Weil et al.[10] have carried some fast solution exchange experiments on the same system. They observed anodic and cathodic current transients after removal of cupric ions and/or formaldehyde from the electrolyte; the current-time diagrams are shown in Figure 14. The broken lines represent the corresponding partial currents recalculated from the deposition rate, which was recorded with the microbalance before solution exchange. From the data these authors concluded that the oxidation of formaldehyde is accelerated by the concomitant reduction of cupric ions. On the other hand, formaldehyde does not donate electrons exclusively to cupric ions for their reduction. It was suggested that a surface catalyst is formed, probably chemisorbed methanediol anions. These conclusions were confirmed recently.[52] They are not in accord, however, with the principle of *Wagner* and *Traud*[53] who claimed independence for the simultaneously occurring oxidation and reduction processes at the mixed potential.[53]

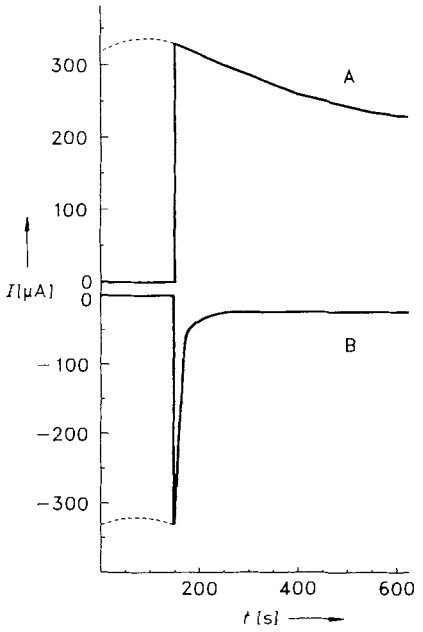

Fig. 14. Fast solution exchange experiments on an electroless copper electrolyte. The current transients occur at the mixed potential due to removal of cupric ions (A) or formaldehyde (B) from a complete electrolyte. The broken lines in (A) and (B) represent the currents recalculated from the deposition rate before solution exchange [10].

4.1.2. Viscoelastic Layers

As concluded by *Crane* and *Fischer*[41] the application of nonmetallic coatings to quartz resonators may cause large errors since these films may behave viscoelastically rather than rigidly. A general theoretical treatment of viscoelastic films which experience shear stress oscillations has not yet been addressed. However, as outlined by *Kanazawa* et al.,[19] thin films with viscoelastic properties can be regarded as rigid if $d \ll 1/k$, where k is a constant for viscoelastic waves propagating through a film of thickness d. This concept holds true for resist films of type AZ 4620 coated on quartz oscillators: the frequency changes observed after the coating agree well with the values predicted according to *Sauerbrey*'s equation.[19] Furthermore, the observed frequency response for long-chain, multilayer systems prepared according to the Langmuir-Blodgett technique was also in accord with *Kanazawa*'s prediction. As demonstrated by *Bruckenstein* et al.[54] a linear relationship is found between the recorded increase in mass and the number of layers deposited on the oscillator. *Buttry* et al.[11] were able to show that polymer films formed by electropolymerization of aniline on metalated quartz oscillator surfaces are also to be regarded as rigid up to a layer thickness of approximately 300 nm. This finding forms the basis for extensive investigations of the growth of polymer films with the quartz microbalance. Some examples are discussed in the following.

The growth of polymer films on metallic substrates has been monitored, both at constant potential as well as potentiodynamically, and evaluated by means of the recorded frequency shifts Δf and the simultaneously recorded charge flux Δq. The linear relationship Δf versus charge Δq as found in potentiodynamic investigations of the formation of thin polymer films such as polypyrrole PP,[55] diheptylviologen bromide DHV,[56] polyvinylferrocene PVF,[12] polyaniline PA,[11,16] and polydithiophene PT[15] indicates that mass transport is not rate-determining.[55] As has been demonstrated[55] for a PP electrode, the film behaves like a dynamically growing electrode, suggesting that the polymer is maintained at an oxidation state which is high enough to sustain growth. It is thought, that this film is able to directly oxidize additional monomers which then react with and add to the end of the polymer chain. In the polymerization of 2,6-dimethylaniline Δf and Δq are independent of each other.[16] This finding is attributed to side reactions such as, e.g., the diffusing-out of oligomeric compounds. In the initial stage, the layer thickness increases linearly with the logarithm of time, which is consistent with a growth law for insulating oxides and inhibitor films.[57] The growth kinetics observed at a constant potential for the electropolymerization of PA reveals that the mass increase below 1000 seconds is negligibly small. In this induction period adsorption and oligomerization take place. Above 1000 seconds nucleation takes place, followed by autocatalytic polymerization, leading to a very rapid increase in film thickness.[16]

An illustrative example for a photochemically-induced film decay is presented in Figure 15. This picture demonstrates, on the one hand, the technological applicability of oscillating quartz resonators as rate monitors (e.g. in microlithography), and, on the other, it reveals some interesting physical features of thin, light-absorbing films.[19] The photochemically induced film dissolution is shown for a Microposit 1470 resist which was in contact with an aqueous Microposit developer and irradiated with light of wavelength 436 nm. The rate of dissolution depends on the light intensity (which was varied between 80 and 160 mJ cm^{-2}), while the unexposed film remains practically unaffected by the developer solution. The modulation in the dissolution rate reflects the interference pattern for thin light-absorbing films and was used to assure the accuracy of thickness data that were determined in-situ with the quartz microbalance.[58]

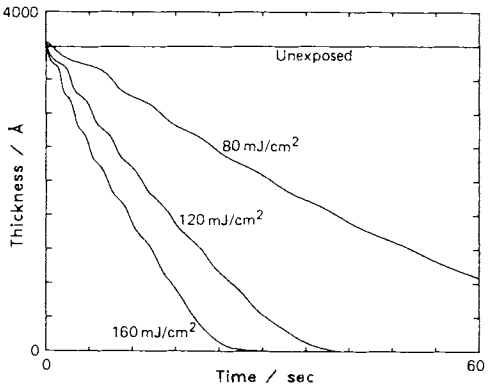

Fig. 15. Photochemical dissolution at $\lambda = 436$ nm of a Microposit 1470 resist which contacts an aqueous Microposit developer [19].

4.2. Ion and Solvent Population in Grown Thin Film Coatings

The contact of a solid with a liquid phase leads, in many cases, to a partial material exchange in both directions. This process is diffusion controlled and leads to an alteration of the bulk properties of the phases involved. The intrinsic transport of ion and solvent molecules in thin films grown on noble metal substrates in a liquid environment by electropolymerization, electrocrystallization etc. strongly depends on their redox state. Ion expulsion and insertion takes place during oxidation and reduction and the resulting mass changes were found to be intrinsic to the electrochemistry of these films. In some cases, solvent exchange at the solid/liquid junction was also observed. The monitoring of these migration processes by means of oscillating quartz resonators furnished detailed information on the distribution of mass and charge in the boundary layers. The various films studied span from pure inorganic materials such as manganese dioxide, tungsten trioxide, and prussian blue films to organic polymer films like polypyrrole PP,[59] polyaniline PA,[11, 14] polythiophene PT,[15] polyvinylferrocene PVF,[12] polycarbonate PC,[60] and polyvinyl chloride PVC.[60]

Using rotating quartz resonators coated with manganese dioxide *Heusler* et al.[20] were able to investigate the migration of manganese ions and the migration of oxygen ions separately under equilibrium conditions. It emerged that the manganese ions are transported without a water sheath, while the oxygen ions are transported together with water molecules. It therefore follows that the exchange current for the naked manganese ions is much larger than for the corresponding oxygen ions. Moreover, it was established that water migrates into the manganese oxide film independent of the ion migration. The incorporation of water in tungsten trioxide films could likewise be demonstrated by in-situ microweighing during coloring-bleaching cycles. The results reveal an aging effect associated with water entrapment.[61]

Mass change measurements during reduction and reoxidation of prussian blue films indicate a change in mass of the films that depends on the electrolyte cation. As shown by *Melroy* et al.[21] reduction of prussian blue films results in the incorporation of alkali metal cations, while oxidation results in alkali metal cation expulsion. For bulky immobile cations, probably proton expulsion occurs. These observations are consistent with a lattice reconstruction upon initial reduction of such films; this can be expressed in terms of Equation (n),

$$Fe_4[Fe(CN)_6]_3 \cdot 6H_2O \xrightarrow[+3M^{\oplus}]{-Fe^{3\oplus},\ -6H_2O} 3MFe_2(CN)_6 \qquad (n)$$

which shows that the net mass changes of the prussian blue film correlates with the mass of the cations $M^{\oplus}$ in the electrolyte.

A thin polyaniline PA electrode is suitable, for demonstrating ion and solvent migration through polymer films. As shown by *Buttry* et al.[11] and confirmed by *Heitbaum* et al.,[14] proton expulsion and anion insertion take place upon oxidation of PA in a moderately acidic solution, thus indicating partial protonation of PA amine nitrogens in the reduced form. Experiments in a strongly acidic environment which were not carried out under steady-state conditions led to a change in solvent content (number of molecules of solvent in the film) during oxidation; this affects the electrochemical response of PA, as is demonstrated in Figure 16, where current A and frequency B responses during potential

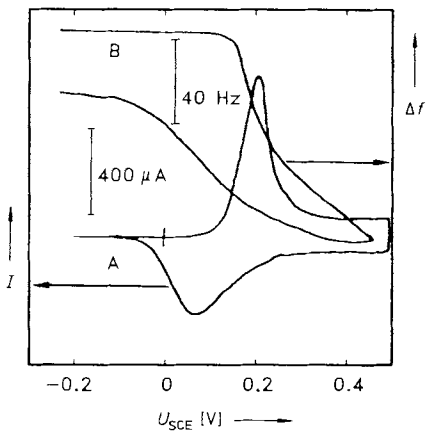

Fig. 16. Electrochemical behavior of a polyaniline PA film in 10 M sulfuric acid in terms of current (A) and frequency (B) [11].

cycling are shown. The frequency changes are much larger than those recorded under steady-state conditions, and the observed slow regain of the frequency to its initial value after the cycle indicates a solvent transport of ca. 500 ng. This is thought to be associated with the dehydrating nature of the electrolyte, in this case concentrated sulfuric acid. This explanation is in accord with the observed positive shift of the anodic peak by 110 mV with respect to the steady state scan. Such effects have been attributed to low solvent levels in the reduced films.

Bimolecular reactions between PVF films and solution species were investigated under open circuit conditions by *Ward*.[13] The observed mass gains on oxidation of the film material with $I_2/I_3^{\ominus}$ are attributed to the formation of PVF-I_3, while the mass losses observed on reduction with $[Fe^{II}(CN)_6]^{4\ominus}$ and $[Ru(NH_3)_6]^{2\oplus}$ are ascribed to the expulsion of counterions.

The technique of in-situ microgravimetry has also been applied to the interesting but complicated biologically related issue of the binding of immunoglobulin IgG and anti-IgG

to silver electrodes in phosphate-buffered electrolytes.[62] The results of this investigation are in accord with the model concepts developed by *Steengard* et al.[63] for this system. Combined microgravimetric and coulometric experiments showed that the composition of IgG/anti-IgG complexes changes from more soluble to an insoluble form which saturates on the silver electrode when the IgG : anti-IgG ratio is 27 : 1.

The isotherms for the adsorption of bovine serum albumin on polysulfone surfaces have been described by *Laatikainen* et al.[64] These authors were able to demonstrate by in-situ microweighing in solution and vacuum that during equilibration of bovine serum albumin with the exposed hydrophilic polysulfone surface, co-deposition of water takes place with formation of a hydrated protein adlayer.

4.3. Processes Associated with Formation and Decay of Adsorbate Adlayers

Heterogeneous surface reactions are often strongly influenced by adsorbate layers. In the classical electrochemical oxidations of formaldehyde and methanol these reactions are catalyzed by under potentially deposited (UPD) layers of lead and tin on platinum electrodes.[65-67] The UPD monolayers are formed by deposition of the corresponding ions which were added to the electrolyte in small amounts.

The formation and decay of adlayers on solid substrates cause a change in surface concentration Γ_{ad}, and, in the case of involvement of charged species, a corresponding change in surface charge q_m is observed. Both quantities are directly measureable, i.e. in-situ and simultaneously, with the oscillating quartz resonator technique and can be used for the calculation of the thermodynamic parameters of the monolayers.[68-72] The electrosorption valency γ of adlayers formed at a constant potential U_{ad} is described by Equation (o), in which the Faraday constant is denoted as F.

$$\left(\frac{\partial q_m}{\partial \Gamma_{ad}}\right)_{U_{ad}} = -\gamma F \qquad \text{(o)}$$

The significance of the thermodynamic quantity γ in the case of the surface dipole moment μ_{ad} of adsorbed species was recently demonstrated by *Schmickler*.[73] It turned out that μ_{ad} values are much smaller than the corresponding values in the bulk phase, indicating that the charge q_m on the adsorbed species is apparently shielded by liquid molecules and surface electrons of the metallic substrate.[73]

Table 1 lists some γ values determined by the quartz oscillator method. The data were measured for both anions and cations on polycrystalline gold substrates. Furthermore, the adsorption of lead and of silver on gold in acetonitrile and of mercury on gold in sulfuric acid were also investigated. The results were not used, however, for determining thermodynamic data.[5, 27]

For comparison we refer to a paper by *Schultze* et al.,[74] who presents a collection of thermodynamic data obtained by various techniques and in different solvent environments.

Model examples for the adsorption/desorption process of ionic species on/from metal surfaces are sulfate and palladium adsorbate formation and decay on polycrystalline gold surfaces.[24, 25] These processes were monitored potentiodynamically using the in-situ microbalance technique (Figs. 17, 18). During the adsorption/desorption process of the sulfate ions on/from the gold surface the differential capacity and the resonance frequency change within the same potential range (Fig. 17). The interesting point, however, is the observed irreversibility of the adsorption and desorption of this anion. As demonstrated by the hatched areas in the cyclic voltammogram the charge fluxes involved during adsorption/desorption are comparable, while frequency and capacitance clearly reveal that adsorption and desorption are inherently different. The reported frequency shift due to adsorption correspondes to about 13 ng and is roughly twice as much as found during desorption. These observations indicate that, upon reduction, only half of the sulfate ions desorb, while the remainder stay adsorbed on the surface, and this in turn would suggest a fairly strong interaction between sulfate anions and the substrate.

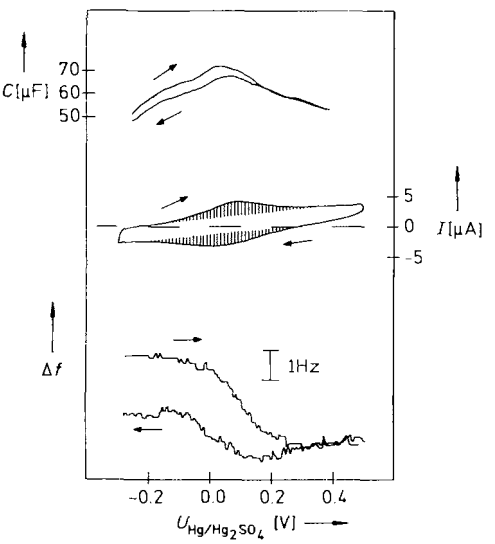

Fig. 17. Formation/decay of a sulfate adlayer on a polycrystalline gold electrode: Potentiodynamic recordings of capacitance, current, and frequency response [24].

A strong anion/adsorbate interaction might also explain the observations shown in Figure 18, which clearly reveal an interference of surface sulfate anions with the adsorption/desorption of palladium ions. Interestingly, the onset potentials for dissolution of under potentially deposited UPD palladium from the gold substrate and for the deposition of sulfate ions are practically identical. The reverse processes, palladium adsorption and sulfate desorption occur under comparable conditions. All these processes occur, as can be seen in Figures 17 and 18, at a potential of around 0.1 V. In

the absence of palladium ions the observed current and frequency pattern are due to the adsorption/desorption of sulfate anions as shown in Figure 17.

A strong interaction of sulfate anions with a copper substrate was recently discussed on the basis of an in-situ EXAFS study.[75, 76] The observed Cu–O distance of 2.08 Å is indicative of sulfate ions which are in direct contact with the copper surface.

4.4. Electrochemical Passivation of Metals

Surface processes associated with the formation and decay of oxidic overlayers on metal electrodes can be characterized cyclovoltammetrically.[77, 78] Oxidation/reduction processes which occur in the intermediate potential range between oxygen and hydrogen evolution appear as pronounced anodic/cathodic current waves. Since, however, the non-specific observable current does not allow discrimination between the growth/decay of oxide adlayers and other surface related processes, the extraordinary mass sensitivity of shear stress oscillations provides further insights into these processes. If an oxide adlayer is formed, oxygen containing species are expected to diffuse into the surface, and thus to increase its weight. The reverse reductive process leads to a loss of weight, since these species diffuse out of the solid. The weight changes are recorded as frequency changes in the oscillating crystals, and are expected to coincide with the onset potentials for anodic/cathodic current fluxes. This does, in fact, occur on a gold electrode in contact with an alkaline electrolyte, as shown in Figure 9. On the other hand, no frequency changes are observed in the intermediate potential range between oxygen and hydrogen evolution if the gold electrode is immersed in an acid environment.[8] Interestingly, the current response still shows pronounced waves, indicating some surface related chemistry. This observation is a clear indication that anodic/cathodic surface processes on gold in an acidic medium and in the intermediate potential range are not related to formation and decay of oxide adlayers since otherwise a parallel mass change would have to be indicated. It seems feasible that, in an acidic environment, adsorbed water molecules are oxidized to hydroxide and vice versa. A loss or gain of one hydrogen atom per adsorbed molecule is probably too small to be detected. For instance, a monolayer of hydrogen accounts for a frequency shift of less than 1 Hz with respect to a 5-MHz oscillator. The results described here for gold electrodes are conclusive and explain the formation and decay of oxide layers on gold in various electrolytic environments. They are in accord with ex-situ spectroscopic investigations and investigations with the Kelvin probe.[79, 80]

Figure 19 shows an interesting experimental result concerning the passivation of metal surfaces: the response of current and frequency on a copper electrode to a variation of

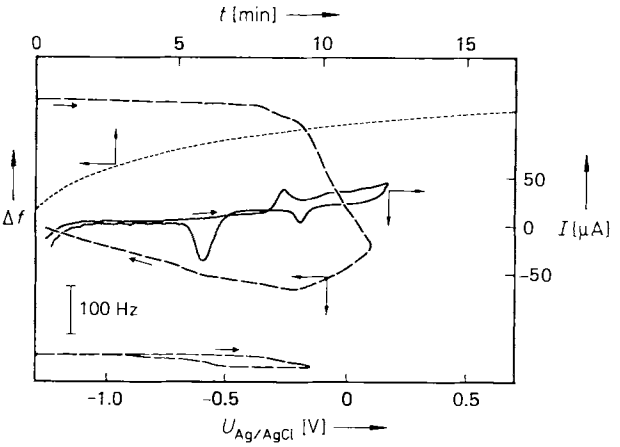

Fig. 19. Potentiodynamic recordings of current and frequency on a polycrystalline copper electrode in the region of oxide formation and dissolution. The regain in frequency with time upon reduction is indicated by a dotted line [28, 29].

potential in alkaline medium.[28, 29] As expected, the two oxidative and reductive current waves which are related to the formation and decay of cuprous- and cupric-oxide films, are paralleled with the frequency response of the oscillator. As shown in the lower part of this diagram, formation and decay of cuprous oxide is reversible in terms of mass changes. But the drastic frequency changes observed in the potential range of cupric oxide formation do not disappear upon reduction. This observation underscores the irreversible nature of processes involved on the time scale of cycling. Interestingly, however, the frequency reaches its starting value again within about 20 minutes, indicating that some time is needed to re-establish the initial state of the surface. The agreement of this frequency–time feature with *Tammann*'s law[81] supports the idea that the oxidized surface needs some relaxation time to rearrange itself after the reduction. *Tammann*'s law relates the mass transport in annealed surface layers to diffusion processes. Since the increase in mass Δm_q (derived from the charge flux) is much smaller than the total mass increase Δm_f (derived from the frequency decrease) an incorporation of water into the oxide layer is postulated. Thus, it is most likely the out-diffusion of these water molecules, after the oxide film is reduced, that determines the rearranging period. A similar result is observed on silver electrodes; however, the degree of surface roughness which goes along with the formation and decay of oxide adlayers is, for this material, much more pronounced.[28, 29]

The electrochemical passivation of titanium[30] and aluminum[34] has also been investigated in terms of frequency

and current changes using the in-situ microbalance. The results for titanium electrodes are shown in Figure 20. By comparing mass changes evaluated from charge fluxes Δm_q with those obtained from frequency shifts Δm_f, it is found that $\Delta m_q \gg \Delta m_f$, which contradicts the results reported for gold, copper and silver electrodes.[4, 28, 29] From the plot Δm_q vs Δm_f it can be estimated that only one third of the

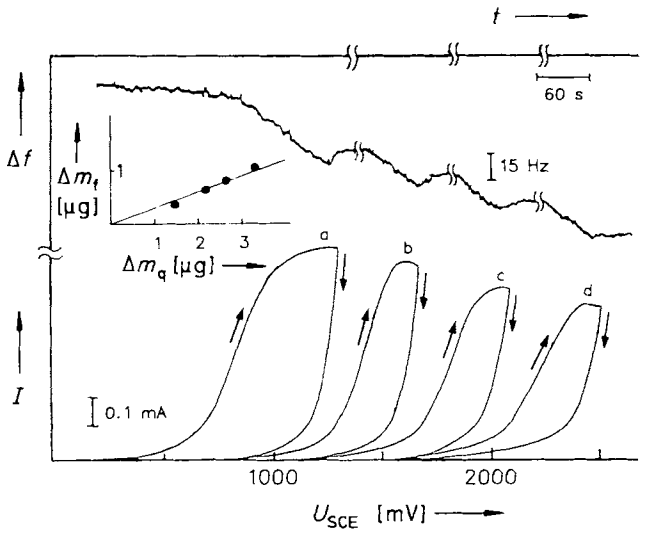

Fig. 20. Electrochemical passivation of a titanium electrode. The current waves a–d represent a consecutive growing oxide film which leads to a frequency decrease as shown in the upper part of the diagram. The evaluation of these data in terms of a mass gain according to charge flux, Δm_q, and frequency response, Δm_f, is given in the inset [30].

charge transported is used in the passivation of the metal surface. The remainder probably leads to the formation of oxygen, which diffuses into the electrolyte. This estimation neglects water entrapment in surface pockets (cf. Section 3.3), although according to the impedance pattern a certain roughness is indicated. The semicircles representing Z_r and Z_i (real and imaginary parts of the impedance, respectively) are twisted clockwise and decrease with increasing thickness of the passive layer. These observations could be recalculated on the basis of a fractal structured surface pattern.[30]

4.5. Surface Sites and Their Influence on the Degree of Electrode/Electrolyte Coupling

In the previous sections we have discussed cases in which the amount of a liquid deposit according to Equations (d) and (e) does not change, so that the frequency responses obtained could be related to mass changes which occur on the solid side of the solid/liquid junction. In this type of experiment, the coupling of shear stress oscillations of the resonator surface to the viscous liquid remains unaffected. However, this requirement does not hold for cases where surface processes are involved that affect the coupling of shear stress oscillations of the resonator surface to the first liquid layer.

A convincing example which demonstrates that the degree of resonator–liquid coupling is affected by the formation/decay of effective surface sites is presented in Figure 21. In this diagram the observables frequency response and current flux are shown under potentiodynamic conditions for a platinum electrode in contact with an acid medium. Interesting is the region of adsorption/desorption of hydrogen atoms and protons, respectively, at potentials below 0.5 V. In this potential region a drastic increase in frequency of ca. 120 Hz occurs, which corresponds to a mass change of ca. 2.5 μg. This change in mass is much larger than changes in weight associated with the formation and decay of a hydrogen monolayer that occurs in this potential region. As has already been mentioned, the frequency changes associated with the formation and decay of a hydrogen monolayer are less than 1 Hz for a 5-MHz resonator. To explain these drastic changes in frequency we refer to a recent study by *Benzinger* et al.[82] who investigated emersed platinum electrodes by means of surface IR spectroscopy. From their results they concluded, in agreement with *Bewick* et al.,[83] the formation of chemisorbed surface sites **A** in the hydrogen region. They

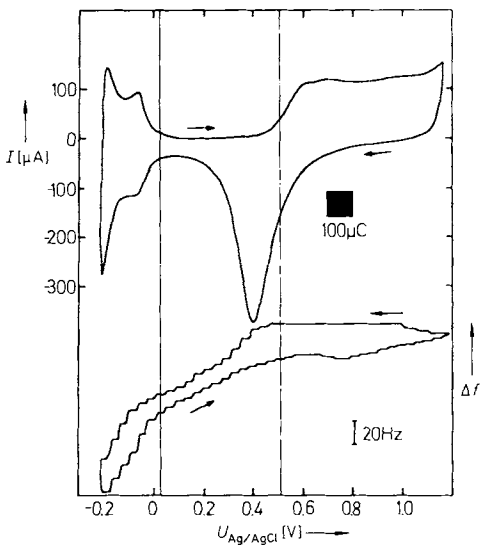

Fig. 21. Potentiodynamic recordings of current and frequency on a polycrystalline platinum electrode in contact with a sulfuric acid solution [8].

A

are formed in the region of hydrogen adsorption/desorption with participation of water molecules. Consistent with this is that the surface is hydrophilic in this potential range. On the other hand, the surface was found to be hydrophobic in the double layer region, for which a featureless infrared spectrum was observed. These hydrophilic-hydrophobic transitions may create an interfacial slip which changes the coupling between electrode and electrolyte. This, of course, affects the characteristic decay length k_1 for shear waves traveling normal to the surface. As a consequence, the thickness of the attached liquid layer changes and a drastic frequency shift is observed which is much larger than the changes in weight associated with the surface chemistry involved.

A similar result was obtained with titanium oxide electrodes which were investigated in an alkaline environment.[30] The observed strong frequency changes expressed in terms of $\Delta f/\Delta t$ (cf. Fig. 22), which occur under potential

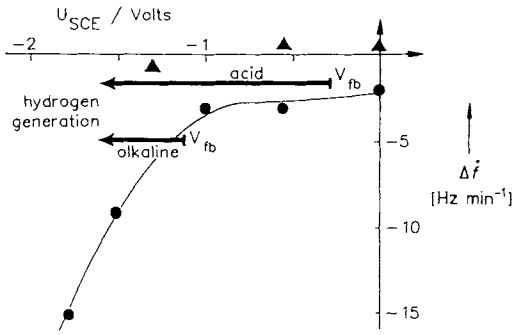

Fig. 22. Decrease in frequency with time Δf for some potentials on an electrochemically passivated titanium electrode. The points represent data measured in acid (▲) and alkaline (●) media. The potential region of hydrogen generation in marked by arrows [30].

conditions where hydrogen atoms are generated on the surface, are related to a surface species **B** which mediates the

B

coupling between electrode and electrolyte. These sites are formed from $TiO^{\ominus}$ surface species, protons, and water molecules. The protons were either generated by a solid-state reaction of hydrogen atoms and the titanium oxide electrode or they originated from the electrolyte. The former mechanism is based on the diffusion of hydrogen atoms into the solid oxide,[84–86] which in the case of n-type semiconductors like titanium oxide occurs at potentials below the flat band potential V_{fb}. The potential region in which hydrogen atoms are generated at the surface depends on the pH and is indicated in Figure 22 for a strong acid and a strong alkaline solution. Once inside the oxide these hydrogen atoms donate their electrons to the conduction band, leaving behind surface protons $H_s^{\oplus}$ which either diffuse into the solid bulk or equilibrate with $TiO^{\ominus}$ surface sites to form TiOH.[87] These newly formed TiOH sites couple with water molecules, as was observed for a platinum surface in the hydrogen region. How densely the oxide surface is populated with species **B**, depends on the number of $TiO^{\ominus}$ sites and on the $H_s^{\oplus}$ concentration. This of course depends on the generation rate of hydrogen atoms which is potential controlled. As a consequence, in alkaline solutions the coupling changes with the potential as shown in Figure 22.

The insignificant frequency shifts observed upon variation of the potential in an acidic environment (cf. Fig. 22) are also consistent with this interpretation. At low pH the presence of a high electrolyte proton concentration will yield protonated surface groups, so that the surface density of TiOH sites in an acidic solution is independent of $H_s^{\oplus}$ formation. Thus, the frequency shifts remain unaffected by the potential, regardless of the generation of $H_s^{\oplus}$ below 0.5 V.

5. Summary and Outlook

The technique of in-situ microweighing with oscillating quartz resonators immersed in a fluid has proven capable of sensing interfacial processes on a microscopic level. This novel approach has also testified its applicability to a variety of surface related processes; these are summerized in Table 2.

Table 2. In-situ applications of the quartz microbalance at the solid/liquid junction.

Application	Information
Rate monitor	– deposition [3, 10–12, 15–16, 55–56] dissolution [17, 19]
Surface weighing	adsorbate formation [22–26, 64] – mass transport through thin films [11–15, 20, 59–61] – passivation [4, 29–30] – roughness [4, 29]
Surface stress	– adsorbate formation [48]
Coupling	physical/chemical nature of the surface [8, 30]

The information obtained is unique and undoubtedly provides new insights into the complicated mechanisms of interfacial processes. In contrast to the results obtained for the solid/vacuum interface the data observed for the solid/liquid junction are less straightforward. It turned out for the latter case, that recorded changes in the resonance frequency of the oscillating quartz disks are not necessarily associated with a change in mass on the solid side of the solid/liquid junction. It would seem that the state of the surface and its interaction with the bulk liquid (electrolyte) can cause dramatic frequency shifts. These shifts probably reflect a change in thickness of a liquid deposit which moves parallel to the vibrating surface. The results indicate that special surface sites mediate the coupling of the two phases. But also surface roughness and surface stress account for frequency shifts which can accumulate to about 80% of the total frequency shift involved.

As already mentioned in the introductory section the specifity of weight changes, even when they are recorded with nanogram resolution, is inherently insufficient. However, as has been demonstrated, a noticeable improvement is made by recording charge flux and interfacial capacitance simultaneously. This observation suggests the implementation of further specific surface sensitive techniques which can be used along with microgravimetry and can be applied in-situ. A good choice might be spectroscopic in-situ techniques such as surface IR spectroscopy, surface enhanced Raman spectroscopy, EXAFS, etc. A powerful combination would be microgravimetry and scanning tunneling microscopy.

Since our understanding of the fundamental principles associated with the coupling of an oscillator surface to a fluid is still in a poor state, further theoretical work on the treatment of viscoelastic overlayers is called for. And finally, the influence of driver electronics on changes in the resonance frequency requires further investigation.

The author is indebted to Ms. G. Cordes and to HGS for designing and preparing the graphic artwork.

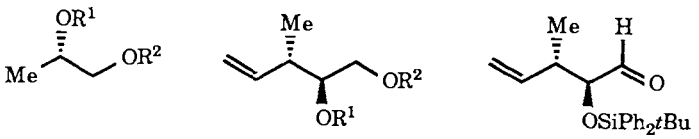
Multiple 1,2-*O*,*O*-Shift of *tert*-Butyldiphenylsilyl Groups in Polyols

By *Johann Mulzer** and *Bernd Schöllhorn*

tert-Butyldimethylsilyl (TBDMS) and *tert*-butyldiphenylsilyl (TBDPS) groups are standard protecting groups for OH functions.[1] The *O*,*O* silyl migration to be expected in polyols was hitherto chiefly observed in the case of the less stable TBDMS unit.[2] In the case of the TBDPS group two examples have been described in the literature, namely a 1,3-shift[3] and 1,2-shift.[4] We now report a multiple 1,2-*O*,*O* migration of TBDPS groups in the polyol derivatives **1**, **2**, **4**–**6**, **8**, **9** and **13**.[5]



1 **2** **3**

a, $R^1 = t\text{BuPh}_2\text{Si}$, $R^2 = H$
b, $R^1 = H$, $R^2 = t\text{BuPh}_2\text{Si}$

The silyl migration requires base catalysis (standard conditions: potassium carbonate in methanol, 22 °C). **1a** and **2a** then isomerize completely to **1b** and **2b**, respectively. Under neutral or acid conditions the TBDPS group is stable towards migration. Reduction of the aldehyde **3** with lithium aluminum hydride in diethyl ether therefore leads uniformly to **2a**, whereas that with sodium tetrahydroborate in methanol yields **2b** quantitatively. During the reaction **2a** is detectable as intermediate.

Under standard conditions, the triol derivative **4a** forms an 87:7:6 equilibrium mixture (HPLC analysis) of **4c**, **4b** and **4a** in 20 min, from which **4b** can be separated and used again. After 15 min, the same product ratio as from **4a** is obtained, thus proving that the silyl migration proceeds reversibly in both directions. Responsible for the equilibrium

b	H	$t\text{BuPh}_2\text{Si}$	H
c	$t\text{BuPh}_2\text{Si}$	H	H

position is the preference of the bulky TBDPS group for the primary position, which is favored by ca. 8–9 kJ mol^{-1} compared to the secondary positions, but, because of the reversibility of the migration step, is only reached by trial and error. The establishment of equilibrium therefore takes longer the larger the number of the participating OH functions.

The pentol **5a** derived from D-mannitol isomerizes to **5b**, which, because of the C_2 symmetry of the unprotected mol-

b	H	$t\text{BuPh}_2\text{Si}$

ecule, can be formed by two- or threefold *O*,*O* migration. Both routes are possible, as demonstrated by the uniform formation of **7** from **6a** and **6b**. The *syn*- or *anti*-position of the OH functions to be traversed, and thus the conformational strain in the postulated intermediate **Z**,[2b] apparently have no influence on the product pattern. This experiment also proves that the silyl migration—consistent with **Z**—proceeds with retention at the carbinol centers, since **7** would otherwise be epimerized differently compared to the precursors **6a/b**.

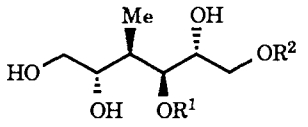
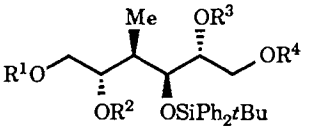
Takustrasse 3, D-1000 Berlin 33.

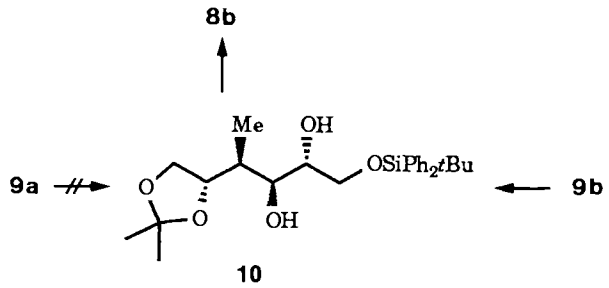
By incorporation of a methyl branch, the migration in the direction of this branching is prevented: under standard conditions derivative **8a** affords only **8b**; of the two monoacetals **9**, **9a** remains unchanged, whereas **9b** quantitatively forms **10**, which furnishes **8b** again upon cleavage of the acetal. A 1,3 shift[3] apparently does not take place. To further check this finding the 1,3-diol **11a** was investigated. Under standard conditions it does not isomerize to **11b**; only concentrated methanolate enforces this reaction, albeit with a small conversion over several days.

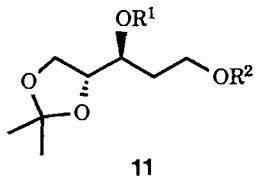




8	R^1	R^2
a	tBuPh$_2$Si	H
b	H	tBuPh$_2$Si

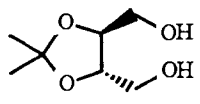
9	R^1	R^2	R^3	R^4
a	H	H	$-CMe_2-$	
b	$-CMe_2-$		H	H





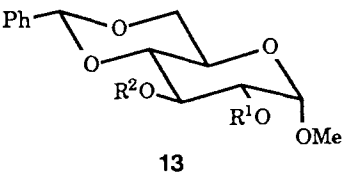
11	R^1	R^2
a	tBuPh$_2$Si	H
b	H	tBuPh$_2$Si

The silyl group migrates intramolecularly. This follows from the fact that di- or desilylation have never been observed under standard conditions. Also diol **12** added to **4a** is recovered unsilylated after establishment of the equilibrium of **4**, despite the two primary OH functions.



The structures of the products mentioned so far are unequivocally confirmed via the ^{1}H-NMR spectrum; primary OH functions are recognized by the OH multiplet, secondary OH functions by the OH doublet.[5]

Also cyclic 1,2-diols display the phenomenon of TBDPS migration. Thus, the glucose derivative **13a** is silylated with TBDPS chloride under kinetic conditions to give a 94:6 mixture of the monosilyl ethers **13b** and **13c**. Under our standard conditions, however, a 2:1 mixture of **13c** and **13b** is formed within a few minutes. Thus, kinetic and thermodynamic control afford extremely different results.



13	R^1	R^2
a	H	H
b	tBuPh$_2$Si	H
c	H	tBuPh$_2$Si

These findings can be exploited preparatively, on the one hand to obtain terminally monosilylated polyols such as **5b** or **8b** without having to deal with the relatively strongly hydrophilic and thus difficultly handleable free polyols; small amounts of secondary silyl ethers can be readily separated by column chromatography. On the other hand, two primary terminal groups can be easily differentiated via this migration. Thus, **7** is readily accessible from **6**, and its free secondary OH functions can then be benzylated together. Finally, the terminal protecting groups can be removed, separately. The same is also accomplished with the methyl derivatives **8** and **9**, so that such large monosaccharides blocks can be used in "ex-chiral pool syntheses".

General Procedure

A mixture of TBDPS-protected polyol (1.0 g in 10 mL of methanol) and saturated methanolic potassium carbonate solution was stirred at 22 °C for 10 min to 12 h (TLC control). The mixture was then neutralized with saturated ammonium chloride solution, evaporated down (rotary evaporator), taken up in dichloromethane, washed with water, dried over magnesium sulfate, and chromatographed on silica gel with hexane/ethyl acetate or ethyl acetate/methanol (**5b**/**8b**). By using a few drops of methanolic sodium methanolate solution instead of potassium carbonate the rate of migration of the silyl group could be increased considerably.

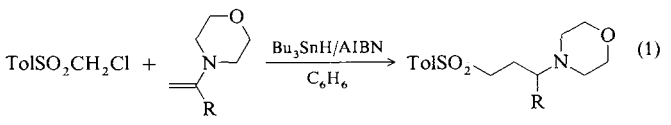
Reductive Alkylation of Enamines with Chloromethyl *p*-Tolyl Sulfone via a Radical Chain Process**

By *Philippe Renaud** and *Serge Schubert*

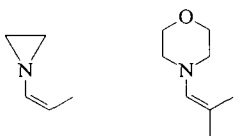
In the past few years, the addition of radicals to olefins by chain processes has emerged as a very valuable alternative to ionic reactions for the formation of carbon–carbon bonds.[1] For intermolecular reactions, the use of activated olefins is usually necessary. In most reported cases, activation is performed by lowering the LUMO of the olefins by introduction of electron withdrawing groups in order to favor their reaction with nucleophilic radicals. A few reports have been in connection with the reverse process,[2, 3] i.e. the use of olefins with high energy HOMO (electron-rich olefins) and electrophilic radicals.[4] Surprisingly, enamines have never been used for performing such reactions in a preparative way.[5] However, their use should allow the development of new strategies for the synthesis of nitrogen-containing compounds. We report here a method for the reductive alkylation of enamines with chloromethyl sulfones via a radical chain process. Particular attention has been given to the stereochemical course of the reaction[6] together with factors influencing the reaction rate.

The chloromethyl sulfone **1** reacts in the presence of tributyltinhydride and azobis(isobutyronitrile)(AIBN), with enamines which, like **2** and **3** are not substituted in the β-position, to give the products of reductive alkylation **4** and **5** in 55% and 75% yield respectively [Eq. (1)]. In the absence of AIBN no reaction takes place, and thus an ionic mechanism for these reactions can be ruled out. *cis*-*N*-(1-Propenyl)-aziridine **6** and *N*-(2-methyl-1-pro-penyl)morpholine **7** failed to react under these conditions and the product of direct reduction (methyl *p*-tolyl sulfone) was isolated in quantitative yield.



(1)

1 **2**: R = *t*Bu; **3**: R = Ph **4**: R = *t*Bu; **5**: R = Ph



6 **7**

Under the same reaction conditions, **1** reacts with cyclic enamines derived from morpholine (**8**, **9**), pyrrolidine (**10**) and azetidine (**11**) [Eq. (2), Table 1]. The major products all possess the *cis* configuration, the selectivity being especially high in the formation of the cyclohexane derivatives **13** and **14** (>95% *cis*) and somewhat lower for the cyclopentane derivative **12** (84% *cis*). The relative configurations were determined ^{1}H-NMR spectroscopically from the coupling constants and in the case of **12** and **14** by reduction with sodium amalgam[7] to the known[8] *cis*-4-[(2-methyl)cyclopentyl]morpholine and *cis*-1-[(2-methyl)cyclohexyl]pyrrolidine respectively.

Rationalization of these results in the case of the cycohexane derivatives is depicted in Figure 1. The radical adduct may exist in conformations **A** and **B**. We believe that the very high selectivity observed for the formation of **13** and **14** arises from the fact that only **A** is involved in the transition state (reaction of **B** should be less stereoselective). Kinetically, the formation of conformer **A** is favored for the same stereoelectronic reasons which govern the alkylation of

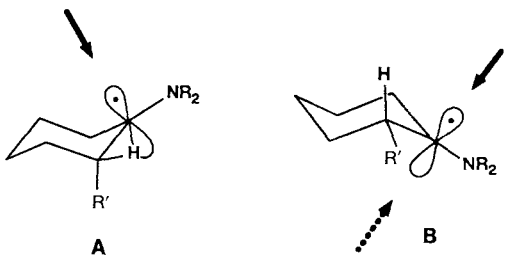

Fig. 1. Model for stereoselective H-atom transfer. Preferred and possible attacks are shown with unbroken and broken arrows, respectively. R' = CH_2SO_2Tol.

enamines.[9] The assumption that **A** is also the more stable conformer may be supported by the existence of steric interactions between the *p*-tolylsulfonylmethyl and the NR_2 groups which destabilize **B**. But even then, if **B** is the more stable conformer, the ring flip may be slower than reaction with Bu_3SnH and thus only **A** is present at the time of the reaction. A simple estimation of the interconversion rate shows that under our reaction conditions this is the case for energy barriers ≥ 12 kcalmol^{-1} (we have used an estimated value of 5×10^5 L mol^{-1} s^{-1} for the hydrogen abstraction rate constant of the radical adducts **A** and **B**.[10]) In the cyclopentane derivative **12**, the conformational changes of the radical adduct are much faster than for cyclohexane derivatives and about 16% *trans* isomer is formed.

On the basis of competition experiments, it was possible to show that the reaction of the radical generated from **1** with 1-cyclohexenylpyrrolidine (**10**) was occurring at a rate (k_a) similar to that found for hydrogen abstractions from Bu_3SnH (k_H). Since no value for k_H has been specifically reported for primary sulfonylated radicals, we assumed that

[**] We thank the Swiss Science Foundation for generous financial support.

it is of the same order of magnitude as for primary alkyl radicals[11] ($k_H = 2 \times 10^6$ L mol^{-1}s^{-1}.[12,13] A k_a value of about 10^6 L mol^{-1} s^{-1} may be deduced, indicating that the addition process is very fast. For comparison, this rate constant is similar to the one for the classical addition of a primary alkyl radical to acrylonitrile. Such a high rate constant can be, caused by two factors: a) by the stabilization of the radical intermediate via spin delocalization to the nitrogen atom,[14] and b) by the strong electron donor character of pyrrolidine enamines. The first point is important only if the addition is a late transition state process, which is usually not the case for radical additions to olefins.[15] Moreover, this contribution is similar for the different enamines. The second point plays a crucial role and has been quantified by measuring the oxidation peak potential of the enamines in acetonitrile (Table 2). Values for the first ionization potential, when found in the literature, are also reported and are in agreement with the oxidation peak potentials we have determined. Pyrrolidine enamines are easier to oxidize than morpholine enamines; this is consistent with the observation that in direct competition **10** reacts about 20 times faster than **9**. We can now explain why *cis-N*-(1-propenyl)aziridine **6** does not react: **6** is a very weak electron donor, as shown by its very high oxidation potential ($> +1.50$ V vs. Ag/Ag$^{\oplus}$). Such a behavior is characteristic for unactivated alkenes. This confirms the calculations of *Müller* and *Previdoli*[16] which predict that **6** may exist in a *trans*-bisected conformation with no possibility for n–π delocalization. As expected for radical additions,[15] steric effects also play an important role in determining the reactivity of enamines. Although the reaction of **7** with radicals is favored by electronic effects, this enamine does not react because of steric hindrance by the two methyl substituents in the β-position.

Table 2. Oxidation peak potential OP [V] vs. Ag/Ag$^{\oplus}$ (cyclic voltammetry, glassy carbon electrode, CH_3CN, 0.2 M $LiClO_4$) and first ionization potential IP_1 [eV] [17] of enamines **6**–**11**.

	6	7	**8**	**9**	**10**	**11**

[a] Irreversible oxidation (100 mVs^{-1}).

In conclusion, we have developed a new method of reductive alkylation of enamines based on a radical chain process. High diastereoselectivities have been observed with cyclic enamines. Moreover, the rate of addition of sulfinylated and sulfonylated carbon centered radicals to enamines is high enough to make the method widely applicable in inter- and intramolecular reactions.

Experimental

1 was prepared from chloromethyl p-tolylsulfoxide[18] by oxidation with 1 equivalent of *m*-chloroperbenzoic acid in CH_2Cl_2. The enamines **2**[19], **3**[20], **6**[21], 7[19] and **11**[21] were prepared by known methods. **8**–**10** are commercially available and were distilled prior to use. The new compounds were characterized by ^{1}H NMR (250 MHz), ^{13}C NMR (62.5 MHz), IR, MS and elemental analysis.

Typical procedure: A solution of 1 mmol of **1** in benzene (15 mL) was treated with 4 mmol of enamine, 0.6 mmol of Bu_3SnH and 10 mg of AIBN and the mixture heated under reflux. After 1 h, a further 0.6 mmol of Bu_3SnH and a further 10 mg of AIBN were added and reflux continued for 5 h. The reaction mixture was poured into Et_2O/toluene (1:1) and extracted with 1M HCl. The aqueous phase was treated with an excess 3 M NaOH and extracted with CH_2Cl_2. The crude product was purified by recrystallization or flashchromatography.

4: colorless oil. ^{1}H NMR ($CDCl_3$): 0.89 (s, 9H); 1.80–1.95 (m, 2H); 2.12 (dd, J = 4.0, 10.0 Hz, 1H); 2.42 (s, 3H); 2.65–2.75 (m, 4H); 3.05–3.19 (m, 1H); 3.25–3.40 (m, 1H); 3.45–3.58 (m, 4H); 7.38 (m, 2H); 7.80 (m, 2H).

5: colorless oil. ^{1}H NMR ($CDCl_3$): 1.96–2.13 (m, 1H); 2.20–2.40 (m, 5H); 2.45 (s, 3H); 2.95 (A part of an ABXY system, J_{AB} = 14.0, J_{AX} = 10.5, J_{AY} = 5.0 Hz, 1H); 3.10 (B part of an ABXY system, J_{AB} = 14.0, J_{BX} = 5.5, J_{BY} = 11.0 Hz); 3.32 (t, J = 7.0 Hz, 1 Hz); 3.60–3.68 (m, 4H); 7.05–7.12 (m, 2H); 7.20–7.40 (m, 5H); 7.72 (m, 2H).

12: m.p. 114–115.5 °C; ^{1}H NMR ($CDCl_3$): 1.10–1.28 (m, 1H); 1.60–1.88 (m, 5H); 2.20–2.40 (m, 5H); 2.45 (s, 3H); 2.50–2.60 (m, 1H); 2.70 (dd, J = 10.0, 13.0 Hz, 1H); 3.55–3.65 (m, 5H); 7.35 (m, 2H); 7.78 (m, 2H).

13: m.p. 110–111 °C; ^{1}H NMR ($CDCl_3$): 0.70–0.90 (dq, J = 3.5, 12.5 Hz, 1H); 1.10–1.55 (m, 4H); 1.70–1.85 (m, 2H); 1.95–2.10 (m, 2H); 2.20–2.35 (m, 4H); 2.45 (s, 3H); 2.52–2.62 (m, 1H); 3.08 (dd, J = 10.5, 14.0 Hz, 1H); 3.52 (m, 4H); 3.62 (d, J = 14.0 Hz, 1H); 7.37 (m, 2H); 7.80 (m, 2H).

14: m.p. 110–111 °C; ^{1}H NMR ($CDCl_3$): 0.90–1.50 (m, 5H); 1.53–1.80 (m, 6H); 1.88–2.00 (m, 1H); 2.03–2.12 (m, 1H); 2.25–2.38 (m, 4H); 2.42 (s, 3H); 2.50–2.60 (m, 1H); 3.12 (dd, J = 11.0, 14.0 Hz, 1H); 3.54 (d, J = 14.0 Hz, 1H); 7.32 (m, 2H); 7.80 (m, 2H).

15: m.p. 108–110 °C; ^{1}H NMR ($CDCl_3$): 0.60–1.00 (m, 1H); 1.10–2.20 (m, 10H); 2.30–2.45 (m, 1H); 2.46 (s, 3H); 2.85–3.05 (m, 4H); 3.04 (dd, J = 10.5, 14.5 Hz, 1H); 3.44 (d, J = 14.5 Hz, 1H); 7.35 (m, 2H); 7.80 (m, 2H).

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Comprehensive Organic Transformations. By *R. C. Larock*. VCH Publishers, Inc., New York/VCH Verlagsgesellschaft, Weinheim 1989. xxxiv, 1160 pp., hardcover, $55.00.— ISBN 0-89573-710-8/3-527-26953-3

This monograph represents a most courageous attempt by a lone author to provide in a single volume a comprehensive, highly condensed, systematic collection of literature references designed to allow for the most effective selection of a protocol for accomplishing a specific organic transformation. The outcome is an especially useful reference book that makes available at one's fingertips a wealth of information concerning a broad range of reaction types. Its nonannotated format causes it to stand apart from the Wagner and Zook compilation of the 1950s, the Buehler and Pearson two-volume set of the 1970s, and the popular Fieser series of the last two decades. The organization is based on the functional group being synthesized, each subsection focusing on a specific aspect of methodology. The innumerable reagent combinations and accompanying literature citations that are found on every page are a mine of information. The author is to be congratulated on meeting his challenging objectives so successfully.

The book treats with great thoroughness the present state of knowledge surrounding the synthesis of alkanes and arenes, alkenes, alkynes, halides, amines, ethers, alcohols and phenols, aldehydes and ketones, nitriles, and carboxylic acids and their derivatives. No attempt has been made to cover less important functional groups unless they impact indirectly on the above. Although it is possible to quarrel with the author's subjective exclusions, the wealth of topics included and their coordination have to be regarded as highly commendable.

It is relevant to deal explicitly with two chapters in order to transmit the scholarly approach taken by the author. The second chapter (Alkenes) contains ten sections, each detailing specifically a type of synthetic method useful for gaining access to this class of compounds. Under the topic of elimination can be found 51 subsections, each identifying a different precursor type (37 pages in all). Although not as lengthy, the coverage of the Wittig and allied reactions, metal-promoted couplings, and alkyne/diene addition reactions is vast and very densely referenced. The chapter dealing with aldehydes and ketones begins immediately with the topic of carbonyl transposition. Rearrangement processes are given extensive attention as are condensation, cyclization, annulation, carbonylation, and acylation schemes, to include only a few.

The literature coverage extends through 1987. A special attempt has been made to highlight reviews and significant publications separately. For this purpose, each chapter begins with a listing of general references. Although the table of contents is very adequately detailed, an extensive transformation index spanning 160 pages has been included at the rear of the book to provide additional assistance in locating citations central to the transformation in question.

In light of the rapidity of computer searches and the availability of software packages dedicated to entirely similar objectives, one might argue that such a text is superfluous today. While this reviewer does not deny the advantages of computer technology, which he profits from regularly, it is important to recognize that this book is hard copy and, as such, brings with it the many benefits associated with textual material. These benefits include the capability to scan quickly across reaction types, to browse, and to encounter relevant reactions that were not included in the initial search menu. The book presents synthetic organic transformations in a visually receptive manner and contains much of what every synthetic chemist is interested in. The density of information is unrivaled. All in all, we have in this book a manifold demonstration of the power of synthetic methodology.

This monograph will be especially useful to those who are engaged in laboratory work, since discussion and comparative analysis are nonexistent. The possibility exists for developing a course around the text, but extensive "fleshing out" would be required on the part of the instructor. The attractive price of this large volume should allow it to be purchased by all who are serious about synthesis. The possibility is real that the author has compiled during 25 years of diligent effort a reference book destined to become a classic of its time.

The Logic of Chemical Synthesis. By *E. J. Corey* and *Xue-Min Cheng*. Wiley, Chichester 1989, 436 pp., hardcover, £ 19.15.— ISBN 0-471-50979-5

The importance of synthesis for the development of organic chemistry can hardly be overestimated. The number of compounds synthesized, whether natural products or substances which have not yet been detected in nature, has increased considerably. One of the factors which has contributed to this rapid development is the formulation of rules for systematically analyzing a synthetic problem. An important additional motivation was the development of computer programs for retrosynthetic analysis.

In view of this, it is fortunate that one of the most important organic chemists who has made major contributions to the synthesis of natural products and to the development of computer programs for the planning of syntheses has taken the time to join in the writing of a book on the synthesis of natural products. The book is divided into three parts. In the first part, in six chapters, the concepts of retrosynthetic analysis are introduced. After a short historical overview there follows a discussion on the importance of the different types of reactions, and the nomenclature used to describe retrosyn-

thetic analyses is introduced. The following four chapters describe different strategies for retrosynthesis. The mix of general rules and theoretical considerations on the one hand, with the discussion of specific examples on the other, is very effective. Chapter 2 deals with the Diels-Alder reaction, the Claisen rearrangement and the Sharpless expoxidation as examples of key transformations. Chapter 3 discusses examples of the analysis of a synthetic problem starting from the educt, and the rules for the analysis of complex ring systems. These rules have here been summarized in a clear and perceptive way, relieving the reader of the laborious task of extracting them from the literature. The synthesis of diastereomerically and enantiomerically pure compounds is the subject of Chapter 4. Here there is less emphasis on systematically treating the various theoretical concepts than on specific examples of diastereoselective and enantioselective syntheses. Chapter 5 treats the synthesis of carbon skeletons using functional group transformations. Especially noteworthy are the examples of coupled transformations. Finally, in the last chapter of this part the retrosynthetic analysis of seven natural products is discussed.

The second part (six chapters) describes syntheses (with flow schemes) of over 140 compounds, mainly natural products, which have been synthesized in the laboratory of the principal author (*Corey*) during the last 30 years. The syntheses have been arranged according to the structural types of the natural products. If the reader, instead of following this sequence, reads the synthetic schemes in chronological order, he or she will gain a very good insight into the extraordinary progress of organic synthetic methodology during this period. This, together with the discussions of well chosen examples of new reactions which have been developed by *Corey*'s group to solve specific problems, gives the reader a fascinating insight into the process which the authors have called "Synthesis in Action". The chapters on prostaglandins and leucotrienes are especially well done. Several generations of synthetic approaches are discussed and compared. This well illustrates the evolutionary process, which also applies to synthetic strategies. In the other chapters one sometimes misses such comparisons with syntheses carried out in other laboratories.

Part 3 balances and complements the first two sections of the book. A compilation of some 600 structures is given, together with references to the original literature on successful chemical syntheses. In each case the structural formula and the name of the compound are followed by the principal author and the literature reference. The aim is to provide as complete as possible a review of total syntheses carried out up to 1988. The diversity of compounds which have been synthesized by nature and later by chemists is impressive. It is also interesting to see how many complex naturally occurring molecules have already been synthesized by more than one group. It is not uncommon to find ten or even more reported syntheses of one natural product within only a few years. However, it is not easy for the student to find the necessary information on these syntheses. For the inexperienced it is difficult to choose from the numerous structures and literature references, and to decide which of the reported syntheses are worth studying when planning a new synthesis.

Finally, who are the readers whom one should recommend to buy this book? In the blurb on the jacket of the book the main aim is stated to be: "to help students and research workers in chemistry to master the analysis of complex synthetic problems and the planning of syntheses". All those who are concerned with the synthesis of natural products, either as teachers or in their own research, should buy the book. Even though the first part is rather difficult to read because a special vocabulary has been introduced, the compilation of the rules for developing synthetic strategies and the illustration of these by examples are always interesting. The second section, which traces the story of the natural products synthetic work by *Corey*'s group, is full of stimulating examples. During the period covered here, natural products synthesis has developed from something of an art carried on only at a few places into a skilled craft successfully used by many groups throughout the world. In "The Logic of Chemical Synthesis" the development and applications of the concept of retrosynthesis from the standpoint of *Corey*'s group have been traced in an attractive manner. We can only hope that a paperback version will follow soon, so that undergraduate and post-graduate students too can afford to buy it. However, work on the synthesis of natural products has been pursued in many other laboratories besides that at Harvard, and it is therefore to be hoped that other eminent synthetic chemists will be stimulated to describe their work in an equally attractive manner for the benefit of the chemical community.

Chemiluminescence and Photochemical Reaction Detection in Chromatography. Edited by *J. W. Birks*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. X, 291 pp., hardcover, DM 138.00.—ISBN 3-527-26782-4/0-89573-281-5

Chemiluminescence and photochemical detectors for both gas (GC) and high pressure liquid (HPLC) chromatography are the subjects of this slim volume. There are seven chapters, which include an introduction to photochemistry, chemiluminescence detection for GC, GC detectors based on the reaction between NO and O_3, a general discussion of chemiluminescent detection in HPLC, HPLC detection based on the chemiluminescent reaction of peroxyoxalates, a general discussion of photochemical HPLC detectors, and photochemical HPLC detection based on singlet oxygen sensitization.

In the preface, the editor states that the book is "addressed to the adventurous analytical chemists who are willing to try something a little out of the ordinary to solve their analysis problems and to those researchers who would like to contribute to this very fertile field." The book appears to succeed in achieving this purpose.

Although compressed, Chapter 1 gives the novice the important aspects of photochemistry and adequate exposure to the terminology to understand the remainder of the book. Chapter 2 describes GC detection based on several chemiluminescent reactions. These reactions involve active nitrogen (an excited state produced in a discharge); a variety of reactions of ozone, including those with NO; a sulfur-specific detector based on reaction with F_2; a similar detector which uses atomic F (both detectors use microwave discharge decomposition of SF_6); a halocarbon detector that uses sodium vapor; and additional sulfur detectors that use a reaction with ClO_2 or a combination of combustion and ozone addition. These methods all require the combination of the GC effluent with the reagent in a post column mixer, where the luminescence is observed. None of these methods appears to surpass the FID in sensitivity; specificity is the attraction, particularly when the analytes are in a complex matrix.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0404-0436 $ 02.50/0

Chapter 3 discusses detectors based on the reaction of NO with ozone. A post column reactor is used to generate NO by a reaction of the analyte; ozone is then added downstream and the chemiluminescent emission measured. The first such system is specific for N-nitroso compounds which undergo catalyzed pyrolysis to form NO. Specificity for nitrogen compounds is obtained by catalytic oxidation of the effluent with O_2, since only nitrogen compounds form NO. A general detector is obtained by use of NO_2 as a reagent, which reacts with most analytes on a hot gold surface to yield NO.

HPLC detection based on solution-phase chemiluminescence is discussed in Chapter 4. Systems include luminol, lucigenin, peroxyoxalates, tris(2,2'-bipyridine)ruthenium(II), electroluminescence, and luciferin. One, or sometimes two, post-column reagent-introduction systems are used. The analytes may be catalysts which stimulate emission, or catalyst suppressors which lower emission levels. Labeling the analytes with, for example, luminol is also discussed. The entirety of Chapter 5 is devoted to the peroxyoxalate chemiluminescence reaction; the mechanism and kinetics of the process are reviewed. Hydrogen peroxide reacts with one of several aryl oxalate esters to produce an energetic intermediate, which then reacts with an acceptor (fluorophore) from which the actual light emission occurs. Hydrogen peroxide and certain classes of organic fluorophores can be detected.

Photochemical reaction HPLC detection is reviewed lucidly in Chapter 6. The introductory sections of this chapter present the limitations of HPLC detectors currently in use, the rationale for use of photochemical detectors of generally greater complexity, and the effect of post-column reactors on chromatography. This may be the best chapter in the book for the scientist unfamiliar with this field since it clearly delineates why anyone would bother with these rather complex systems and gives a good overview of their limitations as well as their advantages.

Chapter 7 discusses the use of singlet oxygen sensitization, by which the authors mean analyte-induced photooxidation of a singlet oxygen acceptor which has been spiked into the HPLC mobile phase. Here, the change in UV absorption caused by the photooxidation reaction is monitored. In favorable cases, detection limits are improved by 10–100 fold over usual UV detection.

The book is attractively produced, thoroughly referenced, and appears to be free of errors. It is recommended to anyone interested in the subject matter.

Ion and Cluster Ion Spectroscopy and Structure. Edited by *J. P. Maier*. Elsevier, Amsterdam 1989. xiv, 484 pp., hardcover, DFl. 330.00.–ISBN 0-444-87283-3

This book provides the reader with in depth and up to date knowledge concerning various aspects of the physics and chemistry of ions (including cluster ions). In particular this book, written by several leaders in their respective fields, aims to cover the subject of photon-ion interaction (spectroscopy, photodissociation and photodetachment). In addition, Coulomb explosion, high pressure mass spectrometry and metastable fragmentations are discussed as methods to elucidate the structure of ions. Some of the chapters are written very well, are based on a large basis of new and interesting findings and constitute hoped-for first competent reviews on these subjects.

The book starts with a chapter (*Z. Vager, R. Naaman, E. P. Kanter*) describing a new approach to the study of molecular structure—Coulomb Explosion Imaging—and its application to systems where classical spectroscopic methods are limited, i.e. non rigid molecules and molecular ions. This is followed by a chapter (*R. C. Woods*) on recent advances in microwave spectroscopy, including details of (22) molecular ions studied so far and their detection in interstellar space by radioastronomy. Chapter 3 (*P. Botschwina*) provides a review on spectroscopic properties obtained by the author for molecular ions with up to 7 nuclei. Special emphasis is given to effects of vibrational anharmonicity. Chapter 4 (*H. F. Schaefer III*) and Chapter 5 (*J. V. Coe, R. J. Saykally*) demonstrate the profitable alliance between a theoretical and an experimental group in order to unravel the infrared spectra of 6 polyatomic molecular ions (H_3O^+, NH_4^+, H_2CH^+, HCO_2^+, HN_2O^+, $C_2H_2^+$). Besides a brief chronology *Saykally* et al. describe several new developments in the field of high resolution infrared laser molecular ion spectroscopy. Chapter 6 (*D. M. Neumark*) discusses high resolution photodetachment studies, including both direct photodetachment and autodetachment spectra of molecular negative ions. Chapter 7 (*J. P. Maier*) consists of current progress in the characterization of open-shell cations by means of their electronic transitions. As an example, the $\tilde{B}^4\Sigma_u^- - \tilde{X}^4\Sigma_g^-$ transition of C_2^+ is discussed in detail, demonstrating the first successful probing of a fragment ion.

Chapter 8 through 13 deal with the rapidly growing field of cluster ions. This part of the book starts with a Chapter (*R. A. Kennedy, C. Y. Kung, T. A. Miller*) describing a prototype instrument in which cluster ions are analysed by time of flight mass spectrometry after spectroscopic probing by laser induced fluorescence. Chapter 9 (*M. T. Bowers*) gives a comprehensive overview on the photodissociation dynamics of small cluster ions (21 dimers and trimers). These studies yield information on the location and nature of the electronic excited states, on product branching ratios and product energy disposal. Chapter 10 (*R. G. Keesee, A. W. Castleman, Jr.*) summarizes the importance of thermochemical data for inferring structural information of solvated cluster ions and demonstrates the supportive role of adequate calculations concerning cluster ion stability. Moreover, this chapter also contains new results from photodissociation, unimolecular and collision induced dissociation of cluster cations. Chapter 11 (*N. Heinrich, H. Schwarz*) contains an essay demonstrating the intriguing gas phase chemistry of metastable cations of some keto/enol tautomers using recent experimental and theoretical data. It is postulated that loosely bound H-bridged ion/dipole complexes have to be seen as central intermediates in the low energy metastable ion decomposition of these ions. The remaining two chapters by *R. E. Smalley* and coworkers and *K. H. Bowen* and coworkers deal with the recent development of cluster anion photodetachment spectroscopy, using pulsed cluster ion sources and continuous cluster ion sources, respectively. These methods permit the study of ultraviolet photoelectron spectra of virtually any cluster of any element or combination of elements.

This book constitutes a valuable source of reference in the rapidly expanding topic of ion physics and chemistry and appears to be a must for every scientist working in the field of molecular and cluster ions.

Organometallics. A Concise Introduction. By *C. Elschenbroich* and *A. Salzer*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York 1989. 479 pp., softcover, DM 58.00.—ISBN 3-527-27817-6/0-89573-868-6

Although courses in organometallic chemistry are now offered by nearly all chemistry departments that grant graduate degrees, there are only a handful of books that are suitable as texts. The new book by *Elschenbroich* and *Salzer* on Organometallics is an attention-getting and innovative addition to this genre. As befits its moderate length (479 pp), this richly illustrated text constitutes both a dynamic and tractable choice for a ten- to fifteen-week course.

The most striking feature of this book, and one that is lacking in its chief competitors, is the extensive coverage of main group organometallic chemistry. These sections, which comprise nearly half of the book, are organized by groups of the periodic table. Admirably, the authors do far more than simply outline preparative methodology and descriptive chemistry. For example, structural features of most classes of compounds are detailed. These are frequently accompanied by MO analyses.

In the same vein, a variety of spectroscopic techniques are covered (^{6}Li, ^{7}Li, ^{11}B, ^{119}Sn NMR; Mössbauer spectroscopy), usually in the context of brief digressions entitled "excursions". As might be expected, only selected group 15 (As, Sb, Bi) and group 16 (Se, Te) elements are treated. Overall, the descriptive chemistry within the main group sections is refreshingly modern. For example, mention is made of recent work with optically active boron reagents for enantioselective organic synthesis, as well as syntheses and properties of molecules with Si=Si, Ge=Ge, and As=As bonds.

The sections on transition metal organometallic chemistry begin, predictably, with the eighteen electron rule and electron counting. Both commonly used protocols ("closed shell" and "neutral ligand" methods) are presented, but without endorsement or extensive exemplification. Hence, some supplementation may be appropriate in a course.

The subsequent chapters are organized, in contrast to the main group portion of the book, by ligand type: σ donor ligands, σ donor/π acceptor ligands, and σ,π donor/π acceptor ligands. Preparative routes to and fundamental reactions of dozens of types of ligands are systematically outlined over the course of nearly 200 pages. In common with the main group portion of the book, there are frequent and informative digressions into structural, MO, and spectroscopic topics. The authors, for reasons noted in their preface, deliberately underemphasize mechanism. One consequence is a greater "breadth of exposure" for the reader.

The book concludes with chapters on metal–metal bonds/clusters, and catalysis. The former includes an extended discussion of *Hoffmann*'s isolobal analogy. The latter focuses on homogeneous systems, and is the most mechanistically oriented portion of the text. In addition, the authors touch upon several interfaces of organometallic chemistry and biology throughout the book.

Mention should also be made of the nice historical overview of organometallic chemistry and related introductory material that is provided at the beginning of the text. However, direct literature citations are not generally given, which limits the utility of the book as a desktop reference source. Nonetheless, many key discoveries are designated by a year and the name of the principal investigator. An extensive bibliography is provided at the end of the text. The book is well indexed. However, as with most competitive texts, student homework problems are not given.

In summary, *Elschenbroich* and *Salzer* have written the textbook of choice for graduate or senior-level courses that place an equal emphasis on main group element and transition metal organometallic chemistry. They and the publisher are to be further commended for the moderate price of the softcover edition. Hence, this book can be unequivocally recommended to any teacher or student of organometallic chemistry.

Two-Dimensional Model Networks

By Heinz Rehage* and Madeleine Veyssié*

This article is concerned with the structure and dynamic properties of thin films that have been chemically stabilized by polymerization and cross-linking reactions. By using different types of monomers it is possible to construct networks with rubber-like elasticity or with glassy properties, or temporary networks, in the interfacial region between oil and water. The systematic study of these ultrathin membranes offers new insights into aspects of current research, and opens up a wide range of potential new applications.

1. Introduction

Monolayers of surface active compounds have properties resembling those of biological membranes. Such monomolecular films stabilize the boundary layer and control the exchange of material between the media on either side. Films formed from commonly used surface active agents are usually in a two-dimensional phase analogous to a gas or a liquid. Structures of this kind are by their nature very unstable, and can easily be broken down by external forces. Questions relating to stability are crucially important in technological applications. There has therefore been much interest in techniques for transferring such films onto solid materials such as mica, glass, silicates, metals, or even semiconductors (Langmuir–Blodgett films). The strength of the membranes can thereby be greatly increased due to the reinforcing effect of the solid support, and this opens up a wide range of new applications.

Polymerization and cross-linking reactions offer an alternative method of stabilization (Fig. 1) which is completely different in nature. The most detailed studies carried out up to now on the mechanisms of the reactions involved have been concerned with the water-air interface. A detailed discussion of recent developments and current topics of interest in this area can be found in the comprehensive review article by *Ringsdorf* et al.[1] During surface polymerization the conformations and spatial arrangement of the monomers alter,

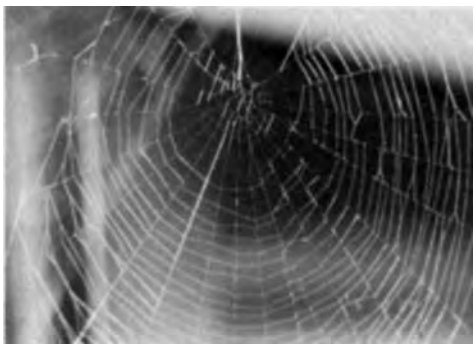

Fig. 1. A fiber net as a simple example of a "two-dimensional cross-linked" system. The thickness is practically constant ("invariance"), whereas the other two dimensions are not fixed. Two parameters are therefore sufficient to describe the dimensions.

in a way similar to that in three-dimensional polymerization. This usually leads to experimental difficulties caused by contraction or (surface) dilatation of the film. In extreme cases this can completely prevent the formation of a continuous film. At the interface between water and air these processes can be controlled; the equilibrium distance between the molecules is continuously monitored during the polymerization by measuring the surface pressure, and the reaction variables are adjusted as necessary.[1] This can be achieved by using a film balance or by other experimental techniques. In this way one can obtain orientated macromolecular layers of high stability. Films of this kind often exist in a solid two-dimensional phase, and their properties have been intensively studied, especially in the case of diacetylenes.[2, 3]

Similar problems due to shrinkage processes during polymerization arise in the case of the oil-water interface. However, these effects can be more effectively controlled than at the water-air interface, and even automatic correction is possible. In this case the monomers are soluble in one of the two phases of different polarities, resulting in a large excess concentration in that phase. If film defects then occur during the polymerization, diffusion of monomer molecules from the adjacent phase brings about a repair process, leading to an intact network structure. Comparable repair mechanisms are only possible at the water-air interface by using monomers that are to some extent soluble in water. However, most macromolecular compounds are hydrophobic, and can only be converted into water-soluble compounds by attaching strongly polar groups. Nevertheless, the monomer should not possess too much surface-active character, since that would lead to the formation of aggregates (micelles) in which the molecules are tightly packed. Under these circumstances the surface polymerization is also accompanied by chemical reactions occurring within the micelles, leading to further complications. For this reason one aims to have a system in which only single monomer molecules are in solution in the water phase. With a suitable choice of conditions at the interface one can arrange that the average distance between the reacting molecules in the solvent is very large, whereas the molecules at the interface are densely packed owing to adsorption. Under these conditions the polymerization and cross-linking reactions are confined to the interfacial region itself. The adjacent phase acts only as a reservoir, supplying new monomer molecules as required for the formation of the network. Mechanisms of this type are especially easy to control at the water-oil interface. After polymerization and crosslinking one obtains stable films, leading to a number of interesting technological applications, such as microlithography, dialysis, ultrafiltration, reverse osmosis, separation of gases, and desalination of sea-water. As well as industrial applications there are many potential applications in biological fields. The functions and importance of two-dimensional networks in living organisms have been thoroughly reviewed in two articles by *Burchard*.[4, 5]

In interfacial polymerization one is not restricted to flat surfaces; the methods based on it can also be used with curved phase boundaries. Oil droplets suspended in water can be encapsulated in thin network structures by polymerization of surface active molecules. The cross-linked films on the surfaces of the droplets have an appreciable stabilizing effect on the spherical shape. Such emulsions represent a new kind of microencapsulation. As in the case of living cells, the deformation of the droplets depends on the elasticity of the surrounding membrane. In a flow field one observes quite marked deformations and orientation processes similar to those occurring in red blood cells (erythrocytes) and other living cells. The encapsulated oil droplets have a very simple structure, and therefore represent a suitable model system for studying these phenomena. Microcapsules of this kind are also suitable for controlled release of active substances stored in either the oil or the water phase. The network of the surrounding membrane acts as a semipermeable barrier, allowing only a limited diffusional flow though the boundary layer. Thus it is possible, for example, to release drugs in a controlled manner over long periods. Because of these numerous areas of application, there is now worldwide interest in synthesizing new types of polymer films, and the microscopic and macroscopic properties of these substances are the subject of extensive studies ranging from fundamental problems to technological products.

2. Monomer Systems

Cross-linked membranes can be divided into two classes according to the nature and strength of the bonding forces. In so doing one is essentially making a distinction between temporary and permanent networks. When the bonding between the molecules is a result of chemical reactions, the structures are always of the permanent type. The strength of covalent bonds between carbon atoms is of the order of 100 to 400 kJ mol^{-1}, resulting in very high stability of the corresponding structures. The opposite extreme occurs when the linking arises from entanglements, i.e. frictional interactions

Heinz Rehage was born in 1952 in Aachen, FRG. He studied chemistry at the universities of Clausthal-Zellerfeld (Vordiplom in 1976), Göttingen (Diplom in 1979) and Bayreuth, where he earned his Ph. D. under the supervision of Prof. H. Hoffmann (1983). He spent one year as a postdoctoral fellow at the Collège de France in Paris (Physique de la matière condensée), where he started his work on two-dimensional model networks in cooperation with Prof. P. G. de Gennes and Prof. M. Veyssié. After his Habilitation in 1989 he was appointed to his current position as "Privatdozent" in the department of physical chemistry at the University of Bayreuth. His research interests include rheology, surfactants, ultrathin organic films and microcapsules. He has been awarded the "Dozentenstipendium" of the Fonds der Chemischen Industrie.

and mechanical interferences between the molecules. For small external forces and over short periods these attachments act in a similar way to permanent linkages, and confer elastic properties on the structures. However, under greater external forces and longer loading times these mechanical linkages can become broken by diffusional motion of the molecules, resulting in a reduction in the number of cross-linking sites. These dynamic molecular rearrangement processes, referred to as relaxation phenomena, ultimately result in the external stresses decaying to zero. In the ideal case the behavior of the system after a long period is characteristic of a liquid. Thus, networks in which the contacts between the molecules arise solely from mechanical attachments exhibit both elastic and viscous properties. The fundamental physical properties show a marked dependence on the duration of the measurements or on the frequency, a type of behavior well described by the expression "temporary network".

A wide variety of other types of bonding, lying between the two extreme cases of chemical and physical network forming mechanisms, are now known. Most of these are physical contact mechanisms, and include hydrogen bonding, complex formation, coulombic interactions and dipolar forces. It is usually possible to break these types of bonds by heating or adding suitable solvents giving non-cross-linked systems which can be reversibly restored to the gel state by cooling. Systems with these special properties are described as "thermoreversible". The bond energies for physical contacts are low in comparison with those for covalent bonds, usually being of the same order as the thermal energy kT. For this reason only a small fraction of the maximum possible cross-linking sites usually contributes to the stability of the gel. Thus a thermodynamic equilibrium is established between the points of attachment and other sites that are potential linkage points but still remain free. In the equilibrium condition the number of new cross-links formed per unit time is constant, and is exactly equal to the number of existing linkages broken during the same interval. Consequently, on a time-averaged basis no change is observed in the concentration of cross-linking sites.

However, there are positional variations, which occur as a result of kinetic effects (Fig. 2). When the period of observation is appreciably shorter than the average lifetime of a point of attachment, a gel of this type appears to be fully cross-linked. However, over longer periods variations appear, and some of the linkages that are subjected to mechanical forces become broken. As a result those molecules that are under stress have more degrees of freedom and can undergo diffusional motions which have the effect of relieving the forces. Consequently any external work applied to the system becomes completely dissipated after a time, i.e. it is converted irreversibly into heat. Under these conditions the viscous properties of the temporary cross-linked structure are dominant. Thus, in contrast to permanent networks, the dynamics and kinetics of temporary gels play a considerable role, with the result that the structures show quite different behavior patterns depending on the time scale of the observations.

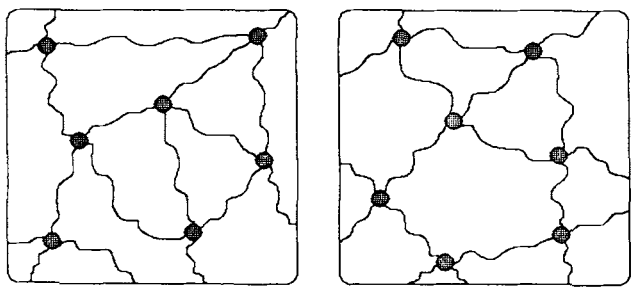

Fig. 2. Diagrammatic representation of the fluctuations in a dynamic network. Both figures contain the same number of cross-linking sites, but these are in different positions.

In order to synthesize two-dimensional networks with this temporary character, monomers with certain properties are needed. In addition to a functional group which can form linkages to neighboring molecules, hydrophilic and hydrophobic chains are essential to give the molecules the required amphiphilic character. Stabilization mechanisms depending on hydrogen bonding are very common in nature. Phenomena of the same kind can readily be recognized in the behavior of surface active agents, in circumstances where the polar head-group of the molecule has access to a large number of free hydroxyl groups. This is the case for "sugar-type" surface active agents, a class of compounds obtained by the esterification of various polysaccharides with long-chain fatty acids. The elasticity of the corresponding films is only noticeable in observations on a short time scale. When a force is applied for a longer period such films begin to flow, and the molecules rearrange to form new structures with quite different properties. When the external forces are removed the original condition starts to reestablish itself by kinetic processes, and the intact structure is restored. Thus, films of this type show "self-repairing" behavior, which opens up interesting possibilities for new technological applications.

For chemically cross-linked systems, other types of reactive groups which can form bonds to neighboring molecules are needed. Those reported in the literature up to now are various classes of surface active monomers, often related to naturally occurring lipid molecules. A detailed review of these is given in the article by *Ringsdorf* et al.[1] As well as conventional surface active agents such as dialkylmethylammonium salts, the types of compounds investigated have included phospholipids, diacetylenes and esters of various acids. All the experiments carried out have been concerned with the water-air interface, and the measurements have usually been made using a film balance. Surprisingly, there have been few studies of the rheological properties of the polymerized films. For the oil-water interface the choice of suitable monomers is determined not only by the criteria of reactivity and surface activity, but also by solubility considerations. The nature and mechanism of the two-dimensional polymerization reaction raise further questions that need to be considered when synthesizing the network. In principle, one can prepare macromolecular membranes using the same methods as are already used to form three-dimensional networks. Among the most important of these reactions are typical synthetic methods of macromolecular chemistry, such as polycondensations and free radical polymerizations.

The best known heterogeneous polycondensation reaction carried out at the oil-water interface is a variant of the Schot-

ten-Baumann reaction, in which a dicarboxylic acid dichloride is reacted with the appropriate diamine or diol.[6-9] A graphic demonstration of this, which is also suitable for illustrating a lecture, is the following experiment: 3 mL of sebacyl dichloride (1,8-octanedicarboxylic acid dichloride) is dissolved in 100 mL of carbon tetrachloride, and a solution of 4.4 g hexamethylenediamine in 50 mL of water is carefully added to form a top layer; an ultrathin film then forms at the interface, and this can easily be lifted off using a fine glass tube ("nylon rope trick").[7] This process is technologically important in the manufacture of polycarbonates, and can be used to synthesize polymers with high molecular mass. However, detailed studies of the polymerization kinetics, in particular by *Enkelmann* and *Wegner*,[8, 9] have shown that reactions of this type are largely diffusion-controlled. The hydrated diamine molecules are also slightly soluble in the oil phase, and can therefore diffuse through the film at the interface and react at their non-polar ends with further acid chloride. This leads to the formation of stable films whose thickness increases as the reaction continues.[8, 9] By using solutions of different concentrations the growth of the thin films can be controlled over a wide range. However, this gives structures whose thicknesses are not very well defined, and their use for investigating true two-dimensional phenomena is therefore somewhat limited.

Free radical polymerizations at the interface between two liquids can be performed using relatively simple techniques. Unlike the situation with polycondensations, only one chemically active component is needed, and the reaction can be initiated very easily using UV irradiation. This gives simple systems which can be studied under well-defined conditions. By controlling the light intensity and choosing suitable wavelengths one can vary the radical concentration over a wide range, giving complete control over the growth of the network.

The simplest monomers capable of undergoing photopolymerizations of this kind are bifunctional esters such as diacrylates, dimethacrylates or diallyl esters. Depending on the molecular structure and rigidity of the hydrocarbon chain, molecules of this kind can be used to prepare cross-linked membranes with either rubber-like or glassy properties. The special properties of such structures will be briefly described in the following sections.

3. Experimental Techniques

3.1. Synthetic Methods

Many of the amphiphilic compounds capable of forming cross-linked films at an interface are commercial products available from a variety of chemical manufacturers, and can therefore be obtained relatively cheaply in large quantities. An example of such a compound is Span 65, a trioctadecanyl ester of sorbic acid, which forms temporarily cross-linked membranes even at relatively low concentrations. Chemically stabilized neworks, on the other hand, can be prepared using unsaturated diesters such as tetramethylene diacrylate or bisphenol-A dimethacrylate. Some of these compounds are obtainable in commercial quantities, and others can easily be synthesized in the laboratory by reacting acid chlorides with the appropriate diols. However, in order to form network structures that are as perfect as possible, careful purification of all the monomers used, including solvents, is essential. It has been found that even the minutest amounts of contaminants can interfere with the formation of the film, and the requirements with regard to the purity of the substances involved are therefore extremely stringent. These difficulties can be avoided by using chromatographic separation methods such as MPLC (medium pressure liquid chromatography) or HPLC (high performance liquid chromatography); the efficiency of these methods has reached remarkable levels in the last few years. It is now possible, by using these techniques, to quickly and reliably purify even quite large quantities of substances.

3.2. Apparatus

The first requirement for synthesizing two-dimensional networks is a knowledge of the adsorption behavior of the monomers. This is obtained by measuring the surface tension at the interface, which is related to the characteristic properties of the film. Various measuring techniques are available for precisely determining the fundamental quantities; these include the ring method, the stirrup method, and the pendant drop method. Details of the execution of such experiments and the calculation of results from the experimental data can be found in the literature.[10, 11]

The physical properties at an interface are different from those of the three-dimensional phases on either side of the boundary. The elastic and rheological properties of the film are determined using special instruments called surface rheometers or interfacial rheometers which are described in the literature. The measuring probe consists of a thin disk or platinum ring which is precisely positioned in the interface. This device then undergoes either a sinusoidal or a square-wave deformation, and one measure the torque which this motion produces. Full details of the apparatus and the method of carrying out the measurements are described in a number of review articles.[12-28]

The flow properties of encapsulated emulsion droplets can be determined by using sensitive capillary rheometers or rotating viscometers.[29, 30] The deformations of the droplets are investigated using a flow cell which is incorporated into a microscope. In this way one can study rheological phenomena at high optical magnifications.[28, 31, 32]

4. Adsorption Properties

Thermodynamic arguments indicate that the higher concentrations of amphiphilic monomers which occur in the interfacial layer between oil and water are associated with a lowering of the interfacial tension. For dilute solutions and under conditions in which there are no interactive forces between the molecules, this process can be described by the Szyskowski equation [Equation (a)].[33]

$$\gamma = \gamma_0 - RT\Gamma_0^{\infty} \ln(1 + cB^{-1}) \qquad \text{(a)}$$

In this equation Γ_0^{∞} is the saturation concentration of the film (maximum number of molecules per m^2) and γ is the

interfacial tension. The thermodynamic properties of the pure oil-water interface are represented by the symbol γ_0. c is the monomer concentration in one of the adjacent three-dimensional phases. The quantity B is a constant which is specific to the particular monomer, and is related to the chemical adsorption potential $\Delta\mu_0$ as shown in Equation (b).

$$B = 55.4 \exp[\Delta\mu_0^\sigma (RT)^{-1}] \quad \text{(b)}$$

The Szyskowski equation is obtained by combining the Langmuir adsorption isotherm with the Gibbs adsorption law. These two fundamental equations are only valid under ideal conditions in which there are no interactions, and in which the adsorption process is limited to the formation of monomolecular layers. The Szyskowski equation can therefore only be applied to simple systems. The special importance of this relationship lies in the fact that it gives a complete description of the experimental data. By performing a dual parameter fit one obtains the characteristic saturation concentration for the film and the chemical adsorption potential. From these two quantities the excess Γ of the surface active component can be calculated (Langmuir adsorption isotherm, Equation (c)).

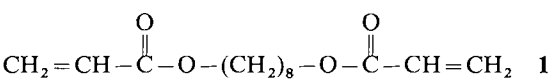
$$\Gamma^\sigma = \Gamma_0^\sigma c(B + c)^{-1} \quad \text{(c)}$$

The quantity Γ^σ specifies the degree of enrichment of the amphiphilic molecules in the surface layer. Monomer molecules are also present in the adjacent solvent phase, and the term Γ^σ thus gives the excess of adsorbed molecules compared with the concentration in the solvent. For low monomer concentrations Γ^σ is a measure of the packing density of the molecules (number of molecules per m^2 of surface). The area occupied by one monomer molecule is given by Equation (d).

$$F = (\Gamma^\sigma)^{-1} \quad \text{(d)}$$

The quantity F is related to the conformation and dynamic properties of the monomer molecule. With the help of suitable computer models it is possible to deduce important information about the adsorption process from the value of F.

Some typical results from measurements of the interfacial tension of octamethylenediacrylate **1** as a function of the ester concentration are shown in Figure 3. In this experiment



the monomer **1** under investigation has two terminal double bonds and therefore readily forms cross-linked membranes. For very low ester concentrations the interfacial tension between water and *trans*-decalin was found to be 5.12×10^{-2} Nm^{-1}, which agrees with the literature value for the pure oil-water interface. With increasing ester concentration the interfacial tension between the two liquids becomes smaller. The downward trend of the curve is related to the formation of a monomolecular film. It can be seen from Figure 3 that there is good agreement between the results obtained by the different experimental methods. The continuous line is the theoretical curve for the values $\Gamma_0^\sigma = 1.1 \times 10^{18}$ m^{-2} and $\Delta\mu_0^\sigma = -25$ kJ mol^{-1} (dual parameter least squares fit). From these two values one can calculate further properties of the surface active molecules. If it is assumed that each electron lone pair of the oxygen atoms can form not more than one hydrogen bond, with an average bond energy of 4 kJ mol^{-1}, the observed value of $\Delta\mu_0^\sigma$ indicates that there are about six bonds per molecule. As the octamethylene diacrylate molecule has a symmetrical structure, it appears on energetic grounds that both head-groups take part in the same type of adsorption. According to this only even hydration numbers occur. When the ester molecule is adsorbed the chain conformation alters, and on grounds of symmetry it must be concluded that instead of the low-energy *trans* conformation there are now three *cis* or *gauche* conformations. For this to occur requires an energy contribution of approximately 3 kJ mol^{-1} per chain segment. Thus the observed value of 25 kJ mol^{-1} is in excellent agreement with a symmetrical arrangement of the molecules in the interfacial layer, with all the electron lone pairs of the oxygen atoms fully hydrated. From the saturation value Γ_0^σ one obtains a value of 0.9 nm^2 for the area occupied by each molecule. From this one can calculate the molecular arrangement of the adsorbed diester molecules at the interface (Fig. 4). Here the value of 0.9 nm^2 for the interfacial area per molecule corresponds to a molecular arrangement in which the two polar head-groups are anchored in the aqueous phase, while the octamethylene chains form an arc across the molecule. If we assume that there is free rotational motion, the

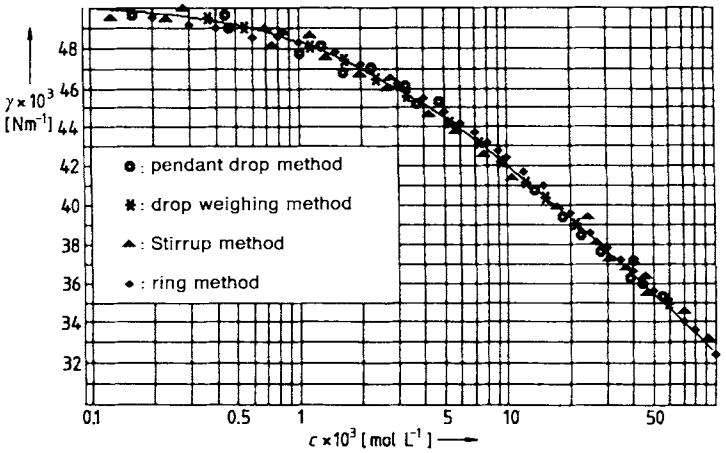


Fig. 3. The interfacial tension of octamethylene diacrylate as a function of ester concentration. Interface: water-*trans*-decalin, $T = 20$ °C.

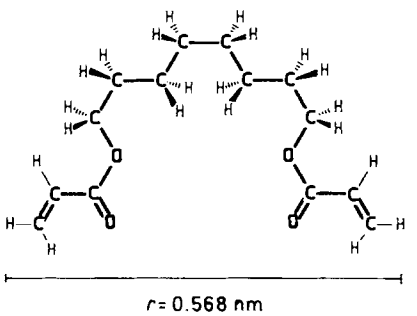

Fig. 4. Conformation of octamethylene diacrylate at the oil-water interface ($T = 20$ °C).

observed surface requirement per molecule gives an average molecular radius $r \simeq 0.54$ nm, in fairly good agreement with the theoretical value of 0.568 nm. Similar conformations have also been found for monolayers of other diesters,[28, 34–36] The theoretical relationships discussed here can therefore be applied in a similar way to other related systems.

5. Films with Rubberlike Elasticity

Diesters with flexible hydrocarbon chains form membranes with rubber-like elasticity when the polymerization is complete. This behavior is visible even with the unaided eye, and can be shown by the following simple experiment, which is also suitable as a lecture demonstration.

Some water in a glass beaker is covered by adding a 0.01 molar solution of hexamethylene diacrylate in dodecane, and this is then irradiated for about 4 h with a low pressure mercury vapor lamp (wavelength 253.7 nm). After allowing about 8 h for the reaction to proceed, a fully cross-linked film is obtained. The highly elastic nature of this membrane can be shown by scattering tracer particles (paper or metal filings) on the interface and deflecting the film mechanically with a needle. On removing the pressure the film springs back sharply, as is seen from the motion of the tracer particles. This simple experiment can also be shown to a large audience by placing the beaker on an overhead projector and thus observing the motions of the tracer particles.

The polymerization and cross-linking of the adsorbed molecules can easily be followed by monitoring the rheological properties of the film as a function of time. Some typical results on the kinetics of network growth are shown in Figure 5. The curve shows the increase of the two-dimensional modulus of elasticity as a function of the reaction time t. The irradiation was stopped after 250 min; the growth of the network was allowed to continue, and this resulted after 460 min in a transition from a sol to a gel. Below this transition point the polymer consists mainly of linear chains, whereas above it cross-linked chains predominate. The gel point is defined in terms of the coherence of the system, and is the critical point at which a single "infinitely" large molecule is formed. The two-dimensional phase transition can be described mathematically using percolation theory.[37, 38] If the number of chemical bonds formed is assumed to be proportional to the reaction time, the relationship shown in Equation (e) is obtained.[16, 36, 39–41]

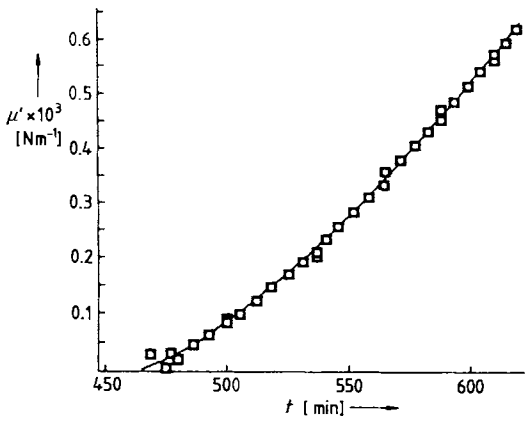

Fig. 5. The two-dimensional elastic modulus as a function of reaction time in the photopolymerization of octamethylene diacrylate at the interface between water and *trans*-decalin ($T = 20$ °C, UV wavelength 254 nm, radiation intensity 5×10^{19} photons m^{-2} s^{-1}, duration of irradiation: 250 min, $c = 5$ mmol L^{-1}, deformation = 0.15%).

$$\mu' \approx C(t - t_{gel})^x \qquad \text{(e)}$$

A simple analysis by *de Gennes* shows that x is approximately equal to the two-dimensional exponent for the electrical conductivity.[16, 37, 42] This number is of the order of 4/3.[37, 38] According to this, one expects to find a steep increase in the elastic modulus after passing the gel point. The individual squares in Figure 5 correspond to the experimental data, and the continuous line shows the result of fitting these to the theoretical equation (e). From the dual parameter fit one obtains a value $x = 1.4 \pm 0.1$ for the critical exponent. The gel time is $t_{gel} = 460 \pm 5$ min. Experiments with different conditions still give values of the same order of magnitude for the exponent, and the average value from several experiments[16, 28, 36, 41] is $x = 1.4 \pm 0.1$. It is interesting to note that the same value for the exponent has also been found for cross-linked membranes of the glassy type.[28, 41] Thus Equation (e) is a universal relationship which is independent of the type of network. However, more detailed considerations force one to recognize that the analogy between elasticity and electrical conductivity rests on simplified assumptions, which are not always valid in practice. In particular, the effects of ring closures, entanglements and the free ends of chains are matters which continue to provoke further discussion. Kinetic processes such as diffusion and relaxation phenomena can also cause departures from the simple theory. It has recently become possible to study these types of phenomena by Monte-Carlo computer simulation methods, but owing to the large amounts of computer time needed such calculations have only been carried out for a few cases. However, in view of the rapid progress in the field of digital electronics one can expect that calculations of this kind will become increasingly important in the next few years. Also of interest are other theoretical approaches concerned with analyzing network formation by means of fractals. Cross-linked membranes are suitable models for all these fields of study, and can therefore be used in a variety of ways for testing theories.

Percolation theories only describe the formation of the network in the regime near to the sol-gel transition. A generalized description of two-dimensional polymerization can be derived from kinetic theories based on the fundamental studies by *Flory*.[28, 36, 44]

Four reaction stages are distinguished, as described in Equations (f) to (i).

$$\text{Chain initiation:} \quad M \xrightarrow{UV} R \qquad \text{(f)}$$

$$\text{Chain growth:} \quad R + M \xrightarrow{k_p} P_1 \qquad \text{(g)}$$

$$\text{Cross-linking:} \quad P_1 + R \xrightarrow{k_p} P_v \qquad \text{(h)}$$

$$\text{Termination:} \quad R + R \xrightarrow{k_a} R - R,\ R_1 + R_2 \qquad \text{(i)}$$

A fraction of the monomer molecules are converted by the UV radiation into reactive radicals. These can then grow into linear chains with the rate constant k_p. Linear chains and free radicals then react further to give a cross-linked polymer. If two radicals collide this results in a chain-terminating reaction, which has the rate constant k_a.

From Equations (f) to (i) one can derive a simple relationship describing the increase in elastic modulus [Equation (j)].[26]

$$\mu'(t) = \mu'(\infty)\{1 - \exp(-k_p[R](t - t_{gel}))\}^2 \quad (j)$$

In this equation [R] is the free radical concentration and t_{gel} is the time to gel formation. $\mu'(\infty)$ is the final elastic modulus attained by the network. By applying Equation (j) it is possible to obtain more detailed information about the polymerization mechanism. Figure 6 shows a comparison between theoretical calculations and experimental results.

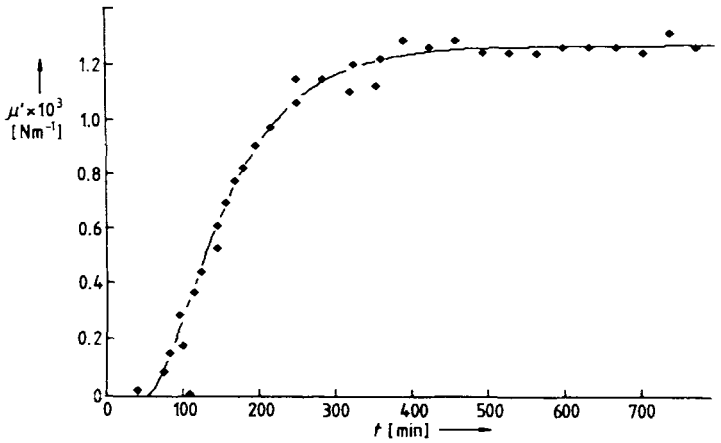

Fig. 6. The two-dimensional storage modulus as a function of reaction time in the photopolymerization of octamethylene diacrylate at the water-dodecane interface ($T = 20\,^{\circ}C$, UV wavelength 254 nm, radiation intensity 8.5×10^{19} photons $m^{-2}\,s^{-1}$, duration of irradiation 150 min, $c = 5$ mmol L^{-1}).

The individual points correspond to the experimental data, and the curve was obtained by fitting Equation (j), with a value k_p [M] $= 2 \times 10^{-4}\ s^{-1}$ for the network growth rate. The four-stage reaction model (Equations (f)–(i)) thus appears to represent a good approximation. As predicted by the theory, the formation of the coherent network begins only when the gel point ($t = 50$ min) is passed. In this region the elastic modulus increases rapidly, as predicted by the kinetic equations and also by percolation theories. At longer reaction times a constant final value is reached. In this region all the chemical reactions have ceased and the two-dimensional structure is fully formed.

The final value of each of the elastic properties that can be measured is unaffected by the growth parameters. If the rheological properties are measured at different frequencies, constant values are obtained for the moduli, showing no evidence of relaxation processes. By analogy with three-dimensional systems, the behavior is described as showing a rubber-like elasticity plateau. The elastic modulus remains constant up to quite large deformations, and evidence of a breakdown of the structure only begins to appear at about 60% elongation. If one assumes that the diester molecules are in a symmetrical arrangement (Fig. 5), this strain value corresponds to a situation in which the monomer molecules are stretched into the all-*trans* conformation. Thus the elastic properties of the cross-linked membranes are a direct consequence of molecular motion mechanisms. The "source" of the elastic behavior must therefore be sought within the monomer unit, and the rheological phenomena can be attributed, in the simplest cases, to mechanisms involving deformations of the hydrocarbon chain. Under these ideal circumstances one expects to find a simple relationship between the final elastic modulus $\mu'(\infty)$ and the number of adsorbed monomer molecules Γ^{σ}. Applying the theory of rubber elasticity to two-dimensional systems gives the simple relationship shown in Equation (k).[28, 36, 43]

$$\mu'(\infty) = A\Gamma^{\sigma}kT \quad (k)$$

The proportionality constant A is called the structural factor. It depends on the type of network and on the functionality of the linkage. For three-dimensional systems proportionality factors of the order of 1/3 to 1 are found, and similar values are expected to apply for cross-linked membranes. However, the exact form of the relationship between network structure and the proportionality factor A is not yet known, for either the three- or the two-dimensional case.

According to Equation (k) the final elastic modulus of the cross-linked membrane is determined essentially by the surface concentration of the adsorbed molecules. Ring closures, entanglements and free chain ends have initially been disregarded in deriving this expression, and if necessary they must be taken into account by including additional terms. Thus, Equation (k) is valid only under ideal conditions, but these are quite easy to achieve in the two-dimensional case. Since both $\mu'(\infty)$ and Γ^{σ} can be determined quite well by rheological experiments and measurements of the interfacial tension, there are a number of ways whereby theoretical predictions can be tested. For all the rubbery elastic networks that we have investigated so far, Equation (k) has been shown to be valid, the proportionality factor A being of the order of 1.[28, 36, 45] Thus the cross-linked membranes behave as ideal networks and obey the elasticity relationships that apply for rubbery materials.

6. Membranes with Glassy Properties

Diesters which contain rigid hydrocarbon chains form, on completion of photopolymerization, networks that exist in a glass-like state. This phenomenon can also be observed easily with the unaided eye. It can be demonstrated by the following simple experiment.

Some water in a glass beaker is covered by a 0.005 M solution of bisphenol-A dimethacrylate in dodecane, and this is irradiated for 4 h with a low-pressure mercury vapor lamp (wavelength 253.7 nm, or better still the 365 nm line). After a reaction time of 24 h the cross-linked film is obtained. The strength of the structure can be demonstrated by scattering tracer particles (paper fragments or metal filings) onto the interface and carefully deflecting the film with a

needle. In contrast to the rubbery elastic films, no elastic recovery is observed; instead there is only a viscous resistance caused by the cross-linked membrane.

During the photopolymerization of such a glassy film one observes phenomena similar to those seen for rubbery elastic structures. The sol-gel transition can be fully described by percolation theories, and the growth of the network is subject to the same kinetic relationships.[28,41] As well as monomolecular films it is possible, at high ester concentrations, to form multilayer films. This can be seen from Figure 7, which clearly shows the stepped form of the network growth process.

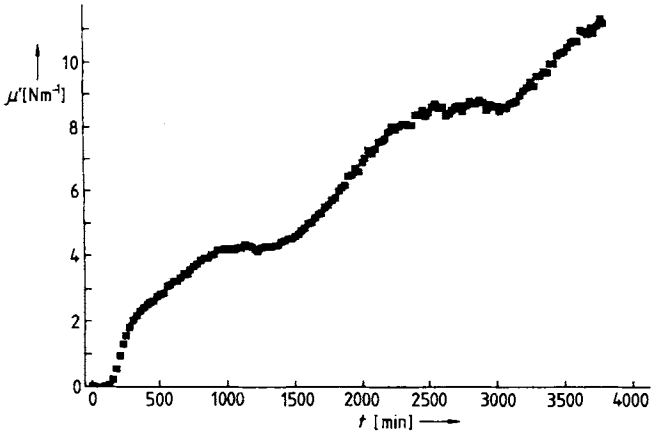

Fig. 7. The two-dimensional storage modulus as a function of reaction time in the photopolymerization of bisphenol-A dimethacrylate at the water-dodecane interface ($T = 20\,^{\circ}C$, UV wavelength 254 nm, duration of irradiation: 180 min, $c = 12$ mmol L^{-1}, angular frequency $\omega = 0.01\ s^{-1}$, radiation intensity 4.1×10^{18} photons $m^{-2}\ s^{-1}$).

With increasing ester concentration one expects to find that polymer molecules are also formed in the solvent. However, the highest ester concentrations occur at the oil-water interface, and it can be assumed that this is where the radical chain reaction is initiated.

Evidently the growth of the network takes place in several stages. The UV irradiation was switched off after 180 min. This period of time corresponds to that needed to reach the sol-gel transition. At about $t = 1300$ min a cross-linked membrane is formed, and this acts as the seed for the further growth processes that follow. Evidently, new layers can form on top of this basic structure, and the first of these is complete at about 2800 min. The (two-dimensional) elastic modulus now has twice the value found for the original film. As the reaction proceeds more of these networks are added, until eventually the polymerization ceases as a result of chain-terminating radical reactions. The tendency to form multiple layers increases with the ester concentration and the duration of UV irradiation. True monomolecular films are only obtained when the values of both these variables are small.

The main difference between the rubbery elastic membranes and the glassy cross-linked films is in the order of magnitude of the rheological constants. The first thing one notices is that the networks formed by rigid monomer molecules already suffer irreversible damage when subjected to deformations as small as 0.1%. The (two-dimensional) shear modulus is of the order of 5 Nm^{-1}. Since the film has a uniform thickness of 10^{-9} m, this corresponds to a three-dimensional "equivalent shear modulus" of $5 \times 10^{9}\ Nm^{-2}$. For normal polymers in the glassy range the shear modulus is between 10^{9} and $10^{11}\ Nm^{-2}$, and the two-dimensional structure therefore resembles a phase with frozen segmental mobility. From the threshold strain value (0.1%) and the equivalent shear modulus one obtains a yield stress of $5 \times 10^{6}\ Nm^{-2}$. The tensile strength of three-dimensional glassy polymers is of the order of $10^{7}\ Nm^{-2}$. These simple comparisons show that there are clear parallels with the three-dimensional glassy state.

7. Temporary Films

To prepare films that are physically cross-linked one requires molecules with polar head-groups that are capable of forming hydrogen bonds. Sugar-type surface active compounds are well suited for this purpose, as they have active centers with free hydroxyl groups. A typical surface active agent with these special properties is sorbitol trioctadecanate, which is commercially available under the name Span 65.

If some water in a glass beaker is covered with a 5×10^{-4} M solution of Span 65 in dodecane, a cross-linked film is formed. The strength of the structure can be shown by scattering tracer particles onto the interface and carefully deflecting the membrane with a needle. A viscous resistance is observed, and this is easily seen if the motions are rapid. For slow deformations, however, there is no noticeable hindrance to the motion.

The rheological properties of such membranes indicate the existence of temporary cross-linking points. This can be seen from Figure 8, which gives an insight into the structural

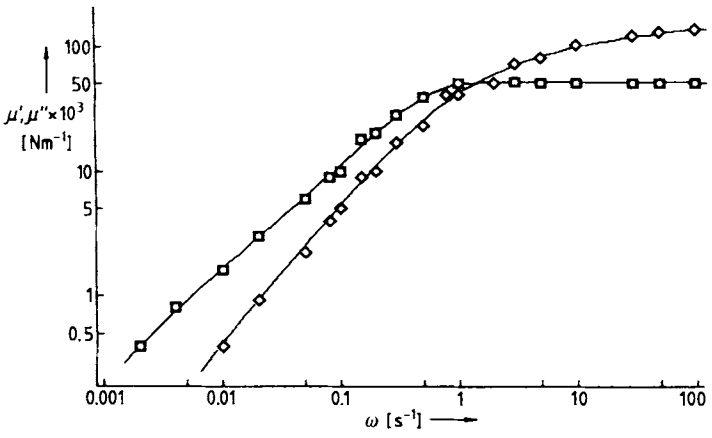

Fig. 8. The two-dimensional storage modulus μ' and two-dimensional loss modulus μ'' as functions of the angular frequency for a temporarily cross-linked film of Span 65 at the water-dodecane interface (deformation 0.2%, $T = 20\,^{\circ}C$, $c = 0.5$ mmol L^{-1}).

dynamics. In this experiment the two-dimensional storage modulus and the two-dimensional loss modulus were measured as functions of the angular frequency ω; μ' is propor-

tional to the elasticity of the film and μ'' is related to the dissipated energy, and thus to the viscosity. From the results we can recognize the characteristic behavior of such films.

At high frequencies μ' reaches a plateau value. Under these conditions the elastic properties of the film are dominant, and it is capable of storing mechanical energy. For monomolecular films the shear modulus is of the order of 0.1 Nm^{-1}.[28] If we compare this value with the concentration of the ester molecules at the interface we find the interesting relationship shown in Equation (l).[28]

$$\mu' = 15\Gamma^{\sigma}kT \qquad (l)$$

One molecule of sorbitol trioctadecanate has a total of 16 electron lone pairs on its oxygen atoms, and it can therefore form this number of hydrogen bonds. The observed proportionality factor of 15 indicates that each bond contributes an energy of about 1 kT.

At low frequencies the storage modulus is reduced and the viscous properties are dominant. In this region relaxation processes occur, and the film behaves like a liquid. The behavior in the intermediate frequency range shows a dual character, and both elastic and viscous phenomena are observed.

The rheological data show that the film has properties that are characteristic of temporary networks. Since the polar head-groups of the surface active molecules have free hydroxyl groups, it is possible for the linking of the molecules to occur by hydrogen-bonding. However, our experiments indicate that viscoelastic films are only obtained when the surface active molecule also has several hydrocarbon chains. Thus Span 60, which, unlike Span 65, has only one alkyl chain, does not form cross-linked membranes, despite the fact that the molecular structure of the head-group is the same in both compounds. (In fact, Span 60 should in principle be capable of forming even more hydrogen bonds than Span 65.) The three alkyl chains result in a greater oil solubility, and it therefore seems possible that the head-group of Span 65 is partly drawn into the non-polar phase. Under these conditions hydrogen bonds can form between the polar centers within the oil phase. It is also possible that in some cases the molecules need to have a particular orientation at the interface in order for cross-linking to occur. The value of 0.4 nm^2 for the area occupied by each molecule, as determined from interfacial tension measurements, indicates a high degree of anisotropy and molecular ordering in the adsorbed layer.

It thus appears possible that the surface active monomer molecules need to have a particular orientation to form temporary contacts.

8. Outlook

Ultrathin polymer networks are of great interest for many technological applications, and they can also be used, for example, to produce emulsions with exceptionally high stability. Oil droplets that are encapsulated by a network of this kind are thereby stabilized. Since the elastic properties of the surrounding membrane can be adjusted by chemical means, such encapsulated oil droplets provide simple model systems for studying complex biological processes. The topics that have so far been investigated in this way are material transport through membranes and the deformation of such droplets in a flow field. The first of these problems concerns the density of cross-linking in the covering layer; obviously the size of the mesh is the crucial factor in the controlled release of active substances (permeability barriers). Information about the density of cross-linking can be obtained from rheological measurements or, very elegantly, from ESR experiments.[46, 47] In this latter method spin-labeled species of different molecular sizes, soluble in both the oil and water phases, are allowed to diffuse through the membrane. The changes in concentration with time are then measured, and from this one can calculate the resistance of the membrane to the diffusional flow. This quantity is of crucial importance in relation to the use of such membranes for separation processes or for controlled release of substances.

The second area of study is concerned with the deformational behavior of the stabilized oil droplets in a flow field. This is of interest in relation to fundamental problems that arise in many biological systems, but are difficult to study in those systems because of their complexity. It has long been known that red blood corpuscles are able to flow through vessels that are very much narrower than the average diameters of the erythrocytes. This can be clearly seen in the conjunctive tissue of the human eye with the help of a strong magnifying lens. In these very fine capillaries the blood cells are severely deformed, and the question arises as to what is the hydrodynamic cause of this behavior.

Human blood has interesting properties. When stationary it is quite glutinous and has a high viscous flow resistance. However, when it is brought into a flowing condition the viscosity rapidly falls, and the blood then circulates much more easily. If the flow properties of blood are measured as a function of flow velocity, a falling viscosity curve is obtained. Several different factors contribute to this behavior. In the quiescent state the erythrocytes arrange themselves in a sort of superlattice structure resembling a network, resulting in high viscosity and elastic modulus. In the flowing state these "supermolecular" structures begin to break down, leading to a drastic reduction of the viscous resistance. At high shear rates practically all the aggregates are broken down, and the blood cells undergo reorientations and deformations. It would be interesting to discover the exact relationship between the elastic properties of the membrane and the deformation behavior, since this would open up the possibility of using simple viscosity measurements to diagnose blood diseases which involve abnormal changes in the flexibility of the membrane. A number of theoretical studies have already been made in relation to this problem, but experimental confirmation of the equations has not yet been possible, owing to the lack of suitable model systems.[48–50] Microencapsulated oil droplets now offer a possible solution to this problem, and afford an insight into basic processes which are of fundamental importance for biological systems.

Figure 9 illustrates this by a simple example. This shows the flow-induced deformation of oil droplets. Processes of this kind can be studied by means of an optical rheometer built into an inverse microscope giving a high magnification.[28] The image is recorded by means of a special video system which feeds into an electronic image processor.[28]

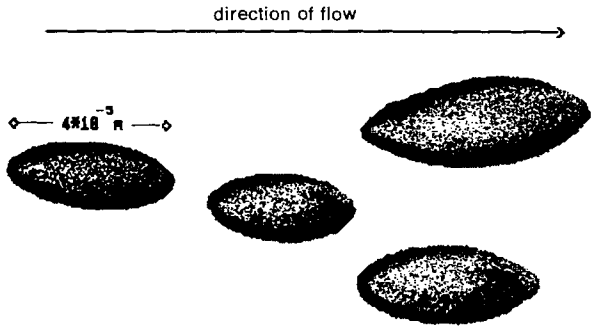

Fig. 9. Shear-induced deformation of oil droplets in a flow field ($T = 20\,^{\circ}C$, shear rate: $80\ s^{-1}$).

The droplet on the left of the figure is about 40 μm in length, and the dimensions of the other droplets can easily be calculated by means of an electronic scaling system. It can be seen that the larger droplets are much more severely distorted than the smaller ones. This behavior is predicted by the theory; in the ideal case the distortion should show a quadratic dependence on the droplet radius.[48-50] There is now particular interest in studying the deformations for membranes with different elastic moduli, as this has direct relevance to problems of medical importance. The experimental technique described here also offer a simple way of studying the flow behavior of clusters and aggregates, thus enabling one to investigate the two main types of blood rheological phenomena in isolation from each other. This has great advantages for developing a theoretical description of such systems, as it opens up the possibility of breaking down complex processes into simple stages that can be more easily analyzed. In this area and many others there exist innumerable possibilities for new applications, and two-dimensional networks thus open up a large new field of research for industrial and academic laboratories.

We thank the Deutsche Forschungsgemeinschaft for financial support of this work. We also thank Professor P. G. de Gennes and Professor H. Hoffmann for their very generous support of these studies, and for many valuable discussions that have stimulated interesting new experiments.

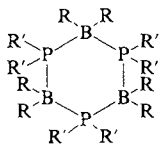
Boron-Phosphorus Compounds and Multiple Bonding

By Philip P. Power*

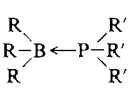
Boron-phosphorus compounds have not been as thoroughly studied as their boron-nitrogen counterparts. Until recently many classes of B-P compounds that had been well established in B-N chemistry were either unknown or poorly characterized. This statement is particularly true for compounds involving possible multiple bonding between boron and phosphorus. For example, detailed structural information on simple monomeric phosphino-boranes, $R_2BPR'_2$, did not become available until 1986 even though the isoelectronic SiC double bonded species, the silenes, had already been reported. However, new work has shown that it is possible to prepare and characterize several novel types of boron-phosphorus compounds with varying degrees of multiple B–P bonding. These include not only monomeric phosphinoboranes but also phosphanediylborates (borylphosphides), three- and four-membered rings (diphosphadiboretanes), boron phosphorus analogues of borazine, B-P skeletal analogues of allyl cations and anions, butadiene and cage compounds. Structural, spectroscopic (mainly NMR) and theoretical studies reveal some important differences between B-P and B-N compounds which in many cases can be traced to the presence of a high inversion barrier at phosphorus that reduces the π interaction. This usually causes compounds such as $R_2BPR'_2$ to associate through σ bonding between B and P. Supporting evidence for this view comes from species that involve phosphorus and nitrogen in competitive π bonding with a boron p orbital in which the dative interaction between B and N is dominant and the phosphorus center remains pyramidal. Recently published work has shown that steric and electronic factors can be used to favor π bonding and give an approximately planar $\geq$B–P$\leq$ system. Furthermore, theoretical studies reveal that p–p π overlap in a planar B-P system is of similar efficiency to its B-N analogue. Good examples are seen in the phosphanediyl borates, the boron-phosphorus analogues of borazine and the π-allyl cations, whose molecular configurations and B–P bond lengths support strong boron–phosphorus π bonding.

1. Introduction

Since the discovery of borazine by *Stock* et al. in 1926[1] boron-nitrogen compounds have enjoyed continued popularity.[2] The widespread interest in such compounds stems, in large measure, from their isoelectronic relationship to carbon species. Interest in compounds having boron bonded to the heavier main group 5 elements P,As,Sb or Bi has been much slower to develop.[3] One reason for this has been the much greater tendency of simple units such as $R_2BPR'_2$ to associate through donation of the lone pair on phosphorus to an empty p orbital on boron. This usually results in highly stable, generally cyclic, oligomeric, σ-bonded species with low reactivity in which boron and phosphorus are invariably four-coordinate (e.g., **1**).[3] Other species involving four-coordination are the donor-acceptor adducts of formula $R_3BPR'_3$, **2**, which also exhibit high thermal stability.



1



2

In contrast, well-characterized compounds involving bonding between boron and phosphorus centers that are three-coordinate have proved much more elusive. Unlike the four-coordinate compounds the coordination number three (or lower) allows for the possibility of π bonding between the boron and phosphorus p orbitals and this review is primarily concerned with compounds that involve varying degrees of B–P π bonding.

Early cryoscopic measurements on the compounds **3**–**5**

Ph_2BPPh_2 **3** $(Ph_2B)_2PPh$ **4** $PhB(PPh_2)_2$ **5**

(and related derivatives) showed that they were monomeric in benzene at concentrations of about one wt.%.[4, 5] In addition it was concluded, on the basis of dipole moment and infrared measurements, that phosphinodiarylboranes were unassociated, not because of π bonding to phosphorus, but because the boron center undergoes π bonding with its aryl substituents. Prior work, using isopiestic molecular weight measurements, had indicated that Me_2BPH_2 was monomeric in ether but polymerized over a period of days.[6] Furthermore, the synthesis of the interesting cyclic diphosphadiboretane species **6**[5] was claimed but it was only characterized on the basis of molecular weight measurements. Other work postulated the existence of the species **7**[7] and a mixture of compounds of formula **8**.[8] None were sufficient-

ly characterized to enable structures to be assigned. In addition, it was reported that molecular orbital calculations indicated that analogues of borazine with P instead of N might exist as stable compounds.[9] In view of these encouraging results it is surprising to note that it was not until 1986 that the first compound having B–P multiple bond character was structurally characterized.[10] In fact, until recently there were little structural or spectroscopic, i.e. ^{1}H,^{11}B and ^{31}P NMR, data on any compounds involving bonding between three-coordinate boron and phosphorus. Rare exceptions were the compounds **9**,[11] the first diphosphadiboretanes to be spectroscopically characterized, and the three-membered ring compound **10**,[12] whose X-ray crystal structure (vide infra) was the first such report for a compound involving bonding between three-coordinate boron and phosphorus centers. It is of significant interest that the last five years have seen an exciting series of papers from a number of groups that have described the first structurally characterized phosphanediylborates (also to be formulated as borylphosphide

$(RBPSiMe_3)_2$, R = NMe_2, Ph $Et_2NB(PtBu)_2$

9 **10**

anions),[10,13–15] 1,2-[16] and 1,3-[13,14,17–20] diphosphadiboretanes, the B-P analogues of borazines (compounds of type **34**),[20] a large number of heterocycles with boron–phosphorus bonds in addition to other atoms (see Sections 4.3, 5.1, 6), monomeric phosphinoboranes,[17,21] B-P skeletal analogues of the allyl cation,[22,23] anion,[22,23] butadiene,[24] and cage compounds.[25] These results have already yielded much new information on B–P multiple bonding and they represent the beginning of what should prove to be a rich vein of chemistry.

A feature common to a number of these recently characterized compounds is the presence of relatively short (1.8–1.9 Å) B–P bonds.[10,20–23] This has given rise to considerable speculation on the strength of the bonding arising from the overlap of the empty boron p orbital and the phosphorus lone pair. This aspect of the structures is also of considerable current interest in the context of multiple bonding in the main group elements owing to the isoelectronic relationship of the pairs BP, CSi and AlN. It is, perhaps, because of such analogies and the implications for other main group 3–5 species, involving pairs such as Ga-As, Al-P, and In-P, that B-P compounds are currently enjoying a revival in interest.

2. B–P Bonding

A key parameter in the discussion of bond order is bond length. Numerous other factors such as coordination number, type of substituent, molecular configuration and the presence of delocalization also affect the length of a bond. Any proposal for the existence of multiple bonding due to π overlap has to be considered in the light of these influences. Addition of the covalent radii of phosphorus (1.11 Å) and boron (0.82 Å) suggests that a boron–phosphorus single bond involving three-coordinate boron and phosphorus should be about 1.93 Å long.[26] It is thus instructive to consider this prediction in the light of theoretical studies on the hypothetical molecules H_2BPH_2 and the related compound H_2BNH_2. Experimental results on the various substituted derivatives of H_2BPH_2 will be discussed in Section 4.

The theoretical data clearly illustrate the large influence that the molecular conformation can have on the length of the B–P bond in H_2BPH_2.[27] Calculations have been carried out on four different states of this molecule (Fig. 1). In the

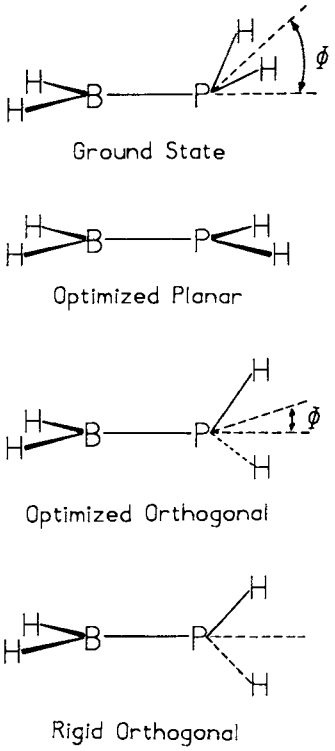

Fig. 1. Schematic drawings of four possible configurations of H_2BPH_2 [27].

lowest energy (or ground) state the phosphorus center is pyramidal (although it is somewhat flattened in comparison to PH_3) and the B–P distance is 1.91 Å. In the optimized planar and orthogonal forms the B–P bond lengths are 1.83 Å and 1.98 Å. It is clear from the calculations that B-P compounds do not show the same ability to form planar species as B-N compounds. Furthermore, this is very probably a reflection of the high inversion barrier at phosphorus (36.7 kcal mol^{-1} for PH_3)[28] rather than inherently poor and inefficient overlap between the boron and phosphorus p orbitals. The inversion barrier at phosphorus is, in fact, reduced to only 8.14 kcal mol^{-1} in H_2BPH_2 which indicates that there is strong conjugation in the planar form.[27] The energy difference between the optimized planar form and the non-optimized orthogonal form was calculated to be 40.4 kcal mol^{-1}. This is only 2.2 kcal mol^{-1} less than that in H_2BNH_2. In addition, the results of population analyses are in agreement with these calculations. For example, the total and π overlap populations in the planar form of H_2BPH_2 are 0.99 and 0.29, respectively, in comparison to 0.70 and 0.30 for H_2BNH_2. During rotation from planar to the non-optimized orthogonal form, the electron population in the vacant p orbital on boron is reduced from 0.29 to 0.01 in H_2BPH_2 whereas in H_2BNH_2 it is reduced from 0.29 to 0.04.

In short, the conjugation in planar H_2BPH_2 is predicted to be about the same as H_2BNH_2. However, non-planarity at P is favored because of the fairly high inversion barrier at the phosphorus center.

A further important consideration for the bonding in boron-phosphorus compounds is the polarity of the B-P pair. The electronegativity difference between boron and phosphorus is very small (B = 2.01; P = 2.06, cf. N = 3.07).[29] Thus, a purely σ-bonded boron-phosphorus pair would possess only a small partial charge separation. In a multiply bonded boron-phosphorus system charge is transferred from phosphorus back to boron via the π interaction so that the σ and π bond polarities tend to cancel each other. Thus, it is possible to argue that the B-P pair could be significantly less polarized than the corresponding B-N system. Such differences may become important when the aromaticity or reactivity of B-P systems is considered.

3. Synthetic Strategies

The major synthetic approaches to the title compounds involve either the use of sterically crowding groups or electron-rich substituents to reduce or prevent association of the boron and phosphorus centers. Since boron is considerably smaller than phosphorus it requires less highly hindering substituents to block access of σ donors to the empty boron p orbital. It has been shown in a number of laboratories that two mesityl substituents on boron are generally sufficient to restrict its coordination number to three.[30] In a different context, the Mes_2B group has found use in the stabilization of carbanions,[30, 31] and the reactions of these ions display many of the characteristics of ylides.[32] Presumably, a similar restriction in access to the boron center could be obtained with most substituents that are similar in size or configuration to the mesityl group. It should be emphasized that the kinetic stabilization of the boron center is primarily due to steric effects, and any reduction in the Lewis acidity of the boron p orbital by interaction with the ring π electrons of the mesityl substituents must necessarily be small or non-existent because of the high dihedral angle between the mesityl rings and the boron plane.[31]

An alternative method of preventing association of boron-phosphorus compounds involves the use of π-bonding substituents on boron. The most commonly used group to date has been the 2,2,6,6-tetramethylpiperidino ligand (tmp).[13, 14, 17, 18] This species forms a π bond through a side-on overlap of the nitrogen lone pair in a p orbital with the empty p orbital on boron. This effectively reduces the Lewis acid character of boron so that it is no longer very susceptible to attack by other donors. Although tmp is a large group, its effectiveness is primarily a result of the π bonding to boron. The multiple nature of the boron–nitrogen bond in the tmp derivatives implies that when phosphorus substituents are included in the molecule they are, in effect, competing with nitrogen for the boron p orbital. The evidence to date shows that nitrogen is more effective than phosphorus in this process.[13, 17, 18] Presumably, this is due mainly to the lower barrier to inversion at nitrogen. The use of other electron donating groups, such as –OR[23] or –SR, to reduce boron Lewis acidity is also possible. This aspect of the boron-phosphorus compounds has been little investigated to date.

Various synthetic pathways for the formation of B–P bonds are outlined in Equations 1–6.

$$R_{3-n}BX_n + n\,LiPR'_2 \longrightarrow R_{3-n}B(PR'_2)_n + n\,LiX \quad (1)$$
n = 1,2 or 3; R and R′ = large group

$$R_2BX + LiPHR' \xrightarrow{-LiX} R_2BPHR' \xrightarrow{n\text{BuLi}} R_2BP(Li)R' \quad (2)$$
R and R′ = large group

$$RBX_2 + 2\,LiPHR' \longrightarrow 1/n\,(RBPR')_n + 2\,LiX + H_2PR' \quad (3)$$
n = 2 or 3; R and R′ = large group

$$RBX_2 + LiP(SiMe_3)R' \xrightarrow{-LiX} RB(X)P(SiMe_3)R' \xrightarrow{-Me_3SiX} 1/2\,(RBPR')_2 \quad (4)$$

$$RBX_2 + LiPHR' \xrightarrow{-LiX} RB(X)PHR' \xrightarrow[\text{or } NaN(SiMe_3)_2]{n\text{BuLi}} 1/2\,(RBPR')_2 \quad (5)$$

$$R_2NBX_2 + 2\,LiP(SiMe_3)_2 \xrightarrow{-2\,LiX} R_2NB\{P(SiMe_3)_2\}_2 \xrightarrow{-P(SiMe_3)_3} 1/2\,(R_2NBPSiMe_3)_2 \quad (6)$$

The simplest route involves the reaction between boron halide derivatives and alkali metal salts of the phosphorus precursors. This is currently the method of choice in the synthesis of phosphinoboranes (Eq. 1),[21] the B-P allyl analogues (Eq. 1),[22, 23] phosphanediylborates (Eq. 2)[10] and the boron-phosphorus analogues of benzene and cyclobutadiene (Eq. 3).[20] In the case of the latter ring compounds the reaction involves the elimination of a primary phosphane. Synthetic pathways involving either the elimination of Me_3SiCl, from adjacent $=PSiMe_3$ and $=BCl$ moieties (Eq. 4)[13, 14, 17, 18, 25] or HCl from $=P-H$ and $=BCl$ groups in the presence of various bases (Eq. 5)[13, 14, 17, 18] or disproportionation reactions with the elimination of $P(SiMe_3)_3$ (Eq. 6)[11] have also proved extremely effective.

4. Structural Data

4.1. Phosphinoboranes

Detailed structural information on a range of three-coordinate boron-phosphorus compounds did not become available until recently. In addition to the structural report on a three-membered ring in 1981,[12] the first X-ray crystal structures of several types of boron-phosphorus compounds only appeared in 1986.[10, 13, 17, 18, 21] The simplest compounds are derivatives of the parent phosphinoborane (H_2BPH_2).[14, 17, 21] These are the species **11**[14, 17] (Fig. 2) and **12**[21] (Fig. 3) which are accessible by addition of lithium

(tmp)ClBP(H)Mes Mes_2BPPh_2

11 **12**

phosphide to the substituted boron halide [cf. Eq. (1)]. Both compounds are monomeric and feature a planar three-coordinate boron center and phosphorus geometries that have different degrees of pyramidicity. Three further monomeric phosphinoborane structures have also been determined[33, 34] and the important structural data for the five compounds are presented in Table 1. The most notable feature of the data is the good correlation between the pyra-

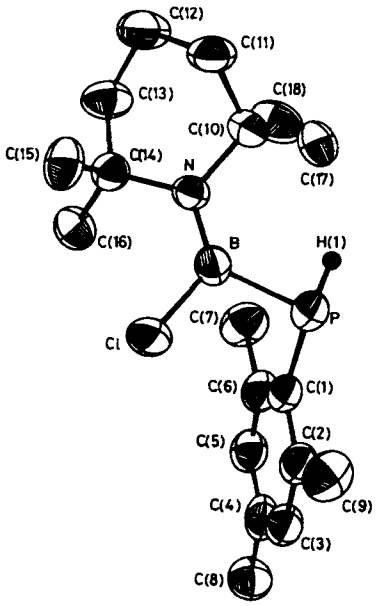

Fig. 2. A thermal ellipsoidal plot of (tmp)ClBP(H)Mes **11** [17]. The B–P distance is 1.948(3) Å and the sum of the angles at P is 307.1°.

midicity at phosphorus and the B–P bond lengths. There is also remarkably good agreement with the theoretical predictions. When planarity is forced upon phosphorus by using bulky mesityl substituents[33] a bond length as short as 1.839(8) Å is observed (vs. 1.83 Å predicted for the planar form of H_2BPH_2). At the other extreme, a long boron–phosphorus distance of 1.948(3) Å is seen when there is a nitrogen substituent on boron. The structure in Figure 2 neatly illustrates the dominance of the nitrogen lone pair interaction with the boron p orbital. Not only is the B–P distance long, the angles at phosphorus are typical of trivalent phosphanes and the B–N distance is 1.380(3) Å which is indicative of a strong dative π interaction. The structure of **15**[34] perhaps most closely resembles the ground state of H_2PBH_2 (B–P = 1.91 Å) and again the agreement between theory and experiment is good. The inversion barriers in **12** and **15**, measured by variable temperature ^{1}H NMR, are near 10 and 11.4 kcal mol^{-1} [33] (slightly higher than the value calculated for H_2BPH_2).

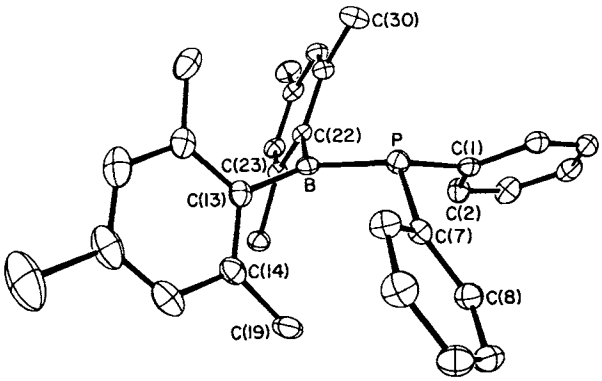

Fig. 3. A thermal ellipsoidal plot of Mes_2BPh_2 **12** [21]. The B–P distance is 1.859(3) Å and the sum of the angles at P is 339.4°.

4.2. Phosphanediylborates (or Borylphosphides)

The phosphinoboranes above are of further interest because when there is a hydrogen substituent on phosphorus it can easily be removed with *n*BuLi to give lithium salts having the phosphanediylborate (or borylphosphide) anion $[R_2BPR']^{\ominus}$. The structures of the salts **16a–c** and **17–20** have been determined.[10] **20** features a naked $[PMesBMes_2]^{\ominus}$ ion. The structure of **16b**[10a] is illustrated in Figure 4. When [12]crown-4 is added to **16a, b, d** to remove the $Li^{\oplus}$ion, salts like **20** with anions of the type illustrated in Figure 5 are obtained. In contrast to the neutral phosphinoborane precursors, the deprotonated phosphorus centers are planar at phosphorus. Furthermore, the dihedral angles between the boron and phosphorus planes are small (usually $<10°$). The B–P distances are short and vary from 1.810(4) to 1.836(2) Å. These features indicate considerable multiple bond character in the B–P bond. The planarity at P is probably due to an enhanced π interaction owing to a greater electron density at the phosphorus atom. Recent, more sophisticated calculations[35] on the molecules Li[H_2BPH] and $[H_2BPH]^{\ominus}$ are in close agreement with experimental findings and indicate essential double bond character in these planar molecules and also in the planar configuration

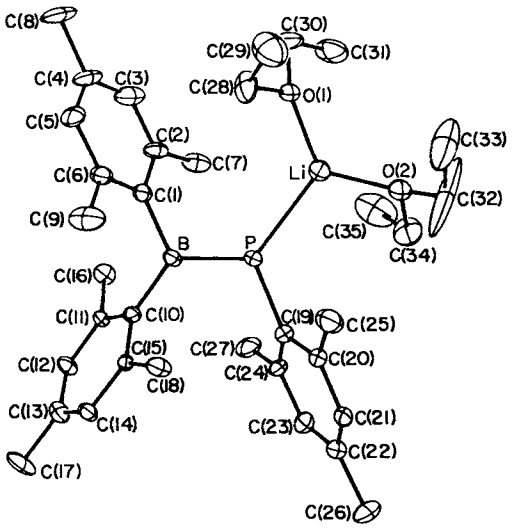

Fig. 4. Structure of $[Li(Et_2O)_2][Mes_2BPMes]$ **16b** [10a]. The B–P distance is 1.823(7) Å.

of H_2BPH_2. For example, calculations of the bond order in $[H_2BPH]^{\ominus}$ using two different approaches[36,37] indicate B–P bond orders of 1.83 and 2.01, respectively. Treatment of the chloroborylphosphane **21** with *t*BuLi also gives the anion **23**.

$[Li(Et_2O)_2][Mes_2BPR]$ **16**

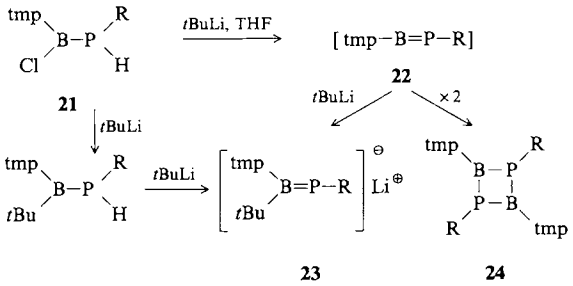
$[Li(Et_2O)_2][Mes(H)PB(Trip)PMes]$ **19**

$[Li([12]crown\text{-}4)_2][Mes_2BPMes]$ **20**

An interesting feature of this reaction is the concomitant formation of the ring compound **24**. This has led to the B=P species **22** being postulated as intermediate.[14] This intermediate was reported to be detectable by mass spectroscopy of the dimer which apparently dissociates at high temperature.[13,14]



R = 2,4,6-$tBu_3C_6H_2$

4.3. B–P Ring and Cage Compounds

The first diphosphadiboretanes to be characterized by NMR and mass spectroscopy data and elemental analysis were reported in 1977.[11] These were the compounds **9**, which were synthesized by the thermolysis of **25** at 150 °C [see Eq. (6)].[11] The synthesis and X-ray structure of the related three-membered ring compound **10** were reported in 1981.[12] This was the first X-ray crystal structure report of a compound with bonding between three-coordinate boron and phosphorus centers (Fig. 6). The B–P distances average

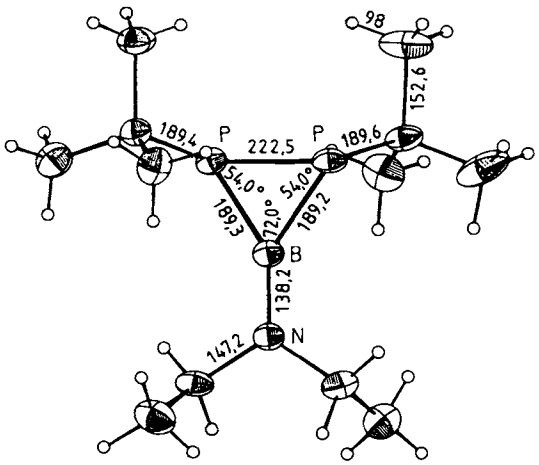


Fig. 6. A thermal ellipsoidal plot of the diphosphaborirane $Et_2NB(PtBu)_2$ **10** [12].

1.893(2) Å and the B–N distance is 1.382(3) Å. Although the B–P bond is somewhat shortened relative to a single bond it is notable that the B–N bond is consistent with considerable

B–N π bonding. The first X-ray structures of diphosphadiboretanes, involving the compounds **24**,[13] **26**,[17] (Fig. 7), and **27a**,[18] were reported in 1986. They were synthesized

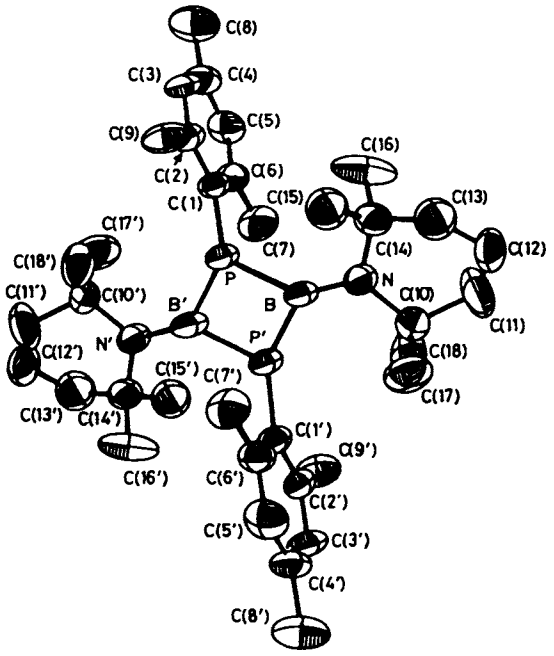

Fig. 7. Structure of the diphosphadiboretane $(tmpBPMes)_2$ **26** [17]. The B–P bond length is 1.916(3) Å.

by reaction of $tmpBCl_2$ with $LiP(SiMe_3)R$ (→**24**), with one equiv. of a 1:1 mixture of LiPHMes and Li_2PMes (→**26**) or with $LiPHCEt_3$ (→**27a**) followed by elimination of Me_3SiCl or HCl in the second step [see Eq. (4)]. These featured a planar B_2P_2 core. The phosphorus centers are pyramidal and trigonal planar geometries were observed at both boron and nitrogen with B–N distances of 1.38 Å–1.431 Å. The B–P distances are 1.916(3) Å, 1.96(2) Å and 1.925 Å (av.), and the sum of the angles at P are 329.0° and 339.9°. Accordingly, there is little evidence for dative P → B π bonding. It is also notable that the exocyclic π bonding in these compounds is stronger than that in the diazadiboretane **28** ($B–N_{exo}$ = 1.465(3) Å) where the ring nitrogens compete for the boron p orbital.[38] However, the B–N distance in **27a**,[18] 1.431(2) Å, is unusually long, although it remains consistent with significant B–N π bonding. These data also support the calculations (see Section 5.2)[27, 35] which indicate a reluctance of the phosphorus center to participate in delocalization. Several other diphosphadiboretanes involving amino substituents on boron have been reported, and three different synthetic methods have been described.[18b] Three of the products, the compounds **29**–**31**, have been structurally characterized[18b] and reveal features that are broadly similar to those that had already been reported.[13, 17, 18] Long

$(tBu_2NBPTrip)_2$	$(tBu_2NBPSiMe_3)_2$	$(tmpBPSiMe_3)_2$
29	**30**	**31**

B–P bonds were observed in the compounds **30** and **31** [1.947(4)–1.969(12) Å]. This shows that increased steric congestion increases the B–P bond length, as already observed in **24**.[13, 17] It is notable that these B–P bond lengths approach those found in four-coordinate B-P compounds. This trend suggests that it should be possible to induce dissociation of the ring to give the interesting monomeric species R_2NBPR' by increasing the steric hindrance further. However, it is notable that the barrier for dimerization of the hypothetical $H_2N–B=PMe$ to $(H_2N–BPMe)_2$ has been calculated (by MNDO III) to be only 5 kcal mol^{-1}.[18b]

It has also proved possible to obtain diphosphadiboretane compounds without amine substituents on boron.[20b, 33, 34] The absence of competition for the boron p orbital allows its tendency for interaction with the phosphorus lone pair to be more accurately gauged. Alkyl- or aryl-substituted diphosphadiboretanes can be readily synthesized by treatment of an organodihaloborane with two equiv. of LiPHR [see Eq. (3)]. Two examples are $(ThexylBPMes)_2$[20b] and (1-AdPB-

$(ThexylBPMes)_2$	$(MesBP(1\text{-}Ad))_2$
32, Thexyl = CMe_2CHMe_2	**33**

$Mes)_2$[33, 34] (Fig. 8). The B_2P_2 ring is planar and the phosphorus centers are pyramidal. The observed ^{11}B NMR

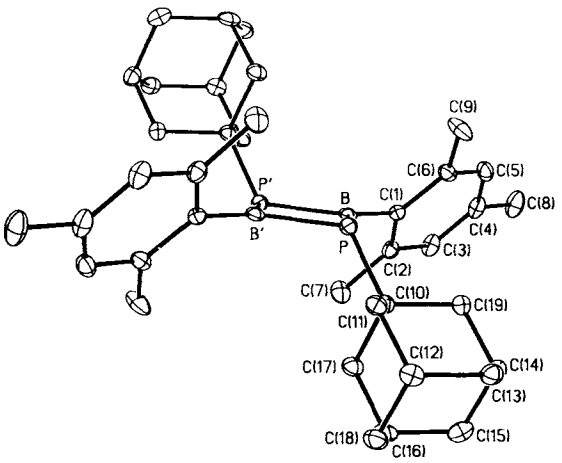

Fig. 8. Structure of the diphosphadiboretane $(MesBP(1–Ad))_2$. The B–P distance averages 1.900(2) Å. The sum of the angles at phosphorus is 328.9° [33, 34].

chemical shifts are consistent with three coordinate boron whereas the ^{31}P NMR δ values (ca. −70) are well upfield. The latter values are, in fact, more than $\Delta\delta = 100$ upfield of those (see Table 2 below) observed in the delocalized six-

membered ring $(RBPR')_3$ compounds which emphasizes the very different bonding in the ring systems. The sums of the angles at phosphorus are 331.3° and 328.9°, respectively, and the B–P bond lengths are 1.897(6) Å and 1.899(2) Å.[20b, 33] These bonds are somewhat shorter than those usually observed in B_2P_2 rings with $-NR_2$ groups on boron. A shortening is certainly predicted in the absence of competition from the amino groups on boron. However, in view of the large substituents on B and P a more planar phosphorus configuration might be expected. These results can be explained by regarding the species in Figure 8 as a substituted cyclobutadiene analogue. In this case delocalization of the phosphorus lone pairs onto the borons offers little energy advantage since two of these electrons would occupy non-bonding π-energy levels. The energy gain (if any) upon delocalization is probably insufficient to overcome the inversion barrier at

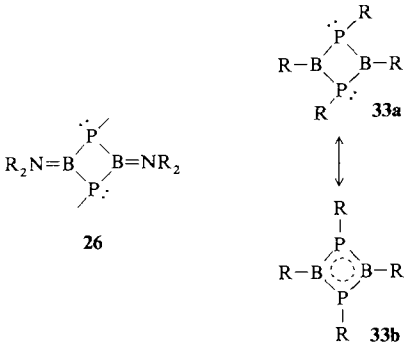

Fig. 9. Schematic drawings of an amino-substituted diphosphadiboretane **26** (cf. Fig. 7) and two resonance forms **a** and **b** of an organo-substituted diphosphadiboretane **33** (cf. Fig. 8).

phosphorus. The bonding in the compounds in Figures 7 and 8 is illustrated schematically in Figure 9. In the amino-substituted compound **26** there is no delocalization and B–P single bonding and B–N π bonding is observed. Although structure **33a** most closely represents the bonding of the molecule in Figure 8, it may be that structure **33b** also makes a small contribution owing to the shorter B–P bonds and the flattened geometry at phosphorus.

Other interesting four-membered ring systems involving BP_2N or AsB_2N rings have also been reported.[39] Examples are **35a** and **35b** (Fig. 10). These involve long B–P and B–As

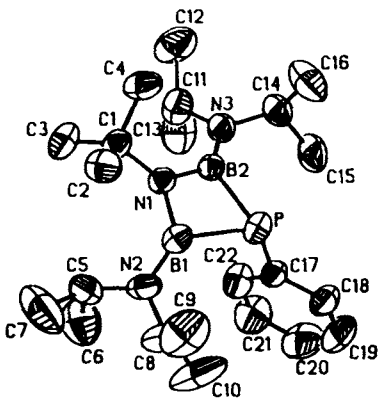

Fig. 10. Structure of the azaphosphadiboretane **35a** with B-P distances averaging 1.955(3) Å. The nitrogen center is planar, the sum of the angles at phosphorus is 280.7° [39].

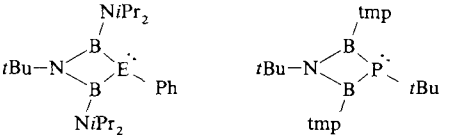
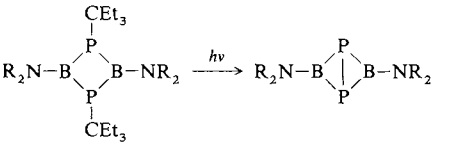
distances which average 1.955(3) Å and 2.066(4) Å as the boron atoms are substituted by exocyclic NR_2 groups. Even longer B–P distances 1.97(1) Å were observed in the more encumbered ring system **36**[40]. Interestingly, the nitrogen



a, E = P; **b**, E = As

centers in all these rings are essentially planar whereas the P (or As) centers are very pyramidal.

Details of other rings systems involving boron–phosphorus bonds have also appeared. Three-membered BP_2 rings with various amino substituents on boron have been known since 1981.[12] These were synthesized by the reaction of the bis(alkali metal) salt of a diphosphane with the aminoboron dihalide. More recent results[41] have extended the range of these compounds to three-membered ring species involving various combinations of B,N,Si and P and their reactions with a variety of reagents. Fused three-membered boron-phosphorus ring systems **37** can be prepared by the photolysis of the four-membered ring precursor **27**.[42] The structure



27 **37**

a, NR_2 = tmp; **b**, NR_2 = N*t*Bu$_2$

of the product **37a** is illustrated in Figure 11.[42] The B–P distances average 1.906(6) Å and the P–P distance, 2.349(2) Å, is extremely long indicating, perhaps, considerable ring

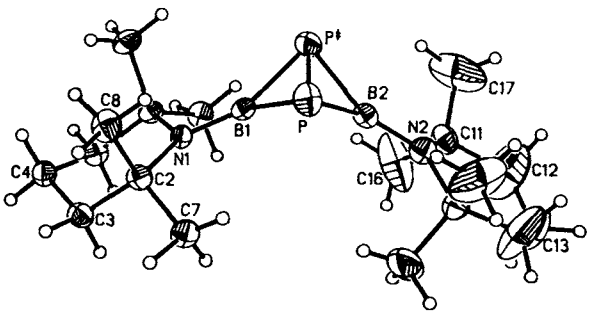


Fig. 11. A thermal ellipsoidal plot of the bicyclic system **37a** featuring two three-membered BP_2 rings [42]. Some details are given in the text.

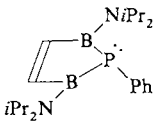
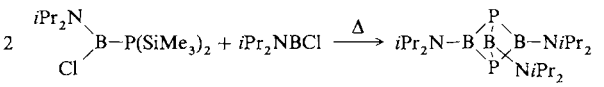
strain. The B–N distances averaging 1.383(8) Å are indicative of an undiminished B-N π interaction. Another interesting ring system is the five-membered phosphadiborole derivative **38**.[43] Here the sum of the angles at phosphorus is



38

295.9° and the B–P distance is 1.949(2) Å. The inversion barrier at phosphorus was estimated at 10–15 kcal mol^{-1} on the basis of variable temperature ^{1}H NMR spectroscopy. Other notable B-P ring systems have also been reported recently. However, they involve either pentavalent[44] or four-coordinate[45] phosphorus and thus do not fall within the scope of this review.



39 40 41

Reaction of the phosphinoborane **39** with the borane **40** at 160 °C affords the bicycle **41** (Fig. 12), the first example of a cage compound involving three-coordinate boron and phosphorus.[25] It has a trigonal bipyramidal B_3P_2 framework. The B–P distance 1.969(8) Å is slightly longer than those found in the four-membered ring compounds. The B–N distance 1.34(2) Å is consistent with a high degree of B-N overlap which precludes B–P multiple bonding.

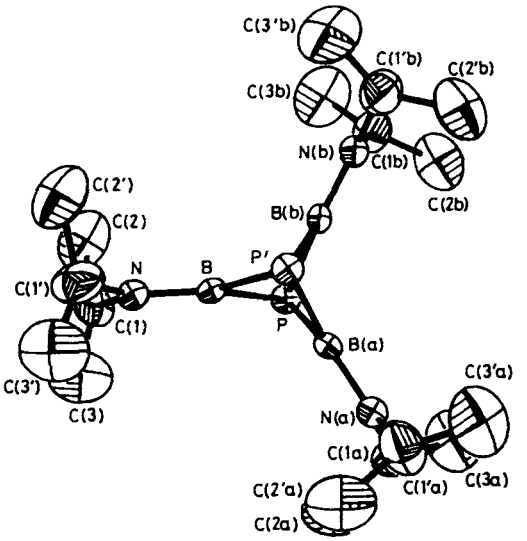


Fig. 12. Structure of the first cage compound **41** involving three-coordinate boron and phosphorus [25].

5. Possible Aromaticity in Delocalized B-P Rings and Acyclic Systems

5.1. Benzene or Borazine Analogues

The foregoing discussion has shown that, with a few notable exceptions, the majority of currently known ring compounds with *endo*-B–P bonds also involve boron bonding to an exocyclic $-NR_2$ group which, for the most part, effectively prevents delocalization or dative π bonding between phosphorus and boron. In the two cases that involved no amino substituents on boron it was argued that delocalization did not occur because of the energetically unfavorable anti-aromatic cyclobutadiene structure of the molecule.[20b, 33, 34] Conversely, a six-membered ring with alternate three-coordinate B and P atoms should show extensive delocalization since three of the π-molecular orbitals would be bonding in this case. It was found that, if the substituents on boron and phosphorus in reaction (7) were of suitable size, good yields

$$RBX_2 + 2LiPHR' \rightarrow 1/3(RBPR')_3 + H_2PR' + 2LiX \quad (7)$$

34

of these six-membered rings of type **34** could be obtained.[20] One of the products is illustrated in Figure 13.

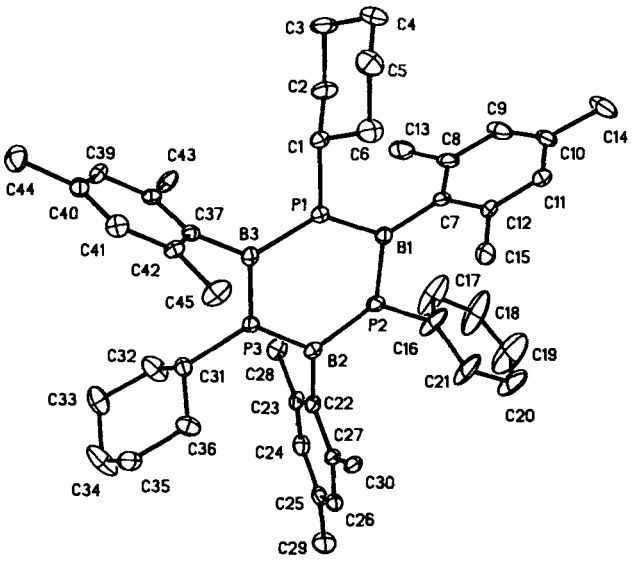

Fig. 13. Structure of the borazine analogue (MesBP*cyclo*-C_6H_{11})$_3$ **34b** [20]. The B–P bonds are all equal and about 1.84 Å long.

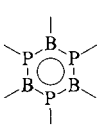
The most important features of the rings are: a) the B_3P_3 array and the six *ipso*-carbon atoms of the substituent groups are coplanar; b) all the B–P distances are essentially equal; c) the B–P bonds are short and about 1.84 Å in length. These structural data clearly suggest considerable delocalization of the phosphorus lone pairs over the six-membered ring system.



34

The structural differences between these systems and the organo-substituted four-membered rings[20b, 33, 34] discussed in Section 4.3 are striking. In the latter compounds the phosphorus centers are pyramidal and the B–P bonds are

about 1.9 Å long. Important spectroscopic differences were also observed. For example, the data in Table 2 indicate that in the ^{31}P NMR spectra there are large chemical shift differences between the four- and six-membered rings. The ^{1}H NMR data also show interesting differences. In acyclic boron and phosphorus compounds and the four-membered ring species the differences in chemical shift between the *ortho*- and *para*-methyl protons tend to average ca. 0.2 ppm. In contrast, larger differences of 0.42–0.75 ppm were observed for the benzene-like compounds. One possible explanation is that a ring current induced in the B_3P_3 π system as depicted in Figure 14 may account for the observed differences. With regard to the possible aromatic character of the

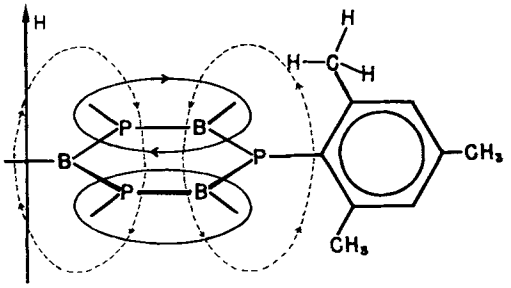


Fig. 14. Schematic drawing of the possible origin of the anomalously large difference in chemical shift between the *ortho*- and *para*-methyl protons of the mesityl groups.

B_3P_3 array it should be borne in mind that the B–P bonds are not very polar. Thus, the low polarity in the B_3P_3 ring should facilitate ring current. However, proof of the aromatic character of these molecules awaits more sophisticated spectroscopic studies and theoretical calculations.

5.2. Acyclic Delocalized Systems

Further extended π-bonded systems involving B-P skeletons have also been synthesized. Several analogues of both the π-allyl cation and anion featuring B_2P or BP_2 arrays with a variety of substituents have been reported.[22, 23] Examples are **42** (Fig. 15) and **43**, which were synthesized by simple salt elimination procedures.[22] They may be regarded as ana-

$(Mes_2B)_2PPh$ **42** $MesB(PPh_2)_2$ **43**

logues of the allyl cation and anion, respectively. The allyl cation analogue **42** features a twofold rotation axis along the P–C bond. The CPB_2 center is therefore planar but the planarity also extends to the two *ipso* carbon atoms on each boron. There is also a wide BPB angle of 133°. Although planar three-coordinate phosphorus is a common feature of the structure of numerous phosphanediyl-metal complexes of the type $RP[M(CO)_n]_2$,[47] the phosphorus in **42** differs fundamentally from these because its valence shell possesses four electron pairs. Three are used for σ bonding to one carbon and two boron atoms. The remaining pair is available for π donation to the empty boron p orbitals. Conversely, in the bridging metal-phosphanediyls the phosphorus be-

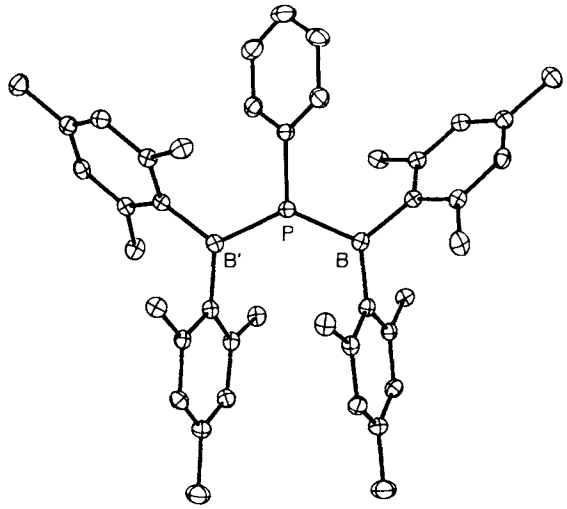

Fig. 15. Structure of the allyl-cation analogue $PPh(BMes_2)_2$ **42** [22]. The $B_2PC(ipso)_2$ array is planar and the B–P bond is 1.871(2) Å and the BPB angle is 131.0(2)°.

haves as a π acceptor. The planar nature of the B_2PC_5 array is good evidence for π bonding in the BPB moiety, which is maximized by having all three p orbitals parallel to each other even at the expense of considerably greater steric congestion caused by the coplanarity of the five organo groups and the short B–P distance of 1.87 Å

In **43** the boron is planar with B–P distances 1.89 Å. However, the phosphorus centers in this case are pyramidal. There is a slight asymmetry in the B–P distances which is reflected in slightly differing degrees of pyramidicity.[22] The almost equal B–P distances in both compounds are consistent with the π-molecular orbital picture of the allyl group since the extra pair of electrons is accommodated in a nonbonding orbital. This is also consistent with the slightly longer B–P distance (1.89 vs. 1.87 Å) on the basis of increased interelectronic repulsion. The preparation and structures of the compounds **44** and **45**[23] show that the electronic properties of the boron substituent exert considerable influence on the degree of multiple P → B bonding. In the case of **44** with Br as substituent (–I effect, Fig. 16) the B–P distances average 1.83 Å, whereas in the OEt (+I) derivative **45** the B–P distances average 1.93 Å in length.

$XB(PMes_2)_2$

44, X = Br; **45**, X = OEt

Other B–P analogues of carbon compounds are also possible. For example, during reactions of **16** (a phosphido ligand precursor with reduced bridging tendency owing to the P → B effect) with some transition metal halides it was found that the phosphido group could be oxidized to give the 1,2-diboryldiphosphanes **46**.[24] These compounds constitute

$[Li(Et_2O)_2][Mes_2BPR]$ **16** $Mes_2B–PR–PR–BMes_2$ **46**, **a**, R = 1-Ad; **b**, R = Mes

a new class of diphosphanes with a number of unusual features (Fig. 17). The most notable are the short P–P bond

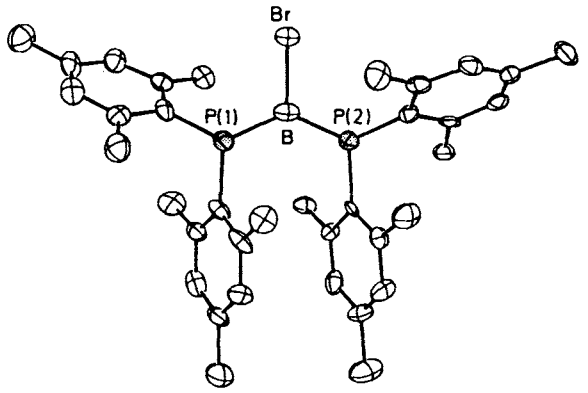

Fig. 16. Structure of the allyl-anion analogue $BrB(PMes_2)_2$ **44** [23]. The B–P distances of ca. 1.83 Å are quite short owing to the –I effect of the halogen.

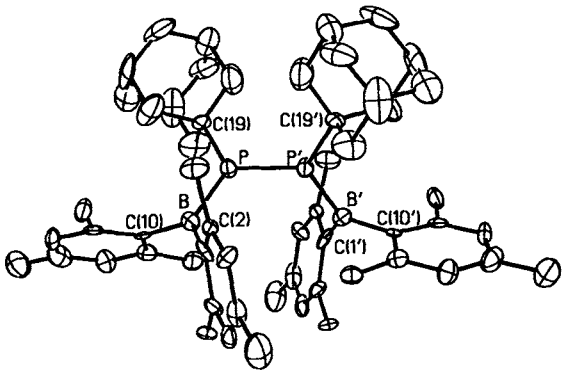

Fig. 17. A thermal ellipsoidal plot of the butadiene analogue $[P(1\text{-Ad})BMes_2]_2$ **46a** [24]. The P–P single bond of ca. 2.1 Å is extremely short.

distances, ca. 2.11 Å, and the planar phosphorus and boron centers. Clearly, an analogy could be drawn between these compounds and butadiene. However, the twist angle between the two phosphorus planes is ca. 70° so that there is little conjugative interaction between the two B-P π systems. The short P–P bonds may be due to the changes in hybridization at phosphorus which now has $\sim sp^2$ hybridized orbitals. Overlap of these sp^2 hybrids may result in shorter P–P bonds than those in normal diphosphanes, where the P–P distances are about 2.22–2.23 Å. In the latter, the hybridization of the bonding orbitals is less than sp^3 (between sp^3 and pure p) since the angles at phosphorus are generally less than tetrahedral values. Interestingly, the "mixed" diphosphane, **47**,

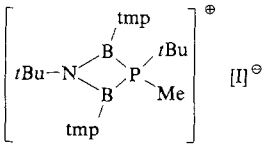
$Mes_2BP(1\text{-Ad})PPh_2$

47

with one normal P-bound phosphorus atom and one sp^2-hybridized B-bound phosphorus atom has a P–P bond length of 2.173(2) Å,[33] which is close to that predicted by interpolation of the 2.11 and 2.22–2.23 Å P–P values. These structural data imply that about half of the contraction observed in P–P double bonds (ca. 2.02 Å long) is due to the rehybridization, the remainder being due to p–p π overlap. This is in contrast to doubly bonded carbon compounds where only 25–30% of the shortening can be traced to rehybridization.

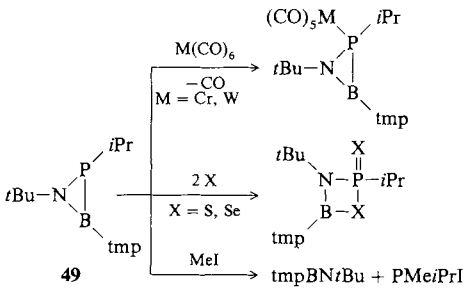
6. Reactivity Studies

Since many of the compounds described in the preceding sections have only been recently discovered the investigation of their chemistry is in the preliminary stage. In many cases the boron-phosphorus compounds are sensitive to air and moisture. However, the quasi-aromatic compounds described in Section 5.1 react only slowly (several days in "wet" THF) with water to give a primary phosphane and various boron-oxygen compounds.[20] The ring systems also react rapidly with Br_2 to give $RPBr_2$ and $RBBr_2$ products. The four-membered 1,3-diphosphadiboretanes have been shown to undergo an interesting photolysis reaction to give fused ring systems as in **37a** (Fig. 11).[42] The related four-membered 1,3,2,4-azaphosphadiboretane skeleton has also been investigated.[40] Addition of methyl iodide led to formation of the methylphosphonium salt **48**, which was characterized by ^1H, ^{11}B, ^{13}C and ^{31}P NMR spectra and by an elemental analysis.[40] The phosphorus lone pair may also form



48

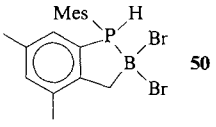
a bond to $W(CO)_5$. With selenium the P(*t*Bu) moiety is displaced from the ring and a cyclic four-membered ring involving NB_2Se is produced instead. The three-membered ring system **49** also undergoes a variety of reactions, e.g. with $M(CO)_6$, S, Se or MeI.[41] These facile reactions clearly



49

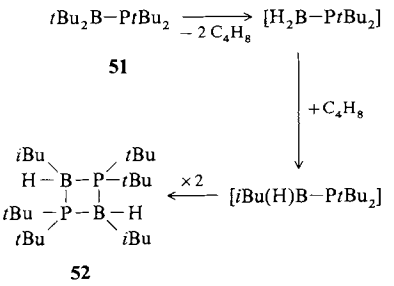
demonstrate the ready availability of the phosphorus lone pair in **49** and its almost negligible involvement with the boron p orbital in this case.

Compounds involving bonding between four-coordinate boron and phosphorus are generally very stable. However, when coordinative unsaturation is introduced rearrangement and elimination reactions may occur. For example, the attempted synthesis of Br_2BPMes_2 led instead to the novel heterocycle **50**, which presumably arose from the activation



50

of the C–H bond on one of the *ortho*-CH_3 groups of a mesityl substituent.[23] Activation of C–H has also been observed during the attempted synthesis of the phosphinoborane **51**; in this case the dimer **52** was isolated.[47] The proposed reaction sequence which led to this unexpected compound is believed to involve a double elimination (retro-hydroboration) of isobutene followed by an anti-Markovnikov hydroboration and dimerization to give the product **52**.



7. Outlook

Several decades after the first phosphinoboranes and borane–phosphane adducts were reported, the first compounds involving multiple boron–phosphorus bonding are being investigated. It is ironic to note that exotic compounds involving isoelectronic carbon–silicon double bonded systems were isolated and structurally characterized some years before their simple boron–phosphorus counterparts the phosphinoboranes. Similarly, the synthesis of the boron-phosphorus counterparts of borazines involved nothing more complicated than the addition of two equivalents of LiPHR to $R'BHal_2$. The initial findings suggest that there are many exciting discoveries to be made. The synthesis of stable B-P analogues of the iminoboranes, RBPR', remains an obvious goal. The coordination chemistry of the compounds already synthesized and the synthesis of a large variety of boron-phosphorus cage compounds are areas of considerable potential. A striking feature of the work already published is the very large effect that the boron substituents can have on B–P multiple bonding and in most cases where nitrogen is bonded to boron little or no multiple bonding to phosphorus is observed. On the other hand, when there is an electron-withdrawing substituent on boron enhanced multiple bonding to phosphorus is seen. It should therefore be possible to control boron–phosphorus multiple bonding very accurately with the appropriate substituent.

Note added in proof (April 3, 1990): Species involving two-coordinate boron and boron–phosphorus multiple bonds have now appeared. The Zintl anions $[BP_2]^{3\ominus}$ and $[BAs_2]^{3\ominus}$ were crystallized as their $K^{\oplus}$ salts from the reaction of the elements at 1000–1100 K. The bond lengths are B-P = 1.767 Å and B-As = 1.868 Å. These short distances are in line with earlier predictions[10] and with the two-coordination and sp hybridization at boron.[49]

The author is grateful to his many coworkers named in the bibliography who carried out many of the experiments described with skill and enthusiasm. The financial assistance of the National Science Foundation and the A. P. Sloan Foundation are also gratefully acknowledged.

[26] The radius of boron is the subject of some controversy [10a], much of which can be resolved by consideration of the coordination number for boron. The value 0.82 Å appears to be a reasonable one for three-coordinate boron. For example, compounds involving three-coordinate boron-carbon bonds usually have B–C bond distances of *ca.* 1.58–1.60 Å [26a]. If the usually accepted carbon radius (0.77 Å) is subtracted, a value of 0.81–0.83 Å is obtained for boron. Longer distances are observed when boron is four-coordinate. Typical B–P distances for such compounds are about 2.0 Å or an effective radius of 0.9 Å for four-coordinate boron.

[28] J. M. Lehn, B. Munsch, *Mol. Phys. 23* (1972) 91. However, the presence of substituents such as silyl groups can have a dramatic effect on the inversion barrier e.g. 18.9 kcal mol^{-1} in the silylphosphane $Me_3SiPPh(iPr)$, see R. D. Baechler, K. Mislow, *J. Am. Chem. Soc. 92* (1970) 4759 and A. Rauk, J. D. Andose, W. G. Frick, R. Tang, K. Mislow. *ibid. 93* (1971) 6507. The studies show that there is a strong correlation between substituent electronegativity and the inversion barrier. Presumably, some of the lowering of the barrier in phosphinoboranes is due to the low electronegativity of the boryl group. However, it is notable that the calculated and experimental inversion barriers in these compounds (8–11 kcal mol^{-1}) are very much lower than those in the silyl compounds, whereas the electronegativity of boron (2.01) is greater than silicon (1.74) [29].

The Chemistry of Vitamin A and Vision

By Robert R. Rando*

Vision is initiated in the retina by the photochemical isomerization of an 11-*cis*-retinal Schiff base to its all-*trans* counterpart in the photosensitive protein rhodopsin. All-*trans*-retinal is released, reduced to form all-*trans*-retinol (vitamin A), and finally esterified. In order for vision to proceed an 11-*cis*-retinoid must be regenerated in the eye. *Kühne* observed in the 1870s that the pigment epithelium must be in place behind the retina in order for rhodopsin to form. And indeed it was in the pigment epithelium that an isomerase system was recently discovered that can produce 11-*cis*-retinol from added vitamin A. *Pauling* predicted in the 1930s that certain *cis* double bonds in carotenoids and retinoids, including 11-*cis*-retinoids, should be quite unstable with respect to their all-*trans* congeners. This prediction is borne out by experiment, but leaves open the crucial question as to where the energy comes from to drive the isomerization process in the eye. This question was answered by the demonstration that the energy is found in the membrane phospholipids. The fact that membranes may serve as an energy source reveals a previously unsuspected biological function of membranes. The chemistry of the novel energy-linked isomerization process is explored in this review.

1. Introduction

The chemistry of the visual cycle provides the crucial link between the physical phenomenon of light and the biological act of perception. Since at least the 1870s it has been understood that light causes the rhodopsin in the retina to bleach from red to white when we see.[1] This bleaching destroys the chromophore and is the first event of the visual cycle. The rest of the cycle is the recovery from vision, the preparation to see again, as the rhodopsin is reformed. Only recently has the second half of the visual cycle begun to be understood in detail.

An analogy is often made between a camera and the human eye. Each has a lens system, and the iris of the eye, like the aperture of the camera, governs the amount of light that enters. The retina, like the film, is "exposed" by the light. But like all other animal–machine analogies, this one, too, is imperfect and does not nearly describe the complexity and beauty of the biological system. For example, the retina is considerably more versatile than camera film. Certainly, both camera film and the retina contain photosensitive materials. The retina contains photosensitive proteins, called rhodopsins, in organelles known as rods and cones. However, this is where the analogy ends. Two major differences are that the retina can adjust its sensitivity to match the strength of the ambient light and, most importantly, that the photosensitive pigments of the retina are renewable. That is, the pigmented material is continually renewed after transformation by light so that new images can be formed on it. The capacity of the retina to adjust its sensitivity to low light levels and the renewability of rhodopsin depend on the latter's ability to be altered to a non-visible-light-absorbing form by light and then to be reconstituted in the dark. In this way light itself may adjust the sensitivity of the retina to its ambient level by titrating the amount of pigment in the retina.

Rhodopsin is a holoprotein consisting of 11-*cis*-retinal, as the chromophore, and opsin, which is transparent. A particularly vexing problem in visual science has been the thermal mechanism by which 11-*cis*-retinal is biosynthesized in the vertebrate eye. The eye is the only organ in the body in which this isomeric form of retinoid is found to a significant extent. *Wald*[2] showed that the exposure of rhodopsin to light transforms the 11-*cis*-retinal of rhodopsin into all-*trans*-retinal. Subsequently it was reported[3, 4] that soluble isomerase enzymes can act on all-*trans*-retinal from homogenized eye tissue to regenerate 11-*cis*-retinal, thereby completing the visual cycle. Further experimentation, however, has shown these latter two reports to be in error. Upon reexamination, it was found that, under the reported conditions, nonphysiological 9-*cis*-retinal and isorhodopsin (the adduct of 9-*cis*-retinal and opsin) were formed, rather than 11-*cis*-retinal and rhodopsin.[5, 6] The lability of all-*trans*-retinal towards chemical isomerization, coupled with the extreme difficulty of separating the various retinoid isomers prior to the advent of HPLC, has cast into doubt any earlier report on the isomerase problem. As of 1986, no system capable of forming 11-*cis*-retinoids in vitro in darkness had yet been confirmed.

How then does the biosynthesis of 11-*cis*-retinal occur in the eye? It is the purpose of this review article to illuminate the nature of this process and to explore its chemical basis as revealed by recent findings.

2. Vitamin A and Vision

Since proteins do not absorb visible light, it was clear that an organic chromophore must be in some way involved. It was known in antiquity that night blindness could have a dietary etiology.[7] The ancient Egyptians discovered that fresh liver contained a material that could combat this problem. It was not until much later, however, that the material was identified as vitamin A and its role in vision elucidated. The absence of vitamin A from the diet will produce night blindness. Eventually, if the deficiency is not treated, permanent total blindness will result.[8] Even today, vitamin A

deficiency is the single greatest cause of blindness, occurring primarily in Third World countries.

Vitamin A, or all-*trans* retinol (Fig. 1), is a diterpene derived from β-carotene by an oxidative mechanism which

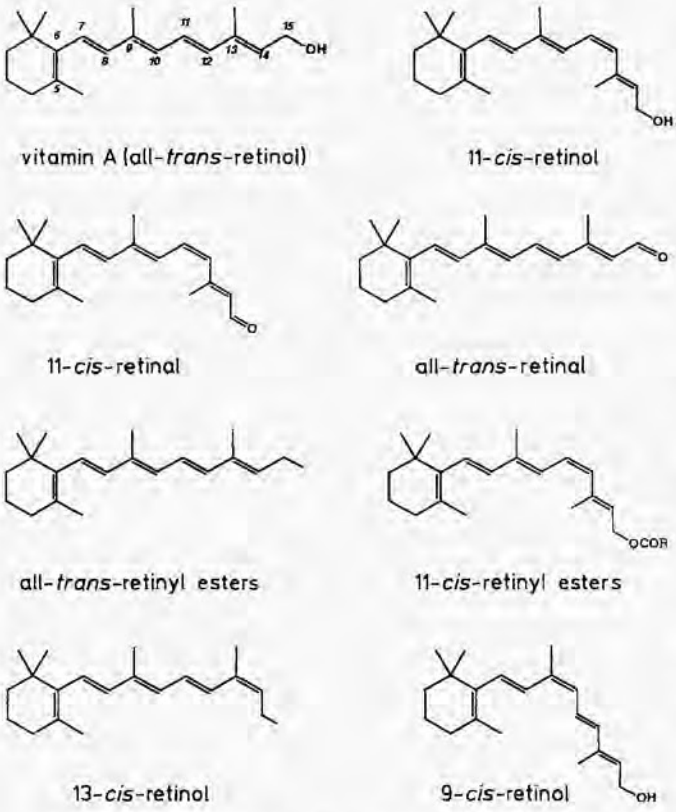

Fig. 1. Structures of vitamin A and other retinoids important in vision

to this day remains somewhat of a puzzle. Nevertheless, the β-carotene is certainly cleaved in the gut, producing all-*trans*-retinal, which is then enzymatically reduced and esterified, thus producing retinyl esters, which are carried to the liver, hydrolyzed to all-*trans*-retinol, and then distributed to various tissues, including the eye. In the eye the retinol is delivered to the retinal pigment epithelium (PE), which sits directly behind the retina and is intimately associated with it (Fig. 2). It has been known for years that the PE is important for the maintenance of a healthy retina. The separation of

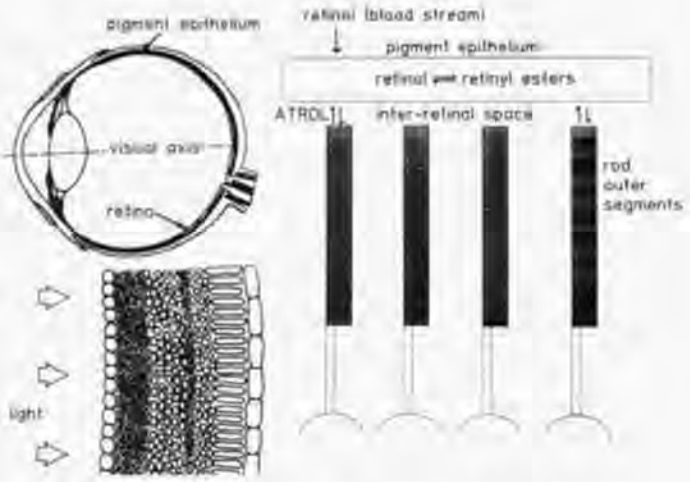

Fig. 2. The retina and pigment epithelium. Schematic views of the retina and pigment epithelium at different levels of resolution. In the upper left, a cross-section of an eye is shown with the retina and pigment epithelium labeled. Below the eye, a blowup of the retina and the pigment epithelium is shown. The rightmost rectangular shaped cells represent the pigment epithelium and to its immediate left are the rod outer segments. Finally, the cartoon on the right half of the figure shows the pigment epithelium and the rod outer segments in close apposition. The flux of retinoids between the two cell types is also indicated. ATROL is all-*trans*-retinol.

the retina from the PE produces a detached retina, which can lead to blindness if not treated. One important role of the PE is to supply the retina with retinoids, the precursors to the visual chromophore.

In the 1930s, the knowledge that vitamin A or some product derived from it is critical in vision led *George Wald* and others to formulate the idea that it was 11-*cis*-retinal, one of the products derived from vitamin A, that was the crucial component of rhodopsin.[2] Since 11-*cis*-retinal absorbs light maximally at approximately 380 nm and rod rhodopsin absorbs maximally at approximately 500 nm, the protein needs to significantly perturb the 11-*cis*-retinal chromophore. It was shown that 11-*cis*-retinal readily formed a Schiff base with the protein opsin to form rhodopsin (Fig. 3).[9] This adduct, in the protonated form, is the actual chromophore of the visual pigments. It should be noted that 11-*cis*-retinoids exist only in the eyes of sighted animals and are not otherwise dietary constituents. Of further interest is the fact that the three phyla with sight—the vertebrates, the arthropods, and the molluscs—all utilize 11-*cis*-retinal as their visual chromophore.

Dr. Rando was born in New York City in 1941. He received a doctorate in physical organic chemistry with Professor William von E. Doering in 1966 at Yale University. He then studied with Professor Konrad Bloch in the Department of Chemistry, Harvard University, where he investigated the mechanism of action of β-hydroxydecanoyl thioester dehydrase. He also carried out mechanistic studies on the first mechanism-based irreversible enzyme inhibitor, 3-decynoyl-N-acetyl cysteamine. Dr. Rando has worked on the development of new kinds of mechanism-based inhibitors and also discovered natural products which follow this mechanistic paradigm. His recent work has involved a study of biochemical mechanisms in vertebrate vision and membrane biochemistry. Dr. Rando is currently the Gustavus Adolphus Pfeiffer Professor of Biological Chemistry and Molecular Pharmacology at Harvard Medical School.

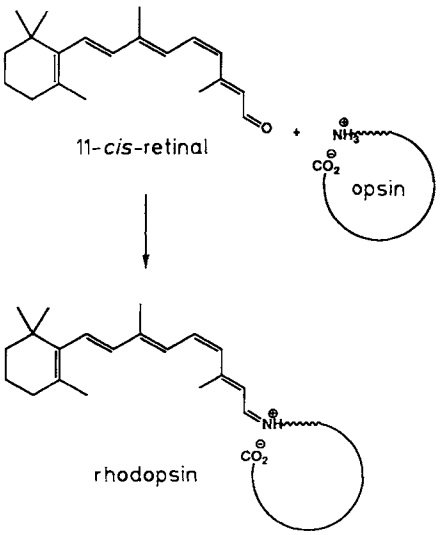

Fig. 3. Formation of rhodopsin from the protein opsin and 11-*cis*-retinal.

3. A Photochemical *cis*-to-*trans* Isomerization Initiates Vision

The isolation of rhodopsin immediately reveals its great light sensitivity. The integral membrane protein rapidly loses its red color when exposed to light, in a process called bleaching (Fig. 4). The products of this light exposure are all-*trans*-retinal and the protein component opsin. In the dark, there is no measurable tendency for 11-*cis*-retinal to form when rhodopsin is in an isolated retina or when it is in a detergent solution. The photochemical isomerization of rhodopsin occurs with a high quantum efficiency of approximately 0.67.[10] This is about 100-fold higher than that of a protonated retinal Schiff base by itself.[10] This photochemical *cis*-to-*trans* conversion occurs within picoseconds and is the only process where light is involved in the visual response.[11] As will be shown in Section 5.2, 11-*cis*-retinoids are approximately 4 kcal mol^{-1} higher in energy than their all-*trans* congeners. Thus, unlike other photochemical processes where light energy is used to drive thermodynamically unfavorable reactions, in the visual process light initiates an otherwise exothermic reaction.

The photochemical isomerization of the chromophore in rhodopsin leads to a series of intermediates, ending in the hydrolysis of the all-*trans*-retinyl Schiff base to produce all-*trans*-retinal and opsin as shown in Figure 5.[9] The isomerization itself is largely complete by the time the first well-established intermediate, bathorhodopsin, is formed.[12] It is interesting to note that bathorhodopsin retains a substantial portion of the energy of the incident photon.[13] A mole of photons at 500 nm carries 57 kcal with it. Photomicrocalorimetric measurements determined that bathorhodopsin is approximately 35 kcal mol^{-1} higher in energy than rhodopsin.[13] Possible ways this energy might be retained include strain energy in the chromophore, and charge separation, induced by the isomerization reaction, between the protonated Schiff base and its protein-bound counterion[14] as shown in Figure 6.

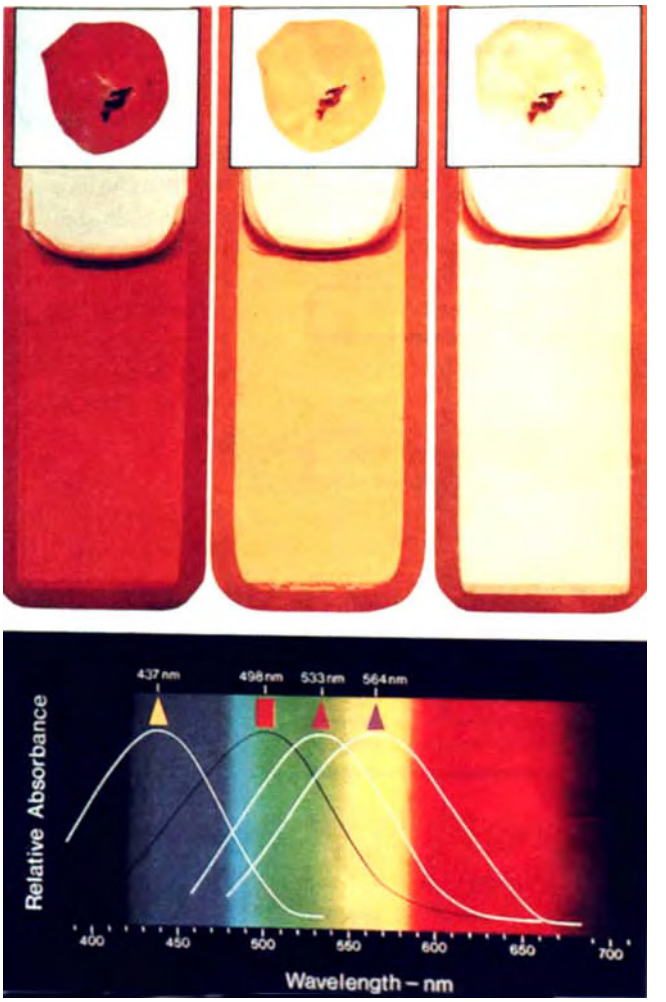

Fig. 4. Top: The bleaching of rhodopsin by light in the retina and in detergent solution [21]. Bottom: The absorption characteristics of rod rhodopsin and the cone rhodopsins. The latter rhodopsins are responsible for color vision [21]. The retina and extracts were prepared by *P. K. Brown* and *J. E. Dowling*. The inset was prepared by *P. K. Brown*. (Taken from [21] with permission).

The remaining intermediates in the visual cascade have also been studied in some detail.[11] Presumably, these spectroscopically defined intermediates reflect conformational alterations in the protein which are induced by the photoisomerization. Of great interest is metarhodopsin II, because it is the intermediate (R*) that transmits the information that light has been absorbed. Unlike the other intermediates, metarhodopsin II contains a deprotonated Schiff base.[14] Abolishing the possibility of deprotonation by monomethylating the active-site lysine of rhodopsin prevents the formation of metarhodopsin II, and hence the R* stage is never reached.[15, 16] Thus, Schiff base deprotonation is obligate in the biochemical activation of rhodopsin. It is also clear that major conformational changes in the rhodopsin molecule accompany the formation of metarhodopsin II, and these alterations are transmitted to the next molecular entity in the visual cascade, the retinal G-protein.

The interaction of R* with its G-protein partner has been well studied.[17] This interaction results in catalysis of the exchange of GDP for GTP at the active site of the G-protein. When GTP is bound to the active site of the G-protein, the

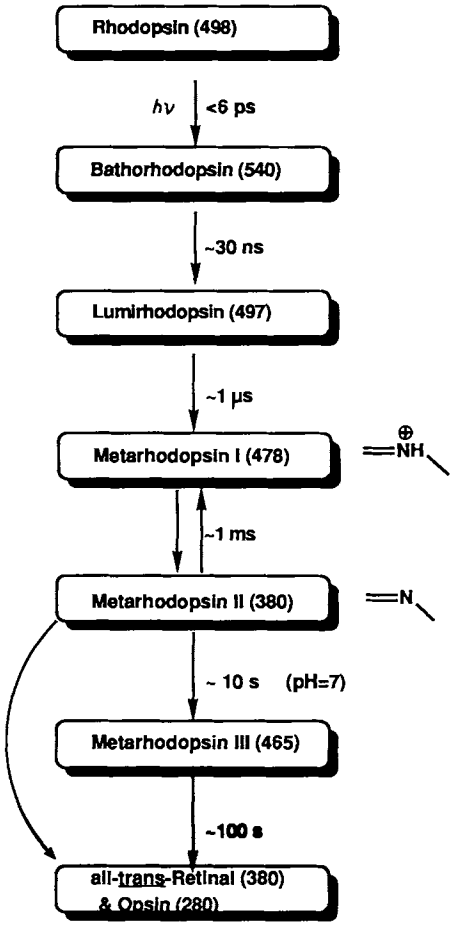

Fig. 5. Photochemistry of rhodopsin. The bleaching of rhodopsin results in the formation of the spectroscopically defined intermediates shown in the above figure. The λ_{max} values for the different intermediates are given in parentheses and their half-lives at room temperature are provided adjacent to the arrows.

latter becomes activated, enabling it to free from inhibition the rod outer-segment phosphodiesterase specific for cyclic-GMP (cGMP). And when this enzyme in turn is activated, it can hydrolyze cGMP at the diffusion-controlled limit.[18] This hydrolysis is thought to lower the free concentration of this effector. Since the sodium ion permeability of the rod outer-segment sodium channels is gated by cGMP,[19] hydrolysis of the latter results in the hyperpolarization of the rod outer segments. This change in membrane potential is signaled to other nerve cells in the retina and communicated to the brain, where the visual image can then be constructed.

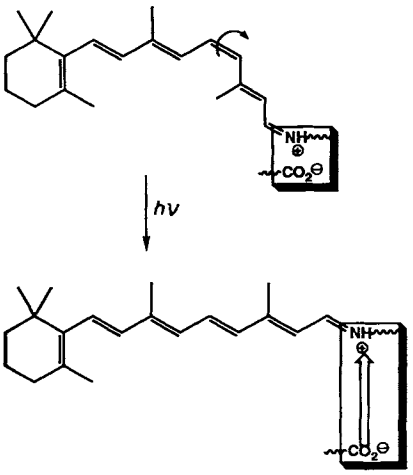

Fig. 6. Possible mechanism for charge separation caused by the *cis*-to-*trans* photoisomerization of the 11-*cis*-retinal protonated Schiff base. The carboxylate ion in the figure is part of the polypeptide backbone.

Subsequent to the formation of metarhodopsin II, its direct hydrolysis can occur to provide all-*trans*-retinal and opsin.[17] Metarhodopsin III can also be produced from metarhodopsin II, and the former intermediate may serve as a storage form for the latter physiologically active conformer.[17]

The fact that all-*trans*-retinal is liberated as a consequence of bleaching requires that a physiological mechanism be in place for the regeneration of 11-*cis*-retinal. Otherwise, vision would have the character of a once-in-a-lifetime event. The reason why vertebrate vision operates via a bleaching mechanism is presumably related to the role that bleaching plays in visual adaptation.[20] Sensory adaptation, including of course visual adaptation, refers to the ability of a sensing system to alter its sensitivity to match the strength of the ambient signal. This ability can be prodigious, for in the case of vision the eye must be able to distinguish between light intensities differing from the background by only a few percent over a range of approximately 10^{10} in ambient light intensity.[21] Although this process is multifactorial, one important aspect of it, namely, dark adaptation, is importantly controlled by the amount of rhodopsin in the rods. Dark adaptation is usually experienced when we move from a well-lit environment to a darkened one, such as a theater. Initially our sense of vision is quite limited, but it improves slowly with time. This slow phase of dark adaptation is described by a rate which is congruent with the overall rate of 11-*cis*-retinal regeneration.[21] This rate is characteristic for a given species; for humans, $t_{1/2}$ is 5 min, while for amphibians and rats it is 30 min and 40 min, respectively.[21, 22] Since there is a logarithmic relationship observed between the amount of rhodopsin and visual sensitivity,[21] an alteration in the level of rhodopsin will have a marked effect on visual sensitivity. The immense sensitivity of human vision, which can operate at the single photon level,[23] is partly a reflection of the exceedingly high concentration of rhodopsin in the rod outer segments (10^9 rhodopsin molecules per rod).[21] To decrease the inherent sensitivity of this system requires that the amount of pigment be modulated by the bleaching–regeneration cycles.

4. The Regeneration of Rhodopsin

4.1. The Visual Cycle

More than a half-century before it was understood that a vitamin A derivative is the photosensitive chromophore in vision, the great German physiologist *Kühne* had already achieved substantial insights into the visual process. For example, he had understood that the retina contained a photosensitive material that turned white (i.e., bleached) when it was exposed to light.[1] Furthermore, he discovered that the red color would not return in an isolated retina but required

the close apposition of the retinal pigment epithelium (PE) in order to regenerate its red color. This discovery was of great importance and has stood the test of time; in all the years since *Kühne*'s work—more than a century—no one has convincingly demonstrated rhodopsin rgeneration in an isolated retina.

The discovery of the role of vitamin A in vision led to analysis of the bleaching–regeneration cycle on a molecular level. It was quickly understood that the enzymological processing of vitamin A was at the heart of these transformations. The all-*trans*-retinal liberated by the bleaching of rhodopsin was shown to be rapidly reduced enzymatically in the retina by specific nicotinamide-linked retinol dehydrogenases to produce vitamin A.[24] The vitamin A is then transported to the pigment epithelium, where it is esterified, largely to long-chain saturated fatty acid esters, such as those in the palmitate and stearate series. For each of the three all-*trans*-retinoids, there is a corresponding 11-*cis*-retinoid (see Fig. 7), and the totality of biochemical reactions required to interconvert these six molecules comprises the classical and oversimplified visual cycle (Fig. 7). Thus, the double-bond isomerization reaction could potentially occur with any of three substrates and produce any of the three corresponding products, and it could occur either in the pigment epithelium or in the retina. After isomerization has occurred, the 11-*cis*-retinoid, in either the alcohol or the aldehyde form, must be transported back to the rod outer segments, by means of specific binding proteins,[25–28] where it can be used for rhodopsin regeneration (after oxidation, if 11-*cis*-retinol is transported back).

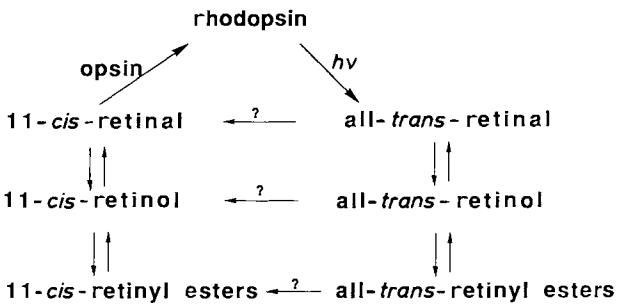

Fig. 7. The classical visual cycle.

The dynamic nature of the visual cycle can be understood from experiments designed to measure the amounts of the various retinoids during dark and light adaptation in living animals.[29, 30] In the albino rat, there is only a slight excess of retinoids; that is, all the opsin is bound to retinoids and there is only a small amount of retinoids left over. In this simple case, a striking flow of retinoids from the retina to the PE can be observed in the light, with the reverse occurring in the dark (Fig. 8).[21] In higher vertebrates and in amphibians there is an approximately threefold excess of retinoids over opsin. In these cases, the excess retinoids are stored in the PE as esters.[29] In the dark, the retinoid pool in an animal such as the frog can consist of up to 75% 11-*cis*-retinoids, of which 11-*cis*-retinal bound to opsin in the retina and 11-*cis*-retinyl esters in the pigment epithelium are the major components.[29, 31] In the light, there is a major shift to the all-*trans*-retinoid congeners, with the esters being the predominant form. Dark adaptation reverses this shift.[29, 31] Since none of the enzymes of the visual cycle has as yet been completely purified or characterized, possible elements of control remain unidentified.

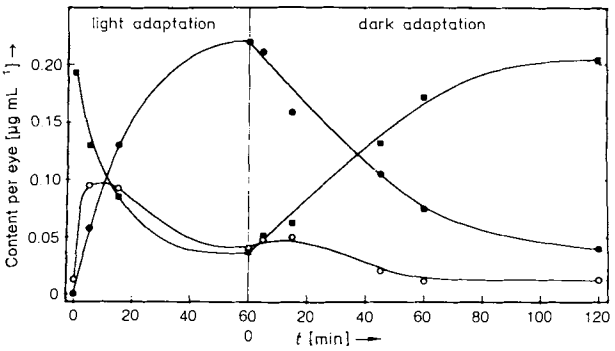

Fig. 8. Retinoid fluxes between the retina and pigment epithelium of the rat in the dark and in the light [29]. In the light the rhodopsin is bleached and the retinal is reduced and transported to the PE. The process is reversed in the dark. ▪-▪, retinal in retina; o-o, vitamin A in retina; •-•, vitamin A in pigment epithelium. (Taken from [29] with permission.)

4.2. A Thermal Isomerization Completes the Visual Cycle

In considering the nature of the isomerization process which provides the required 11-*cis*-retinoids in vision, it must first be determined if the reaction is photochemical or thermal in nature. It is quite clear that 11-*cis*-retinoids are regenerated in the dark from all-*trans*-retinoids. Furthermore, the rates of rhodopsin regeneration in dim light are independent of the wavelength of light that the animal is being exposed to.[32] These two facts support the idea that, unlike the bleaching process, the physiologically relevant reverse *trans*-to-*cis* isomerization phenomenon is purely thermal in nature. Although this presents chemical difficulties, there are clear teleological advantages in the process being a thermal enzymatic one. Two major advantages are that a thermal regeneration process will be independent of the wavelength and intensity of the ambient light and that an enzymatic process can be subjected to efficient control mechanisms unavailable in a photochemical process.

5. The Isomerization Problem

5.1. Introduction

Uncovering the nature of the isomerization reaction presents many nontrivial difficulties. One must determine both the substrate and the product of the isomerization reaction. As mentioned in Section 4.1, retinoids are found as retinols, retinals, and retinyl esters in the visual system (Fig. 9). Any one of the three all-*trans*-retinoids might be the substrate and any one of the three 11-*cis*-retinoids might be the isomerization product. A second crucial issue, which turns out to be inextricably linked to the nature of the substrate, is con-

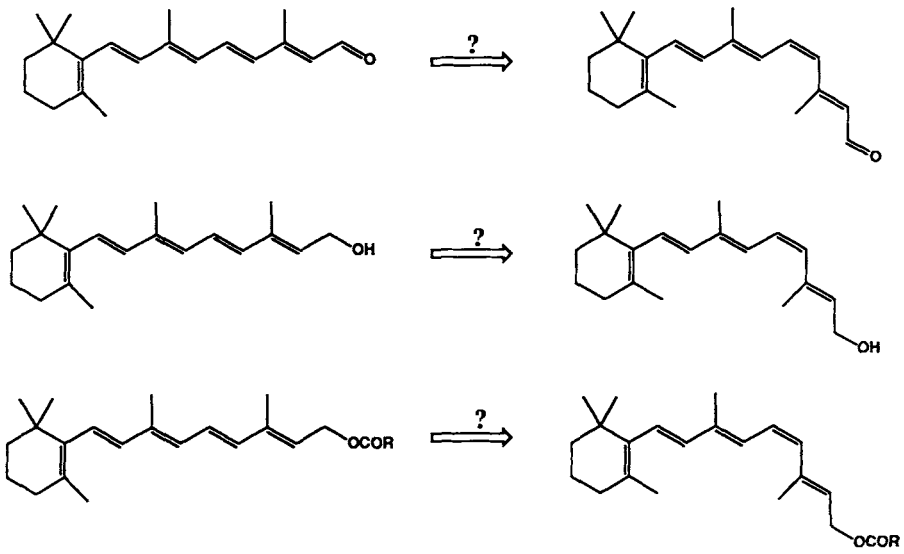

Fig. 9. Possible isomerization substrates.

cerned with where the energy comes from to drive the *trans*-to-*cis* isomerization reaction.

5.2. Thermodynamic Considerations

This thermodynamic issue was first pointed out in the 1930s by *Pauling*, who was considering carotenoid structures at the time.[33, 34] *Pauling* deduced from structural principles that certain *cis* double bonds should be unstable with respect to their all-*trans* counterparts (Fig. 10). In retinols, planar double bonds would cause the methyl groups to overlap with the hydrogen atoms indicated in Figure 10 if the polyene system as a whole remained planar. *Pauling* predicted large energetic differences between the sterically strained *cis* isomers and their *trans* counterparts due to the loss of resonance stabilization caused by a steric retreat from planarity. For example, he predicted that dividing an all-*trans*-carotenoid containing eleven double bonds into three noninteracting fragments containing three or five conjugated double bonds would raise the energy of the system by 16.1 kcal mol^{-1}.[34] As applied to the retinals, it could be estimated that 11-*cis*-retinal should be 8–9 kcal mol^{-1} higher in energy than all-*trans*-retinal.[35] It was assumed that relatively small deviations from planarity would eliminate conjugative interactions and thus resonance stabilization. Furthermore, although 7-*cis*-retinal would be predicted to be unstable, both 9-*cis*- and 13-*cis*-, as well as 9-*cis*,13-*cis*-retinal should be relatively stable (cf. Fig. 10). The 7-*cis*-retinal suffers from severe steric crowding, whereas the other isomers are relatively free of this problem.

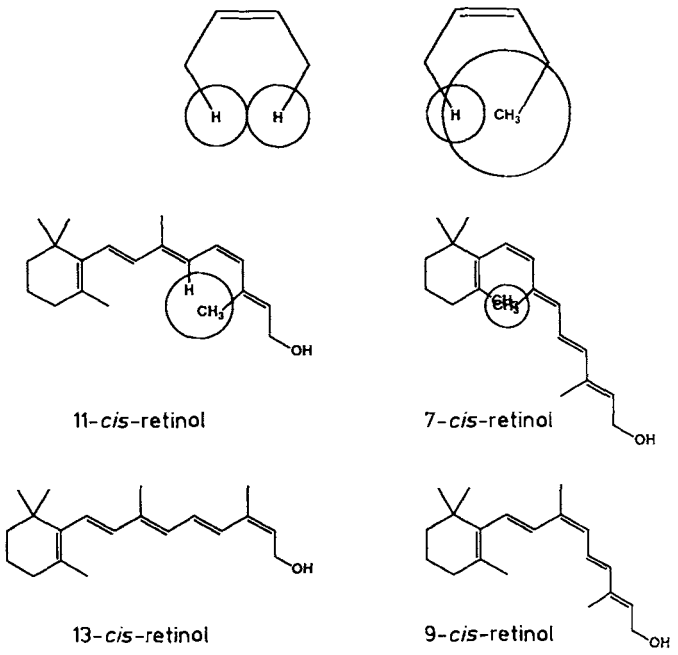

Fig. 10. Methyl–hydrogen repulsion as a source of strain in 11-*cis*-retinoids.

Early equilibrium measurements on the retinals were incorrect and greatly overestimated the stability of 11-*cis*-retinoids.[36] NMR measurements on retinal in trifluoroacetic acid showed none of the typical olefinic C–H resonances attributable to the 11-*cis* double bond, suggesting that 11-*cis*-retinal was not a major contributor at equilibrium.[37] These experiments were confirmed by HPLC measurements.[38] Furthermore, when the various isomers of the retinals and retinyl esters were brought into equilibrium with either iodine or trifluoroacetic acid, it was found that 11-*cis*-retinoids accounted for approximately 0.1 % of the equilibrium mixture.[39] The same results are obtained when the retinols are brought into equilibrium with iodine. There is a difference of 4.1 kcal mol^{-1} between 11-*cis*-retinal and its all-*trans* counterpart, with similar differences being observed between the other retinoid congeners. Since the destabilizing interaction involves intramolecular steric repulsion between the hydrogen at C10 and the methyl group at C13 (or the C13 vinyl moiety when the molecule is in the 12-s-*cis* form), the nature of the substitution at C15 does not have a marked effect on the equilibrium position. Thus, *Pauling*'s brilliant structural hypothesis is qualitatively correct. Quantitatively, it somewhat missed the mark, largely because it was not understood at the time that resonance interactions between conjugated double bonds were still possible even when the double bonds were not completely coplanar.

The three-dimensional structure of 11-*cis*-retinal has been determined by X-ray analysis and is in accord with *Pauling*'s hypothesis, because rotation about the C12–C13 bond is obvious in comparison to the structure of all-*trans*-retinal (Fig. 11).[40] In the crystalline state there is a large torsion

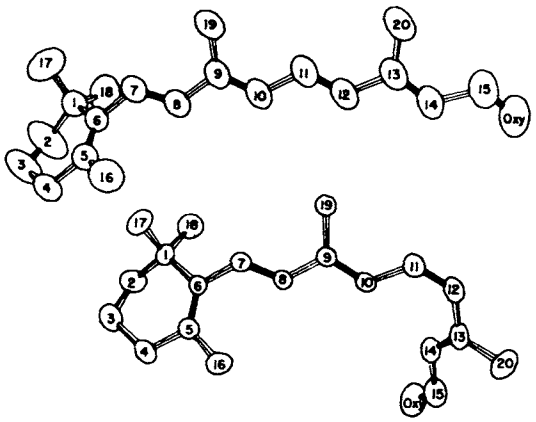

Fig. 11. X-ray structures of 11-*cis* and all-*trans*-retinal [40]. (Taken from [40] with permission.)

about the C12–C13 bond such that the C12 to O moiety is no longer coplanar with the rest of the molecule.[40] In addition, the bond angles at C11 and C12 are 127.3 and 130.3°, respectively, and the 12-s-*cis* conformer is favored.[40] Furthermore, as expected, 11-*cis* isomers are major contributors at equilibrium in both 13-desmethylretinal and the C11-substituted retinal shown in Figure 12.[41,42] In the former compound, removal of the methyl group at C13 abolishes the destabilizing steric interaction, and in the latter molecule the substituent at C11 destabilizes the all-*trans* but not the 11-*cis* configuration. It should be emphasized that destabilization of the 11-*cis*-retinoid configuration by an intramolecular steric interaction means that solvent perturbations should have little or no effect on the equilibrium position. This view has been confirmed in hydrocarbons, chlorinated hydrocarbons, and alcohols as solvents.[43] In addition, the equilibrium position is not measurably perturbed by phospholipid-based vesicles prepared from egg-yolk lecithin containing *cis*-unsaturated fatty acid esters.[44] Therefore, we can be reasonably certain that the equilibrium constraints measured in vitro will be quite relevant to the situation in vivo, and hence an energy source will have to be identified to account for the preponderance of the 11-*cis*-retinoid configuration in the eye.

5.3. Catalysis of Isomerization in Model Systems

Another concern, in addition to the thermodynamic considerations, relates to the mechanisms by which the isomerization of retinoids may be catalyzed. It is of interest to consider the thermochemistry of the uncatalyzed isomerization reactions. Here only the retinals have been seriously investigated, and then largely the conversion of 11-*cis*-retinal to all-*trans*-retinal.[36] The activation energy E_A for the purely thermal conversion is 25 kcal mol^{-1}.[36] This number is far below the bond energy of a π bond of approximately 64 kcal mol^{-1}. This means that the presumed diradical centers are strongly stabilized by the flanking double bonds—a result that is expected based on what is known about the isomerization of conjugated olefins.[45] The E_A value of 25 kcal mol^{-1} is interesting, because it means that a relatively small decrease in the E_A of approximately 5 kcal mol^{-1} would allow the reaction to occur at a significant rate at physiological temperatures. In principle, this decrease might be achieved by extending the conjugation of the polyene system even further by Schiff base formation with an aromatic amine (Fig. 13).[46] This could have biological relevance, because aromatic amines abound in nature. In fact, however, aromatic Schiff bases of the kind shown in Figure 13 actually thermally isomerize more slowly than their retinal precursors.[46]

There have been several studies on the catalyzed isomerizations of retinoids and carotenoids. Much of the early literature on this subject was concerned with free-radical-induced isomerization reactions of the carotenoids and retinoids, with iodine as the usual catalyst.[47] Clearly, the retinoids can be brought into equilibrium by free radicals, almost certainly via addition–elimination processes, but these kinds of mechanisms are probably not relevant to the biological situation.

Although Schiff base formation with the retinals in and of itself will not catalyze the isomerization reaction, protonated Schiff bases readily isomerize.[46] It is likely that base catalysis is also involved, because the isomerization rates are markedly affected by the nature of the counterions.[46] For example, the first-order rate (25 °C) of isomerization of the *N*-butylamine Schiff base of 11-*cis*-retinal catalyzed by HCl

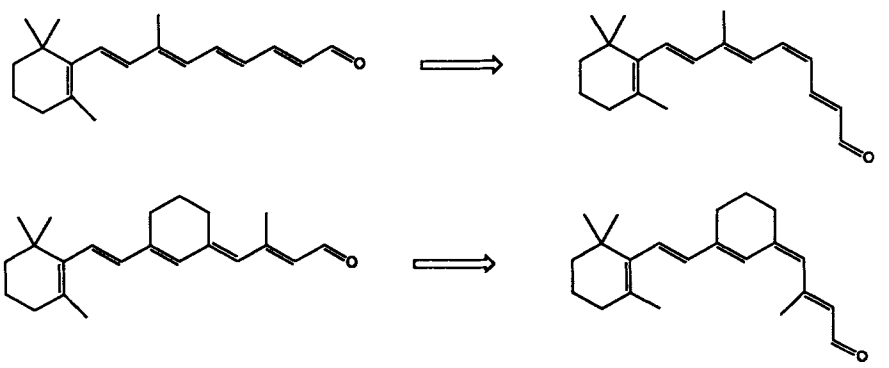

Fig. 12. Retinals in which the 11-*cis* isomer is relatively stable compared to the all-*trans* congener.

