and quasi-linear cumulenes of the general structure XC_nY (X,Y = lone pair, H_2, O, S; n ≥ 2). The compounds, some of which have been postulated as key intermediates in the formation of interstellar species, possess unusual spectroscopic properties, and their reactivity/stability, as well as their electronic ground state (singlet versus triplet), is governed by an "even/odd alternation". Although many combinations of XC_nY have long been known for n = 3, 5, the even-numbered analogues (n = 2, 4, 6) have often eluded unambiguous experimental identification. However, this situation is not due—as originally assumed[2]—to an intrinsic instability of these cumulenes, but rather must be the result of fast bimolecular reactions. For example, the dithiocumulenes SC_nS (n = 2, 4, 6)[1, 3, 4] and also the mixed S/O cumulenes SC_2O[5] and SC_4O[6] have been identified in the gas phase by neutralization-reionization mass spectrometry (NRMS).[7]

On the other hand, all attempts so far to prepare and characterize even-numbered cumulenediones OC_nO (n = 2, 4, 6) have been unsuccessful. Although ethylenedione, OC_2O, for example, is expected to be a kinetically extremely stable triplet on the basis of ab initio calculations,[8] from the earlier attempts of *Staudinger*[9] to this day no group has succeeded in generating and identifying this compound.[10]

Here we report the generation of the radical anion, radical cation, and neutral molecule of butatrienedione, OC_4O, in the gas phase. These experiments complement the recent matrix studies of *Maier* et al.[11]

Dissociative electron attachment[12] to **1**[13] affords an intense signal at *m/z* 80, which corresponds to a compound having the elemental formula $C_4O_2^{\odot\ominus}$. Mass selection of $C_4O_2^{\odot\ominus}$ via B(1)E and subsequent collisional activation of the 8-keV ion beam (collision gas O_2; 80% transmission *T*) afford the collisional activation (CA) spectrum shown in Figure 1a. All anionic decomposition products in Figure 1a can be explained by direct bond cleavage in $\mathbf{2}^{\odot\ominus}$. The assignment of the connectivity $OCCCCO^{\odot\ominus}$ to $C_4O_2^{\odot\ominus}$ is supported by the fact that the tendency to undergo skeletal rearrangements is appreciably less for radical anions than for radical cations.[14] Accordingly, we conclude that $\mathbf{1}^{\odot\ominus}$ eliminates CO_2 and $(CH_3)_2CO$ and is transformed into $\mathbf{2}^{\odot\ominus}$ (Scheme 1). We further maintain that, except for $CO^{\odot\ominus}$ (whose electron affinity (EA) is negative), all other species (C_4O_2, C_4O, C_3O, C_2O, C_3, C_2, and C_1) must have positive EA values.

Subjection of $\mathbf{2}^{\odot\ominus}$ in a further collision experiment to a vertical charge reversal (CR)[14b, 15, 16] results in the spectrum given in Figure 1b. This spectrum contains an intense "recovery signal" for $C_4O_2^{\odot\oplus}$ and establishes that not only $C_4O_2^{\odot\ominus}$ but also $C_4O_2^{\odot\oplus}$ exists in a potential minimum. Again remarkable is that, typical for a cumulene structure $\mathbf{2}^{\odot\oplus}$, decomposition occurs via cleavage of individual bonds.

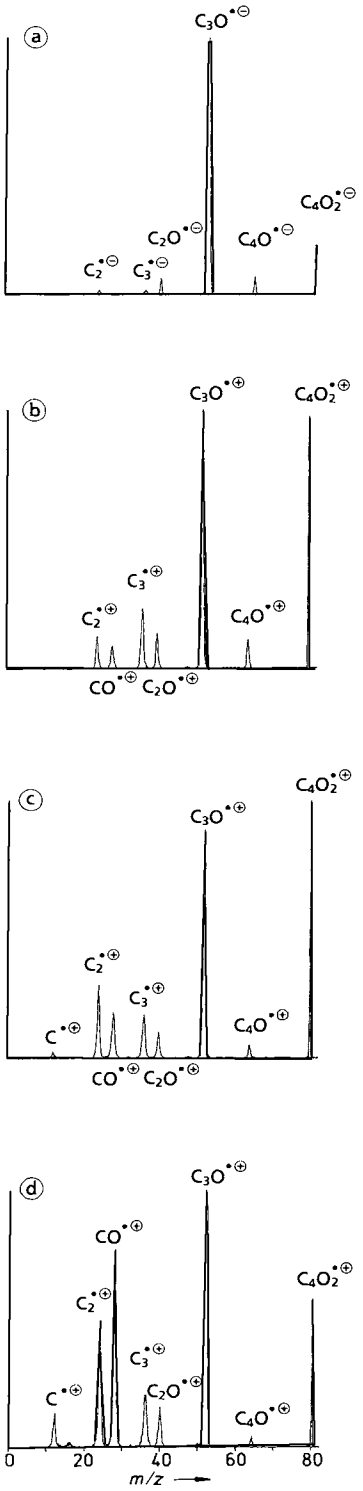

Fig. 1. a) CA spectrum of $C_4O_2^{\odot\ominus}$ (collision gas O_2, 80% T); b) CR spectrum of $C_4O_2^{\odot\ominus}$ (O_2, 80% T); c) NR spectrum of $C_4O_2^{\odot\ominus}$ (O_2, 80% T; O_2, 80% T); d) NR spectrum of $C_4O_2^{\odot\oplus}$ (Xe, 70% T; O_2, 80% T).

Is it possible to prepare neutral butatrienedione (**2**) from the radical anion $\mathbf{2}^{\odot\ominus}$ and/or radical cation $\mathbf{2}^{\odot\oplus}$ (also accessible by direct 70-eV electron-impact ionization of **1**) by electron transfer and to characterize **2** in an NRMS experiment? As revealed by Figure 1c, the answer is unequivocally yes. Oxidation of $\mathbf{2}^{\odot\ominus}$ generates **2**, which is further oxidized to $\mathbf{2}^{\odot\oplus}$ (Fig. 1c). Analogously, reduction of $\mathbf{2}^{\odot\oplus}$ yields **2**, which, upon subsequent reionization, affords the spectrum shown in Figure 1d. Noteworthy features include (1) the unusually intense recovery signal, which indicates favorable Franck–Condon transitions, and (2) the excellent agreement with the NR spectra generated under various conditions. This finding can also be viewed as evidence for comparably minor structural changes in the system $\mathbf{2}^{\odot\ominus} \rightarrow \mathbf{2} \rightleftarrows \mathbf{2}^{\odot\oplus}$.

Summary: Neutral butatrienedione, its radical anion, and its radical cation are perfectly stable molecules. If still further evidence were needed for this claim, it would be provided by an independent tandem experiment. If the reionized $C_4O_2^{\odot\oplus}$ formed via the sequence $\mathbf{2}^{\odot\oplus} \rightarrow \mathbf{2} \rightarrow \mathbf{2}^{\odot\oplus}$ is again mass-selected and subjected to collisional activation, the resulting interference-free NR spectrum is identical with the CA spectrum of $\mathbf{2}^{\odot\oplus}$ generated by direct collisional activation.

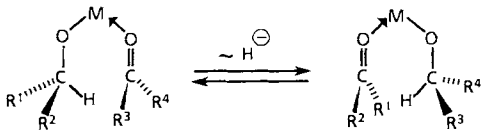
Iron(II)-Mediated Hydride and Methanide Transfer to Carbonyl Groups**

By *Detlef Schröder* and *Helmut Schwarz**

Dedicated to Professor Dr. Günther Wilke on the occasion of his 65th birthday

The course of the metal-induced hydride transfer in the Meerwein–Ponndorf–Verley–Oppenauer (MPVO) reaction [Eq. (1)][1] still cannot be described by a single mechanism despite the claims of most textbooks. The metal M and the solvent affect the kinetics through the degree of aggregation,[2] and the substituents R govern, in addition to the reaction rate, the extent to which one-electron transfers[3] occur. There is unanimous agreement, however, that alkyl- and aryl-group transfer cannot compete with hydride migration; rearrangements with R ≠ H have not yet been described.[4]



(1)

Here we report a gas-phase reaction analogous to the MPVO reaction but with the important differences that (1) the transition-metal ion $Fe^{\oplus}$ serves as metal M and (2), in addition to hydride transfer, methanide transfers have been observed for the first time. For the migration of $R = CH_3^{\ominus}$, we have found that steric manipulation on the alkoxide moiety leads to a dramatic change in the course of the reaction. Furthermore, kinetic isotope effects for the hydride transfer were determined.

We performed Fourier transform ion cyclotron resonance (FTICR) experiments, which allow the study of sequential ion/molecule reactions[5] unobscured by aggregation phenomena or the effect of counterions. In the reaction sequence (Fig. 1a–g), metal ions $M^{\oplus}$ (M = Cr, Mn, Fe, Ni) are generated by laser desorption/ionization[6] from V2A steel in the external ion source[7] of a Spectrospin CMS 47X ICR instrument[8] by use of an Nd:YAG laser (Spectron System, 1064 nm). The ions are transferred to the actual ICR cell through a system of electric potentials and lenses. The ions $M^{\oplus}$ are decelerated to nearly thermal energies and trapped in the field of a superconducting magnet (Oxford Instruments, maximum field strength 7.05 T) (Fig. 1a). Except for the ^{56}Fe isotope, all other ions present are ejected from the cell by suitable pulse sequences (Fig. 1b). The alkoxide ions $FeOR^{\oplus}$ ($R = CH_3$, C_2H_5, $i\text{-}C_3H_7$, $t\text{-}C_4H_9$, and isotopomers) required for the MPVO reaction are generated by ion/molecule reactions of $Fe^{\oplus}$ with pulsed-in[1a] neutral molecules. Nitroalkanes, alkyl nitrites, alkyl nitrates, and alkyl peroxides have proven useful for this purpose.[11] However, since ketones (necessary for the actual MPVO reaction) and argon[12] are also present in the ICR cell ($P_{ketone} \approx 10^{-8}$ mbar; $P_{Ar} \approx 10^{-7}$ mbar), numerous primary, secondary, and tertiary ions are formed in the diverse ion/molecule reactions (Fig. 1c). In the system $Fe^{\oplus}/CD_3NO_2/(CH_3)_2CO$, for example, "pure" $FeOCD_3^{\oplus}$ (1; m/z 90) can

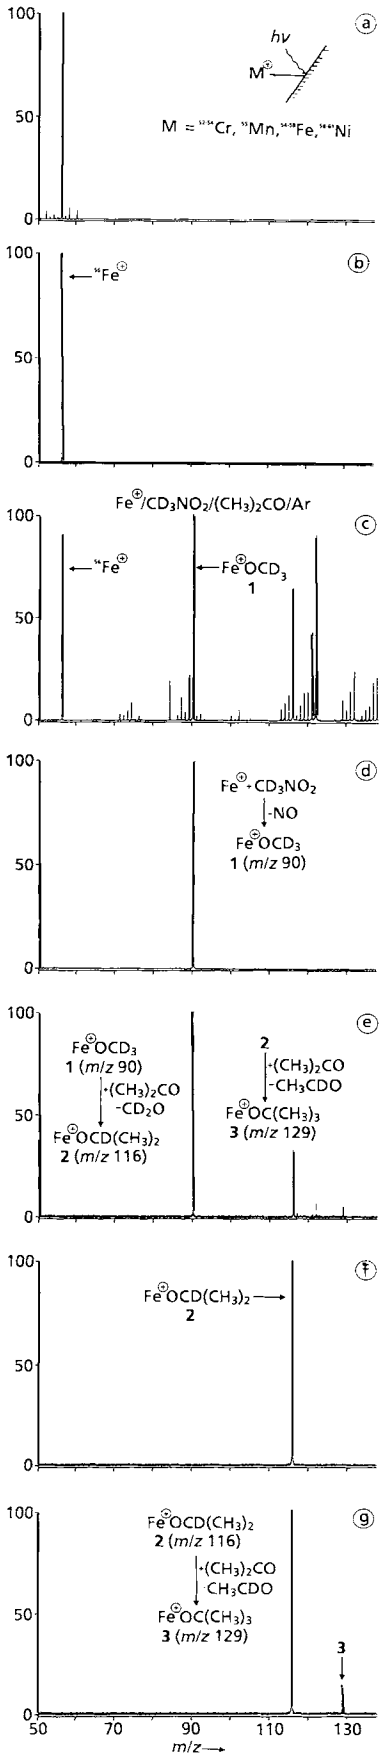


Fig. 1. a) Laser desorption/ionization of a V2A steel; b) "isolation" of $^{56}Fe^{\oplus}$; c) reaction of $^{56}Fe^{\oplus}$ with pulsed-in CD_3NO_2 and acetone (10^{-8} mbar) in the presence of Ar (10^{-7} mbar); d) "isolation" of $FeOCH_3^{\oplus}$ (m/z 90); e) reaction of $FeOCD_3^{\oplus}$ with acetone; f) "isolation" of $FeOCD(CH_3)_2^{\oplus}$ (m/z 116); g) reaction of $FeOCD(CH_3)_2^{\oplus}$ with acetone.

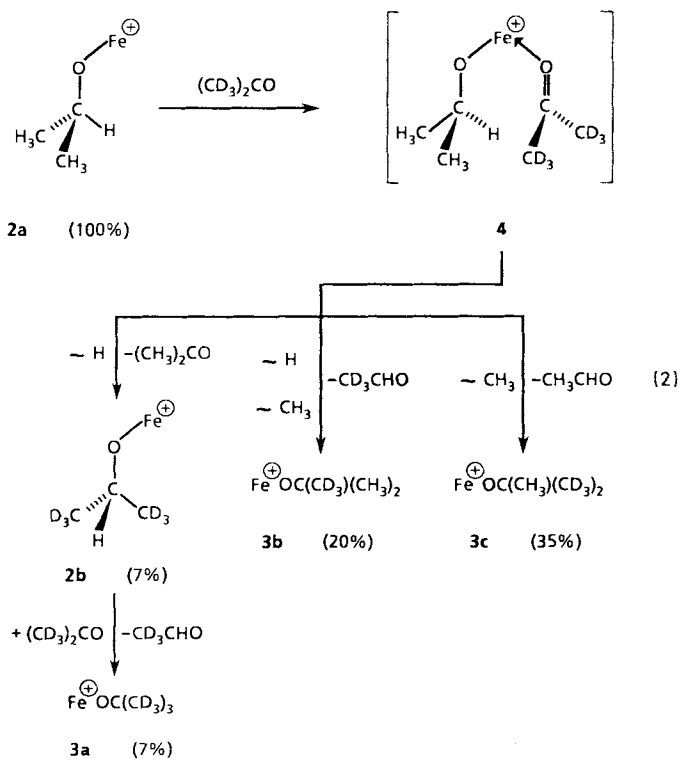
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der Technischen Universität Berlin.

be easily isolated from the palette of products by using a suitable sequence of pulses (Fig. 1d). Reaction of **1** with $(CH_3)_2CO$ affords products **2** and **3** (*m/z* 116 and 129, respectively; Fig. 1e); the "interfering signal" appearing at *m/z* 122 is due to a reaction of **1** with residual CD_3NO_2.[13] The generation of **3** and **2** can be confirmed by "isolating" the latter (Fig. 1f) and allowing it to react selectively with acetone to give **3** (Fig. 1g). It should be noted in passing that the overall reaction sequence $M^{\oplus} \rightarrow$ **3** constitutes a fourth-order MS experiment. However, two further steps are required to characterize structurally the $FeO\textit{t}\text{-}C_4H_9^{\oplus}$ ion **3**: (1) the isolation and (2) the collision-induced decomposition of **3**.[14] Before the results of these experiments are described, we should mention briefly several other $FeOR^{\oplus}$/ketone systems in order to demonstrate that the hydride and methanide transfers implied in Figure 1 are, in fact, general.

For example, the system $Fe^{\oplus}/CH_3NO_2/(CD_3)_2CO$ affords the ions $FeOCH_3^{\oplus}$ (*m/z* 87), $FeOCH(CD_3)_2^{\oplus}$ (*m/z* 121), and $FeOC(CD_3)_3^{\oplus}$ (*m/z* 138), which are isotopomeric to **1**, **2** and **3**.[15]

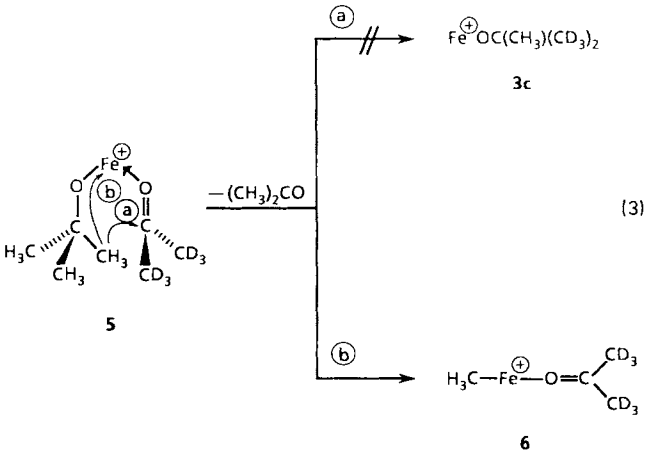
That the hydride transfer occurs with a kinetic isotope effect can be shown by investigation of the pair $FeOCD_2H^{\oplus}$ (generated from $Fe^{\oplus}$ and CHD_2NO_2) and $(CH_3)_2CO$. $FeOCH(CH_3)_2^{\oplus}$ and $FeOCD(CH_3)_2^{\oplus}$ are obtained in a ratio of 0.78:1, which, after statistical correction, gives $k_H/k_D = 1.6$.

Groups R other than methyl can also serve as alkoxide ligands RO. This is exemplified by two reactions, which, in addition, reveal further aspects of the course of the reaction. The reaction of $FeOCH(CH_3)_2^{\oplus}$ (generated from $Fe^{\oplus}$ and $(CH_3)_2CHONO$) with $(CD_3)_2CO$ affords, after two seconds, the distribution of products shown in Equation (2) (given in % relative to $FeOCH(CH_3)_2^{\oplus}$). Whereas the D_6-labeled product **3c** is formed by a simple $CH_3^{\ominus}$ migration from the "nonisolated" intermediate **4** and the D_9 compound **3a** is the result of a consecutive reaction (**4** → **2b** → **3a**), the appearance of the D_3-labeled alkoxide **3b** necessitates that the lifetime of **4** be sufficiently long to allow an internal reciprocal H/CD_3 migration.



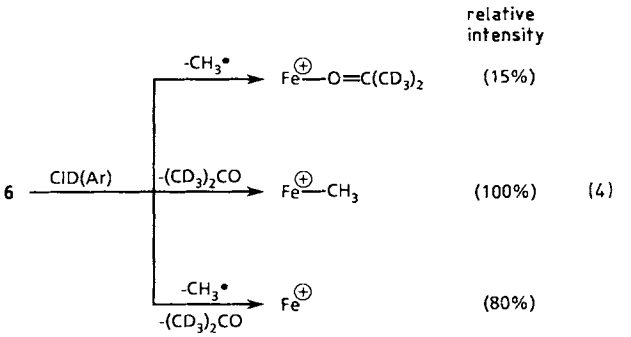
(2)

We observed a *seemingly* analogous reaction pattern for the reaction of $FeOC(CH_3)_3^{\oplus}$ (generated from $Fe^{\oplus}$ and $(CH_3)_3COOC(CH_3)_3$) with $(CD_3)_2CO$. Besides clusters, the only product is an ion that demands a transfer of $CH_3^{\ominus}$. In this case, however, an MPVO-like migration of $CH_3^{\ominus}$ to the carbonyl center of $(CD_3)_2CO$ is not involved. Otherwise, the resulting product would have contained three equivalent methyl groups [Eq. (3): **5** → **3c**]. This is not the case, as evi-



(3)

denced by the following experiment. If the product (**6**) is subjected to a CID experiment, the resulting product distribution unequivocally rules out an equivalence of CH_3/CD_3 [Eq. (4)]. Moreover, a comparison with the CID spectrum of authentic $FeOC(CH_3)_3^{\oplus}$[16] (generated directly from $Fe^{\oplus}$ and $(CH_3)_3COOC(CH_3)_3$) excludes the reaction pathway **5** → **3c**. Instead, a β-CH_3 migration to the metal center occurs.[17] The cause of this abrupt change in the reaction



(4)

trajectory is still not clear; possibly, the steric crowding leads to a change in the geometric details at the $Fe^{\oplus}$ center (for example, an increase in the O–Fe–O angle).

It should be mentioned that the $Fe^{\oplus}$-mediated hydride/metnanide migrations of the MPVO type are not limited to acetone as acceptor. Preliminary investigations have shown that acetaldehyde, 3-pentanone, and 4-heptanone may also be reduced,[18] and the data in Table 1 for the system $FeOCHDCH_3^{\oplus}/CH_3CHO$ confirm that three kinds of reaction occur: (1) unidirectional transfer of $H^{\ominus}$, $D^{\ominus}$, or $CH_3^{\ominus}$ coupled with the loss of CH_3CDO, CH_3CHO, or CH_2O, respectively; (2) reciprocal migration of $H^{\ominus}/CH_3^{\ominus}$, followed by CH_2O loss from the original CH_3CHO moiety; (3) the formation of tertiary products of the type $FeOC(CH_3)_3^{\oplus}$.

Table 1. Reaction products of unidirectional, reciprocal, and consecutive migration of $X^{\oplus}$ (X = H, D, CH_3) in the system $FeOCHDCH_3^{\oplus}/CH_3CHO$.

		Yields of product ions [%] [a]			
t [s]	$FeOCH_2CH_3^{\oplus}$	$FeOCHDCH_3^{\oplus}$ [b]	$FeOCH(CH_3)_2^{\oplus}$	$FeOCD(CH_3)_2^{\oplus}$	$FeOC(CH_3)_3^{\oplus}$
0	–	100	–	–	–
10	14	100	39	11	2
30	11	31	100	23	28

[a] The "yields" are based on the most intense signal (100%). [b] In the present experiment, the ion generated by D transfer is identical with the precursor $FeOCHDCH_3^{\oplus}$. As a result, no H/D isotope effect is given.

Not surprisingly, the latter two reactions become increasingly important as the reaction time increases (Table 1).

[12] Argon fulfills two functions by (1) contributing to collisional stabilization and possibly excited-state deactivation and (2) serving as a collision gas for collision-induced decompositions (CID). The latter are used for the structural characterization of the products resulting from ion/molecule reactions.
[13] This can be demonstrated, for example, by reducing the partial pressure of CD_3NO_2.
[14] According to a recently published basic text on tandem mass spectrometry, the practical limit should be $(MS)^5$ and only in extremely favorable cases should $(MS)^6$ be possible: K. L. Busch, G. L. Glish, S. A. McLuckey: *Mass Spectrometry/Mass Spectrometry. Techniques and Applications of Tandem Mass Spectrometry*, VCH Publishers, New York 1988, p. 47. A "world record" is described by *Cooks* et al., who succeeded in realizing an $(MS)^{12}$ experiment by using a modified Paul ion trap: J. N. Louris, J. S. Broadbelt-Lustig, R. G. Cook, G. L. Glish, G. J. van Berkel, S. A. McLuckey, *Int. J. Mass. Spectrom. Ion Processes 96* (1990) 117.
[15] For the system $Fe^{\oplus}/CH_3ONO/(CD_3)_2CO$, we have succeeded in structurally characterizing the encounter complex with m/z 151 in a CID(Ar) experiment. The observed fragments [intensities in % relative to m/z 151 = 100%: $HFeO(CD_3)_2^{\oplus}$ (loss of CH_2O; 44%), $CH_3OFe^{\oplus}$ (loss of $(CD_3)_2CO$; 34%), $FeCD_3^{\oplus}$ (5%), $FeH^{\oplus}$ (loss of $CH_2O/(CD_3)_2CO$; 14%), and $Fe^{\oplus}$ (elimination of $CH_3O/(CD_3)_2CO$; 10%)] are in agreement with a connectivity CH_3O-Fe-$OC(CD_3)_2^{\oplus}$.
[16] In the CID spectrum of $FeOC(CH_3)_3^{\oplus}$, we find a loss of CH_3, CH_4, $(CH_3)_2CO$ and $(CH_3)_3CO$.

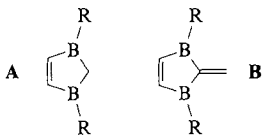
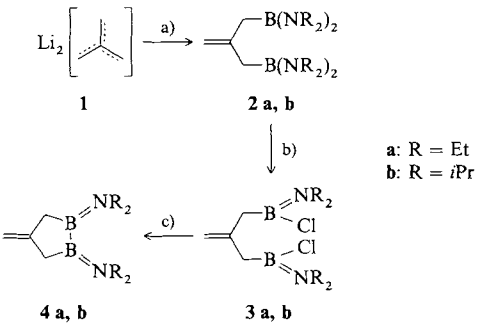
Unsaturated C_3B_2 Rings with Neighboring Boron Atoms: Derivatives of 4-Methylene-1,2-dibora-cyclopentane, Dilithium 2,3-diboratafulvene, and 1,2-Dibora-3-cyclopentene**

By *Gerhard E. Herberich,* Christian Ganter, Lars Wesemann*, and *Roland Boese*

Unsaturated C_3B_2 rings with non-neighboring boron atoms have long been known: for example, derivatives of 1,3-dibora-4-cyclopentene (**A**)[1] and 2-methylene-1,3-dibora-4-cyclopentene (**B**).[2] Unsaturated C_3B_2 rings with *neighboring* boron atoms, by contrast, have been inaccessible so far.



Here we describe examples of this type of compound. To form the C_3B_2 ring framework, we started from $Li_2[C(CH_2)_3]$ (**1**)[3] and used synthetic steps that have been well-tested with saturated compounds (Scheme 1). Borylation with $ClB(NR_2)_2$ (R = Et, *i*Pr) affords the diborylisobutenes **2a,b**, which react with HCl to give the chloroboryl compounds **3a,b**;[4] subsequent B–B bond formation, carried out with Na/K alloy in hexane,[5] leads to the 4-methylene-1,2-diboracyclopentanes **4a,b**. The alternative, direct formation of the C_3B_2 ring by reaction of **1** with the diborane(4) building block $Cl_2B_2(NMe_2)_2$ was unsuccessful.



Scheme 1. a) $ClB(NR_2)_2$, THF, 0 °C; b) HCl (Et_2O), −78 °C; c) $NaK_{2.8}$, hexane, 20 °C.

The X-ray structure analysis of **4b**[6] (Fig. 1) confirms the presence of a B–B bond. Compound **4b** shows an unusual twist conformation: the dihedral angle N2-B2-B1-N1 is 56.0° and the interplanar angle between the planes C3-B2-N2 and C1-B1-N1 36.8°. The aminoborane groups are also nonplanar with dihedral angles of 14.2° between the planes C5-N1-C8 and B2-B1-C1 and of 9.4° between the planes

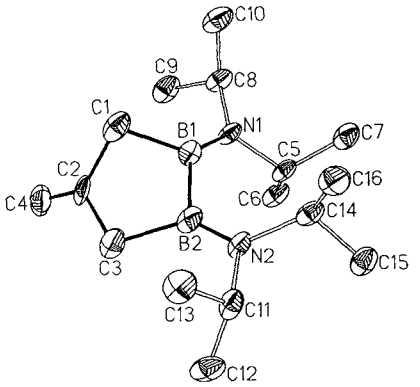

Fig. 1. Molecular structure of **4b**. Selected bond lengths [pm]: N1-B1 138.9(7), N2-B2 140.2(7), B1-B2 172.3(8), B1-C1 161.8(7), B2-C3 161.3(7), C1-C2 149.7(7), C2-C3, 151.7(7), C2-C4 130.0(8).

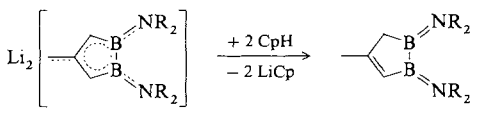
C11-N2-C14 and C3-B2-B1. The unusual features of the structure are due to the high steric demands of the iPr$_2$N groups. The B–C bonds (161.3(7) and 161.8(7) pm) are slightly lengthened,[7] whereas the B–N bonds (138.9(7) and 140.2(7) pm) are slightly shortened.[8]

Compound **4a** can be metalated with lithium 2,2,6,6-tetramethylpiperidide (LiTMP) in THF to give the moderately soluble, red dilithium 2,3-diboratafulvene derivative **5a**. Similarly, **4b** reacts with *tert*-butyllithium in hexane to give the orange-red bis(diisopropylamino) derivative **5b**. A singly metalated intermediate cannot be observed by NMR spectroscopy. The metalation products **5** react with tetramethylethylenediamine (TMEDA) to give the crystalline adducts **6** ($\equiv$**5** · (TMEDA)$_2$). The ^{11}B NMR signals of **6a,b** ($\delta = 43$) are slightly shifted to higher field compared with those of **4a, b** ($\delta = 52$ and 54, respectively) and lie in the same region as those of simple borataethene ions.[9]

Dianions **5** are transformed by cyclopentadiene, without any side reaction, into the 4-methyl-1,2-dibora-3-cyclopentene rings **7**, which are isomeric to the 4-methylene derivatives **4** but now contain an endoyclic double bond.



5 a, b **7 a, b**

Experimental Procedure

Standard for ^{1}H and ^{13}C NMR spectra, TMS int.; for ^{11}B NMR spectra, $BF_3 \cdot OEt_2$ ext.

2a: Distillation at 115 °C/10^{-6} bar (81%). ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 4.54$ (quint., $^4J = 1.3$ Hz, $H_2C=$), 1.63 (t, $^4J = 1.3$ Hz, 2 BCH_2), Et_2N: 2.98(q), 1.02(t). ^{11}B NMR ($CDCl_3$): $\delta = 34$.

2b: Crystallization from hexane (53%), m.p. 98–99 °C. ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 4.62$ (m, $H_2C=$), 1.71 (m, 2 BCH_2), iPr$_2$N: 3.56 (sept.), 1.15(d). ^{11}B NMR ($CDCl_3$): $\delta = 36$.

3a,b: Filtration and distillation at 85 °C/10^{-6} bar (94%) and at 150 °C/10^{-6} bar (89%).

4a: A stirred solution of **3a** (16.0 g, 0.055 mol) in hexane was allowed to react at 20 °C with $NaK_{2.8}$ (7.0 g, 0.053 mol) for 3 d. Filtration through kieselguhr, removal of the solvent, and distillation (45 °C/10^{-6} bar) gave 6.0 g (50%) of **4a**. MS: m/z 220 (100%, $M^{\oplus}$). ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 4.57$ (quint., $^4J = 1.6$ Hz, $H_2C=$), 1.89 (t, $^4J = 1.6$ Hz, 2 BCH_2); Et_2N: 3.24(q), 3.14(q), 1.11(t), 1.08(t) ^{11}B NMR ($CDCl_3$): $\delta = 52$.

4b: **3b** (3.3 g, 9.5 mmol) was allowed to react with 1.0 mL of $NaK_{2.8}$ as described for **4a** followed by refluxing for 24 h. Distillation (90 °C/10^{-6} bar) afforded 2.0 g of **4b** (76%), m.p. 47–48 °C. MS: m/z 276 (87%, $M^{\oplus}$). ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 4.58$ (quint., $^4J = 1.6$ Hz, $H_2C=$), 2.06 (t, $^4J = 1.6$ Hz, 2 BCH_2), iPr$_2$N: 3.72 (sept.), 3.34 (sept.), 1.25(d), 1.11(d). ^{11}B NMR ($CDCl_3$): $\delta = 54$.

6a: **4a** (2.0 g, 0.0091 mol) was treated in THF at −78 °C with LiTMP (2.7 g, 0.018 mol). The reaction mixture was then allowed to warm to 20 °C and the volatile components were removed under vacuum (finally, for 12 h at 10^{-6} bar). Crystallization from 10 mL of hexane and 3 mL of TMEDA (0.02 mol) at −30 °C afforded dark orange crystals. ^{1}H NMR (80 MHz, [D_8]THF): signals of 2 H6 and H1/H4 at $\delta = 1.05$ overlapped; Et_2N: 3.15(q), 1.05(t), TMEDA: 2.29(s), 2.18(s). ^{11}B NMR ([D_8]THF): $\delta = 43$. ^{13}C NMR (67.88 MHz, [D_8]THF, 203 K): $\delta = 79.4$ (t, $^1J = 150$ Hz, C6), 76.4 (d, $^1J = 130$ Hz, C1), 72.8 (d, $^1J = 128$ Hz, C4), 163.9 (s, C5), Et_2N: 47.3(t), 46.8(t), 44.6(t), 44.3(t), 16.9(q), 16.5(q), 14.9(q), 14.5(q), TMEDA: 57.4(tm), 45.9(qm); at 300 K, C1 and C4 are equivalent, as are the four Et groups.

6b: **4b** (1.0 g, 3.6 mmol) in 25 mL of pentane was treated at −78 °C with 4.5 mL of 1.7 M tBuLi (7.6 mmol, in hexane) and 1.2 mL (7.7 mol) of TMEDA. The reaction mixture was then stirred for 24 h at 20 °C. Concentration to 10 mL and crystallization at −30 °C afforded dark orange crystals. ^{1}H NMR (80 MHz, [D_{10}]Et_2O): signals of 2 H6 and H1/H4 at $\delta = 1.2$ overlapped, iPr$_2$N: 3.72 (sept.), 1.21(d), TMEDA: 2.28(s), 2.24(s), ^{11}B NMR ([D_{10}]Et_2O): $\delta = 43$. ^{13}C NMR (67.88 MHz, [D_{10}]Et_2O, 213 K): $\delta =$ 167.0 (s, C5), 77.8 (d, $^1J = 131$ Hz, C1,4), 74.4 (t, $^1J = 150$ Hz, C6), iPr$_2$N: 53.8(d), 24.3(q), 23.5(q) (at 300 K equivalent), TMEDA: 57.2(t), 46.3(q).

7a: Cyclopentadiene (3.6 g, 55 mmol) was added to **5a**, prepared from **4a** (5.45 g, 24.8 mmol) and LiTMP (7.7 g, 52.4 mmol), in THF at −78 °C. The THF was removed, the residue dissolved in hexane, and the resulting solution filtered through kieselguhr to remove the LiCp. Removal of volatile components and distillation (50 °C/10^{-6} bar) gave 4.0 g of **7a** (73%). MS: m/z 220 (68%, $M^{\oplus}$). ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 6.00$ (s, =CH), 1.97 (s, Me), 1.57 (s, BCH_2), Et N: 3.29(q), 3.26(q), 3.20(q), 3.12(q), 1.14(t), 1.12(t), 1.09(t), 1.08(t), ^{11}B NMR ($CDCl_3$): $\delta = 49$.

7b: 9.0 mL of 1.7 M tBuLi (15 mmol, in hexane) was added to **4b** (2.0 g, 7.2 mmol) in 30 mL of pentane at −78 °C and the reaction mixture was stirred for 24 h at 20 °C. The resulting precipitate was washed several times with pentane. After addition of 30 mL of pentane, cyclopentadiene (1.2 g, 18 mmol) was added at −78 °C and the reaction mixture was stirred at 20 °C until the red color had vanished (2 h). Filtration to remove LiCp, concentration, and distillation (90 °C/10^{-6} bar) gave 0.2 g of **7b** (10%), m.p. 50 °C. ^{1}H NMR (80 MHz, $CDCl_3$): $\delta = 6.23$ (s, HC=), 1.95 (s, Me), 1.72 (s br, BCH_2), iPr$_2$N: 3.74 (sept.), 3.33 (sept.), 1.24(d), 1.11(d), ^{11}B NMR ($CDCl_3$): $\delta = 51$.

Low-Dimensional Compounds Incorporating Polychalcogenide Ligands. The Unusual Polymeric Structures of $[AuSe_5]_n^{n\ominus}$ and $[AuSe_{13}]_n^{3n\ominus}$

By *Younbong Park* and *Mercouri G. Kanatzidis**

Solid-state compounds incorporating the versatile polychalcogenide ligands $Q_x^{2\ominus}$ are rare. These ligands are thermally unstable and release chalcogen at the high temperatures commonly used in solid-state reactions. On the other hand, room-temperature synthesis of molecular polychalcogenides is a thriving field of research.[1] We believe that an enormous number of interesting polychalcogenide compounds occur at intermediate (i.e., 150–350 °C) temperatures and could be discovered, provided suitable solvents (e.g., molten salts) were available. This intermediate temperature regime has not been explored as a synthetically useful area[2] either for solid-state or molecular compounds. These temperatures do not support the conventional (non)aqueous solvents commonly used near room temperature, nor do they favor true solid-state reactions (exceedingly slow ion diffusion). This has been particularly true in chalcogenide chemistry.[3] Molten salts have been used previously at high temperatures ($T > 700$ °C) to obtain crystals of binary semiconductors.[4, 5] Alkali-metal polychalcogenide melts, in particular, show melting points as low as ca. 150 °C[6] and can serve not only as solvents but also as reagents (i.e., chalcogen and alkali-metal donors). The deliberate use of these systems for the synthesis of new materials has not been seriously pursued. Recently, the compounds $K_4Ti_3Si_{14}$,[7] $Na_2Ti_2Se_8$,[8] $K_3Nb_2Se_{11}$,[9] α- and β-$KCuS_4$,[10] $K_2Hg_3Q_4$[11] (Q = S,Se), and $K_2Hg_6S_7$[11] were reported to form in polychalcogenide melts at 210–375 °C. Here we report two remarkable ternary compounds, $KAuSe_5$ (**1**) and K_3AuSe_{13} (**2**), prepared by using a molten-salt synthetic procedure at 250 °C. The structures of **1** and **2** were established by single-crystal X-ray diffraction studies[12] and represent the first examples of solid-state gold-polyselenide compounds.

The structure of **1** is shown in Figure 1. It is made up of covalent one-dimensional $[AuSe_5]_n^{n\ominus}$ anionic chains and

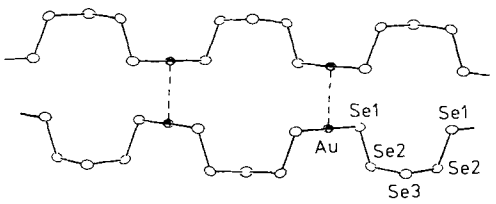

Fig. 1. ORTEP representation of the structure of the $[AuSe_5]_n^{n\ominus}$ chains with labeling scheme, showing the mode of "dimerization" via the Au···Au short contacts. Selected bond distances [Å] and angles [°]: Au-Se1 2.410(4), Se1-Se2 2.363(6), Se2-Se3 2.343(5); Se1-Se2-Se3 104.2(2), Se2-Se3-Se2 104.2(3), Au-Se1-Se2 101.4(2).

charge-compensating $K^{\oplus}$ ions. The $[AuSe_5]_n^{n\ominus}$ chains are composed of $Se_5^{2\ominus}$ ligands bridging two Au atoms via terminal Se atoms. The structure of $[AuSe_5]_n^{n\ominus}$ may be formally derived from that of $[AuSe]_n^{n\ominus}$[13] by replacing the $Se^{2\ominus}$ ions with $Se_5^{2\ominus}$ ligands. The $Au^{\oplus}$ centers show a linear coordination with a Se–Au–Se bond angle of 179.0(2)°. The $[AuSe_5]_n^{n\ominus}$ chains lack a center of symmetry, but they possess a perpendicular mirror plane passing through the Se3 atom. The chains in **1** are parallel to the crystallographic *c* axis. These chains interact with each other forming dimers through close Au···Au d^{10}–d^{10} contacts,[14] (2.950(3) Å) as depicted in Figure 1. The Au–Au contacts are considerably shorter than those observed in KAuSe[13] and in α- and β-AuSe.[15] and comparable to those in Ag_3AuSe_2.[14a] This is a beautiful example of a well-defined d^{10}–d^{10} interaction in the solid state. In general, d^{10}–d^{10} bonding contacts are not fully understood. Normally, the interaction of two filled metal orbitals results in a nonbonding situation due to the formation of a bonding and an equally antibonding state. However, recent theoretical investigations into this issue have invoked a significant admixture of s and p character (from the empty s and p orbitals) into the predominantly d metal orbitals.[16] This hybridization gives rise simultaneously to a more bonding and a less antibonding M–M interaction and therefore an overall stabilization.

The obseved Au–Se bond distances (2.410(4) Å) are similar to those found in KAuSe[13] at 2.414(1) Å. The average Se–Se bond distances in $KAuSe_5$ are normal (2.353(6) Å) and in the range found for other Se–Se bond distances in polyselenide complexes.[1] The shortest K···Se distances in $KAuSe_5$ are K1-Se1 (3.339(4) Å) and K2-Se1 (3.384(4) Å).

The structure of K_3AuSe_{13} is shown in Figure 2 and it is even more intriguing. This is a $Au^{3\oplus}$ compound, composed of centrosymmetric one-dimensional $[Au(Se_3)(Se_5)_2]_n^{3n\ominus}$ chains running parallel to the *c* axis. The makeup of the chains can be regarded as a one-dimensional assembly of square-planar $Au^{3\oplus}$ centers (situated on a center of symmetry) with two armlike *trans* $Se_5^{2\ominus}$ ligands and bridging $Se_3^{2\ominus}$ ligands. The bridging mode of the $Se_3^{2\ominus}$ ligands in **2** is similar

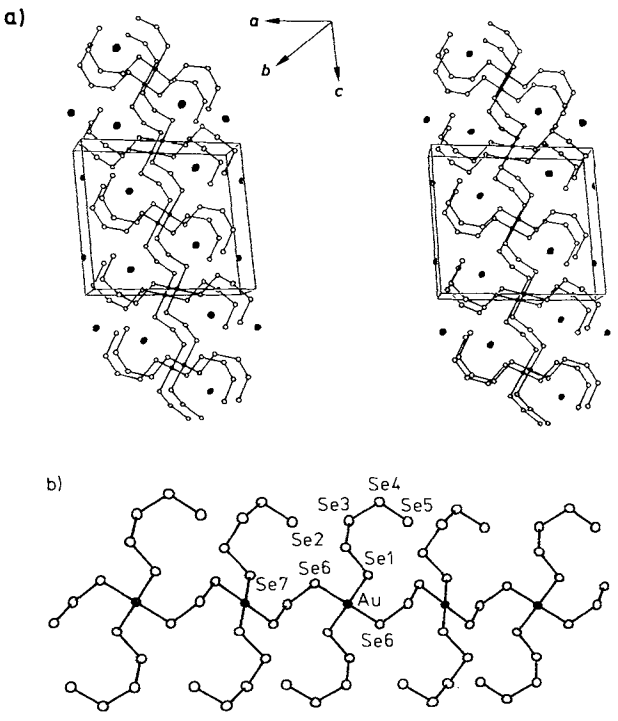

Fig. 2. ORTEP representation of the structure of the $[AuSe_{13}]_n^{3n\ominus}$ chains. a) Stereoscopic view of the unit cell. ●, K; ●, Au; ○, Se. b) A single chain with labeling scheme. Selected bond distances [Å] and angles [°]: Au-Se1 2.465(2), Au-Se6 2.485(2), Se1-Se2 2.349(3), Se2-Se3 2.368(3), Se3-Se4 2.348(3), Se4-Se5 2.343(3), Se6-Se7 2.351(3); Se1-Au-Se1 180, Se6-Au-Se6 180, Se1-Au-Se6 90.82(6); Se1-Au-Se6 89.19(6), Au-Se1-Se2 111.9(1), Au-Se6-Se7 108.92(8), Se3-Se4-Se5 109.2(1). Average Se–Se–Se angle 105.

to that of the $Se_5^{2\ominus}$ ligands in **1**. The Au···Se distances in **2** compare well with the corresponding distances in AuSe[15] (2.48 Å) and in the molecular compound $[Au_2Se_{10}]^{2\ominus}$[17] (2.45 Å). Unlike **1**, there are no close Au···Au contacts in **2**. Selected bond distances for K_3AuSe_{13} are given in the caption of Figure 2. The $K^{\oplus}$ ions reside in the cavities created by the Se atoms in the polyselenide chains. Compound **2** is the first solid-state compound to contain both $Se_3^{2\ominus}$ and $Se_5^{2\ominus}$ ligands and to our knowledge it is the most Se-rich Au compound to date. Conceptually, the $[Au(Se_3)(Se_5)_2]_n^{3n\ominus}$ chains can be viewed as the oxidative addition product of a $Se_{10}^{2\ominus}$ chain to the $Au^{\oplus}$ atoms of a hypothetical $[AuSe_3]_n^{n\ominus}$ chain, the latter being homologous to $[AuSe_5]_n^{n\ominus}$. The $[Au(Se_3)(Se_5)_2]_n^{3n\ominus}$ chain also represents the first example of a monodentate long polyselenide (i.e., $Se_5^{2\ominus}$), where one negative end is coordinated to a transition metal while the other is loose, ionically interacting with an alkali-metal ion. It should be noted that the usual binding mode of $Se_5^{2\ominus}$ is bidentate, either bridging as in **1**, $[V_2Se_{13}]^{2\ominus}$,[18] and $[In_2Se_{21}]^{4\ominus}$[19] or chelating as in $[Fe_2Se_{12}]^{2\ominus}$[20] and Cp_2TiSe_5.[21]

It is surprising that **2** forms by just changing the $K_2Se:Au:Se$ ratio from 2:1:8 (the ratio favoring formation of **1**) to 1.8:1:8. The small decrease in the K_2Se concentration results in a different K_2Se_x melt with a longer average polyselenide chain length compared to that present in the synthesis of **1**. The longer $Se_x^{2\ominus}$ chains would be more oxidizing than the corresponding short ones, which is consistent with the formation of **2**, a $Au^{3\oplus}$ compound. The slight but significant variation in the composition of the polyselenide melt (solvent) and the isolation of both $Au^{\oplus}$ and $Au^{3\oplus}$ polyselenide compounds underscores the complexity of these reaction mixtures and the delicate coordination and redox equilibria between the various $Au^{m\oplus}$ (m = 1,3) and $Se_x^{2\ominus}$ species. Such effects have been noted earlier in room-temperature solution studies on molecular Au/Se complexes.[17]

Further exploration of the effect of the polychalcogenide composition on the nature of the final K/Au/Se products is in progress.

Experimental Procedure

$KAuSe_5$, **1**: K_2Se, 0.157 g, 1.00 mmol), Au powder (0.098 g 0.5 mmol; 99.95%, Cerac), and Se powder (0.316 g, 4 mmol; 99.5%, Aldrich) were mixed in a Pyrex tube and sealed under vacuum (ca. 10^{-3} Torr). The reaction was carried out at 250 °C for 99 h before being cooled to room temperature at 2 °C h^{-1}. The reddish black needle-shaped crystals were obtained in a 74% yield by removing excess potassium polyselenides with water under inert atmosphere.

K_3AuSe_{13}, **2**: Same as for $KAuSe_5$ except that a 1.8:1:8 $K_2Se:Au:Se$ ratio was used. Black parallelpipeds were obtained. Yield 57%. The presence of K Au, and Se (semiquantitative analyses), as well as the homogeneity of the products, was established for all compounds by energy dispersive spectroscopy (EDS) in a scanning electron microscope.

Biomimetic Catalysis of an S_N2 Reaction Resulting from a Novel Form of Transition-State Stabilization**

By *David A. Stauffer, Richard E. Barrans, Jr.*, and *Dennis A. Dougherty**

Cyclophane host **1** is a general receptor for quaternary ammonium and immonium guests.[1] Complexation arises, in part, from an attractive "cation–π" interaction[1–3] between the positive charge of a guest and the polarizable, electron-rich π systems of the host. We now report that hosts such as **1** can act as biomimetic catalysts in aqueous media

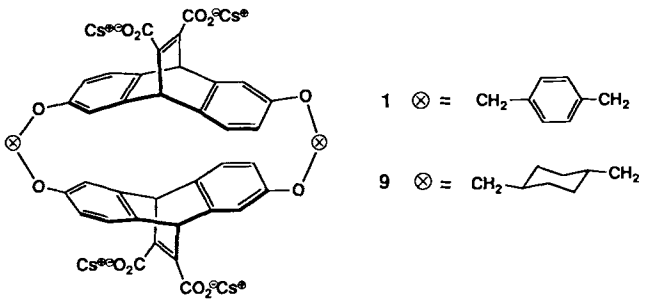
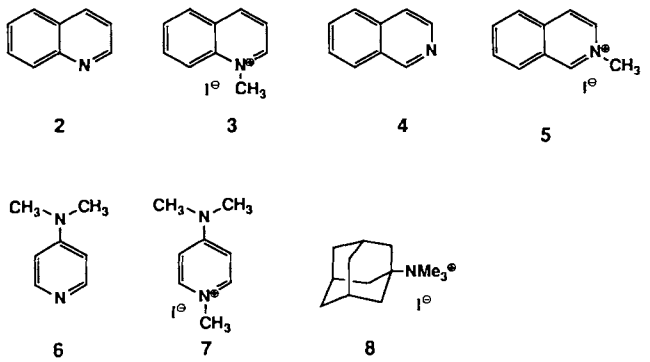
[**] This work (contribution No. 8010) was supported by the Office of Naval Research and the National Institutes of Health, *R.E.B.* was a Department of Education Graduate Assistance in Areas of National Need Fellow, 1989. Portions of this work were reported at the 187th National Meeting of the American Chemical Society, Dallas, TX, April 9–12, 1989.

for S_N2 reactions that develop a positive charge in their transition states.[4] In particular, the Menschutkin reaction[5] of methyl iodide with nucleophiles such as quinoline (**2**) is substantially accelerated by host **1**. We postulate that the cation–π interaction is also a major factor in the catalysis and that our findings may have implications for a broad range of biological methylation reactions.





Alkylation of nucleophiles such as **2**, **4**, and **6** with CH_3I in D_2O/borate buffer[1] (pD = 9) proceeds slowly to give **3**, **5**, and **7**. Addition of host **1** greatly accelerates the reactions. When excess CH_3I is used (pseudo-first-order conditions), the results are consistent with the kinetic scheme of Figure 1.[6] This is essentially a Michaelis–Menten scheme with

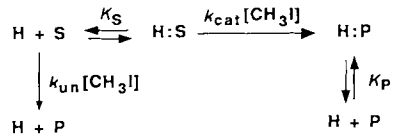


Fig. 1. Kinetic scheme applied to the alkylation reactions studied. H = host, S = substrate, P = product. k_{un} = rate constant for the uncatalyzed reaction.

some small, but important, distinctions. Since we already know[1] the binding constants for S and P (K_S and K_P), all ambiguities concerning the interpretations and interrelations[7] of the conventional Michaelis parameters (k_{cat} and K_M) are removed.[8] Another simplification is that all alkylation reactions are completely irreversible under the present conditions. Thus, the only unknown in Figure 1 is k_{cat}. A fit to the concentration vs. time data involves only one adjustable parameter, k_{cat}, so such rate constants can be obtained in a straightforward manner.

A variety of observations support the overall scheme. The reaction is first-order in CH_3I, and no rate acceleration is seen when the nonmacrocyclic analogue of **1** (dibenzyloxy derivative of 9,10-dihydro-9,10-ethenoanthrancene building block[11]) is used. In further support of the proposed kinetic scheme, the system shows competitive inhibition. Addition of adamantyltrimethylammonium iodide (**8**)[1] at a concentration that would occupy 40% of the host binding sites leads to a 40% decrease in the apparent k_{cat}. Product inhibition is also found, since the products (immonium ions) are always more tightly bound than the substrates.[1] Nevertheless, in optimal cases as many as five catalytic turnovers per host have been seen before product inhibition effectively shuts down the system. As shown in Table 1, k_{cat}/k_{un} can

attain values as high as 100, indicating substantial catalysis for these simple reactions.

Figure 2 places all quantities on a free energy scale. It is a trivial matter to determine ΔG°_T, the free energy of binding of

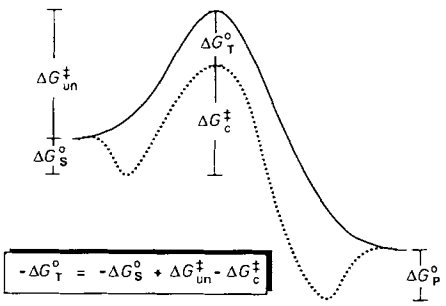

Fig. 2. Free energy diagram for catalyzed and uncatalyzed alkylations. Note that, by convention, activation energies are positive numbers, but favorable free energies of binding are negative numbers.—,uncatalyzed reaction; ····, catalyzed reaction.

the transition state (Table 1). There is no ambiguity as to the nature of ΔG°_T: it is precisely the free energy change on moving the S_N2 transition state out of water and into the receptor. Figure 3 provides a schematic of our model for the catalyzed reaction, with the receptor in the "rhomboid" conformation implicated by our previous studies[1] of the binding of flat, aromatic guests.

There are several possible interpretations of these findings. One could argue that we are simply desolvating the nucleophile by binding it, thereby enhancing its nucleophilicity. However, such reactions are generally accelerated in polar solvents,[5] and for the present systems, we have determined that the reactions of methyl iodide with both quinoline (**2**) and isoquinoline (**4**) are faster in our buffer system (without host) than in chloroform or benzene.[9] The catalysis we observe is therefore not a simple desolvation effect. Host **1** shows a substantial preference for electron-deficient guests,[1] and so it is difficult to ascribe any strong binding component to the leaving group, with its developing negative charge. The most likely origin of the catalysis, then, is the cation–π interaction. Host **9**, which is known to show a weaker cation–π effect than **1**,[1] is also a weaker catalyst (Table 1).

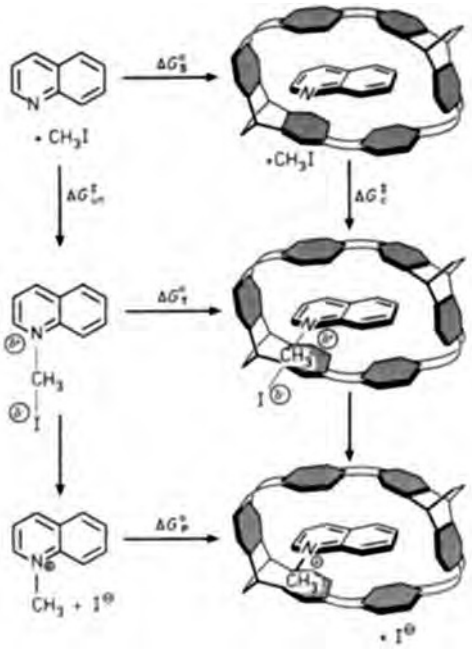

Fig. 3. Schematic of the catalyzed and uncatalyzed reactions of methyl iodide with quinoline.

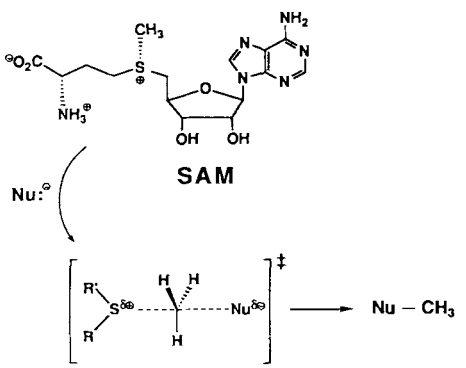
Interestingly, the transition state, with only a partial positive charge, is more tightly bound than the product, with a full positive charge, in all cases. We propose that the most reasonable explanation for this observation is that transition states, because of their long, weak bonds, are inherently more polarizable than ground states.[10] Host **1** completely surrounds a guest with electron-rich π systems (Fig. 3), and we suggest that the polarization of these π components in response to a guest dominates the binding behavior of **1**. With neutral guests, electron-deficient structures such as **2** are preferred over electron-rich indoles because of π-polarization effects.[1] With a positive charge, as in **3** or **8**, even more host polarization occurs. A transition state (Fig. 3) polarizes the host, and is itself polarized, creating even more favorable interactions. Water as a surrounding medium would be much less effective in this regard. The large dielectric constant associated with water is a low-frequency dielectric constant—that is, water stabilizes charges by reorienting its molecular dipoles, a relatively slow process. However, the high-frequency dielectric constant of water is quite low (i.e., water is not at all polarizable).[11] Because transition states are very short-lived, the high-frequency component is relevant to the present case. Water is simply not capable of an instantaneous response to the changes occurring in a transition state the way π electrons are.[12]



Scheme 1. Nu = DNA, tRNA, protein, sugar, olefins.

If, indeed, cation–π interactions are predominantly responsible for the transition-state binding, then the present system would represent an especially parsimonious realization of *Pauling*'s surmise[13] that enzymes preferentially bind transition states. One uses the same force—the polarization of π systems at the active site—to bind substrate, transition state, and product. The nature of the binding force, though, is such that it is most effective in binding a transition state.

Finally, we note that the overwhelming majority of biological methylation reactions are mediated by *S*-adenosylmethionine (SAM) (Scheme 1).[14] The transition states of these reactions resemble those bound by **1**, and we speculate that perhaps nature uses similar cation–π interactions to enhance these reactions. Efforts to find support for this hypothesis and to expand the scope of this type of catalysis are underway.

[2] a) In our previous work [1] we described this interaction as an "ion–dipole" effect. Although the term was intended to be descriptive only, we now believe it has an overly specific connotation. The stabilization of a positive charge by an electron-rich π system is no doubt a complex phenomenon, involving charge–dipole, charge–quadrupole, charge-induced dipole, π-polarization, and other effects. Ion–dipole implies, for example, a definite distance dependence ($1/r^2$) which may not be appropriate here. For a recent discussion of these various interactions as applied to protein chemistry, see [3a]. b) In the current system, the substrates are presumed to bind to the "rhomboid" conformation [1b] of the host. In this arrangement, face-to-face, π-stacking interactions are predominant, with both "linker" rings and two of the four aromatic rings of the ethenoanthracenes involved (see Fig. 3).

[6] Typical conditions: host concentration, 200 μM; initial concentration of substrate, 1 mM; CH_3I in at least 40-fold excess to ensure pseudo-first-order conditions. Reactions were monitored by 400-MHz ^1H NMR in a pD = 9 cesium borate buffer [1]. The (*S,S,S,S*) isomer of **1** and the (*R,R,R,R*) isomer of **9** were used. No evidence for binding of MeI to host or host–substrate complex was found. The formation of the host–substrate complex is much more rapid than alkylation and so is not rate-limiting [1].

[7] See, for example, C. Walsh: *Enzyme Reaction Mechanisms*, Freeman, New York 1979.

[8] Our model assumes that the thermodynamic host–substrate complex is kinetically competent. If, instead, a less stable binding mode is the productive one, then the value of k_{cat} would have to increase in order to compensate for the smaller percent of substrate bound (productively), and $\Delta G_T^{\ddagger}$ would, in fact, remain unchanged.

[9] $\Delta G_{298}^{\ddagger}$ [kcalmol^{-1}] for the reaction CH_3I + **2** (solvent): 24.8 (C_6H_6) [5b]; 24.4 ($CHCl_3$) [5b]; 23.9 (present borate buffer).

[10] Theoretical studies of S_N2 reactions support this notion: a) F. Carrion, M. J. S. Dewar, *J. Am. Chem. Soc. 106* (1984) 3531–3539; b) J. Chandrasekhar, S. F. Smith, W. L. Jorgensen, *ibid. 107* (1985) 154–163; c) *ibid. 106* (1984) 3049–3050; d) C. Bunton: *Nucleophilic Substitution at a Saturated Carbon Atom*, Elsevier, New York 1963; e) E. M. Arnett, R. Reich, *J. [12] One might argue that benzene as a solvent should also be able to stabilize the transition state through cation–π interactions. However, the host enforces a perfect alignment of the π systems, whereas the fluid solvent may not have the correct orientation as the transition-state forms.

1,2-Dimethyl-1,2-disila-*closo*-dodecaborane(12), the First Silicon Analogue of an *ortho*-Carborane **

By *Dietmar Seyferth,* Klaus Büchner, William S. Rees, Jr.*, and *William M. Davis*

The icosahedral carboranes, especially those in which the two cluster carbon atoms are vicinal (*o*-carboranes), have received much attention since the first reports of their existence in 1963.[1] Notably absent in the many publications on this class of boron cluster compounds over the intervening 25 odd years have been examples of icosahedral clusters in which the two monosubstituted carbon atoms of an *o*-carborane have been replaced by two monosubstituted silicon, germanium, tin, or lead atoms. We report here the synthesis and structural characterization of **1**, the first such fourth-main-group analogue of an *o*-carborane: 1,2-dimethyl-1,2-disila-*closo*-dodecaborane(12) (or 1,2-dimethyl-*o*-silaborane). This compound is notable also in that it is the first example of a *formal* derivative of a disilyne, $H_3CSi \equiv SiCH_3$ in the present case, a class of unsaturated organosilicon compounds of which there are to date no known examples.

The synthesis of 1,2-dimethyl-*o*-silaborane, **1**, was the result of a deviation from the expected reaction course when a benzene solution of decaborane(14) and bis(dimethylamino)methylsilane, $CH_3(H)Si[N(CH_3)_2]_2$, **2**, was heated at reflux under nitrogen. In prior work,[2] such a reaction of $B_{10}H_{14}$ with $(CH_3)_2Si[N(CH_3)_2]_2$ in refluxing benzene had resulted in formation of a linear polymer, $[6,9\text{-}(CH_3)_2NSi(CH_3)_2N(CH_3)_2 \cdot B_{10}H_{12}]_x$, a pale yellow, resinous material from whose melt fibers could be drawn and whose pyrolysis in a stream of ammonia to 1000 °C gave boron nitride containing 2–4% Si in high yield. However, the reaction of $B_{10}H_{14}$ with **2** in refluxing benzene or toluene resulted in formation of a mixture of two white solids, **1** in 15% yield, based on $B_{10}H_{14}$, and $6,9\text{-}[(CH_3)_2NH]_2B_{10}H_{12}$, **3**, in 58% yield [Eq. (1)]. The former could be purified by sublimation at 90 °C (0.01 Torr). Its yield has not been optimized. Compound **1** may be handled without exclusion of the laboratory atmosphere since it is stable to air and moisture.

$$B_{10}H_{14} + \underset{\mathbf{2}}{CH_3(H)Si[N(CH_3)_2]_2} \xrightarrow[-2H_2,\ -2(CH_3)_2NH]{\Delta} \underset{\mathbf{3}}{6,9\text{-}[(CH_3)_2NH]_2B_{10}H_{12}} + \underset{\mathbf{1}}{\text{Si}_2\text{C}_2\text{B}_{10}\text{H}_{12}} + \cdots \quad (1)$$

Very slow crystallization of **1** from dilute benzene solution at 3 °C gave the 1:1 solvate **1** · C_6H_6 as rods whose structure was determined by single-crystal X-ray diffraction.[3] The *o*-silaborane, like the *o*-carboranes, has a slightly distorted icosahedral structure (Fig. 1). The Si–Si bond distance of

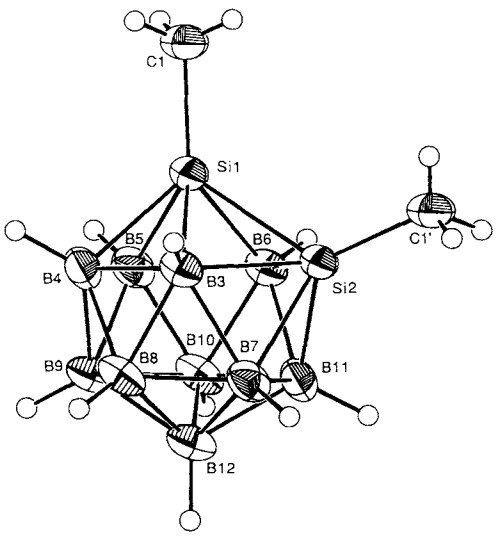

Fig. 1. ORTEP representation of **1**, drawn with 35% probability ellipsoids. Hydrogen atoms have been given arbitrary thermal parameters for clarity. Due to molecular symmetry, distances involving Si2 are equivalent to those involving Si1. Other symmetry related atoms are C1 and C2, B3 and B6, B4 and B11, B5 and B7, B8 and B10, and B9 and B12. Selected interatomic distances [Å] (standard deviations of the last digit given in parentheses): Si1-C1 1.827(3), B3-B4 1.848(5), Si1-Si2 2.308(2), B4-B5 1.859(5), Si1-B3 2.116(3), B4-B8 1.774(5), Si1-B4 2.018(3), B4-B9 1.765(5), Si1-B5 2.017(3), B5-B6 1.849(5), Si1-B6 2.113(4), B5-B9 1.769(5), B6-B10 1.771(4), B5-B10 1.765(5), B8-B12 1.782(5), B9-B12 1.775(8), B10-B12 1.784(5).

2.308(2) Å is slightly less than that of "normal" Si–Si single bonds (≈2.33–2.34 Å),[4] but significantly longer than known Si–Si double bonds.[5] In comparison, the C–C bond distances in *o*-carboranes (1.655 Å, the mean value found in X-ray and gas-phase electron diffraction studies[6]) are longer than the normal $C(sp^3)$–$C(sp^3)$ distance of 1.54 Å. This is understandable in terms of the larger size of a silicon atom (covalent radius 1.18 Å), compared with a carbon atom (covalent radius 0.77 Å). The Si–B bond distances in **1** (2.017(3), 2.018(3), 2.113(4), and 2.116(3) Å) are very close to the sum of the covalent radii of Si and B, 2.07 Å (using 0.89 Å as the average boron covalent radius in *o*-carboranes[6]). These distances may be compared to those of the

Si–B bonds in *commo*-3,3'-Si(3,1,2-$SiC_2B_9H_{11})_2$, which contains a single silicon atom bonded within a 12-atom boron-containing cluster: 2.05(1) and 2.14(1) Å.[7]

The ^1H, ^{13}C, ^{29}Si, and ^{11}B NMR spectra of **1** were recorded.[8] The ^{11}B NMR spectrum (160.367 MHz, [D_6]acetone, 25 °C, external $BF_3 \cdot OEt_2$) was in agreement with the 1,2-disila-*closo*-dodecaborane(12) cage structure, showing four doublets in 2:2:2:4 intensity ratio at $\delta = -11.2$ (d, $J = 147$ Hz, B9, 12), -12.6 (d, $J = 144$ Hz, B8, 10), -13.5 (d, $J = 152$ Hz, B3, 6), and -14.5 (d, $J = 147$ Hz, B4, 5, 7, 11). The assignments are based on a 2D proton-decoupled ^{11}B–^{11}B NMR spectrum. The CH_3 resonance was observed at $\delta = -0.07$ in the ^1H NMR spectrum of **1** in C_6D_6 solution. The proton-decoupled ^{29}SiNMR spectrum of **1** in C_6D_6 solution at 50 °C showed a singlet at $\delta = -37.77$, the proton-decoupled ^{13}C NMR spectrum, also in C_6D_6 at 40 °C, a singlet at $\delta = -12.80$. The upfield shifts observed in the ^{13}C and ^{29}Si spectra of **1** taken in C_6D_6 solution, as compared with TMS, are consistent with the well-documented electron-deficient nature of boron cages.

Compound **1** is less stable than the *o*-carboranes. It melts at 201–203 °C (sealed capillary) and decomposes with gas evolution above 230 °C. It remains undecomposed when heated at reflux in wet tetrahydrofuran solution for several days. It was unaffected when treated with an excess of CF_3CO_2H in THF at room temperature and remained largely undecomposed when this solution was heated at reflux for 14 hours. It was found to be stable toward $AlCl_3$ in refluxing benzene. It reacts with and is degraded by alcoholic KOH in THF at room temperature within minutes and it decolorizes a solution of bromine in carbon tetrachloride after several hours at reflux.