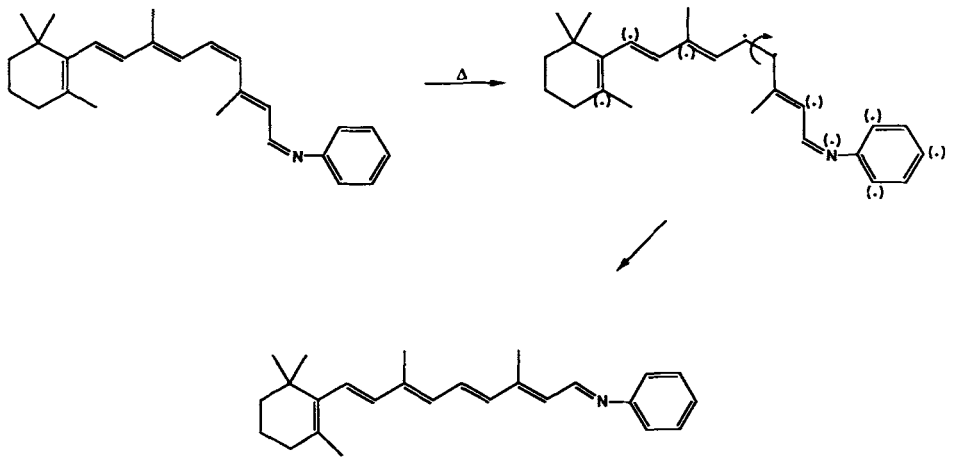

Fig. 13. Thermal isomerization of an aromatic amine Schiff base of 11-*cis*-retinal.

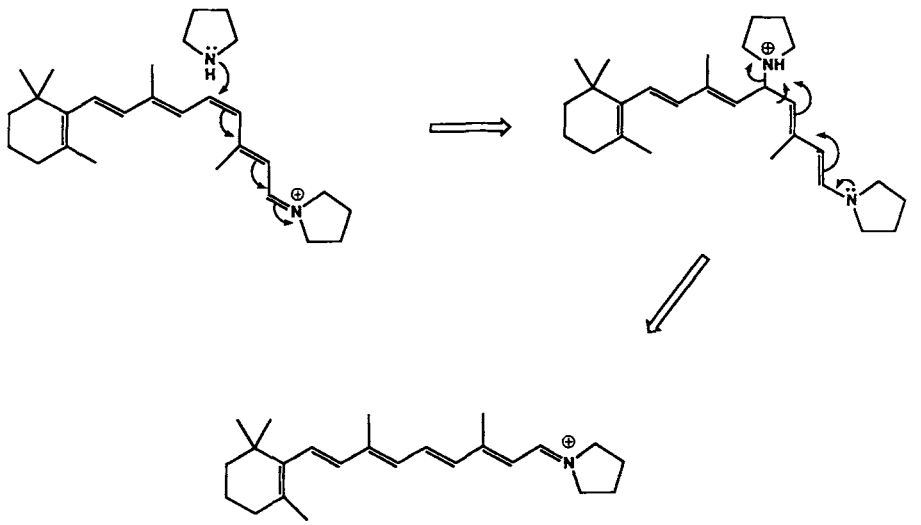

Fig. 14. Secondary amine catalysis of the isomerization of 11-*cis*-retinal.

is $2 \times 10^{-2}\ s^{-1}$, whereas, under the same conditions, it is only $2.6 \times 10^{-6}\ s^{-1}$ with trifluoroacetic acid.[46]

To explore the base-catalyzed mechanism, Schiff bases formed with secondary amines such as piperidine were studied.[46] The difficulty with protonated primary amine Schiff bases is that strong bases cannot be used as catalysts, because they will simply deprotonate the protonated Schiff base. When 11-*cis*-retinal was treated with an equivalent of piperidine hydrogen perchlorate and a catalytic amount of piperidine, the rate-limiting step in the isomerization pathway turned out to be Schiff base formation (Fig. 14).[46] Therefore, it appears that acid-base catalysis markedly enhances the rates of isomerization of retinal Schiff bases. These kinds of reactions can also occur under physiological conditions. The retinals can be isomerized both by reduced flavins[48] and by phosphatidylethanolamines.[49] Both isomerization reactions are thought to require Schiff base formation prior to the actual isomerization reaction. For catalysis by phosphatidylethanolamine, it is possible that a phosphate oxygen acts as the base.[49]

Although several model isomerization studies have been performed on the retinals, no substantial studies have been reported on the retinols or retinyl esters. Both series of compounds would be expected to form carbonium ions easily, and these could then isomerize. The reason why model isomerization studies have not been reported on these molecules might have to do with their propensities to undergo elimination reactions. At least with the retinols, it has been found that their treatment with HCl produces anhydroretinols as the major product (Fig. 15).[50]

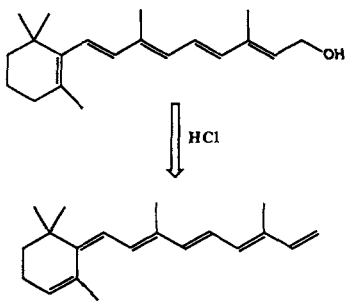

Fig. 15. Acid-catalyzed formation of an anhydroretinol from all-*trans*-retinol.

6. The Nature of the Isomerase Reaction

6.1. The Energy Source Cannot Be a Binding Protein

The key issue in approaching the isomerase question is to understand the nature of the energy source that drives the

thermodynamically uphill process. Superficially one might argue that the availability of opsin can serve as the thermodynamic sink to drive the isomerization process towards 11-*cis*-retinal formation. This could be possible in instances where there are equivalent amounts of vitamin A and opsin, but not where there are excess amounts of vitamin A, as in humans, where 11-*cis*-retinoids build up in the eye in the dark even after rhodopsin synthesis has already been completed. Another possibility for an energy source might be specific binding proteins that could recognize the 11-*cis*-retinoid moiety. Indeed, several retinoid binding proteins have been identified in the visual system, although only one of them is reported to be specific for the 11-*cis* linkage.[25] Ths binding protein, however, is only found in amounts of about 10–20% relative to vitamin A levels in the eye and hence can probably be discounted as a possible energy source. It would have to be found in at least stoichiometric amounts to be useful. Furthermore, 11-*cis*-retinyl esters, which are the major 11-*cis*-retinoid storage form, are known to exist in the pigment epithelium in an uncomplexed form in oil droplets, at least in amphibians.[51] Nevertheless, it was possible that hitherto undescribed retinoid binding proteins might be important, and it was critical to determine whether this mode of energy transduction was possible. The use of aromatic amines that "short-circuit" the visual cycle provided an unanticipated solution to this problem.

We had found that retinotoxic aromatic amines of the type shown in Figure 16 were capable of depleting previously

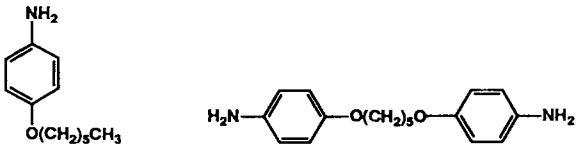

Fig. 16. Retinotoxic aromatic amines.

formed 11-*cis*-retinoids in the dark.[52–54] These molecules were capable of engaging in Schiff base formation with 11-*cis*-retinal in vitro and rapidly catalyzing its exothermic isomerization to all-*trans*-retinal in phosphatidylcholine-based vesicles (Fig. 16).[53, 54] These same Schiff bases were also found to be present in vivo after the administration of these amines. This led to the hypothesis that these aromatic amines depleted 11-*cis*-retinoids in vivo, in essence short-circuiting the visual cycle by depleting the 11-*cis*-retinal as it was formed.[53] This mechanism has important consequences for the operation of the visual cycle. First, it demonstrates that a non-energy-linked retinal isomerase cannot exist, because that is what the aromatic amines are, and their effects are entirely destructive. Second, it shows that the enzymes of the visual cycle are active in the dark. Third, it demonstrates a general mechanism of toxicity in the retina. Finally, and most importantly, it shows that specific 11-*cis*-retinoid binding proteins cannot be important as an energy source to produce these retinoids in vivo. If specific 11-*cis*-retinoid binding proteins were present, then the aromatic amines should not have depleted the endogenous 11-*cis*-retinoids.

6.2. The Nature of the Substrate in Vivo

The results described in Section 6.1 show that simple stabilization mechanisms are not in and of themselves sufficient to favor the production of 11-*cis*-retinoids. In order to begin to address the issue of the energy source, it was important first to gain some understanding of the nature of the isomerase substrate. At the time these experiments were performed, no in vitro system capable of carrying out the *trans*-to-*cis* isomerization reaction had yet been uncovered. To approach the issue of substrate, the in vivo double-labeling experiment diagrammed in Figure 17 was performed.[55] The idea behind this experiment is straightforward. A racemic mixture of [(15*S*)-^{3}H]- and [(15*R*)-^{3}H]-all-*trans*-retinol plus [15-^{14}C]-all-*trans*-retinol was administered to either rats or frogs.[55] From previous experiments we knew that this mixture would be incorporated into the visual systems of the animals. If isomerization occurs at the aldehyde level of oxidation, then one-half of the ^{3}H should be lost in the initially formed 11-*cis*-retinol (ester), whereas ^{3}H should be retained if isomerization occurs at the alcohol level of oxidation.

In an in vivo double-labeling experiment such as this, a number of implicit assumptions must be made if the results are to be interpretable. These assumptions and their conse-

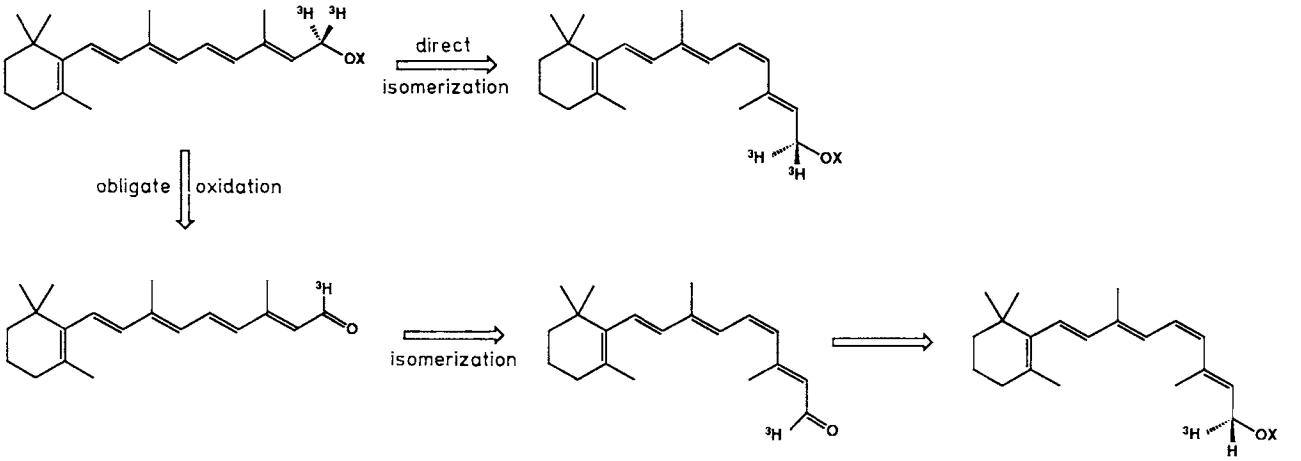

Fig. 17. Double-labeling experiment designed to determine if isomerization occurs at the alcohol or aldehyde oxidation state.

quences are as follows: (1) Nonspecific (i.e., nonenzymatic) loss of ^3H is minimal in vivo. If it were substantial, then ^3H loss might exceed the 50% limit, and the loss would be observed to continue over time. However, this type of loss is unlikely, since the ^3H label in retinol is quite resistant to exchange in protic solvents. (2) Kinetic isotope effects that would alter $^3H/^{14}C$ ratios from expected values are assumed to be small. Neither a primary ^{14}C isotope effect nor a secondary ^3H isotope effect would be expected to decrease reaction rates by even 10%. Because the ^3H label is released during oxidation, a primary ^3H isotope effect on product formation is not possible. Hence, the $^3H/^{14}C$ ratios in retinal will not be affected by possible primary isotope effects. $^3H/^{14}C$ ratios of the reactants in an oxidation reaction could be increased by a primary ^3H isotope effect, but only if the reaction had gone substantially to completion; this situation would not be expected in the experiments described here where low conversions occurred. (3) It is important that redox reactions of the retinols mediated by retinol dehydrogenases should not be too rapid relative to the isomerization time scale. However, these reactions can be slowed with retinol dehydrogenase inhibitors.

Given these assumptions, the double-labeling experiments, as performed on the rat, produced unequivocal results.[55] Approximately 70% of the ^3H of the starting material was retained in the initially formed 11-*cis*-retinyl esters, and this number could be increased to greater than 80% by the inclusion of 4-methylpyrazole, a well-known inhibitor of the retinol dehydrogenases.[55] After a long period of incubation (24 h), the ^3H loss for all of the retinoids was approximately 50%, a result that shows that only stereospecific loss of ^3H occurred. (The issue of the stereochemistry of the dehydrogenases will be further addressed in Section 6.4.) Thus, isomerization must occur at the alcohol level of oxidation; that is, all-*trans*-retinal cannot be the substrate. Although these experiments still leave both ester and alcohol as possible substrates, they favor the former, because, under all conditions, the recovered all-*trans*-retinol had lost 50% of its ^3H and hence could not easily have served as an isomerase substrate, given that the products retained substantially greater than 50% ^3H. The all-*trans*-retinyl esters, on the other hand, retained approximately 90% of their ^3H and hence could be isomerase substrates.

6.3. 11-*cis*-Retinoid Regeneration in Vitro

As mentioned in Section 4, *Kühne*[1] demonstrated that a bleached frog retina would not regenerate its visual pigment unless it was placed in contact with its pigment epithelium. The usual experience of subsequent investigators was that 50–85% pigment regeneration occurs in these in vitro preparations after a single strong bleaching.[29, 56–58]

However, even this degree of regeneration might be accounted for by the use of endogenous, preformed 11-*cis*-retinoids for rhodopsin regeneration, without any de novo biosynthesis of these retinoids prior to regeneration, especially if the preparations had not been adequately bleached to deplete stores of 11-*cis*-retinyl esters in the pigment epithelium. This possibility, along with the repeated failures to demonstrate a retinal isomerase or, for that matter, any retinoid isomerase, led to a hypothesis that perhaps the biosynthesis of 11-*cis*-retinoids does not occur outside the living organism, either because a necessary efferent neural input controlling dark adaptation is disrupted when the optic nerve is severed, or perhaps because the in vitro culture systems are inadequate to maintain tissue viability.

Initial investigation of this problem proved that efferent neural control of rhodopsin regeneration does not occur, because, when the optic nerve was severed unilaterally in living frogs, both of the animal's eyes regenerated rhodopsin at an identical rate.[59] When amphibian eyecup preparations (in which there is an intact retina and pigment epithelium) were placed in an amphibian tissue culture medium, clear evidence for the de novo biosynthesis of 11-*cis*-retinoids was obtained.[59] Rhodopsin regeneration occurred after repeated bleaching–regeneration cycles, and unambiguous data for the de novo biosynthesis of 11-*cis*-retinyl esters in these eyecup preparations was also obtained.[59]

Based on the experiments described above, it was of interest to simplify this in vitro 11-*cis*-retinoid biosynthetic system to facilitate its eventual characterization and purification. A $600 \times g$ supernatant membrane preparation from amphibian retina/pigment epithelium proved capable of converting added all-*trans*-retinol into a mixture of 11-*cis*-retinol, 11-*cis*-retinal, and 11-*cis*-retinyl palmitate.[60] All-*trans*-retinyl palmitate and all-*trans*-retinal were also generated by these membranes. A time-dependent, approximately linear increase in the absolute amount of [^3H]-11-*cis*-retinol formed was found, while, in the absence of eye tissue, none was produced.[60] In Figure 18A, data are shown for the relative amounts of the various isomers of [^3H]retinol present as a function of time in an incubation with eye tissue. It is clearly shown that [^3H]-13-*cis*-retinol, a retinol isomer of no known visual function, is not formed in substantial amounts. Figure 18B gives the results of a control experiment in which retina/pigment epithelium supernatant was not included. A small amount of nonspecific isomerization of all-*trans*-retinol to 13-*cis*-retinol was observed, but a measurable amount of 11-*cis*-retinol was not formed. As would be expected of a biologically significant process, the membrane-bound 11-*cis*-retinoid biosynthetic activity proved to be heat sensitive.[60] Intact protein and membrane are required, because activity was abolished by treatment with proteinase K or phospholipase C.[61]

Great care was taken not to misidentify the 11-*cis*-retinoids produced by the membrane system, since this has been a source of serious errors in the past. The 11-*cis*-retinoids described were identified by both chromatographic and chemical means.[60] When biosynthetically formed 11-*cis*-retinol was chromatographically purified and either isomerized with iodine or esterified with palmitoyl chloride, it behaved identically to authentic material.[60]

The results described above unequivocally demonstrate the presence of an 11-*cis*-retinoid biosynthetic activity which was able to produce substantial quantities of 11-*cis*-retinoids. For example, 11-*cis*-retinol could constitute up to 40–50% of the isolated retinol pool, a figure far removed from the equilibrium value. It was of interest to determine whether the isomerase activity is located in the retina or the pigment epithelium and to determine the precise nature of the substrate for isomerization. Studies on the amphibian

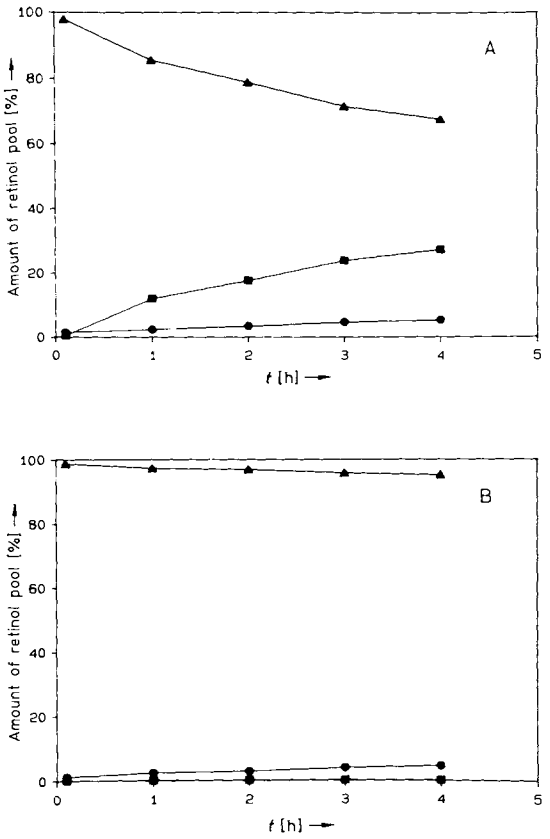

Fig. 18. Isomeric distribution of [^{3}H]retinol during in vitro incubation [60]. 1.0 mL of 600 × g supernatant from light-adapted retina pigment epithelium of two frog eyes (A) or 1.0 mL of phosphate buffer (B) was incubated in the dark with 50 μL of 10% bovine serum albumin and 4 μCi of [11,12-^{3}H]-all-*trans*-retinol in 4 μL of ethanol. Hexane extraction and HPLC analysis of [^{3}H]retinol isomers were performed hourly on 200-μL samples. ■-■, [^{3}H]-11-*cis*-retinol; ●-●, [^{3}H]-13-*cis*-retinol; ▲-▲, [^{3}H]-all-*trans*-retinol. (Taken from [60] with permission.)

showed that the isomerization activity was almost entirely located in the membranes of the pigment epithelium.[60] The trivial amount of activity found in the retinal fraction was almost certainly due to contamination by a small amount of adherent pigment epithelium. The isomerization activity has also been observed in the bovine system, where a more complete separation of the retina from the pigment epithelium is possible, and there the activity was found only in the pigment epithelium membranes.[62]

These results explain why previous attempts to obtain pigment regeneration by adding various all-*trans*-retinoids to isolated retinas were negative.[63, 64] On the other hand, they are in conflict with two published reports in which it was claimed that pigment epithelium tissue and homogenates derived from it were incapable of transforming added all-*trans*-retinol into any 11-*cis*-retinoids.[65, 66] However, these reports are now known to be in error because the all-*trans*-retinol was added in 2–4% ethanol in the absence of any carrier protein. The membrane-bound isomerization system is denatured under these conditions.[60, 61] The successful demonstration of isomerase activity in the pigment epithelium membranes depended on the use of very low ethanol levels, 0.5% bovine serum albumin as carrier, and the detection and confirmation of the 11-*cis*-retinol product.[60] Recently, it has been demonstrated that added all-*trans*-retinol is processed into 11-*cis*-retinoids by intact pigment epithelium cultures.[67, 68]

6.4. Substrate Specificity of the Isomerase

Since labeled all-*trans*-retinol can be converted into all-*trans*-retinal, all-*trans*-retinyl palmitate, and the three 11-*cis* congeners by the pigment epithelium membrane preparation described in Section 6.3, it cannot be assumed that all-*trans*-retinol is the substrate for the isomerase system or that 11-*cis*-retinol is the direct product of the isomerase action. The possibility that all-*trans*-retinal is the isomerization substrate was easily ruled out. Both unwashed membranes and membranes thoroughly washed to remove nicotinamide-based cofactors were able to isomerize added all-*trans*-retinol equally well.[60] However, only the unwashed membranes, in which redox reactions occur, substantially processed all *trans*-retinal. In the bovine system, isolated pigment epithelium membranes will not isomerize all-*trans*-retinal to 11-*cis*-retinal.[62] The proposition that free all-*trans*-retinal cannot be the isomerization substrate was directly demonstrated by the finding that [15-^{3}H,15-^{14}C]-all-*trans*-retinol is processed to 11-*cis*-retinol by the native frog and bovine pigment epithelium membranes with complete retention of the tritium label (Fig. 19).[61] This result is completely consistent with the in vivo variant of the double-labeling experiment described in Section 6.2[55] and rules out the possibility that free all-*trans*-retinal is the isomerase substrate, since tritium would be lost if the retinol were oxidized before isomerization.

The experiments described above show that retinal cannot be the substrate, but they do not distinguish between retinol and retinyl palmitate as possible substrates. When all-*trans*-retinol is processed by bovine pigment epithelium membranes that have been irradiated with UV light and washed, virtually all of the retinol is esterified to form retinyl esters (Fig. 20 A).[69] Subsequently, 11-*cis*-retinol is produced concomitant with a decrease in the amount of all-*trans*-retinyl esters. Furthermore, when all-*trans*-retinyl palmitate is processed by these membranes, 11-*cis*-retinol is produced, as shown in Figure 20 B.[69] Other retinyl esters, such as the oleate and decanoate esters, are also processed to 11-*cis*-retinol, but not to their corresponding 11-*cis*-retinyl esters.[70] Although these experiments taken together do not prove the point unequivocally, they strongly suggest that retinyl esters are the actual isomerase substrates and that the esters are directly converted into 11-*cis*-retinol. The ramifications of this kind of process will be discussed in Section 7.1, when energetic questions are addressed.

The specificity of the isomerase system towards particular retinol isomers is considerable. In washed pigment epithelium membranes, added 9-*cis*- and 13-*cis*-retinol are efficiently esterified; however, neither is isomerized to a significant extent.[61] Methylated analogues of all-*trans*-retinol such as the *O*-methyl and 15-methyl derivatives have been studied. The *O*-methyl ether derivative is completely inactive, whereas the 15-methyl derivative is an exceedingly weak substrate for the isomerase.[71] Thus, the isomerase system appears to be highly specific for all-*trans*-retinoids.

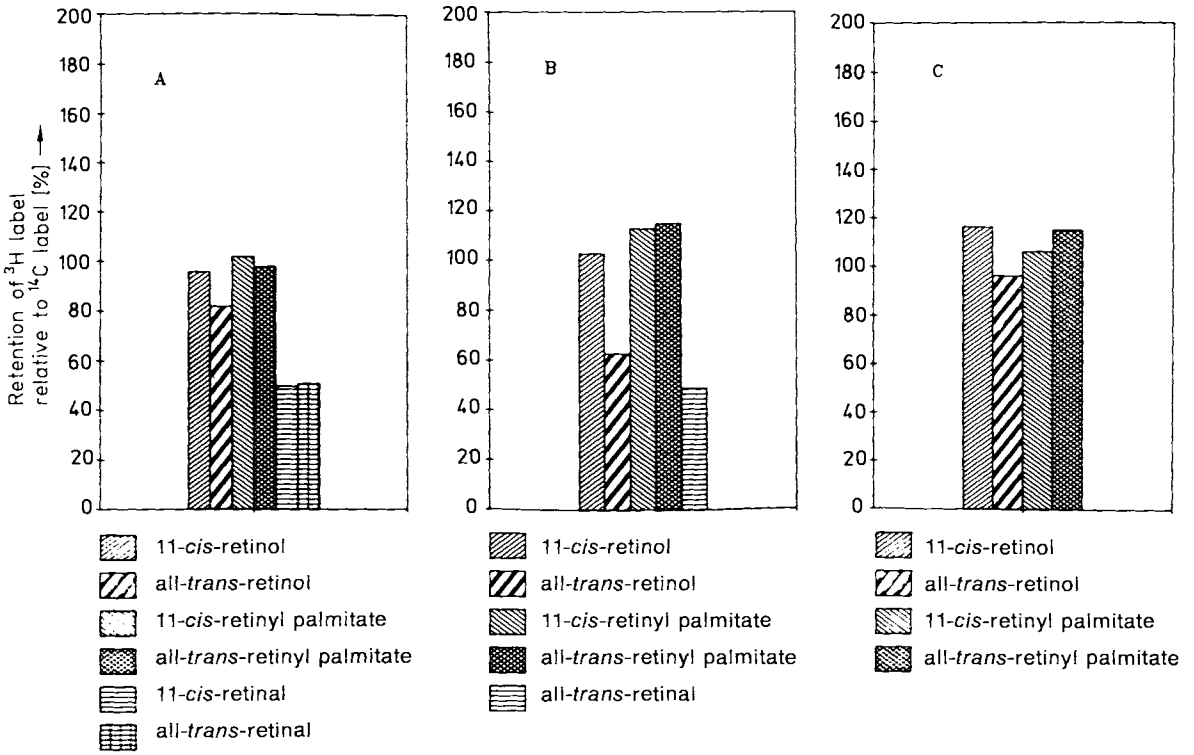

Fig. 19. Double-labeling experiments on frog epithelium 600 × g supernatant (A), on frog retina pigment epithelium washed 600 × g particulate fraction (B), and on bovine pigment epithelium 150000 × g particulate fraction (C) [61]. A) A mixture of [15-^{3}H]- and [15-^{14}C]-all-*trans*-retinol containing 0.1 μCi of ^{3}H (^{3}H:^{14}C = 5.2:1) was incubated with 4 mL of retina pigment epithelium 600 × g supernatant from four light-adapted *Rana pipiens* frogs and 100 μL of 10% bovine serum albumin for 3 h at room temperature. The retinoids were analyzed by standard methods. B) The washed 600 × g particulate fraction was prepared by two successive pelletings of the 600 × g supernatant at 50000 g for 20 min at 4 °C, followed by resuspension each time in the original volume of buffer. A mixture of [15-^{3}H]- and [15-^{14}C]-all-*trans*-retinol containing 0.1 μCi of ^{3}H (^{3}H:^{14}C = 5.2:1) was incubated with 4 mL of retina pigment epithelium washed 600 × g particulate fraction from four light-adapted *Rana pipiens* frogs at room temperature for 3 h. The retinoids were analyzed by standard methods. No appreciable radioactivity associated with 11-*cis*-retinal was found. C) The same amount of [^{3}H]- and [^{14}C]-labeled all-*trans*-retinol in 100 μL of 10% bovine serum albumin (as retinol carrier) was incubated with 3 mg of protein from bovine pigment epithelium suspended in 4 mL of 50 mM phosphate buffer (pH 7.2) at 35 °C for 1 h. The retinoids were analyzed by standard methods. This homogenate preparation is essentially free of redox activity since appreciable quantities of 11-*cis*- and all-*trans*-retinal were not formed. All four retinoid isomers analyzed completely retained their ^{3}H label. (Taken from [61] with permission.)

The specificity of the isomerase described above needs to be reconciled with the observed lack of stereospecificity found in vivo.[72] It is a fact that the intraocular injection of [15-^{14}C]-13-*cis*-retinol and [11,12-^{3}H]-all-*trans*-retinol leads to the incorporation of both isotopes into rhodopsin with roughly equal efficiency.[72] This in vivo result can also be reproduced in vitro under appropriate conditions. For example, with unwashed pigment epithelium membranes, 13-*cis*-retinol appears to be isomerized to 11-*cis*-retinoids approximately as rapidly as all-*trans*-retinol itself.[61]

These results can be reconciled when it is realized that unwashed membranes contain nicotinamide-based cofactors along with the enzymes necessary to oxidize the added 13-*cis*-retinol to 13-*cis*-retinal. Nonenzymatic isomerization of 13-*cis*-retinal gives all-*trans*-retinal, which is then reduced to all-*trans*-retinol. The kinetically facile and thermodynamically favorable isomerization of 13-*cis*-retinal to all-*trans*-retinal has previously been shown to occur in the presence of phosphatidylethanolamine or lipids derived from the retina.[49] Indeed, the retinals are readily isomerized by various primary and secondary amines (cf. Section 5.3).[46] The possible physiological significance of this "chemical" isomerization pathway remains to be determined, although it would explain why 13-*cis*-retinoids are not normally found in the eye. The rapid chemical and non-isomerase-mediated isomerization of 13-*cis*-retinal to all-*trans*-retinal, followed by the reduction of the latter to the isomerase system precursor, all-*trans*-retinol, could rapidly utilize any 13-*cis* retinoids present and would act as a form of salvage pathway.

Structure–activity studies were also performed on a variety of dihydroretinols (Fig. 21).[73] None of the dihydro isomers was substantially processed into its 11-*cis* counterpart, although vitamin A_2 (3,4-didehydro-all-*trans*-retinol) was. Thus, an intact polyene chain is essential if a molecule is to be an isomerase substrate.[73] The mechanistic ramifications of this will be discussed in Section 8. It is interesting to note that vitamin A_2 is an important visual chromophore in early amphibian development and, as mentioned, was processed by the isomerase system.[73]

6.5. Biochemical Characterization of the Isomerase System

As already mentioned in Section 6.3, the isomerase system is membrane bound. The isomerase activity can be removed from the supernatant by centrifugation, with the concomitant appearance of the activity in the pellet.[60] The isomer-

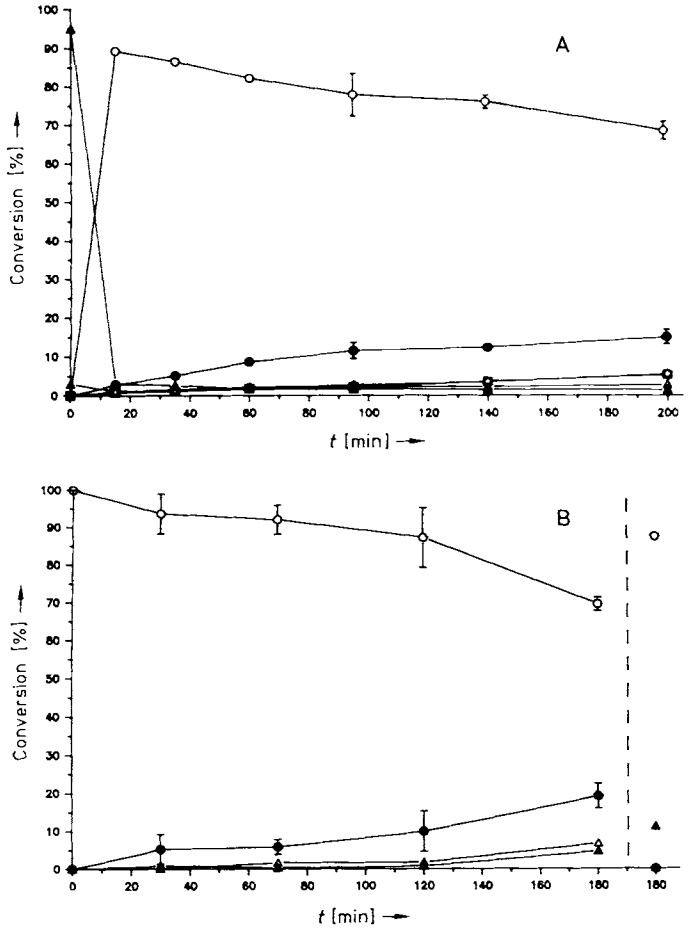

Fig. 20. Processing of vitamin A (A) and all-*trans*-retinyl palmitate (B) by irradiated pigment epithelial membranes [69]. A) Bovine pigment epithelial membranes were irradiated and washed. The membranes (2 mg mL^{-1}) were incubated with 0.05 μM of [11,12-$^3H_2$]-all-*trans*-retinol (50 Ci mM^{-1}, Amersham) and bovine serum albumin. In the absence of membranes no 11-*cis*-retinol was formed. At the indicated times, the retinoids were extracted with methanol–hexane and analyzed by HPLC. Individual experiments were run in duplicate and repeated several times. Small amounts of the retinals (<5%) were also found after incubation. B) Membranes were incubated with synthetic [^{3}H]-all-*trans*-retinyl palmitate (0.3 μM, 5 Ci mM^{-1}). At the indicated times samples were removed, and the retinoids were analyzed as in A. Control incubations in the absence of membranes showed substantially larger amounts of all-*trans*-retinol formed (approximately 10% of the total radioactivity at end of incubation) than in the case where membranes were added. ○-○, retinyl esters; ●-●, 11-*cis*-retinol; △-△, 13-*cis*-retinol; ▲-▲, all-*trans*-retinol. vitamin A_2

Fig. 21. Dihydroretinoids and vitamin A_2 as isomerase substrates.

ization activity also appears to distribute, without great preference, throughout the various membrane fractions, as determined by centrifugation studies.[62] These studies are complicated by the large amount of ester synthetase activity that appears to comigrate with the isomerase activity.[60, 62] However, extensive sonication of amphibian PE membranes produced a 100 000 × g supernatant of light membranes so strongly depleted in their ability to process all-*trans*-retinol by routes other than isomerization that less than 8% of the added retinol was esterified.[61] The isomerase activity in these membranes was saturable upon addition of all-*trans*-retinol, as required of a biologically significant process, and showed an apparent V_{max} of 5 pmol h^{-1} per milligram of protein and an apparent K_M of 0.8 μM. The origin of this low V_{max} value is discussed below. The pH optimum is 8.0.[61] In a less purified 600 × g supernatant, it is estimated that the V_{max} is 100 pmol h^{-1} per eye. This value is a lower limit, because a substantial portion (approximately one-half) of the isomerase activity remains in the 600 × g pellet, and activity is lost during homogenization. In living *Rana pipiens* frogs, the rate of 11-*cis*-retinoid synthesis during dark adaptation is 1–2 nmol h^{-1} per eye, and 11-*cis*-retinyl palmitate is formed during prolonged darkness about one tenth as fast.[29, 31] Therefore, even in the absence of any unknown rate-limiting cofactors, the in vitro rate of 11-*cis*-retinoid formation is substantial and comparable to the physiological rate.

In a 600 × g supernatant from bovine pigment epithelia, the V_{max} for isomerization is approximately 1 nmol h^{-1} per milligram of protein. The low V_{max} described above in the amphibian case was measured in a system that had purposefully been depleted of ester synthetase activity. Later experiments demonstrated that the esters are obligate intermediates in the isomerization process. This explains the much higher rates found with crude membranes compared to membrane preparations that had been depleted of their ester synthetase activity.

Although the isomerase and ester synthetase activities are quite easily destroyed by a wide range of detergents, it has recently proven possible to find adequate detergents for their solubilization and further purification.[74]

6.6. Detergent Solubilization and Partial Purification of the Isomerase and Ester Synthetase

The isomerase and ester synthetase enzymes are readily denatured by a wide variety of detergents.[61] However, we have recently been able to solubilize both activities successfully in the zwitterionic detergent Zwittergent-3,14 [3-(*N*,*N*-dimethyl-*N*-tetradecylammonio)-1-propanesulfonate].[75] Using ion exchange and gel filtration chromatography, the ester synthetase was purified approximately 200-fold.[74] The isomerase was purified approximately 10–14-fold after anion exchange chromatography.[74]

Several interesting observations were made on the enzymes as a consequence of these purification studies. As previously mentioned (Section 6.4), PE membranes are capable of producing retinyl esters from added retinols in the absence of added acylating agents, such as fatty acyl CoA derivatives. This was first discovered by *Krinsky*[75] and sug-

gests that the membranes themselves contain the acyl donors. Solubilization and substantial purification of the retinyl ester synthetase readily revealed the source of the acyl donor. It is the membrane constituent lecithin (phosphatidylcholine), and the transfer occurs from the 1-position of the phospholipid to the retinol, producing a retinyl ester and a 2-acyl lysophospholipid (Fig. 22).[74] Hence, the enzyme is a lecithin:retinol acyltransferase (LRAT). Similar

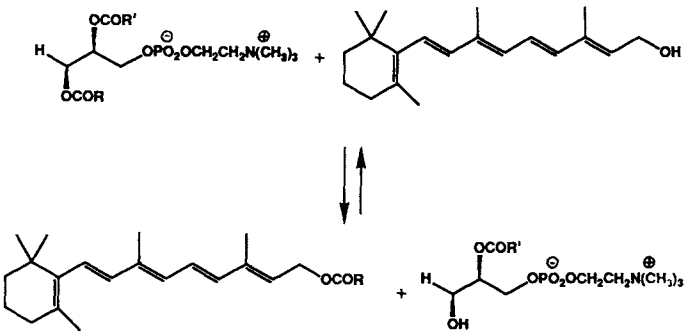

Fig. 22. Transesterification of retinol with phosphatidylcholine (lecithin) catalyzed by the enzyme lecithin:retinol acyltransferase (LRAT).

conclusions were drawn by *Saari* et al. working with crude membrane fractions.[76] Thus, the retinyl ester synthetase operates by a transesterification route similar to that found in the liver.[77] Of interest is the fact that this reaction is reversible and could liberate retinol from a retinyl ester by a back transesterification without hydrolysis in vivo. This would obviously save energy because, when retinol is required, it can be formed without, in effect, requiring the hydrolysis of a phospholipid. A second point of interest is that the isomerase and ester synthetase activities copurified after anion exchange and gel filtration chromatography, suggesting the possibility of a multienzyme complex or some other functional linkage.[74]

7. Finding the Energy Source

7.1. Retinyl Esters Are the Isomerase Substrates

As stated in Section 6.3, pigment epithelium membranes are capable of processing added vitamin A into 11-*cis*-retinoids in the absence of added energy sources. The fact that thorough washing of the membranes did not seem to affect isomerase activity suggests that it is not a soluble energy source that provides the needed energy. Indeed, the addition of high-energy compounds, such as MgATP, MgGTP, or palmitoyl CoA, to the preparations did not stimulate isomerase activity.[61] An issue of some interest relates to the energization mechanism. In vivo experiments with aromatic amine isomerization catalysts would appear to rule out the possibility that hitherto undescribed binding proteins provide the necessary energy. Other mechanistic possibilities must be entertained to explain the energy-requiring isomerization process. The possibility that an irreversible process might provide the energy was eliminated when it was shown that all of the reactions of the visual cycle are reversible.[69] Thus, another type of energy source must be considered.

The intriguing relationship existing between endogenous retinyl ester synthesis and isomerization provides the key.[62] Thus far, studies on the membrane localization of the isomerase and of the ester synthetase activities have shown that the two activities cannot be dissociated from one another either by differential or density gradient centrifugation studies. As mentioned in Section 6.6, the solubilized enzymatic activities also copurify. Finally, chemically diverse reagents, such as ethanol, hydroxylamine, and *p*-hydroxymercuribenzoate, all appear to inhibit both activities in a roughly parallel manner.[62] Ethanol can denature enzymes. Hydroxylamine is an agent known to inhibit retinyl ester synthesis, presumably because it can react with a high-energy acyl intermediate.[75] The observation that both ester synthetase and retinoid isomerase activities are inhibited to approximately the same degree by pretreatment with hydroxylamine suggests a linkage between the two enzymatic processes. The results with *p*-hydroxymercuribenzoate, an alkylating agent specific for sulfhydryl groups, are equally striking.[62] This reagent affects both activities in a roughly parallel, multiphasic fashion, implying that the two activities are linked in a fundamental way.

Recent studies using all-*trans*-retinyl α-bromoacetate as a specific inhibitor of retinyl ester synthesis by the pigment epithelial membranes bear importantly on the issue of the actual substrate of the isomerase.[78] In the pigment epithelial system, all-*trans*-retinyl α-bromoacetate does not inactivate the synthetase, but rather, at micromolar concentrations, is an exceedingly potent inhibitor of it. When pigment epithelial membranes are pretreated with this molecule and then with all-*trans*-retinol, there is virtually no ($< 5\%$) conversion of the vitamin to retinyl esters and no 11-*cis*-retinoids are generated. However, when the membranes were first treated with all-*trans*-retinol, producing largely all-*trans*-retinyl esters, and then were treated with inhibitor, 11-*cis*-retinol production proceeded close to control levels (i.e., with no added inhibitor). These experiments leave little doubt that it is an all-*trans*-retinyl ester and not all-*trans*-retinol that is processed to 11-*cis*-retinol and that retinyl ester formation is an obligate part of the isomerase pathway. Had a direct isomerization of all-*trans*-retinol to 11-*cis*-retinol occurred, then pretreatment of the membranes with all-*trans*-retinyl α-bromoacetate should have enhanced the isomerization, since less substrate would have been lost to ester formation. Furthermore, it was also found that, in the presence of inhibitor, all-*trans*-retinyl esters were processed into 11-*cis*-retinol without the formation of 11-*cis*-retinyl esters. This experiment eliminates an ester–ester isomerization route from consideration.

Why might the linkage of ester synthesis to isomerization be of interest? Esters are "high-energy" compounds and are hydrolyzed with free energies of hydrolysis of around $-5\ \text{kcal mol}^{-1}$.[79] If the free energy of hydrolysis of an ester could be coupled to the isomerization process, more than enough energy would be provided to drive the latter process. The free energy of any complex chemical reaction can be calculated if it can be formally broken down into

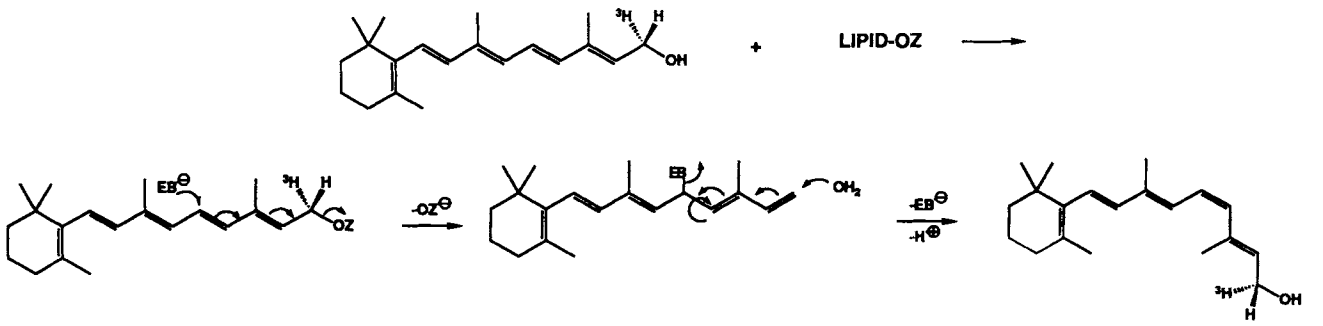

Fig. 23. A coupled reaction can drive the thermodynamically unfavorable isomerization reaction [69]. $EB^{\ominus}$ = enzyme active-site nucleophile; $OZ^{\ominus}$ = carboxylate.

all-*trans*-retinyl ester + H_2O	→ all-*trans*-retinol	$\Delta G^0 \approx -5$ kcal mol^{-1}
all-*trans*-retinol	→ 11-*cis*-retinol	$\Delta G^0 \quad +4$ kcal mol^{-1}
all-*trans*-retinyl ester + H_2O	→ 11-*cis*-retinol	$\Delta G^0 \quad -1$ kcal mol^{-1}

simpler chemical reactions whose free energy changes are known. As applied here, the energies sum as shown in Figure 23 to yield a possible mechanism by which ester hydrolysis could be linked to isomerization.[69] Here, the substrate would be an all-*trans*-retinyl ester, and the product, 11-*cis*-retinol. The enzyme catalyzing the isomerization reaction is actually an "isoesterase" rather than a simple isomerase. The isomerization reaction is here broken down into two independent reactions. The overall free energy change is the sum of the free energy changes of the two component reactions, resulting in an exothermic isomerization. It is important to note that these two reactions do not occur independently of one another. Most interestingly, the energy to drive the reaction would originate in the membrane phospholipids, since retinyl esters arise by a transesterification reaction with lecithin. In this case, therefore, the phospholipids would act as an ATP surrogate.

That an all-*trans*-retinyl ester is the substrate for isomerization is consistent with previous observations. As already mentioned in Section 6.4, added all-*trans*-retinol is rapidly processed to all-*trans*-retinyl esters prior to the formation of 11-*cis*-retinol.[60, 69] In addition, all-*trans*-retinyl esters are processed to form 11-*cis*-retinol by the isomerase-containing membranes.[69] Finally, the in vivo double-labeling experiments using [(15*S*)-^{3}H]- and [(15*R*)-^{3}H]-all-*trans*-retinol plus [15-^{14}C]-all-*trans*-retinol showed that only the all-*trans*-retinyl esters were of high enough specific activity to serve as 11-*cis*-retinoid precursors.[55] The mechanism shown in Figure 23 also makes understandable the structure–activity studies performed on the dihydroretinoids. Finally, the experiments with the retinyl ester synthetase inhibitor all-*trans*-retinyl α-bromoacetate described above are also fully consistent with this mechanism.

7.2. C–O Bond Cleavage Accompanies Isomerization

The mechanism shown in Figure 23 allows experimentally testable predictions. One prediction is that C–O bond cleavage accompanies isomerization. Furthermore, this cleavage could have an effect on the stereochemistry of suitably labeled retinoids at C15, since the prochiral center becomes symmetrical at the intermediate state. The prediction of C–O bond cleavage was readily testable by studying the fate of the ^{18}O of [15-^{18}O]-all-*trans*-retinol after enzyme-catalyzed isomerization in $H_2{}^{16}O$-containing buffer using field desorption mass spectrometry.[69] This experiment demonstrated unequivocally that the 11-*cis*-retinol product formed contained only ^{16}O (Fig. 24).[69] Hence, complete cleavage and replacement of the C–O bond accompanies isomerization.

7.3. Stereochemical Course of the Reactions Catalyzed by the Isomerase and Related Enzymes

The ^{18}O release experiments (Fig. 24) are consistent with the type of mechanism shown in Figure 23. Since this mechanism proposes that C15 undergoes an sp^3-to-sp^2 conversion during isomerization, it is possible to probe this process with stereochemical experiments. It was of interest to determine whether retention or inversion occurs at C15 as a consequence of the isomerization reaction (Fig. 25).

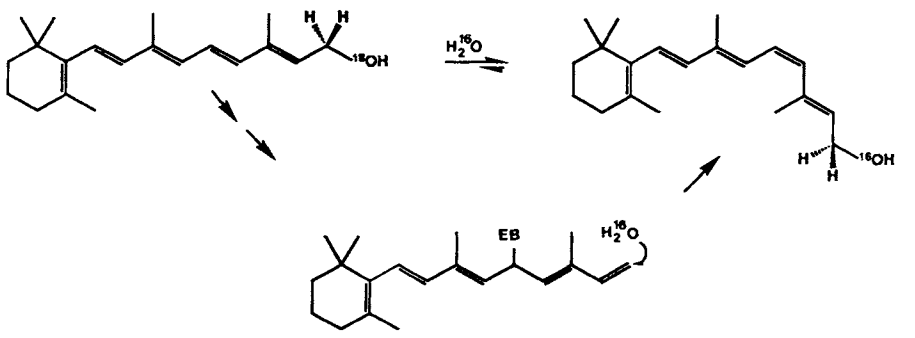

Fig. 24. The isomerization reaction occurs with C–O bond cleavage.

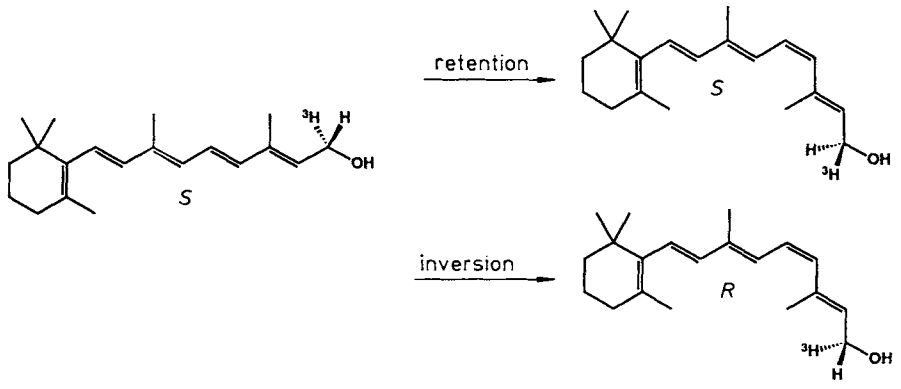

Fig. 25. Isomerization can occur with retention or inversion of stereochemistry at the C15 prochiral center of vitamin A.

To this end, stereochemical experiments were performed using chirally labeled [(15*R*)-^{3}H]- and [(15*S*)-^{3}H]-all-*trans*-retinol.[80] [(15*S*)-^{3}H]-all-*trans*-Retinol was prepared by the reduction of [15-^{3}H]-all-*trans*-retinal with horse liver alcohol dehydrogenase (HLADH) and NADH.[80] [(15*R*)-^{3}H]-all-*trans*-Retinol was prepared by incubation of all-*trans*-retinol with [α-^{3}H]benzyl alcohol, HLADH, and NAD. The labeled retinols, along with [15-^{14}C]-all-*trans*-retinol, were incubated with either amphibian or bovine pigment epithelial membranes.[80] At the end of the incubation period, the retinols and retinyl esters were collected and analyzed. The analyses of the isolated retinols and retinyl esters were performed as indicated in Figure 26. The enzymatically formed 11-*cis*-retinol was isomerized with I_2, which is without effect on the stereochemistry at C15, to produce all-*trans*-retinol. The retinyl esters were hydrolyzed to produce the corresponding retinols. Then, using HLADH, it could readily be decided if inversion or retention of absolute configuration had occurred.[80]

The results were striking in that, within experimental error, complete inversion of configuration had occurred as a consequence of isomerization in both the bovine and amphibian cases.[80] This result can be interpreted mechanistically with the addition of two further pieces of information to the fact that the C–O bond is cleaved during isomerization. First, isomerization must occur at the alcohol oxidation state, and, second, it is highly improbable that there is a mechanism by which enzyme-bound all-*trans*-retinol is oxidized to retinal followed by isomerization and reduction at the opposite face to produce 11-*cis*-retinol, because no evidence for any isotope effect has been found. This kind of mechanism would predict a primary isotope effect that would be extremely large, since it would be the product of two separate isotope effects. Furthermore, added all-*trans*-retinal is not isomerized.

The stereochemical inversion result is readily understandable in terms of the mechanism shown in Figure 23 and supports this mechanistic interpretation. The inversion of stereochemistry during isomerization allowed us to determine that the isomerase acts in reverse.[69] Chirally labeled 11-*cis*-retinol is processed by the isomerase to produce all-*trans*-retinol of the opposite absolute stereochemistry.[69] 11-*cis*-Retinol is relatively unstable with respect to isomerization, but it isomerizes to all-*trans*-retinol with the expected retention of absolute configuration at C15.

In chemical reactions in solution it is possible to interpret the result of a stereochemical experiment mechanistically. In the case of enzymes, however, a straightforward interpretation is often not possible. It is of interest to consider further the inversion result obtained here. Because of the approxi-

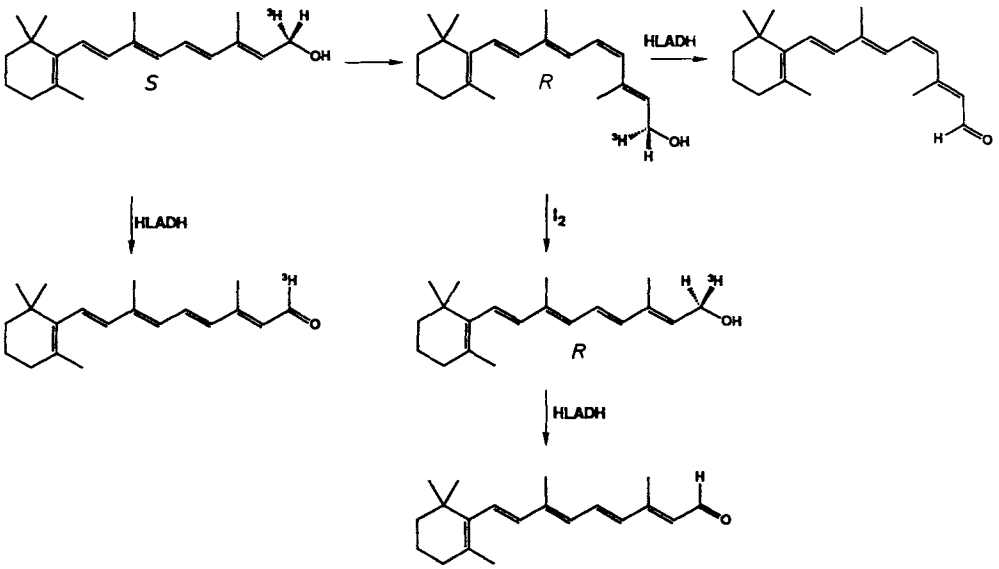

Fig. 26. Analysis of the stereochemical outcome of the isomerization reaction.

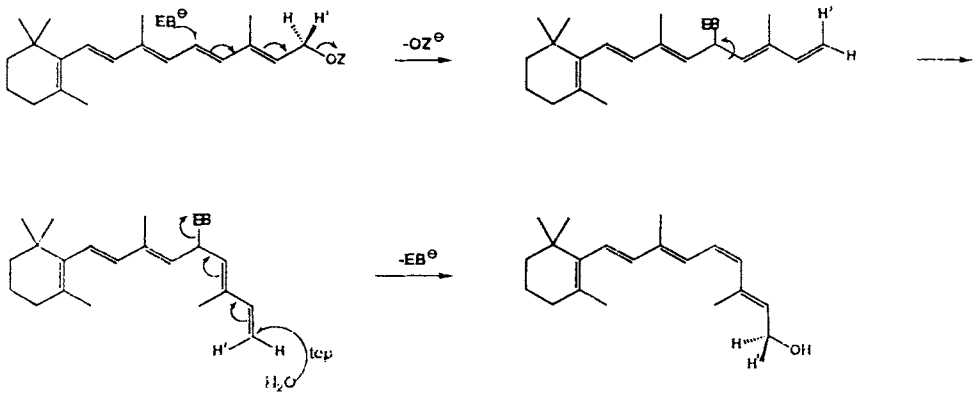

Fig. 27. Same-face C–O bond cleavage and reformation can result in apparent stereochemical inversion.

mately 180° rotation about the C11–C12 bond during the isomerization reaction, an inversion result could be obtained even though C–O bond cleavage and formation occurred from the same face of the molecule with respect to the active site of the enzyme (Fig. 27).

The inversion of stereochemistry at C15 must be reconciled with the fact that a maximum of 50% loss of ^3H from [15-^3H]-all-*trans*-retinol was found in the various retinoids after administration of the labeled retinol to rats.[55] Since the retinols were either *R* or *S* (they were prepared by NaB^3H_4 reduction of all-*trans*-retinal), stereochemical inversion and oxidation by retinol dehydrogenases of the same specificity with respect to the hydrogen removed would result in the eventual complete washout of ^3H from the retinoids. It was found that HLADH has the same stereospecificity towards 11-*cis*-retinol as it does towards all-*trans*-retinol, which is assumed to be pro-*R* specific by analogy with other alcohol substrates of this enzyme.[80, 81] However, it was also found that the ocular all-*trans* and 11-*cis*-retinol dehydrogenases showed opposite stereochemistries with respect to substrates.[80, 82] With respect to the NAD cofactors, the situation is quite clear in the amphibian, where the multiple all-*trans*-retinol dehydrogenases found in the bovine case do not exist. In the amphibian, the 11-*cis*-retinol dehydrogenase is again pro-*S* specific with respect to NAD, whereas the opposite stereochemistry is obtained with the all-*trans*-retinol dehydrogenase.[82]

In the bovine case, the 11-*cis*-retinol dehydrogenase again proved to be pro-*S* specific with respect to cofactor.[82] The all-*trans*-retinol dehydrogenases, both from the rod outer segment and from the pigment epithelium, were pro-*R* selective, although substantial processing of the pro-*S* hydrogen also occurred.[82] In light of the fact that the redox potentials for all-*trans* and 11-*cis*-retinol are the same, it is not apparent what mechanistic significance the stereochemistry of these redox reactions might have.[82] With respect to the cofactors, *Bernhard* et al.[83] have suggested that opposite chiral specificity of dehydrogenases with respect to the C4 H of NADH means that the cofactors are transferred directly from one dehydrogenase active site to another.

8. Possible Mechanisms for the Isomerization Reaction

The stereochemical and isotopic release studies described above entirely support the kind of mechanism shown in Figure 23, as do the structure–activity experiments conducted with the dihydroretinoids. In Figure 23, an S_N2' mechanism is drawn for simplicity's sake, although other mechanistic possibilities must be considered (Fig. 28). Many different mechanisms are possible, as long as they postulate intermediates higher in energy than 11-*cis*-retinol. For example, in Figure 28, three other categories of mechanisms are shown. Carbonium ion mechanisms (Fig. 28 A) are certainly possible given the polyene nature of the retinols. C–H abstraction mechanisms (Fig. 28 B) are also attractive candidates, especially if a C–H bond of the C9 methyl group is cleaved. C–H abstraction at the C13 methyl would not affect the C11–C12 double bond and abstraction at the C5 methyl or at the cyclohexyl ring would produce very stable intermediates. The last mechanism (Fig. 28 C) involves purely thermal reactions in which the ester moiety "walks" down the polyene backbone. Although we cannot at present distinguish among the different mechanisms, further structure–activity studies with various retinoids bear on this issue (Fig. 29).[84] All of the retinoids shown are processed to all-*trans*-retinyl esters prior to any possible isomerization reaction. Of the C–H abstraction mechanisms, only C–H abstraction at the C9 methyl group is viable at this time, since 9-desmethyl-all-*trans*-retinol (**3**) was not isomerized after esterification. The fact that vitamin A_2 (Fig. 21), 5-desmethyl-all-*trans*-retinol (**4**), and 13-desmethyl-all-*trans*-retinol (**2**) are all isomerase substrates (after esterification) eliminates other possible C–H abstraction mechanisms. There is currently no information that would rule in or out the other mechanisms shown (Fig. 28 A and C).

9. The Membrane as an Energy Source

Although it is possible to speculate on the exact nature of the isomerization mechanism, the broad outlines are clear. Most importantly, all of the mechanisms shown provide a solution to the issue concerning the nature of the energy source used to drive the isomerization reaction. The energy is provided by the free energy of hydrolysis of the retinyl esters. Since the retinyl esters are formed by a transesterification reaction with membrane phospholipids, it is the membrane itself that provides the energy to drive the uphill isomerization reaction (Fig. 30).

The group-transfer strategy used here is similar to cases where ATP, which has a free energy of hydrolysis of

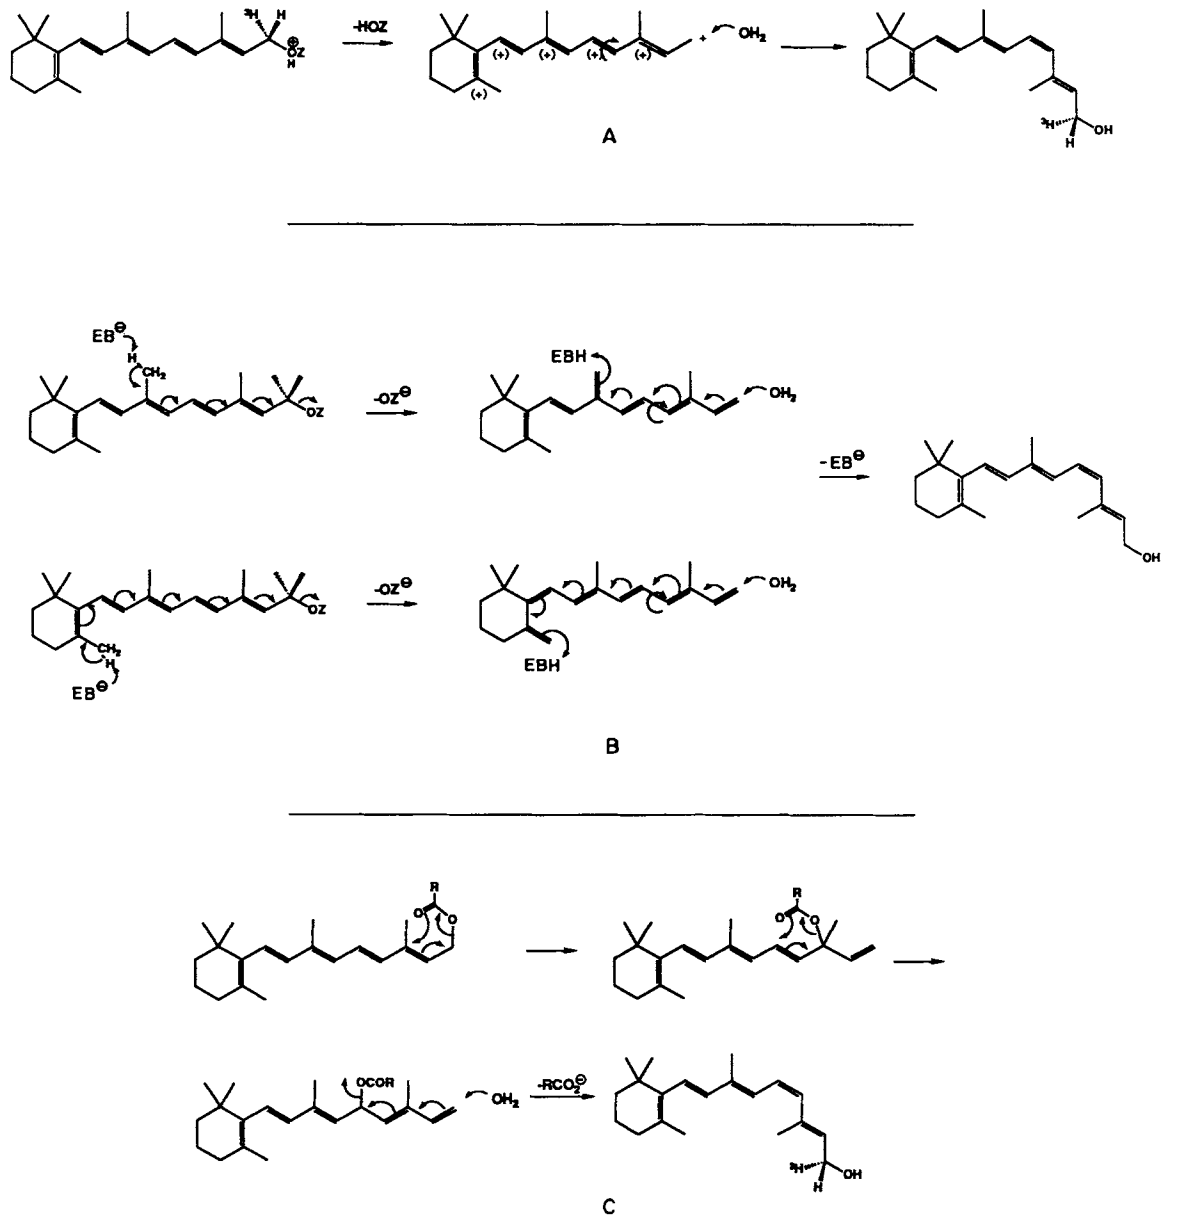

Fig. 28. Possible isomerase mechanisms. A) Carbonium ion mechanism; B) C–H abstraction mechanism; C) thermal reaction.

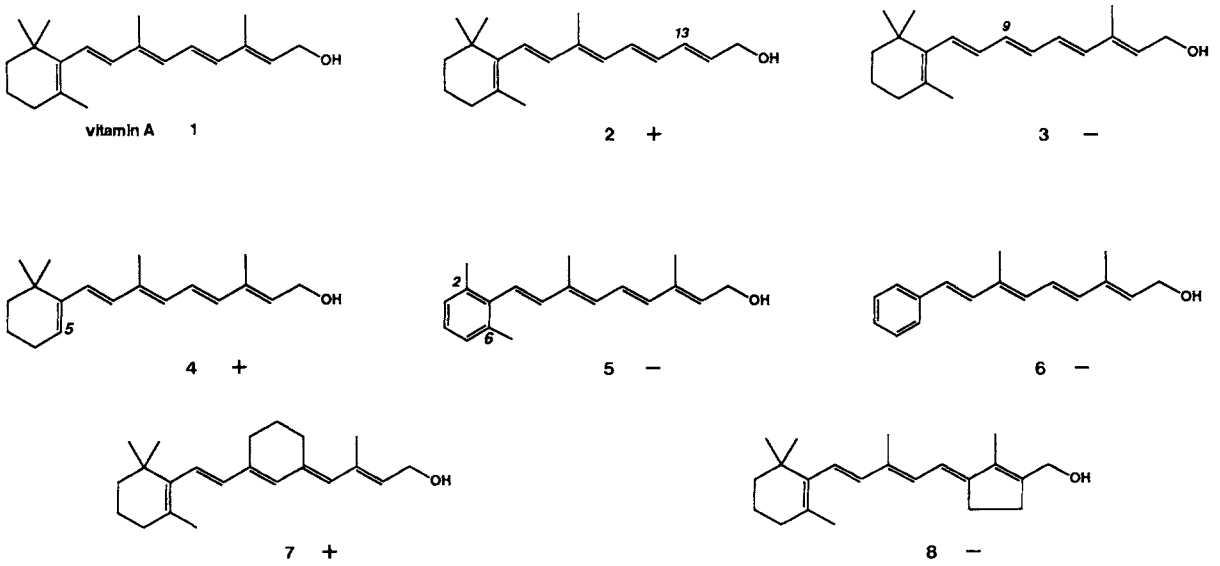

Fig. 29. Structure–activity studies on the isomerase. +, active; −, inactive.

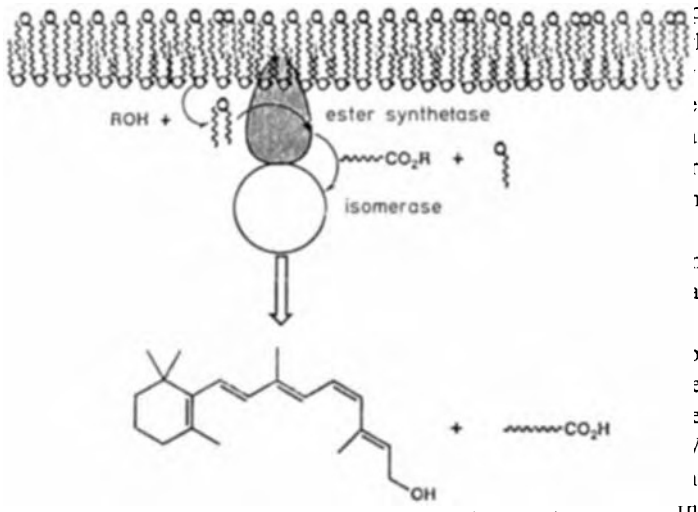

Fig. 30. The biosynthesis of 11-*cis*-retinol showing the involvement of membrane phospholipids.

$-7.3\ \text{kcal mol}^{-1}$, is utilized as the energy source to drive otherwise thermodynamically unfavorable reactions. In many of these cases, such as the biosynthesis of sucrose from fructose and glucose, phosphorylation of a hydroxyl group occurs followed by displacement reactions which occur sequentially rather than in a concerted fashion. Nevertheless, in terms of driving force, these mechanisms are very similar to the proposed isomerase mechanism. This latter mechanism could be of general interest as a new mechanism of energy transduction in membranes with phospholipids being used as an energy source. This also provides a hitherto unsuspected role for membranes.

Finally, coming back to the visual cycle itself, our current understanding is depicted in Figure 31. The idea that the

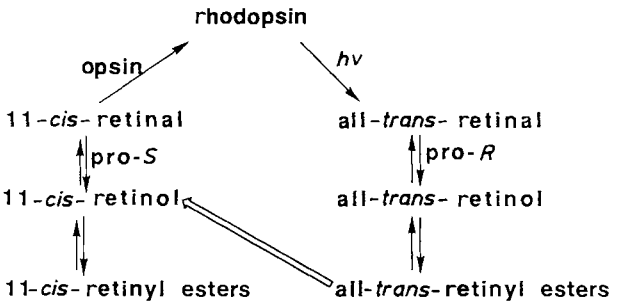

Fig. 31. Current model of the visual cycle (cf. Fig. 7).

retinyl esters play a mere passive role as a storage form of retinol must be discarded and replaced with a vision of them in a critical dynamical role as the precursors of the 11-*cis*-retinoid chromophores.

10. Summary and Outlook

The studies described here provide a brief survey of the molecular mechanisms of 11-*cis*-retinoid biosynthesis in the eye. Interestingly, the solution depended on strictly chemical approaches. That is, the work began with the question of where the energy comes from to drive the thermodynamically uphill isomerization of all-*trans*-retinoids to 11-*cis*-retinoids. Simple solutions to the problem, such as that enabled in the retinal isomerase conjecture, could not be and are not correct because they do not provide a mechanism for energy transduction. Unlike retinol, retinal does not contain a group that can be activated by a group-transfer reaction and, hence, retinal cannot be activated in a thermodynamically fruitful way.

Many intriguing questions remain to be solved. With respect to the isomerization process, it will be important to determine what the actual mechanism of the isomerase is. Several mechanistic possibilities have been considered. Which if any of these possibilities apply will have to be determined. Moreover, the exact relationship that holds between the ester synthetase and the isomerase needs to be elucidated, as does the relationship among the remaining enzymes of the visual cycle. The isomerase, or perhaps more properly, the "isoesterase", and ester synthetase will have to be purified and sequenced to determine their possible relationships to other known enzymes. Knowing the primary sequences of these enzymes will be important in determining whether any of the important diseases of vision might find an etiology in mutations in these enzymes.

Perhaps of greatest importance biologically is to determine if the group-transfer mechanisms described here involving membrane phospholipids are general. Although ATP has been singled out as the energy currency of the cell, the studies described here show that other possibilities exist and will need careful consideration.

I wish to gratefully acknowledge the important contributions of Dr. Robert Barry, Dr. Paul S. Bernstein, Dr. Francisco J. Cañada, Dr. Andrew Chang, Dr. Peter Deigner, Dr. Brian S. Fulton, Dr. Wing C. Law, and John Lichtman to the research described here. The work from the author's laboratory was supported by U.S. Public Health Service Research Grant EY 04096 from the National Institutes of Health.

Five Decades Ago: From the "Transuranics" to Nuclear Fission**

By Günter Herrmann*

The discovery of nuclear fission is one of the most outstanding episodes in the history of chemistry: It starts in the spring of 1934 when *Enrico Fermi* and his group irradiate uranium with neutrons and seem to succeed in going beyond uranium, the then heaviest known element, reaching the first transuranic element; it continues with *Otto Hahn, Lise Meitner* and *Fritz Strassmann* who believe to have found additional transuranic elements; with *Irène Curie* and *Paul Savitch* who observe an activity which somehow does not fit into that scheme; again with *Otto Hahn* and *Fritz Strassmann* who first identify this activity as radium but then on the 17th of December 1938 after rigorous chemical tests realize that the activity is instead barium, thus discovering the fission of the uranium atom into two lighter nuclei; and with *Lise Meitner* and *Otto Robert Frisch* who explain nuclear fission on the basis of an already known nuclear model; *Otto Robert Frisch* finally performs a physical experiment on the 13th of January 1939 which corroborates the fission of uranium. This discovery of nuclear fission is not only an event of historic dimensions, it is also an excellent example of how science evolves, not by successive logical steps but rather through strange detours.

1. The "Transuranic Elements"

1.1. Rome 1934: Element 93, Eka-Rhenium?

When *Enrico Fermi* and his group irradiate uranium with neutrons in the spring of 1934 they do not figure at all on fissioning uranium into two medium sized nuclei. Their intention is quite different: They want to go beyond the heaviest naturally occurring element in the periodic table, uranium (atomic number $Z = 92$) and to reach element 93, the first transuranic element. This became feasible after *Fermi* and co-workers succeeded in obtaining radioactive isotopes of a number of elements by irradiation with neutrons, which had been discovered only shortly before. In contrast to α-particles, which were previously used to induce nuclear transformations, the uncharged neutrons attach very easily to the positively charged atomic nuclei, even in heavy elements.[1, 2] In this case one obtains isotopes of the starting element[2, 3] which subsequently undergo β^--decay. In β^--decay the isotope emits an electron from the nucleus and is transformed into the element with the next higher atomic number. The stable silver isotope 109 ($Z = 47$), for example, captures a neutron to form silver-110 which decays by β^--emission with a 24s half-life into the stable cadmium-110 [Reaction (1)].

$$^{109}_{47}\mathrm{Ag} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{110}_{47}\mathrm{Ag} \xrightarrow[24\mathrm{s}]{\beta^-} {}^{110}_{48}\mathrm{Cd} \qquad (1)$$

If the same kind of reaction could be induced also with uranium, one would expect formation of element 93 [Reaction (2)].

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{239}_{92}\mathrm{U} \xrightarrow{\beta^-} {}^{239}93 \qquad (2)$$

This element should be radioactive and, if it is again a β^--emitter, might even decay into another transuranic element, 94 [Reaction (3)].

$$^{239}93 \xrightarrow{\beta^-} {}^{239}94 \qquad (3)$$

This concept seems indeed to be correct: In several publications[2, 4, 6-8] *Fermi* et al. report on at least five β^--emitters with half-lives of 10 s, 40 s, 13 min, 40 min and about 1 d which are observed in their Rome laboratory after the irradiation of uranium with neutrons.

It is not sufficient, however, to simply rely on the detection of β^--emitters. One has to prove the formation of the new elements in a more direct way which can only be achieved by chemical methods. For this purpose one relies on similarities between the elements of the periodic table: One attempts to prove that the activities,[*] which are ascribed to the transuranic elements, behave chemically in a way which is expected according to their location in the periodic table. This concept is shown in Figure 1.

The task of element identification is quite difficult, because the β^--emitters are produced in tiny amounts which are neither visible nor weighable. The only means of identification is their radioactivity which allows one to detect even single atoms. These problems, however, did not appear for the first time, because some of the naturally occurring radioactive elements were also found in such small quantities. Therefore, as early as at the end of the last century, radiochemists had to find out when trace amounts start to behave chemically in the same way as macroscopic quantities.[9] Radium, for example, is co-deposited with a number of insoluble barium compounds, because its corresponding salts are also insoluble. Later, when radioelements were accessible

[**] Based on a paper "Discovery and Confirmation of Fission" presented at the conference "Fifty Years Research in Nuclear Fission" in Berlin on April 4, 1989.

[*] In the historical context we use the then common word "activity" or "body" to name a radioactive species; the more modern expressions are "nuclide" or "isotope". We also use the old nomenclature of isotopes even though it is somewhat misleading. Mesothorium 1 (MsTh 1), for example, is not a thorium but a radium isotope. We will, however, usually add today's nomenclature with element symbol, mass number, and often also the half-life; for example: Mesothorium 1, 5.8-y radium-228.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0505-0481 $ 02.50/0

in visible amounts, these findings obtained with unweighable quantities were confirmed. On occasions, however, irregular chemical behavior had also been noticed.

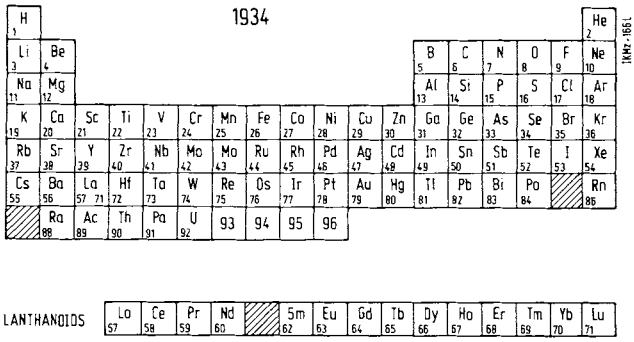

Fig. 1. The periodic table of the elements in 1934. Missing elements at that time are shown as shaded boxes. The present symbols for the elements are used, except for masurium (43).

Thus, for the activities ascribed to transuranic elements it has to be shown that they behave in the same way as their homologous elements during characteristic chemical operations. For these tests *Fermi* et al., and all other groups who perform experiments with transuranic elements, rely on two assumptions which seem to be justified by both theory and experiment but which later turn out to be wrong: First, as a result of nuclear reactions—whether they occur spontaneously during radioactive decay or whether they are induced by particle irradiation—the atomic number changes only slightly. Thus, only elements in the vicinity of the initial element can be formed. Second, in the periodic table thorium, protactinium, and uranium are placed in the 4th, 5th and 6th group of transition elements; therefore, the sought after element 93 should belong to the 7th group of transition elements, it would be eka-rhenium, and the elements 94 through 96 would be eka-platinum metals. Therefore, one has to prove chemically that elements to the right of uranium are formed and that elements in its close vicinity to the left can be excluded.

All experimental facts known until then[3] suggest that the products of nuclear reactions are confined to the vicinity of the original nucleus; a differing phenomenon had never been observed. This view is also reflected in a then introduced illustrative description of nuclear reactions.[10] But also theory corroborates this view. According to *Gamow*'s theory of α-decay,[12] one of the early triumphs of quantum mechanics, even the α-particle with its two nuclear charges can hardly tunnel through the electrostatic Coulomb barrier of the nucleus; for larger fragments this barrier increases rapidly and tunneling becomes extremely unlikely.[13] This reasoning is indeed correct; only decades later is the extremely rare emission of carbon-13 nuclei from radium-223 discovered.[14] The crucial point is, however, that the breakup of a heavy nucleus into two fragments of similar size should not be treated as a tunneling process. Quantum mechanics was more of an obstacle than a help for the discovery of fission.

In the periodic table thorium is so closely related to hafnium, protactinium to tantalum, and uranium to tungsten that an ordering different from the one shown in Figure 1 is not seriously considered, even though a second series of f-elements similar to the rare earths have repeatedly been postulated since *Niels Bohr*'s Nobel talk in 1922;[15] however, this series is suspected as being rather to the right than to the left of uranium.[16–19] In contrast, *A. von Grosse*[20] explicitly argues again in the early thirties that the elements 93 and 94 might have properties completely different from eka-rhenium and eka-osmium.

The presumption that element 93 is eka-rhenium is not easy to integrate into chemical separation procedures, because one has to work with the least familiar group of the periodic table. The two homologous elements 43 and 75, masurium (later technetium) and rhenium, were discovered just a few years earlier by *Walter Noddack, Ida Tacke* (who later married *Noddack*) and *Otto Berg*.[21,22] Even though the properties of rhenium have not yet been well understood it is already available in small quantities, in contrast to masurium of which hardly anything is known. For the eka-platinum metals a complicated chemistry has to be expected as well, as is obvious from their homologues.

Therefore, in order to chemically prove the identity of element 93, *Fermi* and his coworkers focus their attention on manganese. As a characteristic reaction they choose the precipitation of manganese dioxide in strong nitric acid by adding chlorate; this is not a fortunate choice, because the precipitate has a large surface and all kinds of elements get attached to it. Initially, however, their concept seems to be correct: the 13-min activity, which for such experiments is the best suited one of the new activities, is found in the

Günter Herrmann was born in 1925 in Greiz (Thüringen). From 1946 until 1956 he studied chemistry at the University of Mainz where he received his doctorate for work on nuclear fission under the supervision of Fritz Strassmann. In 1962 he habilitated and became privatdocent at Mainz. In 1967 he was offered but did not take up an appointment as full professor at the Kansas State University in Manhattan. Since 1968 Herrmann has been full professor and Director of the Institut für Kernchemie an der Universität Mainz, and, since 1970 he has in addition been directing a nuclear chemistry research department of the Gesellschaft für Schwerionenforschung Darmstadt. His main fields of interest are: rapid methods of chemical separation, nuclear fission and reactions between heavy atom nuclei, exotic atomic nuclei, the search for superheavy elements, radionuclides in the environment. The honors conferred on him include, inter alia: since 1984 corresponding member of the Academie der Wissenschaften und der Literatur zu Mainz; 1987 Miller guest professor at the University of California in Berkeley; 1988 Nuclear Chemistry Award of the American Chemical Society.

precipitate, in contrast to uranium and the lighter elements down to lead, as is verified with radioisotopes.[2, 4, 6–8] The 13-min activity also coprecipitates with rhenium sulfide in strong hydrochloric acid;[2, 6–8] this is a reaction by far more specific than the precipitation of manganese dioxide. The 90-min activity chemically behaves very similarly to the 13-min activity. The conclusion that elements heavier than uranium have been found, is presented by *Fermi*[7] only reluctantly, however, as is obvious from the title of the publication; he is not content with the more definite public statements of his mentor *Carbino*.[23]

1.2. Objections and Their Consequences

Objections are being raised. *Von Grosse* and *Agruss*[25–27] ascribe *Fermi*'s activity to element 91, protactinium, which they succeed in coprecipitating completely with manganese dioxide and to a large extent with rhenium sulfide. Also *Fermi* et al. meet some problems in connection with protactinium and its coprecipitation with manganese dioxide.[2, 4, 8] Being aware of this controversy, *Otto Hahn* and *Lise Meitner* feel challenged, since they are the ones who found the only protactinium isotope which in nature is available in weighable quantities, the 3.3×10^4-y protactinium-231,[28] and who had also named the element. Moreover, *Hahn*[29] had discovered with protactinium-234 the phenomenon of nuclear isomerism, namely the existence of two nuclei with the same numbers of protons and neutrons but with different half-lives of 1.17 min for the metastable (m) and 6.75 h for the ground state (g). *Lise Meitner* is immediately attracted[30, 31] by *Fermi*'s neutron-induced nuclear reactions; she persuades[32, 34] *Otto Hahn* to resume their collaboration after twelve years of interruption and to focus attention on the transuranic elements.

In a first note[35] they present evidence in favor of *Fermi*'s interpretation: the 13-min and the 90-min activities can be separated from protactinium in two ways. First, both activities can be coprecipitated with platinum sulfide, with protactinium remaining completely dissolved. The second procedure is just the opposite, where the new activities remain dissolved if protactinium is co-precipitated with zirconium phosphate. To obtain these results the transuranic activities are mixed with natural 6.7-h protactinium-234g and in the course of the subsequent separation the distribution of the three activities among different fractions is determined. The two transuranic elements are more similar to platinum than to rhenium and they might be chemically different,[35] the 13-min activity could possibly be element 93, the 90-min activity element 94. *Fermi* et al.[36, 37] obtain similar results and presume the decay of the 13-min into the 90-min activity. This was the last word from Rome with respect to the "uranium case"; they leave it to those who are more experienced in radiochemistry[38] and turn to an exciting new problem, the intense reaction of slow neutrons with atomic nuclei, a phenomenon which is also discovered in Rome.

Ida Noddack's criticism[39] is of a more conceptual nature. In an article[40] dealing with yet unknown elements in the periodic table she conjectures that the transuranic elements, with increasing atomic number, should tend to be more and more short-lived and rare, with the even numbered elements 94 and 96 possibly still within the realm of being found; apparently she is speaking of a search in nature. In a Supplementary note[39] she discusses two discoveries of element 93. The first case,[41] a natural element 93 in the Joachimsthal pitch-blende, is closed quickly because she does not detect element 93 in the original samples either chemically or by X-ray spectroscopy. In the second case, namely *Fermi*'s[7] element 93, she objects that only the heaviest known elements were excluded; *Fermi* ought to have compared his new element with *all* the known elements. According to her own studies, a large number of ordinary elements are being coprecipitated with manganese dioxide; in her opinion the coprecipitation with rhenium sulfide is not a strong proof either. *Ida Noddack* notes:[39][*] "Es wäre denkbar, daß bei der Beschießung schwerer Kerne mit Neutronen diese Kerne in mehrere *größere*[**] Bruchstücke zerfallen, die zwar Isotope bekannter Elemente, aber nicht Nachbarn der bestrahlten Elemente sind".

Can this statement be taken as the prediction of nuclear fission, as it is done sometimes?[42, 43] Not really, because *Ida Noddack* herself does not consider her proposition of a new and surprising nuclear reaction to be that meaningful to test it experimentally. She seems more concerned, according to contemporaries, to render the detection of element 93 as inconclusive; her objection is not relevant for the future developments.[44] She may plan herself to search for eka-rhenium in nature, since the 7th group of transition elements is already well known to her. Her objection is hardly noticed in Rome[45] and Berlin;[46] *Strassmann* even calls it a chance coincidence.[48] This ignorance is certainly influenced by *Noddack*'s dubious and irreproducible discovery of the natural element 43.[45, 50, 51] When *Ida Noddack* later complains about this attitude in a note,[52] *Hahn* and *Strassmann* refrain from submitting an already formulated harsh reply[50] and leave it to the editors to react.[53] The relationship between the *Noddacks* and *Hahn* and *Meitner* remains reserved, also caused by political controversies,[50] even though—or maybe because—they work in the same city.

1.3. Berlin 1935–1938: Elements 94 through 96, the Eka-Platinum Elements?

From now on further studies of the transuranic elements are mainly carried out by *Otto Hahn* and *Lise Meitner*; they soon ask the much younger *Fritz Strassmann* to join them in their efforts, since he has shown a talent for difficult chemical separations. No photograph exists from that time showing all three together, so one has to combine two separate photographs—Figure 2—or use a later common one—Figure 3. The experiments are performed in three different rooms on the ground-floor of the Kaiser-Wilhelm-Institut für Chemie[***] in Berlin-Dahlem, the plan of which is depicted in Figure 4.

---

[*] "It is conceivable that during the irradiation of heavy nuclei with neutrons these nuclei may disintegrate into a number of *larger* [**] fragments which are isotopes of known elements but not necessarily neighbors of the elements irradiated originally.

[**] Emphases as in the original.

[***] The Kaiser-Wilhelm-Institut für Chemie is heavily damaged by bombs in February 1944. The institute and its members temporarily move to Tailfingen in Württemberg. After the war the institute finds a new home in Mainz and is called the Max-Planck-Institut für Chemie. The Berlin building, after reconstruction, now serves as the Otto-Hahn-Bau of the Freie Universität.

Fig. 2. *Otto Hahn* (1879–1968) and *Lise Meitner* (1878–1968) at an institute outing, ca. 1934/35, and *Fritz Strassmann* (1902–1980), Berlin, ca. 1936 (after [48]).

The equipment is very simple. Near the front of the table depicted in Figure 5 two brick-like lead blocks can be seen in which the counters are housed in order to reduce the radiation background. In the right block, which is open, one sees a cylindrical Geiger-Müller counter. The samples to be measured are glued on "boat-shaped" lead holders and placed underneath the counters; samples, lead holders, and absorber foils can be found between the two blocks. The counters are made of a 0.01 cm thick aluminum tube of 6 cm length and 2 cm diameter, the two ends of which are closed with rubber plugs and gas-tightened with pizein wax. The central counting wire, made of a piano string, is fixed in the same way, as is also a glass tube which is used for pumping and filling the counter with an argon-ethanol-mixture 10:1 at a pressure of about 10 kPa. The wire is at a positive potential of about 1500 volts, to collect the electrons which are created by β^--rays ionizing the counting gas; to increase the signal height the electrons are accelerated in the strong electric field of the counter forming an electron avalanche.

In the center of the table one sees two amplifiers with two amplifier tubes each; to the left of both amplifiers is a mechanical counting unit which registers the number of electrical pulses. Each counting unit is equipped with a stop-watch, which is not shown on the table.[48] The counters are coupled to the amplifiers via high-impedance resistors, which can be seen to the right of the tubes; the resistors consist[56] of a glass tube filled with toluene and imbedded in paraffin. The power supplies producing the necessary voltages are located at the back of the table; the voltages for the counters are supplied by a chain of anode batteries underneath the table.

Neutrons are produced according to Reaction (4) by irradiating beryllium with α-particles from natural radioisotopes.

$$^{9}_{4}\mathrm{Be} + {}^{4}_{2}\alpha \longrightarrow {}^{12}_{6}\mathrm{C} + {}^{1}_{0}\mathrm{n} \qquad (4)$$

The neutron sources which consist of six brass tubes of about 6 cm length can be seen in the upper right part of Figure 5. Each one is made of a fused glass tube containing beryllium powder and either about 100 mg of radium sulfate or short-lived radon gas, which is freshly obtained once a week by separation from radium performed in a separate hut in the institute's yard.[56] If slow neutrons are to be used for irradiation, the sources are installed in a cyclindrical paraffin block (upper right) on top of which the sample is to be placed. The flux of thermal neutrons is about 10^4 neutrons per $cm^2 \cdot s$.

Fig. 3. *Fritz Strassmann*, *Lise Meitner*, and *Otto Hahn* (from left to right) 1956 in Mainz at the inauguration of the Max-Planck-Institut für Chemie (from [54]).

Finally, a filter flask is to be seen in the lower right of Figure 5; this is used for rapid filtration of radioactive precipitates in the so crucial radiochemical experiments. Below the filter flask one sees the historical note-book "Chem. II".

As experiments are performed at quite different levels of activity, strict precautions have to be followed in order not to accidentally spread radioactivity, as this would make sensitive measurements impossible in the long run. Toilet paper is affixed to the doors of coffee rooms, rest rooms, and corridors and is supposed to be used when touching door handles. In the lecture hall and the library one finds light and dark colored chairs for those working with "strong" and "weak" radioactivities. One does not shake hands either; if practiced at all, greetings are reduced to the touching of each others little finger tips. Laboratory tables are covered with absorbent paper; for this purpose waste paper from the printing office of the Reichsbahn[*] is well suited and is available cheaply. On the other hand, the institute has quite an advanced local telephone system to facilitate communication without direct contact.

The natural radioactivity of uranium creates a severe problem. To obtain statistically significant count rates of the artificial activities—about a hundred pulses per minute—using the weak neutron sources ten- to hundred-gram samples of uranium have to be irradiated. These sources contain

[*] National Railway.

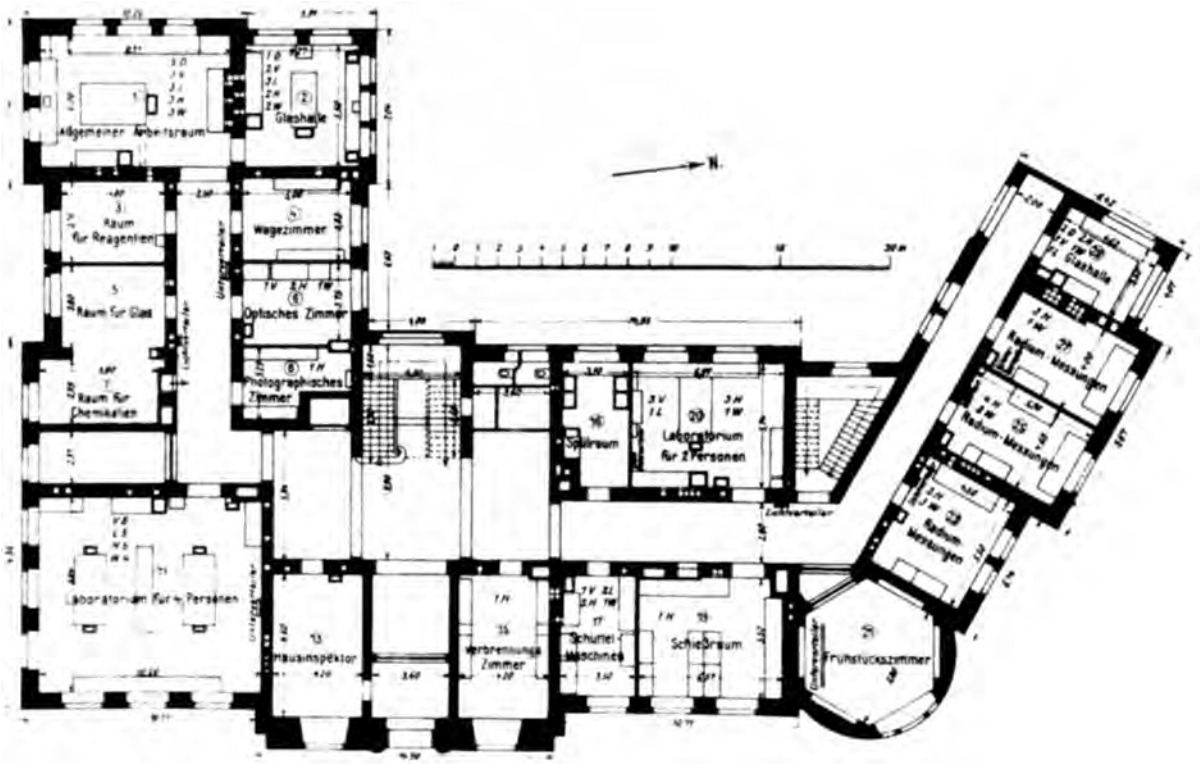

Fig. 4. Kaiser-Wilhelm-Institut für Chemie at Berlin-Dahlem, plan of the ground-floor. Irradiations with neutron sources were carried out in room 29, *Hahn*'s "private laboratory"—room 20—was used for the chemistry, and in room 23 the radioactivity was measured; *Lise Meitner*'s office was located between rooms 7 and 11, *Otto Hahn*'s office was on the first floor (from [55]).

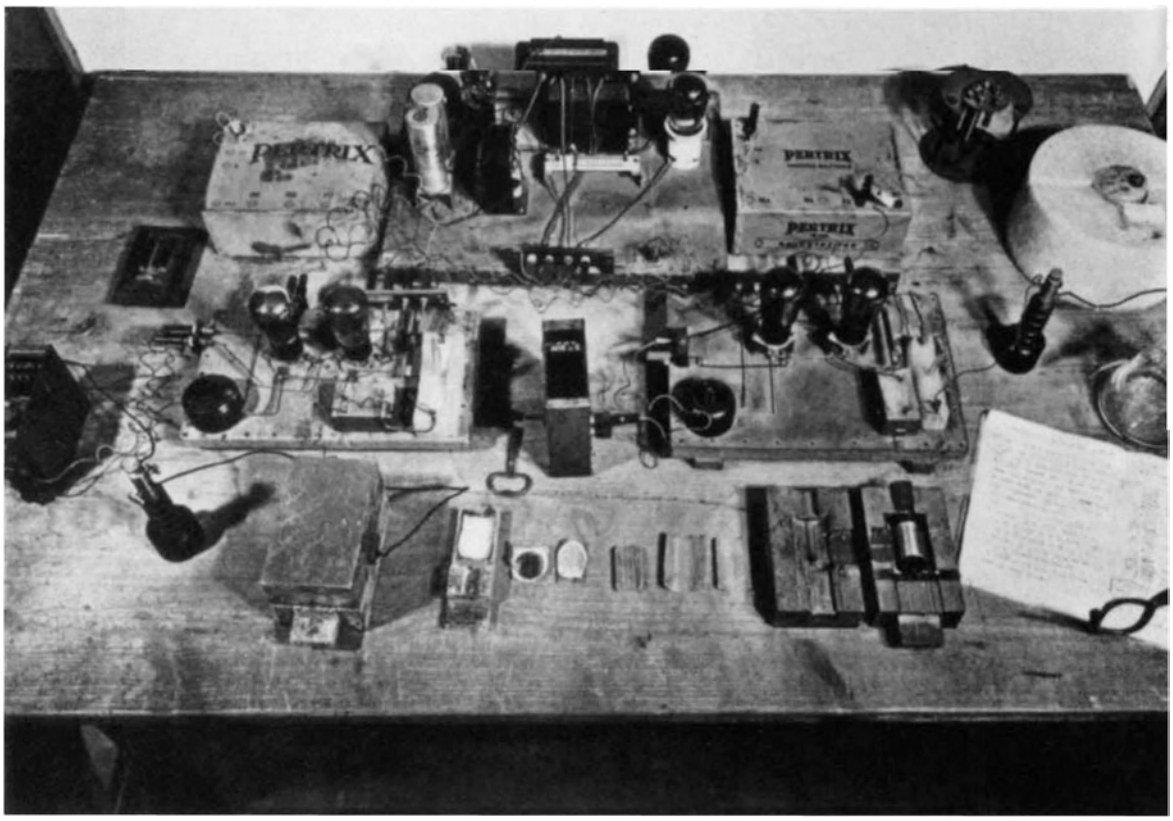

Fig. 5. Some of the Berlin team's instruments, now in the Deutsches Museum in München: Geiger-Müller counters (front part), pulse amplifiers and mechanical counters (middle part), high voltage supply (rear part), neutron source and paraffin block (upper right); additional details in the text. The instruments shown here were located in the rooms 20, 23, and 29 of Figure 4.

four to five orders of magnitude more activity in the decay chain (5).

$$^{238}_{92}\mathrm{U} \xrightarrow[4.5\times10^{9}\,\mathrm{y}]{\alpha} {}^{234}_{90}\mathrm{Th} \xrightarrow[24.1\,\mathrm{d}]{\beta^-} {}^{234m}_{91}\mathrm{Pa} \xrightarrow[1.17\,\mathrm{min}]{\beta^-} {}^{234}_{92}\mathrm{U} \xrightarrow[2.5\times10^{5}\,\mathrm{y}]{\alpha} {}^{230}_{90}\mathrm{Th} \quad (5)$$

The energetic β^--rays of 1.17-min protactinium-234m pass through the aluminum tube of the counters. It is certainly possible to chemically separate protactinium-234 and its precursor thorium-234 from uranium; however, both activities are growing continuously from the decaying uranium, which therefore must be purified immediately before the irradiation.[57] For this purpose uranium is precipitated with a mixture of ammonia and ammonium carbonate in the presence of some iron and is dissolved again as a complex uranyl carbonate; thorium- and protactinium-234 remain attached to the precipitated iron hydroxide. From the filtrate, ammonium diuranate is precipitated; this is usually used for the irradiation.

The more the Berlin group progresses with the radiochemical analysis of the uranium-born activities and with refining the separation techniques, the more puzzling are the results. During the next three years new transuranic activities are discovered;[58, 59] and the respective formation reactions,[57, 60, 61] decay properties,[62] and chemical behavior are studied.[63] In May 1937 the results are presented in detail in two publications.[61, 63] A few days before *Lise Meitner*'s escape from Germany the last joint note[64] which includes a new activity, the 60-d eka-iridium, is submitted.

The scheme of transuranic elements now looks as depicted in Figure 6. Three β^--emitters are assigned to uranium. Two

$_{92}$U	$_{93}$Eka-Re	$_{94}$Eka-Os	$_{95}$Eka-Ir	$_{96}$Eka-Pt	$_{97}$Eka-Au

23 min	→ ?				

Fig. 6. Decay chains of uranium and of the transuranic elements produced by irradiation of uranium with neutrons; situation as of June 1938 according to the last joint publication by *O. Hahn, L. Meitner*, and *F. Strassmann* [64].

are the origin of two long β^--decay chains with seven transuranic activities; one chain ends with element 95, eka-iridium, the second extends even to element 96, eka-platinum. No decay product is found for the strongest activity, the third uranium isotope with 23-min half-life, even though it is clearly identified chemically as uranium and shown to be a β^--emitter by using a cloud chamber;[57] thus, it must decay into element 93. As even in pure samples of this activity no decay product is found, *Hahn* et al. presume it to be a long-lived eka-rhenium.[63] Finally,[61] all uranium activities are ascribed to the same isotope, uranium-239. However, such a triple nuclear isomerism which even continues in the decay products is difficult to understand; this is certainly realized by *Meitner, Hahn*, and *Strassmann*.[61] Another peculiarity is the stability against α-decay in the chains approaching a region where α-decay should increasingly dominate. However, no α-emitters are observed among the transuranic elements.[65] This stability is theoretically explained[66] by the assumption that transuranic nuclei might be elongated rather than spherical. The nuclei in that region are indeed elongated, as is found much later. The same results and an additional product with a 17-h half-life[65] are obtained at the Berkeley cyclotron, which has a neutron flux larger by many orders of magnitude. Several β^--emitters are also produced[67] when uranium is bombarded with energetic neutrons.

The scheme of parallel decay chains is based on a number of different arguments, which, taken together, make up a reasonable picture. First of all one has the cloud chamber experiments[57, 62] which prove that β^--emitters are formed. Genetic relationships within the chains are obtained by chemically isolating one of the activities and by tracing its decay into another activity; for example, 16-min eka-rhenium decays into 5.7-h eka-osmium[61] and 66-h eka-iridium into 2.5-h eka-platinum.[63] Even in cases where such relationships are difficult to establish, those activities already present after a short irradiation time should be near the beginning of a decay chain; they cannot be formed from the decay of later members. Using this argument the 10-s, 40-s, 2.2-min, and 16-min activities are ascribed to either uranium or eka-rhenium.[61] An additional criterion is the influence of the neutron energy on the production of the activities. The two long decay chains can be produced with either thermal, slow, or fast neutrons without any noticeable difference, the 23-min activity, however, only by resonance capture of neutrons with 25 electron volts energy.[61] The production cross-sections obtained for the three chains seem to be only compatible with uranium-238 as the primary nucleus rather than with the much less abundant uranium isotopes 235 and 234.[61] Thus, the conclusion is that all three chains emerge from uranium-239. During experiments which focus more on aspects of nuclear physics chemical methods are also used for disentangling the reaction mixture.

The main emphasis in identifying the unknown activities is, however, placed on their chemical properties, still with the assumption that one is dealing with uranium, eka-rhenium, and eka-platinum elements. A large variety of methods is used in these chemical studies,[63] either based on group separations which focus on all four transuranic or all three eka-platinum elements, or on methods which are very specific for individual elements. In the case of the first and the last members of the chains, the chemical studies are quite straightforward. The 16-min, 23-min, and 59-min activities dominate after a short irradiation and are still long-lived enough to allow for more complicated chemical operations. If, on the other hand, one carries out the irradiation and then waits for a long time, only the 66-h activity and its 2.5-h decay product remain. The treatment of the intermediate products is more problematic due to the complex mixture of decaying and growing activities. It also seems easier to distinguish between uranium, eka-rhenium, and the group of all eka-platinum elements rather than between the individual eka-platinum elements.

The almost quantitative coprecipitation of all transuranic elements with platinum sulfide in medium-strong hydrochloric acid is thought to be a very characteristic reaction; in this way, transuranic elements can be separated from large amounts of uranium and strong activities of natural decay products.[63] In the framework of the periodic table of that time, this sulfide formation is considered to be the most

striking difference between the transuranic elements on the one hand and uranium and the cisuranic elements on the other. The 23-min activity can be isolated[63] from the filtrate of such a sulfide precipitate together with the insoluble sodium uranyl acetate, which is characteristic of uranium. If the precipitation from the bulk of the irradiated uranium is performed quicker, a shorter-lived activity is noticeable; thus, also the 40-s activity seems to be a uranium isotope[63] according to this nice early example of fast radiochemical separations of complex mixtures.

As expected, eka-rhenium is found electrochemically to be the least noble transuranic element; in contrast to the eka-platinum elements it is not deposited on noble metal foils placed in solutions nor can it be reduced to the metal state with bismuth as carrier. With some reagents the transuranic elements can even be sequenced. In a precipitation of uranium by sodium hydroxide the following order of coprecipitation is obtained: eka-Os > eka-Ir > eka-Re > eka-Pt. If precipitation is performed with rhenium sulfide in strong hydrochloric acid the order is eka-Os > eka-Re ≥ eka-Ir > eka-Pt. In contrast to uranium and the cisuranic elements the transuranic elements have in common that they are volatile at medium and higher temperatures. If a sulfide precipitate is heated under aerobic conditions, the volatility increases in going from eka-rhenium to eka-platinum; if it is treated with aqua regia to form chlorides before heating, the sequence is reversed. Finally, two very specific reactions seem to corroborate this scheme: eka-rhenium coprecipitates with nitron perrhenate and eka-platinum with ammonium platinum hexachloride; thus, element 93 obviously forms a species analogous to perrhenate while element 96 forms one analogous to platinum hexachloride.

Hahn, Meitner and *Strassmann*[63] finish their article about the chemistry of the transuranic elements by discussing similarities to and differences from rhenium and the platinum metals. The similarities prevail and the trends seem to continue plausibly. There should no longer be any doubts about their place in the periodic table and, above all, their difference from all other known elements is firmly established.[63] This conclusion, however, is premature; what one could not imagine was that a complex mixture of lighter elements could simulate these results.

The Berlin team refrains from suggesting names for the transuranic elements. The group in Rome instead feels confident enough to start using the names ausonium for 93 and hesperium for 94.[3, 68] *Enrico Fermi*, too, uses them when he receives the Nobel Prize on December 10, 1938, partly for the synthesis of new elements. In the published version of his lecture[69] he adds a footnote, noble indeed, that after the discovery of nuclear fission—a few days after the lecture—all transuranic elements should be reexamined because they might in fact be fission products. *Fermi* does not return to Italy. Shortly before, a detailed review article appears dealing with the transuranic elements.[70] Even the discovery of element 93 in nature by X-ray-spectroscopy is again reported.[71, 72]

1.4. Interlude: Radium from Thorium?

Not only uranium, but also thorium is especially interesting regarding activation by neutrons. In this case the focus is not on transuranic elements which should not be accessible from thorium; still there is some connection with our topic, as we shall see later. Radiochemists were fascinated,[73, 74] instead, by the possibility of reaching the long sought 4n + 1 decay series via reactions like (6) and (7).

$$^{232}_{90}\mathrm{Th} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{233}_{90}\mathrm{Th} + \gamma \qquad (6)$$

or

$$^{232}_{90}\mathrm{Th} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{229}_{88}\mathrm{Ra} + {}^{4}_{2}\alpha \qquad (7)$$

For the three radioactive decay series starting with uranium-238, uranium-235, and thorium-232 the mass numbers of all members of the respective chains can be divided by either 4n + 2, 4n + 3, or 4n. Therefore, a 4n + 1 series is postulated which, however, is not found in nature.

Upon irradiation of thorium one has to cope with all nine members of the 4n decay series.[75] Even when thorium samples are used which have been repeatedly purified from decay products over many years[76] so that these have almost disappeared, one still has to perform cumbersome purifications and additional test experiments.[73, 75, 78]

Fermi and his co-workers[2, 8] are again the first ones to start with experiments; they find two β^--emitters with half-lives of 1 min and 15 min, respectively. The latter is soon corrected to a value of 24 min.[36, 37] This activity has the characteristic chemical properties of thorium. It coprecipitates with thorium fluoride and thorium peroxide and can be separated from all other elements between lead and uranium.[37] *Hahn* and *Meitner*[73] confirm the two activities and also identify the longer-lived one as being thorium-like. As the short-lived activity is produced with fast neutrons they assign it to radium-229, which is formed by an (n,α)-reaction according to Equation (7); they argue that an additionally observed 11-min activity might be its actinium decay product.

But soon the situation becomes more complex, as in the case of uranium. In Paris, *Irène Curie, Hans von Halban* and *Pierre Preiswerk* first find four,[74] then a total of five[79] β^--emitters with half-lives of[80] 1 min, 2.5 min, 12 min, 25 min, and 3.5 h, respectively. They assign them all to thorium and its neighbors, for example the 3.5-h activity to actinium, because it coprecipitates with lanthanum fluoride.[80] Finally, a 42-h actinium is added.[78] It remains controversial whether the 4n + 1 series is believed to have been found first in Berlin or in Paris; this may be the reason why the Berlin group remains quite reserved[10] towards the following work of the group in Paris.

The mixture of activites, however, becomes more and more puzzling. *Lise Meitner, Fritz Strassmann* and *Otto Hahn*[75] show that 23-min thorium is formed via a resonance capture (n,γ)-process (6) and correctly conclude that it must be thorium-233. They identify its decay product—again correctly—as 27-d protactinium-233. With fast neutrons they even find three β^--emitting radium isotopes (Fig. 7), one of them with a 0.8 min half-life; all three are chemically identified as radium and can be connected with three actinium isotopes. They are presumed to be formed by a Th(n,α)Ra reaction (7), although (n,α)-reactions have up to then been observed only for light elements;[3] the instability of thorium against α-particle emission, apparent in its

$^{232}Th\ (n,\alpha) \longrightarrow {}^{229}Ra \xrightarrow[<1\ Min.]{\beta} {}^{229}Ac \xrightarrow[\sim 18\ Min.]{\beta} Th?$

Fig. 7. Three isomeric decay chains for radium and actinium formed by irradiation of thorium with fast neutrons; after *L. Meitner, F. Strassmann,* and *O. Hahn* [75], May 1938.

natural decay, is taken as an argument for this explanation.[75] It seems to be further corroborated by a note[81] dealing with energetic α-particles which appear during the irradiation of thorium with neutrons; in *Meitner*'s group, however, a search for these prompt α-particles is not successful.[82] The activities of the Berlin group are confirmed by using much stronger neutron sources, and a new decay product, 24-h thorium-231, is added.[83] Since natural thorium mainly consists of thorium-232, all three radium activities have to be assigned to radium-229 and its decay products to actinium-229 (Fig. 7). This triple nuclear isomerism is, however, difficult to understand,[75] as is already the case with uranium (Fig. 6).

Today, the $4n+1$ series[84] is known to start with neptunium-237, which, due to its half-life of 2.14×10^6 y, does not exist in nature any more; neither does the rest of the decay series. Among the nuclides which are correctly assigned in these early experiments, 27.0-d protactinium-233 is indeed a member of the chain, but not 22.3-min thorium-233.

1.5. Paris 1937–1938: The 3.5-hours Activity

Let us now go back to the artificial activities produced from uranium. The cumbersome purification of uranium prior to irradiation can be omitted if the energetic β^--rays of the natural decay product, protactinium-234m, are discriminated by covering the sample with a copper foil through which these β^--rays cannot pass. Then, naturally only those activities can be detected whose β^--rays are even more energetic. *Irène Curie* and *Paul Savitch*,[85] in the summer of 1937, decide to proceed thus in dealing with the artificial uranium-born activities. In addition to the known 40-s, 2-min and 16-min components they find[86] a new activity with 3.5 h half-life as depicted in Figure 8. The 3.5-h activity appears without absorber foil, too, if the activity of irradiated and non-irradiated uranium is followed with a compensation method. It is not noticed, however, that a very similar activity appears also upon irradiation of thorium with neutrons.[80] The 3.5-h activity does not coprecipitate with sulfides in acid solution[85] and can be separated this way from the transuranic elements reported until then. It seems to follow the natural decay product of uranium, thorium-234. This assignment to thorium from the reaction (8) cannot

$$^{238}_{92}U + {}^{1}_{0}n \longrightarrow {}^{235}_{90}Th + {}^{4}_{2}\alpha \qquad (8)$$

be confirmed in Berlin, however, where again—as already before[61]—thorium is not found. A letter is written to the researchers in Paris suggesting the withdrawal of these results.[87]

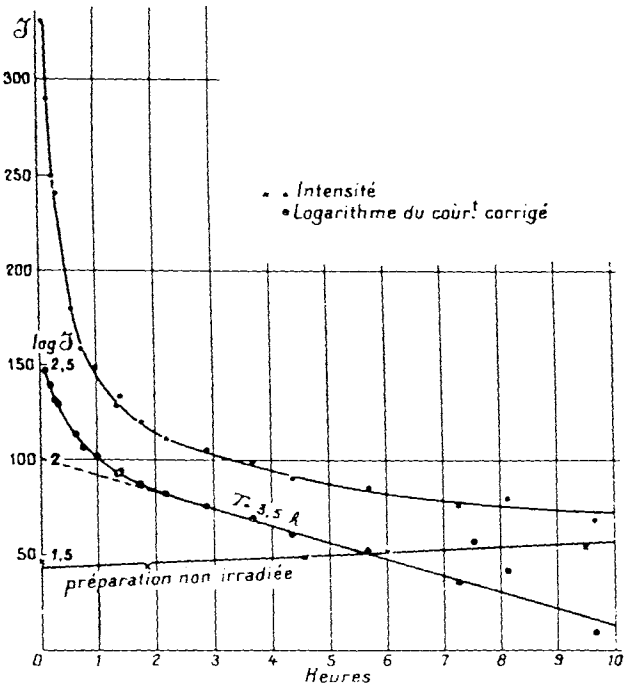

Fig. 8. The 3.5-h activity found in uranium irradiated by neutrons and measured directly as published by *I. Curie* and *P. Savitch* [86] in Paris, July 1938. Upper curve: activity measured with the sample covered by a copper foil of 0.48 g · cm^{-2} thickness, depicted linearly as a function of time; lower curve: build-up of natural decay products in uranium, also depicted linearly; middle curve: difference between the two measurements in semilogarithmic representation with 16-min "eka-rhenium" at the beginning followed by a pure decay with 3.5 h half-life.

A following note by *I. Curie* and *P. Savitch*[88] is indeed modified with regard to this after they succeed in chemically separating the 3.5-h activity from thorium and protactinium. What they further find is even more remarkable: the chemical properties of the activity are similar to those of the lanthanoids; it is likely that it is either actinium, the heavier homologue of this group of elements, or a new transuranic element with properties completely different from eka-rhenium or the eka-platinum elements. In the next note[89] additional lanthanoid properties are ascribed to the 3.5-h activity, for example its coprecipitation with fluorides and oxalates. As they are able to separate the 3.5-h activity chemically from actinium *I. Curie* and *Savitch* favor the hypothesis of a new transuranic element, even though they find it difficult to understand. For this separation the activity is isolated with lanthanum as a carrier. Natural radio-actinium is added followed by a fractional precipitation of lanthanum oxalate. The 3.5-h activity is found in the head fraction and actinium—as expected—in the tail fraction.

All these results along with some others are presented in detail in the following publication[86] which is supplemented by a note[90] about the maximum β^--energy of the 3.5-h activity, 3.2 MeV. *I. Curie* and *Savitch* present additional chemical evidence against actinium. The similarity to the lanthanoids is summarized:[86] "Dans l'ensemble, les propriétés de $R_{3,5h}$ sont celles du lanthane, dont il semble jusqu'ici qu'on ne puisse le séparer que par fractionnement".[*] One is

[*] "On the whole the properties of $R_{3.5h}$ are those of lanthanum, from which, it seems so far, it can be separated only by fractionation."

tempted to think that if *I. Curie* and *Savitch* had simply omitted the second half of the sentence the puzzle would have been solved; the observation of fractionation, however, is correct, as we will see below. According to a later remark[91] *I. Curie* and *Savitch* even consider uranium breaking into lighter elements; yet, they reject this explanation because the 3.5-h activity as well as the transuranic elements, represented by the 16-min eka-rhenium, show the same behavior with respect to different neutron energies[86] and thus seem to be related. In conclusion, albeit with some hesitation, they favor the hypothesis of a transuranic element with completely different properties and probably being at the beginning of this series of elements:[86] "On pourrait imaginer, par exemple, que ce corps a le nombre atomique 93 et que les corps étudiés par *Hahn, Meitner* et *Strassmann* ont des nombres atomiques de 94 à 97"[*] This, of course, is a challenge for the group in Berlin. At last, enough details are known to critically test the foundation of these results. In Berlin one is sceptical, as *Otto Hahn* tells *Frédéric Joliot—Irène Curie*'s husband—when they meet in May 1938 during a congress in Rome.[10, 92] In Berlin, somewhat jokingly, one speaks of "*Curio*sum".[76]

2. Alkaline Earth Metals from Uranium

2.1. Berlin, Autumn 1938: the "Radium" Activities

As soon as the detailed publication by *I. Curie* and *Savitch*[86] appears in the third week of October 1938, *Hahn* and *Strassmann* are able to reproduce the 3.5-h activity.[93] The best method, as recommended in Paris, to chemically isolate the activity is its coprecipitation with sparingly soluble potassium lanthanum sulfate. *Strassmann* immediately notices[48] that if radium should be present it would coprecipitate as sulfate and later during fractionation appear in the head fraction, as prescribed for the 3.5-h activity. Radium could be formed if thorium from a U(n,α)Th reaction disintegrates by α-decay [Reaction (9)].

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{4}_{2}\alpha + {}^{235}_{90}\mathrm{Th} \xrightarrow{\alpha} {}^{231}_{88}\mathrm{Ra} \xrightarrow{\beta^-} {}^{231}_{89}\mathrm{Ac} \qquad (9)$$

Finally, actinium could result from β^--emitting radium. An α-emitting thorium may well not have been noticed before. This hypothesis would serve to trace back the puzzling chemical properties of the 3.5-h activity to a mixture of already known elements. Of these elements, radium can be identified more easily than a lanthanum-like element. *Strassmann* suggests,[76, 94] not to coprecipitate radium as usual with barium sulfate, which has a large surface, but with barium chloride instead; this salt crystallizes from concentrated hydrochloric acid as beautiful, colorless, and particularly pure needles and can easily be reprecipitated after having been dissolved in water. With this elegant method radium can quickly and unambiguously be identified; it is accompanied only by barium.

Within a matter of days *Hahn* and *Strassmann* obtain their first important results, as *Hahn* notes on October 25, 1938 in a letter to *L. Meitner*.[93] The "countdown" for the discovery of nuclear fission has started; it is documented in the laboratory notebook "Chem. II",[96] a plain booklet bound in wax-paper of about 18 × 24 cm format and 94 pages.[*] We are well informed about the subsequent events by a series of letters exchanged between *Otto Hahn* and *Lise Meitner*, which were edited under somewhat different aspects.[97, 98] Whatever seems important to one of them is written down and the answer often arrives within two days. It is especially informative to read the scientific part of the letters and the laboratory notes in chronological order.[98] *Hahn* urgently asks for explanations of these unexpected results, *Lise Meitner* for more information. All this occurs in quite a troubled period of time, as one notices clearly from *Hahn*'s autobiographic notes of 1945[76] and, in a more condensed and dramatic way, from his pocket-book of 1938.[99] Even when *Lise Meitner* is still with him, *Hahn* has already isolated

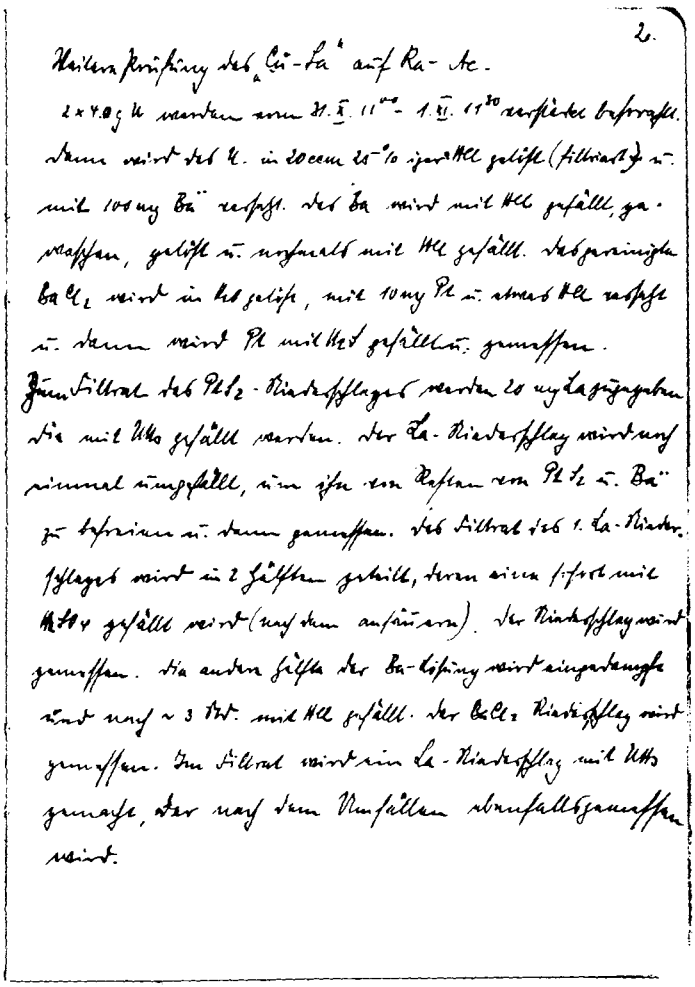

Fig. 9. Beginning of the note-book "Chem. II" by *O. Hahn* and *F. Strassmann* [103]: Chemical separation for "Weitere Prüfung des "Cu-Sa" auf Ra-Ac" ("Further tests of "Cu-Sa" for Ra-Ac") on November 1, 1938, written by *F. Strassmann*; separation of a radium fraction from irradiated uranium by precipitation of barium chloride from strong hydrochloric acid. "Cu-Sa" represents the 3.5-h activity of *I. Curie* and *P. Savitch* [86].

[*] "One could imagine, for example, that this body has the atomic number 93 and that the bodies investigated by *Hahn, Meitner*, and *Strassmann* have the atomic numbers 94 to 97."

[*] The author is indebted to *Ernst Berninger* for a copy of the booklet "Chem. II". A previous note-book "Chem. I" seems to have been lost. The subsequent books starting with "Chem. III" and the corresponding larger decay-curve drawings are stored in the Landeshauptarchiv Koblenz, legacy *Fritz Strassmann*.

himself completely;[101] no one else in the institute is told what is about to happen. It is the time of the Reichskristallnacht. Some of the institute's senior scientists are fanatic supporters of the "National Socialists" (Nazis), others, like *Fritz Strassmann*, succeed in remaining aloof though it meant facing disadvantages. A potential successor for *Hahn*, who is considered politically unreliable, is already in the institute. In this atmosphere the problem of safeguarding *Lise Meitner*'s property has to be solved. *Hahn*'s wife *Edith* starts to suffer from a mental disease and *Hahn* also feels completely exhausted at times. The exciting results with uranium distract him and save this extremely difficult situation.[76] The secluded *Fritz Strassmann*, whom he also trusts politically, cares for the continuous progress of the experiments.

"Chem. II" starts on November 1, 1938, with a note[103] shown in Figure 9. To verify whether "Cu-Sa", the 3.5-h activity of *I. Curie* and *Savitch*, might be radium or actinium, the respective homologous elements barium and lanthanum are separated from the bulk of irradiated uranium and accompanying "transuranic elements" are then removed with platinum sulfide. To this purpose 8 g of uranium are irradiated with slow neutrons for one day, dissolved in hydrochloric acid, and barium chloride is precipitated from the resulting solution. After reprecipitating barium chloride and dissolving it again, platinum is separated as sulfide and lanthanum as hydroxide. One half of the barium–radium fraction is immediately processed to yield a sulfate, the remaining half is put aside to allow for actinium to be formed and is later separated into a barium–radium fraction and a lanthanum–actinium fraction.

The barium–radium fractions are especially active. The decay curves indicate the presence of even three radium isotopes, having half-lives of about 25 min, 110 min, and several days; they seem to be related to three actinium decay-products, as shown in Figure 10. *Hahn* and *Strassmann* soon

$$^{231}_{88}\mathrm{Ra}_1 \xrightarrow[\sim 25\ \mathrm{Min.}]{\beta} {}_{89}\mathrm{Ac}_1 \xrightarrow[\sim 40\ \mathrm{Min.}]{\beta} {}_{90}\mathrm{Th}?$$

$$_{88}\mathrm{Ra}_2 \xrightarrow[\sim 110\ \mathrm{Min.}]{\beta} {}_{89}\mathrm{Ac}_2 \xrightarrow[\sim 4\ \mathrm{Std.}]{\beta} {}_{90}\mathrm{Th}?$$

$$_{88}\mathrm{Ra}_3 \xrightarrow[\text{mehrere Tage}]{\beta} {}_{89}\mathrm{Ac}_3 \xrightarrow[\sim 60\ \mathrm{Std.}]{\beta} {}_{90}\mathrm{Th}?$$

Fig. 10. Three radium isomers and their respective actinium decay products in the barium fraction of neutron-irradiated uranium; note by *O. Hahn* and *F. Strassmann* [104], November 1938.

describe these findings in a note.[104] All three radium activities are ascribed to radium-231; thus, as already in the case of the activities isolated from thorium and ascribed to radium-229, an inherited triple isomerism is assumed. It is obviously not recognized that the half-lives are quite similar in both cases, probably because different radium isotopes are postulated. Strangely enough, the (n,α)-reaction (9) of uranium already occurs with slow neutrons;[104] this effect is observed for the first time.

In the following publication which is submitted to "Naturwissenschaften" on December 22, 1938, *Hahn* and *Strassmann*[105] present details of these activities. The editor, *Paul Rosbaud*, realizes the significance of some of the results reported at the end and has the publication appear already in the next issue on January 6, 1939. However, four out of the five printed pages deal with interesting but not really spectacular results. At first, one only notices that the title speaks of "alkaline earth metals" instead of "radium" as in the case of the preceding note. In the text it again says "radium", mostly in quotation marks, as well as in the decay chains (Fig. 11) which are now supplemented. Proof is shown of all

$$\text{„Ra I"}? \xrightarrow[<1\ \mathrm{Min.}]{\beta} \mathrm{Ac\ I} \xrightarrow[<30\ \mathrm{Min.}]{\beta} \mathrm{Th}?$$

$$\text{„Ra II"} \xrightarrow[14 \pm 2\ \mathrm{Min.}]{\beta} \mathrm{Ac\ II} \xrightarrow[\sim 2{,}5\ \mathrm{Std.}]{\beta} \mathrm{Th}?$$

$$\text{„Ra III"} \xrightarrow[86 \pm 6\ \mathrm{Min.}]{\beta} \mathrm{Ac\ III} \xrightarrow[\sim \text{mehrere Tage?}]{\beta} \mathrm{Th}?$$

$$\text{„Ra IV"} \xrightarrow[250\text{–}300\ \mathrm{Std.}]{\beta} \mathrm{Ac\ IV} \xrightarrow[<40\ \mathrm{Std.}]{\beta} \mathrm{Th}?$$

Fig. 11. The decay chains of Figure 10 in the detailed publication by *O. Hahn* and *F. Strassmann* [105] from December 22, 1938, in a more complete form and with the radium symbols in quotation marks.

activities by decay curves which are obtained after different irradiation and separation times; Figure 12 presents an example. The chemical separation is discussed in detail and it is stressed that the activity precipitated with the barium salts can only stem from radium, "wenn man das Barium selbst als allzu unwahrscheinlich vorerst außer Betracht läßt[105]",[*] as it still says in the beginning of the text.

2.2. Berlin, December 17, 1938: Radiochemical Detection of Barium

The big surprise comes only at the end of the paper;[105] one hardly suspects it in a publication entitled "Über den Nachweis und das Verhalten der bei der Bestrahlung des Urans mittels Neutronen entstehenden Erdalkalimetalle".[**] *Hahn* and *Strassmann* report on some recent investigations which they only publish with hesitation. They have decided to prove more rigorously the occurrence of radium. Since *Marie Curie*'s time it has been known how to achieve this:[106] Upon fractional crystallization of certain barium salts, for example the chloride, radium becomes enriched in the head fractions and, after many repetitions, can even be obtained in pure form. *Hahn* became acquainted with these methods during his time with *Ramsay* in London[76, 107] and discovered his first radioactive species this way,[109] the 1.9-y thorium-229, then called radiothor. Until the thirties, the study of such coprecipitation reactions was one of his main research interests.[9]

Presumably these control experiments are motivated by some doubts which theorists raised against the inherited isomerism.[13] Already then nuclear isomerism is correctly

[*] "if one does not consider the quite unlikely candidate barium for the time being."

[**] "On the identification and behavior of the alkaline earth metals formed upon irradiation of uranium with neutrons"

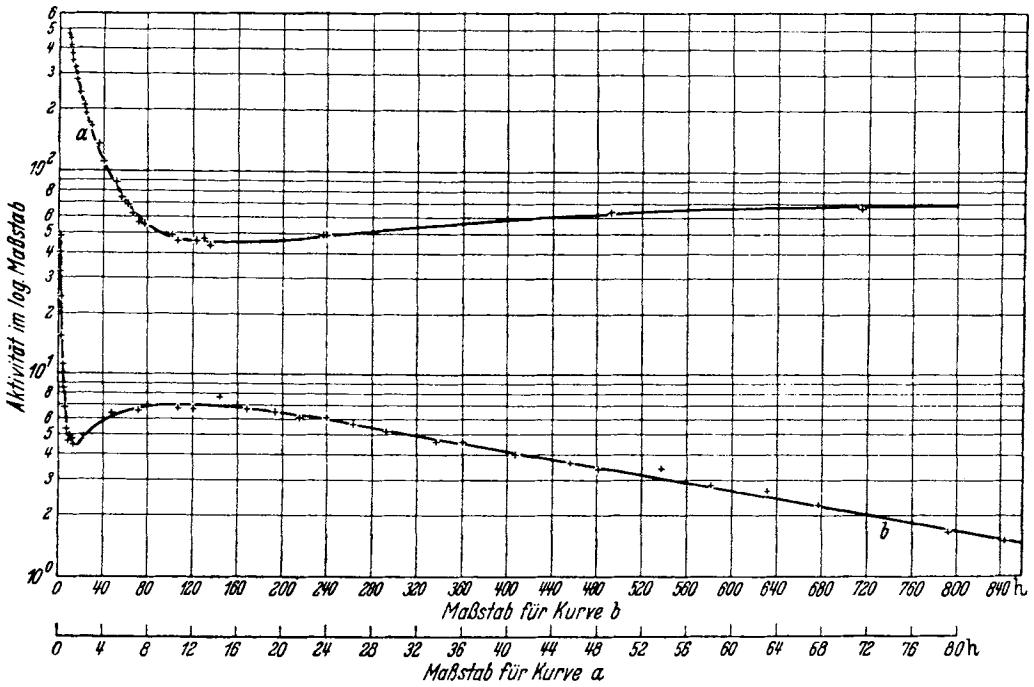

Fig. 12. One of the decay curves from the same publication [105] as Figure 11: The three radium isotopes after four days of irradiation. The measured activity is depicted logarithmically versus time (lower curve), its initial decrease with a ten-times extended time axis (upper curve). The initial decrease is mainly due to 86-min "Ra III", the subsequent rise is caused by the 40-h "Ac IV", the decay product of the long-lived 12-d "Ra-IV", which dominates the final decrease.

understood as an effect of nuclear spin[110]—large spin differences hinder the transition from excited nuclear states to the ground states; but it is thought to be very unlikely that such an effect is preserved in a decay chain. Therefore, starting with the idea of deformed transuranic nuclei,[66] another kind of isomerism is suggested,[111] namely the possibility of nuclei having the same numbers of protons and neutrons but with different deformations and, in turn, differences in half-lives. Much later, this shape isomerism is indeed found for the real transuranic elements[112–115] via their spontaneous nuclear fission. The formation reaction is a second point which raises scepticism;[116] it is understood by many to be a very peculiar, successive detachment of two α-particles[13, 117] [cf. (10)], although *Hahn* and *Strassmann*[104]

$$^{238}_{92}\mathrm{U} + {}^{1}_{0}\mathrm{n} \longrightarrow {}^{231}_{88}\mathrm{Ra} + 2\,{}^{4}_{2}\alpha \qquad (10)$$

explicitly point to one or more α-emitting thorium isotopes as intermediate products. But *Hahn* also sometimes speculates about an (n,2α)-reaction.[48, 116] For *Hahn*[76, 117] the most substantial doubts are probably the ones that he hears in Copenhagen on November 13–14, 1938, when he visits *Niels Bohr* to give a talk; on this occasion he also meets[99] *Lise Meitner* and her nephew *Otto Robert Frisch*, who works as an experimental physicist in *Bohr*'s institute. In the Berlin institute, too, doubts are being raised,[118] some based on theoretical arguments, others because prompt α-particles from an (n,α)-reaction are not observed[82] upon irradiation of uranium with neutrons.

Later, however, *Hahn* mentions also a more trivial reason for the fractionations:[46, 94, 117] Due to the thickness of the barium samples the β-rays of especially the most long-lived new activities are strongly absorbed. Therefore, by enrichment of radium in a smaller portion of barium the counting efficiency is to be improved. This is crucial for the long-lived 12-d component in Figure 12 which is only evident by growth of its 40-h daughter substance.

The first fractionation is performed on November 25, 1938. Figure 13 depicts the notes of this amazingly simple experiment.[119] 8.5 g of uranium are irradiated over night, dissolved in strong hydrochloric acid, and barium ions (1 g) are added to the solution. Barium is precipitated as chloride, the precipitate, in turn, is dissolved in water, and hydrochloric acid is added again; after cooling, barium chloride is precipitated in several portions. The barium precipitates are measured one after the other and, as can be read at the end of the protocol, are converted into barium carbonate after about two hours. In addition, further elements are isolated, which we will not discuss, however.

The data of the first measurement of each of the three barium chloride precipitates are collected in Figure 14. The corrected count rates are placed in the next to the last column. They develop continuously within error limits when switching from one fraction to the next. The half-life turns out to be about 40 minutes; thus, mainly the short-lived species "radium" II and III are present. No sudden decrease can be perceived between the first and second and between the second and third fractions. In contrast to what was expected originally, "radium" is not enriched in the first fraction. No comment on that is found in the notes; in the headline, however, "Ra" is put in inverted commas—Figure 13—whereas in the following notes and in the letters of *Hahn-Meitner* it is not.

The next fractionation is attempted on November 28, this time with 86-min "Ra III" and by using barium bromide,[120] in which radium is enriched to a larger extent than

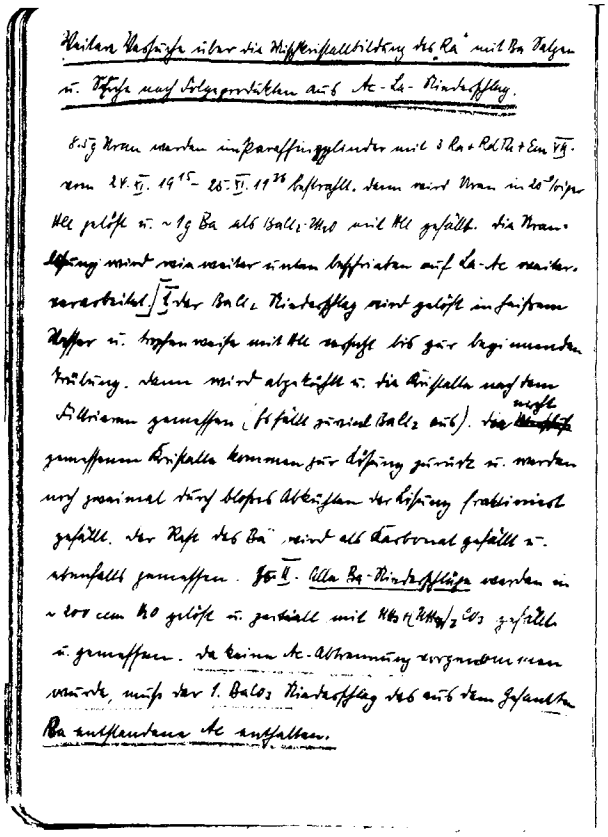

Fig. 13. First chemical fractionation of the radium activity from irradiated uranium with barium as carrier element, November 25, 1938 [119]: Beginning of the chemistry protocol concerning "Weitere Versuche über die Mischkristallbildung des "Ra" mit Ba Salzen u. Suche nach Folgeprodukten aus Ac-La-Niederschlag" ("Further experiments about the formation of mixed crystals of "Ra" with Ba salts and search for decay products from Ac-La precipitate"), written by *F. Strassmann*. The irradiated uranium is dissolved in hydrochloric acid. Barium chloride is precipitated from the solution, dissolved again in water, and, after cooling, precipitated in fractions. After a quick measurement the precipitates are converted into barium carbonate. Note the quotation marks for Ra in the title.

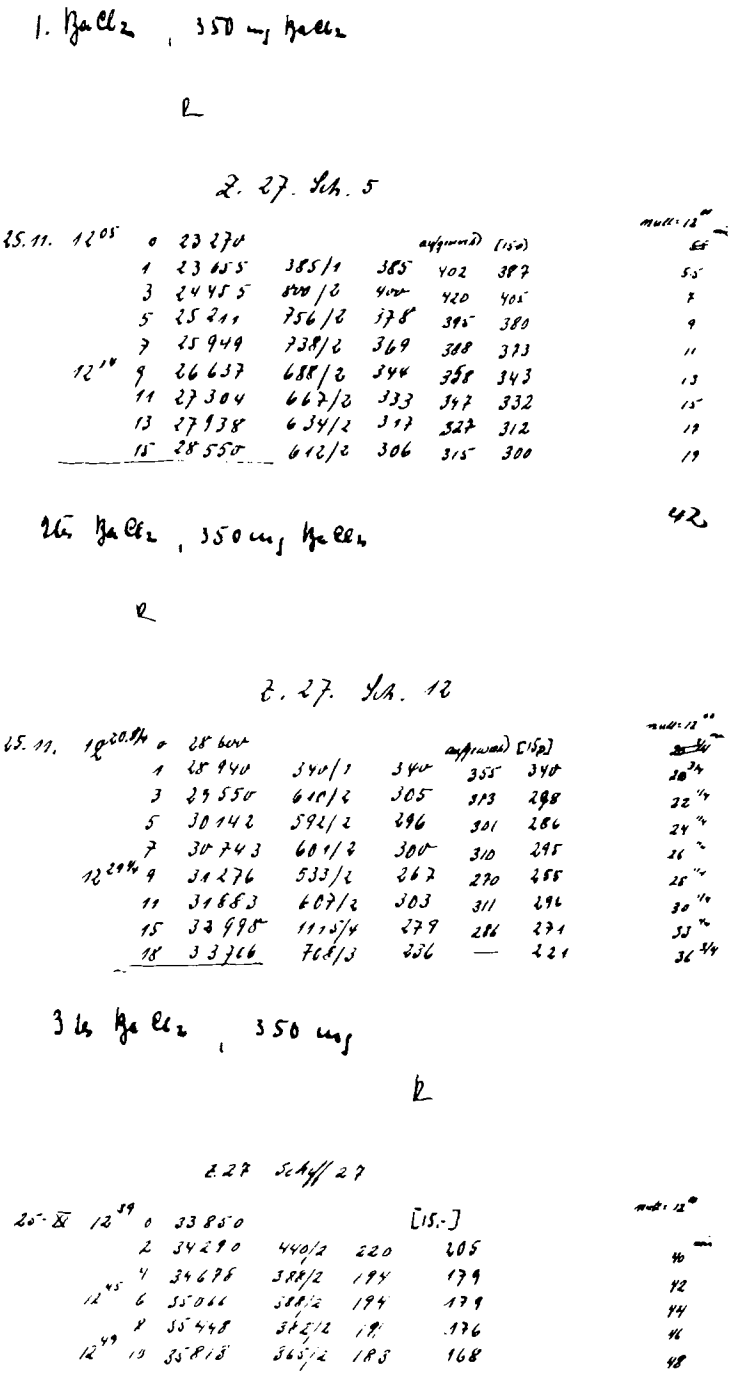

Fig. 14. Some of the data of the fractionation experiment from November 25, 1938 [119]: First indication that the "radium" isotopes from uranium do not behave like radium because they are not enriched in the head fraction. The first measurements of each of the three successive barium chloride fractions are depicted; the samples were placed on different holders (Sch) and measured with the same counter (Z.27). The columns represent from left to right: 1 date, 2 time, 3 elapsed time, 4 counts on the meter, 5 difference between the counts and duration of the measurement in minutes, 6 count rate in counts per minute, 7 count rate corrected for counting losses, 8 count rate after subtraction of the background of 15.0 counts/min, 9—on the right—normalized elapsed time. During these 43 min, the activity—a mixture of "radium" II and III—decreases continuously over all three fractions without the sudden decrease between successive fractions that is expected for radium. Remarks concerning the chemistry were written by *Hahn*, other notes by *Irmgard Bohne*, *Clara Lieber*, and *F. Strassmann*.

in the chloride. Due to the longer half-life the fractions can now be measured alternately and thus, the count rates can be compared better. Again, the activity is distributed equally among four fractions. The third attempt, from December 6 to 8, again makes use of the bromide but is performed with the long-lived "Ra IV"; the results are the same as before.[121]

In a first hypothesis the unexpected behavior of radium is assumed to be caused by its extremely low concentrations, much lower than at the time when the fractionation of radium was studied with radiation detectors which were far less sensitive. In the "active" laboratory on the 1st floor *Hahn*[76] starts to fractionate radium in amounts which were common earlier. When switching to the small amounts typical of artificial isotopes no difference is observed—the behavior is as usual.[46, 76]

Now there is only one more consequent step left: The chemical behavior of the artificial and the natural radium isotopes has to be compared directly—the famous indicator experiment by *Otto Hahn* and *Fritz Strassmann* on December 17, 1938, a Saturday.[122] 86-min "radium" obtained from uranium is compared with natural radium-228, mesothorium 1. This long-lived radium isotope, half-life 5.8 y, decays into the short-lived 6.1-h actinium-228, mesothorium 2. The discovery of radium-actinium-228 was *Hahn*'s first important achievement in Berlin.[123–125] The

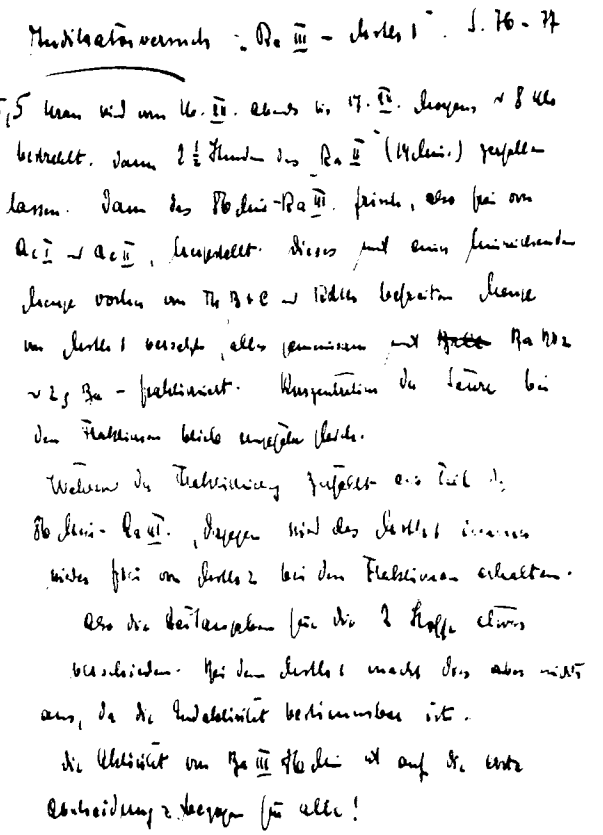

Fig. 15. Discovery of nuclear fission at Berlin on December 17, 1938: The indicator experiment "Ra III–Msth 1"; comparison of the behavior of artificial and natural radium in the fractional crystallization of barium bromide. Eight lines are sufficient for *Otto Hahn* to describe the chemical procedure [126]: "15,5 [g] Uran wird am 16. XII. abends bis 17. XII. morgens ≈ 8 Uhr bestrahlt. Dann 2 1/2 Stunden das "Ra II" (14 Min.) zerfallen lassen. Dann das 86 Min-Ra III frisch, also frei von Ac I und Ac II, hergestellt. Dieses mit einer hinreichenden Menge vorher von Th B + C und Rdth befreiten Menge von Msth 1 [= 5.8-a Radium-228] versetzt, alles gemeinsam mit $BaBr_2$ [−] ≈ 2 g Ba-fraktioniert. Konzentration der Säure bei den Fraktionen blieb ungefähr gleich". (15.5 [g] of uranium was irradiated from the evening of Dec. 16 until the morning of Dec. 17 ≈ 8 a.m. Then "Ra II" (14 min) was allowed to decay for 2 1/2 h. Then the 86-min Ra III freshly prepared, viz. free of Ac I and Ac II. To this a sufficiently large amount of Msth 1 [= 5.8-y radium-228] was added from which Th B+C and Rdth had been removed beforehand; the complete mixture was fractionated with $BaBr_2$ [−] ≈ 2 g Ba. The concentration of acid for the fractions remained approximately constant".)

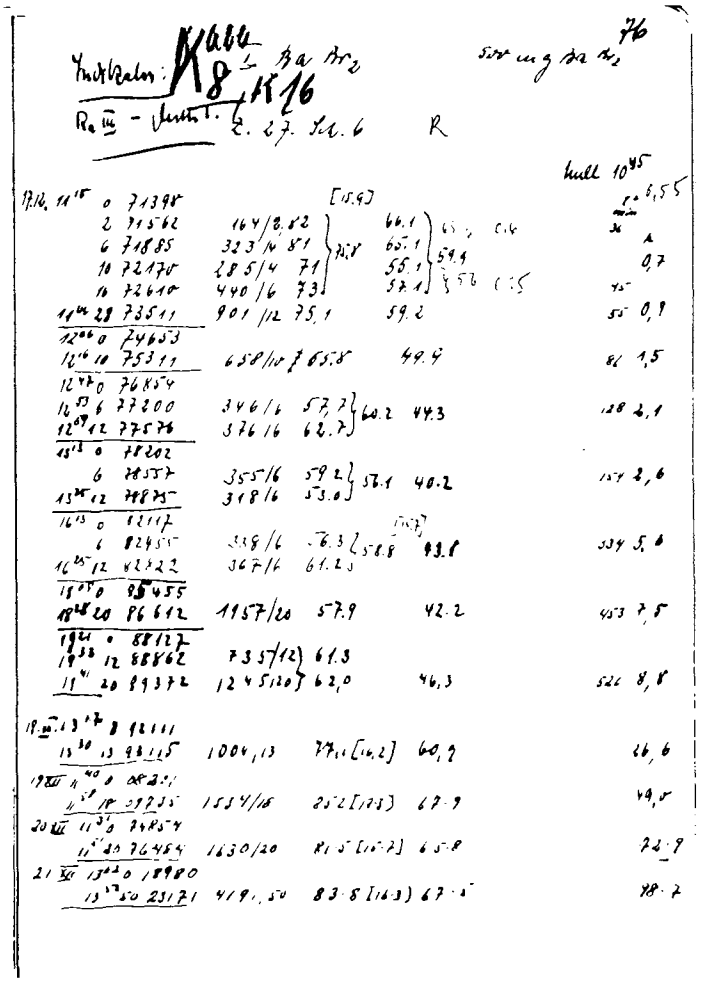

Fig. 16. Counting data for the first of three barium bromide fractions from the indicator experiment radium III–mesothorium 1 using 500 mg $BaBr_2$, measured on December 17, 1938 from 11:15 h until 20:01 h; measurements of the growth of mesothorium 2 from mesothorium 1 until December 21 are included [127]. The columns represent from left to right: 1 date, 2 time, 3 elapsed time in minutes, 4 meter counts, 5 difference between the meter counts and counting time in minutes, 6 count rate in counts per minute, 7 count rate after subtraction of the background, 8 elapsed time in minutes and in hours. "K 8, K 16" are remarks added later concerning the corresponding sheets with decay curves. The notes were taken by *I. Bohne, O. Hahn, C. Lieber*, and *F. Strassmann*.

experiment is simple in principle and the record of the chemical part is correspondingly short;[126] it is reproduced in Figure 15. As before, barium bromide is precipitated in fractions.

By the evening of the same day the artificial radium in the three fractions of barium bromide has already decayed; for several days the growth of actinium-228 is being measured until it is in equilibrium with its "mother substance" radium-228. In Figure 16 the data[127] for the first fraction of 500 mg barium bromide is depicted; facsimiles of the two remaining data sheets can be found elsewhere.[128] The conclusion[129]—Figure 17—is drawn by *Hahn* at the end of the data sheet for the third barium bromide fraction and even more concisely in his note-book:[99] "Indikatorversuch Msth 1 + unser Ra III. Ra III reichert sich nicht an. Msth 1 stark!!".[*]

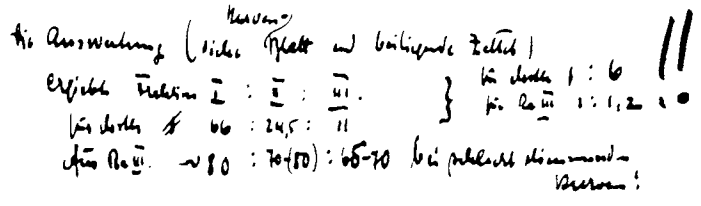

Fig. 17. *Otto Hahn*'s conclusion from the indicator experiment radium III–mesothorium 1 of December 17, 1938, at the end of the data sheet of the third barium bromide fraction [129].
„Die Auswertung (siehe Kurven-Blatt und beiliegende Zettel)
ergibt Fraktion I : II : III } für Msth 1:6
für Msth 66:24,5 :11 } für Ra III 1:1,2
für Ra III ≈80:70(−80):65–70 bei schlecht stimmenden Kurven!"
("The evaluation (see decay-curve sheet and attached paper)
yields fraction I : II : III } for Msth 1:6
for Msth 66:24,5 :11 } for Ra III 1:1,2
for Ra III ≈80:70(−80):65–70 for curves not well matching!")

On the evening of the following Monday, December 19, he informs *Lise Meitner*:[130] "Zwischendurch arbeite ich, soweit ich dazu komme, und arbeitet Straßmann unermüdlich an den Urankörpern, unterstützt von Lieber und

[*] "Indicator experiment Msth 1 + our Ra III. Ra III is not enriched. Msth 1 strongly!!"

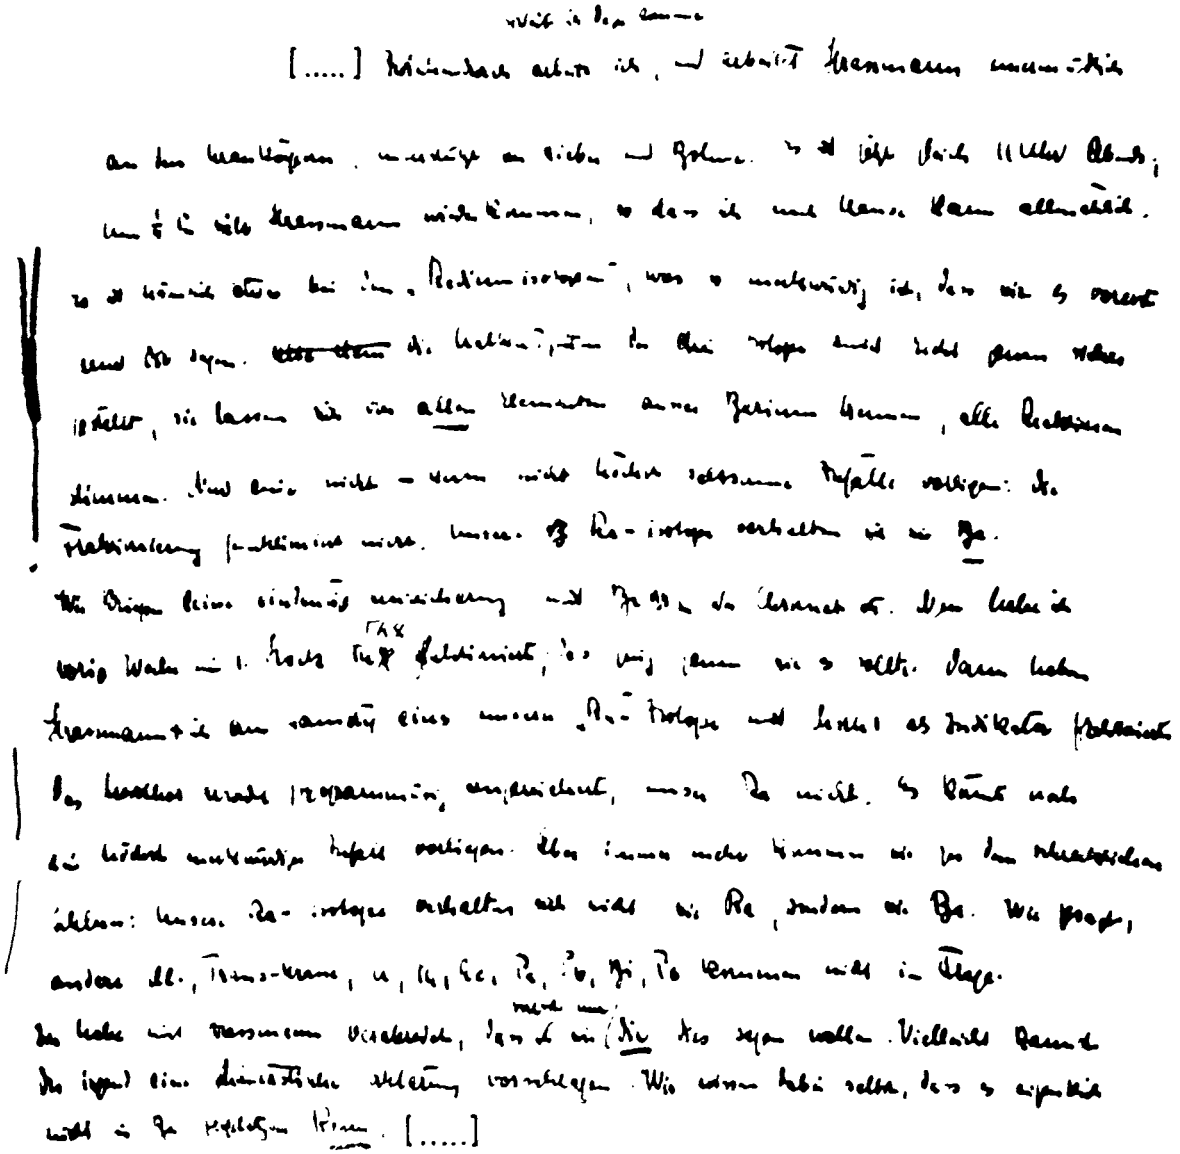

Fig. 18. *Otto Hahn* informs *Lise Meitner* on the evening of December 19, 1938, about the detection of barium in irradiated uranium; excerpt from page 2 of the letter [130], transcription in the text.

Bohne. Es ist jetzt gleich 11 Uhr abends; um 1/4 12 will Straßmann wiederkommen, so daß ich nach Hause kann allmählich. Es ist nämlich etwas bei den "Radium-Isotopen", was so merkwürdig ist, daß wir es vorerst nur Dir sagen. Die Halbwertszeiten der drei Isotope sind recht genau sichergestellt; sie lassen sich von *allen* Elementen außer Barium trennen; alle Reaktionen stimmen. Nur eine nicht— wenn nicht höchst seltsame Zufälle vorliegen: Die Fraktionisierung funktioniert nicht. Unsere Ra-Isotope verhalten sich wie *Ba*. Wir kriegen keine eindeutige Anreicherung mit $BaBr_2$ oder Chromat etc. Nun habe ich vorige Woche im 1. Stock ThX [$=^{224}$Ra] fraktioniert; das ging genau, wie es sollte. Dann haben Straßmann + ich am Samstag eines unserer "Ra"-Isotope mit Msth 1 als Indikator fraktioniert. Das Mesothor wurde programmäßig angereichert, unser Ra nicht. Es könnte noch ein höchst merkwürdiger Zufall vorliegen. Aber immer mehr kommen wir zu dem schrecklichen Schluß: Unsere Ra-Isotope verhalten sich nicht wie Ra, sondern wie Ba. Wie gesagt, andere Ele[mente], Trans-Urane, U, Th, Ac, Pa, Pb, Bi, Po kommen nicht in Frage. Ich habe mit Straßmann verabredet, daß wir vorerst nur *Dir* dies sagen wollen. Vielleicht kannst Du irgendeine phantastische Erklärung vorschlagen. Wir wissen dabei selbst, daß es eigentlich nicht in Ba zerplatzen *kann*".[*] This part of the

[*] "Whenever I have the time I do some work and Strassmann works tirelessly on the uranium bodies, assisted by Lieber and Bohne[**]. It is almost 11 p.m.; at 11:15 h Strassmann will return, so I can go home at last. You know, there is something so strange about the "radium isotopes" that for the time being we only want to tell it to you. The half-lives of the three isotopes are quite well determined; they can be separated from *all*[***] elements except barium; all reactions are fine. Except one—unless there are some really odd coincidences: The fractionation does not work. Our Ra-isotopes behave as *Ba*. We do not obtain an unambiguous enrichment using $BaBr_2$ or chromate etc. Last week I fractionated ThX [$=^{224}$Ra] on the 1st floor; this worked exactly as it should. Then, on Saturday, Strassmann + I fractionated one of our "Ra"-isotopes with Msth 1 as indicator. Mesothor was enriched as expected, not so our Ra. All this may still be due to a very peculiar coincidence. But more and more we come to the frightening conclusion: Our Ra-isotopes do not behave like Ra but like Ba. As I said, other ele[ments], trans-uranics, U, Th, Ac, Pa, Pb, Bi, Po are ruled out. I agreed with Strassmann that we only tell *you* about all this for now. Maybe you can suggest some phantastic explanation. We know ourselves that it *cannot* really break into Ba."

[**] *Clara Lieber* was an American guest scientist, *Irmgard Bohne* was a technician at the Kaiser-Wilhelm-Institut für Chemie.

[***] Emphases as in the original.

Über den Nachweis und das Verhalten der bei der Bestrahlung des Urans mittels Neutronen entstehenden Erdalkalimetalle.

O. Hahn und F. Strassmann

22. Dezember 1938

Nun müssen wir aber noch auf einige neuere Untersuchungen zu sprechen kommen, die wir der seltsamen Ergebnisse wegen nur zögernd veröffentlichen. Um den Beweis für die chemische Natur der mit dem Barium abgeschiedenen und als „Radiumisotope" bezeichneten Anfangsglieder der Reihen über jeden Zweifel hinaus zu erbringen, haben wir mit den aktiven Bariumsalzen fraktionierte Kristallisationen und fraktionierte Fällungen vorgenommen, in der Weise, wie sie für die Anreicherung (oder auch Abreicherung) des Radiums in Bariumsalzen bekannt sind.

Bariumbromid reichert das Radium bei fraktionierter Kristallisation stark an, Bariumchromat bei nicht zu schnellem Herauskommen der Kristallchen noch mehr. Bariumchlorid reichert weniger stark an als das Bromid, Bariumkarbonat reichert etwas ab. Entsprechende Versuche, die wir mit unseren von Folgeprodukten gereinigten aktiven Bariumpräparaten gemacht haben, verliefen ausnahmslos negativ: *Die Aktivität blieb gleichmäßig auf alle Bariumfraktionen verteilt*, wenigstens soweit wir dies innerhalb der nicht ganz geringen Versuchsfehlermöglichkeiten angeben können. Es wurden dann ein paar Fraktionierungsversuche mit dem Radiumisotop ThX und mit dem Radiumisotop $MsTh_1$ gemacht. Sie verliefen genau so, wie man aus allen früheren Erfahrungen mit dem Radium erwarten sollte. Es wurde dann die „Indikatorenmethode" auf ein Gemisch des gereinigten langlebigen „Ra IV" mit reinem, radiumfreien $MsTh_1$ angewandt: das Gemisch mit Bariumbromid als Trägersubstanz wurde fraktioniert kristallisiert. *Das $MsTh_1$ wurde angereichert, das „Ra IV" nicht*, sondern seine Aktivität blieb bei gleichem Bariumgehalt der Fraktionen wieder gleich. Wir kommen zu dem Schluß: Unsere „Radiumisotope" haben die Eigenschaften des Bariums; als Chemiker müßten wir eigentlich sagen, bei den neuen Körpern handelt es sich nicht um Radium, sondern um Barium; denn andere Elemente als Radium oder Barium kommen nicht in Frage.

Schließlich haben wir auch einen Indikatorversuch mit unserem rein abgeschiedenen „Ac II" (H.Z. rund 2,5 Stunden) und dem reinen Actiniumisotop $MsTh_2$ gemacht. Wenn unsere „Ra-Isotope" kein Radium sind, dann sind die „Ac-Isotope" auch kein Actinium, sondern sollten Lanthan sein. Nach dem Vorgehen von Mme Curie[1] haben wir eine Fraktionierung von Lanthanoxalat, das die beiden aktiven Substanzen enthielt, aus salpetersaurer Lösung vorgenommen. Das $MsTh_2$ fand sich, wie von Mme Curie angegeben, in den Endfraktionen stark angereichert. Bei unserem „Ac II" war von einer Anreicherung am Ende nichts zu merken. In Übereinstimmung mit Curie und Savitch[2] über ihren allerdings nicht einheitlichen 3,5-Stunden-Körper finden wir also, daß das aus unserem aktiven Erdalkalimetall durch β-Strahlenemission entstehende Erdmetall kein Actinium ist. Den von Curie und Savitch angegebenen Befund, daß sie die Aktivität im Lanthan anreicherten, der also gegen eine Gleichheit mit Lanthan spricht, wollen wir noch genauer experimentell prüfen, da bei dem dort vorliegendem Gemisch eine Anreicherung vorgetäuscht sein könnte.

[1] Mme Pierre Curie, J. Chim. physique etc. 27, 1 (1930).
[2] I. Curie u. P. Savitch, C. r. Acad. Sci. Paris 206, 1643 (1938).

Ob die aus den „Ac-La-Präparaten" entstehenden, als „Thor" bezeichneten Endglieder unserer Reihen sich als Cer herausstellen, wurde noch nicht geprüft.

Was die „Trans-Urane" anbelangt, so sind diese Elemente ihren niedrigeren Homologen Rhenium, Osmium, Iridium, Platin zwar chemisch verwandt, mit ihnen aber nicht gleich. Ob sie etwa mit den noch niedrigeren Homologen Masurium, Ruthenium, Rhodium, Palladium chemisch gleich sind, wurde noch nicht geprüft. Daran konnte man früher ja nicht denken. Die Summe der Massenzahlen Ba + Ma, also z. B. 138 + 101, ergibt 239!

Als Chemiker müßten wir aus den kurz dargelegten Versuchen das oben gebrachte Schema eigentlich umbenennen und statt Ra, Ac, Th die Symbole Ba, La, Ce einsetzen. Als der Physik in gewisser Weise nahestehende „Kernchemiker" können wir uns zu diesem, allen bisherigen Erfahrungen der Kernphysik widersprechenden, Sprung noch nicht entschließen. Es könnten doch noch vielleicht eine Reihe seltsamer Zufälle unsere Ergebnisse vorgetäuscht haben.

Es ist beabsichtigt, weitere Indikatorenversuche mit den neuen Umwandlungsprodukten durchzuführen. Insbesondere soll auch eine gemeinsame Fraktionierung der aus Thor durch Bestrahlen mit schnellen Neutronen entstehenden, von Meitner, Strassmann und Hahn untersuchten Radiumisotope mit unseren aus dem Uran entstandenen Erdalkalimetallen versucht werden. An Stellen, denen starke künstliche Strahlenquellen zur Verfügung stehen, könnte dies allerdings wesentlich leichter geschehen.

Zum Schlusse danken wir Frl. Cl. Lieber und Frl. I. Bohne für ihre wirksame Hilfe bei den sehr zahlreichen Fällungen und Messungen.

Die Naturwissenschaften Heft 1. 6. 1. 1939

Fig. 19. Last three columns of the first historical publication by *Otto Hahn* and *Fritz Strassmann* [105] where nuclear fission is still announced hesitatingly; it was submitted to "Naturwissenschaften" on December 22, 1938, and appeared on January 6, 1939. The figures not belonging to this part of the text are taken out and the layout is slightly modified. Emphases by the author. The "vorerst" (earlier in the text, see end of Sect. 2.1) and the paragraph "Was die ... ergibt 239!" were added by *Hahn* on December 27, 1938, upon correction of the proofs [139]; in the paragraph "Als Chemiker ... vorgetäuscht haben" the expression "Gesetze" ("laws") was replaced by "Erfahrungen" ("experiences"), since (natural) laws were not encountered.

letter is depicted in Figure 18. *Hahn* mentions that they want to check whether the "actinium" isotopes growing from "radium" behave like lanthanum.

When the letter is written this experiment[132] is already being carried out. The 40-h "actinium IV" is obtained from the long-lived "radium IV", which is still present in the samples of December 17, and is mixed with natural actinium-228 and lanthanum carrier. Upon fractionation of lanthanum oxalate in nitric acid solution natural actinium, as is expected, becomes strongly enriched in the tail fraction whereas "actinium IV" from uranium is distributed uniformly: it is lanthanum.

All these results are presented in the last three columns of *Hahn* and *Strassmann*'s first historical publication;[105] they are depicted in Figure 19. The authors still hesitate in the often quoted passage "Als Chemiker ... als Kernchemiker"[*] to replace radium, actinium, and thorium by the elements barium, lanthanum, and cerium. The results about these fission products, however, are surprisingly good; comparing the decay chains in Figure 11 with today's situation, Figure 20, one notices that everything was determined correctly; only chain II later had to be divided into two similar chains. Soon it is realized in Berlin that the barium activities emerge from short-lived cesium and xenon precursors.

It is probably quite unique that a result of such significance was presented so indirectly and with that much understatement. This may explain why some of the later publications by others sound as if *Hahn* and *Strassmann* had not really noticed what they had found. Also recently it is argued[134] that it was only after *Lise Meitner*'s positive comment that *Hahn* was encouraged to formulate more explicitly the breakup into two nuclei. However, already in his letter of December 19 (Figure 18) he speaks of "Zerplatzen".

The peculiar presentation of the discovery of nuclear fission can, however, be accounted for by the hurry in which this manuscript[105] was written. As *Hahn* explains later,[135] he starts with an almost finished text about the radium isotopes, a more detailed publication of what was reported previously[104] in a note. The results of the indicator experiments are added at the end. The mention of "barium" in the title is considered instead of the initially chosen "radium", but then the whole manuscript would have to have been rewritten; the choice of "alkaline earth metals" is a way

[*] "As chemists ... as nuclear chemists".

out.[135] There is no time for major modifications because on December 21 all the personnel go on a 2-week Christmas vacation; in view of the competition with the Paris group it seems to be risky to wait this long. The evidence for barium instead of radium is written down on December 21–22 and the manuscript is picked up[99] by *Rosbaud* on the evening of the 22nd for publication in "Naturwissenschaften". The hurry does not allow for a careful checking or for detailed arguments. Thus, strange inconsistencies remained unnoticed: The printed text says that the indicator experiments were carried out with "langlebigen RaIV"[*] and with "AcII (H. Z. rund 2,5 Stunden)",[**] as one can read in Figure 19; what was used in fact was 86-min "Radium III" (as is obvious from the protocol, Figures 15 through 17) and[132] 40-h "Actinium IV". This inconsistency is never commented on later.

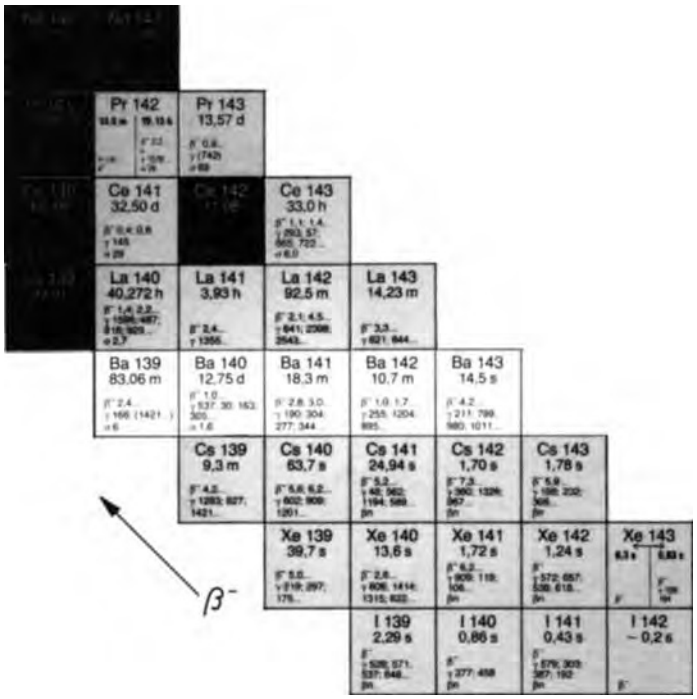

Fig. 20. The historical barium–lanthanum decay chains and the respective precursor nuclides today [133]. "Ra III" is Ba-139 and "Ra-Ac IV" are Ba-La-140, "Ra-Ac-II" later turned out to be complex, namely Ba-La-141 mixed with Ba-La-142; the presence of a very short-lived "Ra I" was also realized correctly. The β^--decay proceeds diagonally from the lower right to the upper left with constant mass number; stable nuclides are shown in black.

On December 21 *Hahn* informs *Lise Meitner* about his intention to publish quickly and writes that he is sending a copy of the manuscript to her.[136] He submits the paper without waiting for *Lise Meitner*'s comment on his letter of December 19 with the unexpected results. He receives her reply[137] on December 23;[138] she writes that the assumption of such a drastic breakup appears difficult for her to understand but that in nuclear physics there have been so many surprises that one cannot really call anything impossible. During the many years of collaboration *Lise Meitner* became acquainted with the accuracy of radiochemical methods in such a classic system like radium–barium; therefore, she is more inclined to give up nuclear-physics dogma rather than to question the results.[34] She also asks for the transuranic elements which may have caused *Hahn* on the same day to formulate a short paragraph "Was die ... ergibt 239!"[*] when modifying[99] the manuscript somewhat; upon correction on December 27 this paragraph is added to the text.[139] There he indicates, Figure 19, that the transuranic elements might be lighter rather than heavier homologues of rhenium and the platinum metals, because the sum of the mass numbers of barium and masurium is 239, the initial mass. Thus, a breakup into two large nuclei rather than a breakup into many nuclei is clearly referred to here. *Hahn* realizes,[139] however, that the argument is problematic, since not the sum of masses but the sum of the nuclear charges instead is of importance: krypton, element 36, is the complementary fragment of barium, element 56, rather than "masurium", element 43. The suspicion, however, that the transuranic elements might in fact be lighter homologues, for example element 43 instead of eka-rhenium, is correct.

The decay curves of the indicator experiment of December 17 are presented in the second historical publication by *Otto Hahn* and *Fritz Strassmann*,[140] which is submitted on January 28, 1939. This time the title clearly indicates the main theme: "Nachweis der Entstehung aktiver Bariumisotope aus Uran und Thorium durch Neutronenbestrahlung."[**] Chemistry and data are described and discussed in detail for the correct isotopes. In part A of Figure 21 the radioactivity of the three barium bromide fractions is shown to decrease first, followed by an increase towards plateaus of different height; curve I depicts the data from the protocol, Figure 16. Part B indicates how this increase of actinium-228 in the radium indicator radium-228 is corrected for. After subtracting this contribution the resulting decrease is shown in part C: The data points for the three fractions fall on one single decay curve for 86-min barium III. The reason why *Hahn* is not completely satisfied with the curves, as he mentioned in the note book—Figure 17—, is obvious: the last data points for fractions I and III in part C are clearly above the decay curve.

The contents, however, of this publication are even more profound: "The experiments described in *Hahn* and *Strassmann*'s "second" paper rank among the most careful and unambiguous ever carried out in radiochemistry."[141] *Hahn* and *Strassmann* now demonstrate the whole range of their radiochemical virtuosity; between January 4, when work is resumed at the Kaiser-Wilhelm-Institut,[142] and the formulation of this second manuscript a wealth of results is obtained. The fractionations are repeated with other activities and other barium salts: 86-min barium III is mixed with natural thorium X, 3.7-d radium-224, and fractionated as chromate; this works extremely well, since natural radium is enriched in the first fraction by a factor 19.5 with respect to

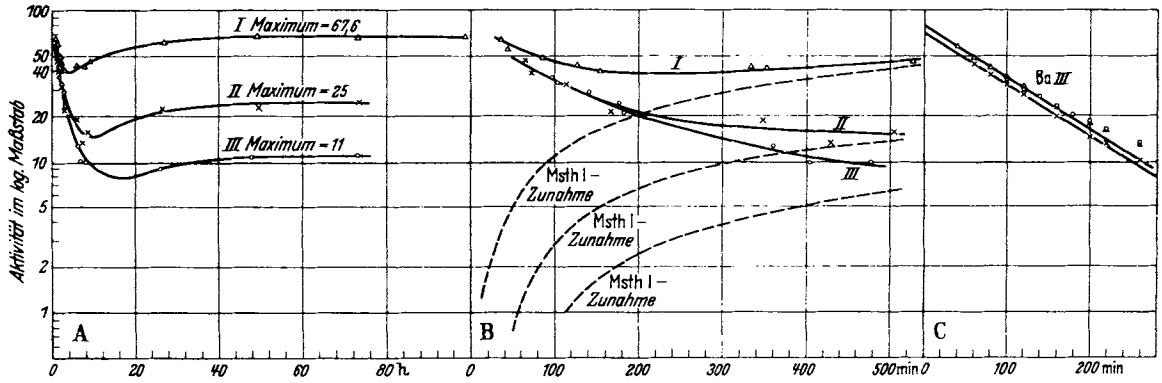

Fig. 21. Decay curves of the radioactivity in the three barium bromide fractions I,II,III from the indicator experiment barium III–mesothorium 1 of December 17, 1938; they were published in the second historical paper by *Otto Hahn* and *Fritz Strassmann* [140] on January 28, 1939. The count rate is displayed logarithmically as a function of time. The raw data are depicted in part A, compare the protocol of fraction 1 in Figure 16. The initial decrease is followed by an increase until radioactive equilibrium is established between the indicator mesothorium 1, 5.8-y radium-228, and its decay product mesothorium 2, 6.1-h actinium-228, in this section the decay curves differ appreciably, because the radium indicator is enriched in the order fraction I > II > III. Part B shows, how this growth is subtracted. Then, part C results with three practically identical decay curves for the initial portion, the barium III, 86-min barium-139. In contrast to natural radium, its activity is distributed equally among the three fractions. The conclusion shown in Figure 17 is based on these curves.

the second whereas the barium activities remain unchanged. The same procedure is performed for long-lived barium IV and radium-224. Finally, for barium IV a cyclic experiment is performed, namely a successive preparation of barium compounds: chloride, succinate, nitrate, carbonate, again chloride, iron(III) mannite, and again chloride; the activity of equal amounts of barium is again constant for all samples. Joy in experimenting and not—as is alleged[134]—lack of certainty is the likely reason for these variations. This is reflected in *Lise Meitner*'s comment:[143] "Euere Versuche stellen eine wunderbar geschlossene Beweiskette dar und es ist fabelhaft, was Ihr in diesen kurzen Wochen alles gemacht habt."[*]

The 15-min and 4-h "radium" from thorium, Figure 7, are also identified as barium by fractionation as barium chromate using radium-224 as indicator; thus thorium fissions too.[140] At last the "radium" decay-chains emerging from thorium are interpreted correctly. The right mass number 139 is assigned to barium III from uranium, for barium IV the mass number 140 is assumed. It is still left open whether the barium isotopes from uranium and thorium are identical, even though the half-lives are quite similar.

The main focus is, however, on the search for complementary fragments of uranium in the vicinity of krypton[140] which, via β^--decay, might turn into rubidium, strontium, and yttrium; this important aspect is also underlined by *Lise Meitner* and *Otto Robert Frisch*,[144] of which *Hahn* is informed by a preprint when the corresponding radiochemical experiments have just started.[145] By precipitation of the nicely crystallizing strontium nitrate using fuming nitric acid, strontium is isolated, from which yttrium is separated; both are active. A radioactive noble gas is found which decays into an alkaline metal that is active as well; it is temporarily left open whether the two are krypton and rubidium or xenon and cesium. When uranium breaks into two fragments of equal size palladium, element 46, should be formed; however, neither palladium nor the neighboring element silver are found among the fission products. For the first time the strange asymmetry of uranium fission, namely the breakup into a lighter and a heavier fragment, is thus apparent—a fact which will raise questions for both experimentalists and theorists for years to come. Only later[146] are products of symmetric fission into fragments of equal size detected after irradiation with energetic neutrons.

Naturally, the question as to what to think of the earlier transuranic elements is also discussed. In the course of the intensifying correspondence between *Hahn* and *Meitner*[97, 98] this problem is raised again and again with changing points of view—and not without some ill feeling between the two. For *Lise Meitner* this point is especially important,[134] because if all the transuranic elements were in fact fission products her work during the last years would be lost without her having the opportunity to participate in a discovery of even greater significance. After additional chemical experiments and some reflection, the suspicion[105] that the transuranic elements are lighter homologues of rhenium and the platinum elements is dismissed for the time being; it is expressed instead that the transuranic elements continue to exist.[140] We will come back to this later.

3. Confirmation of Nuclear Fission

3.1. Physical Experiments and Theoretical Explanations

Through letters and a copy of the manuscript *Lise Meitner* and *Otto Robert Frisch* know what has happened; the scientists at the institute in Berlin, however, are informed only[13, 118] on returning from their Christmas vacation at the beginning of January 1939 when the "first" publication appears. *Lise Meitner* meets *Otto Robert Frisch* at Christmas 1938 in Kungälv on the western shore of Sweden.[34, 147] When walking together out in the snow they come upon a very simple explanation[144] of this unexpected nuclear reaction. The separation of large fragments from heavy nuclei should not be viewed as a quantum-mechanical tunnel process;[12] another concept[148] which describes nuclei as liquid

[*] "Your experiments are a beautifully consistent series of proofs and it is marvellous how much you could achieve during these few weeks".

drops has to be applied. Nuclei, too, have a surface tension which protects them from disintegrating due to the repulsive electrical forces between the protons. For the uranium nucleus, however, this protection has almost vanished. Thus, after capture of a neutron, such a nucleus first starts to vibrate strongly, then elongates, and finally divides into two nuclei. These two fragments repel each other electrostatically with a kinetic energy of about 200 MeV, as can be estimated from the nuclear radii and charges. This energy is indeed available, since two nuclei of medium size are bound stronger than uranium just by this amount. Thus, energetically this process is possible; due to its similarity to the fission of cells they call it "fission",[144] after a suggestion by the biochemist *W. A. Arnold*.[147] *Meitner* and *Frisch*[144] express their ideas in a publication whose essential paragraph is depicted in Figure 22.

Disintegration of Uranium by Neutrons: a New Type of Nuclear Reaction

It seems therefore possible that the uranium nucleus has only small stability of form, and may, after neutron capture, divide itself into two nuclei of roughly equal size (the precise ratio of sizes depending on finer structural features and perhaps partly on chance). These two nuclei will repel each other and should gain a total kinetic energy of c. 200 Mev., as calculated from nuclear radius and charge. This amount of energy may actually be expected to be available from the difference in packing fraction between uranium and the elements in the middle of the periodic system. The whole 'fission' process can thus be described in an essentially classical way, without having to consider quantum-mechanical 'tunnel effects', which would actually be extremely small, on account of the large masses involved.

Fig. 22. Interpretation of nuclear fission in the framework of the liquid drop model of atomic nuclei by *Lise Meitner* and *Otto Robert Frisch* according to their ideas developed in Kungälv. Part of the publication submitted on January 16, 1939 [144].

In addition, krypton is thought[144] to be the complementary fragment and the activities previously ascribed to the transuranic elements are rather considered to be related with lighter homologues of rhenium and the platinum metals; this would make the isomeric chains superfluous. The similarity is realized between the "radium-actinium" chains from thorium, Figure 7, and the activities identified as barium-lanthanum, with the conclusion that thorium is fissile, too. At the end they discuss the 24-min uranium; its existence, they argue, demonstrates that not all vibrations of the uranium nucleus would lead to fission.[144]

Back in Copenhagen, *Frisch* informs *Bohr* in detail on January 3, 1939 and on the next day *Hahn* in a brief letter.[149] *Bohr*'s reaction is drastic:[147] "Oh what fools we have been! We ought to have seen that before". Presumably he had not been taking the liquid-drop model that seriously[150] because it was initially developed to describe static nuclear properties like the nuclear masses without paying much attention to its dynamic aspects. On the telephone, *Meitner* and *Frisch* then prepare[147] a note which is drafted by *Frisch* on January 6 and modified after a discussion with *Bohr*; on January 7, with *Bohr* already at the railway station ready to depart for the U.S.A. by train and ship, *Frisch* gives him the first two pages of the note.[151] *Bohr* promises not to release anything before the note is published.[150]

Meanwhile *Hahn* and *Strassmann*'s "first" publication has appeared. *Frisch* discusses the new phenomenon with *G. Placzek* who is very sceptical about it.[151] This motivates[147] *Frisch*, who at first had not intended to perform an experiment, to think of a possibility of physically detecting the fast fission fragments. In a gas they should create an unusually large number of ions, by far more than α-particles for example; this should yield extraordinarily large signals. The corresponding experiment is very simple[147] taking only two days, January 13 and 14, 1939. In Figure 23 the important part of the protocol[152] is shown, in Figure 24 its author. The note about the interpretation of fission[144] is not submitted until *Frisch*, on January 16, is able to report on his experiment also:[154] "By means of a uranium-lined ionization chamber, connected to a linear amplifier, I have succeeded in demonstrating the occurrence of such bursts of ionization". Using an oscilloscope he observes large pulses above the background of α-particles from uranium which he concludes are caused by nuclei of at least a mass number of 70. Thorium produces the same effect.

Frisch does not show a picture of the fission-fragment pulses; the picture in Figure 25 is taken during the first detection[155, 157, 158] of nuclear fission on the American continent in New York on January 25, 1939. The most direct way of identifying the fission fragments escaping in opposite directions is to use a cloud chamber. One of the first two of such exposures[159, 160] is shown in Figure 26.

The notes by *Meitner* and *Frisch* "Disintegration of Uranium by Neutrons: a New Type of Nuclear Reaction"[144] and by *Frisch* "Physical Evidence for the Division of Heavy Nuclei under Neutron Bombardment"[154] do not appear until February 11 and 18, 1939, respectively; they had not insisted on rapid publishing.[34] Meanwhile, however, the phenomenon of nuclear fission has become known through *Hahn* and *Strassmann*'s first publication.[105] The first ones to react in Berlin are the theoreticians;[66, 111] they develop ideas similar to the ones of *Meitner* and *Frisch* discussing[161] the energetics of the process and reasons for the formation of just barium.

Within a short time the huge pulses of fission fragments are observed at several places, in New York,[155] Berkeley,[162] Baltimore,[163] Washington,[164] and Vienna;[165] in Berlin the experimental physicists react somewhat later.[166] Two quite different groups of fragment energies are found, which correspond to the light and heavy fragment; their mean kinetic energies are already determined surprisingly well by *W. Jentschke* and *F. Prankl*[165] to be 61 and 98 MeV, resulting in a kinetic energy release of altogether about 160 MeV.

F. Joliot[167] in Paris chooses another way for a physical detection of the fission process; he had learned early of the

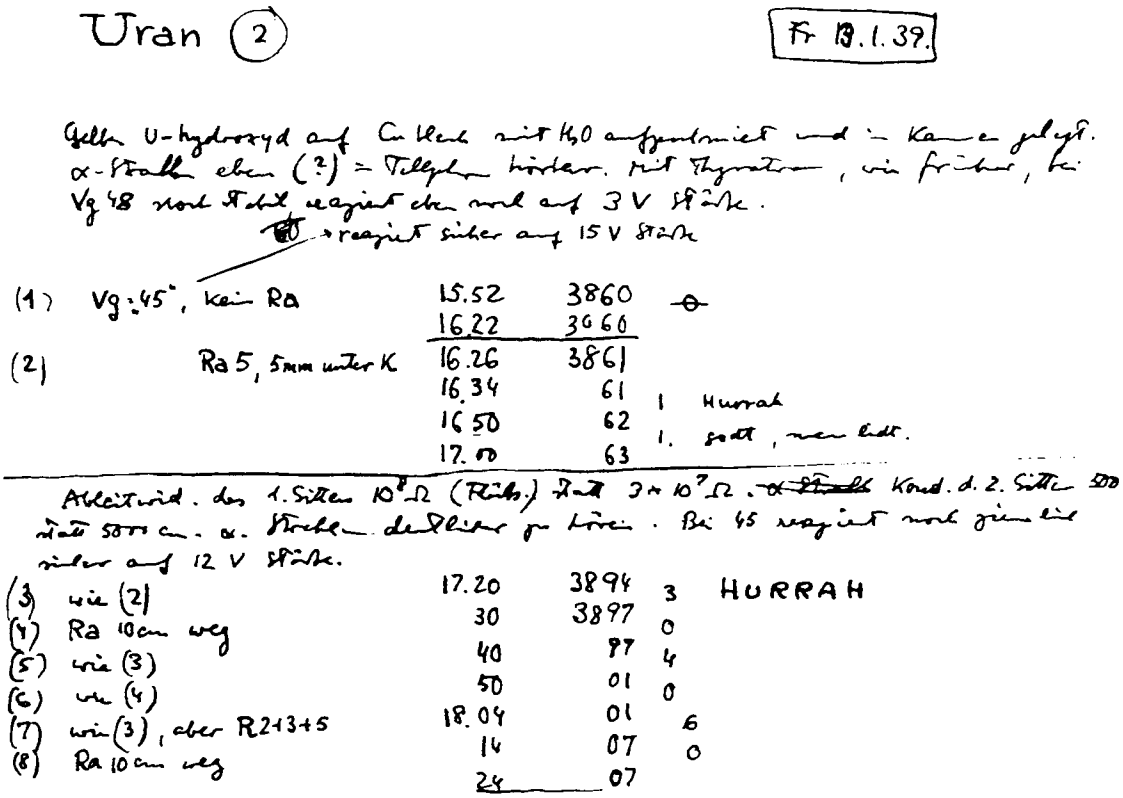

Fig. 23. The first physical detection of nuclear fission by *Otto Robert Frisch* in Copenhagen on January 13, 1939; upper half of the protocol sheet "Uran 2" [152]. A uranium sample is installed inside a hydrogen-filled ionization chamber of 1 cm depth and 3 cm diameter and is irradiated with neutrons from a radium-beryllium source, 100 mg Ra. The electrical pulses are transmitted by a thyratron, whose threshold voltage rejects pulses of the natural α-particles and only accepts larger pulses. The upper line of the text says: "Gelbes U-hydroxid auf Cublech mit H_2O aufgeschmiert und in Kammer gelegt". ("Yellow U-hydroxide smeared on Cu-plate with H_2O and put into the chamber".) The subsequent lines at the top and in the middle contain information about the eletronics used. Readings are alternately taken without (1,4,6,8) and with the neutron source "Ra" (2,3,5,7). The numbers of the third column represent the time, those of the fourth column the meter rating, and those of the fifth column the number of registered pulses. The first fission event between 16:34 and 16:50 h is welcomed with "Hurrah". Pulses only appear with the neutron source installed.

Fig. 24. *Otto Robert Frisch* (1904–1975) around the time of the "Frisch-experiment" [153].

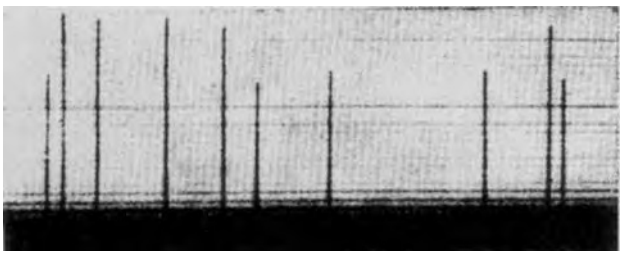

Fig. 25. Oscilloscope picture of the strongly ionizing fission fragments obtained with an ionization chamber during the irradiation of uranium with neutrons; a background of natural α-rays from uranium-238 can be seen [156]. The picture was taken upon the first observation of nuclear fission on the American continent by *H. L. Anderson, E. T. Booth, J. R. Dunning, E. Fermi, G. N. Glasoe*, and *F. G. Slack* in New York on January 25, 1939 [155].

Berlin results through a letter from *O. R. Frisch* addressed to his friend *H. von Halban* who works with *Joliot*; it is not possible to establish[168,169] exactly when this happened. For his experiment on January 26, 1939[170] *Joliot* makes use of the pronounced recoil of fission fragments caused by their large kinetic energy. Uranium or thorium is spread onto the surface of a hollow cyclinder which contains a neutron source. Within 3 mm distance from the surface a bakelite cylinder is mounted concentrically; on the latter, radioactive products are found after irradiation which could have reached there only by recoil. *Joliot*'s work "Preuve expérimentale de la rupture explosive des noyaux d'uranium et de thorium sous l'action des neutrons"[167][*] is reported to the

[*] "Experimental proof of the explosive rupture of uranium and thorium nuclei caused by neutrons."

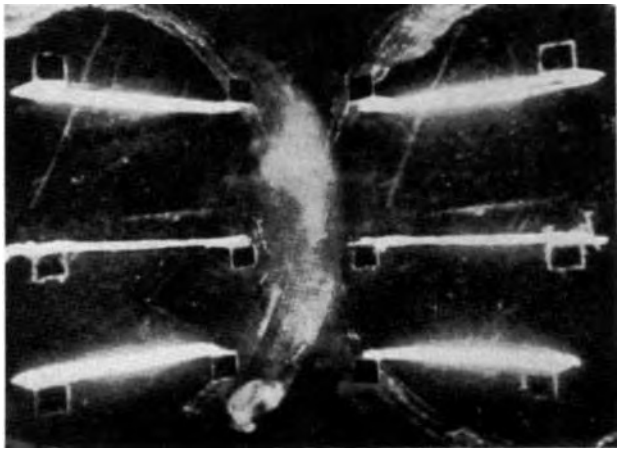

Fig. 26. One of the first photographs of the detection of nuclear fission using a cloud chamber with three pairs of fission fragments flying in opposite directions. The stereo picture was taken at Berkeley [159]; it consists of two halves, left and right.

French Academy of Sciences on January 30, 1939, even before *Meitner* and *Frisch*'s publications[144, 154] appear. The experiment by *E. McMillan*[171] at Berkeley is quite similar; he already determines the penetration depth of fission fragments in aluminum foils and cigarette paper which corresponds to 2.2 cm if converted to air at normal pressure. This is less than for α-particles even though the kinetic energy is far larger; fission fragments carry a much higher charge and therefore interact with matter more strongly.

In the U.S.A. the situation is dramatic.[150, 172] On the journey *Bohr* is accompanied by *L. Rosenfeld*, a theoretical physicist with whom he has intense discussions. He does not tell him, however, of the obligation to be silent. Thus, on January 16 the physicists at Princeton, *Rosenfeld*'s first stop, learn of the big news.[173] When on January 20 *Bohr* still does not know whether *Frisch*'s interpretation[144] has been accepted—he has no idea of *Frisch*'s intermittent experiments—and after having seen *Hahn* and *Strassmann*'s publication at Princeton he submits a note,[174] which describes the fission process in the framework of the liquid drop model. Not until January 22 does he receive news from *Frisch*. *Bohr* departs to attend a theory conference in Washington; on January 25 he stops by in New York and talks to *H. L. Anderson*, a student of *Fermi*, who immediately starts preparing the experiment furnishing Figure 25. On January 26 the conference is opened with *Bohr* and *Fermi* reporting the spectacular news, the main event of the conference.[175] A number of groups immediately start to carry out experiments similar to the one by *Frisch* and thus, on January 28 the conference is closed with positive results being presented;[155, 163, 164] the local group can even demonstrate to *Bohr* and *Fermi* the fission phenomenon.[158, 164] Newspapers report on it.[172, 176] *Bohr* has some trouble defending the priority of *Meitner* and *Frisch* with regard to the physical results.

Literally a flood of studies on fission and fission products is set in motion. The rare uranium isotope 235, with its 0.72% abundance only discovered a few years before,[178] is recognized by *Bohr*[177] to be that component of uranium which is fissile with thermal neutrons. A quantitative formulation[111, 179, 180] of the concept of a fissioning liquid drop is developed; it forms the basis of *Bohr* and *Wheeler*'s[181] pioneering theoretical study, which appears at the beginning of the second world war. As first step towards a chain reaction the neutrons are found that are being released in the course of fission.[182, 183] *Flügge*[184] is the first to clearly announce the feasibility of an energy producing "uranium machine" and of a nuclear explosion. About one year after the discovery, *L. A. Turner*[44] completes the first review article which is based on close to one hundred publications. Almost all important aspects are already mentioned. As early as December 2, 1942, *Enrico Fermi* and his team[185] succeed in Chicago in carrying out the first chain reaction. Only much later is the public informed about this result because very soon almost everything that deals with fission is kept secret.

Not the slightest doubt is raised against the phenomenon, yet there is some trouble for the discoverers which is expressed in the letters between *Hahn* and *Meitner*.[97, 98] A number of publications—for example *Bohr*'s first notes[174, 177]—sound as if it was not *Hahn* and *Strassmann* who had realized the significance of the process but only *Meitner* and *Frisch*. Elsewhere,[182] this realization is even ascribed to *Joliot* as well as *Meitner* and *Frisch* without even mentioning *Hahn* and *Strassmann*; interestingly enough, the respective publication is immediately followed by another one[186] which starts with the names of *Hahn* and *Strassmann*. At times[167, 187] the story is told in such a way as if *Hahn* and *Strassmann* had simply confirmed results by *I. Curie* and *Savitch*; in one case, upon intervention by *Hahn*, a correction[188] is made. Quite likely the peculiar style of *Hahn* and *Strassmann*'s "first" publication has to some extent provoked this confusion: Upon taking a brief look at the article, hardly anybody would anticipate the discovery of nuclear fission hiding behind the "alkaline earth elements"[105] mentioned in the title—Figure 19. Even a reader who has become more inquisitive will, after reading a few paragraphs, no doubt put aside the detailed radiochemical report about radium from uranium. And those who finally make their way through and even realize the significance of the chemical fractionations will again be made helpless by the famous ambivalent paragraph "Als Chemiker—als Kernchemiker" which *Strassmann* would have formulated not as undecidedly.[48] In contrast, the subsequent physical articles[144, 154, 167] with their imaginative titles are much more readable. Today, however, some reader may discover a particular attraction just in the style of the "first" publication.

3.2. Missed Opportunities

Before moving on to some of the later results we want to look back wondering why nuclear fission had not been discovered earlier, since it is so simple to observe fission fragments with an ionization chamber. Experiments similar to the one by *Frisch*[154] are at that time being performed in a number of laboratories. They are designed to search for energetic α-particles from an (n, α)-process [cf. Reaction (8, 9)], which may occur when uranium or thorium are irradiated with neutrons, and thus to corroborate the production of "radium" activities from uranium or thorium. Such experiments are being carried out at Berkeley,[189] Berlin,[82] Cambridge,[190] Heidelberg,[191] Rome,[38, 192] Zürich,[81] and

presumably elsewhere, too. To this purpose the disturbing background of natural α-particles, visible in Figure 25, is suppressed by absorber foils and not by electronics, as in *Frisch*'s experiment; in this way, however, the fission fragments are suppressed, too. As soon as fission is discovered, the foils have only to be removed in order to see the fragments. "But who can say whether even *Fermi* would have recognized them for what they were if he had seen them?"[192] Although perceived at times, they are ignored as being electrical noise;[190] this is *von Droste*'s opinion in Berlin[118] and presumably also that of researchers in Zürich, since an announced[81] detailed article on prompt α-particles is never published.

P. Abelson, a graduate student at Berkeley, has also come very close. Using a strong sample he measures the energies of the characteristic X-rays of 66-h eka-iridium—Figure 6—in a crystal spectrometer; while the exposure is taken, *Abelson*[193] reads the news from Berlin in a newspaper. He immediately modifies the experiment to measure the absorption of the radiation, which works faster, and finds the characteristic K-X-rays of iodine emitted after the β^--decay of its mother substance 66-h eka-iridium. The latter is thus identified as an isotope of tellurium, as is reported in a note[194] of nine lines length; later *Abelson*[195] presents details. Nuclear fission is thus again corroborated by detection of a fission product.

The Berlin group, too, could have arrived at fission as early as 1936 had only some night-time playful chemistry by *Fritz Strassmann*[196] been taken more seriously. In order to find a fast chemical separation for 16-min eka-rhenium he attempts to coprecipitate it with barium sulfate. Potassium permanganate gets incorporated into crystals of barium sulfate. The homologous eka-rhenium might behave the same way if present in a modification corresponding to perrhenate. The precipitate is active; however, the activities are not those of the 16-min species. *Strassmann* has to admit to *Lise Meitner* that adsorption effects cannot be ruled out. In turn, she rejects the results, in a friendly manner but quite firmly.[196]

It is difficult to judge from *I. Curie*'s short remark[91] how close she came to seeing the lighter elements. In the fall of 1939 she tells[34, 151] *G. von Hevesy* that at times she thinks the whole periodic table is in the irradiated uranium samples. In spite of intensive discussions during seminars no one finds a solution to the puzzle, as a participant recalls.[197] Also in Berlin lighter elements are being considered but this idea is not pursued because of the seemingly insurmountable Coulomb barrier.[118]

In contrast to a recent suggestion,[43] element 43, the masurium of *Walter* and *Ida Noddack*,[21, 22] should not be considered as one of the missed opportunities. All isotopes of this element are short-lived having already decayed since the heavy elements were synthesized in the interior of stars. On the other hand, element 43 is continuously being produced on the Earth by the spontaneous nuclear fission of uranium, which we will discuss below. Its quantity, however, is minute. In order to detect this amount and thus to—unconsciously—observe fission the *Noddack*'s X-ray fluorescence spectroscopy would have had to be five orders of magnitude more sensitive than according to their own claim; there are no arguments in favor of this.[198]

3.3. Further Fission Products

What is left now of the uranium-transuranium decay chains of Figure 6 and what is the story behind the "transuranic elements"? It has just been mentioned that *Abelson*[194, 195] identifies the 66-h eka-iridium as a tellurium isotope and thus the daughter substance 2.5-h eka-platinum as iodine. His result is confirmed[199] by the same method, namely X-ray absorption, and by *Hahn* and *Strassmann*[200] who investigate in detail the chemical properties of this eka-iridium. In these experiments they find a second activity with a quite similar half-life which they correctly identify as molybdenum. They discuss how the 2.5-h iodine could have been taken for a platinum metal: The crystallization of ammonium hexachloroplatinate[63] was thought to be a selective reaction for platinum. The possibility that iodine would precipitate as the analogous ammonium hexaiodoplatinate was not taken into account since fission was not envisaged. In the platinum sulfide precipitate 2.5-h iodine appears, because it is formed from the coprecipitating 66-h tellurium. Additional experimental studies concerning the transuranic elements are not published, even though they were announced[200] by *Hahn* and *Strassmann*.

Instead of looking at individual activities of "transuranic elements", *Meitner* and *Frisch*[186] examine the complete mixture coprecipitated with platinum sulfide as a whole. To this purpose recoiling fission fragments emitted from irradiated uranium are collected in a water layer from where they are coprecipitated with platinum sulfide. The decay curve is compared with a precipitate of platinum sulfide which is directly isolated from irradiated uranium without exploiting the recoil effect. The two decay curves match perfectly. Therefore, the "transuranic elements" are fission products, which are the only species having such a high recoil energy. In the same way fission products of thorium are identified;[201] thus, similar products result from the fission of uranium and thorium. Using such recoil experiments, other authors[202, 203] reach similar conclusions.

In his autobiography[204] *Hahn* reflects, on the basis of comments by *Strassmann*,[205] on what might have simulated the other "transuranic elements". Later, this problem is also approached experimentally[206] with high-resolution γ-ray spectroscopy by examining precipitates of platinum sulfide and other transuranic fractions produced according to *Hahn, Meitner* and *Strassmann*. These components are found to be complex, too. One half of the historically most important activity, the 16-min eka-rhenium, consists of technetium-101, the remaining half is a mixture of molybdenum-101, antimony-130g, antimony-131, and tellurium-131g. The 55-min activity is dominated by iodine-134, with some tellurium-134 and tin-128, and the 5.5-h activity by ruthenium-105, with some antimony-129 and iodine-133. The 16-min activity precipitating with manganese dioxide, which was considered by *Fermi* et al. to be element 93, is also complex; mainly molybdenum-101 is precipitated, from which technetium-101 is formed.[207]

With respect to the 3.5-h activity of *I. Curie* and *Savitch* it is soon realized[44] that it is related to 3.5-h yttrium-92; its 3.6 MeV β^--radiation is much more energetic than that of natural protactinium-234m with 2.3 MeV. In addition, contributions are to be expected by 3.90-h lanthanum-141, 93-

min lanthanum-142, and, in the chemically unprocessed mixture, by 76-min krypton-87. Now it is understandable, with yttrium-92 as the main constituent, that the 3.5-h activity can be fractionated from lanthanum; thus, this finding turns out to be correct. Since *I. Curie* and *Savitch* isolate this activity directly from irradiated uranium, their lanthanoid fraction always contains yttrium-92. *Hahn* and *Strassmann*, on the other hand, do not obtain the lanthanoid elements directly but only as decay products of "radium"-barium; this way they exclude yttrium because its mother substance strontium is not contained in their barium fraction.

The fission products prove to be an extremely complicated mixture of elements with several isotopes each. They form long β^--decay chains, often branching out into different isomers. Some of them are depicted in Figure 20. During the subsequent years the small group at Berlin, which has been joined by *H. J. Born*, *H. Götte*, and *W. Seelmann-Eggebert*, is busy unravelling these chains, at least to the extent it is possible in a war-time situation that is becoming more and more difficult. These experiments are all published. As *Hahn* reports in his Nobel Prize lecture,[46] in the beginning of 1945 about 100 products of 25 elements have been found.[208] Around this time the corresponding American results are released which have been obtained by *Charles Coryell*[209] at "Met Lab" under superior conditions; they first appear in tabulated form,[210] later in more detail.[211] Here, 170 products of 37 elements are listed. Very few of the products observed in Berlin are not contained in these American tables; focusing on some of the unsettled cases, work is resumed by *Fritz Strassmann* and his students as soon as it is possible after the war.[212]

In Berlin, only the first steps[213] towards quantitative measurements of the abundance of individual fission products are made which would indicate into what kind of fragments the uranium nucleus tends to fission predominantly. For this aspect the American groups can already present a complete distribution as a function of the mass number.[210, 211] The mass distribution is chosen, because the mass number does not change during β^--decay; if one waits for β^--decay to reach the long-lived final members of the decay chains, the total yield of all members of a chain is summed up in quite a natural way. The element distribution, however, continuously changes with time due to β^--decay. The initial distribution just after the breakup of the uranium nucleus is more difficult to establish experimentally because—as can be seen from some examples in Figure 20—the fission products at the beginning of the decay chains are usually very short-lived. In order to establish the initial abundance of individual elements the yields of all the respective isotopes have to be determined and added. Data of this kind have only been obtained in more recent times. The abundance of elements formed by fission of uranium-235[214] is shown in Figure 27. The lighter and the heavier fragment from the asymmetric fission process can be seen with five elements each created predominantly, krypton to zirconium and tellurium to barium. *Hahn* and *Strassmann*'s barium isotopes are mainly formed indirectly via β^--decay of short-lived xenon and cesium nuclei, which are close to the center of the heavy fragment wing.

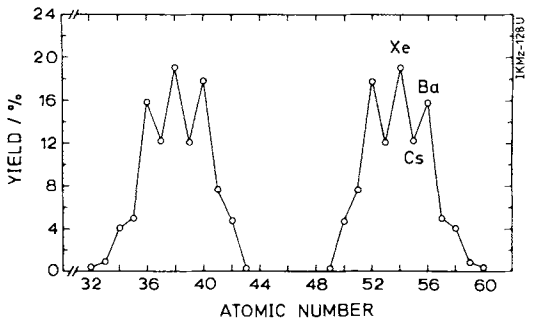

Fig. 27. Element distribution in the fission of uranium-235 by thermal neutrons: primary abundance in percent as a function of the atomic number. The asymmetry of fission into a smaller and a larger fragment is evident; xenon, cesium, and barium, key elements for the discovery, are located in the heavy branch. After [214].

4. Transuranic Elements Again

4.1. Element 93, Neptunium

We are left with one member of the decay chains of Figure 6, the 23-min uranium-239, which is chemically[63] verified to be uranium and whose assignment to mass number 239 is established physically[61] in uranium-238. As a β^--emitter it must decay into the isotope 239 of element 93. The detection of this decay product, however, proves to be very difficult. *E. McMillan*[171] takes a first decisive step. When measuring the range of fission products in cigarette paper he examines the thin uranium layer as well and notices two strong activities: one with a 23-min half-life, which he ascribes to uranium-239, and one with about a 2 d half-life, which is strong compared to the activities of fission products of similar half-life. Even the natural activity of uranium is negligible compared to this. This hint[171] causes a reader—was it *Hahn* himself?—at the Berlin institute to put a large exclamation mark at the edge of the publication which is still nicely visible today; the much superior means of the American competitors start to take effect.

Is this the sought after element 93, whose recoil energy is expected to be so small not to recoil out of the uranium target? Based on decay curves, *E. Segrè*[215] first draws the conclusion that the 2.3-d activity does not emerge from 23-min uranium-239; at this point he is misled[216] by its low β-energy. He then attempts to chemically identify the long-lived activity again assuming element 93 to have the properties of eka-rhenium. As one of the discoverers[217] of element 43 he already had experience with chemical studies in the 7th group of transition elements. *Segrè* finds, however, that the 2.3-d activity does not coprecipitate with rhenium sulfide but rather behaves like a lanthanoid element: it coprecipitates with lanthanum fluoride and oxalate, with potassium lanthanum sulfate and other typical precipitates and it can be separated from actinium by fractionation of lanthanum oxalate. Segrè[215] ascribes the 2.3-d activity to a lanthanoid fission product and concludes that 23-min uranium should decay into a long-lived element 93 which has not yet been found. Also other experiments[218] where element 93 was to be isolated with rhenium sulfide from highly enriched samples of 23-min uranium end with negative results.

After one year *E. McMillan* resumes his studies[171] applying a larger neutron flux which allows the use of a thinner uranium layer. Even then the 2.3-d activity remains inside uranium and can be completely separated from fission products this way. It is obtained with resonance neutrons just as well as the 23-min uranium-239. *P. Abelson*, who is now at Washington, observes that the 2.3-d activity does not always behave like a lanthanoid. The two start working together at Berkeley and within five days[193] they find the solution:[219] In a strongly oxidizing medium, bromate in strong acid, the 2.3-d activity does not coprecipitate with cerium fluoride; however, in a reducing medium, sulfite, it precipitates quantitatively. After oxidation the activity co-precipitates with sodium uranyl acetate, and after reduction it accompanies thorium iodate and peroxide. Properties typical of rhenium, like the sulfide precipitation, are not observed. Obviously, like uranium the finally discovered element 93 has two main oxidation states, four and six, the lower state being the more stable one, in contrast to uranium. *McMillan* and *Abelson*[219] presume a new series of related elements starting with uranium. Uranium is also the basis for the "astronomical" name of element 93: neptunium.