Now that the first member of this new class of boron cluster compounds has been isolated, it may be expected that other 1,2-$R_2Si_2B_{10}H_{10}$ compounds can be prepared. The development of their chemical reactivity at silicon and at boron will be of some interest as will a comparison of their chemistry with that of the *o*-carboranes.

Experimental Procedure

A 250-mL three-necked flask equipped with a reflux condenser, an addition funnel, and a magnetic stirring bar was flushed with argon and charged with $B_{10}H_{14}$ (6.6 g, 54.0 mmol) and dry toluene (120 mL). To the resulting solution was added dropwise at room temperature **2** (7.1 g, 53.7 mmol)[9]. The reaction mixture was stirred and heated at reflux under argon for 24 h. During this time a white solid precipitated. The reaction mixture was filtered and the filtrate evaporated at reduced pressure. The residue was extracted with two 100-mL portions of hot benzene. Filtration of the extracts and cooling to 3 °C resulted in deposition of 1.45 g of **1** as an amorphous white powder that contained a small amount of white needles. Evaporation of the remaining benzene solution gave 0.6 g of **3**, identified on the basis of its ^1H and ^{11}B NMR and mass spectra. The solid that had precipitated during the reaction was sublimed at 90 °C (0.01 Torr) to give an additional 0.15 g of **1**. The sublimation residue was 6.0 g of **3**. The total yield of the latter was 6.6 g, (58%). The total yield of **1** was 1.60 g, a yield of 15% based on $B_{10}H_{14}$. Correct C, H, Si elemental analyses; correct high-resolution mass spectrum.

Helicene Dianions: Paratropicity of Twisted Phenanthrene Dianions

By *Ron Frim, Albrecht Mannschreck,* and *Mordecai Rabinovitz**

The smallest polycyclic molecule with an enforced helical structure[1] is a three-ring system, namely, phenanthrene substituted at the 4,5 positions.[2] Like the other members of the helicene series, it belongs to the C_2 point group and hence is chiral. Such systems can be resolved into stable enantiomers if the barrier to racemization is sufficiently high. The neutral hydrocarbon species do not show a severe perturbation of the diatropicity according to their ^1H NMR spectra. In the neutral system where the HOMO–LUMO gap is wide, σ_{para} has an insignificant effect on the chemical shift.[3] Therefore, variations in the helicity do not significantly modify the ^1H NMR parameters.[4, 5] This phenomenon is illustrated by the chemical shifts of the protons at positions 9 and 10 in phenanthrenes **1**–**4** (Table 1). Reduction of these hydrocarbons with alkali metals can, in principle, give paratropic dianions.

These $4n\pi$ polycyclic dianions have been studied by NMR spectroscopy[3] with respect to two major parameters: (1) the electronic structure as related to paratropicity and (2) the detailed mode of electron delocalization. The correlation between the calculated HOMO–LUMO energy gap and the paratropicity as well as the NMR line shape was studied[5] without taking into account the different paths for delocalization of the various systems.

However, no study has taken into account the effect of the potential nonplanarity of such systems on their spectroscopic parameters. Our approach is to study a series of hydrocarbons and their double negatively charged derivatives, all of which have the same sp^2 skeleton and show a known degree of deviation from planarity[2] (see above). We assume that

the gross delocalization pattern is the same as long as the sp^2 carbon skeleton is maintained, and hence the relationship between the nonplanarity of the $4n\pi$ system and the NMR spectroscopic parameters can be studied. A system of choice is the charged $4n\pi$ helicene series in general and 4,5-disubstituted phenanthrenes in particular. The effects of their deviation from planarity should be reflected by both their electronic structure and their NMR spectra. Here we report the influence of the deviations from planarity on the ^1H NMR parameters of a series of dianions of 4,5-disubstituted phenanthrenes.

We chose to concentrate on alkyl-substituted phenanthrenes for two reasons: (1) the ability to modify the twist of the phenanthrene moiety by alkylation; (2) phenanthrene dianion shows a very significant dependence of its ^1H NMR line shapes on the type of reducing metal on the one hand and temperature and solvent on the other.[5] The $4n\pi$ phenanthrene dianion displays an intermediate HOMO–LUMO energy gap.[3–5] Systems with narrower energy gaps do not show resolved NMR spectra because of the relatively high concentration of a thermally excited or even a ground-state triplet. A wider energy gap will always give well-resolved NMR spectra, since thermal excitation to the triplet state is not possible. For that very reason, we thought that any minor change in the system's geometry and therefore in its energy gap would give rise to a very significant change in the NMR spectra. Indeed, twisted dianions derived from substituted phenanthrenes show a reduced degree of paratropicity and much narrower line shapes (Fig. 1 and Table 1). Our conclusion that these ions are twisted is confirmed by DNMR studies[6] and by theoretical calculations (MNDO,[7] MMX[8a]). The theoretical calculations are in good agreement with X-ray studies.[8b]

On going from the almost planar unsubstituted phenanthrene dianion ($\mathbf{1}^{2\ominus}$) to the dianions substituted by bulky alkyl groups, the ^1H NMR line shapes become much narrower and fine structures can be observed (Table 1). Phenanthrene dianion $\mathbf{1}^{2\ominus}$ with sodium as countercation shows no ^1H NMR spectrum down to a temperature as low as $-70\,^\circ C$. When lithium is the reducing metal, broad lines emerge at $-20\,^\circ C$. The spectrum is improved in terms of line shape as the temperature is further reduced. At $-70\,^\circ C$ one observes a well-resolved, easily interpretable NMR spectrum. The NMR results for 4-*tert*-butylphenanthrene dianion are very similar to those of phenanthrene dianion itself. The reason

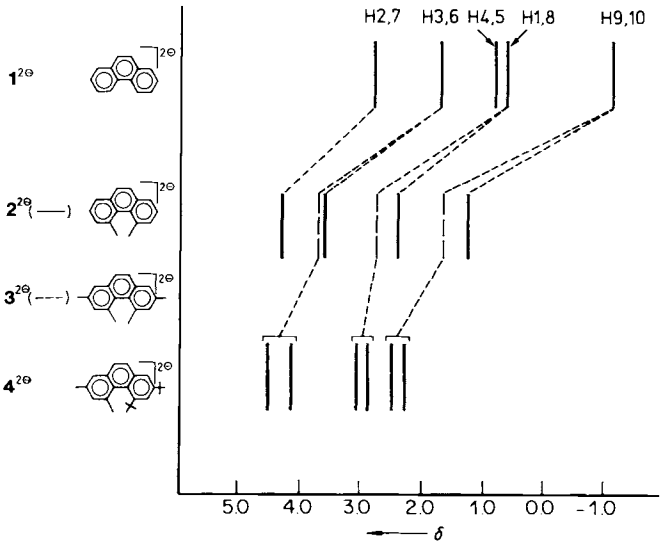

Fig. 1. ^1H NMR (200 MHz) chemical shifts of substituted phenanthrene dianions (as dilithium salts) represented by the stick diagram. The effect of helical twisting on the paratropic shift is clearly shown.

for this is the toothed-wheel effect that can take place when phenanthrene bonds become a little longer upon charging of the molecule. A greater degree of twisting can be achieved in 2,4,5,7-tetramethylphenanthrene dianion ($\mathbf{3}^{2\ominus}$), for which a significant narrowing in the line shapes is observed. When sodium was used to reduce the parent $(4n+2)\pi$ system **3**, we observed broad lines at $-20\,^\circ C$. At $-70\,^\circ C$ a spectrum with rather narrow lines (although without observable spin–spin couplings) is obtained. The lithium salt of this dianion shows a well-resolved spectrum even at room temperature. Conversion of 2,4-di-*tert*-butyl-5,7-dimethylphenanthrene (**4**) to its dianion resulted in an even more significant effect: $\mathbf{4}^{2\ominus}/2Na^{\oplus}$ shows already at $-20\,^\circ C$ a resolved spectrum, whereas, as expected, the dilithium salt shows a very well resolved spectrum at room temperature.

Dianions with additional alkyl substituents at positions other than 4 or 5 show line shapes very similar to those of the phenanthrene dianion substituted at positions 4 and 5 only

($\mathbf{2}^{2\ominus}$, Table 1). The more twisted the helicene is, the more the paratropicity of the 4nπ system is quenched.[4]

In order to study this phenomenon, we concentrated on the proton chemical shifts at positions 9 and 10 of the substituted phenanthrenes. The same trend is observed for the protons of the other positions. The 9,10 positions have the largest charge density, as deduced from NMR spectra and ωβ-HMO calculations for a doubly charged phenanthrene ($\mathbf{1}^{2\ominus}$). Without exception, the more twisted the phenanthrene moiety is, the less the spectrum is shifted towards higher field (Table 1). For example, in the spectrum of phenanthrene dianion ($\mathbf{1}^{2\ominus}/2Li^{\oplus}$) the resonances of protons at positions 9,10 are shifted to $\delta = -1.14$, whereas the resonances of the same protons in 2,4,5,7-tetramethylphenanthrene dianion ($\mathbf{3}^{2\ominus}/2Li^{\oplus}$) are shifted to $\delta = +1.65$. Thus, a dramatic chemical shift difference of 2.79 ppm results from the different paratropicities of $\mathbf{1}^{2\ominus}$ and $\mathbf{3}^{2\ominus}$. In the spectrum of 2,4-di-*tert*-butyl-5,7-dimethylphenanthrene dianion ($\mathbf{4}^{2\ominus}/2Li^{\oplus}$) those proton resonances appear at $\delta = 2.49$ and 2.28. In all cases studied the same charge distribution pattern has been observed. Changing the countercation, solvent, and temperature did not affect the observed trend of line shape and chemical shift differences.

The paratropicity of 4nπ "antiaromatic" systems and the line shapes of their ^1H NMR signals thus correlate with the degree of twisting. Since antiaromaticity (as well as aromaticity) requires an efficient delocalization, we believe that twisting of the system quenches its antiaromatic properties. Therefore, the paratropic shift and the NMR line shapes can be applied as probes for so-called "antiaromaticity".

The frozen solution was degassed and sealed under vacuum. The solution was then brought into contact with the metal by turning the tube upside down.

Correlations between Magnetism and Structure in Dinuclear $Cu^{II}Fe^{III}$ Complexes with Integer Spin EPR Signals**

By *Theodore R. Holman, Kevin A. Andersen, Oren P. Anderson, Michael P. Hendrich, Carlos Juarez-Garcia, Eckard Münck,* and *Lawrence Que, Jr.**

The relationship between structure and magnetism in coupled dinuclear transition metal complexes has attracted great interest among inorganic and bioinorganic chemists, due to the unique physical properties of these complexes[1] as well as their relevance to biological systems.[1, 2] The magnetism of these systems depends on the electronic configurations of the individual metal centers, which, in turn, determine their fundamental spectroscopic properties. Recently, we have developed a systematic method for synthesizing heterobimetallic complexes of the dinucleating ligand 2,6-bis(bis-2-pyridylmethylamino)methyl)-4-methylphenol (Hbpmp),[3] affording a series of $M^{II}Fe^{III}$ compounds.[4, 5] Herein, we report the structures of two $Cu^{II}Fe^{III}$ complexes[6] of $bpmp^{\ominus}$ which exhibit integer spin EPR signals that correspond to their markedly different magnetochemistry.[7]

$[Cu^{II}Fe^{III}(bpmp)(O_2CC_2H_5)_2](PF_6)_2$ **1a**

$[Cu^{II}Fe^{III}(bpmp)(O_2CCH_3)(OCH_3)](BPh_4)_2 \cdot 0.22\ CH_3CO_2H$ **2a**

X-ray structure analyses of **1a**[8, 9] and **2a**[9, 10] revealed the following features:

In **1a** the cation consists of a discrete, dinuclear $Cu^{II}Fe^{III}$ complex (Fig. 1, top), in which the two metals are bridged by the phenolate oxygen atom of the $bpmp^{\ominus}$ ligand and by two propionate groups. The $Fe^{III}\cdots Cu^{II}$ distance is 3.401(4) Å, consistent with those of similar triply bridged dinuclear cores.[4] The $bpmp^{\ominus}$ ligand and the propionate groups provide a six-coordinate, roughly octahedral ligand array about each of the metal atoms in **1a**, but the coordination environment about the Cu^{II} atom shows the effects of Jahn-Teller elongation along the N2–Cu–O3 axis.

In **2a** (Fig. 1, bottom), one of the bridging carboxylate groups of **1a** is replaced by a terminal methoxide ligand that is coordinated only to the roughly octahedral Fe^{III} atom, leaving the Cu^{II} atom five-coordinate. One Cu-ligand bond (Cu–O1 = 2.176(4) Å) is elongated considerably relative to the other four in **2a**; this pattern suggests that the bridging phenolate oxygen atom, O1, is best regarded as the apical ligand atom of a square pyramidal coordination array about Cu^{II}. The Fe–O1 bond is also elongated due to the influence of the methoxide ligand, as the strong Fe–OCH_3 interaction affords a short (1.849(4) Å) Fe–O bond and decreases the affinity of the Fe for the phenolate bridge. The lengthening of both M–O1 bonds in **2a**, relative to those in **1a**, is the primary factor in the elongation of the Fe···Cu distance by 0.24 Å, to 3.641(1) Å.

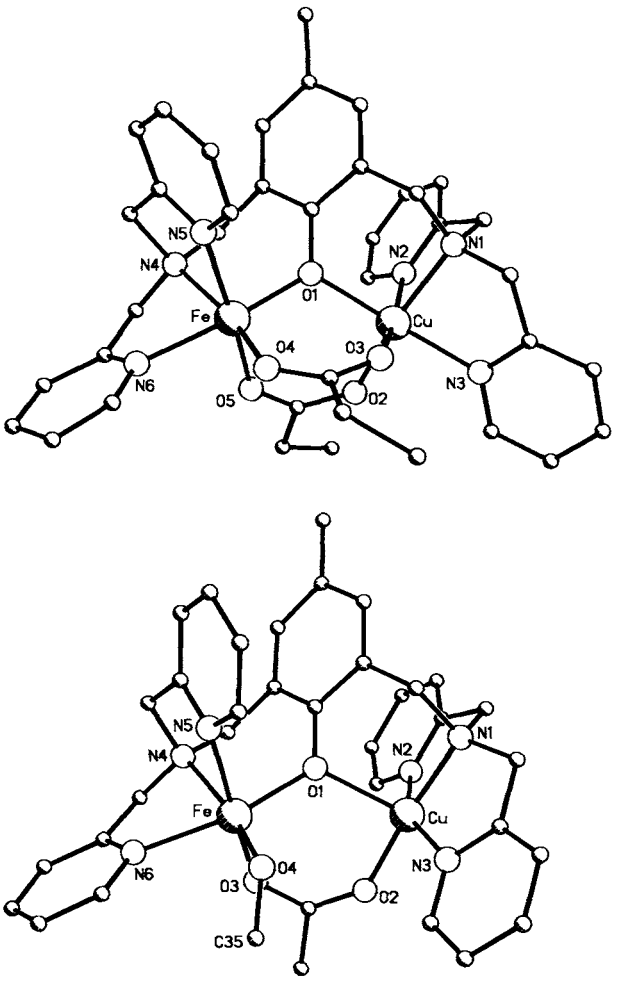

Fig. 1. Top: Structure of the dinuclear complex cation of **1a** in the crystal. Atoms are represented as spheres of arbitrary radii. Selected distances [Å] and angles [°]: Fe···Cu 3.401(4), Fe-O1 1.93(1), Fe-O4 1.90(2), Fe-O5 2.11(1), Fe-N4 2.15(1), Fe-N5 2.15(2), Fe-N6 2.12(2), Cu-O1 2.01(1), Cu-O2 1.94(1), Cu-O3 2.31(2), Cu-N1 2.09(1), Cu-N2 2.19(1), Cu-N3 2.03(1), <Fe-O1-Cu 119.3(5). Bottom: Structure of the dinuclear complex cation of **2a** in the crystal. Atoms are represented as spheres of arbitrary radii. Selected distances [Å] and angles [°]: Fe···Cu 3.641(1), Fe-O1 1.975(4), Fe-O3 2.016(4), Fe-O4 1.849(4), Fe-N4 2.255(5), Fe-N5 2.132(4), Fe-N6 2.175(5), Cu-O1 2.176(4), Cu-O2 1.945(4), Cu-N1 2.034(5), Cu-N2 2.006(4), Cu-N3 1.975(5), <Fe-O1-Cu 122.5(2).

The spectroscopic properties of the two complexes correlate well with their crystal structures. The Mössbauer parameters of **1b** ($\delta = 0.46$ mm/s; $\Delta E_Q = 0.42$ mm/s) are similar to those of other triply bridged complexes in this series.[4] In contrast, **2b** ($\delta = 0.49$ mm/s; $\Delta E_Q = 1.27$ mm/s) has the larger ΔE_Q value, most likely due to the presence of the short Fe–OMe bond. Magnetic susceptibility studies[11] indicate that the dinuclear center in **1b** is antiferromagnetically coupled ($J = 50\ cm^{-1}$ for $\mathcal{H} = JS_1 \cdot S_2$, $S_1 = 5/2$, $S_2 = 1/2$), while the center in **2b** is weakly ferromagnetically coupled ($J = -3\ cm^{-1}$) (Fig. 2). This difference in coupling

$[Cu^{II}Fe^{III}(BPMP)(O_2CCH_3)_2](BPh_4)_2$ **1b**

$[Cu^{II}Fe^{III}(BPMP)(O_2CC_2H_5)(OCH_3)](BPh_4)_2$ **2b**

interaction can be rationalized by inspection of the magnetic orbitals in the two complexes, assuming that the phenolate provides the principal coupling pathway.[1, 6c] For **1a**, the Jahn-Teller distortion on the Cu^{II} atom directs the magnetic

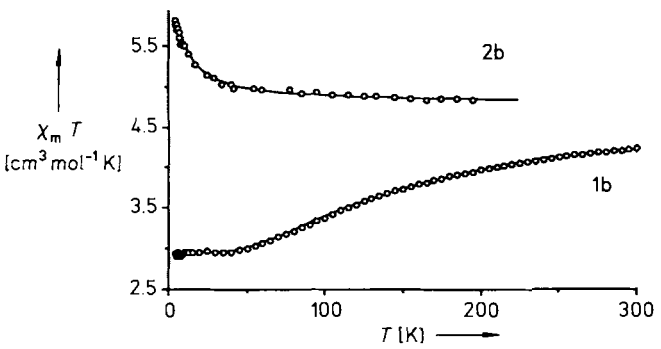

Fig. 2. Experimental (○○○) and theoretical (—) temperature dependence of $\chi_m T$ for **1b** and **2b**. Fitting parameters: **1b**, $J = 50\ cm^{-1}$, $D_{Fe} = 0.5\ cm^{-1}$, $E/D = 0.23$, $g_x = g_y = g_z = 2.0$, $D_{Cu} = 0$, $g_x = g_y = 2.08$, $g_z = 2.35$; **2b**, $J = -3\ cm^{-1}$, $D_{Fe} = 0.8\ cm^{-1}$, $E/D = 0.23$, $g_x = g_y = g_z = 2.0$, $D_{Cu} = 0$, $g_x = g_y = 2.12$, $g_z = 2.40$.

orbital along the axis of the phenolate bond and allows it to interact antiferromagnetically with the Fe^{III} magnetic orbitals. The elongation axis for the Cu^{II} atom in **2a**, however, is along the phenolate bridge; this places the magnetic orbital in the plane perpendicular to the phenolate bond and renders it orthogonal to the magnetic orbitals of the Fe^{III} atom, engendering the ferromagnetic interaction.

Interestingly, complex **1b** gives rise to a low field EPR signal at $g = 8$, while complex **2b** exhibits signals at $g = 12$ and $g = 8$ (Fig. 3). The intensity of the low field resonances

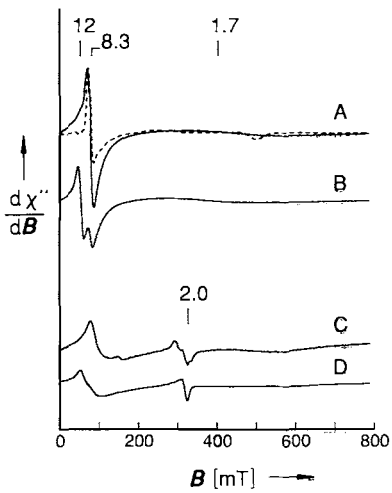

Fig. 3. EPR spectra of **1b** and **2b** in CH_3CN (4 mM) at 3 K. A) **1b**, $B_1 \| B$; B) **2b**, $B_1 \| B$; C) **1b**, $B_1 \perp B$; D) **2b**, $B_1 \perp B$. The dashed spectrum in A is a polycrystalline sample of **1b**. The signal at $g = 2.0$ is a preparation-dependent species, presumably a Cu^{II} impurity. An extremely broad signal at $g \approx 1.7$ has significant area under the absorption spectrum, but its origin is yet unclear. Instrumental parameters: 9.1 GHz at 0.02 mW, all below microwave saturation; modulation 100 kHz at 0.1 mT_{pp}; dB/dT, 3.3 $mT\,s^{-1}$. The frozen solution spectra are all properly normalized.

is approximately four times stronger when the microwave magnetic field B_1 is parallel to the static field B (parallel mode). The signal positions and enhanced parallel field intensities are indicative of transitions between levels of an integer-spin system.[12] The spectrum of polycrystalline **1b** (Fig. 3A, dashed) is similar to that of the dilute, frozen solution spectrum. This indicates that intermolecular magnetic interactions are small for the polycrystalline material and do not significantly affect the determination of J. The temperature dependence of the resonance at $g = 8$ for the complex

1b (Fig. 3A) indicates that it results from a ground-state doublet. A temperature study of complex **2b** indicates that the signals at $g = 12$ and $g = 8$ (Fig. 3B) are from ground and excited doublets, respectively. The line positions and temperature data suggest the following: for complex **1b**, the $g = 8$ resonance is from the ground state with $S = 2$ (antiferromagnetic coupling). For complex **2b**, the $g = 12$ signal is from the lowest doublet of the ground state with $S = 3$ (ferromagnetic coupling) and the $g = 8$ signal is from an excited doublet of either the $S = 2$ or $S = 3$ manifolds. The relative signs of the exchange couplings are in agreement with the magnetization results. The observation of integer spin signals from **1b** and **2b** and their correspondence to the magnetostructural data provide us with a set of complexes for further studies of integer spin systems and their spectroscopic manifestations.

Experimental

1a: A methanolic solution of Hbpmp (20 mL, 3.8 mM) was treated sequentially with 1 equiv. of $Fe(NO_3)_3$, 1 equiv. of $Cu(NO_3)_2$, and 2 equiv. of $NaO_2CC_2H_5$ to produce a purplish brown solution. After addition of 1 equiv. of NH_4PF_6, the solution was allowed to evaporate slowly to yield the crystals used for the X-ray diffraction study.

1b: A methanolic solution of Hbpmp (20 mL, 3.8 mM) was treated sequentially with 1 equiv. of $FeCl_3$, 1 equiv. $CuCl_2$, and 4 equiv. of $NaBPh_4$, resulting in a green solid (75% yield) formulated as $[Cu^{II}Fe^{III}bpmpCl_2](BPh_4)_2$. Treatment of an acetone solution of the green complex with 2.2 equiv. of AgO_2CCH_3 afforded a purplish brown solution, which was filtered to remove the AgCl solid. Vapor phase diffusion of ethyl acetate into the acetone solution furnished crystals of **1b** (50% yield). UV/VIS (CH_3COCH_3): $\lambda_{sh} = 500$ nm.

2b: A methanolic solution of Hbpmp (20 mL, 3.8 mM) was treated sequentially with 1 equiv. of $Fe(NO_3)_3$, 1 equiv. of $Cu(NO_3)_2$, and 4 equiv. of $NaO_2CC_2H_5$ to produce a red/brown solution. Metathesis with $NaBPh_4$ yielded a brown solid, which was recrystallized from acetone/methanol to yield crystals with the composition **2b** · $C_2H_5CO_2H$ (75% yield). UV/VIS(CH_3COCH_3): $\lambda_{sh} = 485$ nm.

2a: This complex was synthesized according to the procedure for **2b** with the exception that NaO_2CCH_3 was used in place of $NaO_2CC_2H_5$.

[8] **1a** was obtained mainly as highly efflorescent crystals which diffracted poorly. Among these crystals were a few thin, stable, plate-like crystals that belonged to the orthorhombic system, space group *Pnma* or $Pna2_1$, $Z = 4$, with $a = 20.849(6)$ Å, $b = 17.411(4)$ Å, $c = 12.587(3)$ Å, and $V = 4569$ Å^3 at 143 K. The structure was solved in $Pna2_1$ by using direct methods on 2530 unique reflections, 3371 measured. Refinement (anisotropic thermal parameters on non-hydrogen atoms, H atoms in idealized positions, 294 least squares parameters) converged at $R = 0.094$, $R_w = 0.124$, and GOF = 1.34.

[9] Details of crystallographic experiments: Nicolet R3m diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 0.7107$ Å), $\theta/2\theta$ scans, $4° < 2\theta < 45°$, $I > 1.25\sigma(I)$. Further details of the crystal structure analyses are available on request from the Director of the Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB21EW (UK), on quoting the complete journal citation.

[10] **2a** was obtained as red/green dichroic crystals in the triclinic system, space group $P\bar{1}$, $Z = 2$, with $a = 13.135(3)$ Å, $b = 13.503(3)$ Å, $c = 20.940(5)$ Å, $\alpha = 93.62(2)°$, $\beta = 93.81(2)°$, $\gamma = 92.76(2)°$, $V = 3693$ Å^3 (at 146 K). The structure was solved by using direct methods on 8886 unique reflections, 13899 measured. Refinement (anisotropic thermal parameters on non-hydrogen atoms, H atoms in idealized positions, 909 least squares parameters) converged at $R = 0.086$, $R_w = 0.082$, and GOF = 1.34 after placement of a fractional (occupancy factor = 0.22) molecule of acetic acid in the structural model.

[11] Magnetization data were collected on microcrystalline powders using a Quantum Design SQUID susceptometer over the temperature range from 1.9 to 300 K for **1b** and 1.9 to 200 K for **2b**, both at 0.31 T. We thank Dr. *E. P. Day* for his valuable help.

[12] Similar low field signals have been observed in other coupled FeCu systems [6e, 7b, 13].

Torand Synthesis by Trimerization—New Receptors for Guanidinium **

By *Thomas W. Bell** and *Jia Liu*

Toroidal complexing agents having exceptionally rigid, yet accessible cavities, may be composed entirely of smaller rings fused to form the perimeter of a macrocycle.[1, 2] The first examples of such hosts, termed "torands", are **1**[2] and the parent dodecahydrohexaazakekulene.[1] Preorganization of six pyridine dipoles by the hexagonal framework of **1** leads to exceptionally stable complexes of alkali metal cations.[2] Extension of this architecture to a molecular cleft[3] afforded "hexagonal lattice receptor" **2**,[4] which tightly binds a neutral organic molecule (urea), despite the inherently weaker interactions between neutral hosts and guests. Here we describe effective syntheses of a larger torand (**3**) and its nonmacrocyclic analogue (**4**), as well as the formation of 1:1 complexes between both new hosts and guanidinium chloride.

The 1,8-naphthyridine units of both new receptors were synthesized via Friedlander condensation of heteroaromatic *o*-aminoaldehydes with annelated cyclohexanones (Scheme 1). The common intermediate in the syntheses of **1**–**4** is benzylideneketone **5**, which was prepared in five steps from cyclohexanone and pentanal by previously described methods[2, 5] (23% overall yield). Condensation of **5** with 4-aminopyrimidine-5-carboxaldehyde gave **6**, which underwent acidic hydrolysis to aminoaldehyde **7**, isolated as its HCl salt. Condensation of **7** with **5**, followed by ozonolysis afforded diketone **2**, as previously reported.[4] This urea receptor was then converted into novel guanidinium receptor **4** in one step by alkaline condensation with 2-aminonicotinaldehyde.

A key to our new torand synthesis is the discovery that the *o*-aminoaldehyde functionality of **7** survives ozonolytic cleavage of the benzylidene group. Crude ketoaminoalde-

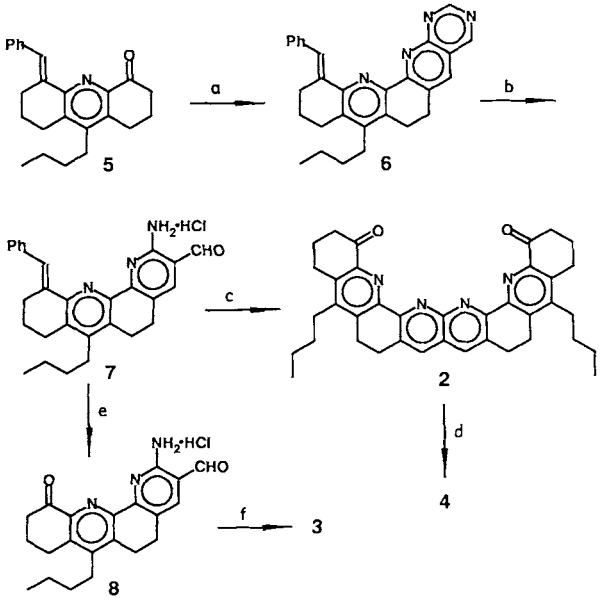
4

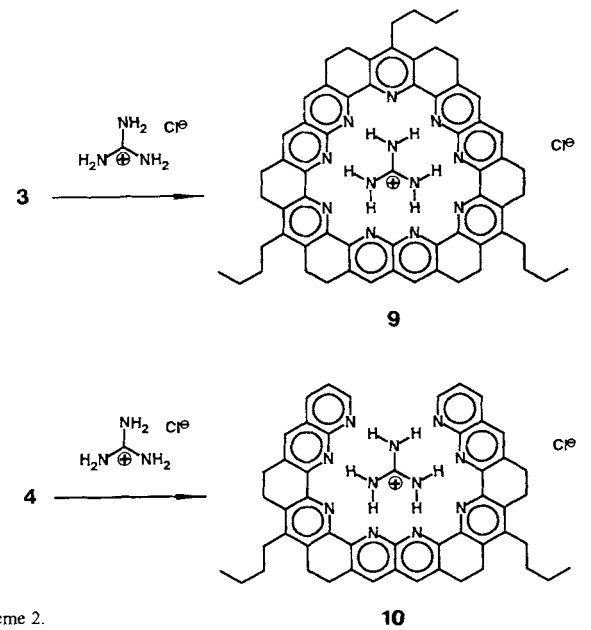
hyde **8** was obtained quantitatively by ozonolysis of **7** as the HCl salt. Ozonolysis of **7** as the free base did not produce isolable quantities of **8** or its free base. Intermediate **8** contains both the ketone and *o*-aminoaldehyde groups required to form **3** by cyclotrimerization. When **8** was treated with 1.1 equivalents of cesium hydroxide in ethanol, this new torand was formed in 38–49% yield according to ^{1}H-NMR analysis of the crude product with *p*-dimethoxybenzene as internal standard. It was isolated from the product mixture as a precipitate containing 1.1–1.5 equivalents of cesium per host molecule. Complexation of cesium was also demonstrated by appearance of the ion **3**·$Cs^{\oplus}$ (m/z = 1072) in the fast-atom bombardment mass spectrum (FABMS). In contrast to the high affinity of **1** toward alkali metal cations,[2] free torand **3** could be liberated simply by heating the cesium complex in boiling water. ^{1}H-NMR and ^{13}C-NMR spectra of **3** are consistent with the expected time-average symmetry (D_{3h}) and the protonated macrocycle gives rise to the base peak m/z = 940 of the FAB mass spectrum.

Torand **3** is the largest cycloarene derivative known to date.[6] Despite its larger size, **3** is available via trimerization in fewer steps and in higher overall yield than torand **2**.[2] Should this simple synthesis of a complex product be considered an example of "structure-directed" synthesis,[7] is it an example of the "cesium effect" in macrocyclization reactions,[8] or does it involve a more conventional "template effect"?[9] To address these questions we performed the cyclocondensation of **8** in the presence of potassium hydroxide, obtaining **3** in an optimum yield of 23% according to NMR spectroscopic measurements. For both CsOH and KOH, the yield of **3** was largest with 1.1 equivalents of base and dropped precipitously when more or less base was used. Whereas trimerization of intermediate **8** is in a sense preprogrammed by the geometric ideality of the product, cesium ion clearly enhances the yield of **3** relative to side products, which are probably nonmacrocyclic, higher molecular weight oligomers. Molecular modeling results suggest that although the cavity of **3** is somewhat large for cesium, this cation likely serves as a template by forming a complex with the trimeric helical intermediate, thus reducing the distance between reactive centers.[10]

Also according to molecular models, **3** and **4** are expected to bind guanidinium salts, forming 1:1 complexes **9** and **10**, respectively (Scheme 2). Results of molecular mechanics calculations (Macromodel) suggest that the lowest energy conformations of torand **3** are nearly planar, whereas those of **4** are helical, placing the terminal nitrogen nuclei approximately 7.3 Å apart. Thus, **3** should bind guanidinium to form six nearly ideal hydrogen bonds in **9** with little change in host conformation, whereas **4** must adjust to a more planar conformation in complex **10**.



Scheme 1. a: 4-aminopyrimidine-5-carboxaldehyde, KOH, MeOH, reflux (93%). b: 2N HCl, reflux (97%). c: 1. **5**, KOH, MeOH, reflux (97%); 2. O_3, MeOH, CH_2Cl_2, −78°C; 3. Me_2S (100%, 2 steps); 4. cryst. from CH_2Cl_2, *i*PrOH (71%). d: 2-aminonicotinaldehyde, KOH, EtOH, reflux (70%). e: 1. O_3, MeOH, CH_2Cl_2, −78°C; 2. Me_2S (100%, 2 steps); f: 1. CsOH, EtOH; 2. H_2O, reflux (28%).



Scheme 2.

In the experiment, solid guanidinium chloride is dissolved in CD_2Cl_2 solutions of **3** and **4** to form **9** and **10** respectively, as shown by guanidinium NH resonances occurring at $\delta = 10.4-10.9$ in the ^{1}H-NMR spectra. The stoichiometries of both complexes were confirmed by microanalysis, and peaks corresponding to $\mathbf{3} \cdot CH_6N_3^{\oplus}$ and $\mathbf{4} \cdot CH_6N_3^{\oplus}$ are observed in the FABMS spectra of **9** and **10**, respectively. The

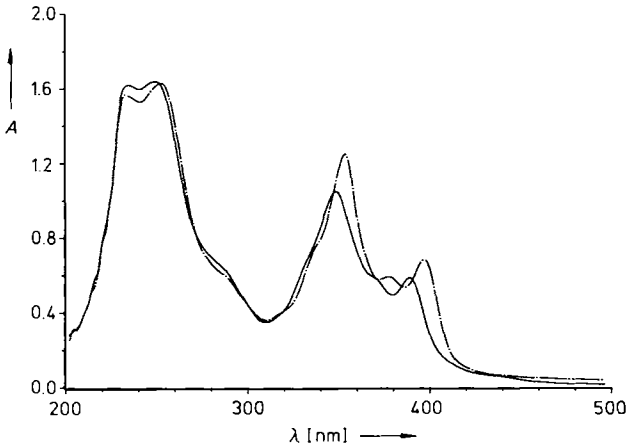


Fig. 1. UV/VIS spectra of receptor **4** in CH_2Cl_2 (1.5×10^{-5} M) before (solid line) and after addition of guanidinium chloride (broken line). A = absorbance.

UV absorption spectra of torand **3** and guanidinium complex **9** are nearly identical, whereas absorption maxima of **4** intensify and shift to longer wavelengths upon formation of **10** (Fig. 1). This result is consistent with the increased conjugation expected by modeling the "induced fit" of helical receptor **4** to guanidinium salts.

In summary, expedient synthesis of a geometrically ideal macrocycle by trimerization suggests that oligomerization approaches might be more generally applied to the preparation of complex unnatural products[11] and designed materials.[7] Exquisite preorganization of hydrogen bonding sites in **3** should result in molecular recognition of guanidinium salts. In contrast, the transduction of optical signals by flexible analogue **4** illuminates a path for the development of selective chemical sensors.[12]

Experimental

8: Ozone was bubbled through a yellow-orange solution of 0.92 g (2 mmol) of **7** in 110 mL of CH_2Cl_2 and 40 mL of methanol at −78 °C until the color of the solution changed to a pale greenish-yellow. Nitrogen was bubbled through the resulting solution for 5 min, then 1 mL of dimethyl sulfide was added and the reaction mixture was allowed to warm to room temperature. Solvents were removed by rotary evaporation. The residue was washed with 100 mL of ether, then dried to yield 0.78 g (100%) of crude **8**, which was suitably pure for direct conversion into **3**. Washing with $CHCl_3$ gave an analytically pure sample, m.p. 160 °C (dec). ^{1}H NMR (300 MHz, [D$_6$] DMSO): $\delta = 9.98$ (s, 1H; CHO), 8.73 (bs, 2H; NH_2), 8.60 (s, 1H; ArH), 3.11 (m, 4H; $ArCH_2CH_2Ar$), 3.00 (m, 2H; CH_2CO), 2.76 (m, 4H; $ArCH_2$-*n*-Pr, $CH_2CH_2CH_2CO$), 2.14 (m, 2H; $ArCH_2CH_2CH_2CO$), 1.45 (m, 4H; $ArCH_2CH_2CH_2CH_3$), 0.95 (t, ^3J(H, H) = 7 Hz, 3H; CH_3). ^{13}C NMR (75 MHz, [D$_6$]DMSO): $\delta = 195.7$, 191.8, 152.5, 151.0, 150.7, 146.1, 144.0, 143.0, 142.1, 137.7, 121.8, 117.5, 30.2, 27.9, 25.8, 23.3, 23.0, 22.6, 22.5, 21.6, 13.8. IR(KBr): $\tilde{\nu}$[cm^{-1}] = 3424, 3365 (NH), 1706 (C = O).

3: A mixture of **8** (0.35 g, 1 mmol), CsOH (0.2 mL of aq. solution, 1.1 mmol) and 150 mL of ethanol was stirred at room temperature under nitrogen for 30 min. Solvent was removed by rotary evaporation and 5 mL of $CHCl_3$ was added to the residue. The resulting mixture was cooled to 0 °C and filtered. The solid was recrystallized from 95% ethanol, then boiled in 25 mL of water for 3 h. The resulting mixture was cooled to room temperature and filtered to give **3** as a yellow solid (89 mg, 28%), m.p. 310 °C (decomp.). ^{1}H NMR (CD_2Cl_2): $\delta = 8.08$ (s, 6H, NaphH), 3.20 (m, 12H; $NaphCH_2CH_2Py$), 3.13 (m, 12H; $NaphCH_2CH_2Py$), 2.84 (m, 6H; $PyCH_2$-*n*-Pr), 1.55 (m, 12H; $PyCH_2CH_2CH_2CH_3$), 1.01 (t, ^3J(H, H) = 7 Hz, 9H; CH_3). ^{13}C NMR (CD_2Cl_2): $\delta = 156.0$, 150.6, 147.1, 135.8, 134.4, 134.3, 133.6, 123.0, 31.9, 28.9, 28.6, 24.8, 23.4, 14.0. UV/VIS (CH_2Cl_2): λ_{max} [nm](ε) = 226 (63000), 254 (130000), 290sh (40000), 370 (100000). FABMS (Xe$^{\oplus}$, 6–8 kV): m/z 940 ($M^{\oplus}$ + 1, 100%). Correct C, H, N analysis.

4: A solution of 0.59 g (1.0 mmol) of **2** and 0.3 g (2.5 mmol) of 2-aminonicotinaldehyde [13] in 25 mL of ethanol was heated to reflux, then 0.01 mL of 15% methanolic KOH was added. The resulting mixture was stirred at reflux under nitrogen for 24 h then cooled to room temperature. The crude product was collected by vacuum filtration and dissolved in 60 mL of CH_2Cl_2. The resulting solution was filtered to remove insoluble impurities. Ethanol (20 mL) was added to the filtrate, then the product was crystallized by slow evaporation at room temperature. Filtration gave 0.53 g (70%) of analytically pure **4** as a yellow solid, m.p. 220–240 °C (decomp.). ^{1}H NMR (CD_3OD): $\delta = 8.94$ (m, 4H; H-2,5,18,21), 8.77 (d, $^3J = 8$ Hz, 2H; H-4,19), 8.70 (s, 2H; H-11,12), 7.89 (dd, $^3J = 4$, 8 Hz, 2H; H-3,20), 3.49 (m, 16H, CH_2-6, 7, 9, 10, 13, 14, 16, 17), 3.11 (m, 4H, CH_2-*n*-Pr), 1.67 (m, 8H, $CH_2CH_2CH_3$), 1.09 (t, $^3J = 7$ Hz, 6H; CH_3). ^{13}C NMR (CD_3OD): $\delta = 156.3$, 155.8, 153.2, 151.6, 150.6, 146.7, 143.9, 142.5, 141.1, 140.8, 140.5, 139.2, 138.9, 136.2, 135.2, 126.7, 126.1, 126.0, 31.9, 30.0, 27.4, 26.9, 24.7, 24.3, 24.1, 14.2. UV/VIS (CH_2Cl_2): λ_{max} [nm] (ε) = 390 (32000), 349 (50000). FABMS: m/z 757 ($M^{\oplus}$ + 1, 100%).

[10] The macrocyclization intermediate, like **4**, is expected to have a helical minimum-energy conformation resulting from a 15–20° twist across each 2,2-bipyridyl linkage. Binding of Cs$^{\oplus}$ would stabilize conformations in which the heterocyclic dipoles converge. This effect can be significant despite the inexact match between the cavity radius of **3** (2.3–2.5 Å) and the ionic radius of cesium (1.7–1.9 Å, R. D. Shannon, *Acta Crystallogr. A 32* (1976) 751).

Topologically Interesting Cages for Negative Ions with Extremely High "Coordination Number": An Unusual Property of V-O Clusters**

By *Achim Müller,* Michael Penk, Ralf Rohlfing, Erich Krickemeyer*, and *Joachim Döring*

Dedicated to Professor Edwin Hengge on the occasion of his 60th birthday

Although the inclusion of molecules in oxidic solids, e.g. zeolites, has been known for some time and finds wide application, the first soluble oxide inclusion complex has only recently been obtained in the form of $[V_{12}O_{32}(CH_3CN)]^{4\ominus}$.[1a] Moreover, very little is known about other discrete inorganic host-guest systems. Mixed valence V^{IV}/V^{V}-O and V^{IV}-O clusters are, according to the results of our investigations, remarkable regarding their molecular and electronic structure, since, on the one hand, V^{IV}- and V^{V}-centers are present in almost any desired ratio, and, on the other, the coordination of the vanadium can be widely varied.[1] The formation of "hollow spheres" with unusual "cryptand properties" and interesting topology is possible by the linking of VO_5 pyramids.

The spherical cluster shells $\{V_{18}O_{42}\}$ **1** and $\{V_{15}O_{36}\}$ **2**, which deserve special mention here because of their topological properties, have in the compounds **1a, b** and **2a, b** (**2c** is included only for the discussion of the type of bonding) the

$Cs_9[H_4V_{18}O_{42}(X)] \cdot 12H_2O$ **1a**, X = Br; **1b**, X = I

$(NMe_4)_6[V_{15}O_{36}(Y)] \cdot 4H_2O$ **2a**, Y = Cl; **2b**, Y = Br

$Li_7[V_{15}O_{36}(CO_3)] \cdot$ ca. $39H_2O$ **2c**

remarkable and hitherto virtually unknown property of being able to encapsulate *negatively* charged ions, and even *such ions with significantly different radii.*

The characterization of the clusters was achieved by elemental analysis (including manganometric titration of V^{IV}), magnetic measurements, IR spectroscopy, thermogravimetry (for determination of the content of water of crystallization), and single-crystal X-ray structure analysis.[2] **1** is also present in the corresponding potassium salts containing water of crystallization (e.g. in $K_9[H_4V_{18}O_{42}(Cl)] \cdot 16H_2O$) with encapsulated $Cl^{\ominus}$ (**1c**), $Br^{\ominus}$ (**1d**), and $I^{\ominus}$ ions (**1e**); the complete X-ray crystallographic characterization, however, is more difficult than that of the cesium compounds,[3] which are less stable.

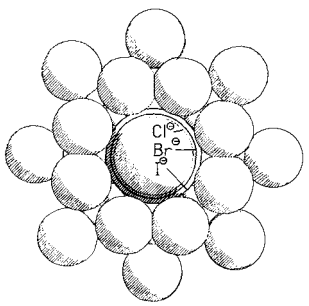

Fig. 1. Structure of a hemisphere of the inclusion compound of **1** with effective ionic radii (see text) and view along the virtual S_8 axis. Range of distances [pm] and mean values in brackets: $Hal^{\ominus}\cdots V$ 367.5–385.1 (374.7, **1a**), 368.3–386.4 (375.3, **1b**); $Hal^{\ominus}\cdots(\mu\text{-O})$ 363.6–370.1 (366.8, **1a**), 365.3–371.5 (368.2, **1b**).

In the inclusion compounds **1a, b** the distance from the center of the cluster to the O-atoms of the periphery is 367.5 pm and to the V-atoms 375.0 pm (mean value; cf. Fig. 1). A "close packing" of O-atoms and halide ions is therefore only possible in **1b** (effective ionic radii: $Cl^{\ominus} = 181$, $Br^{\ominus} = 196$, $I^{\ominus} = 220$, $O^{2\ominus} = 136$ pm;[4] formal consideration because of the covalently bound oxygen). **1**, with approximate D_{4d} symmetry, can be formally converted into $\{V_{18}O_{42}\}$ (**3**) by a 45° rotation of one hemisphere perpendicular to the S_8 axis[5] (Fig. 2), which, despite its size still has T_d symmetry and can be regarded as an enlarged Keggin shell.[6] **3** is formed in aqueous solution when only tetrahedral ions such as $SO_4^{2\ominus}$ or $VO_4^{3\ominus}$ are present, whereas **1** is formed in the presence of spherically symmetrical anions such as $Cl^{\ominus}$, $Br^{\ominus}$ or $I^{\ominus}$.

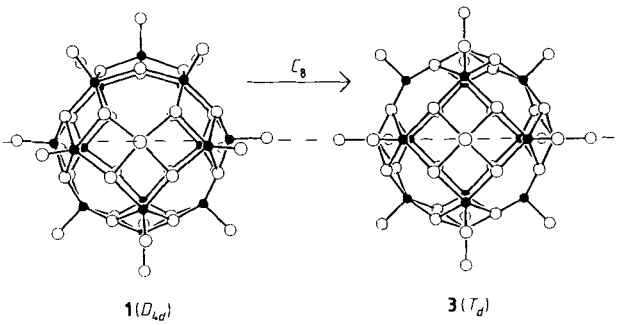

Fig. 2. Comparison of the structures of **1** and **3** (V = black, O = white), which can be interconverted by a C_8 rotation of a hemisphere (marked by a dotted line). The O-atoms of the shell in **1** form the "14th Archimedean solid" (cf. [9b]) and in **3** a distorted rhombicuboctahedron.

2 could be isolated with an encapsulated $Cl^{\ominus}$[1b] or $Br^{\ominus}$ ion, but also as the first heteropolyanion containing a $CO_3^{2\ominus}$ group (Fig. 3). **2** has crystallographic (**2a, b**) or approximate (**2c**) D_{3h} symmetry and formally contains eight V^{IV} centers and seven V^{V} centers. The atoms of the spherical shell in the anions containing **2** are at a distance of 323.6–388.2 pm from the center (cf. Fig. 3.), and the mean value (344.3 pm) corresponds approximately to the sum of the effective ionic radii of $Br^{\ominus}$ and $O^{2\ominus}$. In **2a** the $Cl^{\ominus}$ ion, despite its smaller radius, is, like the $Br^{\ominus}$ ion in **1a**, not disordered.

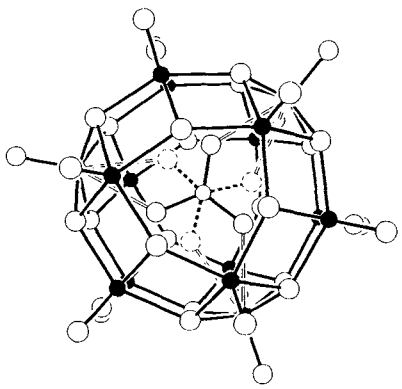

Fig. 3. Structure of the anion in **2c** in the crystal (V = black, O and C = white). The central $CO_3^{2\ominus}$ group is disordered at two positions one of which is dotted. Ranges of the distances [pm] and mean values in brackets for species containing **2**: center$\cdots$V 333.1–352.6 (343.0, **2a**), 335.6–354.6 (345.2, **2b**), 323.6–350.0 (342.6, **2c**); center$\cdots(\mu_3\text{-O})$ 333.4–339.2 (335.3, **2a**), 335.9–340.8 (337.5, **2b**), 329.6–347.0 (341.2, **2c**); center$\cdots(\mu_2\text{-O})$ 388.2 (**2a**), 383.6 (**2b**) 381.6–384.2 (383.3, **2c**).

[**] We thank Professor *K. Wieghardt*, Bochum, for carrying out the magnetic measurements.

In anions containing **1**, the central ion is surrounded by 18 V-atoms and 24 O-atoms (a grouping which seems to be crucial for inclusions,[7]), and in those containing **2** by 15 V-atoms and 21 O-atoms. Apparently, despite the large distances between the central halide ion and the V-atoms in the species containing **1** and **2** there are probably very weak covalent bonds which are decisive for the stability. Such interactions have hitherto never been discussed. In the case of classical covalent bonds, as in **2c**, where the three O-atoms of the central $CO_3^{2\ominus}$ group each form an O–V bond (225.6 to 232.5 pm), the distance of these three V-atoms from the center is significantly diminished (325.1 instead of 344.1 pm) and the O_{term}–V–(μ-O) angle is also reduced (101.4 instead of 106.8° in **2a** and **2b**).

In all compounds the metal centers are coupled antiferromagnetically, whereby some V^{IV}-centers in the mixed valence V_{15}-species are localized, as shown by the values of the valence bond sums.[8]

The 24 oxygen atoms of the spherical shells of **1** and **3** form (idealized) the corners of convex polyhedra having sides of equal length.[9] In **1** the so-called "fourteenth Archimedean solid" is present,[9b] in which all corners are equivalent. It can be easily converted into the rhombicuboctahedron (one of the usual Archimedean solids) by rotation of the upper hemisphere by 45° (cf. Fig. 2). This solid is formed by the corresponding 24 O-atoms of **3** with a strong "tetrahedral distortion". The basic solid of **2** cannot be attributed to a polyhedron with sides of equal length.

The reason for **1** and **2** being able to encapsulate species of different size, traces back to the preferred linking of tetragonal pyramids and the *trans* effect of the $V=O_{term}$ groups. In the case of polymolybdates and polytungstates the formation of hollow spheres is *not* observed because these elements prefer the MO_6 octahedral linking.

Experimental

1a: A stirred solution of $CsVO_3$ (1.16 g, 5.0 mmol) in H_2O (100 mL) was treated in a 100-mL Erlenmeyer flask (wide-necked) at 90 °C with 180 μL (3.7 mmol) of hydrazinium hydroxide (100%). Stirring was continued for 1 min, and then the flask and its contents (covered with a clock glass) were transferred to an oil bath and heated at 90–95 °C for 1 h. The dark brown solution (pH ≈ 8.2) was adjusted to a pH value of 7.9–8.0 by dropwise addition of a 47% aqueous HBr solution until the pH value remained constant. Then the flask and its contents were again placed in an oil bath at 90–95 °C for 1.5 h and finally cooled slowly within 5 h to 20 °C. The black crystals which precipitated were filtered off, washed with 50% aqueous 2-propanol, and dried on filter paper. Yield 0.2 g.

1b was prepared analogously to **1a** using a 57% aqueous HI solution. Yield: 0.2 g. The more stable potassium salts **1c**–**1e** were prepared analogously to the cesium salts **1a** and **1b** using KVO_3.

2b: A solution of $(NMe_4)Br$ (5.0 g, 32.5 mmol) in H_2O (75 mL) was treated at 60 °C with $(NH_4)_3[VS_4]$ (1.0 g, 4.3 mmol) in a 100-mL Erlenmeyer flask (wide-necked; covered with a clock glass); the flask and its contents were then placed on a hot plate (temperature of reaction mixture 60–65 °C) for 16 h. The color of the mixture changed from reddish-violet to dark brown. After filtration, the solution was allowed to stand for a further 5 d on the hot plate at 60–65 °C. The precipitated black crystals of **2b** were filtered off from the almost colorless supernatant solution, washed with H_2O, 2-propanol, CS_2 and diethyl ether, and dried in air. Yield 0.5 g.

2c: A suspension of Li_2CO_3 (5.88 g, 79.6 mmol) in H_2O (150 mL) was treated portionwise with stirring with 12 g (66 mmol) of V_2O_5 (evolution of CO_2) and stirring continued for 5 min. After filtration, the solution was treated portionwise with stirring at 90 °C in a 300-mL Erlenmeyer flask with 1.5 g (11.5 mmol) of hydrazinium sulfate and finally allowed to stand (covered with a clock glass) on a hot plate at 90 °C for 1 h. After renewed filtration the greenish-black solution was cooled to 20 °C in a sealed flask and treated with shaking with 50 mL of 2-propanol. The black crystals which precipitated out within 2–3 d at 5–7 °C were filtered off, washed with 50% aqueous 2-propanol, and dried on filter paper. Yield: 2.5 g. Characteristic IR absorption bands (solid: CsI pellet) for all compounds containing the cages **1** and for **2a, b**: $\tilde{\nu}$[cm^{-1}] = ca. 965 (vs) ($\tilde{\nu}(V=O_{term})$), 700, 615 (s) ($\tilde{\nu}_{as}$(V–O-V), **1**); 980 (vs) ($\tilde{\nu}(V=O_{term})$), 720 (m), 655 (s) ($\tilde{\nu}_{as}$(V–O–V), **2**); magnetic measurements (Faraday balance, microcrystalline solids): e.g. **1e**: μ_{eff} = 4.5 μ_B (293 K), 3.4 μ_B (81 K); comparable values for the remaining compounds.

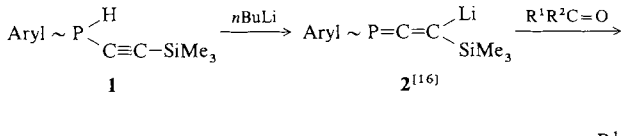
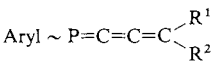
synthesis of phosphacumulenes. Thus, the phosphabutatrienes **3**, for example, were synthesized by reaction of **2** with carbonyl compounds in a Wittig-Peterson reaction.[2]



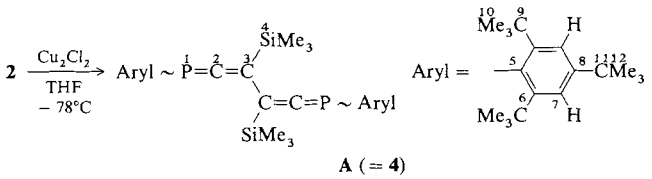
1 **2**[16]

Aryl = 2,4,6-tBu$_3$C$_6$H$_2$

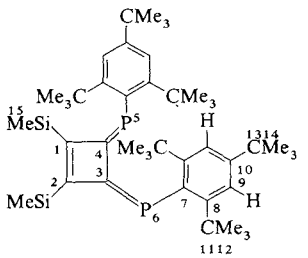


3

We have now found that **2** can be formally coupled oxidatively with Cu_2Cl_2 at $-78\,^{\circ}C$ in THF in the sense of the reaction of vinyl-carbenoids with $Ag^{\oplus}$, $Cu^{2\oplus}$, $Fe^{3\oplus}$ (formation of butatrienes) described by *G. Köbrich*.[3] Three products, **4** (colorless crystals, m.p. 131–133 °C, ^{31}P NMR (101.26 MHz, C_6D_6/C_6H_6): $\delta = 45.07$), **5** (yellow crystals, m.p. 145–147 °C (decomp), ^{31}P NMR: $\delta = 164.91$), and **6** (red needles, m.p. 187 °C (decomp), ^{31}P NMR: $\delta = 131.9$) are obtained, which, according to the mass spectra (m/z = 747.2), have the empirical formula $C_{46}H_{76}P_2Si_2$ of the primarily expected coupling product **A** (numbering arbitrary). That **4**, **5** and **6** are closely related is also indicated by their almost identical mass spectra (EI-MS, 70 eV).

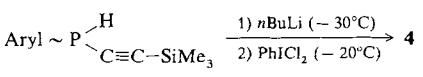


A (= **4**)



5

According to an X-ray structure analysis (Fig. 1; note: numbering different from the likewise arbitrary numbering in the formula),[4] the yellow compound is the unsymmetrical bis(arylphosphanediyl)cyclobutene **5**.[5] The cyclobutene ring of **5** is almost planar, the folding angle at the C1–C3 axis is 1.5°. The two phenyl rings (C5–C10 and C23–C28) are almost perpendicular to the four-membered ring (86.7, 95.6°).



1

The 1,6-diphospha-1,2,4,5-hexatetraene **4**, whose spectroscopic data[7] are consistent with the proposed constitution,

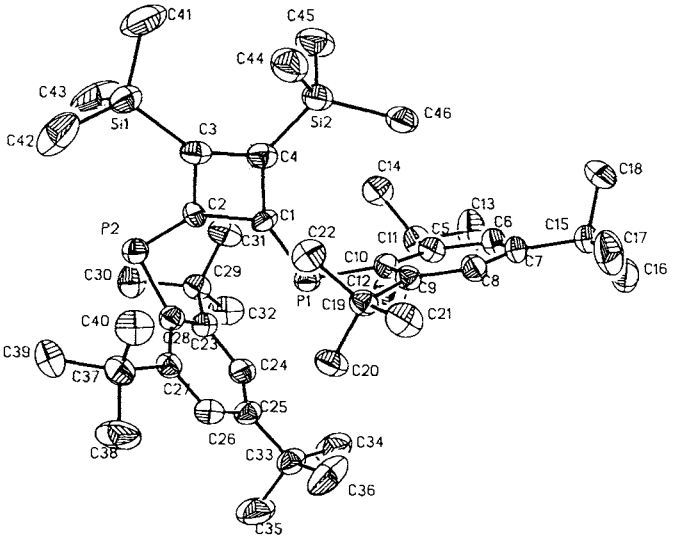


Fig. 1. Structure of the bis(arylphosphanediyl)cyclobutene **5** in the crystal(ORTEP). Selected bond lengths [pm] and angles [°]: P1-C1 166.8(4), P2-C2 166.8(3), Si1-C4 188.0(4), Si2-C3 188.3(4), C1-C2 151.3(5), C2-C3 148.5(5), C1-C4 150.7(5), C3-C4 139.0(5); C1-P1-C10 108.8(2), C2-P2-C28 102.6(2), P1-C1-C2 125.4(2), P1-C1-C4 147.0(3), P2-C2-C3 129.9(3), P2-C2-C1 142.3(3), C1-C2-C3 87.7(3), C1-C4-C3 91.6(3), C2-C3-C4 93.1(3).

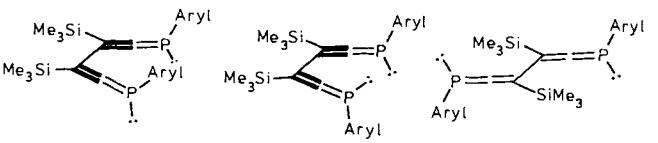
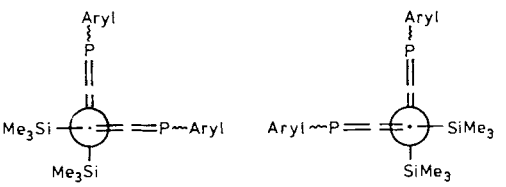
is also accessible by reaction of the lithium compound **2** with $PhICl_2$ at $-20\,^{\circ}C$ in an ionic coupling reaction.[6]

The colorless coupling product **4** slowly transforms into **5** in $CHCl_3$ solution at room temperature. The following interpretation provides for the correlation of **4** with **5** and **6**: the radical coupling of **2** with Cu_2Cl_2 leads statistically to three stereoisomeric (axially chiral allenes) hexatetraenes **4a** (*meso* form) and **4b** (racemate: *R,R* and *S,S*).



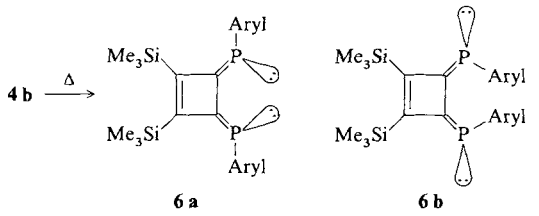
meso-**4 a**(s-*cis*) *rac*-**4 b**(s-*cis*) *meso*-**4 a**(s-*trans*)



M-**4** *P*-**4**

Furthermore, the *meso*-form as well as the racemate are not planar, but are present in the two mirror image orthogonal helical conformations *M*-**4** and *P*-**4**, whose interconversion can only take place via the energy-rich planar s-*trans* or s-*cis* transition states.[9]

The electrocyclic reactions of **4** to **5** and **6** are only possible via the planar s-*cis* conformations of **4**; the energy barrier for rotation of *M,P*-**4** to s-*cis*-**4** should be markedly higher than that for the rotation to s-*trans*-**4**. The conrotatory ring closure reaction of the 1,3-diene system of *meso*-**4a** (s-*cis*) affords **5**. The cyclization of *rac*-**4b** (s-*cis*) must lead to the bis(phosphanediyl)cyclobutenes **6a, b**; the steric hindrance in **6b**, however, would suggest that exclusively the red isomer **6a**[10] is formed.



Because of the *trans* arrangement of the sterically very demanding aryl residues, *rac*-**4b** can rotate more easily into the s-*cis* conformation, i.e. *rac*-**4b** cyclizes quantitatively to **6a** under the reaction conditions. In *meso*-**4a**, s-*cis* geometry is sterically more strongly hindered because of the *cis*-arrangement of the aryl residues. Hence, the isolable, colorless coupling product **4** ought to be s-*trans*-*meso*-**4a**, which—due to the stability of the substituents at the phosphorus atoms toward inversion—converts only slowly and exclusively into **5** in solution (e.g. in $CHCl_3$). A slow electrocyclic ring opening of **5** to give the open-chain hexatetraene **4** is observed at 120 °C, whereas **6a** remains unchanged upon heating to 150 °C.

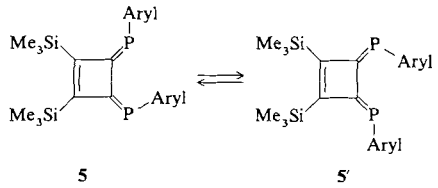
[7] **4**: 25%, recrystallization from EtOH; ^{1}H NMR: $\delta = 0.17$ (s; $SiMe_3$), 1.41 (s; *p*-*t*Bu), 1.49 (s; *o*-*t*Bu), 7.32 (br. s; phenyl-H); ^{13}C NMR (C_6D_6): $\delta = 234.02$ (br. d, $^1J(P/C) = 37.6$ Hz; C-2), 115.60 (dd, $^2J(P/C) = 18.7$ Hz, $^3J(P/C) = 13.2$ Hz; C-3), 0.45 (s; C-4), 130.16 (d, $^1J(P/C) = 66.3$ Hz; C-5), 154.77 (d, $^2J(P/C) = 2.6$ Hz; C-6), 122.04 (s; C-7), 149.59 (s; C-8); UV (*n*-hexane): $\lambda_{max} = 218$ nm ($\lg \varepsilon = 4.69$), 260 (4.54), 310 (sh, 4.01) [8].

[8] The phosphaallenes Aryl–P=C=CHR absorb at 220 nm, the molar extinctions $\varepsilon = 20\,000$–$25\,000$ are about half that of **4**.

[9] a) The G^* values of the thermal s-*cis*/s-*trans* racemization were determined for several 2,3-hexadienes. For the structural element =CCl–CCl=, G^* values of 68–70 were found [9b], for =CBr–CBr=, values of 102–104 [9c, d], and for =CMe–CMe=, values of 58–73 kJ mol^{-1} [9e]. b) H.-O. Bödecker, V. Jonas, B. Kolb, A. Mannschreck, G. Köbrich, *Chem. Ber. 108* (1975) 3497; c) M. Rösner, G. Köbrich, *Angew. Chem. 86* (1974) 775; *Angew. Chem. Int. Ed. Engl. 13* (1974) 741; d) G. Becher, A. Mannschreck, *Chem. Ber. 114* (1981) 2365; e) *ibid. 116* (1983) 264.

[10] **6a**: 15%, recrystallization from benzene/CH_3CN; ^{1}H NMR: $\delta = -0.25$ (s; $SiMe_3$), 1.39 (s; *p*-*t*Bu), 1.70 (s; *o*-*t*Bu), 7.47 (br. s; phenyl-H); ^{13}C-NMR ($CDCl_3$): $\delta = 180.9$ (pt, $J = 6.6$ Hz; C-3), 177.8 (pt, $J = 6.2$ Hz; C-1), 127.9 (pt, $J = 8.8$ Hz; C-7), −0.40 (s, C-15); UV (*n*-hexane): $\lambda_{max} = 230$ nm ($\lg \varepsilon = 4.40$), 289 (4.51), 306 (4.42), 360 (sh, 3.97).

[11] Thus, the fact that all NMR signals appear only singly in **5**, despite the unsymmetrical structure, cannot be explained in terms of a rapid ring-opening **5** → **4** and renewed conrotatory ring closure. The mechanism required from the



(a)

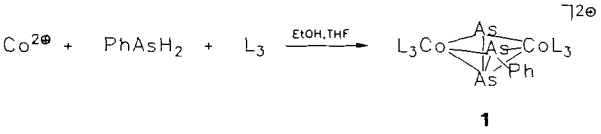
NMR data, rapid degenerated rearrangement (a)—with exclusion of a synchronous inversion at the phosphorus atoms—is still unclear.

The Azide Homologues Et–PPP and Ph–AsAsAs as Bifacially Coordinated Ligands in Tripod-Cobalt Complexes: Synthesis, Structure and Molecular Dynamics**

By *Annette Barth, Gottfried Huttner,* Martin Fritz,* and *Laszlo Zsolnai*

Dedicated to Professor Luigi Sacconi

It is already known from the works of *L. Sacconi* et al.[1] that tripod-metal complex fragments (tripod)M (tripod = $CH_3C(CH_2PPh_2)_3$) are especially suitable for the stabilization of unusual ligands. On attempting to exploit tripod-cobalt complex fragments for the synthesis of arsinidene complexes[2, 3] we at first unexpectedly obtained complexes of the type $[(tripod)Co\text{-}\mu_2\text{-}(\eta^3\text{-}PhAs_3)Co(tripod)]^{2\oplus}$ **1**, which contain the azide-homologous fragment $PhAs_3$.



1

$CH_3C(CH_2PPh_2)_3$ = L_3

The cationic complex **1** is formed upon reaction of $Co(BF_4)_2 \cdot 6H_2O$ with $PhAsH_2$ in the presence of tripod. The reaction is accompanied by evolution of gas. After evaporation of the black reaction solution to dryness, **1** crystallizes as the $BF_4^\ominus$ salt in yields of 50% within three days.