With these chemical results *McMillan* and *Abelson*[219] are able to prove that the 2.3-d activity is the daughter of 23-min uranium. This experiment is depicted in Figure 28. Every 20

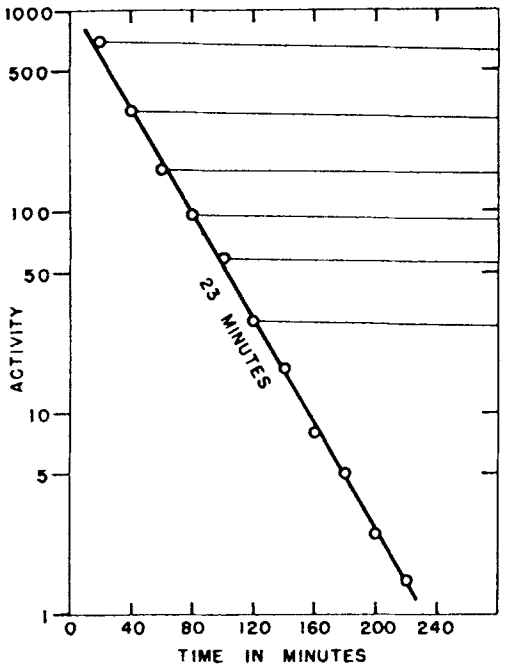

Fig. 28. Discovery of element 93, neptunium, by *E. McMillan* and *P. Abelson* at Berkeley [219]: Proof of the genetic relationship between the 23-min uranium-239 and its 2.3-d decay product. The initial count rates of the 2.3-d activity are measured in cerium fluoride precipitates obtained upon successive precipitations from the same solution of uranium-239. When depicted logarithmically as a function of time these count rates decrease with the half-life of uranium-239, 23 min. Thus, uranium-239 decays into the 2.3-d activity which is therefore identified as neptunium-239.

minutes cerium fluoride is precipitated from a reducing solution of the 23-min activity; thus, each time the 2.3-d activity continuously formed from 23-min uranium-239 is "milked" from its parent. The initial intensities of these samples decrease with a half-life of 23 minutes if displayed as a function of the time of precipitation, as is shown in Figure 28. According to the laws of radioactive decay, this proves that the 2.3-d activity arises from 23-min uranium and thus must be neptunium-239. Neptunium-239 has soft β^--rays of only 0.47 MeV energy. A decay product, element 94, is sought after but not found.[219]

In Berlin, following *McMillan*'s first publication,[171] one does not succeed in observing the 2.3-d activity, even in samples which have been more strongly irradiated[220] at the Copenhagen high voltage facility. The explanation is simple: the activity is not contained in a platinum sulfide precipitate; in the uranium fraction it is only weakly produced from 23-min uranium. In addition, the activity is difficult to detect due to the strong absorption of its low energy radiation. Therefore, in Berlin special enrichment procedures have to be developed for 23-min uranium. This is achieved by *K. Starke*[221, 222] based on a Szilard-Chalmers-separation.[223] This technique exploits the fact that atoms having become radioactive as a result of nuclear reactions may be transformed into a chemical state different from the one of the irradiated species. If uranium is irradiated as uranyl benzoyl acetonate, 23-min uranium-239 becomes partly converted into an inorganic species and can thus be concentrated from a large bulk of uranium. In strongly enriched uranium-239 samples of this kind *Starke*[224, 225] finds the 2.3-d activity even before the paper of *McMillan* and *Abelson*[219] arrives at Berlin[226] at the end of August 1940. Due to the war, however, *Starke*'s results are published later.[221, 222, 224, 225]

Hahn and *Strassmann* also start working on element 93; again they encounter some difficulties in finding the 2.3-d activity[227] and therefore construct a counter with a thin entrance window. They develop a chemical procedure to isolate element 93 directly from large amounts of uranium and perform a detailed study[228] of the chemistry of element 93. Properties already described[215, 219] are partly confirmed and new ones are added. They all point at a discontinuity in the periodic table: Element 93 has nothing in common with eka-rhenium.

4.2. Eka-Rhenium, Element 107

Now starts the era of nuclear chemical element syntheses. The periodic table extends more and more and takes a course different from the one originally expected: The series of actinoids is recognized, first by *Seaborg*.[229] It extends as far as lawrencium, 103, and then returns to the transition elements with element 104, presently reaching up to element 109.[230] Today's periodic table is shown in Figure 29.

Element 107 is placed below rhenium, and it takes almost four decades until this eka-rhenium is finally produced by *Gottfried Münzenberg, Peter Armbruster*, and the SHIP-group[231] at the heavy-ion accelerator UNILAC in Darmstadt by nuclear fusion of chromium-54 with bismuth-209 [Reaction (11)].

$$^{54}_{24}Cr + {}^{209}_{83}Bi \longrightarrow {}^{262}107 + {}^{1}_{0}n \qquad (11)$$

Its detection is again based on the genetic connection with decay products: The isotope 262 decays with 8.2 msec half-

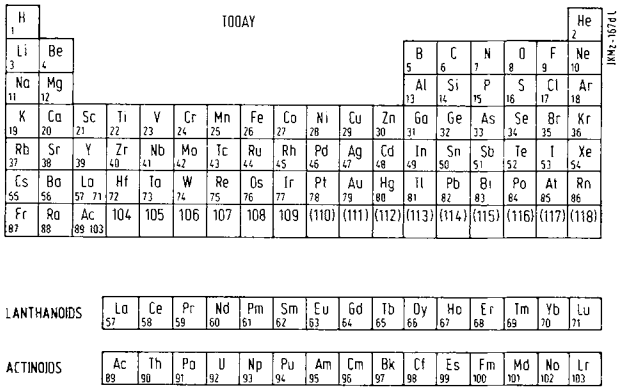

Fig. 29. The periodic table of the elements today. The atomic numbers of unknown elements are given in brackets.

life via α-emission into the known isotope 258 of element 105 and its well-known decay chain; an example for the decay chain of an individual atomic nucleus is depicted in Figure 30.

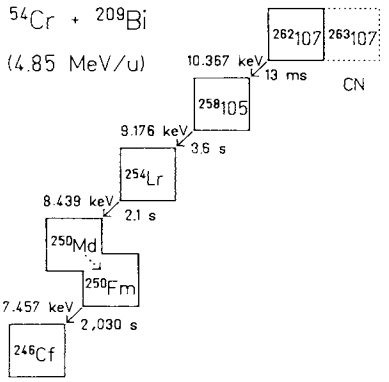

Fig. 30. Discovery of element 107, eka-rhenium, by the SHIP-group at Darmstadt [231]: one of five observed decay chains of a short-lived α-emitter which decays into the known nuclide 105–258 and its known decay products; the α-emitter therefore has to be assigned to the isotope 262 of element 107. This element 107 is produced by nuclear fusion of chromium-54, element 24, with bismuth-209, element 83.

Nothing is known as yet about the chemistry of eka-rhenium; thus, it is not clear whether the extrapolations of chemical properties will eventually be correct. Due to short half-lives and extremely low production rates, studies of this kind are not feasible for the time being. Chemical experiments with transactinoids have been performed up to element 105 and are described in review articles[232–234] and several more recent publications[236–238].

5. Nuclear Fission in Nature

The fission of uranium is a natural process; uranium already fissions spontaneously without an additional energy input. This spontaneous fission is discovered in 1940 by *G. N. Flerov* and *K. A. Petrzhak*,[239, 240] who use a large ionization chamber where about 10 g of uranium is spread to a thin layer. They observe about six fission events per hour and estimate the half-life of uranium-238 with respect to spontaneous fission to be in the range of 10^{16} to 10^{17} years,[239, 241] already the right order of magnitude. For the transuranic elements spontaneous fission becomes an important decay mechanism which in the end limits the periodic table.[230]

But also the chain reaction has occurred in nature. The possibility of a natural nuclear reactor is discussed early[184, 242] but is first dismissed with the argument that in such a case uranium deposits should not exist; later this question is raised again and it is realized[243] that a natural chain reaction is possible. A natural nuclear reactor is indeed discovered due to minute deviations of the uranium-235 concentration of some uranium delivered to France, namely[243] 0.7171% as compared to the usual value of 0.7202%. This deviation was caused by a uranium ore from Oklo, Gabon; at the respective mining site samples are found with uranium-235 depleted down to a concentration of 0.29%. About 1.8 billion years ago the reactor was operating for about 600 000 years and has released roughly 10 000 megawatt-years of energy, the amount delivered by a large power reactor within about three years; upon operation 4 tons of uranium-235 were consumed.[245, 246] It is interesting to note that the fission products formed have not migrated from the site during this long time interval.[245, 246]

6. Conclusion

The discovery of nuclear fission has given access to the energy hidden in atomic nuclei intensively discussed for several decades.[172] Not only was the discovery itself exciting but also the way in which it came about: The breakup of the uranium nucleus was not observed directly, but only some resulting secondary products. Looking back, however, this was probably the most straightforward path towards this discovery; there was no way to circumvent the barium in the Berlin beakers: "It was good solid chemistry that got things on the right track."[147] *Otto Hahn* and *Fritz Strassmann* and their predecessors had intended to pursue a different goal. This, however, does not make the discovery of nuclear fission a chance happening; they did not simply stumble on it, instead it was the fruit of many years of intensive work in radiochemical analysis. To think of chances may be more appropriate when imagining how strongly the events described here depend on minor fluctuations of the nuclear binding energy, which is, however, governed by subtle quantum mechanical effects. These fluctuations cause the asymmetry of the fission process with a heavy fragment just in the region that *Hahn* and *Strassmann* studied in their search for radium. On the other hand, such local fluctuations cause the β^--decay of neptunium-239 to be of an unusually low energy; for this reason, *Otto Hahn*, *Lise Meitner*, and *Fritz Strassmann* could not find element 93, even though it is formed from uranium with an abundance one order of magnitude greater than that of the strongest fission products. Thus, to *Hahn*'s disappointment,[247] whereas protactinium, the neighbor to the left of uranium in the periodic table, was found in Berlin, the corresponding neighbor to the right escaped discovery.

The history of nuclear fission tells us of how science often evolves, not by successive logical steps but rather through strange detours; how for many years the most experienced groups miss the central point in their experiments and in their thinking because they remain attached to seemingly well founded but erroneous concepts; how in the end they intuitively find the right track; and how after decades a scientist returns to the kind of work he pursued as a beginner.

The author thanks Peter Brix, Hans Otto Denschlag, Helmut Folger, Jens-Volker Kratz, Klaus Lützenkirchen, Chaturvedula Sastri, Matthias Schädel and Norbert Trautmann who have critically read this article, and Karl-Heinz Gläsel, Ursula Othmer and Annette Zauner, who have helped to prepare the manuscript.

Kinetic Isotope Effects as a Mechanistic Tool for the Elucidation of the Rate-Determining Step(s) in the Transition-Metal-Ion-Mediated Activation of CH/CC Bonds. Ethylene Loss from Metastable 4-Octyne/$M^{\oplus}$ Complexes in the Gas Phase**

By *Christian Schulze* and *Helmut Schwarz**

Dedicated to Professor Wolfgang R. Roth on the occasion of his 60th birthday

While there exist quite a number of case studies in which the mechanistic details of CH/CC bond activation by transition-metal complexes in solution were uncovered by using kinetic isotope effects,[1] analogous investigations in the gas phase are scarce as far as the elucidation of the rate-determining step(s) (RDS) is concerned.[2, 3] Here we report a study of the transition-metal-ion-mediated generation of ethylene from metastable 4-octyne/$M^{\oplus}$ complexes (M = Cr, Mn, Fe, Co, Ni, Cu) in the gas phase.[4–6] It will be demonstrated that, depending on $M^{\oplus}$, three distinct cases can be distinguished: (1) The rate-determining step corresponds to the activation of a CH bond, (2) the olefin detachment is rate-determining, and (3) the hydrogen transfer and the loss of ethylene are associated with kinetic isotope effects.

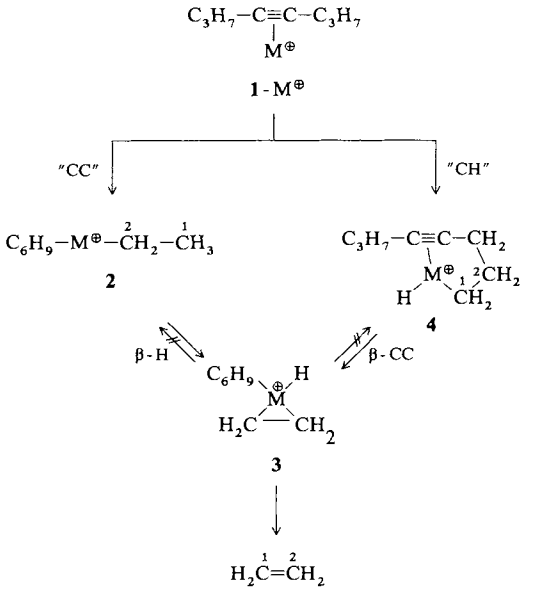
The analysis of the data displayed in Table 1 is straightforward. For all metal ions, except $Mn^{\oplus}$,[5] the reaction involves exclusively the C1/C2 positions of the substrate. Hydrogen exchange reactions do not take place. In addition, the reactions **2** → **3** and **4** → **3**[7] are strictly irreversible. Thus, **3** is more likely to dissociate than to revert to the intermediates involved in its formation (Scheme 1).

A further analysis of the isotope distribution reveals the following: (1) Comparison of the data for the $Cr^{\oplus}$ and $Cu^{\oplus}$ complexes **1a** and **1b** clearly demonstrates that the ligand detachment **3** → **5** is *not* associated with a kinetic isotope effect (C_2H_4 and $C_2H_2D_2$ are eliminated to the same extent from **1b**). Rather, for these metal-ion complexes it is the CH bond activation step **2** → **3** (or **1**-$M^{\oplus}$ → **4**) which constitutes the RDS. The fact that this primary isotope effect is relatively small (1.38 for $Cr^{\oplus}$ and 1.94 for the $Cu^{\oplus}$ system) points to bent transition structures,[8] which may indicate that the reaction actually proceeds via the route **1**-$M^{\oplus}$ → **2** → **3**. (2) In distinct contrast, for $M^{\oplus} = Fe^{\oplus}$ it is the loss of $C_2H_{4-x}D_x$ which is affected by isotopic substitution. If the C–H bond activation constituted the RDS, one should observe a primary kinetic isotope effect discriminating against loss of $C_2H_2D_2$ versus C_2H_4 from **1a**-$Fe^{\oplus}$ relative to **1b**-$Fe^{\oplus}$. This is not the case. Rather, both isotopomers give exactly the same isotope distribution from which we obtain a value of $k_H/k_D = 1.22$ (or of 1.10 per deuterium). This value is in line with what one would expect for secondary isotope effects caused by rehybridization $sp^x \rightarrow sp^2$ ($x > 2$) of the carbon

Table 1. Ethylene loss from the metastable 4-octyne/$M^{\oplus}$ complexes [a, b] **1a**, $CD_3CH_2CH_2C{\equiv}CC_3H_7$; **1b**, $CH_3CD_2CH_2C{\equiv}CC_3H_7$; **1c**, $CH_3CH_2CD_2C{\equiv}CC_3H_7$; **1d**, $CD_3CD_2CH_2C{\equiv}CC_3H_7$.

Substrate	$C_2H_{4-x}D_x$	$Cr^{\oplus}$	$Mn^{\oplus}$ [c]	$Fe^{\oplus}$	$Co^{\oplus}$	$Ni^{\oplus}$	$Cu^{\oplus}$
1a	C_2H_4	58	55	55	58	60	66
	C_2H_3D						
	$C_2H_2D_2$	42	45	45	42	40	34
	C_2HD_3						
	k_H/k_D	1.38	–	1.22	1.38	1.50	1.94
1b	C_2H_4	50	45	55	55	55	51
	C_2H_3D		10				
	$C_2H_2D_2$	50	45	45	45	45	49
	k_H/k_D	1.00	–	1.22	1.22	1.22	1.04
1c	C_2H_4	100	82	100	100	100	100
	C_2H_3D		13				
	$C_2H_2D_2$		5				
1d	C_2H_4	57	45	59	61	62	66
	C_2H_3D		2				
	$C_2H_2D_2$		2				
	C_2HD_3		8				
	C_2D_4	43	43	41	39	38	34
	k_H/k_D	1.32	–	1.44	1.56	1.63	1.94

[a] Intensities are normalized to $\sum C_2H_{4-x}D_x = 100\%$: the reproducibility of the data is better than ±3%. [b] Elimination of ethylene (% total ion fragment current) from metastable 4-octyne/$M^{\oplus}$ amounts to: 15% ($Cr^{\oplus}$), 40% ($Mn^{\oplus}$), 98% ($Fe^{\oplus}$), 94% ($Co^{\oplus}$), 98% ($Ni^{\oplus}$), and 84% ($Cu^{\oplus}$). [c] For $Mn^{\oplus}$, due to the partial scrambling between C2 and C3, no k_H/k_D data are given.



Scheme 1.

atoms in the step $\mathbf{3} \rightarrow \mathbf{5}$.[1a, b, 9] (3) It is obvious from Table 1 that for the $Co^{\oplus}$ and $Ni^{\oplus}$ complexes of 4-octyne both steps, i.e., C–H bond activation *and* ligand detachment, are subject to a kinetic isotope effect. For the ligand detachment $\mathbf{3} \rightarrow \mathbf{5}$ the data for **1b** and **1d** permit the estimation of an isotope effect $k_H/k_D = 1.10$ (per deuterium) for either $Co^{\oplus}$ or $Ni^{\oplus}$. The C–H bond activation step $\mathbf{2} \rightarrow \mathbf{3}$ (or, less likely, $\mathbf{1}\text{-}M^{\oplus} \rightarrow \mathbf{4}$) is associated with slightly differing k_H/k_D values of 1.25 and 1.36 for $Co^{\oplus}$ and $Ni^{\oplus}$, respectively.[10] *Obviously, the various transition-metal ions cause a switching in regard to the bottleneck of the multistep event* which is shown in Scheme 1 in a simplified manner.

As indicated in Figure 1, a quite remarkable *inverse* relationship exists between the magnitude of the kinetic isotope

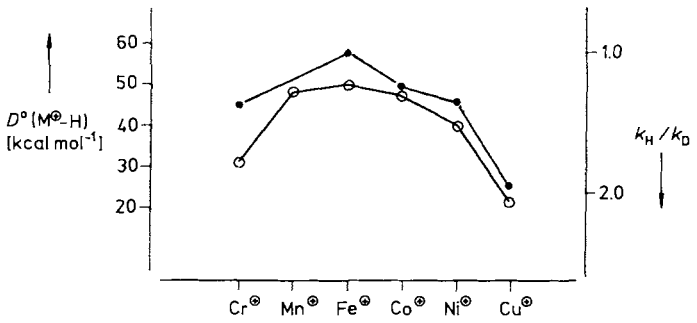

Fig. 1. Qualitative relationship between $D°(M^{\oplus}\text{-H})$ (-○-○-○-) and kinetic isotope effects (-●-●-●-) for C–H bond activation ($\mathbf{2} \rightarrow \mathbf{3}$ or $\mathbf{1}\text{-}M^{\oplus} \rightarrow \mathbf{4}$). The data for $D°(M^{\oplus}\text{-H})$ are taken from [11]. For $Mn^{\oplus}$ no accurate k_H/k_D value can be given (see text).

effect of the oxidative addition of a CH bond to a metal-ion center and the strength of the $M^{\oplus}$–H bond, $D°(M^{\oplus}\text{-H})$, to be formed.[11] In a qualitative sense the *data suggest that weaker and stronger $M^{\oplus}$–H bonds cause larger and smaller isotope effects, respectively*. The origin of this relationship remains to be established through further experimental and theoretical studies.

[4] Preliminary results were previously described for $M^{\oplus} = Fe^{\oplus}$, $Cr^{\oplus}$: a) C. Schulze, T. Weiske, H. Schwarz, *Chimia 40* (1986) 362; b) C. Schulze, H. Schwarz, D. A. Peake, M. L. Gross, *J. Am. Chem. Soc. 109* (1987) 2368; c) [3b].

[5] In the present study $Mn^{\oplus}$ is not included in the discussion on the grounds that, in contrast to the other transition-metal ions, ethylene loss is preceded by exchange processes involving the CH bonds at positions C2 and C3 of the substrate (see Table 1). This fact prevents a reliable determination of the kinetic isotope effects. See also: a) C. Schulze, H. Schwarz, *J. Am. Chem. Soc. 110* (1988) 67; b) [3b].

[6] The 4-octyne/$M^{\oplus}$ complexes were generated in the ion source of a VG Instruments ZAB-HF-3F by reacting 4-octyne with $M^{\oplus}$; the latter ions were generated by either 100-eV electron impact ionization of a suitable organometallic compound or by fast atom bombardment of appropriate transition-metal salts. The complexes thereby formed were accelerated to 8 keV kinetic energy, mass selected by means of $B(1)E$ (B stands for magnetic and E for electric field) at a resolution sufficient to separate isobaric species, and the unimolecular dissociations occurring in the field-free region between E and $B(2)$ recorded by scanning of $B(2)$. Averaging techniques were employed to significantly improve the signal-to-noise ratios such that the intensity measurements were better than ±3%. For a full description of the apparatus and the techniques used, see: a) [3, 5a]; b) H. Schwarz, *Acc. Chem. Res. 22* (1989) 282; c) C. Schulze, *Ph.D. Thesis, Technische Universität Berlin, 1989*.

[7] The description of **3** as a metallacyclopropane derivative is somewhat arbitrary; of course, the species could also correspond to an η^2-olefin complex.

[10] Since two factors determine the experimental value, the calculations include a deconvolution to separate both effects. For details of the procedure, see [6c].

[11] The $D°(M^{\oplus}\text{-H})$ data are taken from: P. B. Armentrout, J. L. Beauchamp, *Acc. Chem. Res. 22* (1989) 315.

Rhodium-Catalyzed Synthesis of Trisubstituted Olefins from Ethene Derivatives and Diazoalkanes**

By *Justin Wolf, Lutz Brandt, Arno Fries,* and *Helmut Werner**

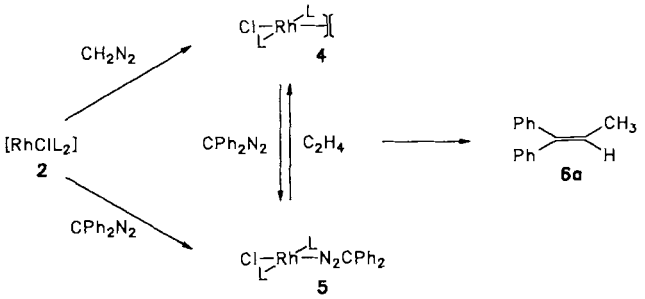
During attempts to prepare square-planar carbene metal complexes of type **1**, we discovered a new catalytic reaction for forming C–C bonds. The vinylidene rhodium and iridium complexes *trans*-$[MCl(=C=CRR')(PiPr_3)_2]$, which are structurally related to **1**, are known[1] and (for M = Ir) have been used for the synthesis of the cationic carbyne complexes *trans*-$[MCl(\equiv C\text{-}CHRR')(PiPr_3)_2]^{\oplus}$.[2]

trans-$[MCl(=CRR')(PiPr_3)_2]$ **1**, M = Rh, Ir

$[RhCl(PiPr_3)_2]$ **2**

trans-$[RhCl(=CH_2)(PiPr_3)_2]$ **3**

The monomeric three-coordinate rhodium compound **2** (Scheme 1), used as starting material for the preparation of the vinylidene complex *trans*-$[RhCl(=C=CH_2)$-



Scheme 1. L = $PiPr_3$.

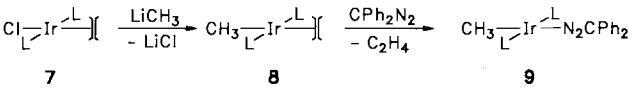
[*] Prof. Dr. H. Werner, Dr. J. Wolf, L. Brandt, A. Fries
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Commission of the European Communities, and the Fonds der Chemischen Industrie.

$(PiPr_3)_2]$,[1a,c] reacts with diazomethane in ether to give mainly the ethene complex **4**[3] instead of the carbene complex **3**. Whether **3** is formed as an intermediate is unclear. Similarly, the reaction of **2** with diphenyldiazomethane does not lead to a carbene complex but to the diazoalkane complex **5**,[4] which is stable at room temperature under argon. The position of the N-N stretching frequency at 1940 cm^{-1} in the IR spectrum of **5** suggests an end-on coordination of the CPh_2N_2 ligand.[5] Similar iridium compounds with the general composition *trans*-$[IrCl(\eta^1\text{-}N_2CR_2)(PPh_3)_2]$ with conjugatively stabilized diazoalkanes such as $N_2C_5X_4$ (X = Cl, Br) or $N_2C(COPh)_2$ have been described by *Ibers* et al.[6] and *Cowie* et al.[7] The compound containing $N_2C_5Cl_4$ as a ligand was characterized by X-ray structural analysis.[6]

Attempts to use complex **5** for cyclopropanation reactions have failed. On treatment of **5** (in benzene) with ethene at room temperature, an equilibrium between **4** and **5** is reached, which in ethene atmosphere lies mainly on the side of the ethene complex. In a *catalytic* reaction addition of excess diphenyldiazomethane and warming to ca. 40 °C unexpectedly produces 1,1-diphenylpropene **6a** (Scheme 1), which is formally built up by the linking of the $:CPh_2$ fragment of the diazoalkane with the ethene isomer $:CHCH_3$.[8] Turnover numbers of ca. 30 have been observed for **6a** at 35–40 °C in acetone, benzene, or toluene solution, after which deactivation of the catalyst occurs.

The iridium analogue of **5** cannot be obtained from the reaction of CPh_2N_2 with *trans*-$[IrCl(C_8H_{14})(PiPr_3)_2]$, which is generated in situ from $[IrCl(C_8H_{14})_2]_2$ and $PiPr_3$ and is used in the synthesis of organoiridium compounds.[1a,b,9] The main product in this reaction, as well as in the reaction of the Ir complex **7** with CPh_2N_2, is the dinitrogen complex *trans*-$[IrCl(N_2)(PiPr_3)_2]$.[10] If, however, the chloro ligand in **7** is displaced by CH_3 and the resulting methyl derivative **8** (Scheme 2) is treated with CPh_2N_2 under mild conditions in



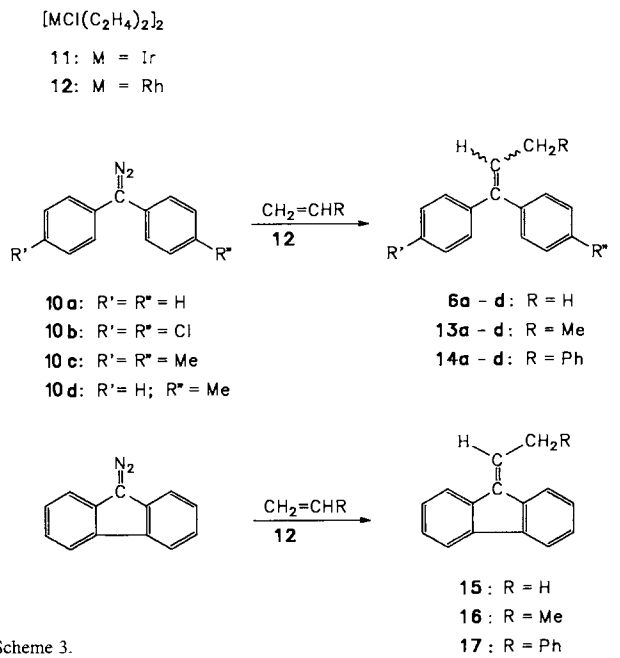
7 **8** **9**

Scheme 2. L = $PiPr_3$.

ether, the corresponding diphenyldiazomethane complex **9** is formed in almost quantitative yield.[11] Complex **9** is completely inert toward ethene even if it is stirred at 60 °C in an ethene atmosphere. On treatment of **7** with excess CPh_2N_2 in toluene at 60 °C, only small amounts of **6a** (ca. 10% yield with regard to **7**) can be detected.

The iridium complex **11** and the rhodium analogue **12** (Scheme 3) are significantly more reactive than **7** and **8** toward mixtures of ethene and the diaryldiazomethanes **10a–d**.[12] **12** is particularly reactive for it allows a *catalytic* synthesis of trisubstituted olefins. With 3 mg of **12** in 15 mL of toluene, turnover numbers of 125, 460, 515, and 105 for **6a–d** are observed after 6 h at 50 °C. If propene or styrene is used instead of ethene, the ethene derivatives **13a–d** and **14a–d** are formed. In this case, however, the yield of the olefinic product is lower than in the reactions with ethene. The trisubstituted olefins are separated from the metal-containing species by column chromatography (Al_2O_3, activity grade III) using pentane as solvent; they were identified by mass spectrometry and ^1H NMR spectroscopy.

Treatment of 9-diazofluorene with ethene, propene, or styrene as parent olefin gives the compounds **15–17**. After the catalytic reaction leading to the olefins is nearly finished, the formation of cyclopropane derivatives such as 1,1,2-triphenylcyclopropane (from **10a** and styrene) can also be detected. In addition, thermal cyclopropanation of styrene with **10a** is possible but has not been observed in the absence of **12** under the conditions employed in our experiments.

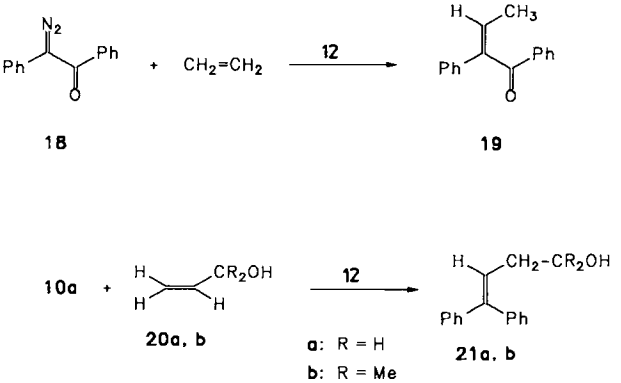


Scheme 3.

The turnover numbers for the formation of **6a–d** do not depend on the solvent; they remain almost the same regardless whether a nonpolar solvent such as benzene or toluene or a polar solvent such as acetone is used. In methanol, the reaction of ethene with **10a** affords not only **6a** but also the insertion product $MeOCHPh_2$.

The new method for forming C–C bonds can also be applied to diazoketones and to olefins containing a functional group (Scheme 4). For example, the reaction of ethene with diazodiphenylethanone (**18**) gives the α,β-unsaturated carbonyl compound **19**, whereby only the *Z* stereoisomer is obtained. At 50 °C in toluene, the turnover number is ca. 15. Treatment of **20a,b** with CPh_2N_2 (**10a**) leads to the unsaturated alcohols **21a** and the previously unknown **21b**.

Concerning the mechanism of this new olefin synthesis, it is important to note that **6a** is obtained from **4** and CPh_2N_2 as well as from **5** and C_2H_4. We therefore assume that in the initial stage of the reaction *both* substrates, the olefin and the



Scheme 4.

diazoalkane, are coordinated to the metal and form an MN_2C_3 six-membered ring via a cycloaddition reaction promoted by the metal center. After elimination of N_2, a metallacyclobutane derivative may be generated, from which an η^3-allylhydrido intermediate is obtained by a β-H shift. Finally, migration of the hydride ligand to a terminal carbon of the allyl group can lead to the product olefin, thus reforming the catalytically active species. We are currently trying to prepare independently metallacyclobutane derivatives related in structure to the intermediate in the catalytic cycle to find out whether they can generate the observed olefin.

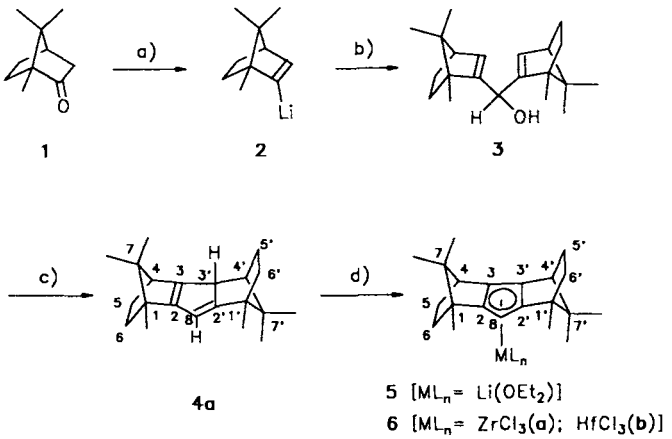
Enantioselective Catalysis with a New Zirconium Trichloride Lewis Acid Containing a "Dibornacyclopentadienyl" Ligand**

By *Gerhard Erker** and *Adolphus A. H. van der Zeijden*

Important aldol-type C–C coupling reactions are catalyzed by Lewis acids.[1] Enantioselectivity is usually achieved by the use of stoichiometric amounts of chiral auxiliaries.[2] Only in a few exceptional cases have chiral Lewis acids recently been employed in stoichiometric amounts or as catalysts.[3] Here we describe the synthesis of the new organometallic Lewis acid **6a**, which contains a "dibornacyclopentadienyl" ligand, and its use as an effective catalyst for the enantioselective C–C coupling of pyruvic esters with a reactive arene.

The "chiral pool" synthesis of the dibornacyclopentadienyl ligand started from (+)-camphor (**1**),[4] which was converted, via Shapiro reaction, into 2-bornen-2-yllithium (**2**).[5] Reaction of **2** with ethyl formate in a 2:1 molar ratio afforded, under optimal conditions, bis(2-bornen-2-yl)methanol (**3**) in nearly quantitative yield (spectroscopically clean). Cyclization of **3** with $KHSO_4$ at 100–150 °C gave the cyclopentadiene system **4**[6] (80%, m.p. 87 °C, two isomers in a 75:25 ratio, presumably H *endo* (**4a**) and *exo* (**4b**) at C3').[7] Deprotonation of **4** with *n*-butyllithium in ether gave **5**. Subsequent reaction of **5** with zirconium tetrachloride in toluene (molar ratio 1:1) afforded **6a** (40%). The analogous sequence of reactions with $HfCl_4$ led to the corresponding hafnium compound **6b** (40% based on **4**).[7]



Scheme 1. a) 1. 2,4,6-$iPr_3C_6H_2SO_2NHNH_2$, 2. *s*BuLi; b) HCO_2Et; c) $KHSO_4$, 100–150 °C; d) 1. *n*BuLi, Et_2O, 2. $ZrCl_4$ ($HfCl_4$) toluene.

Pharmacologically interesting 2-(2-hydroxyaryl)lactic esters can be prepared from pyruvic esters and hydroxyarenes in a reaction catalyzed by Lewis acids.[8] For example, reaction of 1-naphthol (**7**), as its Li salt, with ethyl pyruvate (**8a**) in the presence of 1 molar equivalent of $AlCl_3$ affords ethyl 2-(1-hydroxy-2-naphthyl)lactate (**9a**) as a racemate. To synthesize optically active **9a**, for example, (−)-menthyl-O-(Et)AlCl was used in stoichiometric amount.[8a] Asymmetric catalysis of this C–C coupling reaction proceeds under mild reaction conditions with the chiral Lewis acid **6a** ($[\alpha]_D$ = +51°). Reaction of **7** with **8a** at room temperature in the presence of a catalytic amount of **6a** (ratio **7**:**8a**:**6a** ≈ 100:100:1, catalyst concentration ca. 3 mmol L^{-1}) affords **9a** (70% after 2 h) with 27% *ee*. The enantiomeric excess was determined by ^1H NMR spectroscopy after complete conversion of ester **9a** to mixtures of the diastereomeric amides **10**/**11** by treatment with enantiomerically pure (*R*)- or (*S*)-1-phenyl-ethylamine in excess[9] and then checked independently and confirmed by ^1H NMR spectroscopy using the shift reagent $Eu(hfc)_3$. Use of catalyst **6a**, which has (1*R*,4*S*,1'*R*,4'*S*) configuration and is dextrorotatory, gives an excess of product **9a** with (*R*) configuration. This assign-

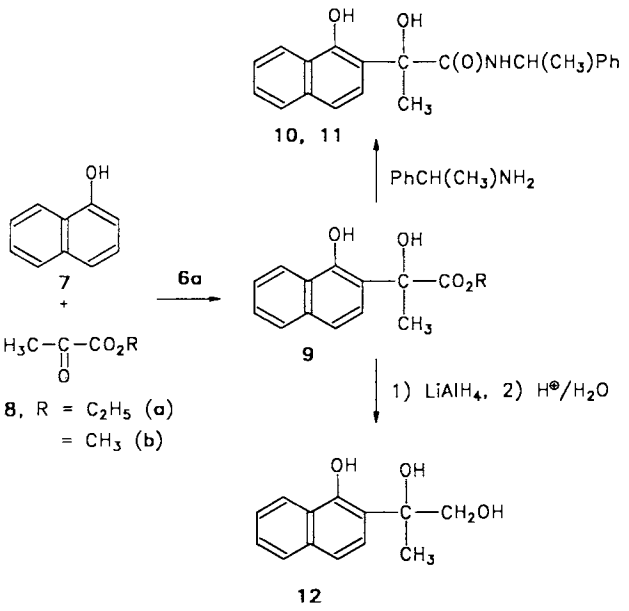
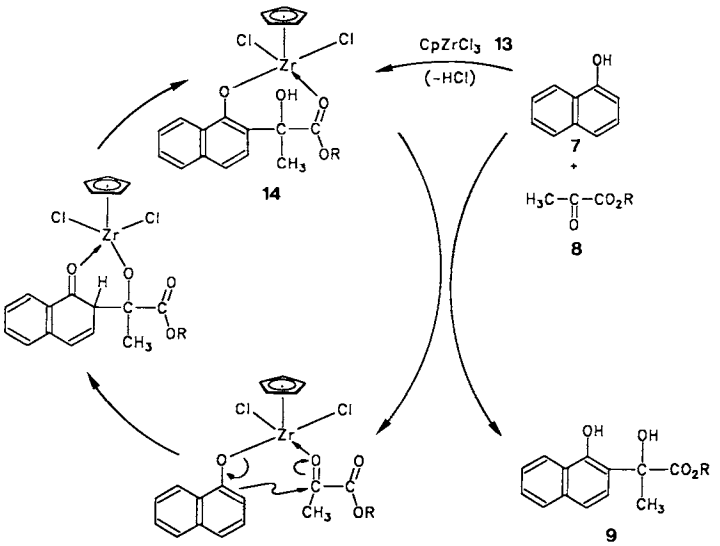
ment is based on ^1H NMR analysis of the resulting diastereomeric carboxamides (**10**/**11**) according to the method of *Helmchen* et al.[10] and on the reduction of the isolated product **9a** (84% *ee*, $[\alpha]_D = +118°$) to the enantiomer **12** ($[\alpha]_D = +26°$) of the known compound (*S*)-2-(1-hydroxy-2-naphthyl)propane-1,2-diol ($[\alpha]_D = -28.8°$).[8a]



Initial attempts to optimize the enantioselective formation of (*R*)-**9a** showed that a lowering of the reaction temperature to $-10\,°C$ under otherwise identical conditions (**7**:**8a**:**6a** = 100:100:1, CH_2Cl_2, reaction time 24 h) leads to an increase in *ee* (20 °C, 21% *ee*; 0 °C, 32% *ee*; −5 °C, 46% *ee*; −10 °C, 54% *ee*). Further lowering of the temperature did not result in higher enantioselectivity. At −10 °C, the selectivity decreases markedly with increasing conversion (reaction time 2 h, 40% conversion, 78% *ee*; 5 h, 65% conversion, 70% *ee*; 24 h, 75% conversion, 54% *ee*; 48 h, 85% conversion, 49% *ee*). Changing the solvent (with the exception of coordinating solvents like THF) and variation of the $RCOCO_2R'$ components (R = methyl, isopropyl; R′ = methyl, ethyl, isopropyl, cyclohexyl) have little effect on the stereochemistry of the catalyzed C–C coupling process. An increase in the concentration of 1-naphthol appears to have a negative effect on the selectivity (**7**:**8a**:**6a** = 500:100:1, CH_2Cl_2, −10 °C: 2 h, 50% conversion, 53% *ee*; 5 h, 70% conversion, 42% *ee*; 24 h, 90% conversion, 32% *ee*). Presumably, under the acidic reaction conditions, catalyst **6a** is not stable over long periods but, instead, gradually loses the dibornacyclopentadienyl ligand to form an achiral, though still catalytically active, species. In agreement with this interpretation, an increase in the concentration of **8**, as well as the use of more catalyst **6a**, leads to considerably higher enantioselectivity, even for complete conversion of the limiting component **7** (e.g., **7**:**8a**:**6a** = 100:500:5, CH_2Cl_2, −10 °C; 2 h, 70% conversion, 80% *ee*; 5 h, 85% conversion, 80% *ee*; 24 h, quantitative conversion, 72% *ee*).

The addition of small amounts of water has a surprisingly positive effect. We have reproducibly obtained increases of about 10% in enantiomeric excess (e.g., molar ratio **7**:**8a**:**6a**:H_2O = 100:500:5:27, CH_2Cl_2, −10 °C; 2 h, 55% conversion, 89% *ee*; 5 h, 70% conversion, 89% *ee*; 24 h, 90% conversion, 84% *ee*).

It is known that the achiral organometallic Lewis acid (η-cyclopentadienyl)zirconium trichloride (**13**)[11] forms adducts with many organic carbonyl compounds as well as with HO-containing substrates.[12] We were unable to obtain a defined adduct of **13** with the individual components 1-naphthol (**7**) or pyruvic esters (**8**). However, if a mixture of **7** *and* **8b** is added to $CpZrCl_3$, then the addition product **14b** of the C–C coupling product of the organic starting materials can be isolated in 59% yield[13] (Scheme 2). Compounds



Scheme 2. **a**, R = C_2H_5; **b**, R = CH_3.

14 [R = C_2H_5 (**a**), CH_3 (**b**)] catalyze the reaction of **7** with **8** to give **9**. The enantioselective C–C coupling reaction involving the chiral organometallic Lewis acid **6a** presumably proceeds according to a similar reaction scheme. We hope to elucidate the details of this catalytic process, such as the surprising role of small amounts of water,[12b] by studying model reactions, based on the achiral $CpZrCl_2X$ system, of the isolated intermediate **14** of the catalytic cycle.

Experimental Procedure

Synthesis of ethyl (*R*)-2-(1-hydroxy-2-naphthyl)lactate (**9a**) with **6a** as catalyst: 1-Naphthol (**7**) (0.94 g, 6.53 mmol), ethyl pyruvate (**8a**) (2.5 mL, 23 mmol), and water (30 mg, 1.7 mmol) were added to a solution of catalyst **6a** (154 mg, 0.38 mmol) in 26 mL of CH_2Cl_2 at −60 °C. The reaction mixture was stirred for 24 h at −10 °C and then worked up as usual [8] to give 0.95 g (56%) of **9a**, m.p. 47 °C. Correct elemental analysis; $[\alpha]_D = +118°$ (corresponds to 84% *ee*). This value was confirmed independently by an ^1H NMR experiment with the shift reagent tris[3-((heptafluoropropyl)hydroxymethylene)-d-camphorato]europium as well as by reaction with enantiomerically pure 1-phenylethylamine.

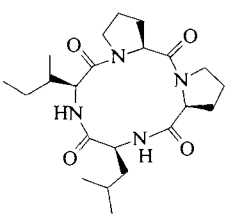
[13] **14a** (R = C_2H_5): 71% isolated, correct elemental analysis (C, H). IR (KBr): ν(C=O) = 1641 cm^{-1}. ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 2.04 (s, 3H; Ar-C(CH_3)OH-), 4.36 and 1.25 (OCH_2CH_3), 6.76 (s, 5H; Cp), 5.8 (OH), 7.21 (1H) 7.31 (1H), 7.50 (2H), 7.71 (1H), 8.26 (1H; naphthyl). ^{13}C NMR ($CDCl_3$, 50 MHz): δ = 22.6 (ArC(*C*H_3)OH), 81.4 (Ar*C*(CH_3)OH), 178.3, 67.3, 13.5 (-CO-OC_2H_5), 118.1 (Cp), 121.8, 123.6, 125.6, 126.7, 127.2, 127.6 (naphthyl-CH), 158.1 (naphthyl-CO), 114.2, 126.7, 135.7 (naphthyl-*ipso*-C); the structural assignment is supported by ^{1}H NMR NOE spectra [irradiation of Ar-C(CH_3)OH-, for example, leads to NOEs at Ar-C(CH_3)O*H* (15%) and the 3-H of the aromatic ring (24%)]. **14b** (R = CH_3): 59% isolated, correct elemental analysis (C, H). IR (KBr): ν(C=O) = 1643 cm^{-1}. 1H/^{13}C NMR spectra similar to those of **14a**.

What Are the Structures of Fenestin A and Fenestin B?**

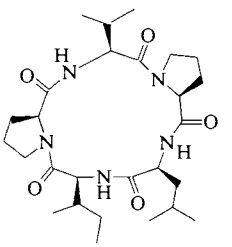
By *Ulrich Schmidt,* Albrecht Lieberknecht, Uli Kazmaier,* and *Ernst Haslinger*

Dedicated to Professor Wolfgang Lüttke on the occasion of his 70th birthday

Numerous linear and cyclic peptides and peptolides have been isolated in recent years from lower marine organisms.[1–8] They consist in part of (*R*)-amino acids, didehydroamino acids, and nonribosomal amino acids. Two natural products were recently isolated from the sponge *Leucophloeus fenestrata* and were assigned structures **1** (fenestin A) and **2** (fenestin B), the rings of which contain exclusively (*S*)-amino acids.[9]



1



2

We questioned these structural proposals for the following reasons:

1. Except for bottromycin,[6] tentoxin,[7] and dihydrotentoxin,[8] the few known natural cyclotetrapeptides contain at least one (*R*)-amino acid. Tentoxin consists of an alternating arrangement of two tertiary and two secondary amide groups.[10] This allows a stable *cis–trans–cis–trans* conformation of the amide bonds, since the *cis* and *trans* conform-

[**] Amino Acids and Peptides, Part 73. This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and BASF AG. Part 72: U. Schmidt, R. Meyer, V. Leitenberger, A. Lieberknecht, *Angew. Chem. 101* (1989) 946; *Angew. Chem. Int. Ed. Engl. 28* (1989) 929.

ers of tertiary amides differ in energy by only a small amount. Bottromycin is a special case insofar as it contains three amide bonds and one amidine bond.[11] The structure proposed for fenestin A contains exclusively (*S*)-amino acids and neighboring tertiary amide bonds; this type of structure has not been found so far in naturally occurring compounds.

2. For fenestins A and B, the ^{1}H NMR signals of the α-protons of the amino acid units range from $\delta = 3.9$ to 4.09, near the limit of the region where the α-H signals of peptides are usually found.[12] In all cyclopeptides we have studied, these signals ranged from $\delta = 4.0$ to 4.6.

We therefore decided to reexamine these structural proposals by synthesizing **1** and **2**. The linear precursors were prepared in an unambiguous way according to Schemes 1 and 2. We accomplished the ring closure by catalytic hydro-

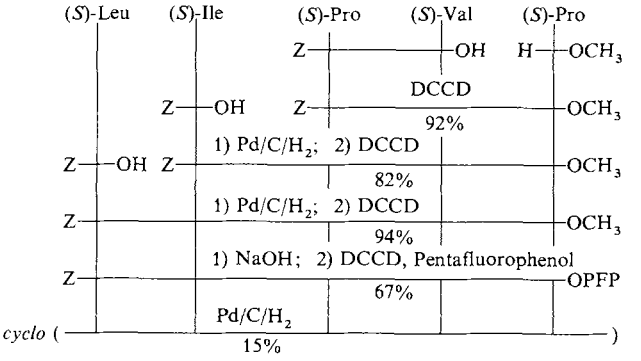

Scheme 2. Synthesis of **2**.

genation of the ω-benzyloxycarbonyl pentafluorophenyl ester.[13] Monomeric fenestin A was thereby formed not at all or only in very small amounts (<5%). A cyclooctapeptide (fenestin A dimer) was isolated in 18% yield (Table 1). Monomeric fenestin B was obtained in 15% yield (Table 1). Large differences were found between the NMR and mass spectra of natural fenestin B and the synthetic product. As expected, the ^{1}H NMR spectrum shows the α-H signals of the amino acid units in both the synthetic cyclopentapeptide and the cyclooctapeptide in the region of $\delta = 4.0-4.65$. The signals of the δ-H atoms of the two proline residues of **2** are found at $\delta = 3.5-3.7$, the NH signals at $\delta = 5.64$, 6.37, and 7.56 (see Table 1). The latter are markedly split by coupling with the α-H atoms. The ^{1}H NMR data published for the natural product differ considerably from this spectrum, especially with respect to the position of the α-H signals of the amino acid units (3.9–4.09). The ^{13}C signals of the two compounds are overall in good agreement. Large differences in the region of $\delta = 2.7-4.8$ occur particularly for resonances assigned to the proline carbon atoms of the natural product. This also holds true for the valine between the proline residues. The previously assigned structure of fenestin B is therefore wrong and that of fenestin A appears questionable.

Table 1. Physical data for compounds **1** (dimer) and **2**. The NMR spectra were recorded with a Bruker AM 500, the mass spectra with an MAT 8500 (LSIMS, ionization with cesium).

1 (dimer): ^{1}H NMR (500 MHz, $CDCl_3$): $\delta = 0.83-0.98$ (sh, 12H), 1.25–2.20 (sh, 11H), 2.30 (m, 1H), 3.45–3.70 (sh, 4H), 3.89 (dt, $J = 9.7$, 7.0 Hz, 1H), 4.20 (dd, $J = 8.8$, 6.0 Hz, 1H), 4.30 (m, 1H), 4.43 and 4.56 (t each, $J = 8.0$ Hz, 1H), 4.61 (dd, $J = 10.3$, 8.1 Hz, 1H), 4.73 (m, 1H), 5.42 (d, $J = 6.6$ Hz, 0.3H), 7.17 (d, $J = 7.2$ Hz, 0.7H), 7.40 (d, $J = 10.3$ Hz, 0.7H), 7.81 (d br, $J = 9.4$ Hz, 0.3H). ^{13}C NMR (125 MHz, $CDCl_3$, decoupled): $\delta = 11.58$, 12.19, 14.43, 15.88, 20.86, 21.86, 22.98, 23.36, 24.67, 24.75, 25.35, 25.40, 25.44, 25.59, 25.92, 26.08, 27.44, 27.77, 29.04, 29.42, 35.38, 36.39, 40.86, 41.50, 46.58, 46.72, 46.99, 47.62, 51.06, 53.59, 54.46, 58.44, 62.12, 62.84, 64.27, 169.10, 169.15, 171.10, 171.21, 171.49, 172.60, 172.78, 173.70. *m/z*: 843, 842 ($M^{\oplus}_{dim}$), 631, 535, 534, 421 ($M^{\oplus}$), 393, 379, 369, 325, 317, 308, 277, 275, 242, 225, 211, 186, 183, 167, 165, 133.

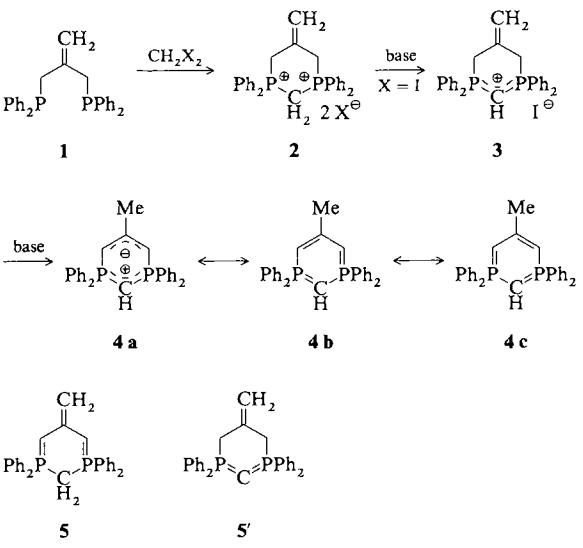
5-Methyl-1,1,3,3-tetraphenyl-1λ⁵,3λ⁵-diphosphabenzene**

By *Hubert Schmidbaur,* Christos Paschalidis, Oliver Steigelmann*, and *Gerhard Müller*

Ever since their discovery,[1, 2] phosphabenzenes (phosphinines), with λ⁵-P atoms, have attracted considerable attention. In particular, the chemistry of monophosphabenzene has developed into an important area of heterocyclic chemistry.[3, 4] Little is known, however, about the chemistry of *poly*phosphabenzenes. Although *Märkl* obtained evidence suggesting the existence of 1λ⁵,3λ⁵-diphosphabenzenes as early as 1963, adequate characterization was not provided by these initial studies.[5] It was not until recently that *Fluck* et al. were able to synthesize a 1,3-diphosphinine, with a special substitution pattern, and also characterize its structure.[6] 1λ⁵,4λ⁵-Diphosphinines were described in 1970 and 1972,[7, 8] but very little work has been carried out on this class of compounds. Finally, 1,3,5-triphosphabenzenes have also only recently been obtained, the few known representatives containing at least one λ³-P atom in the molecule.[9]

As a continuation of our earlier studies on open-chain and cyclic double ylides ("carbodiphosphoranes")[10, 11] and phosphoniopropenides,[12, 13] we now report a simple, high-yield synthetic route for the title compound **4**, which opens up many new preparative possibilities.

The dication of **2**,[12] obtained by double quaternization of 1,1-bis[(diphenylphosphino)methyl]ethene (**1**) with dihalomethanes, can be treated with one equivalent of *n*-butyllithium or triethylethylidenephosphorane (as a transylidation reagent) to give, for X = I, the semi-ylidic quaternary salt **3**. The addition of a second equivalent of base surprisingly does not result in the conjugated double ylide **5** or in the cumulated double ylide **5'**, but leads directly to the formation of the title compound **4** in high yields (by-products: LiI and Et_4PI, respectively), although numerous analogues of **5** and **5'** with saturated ring systems have already been characterized.[10, 11]



Scheme 1. X = Cl,Br,I.

It appears that the reaction includes a proton transfer from an endocyclic to an exocyclic methylene group leading to formation of a methallyl anion moiety $[CHC(Me)CH]^{\ominus}$, which couples the P atoms of $[Ph_2PCHPPh_2]^{\oplus}$. This resonance form is depicted in formula **4a**, whereas **4b** and **4c** represent the corresponding cyclic "ylene forms".[14]

Elemental analyses and mass spectra confirm the composition of **4**. The NMR spectra are compatible with C_{2v} symmetry of the framework in solution. The chemical shifts of the equivalent P, C, and H atoms of the (MeC)-*CH*-*P* groups and the corresponding coupling constants are indicative of the partially ylidic character of these units. The same result holds for the PCHP unit, for which numerous precedents are available.[10, 11] The yellow color of **4** is consistent with *Märkl*'s observations.[5]

The X-ray structure analysis[15] of **4** revealed the absence of crystallographic symmetry in the solid state, but the molecule is found to at least approach the expected C_{2v}(or C_s) symmetry (Fig. 1). The ring system is almost planar (with a maximum deviation from planarity for C4 of 0.03 Å). Accordingly, the sum of the angles at C3 is exactly 360.0°, and the sum of the angles at the ring atoms is 719.9° (the corresponding inner angles at C1–C4 are significantly larger than 120°, and those at P1 and P2 significantly smaller). The P1–C1 and P2–C1 distances (average 1.697 Å) as well as the P1–C4 and P2–C2 distances (average 1.726 Å) reflect the ylidic character of **4**, as also suggested by the P-phenyl distances (average 1.827 Å).

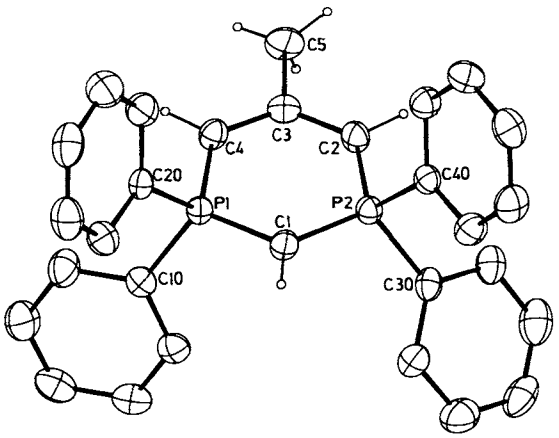


Fig. 1. Structure of **4** in the crystal (ORTEP, vibration ellipsoids at the 50% probability level, phenyl H atoms not shown); atomic numbering *not* consistent with the numbering used for the nomenclature. Selected bond distances [Å] and angles [°]: P1-C1 1.699(3), P2-C1 1.695(3), P1-C4 1.729(3), P2-C2 1.724(3), C2-C3 1.393(4), C3-C4 1.387(4), C3-C5 1.516(4); P1-C1-P2 123.1(2), C1-P1-C4 110.2(1), C1-P2-C2 110.4(1), P2-C2-C3 124.2(2), C2-C3-C4 127.8(3), P1-C4-C3 124.2(2), C2-C3-C5 116.0(2), C4-C3-C5 116.2(2), C10-P1-C20 102.4(1), C30-P2-C40 101.3(1). The rings at C10, C20, C30, and C40 form dihedral angles of 70.1, 106,7, 130.2, and 71.0° with the heterocycle, respectively.

The C3–C5 distance [1.516(4) Å] indicates the presence of a C–C single bond, as opposed to the double bond value of **1** (1.307(5) Å.[16] The methyl hydrogen atoms could also be located by crystallography (and confirmed by the ^1H-coupled ^{13}C NMR spectrum). The C2–C3 and C3–C4 distances

with their average value of 1.390 Å are in agreement with the methallyl anion character of the corresponding structural unit.

Theoretical studies on λ^5-phosphabenzenes[2, 17] and related phosphazenes have shown that the four-coordinate λ^5-phosphorus atom acts as a "conjugation barrier". The model can be adopted for $1\lambda^5,3\lambda^5$-diphosphabenzenes. **4** is best represented by the zwitterionic resonance structure **4a** with two "regions of conjugation". Rather than an aromatic system, the π systems of the methallyl anion and the diphosphoniomethanide cation are sufficient to account for the high tendency of formation of the molecule.

Experimental Procedure

3: 0.42 mL of a 4.02 M solution of *n*-butyllithium in hexane was added at −78 °C to a stirred suspension of **2** (X = I, 1.18 g, 1.70 mmol) in 70 mL of tetrahydrofuran (THF). After 6 h the yellow suspension was filtered, and the precipitate washed with cold water and THF. Yield: 0.90 g (94%), **3**, m.p. 205 °C, correct elemental analysis. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta = 15.5$; $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta = -3.49$ (t, $J(PC) = 107.9$ Hz, CHP_2), 33.18 (d, $J(PC) = 58.7$, CH_2P), 121.0 (t, $J(PC) = 9.9$, $H_2C=$), 128.6 (t, $J(PC) = 9.5$, C=), 127.6, 132.0, 129.3, 133.0 (m, phenyl-C); ^1H NMR ($CDCl_3$): $\delta = 1.35$ (t, $J(PH) = 3.8$ Hz, 1H, CHP_2), 3.87, (AXX', $N = 16.8$ Hz, 4H, CH_2), 5.03 (t, $J(PH) = 3.8$, 2H, $=CH_2$), 7.48–7.79 (m, 20H, phenyl-H).

4: A suspension of **2** (X = I, 0.58 g, 0.84 mmol) in 50 mL of THF at −78 °C was treated with a solution of $Et_3P{=}CHMe$ (0.25 g, 1.68 mmol) in 25 mL of THF. After warming to 20 °C the reaction mixture was stirred for another 10 min. The precipitate was separated (0.40 g Et_4PI), and the filtrate evaporated in vacuo and cooled until crystallization of **4** started (at −25 °C). Yellow crystals, yield: 0.32 g (87%), m.p. 115 °C (dec.).—$^{31}P\{^1H\}$ NMR (C_6D_6): $\delta = 7.1$; $^{13}C\{^1H\}$ NMR (C_6D_6): $\delta = -3.0$ (t, $J(PC) = 109.1$ Hz, PCHP), 30.46 (t, $J(PC) = 17.9$, CH_3), 51.79 (AXX', $N = 120.54$ Hz, CHP), 159.52, (t, $J(PC) = 6.9$, CCH_3), 139.3, 131.2, 128.0, 129.7 (m, phenyl-C); ^1H NMR (C_6D_6): $\delta = 1.15$ (br. s, 1H, PCHP), 2.26 (t, $J(PH) = 1.5$ Hz, 3H, CH_3), 3.40 (br. s, 2H, CHP), 7.0–7.7, (m, 20H, phenyl-H).

Unraveling Overlapping Multiplets in Two-Dimensional NMR Correlation Spectra by Selective Inversion of Coupling Partners**

By *Lyndon Emsley, Peter Huber*, and *Geoffrey Bodenhausen**

Two-dimensional NMR correlation spectroscopy (COSY) is a widely used, simple and efficient technique for identifying systems of coupled spins.[1] The coupling networks that can be determined from such spectra contain information about the number of spins, magnetic or chemical equivalence, and magnitudes and signs of scalar couplings.[2–4] In many cases, a large portion of a spin system can be identified from a low-resolution survey spectrum that can be acquired in less than an hour, preferably with the double-quantum filtered COSY experiment.[5] In order to confirm a hypothesis regarding the network of coupled spins, it may be necessary to study the fine-structure of the multiplets by increasing resolution. One should then take recourse to more informative spectra such as E.COSY,[6, 7] PE.COSY[8] or *z*-COSY.[9, 10] Very often, however, it is not really necessary to subject the entire two-dimensional spectrum to such a detailed investigation. Typically, only one or two multiplets in a low-resolution survey spectrum present problems for interpretation, and in such cases it is much more time efficient to "zoom in" on the multiplets of interest, which can be done by pseudo-COSY[11] or by soft-COSY[12] and related experiments.

These methods can greatly enhance the resolution of a chosen multiplet, but they fail to exploit all the information available to the spectroscopist. Typically, when confronted with a difficult multiplet in COSY, one does not only know the shifts Ω_{A1} and Ω_{A2} of the *active spins* (i.e., spins A_1 and A_2 that carry the transverse magnetization in the evolution and detection periods t_1 and t_2 of the experiment), but one usually has at least an idea about the shifts Ω_{P_i} of the *passive spins* (i.e., spins P_i that are coupled to the active spins in the evolution and/or detection periods). Such coupling partners should give rise to cross-peak multiplets in other parts of the two-dimensional spectrum, though in systems with many degeneracies among the shifts this evidence is perhaps not unequivocal. Nevertheless, a hypothesis regarding the existence and chemical shifts of coupling partners is likely to be available, not only in manual analysis, but also as a result of a computer-supported analysis of a survey spec-

trum.[3,4,13-15] This typically yields various proposals of *fragments* of the coupling network.[3,4,15] Usually, there are too many proposals of this type, often mutually exclusive, and even if they can be ranked by some sort of likelihood function,[3,4,15] it is not easy to discriminate proposals that are reasonable from those that are not. In this communication, we present a variant of soft-COSY that allows one not merely to focus on a multiplet of interest, but also to test a hypothesis about the identity of one or more passive spins. The method is shown to be particularly powerful when multiplets belonging to different coupling networks (e.g., to different isomers or different amino acid residues) partly or completely overlap.

Figure 1a shows the pulse sequence suitable for a soft-COSY experiment,[12] which may be regarded as a selective version of *z*-filtered COSY.[9,10] The sequence comprises three semiselective Gaussian 270° pulses which affect the magnetization of one multiplet (or set of overlapping multiplets) at a time. The first two of these pulses, which precede and follow the evolution interval t_1, are centered at the carrier frequency Ω_{A1}. The third pulse, which precedes the detection period t_2, is applied at Ω_{A2}. These three pulses achieve a similar effect as in selective two-dimensional exchange spectroscopy (soft-NOESY),[16,17] except that the

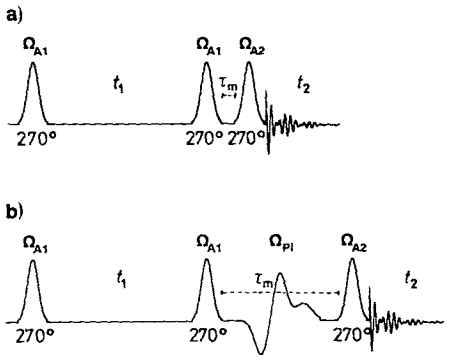

Fig. 1a. Pulse sequence for normal soft-COSY using three self-refocusing 270° Gaussian pulses.[17] The first two pulses are applied at the frequency Ω_{A1} and the last at Ω_{A2}. b) The sequence for soft-COSY with selective inversion of a passive coupling partner P_i (selectively-inverted-soft-COSY, or SIS-COSY), where a G^3 Gaussian pulse cascade[19] has been inserted in τ_m at frequency Ω_{Pi}. The G^3 cascade is a pulse of duration t_p having an envelope consisting of a superposition of three Gaussians with maxima at 28.7, 50.8 and 79.5% t_p, half-height widths of 18.9, 18.3 and 24.3% t_p and relative amplitudes of $-1:1.37:0.49$. The total amplitude of the cascade was adjusted to obtain an overall on-resonance flip-angle of 180°. In both sequences (a & b) the phase of the first pulse is alternated through 0 and 180° in conjunction with addition and subtraction of the signals.

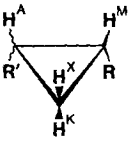
interval τ_m between the last two pulses is so short that no significant relaxation effects can occur. An important advantage of this technique is that there can be no signal contributions from zero-quantum coherences,[17] which is a major disadvantage of normal *z*-COSY.[9,10] The Gaussian envelope and 270° on-resonance flip angle of the pulses allow one to obtain good frequency selectivity with much reduced phase errors when compared to an experiment using soft 90° pulses.[17,18] If even better selectivity and phase properties are required, a more sophisticated pulse, such as a "G^4 cascade",[19] should be used. Although such longer pulses make the experiment more sensitive to relaxation, the sequences are nevertheless still short compared to typical transverse relaxation times, and in the limit where relaxation is so fast as to obliterate the fine structure of the multiplet there is no need for a soft COSY experiment in any case. So far, we have not encountered any problems with relaxation in this type of experiment.

The basic cross-peak pattern in all COSY-type spectra consists of a square spanned by two positive and two negative peaks (filled and open symbols in Fig. 2) separated by the active coupling J_{A1A2} in both frequency domains. If the spin system contains a passive spin P_i that is coupled to both active spins A_1 and A_2, and provided that the polarization of P_i is not affected in the pulse sequence, one obtains two basic patterns displaced with respect to each other by a vector $\boldsymbol{J}_{Pi} = (J_{A1Pi}, J_{A2Pi})$. If both components of this displacement vector are non-vanishing, we speak of a *common* passive coupling partner. If there are N passive spins, there are 2^N basic patterns. Figure 2a shows a typical cross-peak multiplet in a four-spin system, with couplings corresponding to the A^{cis}-X^{cis} cross-peak of *cis* 2-phenylcyclopropanecarboxylic acid methyl ester *cis*-**1** (R = $COOCD_3$, R′ = C_6H_5).



1

The four basic patterns are displaced with respect to each other by $\boldsymbol{J}_M = (J_{AM}, J_{XM}) = (7.7, 9.2\ \text{Hz})$ and $\boldsymbol{J}_K = (J_{AK}, J_{XK}) = (7.5, -5.1\ \text{Hz})$. It is possible to change the apparent sign of the second (horizontal) component of the displacement vector by selectively inverting a passive spin during the interval τ_m. This allows one to manipulate the pattern of the multiplet. If all of the passive spins are inverted one obtains a pattern like in complementary E.COSY[7] or anti-*z*-COSY[9] with displacement vectors $\boldsymbol{J}'_M = (J_{AM}, -J_{XM})$ and $\boldsymbol{J}'_K = (J_{AK}, -J_{XK})$. If, on the other hand, only the passive M proton is inverted selectively, one expects the multiplet shown in Figure 2b with displacement vectors $\boldsymbol{J}'_M$ and $\boldsymbol{J}_K$, while inversion of the passive K proton leads to the multiplet in Figure 2c with displacement vectors $\boldsymbol{J}_M$ and $\boldsymbol{J}'_K$. In effect these new experiments allow us to explore the energy-level diagram and the connectivity diagram[4] of the spin system systematically. In a normal *z*-COSY experiment we observe only correlations between transitions that share common energy-levels, while in anti-*z*-COSY we observe only remotely connected transitions.[9] If only selected coupling partners are inverted we are able to correlate transitions that are remote with respect to the inverted passive spins and connected for the other spins.

Figure 1b shows a pulse sequence suitable for achieving the multiplet manipulations described above. We have inserted a cascade of Gaussian pulses (a so-called "G^3 cascade") in interval τ_m of Figure 1a in order to invert the magnetization over a well-defined rectangular frequency window.[19] The performance of an ordinary Gaussian 180° pulse was found to be insufficient in this experiment, since it was not possible to achieve complete inversion without affecting the other multiplets. The carrier frequency of the pulse cascade is adjusted to a trial frequency Ω_T which should correspond to the chemical shift of a spin that is suspected of playing a passive role. If inversion leads to a new pattern, this provides evidence that Ω_T is indeed the frequency Ω_{Pi} of the passive spin P_i, and the resulting pattern can be analyzed to obtain the magnitudes and relative signs of the passive coupling constants J_{A1Pi} and J_{A2Pi}. If no effect is observed, then the spin with the shift Ω_T can be excluded as a common

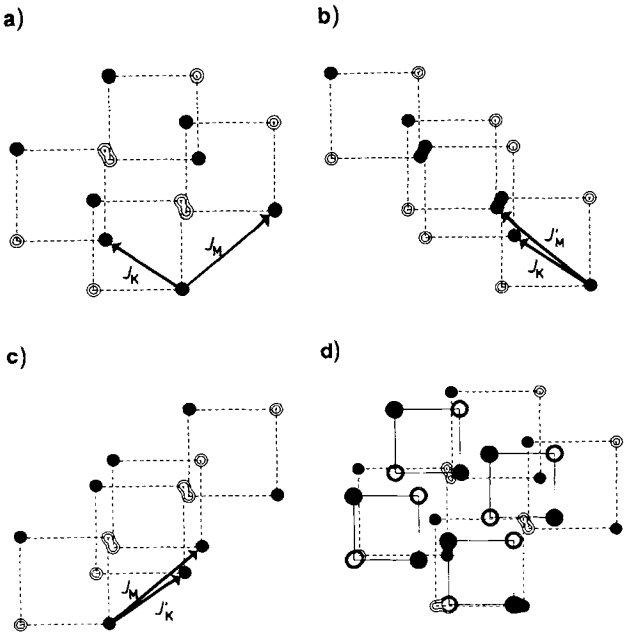


Fig. 2. Simulated A–X multiplets corresponding to *cis* and *trans* isomers of **1**. Protons A and X are coupled to both M and K in each isomer. The shifts of the active spins are pairwise nearly degenerate $\Omega_{Acis} \approx \Omega_{Atrans}$, $\Omega_{Xcis} \approx \Omega_{Xtrans}$, and the active and passive couplings are all in the range of -5.1 to $+10$ Hz. a) Simulated A^{cis}–X^{cis} multiplet as obtained with the sequence of Figure 1a. b) Simulated multiplet, corresponding to selective inversion of the passive spin M^{cis} in the sequence of Figure 1b. c) Simulated multiplet corresponding to selective inversion of the passive spin K^{cis}. The displacement vectors J_M and J_K are affected as described in the text. d) Simulation corresponding to the superposition of the two cross-peak multiplets A^{cis}-X^{cis} and A^{trans}-X^{trans} with relative intensities of 1:3.

passive spin. Note that if P_i is coupled to only one of the active spins, selective inversion will not affect the pattern. This corresponds to the case where J_{Pi} has one component equal to zero.

Figure 2d shows a simulation of the superposition of two A–X cross-peaks arising from a 1:3 mixture of the *cis* and *trans* isomers of the same compound. Neither of the two patterns has been manipulated by selective inversion. Clearly, such a superposition is very difficult to analyze. However, the new experiment presented above provides a simple and effective procedure for separating overlapping multiplets. Figures 3a and b illustrate how overlapping experimental multiplets are modified if one of the passive spins (of the minor *cis* isomer in these examples) is inverted using the sequence shown in Figure 1b. Of course, the multiplet belonging to the major *trans* isomer remains invariant, so that the difference spectrum shown in Figure 3c features *only* a multiplet of the minor *cis* isomer. This latter multiplet contains two sets of four basic square patterns, half of which have opposite phase to the usual situation of Figure 2a. It may be appreciated that the multiplet in the difference spectrum of Figure 3c possesses C_{2v} symmetry, unlike the C_2 symmetry of ordinary multiplets in E.COSY or *z*-COSY.[14] In our experimental example, no residual peaks from the *trans* isomer were left after subtraction, but any misleading residual could have been removed by C_{2v} symmetrization.

The difference procedure illustrated in Figure 3c is of course not restricted to four-spin systems. It can be used to extract a partly or completely hidden multiplet of an arbitrary fragment, provided it contains at least one *common* passive spin (i.e., coupled to *both* active spins), and provided the chemical shift of this passive spin is not accidentally degenerate with that of a passive spin belonging to other fragments that give rise to overlapping cross-peaks in the same region. These constraints do not appear to be too restrictive, so that the new selectively inverted soft COSY (SISCOSY) technique should be useful in many practical situations. The new method is not only useful to unravel overlapping multiplets, but also to verify a hypothesis about the identity of one or more passive spins. The procedure

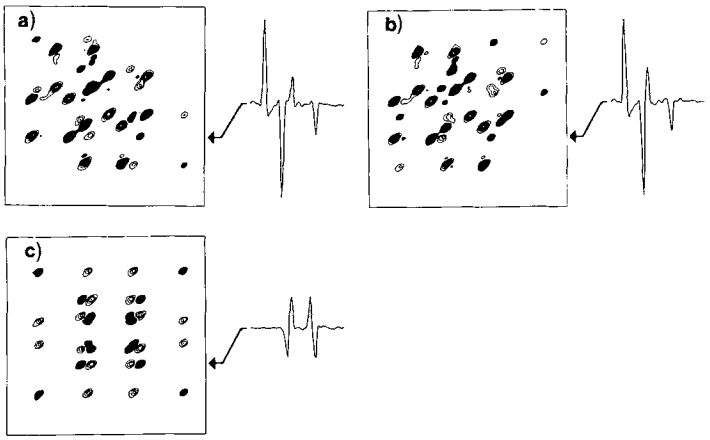

Fig. 3. Experimental multiplets corresponding to a 1:3 mixture of *cis* and *trans* isomers of **1**. a) Multiplets obtained with selective inversion of the passive spin M^{cis} using the sequence of Figure 1b. b) Multiplets obtained with selective inversion of the passive spin K^{cis}. c) Difference of (a) and (b), leading to a multiplet of the minor *cis* isomer only. Cross-sections show the amplitudes of the signals due to the major *trans* and minor *cis* isomers. The multiplets were all obtained using a Bruker AM 400 spectrometer equipped with an Oxford Research Systems Selective Excitation Unit. The 270° pulses were all 40 ms in duration and the inversion pulses had a duration of 110 ms. The matrices consisted of 100 × 1024 data points before and 512 × 1024 data points after zero filling and Fourier transformation; no weighting functions were applied to the data. The spectral widths in the ω_1 and ω_2 domains were 40 and 250 Hz, only a section of 35 × 35 Hz is shown in the figures.

allows one to record routine survey COSY spectra with much reduced resolution, and the time saved can be used to investigate selected areas in detail if required. Typically the spectrum of a single multiplet can be recorded in only 2–20 minutes, depending on the relaxation time and the desired degree of resolution.

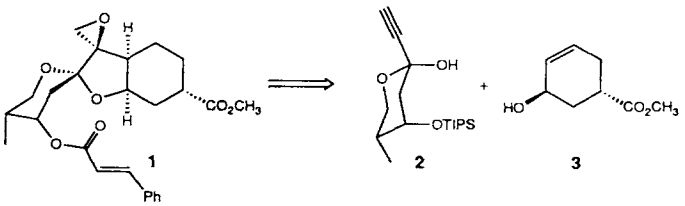
Synthesis of (±)-Phyllanthocin via a Metal-Catalyzed Cycloreduction**

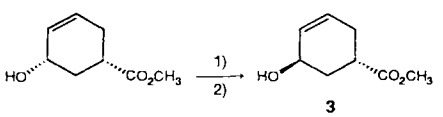
By *Barry M. Trost** and *Eric D. Edstrom*

The novel molecular architecture and promising biological activity of phyllanthoside[1] has made its aglycone, phyllanthocin (**1**),[2] an attractive synthetic target.[3] The development of a cycloisomerization[4] and of a reductive cyclization[5] of enynes under very mild conditions suggested a convenient convergent strategy from two relatively simple building blocks of about equal size (cf. Scheme 1). The failure of many transition-metal-catalyzed reactions with more elaborate structures led us to test the feasibility of such processes for the construction of oxygen heterocycles in general[6] and to assess the feasibility of its applicability for complex molecule construction by undertaking a synthesis of (±)-phyllanthocin (**1**).



Scheme 1.

The known cyclohexenol **3**[7] is conveniently available from the *cis*-diastereomer[8] in 85% yield by application of the Mitsunobu reaction (Scheme 2).[9]



Scheme 2. Synthesis of the cyclohexenol component **3**. 1) PPh_3, DEADCAT ($C_2H_5O_2CN{=}NCO_2C_2H_5$), HCO_2H, THF; 2) $KHCO_3$, CH_3OH.

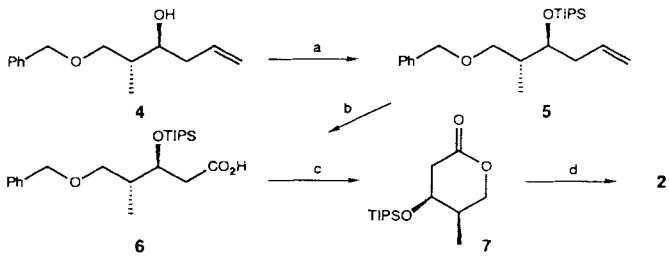
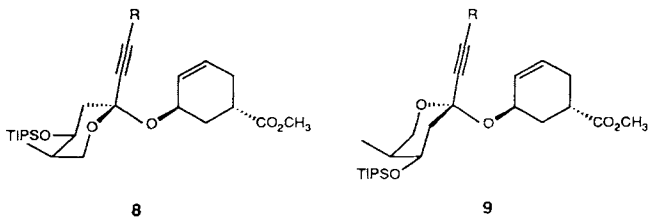
The lactol **2** is available in four steps from the known (2*R**,3*S**)-2-methyl-1-(phenylmethoxy)hex-5-en-3-ol (**4**)[10] (Scheme 3). The choice of protecting group proved crucial owing to the ease of β-elimination during nucleophilic additions to lactone **7**. The triisopropylsilyl protecting group (TIPS) proved efficacious both in terms of its introduction and removal, as well as in terms of its chemical stability in subsequent transformations.[11] Oxidative olefin cleavage proceeded efficiently with buffered potassium permanganate under phase transfer conditions[12] or, for this particular substrate, using the *Lemieux* and *von Rudloff* protocol.[13] Hydrogenolysis of the benzyl ether **6** followed by acidification produces the lactone **7**.[14] Maintaining the acetylide addition at −78 °C followed by quenching with methanol:acetic acid (10:1) prevents the undesired β-elimination. In this way, the lactol **2**[14] is available in 68% overall yield from olefin **4**.



Scheme 3. Synthesis of the lactol component **2**. a) TIPS-OSO_2-CF_3, 2,6-lutidine, CH_2Cl_2, 99%. b) $NaIO_4$, $KMnO_4$ (cat.), *tert*-C_4H_9OH, H_2O, RT, pH 7. c) H_2, 10% Pd/C, C_2H_5OH, directly thereafter pyridinium *p*-toluenesulfonate, 5 Å molecular sieve, benzene, 74% overall yield referred to **5**. d) $(CH_3)_3SiC{\equiv}CLi$, THF, −78 °C, 93%. TIPS = $[(CH_3)_2CH]_3Si$.

The glycosidic coupling event entails treating a solution of the lactol **2** with 2 equivalents of hydroxy ester **3** in benzene (0.3 M) containing K 10 montmorillonite clay[15] and powdered 5 Å molecular sieves at room temperature (75% yield). Due to the fact that our starting materials are racemic, a mixture of **8a**[14] and **9a** is produced which cleanly separates after desilylation to **8b**[14] and **9b**[14] (K_2CO_3, CH_3OH, 0 °C) (Scheme 4). The production of such a mixture does not



Scheme 4. Products of the reaction of **2** with **3**. **a**, R = $(CH_3)_3Si$; **b**, R = H.

constitute a shortcoming of the synthesis since it can be totally avoided simply by using enantiomerically pure building blocks **2** and **3**.[16] For our purposes, exploring the cyclization of both isomers (**8b** and **9b**) is desirable. Using carefully defined catalytic conditions with proper choice of silane effects (Scheme 5) excellent yields (86% and 78% of **10a**[14] and **11a**,[14] respectively) of the requisite polyhydrobenzofurans. For characterization, **10a** and **11a** were

were completely replaced within 1 h by a new set of signals attributable to the expected selenepine **1c** without evidence of other products (see Table 1). When the solution was allowed to warm to room temperature, **1c** extruded selenium to give diethyl 4,5-di-*tert*-butylphthalate (**9**) quantitatively; this reaction is consistent with the structure of **1c**. Nonetheless, attempted isolation of pure **1c** met with failure due to contamination with **9** even at low temperature. This provides a striking contrast to the pronounced thermal stabilities of 2,7-di-*tert*-butylthiepine and its derivatives.[5]

The clean extrusion of selenium from **1c** to give **9** obeys first-order kinetics in the temperature range 15–35 °C (^{1}H-NMR monitoring in $CDCl_3$).[8] An Arrhenius plot of the data gives the following approximate activation parameters: $\Delta H^{\neq} = 26$ kcal mol^{-1}, $E_a = 26$ kcal mol^{-1}, $\Delta S^{\neq} = 9.3$ J K^{-1}.

The corresponding activation parameters for the sulfur extrusion reaction of ethyl 2,7-di-*tert*-butyl-5-methyl-4-thiepinecarboxylate (**10**) are $\Delta H^{\neq} = 22.4 \pm 3.4$ kcal mol^{-1}, $E_a = 23.3 \pm 3.4$ kcal mol^{-1}, and $\Delta S^{\neq} = -26.9 \pm 3.7$ J K^{-1}.[9] Most conspicuous is the large difference in the activation entropies. The large negative $\Delta S^{\neq}$ value for the thiepine can be attributed to severe nonbonding interaction between two *tert*-butyl groups in a thianorcaradiene intermediate.[10] On the other hand, the selenium extrusion reaction of the selenepine **1c** presumably proceeds via incipient fission of a C–Se bond, whereby the bulky *tert*-butyl groups at the 2- and 7-positions do not play a decisive role. The detailed pathway of the selenium-extrusion reaction must await further study. Nonetheless, our work clearly shows that, although detailed studies on selenophene have confirmed its striking similarity to thiophene, the thermal stability of the vinylogous selenepine is markedly different from that of thiepine.

Facile Synthesis of a β(1-3)-Linked gal-galactal Disaccharide and Its Use in *N*-Iodosuccinimide-Activated *O*-Glycopeptide Synthesis **

By *Horst Kessler*,* *Andreas Kling*, and *Matthias Kottenhahn*

α-*O*-Glycopeptides with gal-β(1-3)-gal*N*Ac disaccharide building blocks are widespread in Nature.[1] The disaccharide gal-β(1-3)-gal*N*Ac forms the core A of many *O*-glycopeptides, and, moreover, has been identified as the immune-determining structural unit of a tumor associated antigen, of the so-called T-antigen (*T*homson-Friedenreich antigen).[2] Since T-specific immunoreactive structural units have been detected in certain types of carcinoma but not in healthy tissues, the T/anti-T system could prove useful in the diagnostics of cancerous diseases.[3] The keen interest being shown in T-antigen structures is evident from the numerous works on the synthesis of the core A disaccharide[4] and corresponding *O*-glycopeptides.[5]

In our investigations of the synthesis of 2-deoxyglycopeptides by *N*-iodosuccinimide(NIS)-activated addition of amino acids and peptides as glycosyl acceptors to glycals[6, 7] we therefore also checked the addition of amino acid derivatives to the gal-β(1-3)-galactal building block **1** (Fig. 1).

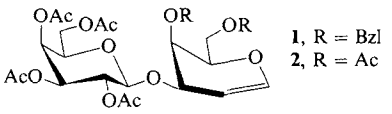

Fig. 1. Protected gal-β(1,3)-galactal disaccharide.

A twelve-step synthesis of the disaccharide **2** (11.5–14% overall yield) has already been described by *Bencomo, Jacquinet* and *Sinay*.[4b] This route appeared to us to be too tedious for such a small overall yield. Therefore, the strategy employed in our synthesis of the disaccharide glycal **1** is based on another concept (Scheme 1).

First, the 3-OH-unprotected galactal derivative **5** is generated by selective benzylation of the 4-OH and 6-OH functions of galactal **4**. Subsequently, **5** and **3** are coupled under Koenigs-Knorr conditions to give the disaccharide glycal **1**.

The selective introduction of protecting groups into **4** constitutes the major problem of this synthetic concept. According to *Kinzy* and *Schmidt*[8] a selective silylation of the 4-OH and 6-OH functions of galactal **4** is not possible; also in the benzoylation of **4** it emerged that the allylic 3-OH function is clearly more reactive than the 4-OH function;[9] according to *Holla*,[10] a selective enzymatic deacetylation of peracetylgalactal is, other than in the case of the glucal analogue, likewise not possible. In contrast, selective benzylation of the 4-OH and 6-OH functions can be achieved, as shown in Scheme 1. The byproduct of this reaction is the perbenzylated galactal.

Flowers[11] had already demonstrated with methylgalactopyranosides that the 4-OH group is more reactive in the benzylation, and, in 1983, *Bovin* et al.[12] described a possible

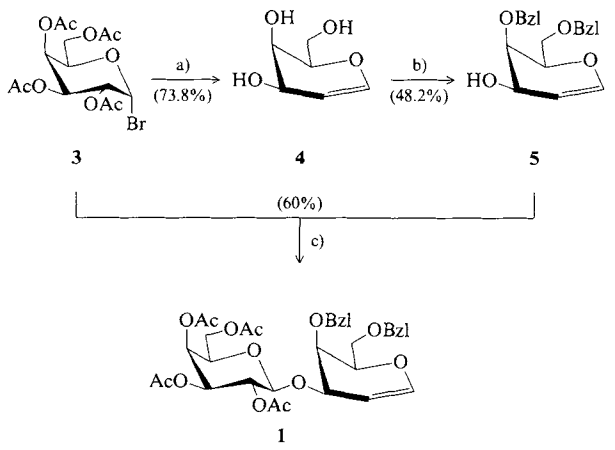

Scheme 1. Synthesis of the disaccharide glycal 2',3',4',6',-tetra-*O*-acetyl-D-galactopyranosyl-β(1-3)-4,6-di-*O*-benzyl-D-galactal **1** in 21.3% overall yield in four steps. a) 1) Zn/glacial acetic acid (90%); 2) KCN/methanol (82%). b) Dimethylformamide (DMF), 2.2 equiv. NaH, 0 °C, 2 h; 2.2 equiv. benzyl bromide BzLBr, 0 °C, 3 h. c) 1.8 equiv. Ag_2CO_3/0.2 equiv. Ag-triflate, 2.7 equiv. **3**, CH_3NO_2, RT, 2 h.

synthesis of 4,6-di-*O*-benzyl-D-galactal by reaction of galactal with NaH/benzyl bromide, but attached little importance to this fact, for they synthesized the glycal **5** in eleven steps with 13.5% overall yield via another route. The entry to **5** according to Scheme 1 seems distinctly superior to such a complex synthesis.

The coupling of **5** and **3** under Koenigs-Knorr conditions to give **1** necessitates a careful choice of catalyst. The allylic enol-acetal structure of the product can easily lead in the presence of nucleophiles and catalytic amounts of Lewis acid to side reactions in which complex mixtures of disaccharides are formed. The combination of reagents quoted in the caption to Scheme 1 have proven to be the most suitable for the synthesis (Table 1); they afforded **1** in ca. 21% overall yield.

The disaccharide glycal **1** was now allowed to react under conditions of NIS activation[6, 14] with the amino acid building block Fmoc-Ser-OBzl. Thereby it showed the expected high reactivity (83.5% overall yield). However, the almost complete α-diastereoselectivity observed in the addition to monosaccharide glycals[6] could not be achieved. Besides the desired 1,2-*trans*-α-product **6** (250 MHz ^{1}H-NMR: $^3J(1, 2) = 2.7$ Hz), both the 1,2-*trans*-β-product **7** (270 MHz ^{1}H-NMR: $^3J(1, 2) = 9$, $^3J(2, 3) = 7.4$ Hz) as well as the 1,2-cis-α-product **8** (270 MHz ^{1}H-NMR: $^3J(1, 2) = 3.78$, $^3J(2, 3) = 11.2$ Hz) were formed (Fig. 2). Because of the increased reactivity of the enolic double bond[12] *both* possible iodonium structures are formed, thus explaining formation of the products **6**–**8**. Owing to the high electron density of the arene substituents on C-4 and C-6, respectively, an opening of the α-iodonium intermediate to give the C-1 carbocation can result, whereby formation of the 1,2-*cis* product **8** is possible. **6** and **8** furnish the same 2-deoxy-α-O-glycosylamino acid after deiodination.

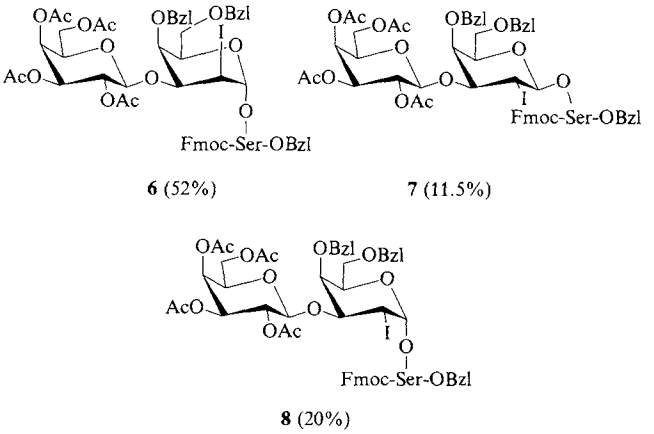

Fig. 2. Products and yields in the NIS-activated addition of Fmoc-Ser-OBzl to disaccharide glycal **1**.

In immunological tests it could be shown that a partial structure of asialoglycophorin A with the amino acids 43–48 exhibits a strong T-antigen activity.[15] After *Paulsen* et al.[5c] had synthesized the linear diglycohexapeptide we directed our attention to the synthesis of the corresponding cyclic peptide analogue cyclo(Val^{43}-Ser-Glu(OBzl)-Ile-Ser-D-Val^{48}) **9** and its conversion into the 2-deoxy-analogue of the T-antigen by direct glycosidation according to the NIS method.

The linear hexapeptide was obtained in a convergent synthesis according to the classical methods of peptide chemistry. Subsequent azide cyclization[16] and HPLC purification afforded the cyclic hexapeptide **9** in 37% yield.[17]

Reactions leading to *O*-glycopeptides according to the NIS method proceed with distinctly better yields at higher temperatures; nevertheless, the glycosidation of **9** could only

be carried out at room temperature because of its thermolability. The crude product obtained (33% yield) after work-up[6] and silica gel filtration ($CHCl_3$/acetone 4/1, subsequent elution of the product with 2-propanol) shows exclusively the molecular peak for a monoglycosidation product ($M + Na^{\oplus} = 1509$) in the FAB mass spectrum. Investigations concerning the exact structure are currently under way.

Herein we have described a simple synthesis of the versatile disaccharide glycal **1** and its use in *O*-glycopeptide synthesis. In the case of the addition to Fmoc-Ser-OBzl using the NIS method, a diastereomeric mixture is formed which also contains an unexpected *cis*-addition product. The desired α-epimer, however, is formed in appreciable excess.

Experimental

5 (M = 326.39, $C_{20}H_{22}O_4$): A stirred solution of **4** (8.9 mmol) in 14 mL of anhydrous DMF under argon was treated at 0 °C with 19.58 mmol of NaH (60% in mineral oil). After 2 h at 0 °C the mixture (suspension) was treated dropwise and rapidly with 19.58 mol of BzlBr and then allowed to stand for 3 h at 0 °C. The mixture solidified. It was then thawed out, treated with 50 mL of benzene, washed with 20 mL of water, the aqueous phase back extracted with 3 × 15 mL of benzene and the combined organic phases finally evaporated to dryness in a vacuum (water pump). The residue was purified by chromatography on silica gel with ethyl acetate/isohexane 3/5. The main fraction contained (1.4 g = 48.2%) of **5**. One secondary fraction (39%) contained perbenzylated **4**, a further secondary fraction (8%) another dibenzylated **4**. Oily **5** crystallized out on cooling the main fraction and could be recrystallized from isohexane. M.p. = 65 °C (68 °C [14]), $[\alpha]_D^{20} = 12.06$ ($c = 0.6$ in $CHCl_3$) ($[\alpha]_D = -17$ [14]) (no details of temperature and solvent); the rotation quoted by us was reproduced several times). $R_f = 0.64$ (ethyl acetate/isohexane 1/1), 0.37 (ethyl acetate/isohexane 1/2).—250 MHz ^{1}H-NMR ([D$_6$]DMSO): $\delta = 7.15-7.4$ (m, 10H, H_{phenyl}), 6.27 (dd, 1H, H-1, $^3J(1,2) = 6.19$, $^4J(1,3) = 1.75$ Hz), 4.86 (d, 1H, OH-3, $^3J(OH,3) = 5.83$), 4.85, 4.5 (je d, 2H, Ph-CH_2), 4.46 (d, 2H, Ph-CH_2), 4.63 (ddd, 1H, H-2, $^4J(2,4) = 1.39$ Hz), 4.35 (m, 1H, H-3), 4.14 (m, 1H, H-5), 3.72 (dd, 1H, H-4), 3.7–3.53 (m, 2H, H-6).—75 MHz-^{13}C NMR ($CDCl_3$): $\delta = 144.2$ (C-1), 137.7 (quarternary C_{phenyl}), 127.8–128.6 (C_{phenyl}), 102.9 (C-2), 75.2 (C-5), 74.2, 73.5 (Ph-CH_2), 73.2 (C-4), 68.1 (C-6), 62.8 (C-3).

1 (M = 656.68, $C_{34}H_{40}O_{13}$): A suspension of 300 mg of molecular sieve, 100 mg of calcined $CaSO_4$ and 0.55 mmol of Ag_2CO_3/0.061 mmol Ag-triflate in 5 mL of nitromethane was prepared in a pre-heated dark glass flask and stirred for 1 h at room temperature. 0.826 mmol of **3** co-evaporated with toluene was subsequently dissolved in 5 mL of nitromethane and added to the catalyst suspension at room temperature. After 15 min, solid **5** (0.306 mmol) was added and the mixture stirred for 2.0–2.5 h. The reaction mixture was now filtered through celite into an excess of toluene. After evaporation to dryness in a Rotavapor (35 °C) the residue was extracted with diethyl ether/water. The residue remaining after evaporation of the diethyl ether phase was chromatographed on silica gel with diethyl ether/isohexane 4/1. 120 mg of of colorless oil = 60%, $[\alpha]_D^{20} = -42.5$ ($c = 1.3$ in $CHCl_3$), $R_f = 0.23$ (diethyl ether/isohexane 4/1).—250 MHz ^{1}H-NMR ($CDCl_3$, interner standard TMS): $\delta = 7.2-7.4$ (m, 10H, H_{phenyl}), 6.37 (dd, 1H, H-1, $^3J(1,2) = 6.4$, $^4J(1,3) = 1.9$ Hz), 5.4 (dd, 1H, H-4', $^3J(4',5') = 1.5$ Hz), 5.27 (dd, 1H, H-2', $^3J(2',3') = 10.45$ Hz), 5.03 (dd, 1H, H-3', $^3J(3',4') = 3.53$ Hz), 4.9, 4.56 (each d, 2H, Ph-CH_2), 4.70 (m, 1H, H-2, $^3J(2,3) = 7.9$ Hz), 4.63 (d, 1H, H-1', $^3J(1',2') = 7.97$ Hz), 4.54 (m, 1H, H-3), 4.42 (dd, 2H, Ph-CH_2); 4.14, 4.15 (m, 3H, H-5, H-6', superposed), 3.91, 3.92 (m, 2H, H-5', H-4, superposed) 3.52–3.68 (m, 2H, H-6), 1.95–2.15 (4 × s, 12H, CO-CH_3).—62.9 MHz-^{13}C NMR ($CDCl_3$): $\delta = 169.1-170.3$ (CO-CH_3), 144.8 (C-1), 137.9–138.5 (quarternary C_{phenyl}), 127.5–128.3 (C_{phenyl}), 99.5 (C-1'), 98.4 (C-2), 75.75 (C-5), 73.2 (Ph-CH_2), 71.0, 70.8 (C3, C4, C3', C5'), 68.8 (C-2'), 68.4 (C-6), 67.0 (C-4'), 61.2 (C-6'), 20.5–20.6 (4 × CO-CH_3).

Permethyl-β-cyclodextrin, Chemically Bonded to Polysiloxane: a Chiral Stationary Phase with Wider Application Range for Enantiomer Separation by Capillary Gas Chromatography**

By *Peter Fischer,* Reiner Aichholz, Uwe Bölz, Markus Juza* and *Sigfried Krimmer*

Dedicated to Professor Franz Effenberger on the occasion of his 60th birthday

The use of *O*-derivatized cyclodextrins as chiral stationary phases in capillary gas chromatography has attracted increasing interest in recent years.[1–3] So far, capillary columns have been described which are statically coated with differently derivatized cyclodextrins[1,3] (these are also commercially available), as well as columns where a physical mixture of polysiloxane and cyclodextrin is employed as stationary phase (e.g. OV-1701 with 10% permethyl-β-cyclodextrin[2]). Some spectacular GLC enantiomer separations have been achieved with these phases; unfortunately, individual separation problems frequently require a specially tailored derivatization of the cyclodextrins (e.g. tripentyl-, dipentyl/acetyl- etc.).[3] Pure cyclodextrin phases present the additional disadvantage that the inevitably polar chiral selector is also used for building the phase backbone, which thence obtains an unnecessarily polar character.

We have attempted, therefore, to utilize the building principle of chiral amide phases, such as Chirasil-val,[4] also for cyclodextrin phases, and to likewise *chemically* bond this chiral selector to a polysiloxane backbone. Thus, more generally applicable, perhaps even thermally and chemically

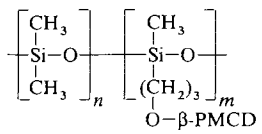
[**] Chiral Recognition in Capillary Gas Chromatography, Part 3. For generous support of this work, we are indebted to Carlo Erba Instruments. D-6238 Hofheim (FRG). – Part 2: R. Aichholz, U. Bölz, P. Fischer, *HRC CC J. High Resolut. Chromatogr. Chromatogr. Commun. 13* (1990), in press.

more stable cyclodextrin phases should obtain. In this communication, we report first results with a chiral phase, derived from poly(dimethylsiloxane) which has been modified with ca. 5% of permethyl-β-cyclodextrin (PMCD) as chiral side chain (Scheme 1).



Scheme 1. Structure of the poly(dimethylsiloxane)-cyclodextrin phase; $m:n = 1:20$, i.e. ca. 5% chiral side chain.

The synthesis of this material starts with the reaction of allyl bromide with β-cyclodextrin.[5] Allyloxy groups are formed from ca. 30% of the OH groups in the 6-position. The remaining free OH groups are subsequently subjected to exhaustive methylation (NaH in Me_2SO/CH_3I). The *O*-allylpermethyl-β-cyclodextrin thus obtained is bonded *via* hydrosilylation (catalyst H_2PtCl_6)[6] to a polysiloxane, containing 7% Me-Si-H besides 93% Me_2Si groups. Unconsumed Si-H is alkylated in a final step. The crude phase material is purified by repeated reprecipitation, and statically coated onto an appropriately silylated glass surface. A capillary column, prepared in this manner, may be used, with temperature programming, up to 280 °C without either serious bleeding or notable racemization, even though the stationary phase is neither cross-linked nor chemically bonded to the glass surface.

The enantiomeric resolution potential of the new phase is demonstrated in Figure 1 for a series of alkanediols. The diols were analyzed as a batch, *without* derivatization (4°/min temperature program). The chromatogram shows baseline, or at least 90% valley separation for all *R*/*S* pairs. So far, gas chromatographic separation of enantiomeric diols required trifluoroacetylation[3g] and/or recording under isothermal conditions.[7] The weak tailing of all the diol peaks, despite two free OH groups, bears witness to the inertness of the column and the new phase.[8]

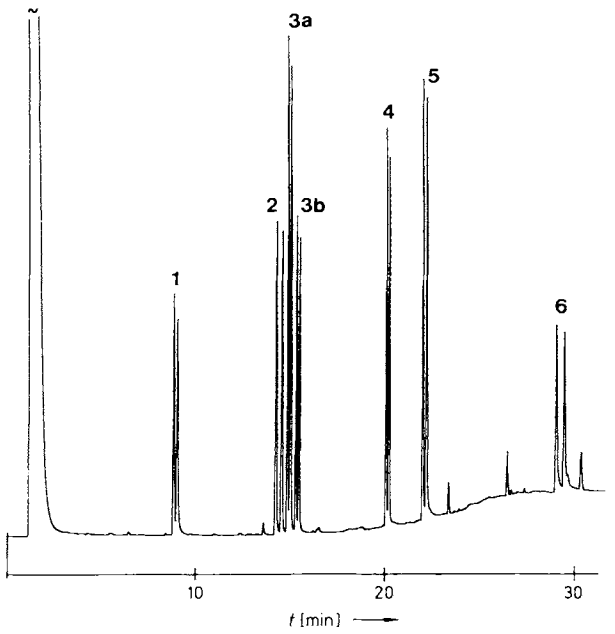


Figure 1. Enantiomer separation of alkanediols: 30 m × 0.3 mm glass capillary, statically coated with poly(dimethylsiloxane), modified with 5% trimethylenoxypermethyl-β-cyclodextrin side chain (see text); 0.8 bar H_2; 100–220 °C; 4°/min; FID detection. **1** = 1,2-pentanediol; **2** = *trans*-1,2-cyclohexanediol; **3a,b** = 2-cetyl-1,3-hexanediol (pair of diastereoisomers); **4** = 1-cyclohexyl-1,2-ethanediol; **5** = 1-phenyl-1,2-ethanediol; **6** = 1-(4-chlorophenyl)-1,2-ethanediol.

Excellent chiral resolution is likewise obtained for the methyl esters of α-hydroxycarboxylic and dicarboxylic acids (without α-OH derivatization; see Table 1, Fig. 2a). Even α-bromomethylcarboxylates are baseline-separated (Fig. 2b).[9] The separation factors (α-values, see Table 1) naturally decrease rapidly with increasing distance between the stereogenic center and the COOR function; however, 4-bromomethylhexanoate, is still clearly separated.

The new phase likewise resolves optically active alkanoic acids, in free, underivatized form, into the enantiomers (Fig. 2c). Even compounds lying more or less at extremes of

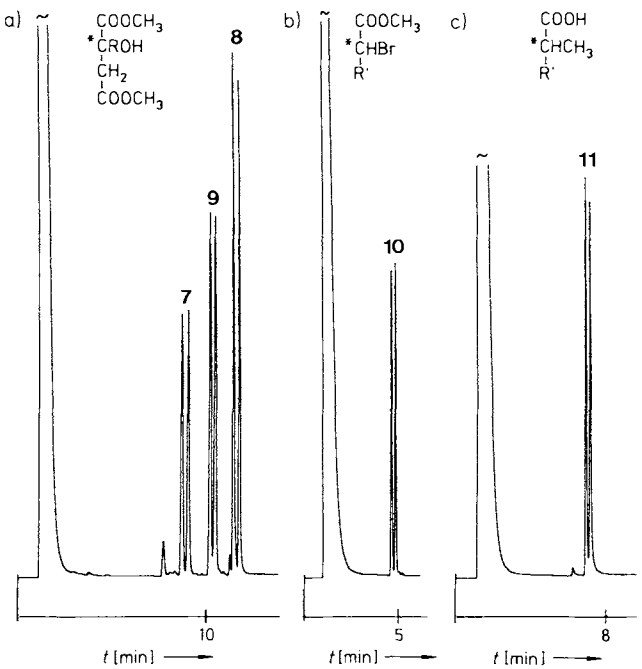

Figure 2. Enantiomer separation on the chiral phase glass capillary, described in Figure 1 of a) malic, 2-ethylmalic acid methyl esters and 2-methylmalic (citramalic), **7** (R = H), **8** (R = Et) and **9** (R = Me), respectively; b) methyl-2-bromohexanoate **10** (R' = *n*Bu); c) 2-methylhexanoic acid, underivatized, **11** (R' = *n*Bu); **7** (R = H), **8** (R = Et) and **9** (R = Me), respec.; conditions as given in Figure 1.

the polarity range, such as chiral alkanes and, for example, methyl-*N*-acetylprolinate, are fully *R*/*S*-resolved in one run on the same column (see Table 1).

A further advantage of the new material is that, if derivatization is required, acetylation suffices, as demonstrated by the separation of the cyanohydrins (Table 1).[10] The chiral resolution for *R*- and *S*-benzaldehydecyanohydrin ($\alpha = 1.3$) lies at the upper limit of all gas-chromatographic enantiomer separations reported so far. The extraordinarily high basic resolution in the case of the structural unit, -C*H(OH)CN enables the smooth resolution of other cyanohydrins, and even of the *o*-chlorobenzaldehyde derivative (see Table 1).

So far, only amines and amino alcohols have proven problematical. Most likely, these classes of compounds require

Organometallic Macrocycles: Synthesis and Molecular Structure of Trimeric Tartratodiruthenium Complexes**

By *Georg Süss-Fink,* Jean-Luc Wolfender, Frank Neumann,* and *Helen Stoeckli-Evans*

It has been known since 1969 that dodecacarbonyltriruthenium reacts with carboxylic acids to give carboxylato complexes containing the $Ru_2(CO)_4(\mu\text{-}OOCR)_2$ structural unit.[1] In the solid state, these complexes form polymer chains in which the dinuclear building blocks are coupled via Ru–O bonds;[2, 3] in solution, the chains depolymerize with uptake of two-electron ligands.[1] The X-ray structure analysis of the bis(tri-*tert*-butylphosphane) derivative **1** shows a molecule with a characteristic saw-horse structure.[4] Of the dicarboxylic acid derivatives, complex **2**, which has been described as a polymer,[5] and the dinuclear complex **3** have already been reported.[6] The X-ray crystallographic investigation of a glutaratotributylphosphane compound of composition **4** revealed that $Ru_2(CO)_4$ units are coupled intramolecularly via glutarato ligands.[7]

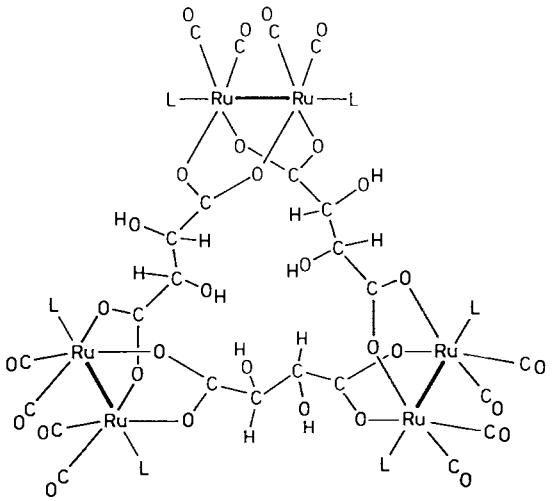
[**] This work was supported by the Fonds der National Suisse de la Recherche Scientifique and the Volkswagen-Stiftung.

We have now found that trimeric tartratodiruthenium complexes, which can be regarded as organometallic macrocycles, are accessible with tartaric acid. The compounds **5**–**7** are formed upon reaction of $Ru_3(CO)_{12}$ with tartaric acid (*R,R*, *S,S*, and *R,S*) in a pressure Schlenk tube, and can be obtained as acetonitrile adducts in the form of yellow crystals. These are unstable in air and in vacuo and lose both coordinated and uncoordinated acetonitrile. Therefore, in the ^{1}H-NMR spectra integrals that are always too small are found for the CH_3 groups of **5**–**7**. Substitution of the



5: all-(*R,R*), L = MeCN; **6**: all-(*S,S*), L = MeCN

7: all-(*R,S*), L = MeCN; **8**: all-(*S,S*), L = PPh_3

acetonitrile ligand in **6** by PPh_3 provided access to the air-stable triphenylphosphane derivative **8**, for which a satisfactory elemental analysis was obtained.

A solid-state structural investigation of the complex **5** revealed the trimeric macrocyclic structure of the compound, in which three $Ru_2(CO)_4$ units are coupled via tartrato bridging ligands to give a tricycle.[8] With acetonitrile, **5** forms hexagonal crystals containing three symmetry-independent molecules A, B and C per asymmetric unit. The crystals contain randomly distributed uncoordinated acetonitrile molecules. The molecular structure of the independent molecule A is shown in Figure 1; the differences with respect to B and C are small. A C_3 axis is the only symmetry element of the chiral compound. Each Ru atom is surrounded almost octahedrally by its ligands. The Ru–Ru distance of 2.6545(13) Å is only slightly shorter than in other carboxylato complexes containing an Ru–Ru single bond such as **1** (2.728(1) Å)[4] or **9** (2.734(3) Å).[7] The planes through the atoms Ru1, Ru2, C1 and Ru1, Ru2, C4 are almost orthogonal to each other (80°), with the accompanying oxygen atoms O1, O2 and O3, O4 located at an average of 0.327 Å above and below the respective planes. Such a twisting of the carboxylato groups is also known, for example, in the case of **10**.[3] The positions of the carbonyl groups and of the acetonitrile ligands are likewise similar to those in monomeric carboxylato complexes. The six OH groups of the macrocycle are all located on one side of the plane through Ru1, Ru1a and Ru1b and are alternately bent towards and away from the C_3 axis.

Experimental

All operations were carried out under nitrogen in anhydrous N_2-saturated solvents.

Synthesis of **5**–**7**: A solution of $Ru_3(CO)_{12}$ (320 mg, 0.50 mmol) in THF (50 mL) was treated with 113 mg (0.75 mmol) of *R,R*- or (*S,S*)-tartaric acid (in the case of **5** and **6**, resp.) or 126 mg (0.75 mmol) of (*R,S*)-tartaric acid monohydrate (in the case of **7**) in a pressure Schlenk tube and the mixture heated to 120 °C and magnetically stirred (**5**, **6**: 15 h; **7**: 13 h). To avoid a back reaction, the gases evolved (CO and presumably H_2) were drawn off from time to time. On completion of reaction the clear orange-colored solutions were evaporated to dryness and the residues heated with acetonitrile until a clear solution was obtained. After storage for several days at 2 °C, **5**–**7** were obtained in crystalline form. **5**: (331 mg, 81%); IR (CH_2Cl_2): ν(CO) = 2045(s), 1995(m), 1963(vs); IR (KBr): ν(OCO) = 1592(s), 1422(m), ν(OH) = 3468(m) cm^{-1}; ^{1}H NMR ([D$_6$]DMSO, 200 MHz): δ = 2.06 (s, <18H, CH_3), 4.13 (d, 6H, J_{HH} = 8 Hz, CH), 5.30 (s, 6H, J_{HH} = 8 Hz, OH).—**6**: (326 mg, 80%); IR (CH_2Cl_2): ν(CO) = 2043(s), 1992(m), 1963(vs); IR (KBr): ν(OCO) = 1592(s), 1422(m), ν(OH) = 3469(m); ^{1}H-NMR ([D$_6$]DMSO, 200 MHz): δ = 2.05 (s, <18H, CH_3), 4.13 (d, 6H, J_{HH} = 8 Hz, CH), 5.30 (d, 6H, J_{HH} = 8 Hz, OH). —**7**: (311 mg, 76%); IR (CH_2Cl_2): ν(CO) = 2042(s), 1989(m), 1966(vs); IR (KBr): ν(OCO) =
1597(m), 1420(m), ν(OH) = 3451(m); ^{1}H NMR ([D$_6$]DMSO, 200 MHz): δ = 2.06 (s, <18H, CH_3), 3.81 (d, 6H, J_{HH} = 4 Hz, CH), 5.54 (d, 6H, J_{HH} = 4 Hz, OH).

Synthesis of **8**: A solution of **6** (272 mg, 0.17 mmol) in THF (50 mL was treated with 262 mg (1.00 mmol) of PPh_3 and the mixture magnetically stirred for 1 h at room temperature. The clear yellow solution was evaporated to dryness, and the resulting residue was dissolved in a little dichloromethane and purified by thin-layer chromatography (eluent cyclohexane/dichloromethane 2/1). Evaporation of the eluent to dryness in vacuo furnished **8** as a yellow solid (281 mg, 57%). IR (CH_2Cl_2): ν(CO) = 2024(s), 1983(m), 1952(vs); IR (KBr): ν(OCO) = 1597(m), 1421(m), ν(OH) = 3524(m); ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 2.30 (s, br. 6H, CH), 3.61 (s, br, 6H, OH), 7.15 and 7.43 (each m, 90 H, C_6H_5); ^{31}P{^{1}H} NMR ($CDCl_3$, 81.03 MHz): δ = 16.8 (s, 6P, PPh_3).

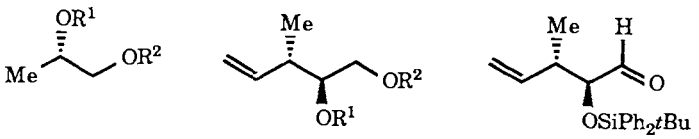
Multiple 1,2-*O*,*O*-Shift of *tert*-Butyldiphenylsilyl Groups in Polyols

By *Johann Mulzer** and *Bernd Schöllhorn*

tert-Butyldimethylsilyl (TBDMS) and *tert*-butyldiphenylsilyl (TBDPS) groups are standard protecting groups for OH functions.[1] The *O*,*O* silyl migration to be expected in polyols was hitherto chiefly observed in the case of the less stable TBDMS unit.[2] In the case of the TBDPS group two examples have been described in the literature, namely a 1,3-shift[3] and 1,2-shift.[4] We now report a multiple 1,2-*O*,*O* migration of TBDPS groups in the polyol derivatives **1**, **2**, **4**–**6**, **8**, **9** and **13**.[5]



1 **2** **3**

a, $R^1 = t\text{BuPh}_2\text{Si}$, $R^2 = H$
b, $R^1 = H$, $R^2 = t\text{BuPh}_2\text{Si}$

The silyl migration requires base catalysis (standard conditions: potassium carbonate in methanol, 22 °C). **1a** and **2a** then isomerize completely to **1b** and **2b**, respectively. Under neutral or acid conditions the TBDPS group is stable towards migration. Reduction of the aldehyde **3** with lithium aluminum hydride in diethyl ether therefore leads uniformly to **2a**, whereas that with sodium tetrahydroborate in methanol yields **2b** quantitatively. During the reaction **2a** is detectable as intermediate.

Under standard conditions, the triol derivative **4a** forms an 87:7:6 equilibrium mixture (HPLC analysis) of **4c**, **4b** and **4a** in 20 min, from which **4b** can be separated and used again. After 15 min, the same product ratio as from **4a** is obtained, thus proving that the silyl migration proceeds reversibly in both directions. Responsible for the equilibrium

b	H	$t\text{BuPh}_2\text{Si}$	H
c	$t\text{BuPh}_2\text{Si}$	H	H

position is the preference of the bulky TBDPS group for the primary position, which is favored by ca. 8–9 kJ mol^{-1} compared to the secondary positions, but, because of the reversibility of the migration step, is only reached by trial and error. The establishment of equilibrium therefore takes longer the larger the number of the participating OH functions.

The pentol **5a** derived from D-mannitol isomerizes to **5b**, which, because of the C_2 symmetry of the unprotected mol-

ecule, can be formed by two- or threefold *O*,*O* migration. Both routes are possible, as demonstrated by the uniform formation of **7** from **6a** and **6b**. The *syn*- or *anti*-position of the OH functions to be traversed, and thus the conformational strain in the postulated intermediate **Z**,[2b] apparently have no influence on the product pattern. This experiment also proves that the silyl migration—consistent with **Z**—proceeds with retention at the carbinol centers, since **7** would otherwise be epimerized differently compared to the precursors **6a/b**.

Carbonyl Oxides: Zwitterions or Diradicals?

By Wolfram Sander*

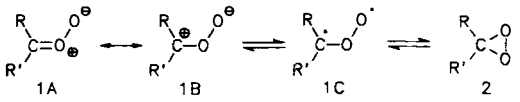
Over the last few years new experimental and theoretical methods have made it possible to gain a more detailed insight into the chemistry of short-lived reaction intermediates. In 1949 *Criegee* postulated the intermediacy of carbonyl oxides in the mechanism of ozonolysis, and since then these species have become the goal of much research effort. Even though the formation of "Criegee zwitterions" during ozonolysis and carbene oxidations was proven by scavenger experiments, the electronic structure—zwitterion or diradical—of this short-lived species is still a subject of debate. To date no stable carbonyl oxide has been found to exist under "normal" laboratory conditions, although by using matrix isolation and laser spectroscopy, it has been possible to obtain highly resolved IR and UV/VIS spectra of carbonyl oxides as well as to determine their dipole moments experimentally. The influence of substituents, exact kinetic data on modes of formation, and the subsequent reactions of carbonyl oxides as well as their photochemistry complete the picture. In accordance with ab initio calculations carbonyl oxides are best viewed as polar diradicals. The zwitterionic state lies at higher energies and should be stabilized by π donors.

1. Introduction

Carbonyl oxides **1** and their isomeric form, the dioxiranes **2**, have become an intensively studied species over the last few years owing to their role in oxygen-transfer reactions. The occurrence of **1** and **2** as short-lived reaction intermediates has been discussed for combustion processes,[1] many "organic" oxidations (ozonolysis, Baeyer–Villiger reaction),[2–5] and enzymatic processes.[6] Furthermore, the use of **1** and **2** in selective oxidations is becoming increasingly important.[3,4,7] The introduction of appropriate substituents causes these species to react with substrates by transfer of O atoms, either in a nucleophilic or electrophilic manner. In contrast to the extremely labile **1**, which has so far only been characterized indirectly or spectroscopically, a number of derivatives of **2** have been isolated in solution or in their pure form at room temperature.[3,4,7]

Carbonyl oxides **1** were first postulated as intermediates in the ozonolysis of olefins by *Criegee* in 1949[2,8] and are also referred to as Criegee zwitterions in the literature. Since then the many experimental and theoretical studies in this area have on the whole substantiated the postulated mechanism in Section 2 [Eq. (2)] in its key points. Nonetheless, a direct proof of the existence of a carbonyl oxide was not achieved until 1983.[9] To prove the existence of **1**, the application of relatively new experimental procedures such as matrix isolation and time-resolved laser spectroscopy was necessary.

Carbonyl oxides are also interesting species from a theoretical point of view. Their isomeric form, the dioxiranes, are molecules with a complete valence shell and are thus easily described in theoretical terms;[10,11] the electronic structure of carbonyl oxides, on the other hand, is still a subject of debate. In most of the experimental work the description as an ylide, **1A** and **1B** [Eq. (1)], originally introduced by *Criegee*, has been invoked. Quite a few important reactions of carbonyl oxides such as 1,3-dipolar cycloaddition, dimerization, and addition to alcohols may be explained in terms of this species. Some of the semiempirical calculations that have been performed postulate a zwitterionic ground state,[12] while ab initio[13–15] and other semiempirical calculations[16,17] predict a diradical ground state **1C**. Experimental evidence also favors a diradical ground state.[12] In a review on ozonolysis in 1975, *Criegee* wrote:[2]



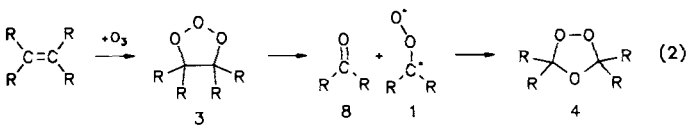
(1)

> Can the view recently expressed by *Goddard* that the so-called carbonyl oxides are singlet diradicals also in solution be confirmed or disproved? Solution of this problem will be of crucial importance for our understanding of the events occurring during the ozonolysis of olefins.

From 1980 onward the development of new experimental and theoretical methods has led to an enormously increased interest in carbene oxidations, carbonyl oxides, and dioxiranes. The use of these new methods in the field of carbonyl oxides is the focus of discussion in this article.

2. The Criegee Zwitterion in Ozonolysis

In the three-step mechanism [Eq. (2)] describing ozonolysis,[2] the initial step involves the 1,3-dipolar cycloaddition of ozone to an olefin, resulting in the formation of a 1,2,3-trioxolane (**3**; "primary" ozonide). In the second step, **3** decomposes to afford a carbonyl compound and **1**. These components react in a further cycloaddition to yield a 1,2,4-trioxolane (**4**; "molozonide"), which may often be isolated from the reaction mixture. The great importance of ozonolysis in



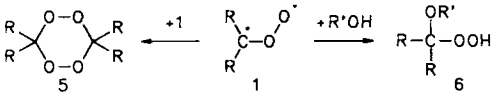
(2)

[*] Priv.-Doz. Dr. W. Sander
Organisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg (FRG)

organic chemistry and recently also in the chemistry of the upper atmosphere is reflected in the large number of publications and reviews covering this area.[18-20]

It was possible to confirm the Criegee mechanism by detecting cross products, by carrying out trapping and isotopic labeling experiments, and, finally, by direct detection of the unstable primary ozonides **3**.[2, 18, 19] Recently, the parent compound **3** was detected by microwave spectroscopy as one of the products in the ozonolysis of ethylene.[21] A weak point of the Criegee mechanism is the observed stereoselectivity of ozonolysis: If the proposed three-step mechanism is to operate, *cis* and *trans* olefins should give the same ratio of stereoisomeric molozonides **4** and thus lead to loss of stereochemical information. In fact, *trans* and *cis* olefins with bulky substituents lead mainly to the *trans* and *cis* forms of **4**, respectively. According to a proposal by *Bailey*, the observed stereoselectivity can be explained by a modified mechanism, which rests upon the following points: the cleavage of **3** is presumed to be a concerted process and **1** exists as *syn* or *anti* isomer, the two of which do not equilibrate at room temperature.[14b, 20, 22, 23] With these refinements, the stereochemistry of ozonolysis is determined by the conformation of the primary ozonides **3** and is dependent on the configurational stability of **1**.

In some cases the products of ozonolysis are 1,2,4,5-tetroxanes **5**, which can be viewed as dimers of **1**.[18] Performing the ozonolysis in the presence of alcohols affords alkoxy hydroperoxides **6**, which are formed by addition, no definite spectroscopic evidence exists so far for the alcohol to **1** [Eq. (3)].[18] Apart from these indirect indications, no definite spectroscopic evidence exists so far for the existence of **1** as a reactive intermediate during ozonolysis.



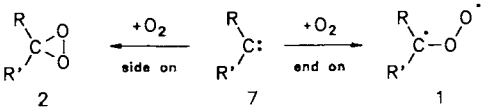
5 1 6 (3)

Suenram and *Lovas* were able to detect the unstable dioxirane **2a**[*] during the gas-phase reaction between ethylene and ozone. Its structure was determined by microwave spectroscopy.[24] Presumably, the thermal relaxation of the "hot" formaldehyde oxide **1a**, formed in the gas phase, is too slow to inhibit the rearrangement to **2a**. Ozonolysis in solution does not produce dioxiranes **2**.

[*] The substituents are given in Scheme 1 (Section 4.2).

3. Oxidation of Diazo Compounds and Carbenes in Solution

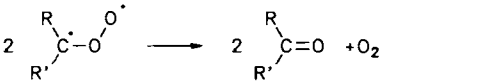
Apart from ozonolysis, there are two alternative methods for the preparation of **1** and **2**: the direct reaction of free carbenes **7** with triplet oxygen ($^3O_2$, "triplet path") and the oxidation of diazo compounds **9** with singlet oxygen ($^1O_2$, "singlet path"[25]). A formal "end-on" addition would result in **1**, a "side-on" addition in **2** [Eq. (4)].



2 7 1 (4)

Kirmse et al. were the first to conduct a selective study in this field.[26] The photooxidation of diphenyldiazomethane (**9b**) in a variety of solvents yielded up to 73% of benzophenone (**8b**); no other products containing oxygen could be detected. It was postulated that the primary adduct arising from photooxidation is benzophenone *O*-oxide, which, in the following step, transfers its terminal O atom to a further molecule of carbene **7b** or diazomethane **9b**.

Bartlett and *Traylor* studied the photooxidation of **9b** with $^{16}O_2$ and $^{18}O_2$ in solid chlorobenzene at $-78\,^{\circ}C$.[27] Under these reaction conditions it was possible to isolate 15% of the tetroxane **5b**, a dimer of **1b**. From their experiments with mixtures of $^{16}O_2$ and $^{18}O_2$, *Bartlett* and *Traylor* were able to conclude that the elimination of O_2 from two molecules of **1b** does not proceed to a significant extent.[27] More recent results by *Girard* and *Griller* show that, if no trapping reagents are present, the extrusion of O_2 from two separate molecules of **1b** can become the main reaction pathway for **1b**, and the formation of **5b**—at least in solution at room temperature—does not occur [Eq. (5)].[28] The activation barrier for this reaction amounts to only 1.8 kcal mol^{-1}.

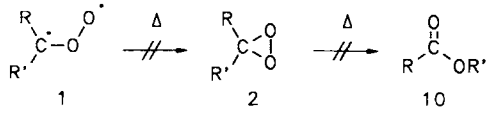


1 8 (5)

Apart from **8** and **5**, other oxidation products that arise from the reaction of **9** are esters (or lactones) **10**. The mechanism of ester formation was elucidated in a number of pub-

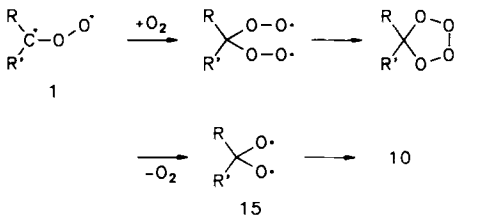
Wolfram Sander was born in 1954 in Heidelberg. From 1973 to 1979 he was a student at the Universität Heidelberg, where he subsequently received his Ph.D. in 1982 under R. Gleiter and completed his Habilitation in 1989. He was introduced to the matrix isolation technique as a postdoc with O. L. Chapman in Los Angeles (1982 to 1984). His interests include the characterization of reactive intermediates, oxidation reactions with molecular oxygen, and effect of electron spin on chemical reactivity. In 1988 he was awarded the Karl-Freundenberg-Preis of the Heidelberger Akademie der Wissenschaften, and in 1990 he received a Heisenberg-Stipendium and a Winnacker-Stipendium.

lications by *Sawaki* et al.[29] At first, the formation of **10** was thought to proceed through an intramolecular rearrangement of **2**.



1 2 10 (6)

Since mixed isotopomers of **10** with one atom of ^{16}O and ^{18}O each are formed when mixtures of $^{16}O_2$ and $^{18}O_2$ are used, two molecules of O_2 must participate to form **10**. This excludes **2** as the direct precursor of **10**.[29a] *Sawaki* et al. proposed an alternative explanation in which they presume the presence of **1** as an intermediate. Species **1** reacts with a further molecule of O_2 and then decomposes via different peroxidic species to yield **10** [Eq. (7)].[29a]

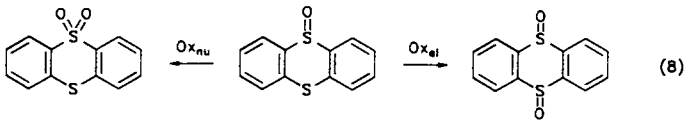


1 15 10 (7)

However, this mechanism is also incompatible with the experimental findings, since the yield of **10** is nearly independent of O_2 pressure. In recent work a radical chain mechanism seems to give a plausible explanation.[29b] According to these results, ester **10** is formed by radical oxidation of a diazo compound (**9**) and not of a free carbene (**7**). The ^{18}O labeling experiments also showed that the rearrangement **1** → **2** is not a thermal process [Eq. (6)].

In the reaction of difluoromethylene (**7s**) with O_2, *McKee* et al. found a species that transfers O atoms stereospecifically onto alkenes.[30] This species was not characterized in detail, yet ab initio calculations make formation of **2s** from the primarily formed compound **1s** plausible.

Besides mechanistic studies, much research has been directed toward the use of the intermediates resulting from the oxidation of **9** as reagents for oxidation. Predominantly the formation of **1** is presumed in these complex reaction mixtures. The most important reactions are the transfer of oxygen onto alkanes,[12] alkenes,[12, 31, 32] sulfides and sulfoxides,[33a, 33b, 34] and aromatic compounds.[35, 36] In the presence of H donors, **1** can react to form autoxidation products.[12] Furthermore, cycloadditions with carbonyl compounds[37, 38] and olefins[39–41] have been reported. The inherent instability of **1** makes it difficult to exclude the possibility that the oxidation proceeds through other peroxidic species, expecially **2**. *Adam* et al. developed an elegant method to distinguish between oxygen-transfer reagents by examining their different nucleophilicities.[33] Thianthrene 5-oxide (**11a**) is prone to nucleophilic oxidation at the sulfoxide S atom, but is oxidized in an electrophilic manner at the sulfide S atom [Eq. (8)].



11 11a 12 (8)

From the relative amounts of thianthrene 5,5-dioxide (**11**) and thianthrene 5,10-dioxide (**12**), an X_{Nu} scale ($X_{Nu} = 0$ for electrophiles, $X_{Nu} = 1$ for solely nucleophilic reagents) was developed.[3, 33] Generally, dioxiranes **2** are less nucleophilic ($X_{Nu} \approx 0.7$) than carbonyl oxides **1** ($X_{Nu} > 0.8$). Typical electrophilic oxygenation reagents have even smaller values on the X_{Nu} scale (*m*-chloroperbenzoic acid in CH_2Cl_2, for instance, has $X_{Nu} = 0.36$). According to *Murray*,[4] the nucleophilic properties of dioxiranes are definitely smaller than indicated by an X_{Nu} value of 0.7 and, therefore, the difference to the carbonyl oxides is larger.

From sulfide oxidations[34] and oxidations of naphthalene[42] with a number of *p*-substituted arylcarbonyl *O*-oxides, *Agarwal* and *Murray* obtained positive Hammett constants and came to the conclusion that these oxidations are electrophilic in character. *Ogata* et al. also obtained positive Hammett constants for the oxidation of diphenyl sulfoxide, which indicates the presence of an electrophilic O-transfer process.[12] Obviously, the properties of carbonyl oxides depend strongly on the experimental conditions. Therefore, it became necessary to employ direct spectroscopic methods to come closer to an understanding of the electronic properties and bonding of carbonyl oxides.

4. Spectroscopic Identification of Carbonyl Oxides

To date, all spectroscopically identified carbonyl oxides have been generated by oxidation of free carbenes or diazo compounds. Two techniques—matrix isolation and time-resolved laser spectroscopy—have played an important part in the detection of short-lived species. In both methods the free carbenes are generated by photolysis of either a diazo compound (**9**) or a diazirine (**14**). In contrast to the matrix technique, where the carbene is produced under conditions at which it is stable (low temperature, inert media), the method used by time-resolved spectroscopy is fast detection (μs to ps) under normal laboratory conditions (room temperature, organic solvents). Thus, the two methods go hand in hand.

4.1. Matrix Isolation Technique

Pimentel et al.[43] and *Norman* and *Porter*[44] were the first to use inert-gas matrices to study reactive intermediates. In contrast to organic glasses, which react more or less quickly with free carbenes, the noble gases used in this technique, such as Ne, Ar, Kr, and Xe or nitrogen, are all inert. Through matrix isolation in inert gases it is possible to record highly resolved IR, UV/VIS, luminescence, and ESR spectra and thus to carry out an extensive characterization of reactive intermediates.

A prerequisite for the practicability of the matrix technique as a method to be used extensively in organic chemis-

try was the development of closed-cycle helium cryostats. They allow temperatures as low as 10 K to be attained on a routine basis.[45, 46]

Photolysis of **9** and **14** in a matrix (usually Ar or N_2 at 10 K) generates carbenes **7**, which are stable if they satisfy the following requirements: (1) They do not rearrange intramolecularly. This is why simple alkyl-substituted carbenes that rearrange by a 1,2-shift to give olefins cannot be isolated in a matrix. (2) They are stable to the irradiation that is necessary to photolyze the precursor. Many carbenes are photolabile (phenylmethylene, for instance, easily rearranges photochemically to cycloheptatetraene[47]); therefore, the photolysis should be carried out using the longest wavelength possible and irradiating monochromatically in order to inhibit these side reactions.

The temperature of the matrix influences diffusion processes in a complicated manner[48]. To induce the reaction of **7** with O_2, the matrix is first doped with O_2 (0.2–5%) and then annealed (30–45 K). As long as the matrix is kept at 10 K, even a large excess of O_2 will not lead to a reaction. Once 35 K is reached, however, the oxidation is complete within a few minutes.[49–52] An argon matrix containing small molecules is shown schematically in Figure 1.

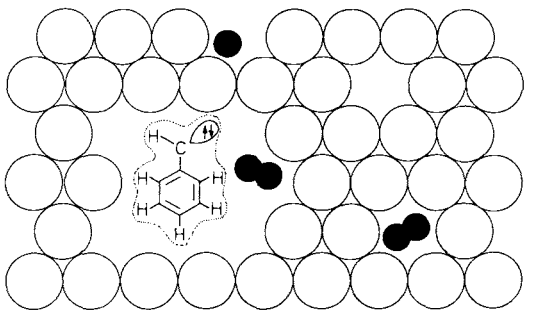


Fig. 1. Schematic representation of an Ar matrix. Open circles, argon atoms; dark circles, small molecules such as N_2 or O_2. At 10 K, diffusion of O_2 is so slow that, even after hours, no oxidation products of carbenes are formed. At 35 K, on the other hand, oxidation is complete within a few minutes.

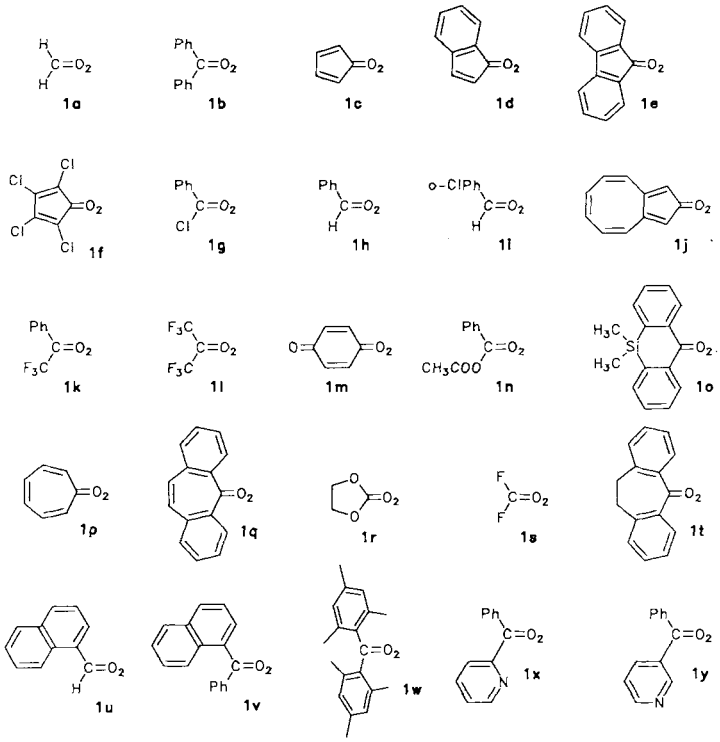
4.2. Laser Spectroscopy

The great advantage of time-resolved spectroscopy is that it allows the measurement of absolute kinetics; its disadvantage is that the spectroscopic possibilities for structural determination are restricted to the near-UV and visible range with relatively low resolution.[53] Recently, the range has been extended to cover the infrared as well.[54–57] In time-resolved laser spectroscopy, carbonyl oxides **1** are easily detected by observation of their strong band in the visible part of the spectrum, whereas their photoproducts with absorption maxima below 300 nm cannot be monitored.

In order to study carbene oxidations in solution, time resolution in the ns range will suffice. The sample (generally a solution at room temperature) is photolyzed by a short laser pulse, the time resolution being defined by the length of the pulse. The nitrogen (337 nm) and excimer (249 or 308 nm) lasers usually employed have pulse lengths of 5–10 ns.[53] The detection system consists of a source of intense white light and a photomultiplier (for single-channel detection) or an array of diodes (for multichannel detection).

Scheme 1 provides a summary of the carbonyl oxides for which spectroscopic or theoretical data are available.

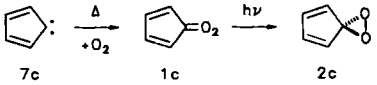


Scheme 1.

4.3. Cyclopentadienone *O*-Oxide

Independently of one another, *Chapman* et al.[58–60] and *Dunkin* et al.[49, 52a] reported the formation of cyclopentadienone *O*-oxide (**1c**) from the matrix oxidation of cyclopentadienylidene (**7c**). *Chapman*'s group studied the photooxidation (irradiation with light at $\lambda > 418$ nm) of diazocyclopentadiene (**9c**) in matrices with high O_2 content (20%). They discovered a product which was assigned structure **1c** owing to its intense IR bands at 1395, 1385, 895, and 741 cm^{-1}.[60]

On the other hand, *Dunkin* et al. described the formation of a different product with IR bands at 1398, 1321, 888, and 758 cm^{-1}. This species, generated by monochromatic irradiation ($\lambda = 296$ nm) of **9c** isolated in a matrix in the presence of 10% O_2, was also assigned structure **1c**.[49] The same IR spectrum was observed when a matrix doped with 1% O_2 and containing carbene **7c** was warmed to 35 K[49] [Eq. (9)].



(9)

In a later publication *Dunkin* et al. showed that **1c** is extremely photolabile and that the molecule described by *Chapman* et al. must be an isomer of **1c**, the dioxirane **2c**.[52a] To prove the differing symmetry of **1c** (C_s) and **2c** (C_{2v}),

isotopic labeling with ^{18}O was used.[52a] These experiments indicate clearly that **1c** contains equivalent and **2c** nonequivalent O atoms. A further proof for the structure of **2c** is that, on UV irradiation ($\lambda > 220$ nm), it rearranges to α-pyrone.[46, 52a]

The largest ^{18}O isotopic shifts in **1c** are found for the bands at 1014 (−28) and 947(−22) cm^{-1} (Table 1).[49] These bands lie in a region typical for stretching modes of single bonds and can approximately be assiged to O–O or C–O stretching vibrations. In the region of visible light the spectrum shows an intense absorption with a maximum at 420 nm (Table 1).[61a]

Table 1. Characteristic IR and UV spectroscopic data for some carbonyl oxides **1**.

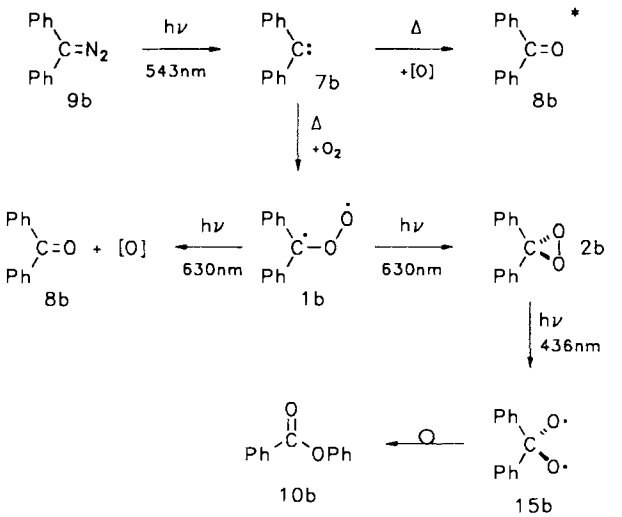
Dunkin et al. also studied indenone *O*-oxide (**1d**),[52b, 61a] fluorenone *O*-oxide (**1e**),[52b, 61a] and tetrachlorocyclopentadienone *O*-oxide (**1f**).[61] The strongest IR bands for **1d** are observed at 912 cm^{-1} and for **1e** at 898 cm^{-1}.[52b] Even though no ^{18}O labeling experiments were performed with **1d** and **1e**, comparison with other carbonyl oxides **1** (see below) convincingly shows that these bands can best be interpreted as O–O stretching modes (Table 1).

Carbonyl oxides **1c**–**1f** show strong absorptions in the visible part of the spectrum between 395 and 460 nm (Table 1).[61a] Absorption in this region is characteristic for **1** and can be used to detect such species in laser photolysis experiments. Of the variety of substituted cyclopentadienone *O*-oxides, only **1e** has been characterized in laser photolysis experiments by *Scaiano* et al.[62] To generate the carbonyl oxide **1e**, diazofluorene (**9e**) was either irradiated in solution at room temperature in the presence of $^3O_2$ (triplet path) or allowed to react with $^1O_2$ (singlet path). Independent of the method of generation, both paths led to a transient species with an absorption maximum at 450 nm.[62] The half-life is strongly dependent on the solvent used and ranges from > 800 μs in benzene to only 9 μs in CH_2Cl_2. On the basis of the kinetic data and the observed absorption maximum, structure **1e** was proposed for the transient species. The above results are in accordance with the data obtained in a matrix and show that the same reactive species is formed both in solution at room temperature and in an inert gas at 10 K. Just as *Criegee* had postulated, **1e** is quickly trapped by reaction with aldehydes.[2] At large enough concentrations of aldehyde, pseudo-first-order kinetics with rate constants between 107 and 109 $mol^{-1}\,s^{-1}$ (in Freon-113) are observed.[62]

4.4. Benzophenone *O*-Oxide and Other Arylcarbonyl Oxides

The chemistry of benzophenone *O*-oxide (**1b**) is well established by trapping experiments in solution, but has also been studied by IR and UV spectroscopy in matrices and with the aid of laser photolysis. In the thermal reaction of diphenylmethylene (**7b**), isolated in a matrix containing $^3O_2$ (Ar, 30–40 K), **1b** is produced in high yield. The product was characterized by UV/VIS and IR spectroscopy as well as by its subsequent photochemistry (Scheme 2).[63, 51] In agreement with the findings from laser photolysis experiments, an intense broad band with $\lambda_{max} = 422$ nm was observed in the visible region of the spectrum (Table 1).[63] This can be taken as proof for the existence of the same products in solution at room temperature and in a matrix at cryogenic temperatures.

The structure of **1b** has been further elucidated by carrying out IR experiments in connection with isotopic labeling analysis. The reaction of [1-^{12}C]-**7b** and [1-^{13}C]-**7b** with $^{16}O_2$ and $^{18}O_2$ leads to four isotopomers of **1b**, thereby



Scheme 2.

allowing a nearly complete assignment of the IR bands.[51] The most intense band in the spectrum is observed at 896 cm^{-1} and exhibits an ^{18}O isotopic shift of 35 cm^{-1} (Table 1). Because of the small shift on labeling of the carbonyl C atom with ^{13}C, one can conclude that this band arises from the O–O stretching vibration. The O–O deformation mode is a weak band at 550 cm^{-1}; in the region typical for the carbonyl vibration, no band is observed.

Like all other carbonyl oxides that have been matrix isolated to date, **1b** is extremely photolabile. Irradiation with light far to the long-wavelength side of the absorption band ($\lambda > 630$ nm) leads to rearrangement (main reaction) to afford diphenyldioxirane (**2b**) or results in cleavage of O atoms (side reaction) to form **8b** (Scheme 2). Presumably, there exists a long-wavelength band of weak intensity that has not been detected so far.[17]

Under these conditions, dioxirane **2b** is stable. On short-wavelength irradiation ($\lambda > 400$ nm), however, it rearranges to the phenyl benzoate (**10b**). On oxidation of **7b** in the matrix, one can also detect an intense chemiluminescence that has been identified as the phosphorescence of **8b**.[51]

Two further carbonyl oxides with absorption maxima at about 400 nm are benzaldehyde *O*-oxide (**1h**)[51] and *ortho*-chlorobenzaldehyde *O*-oxide (**1i**).[64] The absorption spectra of both compounds exhibit distinct vibrational fine structure; for **1i**, ^{18}O isotopic labeling experiments indicate that the vibrational progression corresponds to the O–O stretching mode of its electronically excited state.[64] The vibrational frequency of 901 cm^{-1} in the ground state (Table 1) is reduced to 790 cm^{-1} in the excited state.

Other arylcarbonyl oxides that have been characterized in the matrix are benzoyl chloride *O*-oxide (**1g**)[65] and the CF_3-substituted carbonyl oxides **1k** and **1l**.[50] Whereas the chloro substituent in **1g** hardly has any effect on the characteristic spectroscopic data, the strongly electron-withdrawing CF_3 groups in **1k** and **1l** bring about an increase in the O–O stretching mode—an effect attributed to a strengthening of the O–O bond. On top of that, the UV/VIS absorption maximum is shifted to shorter wavelength (Table 1)[50] in the latter two compounds. The reaction of **7g** with $^3O_2$ is a formally "spin-forbidden" process, because the carbene **7g** has a singlet ground state. As expected, the oxidation proceeds considerably slower than that of triplet carbenes.[65, 64]

Scaiano et al. were able to generate **1b** by laser photolysis in solution at ambient temperatures, via both the triplet-path[66] and the singlet-path.[67] Its existence as a short-lived intermediate was proven by the observation of an intense absorption at 410 nm.[66, 67] If no special trapping reagent is present, **1b** will react according to second-order kinetics.[68] A similar result was obtained by *Girard* and *Griller* with the aid of optical modulation spectroscopy (this method can achieve time resolution into the μs range).[28] Just like *Scaiano*, they found that **1b** disappears in a reaction with bimolecular kinetics, yet they were not able to isolate the dimer **5b**. This observation was made plausible by an alternative reaction path of two molecules of **1b** to yield **8b** and O_2 [Eq. (5)].

Like **1e**, species **1b** is rapidly trapped by aldehydes. The rate constants of the pseudo-first-order reaction in acetonitrile amount to about 10^6 $mol^{-1}\,s^{-1}$[68] and are thus considerably smaller than the corresponding values for **1e**.[62]

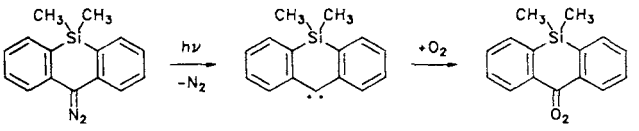
Using time-resolved dielectric-loss spectroscopy, *Fessenden* and *Scaiano* estimated the dipole moments of **1b** and **1t** to be 4.0 D and 3.8 D, respectively.[69] These dipole moments are larger than expected for a diradical but considerably smaller than anticipated for a zwitterion, and they give an indication of the complex electronic structure of carbonyl oxides.

Scaiano et al. later studied the absorption spectra and kinetic data of a series of substituted arylcarbonyl *O*-oxides (Table 1).[62, 68, 70] With the exception of **1e**, all absorption maxima fall into the range of 410 ± 20 nm and are hardly dependent on the solvent used. Because of steric interaction, the formation of **1w** from **7w** and $^3O_2$ proceeds more slowly, and the lifetime of **1w** is longer than that of the other carbonyl oxides.[68]

Itoh et al. studied the photooxidation of methyl α-diazophenylacetate (**9n**) and were able to generate carbonyl oxide **1n**.[71] The reaction of **1n** with an excess of methanol was pseudo first order; without methanol, bimolecular kinetics were observed.

4.5. Other Carbonyl Oxides and Analogous Compounds

By laser photolysis of the diazo compound **9o** at room temperature in cyclohexane, *Iwamura* et al. obtained 10,10-dimethyl-10-silaanthracene-9(10*H*)-ylidene (**7o**), which has a lifetime of 870 ns.[9] If the photolysis was carried out in the presence of O_2, carbonyl oxide **1o** was produced, which has a lifetime of 45 μs and exhibits an absorption maximum at 425 nm [Eq. (10)].[9]

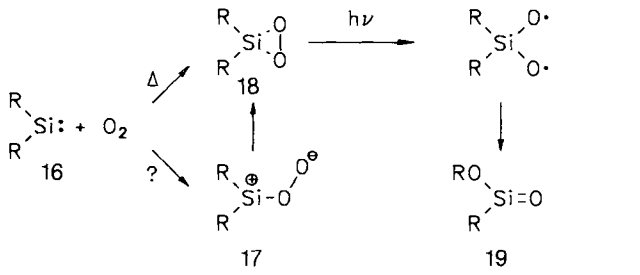


9o 7o 1o (10)

Another cyclic carbonyl oxide that has been monitored in a matrix is *para*-benzoquinone *O*-oxide (**1m**).[72] Since **1m** not only contains a carbonyl group but also a carbonyl oxide functionality, a direct comparison of these two functional groups becomes possible. The O–O stretching mode at 1034 cm^{-1} shows an intensity similar to that of the C–O stretching vibration of the carbonyl group and exhibits an ^{18}O isotopic shift of 57 cm^{-1}. This large isotopic shift indicates that little coupling with other vibrations occurs, so that a force constant corresponding to an O–O single bond may be taken as a good estimate.[72] In contrast to **1m** with its π-acceptor group, bicyclo[6.3.0]undeca-2,4,6,8,11-pentaen-10-one *O*-oxide (**1j**) contains a π-donor group.[73] This effects a strong redshift of the $\pi \rightarrow \pi^*$ band (see Section 5.3.2). The photochemistry of **1m** and **1j** is analogous to that of other carbonyl oxides (Scheme 4): long-wavelength irradiation (630 nm for **1m** or 480 nm for **1j**) yields the spirodioxiranes **2m** and **2j**, respectively. These compounds rearrange to the lactones **10m** and **10j** if irradiation is continued at shorter wavelength (436 nm for **2m** or 350 nm for **2j**).[72, 73]

The reaction of methylene (**7a**) with O_2 in an Ar matrix was studied by *Lee* and *Pimentel*.[74] They were not able to detect **1a** or **2a**, but found formic acid as the main product, which in part is produced in an electronically excited state.

In contrast to the reaction of carbenes **7**, little is known about the reaction of silanediyls ("silylenes") **16** with O_2.[75] The formation of an adduct of dimesitylsilanediyl (**16a**) and O_2 was described by *Ando* et al. (Scheme 3).[76] On the basis of isotopic labeling experiments and ab initio calculations, the adduct was assigned the structure of dimesitylsilanone *O*-oxide (**17a**). Compound **17a** is photolabile, but the photoproducts were not characterized. In contrast to **16a**, the thermal reaction of dimethylsilanediyl (**16b**) with O_2 leads to the formation of dimethyldioxasilirane (**18b**) as the sole product, which on irradiation rearranges to methoxymethylsilanone (**19**) [Eq. (12)].[77a]



Scheme 3.

The halogenated silanediyls **16c** and **16d** do not react thermally with O_2 in the gas phase or in the matrix to an appreciable extent, yet on irradiation they are photooxidized to the dioxasiliranes **18c** and **18d**, which are stable towards UV irradiation.[77b]

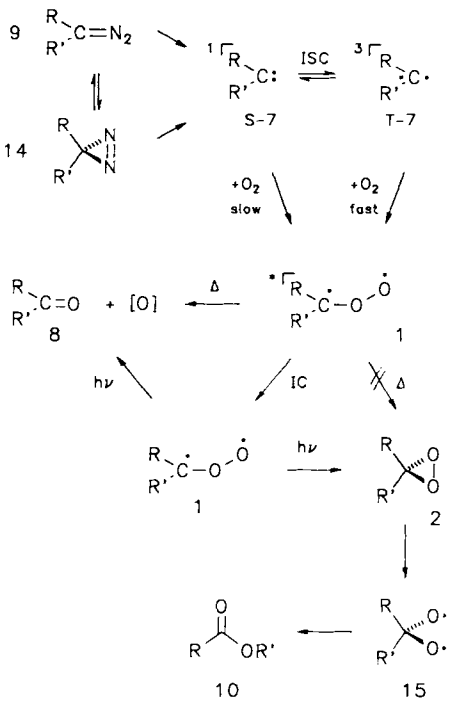
5. Formation and Properties of Carbonyl Oxides

5.1. Mechanism of Carbene Oxidation

Carbenes **7** formed by photolysis of **9** or **14** are primarily generated in the singlet state; in the case of triplet carbenes the triplet ground state is reached through fast intersystem crossing (ISC). Thermal reactions in the matrix generally occur from the ground state, whereas, in reactions in solution at room temperature, low-lying excited states may play an important part (Scheme 4).[78]

The reaction of triplet carbenes (T-7) with $^3O_2$ is an extremely fast process (controlled by diffusion); the formally "spin-forbidden" reaction of singlet carbenes, on the other hand, is very slow[64,65] and cannot be detected by time-resolved spectroscopy in solution.[79]

Since the reaction of **7** with O_2 is very exothermic (for the formation of **1a**, ca. 47 kcal mol^{-1}),[15] the primary products of carbene oxidations, carbonyl oxides **1**, are generated in vibrationally excited states. Their stabilization occurs either through relaxation to the thermal ground state (internal



Scheme 4.

conversion, IC) or by extrusion of an O atom and subsequent formation of a carbonyl compound (**8**, Scheme 4). The ratio of **1** to **8** is strongly dependent on the substituents at the carbene center. Especially in the case of H atoms as substituents (**1h**, **1i**), the extrusion of O atoms predominates and **1** is formed only in low yields.[51,80]

According to ab initio calculations (MP2/6-31G*) performed by *Cremer* et al., the rearrangement **1a** → **2a** shows an activation barrier of 22.8 kcal mol^{-1} and is exothermic by 34.5 kcal mol^{-1} (according to *Kafafi* et al., 44.1 kcal mol^{-1}[15]) (Fig. 2).[14d] The activation barrier depends on

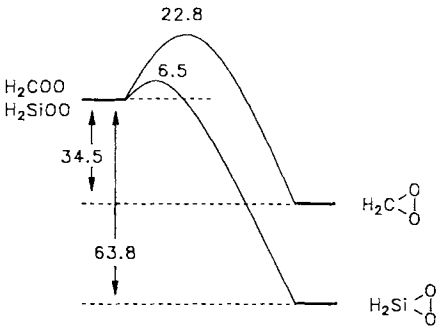


Fig. 2. MP2/6-31G*-calculated barrier of activation and reaction energies [kcal mol^{-1}] for the rearrangements **1a** → **2a** (Ref. [14d]) and **17** → **18**, R = H (Ref. [77a]).

the substituents and is diminished by π-donor ligands. In agreement with these findings, the thermal rearrangement does not occur in solution or in the matrix. In contrast, the rearrangement of silanone *O*-oxides **17** to dioxasiliranes **18** exhibits an activation barrier of only 6.5 kcal mol^{-1} and, consequently, the formation of the three-membered ring **18** is observed.[77a]

Since **1** reacts quickly with alcohols[71] and aldehydes,[68] an important step in the Criegee mechanism of ozonolysis could be verified by direct observation. A reaction competing with the formation of trapped species is that of **1** with itself to yield **5** or **8** and O_2.[27,28]

Irradiation of **1** with red light (presumably into an $n \rightarrow \pi^*$ transition) will either lead to the rearranged species **2** or to the formation of **8** with concomitant extrusion of O atoms. The ratio of **2** to **8** is again influenced by the substituent on **1**. For example, **1m** rearranges completely to **2m**, whereas the aldehyde *O*-oxides (**1h** and **1i**) afford mainly **8**. Therefore, one can selectively generate either **1**, **2**, or free O atoms just by choosing the appropriate substituents and reaction conditions. O atoms in their $O(^3P)$ state (ground state) are only detected indirectly in the matrix. A reaction easily monitored by IR spectroscopy is the oxidation of arylaldehydes to carboxylic acids. This insertion presumably proceeds via intermediate formation of benzoyl and hydroxyl radicals, which recombine instantly to yield carboxylic acids. The activation barrier for the reaction of $O(^3P)$ with acetaldehyde was determined in molecular beam experiments (gas phase) to be 2.4 kcal mol^{-1} by *Kleinermanns* and *Luntz*.[81] In analogy to the H-atom abstraction reactions of free carbenes at cryogenic temperatures[82] described by *Platz*, these H-atom abstractions may also be explained by invoking a quantum-mechanical tunneling effect.

Dioxiranes **2** are much more photostable than carbonyl oxides **1**, so that irradiation with blue or UV light is necessary to form **10**. The rearrangement proceeds by primary cleavage of the weak O–O bond (activation barrier 12–15 kcal mol^{-1})[15] and subsequent migration of a substituent R (Scheme 4). An extrusion of O atoms from **2** and formation of **8** was not observed.

5.2. Chemiluminescence

An interesting phenomenon in carbene oxidations, discovered by *Trozzolo* et al., is chemiluminescence.[83] On warming a solution of carbene **7b** (generated by photolysis of **9b**) in an organic glass in the presence of O_2, an intense blue light is emitted. A similar phenomenon was observed by *Wasserman* et al. when bis(trifluoromethyl)diazomethane (**9l**) was photooxidized.[84] In both cases the chemiluminescence spectra match the phosphorescence spectra of the corresponding carbonyl compounds **8b** and **8l**. *Turro* et al. were able to show that chemiluminescence is a general occurrence in the reaction of arylcarbenes with organic glasses as long as the corresponding carbonyl compound **8** also shows phosphorescence.[85] To explain these observations, a mechanism involving the transfer of a terminal O atom of **1** onto a molecule of O_2 was proposed [Eq. (14)], although it was not possible to detect ozone and **1** in these experiments.[85]

An alternative explanation for this chemiluminescence was provided by *Sawaki* and *Iwamura*.[29a] They proposed that the decomposition of cyclic peroxides [Eq. (7)] may be the cause of chemiluminescence. However, their hypothesis was not substantiated by any experiments.

In all cases the chemiluminescence spectrum is equivalent to the phosphorescence spectrum of the carbonyl compound generated by carbene oxidation. It should be noted that for aryl ketones spin inversion (ISC) of the electronically excited singlet state to the triplet state is extremely effective, so that, on excitation with light, only phosphorescence and no fluorescence is emitted.[86] Therefore, the observation of phosphorescence does not prove that the carbonyl compound is formed directly in the triplet state. Considering the case of bis(trifluoromethyl)methylene (**7l**), where, on oxidation, the chemiluminescence corresponds solely to the phosphorescence of **8l** (on excitation with light, both fluorescence and phosphorescence are observed),[87] one can conclude that hexafluoroacetone (**8l**)—and most probably also the other ketones—is formed directly in its triplet state.[50]

Possible reaction sequences that can lead to triplet carbonyl compounds—and thus to chemiluminescence—are listed in Equations (11)–(14). Reactions (11)–(13) are examples of the transfer of O atoms from a variety of sources onto a free carbene. Reaction (14) corresponds to the mechanism proposed by *Turro* et al.[85]

$$RR'C: + {}^3O_2 \longrightarrow {}^3RR'C{=}O + [O] \quad (11)$$

$$RR'C: + O(^3P) \longrightarrow {}^3RR'C{=}O \quad (12)$$

$$RR'C: + O_2{=}CRR' \longrightarrow {}^3RR'C{=}O + O{=}CRR' \quad (13)$$

$$RR'C{=}O_2 + {}^3O_2 \longrightarrow {}^3RR'C{=}O + O_3 \quad (14)$$

In the matrix, chemiluminescence occurs immediately after warming to temperatures above 10 K. At temperatures lower than 25 K, even the diffusion of small molecules such as O_2 is slow.[48] The observation of chemiluminescence at temperatures below 20 K cannot be explained by reactions (11), (13), and (14). Reaction (14) can also be excluded on other grounds. First, ozone is formed only as a byproduct at high O_2 concentrations, whereas reaction (14) requires the formation of equimolar amounts. Second, chemiluminescence already commences at temperatures below 20 K, when no carbonyl oxide has been formed in the matrix yet, and subsides after only a few minutes at 30 K, even though plenty of carbonyl oxide is now present in the matrix and the mobility of O_2 is very large.[50,51,64]

To exclude O_2 as a reaction component, the rate of formation of carbonyl oxides (a reaction in which O_2 participates) was compared to the rate at which the intensity of chemiluminescence decreases at constant temperature. It could be shown that chemiluminescence decreases four times as fast as carbonyl oxides are formed. It seems reasonable to conclude that the occurrence of chemiluminescence arises from diffusion of a species smaller than O_2.[51] Finally, reaction (11) is endothermic according to thermochemical estimates—at least for **7h**—and may also be excluded.[51]

The best explanation for all of the observations made is the presumption that the reaction of an O atom with **7** is the cause of chemiluminescence [Eq. (12)]. The multiplicity of the carbene (triplet or singlet) does not have much influence on this reaction and the carbonyl compounds are formed directly in their triplet states.

5.3. Influence of Substituents

5.3.1. IR Spectra

A characteristic feature of the IR spectrum of **1** is its intense bands between 890 and 1050 cm^{-1}, which show a large ^{16}O–^{18}O isotopic shift (30–60 cm^{-1}) and are assigned to O–O stretching modes (Table 1). In some cases, a splitting of the bands into two components is observed. This can be attributed either to Fermi resonance or to matrix cage effects. When **1** is unsymmetrically substituted, the occurrence of two bands could also be caused by the existence of *syn* and *anti* isomers. However, there is no experimental evidence for this suggestion.

According to the simple model for a diatomic harmonic oscillator, the highest possible isotopic shift for the O–O vibration amounts to 5.7% if both ^{16}O atoms are replaced by ^{18}O atoms. This maximum value is almost reached by the values monitored for **1g** (5.6%) and **1m** (5.5% and 5.7%; Table 1). These carbonyl oxides exhibit nearly pure O–O vibrations without coupling with other vibrations. For **1b** with its isotopic shift of 3.9% for the band at 896 cm^{-1}, the calculated contribution of the O–O vibration is 68%. The estimated force constant is typical for O–O single bonds.[72] Therefore, O–O bonds in **1** should best be described as single bonds.

The relationship between the position of the O–O stretching mode and the substituents of **1** becomes evident from Table 1. Electron-withdrawing groups shift the bands to higher frequencies. Compared to a phenyl group, a CF_3 group induces a shift of 50 cm^{-1}. Even more effective is the dienone moiety as π acceptor in the quinone **1m**: here, the band is shifted by 138 cm^{-1} to higher frequencies as compared to **1b**. On the other hand, replacing a phenyl group by an H or Cl atom hardly influences the O–O vibration at all. The O–O bond is stabilized by electron acceptors, π acceptors giving rise to larger effects than σ-acceptors.

A weak IR band in the region between 550 and 740 cm^{-1} also shows a marked ^{16}O–^{18}O isotopic shift (0.7–1.9%) and is assigned to an O–O deformation vibration.[51, 72]

Whereas the O–O stretching vibration of **1** is a characteristic group frequency, it is difficult to unequivocally assign the C–O stretching vibration to any of the observed bands. In the "carbonyl region" no absorptions are registered. The C–O stretching vibration is strongly coupled with other vibrations, is of low intensity, and—in comparison to C=O vibrations of carbonyl compounds—is shifted to lower wave numbers. Thus, the electronic structure of a carbonyl oxide group is characterized by a C–O bond of low polarity and a C–O bond order of less than 1.5 and is fundamentally different from that of a normal carbonyl group.

To verify the assignments mentioned above, a comparison of the experimental data with quantum-mechanical calculations seems in order. Unfortunately, the calculation of IR spectra by exact ab initio methods can only be achieved through great computational effort, so that, to date, only calculations on **2a** have been performed on this scale (Table 2).[14c] The comparison with the experimental data for **1m** indicates that not only the position but also the amount of the isotopic shift of the O–O stretching mode and the O–O deformation vibration is well reproduced by the calculations.

Table 2. Comparison of MP2/6-31G* vibrational frequencies of **1a** with experimental frequencies of **1m**.

Assignment	**1a** ν(O-O) [a] [cm^{-1}]	Δ [b] [cm^{-1}]	**1m** ν(O-O) [c] [cm^{-1}]	Δ [b] [cm^{-1}]
ν_4/δ(COO)	1222 (7)	−32 (2.6)	1241 (m)	−6 (0.5)
ν_5/ν(CO)	1116 (52)	−22 (2.0)	1327 (w)	−16 (1.2)
ν_6/ν(OO)	1028 (100)	−49 (4.8)	1034 (vs)	−57 (5.5)
ν_7/δ(COO)	522 (1.2)	−18 (3.4)	570 (w)	−11 (1.9)

5.3.2. UV Spectra

In the near-UV and visible region of the spectrum of **1** (λ = 380–460 nm) one observes intense and broad absorptions that, in some cases, also exhibit fine structure (Table 1). For **1i** the fine structure is caused by the O–O stretching vibration of the COO group.[64] Owing to this absorption in the visible region of the spectrum, carbonyl oxides isolated in a matrix are yellow to orange, except for **1j**, which is blue.

In order to calculate the UV/VIS transitions, the semiempirical CNDO/S method[88] is appropriate, since it is ideally suited to compute $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions (Table 1). According to the CNDO/S calculations, one expects two characteristic absorptions for carbonyl oxides in the visible region of the spectrum: a very strong $\pi \rightarrow \pi^*$ transition and a weak $n \rightarrow \pi^*$ transition.[17]

The $\pi \rightarrow \pi^*$ transition with $\lg \varepsilon \approx 4$ is the strongest transition in the spectrum and is situated between 378 and 582 nm depending on the substituents (Table 1). Because of the strong intensity and the favorable position of this band in the spectrum, it is especially important for the detection of carbonyl oxides. The comparison of the calculated data with experimental results derived from matrix and laser photolysis studies (Table 1) reveals an excellent agreement between theory and experiment. The largest discrepancy in the calculated and experimental maxima is observed for **1b** (33 nm).

The position of the $\pi \rightarrow \pi^*$ transition depends on the size of the π system and the electronic properties of the substituents (π donor or π acceptor). Large conjugated π systems such as those in **1e**, **1c**, **1m**, or **1p** induce a redshift when compared to **1a**. However, a large redshift is found for **1r**, which features only a small π system (Table 1). Consequently, π donors (like the O atoms in **1r**) also lead to a redshift of the $\pi \rightarrow \pi^*$ transition. The opposite is true for electron acceptors: the $\pi \rightarrow \pi^*$ transition of shortest wavelength is observed at 378 nm for **1k**.

The influence of the π system becomes evident from the comparison of **1c** and **1p** with their benzoannelated derivative **1e** and **1q** (Table 1).[17] Compared to **1a**, the tropylidene group (a π donor) in **1p** induces a redshift of 162 nm. In contrast, the cyclopentadienyl group in **1c** shifts the band into the red by only 40 nm. Benzoannelation leads to reverse effects in both compounds: in **1p** to a blueshift (from 546 nm in **1p** to 493 nm in **1q**) and in **1c** to a redshift (from 424 nm in **1c** to 489 nm in **1e**). This can be explained by the larger π systems in the benzoannelated derivatives, in that they can delocalize the charge more effectively and consequently reduce the influence of the tropylidene or cyclopentadienyl group on the COO moiety. The calculated redshift of the

$\pi \rightarrow \pi^*$ transition induced by π donors[17] was impressively verified by experiment: the carbonyl oxide **1j**, which contains the bicyclo[6.3.0]undecapentaenyl framework as a π donor, is blue and exhibits the highest long-wavelength absorption, with a maximum at 582 nm.[73]

The calculated, extremely weak $n \rightarrow \pi^*$ transitions are situated in the red part of the spectrum (598–895 nm) and have not actually been measured up to now. An indirect indication of their existence is the photochemistry carried out at long wavelengths. The rearrangement of **1** to **2** on irradiation at wavelengths lying far from the $\pi \rightarrow \pi^*$ transition can best be explained by a long-wavelength transition of low intensity.

5.3.3. *Calculations*

Whereas only a few simply substituted carbonyl oxides have been subject to calculation by ab initio methods (**1a**[13, 14a, 14d, 15, 89, 90] and **1s**[14d, 30] as well as some alkyl-substituted derivatives[14a, 14d, 15]), the semiempirical MINDO/3 method[91, 92] allows the inclusion of larger substituents.[17] Nonetheless, just as in the ab initio methods, the semiempirical calculations require that one exceed the RHF level and perform 2X2 CI[16] or UHF calculations.[17, 93]

The calculated spin densities indicate that in π-substituted carbonyl oxides—like **1b** and **1h** or the cyclic carbonyl oxides **1m**, **1c**, and **1p**—the wave functions have diradical character.[17] The spin polarization of the π system and the O–O bond length (Table 3) are influenced by the substituent only to a minor extent. The influence of the phenyl group largely manifests itself in the extension of the π system and transfer of some π-electron density onto the COO group. The result is an enhanced p_π–p_π repulsion in the 3-center 4π-electron system and thus a lengthening of the C1–O1 and O1–O2 bond.

Table 3. Ground-state properties of some carbonyl oxides, calculated with the MINDO/3-UHF procedure (bond lengths R, bond angles, atomic charges, p_π-spin densities).

	R(CO) [Å]	R(OO) [Å]	<COO [°]	Atomic charge C(1)	O(1)	O(2)	N_π [a]	p_π-Spin densities [b] C(1)	O(1)	O(2)

[a] Number of π electrons in the COO group. [b] Positive values correspond to an excess of α-spin density, negative values to an excess of β-spin density.

In the cyclic carbonyl oxides the π-electron density in the COO group can either be enhanced (ring as π donor as in **1p** or **1g**) or diminished (ring as π acceptor as in **1e**, **1c**, or **1m**); π donors effect a lengthening of the C1–O2 bond, π acceptors a reduction. The stabilization of the COO group by π acceptors and its destabilization by π donors is not reflected by the calculated O1–O2 bond lengths, which are almost constantly calculated at 1.28 Å (Table 3) but is in agreement with the experimental results. The O–O stretching vibration is shifted to higher wavelengths by electron acceptors, which indicates a stabilization of the O1–O2 bond.

A more dramatic influence on the wave function is calculated for electronegative elements such as O in **1r** and F in **1s**. In these cases only a small amount of spin polarization of the π system remains and the UHF result is identical to the RHF result to a high degree; the wave function is that of a zwitterion. Carbon atom C1 bears a large positive charge in **1r** and **1s** (Table 3).

From the MINDO/3 calculations some general conclusions can be drawn:

1. π acceptors lead to a transfer of π-electron density from the COO group onto the substituent. In consequence, the COO group is stabilized.
2. π donors lead to a transfer of π-electron density of the substituent onto the COO group. Thus, the COO group is destabilized.
3. The C–O bond length is more strongly influenced by substituents than the O–O bond length.
4. Strong σ-acceptors (e.g., O or F) can compensate for the π-electron effects and, in particular, may lead to a more stable zwitterionic state.

On comparing theoretical and experimental results it is important to consider the influence of solvent effects. Polar solvents can stabilize zwitterionic states more strongly than diradical states and can therefore counteract the substituent effects discussed above.[13]

6. Conclusion and Outlook

The experimental and theoretical research discussed in this review gives a relatively consistent picture of the electronic structure of carbonyl oxides. Thus, carbonyl oxides in the ground state in the matrix are polar diradicals. This form should not be mistaken with a zwitterionic state, which lies at higher energy. the O–O bond is best described in terms of a polar single bond, while the C–O bond is less polar and exhibits a bond order of ca. 1.5. Considering that the absorption spectra of carbonyl oxides are very similar in the matrix and in solution at room temperature (Table 1) and that the absorption maxima are only slightly influenced by the polarity of the solvent, it can be concluded that, also in solution, the ground state is best described as a diradical species. Once π-electron donors are introduced (e.g., as in **1r**) carbonyl oxides with a zwitterionic ground state should arise. The experimental verification of a carbonyl oxide with such a zwitterionic ground state has yet to be achieved.

I thank my co-workers G. Bucher, A. Patyk, and A. Runge, whose particular dedication—often at unearthly times of the day—made a completion of our work in the field of matrix spectroscopy possible. My thanks are also due to Prof. Dr. R. Gleiter for generous support over the last years, Dr. P. Bischof for assistance in theoretical matters, Prof. Dr. D. Cremer for excellent cooperation on the calculation of the properties of carbonyl oxides, and Prof. Dr. B. Giese for his help concerning instrumental aspects.—This work was supported by the

Enzymic Reaction Selectivity by Negative Catalysis or How Do Enzymes Deal with Highly Reactive Intermediates?

By János Rétey*

Our current understanding of enzyme catalysis is dominated by the hypothesis of transition-state binding launched by *Linus Pauling* in 1946. Transition-state binding and the interplay of properly positioned, catalytically active functional groups can largely explain both the acceleration and specificities of many enzymic reactions for which chemical analogy exists. Here it is postulated that, for chemically "difficult" or "improbable" reactions, enzymes may resort to an additional device. Using cofactors of potentially high energy (such as coenzyme B_{12}), stabilized radicals, or light, they can transform the bound substrate into a highly reactive (i.e., unstable) intermediate. Selectivity is now achieved by *negative catalysis*, that is, by preventing the "hot" intermediate from undergoing reactions that would occur in solution or in the gas phase and thus prolonging its lifetime. The highly reactive intermediate may then undergo reactions whose activation energy is relatively high and which would therefore be suppressed without negative catalysis. Reaction selectivity is thus achieved by preventing undesired reactions rather than by facilitating the target ones. The high reactivity may be transferred reversibly if its source is, for instance, coenzyme B_{12} or irreversibly if it is generated by light or ATP. Highly reactive intermediates are often radicals but can also be other unstable species. In this article a number of enzymic reactions are discussed that seem to support the above postulate.

1. Introduction

Although the real nature of enzyme catalysis is still elusive, many important details of enzyme structure and enzyme–substrate interaction have been uncovered in the last decades. As a result, some general conclusions may be drawn and it is possible to identify principles that make enzyme action possible. Substrate binding is the first and obligatory step in all enzymic reactions. Although this step is essential, it is not sufficient for catalysis. However, as pointed out by *Linus Pauling* in 1946,[1] the binding site of enzymes is complementary to the transition state rather than to the substrate. Put another way, the lower energy barrier for the enzymic reaction (compared with the uncatalyzed one) results from destabilization of the ground state of the substrate and from concomitant stabilization of the transition-state–enzyme complex. Strictly speaking, this dissection is not completely correct, since, after substrate binding, the whole complex should be treated as a single entity. Allowing for such "sloppiness", one can argue that the measurable binding energy is much less than the intrinsic one, since a portion thereof is "used up" to force the substrate toward the transition-state structure. This may involve locking the substrate into an unfavorable but reactive conformation, desolvation, a change in polarization, or covalent binding to the enzyme. Here it is important to emphasize the role of the nonreacting part of the substrate or of the coenzyme molecule. The binding energy associated with this portion may be used to force the reacting moiety into an "unwelcoming" hole.[2] In many cases (e.g., acyl-CoA, SAM, $NAD^{\oplus}$, and FAD[**]) such a nonreacting portion is attached to the substrate or to the reactive part of the coenzyme. Such a device may serve a double role: for example, it can allow both chemical activation as thioester or sulfonium ion and strong binding by interaction with a complementary site of the enzyme (e.g., the adenosine binding portion). Similar effects can be achieved by phosphorylation or pyrophosphorylation, as in pyridoxal phosphate or thiamine pyrophosphate, which might be bound partly by ionic interactions. A portion of the binding energy can be used not only to destabilize the substrate but also for conformational and structural changes of the enzyme.

A further consequence of *Pauling*'s postulate is the very tight binding of the so-called transition-state analogues to enzymes. These are compounds whose structure resembles that of the putative transition state of the enzymic reaction. Such transition-state analogues have been used as powerful inhibitors and potential drugs and, more recently, in the preparation of catalytic antibodies.[3,4] It is natural that most investigators have focused their efforts on enzymic reactions that are relatively simple and chemically plausible. These include proton transfers, such as tautomerizations, epimerizations, and racemizations as well as hydrolytic reactions such as those of esters and amides.[5–7] Even so, some problems are still unsolved. Since most enzymic reactions consist of several elementary steps, the following question arises: Which is the step whose transition state is relevant for binding-site complementarity? Is it the rate-determining step, or is the enzyme capable of producing complementary binding sites for several transition states following each other in a reaction sequence by subtle and rapid conformational changes?

It is also customary to estimate the rate acceleration that an enzyme is able to achieve by comparing the enzyme-catalyzed reaction with the uncatalyzed reaction. Such an acceleration is said to be roughly equal to the ratio of the dissociation constants for the enzyme–substrate and the

enzyme–transition-state complexes, K_S and K_T, respectively [Eq. (a)].[8]

$$\frac{k_e}{k_n} = \frac{K_S}{K_T} \qquad (a)$$

Rate accelerations of between 10^{10} and 10^{20} have been estimated. Still another outstanding property of enzymes is their very high specificity. Their substrate specificities and stereospecificities have been demonstrated and discussed on numerous occasions.[9–12] Let us focus here on their reaction specificity; that is, more than one enzyme can act on the same substrate but each will catalyze only one specific reaction yielding only one specific product. Of course, this follows from *Pauling*'s theory of transition-state binding. In other words, many enzymes work according to the following strategy: They select one reaction and lower its energy barrier by stabilizing the corresponding transition state. Other possible reactions cause no problem since their activation energies are and remain high (i.e., the substrate is stable).

There are, however, an increasing number of known enzymic reactions that are neither simple nor chemically plausible. Their enzymic rate acceleration is virtually infinite since the rate of the uncatalyzed reaction is zero. How can enzymes make possible such chemically improbable reactions? Can transition-state binding theory also provide a full explanation for these reactions? To convey to the bound substrate sufficiently high reactivity, enzymes can resort to "energy-rich" agents such as ATP, radical-generating species (e.g., the combination of iron complexes with radical-forming agents like tyrosine or coenzyme B_{12}), or even light. In the case of coenzyme B_{12}, homolysis of the cobalt–carbon bond can generate a highly reactive radical that is able to abstract a hydrogen atom from a nonactivated position of the substrate. The latter, thus destabilized, is now prone to undergo spontaneous reactions. The main task of the enzyme is to prevent stabilization reactions that are typical for free radicals in solution. Such "negative catalysis" may be achieved by isolating the reactive intermediate from groups that might react with it and by preventing conformations from which undesired reactions could occur. This allows the radical intermediate to undergo atypical reactions such as rearrangements involving 1,2 migrations.

In other words, reaction selectivity can be achieved by specific acceleration of a certain reaction or, alternatively, by producing, under energy input, a highly reactive intermediate that is prevented from undergoing undesired reactions. If the lifetime of the highly reactive intermediate is prolonged in this way, unusual transformations can follow. In contrast to ATP, light, or other energy sources, the energy spent by coenzyme B_{12} must be regained at the end of the catalytic cycle.

What is the experimental support for such an alternative or, better, additional principle of reaction selectivity and what is its importance in the realm of enzymic reactions?

2. Rearrangements Catalyzed by Coenzyme-B_{12}-Dependent Enzymes

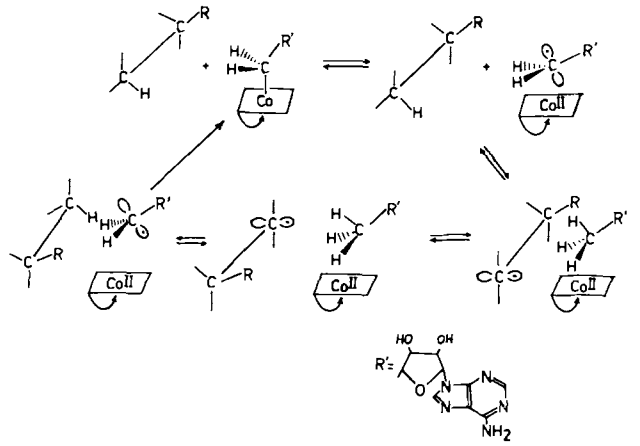
About a dozen coenzyme-B_{12}-dependent rearrangements are known and they are remarkable in several respects. Coenzyme B_{12} and some of its derivatives are the only bona fide natural products containing a covalent metal–carbon bond. The thermal stability of this bond, particularly in aqueous solution, is also noteworthy. Its homolysis energy has been reported to be about 30 kcal mol^{-1};[13, 14] its photolysis is fast but probably of no relevance for the enzymic reactions. Even more astonishing are the rearrangements. They consist of an interchange of a hydrogen atom and a variable group between adjacent carbon atoms [Eq. (b)].

(b)

If R is an organic residue such as the groups -COSCoA, $-C(H)(NH_2)COOH$, or $C(=CH_2)COOH$, then we talk of carbon-skeleton rearrangements, as in the case of methylmalonyl-CoA, glutamate, and methylene glutarate mutases. All these cases involve attack at a nonactivated methyl group. If, on the other hand, R is an "inorganic" group such as OH or NH_2, then we talk of dioldehydratases or ammonia lyases or amino mutases. An example of the latter is β-lysine mutase.

Whereas the migration of R is strictly intramolecular,[15, 16] that of the H atom is partially intermolecular.[17–20] In 1966, *Frey* and *Abeles*[18] discovered that the migrating H atom scrambles with those of the cobalt-bound methylene group. They concluded that the reaction involves transient cleavage of the cobalt–carbon bond and the intermediacy of 5′-deoxyadenosine. As a further consequence, one has to assume another chemically difficult step, namely, the attack at a nonactivated methyl group of 5′-deoxyadenosine, which is necessary to regenerate the catalyst. Such a minimal mechanism is depicted in Scheme 1.

János Rétey, born in 1934 in Szeged (Hungary), studied chemistry between 1957 and 1960 at ETH Zürich and finished his Ph.D. work on the stereospecificity of oxidoreductases in 1963 with V. Prelog. After postdoctoral years with F. Lynen (Munich, 1963–1965) and D. Arigoni (ETH Zürich, 1965–1968), he became "Oberassistent" and lecturer at ETH Zürich. Since 1972 he has been professor of biochemistry at the University of Karlsruhe. In 1971 he received the Alfred Werner prize of the Swiss Chemical Society. His fields of interest are the mechanism and stereospecificity of enzyme action, synthetic enzyme models, bioorganic and bioinorganic chemistry, and the investigation of enzyme structures by molecular biological methods.



Scheme 1.

The postulated cleavage of the cobalt–carbon bond is likely to be homolytic. Not only is this the mode of cleavage requiring the least energy, but in some cases experimental support (ESR, UV) exists for the intermediacy of a paramagnetic Co^{II} species and an organic radical.[21 - 29] A highly reactive organic radical also has the potential to attack a nonactivated methyl group, for example in reactions involving methylmalonyl-CoA,[30] isobutyryl-CoA,[31] or methylaspartate.[32] Whereas direct evidence for radical intermediates in these carbon-skeleton rearrangements has not yet been provided, ESR spectra of enzyme–substrate complexes with ethanolamine ammonia lyase,[21, 23, 24] dioldehydratase, [25 - 27] and ribonucleotide reductase[28] have been published. They suggest that the paramagnetic Co^{II} center and the 5'-methylene radical of the adenosine moiety are 10–12 Å apart during catalysis. It is tempting to postulate that substrate binding triggers a conformational change of the enzyme that pulls the two moieties apart. The substrate may penetrate into the space created by such a movement. Exact positioning of the methylene radical and substrate is probably required for specific abstraction of the migrating hydrogen atom.

2.1. Dioldehydratase and Ethanolamine Ammonia Lyase

Many interesting and surprising stereochemical details have been revealed in the reactions catalyzed by dioldehydratase and ethanolamine ammonia lyase. In both reactions a pair of homologous substrates can be processed in a similar but stereochemically distinct way [Eqs. (c) and (d)].

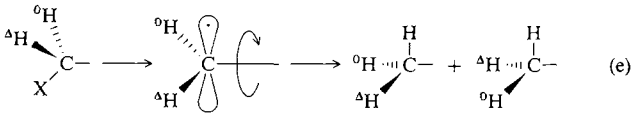
$$R{-}\underset{\displaystyle OH}{\underset{|}{CH}}{-}CH_2OH \longrightarrow R{-}CH_2{-}CHO + H_2O \qquad (c)$$

R = H, CH_3

$$R{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}CH_2OH \longrightarrow R{-}CH_2{-}CHO + NH_3 \qquad (d)$$

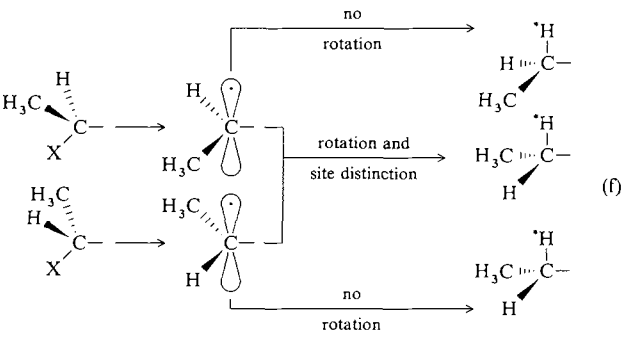
R = H, CH_3

The results and their consequences for the relevant mechanisms have been reviewed.[11, 12] They support the occurrence of radical intermediates previously indicated by ESR spectra.[21 - 29] In particular, the racemization consistently observed when a reaction proceeds via a methylene radical, indicates that the radical rotates rapidly around the C–C bond, thereby making the homotopic faces indistinguishable [Eq. (e)].



(e)

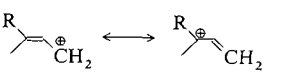
Replacing one of the hydrogens by a methyl group either prevents rotation at the binding site as in the case of dioldehydratase[33] or, for a low rotational barrier, it renders the two faces of the trigonal center *distinguishable* for the enzyme as in the case of ethanolamine ammonia lyase[34] [Eq. (f)]. Experimentally, a uniform steric course (e.g., inversion) is observed in the first case, and a non-uniform stereospecificity, independent of the substrate configuration, in the second case.



(f)

Thus, stereochemical analysis of enzymic reactions is an excellent probe for the occurrence of methylene radical intermediates. Anionoid methylene groups, such as those implicated in the condensation reactions involving acetyl-CoA, have a high barrier of rotation and are handled by enzymes throughout stereospecifically.[35 - 38]

Enzymic processes where methylene cations might be surmised are rare. In terpene biosynthesis during condensation of the biological isoprene units, isopentenyl and dimethylallyl diphosphate, the putative intermediate is an allylic cation (see **1**).

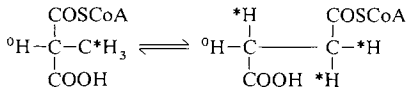


1

The use of stereospecifically labeled substrates showed complete selectivity for the enantiotopic methylene faces, which points to a high rotational barrier in **1**.[39]

2.2. Methylmalonyl-CoA Mutase

Among the coenzyme-B_{12}-dependent carbon-skeleton rearrangements, the methylmalonyl-CoA mutase reaction [Eq. (g)] has been investigated the most thoroughly.



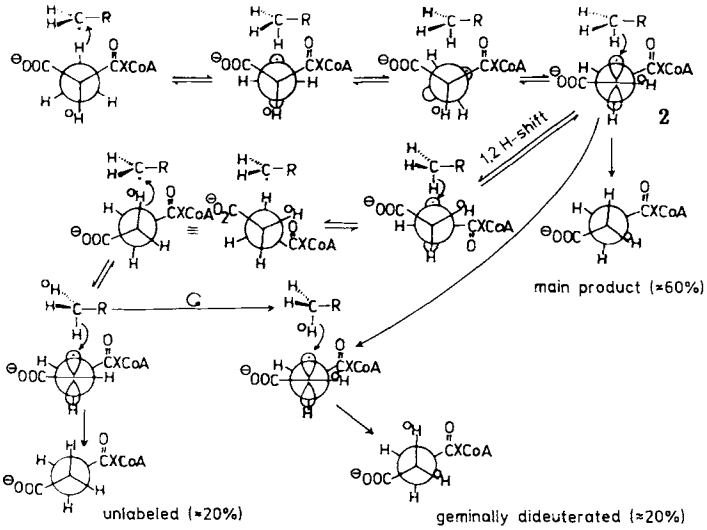
(g)

The steric course of the substitutions at the migrating centers was elucidated using deuterium as a label[40,41] or the substrate analogue ethylmalonyl-CoA.[42] The substitutions occur at both centers mainly but not exclusively with retention. Furthermore, starting from monodeuterated [2-$^2H_1$]-methylmalonyl-CoA, the product succinyl species contained unlabeled and dideuterated molecules, 15–20% of each.[40,41] Because enzymes were thought to be strictly stereospecific, these results were first attributed to impure enzyme preparations or experimental errors. Only 20 years later, when HPLC-purified enzyme preparations were available and high-resolution NMR spectrometers allowed enzymic reactions to be monitored directly in the NMR tube, could it be shown that the surprising deuterium distribution arose not from experimental error but as a consequence of the reaction mechanism.[43,44] Especially clear-cut results were obtained using the carba(dethia)coenzyme A (CH_2CoA) analogue of methylmalonyl-CoA.[45] This is almost as good a substrate as the natural thioester but has the advantage of complete stability to hydrolysis. Thus, in contrast to succinyl-CoA, which is hydrolyzed easily under physiological conditions, the production and deuteration of succinyl-CH_2CoA could be monitored for a day or so in the NMR tube.

The kinetic NMR study[45] confirmed the surprising scrambling of the "nonmigrating" deuterium among the succinyl species produced. Thus, instead of the expected "100%" monodeuterated product molecules, only about 60% were formed, the remainder being unlabeled or geminally dideuterated. In the presence of methyl-malonyl-CoA epimerase, any unlabeled methylmalonyl-CH_2CoA produced in the backward reaction instantly incorporated deuterium into its α-position from the solvent. Repeated rearrangements led once more to some unlabeled product, which was consistently deuterated at the methylmalonyl stage. This process constituted a leak in the system which allowed a continuous deuterium incorporation from the solvent into the product and could be monitored by ^{1}H NMR spectroscopy during a longer period of time.[45] In the strict absence of methylmalonyl-CoA epimerase, the scrambling reached a stationary phase with a statistical distribution of unlabeled, monodeuterated, and geminally dideuterated (1 : 1 : 1) species.[46]

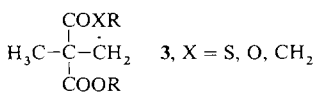
Since the deuterium scrambling occurs before equilibrium is reached, it cannot be explained by lack of stereospecificity in the backward reaction, that is, incomplete distinction between the two diastereotopic 3-methylene hydrogen atoms of the succinyl moiety. Furthermore, in experiments with the natural thioester substrate in deuterium oxide, the monodeuterated succinyl-CoA was about 90% optically pure.[40,47] A mechanism that takes account of all these facts is summarized in Scheme 2.

In Scheme 2 it is assumed that, after homolytic cleavage of the cobalt–carbon bond, the paramagnetic Co^{II} center has the role of a "spectator" only. The adenosine 5′-radical is positioned in a way that it can abstract a methyl hydrogen atom from the substrate, whereby it becomes itself a nonactivated methyl group. After migration of the carbonyl-XCoA group (X = S or CH_2), the product radical **2** can reabstract a hydrogen atom from the 5′-methyl group of adenosine, affording the expected stereospecifically deuterated product. To explain the presence of unlabeled and doubly labeled species, one can assume a 1,2 hydrogen shift which is stereoelectronically favored and may take place in competition with the "intermolecular" H abstraction. The configuration at the "front" center is thereby inverted so that deuterium comes within reach of the 5′-methylene radical.



Scheme 2.

The latter is regenerated after hydrogen transfer to the "rear" center and is now able to abstract deuterium from the front center of the bound product. Since methyl groups have a low torsional barrier even at the enzyme's active site, back-transfer of an H atom may lead to unlabeled succinyl-CH_2CoA with concomitant deuterium incorporation into the 5′-methylene group of the coenzyme. In the next catalytic cycle, such a deuterated coenzyme may deliver deuterium to the monodeuterated radical intermediate **2**, affording the observed geminally dideuterated succinyl product.



3, X = S, O, CH_2

When the postulated methylmalonyl thioester radical **3** is generated in nonenzymic model systems, relatively low yields of 1,2-migration products are observed.[48–53] Stabilization by direct hydrogen abstraction usually prevails. The migra-

tory aptitude of the groups decreases in the following order: -COR > -COSR > -CN > -COOR.[48, 51, 52, 54] A bona fide 1,2-migration of H atoms in organic radicals has not yet been reported.

It has been noted[51] that the methylmalonyl-CoA mutase reaction is relatively slow compared with the lifetimes of free radical species generated in model studies. This indicates that the enzyme prolongs the lifetime of the free radical intermediates by preventing stabilization pathways typically occurring in solution.

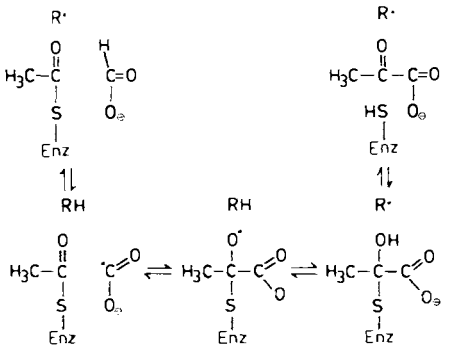
3. Radical Enzymic Reactions Independent of Coenzyme B_{12}

During the last few years more and more enzymic reactions have become known in which radical intermediates have been postulated. Most of them involve unusual chemical transformations that cannot be explained by conventional or ionic mechanisms. Although the postulated mechanisms are not strictly proven, a review of them should illustrate and support the ideas developed in this paper.

Pyruvate formate lyase catalyzes the reversible cleavage of pyruvate to formate and acetyl-CoA [Eq. (h)]. In contrast to

$$H_3C{-}\overset{O}{\overset{\|}{C}}{-}COOH + CoASH \rightleftharpoons H_3C\overset{O}{\overset{\|}{C}}SCoA + HCOOH \qquad (h)$$

the oxidative decarboxylation of pyruvate, the pyruvate formate lyase reaction is independent of thiamine pyrophosphate.[55] *Knappe* et al.[56] found the purified enzyme to contain a radical of unknown nature and postulated[57] independently from others[58] the mechanism depicted in Scheme 3. The key step is the abstraction of a hydrogen atom



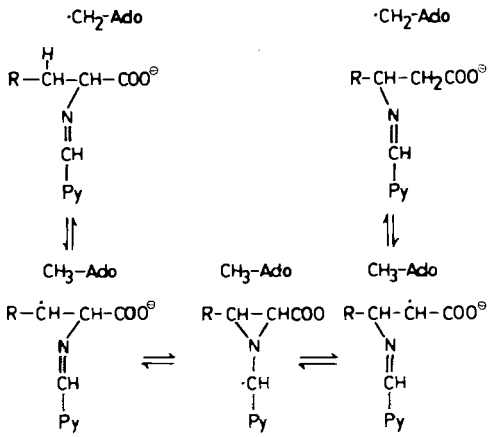
Scheme 3.

from the thiohemiketal intermediate in the forward reaction and from formate in the reverse reaction. The cleavage/formation of the C–C bond is of radical nature, thus avoiding the difficulty of bond formation between two carbon atoms polarized in the same sense. As in the coenzyme-B_{12}-catalyzed reactions, the high reactivity is only "borrowed" by the substrate and must be returned to the catalyst at the end of each catalytic cycle.

Lysine 2,3-aminomutase from *Clostridium* species catalyzes the migration of an amino group in lysine from position 2 to 3 [Eq. (i)].[59] The enzyme is dependent on pyridoxal phosphate and *S*-adenosyl-methionine (SAM) as cofactors. *Frey* and co-workers found a tritium transfer from the 5′-position of the adenosine moiety of SAM to position 2 of β-

$$H_2N{-}(CH_2)_3{-}CH_2{-}\underset{NH_2}{CH}{-}COOH \longrightarrow H_2N{-}(CH_2)_3{-}\underset{NH_2}{CH}{-}CH_2COOH \qquad (i)$$

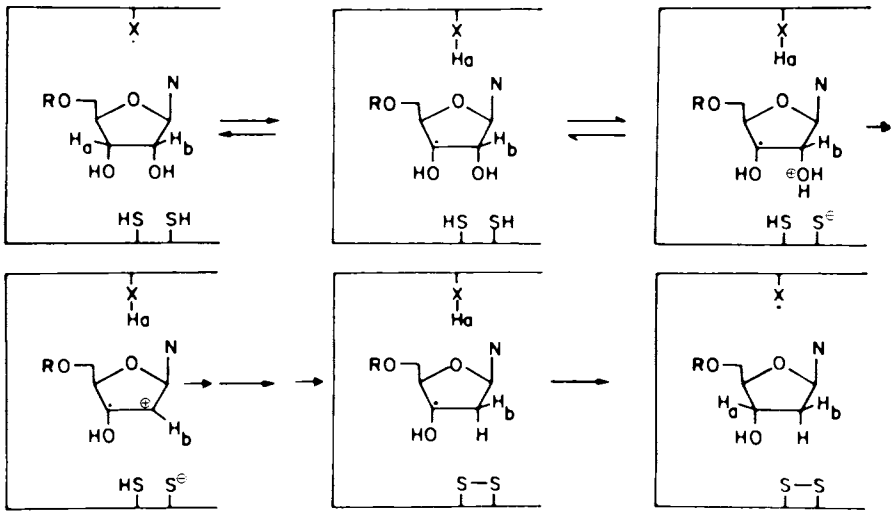
lysine.[60, 61] This is reminiscent of coenzyme-B_{12}-dependent mutases, and the authors proposed a mechanism in which some elementary steps are very similar (Scheme 4).



Scheme 4.

In analogy to coenzyme-B_{12}-dependent reactions, they postulate a homolytic cleavage of the sulfur–carbon bond to form a 5′-adenosyl radical which is able to abstract a hydrogen atom from the unreactive 3-position of lysine. The radical thus formed attacks the neighboring imino nitrogen atom of the Schiff base between lysine and pyridoxal phosphate. The resulting new radical is stabilized by both the aromatic ring and the aziridine ring. Rearrangement finally leads to a radical α to the carboxylic group, which is then stabilized by H-atom transfer from the 5′-deoxyadenosine bound to the active site. *Aberhart* et al. carried out an independent investigation using deuterium as a label.[62, 63] They were not able to demonstrate deuterium transfer from the 5′-position of SAM to α- or β-lysine and came to a conclusion different from that of *Frey* and co-workers. Different conditions and enzyme preparations may be the cause of this discrepancy.[61]

One of the best characterized enzymes containing a "stabilized" radical is the ribonucleoside diphosphate reductase from *E. coli*.[64] This was the first case in which a tyrosyl radical "stabilized" by a neighboring binuclear iron(III) complex was identified.[65] It is intriguing that the corresponding enzyme in *Lactobacillus leichmannii* is coenzyme B_{12} dependent. Indeed, it has been postulated[66] that in both cases the different radical-forming centers have similar roles and abstract hydrogen atoms from SH groups and/or from the 3′-position of the nucleotide (Scheme 5).[67] The surprising participation of 3′-H in the reaction is indicated by a substantial deuterium kinetic isotope effect. This mechanism



Scheme 5.

shows an interesting analogy to the methylmalonyl-CoA mutase reaction in which a seemingly nonparticipating hydrogen atom is also involved in the rearrangement.[45,46]

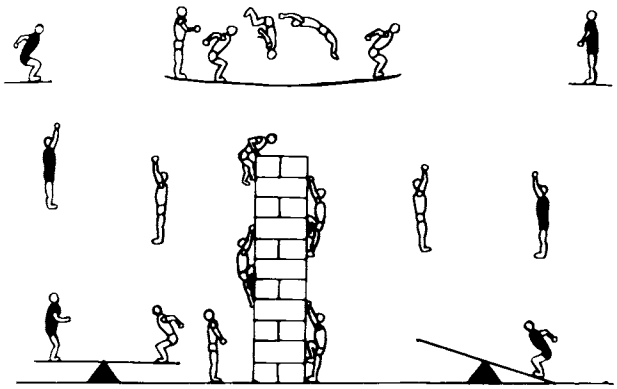
There are a great number of other enzymic processes in which highly reactive intermediates, mostly radicals, are implicated. Among them are various oxidations catalyzed by flavoenzymes as well as cytochrome P-450 enzymes and other iron-containing enzymes. In all these cases an important task of the enzyme is to prevent the highly reactive intermediate from undergoing unwanted reactions. Such a control by *negative catalysis* may be equally important as *positive catalysis* when the enzyme deals with unreactive substrate species or intermediates.

In photosynthesis, in which enormous progress has recently been made, negative catalysis may play a role, too. In the thylakoid membrane, electrons are promoted to a higher energy level by light absorption. In most model systems they fall back, dissipating their energy in some useless form. In the chloroplast, enzymes and membranes prevent the electron from doing so and channel it to ferredoxins, NADP, etc., that is, an electron transport chain that is coupled with ATP formation. In contrast to coenzyme-B_{12}, light is an energy donor and not an energy "lender".

4. Conclusions

Highly reactive intermediates are involved in many organic reactions. The unusual outcome of some enzymic reactions can be explained by the control of such highly reactive intermediates in the enzyme-bound state. By suppressing typical stabilization reactions, such intermediates may undergo unexpected rearrangements or group transfers. The mechanisms of some enzymic radical reactions, dependent on or independent of coenzyme B_{12}, show how such chemically improbable conversions become feasible.

The cartoon shows an anthropomorphic view of coenzyme-B_{12}-dependent rearrangements. The potential energy of the cofactor is used to generate a high-energy intermediate which, after rearrangements but without substantial energy loss, returns the borrowed energy to the cofactor. One of the most important tasks of the protein is to prevent the high-energy intermediate from falling down to a lower energy level. The uncatalyzed reaction is symbolized by a man climbing over a wall.



I thank my younger colleagues whose contributions are cited and provided the basis for the ideas described in this paper. The paper was written during a visiting professorship at the Technion-Israel Institute of Technology sponsored by the Swiss Technion Society. I thank the colleagues at Haifa for their kind hospitality and for stimulating discussions, particularly with Professor A. Halevi. The experimental work in the author's laboratory has been supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Land Baden-Württemberg.

Chemiluminescence Techniques for the Characterization of Materials

New Analytical Methods (41)

By G. David Mendenhall*

Photons are emitted at low levels from a wide variety of organic materials at wavelengths ranging from the visible to infrared. This light emission accompanies free-radical autoxidation and charge-recombination processes and is particulary useful in assessing thermal oxidation and radiation damage as well as polymer curing reactions. IR chemiluminescence, which offers advantages because of reduced self-absorption, has been shown to mark the end of induction periods in inhibited systems. With the introduction of sensitive solid-state devices, the chemiluminescence technique has been extended to two-dimensional imaging and presentation.

1. Introduction

The progressive replacement of metal and ceramic materials with organic-based polymers and composites has created a practical interest in slow oxidation rates which may determine the lifetime of the replacements. Weak light emission is associated with peroxidic oxidation products of organic materials and with certain physical processes described below. Chemiluminescence is a very attractive way to measure oxidation in real time because of the large molar gain factor $N_{av}\Phi_{em}$ (Avogadro number times the quantum yield for emission) coupled with the availability of sensitive and reliable photon-counting systems.

I reviewed a number of empirical applications of chemiluminescence (CL) from condensed-phase materials in 1977.[1] Since that time, advances in the field have been arithmetic rather than exponential, although a considerable body of information on the technique exists as arcana with various industries. Most studies in this area consist of the effects of temperature and atmosphere on CL as a function of sample composition and history. The purpose of this article is to present updated theories on the origin of light emission, some recent, rather successful applications, and technological advances which promise to make the technique more widely used in the future.

2. Experimental Aspects

The apparatus for CL measurement is fundamentally simple, since no resonant conditions, or high- or low-temperature extremes are involved. The most important requirements are the exclusion of extraneous light and the reproducible placement of the samples with respect to the device for light detection.

Liquids at temperatures below about 90 °C may be examined conveniently in a glass or quartz cell jacketed with circulating water at a constant temperature. For higher temperatures an insulated metal block with heating elements (Fig. 1a) is preferable to baths of silicone and other traditional oils, which themselves give abundant chemiluminescence at elevated temperatures.

Luminescence from solids at near-ambient temperatures and light-stimulated luminescence may be measured reproducibly with the apparatus in Figure 1 b.[2] Light from solids at elevated temperatures may be measured in a heated oven (see, e.g., Ref. [3]) or with fiber-optic techniques and a small sample container in a hot block or bath.[4]

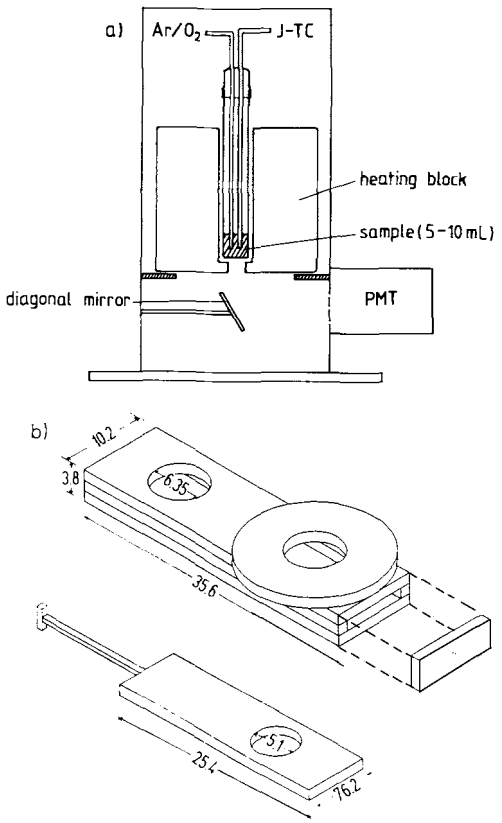

Fig. 1. a) CL apparatus for liquid samples (see also [36]). J-TC = thermocouple b) Apparatus for solids and for study of delayed luminescence (measurements in cm) [2]. The photomultiplier tube (PMT) and constant-temperature housing are placed over the hole with the large flange, and samples contained in a small dish in the sliding insert may be irradiated through the hole at left.

In most of our work, a cooled housing containing a 2"-diameter photomultiplier tube is connected to each apparatus as required. The data acquistition is usually carried out in the single-photon mode with a frequency counter whose output is stored in the memory of a small computer.

The sensitivity limits of any system are determined by the precision with which the sample emission and background noise can be measured and are subject to the usual statistical relations concerning collection times and signal-to-noise levels. A standard deviation of $\pm$ 2 Hz with a noise level of 5–20 Hz is typical for a cooled, 2″ tube under favorable conditions with samples at ambient temperature and with collection times of 40–120 s. Frequency counters with compensating devices, signal chopping, and selection of low-noise tubes or tubes with smaller active areas can reduce background signals even further. The difficulty with CL, however, is usually not signal strength but in devising suitable experimental protocols to study the wide variety of organic materials that are amenable to the technique and in divining trends from the resulting data.

Chemiluminescence can be enhanced from solids and liquids by addition of highly fluorescent molecules which can accept energy from less emissive excited states. The most commonly used fluorescent substances, 9,10-dibromoanthracene and 9,10-diphenylanthracene, can be destroyed by free-radical attack, especially at elevated temperatures.[5] This can sometimes complicate the interpretation of changes in CL with time.[6]

3. Mechanisms of CL

At present there appear to be at least three sources of adventitious photon emission from condensed-phase organic materials. Two mechanisms involve peroxy radicals, the other is due to charge recombination.

3.1. Peroxy Radicals

Peroxy–peroxy reactions via a tetroxide [Eq. (a)] have long been regarded on kinetic and thermochemical grounds as a major source of excited states when organic materials are heated in air. In the condensed phase the excited-state

$$2\,R^1R^2CHOO^{\cdot} \rightarrow R^1R^2CHOOOOCHR^1R^2 \rightarrow\rightarrow R^1R^2CO(S_0, S_1, T_0) + R^1R^2CHOH + O_2 \quad (a)$$

$$R^1R^2CO^*(S_1, T_0) \rightarrow R^1R^2CO(S_0) + h\nu$$

R^1, R^2 = alkyl, H

products appear to be primarily triplet aldehydes and ketones.[7, 8] Interaction of 2-propylperoxy radicals in the gas phase gives rise, interestingly, to CL with rotational fine structure ascribed to the emission from the $^1\Sigma_g$ state of molecular oxygen.[9]

Thermolysis of peroxides in which an alkyl group has an α-hydrogen can give rise to excited states [Eq. (b)]. The simplest example of this reaction is the decomposition of methyl peroxide to give excited formaldehyde. This exothermic reaction sequence can proceed explosively in the gas phase and produces an easily visible blue glow from formaldehyde fluorescence.[10] Triplet formaldehyde emission can also be observed from methoxy radical self-reactions ($2\,CH_3O^{\cdot} \rightarrow CH_2O + CH_3OH$) in the absence of oxygen.[11]

$$R^1R^2CHOOR \rightarrow [R^1R^2CHO^{\cdot}\ {}^{\cdot}OR]_{cage} \rightarrow R^1R^2CO^*(S_0, S_1, T_0)$$
$$R^1R^2CO^* \rightarrow R^1R^2CO + h\nu \quad (b)$$

In any given system the two mechanisms [Eqs. (a) and (b)] may appear simultaneously depending on the temperature and the concentrations of peroxidic species. For instance, saturated aliphatic hydrocarbon radicals or the radical $R^1R^2CHO^{\cdot}$ can produce a peroxy radical $ROO^{\cdot}$ by H abstraction from any ROOH present. The $ROO^{\cdot}$ radicals can also arise from other radicals by several other mechanisms in the presence of oxygen. The peroxy radicals so formed, even in the absence of oxygen, can give light emission via reaction (a). They can also give peroxides and subsequently excited ketones via reaction (b), by either a Vaughan-type termination step [Eq. (c)] or coupling with carbon radicals to form a chemiluminescence peroxide [Eq. (d)].

$$2\,R^1R^2CHOO^{\cdot} \rightarrow O_2 + R^1R^2CHOOCHR^1R^2 \rightarrow R^1R^2CO^* \rightarrow h\nu \quad (c)$$

$$R^1R^2CHOO^{\cdot} + R^{\cdot} \rightarrow R^1R^2CHOOR \rightarrow ROH + R^1R^2CO^* \rightarrow h\nu \quad (d)$$

3.2. Recombination Luminescence

The third source of light from materials is a delayed emission that is usually ascribed to charge-recombination luminescence.[2, 12–15] This is actually a physical phenomenon, but it is very frequently observed with the sensitive apparatus that investigators use to measure chemiluminescence. A regular, crystalline lattice is not a requirement. Examples of some typical decay curves from our work are given in Figure 2, although most workers have studied the phenomenon at much shorter time scales.

The current portrayal of the process (see, e.g., Ref. [15]) involves formation of an electronically excited chromophore in a material which can eject an electron to give a cation–electron pair. In the absence of an applied electric field, this

G. David Mendenhall received a B. S. degree in chemistry from the University of Michigan in 1966 and a Ph. D. in physical organic chemistry from Harvard University in 1971 under the supervision of Prof. Paul Bartlett. He also attended the Universität Freiburg in 1965. After postdoctorate positions at the National Research Council of Canada (Ottawa) and Stanford Research Institute, he worked at a contract research firm for six years before joining the Department of Chemistry and Chemical Engineering, Michigan Technological University, in 1980, where he is now Professor of Chemistry. He has taught part-time at Otterbein College, worked on drug synthesis at Parke-Davis & Company (Ann Arbor), and carried out consulting work with a number of companies.

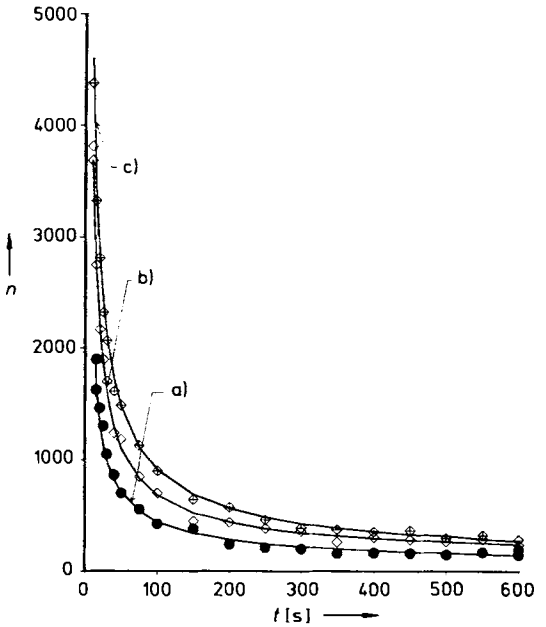

Fig. 2. Delayed emission from polymers fitted to Equation (e). Selected data points and the fitted curve are shown [2]. a) Wheat starch; b) polycarbonate; c) styrene maleic anhydride. n = counts per 5-s interval.

solid-state ionization is usually rather inefficient. Thermal motions in the solid result in a diffusive hopping of the charge through the material, where it resides in potential wells of various depths. Eventually charge recombination occurs with a finite probability of excited-state formation, followed by reionization, radiationless decay, or emission of light. The motion of the charges through the solid is initially rapid, but becomes progressively slower as the charges encounter deeper potential wells. Both electrons and cationic sites, or "holes", can migrate in this fashion, although sometimes only one may do so in a given material.

Such charge-recombination luminescence can be recognized by its dependence on a stimulus (overhead fluorescent room lights were traced as the source in our original discovery), a nonexponential, hyperbolic decay, often extending to tens of minutes, and a small temperature dependence of the recombination rate. Several theoretical treatments[12-16] of the time dependence of the emission have been carried out which lead to a power function [Eq. (e)] as an approximation ($t > 0$; $0.6 < m < 2.0$; B = intensity of background signal; A = preexponential factor).

$$I(t) \equiv \mathrm{d}\,h\nu/\mathrm{d}t = At^{-m} + B \qquad \text{(e)}$$

The cited limits on m are those that we and others have observed empirically. It is important to note in the application of Equation (e) that zero time is not arbitrary.

Some polymers that we studied and their derived values of $\lg A$ and m for delayed emission lasting up to 10 min are given in Table 1. In none of 98 polymers examined did the stimulated emission fit a simple exponential function,[2] although some undoubtedly would if examined at conventional, very short times after excitation.

The decay curves obtained in this manner, however, can also be fitted to a stretched exponential ($I = Ae^{-kt^{\beta}}$) or to a sum of two or three exponential terms.[16] The assignment of a mechanism based on charge-recombination to curves of this sort may not be correct in every case. For instance, the decay of luminescence from solid, tryptophan-containing proteins follows a power function.[17] *Strambini* and *Gabellieri* have interpreted this behavior in terms of phosphorescence from molecules in the matrix with a distribution of first-order decay times (cf. Refs. [16, 18]). Unequivocal proof of a mechanism is not necessarily straightforward, since the chemiluminescence apparatus can respond to light from either radicals or hole–electron pairs that are well below the ESR detection limit, and perturbation of the emission from solids with an applied electric field is characteristic of both correlated radical-ion pairs and localized excited states.[19]

Table 1. Parameters for Equation (e) for commercial polymers stimulated by incandescent light [2].

Polymer	lg A [a]	m [a]
Sodium alginate	4.92	0.924
Methyl cellulose	4.95	0.846
Nylon 6/6	4.43	1.02
Nylon 6/9	4.52	0.942
Nylon 11	4.91	0.973
Nylon 12	5.12	0.943
Poly(*N*-vinylcarbazole) (PVK)	7.81	1.792
Polycaprolactone	6.07	1.059
Poly(phenylene sulfide)	5.33	0.981
Vinylidene chloride/20% acrylonitrile	5.02	0.876
Soluble starch	3.30	0.680
Starch, wheat powder	3.49	0.682
Albumin, egg powder	4.51	0.932
Poly(α-methylstyrene)	4.37	0.600

[a] Variables fitted to the equation $\lg(I\Delta t) = \lg A - m \lg(t/\Delta t)$, with $\Delta t = 5$s and I = counts per time interval Δt.

We concluded from a survey of commercial polymers with incandescent stimulation that nonextractable impurities played a major role in their charge-recombination luminescence.[2] We could stimulate luminescence that decayed according to Equation (e) in a nonemissive (under our conditions) polymer, Nylon 6, by adding a fluorescent, orange dye, Hoechst 3400, which is bound strongly by polyamides.

An aspect of this phenomenon which we have not explored is its possible role in causing polymer photodegradation, especially since wavelengths throughout the visible region of the spectrum are often active.[2]

In the earlier review[1] the delayed emission after incandescent stimulation was ascribed to slow termination of free radicals followed by light production according to Equation (a). This non-steady-state process has been reported in liquids,[20] but the kinetic expressions such as Equation (f) that can be derived to describe the time dependence of the decay of emission do not in our experience usually fit the long-lived

$$t = \frac{1}{\text{constant}} \ln \frac{(I_{\infty}^{1/2} + I_t^{1/2})(I_{\infty}^{1/2} - I_0^{1/2})}{(I_{\infty}^{1/2} - I_t^{1/2})(I_{\infty}^{1/2} + I_0^{1/2})} \qquad \text{(f)}$$

stimulated luminescence from solids. The lack of fit of Equation (f) to the data was recognized at the time of my first review,[1] but dismissed with the very incorrect assumption that the delayed luminescence from a manufactured item, of complicated and often nonhomogeneous composition, could not be expected to obey simple rate expressions.

Under some circumstances, irradiation of samples with UV light does give complicated decay curves due to the simultaneous production of free-radical and charge-recombination luminescence.[21] Inorganic materials also sometimes give luminescence which decays according to Equation (e). Equations similar to (f) have been derived to treat the decay of CL from autoxidizing polymers after changing to an inert atmosphere.[22] Free-radical oxidation of most organic materials would be expected to produce a collection of $RO_2^{\cdot}$ radicals with different R groups, so that the CL may arise simultaneously by way of a number of termination reactions. The rate constants derived from such kinetic methods may therefore represent averaged quantities.

3.3. Other Mechanisms

Other sources of CL from materials, such as acyl radical recombination to give luminescent states,[23] may be important under certain circumstances. 1,2-Dioxetanes are among the most luminescent class of peroxides, but there is no conclusive evidence for their formation during autoxidation of simple hydrocarbons. The autoxidation of α-phenylpropionaldehyde has been proposed to give acetophenone through a dioxetane intermediate[24] and dioxetanes are responsible for the luminescence in air of tetrakis(dimethylamino)ethylene.[25] Chemiluminescent dioxetanes are also produced in the enzymic oxidation of specialized organic substrates.[26]

4. Models for Charge-Recombination Luminescence

We have also studied delayed luminescence from poly(*N*-vinylcarbazole) (PVK), alone and containing 2,4,7-trinitrofluorenone (TNF) as a simulated impurity.[27] This pair is very well known and was a component of one of the first commercial photocopiers.[28] The photoejection of electrons from the PVK–TNF complex (or from more modern substitutes) discharges the surface of an electrified drum in the photocopier and is thus an integral part of the reproduction process. We found that PVK displayed the strongest delayed luminescence of any substance we have ever examined, with the emission in each case following Equation (e). The emission from purer lots of material was greatly reduced, but was enhanced upon addition of TNF, reaching a maximum at a (monomer) mole fraction of 10^{-4} of TNF (Fig. 3). This strong *increase* in charge-recombination luminescence with TNF stands in contrast to its ability to *quench* the prompt fluorescence emission of PVK.[29] The increase in delayed emission is caused by increased absorption of the incandescent light because of the appearance of "charge-transfer" bands in the visible region in the presence of TNF, augmented by the ability of the electronegative TNF to facilitate charge separation.

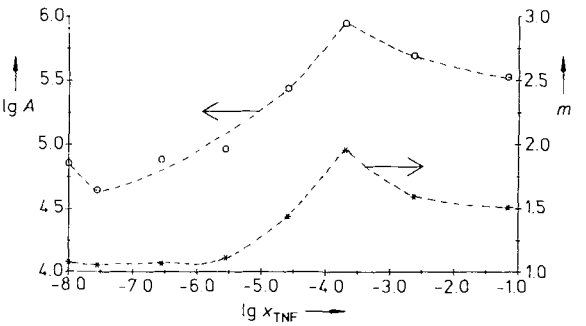

Fig. 3. Values of m and A (per gram of substance) in Equation (e) for light-stimulated PVK films as a function of added TNF. The films were evaporated from PVK–TNF solutions in $CHCl_3$ onto quartz and examined as described in [2, 24].

5. Applications of CL to Polyolefins

5.1. Measurement of Effects of Heat and Ionizing Radiation

Chemiluminescence was recognized in early work (cited in Ref. [1]) as a convenient way to monitor oxidation even in inhibited systems, where most of the peroxy radicals are intercepted by an added reagent [Eq. (g)].

$$\begin{aligned} &ROO^{\cdot} + AH\ (\text{phenol, aromatic amine}) \rightarrow ROOH + A^{\cdot} \\ &A^{\cdot} + ROO^{\cdot} \rightarrow ROOA \end{aligned} \qquad (g)$$

The complete consumption of an inhibitor by reaction (g) at elevated temperatures is often marked by a sudden increase in the chemiluminescence emission due to the resumption of reaction (a), but frequently the level of emission in the preinduction period is significant and proportional to the induction period itself. Polypropylene (PP) appears to be an especially favorable substrate for chemiluminescence studies. Experiments with γ-irradiated, formulated sheets[4] have shown a rough correlation between the light emitted at ambient temperature a week after irradiation (Fig. 4, bottom) and the impact strengths of the sheets measured at the same temperature (Fig. 4, top). Although the apparatus for this work was designed to measure photocurrent, which is converted to a digital display,[30] the lower levels of light emission that we (Fig. 4, bottom) measured correspond to only about 100 photons per second from a sample 1″ in diameter.

A dramatic change in the order of stability of the same formulated polypropylene samples occurred when they were stored at 60 °C (Fig. 4, middle) rather than 25 °C (Fig. 4, top). The sulfide inhibitor is effective at the elevated temperature, but appears to be rather inert at ambient temperatures. The relative chemiluminescence emission from the samples at 150 °C in air, on the other hand, leads to the same ranking of the stabilities of the samples as the results of impact tests at 60 °C. Anomalous behavior of CL from sulfide-stabilized polymers has been noted by others as well.[31]

When powdered polypropylene containing low levels of a phenolic processing stabilizer was irradiated at low dosages with γ-rays from a ^{60}Co source and the chemiluminescence measured immediately after removing the sample from the radioactive source, we observed[32] a slow decay of luminescence that fit a power function fairly well (Fig. 5a). Polypropylene freed from antioxidant by extraction showed similar behavior. When phenolic inhibitor was added to the extracted polymer, the luminescence decay after irradiation changed to a first-order process (Fig. 5b).

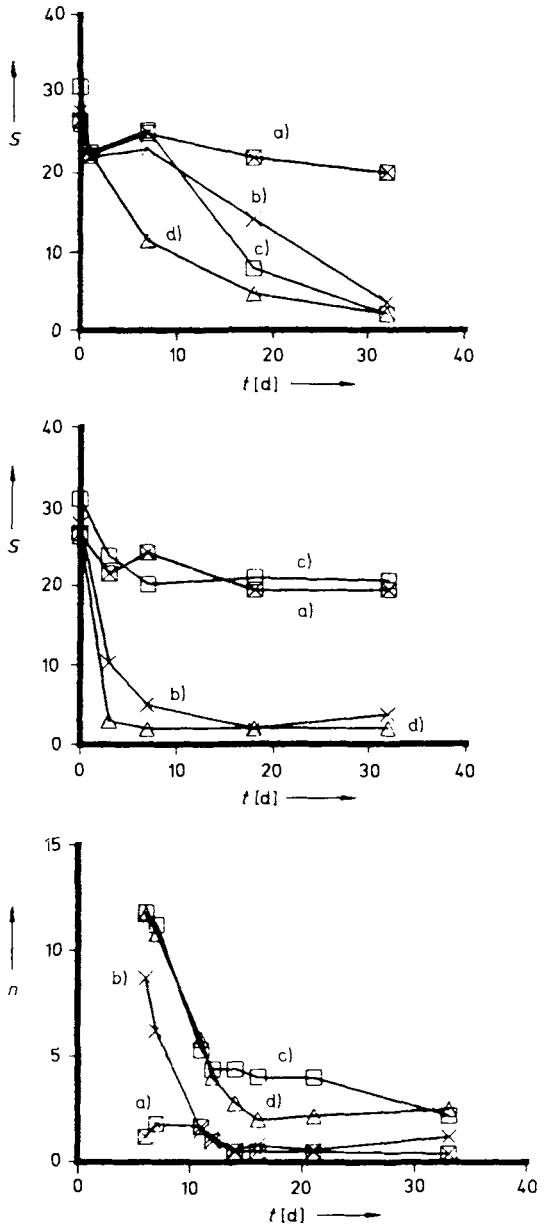

Fig. 4. Top and middle: Loss of impact strength S [inch-1 b] of polypropylene, irradiated to 5 mrd versus storage time at 25 and 60 °C, respectively. Bottom: Ambient chemiluminescence from γ-irradiated (5 mrd) polypropylene samples versus subsequent storage time at 25 °C [4]. a)–c) A "comb" sample contained 0.030% Goodrite 3114 (Phenol) *and* 1.0% of di-*n*-dodecyl 2,2'-dithiodipropionate (Thia). Other samples had just one stabilizer. See Ref. [4]. d) pure PP. n = counts per 2-min interval.

Fig. 5. $$P_pOO^{\bullet} + P_tOO^{\bullet} \xrightarrow{k_t} h\nu + \text{termination}$$

$$P_pOO^{\bullet} + AH \xrightarrow{k_i} P_pOOH + A^{\bullet}$$

$$A^{\bullet} + P_tOO^{\bullet} \dashrightarrow \text{termination (fast)}$$

$$dh\nu/dt \equiv I = \Phi k_t[P_pOO^{\bullet}][P_tOO^{\bullet}]$$

$$d[P_pOO^{\bullet}]/dt = -k_t[P_pOO^{\bullet}][P_tOO^{\bullet}] - k_i[P_pOO^{\bullet}][AH]$$

Scheme 1. Possible explanation for first-order decay curves. Φ = quantum yield per $RO_2^{\bullet}$ pair.

The antioxidant in the experiment described above had been added to the sample by evaporation of a slurry containing the polymer and a solution of antioxidant. We suspected that the antioxidant had been deposited principally on the surface, and, indeed, when an unirradiated sample of this same preparation was fused unter nitrogen and then ground to a powder at 77 K, the chemiluminescence after irradiation (all at 25 °C) once again decayed according to a power function. When a relatively large amount of antioxidant (0.4%) was added to another polypropylene sample by fusing and cryogrinding, the subsequent ^{60}Co-stimulated luminescence reverted to an exponential.

There are a number of possible explanations for the kinetic laws that describe these decay curves. A power function may be derived as a limiting case for several sets of initial conditions. Factors such as inhomogeneous distributions of peroxy radicals may play a role in determining the shapes of the decay curves.[33]

The first-order decay curves, on the other hand, may be explained by the sequence in Scheme 1, where AH is a phenolic antioxidant and P_p and P_t are nontertiary and tertiary alkyl sites on the polymer chain, respectively.

If $[P_tOO^{\bullet}]$ and [AH] are nearly constant during the decay of light emission, Equation (h) is obtained.

$$[P_pOO^{\bullet}] \cong [P_pOO^{\bullet}]_0 e^{-k't} \qquad (h)$$
$$k' = k_t[P_tOO^{\bullet}] + k_i[AH]_x$$

Substituting Equation (h) in the rate law of Scheme 1, we obtain Equation (i) and, identifying I_0 as the emission at $t = 0$ we, have Equation (j).

$$I = \Phi[P_tOO^{\cdot}][P_pOO^{\cdot}]_0 \, e^{-k't} \quad (i)$$

$$I = I_0 e^{-k't} \quad (j)$$

The exponential decay constant k' is expected to be a function of the antioxidant concentration and the concentration of tertiary peroxy radicals. The decay rates of CL are indeed faster with higher starting concentrations of AH (Fig. 5b). This simple derivation neglects interconversion of $P_pOO^{\cdot}$ and $P_tOO^{\cdot}$, among other steps, and should be viewed as an approximation.

Recent experiments in our laboratory with formulated samples of PP and higher dose rates have revealed chemiluminescence behavior within the first few minutes after γ-irradiation that sometimes follows neither an exponential nor a power law, probably due in part to sample heating during the irradiation. *Fisher*[34] has shown with CL techniques that rates of oxygen diffusion into polyethylene are comparable to rates of radical production during irradiation of the polymer with an electron beam. Japanese workers[35] have shown a monotonic relation between CL under certain conditions and γ-dosages with several polyolefins, also at high dose rates. Applications of CL to the study of irradiated foodstuffs would appear to be a promising area.

5.2. IR Laser Heating

With γ-irradiated polypropylene again as a substrate, we examined the chemiluminescence in samples heated very rapidly in the apparatus shown in Figure 6.[32] A few milligrams of the powdered polymer were contained in an evacuated, sealed melting point capillary. The IR beam from a continuous, 4-W CO_2 laser passed through a germanium window (which blocked wavelengths in the visible) and heated the tube rapidly above the melting point of the polymer.

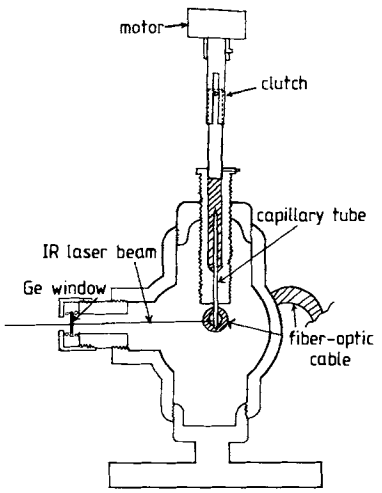

Fig. 6. Apparatus for heating samples with a 10.6-μm laser beam for measurement of CL.

To obtain reproducible results it was necessary to draw the capillary containing the sample slowly through the fixed laser beam. The light was collected with fiber optics and measured in the usual way. The emission from γ-irradiated polypropylene was linearly proportional to γ-dosage and to the peroxide value (POV, equivalents of peroxide per kilogram of material) of the sample, although the proportionality constants were dependent on the polymer formulations.[32]

6. Other Applications

Long-lived recombination luminescence appears to be useful to monitor the formation of chromophores on natural or artificial weathering of polymers, as suggested by an experiment with Nylon 6 (Fig. 7). A number of proprietary examples exist which show that the decay parameters are sensitive to composition and processing conditions of organic materials. A typical result is shown in Figure 8.

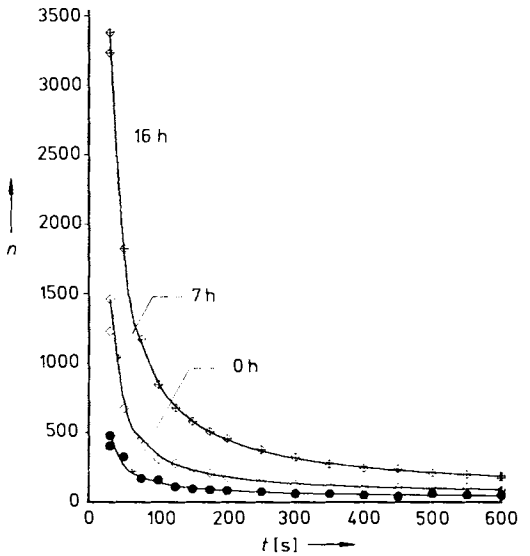

Fig. 7. Charge-recombination luminescence from Nylon 6 immediately after incandescent stimulation from samples that had previously been heated in air at 100 °C for 16, 7, and 0 h [2]. n = counts per 5-s interval.

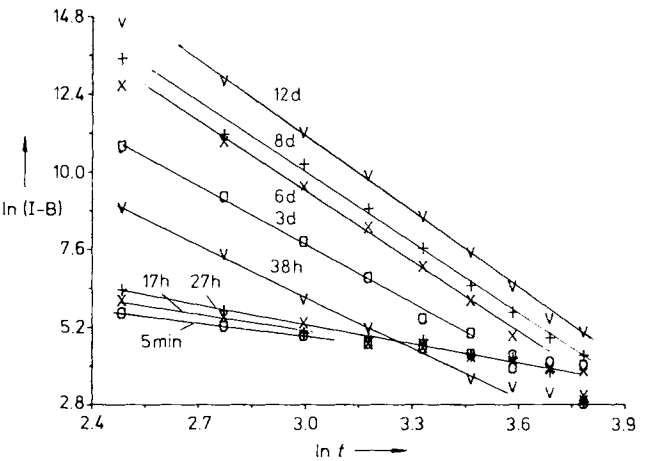

Fig. 8. Charge-recombination luminescence from epoxy cement (TRA-CON BB-2101) plotted in accord with Equation (e) (X. Guo, unpublished work). I − B = signal minus background; time at 25 °C since mixing of the components; t in seconds.

Chemiluminescence under an inert atmosphere can give information on the extent of oxidation in a more sensitive way than conventional methods. The IR-laser approach is one example of this. A second example appears in Figure 9, where the POV of samples was nearly constant within error in the early stages of oxidation while the CL from samples at corresponding times showed significant increases (inset in Fig. 9b).

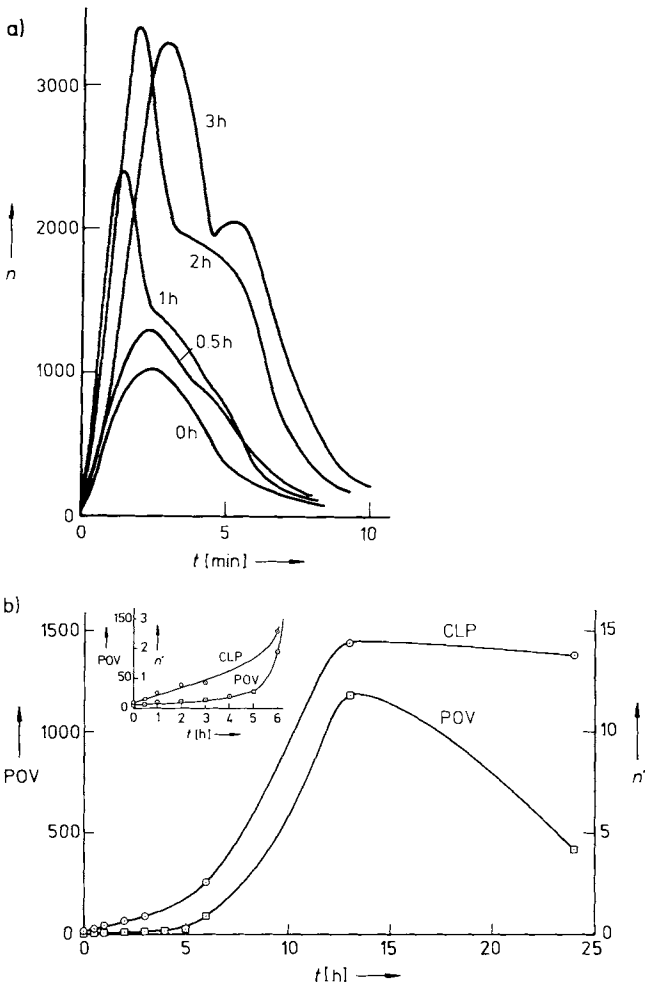

Fig. 9. a) Chemiluminescence from samples of peanut oil, previously oxidized at 100 °C in air for 0 to 3 h Aliquots containing 10^{-3} M 9,10-diphenylanthracene were flushed with N_2 and placed in a preheated oven at 200 °C to generate the curves shown. n = counts per 1-s interval. b) Values of total CL (areas under curves of Fig. 9a; CLP = *CL* on *P*yrolysis) and POV from the aliquots. $n' = 10^{-6}$/CL (number of photons). The inset shows an enlargement of the curve during the first six hours.

The fine structure in the plots of the more oxidized aliquots in Figure 9b is an indication of peroxidic species with differing thermal stabilities. It is noteworthy that the POV drops in the highly oxidized oil whereas the total CL values remain at high levels (Fig. 9b). Plots of this sort with other hydrocarbon substrates may not always show these features, however.[21]

Spilners reported a good correlation between chemiluminescence from a series of lubricating oils and their stabilities as measured by ASTM and other time-consuming procedures.[36] This work has been extended recently by others.[37, 38]

An interesting result was obtained from a sample of paper upon cycling the humidity above the sample (Fig. 10). The CL response was ascribed to free radicals produced by stresses incurred by the absorption and desorption of water.[39]

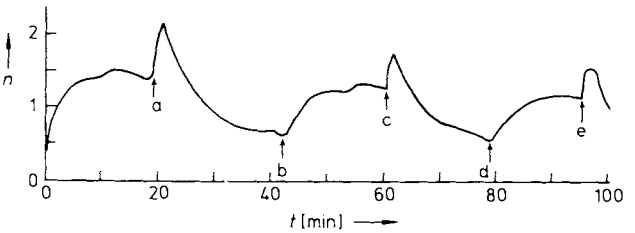

Fig. 10. Effects of cycling between moist and dry air on CL emission from treated Kraft paper at 70 °C [39]. At t = 0, the sample was placed in dry air. At a, c, and e, the dry air was replaced by moist air. At b and d, the moist air was replaced by dry air.

The practice by curators of storing book collections at constant humidity as well as constant temperature would appear to be justified.

7. Wavelength Distribution of CL

Conventional spectrometers are usually not practical for measurement of the spectral distribution of chemiluminescence emitted from materials at temperatures at which the autoxidation is comparatively slow, because of the weakness of the signal. A spectrometer with a 12″ mirror has been constructed for oxidation studies,[40] but most workers in the field have created histograms from the fractions of the light passing through a set of cutoff or interference filters[41, 42] or through a variable interference filter.[43] Using a number of physical and mathematical techniques we attempted to devise an inexpensive alternative[44] with a cell of adjustable thickness containing colored solutions (Fig. 11a). For instance, we could cut off in a progressive manner the wavelengths of light reaching a detector from a source of CL by increasing the optical path of the cell (Fig. 11b). If we obtained data with a perfect step-function cutoff filter, the spectrum could be reconstructed in principle by differentiating the resulting curve of total transmitted intensity versus filter thickness. Although our variable filter itself was more reliable than an expensive commercial one we originally purchased, the applications were not entirely successful because (1) a sharp cutoff was necessary for the computer programs to converge in the subsequent data analysis, even when the input data were calculated from the measured spectra of the dye solutions and an artificial emission spectrum, (2) solutions that showed a sharp cutoff did so over a limited range in wavelengths, so that a series of dye solutions was necessary to cover the visible region, (3) satisfactory spectra could be reconstructed only from extremely precise input data, a requirement not compatible with the nature of the source, and (4) thick dye solutions showed significantly decreased transmittance even at wavelengths where no absorption bands were present. This is apparently a scattering phenomenon and was not due to dust in the solutions.

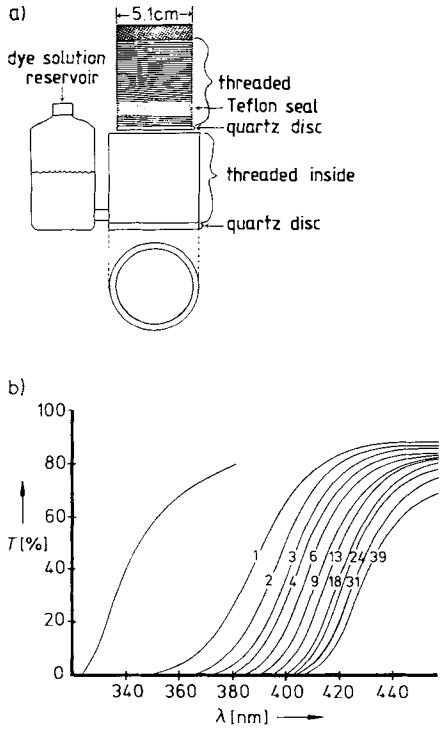

Fig. 11. a) Variable-path filter [44]. The threaded portions were of brass and the dye reservoir of plastic. b) Experimental transmission curves of *m*-nitrophenol in water (ca. 4 g l^{-1}). The numbers refer to the turns from the closed position (0.94 mm per turn). The curve at the extreme left is the transmission curve of a Corning filter No. 3-74.

8. Does Chemiluminescence Arise from the Surface?

This question is asked more frequently than any other when I have given talks on the subject. Imagine a sample of chemiluminescent material of uniform composition and consider only a volume element $1 \times 1 \times dx$ cm with its face normal to the detector (Fig. 12).

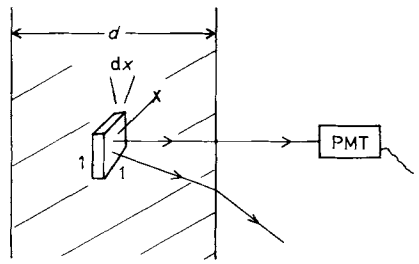

Fig. 12. Absorbed, transmitted, and refracted rays from a volume element in a chemiluminescent material of thickness *d*. PMT = photomultiplier tube.

Consider the case where an absorber is present with concentration C_a and molar absorptivity ε at wavelength λ. The light from a section at distance x from the surface will be attenuated by a factor of $e^{-\varepsilon C_a x}$. The net attenuation for the entire sample is given by integrating from the front surface to the back [Eq. (k), N_{av} = Avogadro number, C_e = emitter concentration, k' = rate constant of the light emission times detection efficiency].

$$I_{det} = \int_{x=0}^{x=d} (N_{av} C_e k'/1000)\, e^{-\varepsilon C_a x}\, dx = (N_{av} C_e k'/1000)\,[1 - e^{-\varepsilon C_a d}] \quad (k)$$

Dividing this result by the light that would have been detected without self-absorption (I), we obtain Equation (l).[45]

$$I_{det}/I = (1 - e^{-\varepsilon C_a d})/\varepsilon C_a d \quad (l)$$

Since the term $\varepsilon C_a d$ is the absorbance of the entire sample along d, the expression can be simplified further. Values of the fractional absorption for various total absorbances appear in Table 2. It can be seen that for absorbances (A) less than 0.2, over 90% of the emission escapes, and for high values of A, the correction factor approaches 1/A.

Table 2. Fractional emission of homogeneously emitted light for various absorbances A.

A	$(1-e^{-A})/A$	A	$(1-e^{-A})/A$
0.05	0.975	1.0	0.63
0.10	0.95	2.0	0.43
0.20	0.906	3.0	0.32
0.50	0.79	10.0	0.10

In general terms, we infer from this calculation that with transparent or translucent materials (lightly colored oils, thin polymer films, biological suspensions, etc.), chemiluminescence will be detected from the surface and interior and will be proportional to sample mass, provided that the initial assumptions are correct. For opaque materials (most edible substances, filled or dyed rubbers, dark liquids, composites, light-scattering polymers), chemiluminescence will be proportional to the area exposed to the detector. For this reason, most of our sample holders for weakly emitting solids are wide and shallow. The CL of light-absorbing substances is maximized and made reproducible merely by filling the container with an opaque layer of material.

The correction factor in Table 2 is usually not applied to the data because (1) a separate factor would usually be required at each wavelength, (2) the absorbance of many relatively opaque or powdered materials of interest is not easily measured, (3) a rigorous treatment would require additional corrections for internal reflections at the air–sample interface, and, (4) since one is invariably comparing samples of different composition or history, the relative values of CL are normally sufficient. Significant spectral differences between samples can be detected in a simple and relatively rapid fashion by measurement of changes in the fraction of light transmittted by a given cutoff filter (f value[3]).

It might be noted that if CL is measured from a translucent sample in a rectangular cell normal to two different faces, the corresponding absorbance of the sample can be calculated from the data by applying the integrated equation (l). The absorbance can also be determined from two measurements with a sample in a cell with reflecting versus absorbing backings.[45]

If the chemiluminescence emission and the sample absorption spectra overlap, only in exceptional cases will chemiluminescence that is emitted homogeneously show the same spectral distribution as the emission in the absence of self-absorption. A reported[46] shift in wavelengths for stretched versus static polymers may have arisen in an analogous manner, if the same excited states were generated at different depths from the surface under the two conditions. With static samples, it is a simple matter to check for surface versus bulk emission by ablating the surface and remeasuring the chemiluminescence, although the treatment itself may generate light emission from mechanochemically produced free radicals.

9. Surface Oxidation

Equation (l) was derived under the assumption that the chemiluminescent species was distributed homogeneously in the sample, which is generally true in liquids but less generally so in solids. For instance, *Carlsson* and *Wiles*[47] established that conventionally extruded polypropylene fiber contains a highly oxidized surface layer. We have measured[48] chemiluminescence from fibers extruded at different rates through a die orifice. The fibers were wound as a monolayer around a mandril (Fig. 13a). The similarity in the curves was

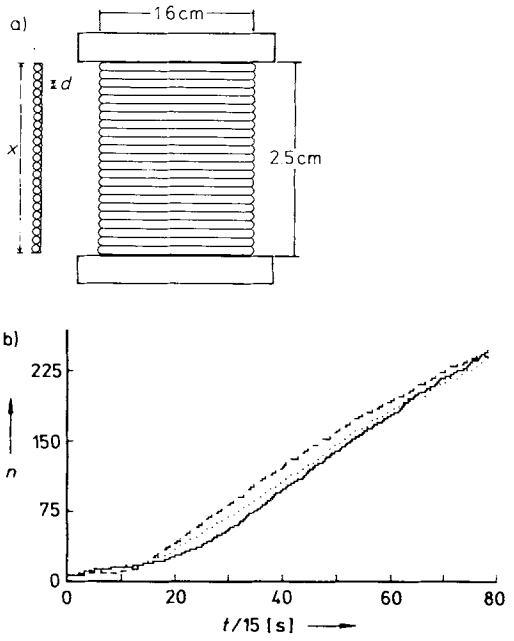

Fig. 13. a) Mandril with a length of 2.5 cm for examination of CL from fibers (air, 150 °C). b) CL from unstabilized polypropylene fiber. Solid line, $d = 0.41$; broken line, $d = 0.66$; dotted line, $d = 1.3$ mm [48]. Unit of $n = 1000$ photons per 15-s interval.

interpreted as a demonstration that CL arose from their similar exposed surface areas πxl ($l = 1.6$ cm, n = number of fibers) which are independent of d, rather than the total exposed mass of the sample $\pi xdl/4$, which increases with d. This result may have important implications for the interpretation of CL from stabilized polypropylene in the preinduction period. *Shard*[49] concluded from an early study of this polymer that CL at elevated temperatures arose from the surface, since the intensity did not change significantly as the film thickness was varied by a factor of ten.

10. Infrared CL at 1.27 μm

The autoxidation process produces singlet molecular oxygen, whose phosphorescence emission appears as a narrow band around 1.27 μm.[50] We have recently measured induction times for systems containing free-radical initiators and phenolic antioxidants (Fig. 14). The appearance of the 1.27 μm emission marks the complete consumption of antioxidant according to Equation (g) and production of $^1O_2$ by the termination reaction (a). The emission equation does not appear in samples with conventional amounts of diphenylamines because (1) the oxidation products of diphenylamines, in contrast to the phenols, are themselves good antioxidants and (2) a portion of the amine is converted into the corresponding nitroxide, which is a good quencher for singlet oxygen.

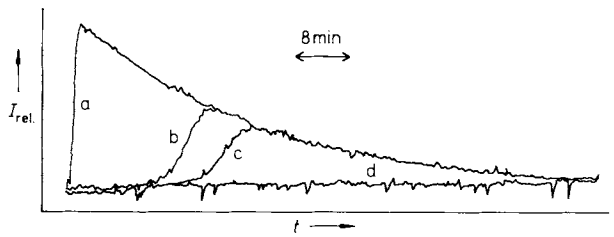

Fig. 14. a) IR CL at 1.27 μm from oxygen-saturated diphenylmethane at 70.6 °C initially containing 0.030 M di-*tert*-butylhyponitrite. b)–d) The solutions contained initially 0.010 M, and 0.012 M 2.6-di-*tert*-butyl-4-methylphenol, respectively. Only the rising portions of curves b) and c) are shown (Q. Niu, unpublished work).

IR chemiluminescence from singlet oxygen is an attractive way to monitor autoxidation because the emission is from a single, well-defined molecule. Scattering and self-absorption of light of this long wavelength is expected to be generally less as well. The principal disadvantages are the larger contribution of thermal (black-body) noise at IR wavelengths and the lower inherent sensitivity of IR detectors.

11. Biological Oxidation

A number of workers have reported weak light emission from both plant and animal sources.[51, 52] Light emission from plant roots has been suggested as a way to monitor oxygen transport.[53] One of the more interesting of the earlier studies resulted in a tabulation of CL from the body organs of a 24-year-old Russian who died of gunshot wounds.[54] Updated versions of the experiment have been reported recently with live rats.[55] The CL emission of the rodents increased after they were injected with halomethanes. A very popular approach among biochemists in recent years has been to monitor enzymatic or whole-cell free-radical generation with luminol, which reacts with oxygenated

radicals in the cells to produce light with high efficiency. The latter subject has also been reviewed recently[56] (see also Ref. [57]).

12. Chemiluminescence Imaging and Other Developments

Recently there have been a number of significant advances in imaging technology at both visible and IR wavelengths. The commercial availability of intensified channel-plate detectors has enabled scientists to obtain conventional spectra and 2D "self-portraits" from materials with comparative ease and in reasonable times. An image of a piece of autoxidizing polybutadiene is shown in Figure 15 along with a

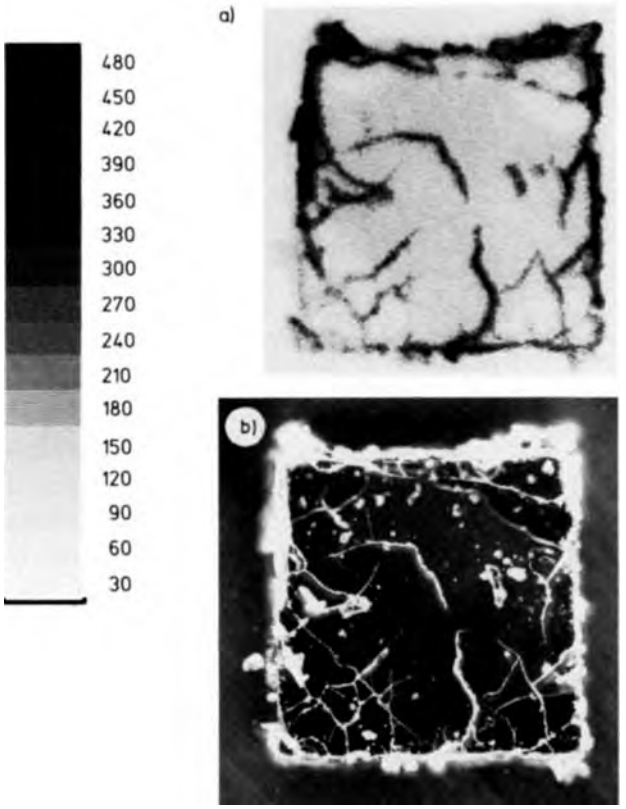

Fig. 15. a) Chemiluminescence image (20-min collection time, 92 °C) and b) conventional photograph of a 1-cm² sample of *trans*-1,4-polybutadiene [58]. The numbers 30–480 on the left signify number of photons per pixel.

photograph of the same sample under ambient lighting conditions. The images are quite similar. The accentuation of CL from cracks and edges in this particular sample is probably an optical scattering phenomenon rather than an indication of enhanced oxidation. Two-dimensional data obtained from emission measurements at two temperatures can be manipulated to give images constructed from spatially resolved values of apparent activation energy and A factor.[58]

Dickenson and co-workers[59] have used a monochromator with an image intensifier to obtain spectra of light simultaneously at all wavelengths emitted from fractured or separated surfaces. When adhesive tape is peeled from its backing, it shows light emission corresponding to bands from molecular nitrogen, which is ionized by sparks in contact with air. The separation of charges with stress is a general phenomenon, and it is not surprising that, when samples of some polymers are crushed, the light that is emitted shows a hyperbolic decay with time that is entirely reminiscent of charge-recombination curves (Fig. 16). Although these phenomena are not due to CL, they are commonly observed in our apparatus and it is appropriate to mention them.

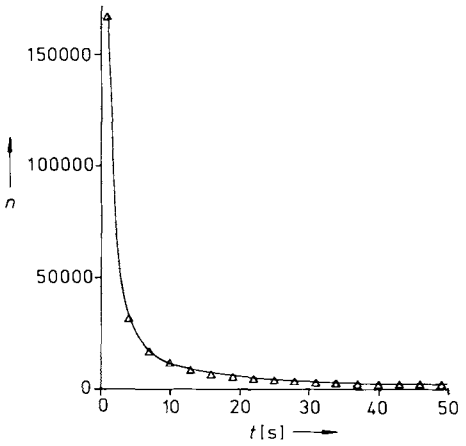

Fig. 16. CL from crushed sample of amorphous PVK (H. K. Agarwal, unpublished work). n = counts per 1-sec interval.

Three-dimensional plots with two time axes are a convenient way to condense data from a series of experiments (Fig. 17). One time axis represents the aging of the sample during storage, and the other the much shorter time of examination at elevated temperature.[4]

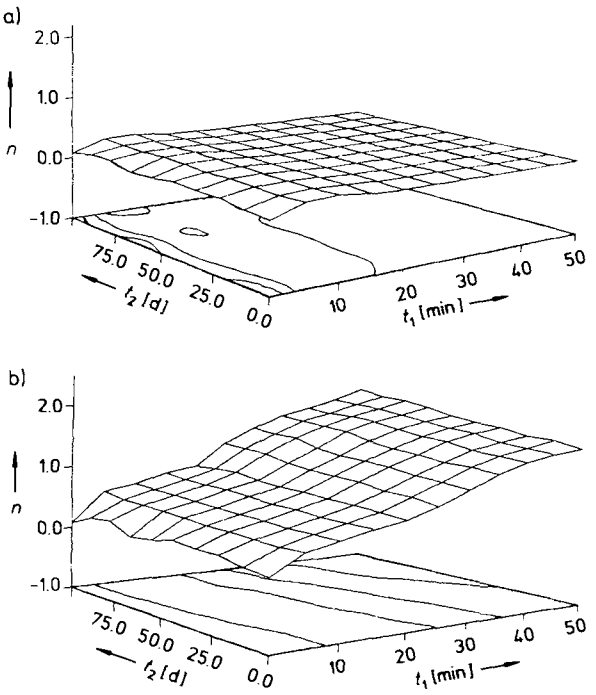

Fig. 17. Plots of CL in air at 150 °C versus storage time at 25 °C from end of irradiation [4]. n = counts per 10^4 s interval. a) Thia, b) Phenol (see Fig. 4).

Oscillating CL at visible wavelengths from oxidizing samples of polypropylene[60] and hydrocarbon liquids[61] has been reported.

Chemiluminescence measured from samples under non-isothermal conditions with photon counting can be analyzed in a manner similar to DSC experiments, to give values of the activation parameters E_a und lg A directly.[62]

13. Conclusions

In our experience, the general approaches for examining CL and other weak light emission from bulk organic materials may be summarized as follows:

1. Heating O_2-free samples above 200 °C rapidly decomposes all peroxidic groups and gives a total CL emission that is proportional to peroxide content, although the proportionality usually varies with the nature of the hydrocarbon.
2. CL from air-saturated samples at any temperature is proportional to the rate of oxidation. The best correlations between CL and a material property are usually obtained when a single organic substrate (which itself may be a complicated mixture) is being tested with small concentrations of additives, especially antioxidants. Direct comparison of CL data from different base stocks of oils or from polymers of different structural types, on the other hand, can be less rewarding. In favorable cases, well-defined induction periods are observed which are not particularly dependent on the nature of the material.
3. Delayed luminescence after *incandescent* stimulation, which decays according to Equation (e) is useful for monitoring material composition as well as changes in materials resulting from heat or photochemical aging. Polyolefins do not usually show delayed emission but aromatic polymers and polyamides, as well as natural materials, usually do (e.g., dry tea leaves, paper, and cereals, but not lettuce).

The application of chemiluminescence techniques to oxidative changes in materials is difficult because the outcome is a dynamic measure of a complicated radical chain reaction followed by excited-state reactions, modified by the optical properties of the bulk sample. The convolution of all of these factors actually is very useful in some cases (e.g., quality control), but it renders the interpretation of results less straightforward in comparison say with IR or NMR spectroscopy.

Familiar measurements, however, such as oxygen uptake and peroxide value also reflect complicated reaction sequences and mixtures of species. As progress is made in unraveling the steps of the autoxidation process in condensed media, and the nature of the reactions giving excited states is better established, investigators will use the technique with increasing confidence. The essential simplicity of the technique is always appealing.

It would be helpful also if academic reviewers for applied journals would bear in mind that empirical analytical procedures, as in medicine, are useful and of interest to people with real-world problems even when the mechanistic details of the analysis are not completely clear.

The work described here was generously supported by the U.S. Army Research Office, 3M Co., Himont USA, Exxon Chemical Co., and numerous other organizations. Indispensable contributions by graduate students Kelly Flaherty, Hamender Agarwal, Honsik Byun, Su-Hua Lee, Xiaoping Guo, Qingshan Niu, and Xiaoning Sheng, and colleagues Drs. Craig A. Ogle, John R. Nixon, and Joel M. Cooke are also gratefully acknowledged. We thank the late Mr. George Turner for loan of an apparatus in earlier stages of the work and Dr. Stephen E. Bialkowski for discussions of techniques for spectral resolution.

Modern NMR Pulse Experiments: A Graphical Description of the Evolution of Spin Systems

By Urs Eggenberger and Geoffrey Bodenhausen*

Many modern methods designed to enhance the power of NMR spectroscopy have been widely adopted by the scientific community. Some of the best known among these techniques are one-dimensional methods for polarization enhancement and spectral editing ("INEPT" and "DEPT") and various two-dimensional experiments such as correlation spectroscopy ("COSY") and nuclear Overhauser spectroscopy ("NOESY"). Most of these methods cannot be described in terms of classical magnetization vectors, and although they can be understood with the help of the density operator formalism, this approach remains difficult for many users, in part because of its cumbersome notation, which prevents one from recognizing the important features at a glance. In this paper, a set of graphical conventions is described which allows one to represent the effect of sequences of radio-frequency pulses on spin systems in a variety of experiments. The graphs provide a concise description of the network of spins that are coupled through scalar and dipolar interactions, of the state of a spin system expressed in terms of products of operators, and, most importantly, of the transformations from one state to another due to the effect of radio-frequency pulses, chemical shifts, and scalar couplings. The graphical approach also allows one to represent the effect of phase-cycling and multiple-quantum filtration, cross-relaxation (Overhauser effects) and cross-correlated relaxation.

1. Introduction

In the last decade or so, high-resolution nuclear magnetic resonance has undergone a remarkable development, which is largely due to the extensive use of sophisticated pulse sequences in conjunction with one- and multi-dimensional Fourier transforms. In the early days of what is sometimes called "modern" NMR spectroscopy, a variety of more or less formal approaches were used to describe these experiments, ranging from semiclassical vector models to cumbersome density-matrix transformations. In recent years, the discussion of modern NMR experiments has been increasingly unified with the help of new descriptive tools: product operators[1-4] and coherence transfer pathways.[5-7] It has been shown that calculations can not only be considerably simplified but also made much more intelligible if the density operator is expanded into a superposition of products of angular momentum operators.[1-4] In former days, before the advent of modern NMR spectroscopy, it was customary (and indeed sufficient for most purposes) to speak of "longitudinal M_z magnetization" or of the "M_x component of transverse magnetization". The language has undergone such a development in recent years that one now tends to speak in terms of "longitudinal $\boldsymbol{I}_z$ polarization", of "in-phase $\boldsymbol{I}_x$ coherence", of "antiphase $2\boldsymbol{I}_x\boldsymbol{S}_z$ coherence", and of "multiple-quantum coherence $2\boldsymbol{I}_x\boldsymbol{S}_x$", to name but a few examples. The shift in language corresponds to a transition from a semiclassical discussion to a more fundamental approach which is rooted in the accurate density-operator formalism. While the new language does not appear to meet much resistance and is widely accepted, the notation that is used for product operators remains cumbersome, involving unwieldy symbols overloaded with indices, which are required to label the cartesian components ($\boldsymbol{I}_x$, $\boldsymbol{I}_y$, $\boldsymbol{I}_z$) and the relevant spins (for example $\boldsymbol{I}^A$, $\boldsymbol{I}^M$, $\boldsymbol{I}^X$, unless one chooses to use different symbols for angular momentum, e.g. $\boldsymbol{I}$, $\boldsymbol{R}$, $\boldsymbol{S}$). In order to describe the development of the system under shifts and couplings, one has to specify coefficients which are usually products of trigonometric functions with arguments like $\Omega_A t_1$ or $\pi J_{AM} t_1$. These trigonometric terms have to be carried over from one equation to the next, so that one tends to be confronted with very complex expressions which not only demand a time-consuming book-keeping, but also represent an obstacle to anyone who wishes to get a simple physical picture of the experiment.

In parallel with the development of the product operator formalism, the description of phase-cycles and multiple-quantum phenomena has been greatly simplified by the introduction of coherence transfer pathways.[5-7] The strength of this formalism hinges on a graphical convention, which does not require any unwieldy symbols overloaded with lots of indices. Since a simple graphical convention has brought so much clarification to phase-cycling prescriptions, it seems legitimate to ask whether one could not invent a graphical approach that would make the world of product operators more transparent. It is indeed the ambition of the present paper to define a set of graphical conventions for this purpose. Our graphs, if wisely used, achieve the dual purpose of simplifying the notation and of providing a physical picture of the evolution of product operators. The graphs also reveal important features regarding the phases of the signals (absorption or dispersion), which turn out to be related to symmetry relationships between the evolution and detection periods of two-dimensional experiments.

We assume that the reader is acquainted with some of the basic ideas of modern one- and two-dimensional NMR experiments, and that he is familiar with the practical aspects of the product operator formalism, for example at the introductory level discussed by *Kessler, Gehrke* and *Griesinger*.[8] We hope that our graphical approach can help to foster some intuition for the way in which various terms

[*] Prof. Dr. G. Bodenhausen, Dipl. Chem. U. Eggenberger
Section de Chimie, Université de Lausanne
Rue de la Barre 2, CH-1005 Lausanne (Switzerland)

describe the essential features of a particular experiment. It is only by practice that one can gain a "working knowledge" of the product operator formalism, and for a newcomer to the field it is probably necessary to proceed by trial and error to see which terms should be considered, e.g. which terms can lead to coherence transfer, which terms can contribute to the observable signal, etc. We hope that our graphical representation will allow one to facilitate this learning process, and we are confident that the process should be much less strenuous than if one uses the traditional algebraic notation, although we should warn the reader that we have made no concessions in terms of accuracy, so that full density operator formalism remains valid in all its rigor.

In this paper, we shall discuss applications of our graphical approach to describe correlation spectroscopy ("COSY"), nuclear Overhauser effect spectroscopy ("NOESY"), double- and triple-quantum filtered COSY ("DQF-COSY" and "TQF-COSY"), and triple-quantum filtered NOESY ("TQF-NOESY"). We also illustrate applications to relaxation-allowed coherence transfer due to correlated dipolar interactions,[9, 10] to the so-called INADEQUATE double-quantum technique[11, 12] and to a heteronuclear relayed magnetization transfer experiment.[13]

2. Pulse Sequences and Coupling Networks

All illustrations in this paper follow the general pattern of the operator evolution graph of Figure 1. The pulse sequence is drawn horizontally along the bottom; as usual, the durations of the pulses and delays do not necessarily give a realistic picture of the timing of the events. Unless otherwise specified, narrow and wide pulses represent flip angles of 90° and 180°. The RF phases in the rotating frame are indicated for the basic experiment, i.e. for the first step in a phase-cycle. We tend to prefer pulses applied along the y-axis, unless of course the experiment demands different RF phases. In the left margin of the figure, drawn vertically before the first pulse, a simple graph represents the coupling network, i.e., the set of spins subjected to the pulse sequence. These graphs are drawn using the following conventions:

1. The spins I_k are represented by circles. The labels k, l, m ... of the spins may be written into these circles if desired.

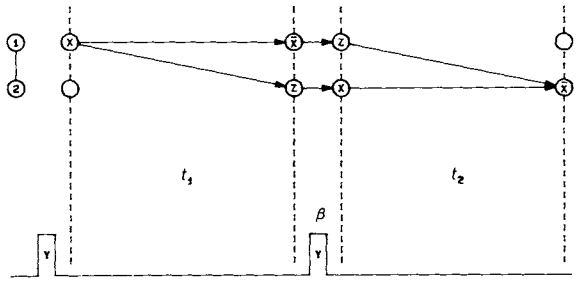

Fig. 1. Operator evolution graph showing a typical sequence of transformations of a two-spin system in the course of a COSY pulse sequence. Only the pathway that contributes to cross-peak signals is shown. The symbols are explained in the text.

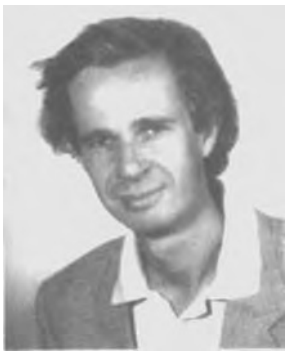
2. Non-vanishing scalar couplings J_{kl} are indicated by solid lines. If known, the values of the coupling constants may be written along these lines.
3. Dipolar interactions D_{kl} that are relevant to the sequence of events are indicated by dotted lines.
4. If scalar and dipolar interactions occur simultaneously and if they are both relevant to the experiment, two parallel lines are drawn, one solid and one dotted.

In this paper, dipolar interactions D_{kl} are understood to be averaged by molecular motion, so that they give rise to relaxation effects but not to resolved splittings. Our conventions are somewhat different from those used by *Levitt* et al.[14] and by *Radloff* et al.[15]

3. Density Operator Terms

At various points in time, indicated by vertical dashed lines (see Fig. 1), selected density operator terms are described, again using circles, but with labels x, y or z that indicate if spin I_k is associated with an angular momentum component I_{kx}, I_{ky} or I_{kz}. An open circle indicates that the operator product formally involves a unity operator. Negative signs are symbolized by overbars. In Figure 1, the four pairs of circles drawn above the pulse sequence represent, in chronological order from left to right, the following terms: I_{1x}, $-2I_{1x}I_{2z}$, $2I_{1z}I_{2x}$, and $-I_{2x}$. The normalization factors are not indicated explicitly; one should remember that these factors depend on the number of terms in the product, i.e., $N = 2^{(q-1)}$ for a product containing q terms.



Geoffrey Bodenhausen was born on May 7th, 1951 in The Hague, Netherlands. On completion of his school education in the Netherlands and in Geneva in Switzerland he studied chemistry at the ETH Zürich (1970–1974) and then as post-graduate under Professor Ray Freeman at the Physical Chemistry Laboratory of Oxford University (1975–1977), where he gained his D.Phil. After post-doctoral studies with Robert L. Vold and Regitze R. Vold at the University of California at San Diego, 1978, he joined the research staff of the Francis Bitter National Magnet Laboratory, Massachusetts Institute of Technology, 1979–1980. He then worked as assistant, later senior assistant, in Richard R. Ernst's group in the Laboratory for Physical Chemistry at the ETH Zürich. In 1984 he was Privatdozent for physical chemistry at the ETH. Since 1985 he has been Professeur associé in the Department of Chemistry at the University of Lausanne. Professor Bodenhausen is married and has two daughters (born 1977 and 1979).

4. Transformations of Operator Terms

Transformations under RF pulses are represented symbolically by short, solid arrows, as drawn above the symbol β in Figure 1.

For y-pulses with $\beta = 90°$, the transformations are:[2]

$$z \rightarrow x \rightarrow \bar{z} \rightarrow \bar{x} \tag{1}$$

For x-pulses with $\beta = 90°$, the transformations are:[2]

$$z \rightarrow \bar{y} \rightarrow \bar{z} \rightarrow y \tag{2}$$

It is understood implicitly that each short horizontal arrow is associated with a trigonometric term $\sin\beta$, where β is the flip angle of the RF pulse. In some cases, one must focus attention on a component of the density operator which remains in its initial state in spite of the RF pulse. For example, if a y-pulse is applied to an operator I_{kz}, a fraction $\cos\beta$ of the I_{kz} component remains invariant. This "non-transformation" is rendered graphically by a short dotted horizontal arrow, which is understood implicitly to be associated with a term $\cos\beta$. Finally, if a pulse leaves an operator term invariant (e.g. a y-pulse applied to an operator I_{ky}), there is no need for drawing an arrow.

Transformations under the combined effects of shifts and couplings are illustrated in Figure 2. In weakly-coupled systems, the relevant Hamiltonians commute, which implies that one may consider their effect separately and in arbitrary sequence. If both shifts and couplings are operating in a given interval, it is sometimes convenient to define a virtual state, drawn arbitrarily in the middle of the interval, and represented by dashed circles, which symbolize the state of the system resulting from the effect of one of the interactions, say, of the shift alone. We shall see that in practice one can usually skip the explicit representation of such virtual states, by concatenating the effects of several interactions into one overall transformation. The left-hand side of Figure 2 shows the effects of shifts and couplings drawn separately in two sequential steps involving virtual states, while the right-hand side of Figure 2 shows equivalent diagrams where the virtual states have been skipped for simplicity.

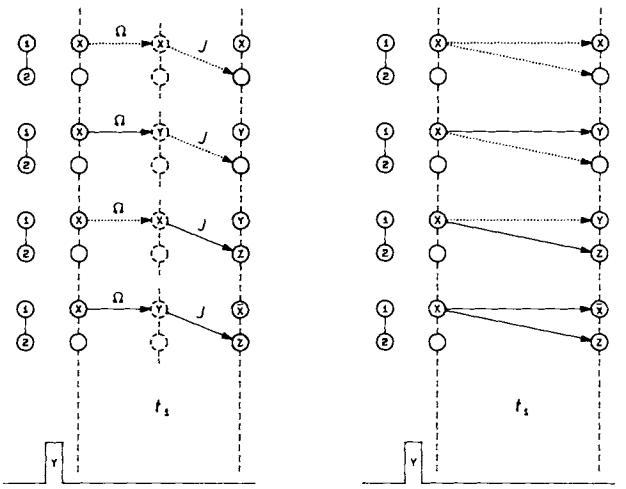


Fig. 2. Representation of the effects of chemical shifts and couplings in a two-spin system. The graphs on the left involve "virtual states" that represent the system after considering the effect of the chemical shift taken in isolation; those on the right represent the overall effect of shifts and couplings.

Transformations under chemical shifts are represented in Figure 2 by long horizontal arrows, which may be labeled for clarity with the symbol Ω representing the offset Ω_k of the spin I_k that appears on the left of the figure. In practice, these labels may often be dropped for simplicity. The shift is represented by a solid arrow if a transformation of the density operator under the effect of the chemical shift is required to obtain a new term that is relevant for the subsequent chain of events. In this case, a trigonometric term $\sin\Omega_k t$ must be included. The signs obey the usual rules:[2]

$$x \rightarrow y \rightarrow \bar{x} \rightarrow \bar{y} \tag{3}$$

The shift is represented by a dotted arrow if such a transformation is not required. In this case, a trigonometric term $\cos\Omega_k t$ must be included.

Transformations under scalar couplings are represented in Figure 2 by sloping arrows, which are solid if the coupling is active, and dotted if it is passive. These arrows may be labeled with the symbol J representing the coupling J_{kl} between the spins I_k and I_l that appear on the left of the figure. Solid sloping arrows (active couplings) imply that a trigonometric term $\sin\pi J_{kl} t$ must be included. The following rules determine the signs of the terms:[2]

$$x \rightarrow yz \rightarrow \bar{x} \rightarrow \bar{y}z \tag{4}$$

$$y \rightarrow \bar{x}z \rightarrow \bar{y} \rightarrow xz \tag{5}$$

Dotted sloping arrows (passive couplings) are intended to remind the reader that a transformation under a coupling has failed to occur, and that a modulation term $\cos\pi J_{kl} t$ must therefore be included. Note that these arrows point at empty circles, so that they might give the impression of a somewhat artificial construct. It is important to remember however that each scalar coupling (i.e., each solid line appearing in the networks drawn on the left-hand side of the figures) must be represented by a sloping arrow, which may be either solid or dotted depending on the transformation that one wishes to represent in the operator evolution graph. The only exceptions to this rule occur if refocusing pulses are employed (see Section 11).

Transformations due to relaxation processes are represented by wavy arrows. To describe cross-relaxation (Overhauser effects), a wavy arrow is used to indicate a partial conversion $I_{iz} \rightarrow I_{jz}$. In the initial rate approximation, the extent of the conversion is expressed by a coefficient $-\sigma_{ij}\tau_m$, where σ_{ij} is the cross-relaxation rate in *Solomon*'s notation, and τ_m the duration of the relaxation interval. Since $\sigma_{ij} = (W_2^{ij} - W_0^{ij})$, σ_{ij} is negative for large molecules, so that $-\sigma_{ij}\tau_m > 0$ in this case, while the opposite situation applies to small molecules in the extreme narrowing limit.[7] The decay of a Zeeman term (i.e., the partial loss in the process $I_{iz} \rightarrow I_{iz}$) can be represented by a dotted wavy arrow. In the initial rate approximation, the extent of this decay is expressed by a factor $(1 - \varrho_i\tau_m)$, where the spin-lattice relaxation rate ϱ_i is defined as positive.[7]

In systems with three or more spins where the time-dependencies of different dipolar interactions are correlated,[16] wavy arrows can be used to represent the conversion of Zeeman order into longitudinal three-spin order (e.g., $\mathbf{I}_{1z} \rightarrow 4\boldsymbol{I}_{1z}\boldsymbol{I}_{2z}\boldsymbol{I}_{3z}$). In the initial rate approximation, the extent of this conversion, which is due to the correlation of the dipolar interactions D_{12} and D_{13}, is represented by a factor $\delta_{1213}\tau_m$. The cross-correlation rate δ_{1213} depends, inter alia, on the angle subtended by the internuclear vectors $\boldsymbol{r}_{12}$ and $\boldsymbol{r}_{13}$.[16] As discussed in Section 9, the appearance of longitudinal three-spin order can be monitored experimentally by triple-quantum filtered NOESY.[17-19]

In a similar fashion, wavy arrows can be used to represent the conversion of Zeeman order into longitudinal two-spin order (e.g., $\boldsymbol{I}_{1z} \rightarrow 2\boldsymbol{I}_{1z}\boldsymbol{I}_{2z}$). In this case, the initial rate factor is denoted $\delta_{112}\tau_m$, and the conversion is due to the correlation of the chemical shift anisotropy of spin $\boldsymbol{I}_1$ and the dipolar interaction D_{12}.[20, 21] The build-up of longitudinal two-spin order can be monitored by double-quantum filtered NOESY.[22]

The decay of longitudinal two- or three-spin order, i.e. the partial losses in the processes $2\boldsymbol{I}_{iz}\boldsymbol{I}_{jz} \rightarrow 2\boldsymbol{I}_{iz}\boldsymbol{I}_{jz}$ or $4\boldsymbol{I}_{iz}\boldsymbol{I}_{jz}\boldsymbol{I}_{kz} \rightarrow 4\boldsymbol{I}_{iz}\boldsymbol{I}_{jz}\boldsymbol{I}_{kz}$, can also be represented by dotted wavy arrows. In the initial rate approximation, the extent of these decay processes is expressed by factors $(1 - \varrho_{ij}\tau_m)$ and $(1 - \varrho_{ijk}\tau_m)$, respectively, in analogy to the decay of Zeeman order.[19, 22]

Finally, wavy arrows can be used to denote the conversion of in-phase transverse magnetization into doubly-antiphase coherence (e.g., $\boldsymbol{I}_{1x} \rightarrow 4\boldsymbol{I}_{1x}\boldsymbol{I}_{2z}\boldsymbol{I}_{3z}$), which can occur in systems with correlated dipolar interactions. We shall denote the extent of such a conversion, which is generally a multi-exponential function of time that depends on the correlation of the dipolar interactions D_{12} and D_{13}, by a function $f_{1213}(t)$. Explicit expressions for these functions can be found elsewhere.[10]

5. The COSY Pulse Sequence

Figure 3 shows five distinct operator evolution graphs for a two-spin system in two-dimensional correlation spectroscopy (COSY). We assume that in the detection period the receiver picks up the magnetization along the x-axis of the rotating frame. This amounts to focusing on the in-phase terms $\boldsymbol{I}_{1x}$ and $\boldsymbol{I}_{2x}$. With the conventions of dotted and solid arrows defined above, it is immediately clear that the five diagrams (a) to (e) in Figure 3 represent the following terms:

$$\sigma^{(a)}(t_1, t_2) = +\boldsymbol{I}_{1x} \cos\Omega_1 t_1 \cos\pi J_{12} t_1 \cos\beta \cos\Omega_1 t_2 \cos\pi J_{12} t_2 \quad (6)$$

$$\sigma^{(b)}(t_1, t_2) = -\boldsymbol{I}_{1x} \sin\Omega_1 t_1 \cos\pi J_{12} t_1 \sin\Omega_1 t_2 \cos\pi J_{12} t_2 \quad (7)$$

$$\sigma^{(c)}(t_1, t_2) = -\boldsymbol{I}_{1x} \cos\Omega_1 t_1 \sin\pi J_{12} t_1 \cos\beta \cos\Omega_1 t_2 \sin\pi J_{12} t_2 \quad (8)$$

$$\sigma^{(d)}(t_1, t_2) = +\boldsymbol{I}_{1x} \sin\Omega_1 t_1 \sin\pi J_{12} t_1 \cos^2\beta \sin\Omega_1 t_2 \sin\pi J_{12} t_2 \quad (9)$$

$$\sigma^{(e)}(t_1, t_2) = -\boldsymbol{I}_{2x} \sin\Omega_1 t_1 \sin\pi J_{12} t_1 \sin^2\beta \sin\Omega_2 t_2 \sin\pi J_{12} t_2 \quad (10)$$

It is important to realize that these terms result from processes that may occur simultaneously. The first four terms contribute to the diagonal multiplet centered at $(\omega_1, \omega_2) = (\Omega_1, \Omega_1)$, while the fifth term gives rise to a cross-peak multiplet centered at $(\omega_1, \omega_2) = (\Omega_1, \Omega_2)$. The first two terms lead to an in-phase doublet structure in both dimensions (modulation in $\cos\pi J_{12} t$), the latter three terms to an antiphase doublet structure (modulation in $\sin\pi J_{12} t$).

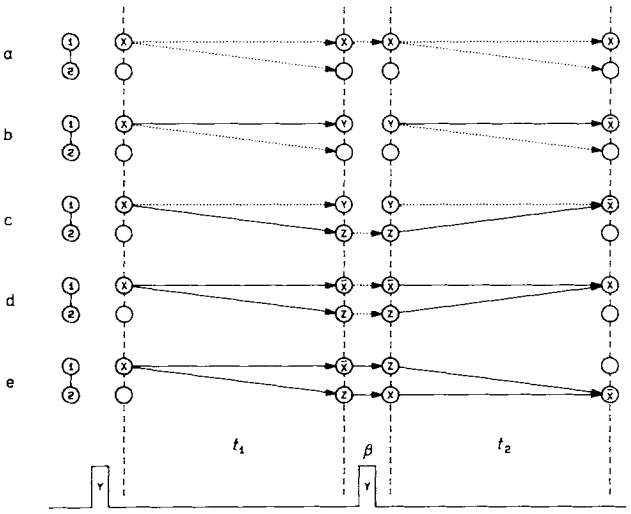

Fig. 3. Set of five operator evolution graphs relevant to the description of signals of a two-spin system in a COSY pulse sequence. Graph (e) is reproduced from Figure 1.

The graphs also inform us about the phases of the signals. If a cosine Fourier transform is used with respect to both t_1 and t_2, the signals will be in absorption if the modulation factor contains an even number of sine terms (even number of solid lines) in both t_1 and t_2 intervals.[7] Thus graphs (a), (d) and (e) correspond to signals that are in absorption in both frequency domains, while the graphs (b) and (c) describe two-dimensional dispersive contributions. For $\beta = 90°$, only the terms (b) and (e) survive, while the pathways (a), (c) and (d), which contain short dotted arrows symbolizing $\cos\beta$, have vanishing intensities. For $\beta = 90°$, we therefore obtain a pure absorption antiphase cross-peak multiplet from term (e) and a pure dispersion in-phase diagonal multiplet from term (b). These rules have of course been established before,[7] but so far it has not been possible to derive them by mere inspection of a set of simple graphs.

To describe the fate of a two-spin system in a COSY experiment, the complete list of all possible pathways that start with the term $\boldsymbol{I}_{1x}$ would consist of no less than 30 operator evolution graphs, and another 30 graphs start with $\boldsymbol{I}_{2x}$. Fortunately, there is no need for such an exhaustive description, since we can easily discard all pathways that do not lead to in-phase magnetization $\boldsymbol{I}_{1x}$ or $\boldsymbol{I}_{2x}$. In particular, we may ignore pathways that yield antiphase terms like $2\boldsymbol{I}_{1x}\boldsymbol{I}_{2z}$ or products like $2\boldsymbol{I}_{1x}\boldsymbol{I}_{2x}$ and pathways that yield longitudinal terms $\boldsymbol{I}_{1z}$ and $2\boldsymbol{I}_{1z}\boldsymbol{I}_{2z}$. It is therefore a simple matter to select the five graphs of Figure 3 that are relevant to the understanding of COSY.

6. The NOESY Pulse Sequence

Figure 4 shows the operator evolution graph relevant to the description of cross-peaks in two-dimensional exchange or nuclear Overhauser spectroscopy (NOESY). We consider a two-spin system which, for the sake of illustration, is as-

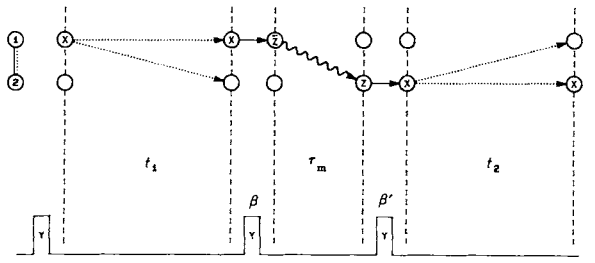

Fig. 4. Evolution of a two-spin system having both scalar and dipolar couplings in a NOESY pulse sequence. Only the pathway that contributes to cross-peak signals arising from cross-relaxation (Overhauser effect) is shown.

sumed to have a resolved coupling J_{12} in addition to a dipolar interaction D_{12}. If we start with the term I_{1x} and focus on the term I_{2x} in the detection period, we can immediately read the following factors from the graph:

$$\sigma(t_1,t_2) = I_{2x}\cos\Omega_1 t_1 \cos\pi J_{12} t_1 \sin\beta(-\sigma_{12}\tau_m) \times \sin\beta' \cos\Omega_2 t_2 \cos\pi J_{12} t_2 \quad (11)$$

In this example, the transformation expressed by the wavy line is associated with a change in sign ($I_{1z} \rightarrow -I_{2z}$) since $-\sigma_{12}$ is negative, a characteristic feature of small molecules with short correlation times $\tau_c < 1/\omega_0$. The opposite sign would be obtained for slowly-tumbling macromolecules.[7]

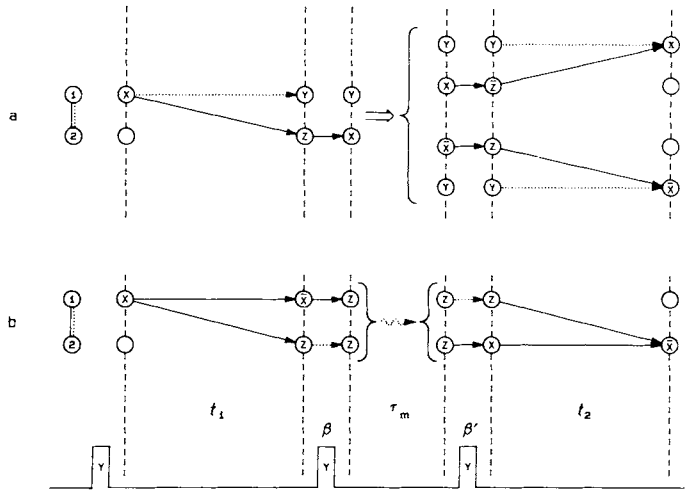

Fig. 5. Pathways that give rise to undesirable signals in NOESY spectra of a two-spin system with dipolar and scalar couplings. a) Two pathways involving zero-quantum coherences, where the double arrow (⇒) represents the effect of the phase cycle; b) pathway involving longitudinal two-spin order.

In view of the tremendous popularity of the NOESY method, it is important to be aware of the fact that serious artifacts may occur in systems with scalar couplings. Figure 5a shows what happens if an antiphase term $2I_{1y}I_{2z}$ is converted into $2I_{1y}I_{2x}$ by the second pulse (β). The term $2I_{1y}I_{2x}$ consists of a superposition of zero- and double-quantum coherences.[2] The phase-cycle used in NOESY, which amounts to a filter that retains only populations and zero-quantum coherences in the τ_m period, causes a split-up of $2I_{1y}I_{2x}$ into $\frac{1}{2}(2I_{1y}I_{2x} - 2I_{1x}I_{2y})$, as discussed in more detail in Section 7. The two resulting pathways shown in Figure 5a give rise to misleading contributions to the diagonal and cross-peak multiplets respectively.[23] The latter contribution has the following form:

$$\sigma(t_1,t_2) = -I_{2x}\cos\Omega_1 t_1 \sin\pi J_{12} t_1 \sin\beta \times \tfrac{1}{2}\sin\beta' \cos\Omega_2 t_2 \sin\pi J_{12} t_2 \quad (12)$$

The factor $\frac{1}{2}$ arises from the split-up into two terms due to the phase cycle. If one uses a cosine/cosine transform so that the desirable pathway of Figure 4 leads to pure two-dimensional absorption, the zero-quantum multiplets due to the pathways of Figure 5a will be dispersive in both dimensions. The precession of the zero-quantum coherence in the τ_m interval under the effect of the chemical shifts is not included in Equation (12). As discussed in Section 12, this would lead to a factor $\cos(\Omega_1 - \Omega_2)\tau_m$.

Another potentially important source of artifacts in NOESY spectra of systems with scalar couplings is illustrated in Figure 5b. The antiphase term $-2I_{1x}I_{2z}$ can be transformed unwittingly into longitudinal two-spin order $2I_{1z}I_{2z}$, which can be subsequently converted into $2I_{1z}I_{2x}$. This leads to a contribution of the form

$$\sigma(t_1,t_2) = -I_{2x}\sin\Omega_1 t_1 \sin\pi J_{12} t_1 \sin\beta\cos\beta(1-\varrho_{12}\tau_m) \times \cos\beta' \sin\beta' \sin\Omega_2 t_2 \sin\pi J_{12} t_2 \quad (13)$$

where the factor $(1 - \varrho_{12}\tau_m)$ represents the fraction of the two-spin order that has not decayed in the τ_m interval. Clearly, accurate calibration of the pulses to $\beta = \beta' = 90°$ (or, preferably, the use of suitable composite pulses) leads to the suppression of these undesirable pathways.[24]

7. Double-Quantum Filtered COSY

In double-quantum filtered COSY (Fig. 6), a term $2I_{1y}I_{2x}$ is generated at the beginning of the Δ interval. The phase cycle selects the double-quantum coherences contained in this $2I_{1y}I_{2x}$ term, thus leading to a transformation symbolically represented by a short double arrow (⇒):

$$2I_{1y}I_{2x} \Rightarrow \tfrac{1}{2}(2I_{1y}I_{2x} + 2I_{1x}I_{2y}) \quad (14)$$

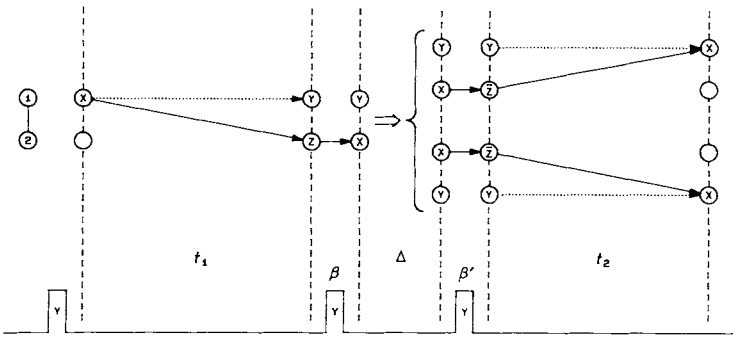

Fig. 6. Evolution of a two-spin system in double-quantum filtered COSY. The two pathways give rise to a diagonal peak and a cross peak. The double arrow (⇒) represents the effect of the phase cycle.

This transformation can easily be verified by expanding the cartesian operators into linear combinations of shift operators, $I_{1y} = -i\frac{1}{2}(I_1^+ - I_1^-)$ and $I_{2x} = \frac{1}{2}(I_2^+ + I_2^-)$, deleting the zero-quantum components $I_1^+ I_2^-$ and $I_1^- I_2^+$ from the product to retain only the double-quantum terms $I_1^+ I_2^+$ and $I_1^- I_2^-$, and transforming the remaining shift operators back into cartesian operators [cf. Eq. (118) of *Sørensen* et al.[2]].

The split-up of one term into two products implied in Equation (14) is represented symbolically in Figure 6. The upper pathway leads to a diagonal peak, the lower pathway to a cross-peak. Both pathways are obviously associated with similar trigonometric modulation terms. This symmetry explains why diagonal and cross-peak multiplets have identical phases and multiplet structures in double-quantum filtered COSY spectra of two-spin systems, in contrast to the situation that arises in conventional COSY (Fig. 3).

The form of the cross-peak multiplet is determined by modulation terms that can be read directly from the lower pathway in Figure 6:

$$\sigma(t_1, t_2) = I_{2x} \cos\Omega_1 t_1 \sin \pi J_{12} t_1 \sin\beta \tfrac{1}{2} \sin\beta' \times \cos\Omega_2 t_2 \sin \pi J_{12} t_2 \quad (15)$$

Note the factor $\frac{1}{2}$ which arises from the split-up into two terms. The experienced reader will recognize a cross-peak multiplet which is in antiphase with respect to the coupling J_{12} in both frequency dimensions. If one uses a cosine/cosine transformation, the multiplet is dispersive in both frequency dimensions. Pure two-dimensional absorption can be obtained by switching to a sine/sine transform or by using a 90° phase correction in both ω_1 and ω_2. Alternatively, one could shift the phase of the first pulse from y to x, so as to start with $-I_{1y}$, which is then converted into $2 I_{1y} I_{2z}$ in the evolution period with a modulation $\sin\Omega_1 t_1 \sin \pi J_{12} t_1$. At the same time, one could observe the y rather than the x component in the detection period. In this case, one obtains two solid arrows in both t_1 and t_2, and hence pure two-dimensional absorption with a cosine/cosine transform, as we have seen above.

Equation (14) and related transformations due to double-quantum filtration can be written in shorthand notation:

$$yx \Rightarrow \tfrac{1}{2}(yx + xy) \quad (16)$$
$$xy \Rightarrow \tfrac{1}{2}(xy + yx) \quad (17)$$
$$xx \Rightarrow \tfrac{1}{2}(xx - yy) \quad (18)$$
$$yy \Rightarrow \tfrac{1}{2}(yy - xx) \quad (19)$$

It is interesting to compare these transformations with those induced by zero-quantum filtration, as employed in the mixing time τ_m of the NOESY experiment and in a variety of experiments involving so-called z-filters. The effect of such filters can be predicted by replacing the cartesian operators by shift operators, deleting the double-quantum components $I_1^+ I_2^+$ and $I_1^- I_2^-$, and transforming the remaining terms $I_1^+ I_2^-$ and $I_1^- I_2^+$ back into cartesian operators:

$$yx \Rightarrow \tfrac{1}{2}(yx - xy) \quad (20)$$
$$xy \Rightarrow \tfrac{1}{2}(xy - yx) \quad (21)$$
$$xx \Rightarrow \tfrac{1}{2}(xx + yy) \quad (22)$$
$$yy \Rightarrow \tfrac{1}{2}(yy + xx) \quad (23)$$

Such transformations can easily be represented graphically in the manner of Figures 5a and 6. In all cases, the effect of the phase cycle is symbolically represented by a short double arrow (⇒).

8. Triple-Quantum Filtered COSY

The pathways relevant to triple-quantum filtered COSY are slightly more involved, as shown in Figure 7. The net effect of triple-quantum filtration can be predicted by substituting the cartesian operators using the relations $I_{1y} = -i\frac{1}{2}(I_1^+ - I_1^-)$ and $I_{2x} = \frac{1}{2}(I_2^+ + I_2^-)$, by deleting from the product all terms except the triple-quantum coherences $I_1^+ I_2^+ I_3^+$ and $I_1^- I_2^- I_3^-$, and by transforming these back into cartesian operators. This procedure leads to the transformation (24).

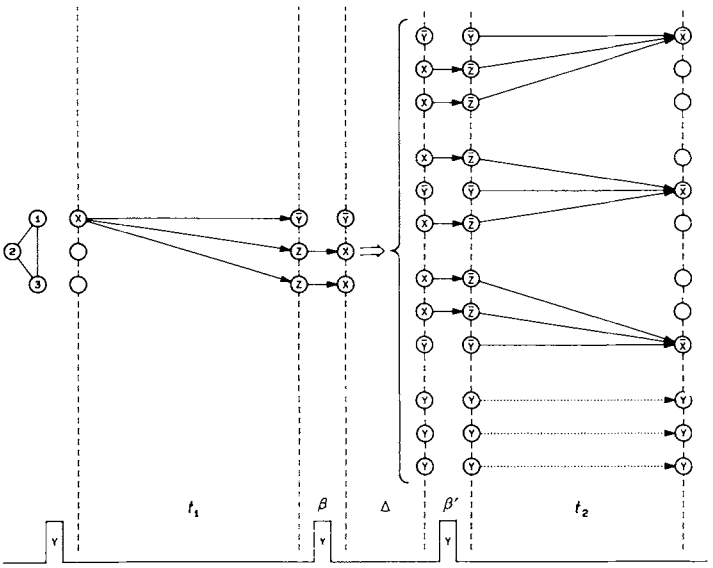

Fig. 7. Evolution of a three-spin system in a triple-quantum filtered COSY experiment.

$$4 I_{1y} I_{2x} I_{3x} \Rightarrow \tfrac{1}{4}(4 I_{1y} I_{2x} I_{3x} + 4 I_{1x} I_{2y} I_{3x} + 4 I_{1x} I_{2x} I_{3y} - 4 I_{1y} I_{2y} I_{3y}) \quad (24)$$

The split-up of one term into four operator products is shown in Figure 7. Although the signs in the Figure are opposite to those in Equation (24), the order of the terms is retained for clarity. The first pathway leads to a diagonal multiplet, while the second and third pathways lead to two distinct cross-peak multiplets. The fourth pathway cannot lead to any observable magnetization, since it yields a superposition of triple-quantum coherence and three-spin single-quantum coherences. The second pathway in Figure 7 is associated with the following modulation terms:

$$\sigma(t_1, t_2) = -I_{2x} \sin\Omega_1 t_1 \sin \pi J_{12} t_1 \sin \pi J_{13} t_1 \sin^2\beta \times \tfrac{1}{4} \sin^2\beta' \sin\Omega_2 t_2 \sin \pi J_{12} t_2 \sin \pi J_{23} t_2 \quad (25)$$

One recognizes a multiplet structure which is in antiphase with respect to J_{12} and J_{13} in ω_1 and in antiphase with respect

to J_{12} and J_{23} in ω_2. The symmetry of the three upper pathways in Figure 7 (three solid arrows in each case) indicates that the multiplet structures and the phases of the diagonal and cross-peak signals are the same. If one uses a sine/sine transform, all signals appear in pure two-dimensional absorption.

In shorthand notation, transformations of the type shown in Equation (24), which describe the effect of triple-quantum filtration, may be written as follows:

$$\mathrm{xxx} \Rightarrow \tfrac{1}{4}(\mathrm{xxx} - \mathrm{xyy} - \mathrm{yxy} - \mathrm{yyx}) \quad (26)$$
$$\mathrm{yxx} \Rightarrow \tfrac{1}{4}(\mathrm{yxx} + \mathrm{xyx} + \mathrm{xxy} - \mathrm{yyy}) \quad (27)$$
$$\mathrm{xyx} \Rightarrow \tfrac{1}{4}(\mathrm{xyx} + \mathrm{xxy} + \mathrm{yxx} - \mathrm{yyy}) \quad (28)$$
$$\mathrm{xxy} \Rightarrow \tfrac{1}{4}(\mathrm{xxy} + \mathrm{yxx} + \mathrm{xyx} - \mathrm{yyy}) \quad (29)$$
$$\mathrm{yyx} \Rightarrow \tfrac{1}{4}(\mathrm{yyx} + \mathrm{xyy} + \mathrm{yxy} - \mathrm{xxx}) \quad (30)$$
$$\mathrm{yxy} \Rightarrow \tfrac{1}{4}(\mathrm{yxy} + \mathrm{yyx} + \mathrm{xyy} - \mathrm{xxx}) \quad (31)$$
$$\mathrm{xyy} \Rightarrow \tfrac{1}{4}(\mathrm{xyy} + \mathrm{yxy} + \mathrm{yyx} - \mathrm{xxx}) \quad (32)$$
$$\mathrm{yyy} \Rightarrow \tfrac{1}{4}(\mathrm{yyy} - \mathrm{yxx} - \mathrm{xyx} - \mathrm{xxy}) \quad (33)$$

Such transformations can readily be represented graphically in the manner of Figure 7, using a double arrow (⇒) to represent the net effect of the phase cycle.

9. Triple-Quantum Filtered NOESY

Recently, we have shown[18, 19] that it is possible to obtain evidence about correlated dipolar relaxation by combining the normal NOESY sequence with triple-quantum filtration. The basic phenomenon that we wish to highlight is the spontaneous conversion of Zeeman order into longitudinal three-spin order, a process which occurs whenever the time-dependencies of the two dipolar interactions D_{12} and D_{13} are correlated.[16–19] This conversion is represented by the wavy arrow in Figure 8. The term $-4\,I_{1z}I_{2z}I_{3z}$ is transformed into $-4\,I_{1x}I_{2x}I_{3x}$ by the third RF pulse. The net effect of triple-quantum filtration is given by Equation (26), and is represented by a double arrow (⇒) in Figure 8. The terms are drawn in the same order as in Equation (26), but they have opposite signs. It can clearly be seen from the figure that the last pulse in the sequence must be about the x-axis, otherwise none of the four terms that make up the triple-quantum coherence can be converted into observable magnetization.[17, 19] Of the four pathways in Figure 8, the second and fourth lead to cross-peak multiplets and the third to a diagonal multiplet. The fourth pathway for example is associated with the modulation pattern (34).

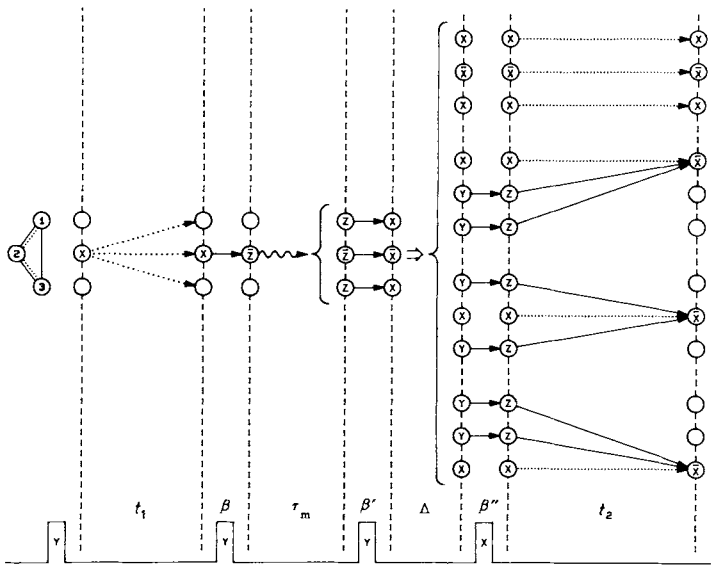

Fig. 8. Evolution of a three-spin system with three scalar couplings and two partly correlated dipolar interactions D_{12} and D_{23} in a triple-quantum filtered NOESY sequence. The double arrow (⇒) represents the effect of the phase-cycle.

$$\sigma(t_1, t_2) = -I_{3x}\cos\Omega_2 t_1 \cos\pi J_{12} t_1 \cos\pi J_{23} t_1 \sin\beta\, \delta_{1223}\tau_m \sin^3\beta' \times \tfrac{1}{4}\sin^2\beta'' \cos\Omega_3 t_2 \sin\pi J_{13} t_2 \sin\pi J_{23} t_2 \quad (34)$$

The amplitude is proportional to the cross-correlation rate δ_{1223}. The measurement of this rate may provide information about the angle subtended by the internuclear vectors r_{12} and r_{23}.[19] One recognizes an in-phase multiplet structure in the ω_1 domain and a doubly-antiphase structure in ω_2. Note the symmetry of the three lower pathways of Figure 8. All signals are in pure two-dimensional absorption if we use a cosine/cosine transform, since all pathways contain an even number of solid arrows in both intervals t_1 and t_2.

10. Relaxation-Allowed Coherence Transfer

Ordinarily, it is assumed that correlation spectra ("COSY") merely provide information about the presence or absence of scalar couplings: if a cross-peak is observed,

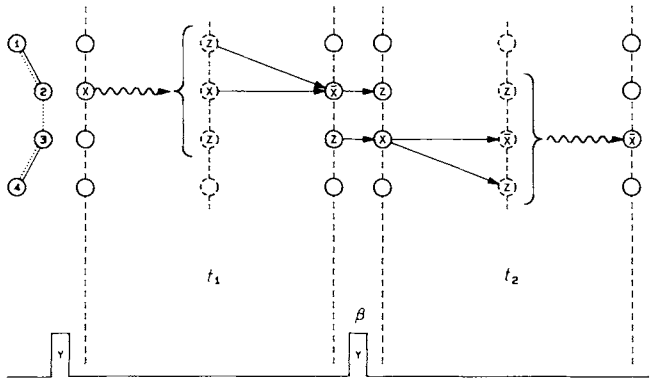

Fig. 9. Evolution of a four-spin system with two scalar couplings and three partly correlated dipolar interactions in the conventional COSY sequence. A pathway is shown that gives rise to cross peaks between spins 2 and 3 although there is no scalar coupling between these spins. The virtual states discussed in the text are represented by dashed circles.

this is taken as evidence that the corresponding spins must be scalar coupled. Under certain circumstances however, it may be possible to observe cross-peaks in COSY spectra between spins that are *not* scalar coupled. Figure 9 shows a four-spin system with three dipolar couplings D_{12}, D_{23} and D_{34} in addition to two scalar couplings J_{12} and J_{34}. If the time-dependencies of the D_{12} and D_{23} interactions are correlated, a coherence I_{2x} can be partly converted into doubly antiphase coherence $4\,I_{1z}I_{2x}I_{3z}$.[9, 10] Subsequent evolution under the

combined effects of the shift Ω_2 and the coupling J_{12} can convert this into $-2\,I_{2x}I_{3z}$, which is partly transformed into $2\,I_{2z}I_{3x}$ by the RF mixing pulse of flip angle β. This term develops into $-4\,I_{2z}I_{3x}I_{4z}$, and is finally converted into $-I_{3x}$ under the effect of correlated relaxation involving the D_{23} and D_{34} interactions. Figure 9 allows one to determine the coefficients:

$$\sigma(t_1,t_2) = -I_{3x}f_{1223}(t_1)\sin\Omega_2 t_1 \times \sin\pi J_{12}t_1\,\sin^2\beta\,\sin\Omega_3 t_2\,\sin\pi J_{34}t_2 f_{2334}(t_2) \quad (35)$$

where the functions $f_{1223}(t_1)$ and $f_{2334}(t_2)$ describe the conversion of in-phase magnetization into antiphase coherence and vice-versa due to correlated relaxation.[10] In both intervals t_1 and t_2 of Figure 9 we show as two sequential steps, the effects of relaxation on the one hand, and of the chemical shifts and couplings on the other, drawing "virtual states" in the middle of the intervals, in analogy to Figure 2. This is justified because the (super)operators relevant to relaxation and free precession commute. Of course, the virtual states represented by dashed circles need not be drawn explicitly. Relaxation, chemical shifts and couplings act throughout the entire durations of these intervals.

The modulation term of Equation (35) describes a cross-peak multiplet centered at the chemical shifts of spins I_2 and I_3, i.e. $(\omega_1,\omega_2) = (\Omega_2,\Omega_3)$, with an antiphase structure due to the couplings J_{12} in ω_1 and J_{34} in ω_2. On superficial inspection such a cross peak might seem to indicate that $J_{23} \neq 0$, but in this case coherence transfer can occur despite the fact that J_{23} vanishes. The appearance of misleading cross peaks in this context may be referred to as the "Wimperis effect".[9, 10]

11. Refocusing

If refocusing pulses are used in pulse sequences, the following rules must be observed:

1. Refocusing pulses eliminate the effects of chemical shifts, so one should not draw any horizontal arrows (neither solid nor dotted) in the relevant intervals.
2. Refocusing pulses do not eliminate the effects of homonuclear couplings, so for each homonuclear coupling a solid or dotted sloping arrow must be drawn, depending on whether the coupling plays an active or a passive role in the interval.
3. Heteronuclear couplings J_{IS} are refocused by 180° pulses applied to either I or S spins. Neither solid nor dotted sloping arrows should be drawn for these couplings.
4. Heteronuclear couplings J_{IS} do play a role if 180° pulses are applied to both I and S spins. These couplings should therefore be represented either by solid or dotted sloping arrows.

Examples of pulse sequences where these rules must be applied are discussed in the next two sections.

12. Multiple-Quantum Evolution

In the preceding sections, we have discussed experiments where multiple-quantum coherences appear only in a transient fashion in brief intervals. If these coherences are allowed to evolve however, their precession under the effects of chemical shifts are described by Equation (90) of *Sørensen* et al.[2] or by Equation (5.3.38) of *Ernst* et al.[7] For double-quantum coherences we have

$$\tfrac{1}{2}(xx - yy) \rightarrow \tfrac{1}{2}(xy + yx) \rightarrow -\tfrac{1}{2}(xx - yy) \rightarrow -\tfrac{1}{2}(xy + yx) \quad (36)$$

or in symbolic notation:

$$\begin{Bmatrix} xx \\ \bar{y}y \end{Bmatrix} \rightarrow \begin{Bmatrix} xy \\ yx \end{Bmatrix} \rightarrow \begin{Bmatrix} \bar{x}x \\ yy \end{Bmatrix} \rightarrow \begin{Bmatrix} \bar{x}y \\ \bar{y}x \end{Bmatrix} \quad (37)$$

The transformations are represented graphically by horizontal arrows (Fig. 10). To avoid confusion with the precession of single spins under the effect of chemical shifts, these arrows are labeled with the frequencies $(\Omega_i + \Omega_j)$ corresponding to the sums of the chemical shifts. Plain arrows correspond to modulation factors $\sin(\Omega_i + \Omega_j)t$, dotted arrows represent factors $\cos(\Omega_i + \Omega_j)t$.

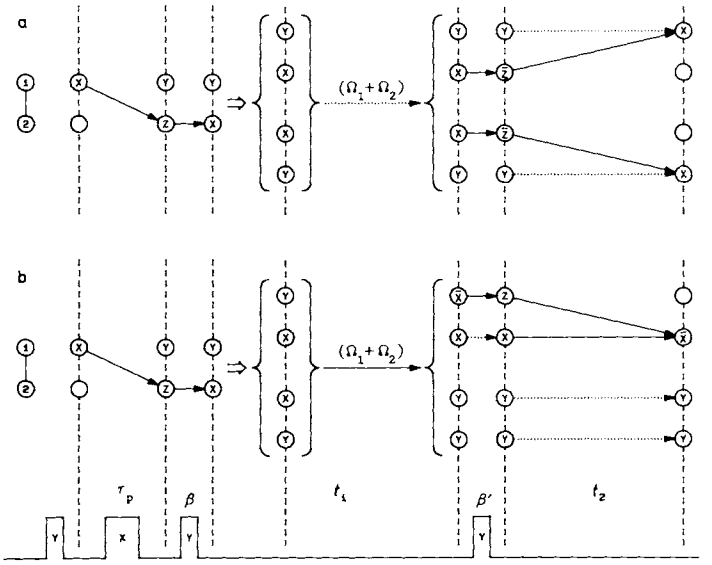

Fig. 10. Evolution of a two-spin system in a double-quantum experiment (INADEQUATE pulse sequence). The double arrows (⇒) represent the effect of the phase cycle. T modulation factors of the transformations are a) $\cos(\Omega_1 + \Omega_2)t_1$ and b) $\sin(\Omega_1 + \Omega_2)t_1$.

Figure 10 illustrates two possible operator evolution graphs that may occur in INADEQUATE (Incredible Natural Abundance DoublE-QUAntum Transfer Experiment), which has proven useful for correlating the signals of neighboring carbon-13 sites.[11, 12] The second pathway from the top in Figure 10 leads to a component

$$\sigma(t_1,t_2) = I_{2x}\sin\pi J_{12}\tau_p\sin\beta\tfrac{1}{2}\cos(\Omega_1 + \Omega_2)t_1 \times \sin\beta'\cos\Omega_2 t_2\,\sin\pi J_{12}t_2 \quad (38)$$

On the other hand, the third pathway from the top in Figure 10 leads to a component

$$\sigma(t_1,t_2) = -I_{2x}\sin\pi J_{12}\tau_p\sin\beta\tfrac{1}{2}\sin(\Omega_1 + \Omega_2)t_1 \times \sin\beta'\cos\beta'\sin\Omega_2 t_2\,\sin\pi J_{12}t_2 \quad (39)$$

Clearly, this latter pathway, which is modulated as a function of $\sin(\Omega_1 + \Omega_2)t_1$, can only play a role if $\beta' \neq 90°$.[12]

For zero-quantum coherences, free precession obeys the following rules:[2]

$$\tfrac{1}{2}(xx + yy) \rightarrow \tfrac{1}{2}(yx - xy) \rightarrow -\tfrac{1}{2}(xx + yy) \rightarrow -\tfrac{1}{2}(yx - xy) \tag{40}$$

or in symbolic notation:

$$\begin{Bmatrix} xx \\ yy \end{Bmatrix} \rightarrow \begin{Bmatrix} yx \\ \bar{x}y \end{Bmatrix} \rightarrow \begin{Bmatrix} \bar{x}x \\ \bar{y}y \end{Bmatrix} \rightarrow \begin{Bmatrix} \bar{y}x \\ xy \end{Bmatrix} \tag{41}$$

In this case, solid and dotted arrows correspond to modulation factors $\sin(\Omega_i - \Omega_j)t$ and $\cos(\Omega_i - \Omega_j)t$ respectively.

With regard to scalar couplings, it is important to remember that interactions between active spins are ineffective, since the coupling Hamiltonians commute with the multiple-quantum coherences. Scalar couplings between active spins should therefore not appear in the graphs (neither solid nor dotted sloping arrows). Scalar couplings to passive spins lead to transformations given by Equation (94) of *Sørensen* et al.[2] or by Equation (5.3.39) of *Ernst* et al.[7]

13. Relayed Proton–Proton–Carbon Transfer

To conclude, we shall give an example of a "relayed" experiment involving a homonuclear transfer of coherence from one proton to another, followed by a transfer to a ^{13}C-nucleus. The pulse sequence of Figure 11 was recently

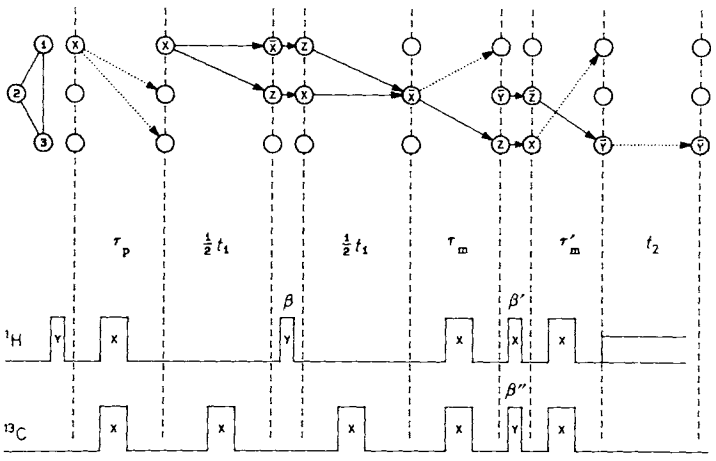

Fig. 11. Evolution in a heteronuclear spin system consisting of a remote proton I_1, a neighboring proton I_2 and a C^{13}-spin I_3. The pulse sequence is designed to bring about relayed coherence transfer $I_1 \rightarrow I_2 \rightarrow I_3$. Only the pathway that gives rise to relayed signals is shown.

developed to facilitate automated analysis of molecular fragments by pattern recognition.[13] The coupling network consists of a "remote" proton spin I_1, a "neighboring" proton spin I_2, and a carbon spin I_3. The pathway shown starts off with transverse magnetization I_{1x} of the remote proton, and ends up with $-I_{3y}$ coherence of the ^{13}C-spin. This pathway is associated with the modulation pattern (42).

$$\begin{aligned}\sigma(t_1, t_2) = & -I_{3y} \cos \pi J_{12} \tau_p \cos \pi J_{13} \tau_p \sin \Omega_1 \tfrac{1}{2} t_1 \\ & \times \sin \pi J_{12} \tfrac{1}{2} t_1 \sin^2 \beta \sin \Omega_2 \tfrac{1}{2} t_1 \\ & \times \sin \pi J_{12} \tfrac{1}{2} t_1 \cos \pi J_{12} \tau_m \sin \pi J_{23} \tau_m \\ & \times \sin \beta' \sin \beta'' \cos \pi J_{13} \tau'_m \sin \pi J_{23} \tau'_m \cos \Omega_3 t_2\end{aligned} \tag{42}$$

In deriving the trigonometric functions from the figure, we have made use of rules (1) to (4) of Section (11):

1. Because of refocusing of the chemical shifts, no horizontal arrows appear in the intervals τ_p, τ_m, and τ'_m.
2. The homonuclear coupling J_{12} is represented by sloping arrows in the intervals τ_p, $\frac{1}{2}t_1$, and τ_m because it is not refocused.
3. The heteronuclear couplings J_{13} and J_{23} are refocused by the 180° pulses applied to the ^{13}C-spins in the middle of the two halves of the evolution period. As a result, neither J_{13} nor J_{23} have any effect in these intervals (neither solid nor dotted sloping arrows).
4. The heteronuclear couplings J_{13} and J_{23} appear as dotted or solid sloping arrows in the intervals τ_p, τ_m, and τ'_m because they are not refocused.

Finally, it is obvious that heteronuclear interactions are ineffective when the proton decoupler is switched on, so that the couplings J_{13} and J_{23} do not appear in t_2.

The pathway illustrated in Figure 11 is only one of many possibilities, most of which give rise to undesirable artifacts in the spectra. It is the bewildering variety of pathways in this experiment which provided the incentive for developing the graphical conventions discussed in this paper. However, the detailed discussion of relayed coherence transfer is beyond the scope of the present work.

14. Recapitulation

At this point, it may be helpful to briefly recapitulate the essential conventions used in the graphs:

1. A short solid horizontal arrow represents a rotation under an RF pulse (coefficient $\sin\beta$). The relevant transformations of the terms are given in Equations (1) and (2).
2. A short dotted horizontal arrow represents a lack of rotation under the influence of an RF pulse (coefficient $\cos\beta$).
3. The absence of a short horizontal arrow indicates that the term is invariant under influence of an RF pulse (coefficient 1).
4. A long solid horizontal arrow represents a rotation under the effect of a chemical shift (coefficient $\sin\Omega_i t$). The relevant transformations of the terms are given in Equation (3).
5. A long dotted horizontal arrow represents a lack of rotation under the effect of a chemical shift (coefficient $\cos\Omega_i t$).
6. The absence of a long horizontal arrow indicates that the chemical shift has been refocused (coefficient 1).
7. A long solid sloping arrow represents a rotation under a scalar coupling (coefficient $\sin\pi J_{ij} t$). The relevant transformations of the terms are given in Equations (4) and (5).

8. A long dotted sloping arrow represents the lack of rotation under a scalar coupling (coefficient $\cos \pi J_{ij} t$).
9. The absence of a long sloping arrow indicates that the scalar coupling has been refocused (coefficient 1).
10. Wavy arrows represent transformations due to various relaxation processes, as discussed in Section 4.
11. A short double arrow ($\Rightarrow$) represents a transformation due to phase-cycling, which amounts to the selection of multiple-quantum coherences of specified order. The relevant transformations are given in Equations (16)–(19), (20)–(23) and (26)–(33).

15. Conclusions and Prospects

It appears that our graphical conventions can be useful to rationalize the mechanism of a wide variety of pulse sequences. The graphs allow one to gain a "feeling" for the relevant terms, i.e., for terms that undergo certain coherence transfer processes and contribute to the observable signals. It is an easy matter to sketch a few pathways to check whether they can give rise to interesting signal contributions or not. The operator evolution graphs can be used not only for qualitative discussions, but also yield the trigonometric functions that determine the time-domain modulation terms, and hence the frequency-domain multiplet patterns and phases of the signals. In fact, the graphs ensure that relevant terms are not accidentally left out, and that the trigonometric terms are correctly accounted for.

We are not aware of any serious limitations, except of course that the use of product operators should preferably be limited to weakly-coupled systems (complications arising in strongly-coupled systems have recently been discussed elsewhere).[25] Another difficulty arises if one attempts to describe the evolution of p-quantum coherences in systems with more than p spins. In such cases, the use of sloping arrows to depict the effect of couplings to passive spins tends to become somewhat confusing, and it might be advisable to define special symbols for the x and y components of multiple-quantum coherences and for their antiphase counterparts. Although we have refrained from introducing such symbols in this paper, it appears that Figure 10 might have been simplified, for example by drawing a rectangular box around the spins that actively participate in the double-quantum coherence. Other graphs could be drawn to depict the fate of shift operators, polarization operators, and irreducible tensor operators.[7] Of course, the meaning of various arrows would have to be defined from case to case.

The figures shown in this paper were drawn with a computer program designed to position various symbols and interconnecting arrows in suitable locations. In principle, it would be possible to incorporate the rules that govern the transformations into this program, although it might be wiser to leave some initiative to the spectroscopist. We hope that these graphs may be helpful not only for teaching but also to pave the way for developing further novel experiments.

The authors gratefully acknowledge useful comments by Dr. Nicolau Beckmann of the Biozentrum of the University of Basel. Radiation-Induced Copolymerization of *cis*-$[PdCl_2\{CN(CH_2)_3\text{-}OC(O)\text{–}CH=CH_2\}_2]$: A Novel Route to Organometallic Cross-linked Copolymers Useful for Catalytic Applications

By *Benedetto Corain,* Marco Zecca, Felix Okon Sam, Giancarlo Palma*, and *Silvano Lora*

The copolymerization of organometallic monomers with other conveniently chosen comonomers may be a procedure for the synthesis of macromolecular materials containing homogeneously distributed and chemically well-defined organometallic groups. Such polymers may be useful as hybrid catalysts,[1] tailored precursors of highly dispersed metal catalysts, or designable organometallic materials potentially useful for diverse applications.[2] The radical-initiated copolymerization of organometallic monomers in which alkenyl residues are connected to η^5- or η^6-coordinated aromatic ligands, albeit somewhat troublesome, is well documented.[3]

We have now found that the bifunctional organometallic monomer **1** can be copolymerized under γ-ray irradiation

cis-$[PdCl_2\{CN(CH_2)_3OC(O)\text{–}CH=CH_2\}_2]$ **1**

with dimethylacrylamide (DMAA) in the presence of *N,N'*-methylenebisacrylamide (MBAA), as a cross-linking agent, to give a solid polymer, "Pd-Pol".

Complex **1** is obtained in high yield as a white microcrystalline powder[4] from $[PdCl_2(NCPh)_2]$ and 3-isocyanopropyl acrylate in $C_2H_4Cl_2$ at room temperature.[5] No monoisocyano intermediate is observed in this reaction. Complex **1** is air-stable and melts at 72–73 °C in argon atmosphere, giving rise to a phase which is stable up to 180 °C (DSC control). At 180–240 °C the molten phase undergoes polymerization ($\Delta H \cong -39$ kcal mol^{-1}). The most prominent feature in the IR spectrum of **1** is a double absorption band centered at 2265 cm^{-1} (maxima at 2271 and 2256 cm^{-1}), which is attributed to a *cis*-$[Pd(CNR)_2]$ moiety.[6] The X-ray single-crystal diffraction analysis of **1** was prevented by X-ray-induced polymerization of the sample.

Complex **1** undergoes γ-ray-induced copolymerization with DMAA at −78 °C in the presence of water; the product separates as microcrystals[7] and an overall polymerization conversion of 95% is attained. Similar results are obtained by employing *cis*-$[PdCl_2(PPh_3)(CN(CH_2)_3OC(O)\text{-}CH=CH_2)]$[8] as monomer. The presence of the doublet centered at about 2216 cm^{-1} in the IR spectrum of Pd-Pol strongly suggests the maintenance of the *cis*-$[Pd(CNR)_2]$ moiety in the copolymer.

The bathochromic shift ($\Delta\tilde{\nu} = 49$ cm^{-1}) is similar to that observed on going from $[Pd(NCCH_3)_4]^{2\oplus}$ to $[Pd(NC\text{-}Ⓟ)_4]^{2\oplus}$.[9] Pd-Pol is obtained in the form of beads which are about 0.2 mm in diameter and exhibit a moderately porous structure. It swells appreciably in methanol, dichloromethane, water, and acetone (equilibrium swelling degree around 100%), but to a very limited extent in diethyl ether and tetrahydrofuran. X-ray microprobe analysis reveals a fairly uniform metal distribution inside the polymer beads. The low Pd content in Pd-Pol is explained either by assuming that **1** is substantially less reactive than other comonomers or, more likely, that it partially separates from the reaction mixture when the latter is cooled to the temperature at which polymerization is carried out.[7]

Pd-Pol has been tested as a catalyst in the hydrogenation of phenylacetylene, styrene, and nitrobenzene in methanol under ambient conditions. It shows good activity, is easily separated from the reaction mixture, and may be reused. Turnover numbers of 500 to 900 (not optimized) are obtained after 24 h.

After the first catalytic run, the IR spectrum of Pd-Pol reveals the complete disappearance of the Pd(CNR) unit, which suggests the reduction of Pd^{II} to Pd^0. This is confirmed by a test in which the reduction of **1** to palladium metal is found to take place in methanol under hydrogen under the same experimental conditions after a comparable reaction time.

The reaction mixtures recovered after catalytic runs do not exhibit any catalytic activity in accordance with negligible metal leaching. In view of the general high reactivity of isocyanides with metal complexes[10, 11] and, in particular, with metal halides, our approach is quite likely to be extendible to many different metal centers in various oxidation states.

Experimental Procedure

Synthesis of the monomer: To a solution of $[PdCl_2(NCPh)_2]$ (1.3 g, 3.4 mmol) in dichloroethane (5 mL), a solution of 3-isocyanopropyl acrylate (1.43 g, 10.3 mmol) in the same solvent (5 mL) was added under vigorous stirring. An immediate color change from brownish-yellow to yellow was observed. The solution was stirred for 15 min. The volume of the solvent was then reduced to about 5 mL and 40 mL of diethyl ether was slowly added to the stirred solution. The resulting yellow precipitate (1.97 g) was collected, dissolved in a small amount of dichloroethane, and recrystallized from diethyl ether to give a white microcrystalline powder (overall yield 75%).

Synthesis of Pd-Pol: A mixture of **1** (0.18 g), DMAA (0.79 g), MBAA (0.05 g), and water (0.56 g) was injected dropwise (ca. 1 mL min^{-1}) by means of a syringe (needle inner diameter ca. 0.45 mm) into a cylindrical Pyrex vial (outer diameter 2.5 cm) containing an excess volume of petroleum ether maintained at −78 °C[7]. The system was then irradiated with γ-rays from a ^{60}Co source at a rate of 0.50 Gy s^{-1} for 17 h. Beadlike polymer particles were recovered, washed with ethanol and diethyl ether, and finally dried under vacuum.

Catalytic runs: The reactions were carried out in 100-mL cylindrical vials under vigorous magnetic stirring. The reaction mixtures, prepared volumetrically and degassed by three freezing-thawing cycles, were finally saturated with H_2 at atmospheric pressure, supplied from a large reservoir. The reactions were monitored by gas chromatography $\tilde{\nu}_{NC} = 2237$ (w), 2200 (w, sh). Elemental

Grahamine, an Unusual Tropane Alkaloid from *Schizanthus grahamii***

By *Rudolf Hartmann, Aurelio San-Martin, Orlando Muñoz,* and *Eberhard Breitmaier**

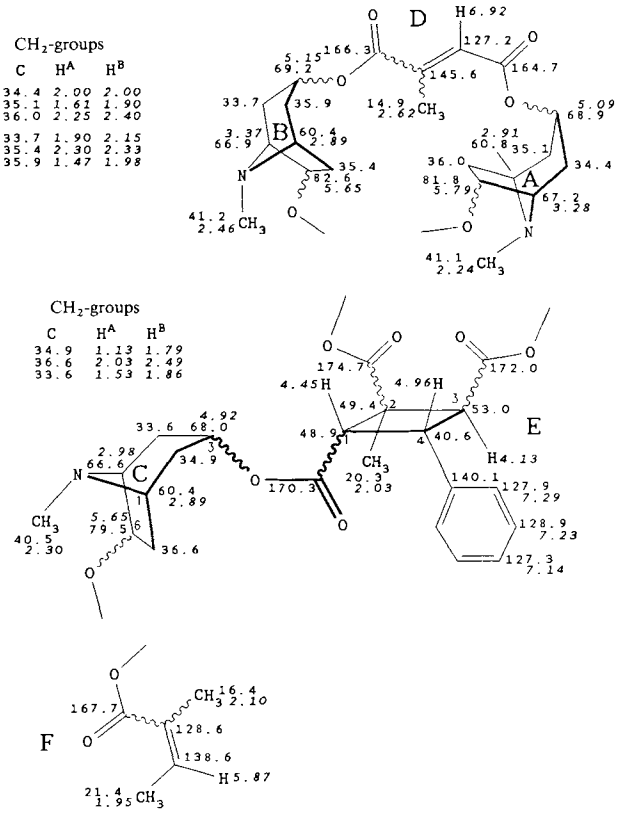
Alkaloids with cyclobutane partial structure are rare. A CAS on-line search resulted in bis(2-methoxycarbonyltropyl) α-truxillate from leaves of the coca plant, *Erythroxylum coca*,[1] and santiaguine, the diamide formed from truxillic acid and 1,2,3,4-tetrahydro-5-(2-piperidyl)pyridine.[2] In *Schizanthus grahamii*, we have now found a further tropane alkaloid containing a 2-methyl-4-phenylcyclobutane-1,2,3-tricarboxylic triester as central partial structure.

Schizanthus grahamii (Gill) belongs to the *Solanaceae* or nightshade family and to the Salpiglossideae branch native to Chile. The plant grows up to 60 cm high and possesses doubly pinnatifid leaves and large, butterfly-like, purple-pink blossoms.[3] Several tropane alkaloids have been isolated from the plant, including hygrolinhydroxytropane esters and schizanthine, in which two 3α-(6β-hydroxytropane) esters of angelic acid are linked as a mesaconic diester.[4, 5]

Using previously described methods,[5] we isolated an extract from the dried and pulverized aboveground parts of the plant and subjected it to countercurrent distribution (dichloromethane and McIlvaine buffer, pH = 5.4). Column chromatography of the first nine fractions (alumina 60/E, petroleum ether (40–60 °C): ethyl acetate = 4:5) gave, besides the known schizanthine, the new compound grahamine as an oily, but pure, fairly stable substance $[[\alpha]_{586}^{20} = +6.21°$ (c = 0.0016 M in $CHCl_3$), R_f = 0.1125 (thin layer chromatography, neutral alumina, $CHCl_3$)].

Fast atom bombardment (FAB) mass spectrometry gave a molecular mass of 871 for grahamine. The best-resolved NMR spectrum in the proton region was obtained in hexadeuteriobenzene as solvent.[6] The ^{1}H-broadband-decoupled ^{13}C-NMR spectrum contains 46 signals, two of which, displaying double intensity, belong to a monosubstituted benzene ring, so that 48 C atoms may be assumed. The DEPT subspectra reveal seven methyl (C_7H_{21}), nine aliphatic methylene (C_9H_{18}), twenty-two methine ($C_{22}H_{22}$), and ten quaternary C atoms (C_{10}). The sum of these CH_n fragments, $C_{48}H_{61}$, corresponds to a molecular mass of 637, a difference of 234 from the actual molecular mass of 871. The typical shifts (δ = 40.5, 41.1, 41.2), splittings (quartets), and CH coupling constants (^1J = 134–140 Hz) of *N*-methyl groups indicate the presence of three nitrogen atoms. If their molecular mass of 42 is subtracted from the above difference, the resulting mass (192) corresponds exactly to twelve oxygen atoms. The empirical formula thereby obtained, $C_{48}H_{61}N_3O_{12}$, respresents twenty double-bond equivalents.

Further structure elucidation was accomplished by one- and two-dimensional NMR methods (400- and 600- MHz ^{1}H NMR; 100- and 150-MHz ^{13}C NMR; Scheme 1). All 38



Scheme 1. Partial structures **A**–**F** of grahamine (**1**). ^{13}C- and ^{1}H-NMR chemical shifts, the latter in italics.

CH_n fragments of the molecule can be assigned in the C,H COSY contour diagram. All 61 H atoms of the molecule are bonded to carbons, so that no OH or NH groups are present. The cross signals of an H,H COSY diagram reveal three 3,6-dihydroxytropane rings, **A**, **B**, and **C**, as well as a methyl-

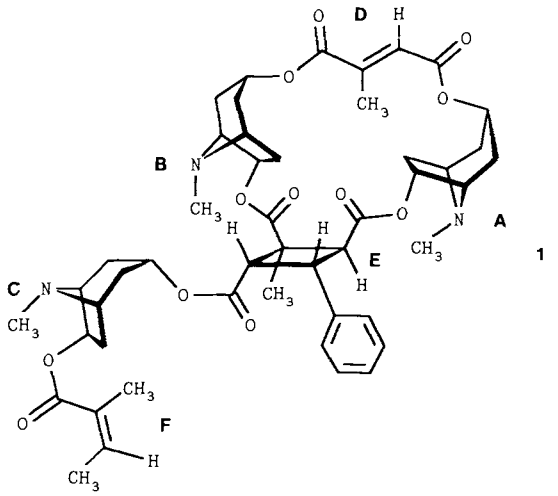
cyclobutane partial structure, which was identified from the typical CH coupling constants (^1J = 140–145 Hz) in the coupled ^{13}C-NMR spectrum. In the C,H COLOC diagram, the connectivity of all six carboxyl C atoms (δ = 164.7–174.7) is clearly revealed by the two- and three-bond coupling constants $^2J_{CH}$ and $^3J_{CH}$, respectively. Accordingly, tropane rings **A** and **B** are linked as mesaconic diester **D**. Further cross signals in the C,H COLOC diagram show that a 2-methyl-4-phenylcyclobutane-1,2,3-tricarboxylic ester **E** is present, whereby the carboxylic acid function on C1 forms an ester linkage with the third 3,6-dihydroxytropane **C** at its 3-hydroxyl group. Furthermore, the C,H COLOC diagram reveals an angelic ester partial structure **F**, which is linked to tropane ring **C** through the 6-hydroxyl group. Combination of all partial structures gives the constitution of grahamine (**1**), which accounts for the twenty double-bond equivalents.

The relative configuration of the *O*-acyl groups on the tropane rings may be derived from the HH coupling constants. All signals of protons in a 3-position are split into a doublet of doublets ($^3J_{HH}$ = 4–5 Hz) owing to coupling with the pseudo-axial protons 2-H and 4-H (interplanar angle ca. 60°). Signal broadening occurs as a result of unresolved HH coupling to the pseudo-equatorial protons in 2- and 4-positions (interplanar angle ca. 90°). Accordingly, the 3-H protons are pseudo-equatorial and the 3-*O*-acyl groups pseudo-axial. The signals of the 6-H protons are each a doublet of doublets with $^3J_{HH}$ = 7.8–8.8 Hz to 7-H_{endo} and 3.5–3.8 Hz to 7-H_{exo}. Further couplings with 5-H are again unresolved (interplanar angle nearly 90°); examination of the interplanar angle between the protons 5-H and 6-H in a Dreiding model reveals that only 6-H in *endo* position allows an interplanar angle to 5-H of about 90°. Thus, the 6-*O*-acyl groups are *exo*.

The CH coupling constants of the carboxyl C atoms at δ = 166.3 (**D**) and 167.7 (**F**) reflect the relative configuration of the two C–C double bonds. A $^3J_{CH}$ coupling of 15 Hz between the carboxy signal at δ = 167.7 and the proton signal at δ = 5.87 is characteristic of the *trans* configuration of the methyl group of angelic ester **F**. A correspondingly large coupling with the proton signal at δ = 6.92 is absent for the carboxyl signal at δ = 166.3, which confirms the **E** configuration of the mesaconic diester partial structure **D**.



Since the $^3J_{HH}$ couplings of the *cis* and *trans* protons in cyclobutane derivatives differ only slightly,[7] the relative configuration of this ring was determined by H,H NOE difference spectroscopy. Pronounced nuclear Overhauser effects corresponding to a *cis* relationship are found between the protons at δ = 4.45 and 4.96 as well as 4.13 and 2.03 (methyl). Saturation of the resonance at δ = 2.03 also leads to an NOE at the *N*-methyl proton of tropane ring **B** (δ = 2.46). Accordingly, the partial structures may be joined as shown by **1**.

Presumably, the plants, which grow at sunny sites, form the cyclobutane ring from mesaconic diester (left half in **1**) and cinnamic ester (right half) by [2+2] cycloaddition.

Enzyme-Catalyzed Synthesis of (*S*)-Cyanohydrins**

By *Uwe Niedermeyer* and *Maria-Regina Kula**

The enzyme-catalyzed addition of hydrogen cyanide to aldehydes leads to optically active cyanohydrins.[1] These compounds open up a simple route to chiral β-amino alcohols,[2] α-hydroxy acids, and pyrethroid insecticides.[3] However, obtaining cyanohydrins with high optical purity is fundamentally difficult, since the optical yield of the enzyme-catalyzed asymmetric synthesis is decreased by the concomitant nonselective chemical addition of hydrogen cyanide. This reaction cannot be completely suppressed in most solvent systems.[4] The importance of optically active cyanohydrins, on the one hand, and the lack of methods for asymmetric synthesis of cyanohydrins, on the other, prompted us to investigate in more detail the potential of enzyme-catalyzed cyanohydrin formation.

The synthesis of (*R*)-cyanohydrins is documented by numerous examples. One of the most effective catalysts is an oxynitrilase (4.1.2.10) from *Prunus amygdalus* (bitter almond).[1, 5, 6] By contrast, the enzymatic synthesis of (*S*)-cyanohydrins has not yet been studied.[***] We have now found that an oxynitrilase from *Sorghum bicolor* (4.1.2.11), which was described mainly from a botanical viewpoint in the 1960s,[7a, b] allows the preparative synthesis of (*S*)-cyanohydrins with high optical purity.[8]

[***] Editorial note (March 16, 1990): A communication concerning the enzyme-catalyzed synthesis of (*S*)-cyanohydrins has been published in issue No. 9/1990 of *Tetrahedron Lett.*: F. Effenberger, B. Hörsch, S. Förster, T. Ziegler, *Tetrahedron Lett. 31* (1990) 1249 (Received: December 22, 1989).

By detailed investigations of the reaction kinetics of enzymatic and nonenzymatic cyanohydrin formation, we were able to show that the enantiomeric excess of the product could be controlled, especially through the pH value. Figure 1 shows, for example, the pH dependence of the enzymatic reaction of 4-hydroxybenzaldehyde. Under otherwise identical conditions, lower pH values clearly result in higher optical rotations, that is, higher enantiomeric purity, but lead to a decrease in reaction rate.

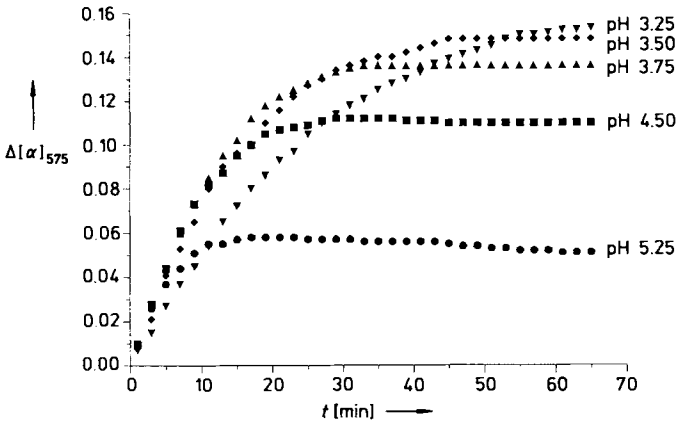

Fig. 1. Effect of the pH value on the asymmetric cyanohydrin synthesis at 25 °C (determined from the change in optical rotation $\Delta[\alpha]_{575}$). Starting concentrations: 27.5 mM 4-hydroxybenzaldehyde, 500.0 mM HCN, 1.7 U mL^{-1} (*S*)-oxynitrilase.

Carbonyl compounds react with hydrogen cyanide at different rates in the nonenzymatic reaction.[9] This differing reactivity of the starting materials in the spontaneous formation of cyanohydrins, as well as the affinity of the enzyme for the substrates, governs the conditions under which almost exclusive enzyme-catalyzed cyanohydrin formation occurs.

Although the rate of the reaction catalyzed by the (*S*)-oxynitrilase decreases with decreasing pH value, reactions can be carried out down to a pH value of 3.0. Thus, a relatively broad pH range is available for optimizing the reaction. The results obtained in batch runs with a number of aldehydes under optimized conditions are summarized in Table 1. In contrast to the (*R*)-oxynitrilase from *Prunus amygdalus*, the (*S*)-oxynitrilase from *Sorghum bicolor* is apparently unable to catalyze the reaction of aliphatic aldehydes. The procedure presented here affords homocyclic aromatic (*S*)-cyanohydrins with very high optical purity.

Table 1. Enzymatic synthesis of (*S*)-cyanohydrins in sodium citrate buffer at 20 °C. The starting material (0.5 mmol) was treated with excess hydrogen cyanide and the (*S*)-cyanohydrin was isolated after the reaction times indicated (batch runs).

Carbonyl compound	*t* [min]	pH	Yield [%]	*ee* value [%]
Benzaldehyde	45	3.25	80	96
3-Hydroxybenzaldehyde	40	3.20	90	98
4-Hydroxybenzaldehyde	25	3.75	87	99
3-Methylbenzaldehyde	90	3.25	80	96
Furfural	60	4.00	no conversion	
Acetaldehyde	60	3.25	no conversion	
(*R*/*S*)-3-Methylcyclohexanone	60	4.50	no conversion	

In a continuous run the (*S*)-oxynitrilase, immobilized on Eupergit C,[10] was employed in a stirred tank reactor (10 mL); 4-hydroxybenzaldehyde (21 mM) was converted under identical conditions as described above into the corresponding (*S*)-cyanohydrin (*ee* value 98%). For a residence time of 66 min and a conversion of 85%, a space–time yield of 58 g L^{-1} d^{-1} was obtained. The productivity, as well as the enantiomeric excess, can be further improved by using higher concentrations of catalyst.[11]

To determine the *ee* values, the cyanohydrins were reduced to the corresponding aminoethanols.[12] These compounds were perfluoropropionylated and then analyzed directly by gas chromatography on a chiral column.[13]

Experimental Procedure

The enzyme preparation was obtained from five-day-old shoots of *Sorghum bicolor* by standard biochemical methods of protein isolation. The (*S*)-oxynitrilase stock solution had an activity of 83 U mL^{-1} (53 U mg^{-1}), whereby 1 U catalyzes the formation of one micromole of 4-hydroxymandelonitrile per minute at 20 °C at pH 3.75.

Example: 4-Hydroxybenzaldehyde (61 mg, 0.5 mmol) was dissolved in 9.4 mL of 50 mM sodium citrate buffer (pH 3.75) and incubated at 20 °C. After addition of 500 μL of oxynitrilase solution and 800 μL of 4.2 M aqueous HCN solution, the reaction was monitored polarimetrically. The reaction is complete after 15–30 min (constant optical rotation). The reaction mixture was extracted with 4 × 10 mL of diethyl ether and the combined organic phases were dried over Na_2SO_4. The solvent was then removed with a rotary evaporator, the residue washed with 3 × 10 mL of pentane, and the product dried in vacuo. Yield: 64.8 mg (83%).

To determine the optical purity, 1–2 mg of the cyanohydrin was reduced by treatment with 250 μL of a 1 M solution of diborane (Aldrich Chemie, Steinheim) in tetrahydrofuran at room temperature for 30 min. After hydrolysis of the excess diborane with a few drops of ethanol and removal of the solvent, the resulting amino alcohol was acylated directly by treatment with 20 μL of pentafluoropropionic anhydride at room temperature in dichloromethane. The excess anhydride was removed in a rotary evaporator and the residue was dissolved in dichloromethane and then analyzed by gas chromatography (FS-Chirasil-Val, Macherey-Nagel, Düren).

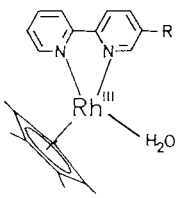
Continuous Generation of NADH from NAD$^{\oplus}$ and Formate Using a Homogeneous Catalyst with Enhanced Molecular Weight in a Membrane Reactor**

By *Eberhard Steckhan,** *Sabine Herrmann, Romain Ruppert, Jörg Thömmes*, and *Christian Wandrey*

Homogeneous catalysts, which are often highly efficient and selective even at low reaction temperatures, have usually been restricted to use in batch processes. On the other hand, heterogeneous catalysts, though well suited for continuous processes, often exhibit low selectivity. Only moderate success has been achieved so far in attempts to exploit the potential advantages of homogeneous catalysts by binding them to polymers in order to make them heterogeneous. Many problems remain to be solved; these include the nonuniform and partly unknown structures of the heterogeneous catalysts thereby obtained, hindered diffusion due to extensive crosslinking of the polymer matrix, low catalytic activity, loss of metal, and self-poisoning of the active centers.[1] Recently, we reported that the Rh^{III} complex **1** is an effective homogeneous catalyst for regeneration of the enzyme cosubstrates nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide phosphate (NADPH) either with formate as hydride donor[2] or electrochemically. The rhodium catalyst reacts with NAD(P)$^{\oplus}$ much faster than with carbonyl compounds, thereby allowing selective reduction of the cofactors, provided that suitable concentration ratios are chosen.[3] After 100 catalytic cycles involving **1**, no formation of 1,6-NADH could be detected enzymatically.



1, R = H
2, R = CH_2OPEG
3, R = CH_2OEt

An effective system for in situ regeneration of these expensive cosubstrates in enzymatic reactions is a prerequisite for the use of oxidoreductases as extraordinarily active catalysts in stereospecific organic synthesis. The usual enzymatic regeneration is not unproblematic.[4] A system employing formate dehydrogenase (FDH) as regeneration enzyme and formate as hydride donor has been brought to technical perfection.[5] Continuous production of enantiomerically pure amino acids is achieved by retaining the amino acid dehydrogenases, FDH, and polymer-bound high-molecular-weight NADH (PEG-NADH)[6] in an enzyme membrane reactor (EMR) behind an ultrafiltration membrane.

In principle, **1** could serve the same function as FDH.[2] Compared with the FDH system, this nonenzymatic generation of NADH has the following important advantages: (1) The reaction is zero order in NAD$^{\oplus}$ and, in contrast to FDH, **1** exhibits no product inhibition. (2) NADPH can be generated under the same conditions. (3) Complex **1** is more stable than an enzyme and not oxygen-sensitive.

By binding **1** to polyethyleneglycol (PEG, MW 20000), we have obtained, for the first time, a homogeneous catalyst (**2**) that can be retained by an ultrafiltration membrane, but which does not give rise to the problems associated with a heterogeneous catalyst, since it remains water soluble. The properties of **1** are therefore largely maintained. We were thus able to replace the FDH in the ultrafiltration flow reactor and generate NADH continuously in a homogeneous catalytic reaction. Because of the improved solubility of the PEG-bound complex, the stationary concentrations of catalyst can be larger than those possible with FDH. In addition, the reaction parameters can be widely varied.

In order to demonstrate that the catalytic properties of the rhodium complex **2**,[7] with enhanced molecular weight, are maintained in the ultrafiltration flow reactor, the kinetic parameters for the reduction of NAD$^{\oplus}$, NADP$^{\oplus}$, and PEG-NAD$^{\oplus}$[6] with formate catalyzed by **2** must be determined and compared with the values obtained for the analogous low-molecular-weight complex **3**.[8] The turnover frequencies[9] for the reduction of (PEG-)NAD(P)$^{\oplus}$ are only lowered by a factor of 0.56–0.66 by the increased molecular (MW 20000) weight of the rhodium complex (Table 1). The

Table 1. Turnover frequencies [h^{-1}] for complexes **2** and **3** in the catalysis of the reduction of NAD$^{\oplus}$, NADP$^{\oplus}$, and PEG-NAD$^{\oplus}$ (0.5 M HCOONa, 3.8×10^{-4} M cosubstrate, 2.5×10^{-5} M **2** or **3** in degassed, thermostated 0.1 M sodium phosphate buffer at pH 7.0; UV absorption at 340 nm monitored as a function of time).

	NAD$^{\oplus}$		NADP$^{\oplus}$		PEG–NAD$^{\oplus}$	
T [°C]	**3**	**2**	**3**	**2**	**3**	**2**
25	20.3	13.3	20.7	12.3	16.6	9.9
38	67.5	43.3	67.5	39.5	56.4	31.8

increase in molecular weight has no effect, however, on the activation energies of the reactions determined from the Arrhenius equation.[10] The reaction catalyzed by **2** is also zero order in NAD$^{\oplus}$. This can be determined by simple variation of the initial concentration of NAD$^{\oplus}$.[11] The reaction mechanism may be formulated as follows:

$$[Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)(H_2O)]^{2\oplus} + HCOO^{\ominus} \rightleftharpoons [Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)(HCOO)]^{\oplus} + H_2O$$

$$[Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)(HCOO)]^{\oplus} \rightleftharpoons [Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)H]^{\oplus} + CO_2$$

$$[Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)H]^{\oplus} + NAD^{\oplus} + H_2O \rightleftharpoons [Cp^*Rh(bpy\text{-}5\text{-}CH_2OPEG)(H_2O)]^{2\oplus} + NADH$$

The retention of the catalytic properties of **2**, even in the reduction of PEG-NAD$^{\oplus}$, is of great importance, because this allows **2** to be used in a membrane reactor as shown in Figure 1. NADH generation was used to check the suitability of the polymer-bound high-molecular-weight complex **2** for use in a flow reactor. For this purpose, a novel, pressure-stable (to 3 bar) glass flow reactor equipped with an overhead stirrer was employed (Fig. 2). Unlike the reaction in the EMR, the reaction chamber is situated above the ultrafiltration membrane. This reactor has several basic advantages: Since it is made of glass, the reaction can be followed visual-

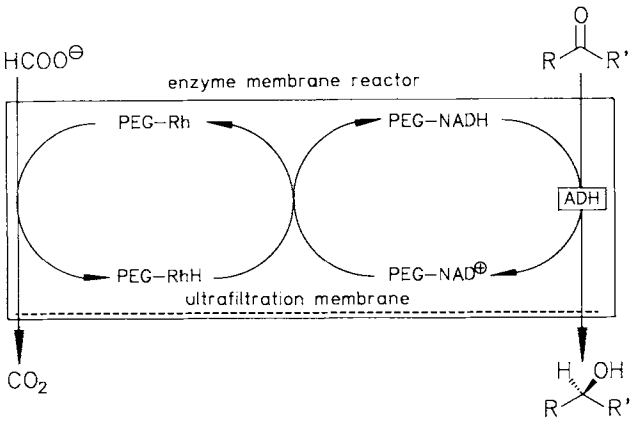

Fig. 1. Concept for the use of **2** in an enzyme membrane reactor (ADH: alcohol dehydrogenase).

ly. In addition, the reactor material should have no effect on the reaction. Moreover, the reactor can be employed for a wide variety of purposes; for example, a continuous electrochemical generation of NADH could be easily achieved by

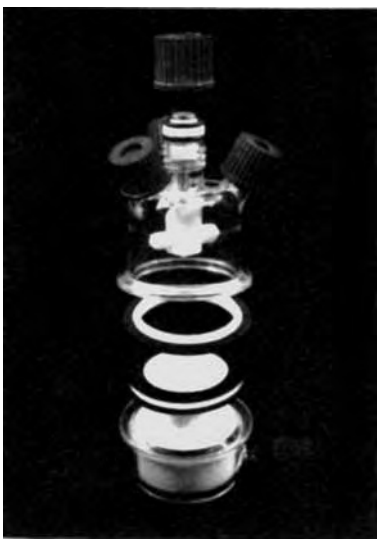

Fig. 2. Flow-through membrane reactor for continuous generation of NADH.

introducing electrodes. Reactions involving gaseous species also pose no problems. A schematic drawing of the experimental setup for continuous generation of NADH is shown in Figure 3.

With the aim of easily isolating the NADH formed, we used an unbuffered ammonium formate/$NAD^{\oplus}$ substrate solution (pH 5.6) in the initial continuous run. After addition of **2**, the conversion of $NAD^{\oplus}$ rapidly climbs to 70%, whereby **2** affords a turnover frequency of 26.3 h^{-1} (Fig. 4A). Although the subsequent decrease in conversion can be slowed by a longer residence time (Fig. 4B), only after replacement of ammonium formate by sodium formate after 30 h of continuous operation (Fig. 4C) does the conversion increase from 30 to 45%. A stationary state is then reached. The large decrease in conversion in the presence of ammonium formate could be due to the incorporation of NH_3 into the ligand sphere of the Rh atom. This ligand exchanges more slowly than H_2O and $Cl^{\ominus}$ with formate. Accordingly, the use of strongly coordinating ligands in the reaction medium should be avoided. In a second experiment with an $NAD^{\oplus}$/sodium formate substrate solution (4.1 mM/0.5 M) buffered to pH 8 with phosphate (0.1 M), the conversion increases at 25 °C in the presence of a doubled concentration of

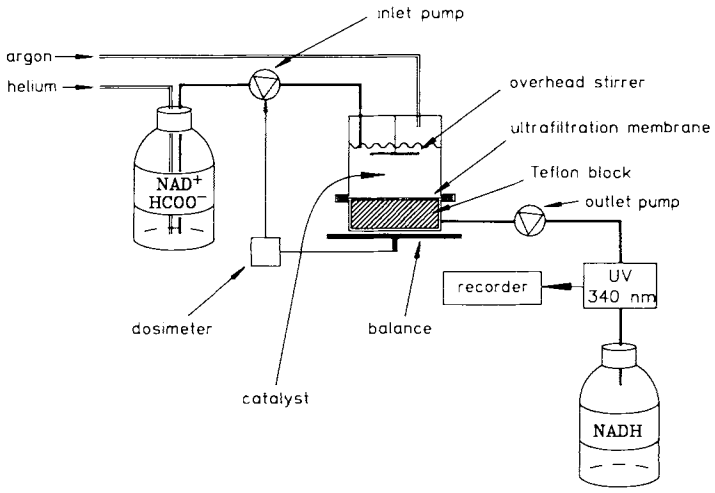

Fig. 3. Experimental setup for continuous generation of NADH.

2 to 70% and then decreases, though more slowly than in the first experiment, over twenty residence times to a stationary conversion of 50%. Before the stationary state was reached, the residence time was doubled by doubling the reaction volume. Conversions of up to 80% were sometimes

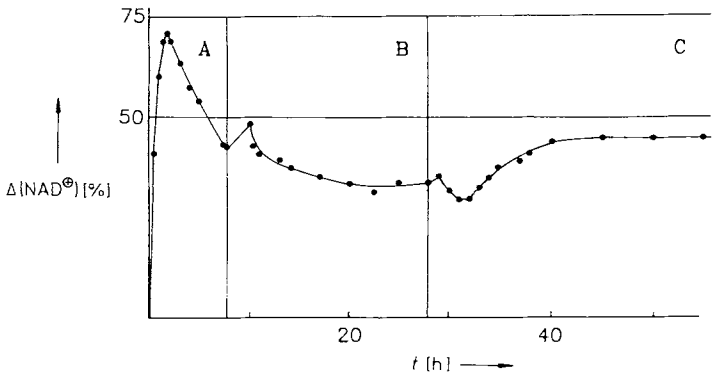

Fig. 4. Dependence of $NAD^{\oplus}$ conversion $\Delta(NAD^{\oplus})$ on time t for continuous generation of NADH (5 mM $NAD^{\oplus}$, 0.13 mM **2**; A,B, 0.5 M $HCOONH_4$; C, 0.5 M HCOONa; residence time A,C, 1 h; B, 2 h; membrane precoated with 300 mg PEG 35000).

achieved. The quantification of $NAD^{\oplus}$ in the substrate and product solution shows that material balance is maintained over the entire period of the experiment. The cause of the decrease in conversion has not yet been determined. However, loss of complex end groups due to hydrolysis, as well as washing out of **2**, can be excluded.[12] The increase in the conversion caused by temporarily doubling the reaction volume in the second experiment shows that an irreversible deactivation of **2** cannot be a reason for the decrease in conversion.

The experiments show that the increased-molecular-weight redox catalyst **2** exhibits the same properties as the low-molecular-weight model. In the flow reactor, a continu-

ous conversion of 45–50% can be maintained after the stationary state has been reached. The redox catalyst thereby displays a turnover frequency of 16.9 h^{-1}. The entire period of the experiment involved more than 1000 reaction cycles. The space–time yield is 44.4 mmol L^{-1} d^{-1}. Taking into consideration the kinetic reaction data, complete conversion can be expected for analogous runs at the stationary state when a 2.2-fold concentration of **2** is employed. This would correspond to a space–time yield of 98.4 mmol L^{-1} d^{-1}. Thus, the rhodium catalyst **2**, with enhanced molecular weight, is very well suited for the continuous regeneration of NADH and NADPH, as well as of their polymer-bound high-molecular-weight forms in coupled enzymatic reactions. The procedure described here offers a widely variable alternative for the enzymatic regeneration of NAD(P)H.

[7] Experimental procedure for **2**: Freshly sublimed potassium *tert*-butyl alkoxide (115 mg, 1 mmol) was added under argon atmosphere to a solution of PEG (MW 20000; 5 g, 0.25 mmol) in 1 L of dry THF. After refluxing for 20 h, the reaction solution was treated with 5-bromomethyl-2,2′-bipyridine (500 mg, 2 mmol) and then refluxed for an additional 28 h. It was then allowed to cool, 200 mL of water was added, and the THF was removed in vacuo. After dialysis and freeze-drying, 4.7 g of colorless, cotton-wool-like product was obtained. UV: λ_{max} [nm] = 242, 303. Part of the product (4.3 g) was dissolved in 1 L of dry methanol and the resulting solution was treated with di-μ-chloro(dichloro)bis(pentamethylcyclopentadienyl)dirhodium(III) (400 mg, 0.65 mmol) (synthesis: B. L. Booth, R. N. Hazeldine, M. Hill, *J. Chem. Soc. A. 1969*, 1299) and stirred for 1 h. Water (1 L) was then added and the organic solvent was removed in vacuo. After dialysis and freeze-drying, 4.1 g of a pale orange product was obtained. UV (H_2O, pH 7.5, 25 °C): λ_{max} [nm] (ε[L mol^{-1} cm^{-1}]) = 233 (12700), 308 (6150), 318 (6300).
[8] Physical data for 5-ethoxymethyl-2,2′-bipyridine and for **3**: Synthesis of 5-ethoxymethyl-2,2′-bipyridine from 5-bromomethyl-2,2′-bipyridine (synthesis: J. G. Eaves, H. S. Munro, D. Parker, *Inorg. Chem. 26* (1987) 644) by reaction with $EtO^{\ominus}$. ^1H NMR (60 MHz, $CDCl_3$, TMS int.): δ = 1.26 (t, 3H, ^3J = 7 Hz), 3.57 (q, 2H, ^3J = 7 Hz), 4.53 (s, 2H), 7.07–8.73 (m, 7H). MS (70 eV, 300 μA): *m/z* 214 ($M^{\oplus}$, 42%), 185 ($M^{\oplus}$ – Et, 28), 169 ($M^{\oplus}$ – OEt, 100), 157 (bpy + H, 55), 141(22), 115(5), 78 (py, 13), 51(8). UV (H_2O; pH 3.0; 25 °C): λ_{max} [nm] (ε[L mol^{-1} cm^{-1}]) = 242 (8900), 304 (1680). Preparation of the rhodium complex was carried out in analogy to U. Kölle, M. Grätzel, *Angew. Chem. Int. Ed. Engl. 26* (1987) 567; ^1H NMR (60 MHz, D_2O): δ = 1.23 (t, 3H, ^3J = 7 Hz), 1.58 (s, 15H), 3.63 (q, 2H, ^3J = 7 Hz), 7.57–8.97 (m, 7H). UV (H_2O; pH 7.5; 25 °C): λ_{max} [nm] (ε[L mol^{-1} cm^{-1}]): 233 (31600), 308 (15300), 318 (15700). Correct elemental analysis (C, H, N).
[9] Turnover frequency = (PEG-)NAD(P)H concentration/(catalyst concentration × time).
[10] The activation energies for the reaction of $NAD^{\oplus}$ and (PEG-)$NAD^{\oplus}$ (3.8×10^{-4} M each) in sodium formate (0.5 M) in the presence of **2** and **3**, respectively (2.6×10^{-5} M each) were determined at 17.3, 25.7, 32.1, and 40.0 °C in sodium phosphate buffer at pH 7.0. For the reduction of $NAD^{\oplus}$, E_a is 64.0 and 68.2 kJ mol^{-1} for **2** and **3**, respectively; for the reduction of (PEG-)$NAD^{\oplus}$, E_a is 70.3 and 68.6 kJ mol^{-1} for **2** and **3**, respectively.
[11] The reaction order of zero in $NAD^{\oplus}$ was confirmed by applying a differential method of determining the reaction order to two NADH concentration–time curves.
[12] Complex **2** is stable upon dialysis (six times against 9 L of bidistilled H_2O) and under flow-through conditions in H_2O (six residence times) in an Amicon ultrafiltration unit.

$Se_{10}^{2\ominus}$, a Bicyclic Polyselenide

By *Dieter Fenske, Gertrud Kräuter*, and *Kurt Dehnicke**

With the exception of the undecaselenide **1**, whose anion has a spirocyclic structure,[1] and the recently described hexadecaselenide 2, whose anion consists of Se_6 rings and two $Se_5^{2\ominus}$ chains,[2] all other structurally investigated polyselenides are acyclic. Known compounds are the diselenide **3**,[3] the tetraselenides **4**–**8**,[4–7] the pentaselenides **9**–**12**,[7–10] and the hexaselenides **13** and **14**.[11,12]

$(PPh_4)_2Se_{11}$ **1** Cs_4Se_{16} **2** Na_2Se_2 **3** [Ba(222-Crypt)]Se_4 **4** $[Ba(en)_4]Se_4$ **5**

$(NC_4H_8O)_2Se_4$ **6** $(NC_5H_{10})_2Se_4$ **7** $[Ph_3PNPPh_3]_2Se_4 \cdot 4CH_3CN$ **8**

Rb_2Se_5 **9** Cs_2Se_5 **10** $[Cs([18]crown-6)]_2Se_5 \cdot CH_3CN$ **11** $(PPh_4)_2Se_5$ **12**

$(NBu_4)_2Se_6$ **13** $[(CH_3)_3N(CH_2)_{13}CH_3]_2Se_6$ **14**

Although the conditions leading to formation of polyselenides are not understood in detail, important factors include reaction conditions such as solvent and temperature in addition to the size, charge, and shape of the counterion. For instance, the tetraselenide **8** is formed from Cs_3TaSe_4 in acetonitrile in the presence of $[Ph_3PNPPh_3]Cl$ at room temperature,[7] whereas, as we report here, heating of a polyselenide solution in dimethylformamide (DMF) at 100 °C in the presence of $[Ph_3PNPPh_3]Cl$, followed by cooling of the solution, affords the previously unknown bicyclic decaselenide $[Ph_3PNPPh_3]_2Se_{10} \cdot DMF$ as black crystals in very good yield.

The crystal structure analysis[13] showed that, per formula unit, the compound contains one molecule of DMF disordered over two mutually orthogonal positions. The $Se_{10}^{2\ominus}$ ion is located on a crystallographic twofold axis; its symmetry corresponds to point group C_2. The two selenium six-membered rings have chair conformation (Fig. 1). Compared to the decalin molecule, the decaselenide ion contains four additional valence electrons if a selenium atom is regarded as isolobal to a CH_2 group. This has several consequences for the central Se–Se unit: The selenium atoms are coordinated in a distorted pseudo-trigonal-bipyramidal fashion, whereby the selenium atoms Se3 und Se3′ are linked equatorially. The two lone pairs on these selenium atoms can

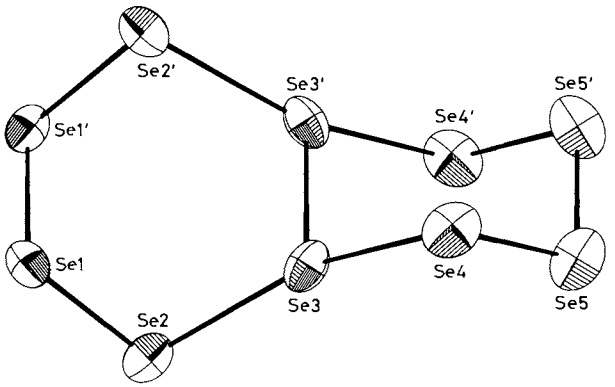

Fig. 1. Molecular structure of the $Se_{10}^{2\ominus}$ ion (ORTEP plot, 50% probability level at −70 °C).

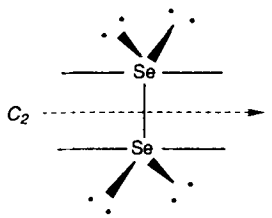
occupy equatorial positions as well, in accordance with the Gillespie–Nyholm rules[14] (Scheme 1).



Scheme 1. Idealized formulation of the central Se3–Se3′ unit of the $Se_{10}^{2\ominus}$ ion with equatorial-equatorial linking of the two selenium atoms having trigonal-bipyramidal bonding geometry.

This arrangement allows a relatively short Se3–Se3′ bond (246 pm), whereas the Se–Se distances to the axially arranged Se atoms are 257 and 276 pm. These distances permit the $Se_{10}^{2\ominus}$ ion to be regarded also as consisting of a central $^{\oplus}\dot{\dot{S}}\dot{\dot{e}}$-$\dot{\dot{S}}\dot{\dot{e}}^{\oplus}$ fragment and two $Se_4^{2\ominus}$ ions, insofar as the Se–Se distances of these fragments are in good agreement with those in tetraselenide ions.[4–7]

Table 1. Bond lengths [pm] and angles [°] in the $Se_{10}^{2\ominus}$ ion.

Se1-Se2	232.0(2)	Se2-Se1-Se1′	105.62(6)
Se1-Se1′	232.6(2)	Se1-Se2-Se3	100.65(7)
Se2-Se3	275.9(3)	Se2-Se3-Se4	159.85(8)
Se3-Se3′	246.0(2)	Se2-Se3-Se3′	101.61(8)
Se3-Se4	257.2(3)	Se4-Se3-Se3′	98.32(9)
Se4-Se5	231.8(3)	Se3-Se4-Se5	101.94(8)
Se5-Se5′	234.2(3)	Se4-Se5-Se5′	102.76(6)

Dichalcogen units are also found in the inclusion compound $(Te_2)_2I_2$,[15] in which the Te_2 "dumb-bells" have a Te–Te distance of 271 pm and are arranged to form double layers through longer Te–Te bonds (332 pm). The structure reveals electronic and topological relationships to compounds from β-SnS to black phosphorus.[16] The formulation of partially oxidized units, $^{2}_{\infty}[Te_2^{\delta\oplus}]$, which are indicated by extended Hückel calculations, is reflected in the lengthening of the I–I distances in the intercalated iodine molecules.[17]

Experimental Procedure

Gray selenium (0.96 g, 12.16 mmol) and a trace of iodine as catalyst for polyselenide formation were added to a mixture of Li and Se in a molar ratio of 1:1 (0.26 g = 1.52 mmol) and $[Ph_3PNPPh_3]Cl$ (1.75 g, 3.04 mmol). The resulting mixture was heated for 3 h in 30 mL of DMF at 100 °C. After cooling, the reaction mixture was filtered to remove LiCl and unreacted selenium, 20 mL of ether was added, and the solution was allowed to stand for 2 d. The resulting black single crystals were filtered, washed with EtOH, and dried briefly in vacuo. Yield 2.1 g (72%, based on $[Ph_3PNPPh_3]Cl$).

Water-Soluble Metal Complexes of the Sulfonated Triphenylphosphane TPPTS: Preparation of the Pure Compounds and their Use in Catalysis**

By *Wolfgang A. Herrmann,** *Jürgen A. Kulpe, Jürgen Kellner, Herbert Riepl, Helmut Bahrmann,* and *Werner Konkol*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

The large-scale industrial use of water-soluble rhodium complexes of the sulfonated triphenylphosphane $P(C_6H_4\text{-}m\text{-}SO_3^{\ominus}Na^{\oplus})_3$ (TPPTS) in the Ruhrchemie/Rhône-Poulenc process can be regarded as a methodological advance in homogeneous catalysis by means of organometallic complexes.[1,2] The use of water as the solvent for the catalyst in a two-phase system makes possible its ready separation from the hydrophobic products. In addition, the hydroformyla-

[**] Water-soluble Metal Complexes and Catalysts, Part 1.—TPPTS = sodium salt of 3,3′,3″-phosphanetriyltribenzenesulfonic acid

tion of propene in this process occurs with increased regioselectivity;[3] the scale of butyraldehyde production lies presently at about 300 000 tons per year. Catalysts whose water-solubility is based on the presence of COOH, NH_2, and SO_3H groups in the ligand appear also to be slowly gaining in importance in other processes[4] and in the stabilization of metal colloids.[5]

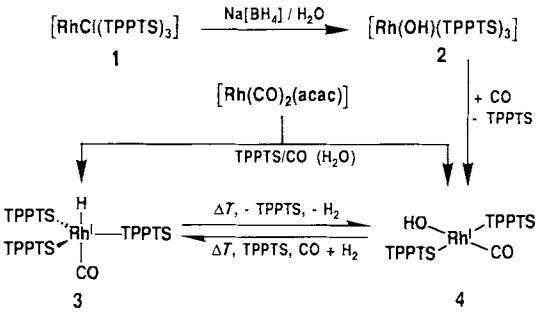
Of particular importance is the TPPTS ligand introduced by *Kuntz*, since it is inexpensive and can easily be prepared in large quantities.[6] It is also expected to form complexes with most transition metals, just as does triphenylphosphane (TPP). However, the analytical characterization of the TPPTS–metal complexes described previously in the literature has been either incomplete or inaccurate.[1, 7] This is mainly due to the extreme water-solubility of TPPTS (ca. 1.1 kg L^{-1} [1b]), which poses extreme limits to the choice of solvents and purification methods which can be used.

By means of adaption and optimization of the *gel permeation chromatography* technique we have now established the prerequisites for a wide-ranging development of the water-soluble TPPTS complexes: about 40 analytically pure complexes of the general type $[L_xM_y(TPPTS)_z \cdot (H_2O)_{3z}]$ have been synthesized.[8] The syntheses are carried out either by replacing other ligands such as CO, THF, or TPP by TPPTS or by reacting TPPTS with metal salts, if necessary in the presence of additional reagents which act as ligands or reducing agents. Product mixtures are separated in aqueous solution using hydrophilic gels with eluents which are suited for the particular separation problem in hand. The best carrier materials within the temperature range 0–40 °C have been found to be Sephadex G-15/G-25 and Fractogel TSK HW-40. Decomposition occurs very seldom, and the chromatographic separation is followed via either UV/VIS or refractive index detectors. Such a procedure makes it possible to separate amounts of substance up to 10 g on a laboratory scale in one step.[2e] In contrast to previous work,[6] it is also possible to obtain the free ligand TPPTS rapidly and without losses in a pure state using Sephadex G-15; phosphane oxide impurities ($\delta(P) = 34.8$) that cannot be removed by other means can be reduced to below 0.1 % (according to HPLC measurements).

The TPPTS complexes contain *one water molecule per sodium ion* after drying in vacuo (oil pump) at room temperature. The following information may be useful for practical applications of this procedure:

1. TPPTS forms soluble complexes with transition-metal salts in water, though these are not necessarily stable in an aqueous medium. The solvent water can lead to the formation of hydroxo complexes, which are seldom encountered in the chemistry of TPP: examples are the isolable rhodium complexes **2** and **4** (Scheme 1). The former rather than the expected hydrido complex is formed rapidly in attempts to carry out a Cl/H exchange starting from the nonahydrate of **1**, and more slowly directly from $RhCl_3 \cdot 3H_2O$ and TPPTS. If a solution of the hydroformylation catalyst **3** in water is heated at reflux, the hydroxo complex **4** is formed; however, the latter is reconverted quantitatively into **3** under process conditions (CO/H_2) and therefore does not interfere with the hydroformylation reaction. In spite of the importance of TPPTS-containing rhodium complexes for hydrogenation and hydroformylation, this aspect has previously not been taken into account. Both types of complex (hydrido and hydroxo complexes) are formed in TPPTS/water, even when no other hydride source is present (Scheme 1). This is probably due to the catalytic shift of the water gas equilibrium according to Equation (a), which leads to the formation of hydride.

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \qquad (a)$$

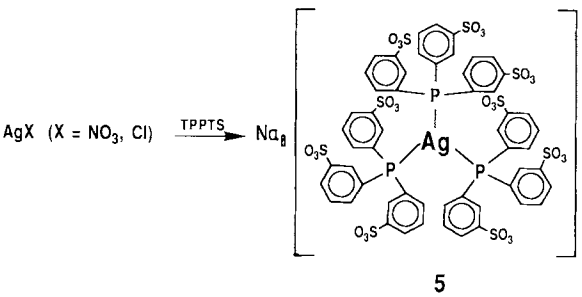


Scheme 1. Solvate water molecules are not shown; acac = acetylacetonate.

2. TPP and TPPTS complexes of analogous composition have almost identical ^{31}P NMR data, and the spectroscopic data for other ligands (e.g., NO, CO, H) are also similar; thus, the ligand TPPTS does not exhibit stereoelectronic peculiarities.

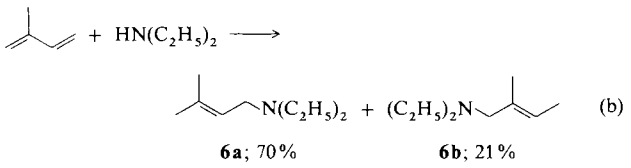
3. TPPTS complexes generally have lower coordination numbers (CN) than homoleptic TPP analogues. Thus, while the complex $Ni(TPP)_4$ is known, the nickel complex described incorrectly in the literature as $Ni(TPPTS)_4$[1] in fact has the formula $Ni(TPPTS)_3$ (as nonahydrate; Pd shows the same behavior[8b]). The TPPTS analogue of $[HRh(TPP)_4]$ is also nonexistent; attempts to prepare such a complex via ligand exchange led to the new binuclear hydroxo complex $[(TPPTS)_2Rh(\mu\text{-}OH)]_2$. We believe this tendency for the formation of phosphane-poorer complexes to be due to the high charge accumulation within the ligand sphere (three electrons per TPPTS!).

4. A sodium-poorer form of complexed TPPTS is possible if the excess of negative charge is compensated by the complexed metal ion. A typical example is provided by the silver complex **5** (CN = 3) with eight rather than nine sodium ions[9] (Scheme 2). The corresponding TPP complex has the formula $[Ag(TPP)_4]^{\oplus}$ (CN = 4). This example indicates the larger diversity of complexation to be expected from sulfonated phosphane ligands.



Scheme 2.

5. The specific advantage of the new TPPTS complexes lies in their ready separability in catalytic reactions. This property has, for example, been taken advantage of in the 1,4-addition of diethylamine to isoprene using the new catalyst *cis*-$[PtCl_2(TPPTS)_2 \cdot 6H_2O]$ according to Equation (b). At an amine/catalyst ratio of 1000/1 (temperature 80 °C) the amine consumption after 48 h is 99 % and the 1,4-selectivity 91 %. The aqueous catalyst solution can be reused after phase separation.



6a; 70% **6b**; 21% (b)

Gel-chromatographic purification has thus made possible the systematic preparation of analytically pure, water-soluble TPPTS complexes, so that their lack of volatility and the unwillingness of such compounds to crystallize is no longer a problem. The availability of pure samples of these complexes now also makes it much easier to probe the mechanisms by which such compounds act as catalysts.

Experimental Procedure

a) Purification of TPPTS: A solution of crude TPPTS in water, obtained from the sulfonation of TPP with subsequent amine extraction[6] contains ca. 30% (w/w) TPPTS. Purification was carried out by introducing 50 mL of such a solution onto a Sephadex G-15 column ($l = 95$, $d = 4$ cm). At a flow rate of 54 mL cm^{-2} h^{-1}, five fractions were obtained (UV detection at $\lambda = 330$ nm and refractive index detection) after 85, 123, 159, 201, and 268 min. The fourth fraction contained pure TPPTS (as the trihydrate after drying under oil-pump vacuum at room temperature). ^{31}P NMR (D_2O, 5 °C). $\delta = -5.3$ ppm. Correct elemental analysis (C, H, O, P).

b) **2**: To a solution of $RhCl_3 \cdot 3H_2O$ (260 mg, 1 mmol) in 20 mL of H_2O was added TPPTS (10 mmol) in 10 mL of H_2O; the mixture was stirred for ca. 40 h at room temperature. The solution, which contained **1**, **2**, TPPTS-oxide (phosphane oxide), and $[Rh(\mu\text{-}OH)(TPPTS)_2]_2$, was chromatographed over Sephadex G-15; chloride-free **2** (nonahydrate) was obtained in 92% yield as a red glass. Correct elemental analysis (C, H, O, P, Rh, S). ^{31}P NMR (109.3 MHz, D_2O, 21 °C): $\delta = 35.2$ [dd; $^1J(Rh, P_A) = 144$ Hz], 53.5 [dt; $^1J(Rh, P_B) = 195$, $^2J(P, P) = 41$ Hz]. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 1220 (sh,vs), 1196 (vs), 1038 (vs), 787 (m), 624 (m), 527 (s).

c) Hydroamination of isoprene: a solution of *cis*-$[PtCl_2(TPPTS)_2 \cdot 6H_2O]$ (120 mg, 0.08 mmol)[8b] in 6 mL of H_2O, isoprene (8.16 g, 0.12 mmol), and diethylamine (5.86 g, 80 mmol) were introduced into a 100-mL laboratory autoclave. The mixture was warmed for 2 d to 80 °C. After cooling and phase separation, the following components were obtained from the organic phase: 70% **6a**, 21% **6b**, and 8% *N,N*-diethylaminodimethyloctadiene (characterization by means of GC/MS, GC/IR, and ^1H NMR after product isolation); amine consumption 99%.

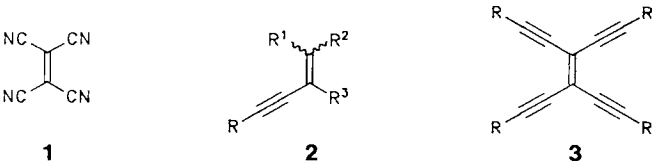
Novel Planar π-Systems

By *Henning Hopf** and *Martin Kreutzer*

Tetracyanoethylene **1**, discovered in 1957,[2] is the most frequently used cyanocarbon compound in organic synthesis.[1] In the eyes of the hydrocarbon chemist, **1** may be regarded as a tetraaza derivative of the hitherto unknown tetraethynylethene **3**, R = H, presumably also a very reactive and preparatively valuable cross-conjugated π-system. We have set ourselves the target of preparing both **3**[3] as well as the cyano(ethynyl)ethenes **2a–d**, which are formally formed from **1** by successive replacement of its cyano functions by $Me_3Si-C\equiv C-$ groups. In addition we are interested in the lower substituted cyano(ethynyl)ethenes **2e–j** for comparison. What some of the intermediary members **2**, which are listed in Table 1 without taking into account diastereomers, lack in symmetry, they might—because of the polarization of their π-electrons—gain in reactivity. Herein we describe the synthesis of **2b** and **2g** and a modified route to **2e**,[4] and report on the first reactions of these novel, electron-rich π-systems.



1 **2** **3**

Table 1. Structures of the cyano(ethynyl)ethenes **2** presented in this communication. 2-[3-trimethylsilyl-1-(trimethylsilylethynyl)-2-propynylide]malononitrile **2b** and 5-trimethylsilyl-3-(trimethyl-silylethynyl)pent-2-en-4-yne nitrile **2g** were synthesized for the first time; in the case of **2e** [4] a modified route was developed. R in **2** is always $SiMe_3$.

	R^1	R^2	R^3		R^1	R^2	R^3
2a	CN	CN	CN	**2f**	CN	H	CN
2b	CN	CN	C≡CR	**2g**	CN	H	C≡CR
2c	C≡CR	CN	CN	**2h**	C≡CR	CN	H
2d	CN	C≡CR	C≡CR	**2i**	CN	H	H
2e	CN	CN	H	**2j**	H	H	CN

As starting material for the two novel dialkynes we used 1,5-bis(trimethylsilyl)-1,4-pentadiyn-3-one **4**,[5] which can be condensed in a Wittig reaction with diethylphosphonoacetonitrile to give **2g**[6] and with malononitrile to give **2b**, and the yields are good in each case.[6] The reaction **4** → **2b**, instead of being carried out under the conditions quoted in Scheme 1, can also be carried out under typical Knoevenagel conditions (β-alanine; ethanol/acetic acid; 72%); this type of reaction has hitherto rarely been described for conjugated acetylenic ketones or aldehydes.[4] The aluminum oxide-catalyzed reaction[7] proved to be better than the procedure described in the literature,[4] even for the coupling of trimethylsilylpropynal **5**[8] with malononitrile to give **2e**.

Since the derivatives **2** are formally enynes, and these have been employed as diene components in Diels-Alder additions,[9] attempts were first made to react **2b** and **2e** with maleic anhydride and tetracyanoethylene **1**; however, no reaction took place, even after prolonged reaction times (2 weeks, room temperature). As expected the three model dienes 2,3-dimethyl-1,3-butadiene **8**, cyclopentadiene **11**, and

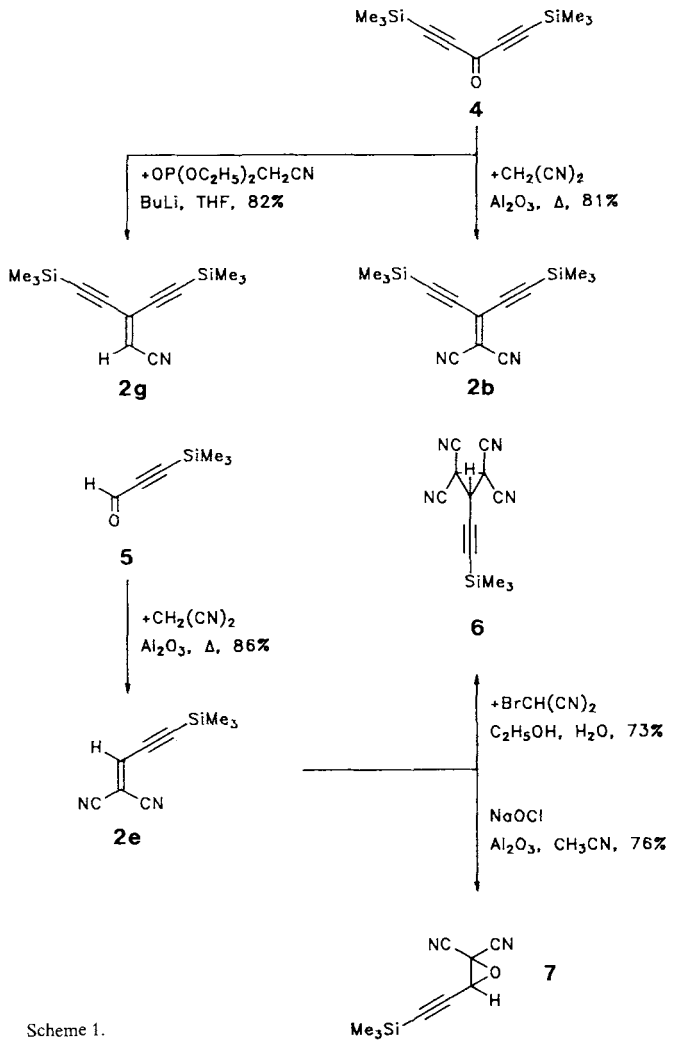
Hagenring 30, D-3300 Braunschweig (FRG)



Scheme 1.

9,10-dimethylanthracene **14** underwent smooth [2+4]-cycloadditions, which, however, were markedly different in their positional selectivity.[10] Their reactions with **2e** led to formation of the expected adducts **10**, **13** and **15**[6] (the electron attracting effect of the cyano substituent manifests itself directly at the neighboring double bond), whereas **2b** reacts with **8** and **11** in the sense of a vinylogous dienophile whose double bond remains intact. To what extent this drastic difference in reactivity also occurs in other dienes or whether a change in the reaction mechanism is involved, will have to be established by further investigations. The relative reactivity of double and triple bonds in addition reactions is often difficult to predict; it strongly depends on the type of reaction and can also be influenced by comparatively simple changes in structure.[11, 12] **2b**, which is less reactive than **2e**, does not react with **14**; neither **2b** nor **2e** participate in Diels-Alder additions with inverse electron demand (no addition to tetracyclone and 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene). The greater reactivity of **2e** also manifests itself in a cyclopropanation reaction[13] with bromomalononitrile and in the epoxidation with sodium hypochlorite,[14] which lead in good yields to the ethnylcyclopropane **6**[6] and to the oxirane **7**, respectively.[6] Under the conditions quoted in Scheme 1, **2b** does not undergo these reactions. The above condensation reactions can also be extended to aryl-substituted acetylenic ketones and aldehydes[15] and thus open up a general route to substituted cyano(ethynyl)ethenes **2**.

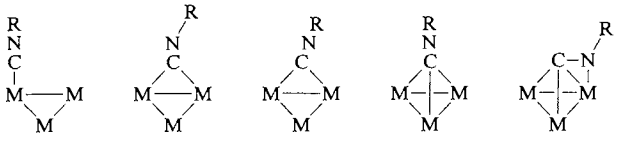
$[Ni_3(\mu_3\text{-}CNMe)(\mu_3\text{-}I)(CNMe)_2(Ph_2PCH_2PPh_2)_2]I$, a *triangulo* Nickel Cluster with an Unprecedented Symmetric Linear μ_3-η^1 Isocyanide Ligand**

By *Kevin S. Ratliff, Gregory K. Broeker, Phillip E. Fanwick,* and *Clifford P. Kubiak**

There continues to be much interest in the interactions between small unsaturated molecules and metal clusters. While much work has been devoted to the reactivity of carbon monoxide with metal clusters and surfaces, the isoelectronic isocyanides, CNR, have received little attention. Isocyanides can bind to trinuclear clusters by adopting any of the five limiting structures **I**–**V**. *Muetterties* found that



methyl isocyanide is bound to nickel surfaces in an η^2 fashion (**V**) with a considerable interaction between the nitrogen atom of the isocyanide and the metal surface.[1]

Molecular examples of the type-**V** interaction have been observed in only a few cases. The complexes $[Pt_7(2,6\text{-}Me_2C_6H_3NC)_{12}]$,[2] $[Os_6(CO)_{18}(4\text{-}MeC_6H_4NC)_2]$,[3] and $[Fe_3(CO)_9(CNtBu)]$[4] all possess μ_3-η^2 isocyanides. The complex $[Ru_5(CO)_{14}(CNtBu)_2]$ contains an isocyanide which is bound to all five ruthenium atoms in a μ_5-η^2 fashion and acts as a six-electron donor.[5] The striking feature common to all of these isocyanide clusters is that the bridging isocyanides prefer η^2 coordination with considerable interaction between the isocyanide nitrogen and the metal atoms. *Fortune* et al. have described the crystal structure of $[Co_3(C_5H_5)_3(\mu_3\text{-}CNC_6H_{11})(\mu_3\text{-}S)]$, which was refined only to $R = 0.092$ and $R' = 0.120$ and which showed no significant interaction between the nitrogen atom and the three cobalt atoms.[6] The isocyanide C–N–C bond angles of 141° and 129° for the two independently refined isomers of the cobalt cluster, however, was unexpected and puzzling. If a capping isocyanide is truly symmetrically bound to a *triangulo* cluster, the π^* orbitals of the μ_3-CNR ligand are degenerate and thus no isocyanide bending should occur.

We report here the first example of a symmetric, linear, μ_3-η^1, type-**IV** isocyanide. Several symmetric μ_3-η^1 CO clusters are known. These include $[Pt_3(\mu_3\text{-}CO)(dppm)_3]^{2\oplus}$ (dppm = $Ph_2PCH_2PPh_2$),[7] $[Pd_3(\mu_3\text{-}CO)(dppm)_3]^{2\oplus}$,[8] and $[(C_5H_5)_3Ni_3(\mu_3\text{-}CO)_2]$,[9] which has two CO ligands capping each face of the Ni_3 triangle. A unique example of a coordinatively unsaturated μ_3-η^1 CO nickel cluster, $[Ni_3(\mu_3\text{-}CO)(Me_2PCH_2PMe_2)_4][Na(NCBH_3)_3]_2$, was recently prepared by *Puddephatt* et al.[10] This recent result, together with our work described here, strongly suggests that diphosphino ligands can be used to stabilize *triangulo* Ni_3 clusters with unusual properties.

$[Ni_2(\mu_2\text{-}CNMe)(CNMe)_2(dppm)_2]$ **1**

The binuclear Ni^0 complex **1** reacts with electrophiles and other metal ions by both μ-CNMe ligand-centered[11,17] and metal-centered[12,13] pathways. Reaction of **1** with CH_2I_2 in toluene at 50 °C gives the *triangulo* cluster **2** in high yield.[14]

$[Ni_3(\mu_3\text{-}CNMe)(\mu_3\text{-}I)(CNMe)_2(dppm)_2]I$ **2**

IR spectroscopy reveals a strong terminal methyl isocyanide band at 2170 cm^{-1}. The single μ_3-CNMe ligand $\tilde{\nu}$(CN) band occurs at unusually high energy ($\tilde{\nu}$(N) = 1943 cm^{-1}),[15] as compared to $\tilde{\nu}$(CN) = 1550 cm^{-1} for $[Co_3(C_5H_5)(\mu_3\text{-}CNC_6H_{11})(\mu_3\text{-}S)]$.[6] Replacement of the μ_3-CNMe ligand with $^{13}CNMe$ resulted in $\tilde{\nu}(^{13}CN)$ = 1910 cm^{-1}. The ^1H NMR spectrum of **2** shows two inequivalent methyl isocyanides in a 2:1 ratio at $\delta = 3.17$ and 3.70, respectively, in CD_3CN. The ^{31}P NMR spectrum of **2** is an AA'BB' spin system centered at $\delta = 0.5$, characteristic of an asymmetrically coordinated dppm complex. X-ray-quality crystals were obtained by slow diffusion of Et_2O into an acetone solution of **2**. An ORTEP drawing of **2** is shown in Figure 1.[16]

The most striking feature of the cluster is the symmetrically triply bridging methyl isocyanide. The capping isocyanide

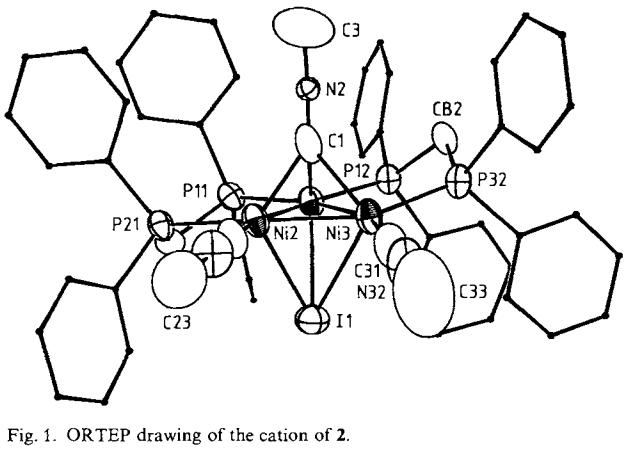


Fig. 1. ORTEP drawing of the cation of **2**.

[**] This work was supported by the National Science Foundation (CHE-8707963).

is essentially linear with a C–N–C angle of 170(1)°. The remainder of the cluster consists of a trinuclear nickel core with similar nickel–nickel distances (d_{Ni-Ni} (average) = 2.38(1) Å), consistent with a strongly bonded $Ni_3^{2\oplus}$ core. Ni1 is bridged to Ni2 and Ni3 by two dppm ligands. Both Ni2 and Ni3 have two terminally bound isocyanides, thus completing a nearly planar $[Ni_3L_6]^{2\oplus}$ core. The three nickels are capped by a μ_3-iodide (d_{Ni-I} (average) = 2.75(3) Å). A triply bridging isocyanide occupies the other capping position (d_{Ni-C} (average) = 2.04(4) Å). A skeletal view of the cluster core with bond distances is given in Figure 2.

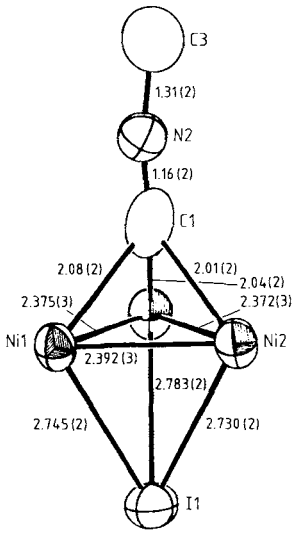

Fig. 2. Skeletal view of **2** with bond distances. Selected bond angles [°]: Ni1-Ni2-Ni3 59.79(8), Ni2-Ni1-Ni3 59.68(8), Ni2-Ni3-Ni1 60.53(8), Ni1-C1-Ni2 71.5(6), Ni2-C1-Ni3 71.6(6), Ni3-C1-Ni1 70.4(6), Ni-I-Ni 51.2(5) (average), C1-N1-C3 170(1).

Preliminary reactivity studies indicate that the capping iodide is essential to the stability of the cluster. For example, reaction of **1** with CH_2Br_2 in toluene results in precipitation of an intermediate which decomposes in all solvents. Similarly, removal of $I^{\ominus}$ by treatment of **2** with two equivalents of CF_3SO_3Ag leads to cluster degradation to $[Ni_2(CNMe)_3(dppm)_2]^{2\oplus}$ [17] and an unidentified nickel species. The capping iodide also poses an intriguing question concerning the electron count of the cluster. If the capping $I^{\ominus}$ is counted as a two-electron donor, then the resulting cluster electron count would be 44, suggesting coordinative unsaturation. The triply bridging iodide, however, could act as a four- or even six-electron donor. All previous examples of nickel clusters are coordinatively saturated with 48 or more electrons.[10] If $I^{\ominus}$ is viewed as a six-electron donor, then cluster **2** can achieve coordinative saturation without the usual μ_3-η^2 (type **V**) isocyanide bonding. MO calculations may clarify the nature of the donor/acceptor relationship between the capping iodide and the unprecedented μ_3-η^1 isocyanide.

$[\{Ni_2(\mu\text{-}CNMe)(CNMe)_4(Ph_2PCH_2PPh_2)\}_2Hg][NiCl_4]$, a Spirocyclic Ni_4Hg Cluster with an Hg^{II}-Center**

By *Jinkang Gong, Jean Huang, Phillip E. Fanwick,* and *Clifford P. Kubiak**

Metal–metal bonds between two or more different metals are of fundamental interest. The chemical and physical consequences of combining different metals on a molecular level may include (1) cooperative reactivity, (2) charge-separated excited states, and (3) unusual magnetic properties. The N-atom Lewis basicity of the μ-isocyanide ligand of complex **1** is quite well established.[1] Metalations of **1** afford a surprising variety of structures. For example, metalation of **1** with $[Pd(CNMe)_4]^{2\oplus}$, $(PPh_3)AuCl$, or NiI_2 produces linear trinuclear Ni-Pd-Ni,[2a] linear binuclear Ni-Au,[2b] and *triangulo*-Ni_3 frameworks, respectively.[2c,d] Complex **1** may react by either μ-ligand-[1] or metal-centered[2,3] pathways. We now report the reaction of **1** with $HgCl_2$, which gives an extraordinary metalation product.

$[Ni_2(\mu\text{-}CNMe)(CNMe)_2(PPh_2CH_2PPh_2)_2]$

1

$[\{Ni_2(\mu\text{-}CNMe)(CNMe)_4(Ph_2PCH_2PPh_2)\}_2Hg][NiCl_4]$

[**] This work was supported by the National Science Foundation (CHE-870963) and NASA (NAG-3-977). *J.H.* gratefully acknowledges a fellowship from Upjohn Corporation.

The reaction of **1** with $HgCl_2$ (molar ratio 1:1) in THF at 25 °C for 12 h produces the Ni_4Hg cluster **2** in 25% yield. Complex **2** has also been prepared quantitatively by the direct reaction of $Ni(CNMe)_4$, $Ph_2PCH_2PPh_2$, and $HgCl_2$ (molar ratio 5:2:2) in THF. IR spectroscopy (KBr) reveals the presence of both terminal ($\tilde{\nu}$(CN) = 2151 vs) and bridging ($\tilde{\nu}$(CN) = 1737, 1718 cm^{-1}) isocyanides. The $^{31}P\{^1H\}$ NMR spectrum consists of a singlet (δ = 44.2) with weak ^{199}Hg satellites ($J_{P\text{-}Hg}$ = 603 Hz). The values of $^1J_{P\text{-}Hg}$ for complexes with direct P–Hg bonds typically range from about 4300 to 5700 Hz.[4, 5] The $^{31}P\{^1H\}$ data are therefore clearly not consistent with direct P–Hg bonding. The ^1H NMR data indicate the presence of $Ph_2PCH_2PPh_2$ (δ = 7.22–7.61 (m, 40H, Ph_2P), 2.77 (m, 4H, CH_2) as well as terminal (δ = 3.10 (s, 24H, $CNCH_3$)) and bridging (δ = 2.19 (s, 6H, μ-$CNCH_3$) isocyanides. X-ray-quality crystals were obtained by slow diffusion.[6] An ORTEP drawing of the cation of **2** is shown in Figure 1.

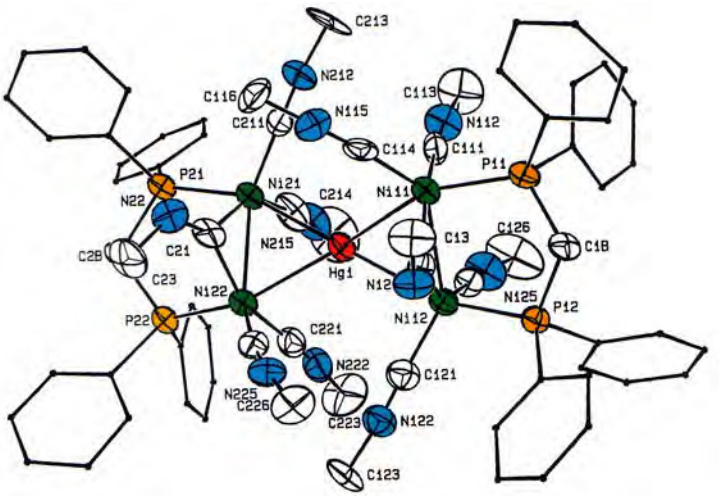

Fig. 1. ORTEP drawing of the molecular cation of **2**: Hg (red), Ni (green) P (orange) N (blue) C (black). Selected bond distances [Å] and angles [°]: N22-C21 1.23(2), N222-C221 1.18(2), N225-C224 1.17(2), Ni12-C121 1.86(2); Ni11-C11-N12 82.1(6), Ni21-C21-Ni22 82.6(7), Hg1-Ni11-Ni12 62.40(6), Hg1-Ni12-Ni11 62.48(6), Hg1-Ni21-Ni11 62.15(6), Hg1-Ni22-Ni21 62.75(6).

The cation of **2** consists of a central mercury(II) ion coordinated only by four nickel atoms ($d_{Ni\text{-}Hg}$ (average) = 2.65(3) Å). The four nickel atoms exhibit two close pairwise Ni–Ni interactions ($d_{Ni\text{-}Ni}$ (average) = 2.542(2) Å). Each Ni_2 pair is bridged by one $Ph_2PCH_2PPh_2$ and one CNMe ligand. Each nickel atom is additionally coordinated by two terminal CNMe ligands. The overall structure can be viewed as a central $Hg^{2\oplus}$ ion coordinated by two neutral $[Ni_2(\mu\text{-CNMe})(CNMe)_4Ph_2PCH_2PPh_2)]$ fragments. The μ-CNMe ligands are *cis* with respect to one another. A skeletal view of the $[HgNi_4(Ph_2PCH_2PPh_2)_2]$ core is presented in Figure 2.

The $[HgNi_4]^{2\oplus}$ core is slightly nonplanar with a torsion angle of 34.6(1)°. The Ni–Hg bond lengths vary from 2.617(2) to 2.682(2) Å and are somewhat longer than the value of 2.462(3) Å reported for the only other structurally characterized example of a Ni–Hg bond, $[(Ph_3Ge)Hg\text{–}Ni(GePh_3)(C_5H_5)]_x$.[7] We note that the overall interaction between the two $[Ni_2(\mu\text{-CNMe})(CNMe)_4(Ph_2PCH_2PPh_2)]$ fragments and $Hg^{2\oplus}$ may be viewed similarly to that of a linear (π donor)$_2$Hg complex. The midpoints of the Ni11–Ni12 and Ni21–Ni22 bonds are separated from the central $Hg^{2\oplus}$ ion by 2.002(2) Å and 1.963(2) Å, respectively. The angle (Ni11-Ni12)-Hg-(Ni21-Ni22) is 170.3°. Extended

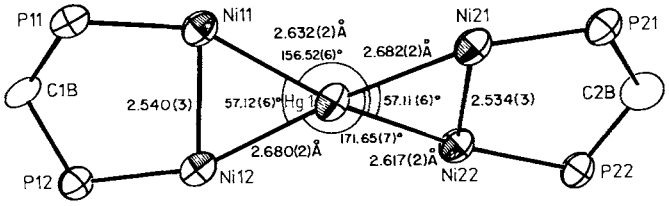

Fig. 2. ORTEP drawing of the $[HgNi_4(Ph_2PCH_2PPh_2)_2]$ core (phenyl rings omitted for clarity), with selected bond distances and angles.

Hückel calculations indicate that the HOMO of **1** possesses $Ni_2(d_{\pi^*})$ character.[1d, 8] The stability of **2** therefore appears to result in part from an $Ni_2(d_{\pi^*}) \rightarrow Hg^{2\oplus}(p_\pi)$ interaction. Complex **2** is unprecedented. *Shaw* et al. have prepared several Ni–Hg mixed-metal binuclear complexes, but they apparently do not contain direct Ni–Hg bonds.[4] Perhaps the closest analogues to **2** are $[\mu_4\text{-}Hg\{(\mu_3\text{-}C_2tBu)(CO)_9Ru_3\}_2]$ prepared by *Rosenberg*[9] and the linear "sandwich" cluster $[\{Hg(Pt_3(2,6\text{-}Me_2C_6H_3NC)_6\}_2]$ prepared by *Yamamoto* et al.[10]

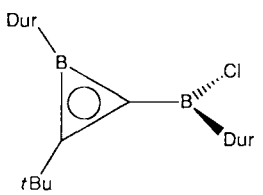
Structure of a Non-classically Bridged Methyleneborane in the Crystal**

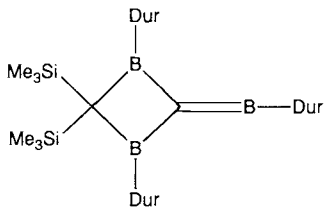
By *Christine Wieczorek, Jürgen Allwohn, Günter Schmidt-Lukasch, Ralf Hunold, Werner Massa,* and *Armin Berndt**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

Three-membered ring systems with boron as ring member are effective σ-components for strong σ-π interactions. We have recently described the geometric consequences of such interactions in **1** with tricoordinated boron as π-component.[1] Dicoordinated boron atoms with formally empty p-orbital on boron are effective π-components for σ-π interactions, which give rise to significant changes in bond



1



2

lengths[4] in **2**[2] and similar methyleneboranes.[3] The combination of a boracyclopropane unit with a dicoordinated boron atom in **3** (**3a**[6]) would lead one to expect a particularly strong σ-π interaction. According to calculations[7, 8] this results in the bridged structure[9] **4** with a B–C–B angle not less than 65° smaller than in **3** (Scheme 1). In the present communication we report experimental confirmation of this prediction.

The crystalline methyleneboranes **4b, c** are accessible from **5b, c**[11] and Bogdanović magnesium[12] in diethyl ether (3

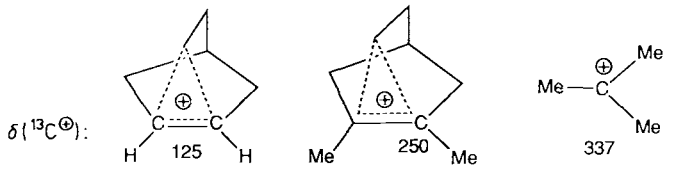
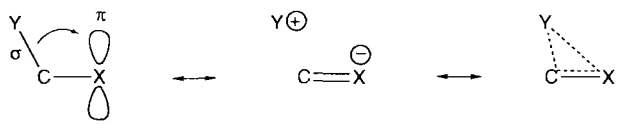
the corresponding boron atom in the unbridged species **2** (see Table 2). This is consistent with the finding that cationic C atoms in non-classical carbocations such as the symmetrically bridged species **6**[17] and the unsymmetrically bridged species **7**[18] are much more strongly shielded than in classical cations such as **8**.



6 **7** **8**

Structural deformation and NMR spectroscopically detectable shielding of the π-centers, as depicted in Scheme 2, are general consequences of appreciable σ-π interaction.



Scheme 2. Consequences of a σ-π interaction for the structure and electron density distribution.

This is also demonstrated by recent calculations for the isopropyl and other carbocations.[19]

A Mesityl-bridged Methyleneborane**

By *Monika Pilz, Jürgen Allwohn, Werner Massa*, and *Armin Berndt**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The bridging of electron-deficient sites by aryl groups is well known in dimeric arylaluminum compounds **1**.[1] With **2**, we now present a molecule in which two boron atoms are bridged by an aryl group.

Opening of the aryl bridge in **1** can already be accomplished with the weak Lewis base diethyl ether (Scheme 1), whereas in the case of **2** the stronger Lewis base 4-*tert*-butylpyridine is required. The formation of the adduct **3** compares with the formation of **5**[2] from the bridged methyleneborane **4**.[3] We therefore regard **2** as a mesityl-bridged methyleneborane. **2** differs appreciably from **6**,[4] whose strong B–H–B bridge is inert towards 4-*tert*-butylpyridine and even towards *tert*-butyllithium.

2 is formed upon oxidation of the dilithium compound **7**[5] with $SnCl_2$ (yield 86%). Intermediates of this reaction, in which a mesityl residue migrates from boron to carbon, may well be the electrophilic diborylcarbene **8** and the methyleneborane **9**. The mesomerism characteristic for *C*-borylmethyleneboranes[6] creates, corresponding to resonance formula **9B**, a marked deficiency of electrons at the dicoordinated boron atom, which is compensated by bridging with the mesityl group at the other boron atom.

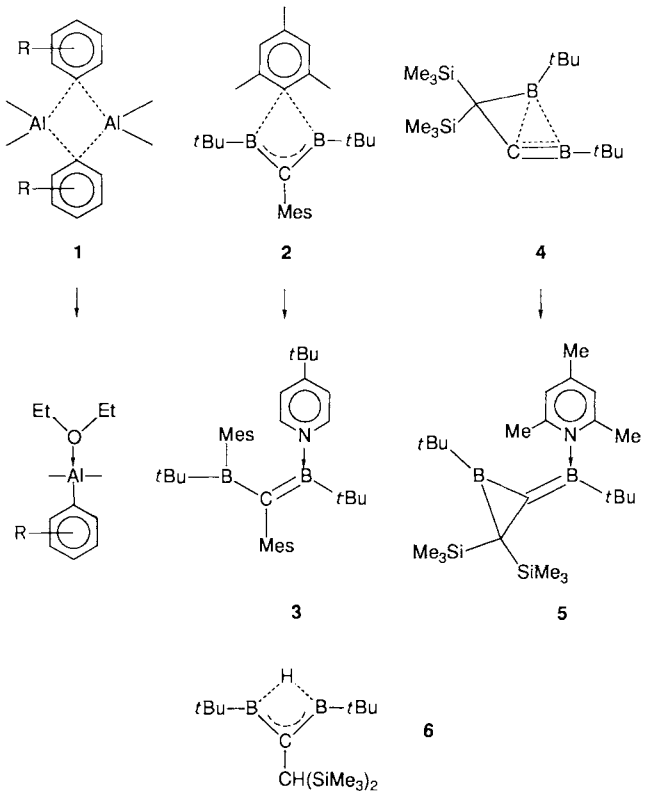
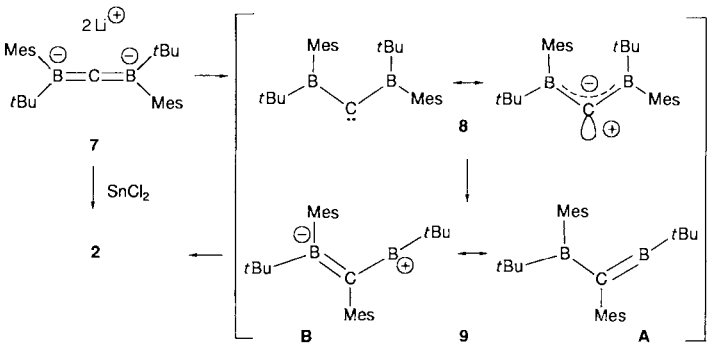
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



Scheme 1. Mes = 2,4,6-trimethylphenyl.

Figure 1 shows the crystal structure of **2**.[7] The bridging bonds from the boron atoms to the mesityl ring (174.8(9) and 176.9(8) pm, respectively) are comparable in length with the corresponding Al–C bridging bonds in **1** (R = *o*-CH_3: 213 pm[1a]), if one takes into account the 38 pm greater covalent radius of aluminum. The bridging aryl ring in **1** is perpendicular (91.0°) to the least-square plane through C–Al–C–Al, while that in **2** is perpendicular (89.1°) to the least-square plane through B1–C2–B3–C4. The mesityl ring bound to C2 forms an angle of 85.9° with this plane.



The NMR data (Table 1) indicate that the bridged structure **2** is also present in solution. A rapid topomerization of **9** with migration of the mesityl group from the tricoordinated to the dicoordinated boron atom (Scheme 2) should have no influence on the chemical shifts of the mesityl groups bound to the boron.

The *ortho* and *para* C atoms of this mesityl group are, however, noticeably deshielded (Table 1, δ = 160.8 and

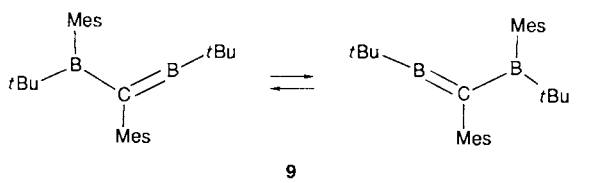
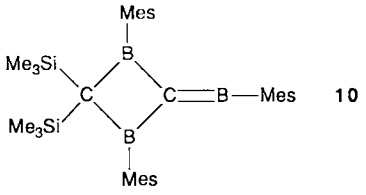
3: yellow crystals, m.p. = 142 °C, yield: NMR spectroscopically quantitative.—^{1}H NMR (300 MHz, 25 °C): δ = 0.37, 0.51, 1.27 (each s, each 9H, $C(CH_3)_3$), 2.06, 2.27 (each s, each 3H, *p*-CH_3), 2.17, 2.47 (each s, each 6H, *o*-CH_3), 6.26, 6.83 (each s, each 2H, *m*-H), 7.00, 7.92 (each d, each 2H, *m*-, *o*-H_{pyr}); ^{13}C NMR (75 MHz, 25° C): δ = 21.3, 24.3, 24.4 (each q, each 2C, *o*- und *p*-CH_3), 25.2, 27.1 (each s, each 1C, $BC(CH_3)_3$), 29.9, 30.3, 31.2 (each q, each 3C, $C(CH_3)_3$), 35.5 (s, 1C, $C(CH_3)_3$), 117.6 (br. s, 1C, CB_2), 120.2 (d, 2C, *m*-C_{pyr}), 126.8, 127.4 (each d, each 2C, *m*-C), 131.4, 131.7 (each s, each 1C, *p*-C), 135.6, 137.6 (each s, each 2C, *o*-C), 142.6 (d, 2C, *o*-C_{pyr}), 149.8 (s, 1C, C-*i*-C), 153.9 (s, 1C, B-*i*-C), 164.8 (s, 1C, *p*-C_{pyr}); ^{11}B NMR (96 MHz, 25 °C): δ = 48, 65 ($\nu_{1/2}$ = 1088, 1769 Hz).

146.3, resp.) relative to the corresponding atoms in **3** (δ = 135.6 or 137.6 and 131.4 or 131.7, resp.), whereas the *ipso* C atom is, in contrast, strongly shielded (δ = 113.4) as compared to **3** (δ = 153.9). Similar consequences of bridging were observed in the case of **1**[8] (R = *p*-CH_3; δ: *o*-C 155, *p*-C 150, *i*-C 118). The chemical shifts of the tri- and dicoordinated B atoms would be averaged in a rapid equilibrium (Scheme 2). On the basis of the classical methyleneborane



Scheme 2.

10[3] the unaveraged shifts for **9** can be predicted to be $\delta = 65 \pm 5$ and 70 ± 5. The average value $\delta = 65 \pm 5$ differs very markedly from that measured for **2** (δ (^{11}B) = 42).



10

Aryl bridging is, after π-π[9] and σ-π conjugation,[3, 6] a third route to the stabilization of methyleneboranes by intramolecular filling of the empty p-orbital on the boron atom.

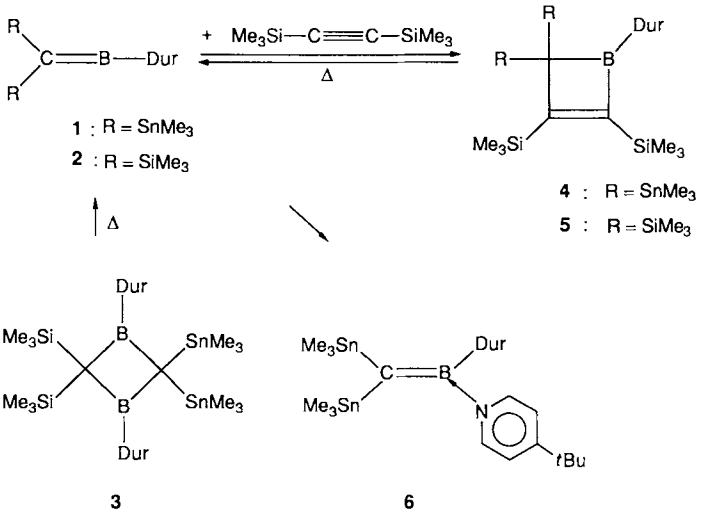
portant role as β-Si effect[5] in organic chemistry. However, such cations have proven to be too unstable for NMR spectroscopic investigations.[6] Recently,[7] we were able to show that hyperconjugation and stronger σ-π interactions in methyleneboranes have similar consequences as in carbocations. We now demonstrate NMR spectroscopically the consequences of strong C–Sn hyperconjugation in the methyleneborane **1**.

The bis(*C*-stannyl)methyleneborane **1** postulated as a product of the thermolysis of the 1,3-diboretane **3** (Scheme 1) can



Scheme 1. Dur = 2,3,5,6-tetramethylphenyl.

be detected NMR spectroscopically along with **2**[8] after rapid removal from the reaction mixture by condensation and trapping in cooled solvents. The separation of **2** is accomplished via the cycloadduct **4**, which is formed from **1** and bis(trimethylsilyl)acetylene at room temperature; **2** reacts only at 135 °C to give **5**. **4** can be separated from the mixture of **4** and **2** by crystallization at −30 °C (pentane).

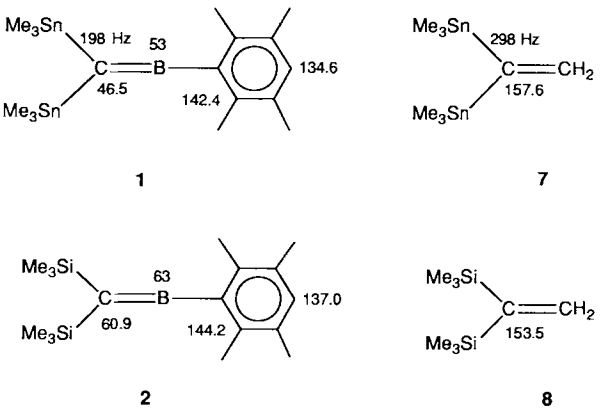
The thermal cycloreversion of **4**, the first reported for a 1,2-dihydroborete, already takes place at 120 °C. Destillation into CD_2Cl_2 cooled to −80 °C afforded a solution of **1** and bis(trimethylsilyl)acetylene, which was investigated ^{13}C- and ^{11}B-NMR spectroscopically (Table 1). Treatment of this solution at −78 °C with 4-*tert*-butylpyridine yielded the adduct **6**, whose $^1J(^{119}Sn,^{13}C)$ value is required for comparison purposes (see below). NMR data of **1**, **2**, **7**, and **8** relevant for the following discussion are collected in Scheme 2.

Strong C–Sn Hyperconjugation in a Distannylmethyleneborane**

By *Monika Pilz, Holger Michel,* and *Armin Berndt**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

Kinetic measurements show that carbocations are more strongly stabilized by C–Sn hyperconjugation[1–4] than by C–Si hyperconjugation, an interaction which plays an im-



Scheme 2.