The field desorption mass spectrum of **1**-$(BF_4)_2$ shows the signal with $m/2z = 834$ expected for the dication **1**. In the ^{1}H-NMR spectrum of **1**-$(BF_4)_2$ the signals corresponding to the organic building blocks are observed in the expected intensity ratio. In the ^{31}P-NMR spectrum, a broad signal appears at $\delta = 25.4$ for the tripod ligands. Proof of the identity of **1** was afforded by an X-ray structure analysis[4] (Fig. 1).

The As–As distances confirm that there is no direct bonding between the terminal arsenic centers As1 and As3. The bonding As–As distances in **1** are large in comparison to those in the recently described monofacially coordinated

[**] This work was supported by the Fonds der Chemische Industrie and the Deutsche Forschungsgemeinschaft (SFB 247).

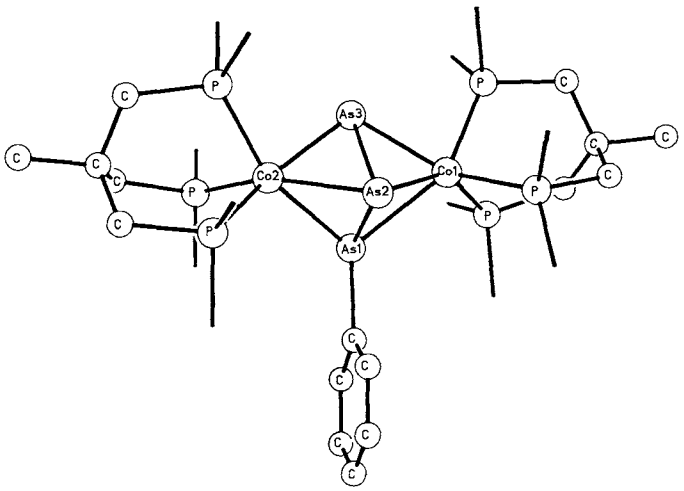

Fig. 1. Structure of **1**-$(BF_4)_2$ in the crystal (phenyl rings of the tripod ligand not shown). Selected bond lengths [pm] and angles [°]: Co–P 220.3–228.5, Co1–As1 261.3, Co2–As1 255.5, Co1–As2 242.3, Co2–As2 245.0, Co1–As3 238.1, Co2–As3 234.4, As1–As2 240.3, As2–As3 247.6, As1···As3 283.0; As1–As2–As3 72.0 (deviation maximally 0.7 units referred to the last decimal place).

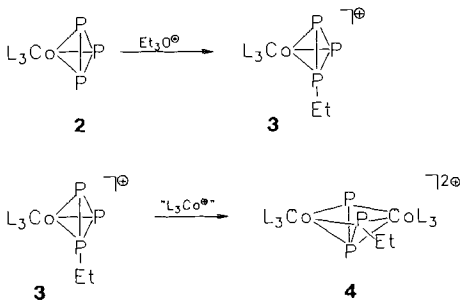
Ph_2As_3 in $[Cp^*(CO)_2Mo(\eta^3\text{-}Ph_2As_3)]$ (As–As distances 236 pm).[5] In spite of the bifacial coordination of the $PhAs_3$ ligand in **1**, the mean value of the As–As distances is shorter than an As–As single bond.[6]

Attempts to prepare the phosphorus compound analogous to **1** with $PhPH_2$ as source of PhP_3 ligand have so far met without success. The dication **4** $[(tripod)Co\text{-}\mu_2\text{-}(\eta^3\text{-}EtP_3)Co(tripod)]^{2\oplus}$ analogous to **1** could, however, be synthesized via a circuitous route. The reaction of **2**[7] with $Me_3O^\oplus$ leading to $[(tripod)Co(\eta^3\text{-}MeP_3)]^\oplus$ is already well known.[8] **2** reacts analogously with $Et_3O^\oplus$ to give **3**. This, in turn, reacts with $Co(BF_4)_2 \cdot 6H_2O$ and tripod to give **4**-$(BF_4)_2$, which initially precipitates as microcrystalline, analytically pure solvent adduct **4**-$(BF_4)_2 \cdot 2EtOH$. Crystals



suitable for an X-ray structure analysis were obtained by recrystallization as the solvent-adduct **4**-$(BF_4)_2 \cdot 0.5$ THF from $THF/CH_2Cl_2/Et_2O$. The X-ray structure analysis verifies the analogous structure of **1** and **4**.[4]

The P1–P3 distance (262 pm) confirms the open structure of the EtP_3 unit in **4**. The P–P distances in the EtP_3 ligand are, on average, shorter than a P–P single bond;[9] the distribution of short and of long bond lengths in the EtP_3 unit of **4** does not correspond to the distribution of the As–As bond lengths in the $PhAs_3$ unit of **1** (Fig. 1 and Fig. 2). Hence, it may be assumed that the bifacially coordinated ligands RX_3 (X = As, P) are fluctional systems. This assumption is confirmed by the temperature dependence of the ^{31}P-NMR spectrum of **4**-$(BF_4)_2$. At 293 K, a broad signal is observed for the phosphorus centers of the tripod ligands ($\delta = 17.8$),

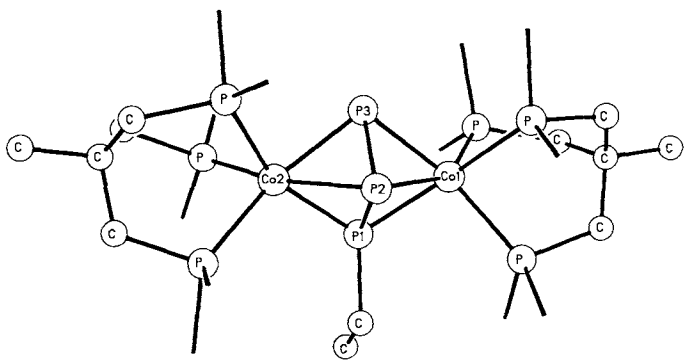


Fig. 2. Structure of **4**-$(BF_4)_2 \cdot 0.5$ THF in the crystal (phenyl rings not shown): selected bond lengths [pm] and angles [°]: Co-P (tripod) 219.0–232.6, Co1-P1 221.4, Co2-P1 218.9, Co1-P2 243.7, Co2-P2 239.3, Co1-P3 228.9, Co2-P3 229.9, P1-P2 222.1, P2-P3 211.0, P1···P3 262.0; P1-P2-P3 74.1 (standard deviations maximally one unit referred to the last decimal place).

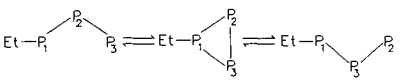
which splits at 221 K into three narrowly separated singlets ($\delta = 28.8, 16.4, 8.1$). The broad signal observed at 293 K for the EtP_3 ligand ($\delta = 158$) becomes a broad doublet ($\delta = 178$) at 221 K. In addition, a doublet appears at $\delta = 260$ ($^1J(PP) = 300$ Hz) and a triplet at $\delta = -270$ ($^1J(PP) = 300$ Hz). These two new signals reversibly coalesce on heating the sample, but are not visible at room temperature. The limiting case of the rapid exchange of the two phosphorus centers, which should lead to a sharp signal at $\delta = -5$ cannot be observed, since the sample cannot be heated to the required temperature without decomposition. The low-temperature spectrum corresponds to a static structure of **4** resembling that depicted in Figure 2. The doublet at $\delta = 260$, with two almost identical $^1J(PP)$ coupling constants (300 Hz), can be assigned to the terminal phosphorus P3, the triplet at $\delta = -270$ to the "central" P2, and the doublet at $\delta = 178$ to the ethyl-substituted P1.

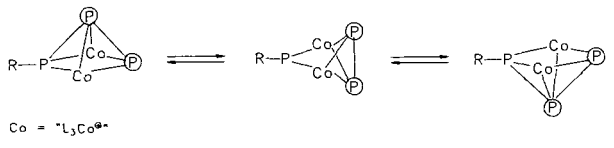
Three signals for the phosphorus centers of the tripod ligands correspond to the different environment of these atoms in the static structure (Fig. 2). The coalescence of the signals of P2 and P3 in **4** confirms the dynamic exchange of the two unsubstituted phosphorus centers of the EtP_3 ligand (Scheme 1). The signal assigned to P1 remains virtually unchanged during the coalescence. This means that P1 has, on average, a chemical environment similar to that in the static structure during the exchange.



Scheme 1. Exchange of P2 and P3 via a three-membered ring.

The observed dynamics can be explained with a model in which the phosphorus centers P2 and P3 exchange places by intermediate formation of a three-membered ring (Scheme 1). The existence of monofacially coordinated *cyclo*-RP_3 ligands has already been demonstrated;[8] a *cyclo*-EtP_3 ligand is also present in **3**, as follows from the ^{31}P-NMR spectrum (see *Experimental*). The preference for the open geometry of bifacially coordinated RP_3 ligands can be illustrated quite easily using a theoretical approach based on the analysis of triple-decker complexes by *R. Hoffmann* et al.[10] and on the specific analysis of (tripod)M systems by *L. Sacconi* et al.[11]

In a 32-valence-electron triple-decker complex $[(tripod)\text{-}Co\text{-}\mu_2\text{-}(\eta^3\text{-}P_3)Co(tripod)]^\oplus$, with C_3 symmetry of the P_3 unit, the HOMO to be occupied by two electrons is doubly degenerate. The Jahn-Teller distortion to be expected thereby has been confirmed in the case of the isoelectronic system

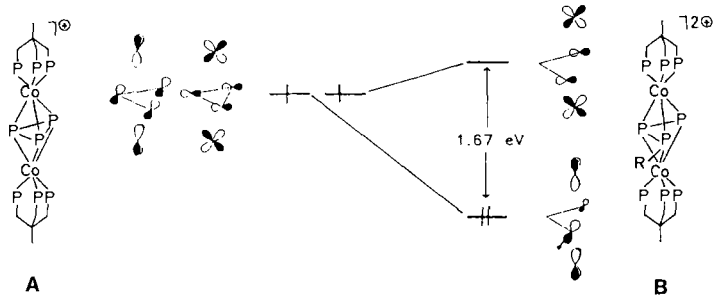


Scheme 2. Skeletal rearrangement of **4**.

[(tripod)Ni-μ_2-(η^3-P_3)Rh(tripod)]$^{2\oplus}$,[11] in which markedly different P–P bonds are observed in the P_3 ring. The idealized square pyramidal structure of **1** and **4** with 14 electrons in the skeleton conforms with the cluster count rule.[12]

The observed dynamics are consistent with a rearrangement of a square pyramidal cluster.[13] The equivalent in organic chemistry is the conversion of a tricyclic carbenium ion $(CH)_5^{\oplus}$ into a square pyramidal carbenium ion.[14]

4 can be formally derived from [(tripod)Co-μ_2-(η^3-P_3)Co(tripod)]$^{\oplus}$ by addition of an $Et^{\oplus}$ group to a free electron pair of *cyclo*-P_3; the two complexes are thus isoelectronic. The symmetry in **4** is, however, disturbed by the ethyl group, so that the orbitals to be occupied by two electrons are no longer degenerate. The lower lying of these two orbitals is so stabilized by complete opening of a P–P bond of the ring that the diamagnetic species with the structure found for **4** results (Scheme 3).



Scheme 3. The geometry of **4** (**B**). The EHT (extended Hückel type) modeling shows the removal of the degeneration of the HOMOs in the 32-electron tripledecker [(tripod)Co-μ_2-(η^3-P_3)Co(tripod)]$^{\oplus}$ **A** by addition of $R^{\oplus}$ (R = H) and opening of the P_3 ring **B** [17]. The geometry of **A** was modeled on [(tripod)Co-μ_2-(η^3-P_3)Co(tripod)]$^{2\oplus}$ [1], that of **B** on that of **4**.

A dynamic process as formulated in Scheme 1 can also take place in **4** if the closed ring with bonds of almost equal length is a transition state and not an intermediate compound. In constrast, a transition state with bonds of equal length cannot occur in the isoelectronic complexes containing *cyclo*-P_3.[15] To our knowledge, nothing has so far been reported about the dynamics of potential Jahn-Teller active *cyclo*-P_3 complexes; however, it is known that the system isoelectronic with **4**, with As_2S instead of EtP_3, contains open As_2S groups in the solid state.[16]

Experimental

All operations were carried out under N_2 in freshly distilled solvents. NMR: solvent $CDCl_2$; ^1H NMR (200 MHz), ^{31}P NMR (81 MHz, standard: $P(OMe)_3$, $\delta = 139$, ext.), Bruker AC-200. Mass spectra: Finnigan MAT 8230.

1: Equimolar amounts of tripod (624 mg, 1 mmol) in 25 mL of THF and $Co(BF_4)_2 \cdot 6H_2O$ (340 mg, 1 mmol) in 15 mL of EtOH were mixed, and the resulting orange-red solution treated dropwise with stirring at room temperature with 0.15 mL (1 mmol) of $PhAsH_2$ in 5 mL of THF. An immediate change in color of the solution to black, with concomitant evolution of gas, was observed. After 2 h, the reaction mixture was filtered over silanized silical gel and the solution evaporated to half of its original volume. Within three days, blackish-green, analytically pure crystals of $\mathbf{4} \cdot (BF_4)_2$ separated out. (It is important that the crystallization vessel be closed with a rubber stopper, which by slow swelling further reduces the amount of solvent.) $M = 1842.3$ g/mol $C_{88}H_{83}P_6Co_2As_3B_2F_8$, yield 460 mg (50% based on consumed $Co^{2\oplus}$). FD mass spectrum: m/z 1536 [$M^{\oplus} - CH_3C(CH_2)_2$, $-Ph$], $m/2z$ 834 ($M^{2\oplus}$). ^1H NMR (293 K): $\delta = 1.76$ (CH_3, 6H), 2.76 (CH_2, 12H), 6.8–7.35 (Ph, 66H); ^{31}P NMR (293 K): $\delta = 25.4$.

3: A suspension of **2** [7] (340 mg) in CH_2Cl_2 (50 mL) was treated with excess $[Et_3O]BF_4$. The color changed within 2 h from yellow to deep-red, and **2** went completely into solution. After removal of solvent there remained an oily-red residue; this was washed three to four times with 10 mL of EtOH and finally with petroleum ether. Upon drying in a high vacuum **3** was obtained as an analytically pure red powder. $M = 892.3$ g/mol $C_{43}H_{44}P_6CoBF_4$, yield: 310 mg (79% based on **1**). FD mass spectrum: m/z 805 ($M^{\oplus}$). ^1H NMR (293 K): tripod: $\delta = 2.58$ (CH_2 6H), 1.82 (CH_3 3H), 7.1–7.3 (Ph, 3OH); ethyl: 1.34 (CH_3 dt, $^3J(PH) = 25$ Hz, 3H); 2.80 (CH_2, $^2J(PH) = 4.7$ Hz, 2H); ^{31}P NMR (293 K): 33.1 (s, 3P), -103 (t, $^1J(PP)$) 360 Hz), -339.4 (d, $^1J(PP) = 360$ Hz).

4: A solution of **3** (300 mg, 0.33 mmol) in CH_2Cl_2 (30 mL) was treated with stirring with a mixture of equimolar amounts of $[Co(BF_4)_2 \cdot 6H_2O]$ (113 mg, 0.33 mmol) in EtOH (10 mL) and tripod (205 mg, 0.33 mmol) in THF (10 mL). The initially red solution slowly turned dark brown. After one hours' stirring the solution was filtered over silanized silica gel and the solution then covered with a layer of 30 mL of Et_2O. After 14 h at room temperature a microcrystalline precipitate of **4** as adduct with EtOH had formed. Yield 260 mg (39% based on **3**). $M = 1754.9$ g/mol, $C_{88}H_{95}P_9O_2Co_2B_2F_8$. Correct C, H, P analysis. FD mass spectrum m/z 1488 ($M^{\oplus}$, ($tripod_2Co_2EtP_3)^{\oplus}$), m/z 1460 ($M^{\oplus} - C_2H_4$), $m/2z$ 744 ($M^{2\oplus}$). ^1H NMR (293 K): tripod: $\delta = 1.65$ (CH_3, 6H); 2.53 (CH_2, 12H), 7.0–7.3 (Ph, 60H); ethyl: $\delta = -0.16$ (CH_2, 2H), 1.79 (CH_3, 3H). ^{31}P NMR (293 K): tripod: $\delta = 17.8$, ($b_{1/2} = 70$ Hz), EtP_3: $\delta = 158$; (221 K): tripod: $\delta = 28.8$, 16.4, (8.1 $b_{1/2} = 100$ Hz), EtP_3: $\delta = 260$ ($b_{1/2} = 120$ Hz; d, $^1J(PP) = 300$ Hz), $\delta = 178$ ($b_{1/2} = 180$ Hz; d, $^1J(PP) = 280$ Hz), $\delta = -270$ ($b_{1/2} = 100$ Hz); (t, $^1J(PP) = 300$ Hz). Crystals suitable for an X-ray structure analysis were obtained by recrystallization as $4\text{-}(BF_4) \cdot 0.5$ THF from $THF/CH_2Cl_2/Et_2O$.

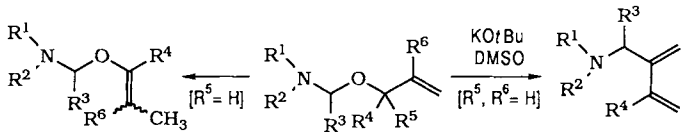
A Novel Synthesis of 2-Aminomethyl-1,3-butadienes from *N,O*-Acetals

By *Thomas Arenz* and *Herbert Frauenrath**

Dedicated to Professor Hans-Dieter Scharf on the occasion of his 60th birthday

Despite the importance of the Mannich reaction in the synthesis of natural products, so far only few diastereo- and enantioselective Mannich reactions have been described in the literature.[1-3] We have therefore investigated to what extent *N,N*-dialkyl-*O*-vinyl acetals **2** are suitable as starting compounds for the stereoselective synthesis of Mannich bases **4**, in analogy to the stereoselective synthesis of aldol ethers by acid-catalyzed rearrangement of alkyl vinyl acetals.[4, 5] The compounds required should be readily accessible from **1** by base-catalyzed C=C isomerization.[6]

N,N-Dialkyl-*O*-allyl acetals **1** can be synthesized in good yields by known methods[7, 8] from secondary amines, allyl alcohols, and aldehydes, usually formaldehyde ($R^3 = H$) (Table 1).



2 **1** **3**

However, in our first investigations concerning the C=C isomerization of **1** ($R^3 = H$) with KO*t*Bu in dimethyl sulfoxide (DMSO), we could only isolate the 2-aminomethyl-substituted butadiene derivatives **3** (Table 1) in 50–70% yield.

Table 1. *N,N*-Dialkyl-*O*-allyl acetals **1** und 2-(*N,N*-dialkylaminomethyl)-1,3-butadienes **3** [9].

	R^1/R^2	R^3	R^4	R^5	R^6	Yield [%] **1**	Yield [%] **3**
a	C_2H_5	H	H	H	H	82	52
b	$-(CH_2)_5-$	H	H	H	H	79	65
c	$CH(CH_3)_2$	H	H	H	H	84	70
d	$CH(CH_3)_2$	H	CH_3	H	H	78	63
e	$CH(CH_3)_2$	H	CH_3	CH_3	H	78	–
f	$CH(CH_3)_2$	H	H	H	CH_3	75	–
g	C_2H_5	C_6H_5	H	H	H	83	–

This, initially unexpected finding, could be resolved by using substituted allyl alcohols for the synthesis of **1** and the use of [D$_6$]DMSO. For example, starting from 1-buten-3-ol, the 3-methyl-substituted diene **3d** is obtained from **1d**. From **1c**, the dideuteriated diene **3h** is formed upon reaction with [D$_6$]DMSO.

4 **5** **7** **6**

We assume, therefore, that the C=C isomerization leading to **2** and the rearrangement of **2** to give the Mannich bases **4** proceed in the desired way, and that the dienes **3** are formed under the reaction conditions by further reaction of **4** with DMSO.

After nucleophilic addition of the methylsulfinylmethide anion to the Mannich base **4** ($R^6 = H$), subsequent dehydration to give the vinyl sulfoxide **6** and isomerization of **6** should lead to formation of the allyl sulfoxide **7**. Such reactions of carbonyl compounds are already well documented.[10] The allyl sulfoxide **7** could then immediately react further to give the diene **3**. This assumption finds further support from the reaction of conventionally synthesized Mannich bases with DMSO, whereupon the dienes **3** have also been obtained, albeit in poor yields so far.[11]

As expected, with *N,O*-acetals of type **1e** the synthesis of **3** does not succeed, since the double-bond isomerization to give **2** cannot take place. In the same way, no diene can be obtained on using **1f**, since, in this case, no isomerization of **6** to give the allyl sulfoxide **7** is possible.

Table 2. Some physical data of the compounds **3**.

3a: b.p. 56 °C/18 torr; ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 6.38$ (dd, $J = 11$, 18 Hz, 1H; $H_2C=CH$), 5.48 (d, $J = 18$ Hz, 1H; $HCH=CH$, *trans*), 5.20, 5.10 (each br. s, 2H; $H_2C=C-CH_2$), 5.03 (d, $J = 11$ Hz, 1H; $HCH=CH$, *cis*), 3.15 (br. s, 2H; $H_2C-NR^1R^2$), 2.55 (q, $J = 7$ Hz, 4H; $N(CH_2-CH_3)_2$), 0.98 (t, $J = 7$ Hz, 6H; $N(CH_2-CH_3)_2$); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 144.3$ ($C-CH_2$), 138.0 ($H_2C=CH$), 116.9, 113.9 ($H_2C=CH$, $C=CH_2$), 47.2, 45.1 ($N(CH_2-CH_3)_2$, $H_2C-NR^1R^2$), 12.1 ($N(CH_2-CH_3)_2$

The dienes **3** can be unequivocally characterized ^{1}H- and ^{13}C-NMR spectroscopically (Table 2). In contrast to 1-aminomethyl-1,3-butadiene derivatives, which have proven to be effective antimycotics,[12] very little is known about compounds of type **3**.[13–16] So far, we have been unable to observe dimer formation as has been described for 2-aminomethyl-1,3-butadiene[13] and its quaternary ammonium salt.[16] We are presently investigating whether other dienes **3** can be synthesized by substitution of **1** (e.g. **1g**), and whether the base-catalyzed reaction of DMSO with carbonyl compounds involves a generally applicable principle for the synthesis of dienes.

Experimental

A solution of KO*t*Bu (5.9 g, 52 mmol) in DMSO (50 mL) was treated slowly with 52 mmol of **1** and the resulting mixture stirred for 12 h at 80 °C. After cooling to room temperature the mixture was poured into ice-water, the organic phase separated off, and the aqueous phase extracted several times with ether. The combined organic phases were washed with saturated NaCl solution to remove residual DMSO and then dried over K_2CO_3. After removal of the solvent, the dienes **3a–d** were isolated by distillation in vacuo.

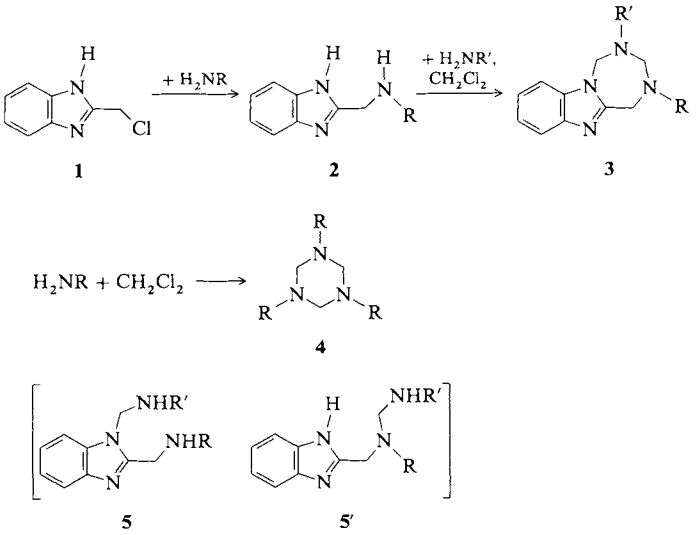
Imidazo[1,2-*e*][1,3,5]triazepine Derivatives: First Representatives of a New Heterocyclic System**

By *Gerd Kaupp** and *Klaus Sailer*

Dinuclear heterocycles containing four nitrogen atoms play an important role in living Nature. Thus, the biological activities of purines, pteridines and related classes of substances are unimaginably diverse.[1] We report here on a simple synthesis of a novel tetraazaheterocyclic system in which a five-membered ring is coupled to a seven-membered ring.[2]

Reaction of methylamine or ethylamine with 2-chloromethylbenzimidazole **1** in dichloromethane leads to direct formation of **3a** (60%) and **3b** (53%; in this case together with 34% **2b**), respectively.



a: R = R′ = CH_3; **b**: R = R′ = C_2H_5; **c**: R = C_2H_5, R′ = CH_3; **d**: R = H, R′ = CH_3; **e**: R = C_6H_5, R′ = CH_3

In these complex reactions, two equivalents of primary amine and two equivalents of dichloromethane are so incorporated into **1** without rearrangement and with multiple HCl elimination that a seven-membered ring is formed as part of the previously unknown heterocyclic system **3**. The high tendency of formation of **3** is surprising and points to high stability.

As expected, the synthesis can be carried out in two steps, if **2** is first synthesized in diethyl ether or chloroform. This procedure, however, is preferred only when different residues R and R′ are to be inserted, as in **3c** (54%), **3d** (57%), and **3e** (88%). Possible intermediates are **5** or **5′**, which, after reaction with dichloromethane, cyclize to **3**.

The readiness with which anhydrous dichloromethane undergoes substitution with primary amines is remarkable. According to the literature dimethylamine, as secondary amine, does not react with dichloromethane below 70 °C in a pressure vessel (to give tetramethylenediamine), cyclic bases such as pyrrolidine react at room temperature in the presence of NaOH.[3] Under our very mild reaction conditions we observed the formation of small amounts of **4a**, **b** as byproducts, which apparently are formed from dichloromethane and primary alkylamines without the assistance of further reagents.[4] This is consistent with the mechanistic concepts.

In the case of starting materials such as the theophylline derivative **6**,[5] the question of the regioselectivity arises, since the reaction should lead to intermediates analogous to **5** or **5′** via the deprotonated imidazole system. In the case of **6**, only a cyclization to N-7 with formation of **7** and not a cyclization to N-9 (of **6**) was observed. This is consistent with semiempirical AM1 and PM3 calculations,[6] according to which **7** is 8.3 and 6.2 kcal mol^{-1}, respectively, more stable

than the analogous product of cyclization to N-9 (of **6**), and which indicate that the latter would be strongly sterically hindered.

The structure **7** can be unequivocally established ^{13}C-NMR spectroscopically by the signal at $\delta = 65.4$, which is due to the aminal carbon atom bound to the imidazole-N, and for which the C13-NMR/IR data bank[7] predicts a value of $\delta = 67.7 + 3.7$ (for the alternative structure 58.9 + 2.1).

Compound **7** is the first derivative of a 1,3-dimethyl[1,3,5]-triazepino[7,1-*f*]xanthine. Like **3**, it contains the partially hydrogenated imidazo[1,2-*e*][1,3,5]triazepine subunit. No doubt further examples of the new heterocyclic system can be synthesized, and interesting regioselectivities studied in the case of unsymmetrical substitution.

The advantage of dichloromethane over formaldehyde/hydrochloric acid[8] (avoidance of water and strong acid) is also clearly demonstrated by the synthesis of **9** from **8** (45%).

The structure of the compounds **3**, **7**, and **9** is supported by analytical as well as spectroscopic data (Table 1) and is confirmed by ^{13}C-NMR spectral simulation,[7] so that alternative structures can be ruled out with certainty.[9] Also helpful here is a comparison of **3** and **9**.

The novel heterocycles **3**[2] and **7**[2] can be expected to exhibit interesting biological activities: imidazo[1,2,-*e*]-[1,3,5]triazepines are related to the pteridines in the same way as azulene to naphthalene. By further development of the synthetic route, derivatives **3** with R = R′ = H ought to be accessible, whose oxidation should lead to tetraazaazulene cations.

Experimental

2a: A weak stream (150 mL min^{-1}) of methylamine was passed into a mixture of 500 mg (3.0 mmol) of **1** and 50 mL of anhydrous chloroform or diethyl ether for 30 min at 0 °C and the resulting solution allowed to stand for 10 h at room temperature. The still clear solution was then heated under reflux for 30 min for complete separation of methylamine hydrochloride; the solvent was then removed by evaporation, and the compound **2a** extracted from the residue with diethyl ether. Yield 450 mg (93%), m.p. 128 °C (Et_2O). **2b** [10], **2c** [13] and **2e** [12] were obtained analogously with ethylamine (0°), ammonia (− 35 °C), and aniline (62 °C), respectively.

3a, **b**, **7**: A weak stream (150 mL min^{-1}) of methylamine (ethylamine in the case of **3b**) was fed from a steel cylinder into a slurry of 500 mg (3.0 mmol) of **1** or 1.73 g (7.6 mmol) of **6** in 50 mL of anhydrous ($CaCl_2$) dichloromethane at − 30 °C for 30 min. The resulting solution was allowed to stand at room temperature for 10 h and then heated under reflux for 30 min, whereby excess amine was distilled off and amine hydrochloride was deposited. The reaction solution was then, evaporated to dryness in vacuo and **3a** (390 mg, 60%), **3b** (390 mg, 53%) or **7** (723 mg, 34%) [besides 180 mg (34%) **2b** and 390 mg (23%) of the amine **6** with $NHCH_3$ instead of Cl corresponding to **2a**], respectively extracted from the yellow paste with diethyl ether; adherent **4a**, **b** (100–200 mg) was removed by evaporation in vacuo. When the synthesis was carried out with **2a** as starting material, **3a** was obtained in 92% yield. In the same way, **3c** (54%), **3d** (57%), and **3e** (88%) were obtained from **2b**, **2d**, and **2e**, respectively, and **9** (45%) from **8** [14].

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

One and Two Dimensional NMR Spectroscopy. By *Atta-ur-Rahman*. Elsevier, Amsterdam 1989. xix, 578 pp., hard cover, HFl 355.00. – ISBN 0-444-87316-3

This book makes an attempt at providing a comprehensive overview of modern high resolution NMR techniques. The principles of many of the latest generation one- and two-dimensional (1D and 2D) NMR techniques are described in a manner that makes the book easy to read. Descriptions of the tremendous number of pulse sequences contained in this book rely entirely on the popular vector picture approach. As a drawback of this oversimplified approach, explanation of many of the techniques relying on multiple quantum phenomena suffers.

The book starts with a chapter that introduces many of the commonly used concepts in modern NMR. Topics vary from a simplified description of spectrometer hardware to data acquisition and dynamic range, Fourier transformation, phase cycling, solvent suppression, nuclear Overhauser enhancement, and advanced concepts such as coherence transfer and multiple quantum filtration. This chapter includes a brief description of the operator formalism which has played a crucial role in the development of modern pulsed NMR, but the author does not use this formalism in later chapters. A more detailed description of the operator formalism is presented in the last chapter (Chapter 14).

Chapters 2, 3 and 4 are concerned with modern 1D NMR techniques. Chapter 2 starts with an explanation of the "spin-echo" phenomenon in homo- and heteronuclear spin systems, and spectral editing using the large number of different pulse schemes, including all of the "Sørensen variations." Chapter 3 is devoted to the once-popular 1D INADEQUATE technique, again including many of its variations. Chapter 4 gives a very qualitative but useful description of common relaxation mechanisms with emphasis on the NOE effect and its use in structural chemistry.

Starting with a simple introduction of the concept of 2D Fourier transformation in Chapter 5, the remainder of the book describes the tremendous variety of different pulse schemes that have been developed in the past decade. The first "real" 2D chapters deal with heteronuclear and homonuclear *J*-resolved spectroscopy.

Chapter 8 treats homonuclear *J*-correlation techniques such as COSY and its relay derivatives. The chapter includes a description of phase-sensitive COSY without multiple quantum filtration, but remarkably, the multiple quantum filtered E. COSY experiment is briefly discussed. The much simpler P. E. COSY technique is not described. Among a variety of SECSY and Super-SECSY experiments, I was very surprised to find a section on TOSCY spectroscopy, whereas, without any cross-referencing, a later chapter (Ch. 11) is devoted to this topic.

Chapter 9 deals with techniques for delineating cross-relaxation and chemical exchange pathways. Although critical for macromolecular structure analysis, NOE studies of smaller substances are usually carried out more efficiently in a one-dimensional manner, and the description is correspondingly brief. This chapter also includes a brief discussion of the rotating frame NOE experiment, but without any mention of the theoretical basis of this technique.

Heteronuclear shift correlation techniques are treated in Chapter 10. Most of this chapter is related to the low-γ detected variety, including experiments such as HETCOR and COLOC, but their more sensitive ^{1}H-detected counterparts, HMQC and HMBC, are also discussed. Chapter 12 deals with multiple quantum spectroscopy, including the 2D INADEQUATE experiment and multiple quantum filtration of regular homonuclear 2D experiments such as COSY. Chapter 13 provides advice for the practising structural NMR spectroscopist with regard to what set of experiments may typically be most useful for problems concerning natural products. In this respect, Appendix 2 provides a very valuable summary of the most popular experimental techniques currently available, including their strong and weak points.

I noted several (minor) errors in pulse sequences, which may make it necessary to consult the original literature. Also the discussion of quadrature detection and folding applies only to older Bruker spectrometers, and owners of instruments with simultaneous detection of complex data may get

confused. The main weakness of the book is that the author has not been able to get hands-on experience with all the hundreds of techniques described. As a consequence, statements in the book often reflect the subjective and optimistic views of the inventors of such techniques.

This book is most valuable for NMR spectroscopists who are primarily dealing with relatively small molecules for which the tremendous variety of 1D and 2D NMR pulse sequences may be applicable. The absence of any serious mathematics makes the book easy to read, but necessarily makes it lacking in depth. At the end of most chapters, a problem and answer section is included which should be helpful to many readers. The book includes a list of commonly used acronyms plus a substantial number of valuable references.

Compact Wörterbuch der exakten Naturwissenschaften und der Technik. Band 1. Englisch-Deutsch. By *A. Kučera*. Oscar Brandstetter Verlag, Wiesbaden 1989. xxxi, 1460 pp., hard cover, DM 130.00.—ISBN 3-87097-146-0

As a German-speaking student one spends many years glued to school and lecture theatre benches; after this one continues to pursue one's subject, then suddenly it becomes necessary to work on specialist texts in English, containing words such as primer, multitasking, solenoid valve, drybox, puckering, dose rate, weathering, backing, or plane-polarized. Depending on what specialized training one has had, a few of the words may be familiar, and in some cases one may have an idea of their meaning. But where can one look up completely unknown words or find out their meanings with certainty? Even with a good English dictionary one quickly comes up against its limitations, as there is not space in such a work to include all specialist words or specialist meanings attached to everyday words. One therefore needs a specialist dictionary such as that reviewed here, which was published last year in its second, revised edition. The entries, totalling about 117400, are mainly drawn from monographs and specialist encyclopedias which are listed in the introduction. However, with regard to chemistry and chemical technology it is a little surprising that, although "Römpp" has been referred to in compiling the dictionary, "Ullmann" has not. The introduction also includes a glossary of the abbreviations used and an alphabetical list of the specialist fields used as a basis for classifying the words. These two lists are also summarized on a plastic card in the form of a bookmark; unfortunately most of this information can only be read when the card is not inside the book, since otherwise everything is upside-down. There is an appendix consisting of an addendum ("carrier" and compound expressions containing this word) and a short comparison of how scientific and technical words are formed in English and German.

However, I would have liked to see detailed explanations of the conventions used in the entries, e.g. what is the significance of double vertical slashes (‖), oblique slashes (/) and dots (e.g. in "plasma··sprayed"), and where is it explained that in an entry such as "wrap jack"..."~mode" the wavy line ~ stands for "wrap", not for "wrap jack"? Also it is not quite clear why, for example, there need to be three independent English entries corresponding to the German "Spiegeleisen" (namely "spiegel", "spiegeleisen" and "spiegel iron"), nor why, for abbreviated terms, the (very welcome) explanation of the meaning is not reinforced by also giving the complete English expression. For example, I would find it quite interesting to discover why fuel made from refuse is known in English as RDF. Again, it is surprising that although "work electrode", "working electrode" and "reference electrode" are all included, the abbreviations WE and RE are not, nor is "counter electrode", which is the third type of electrode.

The question of whether or not the German translations are always exact is one on which I cannot give an opinion, but it seemed to me that a few of the chemical expressions did not quite correspond to the most common usage, e.g. "dihedral angle:Dihedralwinkel" (instead of Diederwinkel), "methacrylic acid:Methakrylsäure" (instead of Methacrylsäure), "methyltert-butyl ether" (an unfortunate way of linking the parts of the word!): "Butylmethylether (tertiäres)" (instead of *tert*-Butylmethylether). Whether "impact strength" should be translated as "Kerbschlagfestigkeit", as given here, or as "Kerbschlagzähigkeit", as I have been assured by polymer experts, is something which I cannot decide.

Unfortunately the quality of the printing in this dictionary is not very good. For example, the first few pages distinctly show shadows caused by double printing, and the top entry on page 1137, "shock", appears as "shock". It has, of course, not been possible to completely avoid typesetting errors, but at least those which seriously alter the meaning should have been noticed. Or would you immediately understand the explanation given for "landfall": "Punkt, an dem der MFK nach Flug über Sei die Küste erreicht"? First fault: the abbreviation is not explained (Marschflugkörper); second fault: "Sei" should have read "See". Again, "Wiener filtering", a technique used in electronic reconstruction of images, involves not "Wideraufbau" but Wiederaufbau.

Despite these critical comments I did find the dictionary quite useful when I used it (sporadically) over a period of several months, specifically for looking up specialist words in technological fields. Finally, then, for each of the English terms mentioned at the beginning of this review I list here at least one of the German equivalents given, although one cannot avoid a slight furrowing of the brow here and there: Starter, Multitasking (explained as the simultaneous execution of several tasks by a digital computer), Elektroventil, Trockenschrank, Fältelung (!?), Dosisleistung, Freiluftbewitterung, Schutzschicht and linear polarisiert.

Bimolecular Collisions. (Series: Advances in Gas-Phase Photochemistry and Kinetics). Edited by *M. N. R. Ashfold* and *J. E. Baggott*. VCH Verlagsgesellschaft, Weinheim 1989. xvii, 416 pp., hard cover, £ 85.00.—ISBN 0-85186-393-0

The study of bimolecular collision processes at a molecular level has been extended into new areas in the last few years, in particular through the development of sensitive laser spectroscopic techniques capable of identifying excited states. It has become possible to obtain detailed information on the dynamics of chemical reactions and energy transfer processes, and on topics at research frontiers such as the gas-solid transition in metal clusters and the gas-liquid transition in solvent clusters, at a level which enables one to test results from *ab initio* calculations.

The first chapter of the book already provides an excellent example of the progress that has been achieved. Here *Valen-*

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0808-0936 $ 3.50+.25/0

tini and *Phillips* show how laser spectroscopic techniques such as multiphoton resonance ionization and coherent anti-Stokes Raman scattering (CARS) allow one to study the classical hydrogen-deuterium exchange reaction $H + D_2 \rightarrow HD + D$ under single collision conditions for selected states, and to measure rotational and vibrational excitations of the H_2 product molecule for different collision energies. The agreement between the results thus obtained and the populations of the states as predicted by *ab initio* calculations is impressive. New measurements of the partial cross-sections for the reaction $H + p\text{-}H_2(v = 0,\ j = 0,\ 2) \rightarrow o\text{-}H_2(v = 1,\ j) + H$ give sharp maxima for the formation of $o\text{-}H_2(v = 1,\ j)$ at collision energies which, according to quantum dynamics calculations, correspond to vibrational levels of the linear H_3 transitional state. *Valentini* describes this as a "vibrational spectrum of the transition state".

In Chapter 2 *Smith* describes the influence of vibrational excitations of the reactants on bimolecular reactions, with examples which again include the hydrogen-deuterium exchange reaction. Other examples are the reactions of F, $O(^3P)$ and $O(^1D)$ atoms with H_2 and of $O(^3P)$ with HCl and HBr, reactions with four atoms, e.g. $OH + H_2$, OH + HBr, CN + HCl or OH + CO, four-center reactions, and radical-radical reactions. One expects to find large increases in reaction rates following vibrational excitations, especially for endothermic and direct reactions with "late" energy barriers, and this is confirmed to some extent. The transition state theory assuming adiabatic behavior as regards vibrational energy has proved to be a useful theoretical framework for understanding the observed effects.

In Chapter 3 *Davies* and *Pilling* describe the association reactions $H + C_2H_4 \rightarrow C_2H_5$, $CH_3 + CH_3 \rightarrow C_2H_6$, $CH_3 + H \rightarrow CH_4$, $O + OH \rightarrow HO_2$ and $HO_2 + HO_2 \rightarrow H_2O + O_2$; here again the transition state theory of the kinetics provides the theoretical background, as discussed in Chapter 4 by *Hase* and *Wardlaw*. Since reactions of this type often take place via potential wells as opposed to barriers, one cannot assume a transition state at the position of the barrier, but must instead use alternative definitions.

Energy transfer by non-reactive collisions is treated in Chapter 5 by *Hippler* and *Troe*. Here the experimentally measured quantities are the average energy transfered per collision $<\Delta E>$ and the factors that influence $<\Delta E>$. The measured values can be compared with the corresponding values obtained from quasi-classical trajectory calculations and quantum scattering calculations. More detailed information about the dependence of the average collisional energy transfer on the excitation state of the molecule can be obtained from other experimental methods, especially from newer techniques such as "hot" UV absorption spectroscopy, time-resolved multiphoton IR spectroscopy, and multiphoton ionization measurements. Most of the experimental methods used up to now give averaging over sequences of collisions, whereas there have been very few state-specific single collision experiments on highly excited polyatomic molecules. Such experiments would allow a more direct comparison with theory.

In Chapter 6 *Husain* and *Roberts* describe laser spectroscopic techniques which enable one to excite lanthanoid metal atoms to particular states and then to follow their decay by reactive and inelastic collisions in a time-resolved manner. Reactions with oxidizing agents especially are often accompanied by strong chemiluminescence, and this can be used to identify different reaction pathways. By comparing these results with those from *ab initio* calculations and with adiabatic correlation diagrams it is often possible to deduce detailed reaction mechanisms.

In Chapter 7 *Jarrold* deals with the preparation, characterization and reactivity of metal clusters. From this it appears that clusters of certain sizes are particularly inert. Very little is yet known about the effects of electronic and molecular structure on the reactivity of clusters. The aim of these studies is to gain a deeper understanding of chemisorption and catalysis at a molecular level.

In Chapter 8 *Leone* summarizes results from experimental and theoretical studies on bimolecular collision processes for ions in drift fields. Using laser spectroscopy it is now possible to make detailed measurements of state populations and spatial orientation of the ions. A correspondingly detailed form of spectroscopy for investigating simple ion-molecule reactions now seems to be within reach.

The book provides a critical appreciation of some current areas of research in kinetics, together with much useful background material. In the areas with which I am most familiar I found no gaps, inaccuracies or unreliable material. However, it is regrettable that there is scarcely any mention of the extensive studies that have been made of inelastic and reactive scattering in crossed molecular beams. The high price of DM 260.00 is also a drawback. To summarize, the book can be recommended to chemists with interests in this special field.

VCH TransDict, Übersetzersoftware, Version 2.2. By *Ulrich Hellinger*. VCH Verlagsgesellschaft, Weinheim 1988. DM 780. ISBN 3-527-26873-1

Translation is an exacting process. Some call it an art, some a craft, some a boring task. At one extreme is the translation of, say, *Paul Celan*'s poetry. *Celan*, himself a polyglot and a prolific translator of other poets, including *Emily Dickinson* and *Robert Frost*, wrote in German. His poems are often difficult to understand in the original and, with their layers of allusion and borrowings from other languages, they are a challenge to translate. At the other extreme is the translation of the experimental protocol of a chemical synthesis. Here, what the linguist *Leonard Bloomfield* termed "operationally equivalent wordings" are required. The translation should merely allow repetition of the synthesis. However, the scientist who wants to publish in a foreign language, usually English, most likely confronts problems lying between these two extremes. The translation has to be accurate, that is, free of scientific ambiguity: a *Hydrierung* in German must be translated as a hydrogenation in English and not as a hydration (*Hydratisierung*). At the same time, the translation should do justice to the author's style of writing. *VCH TransDict* is a potentially useful tool for scientists and translators in meeting both requirements.

No, *TransDict* is not one of those computer programs that translates between several languages at the stroke of the return key. High-quality computer translation is a tantalizing goal. But not even Japan's Fifth Generation Computer Project, now in its ninth year, has been able to fulfill all the needs of the scientist publishing in a foreign language.

TransDict is basically a word-processing program that also allows rapid searching of electronic dictionaries and card files. It requires a computer operating with MS-DOS (version 2.1 or later), having at least a 640-kilobyte main memory, and equipped with a hard disk (20 megabytes or more) and a graphics card. The pull-down menus enable the user to

load, save, and print documents, to work simultaneously with several documents ("windows"), to mark, format, and move within the text, to search for and replace text elements, to make tables, to specify the parameters of the display screen and printer, to perform simple calculations, to create macros (sequences of commands performed together), and to access the disk operating system—in short, to carry out the essential operations of word processing. Simple keyboard codes (consisting of the control key plus a letter or number) are shown conveniently in the upper left-hand corner of the screen when the menus are activated. They allow most commands to be performed more quickly directly from the keyboard. Finally, a Help command provides an explanation of each function.

The dictionary menu, activated by pressing the Alt-W (for *Wörterbuch*) combination, provides access to electronic dictionaries, which can be searched for a particular word or according to phonetic criteria (for example, Hofman, Hofmann, Hoffman, and Hoffmann are treated identically). The user can also leaf—or, in computer jargon, scroll—through the dictionaries. Several German–English dictionaries are currently available on diskette, including a *Langenscheidt* dictionary and the *parat Dictionary of Information Technology*. One of these is included in the price of *TransDict*. In addition, file cards, containing up to ten lines with maximally 60 characters per line and 255 characters per card, can be created and searched in a similar fashion. Lists of words can also be saved under the dictionary function; they are stored chronologically but may be alphabetized by a subprogram. The individualized lists and file cards offer considerable leeway in establishing a personal style of writing in a foreign language.

TDRES, a subprogram containing only the dictionary and file-card functions, allows these to be used with many common word-processing programs such as *Microsoft Word* and *Wordstar*. This feature is especially valuable for writers accustomed to a particular program and should be offered separately at a lower price. An English version of *TransDict*, as well as a version suitable for the widely used Macintosh computer, should also be made available.

Of course, *TransDict* does not absolve the user from learning the grammar and syntax of a language, nor does it guarantee good usage. Only by reading as widely and as attentively as possible in a particular language is it possible to develop a good feel for what constitutes effective writing. Moreover, the electronic dictionaries eventually offered must be accurate and up-to-date. However, *TransDict* does facilitate the process of scientific translation by providing, at the touch of a finger, essential words, phrases, and concepts. Scientists writing the first version of their manuscript in a foreign language will find the software particularly useful.

Greater insight into the process of translation is provided by a recent book, *The Craft of Translation* (University of Chicago Press, Chicago, 1989), edited by *John Biguenet* and *Rainer Schulte*. This excellent collection of articles on the problems facing translators of literary texts includes an essay on the translation of *Celan*'s poetry. The author, *John Felstiner*, notes that "translating Celan—translating any poet, in fact—appropriates all the resources of interpretive criticism." There is a little of the poet in every scientist. Keeping this in mind will make the task of translating a scientific paper no less exacting, but certainly more interesting.

Gas Chromatographic Separation of Enantiomers on Cyclodextrin Derivatives**

New Analytical Methods (42)

By Volker Schurig* and Hans-Peter Nowotny

In investigations concerned with the phenomenon of molecular chirality, the use of gas chromatography for the enantiomeric analysis of stable, volatile compounds is a technique of steadily growing importance.[1] In the last three years an important breakthrough in gas-chromatographic separation of enantiomers has been achieved by using alkylated cyclodextrins (α, β, and γ) as chiral stationary phases in high-resolution capillary columns. In academic and commercial practice two different and complementary strategies have been adopted up to now. In the first, alkylated cyclodextrins are diluted with polysiloxanes and coated on glass or fused silica capillary columns. In the second, lipophilic per-*n*-pentylcyclodextrins and hydrophilic di-*n*-pentyl- and hydroxyalkylpermethylcyclodextrins are coated directly in the form of liquid phases onto suitably pretreated glass or fused silica surfaces. These techniques permit enantiomer separations not only for polar diols and alcohols, derivatized hydroxycarboxylic acids, amino acids, sugars, and alkyl halides, but also for nonpolar alkenes, cyclic saturated hydrocarbons, and metal π complexes. An important aspect for practical applications is that in many cases the enantiomers can be separated without previous derivatization. Whereas the resolution of racemates of unfunctionalized hydrocarbons is attributed to an enantioselective host–guest inclusion complex, some observations indicate that for polar guest molecules additional enantioselective interactions are also involved. The new chiral stationary phases can be used over a wide range of temperatures (25 to 250 °C). The technique described is likely to become widely adopted as a simple, accurate and highly sensitive method for the enantiomeric analysis of chiral compounds that can be vaporized without decomposition. It will also stimulate future research aimed at finding universal cyclodextrin phases and elucidating the mechanisms of enantioselectivity.

1. Introduction

The problem of determining enantiomeric compositions (enantiomeric excess, *ee*) is central to all contemporary research concerned with the synthesis, characterization, and use of chiral compounds.[1] Gas chromatography offers an accurate and reliable modern analytical method for separating enantiomers of compounds that can be vaporized without decomposition. Its inherent advantages include simplicity, speed, reproducibility, and sensitivity.[2–5]

The availability of high-resolution capillary columns—that is, wall-coated open-tubular (WCOT) columns—and the use of highly sensitive chromatographic detectors allow analyses to be carried out on nanogram quantities of sample, often without the need for tedious sample pretreatment.

[+] Present address: F. Hoffmann-La Roche
CH-4002 Basel (Switzerland)

[**] Gas Chromatographic Separation of Enantiomers on Optically Active Metal-Complex-Free Stationary Phases, Part 2: Part 1. [7].

Mixtures of different enantiomers can be separated simultaneously (e.g., all proteinogenic amino acids). By combining the method with ancillary techniques such as multidimensional chromatography and/or coupling to spectrometric methods, one can analyze enantiomers even in complex biological matrices. The use of an inert gas as the mobile phase avoids complications due to solvent effects and other variables, such as gradient elution and the use of buffers, modifiers, and additives, which influence liquid-chromatographic enantiomer separation.

The chiral stationary phases that have become particularly important in gas-chromatographic enantiomer separation belong to three classes:

1. amino acid derivatives which form hydrogen bonds[3] (e.g., the commercially available phases Chirasil-Val[4] and XE-60-L-Val(R)-α-pea)[5]
2. carbohydrate derivatives, notably cyclodextrins with a propensity to form inclusion complexes
3. metal complexes ("complexation gas chromatography")[6]

Stationary phases derived from amino acids have already been reviewed;[7] the present article deals with the use of cyclodextrin derivatives for gas-chromatographic separation of enantiomers.

In contrast to the stationary phases of classes 1 and 3, cyclodextrins have only been applied for routine enantiomer separation by high-resolution capillary gas chromatography during the last three years.

2. Cyclodextrins

Cyclodextrins—cycloamyloses, cycloglucans, or cyclomaltooligoses—were isolated as degradation products of starch by *Villiers* as long ago as 1891,[8] but it was not until 1904 that they were characterized by *Schardinger* as cyclic oligosaccharides (the "Schardinger dextrins").[9] Almost two decades before *Pedersen*'s synthesis of crown ethers,[10] *Freudenberg* and *Cramer* in 1948 recognized the ability of cyclodextrins to form molecular inclusion complexes.[11] Cyclodextrins are a homologous series of nonreducing cyclic oligosaccharides made up of six or more (α)-D-glucopyranose units linked together by α-1,4-glycoside bonds[12, 13] (Fig. 1[14]).

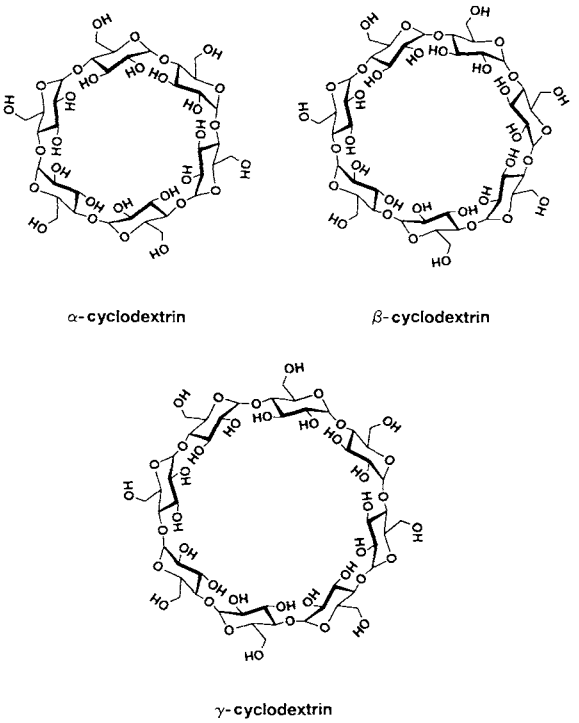

Fig. 1. α-Cyclodextrin (cyclohexaamylose), β-cyclodextrin (cycloheptaamylose), and γ-cyclodextrin (cyclooctylamylose) [14].

Cyclodextrins are obtained biotechnologically via enzymatic degradation of the glucose units of the polysaccharide starch by cyclodextrin glycosyltransferases of *Klebsiella pneumonia*, *Bacillus macerans*, or other types of bacillus. This reaction results in detachment of a turn from the starch helix accompanied by cyclization. The relative quantities of the individual cyclodextrins depend on the type of enzyme employed and can be influenced by the addition of organic compounds.[15]

So far, α-, β-, γ-, and δ-cyclodextrins with six to nine glucopyranose units have been isolated and characterized. Cyclodextrins with up to twelve glucopyranose units have been observed,[15, 16] but only the three lowest members of

Volker Schurig was born in 1940 in Dresden and began studies in chemistry in 1959 at the Universität Tübingen, where he received his doctorate under Ernst Bayer in 1968. He then spent two years in Israel as a postdoc at the Weizmann Institute of Science, where he began his work on the gas-chromatographic separation of enantiomers with Gil-Av. After pursuing this work at the University of Houston, he completed his "Habilitation" in Tübingen with work on complexation gas chromatography. He has been a guest professor at the Université Paris-Sud and the Weizmann Institute. His areas of interest include homogeneous catalysis with soluble polymeric metal compounds, the formation of highly ordered solid-state structures by chiral control, enzymatic epoxidations, chiral NMR shift reagents, chromatographic enantiomer separations, and the stereochemical analysis and synthesis of flavors and pheromones.

Hans-Peter Nowotny was born in Herrenberg in 1959 and began studies in chemistry in 1979 at the Universität Tübingen, where he received his doctorate under Volker Schurig in 1989 on enantiomer separation by inclusion gas chromatography on peralkylated cyclodextrins. He is presently employed by Hoffmann–La Roche in Basel.

the homologous series are at present commercially available (α, β, γ). Strained cyclodextrins with less than six glucopyranose units have not been observed up to now.

Each of the chiral glucose units of the cyclodextrins possesses a rigid $^4C_1$ chair conformation. The macrocyclic conformation of the cyclodextrins corresponds to a torus in both the solid state and in solution; the wider opening is occupied exclusively by secondary hydroxyl groups (C2-OH and C3-OH), while the opposite, narrower opening is occupied exclusively by primary hydroxyl groups (C6-OH). Table 1 lists some molecular dimensions and physical properties of the cyclodextrins.

Table 1. Molecular dimensions and physical data for cyclodextrins.

	Cyclodextrin		
	α	β	γ
Number of glucose units	6	7	8
Number of chiral centers	30	35	40
Molecular mass	972.86	1135.01	1297.15
External diameter [pm]	1370–1460	1530–1540	1690–1750
Internal diameter [pm]	470–520	600–650	750–850
Volume of cavity [nm^3]	0.176	0.346	0.510
pK_a of hydroxyl groups		12.1–12.6 (all)	
Solubility in water [g per 100 mL, 25 °C]	14.50	1.85	23.20
Molarity of saturated solution [M]	0.114	0.016	0.179
Melting and decomposition point [K]	551	572	540

It can be seen that the height of the molecular cavity is constant, whereas its diameter varies. The inside face of the torus comprises two sets of C-H groups (C3 and C5) and, between them, sets of glycoside ether linkages (C1 and C4). The cavity has a high electron density due to the lone pairs of the oxygen atoms. Because of the absence of hydroxyl groups directed inward, the cavity is both hydrophobic and nonpolar.[17] The outer hydroxyl groups at the cavity openings make the underivatized cyclodextrins hydrophilic. The macrocycle derives additional rigidity from the formation of stable intramolecular hydrogen bonds between secondary hydroxyl groups, O3-H···O'2 and O3···H-O'2.

The complexing properties of cyclodextrins, which can be regarded as empty molecular cavities of different sizes, have been thoroughly studied.[12–20] Hydrophobic interactions favor the formation of inclusion complexes. The propensity of cyclodextrins to form complexes with guest molecules is employed in many different technological applications.[15, 21] The observation that, by formation of inclusion complexes, the stability, solubility, bioavailability, residence time, toxicity, and odor properties of guest molecules are beneficially altered commands particular interest for the pharmaceutical and food industries.[14–16, 22]

Numerous X-ray structural studies have been carried out on a variety of inclusion complexes of β-cyclodextrin.[23, 24] In addition to 1:1 inclusion complexes, 2:1 host–guest complexes, in which the cyclodextrin molecules are linked by hydrogen bonds between the secondary hydroxyl groups, can also be formed. Studies on heptakis-(2,6-*O*-dimethyl)-β-cyclodextrin showed that protection of the free hydroxyl groups prevents the formation of cyclodextrin dimers and also that the presence of the methoxy groups can slightly increase the space available to a hydrophobic guest molecule compared with that of the cyclodextrin cavity itself.[24] This example illustrates that the conformation and complexing ability of cyclodextrins can be tailored by chemical modification.

In addition to host–guest selectivity, cyclodextrins exhibit some catalytic properties related to those of enzymes (competitive inhibition and Michaelis–Menten kinetics).[15, 16] Cyclodextrins have therefore been studied as enzyme models for α-chymotrypsin, carbonic anhydrase, and ribonuclease.[25]

A total synthesis of α-cyclodextrin has been achieved.[26] Derivatizations of cyclodextrins, such as alkylations and acylations, can be carried out regioselectively at the hydroxyl groups.[27] Monofunctionalizations,[28] a specific bifunctionalization,[29] and bridging across the cavity (yielding "capped cyclodextrins") have also been reported.[30]

The inherent molecular asymmetry of cyclodextrins, which arises from the fact that the cyclooligomers contain only D-glucose units, widens considerably the scope of potential applications. As a consequence of their biotechnological origin from natural starch, only the dextrorotatory enantiomers of cyclodextrins are known; the racemic forms and the levorotatory antipodes are not available. In many cases, the inclusion of chiral guest molecules into cyclodextrins represents an enantioselective process. Thus, different complex formation constants were found for the two fenchone enantiomers in ESR studies on the formation of inclusion complexes of β-cyclodextrin with (+)- and (−)-fenchone via the competitive displacement of a paramagnetic species from the cyclodextrin cavity.[3] Cyclodextrins have also been used as chiral auxiliary reagents in NMR spectroscopy. In the cyclodextrin complex of 2,2,2,-trifluoro-1-phenylethanol, for example, the CF_3 resonance of the (*S*)-(+) enantiomer appears at higher field than that of the (*R*)-(−) enantiomer.[32] A direct proof of the *enantioselective* complexation of (*R*)- and (*S*)-2-(3-phenoxyphenyl)-propanoic acids (fenoprofen) with β-cyclodextrin has recently been accomplished by crystal structure analysis.[33] The inclusion of optically inactive compounds in cyclodextrins can lead to a measurable circular dichroism, caused by the induction of chiral conformations.[18, 34, 35] Furthermore, diastereomers formed in β-cyclodextrin by the inclusion of a *prochiral* compound were distinguished by ENDOR measurements.[36] Numerous asymmetric catalytic reactions using cyclodextrins have also been described.[16, 37] Kinetic studies on the cyclodextrin-catalyzed hydrolysis of racemic oxazolones provided evidence for enantioselectivities that were of opposite senses for α- and β-cyclodextrins.[38]

An obvious method for separating racemic mixtures using enantioselective complexation in cyclodextrins is to carry out a fractional crystallization on the diastereomeric inclusion complexes. Indeed, racemic carboxylic acid esters, menthol and several carboxylic acids,[39, 40] *O*-alkyl alkylphosphinates,[41] sulfoxides,[42] *O*-alkyl alkylsulfinates,[43] and 2-bromo-2-chloro-1,1,1-trifluoroethane (halothane)[44] have been separated into their enantiomers in this way. However, the enantiomeric purity (*ee*) of the products was low in most cases. The highest reported value was *ee* = 84% for *O*-isopropyl methylphosphinate,[41] but this was only achieved after repeating three times the cycle of complexation, fractional crystallization, and release of the enriched

product. This cumbersome procedure is avoided when the reversible enantioselective inclusion reaction is coupled to a chromatographic (i.e., a multistage) separation process.[45-47]

3. Chromatographic Separation of Enantiomers on Cyclodextrins

Cyclodextrins are used in many chromatographic procedures for selective separations of compounds, including enantiomers.[47, 48] Table 2 gives a summary of representative applications.

Table 2. Applications of cyclodextrins in chromatography [47, 48]. S = in the stationary phase, M = in the mobile phase. Electrokinetic methods: electroosmosis, electrophoresis, isotachophoresis.

	Type of chromatography					
	Thin layer (TLC)	Gas-solid and gas-liquid (GSC, GLC)	Gel inclusion (GIC)	High-pressure liquid (HPLC)	Affinity (AFC)	Electrokinetic (EKC)
Cyclodextrins	M	S		M	M	M
Modified cyclodextrins	M	S		M/S		M
Soluble cyclodextrin polymers	M					
Insoluble cyclodextrin polymers		S	S			
Immobilized cyclodextrins	S			S	S	

In thin layer chromatography (TLC) cyclodextrins can be used as either the stationary or the mobile phase.[49] For example, aqueous solutions of α-cyclodextrin, dimethyl-β-cyclodextrin, γ-cyclodextrin, and soluble polymers of β-cyclodextrin have been used as chiral mobile phases.[47] β-Cyclodextrin itself is not suitable, since it is only sparingly soluble in water. However, its hydrophilicity can be improved by adding urea[50] or by partial derivatization to hydroxyethyl- or hydroxypropyl-β-cyclodextrin.[51] β-Cyclodextrins chemically bound to silica gel have also been used for separating enantiomers.[52, 53] Furthermore, cyclodextrins have been employed for separating enantiomers in electrokinetic chromatographic techniques such as capillary isotachophoresis (CITP)[54] and high-performance capillary zone electrophoresis (HPCZE).[55] Especially noteworthy is the use of cyclodextrins with singly charged substituents in inverse micellar electrokinetic chromatography, as described by *Terabe* et al.[57] In gel inclusion chromatography (GIC)[58] mandelic acid derivatives and indole alkaloids have been separated into their enantiomers both analytically and on a preparative scale on insoluble polymers of β-cyclodextrin.[46, 47, 59]

The use of cyclodextrins for separating enantiomers in high-pressure liquid chromatography (HPLC) has proved especially successful.[60-62] Unlike many of the well-known chiral stationary phases, the cyclodextrin stationary phases described so far are compatible with aqueous and strongly polar mobile phases in the reversed phase mode of operation. The cyclodextrin stationary phases can also be used with subcritical carbon dioxide (subFC) as the mobile phase.[63] Enantiomer separations by liquid chromatography on acetyl and carbamoyl derivatives of β-cyclodextrin have also been recently reported.[64, 65]

In HPLC, as in thin layer chromatography, cyclodextrins were initially used not as immobilized stationary phases but as additives in the mobile phase in conjunction with conventional reversed phases (RP-18).[45, 66] An important advantage of this approach is that the formation of the inclusion complex enhances the fluorescence,[67] giving an appreciable reduction in the lower limit of detection when a fluorescence detector is used. This principle has also been employed in a method whereby β-cyclodextrin as a chiral stationary phase is combined with β-cyclodextrin as an additive in the mobile phase.[68] Partially and fully methylated α- and β-cyclodextrins have also been applied as additives in the mobile phase.[69]

The use of cyclodextrins for gas-chromatographic separation of enantiomers will be described in Section 4.2.

4. Cyclodextrins in Gas Chromatography

4.1. Gas Chromatographic Separation of Achiral Compounds

As long ago as the early sixties, peracylated α- and β-cyclodextrins were used above their melting point (i.e., above 220 °C) as stationary phases in packed columns for the selective separation of fatty acid esters.[70] The analysis of the retention data did not provide conclusive evidence for the formation of inclusion complexes in this case. However, permethylated α- and β-cyclodextrins, when used above their melting point or as solutions in polysiloxane (DC-710) in packed columns, gave retention times that were greater for *iso*-alkanes than for *n*-alkanes, and this was attributed to the formation of inclusion complexes.[71] In gas-solid chromatography (GSC) α- and β-cyclodextrin polyurethane resins,[72] α-, β-, and γ-cyclodextrins,[73, 74] hexakis(2,6-di-*O*-methyl)-α-cyclodextrin, and heptakis(2,6-di-*O*-methyl)-β-cyclodextrin[75] were applied for the selective separation of positionally isomeric arenes (e.g., xylene and lutidine isomers); β-cyclodextrin polymers were found to be unsuitable for this purpose.[76] The packed columns used have low efficiencies, and consequently it was not possible to observe separation of enantiomers.[77] For applications in gas-liquid chromatography (GLC) the hydrophilic nature of underivatized cyclodextrins proved to be a disadvantage, since these require highly polar solvents as achiral stationary phases. This difficulty can be avoided by using peralkylated cyclodextrins, which are lipophilic and low-melting. The first breakthrough was obtained with permethyl-β-cyclodextrin and perpropanoyl-β-cyclodextrin, the latter being covalently bonded onto a polysiloxane.[78] Underivatized α- and β-cyclodextrins, dissolved in formamide or ethylene glycol allowed the separation of positional isomers of xylene, diethylbenzene,[79] and dimethylcyclohexane, as well as *cis*- and *trans*-decalin.[80] Even more remarkable is that with these packed columns the first gas-chromatographic separations of enantiomers on cyclodextrin phases were observed for pinenes and pinanes.[81, 82]

4.2. Gas Chromatographic Separation of Enantiomers of Chiral Compounds

Although numerous gas-chromatographic studies had already been carried out with cyclodextrin stationary phases, notably the pioneering experiments of *Smolková-Keulemansová* et al.,[73, 79, 83] the important breakthrough in enantiomer separation was only achieved quite recently through the use of high-resolution capillary columns. Thus, in a 1987 monograph on the practice of enantiomer separation by capillary gas chromatography, the great potential of cyclodextrins for separating enantiomers of nonpolar molecules is mentioned only in the preface by *Gil-Av*.[84] The attempts by *Kim* in 1981 to separate enantiomers of saturated aliphatic hydrocarbons with the general formula $CR^1R^2R^3R^4$ (R = alkyl), such as 2,2,3-trimethylheptane, on stainless steel capillaries coated with a solution of permethyl-β-cyclodextrin in polysiloxane (20% in OV-101) were unsuccessful, although the retention data led to the conclusion that inclusion complexes were formed.[85a] Finally, *Kościelski* et al., from 1983 onwards, achieved enantiomer separations of some chiral bicyclic alkenes (α- and β-pinene and carene) and bicyclic alkanes (*cis*- and *trans*-pinane) on packed columns in which the supporting material was coated with a solution of α-cyclodextrin in formamide (Fig. 2).[81, 82]

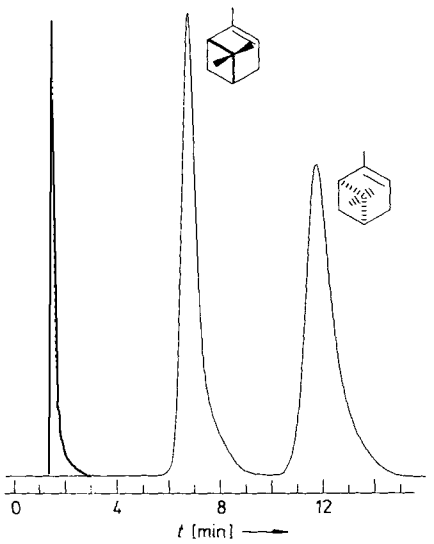

Fig. 2. Separation of the enantiomers of α-pinene on α-cyclodextrin in formamide solution supported on Celite at 44 °C. Packed column, 2 m × 4 mm. The chromatogram shown as a broken line was obtained on pure formamide (without cyclodextrin) supported on Celite. Carrier gas: helium, 2.75 bar [82].