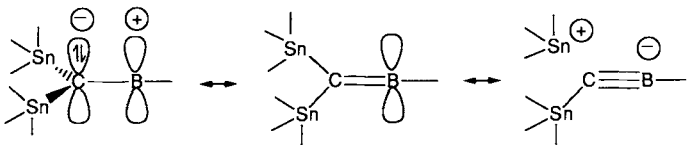
Table 1. Some physical data of the compounds **1**, **4** and **6**. Standard for ^{1}H- and ^{13}C-NMR spectra TMS, for ^{11}B-NMR spectra $BF_3 \cdot OEt_2$.

1: yield, NMR spectroscopically ca. 95% – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 0.27$ (s, 18H, $Sn(CH_3)_3$), 2.23, 2.59 (each s, each 6H, *o*- and *m*-CH_3), 7.09 (s, 1H, p-H); ^{13}C NMR (100 MHz, CD_2Cl_2, −80 °C): $\delta = -5.2$ (q, 6C, $Sn(CH_3)_3$, $^1J(^{119}Sn, ^{13}C) = 355.7$), 19.7, 21.3 (each q, each 2C, *o*- and *m*-CH_3), 46.5 (br. s, 1C, CB, $^1J(^{119}Sn,^{13}C) = 198$ Hz), 126.5 (br. s, 1C, *i*-C), 133.6, 142.4 (each s, each 2C, *m*- and *o*-C), 134.6 (d, 1C, *p*-C); ^{11}B NMR (96 MHz, CD_2Cl_2, 20 °C): $\delta = 53$ ($\nu_{1/2} = 680$ Hz)

4: pale yellow, m.p. = 106 °C, yield 12%. – ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 0.00$ (s, 18H, $Sn(CH_3)_3$), 0.09, 0.32 (each s, each 9H, $Si(CH_3)_3$), 2.07, 2.16 (each s, each 6H, *o*- and *m*-CH_3), 6.82 (s, 1H, *p*-H); ^{13}C NMR (100 MHz, $CDCl_3$, −40 °C): $\delta = -6.9$ (q, 6C, $Sn(CH_3)_3$, $^1J(^{119}Sn,^{13}C) = 313.6$ Hz), 0.0, 0.6 (each q, each 3C, $Si(CH_3)_3$), 19.9 (q, 4C, *o*- and *m*-CH_3), 54.3 (br. s, 1C, Sn_2CB, $^1J(^{119}Sn,^{13}C) = 277.7$ Hz), 129.7 (d, 1C, *p*-C), 132.5, 133.6 (each s, each 2C, *o*- and *m*-C), 138.4 (br. s, 1C, *i*-C), 171.8 (s, 1C, SiCC, $^2J(^{119}Sn,^{13}C) = 37$ Hz), 197.1 (br. s, 1C, SiCB, $^3J(^{119}Sn,^{13}C) = 101$ Hz); ^{11}B NMR (96 MHz, $CDCl_3$, 25 °C): $\delta = 39$ ($\nu_{1/2} = 764$ Hz)

6: yield NMR spectroscopically quantitative.—^{1}H NMR (300 MHz, CD_2Cl_2, 25 °C): $\delta = -0.41$, −0.30 (each s, each 9H, $Sn(CH_3)_3$), 1.26 (s, 9H, $C(CH_3)_3$), 2.05, 2.21 (each s, each 6H, *o*- and *m*-CH_3), 6.72 (s, 1H, *p*-H), 7.19, 8.39 (each br. s, each 2H, *o*- and *m*-H_{pyr}); ^{13}C NMR (100 MHz, CD_2Cl_2, −80 °C): $\delta = -6.8$, −6.2 (each q, each 6C, $Sn(CH_3)_3$, $^1J(^{119}Sn,^{13}C) = 294.2$, 299.7 Hz), 20.2, 20.7 (each q, each 2C, *o*- and *m*-CH_3), 29.6 (q, 3C, $C(CH_3)_3$), 34.3 (s, 1C, $C(CH_3)_3$), 80.1 (br. s, 1C, CB, $^1J(^{119}Sn\text{-}^{13}C) = 325$ Hz), 122.7 (d, 2C, *m*-C_{pyr}), 129.3 (d, 1C, *p*-C_{dur}), 132.4, 135.6 (each s, each 2C, *o*- and *m*-C_{dur}), 142.7 (d, 2C, *o*-C_{pyr}), 165.1 (s, 1C, *p*-C_{pyr}), *i*-C could not be located; ^{11}B NMR (96 MHz, CD_2Cl_2, 25 °C): $\delta = 41$ ($\nu_{1/2} = 1445$ Hz).

The C atom of the B–C bond in **1** is $\Delta\delta = 14.4$ more strongly *shielded* than in **2**, whereas the correspondingly substituted C atom in **7**[9] is *deshielded* by $\Delta\delta = 4.1$ relative to that in **8**.[10] Apparently the B–C double bond is more strongly polarized in corresponding to resonance formula **B** in **1** than in **2**.[11] The *ortho* and *para* C atoms in **1** are less deshielded than in **2**. The thus indicated smaller delocalization of π electrons of the duryl ring to the boron atom and the stronger polarization of the B–C double bond according to **B** point to a smaller π-electron density at the boron atom of **1** than of **2**. This should lead to a small *deshielding* of the boron atom in **1** relative to that in **2**. Experimentally, however, we find a *shielding* of $\Delta\delta = 10$, which we attribute to C–Sn hyperconjugation corresponding to resonance formula **C**. In methyleneboranes with extremely strong σ-π interaction (bridging),[7] $\delta(^{11}B)$ is 18–20, $\Delta\delta \approx 45$.



B **A** **C**

The weakening of the C_{sp^2}–Sn bonds to be expected in accord with the corresponding resonance formula **C** is experimentally confirmed[13] by the small coupling constant $^1J(^{119}Sn, ^{13}C)$ of **1**, which is only 198 Hz.[12] In the adduct **6**, in which C–Sn hyperconjugation plays no role because of the filling of the p-orbital on the boron atom by 4-*tert*-butylpyridine, the corresponding coupling (325 Hz) lies in the range characteristic for C_{sp^2}–Sn bonds in geminal trimethylstannyl groups (cf. 298 Hz in **7**[9]).

[13] That the $^1J(^{119}Sn,^{13}C)$ coupling within the $SnMe_3$ groups in **1** is 56 and 61.5 Hz *greater* than in **6** can also be regarded as an indication of the participation of resonance formula **C**.

Transition-Metal-Induced Generation of C_2H_4 from 1,7-Octadiene: Regiospecific Activation of Internal C–C Bonds instead of Metathesis-like Coupling of Terminal CH_2 Groups**

By *Norbert Steinrück, Oliver Dange, Detlef Stöckigt*, and *Helmut Schwarz**

The metathesis reaction of 1,7-octadiene (**1**) has been more extensively studied than that of almost any other olefin.[1] *Grubbs* et al.[2] were able to show that ethylene is generated from **1** and metal carbene complexes **2** in a chain reaction; metallacyclobutanes **3** are involved as intermediates, and carbene complexes **4** are presumed to be the second product [Eq. (a)]. Metathesis reactions have also been observed repeatedly in bimolecular and unimolecular reactions of transition-metal ions in the gas phase.[3, 4]

Here we report on a reaction of "naked" transition-metal ions $M^{\oplus}$ (M = Fe, Ni, Cr) with **1** which cannot be explained

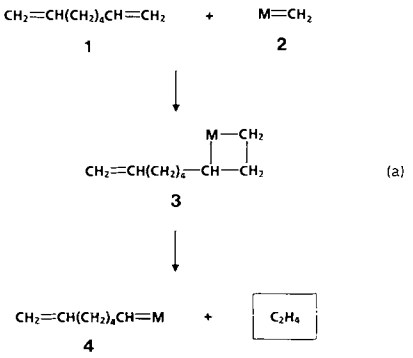
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, the Fonds der Chemischen Industrie, and the Gesellschaft von Freunden der Technischen Universität Berlin. We thank Prof. *H. Lehmkuhl*, Max-Planck-Institut Mülheim, and Dr. *K. Weiss*, Universität Bayreuth, for stimulating discussions.

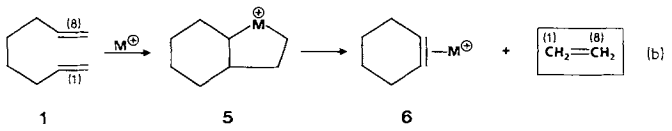


in terms of the type of metathesis reaction predominating in solution. Instead, the reaction for $M^{\oplus} = Fe^{\oplus}$ is presumably a rare example of *directed* activation of C–C bonds *without* prior C–H bond activation.[5]

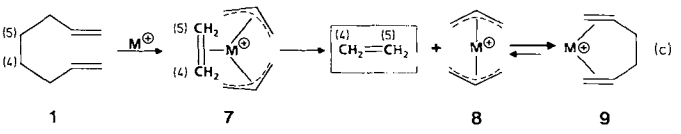
Electron-impact ionization (100 eV) of a 10:1 mixture of **1** and a suitable substrate for the generation of $M^{\oplus}$ (such as $Fe(CO)_5$, $Ni(acac)_2$, or $Cr(acac)_3$) in the ion source of a modified ZAB-HF-3F mass spectrometer with BEBE configuration (B, magnetic sector; E, electric sector) affords ionic complexes of the type **1**-$M^{\oplus}$. The ions, accelerated to 8 keV, are mass-selected with sectors B(1)E(1), and their unimolecular decompositions[6] are monitored by scanning B(2). All three metal ions, $Fe^{\oplus}$, $Ni^{\oplus}$, and $Cr^{\oplus}$, induced loss of C_2H_4 from **1** (8, 7, and 10% of the total ion current, respectively).

Investigations using partially deuterated (and ^{13}C-labeled) isotopomers of **1** and naked metal ions (Table 1) allow the following conclusions to be drawn:

1. The fact that C_2D_4 ($\Delta m = 32$) was formed from none of the complexes [1,1,8,8-$^2H_4$] **1**-$M^{\oplus}$ compellingly rules out a metathesis reaction involving coupling of the terminal methylene groups, for example, isomerization to a bicyclo[4.2.0]octane derivative and metal insertion to give **5**, which could react to give **6** and ethylene [Eq. (b)].



2. The relative intensity for $\Delta m = 28$ requires that, for the complexes with $Fe^{\oplus}$, more than 90% of the total ethylene formed originate from the *internal* CH_2 groups, C(4) and C(5) [Eq. (c)]. Although these experiments still do not distinguish among the many possible mechanistic variants[7] for the highly selective generation of C_2H_4 from



1-$Fe^{\oplus}$, we favor the reaction via **7** shown in Equation (c), which provides a further example of an activation of C–C bonds without prior activation of C–H bonds.[5] For **1**-$Cr^{\oplus}$, we estimate that this mechanism accounts for ca. 20% of the reaction;[8] for **1**-$Ni^{\oplus}$, not even a semiquantitative estimate is possible owing to substantial exchange processes. However, the internal positions are also unquestionably involved in C_2H_4 generation from **1**-$Ni^{\oplus}$.

3. The data in Table 1 indicate that, for the generation of ethylene from **1**-$Cr^{\oplus}$, two further, independent processes presumably take place. The first is the generation of C_2H_4 from C(3) and C(4); we estimate that this process accounts for ca. 30% of the reaction. The second process, accounting for ca. 50% of the reaction, involves coupling of one of the two vinyl groups in a transannular fashion with a hydrogen atom of the allylically activated CH_2 group to give C_2H_4. The mechanistic details of this reaction pathway have not yet been explored.
4. Decomposition of the iron complex of **1** proceeds extremely selectively and three reaction pathways could be characterized for **1**-$Cr^{\oplus}$. However, the nickel complex **1**-$Ni^{\oplus}$ defies clear analysis, since ethylene loss is preceded by extensive exchange processes.[9]

The high selectivity with which C_2H_4 is formed from **1**-$Fe^{\oplus}$ encouraged us to carry out an experiment to determine whether the resulting ions have the structure **8** or **9**. Mass selection of the corresponding ion in a tandem experiment,[10] followed by collisional activation (CA[11]), affords a CA spectrum that is identical with the CA spectrum of $Fe(C_3H_5)_2^{\oplus}$ generated independently by reaction of $Fe^{\oplus}$ with $CH_2=CHCH_2Cl$.[12] This result does not mean, however, that the loss of C_2H_4 from **1**-$Fe^{\oplus}$ necessarily leads to **8**, since the CA spectrum of an authentic (1,5-hexadiene)$Fe^{\oplus}$ complex is also indistinguishable from the spectrum given in Ref. [12]. A coupling of the two allyl fragments also presumably occurs during C_2H_4 loss from **1**-$Fe^{\oplus}$ (i.e., **8** rearranges to **9**), as indicated by the following observation: in the CA spectrum of the ion obtained after C_2H_4 loss from [1,1,3,3-$^2H_4$] **1**-$Fe^{\oplus}$, for example, the entire signal group of the base peak ($\Delta m = 42$, loss of propene) is distributed over five m/z values ($\Delta m = 42-46$). This is best explained by a C–C coupling of the two ligands followed by H rearrangements.[13]

[a] $\Delta m = 29$ presumably corresponds to a doublet $C_2H_3D/^{13}CCH_4$; analogously, $\Delta m = 30$ may have been formed from a doublet $C_2H_2D_2/^{13}CCH_3D$. The resolution attainable in a MIKES experiment (MIKE = mass-analyzed ion kinetic energy spectrometry) was not sufficient to achieve separation.

[6] Besides loss of C_2H_4 ($\Delta m = 28$), further unimolecular reactions have been observed: **1**-$Fe^{\oplus}$: $\Delta m = 2$ (7%), 4 (9), 16 (13), 18 (4), 28 (8), 42 (50), 44 (1), 56 (8). **1**-$Ni^{\oplus}$: $\Delta m = 2$ (8), 4 (< 1), 16 (2), 18 (< 1), 28 (7), 42 (69), 54 (< 1), 56 (12). **1**-$Cr^{\oplus}$: $\Delta m = 2$ (38), 28 (10), 42 (15), 54 (13), 56 (24). For a discussion, see O. Dange, *Diplomarbeit*, Technische Universität Berlin 1989.
[7] We thank Dr. *Karin Weiss* for pointing out an alternative mechanism, according to which **1** first undergoes $Fe^{\oplus}$-induced isomerization to 2,6-octadiene and then loses the originally internal C(4) and C(5) methylene groups via Cope rearrangement and metathesis reaction.
[8] Primary and secondary isotope effects of unknown magnitude prevent a precise description of the process involved in C_2H_4 generation from **1**-$Cr^{\oplus}$. The values given in the text are therefore only rough estimates.
[9] Diverse isomerizations of olefins catalyzed by M(CO), (M = Fe, Ni), although they cannot explain the results reported here, have been described in J. E. Arnet, R. Pettit, *J. Am. Chem. Soc. 83* (1961) 2954; P. A. Pinke, R. D. Stauffer, R. G. Miller, *ibid. 96* (1974) 4229.
[10] F. W. McLafferty (Ed.): *Tandem Mass Spectrometry*, Wiley, New York 1983; K. L. Busch, G. L. Glish, S. A. McLuckey: *Mass Spectrometry/Mass Spectrometry: Techniques and Applications of Tandem Mass Spectrometry*, VCH Publishers, New York 1988.
[11] K. Levsen, H. Schwarz, *Mass Spectrom. Res. 2* (1983) 77.
[12] In CA spectra (collision gas, helium; 80% transmission) of $Fe(C_3H_5)_2^{\oplus}$, the following signals are observed: $\Delta m = 2$ (14%), 16 (3), 28 (15), 56 (5), 67 (4), and $Fe^{\oplus}$ (13).
[13] The most recent results of other research groups indicate that $M(C_3H_5)_2^{\oplus}$ complexes are also formed in the reaction of $Fe(CO)_x^{\oplus}$ with C_3H_5Cl or of $Co(C_3H_6)^{\oplus}$ with 1-propene; these complexes are best described as **9**. (H. Mestdagh, C. Rolando, *J. Am. Chem. Soc. 111* (1989) 3476; R. L. Hettich, B. S. Freiser, *Organometallics 8* (1989) 2447). Our attempts to achieve a differentiation between **8** and **9** by selective ligand exchange and use of Fourier transform ion cyclotron resonance (FTICR) have so far failed.

Ionic Isomer Distinction by Neutralization-Reionization Mass Spectrometry (NRMS): Carbonic Acid Radical Cations, $(HO)_2CO^{\cdot\oplus}$ versus $(H_2O/CO_2)^{\cdot\oplus}$ Clusters **

By *Johan K. Terlouw, Detlev Sülzle*, and *Helmut Schwarz* *

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The interaction of carbon dioxide with water is a topic of central importance in biological, atmospheric, and industrial processes.[1] Whereas earlier studies[2] suggested the occurrence of free carbonic acid, $(HO)_2CO$ (**1**), in the gas-phase reactions of H_2O with CO_2, both theoretical[1h, 3] and experimental studies[4] later provided evidence that a weakly bound van der Waals complex was generated. From the detailed spectroscopic analyses it was further concluded that a planar structure **2** (C_{2v}) rather than a hydrogen-bridged isomer **3** (C_s) was formed. The long-sought free carbonic acid **1** is, however, readily accessible by thermolysis of NH_4HCO_3.[5] Mass-spectrometric studies further demonstrate[5] that both **1** and its radical cation $\mathbf{1}^{\cdot\oplus}$ are perfectly stable species in the gas phase, since they are prevented by significant barriers (> 40 kcal mol^{-1})[1g, h, 5, 6] from undergoing spontaneous isomerization and dissociation reactions. In addition, by using neutralization-reionization mass spectrometry (NRMS),[7] it was possible to reduce $\mathbf{1}^{\cdot\oplus}$ to its neutral counterpart.[5]

Here we describe experiments on the electron-impact ionization (70 eV) of an H_2O/CO_2 mixture (90% CO_2/10% H_2O, total ion source pressure ca. 2×10^{-4} torr). We shall demonstrate that the charged cluster $(H_2O/CO_2)^{\cdot\oplus}$ formed under these conditions by ion/molecule reactions does not have the structure of the radical ions $\mathbf{1}^{\cdot\oplus}$ or $\mathbf{2}^{\cdot\oplus}$ but rather is the proton-bridged radical ion $\mathbf{3}^{\cdot\oplus}$.[8] In addition, the data presented clearly support the view[9] that NRMS can also be used to characterize *isomeric ions*. The experimental findings are supported by ab initio MO calculations (HF/6-31G** + ZPVE)[10] (Table 1).

Table 1. Total energies, zero-point vibrational energies (ZPVE), relative energies, and $<S^2>$ values (6-31G**//6-31G**).

Electron-impact ionization of a mixture of H_2O and CO_2 gives rise to, among others, a signal at m/z 62, which, according to exact mass measurements, corresponds to the elemental composition CH_2O_3. Mass selection of this ion in an MS/MS experiment,[11] followed by collisional activation (CA),[12] yields the CA mass spectrum shown in Figure 1b. The ion is characterized by three major dissociation processes yielding $HOCO^{\oplus}$ (m/z 45) + $OH^{\bullet}$, $CO_2^{\bullet\oplus}$ (m/z 44) + H_2O, and $H_2O^{\bullet\oplus}$ (m/z 18) + CO_2 with enthalpies of formation, derived from known thermochemical data,[13] of 150, 165, and 139 kcal mol^{-1}, respectively. These results are fully compatible with a radical cation having the connectivity **3**, which should undergo three competing bond cleavages to afford the radical cations $HOCO^{\bullet\oplus}$, $CO_2^{\bullet\oplus}$, and $H_2O^{\bullet\oplus}$. For the isomers $\mathbf{1}^{\bullet\oplus}$ and $\mathbf{2}^{\bullet\oplus}$, on the other hand, rearrangement prior to dissociation has to be invoked to account for the formation of fragments with m/z 44 (loss of H_2O) and m/z 18 (loss of CO_2) from $\mathbf{1}^{\bullet\oplus}$ and m/z 45 (loss of $OH^{\bullet}$) from $\mathbf{2}^{\bullet\oplus}$. This is at odds with the result obtained for the $[H_2{}^{18}O/CO_2]^{\bullet\oplus}$ system (Fig. 1a); the CA mass spectrum clearly demonstrates the nonoccurrence of oxygen exchange or hydrogen migration. In addition, a comparison of Figure 1b with the CA spectrum of authentic $\mathbf{1}^{\bullet\oplus}$ [5] (in particular the loss of $OH^{\bullet}$ versus H_2O) rules out the generation of $\mathbf{1}^{\bullet\oplus}$ in the reaction of $H_2O^{\bullet\oplus}$ with CO_2. The ab initio MO calculations also support our conclusion: $\mathbf{2}^{\bullet\oplus}$ does not correspond to a minimum but rather to a transition structure (one negative eigenvalue), which is 93.2 kcal mol^{-1} higher in energy than $\mathbf{3}^{\bullet\oplus}$. The latter ion is 8.6 kcal mol^{-1} less stable than the two conformers of $\mathbf{1}^{\bullet\oplus}$ (which are practically isoenergetic, with $\mathbf{1s/a}^{\bullet\oplus}$ 0.1 kcal mol^{-1} more stable than $\mathbf{1s/s}^{\bullet\oplus}$).

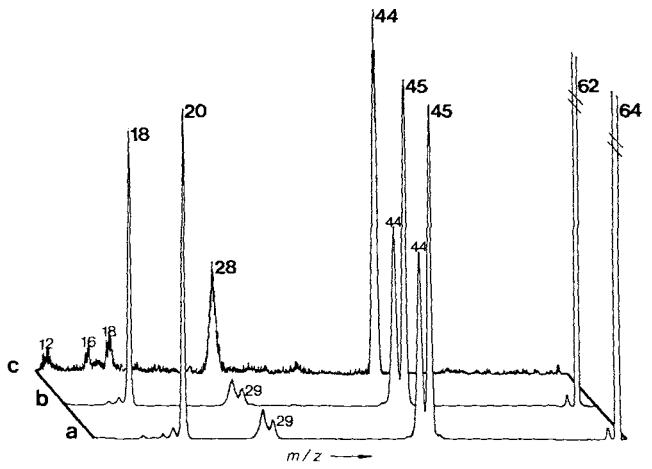

Fig. 1. a) CA mass spectrum (collision gas: helium) of $(H_2{}^{18}O/CO_2)^{\bullet\oplus}$. b) CA mass spectrum of $(H_2O/CO_2)^{\bullet\oplus}$ obtained under the same conditions. c) NR mass spectrum of $(H_2O/CO_2)^{\bullet\oplus}$ (xenon for neutralization, oxygen for reionization).

Obviously, under the prevailing reaction conditions, the Lewis acid-base type interaction so characteristic for the generation of many *neutral* van der Waals complexes (including **2**) cannot compete with the formation of a proton-bound radical cation complex $\mathbf{3}^{\bullet\oplus}$. The fact that $\mathbf{3}^{\bullet\oplus}$ is not capable of surmounting the high barrier leading to the most stable isomer $\mathbf{1}^{\bullet\oplus}$ is quite likely a result of collisional stabilization of the encounter complex formed under high-pressure conditions.

What happens if $\mathbf{3}^{\bullet\oplus}$ is subjected to an NRMS experiment? Is the unknown *neutral* van der Waals complex **3** formed? Or does $\mathbf{3}^{\bullet\oplus}$ undergo rearrangement/dissociation processes? The prospects of generating a stable, neutral, hydrogen-bridged complex **3** are not very promising. In view of the fact that the electron transfer operative in NRMS is a vertical process, large structural differences between the ionic and neutral counterparts will strongly diminish the Franck–Condon factors; to put the situation in a different perspective, a vibrationally "hot" species will be formed having a lifetime too short for detecting a recovery signal.[14] A comparison of the calculated data for $\mathbf{3}^{\bullet\oplus}$ and **3** (Table 2)

Table 2. Molecular data of **3** and $\mathbf{3}^{\bullet\oplus}$ calculated at the 6-31G** level [a] and charge distributions of $\mathbf{3}^{\bullet\oplus}$.

Bond length [Å]	**3**	$\mathbf{3}^{\bullet\oplus}$	Charge distribution of $\mathbf{3}^{\bullet\oplus}$	
O1-C2	1.141	1.122	O1	−0.31
C2-O3	1.146	1.164	C2	0.98
O3-H4	2.317	1.477	O3	−0.60
H4-O5	0.944	1.028	H4	0.56
O5-H6	0.943	0.975	O5	−0.11
			H6	0.48
Bond angle [°]	**3**	$\mathbf{3}^{\bullet\oplus}$		
O1-C2-O3	179.8	179.3		
C2-O3-H4	139.5	201.0		
O3-H4-O5	171.0	177.5		
H4-O5-H6	105.9	113.2		

[a] Molecular data of the remaining molecules discussed in the text: *H. Schwarz* et al., unpublished.

leaves little doubt that the chances of generating stable **3** by vertical reduction of $\mathbf{3}^{\bullet\oplus}$ are quite remote indeed. Whereas, for example, the O3–H4 bond length of $\mathbf{3}^{\bullet\oplus}$ (1.477 Å) is quite normal for this kind of proton-bridged structure,[15] the corresponding bond of the neutral analogue **3** is elongated to 2.317 Å. Another significant geometry change concerns the decrease of the H4–H5 bond length from 1.028 Å in $\mathbf{3}^{\bullet\oplus}$ to 0.944 Å in **3**. In fact, the NR mass spectrum of $\mathbf{3}^{\bullet\oplus}$ (Fig. 1c) shows not even a trace of a recovery signal. The spectrum is dominated by a signal at m/z 44, due to collisionally ionized CO_2 generated by dissociative neutralization ($\mathbf{3}^{\bullet\oplus} + e^{\ominus} \rightarrow CO_2 + H_2O$). The much lower intensity of the complementary $H_2O^{\bullet\oplus}$ signal (m/z 18) may reflect a lower collisional ionization cross-section of H_2O versus CO_2, due in part to a translational energy effect.[7g] We note that the absence of a recovery signal at m/z 62 in Figure 1c provides further evidence that the $CH_2O_3^{\bullet\oplus}$ species (m/z 62) formed from $H_2O^{\bullet\oplus}$ and CO_2 does *not* correspond to the radical cation of carbonic acid ($\mathbf{1}^{\bullet\oplus}$): authentic $\mathbf{1}^{\bullet\oplus}$, generated upon electron-impact ionization of **1**,[5] gives rise to an intense recovery signal and a strong peak at m/z 45 ($CO_2H^{\oplus}$).

In conclusion, the ion/molecule reactions occurring in the $(H_2O/CO_2)^{\bullet\oplus}$ system generate exclusively the proton-bridged radical cation $\mathbf{3}^{\bullet\oplus}$. The ionic form of the van der Waals complex **2** (which is formed in *neutral* mixtures of H_2O and CO_2[3,4]) is not generated nor is the radical cation of carbonic acid, $\mathbf{1}^{\bullet\oplus}$.[16]

[8] On thermochemical grounds it is most likely that the reactants in the formation of $(H_2O/CO_2)^{\cdot\oplus}$ are $H_2O^{\cdot\oplus}$ and neutral CO_2 and *not* H_2O and $CO_2^{\cdot\oplus}$. This is based on the different ionization energies of H_2O (12.62 eV) and CO_2 (13.78 eV): K. Kimura, S. Katsumata, Y. Achiba, T. Yamazaki, S. Iwata: *Handbook of HeI Photoelectron Spectra of Fundamental Organic Molecules*, Japan Scientific Press, Tokyo 1981.

[9] For an extensive discussion of this *analytical* aspect of NRMS, see F. W. McLafferty, C. Wesdemiotis, *Org. Mass Spectrom. 24* (1989) 663.

[10] The MO calculations were performed using the CRAY-XMP version of *Pople*'s GAUSSIAN 82 and 86 series of programs. Stationary points (minima and transition structures) were characterized by analyzing the force constant matrix. Uncorrected zero-point vibrational energies (ZPVE) were included in the calculations of relative energies. The degree of spin contamination for the radical cations was estimated by calculating the $<S^2>$ values. For the species of interest the values were very close (< 10%) to the "pure" value $<S^2> = 0.75$.

Vanadium Tetrafluoride**

By *Stephan Becker* and *Bernd G. Müller**

The tetrafluorides of numerous transition metals have long been known, but little information is available on their structure and actual composition (e.g. $OH^{\ominus}$ or $O^{2\ominus}$ instead of $F^{\ominus}$).

In some cases (e.g., PdF_4[1]), neutron diffraction studies of powders have led to structural proposals. However, structure determinations of single crystals have been carried out for only a few compounds (e.g., ZrF_4[2] and NbF_4[3]). Whereas several tetrafluorides MF_4 could be assigned to known structure types on the basis of powder data (e.g., the tetrafluorides of M = Pt, Rh, Ir are isotypes of the PdF_4 structure and those of M = Hf, Ce, Th of the ZrF_4 structure), such information is completely lacking for the corresponding compounds of the 3d metals (with the exception of MnF_4[4]). It was expected that these compounds—like MnF_4—might form unique structures, as already indicated by the literature data on the unit cell of VF_4 (according to Ref. [5], hexagonal with $a = 5.38$, $c = 5.16$ Å, according to Ref. [6], orthorhombic with $a = 5.33$, $b = 5.16$, $c = 9.35$ Å, no further structural details).

Preparative difficulties—for example, the tendency to disproportionate (e.g., with M = V, Cr, Ru, Re) or the ready thermal decomposition to lower-valent compounds and elemental fluorine (e.g., with M = Pd, Rh, Ni)—have been the primary factors preventing the growth of suitable single crystals.

Preparation of VF_4, however, is achieved relatively "simply" by reaction of vanadium powder (99.99%, under argon) with elemental fluorine in a Monel autoclave. Use of a slight excess of F_2 ($V:F \approx 1:4.1$) should influence the disproportionation equilibrium ($2\,VF_4 \rightleftarrows VF_3 + VF_5$) by leading to formation of small amounts of volatile VF_5; in addition, formation of VOF_3 should result in removal of traces of oxygen).

In this way, bright, light-green, coarse, relatively moisture-sensitive crystals were obtained after a reaction time (annealing in a temperature gradient: $T_1 = 280 \rightarrow T_2 = 180\,^{\circ}C$) of about ten weeks. Under dry argon or perfluoroalkanes, the crystals may be handled without decomposition.

Careful analysis of long-exposure films (Weissenberg and precession photographs) unequivocally confirmed monoclinic symmetry. To calculate the interatomic distances listed in Table 1, the lattice constants derived from Guinier–de Wolff photographs were used. In addition, the motives of mutual adjunction[8] and the coordination number are given; all F–V–F angles within an octahedron lie very close to 90 or 180°.

Table 1. Motives of mutual adjunction, distances [pm], and coordination numbers (C.N.).

	F1	F2	C.N.
V	2/1 169.6	2 + 2/2 191.8 + 192.3	6
C.N.	1	2	

In order to show clearly the relationship with the SnF_4 structure,[8, 9] a monoclinic unit cell for VF_4 in the arrangement $P2_1/n$ of space group No. 14 (with $a = 5.381$, $b = 5.170$, $c = 5.340$ Å, $\beta = 59.74°$) is drawn instead of one in the usual $P2_1/c$ arrangement in the tetragonal unit cell of SnF_4 in Figure 1. The relationship between the two arrangements is given by the following transformation matrix:

$$P2_1/c \rightarrow P2_1/n: \quad \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 1 & 0 & 1 \end{pmatrix}$$

[*] Dr. B. G. Müller, Dipl.-Chem. S. Becker
Institut für Anorganische und Analytische Chemie I
Heinrich-Buff-Ring 58, D-6300 Giessen (FRG)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Prof. Dr. *Rudolf Hoppe* for his personal and material support.

The relationship of the two structures is thereby directly shown. Both structures contain layers of corner-sharing $[VF_6]$ octahedra in accordance with $^2_\infty[VF_{4/2}F_{2/1}]$ with two *trans* $F^\ominus$ ions; the layers are also stacked in the same way. The crucial difference between the two structure types is that the $[VF_6]$ octahedra within a layer are tilted toward one another; the bond angle of the fluorine bridge V-F2-V is 150.7° (SnF_4: 180°).

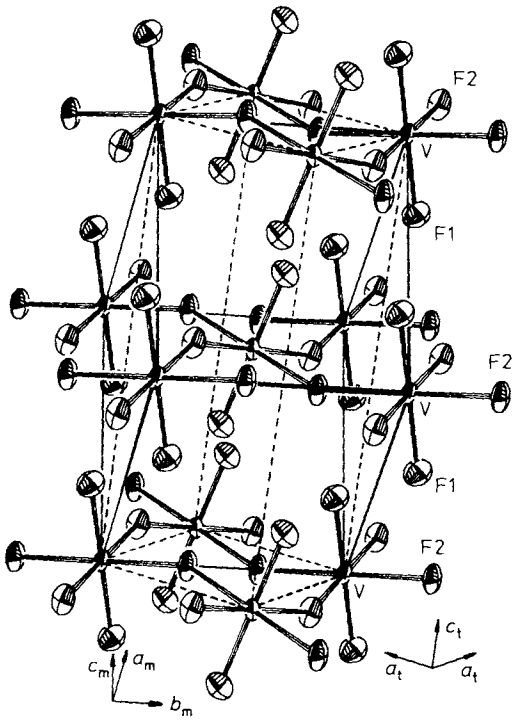

Fig. 1. Unit cell of SnF_4 (dashed line) and VF_4 (solid line) [7].

Comparison of the interatomic distances of the three isotype or structurally related compounds MF_4 (M = Sn, Nb, V) reveals that, for VF_4, the difference between the distances d(M-terminal $F^\ominus$) and d(M-bridging $F^\ominus$) is more pronounced than for SnF_4 or NbF_4[9] (Table 2).

Table 2. Comparison of the interatomic distances in four compounds of the type MF_4.

M	V	Nb	Sn	Mn
d_1 (M-F)$_{\text{term.}}$	1.696	1.859	1.861	1.697
d_2 (M-F)$_{\text{bridging}}$	1.918	2.042	2.024	1.948
d_1/d_2	0.884	0.919	0.910	0.871

The reason for this is unclear, since, even for MnF_4—albeit with *cis*-oriented terminal $F^\ominus$ and $d = 0.871$—a comparable quotient is found.

Susceptibility measurements on several samples of VF_4 crystals between 4.2 and 251 K (μ_{eff}(251 K) = 1.43 B.M.) provided evidence for the absence of oxygen (VOF_3 is diamagnetic) and confirmed the complicated collective magnetic interactions;[5] the determination of the magnetic structure by neutron diffraction is in progress.

Experimental Procedure

Vanadium powder (500 mg, Ventron) was placed in a Monel autoclave under inert gas (Braun glovebox). At −196 °C, 0.8 mL of F_2 was condensed into the autoclave, which was then placed in an oven preheated to 280 °C and kept for about ten weeks at this temperature. After stepwise cooling (25 °C per day), the autoclave was opened under inert gas (Ar, glovebox) and the VF_4 thus obtained was transferred to glass ampoules for further analysis.

Intramolecular Interconversion of *syn*- and *anti*-Tricarbonyl(1-ethoxy-1,2-dihydrocyclobutabenzene)chromium. Trapping of the *ortho*-Quinodimethane Intermediate**

By *Ernst Peter Kündig,* Gérald Bernardinelli, James Leresche,* and *Patrick Romanens*

1,2-Dihydrocyclobutabenzenes are convenient and widely used precursors of the highly reactive *ortho*-quinodimethanes, which are synthetically important dienes in Diels-Alder reactions.[1, 2] Although syntheses of π-cyclobutabenzene-transition metal complexes have been reported and reactions of the complexed cyclobutabenzene (nucleophilic addition, lithiation) have been the subject of several studies,[3 – 5] the effect of coordination on the transformation cyclobutabenzene/*ortho*-quinodimethane has thus far remained unexplored. We report here on the thermal ring opening of complexed 1-ethoxy-1,2-dihydrocyclobutabenzene **1**, and on a [4 + 2]-cycloaddition of the postulated intermediary *ortho*-quinodimethane complex.

We chose **1** in this study for the following reasons: firstly, reversible electrocyclic ring-opening of 1-alkoxy-substituted 1,2-dihydrocyclobutabenzenes occurs at moderate temperatures (80–110 °C)[6] and, secondly, the $Cr(CO)_3$ complexes of **1** are readily accessible by exchange of the arene ligand of tricarbonyl(naphthalene)chromium; the 2:3 mixture of diastereomers (*syn*-**2** and *anti*-**2**) that is formed[7] can be readily separated by flash chromatography. The benzyl protons in benzocycloalkene complexes readily undergo stereoselective

base-catalyzed hydrogen/deuterium exchange;[8] this enables assignment of the structures of *syn*-**2** and *anti*-**2**. Upon addition of a catalytic amount of *t*BuOK to *syn*-**2** or to *anti*-**2** in [D_6]DMSO, the ^{1}H-NMR signal of one of the two methylene protons disappeared, and monodeuteriated complexes were formed. These signals were assigned to the *anti*-H atoms. The tertiary benzylic C–H bond remained unaffected in both diastereomers. The vicinal coupling constant of the remaining benzyl protons is 4 Hz in *anti*-**2** (J_{cis}) and 1.5 Hz in *syn*-**2** (J_{trans}), in accord with data on uncomplexed 1-substituted 1,2-dihydrocyclobutabenes.[9] This assignment was confirmed by an X-ray analysis of *syn*-**2** (Fig. 1).

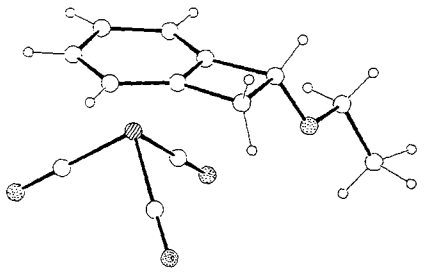

Fig. 1. Structure of *syn*-tricarbonyl(1-ethoxy-1,2-dihydrocyclobutabenzene)-chromium *syn*-**2** in the crystal; ◎ = Cr, ◎ = O [10].

On heating in benzene, *syn*-**2** and *anti*-**2** interconvert. The reaction can be conveniently followed by ^{1}H NMR in a sealed tube. Clean first-order kinetics are observed for the reversible reaction in the temperature range of 130–180 °C (Fig. 2).

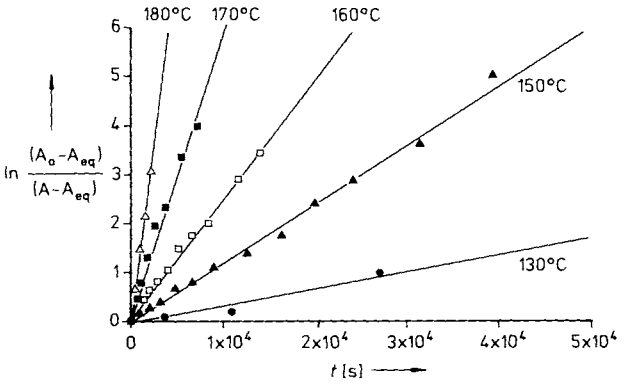

Fig. 2. First order kinetic plots for the interconversion of *syn*-**2** and *anti*-**2**, as measured by growth and decay of the 1H-NMR signals of the methyl protons.

Attempts to detect an intermediate failed. The ^{1}H-NMR spectrum at 150 °C merely showed the resonances of *syn*-**2** and *anti*-**2**. The activation parameters calculated from the data listed in Table 1 are: $\Delta H^{\neq} = 29.9 \pm 1.0$ kcal mol^{-1} and $\Delta S^{\neq} = -8.5 \pm 3$ cal mol^{-1} K^{-1}.[11] For comparison, the values calculated from the data obtained by *Sammes* et al. for the racemization of 1-methoxy-1,2-dihydrocyclobutabenzene are $\Delta H^{\neq} = 30.7$ kcal mol^{-1} and $\Delta S^{\neq} = 3.0$ cal mol^{-1} K^{-1}.[6]

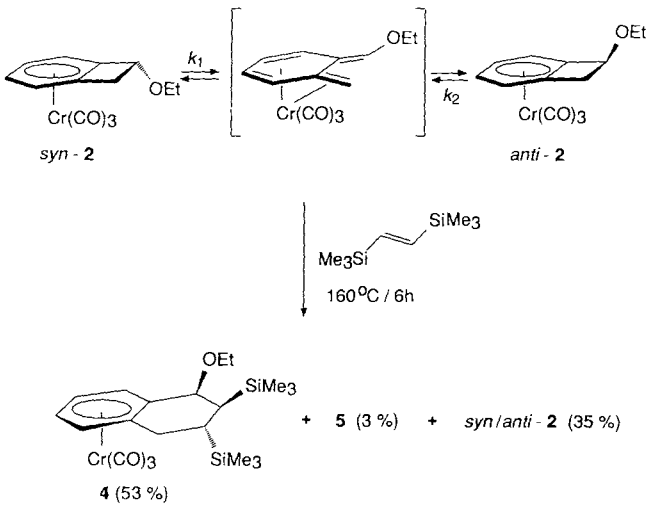
At 130 °C, the reaction of **2** is about 100 times slower than that of non-complexed 1-methoxy-1,2-dihydrocyclobutabenzene ($k = 1.14 \times 10^{-3}$ s^{-1}).[6] Comparison of the activation parameters show the activation entropy rather than the

Table 1. Rate constants for the reaction *syn*-**2** ⇌ *anti*-**2**. A first order reversible reaction was assumed by using the equation $\ln (A_o\text{-}A_{eq})/(A\text{–}A_{eq}) = (k_1 + k_2)\,t$. The correlation was in the range 0.992 to 0.999 for all plots.

T [°C]	k_2 [s]	$t_{1/2}$ [h]	k_1 [s]	$t_{1/2}$ [h]
130	0.78×10^{-5}	25	1.0×10^{-5}	19
140	2.1×10^{-5}	13	2.8×10^{-5}	7
150	5.2×10^{-5}	4	6.8×10^{-5}	2.8
160	10.0×10^{-5}	2	13.3×10^{-5}	1.43
170	23.0×10^{-5}	0.8	30.3×10^{-5}	0.63
180	56.0×10^{-5}	0.33	74.4×10^{-5}	0.26

enthalpy to be the source of this rate difference. If we assume an *o*-quinodimethane-$Cr(CO)_3$ complex as intermediate, the activation entropy difference may indicate a more ordered transition state.[12] An 18-electron configuration of Cr^0 would be achieved if the metal coordinates to the cyclic diene as well as to one of the exocyclic double bonds of the *o*-quinodimethane. This presumably would increase the barrier of rotation around the metal ligand bond and could be the cause of the entropy difference (loss of a degree of freedom). An intramolecular process for the interconversion of *syn*-**2** and *anti*-**2** also concurs with the observation that no arene exchange with the solvent (C_6D_6) takes place in the temperature range investigated. This would have been expected if the $Cr(CO)_3$ group were coordinated only to the diene portion of the *o*-quinodimethane or if the mechanism of interchange involved metal-arene bond dissociation. Similar bonding situations are known in an *o*-quinodimethane complex[13] and a methylene/cyclohexadiene complex[14] with tricarbonylchromium as well as in η^6-fulvene and η^6-azulene complexes.[15]

Experimental evidence for the proposed *o*-quinodimethane intermediate was obtained via a [4 + 2]-cycloaddition reaction. Slow addition of several olefin dienophiles to the equilibrating mixture of *syn*- and *anti*-**2** resulted in decomposition of the complex, possibly due to a CO/olefin exchange. We therefore turned to *trans*-1,2-bis(trimethylsilyl)ethene,[16] which we considered to be too bulky to interact readily with the metal. Thermolysis of *syn*-**2** in this dienophile (solvent and reactant) at 160 °C for 6 h resulted in a 56% conversion of **2** into a 17:1 mixture of complexes **4** and **5**.



35% of **2** was recovered from the reaction as a *syn*/*anti* mixture.[17] Structural assignment of complex **4** was based

on NMR spectral analysis and an X-ray diffraction study (Fig. 3). The X-ray structure of complex **4** reveals a boat conformation of the saturated ring of the tetralin complex with a *cis* arrangement of the C(1) ethoxy and the C(2) trimethylsilyl groups. The structure of **5**, a stereoisomer of **4**, has not yet been assigned unequivocally.

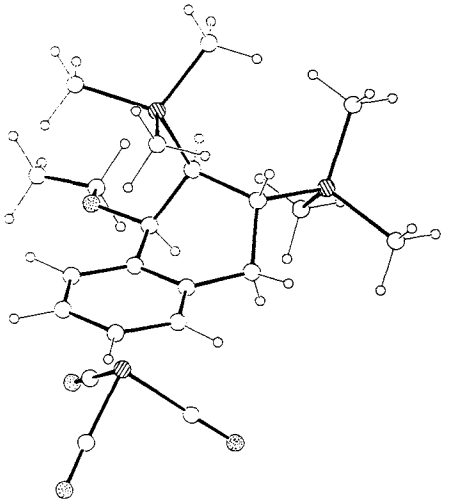


Fig.3. Structure of the adduct **4** in the crystal; ⊗ = Si [10].

This first study of a transition metal bound 1.2-dihydrocyclobutabenzene/*o*-quinodimethane reaction has focused on mechanistic aspects. We are presently extending these studies to more synthetically oriented projects. As the metal completely shields one face of the *o*-quinodimethane intermediate, high stereoselectivity can be expected in Diels-Alder reactions and this will be of particular import in reactions with chiral complexes. The present, severe limitation of useful dienophiles may be overcome by judicious choice of benzocyclobutene complexes with other organometallic fragments, by using milder ring opening reactions and/or different routes to π-complexed *ortho*-quinodimethane complexes.

Experimental

The mixture of diastereomers *syn*-**2** and *anti*-**2** obtained in 70% yield from the arene exchange in tricarbonyl(naphthalene)chromium was separated by flash chromatography using hexane/ether 4/1 (*syn*-**2**: $R_f = 0.13$; *anti*-**2**: $R_f = 0.19$).

syn-**2**: M.p.(hexane): 59–60 °C. IR (hexane, ν(CO)): $\tilde{\nu}$ [cm^{-1}]): 1984 (s), 1918 (s). ^{1}H NMR (360 MHz, C_6D_6): $\delta = 1.18$ (t, 3H, $J = 7$ Hz; $-CH_3$), 2.60 (dd, 1H, $J = 5.5$, 14 Hz; H_{anti}-C(2)), 2.80 (dd, 1H, $J = 1.5$, 14 Hz; H_{syn}-C(2)), 3.18–3.46 (m, 2H; OCH_2CH_3) 4.12 (t, 1H, $J = 6$ Hz; $H_{arom.}$), 4.20 (dd, 1H, $J = 2$, 5.5 Hz; *H*-C(1), 4.46 (t, 1H, $J = 6$ Hz; $H_{arom.}$), 4.52 (d, 1H, $J = 6$ Hz; $H_{arom.}$), 4.83 (d, 1H, $J = 6$ Hz; $H_{arom.}$). Correct elemental analysis.

anti-**2**: M.p.(hexane): 71.5–72.5 °C. IR (hexane, ν(CO) [cm^{-1}]): 1984 (s), 1918 (s). ^{1}H NMR (360 MHz, C_6D_6): $\delta = 1.02$ (t, 3H, $J = 7$ Hz; CH_3), 2.59 (dd, 1H, $J = 1.7$, 14 Hz; H_{anti}-C(2)), 2.98 (dd, 1H, $J = 4$, 14 Hz; H_{syn}-C(2)), 3.08–3.24 (m, 2H; OCH_2CH_3), 4.16 (t, 1H, $J = 6$ Hz; $H_{arom.}$), 4.33 (t, 1H, $J = 6$ Hz, $H_{arom.}$), 4.60 (d, 1H, $J = 6$ Hz; $H_{arom.}$), 4.69 (dd, 1H, $J = 1.7$, 4 Hz; H-C(1)), 5.02 (d, 1H, $J = 6$ Hz; $H_{arom.}$). Correct elemental analysis.

4: A degassed solution of complex *syn*-**2** (0.200 g, 0.70 mmol) in *trans*-bis(trimethylsilyl)ethene was stirred at 160 °C for 6 h in a closed tube. After cooling to 20 °C, the excess olefin was recovered by short path distillation, the residue was taken up in ether, filtered, and evaporated to dryness. Flash chromatography on silica (hexane/ether = 4/1) furnished **4** (170 mg, 53%, $R_f = 0.48$) followed by **5** (10 mg, 3%, $R_f = 0.35$) and *syn*/*anti*-**2** (70 mg, 35%).

M.p.(EtOH/H_2O): 78–80 °C. IR (hexane, ν((CO):$\tilde{\nu}$ [cm^{-1}]): 1970 (s), 1900(s). ^{1}H NMR (200 MHz, C_6D_6): $\delta = -0.20$ (s, 9H, $Si(CH_3)_3$), 0.00 (s, 9H, $Si(CH_3)_3$), 0.80–0.94 (m, 1H, H–C(3)), 1.10 (t, 3H, $J = 6.9$ Hz; CH_3CH_2O), 1.55 (dd, 1H, $J = 4$, 6.7 Hz, H–C(2)), 2.00 (dd, 1H, $J = 7.5$, 15.6 Hz; H_{anti}-C(4)), 2.55 (dd, 1H, $J = 13$, 15.6 Hz; H_{syn}–C(4)), 3.42–3.58 (m, 2H, OCH_2CH_3), 4.44 (d, 1H, $J = 6.7$ Hz; H–C(1)), 4.49–4.58 (m, 2H, H–C(6,7)), 4.70 (d, 1H, $J = 5.5$ Hz; H–C(5)), 5.55 (d, 1H, $J = 5.7$ Hz; H–C(8)). ^{13}C NMR (50 MHz, C_6D_6): $\delta = 234.20$, 112.74, 110.14, 93.23, 92.29, 90.75, 90.56, 77.71, 66.47, 28.16, 27.71, 18.65, 15.58. Correct elemental analysis.

The structure was solved by direct methods (Multan 87) and refined by full matrix least squares methods (XTAL 2.4). The final *R* factor, based on 1864 observed reflexions, was 0.072. $R_w = 0.044$. Further details of the crystal structure investigations are available on request from the Director of the Cambridge Crystallographic Data Center, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW (UK).
[11] The error limits for the activation parameters represent 90% confidence limits in the rate constants.
[12] While an *o*-quinodimethane intermediate is a plausible proposal in view of the structural analogy of isolated complexes [13–15], other intermediates, e.g. an η^6-arene diradical complex, cannot be excluded as yet. Likewise, the entropy effect could result from a transition state with more (zwitter)-ionic character.

[PhLiNCH$_2$CH$_2$NLiPh] · 3HMPA, a Monomeric Dilithiumethylenediamide Complex with N_2Li_2 Double Bridging: Synthesis, Crystal Structure, and Model MO Calculations**

By *David R. Armstrong, Donald Barr, Alan T. Brooker, William Clegg, Karina Gregory, Susan M. Hodgson, Ronald Snaith,** and *Dominic S. Wright*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

We have recently begun to investigate the lithiation of amines having heteroatom groups (e.g., Me_2N,[1a] MeO,[1b] >C=S[1c]) nearby (α,β,γ) their NH centers. The aim has been to probe the inter- and intra-molecular involvements that these heteroatoms may have with the *N*-attached Li in the resulting lithium amide structure.[2] For example, in the structure of [{PhCH(CH$_2$OMe)}$_2$NLi]$_2$ the MeO-side arms merely add to the coordination sphere of the Li centers in their (NLi)$_2$ ring.[1b] In contrast, in the dilithiated thiourea [PhNLiC(=NPh)SLi·2HMPA]$_2$ the >C=S moiety becomes much more crucially involved: the monomeric units contain both N(μ_2-Li)N and S–Li bonds, these monomers then associating through N → Li coordinations.[1c] As part of this study, it was of interest to dilithiate a diamine, i.e. a precursor whose heteroatom group is a further N(H). In particular, it seemed likely that the two $N^{\delta\ominus}$ centers generated after dilithiation would become mutually involved with the two $Li^{\delta\oplus}$ centers. This would be the di-heteroatom equivalent of the double bridged C_2Li_2 "ion-triplet" structures shown, through the many studies (theoretical and experimental) of *Schleyer* et al.[2a, 3–5] and *Streitwieser* et al.,[6] to be frequently adopted by dilithiated hydrocarbons.

Here we describe the results of dilithiating *N,N'*-diphenylethylenediamine, PhHNCH$_2$CH$_2$NHPh, in the presence of hexamethylphosphoric acid triamide [HMPA, O=P(NMe$_2$)$_3$], which leads to the dilithium diamide **1**. The crystal structure of the product, **1**, reveals a monomeric binuclear complex containing the anticipated N_2Li_2 double bridging and, in addition, a Li(μ_2-O)Li bridge provided by one of the HMPA ligands.

[PhLiNCH$_2$CH$_2$NLiPh] · 3HMPA **1**

Prior to the experimental work, ab initio MO calculations (at the 6-31G basis set level) were performed on the model species ethylenediamine as well as on the *N*-mono and *N,N'*-dilithiated derivatives. The minimum energy optimized structures (confirmed by frequency analysis using the complete harmonic force constants) are shown in Figure 1; these structures were freely optimized, without symmetry constraints. The amine itself adopts a *gauche*-like structure, with the –NH$_2$ and –CH$_2$ groups being slightly twisted relative to each other (Fig. 1a). In the mono-lithium derivative, this orientation persists, but the key finding is that the Li involves itself with *both* N centers (Fig. 1b). Such involvement is asymmetric, with a short (H)$N^{\delta\ominus}$–$Li^{\delta\oplus}$ distance of 1.784 Å and a much longer (H$_2$)N–$Li^{\delta\oplus}$ one of 2.032 Å. The optimized structure of HLiNCH$_2$CH$_2$NLiH (Fig. 1c) confirms the anticipated N_2Li_2 double bridge arrangement. The two

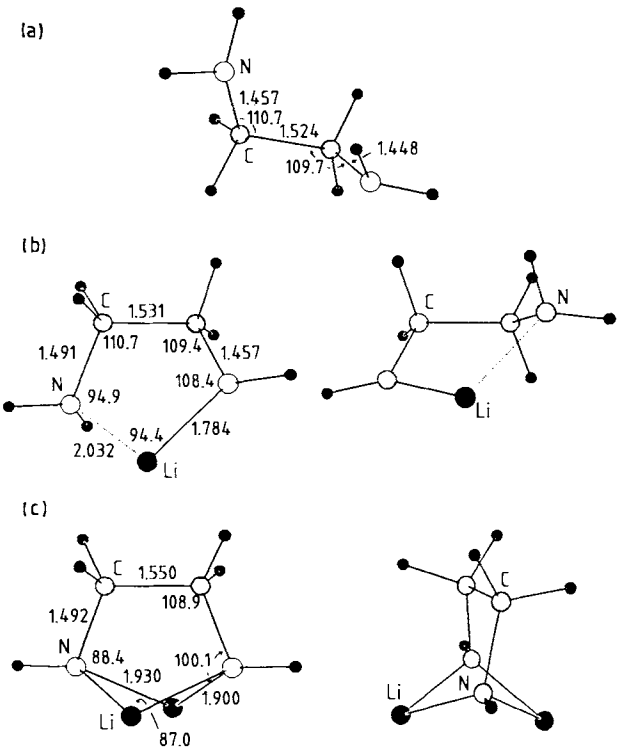

Fig. 1. Bond distances [Å] and angles [°] of the ab initio (6-31G) optimized structures of a) H$_2$NCH$_2$CH$_2$NH$_2$, b) HNLiCH$_2$CH$_2$NH$_2$, and c) HNLiCH$_2$CH$_2$NHLi.

$Li^{\oplus}$ centers sit on either side of the HNCH$_2$CH$_2$NH framework, so forming an Li_2N_2 "butterfly". However, this situation is again asymmetric, with each $Li^{\oplus}$ having distances to two N centers of 1.900 and 1.930 Å. The asymmetry seems to be caused by the continued slight twist of the CH$_2$ groups relative to each other: when C_{2v} symmetry is imposed, making the CH$_2$ groups equivalent (i.e., eclipsed), the resulting structure, with all N–Li distances equal (1.906 Å), is slightly less stable (by 1.2 kcal mol^{-1}).

In the experimental study, PhHNCH$_2$CH$_2$NHPh in hexane/toluene was allowed to react with two equivalents of *n*-butyllithium in the presence of just two equivalents of HMPA. In fact, the tris-complexed dilithium diamide, **1**, was isolated (see *Experimental*). The molecular structure of **1**, determined by X-ray diffraction,[7] is shown in Figure 2. As predicted by theory, the two $Li^{\oplus}$ ions are positioned on opposite sides of the NCH$_2$CH$_2$N dianion framework. The four N–Li distances fall into two sets, each Li having a short and a long bond to two N centers [Li(1)–N(1) 2.055(8), Li(1)–N(2) 2.137(7) Å; Li(2)–N(1) 2.146(9), Li(2)–N(2) 2.088(8) Å]. Two HMPA ligands are attached terminally to the Li atoms [Li(1)–O(2) 1.888(6), Li(2)–O(3) 1.868(7) Å]. The third HMPA ligand bridges these metal atoms so that

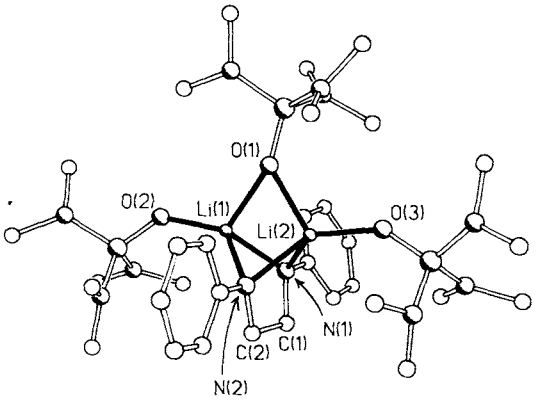

Fig. 2. Molecular structure of **1** [7].

the core of the molecule can be viewed as three co-fused "butterflies" (one NLi_2N, two OLi_2N frameworks). The bridging O–Li distances are also unequal, the shorter one involving Li(2) [Li(1)–O(1) 2.068(9), Li(2)–O(1) 1.994(7) Å]; perhaps significantly, the summed or mean N–Li distances are rather longer for Li(2) than for Li(1).

The structure of **1** (to our knowledge, the first dilithiated diamide to be so characterized) fits clearly into the pattern established earlier for dilithiated hydrocarbons. In particular, numerous studies have shown a marked preference for double bridged C_2Li_2 arrangements, e.g., by theory for species such as dilithiopropene[3, 5, 6] and by crystallography for species such as *o,o'*-dilithiobiphenyl.[2a, 4, 5] The explanation[6] of such a preference is based on simple electrostatics: a doubly bridged $Li^{\oplus}(C^{\ominus}\cdots C^{\ominus})Li^{\oplus}$ "ion triplet", having four attractive $Li^{\oplus}\cdots C^{\ominus}$ terms and only two repulsive terms ($Li^{\oplus}\cdots Li^{\oplus}$, $C^{\ominus}\cdots C^{\ominus}$), will have electrostatic stability except when one set of charges is quite far from the other (specifically, when $R_{--}/R_{++} < 0.14$ or > 6.9, R being the charge-charge distance). In **1**, the core can be considered as a collection of three ion-triplets, one $Li^{\oplus}(N^{\ominus}\cdots N^{\ominus})Li^{\oplus}$ and two $Li^{\oplus}(N^{\ominus}\cdots O^{\delta\ominus})Li^{\oplus}$. The Li(1)–Li(2) distance (2.286(8) Å) is one of the shortest known; the closest analogy is with the O_2Li_2 ring dimer $[Me_2PCH_2CtBu_2OLi]_2$ ($Li\cdots Li$, 2.30 Å),[8] though even shorter contacts (ca. 2.20 Å) occur in the complicated Li_8 core of $(o\text{-}LiC_6H_4CH_2NLiCH_2CH_2NMe_2)_4$.[1a] However, such a short distance does not reflect metal $\cdots$ metal bonding (the interaction is a repulsive one). It is rather, as described above, the balanced and optimized separation when taken in conjunction with the $N\cdots N$ distance [2.68(1) Å], the two $N\cdots O$ distances (mean, 3.14(1) Å), and the four N–Li and two O–Li ones.

The other significant feature of **1** is the incorporation of a third HMPA ligand; **1** is obtained whether two (one per Li), three, or four equivalents of HMPA are provided experimentally. Its presence, as an intramolecular bridging ligand, allows each Li to attain four-coordination. Several other examples of lithium structures (with both organic and inorganic anions) containing μ_2-HMPA ligands have been reported,[2a] e.g., the O_2Li_2 isomer of [Ph(2-py)NLi·HMPA]$_2$ (mean Li–O length 1.924 Å)[9a] and the cation of $[Li(H_2O)_2.HMPA]_2Cl_2$ (mean Li–O length 1.976 Å).[9b] However, in all of these examples the μ_2-HMPA operates intermolecularly, usually causing dimerization.

Experimental

1: *n*BuLi (2.5 mL of a 1.60 M solution in hexane, 4 mmol) was added under nitrogen to a chilled solution (−50 °C) of *N,N'*-diphenylethylenediamine (0.42 g, 2 mmol) in hexane/toluene (5 mL/5 mL) containing HMPA (0.72 g, 4 mmol). At room temperature a cloudy yellow solution was obtained. After filtration, the filtrate was stored in dry-ice, producing an oil from which small crystalline blocks formed. These were filtered, washed with hexane, and identified as **1**, [yield 0.70 g (69% based on 4 mmol HMPA), m.p. 141–143 °C; correct elemental analysis. ^{1}H NMR (C_6D_6, 250 MHz, 20 °C) δ = 7.39 (t, 4H), 6.80 (d, 4H), 6.52 (t, 2H), 3.70 (s, 4H, $(CH_2)_2$), 2.35 (d, 54H, 3HMPA). Single crystals suitable for X-ray crystallography were sealed under N_2 in Lindemann capillary tubes prior to data collection.

The ab initio optimized geometries described were obtained from the computer program GAMESS [10] using the 6-31G basis set [11]. The total energies (in a.u.) calculated for the optimized structures of $H_2NCH_2CH_2NH_2$, $HNLiCH_2CH_2NH_2$, and $HNLiCH_2CH_2NHLi$ are −189.19058, −196.08025, and −202.98654 respectively.

Reversible Photoisomerization of Ketene to Ethynol**

By *Remo Hochstrasser* and *Jakob Wirz**

Ethynol and substituted hydroxyacetylenes have been characterized in recent years by tandem mass spectrome-

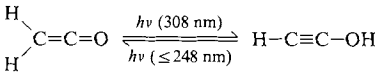
[**] This work is part of project No. 2000-5.515 of the Swiss National Science Foundation. Support by Ciba-Geigy SA, Sandoz SA, F. Hoffmann–LaRoche & Cie. SA, the Ciba-Stiftung, and the Stipendienfonds der Schweizerischen Chemischen Industrie is gratefully acknowledged.

try,[1] matrix IR spectroscopy,[2] and flash photolysis in aqueous solution.[3] They were generated by cycloreversion reactions induced by electron impact[1] and thermal[2a] or photochemical[2b, 3] activation of suitable precursors. We now report that prolonged irradiation of matrix-isolated ketene with 308-nm pulses from a XeCl excimer laser cleanly yields ethynol which is free from the perturbing effects of eliminated fragments such as CO in the matrix cage. The reverse photoisomerization of ethynol to ketene takes place upon deep-UV irradiation (248, 222, or 185 nm), as reported previously (Scheme 1).[2b]



Scheme 1.

Ketene was generated by pyrolysis of acetic anhydride,[4] mixed with 200 to 500 parts of argon, and matrix-isolated on a CsI target window which was held at 23 K in order to allow annealing of the matrix during the deposition. The sample was then cooled to 12 K and its FTIR spectrum recorded in the range of 3630 to 630 cm^{-1} at a resolution of 0.2 cm^{-1} using a mercury-cadmium-telluride (MCT) narrow-band detector cooled with liquid nitrogen. Six different isotopomeric mixtures of acetic anhydride were prepared by allowing sodium acetate to react with $POCl_3$ in order to identify the six $^1H/^2H$ and $^{16}O/^{18}O$ isotopomers of ketene.[5] The fundamental bands are listed in Table 1; the band positions of the three $^1H/^2H$ ketenes agree within a few cm^{-1} with those reported by *Moore* and *Pimentel*.[6]

Ketene exhibits a weak absorption band in the near UV; $\lambda_{max} = 310$ nm ($\varepsilon = 10\ M^{-1}\ cm^{-1}$),[7] where ethynol is expected to be transparent. Therefore, the samples were irradiated with a XeCl excimer laser (308 nm, 20 ns, 50 mJ per pulse) and the reaction progress was monitored by IR spectroscopy; irradiation for 5 d at pulse repetition rates of 20 Hz was necessary to convert about 90% of the starting material. Most of the new bands were readily attributed to the ν_1 to ν_5 bands of ethynol and its isotopomers (Table 2) by comparison with our earlier results.[2b] All of these bands gained in intensity with increasing irradiation dose and were free from site splittings; moreover, their intensity ratios remained constant throughout the experiment. Three new bands were identified as belonging to carbon monoxide (2138 cm^{-1} for $C^{16}O$ and 2087 cm^{-1} for $C^{18}O$) and to ethene (1439 and 952 cm^{-1}); some weak bands between 2110 and 1900 cm^{-1} could not be assigned. The OH group proved

[a] Broad (ca. 5-cm^{-1} width at half height). Based on the sum rule, this band is expected to lie at ca. 1049 cm^{-1}.

to be most sensitive to changes in the matrix environment: the O^1H stretching vibrations of the CO-complexed sites[2b] were red shifted by 90–130 cm^{-1} relative to that of isolated ethynol.

A DTGS detector (DTGS = deuterated triglycine sulfate) was used to monitor the region from 630 to 220 cm^{-1}; here the resolution had to be kept at 1 cm^{-1} in order to avoid interference caused by vibrations of the closed-cycle He-refrigerator. The spectral changes arising from the photolysis of ketene were, however, too small to allow an unambiguous identification of the ethynol bending modes ν_6 to ν_9. Higher concentrations of ethynol could be built up by irradiation of hydroxycyclobutenedione,[2b] but this reaction gave rise to site splittings which could not always be cleanly resolved. Ranges for the position of the bending vibrations ν_6 to ν_9 are listed in Table 3. Some of these assignments remain questionable and it must be recalled that these values are perturbed by interaction of the ethynol molecules with the CO fragments in the matrix.

Table 3. Ranges of fundamental modes [cm^{-1}] below 630 cm^{-1} (including all sites; intensity designated as medium, weak, or very weak) of ethynol and its ^2H isotopomers formed by photolysis of hydroxycyclobutenedione.

	ν_6 (A′, δ(CCH))	ν_7 (A′, δ(CCO))	ν_8 (A″, γ(CCH))	ν_9 (A″, γ(CCO))

$^2HCCO^1H$	450–460(w)	380–390(vw) [b]	370–380(m) [b]	330–350(w)
$^2HCCO^2H$	450–460(w) [a]	290–300(vw)	370–380(m)	260–270(w)

[a] Not unambiguously identifiable due to overlap with the ν_6 band of the O^1H isotopomers present in the mixture. [b] Ranges of sites may be overlapping.

Two theoretical force fields for ethynol have been reported (3-31G[8a] and MP2/6-31G**[8b]). The observed band positions of the fundamental vibrations ν_1 to ν_5 of all isotopomers agreed within 2% with those calculated[9] from the purely ab initio (unscaled) harmonic force field obtained by the second calculation.[8b] The five highest diagonal elements of the computed force field were then adjusted to fit the experimental data of Table 1. The resulting semiempirical force constants[10] gave satisfactory agreement (40 data pairs, 15-cm^{-1} standard deviation). Further adjustment of cross terms did not significantly improve the quality of the fit. Relatively large deviations were found for the O^1H/O^2H ratio of the stretching mode ν_1 (found 1.35, calculated 1.40; presumably due to anharmonicity effects) and for the C≡C

stretching modes ν_3 of $^2HCC^xO^yH$. The latter deviations may be attributed to Fermi coupling of $2\nu_4$ with ν_3, which is negligible when the acetylenic hydrogen is not labeled. This is also borne out by significant deviations from the sum rule in the ν_3 bands and by the fact that these are red shifted by ca. 60 cm^{-1} upon complexation with CO[2b] for $^2HCC^xO^yH$, whereas the corresponding bands for the $^1HCC^xO^yH$ isotopomers are shifted by only 7 cm^{-1}.

By combining the vibrational data obtained in this work with the theoretical rotational constants,[8b] a reliable estimate for the absolute entropy, $S_m^\ominus$ (298 K) = 250 J $K^{-1}mol^{-1}$, and the thermal heat content, $H_m^\ominus$ (298 K) − $H_m^\ominus$ (0 K) = 12.8 kJ mol^{-1}, of gaseous ethynol can be made using standard statistical mechanics. The entropy change for the conversion of ketene[6b] to ethynol is calculated to be $\Delta_r S_m^\ominus$ (298 K) = 8 J K^{-1} mol^{-1}.

Our experiments establish that ethynol is formed by photolysis of ketene in an argon matrix. The following observations suggest that this reaction takes place via decarbonylation of ketene, followed by insertion of CO into the C–H bond of methylene. 1) The quantum yield of ketene photoenolization in the matrix is quite low, $\phi \approx 10^{-3}$.[11] Decarbonylation of ketene is known to occur with high quantum yield upon 308-nm photolysis in the gas phase.[12] Presumably, the in-cage recombination of the primary fragments CH_2 and CO yields predominantly ketene rather than ethynol. 2) Irradiation of matrix-isolated methylketene yields CO and ethene exclusively, as expected if methylcarbene is the primary photoproduct formed by decarbonylation. 3) The reaction of parent ketene is clean at sufficiently high dilution. At lower host/guest ratios, dimerization of two methylene fragments to ethene becomes increasingly important.

Oxirene, oxiranylidene, and formylmethylene have been considered as possible intermediates in isomerization reactions of ketene and ethynol.[13] The same species may play a role in the Wolff rearrangement.[14] We find no evidence for the occurrence of such intermediates in the reversible photoisomerization of ketene to ethynol in an argon matrix at 12 K.

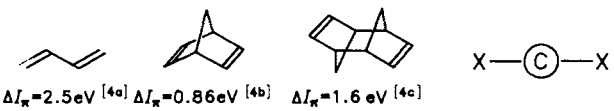
The Bicyclo[1.1.1]pentane Framework—an Excellent Relay for π/σ Conjugation**

By *Rolf Gleiter,* Karl-Heinz Pfeifer, Günter Szeimies,** and *Uwe Bunz*

Dedicated to Professor Franz Effenberger on the occasion of his 60th birthday

A convenient measure for the interaction of two π moieties, such as two vinylene units, is the energy difference between their occupied π MOs. This interaction can be a direct one (through space)[1] or it can be mediated via a σ skeleton (through bond)[1, 2]. By means of He(I) photoelectron (PE) spectroscopy, such an interaction can be measured. If the validity of Koopmans' approximation is assumed,[3] the above effects can be directly observed in the PE spectra. Examples of conjugation, homoconjugation, and through-bond interaction are shown in Scheme 1, together with the corresponding splitting, ΔI_π, of the ionization energies assigned to the π MOs.[4]



1 2 3 4

Scheme 1.

Instead of a σ bond connecting two π systems, one can also use a rigid σ skeleton of a bicyclic system as shown in **4**. Recent experiments with cubane,[5a] bicyclo[2.2.1]heptane,[5b] and bicyclo[2.2.2]octane[5c] as central unit, with two bromine atoms or two ethynyl moieties as X, showed only a very small splitting.[5]

Here we report that the splitting is large when the bicyclo[1.1.1]pentane framework is used as a relay. To demonstrate this, we show in Figure 1 the PE spectra of bicyclo[1.1.1]pentane[6a] (**5**), 1,3-diethynylbicyclo[1.1.1]pentane[6b] (**6**), and 1,3-dibromobicyclo[1.1.1]pentane[6c] (**7**). For comparison we also list in Table 1 the PE data of 1-ethynyl-

bicyclo[1.1.1]pentane[8a] (**8**) and 1-bromo-3-*tert*-butylbicyclo[1.1.1]pentane[6d] (**9**).

A comparison between the calculated results[9] (Table 1) and the PE data suggests that the first two peaks (bands ①, ②, and ③, ④) in the PE spectrum of **6** can be assigned to the ionizations from the π MOs 2e″ and 4e′. The small splitting of the peaks (Jahn–Teller effect) confirms this assignment. The same assignment is given for the first four bands in the PE spectrum of **7**. Here the ^{2}2E″ and the ^{2}4E′ states are split by 0.2–0.3 eV owing to the spin–orbit coupling usually observed for bromine compounds.[12] Both **6** and **7** show an energy splitting between ^{2}2E″ and ^{2}4E′ of about 0.7 eV, which indicates a considerable interaction between the π units.

Table 1. Comparison between the vertical ionization energies $I_{v,j}$ for **5**–**11** and the calculated orbital energies ε_j. All values in eV.

[a] The assignment and the calculated orbital energies refer to 1-bromo-3-methylbicyclo[1.1.1]pentane.

This splitting is due to a difference in the interaction between the valence MOs of **5** with the π MOs of the substituents. The assignment of the PE spectrum of **5** yields five close-lying MOs (2a″, 3e′, 1e″) with high 2p character (see Table 1, Fig. 2). For reasons of symmetry only 1e″ and 3e′

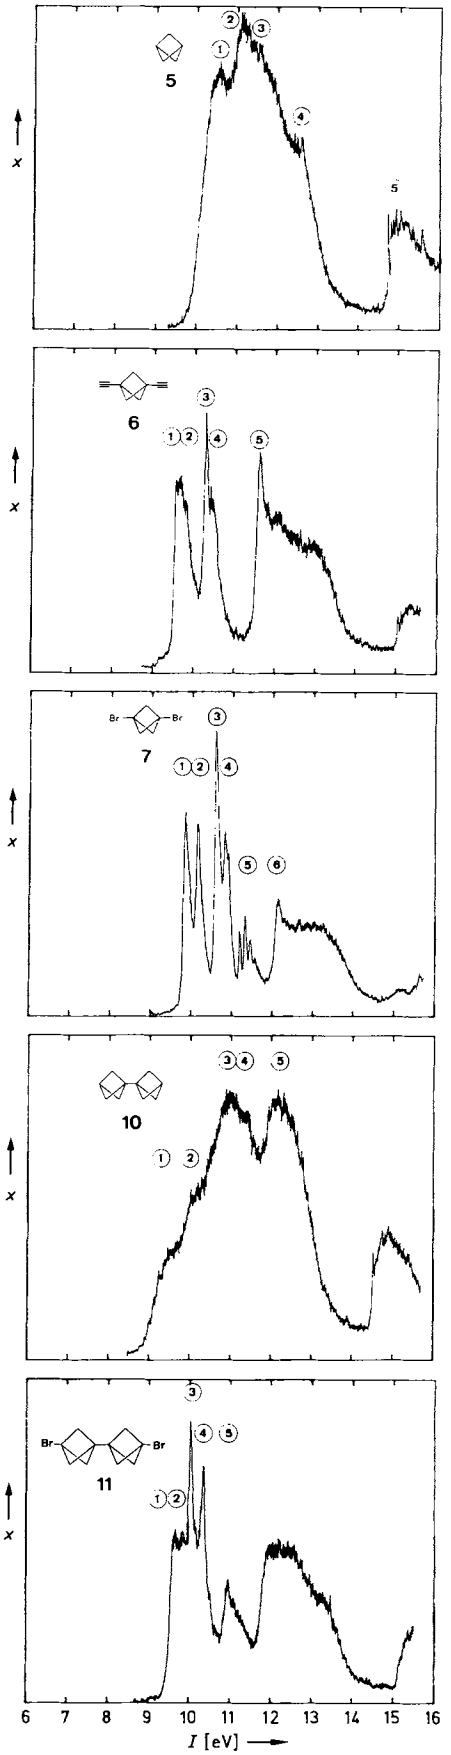

Fig. 1. He(I) PE spectra of **5**–**7**, **10**, and **11**. x = count rate.

interact with the π MOs of the substituents in **6** and **7**. Owing to the localization of e″ at the carbon skeleton only, the interaction between e″ (π) and e″ (σ) is stronger than the interaction between the two e′ linear combinations.

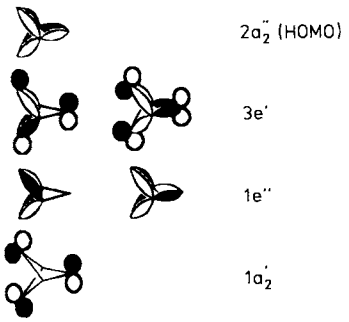

Fig. 2. Schematic drawing of the highest occupied MOs of **5**.

In view of efforts to use the bicyclo[1.1.1]pentyl moiety as a building block for oligomers,[13] it was also of interest to study the PE spectra of 1,1′-bi(bicyclo[1.1.1]pentane)[8b] (**10**) and 3,3′-dibromo-1,1′-bi(bicyclo[1.1.1]pentane)[6c] (**11**) (Fig. 1, Table 1). Our investigations of **10** reveal a region between 9 and 13 eV with strongly overlapping bands. The MO calculations carried out on **10** show that the valence MOs of **10** corresponding to these bands[3] can be described as linear combinations of those of **5** (Table 1). For **11** we notice a broad band on top of which are two small peaks (① and ② in Fig. 1, bottom) followed by two sharp peaks (③ and ④). The first broad peak is assigned to $5e_g$. The corresponding wave function is predicted to be a mixture between 4p orbitals at the bromine centers and large coefficients at the carbon skeleton (Fig. 3). This explains why the spin–orbit coupling is difficult to detect. The two sharp peaks are due to a spin–orbit splitting of the $5e_u$ band. The wave function of the latter is mainly centered at the bromine atoms (Fig. 3). Based on this interpretation, the splitting between $5e_g$ and $5e_u$ is 0.4 eV, indicating also good relay properties for the bi(bicyclo[1.1.1]pentane) unit. This effect is also important in view of energy-transfer processes via a σ skeleton.[14]

A Stable Triradical Compound and its Unusual Magnetic Properties**

By *Lothar Dulog** and *Jeong Soo Kim*

Organic ferromagnetism is a subject of current controversy, and several theoretical models for it have been proposed.[1] The spin polarization model of *McConnell* and the spin multiplicity of the ground state have been used to explain organic ferromagnetism.[2] A spin multiplicity different from 1 is much more difficult to obtain for organic compounds than for inorganic compounds, since the former usually possess low symmetry and orbital orthogonality. Here we report on the synthesis and unusual magnetic properties of compound **4**, which contains three stable $^{\ominus}O\text{–}\overset{\oplus}{N}R = CR'\text{–}NR'' \dot{-} O$ units ("nitronyl nitroxide" radicals) in a single molecule.

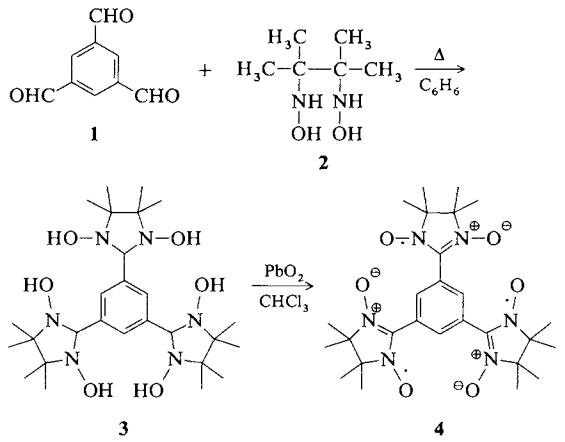
[**] We thank Prof. Dr. *A. Simon* and Dr. *R. Kremer*, Max-Planck-Institut für Festkörperforschung, for the measurements of magnetic susceptibility.

To generate the triradical compound **4**, we used the known condensation reaction between an aldehyde (**1**) and a hydroxylamine (**2**), followed by oxidation (**3** → **4**) with lead dioxide.[3]



The product, **4**, is a blue powder, which is readily soluble in chloroform and dichloromethane. We have not found further solvents for **4** and have been unsuccessful in growing crystals of **4**.

The ESR spectrum of a dilute solution of **4** displays a broad maximum, which indicates strong intramolecular spin–spin interaction (Fig. 1).

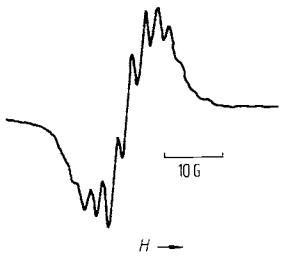


Fig. 1. ESR spectrum of triradical **4** in chloroform ($c = 3.38 \times 10^{-5}$ mol L^{-1}).

The magnetic susceptibility of **4** is very unusual. It shows strong deviations from the Curie law and surprisingly high values at high temperatures (Fig. 2). The findings can be explained neither by ferromagnetism nor by antiferromagnetism. Such properties are unknown for organic compounds and rarely observed for transition-metal complexes.

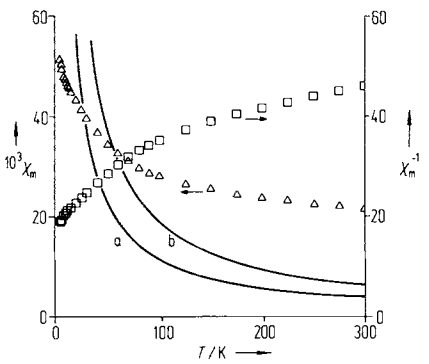

Fig. 2. Molar susceptibility (left axis, △) and reciprocal molar susceptibility (right axis, □) of **4** at a field strength of 10 000 Gauss. a) Theoretical curve for χ_m according to the Curie law with three radical centers per molecule. b) Theoretical curve for χ_m according to the Curie law for an $S = 3/2$ ground state. Unit of χ_m: 10^{-6} m^3 mol^{-1} = emu mol^{-1}.

The effective spin per molecule is larger than the theoretical value of 3.87 (without spin–orbit coupling) for $S = 3/2$ metal atoms (Fig. 3). Because of the weak spin–orbit coupling between the spin and the p orbital, we presume that this coupling can be nearly neglected for **4**. The molar susceptibility of triradical **4** shows field-strength dependence, which is not characteristic of usual paramagnetism (Fig. 4).

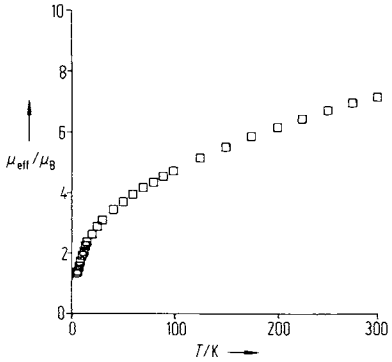

Fig. 3. Effective spin per molecule of **4** at a field strength of 10 000 Gauss.

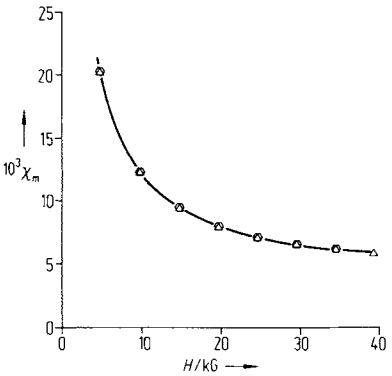

Fig. 4. Field-strength dependence of the molar susceptibility of **4** at 270 K. Susceptibility determined for increasing field strength (△) and for decreasing field strength (○).

In order to interpret the high molar susceptibility as a property of **4**, it is necessary to rule out the presence of ferromagnetic impurities introduced by the oxidizing agent, lead dioxide. Reaction of **4** with HCl gas results in an equilibrium between **4** and its "hydrochloride", which only contains nitroxyl radicals.[3] After reaction for three hours, 71% of the initial molar susceptibility is still found, as observed earlier for other $^{\ominus}O-\overset{\oplus}{N}R = CR'-NR'' \doteq O$ radicals.[3] By contrast, ferromagnetic particles in lead dioxide are rapidly reduced by HCl vapor and show no noticeable susceptibility after three hours. The susceptibility remaining after treatment of **4** with HCl indicates that the high susceptibility is indeed a property of **4**.

Elemental analysis of **4** left no ash. The molecular mass determined by vapor-pressure osmometry was 559.02 g mol^{-1} (calcd 543.64 g mol^{-1}). A molecular mass of 543.2921 g mol^{-1} was obtained from the mass spectrum. The hydroxylamine **3** can also be oxidized with diamagnetic sodium periodate; the resulting triradical **4** also exhibits high susceptibility, greater than the value calculated for a paramagnetic substance.

The magnetic properties of **4** appear to be similar to those of some low-symmetry or noncrystalline inorganic compounds, such as FeF_3. The unusual properties of these inorganic compounds have been explained in terms of the antiferromagnetic interaction in the lattice and the ferromagnetic interaction between the lattices.[4] Extension of this explanation to **4** would mean that, in **4**, an intramolecular antiferromagnetic and an intermolecular ferromagnetic interaction are present.

A quantitative explanation of the molar susceptibility of **4** might be possible in terms of the intermolecular ferromagnetic spin polarization perpendicular to the benzene plane and a weak intramolecular antiferromagnetic interaction. Further investigations are in progress.

The magnetic susceptibility of **4** at room temperature varies from 16 to 57×10^{-3} emu mol^{-1} depending on the pretreatment, whereas the calculated value is 3.75×10^{-3} emu mol^{-1}. This may support the explanation proposed above.

Experimental Procedure

1: 1,3,5-Benzenetricarboxylic acid was converted into 1,3,5-benzenetricarbonyl chloride, which was then hydrogenated with $Pd/BaSO_4$ as catalyst to give **1**; see [5].

2: 2-Nitropropane was coupled to give 2,3-dimethyl-2,3-dinitrobutane, which was then reduced with Zn/NH_4Cl to **2**; see [6].

Compounds **1** (0.50 g, 3.08 mmol) and **2** (1.40 g, 9.44 mmol) were placed in 150 mL of benzene. The vigorously stirred reaction mixture was then heated while N_2 was admitted. The water thereby formed was removed. Slow cooling of the solution resulted in precipitation of **3**. The crude product was collected by filtration and, after drying, could be used in subsequent reaction. Yield: 0.75 g (44%). IR(KBR): $\tilde{\nu} = 3440$, 2980, 1450, 1370, 1160 cm^{-1}. ^1H NMR(60 MHz, CD_3OD): $\delta = 1.37$ (s, 12 CH_3), 3.40 (br., 3 CH), 5.00 (s, 6 OH), 8.83 (s, C_6H_3).

4: The crude product **3** (0.1 mg) was suspended in 10 mL of chloroform and 1.5 g of lead dioxide was added. The reaction mixture was then vigorously stirred at room temperature and the lead dioxide subsequently separated. After removal of chloroform in vacuo, **4** was isolated as a dark blue powder. The oxidation was quantitative. Purification of **4** was accomplished by redissolving it in chloroform and adding benzene dropwise to the gently stirred solution. The blue powder reprecipitated. IR(KBr): $\tilde{\nu} = 3100$, 2980, 2930, 1450, 1265, 1210, 1170, 1130, 860, 670 cm^{-1}. MS(70eV): *m/z* (%) 543 (2.2; $M^{\oplus}$), 527 (1.8; $M^{\oplus} - O$), 511 (2.0; $M^{\oplus} - O_2$), 480 (3.8; $M^{\oplus} + 1\text{–}2O_2$), 465 (4.4; $M^{\oplus}\text{–}NO_2\text{–}O_2$), 450 (31.1; $M^{\oplus}\text{–}1\text{–}2\ NO_2$), 433 (15.6; $M^{\oplus}\text{–}NO_2\text{–}2O_2$). Elemental analysis: found C 59.45, H 7.25, N 15.02; calcd C 59.65, H 7.23, N 15.46.

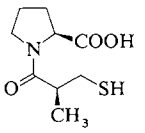
Isolation of an L-Stereospecific *N*-Acyl-L-proline-Acylase and its Use as Catalyst in Organic Synthesis**

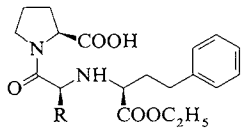
By *Ulrich Groeger,** *Karlheinz Drauz*, and *Herbert Klenk*

Dedicated to Professor Franz Effenberger on the occasion of his 60th birthday

The importance of the amino acid L-proline has increased tremendously in the past few years. Aside from the now already classical use of L-proline and its derivatives in asymmetric synthesis,[1] L-proline is a constituent of the three most important ACE (angiotensin converting enzyme) inhibitors captopril **1**, enalapril **2a**, and lisinopril **2b**, which count among the world's most successful antihypertensive agents. The demand for L-proline is currently satisfied by fermentation methods[3] as well as by the hydrolysis of gelatins and extractive recovery of the proline with ion-exchangers.[2]



1



2a: R = CH_3
2b: R = $(CH_2)_4\text{–}NH_2$

Although some good syntheses are known for D,L-proline,[2, 4a] the usual route of racemate resolution (either via separation of diastereomeric pairs of salts or via an enzymatic cleavage of suitable precursors[5]) used in the case of many amino acids could thus far not be realized in the case of L-proline. Even transformations of other chiral amino acids into L-proline have not, as yet, acquired any importance as preparative methods.[6] Our interest therefore focused on an enzyme system with which L-proline should be obtainable from an *N*-acyl-D,L-proline precursor.

Enrichment cultures of a sewage clarifier sample led to selection of the microorganism *Comamonas testosteroni* DSM 5416. Upon growth in the presence of *N*-acetyl-L-proline, this bacterium produces an enzyme which hydrolyzes *N*-acetyl-L-proline. This *N*-acyl-L-proline-acylase was enriched 53-fold with a yield of 50% from the cell-free extract by heat treatment, membrane filtration, and ion-exchange chromatography. The enzyme, with a molecular weight of 380 000 ± 40 000 Da is made up of eight identical subunits (molecular weight 45,000 ± 5,000 Da). The enzyme does not only exhibit a good pH-stability (four weeks at room temperature in the pH range 5–10) but also a remarkable temperature stability (30 min at 70 °C and pH 7.5). A pH of 6.8 ± 0.5, a temperature of 65 °C and a K_M value of 5 mM [0.1 M 2-amino-2-(hydroxymethyl)propane-1,3-diol(tris)-HCl, pH 7.0; 30 °C] were found to be optimal for the resolution of *N*-acetyl-L-proline. Figure 1 shows plots of the hydrolysis versus time of *N*-acetyl-L-proline, *N*-acetyl-D,L-proline and *N*-acetyl-D-proline.

The enzyme hydrolyzes *N*-acetyl-L-proline stereospecifically. After 2 hours the conversion of *N*-acetyl-L-proline was quantitative, that of *N*-acetyl-D,L-proline 48% (theoretically 50%). *N*-acetyl-D-proline was not hydrolyzed. This permits

[**] Amino Acid Transformation, Part 4.—Part 3: H.-P. Krimmer, K. Drauz, A. Kleemann, *Chem.-Ztg. 111* (1987) 357.

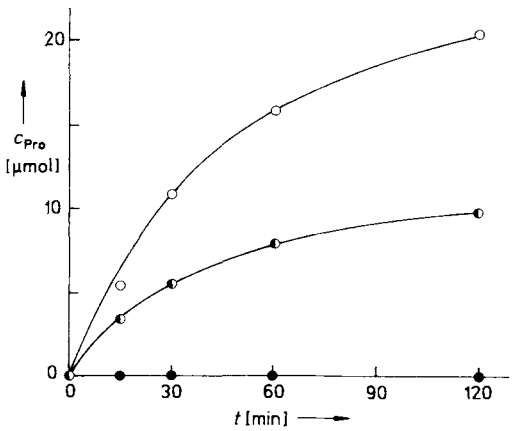

Fig. 1. Reaction kinetics of the hydrolysis of *N*-acetyl-L-proline (○), *N*-acetyl-D,L-proline (◐), and *N*-acetyl-D-proline (●). The reaction mixture (2 mL) contained 0.2 mmol of tris-HCl pH 7.0, 20 μmol of substrate, and 0.4 U of purified *N*-acyl-L-proline-acylase from *Comamonas testosteroni* DSM 5416. The specific activity of the purified enzyme was 85.2 U mg^{-1} at 30 °C and pH 7.0 with *N*-acetyl-L-proline as substrate. One unit (U) of the enzyme activity corresponds to the amount of enzyme which catalyzes formation of 1 μmol of proline per minute. The reaction mixture was incubated at 30 °C and treated for the quoted times with one aliquot of 10% (w/v) trichloroacetic acid. The precipitated protein was centrifuged off (10 min, 11 000 pm), the supernate diluted 1:5 or 1:50 with a 0.1 M citrate buffer, 0.1% (v/v) phenol, 0.5% (v/v) thiodiethanol, pH 2.2, and the resulting proline quantified with a Biotronic LC 5001 amino acid analyzer. The enzyme activity was determined in the usual way by ninhydrin detection of the reaction product L-proline according to the method of *Yaron* and *Mlynar* [7].

an enzyme-catalyzed racemate resolution of D,L-proline via *N*-acetyl-D,L-proline, a technique analogous to that already used for the industrial production of L-amino acids employing an aminoacylase from *Aspergillus oryzae*;[8] However, this technique could not be used for the recovery of L-proline, since the aminoacylases known so far do not hydrolyze *N*-acyl-L-proline because of their substrate specificity.[9]

The following *N*-acetyl- and *N*-chloroacetyl-amino acids are converted by the *N*-acyl-L-proline-acylase: *N*-acetyl-L-proline (relative activity ≡100) *N*-acetyl-L-alanine (9) *N*-chloroacetyl-L-proline (362), *N*-chloroacetyl-L-thiazolidine-4-carboxylic acid (462), *N*-chloroacetyl-L-methionine (17), *N*-chloroacetyl-L-valine (14), *N*-chloroacetyl-L-leucine (2), *N*-chloroacetyl-L-phenylalanine (1), *N*-chloroacetyl-L-tyrosine (1). In the case of the following *N*-acetyl- and *N*-chloroacetylamino acids the relative activities are less than 1: *N*-acetyl-L-valine, *N*-acetyl-D,L-serine, *N*-acetyl-L-cysteine, *N*-acetyl-L-tyrosine and *N*-chloroacetyl-L-isoleucine.

These findings illustrate the high substrate specificity of the enzyme for acylated *L*-proline and its derivatives. Aside from the acyl-*D*,*L*-proline compounds, the *N*-acylthiazolidine-4-carboxylic acid readily accessible from cysteine and formaldehyde is also cleaved. This concomitantly opens up a novel entry to *L*-cysteine and *L*-cysteine derivatives by enzymatic racemate resolution.

The chloroacetyl compounds of *L*-proline and of *L*-thiazolidine-4-carboxylic acid are hydrolyzed respectively 3.6 times and 4.6 times more rapidly than *N*-acetyl-L-proline. This is consistent with findings for other aminoacylases, and is due to the electronegativity of the chloroacetyl group.[9] Table 1 shows further data for the substrate- and stereospecifity of the enzyme.

The derivatization of the carboxyl group of *N*-acetyl-L-proline results in a complete loss of the enzymatic activity, from which it can be presumed that this group is essential for the binding of the substrate to the enzyme. On introducing an OH group into the 4-position of the proline the activity decreases by a factor of 10. *N*-Protecting groups of the urethane type are not hydrolyzed. The enzyme has no amidase activity, and only minimal peptidase activity.

Table 1. Substrate- and stereo-specificity of *N*-acyl-L-proline-acylase towards some proline compounds. The reactions were carried out under the conditions described in the caption to Figure 1. *N*-Ac-L-Pro-OH: relative activity ≡100.

Substrate	Relative activity
N-Ac-L-Pro-OH	100
N-Ac-D-Pro-OH	0
N-Ac-L-Pro-NH_2	0
N-Ac-L-Pro-OMe	0
N-Ac-L-Pro(4-OH)-OH	10
N-ClAc-L-Pro-OH	362
N-ClAc-L-thiazolidine-4-carboxylic acid	462
N-Z-L-Pro-OH	0
N-Z-D-Pro-OH	0
N-Z-L-Pro-NH_2	0
N-Boc-L-Pro-OH	0
H-L-Pro-NH_2	0
N-Ac-L-Ala-L-Pro-OH	0
N-Z-L-Pro-L-Ala-OH	0
N-Z-Gly-L-Pro-OH	11
H-L-Ala-L-Pro-OH	0
H-Gly-L-Pro-OH	4
H-L-Pro-Gly-OH	0

The enzyme is inhibited, in particular, by phosphate, 1,10-phenanthroline, 2-mercaptoethanol, 4-(chloromercurio)-benzoate, 4-(hydroxymercurio)-benzoate, $Hg^{2\oplus}$, $Cu^{2\oplus}$, $Fe^{2\oplus}$, $Fe^{3\oplus}$, $Sn^{2\oplus}$, and $Zn^{2\oplus}$ ions. An activation of the native enzyme by divalent metal ions was not observed, but the enzyme inactivated by 1,10-phenanthroline could be reactivated to 80% and 54% of the starting activity by addition of $Co^{2\oplus}$ and $Zn^{2\oplus}$ ions, respectively. This indicates that the *N*-acyl-L-proline-acylase from *Comanomas testosteroni* DSM 5416 is a cobalt- or zinc-dependent amidohydrolase, which according to the EC classification is assigned to the subgroup EC 3.5.1.[10]

The novel, thermostable *N*-acyl-L-proline-acylase from *Comamonas testosteroni* DSM 5416 is a highly specific and robust enzyme by which L-proline can be recovered from acyl-D,L-precursors. A similar enzyme from *Pseudomonas spec.* has been described by *Kikuchi* et al.[11]

This enzyme, however, is much more temperature-labile (rapid inactivation at 50 °C) and considerably larger (597,000–623,000 Da, ten to twelve identical subunits of 55,000 Da), and it has a noticeably higher peptidase activity (*N*-Z-Gly-L-Pro-OH is hydrolyzed 2.7 times and H-Gly-L-Pro-OH 1.2 times more rapidly than *N*-Ac-L-Pro-OH).

Facile Synthesis of 3-(ω-Haloalkyl)thiophenes as Key Building Blocks for Functionalized Thiophenes and Polythiophenes**

By *Peter Bäuerle,* Frank Würthner,* and *Stephan Heid*

Dedicated to Professor Franz Effenberger on the occasion of his 60th birthday

3-Alkylthiophenes containing a terminal leaving group in the alkyl chain are central intermediates for the synthesis of functionalized 3-alkylthiophenes and poly(3-alkylthienylenes), which are currently under intensive investigation.[1] The coupling of monomeric thiophenes to form conjugated polymers occurs at the 2- and 5-positions,[2] thereby allowing covalent attachment of functional groups via alkyl chains in the 3-position (or 4-position). Functionalized 3-alkylthiophenes were previously only accessible starting from 3-methylthiophene[3] or 3-(2-hydroxyethyl)thiophene[4] by a tedious sequence of chain-lengthening steps. Moreover, those with shorter alkyl chains are difficult to polymerize.[4a]

We have now developed a facile synthesis of 3-alkylthiophenes containing a terminal halogen substituent on an alkyl chain of length $n \geq 4$. These compounds may be used as key building blocks for the preparation of functionalized 3-alkylthiophenes and poly(3-alkylthienylenes).[5]

Since the use of 3-lithiothiophene in alkylation reactions is restricted,[6] the synthesis of 3-alkylthiophenes was approached via nickel-catalyzed Grignard couplings[7] of alkylmagnesium bromides with 3-bromothiophene, which is readily accessible by a new procedure.[8] The direct extension of this reaction to α,ω-dihaloalkanes, however, does not lead to the necessary mono-Grignard compounds.[9] On the other hand, the ω-(*p*-methoxyphenoxy)alkyl bromides **1**, easily prepared from α,ω-dihaloalkanes and hydroquinone monomethyl ether (HCM),[10] react readily with magnesium to give the corresponding Grignard compounds **2** [Eq. (a)]. Compounds **1a–e** (n = 4–6, 8, 10) undergo nearly quantitative Grignard reaction to afford **2a–e** (GC monitoring), whereas 3-(*p*-methoxyphenoxy)propyl bromide (**1**, n = 3),[10d] like 1,3-dihalopropanes, undergoes elimination on reaction with magnesium to yield cyclopropanes.[11]

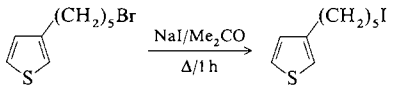
[**] Thiophenes, Part 1. This work was supported by the Volkswagen-Stiftung (AZ I/61584), the Deutsche Forschungsgemeinschaft, and Hoechst AG (donation of 3-bromothiophene). We thank Dr. *A. Bandi* (Universität Stuttgart) for the GC/MS(EI) analyses.

by chromatographic and distillative workup, halides **5** and **6** were obtained as analytically pure compounds in 51–76% yield[15] (Table 1). The 3-(ω-iodoalkyl)thiophenes **6** are also accessible by Finkelstein reaction[10] from bromides **5**, as was shown for the conversion of bromide **5b** to iodide **6b** (85% yield).



(d)

5b **6b**

The methods described here allow a two-step synthesis—with the exception of **6a**[4b]—of the previously unknown terminal bromine- and iodine-substituted 3-alkylthiophenes **5** and **6**, respectively, with chain lengths $n \geq 4$, starting from 3-bromothiophene (**3**).

General Experimental Procedure

4: Compound **1** (0.125 mol) in 40 mL of anhydrous ether was added under inert atmosphere to magnesium turnings (3.16 g, 0.13 mol) in 10 mL of ether. The reaction mixture was then refluxed for 5–6 h. The Grignard solution of **2** was subsequently transferred via cannula to a second apparatus and added dropwise at 0 °C to $NiDPPPCl_2$ (70 mg, 0.1 mol%) and **3** (17.2 g, 0.106 mol) over 1 h. The reaction mixture was refluxed for 12–15 h and afterwards hydrolyzed with 40 mL of 1 N HCl and 150 mL of ice water followed by extraction with several portions of ether. Washing to neutrality and drying of the combined organic phases and removal of the solvent in vacuo afforded a yellowish-white solid, which was recrystallized from *n*-hexane or methanol to give analytically pure **4**.

5: A mixture of HBr (48%; 20.2 g, 0.12 mol) and acetic anhydride (20.2 g, 0.198 mol) was added under inert atmosphere to **4** (0.02 mol) and the reaction mixture was heated at 100 °C for 20–25 h. After dilution with water, the mixture was extracted several times with ether and the combined organic phases were washed to neutrality with saturated $NaHCO_3$ solution. Drying of the organic phase and removal of the solvent afforded a yellow-brown oil, from which hydroquinone was precipitated by addition of an *n*-hexane/ether mixture. The solution was then filtered, transferred to a short silica gel column, and eluted with hexane. Removal of the solvent gave **5**, mostly analytically pure, as a colorless oil, which may be further purified by kugelrohr distillation.

6: A mixture of freshly distilled HI (57%; 26.9 g, 0.12 mol) and acetic anhydride (20.2 g, 0.198 mol) was added under inert atmosphere to **4** (0.02 mol) and the reaction mixture was heated at 80 °C for 15–25 h. After dilution with water, the mixture was extracted several times with ether and the combined organic phases were decolorized by treatment with a thiosulfate solution. Further workup was carried out as described for **5**.

CH Activation of Acetonitrile by Alkyl Compounds of the Early Lanthanoids: Dimeric Cyanomethyl-Lanthanoid Complexes with CH_2CN Bridges**

By *Hero J. Heeres, Auke Meetsma*, and *Jan H. Teuben**

Considerable progress has been made in the exciting field of CH bond activation of saturated and unsaturated hydrocarbons by highly electrophilic $d^0(f^n)$ organolanthanoids, actinoids and early transition metal compounds.[1] An outstanding example is the activation of the normally inert CH bonds of methane by complexes of the type Cp^*_2MMe ($Cp^* = \eta^5$-pentamethylcyclopentadienyl; M = Lu, Sc and Y).[2] Recently, we have shown that $Cp^*_2LnCH(SiMe_3)_2$ compounds (Ln = La and Ce) are efficient catalysts for the cyclodimerization of alkynes $MeC{\equiv}CR$ (R = Me, Et, *n*Pr) to substituted 3-alkylidenecyclobutenes.[3] The first step in the reaction sequence is a propargylic metalation of one of the relatively acidic methyl protons of $MeC{\equiv}CR$. This prompted us to study the interactions between Cp^*_2Ln-alkyl compounds and other substrates containing active C–H bonds. Initially, we focused our attention on nitriles containing at least one α-C–H bond. Metalated nitriles, well-known for group 1 elements,[4] are highly reactive species which are very useful intermediates in organic synthesis.[5] In this communication the novel and facile metalation of acetonitrile by pen-

1a, Ln = La — **2a**, Ln = La, n = 2 — **3**

1b, Ln = Ce — **2b**, Ln = Ce, n = 2

2a and **2b** were isolated as beautiful crystals (whitish and pink, respectively) in good yields (65–70%). Both compounds are only sparingly soluble in all the solvents investigated (THF, toluene, benzene, pentane). The compounds show almost identical IR spectra with cyanomethyl absorptions at 2140, 2120 and 2050 cm^{-1} (**2a**) implicating a somewhat reduced C≡N bond order.[6] The NMR spectrum of the diamagnetic compound **2a** ([D_8]toluene, 70 °C) shows two singlets at $\delta = 2.03$ and 0.55 for the Cp* and CH_2 protons respectively.

Interactions of nitriles with group 3, lanthanoid and actinoid alkyls and hydrides normally lead to insertion of the C≡N bond into the M–C or M–H σ-bond and the formation of monomeric or dimeric azomethine complexes.[7] Metalation of nitriles by these elements has hitherto not been observed. The compounds **2a** and **2b** represent the first examples of cyanomethyl compounds of the said elements.

To determine the bonding mode of the CH_2CN fragment, an X-ray diffraction study was conducted on the lanthanum species **2a** (Fig. 1).[8] **2a** crystallizes in dimeric units. Each

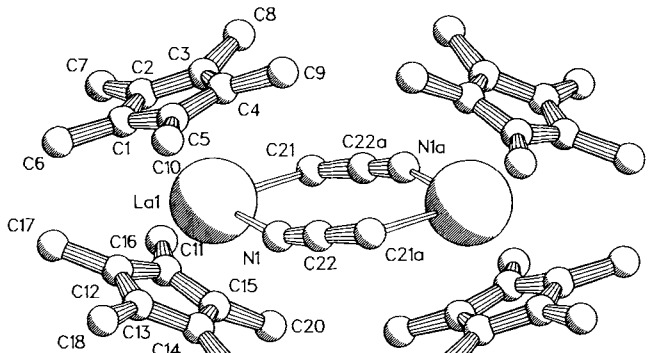

Fig. 1. Molecular Structure of $[Cp^*_2LaCH_2CN]_2$ **2a** (hydrogen atoms omitted for clarity). Selected bond lengths [Å] and angles [°]: La(1)-La(1A) = 5.8479(8), La(1)-C(21) = 2.748(4), La(1)-C(1) = 2.817(4), La(1)-C(2) = 2.808(4), La(1)-C(3) = 2.790(5), La(1)-C(4) = 2.802(5), La(1)-C(5) = 2.807(4), La(1)-N(1) = 2.537(4), N(1)-C(22) = 1.162(6), C(22)-C(21a) = 1.393(6) Å, N(1)-La(1)-C(21) = 95.7(1), N(1)-C(22)-C(21a) = 175.6(5), La(1)-C(21)-C(22a) = 105.6(3) La(1)-N(1)-C(22) = 157.5(4)°.

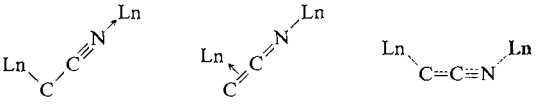
molecule consists of two Cp^*_2La units connected by two almost linear CCN fragments which form an eight-membered $La(CH_2CN)_2La$ ring in a chair conformation. Particularly interesting is the bonding situation of the bridging CH_2CN groups. The La–C(21) bond length (2.748(4) Å) is significantly longer than a pure La–C σ-bond (2.52–2.65 Å),[9] whereas the La–N(1) distance (2.537(4) Å) is much shorter than an La–N dative bond (ca. 2.77 Å).[10] Furthermore, the CCN units are almost linear (N(1)–C(22)–C(21a) = 175.6(5)°) with a short C(22)–C(21A) bond length of 1.393(6) Å. Hence, the bonding of the CCN unit is best described as intermediate between a *C*-metalated structure **A** and an *N*-metalated ketenimine **B**. Structures of type **B**, but



with both metal atoms coordinated to nitrogen, have already been detected in a number of dimeric lithiated nitriles,[11] whereas structures of type **A** are present in various square-planar late transition metal complexes.[12] To our knowledge, compound **2a** is the first structurally characterized example with a CCN coordination of type **C**. Interestingly, MNDO calculations by *Schleyer* et al. for unsolvated lithiated acetonitrile have predicted that an eight-membered $M(CH_2CN)_2M$ ring dimer, similar to what we actually observe for **2a**, is the most favorable structure.[13]

This study provides evidence that metalation of heteroatomic substrates containing active C–H bonds by alkyl(organo)lanthanoid compounds is well possible. In this regard, monomeric Cp^*_2Ln-alkyl compounds strongly resemble organic compounds of group 1 elements[5, 11] and indicate that the Ln–C σ-bonds in these compounds are very polar.

Experimental

2a: Acetonitrile (75 µL, 1.34 mmol) was added to a solution of 762 mg (1.34 mmol) of **1a** in benzene (15 mL). Upon standing at room temperature without stirring, colorless crystals of **2a** deposited. 397 mg (0.44 mmol, 66%) of **2a** could be isolated as beautiful, whitish crystals. IR (KBr/Nujol): $\tilde{\nu}$ [cm^{-1}] = 2710(w), 2140(s), 2120(sh), 2050(m), 1030(m), 1020(m), 800(w), 750(s), 670(w), 540(w), 440(m); ^1H NMR (300 MHz, [D_8]toluene, 70 °C): $\delta = 2.03$ (s, 30H; C_5Me_5), 0.55 (s, 2H; $LaCH_2$); ^{13}C NMR (75 MHz, [D_8]toluene, 50 °C): $\delta = 119.6$ (s; C_5Me_5), 11.2 (q, $^1J(C,H) = 124$ Hz; C_5Me_5), unequivocal assignment of the cyanomethyl carbon resonances was not possible.—Correct elemental analysis.

2b was prepared by a similar procedure and isolated as pink crystals in 72% yield. IR (KBr/Nujol): $\tilde{\nu}$ [cm^{-1}] = 2710(w), 2150(s), 2120(sh), 2060(m), 1030(m), 1020(w), 800(w), 750(s), 550(w), 460(m); ^1H NMR (300 MHz, [D_6]benzene, 30 °C): $\delta = 3.12$ (s, 30H, lw = 23 Hz; C_5Me_5), −45 (s, 2H, lw = 80 Hz; $CeCH_2$).—Correct elemental analysis.

Synthesis and Structure Determination of Bicyclic $[Li(tmeda)]_2[S_6]$***

By *Kazuyuki Tatsumi,* Yoshihisa Inoue, Akira Nakamura,* Roger E. Cramer,* William VanDoorne*, and *John W. Gilje*

Despite the recognized potential of the lithium–sulfur battery as a high-energy density power source,[1] there are so far no well characterized examples of lithium sulfides. In the binary lithium–sulfur system, only Li_2S and Li_2S_2 have been considered stable, although higher polysulfides may exist as in the analogous sodium–sulfur system.[2, 3] On the other hand, the crystal structures of some heavier alkali- and alkaline earth-polysulfides are known.[4, 5] These all contain ionic zigzag chains of $S_x^{2\ominus}$ (x = 3–6) which are well separated from the counterions. Here, we report that addition of *N,N,N',N'*-tetramethylethylenediamine (tmeda) to Li_2S_x (x = 2–6) in toluene induces formation of orange crystals of **1**,*** the X-ray analysis of which reveals a bicyclic Li_2S_6 molecular frame.[6]

$[Li(tmeda)_2][S_6]$ **1**

[***] Editorial note (March 16, 1990): Another synthesis of **1** and its structural characterization are described in a communication which appeared after this manuscript had been accepted: A. J. Banister, D. Barr, A. T. Brooker, W. Clegg, M. J. Cunnington, M. J. Doyle, S. R. Drake, W. R. Gill, K. Manning, P. R. Raithby, R. Snaith, K. Wade, D. S. Wright, *J. Chem. Soc. Chem. Commun. 1990*, 105.

The crystal structure of **1** is not an ionic lattice, but consists of discrete molecular units, in each of which two lithiums coordinate to one $S_6^{2\ominus}$ anion. A perspective drawing is shown in Figure 1, along with the salient intramolecular metric parameters. The most important aspect of the structure of **1** is that two lithium ions bridge the terminal sulfurs of $S_6^{2\ominus}$, one from above the $S_6^{2\ominus}$ unit and the other from below, thus making an unusual bicyclic Li_2S_6 geometry. This type of coordination is unique among the alkali- and alkaline earth-sulfides and also differs from the known structures of transition metal polysulfides.[7] For BaS_3, BaS_4, K_2S_5, and Cs_2S_6, the polysulfides have ionic acyclic geometries, and the cations do not bind specific sulfur atoms. In contrast, lithium in **1** is not an innocent counter cation. Instead its coordination to sulfur atoms is sufficiently strong to hold together the two ends of the semicircular S_6 chain, and is indicative of some degree of covalency in the Li–S bonds.

A crystallographic twofold axis passes through the midpoint of a line connecting the two terminal sulfur atoms and that of the two central sulfurs. The four "inner" sulfur atoms, of which two, S(2x) and S(3x), are related to the other two by the twofold axis of symmetry, are disordered with an occupancy factor of 0.591(9). Their complements, which are 0.409(9) occupancy, are labeled as S(2y) and S(3y). The two sets of S_6^{2-} ligands are located so that S(1) and S(1'), as well as Li and Li', are at the same position for both sets. In each the $S_6^{2\ominus}$ adopts a 'crown' conformation. In Figure 1, only the $S_6^{2\ominus}$ unit of 59% occupancy is shown for clarity.

The mean value of the S–S bond distances at 2.018 Å is normal.[8] The LiS(1)Li'S(1') quadrilateral is puckered with the dihedral angle between the two LiS_2 triangular faces being 10.6°. The Li–S distances (av. 2.493 Å) compare favorably with those in the compounds **2** (2.4 Å),[9a] **3** (2.52 Å),[9b] **4** (av. 2.42 Å),[9c] and **5** (av. 2.48 Å),[9d] and are shorter than

$[CH_3SLi]_n$ **2**

$[Li(tmeda)]_2[SCH_2CH_2CH_2SC(CH_3)]_2$ **3**

$[Li(dme)]_4[U(SCH_2CH_2S)_4]$ **4**

$[Li(dme)_2]_2(S_2CSCH_2CH_2SCS_2)$ **6**

the Li–S bonds in **6** (av. 2.747 Å).[9c] Further chelation by tmeda completes each lithium's pseudo-tetrahedral LiS_2N_2 coordination sphere. In order to ease steric congestion between the tmeda methyl groups and the $S_6^{2\ominus}$ ligand, the tmeda swings away from the polysulfide, as reflected by the notably larger S(1,1')–Li–N(1) angles relative to the S(1,1')–Li–N(2) angles.

The Raman spectrum of **1** (crystals) shown by the solid curve in Figure 2 is of interest. Alkali- and alkaline earth-polysulfides characterized thus far exhibit Raman bands in

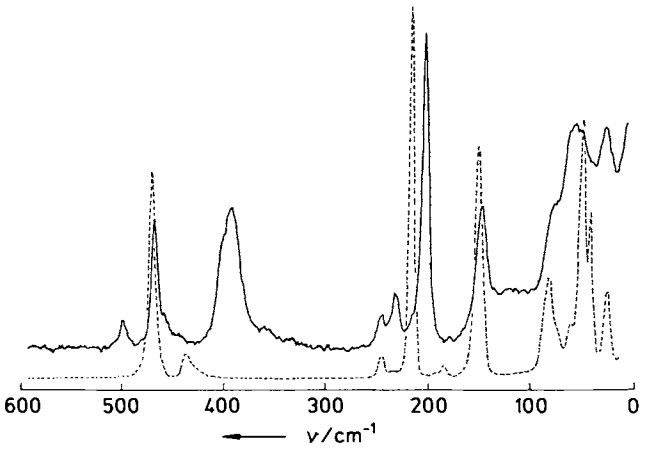

Fig. 2. Comparison of the Raman spectra of crystalline $[Li(tmeda)_2][S_6]$ **1** (——) and S_8 powder (– – –). The spectra were measured with a JASCO R-800 spectrometer equipped with an He–Ne laser. The samples were mounted in glass capillaries.

the 350–500 cm^{-1} region arising from S–S stretching vibrations.[10] Likewise for **1** the S–S stretches probably give rise to the bands at 395 cm^{-1} (broad) and 471 cm^{-1}. No other intense bands usually appear in the spectra of other polysulfides, while rather weak low-frequency bands have been assigned to lattice or bending modes. In this respect, the presence of strong lines at 205 cm^{-1} and 148 cm^{-1} for **1** deserves comment. These low-frequency Raman lines are not due to tmeda, and seem to be associated with the cyclic arrangement of Li_2S_6. As a matter of fact, the spectrum of **1** closely resembles that of elemental sulfur, S_8 (powder), which also shows intense lines at 218 cm^{-1} and 152 cm^{-1} (Figure 2, dashed curve). The two low-frequency S_8 bands were interpreted as e_1 and e_2 bending modes characteristic of the cyclic S_8 geometry,[11] and we think the corresponding bands for **1** are of a similar origin.

The complex **1** is the only lithium sulfide we could isolate from the tmeda/Li_2S_x (x = 2–6) system.[12] At present it is not entirely clear how the sulfur composition of **1** is controlled. In most transition metal polysulfides, a specific polysulfide ring size is thermodynamically stable. In other words, the ring size varies depending on the choice of the transition metal moiety.[13] Therefore, it would be interesting to examine whether a change in the 'auxiliary' ligand at Li affects the size of the $S_x^{2\ominus}$ fragment; and further studies in this direction are currently underway.

Experimental

An excess of tmeda (6 ml, 40 mmol) was added to a toluene slurry (60 mL) of a yellow powder obtained from the brown-red THF washings (4 × 30 mL) of Li_2S_2 [14] (2.6 g, 34 mmol), to give a homogeneous orange-red solution. Orange crystals (1.6 g, 3.7 mmol, 11% isolated yield based on Li) of **1** formed after the solution was concentrated and stored overnight at −20 °C [15]. The highly hygroscopic product is soluble in benzene, toluene, and THF, assuming a yellow color, but is not soluble in hexane. On the other hand, a DMF solution of **1** assumes a blue color (absorption maximum at 615 nm), which may be attributed to generation of the $S_3^{\ominus}$ radical anion in solution [16].

Scand. 22* (1968) 3029.

[5] $(Ph_4P)_2S_7$ and Tl_2S_5 contain ionic acyclic polysulfides as well. Cf. a) M. G. Kanatzidis, N. C. Baenziger, D. Coucouvanis, *Inorg. Chem. 22* (1983) 290; b) B. Leclerc, T. S. Kabré, *Acta Crystallogr. Sec. B: Struct. Crystallogr. Cryst. Chem. 31* (1975) 1675.

[6] A single crystal of **1** was mounted in a glass capillary and sealed under argon. Crystal size 0.7 × 0.5 × 0.2 mm, monoclinic, space group *C2/c*, $a = 22.808(4)$, $b = 9.194(1)$, $c = 15.038(2)$ Å, $\beta = 129.80(1)°$, $\varrho_{calcd} = 1.48$ g cm^{-3}, $Z = 4$, $\mu(Mo_{K\alpha}) = 5.13$ cm^{-1}. X-ray data were collected on a Nicolet *P3* diffractometer in the $\theta/2\theta$ mode using graphite-monochromated $Mo_{K\alpha}$ radiation. The data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied. The 931 observed reflections with $F_o^2 > 3.0\,\sigma(F_o^2)$ from 1255 measured reflections were used for the structure determination. The structure was solved by direct methods and the subsequent full-matrix least squares refinements gave final R values of $R = 0.0463$ and $R_G = 0.0444$. The inner four sulfur atoms of the S_6 unit, of which two are related to the other two by a crystallographically imposed C_2 axis, were found to be disordered with 0.591(9)/0.409(9) occupancy factors (x/y series). GOF = 1.81, $\Delta/\sigma = 0.49$, $(\varrho)_{max} = 0.20$ e $Å^{-3}$, $N_o/N_v = 8.8$. All computations with a Nicolet SHELXTL PLUS package with micro VAX II. Further details of the crystal structure analysis can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), by quoting the depository number CSD-54331, the names of the authors, and the journal citation.

[12] Lithium polysulfides in liquid ammonia have recently been characterized by Raman and UV/VIS spectroscopy; suggest existence of Li_2S_2, Li_2S_4, Li_2S_5, and Li_2S_6, in addition to $S_3^{\ominus}$ and probably Li_2S. Interestingly, the least reduced polysulfide in the solution was claimed to be $S_6^{2\ominus}$: P. Dubois, J. P. Lelieur, G. Lepoutre, *Inorg. Chem. 27* (1988) 73.

[13] For example, the size of the polysulfide ring in the $(C_5H_5)_2MS_x$ and $(C_5Me_5)_2MS_x$ systems seems to depend on the organometal fragment; x = 5 for $(C_5H_5)_2M$ (M = Ti, Zr, Hf, V) and $(C_5Me_5)_2Th$, x = 4 for $(C_5H_5)_2Mo$ and $(C_5H_5)_2W$, x = 3 for $(C_5Me_5)_2Ti$: E. [14] "Li_2S_2" was prepared as a light yellow powder by reaction of lithium metal and elemental sulfur (1:1) in liquid ammonia. According to the Raman spectra, this material is nearly identical with that prepared from $LiEt_3BH$ ("superhydride") and 1/8 S_8, and presumably contains small quantities of other lithium sulfides, e.g., Li_2S, Li_2S_3, Li_2S_4 as well as S_8. Disproportionation might occur in THF, and in view of the dark color, the sulfur content in the THF washings is probably higher than the original Li_2S_2 stoichiometry. The other polysulfides Li_2S_x (x = 3–6) were also prepared in liquid ammonia.

[15] a) All manipulations were carried out under argon using dry solvents. b) Addition of tmeda directly to a slurry of "Li_2S_2" in toluene followed by standard work-up furnished crystals of **1** in a higher yield, but this method occasionally gave a small amount of S_8 crystals as a side product. As was to be expected, **1** was obtained from Li_2S_x (x = 3–6) + tmeda systems as well. ^{1}H NMR of **1** (100 MHz, C_6D_6, room temperature) $\delta = 2.00$ (s, 4H, CH_2), 2.18 (s, 12H, CH_3). c) The ^{1}H-NMR spectrum of free tmeda (neat) shows two singlets at $\delta = 2.39$ (CH_2) and 2.26 (CH_3).

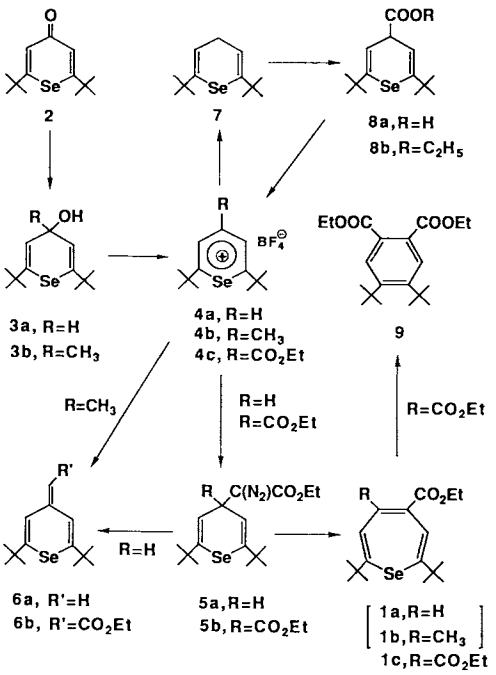
A Monocyclic Selenepine: Synthesis and Characterization of Diethyl 2,7-Di-*tert*-butyl-4,5-selenepinedicarboxylate**

By *Hideaki Hori, Shoko Yamazaki, Kagetoshi Yamamoto,** and *Ichiro Murata**

Although much interest has recently been focused on selenium heterocycles,[1] the field of selenepines still remains unexplored.[2] Preparation and characterization of selenepines have been confined to only a few dibenzo[*b*,*f*]-selenepine derivatives owing to facile loss of selenium.[3] The characteristic features of bond length, bond angle, and bond dissociation energy associated with the C–Se bond predict that selenepines should have a different geometry from that of other "heteropines" and should be thermally less stable than thiepines.

The synthesis of monocyclic selenepines, like that of monocyclic thiepines, must take into account their expected thermal instability. The findings on monocyclic thiepines[4, 5] and 1,4-thiazepine[6] indicate that an isolable selenepine has to posses at least one bulky group at both C-2 and C-7 positions. Here we report the first synthesis and characterization of diethyl 2,7-di-*tert*-butyl-4,5-selenepinedicarboxylate (**1c**).

The synthesis of the three selenepines **1a**–**1c** was carried out via the key intermediate cation salts **4a**–**4c**, prepared in the usual manner. Reaction of **2**[7] with lithium aluminum hydride and with methyllithium in ether gave the alcohols **3a** and **3b**, respectively, which were not isolated owing to their susceptibility to air oxidation. Treatment of **3a** and **3b** with aqueous 42% HBF_4 gave **4a** (66%) and **4b** (86%), respectively. The cation **4a** was reduced with $LiAlH_4$ to the selenapyran **7**. Treatment of **7** with lithium diisopropylamide at −78 °C in THF–HMPA gave the corresponding anion, which was quenched with dry CO_2 to afford the carboxylic acid **8a**. Compound **8a** was converted into the ester **8b** (68%) with diazoethane. On treatment with Ph_3CBF_4 in dichloromethane at room temperature for 20 h, **8b** was transformed into the cation **4c** (58% from **4a**).



Reaction of **4a** and **4c** with ethyl lithiodiazoacetate, generated in THF–ether at −110 °C from ethyl diazoacetate, gave **5a** (16%) and **5b** (21%), respectively. The 4-position of the diazoester group is clearly shown by the symmetrical signal patterns in the ^{1}H-NMR spectra. Unfortunately, reaction of **4b** with ethyl lithiodiazoacetate led to exclusive formation of a deprotonation product **6a** under the usual conditions as well as under a variety of modified conditions.

The final conversion of **5a** to **1a** met with obstacles. Treatment of **5a** with a catalytic amount of di-μ-chlorobis(π-allyl)palladium(II) gave **6b** instead of **1a**. No identifiable product could be isolated from **5a** under acidic conditions. However, the ring expansion of **5b** proceeds smoothly in the presence of $[Pd(C_3H_5)_2Cl_2]$ at −20 °C and can be monitored by ^{1}H-NMR spectroscopy in $CDCl_3$. The signals due to **5b**

Table 1. Some physical data for compounds **1c**, **4a**, **4b**, **4c**, and **8b**.

1c: ^{1}H NMR (90 MHz, $CDCl_3$): $\delta = 1.17$ (s, 18H; $C(CH_3)_3$), 1.24 (t, $J = 7.0$ Hz, 6H; OCH_2CH_3), 4.25 (q, $J = 7.0$ Hz, 4H; OCH_2CH_3), 6.58 (s, 2H; H-3)

4a: colorless crystals, m.p. 183–183.5 °C (from EtOH/hexane, (1:1)); ^{1}H NMR (100 MHz, CD_2Cl_2): $\delta = 1.66$ (s, 18H; $C(CH_3)_3$), 8.56 (AB_2, $J = 6.7$ Hz, 2H; H-3, H-5), 8.95 (AB_2, $J = 6.7$ Hz, 1H; H-4); IR (KBr): $\tilde{\nu} = 1083$ cm^{-1} ($BF_4^{\ominus}$)

4b: colorless needles, m.p. 153–154.5 °C (from EtOH/hexane, (1:1)); ^{1}H NMR (60 MHz, $CDCl_3$): $\delta = 1.64$ (s, 18H; $C(CH_3)_3$), 2.78 (s, 3H; CH_3), 8.24 (s, 2H; H-3, H-5); IR (KBr): $\tilde{\nu} = 1055$ cm^{-1}

8b: colorless oil. ^{1}H NMR (60 MHz, $CDCl_3$): $\delta = 1.16$ (s, 18H; $C(CH_3)_3$), 1.30 (t, $J = 7$ Hz, 3H; OCH_2CH_3), 4.20 (q, $J = 7$ Hz, 2H; OCH_2CH_3), 3.03 (t, $J = 4$ Hz, 1H; H-4), 5.96 (d, $J = 4$ Hz, 2H; H-3, H-5). IR (neat): $\tilde{\nu} = 1730$ cm^{-1}

4c: colorless crystals, m.p. 161.5–162.5 °C (from THF). ^{1}H NMR (90 MHz, $CDCl_3$): $\delta = 1.70$ (s, 18H; $C(CH_3)_3$), 1.49 (t, $J = 7.0$ Hz, 3H; OCH_2CH_3), 4.56 (q, $J = 7.0$ Hz, 2H; OCH_2CH_3), 8.86 (s, 2H; H-3, H-5). IR (KBr): $\tilde{\nu} = 1720$, 1050 cm^{-1}

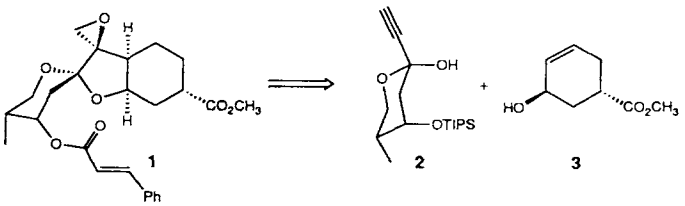
Synthesis of (±)-Phyllanthocin via a Metal-Catalyzed Cycloreduction**

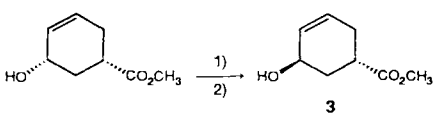
By *Barry M. Trost** and *Eric D. Edstrom*

The novel molecular architecture and promising biological activity of phyllanthoside[1] has made its aglycone, phyllanthocin (**1**),[2] an attractive synthetic target.[3] The development of a cycloisomerization[4] and of a reductive cyclization[5] of enynes under very mild conditions suggested a convenient convergent strategy from two relatively simple building blocks of about equal size (cf. Scheme 1). The failure of many transition-metal-catalyzed reactions with more elaborate structures led us to test the feasibility of such processes for the construction of oxygen heterocycles in general[6] and to assess the feasibility of its applicability for complex molecule construction by undertaking a synthesis of (±)-phyllanthocin (**1**).



Scheme 1.

The known cyclohexenol **3**[7] is conveniently available from the *cis*-diastereomer[8] in 85% yield by application of the Mitsunobu reaction (Scheme 2).[9]



Scheme 2. Synthesis of the cyclohexenol component **3**. 1) PPh_3, DEADCAT ($C_2H_5O_2CN{=}NCO_2C_2H_5$), HCO_2H, THF; 2) $KHCO_3$, CH_3OH.

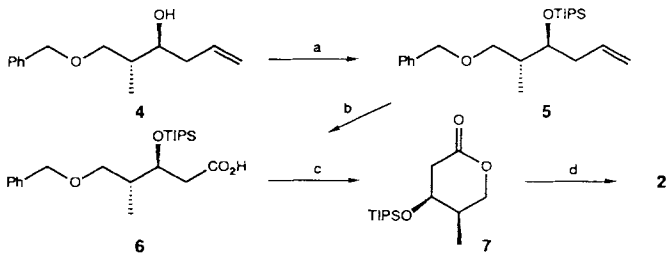
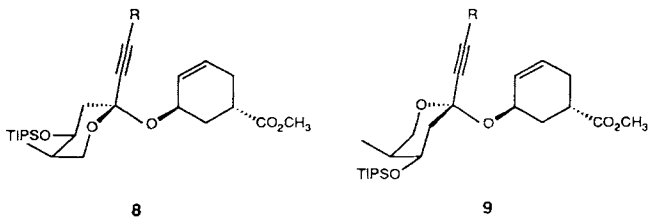
[**] This work was supported by the National Institutes of Health (NIH), Institute of General Medical Sciences. Mass spectra were provided by the Mass Spectrometry Facility, University of California-San Francisco, supported by the NIH Division of Research Resources.

The lactol **2** is available in four steps from the known (2*R**,3*S**)-2-methyl-1-(phenylmethoxy)hex-5-en-3-ol (**4**)[10] (Scheme 3). The choice of protecting group proved crucial owing to the ease of β-elimination during nucleophilic additions to lactone **7**. The triisopropylsilyl protecting group (TIPS) proved efficacious both in terms of its introduction and removal, as well as in terms of its chemical stability in subsequent transformations.[11] Oxidative olefin cleavage proceeded efficiently with buffered potassium permanganate under phase transfer conditions[12] or, for this particular substrate, using the *Lemieux* and *von Rudloff* protocol.[13] Hydrogenolysis of the benzyl ether **6** followed by acidification produces the lactone **7**.[14] Maintaining the acetylide addition at −78 °C followed by quenching with methanol:acetic acid (10:1) prevents the undesired β-elimination. In this way, the lactol **2**[14] is available in 68% overall yield from olefin **4**.



Scheme 3. Synthesis of the lactol component **2**. a) TIPS-OSO_2-CF_3, 2,6-lutidine, CH_2Cl_2, 99%. b) $NaIO_4$, $KMnO_4$ (cat.), *tert*-C_4H_9OH, H_2O, RT, pH 7. c) H_2, 10% Pd/C, C_2H_5OH, directly thereafter pyridinium *p*-toluenesulfonate, 5 Å molecular sieve, benzene, 74% overall yield referred to **5**. d) $(CH_3)_3SiC{\equiv}CLi$, THF, −78 °C, 93%. TIPS = $[(CH_3)_2CH]_3Si$.

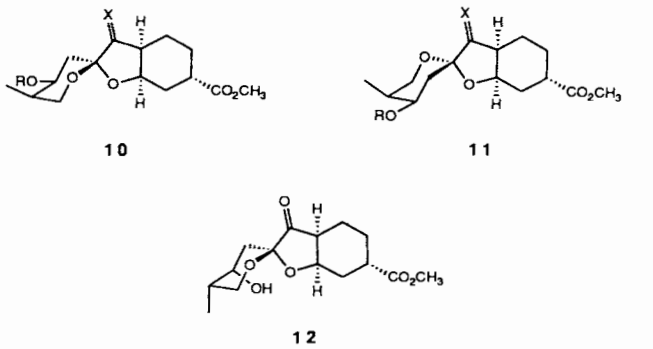
The glycosidic coupling event entails treating a solution of the lactol **2** with 2 equivalents of hydroxy ester **3** in benzene (0.3 M) containing K 10 montmorillonite clay[15] and powdered 5 Å molecular sieves at room temperature (75% yield). Due to the fact that our starting materials are racemic, a mixture of **8a**[14] and **9a** is produced which cleanly separates after desilylation to **8b**[14] and **9b**[14] (K_2CO_3, CH_3OH, 0 °C) (Scheme 4). The production of such a mixture does not



Scheme 4. Products of the reaction of **2** with **3**. **a**, R = $(CH_3)_3Si$; **b**, R = H.

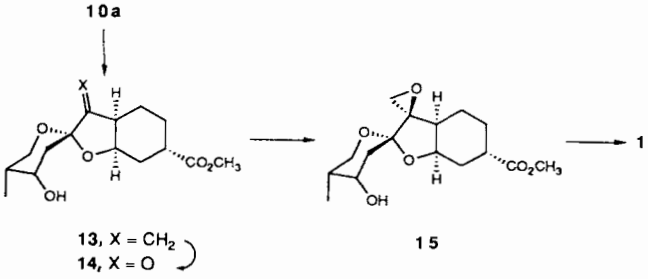
constitute a shortcoming of the synthesis since it can be totally avoided simply by using enantiomerically pure building blocks **2** and **3**.[16] For our purposes, exploring the cyclization of both isomers (**8b** and **9b**) is desirable. Using carefully defined catalytic conditions with proper choice of silane effects (Scheme 5) excellent yields (86% and 78% of **10a**[14] and **11a**,[14] respectively) of the requisite polyhydrobenzofurans. For characterization, **10a** and **11a** were

subjected to ozonolysis and hydrolysis; the ketols **10b**[14] and **11b**[14, 17] were formed in 89% and 88% yields, respectively. For subsequent comparison purposes, the cyclized product **11a** was also transformed into the *epi*-compound **12**.



Scheme 5. Products derived from **8b** and **9b**. **a**, R = TIPS, X = CH_2; **b**, R = H, X = O. Reactions **8b** → **10a** and **9b** → **11a**: polymethylsilanol, $[(dba)_3Pd_2CHCl_3]$ (dba = dibenzylideneacetone), *N*,*N*′-dibenzylideneethylenediamine, CH_3COOH, CH_2Cl-CH_2Cl, RT. Reactions **10a** → **10b** and **11a** → **11b**: 1) O_3, CH_3OH, CH_2Cl_2, −78 °C; 2) $ZnBr_2$, CH_2Cl_2, RT; 3) O_3, CH_3OH, CH_2Cl_2, −78 °C.

In pursuing our objective of phyllanthocin, its entire carbon skeleton with the correct stereochemistry (see **13**[14]) arises by desilylation of **10a** as readily discerned by the appearance of the protons at C-6′ [3.76 (t, J = 11.8 Hz) and 3.48 (dd, J = 11.8, 4.9 Hz)] (cf. Scheme 6). Ozonolysis provides the ketone **14**[14]—a common intermediate in many of the previous syntheses of phyllanthocin. Following the literature sequence of epoxidation with dimethylsulfonium methylide (96%) and cinnamoylation (68%)[3] completes the formation of synthetic phyllanthocin, spectroscopically identical to the natural product.



Scheme 6. Last step of the synthesis of **1**. Reaction **10a** → **13**: aqueous HF (30%), CH_3CN, RT, 82%. Reaction **13** → **14**: O_3, CH_3OH, CH_2Cl_2, −78 °C, 95%.

Three aspects of this synthesis are noteworthy. The successful glycosylation catalyzed by K 10 montmorillonite clay efficiently joins the two halves and should prove more generally useful (**2** + **3** → **8** + **9**). The excellent yields in the reductive cyclization (**8b** → **10a**) are particularly gratifying, especially since attempts to close the ring by thermal Alder ene reactions completely fail. The availablity of this new reaction for the synthesis of oxygen heterocycles creates a very simple strategy to phyllanthocin which proceeds in only five steps (38% unoptimized overall yield) from the two halves which, themselves, require few steps (two and four, respectively) from simple known starting materials. The introduction of this palladium-catalyzed cycloreduction appears to be a powerful complement to Alder ene chemistry in not only effecting reactions that otherwise fail but also providing novel variation of the types of products available.

Table 1. Selected spectroscopic data for key intermediates. IR (neat); 400-MHz ^1H NMR ($CDCl_3$); ^{13}C NMR ($CDCl_3$). J in Hz. Correct elemental analyses (C,H).

7: IR: $\tilde{\nu}$ = 1730, 1460 cm^{-1}. ^1H NMR: δ = 4.30 (t, J = 10.3, 1H), 4.23 (m, 1H), 4.16 (dd, J = 10.8, 4.4, 1H), 2.68 (t, J = 4.0, 2H), 2.12 (m, 1H), 1.07 (b, 21H), 1.02 (d, J = 6.8, 3H). ^{13}C NMR (75 MHz): δ = 170.1 (C), 70.3 (CH), 67.8 (CH_2), 39.4 (CH), 33.7 (CH_2), 17.8 (CH_3), 12.2 (CH_3), 11.8 (CH)

Bis(*N,N*-diisopropylamino)trimethylsiloxyphosphane: A Novel Flexible Phosphitylating Reagent in Nucleoside Chemistry and Its Application in the Synthesis of *P*-Modified Nucleotides **

By *Wojciech Dąbkowski, Jan Michalski,** and *Wang Qing*

Dedicated to Professor Günther Wilke on the occasion of his 65th birthday

In 1976, *Letsinger* et al.[1] developed a method for the linking of nucleosides via phosphite groups with phosphorochloridites which was more convenient than earlier routes. This method was further improved by the phosphoroamidite approach of *Caruthers* et al.[2] Since then a variety of modified Letsinger reagents have been proposed.[3] However, only those containing simple alkoxy groups attached to the tricoordinate phosphorus are suitable for constructing intermediates for the synthesis of *P*-modified nucleotides via the Michaelis-Arbuzov reaction.[4] Prior to our present studies phosphitylating reagents containing siloxy groups were almost unknown.[5]

Bis(*N,N*-diethylamino)trimethylsiloxyphosphane had already been characterized by *Alfonsov* et al. in 1976 and was used for the silylation of ethyl alcohol.[6]

$$(Et_2N)_2POSiMe_3 + EtOH \rightarrow (Et_2N)_2P(O)H + EtOSiMe_3$$

In contrast we were able to demonstrate that bis(*N,N*-diisopropylamino)trimethylsiloxyphosphane (**1**) as well as other *N,N*-dialkylamino analogues exhibit phosphitylating properties in the presence of 1*H*-tetrazole. Due to its ready availability, stability, and relatively high phosphitylating power, the phosphane **1** seems to be the current reagent of choice.

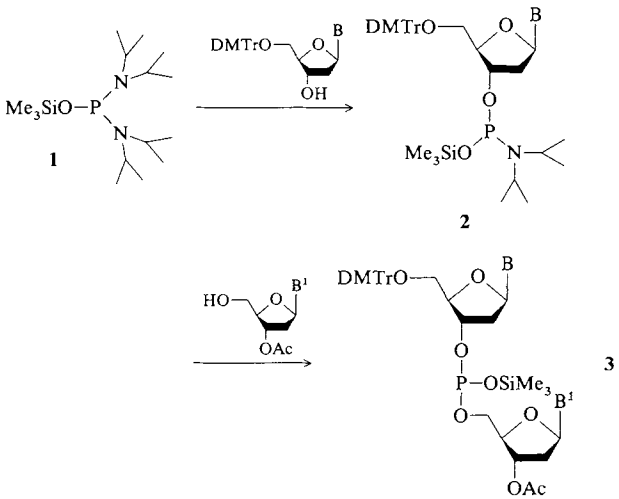
The title phosphane **1** was prepared from readily available chlorobis(*N,N*-diisopropylamino)phosphane[7] in almost quantitative yield (Scheme 1). This new phosphitylating reagent, which can be distilled without decomposition in vacuo, solidifies to a low-melting solid. It can be stored at room temperature and used in phosphitylating procedures without special precautions.

$$(iPr_2N)_2PCl \xrightarrow{H_2O} (iPr_2N)_2POH \xrightarrow{Me_3SiCl} (iPr_2N)_2POSiMe_3$$

1

Scheme 1. One-pot synthesis of **1**. H_2O/Et_3N (1/1) in ether, 2 h, 20 °C; Me_3SiCl/Et_3N (1/1), 2 h, 20 °C; yield 90%. **1**, b.p. 100–102 °C/0.01 torr; ^1H NMR ($CDCl_3$, TMS int.): δ = 0.3 (s, 9H), 0.9 (d, 24H), 3.0–3.7 (m, 4H); ^{31}P NMR ($CDCl_3$, 85% H_3PO_4 ext.): δ = 108.23. DMTr = 4,4′-dimethoxytrityl.

The most important property of the siloxyphosphane **1** is its ability to undergo highly selective nucleophilic substitution at the tricoordinate phosphorus atom without affecting the silicon center under conditions which are commonly used in the phosphite triester approach. In the phosphitylation of alcohols the reactivity of the phosphane **1** is similar to that of the corresponding alkoxy derivatives. A number of 3′,5′-dinucleoside trimethylsilylphosphites **3** have been prepared in this way in very high yield without isolation of the intermediate **2** (Scheme 2).



3a, B = B¹ = Thy[8a]; 3b, B = B¹ = Ade(bz); **3c**, B = Thy, B¹ = Ade(bz); **3d**, B = Ade(bz), B¹ = Thy

Scheme 2. One-pot synthesis of **3** (via **2**). Nucleoside with a free 3′-hydroxy-group/diisopropylammoniumtetrazolide (1/1), 15 min, 20 °C, CH_3CN; nucleoside with a free 5′-hydroxy group/diisopropylammonium tetrazolide, 5 min, 20 °C, CH_3CN. Yield (determined by ^{31}PNMR spectroscopy) 95–97%. ^{31}P NMR ($CDCl_3$, 85% H_3PO_4 ext.): δ = 117.6, 116.8 (**3a**); 117.6, 116.0 (**3b**); 118.1, 117.5 (**3c**); 118.5, 118.0 (**3d**). The mononucleoside **2** can be isolated quantitatively.

The trimethylsilylphosphites of type **3** can also be obtained by silylation[8] of phosphonates with P–H bonding.[9]

The esters **3** exhibit remarkable chemical properties characteristic of trimethylsilylphosphites.[10] The value of the esters **3** in nucleotide chemistry is clearly evident from their selective and efficient participation in Michaelis-Arbuzov-

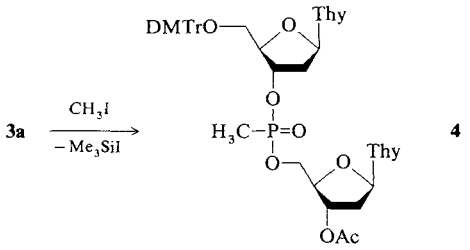
[+] Permanent address: Chemical Research Institute, Beijing (Peoples Republic of China)

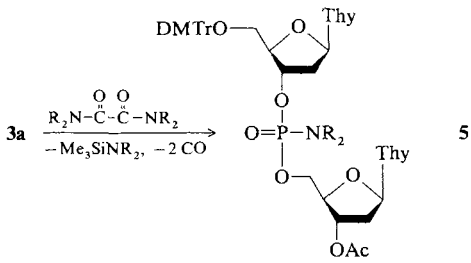
[**] The authors thank Prof. *Friedrich Cramer*, the Polish Academy of Sciences and the Max-Planck-Gesellschaft for support of this work. We are grateful to Dr. *Dieter Gauss* for help in preparing the manuscript.

type reactions and from reactions which are unique for this reagent, for example the one-pot synthesis of the biologically interesting methylphosphonates of type **4**[11] (Scheme 3) and phosphorofluoridates.[12] The chemical and enzymatic properties of **4** compare with those of other dinucleoside methylphosphonates.[4, 5]



Scheme 3. Synthesis of **4** (2 h, 20 °C) [8b]. ^{31}P-NMR ($CDCl_3$, 85% H_3PO_4 ext.): δ = 32.7, 32.5.

Unique for reagents of type **3** is the reaction with oxalylazolides and anilides to form in excellent yields the dinucleotide azolides **5a, b** and anilides **5c** (Scheme 4).

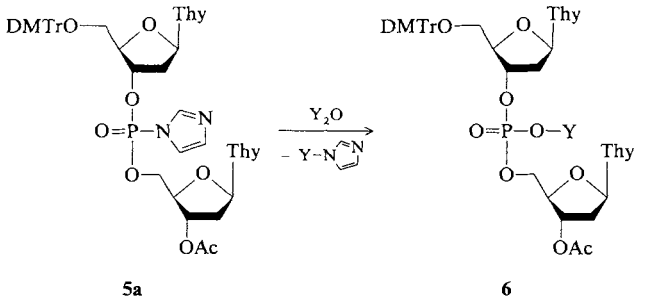


5a, R_2NH = imidazole; **5b**, R_2NH = triazole; **5c**, R_2NH = aniline

Scheme 4. Synthesis of **5** from **3a** and $(R_2N-CO)_2$ (1/1); 3 h, 20 °C. Yield. (determined by ^{31}P NMR spectroscopy) 90–94%. ^{31}P NMR ($CDCl_3$, 85% H_3PO_4 ext.): δ = −12.0, −11.5 (**5a**); −10.6, −10.3 (**5b**); +2.0, +1.6 (**5c**).

In this way the anilides of type **5c** have become readily accessible for the first time. Nucleotide anilides are of importance for the stereospecific synthesis of nucleoside phosphorothioates.[13]

The reaction of **5a** leading to the anhydrides **6a** and **6b** further illustrates the potential of this approach (Scheme 5).



6a, Y = CH_3SO_2; **6b**, Y = CF_3CO

Scheme 5. Synthesis of **6** (15 min, 20 °C, CH_3CN). Yield (determined by ^{31}P NMR spectroscopy) 95–97%. ^{31}P NMR ($CDCl_3$, 85% H_3PO_4 ext.): δ = −15.6, −15.3 (**6a**); −9.8, −9.5 (**6b**).

All compounds **3**–**6** are mixtures of diastereoisomers. Phosphonates with P–H bonding, which are versatile intermediates in nucleotide chemistry, can be readily obtained by hydrolysis from **2** and **3** in a one-pot procedure.

Catalytic Hydration of Acrylonitrile to Acrylamide under Mild Conditions**

By *Jik Chin** and *J. H. Kim*

Numerous articles have been written on the development of catalysts that hydrolyze amides, esters and nitriles. Due to the stability of these substrates, most studies have been focused on model systems involving activated substrates[1] or intramolecular catalysis.[2] Perhaps it is now time to exploit

[*] Prof. J. Chin, J. H. Kim

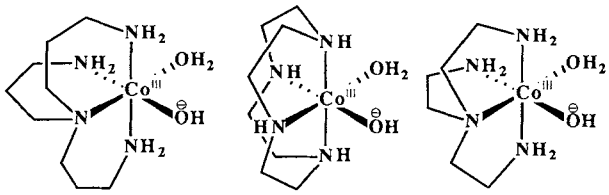
[**] Support by the National Science and Engineering Research Council of Canada is gratefully acknowledged.

the knowledge gained from extensive model studies to the development of true catalysts that hydrolyze unactivated substrates.[3] We recently showed[4] that **1** is highly efficient at catalyzing the hydrolysis of unactivated esters such as methyl acetate. The hydrolysis of amides and nitriles poses an even greater challenge than the hydrolysis of esters, since amides and nitriles are thousands of times more stable than esters. For example, the second-order rate constants for hydroxide-catalyzed hydrolysis of methyl acetate,[5] acetonitrile[6] and acetamide[7] are 1.5×10^{-1} M s^{-1}, 1.6×10^{-6} M s^{-1}, and 7.4×10^{-5} M s^{-1}, respectively. Herein we report on the hydrolysis of acetonitrile under mild conditions using **1**, **2** and **3** as catalysts.



1 2 3

In a typical kinetically controlled experiment, acetonitrile (0.1–0.5 M) was added to a D_2O solution of **2** (0.01 M, perchlorate salt) at pD 7.0 and 40 °C. Figure 1 shows that, as the reaction proceeds, the ^{1}H-NMR signal of acetonitrile

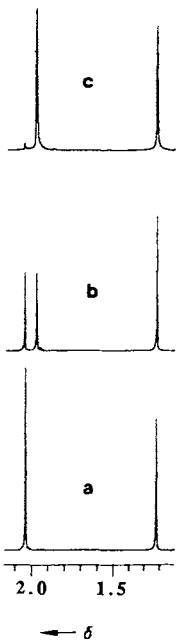


Fig. 1. ^{1}H-NMR chemical shift of the α proton of acetonitrile (0.1 M) after addition of **2** (0.01 M) at pD 7.0 and 40 °C. *tert*-Butyl alcohol as standard ($\delta = 1.22$). Measurements after a) 0 h, b) 5.5 h, c) 23 h.

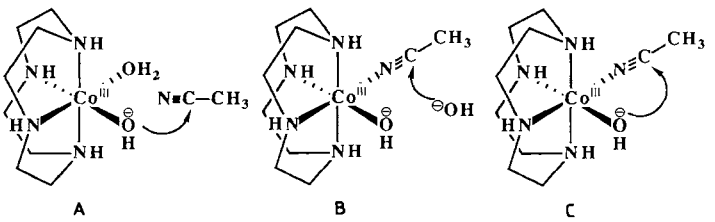
($\delta = 2.04$) decreases while that of acetamide ($\delta = 1.96$) increases. The reaction is zero order with respect to acetonitrile concentration and first order with respect to the catalyst concentration. Under the above conditions, the rate of the hydrolysis is 3.2×10^{-6} M s^{-1}. **3** is about 20 times less reactive than **2**. **1** is active but deligates to give free tris(3-aminopropyl)amine after initial production of acetamide.

$Cu^{2\oplus}$, $Ni^{2\oplus}$ and $Zn^{2\oplus}$ have all been shown to catalyze the hydration of nitriles when the nitrile function is covalently linked to metal-coordinating functional groups.[8, 9] For example, 2-cyanopyridine and 2-cyano-1,10-phenanthroline are rapidly hydrated to the corresponding amides when $Cu^{2\oplus}$ is added to the aqueous reaction mixture under mild conditions. It has been shown that, under reflux conditions, $Pt^{2\oplus}$-complexes catalyze the hydrolysis of simple nitriles that do not contain any additional metal-coordinating functionalities.[10] Simple nitriles directly coordinated to Co^{III}-,[6] Rh^{III}-,[11] Ru^{III}-[12] and Ir^{III}[11]-complexes can be easily hydrolyzed to the corresponding amido complexes at ambient temperature. However, there is no catalytic turnover with the substitutionally inert Co^{III}-, Rh^{III}-, Ru^{III}- and Ir^{III}-complexes. Interestingly, ten turnovers can be easily detected for the hydrolysis of acetonitrile by **2** in neutral water (pH 7) at 40 °C (Fig. 1). The turnover time is approximately 3×10^3 s. This represents the first example of turnover for a Co^{III}-complex-catalyzed hydrolysis of a nitrile. Although Co^{III}-complexes are generally substitutionally inert the coordinated water molecules in **2** can be rapidly displaced under mild conditions.[13]

There are three possible mechanisms for the hydrolysis of acetonitrile when catalyzed by **2**. The first mechanism involves intermolecular attack of the metal hydroxide on acetonitrile (**A**). The second involves coordination of acetonitrile followed by intermolecular hydroxide-attack (**B**).[6] The third involves coordination of acetonitrile followed by intramolecular attack of the metal hydroxide (**C**). Mechanism



A B C

A can be ruled out on the basis that **3** is much less reactive than **2**. If mechanism **A** were correct, **2** and **3** would be expected to have comparable reactivities, since the basicities of the metal hydroxides are about the same.[16] Mechanism **B** can also be ruled out. The pseudo-first-order rate constant for the hydrolysis of $[(NH_3)_5Co(NCCH_3)]^{3\oplus}$ in water to give the acetamide-bound cobalt complex is 3.4×10^{-7} s^{-1} at pH 7.0 and 25 °C.[6] Hence, if mechanism **B** is correct, the expected maximum rate constant for hydrolysis of acetonitrile (0.5 M) catalyzed by **2** (0.01 M) would be 3.4×10^{-9} M s^{-1}. This is too slow to account for the observed rate of hydrolysis (3.2×10^{-6} M s^{-1}). Furthermore, hydroxide-catalyzed hydrolysis of $[(NH_3)_5Co(NCCH_3)]$ is accompanied by a proton exchange for the methyl group.[6] In sharp contrast, the hydrolysis of acetonitrile catalyzed by **2** does not show any proton exchange for the methyl group. Mechanism **C** is consistent with the observed rate-enhancement as well as the lack of any proton exchange for the methyl group. Related mechanisms involving intramolecular metal-hydroxide attack on metal-coordinated substrates have been proposed for the Co^{III} complex-promoted hydrolysis of phosphate esters and carboxylate esters.[14]

There has been considerable industrial interest in developing catalysts for the hydrolysis of acrylonitrile to acrylamide without hydrolyzing the carbon–carbon double bond. Intramolecular metal-hydroxide attack on coordinated acrylo-

nitrile according to mechanism **C** should result in clean hydrolysis of the cyano group with retention of the C–C double bond. Indeed acrylonitrile is quantitatively converted into acrylamide by **2** (Fig. 2).

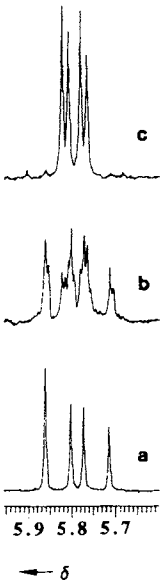


Fig. 2. ^{1}H-NMR chemical shift of the α proton of acrylonitrile (0.1 M) after addition of **2** (0.01 M) at pD 6.3 and 40 °C. Measurements after a) 0 h, b) 3.5 h, c) 20 h.

We have shown that **2** forms four-membered ring intermediates much more readily than does **3**.[14] Since mechanism **C** involves the formation of a four-membered ring intermediate, it is not surprising that **2** is so much more reactive than **3** in hydrolyzing acetonitrile. Although **1** also catalyzes the hydrolysis of acetonitrile, it starts to decompose after initial reaction due to acetamide-promoted deligation of the tetraamine ligand. Amide-promoted deligation of Co^{III}-amine complexes is a known phenomenon.[11] Deligation does not take place with **2**, apparently because the cyclic tetraamine ligand binds very tightly to the cobalt atom.

The three most important criteria in developing a "perfect" catalyst are reactivity, selectivity, and turnover number. Unlike enzymes, simple catalysts are far from being perfect. Nevertheless, **2** is an excellent catalyst for the hydrolysis of nitriles. The catalytic mechanism involving intramolecular metal-hydroxide-attack on the Co^{III}-complex-coordinated nitrile allows for unprecedented reactivity and selectivity. Furthermore, rapid dissociation of the product from the metal complex allows for catalytic turnover to take place for the first time using a Co^{III}-complex.

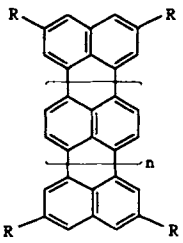
Oligorylene as a Model for "Poly(perinaphthalene)" **

By *Angelika Bohnen, Karl-Heinz Koch, Wolfgang Lüttke*, and *Klaus Müllen**

Dedicated to Professor Wolfgang Roth on the occasion of his 60th birthday

The annelated arenes derived formally by connecting all the *peri*-positions of naphthalene have been designated by *Clar* as "rylenes".[1] Although chemical and physical properties of the first member of this series of naphthalene oligomers, perylene **2a**, have been thoroughly investigated,[2–4] the higher homologues terrylene **3a** and quaterrylene **4a** have resisted all attempts at characterization even though they are known compounds. This is primarily due to the fact that they are difficult to synthesize and extremely insoluble in organic solvents.[5]



1: R = H
2a: R = H, n = 0
3a: R = H, n = 1
4a: R = H, n = 2
2b: R = *t*Bu, n = 0
3b: R = *t*Bu, n = 1
4b: R = *t*Bu, n = 2

Theoretical studies suggest that these higher rylenes should be of considerable interest, however. Thus, a low-lying energy gap has been predicted for poly(*peri*-naphthalene) **1**, which might give rise to intrinsic conductivity.[6, 7]

As part of an attempt to extrapolate from existing experimental data to the properties of **1**, we have succeeded

[**] Polyarylenes and Polyarylenevinylenes, Part 2. This work was supported by the Volkswagen Stiftung and the Bundesministerium für Forschung und Technologie. Part 1: [10].

in developing a straightforward approach to structural analogues of terrylene **3a** and quaterrylene **4a**. The method is based on alkali metal-induced cyclization of oligonaphthalene precursors, and it leads directly to the compounds **3b** and **4b**, which thanks to their alkyl substituents are soluble. The resulting homologous series of soluble rylenes (**2b**–**4b**) now makes it possible to study rylene physical properties as a function of molecular size. We present here various pieces of spectroscopic information together with evidence of significant redox activity and, in the case of doped derivatives, electrical conductivity.

The starting point for the syntheses is 2,7-di-*tert*-butylnaphthalene **5**, which is readily prepared by Friedel-Crafts alkylation of naphthalene. This compound can be separated via its thiourea inclusion complex from the 2,6-isomer that forms concurrently.[8] **5** is subsequently converted into the monobromo derivative **6**[9] (86%) by a method we have described previously,[10] after which it is transformed into the monoboronic acid **7** (76%). Palladium-catalyzed coupling of **7** with **6** (molar ratio 1:1), with 1,4-dibromonaphthalene **8** (2:1), or with 4,4'-dibromo-1,1'-binaphthyl **9** (2:1) leads to the 1,4-coupled oligonaphthalenes **10** (74%), **11** (83%), and **12** (75%).[11]

In preparing the rylenes themselves we took advantage of the fact that 1,1'-binaphthyl cyclizes spontaneously to perylene upon reduction with alkali metals.[12] The corresponding cyclization of the oligonaphthalenes **10**–**12** was accomplished by treatment with potassium (vacuum, 1,2-dimethoxyethane, room temperature, 3d), followed by oxidation with anhydrous cadmium chloride and column chromatographic purification over aluminum oxide. The perylene **2b** is obtained in a yield of 40%. Ternaphthyl **11** leads to two cyclization products: the naphthylperylene **13** (42%) and the terrylene **3b** (24%). Cyclization apparently occurs only at the *peri*-positions of the naphthalene. The course of the cyclization evidently depends upon the extent of the redox activity of the π system, since the quaternaphthyl derivative **12** leads to the biperylenyl **14** (48%) rather than to the desired quaterrylene **4b**. Byproducts include the nonseparable naphthylperylenes (10%), as well as the naphthylterrylene derivative **15** which could be isolated (5%). Cyclization to **4b** can nevertheless be accomplished by treatment of **14** with copper(II) chloride and aluminum chloride in carbon disulfide (Kovacic conditions[13]). Chromatographic purification of the crude product (aluminum oxide, cyclohexane) results in elution only of the byproducts (perylene chromophores). The target compound **4b** was recovered from the column packing (dried under nitrogen) by multiple extraction with refluxing chloroform (48%). In an analogous fashion, **13** can be cyclized to the terrylene **3b** (42%).[11]

The parent compounds **3a** and **4a** can be prepared by dealkylation of **3b** and **4b**, respectively (aluminum trichloride/sodium chloride melt, 5:1, 130°C, 15 min).

As can be seen from Table 1, the series of soluble rylenes **2b**, **3b**, and **4b** exhibits an intense bathochromic shift for the longest wavelength ^1L_a band, which is in each case characterized by a similar vibrational structure. The observed peak positions are in good agreement with calculated values (PPP-SCF[14]). As with perylene, the fluorescence spectra of the homologues show only very small Stokes shifts. Whereas both perylene **2b** and terrylene **3b** demonstrate very intense fluorescence (fluorescence quantum yields Φ_F of 0.94 and 0.70, respectively[15a]), the fluorescence intensity of **4b** is surprisingly weak ($\Phi_F \approx 0.05$[15]).

Table 1. Selected spectroscopic data for the compounds **2b**, **3b**, and **4b**.

Cpd.	Color	Absorption [nm]			Fluorescence [nm] [c]	
		λ_{max}	(ε) [a]	$\lambda_{PPP}(f)$ [b]	λ_{max}	Φ_F [d]

[d] Reference material for fluorescence measurements: [15a] **2b**: perylene; **3b**: rhodamine 101; **4b**: 3-diethylamino-7-diethyliminophenoxazonium perchlorate (oxazine 1).

Electrochemical oxidation and reduction under cyclovoltammetric control reveals the oligorylenes to be very effective electrophores (Table 2). **2b** is transformed reversibly into a radical cation and a dication as well as a radical anion and a dianion. In the case of **3b** a radical trication is also formed, and with **4b** it is even possible to demonstrate a reversible redox sequence covering seven successive steps

Table 2. Cyclovoltammetrically determined redox potentials for the oligorylenes **2b**, **3b**, and **4b**. [a]

	E° (Oxidation)				E° (Reduction)		
	−4e	−3e	−2e	−1e	+1e	+2e	+3e
2b			1.45	0.78	−1.99	−2.55	
3b		2.43 [b]	0.94	0.43	−1.57	−1.98	
4b	2.23 [c]	1.90 [b]	0.66	0.23	−1.42	−1.72	−2.97 [b]

[a] Oxidation in CH_2Cl_2; reduction in tetrahydrofuran; redox potentials of reversible pairs in V vs. SCE (ferrocene calibration 310 mV); nBu$_4$N$^\oplus$PF$_6^\ominus$ as supporting electrolyte; scan rate 100 mV s^{-1}; temperature 0 °C. [b] Temperature −25 °C. [c] Temperature −50 °C.

from a tetracation to a radical trianion. Not surprisingly, electron transfer is also possible by chemical means. Thus, reduction of **2b** and **3b** with potassium, for example, leads to the dianionic salts **2b**$^{2\ominus}$/2K$^\oplus$ (violet) and **3b**$^{2\ominus}$/2K$^\oplus$ (blue), as shown by the corresponding ^{1}H-NMR spectra.[16]

The energy gap in polymer **1** is a quantity of considerable significance from the standpoint of electrical conductivity. In the case of the discrete molecules **2b**–**4b** this corresponds to the HOMO/LUMO energy difference ΔE(Table 3). One of

Table 3. HOMO-LUMO energy differences ΔE [eV] as a function of degree of annelation [18] (cf. Tables 1 and 2).

	ΔE_{elec} [a]	ΔE_{opt} [b]	ΔE_{theor} [c]
2b	2.77	2.67	2.78
3b	2.00	2.14	2.19
4b	1.64	1.80	1.84

[a] Difference between the electrochemically determined redox potentials for the radical cation and radical anion. [b] Based on the energy of the longest wavelength optical transition, determined at 1/10 of the maximum absorption. [17] [c] Corresponds to the energy determined by the PPP–SCF method [14] for the transition $S_0 \rightarrow S_1$.

the ways of characterizing it experimentally is to measure the potential difference for the first stage of reduction or oxidation. Alternatively, one can determine the energy of the longest wavelength optical transition[17, 18] (Tables 1 and 2). A graphic treatment of the observed ΔE values as a function of the number of naphthalene units present fails to display convergence, but it does reveal a considerable decrease with increasing molecular size. The observed ΔE for the discrete species **4b** (ca. 1.6 eV) is significantly less than that for polymers of either the polyphenylene (ca. 3.4 eV)[19] or poly-*p*-phenylenevinylene type (ca. 2.5 eV),[20] and is comparable to that determined for polyacetylene.[20]

p-Doping with iodine in saturated dichloromethane solution converts **3b** and **4b** into slightly soluble charge-transfer complexes, whereas the complex from **2b** remains in solution. The powder conductivity was found to be 10^{-2} S cm^{-1} for **3b** and, interestingly, 5 S cm^{-1} in the case of **4b**.

Synthesis of Enantiomerically Pure Heterosteroids by Intramolecular Hetero-Diels-Alder Reaction**

By *Lutz F. Tietze*,* *Uwe Beifuss, Magdolna Lökös, Matthias Rischer, Axel Göhrt*, and *George M. Scheldrick*

Heterocyclic steroids[1] are of considerable interest because of their pharmalogical properties, which frequently deviate from those of the carbocyclic compounds.[2] Although the synthesis of carbocyclic steroids by intramolecular Diels-Alder reaction of *o*-quinodimethanes according to the synthetic scheme AD → ABCD has been the subject of numerous studies for about ten years,[3] heterosteroids have so far never been synthesized in this way. As the first example of a novel, general, convergent and enantioselective entry to heterosteroids we describe here the synthesis of enantiomerically pure 6-oxa-2,4-diazasteroids and related compounds. The synthetic strategy employed is based on the tandem Knoevenagel-hetero-Diels-Alder reaction, which has already proven to be a valuable method for the stereoselective synthesis of annulated dihydropyrans.[4]

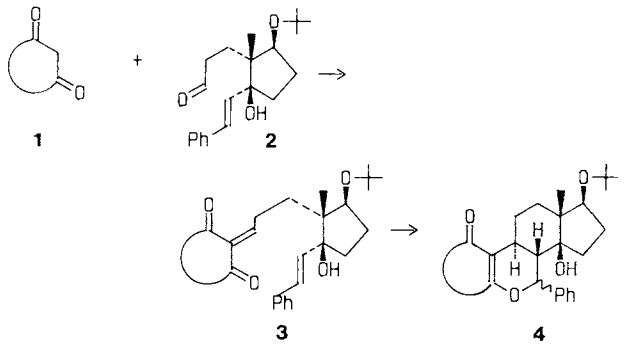
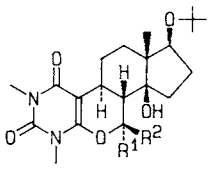
[**] Inter- and Intramolecular Hetero-Diels-Alder Reactions, Part 29. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 28: [4c].

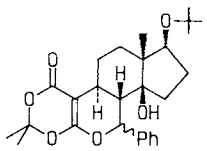
Knoevenagel condensation of the enantiomerically pure cyclopentane derivative **2** with cyclic 1,3-dioxo compounds **1** in the presence of catalytic amounts of ethylenediammonium diacetate (EDDA) affords the alkylidene compounds **3**, which react in situ to give the cycloadducts **4**. Thus, reaction



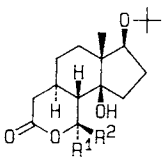
of **2** with *N,N'*-dimethylbarbituric acid in boiling acetonitrile ultimately furnishes the *trans*-annulated hetero-Diels-Alder products **5a** and **5b**, which differ only in the configuration at C-7, in 55 and 24% yield, respectively. The constitution and configuration of the two epimers were determined by analysis of the ^{1}H- and ^{13}C-NMR spectra,[5] and, in the case of **5a**, also by X-ray structure analysis.[6] For both isomers, the *trans*-fusion of the rings B and C follows from the coupling constants $^3J_{8-H,9-H} = 11$ Hz. In the reaction of **2** with Meldrum's acid in boiling toluene the cycloaddition is followed by cleavage of acetone and CO from the initially formed cycloadducts **6**, so that in this case the lactones **7a** (57%) and **7b** (18%) were the only products isolated. Similar results, i.e. exclusive formation of products with *trans*-annulated rings B and C, are found for the cyclization reactions of **2** with indane-1,3-dione and 3-methyl-1-phenylpyrazolin-5-one. In non-optimized reactions the cycloadducts **8** and **9** were obtained in 58 and 45% yield,



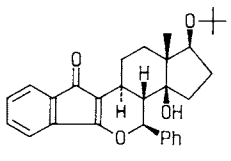
5a: R^1 = H, R^2 = Ph
5b: R^1 = Ph, R^2 = H



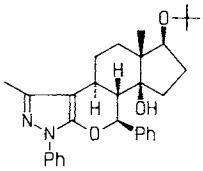
6



7a: R^1 = H, R^2 = Ph
7b: R^1 = Ph, R^2 = H

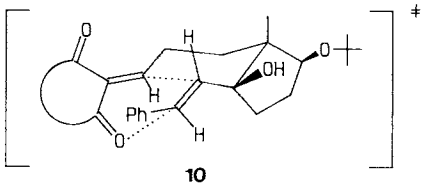


8



9

respectively. The remarkably high diastereoselectivity in the formation of the *trans*-annulated products can best be explained by assuming an *exo-E-anti*-transition state as depicted in **10**. The poor stereochemical control in the formation of the stereogenic center C-7 in **5a/b** is attributed to a carbocationic intermediate in the cycloaddition. On the basis of isomerization experiments with **5a, b** a thermodynamically controlled epimerization at C-7 after the cycloaddition should also be taken into consideration.[7]



10

The synthesis of the aldehyde **2** required for the intramolecular cycloadditions was accomplished by using the readily accessible tetrahydroindanedione **11**[8] as starting material, which was converted into the *tert*-butyl ether **12a**.[9] Oxidative cleavage of the C–C double bond in **12a** with ozone[10] and subsequent esterification of the initially formed oxocarboxylic acid **13a** with methyl iodide and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in acetonitrile[11] afforded the methyloxocarboxylate **13b** (86%).

Aside from the *tert*-butyl ether **12a**, the ethers **12a–f** were prepared and converted into the enantiomerically pure oxocarboxylates **13c–g** in 67–83% yield.[12] The *tert*-butoxide **13h** was accessible by ozonolysis of **12h** and subsequent treatment with *tert*-butyl alcohol in the presence of dicyclohexylcarbodiimide and 4-(dimethylamino)pyridine (Table 1).[13] Due to their availability in both enantiomeric forms,

Table 1. Preparation of enantiomerically pure cyclopentanones **13** by ozonolysis of the tetrahydroindanedione derivatives **12**.

Educt R		Product	R^1	R^2	Yield [%]
12a	*t*Bu	**13a**	*t*Bu	H	–

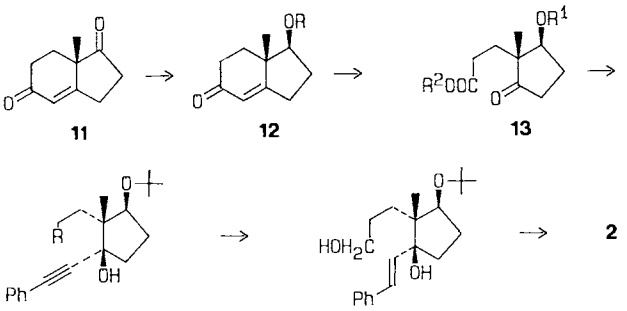
their ready accessibility, and their different functional groups, oxocarboxylates **13b–h** could be of general interest for the synthesis of cyclopentanoid natural products and related compounds.

The addition of lithiophenylacetylene[14] in THF at 0 °C to the methyl ester **13b** does not proceed chemoselectively. Besides 34% of the expected product **15** also 14% of the trisadduct **16** is formed. To avoid addition of the nucleophile to the carboxylate group, the bulky *tert*-butoxide **13h** was employed; thus, exclusively **17** (77%) is obtained in a completely chemo- and diastereoselective reaction. The stereoselective addition of the nucleophile to the keto group in **13h** probably succeeds as a result of the shielding of the Re-side by the *tert*-butyl ether group. Since the configuration of the



15: R = CO_2Me
16: R = $C(OH)(C{\equiv}C\text{-}Ph)_2$
17: R = CO_2tBu

products **15** and **17** could not be unequivocally determined by NMR spectroscopy, an X-ray structure analysis was carried out on **15**.[6] Reaction of **17** with $LiAlH_4$ led, with reduction of the ester to the alcohol and reduction of the triple bond to the *E*-double bond, to **14** (91%). Swern oxidation[15] of the light- and acid-sensitive alcohol **14** finally gave the aldehyde **2** (68%) required for the tandem-Knoevenagel-hetero-Diels-Alder reaction.

By variation of the diene, of the dieneophile, and of the connecting chain, the synthetic strategy presented here enables the synthesis of a variety of other heterocyclic steroid derivatives.

Synthesis of the First Silaamidide **

By *Gail E. Underiner* and *Robert West**

Amidines and their conjugate bases (amidides) have been extensively studied in carbon chemistry,[1] and while their silicon analogues $R_2N-Si(R)=NR$ are unknown,[2] a 1,3-diphospha-2-silaallyl anion has recently been reported.[3] We now report the isolation and characterization of the first silaamidide anion, as the salt lithium *N,N'*- bis(2,4,6-tri-*tert*-butylphenyl)phenylsilaamidide (**3**) and its ether complexes **2** and **4**.

Reaction of *n*BuLi with 2,4,6-tri-*tert*-butylaniline followed by addition of one-half equivalent of $PhSiCl_3$ affords silanediamine **1** (Table 1). Treatment of **1** with two equivalents of *t*BuLi in diethyl ether yields lithium silaamidide **2**,

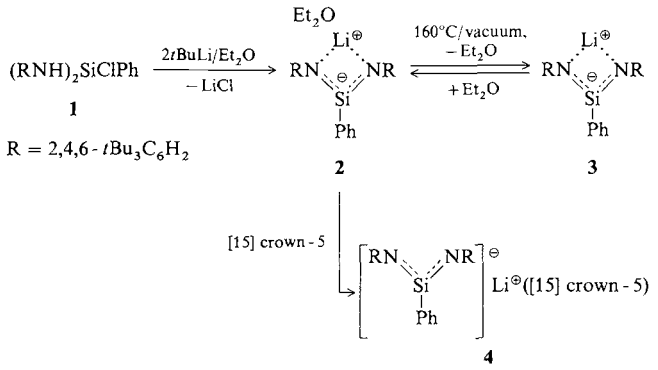
[**] This work was supported by the Air Force Office of Scientific Research, Air Force Systems Command, USAF under Contract No. F49620-86-C-0010 and the National Science Foundation, Grant No. CHE-8318810-02.



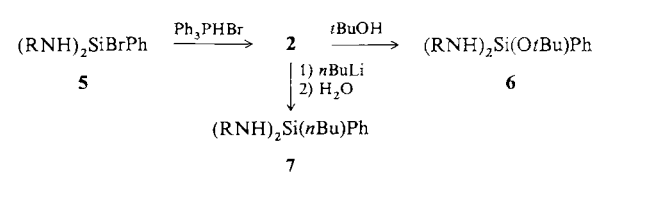
in which the lithium cation is coordinated to two N atoms of silaamide and to one molecule of diethyl ether. Ether may be reversibly removed from **2** by heating at 160 °C for several hours under vacuum to give the ether-free silaamidide salt **3**. Addition of [15]crown-5 to a benzene solution of **2** yields the salt **4** in the form of large yellow benzene-containing crystals. The lithium cation is no longer coordinated to the two N atoms, and the crystals lose benzene on exposure to X-rays and become a powder that cannot be fully characterized. The silaamidide salts are thermally stable but decompose rapidly upon exposure to atmospheric moisture or oxygen.

Table 1. Melting points and ^{29}Si NMR Data for **1**–**7**.

Compound	M.p. [°C]	^{29}Si NMR [δ values]
1 [a, b]	156–157	−28.8
2 [a]	212 (dec.)	3.2
3 [a]	140 (dec.)	7.0
4		−37.5
5 [b]	160–163	
6 [b]	226–227	−54.6
7 [a, b]	220–228	

[a] Satisfactory elemental analysis obtained for C, H, and N. [b] Correct high-resolution mass spectrum.

The ether-free silaamidide salt **3** exhibits a ^{29}Si NMR resonance at $\delta = 7$, shifted strongly downfield from the resonance for **1** ($\delta = -29$). **2** and **4** have ^{29}Si NMR chemical shifts of $\delta = 3$ and $\delta = -37.5$, respectively. This trend is reasonable, since the Si atom becomes more shielded by the greater negative charge in the allylic system as the lithium cation is more effectively solvated. Silaamidide salts **2**, **3**, and **4** show only one set of resonances for the tBu$_3$C$_6$H$_2$ groups in the ^{1}H and ^{13}C NMR spectra. This suggests that these anions, like amidides in organic chemistry,[5] are symmetrical. Rapid equilibration between unsymmetrical species cannot, however, be excluded. We attribute an intense band in the IR spectra (Nujol mull) of **2** at 1304 cm^{-1} to $\tilde{\nu}_{as}$ of [NSiN]. As expected, this frequency is lower than the previously reported value of $\nu_{Si=N}$ for tBu$_2$NSitBu$_3$ (1326 cm^{-1}).[4]



The silaamidide anion of **2** reacts rapidly with HBr and tBuOH. Since silylamines are prone to cleavage by strong acids, Ph$_3$PHBr was utilized as a gentle source of HBr.[6] It reacts with **2** in solution over several hours at room temperature, protonating one nitrogen atom and adding across the double bond of the silaamidine to afford **5**. Chlorosilane **1** does not react under these conditions. Compound **2** reacts with tBuOH to yield **6**. Addition of nBuLi to **2** followed by quenching with water gives **7**, presumably by addition of nBuLi across an Si···N bond to form the dianion, which is then protonated.

Experimental Procedure

1: 2,4,6-Tri-*tert*-butylaniline (6.0 g, 23 mmol) in 120 mL of hexane was treated with n-BuLi (9.2 mL of a 2.5 M solution in hexane, 23 mmol). After stirring the resulting white suspension for 1 h followed by 40 min of reflux, the reaction mixture was cooled to room temperature and PhSiCl$_3$ (2.4 g, 12 mmol) was added by syringe. After refluxing for 48 h, the solution was filtered and the salts washed several times with hexane. Solvent was removed from the filtrate under vacuum to give a sticky solid. Recrystallization in hexane yielded 5.30 g (67%) of colorless **1**.

2: A solution of **1** (2.00 g), 3.16 mmol) in 10 mL of ether and 50 mL of hexane was treated at −78 °C with tBuLi (3.72 mL of a 1.7 M solution in hexane, 6.32 mmol). After several hours the reaction mixture was warmed to room temperature and stirred for 24 h. Salts were removed by filtration under nitrogen and the filtrate was evaporated to dryness, giving a colorless solid. Recrystallization in hexane furnished 1.24 g (56%) of colorless **2**.

A Facile Synthesis of β-Selenolactams

By *Hideharu Ishihara, Michinari Yoshimi*, and *Shinzi Kato**

Although considerable progress has been made in the chemistry of β-lactams[1] and β-thiolactams[2] during the past forty years, very little is known about the biologically and spectroscopically interesting β-selenolactams because of the difficulties encountered in their synthesis.[3] We now wish to report a convenient method for synthesizing and characterizing β-selenolactams **3a** to **3e** (see Table 1). These β-selenolactams were obtained by reaction of lithium alkyneselenolate **1** with the alkylidenamines **2** below −20 °C. The structures were determined by ^{1}H NMR, ^{13}C NMR, ^{77}Se

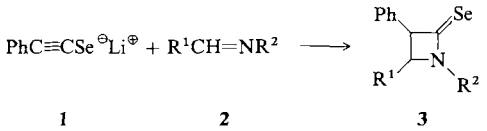
[a] A: Mole ratio of **1**/**2**/AcOH = 1/1/0.5, tetrahydrofuran, −20 °C, 3 h; B: Mole ratio of **1**/**2**/AcOH = 1/1/1.2, tetrahydrofuran, −20 °C, 1 h. [b] Purified by preparative thin-layer chromatography (hexane/ether = 5/1, **3b**: R_f = 0.2, **3b′**: R_f = 0.3). [c] Satisfactorily exact mass data for **3b** and **3b′** as well as elemental analyses for **3a, 3c–e** (C ±0.33, H ±0.16%) were obtained; [d] Relative to Me_4Si in $CDCl_3$. [e] Relative to Me_2Se in $CDCl_3$ (60%). [f] In $CDCl_3$.

NMR, IR, and mass spectra as well as by elemental analysis. The configurations of R^1 and R^2 were determined to be *cis* on the basis of vicinal coupling constants J_{HH} = 4 to 6 Hz.[4] All the reactions of **2** (except for **2b**) led to the exclusive formation of the *cis* isomer of **3**. A plausible explanation for



1 **2** **3**

this [2+2] cycloaddition to **3** is the participation of the canonical resonance structure **1′** in analogy to the reactions of the corresponding thio congeners.[5]

1 **1′**

The reaction pathway described here for synthesizing β-selenolactams, although until now only carried out with 1-alkynes, avoids many difficulties inherent in other methods: (1) The reaction conditions are mild, the procedures very easy. (2) The yields of **3** are high, and *cis* isomers are obtained almost exclusively. (3) The starting compounds are readily available. (4) Since it is conducted in solution, the reaction is free of the small-scale synthesis problems that are encountered in the heterogeneous reaction using phosphorus pentaselenide.[3a]

Experimental Procedure

3a: A solution of **1** (1 mmol), prepared from phenylethynyllithium (1 mmol) and selenium (powder) in tetrahydrofuran (10 mL), was treated with **2a** (181 mg, 1 mmol) for 1 h and then with acetic acid (72 mg, 1.2 mmol) at −20 °C under argon. The mixture was stirred at this temperature for 15 min. After adding ether (20 mL), the mixture was washed with water (3 × 50 mL) and the organic phase dried over anhydrous sodium sulfate. The solvents were removed by evaporation in vacuo. Recrystallization of the residue with ether/hexane (5/1) afforded (**3a**) in 89% yield: m.p. 180–181 °C. ^1H NMR ($CDCl_3$): δ = 4.59 (d, J = 5.49 Hz, 1H, ^3CH), 6.10 (d, J = 5.49 Hz, 1H, ^4CH), 7.0–7.4 (m, 13H, H_{Aryl}), 8.23 (d, 2H, H_{Aryl}). ^{13}C NMR ($CDCl_3$): δ = 63.3 (^3CH), 71.1 (^4CH), 118.2, 126.8–138.9 (C_{Aryl}), 202.0 (C=Se). Satisfactory C,H analysis.

$Zn^{II}Fe^{III}$ and $Fe^{II}Fe^{III}$ Complexes Containing a Novel (μ-Phenoxo)bis(μ-diphenylphosphato)-dimetal(II,III) Core as Model Complexes for Active Sites of Purple Phosphatases**

By *Klaus Schepers, Bernd Bremer, Bernt Krebs,* Gerald Henkel, Erika Althaus, Bernd Mosel,* and *Werner Müller-Warmuth*

Purple, acid phosphatases are important iron-containing non-heme proteins which catalyze the hydrolysis of activated phosphoric acid esters.[1] The active site of uteroferrin (PP 1[1b]) and of phosphatase from bovine spleen[1d,e,f] consists of an $Fe^{II}Fe^{III}$ moiety in its inactive purple form in which

the iron ions have a high-spin configuration and are coupled strongly antiferromagnetically ($-J > 150\ cm^{-1}$[1d]). The enzymatically active pink form of PP1 contains a mixed valence $Fe^{II}Fe^{III}$ center with a more weakly antiferromagnetic coupling of the high-spin ions ($J = -19.8(5)\ cm^{-1}$[2]). A tightly bound phosphate group was detected in the oxidized form of PP1; however, it is so far controversial as to whether this phosphate group is bridging or terminally coordinated.[3] A purple, mixed valence uteroferrin(red)-phosphate complex which shows a pH-dependent absorption maximum between 530 and 561 nm has been characterized both spectroscopically and kinetically.[4] The antiferromagnetic spin interactions are only weak ($J = -6.0(5)\ cm^{-1}$[2]).

In contrast, a phosphatase (PP2) isolated from kidney beans contains a heterobinuclear $Zn^{II}Fe^{III}$ center, whose structure is presumably very similar to that of the $Fe^{II}Fe^{III}$ unit in the reduced form of PP1.[5] PP2 shows an absorption band at $\lambda_{max} = 560$ nm which can be assigned to a charge transfer transition from a tyrosine ligand to the Fe^{III}. A further enzymatically active $Fe^{II}Fe^{III}$ derivative of PP2 has the same ESR spectrum as the mixed valence form of PP1.[6]

Diiron(III) model complexes with (μ-oxo)bis(μ-phosphato), (μ-oxo)bis(μ-phenylphosphato), tris(μ-phosphato) or tris(μ-phenylphosphato) groups could be obtained with the ligand 1,4,7-trimethyl-1,4,7-triazacyclononane; a bridging coordination of diphenylphosphate is present in the dinuclear Fe^{III} complex $[Fe_2O\{O_2P(OC_6H_5)_2\}_2L_2]$ (L = hydrotris(1-pyrazolyl)borate).[7]

Attempts to synthesize and characterize mixed valence phosphate-bridged model compounds for the active form of the purple phosphatases have hitherto failed. We report here on the first model complexes for the active centers of PP1 and PP2, in which phosphoric acid esters are coordinated to the dinuclear $Fe^{II}Fe^{III}$ and $Zn^{II}Fe^{III}$ units. 2,6-Bis[bis(2-pyridylmethyl)aminomethyl]-4-methylphenol (Hbpmp), which has proven to be suitable for the synthesis of dinuclear mixed valence iron complexes,[8] was used as ligand.

Reaction of equimolar amounts of $Fe(ClO_4)_3 \cdot 9H_2O$ and $ZnBr_2$ in methanol with Hbpmp leads, after addition of diphenyl phosphate, to bluish-black crystals of **1**. The analogous reaction with two equivalents of $Fe(ClO_4)_3 \cdot 9H_2O$ yielded dark green crystals of **2**.

$[Zn^{II}Fe^{III}(bpmp)(O_2P(OPh)_2)_2](ClO_4)_2 \cdot 1.5\,CH_3OH \cdot H_2O$ **1**

$[Fe^{II}Fe^{III}(bpmp)(O_2P(OPh)_2)_2](ClO_4)_2 \cdot CH_3OH \cdot H_2O$ **2**

The structure of **1** is shown in Figure 1.[9] The molecule contains a μ-phenoxo-bridged $Zn^{II}Fe^{III}$ unit in which the metal centers are additionally linked by two μ-diphenylphosphato bridges. The nitrogen donors of the ligand $bpmp^{\ominus}$ complete an octahedral environment of the two metal centers by facial coordination. The Zn···Fe distance of 3.695 Å in **1** (and the similar Fe···Fe distance in **2**[10]) is significantly larger than in the carboxylate-bridged $Zn^{II}Fe^{III}$- and $Fe^{II}Fe^{III}$-analogues (3.438 and 3.365 Å, respectively[8d]), presumably as a result of the larger bite distance of the phosphate. This indicates a remarkable structural flexibility of the hydroxo-(alkoxo)-bridged dimetal(II,III) center (possibly important for the catalytic activity). On the other hand, d(Zn···Fe) compares with the value of 3.65 Å determined from EXAFS measurements on the native kidney bean phosphatase in the presence of phosphate.[11]

1 has a magnetic moment of 6.15 μ_B at room temperature. The magnetic susceptibilities (Faraday method) for crystalline **2** between 4.2 and 289.5 K can be fitted based on an isotropic Heisenberg model, $H' = -2J \cdot S_1 \cdot S_2$ ($S_1 = 2$, $S_2 = 5/2$) and $g = 2.06(4)$. Weak antiferromagnetic behavior was established; the coupling constant ($J = -6.2(5)\ cm^{-1}$) is in good agreement with the value determined for the reduced uteroferrin-phosphate complex.

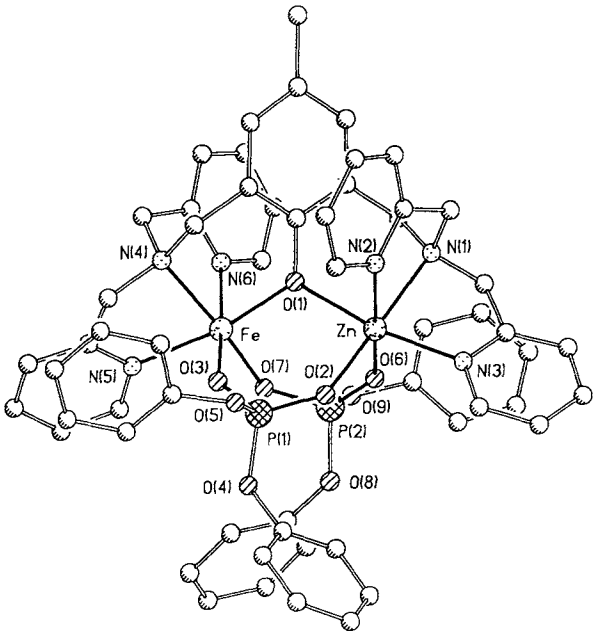

Fig. 1. Structure of the cation $[Zn^{II}Fe^{III}bpmp(O_2P(OPh)_2)_2]^{2\oplus}$ in the crystal of **1**. Important bond lengths [Å] and angles [°]: Fe···Zn 3.695(1), Fe···P1 3.281(1), Zn···P1 3.212(1), Fe···P2 3.183(1), Zn···P2 3.325(1), Fe–O1 2.031(2), Zn–O1 2.176(2), Fe–O3 1.984(3), Zn–O6 2.065(3), Fe–O7 1.966(2), Zn–O2 2.026(3), Fe–N4 2.177(3), Zn–N1 2.180(3), Fe–N5 2.104(3), Zn–N3 2.119(3), Fe–N6 2.125(3), Zn–N2 2.127(3), P1–O2 1.490(3), P1–O3 1.492(3), P2–O6 1.475(3), P2–O7 1.505(2); Fe–O1–Zn 122.8(1).

Electrochemical investigations on **1** show a reversible one-electron charge transfer at a potential of +143 mV. The transfer observed at +765 mV with only a very small peak current can be attributed to slight contamination of **1** with Fe^{II}. In the case of **2** two reversible one-electron transfers are observed at potentials of $E_1 = +135$ mV and

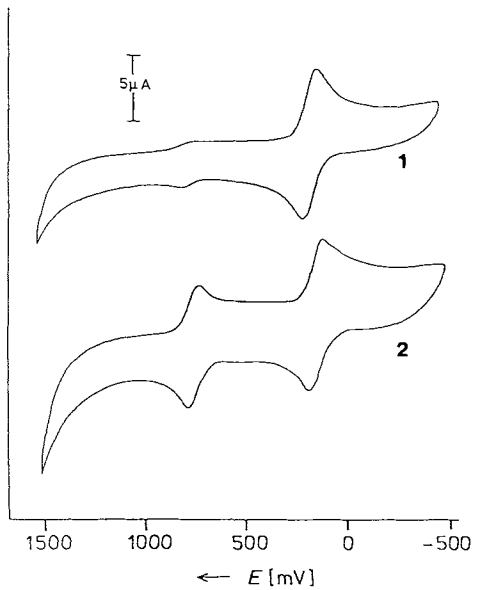

Fig. 2. Cyclovoltammograms of **1** and **2** (vs. SCE). 0.1 M $(n\text{Bu})_4NClO_4$ in MeCN under argon. Measuring rate: 100 mV s^{-1}.

$E_2 = +755$ mV, which are assigned to the redox pairs $Fe^{II}Fe^{II}/Fe^{II}Fe^{III}$ and $Fe^{II}Fe^{III}/Fe^{III}Fe^{III}$. The cyclovoltammograms of **1** and **2** are shown in Figure 2.

Using the relationship $E_2 - E_1 = R \cdot T \cdot F^{-1} \cdot \ln K$, the thermodynamic stability constant of the mixed valence complex **2** can be estimated to be $K = 3.2 \times 10^{10}$ for the comproportionation equilibrium. The Mössbauer spectrum of **1** at

$$(Fe^{II}Fe^{II}) + (Fe^{III}Fe^{III}) \rightleftarrows 2(Fe^{II}Fe^{III})\,.$$

298 K shows, in addition to the Fe^{III} doublet, broad signals that can be assigned to Fe^{II}. At 4.2 K additional splittings are observed which can be ascribed to magnetic hyperfine interactions. The Mössbauer spectra of **2** could be fitted for the temperatures 300, 100 and 50 K (Fig. 3). The values of the

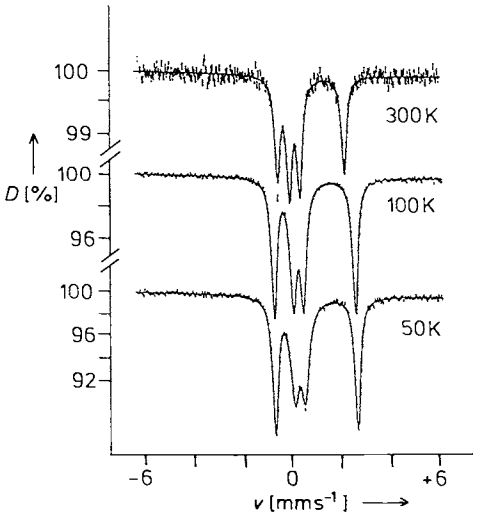

Fig. 3. ^{57}Fe-Mössbauer spectra of a polycrystalline sample of **2**. *v*: rate, *D*: transmission.

isomeric shifts δ (referred to metallic iron at 298 K) and the quadrupole splittings ΔE_Q are listed in Table 1. All the spectra of **2** show two separate quadrupole doublets of equal intensity, indicating localized high-spin-Fe^{II}- and high-spin-Fe^{III}-valence states. The corresponding values for the uteroferrin(red)-phosphate complex at 119 K are $\delta = 1.23$ and 0.54 mm s^{-1} ($\Delta E_Q = 2.76$ and 0.78 mm s^{-1}) respectively, for uteroferrin(red) without phosphate[4] $\delta = 1.22$ and 0.53 mm s^{-1} ($\Delta E_Q = 2.63$ and 1.78 mm s^{-1}), respectively, and for bovine spleen phosphatase(red) at 77 K[1f] $\delta = 1.17$ and 0.67 mm s^{-1} ($\Delta E_Q = 2.65$ and 1.27 mm s^{-1}), respectively. Similar Mössbauer data as for **2** have been obtained for the carboxylate-bridged complex $[Fe_2(bpmp)(OPr)_2](BPh_4)_2$ ($\delta = 1.13$ and 0.48 mm s^{-1}, respectively, $\Delta E_Q = 2.69$ and 0.50 mm s^{-1}, respectively, at 55 K).[8c] A valence fluctuation more rapid than 10^{-7} s is not observed in the room-temperature spectrum of **2**. The spectra at 25, 10 and 4.2 K indicate

Table 1. Mössbauer parameters of **2** ($\delta \pm 0.01$ mm s^{-1}; $\Delta E_Q \pm 0.02$ mm s^{-1}).

	Fe^{II}		Fe^{III}	
T [K]	δ_1 [mm s^{-1}]	ΔE_{Q1} [mm s^{-1}]	δ_2 [mm s^{-1}]	ΔE_{Q2} [mm s^{-1}]
300	1.05	2.75	0.37	0.43
100	1.16	3.35	0.48	0.41
50	1.17	3.39	0.49	0.43

magnetic hyperfine interactions which so far, however, could not be fitted.

The electron spectrum of **1** in methanol shows only one absorption maximum at $\lambda_{max} = 569$ nm ($\varepsilon \approx 800$ cm^{-1} mol^{-1}), which is assigned to a charge transfer transition from phenolate to the Fe^{III} ion. The UV/VIS spectrum of **2** in methanol shows the corresponding transition at $\lambda_{max} = 610$ nm ($\varepsilon \approx 950$ cm^{-1} mol^{-1}). In addition, a shoulder is observed at $\lambda = 365$ nm ($\varepsilon \approx 3480$ cm^{-1} mol^{-1}), which can be assigned to a charge-transfer transition from the Fe^{II} to pyridine.[8d]

Experimental Procedure

1: A solution of 0.44 g of Hbpmp (0.8 mmol) in 30 mL of methanol was treated with a solution of 0.41 g of $Fe(ClO_4)_3 \cdot 9H_2O$ (0.8 mmol) in 10 mL of methanol and a solution of 0.18 g of $ZnBr_2$ (0.8 mmol) in 10 mL of methanol. After addition of 0.4 g of diphenyl phosphate (1.6 mmol) in 10 mL of methanol, bluish-black crystals of **1** separated out. Small amounts of oxidizing agents (H_2O_2, $S_2O_8^{2\ominus}$) did not prevent the slight contamination with Fe^{II}.

2: The synthesis was accomplished by an analogous reaction of 0.82 g of $Fe(ClO_4)_3 \cdot 9H_2O$ (1.6 mmol) with 0.44 g Hbpmp (0.8 mmol) and 0.4 g of diphenyl phosphate (1.6 mmol).

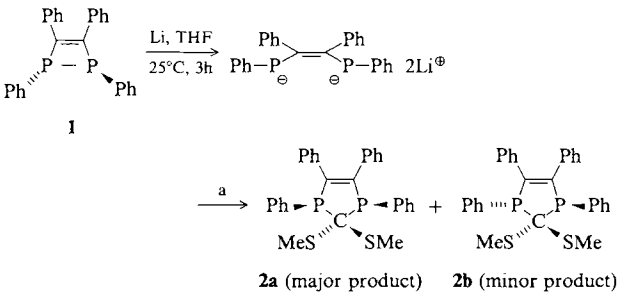
A New Route to 1,3-Diphospholide Ions. Synthesis and X-Ray Structure Analysis of a 1,3-Diphosphaferrocene

By *Nicole Maigrot, Louis Ricard, Claude Charrier,* and *François Mathey**

Presently, only one 1,3-diphospholide ion is known. This 2,4,5-tri-*tert*-butyl derivative is formed as a by-product in the synthesis of the 3,5-di-*tert*-butyl-1,2,4-triphospholide ion from *tert*-butylphosphaacetylene.[1-3] The development of the chemistry of this very interesting species is thus hampered by the lack of a convenient and specific access to derivatives of the 1,3-diphospholide ion. We have now found a way of filling this gap starting from the readily accessible 1,2-dihydro-1,2-diphosphete ring.[4]

The P–P bond of the 1,2,3,4-tetraphenyl-substituted four-membered ring compound **1** was first cleaved by reaction with lithium in THF.[5] Treatment of the resulting dianion with carbon disulfide followed by alkylation with methyl iodide then afforded the five-membered 2,3-dihydro-1,3-diphospholes **2a, b** in 80% yield (Scheme 1).



Scheme 1. a: 1) CS_2, −80 °C, 15 min, 2) 2 equiv. MeI, −80 to 25 °C.

Both isomers were obtained in the pure state by chromatography. The ^1H and ^{13}C NMR spectra of the *cis* isomer **2a** obtained as major product (Table 1) display two nonequivalent MeS groups, whereas the spectra of the *trans* isomer obtained in smaller amounts contain only one MeS signal.

Table 1. Most important spectroscopic data of **2a, 2b, 5** [a].

2a: ^{31}P NMR: $\delta = 60.3$; ^1H NMR: $\delta = 1.62$ (s, 3H, SMe), 2.44 (t, ^4J(H–P) = 1.36 Hz, 3H; SMe); ^{13}C NMR: $\delta = 13.97$ (s, SMe), 14.99 (t, ^3J(C–P) = 21.3 Hz, SMe), 57.90 (t, ^1J(C–P) = 41.5 Hz, P–*C*–P), 147.50 (dd, ^1J(C–P) = 12.5 Hz, ^2J(C–P) = 5.7 Hz, Ph–*C*=); MS = *m/z* 500 ($M^\oplus$, 34%), 453 ($M^\oplus$ − SMe, 100%), 406 ($M^\oplus$ − 2SMe, 27%)

2b: ^{31}P NMR (CH_2Cl_2): $\delta = 74.2$; ^1H NMR: $\delta = 1.98$ (s, 6H, SMe); ^{13}C NMR (C_6D_6): $\delta = 13.27$ (t, ^3J(C–P) ≈ 9 Hz, SMe), 52.79 (t, ^1J(C–P) = 37.9 Hz, P–*C*–P), 147.52 (s, Ph*C*=)

5: ^{31}P NMR: $\delta = 5.1$; ^1H NMR: $\delta = 3.67$ (t, ^2J(H–P) = 32.5 Hz, 1H, P–C*H*–P), 4.54 (s, 5H, Cp), 7.13 (s, 10H, Ph); ^{13}C NMR: $\delta = 74.95$ (s, Cp), 81.59 (t, ^1J(C–P) = 71.6 Hz, P–*C*–P), 110.79 (m, Ph–*C*=); MS: *m/z* 374 ($M^\oplus$, 100%).

[a] NMR spectra in CD_2Cl_2 and 70-eV EI mass spectra unless noted otherwise. ^1H NMR, 200.1 MHz; ^{13}C NMR, 50.3 MHz; ^{31}P NMR 32.4 MHz.

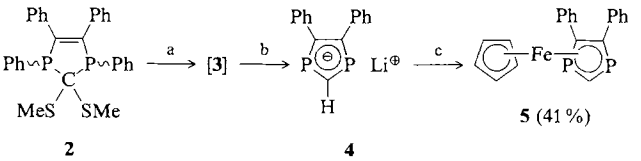
The mixture **2a, 2b** was treated with six equivalents of lithium in THF at room temperature. The initial ^{31}P NMR signals of **2a** and **2b** slowly disappeared and were replaced by a larger signal at $\delta = 229$ (**3**) and a smaller signal at $\delta = 193$ (**4**). Addition of *tert*-butyl chloride (or, alternatively, of dry powdered NH_4Cl) led to transformation of **3** into **4** (Scheme 2). Apparently, **4** is formed by protonation of **3**. Indeed, the phosphorus atoms of **3** show no sizable PH coupling, whereas the phosphorus atoms of **4** are strongly coupled with one proton: $J(^{31}P^1H) = 36.6$ Hz. The position of the P signal of **4** in the ^{31}P NMR spectrum is similar to that recorded for the 2,4,5-tris-*tert*-butyl-1,3-diphospholide ion ($\delta^{31}P = 187.6$ in THF[2]) and the PH coupling is similar to those found in phospholide anions.[6] Compound **4** was unequivocally identified as the 4,5-diphenyl-1,3-diphospholide ion via its reaction with (η^5-cyclopentadienyl)(η^6-*p*-xylene)iron hexafluorophosphate,[7] which afforded the expected 1,3-diphosphaferrocene **5** (Scheme 2).



Scheme 2. a: 6 equiv. Li, THF, 25 °C, 24 h; b: *t*BuCl, 25 °C, 24 h or NH_4Cl, 25 °C, 5 min; c: $[(\eta^5\text{-}C_5H_5)(\eta^6\text{-}1,4\text{-}Me_2C_6H_4)Fe]^\oplus PF_6^\ominus$, 25 °C, 4 h.

Only one 1,3-diphosphaferrocene had been previously described in the literature.[8] It was obtained as a mixture with the corresponding 1,2,4-triphosphaferrocene and was only characterized by ^1H and ^{31}P NMR spectroscopy. Therefore, we decided to carry out the X-ray structure analysis of **5** (Fig. 1). The 1,3-diphospholide ring is almost planar. The two rings are eclipsed and parallel. The iron atom is closer to the phospholide plane [1.6224(7) Å] than to the cyclopentadienyl plane [−1.6694(7) Å]. The two most striking differences between the structure of **5** and 3,4-dimethyl-1-phosphaferrocene[10] are the parallelism of the two planes in **5** (in 3,4-dimethyl-1-phosphaferrocene the dihedral angle is

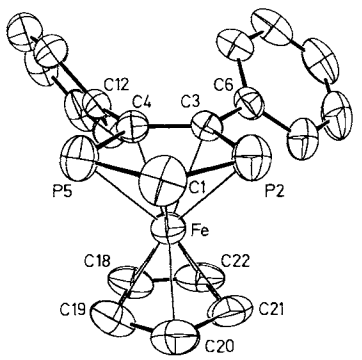


Fig. 1. Structure of **5** in the crystal [9]. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances [Å] and angles [°]: Fe–P2 2.285(1), Fe–P5 2.277(1), Fe–C1 2.094(5), Fe–C3 2.094(4), Fe–C4 2.084(4), Fe–(C18–C22) 2.045 to 2.065(5), P2–C1 1.745(5), P2–C3 1.779(4), P5–C1 1.760(6), P5–C4 1.785(4), C3–C4 1.418(6), C–C (C_6H_5) 1.394(8) to 1.422(8); P2–C1–P5 119.7(3), C1–P2–C3 93.5(2), C1–P5–C4 92.9(2), P2–C3–C4 116.7(3), P5–C4–C3 117.1(3).

3.18° [10]) and the widening of the intracyclic angle at C_1. Open-chain η^3-1,3-diphosphaallyl complexes show smaller P–C–P angles.[11]

The quantitative conversion of **2** into **4** (^{31}P NMR) opens up several new perspectives: (1) the easy variation of the substitution pattern of **4** via the choice of the starting 1,2-diphosphete;[4] (2) the optional η^1-coordination of the two phosphorus atoms of these unhindered 1,3-diphospholide species (such a coordination appears to be difficult in the case of the strongly hindered 2,4,5-tris-*tert*-butyl derivative[8]); (3) the 2-H atom the 1,3-diphospholide ligand in η^5-complexes such as **5** could be substituted. We are currently investigating these possibilities.

Experimental Procedure

Synthesis of **2a, 2b**: The P–P bond of **1** (3.94 g, 10 mmoles) was cleaved under an argon atmosphere by stirring with lithium (140 mg, 20 mmol) in 20 mL of THF for 3 h. The solution was then cooled to −80 °C and one equivalent of CS_2 (600 μL, 10 mmol) was added. After fifteen minutes, two equivalents of methyl iodide (1.24 mL, 20 mmol) were added dropwise. After stirring for an additional fifteen minutes at −80 °C, the reaction mixture was slowly warmed to room temperature. After evaporation of THF, the mixture was chromatographed over silica gel 60 with hexane/toluene (50/50) to remove any unconsumed **1**, and then with toluene. About 10% unconsumed **1** was thus recovered and 80% pale yellow crystals of a mixture of the two isomers **2a** and **2b**.

Synthesis of **5**: A solution of **2** (2 g, 4 mmoles) in 20 mL of THF was stirred with 170 mg (24 mmol) of lithium wire (1% Na) under an argon atmosphere for 24 h at room temperature. The product **3** was treated with 1 mL (12 mmol) of *t*BuCl and the reaction mixture left to stand for an additional 24 h, thus yielding **4**. Finally, **4** was allowed to react with 1.5 g (4 mmol) of $[CpFe(C_8H_{10})]^{\oplus}PF_6^{\ominus}$ at room temperature for 4 h to yield **5**. The reaction mixture was quickly chromatographed on a short silica gel column (20 g, l = 8 cm, ∅ = 26 mm) and eluted with CH_2Cl_2. After evaporation of the solvent, the residue was chromatographed a second time over silica gel (100 g, l = 21 cm, ∅ = 36 mm) and eluted with a mixture of hexane and CH_2Cl_2 (70/30). The expected product **5** is obtained with the bright red head fraction, yield 41%. **5** can be purified by heating under vacuum (0.1 torr) in a sublimer at 120 °C to remove an oily residue that cannot be removed by chromatography. **5** can be recrystallized from a mixture of toluene and methanol (5/95).

[9] Crystals of **5**, $C_{20}H_{16}FeP_2$ were grown at −18 °C from a methanol-toluene solution of the compound. Data were collected at 18° ± 1° on an Enraf Nonius CAD4 diffractometer. The crystal structure was solved and refined using an Enraf Nonius CAD4 diffractometer. The compound crystallizes in the space group $P2_1/n$, a = 10.194(1) Å, b = 9.841(1) Å, c = 16.818(1) Å, β = 95.05(1)°; V = 1680.71() Å^3; Z = 4; ϱ_{calcd} = 1.487 g/cm^3; $Cu_{K\alpha}$ radiation (λ = 1.54184 Å) graphite monochromator; μ = 90.6 cm^{-1}; $F(000)$ = 768. A total of 3683 unique reflexions were recorded in the range $2° \le 2q \le 150.0°$, of which 1683 were considered as unobserved ($F^2 < 3.0\sigma(F^2)$), leaving 2000 for solution and refinement. The structure was solved by direct methods, yielding a solution for 12 of the 23 heavy atoms. The hydrogen atoms positional parameters were refined in the final stages of a least-squares refinement with fixed thermal parameters equal to 1.3 times that of the attached carbon atom while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a p factor equal to 0.08. The final R factors were R = 0.047, Rw = 0.064, G.O.F. = 1.27. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2(FRG), on quoting the depository number CSD-54551, the names of the authors, and the journal citation.

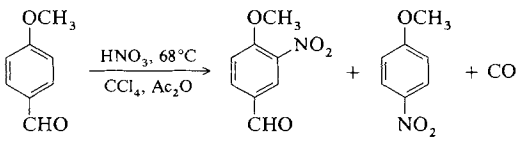
Clays Direct Aromatic Nitration**

By *Christine Collet, Alfred Delville*, and *Pierre Laszlo**

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

Modified clays can act as efficient catalysts of organic reactions.[1–3] Among clays, kaolinites have seldom been used for such purposes,[2] although they do intercalate molecules as polar as water,[4] formamide,[5] *N*-methylformamide,[5] dimethyl sulfoxide,[6,7] and dimethyl selenoxide[7] within their layers. Therefore, we set about exploring the catalytic potential of kaolinites for reactions proceeding through highly polar transition states. Discrimination between transition states differing in polarity and in steric bulk was our goal. We chose to study the nitration of *p*-anisaldehyde (**1**).



1 **2** **3**

The methoxy substituent directs nitration to the *ortho* and *para* positions.[8] In the former case, the resulting Wheland intermediate has only to lose a proton for product **2** to be formed. In the latter case, that of nitration *ipso* to the 4-formyl-substituted position, expulsion of protonated carbon monoxide is a prerequisite for the appearance of product **3**. Accordingly, under *homogeneous* reaction conditions, only minuscule quantities of the minor **3** form (Table 1). The two Wheland intermediates[9,11] leading to products **2** and **3** are highly polar, with calculated dipole moments (MINDO-3[15]) of 4.49 and 5.57 D, respectively. Accordingly, the expectation that the high acidity (Hammett acidity function $H_0 = -6$ to -8)[16] and perhaps also the intense electric field at the interface of a montmorillonite clay[17,18] would favor the **1** → **3** pathway was borne out (Table 1): in the presence of montmorillonite K10[1–3] the proportion of **3** in the product mixture **2** + **3** goes up by more than one order of magnitude, and increases as the Brønsted acidity at

Table 1. Proportion of *p*-nitroanisole formed (±1.2%) as a function of the solid present (0.15 g per mmol of **1**)[a].

Solid support	**3** (%)
(none)	1.1
Silica	2.3
Kieselguhr	1.6
$Cu(NO_3)_2 \cdot 3H_2O$ on kieselguhr	2.2
$Cu(NO_3)_2 \cdot 3H_2O$ on acidic alumina	2.1
$Cu(NO_3)_2 \cdot 3H_2O$	1.3
K10	9.6
Claycop	10
K10-$Cu^{2\oplus}$	13
K10-$Al^{3\oplus}$	15
K10-$Ti^{4\oplus}$	16
K10-$Zr^{4\oplus}$	21
Kaolinite	27 [b]

[a] 1.5 g of the solid + 10 mmol **1** + 3.1 ml Ac_2O i.e. an excess relative to HNO_3 plus the residual water in the clay [12] are introduced in that order in CCl_4 (25 ml) and refluxed for 15 min while 0.5 mL of fuming HNO_3 (Merck, p.a., 99.5% min.) is added dropwise. [b] 73% of **2**. Claycop is clay-supported cupric nitrate [3].

the surface is enhanced by the Lewis-acidic interstitial cations.[1-2] Likewise, in a still more pronounced manner, a kaolinite, also a clay with a strongly acidic surface ($H_0 = -3$ to -6),[16] favors *ipso* nitration: the yield of **3** rises to 27%, boosted by a factor of 25 compared to homogeneous conditions!

The percentage of **3** varies with the amount of kaolinite present (Fig. 1): such a plot, with a strong resemblance to a Langmuir isotherm, is consistent with a single type of catalytic site. In the most conservative estimate, the catalytic turnover is at least 300.[20] The enhanced production of **3** is observed only with phyllosilicates, such as the K10 montmorillonite and kaolinites. Conversion is quantitative when the amount of the nitrating reagent has been well-adjusted to equal that of the aldehyde substrate, taking into account (minor) losses as vapors of nitrogen oxides. Conversion does not occur significantly (Table 1) on the surface of microporous solids such as alumina or silica.

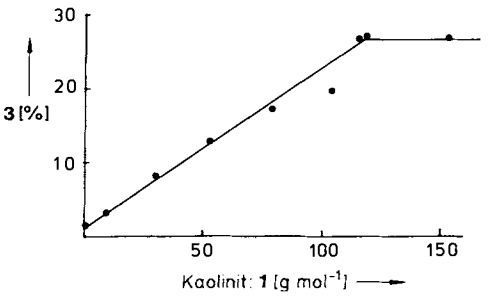

Fig. 1. Percentage of **3** formed as a function of the ratio (g mol^{-1}) of the mass of kaolinite (g) to the amount of **1** (mol).

These effects do not seem to require intercalation.[21] Protonation of the incipient carbon monoxide leaving group,[11] in the adsorbed state, is the probable cause for the considerable increases in the amount of *ipso* nitration in the *para* position, by a factor 10 with the montmorillonite, and by a factor 25 with the kaolinite.

[17] The magnitude of the electric field was calculated from Gauss's law, at a distance of 6 Å from a clay sheet with a charge density, appropriate for a smectite (the Upton bentonite) of 6.8 me $Å^{-2}$. The electric field at the interface has limiting values of 1.6×10^8 V m^{-1} for a dielectric constant of 78.5 (water), and of 1.2×10^{10} V m^{-1} for a dielectric constant of unity. The energy gain for the more polar of two transition states differing by 1 D in their dipole moments is 5.5 kJ mol^{-1} for a local dielectric constant of 5.
[18] The *Bertrán* group has shown recently that strong electric fields of ca. 10^{10} V m^{-1} can remove an activation energy barrier. They showed, using the example of the $F^{\ominus} + CH_3F$ Walden inversion, that increasing the strength of the electric field gradually deletes the barrier [19]. The heuristic interpretation is that electrons donated by the nucleophile follow the field which pumps the system from its initial to its final state.

Formation of an Aminoreductone from Glucose

By *Sabine Estendorfer, Franz Ledl,** and *Theodor Severin**

In many heated foodstuffs, reducing sugars react with amino acids or proteins to give, inter alia, brown products and characteristic aromas of roasting (non-enzymatic browning, Maillard reaction). Such reactions have for some time attracted interest among physicians and biochemists, since one presumes that morbid alterations in diabetic per-

[*] Prof. Dr. T. Severin, S. Estendorfer

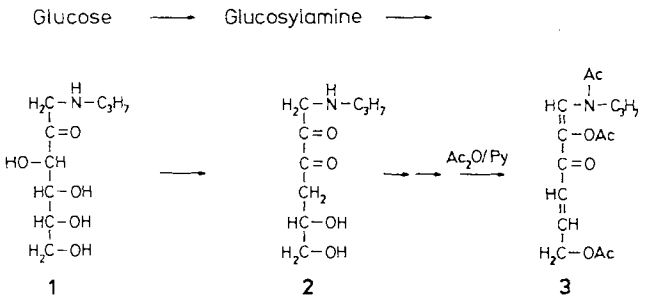
Institut für Lebensmittelchemie der Universität
Pfaffenwaldring 55, 7000 Stuttgart 80 (FRG)

sons, clouding of the eye lenses, cross-linking of proteins, and possibly ageing processes can be attributed to reactions of sugars with proteins.[1]

Only the first steps of the Maillard reaction have so far been elucidated in detail. Glucose reacts with amino acids or other primary or secondary amines, leading firstly to glycosylamines, which readily transform by Amadori rearrangement into the corresponding *N*-substituted 1-amino-1-deoxyfructoses.[2] In proteins, the lysine side chain is preferentially attacked. Secondary reactions lead to the formation of an extraordinarily complex mixture containing many still unidentified compounds. Substances with reductone character, which can protect foodstuffs against oxidative damage and thus contribute to storage stability, are also formed.

We have isolated an open-chain C_6-aminoreductone as transformation product of an Amadori compound. Thus far, only a C_4-aminoreductone which can be formed in very small amounts in heated sugar–amine mixtures has been reported in the literature.[3] The "piperidinohexose reductone" containing a C_5 ring, which was isolated by *Hodge* et al., is formed only with secondary amines[4] and therefore is of no great importance in foodstuffs.[5]



When the Amadori compound **1** obtainable from glucose and propylamine is heated in buffered, neutral, aqueous solution for several days at 37 °C or briefly at elevated temperatures (e.g. 5 h at 60 °C) it decomposes with formation of novel reducing compounds which can be separated by chromatography on silica gel. After acetylation and thin-layer chromatographic separation the aminoreductone **3** could be isolated in pure form. The structure of **3** was derived from its spectral data. The coupling constants of the protons on C-4 and C-5 show that the compound is present in the *trans* form. We were recently able to trap the dicarbonyl compound **2**, formulated as intermediate, with *o*-phenylenediamine.[6] Experiments carried out so far indicate that the Amadori compound **1** releases the amine more readily at elevated temperatures and is thereby transformed, inter alia, into 1-deoxy-2,3-hexodiulose and 3-deoxy-1,2-hexosulose, as well as secondary products.

In reactions of glucose with protein, reductones of type **3** in lysine side chains should be easily detectable by their redox behavior.

Experimental

A solution of the oxalate of 1-propylamino-1-deoxyfructose **1** (4.8 g, 18 mmol) in 20 mL of water was adjusted to pH 7 with ca. 2 g of $NaHCO_3$ and allowed to stand for ca. 70 h at 37 °C (or, e.g., 5 h at 60 °C). The solution was then filtered, evaporated under vacuum and chromatographed on a silica gel column with ethyl acetate/methanol (2/1). The fraction containing reductone colored an alkaline solution of triphenyltetrazolium chloride (TTC). The eluate was evaporated down and acetylated for ca. 12 h at room temperature with Ac_2O/Py. The resulting mixture was taken up in ice-water/dichloromethane and separated on thin-layer plates (silica gel, 0.5 mm) with hexane/ethyl acetate/triethylamine (50/48/2). The fluorescence quenching zone at $R_f = 0.4$ was eluted with warm ethyl acetate. The yield of **3** was 0.1%.

Atomic Structure and Superstructure of α-$RuCl_3$ by Scanning Tunneling Microscopy**

By *Hans-Joachim Cantow**, *Harald Hillebrecht*, *Sergej N. Magonov*, *Heinz Wilhelm Rotter*, *Markus Drechsler*, and *Gerhard Thiele*

Dedicated to Professor Christoph Rüchardt on the occasion of his 60th birthday

Scanning tunneling microscopy (STM) enables the study of conductive and semiconductive surfaces at the atomic level.[1] The tunneling of electrons in such systems is determined by the local density of states (LDOS) at the Fermi level. In many cases the LDOS is strongly modulated by the arrangement of the surface atoms. In the following communication we report on the STM characterization of α-$RuCl_3$.

Figures 1–3 show atomic scale top-view images of the surface of α-$RuCl_3$. Figures 1 and 2 represent the best qual-

ity images obtained in air ($I = 2.6$ nA, $U = -241$ mV) and under silicone oil ($I = 27.3$ nA, $U = 785$ mV). The images depicted in Figure 3 were obtained by variation of the tunneling current. On increasing the tunneling current from 2.6 (Fig. 3, top) to 5.7 nA (Fig. 3, middle) the features of the images change from diffuse to well separated. At still higher tunneling current (44 nA; Fig. 3, bottom) a higher contrast image is observed. The same trend in the quality of the imag-

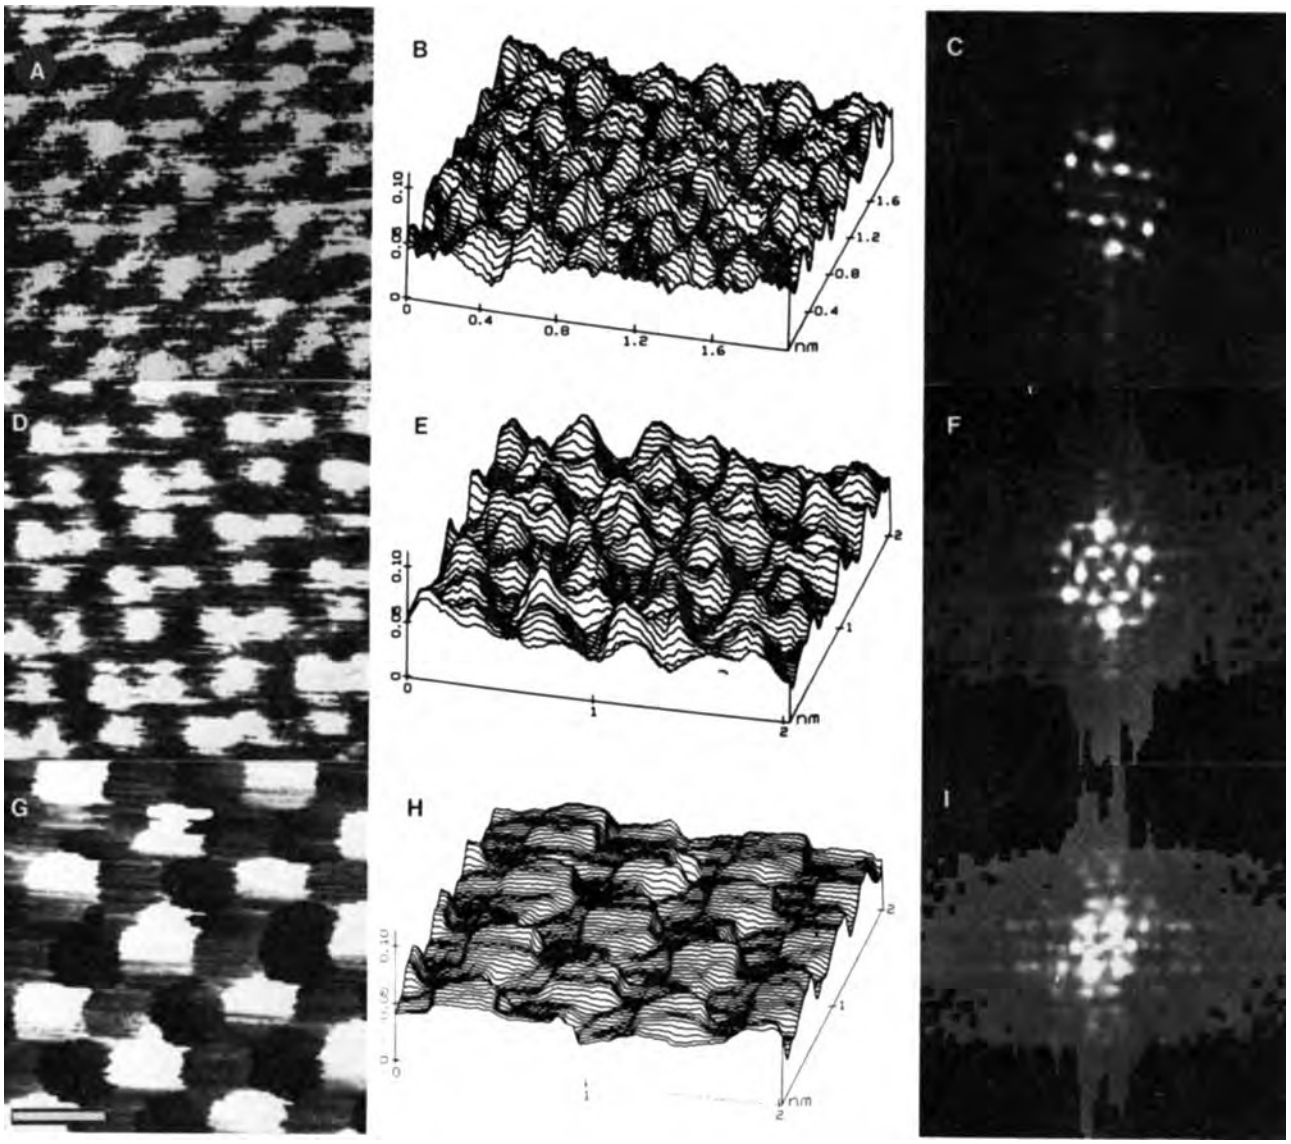

Fig. 3. STM images of α-$RuCl_3$ in air at 300 K. Constant voltage of $U = 300$ mV. Top: $I = 2.6$ nA; middle: $I = 5.7$ nA; bottom: $I = 44$ nA. A, D, G) Top views, bar 5 nm, B, E, H) three-dimensional line plots, C, F, I) two-dimensional Fourier transforms.

ing is achieved even when the polarity of the bias voltage is changed (− 300 mV). The best quality images were observed at higher tunneling currents. The bright areas correspond to increases in the local surface charge density in the z-direction perpendicular to the surface. Increasing the tunnel current induces a flattening of the "hills" of electron density. An increase of current at constant potential generally signifies an increase in the distance between measuring tip and sample surface and thus a stronger influence of the tip on the electronic structure of the sample. In the optimum-quality and high-contrast images of α-$RuCl_3$ these effects are manifested as changes in the size of the round shape patterns and the shape of the corrugation (superstructures).

On using silicone oil between measuring tip and sample surface more stable images are obtained at high tunneling currents. We have found that the best quality images of an α-$RuCl_3$ surface are obtained at a definite tunneling gap resistance. For one of the α-$RuCl_3$ samples the best quality images were obtained at bias voltages of $U = (400 + n \times 50)$ mV and corresponding tunneling currents of $I = (7 + n \times 1)$ nA ($n = 0.1 - 20$). The resistance of the tunneling gap in these cases is 57 MΩ. It varies up to 20% from sample to sample, but the aforementioned dependence remains the same. Attempts to increase the tunneling current under optimum conditions for best quality images without changing the bias voltage led to a disappearance of the image, presumably because of multiple point contacting of the measuring tip with the sample surface. Nevertheless, the tips are not damaged by such possible point contacts, as increasing the voltage or decreasing the current renders this effect reversible.

The two-dimensional Fourier transformed images (Figs. 1C, 2C, 3C, F, I) afford information about the symmetry of the electronic surface features—the "hills" of charge density. They show hexagonally arranged reflections which change in intensity under different experimental conditions. The outer hexagon delineates the "hills" with distances ranging from 2.8 to 4.1 Å, the inner hexagon those with distances ranging from 5.8 to 6.5 Å. Intensity measurements along a line (section images, Figs. 1D, E, 2D, E) yield more accurate information: The difference in the z values between the "hill peaks" for various values of U and I lie in the range 0.2 to 0.5 Å. The difference in the z values between the highest point of a hill and the lowest point of the adjoin-

ing hollow varies between 0.3 and 2.3 Å. A strong dependence of the size of this difference (i.e. the corrugation) on the experimental conditions has been observed in the case of graphite[1] and TaS_2.[4]

Figure 4 shows graphical representations of α-$RuCl_3$ based on X-ray data. The space group $C2/m$ (monoclinic, $AlCl_3$-type) was assumed for the crystal structure of α-

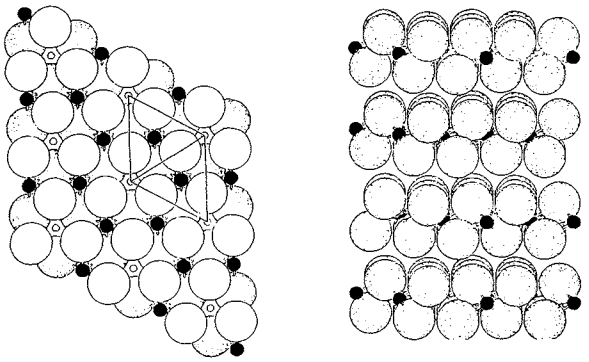

Fig. 4. Layered structure of α-$RuCl_3$ from X-ray data. Left: computer-simulated top view; right: side view of the α-$RuCl_3$ lattice. ●: Ru.

$RuCl_3$.[2] Each layer of the crystal consists of two outer layers of chlorine atoms with an inner layer of ruthenium atoms (octahedral bonding between ruthenium and chlorine atoms). The chlorine atoms lie thereby in an almost undistorted close-packed arrangement, the in-plane distances between the chlorine atoms being 3.265 Å (averaged X-ray data). The ruthenium atoms occupy 2/3 of the vacant positions in the octahedron and are thereby packed hexagonally in a graphite-like manner. The X-ray data yield distances of 3.46 Å between the ruthenium atoms, which leads one to assume that the STM images represent the surface charge density distribution modulated by the chlorine atom positions in the surface layer. If the surface electron density were modulated by ruthenium atoms one would expect a non-centered hexagonal structure in the STM images, which however is not observed. A more detailed assignment of the STM images of α-$RuCl_3$ is presented in Figure 5 (top).

Scanning tunneling microscopy is an attractive technique for the structure analysis of the crystal surfaces of compounds whose surface electron distribution is modulated by the arrangement of the atoms, as is apparently the case with α-$RuCl_3$. STM data for the distances between neighboring chlorine atoms under different experimental conditions are listed in Table 1. The discrepancies between these data and those obtained from X-ray data are of a fundamental nature, since X-ray structure analyses afford average values. With the STM technique, the distorted hexagonal packing of the surface chlorine atoms is detectable. The distortion is mainly due to the lower position of the central atom in the hexagon (0.2 to 0.5 Å). Significant niveau differences of ca. 0.1 Å are detectable however, even between the chlorine atoms of the hexagon. These effects could be caused by weak Ru–Ru pairing interactions. This type of metal-metal bonding with retention of the hexagonal arrangement has also been found for other transition metal halides.[3] The specific distorted structure of α-$RuCl_3$ leads to the formation of a hexagonal superlattice with $R = a\sqrt{3}$ (a = 3.3 Å, averaged lattice constant). The angle between the main axes of the unit cell and the superlattice is 30°. With the STM technique different superstructures were observed in the case of TiS_2, TaS_2, $TaSe_2$[5,6] and VS_2. A comparison of electron diffraction and conductivity data with STM results for TaS_2 and some other layered materials[6] shows that the influences of charge density waves are detected by scanning tunneling microscopy. A correlation of STM results for α-$RuCl_3$ with those obtained by other techniques has not yet been reported.

Figure 5 (bottom) shows the distorted Cl unit cell derived from averaged STM data. The height and width of the hexagon are in good agreement with the X-ray data. In Figure 5 (top) the corresponding subunit is marked. In our

opinion the changes in the STM images on increasing the tunneling current are due to a decrease in the gap between measuring tip and sample surface. This is supported by the similarity of the STM images recorded at different tunneling currents but at the same gap resistance. The variation of the images reflects the profiles of LDOS at different distances from the surface. The more diffuse image of Figure 3a (I = 2 nA, U = 300 mV) may indicate that those orbitals of the chlorine atoms which accept electrons, although localized near atomic positions, are spatially more diffuse. This is not the case with electron-donating orbitals which are more concentrated near atoms. They reflect the smaller z values (z-damping) of one of the chlorine atoms of the unit cell

($I = 2.6$ nA, $U = -241$ mV, Fig. 1A. Orbitals which can accept electrons are actually less sensitive to vertical (z-) deflections of the atoms, as shown by the image measured at $I = 5.7$ nA, $U = 300$ mV (Fig. 3D). The approach of the measuring tip to the sample surface leads to images with well separated patterns of electron density triplets which emphasize the surface distortion of the unit cells. A closer approach of the tip to the surface gives rise to high-quality images with circular patterns and flattened electron density hills. It has been shown that at extremely close tip-to-surface distances, or even at point contact, the resistance no longer decreases exponentially with decreasing distance, but reaches a constant value (plateau).[7] In this case the tip has scarcely any vertical sensitivity and thus causes "flattening". Perhaps attractive intermolecular forces are thereby involved in image formation.[8]

Table 1. Distances r_a, r_b and r_c between neighboring chlorine atoms in the distorted lattice of α-$RuCl_3$ at various bias voltages U and tunneling currents I[a] (cf. Fig. 5, bottom).

[a] Average over all distances 3.29 Å (STM), 3.265 Å (X-ray diffraction). [b] Mean value.

Scanning tunneling microscopy has proven very useful for investigations of the structure of α-$RuCl_3$. It was immediately clear that the hexagonal structure is three-dimensionally distorted. In addition, quantitative evaluations could be carried out. A superlattice exists at room temperature.

Experimental

The α-$RuCl_3$ crystals were prepared by sublimation at 800 to 500 °C; thin-layer samples were cleaved from the crystals with the aid of self-adhesive tape and fixed on metallic supports with conductive silver glue. The measuring tips for the STM investigations (Nanoscope II, Digital Instruments) were mechanically cut from PT(70)/Ir(30) wire, tested on highly oriented pyrolytic graphite, and calibrated in the x and y directions (accuracy ± 0.1 Å). The z values are reproducible within ≤0.1 Å, but variations of up to 30% are possible. The imaging current was plotted against x and y sensitivity at constant tunneling current. All measurements were carried out at room temperature in air or under silicone oil. Oxygen effects could be ruled out.

Bias voltages and tunneling currents of $U = \pm 11$ to ± 1500 mV and $I = 0.01$ to 46 nA, respectively were chosen for the investigations. The scanning frequencies for the y direction were 26 and 39 Hz. Data arrays of 400 × 400 points of top-view images were collected and subjected to 2DFFT or represented as three-dimensional line plots. The images presented here were obtained without applying any filtering routines.

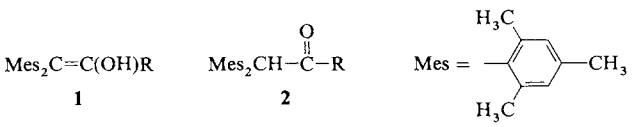
Stability and Cyclization of Enol Radical Cations: A Mechanistic Study of One-Electron Oxidation of β,β-Dimesityl Enols**

By *Michael Schmittel** and *Ulrich Baumann*

The thermodynamic reversal of the keto/enol equilibrium on going from neutral molecules to radical cations has been consistently supported by thermochemical investigations[1] in the gas phase and MO studies.[2] Enol radical cations in the gas phase are always considerably more stable than the tautomeric keto radical cations (e.g., the propen-2-ol radical cation is about 14 kcal mol^{-1} more stable than the acetone radical cation[1]). By contrast, the chemistry of enol radical cations in solution[3] has hardly been investigated, since only a few simple enols[4] are available as stable starting materials.

Two enols of type **1**, investigated initially by *Fuson* et al.[5] and, more recently, by *Rappoport* and co-workers,[6, 7] were chosen as model compounds for the first direct study of the stability and reactivity of enol radical cations in solution. Enols **1** and their tautomeric ketones/aldehydes **2** can be prepared in tautomerically pure form and thus allow the direct determination of their oxidation potentials in solution.



1 **2**

a, R = *t*Bu; **b**, R = H

Cyclovoltammetric measurements in acetonitrile and in dichloromethane at room temperature and −40 °C, however, showed only irreversible oxidation waves,[8] which indicates that the radical cations undergo rapid reaction at the electrodes. Moreover, several attempts to obtain stable radical cations by oxidation of the enols with dioxygen(1+) hexafluoroarsenate at low temperatures[9] failed. Even at −100 °C, no paramagnetic products could be detected by ESR spectroscopy.

In agreement with known ionization potentials,[7] the anodic peak potentials of enols **1** in acetonitrile are considerably lower than those of the tautomeric carbonyl compounds **2**. The peak potentials[8] and the equilibrium constants of

[**] Enol Radical Cations in Solution, Part 1. This work was supported by the Fonds der Chemischen Industrie, the Land Baden-Württemberg, and the Wissenschaftliche Gesellschaft Freiburg. We thank *D. Morat* for her skillful assistance as well as Prof. *J. Heinze* and Dipl.-Chem. *M. Diedrich* for help with the electroanalytical investigations.

the keto/enol equilibrium determined by *Rappoport* and coworkers[6] allow an estimate of the relative stabilities of the tautomeric radical cations $\mathbf{1}^{\bullet\oplus}$ and $\mathbf{2}^{\bullet\oplus}$ in acetonitrile, although the ΔG^0 values for $\mathbf{1} \rightarrow \mathbf{2}$ determined originally in hexane[10] need to be corrected by -1 kcal mol^{-1} in order to account for the greater stabilization of the enols by hydrogen bonding in acetonitrile. However, thermochemical data cannot be derived directly from the kinetically controlled peak potentials E_p. Nonetheless, it is generally true that, for aromatic compounds, heterogeneous electron transfer is rapid and reversible. Accordingly, the standard potentials differ only slightly from the peak potentials.[11] The free energies ΔG^0 ($\mathbf{1}^{\bullet\oplus} \rightarrow \mathbf{2}^{\bullet\oplus}$) are therefore estimated via a thermochemical cycle involving the peak potentials. A marked thermodynamic preference for enol radical cations is also found in condensed phase (Table 1).

Table 1. Peak potentials E_p[8] of **1** and **2** as well as reaction free energies ΔG°.

R	E_p (**1**) [V]	E_p (**2**) [V]	ΔG^0 ($\mathbf{1} \rightarrow \mathbf{2}$) [kcal mol^{-1}]	ΔG^0 ($\mathbf{1}^{\bullet\oplus} \rightarrow \mathbf{2}^{\bullet\oplus}$) [kcal mol^{-1}]
a *t*Bu	0.97	1.85	2.6	−17.7
b H	1.00	1.98	−3.1	−25.7

What reactions do the short-lived enol radical cations undergo? The cyclovoltammogram of **1a** in acetonitrile (Fig. 1) provides an indication of the subsequent reactions of the enol radical cation. It shows, in addition to the irreversible oxidation wave of **1a**, a reversible wave ($E_{1/2} = 1.25$ V, $\Delta E_p = 60$ mV) shifted by 300 mV toward anodic potential. Analogously, a second, though irreversible, oxidation wave at $E_p = 1.39$ V is observed for **1b**.

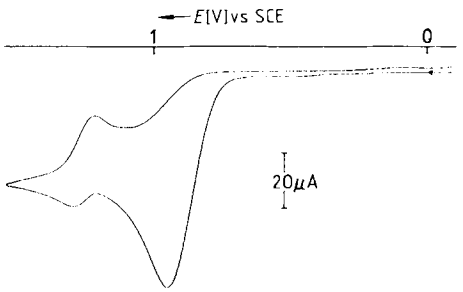

Fig. 1. Cyclovoltammogram of **1a** in acetonitrile [8].

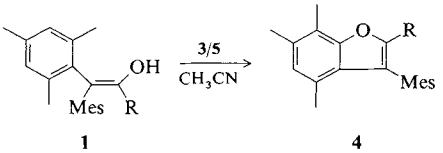
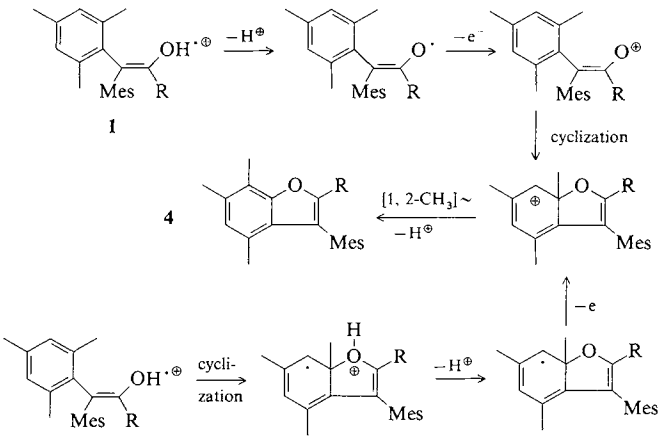
To elucidate the reactions occurring at the electrode, enols **1a,b** were allowed to react in acetonitrile with tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate (**3**) as a one-electron oxidizing agent.[12] Complete conversion was attained with 200 mol% of **3**, which indicates the occurrence of a formal two-electron oxidation. For short reaction times (ca. 20 s), benzofurans **4**[13, 14] were formed in good yields (**4a**, 82%; **4b**, 85%). Tris(*o*-phenanthroline)iron (III) hexafluorophosphate (**5**), known as an "outer-sphere" oxidizing agent,[15] also allows the synthesis of **4** in good yields (**4a**, 91%; **4b**, 81%).



After isolation of benzofurans **4**, it was possible to show by cyclic voltammetry that the second oxidation wave in the enol oxidation (Fig. 1) is due to the benzofurans formed at the electrode.[16] This is sufficient evidence that $\mathbf{1a,b}^{\bullet\oplus}$ are involved as reactive intermediates in formation of the benzofurans.

Two reaction mechanisms are conceivable for the formation of benzofurans **4**; they differ essentially in the primary reaction of $\mathbf{1}^{\bullet\oplus}$ (Scheme 1). According to mechanism 1, the enol radical cation is rapidly deprotonated[17] and then immediately oxidized further, whereas, according to mechanism 2, the enol radical cation first cyclizes and is then deprotonated.



Scheme 1. Possible mechanisms for the formation of **4**. Top: Mechanism 1. Bottom: Mechanism 2.

The thermodynamic reversal of the keto/enol equilibrium by one-electron oxidation in solution opens up interesting synthetic possibilities. By suitable choice of the oxidizing agent, it should be possible, starting from a ketone, to oxidize selectively the enol form alone. Since the enol is continuously formed from the ketone, carbonyl compounds could thus react via enol radical cation intermediates. Corresponding studies have already proved successful.

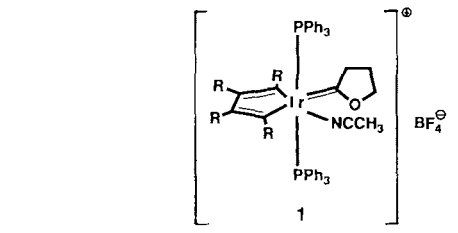
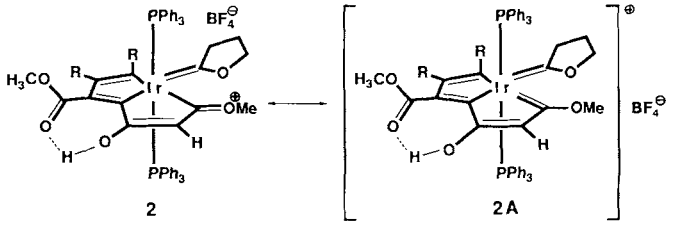
[16] In agreement with the observations on the oxidation of enols **1a,b**, compound **4a** is oxidized reversibly ($E_{1/2}$ = 1.23 V) and **4b** irreversibly (E_p = 1.38 V) at the given potentials.
[17] This mechanism was originally postulated by *Bailey* et al., when they observed the formation of the corresponding benzofuran in 3% yield during ozonolysis of trimesitylethenol: P. S. Bailey, F. E. Potts III, J. W. Ward, *J. Am. Chem. Soc. 92* (1970) 230.





vinylidene ligand was not present, since the only downfield signal detected was at δ = 286 (t, J_{CP} = 7.6 Hz). However, a signal indicative of an acyl carbon was observed at δ = 229.5 (t, J = 7.5 Hz). Elemental and mass spectral analysis indicated a loss of CO_2 and the incorporation of a C_2H_2 fragment from propiolic acid into the original iridium complex.

We resorted to an X-ray crystal structure determination in order to characterize **2** (Fig. 1, Table 1).[6] From the X-ray

Synthesis and Structure of Annelated Carbon Rings Containing a Bridgehead Transition Metal**

By *Joseph M. O'Connor,* Lin Pu*, and *Raj Chadha*

The structure and bonding of metallacycle complexes continues to come under extensive investigation due to the diverse array of catalytic and stoichiometric reactions exhibited by this class of compounds.[1] Herein we report the serendipitous preparation and structural characterization of metallabicyclooctatriene complexes in which a metal occupies the bridgehead site. We recently discovered a new coupling reaction of the carbene ligands in metallacycle-bis(carbene) complexes,[2] and sought to extend this chemistry to the vinylidene ligand. In an attempt to prepare a carbene-vinylidene complex, we examined the reaction of propiolic acid[3] and the cationic metallacycle-carbene complex **1**.[4]

Heating **1** and propiolic acid in $CDCl_3$ at 50 °C leads to the quantitative formation of the new complex **2** as indicated by ^1H NMR spectroscopy. The ^1H NMR spectrum of **2** shows signals at δ = 13.22 (s, 1H) and 5.98 (br, 1H); four singlets at 3.34, 3.48, 3.60, and 3.67 (OCH_3); and the expected resonances attributed to the hydrogen atoms of the triphenylphosphane ligand and the carbene ligand.[5] From the $^{13}C\{^1H\}$ NMR spectrum of **2** it was clear that the desired

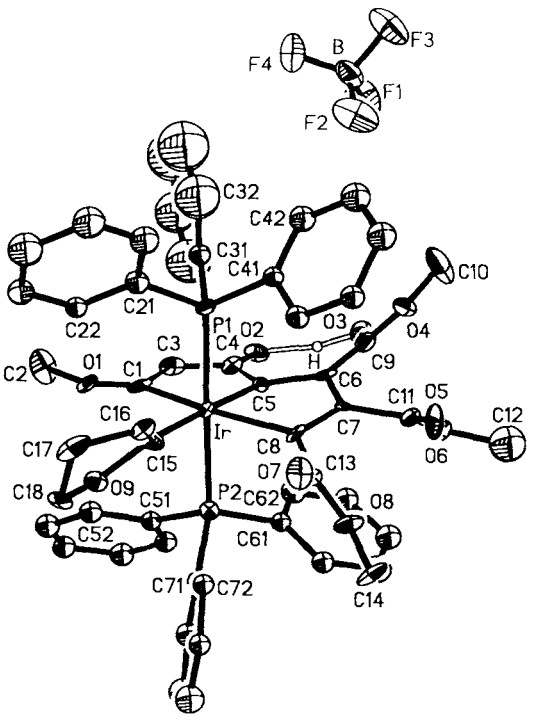


Figure 1. Molecular structure and partial numbering scheme for **2**.

structure it is clear that a new metallacycle unit has formed across one of the original bonds of the metallacycle. The carbon atoms C1 and C3 presumably originate from propi-

C7–C8	1.453(27)	1.389(19)			

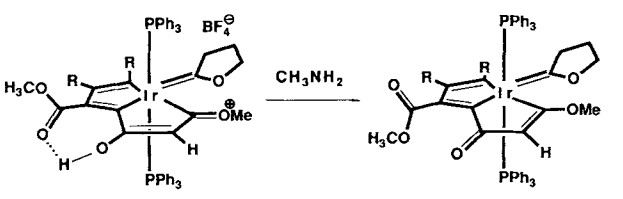
olic acid. Unexpectedly, the methoxy unit from one of the methyl carboxylate ring substituents is now bonded to C1 of the new metallacycle.

The most unusual aspect of the structure of **2** is the presence of iridium at the bridgehead position of a [3.3.0] fused ring system. This bonding feature results in pronounced distortion from ideal octahedral geometry about iridium. The C1-Ir-C8 angle is 166.6(9), the C8-Ir-C15 angle is 95.8(10), and the C1-Ir-C15 angle is 97.4(10)°. The ca. 83° C-Ir-C angle in both metallacycle rings of **2** is opened up by ca. 6° compared to the corresponding angle in related iridacyclopentadiene structures.[1, 7]

A second surprising structural feature of **2** is the presence of a methylated acyl oxygen, indicated by distances of 1.520(33) Å for O1–C2 and 1.157(31) Å for C1–O1. The alternative metallapentalene resonance form, **2A**, is not unreasonable for an Ir–C1 distance of 2.019(25) Å; however, the chemical shift of C1 ($\delta = 230$) is more typical of an acyl carbon than a carbene carbon. The Ir–C5 distance of 2.034(19) Å is unusually short and may indicate some carbenoid character in that bond as well. The C–C bond lengths for C5–C8 indicate a high degree of electron delocalization over these atoms.

The final unusual feature of **2** is the presence of an enol unit (C3, C4, O2, H) within the new metallacycle. The H atom was located by X-ray analysis, and its position is consistent with the observed C–C and C–O bond lengths. We attribute the preference for the enol tautomer in **2** to both hydrogen bonding to O3 and a greater degree of conjugation in the enol form than in the keto form.

In order to further clarify these unusual bonding features, complex **2** was deprotonated with methylamine to give the neutral metallabicyclooctatrienone complex **3**,[8] whose structure was also determined by X-ray crystallography (Fig. 2, Table 1).[9]



2 **3**

With a C1-Ir-C8 angle of 154.6°, complex **3** is even more dramatically distorted from ideal octahedral geometry than **2**. The C4–O2 distance in **3** has shortened to 1.206(17) Å and the methyl carboxylate group bonded to C6 has rotated out of the plane of the metallacycle, an indication that the proton which bridged O2 and O3 is no longer present. In addition, the C–C double bond has shifted from C3–C4 to C1–C3, and the C1–O1 distance has lengthened to 1.354(16) Å. This lat-

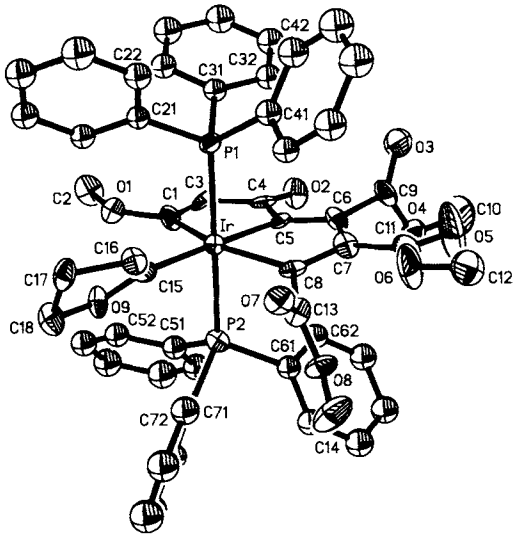


Figure 2. Molecular structure (ORTEP) and partial numbering scheme for **3**.

ter observation is consistent with the existence of a methylated acyl oxygen in **2**. In both **2** and **3** the ring containing Ir and C5–C8 deviates significantly from planarity; the angle between the C5, Ir, C8 plane and the C5–C8 mean plane is 16.9° for **2** and 12.6° for **3**. Efforts are currently underway to determine the mechanism of the formation of **2** from **1** and propiolic acid.

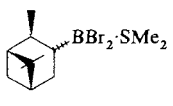
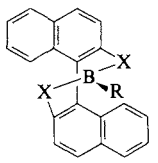
A Borate Propeller Compound as Chiral Catalyst for an Asymmetrically Induced Diels-Alder Reaction

By *Dieter Kaufmann** and *Roland Boese*

We have already reported success in achieving asymmetrically induced Diels-Alder reactions[1] with the aid of catalytic amounts of haloorganoboranes such as **1**, compounds that are derived from naturally occurring terpenes.[2] We subsequently described a seven-step preparation of the axially chiral boron catalyst **2a**, which incorporates a 1,1'-binaphthyl fragment.[3]



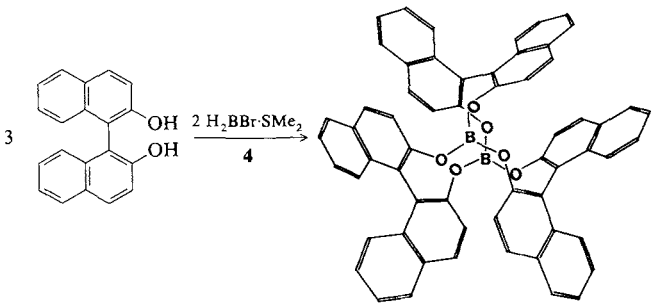
1



2a, X = CH_2, R = Cl
2b, X = O, R = Br
2c, X = O, R = OAryl

An attempted synthesis of the dioxaborepine **2b** by treatment of (*S*)-(−)-1,1'-bi-2-naphthol[4] [(−)-**3**, a substance available in a single step] with monobromoborane dimethylsulfide[5] **4** led to an unexpected result, in that the sole product that actually resulted proved to be a crystalline material with a mass of 874. This can only be explained by assuming reaction of **3** with **4** in a 3:2 molar ratio, together with elimination of both molecular hydrogen and hydrogen bromide. Though lacking spectroscopic proof, *Kelly* et al.[6] have postulated the intermediacy of a *B*-aryloxy substituted dioxaborepine of the structural type **2c** in the reaction of juglone with borane-tetrahydrofuran and (*S*)-3,3'-diphenyl-1,1'-bi-2-naphthol (1:1:1).

To our surprise, X-ray structural analysis[7] of crystals obtained upon treatment of (*R*,*S*)-**3** with **4** revealed exclusive formation of a C_3-symmetric tetradecacyclic diborate **5** (Fig. 1), and no **2b** whatsoever. The unit cell was shown to contain both enantiomers of the compound. To the best of our knowledge, formation of a propeller compound with axially chiral 1,1'-binaphthyl groups as "blades" is heretofore without precedent.



3 **5**

Since both an acyloxyborane catalyst[8] and a borate-activated dienophile[6] had already been successfully employed in asymmetrically induced Diels-Alder reactions, we next examined the applicability of (+)- and (−)-**5** to the reaction of cyclopentadiene **6** with methacrolein **7** at −78 °C. Whereas the uncatalyzed cycloaddition provided only a 15% yield (*exo*-**8**/*endo*-**8** 86/14) after 42 h even at 20 °C, conducting the

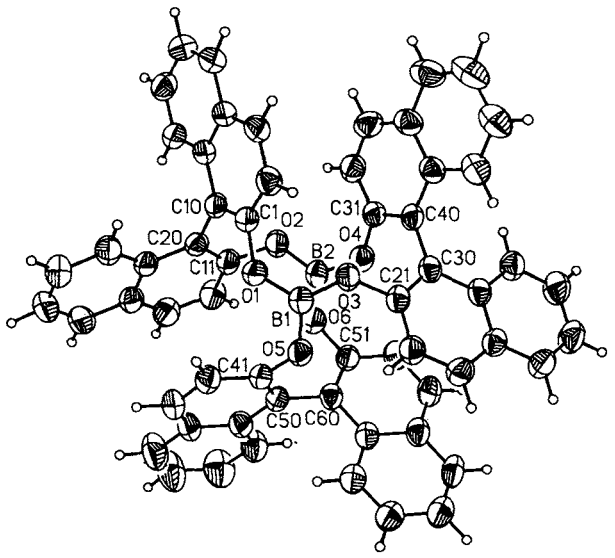


Fig. 1. Structure of crystalline **5**. [7] Average values for important distances [Å] and angles [°] (maximum standard deviations for B-O and B-C bonds 0.004 Å, for C-C bonds 0.006 Å): B-O 1.358, O-C 1.392, C-C bonding of the naphthyl groups (e.g., C10-C20) 1.495, C(O)-C(bonded) (e.g., C1-C10) 1.367; C(O)-C(nonbonded) 1.406, C-C (central bond of the naphthyl groups) 1.419, B···B 3.397; O-B-O 120.0, B-O-C 124.9, O-C-C(bonded) (e.g., O1-C1-C10) 116.8, torsional angle (C(O)-C(bonded)-C(bonded)-C(O) (e.g., C1-C10-C20-C11) 80°.

reaction in dichloromethane at −78 °C in the presence of 3 mol-% (−)-**5** led to the isolation of an 85% yield of the cycloadduct (+)-**8**. The *exo*-selectivity[9] (97.4%) of the reaction is outstanding, as is the observed enantioselectivity (90% *ee*). Use of (+)-**5** leads in analogous fashion to the (−)-*exo*-aldehyde **8**.

6 **7** **8**

Since this new catalyst is available from two commercial[10] reagents in a single step, asymetrically induced cycloaddition becomes an exceptionally simple synthetic operation. In the event that the catalyst is not to be re-used it can be cleaved at room temperature with sodium hydrogen carbonate solution; optically active **3** can be recovered nearly quantitatively, and there is no racemization.

At the present time we can only speculate about the mechanism of the catalysis. The first step is probably complexation of the carbonyl group of methacrolein with a boron atom, which might lead to a distortion of the propeller molecule. Subsequent cycloaddition could then occur within the sphere of influence of the binaphthyl moiety.

Experimental

(−)-**5**: To a solution of 286.3 mg (1.0 mmol) of (*S*)-(−)-**3** in 25 mL of anhydrous dichloromethane was added with a syringe at −20 °C under nitrogen 154.9 mg (1.0 mmol) of **4**. The mixture was allowed to warm slowly to room temperature, after which volatile components were removed in vacuo and the residue was dried at 50 °C/0.01 torr. Yield 282.8 mg (97%) (−)-**5**, mp > 350 °C.—^{1}H-NMR (400 MHz, $CDCl_3$, *J* in Hz): δ = 6.64 and 6.68 (AB system, ^3J = 8.8, 4H), 7.06 (d, ^3J = 8.3, 2H), 7.22 (ddd, ^3J = 8.3, 6.7, ^4J = 1.3, 2H), 7.47 (ddd, ^3J = 8.1, 6.7, ^4J = 1.1, 2H), 7.74 (d, ^3J = 8.1, 2H) (numbers of hydrogens are based on a single binaphthyl unit).

(+)-*exo*-**8**: To a cooled (−78 °C) solution of 282.6 mg (0.32 mmol) of (−)-**5** in 25 mL of anhydrous dichloromethane was added dropwise under nitrogen (through a syringe) 736 mg (10.5 mmol) of methacrolein. This was followed after 15 min by 661 mg (10.0 mmol) of cyclopentadiene. The reaction mixture was kept at −78 °C for 2 d. It was then warmed slowly to 0 °C and washed with two 10 mL portions of saturated aqueous sodium hydrogen carbonate solution. Volatile components were removed at room temperature with a gentle vacuum, after which the product was distilled at 50 °C/0.01 Torr. Yield 1.16 g (85%) of a mixture consisting of 97.4% (+)-*exo*- and 2.6% *endo*-**8** (GC, ^{1}H-NMR). The enantiomeric excess of the *exo* product was determined to be 90% by ^{1}H NMR after addition of the shift reagent Eu(hfc)$_3$ and integration of the aldehyde proton signals.

Fast Heteronuclear 3D NMR Spectroscopy **

By *Peter Schmieder, Horst Kessler,* and *Hartmut Oschkinat**

Three-dimensional NMR spectroscopy plays an important role in the structure determination of complex compounds.[1, 2] Since isotopically labeled proteins readily became accessible by gene-technology techniques, it has been possible to use the chemical shifts of heteronuclei to resolve complicated two-dimensional proton NMR spectra of large proteins by dispersing them into a third dimension. The application of 3D techniques to smaller molecules such as peptides shorter than 20 amino acids seems to be an overkill, since the acquisition time needed to obtain a spectrum with sufficient resolution is prohibitively long. On the other hand, there is a potential demand for 3D NMR spectra when peptides containing many amino acids with long aliphatic side chains such as arginine, lysine, and proline are being investigated. Herein, we wish to show that the time necessary to record a heteronuclear 3D NMR spectrum useful enough for the assignment of side-chain protons of these amino acids is in fact rather short: the net acquisition time needed to record the spectrum of a cyclic hexapeptide without isotopic labeling presented here was 8.2 h. The resolution is comparable to that of a normal 2D spectrum.

Several examples of the use of heteronuclear 3D NMR spectroscopy have already been described.[3, 4] In most cases ^{15}N is used as heteronucleus since its signals appear in a limited range; hence a good resolution can be obtained within a reasonable measurement time. It is more difficult to record a 3D NMR spectrum with ^{13}C as heteronucleus, since the spectral ranges of the carbons and the protons directly attached to them are much larger.

The measurement time needed to record a 3D NMR spectrum with sufficient resolution may then be reduced by restricting the chemical shift ranges in one or both of the two virtual dimensions on the basis of semiselective excitation.[5–8] Using this approach may not always allow an appropriate selection of the chemical shift ranges and may have experimental disadvantages.

Another way to select a certain chemical shift range in the carbon dimension is to excite only certain types of carbon signals by a DEPT-type pulse sequence,[9] which should be extremely useful in assigning side-chain protons of amino

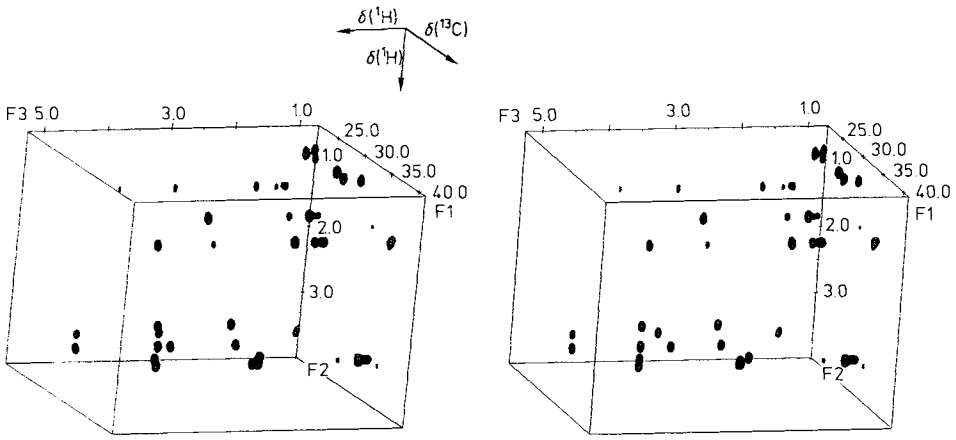

Fig. 1. Stereo picture of the 3D DEPT-TOCSY spectrum of *cyclo*(-D-Ala-Phe-Trp-Lys(Z)-Val-Phe-). 64 experiments were recorded in t_1, 96 experiments in t_2. The delay Δ was set to 3.57 ms, the mixing time to 35 ms. The spectrum was recorded on a Bruker AM 500 spectrometer and processed on a CONVEX with our own software [8]. Residual signal bands at the frequency $\omega_1 = 0$ (^{13}C axial peaks) were removed with a "whitewash" procedure to improve the display.

acids. However, the creation of heteronuclear double quantum coherence by an "inverse" DEPT sequence depends in a different manner on the flip angle of the editing pulse.[10] If, for example, a 90°-pulse is chosen, only CH_2 groups are selected. The particular advantage of this type of selective excitation is its virtually rectangular excitation profile—all CH_2 groups are excited with their full intensity, but other groups are not—which is hardly achievable with soft pulses. This should reduce the spectral width dramatically if the suppression is good enough to prevent distortions from remaining signals, which are then folded into the spectrum.

We have used this approach in combination with a BIRD pulse[11] for saturating protons bound to nonmagnetic carbons to obtain a carbon-resolved TOCSY spectrum of 25 mg of the cyclic hexapeptide *cyclo*(-D-Ala-Phe-Trp-Lys(Z)-Val-Phe-) in 0.5 mL of DMSO (Fig. 1). The application of the BIRD pulse for the inversion of nonsatellite protons prior to the execution of the pulse sequence is not recommendable in all cases, since in molecules with a strong negative NOE a severe attenuation of the signals may occur. However, in the case of small- or medium-sized peptides with positive or weakly negative NOE it provides a powerful method for shortening the measuring time. In our application, a BIRD pulse was inserted into the relaxation delay, splitting it into two delays of length 193 and 255 ms. This, together with an acquisition time of 92 ms, led to a good and simultaneous suppression of nearly all ^1H signals from protons bound to ^{12}C.[12] Since t_1 is usually short in the case of a small peptide, rapid pulsing with two scans per second is possible.

Figure 2 shows the pulse sequence of the 3D DEPT-TOCSY without the BIRD sequence, which can easily be added to any kind of heteronuclear technique. It can be seen from Figure 2 that only CH_2 groups have been excited sufficiently enough to show TOCSY cross peaks. Signals due to the excitation of C_α carbons do not appear at this contour level. The assignment of the signals and the chemical shifts may be taken from the 2D CH_2-selected inverse DEPT-HMQC spectrum shown in Figure 3. To test the quality of the suppression, a similar 3D spectrum with a larger spectral width was recorded, proving that the suppression is better than 90%. In principle, the same editing effect could be achieved by the application of a heteronuclear triple quantum filter,[13] since CH groups cannot form heteronuclear triple quantum coherences. CH_3 groups are suppressed as well, since they form heteronuclear quadruple quantum coherences very effectively and cannot pass the filter.

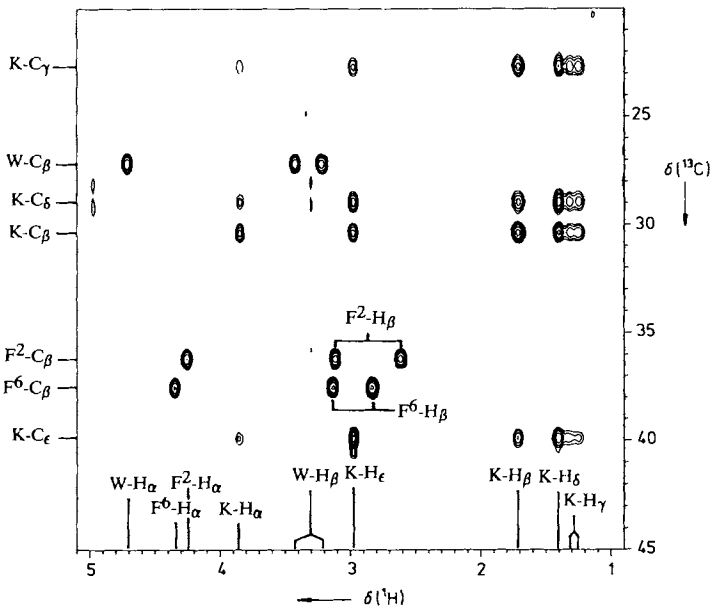

Fig. 3. Region of the 2D DEPT-HMQC spectrum with TOCSY transfer of *cyclo*(-D-Ala-Phe-Trp-Lys(Z)-Val-Phe-) showing the assignment of the resonances that are also visible in Figure 2. This spectrum corresponds to a projection of all signals of the spectrum to the top of the cube shown in Figure 1 (F_1/F_3).

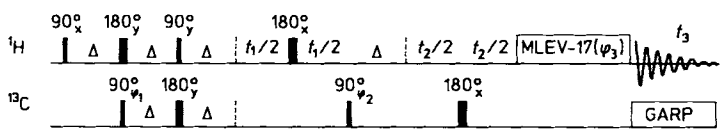

Fig. 2. Pulse sequence of the 3D DEPT-TOCSY, which is a combination of the 2D DEPT-HMQC [10] and the TOCSY experiment. The delays Δ are set to $(2^1J_{CH})^{-1}$, the heteronuclear decoupling during acquisition by the GARP sequence [14] is optional. The MLEV-17 sequence [15] was used during the spin-lock period. The phase cycle is: φ_1 = x, −x, x, −x; φ_2 = x, x, −x, −x; φ_3 = x, x, x, x, −x, −x, −x, −x; rec = x, −x, −x, x. Quadrature detection in t_1 was achieved by applying TPPI (time proportional phase increment) to phase φ_1 and the phase of the following carbon π pulse, in t_2 by applying TPPI to the phase of the first seven pulses of the sequence.

The net acquisition time to record the spectrum with 64 experiments in t_1 and 96 experiments in t_2 was 8.2 h using 8 scans/experiment. On our Bruker AM 500 spectrometer two dummy scans were necessary, since no "buffered acquisi-

tion" is available yet, giving the still acceptable measuring time of 10.2 h. The mixing time was set to 35 ms, the delays Δ were optimized for $^1J_{CH} = 140$ Hz (3.57 ms). The spectral width was 2500 Hz in F_1 and F_2 resulting in a limiting resolution of 0.38 ppm (46.9 Hz) in F_1 and 0.063 ppm (31.3 Hz) in F_2. In comparison the limiting resolution in the 2D NMR spectrum shown in Figure 3 is 0.3 ppm (36.6 Hz) in F_1, which is sufficient in medium-sized compounds.

We have shown that the application of DEPT-type pulse sequences to restrict the spectral width in a 3D spectrum can lead to a well-resolved spectrum in an acceptable measuring time. In the case of small peptides, the described experiment utilizing a BIRD pulse may be completed overnight.

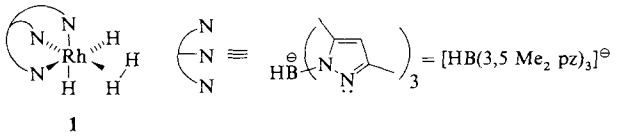
Synthesis and 2D-(^{1}H,^{103}Rh)-NMR Study of the First "Non-Classical" Polyhydrido Complex Stabilized by a Nitrogen Donor Ligand**

By *Urs E. Bucher, Thomas Lengweiler, Daniel Nanz, Wolfgang von Philipsborn*, and *Luigi M. Venanzi**

The so-called "non-classical" transition-metal hydrido-complexes, i.e., those containing coordinated molecular hydrogen, have aroused great interest in recent years.[1–3] Most of the complexes of this type described hitherto have also contained tertiary phosphanes or arsanes as co-ligands.

We report here the synthesis and 2D-(^{1}H,^{103}Rh)-NMR characterization of a new "non-classical" rhodium hydride with the structure $[\{HB(3,5\text{-}Me_2pz)_3\}Rh(H_2)H_2]$, **1**, containing the terdentate anionic tris-(3,5-dimethylpyrazolyl) borate as co-ligand.



1

This off-white solid was obtained from **3**,[4] as shown in Scheme 1. The complex appears to be indefinitely stable in the solid state at room temperature but decomposes slowly in solution with formation of metallic rhodium.

$[HB(3,5\text{-}Me_2pz)_3RhCl_2(MeOH)]$ **3**

↓ $PPh_4Cl / CHCl_3$

$[PPh_4][HB(3,5\text{-}Me_2pz)_3RhCl_3]$ **2**

↓ $NaBH_4 / EtOH$

$[HB(3,5\text{-}Me_2pz)_3Rh(H_2)H_2]$ **1**

Scheme 1.

The ^{1}H-NMR spectrum of **1** (CD_2Cl_2, 253 K) in the hydride region consists of a doublet centered at $\delta = -12.76$ with an apparent $J(^{103}Rh,^1H)$ value of 18.1 Hz. The corresponding longitudinal relaxation time T_1 is extremely short with a minimum value of 42 ms at 166 K (400.13 MHz, $CD_2Cl_2/CDCl_3$ 2/1). On the basis of known relaxation criteria[15] this strongly indicates the presence of coordinated molecular hydrogen.

The presence of four coordinated hydrogen atoms was first inferred from careful integration of this signal relative to those of the organic ligand and was unambiguously confirmed by ^{1}H-detected 2D-(^{1}H,^{103}Rh)-NMR spectroscopy. Although experiments of this type were first reported in 1979[6] only few applications involving the central metal atom of an organometallic complex have been published, e.g. those by *Cabeza* et al.[7] and by *Benn* and *Rufińska*.[8] The technique features a twofold coherence transfer allowing for both initial excitation as well as detection at the higher frequency. In the "classical" pulse sequence (Fig. 1)[9] heteronuclear (H,M) two-spin coherences are generated during the preparation period.

Omission of the refocussing π-pulse leads to an additional modulation of the signal during t_1 due to the coupling of the remaining n – 1 protons of the MH_n fragment with these coherences. The splitting of the signal in $F1$ corresponds to the (M-^{1}H)-coupling, since scalar interactions between the four dynamically equivalent protons do not influence the

spectra. The number of lines in the resulting multiplet is equal to n, in contrast to n + 1 in fully coupled M-NMR spectra. The metal chemical shift and the number of hydrido ligands can be read directly from the spectrum (Fig. 2) if the ^{1}H-transmitter frequency is on resonance with the hydride signal.

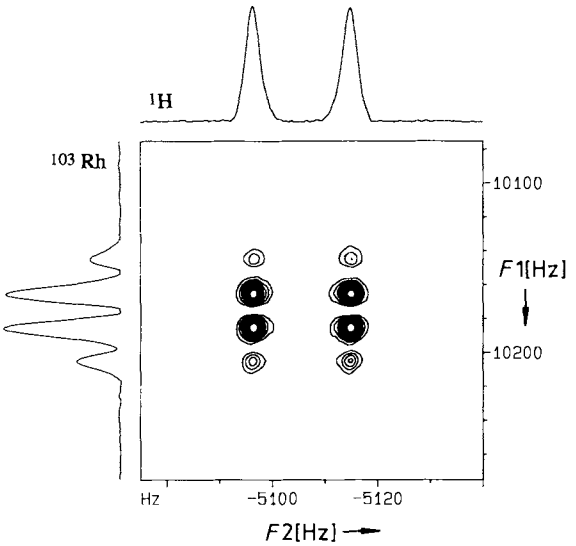

Fig. 2. Contour plot of a two-dimensional (^{1}H,^{103}Rh)-correlated spectrum of **1** in CD_2Cl_2 at 253 K (10 mg in 0.6 mL solvent, measuring time 8 min, Bruker AM-400-WB). Four FIDs were collected for each of the 48 traces in t_1. Prior to Fourier Transformation the data in t_2 and t_1 were weighted with sine and sine squared functions, respectively.

We consider the technique described above to be the method of choice for the determination of the number of protons coupled to a magnetically insensitive spin ½ metal center.

Hamilton et al.[10] have reported the preparation of two rhenium polyhydride complexes containing polypyrazolyl ligands, i.e., $[\{HB(pz)_3\}ReH_6]$ and $[\{CH_2(pz)_2\}ReH_7]$ (pz = pyrazolyl). These, however, contain only "classical" hydride ligands. Furthermore, *Tanke* and *Crabtree*[11] have recently described some iridium hydrido complexes with pyrazolylborate ligands where, however, there are other donors in addition to hydrogen and nitrogen and the Ir–H bonds are of the classical type. To our knowledge **1** is the first example of a platinum metal polyhydrido complex containing only nitrogen donors as co-ligands and also the first example of a complex containing coordinated molecular hydrogen, stabilized only by nitrogen donors.

Thus it appears that, as found in the phosphane-containing polyhydrido complexes, "non-clasical" behavior is more common in compounds of the second than those of the third transition series even when nitrogen donors are present as co-ligands.

Experimental

2: 372.8 mg (1 mmol) of PPh_4Cl was added to a suspension of 500 mg (1 mmol) of compound **3** in 10 mL of $CHCl_3$ and the mixture was refluxed for 3 h. The resulting solution was evaporated to dryness under reduced pressure and the residue was recrystallized from CH_2Cl_2/THF. Yield: 798 mg (95%). Satisfactory C,H,N,Cl analyses. IR (RbI): $\tilde{\nu}$(B–H) = 2532(s), $\tilde{\nu}$(Rh–Cl) = 330 and 316 cm^{-1}(m); ^{1}H NMR (CD_2Cl_2, 200 MHz, 298 K): δ = 7.9–7.6 (m, 20H, phenyl), 5.7 (s, 3H, CH), 2.7 (s, 9H, CH_3), 2.4 (s, 9H, CH_3).

1: 1 g (1.18 mmol) of **2** was suspended in 10 mL of ethanol under argon. A solution of 179 mg (4.7 mmol) of $NaBH_4$, in 5 mL ethanol was then gradually added. After a short time gas-evolution occurred and an off-white solid was formed. This was filtered off, washed with ethanol and methanol successively and dried under high vacuum. Yield: 339.5 mg (71%). Satisfactory C,H,N analyses. IR (RbI): $\tilde{\nu}$(B–H) = 2532 cm^{-1}(s), $\tilde{\nu}$(Rh–H) = 2035 cm^{-1}(vs), ^{1}H NMR (CD_2Cl_2, 250 MHz, 273 K): δ = 5.82 (s, 3H, CH), 2.36 (s, 9H, CH_3), 2.13 (s, 9H, CH_3), −12.76 (d, 4H, Rh–H), ^1J(Rh,H) = 18.1 Hz. ^{11}B NMR (80.2 MHz, CD_2Cl_2, 298 K): δ = − 27.7 (vs. $B(OMe)_3$) ^1J(B,H) = 105 Hz; ^{103}Rh NMR (CD_2Cl_2, 12.6 MHz, 253 K): δ = 805 (Ξ = 3.16 MHz). The compound **1** can also be prepared starting from **3** using the above method. However, it is obtained in lower yield (ca. 20%) and is less pure.

On the Way to Ligating Oligocyclopentadienyls: Synthesis and Preliminary Reactions of the Two Isomeric Tercyclopentadienyls and Their Transition Metal Complexes**

By *Roland Boese, Randy L. Myrabo, David A. Newman,* and *K. Peter C. Vollhardt**

While the synthesis and chemistry of homo- and heterobimetallic organometallic compounds,[1–3] often bridged by ligands[1,2] intended[3] to anchor the metals in close proximity, is well-explored, much less is known about the acyclic higher metal homologues.[2,4] Linked pairs of η^5-cyclopentadienyl (Cp) moieties,[5] as in fulvalene,[5,6] have played a significant role in these developments because of their exceptional binding ability.[7] We report a rational (and potentially generalizable) synthesis of the first "cyclopentadienologs" of fulvalene, namely the two isomers of tercyclopentadienyl,[8] their sequence-specific metal-complexation, the structure determination of two of these trimetallic products, and some preliminary ligand transfer chemistry. The intramolecular nature of the latter bodes well for catalytic applications of systems of this type.

The cornerstone of our synthetic strategy is the discovery that Cp-anions undergo efficient conjugate addition-elimination reactions[9] to 2-cyclopentenones bearing leaving groups at C3. Scheme 1 depicts the synthesis of the title compounds, starting with fulvalene dianion.[10] The respective regioisomeric components, **a** and **b**, of the intermediates **1**–**3**[11] were separated by chromatography and then converted independently into the desired target compounds **6**–**12**.

A 1,1′:3′,1″- and a 1,1′:2′,1″-tercyclopentadienyl compound (**7b** and **8a**, respectively) have been characterized crystallographically (Figs. 1 and 2).[11] Comparison of **7b** and **8a** reveals steric inhibition of coplanarity for only the 1,1′:2′,1″-tercyclopentadienyl ligand.

An iterative synthetic alternative to that shown in Scheme 1 allows complete control of the metal sequence to be associated with the evolving oligocyclopentadienyl chain, as exemplified in Scheme 2 for the heterotrinuclear complexes **15** and **16**, starting from **13**.[6]

A prerequisite for potentially synergistic chemical behavior toward organic substrates of these systems is intramolecular metal-to-metal ligand transfer. Attempts to uncover such rearrangements has led to some remarkable observations. Thus, treatment of the cyclopentadiene intermediates **4a** and **4b** with basic D_2O [CD_3COCD_3, Et_3N, 23 °C, 2 h] resulted in regiospecific deuterium incorporation (95%) into the uncomplexed ring, a process uncomplicated by potential metal transfer along the chain.[14] Surprisingly, *complete* label scrambling between the two terminal rings occurred on conversion of [D_5]**4b** into [D_4]**7b**, whereas [D_4]**7a** was formed from [D_5]**4a** bearing deuterium only on the η^5-$(C_5D_4)W(CO)_3CH_3$ substituent to the fulvalene unit! A

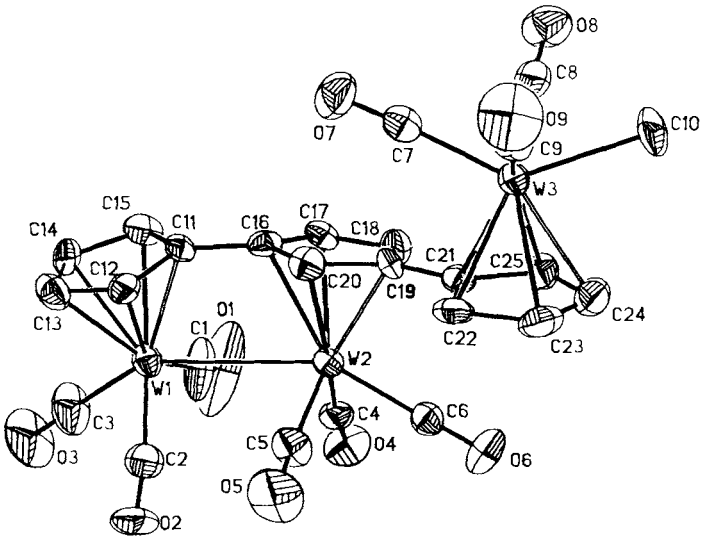

Fig. 1. Molecular structure of **7b** in the crystal (SHELXTL). Selected distances [Å] and angles [°]: W1-W2 3.266(1), W-CO (average) 1.96, W3-C10 2.324(11), W1-Cp1 (ring centroid) 1.975, W2-Cp2 1.994, W3-Cp3 2.017, C23-C24 1.375(18), C22-C23 1.459(16), C11-C16 1.453(13), C19-C21 1.468(14); C21-C22-C23 106.2(9), C22-C23-C24 109.2(10), C12-C11-C16 124.1(9), Cp2-Cp3 9.6, C15-C11-C16-C20 −179.9(1.1), C12-C11-C16-C17 153.7(1.0).

possible rationale for this divergent behavior is that the metal-anion precursor before methylation is responsible for the scrambling in [D_4] **7b** by reversible nucleophilic displacement of the metal-bound tungsten at the other terminus.[15]

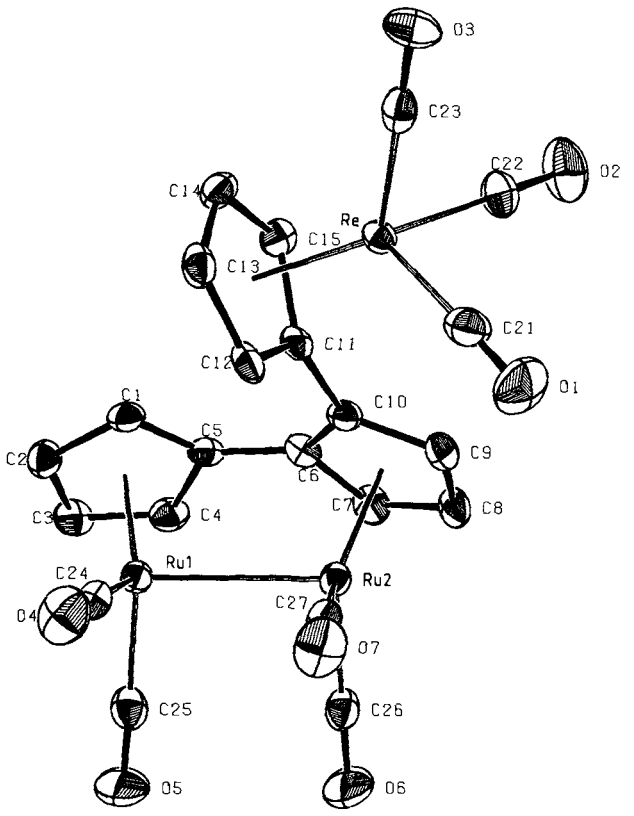

Fig. 2. Molecular structure of **8a** in the crystal (ORTEP). Selected distances [Å] and angles [°]: Ru1-Ru2 2.8190(4), Ru-CO (average) 1.86, Re-CO (average) 1.91, Ru1-Cp1 1.8981(3), Ru2-Cp2 1.8993(3), Re-Cp3 1.9531(2), C14-C15 1.397(6), C6-C10 1.457(6), C5-C6 1.436(6), C10-C11 1.491(5); C1-C5-C4 106.1(4), C8-C9-C10 109.3(4), C4-C5-C6 123.8(4), Cp2-Cp3 104.7(2), C1-C5-C6-C7 162.6(6), C4-C5-C6-C10 −154.1(6).

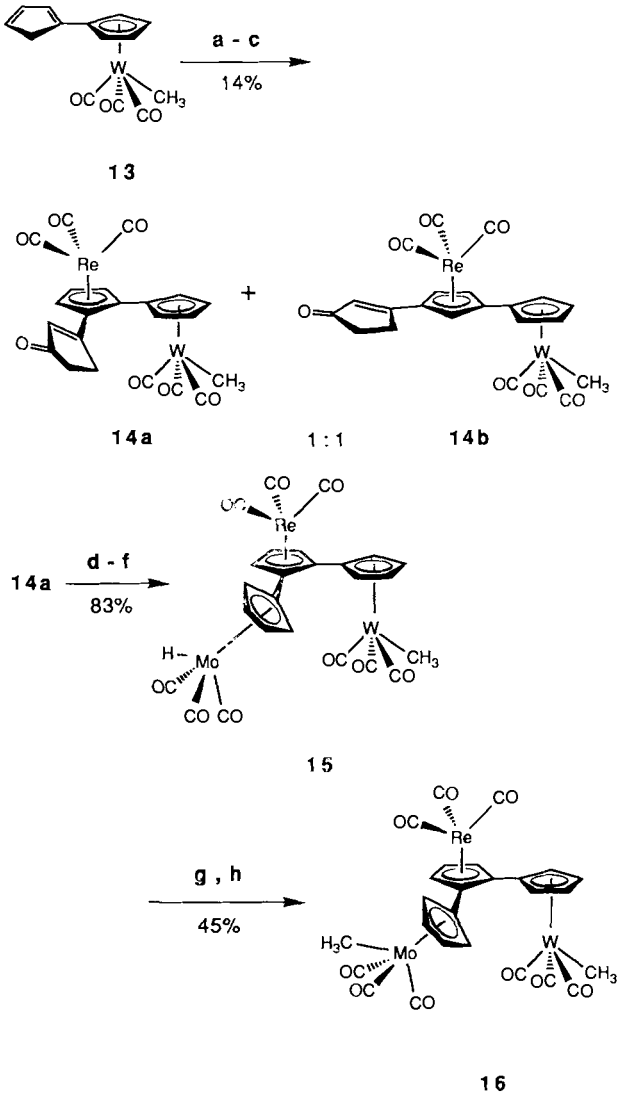
In contrast, in the analogous intermediate on route to [D_4]-**7a**, steric constraints prevent coplanarity (or a favorable angle) of attack of the cyclopentadienyl ring of the attached non-metal-bound anionic tungsten. In support of this mechanism, following the course of the reaction of [D_5]**4b** with [$W(NCMe)_3(CO)_3$] (23 °C, 2 h, 40% conversion) by ^{1}H-NMR spectroscopy revealed the generation of [η^5-(C_5D_4)W(D)(CO)$_3$]{η^5:η^5-(C_5H_3-C_5H_4)}$W_2(CO)_6$], [D_5]-**17b**, "exchange" of label taking place only with time (23 °C,



Scheme 2. Synthesis of **15** and **16**. a) NaH (3 equiv), THF, 0 °C, 20 min; b) 3-chloro-2-cyclopentenone, 0 °C, 1.5 h, then 23 °C, 30 min; c) [$Re(CO)_3(THF)_2Br$] [13], THF, Δ, 4.5 h; d) *i*Bu_2AlH, CH_2Cl_2, 0 °C, 2 h; e) 4-$MeC_6H_4SO_3H$, C_6H_6, 60 °C, 2 min; f) [$Mo(NCEt)_3(CO)_3$], THF, 23 °C, 19 h; g) KO*t*Bu, THF, 23 °C, 40 *min*; h) MeI, 23 °C, 2.5 *h*.

19 h), presumably by dedeuteration at tungsten, since scrambling was suppressed in the presence of added CH_3COOD.[16] Conversely, metalation of [D_4]**4b**$^{\ominus}$ at 23 °C led to instant label redistribution in the resulting anion between two outer Cp units. This process was sufficiently slow at −78 °C to allow access to regiochemically deuterated [D_4]**7b** by methylation, the stability of the latter ruling out methyl transfer[14] as another pathway for exchange. This

species is also stable in this regard on irradiation,[17] significantly, considering that chlorination[18] of $[D_5]$**17a** and $[D_5]$**17b** (CCl_4, THF, 23 °C, 10 min) to tetradeuteriated $[\eta^5\text{-}(C_5H_4)W(CO)_3(Cl)\{\eta^5\text{:}\eta^5\text{-}(C_5H_3\text{-}C_5H_4)\}W_2(CO)_6]$ provided results that completely paralleled those obtained in the generation of $[D_4]$ **7a** and $[D_4]$ **7b** with respect to the integrity of the position of the label.

Methyl migration could, however, be induced by reduction of the W–W bond in **7b** (1% Na–Hg, THF, 23 °C, 1 h) to furnish $[\eta^5\text{:}\eta^5\text{:}\eta^5\text{-}(C_{15}H_{11})W_3(CO)_9(CH_3)]^{2\ominus}$ in the form of two isomers bearing the methyl group at both the terminal and internal positions in a ratio of 1:2.7, respectively, changing to 1:6 on prolonged standing. Treatment with CD_3I furnished $[D_6]$**6b**, the unlabeled methyl remaining mainly (2.2:0.9) bound to the central tungsten. Isomer **7a** behaved similarly, being converted into to the corresponding dianions (1.5:1) and, ultimately, $[D_6]$**6a** (1.2:1.8). The uniquely intramolecular nature of these processes could be established by cross-over experiments involving **7a** and **7b**, respectively, admixed with their $[(\eta^5\text{-}C_5D_4)W(CO)_3(CD_3)]$-substituted counterparts. It appears that in reduced **7a** the terminal Cp-metal fragments are sufficiently mobile to allow for methyl transfer, although other details of this transformation have yet to be established.[14, 15, 19]

Experimental

2a, b: To fulvalenedilithium (1.00 mmol) in THF (15 mL) at −20 °C under nitrogen was added 3-chloro-2-cyclopentenone (116.5 mg, 1.00 mmol). The resulting dark brown mixture was cooled to −78 °C and treated with BuLi/hexane (0.59 mL, 1.70 M, 1.00 mmol). After warming to room temperature, a DME (10 mL) slurry of $[W(NCMe)_3(CO)_3]$ (821 mg, 2.10 mmol) was added. After three hours' stirring, the solution was cooled to −78 °C and allowed to react with a suspension of $AgBF_4$ (428 mg, 2.20 mmol) in THF (5 mL). Once the mixture had been allowed to slowly warm to room temperature, it was preadsorbed on silica gel. Chromatography with acetone/CH_2Cl_2 as eluent [gradient 1:19 to 1:4] afforded two major purple bands, **2a** (198 mg, 25.6%), followed closely by **2b** (154 mg, 19.9%).

4b: To a cooled (0 °C) CH_2Cl_2 (2.5 mL) slurry of **2b** (19.9 mg, 0.0269 mmol) was added a 1 M solution of diisobutylaluminum hydride (0.0403 mmol) in CH_2Cl_2. The resulting purple mixture was stirred for 2 h at 0 °C and then quenched with 10% aq. NH_4Cl (1 mL). The organic phase was filtered through alumina, the alumina washed with acetone, and the solvents removed to yield the cyclopentenol as a mixture of diastereomers (19.1 mg, 95%). A solution of this mixture (72 mg, 0.097 mmol) in benzene (20 mL) was added to a warm (60 °C) benzene solution (70 mL) of *p*-toluenesulfonic acid monohydrate (2.3 mg, 0.012 mmol). After stirring for 3 minutes, the acid was neutralized with saturated $NaHCO_3$ (2 × 35 mL). Filtration through alumina and removal of solvents yielded **4b** (70 mg, 99%) as a mixture of diene isomers.

7b: A solution of **4b** (64 mg, 0.088 mmol) and $W(NCMe)_3(CO)_3$ (69 mg, 0.176 mmol) in THF (12 mL) was stirred for 12 h under nitrogen. The mixture was cooled (−78 °C), treated with 0.1 M $LiN[SiMe_3]_2$ (0.118 mmol) in THF, and then with methyl iodide (30.2 mg, 0.214 mmol). The product was purified by chromatography (silica, acetone/hexane 1:3) to yield crystalline **7b** (73 mg, 82%).

Solid-State NMR Studies of the Structure and Reactivity of Metakaolinite**

By *João Rocha* and *Jacek Klinowski**

Although the kaolinite-mullite reaction series, one of the most important in the entire field of ceramic technology, has been studied for more than 100 years,[1] many questions are still unanswered. The most important are the structure of metakaolinite and the relationship between the various high-temperature phases, whose solution would help to explain the remarkable reactivity of metakaolinite, the starting material for the synthesis of important solids such as zeolites, ultramarine, chinaware, cements and ceramics. We have studied this reaction series using high-resolution ^{27}Al and ^{29}Si solid-state NMR with magic-angle spinning (MAS). Several similar studies have been published,[2-6] but since they fail to provide details of the important NMR parameters used for the acquisition of spectra, it is impossible to evaluate their usefulness.

Samples of kaolinite with different degrees of crystallinity: Cornish (sample 1) and Brazilian (sample 2), with Hinckley Indices[7] of 1.24 (highly crystalline) and 0.42 (poorly crystalline) were calcined in air for 1 h at temperatures in the range 400–1000 °C at 50 °C intervals (bed depths of 6–7 mm). In another experiment a sample of kaolinite was calcined for 24 h at 600 °C and then treated with 1 M KOH at 80 °C for 2 hours.

Kaolinite exhibits one ^{29}Si resonance at $\delta = -91.5$, assigned to a Q^3 Si environment,[1,6] and one ^{27}Al resonance at ca. $\delta = 0$, assigned to hexacoordinate Al (see Fig. 1a). NMR shows the presence of short-range order in metakaolinite and some differences in the dehydroxylation process of kaolinites with different degree of crystallinity. We have been able to resolve clearly, for the first time, three ^{29}Si MAS NMR signals, centered at $\delta = -91.5$, -96.7 and -100.5 in samples of poorly and highly crystalline kaolinite heated at 480 °C and 500 °C, respectively (Fig. 2). These spectra and the spectra of kaolinite treated at 550–900 °C can be simulated in terms of a minimum of five resonances centered at $\delta = -91.5$, -96.7, -100.5, -103.4 and -107.7 (Fig. 2). The presence of fine structure in the ^{29}Si NMR spectra of metakaolinite has been claimed,[5-6] but we are not satisfied that their presence has been convincingly demonstrated; in one case the argument relied on resolution enhancement. Our saturation recovery experiments show that the ^{29}Si spin-lattice relaxation time is about 17 s. However, most published results were obtained using recycle times of 2–5 s, and it is likely that some of the component signals in the spectrum of metakaolinite are saturated under these conditions.

In the temperature range of 480 to 920 °C metakaolinite shows three resolved ^{27}Al resonances at ca. $\delta = 0$, 28 and 57 assigned to hexa-, penta-[8,9] and tetracoordinate Al, respectively. The treatment of metakaolinite with KOH produces dramatic changes in the intensities of the signals due to penta- and hexacoordinate Al. The hexa-:penta-:tetracoordinate Al intensity ratios in untreated and treated metakaolinite are 0.6:1:1 and 0.1:0.4:1, respectively, showing that the treatment converts some penta- and hexacoordinate Al into tetracoordinate. Atomic absorption measurements reveal

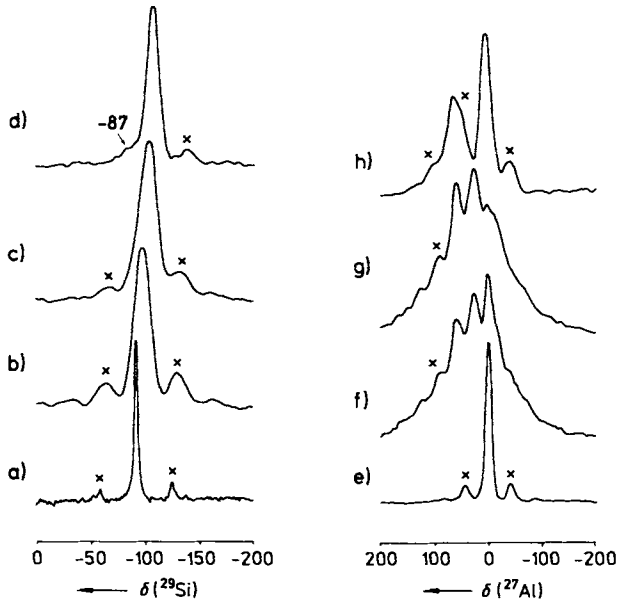

Fig. 1. ^{29}Si (left) and ^{27}Al MAS NMR (right) spectra of sample 1 (a) and e), $T = 20$ °C] and samples prepared from it by thermal treatment at $T = 550$ [(b) and (f)], 800 [(c) and (g)] and 1000 °C [(d) and (h)]. Spectra (a)–(c), and (e), (g) and (h) are characteristic of both kaolinites; spectra (d) and (f) are for the highly crystalline sample 1. ^{29}Si spectra (79.5 MHz) were measured with a Bruker MSL-400 multinuclear spectrometer. An Andrew-Beams probehead was used with rotors spinning at 3 kHz with air as the driving gas. 50°radiofrequency pulses were applied with a 30 s recycle delay. ^{29}Si chemical shifts δ relative to external tetramethylsilane (TMS). ^{27}Al MAS NMR spectra were measured at 104.2 MHz with very short and powerful (0.6 μs, equivalent to 9° pulse angle) rf pulses and a 0.2 s recycle delay. Rotors were spun in air at 5 kHz. Chemical shifts δ relative to external $Al(H_2O)_6^{3\oplus}$. × denotes spinning sidebands.

that only 2.6 mol-% of the Al is dissolved during treatment, which indicates that spectral changes are due to the change of coordination of the aluminum and not to its removal from the solid. It is striking that the ^{29}Si MAS NMR spectra of treated and untreated samples are very similar, which suggests that some regions of the sample contain Al–O–Al and

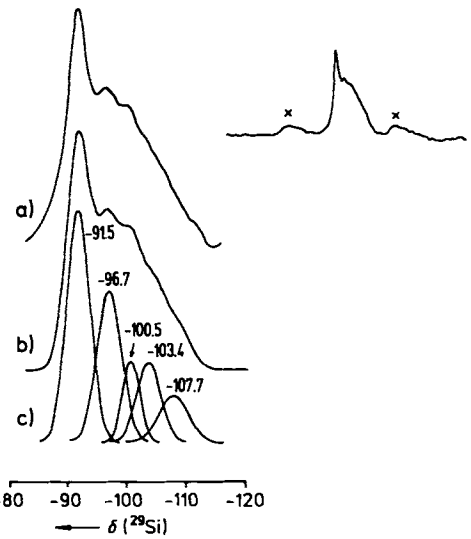

Fig. 2. (a) ^{29}Si MAS NMR spectrum characteristic of both kaolinites after thermal treatment at 480–500 °C; (b) simulated spectrum using (c) a number of Gaussian signals with chemical shifts as indicated. The spectrum on the right is from a highly crystalline kaolinite treated at 500 °C.

[*] Dr. J. Klinowski, J. Rocha
Department of Chemistry
University of Cambridge

[**] We are grateful to E.C.C. International Limited for support and for providing kaolinite samples, to the University of Aveiro for support and to Dr. *G. Engelhardt*, Dr. *J. M. Adams* and Dr. *M. W. Anderson* for discussions.

Al–OH–Al bonds, but not Si–O–Al bonds. We also note that at temperatures as low as 480–500 °C the Q^4 Si environment is already present (at $\delta = -107.7$). These facts are consistent with the incipient separation of Al and Si.

The assignment of all ^{29}Si resonances is still an open question. The possibilities are: a) simultaneous presence of several distinct Si–O–Si bond angles; b) different Q^3 (mAl) and/or Q^4 (nAl) sites[16] with $0 < n,m < 4$ especially[10] Q^3 (1 Al) (at $\delta = -100.5$) and Q^4 (1 Al) and/or Q^4 (2 Al) (at $\delta = -96.7$); c) Si sites with associated residual OH groups.[6]

At 950–1000 °C the ^{29}Si spectra of both kaolinites exhibit an NMR signal centered at ca. $\delta = -110$ with a FWHM (full-width-at-half-maximum) of $\Delta\delta = 13.5$, narrower than the similar signal given by samples heated at lower temperatures (FWHM of $\Delta\delta = 17-20$). This suggests that cristobalite germs are likely to be present in the amorphous matrix in samples heated to high temperatures. The spectrum of sample 1, heated at 1000 °C, clearly shows the presence of an additional faint resonance from mullite at ca. $\delta = -87$. The XRD data reveal the presence in samples 1 and 2 (heated at 950–1000 °C) of mullite and γ-alumina, probes derived from sample 1 being richer in mullite.

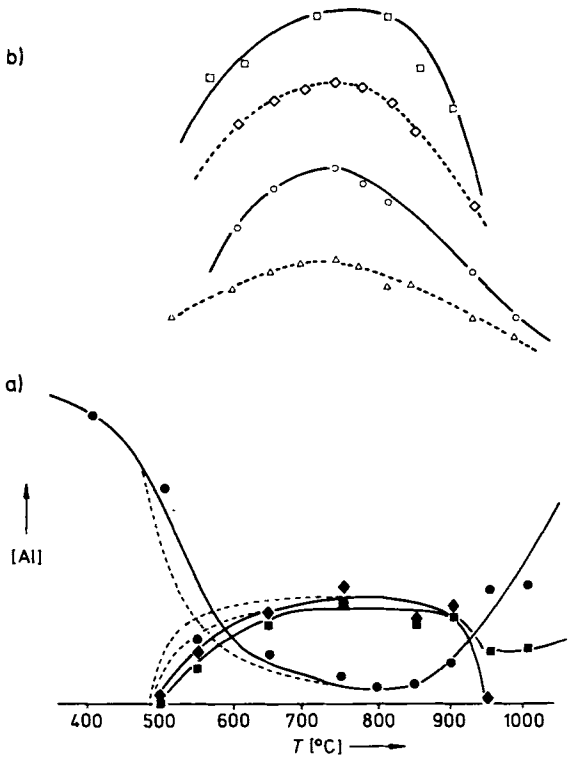

Fig. 3. (a) The change of tetra-(■), penta-(◆) and hexacoordinate (●) Al populations versus the temperature of treatment of kaolinite samples. Dotted lines show the differences between sample 2 (which follows these lines) and sample 1. Deconvolution of the spectra is described elsewhere. [13] (b) Dependence of several properties of metakaolinite on the calcining temperature. △: Variation of the compressive strength of the geomaterials obtained by hydraulic binding of metakaolinite with $Ca(OH)_2$ as chemical activator; ○: IR disorder index of the 460–470 cm^{-1} band; ◇: dissolution enthalpy of kaolinite in HF [14] and □: of the yield of zeolite X synthesis as a function of temperature [15] (in the last case the temperature of firing of the kaolinite precursor).

We suggest that metakaolinite contains: a) segregated amorphous silica regions in which Q^4 units predominate; b) a "main framework" with Q^4 (nAl) units (containing one or two tetracoordinate Al atoms) probably with a small number of associated residual (5–10% as measured by TGA at 650 °C) OH groups; c) traces of the parent kaolinite with Q^3 silicon environments and hexacoordinate Al, probably with a relatively significant amount of associated residual OH groups; d) regions of segregated amorphous alumina in which Al–O–Al (or Al–OH–Al) bonds are present but no Si–O–Al bonds; e) regions where silicon atoms *may* be associated with some residual OH groups; f) penta-coordinate sites, acting as structural defects, randomly and widely distributed in all regions, with a significant number of associated residual OH groups.

Figure 3a shows the variation in the three ^{27}Al populations, monitored by NMR as a function of temperature (a plot of Al occupancy as a function of the degree of dehydroxylation gives a similar plot, Figure 3b) which is compared with the temperature dependence of several known properties of metakaolinite. All the curves go through a maximum at 750–800 °C. Similar curves are obtained for the temperature dependence of the electrical conductivity of solutions of metakaolinite in HF extrapolated to zero time, of the specific initial dissolution rate of metakaolinite in HF,[11] and of the point of zero charge of $H^{\oplus}$-kaolinite/metakaolinite.[12]

It is interesting to consider the changes in the three Al populations in the light of published data. The reactivity of metakaolinite is at a maximum at 750–800 °C when the population of hexacoordinate Al is at a minimum and tetra- and pentacoordinate populations at a maximum. As pentacoordinate Al is a transition state characteristic of the temperature domain in which metakaolinite is metastable, one is tempted to choose this coordination as the best measure of the remarkable chemical reactivity of metakaolinite. On the other hand, the reactivity can only be fully understood in terms of the coexistence of several kinds of regions. It is thus essential that many early literature experiments be repeated and the results discussed in terms of the concepts described above. This work is now in progress.

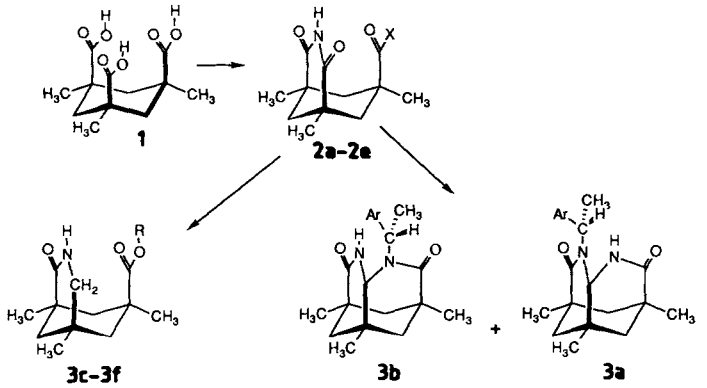
[16] The $Q^{(n)}$ nomenclature defines the number of Si-O-Si bridges that an SiO_4 unit takes part in. For example see H. Eckert, *Angew. Chem. Int. Ed. Engl. Adv. Mater. 28* (1989) 1723; *Angew. Chem. Adv. Mater. 101* (1989) 1763; *Adv. Mater. 1989*, 423. Q^a (b Al) signifies an SiO_4 group which is bound via O atoms to b Al atoms and (a–b) other Si atoms.

New Chiral Auxiliaries for Enolate Alkylations**

By *Kyu-Sung Jeong, Kevin Parris, Pablo Ballester,* and *Julius Rebek, Jr.**

Asymmetric transformations are the concern of modern synthetic chemistry, and chiral auxiliaries are one means by which high stereoselection can be achieved.[1] We recently introduced a system which shows exceptional selectivity in cycloaddition reactions;[2] here we demonstrate its applicability in alkylation reactions.

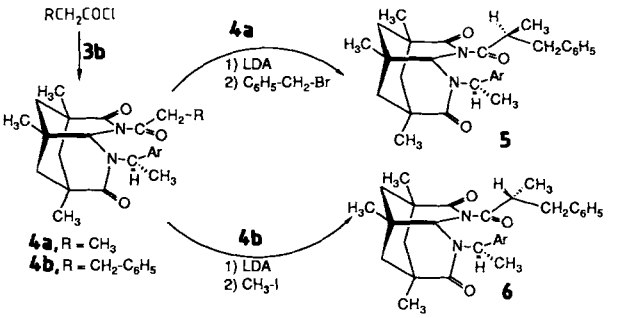
The molecular skeleton of the new auxiliaries derives from the commercially available Kemp triacid **1**.[3] Its imide acid chloride **2a**[4] readily acylates amines or alcohols. For example, the amide **2b** (m.p. 113–115 °C) was obtained from **2a** and (*S*)-1-phenylethylamine, and the ester **2d** (m.p. 160–162 °C) from **2a** and (*S*)-1-naphthylethanol, each in high yield (87 and 70%, respectively).[5] The esters **2c** and **2e** have been described in detail elsewhere[4] (Scheme 1).



Scheme 1. **2a**, X = Cl; **2b**, X = (*S*)-NH-CH(CH$_3$)C$_6$H$_5$; **2c**, X = OMe; **2d**, X = (*S*)-O-CH(CH$_3$)-2-naphthyl; **2e**, X = O-CH$_2$CH$_2$-2-naphthyl; **3c**, R = H; **3d**, R = Me; **3e**, R = 2-naphthyl; **3f**, R = CH$_2$-CH$_2$-2-naphthyl. Ar = phenyl.

Reduction of **2b** (NaBH$_4$/EtOH, 0 °C) followed by acid treatment (*p*-TsOH/CH$_2$Cl$_2$) gave the tricyclics **3a** and **3b** as an easily separable mixture of diastereomers [flash chromatography; **3a** (55%, m.p. 107–109 °C), **3b** (34%, m.p. 187–189 °C)]. The structure of **3b**, established by X-ray crystallography,[6] features the N–H bond near the asymmetric microenvironment. The methyl ester **2c** was reduced, firstly with NaBH$_4$/EtOH and then with Et$_3$SiH/CF$_3$CO$_2$H, to give the bicyclic lactam **3d** (m.p. 141–143 °C). Saponification, activation (SOCl$_2$), then coupling with β-naphthol gave **3f** (m.p. 82–84 °C). A parallel sequence of reductions afforded **3f** from **2e**, and the *optically active* **3c** was obtained from **2d**.

The tricyclic compound **3b** proved to be a most effective auxiliary for asymmetric alkylation reactions. Acylation of **3b** (NaH/RCH$_2$COCl/THF) furnished the propionyl and the 3-phenylpropionyl derivatives **4a** and **4b**, respectively. Deprotonation (LDA/THF, −78 °C) and alkylation of **4a** with benzyl bromide (−78 °C, 10 min → 0 °C, 3–5 h) *gave a single diastereomer* (**5**) (Scheme 2). Parallel alkylation of **4b** with MeI *gave only the other diastereomer* (**6**). With 500-MHz NMR and HPLC as assays, the diastereoselectivity was judged to be at least 200:1. Regeneration of the alkylation products as optically active carboxylic acids[7] with simultaneous recovery of the auxiliaries can be easily achieved using Evans' procedure[8] (LiOH/H$_2$O$_2$).



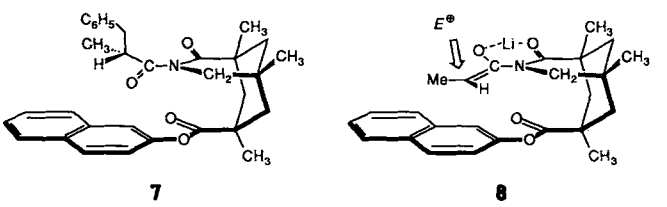
Scheme 2. Ar = phenyl; LDA = lithium diisopropylamide.
5 → (*S*)-C$_6$H$_5$-CH$_2$-CH(CH$_3$)-COOH + **3b** (CH$_3$ = R)
6 → (*R*)-C$_6$H$_5$-CH$_2$-CH(CH$_3$)-COOH + **3b** (CH$_2$-C$_6$H$_5$ = R)

The alkylation results are summarized in Table 1. A comparison of the reactions of the diastereomers **3a** and **3b**, clearly reveals that both the asymmetry of the cyclohexyl moiety as well as that of the α-phenylethyl moiety contributes to the selectivity. An X-ray crystallographic study[6] of the alkylation product of **4b** (No. 5) established its structure as shown in **6**. The product of entry No. 3 was also obtained in suitable form for crystallographic analysis and the structure was established as **7**.

Table 1. Alkylation of enolate derivatives (cf. **8**) from which the acyl derivatives were obtained by lithiation. E = electrophile. The products still contain the auxiliary compound.
R-CH$_2$-COCl → R-CHE-COOH, R = Me, E = PhCH$_2$ or R = PhCH$_2$, R = Me

No.	R	Auxil. cpd.	Acyl deriv.	EX	Product	Diast. ratio	Yield [%]
1	Me	**3a**		PhCH$_2$Br		63:37	76
2	Me	**3b**	**4a**	PhCH$_2$Br	**5**	>99:1	63
3	Me	**3e**		PhCH$_2$Br	**7**	>99:1	56
4	PhCH$_2$	**3a**		MeI		>99:1	84
5	PhCH$_2$	**3b**	**4b**	MeI	**6**	>99:1	64
6	PhCH$_2$	**3e**		MeI		98:2	73

The efficacy of the new systems is demonstrated by their control of electrophile approach to the enolate system. The extended aromatic nucleus in these structures, shown in the



enolate **8**, provides an effective barrier to external reagents, while Li$^{\oplus}$-chelation fixes the configuration of the enolate.

The configuration of the alkylation products (e.g., **6** and **7**) are fully in accord with this analysis.

In summary, chiral auxiliary compounds (**3**) of a new shape have been described, and their action can be related to the stereoelectronics of enolate alkylations. The asymmetric environment of the auxiliary compounds is so well defined in structures such as **3b** that such materials show efficiency as asymmetric protonation agents.

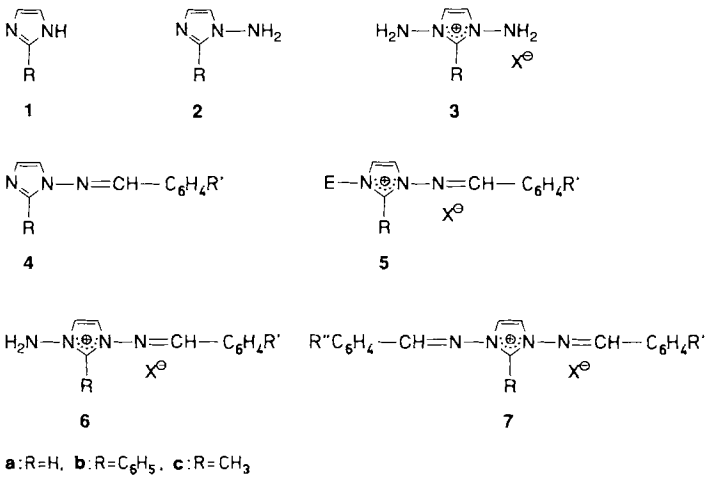
1-Amino- and 1,3-Diaminoimidazolium Salts**

By *Helmut Link*,* *Wilhelm Klötzer*, *Eva Maria Karpitschka*, *Marc Montavon*, *Renate Müssner*, and *Nicolas Singewald*

Stepwise amination of imidazoles to give the previously unknown 1,3-diaminoimidazolium salts **3** may be accomplished with *O*-(diphenylphosphinoyl)hydroxylamine (DPH).[1,2] Some derivatives of these quaternary salts have interesting chemical and biological properties. For example, the 1,3-bis[(*p*-aminobenzylidene)amino]imidazolium salts **7** are surprisingly stable in aqueous media. In screening experiments using the animal models *Litomosoides carinii*/cotton rat and *Onchocerca gibsoni*/cattle, these salts show a high activity against filaria.[3] The latter model is best suited for the evaluation of potential drugs against the human parasite *Onchocerca volvulus*, which causes river blindness (onchocerciasis). Here we report on the synthesis of *N*-aminated imidazolium salts.

The amination of imidazole (**1a**) with sodium hydroxylamine *O*-sulfonate in water leads to a mixture of the 1-amino- and 1,3-diaminoimidazolium salts **2a** · HX and **3a**, respectively, which can be separated as their benzylidenamino derivatives **4a** and **7a**, R′ = R″ = H (Scheme 1). This amination method is also suitable for water-soluble 2-, 4-, and 5-substituted imidazoles such as 2-methyl-, 2-ethyl-, and 2-methyl-4-hydroxymethylimidazole. 2-Isopropylimidazole, 2-phenylimidazole, and 2-methylbenzimidazole can only be diaminated in very small yield by this method. We have now found that DPH is a suitable reagent for the amination of water-insoluble imidazoles. For example, the sodium salt of 2-phenylimidazole (**1b**) reacts in *N*-methylpyrrolidone with 1 molar equivalent of DPH to give 1-amino-2-phenylimidazole (**2b**; 50–70% yield after chromatography). Further amination with DPH in dichloromethane to give 1,3-diamino-2-phenylimidazolium salt **3b** proceeds in high yield (88% after conversion to the chloride with Amberlite). We also obtained product **3b**, X = Cl, in 40–50% yield by treatment of **1b** with *O*-(mesitylenesulfonyl)hydroxylamine (MSH) in tetrahydrofuran in the presence of sodium hydrogen carbonate followed by anion exchange (Amberlite).



Scheme 1.

1-Amino- and 1,3-diaminoimidazolium salts may be stored at room temperature without noticeable decomposition. 1-Aminoimidazole (**2**, R = H, alkyl, phenyl) undergoes condensation with aldehydes such as *p*-dimethylaminobenzaldehyde in glacial acetic acid to give **4**, which reacts, in turn, with electrophilic reagents such as α-halo esters or benzyl halides to give **5**. Treatment of **4** with DPH results in amination to give **6**, which can be converted into **7** by reaction with aldehydes. The 1,3-bis(benzylidenamino)imidazolium salts with identical substituents R′,R″ may also be obtained directly from **3**. The stepwise condensation of **3** with two different aldehydes to give **7** (R′ ≠ R″) is also possible, but requires careful purification of the first condensation product **6**.

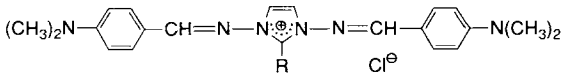
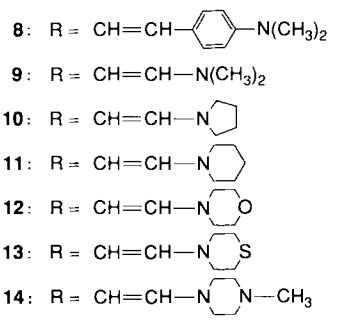
[**] We thank Dr. *W. Arnold* (NMR), Dr. *W. Vetter* and *W. Meister* (MS), Dr. *M. Grosjean* (IR), and Dr. *A. Dirscherl* (microanalysis) for spectroscopic and analytical investigations as well as *B. Schaffner*, *U. Brombacher*, *R. Villard*, *D. Wechsler*, and *R. Schlagbauer* for synthetic work.

The C-methyl group of 2-methylimidazolium chloride (**7c**, $R' = R'' = p\text{-}NMe_2$, X = Cl) can be condensed with aldehydes and amino acetals. For example, refluxing this compound for 20 h with *p*-dimethylaminobenzaldehyde and piperidine (in molar equivalent amounts) in ethanol affords **8** in 89% yield (Scheme 2). Reaction of **7c** with *N,N*-dimethyl-

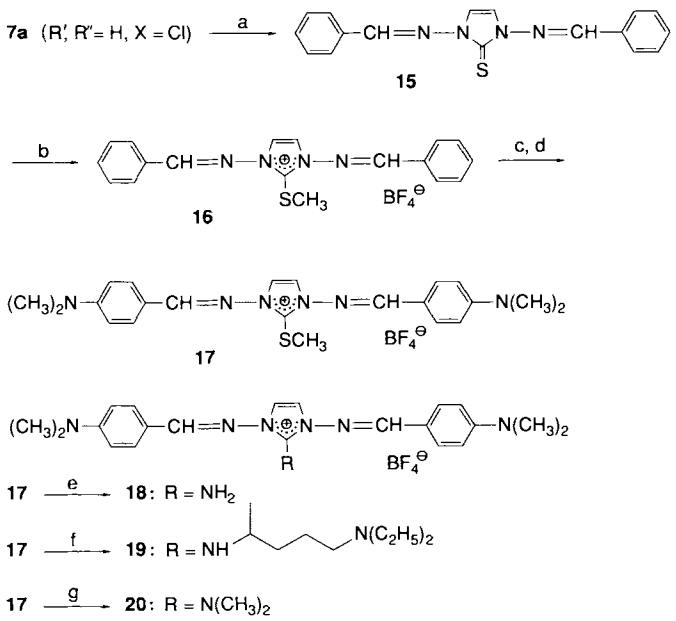




Scheme 2.

formamide diethyl acetal to give **9** requires 4 d in DMF at 50 °C; as expected, the reaction is faster with *N,N*-dimethylformamide di-*tert*-butyl acetal (1 d at room temperature). In both cases, the yield is 84–87%. Compounds **10**–**14** were obtained similarly.

In the following discussion, we wish to report on the synthesis of 2-amino derivatives of **7** (Scheme 3). 1,3-Bis(benzylidenamino)imidazolium chloride (**7a**, R′ = R″ = H, X = Cl) adds sulfur in the presence of triethylamine and pyridine. The resulting compound **15** can be methylated to give 2-(methylthio)imidazolium tetrafluoroborate (**16**) by



Scheme 3. a: 1.0 molar equiv. S, 1.0 molar equiv. NEt_3, Pyridine, 15 min room temperature (RT), 30 min reflux, 85% yield; b: 1.0 molar equiv. $Me_3O^{\oplus}BF_4^{\ominus}$, CH_2Cl_2, 3 h RT, 95%; c: HBF_4, steam distillation; d: 2 molar equiv. *p*-dimethylaminobenzaldehyde, 3 h RT, 75%; e: NH_3, anhydrous DMF, 71%; f: ca. 10 molar equiv. 2-amino-5-(diethylamino)pentane, CH_3CN, 24 h, RT, 50%; g: $NH(CH_3)_2$, anhydrous DMF, 70%.

treatment with Meerwein salt. At this stage in the synthesis, the substituent at position 2 can be replaced by amino groups. Subsequently, the benzylidenamino groups can be replaced by *p*-(dimethylamino)benzylidenamino groups. However, it is also possible (see Scheme 3) to eliminate benzaldehyde by steam distillation in acid medium. The resulting 1,3-diamino-2-(methylthio)imidazolium tetrafluoroborate may then be converted into **17** by treatment with *p*-(dimethylamino)benzaldehyde. Substitution of the methylthio group by ammonia or amines then leads to the desired compounds **18**–**20** (Table 1).

Table 1. Physical data for compounds **7b**, **8**, **9**, and **17**–**20**. The NMR spectra were recorded at 25 °C with TMS as standard on a 250-MHz instrument.

A large number of the 1,3-bis[(*p*-aminobenzylidene)-amino]imidazolium chorides and bromides (**7**) we prepared were only sparingly soluble in water. More soluble salts were desired for biological evaluation. Our observation that hydrogen carbonates are even less soluble prompted us to convert the chlorides and bromides via hydrogen carbonates to more soluble salts such as acetates. This salt interconversion method proved successful and avoided the necessity of interconverting the salts at the stage of the water-soluble salts **3** and **6**.

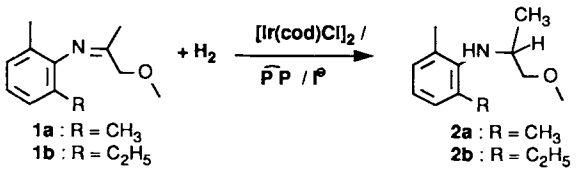
Novel Diphosphinoiridium Catalysts for the Enantioselective Hydrogenation of *N*-Arylketimines

By *Felix Spindler*,* *Benoit Pugin*, and *Hans-Ulrich Blaser*

Homogeneous enantioselective hydrogenation is an important method for the synthesis of optically active compounds;[1] however, most applications are limited to Rh or Ru catalysts and to functionalized olefins or ketones.[2] And despite the reduction of imines to the corresponding amines being preparatively important,[3] only few enantioselective hydrogenations with attractive optical yields have so far been described.[4, 5] The diphosphinorhodium complexes used in these hydrogenations generally show rather low activities, even at high hydrogen pressures (>70 bar). In the present communication we describe novel diphosphinoiridium catalysts for the enantioselective hydrogenation of *N*-arylketimines, which are important intermediates in the synthesis of herbicides.[6, 7]

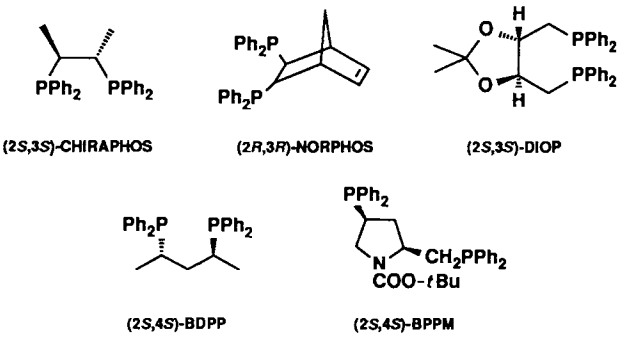
In the presence of a catalyst prepared in situ from bis[(1,5-cyclooctadiene)iridium chloride] $[Ir(cod)Cl]_2$ and a chiral diphosphino compound $\widehat{PP}$, imines of type **1** react with molecular hydrogen in high yields to give the corresponding anilines. Both the structure of the diphosphino compound as well as the anion strongly influence the catalyst's properties (halogen effect).



1a : R = CH_3
1b : R = C_2H_5

2a : R = CH_3
2b : R = C_2H_5

Good activities and enantioselectivities are obtained with chiral ligands which can form a conformationally flexible six- or seven-membered metallacycle (BDPP,[4a] DIOP[8] or BPPM[9]). 1,2-Diphosphino compounds (e.g. CHIRAPHOS,[10] NORPHOS[11]) give catalysts with low



activity. A strong halogen effect is observed: the halogen-free catalytic system $[Ir(cod)_2]BF_4$/(2*S*, 3*S*)-DIOP yields the (*R*)-enantiomer of **2a** with only 4% *ee*, whereas addition of 1 equivalent of iodide leads to a considerably more active catalyst producing the (*S*)-enantiomer of **2a** with 68% *ee* (Table 1). Whether this effect is also observed with other imines was not investigated. In the in-situ preparation of the catalyst from $[Ir(cod)Cl]_2$ and DIOP the addition of $I^{\ominus}$ (less strongly $Cl^{\ominus}$, $Br^{\ominus}$) also has a positive influence on the activity and selectivity: The addition of 2 equivalents of $I^{\ominus}$ leads to an increase in the initial reaction rate from 0.2 min^{-1} to 1.8 min^{-1} (for imine **1a**), and the enantiomeric excess increases from 58% *ee* to 70% *ee* (Table 1). A significant catalyst deactivation is observed, with the iodide-containing catalyst being the less rapidly deactivated. There are indications that inactive dinuclear iridium complexes are formed, as proposed for the hydrogenation of alkenes.[12, 13]

Table 1. Enantioselective hydrogenation of imines **1** with $[Ir(cod)Cl]_2/\widehat{PP}$ to **2**[a].

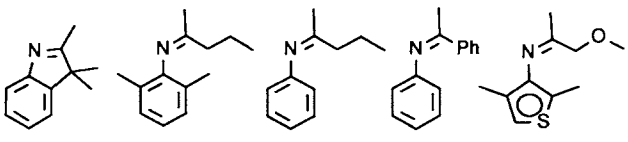
(2*S*, 4*S*)-BDPP[4a]	**1a**	2	18	45	49	72 (*S*)
(2*S*, 4*S*)-BDPP	**1a**	2	0	16	98	84 (*S*)

[a] Reaction conditions: 40 mmol imine, imine/catalyst 100:1, $[Ir(cod)Cl]_2$/PP 1:1.1, solvent 10 mL MeOH/10 mL benzene, $p(H_2)$ = 20 bar, $I^{\ominus}$ from tetrabutylammonium iodide. [b] *ee* determined polarimetrically [14] and ^{1}H-NMR spectroscopically [15]. [c] $Ir(cod)_2BF_4$ instead of $[Ir(cod)Cl]_2$. [d] 0.5 mol imine, imine/catalyst 10000:1, $p(H_2)$ = 100 bar; remaining reaction conditions as in [a].

The reaction conditions influence both the optical yields as well as the productivity. Lower temperatures favor higher enantiomeric excesses (72% *ee* at 18 °C, 84% *ee* at 0 °C; imine **1a** and BDPP). At normal pressure no reaction takes place. At pressures of H > 10 bar, productivities increase with pressure even though the enantioselectivities are not affected. The average turnover number at 20 bar lies in the range 100–500, under optimized reaction conditions around 10000. For the analogous rhodium complexes the average value is 100 at 70 bar H_2 and in the best case 700.

The imines **3**–**7** are further examples of substrates that can be hydrogenated with the catalyst $[Ir(cod)Cl]_2$/DIOP/2$I^{\ominus}$. Under standard conditions (cf. Table 1) the following *ee* values [%][15] are obtained: 66(**3**), 52(**4**), 16(**5**), 22(**6**), 58(**7**).



3 **4** **5** **6** **7**

Our results indicate that the conformational freedom of motion of the imino group has to be restricted (hindered rotation about the *N*-aryl bond), in order to obtain good enantioselectivities.

Postfach, CH-4002 Basel (Switzerland)

All the imines used (aside from **3**) consist of a mixture of *syn*- and *anti*-isomers; in the case of the imine **1a** the *anti*/*syn* ratio is 5:1 (^{1}H-NMR measurements). Since both the equilibrium *syn*-isomer $\rightleftarrows$ *anti*-isomer as well as the equilibrium imine $\rightleftarrows$ enamine proceed more rapidly than the hydrogenation (^{1}H-NMR measurements, H/D exchange with [D_4]-methanol) we conclude that the *anti*/*syn* ratio is not selectivity-determining. More detailed investigations on the elucidation of the reaction mechanism are currently under way.

Experimental

All operations were carried out under argon. A solution of $[Ir(cod)Cl]_2$ (134.4 mg, 0.2 mmol) in 10 mL of a 1:1 solvent mixture of benzene and methanol was treated with 219.7 mg (0.44 mmol) of (2*S*, 3*S*)-DIOP and, after 15 min, with 295.8 mg (0.8 mmol) of tetrabutylammonium iodide; the mixture was then stirred for a further 15 min. A separate solution of the imine **1a** (7.65 g, 40 mmol) in methanol (5 mL)/benzene (5 mL) was now prepared. The imine solution and catalyst solution were successively transferred via a steel capillary into a 50 mL steel autoclave under an inert atmosphere. The inert gas was replaced in the autoclave by hydrogen in three cycles (20 bar/normal pressure). Finally 20 bar of hydrogen were compressed into the autoclave. After completion of reaction the conversion was determined gas chromatographically and the product distilled under high vacuum. After flash chromatographic purification of the crude product **2a** (silica gel, hexane/ethyl acetate 1:1), the optical yield was determined by polarimetry[14] and ^{1}H-NMR spectroscopy[15].

BOOK REVIEWS

Book Reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the following address: Redaktion Angewandte Chemie, Postfach 101161, D-6940 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Anthracycline- and Anthracenedione-Based Anticancer Agents. Edited by *J. W. Lown*. Elsevier, Amsterdam 1988. 738 pp., hard cover, HFl 440.00.—ISBN 0-444-87275-2

"Anthracyclines represent one of the most useful and widely prescribed classes of anticancer agents" writes *J. W. Lown*, the editor of this book in the series with the general title "Bioactive Molecules". In accordance with the great clinical importance of this class of compounds, a wealth of new original papers has appeared since the last interdisciplinary multi-author volumes were published in the years 1980 to 1982. This has brought added urgency to the task of editing an up-to-date review of the field of anthracyclines, including all aspects from synthesis to clinical application.

It must be acknowledged that the editor, who has himself contributed to the field through synthetic and biophysical studies on anthracyclines, has made an excellent choice of topics to be covered. The total of 20 articles are divided into three sections as follows: Section 1: Isolation, Synthesis and Properties; Section 2: Biophysical and Biochemical Studies Related to Mechanisms of Action; Section 3: Pharmacology, Toxicity and Clinical Aspects.

Only two articles are actually devoted to synthesis, that by *F. Arcamone* and *S. Penco* on doxorubicin analogues, and that by *E. M. Acton* et al. on the very promising new class of compounds, the morpholinyl-anthracyclines. This limited choice of topics is justified, since recent comprehensive review articles on anthracycline syntheses already exist. Next comes a contribution by *T. Oki* on anthracyclines of microbial origin, including very recent results on the biogenesis of these compounds. The last three reports in Section 1 deal with topics that have scarcely been reviewed before, namely anthracycline-metal complexes (*A. Garnier-Suillerot*), and the pharmacological aspects of mitoxanthrones and ametanthrones (*F. E. Durr*), and of anthrapyrazoles (*H. D. Hollis Showalter* et al.).

Section 2 on biophysical and biochemical studies is the longest in the book, with eight articles. The interaction with DNA, which is important in relation to the effectiveness of the compounds, is treated first, in articles dealing with quantitative aspects (*E. Stutter* et al.), X-ray diffraction studies (*G. Ughetto*), computer modeling (*J. R. Brown* and *S. Neidle*), and sequence selectivity (*B. Pullman*). However, there is still no consensus among experts on the basic mechanism of action, as is shown by the general articles on anthracyclines by *C. E. Myers* et al. and on anthracenediones by *K. Reszka*. Thus, in addition to the interaction with DNA, there are discussions of the effects on DNA-topoisomerase II (*M. Potmesil*) and on lipid oxidation and prostaglandin formation (*R. F. Novak* et al.).

However, it is in clinical application that biochemical models undergo their ultimate test. This aspect, together with pharmacology and toxicity, is treated in Section 3. The introductory article by *M. Grandi* et al. on screening methods, which is fairly basic in content, is followed by newer aspects of anthracycline resistance (*D. H. Kessel*), of the pharmacology of Menogaril, which has been developed from nogalamycin (*J. P. McGovern* et al.), and that of anthracenedione (*M. D. Green* et al.), together with tumor cell differentiation by anthracyclines (*A. M. Casazza*). The short closing contribution by the editor again emphasizes the fact that, despite the wealth of experimental results, a firm understanding of antitumor activity is still a long way off. However, he urges continued research "... in order to understand the mode of action of these valuable agents and to improve their performance".

This volume is extremely useful for everyone working on synthetic, pharmacological or clinical aspects of anthracyclines or on antitumor therapy in general. Nowadays it is hardly possible for an individual to read every original paper which has an interdisciplinary connection with this topic. This collective volume makes it easier to see beyond the confines of one's own special field. Thus, it enables the synthetic chemist and the natural products chemist, for example, to learn which compounds have progressed from promising animal trials to clinical trials or use. However, sentences such as "Aclacinomycine A is therefore essentially ineffective in the major solid tumors" (p. 672), or "The side effects were in general similar to those seen with doxorubicin" have a sobering effect.

As in the parallel series "Studies in Natural Products Chemistry", also published by Elsevier, the authors' contributions are reproduced in "camera ready" form. Consequently the visual appearance is that of a wide variation in type styles and in the presentation of formulas. The incidence of typographical errors varies considerably from author to author, and in this respect the standard falls far short of that usually found in books that are typeset. These superficial shortcomings would, of course, be acceptable if they were offset by the contributions being more up-to-date and by an advantage in price. Unfortunately, however, in most of the articles the references extend only up to the end of 1986, or occasionally to the beginning of 1987. Even with this method of production it appears that at least a year has elapsed between the submission of the manuscripts and the publication of the book, a delay which this reviewer has also experienced as an author in the parallel series. The subject index consists of 8 1/2 pages. There is no index of cited authors; in the computer age it should have been easily possible to provide such an index, which would have been very useful.

Despite the fact that much of the work of publication has been off-loaded onto the authors, the price of the book is very high. Nevertheless, this should not deter libraries and scientists working in the field from buying it, as this is offset by the wealth of information that is compressed into it.

Die Technik der organischen Trennungsanalyse. Eine Einführung. By *H. Laatsch*. Thieme, Stuttgart 1988. xii, 223 pp., paperback, DM 36.00. – ISBN 3-12-722801-8

Owing to the considerable advances that have occurred in chromatography (thin layer chromatography, column chromatography and gas chromatography), and the relatively little new progress that has been made in the classical organic techniques of separation and analysis ("wet chemical methods"), many chemists will take the view that it was not really necessary to add another survey to the already large number of review articles on the latter topic. However, the author of this book intends it to be used by students of experimental chemistry, who would find a readable and lucid introduction to the subject very helpful. In meeting this aim he has been very successful. However, the book should also serve as a useful introduction for advanced and post-graduate students engaged in isolating and analyzing natural products, a line of research which unfortunately tends to be neglected in the organic chemistry departments of German universities in comparison with preparative studies.

The first part of the book includes (in Section C, pp. 9–25) a very detailed description of the "ether separation process", which is successful for the majority of analytical problems. If the sample contains substances which tend to decompose easily, it is recommended that the separation should be carried out using derivatives, or by column chromatography. Attention is also drawn to the possibilities offered by the color changes exhibited by certain substances at different pH-values, which make it easier to recognize their presence. Section D (pp. 26–40) deals with methods for purifying the crude products of separation and measuring their physical constants. It is commendable that this section even includes a detailed account of the purification of solids by crystallization. Crystallization experiments are nowadays often neglected because of the availability of chromatographic separation methods, but they are in fact indispensable for isolating new natural products. The author emphasizes that one cannot claim to have a pure substance until crystals with a well-defined melting point have been obtained. A mixture of two compounds with identical or similar R_F-values can sometimes be mistaken for a pure compound.

The second part of the book (pp. 53–104) describes the reactions that can be used to demonstrate the presence of particular functional groups. Although not all such reactions are included, the most important ones undoubtedly are, and attention is drawn to compounds which can interfere with the analysis. The author describes how the substances isolated are first assigned to particular compound classes, followed by the preparation of the derivatives that are needed to arrive at an identification. Here again, only the most important derivatives, preferably those which crystallize well, are described. The preparation of crystalline derivatives from oily or amorphous compounds is of considerable interest in natural products chemistry, since in many cases the structures of complex natural products can only be determined by X-ray crystallography. The specimen analytical reports (Section H, pp. 174–195) are probably unnecessary,

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0505-0560 $ 02.50/0

as all students should have already learned in their preparative work how to write reports. In any case, it is not possible to lay down a report structure which can be applied universally. On the other hand, a useful feature are the exercises which the student can work through to test his or her knowledge of the methods for detecting functional groups and of the most important derivatizations for particular classes of compounds. However, the learning content of the exercises could have been further increased by including references to the IR, ^{1}H NMR and ^{13}C NMR spectra of the compounds.

Despite the fact that at some universities wet analytical methods are no longer taught, due to the shortening of studies and to the introduction of essential courses on topics such as spectroscopy and separation techniques, every student should work through this book. The experimental exercises and the practical hints are extremely valuable. It is especially worth mentioning that only a very few errors could be detected. The book has the usual high standard of production of the Thieme publishing house, and its price is reasonable, even for students.

Klaus Weinges [NB 1008 IE]
Organisch-Chemisches Institut

Dictionary of Alkaloids. Edited by *I. W. Southon* and *J. Buckingham*. Chapman and Hall, London 1989. 1161 pp./index 620 pp., hardcover, £ 675.00. – ISBN 0-412-24910-3

The alkaloids, with over 300 structural types and biosynthetic branches, form a group of secondary metabolites whose variety of structures is unrivalled by any other class of substances in nature. Since in many cases they show high toxicity or have other striking physiological effects, they have long attracted the interest of chemists; their structures continue to present challenges to analytical, synthetic and biosynthetic chemists, as befits their great importance in medicine and research, as toxins, and in chemotaxonomy and the classification of plants.

As the number of known natural products has grown, the definition of the term "alkaloid" has become widened to include not only basic plant substances but also non-basic nitrogen compounds. The editors of the present book now take this a step further by including almost all naturally occurring nitrogen-containing secondary metabolites of plant, microbial and animal origin; thus the definition is no longer based on physiological effects, nor on basicity.

In view of this wide definition of alkaloids, it is understandable that the present book contains an enormous number of compounds – about 10000. Thus the extent of this compilation is greater than in any other similar work. The only nitrogen-containing natural products that are omitted or not treated in full are a few simple lower amines, the nucleobases and nucleosides, and the pterins. Besides true peptides, the amino acids are also not covered (with only a few exceptions), but the amines such as tryptamine that are derived from these by decarboxylation are included. However, the peptide alkaloids are covered thoroughly.

In contrast to other well-known compilations, the alkaloids are not arranged according to the types of organisms that produce them, nor on the basis of (bio)chemical criteria, but are instead listed in alphabetical order. In adopting this method the editors define their aim as that of collecting together accurate and critical data on *all* known alkaloids, or at least on those whose structures are known. This necessitates summarizing the information in a concise form; each entry begins with the name, giving the most usual one where several alternatives exist, followed by the systematic name. This is followed by the stereochemical formula according to the current state of knowledge (showing the absolute configuration where this is known); the stereochemical diagrams are well-drawn and essentially free from errors. However, the representation of the sempervirin structure as an N,N-zwitterion seems rather unconventional, in contrast to the more usual representation as given, for example, for the related alkaloid melinonin E. Following the molecular formula, molecular mass and origin, the entry lists the main physical properties (melting and boiling points, specific rotation, refractive index) for the parent compound, and often also for derivatives, together with information on biological activity. For some alkaloids, however, the last item could have been more complete; for example, the toxicities of the various curare alkaloids have been very precisely determined by *Wieland*, whereas this compilation only gives these data for the main alkaloids, and even here instead of LD 50 values in most cases there is only a general statement such as "highly toxic".

For the many alkaloids whose structures are still unknown, this compilation of data is especially useful, since all the information contained in the secondary literature has been extracted from the different sources, critically evaluated, and reduced to a consensus! It would, of course, have been useful to have spectroscopic data too, but this would scarcely have been practicable within the predetermined size of the book. For these the reader is referred to the HEILBRON data bank, from which the present dictionary of alkaloids, like the dictionary of antibiotics from the same publisher, is an extract in book form. This accounts for the contents of the book being very up-to-date, a fact which is especially obvious in the literature citations.

Under each entry there is a bibliography, which includes publications up to the beginning of 1988, and is indexed under various headings such as isolation, structure determination, spectroscopic data and synthesis. Another very useful item included is the Chemical Abstracts Registry Number, which facilitates making a more extensive literature search if needed.

Preceding the alphabetically listed information on individual alkaloids there is a 32-page description of the main types of alkaloids, of which there are about 35. Here nomenclature and biosynthetic relationships are discussed in a condensed but very lucid form, with many examples. A list of review literature is provided with each section.

One can well believe the claim that all alkaloids known up to the beginning of 1988 are listed: the reviewer can hardly be expected to check this, of course, and a few tests will have to suffice. In the main part of the dictionary the simplest alkaloids, such as benzylamine, are, of course, readily found, but one can also find those with highly complex structures, such as leurosin and virotoxin. However, not all of these are listed under the expected names: whereas dimethyltryptamine and bufotenin are included under these names, serotonin appears at first glance to be absent, but is then found under 5-hydroxytryptamine. The isomeric psilocin (and also psilocybin), on the other hand, appear under their systematic names. Yet other alkaloids are not listed separately, but appear under the corresponding parent compounds. As a result one finds, for example, that only the nitrogen-free compound 12-oxooctadecanoic acid appears as a structural formula, whereas the alkaloid derived from it, lycaonic acid piperidide, does not.

In these cases, therefore, one needs to use the separately bound names index, which contains all the systematic names and common trivial names that are listed in the main work. Here it is worth noting that many of the names from the older literature have been altered to conform with modern rules of nomenclature. The index volume also contains a molecular formulas index, a list of CAS Registry Numbers, and an index of compound types. In this each alkaloid is assigned to one or more of 296 groups arranged mainly according to structural types, which enables one to easily obtain a complete survey of alkaloids of a particular type, e.g. mold alkaloids, alkaloid-*N*-oxides, tropane alkaloids, or compounds related to morphine.

The species index, containing nearly 20000 references, is without doubt an especially useful feature, even though it has a few gaps—for example, under the anhalonium types the important alkaloid mescalin is not listed. Under the botanical name *Cortinarius orellanus* one finds, as expected, a reference to orellanin. However, the peptide structure for cortinarin, which although it seems unlikely has not yet been disproved, is not mentioned here—could this be a result of critical selection?

With such an all-embracing definition of alkaloids it is inevitable that the boundaries are somewhat fluid, and this unavoidably leads to some inconsistencies. For example, although indirubin is included, the better-known indigo isomer is absent; also not mentioned are indoxyl and isatin. However, one hardly expects to find these compounds in a book on alkaloids in any case; their omission is therefore a trivial matter in this extremely up-to-date survey of the literature on alkaloids, which is the most complete printed compilation available anywhere on the subject. Of course, it goes without saying that a mammoth work of this nature, which is comprehensive and up-to-date to a degree otherwise only achieved in computerized data banks, is priced accordingly. To read this book is aesthetically pleasurable, in addition to the information that it yields; it should be in every library which is concerned with natural products.

Hartmut Laatsch [NB 1004 IE]
Institut für Organische Chemie
der Universität Göttingen (FRG)

Preparative Polar Organometallic Chemistry. Vol. 1. By *L. Brandsma* and *H. D. Verkruijsse*. Springer, Berlin 1987. 240 pp., paperback, DM 78.00. – ISBN 3-540-16916-4

When one compares the increase in the library budget (at any rate, that in Marburg) with the increase in the cost of journals and books, the effect in recent years has been to cut resources, making it necessary to exercise special care over the purchase of new books. Can we or can we not afford a certain book? In this case the answer must be an unqualified "yes", if only because, pursuing this economic theme, the book by *Brandsma* and *Verkruijsse* enables one to save money. The authors have produced an extremely practical book, a "laboratory manual", as they call it, for chemistry students and for chemists in industrial and university laboratories. Nothing has been left to chance; all the laboratory recipes have been tested several times by the authors themselves, who have a great deal of experience in the field of polar organometallic compounds. Everyone who has ever worked with a recipe which is not reproducible (or which does not work at all!) will appreciate what it means to use one that has been tested and optimized.

The book deals with polar organometallic compounds (intermediates) obtained from sp^2 compounds. Chapter 1 gives an introductory general survey entitled "Organometallic Reagents, Solvents and Laboratory Equipment". This includes useful hints on the safe handling of such compounds, and also on their disposal. The following chapters are: Chapter 2 "Reactivity of Polar Organometallic Intermediates", Chapter 3 "Metallated Olefinic and Allenic Hydrocarbons", Chapter 4 "Metallation of Hetero-Substituted Unsaturated Systems", Chapter 5 "Metallated Hetero-Aromatic Compounds", and Chapter 6 "Metallated Aromatic Compounds". There is a very useful appendix consisting of tables from which the reader can find suitable methods for preparing any particular polar organometallic compound, and for reacting it with an electrophilic species. Another table lists typical reaction conditions with a wide variety of electrophiles.

In summary, anyone who wishes to save money and avoid irritation in preparing and carrying out reactions with polar organometallic compounds should buy this book by *Brandsma* and *Verkruijsse*. The money will be well spent.

Gernot Boche [NB 1010 IE]
Fachbereich Chemie

Spectrometric Titrations. Analysis of Chemical Equilibria. By *J. Polster* and *H. Lachmann*. VCH Verlagsgesellschaft, Weinheim 1989. 433 pp., hardcover, DM 196.00. – ISBN 3-527-26436-1

The meaning primarily attached to the word "titration" is the method introduced by *Gay-Lussac* for the quantitative determination of dissolved substances. The end-point of such a titration is usually determined using an indicator which undergoes a color change. However, it was soon recognized that this method can be used to investigate a wide variety of other equilibrium systems. The changes in the physical condition of the system are observed in either a stepwise or a continuous fashion by means of suitable instruments which detect changes in variables such as pH, electrical conductivity, optical density, fluorescence or optical rotation. From the resulting titration curves it is then usually possible to calculate the equilibrium constants, which play a fundamental role not only in chemistry and physics, but also in biochemistry and medicine, pharmacy and toxicology, and other areas.

Part I of this book deals with the basic theory and methodology of spectrometric titration. The topics covered are the classification of the various methods, the graphical treatment of the experimental data, multiple wavelength spectrometry, and thermodynamic and electrochemical principles.

Part II discusses in detail the formal treatment of titration systems and the calculation of results. Acid-base equilibria involving one, two, three and still more stages are considered, and methods of treating the data by iterative curve fitting and statistical analysis are described. For non-overlapping multi-stage titration systems it is necessary to add an external standard proteolyte whose pK-value is known very accurately; from the simultaneous titrations one can then determine a relative pK-value for the equilibrium being investigated. Branched acid-base equilibria, metal complex equilibria, association equilibria and redox equilibria are also considered.

 © VCH Verlagsgesellschaft mbH, D-6940 Weinheim, 1990 0570-0833/90/0505-0562 $ 02.50/0

Part III of the monograph describes the apparatus needed for spectrometric titrations and the electrochemical and spectrometric techniques involved.

The appendix contains the EDIA program which the authors recommend for use with a personal computer to evaluate relative pK-values (ΔpK), together with the TIFIT program for iterative curve fitting and statistical analysis of data.

The authors have set out to critically evaluate the published work on spectrometric titrations which is widely scattered throughout the literature, and to present this in a clear and easily assimilated form, amplified by results from their own research in this area.

Perhaps it would be possible in a subsequent edition to include more detail on methods for determining points of inflection and stationary points, and measuring the true positions of shoulders in titration curves by repeated differentiation.

The care which has gone into the preparation of the figures, which are excellent from both a visual and a didactic standpoint, deserves special mention, as also does the overall quality of production and presentation. This monograph can be warmly recommended to everyone involved in studying equilibria and seeking a review of the current state of knowledge in this area. The literature references listed at the end of each chapter provide a very useful aid to further, more detailed, reading. Although it is pleasing to note that the publishers, notwithstanding the excellent quality of printing and production, have managed to keep the price down to DM 0.45 per page, one regrets that not all the students of chemistry, physics, biochemistry etc. with an interest in the topic will be able to afford the book. However, it deserves a place in all university libraries and relevant research laboratories.

Methods for the Oxidation of Organic Compounds – Alcohols, Alcohol Derivatives, Alkyl Halides, Nitroalkanes, Alkyl Azides, Carbonyl Compounds, Hydroxyarenes and Aminoarenes. (Series: Best Synthetic Methods, Vol. 8). By *A. H. Haines*. Academic Press, London 1988. xx, 467 pp., hardcover, £ 69.50. – ISBN 0-12-315502-9

Series such as "Organic Synthesis", "Organic Reactions", or "Reagents for Organic Synthesis", or more recently computerized data banks of information on reactions, provide the synthetic chemist with information about preparative methods which he needs for solving problems of synthesis. Nevertheless, difficulties often arise from the fact that it is not always easy to find the required information on chemical reactions, or to decide on the best method of carrying out the search. The series "Best Synthetic Methods", of which the present book has been published as Volume 8, is intended for both advanced students and experienced chemists. It aims to provide them with overviews and critical evaluations, practical advice, and representative examples of important preparative methods, together with guidance on choosing the best one for the purpose. The author, who has already contributed the second volume of the series on methods for oxidation of hydrocarbons, has succeeded in meeting the aims of the series, with the result that this volume too does justice to the general title "Best Synthetic Methods".

A major reason for the success of the volume is the orderly and consistent arrangement of the material according to the degree of oxidation of the educts. Each of the seven chapters is further subdivided according to the reagents used. Since many of the methods described are not restricted to a single class of compounds, cross-references are provided to other chapters in which the same reagents are mentioned, thus providing the reader with additional guidance. The longest chapter is that on the oxidation of alcohols to carbonyl compounds and carboxylic acids, in accordance with the importance of these classes of compounds. Each of the methods described in this chapter is prefaced by a general introduction on "Scope and Limitations". Advantages and disadvantages compared with other reagents are pointed out, and the numerous variants of one basic method which exist in many cases are compared. Discussions of reaction mechanisms, including questions of reactivity, selectivity and stereochemistry provide the reader with additional information to help in deciding whether a method is suitable in a particular case.

Each sub-section contains examples of detailed preparative recipes in which the theory is applied to optimizing the practical results. Most of these are carefully worked out methods which have proved themselves in the exacting area of natural products syntheses.

The clarity and thoroughness of the experimental details contribute to the relative ease with which even those with limited experience can repeat the preparations. Each sub-section is completed by a comprehensive list of references which includes both review articles and important original papers. However, the policy of describing only fully proven methods reduces the topicality of the coverage. The later chapters of the book deal with oxidation reactions which are of less importance from the organic chemistry standpoint. However, the author's balanced and careful treatment of this material succeeds in also providing the user of the book with a useful account of these classes of compounds and the methods of oxidizing them.

Tables at the end of the book provide a summary of all the topics covered. These list in a clear form the educts, reaction conditions, products, yields and key literature references, enabling the reader to quickly see the main features at a glance.

Colloid Chemistry of Polymers. By *Y. S. Lipatov*. Elsevier, Amsterdam 1988. ix, 460 pp., hard cover, $ 155.25.— ISBN 0-444-43006-7

This book by *Y. S. Lipatov* is the seventh volume in an ongoing series with the title "Polymer Science Library", which is published by Elsevier with *A. D. Jenkins* as consulting editor. The main topics of this volume are the microheterogeneity of polymer melts, the morphology of phase-separated systems, the colloidal aspects of polymeric systems, and the importance of interfacial properties in such systems. The main emphasis is on the thermodynamic treatment of the colloid chemistry of polymer systems.

The volume consists of 13 chapters, the first of which is a general introduction to colloid chemistry, especially as applied to dispersed colloidal polymer systems; the aims and methods of investigations of such systems are also described. Chapter 2 is concerned with the microheterogeneous structure of polymeric one- and multicomponent systems, with

the main emphasis on amorphous polymers. Chapter 3 discusses the formation of structures in dispersed polymer systems, including the thermodynamics of phase formation, the theory of spinodal breakdown of dispersed systems, phase separation, and dissipative processes resulting from microheterogeneity in polymeric systems. Chapter 4 deals with the interfacial potential in dispersed systems, including polymer solutions and melts as well as solid polymers. Chapter 5 continues this theme by treating surface active phenomena in polymers and the effects of surface active agents on the properties of polymer solutions; special attention is given to the use of surface active agents for modifying the mechanical properties of polymers. Chapter 6 is devoted to the adsorption of polymers on solid surfaces. Topics dealt with under this heading include the thermodynamic and kinetic principles of the adsorption of polymers from dilute solutions, the role of adsorbed layers in stabilizing dispersed systems, and the adsorption of polymer blends. Chapter 7 describes the theory of polymer adhesion and the thermodynamic aspects; adhesives and their mode of action are also discussed. The structure and properties of polymer boundary layers at surfaces and interfaces are described in Chapter 8; the main aspects discussed are boundary layers of polymers on solid surfaces and in polymer mixtures, structural changes in the neighborhood of interfaces in such mixtures, microheterogeneities in boundary layers, and polymer monolayers. Chapter 9 deals with filled polymers, more particularly with structures formed in the presence of dispersed fillers, the mechanical and rheological properties of filled polymers, the effect of the filler on the properties of the interface, and the use of colloidal metals as fillers. Chapter 10 discusses polymer mixtures, especially the theory of the miscibility and compatibility of different polymers, and experimental methods for measuring compatibility. This chapter also deals with typical features found in the phase diagrams of binary polymer mixtures and in the rheological behavior of polymer mixtures. Polymer-polymer systems, the thermodynamics of their formation and their colloidal and chemical structures are described in Chapter 11. Chapter 12 is devoted to gel formation in polymer solutions and to polymeric gels; aspects treated are the classification of gels, the conditions for and mechanism of gel formation, and the structure and properties of gels. Lastly Chapter 13 deals with emulsions, dispersions and foams containing polymers; topics treated are polymerization in emulsions, suspensions and dispersions, polycondensation in emulsions and at interfaces, and the properties of polymer dispersions and foams.

In all these topics the book treats the most important thermodynamic principles involved. A comprehensive bibliography is appended at the end of each chapter. A disadvantage of the book is that in translating the original 1984 Russion edition into English no more recent work has been included, and the bibliography is therefore no longer completely up-to-date. Work by Russian scientists is, as expected, especially well represented in the literature references, but there is nevertheless adequate citation of papers from the West. Regrettably, experimental results have only rarely been included as a way of elucidating results derived from theory. Despite this, the book provides many stimulating ideas, and it gives a reasonably comprehensive treatment of the field of polymer colloid science. The presentation is clear and readily comprehensible, and is supported by numerous figures and examples.

However, a real disadvantage of the book is the quality of production; it has evidently been made by direct photographic reproduction from a typescript. The Greek characters in the equations and diagram and other embellishments have been inserted by hand. Considering the high price of the book, the text certainly ought to have been properly processed and typeset.

Apart from this lack of visual appeal, the book is of a high scientific quality. The subject matter is equally suitable for chemists, physicists and engineers; however, the clarity of presentation should also enable an interested non-specialist to learn about the latest methods and developments in the colloid chemistry of polymers. For these reasons the book can be recommended.

New Aspects of the Maillard Reaction in Foods and in the Human Body

By Franz Ledl* and Erwin Schleicher*

Translated by Harry E. Nursten

Dedicated to Professor Otto H. Wieland on the occasion of his 70th birthday and to Professor Theodor Severin on the occasion of his 60th birthday

The reactions that occur during the cooking, baking, and preservation of foods of all kinds are of great importance for the production of aroma, taste, and color. However, more recently it has been shown that these reactions may be accompanied by a reduction in nutritive value and the formation of toxic compounds. For these reasons, the very complex reactions between reducing sugars and the free amino groups of amino acids or proteins, known as non-enzymatic browning or the Maillard reaction, have again caught the interest of chemists. The Maillard reaction came to be seen in a new light as it was realized that it actually occurred in the human body. As a general rule, the longer the half-life of a protein, the larger the amount of its Maillard products found, i.e., important factors are the 'age' or persistence of the protein in the body and the glucose concentration, particularly in diabetics. Many of the symptoms developed by diabetics resemble those of premature aging, which leads to the possibility that glucose, because of its reactivity towards proteins, is fundamentally involved in the normally slow progress of aging.

1. Introduction

The first substantial investigation of the reaction of reducing sugars with amino acids was carried out about 75 years ago by *Maillard*.[1] Subsequently, *Amadori*[2] reported the formation of two reaction products, which he described as the stable and the unstable isomer. *Kuhn* and *Weygand* showed later that a glycosylamine (the labile isomer) is formed first and that it then rearranges to the aminoketose (the stable isomer).[3] The elucidation of the mechanism of the reaction intrigued *Simon* and *Kraus*.[4] *Heyns* et al.[5] reported on the corresponding reactions of ketoses with amino acids that result in the formation of aminoaldoses. Further contributions to an understanding of the 'early' stage of the Maillard reaction, both with regard to the reactions occurring and to their products, came amongst others from the schools of *Hodge, Anet, Heyns, Micheel,* and *Kato*.[6] In the following sections, the significance of the Maillard reaction for foods and for the human organism will be outlined on the basis of the more recently achieved results.[7]

2. Reaction Paths

2.1. Preamble

The Maillard reaction, or non-enzymatic browning, embraces not only one reaction but a whole network of different reactions. Accordingly, when sugars react with amines, one obtains an extraordinarily complex mixture of compounds, which are present in very different amounts. Besides substances which may be formed in relatively high yields (up to 30%) under certain conditions, other compounds are formed whose concentrations lie in the ppb range or even lower. Contrary to preparative chemistry, here the significance of a reaction and of a product is determined not so much by the yield but by its effect (e.g., aroma, taste). A few μg of a product may well be sufficient to characterize the aroma of a heated food. The product pattern is subject to large variations, depending on the reaction conditions. In particular, the reaction time, the temperature, the concentrations of the reactants, and the pH play a decisive role. These factors are responsible for the differences in aroma, taste, and appearance of boiled meat and roasted meat.

Although more than 75 years have passed since the first research on the Maillard reaction and although many results have been gathered in the meantime, it is still not possible to present a complete reaction scheme. To date, only a few of the reaction products have been isolated and identified. The products that have been characterized are preponderantly those that are stable and have not undergone further change to any large extent either in the reaction mixture or during isolation or purification. Such compounds can serve as indicator substances for certain reaction paths in the Maillard reaction. Difficulties are encountered in the isolation of reactive intermediates, since they are present only in very low concentrations in the reaction mixture and they usually react further during isolation. Yet it is precisely these compounds that are of the greatest significance for the Maillard reaction, since they play an important role in the formation of browning products, aroma compounds, high molecular weight substances, and so on.

In the following, an attempt will be made to describe the reaction sequence of the Maillard reaction without going into details that can often be unnecessarily confusing. Consequently the results of some studies are not or only partly taken into account, without any intention of detracting from their importance.

2.2. Initial Reactants

In foods, it is essentially the monosaccharides, glucose and fructose, and the disaccharides, maltose and lactose, as well as in some cases (e.g., meat) reducing pentoses, that react with amino acids and/or proteins. Sugar linked glycosidically in glycoproteins, glycolipids, flavonoid compounds, or in disaccharides, such as sucrose, participate in the Maillard reaction only after cleavage of the glycosidic bond. Hexuronic acids, insofar as they occur in the free form at all, behave like pentoses, i.e., in the course of the Maillard reaction decarboxylation takes place. In certain cases (e.g., cheese), biogenic amines can react as the amino component. Ammonia constitutes a special case; it can be formed in small amounts from amino acids during the Maillard reaction (cf. Section 2.7.1) and it is used in large amounts in the production of one type of caramel coloring.

In the human body, the reaction between glucose and the free amino groups of proteins as the amino component has been the primary subject of investigation. More recent results have indicated that fructose and pentoses also play a role as sugar components (cf. Sections 4.2 and 4.5). In general, for the Maillard reaction, primary amines are more im-

Franz Ledl was born in Starnberg, Germany in 1946. He studied food chemistry at the University of Munich where he received his Dr. rer. nat in 1973 under the supervision of Th. Severin and habilitated in 1987. At present he is Professor of Food Chemistry and Analytical Chemistry at Stuttgart University. His research interests include several areas of the Maillard reaction in foods and in vivo.

Erwin Schleicher was born in Bamberg in 1946. He studied chemistry in Munich at the Technical University from 1968–1972. After graduation he remained in Munich studying under the supervision of H. Simon and receiving his doctorate in 1974. He spent the following years (1975–1976) carrying out postdoctoral research with H. G. Floss at Purdue University (Indiana, USA). After returning to Munich he investigated the mechanism of redox enzymes. Since 1977 he has been working as a clinical chemist at the institutes for clinical chemistry and diabetes research group at the academic hospital Munich-Schwabing with O. H. Wieland. In 1986 he habilitated at TU Munich. His interests revolve around the theme of structural-functional relationship of glycoproteins, especially extracellular proteins, and the mechanism of signal transmission through cell membranes.

portant than secondary amines. Thus, in proteins, it is the primary amino groups of the lysine side-chains that react predominantly and, insofar as they occur in foods in the free form, primary amino acids take precedence. However, in cereals and in cereal products (malt, beer), considerable amounts of the secondary amino acid proline occur; since cereals are staple items of the diet, attention will also be paid to the behavior of secondary amines in the Maillard reaction.

2.3. Model Reactions

Investigations of the Maillard reaction in foods and also in vivo have been carried out predominantly with the help of model systems. The main reason for this is to be sought in the wide range of reactants and other substances present in even the simplest of natural systems. Not only do they make the situation that much more complex, but they make the separation, isolation, and purification of Maillard products extremely difficult. Fortunately, it has become evident that the relationships and conditions in foods and in the human organism can be simulated with model systems and that the results obtained can be extrapolated. The knowledge presented in Sections 2.4 to 2.8 on the reaction pathways has been largely obtained from such model systems.

2.3.1. Types of Model Systems

In general, in order to simulate conditions in foods and in vivo, aqueous solutions of the sugar and the amino component have been investigated. To study the processes occurring during roasting, fusion of the reactants has been found appropriate. Bearing in mind that the sugars and also the amines occur in foods in widely different amounts, the number of possible model systems is clearly vast. Yet care must be taken, since several preparative operations involve concentration and it is known that, for example, in drying foods, a range of concentrations has to be traversed that is optimal for the Maillard reaction to occur.

Of central significance for product formation are time and temperature (increases of up to sixfold have been recorded). As a rule of thumb, the rate at least doubles when the temperature is increased by 10 °C. If browning is used to measure the progress of the Maillard reaction, then four weeks at 20 °C, three hours at 100 °C, or five minutes at 150 °C give approximately the same result.

In the main, model systems are buffered to a pH between 4 and 7.5.

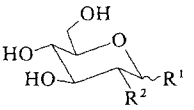
To simulate the conditions in the human or other animal organism, the sugar component, glucose, is incubated with the amine component, e.g., protein, 140 mM sodium chloride, and 5 mM potassium chloride at pH 7.4 and 37 °C (physiological conditions) and the mixture is subsequently analyzed. The progress of the Maillard reaction occurring on proteins under such conditions can be followed fluorometrically.

2.3.2. Studies on Model Systems

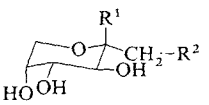
For the analysis, the aqueous reaction solution or the reaction melt dissolved in water is repeatedly extracted with an organic solvent. The non-polar products that are extracted into the organic phase can be analyzed gas chromatographically, provided they are sufficiently volatile, and characterized mass spectrometrically. In recent years, this has been the method by which most Maillard products have been identified. After derivatization (silylation, acylation), some of the polar products can also be identified gas chromatographically. The remaining mixture, however, presents great difficulties for the analyst, yet it constitutes the major part of the reaction products. By conventional chromatographic methods (exclusion, ion exchange, adsorption, partition), fractions are first obtained, which may yield pure substances, but usually only after several separation steps. High-performance liquid chromatography (HPLC) has provided reproducible fractionation and has facilitated the recognition of substances and of class of substance through the use of different types of detector (UV, fluorescence, electrochemical, etc.). To answer more detailed questions regarding a particular reaction mechanism or the elucidation of a new reaction path, starting substances labeled with radioactive and/or stable isotopes have been used. In the following sections, the analyses of some Maillard products are detailed and examples are given of derivatization and trapping reagents. Some problems in the investigation of protein-sugar reaction mixtures are outlined in Section 4.3.

2.4. Initial Phase

The schemes shown are based on glucose as example for the degradation of hexoses; deviations exhibited by pentoses or disaccharides will be indicated. For simplification, open-chain structures will mostly be used. In fact, the sugars and many of their products exist mainly in their cyclic half-acetal form. To start with, the structures of some reactants and primary products are illustrated (Scheme 1).



$R^1 = R^2 = OH$: D-Glucose
$R^1 = NHR$, $R^2 = OH$: D-Glucosylamine **1** (always in β-form)
$R^1 = OH$, $R^2 = NHR$: 2-Amino-2-deoxy-D-glucose **2** (Heyns-product)



$R^1 = R^2 = OH$: β-D-Fructopyranose (also α-form and furanose)
$R^1 = NHR$, $R^2 = OH$: β-D-Fructosylamine (not isolable with aliphatic amines)
$R^1 = OH$, $R^2 = NHR$: 1-Amino-1-deoxy-β-D-fructose **3** (Amadori product; also α-form and furanose)

Scheme 1.

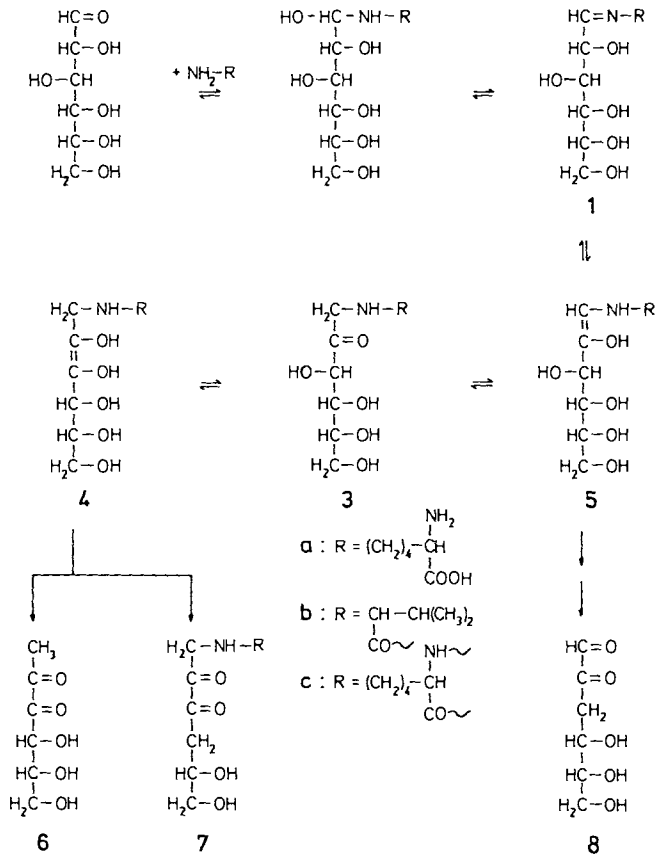
2.4.1. Amines Reacting as Nucleophiles

The reaction of amines as nucleophiles leads, after addition to the carbonyl group of the sugar, to the formation of

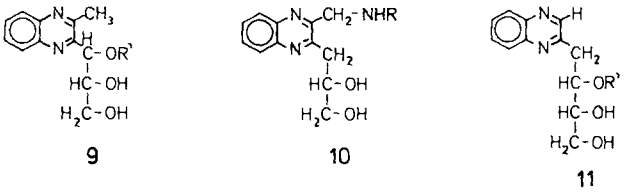
glycosylamines. Relatively stable glycosylamines of type **1** are obtained from aromatic and heterocyclic amines, e.g., purines. A biologically very widely occurring substance of this kind of structure is adenosine triphosphate. Glycosylamines of amino acids or aliphatic amines are usually only detectable in very small amounts in sugar-amine reaction mixtures. They quickly undergo further reactions and rearrange via the aminoenol **5** into the aminoketose **3** and other products.

Aminoketoses (or Amadori compounds) have been shown to be present, alongside other products, in heated and in stored foods,[8] in dried fruit, in vegetable and milk products,[9] as well as in soy sauce.[10] They also occur in infusion solutions containing glucose and amino acids, intended for parenteral nutrition (whether heat sterilized or mixed under sterile conditions).[11] They are also present in the human body, in higher amounts in diabetics (cf. Section 4.4). The biosynthesis of histidine proceeds via an aminoketose, which is formed by rearrangement of an imine.

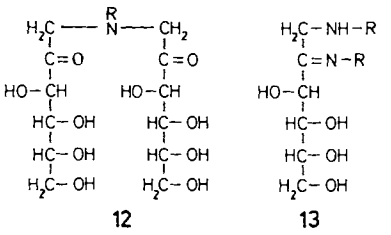
Deoxydiketoses and deoxyaldoketoses are formed as degradation products of the aminoketoses in the pH range 4–7. 1-Deoxy-2,3-hexodiulose **6**, 1-amino-1,4-dideoxy-2,3-hexodiulose **7**, and 3-deoxy-2-hexosulose **8** are formed via the



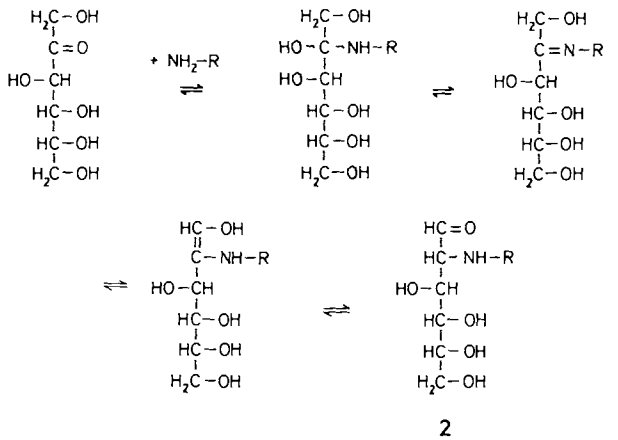
enediol **4** or the aminoenol **5**. To demonstrate the conversion of **3** into these products, trapping with *o*-phenylenediamine is useful, the corresponding quinoxalines **9**, **10**, and **11** being formed.[12] (The Group R′ in the formulas for the quinoxalines **9** and **11** is intended to indicate that, when Amadori compounds derived from disaccharides react further, the glycosidic bond in the corresponding deoxyosones is not severed and therefore the quinoxalines bear an α-glucosyl or β-galactosyl residue, depending on whether they are derived from maltose or lactose.)



Besides the aminoketoses **3**, compounds of the type **12**[13] and **13**[14] are also obtained. The latter type of compound is also known as an intermediate in the formation of osazones.



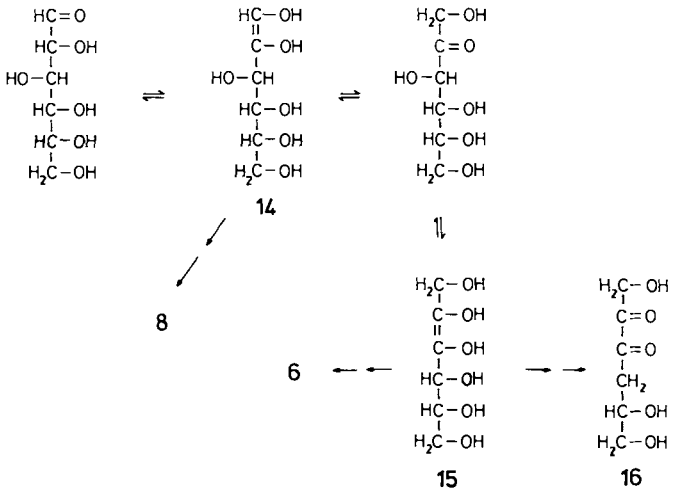
Ketoses react with amines via imines as intermediates to form aminoaldoses such as **2**, the so-called Heyns compounds.[15] In Nature, part of the biosynthesis of *N*-acetylglucosamine and *N*-acetylgalactosamine follows the same principle: fructose reacts with ammonia and rearranges to the activated glucosamine or galactosamine via the Schiff's base. Compounds of type **2** are not very stable; they readily



react further, forming products such as the Amadori compounds.[16] Recent work suggests that aminoaldoses are also formed in the human body. One can assume that Amadori and Heyns compounds decompose in a parallel manner. In presence of *o*-phenylenediamine, aminoaldoses yield predominantly the quinoxaline **11** via **8** as intermediate.[17] In view of the in vivo formation of Heyns compounds, further studies of their properties are called for (cf. Section 4.2).

2.4.2. *Amines as Bases or Acids*

As bases or acids (depending on the prevailing pH), the amines act as catalysts, for example, for the migration of the carbonyl group of the sugar, i.e., aldoses are converted into ketoses (fructose) and vice versa or an imine becomes an aminoketose or aminoaldose (cf. Section 2.4.1) (corresponding to the Lobry de Bruyn-Alberda van Ekenstein rearrangement). Through loss of water, the enediols **14** and **15** give the 3-deoxy-2-hexosulose **8**, and the 1-deoxy-2,3-hexodiulose **6** and the 4-deoxy-2,3-hexodiulose **16**, respectively. On heating



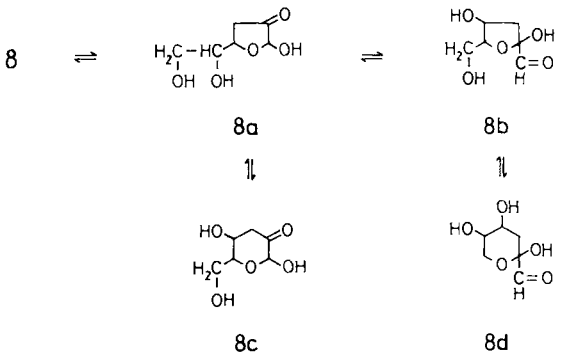
the sugar in the absence of amines, these reactions occur at pH values below 3[18] or above 8[19] or on caramelization, i.e., at temperatures above 130 °C. Thus, the significance of amines in the formation of the deoxyosones **6**–**8** and **16** lies in their ability to catalyze these sugar rearrangements under pH conditions normally encountered in foods and living organisms (pH 4–7).

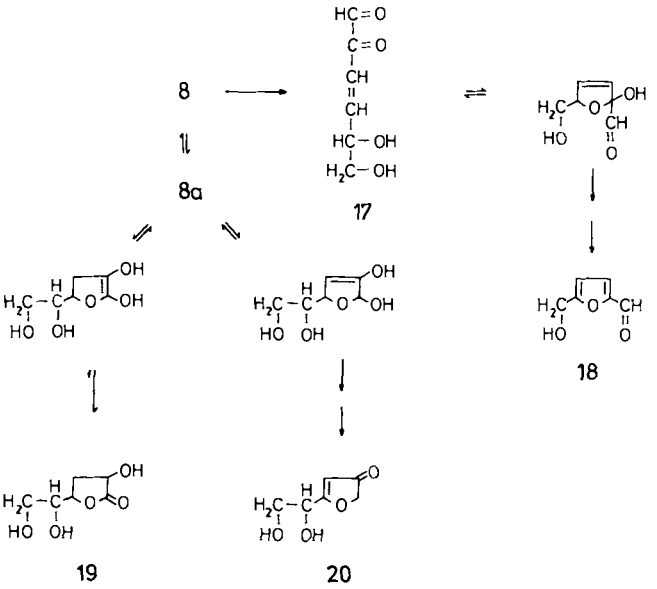
2.5. Deoxyaldoketoses and Deoxydiketoses

As far as is known at present, many important reactions of sugars during the Maillard reaction take place via deoxyaldoketoses or deoxydiketoses. These compounds can be described as intramolecular disproportionation products of sugars which undergo further reactions markedly more rapidly than the original reactants; enolization, cyclization, and loss of water thereby play major roles. The presence of amines leads in addition to the formation of nitrogen-containing compounds. Products that are formed by cleavage of the original sugar's carbon chain will be considered in a separate section.

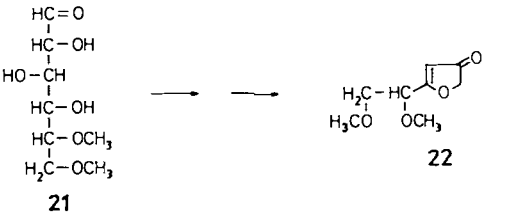
2.5.1. *Reactions of 3-Deoxyaldoketoses*

3-Deoxyhexosuloses were first shown to be present amongst the reaction products of sugars and amines about 30 years ago.[20] In solution, one would expect an equilibrium between the cyclic forms **8a** to **8d**. The best known product derived from these compounds is 5-hydroxymethyl-2-furfural **18**.[21] In the presence of amines, the formation of **18** may be limited in favor of nitrogen-containing compounds. The formation of metasaccharinic acid lactone **19** is noteworthy. Under alkaline conditions, the formation of metasaccharinic acid from **8** takes place by hydride migration.[19] In the Maillard reaction at pH 4–7, it is likely that the lactone **19** is formed from the cyclic precursor **8a** through isomerization of the keto group.[23] Formation of the furanone **20** from **8a** is conceivable after enolization involving C3, followed by elimination of the hydroxy group from the

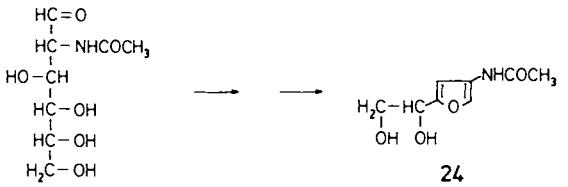




half-acetal function, but this has not yet been demonstrated. It is known that 5,6-dimethoxyglucose **21** rearranges into the corresponding compound **22**.[24] The structurally equivalent aminofuran **24** is obtained as the main product when

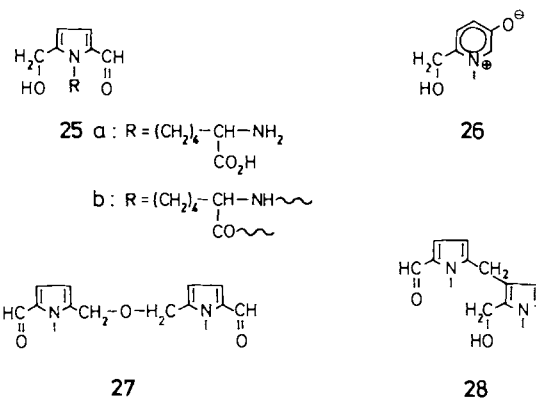


N-acetylglucosamine **23** is heated in the presence of amines. Compound **24** has been known for some time and serves as indicator for *N*-acetylglucosamine or *N*-acetylgalactosamine.[25] In Nature, these aminosugars occur almost exclusively bound glycosidically to protein and so are not available as reactants for the Maillard reaction.



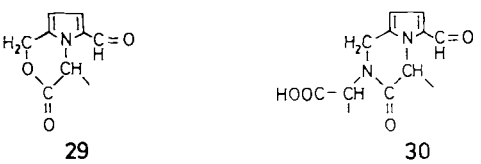
23 **24**

In the Maillard reaction of the deoxyhexosuloses **8** in the presence of larger amounts of primary amines, the formation of hydroxymethylfurfural **18** can be largely suppressed. In its place, are found pyrrolealdehydes of structure **25**,[26] as well as pyridiniumbetaines of type **26**.[27] The fact, that **25** and **26** are obtained only in very poor yield from hydroxymethylfurfural and amines, indicates that the incorporation of amine takes place in a precursor of **18**. Further nitrogen-containing products from compound **8** are the bispyrroles **27** and **28**.[28] The structures allow one to assume a dimerization of the



25 a: R = $(CH_2)_4$–CH(CO$_2$H)–NH$_2$; b: R = $(CH_2)_4$–CH(CO~)–NH~ **26** **27** **28**

pyrrolealdehyde **25**, whose hydroxymethyl OH group is subject to ready nucleophilic substitution (cf. Section 4.5). In the presence of amino acids, additional compounds are found: lactones of the type **29**[29] and lactams of structure **30**.[22] For the formation of these bicyclic compounds, the hydroxy

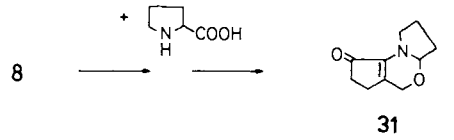


29 **30**

group of the pyrrolealdehyde **25** is again replaced by other nucleophiles. In proteins, nitrogen-containing products are mainly linked to the peptide chain through the ε-amino groups of lysine. To detect pyrrolealdehyde **25b**, an enzyme-linked immuno sorbent assay (ELISA) has been developed.[30] Lysylpyrrolealdehyde **25a** can be determined by reverse-phase HPLC after alkaline or enzymatic hydrolysis.[31]

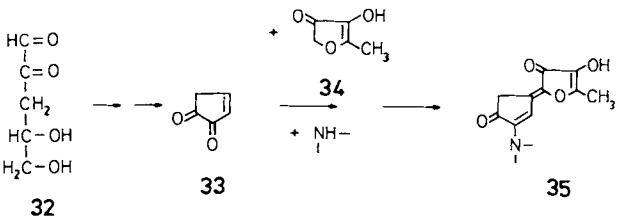
The monosaccharide derivatives **25** and **26** are also obtained by reaction of maltose and lactose with primary amines. This can be understood as a consequence of **17** being an intermediate; for its formation, loss of the oxygen atom attached to C4 is required, regardless of whether a glucosyl or galactosyl residue is attached to it, as in maltose and lactose, respectively. Pentoses also react via the 3-deoxyaldoketoses to give the corresponding pyrroles **25**[32] and pyridiniumbetaines **26**[27] (here, the hydroxymethyl group in structures **25** and **26** needs to be replaced by hydrogen).

When reducing sugars react with secondary amines, hydroxymethylfurfural **18** is usually not formed or, if so, only in small amounts. When the secondary amino acid proline is heated with compound **8**, the so-called maltoxazine **31** can



8 **31**

be isolated as the main product. Maltoxazine is a volatile component of malt and of beer and its formation will be discussed in Section 2.8.2.[33] The reaction of secondary amines and pentoses leads to the formation of the orange-colored condensation product **35**, which can be extracted with organic solvents as the main colored compound.[34] The formation of the hydroxyfuranone **34** will be considered later. Compound **35** is obtained in presence of **34** and secondary amines from the 3-deoxy-2-pentosulose **32** in good yields and from the cyclopentenedione **33** in very good yields. Compounds **31** and **35** are examples of carbocyclic

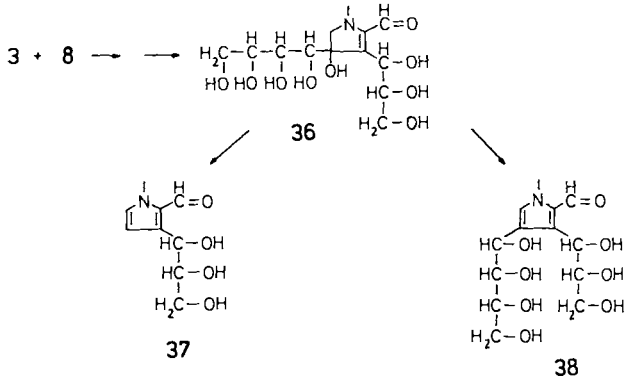


32 **33** **34** **35**

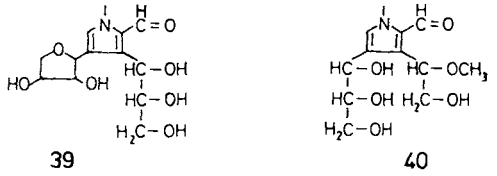
products obtained from 3-deoxyaldoketoses with secondary amines. They illustrate a general principle, found repeatedly; namely, that sugars in the presence of secondary amines are transformed into carbocyclic compounds, sometimes in substantial amounts.

3-Deoxyaldoketoses participate in the formation of yet other pyrrolealdehydes. Thus, the compounds **37** and **38** are formed upon reaction of **8** with the aminoketose **3**. In both cases, **36** functions as intermediate. The electron-attraction by the formyl group in the intermediate **36** leads to retroaldol cleavage and thus to formation of compound **37**.[35] In a competing reaction, the enamine function induces forma-

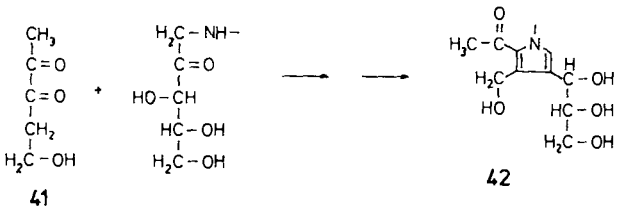
tion of the pyrrole **38**.[36] The formulas refer to products from hexoses, but the condensation proceeds analogously for pentoses.[37] As in the pyrrolealdehydes of type **25**, the hydroxy groups in the neighborhood of the pyrrole ring in **37** and **38** are readily substituted. Examples of this are the in-



tramolecular ether formation in **39** and the partial replacement of the hydroxy group by a methoxy group during chromatographic purification (methanol/ethyl acetate as eluent) of such compounds, leading to formation of, e.g., **40**.[37b]

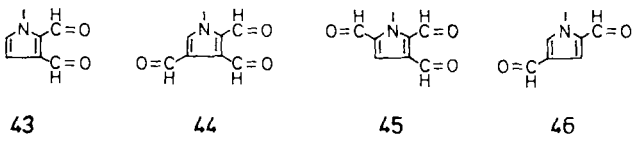


In addition to 3-deoxyaldoketoses, other α-dicarbonyl compounds can also interact with aminoketoses. Thus, the structure of the pyrrole **42** implies that 1,4-dideoxydiketose **41** participates in its formation[37b] (cf. Section 3.4). Further evidence of similar condensation reactions comes from the



structures of the pyrrolealdehydes, which are obtained from the polar fractions from reaction mixtures of glucose and pentoses with alkylamines after addition of sodium periodate. Apart from the pyrroledialdehydes and pyrroletrialdehydes **43** and **44**, their isomers **45** and **46**, respectively, are also obtained, amongst other products, from **37** and **38**.[37b,c]

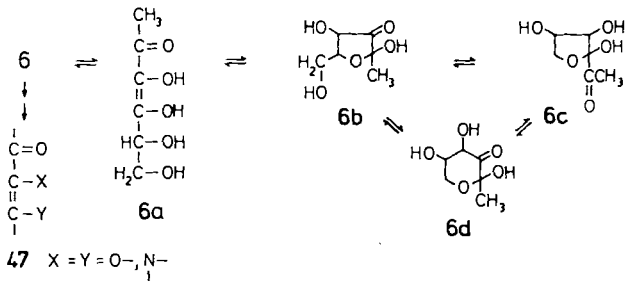
The isolation and identification of the pyrroles **37**, **38**, and **42** proves that the aminoketoses are sufficiently reactive to undergo condensation reactions. Evidence for the participa-



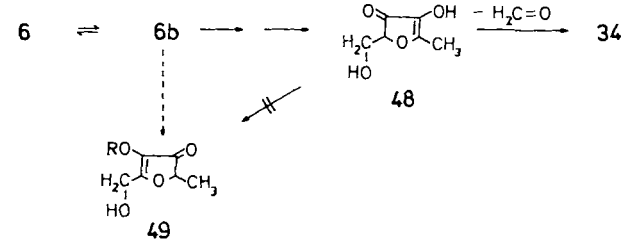
tion of other primary products of the Maillard reaction, such as the aminoaldoses, is provided by the structure of the pyrrolealdehydes obtained on periodate oxidation. This is of particular interest in relation to the Maillard reaction in vivo, since here reactions following formation of pyrroles, such as substitution of the α-hydroxy group, can lead to cross-linking and other changes in protein structure (cf. Sections 4.5 and 5).

2.5.2. Degradation of 1-Deoxydiketoses

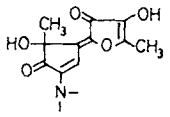
1-Deoxydiketoses were shown only recently to be secondary products of aminoketoses.[12a,b] They are converted into compounds with the general reductone structure **47** (cf. Section 3.4). At present, nothing is known about whether the open-chain reductone **6a** is present in the reaction mixture. One would expect an equilibrium mixture between the cyclic forms **6b** to **6d** in solution.



Enolization and loss of water from the hemiketal form **6b** of the 1-deoxydiketose leads to the furanone **48**,[38] which can be detected gas chromatographically after derivatization (e.g., silylation). It is worth noting that furanone **48** isomerizes to compound **49** (R = H) only to an insignificant extent



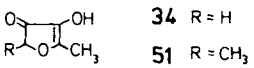
under the conditions of the Maillard reaction. Instead, formaldehyde is split off with formation of the pentose derivative **34** in considerable amounts. In this connection, the structure of the colored main product **50** from the reaction mixtures of hexoses and secondary amines is of interest, since it contains



50

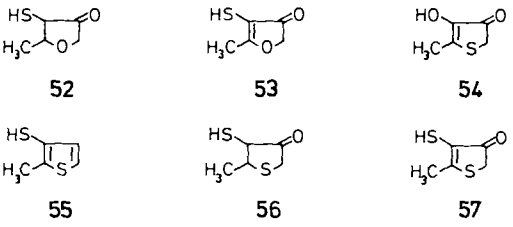
the furanone **34** as a building block (cf. Section 3.3).[34] Furanone **48** can only be formed from disaccharides if the glycosidic bond is broken. If one assumes that the glycosidic bond is still present in the intermediate **6b**, then the glycosylfuranones **49** (R = α-glu, β-gal) should be formed. Evidence for such compounds is, however, still lacking.

From pentoses and 6-deoxyhexoses, such as rhamnose, the corresponding furanones **34**[39] and **51**[40] are formed via



34 R = H
51 R = CH_3

the 1-deoxydiketoses. Compound **34** plays a crucial role in the browning of pentoses (see Section 3.3). In the presence of sulfur-containing compounds (e.g., cysteine), from which hydrogen sulfide is liberated on heating, **34** also exerts a considerable effect on aroma production. Substances are formed that possess interesting aroma notes (mainly resembling heated meat;[41] compounds **52** to **57** are given as exam-

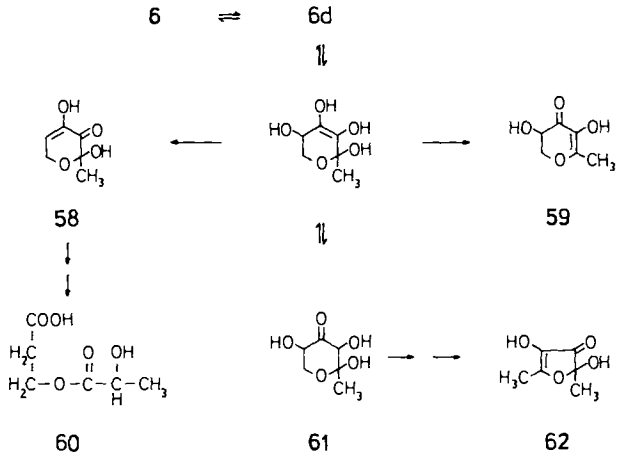


52 **53** **54**

55 **56** **57**

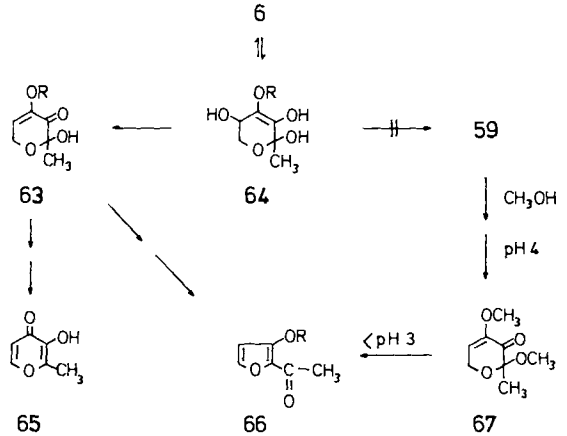
ples). The corresponding S-containing products with an additional methyl group are obtained from furanone **51** on heating with hydrogen sulfide. Compound **51** has a very low odor threshold and an aroma note (fruity-roast-caramel-like) that is perceived as pleasant. It is now manufactured on a relatively large scale and is added to many products.[42] It is interesting that **51** is formed also in plants.[43]

Further products are obtained from 1-deoxydiketoses via the cyclic hemiacetal form **6d**. The pyranone **59** is formed by enolization and loss of the hydroxy group from C2.[44] This compound can be used as the universal indicator substance for the occurrence of the Maillard reaction, since hexoses occur in virtually all foodstuffs. Compound **59** is formed in ppm amounts upon heating foodstuffs and is readily detectable by gas chromatography after extraction with an organic solvent.[45] If the hemiacetal **6d** loses the hydroxy group from C5, the unstable β-pyranone **58** is formed, and this rearranges in part into the lactic acid ester **60**[23] (cf. Section 2.6.1). Tautomerization of **6d** leads to a β-diketone, which is shown in its cyclic hemiacetal form **61**. This compound has not yet been shown to be an intermediate, but one can assume that it would readily undergo β-diketo scission, producing, for example, C_4-aminoreductones[46] (cf. Section 2.6.1). Acetylformoin **62**, which is formed from ketone **61** by elimination of the β-hydroxy group attached to C6 of the original sugar,[26,40] readily undergoes further reactions and is therefore only found, if at all, in low concentration in model systems or foodstuffs.



58 **59** **60** **61** **62**

The reactions of 1-deoxydiketones derived from disaccharides differ in some respects from those of monosaccharide derivatives. This is understandable, if one starts with the cyclic form **64**. After enolization without splitting the glycosidic bond, only elimination of the hydroxy group on C5 is possible, with formation of the β-pyranone **63**. The γ-pyranone **59** is therefore a product typical of monosaccharides, which can only be formed via a free hydroxy group at C4. The presence of small amounts of pyranone **59** among disaccharide reaction products can be explained by some degree of hydrolysis of the glycosidic link during the Maillard reaction (cf. Section 2.5.1), the monosaccharide formed giving rise to **59**. The β-pyranone **63**, which has so far been found in heated milk (R = β-gal)[47] and in steamed ginseng root (red ginseng, R = α-glu),[48] is a key intermediate in disaccharide degradation. Its fate depends on the nature of the glycosidically bound sugar. A β-galactosyl residue allows formation both of five- and of six-membered rings. β-Galactosylisomaltol **66** (R = β-gal), a Maillard product characteristic for lactose,[49] is formed preponderantly. The corre-



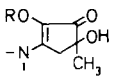
63 **64** **59** **65** **66** **67**

sponding reaction sequence can be observed with monosaccharides, when they are heated in alcoholic solution (in methanol in the scheme). The γ-pyranone **59** is converted at pH 4 into the β-pyranone **67**, which, on further lowering of the pH to split the ketal, rearranges into the isomaltol methyl ether **66** (R = methyl).[47] If these reactions are carried out in aqueous solution, isomaltol **66** (R = H) is formed only in insignificant amounts,[50] even though it corresponds to the above methyl ether. Maltose leads to a higher proportion of maltol **65**,[51] α-glucosylisomaltol **66** (R = α-glu) being formed only in trace amounts.[52] It follows that α-glucosyl-β-pyranone **63** (R = α-glu) must be subject to splitting of its glycosidic bond to a considerable extent. This can be attributed to the greater steric hindrance to flexibility of the ring of the maltose intermediate, which is not relieved by ring-contraction and formation of **66** (R = α-glu).

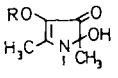
As already indicated, compound **62** is very reactive. The so-called aminohexosereductones **68a** are considerably more stable. They are formed from **62** in presence of secondary amines.[53] Under optimal conditions, aminohexosereductones can be obtained in yields of 30%, based on the amount of sugar employed. Indirectly, this shows the importance of **62** as an intermediate in the Maillard reaction.

The pyrrolinones **69a** have been found in reactions between hexoses and primary amines. These compounds, which can be obtained from **62** in very good yields,[54] fluoresce strongly and, like the aminohexosereductones, possess antioxidant properties (cf. Section 3.4).

Reactions of disaccharides with primary or secondary amines also lead to aminoreductones. The galactosyl and glucosyl residues remain glycosidically linked in compounds **68b** and **69b**, respectively, and the basic pyrrolinone and cyclopentenone systems are identical with those of the monosaccharide products.[55]

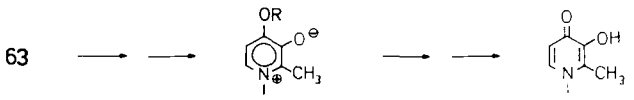


68 a : R = H
68 b : R = α-Glu,β-Gal



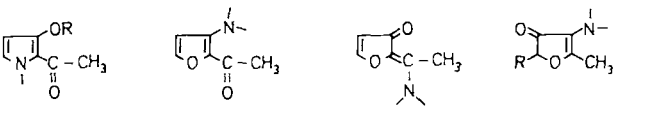
69 a : R = H
69 b : R = α-Glu, β-Gal

The main product, extractable with organic solvents from reaction mixtures of disaccharides and primary aliphatic amines, is the pyridone **71**.[56] Most likely **63** is first converted into the pyridiniumbetaines **70** (R = α-glu, β-gal), which



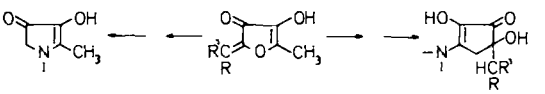
63 **70** **71**

have recently been isolated in crystalline form from mixtures of disaccharides and primary amines.[57] Pyridiniumbetaines are predominantly converted into the pyridones **71** on cleavage of the glycosidic bond. Pyridones with this type of structure are known to bind metals such as iron[58] and aluminum tightly;[59] a study of their effect on the absorption and elimination of trace elements is currently being carried out. The pyrrole derivative **72**, corresponding to galactosylisomaltol **66** (R = β-gal), has been isolated as a byproduct from reactions involving lactose.[47] Upon heating **66** together with primary and secondary amines one obtains, inter alia, the furan derivatives **73** and **74**.[60] Compounds **75**[61] and **76**



72 **73** **74** **75** R=H, CH_3

are nitrogen-containing derivatives from 1-deoxydiketoses of pentoses and 6-deoxyhexoses, respectively. So far, the pyrrolinone **76** has only been obtained from reaction mixtures of condensation products of the type **77** and primary amines. With secondary amines, compounds **77** rearranges into compounds **78**, the structures of which parallel those of aminohexosereductones **68a**.[62]



76 **77** **78**

2.5.3. *Reaction of 4-Deoxydiketoses*

The formation of 4-deoxydiketoses **16** in Maillard reaction mixtures has so far not been confirmed. However, since compounds have been isolated whose formation from sugars is best explained in terms of 4-deoxydiketoses as intermediates, one may assume that such α-dicarbonyl compounds are indeed formed.

Supporting evidence for their formation comes from the structures of compounds **79**–**81**. In the presence of larger amounts of primary amines, the formation of the hydroxyacetylfuran **79** can be largely suppressed in favor of the two nitrogenous heterocycles **80** and **81**.[26, 27, 63]

16 **79** X = O **81**
80 X = N–

As shown in Section 2.4.2, 4-deoxydiketoses are not formed from aminoketoses of type **3**. The compounds **79**–**81** are therefore indicator substances showing that the reactions have not proceeded exclusively via aminoketoses.[12b]

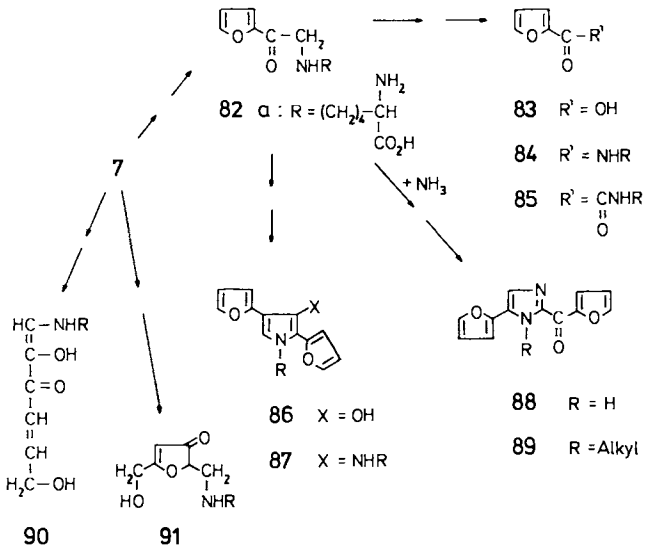
2.5.4. *Reactions of 1-Amino-1,4-dideoxydiketoses*

Proof that 1-amino-1,4-dideoxydiketoses **7** are reaction products of the aminoketoses has only been obtained recent-

ly.[12b,c] Cyclization and loss of water leads to the aminoacetylfuran **82**. As long as 30 years ago, the furan **82a** was obtained by heating Amadori compounds in the presence of strong acids[64] (cf. Section 4.3). In the meantime, it has been shown that **82** is also formed at pH 4 to 7. It should be noted that **82** is present as a stable salt under acid conditions, but that above pH 5 it rapidly undergoes further reactions.

Among the rearrangement and condensation products derived from **82** are the compounds **83** to **87**.[12c] From the structures of furoic acid **83**, of its amide **84**, and of furoylcarboxamide **85** it is immediately apparent that the aminoketone **82** is readily oxidized. The condensation to the aminopyrrole **87** is noteworthy (compounds **86** and **87** were isolated and identified as monoacetyl derivatives after acetylation of the total reaction mixture; the extent to which the compounds exist in the free form as pyrroles has not yet been ascertained). If such cyclizations are attributed to proteins, then aminopyrrole formation by two ε-amino groups of peptide-bound lysine residues constitutes a cross-link. The significance of cross-linking reactions in biological materials will be dealt with in Section 5.1.

In presence of ammonia aminoacetylfurans of type **82** give good yields of the imidazole **88** or its alkyl derivatives **89** respectively.[65] Compound **88** has been described recently as indicator substance for protein cross-linking (see Section 4.5). **88** was assumed to be derived from a cross-link. However, it became evident[65] that the formation of **88** takes place from furosine **82a** and ammonia during and subsequently to the acid hydrolysis of proteins. **82a** is itself formed in the process, as already mentioned, from the lysine Amadori compound **3a** or **3c**, and ammonia is liberated from asparagine and glutamine.



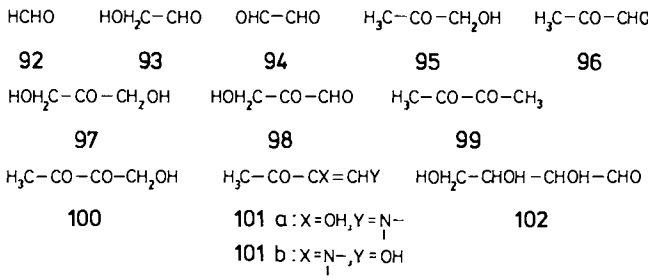
Recently, the isolation of aminoreductone **90** from a glucose-propylamine reaction mixture was achieved.[37d] It can be assumed that a 1-propylamino-1,4-dideoxydiketose of the general type **7** is formed as intermediate. This shows for the first time that an open-chain C_6-aminoreductone is present in a Maillard reaction mixture. The formation of the furanone **91** can also be derived from **7**, but so far structure **91** has been allocated only on the basis of the mass spectrum of a peak in the gas chromatogram of a silylated sugar-amine reaction mixture.[66]

2.6. Cleavage Reactions

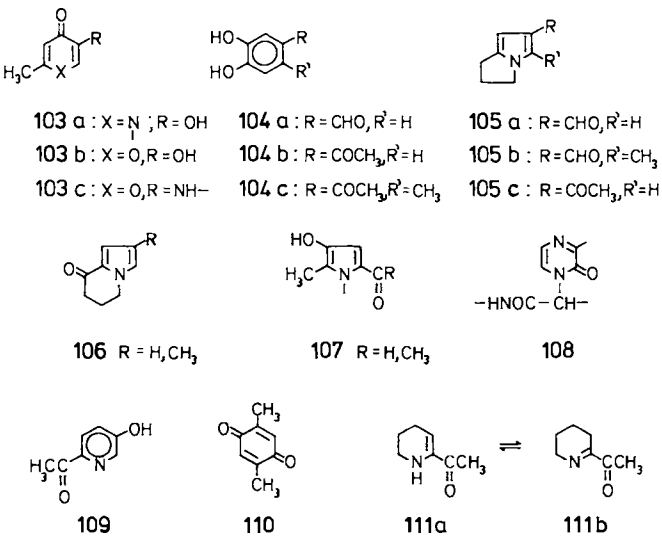
It has already been mentioned several times that, during the reactions undergone by sugars, cleavage of the carbon chain can occur. As will be shown, some cleavage products are very reactive and can substantially accelerate the Maillard reaction.[67] Sugar fragmentation products play a considerable role in aroma formation (cf. Section 3.1).

2.6.1. Retroaldolization

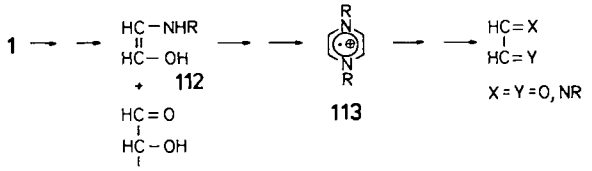
Sugars and many of their derivatives can undergo retroaldol-type reactions. The structures of compounds **92** to **102**[46a,68] permit one to assume that they have been formed



by a retroaldol cleavage. In some cases, oxidation and/or dehydration follows. Some of the cleavage products are very reactive, readily undergoing condensation reactions. The available partners consist of other retroaldol compounds, as well as of sugar derivatives with carbon chains still intact. The condensation products **103** to **111** illustrate the type of structures formed.[69,37c] Further research has shown that the progress of the degradation of the sugar is paralleled by the formation of the cleavage products. In the early phase,



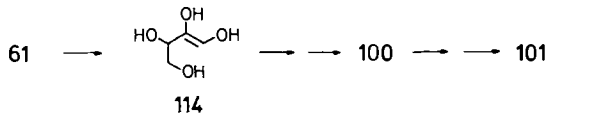
C_2 fragments preponderate, which have been formed from the sugar or the imine **1** provided that an aldose had been the starting point. Electron spin resonance spectra have provided evidence for the partial conversion of the imine cleavage product **112** into the pyridinium radical **113**, from which oxidation produces glyoxal or the corresponding nitrogenous analogs that immediately react further.[70]

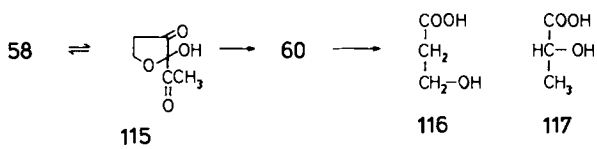


Somewhat later, C_3 compounds appear, but by then ketoses or Amadori products are already present. The amounts of the cleavage products found depends on the pH of the reaction medium, including the foodstuff. At pHs below 7, retroaldol products are likely to play only a subordinate role,[67, 71] but one must remember that even very small amounts of aroma compounds formed in this way may have great impact, if their odor threshold is very low.

If one assumes that the rate of browning depends on the amounts of the C_2 and C_3 products formed, it would follow that solutions of disaccharides become colored more slowly. Certainly, the C_3 products can be formed by retroaldolization only after hydrolysis of the glycosidic bond.[72] Possibly the configuration of the hydroxy group at C4 of glucose and galactose also affects the rates of cleavage and of browning.[73]

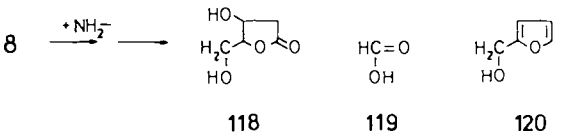
Labeling experiments have shown that C_4 aminoreductones **101** are formed via the β-diketone **61**. Neither C1 nor C6 of the sugar gives rise to the methyl group of the C_4 product **101**.[46] After cleavage of **61** to the tetrose (shown here in the enolized form **114**), the deoxy form **100** incorporates amine to give the product **101**. Retroaldolization is also involved in the formation of the acids **116** and **117**: the unstable β-pyranone **58** is in equilibrium with the furanone **115**, which on β-cleavage gives the ester **60**. Depending on the conditions, this, in turn, is split more or less rapidly into β-hydroxypropionic acid **116** and lactic acid **117**.[23]

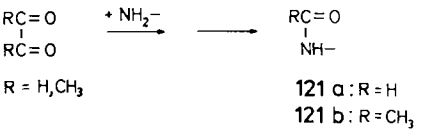




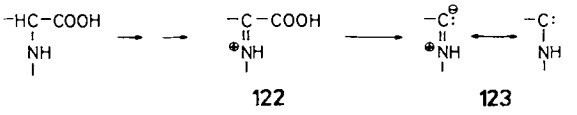
2.6.2. *Cleavage of α-Diketones*

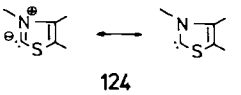
If the 3-deoxyaldoketose **8** is heated under Maillard conditions (i.e., in neutral aqueous solution in the presence of amines), but with exclusion of oxygen, extraction with organic solvents yields amongst other products the lactone **118**, formic acid **119**, and furfuryl alcohol **120**.[74] Model experiments with glyoxal and methylglyoxal had previously already led to the identification of the acid amides **121a** and **121b**.[75] The formation of **118**–**121** requires cleavage of the α-diketo group. Such cleavages are known, even though there are hardly any proposals as to how they occur.

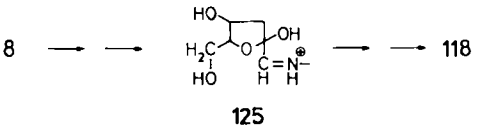


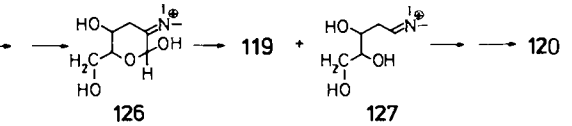


For the decarboxylation of the α-ammoniumcarboxylic acid **122**, an immoniumbetaine of the type **123** has been indicated as an intermediate,[76] which has some resemblance to the thiazoliumbetaine **124** derived from thiamine. If one assumes that, in the fission of the deoxyosone **8**, imine **125** is formed first, then it is to be expected that alongside **118** C_1-immoniumbetaines will be formed. However, so far proof or identification of such derivatives has not been unequivocally achieved. Alternatively, the intermediate **126** could lead to formic acid **119** and the C_5 fragment **127**, the latter reacting further to give furfuryl alcohol **120**. Lactone **118** and formic acid are formed in considerably greater amounts in the presence of oxygen, whereas the amount of furfuryl alcohol **120** decreases. It would seem therefore that



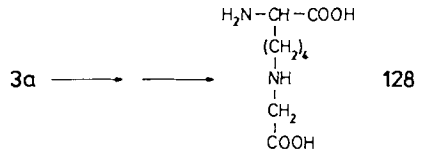






118 and **119** are formed in the reaction mixture predominantly by oxidative degradation of **8**.

Recently,[77] it proved possible to identify carboxymethyllysine **128** in the protein hydrolyzate of biological material (cf. Section 4.5). From the experimental results ob-

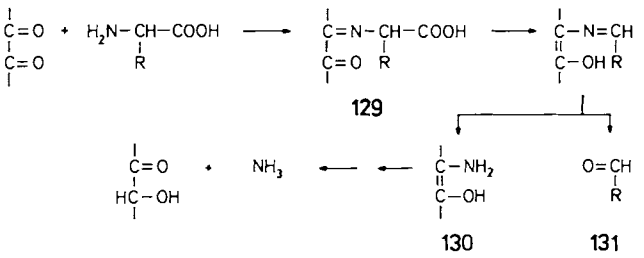


tained to date, it follows that the formation of **128** is due to oxidative cleavage of the corresponding aminoketose **3a**.[78]

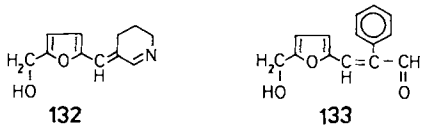
2.7. The Strecker Degradation

2.7.1. Strecker Degradation of Amino Acids

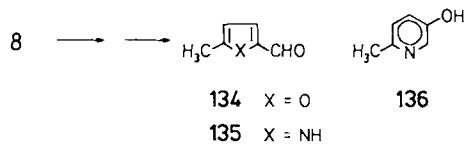
The decarboxylation of amino acids on heating with sugars has been known for many years. The decarboxylation is actually brought about by reaction of the amino acids with α-dicarbonyl compounds.[79] The azavinylogous β-keto acid **129** is formed first and then loses carbon dioxide. The significance of the Strecker degradation lies in the fact that the amino acids furnish ammonia and the reactive aldehydes of type **131**, compounds that can undergo, inter alia, condensa-



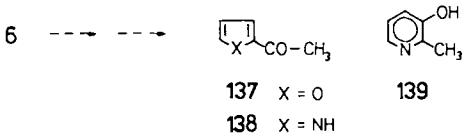
tion reactions. Thus, in reaction mixtures including lysine and phenylalanine as well as hexoses, furans **132**[80] and **133**[81] have been found, whose structures comprise the corresponding Strecker aldehyde. Ammonia in the free form or as the aminoenol **130** participates in the formation of pyridine, pyrazine, imidazole, and other derivatives.[82]



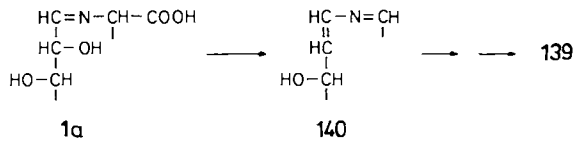
The Strecker degradation of amino acids brings about the reduction of the deoxyaldoketoses and diketoses. Cyclization and loss of water converts **8** into the furan **134** and, with the participation of ammonia, into the pyrrole **135** and the



pyridine **136**.[83] Compounds such as, inter alia, **137**, **138**, and **139** are derivable from 1-deoxydiketoses of type **6**. However, there is evidence that in these compounds the methyl group is not derived from C1 of the hexose. Therefore, a degradation via the imine **1a** has been proposed as a route to the formation of **138** and **139**:[84] loss of water from **1a** leads

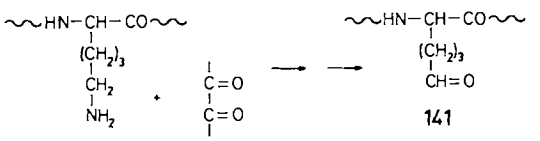


first to the 2-deoxyhexose **140**, which, after hydrolysis of the imine function, reacts further to yield the pyrrole **138** or the pyridine **139**. The Strecker degradation of proline and hydroxyproline will be considered in detail in Section 2.8.2. Another reaction sequence, that also leads to the reduction of α-dicarbonyl compounds, will be dealt with in Section 3.4.