As mentioned earlier, although these columns give large separation factors α for the enantiomers, they have very low efficiencies. Thus, the peak shapes are unusually broad, even for packed columns, as is evident from the low theoretical plate numbers of about 950–1250 for columns two meters long.[79] These columns therefore have lower efficiencies than cyclodextrin columns in HPLC, which give about 8000 theoretical plates for a length of 25 cm.[61] The method is also found to have other disadvantages, namely, the limited temperature range (maximum 70 °C), the short lifetime of the columns owing to the continual loss of solvent and water molecules, which are necessary for separation,[85b] by bleeding, and the fact that the method cannot be adapted for use with capillary columns. This has led to a considerable growth of interest in the development of thermally stable cyclodextrin phases for use in high-resolution capillary columns.

4.3. The Choice of Cyclodextrin Derivatives as Chiral Stationary Phases for High-Resolution Gas Chromatographic Separation of Enantiomers

Because of the physical properties of *underivatized* cyclodextrins, especially their decomposition on melting and their insolubility in polysiloxanes, they appear to be unsuitable for coating capillary columns. On the other hand, many cyclodextrin derivatives with more favorable melting points and/or solubilities are known.[27] Owing to the lability of cyclic oligosaccharides in acid media, only derivatizations carried out in alkaline media can be considered. Peracylated and partially or fully methylated cyclodextrins have already been used as stationary phases in gas chromatography on packed columns.[70, 71] It is essential that the C–O bonds at the chiral centers C2 and C3 remain intact during the acylation or alkylation of the hydroxyl groups in order to avoid epimerizations. In planning the derivatization strategy one must take into account the fact that the newly introduced groups at the wider end of the cyclodextrin torus may participate in the chiral recognition process.[62, 86]

Alkylation offers a number of advantages over acylation:

1. Since the ether group is more stable than the ester group, alkylated derivatives are chemically and thermally more stable and less susceptible to hydrolysis. It can be assumed that the alkoxy groups at the periphery of the cyclodextrin molecule have thermal stabilities similar to those of the glycoside ether linkages in the cyclodextrin skeleton, and the maximum temperature for use as a stationary phase is therefore limited solely by the stability of the cyclodextrin skeleton.

2. Per-*O*-alkyl derivatives are less polar than per-*O*-acyl derivatives. Consequently, the former have lower melting points and are more soluble in nonpolar polysiloxanes.

The C2 hydroxyl group is more acidic and the C6 hydroxyl group is less sterically hindered than the C3 hydroxyl group. Consequently peralkylations do not always proceed to completion. However, this fact can be used advantageously for regioselective derivatization.[87]

In the first enantiomer separations performed by high-resolution capillary gas chromatography, molten permethylated β-cyclodextrin was used, initially by *Juvancz, Alexander*, and *Szetjtli*[88, 89] and later by *Venema* and *Tolsma*.[90] On the other hand, *Schurig* and *Nowotny*[91, 92] employed a solution of permethylated β-cyclodextrin in a moderately polar polysiloxane (e.g., OV-1701) as enantioselective stationary phase. The following cyclodextrin derivatives have successfully been used in solution as stationary phases for gas-chromatographic separation of enantiomers (see Section 5):[91–98]

heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (**1**)
hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin (**2**)

octakis(2,3,6-tri-*O*-methyl)-γ-cyclodextrin (**3**)
heptakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-β-cyclodextrin (**4**)
octakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-γ-cyclodextrin (**5**)
heptakis(3-*O*-heptafluorobutanoyl-2,6-di-*O*-methyl)-β-cyclodextrin (**6**).

The following derivatives have also been investigated, and, although they can be used, they exhibit lower separation factors α:[92]

heptakis(2,6-di-*O*-methyl)-β-cyclodextrin (**7**)
heptakis(2,3,6-tri-*O*-ethyl)-β-cyclodextrin (**8**)
heptakis(2,3,6-tri-*O*-*n*-propyl)-β-cyclodextrin (**9**)
heptakis(2,3,6-tri-*O*-*n*-butyl)-β-cyclodextrin (**10**)
heptakis(2,3,6-tris-*O*-(*S*)-2′-methylbutyl)-β-cyclodextrin (**11**)
heptakis(2,3,6-tris-*O*-trimethylsilyl)-β-cyclodextrin (**12**)

The high melting points of undiluted permethylated cyclodextrins are found to be a disadvantage. Only one of these, **1**, is liquid over a relatively broad range of temperatures and is suitable in the molten state as a stationary phase. Values for the melting point given in the literature vary from 83 to 175 °C.[71, 78, 88, 89] These discrepancies may be explained by the presence of inhomogeneous, incompletely methylated products. *Venema* and *Tolsma*,[90] on the basis of calorimetric measurements, arrived at a melting point of 150 °C for **1**. However, on cooling, **1** did not crystallize but instead gave a supercooled melt, which afforded very good chromatographic results at temperatures above 76 °C. Commercially available **1** can contain 2,6-di-*O*-methyl-β-cyclodextrin.[99]

König and *Wenz*[100] found that per-*n*-pentylated cyclodextrins are liquids even below room temperature. They employed the following cyclodextrin derivatives very successfully for separating enantiomers of many different racemic mixtures on deactivated glass capillary columns (see Section 6):[100–117]

hexakis(2,3,6-tri-*O*-*n*-pentyl)-α-cyclodextrin (**13**)
hexakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)-α-cyclodextrin (**14**)
heptakis(2,3,6-tri-*O*-*n*-pentyl)-β-cyclodextrin (**15**)
heptakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)-β-cyclodextrin (**16**)
octakis(2,3,6-tri-*O*-*n*-pentyl)-γ-cyclodextrin (**17**)
octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin (**18**)

Armstrong et al.[118–123] used the following partially alkylated, liquid cyclodextrin derivatives as stationary phases on untreated fused silica capillary columns for gas-chromatographic separation of enantiomers:

hexakis(*O*-(*S*)-2-hydroxypropyl-per-*O*-methyl)-α-cyclodextrin (PMHP-α-CD, **19**)
heptakis(*O*-(*S*)-2-hydroxypropyl-per-*O*-methyl)-β-cyclodextrin (PMHP-β-CD, **20**)
hexakis(2,6-di-*O*-*n*-pentyl)-α-cyclodextrin (dipentyl-α-CD, **21**)
heptakis(2,6-di-*O*-*n*-pentyl)-β-cyclodextrin (dipentyl-β-CD, **22**)
heptakis(2,6-di-*O*-*n*-pentyl-3-*O*-trifluoroacetyl)-β-cyclodextrin (DPTFA-β-CD, **23**)

Compounds **19**–**22** all have free hydroxyl groups which make these moderately polar derivatives hydrophilic. As has been shown by ^{252}Cf mass spectrometry, the derivatives are present as partially alkylated mixtures, which give rise to the desired liquid consistency. For many racemic mixtures, the order in which the enantiomers are eluted is reversed if the stationary phase is changed from **19** to **20** or from **21** to **22**.[118]

5. Gas Chromatographic Separation of Enantiomers on Diluted Cyclodextrin Derivatives

Solutions of peralkylated cyclodextrins in moderately polar polysiloxanes, either in packed columns as described by *Casu* et al.[71] or in capillary columns as described by *Schurig* and *Nowotny*,[91, 92] are useful for the gas-chromatographic separation of enantiomers for the following reasons:

1. The diluted phase can be used over a wide range of temperatures. The essential requirement is that the cyclodextrin derivatives must be soluble in polysiloxanes; their melting points and phase transitions are unimportant. In principle, it is also possible to employ mixtures of different cyclodextrins (α, β, and γ) simultaneously and to incorporate suitable additives for competitive inclusion.
2. Coating the solutions onto glass or fused silica capillary columns, whose surfaces can be deactivated by high-temperature silylation to give very inert columns,[124] results in separations with high efficiency, even for strongly polar substrates.
3. The choice of appropriate solvents allows the polarity of the stationary phase to be varied over a wide range, independently of the nature of the derivatization of the cyclodextrins.
4. Only small quantities of the substances in solution are needed, allowing the economical use of cyclodextrins that are difficult to obtain (γ and δ cyclodextrins).
5. The low concentrations of cyclodextrins give short analysis times, and experience so far indicates that this does not reduce the separation factors α.
6. Thermodynamic parameters involved in enantiomer discrimination ($\Delta_{R,S}(\Delta G^\circ)$, $\Delta_{R,S}(\Delta H^\circ)$, and $\Delta_{R,S}(\Delta S^\circ)$) can readily be determined from relative retention data using the concept of the retention increase R' derived for complexation gas chromatography.[6, 125]

Peralkylated cyclodextrins of low molecular mass are preferred because, for example in *n*-pentylated cyclodextrins, the conformationally flexible *n*-pentyl groups probably do not contribute to chiral recognition, and they also shield the cavity to some extent.

The polydimethylsiloxane OV-101 (100% methyl groups) has proved to be a versatile solvent for optically active metal chelates in complexation gas chromatography.[6] On suitably prepared glass or fused silica capillary columns it forms stable films. Glass capillary columns coated with a solution of **1** in OV-101 can separate enantiomers of many chiral compounds above 80 °C;[92] below this temperature, peak broadening occurs. It appears that at low temperatures the limit of the solubility of cyclodextrins in the highly nonpolar polysiloxane is reached. Compound **1** is soluble in the poly-

methylphenylsiloxanes DC-550 (75% methyl, 25% phenyl) and OV-17 (50% methyl, 50% phenyl) even at room temperature, thus allowing enantiomer separations to be performed also at low temperatures; however, these phases do not form stable films on glass surfaces.

5.1. Heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin (1) in OV-1701

OV-1701 is a polysiloxane of higher viscosity (a "gum" phase, with 5% cyanopropyl groups, 7% phenyl groups, and 88% methyl groups). It has a polarity comparable to that of OV-17 and forms very stable films on suitably pretreated glass or fused silica capillary columns. Solutions of **1** in OV-1701 are ideal for gas-chromatographic separation of selected enantiomers between 25 and 200 °C.[91–93] Enantiomer separations can be performed for the following classes of compounds: cyclic ethers such as 2,5-dimethyltetrahydrofuran, underivatized cyclic and acyclic ketones, γ-lactones, terpene ketones (e.g., pulegone), underivatized *secondary* aliphatic alcohols, aromatic alcohols, terpene alcohols (e.g., 3-menthanols), underivatized aliphatic diols, esters of 2-bromopropanoic acid, 1,3-dioxolanes, aliphatic and aromatic oxiranes such as phenyloxirane, bicycloalkenes (α- and β-pinene), and bicycloalkanes (*cis*- and *trans*-pinane). Selected examples of the first enantiomer separations achieved are shown in Figure 3.

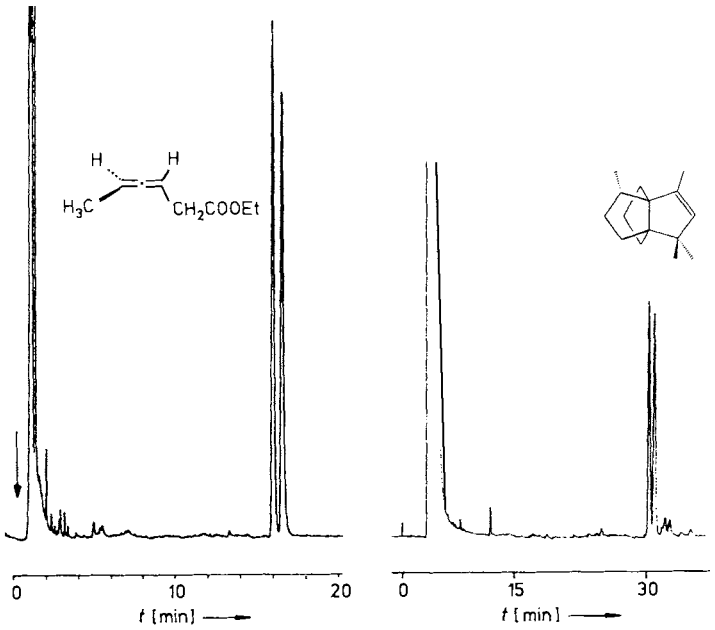

Fig. 4. Separation of the enantiomers of the allene ethylhexa-3,4-dienoate (left) and of the propellane modhephene (right) on **1** in OV-1701 (0.07 M) at 105 °C (left) and 65 °C (right). Deactivated fused silica capillary columns, 40 m × 0.25 mm I.D. (left) and 25 m × 0.25 mm I.D. (right). Carrier gas: H_2, 0.7 bar (left) and 1 bar (right).

Enantiomer separations of particular interest are those for an allene and for an unsaturated propellane (see Fig. 4), as well as the enantiomer separation of unfunctionalized saturated monocyclic hydrocarbons (Fig. 5).[94]

The high degree of deactivation of the fused silica capillary columns used can be seen from the enantiomer separation of underivatized polar diols;[98] no adsorption effects are pres-

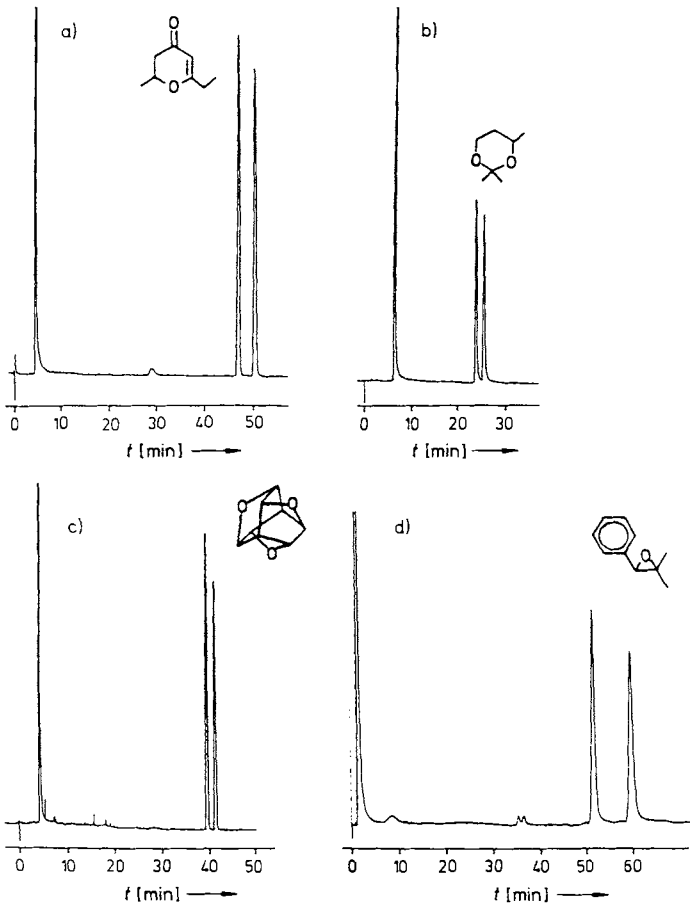

Fig. 3. Separation of the enantiomers of a) 2-ethyl-6-methyl-5,6-dihydro-γ-pyrone, b) 2,2,4-trimethyl-1,3-dioxane, c) 4,7,11-trioxapentacyclo-[6.3.0.$0^{2,6}$.$O^{3,10}$.$O^{5,9}$]undecane [126], and d) 2,2-dimethyl-3-phenyloxirane on **1** in OV-1701 (0.07 M) at 100 °C (a), 60 °C (b and e), 125 °C (c), and 50 °C (d). Glass capillary column, 40 m × 0.25 mm I.D. Carrier gas: 1 bar N_2(a), 0.7 bar N_2(b), 1 bar He (c and d) [93].

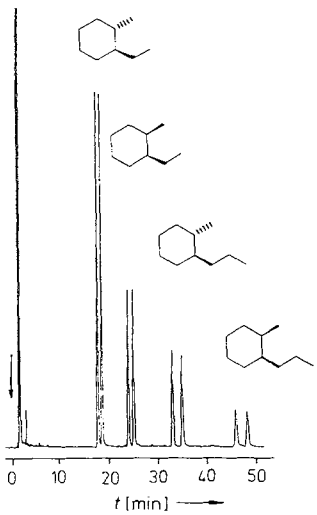

Fig. 5. Separation of the enantiomers of *cis*/*trans*-1-ethyl-2-methylcyclohexane and of *cis*/*trans*-1-methyl-2-*n*-propylcyclohexane on **1** in OV-1701 (0.07 M) at 50 °C. Deactivated fused silica capillary column, 30 m × 0.25 mm I.D. Carrier gas: H_2, 1.5 bar [94].

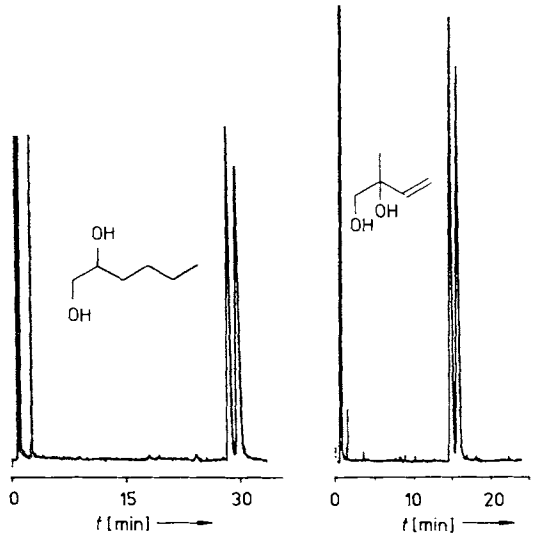

Fig. 6. Separation of the enantiomers of *n*-hexan-1,2-diol and 2-methyl-3-buten-1,2-diol on **1** in OV-1701 (0.07 M) at 75 °C. Deactivated fused silica capillary column, 25 m × 0.25 mm I.D. Carrier gas: H_2, 1 bar [97].

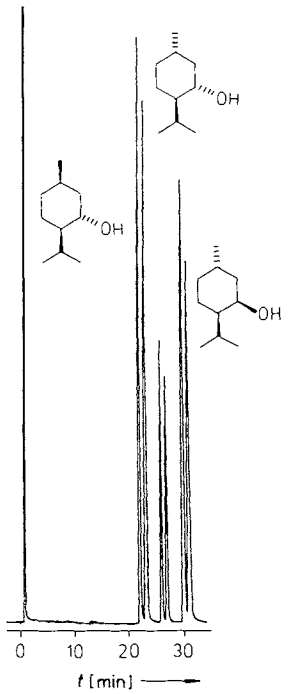

Fig. 7. Separation of the enantiomers of neomenthol, menthol, and isomenthol on **1** in OV-1701 (0.07 M) at 85 °C. Deactivated fused silica capillary column, 25 m × 0.25 mm I.D. Carrier gas: H_2, 1 bar [97].

ent, as is evident from the symmetrical shape of the peaks and the high efficiency of separation (Fig. 6).

Besides enantioselectivity, **1** in OV-1701 shows a pronounced diastereoselectivity, which can be exploited for analytical purposes, as illustrated by the separation of the diastereomeric 3-menthanols (Fig. 7).[97]

5.2. Hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin (2) and Octakis(2,3,6-tri-*O*-methyl)-γ-cyclodextrin (3) in OV-1701

It was thought that altering the dimensions of the cyclodextrin cavity would offer a way of influencing the observed enantioselectivity. This assumption was only partly verified in practice,[92] since the enantioselectivities of **1** and **2** are found to overlap. However, **2** shows a distinct selectivity for phenyloxiranes.[92]

The molecular cavity in **3** is large enough to accommodate compounds such as the spiroketals *trans*-2,3-dimethyl-1,4-dioxaspiro[4.4]nonane (Fig. 8) and 2-ethyl-1,6-dioxaspiro-

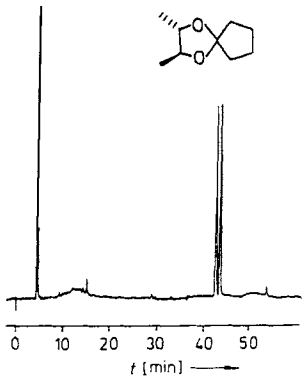

Fig. 8. Separation of the enantiomers of *trans*-2,3-dimethyl-1,4-dioxaspiro[4.4]nonane on **3** in OV-1701 (0.07 M) at 60 °C. Glass capillary column, 40 m × 0.25 mm (I.D.). Carrier gas: 1 bar H_2 [92].

[4.4]nonane and to separate them into their enantiomers.[92] For many of the enantiomers that can be separated on **3**, overlapping was observed with **1** and **2**.[92] Surprisingly, however, **3** showed no enantioselectivity for chiral saturated cyclic hydrocarbons.

5.3. Higher Alkylated Cyclodextrin Derivatives in OV-1701

Peralkylated cyclodextrins with longer *n*-alkyl groups are also soluble in OV-1701 and are suitable for gas-chromatographic separation of enantiomers, giving enantioselectivities that are in some cases different.[92] Since these cyclodextrin derivatives have greater molar masses (with 21 alkyl groups per β-cyclodextrin molecule), their solutions must contain a larger mass fraction of the cyclodextrin to give the same molar concentration. Thus, a 0.07 M solution of permethyl-β-cyclodextrin (**1**) corresponds to 10 wt%, whereas 0.07 M solutions of perethyl-β-cyclodextrin (**8**), per-*n*-propyl-β-cyclodextrin (**9**), and per-*n*-butyl-β-cyclodextrin (**10**) correspond to 12, 14, and 16 wt%, respectively.

Enantiomer separations using diluted per-*n*-pentyl-β-cyclodextrin (**15**) have also been described recently.[127] Surprisingly, blocking of the wider opening of the cyclodextrin torus in **11** by (*S*)-configurated *sec*-pentyl groups did not result in a change in enantioselectivity.[92]

5.4. Heptakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-β-cyclodextrin (4), Octakis(2,6-di-*O*-methyl-3-*O*-trifluoroacetyl)-γ-cyclodextrin (5), and Heptakis(2,6-di-*O*-methyl-3-*O*-heptafluorobutanoyl)-β-cyclodextrin (6) in OV-1701

The β-cyclodextrin derivatives **4**–**6**,[93,95] derived from heptakis(2,6-di-*O*-methyl)-β-cyclodextrin by selective per-

fluoroacylation at the 3-position, give different enantioselectivities in some cases. This is attributed to the fact that the perfluoroacyl groups are able to form additional hydrogen bonds and to induce dipole–dipole interactions. The separation factors for γ-lactones are considerably greater on **4** (Fig. 9) than on **1**, and the increase in size of the cyclodextrin cavity in **5** gives favorable enantioselectivities for δ-lactones. On the other hand, these perfluoroacylated cyclodextrin derivatives cannot be employed for enantiomer separations of chiral monocyclic alkenes and alkanes. Compound **6** is particularly suitable for separating enantiomers of cyclic and acyclic ketones.[95, 96]

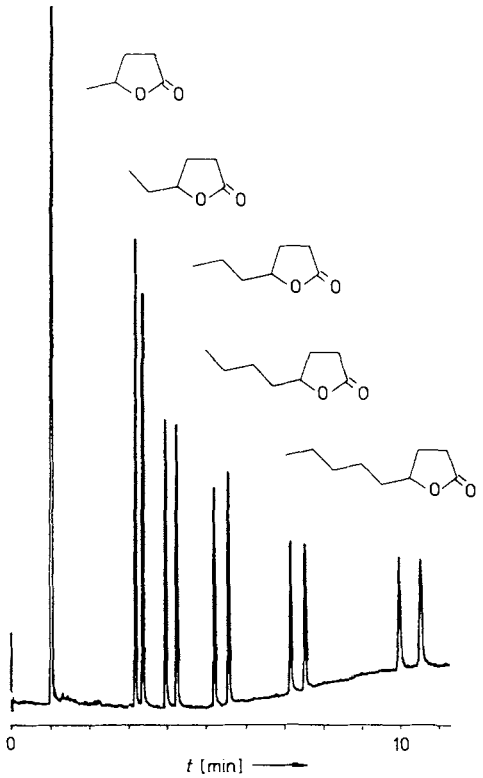

Fig. 9. Separation of the enantiomers of γ-lactones on **4** in OV-1701 (0.07 M) at 160 °C (4 °C min^{-1}). Deactivated fused silica capillary column, 25 m × 0.25 mm I.D. Carrier gas: H_2, 1.3 bar [97].

A dimeric cyclodextrin derivative, bis(permethyl-β-cyclodextrin)glutarate, showed no enantiomer separating properties,[96] despite the fact that this compound was expected to exhibit *cooperative* inclusion behavior.[128, 129]

6. Gas Chromatographic Separation of Enantiomers on Undiluted Liquid Cyclodextrin Derivatives

By introducing *n*-alkyl groups with longer chains (pentyl, hexyl, lauryl), *König* et al. were able to obtain liquid cyclodextrin derivatives preferentially suited for gas-chromatographic separation of many types of compounds on deactivated glass capillary columns.[100–117] These are prepared from α-, β-, or γ-cyclodextrin: for example, regioselective reaction of the cyclodextrin with *n*-pentyl bromide in the presence of a threefold excess of NaOH in dimethyl sulfoxide yields the 2,6-di-*n*-pentylated derivatives.[130] The 3-hydroxyl groups are then further alkylated (in this example, with *n*-pentyl bromide/NaOH) or are acylated using an acyl halide. Per-*n*-pentylcyclodextrins are thermally stable, viscous liquids, which are colorless at room temperature and can be coated onto appropriately deactivated glass surfaces.

The results of *König* et al.[105] more than confirmed the prediction made in 1987 by *Szejtli*,[48] one of the pioneers of cyclodextrin research, who wrote: "It is expected that good complex forming low-melting derivatives of cyclodextrins in capillary columns will result in excellent chiral recognition and resolution of many racemates."

Indeed, the regioselective alkylation and acylation open up the way to a wide variety of possible cyclodextrin stationary phases for gas-chromatographic separation of enantiomers. The range of enantiomer-separation applications

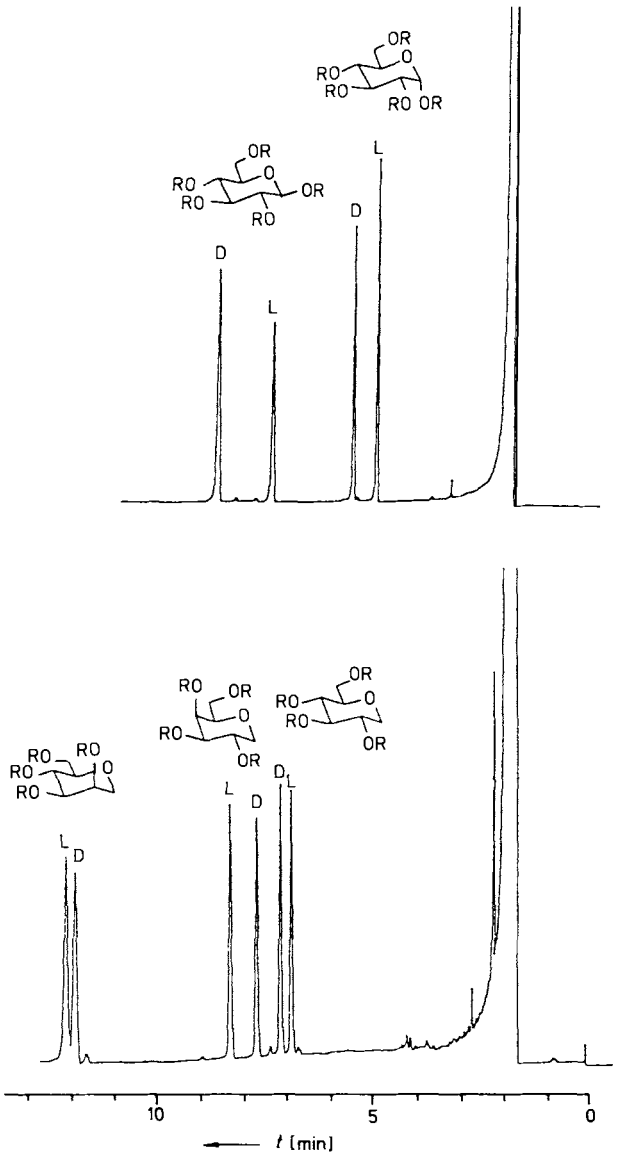

Fig. 10. Separation of the enantiomers of pertrifluoroacetylated carbohydrates and anhydroalditols on **13** at 115 °C and 120 °C. Glass capillary column, 40 m. Carrier gas: H_2, 1 bar. Top: α- and β-glucopyranose. Bottom: 1,5-anhydroglucitol, -galactitol, and -mannitol (R = CF_3CO) [108].

extends from trifluoroacetylated amino and hydroxyl compounds, including carbohydrates, derivatized amino acids, olefins, alkyl halides, and spiro- and bicyclic acetals to diolefin π complexes of metal carbonyls.

6.1. Hexakis(2,3,6-tri-*O*-*n*-pentyl)-α-cyclodextrin (13)

This *lipo*philic cyclo*dex*trin (Lipodex A) stationary phase, which is soluble in dichloromethane, can be used on glass capillary columns to separate racemates of trifluoroacetylated alcohols,[102] epoxy alcohols,[112] diols, triols, carbohydrates (Fig. 10),[108] underivatized 4-methyl-3-heptanone,[106] alkyl halides,[110] spiroacetals,[110] and glycerol derivatives. This phase, or its per-*n*-hexylated analogue, has also been used to resolve enantiomers of *N*-alkylated barbiturates.[116]

6.2. Hexakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)-α-cyclodextrin (14)

This lipophilic cyclodextrin (Lipodex B) stationary phase is particularly effective for separating racemic five-membered heterocycles such as γ-lactones, cyclic carbonates of 1,2-diols, and succinimides.[107] High separation factors are also achieved with this phase for racemic trifluoroacetylated carbohydrates and hydroxy compounds such as aldols, cyanohydrins, and amino alcohols.[106]

6.3. Heptakis(2,3,6-tri-*O*-*n*-pentyl)-β-cyclodextrin (15)

This lipophilic cyclodextrin (Lipodex C) stationary phase allows trifluoroacetylated alcohols, trifluoroacetylated carbohydrates, lower homologues of hydroxycarboxylic acid esters, and cyanohydrins to be separated into their enantiomers.[113] Especially noteworthy is the separation of the enantiomers of the pheromone grandisol, which succeeded despite the fact that the trifluoroacetylated hydroxyl group is separated from the chiral center by two carbon atoms (Fig. 11).

This phase can also be used to resolve the enantiomers of acyclic, monocyclic, and bicyclic olefins and dienes.[109, 113] Here, the enantioselective inclusion process was found to be sensitive to small changes in the structure of the substrate. Thus, 4-methyl-1-hexene and 4-methylcyclohexene could not be separated, in contrast to the 3-methyl isomers. This phase also showed enantioselectivity for cyclic and acyclic alkyl halides with up to eight carbon atoms.[113] For example, racemic mixtures of the 2-chloroalkanes from 2-chlorobutane up to 2-chlorooctane have been resolved (Fig. 11). In contrast to the higher homologues 1,2-dibromoheptane and 1,2-dibromooctane, 1,2-dibromohexane could also be separated into its enantiomers.

6.4. Heptakis(3-*O*-acetyl-2,6-di-*O*-*n*-pentyl)-β-cyclodextrin (16)

This lipophilic cyclodextrin (Lipodex D) stationary phase, whose acetyl groups are capable of forming hydrogen bonds,[106] allows enantiomer separations to be carried out

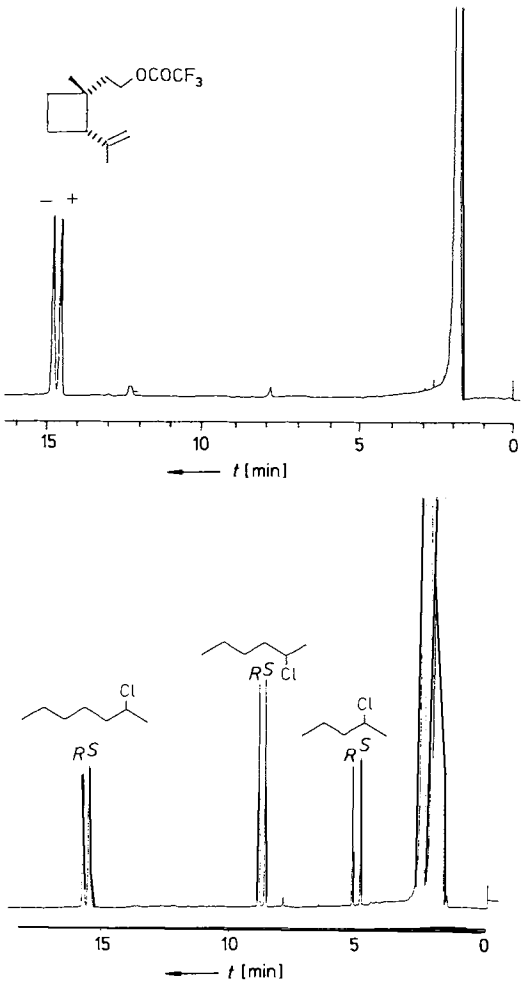

Fig. 11. Separation of the enantiomers of grandisol (top) and alkyl halides (bottom) on **15** at 90 °C and 50 °C, respectively. Glass capillary column, 42 m. Carrier gas: H_2, 1 bar [113].

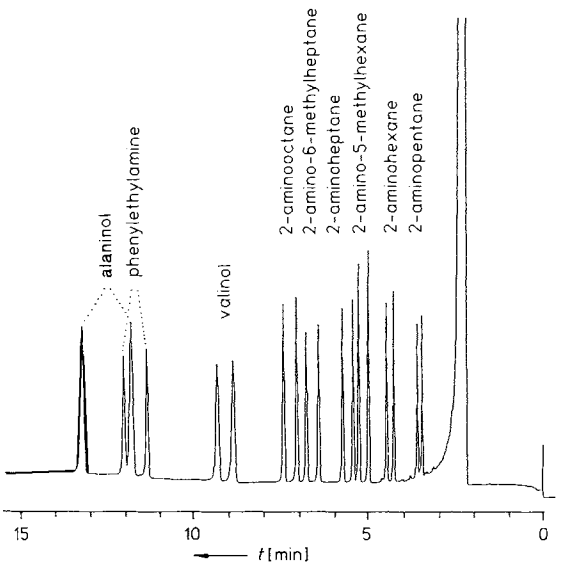

Fig. 12. Separation of the enantiomers of trifluoroacetylated amines and amino alcohols on **16** at 140 °C (2 °C min^{-1}). Glass capillary colum, 45 m. Carrier gas: H_2, 1 bar [103].

on polar compounds such as trifluoroacetylated amines with α- and β-chirality, amino alcohols, esters of β-amino acids, and cyclic *trans*-diols[103] (Figs. 12 and 13).

The presence of the acetyl group gives particularly high separation factors α for trifluoroacetylated amines and amines containing additional functional groups. Many of these derivatized amines could not previously be separated into their enantiomers on amino acid derivatives as stationary phases. Separation of the enantiomers of the methyl ester of α-lipoic acid can also be achieved using **16**.[115]

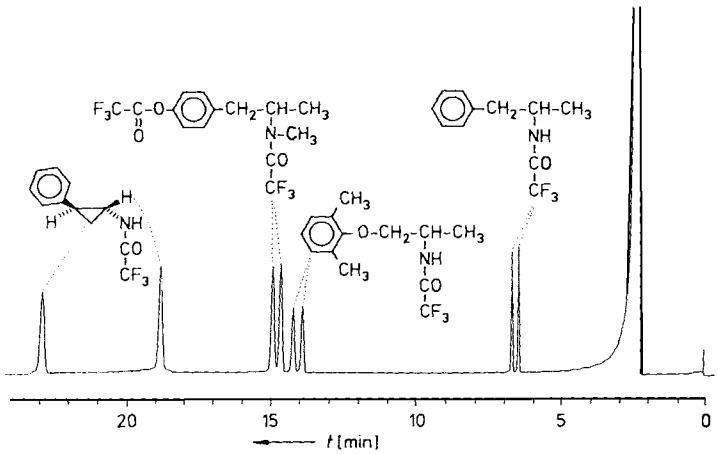

Fig. 13. Separation of the enantiomers of trifluoroacetylated amphetamine, mexiletine, pholedrin, and tranylcypromin (from right to left) on **16** at 175 °C. Glass capillary column, 45 m. Carrier gas: H_2, 1 bar [103].

6.5. Octakis(2,3,6-tri-*O*-*n*-pentyl)-γ-cyclodextrin (17) and Octakis(3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin (18)

For γ-cyclodextrins the greater diameter of the cavity, the increased conformational flexibility of the macrocycle, and the fact that these compounds have been found to form unstable inclusion complexes[49] lead one to expect a reduction in enantioselectivity. Instead, *König* et al.[114, 115] found that **17** and **18** were suitable for separating enantiomers of various types of compounds, giving large separation factors in some cases. Especially noteworthy is the separation of enantiomers of nonpolar substrates such as alkenes with β-chirality: for example, 2,4-dimethyl-1-heptene, the planar-chiral alkene *trans*-3,3,8,8-tetramethylcyclooctene, and the planar-chiral metal carbonyl π complexes tricarbonyl (η^4-2-methylene-1,3-butanediyl)iron(0), and tricarbonyl(η^4-2-methyl-1,3-butadiene)iron(0) have been separated on the hydrophobic liquid **17** (Fig. 14).[115]

Racemic α-alkyl and *N*-methyl α- and β-amino acids in the form of *N*-trifluoroacetyl-*O*-methyl derivatives have also been resolved into their enantiomers on **18**.[114] Except in the case of proline, the D enantiomers of α-amino acids are eluted before the L antipodes, thus facilitating determination of the enantiomeric purity of naturally occurring L-amino acids. However, histidine, tyrosine, and arginine have so far turned out to be unsuitable for analysis.

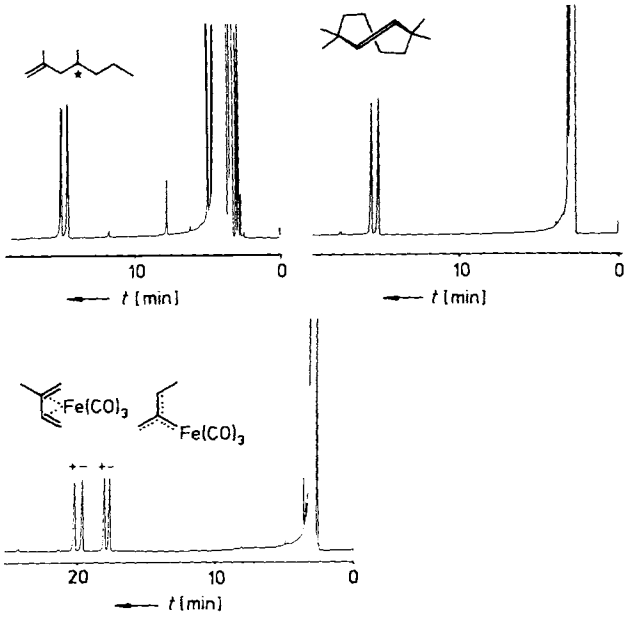

Fig. 14. Separation of the enantiomers of 2,4-dimethyl-1-heptene (top left), *trans*-3,3,8,8-tetramethylcyclooctene (top right), and tricarbonyl(η^4-2-methylene-1,3-butanediyl)iron(0) and tricarbonyl(η^4-2-methyl-1,3-butadiene)iron(0) [117] (bottom) on **17** at 60 °C, 95 °C, and 80 °C, respectively. Deactivated glass capillary column, 50 m. Carrier gas: H_2, 1 bar [115].

O-trifluoroacetylated esters of α- and β-hydroxycarboxylic acids can also be resolved, including the esters of tartaric, malic, and mandelic acid.

Racemic alcohols and diols have been resolved in derivatized form as trifluoroacetyl esters, and a number of terpene ketones such as fenchone, menthone, isomenthone, and camphor have been resolved without derivatization (Fig. 15).

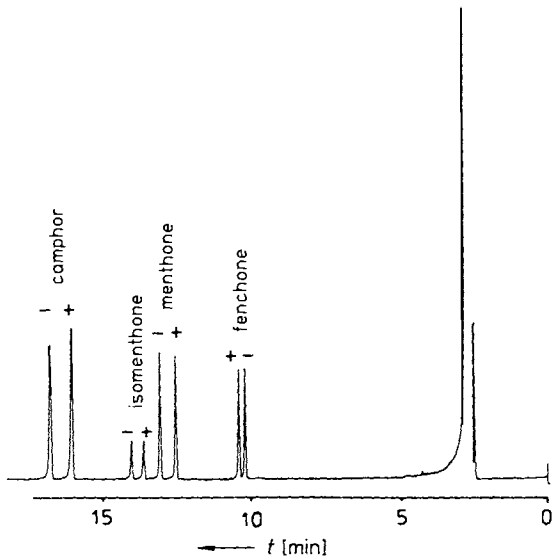

Fig. 15. Separation of the enantiomers of underivatized fenchone, menthone, isomenthone, and camphor on **18** at 100 °C (2 °C min^{-1}). Deactivated glass capillary column, 45 m × 0.25 mm I.D. Carrier gas: H_2, 1 bar [114].

Bicyclic and tricyclic acetals (bark beetle pheromones such as frontalin, *exo*- and *endo*-brevicomin, and lineatin), which were previously separated by complexation gas chromatog-

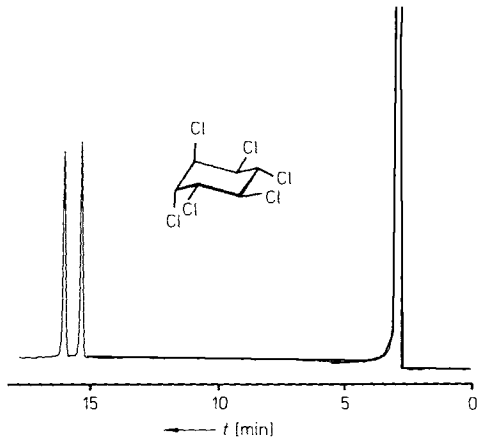

Fig. 16. Separation of the enantiomers of α-hexachlorocyclohexane on **17** at 190 °C. Deactivated glass capillary column, 50 m × 0.25 mm I.D. Carrier gas: H_2, 1 bar [114].

raphy,[2] give large separation factors α with these stationary phases, as also do γ-, δ-, and ε-lactones. Of particular interest is the separation of the enantiomers of α-hexachlorocyclohexane at 190 °C (Fig. 16).[114]

6.6. Heptakis(*O*-(*S*)-2-hydroxypropyl-per-*O*-methyl)-β-cyclodextrin (PMHP-β-CD, 20)

This viscous liquid, which is hydrophilic, relatively polar, and water-soluble, is a suitable enantioselective stationary phase for coating onto fused silica capillary columns.[120] Mass-spectrometric analysis has indicated that the product is a mixture of partially alkylated derivatives. Various types of compounds have been separated into their enantiomers on this phase, including trifluoroacetylated secondary amines, trifluoroacetylated amino alcohols, epoxides, β- and γ-lactones, derivatives of norbornene and norbornane, and monocyclic acetals with five- and six-membered rings. Surprisingly, introducing an additional chiral center via the 2-hydroxypropyl substituent has no effect on the observed enantioselectivity for a wide range of guest molecules, as was shown by comparative experiments using derivatives with substituents having the (*S*) and (*R*) configurations.[120] Apart from some isolated cases, no advantages resulted from using the corresponding α- (**19**) or γ-cyclodextrin derivatives.[120]

6.7. Hexakis(2,6-di-*O*-*n*-pentyl)-α-cyclodextrin (Dipentyl-α-CD, 21) and Heptakis(2,6-di-*O*-*n*-pentyl)-β-cyclodextrin (Dipentyl-β-CD, 22)

These stationary phases, which are more polar than the per-*n*-pentyl cyclodextrin derivatives, can easily be coated onto fused silica capillary columns.[122] For these phases the liquid consistency is again attributed to the presence of a mixture of partially alkylated derivatives. In experiments with 65 racemic compounds, striking differences were found between the enantioselectivities obtained with the α-, β-, and γ-cyclodextrin derivatives.[122] The range of compound types that can be separated on **21** and **22** is similar to that for per-*n*-pentylated cyclodextrins.

6.8. Heptakis(2,6-di-*O*-*n*-pentyl-3-*O*-trifluoroacetyl)-β-cyclodextrin (DPTFA-β-CD, 23)

This phase is especially suitable for separating racemic trifluoroacetylated carbohydrates into their enantiomers.[123] For α-DL-galactose (pyranose) the separation factor α at 120 °C is 2.14.

7. Applications

The main area of application of chiral cyclodextrin phases at present is in *enantiomer analysis* by gas chromatography of chiral compounds that can be vaporized without decomposition. Such applications include the determination of the enantiomeric purity of products obtained by enantioselective reactions and elucidation of the enantiomeric composition of natural substances (e.g., pheromones and flavors) and of pharmaceutical products.[131] An advantage of the method is that many compounds can be analyzed directly without derivatization or sample pretreatment. A few representative examples are briefly mentioned here.

The enantioselective telomerization of butadiene and formaldehyde to *cis*- and *trans*-2,5-divinyltetrahydropyran and the enantiomeric analysis of the products has been described.[127, 132] The stereochemistry of the rhodium(I)-catalyzed hydrogenation of 1-ethyl-2-methylcyclohexene to 1-ethyl-2-methylcyclohexane has been investigated; no enantioselectivity was observed in this case.[96] An analysis of the flavor constituent of hazel nuts, (*E*)-5-methylhept-2-en-4-one (filbertone), revealed a mixture with a preponderance of the *S* antipode.[133]

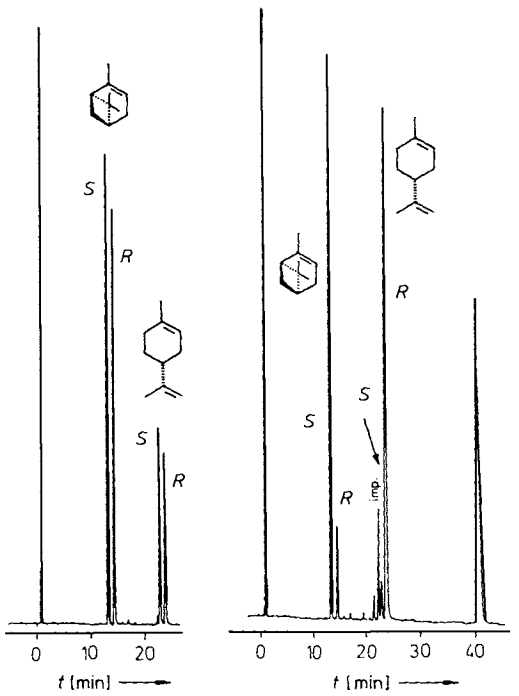

Fig. 17. Separation of the enantiomers of α-pinene and dipentene (limonene) on **1** in OV-1701 at 50 °C. Fused silica capillary column, 25 m × 0.25 mm I.D. Carrier gas: H_2 0.9 bar. Left: racemic mixtures. Right: determination of the enantiomeric purity of the alkenes in a pharmaceutical formulation by headspace analysis [134].

Enantiomeric excesses *ee* differing considerably from 100% were found for optically active α-pinene and limonene in commercial samples and in a pharmaceutical preparation (Fig. 17).[134] The enantiomeric composition of γ-lactones in foodstuffs has been determined by multidimensional gas chromatography.[135]

The absolute configuration of α-damascone and α-ionone in black tea has been investigated (Fig. 18).[136] A number of

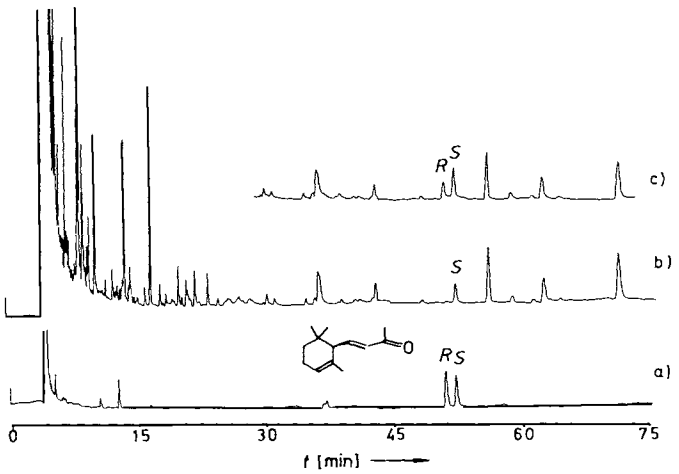

Fig. 18. a) Separation of the enantiomers of α-ionone on octakis(3-*O*-methyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin. b) Gas chromatogram of a fraction from an extract of black tea. c) Coinjection of a) and b). Deactivated glass capillary column, 60 m, 115 °C. Carrier gas: H_2, 1 bar [136].

olefinic algal pheromones (multifidene, aucantene) were separated into their enantiomers using cyclodextrin derivatives, thus laying the basis for clarifying their stereochemical interrelationships.[137] The determination of the enantiomeric composition of chiral *cis*- and *trans*-2,3-epoxy alcohols, which can be prepared by asymmetric epoxidation and have numerous applications, was achieved using per-*n*-pentylated α-cyclodextrin.[12] A particularly interesting application is the gas-chromatographic determination of the enantiomeric purity of tricarbonyl(η^4-2-methylene-1,3-butanediyl)iron(0) and tricarbonyl(η^4-2-methyl-1,3-butadiene)iron(0).[115]

8. Remarks on the Separation Mechanism

As early as 1952, *Cramer*, in a pioneering study of the resolution of racemates on cyclodextrins,[39] wrote: "From this we have discovered a relationship between molecular shape and biochemical activity. Here the cyclodextrin molecule exerts its effect solely as a result of its geometrical shape, not by means of functional groups. However, only those reagents that can enter the molecular cavity can be considered. Thus, striking parallels with the lock and key relationships of biochemical processes are revealed here." On the basis of thermodynamic parameters obtained for cyclodextrin inclusion complexes, *Saenger*[15] concluded that "the inclusion process does not depend primarily on the (chemical) nature of the guest molecule".

The results obtained so far on the gas-chromatographic separation of enantiomers on cyclodextrin derivatives show a remarkably wide range in the types of racemates which can be resolved. They include strongly polar chiral diols, free carboxylic acids, derivatized amino acids and carbohydrates, metal coordination compounds, allenes, propellanes, planar-chiral cycloalkenes, and unfunctionalized monocyclic hydrocarbons. In all cases, molecules that are identical in constitution but differ in their configurations (incongruent mirror-image structures) are discriminated by means of an *aracemic* chiral stationary phase, thereby allowing chromatographic enantiomer separation. The interaction necessary for this to occur can be strong or weak[6] and can consist of an inclusion process and/or other chemical interactions.

With regard to the nature of the host–guest interaction in cyclodextrins, a number of different contributions have been considered:[12, 13, 15, 16, 20] (1) steric fit by conformational change of the guest molecule and/or of the cyclodextrin molecule (induced fit) during the molecular inclusion process,[138–140] (2) hydrogen bonding,[24, 141] (3) van der Waals interactions (London dispersion forces and dipole–induced-dipole interactions), (4) hydrophobic interactions, (5) dipole–dipole interactions, (6) charge-transfer interactions, (7) electrostatic interactions, (8) release of "high-enthalpy" water molecules from the cyclodextrin cavity, (9) release of solvent molecules from the cyclodextrin cavity with a gain in entropy, (10) relief of the ring strain of the macrocycle.

To achieve enantiomer separation by the inclusion process, the molecular geometry should play an important role (shape selectivity and size selectivity). For polar guest molecules chemical interactions can also be important (chemical functionality selectivity). The results obtained so far surprisingly show that the molecular shape of the guest can be varied over a wide range. Thus, in addition to cyclic compounds, branched acyclic molecules such as underivatized ketones, haloalkanes, olefins, and allenes can be separated into enantiomers. Moreover, the molecular size does not appear to be a crucial factor. *Armstrong* et al. have even questioned the importance of the inclusion process, since certain guest molecules do not exhibit selectivity with respect to the diameter of the cyclodextrin cavity (α, β, or γ).[120] Furthermore, peak broadening, which often occurs with inclusion mechanisms due to delayed mass transfer, is not observed here.

Whereas the enantiomer separation of saturated cyclic hydrocarbons such as *trans*-1,2-dimethylcyclohexane can be unambiguously attributed to a molecular inclusion process,[94] for polar substrates one must also take into account additional enantioselective interactions (e.g., hydrogen bonding with cyclodextrins having acyl groups at the 3-position). In this connection it is significant that *Schurig* et al. have also observed enantiomer separations (e.g., of racemic cyclic ethers and aromatic oxiranes) using open-chain per-*n*-pentylated amylose.[142] Thus, enantiomer discrimination can also presumably occur at the outer surface of the cyclodextrin molecule. Surprisingly, modifying the cyclodextrin cavity opening by incorporating chiral anchoring groups has no effect on the enantioselectivity of the host molecule. For example, heptakis(2,3,6-tri-*O*-(*S*)-2′-methylbutyl)-β-cyclodextrin (**11**) does not allow enantiomer separation,[92]

and the configuration of the 2-hydroxypropyl group in derivatives of **19** and **20**[118] does not affect the observed enantioselectivity.[120] On the other hand, the separation of the enantiomers of acylated alcohols and amines on polar cyclodextrin derivatives is dependent on the nature of the acyl group (Fig. 19).[119] Since the acetyl and trifluoroacetyl groups are similar in size and shape, the difference in enantioselectivity is attributed to the different electronic properties of these two acyl groups (polarity and propensity to form hydrogen bonds).[119]

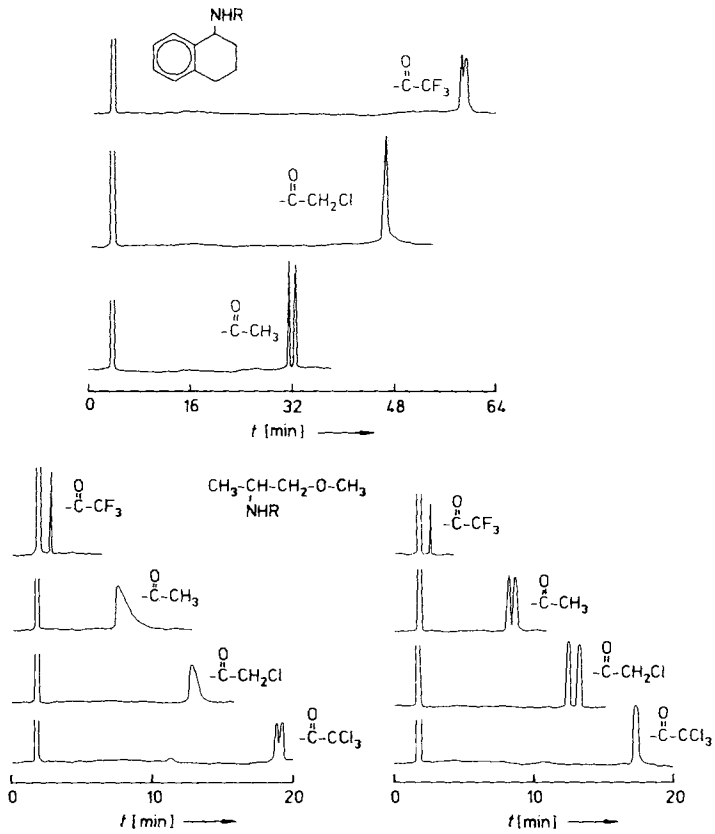

Fig. 19. Effect of derivatization on the separation of the enantiomers of acylated amines. Top: 1,2,3,4-tetrahydro-1-naphthylamine on **22**. Bottom left: 2-amino-1-methoxy-propane on **22**. Right: 2-amino-1-methoxy-propane on **20** [119].

In many cases, minor structural differences in the guest molecules can have dramatic effects on chiral recognition.[92] For example, a comparison of different alkyl-substituted γ-butyrolactones showed that, whereas the chain lengths of alkyl substituents at the γ-position (Fig. 9) and additional substituents at the β-position have only slight effects on the separation factor α, introducing a methyl group at the α-position relative to the carbonyl group leads to inferior separation.[92] Again, whereas 3,3,5-trimethylcyclohexanone was successfully separated quantitatively into its enantiomers on **1**, no separation was obtained for the 2,2,6 isomer.[92]

Methylation of cyclodextrins increases the depth of the molecular cavity (to about 1000–1100 pm) and enhances its conical shape, since the larger opening containing the secondary methoxy groups is increased while the opposite smaller opening containing the primary methoxy groups is narrowed.[138] *Harata* et al. therefore predicted that permethylated cyclodextrins should have a greater propensity for enantiomer differentiation than the corresponding underivatized compounds.[138–140] Contrary to this prediction it is found that, compared with underivatized cyclodextrins in formamide solution (cf. Fig. 2),[81, 82] the separation factors α for pinenes (Fig. 17) and pinanes, for example, on the alkylated and acylated cyclodextrins investigated so far, both in their undiluted and diluted forms, are very small. It is only the very high efficiency of the high-resolution capillary columns used that allows quantitative enantiomer separation in these cases with α values of 1.02 and above. This corresponds to a value of only about 20 cal mol^{-1} for the difference in the free energies for enantiomer discrimination $\Delta_{R,S}(\Delta G^{\circ})$.[7] Enantiomer separations based on such small free energy differences are thus attributed to a rather unpredictable "random effect",[93] which is unlikely to lead to mechanistic conclusions. Accordingly, the observation that minor changes in the host structure can result in reversals of the elution order of enantiomers (Fig. 20)[118] does not seem surprising.

It is known from X-ray crystal structure studies that hydrogen bonding can occur between the host molecule and suitable guest molecules.[24, 86, 141] Crystal structures of inclusion complexes formed by the enantiomer of mandelic acid indicate that such hydrogen bonds can make a crucial contribution to enantiomer differentiation even for permethylated cyclodextrins. Thus, the complex formed between permethyl-α-cyclodextrin and D-mandelic acid contains a hydrogen bond between host and guest which is not present in the complex with L-mandelic acid.[140] It is not clear to what extent the structure in the solid state can be extrapolated to that in solution (packing effects). That some free alcohols undergo enantiomer separation, whereas the corresponding acetates do not,[91–93] may be due to the contribution of hydrogen bonding to chiral recognition. Permethylated cyclodextrins, in contrast to the underivatized compounds, can only act as acceptors for hydrogen bonding to compounds with protic groups.

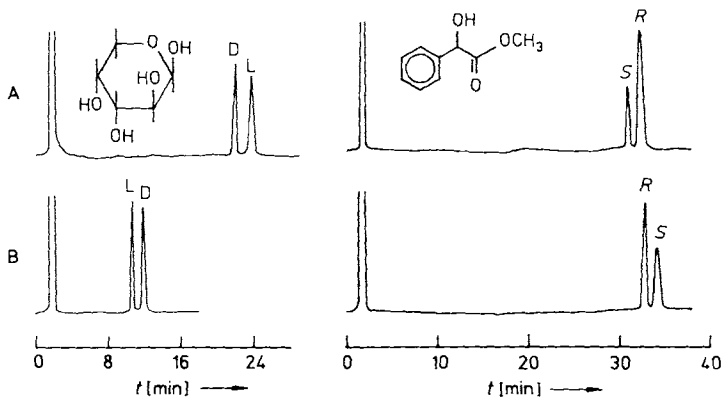

Fig. 20. Reversal of the order of elution of enantiomers on polar cyclodextrin derivatives. Separation of the enantiomers of pertrifluoroacetyl-β-D,L-arabinose (left) and mandelic acid methyl ester (right) on A) **20** and B) **22** at 80 °C and 120 °C, respectively. Fused silica capillary column, 10 m. Carrier gas: N_2 [118].

The so-called classical hydrophobic interactions are mainly caused by entropy effects. Although the formation of the host–guest complex is accompanied by a decrease in entropy, the removal of the hydration shell from the guest molecule and the release of solvent molecules from the cyclodextrin cavity can result in an overall increase in entropy. It will be shown later that the latter type of hydrophobic interaction could also be important for cyclodextrin derivatives diluted in polysiloxane, whereas the effect of any dehydration can be neglected, since water molecules should be completely removed during the conditioning of the gas-chromatographic columns and the injection of the substrate at high temperatures.

Since the formation of the inclusion complex is largely independent of the chemical properties of the guest molecule, it has been suggested that one of the driving forces for the inclusion process is the removal of high-enthalpy water molecules from the molecular cavity, where they reside in an unfavorable, hydrophobic environment.[15] According to the argument above, this contribution should be negligible under the conditions of the gas-chromatographic experiment.

Enantioselective interactions between chiral and prochiral guest molecules and cyclodextrins have been detected by a number of methods.[18, 31, 32, 34] Since the use of cyclodextrins for enantiomer separation in gas chromatography only began quite recently, no theoretical models for the mechanism of chiral recognition have yet been put forward. On the other hand, for the separation of racemates by fractional crystallization with cyclodextrins,[43] for cyclodextrin-catalyzed reactions,[143] and for liquid chromatography (HPLC) on cyclodextrin stationary phases, a three-point interaction model analogous to the models of *Easson* and *Stedman*[144] and of *Dalgliesh*[145] has been proposed.[61, 62] According to this model, a lipophilic, and preferably aromatic, part of the molecule is included in the cyclodextrin cavity, and two polar substituents interact with the secondary hydroxyl groups at the wider opening of the cyclodextrin cavity (e.g., by hydrogen bonding). This model is an appropriate one to account for enantiomer differentiation of arenes with a chiral center in the side-chain and several polar groups at the chiral center (e.g., mandelic acid derivatives and propanolol). However, it is not suitable for alicyclic compounds with chiral centers in the ring, nor for compounds that have no functional groups capable of forming hydrogen bonds. The necessity for an "aromatic presence", as observed in liquid-chromatographic enantiomer separations on carbohydrate stationary phases, is not found in the gas-chromatographic counterpart.

Although van der Waals forces have only a short range (being proportional to r^{-6}), the close contact between host and guest molecules can cause these forces to contribute appreciably to the selective inclusion process. The quantitative enantiomer separation observed for chiral alkanes on **1** (cf. Fig. 5),[82, 94] where other interactions can be excluded, shows that on cyclodextrin phases van der Waals interactions alone are sufficient for differentiating between enantiomers. In a molecular modeling study,[146] force field calculations and molecular dynamics simulations were applied to the inclusion complexes formed by the enantiomers of *cis*- and *trans*-1-ethyl-2-methylcyclohexane with **1**. From Figure 21 (left) it can be seen qualitatively that there is indeed a close contact between the van der Waals surfaces in the complex of *trans*-1-ethyl-2-methylcyclohexane (blue) with **1** (red). The complex is viewed from the side of the secondary methoxy groups, that is, from the wider end of the cavity. Although the guest molecule is completely enclosed by the host, it was not possible on the basis of such a small free energy difference to make predictions about the diastereo- and enantioselectivities, and the calculated values for the stabilities of the complexes were not in agreement with the experimentally observed gas-chromatographic elution order of the *cis* and *trans* isomers (cf. Fig. 5).[92] As already mentioned, carrying out molecular calculations on the basis of crystal structure data and of thermodynamic parameters ($\Delta_{R,S}(\Delta G^\circ)$, $\Delta_{R,S}(\Delta H^\circ)$, $\Delta_{R,S}(\Delta S^\circ)$), determined by gas chromatography for highly enantioselective host–guest complexes, is a worthwhile task for the future.

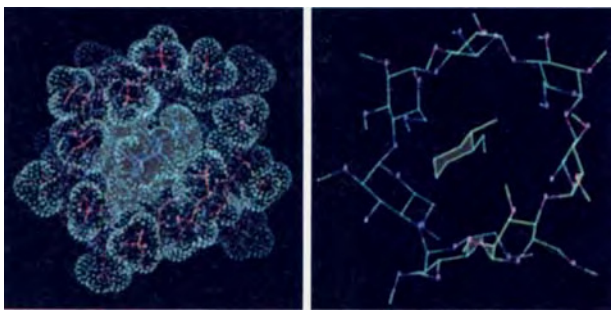

Fig. 21. Molecular modeling study of the inclusion complex of *trans*-1-ethyl-2-methylcyclohexane (one enantiomer) with **1** [146]. Left: with van der Waals radii. Right: without van der Waals radii.

Gas-chromatographic separation of enantiomers is a thermodynamically controlled process. The enantiomer discrimination involving a racemic guest and an aracemic (enantiomerically pure) host is described by the Gibbs–Helmholtz equation (a) and corresponds to the sum of the enthalpy

$$-\Delta_{R,S}(\Delta G^\circ) = -\Delta_{R,S}(\Delta H^\circ) + T\Delta_{R,S}(\Delta S^\circ) \qquad \text{(a)}$$

and entropy differences in the complexation of the enantiomers with the chiral stationary phase. The process is temperature-dependent, and it has recently been observed that the order of elution of the enantiomers on a given chiral phase (amino acid derivatives or metal complexes) is reversed above the "isoenantioselective temperature" T_{iso}.[147]

For a thermodynamic characterization of the mechanism of enantiomer discrimination it is useful to distinguish between the total interaction, as described by $-\Delta G^\circ$, and the difference in free energy between the complexes of the two enantiomers, $-\Delta_{R,S}(\Delta G)^\circ$.[6] One can assume that for a given interaction between host and guest, which can be strong or weak, small additional interactions are sufficient to produce enantiomer discrimination. Accordingly, for the cyclodextrin inclusion process the crucial factor is the competitive behavior of the enantiomers, as determined by the enthalpy and entropy contributions to chiral recognition at a given temperature. Thermodynamic data on enantiomer discrimination have been determined for *cis*-1-ethyl-2-methylcyclo-

hexane and *cis*-pinane on **1** in OV-1701 (0.07 M) (cf. Table 3).[95, 96] The thermodynamic parameters were obtained from relative retention data, using the concept of the retention increase R' adopted from complexation gas chromatography.[6, 125]

Table 3. Thermodynamic parameters for the separation of the enantiomers of *cis*-1-ethyl-2-methylcyclohexane and *cis*-pinane on **1** in OV-1701 (0.07 M) obtained from temperature-dependent measurements between 30 °C and 70 °C using *n*-octane and *n*-decane as standards [95, 96].

Substrate	Standard	$\Delta\Delta H$ [kJ mol^{-1}]	$\Delta\Delta S$ [J K^{-1} mol^{-1}]
	C_8H_{18}	−0.2	0.3
	$C_{10}H_{22}$	−0.2	0.3
	C_8H_{18}	−0.2	0.7
	$C_{10}H_{22}$	−0.2	0.8

Surprisingly, $\Delta_{R,S}(\Delta H^\circ)$ and $\Delta_{R,S}(\Delta S^\circ)$ have opposite signs for the cycloalkanes investigated. It follows from this that no (positive) isoenantioselective temperature exists, and therefore no peak inversions are expected in this system (see also Ref. [118]). The increase in entropy, which is unusual for an association process, may be explained by the fact that the solvent (polysiloxane) molecules released from **1** on inclusion of the hydrocarbon molecules gain individual degrees of freedom. Both $-\Delta_{R,S}(\Delta H^\circ)$ and $\Delta_{R,S}(\Delta S^\circ)$ thus contribute to the enantiomer discrimination, as described by $-\Delta_{R,S}(\Delta G^\circ)$, and a quantitative enantiomer separation occurs even for small entropy and enthalpy differences. A low value of $\Delta_{R,S}(\Delta H^\circ)$ implies that the enantiomer separation shows only a slight temperature dependence, and quantitative separation is obtained even at high temperatures (e.g., 250 °C), as is generally found using cyclodextrin stationary phases.

A systematic search for enantioselective host–guest systems with high separation factors ($\alpha > 2$) is not only a prerequisite for the preparative applications of racemate separation, but is also warranted in order to optimize model systems that can be used for mechanistic studies, thermodynamic measurements of enantioselectivity, crystal structure studies, and computer-aided calculations on the different diastereomeric association complexes.

9. Practical Aspects and Outlook

High-resolution gas-chromatographic separations of enantiomers using cyclodextrin derivatives are achieved at present only with analytical capillary columns. Separations on a semipreparative scale can therefore only be expected in rare cases with the separation factors α that are currently obtained. Enantiomer separations can be performed in the usual temperature range of 25 to 250 °C. For special applications it is also possible to use lower temperatures (−25 °C). The enantioselective phases have a long lifetime if oxygen-free carrier gases are employed (e.g., nitrogen, helium, hydrogen). For samples diluted in solvents the quantities injected should be minimized by using the split injection technique (1:100). The successful coating of glass or fused silica capillary columns with undiluted or diluted cyclodextrin derivatives requires some expertise and can only be carried out satisfactorily on pretreated, deactivated surfaces.[124] Established methods of treatment are leaching, persilylation, or Carbowax deactivation.[124] Capillary columns coated with cyclodextrins are commercially available from well-known chromatography suppliers, including Chrompack (Middelburg, Netherlands) (diluted cyclodextrin **1** on fused silica capillary columns, cf. Section 5),[98] Macherey-Nagel (Düren, FRG) (undiluted *n*-pentylated/acylated cyclodextrin phases **13**–**16** (Lipodex) on glass capillary columns, cf. Sections 6.1–6.5;[105] see also Ref. [127] for the same on fused silica capillary columns), and Astec, Advanced Separation Technologies (Whippany, NJ, USA), and ICT (Frankfurt/Main, FRG) (undiluted polar cyclodextrin phases **19**–**23** on fused silica capillary columns, cf. Sections 6.6–6.8).[120]

For the enantioselective cyclodextrin phases described up to now the user must distinguish between the following factors: availability, performance, reproducibility, long-term stability. The inspection of chromatograms, insofar as they are available, often provides the expert with decisive information. The use of cyclodextrins as solutions in polysiloxanes has resulted in columns of high efficiency, even for strongly polar substrates such as diols (Fig. 6)[97, 98] and alcohols.[127] Thus, for the first eluted peak of *trans*-2,3-dimethyl-1,4-dioxaspiro[4.4]nonane (Fig. 8), the number of effective plates was measured as $N = 79\,400$. For a column length of 40 m this corresponds to a height equivalent theoretical plate (HETP) of 0.50 mm. Accordingly, despite the small separation factor ($\alpha = 1.02$), an almost complete resolution of the peaks ($R = 1.33$) is achieved. For capillary columns with **1** in the molten state at 140–150 °C, HETP values of only 1.6 and 1.4 mm were obtained, and a comparable efficiency (0.3 mm) was only reached at 200 °C.[89] On undiluted polar cyclodextrin derivatives, peak resolution is not always ideal either (Fig. 19).[119] Poorer HETP values were measured for packed columns with β-cyclodextrin in formamide solution (1.8 mm;[79] cf. also Fig. 2) and for gas-solid packed columns with β-cyclodextrin on Chromosorb W (10.8 mm).[74]

Chemically binding the cyclodextrin derivatives to polysiloxanes, in a manner analogous to "Chirasil-Val"[5] or "Chirasil-Metal",[125] is expected to further increase the efficiency and lifetime of the columns.[*] The immobilization of such "Chirasil-Dex" stationary phases on the capillary surface is required for using supercritical gases for enantiomer separation (supercritical fluid chromatography, SFC) or for employing electrically driven chromatographic systems. As mentioned before, the low separation factors α observed up to now render it unlikely that the cyclodextrin phases available at present can generally be used for preparative-scale gas-chromatographic enantiomer separations. Also, there is at present no universal enantioselective cyclodextrin station-

[*] Note added in proof: Successful experiments have been reported recently [148]: e.g., "Chirasil-Dex" [149].

ary phase available, and unsuccessful separation attempts are, regrettably, hardly ever reported in the literature. In our experience, the success rate for quantitative enantiomer separations with a given cyclodextrin phase such as **1** lies well below 50%. Minor changes in the structure of the guest molecules often have a great effect on the enantioselectivity. Even for compounds that are structurally related, often only certain isomers or members of a homologous series can be separated into their enantiomers on cyclodextrin phases. It is therefore difficult to make predictions.

The objective for the future is to discover enantioselective stationary phases based on cyclodextrins that will have as wide a range of applications as possible. A further development still awaited is the preparation of phases with inverse configuration by total synthesis;[26] they are required for carrying out enantiomeric analyses on highly enriched substrates in cases where the trace component is eluted *after* the major component, making integration difficult. Owing to the lack of such inversely configurated phases, in no case has a formal proof of successful enantiomer separation on cyclodextrins, in contrast to phases consisting of amino acids[3] or metal complexes,[150] been possible. Such proof is normally provided by using the racemic form, which gives rise to peak coalescence, or the mirror-image stationary phase, which causes peak inversion.

In the next few years a steady growth of interest in chiral stationary phases based on cyclodextrins for capillary gas chromatography can be expected. Selective achiral separations (of geometrical isomers, diastereomers, positional isomers, etc.), as well as methods for modifying complex elution profiles, will also play an important role. However, cyclodextrin stationary phases are not expected to entirely replace or supersede the amino acid or metal complex stationary phases mentioned in the introduction. Instead, they represent a considerable extension to the range of techniques available to the enantiomer analyst, in accordance with the comment by *Gil-Av*, the pioneer of gas-chromatographic enantiomer separation, that "every phase, whether low or high molecular, will be recognized as suiting best a certain niche of applications".[84]

The authors thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for supporting this work. We are indebted to Professor Berson (New Haven) for providing a sample of ethyl hexa-3,4-dienoate and to Professor Fitjer (Göttingen) for providing a sample of modhephene. We thank Dipl.-Chem. Dieter Schmalzing, Michael Schleimer, and Martin Jung for their valuable contributions to the gas-chromatographic enantiomer separation on cyclodextrin stationary phases. V. S. thanks Professor König (Hamburg), Professor Armstrong (Rolla, Missouri), and Professor Smolková-Keulemansová (Prague) for reprints and preprints of recent work, and especially Professor Gil-Av (Rehovoth) and Professor Bayer (Tübingen) for fruitful scientific exchange over the years.

The Myelin Membrane of the Central Nervous System—Essential Macromolecular Structure and Function

By Wilhelm Stoffel

The neural sheaths that surround the nerve fibers (axons) are composed of myelin-specific complex lipids and are assembled during the myelination phase either by the oligodendrocytes in the central nervous system (CNS) or by the Schwann cells in the peripheral nervous system. These multilayered myelin membranes insulate the axons and permit a rapid, saltatory conduction of excitation and a reduced axon diameter in comparison with noninsulated axons. Myelination was hence the decisive evolutionary event in miniaturization of the central nervous system (brain and spinal cord). The morphology of the myelin membrane has been studied in detail mainly by electron microscopy. Most of its biochemistry has been elucidated in recent years by molecular-level analysis of both the lipid components (cholesterol, phospholipids and sphingolipids) and the constituent proteins. The multilamellar system is distinguished by a characteristic periodicity due to the 5-nm-thick bilayer formed by the myelin-specific lipids. The bilayer interacts with the myelin basic protein (MBP) on the cytosolic side of the plasma membrane process, while the integral membrane protein proteolipid protein (PLP) has hydrophilic domains exposed on both the cytosolic and extracytosolic faces of the bilayer. Numerous protein-chemical and -immunotopochemical findings have been summarized in a model of the myelin membrane. Through molecular biological studies, the genetic structure and chromosomal location of the myelin proteins have been determined. By employing techniques of molecular and cell biology together, it is now possible to analyze the process of myelinogenesis, the time- and location-specific expression of myelin-specific genes in the brain. Gene-technological methods have been used to define the mutations in the models jimpy mouse and myelin-deficient rat. These are animal models that correspond to genetically determined myelin defects (dysmyelinoses) in humans. Using them, it will be possible to study the cell death of oligodendrocytes on a molecular level; this process is the result of expression of mutant myelin proteins and is incompatible with life. Oligodendrocytes and the myelin structures they synthesize are the target structures of cytotoxic lymphocytes (T_c). In the course of the demyelination process in multiple sclerosis, these cause the breakdown of the myelin sheaths, in gradually appearing inflammations. T_c lymphocytes recognize myelin structures as epitopes and destroy them. The picture of the myelin membrane's molecular composition, which we are now perfecting, will also lead to a better understanding of demyelination on a molecular level, and hence to new therapeutic possibilities.

1. Introduction

In the course of evolution, organisms steadily increased in complexity, and a series of mechanisms arose which allowed them to act and react promptly to external influences. The central and peripheral nervous systems (CNS and PNS) were of great importance here, since they allowed information to be transmitted at high speed between the nerve cells (neurons) and the target organs via the nerve fibers (axons). In addition to the neurons, the neuroglia also developed; these form supportive tissue for the neurons and include the astroglia and the oligodendrocytes. The development of an electrical insulation system for the neural fibers, in the form of a myelin sheath constructed by the oligodendrocytes, was a decisive step in evolution. For naked axons, the speed of excitation transmission is proportional to the diameter of the axon. In a myelinated axon transmission occurs up to 100 times faster than in the absence of myelin; the diameter of the axon can hence be significantly decreased, while maintaining the same performance. Apart from the increase in pulse transmission speed, myelination makes room for a far greater number of axons, which makes possible the exceedingly compact structure of the CNS. If the axons of the spinal cord were not myelinated, then in order to achieve the same results the spinal cord would need to have the diameter of an oak tree several hundred years old, and the optic nerve would require a diameter not of 2–4 mm, but of 10–15 cm.

The fatty covering of the CNS axons, which is particularly obvious in the white matter of a brain section (Fig. 1), was first described by *Virchow* in 1854[1] and named myelin (Greek *myelos*, marrow). In 1871, under the light microscope, *Ranvier*[2] observed breaks in the myelin sheath at intervals of 1–2 μm, which today are called the nodes of Ranvier. Here, the axons are bare and carry higher concentrations of the $K^{\oplus}/Na^{\oplus}$ pumps needed to restore the action potential. The high speed of excitation transmission is not achieved by continual depolarization, as in naked axons, but in jumps from one node to the next over the internodal region. This is know as saltatory excitation.[3] Since depolar-

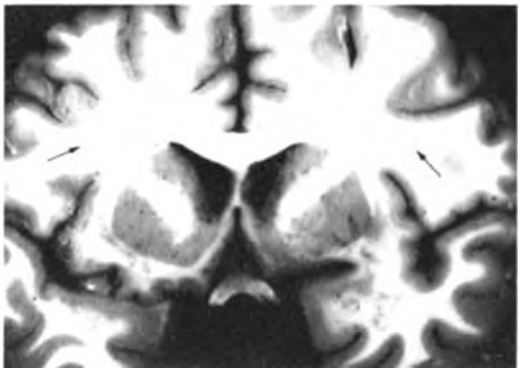

Fig. 1. Macroscopic section through the human brain. The cortex and the white matter (arrows) can be clearly seen.

ization only occurs locally, at the nodes, considerable energy is saved in repolarization.

2. Myelination

Myelin-like neural sheaths first appeared in the evolutionary step that led to the vertebrates (bony fish).[4] The formation of myelin sheaths around the axon gave three advantages; faster information flow, compact organization of the CNS, and energy savings in restoration and maintenance of the resting potential.

Myelination (myelogenesis) takes place in the CNS in a strictly programmed manner, both in when and where it occurs. The program is begun at a characteristic point in time for each species by the precursor cells to O2A astrocytes, which differentiate into oligodendrocytes. In mice and rats this occurs about ten days after birth, in humans at the sixth month of pregnancy. Development of the myelin sheath around the neural fibers of the brain and spinal cord is largely completed in rats and mice by the thirtieth day after birth and in humans by the end of the second to fourth year.[5] During this phase, the oligodendrocyte synthesizes two to three times its own weight in myelin components, lipids and proteins, daily.[6] The oligodendrocytes of the CNS form extended processes of their plasma membranes (Fig. 2A), which approach up to 50 axons and wrap themselves spirally around them. In this process, the cytoplasm is almost entirely squeezed out of the membrane processes. The interior (cytoplasmic) faces lie closely pressed together and appear under the electron microscope as the "main dense line" (MDL), because of their high electron density. In the course of wrapping around the axon, the exterior surfaces of these plasma membrane processes (extracytosolic face) also come into close contact with each other. The contact zone appears as the "intraperiod dense line" (IDL). Figure 2A shows schematically the development of the myelin membrane from the plasma membrane of the oligodendrocytes, Figure 2B the spiral wrapping process, and Figure 2C the

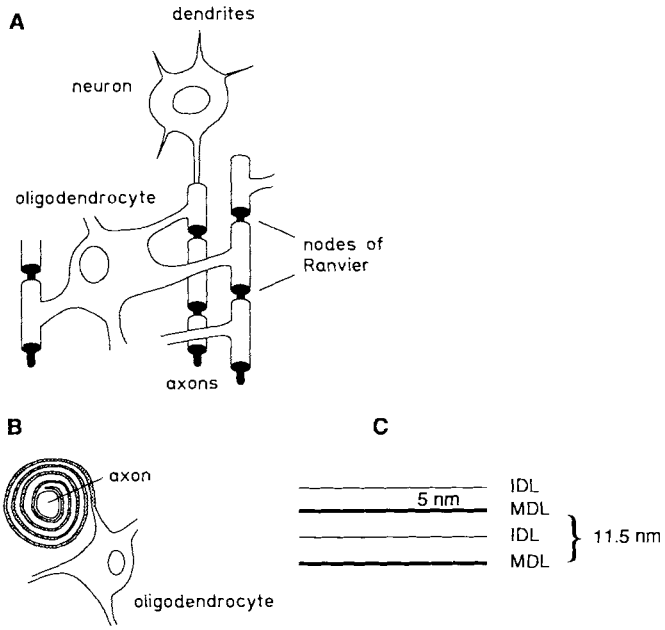

Fig. 2. A) Schematic diagram of plasma membrane processes extending from one oligodendrocyte to many axons, with formation of the nodes of Ranvier. B) Schematic diagram of the spiral winding process in myelination. C) Schematic diagram of myelin periodicity observed under the electron microscope. (see also Fig. 3).

periodicity of the myelin membrane, as seen in the electron microscopic image of a myelinated axon (section in Fig. 3).

The myelin membrane displays a periodicity of 11.5 nm. Each lipid bilayer is about 4–5 nm thick (Fig. 2C) and is therefore significantly larger than the plasma membrane of liver or connective tissue cells (2.5–3 nm). These large di-

Wilhelm Stoffel studied medicine from 1947 to 1952 in Cologne and obtained his doctorate with E. Klenk in physiological chemistry in Cologne. He studied chemistry in Bonn from 1952 to 1957 and received his Diplom with B. Helferich and his doctorate with L. Craig, Rockefeller University, New York, and E. Klenk, Cologne. After postdoctoral study with L. Craig and E. H. Ahrens, Rockefeller University, and C. Martius, ETH Zürich, he habilitated in physiological chemistry in Cologne in 1962 and took up the Chair of Physiological Chemistry in 1967 (now Biochemistry, Medical Faculty of Cologne University). His current research interests include neurochemistry and molecular neurobiology, analysis of atherogenesis (arteriosclerosis research), and structure and function analysis of serum lipoproteins.

Fig. 3. Electron microscopic image of a section through a myelinated axon. The electron-dense main dense line (MDL), corresponding to the cytosolic cleft, can be distinguished, as can the intraperiod dense line (IDL), which results from the extracytoplasmic sides of two myelin membranes packed together. The radial components are also visible.

Table 1. Comparison of the components of oligodendrocyte plasma membranes with those of myelin.

Components	Oligodendrocyte plasma membrane [mol %]	Myelin [mol %]
Proteins	54	21
Lipids	46	79
Cholesterol	36.4	40.9
Cerebrosides	9.4	15.7
Sulfatides	3.0	4.0
Sphingomyelin	5.4	4.7
Phosphatidylcholine	25.4	10.9
Phosphatidylethanolamine	7.3	13.6
Phosphatidylinositol (di)phosphate	7.1	4.7
Phosphatidylserine	5.1	5.0
Gangliosides	0.9	0.5

mensions are the direct result of the various chemical structures of the lipids that form the bilayer, which will be described in the next section.

In the peripheral nervous system, the role of the oligodendrocyte in the CNS is filled by the Schwann cell. Although the PNS myelin is very similar to that of the CNS in its morphological architecture (periodicity), each Schwann cell forms only one internodal sheath.

In the following, four questions concerning the biochemistry and molecular biology of the macromolecular components of the myelin membrane of the central nervous system will be discussed:

1. Which chemical structures are responsible for the compact layering of the myelin lamellae and hence for the insulating effect on the axon, and how is the extraordinary periodicity of the myelin membrane determined?
2. How can the winding of oligodendrocyte plasma membrane processes around the axons be understood?
3. How do the slightest changes in protein structures through mutations lead to complete dysfunction and death?
4. What significance does a knowledge of myelin structures have for the understanding of pathogenic dys- and demyelinating diseases?

3. The Lipid Bilayer of the Myelin Membrane

Myelin may be isolated in homogeneous form for analysis by simple centrifugation steps. The myelin membrane is the most lipid-rich in any animal tissue. About 80% of its dry weight consists of cholesterol and complex sphingo- and phospholipids and only 20% is protein. Table 1 shows the components of myelin, compared with those of the plasma membrane of oligodendrocytes. The lipid bilayer has a very unusual composition in that it has an extraordinarily high cholesterol content of 40 mol%. Hence, for every phospholipid, one molecule of cholesterol is present (sphingomyelin is included with the phospholipids here because it has an identical zwitterionic head group to the phosphatidylcholines); relative to the sphingolipids cerebroside and sulfatide, the proportion is 1:2.

Complete extraction of the myelin lipids from the myelin is only possible with acidic chloroform/methanol (e.g., chloroform–methanol–acetic acid, 2:1:0.1), since the acidic phospholipids and sulfatides form strong ionic bonds to the myelin proteins. The amphiphilic complex lipids are made up of a hydrophobic group—the alkane chains of the fatty acids and of sphingosine, the alkenyl ethers of plasmalogens—which forms the central or core region of the bilayer, and the polar head group, which makes up the surface and faces the aqueous myelin (Figs. 4 and 5).

The hydrophobic portions of sphingolipids (cerebroside and sulfatide) are made up of extremely long fatty acids, from C_{18} (stearic acid) to C_{24} (lignoceric acid). These are present in their saturated, α-D-hydroxy or unsaturated ω-9-monoene forms and are bound to the sphingosine (sphingenine, (2*S*,3*R*,4*E*)-2-amino-1,3-dihydroxyoctadecene) by an amide linkage to give the ceramide. The alkane chains of the fatty acid and sphingosine base portions of the ceramide are hence variable in length. The all-*trans* structure of the long-chain acyl residues ($>C_{24}$) dictates a length of 3.6–4.0 nm. This explains the unusual thickness of the bilayer, 4.5–5.0 nm; the "sticky ends" of the alkane chains overlap in the fluid center of the bilayer.

On the edge of the hydrophilic head group one finds the free hydroxy groups of the sphingosine and of the long-chain α-hydroxy fatty acids. Like the hydroxy group of cholesterol and the amide group of the ceramide, these can undergo hydrogen bonding to the carbonyl groups of the phospho- and sphingolipids. Hydrogen bonds reduce the distance between the groups that form them. The number of free protons available for hydrogen-bond formation allows a cross-linking of all the carbonyl groups in the lipid bilayer and, consequently, its stabilization by a two-dimensional layer of hydrogen bonds (Fig. 4). The acyl groups of the ceramides—sphingomyelin only contains long-chain, saturated, C_{18} and C_{24} fatty acids—would exist in crystalline form at 37 °C, but are converted into a fluid phase by intercalation of cholesterol molecules and of the acyl groups of the phospholipids, which are in part highly unsaturated. Though their function is unknown, the 1-alkenyl ether groups in the phosphatidylethanolamine class are also worth mentioning here.

Regarding the polar head groups of myelin membrane lipids at the water interphase, one finds not only the ubiquitous membrane phospholipids phosphatidylcholine and phosphatidylethanolamine, but also extensive amounts of phosphatidylserine and phosphatidylinositol. Together with

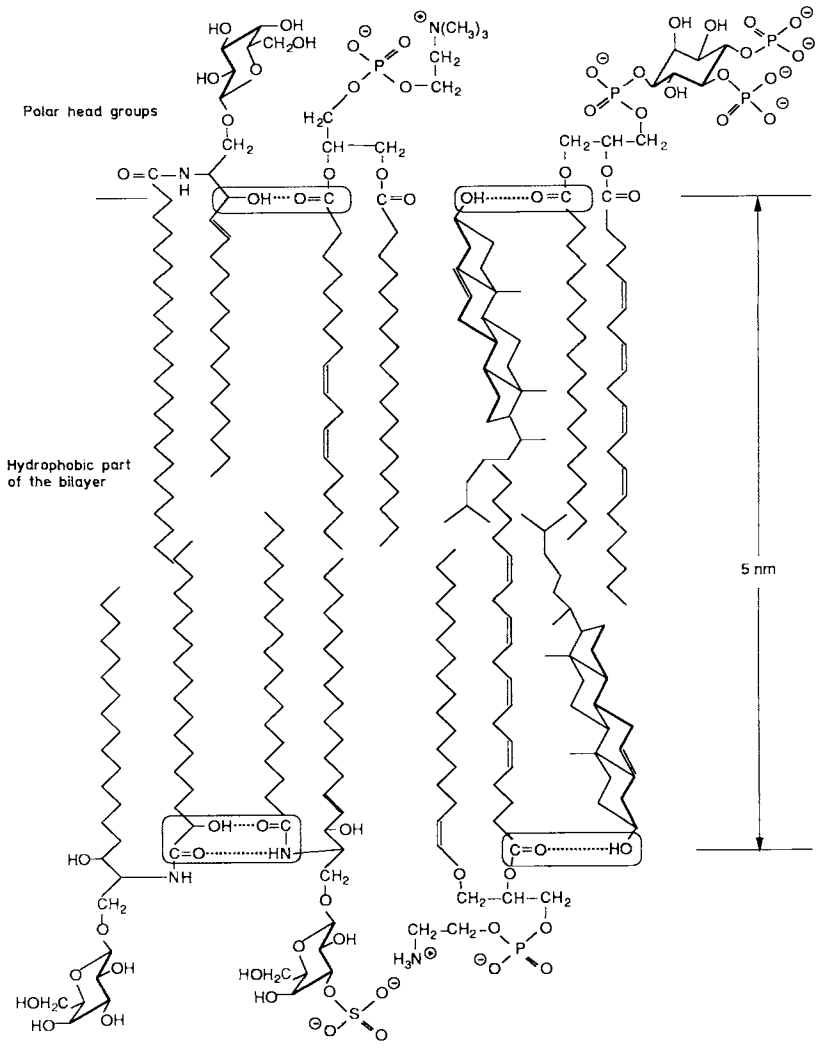

Fig. 4. Diagram of a model lipid bilayer, with cholesterol, the myelin-specific sphingolipids cerebroside and sulfatide, and the acidic phospholipids. The four possible types of hydrogen bonding are emphasized. The chemical structures of myelin lipid species are presented in more detail in Figure 5.

the sulfatides, this means that on average every fourth polar head group of the complex phospho- or sphingolipid type contributes an anionic group to the membrane surface. The gangliosides, which are present as trace lipids in myelin membranes, too, have not been included here (Fig. 5).

At present we know little about the symmetry or asymmetry of lipid distribution in the bilayer. Labeling of the oligodendrocyte plasma membrane and the myelin membrane with anti-galactosylceramide or anti-sulfatide antibodies, however, reveals their dense distribution in the external layers of the membrane sandwich structure.

Because of the zwitterionic head groups of the phospholipids, the hydrophilic, uncharged galactose residues of the cerebroside, and above all the anionic groups, the surfaces of the myelin membrane bilayer have many and varied possibilities for interaction with complementary molecules on both the cytosolic and extracytoplasmic faces of the membrane. These may well be important for compact packing and for the spiral folding process in myelination.

The significance of the relatively high content of phosphatidylinositols, especially with regard to their importance as a "second messenger system", is quite unknown.

4. Myelin Proteins of the CNS

Although the myelin lipids of the PNS and CNS are very similar in composition, significant differences are found for the proteins. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) separates the myelin protein mixture into a few components (Fig. 6).

The bands can be assigned to proteolipid protein (PLP), also called lipophilin, to DM20, an isoprotein derived from PLP, and to the myelin basic protein (MBP) and its isoforms. The latter are lower-molecular-weight forms of MBP, which arise by alternative splicing (see Section 5, Fig. 8). The remaining bands correspond to glycoproteins, Wolfgram proteins (W), and myelin-associated glycoproteins (MAG). Together, PLP and MBP make up about 90% of the total protein.

4.1. Myelin Basic Protein

Myelin basic proteins constitute some 30–40% of the total protein in myelin and can be purified by acid extraction

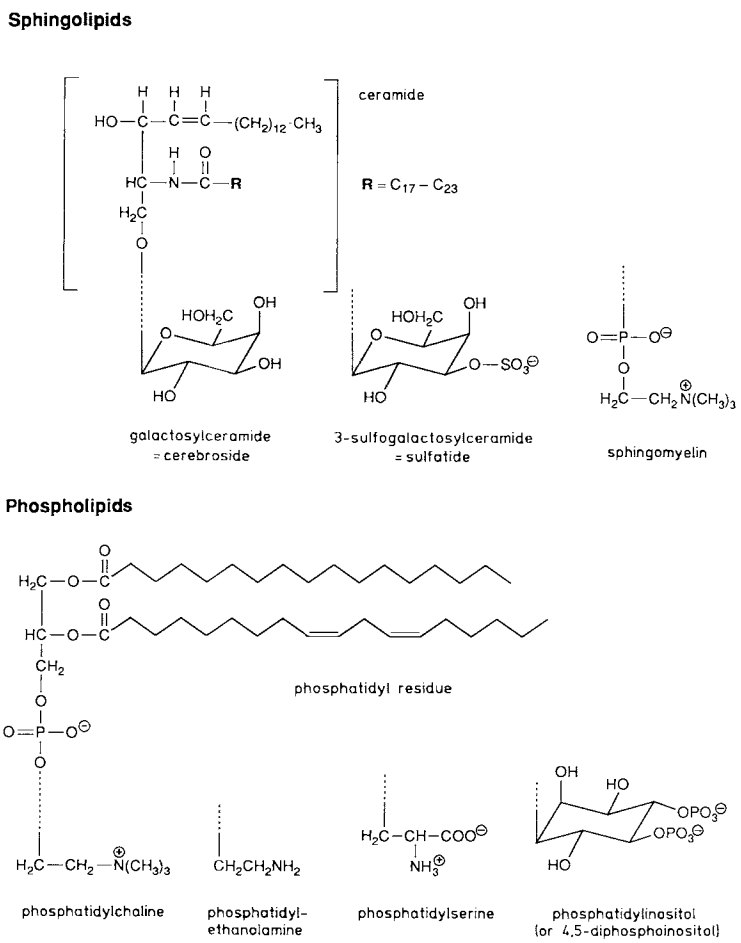

Fig. 5. Structural formulas of the most important classes of lipid in the myelin membrane.

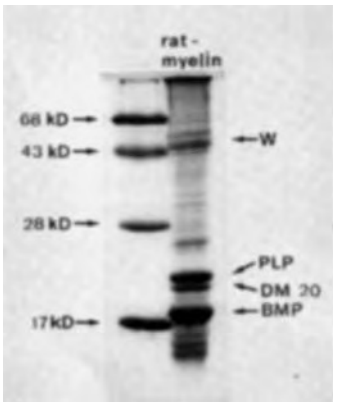

Fig. 6. Right: SDS-polyacrylamide gel electrophoresis of rat myelin proteins. Left: standards. W, Wolfgram proteins; PLP, proteolipid protein; DM 20, isoform of PLP; BMP, myelin basic protein (otherwise abbreviated MBP in this article).

of the myelin with subsequent ion-exchange chromatography and gel filtration.[7] The main component in humans and cattle is an 18.5-kDa MBP with 169 amino acids (bovine) or 170 amino acids (human, with 24% basic amino acids).[9] In humans there are two isoforms, 17.2 kDa and 21.5 kDa in size,[10] while rodents have four isoforms of 14, 17, 18.5, and 21.5 kDa. Here,[10,11] as in humans,[12] these arise by alternative splicing of *one* primary transcript of the MBP gene,[11] which will be discussed in detail with the description of the MBP gene structure (Section 5). MBP shows all the characteristics of a peripheral membrane protein. It has been localized in the cytoplasmic space (visible as the MDL under the electron microscope) with the aid of specific antibodies[13] and by enzymatic degradation of myelin proteins.[14] Because of its high basicity, MBP undergoes ionic interactions with the acidic polar head groups of lipids on the cytoplasmic side of the lipid bilayers, and brings about their compact packing.

In aqueous solution, circular dichroism measurements have shown that MBP occurs predominantly in a random coil conformation.[15] *Stoner*,[16] on the other hand, has proposed a secondary pleated sheet structure, on the basis of secondary-structure parameter weightings in computer calculations.

4.2. Proteolipid Proteins

The proteolipid fraction was first isolated by *Folch* and *Lees* in 1951 from a chloroform–methanol extract of the white matter of the brain.[17] It is the largest protein fraction in myelin, making up 50–55% of the dry weight. SDS-PAGE separates it into two bands, of 26 kDa (PLP) and 20 kDa (DM20). PLP and DM20 are isoproteins, which, because of their high hydrophobicity, are water-insoluble. The principal reason why 30 years elapsed between their discovery and the elucidation of their primary structure in my group in Cologne (1982–1983) was the necessity to develop new separation methods for hydrophobic peptides. These peptides were obtained by chemical cleavage (cyanogen bromide cleavage at methione residues and bromosuccinimide–dimethyl sulfoxide (DMSO) cleavage at tryptophan residues) and enzymic degradation of the PLP; their separation was followed by Edman degradation of the purified peptides.

We studied human and bovine brain. PLP is a polypeptide with 276 amino acids and a molecular mass of 29 891 Da. Surprisingly, we found that the sequences of human and bovine PLP differ at only two positions: Ala 188 and Thr 198 in bovine PLP are replaced by Phe 188 and Ser 198 in human PLP (Fig. 7, top), The sequence is clearly divided into one short and four long hydrophobic sequences, connected by hydrophilic "loops". If one arranges these domains separately (Fig. 7, bottom) and calculates their three-dimensional size, the structures typical of an integral membrane protein emerge. Three domains have just the right size to span the 5-nm bilayer (*trans* helices), while two are present in *cis* configuration, since one domain (40 amino acids) is too long to span the membrane, and the other (12 amino acids) is too short. In addition, both of these contain proline residues in the center of the sequence; proline is an α-helix breaker and leads to a bend and a reversal in the direction of the α-helix. PLP contains 14 cysteine residues, four of them as free cysteines. A disulfide bond is found between Cys 227 and the amino-terminal Cys 5. The hydrophobicity of the polypeptide is increased still further by acylation with a long-chain fatty acid on Thr 198.

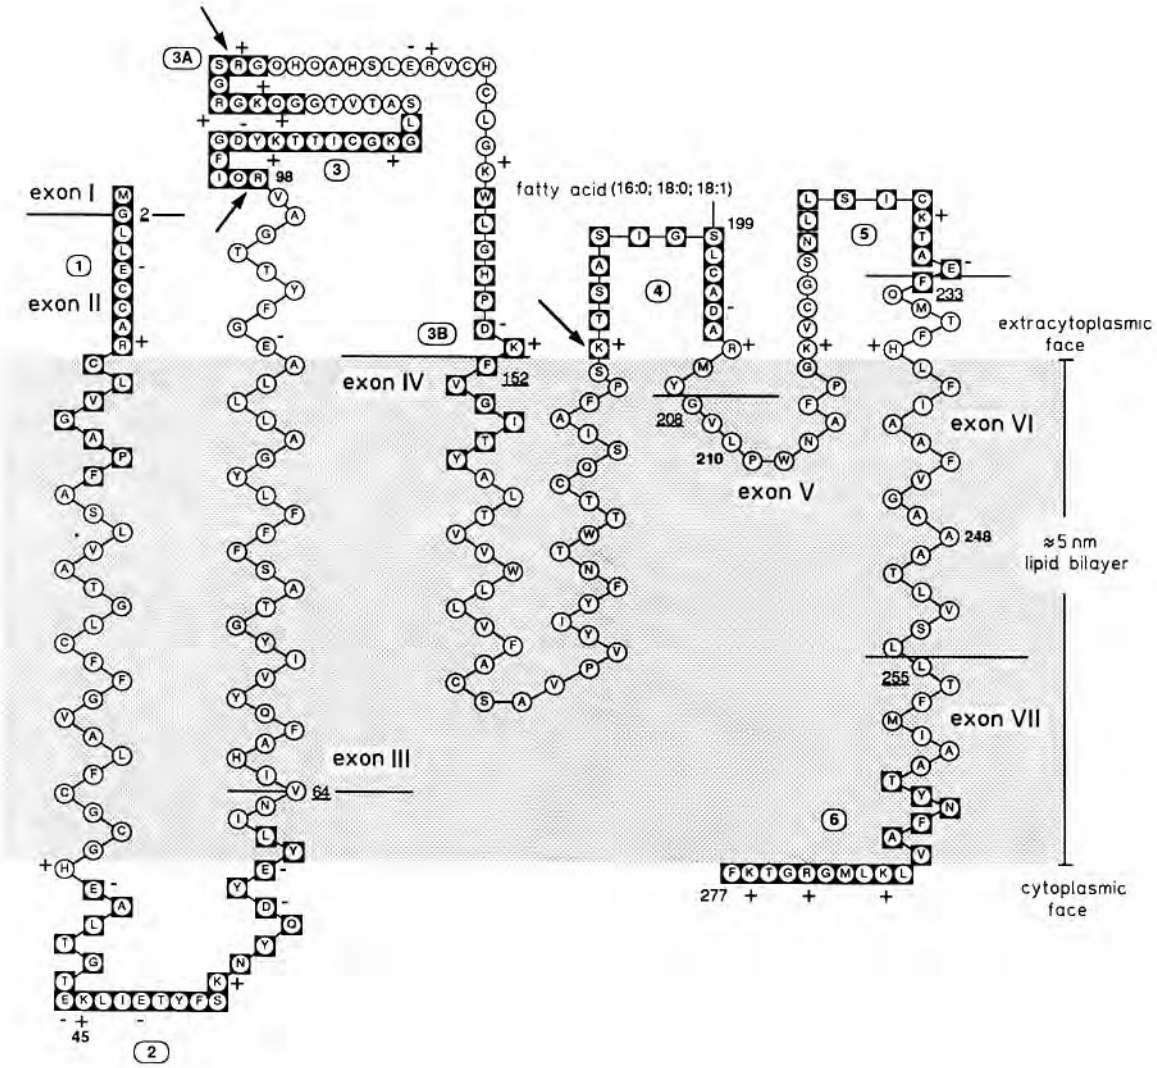
30 amino acids; 8.3 turns; 4.50 nm

4.2.1. Configuration of the Proteolipid Protein in the Myelin Membrane

From the strict division of the PLP polypeptide chain into hydrophobic and hydrophilic domains, a model was proposed for its integration into the myelin lipid bilayer. This was then confirmed by biochemical and immunotopochemical studies. Figure 8 (top) illustrates our current view. On the extracytoplasmic side, one finds a short, hydrophilic, N-terminal sequence, which continues into the first transmembrane α-helix. This, in turn, leads into a hydrophilic domain with two excess negative charges on the cytoplasmic side and folds back onto itself into the second transmembrane helix. The largest, strongly positively charged, hydrophilic sequence (Arg 97 to Arg 150) is found on the extracellular surface. The two *cis* domains also dip into the membrane bilayer from this side, while the C-terminal hydrophobic domain traverses the membrane again, so that the highly positively charged C-terminus of the sequence is oriented towards the cytoplasmic space. The hydrophobic segments are bounded by anionic or cationic amino-acid side chains or by ionic side chains of zwitterionic nature.

In our model, ten cysteine residues lie in the hydrophilic domains on the extracytoplasmic surface and four are found in α-helical domains. On the basis of the disulfide bridge between Cys 5 and Cys 227, and possible disulfide linkages between the *trans* and *cis* helices, we assume a cylindrical aggregation of the hydrophobic helices, as depicted in Figure 8 (bottom). On limited proteolysis of the myelin membrane, we observe facile release of the small hydrophilic domain between Arg 204 and Lys 217 and its ready dissociation from the lipid bilayer. It is quite possible that this domain performs a flip-flop motion into a myelin membrane packed above it, and through intercalation into the lipid bilayer it may hence play a role in fixation and tight apposition to the neighboring membrane, like the long-chain acyl group. These two structural elements could also be important in the dynamics of the spiral winding process.

This model has been substantiated experimentally in two ways. (1) The myelin membrane layers were dissociated by osmotic shock, subjected to tryptic digestion, and separated to give three large polypeptides. On sequencing these, we discovered that the endoprotease had attacked the PLP in the positions indicated by arrows in Figure 8 (top); since the enzyme cannot penetrate the lipid bilayer, this indicates that these sites are accessible on the external surface. Figure 9



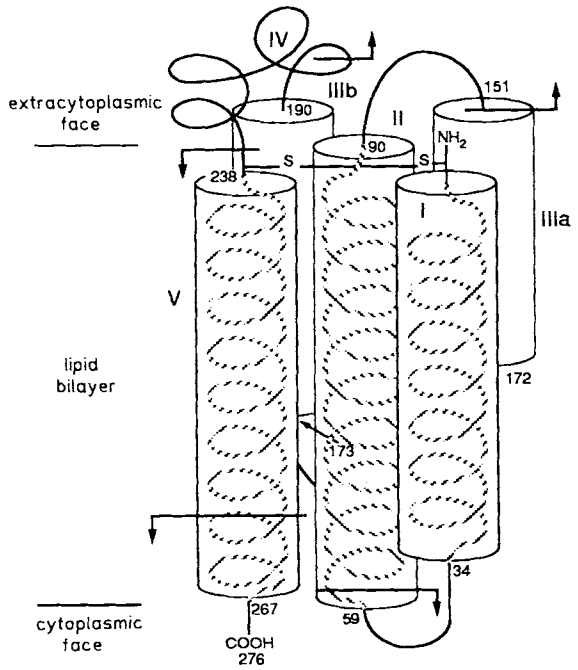


Fig. 8. Top: Model of the membrane integration of proteolipid protein, based on its hydrophobic and hydrophilic domains and on biochemical and immunotopochemical evidence. The peptide sequences framed in black (1, 2, 3, 3A, 3B, 4, 5, and 6) are epitopes which were obtained by solid-phase synthesis and used to generate antibodies. Bars demarcate the exons (Section 5); arrows show points of proteolytic attack by trypsin on intact myelin whose compact layering has been loosened by hyposmotic treatment. Bottom: Suggested association of the intermembrane α-helices within the lipid bilayer, by extracytoplasmic disulfide bonds. The arrows indicate the start of each new exon.

shows the SDS-polyacrylamide gel after proteolytic treatment of the myelin. The PLP band has disappeared, giving smaller polypeptides between 7 and 10 kDa. In contrast, MBP is completely protected from proteolysis, which can only be explained by its localization in the cytoplasmic cleft, shielded by the lipid bilayers. This finding is biochemical evidence for the location of MBP in myelin.

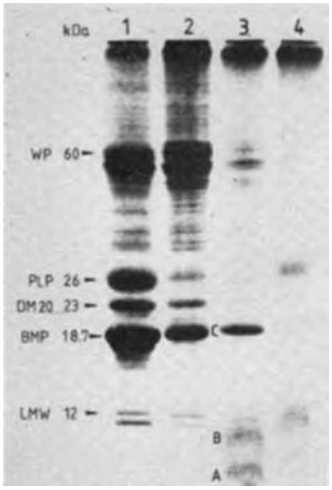

Fig. 9. SDS-polyacrylamide gel electrophoresis of myelin proteins after trypsin treatment of the intact myelin membrane. The PLP band has vanished and is replaced by proteolysis fragments. The cleavage sites are indicated by arrows in Fig. 8 above.

(2) If we accept that it is possible to generate antibodies against synthetic peptide sequences from the various domains of the PLP sequence that are marked as black boxes in Figure 8 (top) and to use them as markers of the nonpermeabilized membrane, then the orientation of PLP should be measurable histologically. For this purpose, we used primary cultures of rat brain oligodendrocytes, taken into culture, 18 days after birth. The expression of myelin proteins is similar in these cells to that in the myelinating rat. The PLP in the plasma membrane should have the final orientation

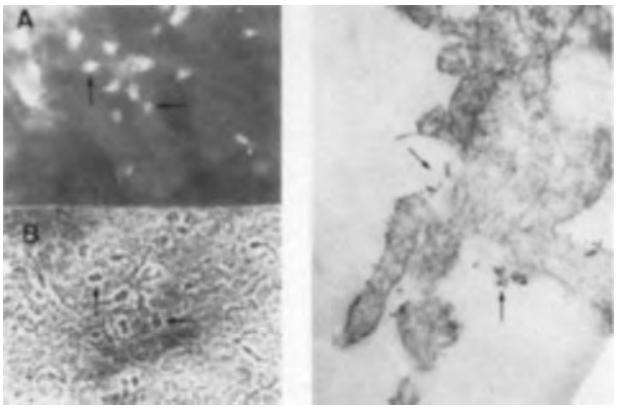

Fig. 10. Immunocytochemical localization of the PLP domains with the aid of antipeptide antibodies. Left: A) Fluorescence labeling, B) phase contrast image. Right: Gold labeling of the oligodendrocyte plasma membrane processes in tissue culture (8150× magnification, electron microscope).

that it will have before it segregates into the growth cone of the oligodendrocyte and on into the myelin membrane process.

Figure 10 (left) shows that only antibodies against peptides in the hydrophilic loop Arg97–Arg150 gave an immunofluorescent labeling of the oligodendrocyte plasma membranes. The same result was obtained with gold-labeled antibodies against this peptide (Fig. 10, right). Hence, both these findings agree with the proposed model for the PLP configuration in the membrane.

Surprisingly, further secondary-structure studies using the rules of *Chou* and *Fasmann*, *Nagano*, and others revealed that all the hydrophilic domains, except for the first third of the largest domain (Arg97–Lys120), are folded as amphipathic helices. These additional secondary structures are included schematically in Figure 11. This result could be of great importance for the packing of the myelin membrane layers.

4.3. Wolfgram and Other Proteins

Further protein components, which are expressed in very low concentrations, are the Wolfgram proteins and the

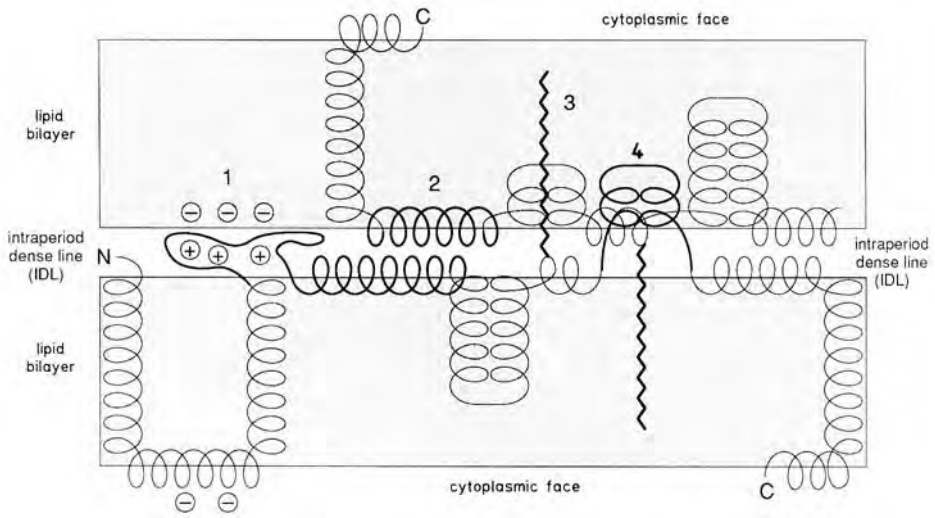

Fig. 11. Contributions to spiral winding and compact packing of the myelin layers by the interaction of (1) charged sequences, (2) the amphipathic helices of extracytoplasmic hydrophilic domains, (3) fatty acid chains, and (4) hydrophobic flip-flop loops of PLP.

"myelin-associated glycoprotein" (MAG, Fig. 6). In 1966, *Wolfgram*[18] isolated a protein fraction from the acidic (pH 5) chloroform–methanol extract. This fraction showed three bands on SDS-PAGE, with molecular masses between 45 and 55 kDa. Of these, the 55-kDa component is α-tubulin, which reacts with specific α-tubulin antibodies in a Western blot, while the 45- and 50-kDa bands can be assigned to the enzyme 2′,3′-cyclic-nucleotide 3′-phosphodiesterase.

Myelin-associated glycoprotein (MAG) is a glycoprotein with a molecular mass of 100 kDa, which is present as a trace protein (1% of total myelin protein). Its amino-acid sequence has recently been deduced from the cDNA; the sequence contains 626 amino acids (100 kDa) and in many regions is homologous to the neural cell adhesion molecule (N-CAM).[19] Its localization in the periaxonal region of the myelin of adult rat points to possible interactions between neurons and oligodendrocytes in myelogenesis.

5. Molecular Biology of Myelin Proteins

5.1. Construction of cDNA Libraries from the RNA of Myelinating Rat Brains and the Isolation of MBP- and PLP-specific Clones

The synthesis of myelin proteins and lipids is at its greatest 18 days after birth.[20] We isolated brain RNA from 18-day-old rats and enriched the poly(A)$^+$-RNA by affinity chromatography on oligo(dT) cellulose.[21] We then synthesized cDNA (complementary or copy DNA) with the aid of reverse transcriptase, by a modified Gubler–Hoffmann method[22] (Fig. 12). Size fractionation by gel electrophoresis in 1% agarose afforded copies of 550- to >6000-bp double-stranded cDNA, which were cloned into the *Pst* I restriction site of the pBR 322 vector. Clones showing specificity for the proteolipid and myelin basic proteins were isolated from this bank by screening colonies by Southern-blot hybridization with labeled oligonucleotides. These nucleotides were derived from the N-terminal, C-terminal, and central regions of our PLP amino-acid sequence and from the C-terminal region of the 18.5-kDa MBP. Of these clones, the 612-bp, MBP-specific cDNA clone contained the entire coding region of the 14.5-kDa MBP isoprotein, while the longest PLP-specific clone was missing about 310 bp of the N-terminal coding sequence.[23] The steps leading to PLP- and MBP-specific clones are summarized in the flow chart shown in Figure 12.

Using these cDNA clones, the size of the mRNA transcripts for PLP and MBP was determined by Northern-blot hybridization. Two strong, PLP-specific RNA bands corresponding to 3.2 and 1.6 kb lengths in a ratio of 2:1, as well as a weak band corresponding to 2.4 kb, were detected in 18-day-old rat brain. The mRNA's do not differ in the coding region, but contain three different 3′-nontranslated sequences; 2062 bases for the longest, 3.2-kb mRNA, 1319 bp for the 2.4-kb mRNA, and 430 bp for the 1.6-kb mRNA in the 3′ direction from the stop codon. Three polyadenylation signals (AATAAA) are present, which are responsible for the varying lengths of the transcripts (Fig. 13). The second sequence required for efficient polyadenylation, TGTGTCTT,

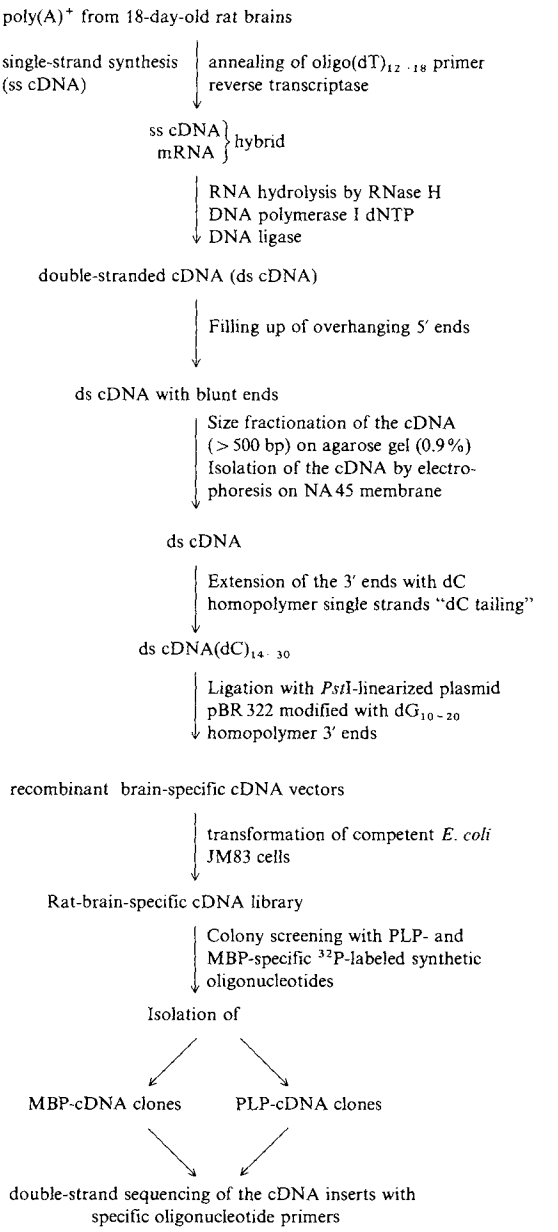

Fig. 12. Flow diagram for preparation of modified, brain-specific cDNA [22] from the brain poly(A)$^+$-RNA of 18-day-old rats and for the isolation of PLP- and MBP-specific clones for DNA sequencing.

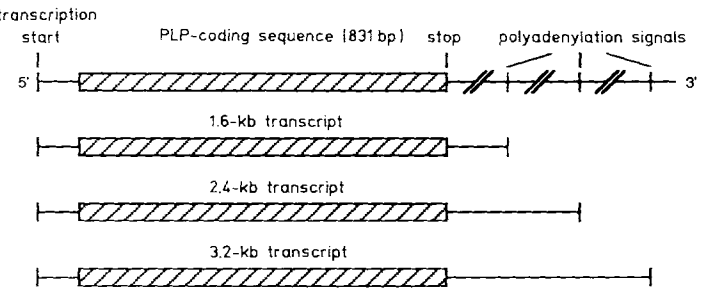

Fig. 13. Layout of the three PLP-specific transcripts. The polyadenylation signals (AATAAA) located 430 bp (1.4-kb transcript), 1310 bp (2.4 kb) and 2062 bp (3.2 kb) in the 3′ direction from the stop codon are used in posttranscriptional modification.

is also present, about 30 bp downstream of the polyadenylation signal.[24] In humans, only the 3.2- and 1.6-kb transcripts are made.

5.2. Genetic Structure of Human Proteolipid Protein and Myelin Basic Protein

With the PLP- and MBP-cDNA clones in hand, we were able to investigate the organization of the two human genes and their chromosomal localization. To do this, we screened human genome libraries in the vectors EMBL-3 and Charon 8, using cDNA probes and oligonucleotides for the coding region and for the 5'- and 3'-noncoding ends of the exons of PLP and MBP.

Analysis of a gene, and in general of large DNA segments, is begun with the preparation of a restriction map, using type II endonucleases, which recognize specific (hexa)nucleotide sequences. With the help of hybridization probes both from the cDNA (restriction fragments) and from synthetic oligonucleotides, the position of the coding sequences (exons) and the segments between them (introns) can be determined. Further, if the 5' and 3' ends of the mRNA have been ascertained with corresponding probes, the map affords information about the size of the sought gene.

5.2.1. *Exon–Intron Structure of the PLPs*[25]

Two overlapping clones were found which contained the entire human PLP gene. Complete digestion with individual restriction enzymes and combinations of two enzymes gave characteristic fragments; logical matching up of the two genomic PLP-specific λ-phage EMBL-3 clones gave the required restriction map.

Figure 14 shows the restriction map, which was drawn up by restriction analysis and Southern-blot hybridization with [^{32}P]-labeled *Pst*I fragments from the PLP clone and 5'-labeled oligonucleotides. It was a great advantage at this stage that we were able to use double-stranded or supercoil sequencing[26,27] and, further, that the time-consuming process of sequencing could be cut short with the aid of synthetic primers from known genomic sequences. Thus, subcloning of small, overlapping restriction fragments of the DNA sequence to be screened (cDNA or genomic DNA) into the

Fig. 14. Top: Restriction map and exon–intron organization of the human PLP gene. The exons are indicated by rectangles. Solid rectangles represent coding regions, open ones 5'- and 3'-nontranslated sequences. Bottom: Nucleotide sequence of the PLP exon and the adjacent intron regions. The DM-20 isoprotein and the mutation sites for jimpy mouse and md rat are shown. Restriction enzymes: B, *Bam*H1; E, *Eco*R1; H, *Hind*III; P, *Pst*1; X, *Xba*1.

M 13-phage system for dideoxynucleotide chain-termination sequencing became unnecessary. The newly obtained sequence data afforded the information needed for the oligonucleotide required as a sequencing primer.

The nucleotide sequences for the coding regions agree with the derived amino-acid sequences from the glycine in position 2 of the PLP onwards. For the glycine, however, only two of the three nucleotides were correct.

At its N-terminus, the rat cDNA sequence contains only an additional Met, compared with the mature PLP.[28, 29] It follows that for the one amino-acid presequence of the PLP primary transcript, a further exon must exist, carrying the Met codon ATG and the first base of the glycine triplet. Downstream, GT should serve as the signal for the 5'-donor splicing sequence for the intervening intron. On the basis of the unusually high homology between the PLP sequences of human and rat, we synthesized a 24-mer oligonucleotide with 18 bases of rat cDNA and the base sequence ATGGGT, and used it as a hybridization probe. The missing exon I was identified in this way on a *Pst*I-*Eco*R1 fragment 8.8 kb upstream of exon II.

Together with the restriction map, the sequencing results yield the following picture. The human PLP gene stretches over 17 kb and consists of seven exons and six introns (Fig. 14, top). Exon I contains the 5'-untranslated region, the triplet of the Met presequence, and the first base of the glycine triplet, the N-terminus of the mature protein. From the bases following the start codon, it is clear that human PLP does not possess a signal sequence. Hence, an internal signal sequence for the primary step of integration into the membrane of the rough endoplasmic reticulum is present. The following sequences lie in the 5' region (Fig. 14, bottom): CAAT box at -174 to -170 (Met $= +1$), Hogness box at -115, and transcription start at -80. Exons II–VII are made up of amino acids 1–63, 64–150, 151–206, 207–231, 232–253, and 254–276. The codons for amino acids 1, 63, and 207 include the exon–intron boundaries and are hence divided between two exons, severely limiting the possibilities for alternative splicing. The entire gene is 17 kb long—since the mRNA resulting from transcription is about 3 kb, the calculated intron/exon length ratio is 4.7:1. However, since only 831 bp contain coding sequences, the ratio is 119:1. The exon–intron transition sequences described by *Breathnach* and *Chambon* (GT-AG) are also strictly conserved in the PLP gene.[30]

5.2.2. *Correlation between Exons and Protein Domains*

The most interesting result arises from the position of the PLP amino-acid sequence coded in exons II–VII, not least with respect to our proposed model for integration into the lipid bilayer. Each *cis* and *trans* membrane domain and the adjoining hydrophobic regions are coded in a single exon. The C-terminal domain is an exception, being coded by two exons (VI and VII). These divisions are indicated in Figure 8 (top) by arrows.

In evolution, a variety of proteins arise by recombination of DNA sequences coding for other proteins, giving rise to special, new functions (exon shuffling).[31] An example of this is the receptor gene for low-density lipoprotein (LDL).[32] To date, no polypeptide sequence with high homology to PLP has been found.

5.2.3. *Alternative Splicing of PLP mRNA*

Alternative splicing of primary transcripts is very pronounced in oligodendrocytes. Through the exon loss that this involves, isoforms of the myelin proteins arise. This is also true for the PLP primary transcript. The DM-20 isoform of PLP is approximately 4.5 kDa smaller than normal PLP. The detection of specific DM-20 RNA in mouse brain and the sequencing data for DM-20 mRNA indicate that 105 bp are lacking, corresponding to 35 amino acids.[33, 34] The 212-bp-long exon III contains a cryptic splice donor sequence (G*GT*AAC, Fig. 14, bottom). Activation of this sequence leads to deletion of the 3' end of exon III and hence of amino acids 115–150. Nothing is yet known about how the activation of this splicing site is regulated.

5.2.4. *Localization of the Human PLP Gene on the X Chromosome.*

The assignment of human genes to eukaryotic chromosomes was made possible by the fusion of human and rodent cells (mouse, hamster) to give somatic cell hybrids. These contain the entire set of rodent chromosomes, plus additional human chromosomes or parts of chromosomes.[35] The

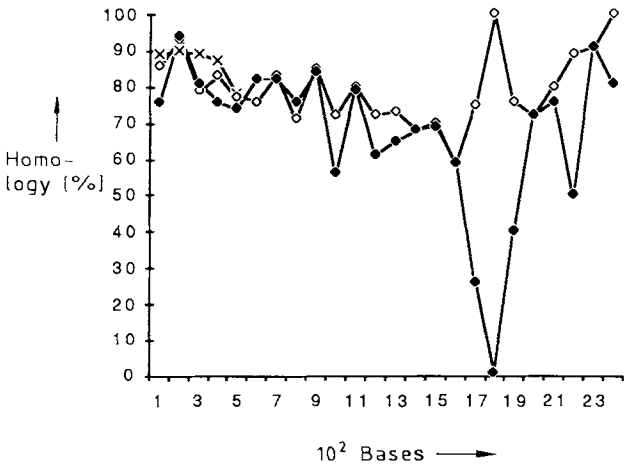

Fig. 16. Top: Comparison of human, rat, and bovine (H, R, and B) amino-acid and nucleotide-coding sequences for PLP. Bottom: Graphic illustration of homology in the 3'-untranslated region. ×, bovine; ○, rat; ◆, mouse.

human chromosomes in each hybrid cell line are defined with the aid of marker gene loci.

The genomic DNA from 15 somatic hybrid cell lines (Fig. 15A, a–q), containing all 23 chromosome pairs, was completely digested with *Bam*H1 (collaboration with Prof. *Grzeschik*, University of Marburg). The fragments were separated by agarose gel electrophoresis and hybridized by Southern-blot hybridization to the ^{32}P-labeled, 1200-bp-long C-terminal *Eco*R1 fragment of the genomic PLP clone. In Figure 15A, the human PLP-specific 9.3-kb *Bam*H1 band in the Southern blot can be distinguished (right-hand arrow, man). The smaller band (right-hand arrow, mouse) is the mouse-specific PLP band. The grid in Figure 15B shows which human chromosomes (1–22, X, Y, upper row) are present in which hybrid, either as complete chromosomes (squares) or in part (triangles). Chromosomes 2, 4, 5, 6, 7, 9, 10, 12, 13, 14, 18, 20, 21, and 22 could be excluded, since the DNA from these cell lines, in tracks b, h, and k, did not

hybridize with the PLP probe. Chromosomes 1, 3, 8, 11, 15, 17, 19, and Y were also eliminated, since hybridization occurred with DNA from cell lines which did not contain them. Hence, the X chromosome remained the sole candidate for the PLP gene locus. The assignment to the X chromosome was supported by hybridization to *Bam*H1 fragments of cell lines with four X chromosomes; strong, PLP-specific signals were clearly visible.

Narrowing down of the PLP locus to the q 13–q 22 region of the X chromosome was possible with the aid of somatic cell hybrids containing only part of the X chromosome. The diagram in Figure 15 C shows the regions of the X chromosome contained in each cell line. Hybridizing cell lines are marked with a (+). Bars c and d reveal the smallest overlapping region between q 13 and q 22. The third phosphoglycerate kinase (PGK) gene is also located in this region. As confirmation, the *Bam*H1 blot was hybridized with a ^{32}P-labeled PGK cDNA. Parallel to our studies, the same result was obtained by *Willard* and *Riordan*[36] and by *Mattei* et al.[37]

5.2.5. *Conservation of PLP during Evolution*

A comparison of the amino-acid sequence and the corresponding coding nucleotide sequence for PLP from species far apart in evolution emphasizes the high level of sequence conservation. A comparison between rat, mouse, human, and, as far as possible, bovine sequences (Fig. 16, top) shows that between human and rat there are no amino-acid exchanges and only 22 nucleotide substitutions out of 831 coding bases. In mouse there are 28 base-pair exchanges, with two conservative amino-acid replacements (Ser → Thr, Tyr → Cys). This extremely high degree of conservation demonstrates the narrow range within which the protein can function. The same is also true for the 3′-noncoding sequence, where very high homology prevails around the potential polyadenylation recognition sequences (Fig. 16, bottom).

5.3. Organization of Human Myelin Basic Protein

The peripheral membrane protein myelin basic protein (MBP) occurs in several isoforms in man, mouse, and rat.[38, 39] Thus, in rat and mouse myelin, the dominant forms are the 18.5-kDa and 14-kDa MBPs. The latter differs from the larger isoform by a deletion of forty amino acids in the C-terminal region. In the mouse, one finds a 21.5-kDa and a 17-kDa form, both with an insertion of 28 amino acids in the N-terminal region.[10, 40]

The relative proportions of the four MBP isoforms change during mouse or rat development.[10, 41, 42] The myelin of the human central nervous system contains three dominant isoforms, the 21.5-kDa, 18.5-kDa, and 17.2-kDa forms. The latter results from a 41-amino-acid deletion in the C-terminal region (140–180 of the 21.5-kDa form).

In Section 5.1 the isolation of a complete MBP-cDNA clone from rat brain cDNA was described. Studies in the laboratories of *Hood*[11, 43] had revealed that the mouse MBP gene is distributed over seven exons, is 30 kb long, and is located on the distal arm of chromosome 18. We isolated the human MBP gene by screening with labeled MBP-cDNA probes from genomic cosmid banks (pcos2 EMBL and Charon 4 A) and analyzed its exon–intron organization. Just as for the human PLP gene, here we also carried out restriction analysis to map the MBP gene. It is distributed over seven exons and 32–34 kb.[44] Figure 17 illustrates its structure and the sequencing strategy.

A comparison of the coding sequence of human and mouse MBP genes makes it clear that though homology in the nucleotide sequence is high, it is not as great as in PLP. Three potential transcription start sites were found by the primer extension method, at −55, −82 and −183 bp in the 5′ direction from the translation start. In the 5′-noncoding region there is neither a TATA box, which is often found in eukaryotic genes, nor a CAAT box. However, there are three direct "repeats", a nonameric sequence and two octameric nucleotide sequences. A decameric sequence at −256 to −265 is absolutely homologous to one in the regulatory region of the PLP gene. Further studies will show whether these motifs are important in transcriptional regulation. The isoforms of MBP arise by alternative splicing. The exons involved here are basically exons II, V, and VI. Figure 18 summarizes the splicing process and the isoforms that result.

6. Animal Models in the Study of Normal and Genetically Defective Myelin Membranes of the CNS (Dysmyelinoses)

Animal models possessing a genetically determined defect in myelin membrane synthesis are extremely useful in (1) investigation of membrane structure and the function of membrane components, especially proteins, (2) analysis of the differentiation process in myelogenesis, and (3) studies of pathogenesis on a molecular level. Myelin mutants of mouse, rat, rabbit, and spaniel are known; two sex-chromosome-linked mutations of mouse and rat will be described.

6.1. Sexually Inherited (X-Chromosomal) Defects

6.1.1. *Jimpy (ji) Mouse*

In 1952, *Falconer* described the Tabby (Ta) marker in mouse.[45] Heterozygous females are distinguished by horizontal stripes on the back, while homozygous males have a light brown coat. The jimpy gene is linked to the Ta marker; it leads to a complete absence of myelin in the affected male mouse and to an early death with symptoms of tremors in the entire striated muscle and of cramps. Females carrying the ji gene display a mosaic pattern, since expression of the X-chromosomal gene is dependent on inactivation of either the mutant or the normal X chromosome.[46, 47] While hypomyelination is compensated for with increasing age in heterozygous females, protein chemical analysis of the brain of affected males shows a marked reduction in PLP and MBP.[48, 49]

The primary effect of the ji mutation was sought first in PLP expression. Southern blots of genomic DNA from ji and

Fig. 17. Top: Exon–intron organization of human MBP gene. Bottom: Nucleotide sequence of the exons and extensive sections of the introns of the MBP gene. Enzymes as in Fig. 14.

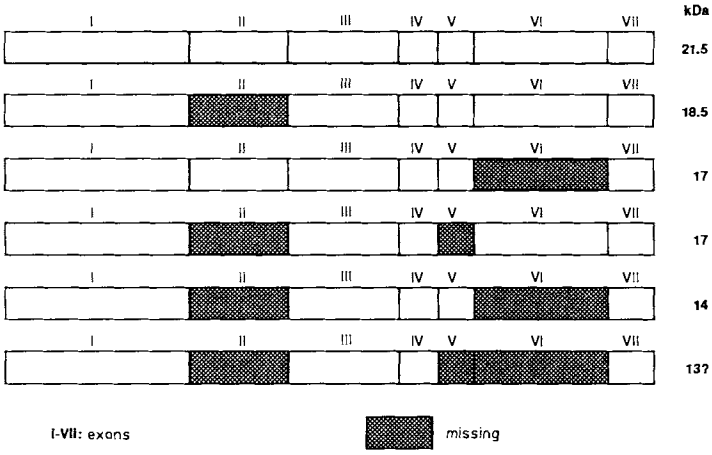

Fig. 18. Isoforms of myelin basic protein arise by alternative splicing. The molecular masses are given in kDa on the right; the exons eliminated by splicing are hatched.

normal mice with PLP cDNA proved to be identical.[34, 37, 50, 51] Exact determination of the ji defect in the mRNA was furnished by isolation and analysis of ji-PLP cDNA.[50] A 74-base-pair deletion was discovered, with a shift in reading frame at the C-terminus of PLP.