2.7.2. Strecker Degradation of Amines?

In many foodstuffs and especially in vivo, the lysine side chain is the most important amine for the Maillard reaction. This raises the question of whether, in the presence of α-dicarbonyl compounds, the formyl derivative **141** is produced. For proteins it would seem likely that reactions would follow that would be comparable to those that take place during the synthesis of collagen and that lead to cross-link-



ing. It is known that primary aliphatic amines in presence of vicinal triketones such as ninhydrin and dehydroascorbic acid are converted into the corresponding aldehydes.[85] In the Maillard reaction, triketones, such as the β-pyranone **58** and oxidized reductones, are indeed formed, but the α-diketo compounds are of far greater significance. The experimental results available at present do not yet provide unequivocal proof that α-diketo compounds can lead to the splitting of

primary aliphatic amines into ammonia and aldehydes under the conditions of the Maillard reaction.

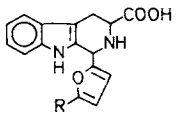
2.8. The Influence of Particular Amino Acids and Amines on the Course of the Reaction

This section is devoted to some special reactions that, due to the specific nature of the amino components, lead to unusual products.

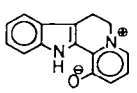
2.8.1. *Tryptophan*

An important finding, particularly with regard to the Maillard reaction in vivo, is that protein-bound tryptophan reacts with reducing sugars only to a limited extent.[86] Thus, this essential amino acid is, in contrast to the essential lysine, hardly damaged in protein-sugar reactions. In foodstuffs, tryptophan can also occur in the free state (e.g., in soy sauce). Then, even under mild conditions, reaction with carbonyl compounds and ring-closure with formation of β-carbolines become possible. The tetrahydro derivatives **142** and **143** have been shown to be present in soy sauce[87] (cf. Section 3.5).

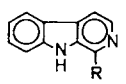
Under drastic reaction conditions, further β-carbolines are formed, some of which have also been found in foodstuffs.[88] It is apparent from structures **144**–**148** that, alongside cyclization, decarboxylations and dehydrogenations take place. It is likely that 3-deoxyaldoketoses participate in the formation of compounds **144** to **148**, which have been isolated from pentose-tryptophan reaction mixtures. If



142 R = H
143 R = CH_2OH



144



145 R = H

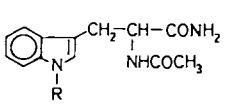
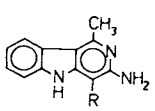
147 R = $COCH_3$
148 R =

the amino group is blocked, formation of glycosyl derivatives **149** (R = β-Glu, β-Xyl) has been observed. Evidence of their further reaction, e.g., to aminoketoses via Amadori rearrangement, has not been obtained so far.[89] To what extent products of the type **149** are formed in the Maillard reaction has not been investigated. More attention has been devoted to the tryptophan derivatives **150** and **151**, because of their strong mutagenic and carcinogenic activity.[90] These substances, which were first detected in pyrolyzates of tryptophan and of tryptophan-containing proteins, have



149 R = ß-Glu,ß-Xyl

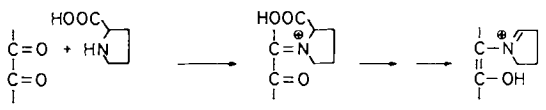


150 R = H
151 R = CH_3

since been found in foodstuffs that have been particularly severely exposed to heat.[91]

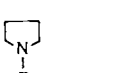
2.8.2. *Proline and Hydroxyproline*

Proline occurs in relatively large amounts in cereals and their products, such as malt. The participation of this imino acid in the formation of volatile compounds contributing to the aroma of malt has been particularly thoroughly researched. It is assumed that the dihydropyrrylium compound **152** plays a central role in the process. **152** is an intermediate of the reaction of proline with α-dicarbonyl compounds. The cation **152**, which is obtained by decarboxylation, leads to a series of nitrogen-containing hetero-



152

cycles by a variety of reactions. From the structures of compounds **31** and **153**–**162**, it can be deduced that the stabilization of the intermediate **152** is achieved by electron uptake (**153**), loss of protons (**154**), addition of heteroatoms (**31**), or



153

R = CH_2COCH_3

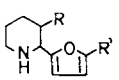
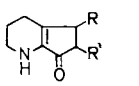
addition of other nucleophiles (**155**).[92] Opening of the dihydropyrrylium ring, followed by intra- or intermolecular condensation, leads to renewed ring closure, for example, with formation of pyridine derivatives **156**–**159**,[93] as well as of



156

R' = H, CH_3
R = H, OH



157

R = R' = H
R = H, R' = CH_3

the dihydroindolizine **160**, and the partially hydrogenated cyclopentazepinones **161**–**162**.[94] For the formation of maltoxazine **31**, a pathway starting from **8** via **152a** has been proposed.

Hydroxyproline occurs almost exclusively in connective tissue protein (collagen) and therefore is of no great signifi-

cance for the Maillard reaction in vivo or in foodstuffs. From model systems, it appears that, as with the degradation of proline, the dihydropyrrylium compound **163** leads to volatile products. In the process, stabilization occurs preponderantly by loss of water and formation of a pyrrole ring (compounds of the type **164**), which may be built into a bicyclic system (compound **165**).[95] Hydroxyproline has a

165

(R' = H, CH_3, CH_2OH)

certain significance, as does proline, as a starting material for the formation of volatile components of tobacco smoke.

2.8.3. Cysteine and Cystine

Cysteine and cystine do not occur free to any large extent in foodstuffs. The great significance of these amino acids for aroma formation is mainly due to the fact that, on heating, hydrogen sulfide is released. Hydrogen sulfide reacts with Maillard products to give a multitude of sulfur-containing compounds. Their important influence on the aroma is in part due to their extremely low odor thresholds. It follows that even small amounts of cysteine or cystine can affect the aroma perceived. If the extensive patent literature and the results of model experiments are taken as a guide, cysteine and cystine play an important role in the formation of the aroma of meat.[96] From model systems of cysteine with pentoses and hexoses, a broad spectrum of sulfur-containing volatile compounds has been isolated and some of these have very intense odors.[97] Mono-, di-, and trisubstituted thiazoles of the general structure **166** predominate. Thiazoles are

166

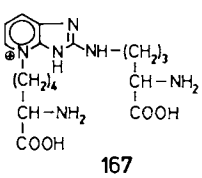
found, inter alia, in the volatile fraction of roasted coffee beans[98] and of cooked meat.[7j, 99]

Some important sulfur-containing aroma compounds are dealt with in Section 3.1. Cysteine has a retarding effect on the Maillard reaction, and this will be discussed in Section 3.7.

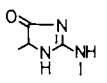
2.8.4. Arginine

In reports on the damage suffered by amino acids when proteins are heated in the presence of sugars, reference is frequently made to the fact that arginine, as well as lysine, undergoes extensive modification during the Maillard reaction.[100] Changes to lysine are often tantamount to loss of this amino acid and are therefore important for the nutritional value of the food, since lysine is an essential amino acid (cf. Section 3.6). During the in vivo Maillard reaction, lysine participates in cross-linking. Recently, it was discovered that arginine can also undergo such cross-linking reactions. From the structure of the product **167** it follows that arginine and lysine are linked via a imidazopyridinium bridge[101] (cf. Sections 4.5 and 5.1).

It is worth noting that the Maillard reaction is not initiated by the guanidino group.[102] Heating glucose with N^{α}-acetylarginine causes no browning of the solution and the hexose remains largely unchanged. The guanidino group of arginine bound in a protein therefore needs reactive Maillard products in order to be converted into, e.g., **167**. Heating aqueous solutions of methylguanidine (as models for arginine) with α- and β-dicarbonyl compounds at pH 7 to 8 led to the isolation of, e.g., imidazolones and pyrimidines of the general type **168** and **169**, respectively (the formation of the imidazolones re-



167



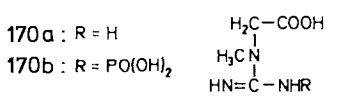
168

169

quires at least one aldehyde function).[103] Further research is required in order to ascertain which Maillard products with this function react preferentially with the guanidino group.

2.8.5. Creatine

Creatine **170a** and creatine phosphate **170b** occur in relatively large amounts (0.5%) in muscle. Heating causes mainly cyclization to creatinine **171**. For some years now, atten-

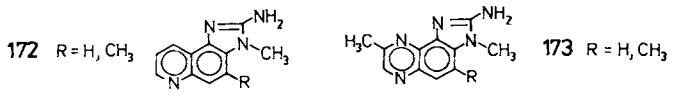


170a : R = H
170b : R = $PO(OH)_2$

171

tion has focused on these meat constituents, since they participate in the formation of the carcinogenic and strongly

mutagenic compounds **172** and **173**. Both compounds have been shown to be present in high-temperature roasted mixtures of amino acids and creatine with[104] and without hexoses[105] and later also in meat and fish products.[106]

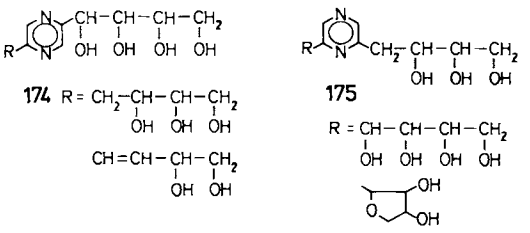


It can be assumed that creatinine, possessing a reactive methylene group, is able to condense with aldehydes (e.g., formed by Strecker degradation of amino acids) and that further reactions with sugar degradation products and ammonia follow. Certainly the concentration of **172** and **173** fell when Strecker aldehydes were trapped with tryptophan.[107] However, such a method cannot readily be adopted for foodstuffs, since tryptophan can form mutagenic and carcinogenic compounds with sugars and aldehydes (cf. Section 2.8.1).

Meanwhile, it has become apparent that the amount of carcinogens formed is largely determined by the conditions under which the foodstuff has been treated and that mild processing can to a great extent avoid their production. For example, if the food is heated to above 130 °C, the concentrations of **172** and **173** formed lie in the lower ppb range, but cooking at the boil leaves them below the limits of detection.

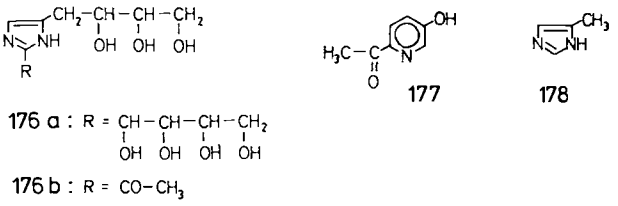
2.8.6. Ammonia

Unless foods have been allowed to spoil, they normally contain ammonia only in very low concentrations. To manufacture caramel as a coloring matter for foodstuffs (e.g., cola beverages), ammonia in large amounts is brought into reaction with sugars. With ammonia, the formation of pyridines,[108] pyrazines,[109] and imidazoles[110] is possible without requiring the cleavage of a C–N bond. As a consequence, these heterocycles occur in relatively large amounts in sugar-ammonia reaction mixtures. Compounds **174**–**177** are given



as examples. They can serve as evidence of the addition of ammonia caramel.[8a,111] This can be important for beer, bread, and other foods, where dark color can simulate the use of certain raw materials.[112]

Compound **176b** is known to reduce reversibly the number of lymphocytes in rats[110a] when fed a diet low in vitamin B_6. The methylimidazole **178** has toxic properties.[113] For both substances, upper concentration limits have been laid down for ammonia caramel.[114] Polyhydroxyalkylpyrazines are formed also from, for example, amino sugars[115] (e.g., 2-aminoglucose), but the occurrence of the



latter in foodstuffs is not significant, as already mentioned in Section 2.5.1.

2.9. High Molecular Weight Compounds (Melanoidins)

If the reaction mixtures of sugars and amines are submitted to exclusion chromatography, fractions can be obtained with molecular weights of about 7000 Da and even greater. So far it has not yet proved possible to isolate homogeneous high molecular weight Maillard products.[116] Very little is known about the structure of the high molecular weight substances, the so-called melanoidins. Knowledge has however been gained from the interpretation of spectral data, although some of the ^{1}H- and ^{13}C-NMR spectra of the melanoidins isolated by different research groups have differed substantially. Melanoidins with groups of signals that largely resemble those of Amadori compounds[117] contrast with those that exhibit signals in the olefin, aromatic, and carbonyl regions.[118] Experiments with ^{13}C- and ^{15}N-labeled sugars or amino acids have shown that the carboxy group of the amino acid survives in part in the melanoidin and that the signal of the α-carbon largely remains in the position in the melanoidin spectrum where it appears in the amino acid spectrum. Somewhat divergent from this, the ^{15}N-NMR spectrum also exhibits signals in the pyrrole, indole, and amide regions.[118] Signals for the C1 atom of the sugar can be found in all parts of the spectrum, consistent with the formation of different deoxyaldoketoses and diketoses and their derivatives. Results, obtained so far by the degradation of melanoidins with ozone and hydrogen peroxide,[119] have not led to any illuminating conclusions as regards the monomers involved in the condensation to melanoidins. Combined pyrolysis-gas chromatography of melanoidins, even when combined with mass-spectrometry, has not so far given unequivocal results either.[120] Differently produced caramel colors have been differentiated by means of Curie Point pyrolysis.[121] Electron spin resonance has also been applied to melanoidins, but so far no deductions have been drawn as regards the structure of the radicals.[122] The absorption of melanoidins in the ultraviolet and visible regions shows that condensation reactions have participated only to a limited extent in the linking of the monomers.[123] It is possible that substitution reactions play a role, as has been discussed in relation to the cross-linking of proteins.

3. Significance of the Maillard Reaction for Foods

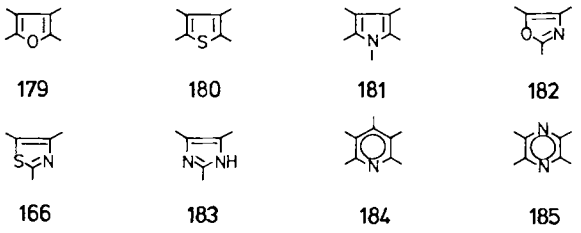
When fire was introduced as an aid in the preparation of foods several hundred thousand years ago, the Maillard re-

action became intimately linked to food chemistry. As evident from the recipes in cookery books down the ages, the Maillard reaction serves in particular to enhance the sensory qualities of many dishes. Who does not recognize the typical aroma of warm, crusty bread, of roasted meat, or of freshly ground roast coffee? The brown shades of color of different beers, as well as of many foods that have been exposed to heat, are equally the result of the Maillard reaction. However, for some years now, it has been known that the Maillard reaction is also involved in the formation of mutagenic and carcinogenic substances and can cause a reduction in the nutritional value of foods.

3.1. Aroma

The great interest shown by the food industry in the Maillard reaction largely stems from a desire to produce and control the characteristic aromas obtained on cooking, baking, roasting, and grilling. Once the analytical technique of combined gas chromatography–mass spectrometry had been developed for the separation and identification of relatively readily volatile substances, the search for compounds with specific odors became greatly intensified. The results have been summarized in a series of review articles.[7j, 124] Herein, therefore, we shall deal only with certain aspects.

Almost invariably, it has proved possible to isolate and identify from each foodstuff (boiled, baked, roasted, etc.) hundreds of volatile compounds. The structures of compounds **166** and **179–185** are intended to give an idea of the

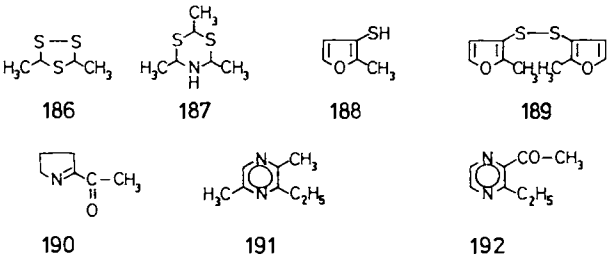


179 **180** **181** **182**

166 **183** **184** **185**

multiplicity of the heterocyclic systems encountered. To these must be added the many components based on proline and mentioned in Section 2.5.2, as well as other volatile Maillard products, such as esters, acids, ketones, aldehydes, alcohols, alkenes, alkanes, aromatic derivatives, amines, and mercaptans, that contribute to the aroma positively or negatively to a greater or lesser extent.

So far, all hopes have not been fulfilled; in particular, the aromas of boiled or grilled meat, of roasted coffee, of chocolate, and of bread cannot yet be satisfactorily reproduced by means of a single substance and one now suspects that this will never be the case. In general, reproduction of such aromas requires several components, which need to be present in the correct proportions. The so-called aromagrams allow one to estimate the contributions of the individual components to the final aroma. Aromagrams are produced by assessing with the nose, at the exit of a gas chromatograph, the volatiles separated from a complex mixture. Decisive for detection of each compound is whether its concentration in the mixture is sufficient for it to exceed the threshold at the odor port. By diluting the mixture in a stepwise manner before injection (usually by doubling the amount of solvent at each step), progressively fewer substances remain to be detected by the nose. The substances left in the later stages of the process usually carry most of the aroma of the mixture. For example, aromagrams have shown that it is not so much the trithiolane **186** and the dithiazine **187**, as previously thought,[125] that are important for the aroma of boiled meat, but the thiofuran **188** and its oxidation product **189**.[126] The acetylpyrroline **190** is one of the important contributors to the aroma of white bread,[127] whereas the typical odor of roasted nuts is in part determined by the pyrazines **191** and **192**.[128] Recently, it was shown that the concentration of the acetylpyrroline **190** is substantially dependent on the amount of C_3 products in the bread. Particularly in white bread, yeast, as well as the Maillard reaction, is an important source of these compounds (e.g., dihydroxyacetone monophosphate).[129]



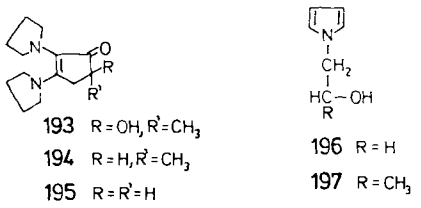
186 **187** **188** **189**

190 **191** **192**

Depending on the detailed processing conditions used and bearing in mind the variability of biological raw materials, it is not surprising that the concentrations of the intensely odorous components in foods differ greatly from sample to sample. This makes for difficulties in regulation, surveillance, and specification. Proof of the addition of aroma compounds that could have been formed by the Maillard reaction is therefore hardly possible.

3.2. Taste

When bread or meat is overheated on its surface during baking or roasting, respectively, the crust usually tastes bitter. The same effect is noted when wort boiling takes place at higher temperatures. Also model mixtures of sugars and amino acids taste bitter when they have been heated under grilling conditions. The most strongly bitter note in such experiments has been achieved with proline.[130] From reaction mixtures of this imino acid and hexoses, bitter substances **193–195** were successfully isolated.[94c, 131] It is noteworthy, that the taste threshold of the bispyrrolidine **193** lies higher by a factor of only 5 than that of quinine, i.e., **193** is already recognized as being bitter at concentrations of a few ppm. Investigations have yet to be carried out on the part played by compounds **193–195** in the bitter taste of highly heated proline-containing cereal products. A bitter taste is also exhibited by the proline-specific cyclopentazepinones **161** and **162**[94b] (cf. Section 2.8.2), as well as by the pyrroles **196** and **197**, which are formed on heating serine and threonine with hexoses.[132] However, with some



193 R = OH, R' = CH_3
194 R = H, R' = CH_3
195 R = R' = H

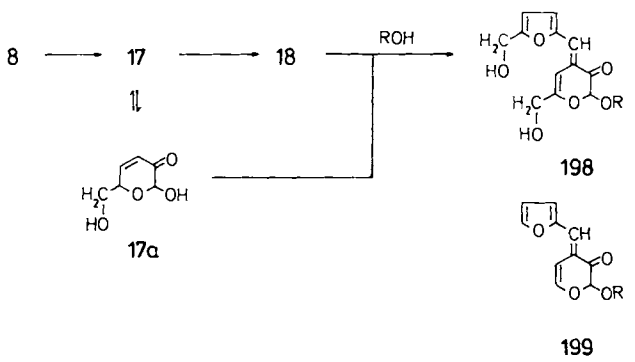
196 R = H
197 R = CH_3

of these compounds, the taste thresholds, so far as they have been investigated, exceed the concentrations in which they are formed.

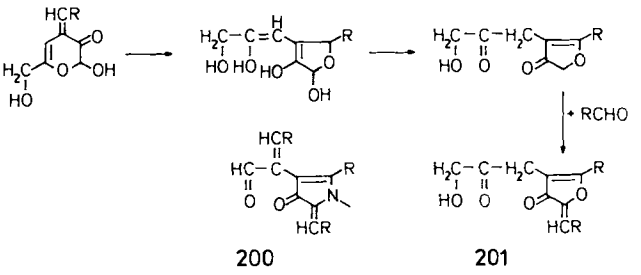
3.3. Color

From the fact that "we also eat with our eyes", the significance of colored compounds in food chemistry can be deduced. However, the Maillard reaction contributes not only to desirable formation of color, but also to discoloration of foods, which is synonymous with a lowering of quality. The determination of the degree of browning (usually through absorbance at 420 nm) is often used analytically to assess the extent to which the Maillard reaction has taken place. Since the concentrations of the sugar and amino components in foodstuffs are very variable, measurement of the color intensity does not readily yield comparable results.

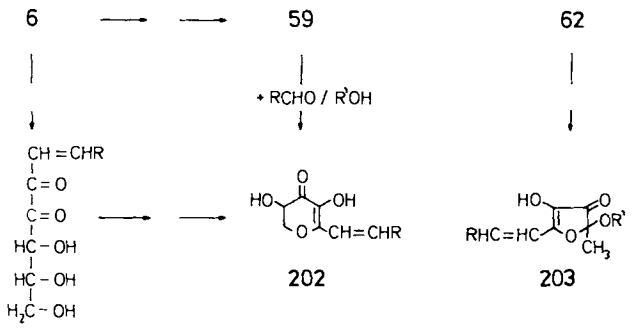
The isolation and identification of colored Maillard products has so far been achieved only with model systems. The structures of substances, in which the carbon chain of the sugar has remained intact, show that the deoxyaldoketoses and diketoses are important intermediates. Thus, the yellow compound **198** is formed by condensation of hydroxymethylfurfural **18** with the pyranone **17a**.[133] Both of these compounds are derived from the 3-deoxyaldoketose **8**. The analogous product **199** is present in reaction mixtures con-



taining pentoses. These compounds may be stabilized as acetals in systems containing little water. Such systems include, for example, bread crust, from which even a short time in the baking oven removes most of the water. Reaction conditions are then favorable for acetal or ketal formation with alcohols (e.g., carbohydrates). In aqueous solution, the hemiacetal **198** (R = H) is not stable; the furanone **201** becomes the main colored product when a carbonyl compound (e.g., furfural) is added to the solution. It can be assumed that rearrangement occurs first and that subsequent condensation leads to the furanone **201**.[133] It is noteworthy that the red pyrrolinone **200** is obtained on heating furfural in the presence of a primary amine and that its structure is very like that of the furanone **201**.[134] One can deduce from this the great potential for condensation which is inherent in the 3-deoxyaldoketoses, the precursors of these colored compounds. In foodstuffs, the condensation could occur with a whole range of carbonyl compounds, so that a multitude of browning products could result by means of this type of condensation alone, quite apart from whether **200** or **201** themselves are stable end products. Indeed, this makes it understandable why the attempted isolation of colored Maillard products from heated foods has not yet been successful.

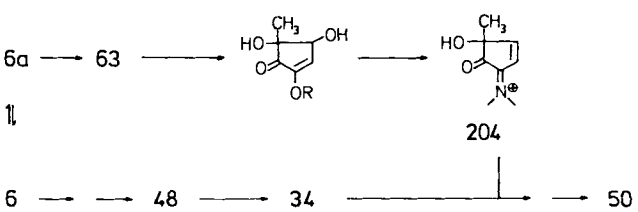


1-Deoxydiketoses can also lead to colored substances. Interaction of Amadori compounds with carbonyl compounds leads, inter alia, to the yellow compounds **202** and **203**,[135]



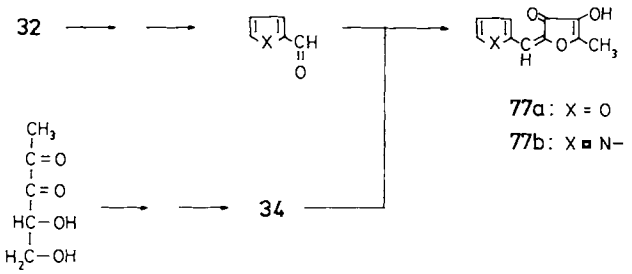
parts of which are clearly derived from 1-deoxydiketoses via **59** and **62**, respectively. The furanone **203** becomes stabilized as the ketal in media poor in water; its hemiacetal quickly reacts further.

Compound **50** (cf. Section 2.5.2) becomes the main colored product, when, to simulate media poor in water, heating is carried out in alcoholic solution. The mechanism shown is only hypothetical. As already mentioned, the furanone **48** readily loses formaldehyde with formation of the hydroxyfuranone **34**. 1-Deoxydiketose reacts in alcoholic solution to some extent as the reductone ether, which rearranges by loss of water and incorporation of the secondary amine to the cyclopentenone derivative **204**. This is subject to

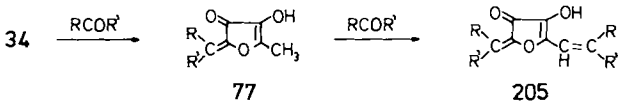


nucleophilic attack by the furanone **34** and oxidation then yields the colored product **50**.

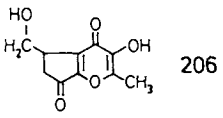
Research on model systems has produced much data on the browning of pentoses. The structures of the yellow main products **77a** and **77b**, which are formed on heating pentoses with primary amines,[136] suggest condensation of the hydroxyfuranone **34** with furfural and pyrrolealdehyde, respectively. The formation of the colored product **35** from pentoses and secondary amines has already been mentioned in Section 2.5.1. **77a**, **77b**, and **35** also contain the hydroxyfura-



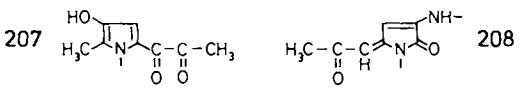
none **34** as part of their molecule. **34** is able to condense under mild conditions even with less reactive aldehydes and ketones to give colored compounds of type **77**, and, with reactive carbonyl compounds, it will even react further to give products of structure **205**.[62] Bearing in mind that, un-



der favorable conditions, **34** may be formed in yields of 5% based on the consumed pentose, it becomes clear that this compound plays a central role in color formation. The pyranone **206** is a further colored product derived from pentoses.[134] Both 3- and 1-deoxydicarbonyl compounds can be formulated as precursors of **206**.

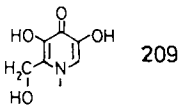


Cleavage products not only participate in the formation of volatile Maillard products, but are also found in the structures of colored compounds. The yellow pyrroles **207** and **208** were isolated from reaction mixtures of primary amines with dihydroxyacetone, pentoses, and hexoses.[34] As expected, the concentration of such pyrroles increases in these sugar reaction mixtures when the pH is raised above 7. Dihydroxyacetone and methylglyoxal, formed on loss of water, occur in smoke, so that browning products, such as **207** and

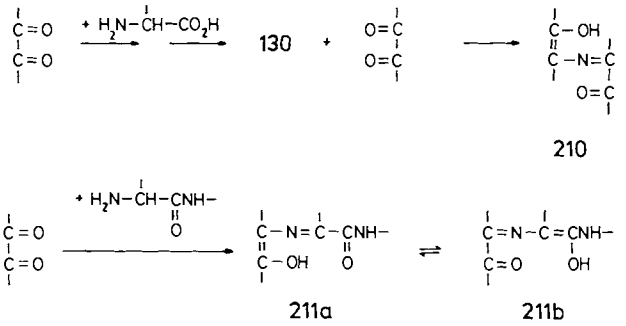


208, must be expected to be found on the surface of smoked meat and fish products.

There are further possibilities for color production during the Maillard reaction. Thus, Maillard products which possess a carbonyl function next to an enol grouping often give colored complexes with metal ions. Aqueous solutions of ferric salts turn red, violet, or blue on addition to solutions of compounds **34**, **48**, **50**, **51**, **59**, **62**, **65**, **68** (R = H), **69** (R = H), **71**, **90**, **101**, and **209**.[137] (Substance **209** is obtained from aminoketoses in the presence of oxidizing agents.) The significance of such colored complexes in the browning of heated or stored foodstuffs remains to be assessed.

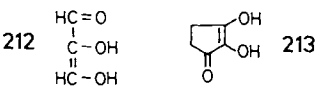


A further possibility for the formation of colored products lies in the reaction of α,β-triketones and α-dicarbonyl compounds with amino acids and peptides. As shown in Section 2.7, the Strecker degradation produces aminoenols of type **130**, which can react with further α-diketones or α,β-triketones to form colored condensation products of the general structure **210**.[138] Peptides give compounds of type **211**.[139]



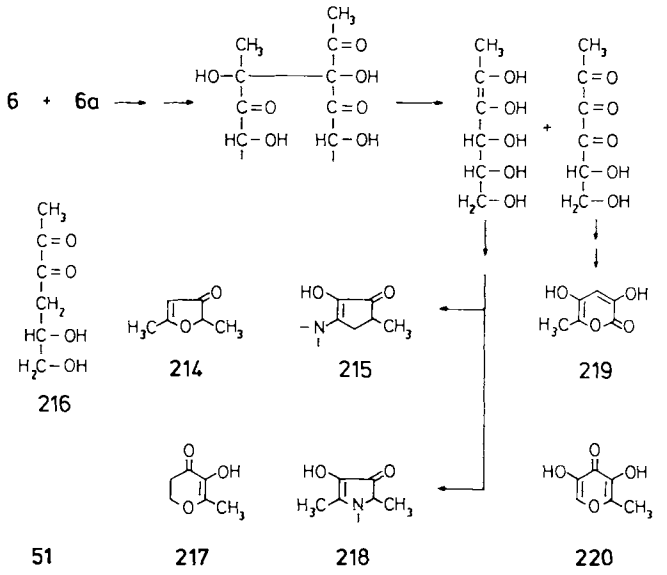
3.4. Shelf Life

It has been known for some time, that beer is stabilized against oxidative changes through substances formed by Maillard reactions occurring during the kilning of germinated barley. Without at first knowing their structure, these compounds were called reductones. The triosereductone **212** and reductic acid **213** can be prepared from sugars, but the

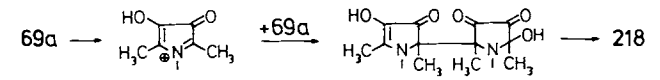


conditions required (heating in alkaline or acid solution) have no relevance to foodstuffs. It is now known that it is reductone ethers of type **34**, **48**, **51**, **59**, and **62** and aminoreductones **68**, **69**, **90**, and **101**, structurally comparable with vitamin C, that act as stabilizers. The formation of reductones in the Maillard reaction has already been dealt with (cf.

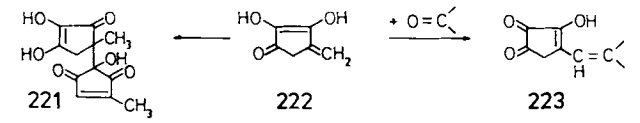
Section 2.5.2). The compounds which are preferentially reduced by reductones are only just being identified. If ascorbic acid or acetylformoin **62** reacts with diacetyl, some 3-hydroxybutan-2-one is formed, i.e., diacetyl is reduced.[140] By analogy, 1-deoxydiketoses should lead to the reduced substances **51**, **214**,[61] **215**,[141] **216**,[140] **217**,[142] and **218**,[143] as well as to the oxidized substances **219**[141] and **220**.[144]



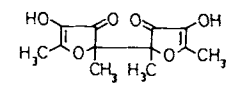
Following the same principle, one would expect the pyrrolinone **218** to be formed directly from the aminoreductone **69a**. Loss of water and addition of a second molecule allows disproportionation to **218** to take place. This mechanism at least affords an explanation for the formation of **218** upon storage of **69a**.[143]



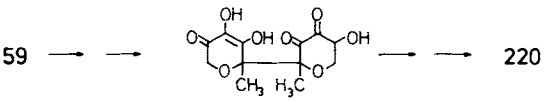
The aminohexosereductones **69a** in acid solution give good yields of the so-called methylenereductinic acid **222**.[145] Evidence for **222** in sugar–amine reaction mixtures and in foodstuffs has not yet been obtained; however, rapid condensation with carbonyl compounds to give cyclopentenediones of type **223**, as well as ready dimerization to **221**[146] provide grounds for thinking that the methylenereductic acid is too reactive to be readily detected in reaction mixtures.



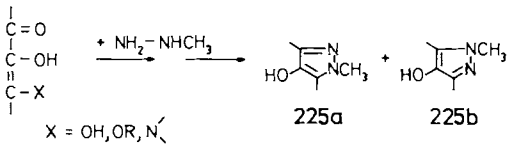
On warming the hydroxyfuranone **51**, some dimer **224** is formed, presumably via radical intermediates.[23] Longer



storage of the pyranone **59** leads to larger amounts of the oxidation product **220**,[144] a compound that has also been detected in heated or stored foodstuffs. The mechanism of this oxidation has not yet been ascertained, but the disproportionation of a dimeric intermediate does not seem unreasonable. Oxidation of **59** with iodine or cupric salts gives predominantly glyceric acid and lactic acid.[23]



In comparative tests for antioxidant activity, aminohexosereductones **68a** perform particularly well, though their relatively high toxicity does not commend them for use in foodstuffs.[147] For detection of reductones in reaction mixtures, two methods are available: selective electrochemical determination after separation by column chromatography[148] or condensation with hydrazine to hydroxypyrazoles of type **225**, which can be determined gas chromatographically after derivatization.[149] Carbocyclic reductones cannot be con-

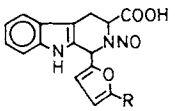


verted into hydroxypyrazoles. On treatment with methanol/toluenesulfonic acid, volatile methoxy derivatives are obtained.[141] Although it has been shown that certain melanoidins possess antioxidative properties,[150] there is no experimental evidence for the assumption that reductone groups are responsible.

3.5. Mutagenic Substances

Since the introduction of the Ames test for mutagenicity, a series of reaction mixtures, fractions, and Maillard products has been subjected to such a test. The results of experiments with foodstuffs,[151] aroma concentrates,[152] model systems,[153] and fractions derived from them are usually not comparable and are in part contradictory. At present, attention is focused on the Maillard products **172** and **173**, the carcinogenicity of which has meanwhile been thoroughly substantiated.[154] Rapid and definite detection of these compounds, which occur in some foodstuffs in ppb and less, still presents certain problems. It has been indicated already in Section 2.8.5, that steps have been taken to greatly reduce their formation. The mutagenic and carcinogenic tryptophan derivatives **150** and **151** also have a certain significance for foods.[91] Mixtures of these compounds with melanoidins isolated from reaction mixtures of glucose and glycine definitely exhibit reduced rates of mutation in the Ames test.[155] The practical implications of such results cannot yet be assessed.

The mutagenic and in part strongly carcinogenic effect of nitrosamines has been known for some time. Secondary amines present in foodstuffs can react with added nitrite during manufacture or preparation and with nitrite from saliva as they pass through the stomach. Secondary amines, such as Amadori compounds, are formed during the Maillard reaction. After addition of nitrite, except for the tryptophan derivative,[156a] no mutagenic activity is found with Amadori and Heyns compounds,[156b] but the tetrahydro-β-carbolines of postulated structure **226**[157] and nitrosothiazolidines of structure **227** exhibit unequivocal mutagenicity.[158] However, the conditions of reaction, including the



226 R = H, CH_2OH

227

concentrations of the reagents, need to be considered. For example, the incubation of soy sauce with an amount of nitrite corresponding to the maximum amount to be expected in saliva, under conditions equivalent to those in the stomach, does not lead to an enhanced rate of mutation in the Ames test, even though compounds **142** and **143** are present in this food in relatively high amounts (50 and 10 ppm, respectively).[159]

Recently, the anticarcinogenic activity of Maillard products has been reported.[160] It is postulated that reactions take place with oxygen radicals, which are trapped and thus converted into less aggressive compounds.

As well as other compounds, the Maillard products **18**, **25a**, and methylglyoxal have been shown to be mutagenic in the Ames test, while **145** and **146** have been shown to be comutagenic.[161] If, for example, one wishes to avoid the formation of compound **18** in foods, one would have to be prepared to substantially forego cooking.

3.6. Reduction in Nutritive Value

The growth of animals, which have been fed with proteins that have been heated in the presence of sugars, may be retarded. Many such studies have been carried out with milk proteins. From these, it became apparent that reaction of the sugar with the ε-amino groups of the lysine side-chains partly leads to products which the animal can no longer utilize. This is equivalent to reducing the nutritive value, since lysine is an essential amino acid. It has been shown unequivocally that the formation of the Amadori compound **3c** leads, after proteolysis of the protein in the alimentary canal, to the lysine derivative **3a**, which is worthless to the organism.[162] One of the consequences of these results has been that, in the production of milk powders and other products preferred in infant nutrition, particular attention must be paid to keeping damage to lysine to the minimum.

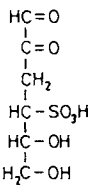
Amadori compounds possess good complexing properties, which lead, for example, to increased zinc excretion via urine after parenteral[11a] or oral[163] administration of such compounds. Experiments with oral intake of reaction mixtures showed that products subsequent to the aminoketoses exhibit similar effects (cf. Substance **71**).[164]

The resorption rates of higher molecular weight Maillard products from reaction mixtures of pentoses and hexoses with amino acids is very low in rats;[165] browning mixtures from proteins and sugar are somewhat better absorbed, the enzymatic hydrolysis of protein in the alimentary canal being hindered by the Maillard reaction, but not blocked.[166]

3.7. Control of the Maillard Reaction

When sterile solutions of glucose and amino acids are mixed in the cold in the preparation of infusions for parenteral nutrition and stored with refrigeration at 2 °C, evidence of the formation of aminoketoses of type **3** can be obtained in two to three weeks, and, after two months, a light yellow coloration becomes apparent.[11] A parallel situation occurs in many foodstuffs. If the Maillard reaction is to be suppressed, this can be achieved, for example, by adding sulfites[167] or, under certain circumstances, by reducing the water content/activity.[168] However, such methods are not appropriate for all foodstuffs.

It has long been known that sulfurous acid hinders the Maillard reaction. One can assume that addition of sulfite to the carbonyl group occurs,[169a] which thus becomes blocked and is no longer available for further reactions. These reactions are not always reversible, since part of the sulfite remains bound, for example, in the higher molecular weight reaction products.[169b] One of the few products isolated and identified to date has the structure **228**.[169a] It



228

seems reasonable to assume that the intermediate **17** undergoes reaction with sulfite. The Maillard reaction is also hindered by the addition of divalent sulfur derivatives, such as thioglycollic acid or cysteine.[170] Since addition of sulfur-containing compounds is expected to lead to large alterations in aroma in foods, their practical application is hardly likely.

Control of the Maillard reaction in vivo by means of aminoguanidine will be discussed in Section 6.2.

4. Formation of Amadori Compounds under Physiological Conditions

4.1. Reactions of Glucose with Proteins

That the Maillard reaction also occurs in vivo only became clear when the heterogeneity of hemoglobin was discovered. Thus, it was found[171] that, when human hemoglobin is chromatographed on weakly acid ion ex-

changers, three hemoglobin fractions (HbA_{1a}, HbA_{1b}, and HbA_{1c}) elute in front of the main fraction, HbA_0 (see Fig. 1). These fast hemoglobins (designated HbA_1 as a group), which normally constitute a few per cent (5–8%) of the total hemoglobin, possess the same amino acid sequence as HbA_0. They differ only through the presence of additional, covalently bound, low molecular weight substances. The elucidation of the structure of HbA_{1c} aroused particular interest, as higher amounts of it were found by chance in the blood of diabetics.[173] With the aid of periodate oxidation, it could be shown that the hexose found in HbA_{1c} is bound at the N-terminal valine of the β-chain in the form of 1-amino-1-deoxyfructose **3b**. Since HbA_{1c} can also be obtained by in vitro incubation of HbA_0 with glucose,[175] it is clear that the formation of HbA_{1c} proceeds via the addition of glucose to the N-terminal amino group of hemoglobin, forming the Schiff's base **1**, and subsequent Amadori rearrangement to **3**. The reaction has been termed the non-enzymatic glycosylation of proteins, since, in contrast to the multitude of enzymatically formed glycoproteins, glucose is here bound to protein without mediation by enzymes. In the American literature the synonymous term 'glycation' also appears.

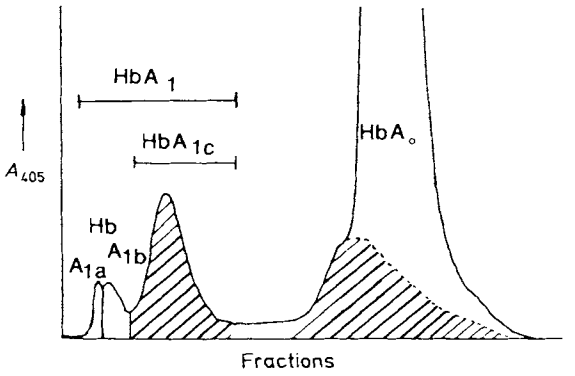


Fig. 1. Elution profile of human hemoglobin after chromatography on a weakly acid ion exchanger. Hemoglobin fraction HbA_{1c}, in which glucose is bound as structure **3b**, elutes before the main fraction HbA_0. Recently, it was shown that fraction HbA_0 also contains fructosylated hemoglobin, in which, however, glucose is bound as structure **3a** [172a]. The composition of the hemoglobin fractions HbA_{1a} and HbA_{1b} remains in part unknown. The shaded portions indicate increases with increased blood glucose concentration (diabetics). A_{405} = absorption at 405 nm.

In medical circles, 'fructosamine' is used as a synonym for **3**. Here, since the Amadori compound **3** formed is always a 1-amino-2-deoxyfructose, the term 'fructosylation' will always be employed. With hemoglobin, the preferred point of fructosylation is the amino terminal of the β-chain. The amino terminal of the α-chain is fructosylated 8–10 times less frequently in comparison.[172] Of the 22 primary amino groups of the α- and β-chains, only 3 are preferentially fructosylated. It is noteworthy, that the non-enzymatic fructosylation shows such an unexpected specificity, in which the pK_a value of the amino groups apparently plays a subordinate role. Limited steric access for glucose to the less reactive amino groups has been discussed as a possible reason for the specificity, but, meanwhile, indications have been obtained that the specificity could also be explained through acid-base catalysis by adjacent proton donor/acceptor groups.[172] As represented in a general way in Equation 1, glucose (G) reacts with the free amino groups of a protein (P), forming a Schiff's base **1**. After rearrangement to the relatively stable aminofructose **3c**, the fructosylated protein persists in the body until it is degraded.[176] The amount of fructosylated protein present in the body at a particular time represents the steady-state concentration $[\mathbf{3c}]_{SS}$.

$$G + P \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{1} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathbf{3c} \xrightarrow{k_3} \text{degradation products} \qquad (1)$$

Under steady-state conditions, when $k_{-2} \ll k_2$,[165] Equation (2) applies.[176]

$$\frac{[\mathbf{3c}]_{SS}}{[P]} = \frac{k_2'}{k_3}[G] \qquad (2)$$

The rate constant for the forward reaction is given by Equation (3),

$$k_2' = \frac{k_1 k_2}{k_{-1} + k_2} \qquad (3)$$

and that for degradation is k_3. The protein half-life can be calculated by means of the expression, $t_{1/2} = \ln 2/k_3$. The concentration of fructosylated protein (degree of fructosylation) in the steady state is therefore proportional to the glucose concentration and the ratio of the formation and decomposition constants. Since the degree of fructosylation in the steady state and the rate constant k_2' can be determined for each protein, one can calculate the decomposition constant and hence the protein half-life, provided the glucose concentration is known and constant (about 4.4 mM in the human body). On the other hand, if the rate of decomposition is known, the degree of fructosylation of a protein becomes a measure of the glucose concentration to which it has been exposed during its 'life'. In addition, the following conditions must also hold: 1. The protein must be freely accessible to the glucose in vivo (which is so for the blood proteins and the proteins of insulin-insensitive cells, where inward transport of glucose is greater than its consumption). 2. The in vivo and in vitro kinetics must correspond. Fructosylation can thus be regarded as an endogenous, non-radioactive way of marking proteins, which can be used for the estimation of the half-life of proteins.

If one determines the steady-state degree of fructosylation of human proteins that have been separated from the serum of normal subjects, and measures the corresponding in vitro rate constants k_2', the protein half-lives can be calculated.[176] Some results are presented in Table 1. The values given in the literature[177] show good agreement with the values obtained by in vitro kinetics for serum proteins. The low value obtained by the latter method for hemoglobin is associated with the fact that hemoglobin is present in red blood corpuscles not in solution, but as a concentrate (330 mg/mL).

Under conditions of increased or decreased protein turnover, as, for example, with thyroid hyper- or hypo-activity, respectively, a decreased or increased degree of fructosylation was indeed found for the human serum lipoprotein, 'low-density lipoprotein' (LDL), which is engaged in choles-

terol transport.[176b] Particularly interesting was the observation that the degree of fructosylation of LDL of normal subjects was correlated with the LDL-cholesterol level: a doubling of the level is reflected in a doubling of the degree of fructosylation of the LDL[176b] (cf. Section 5.2). In Figure 2, an experiment is presented in which a model reaction simulates the in vivo protein turnover.[176b] An albumin so-

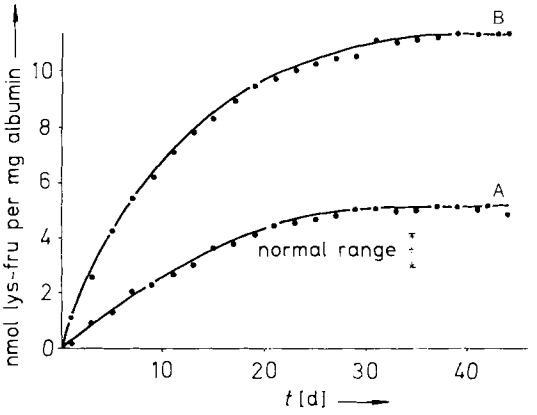

Fig. 2. Simulation of human protein-turnover in vitro. Human serum albumin incubated with 7.2 (A) and 14.4 (B) mM D-glucose, respectively. Each day, a twentieth part of the total was removed and replaced by the same amount of further original medium. Additional details appear in the text.

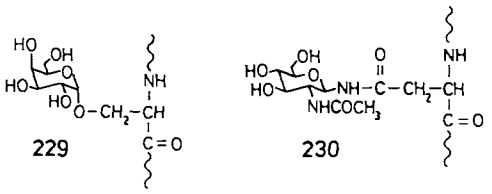
lution was incubated with two different concentrations of glucose and daily a twentieth of the solution was replaced by starting solution. This daily 'elimination' of 5% corresponds to a half-life of 13.8 days in a first-order degradation reaction. The border concentration between normal and raised blood-sugar level was taken to be 7.2 mM and the concentration for diabetics 14.4 mM glucose. After 40 days, equilibrium is more or less achieved. The steady-state value for 7.2 mM glucose was 5.1 nmol lys-fru per mg albumin, whereas, with the doubled glucose concentration, roughly double the degree of fructosylation was obtained (lys-fru indicates structure **3c**). From these values one can estimate that the in vitro steady-state fructosylation of 3.6 nmol albumin required a glucose concentration of about 5 mM. This concentration of glucose agrees well with the mean glucose concentration of normal subjects (4.4 mM), i.e., the in vitro reaction conditions appear to reflect those in the body relatively well.

4.2. Comparison of the Structure of Enzymatically Glycosylated and Non-enzymatically Fructosylated Proteins

In many glycoproteins, different sugars (e.g., galactose) are bound *O*-glycosidically to serine or threonine present in the peptide chain (cf. structure **229**). For a long time, only one type of *N*-glycoside had been characterized, namely, *N*-acetylglucosamine[178] bound *N*-glycosidically to the amide nitrogen of asparagine (cf. structure **230**).



In contrast, the fructosylation of proteins takes place mainly on the free amino groups of the lysine residues[179] (cf. structure **3c** and Section 4.1). The conformation of fructosylated proteins in aqueous solution has been examined by ^{13}C-NMR spectroscopy.[180] RNase A from bovine pancreas was used as the model protein. The results showed that the protein-bound hexoses are almost exclusively present in cyclic form, as would be expected by analogy with the free hexoses. The glucosylamine **1**, as well as the ketosamine, prefers the β-pyranose form (see structural formulas in Section 2.4). Since the reference compounds, *N*-α-formyl-ε-fructoselysine and fructosylated poly-L-lysine, exhibit resonances corresponding to those of the fructosylated enzyme (RNase), it seems that the protein matrix has relatively little influence on the conformation of the hexose.

4.3. Methods for the Quantitative Determination of Non-enzymatically Fructosylated Proteins

Since many of the methods used in food chemistry to detect and determine in vivo fructosylated proteins are not specific and sensitive enough, a series of alternative methods has been developed. Most of the methods of detection depicted in Figure 3 do not proceed stoichiometrically; they constitute therefore not absolute, but only relative methods of determination. Theoretically, it should be possible to quantify **3**, bound in a protein, after hydrolysis of the protein. However, **3** is not stable under the strongly acid conditions of hydrolysis; one obtains about 50% free lysine and about 30% **82a** (cf. Section 2.5.4). It could be shown[64] that **82a**, determined by means of an amino acid analyzer, can be used to measure the degree of heat damage suffered by foodstuffs, especially milk products, through non-enzymatic browning. Considerably smaller amounts of **82a** can be determined by HPLC.[181] Use of this method allowed 50 pmol **3c** in 5–25 μg protein to be determined specifically and precisely. A further advantage of the method is that it

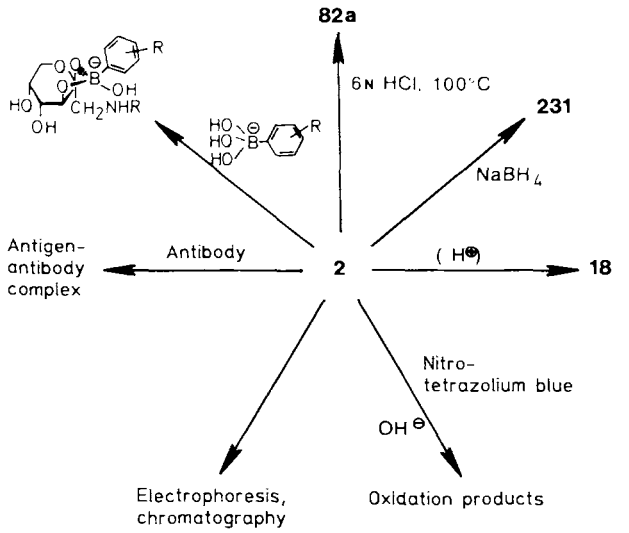


Fig. 3. Reactions providing evidence of the presence of fructosylated proteins. The reactions on the right occur with modification of structure **3**, those on the left without such modification.

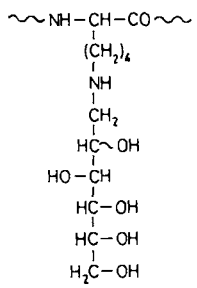
permits insoluble tissues (e.g., collagenous ones) to be investigated.

Fructosylated proteins can also be determined in the amino acid analyzer after sodium borohydride reduction to **231** and subsequent hydrolysis, in which **231** dehydrates to a



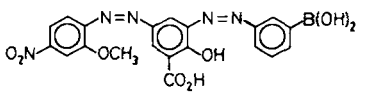
231

considerable extent. Usually the sensitivity needs to be improved, for which purpose tritiated sodium borohydride is employed. The determination of **18**, which is frequently used in food chemistry because it is readily formed from **3** on mild acid hydrolysis (cf. Section 2.5.2), can only be applied here under special circumstances.[182, 183]

The characteristic behavior of Amadori compounds on reduction was employed for their detection relatively early on.[3a, 6] In alkaline solution, **3** enolizes to the strongly reducing enaminol **5**, which can be determined and quantified by means of various redox indicators, such as dichlorophenolindophenol. Since the reductone formed also possesses reducing properties, the reaction without, firstly, unequivocal stoichiometry and, secondly, a clearly defined endpoint. To overcome these problems, it was suggested that the reaction be determined kinetically with Nitrotetrazolium Blue as the reducing agent.[184] It became evident that at pH 10.3 neither glucosylamine nor free glucose participated in the reaction to any marked extent. By appropriate choice of time window, the specificity could be improved, because other reducing substances, present in human serum, have substantially completed their reactions within the first ten minutes. The alteration in the pK_a of hemoglobin fructosylated at valine **3b**, which had led to the discovery of the fructosylated hemoglobins, was used at first by all researchers to separate and quantify **3b** by means of ion-exchange chromatography, electrophoresis, or isoelectric focusing.[185] Since, as already mentioned, most proteins are mainly fructosylated at the ε-amino groups of lysine residues (cf. structure **3a**), which exhibit substantially less change in pK_a these methods are not universally applicable (cf. Fig. 1). Attempts to detect **3** with phenylhydrazine as a carbonyl reagent failed, because of insufficient reactivity and sensitivity.[186]

Although some protein-bound sugar structures exhibit extraordinary antigenicity, early trials showed already that structure **3** becomes antigenic only after reduction to **231**. However, the binding of the antibody to **231** is not quantitative for all fructosylated proteins, probably because of steric hindrance, so that the method is not universally applicable.[187]

Fructosylated amino acids and peptides bind specifically to matrix-bound boric acid, with formation of a boric ester (see Fig. 3), and can be quantified after elution with acid or sorbitol.[188] However, this procedure also is not quantitative for many proteins and therefore not appropriate, probably again because of steric hindrance. Our own investigations have shown that boric ester formation can also take place with substituted phenylboric acids in homogeneous aqueous solution.[189] Since the absorption maximum of **232** moves to shorter wavelengths on esterification, **3** can be quantified photometrically.



232

It can be seen that, in spite of the number of methods described, there is no generally applicable technique for determining precisely and specifically proteins that have been fructosylated in the human body. For each particular protein, the most appropriate method has to be selected from those available.

4.4. Detection of Fructosylated Proteins in Human Blood and Tissues

Only in this decade was it realized that many human proteins, not just hemoglobins, are fructosylated. About ten years ago, it was shown[190] that human serum albumin is also fructosylated. As with hemoglobin, the position of fructosylation is relatively specific. Only nine of 55 ε-amino groups are measurably fructosylated, LYS-525 being most strongly attacked (50% of the total fructosylation). The degree of fructosylation of some blood proteins is listed in Table 1. Since diabetics have higher blood-sugar values (about 2–5 fold), some proteins from diabetics may bind more than 1 mol fructose per mol protein. Other plasma

proteins, such as α_1-antitrypsin, fibronectin, plasminogen, antithrombin-III, ApoE, and ApoC II, can of course be determined, but, mainly because of their short half-life (hours, 1–3 days), they are hardly fructosylated.[191] Not only soluble proteins, but also membrane-bound proteins are subject to fructosylation, as has been demonstrated with erythrocytes.[192] With human tissue proteins, the degree of fructosylation depends, amongst other factors, on whether glucose has ready access to the proteins (as with extracellular proteins such as connective tissue) or whether (as with intracellular proteins) the glucose concentration in the cell is very low. This is particularly relevant for insulin-sensitive tissue, i.e., tissue in which glucose uptake is regulated by insulin. As a consequence, fructosylation could not be detected in the proteins of the muscles of the heart or skeleton.[193]

In contrast, in insulin-insensitive tissue, such as nerve-tissue, **3c** could be detected.[193] Tissue containing collagen has been particularly thoroughly investigated. Figure 4 shows values for the content of **3c** in tendon, aorta-wall,

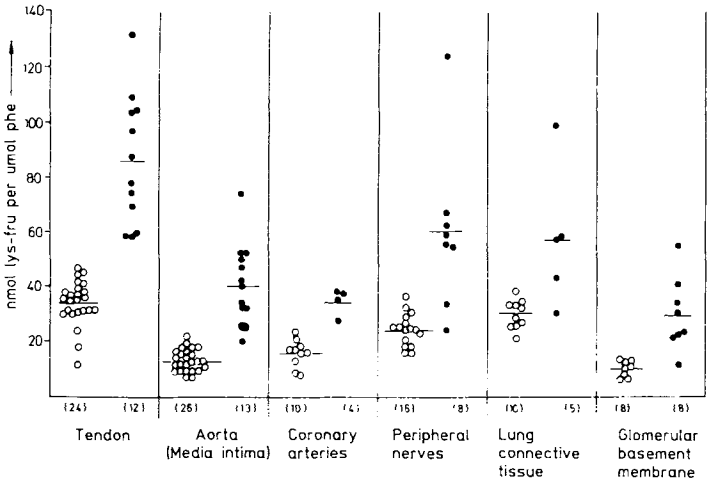


Fig. 4. Non-enzymatic fructosylation of several tissues from diabetic (●) and normal (○) patients. The horizontal lines indicate the arithmetic means. The number of cases is given in brackets for each type of tissue. Fructosylation is expressed in nmol lys-fru per μmol phenylalanine, which serves as an arbitrary measure of the amount of protein. The glomerular basement membrane is the collagenous dialysis membrane of the kidney.

nerve tissue, lung connective tissue, and glomerular basement membrane. **3c** has also been detected in hair and in finger nails (cf. Section 6.1). The mean values for the different tissues of normal subjects correspond roughly to a fructosylation of 1–3% of all the lysine residues. The mean values for individual diabetics are more variable than those for non-diabetics, corresponding to greater differences in metabolism. The degrees of fructosylation of the different tissues correlate well with each other: patients with high fructosylation of tendons also exhibit high fructosylation in other tissues. Mean blood sugar levels also correlate surprisingly well with the degree of fructosylation of tissues.

Of particular interest is the question whether the degree of fructosylation of proteins, especially that of connective tissue, increases during life. Although one paper[194] describes a doubling of the degree of fructosylation of human tendon collagen during a lifetime, other researches, using more specific methods, showed a smaller increase (about 50%) in the fructosylation of tendon and aorta tissue.[176b] However, a very clear relationship between degree of fructosylation and age has been established for lens tissue of the eye.[195]

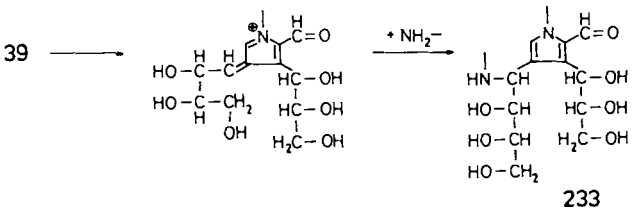
Since, according to present knowledge, fructosylated amino acids cannot be metabolized in the mammalian organism (cf. Section 3.6) and since they have good solubility in water, they should be eliminated largely in the urine. In fact, normal subjects do excrete significant amounts of fructosylated amino acids, about 0.1–0.3 mmol per day.[188, 196] As some foodstuffs contain substantial amounts of free or bound fructoselysine, **3a** and **3c**, respectively, the question arises whether the excreted fructosylated amino acids are not in part of exogenous origin. Evidence that this is not so comes from the fact that fasting for 24 hours leaves the excretion rate unchanged, fasting for 10 days even increasing it. This increase is due to heightened protein degradation (catabolism). With animal experiments it has been shown that exogenous fructosylated amino acids and proteins are degraded by microorganisms in the gut. Mammals cannot make use of fructosylated amino acids. Diabetics excrete increased amounts of fructoselysine in their urine, corresponding to their metabolic state.[188, 196]

4.5. Do Subsequent Reactions also Occur in vivo? Formation of 'Advanced Glucosylation End Products' (AGE)

Whether the Amadori product **3**, in a way corresponding to the browning reaction of food chemistry, also reacts further in vivo and so provides a possible mechanism of aging is an interesting problem. The first support came from finding that the fluorescence specific for browning pigments increased for tendon collagen in a linear manner with age.[197] Samples obtained from diabetics did not give readings falling into the normal range, but exhibited greater fluorescence. Since **3** does not fluoresce, derivatives must have been formed. In model reaction mixtures of bovine serum albumin and glucose, a corresponding fluorescence was clearly present after 30 days.[198] From the solution obtained from the protein after acid hydrolysis, the fluorescent product **88** was isolated. As already outlined in Section 2.5.4, it is probably an artefact. Meanwhile, the pyrrolealdehyde **25b** has been shown to be present in a number of native proteins by means of a specific antibody, thus proving the presence of derivatives of **3** in vivo.[30] The mechanism of formation has already been described in Section 2.5.1.

A further derivative, carboxymethyllysine **128**, also formed in vivo, has been detected in the meantime (cf. Section 2.6.2). This therefore explains the excretion of **128** in urine, which had been known for some time.[199] **128** has also been found in the eye lens, where its concentration increases linearly with age.[199] The interesting observation has been made that in vitro **3a** leads to more browning pigments in the absence of oxygen than in its presence, but without formation of **128**.[77] It was therefore proposed that the excretion of **128** can be used as a general indicator of the age of extracellular protein and the ratio of excreted **3a**/**128** as a general indicator of oxidative stress in the human body.[199] Meanwhile, in a model reaction, a further pyrrolealdehyde,[200] **39**,

has been found, the mechanism of formation of which has already been postulated (cf. Section 2.5.1). In the presence of sodium sulfite, compound **39** accumulates, while, in the absence of sulfite, it very quickly forms cross-links with the free amino groups of proteins. One can assume that compounds of type **233** are formed.



Meanwhile, the Maillard product **167** has also been isolated from human tendon.[101] The structure of this cross-link implies participation of lysine, arginine, and a pentose. Since, so far, nothing is known of the role of arginine and of pentoses in the Maillard reaction in vivo, the significance of **167** for the cross-linking of proteins cannot yet be evaluated.

Recently, it was demonstrated that the Maillard reaction is involved not only with proteins, but also with nucleic acids.[201] Incubation of DNA with reducing sugars leads to the formation of brown fluorescent substances, the spectroscopic properties of which resemble those of AGE-proteins. Such modified DNA (AGE-DNA) on transcription exhibits specific mutations, caused by insertions or deletions. Cross-linking between proteins and DNA was also evident. Whether such protein-AGE-DNA cross-linking also takes place in human cells has not yet been demonstrated, but, on the basis of the above findings, seems not unlikely.

5. Does the Maillard Reaction Lead to Modification of the Structure and Function of Proteins?

5.1. Effects on the Structure of Proteins

Fructosylation of bovine lens protein leads to a dulling of crystallin.[202] Since this opaqueness does not appear in the presence of reducing agents, it is assumed that fructosylation gives rise to a subsequent change in conformation, exposing sulfhydryl groups and thus allowing dimerization of the protein. In cataracts (lens dulling) from diabetic and galactosemic rats, evidence was obtained for aggregates of crystallin, linked by disulfide bonds.[203] As, according to other studies, crystallin is fructosylated in a time- and concentration-dependent manner, one is led to assume that the Maillard reaction plays a role in the development of cataracts with age or diabetes.

Since cross-linking of the free lysine sidechains of the long-persisting connective tissue proteins, collagen and elastin, is of essential significance, the relationship between the fructosylation of collagen and its properties has been extensively investigated. During physiological cross-linking of collagen, a lysyl oxidase oxidizes a few lysyl and hydroxylysyl residues to the corresponding aldehydes, which subsequently cross-link with the ε-amino groups of neighboring collagen molecules. The attack of glucose on a lysyl or hydroxylysyl residue should inhibit the reaction and thus lead to reduced cross-linking of collagen. In actual fact, the opposite was found. To explain these experimental results, one must therefore draw on other mechanisms. As already described (cf. Section 4.5), fructosylated lysyl groups can themselves form cross-links via derivatives such as **39** and **167**. Such non-physiological cross-links are formed in collagen fibers between collagen molecules lying alongside one another, thus increasing the mechanical stability, but lowering the solubilization by acids or enzymes. In model experiments, it has in fact been shown that tendon has greater mechanical strength after incubation with glucose. Incubating tendon with glucose simulates the increase in tensile strength which takes place with age.[204] Using RNase as an example, it has been shown that this enzyme, on fructosylation in vitro, undergoes di- and trimerization in a time-dependent manner.[205] This cross-linking continues even after removal of the glucose and can be almost completely inhibited by simultaneous incubation with L-lysine. The reaction mechanism was considered to involve condensation of an amino group of the protein with **3a** of another protein, thus producing cross-links (structure **13**). Meanwhile, it has been shown that such cross-linking can also take place between different proteins.[200, 206] When serum albumin or immunoglobulin G is added to collagen, previously incubated for a longer period with glucose, they become covalently bound. In fact, with diabetic animals, five times more immunoglobulin G is bound to collagen than with non-diabetic ones. Particularly interesting is the discovery that the cholesterol-transporting serum lipoprotein LDL can be bound covalently in this manner to fructosylated collagen (e.g., in the arterial wall).

5.2. Effects of Fructosylation on the Function of Proteins

Fructosylation occurs primarily on the free ε-amino groups of lysine bound in proteins. These amino groups of lysine are of essential significance in the active centers of numerous proteins with functions in catalysis, transport, binding, and structure. They also play an important role in interactions, such as those between hormone and hormone receptor, antigen and antibody, and enzyme and enzyme inhibitor. Hence, it is an attractive hypothesis to postulate that fructosylation of lysyl residues, occupying strategically important positions, is detrimental to the functionality of the protein affected. However, when transaminases were fructosylated in vitro, no reduction in enzyme activity was found.[189] Evidently, the lysine at the active center, which forms a Schiff's base with the cofactor, pyridoxal phosphate, must be protected from fructosylation. In contrast, on incubation with glucose, ribonuclease A loses 50% of its original activity in 24 hours, whereas cathepsin B and papain lose about 70% in 2 weeks.[207] With these enzymes, it appears that fructosylation of the lysine, which lies close to the active center, is responsible for the reduction in activity.

Changes in conformation are also possible factors, as has been shown with the β-*N*-acetyl-D-glucosaminidase from bovine kidney as example.[208] The activity was already reduced to a half after seven days' incubation with 44 mM D-glucose. Studies with the separated isoenzymes A and B

demonstrated that isoenzyme A is completely inactivated, whereas B remains fully active. The changes in functionality are accompanied by alterations in structure. Thus fructosylation changes the electrophoretic mobility. The molecular mass increases from 130 to 205 kDa. To what extent these reductions in activity and changes in structure play a role also in vivo is so far not known. A series of experiments indicates that fructosylated proteins are less readily split on proteolysis. Thus, it appears that the cross-linking of protein chains, which occurs during the course of the non-enzymatic browning reaction between reducing sugars and proteins, also affects their ease of hydrolysis (cf. Sections 3.6 and 5.1). The proteolytic cascade involved in blood clotting has been the subject of research by many groups. The inhibitory effect of antithrombin III is considerably reduced on incubation for 3 days with 100 mM glucose; 400 mM glucose reduces it to half. Such reduced functionality of antithrombin III leads to higher thrombin activity and to increased formation of fibrin peptide. The greater the degree of fructosylation of the fibrin peptide, the more slowly is it cleaved by plasmin.[209] Hormone activity can also be affected by fructosylation, as can be seen, for example, with insulin. The diminished activity of insulin can be demonstrated on fat cells through reduced glucose oxidation, increased de novo fatty acid synthesis, and reduced antilipolytic properties.[210] Since these effects only appear with very high degrees of fructosylation, it is likely that these results are not relevant to the situation in vivo. The cholesterol-transporting LDL of human blood normally contains about 0.5 mol lys-fru per mol.[191b] Detailed research in vitro showed that modification of the ε-amino groups of LDL led to a reduction in binding to the LDL-receptors, which are attached to the cell membrane.[211] The reduction in binding, uptake, and metabolism of LDL by different human cells could be demonstrated, also for fructosylated LDL, to be dependent on the amount of glucose bound. It is noteworthy that fructosylated LDL in human macrophages can stimulate cholesterol ester synthesis. It seems possible, therefore, that fructosylation of LDL and the corresponding derivatives (AGE products) favor the formation of foam cells (macrophages are taken to be precursors of the foam cells of the atherosclerotic plaques). The relevance, in this connection, of the interesting observation that raised LDL-cholesterol levels are accompanied by increased degrees of fructosylation (cf. Section 4.1), is so far not known.

5.3. Immunogenicity of Fructosylated Proteins and their Reaction Products

Several attempts to detect unequivocally antibodies against structure **3** in human blood have thus far not succeeded. This corresponds to the results of animal experiments, which indicate that fructosylated proteins possess little antigenicity (cf. Section 4.3). Since the amount of AGE products, which has been found in the different long-life body proteins, is much less than had been expected on the basis of in vitro studies, the possibility was investigated of the existence of a mechanism in the living organism that is capable of selectively removing AGE proteins. It was indeed shown that, in immunocompetent cells (macrophages), there is a high-affinity receptor, able to bind AGE proteins, to take them into the cell, and to degrade them.[212] This receptor for AGE proteins has already been extracted from the macrophage membrane and concentrated. However, this degradation system for AGE proteins does not seem to be totally efficient, since the aging products accumulate over the life span of the individual as a function of time and of the blood glucose level.

6. Medical Aspects of the Maillard Reaction

6.1. The Maillard Reaction as Diagnostic of the Metabolic State of Diabetics

The degree of fructosylation of proteins in the human body, under steady state conditions, is proportional to the half-life of the protein and to the glucose concentration (cf. Section 4.1). Thus, provided the protein half-life remains constant, the mean concentration of glucose to which that protein has been exposed during its life time in the body can be calculated. The degree of fructosylation can therefore be used to calculate the blood glucose level retrospectively. The fructosylated proteins represent a sort of blood sugar memory. Depending on the time frame one wishes to investigate, so one selects a protein with an appropriate half-life. Thus, for example, hemoglobin is suitable for checking on the blood sugar level over the last 2–3 months, whilst the determination of the fructosylated serum proteins mirrors the mean blood glucose concentration over the last 2–3 weeks. By means of the furosine method (cf. Section 4.3), raised glucose levels can even be determined from the degree of fructosylation of finger nail or hair proteins.[213] The determination of the fructosylated blood proteins thus leads to the objective assessment of the state of metabolism, which is clinically helpful both for the physician and the patient. The patient is given a straight motivating indicator and the physician can take into account the mean blood sugar values over a considerable time, without the effort of having to determine the individual values.

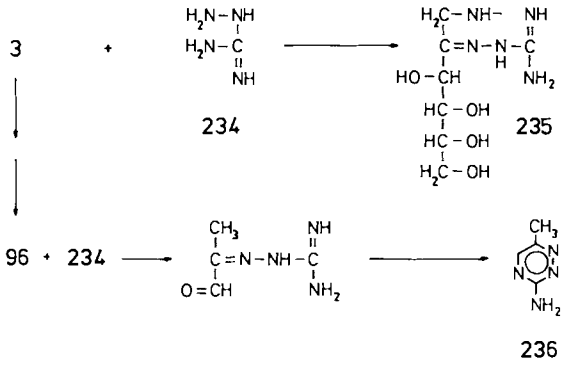
Since the late complications of diabetes appear, in particular, in the insulin-insensitive tissues, the fructosylation of the proteins of these tissues was compared with the severity of the late complications.[193] Diabetics with severe late complications in several organs exhibited a high degree of fructosylation of tendon or aorta tissue. These results point to a connection between poor metabolic control and the development of diabetic late complications. In accordance with this, it could be shown recently that diabetics with high amounts of AGE proteins suffer from increased damage to eyes and kidneys.[214]

6.2. Intervention in the Maillard Reaction in vivo

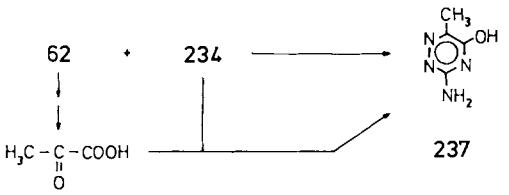
Once the Maillard reaction had been recognized as the cause of undesirable, glucose-dependent cross-linking of proteins in the human body, ways of suppressing the reaction were sought. For many years, food chemists have employed sulfite as an additive to inhibit the formation of Maillard products in foods (cf. Section 3.7). For administration

with **3** or other rearrangement products. It could be shown that aminoguanidine **234** inhibits the formation of AGE substances and the cross-linking of proteins in vivo as well as in vitro.[215] After administration of aminoguanidine, no accumulation was observed of immunoglobulins in the collagen network of the blood vessels of diabetic rats. Further research showed lowered cross-linking of the collagen and less deposition of the cholesterol-transporting lipoproteins on the arterial walls. Studies of toxicity in different mammals and in healthy humans provided evidence that **234** is relatively well tolerated. It is planned to test **234** as a drug to hinder the cross-linking caused by the Maillard reaction and thus to reduce late complications in diabetes and the damaging effects of aging.

It is assumed that aminoguanidine reacts preferentially with **3** to form hydrazones of type **235**. In in vitro experiments, the triazine **236** is formed to some extent. A probable mechanism for its formation is the retroaldolization of **3** to methylglyoxal **96**, which then condenses with amino-



guanidine. Reaction of the hydroxyfuranone **62** with aminoguanidine at pH 7–8 leads to formation of the hydroxytriazine **237**.[216] It can be assumed that **62** is cleaved to give pyruvic acid, which then cyclizes with aminoguanidine



to give **237**. The extent to which the formation of triazines also occurs in vivo still needs to be ascertained.

7. Summary and Outlook

Even 78 years after its discovery, the Maillard reaction with its multitude of reaction pathways and products is still only known in outline. In food chemistry, the objectives are to have the Maillard reaction proceed in such a way that the formation of toxic substances and the reduction in nutritional value are suppressed, whilst, simultaneously, desirable components are formed in optimal amount. Although it was first realized only relatively recently that the Maillard reaction also occurs in the human body, evidence has already been provided for a series of structural and functional changes in fructosylated proteins. However, in the foreseeable future, it will continue to prove difficult to show that, from the confusing multiplicity of Maillard products, specific, defined substances are responsible for the complex processes of aging. Current efforts aim particularly to hinder the undesirable Maillard reaction in the human organism and thus the "Verzuckerung" of man and its consequences during his or her life time.

We are greatly indebted to Prof. Dr. K. D. Gerbitz, Dr. B. Olgemöller, and Dipl.-Chem. S. Prytulla for critically reading the manuscript and to Prof. Dr. Th. Severin for many helpful comments.

The Chemistry of Interstellar Space

By Eric Herbst*

Within the last ten to twenty years, radioastronomers have discovered the existence of almost 100 different molecules in interstellar space. Ranging in complexity from two to thirteen atoms, these molecules are found in cold, rarefied regions called interstellar clouds, which are giant accumulations of gas and dust located in our galaxy as well as many others. Interstellar clouds are also the birthplaces of future generations of stars and are of great interest to astronomers. The observation of the large sample of gaseous molecules, detected mainly via their rotational spectral patterns, tells astronomers about the detailed physical conditions in interstellar clouds, and tells chemists about the extent of molecular synthesis possible under the seemingly harsh conditions of low temperature and density. The molecules are mainly organic in nature and comprise species known to be both stable and common in the laboratory as well as those both unstable and uncommon under terrestrial conditions, including radicals and molecular ions. Although the gas phase of interstellar clouds is well studied via spectroscopic techniques, the dust particles are much more poorly characterized via their scattering and absorption of visible radiation as well as some broad resonances in the ultraviolet and infrared regions of the spectrum. It is normally thought that these submicron-sized particles consist of cores that are composites of silicate and carbonaceous materials with mantles that contain material deposited from the gas such as ices of water, ammonia, and methane. In addition to the dust particles and gaseous molecules, there is some evidence for very large aromatic molecules (the so-called polycyclic aromatic hydrocarbons or PAH's) which occupy a nether region in between large gas-phase species and small dust particles. As our understanding of the chemical processes in interstellar clouds increases, it may be possible to speculate how large interstellar molecules can come into existence and whether or not there is a clear connection between interstellar chemistry and the start of life on earth.

1. Introduction

Although the existence of planets outside of the solar system has yet to be proven unequivocally, organic chemistry is known to be widespread in the universe. Almost 100 different molecular species, both organic and inorganic in nature and ranging in complexity up to thirteen atoms and possibly many more, have been discovered in between the stars, in regions of space called interstellar clouds. These interstellar clouds are large agglomerations of gas and dustlike particles which take up a significant portion of the volume of interstellar space. The largest interstellar clouds have linear dimensions in excess of 100 light years. Unless they are hot enough to emit in the visible region of the spectrum, like stars, interstellar clouds are not immediately apparent on glancing at the night sky. To a trained observer, however, cool interstellar matter is apparent because it scatters and absorbs the light of distant stars, rendering areas of the sky black. Although interstellar clouds are mainly gaseous in content, the approximately 1% of the matter in particulate form is responsible for extinguishing starlight since dust particles interact much more strongly with visible radiation than do gaseous atoms and molecules.

Not all interstellar clouds contain enough matter to extinguish background starlight completely; there are some in which visible radiation manages to penetrate. The gas in these clouds, labeled "diffuse", can be studied via optical and ultraviolet absorption spectroscopy, and it was this technique that was first used to study the interstellar medium. The existence of the interstellar radicals CH, $CH^{\oplus}$, and CN has been known for about fifty years due to this technique; an account of the early identifications can be found in *Herzberg*'s book on diatomic molecules.[1] The gas in diffuse clouds turns out to be mainly atomic in nature since the gas density is very low and since stellar radiation, which penetrates these regions, can photodissociate molecules rather rapidly by astronomical standards. In the years since the initial identification of interstellar molecules, only additional diatomic molecules such as H_2, CO, OH, and C_2 have been found via optical and ultraviolet spectroscopy to be in diffuse clouds.

The story is a very different one for those interstellar clouds in which there is sufficient interstellar matter that stellar radiation cannot penetrate. These clouds, which are labeled "dense", can only be studied at longer wavelengths, which are not extinguished by the tiny dust particles. Most of the studies of dense interstellar clouds performed to date have been accomplished by radioastronomers. The term "radioastronomy" is somewhat of a misnomer in that astronomers use it to refer to studies at all wavelengths longer than infrared, including microwave, millimeter and even submillimeter waves. Radioastronomy can be undertaken from the ground since the atmosphere is relatively benign in this spectral region, whereas infrared astronomy is strongly hindered by atmospheric attenuation due to water. The projected use of satellites to do high-resolution infrared spec-

Durham, NC 27706 (USA)

troscopy will allow infrared astronomers to study dense interstellar clouds in more detail than has previously been the case.

The temperature in most regions of dense interstellar clouds is quite low ($10 < T < 70$ K) and these regions emit only at so-called "radio" wavelengths. The emission is overwhelmingly discrete in nature and derives from the rotational spectra of gaseous molecules; a weak continuum is due both to the 3 K black-body background temperature of the universe and to the dust particles.[2] An emission spectrum of the well-studied Orion Nebula in the millimeter region of the spectrum is shown in Figure 1. Although virtually all of the high-resolution spectral lines in this figure have been identified, there is room to label only a limited number of molecules. There are continuous radio sources in our galaxy and others, and if an interstellar cloud is fortuitously located in the foreground of such a source, absorption spectroscopy can be undertaken. Although infrared radiation is not emitted from the bulk of dense interstellar clouds, these clouds are the sites of star formation since the gas and dust slowly collapse and, in localized regions, heat up sufficiently that nuclear fusion processes are initiated. Around newly formed stars and in areas in which stars are forming, hot dust particles emit a continuum in the infrared which can be used as a background source for absorption spectroscopic studies of molecules located in cooler regions in the foreground. Although this infrared technique does not yet result in spectra with a high signal-to-noise ratio from interstellar clouds, it has been used more successfully to probe selected circumstellar clouds surrounding evolved (old) stars. In the best studied of the circumstellar sources (IRC + 10216), a significant number of molecules have been discovered both in emission in the radio and absorption in the infrared.[3]

Spectra such as those shown in Figure 1 can be used to learn much about dense interstellar clouds. Molecular identification can often be made by comparing interstellar spectral transitions with those previously obtained by spectroscopists in the laboratory. However, a significant percentage of interstellar molecules are highly unusual radicals and molecular ions; these have been tentatively identified by their interstellar rotational spectra since rotational spectral frequencies are uniquely characteristic of molecular structure and, in most cases, confirmed by subsequent laboratory experiment. In addition to molecular identification, analysis of interstellar spectral lines allows a determination of the relative concentrations or "abundances" of molecules and of their temperatures.[4] Given the low gas densities, temperatures of different molecules need not all be the same, since equilibrium is not achieved. However, the derived temperatures are all quite low outside of star-forming regions. In the so-called "dark" clouds, in which star formation is not strongly evident, typical temperatures around 10 K are derived. In the so-called "giant" molecular clouds where star formation is more noticeable, of which the Orion Nebula is the best studied example, bulk temperatures of the order of 70 K are prevalent. In star-forming regions, emission from highly excited states can occur and, in addition, maser emission is far from uncommon.[5] Finally, the existence of spectral features seen in emission implies a minimum overall gas density because of the necessity that the rate of collisional excitation of excited rotational states of molecules at least equal the emission rate of the particular transitions seen. The deduced gas densities in dense interstellar clouds range from a low of 10^3 molecules cm^{-3} to a high of perhaps 10^5 cm^{-3} in regions near the centers of the clouds. In star-forming regions, much higher gas densities can be achieved. Although all of these gas densities are very low compared with the atmospheric density on the earth, the large sizes of interstellar clouds translate into huge masses, up to perhaps a million times the mass of the sun.

Although the gas phase of interstellar clouds is well characterized by spectroscopic studies, the same cannot be said of the dust particles. Based on extremely limited information, it is normally suggested that the dust particles are typically 0.1 microns in size, and composed of a refractory core (e.g., silicates) surrounded by a mantle of material deposited from the gas. The evidence derives mainly from the scattering of visible radiation, from one broad ultraviolet resonance in diffuse clouds, and from broad features in the infrared which coincide with fundamental vibrational transition frequencies.[6] Recently, a series of broad unidentified emission lines in the infrared from warm regions of the interstellar medium has been tentatively assigned to the fluorescence of large aromatic molecules which absorb ultraviolet radiation from nearby stars and reradiate it in the infrared.[7] The assignment is based on a functional group analysis and comparison with laboratory absorption spectra. The intensities and line widths are suggestive of large individual molecules contain-

Born in Brooklyn, New York, USA, on January 15, 1946, Eric Herbst received his B.A. degree in Chemistry from the University of Rochester in 1966, and his M.A. and Ph.D. degrees in Chemistry from Harvard University in 1969 and 1972, respectively. In the latter stages of his thesis work, he became interested in molecular astronomy because of the keen interest of his research supervisor, Professor William Klemperer, in this line of inquiry. After a postdoctoral research position in Professor Klemperer's laboratory, he took a second postdoctoral research position in the laboratory of Professor Carl Lineberger at the Joint Institute for Laboratory Astrophysics, University of Colorado, in the field of laser ion spectroscopy. He then accepted a faculty position in chemistry at the College of William and Mary, Williamsburg, Virginia, where he taught for six years. Since 1980, he has been in the physics department at Duke University, Durham, North Carolina, where he is currently Professor of Physics. His research interests are divided between molecular astronomy and millimeter-wave spectroscopy. During the year 1988–89, he was at the University of Cologne, FRG, as an Awardee of the Alexander von Humboldt Stiftung.

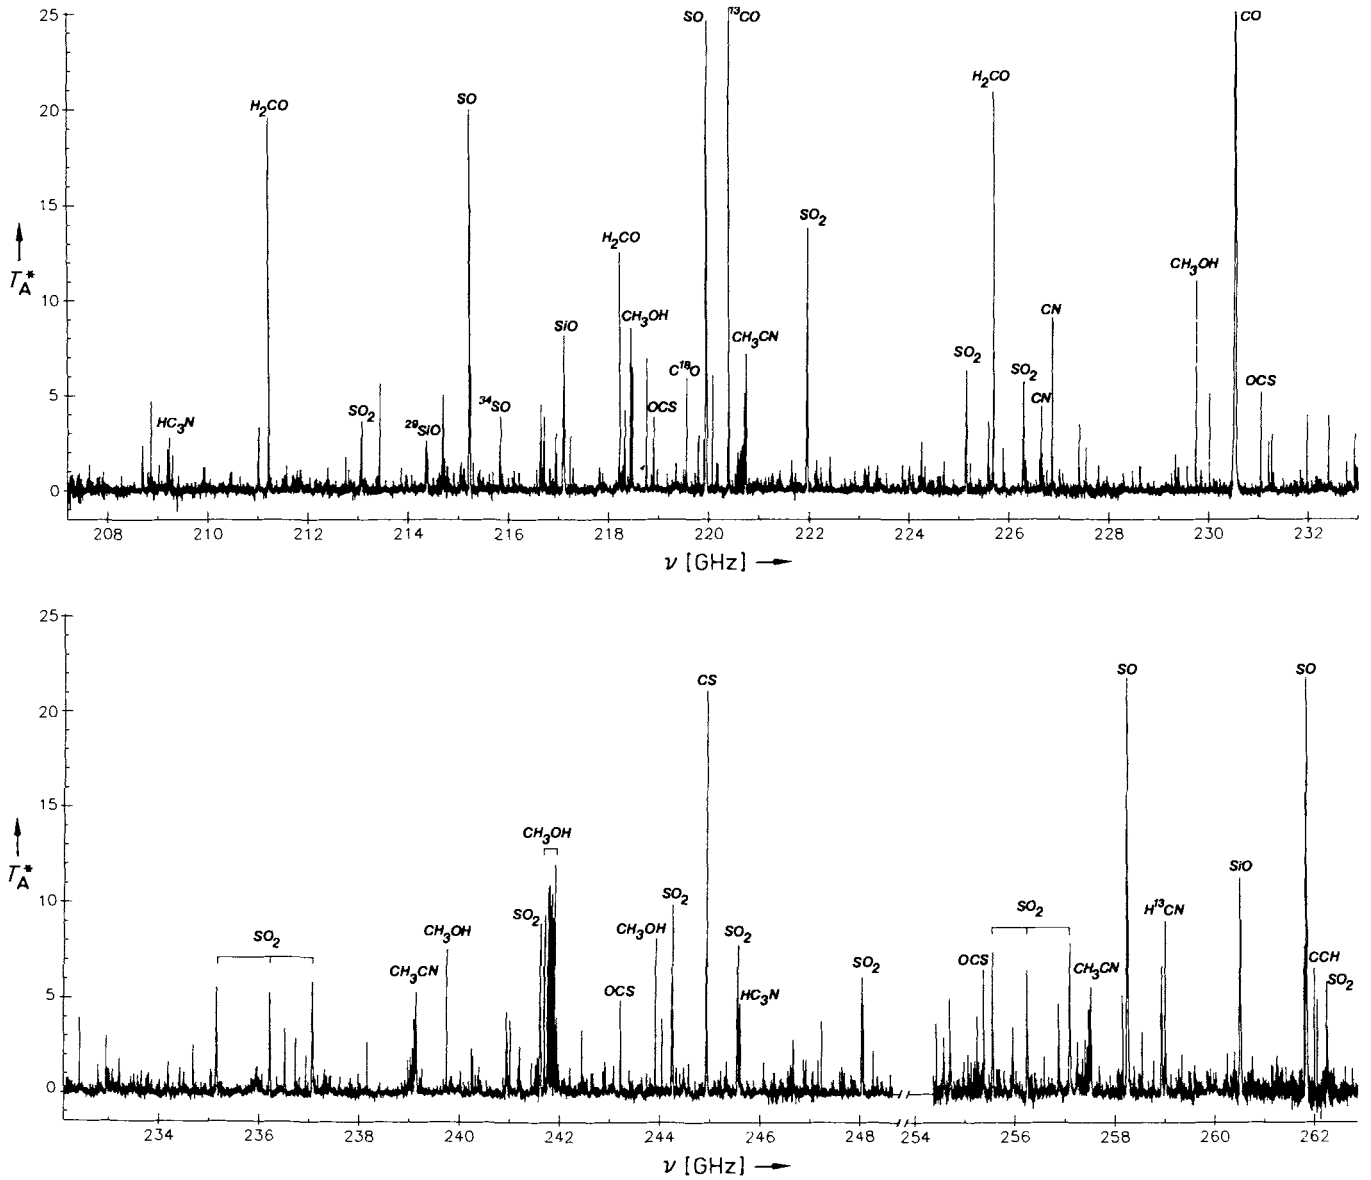

Fig. 1. The millimeter-wave spectrum of the Orion Nebula in the direction of the so-called Kleinmann-Low area. Rotational spectra from many molecules are seen. Taken from [69]. ν = frequency, T_A^* = antenna temperature, a measure of emission intensity.

ing perhaps 50 carbon atoms rather than graphitic particles and the molecules are known as polycyclic aromatic hydrocarbons (PAH's). These molecules are rather stable against ultraviolet radiation and will not be destroyed rapidly by the ultraviolet photons which it is thought lead to the infrared fluorescence which is their signature. Although the spectral assignment is reasonable, laboratory study of the efficacy of the proposed mechanism for the infrared emission of radiation is a prerequisite for further progress. PAH's have also been suggested as the source of a series of unidentified diffuse spectral features seen in absorption spectroscopy in diffuse interstellar clouds.[8]

A list of the nearly 90 interstellar molecules discovered from high-resolution spectral features is given in Table 1. In addition, many of these species have been detected in more than one isotopic variant with deuterium and ^{13}C being the most frequent isotopic atoms encountered. Most of the molecular species have been detected via radio-astronomical

spectra in dense interstellar clouds although I have also included optical and ultraviolet detections in diffuse clouds as well as infrared detections in circumstellar sources. As can be seen from Table 1, many of the molecules are indeed standard organic species, of which the most complex is $H(C\equiv C)_5CN$, a linear unsaturated nitrile. A significant number of molecular ions have been discovered as well. Indeed, the initial discovery of the ion $HCO^{\oplus}$ has helped to promote a vigorous laboratory effort in both infrared and microwave spectroscopy of molecular ions. The story behind the $HCO^{\oplus}$ discovery is of some interest. The original detection of a single line at 89.190 GHz (labeled "X-ogen" by its discoverers) prompted my thesis adviser, Professor *William Klemperer* at Harvard University, to suggest $HCO^{\oplus}$ as the carrier of the line, based on estimated bond lengths (reasonably correct) and ideas concerning the chemistry (not correct).[9] The initial suggestion, derided in some quarters, was confirmed by both the later detection of the analogous line of $H^{13}CO^{\oplus}$ in the interstellar medium[10] and the laboratory detection by *Woods* et al.[11]

In addition to molecular ions, a large number of carbon-containing radicals have been discovered in interstellar space. Prominent among these are the linear C_nH radicals, which are alkynes with one hydrogen removed. Also prominent are the linear organo-sulfur radicals CCS and CCCS, and the linear organo-silicon radical CCCCSi. Unusual ring species include cyclopropenylidene (c-C_3H_2) and SiC_2, as well as a cyclic form of C_3H which is metastable, since it lies higher in energy than the linear species. Another prominent metastable species is HNC. Although these molecules seem bizarre to the terrestrial chemist, their existence in space is proven beyond any doubt and testifies to the differing physical conditions in the interstellar and terrestrial environments.

What are the relative concentrations of the molecules in dense interstellar clouds? By far the most abundant molecule is H_2; it is so much more abundant than any other species that its abundance can be equated to the total gas density. Molecular hydrogen has no dipole moment and consequently does not possess a strong rotational spectrum. However, there is enough of it so that its weak quadrupolar transitions have been identified. In addition, its ultraviolet spectrum in diffuse clouds has been seen and indicates that even in these sources, it is a significant percentage of the total gas density. The next most abundant molecule is carbon monoxide, with a relative concentration ("fractional abundance") of 1×10^{-4} compared with H_2. All more complex molecules have even lower fractional abundances, which vary somewhat depending on which source one is looking at. Fractional abundances for the well-studied source TMC-1 (Taurus Molecular Cloud I) are shown in Table 2. Although organic molecules possess low abundances in a fractional sense, the large masses of interstellar clouds tell us that the absolute amount of material in organic form is very large indeed compared with the amount of such matter on earth. The low fractional abundance of $HCO^{\oplus}$, the most abundant molecular ion yet detected, indicates that the clouds are overwhelmingly neutral in composition.

Why are interstellar clouds dominated by hydrogen? Unlike the earth, which possesses a weak gravitational field, most objects in the universe, be they stars or interstellar clouds, have gravitational fields strong enough to retain atoms independent of their mass. In such objects, a wealth of spectroscopic studies, mainly on stars, shows hydrogen to be the dominant element, with helium in second place, and heavy elements such as carbon, oxygen, nitrogen lower in abundance by factors of 10^4 or so. The distribution of matter among the elements derives from the Big Bang, in which only hydrogen and helium were produced in significant abundance, and nuclear fusion in stars, in which heavier elements are synthesized. Dying stars then release these heavier elements into the interstellar medium, either gently or explosively, and new generations of stars are produced that incorporate them. It is interesting to note that astronomers, whose training in chemistry must be minimal, refer to all elements heavier than helium as "metals".

[a] Fractional abundances are expressed with respect to H_2; a(-b) signifies $a\times10^{-b}$. [b] Theoretical results mainly from the calculations of [52b]. Results of sulfur-containing species from [66].

Although it is difficult to obtain the elemental distribution in the gas phase of dense interstellar clouds, since the material is dominated by molecules, it is possible to obtain such information from diffuse cloud studies. Lists of elemental abundances that pertain to normal stars as well as to the gas phase of diffuse clouds are shown in Table 3. The diffuse

Table 3. Elemental abundances in the gas phase[a].

Element	Abundance in diffuse clouds[b]	Abundance in stars
H	1.0	1.0
He	0.14	0.10
O	1.8(-4)	6.9(-4)
C	7.3(-5)	4.2(-4)
N	2.1(-5)	8.7(-5)
S	8.0(-6)	1.6(-5)
Si	8.0(-7)	4.5(-5)
Fe	3.0(-7)	3.2(-5)
Na	2.0(-7)	1.9(-6)
Mg	7.0(-7)	3.2(-5)

[a] The expression a(-b) signifies $a\times10^{-b}$. [b] The abundances are by number not mass. In dense clouds it is now normally assumed that the elements, S, Si, Fe, Na, and Mg are additionally depleted from the diffuse cloud values by two orders of magnitude.

cloud abundances are depleted in "metallic" elements, which are incorporated into the dust particles. It is often assumed that elemental abundances in the gas phase of dense clouds are similar to those in diffuse clouds with the exception of "heavy metals" such as S, Si, and actual metals, which are further depleted. Astronomers often refer to two sets of "heavy metal" abundances—"high" and "low"—which differ by two orders of magnitude.

Despite the uncertainty in our knowledge of the exact elemental abundances in the gas phase of dense clouds, the large abundance of hydrogen suggests that molecular hydrogen will be dominant and the much smaller abundances of carbon, oxygen, and nitrogen suggest that molecules with these elements will have small fractional abundances. Indeed, the fractional abundance of CO suggests that much of the elemental abundance of carbon resides in this species.

Although the relative abundances of the elements are a boundary condition on the molecular abundances, they do not tell us how the molecules are synthesized. In the next section of the article, the chemical processes that synthesize molecules are discussed.

2. The Formation of Interstellar Molecules

Before a discussion of how interstellar molecules are synthesized, it is necessary to ask where they are formed. Basically there are two possibilities: they are formed in the interstellar clouds where they are seen or they are formed elsewhere. Why should we consider their formation elsewhere? First, physical conditions in dense clouds would not appear to be conducive to chemistry. The very low gas densities mean that collisions between atoms and molecules in the gas do not occur billions of times per second, as on the earth, but instead occur once every day or even longer, depending on the cloud density. In addition, the low temperatures would appear to indicate that the vast majority of collisions will not be reactive. Secondly, conditions in stellar atmospheres, especially extended atmospheres of older stars, include higher densities and temperatures. These regions are known to be the birthplace of dust particles, which are then blown out into space.[12] In addition, polyatomic molecule formation in certain types of extended atmospheres is known to take place.[3, 13] It is therefore tempting to suggest that these molecules can also be blown out into space and eventually form the material in interstellar clouds. However, this scenario cannot be correct. Although it is certainly true that the gas and dust ejected from elder stars is the material from which interstellar clouds are formed, it is also true that ultraviolet radiation in interstellar space is sufficiently intense to photodissociate small molecular species in time periods extremely short compared with the time necessary to travel from a star to an interstellar cloud.[14] Thus, the material that forms interstellar clouds will probably consist of dust particles, which can withstand ultraviolet radiation, and atoms. It is also possible that PAH molecules are large enough to resist photodissociation by ultraviolet radiation for long periods of time. Despite the apparent difficulties, the synthesis of the smaller gas-phase molecules seen in interstellar clouds must be accomplished locally. Once produced inside dense interstellar clouds, molecules are shielded somewhat from the interstellar ultraviolet radiation field by the dust particles.

There are two types of chemical processes that can synthesize molecules from atoms in interstellar clouds—gas-phase reactions and reactions on the surfaces of dust particles. Let us consider gas-phase reactions first. Although it shall be shown in Section 2.2 that gas-phase reactions can indeed account for the abundances of almost all molecules seen outside of star-forming regions, it is difficult to account for the primary step in molecule formation—the synthesis of diatomic species from the initial atomic gas using these reactions. Under the low-density conditions of interstellar clouds, the formation of diatomic species can only occur when two atoms stick together in a binary collision; so-called "three-body" collisions, in which two bodies come together to form an intermediate "collision complex" which is then stabilized by inelastic collision with a third body, while prominent in the laboratory, do not occur.[15] Under low-density conditions, the only manner in which the collision complex can be stabilized is via the emission of radiation. This process, known as "radiative association", is inefficient for atom-atom collisions. In particular, the radiative association of two hydrogen atoms to form molecular hydrogen occurs in fewer than one in 10^{10} collisions and cannot produce enough H_2 to account for its overwhelmingly large abundance.[2] Although several other gas-phase routes to H_2 have been suggested, it is clear that interstellar H_2 must be formed via reactions on the surfaces of dust particles.[16] The mechanisms for this process and other possible reactions on dust surfaces are considered in Section 2.1. In this discussion, the possibility that the dust particles are some type of universal catalyst is ignored (although some astronomers have come perilously close to such an assertion) and the assumption that gas-phase molecules are held onto the dust particles by weak physical adsorption forces is utilized. The possibility of chemisorption for selected species cannot be ruled out.

2.1. Surface Chemistry on Interstellar Dust Particles

The process by which two hydrogen atoms form a hydrogen molecule consists of several steps. First, the two hydrogen atoms must stick to the surface of a dust particle. This is an efficient process, unlike the sticking of hydrogen atoms to each other, because the dust particles are macroscopic particles that possess large numbers of energy modes which can accept the kinetic energy of the impacting hydrogen atoms and convert it into an increase in temperature. Once the hydrogen atoms have stuck to the grain, they must recombine before desorption occurs. Migration on the dust surfaces can occur via a classical random walk mechanism. For the special case of light hydrogen atoms, a more rapid quantum-mechanical tunneling process can occur.[16] Once the hydrogen atoms are in the vicinity of one another, they can form a chemical bond by imparting energy to the dust particle, which then increases its temperature once again. The final step in the synthesis is the thermal evaporation of the newly formed hydrogen molecule. The likelihood that these processes indeed occur has been strengthened by numerous laboratory studies. Under typical dense interstellar cloud conditions, formation of H_2 takes roughly 10^5 years, which

is approximately the time scale for a collision between an individual H atom and a grain. The process accounts for the total conversion of H into H_2 since the molecule, once formed, is relatively immune from photodissociation even under diffuse cloud conditions because it is self-shielded.[17]

If H_2 is formed on grain surfaces, what about other molecules? One must remember that hydrogen atoms are somewhat unique on grain surfaces because of their lightness and consequent ability to tunnel from site to site. If H atoms can rapidly find each other on grain surfaces, then they can also find heavier, more stationary atoms of high abundance such as C, O, and N. The sticking of H atoms to these heavier species will produce the radicals CH, OH, and NH. Subsequent sticking reactions between these species and H atoms should also occur without activation energy, leading eventually to the saturated molecules CH_4, H_2O, and NH_3.[18] The formation of other molecules on dust surfaces is not well understood and a variety of ideas have been presented.[19-23] *Allen* and *Robinson*[19] have listed a large number of reactions which they feel occur on grains. These reactions are sticking processes that occur between atoms and/or radicals so that activation energy barriers are not present. *Allen* and *Robinson* consider only very small grains so that even relatively heavy species can migrate appreciably. Large molecules are synthesized via sequences of sticking reactions in which radicals are formed as well as more stable, and therefore inert isomers. *Tielens* et al.[6, 20] consider larger (standard) grains and therefore are more concerned with which species can migrate appreciably. In their models, only H, H_2, C, N, and O can undergo appreciable migration and react with other, including more stationary species. In addition, they show that certain reactions with small amounts of activation energy can occur. Complex molecules are not built up in their approach. Finally, *Greenberg* et al.[21, 22] have shown from laboratory studies that complex organic molecules can be synthesized via photochemical processes when cold surfaces containing simple species are subjected to intense photon fluxes. These authors argue for a similar chemistry in the interstellar medium despite the very different time scales and far more modest photon fluxes involved.[23]

It can be seen that there is no unanimity of opinion on the synthesis of most molecules on dust particles. In my view, if it is correct that H_2 is formed on grains, it is also most probable that simple saturated species such as water, ammonia, and methane are also formed. The formation of more complex species than these is problematical. In addition to the problem of not really knowing which species are produced on dust particle surfaces, an even more vexing problem is how these species can be desorbed from the dust particles at the low temperatures prevailing in non-star-forming regions of interstellar clouds. Since evaporation is far too slow for molecules heavier than H_2, other mechanisms must be considered. These mechanisms can be divided into two types—continual and intermittent.[24] A variety of continual mechanisms which are nonthermal in origin have been considered; these include photodesorption, grain-grain collisions, grain explosions, use of the exothermicity of chemical reactions either directly or indirectly (grain heating), sputtering by cosmic rays, etc. None of these has been shown conclusively to operate efficiently under interstellar conditions although much research remains to be undertaken. The intermittent mechanisms have to do with the process of star formation. When stars form or are forming, the rise in temperature and the existence of shock waves can drive the desorbed material off interstellar dust particles.[25, 26] In my view, the intermittent mechanisms, especially simple thermal desorption based on a higher temperature, are on a more solid footing. In the simplest scenario then, heavy molecules are not appreciably released from dust particle surfaces unless star formation occurs nearby. One should then look for any evidence of heavy molecules formed on dust grains and desorbed into the gas in the vicinity of protostars and newly formed stars. In regions distant from star-forming regions, there may be no evidence at all in the gas phase of the chemistry of heavy molecules occurring on the surfaces of grains. Since the largest number of interstellar molecules are discovered under such conditions, it is most probable that they are formed in the gas phase.

2.2. Gas-Phase Interstellar Chemistry

Once molecular hydrogen is formed on the surfaces of dust particles and evaporates into the gas phase, gas-phase chemical processes leading to complex molecules occur. These processes are restricted in non-star-forming regions by the low gas densities and temperatures to binary reactions without activation energy. Ternary reactions, in which a collision complex is stabilized via an inelastic collision with a third body, are important in the laboratory[15] but do not occur at the low densities of even the most dense interstellar clouds. In the realm of neutral-neutral chemistry, most reactions have appreciable activation energy even if exothermic. These reactions have rate coefficients k that are given by the simple Arrhenius formula [Eq. (1)].

$$k = A(T)\exp(-E_a/kT) \tag{1}$$

T is the temperature, k is the Boltzmann constant, E_a is the activation energy, and $A(T)$ is a weakly temperature-dependent factor which derives from the actual shape of the reaction potential surface as the reactants approach one another. Activation energies of 1–5 eV are normal; when these are inserted into the right-hand-side of Equation 1, at say a temperature of 10 K, it is easily seen that the rate coefficient approaches zero. As an example, consider a reaction with an activation energy of 1 eV. At a temperature of 10 K, the factor appearing in the exponential is -1160! Since collisions between species are themselves rare in interstellar clouds, it is clear that only efficient gas-phase reactions with no activation energy need be considered.

What types of reactions do not possess activation energy? Probably reactions involving atoms and neutral radicals obey this constraint. However, if these were the only reactions to be considered, it would be difficult if not impossible to produce most of the observed interstellar molecules. In addition, there is little experimental evidence concerning the rates of radical reactions at very low temperatures and current theoretical ideas are widely divergent. More important than neutral-neutral reactions are so-called ion-molecule re-

actions, in which one species possesses a charge (e.g., Equation 2, where the species are atomic or molecular). These

$$A^{\oplus} + B \rightarrow C^{\oplus} + D \quad (2)$$

reactions have been studied in the laboratory by a variety of investigators utilizing different experimental techniques.[15,27-30] A temperature range from considerably above room temperature to near 1 K has been probed and it is found that the vast majority of exothermic ion-molecule reactions do not have rate coefficients that have an exponential dependence on temperature as seen in Equation 1; rather, their rate coefficients are large and only weakly dependent on temperature. The rapidity of ion-molecule reactions can be understood in terms of very attractive long-range potential surfaces that often lead to long-lived collision complexes (potential minima) rather than transition states (potential maxima). The simplest case occurs when the neutral reactant B does not possess a permanent dipole moment. Then, if the long-range attraction is dominated by the ion-induced dipole force and if it is assumed that every strong collision leads to reaction, a simple formula for the rate coefficient is obtained which was first derived by *Langevin*[31] [Eq. (3)]. α is the polarizability of the neutral

$$k = 2\pi e(\alpha/\mu)^{1/2} \approx 10^{-9}\ \mathrm{cm^3\ molecule^{-1}\ s^{-1}} \quad (3)$$

species (in cm^3), μ is the reduced mass of the reactants (in gm), and e is the electronic charge in esu. Note that this expression shows no temperature dependence at all, in good agreement with experiment, and that the absolute value of the rate coefficient is 10–100 times the size of the standard "gas kinetic" value for neutral-neutral reactions at room temperature. Thus, exothermic ion-molecule reactions are rapid and will occur at low temperatures. From the point of view of interstellar chemistry, reactions involving neutrals with permanent dipole moments are even better in that their rate coefficients have been found to increase with decreasing temperature, typically as $T^{-1/2}$.[32-33] Unfortunately, no simple formula can be derived in this case, although much theoretical interest has centered on ion-polar neutral reactions.[34-35] Rate coefficients for these processes can reach $10^{-7}\ \mathrm{cm^3\ molecule^{-1}\ s^{-1}}$ at 10 K.

The above discussion makes it clear that ion-molecule reactions can occur rapidly under interstellar conditions. What is still unclear is (1) how ions are produced in low-temperature clouds and (2) how ion-molecule reactions can actually synthesize polyatomic species. Ions are produced mainly via cosmic ray bombardment.[36] Cosmic rays are high-energy nuclei, mainly protons, and formed in high-energy events such as supernovae; they penetrate dense interstellar clouds, unlike ultraviolet photons. These species ionize neutral atoms and molecules in their paths. The most important ionization process involves the dominant neutral H_2 [Eq. (4)], and leads to the formation of the $H_2^{\oplus}$ ion.[36] The

$$H_2 + \text{cosmic ray} \rightarrow H_2^{\oplus} + e + \text{cosmic ray} \quad (4)$$

first-order rate coefficient for cosmic-ray-induced ionization is designated ζ by astronomers and is equal to approximately $10^{-17}\ s^{-1}$; this small number means that interstellar clouds are not bombarded by large numbers of cosmic rays, which, of course, would destroy rather than enhance molecular buildup, but rather "tickled" by small numbers of these species.

After the $H_2^{\oplus}$ ion is formed, it is "immediately" destroyed by reaction with ubiquitous H_2 via the well-studied reaction shown in Equation 5 to produce the simplest polyatomic ion $H_3^{\oplus}$.

$$H_2^{\oplus} + H_2 \rightarrow H_3^{\oplus} + H \quad (5)$$

In general, if an ion can react with H_2, no other reaction need be considered because reaction with H_2 is so rapid due to the ubiquity of this neutral species. The rate for reaction with H_2 in a standard dense cloud of gas density $n = 10^4\ \mathrm{cm^{-3}}$ is $10^{-9}\ \mathrm{cm^3\ s^{-1}}$ times $10^4\ \mathrm{cm^{-3}}$ or $10^{-5}\ s^{-1}$, which leads to a time scale of $10^5\ s \approx 1$ day. This is "immediate" by interstellar standards! When $H_3^{\oplus}$ is formed, it can react with a wide variety of other neutral species present in the primeval mix. Let us first follow what happens if reaction with oxygen atoms occurs. The following sequence of reactions leading to $H_3O^{\oplus}$ is well-studied in the laboratory [Eqs. (6)–(8)], and consists of a "proton transfer" reaction followed by two "H atom" transfer reactions.

$$H_3^{\oplus} + O \rightarrow OH^{\oplus} + H_2 \quad (6)$$

$$OH^{\oplus} + H_2 \rightarrow H_2O^{\oplus} + H \quad (7)$$

$$H_2O^{\oplus} + H_2 \rightarrow H_3O^{\oplus} + H \quad (8)$$

The oxonium ion $H_3O^{\oplus}$, a saturated species, is resistant to further reaction with H_2, and reacts much more slowly with other species, including the dominant carrier of negative charge in dense clouds. This is normally assumed to be free electrons, formed primarily via cosmic ray bombardment, although the suggestion has been made that if polycyclic aromatic hydrocarbons are present and abundant in dense clouds, electrons will stick to them to form negatively charged ions more abundant than free electrons.[37] Ignoring this possibility for the moment, we must consider the reaction between $H_3O^{\oplus}$ and electrons. Recombination reactions between positive molecular ions and electrons have been studied extensively in the laboratory[38] and proceed rapidly in almost all cases with rate coefficients in the range 10^{-6}–$10^{-7}\ \mathrm{cm^3\ molecule^{-1}\ s^{-1}}$ at room temperature and with a weak inverse temperature dependence. The products of these reactions are neutral fragments rather than the parent neutral species and the reactions are termed "dissociative recombination" reactions. However, it is only recently that laboratory measurements of the neutral-product branching ratios have begun to be available and interstellar chemists previously had to estimate these branching ratios based on a variety of often conflicting simple theoretical models.[39] The simplest such model suggests that there is a 50% probability that one hydrogen atom will dissociate from the parent neutral, a 50% probability that two hydrogen atoms (or an H_2 molecule) will dissociate from the parent neutral, and that breakage of multiple heavy atom-heavy atom bonds is unlikely. This model predicts for the case of $H_3O^{\oplus}$ + e that OH and H_2O will each be produced on 50% of collisions. The reaction between oxonium ions and electrons has now been

studied via laser-induced fluorescence of product OH radicals[40] and found to produce the radical OH (+ either H_2 or 2 H) on 65 ± 10% of collisions, with water presumably being formed on ≤ 35% of collisions since three-body product channels are also exothermic. Thus, $H_3O^{\oplus}$ is a precursor to interstellar OH and (presumably) H_2O as well. Once formed, these species are depleted by gas-phase reactions. Water is a stable neutral species and can only react via ion-molecule reactions, whereas OH is depleted via neutral-neutral reactions as well and, hence, will have a lower concentration.

The ion-molecule synthesis of water is an example of how a polyatomic neutral can be produced via such reactions; first a complex ion is synthesized, then some of this complexity is lost when the ion recombines with electrons. Laboratory studies are currently underway in several places to completely determine the neutral products of a variety of dissociative recombination reactions such as that of $H_3O^{\oplus}$ and electrons via the techniques of laser-induced fluorescence and ultraviolet absorption spectroscopy. Preliminary results indicate a complex pattern in which generalizations are difficult. If the dominant carrier of negative charge in dense interstellar clouds is not electrons but rather $PAH^{\ominus}$ (negatively charged polycyclic aromatic hydrocarbons), the final neutral products of ion-molecule syntheses will form from ion-ion neutralization processes. Although the products of such reactions are not known, it appears on theoretical grounds that in general they will involve less dissociation of the parent neutral than do ion-electron reactions.[39c]

Ion-molecule chemical pathways, whether they synthesize inorganic species, hydrocarbons, or more complex organic molecules, often result in highly unusual neutrals by terrestrial standards. The principal reason for this lies in the assumption that dissociative recombination reactions produce assorted neutral products including radicals (e.g., OH) and metastable isomers (e.g., HNC) seen in Table 1. In the main, this assumption remains to be tested by experimental investigation.

Let us now consider the synthesis of organic molecules via ion-molecule reactions. One initiating reaction is that between $H_3^{\oplus}$ and neutral atomic carbon [Eq. (9)], which has not yet been studied in the laboratory due to the difficulty in producing C. However, ab initio quantum-chemical studies

$$C + H_3^{\oplus} \rightarrow CH^{\oplus} + H_2 \quad (9)$$

show that reaction (9) proceeds readily.[41] Another initiating reaction of importance starts with $C^{\oplus}$ rather than C since, because of the ease in photoionizing atomic carbon, it is probable that the initial atomic population of carbon is mainly in the form of $C^{\oplus}$ once it reaches dense interstellar clouds. Interestingly, there is no exothermic reaction between $C^{\oplus}$ and H_2 and the only possibility under low-temperature conditions is the radiative association reaction[42] [Eq. (10)] in which the $CH_2^{\oplus}$ complex is stabilized by emission of a photon.

$$C^{\oplus} + H_2 \rightarrow CH_2^{\oplus} + h\nu \quad (10)$$

Until recently, this and other radiative association reactions had been studied by theoretical methods only due to their low efficiency and the fact that low gas densities are needed in the laboratory so that three-body association does not dominate.[43] The theoretical methods show that radiative association tends to become more probable as temperature decreases ($k \propto T^{-n}$; $n \geq 2$), as the size of the collision complex increases, and as its dissociation energy increases. For the three-atom system in Equation 10, the latest calculated rate coefficient is $\approx 10^{-15}$ cm^3 molecule^{-1} s^{-1} at 10 K.[44,45] Given the standard Langevin value for the collision rate coefficient, the probability of radiative association is approximately one collision in 10^6. Although this is a low number, it is higher than in the case of two hydrogen atoms mentioned above. In addition, the large abundance of H_2 in dense interstellar clouds makes this process competitive. Very recently, the process shown in Equation 10 has been studied in the laboratory in a low-pressure ion trap and found to have a rate coefficient in reasonable agreement with the theoretical value.[46]

Once $CH^{\oplus}$ and $CH_2^{\oplus}$ are formed, $CH_3^{\oplus}$ is produced "immediately" via well-studied H-atom transfer reactions [Eqs. (11) and (12)]. The H-atom transfer reaction between

$$CH^{\oplus} + H_2 \rightarrow CH_2^{\oplus} + H \quad (11)$$

$$CH_2^{\oplus} + H_2 \rightarrow CH_3^{\oplus} + H \quad (12)$$

$CH_3^{\oplus}$ and H_2 is endothermic and does not occur under interstellar conditions. A slower radiative association process has been proposed and its rate coefficient at 10 K calculated[45] to be $\approx 10^{-13}$–10^{-14} cm^3 molecule^{-1} s^{-1} or even greater.[47] The theoretical values have been somewhat corroborated by two recent and somewhat conflicting experimental values.[48,49] Once $CH_5^{\oplus}$ is produced via radiative association, it can react with electrons to form a variety of single-carbon-atom hydrocarbons such as methane [Eq. (13)].

$$CH_5^{\oplus} + e^{\ominus} \rightarrow CH_4 + H,\ CH_3 + H_2, \text{ etc.} \quad (13)$$

In addition, methane is known to form via the ion-molecule reaction shown in Equation 14; the reactant CO is formed by a series of neutral-neutral and ion-molecule reactions.

$$CH_5^{\oplus} + CO \rightarrow CH_4 + HCO^{\oplus} \quad (14)$$

Once simple hydrocarbons are synthesized, more complex ones can be produced by several different pathways. A well-studied type of reaction in the laboratory, called "carbon insertion",[28] is important in dense interstellar clouds. In this type of reaction, $C^{\oplus}$ reacts with a simple hydrocarbon to produce a more complex hydrocarbon ion and one or more hydrogen atoms. An example is given in Equation 15.

$$C^{\oplus} + CH_4 \rightarrow C_2H_2^{\oplus} + H_2;\ C_2H_3^{\oplus} + H \quad (15)$$

Two-carbon-atom hydrocarbon ions can possibly also be synthesized via analogous insertion reactions involving neutral carbon atoms and hydrocarbon ions; however, these processes have yet to be studied in the laboratory. A third synthetic mechanism involves the so-called condensation reactions in which hydrocarbon ions and neutrals react to

form larger hydrocarbon ions as well as hydrogen atoms or molecules. Equation 16 gives an example; in general, con-

$$CH_3^{\oplus} + CH_4 \rightarrow C_2H_5^{\oplus} + H_2 \quad (16)$$

densation reactions are less efficient than the other two mechanisms under interstellar conditions. Yet a fourth possibility involves radiative association reactions between hydrocarbon ions and neutrals; there is some experimental evidence for this in low-pressure ion cyclotron resonance experiments[28] but further experimental studies are necessary to confirm theoretical determinations of rate coefficients.

After two-carbon-atom hydrocarbon ions are produced, they can react with H_2 or neutrals of lesser abundance, or dissociatively recombine with electrons to produce neutral hydrocarbons such as the radical C_2H or acetylene. In general, reactions between hydrocarbon ions with more than one carbon atom and H_2 do not occur except for very unsaturated ions,[50] presumably because they are endothermic. Thus, for two-carbon-atom ions only $C_2^{\oplus}$, $C_2H^{\oplus}$, and $C_2H_2^{\oplus}$ react with H_2; for $C_2H_2^{\oplus}$, it is currently unclear whether the reaction is predominantly a normal one (to produce $C_2H_3^{\oplus}$ + H) or an associative one. The net result of the difficulty in hydrogenating ions produced in reactions such as (15) is that unsaturated hydrocarbon ions and neutrals are predicted to be dominant despite the large abundance of H_2. This prediction is in agreement with observational results in non-star-forming regions (Table 2).

Let us continue on to three-carbon-atom hydrocarbons. The well-known ion-molecule reaction shown in Equation 17

$$C^{\oplus} + C_2H_2 \rightarrow C_3H^{\oplus} + H \quad (17)$$

produces an ion with a linear backbone which does not react rapidly with hydrogen but does associate with it under high-pressure laboratory conditions. The association, which leads 50% of the time to a cyclic form of the ion $C_3H_3^{\oplus}$, presumably occurs radiatively under low-density interstellar conditions.[51] Once the cyclic $C_3H_3^{\oplus}$ ion is produced, it can recombine dissociatively with electrons to form the widespread interstellar ring molecule c-C_3H_2 (cyclopropenylidene, [Eq. (18)].

$$c\text{-}C_3H_3^{\oplus} + e^{\ominus} \rightarrow c\text{-}C_3H_2 + H \quad (18)$$

Ion-molecule syntheses analogous to what has been described here have been written down for hydrocarbons with up to nine carbon atoms.[52] In general, as the size of the hydrocarbon increases, the amount of laboratory information decreases and it is necessary to deduce reaction pathways by analogy with other reaction studies.

Organic molecules with atoms other than carbon and hydrogen can be formed via reactions that involve hydrocarbon neutrals or ions. For example, organonitrogen species can be formed via ion-atom reactions between hydrocarbon ions and nitrogen atoms; a well-studied example is shown in Equation 19,[53] which presumably leads to cyanoacetylene (HC_3N), a well-known interstellar molecule, via the dissociative recombination channel [Eq. (20)].

$$N + C_3H_3^{\oplus} \rightarrow C_3H_2N^{\oplus} + H \quad (19)$$

$$C_3H_2N^{\oplus} + e \rightarrow HC_3N + H \quad (20)$$

Other organonitrogen species can be formed from the simple precursors HCN and NH_3, both of which are themselves formed by series of ion-molecule reactions.[54] Examples include the above radiative association reactions [Eqs. (21) and (22)], which are calculated to be sufficiently rapid at low

$$CH_3^{\oplus} + HCN \rightarrow CH_3CNH^{\oplus} + h\nu \quad (21)$$

$$CH_3^{\oplus} + NH_3 \rightarrow CH_3NH_3^{\oplus} + h\nu \quad (22)$$

interstellar temperatures, due to the large size and bond energies of the collision complexes, to lead to large amounts of methyl cyanide and methylamine after dissociative recombination.[52, 55]

Oxygenated organic molecules are also formed via a variety of ion-molecule processes. The production of interstellar methanol for example is thought to proceed via a radiative association reaction[52, 55] [Eq. (23)] followed by dissociative recombination, and interstellar ketene is thought to be synthesized via a radiative association reaction [Eq. (24)], followed by dissociative recombination.

$$CH_3^{\oplus} + H_2O \rightarrow CH_3OH_2^{\oplus} + h\nu \quad (23)$$

$$CH_3^{\oplus} + CO \rightarrow CH_3CO^{\oplus} + h\nu \quad (24)$$

All of the association reactions [Eqs. (21)–(24)] have only been studied under high-pressure three-body conditions in the laboratory. A detailed discussion of ion-molecule synthetic pathways to various types of molecular products has recently been published.[52]

2.3. Deuterium Isotopic Fractionation

Ion-molecule processes also explain to a great extent the considerable isotopic fractionation observed in interstellar clouds, especially regarding deuterium. Although the deuterium-to-hydrogen abundance ratio, which is a remnant of the Big Bang, is only of the order of 10^{-5}, the abundance ratio of singly deuterated to normal molecules in dense interstellar clouds can rise orders of magnitude above this for trace constituents of the clouds. The mechanism for such strong isotopic fractionation is the difference in zero-point energy between ordinary and deuterated species. In dense clouds, the repository of deuterium is mainly HD, and the HD to H_2 abundance ratio is approximately twice the Big Bang D/H value, or $\approx 3 \times 10^{-5}$. Consider the well-studied ion-molecule reaction between $H_3^{\oplus}$ and HD [Eq. (25)], which is exothermic by an energy equivalent to a few hundred Kelvin due to zero-point energy differences.

$$H_3^{\oplus} + HD \rightarrow H_2D^{\oplus} + H_2 \quad (25)$$

At temperatures significantly lower than this exothermicity, the back reaction will have a much slower rate than the forward reaction [Eq. (1)] and the equilibrium will lie far to

the right. Thus, it is to be expected that at low temperatures the $H_2D^{\oplus}/H_3^{\oplus}$ ratio will be much larger than 3×10^{-5}. Although this ratio has not been measured in interstellar clouds, many other abundance ratios have been. For example, in TMC-1, a cold cloud with a temperature of 10 K, the $DCO^{\oplus}/HCO^{\oplus}$ abundance ratio is 0.015. The ions $HCO^{\oplus}$ and $DCO^{\oplus}$ arise principally from the reactions of CO with $H_3^{\oplus}$ and $H_2D^{\oplus}$, respectively, so that the measured $DCO^{\oplus}/HCO^{\oplus}$ abundance ratio reflects that of $H_2D^{\oplus}/H_3^{\oplus}$. A complete study of interstellar deuterium fractionation reactions akin to Equation 25 has recently been published.[56] Fractionation can also occur on dust particle surfaces. The abundant ion $DCO^{\oplus}$ recombines with electrons to give deuterium atoms which eventually stick to the grain surfaces and combine with atoms and radicals in a manner analogous to that of H atoms.[57] Unlike the gas-phase processes, processes on dust surfaces can lead to large abundances of doubly deuterated species as well.[57]

3. Chemical Models of Interstellar Clouds

To determine whether or not ion-molecule processes are responsible for most of the interstellar molecules seen, it is necessary to include them in computer models which lead to calculated concentrations. These models consist of coupled kinetic equations. Each kinetic equation relates the time derivative of the concentration of a molecule to its formation and depletion rates. Consider as a simple example the molecule $C^{\oplus}$ formed in the reaction shown in Equation 2 and destroyed by reaction with a species E [Eq. (26)]. The kinetic

$$C^{\oplus} + E \rightarrow \text{products} \tag{26}$$

equation for species $C^{\oplus}$ is presented in Equation 27, where the symbol [ ] indicates concentration or, as the astronomers

$$d[C^{\oplus}]/dt = k_2[A^{\oplus}][B] - k_{26}[C^{\oplus}][E] \tag{27}$$

prefer, abundance. Kinetic equations for all molecules in the model can be written down. Although a few models involving the formation of heavy molecules on dust particles have appeared, most models ignore grain chemistry except for the formation of molecular hydrogen.

When interstellar modeling started in the early 1970s, computers were not as advanced as today and instead of solving large numbers of simultaneous coupled differential equations, investigators used the steady-state approximation in which the time derivatives are all set to zero and algebraic equations obtained. The first such models of diffuse clouds[58] and dense clouds[36, 59] were quite successful. Their success and the detection of interstellar ions have shown that ion-molecule processes do occur in interstellar clouds and can explain much of the chemistry. The original dense cloud model of *Herbst* and *Klemperer*[36] contained only 100 gas-phase reactions involving 35 species of up to five atoms in size.

Although the steady-state hypothesis is fine for diffuse clouds, since chemical steady state can be shown to be reached in a relatively short time due to the rapid photodissociation of molecules via external ultraviolet radiation, the approximation may not be applicable to dense clouds. The first non-steady-state solutions of the coupled kinetic equations in dense clouds showed that steady state can be reached in about 10^7 yrs from standard starting materials (either all atoms or atoms plus those diatomic molecules—especially H_2—seen in diffuse clouds).[60] This time is much longer than the time necessary for a molecule to stick on a grain surface ($\approx$ a few per 10^5 years for a cloud of gas density 10^4 molecules cm^{-3}). Therefore, if a desorption mechanism does not exist, neither can the gas phase of dense interstellar clouds exist past this amount of time. If there is no gas, there is clearly no gas-phase steady-state solution. The paradox remains to this day—workers in the field either ignore the problem, invoke some desorption mechanism, or abandon the steady-state hypothesis.

Compared with early models of dense interstellar clouds, modern models are much larger, include much larger molecules, and incorporate time dependence. The time dependence can be purely chemical, in which case physical conditions such as density and temperature do not change, or it can include physical time dependence. Time dependence of physical conditions can be treated simply (e.g., by simple isothermal free-fall collapse) or hydrodynamically. Complications, such as the effect of ultraviolet radiation on cloud edges, the effect of PAH's, and the effect of photodissociation caused by cosmic ray excitation of H_2 can also be considered.[61, 62] Models of both non-star-forming and star-forming regions have been undertaken in recent years and these are discussed separately. A hydrodynamic model in which chemistry occurs as a star begins to form will not be mentioned[63] nor will current models of diffuse clouds.[64]

3.1. Models of Non-Star-Forming Regions of Dense Clouds

Most models of cool regions of dense interstellar clouds contain only chemical time dependence. Some results from a recent model of this type for a cool dense cloud (T = 10 K, $n = 10^4$ cm^{-3}) containing almost 300 chemical species and 2600 gas-phase chemical reactions (most unmeasured in the laboratory) are depicted in Figures 2 and 3.[52] Somewhat smaller but similar models have been developed by competing groups.[65] Figure 2 shows the fractional abundance of

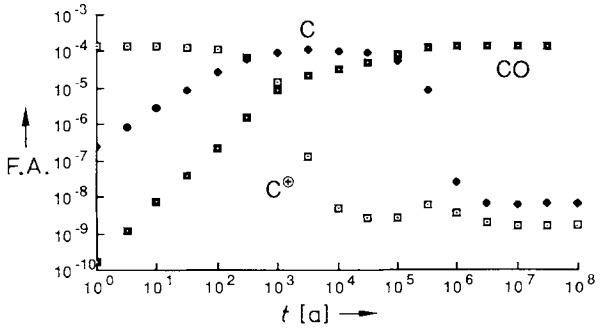

Fig. 2. The calculated abundances with respect to H_2 (F.A.) of the dominant carbon-containing species in a chemical model of cool (10 K) dense interstellar clouds plotted against time (see [52]). □ = $C^{\oplus}$, ◆ = C, ■ = CO.

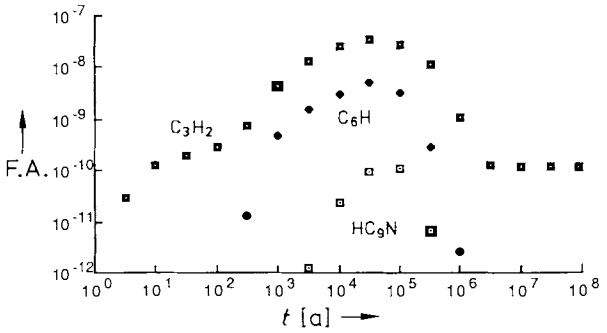

Fig. 3. The calculated abundances with respect to H_2 (F.A.) of several organic molecules in a chemical model of cool (10 K) dense interstellar clouds plotted against time (see [52]). □ = HC_9N, ◆ = C_6H, ■ = c-C_3H_2.

the dominant carbon-containing species as a function of time from initial conditions to steady state. It can be seen that the initially large abundance of $C^{\oplus}$ gradually disappears as the abundance of neutral C increases. Finally, as steady state is reached, the neutral C abundance drops dramatically and the CO fractional abundance rises to its steady-state value of 10^{-4}, in agreement with observation. If one wishes to abandon the steady-state hypothesis because of the dust adsorption problem, one can choose a time as early as $\approx 10^5$ years without a noticeable drop in the calculated CO abundance. In general, this is true for most smaller molecules in the models—choice of a time before steady state is reached such as 10^5 years does not greatly affect the calculated abundances. Use of this so-called "early time" has recently received some support from the observation of large amounts of atomic carbon in selected dense clouds; the calculated steady-state abundance of C is far too small to explain the observations, but at a time of 10^5 years the calculated abundance is indeed quite large. The idea of using "early-time" abundances for dense clouds is still a controversial one since it is clear that the overall ages of clouds are much greater than this. Thus, if one accepts the early-time chemical hypothesis, the time clock in chemical models is not really starting when the cloud is being born but at some later time, perhaps after a dissociative shock wave has ripped through the cloud or material has been processed by turbulent motions pushing it to the cloud edge where it can be photodissociated. In any event, if one wishes to maintain the steady-state hypothesis, as some astronomers do, one can argue either (1) that the atomic C comes from only the outer shells of clouds in which ultraviolet starlight penetrates and dissociates CO into C and O and/or (2) that our knowledge of elemental abundances in the gas phase of dense clouds is quite insecure and that if there is more carbon than oxygen, there will be a large abundance of C even at steady state. The usual assumption is to choose elemental abundances based on stellar and diffuse cloud observations, in which oxygen is normally (but not always) dominant (Table 3). In my view, it is pointless to maintain a steady-state hypothesis unless the problem of desorption from the grains is understood.

Figure 3 shows the calculated abundances of three representative organic molecules. Unlike most smaller species such as CO, the abundances of organic species show an extreme difference between early time and steady state. At a time of 10^5 years, the abundances show clear peaks before diminishing to their steady-state values. The reason for this dichotomy is clear enough—organic molecules are synthesized via reactions involving $C^{\oplus}$ and C. Once most of the carbon is converted into CO and the abundances of $C^{\oplus}$ and C become low, then the synthesis of organic species is inefficient. The more complex the species, the sharper the dichotomy. The calculated early-time peak abundances of organic molecules are much closer to what is observed in some well-studied clouds such as TMC-1, although they can sometimes exceed the observed values even in this remarkable source. Table 2 contains a comparison between observed and peak calculated abundances in TMC-1[52] for almost 40 species. Although it is buried in this table, there appear to be two major problems with using early-time as opposed to steady-state abundances—these concern the small molecules $HN_2^{\oplus}$ and SO, the calculated abundances of which are quite low until times somewhat larger than 10^5 years. Some authors have advocated using slighter longer times than 10^5 years to achieve still better agreement between theory and observation.[66] Still, a glance at Table 2 shows the considerable extent of the agreement. (Of course, if one ignores the dust desorption problem and one carefully chooses a C/O elemental abundance ratio of greater than unity, one can probably achieve general agreement at steady state as well.) The agreement between observation and theory for the cyanoacetylene series (sometimes referred to as the cyanopolyyne series) in TMC-1 is depicted in Figure 4 where the peak results of two

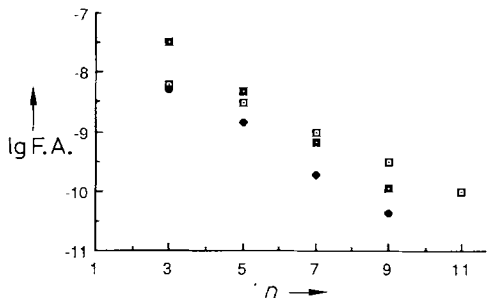

Fig. 4. The peak calculated and observed abundances of cyanopolyynes ($HC_{2n+1}N$) with respect to H_2 (F.A.) plotted against number n of carbon atoms. The observed abundances (□) are from the well-known interstellar source TMC-1. The calculated results (◆, ■) are taken from two slightly different models [52].

slightly different current models are contained.[52] Note that for this series of species, the peak abundances do not greatly exceed the observed values, indicating that if the time evolution shown in Figures 2 and 3 is correct, TMC-1 may be serendipitously at the correct age for peak abundances. Interestingly, the large cyanopolyyne abundances in TMC-1 do appear to be unique!

Within the last year, a novel idea for removing the large dichotomy between early-time and steady-state abundances has been proposed.[67] A large body of observational data shows that the gas in dense interstellar clouds is not homogeneous but is clumped; i.e., relatively dense regions exist inside a lower density medium. This is shown in Figure 5 where a telescope beam of low spatial resolution is shown failing to resolve the clumped material. The diffuse material is pervad-

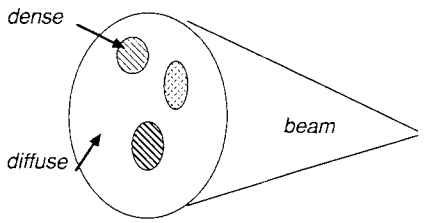

Fig. 5. If the beam of a radiotelescope is large enough, it cannot resolve dense clumps of gas existing in a much more diffuse medium. It is likely that most dense interstellar clouds have such a clumpy nature.

ed by external ultraviolet radiation and the carbon is mainly in the form of C and $C^{\oplus}$. The recent observation of $C^{\oplus}$ as well as C in dense clouds is in harmony with this picture.[68] Since C and $C^{\oplus}$ are the precursors to organic molecule development, the synthesis of organic molecules in the dense clumps would be aided at steady state if mixing between the diffuse gas and the dense gas in the clumps would occur.[67] Models to quantify this effect are currently underway; it would appear that the early-time, steady-state dichotomy can be removed if the diffuse gas is rich in C rather than $C^{\oplus}$. Even if the idea of mixing allows the abundances of complex molecules to be high at steady state, it is unclear what causes the mixing. In addition, the problem of desorption from the dust particles is not solved unless the additional radiation penetrating the dense clumps can photodesorb material.

3.2. Models of Star-Forming Regions of Dense Clouds

In the vicinity of star formation, the collapsing gas results in higher densities and temperatures. It would be surprising if the chemistry were unaffected by this process and there is ample observational evidence to show that it is indeed affected. The chemistry in star-forming regions is clearly a severe function of how distant the material is from the center of the star-formation activity. Present-day observations do not yet have the spatial resolution to peer into the chemistry in the immediate vicinity of stars and protostars although this situation will soon change. Given the spatial resolution that has been brought to bear on the problem, unusual chemistries over wider scales, perhaps 0.3 light year, in the vicinity of protostars have been examined. The best-studied region is the so-called Kleinmann-Low Nebula in the Orion Molecular Cloud, in which three chemically different areas have been observed. These are termed the "Plateau", "Hot Core", and "Compact Ridge" regions.[69] All appear to be associated with a strong infrared source called IRc2 suspected of being a protostar. The "Plateau" source shows very wide line widths in its molecular spectral features and is associated with gas heated strongly (to perhaps thousands of degrees) but temporarily by a shock wave passing outward from the protostar. The other two sources are more quiescent in nature. The "Hot Core" source has a density of 10^6-10^7 cm^{-3} and a temperature of perhaps 100 K or more. It contains high abundances of normal "saturated" species such as H_2O and NH_3, as well as saturated species such as CH_3CH_2CN not even detected in the normal interstellar medium. It does not appear to be associated directly with star formation but is perhaps a piece of material that did not fully take part in the collapse to form a protostar. Finally, the "Compact Ridge" source, although possessing physical conditions similar to the "Hot Core", has abnormally high abundances of the oxygen-containing molecules methanol, methyl formate, and dimethyl ether. Given its physical location, it is probably formed by the intersection of heated gas coming outwards from IRc2 and the quiescent material of the normal interstellar cloud. Models for each of these unusual regions have been proposed.

Much research has gone into the chemical and physical effects of interstellar shock waves.[70-71] The properties of the shocked gas depend critically on the speed of the shock front and the size of the magnetic field. In the absence of a magnetic field, even a shock of moderate velocity can heat the gas to temperatures in excess of several thousand K from which it cools rapidly. Nevertheless, while the gas is hot, numerous exothermic reactions with activation energy barriers and even some endothermic reactions can occur between abundant species, totally changing the chemical composition of the material. In the presence of even a small (μGauss) magnetic field, the shock characteristics change dramatically and the neutral gas does not jump discontinuously in temperature as the shock passes by but rises gradually in temperature. However, a net velocity between the ionic and neutral phases of the gas appears which can power endothermic ion-molecule reactions such as that in Equation 28 which is 0.39 eV endothermic. Reaction (28) is actually thought to be

$$C^{\oplus} + H_2 \rightarrow CH^{\oplus} + H \qquad (28)$$

the process that produces $CH^{\oplus}$ in regions of diffuse interstellar clouds subjected to shock waves.

In the "Plateau" source in Orion, shock models[71] have been proposed to explain the enhanced abundances of certain sulfur-bearing species such as H_2S, OCS, and SO, which cannot be accounted for by normal ion-molecule chemical models.[66, 69] These shock models have met with mixed success and have produced widely differing results.

The chemistry of the "Hot Core" source in Orion has been more successfully explained in terms of the desorption of saturated material from grain surfaces caused by the relatively high temperature ($T \geq 100$ K). Much of the saturation presumably occurs via H-atom addition on grain surfaces, as discussed in Section 2.1. In a current detailed model, it is proposed[72] that the chemistry can be divided into three phases. In the first phase, normal gas-phase chemistry occurs while the cloud undergoes free-fall isothermal collapse and gas-phase molecules stick to the dust particle surfaces. On these surfaces, reactions involving H atoms occur and produce saturated species such as H_2O, NH_3, and CH_4. After a period of time of approximately 10^6 years, the gas phase has been depleted of most of its condensible species whereas the H_2 density has reached the high value characteristic of the "Hot Core". In the second phase, star formation is assumed to occur nearby, with the result that the temperature rises sufficiently to drive adsorbed species off the grains. In the third and final phase, gas-phase chemistry once again occurs. However, at the high gas density, the ion content of the gas is so low that the ion-molecule chemistry is very slow and the chemical makeup of the gas reflects that achieved in the first

phase for a considerable length of time. Although not quantitatively successful, the model results do explain the enhanced abundances of saturated species seen in this source. Improvements will have to await a better understanding of interstellar dust particles and the chemical processes that can occur on them.

No detailed model of the chemistry of the "Compact Ridge" source has yet appeared in the literature although work on such a model is underway.[73] It has been suggested that the oxygen-rich organic molecules found at high abundance in this source are produced by a chemical pathway in which large amounts of water, mixing into the quiescent gas from the protostellar source IRc2, supply the oxygen.[69] Preliminary calculations do not support this view and, currently, it appears as if there is no gas-phase mechanism sufficiently rapid to explain the large abundances of molecules such as methyl formate, methanol, and dimethyl ether. If this tentative conclusion is correct, then dust-based chemistry is responsible.

4. Summary and Outlook

Since the first observations of polyatomic molecules in the interstellar medium about twenty years ago, the field of interstellar chemistry has progressed significantly. Approximately ninety different molecules have been discovered in the gas phase of dense interstellar clouds, ranging up to thirteen atoms in size. In addition to these unambiguous detections, based on high-resolution spectra, there are low-resolution spectra that have been interpreted in terms of large aromatic molecules ("PAH's") as well as material adsorbed on the surfaces on interstellar dust particles. The dust particles themselves have not been well characterized but are presumably mixtures of silicates and carbonaceous material.

Our understanding of the low-temperature chemistry of interstellar molecules has also grown appreciably in the last two decades. Although molecular hydrogen is synthesized on the surfaces of dust particles, it would appear that most interstellar molecules are produced via gas-phase reactions, especially in regions distant from star-forming regions. These gas-phase reactions must possess no activation energy; the major class of such reactions are ion-molecule processes. Chemical models incorporating large numbers of gas-phase reactions, many of which have been studied in the laboratory, have been quite successful in reproducing observed abundances in sources such as TMC-1. This does not mean that reactions on the surfaces of dust particles do not occur, but rather that the products of these reactions remain on these surfaces. Although the gas-phase models appear to be successful, much work remains to be accomplished in understanding the assorted chemical processes, especially dissociative recombination and radiative association. In addition, it is not at all clear that the extreme time dependence calculated in simple one-phase models is correct; work on two-phase models with mixing between the phases is just beginning.

In regions of the interstellar medium where stars are forming, the chemical situation is much more complex. Star formation heats up the surrounding material, driving off the adsorbed layers from dust particles, results in so-called "winds" of outwardly driven material to interact with the quiescent gas, and leads to shock waves which can heat the material in a transient manner to thousands of degrees. Although chemical models have been propounded which take one or more of these effects into account, they do not yet have the success of models of non-star-forming regions. As astronomers begin to use interferometric methods and look at star-forming regions with greater and greater spatial resolution, models of the chemistry in these regions will be further developed.

In addition to using higher spatial resolution, astronomers are beginning to probe the chemistry of interstellar regions in different galaxies from our own. Two particular galaxies of focus are the "Magellanic Clouds" which are seen from the southern hemisphere and are very close to our own galaxy. These galaxies appear to have less matter in the form of atoms heavier than helium than our own galaxy has, with interesting consequences for the chemistry. Chemical models of interstellar clouds in the Magellanic Clouds are already being undertaken.[74]

Another area of future research concerns the extent of the growth of interstellar molecules. Improvements in observational techniques should permit high-resolution spectral detection of larger molecules than seen previously and additional laboratory work on appropriate reactions should enable modelers to make predictions concerning these larger molecules.

Finally, an area of growing interest is the relationship between interstellar chemistry and the chemistry of the solar system. More than five billion years ago, our area of space was a cool dark interstellar cloud in which a low-mass star (our sun) managed to form via gravitational collapse of a portion of the cloud. In the immediate vicinity of the newly formed sun, certainly all traces of a previous chemistry were lost due to the extreme heat. Further away from the new sun however, interstellar molecules could have survived, especially if they had already been adsorbed on the surfaces of dust particles, which subsequently coagulated to form larger bodies such as planetesimals. There is increasing evidence from meteoritic and cometary studies that such a close relationship between interstellar chemistry and at least some of the matter in these objects exists.[75]

In summary, interstellar chemistry is a young and vibrant field in which many advances have been made, but in which much more needs to be learned.

The work carried out by my group was supported by the National Science Foundation (USA).

Stereocontrolled Construction of Complex Cyclic Ketones via Oxy-Cope Rearrangement

New Synthetic Methods (81)

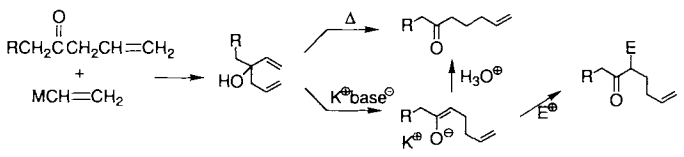
By Leo A. Paquette*

Convergency is a highly serviceable aspect of organic synthesis, particularly when its application is accompanied by high levels of chirality transfer and regiocontrol. A reaction that is notably well suited to these objectives is the oxy-Cope rearrangement. In addition, the benefits that can accrue from suitable condensation of β,γ-unsaturated ketones with a vinyl organometallic and subsequent [3,3] sigmatropic shift are substantive enhancement in structural complexity and the ability to generate a myriad of polycyclic frameworks. Another profitable feature is the complementary regeneration of the carbonyl group in a new structural context. In view of the pivotal role played by the carbonyl functionality in synthetic transformations, reacquisition of such a reaction site translates into heightened chemical versatility. The trajectories followed by vinyl organometallics as they engage in 1,2 addition to ketones are gradually being understood. Proper diastereoselective control of this bond-making process, when coupled with full awareness of the chair or boat topography adopted during the ensuing oxy-Cope electronic reorganization, provides for exciting new strategy-level dimensions not often available in other contexts. The use of this two-step sequence as a prelude to a third chemical event clearly serves to expand the possibilities for molecular construction still more. While a considerable amount of the work to date has focused on the preparation of rather elaborate carbocyclic molecules, principally with a view to gaining access to complex natural products, the possibilities for heterocyclic synthesis are currently being accorded increased attention.

1. Introduction

The philosophy of the financial investor, namely, to buy low and sell high, is often adopted by the synthetic organic chemist at the molecular level. By making recourse to conventional bond constructions known for their high efficiency and subsequently bringing about a structural rearrangement that generates a stereochemically more intricate entity, one can gain considerable complexity relative to the level of input. Thus, the "profit margin" can be substantial.

In this connection, sigmatropic rearrangements have evolved as particularly reliable synthetic tools since a detailed understanding of these processes in terms of orbital symmetry was advanced.[1] Among these, the oxy-Cope rearrangement has been accorded rapidly increasing attention because of its exceptional flexibility and broad applicability.[2–5] As illustrated in Scheme 1, the substrate destined to



Scheme 1. Thermal and anionic oxy-Cope sequences.

undergo isomerization is often prepared by coupling a vinyl organometallic with a β,γ-unsaturated ketone. Such simple condensations can often proceed with exceptional diastereoselectivity. The important issue to emphasize is the convergency associated with this initial step and the considerable latitude this feature can bring to the overall sequence.

While oxy-Cope rearrangements can be effected thermally,[6,7] enormous rate accelerations (up to 10^{15}) can be realized by conversion to the potassium alkoxide.[8] The greatly decreased reaction temperatures made possible by this innovation are often tolerant of sensitive functional groups. The alkoxide oxygen must be linked to the bond that is about to be broken, since it is the "electron push" that induces weakening and facilitates rupture.[9,10]

The thermal and anionic oxy-Cope variants share in common an irreversibility component that distinguishes them from classical Cope reactions and extends their overall utility well beyond that customarily available to classical [3,3] sigmatropic processes. In the first case, irreversibility stems from the greater thermodynamic stability of a carbonyl group relative to a C–C double bond. In the anionic mode, the resonance energy of the enolate anion is key. Note that enolate generation is regiospecific.

Near-quantitative asymmetric transmission can arise as a direct consequence of the highly ordered cyclic transition states involved. Chairlike conformations are often preferred,[11] but boat alternatives are also energetically accessible and can be demanded by the structural features of the system. This aspect needs to be clearly appreciated in every instance, since the exceptional associated stereospecificity can allow for the ready construction of complex molecules having in excess of six stereogenic centers.

While the above features are enormously attractive, attention needs also to be drawn to the fact that Scheme 1 constitutes a fundamental two-step carbonyl regenerative process.[5] Invariably, the ketone end product is appreciably more embellished structurally than the starting material, especially when polycyclic systems are involved.[5,12] Few will discount the importance of the carbonyl functionality to syn-

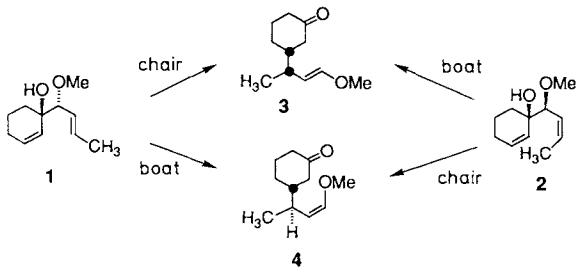
thetic design. In actuality, the oxy-Cope product carries two different sites of unsaturation, either of which can be selectively adapted to specific synthetic goals. In this review, we compile those developments in the area of oxy-Cope chemistry that have application in particular to the elaboration of cyclic and polycyclic ketones, many of which have direct relevance to the field of natural products.

2. Relevant Features of the Sigmatropic Event

As mentioned above, two limiting transition-state conformations can be realized during suprafacial-suprafacial [3,3] sigmatropy. The preference for involvement of a chairlike conformation needs to be correlated with the demands by substituents for occupying equatorial and not axial positions. A direct consequence of this energetic ordering is the formation of *E* double bonds when groups are equatorial. Axial substituents give rise to *Z* olefin geometries. In those examples where both double bonds are β-substituted, two new chiral centers are formed. Chirality transfer then becomes an issue, since the asymmetry inherent in these vinyl groups is translated predictably and specifically into an *erythro* or *threo* product. An instructive example is available from the early work of *Evans* [Eqs. (1) and (2)].[13]



(1)

Since **1** and **2** are exclusive precursors to **3** and **4**, and **5** and **6** afford only **7** and **8**, the operation of one or more nonconcerted pathways seems highly improbable. The product ratios (**1** → **3** (96%) + **4** (4%); **2** → **4** (70%) + **3** (30%); **5** → **7** (77%) + **8** (23%); **6** → **8** (98%) + **7** (2%)) indicate further that **1** and **6** isomerize almost exclusively via the chair transition states **9a** and **9b**, respectively (Scheme 2). The diastereomers with β-methoxyl groups (**2** and **5**) experience greater destabilization during analogous bond relocation because of the presence of a pseudoaxial methoxyl group in **10a** and **10b**. Consequently, the latter two oxy-Cope processes proceed in part (23–30%) via competitive boat geometries. This study eventuated in a stereoselective total synthesis of (±)-juvabione.

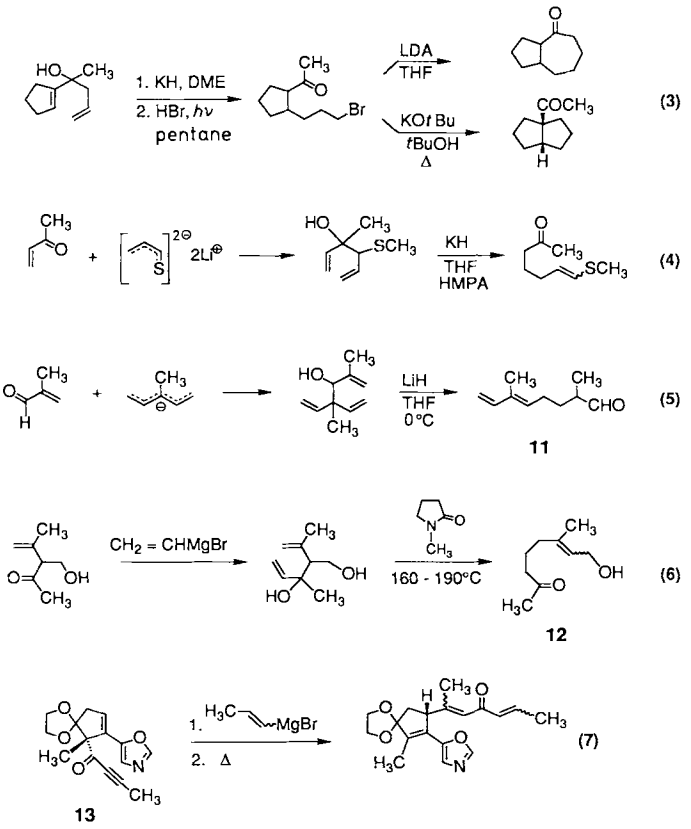
b, $R^2 = H$, $R^1 = CH_3$

Scheme 2. Chair transition states **9a**, **9b**, **10a**, and **10b** for dienols **1**, **6**, **2**, and **5**, respectively.

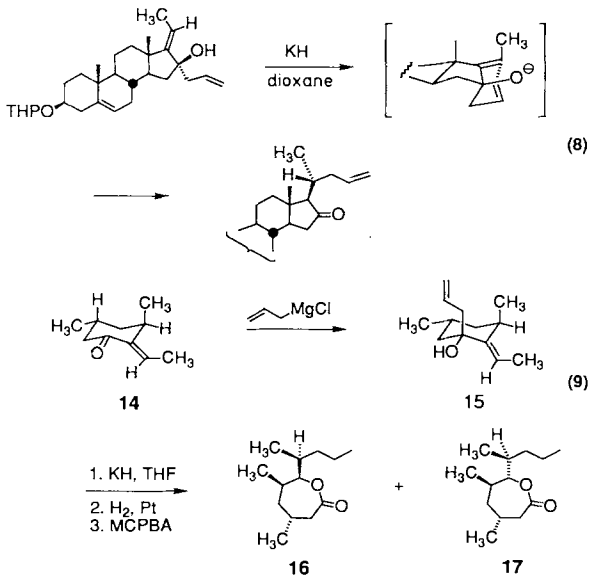
In addition to being serviceable for producing simple bicyclic ketones [Eq. (3)],[14] the oxy-Cope sequence has been utilized for preparing polyfunctionalized molecules of various types [Eqs. (4),[15] (5),[16] (6),[17] and (7)[18]]. These transformations have provided the basis for efficient new syntheses of pseudoionone (from a relative of **11**), (3*E*,8*E*)-suspensolide (from **12**), and gnididione (from **13**).

One of the most advantageous features of the oxy-Cope rearrangement is its ability to generate new stereogenic centers with virtually complete stereospecificity and without need for external chiral reagents and the like. Furthermore,

Leo A. Paquette (born in 1934 in Worcester, Massachusetts) obtained a B.S. in 1956 from Holy Cross College and a Ph.D. in 1959 from the Massachusetts Institute of Technology. In that same year, he joined the Upjohn Company, where he served as a Research Associate in the Discovery Research Department for four years. In 1963, he joined the Department of Chemistry at The Ohio State University as Assistant Professor, becoming Associate Professor in 1966 and Professor in 1969. In 1981, he was appointed Kimberly Professor of Chemistry and has served as University Distinguished Professor since 1987. His research interests include the preparation and properties of unusual organic molecules of theoretical interest, the synthesis of natural products, and the development of new synthetic methodology. The development of chemospecific and stereoselective chemical transformations hold particular attention, as does the possible stereocontrol of organic reactions. His extensive contributions have been recognized by a number of awards, including the Arthur C. Cope Scholar Award (1987) and the American Chemical Society Award for Creative Work in Synthetic Organic Chemistry (1984). Leo Paquette has been a Sloan, Guggenheim, and Humboldt Fellow and was elected a member of the National Academy of Sciences in 1984.



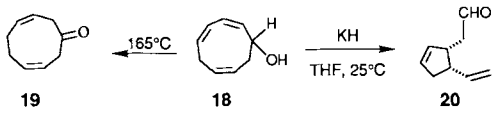
the resultant configuration can often be predicted in terms of simple cyclohexane conformational analysis. *Koreeda*'s clever application of this chemistry to set C-20 of the desmosterol side chain in the correct (*R*) configuration illustrates the point [Eq. (8)].[19] The same group has made the remarkable finding that allylmagnesium chloride adds to **14** with a >50:1 preference for axial entry. This unexpectedly high selectivity makes viable in turn the stereocontrolled conversion of **15** to the isomeric lactones **16** (31%) and **17** (26%) [Eq. (9)].[20]



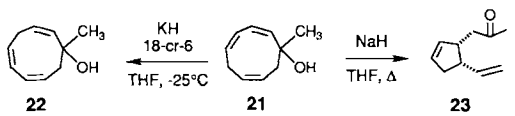
THP = tetrahydropyranyl; MCPBA = *m*-chloroperbenzoic acid

3. Oxy-Cope Ring Contractions

Use of the oxy-Cope rearrangement for effecting ring contraction has seen only limited service because of the relative unavailability of the necessary medium-ring alcohols. However, several important kinetic relationships have been made clearly apparent by these systems. For example, thermal activation of **18** results in exclusive [1,5] hydrogen migration to deliver **19** [Eq. (10)]. This pathway is totally overridden, however, by conversion of **18** to the potassium alkoxide, which is rapidly transformed into **20** at room temperature.[21] This aldehyde holds significance as a precursor to all of the primary prostaglandins[22] as well as to the algal sperm attractant multifidene.[23]



Compound **21**, the methyl analogue of **18**, is cleanly converted into **22** at −25 °C with an excess of potassium hydride in dry tetrahydrofuran containing 18-crown-6. For comparison, heating **21** with sodium hydride in tetrahydrofuran results instead in transformation predominantly (90%) into **23** [Eq. (11)].[24] These observations establish that the fraction of rearrangement of **21** which passes through the oxy-Cope manifold increases as the donor properties of the oxygen center are decreased and the rate of isomerization falls off.



18-cr-6 = 18-crown-6

The high basicity of alkoxides in polar aprotic solvents and the corresponding stability of the enolate anion act in concert to shift the equilibrium toward the carbanion. The addition of complexing agents generally exacerbates the situation and results in rate acceleration. Besides the well-known order of dissociation (Cs > K > Na > Li), steric inhibition to ion pairing, as well as the inherent capability of the substrate for competitive isomerization along a different reaction channel, needs to be reckoned with.

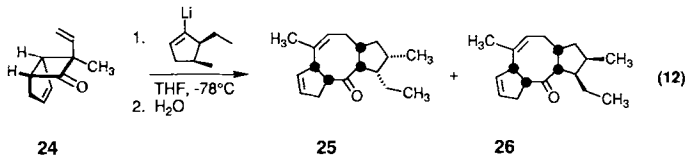
Potassium bases, often in conjunction with 18-crown-6, are most frequently employed to effect anionic oxy-Cope rearrangement. They do not necessarily function identically, particularly in difficult cases. Commercial potassium hydride is quite useful, but impurities should be removed by the Macdonald procedure if the chances for reproducibility are to be maximized.[25] Potassium hexamethyldisilazanide is a conveniently available soluble reagent. However, when rearrangement is slow, silylation of the unrearranged alcohol can often become the kinetically favored process.[26] Potassium diethylamide is reliable, but somewhat tedious to prepare.[27] Finally, potassium *tert*-butoxide is found to work best, if at all, when the substrate alcohol is especially prone to anionic [3,3] sigmatropy.[26]

4. Diastereoselectivity in the Initial Coupling Reaction

Until recently, no example of the first step in the carbonyl regenerative sequence had been documented where both reaction partners are chiral. There exists good reason for this. The 1,2 addition necessarily generates yet another stereogenic center and consequently gives rise to at least eight diastereomeric products. However, the problem can be conveniently dealt with and high levels of molecular recognition attained if the following criteria are accorded proper consideration:[28]

1. Nucleophilic capture by the carbonyl should be relegated exclusively to one prochiral face by suitable steric control. If this stereoselectivity is strictly governed, only a maximum of four diastereomeric alcohols can result.
2. If respectable levels of diastereoselectivity were to operate under these circumstances, then the number of possible products would be halved again. At this point, the use of either reagent in optically pure form would result in net kinetic resolution (single product formation).

Our understanding of the extent and direction of diastereoselection attainable in such reactions is still founded on a limited number of cases. However, interesting trends and predictabilities are beginning to emerge. Bicyclic ketone (±)-**24** adds nucleophiles only from its *exo* surface. However, the conformational mobility of its vinyl group lessens the overall capacity of the molecule for steric discrimination. Consequently, the potential for diastereocontrol falls off rapidly [**25**:**26** = 1.65:1, Eq. (12)].[28] On a positive note, the cyclobutoxide character of the first-formed intermediate results in spontaneous sigmatropy above −78 °C and leads (via boat transition states) to products carrying six stereogenic centers.



24 **25** **26**

Comparative analysis of the response of racemic ketones **27** and **28** to capture by chiral organocerates has revealed that the additional σ bond in **28** does not appreciably enhance key intermolecular interactions of steric origin (Scheme 3).[28] For the series **29**–**33**, the extent of diastereoselection reaches a maximum at **33**.[29] These data have allowed the formulation of a transition-state model consistent with the greater discriminatory power of substituents positioned in the vicinity of the four-membered ring.

The most well understood scenarios at present comprise *endo* addition to such unsaturated 7,7-disubstituted norbornanones as **34**[27] and **35**[30] on the one hand and *exo* addition to **36** and **37** on the other (Scheme 4).[30] The extent of intermolecular recognition can reach quite useful levels when *endo* attack is involved. In contrast, diastereomeric differentiation is significantly reduced when the *exo* trajectory is followed and little sensitivity is reflected toward the *exo*-3-methyl substituent in **36**. These observables can be rationalized in terms of an essentially coplanar arrangement of the reactants with appropriate stacking during the *endo* face-selective process (see **38**). In contrast, a knife-edge alignment as in **39** is presumably adopted by cyclopentenyl anions as *exo* attack on the norbornanone carbonyl group begins. Thus, we see that the trajectories of approach can indeed be widely divergent. It is precisely our awareness of these distinctions that will ultimately allow for broader, more reliable application of oxy-Cope methodology in the future.[31]

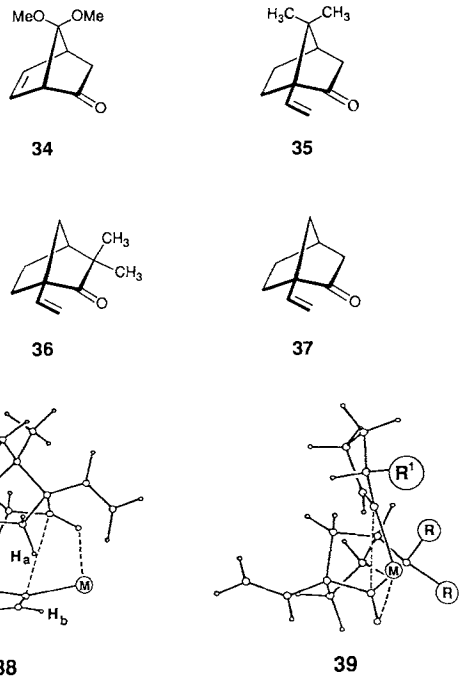
Scheme 3. Select bicyclic β,γ-unsaturated ketones.



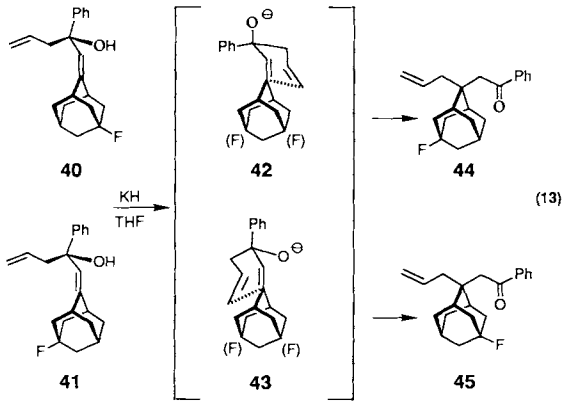
34 **35** **36** **37** **38** **39**

Scheme 4. Unsaturated norbornanones **34**–**37** and prototypical transition-state models for *endo* (**38**) and *exo* addition (**39**) of cyclopentenylmetal derivatives to **35** and **36**, respectively.

In those circumstances where chiral racemic reaction partners are brought into condensation, 1:1 stoichiometry can be used because double diastereoselection operates. The two enantiomers of both reagents are consumed with equal rapidity. However, if either reagent is optically pure, the (*R*)

and (*S*) forms of the racemic coreactant will necessarily be consumed at different rates. Studies involving (*R*)-(−)-isopiperitenone have ascertained that the maximum yields of homochiral 1,2 addends can be most efficiently and economically realized with an RLi-to-ketone ratio of 3:1.[32]

Face selection during the oxy-Cope step proper has been accorded far less attention. The only experiments designed to probe this question involve the (*RR,SS*)- and (*RS,SR*)-fluoroadamantane alcohols **40** and **41** [Eq. (13)].[33] The goal was to assess directly those electronic contributions stemming from the halogen atom. A pair of chair transition states is available to each diastereomer. While **42** has the phenyl group axial, **43** has it equatorial. Consequently, steric factors would favor reaction via **42** in both instances. In contrast,



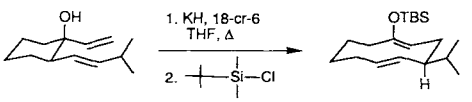
(13)

the hyperconjugative effect of the electronegative fluorine atom would prefer to induce bond formation "*syn*" to the halogen. Whereas **40** gave rise to an 81:19 ratio of diastereomeric acetophenones **44** and **45** (here the effects operate in the same direction), the product distribution from **41** was 36:64. Thus, *syn* approach is favored (by a factor of 1.4), in line with *Cieplak*'s hyperconjugation model.[34]

5. Expansion of Six-Membered Rings

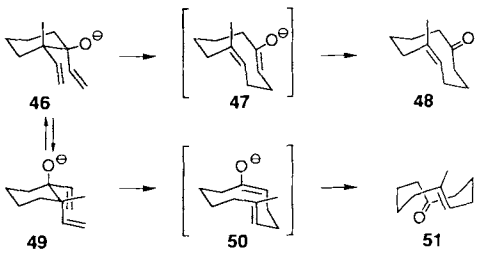
5.1. Expansion of Cyclohexanones

Marvell and *Whalley* recognized twenty years ago that the thermal oxy-Cope rearrangement of *trans*-1,2-divinylcyclohexanol constitutes an excellent means for ring enlargement by four carbon atoms.[35] Moreover, the exclusive formation of *trans*-5-cyclodecen-1-one signaled that isomerization proceeded by way of the chair transition state. This pathway would require that the transient enol double bond have *Z* geometry, a stereochemical feature that was established later by others via trapping experiments conducted under anionic conditions [Eq. (14)].[25]



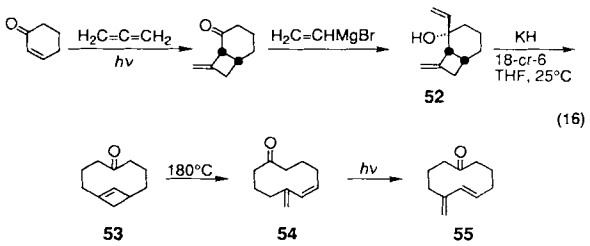
(14)

Comparable heating of *cis*-1,2-divinylcyclohexanol to 220 °C does not eventuate in an equally stereoselective process. A 60:40 mixture of *trans*- and *cis*-5-cyclodecen-1-one results.[35] This loss of stereocontrol was given further attention by *Clive* et al., who examined the fate of potassium alkoxide **46** at a considerably reduced temperature (refluxing tetrahydrofuran).[36] Only 3% of **48** is produced (via **47**), **46** finding it kinetically preferable to undergo conformational inversion to **49** prior to isomerization via **50** to **51** [97%, Eq. (15)]. It remains to establish whether **48** is disadvantaged because of its *Z* double-bond geometry or whether the equatorially disposed electron-rich substituent in **46** is responsible (in **49** the alkoxide oxygen is axial).



(15)

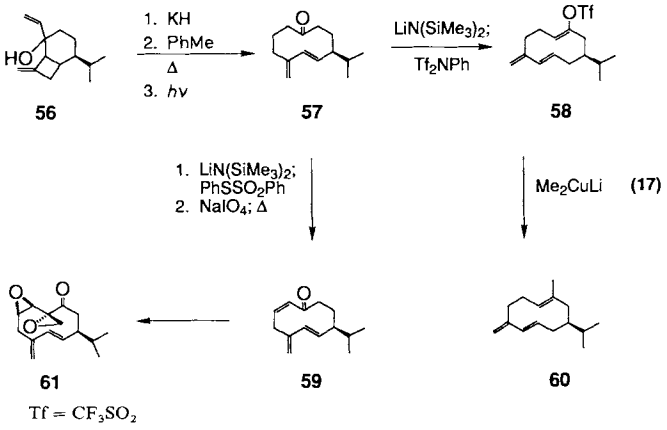
Schreiber et al. have used this effect in an approach to germacrane derivatives [Eq. (16)].[37] An advantage offered by the [2+2] photoaddition of allene to 2-cyclohexenones is its regioselectivity for generation of the β,γ-enone. Forma-



(16)

tion of **52** is followed by anionic oxy-Cope rearrangement to produce the bicyclic bridgehead olefin **53** in 71% yield. Thermolysis of **53** furnished **54** and **55** in a 5:1 ratio. When this mixture was irradiated in cyclohexane, a photostationary state favoring **55** was quickly reached (**54**:**55** = 1:10).

Compound **56**, the isopropyl analogue of **52**, was analogously transformed into **57** [Eq. (17)]. The high re-

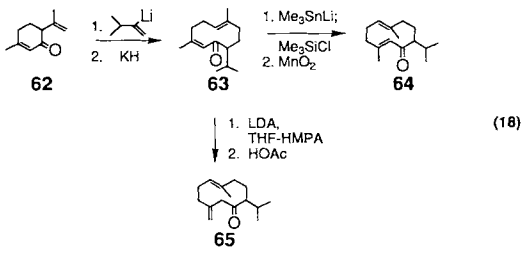


(17)

gioselectivity exhibited by **57** for enolate formation made possible the preparation of **58** and **59**, viable precursors to germacrene D (**60**)[38] and the cockroach sex pheromone periplanone B (**61**)[39].

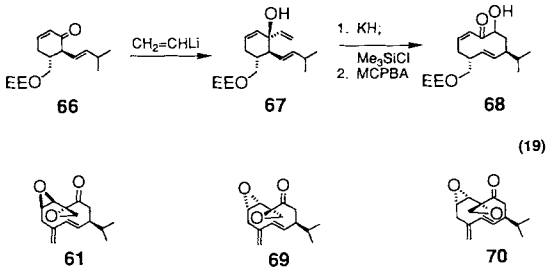
5.2. Expansion of 2-Cyclohexenones

A more expeditious route to germacranes has been realized starting from suitably functionalized 2-cyclohexenones. *Still*'s early syntheses of acoragermacrone (**64**) and preisocalamendiol (**65**) are illustrative of the approach [Eq. (18)].[40] Addition of 2-lithio-3-methyl-1-butene to isopiperitenone (**62**) and anionic oxy-Cope rearrangement of the resultant alcohol afforded **63**. An elegant addition-elimination sequence was next utilized to isomerize the conjugated double bond and arrive directly at **64**. Alternatively, simple "deconjugation" of **63** delivered **65**.



62 63 64 65 (18)

In like fashion, changing the electrophilic partner to **66** permitted arrival at **67**. Ring expansion of this intermediate by the oxy-Cope pathway, direct treatment with trimethylsilyl chloride, and workup with *m*-chloroperbenzoic acid provided **68**. This acyloin was in turn transformed into periplanone B (**61**) and to its inactive diastereomers **69** and **70** [Eq. (19)].[41]



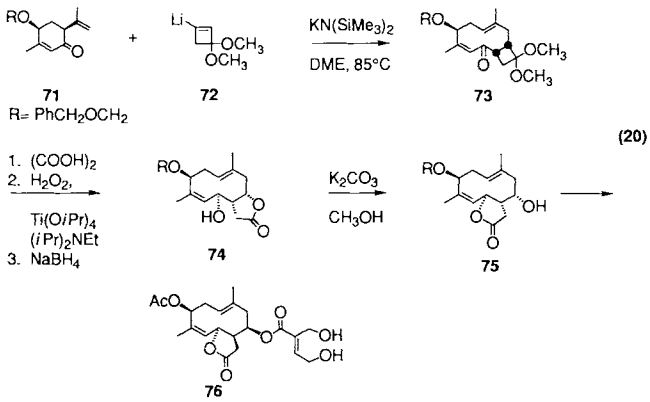
66 67 68 (19)

61 69 70

EE = ethoxyethyl

A more recent, strategically related approach to (±)-**61** has been documented by *Hauptmann* et al.,[42] and *Mori* et al. have prepared (−)-periplanone B in 18 steps from (*S*)-3-cyclohexene-1-carboxylic acid by means of a very similar oxy-Cope ring expansion.[43]

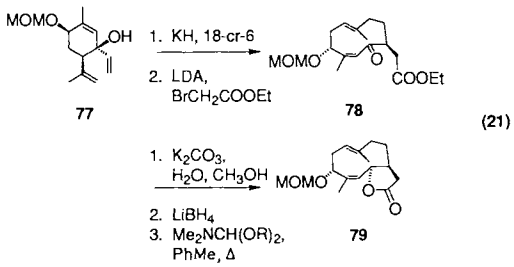
Extension of this protocol so as to permit the concise elaboration of germacranolides has been accomplished independently by *Still* et al.[44] and *Takahashi* et al.[45,46] Not only did stereochemical and regiochemical uncertainties need to be overcome, but potential elimination reactions had to be skirted and the proper direction of lactonization controlled effectively. One way to bypass these possible pitfalls involves the coupling of **71**, prepared readily from (+)-carvone, to lithiocyclobutene **72**. Oxy-Cope ring expansion of the resulting *trans* divinyl alcohol exhibits the usual strong preference for a chairlike transition state since macrocycle **73** was obtained after thermodynamic alkaline equilibration [Eq. (20)]. Hydroxy lactone **74** is obtained after further processing, thereby setting the stage for proper interchange of the direction of lactonization and adjustment of the configurations at C-7 and C-8. This was accomplished via **75** to give eucannabinolide (**76**).[44]



71 72 73 (20)

74 75 76

Preparation of the optically active 3-oxygenated 13-norheliangolide **79** was successfully realized by crafting of **77** from (−)-carvone, oxy-Cope rearrangement followed by alkylative introduction of the final two carbons, and closure of the lactone ring [Eq. (21)].[45]

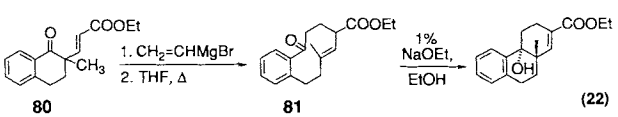


77 78 (21)

79

MOM = methoxymethyl, LDA = lithium diisopropylamide

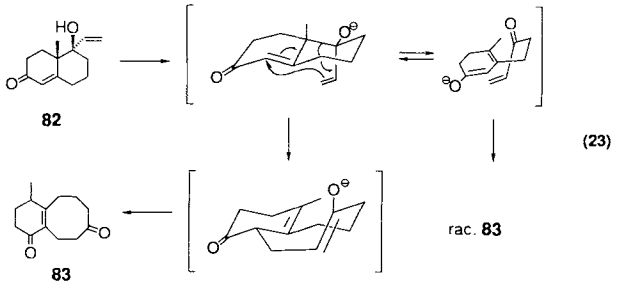
Of significance in the present context is the tolerance of various carbonyl substituents to oxy-Cope sigmatropy. A classic example is due to *Rajagopalan* et al., who noted that addition of vinylmagnesium bromide to **80** and subsequent refluxing in tetrahydrofuran resulted in conversion to **81** [Eq. (22)].[47] The structural features of **81** were recognized to be conducive to transannular cyclization under mildly



80 81 (22)

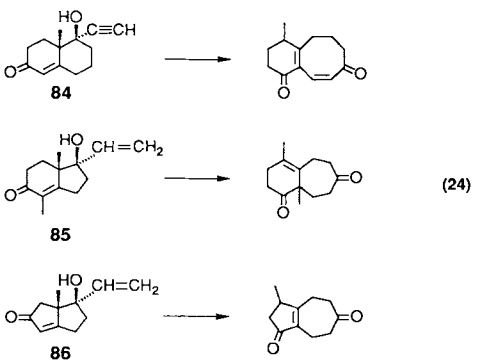
basic conditions. *Sworin* and *Lin* have also carried out interesting studies on ring expansion.[48]

The most well studied oxy-Cope system is undoubtedly the conversion of **82** to **83**. Initially rationalized by *Swaminathan* et al. as the exclusive result of a fragmentation-recombination pathway,[49] the process is currently viewed as capable of operating as well in the concerted sigmatropic mode depending on conditions. These deductions have been made possible chiefly on the strength of studies conducted more recently on optically active substrates.[50] When isomerized with potassium hydride in tetrahydrofuran, the (1*R*,8a*S*) alcohol **82** gives **83** in optically active form. The use of potassium hydroxide in methanol affords racemic product. These findings have been plausibly rationalized at the mechanistic level as outlined in Eq. (23).



(23)

These rearrangements have proven to be general in scope, having been applied successfully, inter alia, to **84**,[51] **85**[52] and **86**[53] [Eq. 24)].

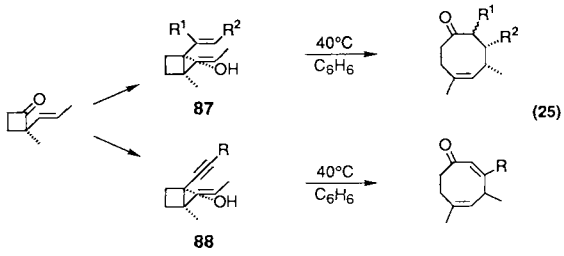


(24)

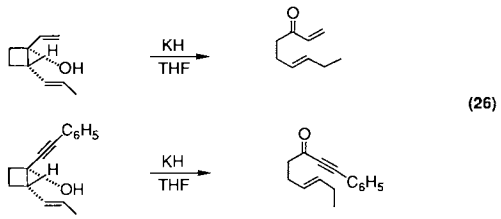
6. Expansion of 2-Vinylcyclobutanones and -cyclopentanones

Recourse to 2-vinylcyclobutanones permits extension of the oxy-Cope strategy to cyclooctenone and cyclooctadienone formation. This aspect of the methodology has attracted interest in recent years because the number of known eight-membered ring natural products has increased substantially during this period. The strain inherent in cyclobutane rings allows for the ready isomerization of alcohols such as **87** and **88** [Eq. (25)].[54]

Gadwood et al. have reported that both *cis*- and *trans*-1,2-dialkenylcyclobutanols undergo [3,3] sigmatropic ring enlargement upon treatment with potassium hydride.[55] Initial *trans–cis* isomerization was invoked to explain the ability of the latter systems to engage in oxy-Cope chemistry. More recently, *Salaun* et al. have pointed out that the reactivity of these isomers is clearly distinguished on the basis of their stereochemical features. Contrary to the earlier claim, the Orsay group has found the *trans* alcohols to be capable only of retro-ene fragmentation [Eq. (26)].[56]

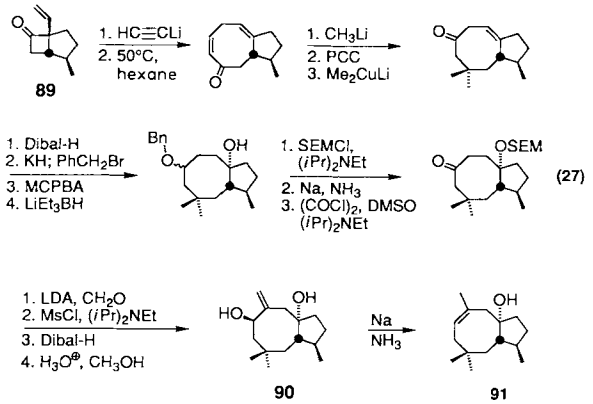


(25)



(26)

Notwithstanding, the methodology represents a powerful tool for the rapid elaboration of cyclooctanoid terpenes. For example, the sesquiterpene alcohols poitediol (**90**) and dactylol (**91**) can be formed via ring expansion of the bicyclic vinylcyclobutanone **89** [Eq. (27)].[57] Good overall yields were realized if the lithium acetylide adduct was isomerized under neutral conditions. Geminal dimethylation and carbonyl transposition then set the stage for proper oxygenation of the framework. Reduction of poitediol (**90**) with sodium in liquid ammonia provided dactylol (**91**).

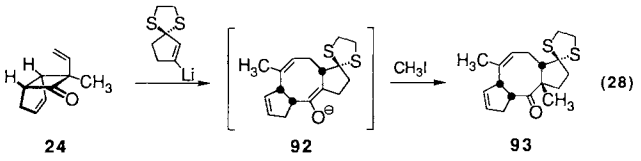


(27)

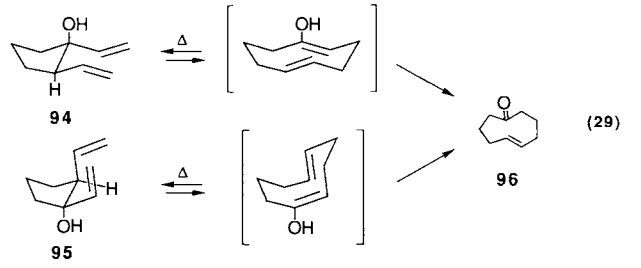
PCC = pyridinium chlorochromate, Dibal-H = diisobutylaluminum hydride, SEMCl = $Me_3Si-CH_2-CH_2-O-CH_2Cl$, MsCl = methansulfonyl chloride

The addition of cyclopentenyllithiums to **24** results in spontaneous oxyanionic Cope rearrangement. If the resultant regiospecifically positioned enolate (e.g., **92**) is trapped with methyl iodide, functionalized all-*cis*-dicyclopenta[*a*,*d*]-

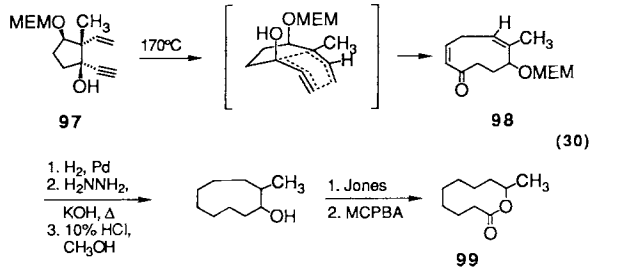
cyclooctane products such as **93** result [Eq. (28)].[58] This angularly fused 5-8-5 framework, which comprises the fundamental architectural element of the ophiobolins, ceroplastols, and fusicoccins, is consequently available in only two laboratory manipulations (**24** is prepared from vinylketene and cyclopentadiene).[59]



Divinylation of 2-chlorocyclopentanone provides for the formation of an 81:19 mixture of isomers **94** and **95**.[60] Thermal activation of the composite sample resulted in exclusive formation of (*E*)-5-cyclononen-1-one [**96**, Eq. (29)]. This stereochemical result conforms to expectation if chair-like transition-state geometries are involved.



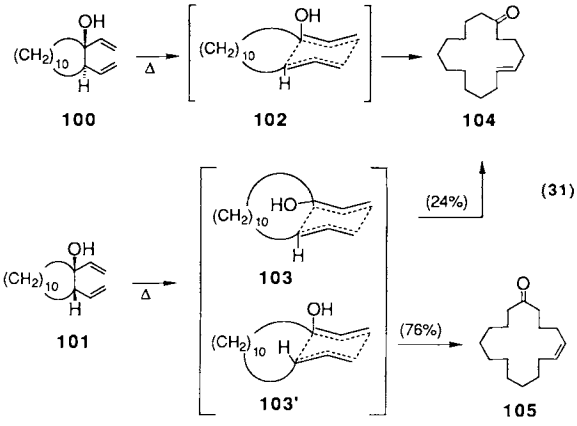
(+)-Phoracantholide I (**99**), the defensive substance of the Australian coleoptera, has been synthesized in concise fashion by taking advantage of the efficient response of **97** to being heated neat at 170 °C. The acetylenic oxy-Cope reaction that is triggered affords the nine-membered *Z,Z* dienone **98** cleanly [Eq. (30)].[61] The *trans* isomer of **97** proved unreactive at temperatures as high as 200 °C. Once **98** was in hand, the volatile oily **99** was arrived at in five additional steps.



MEM = methoxymethyl

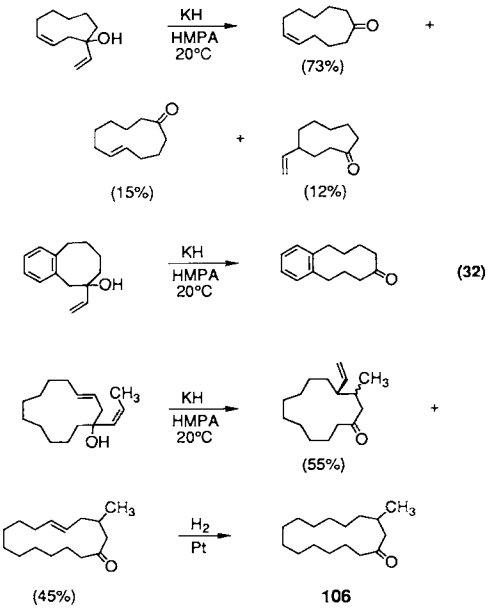
7. Expansion of Medium-Ring Systems

The *trans*- and *cis*-1,2-divinylcyclododecanols have been subjected to thermal rearrangement with interesting results. Thus, while **100** gives **104** as the single product, **101** provides a 24:76 mixture of **104** and **105** under the same conditions [Eq. (31)].[60] To the extent that concerted stereospecific reactions are involved, the *trans* isomer **100** probably passes entirely through chair transition state **102**. This behavior is identical to that followed by *trans*-1,2-divinylcyclohexanol.



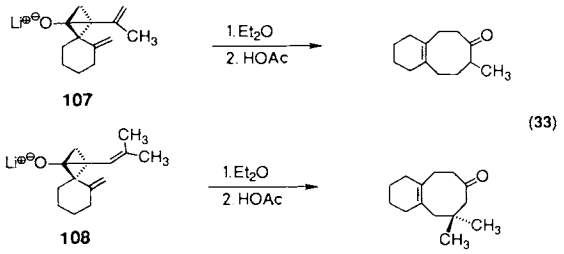
This *cis* arrangement in **101** fosters competition between the involvement of **103** and **103'**. Of these, the pathway leading to *Z* enone **105** clearly dominates, in contrast to the partitioning exhibited by the six-ring lower homologue **46**, which favors formation of the *E* isomer by a small margin. The intermediate ring sizes have not been scrutinized in comparable detail.[60]

When one of the double bonds is endocyclic, the alcohols exhibit a greatly reduced capability for oxy-Cope behavior. A pronounced tendency for undergoing [1,3] sigmatropy surfaces instead. Representative examples are compiled in Equation (32).[62] This alternative ring expansion scheme has been developed by *Thies* et al. into a short synthesis of muscone (**106**).[63]



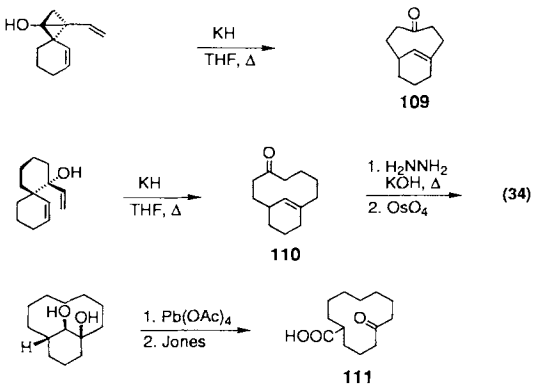
8. Expansion of Spirocyclic β,γ-Unsaturated Ketones

Spirocyclic compounds offer two alternatives as oxy-Cope templates. When the β,γ double bond occurs in the form of a methylene group as in **107** and **108**, octahydrobenzocyclooctenones result [Eq. (33)].[55] As a general rule, the allylic alcohols isomerize too rapidly to permit their isolation, the rigid s-*cis* boat orientation of the double bonds further reducing the activation energy of the rearrangement step.



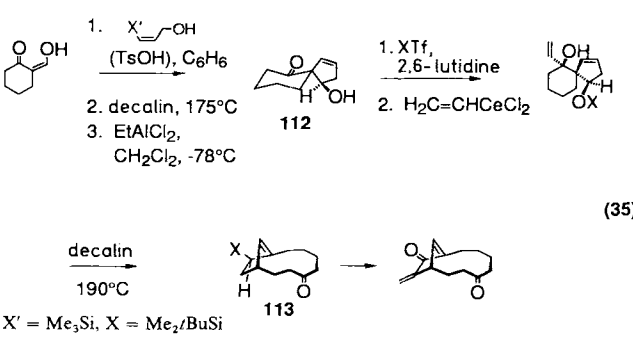
(33)

An important distinction surfaces when the double bond is situated internal to the ring. The *syn* capture of vinyl organometallics by such ketones provides vinyl alcohols, oxyanionic Cope rearrangement of which delivers bicyclic bridgehead olefins having a carbonyl group in the largest bridge [Eq. (34)].[55, 64, 65] Ring systems as small as that found in **109**, a pleuromutilin prototype, can be conveniently acquired in this manner. *Levine* et al. have transformed the homologous ketone **110** into the oxocyclododecanecarboxylic acid **111**.



(34)

An interesting example of this particular isomerization begins with a stereocontrolled three-step synthesis of **112** from 2-(hydroxymethylene)cyclohexanone [Eq. (35)].[66]



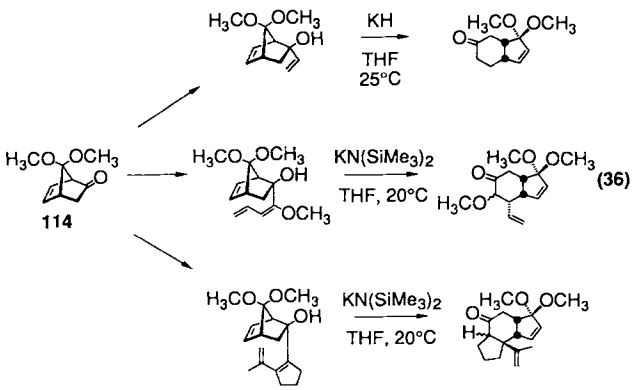
(35)

Once the hydroxyl group is silylated, vinylcerium(III) dichloride is captured selectively to provide a vinyl compound, which, upon heating in decalin, undergoes [3,3] sigmatropy with formation of **113**. A diene dione, which constitutes the bridgehead olefin core of the cytotoxic 8,9-seco-ent-kaurene diterpenes, was subsequently elaborated.

9. Reactions of Bicyclic Ketones with Internal Double Bonds

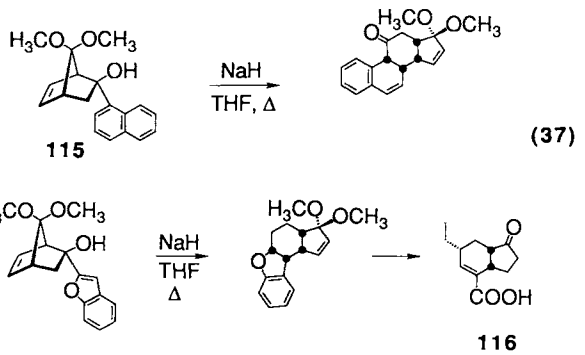
9.1. Reactions of 7-Substituted 5-Norbornen-2-ones

Jung was the first to call attention to the enormous latent potential of 7,7-dimethoxy-5-norbornen-2-one (**114**) in the oxy-Cope area.[67] A nucleophilic vinyl species, forced to approach the ketone carbonyl from the *endo* surface for obvious steric reasons, becomes ultimately positioned in adequate proximity to the strained bicyclic double bond to enable operation of the [3,3] shift. In the examples of Equation (36), richly functionalized *cis*-hydrindanones are seen to form irrespective of other possible bonding options.[67, 68]



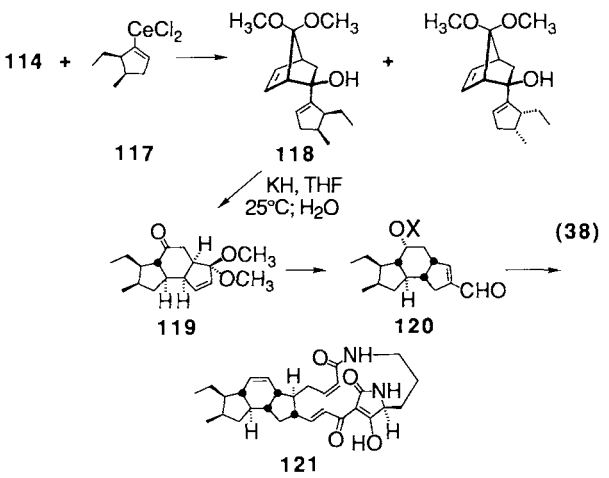
(36)

Bicyclic ketone **114** is sufficiently reactive to enter into anionic oxy-Cope rearrangement with aromatic components, a feat not otherwise easily accomplished.[62, 69] The α-naphthyl derivative **115** illustrates the power of the method for the rapid elaboration of steroidal hormone analogues [Eq. (37)].[67] The benzofuran analogue of **115** has been similarly transformed expeditiously into coronafacic acid (**116**).[68] Another ingenious variant of this concept has resulted in a route to reserpine intermediates.[70]



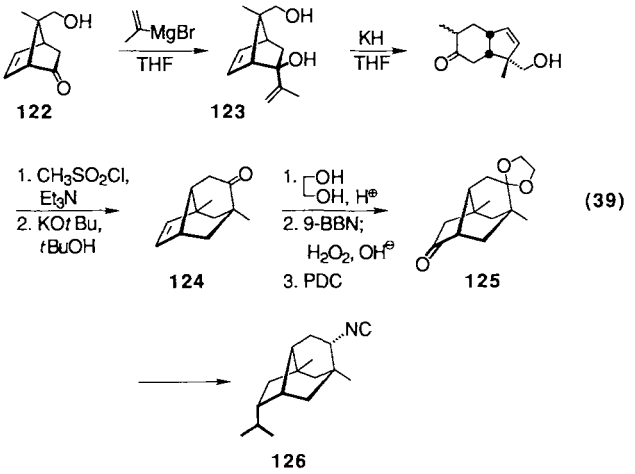
(37)

The coupling of (±)-**114** with racemic **117** exhibits a strong diastereoselectivity bias (12:1) in favor of **118**.[71] Anionic oxy-Cope rearrangement of **118** afforded the trans AB-locked keto ketal **119** efficiently [Eq. (38)]. Later arrival at **120** set the stage for kinetic resolution by the Koga method[72] and a successful total synthesis of natural (+)-ikarugamycin (**121**).[73]



X = Me_2tBuSi

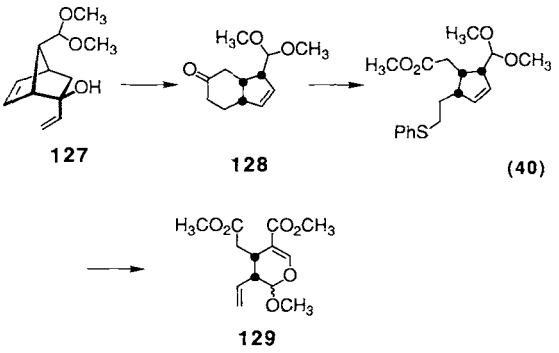
In reality, there need only be a *syn* substituent on C-7 of the norbornenone skeleton to guarantee *endo* directionality for attack by the vinyl organometallic.[74] The geminal methoxyl groups in **114** serve, of course, as a masked ketone carbonyl. This feature need not be relevant for certain specific objectives, *Chang*'s formal synthesis of (±)-9-isocyanopupukeanane (**126**) being a case in point [Eq. (39)].[75] The crucial steps in this study are the stereocontrolled isopropenylmagnesium bromide addition to **122** and anionic oxy-Cope rearrangement of diol **123**. This isomerization



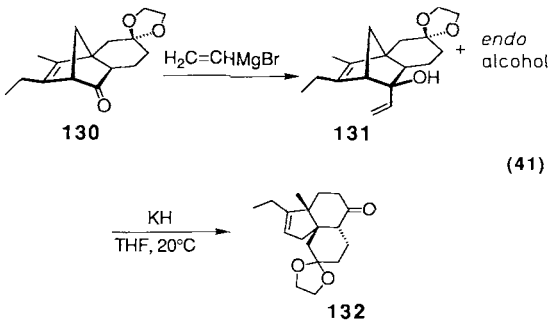
9-BBN = 9-borabicyclo[3.3.1]nonane, PDC = pyridinium dichromate

transforms one of the hydroxyl groups into a ketone carbonyl, thereby allowing for chemospecific mesylation and intramolecular cyclization to form **124**. Hydroboration-oxidation of the ketal of **124** led logically to **125**, a ketone that had been previously transformed into **126**.[76]

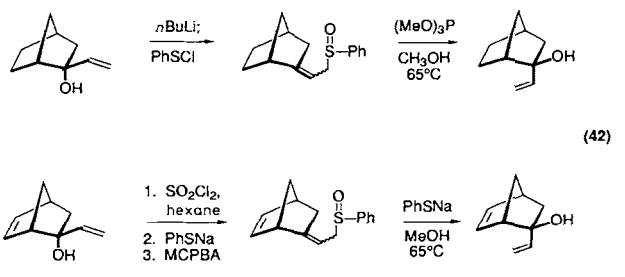
The rearrangement of norbornenol **127** was found to proceed stereoselectively via a boat transition state as in the earlier examples. This geometry serves admirably to provide an all-*cis* product [Eq. (40)].[77] The two rings in **128** were then cleaved sequentially to permit arrival at dimethyl secologanoside *O*-methyl ether (**129**).



Fallis et al. have demonstrated that the presence of an additional *exo*-fused cyclohexane ring on the bicyclic nucleus, as in **130**, is inadequate to direct preferential nucleophilic attack to the *endo* surface of the carbonyl group. Only 25% of the vinylation leads to **131** [Eq. (41)].[78] The potassium salt of **131** is subject to smooth sigmatropic rearrangement in refluxing tetrahydrofuran. The tricyclic ketone **132** so formed is considered to be a prototype for the structurally unique sesterterpene gascardic acid.

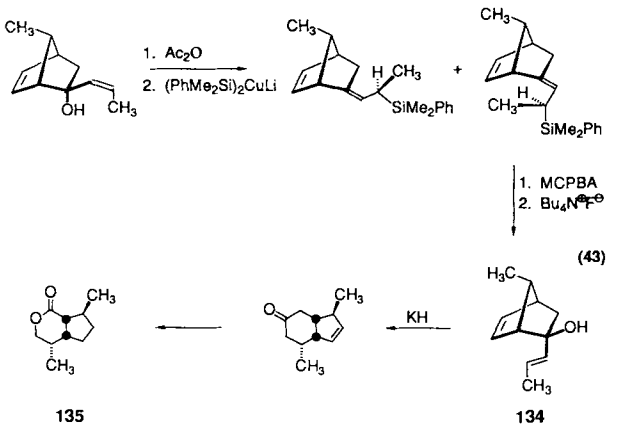


Two protocols are currently available for producing *exo*-norbornenols when the usual methods for preparing these particular isomers are not kinetically favored. The Fallis solution begins with the *endo* alcohol and inverts stereochemistry by implementing a [2,3] sulfenate–sulfoxide rearrangement cycle.[79] Whereas 2-vinylnorbornanols can undergo direct reaction with phenylsulfenyl chloride, a



somewhat more circuitous route is necessitated in the case of **133** because of complications arising from competing electrophilic attack on the strained double bond [Eq. (42)].

In the Fleming scheme, advantage is taken of a stereospecific allylsilane epoxidation [Eq. (43)].[80] The possibility

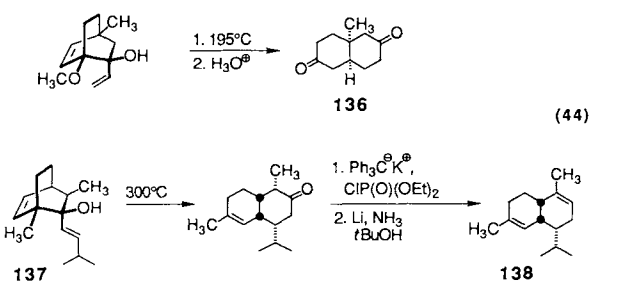


135 134 (43)

of producing **134** cleanly despite the *anti* stereochemistry of its 7-methyl substituent opened the way for an expedient total synthesis of dihydronepetalactone (**135**).

9.2. Reactions of Bicyclo[2.2.2]oct-5-en-2-ones

Established by the seminal studies on bicyclo[2.2.2]oct-5-en-2-ones was the anticipated similarity in transition-state characteristics (boatlike) to the norbornenols. As a consequence, recourse to this class of starting materials serves as an especially efficient stereoselective pathway to *cis*-fused decalins.[8] The preparation of **136** is illustrative [Eq. (44)].[81] An excellent test of the process is the stereospecific synthesis of (±)-α-amorphene (**138**) achieved by *Mirrington* et al.[82] Relevantly, the *Z* isomer of **137** failed to undergo

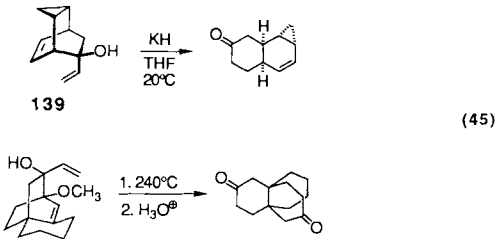


136 (44)

137 138

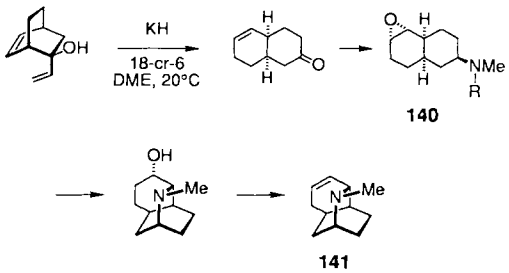
oxy-Cope rearrangement, presumably as a consequence of the considerable steric crowding between the isopropyl group and olefinic bridge as the side chain begins to adopt the conformation necessary for the sigmatropic event.

Variations are possible that result in structurally more complex products. *Rigby* et al. have shown that isomerization of **139** makes directly available the tricyclic ring system of the aristolane sesquiterpenes [Eq. (45)].[83] A general method of [4.4.4]propellane synthesis has also been devised.[81,84]



139 (45)

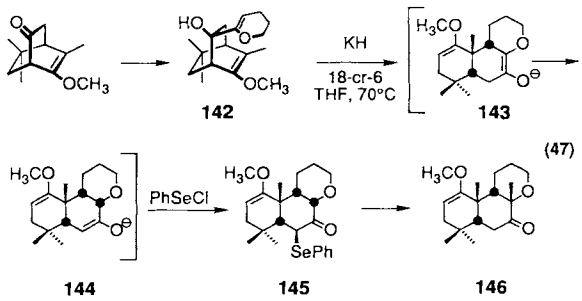
Two groups[85,86] have employed a related alkoxide-accelerated rearrangement to prepare the cranberry constituent cannivonine (**141**), only to find that the structure reported for this compound is incorrect [Eq. (46)]. The unusual isoquinuclidine nucleus was accessed by transannular cyclization of **140**.



140 (46)

141

Introduction of a heteroatom within the allylic alcohol component can seemingly have an influence on the oxy-Cope reaction rate and accelerate enolate anion equilibration after the sigmatropic event. An early manifestation of the latter phenomenon was seen with **142**.[86] Oxy-Cope rearrangement of its potassium salt required heating in tetrahydrofuran. During the short reaction period, initially formed α-alkoxy enolate **143** equilibrated completely to **144**, as reflected in the efficient isolation of **145** following addition of phenylselenenyl chloride [Eq. (47)]. This example illustrates



142 143 (47)

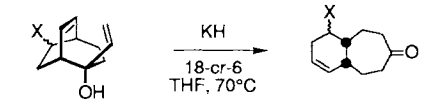
144 145 146

the feasibility of assembling the forskolin prototype **146** in only a few steps. However, compounds related to **142**, but carrying additional substituents on the dihydropyran ring, showed no tendency to undergo a comparable [3,3] shift.[87]

9.3. Reactions of Higher Homologues

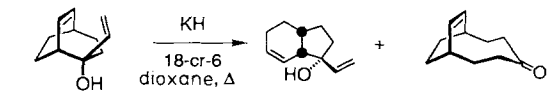
Whereas bicyclo[3.2.2]non-6-en-2-ols typified by **147a** and **147b** are recognized to possess the ability to undergo the

oxyanionic Cope transposition,[88] a dependence on substituent location and type has surfaced [Eq. (48)]. For example, the phenylthio derivative **147c** is destroyed under the same conditions.[88] Furthermore, the parent alcohol **148** and bridgehead functionalized analogues such as **149** experience [1,3] sigmatropy (with inversion of configuration) instead.[89] More study is needed before those factors responsible for this dichotomy are made clear.

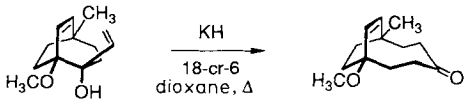


147a, X = *n*BuO
b, X = *n*BuS
c, X = PhS

(48)

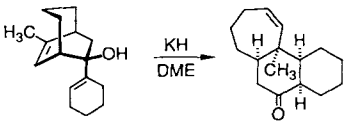


148



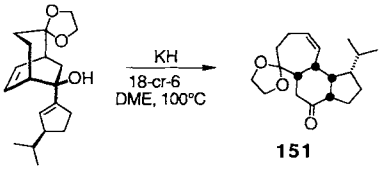
149

Although a smaller number of isomeric 8-ols have been scrutinized, this variant has proven to be spectacularly successful in providing tricyclic ketones such as **150** and **151** having well-defined all-*cis* ring-juncture stereochemistry [Eq. (49)].[90, 91] The chirality transfer exhibited during the formation of **151** is an attractive asset of this strategy.



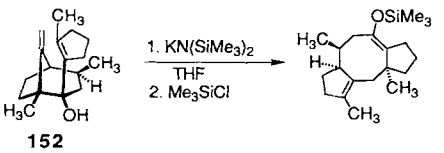
150

(49)



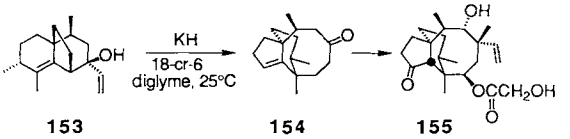
151

Placement of the homoallylic double bond at an exocyclic site as in **152** has the consequence of making available a



152

(50)

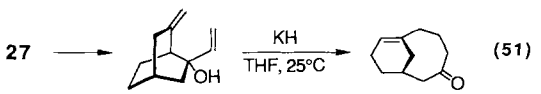


153 **154** **155**

synthetic entry to multiply fused cyclooctanones and their derivatives [Eq. (50)].[92] An elaborate application of this specific rearrangement can be found in *Boeckman*'s stereocontrolled assembly of (±)-pleuromutilin (**155**).[93] Because alcohol **153**, like **152**, possesses only one rotational degree of freedom, isomerization to **154** occurs quantitatively in the presence of potassium hydride and diglyme at 100 °C.