A glance at the exon–intron structure of the human PLP gene shows that the 74-base deletion corresponds exactly to the nucleotide sequence of exon V. The most obvious interpretation was an alternative splicing (Fig. 14, bottom). Indeed, there is a transition at the splice acceptor site (AG → GG), which eliminates exon V, intron IV, and intron V. Exon V ends on the first nucleotide of the glycine (G). Since exon VI starts with the triplet TTC (Phe), a frameshift occurs, leading to synthesis of a missense protein. The result

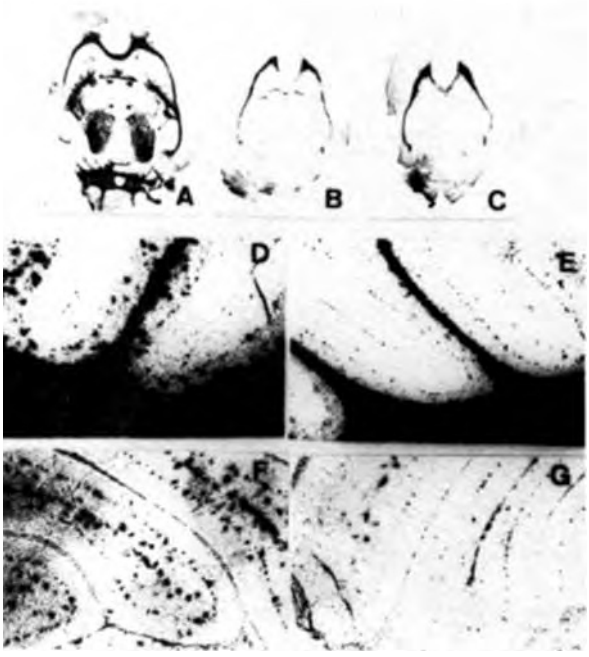

Fig. 19. In situ hybridization of horizontal cryosections of normal and md rat, and of jimpy mouse, with antisense PLP and MBP RNA. A, rat; B, md rat; C, jimpy mouse; D, normal rat hybridized with antisense PLP RNA; E, hybridized with anti-MBP RNA; F, md rat hybridized with antisense PLP RNA; G, hybridized with anti-MBP RNA.

is the loss of myelinated oligodendrocytes and the appearance of immature oligodendrocytes. This is easily recognizable on comparative in situ hybridization of normal, md-rat, and ji brain sections, using antisense PLP and MBP mRNA (Fig. 19).

The disease takes a less dramatic course in the myelin synthesis deficient (msd) mouse, which is phenotypically very closely related to the ji mouse.[52, 53] This mutation is an X-chromosome-linked defect as well. It consists of a single base transition (C → T) in exon IV leading to a homologous amino-acid substitution (alanine → valine) in PLP.[69]

6.1.2. Myelin-Deficient (md) Rat

The md rat is a mutant of the Wistar rat, which in phenotype is very closely related to the ji mouse. The endoplasmic reticulum of the CNS oligodendrocytes is expanded, and fluffy precipitates appear in the cytoplasm.[54] The mRNA of PLP and MBP, and of MAG and CNP, is greatly reduced. Figure 19 compares the in situ hybridizations we performed on brain sections of normal rat, md rat, and jimpy mouse, using [^{35}S]UDPS-labeled antisense PLP and MBP RNA.[55] The markedly reduced number of oligodendrocytes in md and ji brain is recognizable from the insignificant labeling by the specific hybridization probes.

In order to investigate the genetic defect on a molecular level, Southern blots of normal PLP DNA and of md rat were compared. No size differences were observed; the sequences of the 5′-regulatory region and those of exons IV to VII and introns IV to VI were identical. We isolated nucleotide sequences coding for exons I, II, and III from the md-rat-brain-specific cDNA library by the polymerase chain reaction (PCR) method and, at the same time, amplified exon II, intron II, and exon III with suitable oligonucleotide primers. Sequencing of the PCR fragments of the md cDNA revealed a point mutation (A → C transversion), leading to the mutation of Thr 75 into Pro. The point mutation lies in exon III, the sequence coding for the second transmembrane α-helical segment. This transversion generates an *Ava*II restriction site (GGACC), and the resultant *Ava* polymorphism in exon III constitutes a rapid diagnostic test for the md allele (Fig. 20). What are the consequences of this point mutation for the protein structure? Proline, with its preceding glycine, breaks the α-helix structure and leads to a bend and a partial β-turn structure in the helix. This conformation clearly hinders the integration of the C-terminal PLP sequence into the lipid bilayer of the myelin. On a cell biological level, this A → C transversion (i.e., the mutation of one out of 17 000 bases) finds expression in the loss of oligodendrocytes. Myelination does not take place, and this leads to the early death of the affected male animal. We are investigating this pathogenetically important chain of reactions very intensively at the moment.

6.2. Autosomally-Recessively Inherited Dysmyelinoses

One recessively inherited dysmyelinosis is the shiverer defect in mouse (shi). This defect arises from the deletion of five of the seven exons of the MBP gene, which is located on chromosome 18, q 22–qter.[43, 56, 57] The loss of MBP still

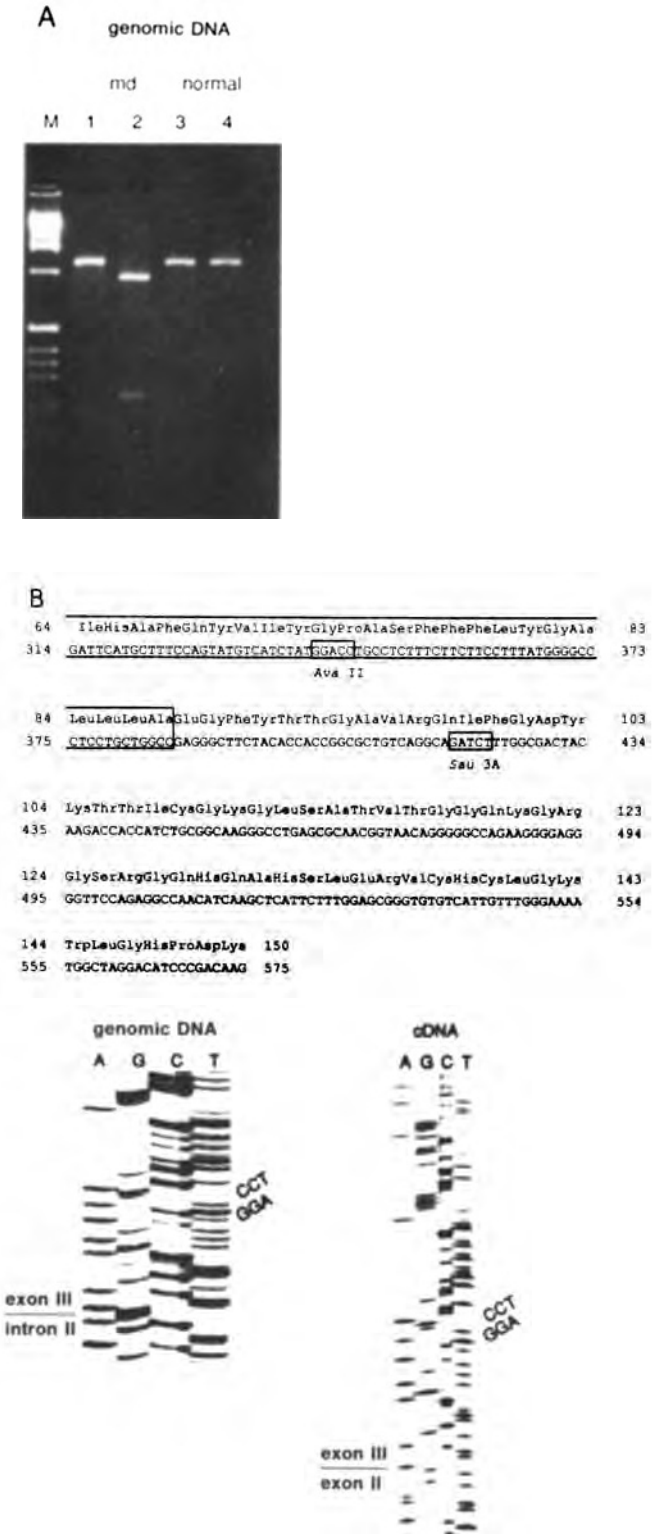

Fig. 20. A) Amplification of exon II–intron II–exon III by the polymerase chain reaction (PCR), using genomic DNA of wild-type and md rat as template (md 1 and normal 3). Restriction of the resulting 1180-bp fragment with *AvaII*. An *AvaII* restriction fragment length polymorphism is apparent. *AvaII* cleaves the fragment derived from the genomic DNA of the md rat into a 960-bp and a 220-bp fragment (md 2), but does not attack the fragment from the genomic DNA of the normal rat (normal 4). B) Nucleotide sequence and derived amino-acid sequence of exon III of the md-rat PLP gene (see also Fig. 16). Sequencing gels of genomic and cDNA from md rat.

permits myelin formation, but the compact cytosolic gap visible under the electron microscope as the main dense line (MDL, Fig. 3) does not develop.[58] This myelination defect was overcome by implanting the intact MBP gene into the germ cells of the mouse in a transgenic model.[59]

A further autosomal mouse mutant is the myelin-deficient mouse. *Hood*'s group has found that, due to an MBP gene duplication and inversion, regulation of gene expression is disturbed, yielding a phenotype similar to that of the shiverer mutant. Here, too, it was possible to generate transgenic mice which made myelin to different extents, by introducing the normal MBP gene into the cells.[60]

The quaking mouse (qk) is the result of a defect linked to chromosome 17. Phenotypically, one sees a much relaxed myelin structure under the electron microscope, with greatly reduced expression of both the PLP and MBP genes. MBP does not seem to be built into the myelin membrane. A molecular biological explanation of this mutation is still awaited.[49, 61]

6.3. Sex-linked Recessive Human Dysmyelinoses

Demyelination leads to the degradation of the existing, intact myelin by inflammatory or toxic agents. In contrast, a series of dysmyelinoses, the leucodystrophies, are the result of genetically conditioned functional disorders in the oligodendrocytes. Human dysmyelinoses with X-chromosomal recessive inheritance (e.g., adrenoleucodystrophy (ALD) and "familial diffuse scleroses", also known as Pelizaeus–Merzbacher disease) are of special importance in this context.[62] In homozygous, male descendants, the severe form, adrenoleucodystrophy, leads to early mental retardation, motor disorders, demyelination of the optic nerve, and blindness, and to death at an age of four to eight years. Characteristic here is the accumulation of very long chain fatty acids ($>C_{24}-C_{26}$) in almost all the tissues, usually as their cholesterol esters.[63] This is used as a diagnostic aid. Gas-chromatographic determination of the long-chain fatty acids in the lipids of leucocytes, skin fibroblasts and cells obtained by amniocentesis is at present the diagnostic method of choice, especially prenatally.[64] The ALD locus on the X chromosome is not yet exactly determined, but a DNA probe specific for the Xq 28 band contains a restriction fragment length polymorphism (RFLP) which is said to be characteristic for the defective allele.[65] However, as long as the exact distance between this probe and the ALD locus is unknown, an uncertainty factor is attached to this RFLP because of possible recombination.

Pelizaeus–Merzbacher disease is a rare form of leucodystrophy. Mental and physical decay begins in infancy and leads to death in the first years of life. The phenotype is very similar to that of ji mouse or md rat. The disease is histologically characterized by a complete lack of white matter in the CNS. Astrocytes in the dysmyelination region reveal fat globules. The defect postulated in phospholipid metabolism[66] is certainly only a peripheral symptom in the complex phenotype of this genetically determined dysmyelinosis. The X-chromosomal linkage, coupled with the complete absence of proteolipid protein[67] and the great immunocytochemical changes in marker enzymes for myelin, points to a mutation in the PLP gene. Cloning and analysis of the Pelizaeus–Merzbacher PLP gene has led to an understanding of the mutation and the pathogenesis of the disease

in four different families: a C → T transition in exon IV leading to a threonine 155 exchange by isoleucine[7a] and proline 14 → leucine,[71] tryptophan 162 → arginine,[72] and proline 216 → serine[73] substitutions.

6.4. Demyelinating Diseases

The commonest and most serious inflammatory disease of the CNS, which very often takes a gradual course, is encephalomyelitis disseminata, also known as multiple sclerosis (MS). Its etiology is still quite unclear, although viral infections—more than twenty have by now been described—are regularly cited as the triggering event. This is especially true of the chicken pox, German measles, and mumps viruses, and, most recently, the human retrovirus HIV-1.[68] An autoimmune reaction plays a significant part in pathogenesis. In animal models it is possible to generate a symptomatically related demyelination experimentally by immunizing rabbits or rats with myelin basic protein. In addition to the sites of inflammatory degeneration that appear in this experimental allergic encephalitis (EAE), T lymphocytes with MBP specificity are activated in the test animal. Transfer of the T lymphocytes to a healthy animal can trigger symptoms of multiple sclerosis. The cerebrospinal fluid of MS patients also contains MBP-specific T lymphocytes, analogously to the animal model.

Independently of the etiology, one can ask whether MBP is the primary antigen for triggering the autoimmune process. In trying to understand pathogenetic events, it is a great help to know the molecular architecture of structures involved in the process. MBP is quite clearly located within the cytoplasmic space of the myelin membrane, where it is shielded from protease attack by the dense lipid bilayers, as has been shown experimentally.[14] If one looks at the myelin membrane model (Fig. 8A), it becomes clear that the proteolipid protein (PLP) has large, hydrophilic domains exposed at the membrane surface, where they are directly accessible as a primary point of attack for the proteases of macrophages, lymphocytes, and leucocytes. Fragmentation of PLP would severely disrupt the membrane organization of the myelin, and this could expose phospholipids to phospholipase attack and, as a result, the myelin basic protein to proteases. The high antigenicity of MBP and its peptide fragments play a dominant role in the autoimmunization process, but only a secondary one in this hypothetical sequence of events, and at a later stage in the pathogenetic process. A knowledge of the crucial epitopes that are recognized primarily by activated T lymphocytes in the demyelination process could be of great importance in understanding the pathogenesis of multiple sclerosis and in its therapy, even if the etiology is not yet fully explained.

7. Summary and Perspectives for Membrane Research in Neurobiology

Because of its relatively small number of components, the CNS myelin membrane is one biological membrane whose morphology and function on a molecular level have largely been described. Chemical and biochemical analysis has revealed that the simple and complex myelin lipids that make up the 5-nm-thick bilayer are the decisive factor in the insulating characteristics of the myelin sheath around the axons. The dense lateral packing of the sphingolipid long-chain fatty acids and the cholesterol in the lipid bilayer is stabilized by a network of hydrogen bonds, described here for the first time. This network is built up between the polar groups at the interphase between the hydrophobic core of the bilayer and the polar heads of the lipids.

The conspicuously high content of acidic polar head groups—one anionic to four polar or zwitterionic—leads to a polyanionic cytoplasmic and extracytoplasmic surface. Both will be involved in ionic interactions. Biochemical and immunotopochemical studies have further revealed that the myelin basic protein in the cytoplasmic space is not accessible from the exterior. Through ionic interactions of the side chains of its basic amino acids with the anionic polar head groups of sulfatides and phospholipids, but also with an anionic domain of proteolipid protein, the MBP causes a compact layering of the oligodendrocyte plasma membrane processes. This is seen in the electron-dense main dense line (MDL) under the electron microscope. Ionic interactions between polar head groups of the lipid bilayer and domains of proteolipid protein must be responsible for the dense packing on the extracytoplasmic side, between the external surfaces of the tightly wrapped myelin processes. This narrow cleft appears in the electron microscope as the intraperiod dense line (IDL). In addition, hydrophobic interactions may occur between opposing membrane surfaces, due to long-chain fatty acid residues. For example, they form an ester bond to Thr/Ser 198 of PLP and can intercalate into the hydrophobic phase. The hydrophobic sides of amphipathic helices could also affect the pattern of outer membrane adhesion surfaces, as could the flip-flop dynamics of a small hydrophobic *cis* loop in the poorly understood spiral winding process (Fig. 2B). Either of these could be a significant stabilizing factor in formation of the dense, multilamellar membrane system. This system is not only responsible for myelin's insulating function, but also for saltatory excitation along the nodes of Ranvier, which proceeds by depolarization of only small areas of the axonal membrane.

The myelination of the CNS axons is a fascinating process of development and differentiation within brain maturation. Following a program that is regulated both in time and in space within the individual regions of the brain, the mass of lipids and myelin proteins is synthesized within a short time span (2–3 weeks in rodents, 1–2 years in humans).

Using the molecular-biological techniques described here, we can now analyze the course and regulation of myelinogenesis and resolve both the controlling elements and factors and the expression of genes coding for myelin membrane proteins and enzymes responsible for synthesis of the complex myelin lipids. In situ hybridization techniques will play a large role here, as will analysis of DNA–protein interactions in the regulatory regions of the genes described. Thus, we will be able to tell whether the gene activity for myelin proteins is "switched on" simultaneously and in conjugation with lipid synthesis, how the myelin building blocks are transported to the axon, where the segregated membrane components of the oligodendrocyte plasma membrane

myelin process are combined. In vitro protein synthesis of PLP and MBP and integration of PLP into the lipid bilayer are currently under experimental investigation, in order to gain understanding of the in vivo process.

Analysis of the genetically determined myelin defects (dysmyelinoses) described here, the jimpy mouse and md rat, furnish convincing evidence of the far-reaching possibilities for molecular biological techniques. They can be used for elucidation not only of defects at the DNA level and their chromosomal locations, but also of the cell biological basis for the pathogenetic process arising from the mutation. Thus, we will soon know why erroneous expression of a structural protein such as PLP causes death of the oligodendrocyte, failure to myelinate, and the early death of the individual. The animal models studied are of eminent importance in explaining analogous dysmyelinoses based on defective myelin synthesis in humans.

A large number of genetically determined myelin defects in animals and in man await the elucidation of the relevant mutations. Transgenic animal models will be indispensable in understanding the pathogenic process in these brain diseases. Elucidation of the myelin membrane topochemistry and the availability of the protein structures has given an important thrust to research on demyelinating diseases, with multiple sclerosis (encephalomyelitis disseminata) the primary example. This is true above all for the autoimmunological aspects of this disease. The antigenic epitopes of the myelin target structures can now be determined, opening up extensive therapeutic possibilities.

The results that have been achieved in biochemical and molecular biological research in recent years in the field of neurobiology, as documented here for the CNS myelin membrane, provide impressive evidence that a solid chemical and biochemical knowledge of macromolecular structure is first required. With the aid of molecular and cell biological techniques and reasoning, it is possible to learn to understand the normal functions linked to these structures and their pathological alterations. The "new biology", in the widest sense, makes molecular neurobiology one of the most exciting fields in biology today.

Our research described in this review article was generously supported by the Deutsche Forschungsgemeinschaft (SFB 74), the Bundesministerium für Wissenschaft und Forschung (Gene Centre, Cologne), and the Fritz-Thyssen-Stiftung. My special thanks go to all the co-workers mentioned and to Dr. B. Tunggal and Dipl.-Chem. K. Hofmann for fruitful and enthusiastic collaboration in a field of neurochemistry that requires a high level of experimental skill. I am grateful to Jochen Teufel for help in preparing the diagrams and the manuscript.

The Directed Synthesis of Biaryl Compounds: Modern Concepts and Strategies

New Synthetic Methods (82)

By Gerhard Bringmann,* Rainer Walter, and Ralf Weirich

The preparation and utilization of specific biaryl systems, particularly those which suffer hindered rotation, is a demanding goal not only in the synthesis of natural products and pharmaceuticals, but also for example in the discovery of new reagents for asymmetric synthesis. This article will attempt to provide a topical review of modern, efficient processes for the specific preparation of biaryls. This appears to be of particular urgency, since, under the pressure of continually increasing demand, a wealth of new or modified synthetic approaches to the ever more important biaryl systems has been realized in recent years. The high standard which has been reached in this field is impressively demonstrated by regio- and stereoselective syntheses of important biaryl natural products such as steganone, ancistrocladine, ancistrocladisine, and dioncophylline A. Besides the utilization of asymmetric induction in the actual coupling step, the thermodynamically or kinetically controlled torsion of biaryl axes belongs to the most important concepts discussed.

1. Introduction

The biaryl axis is the central building block in a very large number of natural products of differing structure, biological activity, and biosynthetic origin, including for example polyketides, terpenes, lignans, coumarins, flavonoids, tannins, peptides, and alkaloids[1] (Fig. 1).

Because of their interesting properties—not only as pharmacologically active natural products, but also as chiral reagents[11] and crown ethers,[12] as chiral host molecules for inclusion compounds,[13] as the basis of chiral phases for chromatography,[14] as inflexible "spacers" between two halves of a molecule[15,16] or also as the basis of chiral liquid crystals[17]—natural and unnatural biaryls constitute attractive synthetic goals. The key step in such syntheses is almost always the coupling of the two aromatic halves of the molecule. This review is not intended to give an all-embracing, encyclopedic list of all the more recent aryl coupling processes but to compare the different *strategies* used. Of particular importance in this direction will be the (still not very numerous) processes which are capable of solving the problems of (in increasing order of priority) "specific cross-coupling/regioselectivity", "stereoselectivity" and finally "chiral economy" and which can then also be applied to the synthesis of actual (when necessary functionalized and sterically hindered) biaryl natural products. The importance of the strategic concept used, for example whether the reaction is carried out in an inter- or intramolecular manner, is demonstrated by the fact that it has recently become possible to separate the two formal goals of stereoselective biaryl synthesis (i.e. C–C bond formation and asymmetric induction) both temporally and methodically (see Section 6.3). This opens up completely novel possibilities which have until now hardly been realized.

We shall however also discuss the most important of those processes which may perhaps not satisfy *all* the criteria presented above (e.g. they may not be stereoselective), but which because of their simplicity are often the methods of choice for the construction of uncomplicated systems (e.g. biaryls that are *not* rotationally hindered) and which have until now dominated the literature.

Because of the large amount of material available we shall deal in this article only with the convergent coupling of pre-

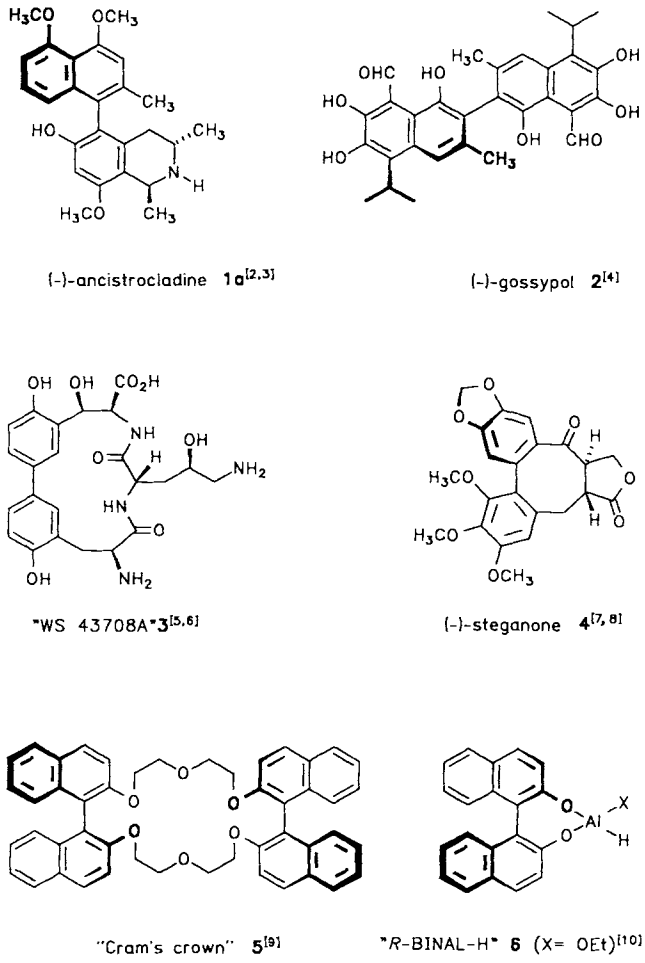

Fig. 1. Some natural and unnatural biaryls.

Institut für Organische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

formed (*iso*cyclic) aromatic compounds; (linear) biaryl systems obtained by subsequent construction of ring systems will be excluded. As the previous comprehensive[18,19] review on modern methods of biaryl synthesis was written ten years ago,[20] the line of demarcation for the synthetic methods covered in the present survey was drawn at about 1980, also because of the fact that up until then almost[21] no *stereoselective* aryl coupling reactions were known.

7

2. Intermolecular (Dimerizing) Aryl Coupling to Give Constitutionally Symmetrical Biaryls

2.1. The Classical Ullmann Reaction and Other Reductive Processes

The reductive dimerization of aryl halides is one of the oldest methods[22] for the preparation of constitutionally symmetrical biaryl compounds. The classical Ullmann reaction[23] using copper bronze as a reducing agent affords the highest yields in the case of *electron-poor* aryl iodides. Thus, nitro groups (even in *ortho* position) are particularly advantageous, but also aldehyde-, ester-, and lactone-functions are tolerated.[24] However, free primary or secondary amine functions or phenolic hydroxyl groups undergo *N*- or *O*-arylation to give biarylamines[25] and biaryl ethers[26], respectively—a behavior that can also be exploited rationally in synthesis (the "Ullmann condensation").

Since the course of the Ullmann reaction is determined by the position of the halogen, it is specific with regard to the *site* of the coupling: the regioselectivity problem is thus shifted to the preceding halogenation step. As the reaction is heterogeneous, it can be accelerated considerably by the use of ultrasound.[27] The yields are also high for non-benzenoid systems such as azulenes.[28] This *classical* variation is thus even today the method of choice for simpler, sterically not too congested[29] target molecules such as 7[30] (Scheme 1).

In order to avoid the often very high reaction temperatures required by this method, a number of new modifications have been introduced recently, based on work by *Semmelhack*.[31] In these, Ni^0 complexes such as $[Ni(cod)_2]$ used in stoichiometric amounts replace copper. In this way aryl halides can be reacted cleanly and in high yields in homogeneous solution at temperatures as low as 40–50 °C. Various substituents such as nitrile or even free amine functionalities are tolerated. Nitro groups, however, are not compatible with this or other nickel-mediated processes, probably because of the formation of nitrosonickel(0) complexes.[32] It must also be taken into account that proton donors change the course of the reaction dramatically, leading to hydrodehalogenation.[31] Instead of the sometimes sensitive Ni^0 complexes, also activated nickel powder can be used under similarly mild reaction conditions.[33,34]

More modern methods, which until now have been applied merely to simple substrates, use only catalytic amounts of nickel reagents. The reactive low-valent nickel species can be regenerated either electrochemically[35,36] or by co-reductants such as zinc[37,38] or sodium hydride.[39] These methods make it possible to use harder halides (aryl chlorides react most rapidly[38]) and more convenient solvents such as THF.[39]

2.2. "Biomimetic" Phenolic Couplings and Related Oxidative Methods

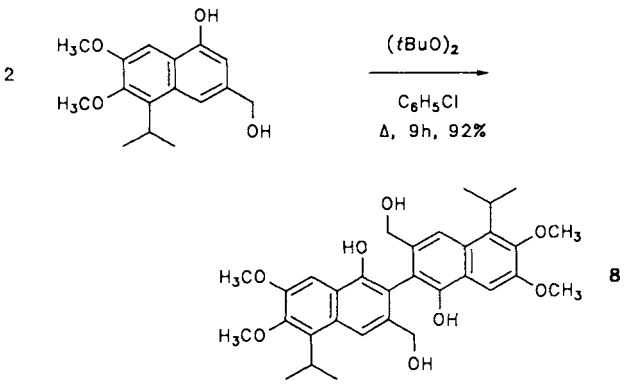
Complementary to the Ullmann reaction, the oxidative phenolic coupling requires the use of *electron-rich* aromatic

Gerhard Bringmann (born 1951) completed his formal education in 1970. He then studied chemistry (and biology) at the Universities of Giessen and Münster (Diploma in 1975, and Doctorate in 1978 under the supervision of Prof. Dr. B. Franck). After a postdoctoral fellowship with Prof. Sir Derek H. R. Barton in Gif-sur-Yvette, France, he returned to Münster (1979) and, following his habilitation (1984), he was offered professorships at the University of Vienna (1986) and the University of Würzburg (1987). His areas of interest cover synthetic and analytical natural product chemistry (isoquinoline alkaloids from tropical herbs, endogenous alkaloids in mammalian organisms, N-containing synthetic building blocks, biaryls). For his outstanding work in these areas, Professor Bringmann has received several awards, including the Otto-Klung-Preis für Chemie in 1988.

Reiner Walter (born 1963) started his studies in chemistry at the Technische Hochschule in Darmstadt. He then moved to Würzburg, where he gained his Diploma (1989) and is presently studying for his doctorate, the theme of which relates to the development of new concepts concerning stereoselective biaryl syntheses.

Ralf Weirich (born 1963) studied chemistry at the Universities of Düsseldorf and Würzburg. He is presently doing research for his doctorate; his thesis concerns the total synthesis of axially chiral natural products.

compounds with free phenolic groups. Although this type of reaction has a long tradition[40] because of its biomimetic character,[41] it is often of only limited preparative use, even when applied to the construction of constitutionally *symmetrical* biaryls. A reason for this is that frequently a number of unwanted side products are formed if the aromatic substrate has several sterically and electronically comparable positions.[42] In addition, side reactions such as the formation of phenyl ethers[43] and attack at benzylic positions often compete with the desired coupling process. In spite of these problems, isolated examples worthy of mention have been reported even recently, in part with excellent yields, as for example the synthesis of the gossypol analogue **8**[44] (Scheme 2).



Scheme 2.

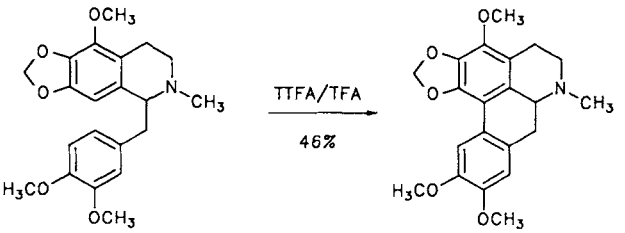
Apart from the often-used "classical" oxidizing agents such as $FeCl_3$[45] (which can be handled quite readily when absorbed on silica gel[46]) and potassium hexacyanoferrate(III),[40] also silver oxide,[47] *tert*-butyl peroxide,[43] iodosobenzene diacetate[48] and potassium dichromate[49] have been used, as well as $Mn(acac)_3$.[50] A further class of reagents such as vanadium oxyfluoride (VOF_3), thallium(III) trifluoroacetate (TTFA) etc. also makes possible a "*non-phenolic*" dehydrodimerization of electron-rich aromatic compounds[51] (see also Section 3.1.).

3. Intramolecular Aryl Coupling (the "Bridge" being Part of the Target Molecule)

3.1. Oxidative Methods

The main problems when applying the above-mentioned *inter*molecular methods to the construction of biaryl axes (the lack of regioselectivity and the often-observed formation of *homo*-coupling products when cross-coupling is required) can in principle be solved by the use of *intra*molecular reaction processes. This is true in particular for oxidative aryl coupling methods involving cyclization,[52] as used for the synthesis of aporphine alkaloids and lignans.[53] In spite of its interesting biomimetic connections,[54, 55] the *classical* phenolic oxidation has only seldom achieved far-reaching preparative importance in alkaloid synthesis because of the usually low yields and the numerous side reactions—with only few important exceptions to this rule.[56]

A better approach to, e.g., the aporphine alkaloids first became feasible after the introduction of new efficient oxidizing agents; these, such as vanadium(V) oxidants[48a, 57] (the most "popular" of which is at present VOF_3[58–61]) make possible the oxidative coupling of phenol *ethers* ("*non-phenolic*" coupling). Recently, the more selective reagent TTFA has been used,[62–67] since nearly no by-products are



Scheme 3.

formed (Scheme 3).[62] If TTFA is prepared *in situ* from thallium(III) oxide and trifluoroacetic acid,[68] the yields can often be increased while the danger of hydrolysis is considerably reduced.

Results comparable to those obtained with such standard reagents can also be achieved using ruthenium(IV) tetrakis(trifluoroacetate),[69, 70] which is prepared *in situ* from RuO_2 and trifluoroacetic acid. In the area of non-phenolic coupling, iron(III) complexes are rather "exotic" oxidizing agents, although in isolated cases very good yields can be obtained.[71] Anodic electrochemical oxidation is less important in natural product synthesis.[72]

For a successful coupling, at least one of the rings of the substrate to be oxidized, e.g. **9** (Scheme 4), must bear oxygen

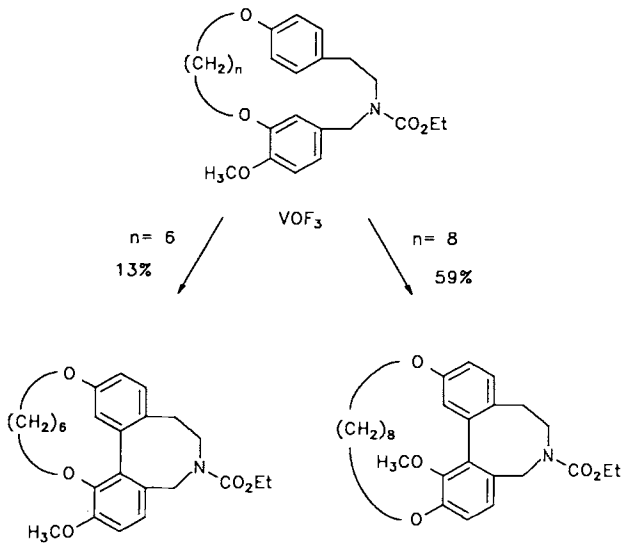
	R^1	R^2	R^3	R^4	R^5	Yield [%]
a	OMe	OMe	H	OMe	OMe	96%
b	OMe	OMe	H	H	H	81%
c	H	H	OMe	OMe	H	-
d	OMe	H	H	OMe	H	-

Scheme 4.

substituents in positions 3 and 4 with respect to the biaryl bridge; this is shown both in systematic studies by *Halton* et al.[58] and by a perusal of the numerous examples in the area of aporphine and lignan synthesis (see Section 6.1.).

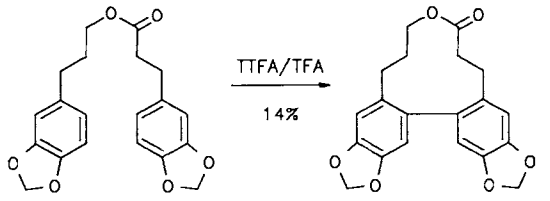
The other ring is then not subject to such constraints and can even be oxygen-free (see **9b**). Benzylic oxygen functionalities which may interfere in the coupling must be introduced subsequently[73] (e.g. in the bisbenzocyclooctadiene skeleton of steganone **4**). Amine nitrogens, as long as they are tertiary or acylated, have no effect.

Apart from its function as an integral element of the target molecule, the bridge between the two aromatic rings to be coupled also induces good yields in cross-coupling and reliable regioselectivities (particularly when the bridge is short) because of the intramolecular nature of the reaction. The loss of regioselectivity observed for larger rings such as eight-membered rings with two equivalent coupling positions can sometimes be compensated by using an additional (auxiliary) bridge, the size of which must be varied according to the particular synthetic problem (Scheme 5).[60]



Scheme 5.

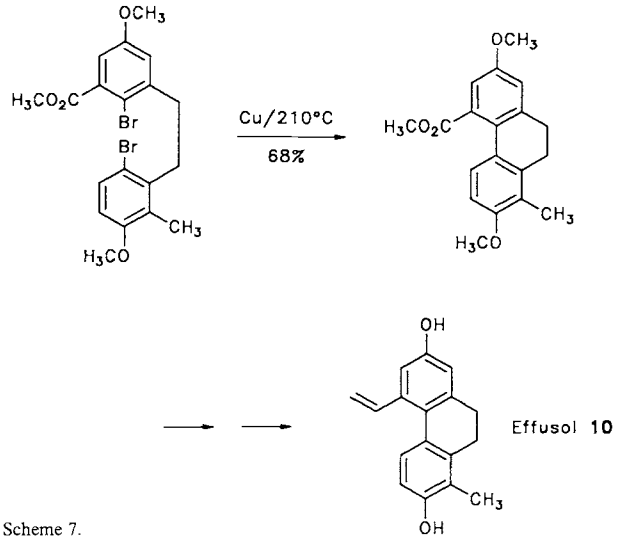
Couplings can also be carried out successfully for analogous seven-membered ring systems (e.g. homoaporphines and colchicine analogues);[62,63] even eleven-membered rings can be obtained in this manner, though with considerably lower coupling yield and regiocontrol (Scheme 6).[74]



Scheme 6.

3.2. Reductive Processes

*Intra*molecular variants have also proved useful for Ullmann couplings and related reactions, though until now there are only few examples[31,75,76] (cf. also Section 6.2).

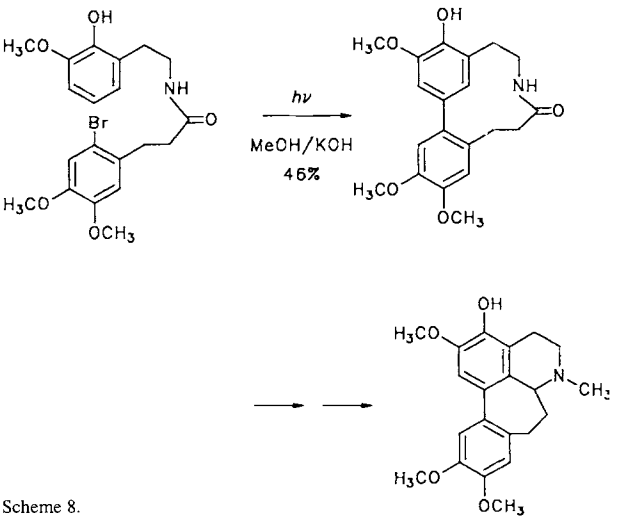


Scheme 7.

The coupling of two different aromatic rings is even possible when these are relatively electron-rich, as in the synthesis of effusol (**10**), a dihydrophenanthrene from marsh grasses (Scheme 7).[77]

3.3. Redox-Neutral Processes

In simple, regiochemically non-problematic cases (e.g. when only *one* free *ortho* position is present next to the bridge) the intramolecular coupling reaction can also be carried out under redox-neutral conditions, e.g., by palladium-catalyzed,[78,79] free radical[80] or photochemical[81] dehydrohalogenation; in some cases it has been possible to obtain unusually large ring systems in surprisingly good yields by intramolecular aryl coupling (Scheme 8).[82]



Scheme 8.

A very important disadvantage of the redox-neutral coupling reaction is that hydrodehalogenation without coupling is almost always observed. Since the by-products so formed can generally not be reintroduced into the reaction process by regioselective halogenation, they are no longer available for the required synthesis.

4. Intermolecular Cross-Coupling to Give Constitutionally Unsymmetrical Racemic Biaryls

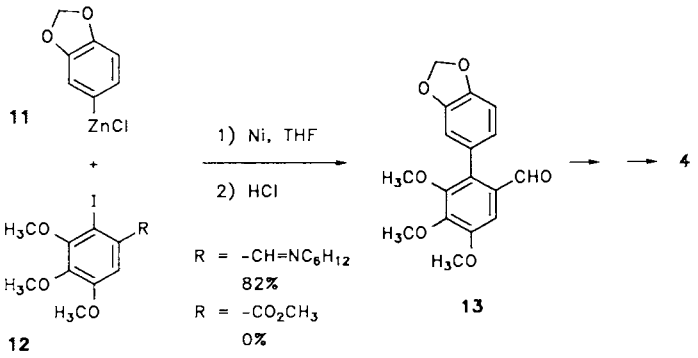
Crossed and, furthermore, regioselective couplings between two different aromatic rings can thus be forced to occur by utilizing *intra*molecular reactions, as shown in the previous section. In *inter*molecular processes, however, satisfactory yields of cross-coupled products can only be obtained if the two aromatic compounds used are functionally or electronically very different. Thus, both in reductive[83-85] and oxidative[86] processes electron-rich compounds must be allowed to react with electron-poor partners in order to shift the normally statistical product distribution towards the crossed products.

It is however much more effective to use the two aromatic compounds in the form of an electrophile/nucleophile pair. This can be done even within the framework of a formal Ullmann coupling in which an arylcopper compound is *first prepared separately* and then allowed to react with an aryl iodide.[87] Another possibility used with success is the reaction of electron-rich aromatic compounds with quinol acetates.[88]

4.1. Ni- and Pd-Catalyzed Grignard Coupling Reactions

A preparatively favorable combination of electrophilic and nucleophilic aromatic molecules is provided by the pairing of aryl halides with arylmetal compounds. Since the discovery that reactions of aryl-Grignard compounds with organic halides (the "Kharash reaction"[89]) can be accelerated by nickel or palladium derivatives,[90] this method has often been used for C–C bond formation.[91,92]

In order to avoid unwanted addition reactions to carbonyl groups, recourse has sometimes been taken to using the less aggressive zinc analogues of the reactive Grignard compounds; such organozinc derivatives can readily be obtained by transmetalation of the corresponding lithium compounds, as in the steganone synthesis reported by *Larson* and *Raphael*.[93] Here, the key step is the regioselective coupling between the organozinc compound **11** and the aryl halide **12** (Scheme 9)—a reaction that poses no steric problems in this



Scheme 9.

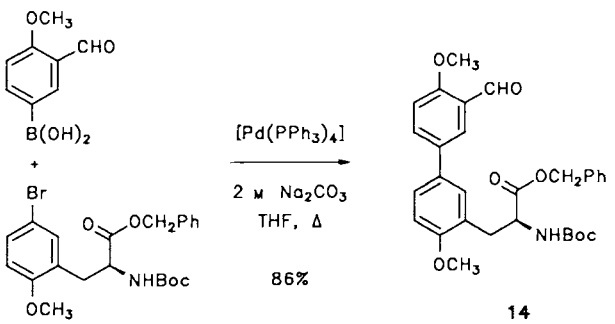
formation of the biaryl **13** which has only two substituents in the *ortho* position with respect to the biaryl axis.

When sterically more demanding reactants are used, however, almost no coupling products are obtained: thus even the presence of one *ortho* substituent on *each* of the two aromatic compounds causes the yield to fall dramatically.[94] Organocopper[95] and organomercury[96,97] derivatives are also capable of undergoing analogous palladium-catalyzed cross-coupling reactions, although such reactions have as yet hardly been applied.

4.2. Coupling Reactions Involving Other Metal(loid)s

The presence of carbonyl groups can lead to the formation of by-products under the conditions used for the above "Grignard coupling";[98] this disadvantage can be avoided by the use of organic derivatives of the less electropositive metal(loid)s boron, silicon or tin[99] because of their reduced nucleophilicity.[96] These arylation reagents can be prepared and purified separately, since they are relatively insensitive towards atmospheric oxygen.[100]

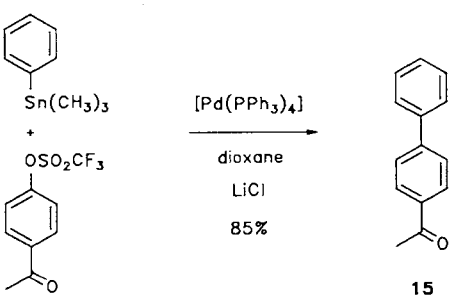
One method which has become of widespread use in organic synthesis is the palladium-catalyzed coupling of the readily available arylboronic acids with aryl halides in the presence of auxiliary bases such as potassium carbonate;[98] examples are the functionalization of an aromatic ring by *ortho*-metalation in the stepwise synthesis of teraryls[101] or the preparation of derivatives of the cyclopeptide **3** (see Fig. 1) via **14**[102] (Scheme 10).



Scheme 10. Boc = *tert*-butoxycarbonyl.

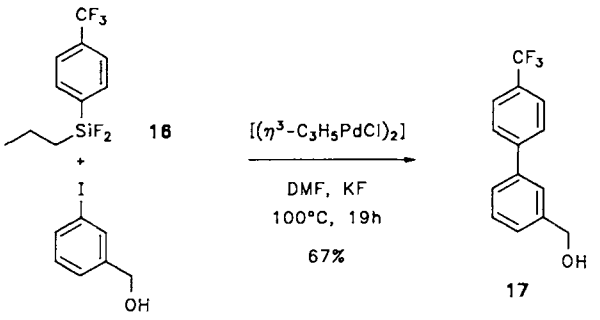
However, steric hindrance of the coupling position by *ortho* substituents, particularly in the boronic acid fragment, has a very negative effect on the yields of coupling product when this method is used.[103]

Phenolic hydroxyl groups can also be exchanged for aryl substituents by palladium-catalyzed reaction of the corresponding aryl triflates with aryltin compounds,[104-106] as in the synthesis of 4-acetylbiphenyl **15**[107] (Scheme 11).



Scheme 11.

Recent reports have dealt with the fluoride-induced cross-coupling of arylfluorosilanes (such as **16**, Scheme 12) with aryl iodides.[108] The palladium-catalyzed synthesis of the biphenyl **17** in a yield of no less than 67% shows that this reaction even tolerates the presence of free hydroxyl groups.

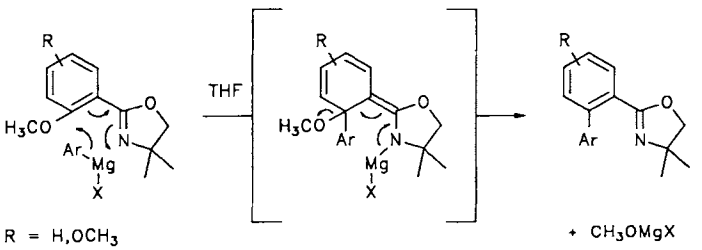


Scheme 12. DMF = dimethylformamide.

4.3. The "Meyers Oxazoline Method"

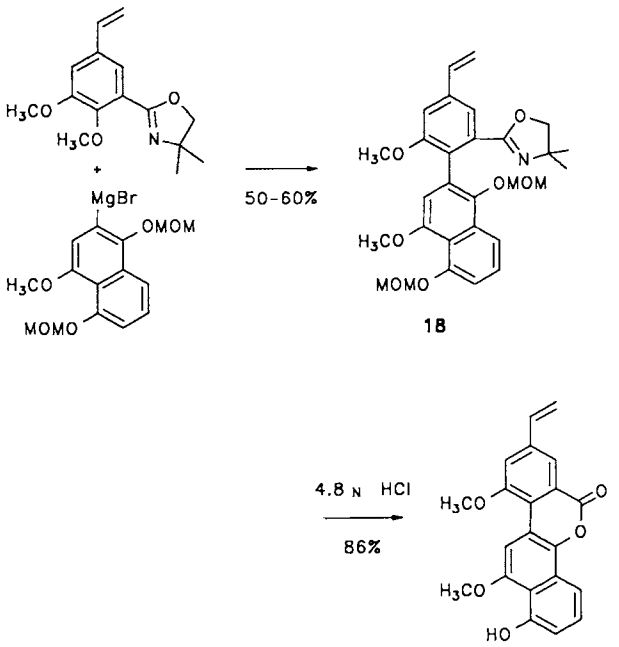
The process for achieving regioselective cross-coupling between two different aromatic compounds which is at present most generally used is, no doubt, the oxazoline method developed by *Meyers*—an efficient route to constitutionally unsymmetrical biaryls.[109]

The aryl residue is introduced in the form of a Grignard reagent by nucleophilic aromatic substitution of a methoxy group bound to an aromatic nucleus. In contrast to the coupling with aryltins described in the previous section, this uncatalyzed reaction requires the activating influence of an oxazoline moiety in the *ortho* position; this increases the electrophilicity at the reaction center and functions at the same time as an additional directing complex ligand for the attacking Grignard species (Scheme 13).



Scheme 13.

The auxiliary group can subsequently undergo hydrolysis to give the biarylcarboxylic acid either under alkaline conditions (after quaternization of the nitrogen with methyl iodide) or under (very harsh) acid conditions; it can also be converted by reductive processes[110, 111] into the corresponding alcohol or aldehyde. In spite of some disadvantages of this method (with respect to the degree of steric hindrance which it tolerates,[110] the sometimes difficult or even impossible preparation of the aryl Grignard reagent,[112] the limitation to certain substitution patterns, etc.: see also Section 5.2.), its popularity can best be seen from the large number of applications in the preparation of biaryl natural products reported in the literature.[113, 114] Thus, besides *rac*-desertorine C[115] and cannabifuran,[116] also the biaryloxazoline **18** has been synthesized; under the reaction conditions used,[117] the latter is directly cyclized to the antimicrobially active lactone defucogilvocarcine V **19**[118] (Scheme 14).



Scheme 14. MOM = CH_3OCH_2-.

5. Intermolecular Atropisomer-Selective Aryl Coupling

5.1. On the Stereochemistry at the Biaryl Axis

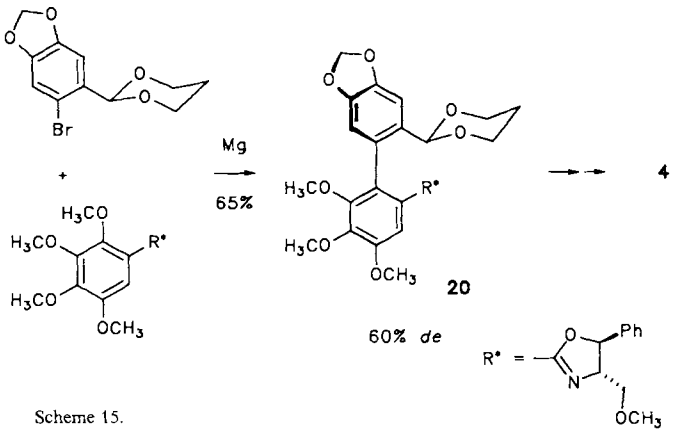
In many of the natural or synthetic biaryls bulky *ortho* substituents next to the coupling position lead to hindrance of free rotation around the biaryl axis and thus to the existence of more or less stable atropisomers, sometimes even when only three *ortho* substituents are present,[119] while in extreme cases only two *ortho* substituents may suffice.[120]

The directed synthesis of such axially chiral compounds requires the unambiguous assignment of the configuration of a biaryl unit thus formed. Certainly the most important method for the direct determination of the *absolute* configuration at the axis is the measurement of circular dichroism (CD)[121]—if necessary after "planarization" of potentially disturbing stereogenic *centers*.[6, 119] X-ray crystal structure determinations will provide information on the *absolute* stereochemistry at the axis less frequently, but will at least afford very reliable statements regarding the axial-chiral situation *relative* to stereocenters likewise present in the molecule.[122, 123] An unambiguous assignment of the relative configuration can also be obtained chemically, by means of an atropisomer-differentiating ring closure reaction to give *ansa*-like macrocycles.[124]

5.2. Nucleophilic Aromatic Substitution

The method of nucleophilic aromatic substitution referred to in Section 4.3[125] can also be carried out in an atropisomer-selective manner when enantiomerically pure chiral oxazolines are used.[110, 111] Very high atropisomeric excess is however generally only obtained with aromatic compounds in which the *ortho* substituents next to the coupling position are very different in size (as for example hydrogen vs. alkyl in **20**, see Scheme 15), i.e. in the synthesis of biaryls which bear only three *ortho* substituents.[110] In biaryls of this type however, in which free rotation is only slightly hindered, a racemization-free removal of the chiral auxiliary is often very difficult because of the low atropisomerization barrier, and can only be carried out by reductive means.

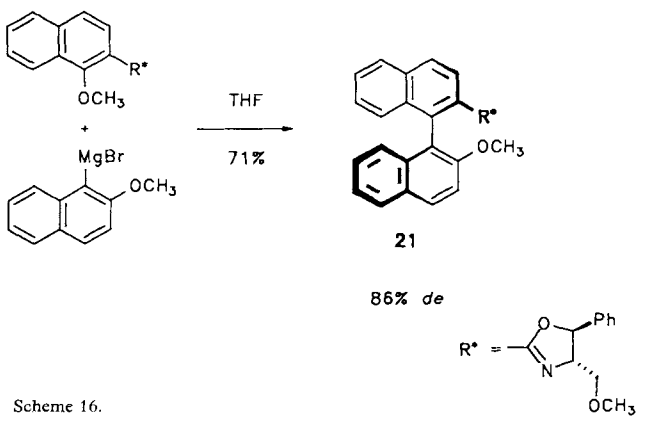
It appears that the only biaryl *natural product* which has been prepared by stereoselective coupling using the oxazoline method is steganone (**4**)[126] (Scheme 15); however, even



Scheme 15.

in this synthesis the information on axial chirality thus generated is lost at a later stage by epimerization at the axis (to give a 1:1 mixture of atropisomers).

Noticeably lower chemical yields and much poorer asymmetric inductions are often observed in reactions which lead to fourfold *ortho*-substituted biphenyls.[110] One exception is provided by the efficient stereoselective synthesis of the binaphthalene **21** (Scheme 16).[111]



Scheme 16.

Other problems can arise due to the commercial availability of only one of the two enantiomers of the chiral auxiliary as well as due to the limitation of the method to particular biaryl substitution patterns.

A decisive influence on *stereoselection* in these nucleophilic substitutions is suggested to be exerted by the metal cation, since the geometry of the primarily formed addition product is determined by the more favorable mode of complexation[111] (Fig. 2).

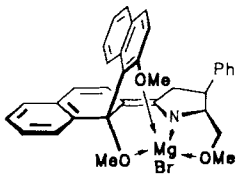


Fig. 2. Presumed intermediates in the arylation to **21** according to *Meyers* et al. [111].

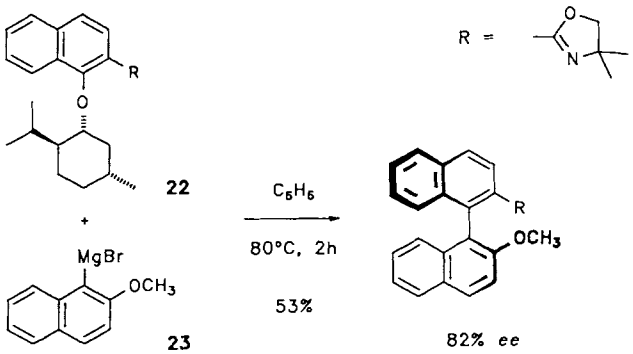
This is also true for the procedure due to *Cram*, in which the required asymmetric induction is obtained by means of a chiral nucleofuge.[127, 128] However, while the use of chiral oxazolines affords diastereomeric mixtures, which can readily be separated by chromatography, the *Cram* procedure may make it necessary to separate the undesired atrop-*enantiomer*. The highest "chirality transfer efficiency" was observed in sterically strongly hindered systems in the reaction

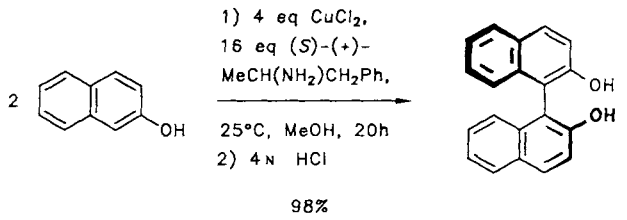


Scheme 17.

of the (−)-menthoxynaphthalene **22** (Scheme 17) with the naphthyl Grignard reagent **23**.[127]

5.3. Coupling with Chiral Copper Complexes

But also when starting from arenes that have not been chirally modified, stereoselective aryl couplings may be carried out, for example by copper complex-mediated phenolic oxidations.[129, 130] Thus, β-naphthol can for example be converted in very good chemical and optical yields into the binaphthol **24** in the presence of a chiral copper-(*S*)-amphetamine complex[129] (Scheme 18). More exact studies, however, show that the excess obtained here does not result from a *kinetic* control, but a subsequent equilibration, i.e. a

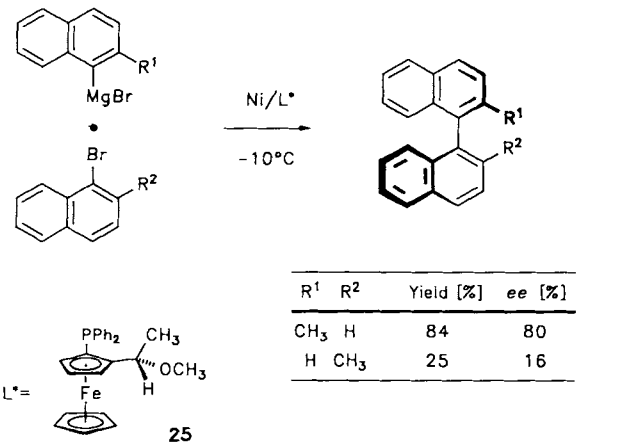


Scheme 18. **24** (96% *ee*)

thermodynamically controlled atropisomer-selective synthesis is involved (see Section 6.3.2). This type of reaction has even been extended to the stereoselective cross-coupling to give teraryls.[131] A disadvantage of this method is the need to have a *more than stoichiometric* amount of chiral auxiliary (up to 16 equivalents of chiral amine per biaryl formed!).

5.4. Coupling with Chiral Catalysts

The development of more economic processes is thus becoming continually more important. Latest results reported by *Hayashi* et al.[132] are a guiding light in the area of *catalytic atrop-enantioselective* crossed Grignard couplings; the catalysts used here are nickel complexes with chiral ferrocenyl ligands such as **25** (Scheme 19).



R^1	R^2	Yield [%]	*ee* [%]
CH_3	H	84	80
H	CH_3	25	16

Scheme 19.

As a comparison of the two reactions presented shows, only certain substrate combinations are possible. Thus, in order to obtain good optical yields the aryl Grignard component must generally have two *ortho* substituents, while in order for the chemical yields to be good only a slight steric hindrance is tolerated for the halide. This method has since been used for the synthesis of a chiral binaphthyl(cyclopentadienyl)titanium complex[133].

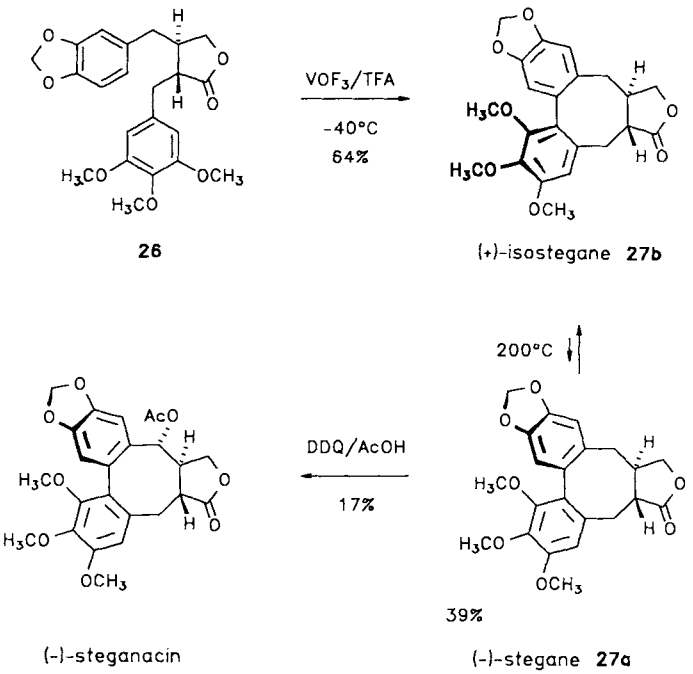
The process can also be employed in the stereoselective synthesis of ternaphthyls.[134] However, an application to the coupling of complex functionalized aromatic compounds, for example for the preparation of particular biaryl *natural products*, is still awaited.

6. Intramolecular Atropisomer-Selective Aryl Coupling

Recently, powerful methods for intramolecular aryl coupling have been increasingly elaborated. Not only does the bridge (as in the examples discussed in Section 3) lead to an improvement in the yield and a reliable regioselectivity due to the intramolecular nature of the reaction, but it also influences the barrier to atropisomerization and can be the site of the chirality from which the asymmetric induction emanates. After coupling has been carried out, the bridge can either completely or in part remain within the molecule (eventually leaving "bridgeheads" behind) or it can be completely removed.

6.1. Using Bridges which are Naturally Present in the Target Molecule

In many oxidative intramolecular coupling reactions to give lignans[68, 135–138] (see Section 3.1) the "bridge" is not only a constituent part of the target molecule but at the same time it determines the steric course of the coupling reaction. Thus, for example, the reaction of **26** (Scheme 20) with VOF_3 gives under kinetic control solely the unwanted atropisomer **27b** (of the "isostegane type"),[139] which on heating can undergo equilibration[140] to yield the atropisomer mixture **27a/b** (ca. 2:3[141], from which the natural rotational isomer **27a** of the "stegane type" can be isolated in 39% yield.



Scheme 20. DDQ = 2,3-dichloro-5,6-dicyanobenzoquinone.

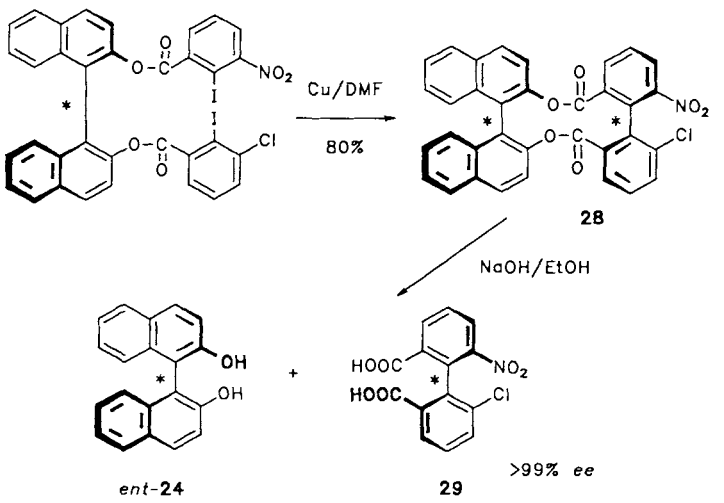
The barrier to atropisomerization as well as the kinetically controlled preferred formation of the isostegane-type isomer is here determined mainly by the configurational inflexibility of the cyclooctadiene system, so that analogous couplings

lead to the isostegane type even when only two substituents *ortho* to the biaryl axis are present[120]—as long as the eight-membered ring formed is kept rigid, for example by an annelated five-membered lactone ring. Without this additional stabilization the barrier to atropisomerization sinks dramatically, and thermodynamically controlled rotational isomer mixtures are formed.[120]

Many of the reactions discussed in Section 3.1 very probably also occur in a stereoselective manner, but unfortunately most publications do not report the configuration at the biaryl axis or even mention the possible existence of atropisomers. Many examples of this type, which could perhaps have been included in this section if a more exact stereochemical study had been carried out, can thus only be treated in this section.

6.2. Coupling in the Presence of Artificial Chiral Auxiliary Bridges

However, even when the target molecule does not contain a "bridge" as an integral part of its structure it is possible to take advantage of an intramolecular stereoselective reaction pathway—by pre-fixing the two aromatic moieties by means of an *artificial* chiral bridge. Thus, *Miyano* developed a process for an atrop-diastereoselective (and if necessary also crossed) intramolecular Ullmann reaction with the help of optically active auxiliary bridges.[142] By far the best results are obtained in this case by using the rigid template formed by a further biaryl, (*R*)-2,2'-binaphthol (*ent*-**24**). Here, complete asymmetric induction is observed, and the product **29** has the same enantiomeric purity as the auxiliary bridge used (Scheme 21).[143]



Scheme 21. DMF = dimethylformamide.

The disadvantage of the high price of the chiral biaryl **24**, which must be used in stoichiometric amounts, is partially compensated by the possibility of its reuse. The asymmetric induction is considerably poorer when other, cheaper chiral diols are used as bridges.[144] The reason for the high degree of stereoselectivity achieved when the binaphthol bridge is used has been suggested to be a double helix-like arrangement of the twelve-membered ring **28**, which represents the energetically most favorable conformation of the coupling product.[145] The generation of the corresponding diastereomeric product can be excluded because of the unfavorable geometrical arrangement required.

However, a more general use of this method, for example in natural product synthesis, is hampered by the often poor yields and by its limitation to electron-poorer coupling substrates and to particular substitution patterns.

6.3. Coupling in Presence of Artificial Auxiliary Bridges without Stereogenic Centers

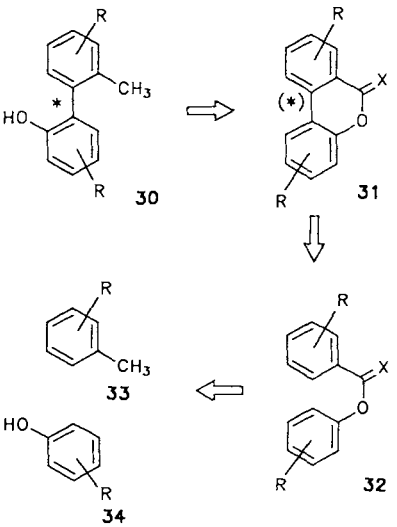
6.3.1. The General Principle

Recently, a new method has been developed for the regio- and stereoselective construction of even highly substituted biaryls for the synthesis of natural products and pharmaceuticals;[7, 124, 146–149] in this procedure the two aromatic residues are brought together at a suitable distance by means of an *achiral* auxiliary chemical bridge and then linked in an intramolecular manner by a coupling proceeding with cyclization. The auxiliary bridge does not need to be an integral part of the target molecule, but is constructed from "bridgeheads" *already present*.

Because of the arrangement of substituents in **30**, which is often found in biaryl natural products, such a prefixation of the two aromatic moieties **33** and **34** was carried out by an ether- or ester-type bridge (as in **32**), which subsequent to the aryl coupling to give **31** can readily be cleaved reductively to yield the final product **30** (Scheme 22).

In this case the auxiliary bridge leads not only to very good coupling yields and to a reliable *ortho* regiospecificity because of the *intra*molecular mode of reaction; in addition there is a dramatic lowering of the atropisomerization barrier in the bridged biaryls **31** in comparison with the ring-opened products **30**.

This effect can be used in a specific manner, since according to the degree of steric hindrance at the biaryl axis the bridged biaryls **31** are either still helically stable (see Section



Scheme 22.

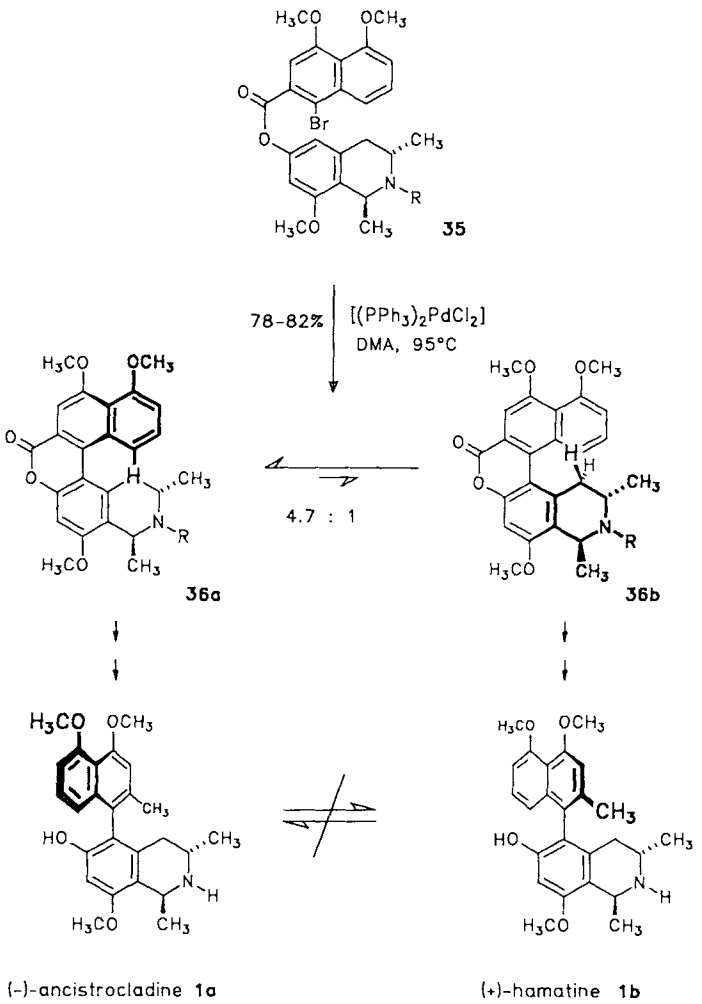
6.3.2) and can undergo ring-opening with retention of configuration at the biaryl axis, or they are stereochemically not yet differentiated, but "*axially prostereogenic*";[146] they can then be ring-opened under kinetic control atrop-diastereoselectively (see Section 6.3.3.1) or *atrop-enantioselectively* (see Section 6.3.3.2)—by stereoselective twisting of an already present but on a time average still planar biaryl system.

6.3.2. *Coupling via Helically Twisted Bridged Biaryls*

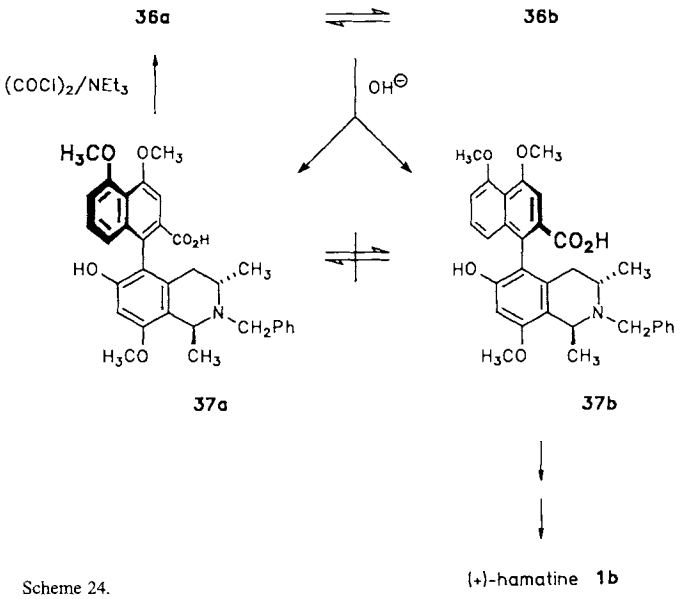
The power of this new arylation concept is shown particularly clearly in the regio- and stereoselective total synthesis[147] of ancistrocladine (**1a**), the most well-known representative of the naphthylisoquinoline alkaloids,[7] which is configurationally stable at its rotationally hindered axis up to over 200 °C. The ester-type pre-fixation of the two halves of the molecule as in **35** now makes it possible to carry out the (*intermolecularly* not realized[112]) aryl coupling in high yield and with a high regioselectivity (Scheme 23). Because of the steric hindrance at the axis, the bridged biaryl precursor (the lactone **36**) is here not planarized but split into *helicene-like distorted atropisomers* **36a/b**, which can be converted into ancistrocladine (**1a**) and its naturally occurring atropisomer hamatine (**1b**)—with a clear atropisomer excess (e.g. 4.7:1 when $R=CH_2Ph$) in favor of the ancistrocladine type, which is also found more frequently in plants.[7]

This atropisomeric excess depends strongly on the conformational rigidity of the tetrahydroisoquinoline ring (and also of the bridge). Thus, the introduction of the *N*-trifluoroacetyl group in **35** shifts the helimer distribution greatly in favor of the ancistrocladine precursor **36a** ("100:0" for $R=COCF_3$);[124] the ring opening can then be carried out under mild conditions with retention of the configuration at the axis—a *thermodynamically controlled atrop-diastereoselective biaryl synthesis*.

In contrast to the situation in the intermolecular atropisomer-selective cross coupling with the aid of chiral copper complexes described in Section 5.2, where the isomer equilibrium is influenced by an *external* chiral auxiliary (the amine ligands on the copper), the reaction is directed here by *internal* asymmetric induction due to the chirality already present in the substrate (stereogenic centers at C-1 and C-3).



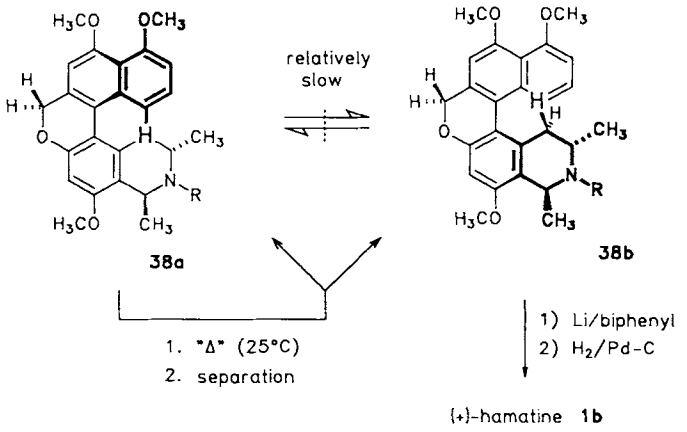
Scheme 23. DMA = *N*,*N*'-dimethylacetamide.



Scheme 24.

A specific synthesis of the minor isomer hamatine (**1b**) by means of isomer separation at the stage of the lactones **36a/b** is made difficult by the fact that these atropisomers interconvert at room temperature with a "half-life" of less than one minute; this is due to the short and planarizing bridge. It is much simpler to open the lactone mixture **36a/b** by means of base-catalyzed ester hydrolysis to give the stable and thus readily separable acids **37a/b** (Scheme 24).[124] Subsequent to the separation, each required atropisomer (e.g. **37b**) can be converted into the corresponding alkaloid (in this case hamatine (**1b**)), while the unwanted stereoisomer (in this case **37a**) can be reintroduced into the reaction process in the sense of "*axially chiral economy*"[124]—a *recycling through recyclization*.

Still more simply, without recourse to the hydrolysis/lactonization cycle, hamatine (**1b**) can be synthesized, via the conformationally more stable and thus readily separable cyclic ethers **38a/b** (Scheme 25)[148] by ring-opening of the



Scheme 25.

now required stereoisomer **38b** and recycling of the unrequired *M*-helical isomer (the "*M*-helimer"[148]) **38a** by equilibration at room temperature and repetition of the procedure thus have possibilities for the synthesis of either of the two atropisomers, hamatine (**1b**) or (in a more direct manner, as described above) ancistrocladine (**1a**), starting from identical precursors.

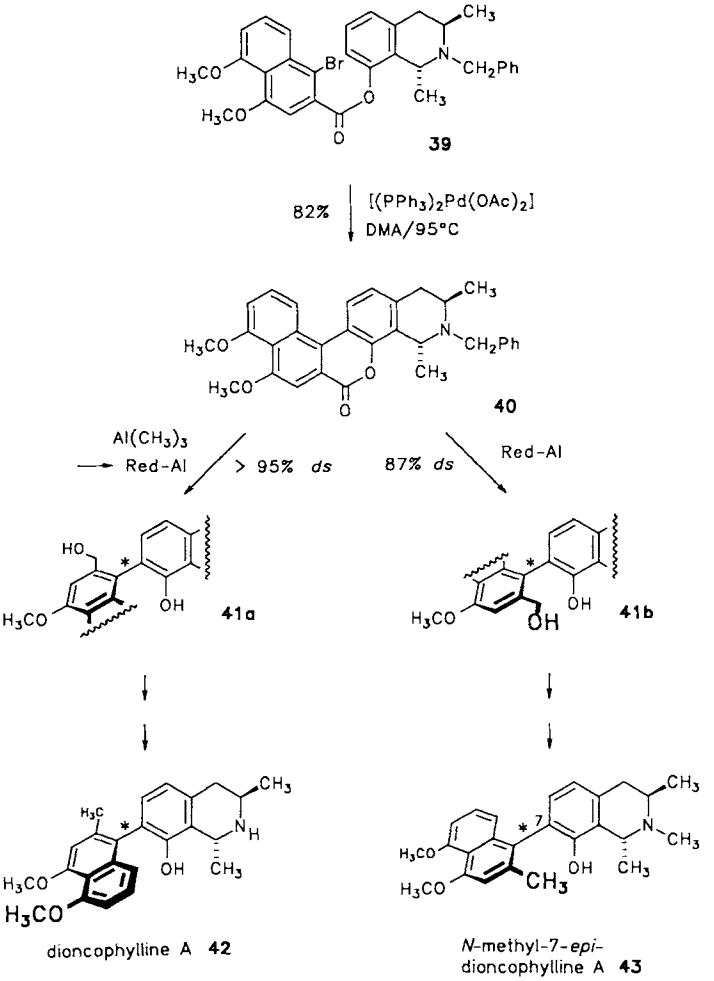
6.3.3. Coupling via Planarized ("Axially Prostereogenic") Bridged Biaryls

6.3.3.1. By Means of Internal Asymmetric Induction

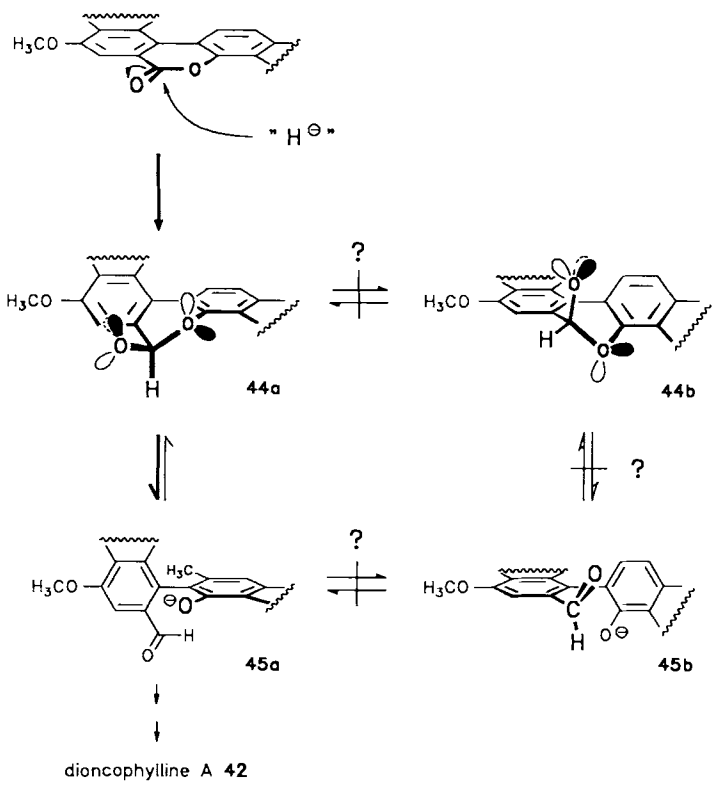
Stereochemically still not defined, however, is the planarized, "*prostereogenic*" axis, e.g. in the alkaloid precursor **40**,[149] which can also be obtained in very good yields by coupling. The selection of suitable reaction conditions makes it possible to control the cleavage of the auxiliary bridge to give the configurationally stable ring-opened biaryls **41a** and **41b** stereoselectively, by making use of *internal* asymmetric induction (Scheme 26):[124] by reduction of **40** with *Lewis acid* hydride transfer reagents (or corresponding combinations) the ring-opened product **41a**, a precursor to (−)-dioncophylline A (**42**), is formed practically exclusively (*ds* > 95%), whereas the use of *basic* hydride transfer reagents (e.g. "Red-Al") instead gives the atropisomer **41b** in good atropisomeric excess; the latter is also found in nature in the form of **43**[150, 151]—a new principle for the (kinetically controlled) atropisomer-selective biaryl synthesis by *diastereoselective twisting and ring-opening of axially prostereogenic lactone precursors* with the help of achiral H-nucleophiles.

The mechanistic concept[124] used here requires that the following three conditions be fulfilled in order that an already present but initially flat biaryl axis undergoes twisting in such a directed manner:

1) The diastereofacial attack of the hydride transfer reagent on the lactone function of **40** must occur from only *one* direction (e.g. merely from below, Scheme 27) with formation of for example only the (metal) lactolate diastereomer **44** with an α-hydrogen; this can be explained in terms of blockage of the upper side of the molecule by the bulky, strongly complexing aluminum reagent, so that attack of the nucleophile can only occur from below.[152]



Scheme 26.

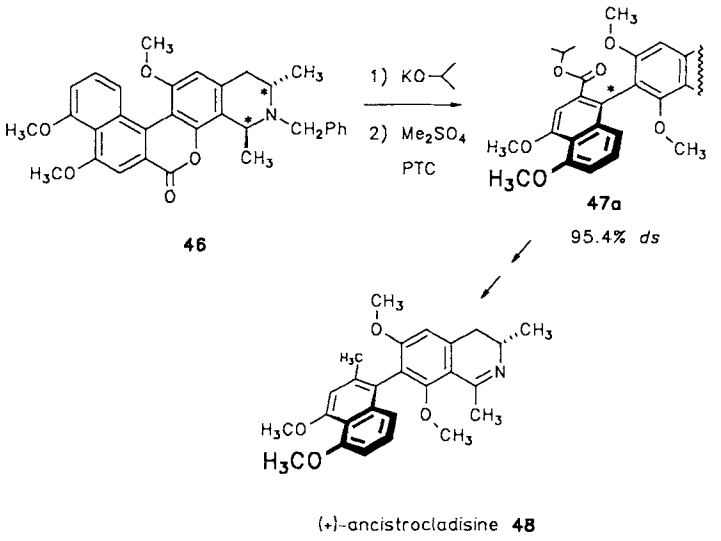


Scheme 27.

2) Preferred ring opening of the (metal) lactolate **44** (possibly stereoelectronically controlled) starting from only *one* of the two possible conformations **a**/**b**; this opening, e.g. of **44a** to give **45a**, would cause the conformation preformed in the lactol to become the final axial "configuration" at the biphenyl axis.
3) The resulting aldehyde **45a** must be reduced rapidly enough to give the configurationally stable alcohol **41a** (see Scheme 26) before it loses its inherent axial chirality information by subsequent recyclization and isomerization processes.

This stereocontrolled synthesis of dioncophylline A (**42**) and (if required) of its atropisomer is at the same time a promising first step in the direction of a general strategy for the specific transformation of a readily-constructed, stereochemically still undefined axis into a stereogenic axis with any required configuration by stereoselective reaction at a coupled stereogenic center (in this case the carbonyl group) followed by a chirality transfer from "centro-chiral" to "axially chiral".

For the stereoselective torsion of the still flat biaryl axis, oxygen nucleophiles can also be used if sufficient steric hindrance is present (see Scheme 28).[153] Thus, the preparative-



Scheme 28. PTC = phase transfer catalysis with benzyl-tri-*n*-butylammonium chloride.

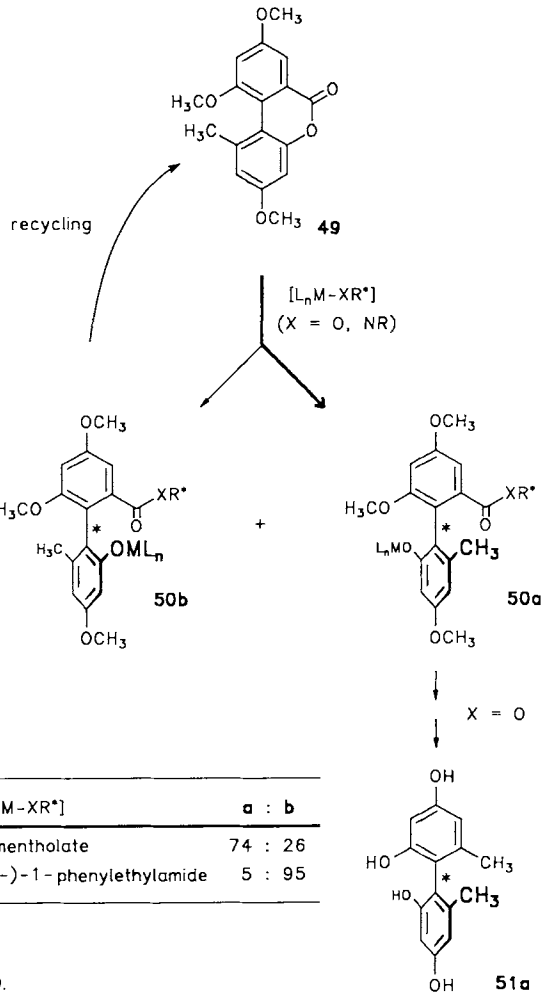
ly facile ring-opening of the related lactone **46** gives very high atropisomeric excesses even when using potassium isopropoxide; these can be increased by the use of (+)-mentholates, while the use of (−)-mentholates (the "mismatch" case) causes them to be reversed to a small extent. The ring-opened ester **47a** is converted with retention of the configuration at the biaryl axis into the alkaloid (+)-ancistrocladine (**48**) (prepared here for the first time), while the other, unwanted isomer can again be recyclized to the axially prostereogenic lactone **46** in the sense of "axially chiral economy".[146]

This example demonstrates an important practical aspect of the new synthetic principle: it is the first example of an atropisomer-selective synthesis of an axially chiral natural product with two identical *ortho* substituents ($2 \times OCH_3$) next to the biaryl axis[154]—a still unsolved problem for all other methods of stereoselective aryl coupling. In such cases it makes no difference energetically whether a locally symmetrical aromatic compound (i.e. one with two identical *ortho* substituents) approaches to form one or the other atropisomer, even when in a *more distant sphere* there are differences with respect to the substituents: *here* this goal is reached without any difficulty whatsoever, since this stereoselective ring opening is subject to completely different control mechanisms (see above).

6.3.3.2. By Means of External Asymmetric Induction

In the case of the alkaloid syntheses described above it was possible to establish the axial chirality by taking advantage of an *internal* asymmetric induction exerted by stereogenic centers already present in the molecule. In view of the large number of important biaryl natural products which contain no further stereogenic elements apart from their chiral axis it is of particular preparative importance that this principle can now also be extended to include atrop-*enantioselective* biaryl synthesis—by stereocontrolled torsion of completely flat, *achiral* lactone precursors by means of optically active ring-opening nucleophiles.

Thus, the stereoselective ring opening of the benzocoumarin-like lactone **49** (Scheme 29)—a model precursor for a



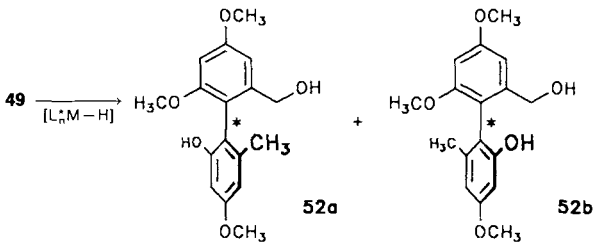
$[L_nM\text{-}XR^*]$	a : b
K-(+)-mentholate	74 : 26
K-(S)-(-)-1-phenylethylamide	5 : 95

Scheme 29.

large number of axially chiral natural products which have similar substitution patterns next to the biaryl axis (e.g. gossypol (**2**))—occurs "right away" in quite good atropisomer ratios with such simple, inexpensive and sterically not particularly differentiating oxygen nucleophiles as (−)-mentholate; it is of mechanistic importance that the best results are always obtained with potassium alcoholates.[155]

The required atropdiastereomer (e.g. **50a**) can be converted into the target molecule (in this case the enantiomerically pure dimeric orcin **51a**) with retention of configuration at the biaryl axis, while the unwanted atropdiastereomer can be reintroduced into the process by recyclization, whereby again the chiral alcohol is reobtained. This method is thus chirally economical with respect to both substrate *and* reagent.

Ring-opening reactions occur in an even more stereoselective manner using the simple nucleophile (*R*)-1-phenylethylamine, which is available cheaply in both enantiomeric forms; again the same surprising tendency is observed for the best results (*dr* 95:5) to be obtained in each case with the corresponding *potassium* amide.[156]



[L*nM−H]	a	:	b
6 (X = H)	10	:	90
53	88	:	12

Scheme 30.

These (overall) *enantioselective* biaryl syntheses starting from achiral bridged biaryl precursors naturally occur in an atrop-*diastereo*selective manner in the actual ring-opening step, since they first lead to diastereomeric products (as in the aforementioned reactions of chiral substrates). The advantage here is the easier subsequent separation (followed by re-use) of the unwanted lesser isomer, while the price to be paid lies in the necessity to remove the chiral auxiliary by cleavage of the previously formed C–O or C–N bond. These additional reactions can be avoided by the use of ring-opening reactions which are actually atrop-*enantio*selective (Scheme 30), e.g. with chiral hydride transfer reagents such as **6** or **53**, which give quite high asymmetric inductions.[157]

7. Summary and Future Prospects

This account clearly shows that, in spite of the great efforts made by different research groups in the last few years, the *single* generally applicable aryl coupling method which can be applied to each individual coupling problem and which satisfies all regio- and stereochemical demands has not yet been found. However, remarkable and powerful new methods have been reported very recently which a) have been shown to be applicable not only to model substances but to the first stereoselective syntheses of actual, functional natural products, in some cases with sterically strongly hindered biaryl axes, b) take account of chiral-economic aspects (e.g. recycling of unwanted isomers, specific syntheses of *both* atropisomers starting from the same precursor, catalytic reaction manner), and c) can even be used successfully when in the target molecule or its precursors the *ortho* substituents next to the biaryl axis are very similar or even *identical*, as for example in ancistrocladisine (**48**).

Further exciting progress can be expected in this field in the future.

We thank the Deutsche Forschungsgemeinschaft (Normalverfahren and Sonderforschungsbereich No. 1373 "Selective Reactions of Metal-Activated Molecules") and the Fonds der Chemischen Industrie for their generous support of our work. Particular thanks are due to the co-workers who have actively taken part in our own aryl coupling concept: Dipl.-Chem. H. Reuscher, Ch. Ewers, B. Schöner, T. Hartung, M. Rübenacker, H. Busse and above all Dr. J. R. Jansen. We also thank Frau L. Kinzinger for valuable technical assistance and Frau M. Lehrmann for producing the typescript.

Computer Simulation of Molecular Dynamics: Methodology, Applications, and Perspectives in Chemistry

By Wilfred F. van Gunsteren* and Herman J. C. Berendsen*

During recent decades it has become feasible to simulate the dynamics of molecular systems on a computer. The method of molecular dynamics (MD) solves *Newton*'s equations of motion for a molecular system, which results in trajectories for all atoms in the system. From these atomic trajectories a variety of properties can be calculated. The aim of computer simulations of molecular systems is to compute *macroscopic* behavior from *microscopic* interactions. The main contributions a microscopic consideration can offer are (1) the understanding and (2) interpretation of experimental results, (3) semiquantitative estimates of experimental results, and (4) the capability to interpolate or extrapolate experimental data into regions that are only difficultly accessible in the laboratory. One of the two basic problems in the field of molecular modeling and simulation is how to efficiently search the vast configuration space which is spanned by all possible molecular conformations for the global low (free) energy regions which will be populated by a molecular system in thermal equilibrium. The other basic problem is the derivation of a sufficiently accurate interaction energy function or force field for the molecular system of interest. An important part of the art of computer simulation is to choose the unavoidable assumptions, approximations and simplifications of the molecular model and computational procedure such that their contributions to the overall inaccuracy are of comparable size, without affecting significantly the property of interest. Methodology and some practical applications of computer simulation in the field of (bio)chemistry will be reviewed.

1. Introduction

Computational chemistry is a branch of chemistry that enjoys a growing interest from experimental chemists. In this discipline chemical problems are resolved by computational methods. A model of the real world is constructed, both measurable and unmeasurable properties are computed, and the former are compared with experimentally determined properties. This comparison validates or invalidates the model that is used. In the former case the model may be used to study relationships between model parameters and assumptions or to predict unknown or unmeasurable quantities.

Since chemistry concerns the study of properties of substances or molecular systems in terms of atoms, the basic challenge facing computational chemistry is to describe or even predict

1. the structure and stability of a molecular system,
2. the (free) energy of different states of a molecular system,
3. reaction processes within molecular systems

in terms of interactions at the atomic level. These three basic challenges are listed according to increasing difficulty. The first challenge concerns prediction of which state of a system has the lowest energy. The second challenge goes further; it involves prediction of the relative (free) energy of different states. The third challenge involves prediction of the dynamic process of change of states.

Chemical systems are generally too inhomogeneous and complex to be treated by analytical theoretical methods. This is illustrated in Figure 1. The treatment of molecular systems in the gas phase by quantum mechanical methods is straightforward; if a classical statistical mechanical approximation is permitted the problem becomes even trivial. This is due to the possibility of reducing the many-particle problem to a few-particle one based on the low density of a system in the gas phase. In the crystalline solid state, treatment by quantum mechanical or classical mechanical methods is made possible by a reduction of the many-particle problem to a few-(quasi)particle problem based on symmetry properties of the solid state. Between these two extremes, that is, for liquids, macromolecules, solutions, amorphous solids, etc., one is faced with an *essentially* many-particle system. No simple reduction to a few degrees of freedom is possible, and a full treatment of many degrees of freedom is required in order to adequately describe the properties of molecular systems in the fluid-like state. This state of affairs has two direct consequences when treating fluid-like systems.

1. One has to resort to numerical *simulation* of the behavior of the molecular system on a computer, which
2. produces a *statistical ensemble* of configurations representing the state of the system.

If one is only interested in static equilibrium properties, it suffices to generate an ensemble of equilibrium states, which

may lack any temporal correlations. To obtain dynamic and non-equilibrium properties dynamic simulation methods that produce trajectories in phase space are to be used. The connection between the microscopic behavior and macroscopic properties of the molecular system is governed by the laws of *statistical mechanics*.

Figure 1 also shows the broad applicability of computer simulation methods in chemistry. For any fluid-like, essentially many-particle system, it is the method of choice.

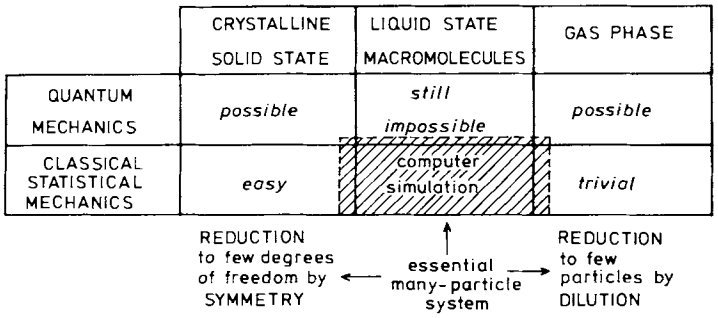

Fig. 1. Classification of molecular systems. Systems in the shaded area are amenable to treatment by computer simulation.

The expanding role of computational methods in chemistry has been fueled by the steady and rapid increase in computing power over the last 40 years, as is illustrated in Figure 2. The ratio of performance to price has increased an order of magnitude every 5–7 years, and there is no sign of any weakening in this trend. The introduction of massive parallelism in computer architecture will easily maintain the present growth rate. This means that more complex molecular systems may be simulated over longer periods of time, or that it will be possible to handle more complex interaction functions in the decades to come.

The present article is concerned with computer simulation of molecular systems. In Section 2 the two basic problems are formulated, a brief history of dynamic computer simulation is presented, the reliability of current simulations is discussed, and the usefulness of simulation studies is considered. Section 3 deals with simulation methodology: choice of computational model and atomic interaction function (Section 3.1), techniques to search configuration space for low energy configurations (Section 3.2), boundary conditions (Section 3.3), types of dynamical simulation methods (Section 3.4), algorithms for integration of the equations of motion (Section 3.5), and finally equilibration and analysis of molecular systems (Section 3.6). In Section 4, a number of applications of computer simulation in chemistry are discussed and examples are given. Finally, future developments are considered in Section 5. For other relatively recent monographs on computer simulation the reader is referred to the literature (see Refs. [1–9]).

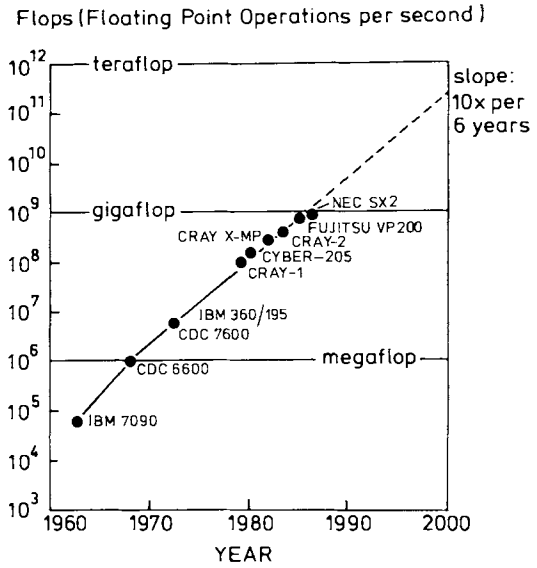

Fig. 2. Development of computing power of the most powerful computers.

2. Computer Simulation of Molecular Systems

2.1. Two Basic Problems

Two basic problems are encountered in the computer simulation of fluid-like molecular systems:

1. *the size of the configurational space* that is accessible to the molecular system, and
2. the *accuracy* of the molecular model or atomic interaction function or force field that is used to model the molecular system.

Wilfred F. van Gunsteren was born in 1947 in Wassenaar (The Netherlands). In 1968 he gained a B.Sc. in physics at the Free University of Amsterdam; in 1976 he was awarded a "Meester" in Law, and in 1976 a Ph.D. in nuclear physics. After postdoc years at the University of Groningen (1976–1978) and at Harvard University (1978–1980) he was, from 1980 until 1987, senior lecturer and, until August 1990, Professor for Physical Chemistry at the University of Groningen. Since September 1987 he has also been Professor of Computer Physics at the Free University Amsterdam. In 1990 he was offered and accepted a professorship of Computer Chemistry at the ETH Zürich. He is holder of a gold medal for research of the Royal Netherlands Chemical Society; in 1988 he was Degussa Guest Professor at the University of Frankfurt. His main interests center on the physical fundamentals of the structure and function of biomolecules.

Table 1. Models at different levels of approximation.

Model	Degrees of freedom left	Degrees of freedom removed	Example of predictable property	Example of force field	
- quantum mechanical	nuclei, electrons	nucleons	reactions	Coulomb	increasing: simplicity, speed of computation, search power, time scale
- all atoms, polarizable	atoms dipoles	electrons	binding charged ligand	ionic models [10]	
- all atoms	solute + solvent atoms	dipoles	hydration	OPLS [11] GROMOS [12]	
- all solute atoms	solute atoms	solvent	gas phase conformation	MM2 [13]	decreasing: complexity, accuracy of atomic properties
- groups of atoms as balls	atom groups	individual atoms	folding topology of macromolecule	LW [14]	

2.1.1. *Size of the Configurational Space*

The simulation of molecular systems at non-zero temperatures requires the generation of a statistically representative set of configurations, a so-called *ensemble*. The properties of a system are defined as ensemble averages or integrals over the configuration space (or more generally phase space). For a many-particle system the averaging or integration will involve many degrees of freedom, and as a result can only be carried out over part of the configuration space. The smaller the configuration space, the better the ensemble average or integral can be approximated. When choosing a model from which a specific property is to be computed, one would like to explicitly include only those degrees of freedom on which the required property is dependent.

In Table 1 a hierarchy of models is shown, in which specific types of degrees of freedom are successively removed. Examples are given of properties that can be computed at the different levels of approximation. If one is interested in chemical reactions, a quantum mechanical treatment of electronic degrees of freedom with the nuclear coordinates as parameters is mandatory. The intranuclear degrees of freedom (nucleon motion) are left out of the model. The computing power required for a quantum mechanical treatment scales at least with the third power of the number of electrons N_e that are considered. Such a treatment is only possible for a limited number of degrees of freedom. At a next level of approximation the electronic degrees of freedom are removed from the model and approximated by (point) polarizabilities. Such a model, allowing for motions of polarizable atoms, could, e.g., be used to compute the binding properties of polar or charged ligands which will polarize the receptor. At this level of modeling the computing effort scales with the square of the number of atoms N_a. This means that many more atoms can be considered than at the quantum level. Removal of the polarizability of the atoms yields a next level of approximation, in which only atomic positional degrees of freedom are considered and the mean polarization is included in the effective interatomic interaction function. Such a model allows for the study of solvation properties of molecules. When studying solutions, a next level of approximation is reached by omitting the solvent degrees of freedom from the model and simultaneously adapting the interaction function for the solute such that it includes the mean solvent effect. When studying protein folding, the configuration space spanned by all protein atoms is still far too large to be searched for low energy conformations. In this case a further reduction in it can be obtained by representing whole groups of atoms, for example an amino acid residue, as one or two balls (3 or 6 degrees of freedom).

From this discussion it is clear that the level of approximation of the model that will be used in the simulation will depend on the specific property one is interested in. The various force fields that are available correspond to different levels of approximation, as is illustrated in the right half of Table 1. There is a hierarchy of force fields.

Once the level of approximation has been chosen, that is, the types of degrees of freedom in the model, one must decide how many degrees of freedom (electrons, atoms, etc.) are to be taken into account. How small a system can be chosen without seriously affecting a proper representation of the property of interest? The smaller the size of the system the better its degrees of freedom can be sampled, or in dynamic terms, the longer the time scale over which it can be simulated.

We may summarize the first basic problem in the computer simulation of molecular systems as follows: the level of approximation of the model should be chosen such that those degrees of freedom that are essential to a proper evaluation of the quantity or property of interest can be sufficiently sampled. In practice any choice involves a compromise between type and number of degrees of freedom and extent of the simulation on the one hand, and the available computing power on the other.

2.1.2. *Accuracy of Molecular Model and Force Field*

When the degrees of freedom are infinitely dense or long sampled the accuracy by which various quantities are predicted by a simulation will depend solely on the quality of the assumptions and approximations of the molecular model and interatomic force field. At the level (Table 1) of quantum mechanical modeling the basic assumption is the validity of the Born-Oppenheimer approximation separating electronic and nuclear motion. The interaction between point atoms and electrons is described by Coulomb's law and the Pauli exclusion principle. When excluding chemical reactions, low temperatures or details of hydrogen atom motion, it is relatively safe to assume that the system is governed by the laws of classical mechanics. The atomic interaction function is called an *effective interaction* since the average effect of the

omitted (electronic) degrees of freedom has been incorporated in the interaction between the (atomic) degrees of freedom explicitly present in the model. To each level of approximation in Table 1 there corresponds a type of effective interaction or force field. For example, a pair potential with an enhanced dipole moment (enhanced atomic charges) may be used as an effective potential that mimics the average effect of polarizability.

In view of the different levels of approximation of molecular models it is not surprising that the literature contains a great variety of force fields. They can be classified along different lines:

- type of compound that is to be mimicked, e.g. carbohydrates, sugars, polypeptides, polynucleotides;
- type of environment of the compound of interest; e.g. gas phase, aqueous or nonpolar solution;
- range of temperatures covered by the effective interaction;
- type of interaction terms in the force field; e.g. bond stretching, bond angle bending, torsional terms, two-, three- or many-body nonbonded terms;
- functional form of the interaction terms; e.g. exponential or 12th power repulsive nonbonded interaction;
- type of parameter fitting, that is, to which quantities are parameters fitted, and are experimentally or ab-initio theoretically obtained values used as target values.

We note that the choice of a particular force field should depend on the system properties one is interested in. Some applications require more refined force fields than others. Moreover, there should be a balance between the level of accuracy or refinement of different parts of a molecular model. Otherwise the computing effort put into a very detailed and accurate part of the calculation may easily be wasted due to the distorting effect of the cruder parts of the model.

2.1.3. *Assumptions, Approximations and Limitations*

When using a particular model to predict the properties of a molecular system, one should be aware of the assumptions, simplifications, approximations and limitations that are implicit in the model. Below, we list the four most important approximations and limitations of classical computer simulation techniques which should be kept in mind when using them.

2.1.3.1. *Classical Mechanics of Point Masses*

A molecular system is described as a system of point masses moving in an effective potential field, which is generally a conservative field, i.e. it only depends on the instantaneous coordinates of the point masses. The motion of the point masses is with a sufficient degree of accuracy governed by the laws of classical mechanics. These assumptions imply the following restrictions to modeling:

- low-temperature (0–10 K) molecular motion is not adequately described;
- detailed motion of light atoms such as hydrogen atoms is not correctly described even at room temperature;
- description of chemical reactions lies outside the scope of classical simulation methods.

For a short discussion of the inclusion of quantum corrections to a classical treatment or of the quantum (dynamical) simulation techniques that are presently under development, we refer to Section 5.1.

2.1.3.2. *System Size or Number of Degrees of Freedom to be Included*

Only a rather limited number of atoms can be simulated on a computer. Simulations of liquids typically involve 10^2–10^3 atoms, simulations of solutions or crystals of macromolecules about 10^3–2×10^4 atoms. Generally, the system size is kept as small as possible in order to allow for a sufficient sampling of the degrees of freedom that are simulated. This means that those degrees of freedom that are not essential to the property one is interested in should be removed from the system. The dependence of the property of interest on the size of the system may give a clue to the minimum number of degrees of freedom required for an adequate simulation of it. The larger the spatial correlation length of the property of interest, the more atoms are to be included in the simulation.

2.1.3.3. *Sufficiency of Sampling of Configuration Space or Time Scale of Processes*

Computer simulation generates an ensemble of configurations of the system. Whether the generated set of configurations is representative for the state of the system depends on the extent to which the important (generally low energy) parts of the configuration space (or, more generally formulated, phase space) have been sampled. This depends in turn on the sampling algorithm that is applied. This should be able to overcome the multitude of barriers of the multidimensional energy surface of the system. In dynamic simulations, the time scale of the process that is mimicked is limited. Presently, molecular simulations cover time periods of 100–1000 picoseconds. In the case of activated processes longer time scales can be reached by using special tricks.[15, 16] Essentially slow processes, like the folding of a protein, are still well out of reach of computer simulation. We note that the observation that a property is independent of the length of a simulation is a necessary but *not* a sufficient condition for adequate sampling. The system may just reside for a period longer than the simulation time in a certain area without being effected by a nearby region of much lower energy from which it is separated by a large energy barrier.

2.1.3.4. *Accuracy of the Molecular Model and Force Field*

As is illustrated in Table 1, there exists a variety of molecular models and force fields, differing in the accuracy by which different physical quantities are modeled. The choice of a particular force field will depend on the property and level of accuracy one is interested in.

When studying a molecular system by computer simulation three factors should be considered (cf. Fig. 3).

1. The properties of the molecular system one is interested in should be listed and the configuration space (or time scale) to be searched for relevant configurations should be estimated.

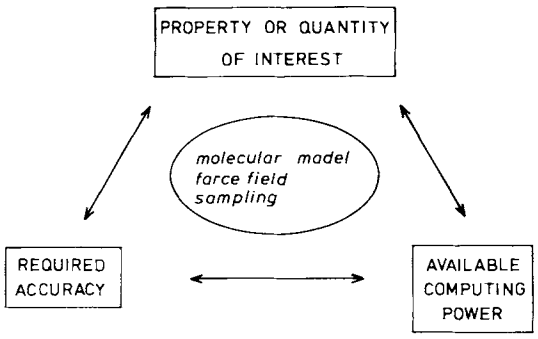

Fig. 3. Choice of molecular model, force field and sample size depends on 1) the property one is interested in (space to be searched), 2) required accuracy of the prediction, 3) the available computing power to generate the ensemble.

2. The required accuracy of the properties should be specified.
3. The available computer time should be estimated.

Given these three specifications the molecular model and force field should be chosen. As is indicated in Table 1 there is a trade off between accuracy of the force field on the one hand and the searching power or time scale that can be attained on the other. We note that in many practical cases one should abandon the idea of trying to simulate the system of interest, since the available computing power will not allow for a sufficiently accurate simulation.

2.2. History of Dynamic Computer Simulation

The growth in the number of applications of computer simulation methods in chemistry and physics is directly caused by the rapid increase in computing power over the last four decades (Fig. 2). Table 2 shows the development of the application of molecular dynamics simulation in chemistry. *Alder* and *Wainwright* pioneered the method using 2-dimensional hard disks. *Rahman*, who can really be considered the father of the field, simulated liquid argon in 1964, liquid water in 1971, and superionic conductors in 1978.[27] He also made many contributions to the methodology, and stimulated the dissemination of the technique in the scientific community. In the seventies, the transition from atomic to molecular liquids was made: rigid molecules like water (1971), flexible alkanes (1975), and a small protein, trypsin inhibitor (1977). The application to molten salts (1971) required the development of methods to handle long-range Coulomb interactions. The eighties brought simulations of biomolecules of increasing size in aqueous solution. For a more thorough review of the past and present of dynamic computer simulation in chemistry and physics we refer to the monographs of *McCammon* and *Harvey*[5] and *Allen* and *Tildesley*.[6]

Table 2. History of computer simulation of molecular dynamics.

Year	System	Length of simulation [s]	Required cpu time on supercomputer [h]
1957	hard two-dimensional disks [17]		
1964	monatomic liquid [18]	10^{-11}	0.05
1971	molecular liquid [19]	5×10^{-12}	1
1971	molten salt [20]	10^{-11}	1
1975	simple small polymer [21]	10^{-11}	1
1977	protein in vacuo [22]	2×10^{-11}	4
1982	simple membrane [23]	2×10^{-10}	4
1983	protein in aqueous crystal [24]	2×10^{-11}	30
1986	DNA in aqueous solution [25]	10^{-10}	60
1989	protein-DNA complex in solution [26]	10^{-10}	300
	large polymers	10^{-8}	10^{3}
	reactions	10^{-4}	10^{7}
	macromolecular interactions	10^{-3}	10^{8}
	protein folding	10^{-1}	10^{9}

From Table 2 it is also clear that a supercomputer is still many orders of magnitude slower than nature: a state of the art simulation is about 10^{15} times slower than nature. Many interesting systems and processes still fall far outside the reach of computer simulation. Yet, with a growth rate of a factor 10 per 5–7 years for (super)computing power the speed of simulation will have caught up with that of nature in about 100 years.

2.3. Accuracy and Reliability of Computer Simulation

The reliability of predictions made on the basis of computer simulation will basically depend on two factors: 1) whether the molecular model and force field are sufficiently accurate, and 2) whether the configuration space accessible to the molecular system has been sufficiently thoroughly searched for low-energy configurations. Although the accuracy of a prediction may be estimated by considering the approximations and simplifications of the model and computational procedure, the final test lies in a comparison of theoretically predicted and experimentally measured properties. In order to provide a firm basis for the application of computer simulation methods the results should be compared with experimental data whenever possible.

In this context we would like to stress that good agreement between calculated and experimental data does *not* necessarily mean that the theoretical model underlying the calculation is correct. Good agreement may be due to any of the following reasons:

1. The model is correct, that is, any other assumption used to derive the model, or any other choice of parameter values would give bad agreement with experiment.
2. The property that is compared is insensitive to the assumptions or parameter values of the model, that is, whatever parameter values are used in the model calculation, the agreement with experiment will be good.
3. Compensation of errors occurs, either by chance or by fitting of the model parameters to the desired properties.

A number of examples of the last case, viz. good agreement for the wrong reason, are given in Ref. [28]. Here, we would only like to remind the reader that it is relatively easy, when modeling high-dimensional systems with many parameters, to choose or fit parameters such that good agreement is obtained for a limited number of observable quantities. On the other hand, disagreement between simulation and experiment may also have different causes: 1) the simulation is *not* correct, the experiment *is*, 2) the simulation *is* correct, the experiment is *not*.

With these cautionary remarks in mind we would like to turn to an evaluation of the accuracy of current simulation studies by comparing simulated with experimental quantities. Table 3 contains a scheme of the atomic quantities of molecular systems for which comparison between simulated and experimental values is feasible. Four phases are distinguished. The most interesting phase from a chemical point of view is that of a molecule in solution. For this phase only few accurately measured *atomic* properties are available for comparison, leaving thermodynamic system properties like the free energy of solvation as a test ground for the simulation. Considerably more atomic data are available from crystallographic diffraction experiments: atomic positions and mobility, although the accuracy of the latter is much lower than that of the former, due to the simplifying approximations (harmonic isotropic motion) used in the crystallographic refinement process.

Table 3. Possible comparison of simulated properties with experimental ones for complex molecules.

Atomic properties	Experimental method	Phase: gas	solution	membrane	crystal
Structure					
- positions	X-ray diffraction				×
	neutron diffraction				×
- distance	NMR		×		
- orientations	NMR			×	
Mobility					
- *B*-factors	X-ray diffraction				×

In the following subsections examples will be given of a comparison of various atomic and system properties for different compounds. The examples are taken from our own work, and so are all based on the GROMOS force field.[12] They only serve as an indication of the degree of accuracy that can be obtained for different properties using current modeling methods.

2.3.1. *Atomic Properties: Positions and Mobilities in Crystals*

From a simulation the average molecular structure can be easily calculated and compared with experiment. Table 4 contains the deviation between simulated and measured atomic positions for a number of molecular crystals. The structural deviation depends on the size of the molecule and ranges from 0.2 Å to 1.2 Å. The numbers are an average over part or over all atoms in the molecules. This means that parts of the molecule will deviate more and other parts will deviate less from the experimental structure. This is illustrated in Figure 4, which shows the deviation for the backbone C_α atoms as a function of residue number averaged over all four BPTI (bovine pancreatic trypsin inhibitor) molecules in the crystal unit cell. Most of the atoms deviate less than 1 Å. Figure 5 shows the root mean square (rms) atomic positional fluctuations calculated from the MD simulation and from the crystallographic *B*-factors. The largest discrepancy is still rather small, about 0.3 Å.

Table 4. Comparison of MD time-averaged structures with experimental X-ray or neutron diffraction structures.

Molecule	Size (number of glucose units or amino acid residues)	Root mean square (RMS) difference in atomic positions [Å]: C_α or C'_3 atoms	all atoms excl. H atoms
cyclodextrin (α/β) [29]	6	0.13/0.35	0.25/0.51
cyclosporin A [30]	11	0.3	0.6
trypsin inhibitor [31]	58	1.0	1.5
subtilisin [32]	275	1.0	1.2

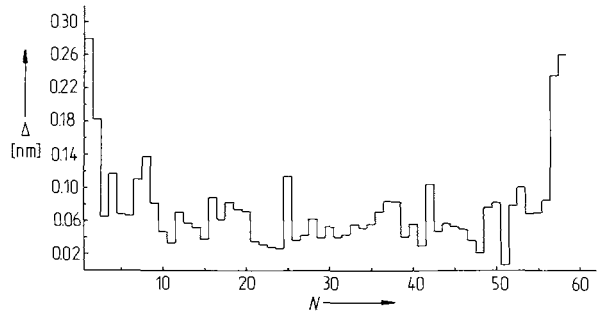

Fig. 4. Root mean square difference between the trypsin inhibitor simulated time- and molecule-averaged C_α atomic positions and the X-ray positions according to [31]. Δ = root mean square deviation, N = aminoacid residue number.

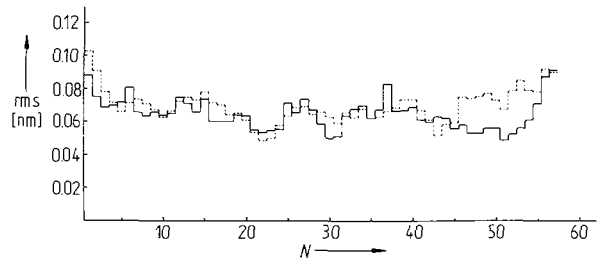

Fig. 5. Root mean square positional fluctations for the trypsin inhibitor atoms averaged over the backbone atoms of each residue according to [31]. Solid line: simulated results. Broken line: fluctuations derived from a set of X-ray temperature factors. rms = root mean square fluctuation, N = amino acid residue number.

A more stringent test of the simulation is to check whether partially occupied atomic sites are reproduced. The neutron diffraction work on β-cyclodextrin shows that 16 hydrogen atoms occupy two alternative sites. In the crystal simulation a non-zero occupancy is observed for 84% of the hydrogen sites, and for 62% of the hydrogen atoms the relative occu-

pancy of the two alternative sites is qualitatively reproduced.[29]

The molecular structure can also be described in terms of hydrogen bonds. Generally the experimentally observed hydrogen bonds are also observed in the simulation. Again cyclodextrin crystals form a sensitive test case for the simulations, since peculiar geometries such as three-center hydrogen bonds, and dynamic processes such as flip-flop hydrogen bonds have been experimentally observed. Almost all experimentally observed three-center hydrogen bonds in crystals of α- and β-cyclodextrin are reproduced in MD simulation, even as far as the detailed asymmetric geometry is concerned.[33] In a so-called flip-flop hydrogen bond the directionality is inverted dynamically. In a MD simulation of β-cyclodextrin, 16 of the 18 experimentally detected flip-flop bonds are reproduced.[34]

2.3.2. Atomic Properties: Distances in Solution

Structural data of solutions can be obtained by two-dimensional nuclear magnetic resonance spectroscopy (2D-NMR) with exploitation of the nuclear Overhauser (NOE) experiments.[35] The data come in the form of a set of upper bounds or constraints to specific proton-proton distances. This affords the possibility of comparing these proton-proton distances as predicted in a simulation with the experimentally measured NOE bounds. In the literature,[25] such a comparison is given for a set of 174 NOE's in an eight base-pair DNA fragment in aqueous solution: 80% of the NOE distances are satisfied by the simulation within experimental error, the mean deviation is 0.22 Å, and the maximum deviation amounts to 2.9 Å.

2.3.3. Atomic Properties: Orientation of Molecular Fragments in Membranes

The degree of order in a membrane or lipid bilayer can be measured selectively along the aliphatic chain by deuterium NMR spectroscopy.[36] In Figure 6[37] both experimental and MD order parameters are displayed for all CH_2 units in a sodium ion/water/decanoate/decanol bilayer system as a function of the position of the carbon atom in the aliphatic chain. The experimentally observed plateau in the order parameters is well reproduced.

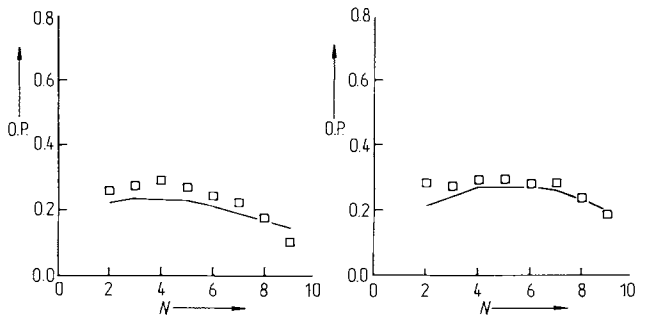

Fig. 6. Carbon-deuterium order parameters as a function of carbon atom number along the aliphatic chain of decanol (upper panel) and decanoate (lower panel) [37]. The head group has number zero. Solid line: simulated result. Squares: experimental values. O.P. = order parameter, N = carbon atom number.

2.3.4. Atomic Properties: Diffusion in Solutions and in Membranes

The dynamic properties of simulations of molecular systems are hard to test by comparison with experiment. An exception is the diffusion constant. Its calculation and comparison with experiment is a standard test for models of liquid water. The diffusion constant of the simple three-point charge (SPC) water model is 4.3×10^{-5} cm^2 s^{-1} compared with an experimental value of 2.7×10^{-5} cm^2 s^{-1} at 305 K.[38] Inclusion of a correction term for self-polarization in the SPC model led to a reparametrization, to the SPC/E (extended simple point charge) model, which yields a considerably smaller diffusion constant of 2.5×10^{-5} cm^2 s^{-1}.[39]

In the bilayered sodium ion/water/decanoate/decanol system mentioned in the previous section the simulated diffusion constants are: 2.7×10^{-6} cm^2 s^{-1} (decanoate) and 5.2×10^{-6} cm^2 s^{-1} (decanol), which values are to be compared with the value of 1.5×10^{-6} cm^2 s^{-1} measured with nitroxide spin labels.

2.3.5. System Properties: Thermodynamic Quantities

Instead of atomic properties, thermodynamic system properties like the density or free energy of solvation can be calculated from a simulation and compared to experimental values.

For a crystal of a cytidine derivative X-ray diffraction data and MD simulation data were compared at two different temperatures.[40] Upon raising the temperature from 113 K to 289 K the volume of the unit cell increased by 2.5% in the simulation at constant pressure, which value is to be compared with an experimentally determined increase of 3.7%. At 289 K the simulated density was only 1.3% too large. A slightly larger discrepancy was found in a MD simulation of crystalline cyclosporin A: the simulated density of 1.080 g cm^{-3} was 3.6% larger than the experimental value of 1.042 g cm^{-3}.[30] Comparable deviations have been found for other systems: the SPC/E model yields 0.998 g cm^{-3} at 306 K, compared with an experimental value of 0.995 g cm^{-3} at 305 K.[39]

Finally, we quote an example of a free energy of hydration. For the solvation of methanol in water the standard GROMOS parameters yield a free enthalpy of 7 kJ mol^{-1} compared with an experimental value of 5 kJ mol^{-1}.[28] However, when charged moieties are involved the accuracy by which free energy of solvation can be calculated is no better than about 10–20 kJ mol^{-1}.[28,41]

2.4. Is Computer Simulation Useful?

The prediction of properties by computer simulation of complex molecular systems is certainly not accurate enough to justify abandoning the measurement of properties. If a measurement is not too difficult it is always to be preferred over a prediction by simulation. The utility of computer simulation studies does not lie in the (still remote) possibility of *replacing* experimental measurement, but rather in its ability to *complement* experiments. Quantities that are inaccessible to experiment can be monitored in computer simulations.

We consider the computer simulation of complex molecular systems to be useful for the following reasons.

1. It provides an *understanding* of the *relation* between *microscopic* properties and *macroscopic* behavior. In a computer a microscopic molecular model and force field can be changed at will and the consequences for the macroscopic behavior of the molecular system can be evaluated.
2. During the last few years computer simulation has become a standard tool in the *determination* of *spatial molecular structure* on the basis of X-ray diffraction or 2D-NMR data.
3. Under favorable conditions computer simulation can be used to obtain *quantitative estimates* of quantities like binding constants of ligands to receptors. This is especially useful where the creation of the ligand or the measurement of its binding constant is costly or time-consuming.
4. Finally we mention the possibility of carrying out simulation under extreme (unobservable) conditions of temperature and pressure.

3. Methodology

Here we briefly describe the methodology of classical computer simulation as it is applied to complex molecular systems.

3.1. Choice of Molecular Model and Force Field

3.1.1. Current Force Fields for Molecular Systems

A typical molecular force field or effective potential for a system of N atoms with masses m_i ($i = 1,2,\ldots,N$) and cartesian position vectors $\boldsymbol{r}_i$ has the form (1).

$$\begin{aligned} V(\boldsymbol{r}_1, \boldsymbol{r}_2, \ldots, \boldsymbol{r}_N) = & \sum_{\text{bonds}} \tfrac{1}{2} K_b [b - b_0]^2 + \sum_{\text{angles}} \tfrac{1}{2} K_\theta [\theta - \theta_0]^2 \\ & + \sum_{\substack{\text{improper} \\ \text{dihedrals}}} \tfrac{1}{2} K_\xi [\xi - \xi_0]^2 \\ & + \sum_{\text{dihedrals}} K_\varphi [1 + \cos(n\varphi - \delta)] \\ & + \sum_{\text{pairs}(i,j)} [C_{12}(i,j)/r_{ij}^{12} - C_6(i,j)/r_{ij}^6 \\ & + q_i q_j / (4\pi\varepsilon_0 \varepsilon_r r_{ij})] \end{aligned} \tag{1}$$

The first term represents the covalent bond stretching interaction along bond b. It is a harmonic potential in which the minimum energy bond length b_0 and the force constant K_b vary with the particular type of bond. The second term describes the bond angle bending (three-body) interaction in similar form. Two forms are used for the (four-body) dihedral angle interactions: a harmonic term for dihedral angles ξ that are not allowed to make transitions, e.g. dihedral angles within aromatic rings, and a sinusoidal term for the other dihedral angles φ, which may make 360 degree turns. The last term is a sum over all pairs of atoms and represents the effective nonbonded interaction, composed of the van der Waals and the Coulomb interaction between atoms i and j with charges q_i and q_j at a distance r_{ij}.

There exists a large number of variants of expression (1).[11-13,42-53] Some force fields contain mixed terms like $K_{b\theta}[b-b_0][\theta-\theta_0]$, which directly couple bond-length and bond-angle vibrations.[42] Others use more complex dihedral interactions terms.[43,44] The choice of the relative dielectric constant ε_r is also a matter of dispute. Values ranging from $\varepsilon_r = 1$[11,12] to $\varepsilon_r = 8$[45] have been used, while others take ε_r proportional to the distance r_{ij}.[22,46,47] Sometimes the Coulomb term is completely ignored.[44] Although hydrogen bonding can be appropriately modeled using expression (1),[11,12,48,49] in some force fields special hydrogen bonding potential terms are used to ensure proper hydrogen bonding.[43-47] Another way to refine expression (1) is to allow for non-atomic interaction centers or virtual sites, that is, interactions between points (e.g. lone pairs) not located on atoms.[50] For solvents, especially water, a variety of molecular models is available,[19,38,51] of which a few have been developed explicitly for use in mixed solute-water systems.[11,49] Models for nonpolar solvents like carbon tetrachloride are also available.[52]

When determining the parameters of the interaction function (1) there are essentially two routes to take. The most elegant procedure is to fit them to results (potential or field) of ab-initio quantum calculations on small molecular clusters. However, due to various serious approximations that have to be made in this type of procedure, the resulting force fields are in general not very satisfactory. The alternative is to fit the force field parameters to experimental data (crystal structure, energy and lattice dynamics, infrared, X-ray data on small molecules, liquid properties like density and enthalpy of vaporization, free energies of solvation, nuclear magnetic resonance data, etc.). In our opinion the best results have been obtained by this semi-empirical approach.[11,53]

We wish to stress that one should fit force field parameters to properties of small molecules, which may be considered as building blocks of larger molecules such as proteins and DNA, and subsequently apply them to these larger molecules as a test without any further adaptations to improve the test results.

The choice of a particular force field should depend on the type of system for which it has been designed. The MM2 force field[13] is based on gas phase structures of small organic compounds. The AMBER[47] and CHARMM[46] force fields are aimed at a description of isolated polypeptides and polynucleotides, in which the absence of a solvent (aqueous) environment is compensated by the use of a distance-dependent dielectric constant ε_r. The ECEPP[43,54] and UNICEPP[55] force fields use $\varepsilon_r = 4$, whereas the GROMOS[12,49] force field uses $\varepsilon_r = 1$, since it has been set up for simulation of biomolecules in aqueous environment. This also holds for the OPLS[11] force field which is aimed at a proper description of solvation properties. Force fields that are applicable to a more restricted range of compounds like ions,[56] liquid metals,[57] salts,[6] or carbohydrates,[58] are manifold. The quality of the various force fields should be judged from the literature concerning their application to molecular systems.

3.1.2. Inclusion of Polarizability

The term in the interaction function (1) representing the nonbonded interactions consists only of a summation over

all pair interactions in the system. Nonbonded many-body interactions are neglected. Yet, inclusion of polarizability of atoms or bonds will be inevitable if one would like to simulate, e.g., the binding of a charged ligand, which will polarize the part of the receptor to which it is binding (Table 1). About 10% (4 kJ mol^{-1}) of the energy of liquid water is polarization energy. The infinite frequency dielectric constant of water is $\varepsilon_\infty = 5.3$, its effective dipole moment changes from 1.85 D in the gas phase to 2.4 D in the liquid. An analysis of the contribution of polarizability to local fields in proteins is given in Ref. [59].

Inclusion of polarizability in the molecular model is not too difficult, as can be observed from the following simple outline.[60] We consider a system of N point dipoles with cartesian position vectors $\boldsymbol{r}_i$, dipole moments $\boldsymbol{p}_i$ and polarizabilities α_i (constant, isotropic). The induced dipoles $\Delta\boldsymbol{p}_i$ obey a field equation (2), where $\boldsymbol{E}_i$ denotes the electric field

$$\Delta\boldsymbol{p}_i = \alpha_i \boldsymbol{E}_i = \alpha_i \sum_{\substack{j=1 \\ \neq i}}^{N} \boldsymbol{T}_{ij}[\boldsymbol{p}_j + \Delta\boldsymbol{p}_j] \tag{2}$$

at position $\boldsymbol{r}_i$ and the field tensor $\boldsymbol{T}_{ij}$ is given by Equation (3). The field equation can be solved for $\Delta\boldsymbol{p}_i$ either by the inver-

$$\boldsymbol{T}_{ij} = (4\pi\varepsilon_0)^{-1}[3\,\boldsymbol{r}_i\boldsymbol{r}_j/r_{ij}^2 - 1]\,r_{ij}^{-3} \tag{3}$$

sion of a matrix of size $3N \times 3N$, or by iteration. The former method is impractical for a molecular system containing thousands of atoms. The latter method is well suited for use in MD simulations, since the induced dipoles at the previous MD integration time step, $\Delta\boldsymbol{p}_i(t - \Delta t)$, will be an excellent starting point for the iterative solution of the field equation (2) at time t, which yields $\Delta\boldsymbol{p}_i(t)$. In this way inclusion of polarizability may increase simulation times by only 20–100%.

Computer simulations that include polarizability have only been performed for a limited number of molecular systems, such as ionic liquids,[10, 61] water,[62] and a single protein.[63, 64] Many aspects of the treatment of polarizability in MD simulations are still under investigation. What is the most practical way to model polarizability?

(1) By inducing point dipoles, as sketched above,
(2) by changing the magnitudes of (atomic) charges,
(3) by changing the positions of (atomic) charges.

How should the size of the atomic polarizabilities α_i be chosen, etc?

3.1.3. Treatment of Long Range Coulomb Forces

The summation of the last term in the interaction function (1) covering the nonbonded interaction runs over all atom pairs in the molecular system. It is proportional to N^2, the square of the number of atoms in the system. Since the other parts of the calculation are proportional to N, computational efficiency can be much improved by a reduction of this summation.The simplest procedure is to apply a cut-off criterion for the nonbonded interaction and to use a list of neighbor atoms lying within the cut-off, which is only updated every so many simulation steps. The cut-off radius R_C usually has a value between 6 Å and 9 Å and the neighbor list is updated about every 10 or 20 MD time steps. This procedure does not introduce any errors as long as the range of the nonbonded interaction is smaller than R_C. However, the Coulomb term in (1) is proportional to r^{-1}, which makes it long-ranged. If the molecular model does not involve bare (partial) charges on atoms, but only dipoles or higher multipoles, the electrostatic interaction term becomes proportional to r^{-3}, which makes it of much shorter range. However, when dipoles are correlated over larger distances, as is the case for secondary structure elements like α-helices in proteins, their interactions again become long-ranged.[65]

In the following subsections we briefly discuss a variety of methods for the treatment of long-range electrostatic interactions in molecular systems.[66, 67]

3.1.3.1. Distance Dependent Dielectric Constant

A simple way to reduce the range of the Coulomb interaction is to introduce a relative dielectric constant proportional to r, viz. $\varepsilon_r = r$ (in Å). The interaction becomes proportional to r^{-2}. It is difficult to find a physical argument in favor of this approximation. Its overall effect is to effectively reduce all types of long-ranged interactions. Due to its simplicity it has been incorporated into a number of current force fields.[46, 47] Nevertheless, we think this approximation is too crude for practical applications.

3.1.3.2. Cut-off Radius and Neutral Groups of Atoms

When applying a cut-off radius R_C, the discontinuity of the interaction at a distance $r = R_C$ will act as a noise source in a MD simulation, and this will artificially increase the kinetic energy of the atoms and thus the temperature of the system. A possible way to reduce the noise is to multiply the nonbonded interaction term in (1) with a so-called switching function (4), which satisfies the conditions $S(R_S) = 1$,

$$S(r) = \begin{cases} 1 & r < R_S \\ (R_C - r)^2(R_C + 2r - 3R_S)/(R_C - R_S)^3 & R_S < r < R_C \\ 0 & r > R_C \end{cases} \tag{4}$$

$\mathrm{d}S/\mathrm{d}r(R_S) = 0$, $S(R_C) = 0$, $\mathrm{d}S/\mathrm{d}r(R_C) = 0$. Its effect is to smoothen the interaction on the interval (R_S, R_C), but there is no physical argument for its use. An empirical evaluation of the use of switching functions can be found in Ref. [68].

When the (partial) atomic charges of a group of atoms add up to exactly zero, the leading term of the electric interaction between two such groups of atoms is of dipolar character, that is, proportional to r^{-3}. For larger r the sum of the r^{-1} monopole contributions of the various atom pairs to the group–group interaction will become zero. Therefore, the range of the electric interaction can be considerably reduced when atoms are assembled in neutral groups, so-called *charge groups*, which have a zero net charge, and for which the electric interaction with other (groups of) atoms is either calculated for all atoms of the charge group or for none.[12, 69] When using the charge group concept the cut-off criterion should be applied to the distance between groups, and a switching function like (4) must *not* be used, since it distorts in the interval (R_S, R_C) the proper r^{-1} weighting of atom–atom monopole interactions.

3.1.3.3. *Cut-off Radius plus Multipole Expansion*

The technique of using neutral groups of atoms is based on the more general fact that a charge distribution of a finite group of atoms can be approximated by a multipole expansion (monopole, dipole, quadrupole, etc.). The electric interaction between two groups of atoms can be formulated as the product of the two multipole expansions. The terms in the resulting expression can be grouped according to their distance dependence: monopole–monopole (r^{-1}), monopole–dipole (r^{-2}), monopole–quadrupole and dipole–dipole (r^{-3}), etc. At long distance only the leading terms in the series need to be taken into account. Application of this multipole expansion approximation in MD simulations was suggested by *Ladd*.[70] It is also used in combination with the "cut-off plus atom pair list" technique in Ref. [46].

3.1.3.4. *Twin Range Method*

The twin range method[66] is illustrated in Figure 7. Two cut-off radii are used. The atoms j lying within a distance R_C^1 from atom i are stored in a neighbor list of atom i. The interaction of the atoms j for which $R_C^1 < r_{ij} < R_C^2$ with atom i, is stored in the form of a so-called long-range force F_i^{lr} on atom i. At each MD time step the nonbonded interaction consists of two contributions: (1) the short-range part which is calculated from the neighbor list using the actual atom positions, and (2) the long range part $\boldsymbol{F}^{lr}$ which is kept fixed during N_C^1 time steps. Neighbor list and long range force $\boldsymbol{F}^{lr}$ are simultaneously updated every N_C^1 (10–100) time steps.

This twin range method is based on the assumption that the high-frequency components of the long range force may be safely neglected. For example, the mean and low frequency field of the correlated peptide dipoles of the long α-helix are accurately accounted for, only the fast ($\lesssim$0.2 ps) vibrations are neglected (see Fig. 7). The twin range method can also be applied using charged groups instead of atoms.[112]

3.1.3.5. *Continuum Approximations to the Reaction Field*

In the previous subsections approximations to the long-range interaction between atoms were discussed that are explicitly taken into account as degrees of freedom in the system that is simulated. If parts of the system are homogeneous, like the bulk solvent surrounding a solute, the number of atoms or degrees of freedom can be reduced considerably by modeling of the homogeneous part as a continuous medium, e.g. a continuous dielectric. In this type of approximation the system is divided into two parts: (1) an inner region where the atomic charges q_i are explicitly treated (dielectric constant ε_1), and (2) an outer region which is treated as a continuous medium with dielectric constant ε_2 and ionic strength I (see Fig. 8). The potential in the inner region

$$\psi_1(\boldsymbol{r}) = \psi_C(\boldsymbol{r}) + \psi_R(\boldsymbol{r}) \tag{5}$$

[Eq. (5)] consists of two terms. The first one [Eq. (6)] is a direct Coulomb term due to the charges in the inner region,

$$\psi_C(\boldsymbol{r}) = (4\pi\varepsilon_0\varepsilon_1)^{-1} \sum_{i=1}^{N} q_i/|\boldsymbol{r} - \boldsymbol{r}_i| \tag{6}$$

which is a solution to the Poisson equation (7) for the inner

$$\vec{\nabla}^2\psi(\boldsymbol{r}) = -\varepsilon_1^{-1} \sum_{i=1}^{N} q_i\delta(\boldsymbol{r} - \boldsymbol{r}_i) \tag{7}$$

region. The second term is the reaction field potential $\psi_R(\boldsymbol{r})$, which satisfies the Poisson equation with zero source terms (no charges), that is, the Laplace equation (8). This means

$$\vec{\nabla}^2\psi(\boldsymbol{r}) = 0. \tag{8}$$

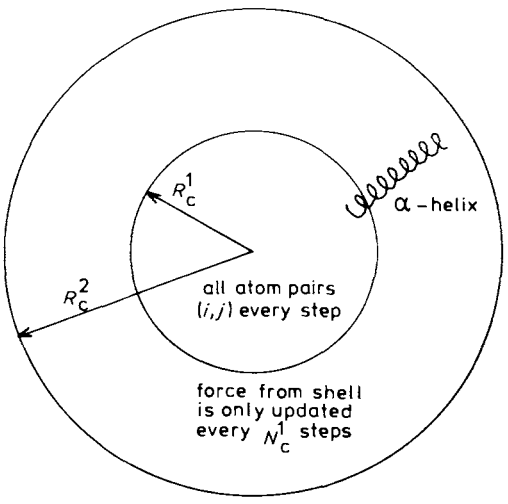

Fig. 7. Twin range method. High-frequency components of the force on the central atom exerted by atoms between R_C^1 and R_C^2 are neglected.

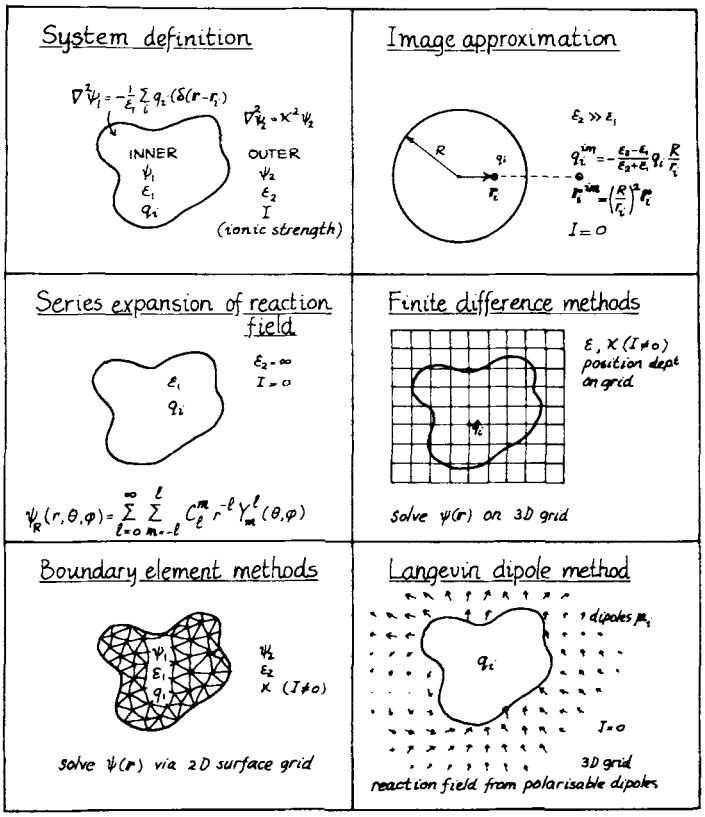

Fig. 8. Non-periodic methods for computing long-range Coulomb forces.

that $\psi_1(\boldsymbol{r})$ is also a solution of (7). The potential in the outer region is denoted by $\psi_2(\boldsymbol{r})$. If the outer region continuum has a finite ionic strength I, the potential $\psi_2(\boldsymbol{r})$ must be a solution of the Poisson-Boltzmann equation (9) with inverse Debye

$$\vec{\nabla}^2\psi(\boldsymbol{r}) = \kappa^2\psi(\boldsymbol{r}) \tag{9}$$

length $\kappa = 2IF^2/(\varepsilon_2 RT)$ in which F is Faraday's constant, R is the gas constant, and T the temperature. For zero ionic strength, (9) reduces to (8). The boundary condition at infinity is given by (10), and at the boundary between the inner

$$\lim_{r\to\infty}\psi_2(\boldsymbol{r}) = 0 \tag{10}$$

and outer regions the potential $\psi(\boldsymbol{r})$ [Eq. (11)] and the dielectric displacement $\varepsilon\vec{\nabla}\psi(\boldsymbol{r})$ [Eq. (12)] must be continuous:

$$\psi_1(\boldsymbol{r}) = \psi_2(\boldsymbol{r}) \qquad \boldsymbol{r} = \text{boundary} \tag{11}$$

$$\varepsilon_1\nabla_n\psi_1(\boldsymbol{r}) = \varepsilon_2\nabla_n\psi_2(\boldsymbol{r}) \qquad \boldsymbol{r} = \text{boundary} \tag{12}$$

where the component of the gradient normal to the boundary is denoted by ∇_n.

The exact form of $\psi(\boldsymbol{r})$ will depend on the shape of the boundary, the values of ε_2 and κ, and the computational method that is used to solve the field equations (7)–(12).

3.1.3.6. Continuum Methods: Image Charge Approximation to the Reaction Field

When the boundary is a sphere of radius R the reaction field due to a charge q_i located at position $\boldsymbol{r}_i$ with respect to the origin of the sphere can be approximated (dipolar approximation, $\varepsilon_2 \gg \varepsilon_1$) by the field that is generated by a so-called image charge $q_i^{\text{im}} = -(\varepsilon_2 - \varepsilon_1)(\varepsilon_2 + \varepsilon_1)q_i R/r_i$ that is located at position $\boldsymbol{r}_i^{\text{im}} = (R/r_i)^2\boldsymbol{r}_i$[71] (see Fig. 8). The name of this approximation is due to the mirror type of behavior of the spherical boundary: if q_i approaches the boundary, q_i^{im} will do likewise, causing a pole in the potential at the boundary. This means that the image approximation breaks down for charges close to the boundary. The other limitations of the method are the requirement of a spherical boundary, and the conditions that $I = 0$ and $\varepsilon_2 \gg \varepsilon_1$.

3.1.3.7. Continuum Methods: Series Expansion of the Reaction Field

When the boundary is of irregular shape the reaction field potential cannot be written in a closed form, but must be approximated numerically. If we assume that $I = 0$ and $\varepsilon_2 = \infty$, the following approach is possible. Since the reaction field potential $\psi_R(\boldsymbol{r})$ must satisfy the Laplace equation (8) it may be expanded in Legendre polynomials, which also satisfy Equation (8) [Eq. (13)]. If $\varepsilon_2 = \infty$, we have $\psi_2(\boldsymbol{r}) = 0$

$$\psi_R(\boldsymbol{r}, \theta, \varphi) = \sum_{l=0}^{\infty}\sum_{m=-l}^{+l} C_l^m r^{-l} Y_m^l(\theta, \varphi). \tag{13}$$

at the boundary, or using (11) and (5) Equation (14), at the boundary, with $\psi_C(\boldsymbol{r})$ fixed by (6). The expansion coefficients

$$\psi_R(\boldsymbol{r}) = -\psi_C(\boldsymbol{r}) \tag{14}$$

C_l^m can be determined numerically by performing a least squares fit of $\psi_R(\boldsymbol{r})$ to the given $-\psi_C(\boldsymbol{r})$ at a chosen number of points on the boundary.

The method works (Berendsen and Zwinderman, private communication), but is rather expensive due to the matrix inversion inherent in the least squares fit procedure. Close to the boundary the approximation is poor. The other limitations are that $I = 0$ and $\varepsilon_2 = \infty$.

3.1.3.8. Continuum Methods: Three-dimensional Finite Difference Techniques

Another numerical approach is to compute the electric potential on a three-dimensional (3D) grid using finite difference methods (Fig. 8). The atomic charges q_i are distributed over grid points. To each grid point a position-dependent dielectric constant ε_1 is assigned. Then the field equations (7)–(12) can be numerically solved.[72] This involves the solution of a set of linear equations for the potential at grid points. The method is too time-consuming to be used in MD simulations, since the density of grid points must be sufficient to adequately represent the atomic charge distribution. The use of a position-dependent dielectric constant introduces an arbitrary element into the method.

3.1.3.9. Continuum Methods: Two-dimensional Boundary Element Techniques

A recent development is the application of Green's function techniques to the electric field problem.[73] The Green's

$$G_1(\boldsymbol{r}|\boldsymbol{r}_0) = \frac{1}{4\pi|\boldsymbol{r} - \boldsymbol{r}_0|} \tag{15}$$

function (15) for the inner region satisfies Equation (16) (a Poisson equation with charge ε_0 at $\boldsymbol{r}_0$). The Green's func-

$$\vec{\nabla}^2 G_1(\boldsymbol{r}|\boldsymbol{r}_0) = -\delta(\boldsymbol{r} - \boldsymbol{r}_0) \tag{16}$$

tion for the outer region [Eq. (17)] satisfies Equation (18) (a Poisson-Boltzmann equation with charge ε_0 at $\boldsymbol{r}_0$).

$$G_2(\boldsymbol{r}|\boldsymbol{r}_0) = \frac{e^{-\kappa|\boldsymbol{r} - \boldsymbol{r}_0|}}{4\pi|\boldsymbol{r} - \boldsymbol{r}_0|} \tag{17}$$

$$\vec{\nabla}^2 G(\boldsymbol{r}|\boldsymbol{r}_0) = \varkappa^2 G(\boldsymbol{r}|\boldsymbol{r}_0) - \delta(\boldsymbol{r} - \boldsymbol{r}_0) \tag{18}$$

The next step is to integrate the following integrand over the

$$[G_1 \times \text{expression (7) for } \psi_1 - \psi_1 \times \text{expression (16) for } G_1] \tag{19}$$

inner region and to convert it by Green's theorem into an integral over the surface of the boundary region. This yields Equation (20), consisting of a surface term and a source term.

$$\psi_1(\boldsymbol{r}) = \int_{\text{surface}} [G_1(\boldsymbol{r}'|\boldsymbol{r})\nabla_n\psi_1(\boldsymbol{r}') - \psi_1(\boldsymbol{r}')\nabla_n G_1(\boldsymbol{r}'|\boldsymbol{r})\,d\sigma + \sum_{i=1}^{N}\frac{q_i}{4\pi\varepsilon_0|\boldsymbol{r} - \boldsymbol{r}_i|} \tag{20}$$

By integrating (21) and conversion we obtain equation (22).

$$[G_2 \times \text{expression (9) for } \psi_2 - \psi_2 \times \text{expression (18) for } G_2] \quad (21)$$

$$\psi_2(\boldsymbol{r}) = \int_{\text{surface}} [G_2(\boldsymbol{r}'|\boldsymbol{r}) \nabla_n \psi_2(\boldsymbol{r}') - \psi_2(\boldsymbol{r}') \nabla_n G_2(\boldsymbol{r}'|\boldsymbol{r})] \mathrm{d}\sigma \quad (22)$$

Application of the boundary conditions (11) and (12) yields two linear integral equations in ψ_1 and $\nabla_n \psi_1$ on the boundary surface. These equations can be solved numerically by discretization on a surface net, and subsequently solved by matrix inversion. The (large) matrix that is to be inverted only depends on the shape and position of the boundary surface, *not* on the positions of the charges in the inner region. This means that in a MD simulation the time-consuming matrix inversion can be avoided as long as the boundary remains fixed.

The promise of this method lies in the reduction of a 3D problem to a 2D problem. On the boundary surface a charge density is generated which produces the proper reaction field. Also the methods of *Shaw*,[74] and of *Zauhar* and *Morgan*[75] transform the problem from a three-dimensional one into a two-dimensional one.

3.1.3.10. Langevin Dipole Model

The Langevin dipole model of *Warshel*[63, 67] uses a 3D-grid, but it is not a continuum method. The medium in the outer region is mimicked by polarizable point dipoles $\boldsymbol{\mu}_i$ on the grid points i of a 3D grid. The dipoles may be thought of as representing the molecular dipoles of the solvent molecules forming the outer region, so the spacing of the grid points corresponds to the size of the solvent molecules. The size and direction of a dipole $\boldsymbol{\mu}_i$ is determined by the electric field $\boldsymbol{E}_i$ at the grid point according to the Langevin formula [Eq. (23)]. Here, μ_0 is the magnitude of the dipole moment

$$\mu_i = \mu_0 \left[\frac{\mathrm{e}^{+C\mu_0 E_i/kT} + \mathrm{e}^{-C\mu_0 E_i/kT}}{\mathrm{e}^{+C\mu_0 E_i/kT} - \mathrm{e}^{-C\mu_0 E_i/kT}} - \frac{1}{C\mu_0 E_i/kT} \right] \frac{\boldsymbol{E}_i}{E_i} \quad (23)$$

of a solvent molecule, and C is a parameter representing the molecular resistance to reorientation. The model has been applied to protein simulations.[64] Questionable features of this model are the representation of the field in the outer region and the discreteness near the boundary.

3.1.3.11. Periodic Lattice Summation Methods

In computer simulations of liquids or solutions, periodic boundary conditions are often used to minimize the boundary effects. The computational box containing the molecular system is surrounded by an infinite number of copies of itself (see Fig. 9). In this way an infinite periodic system is simulated.

The electric interaction in a periodic system is obtained by a summation over all atom pairs in the central box (Fig. 9) and over all atom pairs of which one atom lies in the central box and the other is a periodic image [Eq. (24)].

$$E = (4\pi\varepsilon_0)^{-1} \frac{1}{2} \sum_{\boldsymbol{n}=0}^{\infty} \sum_{\substack{i=1 \\ i \neq j \text{ if } \boldsymbol{n}=0}}^{N} \sum_{j=1}^{N} \frac{q_i q_j}{|\boldsymbol{r}_{ij} + \boldsymbol{n}|} \quad (24)$$

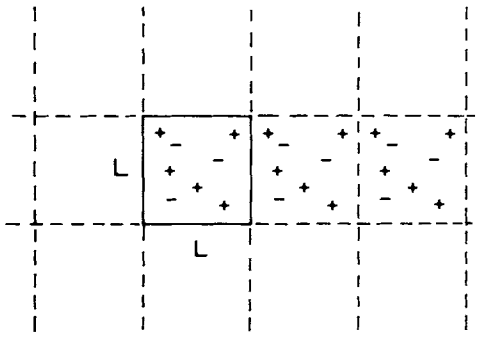

Fig. 9. Periodic cubic system. Central computational box (solid line) with two of the infinite number of periodic image boxes.

The sum over $\boldsymbol{n}$ is a summation over all simple cubic lattice points $\boldsymbol{n} = (n_x L, n_y L, n_z L)$ with n_x, n_y, n_z integers. The infinite sum of point charges must be converted into a form which converges faster than Equation (24).

3.1.3.12. Periodic Methods: the Ewald Sum

The Ewald sum is a technique for computing the interaction of a charge and all its periodic images.[6, 76-78] The charge distribution $\varrho(\boldsymbol{r})$ in the system is an infinite set of point charges, mathematically represented as delta functions [Eq. (25)].

$$\varrho_i(\boldsymbol{r}) = q_i \delta(\boldsymbol{r} - \boldsymbol{r}_i) \quad (25)$$

Each point charge q_i is now surrounded by an isotropic Gaussian charge distribution of equal magnitude and opposite sign [Eq. (26)].

$$\varrho_i^{\mathrm{G}}(\boldsymbol{r}) = -q_i (\alpha/\sqrt{\pi})^3 \mathrm{e}^{-\alpha^2 |\boldsymbol{r} - \boldsymbol{r}_i|^2} \quad (26)$$

This smeared charge screens the interaction between the point charges, so that the interaction calculated using the screened charge distribution (27) becomes short-ranged [Eq. (28)] due to the appearance of the complementary error function (29).

$$\varrho_i^{\mathrm{s}}(\boldsymbol{r}) \equiv \varrho_i(\boldsymbol{r}) + \varrho_i^{\mathrm{G}}(\boldsymbol{r}) \quad (27)$$

$$E^{\mathrm{s}} = (4\pi\varepsilon_0)^{-1} \frac{1}{2} \sum_{\boldsymbol{n}=0}^{\infty} \sum_{\substack{i=1 \\ i \neq j \text{ if } \boldsymbol{n}=0}}^{N} \sum_{j=1}^{N} \frac{q_i q_j}{|\boldsymbol{r}_{ij} + \boldsymbol{n}|} \operatorname{erfc}(\alpha |\boldsymbol{r}_{ij} + \boldsymbol{n}|) \quad (28)$$

$$\operatorname{erfc}(x) = 2\pi^{-1/2} \int_x^{\infty} \mathrm{e}^{-y^2} \mathrm{d}y \quad (29)$$

Thus, E^{s} can be well approximated using a finite summation in (28). Of course a purely Gaussian charge distribution $-\varrho_i^{\mathrm{G}}(\boldsymbol{r})$ must be added to $\varrho_i^{\mathrm{s}}(\boldsymbol{r})$ in order to recover the original charge distribution $\varrho_i(\boldsymbol{r})$. The interaction of these Gaussian distributions is expressed as a lattice sum in reciprocal space minus a self term [Eq. (30)], where

$$E^{\mathrm{G}} = (4\pi\varepsilon_0)^{-1} 2\pi L^{-3} \sum_{k \neq 0}^{\infty} k^{-2} \mathrm{e}^{-k^2/(4\alpha^2)} \left| \sum_{j=1}^{N} q_j \mathrm{e}^{-i\boldsymbol{k} \cdot \boldsymbol{r}_j} \right|^2 - (4\pi\varepsilon_0)^{-1} \pi^{-1/2} \alpha \sum_{j=1}^{N} q_j^2 \quad (30)$$

$\boldsymbol{k} = 2\pi L^{-1}(l_x, l_y, l_z)$ and l_x, l_y, l_z are integers. Due to the presence of the exponential factor the infinite lattice sum can be well approximated by a finite one. The parameter α should be chosen such as to optimize the convergence properties of both sums (28) and (30) which contribute to $E = E^S + E^G$.

The Ewald sum technique is routinely used in simulations of ionic systems. When applied to non-crystalline systems such as liquids or solutions it has the disadvantage of enhancing the artifact of the application of periodic boundary conditions.

3.1.3.13. Periodic Methods: Fourier Techniques

The Poisson equation (31) for the potential $\psi(\boldsymbol{r})$ is a sec-

$$\vec{\nabla}^2 \psi(\boldsymbol{r}) = -\varepsilon_0^{-1} \varrho(\boldsymbol{r}) \tag{31}$$

ond-order partial differential equation in $\boldsymbol{r}$-space. However, when transformed into reciprocal space ($\boldsymbol{k}$-space) it becomes a simple algebraic equation (32) with the solution (33).

$$-k^2 \hat{\psi}(\boldsymbol{k}) = -\varepsilon_0^{-1} \hat{\varrho}(\boldsymbol{k}) \tag{32}$$

$$\hat{\psi}(\boldsymbol{k}) = (\varepsilon_0 k^2)^{-1} \hat{\varrho}(\boldsymbol{k}) \tag{33}$$

Here, the 3D Fourier transformation is defined according to Equation (34), and likewise for the charge density $\varrho(\boldsymbol{r})$. The inverse transform of Equation (33) yields (35).

$$\hat{\psi}(\boldsymbol{k}) \equiv F\{\psi(\boldsymbol{r})\} \equiv (2\pi)^{-3/2} \int \psi(\boldsymbol{r}) e^{-i\boldsymbol{k}\cdot\boldsymbol{r}} d\boldsymbol{r} \tag{34}$$

$$\psi(\boldsymbol{r}) = F^{-1}\{(\varepsilon_0 k^2)^{-1} F\{\varrho(\boldsymbol{r})\}\} \tag{35}$$

Due to the availability of fast Fourier transform techniques Equation (35) is a fast method to solve the Poisson equation on a periodic three-dimensional grid. For a practical implementation of the method we refer to Ref. [1]. It has been employed in the simulation of salts.[1]

3.1.4. Summary

The choice of molecular model and force field is essential to a proper prediction of the properties of a system. Therefore, it is of great importance to be aware of the fundamental assumptions, simplifications and approximations that are implicit in the various types of models used in the literature. When treating molecular systems in which Coulomb forces play a role one should be aware of the way these long-ranged forces are handled. Since these forces play a dominant role in many molecular systems we have tried to give an overview of the different methods—and so the different approximations—that are in use.

From Table 1 and the discussions in the previous sections it should be clear that a "best" force field does *not* exist. What will be the best choice of model and force field will depend on the type of molecular system and the type of property one is interested in. This means that the molecular modeler must have a picture of the strengths and weaknesses of the variety of force fields that are available in order to make a proper choice.

3.2. Searching Configuration Space and Generating an Ensemble

Once the molecular model and force field $V(\boldsymbol{r})$ have been chosen, a method to search configuration space for configurations with low energy $V(\boldsymbol{r})$ has to be selected. Various methods are available, each with their particular strength and weakness, which depend on

- the form and type of the interaction energy function $V(\boldsymbol{r})$,
- the number of degrees of freedom (size of the system),
- the type of degrees of freedom, viz. cartesian coordinates versus other coordinates (e.g. bond lengths, bond angles, torsional angles plus center of mass coordinates of a molecule).

3.2.1. Systematic Search Methods

If the molecular system contains only a small number of degrees of freedom (coordinates) and if $V(\boldsymbol{r})$ does not have too many (relevant) minima upon variation of the degrees of freedom, it is possible to systematically scan the complete configuration space of the system. For example, one can describe conformations of *n*-alkanes in terms of C–C–C–C torsional angles, each of which has three conformational minima, *trans* (0°), *gauche*$^+$ (120°) and *gauche*$^-$ ($-120°$). To find the lowest energy conformation of *n*-decane (seven torsional angles) one would have to compute $V(\boldsymbol{r})$ for $3^7 = 2187$ combinations of torsional angles. The relative weight of the different conformations in the ensemble representing this molecule at temperature T is given by the Boltzmann factor (36).

$$e^{-V(\boldsymbol{r})/k_B T} \tag{36}$$

The computing effort required by a systematic search of the degrees of freedom of a system grows exponentially with their number. Only very small molecular systems can be treated by systematic search methods.[79, 80] The number of degrees of freedom that still can be handled within a reasonable computing time strongly depends on the complexity of the function $V(\boldsymbol{r})$, that is, the time required to compute $V(\boldsymbol{r})$ for each configuration. A possibility for speeding up the calculation is to split the selection of low $V(\boldsymbol{r})$ configurations into different stages. In a first stage a simplified low computing cost energy function $V_{\text{simple}}(\boldsymbol{r})$ is used to quickly discard high $V_{\text{simple}}(\boldsymbol{r})$ configurations. In a second stage the complete $V(\boldsymbol{r})$ is only to be evaluated for the remaining configurations. This type of filtering procedure has been used to predict the loop structure in proteins[81] and to predict the stable conformation of small peptides (five amino acid residues),[82] for example. The basic problem of filtering using simplified forms of $V(\boldsymbol{r})$ is to ensure that the simplified $V_{\text{simple}}(\boldsymbol{r})$ is a correct projection of the complete function $V(\boldsymbol{r})$: when $V_{\text{simple}}(\boldsymbol{r})$ is large, $V(\boldsymbol{r})$ should also be large, otherwise a configuration with low energy $V(\boldsymbol{r})$ might be discarded in the first stage due to a high energy $V_{\text{simple}}(\boldsymbol{r})$.

3.2.2. Random Search Methods

If a system contains too many degrees of freedom, straightforward scanning of the complete configuration space is impossible. In that case a collection of configura-

tions can be generated by random sampling. Such a collection becomes an ensemble of configurations when each configuration is given its Boltzmann factor [cf. Eq. (36)] as weight factor in the collection. Two types of random search methods can be distinguished:

- Monte Carlo methods, in which a sequence of configurations is generated by an algorithm which ensures that the occurrence of configurations is proportional to their Boltzmann factors [Eq. (36)].
- Other methods which produce an arbitrary (non-Boltzmann) collection of configurations, which can be transformed into a Boltzmann ensemble by applying the weight factors from Equation (36).

3.2.2.1. *Monte Carlo Simulation*

The Monte Carlo (MC) simulation procedure by which a (canonical) ensemble is produced consists of the following steps.

1. Given a starting configuration $\boldsymbol{r}_S$ a new configuration $\boldsymbol{r}_{S+1} = \boldsymbol{r}_S + \Delta\boldsymbol{r}$ is generated by random displacement of one (or more) atoms. The random displacements $\Delta\boldsymbol{r}$ should be such that in the limit of a large number of successive displacements the available cartesian space of all atoms is uniformly sampled. This does not mean that the actual sampling must be carried out in cartesian space. It can be done, e.g., in internal coordinate space (r, θ, φ), but since the equivalent volume element is $r^2 \sin\theta \, dr d\theta d\varphi$, the sampling in internal coordinate space must be non-uniform in order to produce a uniform sampling in terms of cartesian coordinates.
2. The newly generated configuration $\boldsymbol{r}_{S+1}$ is either accepted or rejected on the basis of an energy criterion involving the change $\Delta E = V(\boldsymbol{r}_{S+1}) - V(\boldsymbol{r}_S)$ of the potential energy with respect to the previous configuration. The new configuration is accepted when $\Delta E \leq 0$, or if $\Delta E > 0$ when $e^{-\Delta E/k_B T} > R$, where R is a random number taken from a uniform distribution over the interval (0,1).
   Upon acceptance, the new configuration is counted and used as a starting point for the next random displacement. If the criteria are not met, the new configuration $\boldsymbol{r}_{S+1}$ is rejected. This implies that the previous configuration $\boldsymbol{r}_S$ is counted again and used as a starting point for another random displacement.

It is relatively easy to understand that this procedure will generate a Boltzmann ensemble. We consider two configurations $\boldsymbol{r}_1$ and $\boldsymbol{r}_2$ with energies $E_1 = V(\boldsymbol{r}_1) < V(\boldsymbol{r}_2) = E_2$. The probability of stepping from configuration $\boldsymbol{r}_2$ to $\boldsymbol{r}_1$ equals 1, the reverse step has a probability $\exp(-(E_2 - E_1)/k_B T)$. When the populations p_1 and p_2 of the two configurations are in equilibrium, one has detailed balance conditions (37) or (38).

$$p_2 \cdot 1 = p_1 \cdot e^{-(E_2 - E_1)/k_B T} \tag{37}$$

$$p_1/p_2 = e^{-E_1/k_B T}/e^{-E_2/k_B T} \tag{38}$$

Each configuration occurs with a probability proportional to its Boltzmann factor [Eq. (36)].

The advantage of this (Metropolis) Monte Carlo or Boltzmann sampling over random sampling is that most sampled configurations are relevant (low energy), while with random sampling much computational effort is likely to be spent on irrelevant (high energy) configurations. In order to obtain high computational efficiency, one would like to combine a large (random) step size with a high acceptance ratio. This is possible when applying MC techniques to simulate simple atomic or molecular liquids.[6] However, for complex systems involving many covalently bound atoms, a reasonable acceptance ratio can only be obtained for very small step size.[83] This is due to the fact that a random displacement will inevitably generate a very high bond energy of the bonds of the displaced atom. This makes MC methods rather inefficient for (macro)molecular systems.

3.2.2.2. *Distance Geometry Methods*

Distance geometry (DG) is a general method for converting a set of bounds on distances between atoms into a configuration of these atoms that is consistent with these bounds. The emergence of 2D-NMR techniques has spurred a renewed interest in techniques to obtain three-dimensional molecular structures from atom–atom distance information.[84–86] The DG method is also applied in pharmacophore modeling[87] or enzyme substrate docking [*J. M. Blaney*, private communication] to generate a collection of ligand structures compatible with a set of atom–atom distance bounds.

In distance geometry a molecular structure is described in terms of the set of all pairwise interatomic distances, which can be written in the form of a so-called (symmetric) distance matrix. By entering maximum distances between atoms of pairs in the upper right-hand triangle, and minimum distances in the lower left-hand triangle of the distance matrix it becomes a distance bounds matrix. Such a matrix describes the complete configuration space accessible to the molecule within the specified bounds. In a distance geometry calculation a set of random configurations is generated by choosing atom–atom distances at random within the specified bounds, and subsequently converting the resulting distance matrix into a structure in three-dimensional cartesian space using a so-called embedding algorithm.[84–86]

The DG method is a powerful method for generating a set of configurations compatible with a set of atom–atom distances, but also has a number of limitations. It is not possible to apply an energy function $V(\boldsymbol{r})$ like Equation (1) in a DG calculation. The energy function has to be converted into a function of atom–atom distances only, and subsequently it must be simplified to a set of bounds on these distances, by which procedure much of the information present in $V(\boldsymbol{r})$ will be lost. As a consequence the DG method cannot properly handle solvent configurations, since a limited-distance description of a liquid lacks the ability to give proper statistical weight to the great variety of possible configurations. Another problem is the characterization of the distribution of generated three-dimensional configurations. Since the conversion from distance space into three-dimensional cartesian space is non-linear, a uniform sampling of distances between the lower and upper bounds will certainly not produce a set of configurations uniformly distributed in cartesian space.

3.2.2.3. Other Random Search Techniques

There exist infinitely many ways for generating a set of molecular configurations in a random manner. Whether the set of generated configurations may be considered to form an ensemble that can be used for statistical mechanical evaluation of quantities will depend on the sampling properties of the method that is used. It should sample the important (low energy) regions of configuration space and the configurations should occur according to their Boltzmann weight factors. Otherwise the set of configurations can only be viewed as such, not as an ensemble representative of the state of the system that is considered.

3.2.3. Dynamic Simulation Methods

Another way to generate an ensemble of configurations is to apply Nature's laws of motion for the atoms of a molecular system. This has the additional advantage that dynamical information about the system is obtained as well. The two major simulation techniques of this type are Molecular Dynamics (MD), in which Newton's equations of motion are integrated over time, and Stochastic Dynamics (SD), in which the Langevin equation of motion for Brownian motion is integrated over time.

3.2.3.1. Molecular Dynamics Simulation

In the Molecular Dynamics (MD) method a trajectory (configurations as a function of time) of the molecular system is generated by simultaneous integration of Newton's equations of motion (39) and (40) for all the atoms in the

$$\mathrm{d}^2\boldsymbol{r}_i(t)/\mathrm{d}t^2 = m_i^{-1}\boldsymbol{F}_i \tag{39}$$

$$\boldsymbol{F}_i = -\partial V(\boldsymbol{r}_i, \ldots \boldsymbol{r}_N)/\partial \boldsymbol{r}_i \tag{40}$$

system. The force on atom i is denoted by $\boldsymbol{F}_i$ and time is denoted by t. MD simulation requires calculation of the gradient of the potential energy $V(\boldsymbol{r})$, which therefore must be a differentiable function of the atomic coordinates $\boldsymbol{r}_i$. The integration of Equation (39) is performed in small time steps Δt, typically 1–10 fs for molecular systems. Static equilibrium quantities can be obtained by averaging over the trajectory, which must be of sufficient length to form a representative ensemble of the state of the system. In addition, dynamic information can be extracted. Another asset of MD simulation is that non-equilibrium properties can be efficiently studied by keeping the system in a steady non-equilibrium state, as is discussed in Section 5.4. Viewed as a technique to search configuration space, the power of MD lies in the fact that the kinetic energy present in the system allows it to surmount energy barriers that are of order of $k_B T$ per degree of freedom. By raising the temperature T a larger part of conformation space can be searched, as has been shown by *DiNola* et al.,[88] who generated a series of different conformations of the hormone somatostatin by applying MD at $T = 600$ K and at 1200 K. At the elevated temperature the total energy and potential energy are monitored for conspicuous fluctuations which may signal a possibly significant conformational change. When minima in the total energy occur, the system is cooled down and equilibrated at normal temperature (300 K). In this way different conformations with comparable free energy were obtained. We note however that the search at elevated temperature favors selection of higher entropy conformations.

Searching conformation space by MD is expected to be efficient for molecules up to about 100 atoms. For larger molecules, which may and are likely to show a particular topological fold, MD methods will not be able to generate major topological rearrangements. Even when the barriers separating two topologically different low energy regions of conformation space are of the order of $k_B T$, the time needed for traversing them may be much too long to be covered in a MD simulation of 10–100 ps.

3.2.3.2. Stochastic Dynamics Simulation

The method of stochastic dynamics (SD) is an extension of MD. A trajectory of the molecular system is generated by integration of the stochastic Langevin equation of motion (41).

$$\mathrm{d}^2\boldsymbol{r}_i(t)/\mathrm{d}t^2 = m_i^{-1}\boldsymbol{F}_i + m_i^{-1}\boldsymbol{R}_i - \gamma_i \mathrm{d}\boldsymbol{r}_i(t)/\mathrm{d}t \tag{41}$$

Two terms are added to Equation (39), a stochastic force $\boldsymbol{R}_i$ and a frictional force proportional to a friction coefficient γ_i. The stochastic term introduces energy, the frictional term removes (kinetic) energy from the system, the condition for zero energy loss being that given in Equation (42), where

$$\langle \boldsymbol{R}_i^2 \rangle = 6 m_i \gamma_i k_B T_{\mathrm{ref}} \tag{42}$$

T_{ref} is the reference temperature of the system.

SD can be applied to establish a coupling of the individual atom motion to a heat bath,[89] or to mimic a solvent effect.[90, 91] In the latter case the stochastic term represents collisions of solute atoms with solvent molecules and the frictional term represents the drag exerted by the solvent on the solute atom motion. An introduction to SD simulation techniques is given in Refs. [90, 92].

3.2.4. Other Search Methods

There exists a variety of other methods for searching configuration space which are variants of the basic types discussed in the previous subsections.

The method of simulated annealing[93] is a MC or a MD simulation in which the temperature is gradually lowered to 0 K. In this way the system generally ends up in a lower energy state than when an ordinary gradient energy minimizer is used.

In a MD simulation the atomic velocities are large when the system explores the low energy regions of the potential energy function $V(\boldsymbol{r})$, and small when it crosses barriers at higher energy. For an efficient searching of configuration space one would like to invert this behavior: the atoms should move slowly in the valleys of $V(\boldsymbol{r})$. A search algorithm developed along this line seems to perform well for certain systems.[94] Within the framework of MD the ability of atoms to cross barriers can be greatly enhanced by keeping their kinetic energy nearly constant by a tight coupling to a heat bath.

Another possibility is the combination of different techniques; Monte Carlo simulation, gradient minimization, etc. in one computational scheme.[95,96]

3.2.5. *Summary*

The various methods for searching configuration space can be classified as follows:

A. Systematic search methods, which scan the complete configuration space of the molecular system.
B. Methods which aim at generating a representative set of configurations. These may be divided into two types.
   1. Non-step methods, such as the DG method, which generate a (at least in principle) uncorrelated series of random configurations.
   2. Step methods, such as MC, MD and SD, which generate a new configuration from the previous one.

Most search techniques fall in this class. They can be distinguished by the way the step direction and the step size are chosen:

- according to the gradient $-\vec{\nabla}V(\boldsymbol{r})$,
- according to a memory of the path followed so far, or
- at random.

For example, in the MC method, the step direction is chosen at random, the actual step size is determined by the change in energy ΔE (gradient) and a random element in case $\Delta E > 0$. In a MD simulation both step size and direction are determined by the force (gradient) and the velocity (memory). In general a search algorithm will make a step which is a linear combination of the gradient, previous steps (memory) and a random contribution. It will depend on the energy surface $V(\boldsymbol{r})$ which is the optimal linear combination of these three ingredients.

Another classification of algorithms which generate a set of configurations is whether they produce an ensemble or not. Of the schemes discussed above only MC, MD and SD generate a Boltzmann weighted ensemble.

3.3. Boundary Conditions

When simulating a system of finite size, some thought must be given to the way the boundary of the system will be treated. The simplest choice is the vacuum boundary condition. When simulating a liquid, solution or solid rather than a molecule in the gas phase, it is common practice to minimize edge or wall effects by the application of periodic boundary conditions. If the irregularity of the system is incompatible with periodicity, edge or wall effects may be reduced by treating part of the system as an extended wall region in which the motion of the atoms is partially restricted.

3.3.1. *Vacuum Boundary Condition*

Simulation of a molecular system in vacuo, that is, without any wall or boundary, corresponds to the gas phase at zero pressure. When the vacuum boundary is used for a solid or a molecule in solution, properties of atoms near or at the surface of the system will be distorted.[97] The vacuum boundary condition may also distort the shape of a (non-spherical) molecule, since it generally tends to minimize the surface area. Moreover, the shielding effect of a solvent with high dielectric permittivity, like water, on the electric interaction between charges or dipoles in a molecule is lacking in vacuo. We note that the water molecules do *not* need to be positioned between the charges or dipoles in order to produce a screening of the interaction between these. Therefore, simulation of a charged extended molecule like DNA in vacuo is a precarious undertaking. Solvation of DNA in a sphere with solvent molecules will shift the boundary effects from the DNA–vacuum interface to the water–vacuum interface and so improve the treatment of the DNA.[98] The best results in vacuo are obtained for relatively large globular molecular systems.

3.3.2. *Periodic Boundary Conditions*

The classical way to minimize edge effects in a finite system is to use periodic boundary conditions. The atoms of the system that is to be simulated are put into a cubic, or more generally into any periodically space-filling shaped box, which is treated as if it is surrounded by 26 ($= 3^3 - 1^3$) identical translated (over distances $\pm R_{box}$ in the x-, y-, z-directions) images of itself. The next layer of neighbor images of the central computational box contains $5^3 - 3^3 - 1^3 = 98$ boxes, and so on. When an infinite lattice sum of the atomic interactions is to be performed (Sections 3.1.3.11–13), the interactions of an atom in the central computational box with *all* its periodic images are computed. In most cases this is not desirable. Then only interactions with nearest neighbors are taken into account. The black atom in the central computational box in Figure 10a will only interact with atoms or images of atoms that lie within the dashed line (nearest image, NI, or minimum image, MI, approximation). The anisotropy of the interaction due to the cubic shape of the nearest image box can be avoided by the application of a spherical cut-off (radius R_C). The periodic boundary condition affects not only the computation of the forces, but also the positions of the atoms. It is common practice (though not necessary) to keep the atoms together, that is, in the central computational box: when an atom leaves the central box on one side, it enters it with identical velocity at the opposite side at the translated image position.

Application of periodic boundary conditions means that in fact a crystal is simulated. For a liquid or solution the periodicity is an artifact of the computation, so the effects should be minimized. An atom should not simultaneously interact with another atom and a periodic image of that atom. Consequently the length R_{box} of the edge of the periodic box should exceed twice the cut-off radius R_C. Possible distorting effects of the periodic boundary condition[99–102] may be traced by simulation of a system in differently shaped boxes (see below) of different size.

When simulating a spherical solute, use of a more spherically shaped computational box instead of a cubic or rectangular one may considerably reduce the number of solvent molecules that is needed to fill the remaining (after insertion of the solute) empty space in the box. A more spherically shaped space-filling periodic box is a truncated octahedron, (Fig. 10b).[103] It is obtained by cutting off the corners of a cube in such a way that the symmetry of the cube is main-

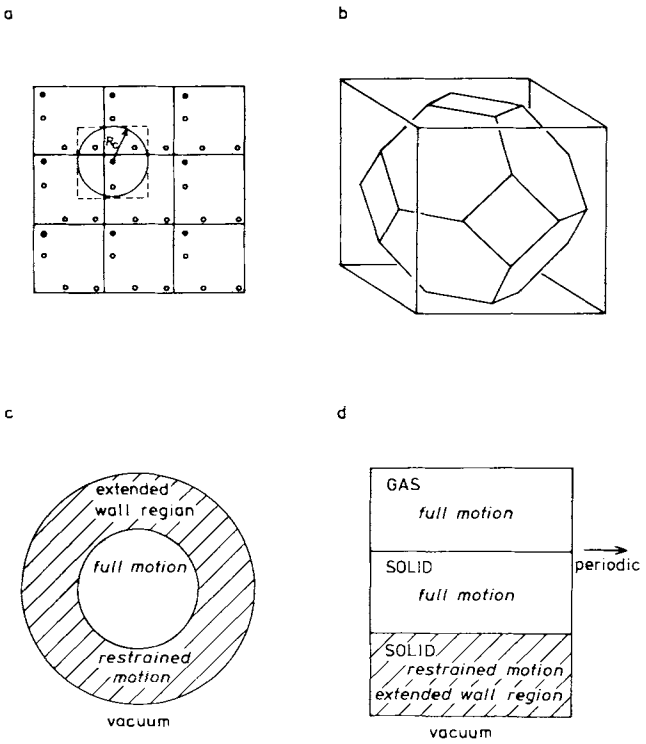

Fig. 10. Types of boundary conditions: a) cubic periodic, b) truncated octahedron periodic, c) spherical extended wall region, d) flat extended wall region for a gas-solid simulation.

tained, and such that the distance between opposite hexagonal planes equals $\frac{1}{2}\sqrt{3}$ times the distance between opposite square planes. In this way half the volume of the original cube is cut away. The ratio of the inscribed-sphere volume to total volume of the truncated octahedron is 0.68, whereas it is only 0.52 for a cube. Use of a truncated octahedron instead of a rectangular periodic box may yield a sizeable reduction of the system to be simulated. For example, the small protein bovine pancreatic trypsin inhibitor (BPTI) (58 amino acid residues) consists of 568 atoms (hydrogen atoms bound to carbons excluded), and its dimensions are 28 Å by 28 Å by 40 Å. If we approximate it by a sphere of radius 16 Å and put it into a cube with a minimum solvent layer thickness of 6 Å to the walls, about 2300 water molecules (6900 atoms) are needed to fill the non-protein part of the cube of volume $[2\times(16+6)]^3$ Å^3. To fill the non-protein part of a truncated octahedron of volume $\frac{1}{2}[4\times(16+6)/\sqrt{3}]^3$ Å^3 takes about 1600 water molecules (4800 atoms). This means a reduction of the system size by at least one quarter of the number of atoms.

3.3.3. Extended Wall Region Boundary Condition

If a molecular system is irregular, i.e. not nearly translationally periodic, periodic boundary conditions cannot be applied. In this case the distorting effect of the vacuum outside the molecular system may be reduced by designating a layer of atoms of the system to be an extended wall region, in which the motion of the atoms is restrained in order to avoid the deforming influence of the nearby vacuum (Fig. 10c, d). The atoms in the extended wall region can be kept fixed[89] or harmonically restrained to stationary positions. Their motion may be coupled to a heat bath, e.g. by applying stochastic dynamics[89] in order to account for exchange of energy with the surroundings. In any case the type of force applied to these atoms should be chosen such that their motion in the finite system resembles as closely as possible the true motion in an infinite system. The extended wall region forms a buffer between the fully unrestrained part of the system and the (unrealistic) vacuum surrounding it.

This extended wall region technique has been applied in the simulation of solids,[104] liquids[105,106] and proteins.[107,108] Although the technique yields considerable savings in computing time, it should be carefully analyzed how far the restraining of the motion of the atoms in the wall region will affect the motion of the freely simulated atoms in the system.

3.4. Different Types of Molecular Dynamics

When Newton's equations of motion (39) and (40) are integrated the total energy is conserved (adiabatic system) and if the volume is held constant the simulation will generate a microcanonical ensemble. For various reasons this is not very convenient and a variety of approaches has appeared in the literature to yield a type of dynamics in which temperature and pressure are independent variables rather than derived properties. When MD is performed in non-equilibrium situations in order to study irreversible processes, catalytic events or transport properties, the need to impress external constraints or restraints on the system is apparent. In such cases the temperature should be controlled as well in order to absorb the dissipative heat produced by the irreversible process. But also in equilibrium simulations the automatic control of temperature and pressure as independent variables is very convenient. Slow temperature drifts that are an unavoidable result of force truncation errors are corrected, while also rapid transitions to new desired conditions of temperature and pressure are more easily accomplished.

3.4.1. Constant-Temperature Molecular Dynamics

Several methods for performing MD at constant temperature have been proposed, ranging from ad-hoc rescaling of atomic velocities in order to adjust the temperature, to consistent formulation in terms of modified Lagrangian equations of motion that force the dynamics to follow the desired temperature constraint. Different types of methods can be distinguished.

1. *Constraint methods*, in which the current temperature $T(t)$ at time point t is exactly equal to the desired reference temperature T_0. This can be achieved by rescaling the velocities at each MD time step[20] by a factor $[T_0/T(t)]^{1/2}$, where the temperature $T(t)$ is defined in terms of the kinetic energy through equipartition [Eq. (43)]. The number of degrees of freedom in the system is N_{df}.

$$E_{kin}(t) = \sum_{i=1}^{N} \frac{1}{2} m_i v_i^2(t) = \frac{1}{2} N_{df} k_B T(t) \tag{43}$$

The same result can be obtained in a more elegant way by a modification of the equations of motion (39),[109-111] such

that the kinetic energy instead of the total energy becomes a constant of motion. This method has two disadvantages. First, numerical inaccuracy of the algorithm may produce a drift in temperature that is not stabilized, since the reference temperature T_0 does not appear in the equations to be integrated. Second, although the system is modeled by a Hamiltonian, this Hamiltonian does not represent a physical system, for which fluctuations in the kinetic energy are characteristic. In practical applications which are aimed at realistically simulating a physical system, the use of a non-physical Hamiltonian is questionable, even though mathematically consistent equations of motion are obtained.

2. *Extended system methods,*[112] in which an extra degree of freedom s representing a heat bath is added to the atomic degrees of freedom of the molecular system. A kinetic and a potential energy term involving this extra degree of freedom are added to the Hamiltonian and the simulation is carried out for the $N_{df}+1$ degrees of freedom of this extended system. Due to the presence of a kinetic term $\frac{1}{2}m_s(ds/dt)^2$ in the Hamiltonian, energy is flowing dynamically from the heat bath to the system and back, the speed being controlled by the inertia parameter m_s. A disadvantage of this type of second-order coupling to a heat bath is the occurrence of spurious energy oscillations, the period of which depends on the value of the adjustable coupling parameter m_s.

3. *Weak coupling methods,*[113] in which the atomic equations of motion are modified such that the net result on the system is a first-order relaxation of the temperature towards the reference value T_0 [Eq. (44)].

$$dT(t)/dt = \tau_T^{-1}[T_0 - T(t)] \tag{44}$$

The kinetic energy can be changed by ΔE_{kin} in a MD time step Δt by scaling all atomic velocities $\vec{v}_i$ with a factor λ. Using (43) we get (45).

$$\Delta E_{kin} = (\lambda^2 - 1)\tfrac{1}{2}N_{df}k_B T(t) \tag{45}$$

If the heat capacity per degree of freedom of the system is denoted by c_V^{df} the change in energy [Eq. (45)] leads to a

$$\Delta T = [N_{df}c_V^{df}]^{-1}\Delta E_{kin} \tag{46}$$

change in temperature [Eq. (46)], which should be equal to ΔT as determined by (44). Solving Equations (44)–(46) for λ we obtain equation (47).

$$\lambda = [1 + c_V^{df}(k_B/2)^{-1}\Delta t\,\tau_T^{-1}(T_0/T(t) - 1)]^{1/2} \tag{47}$$

The heat capacity per degree of freedom c_V^{df} may not be accurately known for the system. This has no consequence for the dynamics since the temperature relaxation time τ_T is an adjustable parameter. This aperiodic coupling to a heat bath through a first-order process has the advantage over the extended system methods that the response to temperature changes is non-oscillatory and that it is rather easy to implement through a simple velocity scaling using Equation (47). The coupling can be chosen sufficiently weak (sufficiently large τ_T) to avoid disturbance of the system and sufficiently strong (small τ_T) to achieve the desired result.

4. *Stochastic methods,* in which the individual atomic velocities $\vec{v}_i$ are changed stochastically. *Andersen*[114] proposed a Maxwellian re-thermalization procedure by stochastic collisions, in which the mean time between collisions plays the role of adjustable parameter determining the strength of the coupling to the heat bath. *Heyes*[115] has suggested a Monte Carlo type technique for selection of new velocities. Others[116] used the Langevin equation (41) to achieve the coupling to a heat bath, the strength of the coupling being determined by the value of the atomic friction coefficients γ_i.

3.4.2. Constant-Pressure Molecular Dynamics

For an isotropic system the pressure is a scalar defined by Equation (48), where V denotes the volume of the computational box and the virial Ξ is defined as in Equation (49).

$$P = 2/(3V)[E_{kin} - \Xi] \tag{48}$$

$$\Xi = -\frac{1}{2}\sum_{\text{pairs }(i,j)}^{N} \boldsymbol{r}_{ij} \cdot \boldsymbol{F}_{ij} \tag{49}$$

Here, $\boldsymbol{r}_{ij} = \boldsymbol{r}_i - \boldsymbol{r}_j$ and $\boldsymbol{F}_{ij}$ is the force on atom i due to atom j. For molecular systems, forces within a molecule may be omitted together with kinetic energy contributions of intramolecular degrees of freedom. A pressure change can be achieved by scaling of the volume of the box and by changing the virial through a scaling of interatomic distances.

The various methods for carrying out MD at constant pressure are based on the same principles as the constant temperature scheme with the role of the temperature played by the pressure and the role of the atomic velocities played by the atomic positions. The following methods can be distinguished.

1. *Constraint methods,*[117] in which the equations of motion are modified such that the pressure instead of the volume becomes a constant of motion. This type of method has the same two disadvantages as its constant temperature counterpart.

2. *Extended system methods,*[114, 118–121] in which an extra degree of freedom V, the volume of the box, is added to the atomic degrees of freedom of the system. A kinetic energy term, $\frac{1}{2}m_v(dV/dt)^2$ and a potential energy term, PV, involving the extra degree of freedom are added to the Hamiltonian, and the simulation is carried out for the $N_{df}+1$ degrees of freedom of the extended system. The rate of volume change is governed by the inertia parameter m_v. A disadvantage of this second-order coupling method is the occurrence of spurious volume oscillations, the period of which depends on the size of the adjustable parameter m_v.

3. *Weak coupling methods,*[113] in which the atomic equations of motion are modified such that the net result on the system is a first-order relaxation of the pressure towards a reference value P_0 [Eq. (50)].

$$dP(t)/dt = \tau_p^{-1}[P_0 - P(t)] \tag{50}$$

Scaling the atomic coordinates $\boldsymbol{r}_i$ and the edges of the computational box by a factor μ leads to a volume change [Eq. (51)].

$$\Delta V = (\mu^3 - 1)V \tag{51}$$

The pressure change ΔP due to this change in volume is given by Equation (52), where the isothermal compressibility of

$$\Delta P = -(\beta_T V)^{-1} \Delta V \tag{52}$$

the system is denoted by β_T. Solving Equations (50)–(52) for μ we get Equation (53).

$$\mu = [1 - \beta_T \Delta t \tau_p^{-1} (P_0 - P(t))]^{1/3} \tag{53}$$

Since the pressure relaxation time τ_p is an adjustable parameter, an accurate value for the compressibility of the system is not required. This first-order pressure coupling method has advantages corresponding to those of the weak temperature coupling method [cf. Eqs. (44)–(47)]. The expressions (48)–(53) can easily be modified to apply to a general anisotropic triclinic system. Virial, kinetic energy, pressure, and the scaling factor μ will become cartesian tensors, and the volume V becomes the determinant of the matrix formed by the vectors $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ representing the edges of the computational box.

4. *Stochastic methods* for constant-pressure MD have not yet been proposed. They would involve random changes of the box volume.

3.5. Algorithms for Molecular and Stochastic Dynamics

3.5.1. Integration Schemes for Molecular Dynamics

Newton's equation of motion (39), a second-order differential equation, can be written as two first-order differential equations (54) and (55) for the particle positions $\boldsymbol{r}_i(t)$ and

$$\mathrm{d}\boldsymbol{v}_i(t)]\mathrm{d}t = m_i^{-1} \boldsymbol{F}_i(\{\boldsymbol{r}_i(t)\}) \tag{54}$$

$$\mathrm{d}\boldsymbol{r}_i(t)/\mathrm{d}t = \boldsymbol{v}_i(t) \tag{55}$$

velocities $\boldsymbol{v}_i(t)$ respectively. The forces $\boldsymbol{F}_i$ are obtained from the potential energy function through Equation (40); they therefore depend on the configuration $\{\boldsymbol{r}_i(t)\}$ of the system. A simple algorithm for integration of Equations (54) and (55) in small time steps Δt is obtained as follows.

Taylor expansion of $\boldsymbol{v}_i(t)$ at time point $t = t_n$ yields the expression (56) when Equation (54) is used.

$$\begin{aligned}\boldsymbol{v}_i(t_n + \Delta t/2) &= \boldsymbol{v}_i(t_n) + \mathrm{d}\boldsymbol{v}_i/\mathrm{d}t]_{t_n} \Delta t/2 \\ &\quad + \mathrm{d}^2\boldsymbol{v}_i(t)/\mathrm{d}t^2]_{t_n} (\Delta t/2)^2/2! + \mathrm{O}(\Delta t^3) \\ \boldsymbol{v}_i(t_n - \Delta t/2) &= \boldsymbol{v}_i(t_n) - \mathrm{d}\boldsymbol{v}_i/\mathrm{d}t]_{t_n} \Delta t/2 \\ &\quad + \mathrm{d}^2\boldsymbol{v}_i(t)/\mathrm{d}t^2]_{t_n} (\Delta t/2)^2/2! + \mathrm{O}(\Delta t^3)\end{aligned}$$

$$\boldsymbol{v}_i(t_n + \Delta t/2) = \boldsymbol{v}_i(t_n - \Delta t/2) + m_i^{-1} \boldsymbol{F}_i(\{\boldsymbol{r}_i(t_n)\}) \Delta t + \mathrm{O}(\Delta t^3) \tag{56}$$

Using the same procedure for Taylor expansions of $\boldsymbol{r}_i(t)$ at time point $t = t_n + \Delta t/2$ and using Equation (55) we obtain Equation (57).

$$\boldsymbol{r}_i(t_n + \Delta t) = \boldsymbol{r}_i(t_n) + \boldsymbol{v}_i(t_n + \Delta t/2) \Delta t + \mathrm{O}(\Delta t^3). \tag{57}$$

Equations (56)–(57) form the so-called leap-frog scheme. Its name is illustrated in Figure 11. It is one of the most accurate, stable, and yet simple and efficient algorithms available for molecular dynamics of fluid-like systems. Our

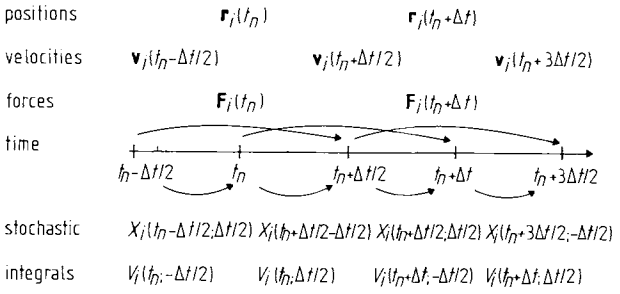

Fig. 11. The leap-frog scheme for integration of Newton's equations of motion and Langevin's equations of motion.

preference for using the leap-frog scheme instead of other algorithms such as those of *Runge-Kutta*,[122] *Gear*,[123] *Verlet*[124] or *Beeman*[125] is a result of performance evaluations[28, 69, 126, 127] and of the following considerations.

1. *Number of force evaluations per time step.* By far the most expensive part of a MD simulation is the force calculation [cf. Eq. (40)], which therefore should not be carried out more than once per integration time step Δt. This rules out algorithms of the Runge-Kutta type.

2. *Order of the algorithm.* It can be shown[69, 127] that the leap-frog, Verlet and Beeman algorithms generate exactly the same trajectory, and are of 3rd-order accuracy in the time step Δt. The application of higher-order, more accurate algorithms like those of *Gear*,[123] which involve the use of higher-order derivatives of the function to be integrated, is of no use as long as this function is a non-harmonic, noisy one. For example, in simulations of polar liquids or macromolecular solutions noise due to the cut-off applied to the long-range Coulomb forces prohibits an increase in accuracy beyond 3rd order.[126] However, if the highest-frequency motions in the molecular system are highly harmonic, as in solids, the higher-order function derivative will possess predictive power, which may lead to improved accuracy by applying higher-order algorithms. Algorithms that are of lower than third order are not efficient in the MD of molecular systems.[127] This is because molecular potential energy functions V generally have positive second derivatives, requiring third- or higher-order algorithms.

3. *Representation of the algorithm.* The much used Verlet algorithm can be obtained from the leap-frog scheme [(56)–(57)] by eliminating the velocities $\boldsymbol{v}_i(t_n + \Delta t/2)$ and $\boldsymbol{v}_i(t_n - \Delta t/2)$ from Equations (56) and (57) and replacement of t_n by $t_n - \Delta t$ in Equation (57).

$$\begin{aligned}\boldsymbol{r}_i(t_n + \Delta t) &= 2\boldsymbol{r}_i(t_n) - \boldsymbol{r}_i(t_n - \Delta t) \\ &\quad + m_i^{-1} \boldsymbol{F}_i(\{\boldsymbol{r}_i(t_n)\}) (\Delta t)^2 + \mathrm{O}(\Delta t^4)\end{aligned} \tag{58}$$

The atomic velocity does not occur explicitly in this algorithm, which makes a coupling of the system to a heat bath by velocity scaling as described in Section 3.4 impossible.

4. *Memory and computational requirements.* In some studies the Beeman algorithm [Eqs. (59) and (60)] is advocated.

$$\boldsymbol{r}_i(t_n + \Delta t) = \boldsymbol{r}_i(t_n) + \boldsymbol{v}_i(t_n)\Delta t + m_i^{-1}[4\boldsymbol{F}_i(t_n) - \boldsymbol{F}_i(t_n - \Delta t)](\Delta t)^2/6 \quad (59)$$

$$\boldsymbol{v}_i(t_n + \Delta t) = \boldsymbol{v}_i(t_n) + m_i^{-1}[2\boldsymbol{F}_i(t_n + \Delta t) + 5\boldsymbol{F}_i(t_n) - \boldsymbol{F}_i(t_n - \Delta t)]\Delta t/6 \quad (60)$$

[44] Although Equations (59) and (60) are much more complicated than Equation (58), the latter follows directly from the former: replace t_n by $t_n - \Delta t$ in Equations (59) and (60), multiply the latter by Δt and subtract the former from it, and add the resulting equation to Equation (59). Reshuffling of terms then gives Equation (58). Since the Beeman, Verlet and leap-frog algorithms generate identical trajectories, we prefer to use the latter because of its minimal computer memory storage and computational requirements.

3.5.2. Integration Schemes for Stochastic Dynamics

Langevin's equation of motion (41) differs from Newton's equation (54) by the occurrence of a stochastic force $\boldsymbol{R}_i(t)$ and a frictional force $m_i\gamma_i\boldsymbol{v}_i(t)$ [Eq. (61)].

$$d\boldsymbol{v}_i(t)/dt = m_i^{-1}\boldsymbol{F}_i(\{\boldsymbol{r}_i(t)\}) + m_i^{-1}\boldsymbol{R}_i(t) - \gamma_i\boldsymbol{v}_i(t) \quad (61)$$

The solution of this equation around $t = t_n$ is formulated in Equation (62).

$$\boldsymbol{v}_i(t) = \boldsymbol{v}_i(t_n)e^{-\gamma_i(t-t_n)} + m_i^{-1}e^{-\gamma_i(t-t_n)}\int_{t_n}^{t} e^{-\gamma_i(t_n-t')}[\boldsymbol{F}_i(t') + \boldsymbol{R}_i(t')]dt' \quad (62)$$

Since the stochastic properties of $\boldsymbol{R}_i(t')$ are given, the integral over $\boldsymbol{R}_i(t')$ can be obtained directly. The integral over the systematic force $\boldsymbol{F}_i(t')$ is, as in the previous section, obtained by expanding $\boldsymbol{F}_i(t')$ in a Taylor series around $t = t_n$ and omitting all terms beyond third order in Δt in the positions, beyond second order in the velocities, and beyond second order in the forces. The SD equivalent of the leap-frog velocity formula (56) then becomes:[128]

$$\boldsymbol{v}_i(t_n + \Delta t/2) = \boldsymbol{v}_i(t_n - \Delta t/2)e^{-\gamma_i\Delta t} + m_i^{-1}\boldsymbol{F}_i(t_n)[1 - e^{-\gamma_i\Delta t}]/(\gamma_i\Delta t) + \boldsymbol{V}_i(t_n; \Delta t/2) - e^{-\gamma_i\Delta t}\boldsymbol{V}_i(t_n; -\Delta t/2) \quad (63)$$

with

$$\boldsymbol{V}_i(t_n; \Delta t/2) \equiv m_i^{-1}e^{-\gamma_i\Delta t/2}\int_{t_n}^{t_n+\Delta t/2} e^{-\gamma_i(t_n-t')}\boldsymbol{R}_i(t')\,dt' \quad (64)$$

When γ_i goes to zero, Equation (63) reduces to Equation (56). The SD equivalent of the leap-frog position formula (57) is obtained by integrating Equation (55) using the expression (62) for the velocity[128] [Eqs. (65), (66)].

$$\boldsymbol{r}_i(t_n + \Delta t) = \boldsymbol{r}_i(t_n) + \boldsymbol{v}(t_n + \Delta t/2)\Delta t[e^{+\gamma_i\Delta t/2} - e^{-\gamma_i\Delta t/2}]/(\gamma_i\Delta t) + \boldsymbol{X}_i(t_n + \Delta t/2; \Delta t/2) - \boldsymbol{X}_i(t_n + \Delta t/2; -\Delta t/2) \quad (65)$$

$$\boldsymbol{X}_i(t_n; \Delta t/2) \equiv (m_i\gamma_i)^{-1}\int_{t_n}^{t_n+\Delta t/2}[1 - e^{-\gamma_i(t_n+\Delta t/2-t')}]\,\boldsymbol{R}_i(t')\,dt' \quad (66)$$

When γ_i goes to zero, Equation (65) reduces to Equation (57).

When using the SD leap-frog algorithm (63–66) it must be noted that $\boldsymbol{V}_i(t_n; -\Delta t/2)$ is correlated with $\boldsymbol{X}_i(t_n - \Delta t/2; \Delta t/2)$, since they are different integrals of $\boldsymbol{R}_i(t)$ over the time interval $(t_n - \Delta t/2;\ t_n)$ (see Fig. 8). The same observation holds for $\boldsymbol{X}_i(t_n + \Delta t/2; -\Delta t/2)$ and $\boldsymbol{V}_i(t_n; \Delta t/2)$ [cf. Eqs. (65) and (63)]. These are different integrals of $\boldsymbol{R}_i(t)$ over the time interval $(t_n, t_n + \Delta t/2)$. This means that these correlated quantities must be sampled in a correlated manner,[128] which makes the SD leap-frog algorithm more complicated than the MD one.

Integration schemes for the generalized Langevin equation involving time-dependent friction coefficients γ_i can be found in Refs. [129, 130].

3.5.3. Application of Constraints in Molecular Dynamics

In Section 3.4 methods to exactly constrain the temperature and pressure of a molecular system were briefly mentioned. Here, methods to constrain molecular bond lengths or bond angles in dynamic simulations will be discussed. They are used to save computing time. The length of the time step Δt in a MD or SD simulation is limited by highest frequency (ν_{max}) motions occurring in the system [Eq. (67)].

$$\Delta t \ll \nu_{max}^{-1}. \quad (67)$$

By freezing the generally uninteresting high-frequency internal vibrations, such as bond-length or possibly bond-angle vibrations, ν_{max}^{-1} is increased, which allows for a longer time step Δt. The application of constrained dynamics makes sense physically and computationally when

1. the frequencies of the frozen (constrained) degrees of freedom are (considerably) higher than those of the remaining ones, thereby allowing a (considerable) increase of Δt,
2. the frozen degrees of freedom are only weakly coupled to the remaining ones, i.e. when the molecular motion is not significantly affected by application of constraints,
3. so-called metric tensor effects[131] play a minor role,
4. the algorithm by which the constraints are imposed on the molecular system does not require excessive mathematical or computational effort.

In molecular simulations typically a factor of 3 in computer time can be saved by application of constraints.[126] The application of constraints implies that the atoms move on a hypersurface in configuration space. While in the full Cartesian configuration space each configuration has equal weight in the partition function, the weighting on the hypersurface will in general depend on its form. The metric tensor defining the hypersurface in terms of Cartesian coordinates will determine these weights. Therefore, when simulating using constraints, metric tensor corrections must be taken into account. Their significance depends on the type of constraint. A discussion of metric tensor effects is given in Refs. [131, 132].

3.5.3.1. Classification of Methods

Several methods exist for integrating the equations of motion of a molecular system in the presence of constraints. They can be classified as follows:

1. *Formulation in terms of generalized coordinates.* In this case the constrained degrees of freedom (e.g. bond lengths, bond angles) are treated as fixed parameters, not as degrees of freedom. For example, a macromolecule may be modeled by only torsional angle degrees of freedom, as is often done in static modeling studies. Two cases can be distinguished.
   a. When dealing with *rigid molecules*, center of mass coordinates and Euler angles can be used as degrees of freedom, leading to the Newton-Euler equations of rigid body motion. A variety of algorithms have been proposed for the integration of these equations.[19, 133–135]
   b. For the more general case of *flexible molecules*, especially when the number of internal degrees of freedom becomes larger than a few, and when inertial terms are not neglected, it is a tedious task to write down explicitly the appropriate equations of motion in generalized coordinates.[136, 137] The reason is that the base vectors of the coordinate system become dependent on time, which has a number of unpleasant consequences.[136] So we think that the use of generalized coordinates, such as torsional angles, is highly unpractical for describing the dynamics of macromolecules.
2. *Formulation in terms of Cartesian coordinates.* Two methods are available for integrating the Cartesian equations of motion of flexible molecules subject to holonomic scleronomous constraints, that is, constraints that are only dependent on atomic coordinates, not on time.
   a. *Matrix methods*[138] bear their name because they involve the (costly) inversion of a matrix of dimension equal to the number of constraints. Thus, these methods are not well suited for application to macromolecular systems.
   b. *Iterative methods*, like the so-called SHAKE method,[138] are especially appropriate for macromolecules, since they treat the constraints in an iterative way.