10. Reactions of Bicyclic Ketones Whose Double Bonds Are Exocyclic

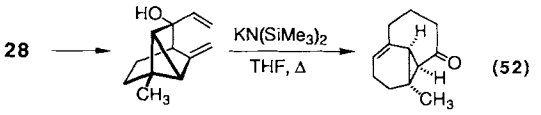
Martin et al. have examined the conversion of **27** and structurally related ketones to alcohols of the **156** variety because anionic-accelerated rearrangement of these compounds delivers products such as **157** that possess the basic [5.3.1]bicyclic unit of the tricyclic taxane diterpenes [Eq. (51)].[94]



156 **157**

(51)

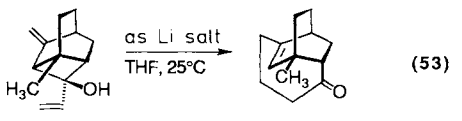
The tricyclic variant **28**,[95] on the other hand, has been shown to serve as a precursor to **158**, a ketone constituting the ABC core of cerorubenic acid-III [Eq. (52)].[96] The molecular architecture of **158** is unique in that a vinylcyclopropane is embedded centrally in such a manner that thermal ring expansion to a cyclopentene is precluded by the constraints of Bredt's rule.



158

(52)

The exceptionally high potential of the oxy-Cope reaction for elaborating ketones carrying bridgehead double bonds has been duly recognized only in the past few years. The readiness with which such fascinating structures[97] can be formed has earlier been outlined in Equations (16), (34), (45), (51), and (52). The rather unique example **159** → **160** uncovered by *Snider* et al. should be included with this group [Eq. (53)].[98]



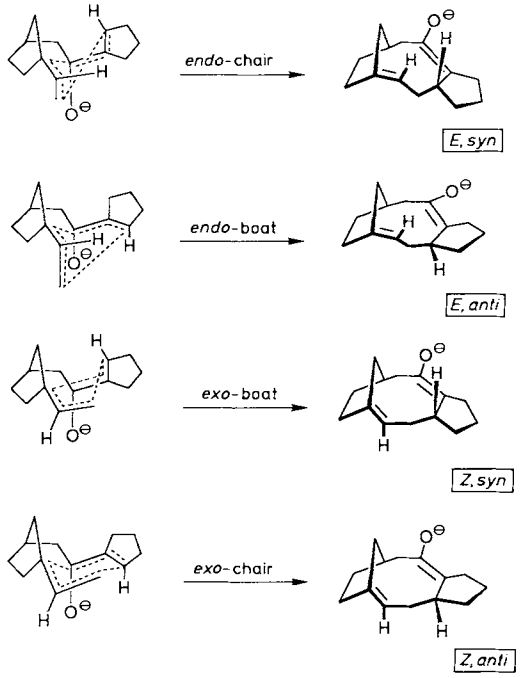
159 **160**

(53)

In all of the examples just surveyed, little conformational latitude is available to the divinyl alcohol because of the rather substantive rigidity of the bicyclic framework where a number of reaction centers are located. 1-Alkenyl-2-(1-cy-

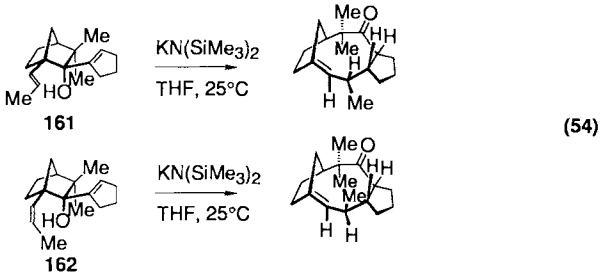
clopentenyl)-*endo*-norbornan-2-ols and their *exo* isomers, in contrast, enjoy a great deal more latitude since neither the bridgehead double bond nor the unsaturated center linked to C-2 is formally constrained [cf. **161** and **162** in Eq. (54)].

In the *endo* series, there exist four possible geometric arrangements that bring the appropriate trigonal carbons into proximity (Scheme 5). Two are chairlike and two are of the



Scheme 5. Transition-state options for 1-alkenyl-2-cyclopentyl-*endo*-norbornan-2-ols (see text).

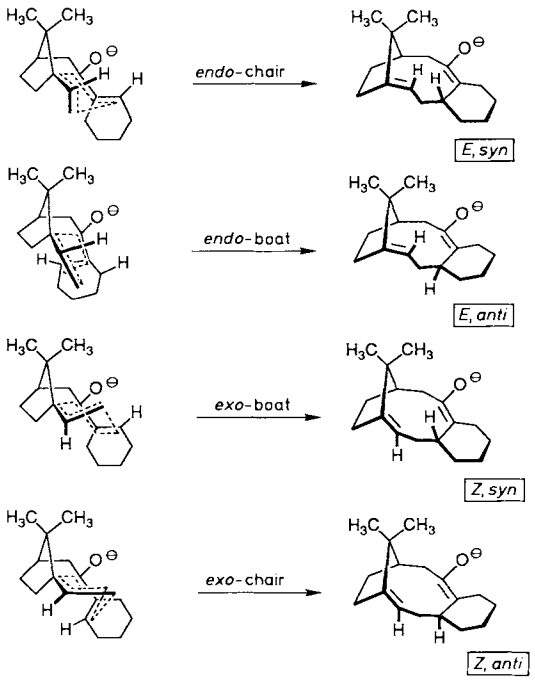
boat type. Each can be categorized uniquely by a combination of two descriptors, the first defining the specific orientation of the bridgehead vinyl group relative to the norbornyl framework and the second the spatial arrangement of the developing six-membered ring. Each orientation generates a product having a very specific and distinctive combination of stereochemical features at the double bond and ring fusion sites. *Endo* alignment of the bridgehead vinyl group serves ultimately to lock the olefinic proton into a *syn* relationship with the methano bridge in the product enolate. The alternative *exo* vinyl orientation necessarily leads to *Z* olefin geometry. The relative stereochemistry of the cyclopentyl ring fusion site that is positioned β to the enolate anion center is inextricably linked to whether chair or boat topography is adopted.



(54)

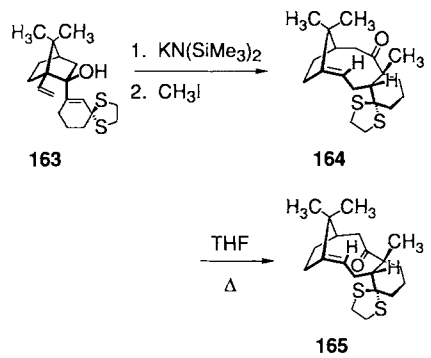
The exclusive formation from **161**, **162**, and related alcohols of the *Z,syn* product requires that each isomerize with a strong kinetic preference for the *exo*-boat transition state [Eq. (54)].[99] In the examples shown, an additional stereogenic center is seen to be unambiguously defined as a consequence of this remarkably exclusive sigmatropic pathway.

For entirely similar reasons, the stereochemistry of the products arising from the epimeric *exo* alcohols is likewise inextricably linked to the particular operational transition state (Scheme 6). Here also, rearrangement proceeds rapidly



Scheme 6. Transition-state options for 1-alkenyl-2-cyclohexenyl-*exo*-norbornan-2-ols (see text).

at room temperature. Strikingly, only a single transition-state geometry, the *endo*-chair, is utilized during [3,3] sigmatropy.[100] For **163**, conversion to **164** proceeds with 100% stereoselectivity [Eq. (55)]. Since the oxyanionic Cope reac-



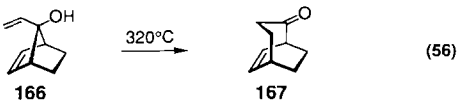
(55)

tion proceeds at 20 °C, an opportunity is offered that would permit the existence of discrete atropisomers. This is indeed the case. When refluxed in tetrahydrofuran for several days, **164** is irreversibly transformed into its conformational iso-

mer **165**. The several σ-bond rotations that must occur during this process are impeded from taking place readily because of the structural features present in **164**. Once the carbonyl oxygen becomes "tucked under" as in **165**, a lower-energy framework is attained. The conversion of **163** to a single atropisomer constitutes an example of a rare atropselective reaction, the first in an oxy-Cope setting.

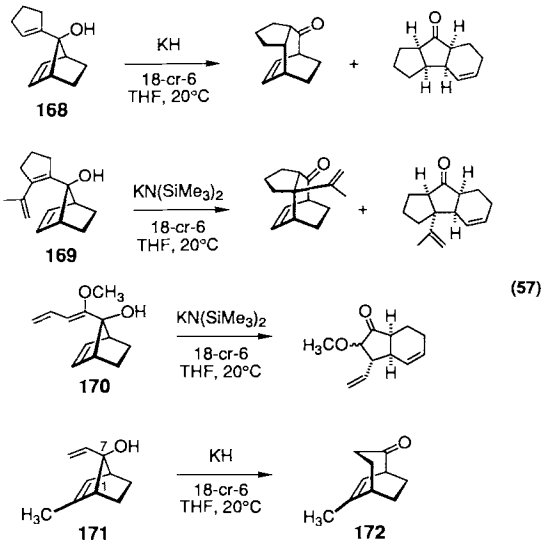
11. 2-Norbornen-7-ones and Other Fragmentation-Prone Substrates

Gas-phase pyrolysis of **166** leads predominantly (88%) to **167**, in accord with the particular susceptibility of this vinylnorbornenol for fragmentation-recombination [Eq. (56)].[7] The study by *Berson* et al. of more heavily substituted examples established that this biradical-mediated [1,3] sigmatropic rearrangement proceeds with retention of configuration in the migrating group.[101]



(56)

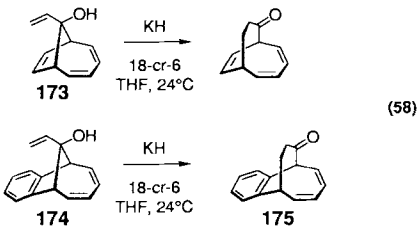
Oxyanion generation within such systems is known to foster rearrangement via antarafacial-retention [1,3] bridgehead-carbon migration. However, oxy-Cope reorganization now takes place concurrently, the product ratio being dependent on the structural characteristics of the 7-vinyl substituent.[102] Alcohol **168** responds by delivering a mixture of two ketones in the relative ratio of 3:1 [Eq. (57)]. The level of



(57)

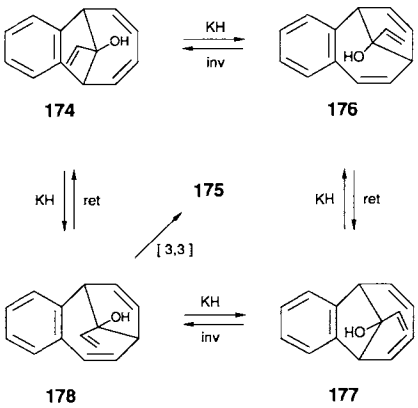
[3,3] sigmatropy is enhanced for **169** (1:20) and becomes exclusive when **170** is the substrate.[68] The pair of [1,3] shifts capable of operating within **171** are not at all competitive, the exclusive formation of **172** revealing a decided preference for C-1/C-7 bond cleavage.[102]

The propensity for two-carbon homologation persists in larger bicyclic frameworks such as found in **173** [Eq. (58)].[103] In parallel fashion, the potassium salt of benzo analogue **174** is transformed quantitatively into **175** within two minutes at 24 °C. On progressing to lower temperatures, *Mukai* et al. were able to establish that treatment of **174** with potassium hydride leads quickly to establishment of



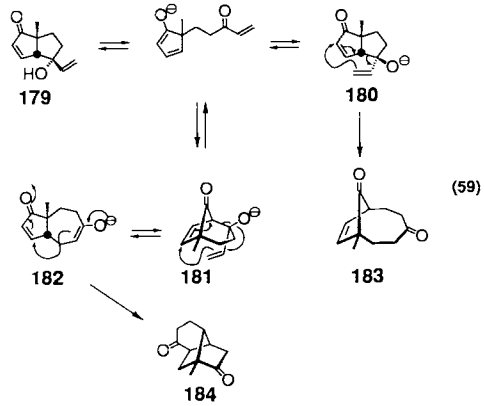
(58)

an equilibrium with the three isomeric allylic alcohols **176**–**178** (Scheme 7). With the passage of time, the proportion of **175** increases at the expense of these base-sensitive benzobicyclononatrienols.[103]



Scheme 7. Anionically accelerated circumambulatory [1,3] sigmatropic rearrangements in **174**.

Hydroxy ketone **179** is so configured that its olefinic centers cannot become proximate. Nevertheless, when exposed to base, **179** is transformed into either **183** or **184** depending on the reaction conditions [Eq. (59)].[104] The use of KOH in aqueous methanol provides **183**. With excess KH in tetrahydrofuran, **184** results. These events have been rationalized in terms of initial ring fission and reclosure to **180** or **181**. Both

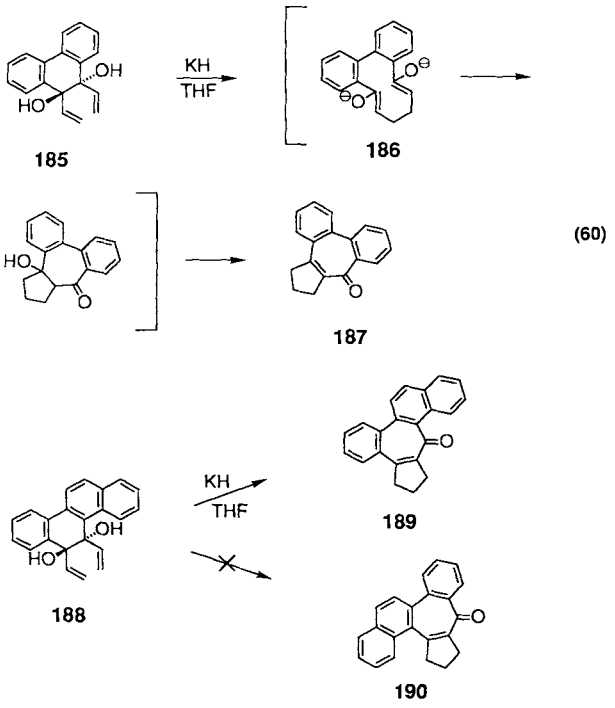


(59)

of these intermediates are structurally disposed for oxy-Cope isomerization. While **180** is the obvious immediate precursor of **183**, the enolate anion formed from **181** must undergo aldol closure prior to arriving at **184**.

12. Dianionic Oxy-Cope Processes

Dianionic oxy-Cope rearrangements have received remarkably little attention, although divinyl alcohols are well recognized to be quite susceptible to thermal [3,3] sigmatropy.[105] In the few examples that have been studied, large ring dienolates have resulted and these intermediates have undergone transannular aldolization during workup. The *trans* diol **185**, available from 9,10-phenanthraquinone, is isomerized initially to **186** when heated with KH in tetrahydrofuran. The actual isolated product is the dibenzotropone **187**, probably formed as indicated [Eq. (60)].[106] The *trans* stereochemistry is a necessary prerequisite for this rearrangement since the vinyl groups must both be equatorially disposed to be within bonding distance.

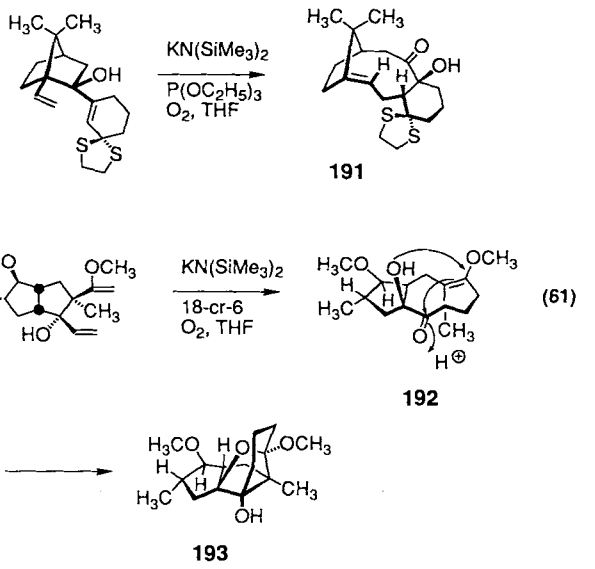


Diol **188** behaves analogously, giving rise to **189** and not to **190**.[106]

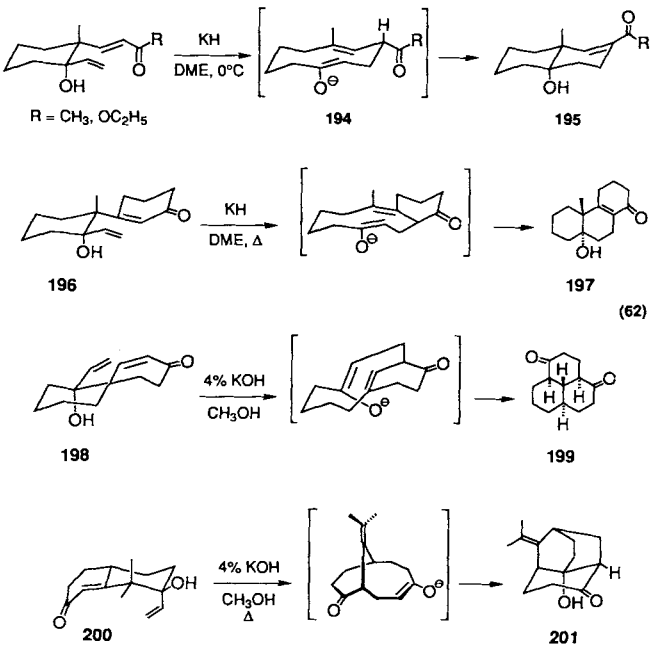
13. Tandem Pairing of the Oxy-Cope Rearrangement with a Second Chemical Event

13.1. [3,3] Sigmatropy Occurring First

The powerful capacity of the anionic oxy-Cope rearrangement for stereoselective molecular construction can be usefully expanded by direct linking of this isomerization to a sequential reaction. Described above are examples where the regiospecifically generated enolate anion is trapped at oxygen [Eqs. (14) and (17)] or alkylated at the α carbon [Eqs. (28) and (55)]. When enolate equilibration operates, advantage can often be taken of the new locus of negative charge [Eq. (47)]. An expedient means for preparing polycyclic α-hydroxy ketones has been developed by taking advantage of in situ enolate hydroxylation [Eq. (61)].[107] The locus of the newly introduced oxygen atom depends, of course, on the regiochemistry of enolate formation. Products **191** and **192** provide two contrasting examples. The acid-catalyzed closure of **192** to **193** adds yet another interesting parameter to these transformations.

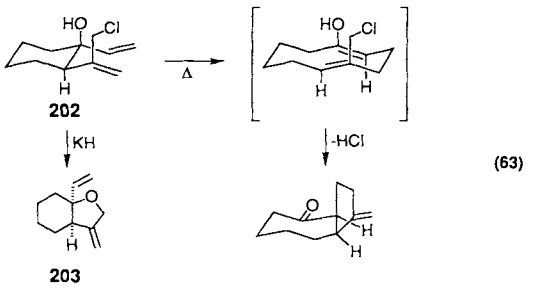


Since the oxy-Cope process is tolerant of various functional groups, it is often convenient to incorporate within the starting alcohol features that are conducive to subsequent transannular cyclization [Eqs. (33), (59), and (60)]. Four ingenious examples are collected in Equation (62). Arrival at



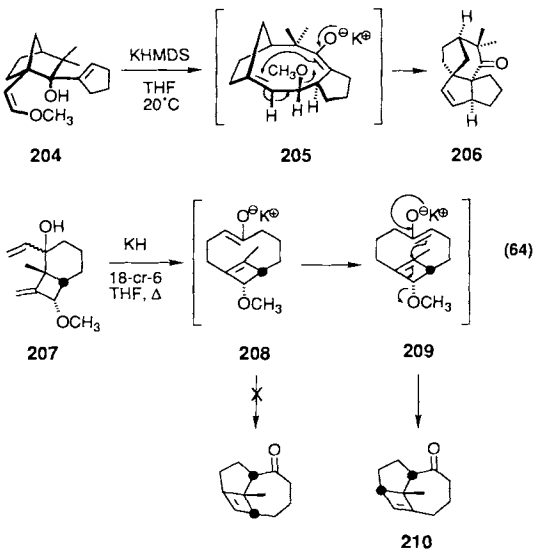
195 is seemingly dependent on proton transfer within **194** to generate a new enolate that is suitably aligned stereoelectronically for intramolecular nucleophilic capture of the nonconjugated carbonyl.[108] The conversions **196** → **197**,[109] **198** → **199**,[51] and **200** → **201**[110] are predicated on similar considerations of orbital overlap control.

The feasibility of trapping an enol in an irreversible intramolecular alkylation step has been demonstrated [Eq. (63)].[48] When a halide leaving group is involved as in **202**, the oxy-Cope rearrangement must be performed thermally. Attempts to implement charge acceleration techniques resulted instead in premature intramolecular ether formation as exemplified by **203**.



(63)

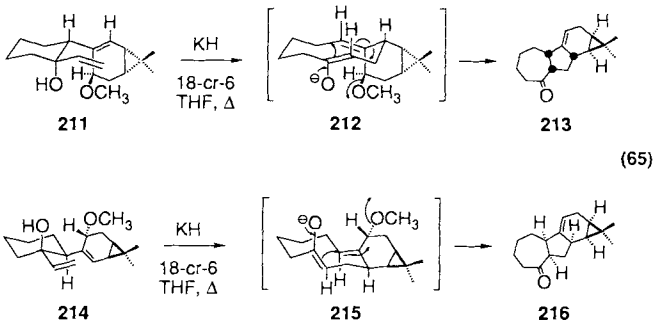
In contrast, medium-ring enolate anions generated by [3,3] sigmatropy do successfully undergo transannular cyclization concomitant with S_N' displacement of a methoxyl leaving group, provided that the C–OCH_3 bond is properly aligned with the flanking π orbital. Structurally intricate polycyclic ketones are thereby constructed with rapidity and efficiency. As an illustrative example, **204** is smoothly transformed in a single maneuver via **205** into the complex diquinane **206** at room temperature [Eq. (64)].[111] In yet another fascinating reaction, heating of the potassium alkoxide of **207** gives **208** as the first-formed intermediate. As a consequence of the enormous strain that would result from intramolecular methoxide displacement within this intermediate, there is ample time for enolate equilibration with **209** to transpire in advance of conversion to **210**.



(64)

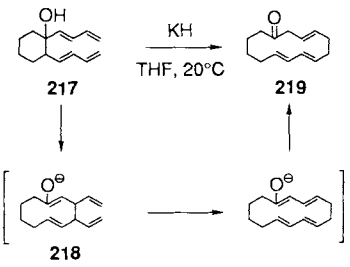
KHMDS = potassium hexamethyldisilazanide

The possibility of achieving the stereocontrolled construction of hydroazulenones by sequential anionic oxy-Cope rearrangement with S_N' allylic ether displacement has been examined with considerable success. Thus, ring expansion of **211** proceeds via **212** to give **213** as the first-formed tetracyclic product [Eq. (65)].[112] Alcohol **214** also enjoys a kinetic predisposition for generation of a *trans,trans*-cyclodecadiene (namely, **215**) and ultimately delivers **216**. Whereas the geometry present in **212** and **215** is necessary to bring the double bonds into a closely proximate arrangement, the ensuing S_N' displacement of methoxide ion is found to occur with equal facility from the frontside or backside.



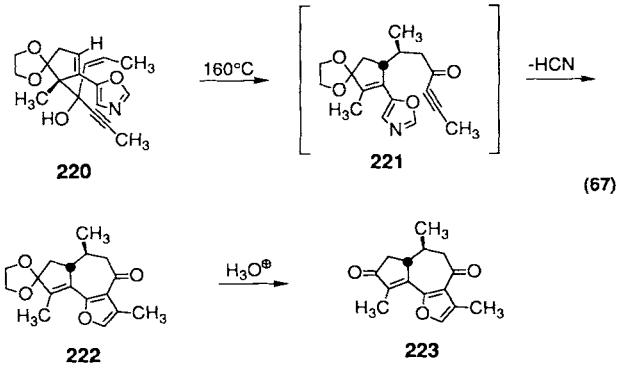
(65)

Wender et al. have found that **217** rearranges under alkaline conditions to give the 14-membered ketone **219**, which has served as a precursor to (±)-muscone[113] and to (−)-(3*Z*)-cembrene A.[114] Although the observed macroexpansion is consistent with the direct involvement of enolate anion **218** or its macrocyclic isomer [Eq. (66)],[115] later investigation has provided solid indication that the stepwise process is the more favored.[116] Since **218** does not accumulate during this fast reaction, it is necessary that the presence of the enolate in **218** accelerate the Cope rearrangement that leads to **219**. The synthetic advantages that accrue to this remarkable type of charge acceleration are beginning to receive attention.[117]



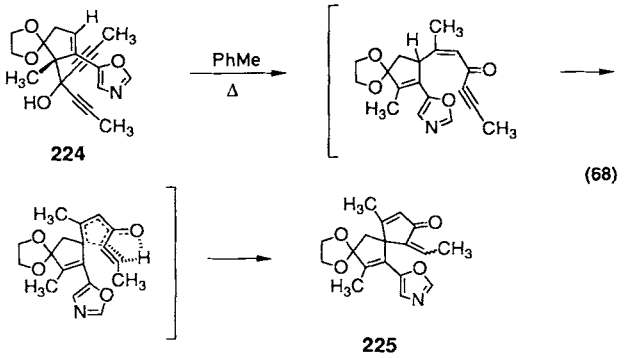
(66)

The regiochemical control assured by the geometrical constraints of the oxy-Cope reaction can be utilized further to set the stage for subsequent intramolecular cycloaddition or electrocyclization. *Jacobi* et al. have been responsible for uncovering examples of each tandem process. Heating the pure *Z* alcohol **220** at 160 °C resulted in direct conversion to ketal **222**, mild acid hydrolysis of which afforded gnididione (**223**) [Eq. (67)].[118] This elegant transformation owes its success to the capacity of intermediate **221** for intramolecular Diels–Alder addition involving the electron-deficient triple bond and isoxazole ring.



(67)

Bis-acetylenic alcohols such as **224** undergo facile oxy-Cope rearrangement to afford mixtures of *E* and *Z* enynones. Upon enolization, these latter compounds experience electrocyclic ring closure with the formation of methylenecyclopentenones (e.g., **225**) [Eq. (68)].[118]



(68)

13.2. [3,3] Sigmatropy Occurring Last

While tandem rearrangements of the Claisen–Cope variety are well known,[119] there appear to be no known examples of two-step reaction sequences where the final stage is of the oxy-Cope type (excluding, of course, syntheses of the alcohols themselves).

14. Summary and Outlook

In either its neutral or anionic version, the oxy-Cope rearrangement constitutes an intrinsically sophisticated means for achieving internal chirality transfer within the context of polycyclic ketone construction. To the extent that diastereoselectivity can be controlled during formation of the divinyl alcohol, the ensuing [3,3] sigmatropic shift will lead to products having well-defined networks of stereogenic centers. Variation of the nucleophile has been very limited and clearly will expand as more complex vinyl anions become increasingly available. Access to more structurally diverse β,γ-unsaturated ketones will undoubtedly bring about new opportunities for isomerizations of this type. All existing signs suggest that growth in this area will not only be feasible but intensively pursued.

The ring systems capable of being accessed by the oxy-Cope process seem limited only by the imagination of the researcher. The convergency of the carbonyl regeneration scheme allows for combinatorial possibilities that assure the exercise of many more options in the future. Perhaps the most exciting and challenging feature of this two-step process will be suitable development of reliable transition-state models that shall ultimately allow for simultaneous kinetic resolution—an area in which studies have been made, but more needs to be done.

The oxy-Cope reaction offers great opportunities for realizing totally new dimensions in the synthesis of complex molecules. The flexibility, stereochemical reliability, brevity, and efficiency of the scheme bode especially well for extensive future application.

The theory and experiment for which we are responsible has been brought to fruition by the enthusiasm, dedication, intellectual prowess, and experimental skills of a relatively small number of students. These efforts have been made possible by the financial support of the National Institutes of Health. Fellowships from the Deutsche Forschungsgemeinschaft (FRG), NATO/SERC (UK), NSERCC (Canada), and the CNRS (France) have contributed support to my postdoctoral associates from these countries.

The Coordination Chemistry and Organometallic Chemistry of Tridentate Oxygen Ligands with π-Donor Properties

By Wolfgang Kläui*

Metal complexes are capable of accomplishing almost anything, provided they contain the proper metal/ligand combinations. A host of essential biochemical transformations—but also a great many industrially significant reactions—occur within the coordination spheres of metal ions. For instance, the particular arrangement of ligands in the zinc-containing enzyme carboanhydrase is responsible for an acceleration in the hydration of CO_2 by a factor of 10^9. It is the ligands that determine whether an iron atom will transfer molecular oxygen, as in the case of hemoglobin, or electrons, as with the cytochromes. By varying the ligands it is possible to establish in advance whether a metal ion in the presence of synthesis gas will cause an olefin to be hydrogenated or hydroformylated. Stated more generally, it is the ligands that stabilize the particular oxidation states of a metal and determine how substrate molecules will be coordinated and undergo reaction. The synthesis of new ligands that confer specific reactivity on metal ions is thus an important challenge for the coordination chemist. The following article describes organometallic compounds of the type $[CpCo\{P(O)R'R''\}_3]^{\ominus}$, which have developed from an extremely unreactive laboratory curiosity into versatile oxygen-containing ligands whose steric and electronic properties promise a series of interesting applications.

1. Introduction

Most chemistry students encounter multidentate ligands (chelating ligands) for the first time in the course of an EDTA determination of the metal content of an aqueous solution. Chelating ligands important in analytical chemistry, biochemistry, and industrial extraction processes often feature one or more nitrogen atoms as donor centers. Important oxygen chelate ligands include the β-diketonates present as components in NMR lanthanide shift reagents, such natural antibiotic ionophores as valinomycin, and the crown ethers introduced by *Pedersen*. The present contribution describes the coordination chemistry of a class of monoanionic tridentate ligands in which all three of the complexing donor atoms are oxygen. These ligands display various remarkable properties. Chemically, they are extremely robust; even though they represent organometallic compounds of the "half-sandwich" type, they nevertheless dissolve without decomposition in aqueous sulfuric acid. They are not oxidized at all by atmospheric oxygen, and only with difficulty by nitric acid. At the same time, some of the ligands offer the surprising ability of producing sodium salts that are highly soluble, not only in water but also in pentane. All the ligands have the general constitution $[(C_5R_5)M\{P(O)R'R''\}_3]^{\ominus}$, with $C_5R_5 = C_5H_5$, C_5Me_5; M = Co, Rh; and R',R'' = alkyl, aryl, or *O*-alkyl (compare **2** in Scheme 1). They will be uniformly abbreviated by $L^{\ominus}$.[1] In Scheme 2, **3** is mentioned as a rhodium analogue.

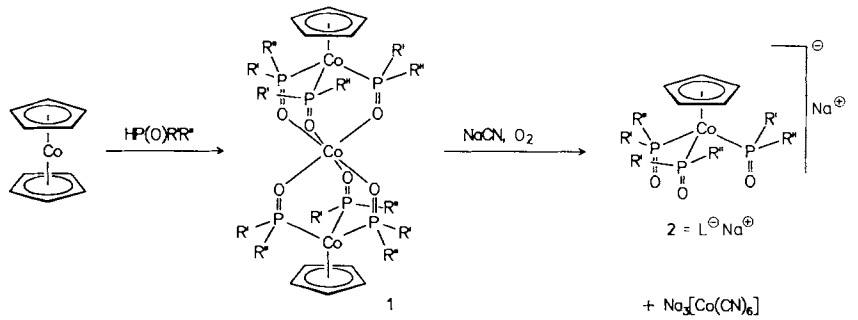
Thus, the species in question are anionic cyclopentadienyl complexes, which because of the three P=O-functions[2] prove to be excellent tridentate oxygen ligands. In order to call attention to their C_{3v} symmetry they have been described[2] as oxygen tripod (i.e., "three-footed") ligands. This article constitutes a summary answer to the following questions: How are such tripod ligands synthesized? What is unusual about them? What can they do that other ligands cannot?

2. Synthesis of the Ligands

When cobaltocene is heated without solvent to ca. 100 °C in the presence of diesters of phosphorous acid[10] or secondary phosphane oxides,[11] one obtains directly the cobalt(II) complexes CoL_2 **1** containing oxygen tripod ligands. The free ligands $L^{\ominus}$ can be released by cleaving the compounds CoL_2 with cyanide in the presence of atmospheric oxygen.[12] The mechanism for the first step is only part explained,[13] but the second step can be regarded as a simple ligand substitution, which is followed by oxidation and further reaction of the intermediate ion $[Co(CN)_5]^{3\ominus}$ to give the stable Co^{III} complex $[Co(CN)_6]^{3\ominus}$. The synthesis can actually be carried out as a one-pot reaction and enables the introduction of almost any substituent R (Scheme 1).

If the two groups R' and R'' differ, what one obtains is a tripod ligand in which the three phosphorus atoms are stereogenic centers. This means that 16 stereoisomeric complexes CoL_2 are possible (seven pairs of enantiomers and two meso compounds), and if substituents R' and R'' are small, then all 16 are formed in comparable amounts.[15,16] On the other hand, if R' and R'' differ in size, cleavage with cyanide leads to a uniform ligand $L^{\ominus}$ consisting only of the (*R*, *R*, *R*)- and (*S*, *S*, *S*)-enantiomers[17] (Fig. 1).

These ligands can also be prepared stepwise. The CO- and iodo-ligands in $[(C_5H_5)M(CO)I_2]$, M = Co, Rh, are first re-



R', R'' = OCH_3, OC_2H_5, $OCH(CH_3)_2$, $OCH_2CH(CH_3)_2$, OC_4H_9, $OCH_2C(CH_3)_3$
CH_3, C_2H_5, C_4H_9, $CH_2C_6H_5$, C_6H_5, p-ClC_6H_4

Scheme 1. Synthesis of **2** = $L^{\ominus}Na^{\oplus}$ from cobaltocene via **1**.

placed by trimethylphosphite, after which the three coordinated trimethylphosphite ligands may be converted successively into dimethylphosphito ligands with the aid of the

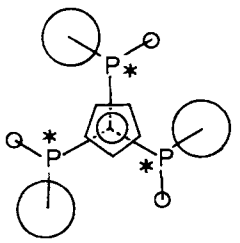


Fig. 1. Newman projection along the three-fold axis of a chiral ligand $L^{\ominus}$ with the (*R,R,R*)- or (*S,S,S*)-configuration.

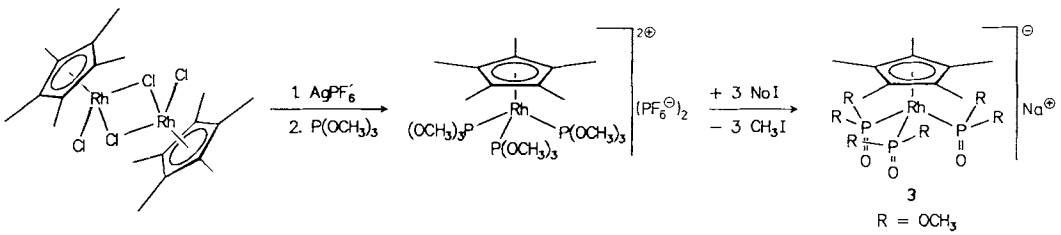
Michaelis–Arbuzov reaction.[18] With this synthetic route one has, in addition to the cobaltocene route, also an entry to the analogous rhodium ligands. The synthesis of ligands of type **3** containing a C_5Me_5 (= Cp*)R fragment is possible via the route shown in Scheme 2.

Phosphorus compounds with the general composition $P(OR)_2(OMe)$ (= dialkylmethylphosphites), $PR(OR)(OMe)$ (= alkylmethylphosphonites), and $PR_2(OMe)$ (= methylphosphinites) can also be introduced in place of trimethylphosphite.

3. What Typifies the Complex Chemistry of the Ligands $L^{\ominus}$?

The two synthetic pathways described above are complementary in the sense that $L^{\ominus}$ is subject to modification at each position, permitting the preparation of an entire class of monoanionic oxygen tripod ligands with C_{3v} symmetry. Were one to attempt a characterization of this new type of ligand, the following questions would all need to be taken into account:



Scheme 2. Synthesis of the rhodium analogue **3** of $L^{\ominus}Na^{\oplus}$ **2** via the Michaelis-Arbuzov reaction.

Wolfgang Kläui was born in 1945 in Zürich, Switzerland. He received his Dipl.-Chem. (1971) and Dr. phil. (1973) degrees at the University of Zürich where he worked under H. Werner. In 1974 he was granted a fellowship of the Royal Society to work with Sir Jack Lewis (now Lord Lewis) in Cambridge (UK). He completed his Habilitation in 1979 at the University of Würzburg (FRG), became a "Privatdozent" there, and was appointed Professor of Inorganic Chemistry in 1982 at the Rheinisch-Westfälische Technische Hochschule in Aachen (FRG).

- With which metals and in what oxidation states do the ligands prefer to form complexes?
- How stable are the resulting complexes?
- What coordination geometries are favored?
- Are the ligands $L^{\ominus}$ strong or weak; i.e., do they induce large or small ligand field splittings Δ?
- Are they hard or soft ligands?

3.1. With which Metals does $L^{\ominus}$ form Complexes?

In the course of our first experiments with the ligand $L^{\ominus}_{OEt}$ [*] we were struck by the fact that it formed complexes with almost every metal ion examined[12, 19–23] (Fig. 2). Its behavior with respect to ions of the third main group[10, 12]

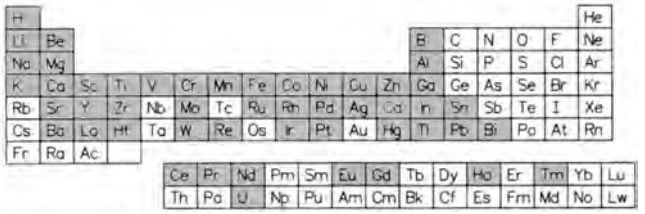


Fig. 2. All the elements shaded in gray are known to form complexes with the ligands $L^{\ominus}$.

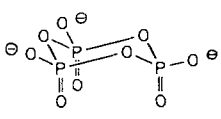
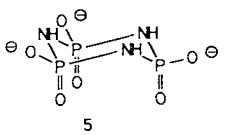
is instructive to consider in this context. In the case of $Al^{3\oplus}$, $Ga^{3\oplus}$, $In^{3\oplus}$, and $Tl^{3\oplus}$ one obtains the expected 2:1 complexes $[ML_2]^{\oplus}$, with an octahedral arrangement of oxygen atoms. Reaction with $BF_4^{\ominus}$ or $BPh_4^{\ominus}$ produces the cations $[LBF]^{\oplus}$ and $[LBPh]^{\oplus}$, which may be regarded as 1:1 complexes of $L^{\ominus}$ with the unknown ions $BF^{2\oplus}$ and $BPh^{2\oplus}$. This is rather remarkable, since relatively few ligands are known to show such a willingness to form both metal and nonmetal derivatives. In this sense $L^{\ominus}$ resembles the fluoride ion, with which it also has much in common electronically (see Section 3.3).

The ligand $L^{\ominus}$ displays a strong tendency to undergo facial tridentate binding even with metal ions that do not favor this coordination (see, e.g., Ref. [23]). Trimetaphosphate $[P_3O_9]^{3\ominus}$ **4** or trimetaphosphimate $[P_3O_6(NH)_3]^{3\ominus}$ **5** would appear to represent simple models for $L^{\ominus}$ if they were characterized by the same coordination behavior as the latter.



4



5

This hypothesis cannot actually be tested in the case of trimetaphosphate, since there are very few trimetaphosphate–metal complexes whose crystal structures have been characterized.[6, 7] By contrast, the coordination chemistry of the isoelectronic trimetaphosphimate ion with metal aqua ions has been thoroughly investigated by *Sokol, Rozanov* et al. The results indicate that this particular *O,O,O*-tripod ligand displays much weaker chelate formation than $L^{\ominus}$ due to the flexibility of its six-membered ring. For example, it acts only as a bidentate P=O ligand with respect to $Cu^{2\oplus}$ in the complex $[Cu(H_2O)_2\{P_3O_6(NH)_3\}_2]^{4\ominus}$.[24] The original chair conformation of the six-membered ring is so distorted that the third coordination site is turned away from the copper ion, leaving the axial position of the CuO_6 octahedron occupied by water. Consequently, the Cu^{II} ion acquires a coordination polyhedron that is quite elongated. On the other hand, the ligands $L^{\ominus}$ in the analogous compound $[Cu(L_{OEt})_2]$ function as tridentate P=O ligands, and the Jahn–Teller distortion of the CuO_6 octahedron is particularly small.[21] Trimetaphosphimate in the polymeric compounds $NaM^{II}\{P_3O_6(NH)_3\}\cdot 7H_2O$, M = Zn, Co, acts as a tridentate ligand bridging two zinc or cobalt ions, forming two M–O bonds to one metal ion and one bond to the other.[25] The praseodymium ion achieves the coordination number eight in the complex salt $K_{1.3}(NH_4)_{1.7}Pr\{P_3O_6(NH)_3\}_2\cdot 8H_2O$ through the fact that one trimetaphosphimate serves as a tridentate terminal ligand, while the second assumes the function of a pentadentate bridging ligand.[26]

3.2. How Stable are the Complexes?

In order to characterize the complexing ability of the ligands $L^{\ominus}$ quantitatively and to ascertain why the observed values are so high, *Anderegg* determined a series of stability constants and conducted thermochemical measurements.[27]

Close examination of the data in Table 1 reveals three striking facts:

Table 1. Complex stability constants $\log K_1$ and $\log \beta_2$ for $L^{\ominus}_{OEt}$ with mono- and divalent ions in 95% methanol/water.

$\log K_1$	$\log K_1/\log \beta_2$	$\log K_1/\log \beta_2$
H 8.8	Mg 9.2/15.9	Mn 9.4/16.6
Li 6.1	Ca 9.1/16.5	Co 9.4/15.6
Na 4.1	Sr 8.1/13.7	Ni 8.6
K 3.6	Ba 7.7/12.9	Cu 9.4/15.8
	Pb 9.2/14.6	Zn 9.1/14.6
		Cd 7.7/14.8

1) K_1 and β_2 are nearly independent of the size of the metal ions; a difference of only 1.5 logarithmic units (corresponding to a factor of 30) separates the smallest ion, $Mg^{2\oplus}$ (r = 65 pm), from the largest, $Ba^{2\oplus}$ (r = 135 pm). Apparently the "bite" of this tripod ligand is sufficiently flexible to accommodate the steric demands of the metal ion with little loss in stability.
2) The 1:1 complex with $Na^{\oplus}$ is less stable than *Lehn*'s cryptand complexes, but it is nevertheless more stable than crown ether complexes of $Na^{\oplus}$.
3) No selectivity is observed with respect to the 3d transition metal ions (Fig. 3). In the case of ethylenediamine, glycinate, malonate, and many other ligands, the complex stability constants increase along the Irving–Williams series from manganese through iron, cobalt, and nickel up to copper, decreasing again with zinc. The effect is especially

[*] In order to specify the substituent R on the phosphorus atom of $L^{\ominus}$, the abbreviation $L^{\ominus}_R$ will be used from this point on.

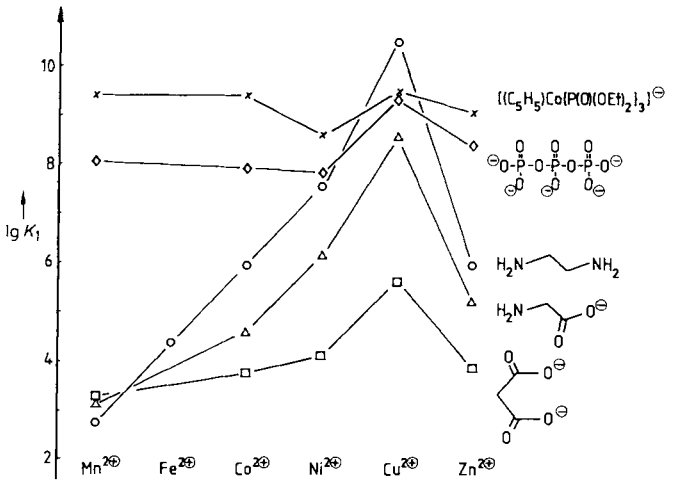


Fig. 3. Graphic representation of the complex stability constants $\log K_1$ of $L^{\ominus}_{OEt}$ and several typical chelating ligands with the metal ions $Mn^{2\oplus}$–$Zn^{2\oplus}$. K_1 is valid for the reaction $M^{2\oplus}$ + ligand $\rightleftharpoons$ M(ligand)$^{n\oplus}$.

prominent with ethylenediamine. Two ligands fail to conform to the Irving–Williams series: the oxygen tripod ligand $L^{\ominus}_{OEt}$ and tripolyphosphate. For both of these ligands, *all* the complex stability constants are high, and they are essentially independent of the nature of the metal ion. Thermochemical data explain the difference: ligands such as ethylenediamine conform to the Irving–Williams series because complex formation becomes increasingly *exothermic* from Mn to Cu, ΔH turning less strongly negative once again only with Zn. By contrast, complex formation with tripolyphosphate is significantly *endothermic*! The large K_1 values for tripolyphosphate are a consequence of an extraordinarily high entropy of complexation. The same is apparently true for the oxygen tripod ligands $L^{\ominus}$ as well.

$$Mg^{2\oplus}_{aq} + 2L^{\ominus} \overset{25\,^{\circ}C}{\rightleftharpoons} MgL_2, \quad \log\beta_2 = 16 \qquad (a)$$
$$\Delta S = 73\ \text{cal mol}^{-1}\,\text{K}^{-1}$$
$$T\Delta S = 22\ \text{kcal mol}^{-1}$$
$$\Delta H = 0\ \text{cal mol}^{-1}$$

Thermodynamic data confirm that the large formation constant in complexation according to Equation (a) (10^{16}) is a consequence solely of the entropy term. The value for ΔS (73 cal mol^{-1} K^{-1}) is many times larger than one would expect for the replacement of 6 mol of water by 2 mol of tripod ligand. An explanation is to be found in the fact that the oxygen tripod ligand $L^{\ominus}_{OEt}$ induces a considerable amount of structure in the solvent water, and this structure largely disappears upon complexation.

3.3. Oxygen Tripod Ligands $L^{\ominus}$; Weak and Hard!

Determining whether a ligand forms stable or unstable complexes with metal ions provides no insight whatsoever into the question of whether the ligand is strong or weak in terms of ligand field theory. The electronic spectra of complexes between oxygen tripod ligands and 3d transition metal ions such as $Ti^{3\oplus}$, $Co^{2\oplus}$, $Ni^{2\oplus}$, and $Cu^{2\oplus}$ present a clear picture: the spectra can be described to a close approximation as representing a summation of the (d-d)spectra for the MO_6 fragment and the ligand-internal transitions. Evaluation[18,28] of the (d-d)band positions makes it possible to arrange a set of ligands in both a spectrochemical[29] and a nephelauxetic series[29,30] (Fig. 4).

The oxygen tripod ligands are among the weakest of the oxygen ligands. They are significantly weaker than water, and fall roughly together with fluoride. They are also extremely hard ligands, with a position in the nephelauxetic series corresponding approximately to that of water or dimethylsulfoxide coordinated via oxygen. This finding may be interpreted as showing that the CpCo and Cp*Rh fragments provide no opportunity for delocalization of the d electron density of metal ions coordinated through the P=O bridges.[31] To a first approximation, the electronic properties of the tripod ligands are equivalent to those of fluoride or oxide.[32]

3.4. $[CoL_2]^{\oplus}$, the First Octahedral "Spin-Crossover" Co^{III} Complex

Co^{III} complexes are unusually numerous, and virtually all of them are hexacoordinate, kinetically inert, and diamagnetic, with d^6 low-spin electronic configurations.[33] This generalization has been a consistent feature of cobalt complex chemistry since the days of *S. M. Jörgensen* and *A. Werner*. The most prominent exception cited in textbooks is the paramagnetic d^6 high-spin ion $[CoF_6]^{3\ominus}$, first described by *Klemm* et al.[34] Since $[Co(H_2O)_6]^{3\oplus}$ displays a low-spin configuration[35] and $L^{\ominus}$ has electronic properties intermediate between those of fluoride and water, a question naturally arises about the magnetic characteristics of cobalt(III) complexes bearing the ligand $L^{\ominus}$. Are the $[CoL_2]^{\oplus}$ complexes also low-spin, or do they represent a second example of

octahedral cobalt(III) with a high-spin configuration, joining $[CoF_6]^{3\ominus}$?

We were able to prepare $[Co(L_{OEt})_2]PF_6$ by electrochemical oxidation of $[Co(L_{OEt})_2]$.[36, 37] The compound is dark green and paramagnetic at room temperature, but cooling causes it to become lemon-yellow and diamagnetic. The energy difference between the d^6/high-spin and d^6/low-spin electronic configurations for this compound apparently is of the same order of magnitude as kT. This situation is depicted graphically in Figure. 5. The magnetic properties of the compound are thus highly temperature-dependent. The observed thermochromism is also easily explained, because d^6/high-spin and d^6/low-spin correspond to two different chromophores.

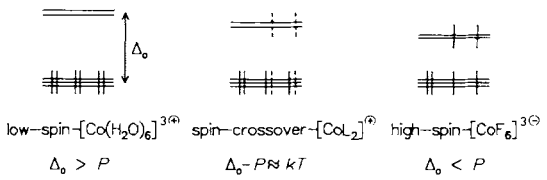

Fig. 5. d-Orbital splitting and magnetism of cobalt(III) complexes in an octahedral ligand field (one-electron approximation, Δ_0 = ligand field splitting, P = spin-pairing energy).

Altering the substituents on the phosphorus atoms of the tripod ligands makes it possible to adjust the state of the spin equilibrium in almost any way desired.[28, 38] Figure 6 illustrates this point through the temperature dependence of the chemical shift δ of the ^{31}P-NMR signal in the complexes $[Co(L_R)_2]^{\oplus}$ (**6a–6e**, R = Et, OMe, OEt, O*n*Bu, O*i*Pr). The cobalt(III) complexes **6b–e** containing O-alkyl-substituted ligands display temperature-dependent high-spin/low-spin equilibria, whereas complex **6a** with an ethyl-substituted ligand is diamagnetic throughout the examined temperature range. Apparently, replacing the electron-withdrawing O-alkyl group by the electron-releasing ethyl substituent leads to a larger ligand-field splitting, which in turn stabilizes the diamagnetic low-spin configuration.

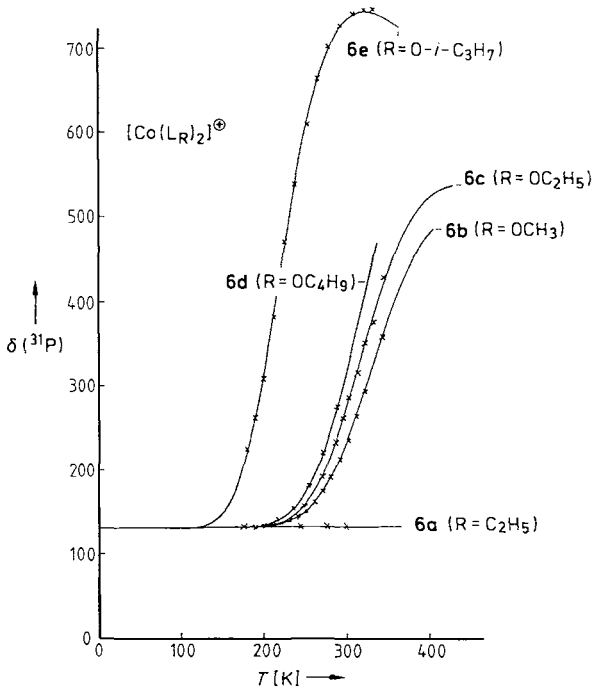

Fig. 6. Temperature dependence of ^{31}P-NMR chemical shifts of the cobalt(III) complexes $[Co(L_R)_2]^{\oplus}$ **6a–e**.

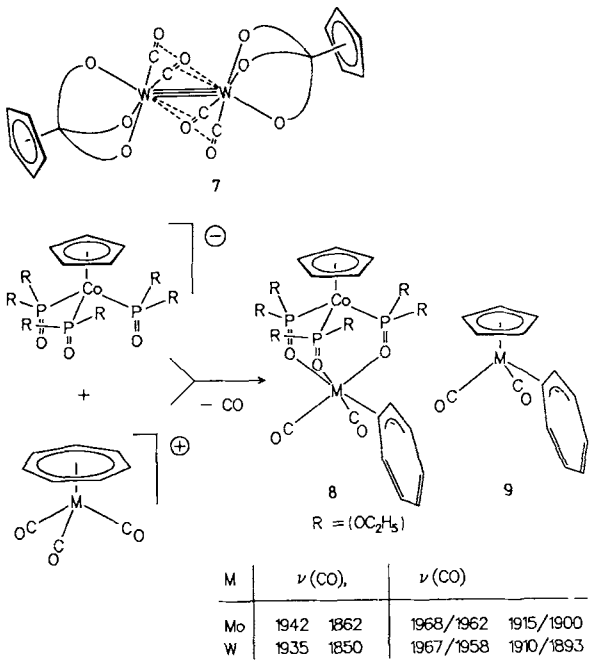
$L^{\ominus}_{OiPr}$ is the weakest ligand—but for steric, not electronic reasons. Repulsive intramolecular ligand-ligand interactions in $[Co(L_R)_2]^{\oplus}$ lead to an increased metal–ligand distance. This causes the ligand field strength to become smaller and the high-spin configuration more stable. The effect is most evident with **6e**, which at room temperature is almost 75% in the high-spin form. Spectroscopic characterizations and magnetic data provide a consistent picture of the tripod ligands: electronic or steric effects of substituents R make it possible to fine-tune the ligand field strength, but the ligands always display the characteristics of oxygen ligands that are both very weak *and* hard.

4. Organometallic Chemistry of the Oxygen Ligands $L^{\ominus}$

The placement of $L^{\ominus}$ between water and fluoride in the spectrochemical series means that these ligands can be compared in terms of their electronic characteristics with oxo ligands. Consequently, one might expect them to be quite effective at stabilizing metal ions in their middle and high oxidation states. Indeed, 2:1 complexes of $L^{\ominus}$ ligands are known for titanium (II, III, or IV) and vanadium(II, III, or IV), as are 1:1 complexes with molybdenum(V) and tungsten(VI).[39] The reduction potentials (III/II) for vanadium, chromium, and iron complexes of the type ML_2 are 950–1050 mV more negative than those of the corresponding aqua ions![37, 39] It is thus remarkable that the ligands $L^{\ominus}$ are also capable of stabilizing carbonylmetal fragments. For example, hexacarbonyltungsten reacts with NaL_{OEt} to produce the air-stable, dark red binuclear compound $[L_2W_2(CO)_4]$ **7**, which consists of two $LW(CO)_2$ fragments joined by a W≡W triple bond.[40]

Scheme 3 shows the reaction of NaL with the tropylium complexes $[(C_7H_7)M(CO)_3]^{\oplus}$ (M = Mo, W). Here, one carbon monoxide ligand is displaced, and the symmetrically η^7-coordinated C_7H_7 ring is transformed into a ring system with allylic (η^3) binding. The resulting free coordination sites are occupied by the three oxygen "teeth" of the tripod ligand. The compounds **8** may be regarded as analogous to the complexes **9**, since both $L^{\ominus}$ and $Cp^{\ominus}$ formally represent facially coordinated, monoanionic 6e ligands. Nevertheless, the CO-vibrational frequencies listed in Scheme 3 indicate that the similarity does not extend to electronic properties: the CO bands in **8** are 25–50 wave numbers lower than the CO bands in **9**.

The fluxional behavior characteristic of η^3 bound tropylium rings is present with both the $L^{\ominus}$ complexes and the isoelectronic cyclopentadienyl compounds[41] (cf. Fig. 7, upper half). Metallotropic rearrangement proceeds much more slowly with the tripod derivatives than in the case of the cyclopentadienyl compounds. This makes it possible by cooling to reduce the rate of the degenerate rearrangement of



M	ν(CO),		ν(CO)	
Mo	1942	1862	1968/1962	1915/1900
W	1935	1850	1967/1958	1910/1893

Scheme 3. Synthesis and CO vibrational frequencies [cm^{-1}] of the tropylium complexes **8**. For purposes of comparison, the corresponding frequencies are also provided at the right for the Cp-analogues **9**.

the tropylium ring to such an extent that the molecules appear static on the NMR time scale (Fig. 7, lower half).

The higher stability of these compounds compared to the corresponding cyclopentadienyl derivatives is astonishing, since no oxygen ligands other than $L^{\ominus}$ are known to be capable of efficiently stabilizing the fragment $[Mo(\eta^3\text{-}C_7H_7)(CO)_2]^{\oplus}$. In contrast to $Cp^{\ominus}$, $L^{\ominus}$ is only weakly basic,[27] so many tripod complexes of carbonyl-metal fragments can be both prepared and subjected to reaction in aqueous medium. For example, the acetonitrile complexes $[(CH_3CN)_3M(CO)_3]$ (M = Cr, Mo, W) react smoothly in

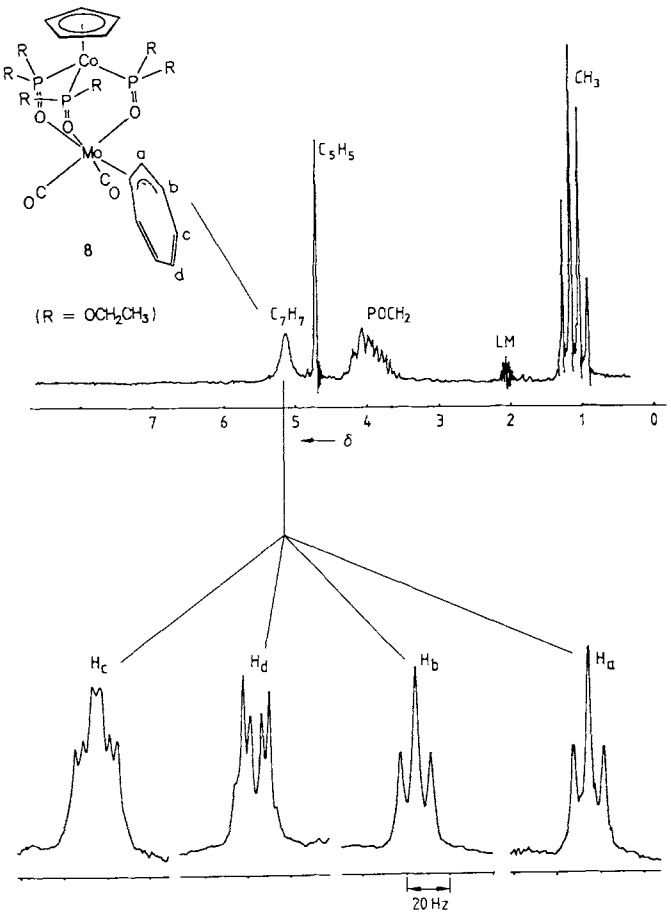


Fig. 7. ^{1}H-NMR spectrum of **8** for M = Mo. Above: entire spectrum (298 K, 60 MHz; LM = solvent [D_6]acetone). Below: region of C_7H_7 signal at 193 K (270 MHz).

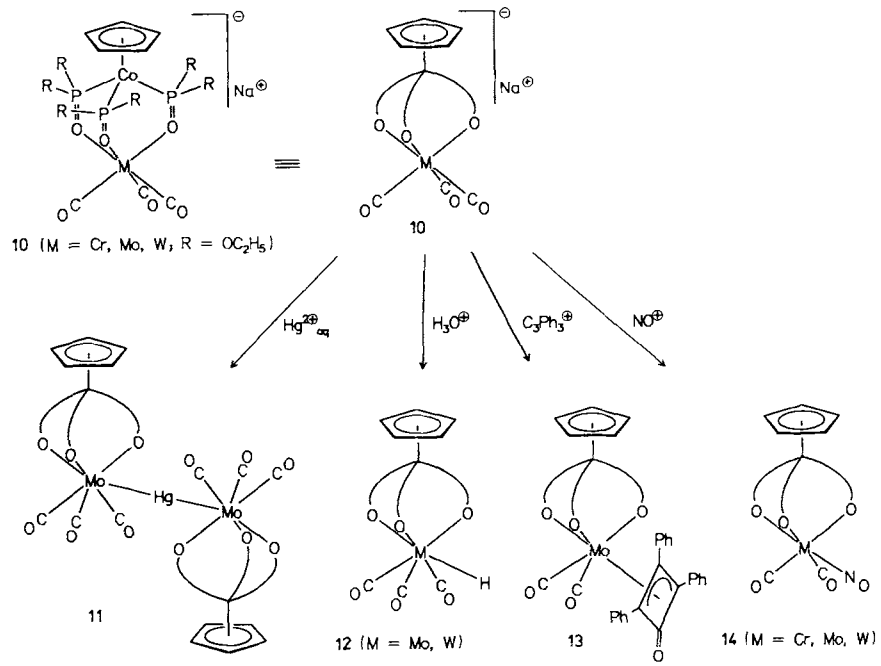
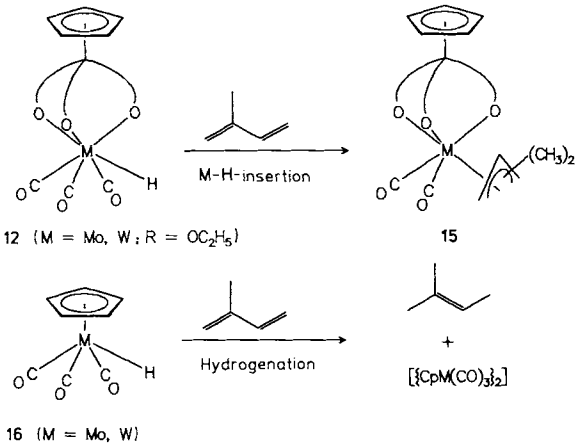
water to give $[LM(CO)_3]^{\ominus}$ **10**.[42] Allyl, hydride, alkyl, and carbyne derivatives of carbonyl molybdenum and tungsten complexes can be equally effectively stabilized by $L^{\ominus}$. The

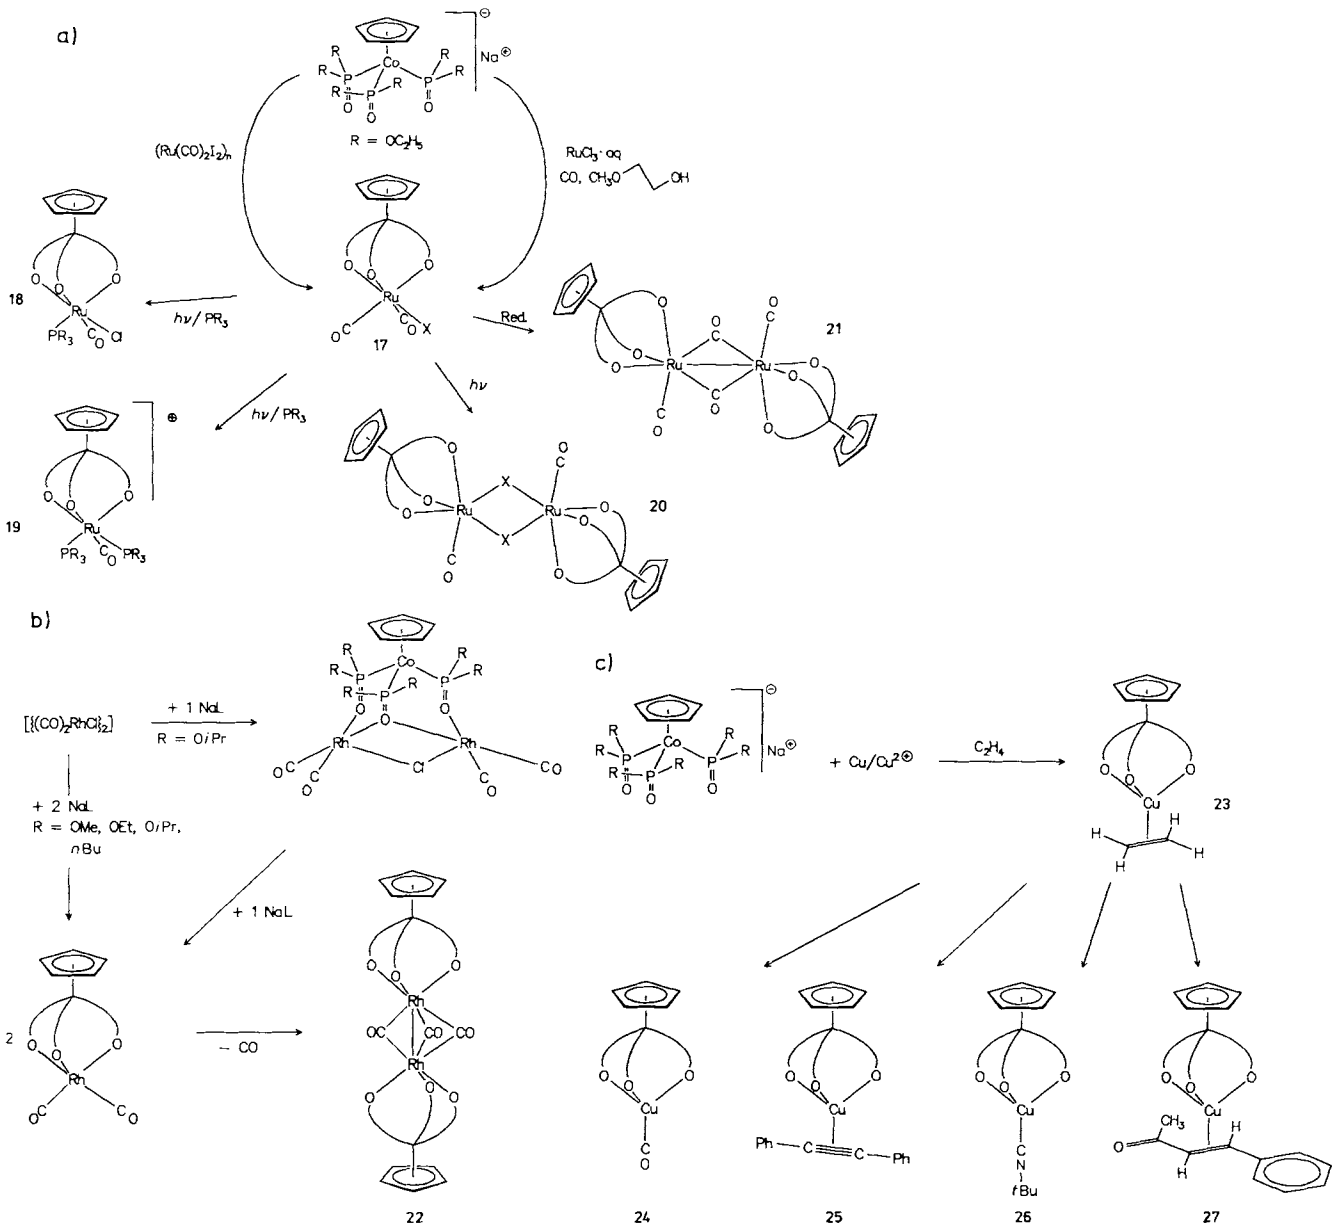




anionic tricarbonyl complexes **10** can be protonated to generate the hydrido species **12**; nevertheless, they also react with typical soft Lewis acids such as $Hg^{2\oplus}$, $C_3Ph_3^{\oplus}$, and $NO^{\oplus}$ to give **11**, **13** and **14**, respectively.[43]

In the reaction sequence $[LW(CO)_3]^{\ominus} \rightarrow [LW(CO)_3H] \rightarrow [L_2W_2O_5]$,[39] tungsten is oxidized from the oxidation state 0 to +VI. The "bite" of the tripod ligand apparently accommodates itself well to the sharply diminishing ionic radius, since the ligand is not cleaved during reaction. Isoprene can be inserted into the metal–hydrogen bond of the hydrido complex **12** (M = Mo, W, R = OC_2H_5), leading to the allylic complexes **15**,[39] while the analogous cyclopentadienyl compounds **16** react with conjugated dienes to give hydrogenation of the olefin and formation of the binuclear complexes $[\{(C_5H_5)M(CO)_3\}_2]$.[44]

The numerous examples of L/Mo and L/W combinations suggest that the oxophilicity of the early transition metals contributes to stability in these compounds. Nevertheless, most of the d elements have now been shown to form organometallic compounds with tripod ligands. Examples



Scheme 4. Synthetic routes to a) ruthenium, b) rhodium, and c) copper(I) complexes with $L^{\ominus}$. **23**: synthesis in H_2O/pentane. ^1H NMR: $\delta = 4.0$ (C_2H_4) (Free C_2H_4: $\delta = 5.3$). **24**, R = C_2H_5: $\nu(CO) = 2040\ cm^{-1}$; cleavage of CO at 150 °C.

include $[LMn(CO)_3]$,[45] $[LRe(CO)_3]$,[45] the ruthenium complexes **17**–**21**,[43] $[LRu(C_6H_6)PF_6$,[18] Rh^I complexes of the type $[LRh(olefin)_2]$,[46] $[LRh(\mu\text{-}CO)_3RhL]$ **22**,[47,48] $[LRh(C_5Me_5)PF_6$,[18] $[LIr(CO)_2]$,[49] [LPd(dmba)] (where dmba = *o*-(*N*,*N*-dimethylaminobenzyl)-C^2,*N*-),[50] $[LPtMe_3]$,[51] and the Cu^I complexes **23**–**27**[16,52] (Scheme 4).

A characteristic feature is the clear increase in compound stability for the sequence 3d < 4d < 5d with metal ions of the sixth through eighth subgroups.

5. Oxygen Tripod Ligands $L^{\ominus}$: Good π-Donor Ligands!

Given the diversity of the organometallic compounds containing oxygen tripod ligands, a basic question arises as to why so many $LM(CO)_x$ complexes are so stable, even though the classification of the ligands $L^{\ominus}$ as "hard" suggests they should be best suited to stabilizing higher oxidation states of the metals. The key to understanding this situation lies in the apparent contradiction that, while $L^{\ominus}$ is a weak ligand according to ligand field theory, it nevertheless induces more extensive M → CO back-bonding in many carbonylmetal derivatives (i.e., a higher electron density at the metal) than is observed with other monoanionic 6e ligands. For example, the wave numbers of the CO vibrations in the molybdenum and tungsten carbyne complexes with the general composition [(6e ligand)M(≡CR)$(CO)_2$] decline by 25–50 cm^{-1} through the sequence $C_5H_5^{\ominus} > C_5Me_5^{\ominus} \approx B(pz)_4^{\ominus} \approx HB(pz)_3^{\ominus} > L_{OMe}^{\ominus} > L_{OiPr}^{\ominus}$ (pz = pyrazolyl).[53] The solution to the problem has already been disclosed in the title of this section: the oxygen tripod ligands are good π-donors. This phenomenon is further clarified in the MO-scheme in Fig. 8, which shows how σ- and π-interactions between metal and ligands affect the ligand field splitting in an octahedral complex.[54] In a), only the σ-donor capacity of the ligands is taken into account. Hence, the t_{2g} orbitals are precisely nonbonding, and the e_g orbitals are antibonding. With increasing σ-donor capacity the energy of the e_g orbitals increases, thus increasing the ligand field splitting Δ_0. The supplemental π interactions are treated separately in b) and c). A π-donor interaction causes the t_{2g} orbitals also to become antibonding, making Δ_0 smaller. On the other hand, π-acceptor interaction lowers the energy of the t_{2g} orbitals, and Δ_0 becomes larger. The experimentally observed ligand field splitting Δ_0 results from a combination of these three factors.

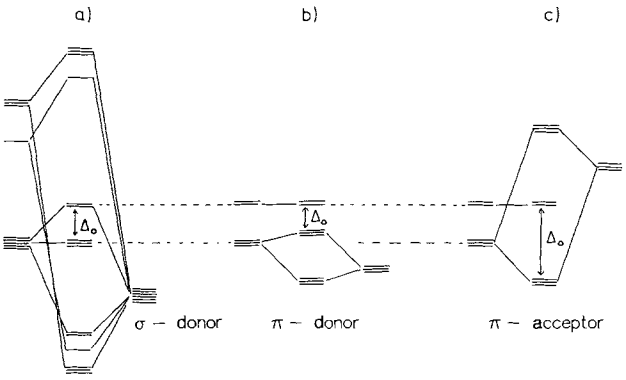


Fig. 8. The influence of σ-donor, π-donor, and π-acceptor capacity on the ligand field splitting Δ_0.

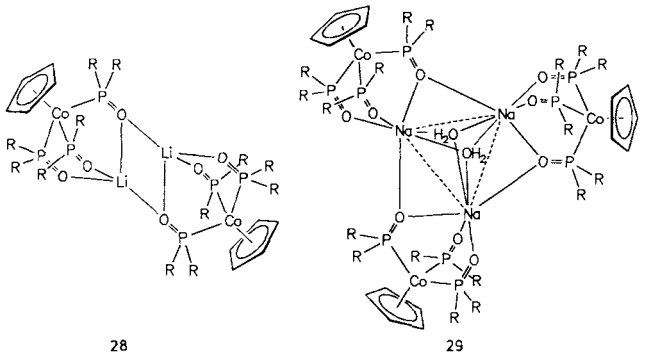
The remarkably small value of Δ_0 for complexes of the oxygen tripod ligands $L^{\ominus}$ can be explained by assuming that in comparison with most other oxygen ligands their π-donor capacity is stronger relative to their σ-donor capacity, whereas their π-acceptor capacity is negligible. The strong π-donor capacity of $L^{\ominus}$ causes an increase in energy in the t_{2g} orbitals, resulting in a smaller energy difference from the π* orbitals of coordinated CO ligands. This implies the possibility of better overlap and consequently stronger M → CO back-bonding, resulting in a lower CO-vibrational frequency. The stability of the $L^{\ominus}$-carbonylmetal derivatives containing oxygen tripod ligands is therefore a consequence of the interaction of two factors: the strong chelating effect of the ligands supports coordination at the metal center, and their extensive π-donor capability induces strong back-bonding in the existing metal-CO bonds. Interestingly, comparable effects can be observed in polyoxometallates, as has been demonstrated in the groundbreaking efforts of *Klemperer* et al.[55] and *Finke* et al.,[56] who showed that these materials can serve as models for metal oxide surfaces, and that they are capable of complexing organometallic fragments in the same way as the ligands $L^{\ominus}$. In the case of the alkoxide complexes of molybdenum and tungsten, the even higher π-donor capacity of the oxygen ligands is largely responsible for reactivity with respect to organic substrates, as demonstrated by *Chisholm* et al. in a series of experimental studies supported by Fenske–Hall MO calculations on model compounds.[57] Just as with complexes of the oxygen tripod ligands, clusters containing alkoxide ligands demonstrate especially large π-donor effects with the early heavy transition metals, an observation that can be explained by the reduction in d orbital energies within a given period as the atomic number increases.

6. Applications and Future Prospects

Several factors would indicate the potential for a broad spectrum of applications for the ligands $L^{\ominus}$, including their strong tendency to form complexes with ions of both transition and main-group metals, the fact that the phosphorus substituent R can be varied as a way of adjusting solubility over the range from exclusive water solubility to high solubility in saturated hydrocarbons, the thermal stability of the complexes, and their insensitivity with respect to acids and oxidizing agents. This review concludes with consideration of a few important new developments and certain specific applications that are already foreseeable.

Shinar and *Navon* have recently discovered the ionophoric characteristics of the ligands $L^{\ominus}$, noting that $L_{OEt}^{\ominus}$ is a very efficient transporter of alkali metal ions through phospholipid membranes. Moreover, the lithium ions in a LiCl/NaCl solution are transported through a membrane composed of phosphatidylcholine vesicles much more rapidly than sodi-

um ions. Competition experiments have shown the lithium/sodium selectivity to exceed a factor of 40.[58] The transport mechanism itself has not yet been fully clarified, but the principal cause of the selectivity may be the fact that the lithium salt LiL_{OEt} exists as the dimer **28** in lipophilic medium,[59] whereas NaL_{OEt} forms trimers with the composition $Na_3L_3(H_2O)_2$ **29**.[39]



28 29

The biochemistry of such ionophores is currently under intensive investigation due to potential medical significance in the context of lithium therapy.

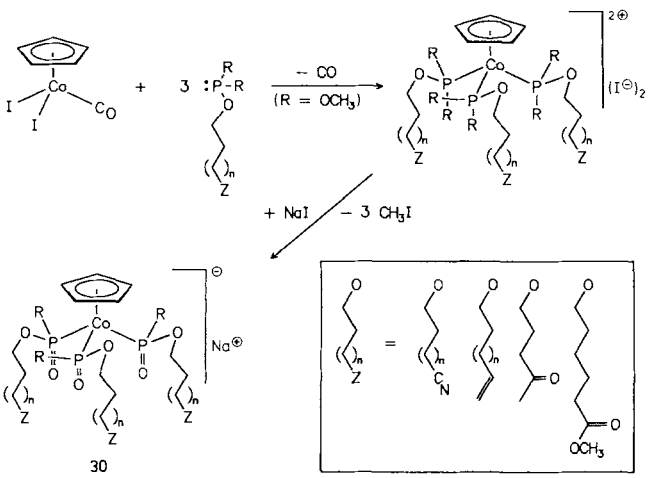
Other studies in which we are currently engaged relate to the use of $L^{\ominus}$ species as components in phase-transfer reactions and in catalysts for organometallic conversions. One particularly attractive feature in this regard is the fact that (see Scheme 2) it is relatively easy to synthesize chiral ligands $L^{\ominus}$ possessing C_{3v} symmetry.

In Section 5, a plausible argument was made for interpreting the stabilization of low oxidation states in transition metal complexes by oxygen tripod ligands as a consequence of synergistic effects between opposing π-donor and π-acceptor ligands. For many catalytic applications this means that either the energies of key intermediates are much too high, or else the tripod complexes formed as intermediates are too stable. On the other hand, the situation becomes considerably more promising if the metal ion coordinated to $L^{\ominus}$ remains in a high oxidation state throughout the catalytic cycle. In this case, stability is essentially a function of the chelate effect and electrostatic interaction between the tripod ligand and the metal ion, a typical situation in oxygen-transfer reactions, for example.

Scheme 5. The oxidation of 1-octene to heptanoic acid by peracetic acid, using $[L_{OEt}Ru(CO)_2Cl]$ as catalyst precursor. Reaction conditions: aqueous solution, 10% excess of peracetic acid, 60 → 20 °C. Yield: 75% (with catalyst 1:4000), 4% (without catalyst)

Scheme 5 illustrates an application of this type, in which a ruthenium tripod complex catalyzes the peracetic acid oxidation of 1-octene to heptanoic acid.[60] The oxoruthenium complex that presumably forms here has not yet been identified. Similarly, oxovanadium tripod complexes can play a role as catalyst precursors in other oxygen-transfer reactions.[61]

Many reactions of low-valent organometallic fragments in tripod ligand complexes might be regarded as attractive models for reactions at the surfaces of heterogeneous metal oxide catalysts, but for the reasons described above the observed catalytic activity is not particularly great. In an attempt to achieve higher reactivities we are currently pursuing two different strategies. On the one hand, we have synthesized tripod ligands such as **30** that contain long, functionalized side-chains. These supplementary donor centers are intended to behave as "dangling ligands" that could assist in the stabilization of unsaturated intermediates in catalytic cycles, adding a type of coordinative stabilization that is easily displaced. Such functionalized ligands have permitted

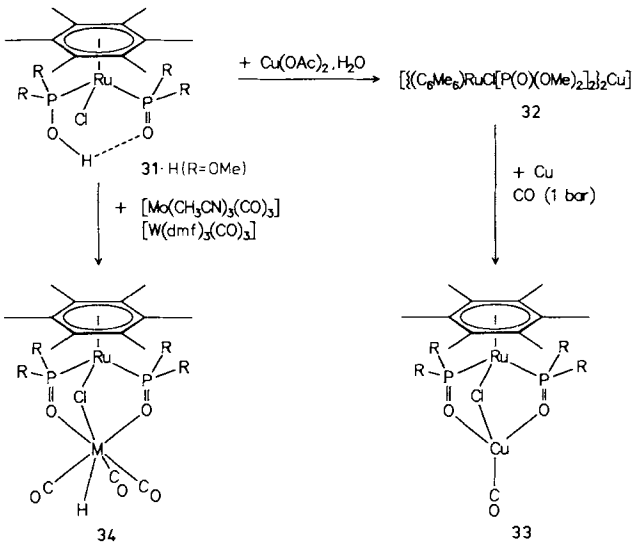


us, for example, to develop catalysts for the hydrogenation of C=C double bonds, the oligomerization of acetylenes, and hydroformylation, catalysts that are significantly more reactive than the corresponding complexes with non-functionalized ligands. Ligands of this novel type appear promising for a host of other catalytic cycles as well.[62]

As a second possibility for controlling the reactivity of tripod ligands, we have designed structures that possess only two strongly coordinating P=O centers, where a halogen, for example, serves as a weak third ligand site. Such an *O,O,X*-tripod ligand must of course be inert—a species that, apart from its function as a chelating ligand, enters into no other chemical reactions—and this imposes severe restrictions on the choice of potential candidates. Of the many systems we have investigated, the ruthenium(II) complex $\mathbf{31}^{\ominus}$ appears to be the most suitable. The protonated form of this *O,O,Cl*-ligand (**31** H) is readily accessible, and we have recently described its synthesis, together with preliminary information regarding its coordination chemistry.[63]

We were somewhat astonished by the discovery that the copper(II) complex **32** is transformed in the space of a few hours into the carbonylcopper complex **33** by room-temperature treatment with CO gas and copper metal in methanol.[63] It is remarkable how rapidly the copper dissolves and **33** forms in this reaction, especially since **32** is virtually insoluble in methanol. Another interesting reaction we have observed is the oxidative addition of the O-H bond of **31** · H to tungsten(0) and molybdenum(0) centers, leading to the hydrido-metal complexes **34**.[64] The willingness with which the

carbonylcopper complex **33** and the hydrido complex **34** arise suggests interesting potential syntheses for these ligands in the field of organometallic chemistry. One can foresee that the synthetic pathway[64] to *O,O,Cl*-ligands **31**$^{\ominus}$ might be broadened to include other *O,O,X*-ligands in which



X might represent not only halogen, but also a sulfur or a nitrogen donor center. The extent to which such ligands would also be suited to conferring other new and interesting reaction possibilities on metal ions remains to be determined.

I wish to express my appreciation to all those colleagues who have been involved in this work, in particular to my co-workers H.-O. Asbahr, E. Buchholz, W. Eberspach, B. Engels, K. Evertz, H. Hamers, B. Lenders, A. Müller, H.-J. Schulte, C-E. Song, and A. Weber-Schuster. I am especially grateful to my colleague M. Scotti for his friendly collaboration, made possible by financial support from the Volkswagen-Stiftung. Thanks are due to the firms Bayer, Hoechst, BASF, Degussa, and Heraeus for gifts of chemicals. The Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie have regularly provided generous support for my scientific efforts.

[1] The systematic names of the ligands L$^{\ominus}$ [e.g., cyclopentadienyltris(diorganylphosphito-*P*)cobaltate, also -phosphinito- or -phosphonito-] are based on the groups P(O)R'R'' bound to the cobalt(III) center. The anions P(O$^{\ominus}$)(OR)$_2$ are called phosphito ligands since they represent phosphorous acid diesters, while the anions P(O$^{\ominus}$)R$_2$ (phosphinito ligands) and P(O$^{\ominus}$)(OR)R (phosphonito ligands) are derivatives of phosphinic and phosphonic acid, respectively.

[3] The complexes of the type L$^{\ominus}$ constitute the first examples of monoanionic tridentate oxygen ligands with C_{3v} symmetry. No organic ligands of this type exist. Hexaethyl-*P,P',P''*-phosphanetriyltris(phosphonate) P{P(O)(OEt)$_2$}$_3$[4] (described by *Weber* and *Fluck*[5]), the trimetaphosphate ion $[P_3O_9]^{3\ominus}$,[6, 7] and the trimetaphosphimate ion $[P_3(NH)_3O_3]^{3\ominus}$[8, 9] are also capable of acting through their P=O groups as tridentate oxygen ligands.

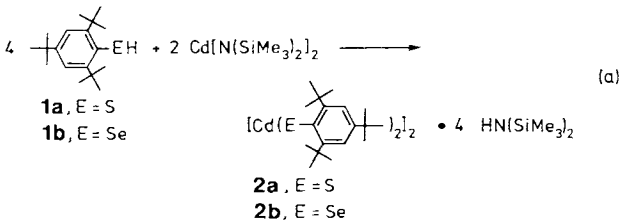
Synthesis, Structure, and Gas-Phase Decomposition of $[Cd(EC_6H_2tBu_3)_2]_2$ (E = S, Se): First Examples of Low-Coordinate Volatile Cadmium Chalcogenolato Complexes[**]

By *Manfred Bochmann,* Kevin Webb, Mary Harman,* and *Michael B. Hursthouse*

As is well known, most thiolato and selenolato complexes of zinc, cadmium, and mercury are soluble only in coordinating polar solvents and possess polymeric nonmolecular lattice frameworks with bridging ligands.[1] For cadmium, these characteristics are exemplified by the polyadamantanoid structure of $[Cd(SPh)_2]_n$.[2] Although attempts have been made to use nonvolatile thiolato compounds such as $[M(SMe)_2]_n$ (M = Zn, Cd) as sources for metal sulfides,[3] polymeric compounds are clearly not suitable for the deposition of metal chalcogenides under more typical MOCVD[4] conditions. However, the introduction of ligands with high steric hindrance is highly effective in reducing the degree of association and thereby increasing the volatility of chalcogenide complexes. Following the demonstration of this principle for the gas-phase deposition of TiS films,[5] we now report the synthesis, structure, and gas-phase thermolysis of volatile cadmium thiolato and selenolato complexes.

The reaction of the bulky thiol **1a** with $Cd[N(SiMe_3)_2]_2$ in hexane at room temperature gives **2a** as colorless crystals [Eq. (a)]. The analogous reaction with the selenol **1b** affords



(a)

the bright yellow complex **2b**. Both complexes are moderately soluble in noncoordinating solvents such as toluene from which they are recrystallized.

The structure of **2a** (Fig. 1)[6] confirms that the complex is dimeric in the solid state with two terminal and two asymmetrically bridging thiolato ligands. Each cadmium is coordinated to three sulfur atoms in a trigonal-planar arrangement; there are no close contacts between neighboring dimer units in the crystal. To our knowledge such a coordination geometry has not been observed before for a cadmium chalcogenide complex.[8] In general, cadmium chalcogenides show a strong preference for a tetrahedral ligand environment, even in cases of significant steric crowding, as found for example in **3**.[9]

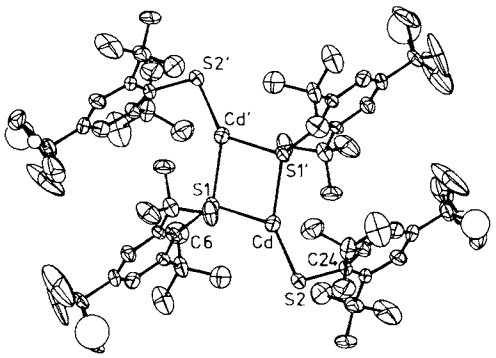


Fig. 1. Molecular structure of **2a** (ORTEP, ellipsoids correspond to 50% probability). Severe disorder in some *tert*-butyl groups required modeling with more than three carbon positions. Selected bond lengths [Å] and angles [°]: Cd-S1 2.499(6), Cd-S1' 2.583(7), Cd-S2 2.377(6), Cd-Cd' 3.798(6); S1-Cd-S1' 83.3(2), Cd-S1-Cd' 96.8(2), S1-Cd-S2 133.4(1), Cd-S1-C6 115.3(6), Cd-S2-C24 97.9(6).

$[Cd(SC_6H_2iPr_3)_2(1\text{-methylimidazole})_2]$ **3**

The Cd_2S_2 four-membered ring forms a planar parallelogram, with the two Cd–S distances differing by almost 0.1 Å [2.499(6) vs. 2.583(7) Å]. In $[Cd(SPh)_2]_n$, by comparison, intermediate Cd–S bond lengths are found (2.543 and 2.530 Å).[2] By contrast, the terminal Cd–S2 distances in **2a** are remarkably short [2.377(4) Å], even compared to Cd–S distances of terminal thiolato ligands in related complexes such as the tetrahedral monomeric complex **3** [average 2.46 Å],[9] and may suggest a degree of Cd–S multiple bonding due to interaction of the coordinatively unsaturated cadmium with a sulfur lone pair. Preliminary X-ray data confirm that **2b** has an analogous dimeric structure.[10]

The ^1H NMR spectra of **2a** and **2b** in weakly coordinating solvents (CD_2Cl_2, $CDCl_3$, $[D_8]$toluene) are surprisingly simple and show only one singlet each for the *ortho*- and *para*-*tert*-butyl groups and the aromatic *meta*-protons. The spectra are essentially temperature-independent. On cooling the solutions to −40 °C the signals for the *ortho*-*tert*-butyl groups broaden due to hindered rotation, before the compounds precipitate on further cooling. There is no evidence for ligand-exchange processes or for the appearance of two separate signal sets which would be expected for the terminal and bridging ligands on the basis of the solid-state structures. The data suggest therefore that the complexes **2a** and **2b** are monomeric in solution, with two-coordinate metal

centers.[11] The cadmium complexes resemble in this respect comparable sterically hindered compounds of mercury, such as $Hg(EC_6H_2R_3\text{-}2,4,6)_2$ (E = S, R = *i*Pr, *t*Bu; E = Se, R = *t*Bu).[12]

Compounds **2a** and **2b** are thermally very stable and sublime at 10^{-2} torr above 320 and 240 °C, respectively. Under mass spectrometry conditions both monomeric and dimeric species are present in the gas phase [**2a**: $Cd(SAryl)_2^{\oplus}$, *m/z* 668, 100%; $Cd_2(SAryl)_3^{\oplus}$, *m/z* 1057, 22%]. Compound **2a** decomposes thermally above ca. 400 °C, **2b** above ca. 300 °C. The volatility of **2a** and **2b** has been utilized for the deposition of metal chalcogenides from the gas phase under reduced pressure. In preliminary experiments on glass targets, **2a** produced smooth transparent golden-yellow films of CdS at 450 °C/10^{-2} torr. The main organic byproduct is $(C_6H_2tBu_3)_2S$. Under comparable conditions at 350 °C, **2b** deposits brown films of CdSe; scanning electron microscopy reveals that these are polycrystalline. The composition of the films was confirmed by energy-dispersive X-ray analysis. Deposition studies on crystalline targets such as GaAs are in progress.

Experimental Procedure

2a: All experiments were carried out under inert gas. To a solution of thiol **1a** (1.0 g, 3.6 mmol) [13] in 20 mL of light petroleum ether (b.p. 40–60 °C) at room temperature was added via syringe a solution of $Cd[N(SiMe_3)_2]_2$ (0.77 g, 1.8 mmol) [14] in 5 mL of petroleum ether. After a few seconds a white precipitate was formed. The mixture was stirred for 1 h before the residue was filtered off and washed with 2 × 20 mL of petroleum ether. The product was recrystallized from warm toluene to give **2a** as colorless needles (0.67 g, 56%). The solid complex is air-stable, but solutions are subject to slow hydrolysis with liberation of **1a**. ^1H NMR (400 MHz, CD_2Cl_2, 25 to −40 °C): δ = 1.25 (s, 9H, *p*-*t*Bu), 1.77 (s, 18H, *o*-*t*Bu), 7.2 (s, 2H).

1b: The compound has been briefly mentioned in a footnote [13]. To a solution of $(C_6H_2tBu_3Se)_2$ (0.685 g, 1.06 mmol) [15] in 40 mL of THF under nitrogen and with exclusion of light was added via syringe 2.1 mmol of $LiBEt_3H$ (1 M solution in THF, 2.1 mL) at room temperature. The pale yellow solution was stirred for 30 min and cooled to −78 °C. After the dropwise addition of $HBF_4 \cdot Et_2O$ (1.0 g, 6 mmol) over 5 min, the mixture was allowed to warm to room temperature. The solvent was removed and the residue taken up in 30 mL of 40/60 petroleum ether, filtered, and concentrated to give **1b** as a white crystalline solid (0.55 g, 1.69 mmol, 80%), m.p. 172–173 °C (lit. [13] 176.5–177.5 °C). Correct elemental analysis. ^1H NMR (60 MHz, $CDCl_3$): δ = 1.40 (s, 9H, *p*-*t*Bu), 1.66 (s, 18H, *o*-*t*Bu), 1.92 (s, 1H, Se-H), 7.35 (s, 2H). ^{77}Se NMR (17.08 MHz, $CDCl_3$, relative to neat Me_2Se): δ = 139.9 (d, ^1J(Se,H) 51.9 Hz).

2b: The complex was prepared following the procedure given for **2a** from **1b** (0.456 g, 1.4 mmol) and $Cd[N(SiMe_3)_2]_2$ (0.31 g, 0.7 mmol) as bright yellow crystals (0.42 g, 0.55 mmol, 79%). Correct elemental analysis. ^1H NMR (90 MHz, $CDCl_3$): δ = 1.28 (s, 9H), 1.56 (s, 18H), 7.24 (s, 2H).

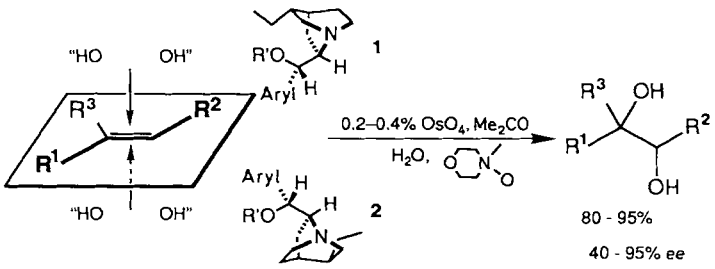
Structural Characterization of the Pseudoenantiomeric *cis*-Dioxo Osmium(VI) Esters of Chiral Diols with Cinchona Alkaloid Ligands**

By *Ronald M. Pearlstein, Brent K. Blackburn, William M. Davis,* and *K. Barry Sharpless**

The catalytic asymmetric dihydroxylation (ADH, Scheme 1) of olefins,[1] utilizing cinchona alkaloid derivatives as chiral ligands, was substantially improved in generality and speed by our understanding of the multiple diol-producing catalytic cycles that are accessible.[2] By maintaining a low olefin concentration via its slow addition throughout the course of the reaction, a nonenantioselective cycle can be avoided. This permits catalytic production of diols with enantiomeric excesses comparable to those obtained in the corresponding stoichiometric reaction. Further enhancements of the ADH reaction are therefore most likely to come from optimization of the chiral auxiliary for its inherent (stoichiometric) enantioselectivity.



Scheme 1. Catalytic asymmetric dihydroxylation of olefins in the presence of dihydroquinidine or dihydroquinine *p*-chlorobenzoate, **1** or **2**, respectively. R' = *p*-ClC_6H_4CO, Aryl = 4-(6-methoxy)quinolyl.

Structural studies on both the free[3] and OsO_4-bound[4] chiral ligands have been reported recently. Though some alkaloid derivatives showed an interesting conformational

[**] This work was supported by the U. S. National Science Foundation (Grant CHE-8303355).

change on metal binding,[4] the origin of face selectivity towards the olefin was unclear. We have now undertaken the structural characterization of the product osmate esters from the stoichiometric reactions of the *trans*-1,2-disubstituted olefins 2,2,5,5-tetramethylhex-3-ene ($R^1 = R^2 = t$Bu, $R^3 = H$) and 2,5-dimethylhex-3-ene ($R^1 = R^2 = i$Pr, $R^3 = H$) with **2** and **1**, respectively, as auxiliaries in order to obtain information regarding the steric interactions possible between various parts of the alkaloid and the reacting olefin. Such studies are aimed at the rational design of new alkaloid derivatives for improved enantioselectivities.

The dioxo[(3*S*,4*S*)-2,2,5,5-tetramethyl-3,4-hexanediolato]osmium(VI) complex containing **2** (**3**)[5] and the dioxo[(3*R*,4*R*)-2,5-dimethyl-3,4-hexanediolato]osmium(VI) complex containing **1** (**4**)[6] were prepared by combining equimolar amounts of OsO_4 with the alkaloid derivative followed by the corresponding olefin. Single crystals suitable for X-ray structure analysis were grown from either CH_2Cl_2/heptane (**3**)[7, 8] or from toluene alone (**4**)[7, 9].

Both structures, shown in Figure 1, show similar coordination geometry, which is approximately trigonal-bipyramidal. The equatorial plane consists of the two terminal oxo ligands and one of the diolate oxygen atoms, with the osmium atom lying <0.11 Å out of this plane. Other osmate esters possessing just one nitrogen donor have crystallized as oxo-bridged dimers,[10] thereby obscuring the five-coordinate geometry assumed[11] to be present in solution. In the complexes containing **1** and **2**, however, there are no nonbonded contacts to the Os atom within 3.6 Å; hence the complexes are monomers.

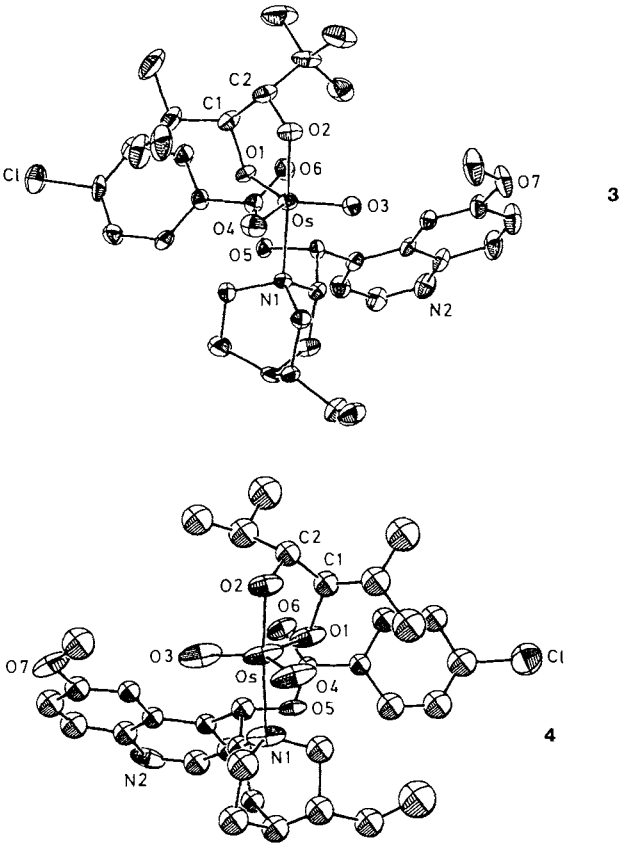

Fig. 1. ORTEP representations of **3** and **4**, showing 35% and 25% thermal probability ellipsoids, respectively. Selected bond distances [Å] and angles [°] for **3**: Os-O1 1.874(5), Os-O2 1.909(5), Os-O3 1.706(5), Os-O4 1.704(5), Os-N1 2.243(5), C1-C2 1.53(1); O1-Os-O2 83.9(2), O1-Os-O3 116.9(2), O1-Os-O4 112.9(3), O1-Os-N1 92.3(2), O2-Os-O3 96.5(2), O2-Os-O4 96.5(3), O2-Os-N1 176.1(2), O3-Os-O4 129.4(3), O3-Os-N1 84.6(2), O4-Os-N1 85.6(2). Selected bond distances [Å] and angles [°] for **4**: Os-O1 1.82(1), Os-O2 1.90(1), Os-O3 1.76(2), Os-O4 1.70(1), Os-N1 2.27(2), C1-C2 1.50(3); O1-Os-O2 85.0(6), O1-Os-O3 113.1(6), O1-Os-O4 110.3(8), O1-Os-N1 91.3(6), O2-Os-O3 97.4(6), O2-Os-O4 95.9(6), O2-Os-N1 175.8(7), O3-Os-O4 135.4(8), O3-Os-N1 85.8(7), O4-Os-N1 83.6(6).

This study therefore represents the first structural characterization of a truly[10, 11] five-coordinate Os(VI)mono-diolate complex, revealing a *cis*-dioxo coordination mode which is exceedingly rare for d^2 transition-metal complexes.[12, 13] The closest previously reported structural analogue is the tris(acetato)dioxoosmate(VI) anion,[14] which has an O=Os=O angle of 125.2(3)°. This value corresponds well with those of 129.4(3)° in **3** and 135.4(8)° in **4**; and all are close to the idealized value of 120°.

The conformation of **1** in complex **4** is virtually identical to that observed in the OsO_4 adduct of the related **1**-dimethylcarbamate.[4] In addition, the α-methylene linkages to the Os-bound quinuclidine moiety of the alkaloid remain staggered relative to the equatorial oxygen atoms. There are, however, two structural differences other than those due to the differing oxygen derivatization. The Os–N distance in **4** has shortened to 2.27(2) Å, indicative of a stronger, more covalent bond. Also, the ethyl group bound in the β-position of the quinuclidine for **4** is rotated towards the nitrogen atom, almost opposite the rotation seen in the OsO_4 adduct of **1**-dimethylcarbamate. This difference may be due to simple crystal-packing forces.

As expected, the absolute configurations of the coordinated diols correspond to those of the major enantiomers reported for the catalytic reactions with the respective chiral ligands. As pointed out in a recent structural study[15] of an asymmetric osmylation system employing a stoichiometric amount of a chiral diamine, explanation of enantioselectivity depends strongly on the basic mechanism of vicinal dihydroxylation, which has not yet been unequivocally determined. Nevertheless, features of **3** and **4** suggest possible interactions between the substituents of the diol and parts of the alkaloid derivatives. These features can be best appreciated in the stereoviews of Figure 2. In both structures, the

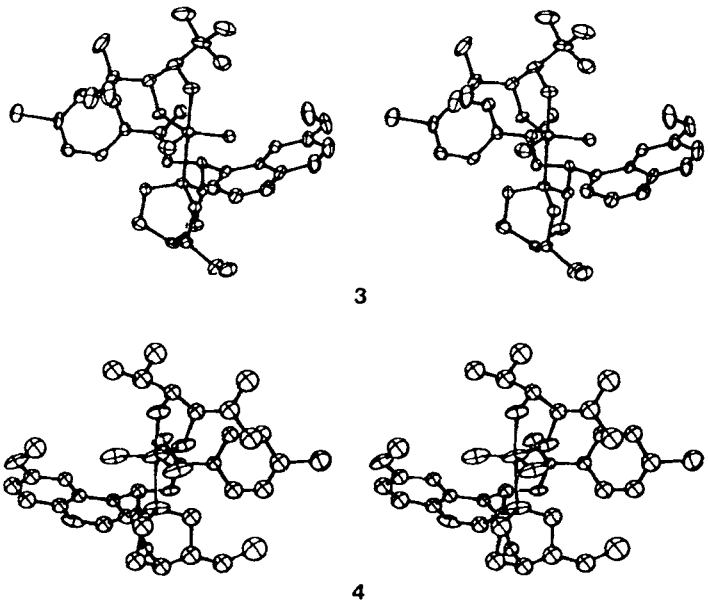

Fig. 2. ORTEP stereoview of **3** and **4**.

planar O5-C = O6 grouping of the ester approaches to within approximately 3 Å of O1, the equatorial diolate oxygen atom. The alkyl substituent of the carbon (C1) that is bound to O1 points away from this ester grouping, leading to the appropriate relative stereochemistry. In practice, it has been noted that the enantiomeric excess of the product diols is exquisitely sensitive to changes in the derivatization of the alcohol moiety of the alkaloids. Furthermore, esters and related derivatives have generally proven to give the highest enantioselectivities.

As may be noted in Figure 1, the 6-methoxy substituent of the quinoline moieties is coplanar with the fused aromatic rings, and in both cases, points towards one of the terminal oxo ligands. Although the nature of the interaction is unexplained, this structural feature is remarkably constant for the osmate esters and the OsO_4 adduct of **1**-dimethylcarbamate.

The most notable difference between the "pseudoenantiomers" **1** and **2** is the stereochemistry of the ethyl substituent on the quinuclidine system. In **4**, this ethyl group approaches the *p*-chlorobenzoyl group, seemingly directing it even closer to the coordinated diolate than in the case of **3**, in which the ethyl group points into empty space. It is tempting to correlate this effect with the rather consistently better *ee* values obtained with quinidine derivatives than with their quinine analogues.

In such a conformationally nonrigid system, it is dangerous to ascribe too much significance to any particular solid-state structural feature; nevertheless, the spectral data[16] are consistent with a similar conformation in solution. The structures of **3** and **4**, therefore, provide a starting point for the development of a structure–activity correlation for the ADH reaction.

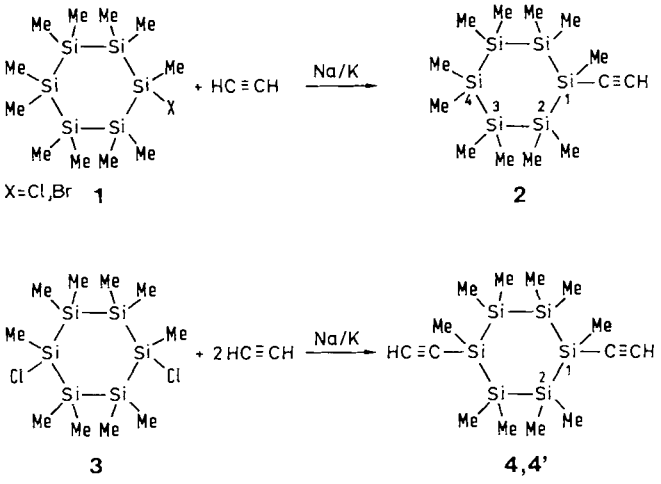
[16] For instance, the unusually low chemical shifts (δ = 0.81 in **3** and 0.60, 0.87 in **4**)[5,6] for the methyl protons of the coordinated diols are consistent with their observed position within the shielding region of the *p*-chlorophenyl rings.

Synthesis of Cyclosilanylethynes

By *Edwin Hengge,* Alfred Baumegger, Markus Eibl, Erhard Hohenester*, and *Christoph Kratky**

Silanylethynes have recently attracted much interest because of the possibility of σ–π interactions between the silicon skeleton and the CC triple bond. Electron delocalizations of this kind have already been observed in simple silanylethynes and cyclic (poly)silanylethynes.[1] We recently reported a method for synthesizing bis(silanyl)-substituted ethynes by reaction of acetylene with halosilanes and alkali metals.[2] Using the same reaction route, we have now succeeded in synthesizing cyclosilanylethynes. As starting materials for these syntheses we used mono- and difunctional cyclosilanes.[3]



Scheme 1. Synthesis of **2** and 4 (**4'**).

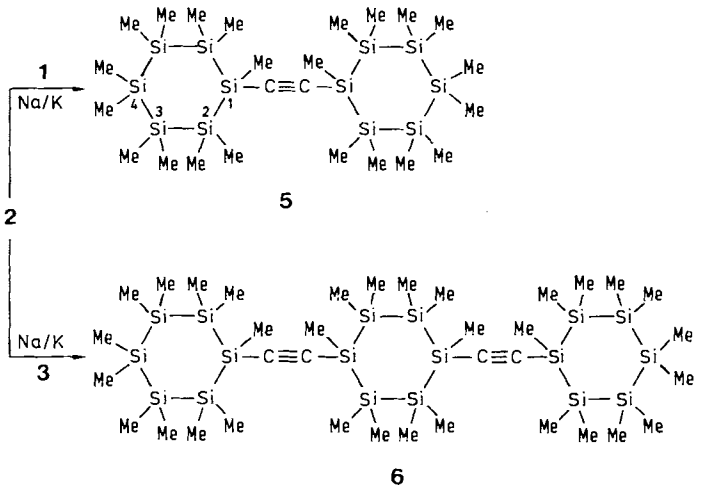
The reaction of the chlorocyclohexasilane derivative **1** (X = Cl) with acetylene and K/Na alloy gives the previously unknown cyclohexasilanylethyne **2**. In an analogous reaction the 1,4-dichlorocyclohexasilane **3** gives the 1,4-diethynylcyclohexasilane **4** (and its isomer **4'**, which will not be discussed separately here; Scheme 1).

Treating **2** with K/Na alloy in an ultrasonic bath gives the corresponding alkali-metal acetylide; this was not isolated, but was allowed to react directly with **1** or **3** to give, respectively, the bis(cyclohexasilanyl)ethyne **5** and the 1,4-bis[(cyclohexasilanyl)ethynyl]cyclohexasilane **6** (Scheme 2). All the



Scheme 2. Synthesis of **5** and **6**.

compounds were thoroughly characterized; they are colorless crystalline compounds that are stable in air and withstand increased temperatures.

From the frequencies of the C≡C vibrations in the Raman and IR spectra it is evident that the silicon ring does not exert an effect on the CC triple-bond system.

The signals in the ^{29}Si NMR spectra have been assigned on the basis of the ^{29}Si–^{29}Si couplings, which were determined by modified INEPT-INADEQUATE experiments.[4] Here again, no change in the bonding could be detected, since the values of $^{1}J_{Si,Si}$ and $^{2}J_{Si,Si}$ show no significant deviation from the coupling constants in other derivatives with the general formula $Si_6Me_{11}X$.[5] The value of $^{1}J_{Si,C\equiv}$ for **2** is also within the expected range.[6] Table 1 lists all the relevant physical data for the compounds **2**, **4**, **5**, and **6**.[7]

An X-ray crystallographic analysis of **5** enabled the structure to be determined very precisely[8] (Fig. 1). The two symmetrically equivalent cyclohexasilane rings are joined diaxially. The C–C distance was determined as 121 pm, which corresponds to that in a normal triple bond, and the value of 177.0° for the C1A–C1–Si1 bond angle is scarcely different

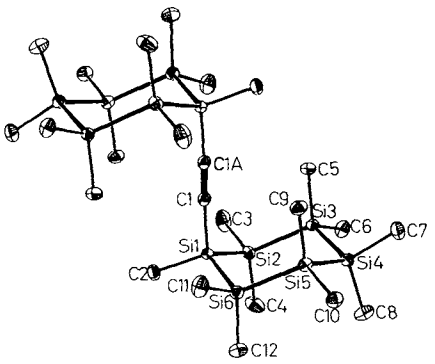


Fig. 1. Crystal structure of **5** (ORTEP, thermal ellipsoids at the 50% probability level, hydrogen atoms not shown). Selected bond lengths [pm] and angles [°]: C1-Si1 183.3(4), C1A-C1 121.2(5); C1A-C1-Si1 177.0(3).

from that expected for an sp-hybridized carbon atom. No useful crystals of **6** could be obtained, possibly owing to the occurrence of two isomeric 1,4-disubstituted cyclohexasilanes,[2] a fact which is also clearly evident from the NMR spectra.

Table 1. Physical data for compounds **2** and **4**–**6** [a].

Experimental Procedures

2: 1.32 g of K/Na alloy was prepared as a suspension in 500 mL of toluene, acetylene was introduced, and simultaneously a solution of **1** (X = Cl) (9.40 g, 25.5 mmol) in 50 mL of toluene was slowly added dropwise. After extraction with water the product was purified by sublimation at 60 °C/0.01 mbar. Yield 6.7 g (73%).

4: 0.85 g of K/Na alloy was prepared as a suspension in 100 mL of toluene, and acetylene was introduced while stirring vigorously; simultaneously a solution of **3** (X = Cl) (1.16 g, 2.98 mmol) in 20 mL of toluene was slowly added dropwise. The solvent was distilled off and the residue was purified by sublimation at 80 °C/0.01 mbar, giving 0.5 g of the product (yield 45%).

5: **2** (0.96 g, 2.7 mmol) was added to a suspension of 0.24 g of K/Na alloy in toluene and ultrasonically irradiated. A solution of **1** (0.9 g, 2.2 mmol) (X = Br) in 20 mL of toluene was then added dropwise to the resulting brown suspension. After filtering and removing the solvent the white residue was recrystallized from benzene. Yield 0.6 g (39%). **5** can be sublimed at 135 °C/0.01 mbar.

6: **2** (2.3 g, 6.4 mmol) was added to a suspension of 0.36 g of K/Na alloy in 80 mL of toluene and ultrasonically irradiated. A solution of **3** (X = Cl) (1.22 g, 3.1 mmol) in 20 mL of toluene was added dropwise to this suspension and the mixture was then stirred for about 12 h. The product was extracted in the same way as for **5**, the colorless crystals being recrystallized from benzene. Yield 0.3 g (9%).

4,7-Dimethyl-4,7-dihydro[1,2,5]thiadiazolo-[3,4-*b*]pyrazine, a Novel Electron Donor with a 12π-Electron Ring System

By *Yoshiro Yamashita,* Junko Eguchi, Takanori Suzuki, Chizuko Kabuto, Tsutomu Miyashi,* and *Shoji Tanaka*

5,10-Dimethyl-5,10-dihydrophenazine (DMPH) is a strong electron donor due to the 16π-electron ring system[1] and affords conducting charge-transfer (CT) complexes with electron acceptors.[2] However, 1,4-dimethyl-1,4-dihydroquinoxaline (**1a**), containing a 12π-electron ring system, has not been isolated, probably due to its extremely electron-donating property,[3] although a derivative, **1b**, containing trimethylsilyl groups was synthesized.[4] In order to enhance the stability of **1a**, we substituted a 1,2,5-thiadiazole ring, an electron-withdrawing heterocycle, for the benzene ring to give the title compound **2**. This substitution is also expected to lead to interactions between sulfur and nitrogen atoms in the solid state, as found in thiadiazole-fused TCNQ derivatives such as **3**.[5] We report here the preparation and properties of **2**, a novel 12π-electron heterocycle.

Compound **2** was obtained as yellow crystals (m.p. 102–104 °C) in 22% yield by reduction of [1,2,5]thiadiazolo[3,4-*b*]pyrazine (**4**)[6] with potassium followed by methylation with methyl iodide. The new donor is stable in the solid state under air and absorbs at longer wavelengths[7] than the benzo derivative **5**.[8] The half-wave oxidation potentials ($E_1 = +0.15$, $E_2 = +0.95$ V (irreversible) versus the saturated calomel electrode) were measured by cyclic voltammetry.[9] Although the first oxidation potential is higher than that of **1a** due to the electron-withdrawing heterocycle, the value is still very low, indicating that **2** is a strong electron donor.

In order to investigate the molecular structure of **2** as well as the possible interheteroatom interactions, X-ray structural analysis of **2** was carried out.[10] The molecule is completely planar except for hydrogens of the methyl groups. The bond lengths given in Figure 1 show a pronounced bond

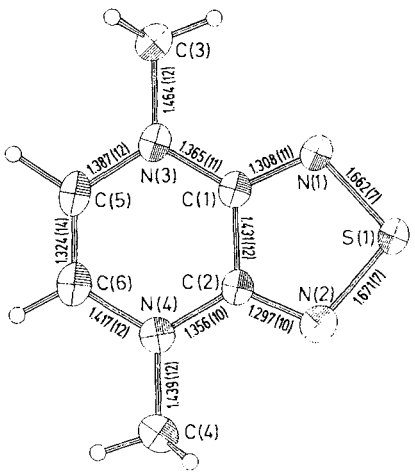

Fig. 1. Molecular structure of **2** with bond lengths [Å] (ORTEP).

alternation. Thus, the C5–C6 bond length (1.324 Å) is very close to a pure C–C double-bond distance, while the C5–N3 (1.387 Å) and C6–N4 (1.417 Å) bond lengths are close to a C–N single-bond length.[11, 12] The S–N and C–N bonds of the thiadiazole moiety are a little longer and shorter, respectively, than the corresponding bonds of 1,2,5-thiadia-

zoles.[13] The increase in the double-bond character of the C–N bonds results in the longer C1–C2 bond.

The molecules of **2** are uniformly stacked along the *a* axis, the dihydropyrazine parts overlapping as shown in Figure 2. The dihedral angle between the upper and lower molecules is

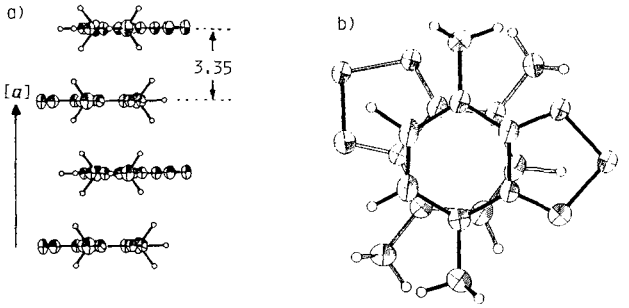

Fig. 2. Crystal structure of **2**. a) One-dimensional column along the *a* axis. b) Overlapping of **2** (projection).

0° and the distance between the molecular planes is 3.35 Å. The molecules are connected by S···N contacts to form a coplanar dyad. The contact distance of 3.05 Å is significantly shorter than the sum of the van der Waals radii (3.35 Å). The dyad is held together by hydrogen bonding (2.50 Å) between olefinic hydrogens and nitrogens of thiadiazole rings to form a coplanar sheetlike network (Fig. 3), which is stacked to give an unusual crystal structure resembling graphite.

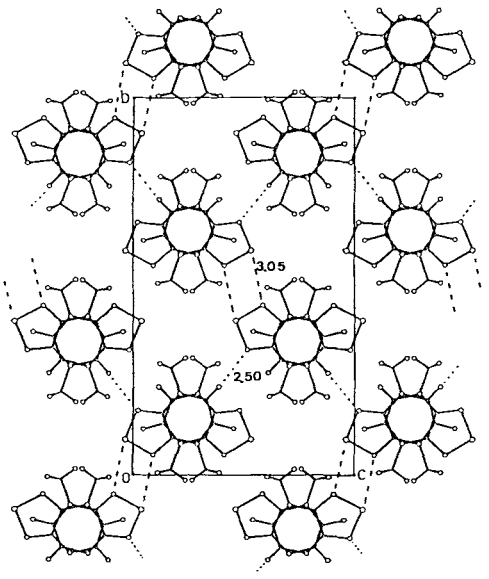

Fig. 3. Sheetlike network of **2**. Broken lines: S···N interactions and hydrogen bonding.

The strong S···N interactions can be attributed to an electrostatic effect, which is suggested from the atomic charges calculated by the MNDO method[14] (Fig. 4). The calculation also shows that, besides the enediamine part, the sulfur atom of the thiadiazole has a large coefficient in its HOMO.

The donor **2** formed no complexes with tetracyanoquinodimethane (TCNQ), chloranil, or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). However, it gave conducting complexes with acceptors **3**, **6a**,[15] and **6b**,[16] which contain a 1,2,5-thiadiazole ring or a selenadiazole ring. This

fact seems to suggest that interheteroatom interactions also play an important role in the complexation. The properties of the complexes are summarized in Table 1.

Asymmetric Heterodinuclear $[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2ML]^{2\oplus}$ Complexes (M = Fe, Mn, V): Electronic Structure and Magnetic Properties**

By *Rainer Hotzelmann, Karl Wieghardt,* Ulrich Flörke,* and *Hans-Jürgen Haupt*

Dedicated to Professor Wolfgang Roth on the occasion of his 60th birthday

Since it was discovered that in some iron- and manganese-containing metalloproteins the active center is a dinuclear μ-oxo-bis(μ-carboxylato)dimetal(III) unit,[1, 2] inorganic chemists have synthesized various low-molecular-weight model complexes of this kind and have determined their structures and investigated their electronic structure and magnetic properties. In this study we have in particular sought to clarify the mechanism of the spin exchange coupling between the two paramagnetic metal centers. In the series of homodinuclear complexes $[L'_2M^{III}_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ (L' = *N,N',N''*-trimethyl-1,4,7-triazacyclononane,[3–7] antiferromagnetic or ferromagnetic coupling can occur, depending on the d-electron configuration of the metal ions (Table 1). We have started to prepare heterodinuclear complexes of this type and to study their magnetic properties, with the object of identifying the magnetic orbitals responsible for the spin exchange coupling in structures of this type.[8]

Table 1. Structural data and magnetic properties for homodinuclear complexes of the form $[L'_2M_2^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{2\oplus}$ [a].

M	M-O_{oxo} [Å]	M···M [Å]	M-O-M [°]	J [cm^{-1}][b]	Ref.
Ti^{III} (d^1)	1.81(2)	3.20(1)	122.7(8)	diamagnetic	[3]
V^{III} (d^2)	1.792(4)	3.250(2)	130.2(2)	> +200	[4]
Mn^{III} (d^4, h.s.)[c]	1.810(4)	3.084(3)	120.9(1)	+9	[5]
Fe^{III} (d^5, h.s.)[c]	1.800(3)	3.120(3)	119.7(2)	−119	[6]
Ru^{III} (d^5, l.s.)[c]	1.884(2)	3.258(1)	119.7(2)	diamagnetic	[7]

[a] L' = *N,N',N''*-trimethyl-1,4,7-triazacyclononane. [b] $H = -2JS_1 \cdot S_2$. [c] h.s. = high spin; l.s. = low spin.

In dinuclear linear oxo-bridged complexes of chromium(III) (d^3) the strong antiferromagnetic coupling (ground state $S = 0$) is attributed to the overlapping of one t_{2g} orbital from each of the chromium ions with a p orbital of the oxo bridge ("magnetic superexchange", Fig. 1).[9] Since this interaction

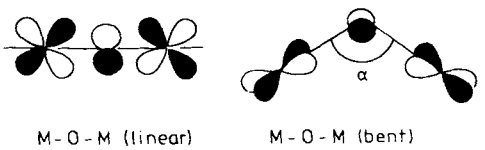

Fig. 1. Schematic representation of the orbitals involved in the magnetic superexchange mechanism.

is in principle independent of the Cr^{III}–O–Cr^{III} bond angle, the same exchange mechanism should also occur in μ-oxo-bis(μ-carboxylato)dimetal(III) complexes if the two corresponding t_{2g} orbitals are each occupied by one electron. To test this hypothesis we have synthesized the asymmetric heterodinuclear complexes **1**–**3**.

$[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2FeL]X_2$ **1**, X = PF_6; **1'**, X = ClO_4
$[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2MnL](PF_6)_2$ **2**
$[L'Ru(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2VL](PF_6)_2$ **3**
L' = *N,N',N''*-trimethyl-1,4,7-triazacyclononane;
L = 1,4,7-triazacyclononane

The hydrolysis of equimolar amounts of $L'RuCl_3$ and $LMCl_3$ (M = Fe, Mn, V) in a methanolic sodium acetate solution, followed by addition of $NaPF_6$, results in precipitation of the crystalline compounds **1**–**3**. Addition of $NaClO_4$ or $NaPF_6$ to aqueous solutions of the respective chlorides yielded single crystals of **1** and **3** suitable for structure determination by X-ray diffraction.

Figure 2 shows the structure of the dication of **1'**.[10] The atoms N3, Fe1, O1, Ru1, and N2 lie in a crystallographic mirror plane. The two metal centers are linked by a weakly asymmetric oxo bridge and two bidentate acetate groups. The Ru···Fe distance of 3.176(3) Å is not consistent with a metal–metal bond. The iron ion is coordinated to L and the ruthenium ion to L'; thus, no ligand exchange occurs during the synthesis.

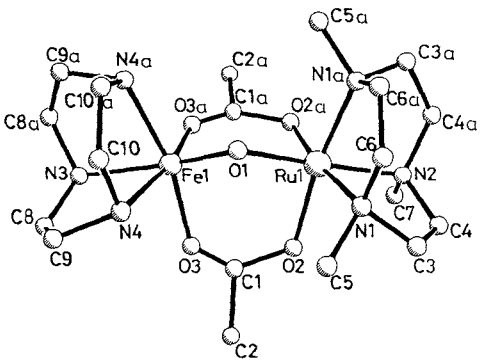

Fig. 2. Structure of the dication in crystals of **1'**, showing important bond lengths [Å] and angles [°]: Ru1···Fe1 3.176(3), Ru1-O2 2.05(2), Ru1-N2 2.10(3), Fe1-O3 2.00(2), Fe1-N4 2.12(2), Ru1-O1 1.95(1), Ru1-N1 2.04(2), Fe1-O1 1.73(2), Fe1-N3 2.26(2); Ru1-O1-Fe1 119.3(8).

[**] This work was supported by the Fonds der Chemischen Industrie. L' = *N,N',N''*-trimethyl-1,4,7-triazacyclononane; L = 1,4,7-triazacyclononane.

Figure 3 shows the structure of the dication of **3**. The Ru–O–V bridge is highly asymmetric: the Ru–O distance is quite long, 2.053(10) Å, whereas the V–O distance is very short, 1.665(8) Å. This points to the existence of a $Ru^{II}V^{IV}$ complex with a $Ru^{II}-O=V^{IV}$ bridge.

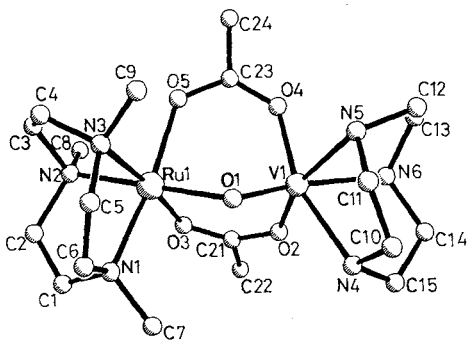

Fig. 3. Structure of the dication in crystals of **3**, showing important bond lengths [Å] and angles [°]: Ru1···V1 3.153(3), Ru1-O1 2.053(10), Ru1-O3 2.12(1), Ru1-O5 2.106(9), Ru1-N1 2.09(1), Ru1-N2 2.08(1), Ru1-N3 2.07(1), V1-O1 1.665(8), V1-O2 1.98(1), V1-O4 1.98(1), V1-N4 2.16(1), V1-N5 2.16(1), V1-N6 2.23(1); Ru1-O1-V1 115.6(5).

Measurements of the susceptibility as a function of temperature[11] on powdered samples of **1**, **2**, and **3** in the range 4.2–295 K using a Foner magnetometer gave temperature-independent magnetic moments (Curie behavior) with values of 4.7 μ_B for **1**, 3.9 μ_B for **2**, and 1.8 μ_B for **3**. These values correspond to spin states of $S = 2$, 3/2, and 1/2 for **1**, **2**, and **3**, respectively.

Assigning oxidation states to the metal ions in **1**, **2**, and **3** is not a trivial matter. Although the syntheses start from the trivalent mononuclear compounds $L'Ru^{III}Cl_3$ and $LM^{III}Cl_3$, there are no a priori grounds for ruling out intramolecular transfer in **1**, **2**, or **3**; thus, **1** could be formulated as a complex of $Ru^{II}Fe^{IV}$, **2** as one of Ru^{II} Mn^{IV}, and **3** as one of $Ru^{II}V^{IV}$, each with a diamagnetic Ru^{II} ion (d^6, low spin) and a paramagnetic M^{IV} ion. On the other hand, the metal ions in **1**–**3** could instead be in their trivalent forms ($Ru^{III}Fe^{III}$, $Ru^{III}Mn^{III}$, $Ru^{III}V^{III}$). In this case the single electron of the Ru^{III} ion (d^5, low spin) would have a very strong antiferromagnetic coupling ($-J > 300\ cm^{-1}$) to one of the unpaired electrons of a high-spin Fe^{III} (5e), Mn^{III} (4e), or V^{III} (2e) ion. Both descriptions are consistent with the observed magnetic behavior. For **1** and **2** the formulas with $Ru^{III}Fe^{III}$ and $Ru^{III}Mn^{III}$ are preferred on the grounds of the electronic spectra (Fig. 4), both of which show at least one strong

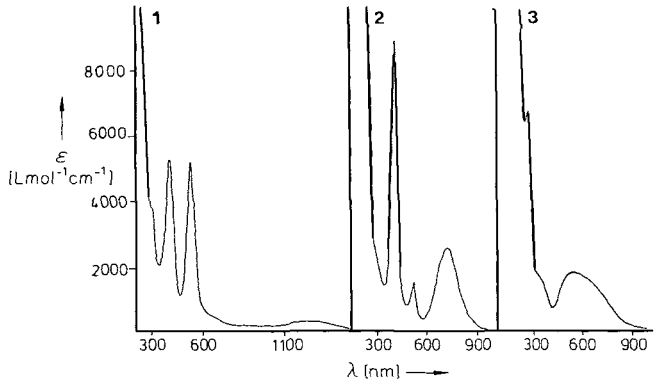

Fig. 4. Electronic spectra of **1**–**3** in acetonitrile.

$O_\mu \rightarrow M(III)$ charge transfer (CT) band in the visible region between 400 and 600 nm. Similar strong CT bands have also been observed for the analogous homonuclear complexes containing Fe^{III}, Mn^{III}, Ru^{III}, and V^{III}.[2–7, 12] In the spectrum of **3**, which resembles that of an octahedral $VO^{2\oplus}$ complex, these absorption peaks are absent. Compound **3** should therefore be described as a $Ru^{II}V^{IV}$ complex, which is also supported by the X-ray structural analysis.

The Mössbauer spectrum of **1** at 78 K with no applied magnetic field[11] shows a symmetrical doublet with an isomer shift of $\delta = 0.42(3)\ mm\ s^{-1}$ and a quadrupole splitting of $\Delta E_Q = 1.58(5)\ mm\ s^{-1}$. These values are typical for an octrahedrally coordinated high-spin Fe^{III} ion and are similar to those for the homodinuclear complex $[L'_2Fe_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](PF_6)_2$.[6] Therefore, **1** is a $Ru^{III}Fe^{III}$ complex.

The assignment of oxidation states is also supported by the X-band ESR spectra of solid samples of the tetraphenylborate salts of **1**, **2**, and **3** at 10 K (Fig. 5).[13] The spectrum of **2** shows ^{99}Ru and ^{101}Ru hyperfine splittings and also a six-line signal at $g \approx 2.0$, which is assigned to the ^{55}Mn hyperfine interaction. However, the spectrum of **3** shows only one well-resolved eight-line signal at $g \approx 2.0$. Such a signal is typical for octahedral V^{IV} complexes.[14] In contrast **1** gives no ESR signal owing to its $S = 2$ ground state.

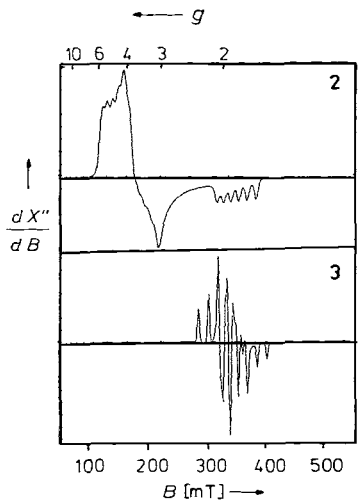

Fig. 5. ESR spectra (X-band) of solid samples of **2** and **3** as BPh_4 salts (not PF_6 salts) at 10 K. (Measurement conditions: 9.436 GHz; 20.0 μW/40 dB; modulation amplitude: 10.0 G).

Thus, the picture that emerges is the following. **1** and **2** are complexes of $Ru^{III}Fe^{III}$ and $Ru^{III}Mn^{III}$ with spin states $S = 2$ and $S = 3/2$, respectively, which are formed by strong antiferromagnetic coupling of the metal centers through a magnetic superexchange mechanism (magnetic orbital "d_{xz}"–"d_{xz}"; spin exchange coupling constant $-J > 300\ cm^{-1}$; $H = -2JS_1S_2$). On the other hand, **3** must be regarded as a complex of $Ru^{II}V^{IV}$ ($S = 1/2$) with a diamagnetic Ru^{II} ion (d^6) and a V^{IV} ion (d^1).

Experimental Procedure

To a solution of 0.5 g of sodium acetate in 40 mL of methanol under argon were added 0.15 g of $L'RuCl_3$ [7] and an equimolar amount of $LMCl_3$ (M = Fe^{III} [15], Mn^{III} [5], or V^{III} [4]), and the mixture was then heated under reflux for 1 h. $NaPF_6$ (0.8 g) was then added, and a stream of argon was passed through until the solution was reduced to half its original volume. At 0 °C crystals of **1**, **2**, or **3** precipitated out; these were then separated by filtration, washed with ethanol

and ether, and dried in air (yield 50–60%). All the complexes gave elemental analyses (C, H, N, Fe, Mn, V) in agreement with the formulas.

^{17}O NMR Spectroscopy of Benzoyl Compounds $Y-C_6H_4-COX$: Sensitivity to Ring Substituents as a Measure of the Electron Demand of the Carbonyl Group**

By *Hans Dahn,* Peter Péchy*, and *Vien Van Toan*

The electrophilicity of a carbonyl group diminishes when it is bound to an electron-donating group (as in $-CONH_2$); however, a numerical scale of electrophilicities seems still to be lacking. The "tool of increasing electron demand"[1] has been devised to measure the electron demand of carbocations. Its principle is that the greater the electron demand of a given center, the more sensitive its properties (reaction rates, spectral data, etc.) will respond to electron-donating or withdrawing substituents; usually the latter are fixed in the *para* position of an aromatic ring directly attached to the center. Applying the "tool" to the problem of carbonyl electrophilicities, one would vary the ring substituent Y in benzoyl compounds $Y-C_6H_4-COX$ and expect that, for a measured carbonyl property, the sensitivity to variation of Y should increase with increasing electrophilicity of the carbonyl group (e.g., aldehydes should be more sensitive than amides). In principle the effect can be measured by any suitable (e.g., spectroscopic) technique; until now, however, promising techniques like determination of IR stretching vibration[2] or bond length[3] have not been successful for this problem. In particular it should be stressed that ^{13}C NMR chemical shifts do *not* yield a measure of the electron density and π-bond order at the carbonyl carbon atom, probably due to internal compensations;[4] moreover, ^{13}C NMR of carbonyl carbon shows an inverse substituent effect; that is, electron-withdrawing substituents increase the shielding instead of diminishing it.[5] We now report results showing that ^{17}O NMR chemical shifts provide an appropriate measure for the characterization of carbonyl groups and for applying the "tool of increasing electron demand" via substituent effects.

^{17}O NMR spectroscopy is distinguished by a large spectral window (>600 ppm for oxygen bound to carbon); shift values are reproducible to ±0.5 ppm, without isotopic enrichment.[6] We have shown that the shift values of carbonyl oxygen atoms, appearing at lower field than bridging oxygen atoms, are particularly sensitive to resonance effects.[7] For instance, while a cyclopropanone (without resonance interaction) shows a shift of $\delta = 524$, a value close to a normal ketone, a cyclopropenone (strong interaction) appears at much higher field ($\delta = 233$), closer to an enolate.[8]

Substituent effects for four series of aromatic carbonyl ^{17}O chemical shifts have already been reported.[9–12] We have measured 12 series of Aryl–COX (Table 1), varying the para substituent Y of the aryl group for each type of –COX (aldehydes, amides, etc.; 6 to 13 compounds in each series).

Table 1. ^{17}O NMR chemical shifts and substituent sensitivity in the aromatic carbonyl compounds *p*- (and *m*-) $Y-C_6H_4-COX$ [a].

We used aprotic solvents (MeCN, CCl_4), with the exception of water for ArCOONa.[13] The substituent sensitivity was expressed by Hammett-type correlations; as expected for carbonyl group properties, the σ^+ scale[14] gave the statistically best fits. Dual substituent parameter treatment,[15] which separates polar and resonance effects, did not improve the correlations.

As shown in Table 1, ϱ^+ diminishes from trifluoroacetophenones to benzoate anions by a factor of 6, following the diminishing electron demand of the group. The order of decreasing sensitivity corresponds to increasing resonance by electron donation from X. The classical qualitative rules of chemical electrophilicity (and acylating power) are well reflected by the ϱ^+ values ($COO^{\ominus} < CONH_2 \ll COMe$; $COF < COCl < COBr$; $COOR < COSR$; $COMe < COCF_3$). Bridging oxygen atoms show smaller sensitivity:[11] we found a Hammett-type $\varrho = 5.6$ for –O– of methyl benzoates.

Table 1 also gives the shift values δ of the unsubstituted benzoyl derivatives (measured in MeCN, except for –COONa). The shielding increases (lower δ) with increasing donor action of X, as expected for increasing importance of the polar bond structure $C(=X^{\oplus})-O^{\ominus}$. We find a general parallel between ϱ^+ and δ values, which can be expressed by a reasonably good correlation with the slope $\delta/\varrho^+ = 13.1$ ($R = 0.950$). On the other hand, purely inductive effects (as in $COCF_3$ and COCOOEt[16]) do not affect the shift values as much as does resonance.

The chemical shifts of ^{17}O are essentially determined by paramagnetic shielding, which is approximated by the Karplus–Pople equation.[7a] It contains an electronic excitation energy term and a bond-order/charge-density matrix term. The latter term is related to the π-electron density and to chemical electrophilicity. Very often, however, the relative importance of the two terms is not known; for some carbonyl groups the preponderance of the bond order term has been demonstrated, either by calculation[9] or via comparison with NQR values.[16, 17] In our results the correlation between δ and ϱ^+ (which is related to bond order) confirms the importance of the π-electron density term in the benzoyl ^{17}O chemical shifts. This means that the electronic excitation energy term of the Karplus–Pople equation does not vary in a systematic way from one type of benzoyl compound to another; indeed, there exists in this class no correlation between ^{17}O NMR and UV spectra.[18]

In conclusion it appears that ϱ^+ values give a convenient measure of electrophilicity; δ values (simpler to obtain) are more sensitive to resonance than to polar effects.

Lithium-Ion-Catalyzed Epoxidation by Triplet Dioxygen: An ab initio Study **

By *Heinz Hofmann* and *Timothy Clark* *

Dedicated to Paul von Ragué Schleyer on the occasion of his 60th birthday

Our recent studies on the metal-ion catalysis of radical,[1, 2] closed-shell,[3] and triplet[4] reactions have demonstrated that complexation to a metal cation or radical cation may facilitate open- or closed-shell reactions, respectively. Most significantly in the context of the present communication, complexation of triplet dioxygen, $^3O_2$, with $Li^{\oplus}$ lowers the barrier to hydrogen abstraction from C-H donors and favors the O-H product thermodynamically.[4] This result, which may have far-reaching consequences for biological systems, encouraged us to consider another important oxidation reaction, the epoxidation of olefins. Both the silver-catalyzed epoxidation of ethylene[5] and the epoxidation of aromatics by cytochrome P450[6] suggest that metals may have a large effect on the course of this reaction. Our H-abstraction work[4] has revealed the predominantly electrostatic nature of this type of catalysis, so that $Li^{\oplus}$ catalysis provides a useful model for the electrostatic component of transition-metal catalysis. We have therefore used ab initio molecular orbital theory[7] to investigate the two related reactions (a) and (b) (adduct formation is indicated by, for example, $[Li:O_2]^{\oplus}$).

$$^3O_2 + C_2H_4 \xrightarrow{(1^*)} {}^3[\underset{\mathbf{2}}{O\text{-}O\text{-}CH_2\text{-}CH_2}] \xrightarrow{(3^*)} \text{oxirane} + {}^3O \qquad \text{(a)}$$

$$^3[Li:O_2]^{\oplus} + C_2H_4 \xrightarrow{(4^*)} {}^3[\underset{\mathbf{5}}{Li:O\text{-}O\text{-}CH_2\text{-}CH_2}]^{\oplus} \xrightarrow{(6^*)} {}^3[\underset{\mathbf{7}}{\text{oxirane}:Li:O}]^{\oplus} \qquad \text{(b)}$$

Both reactions involve two distinct steps with an intermediate minimum (**2** and **5**). The first step, the addition of the

[a] Restricted Hartree–Fock (RHF) for closed-shell systems and unrestricted Hartree–Fock (UHF) for radicals. [b] Energies include correction for zero-point vibrations. [c] Number of imaginary frequencies (1, transition state; 0, minimum). [d] Zero-point energy [kcal mol^{-1}].

dioxygen species to the olefin to give a triplet dimethyleneperoxy diradical, **2**, is calculated to be endothermic by 34.4 kcal mol^{-1} in the unperturbed reaction (a) and to have an activation energy of 40.6 kcal mol^{-1} (via transition state **1**). Although it might be expected on the basis of other UHF-based calculated activation energies[8] that the calculated activation energy should be too high because of spin contamination in the UHF wave function, we can still conclude that the barrier to addition of triplet oxygen to olefins is considerably higher than those for, say, oxygen radicals.[9] This result reflects the expected[10] kinetic inactivity of triplet oxygen, even in a reaction that stays on the triplet potential energy surface.

Complexation of the oxygen with $Li^{\oplus}$ [Eq. (b)] changes this situation considerably. The activation energy for the initial addition reaction leading to **5** via transition state **4** is only 7.8 kcal mol^{-1}. The addition reaction is essentially thermoneutral with a calculated energy of 0.8 kcal mol^{-1}. Thus, both the odd-electron bond stabilization of the transition state **4** observed previously for radical addition to olefins[11] and the thermodynamic preference for products with as many bonds as possible between oxygen and an electropositive element (hydrogen or carbon) are found in the effect of $Li^{\oplus}$ complexation on this addition reaction. Triplet oxygen addition to ethylene becomes a fast, reversible process in the presence of $Li^{\oplus}$.

The second stage of the reaction is the concurrent closing of the oxirane ring and cleavage of the O–O bond. This process is found to have a high (61.6 kcal mol^{-1}, transition state **3**) activation energy for the unperturbed reaction (a). The entire process shown in Equation (a) is found to be endothermic by 27.7 kcal mol^{-1}. The calculated activation energy for the $Li^{\oplus}$-catalyzed reaction (b) is, however, only 22.3 kcal mol^{-1} (transition state **6**) and the reaction sequence (b) as far as the complex **7** is exothermic by 19.3 kcal mol^{-1}. Schematic energy profiles for the two reactions are shown in Figure 1. There is comparatively little effect of the $Li^{\oplus}$ on this second stage of the reaction compared with the first step, but the overall effect is significant. In both transition states for the ring closure/bond cleavage (**3**, **6**), the O–O bond stretching precedes the closure of the C–C–O angle. Because these transition states (**3**, **6**) bear little resemblance to the final products, the intrinsic reaction coordinates were followed from the transition states to the products using the IRC option in Gaussian 88.[11] We also note that the orientation of triplet oxygen addition via an s-*trans* transition state is opposite to the s-*cis* orientation found for singlet oxygen addition to ethylene.[12]

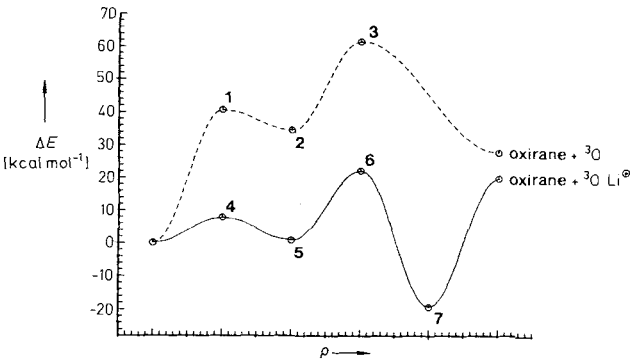

Fig. 1. Schematic energy profiles for the epoxidation of ethylene by $^3O_2$ (dashed line) and by $^3[O_2:Li]^{\oplus}$ (solid line). Energies are relative to the starting materials and the numbering of the stationary points corresponds to that used in the text and structures. ϱ = reaction coordinate.

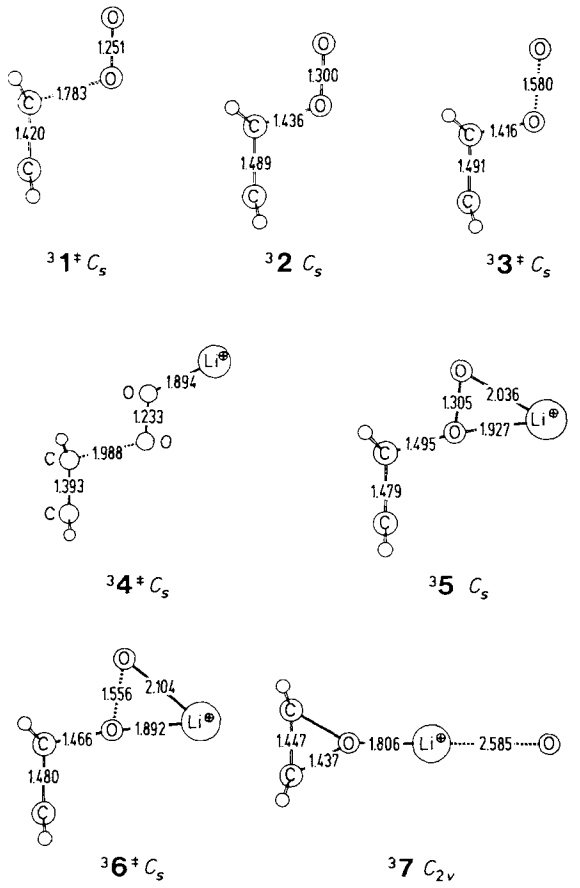
We emphasize once more[1–4] that such results should be quite general for $^3O_2$ complexed to metal cations. Lithium, which is a computationally convenient model, is expected to show a large effect,[4, 13] but should not be unique. Although our model studies cannot be considered to relate directly to enzymatic systems, we should like to point out that $^3[O_2:Li]^{\oplus}$ can perform both hydrogen abstraction[4] and epoxidation reactions analogous to the reactivity of cytochrome P450.[6] Our calculations thus suggest indirectly that the electrostatic component of cytochrome P450 catalysis may be greater than generally thought. Furthermore, reaction (b) also produces an oxygen atom, so that two epoxidations should be possible with one oxygen molecule. Our results and the remarkable gas-phase reactivity of tran-



Scheme 1. Structural parameters for **1**–**7** calculated at the UHF/6-31G* level.

sition-metal ions[14] suggest that "naked ion chemistry" may be a remarkably good model for far more complex systems such as zeolites[3, 15] or enzymes.

Structure Determination of $NaCD_3$ Powders at 1.5 and 300 K by Neutron and Synchrotron-Radiation Diffraction**

By Erwin Weiss, Siegfried Corbelin, Jeremy Karl Cockcroft,* and *Andrew Nicholas Fitch*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

We reported earlier[1] the synthesis of methylsodium containing variable amounts of $LiCH_3$ and were able to determine the structures of these preparations from their X-ray powder data. The preparations were formed from $LiCH_3$ and sodium *tert*-butoxide by a metal–metal exchange reaction [Eq. (a)] and, depending on the composition of the di-

$$LiCH_3 + NaO\mathit{t}Bu \xrightarrow{\text{ether/hexane}} NaCH_3 + LiO\mathit{t}Bu \quad (a)$$

ethyl ether/hexane solvent system, contained $NaCH_3$ and $LiCH_3$ in a molar ratio of about 3:1 to 36:1. The amount of $LiCH_3$ was lowest in pure ether. In all these reactions, $LiCH_3$ was first prepared and dissolved $NaO\mathit{t}Bu$ then added.

X-ray investigation of the fine powder gave a cubic macrocell ($a = 2020$ pm, space group $F\bar{4}3c$) containing 24 tetrameric $(NaCH_3)_4$ aggregates. Although the structure is therefore closely related to that of methyllithium,[2] the arrangement of the $(NaCH_3)_4$ units in the lattice is considerably more complicated. They form a zeolite-like structure with large cavities, which can incorporate complete $(LiCH_3)_4$ units up to the structurally determined $NaCH_3$ ratio of 3:1 without noticeable lattice expansion.

A phase transition, involving formation of a more compact structure, is observed at about 80 °C on drying lithium-poor methylsodium preparations. We have now succeeded in directly preparing this methylsodium by dropwise addition of the $LiCH_3$ solution to a previously prepared $NaO\mathit{t}Bu$

[**] Metal-Alkyl and Metal-Aryl Compounds, Part 43. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank ILL and SERC Daresbury for making possible the neutron and synchrotron-radiation diffraction investigations. We also are grateful to Dipl.-Chem. *H. Viebrock* for his help in analyzing the data. Part 42: N. P. Lorenzen, E. Weiss, *Angew. Chem. 102* (1990) 322; *Angew. Chem. Int. Ed. Engl. 29* (1990) 300.

solution, followed by workup at room temperature without addition of hexane. The dried preparations are stable at room temperature, but they still contain small amounts of $LiCH_3$ (ca. 20:1). As shown by the structure investigation described below, this preparation is, in fact, *true methylsodium*. The formation of the $NaCH_3$–$LiCH_3$ inclusion compounds obtained earlier was apparently due to a template effect. Addition of NaO*t*Bu to methyllithium, which is also tetrameric in diethyl ether,[3] results in precipitation of $NaCH_3$, which forms a unique host lattice around these tetramers.

X-ray structure investigations of the $NaCH_3$ powders afforded diagrams containing numerous lines, which owing to insufficient resolution, could not be indexed. This was only accomplished by neutron-diffraction studies using the high-resolution powder diffractometers of the Laue-Langevin Institut in Grenoble. These investigations required deuterated methylsodium, $NaCD_3$, which we prepared from $LiCD_3$[4] and NaO*t*Bu.[5]

Measurements were carried out at 1.5 and 300 K and revealed no phase transformations. We will report details of these measurements elsewhere[5] (cf. also Refs. [4, 2c]). Although the multilined diagram showed numerous overlaps, it could finally be indexed as orthorhombic *I*-centered.

Further structure determination was possible by synchrotron-radiation diffraction investigations, carried out at the SERC Daresbury Laboratory.[6] These studies allowed determination of the positions of the Na and C atoms by direct methods[7] and then of the total structure (space group *I*222), including the D atoms, from the neutron-diffraction data. Refinement was performed by the Rietveld method[8, 9] (Fig. 1).

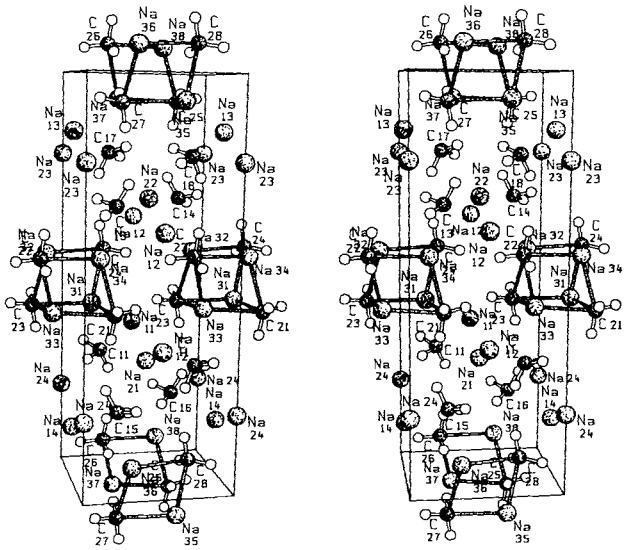

Fig. 1. Stereoscopic view [13] of the unit cell of $NaCD_3$ with atom numbering (symmetry-related atoms differ in the value of the second digit). Tetramers are highlighted by showing the heterocubane framework. $a = 676.86(1)$, $b = 1860.16(4)$, $c = 657.62(1)$ pm, $\varrho_{calcd} = 1.315$ g cm^{-3} ($NaCD_3$); refinement to R_{wp} (profile) $= \{\Sigma[w(y_o - y_c)^2]\}^{1/2}/\Sigma[w(y_o)^2] = 0.057$. Anisotropic for D, isotropic for Na and C (all values for neutron diffraction at 1.5 K). Values for 300 K as well as further details (including those of the synchrotron-radiation investigations) will be presented elsewhere [5].

The use of neutron diffraction to determine complicated structures has so far been used only in special cases. The structure elucidation described here is one of the first ab initio structure determinations combining neutron and synchrotron-radiation diffraction.[11] It gave the structure shown in Figures 1 to 3.

The methylsodium structure is a unique, relatively complicated structure type. The unit cell contains 16 formula units distributed over positions having different coordination numbers [e.g., four Na1 (in *h*), four Na2 (in *i*), and eight Na3 (in *k*)[12]]. Examination of several neighboring unit cells (Fig. 2) clearly reveals that half of the ions (eight Na3, eight

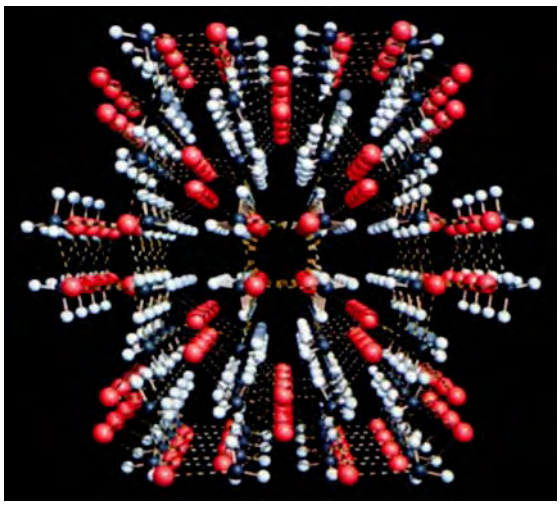

Fig. 2. Ball-and-stick model of the methylsodium lattice ($Na^{\oplus}$, red; C, gray; *x* axis horizontal, *y* axis vertical to projection plane, as in Fig. 1). In the middle of the picture and on the right and left sides are four tetramers, one behind the other (the long yellow broken lines correspond to short Na–C distances). Half tetramers lie at the top and bottom of the picture. The Na–C distances to the ions lying in between and not belonging to the tetramers are shorter (broken lines) or longer (dotted lines) depending on the orientation of the methanide ions.

C2 together with associated D atoms) are part of tetramers, $(NaCD_3)_4$, which are arranged in rows parallel to the *x* and *z* axes. The remaining eight $Na^{\oplus}$ and eight $CD_3^{\ominus}$ ions (Na1, Na2, C1 together with associated D atoms) lie between these rows and the $Na^{\oplus}$ ions form a zigzag chain parallel to the *z* axis. All ions that are not part of tetramers link them through Na–C contacts.

In the tetramers (space-filling model, Fig. 3), the central Na_4C_4 unit forms a strongly distorted cube. The $CD_3^{\ominus}$ ions together with their D atoms are directed outward and, as observed for methyllithium,[2] staggered with respect to the three neighboring $Na^{\oplus}$ atoms.

The Na–C distances to and between the eight $Na^{\oplus}$ and eight methanide ions outside the tetramers vary much more strongly than those within the tetramers (cf. also Fig. 2). They are short (252.8 and 256.9 pm) for direct contact between $Na^{\oplus}$ and the lone pair of the methanide ion and markedly longer when $Na^{\oplus}$ is located on the side opposite the lone pair (283.4 and 291.1 pm; at 1.5 K in each case).

For KCD_3 we have already discussed in detail the structure of the methanide ion.[4] The precise structure determinations of $LiCD_3$[2c] and $NaCD_3$ once again reveal the *trigonal-pyramidal structure of methanide ions* in the solid state. The methanide parameters for $NaCD_3$ (C-D 109.4 pm,

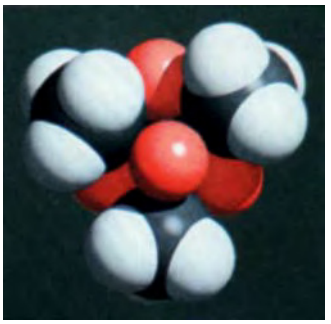

Fig. 3. Space-filling model of the $(NaCD_3)_4$ unit. The $Na^{\oplus}$ radii were arbitrarily set at 110 pm (usual ionic radius 97 pm). Owing to slight distortion, the Na–Na and Na–C distances vary somewhat (Na-Na 297–317, Na-C 257–264 pm, at 1.5 K). Each tetramer is surrounded by four methanide ions (not shown), which are arranged with their lone pairs directed toward the $Na^{\oplus}$ ions, resulting in short distances (256.9 pm).

D-C-D 106.2°; average values, 1.5 K) are in agreement with those for $LiCD_3$ and KCD_3.

This study thus closes the gap that existed for the structures of alkali-metal methanides. The structure of methylsodium is intermediate between that of methyllithium and methyl compounds of the heavy metals,[4, 14, 15] insofar as both tetrameric aggregates (as in methyllithium) and discrete ions (as in methanides of the higher alkali metals) are present. The optimal packing in the crystal causes the density of $NaCH_3$ to be appreciably larger than that of the $LiCH_3$-stabilized forms.

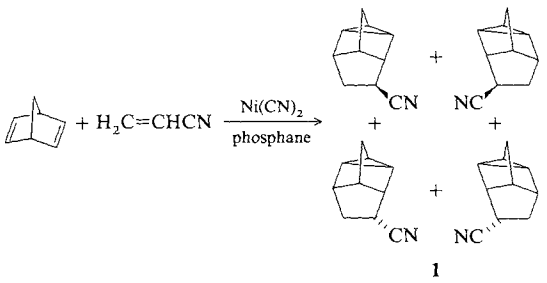
Optically Active Deltacyclanes and Deltacyclenes by Enantioselective Catalysis**

By *Henri Brunner,** *Manfred Muschiol*, and *Franz Prester*

Norbornadiene reacts with olefins and acetylenes in the presence of catalysts to form deltacyclanes and deltacyclenes, respectively. We report here that by carrying out such reactions using enantioselective transition-metal catalysts it is possible to obtain asymmetric inductions with remarkably high values.

Phosphane-modified nickel cyanide catalysts have been found to be effective in catalyzing the reaction of norbornadiene with acrylonitrile to give **1**.[1] 3 mL of norbornadiene is reacted with 3 mL of acrylonitrile in the presence of about 0.2 g of catalyst in an autoclave for 20 h at 120 °C. After filtering to remove the catalyst the product **1** is purified by distillation. The enantiomer analysis is carried out by first saponifying the isomeric nitriles **1** to give the corresponding carboxylic acids, which are then converted to the diastereomeric menthyl esters, and these are separated by gas chromatography in a 50-m CP-Sil-88-Fame quartz capillary column.[2] Using $(PPh_3)_2Ni(CN)_2$ as the catalyst gives **1** in 70–80% yield, with a diastereomeric ratio of 80:20. Enantioselective control was achieved by using, instead of PPh_3, the optically active phosphanes Diop[3] and Norphos.[4, 5] Whereas catalysts containing Diop gave a quantitative yield with a diastereomeric ratio of 60:40, the yield using Norphos-containing catalysts fell to about 10% (diastereomeric ratio 55:45). The asymmetric induction values obtained with catalysts based on Norphos (12 and 15% *ee*) are somewhat higher than those for catalysts based on Diop (4 and 3% *ee*).



1

In contrast to the reaction with acrylonitrile, in the reaction of norbornadiene with phenylacetylene no diastereomers are possible; the deltacyclene **2** consists only of the two enantiomers. For this reaction in situ catalysts based on $Co(acac)_3$, Diphos and Et_2AlCl have been used.[6, 7] When Norphos is used instead of Diphos the reaction of approximately 1 mL of norbornadiene with 1 mL of phenylacetylene in THF at 35 °C is complete in 4 h. The yield of the phenyl-substituted deltacyclene **2** is quantitative. The enantiomeric purity was determined by gas chromatography using a perpentylated β-cyclodextrin column,[8] which gives a peak separation down to the baseline for the enantiomers of **2**. For Norphos-based catalysts the value was 98.4% *ee*, with (−)-**2** having the shorter retention time and (+)-**2** the longer.

[*] Prof. Dr. H. Brunner, M. Muschiol, Dipl.-Chem. F. Prester

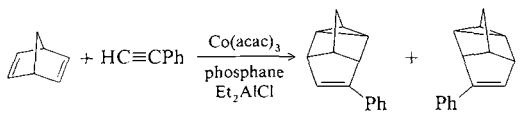
Universitätsstrasse 31, D-8400 Regensburg (FRG)

[**] Asymmetric Catalysts, Paper 55. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie and BASF AG, Ludwigshafen. Paper 54: H. Brunner, M. Muschiol, T. Wischert, J. Wiehl, *Tetrahedron Asymmetry, 1* (1990) 159.

When (−)-Norphos is used the main product is (−)-**2**, no second peak for (+)-**2** being detectable in the gas chromatogram following the large (−)-**2** peak. Catalysts made from (+)-Norphos give predominantly (+)-**2**. In this case the first peak in the chromatogram is that of the minor component (−)-**2**. Under these measurement conditions it was possible to determine the isomer ratio as 0.8:99.2, corresponding to an enantiomeric purity of 98.4% *ee*. With Diop-based catalysts in THF at 35 °C no reaction occurred within 4 h. In benzene there was a reaction giving **2**, but the enantiomeric purity was only about 20% *ee*.



2

The reaction of norbornadiene with acrylonitrile using Ni catalysts made from Diop or Norphos, giving **1**, only occurs under harsh conditions, and gives a mixture of diastereomers with low asymmetric induction; it is not very suitable as a preparative method. The reaction of norbornadiene with phenylacetylene using Norphos-Co catalysts to give **2** proceeds under mild conditions and requires only small amounts of catalyst (0.2–0.3 mol %; norbornadiene:phenylacetylene:Norphos:cobalt = 500:500:1.5:1). The chemical yield is quantitative, with a remarkably high enantiomeric purity of 98.4% *ee*. The reaction of norbornadiene with phenylacetylene to give the deltacyclene **2** therefore ranks as one of the best enantioselective reactions catalyzed by transition-metal complexes that have so far been reported.

Experimental Procedure

4-Phenyltetracyclo[4.3.0.0^{2,9}.0^{3,7}]non-4-ene **2**: 0.95 mL (9.4 mmol) of norbornadiene and 1.00 mL (9.1 mmol) of phenylacetylene were added under nitrogen to 7.1 mg (2×10^{-2} mmol) of Co(acac)$_3$ and 14 mg (3×10^{-2} mmol) of (+)-Norphos in 1 mL of dry THF. The catalytically active Co species was then generated by adding 5 mL of a 1 M solution of diethylaluminum chloride in hexane. The reaction mixture was stirred for 4 h at 35 °C. 5 mL of isopropanol was then dripped in to decompose the Et$_2$AlCl. The volatile constituents were removed by vacuum distillation at room temperature. **2** was then isolated by vacuum distillation at 100 °C in a Kugelrohr apparatus. $[\alpha]_D^{20}$ 56.3 (c = 1, CHCl$_3$). The ^{1}H NMR spectrum and mass spectrum of **2** were identical to those of a reference sample. [6] Yield 100%, enantiomeric purity 98.4% *ee*, both determined by gas chromatography with naphthalene as standard using a 40-m-Lipodex-C column. [8] Retention times: (−)-**2** 120.7 min, (+)-**2** 123.7 min (column temperature 104 °C, carrier gas H$_2$, flow rate 4–5 mL min^{-1} at 1.7 bar, injection temperature 170 °C).

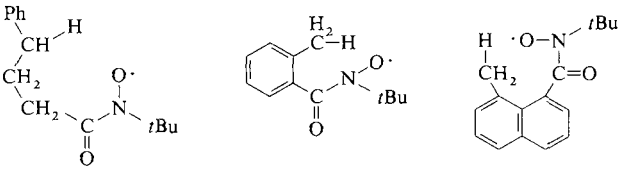
Reactivity in Intramolecular Radical Reactions: A Comparison of Hydrogen Transfer with Alkene Addition**

By *Corrado Berti, Lebert Grierson, Jean A.-M. Grimes, M. John Perkins,** and *Bulent Terem*

Intramolecular hydrogen-atom transfers and intramolecular radical additions have been extensively studied and have found important roles in synthesis,[1] yet the use of effective molarities (EM values)[2] as a means of relating the rates of these free-radical rearrangements to rates of suitable intermolecular models has only occasionally been mentioned.[3]

EM values for ionic reactions have been widely reported, and figures approaching, or greater than, the entropy-controlled limit[4] of ca. 10^8 M have been encountered for examples of nucleophilic attack on carbonyl carbon.[2] In contrast, when the intramolecular process involves rate-limiting proton transfer, EM values are several orders of magnitude smaller (generally less than 100 M). In this communication we examine both published and new rate data, which suggest that in radical chemistry a similar dichotomy exists between intramolecular addition and intramolecular hydrogen-atom transfer.



1 **2** **3**

The new results have been obtained with acyl *tert*-butylnitroxides R′CON(O·)*t*Bu. These may often be isolated,[5] yet are sufficiently reactive to oxidize a variety of organic substrates.[6] Some intramolecular reactions have also been noted;[7] comparison of the reported rate of intramolecular benzylic hydrogen-atom transfer (k_{intra}) in **1** with that of intermolecular reaction (k_{inter}) between undecanoyl *tert*-butyl nitroxide and ethylbenzene yields an EM value close to unity (Table 1).

Table 1. Some EM values for intramolecular reactions of nitroxides.

	Compound	T [K]	EM [M]
Intramolecular benzylic hydrogen abstraction	**1**	382	1.4 [a]
	2	358	12.8 [b]
	3	358	44 [b]
Alkene addition	**5**	398	$5(\pm3)\times10^5$ [b]

[a] Based on data in [7]. [b] This work; for compounds **2** and **3**, inter- and intramolecular rates were measured at the same temperatures.

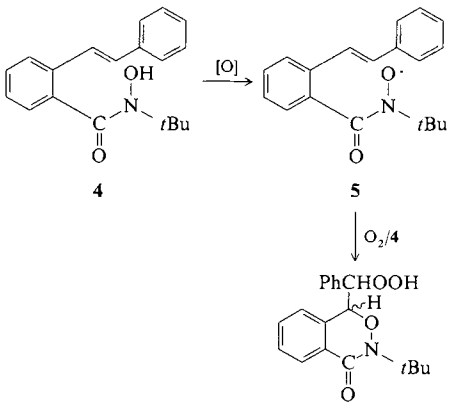
[**] We are grateful to the Royal Society and the S. E. R. C. for financial support. *M. J. P.* is particularly indebted to Dr. *K. U. Ingold* and Dr. *D. Griller* (N. R. C. Ottawa) and Prof. *A. L. J. Beckwith* (A. N. U. Canberra) for their generous hospitality during which parts of this investigation were completed.

We have now examined more constrained species. Thus, rate measurements on intramolecular reaction in **2** (formed by oxidation[5] of the corresponding hydroxamic acid[8]) and on the intermolecular reaction between benzoyl *tert*-butyl nitroxide and toluene give an EM value of 12.8 M for **2**. Although this increase relative to **1** is consistent with an entropic factor of ca. 10 expected for freezing one internal rotation,[9] it takes no account of the small polar effect of the carbonyl substituent in **2**.[10] A somewhat higher EM value (44 M) was obtained for **3** for which any polar effect would be minimized (rate comparison with the reaction between α-methylnaphthalene and α-naphthoyl *tert*-butyl nitroxide).

Recognizing the parallel between these low EM values and those found in proton-transfer reactions, we then turned our attention to intramolecular addition. Benzoyl *tert*-butyl nitroxide affords a 2:1 adduct with *trans*-stilbene.[11] We therefore prepared the hydroxamic acid **4**,[8] which, by one-electron oxidation, was expected to give **5**, whose cyclization rate could then be compared with that of the intermolecular addition of benzoyl *tert*-butyl nitroxide to stilbene.

Compound **4** is *different in kind* from other *N*-*tert*-alkylhydroxamic acids in that it undergoes rapid, spontaneous, and essentially quantitative autoxidation to a mixture of two hydroperoxides identified as the stereoisomers **6**.[12] This



suggests that the cyclization of **5** is indeed very fast. Nitroxide **5** (a_N = 7.8 G) was therefore generated in the absence of oxygen by ultraviolet irradiation of degassed solutions of **4** in *tert*-butylbenzene containing 10% di-*tert*-butyl peroxide and its first-order decay was monitored by ESR spectroscopy over the temperature range −40 to −10 °C, giving $\log A = 9.08$ and $E_a = 12.3$ kcal mol^{-1}.

There is no detectable reaction between benzoyl *tert*-butyl nitroxide and *trans*-stilbene at room temperature, either in the presence or absence of oxygen. The rate constant for the addition of this radical to stilbene was found to be 0.0125 M^{-1} s^{-1} in O_2-free *tert*-butylbenzene at 125 °C.[13] Extrapolation of the cyclization rate data to 125 °C gives an EM value for the intramolecular reaction of $5(\pm 3) \times 10^5$ M. Any polar effect of carbonyl on the intramolecular reaction is again expected to be very small.[14]

Although EM values of ca. 1–100 M have been deduced previously[3] for hydrogen-transfer processes, a similarly low value, ca. 40 M, was also estimated for intramolecular addition (in the rearrangement of 5-hexenyl radicals[15]). However, this estimate is based on comparison with intermolecular reaction *at the unsubstituted* carbon of a terminal alkene. A more acceptable comparison may be made between cyclization of the 6-methyl-5-heptenyl radical (**7**) and alkyl addition to 2-methylbut-2-ene. Careful consideration of published

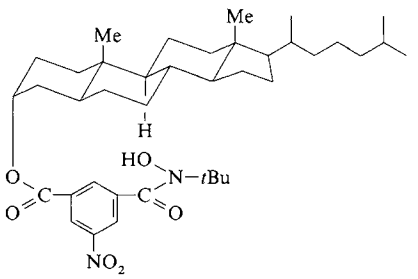
7

rate data for these reactions[16] suggests that EM values for hexenyl rearrangements may be as high as 10^5 M.

These data, taken together with the direct measurements on nitroxide reactions reported here for the first time, support the hypothesis that intramolecular hydrogen-atom transfers, like proton transfers, generally have low EM values, whereas intramolecular radical additions, like their nucleophilic counterparts, may generally have much higher ones.

For ionic reactions, more than one interpretation of this divergent behavior has been considered,[2, 17, 18] and it seems probable that several factors may contribute. The suggestion that intramolecular proton transfer has a significant enthalpic disadvantage due to the inaccessibility of a colinear (X···H···Y) transition state,[18–20] while attractive, seems to be contradicted by recent calculations by *Dorigo* and *Houk*.[21]

From the standpoint of synthesis it is clear that intramolecular atom transfer, like intramolecular addition, is often sufficiently rapid to accomplish preparatively useful transformations, although our efforts to achieve remote functionalization of a steroid by oxidation of the



8

3α-cholestanol derivative **8** (m.p. 159–160°)[8] gave a highly persistent nitroxide showing no evidence of intramolecular reaction.

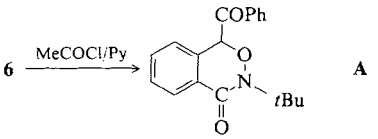
[12] The isomers cocrystallized; only one (m.p. 138–140°) was freed from its diastereomer. The alternative structures that would have arisen from 7-*endo* cyclization were excluded by dehydration of **6** with CH_3COCl/pyridine [N. A. Porter, J. S. Wujek, *J. Org. Chem. 52* (1987) 5085] to give the ketone **A**, characterized by the presence (^{1}H NMR) of an unsubstituted benzoyl group.



[13] [Stilbene] = 0.3 M; competing first-order self-reaction of the radical accounts for only ca. 10% reaction. Pseudo-first-order plots were linear over the radical concentration range studied (ca. 10^{-4} M); at lower concentration there was evidence that the initial radical addition to stilbene is reversible. Experimental rate constants for both this and the intramolecular reaction were halved to allow for reaction of the initial adduct with a second molecule of nitroxide.
[14] Data are not available for nitroxide additions to substituted stilbenes, but the carbonyl substituent might be expected to retard the intramolecular reaction very slightly; c.f. data for CCl_3 addition: J. I. G. Cadogan, P. W. Inward, *J. Chem. Soc. 1962*, 4170.

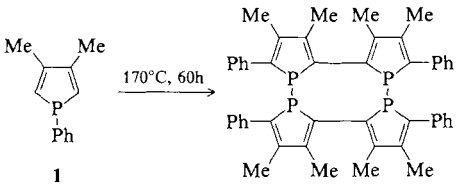
A First Step toward the Phosphorus Analogues of Polythiophenes

By *Marc-Olivier Bevierre, François Mercier, Louis Ricard,* and *François Mathey**

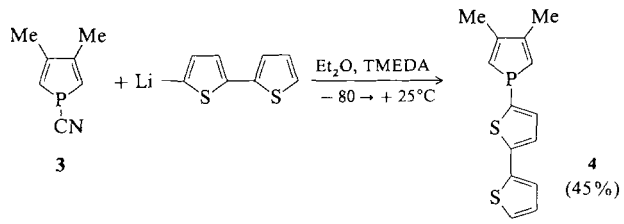
The electroconductivity of polythiophenes has been the subject of considerable study during the last few years.[1] More recently, it has been shown that high carrier mobility could also be achieved with well-defined thiophene oligomers such as α-sexithienyl.[2] Phospholyl anions are strictly isoelectronic with thiophenes and show a high degree of electronic delocalization according to theoretical,[3] NMR,[4] and structural studies.[5] Hence, the idea of replacing thiophene by phospholyl rings in a polythiophene chain was very attractive. Indeed, in contrast to thiophene, the phospholyl ring retains a high coordination ability towards transition metals via its heteroatom.[6] A polyphospholyl conductor or semiconductor might thus offer the opportunity of modifying, for example, the catalytic, redox, or magnetic properties of coordinated metallic centers by an electric current.

In order to investigate such possibilities, it was first necessary to devise a simple access to such still-unknown polyphospholyl chains. The classical routes used for the synthesis of polythiophene chains (e.g., the oxidative coupling of 2-lithio derivatives[7] or the reductive coupling of 2-bromo derivatives[8]) cannot be transposed to their phosphorus analogues because the necessary 2-lithio or 2-bromo derivatives are unknown[9] and because tervalent phosphorus compounds display a high sensitivity toward oxidation at the heteroatom. We now wish to report on a straightforward synthesis of a six-unit mixed chain containing four thiophene and two phospholyl rings.

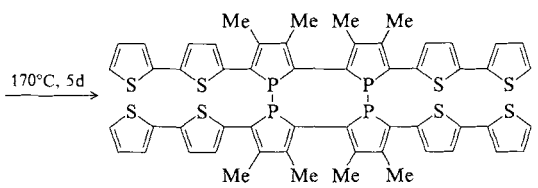
Earlier[10] we showed that prolonged heating of 1-phenyl-3,4-dimethylphosphole (**1**) ultimately leads to the tetramer **2** [Eq. (a)]. Since the various H and Ph migrations involved in



such a transformation were thought to proceed via concerted [1,5] sigmatropic shifts,[11] we reasoned that, if we replaced the phenyl at phosphorus by an α-thienyl substituent, we would retain the α substitution during the thermal conversion, thus creating the desired α-thienyl-α-phospholyl links. Accordingly, we first prepared the bithienyl-substituted phosphole **4** from readily available 1-cyano-3,4-dimethylphosphole (**3**).[12] Under prolonged heating, phosphole **4**[13] undergoes the same transformation as phosphole **1** [Eq. (b)].[14] The poorly soluble red-black tetramer **5**[15]



(b)

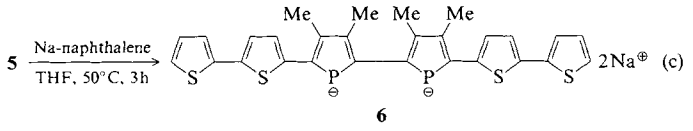


5 (ca. 30%)

could be very slowly recrystallized in 1,3,5-trichlorobenzene at 120 °C.[16]

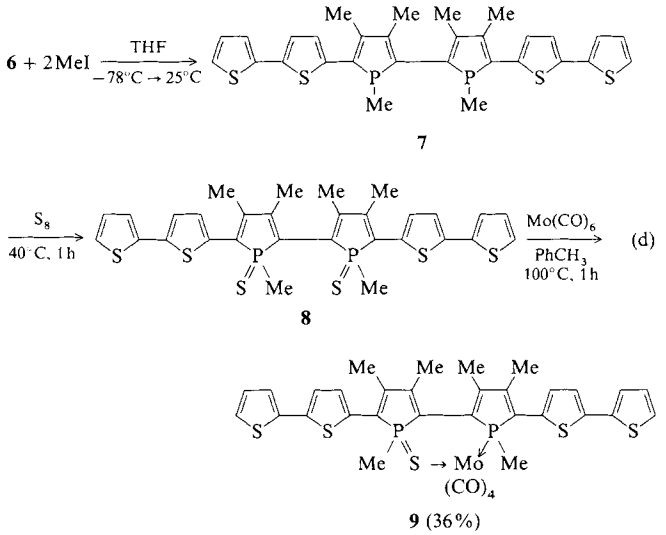
[*] Prof. Dr. F. Mathey, Dr. M.-O. Bevierre, Dr. F. Mercier, Dr. L. Ricard
Laboratoire de Chimie du Phosphore et des Métaux de Transition
DCPH, CNRS-Ecole Polytechnique
F-91128 Palaiseau Cedex (France)

Compound **5** can serve as a convenient starting point for the synthesis of the dianion **6**, which is isoelectronic with α-sexithienyl [Eq. (c)]. The cleavage of the P–P bonds of **5**

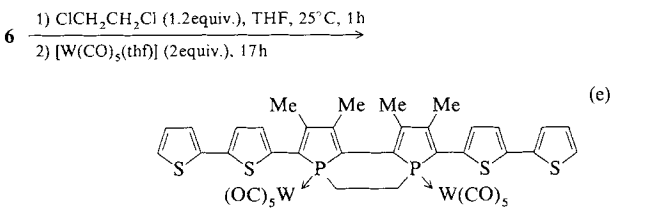


6

appears to be quantitative according to ^{31}P NMR analysis. The ^{31}P NMR resonance of **6** ($\delta = +65$) is in the normal range for a phospholyl anion.[4] Compound **6** was more fully characterized by methylation. The biphosphole **7** ($\delta(^{31}P) = +7.5$) is sensitive to oxidation and was allowed to react with sulfur to give **8** as a mixture of two diastereoisomers[17] [Eq. (d); overall yield of **8** from **5**, ca. 50%].



In order to characterize unambiguously the six-unit chain by X-ray diffraction, we also prepared a molybdenum complex **9** [Eq. (d)] and a tungsten complex **10** [Eq. (e)]. Both



10 (ca. 30%)

complexes **9** and **10** were obtained as single isomers[18, 19] and gave good crystals for the X-ray study[20, 21] (Fig. 1). In complex **9**, the thiophene rings are planar and have normal bond lengths and angles. The phosphole ring containing P1 is also planar, whereas the phosphole ring containing P2 is puckered as expected:[9] P2 lies outside of the C13–C16 mean plane by 0.115(2) Å. The first half of the chain (S_1, S_2 and P_1 rings) is quasi-planar. The angles between the rings are 4.81 ± 3.15 and $2.57 \pm 4.72°$, respectively. The other half of the chain is more puckered (15.25 ± 1.26 and $154.75 \pm 0.71°$, respectively.). The angle between the two phosphole rings is $55.6 \pm 0.3°$. The C–C links between the rings are shorter in the first half of the chain (1.42(1) and 1.43(1) Å, respectively) than in the second half (1.46(1) and 1.47(1) Å, respectively.). All these data suggest a higher delocalization in the first than in the second half.

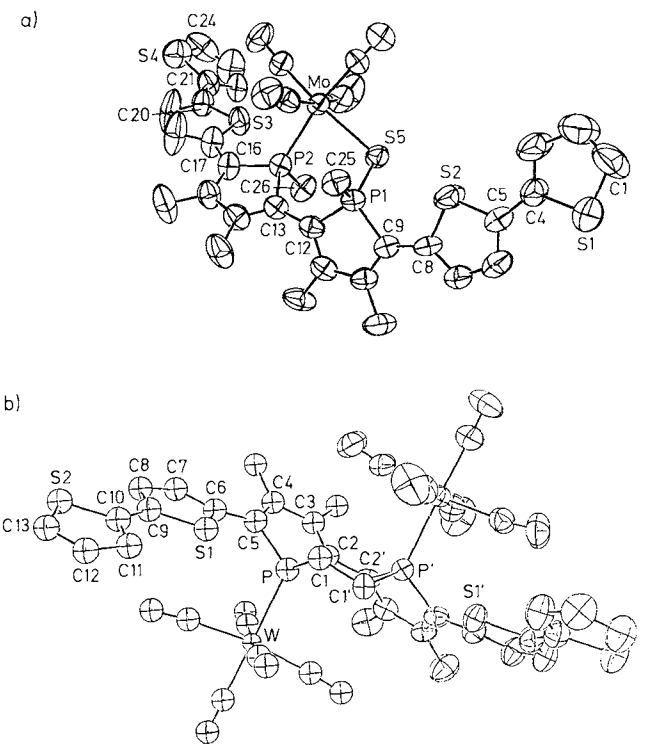


Fig. 1. Structures of **9** (a) and **10** (b) in the crystal. Ellipsoids are scaled to enclose 50% of the electronic density. Hydrogen atoms are omitted for clarity. Important bond distances [Å] and angles [°]: **9**: Mo-S5 2.632(2), Mo-P2 2.525(2), S5-P1 1.980(3), S1-C1 1.73(1), S1-C4 1.676(8), S2-C5 1.701(8), S2-C8 1.740(7), S3-C17 1.695(8), S3-C20 1.702(8), S4-C21 1.692(9), S4-C24 1.73(1), P1-C9 1.810(7), P1-C12 1.773(8), P1-C25 1.795(8), P2-C13 1.800(8), P2-C16 1.798(8), P2-C26 1.814(8), C4-C5 1.43(1), C8-C9 1.42(1), C12-C13 1.43(1), C16-C17 1.46(1), C20-C21 1.47(1); S5-Mo-P2 84.52(7), Mo-S5-P1 106.2(1), C1-S1-C4 92.3(5), S1-C4-C5 121.1(7), C4-C5-S2 121.5(7), C5-S2-C8 95.1(4), S2-C8-C9 120.6(6), C8-C9-P1 122.6(6), C9-P1-C12 95.3(4), P1-C12-C13 124.4(6), C12-C13-P2 121.7(6), C13-P2-C16 92.2(4), P2-C16-C17 123.4(7), C16-C17-S3 121.5(6), C17-S3-C20 93.9(4), S3-C20-C21 121.1(7), C20-C21-S4 120.7(7), C21-S4-C24 90.6(6). **10**: W-P 2.495(2), S1C6 1.732(8), S1-C9 1.735(7), S2-C10 1.699(7), S2-C13 1.695(9), P-C1 1.856(6), P-C2 1.798(6), P-C5 1.807(7), C1-C1' 1.529(12), C2-C2' 1.442(12), C2-C3 1.349(8), C3-C4 1.487(10), C4-C5 1.353(10), C5-C6 1.453(12), C6-C7 1.387(10), C7-C8 1.395(10), C8-C9 1.348(10), C9-C10 1.453(11), C10-C11 1.396(12), C11-C12 1.410(12), C12-C13 1.307(13); W-P-C1 118.3(2), W-P-C2 114.9(2), W-P-C5 118.2(2), C1-P-C2 101.2(2), C1-P-C5 107.8(3), C2-P-C5 92.1(3), P-C1-C1' 111.9(4), P-C2-C2' 116.9(3), P-C5-C6 121.0(5), C5-C6-S1 118.7(5), C6-S1-C9 93.6(4), S1-C9-C10 119.6(6), C9-C10-S2 120.1(6), C10-S2-C13 91.2(4).

In complex **10**, the four thiophene rings are planar, whereas the phosphorus atoms are outside of the corresponding diene mean planes by 0.15 Å. The thiophene–thiophene, thiophene–phosphole, and phosphole–phosphole interplane angles are, respectively, 6.35 ± 1.63, 24.34 ± 0.46, and $66.26 \pm 0.14°$. The C–C links between the rings are almost equal at 1.44–1.45 Å and similar to those found in α-terthienyl.[22]

The comparison between the structures of **9** and **10** underlines the flexibility of the six-unit chain and the sensitivity of the electronic delocalization within the chain to the substitution patterns of the phosphorus atoms. We are currently

studying the electrochemistry of these new types of conjugated oligomers.

Experimental Procedure

All reactions were carried out under argon.

4: Compound **3** was prepared in situ from 40 g (210 mmol) of **1** as previously described [12]. *n*-Butyllithium (95 mL, 1.6 M in hexane) was added dropwise at room temperature to 2,2'-bithienyl (25 g, 150 mmol) and anhydrous TMEDA (22.7 mL) in 150 mL of anhydrous Et_2O. The mixture was stirred for 3 h and was then added dropwise to the solution of **3** at $-80\,^{\circ}C$. The temperature was subsequently raised to 25 °C. After hydrolysis, neutralization, extraction with Et_2O, drying, and evaporation, the crude residue was chromatographed on silica gel with hexane. Overall yield 45%. The product could be recrystallized in hexane at 6 °C.

5: A sample of recrystallized phosphole **4** (6 g, 22 mmol) was sealed in a glass tube under argon. The tube was heated for 5 d at 170 °C. Compound **5** slowly precipitated as pure red-black crystals from the reaction mixture. These crystals were washed with dichloromethane. Yield ca. 30%.

6: A solution of sodium naphthalenide was first prepared from sodium (0.08 g, 3.5 mmol) and naphthalene (0.46 g, 3.5 mmol) in THF (10 mL). Compound **5** (1 g, 0.9 mmol) was then added without precaution to the dark green solution at room temperature. The reaction was complete after stirring for 3 h at 50 °C. Pure **6** could also be obtained by cleavage of **5** with sodium in diglyme at 120 °C.

8: To the solution of dianion **6** was added 0.23 mL (3.7 mmol) of methyl iodide at $-80\,^{\circ}C$. The temperature was raised to 25 °C. Then, sulfur (0.2 g, 6.2 mmol) was added to the reaction medium. After 1 h at 40 °C, the solution was filtered, the THF evaporated, and the naphthalene sublimed. The residue was chromatographed on silica gel with hexane/CH_2Cl_2 30/70 as the eluent. The product thus obtained (0.5 g, 43%) could be recrystallized in hexane/CH_2Cl_2 20/80.

9: Disulfide **8** (0.64 g, 1 mmol, major isomer) and $Mo(CO)_6$ (0.53 g, 2 mmol) were heated in toluene (20 mL) at 100 °C for 1 h. After filtration and evaporation, the organic residue was chromatographed on silica gel. Hexane/CH_2Cl_2 50/50 was first used as the eluent to remove impurities, then complex **9** was eluted with pure CH_2Cl_2 (0.3 g, 36%).

10: To the solution of dianion **6** was added dropwise 0.17 mL (2.2 mmol) of 1,2-dichloroethane with 2 mL of THF at $-80\,^{\circ}C$. The temperature was raised to 25 °C. Then, the reaction mixture was added to a solution of [$W(CO)_5$(thf)] obtained by UV irradiation of 1 g (2.8 mmol) of $W(CO)_6$ in 100 mL of THF for 1 h (125-W medium-pressure mercury lamp). After stirring for one night, the solvent was evaporated and the residue dissolved in dichloromethane. The solution was filtered and chromatographed on silica gel with hexane/CH_2Cl_2 80/20 as the eluent. The product thus obtained could be recrystallized in toluene/hexane 80/20 at room temperature.

[16] X-ray structure determination for **5**: Because of the low solubility of the compound, crystals were grown in a 100 K temperature gradient using $C_6H_3Cl_3$ as solvent. Data were collected at 20 ± 1 °C on an Enraf-Nonius CAD4 diffractometer. The structure was solved and refined using the Enraf-Nonius-supplied SDP package. The compound crystallizes in space group *P*1; $a = 11.463(2)$, $b = 16.528(2)$, $c = 27.185(3)$ Å, $\alpha = 91.96(1)$, $\beta = 101.91(1)$, $\gamma = 89.90(1)°$; $V = 5036.64(2.3)$ Å^3; $Z = 4$; $\varrho_{calcd} = 1.447$ g cm^{-3}; $Cu_{K\alpha}$ radiation ($\lambda = 1.54184$ Å), graphite monochromator; $\mu = 47.7$ cm^{-1}; $F(000) = 2272$. A total of 12233 unique reflections were recorded in the range $2° \le 2\theta \le 130.0°$; 7319 were considered as unobserved ($F^2 < 3.0\sigma(F^2)$), leaving 4914 for solution and refinement. The crystals were of medium quality and a scan width of 1.3° had to be adopted for data collection. Moreover, since the diffraction intensity falls off quite rapidly, a scan time of two min was used to improve the signal to noise ratio. The structure was solved by direct methods, yielding a solution of 90 of the 136 independent heavy atoms. Although the general shape of the molecule can be well established from the present study, it has not yet been possible to refine the structure to a level suitable for full publication. Three factors make it difficult to refine the model: the large average thermal agitation of the molecule, the large correlation coefficients between atoms of the two molecules that result from the presence of a pseudo mirror plane at [0,0,1/2], the lack of data with *l* odd (ten percent of all observed data) that results from this special packing. A non-Poisson weighting scheme was applied with a *p* factor equal to 0.08. The present isotropic *R* factors are $R = 0.156$, $R\omega = 0.200$, GOF = 3.79.

[17] **8** (main isomer): ^{31}P NMR ($CDCl_3$): $\delta = 48.9$. ^1H NMR($CDCl_3$; selected): $\delta = 2.04$ (d, ^2J(H,P) = 15.4 Hz, 6H, Me-P), 2.06 (s, 6H, Me-C), 2.35 (s, 6H, Me-C). ^{13}C NMR($CDCl_3$; selected): $\delta = 15.86$ (d, ^3J(C,P) = 12.6 Hz, *Me*-C), 16.81 (d, ^3J(C, P) = 12.6 Hz, *Me*-C), 21.10 (d, ^1J(C,P) = 50.3 Hz, Me-P); MS (EI, 70 eV): *m/z* 642 ($M^{\oplus}$, 100%), 610 ($M^{\oplus}$–S, 87%), 565 (88%). Correct C,H analysis.

[18] **9**: ^{31}P NMR(CD_2Cl_2): $\delta = +53.1$, +47.4 (^3J(P,P) = 7.3 Hz). MS (70 eV): *m/z* 786 ($M^{\oplus}$–S, 2%), 702 ($M^{\oplus}$–S–3CO, 3%), 578 ($M^{\oplus}$–S–4CO–Mo, 100%). IR(CH_2Cl_2): $\tilde{\nu}$-(CO) = 2018 s, 1915, 1900 vs, 1860 s. Correct C,H analysis.

[19] **10**: ^{31}P NMR(C_6D_6): $\delta = +30.5$ ($^1J(^{31}P,^{183}W) = 231.9$ Hz). ^1H NMR (C_6D_6): $\delta = 1.94$ (d, ^4J(H,P) = 1.7 Hz, 6H, Me), 1.99 (s, 6H, Me), 2.34–2.73 (m, 4H, CH_2), 6.64–7.08 (m, 10H, thiophene).

[20] a) X-ray structure determination for **9**: Crystals were grown by slow evaporation of a dichloromethane solution of the compound. Data were collected at 18 ± 1 °C on an Enraf-Nonius CAD4 diffractometer. The crystal structure was solved and refined using the Enraf-Nonius-supplied SDP package. The compound crystallizes in space group *C*2/*c*; $a = 30.001(3)$, $b = 11.322(1)$, $c = 26.54(3)$ Å, $\beta = 128.01(1)°$; $V = 7104.59(3.10)$ Å^3; $Z = 8$; $\varrho_{calcd} = 1.531$ g cm^{-3}; $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), graphite monochromator; $\mu = 7.7$ cm^{-1}; $F(000) = 3328$. A total of 6228 unique reflections were recorded in the range $2° \le 2\theta \le 50.0°$; 3469 were considered as unobserved ($F^2 < 3.0\sigma(F^2)$), leaving 2759 for solution and refinement. The structure was solved by direct methods, yielding a solution for the twenty atoms. The hydrogen atoms were included as fixed contribution in the final stages of least-squares refinement while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a *p* factor equal to 0.08. The final *R* factors were $R = 0.046$, $R_\omega = 0.063$, GOF = 1.21. b) Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-7514 Eggenstein-Leopoldshafen 2 (FRG), on quoting the depository number CSD-54479, the names of the authors, and the journal citation.

[21] X-ray structure determination for **10**: Crystals were grown at room temperature from a toluene-pentane solution of the compound. Data were collected at 18 ± 1 °C. The compound crystallizes in space group *Pbcn*; $a = 17.547(1)$, $b = 8.404(1)$, $c = 29.125(3)$ Å; $V = 4294.87(1.2)$ Å^3; $Z = 4$; $\varrho_{calcd} = 1.877$ g cm^{-3}; $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), graphite monochromator; $\mu = 57.3$ cm^{-1}; $F(000) = 2352$. A total of 6240 unique reflections were recorded in the range $2° \le 2\theta \le 60.0°$; 3336 were considered as unobserved ($F^2 < 3.0\sigma(F2)$), leaving 2904 for solution and refinement. The structure was solved by Patterson methods, yielding a solution for the tungsten and phosphorus atoms. The hydrogen atoms were included as fixed contribution in the final stages of least-squares refinement while using anisotropic temperature factors for all other atoms. A non-Poisson weighting scheme was applied with a *p* factor equal to 0.07. The final *R* factors were $R = 0.035$, $R_\omega = 0.047$, GOF = 1.07 [20b].

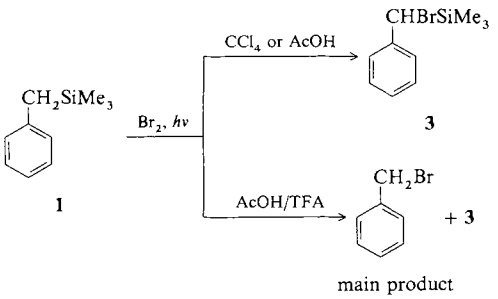
Solvent and Structure Effects in the Photobromination of Benzyltrimethylsilanes. A Mechanistic Changeover from Hydrogen-Atom Transfer to Electron Transfer**

By *Enrico Baciocchi** and *Manuela Crescenzi*

It has long been known that the bromine atom is very effective in abstracting benzylic hydrogens.[1] However, $Br^{\cdot}$ is also a good oxidant ($E^{\circ} = 2.0$ V vs NHE in H_2O)[2] and, with electron-rich substrates, it could behave as an electron-abstracting species as well. This mechanistic dichotomy, it is recognized nowadays, should characterize all reactions occurring between species with complementary electron-donor/electron-acceptor properties.[3]

We wish now to report on quite dramatic solvent and structure effects observed during a study of the photobromination of benzyltrimethylsilane (**1**) and (4-methoxybenzyl)trimethylsilane (**2**). We suggest that these effects provide us with the first evidence of a mechanistic dichotomy (hydrogen-atom transfer versus electron transfer) in the reactions of $Br^{\cdot}$ with aromatic compounds.

When **1** (1 mmol) is allowed to react (20 min at 60 °C) with Br_2 (1 mmol) in CCl_4 or AcOH (10 mL), under external irradiation (Pyrex filter) by a 500-W high-pressure mercury vapor lamp, only the expected product of side-chain substitution, (α-bromobenzyl)trimethylsilane (**3**), is obtained. There is little doubt, also on the basis of a recent kinetic study,[4] that this reaction occurs by a mechanism involving hydrogen-atom transfer.



Scheme 1.

When the solvent is changed to an 1:1 AcOH:TFA mixture (TFA = trifluoroacetic acid), however, a drastic change in the product composition occurs (Scheme 1). Compound **3** is now a minor product (15%), whereas most of the reaction leads to benzyl bromide (52%).[5] Of course, we have checked that both **1** and **3** are photochemically stable in the mixed solvent and that, in the absence of light, no desilylation occurs but only ring-brominated products form.

It is difficult to rationalize this observation by simply suggesting that in AcOH-TFA an attack of $Br^{\cdot}$ at silicon is also occurring. Apart from the very scanty information on such a process,[6] there is no plausible reason why no hint of it has been found in both AcOH and CCl_4. The homolytic substitution by $Br^{\cdot}$ at hydrogen and at silicon would have to be subject to drastically different solvent effects, which is not reasonable.

On the other hand, there is overwhelming evidence that benzyltrimethylsilane radical cations undergo an extremely fast desilylation reaction to give benzyl radicals.[7] The formation of benzyl bromide observed in AcOH-TFA can be much better interpreted on the basis of a mechanism [Eqs. 1–3] involving the transfer of an electron from **1** to $Br^{\cdot}$ as the first step. The radical cation thereby formed then undergoes a nucleophile-assisted reaction (presumably by the solvent)[7a, 8] to give the benzyl radical, which propagates the chain by reaction with Br_2, leading to benzyl bromide.

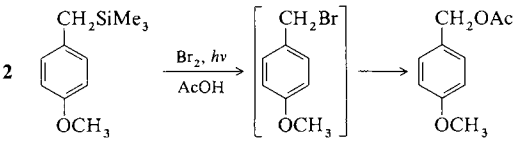
$$Br^{\cdot} + ArCH_2SiMe_3 \rightarrow Br^{\ominus} + ArCH_2SiMe_3^{\cdot\oplus} \quad (1)$$

$$ArCH_2SiMe_3^{\cdot\oplus} + AcOH \rightarrow ArCH_2^{\cdot} + Me_3SiOAc + H^{\oplus} \quad (2)$$

$$ArCH_2^{\cdot} + Br_2 \rightarrow ArCH_2Br + Br^{\cdot} \quad (3)$$

There are at least two factors which can contribute to shift the mechanism from hydrogen-atom transfer to electron transfer on going from AcOH to AcOH-TFA. First, increasing the acidity of the solvent should result in a higher E° value of the $Br^{\cdot}/Br^{\ominus}$ couple, due to better solvation of $Br^{\ominus}$ via hydrogen bonds. Second, TFA is very effective in solvating aromatic radical cations,[9] thereby lowering the oxidation potential of **1** ($E_p = 2.09$ V vs. NHE in MeCN).[7b, 10] Thus, in AcOH-TFA, $Br^{\cdot}$ and **1** are a better oxidant and a better reductant, respectively, than in AcOH. We therefore suggest that the combined effect of these two factors in AcOH-TFA so much facilitates the electron-transfer step as to make this step competitive with hydrogen-atom transfer.[11]

A similar mechanistic shift can also be induced, in the same solvent, by increasing the electron availability of the substrate. Accordingly, whereas photobromination of **1** in AcOH leads exclusively to (α-bromobenzyl)trimethylsilane, in the corresponding reaction of **2**, 4-methoxybenzyl acetate,[5] which certainly derives from the acetolysis of the initially formed 4-methoxybenzyl bromide (Scheme 2), is the exclusive product of the side-chain process.[14]



Scheme 2.

Thus, in AcOH, on going from **1** to **2** the nature of the products changes, again suggesting a changeover from a hydrogen-transfer to an electron-transfer mechanism, this time induced by the much easier oxidizability of the latter substrate (the E_p value of **2** is ca. 0.5 V lower than that of **1**).[7a]

Clearly, these results confirm the previous view[7b] that the study of the reactions of benzyltrimethylsilanes can be an excellent tool for distinguishing hydrogen-transfer from electron-transfer mechanisms.

[10] A higher value is, however, reported in [7a].
[11] It is also conceivable that benzyltrimethylsilane radical cation is formed by irradiation of the charge-transfer complex between **1** and Br_2 [12]: $(PhCH_2SiMe_3,\ Br_2) \xrightarrow{h\nu} (PhCH_2SiMe_3,\ Br_2)^* \longrightarrow PhCH_2SiMe_3^{\bullet\oplus}Br_2^{\ominus}$ However, the excitation of the charge-transfer complex is unlikely since its λ_{max} is around 300 nm in CCl_4 and lower values are expected in AcOH-TFA [13].

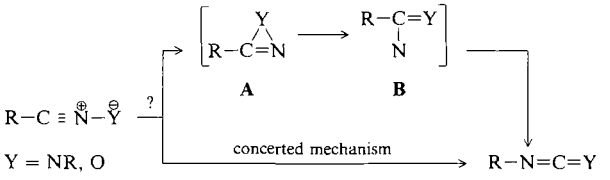
[14] Small amounts of ring-brominated products also form. It was confirmed that these are the exclusive reaction products of the bromination of **2** in the dark.

Direct Evidence for a Nitrile Imine–Imidoylnitrene Rearrangement: X-Ray Crystal Structure of an Unusual Nitrene Complex

By *Michel Granier, Antoine Baceiredo, Hansjörg Grützmacher, Hans Pritzkow*, and *Guy Bertrand**

Dedicated to Professor Rolf Huisgen on the occasion of his 70th birthday

Diazomethane is unique among small molecules with regard to the number of its potentially accessible isomers.[1] Usually, six of them are considered: cyanamide, diazirine, carbodiimide, isocyanamide, nitrile imine, and isodiazirine. According to theoretical calculations,[2] cyanamide is the most stable isomer; the less stable ones, namely, nitrile imine[3] and isodiazirine are higher in energy by 84.8 and 99.0 kcal mol^{-1}, respectively. Most of these isomers are interconvertible. The rearrangement of nitrile imine to carbodiimide has been detected only at very high temperature (> 500 °C)[4a] or photochemically in a matrix.[4b] It is of particular interest since it is isoelectronic with the nitrile oxide–isocyanate rearrangement,[5] and it is strongly related to the Wolff-type rearrangement starting from imidoyl azide (or acyl azide).[6] If the nitrile imine is regarded as a carbene, this process is also analogous to the rearrangement of acyl carbenes to ketenes.[7] One of the remaining questions is to know whether these rearrangements are concerted or involve isodiazirine (or oxazirene) **A** and imidoylnitrene (or acylnitrene) **B** as intermediates.



According to theoretical calculations, the rearrangement of RCNO to RNCO is predicted to pass through structures which may be termed oxazirine and (singlet) acylnitrene, but they are not true intermediates and should not be observable compounds.[8] *Wentrup* et al. reported evidence for nitrile imine–imidoylnitrene rearrangement through an isodiazirine intermediate, based on the nature of the products obtained in the pyrolysis at 500 to 960 °C of different nitrile imine precursors.[4a] Here we wish to report definitive proof for the nitrile imine–imidoylnitrene rearrangement including the X-ray crystal structure of a nitrogen-substituted oxonium compound.

We have shown that *C*-[thiophosphoranyl]-*N*-phosphanyl nitrile imine **1a** is stable at room temperature (m.p. 100 °C) and rearranges to the isomeric diazo derivative **2a** only on heating in solution at 55 °C for six hours. The *C,N*-diphosphanyl nitrile imine **1b**, on the other hand, is not stable enough to be spectroscopically observed even at −78 °C.[9]

From these results, it is clear that the hybridization state of the phosphorus atom is of primary importance to the stability of the nitrile imine. *o*-Quinones are well-known to react with phosphanes to give the corresponding pentacoordinated, pentavalent phosphoranes. Thus, we chose to study the reaction of tetrachloro-*o*-benzoquinone (TCBQ) with nitrile imine **1a**. A very clean reaction occurred leading, after workup, to product **3** as colorless crystals. A doublet of quintets at $\delta = -24.1$ ($J_{PP} = 2.6$, $J_{PH} = 16.0$ Hz) in the ^{31}P NMR spectrum was in the range expected for a $\sigma^5\lambda^5$-phosphorus atom bearing two diisopropylamino groups and the quinone residue; its counterpart at $\delta = 56.5$ (d quint., $J_{PP} = 2.6$, $J_{PH} = 21.9$ Hz) was in good agreement with the

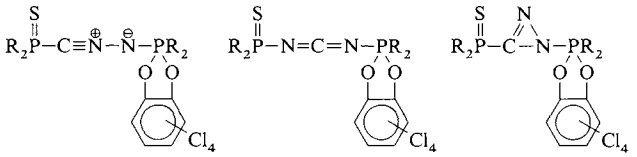
presence of a bis(diisopropylamino)thiophosphoranyl group. The absence of IR absorptions above 2000 cm^{-1} allowed us to rule out nitrile imine **4** or carbodiimide **5** as possible structures, but the mass spectrum (EI *m/z* 778) demonstrated that no nitrogen elimination had occurred, indicating that **3** was a structural isomer of **4** and **5**. These spectroscopic data as a whole and the presence of a signal at $\delta = 154.3$ (dd, $J_{PC} = 183.3$, 6.1 Hz) in the ^{13}C NMR spectrum[10] left only the isodiazirine derivative **6** as a possible candidate from the usual R_2CN_2 isomers.



4 **5** **6**

R = N*i*Pr$_2$

The surprising thermal stability (m.p. > 300 °C without decomposition) and lack of chemical reactivity (no reaction in boiling methanol) made it necessary to carry out an X-ray diffraction study of **3** for unambiguous structural characterization (Fig. 1).[11] The most surprising feature is the presence of a planar tricoordinate oxygen bonded to the aryl ring (O2-C7 1.378(5) Å), to P1 (O2-P1 1.729(3) Å), and also to N2 (O2-N2 1.394(4) Å). C1 is also planar and the C1–N1 and C1–N2 distances (1.332(4) and 1.290(5) Å) are between those of a single and a double bond. P1 is at the center of a slightly distorted trigonal bipyramid with expected P–O and P–N bond lengths. The P1-O1-C2-C7-O2 and P1-O2-N2-C1-N1 fragments are almost planar (maximum deviation ± 0.055 and 0.043 Å, respectively). Thus, this compound is best represented as **3a** but can also be regarded as an imidoylnitrene **3b** stabilized by a donor–acceptor interaction with an oxygen atom. Note that the stabilization of nitrenes by coordination at nitrogen is well known,[12] but has only previously been postulated for oxygen.[13]

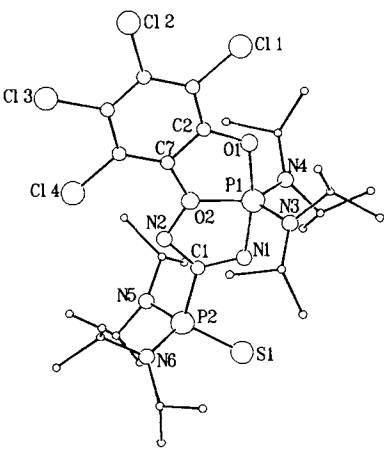


Fig. 1. Molecular structure of **3**. Important bond lengths [Å] and angles [°]: P1-N1 1.743(3), P1-O1 1.741(3), P1-O2 1.729(3), P1-N3 1.657(3), P1-N4 1.658(3), C1-N1 1.332(4), C1-N2 1.290(5), C1-P2 1.854(4), N2-O2 1.394(4), O1-C2 1.349(4), O2-C7 1.378(5), C2-C7 1.387(6); O1-P1-N1 167.7(1), O2-P1-N1 82.9(1), O2-P1-O1 85.0(1), N3-P1-N1 92.8(1), N3-P1-O1 95.3(1), N2-P1-O2 123.3(1), N4-P1-N1 94.9(1), N4-P1-O1 90.8(1), N4-P1-O2 125.8(1), N4-P1-N3 110.9(1), N2-C1-N1 118.3(3), P2-C1-N1 119.2(2), P2-C1-N2 122.4(2), C1-N1-P1 114.0(2), O2-N2-C1 105.4(2), C2-O1-P1 115.2(2), N2-O2-P1 118.9(2), C7-O2-P1 117.8(2), C7-O2-N2 123.3(2).

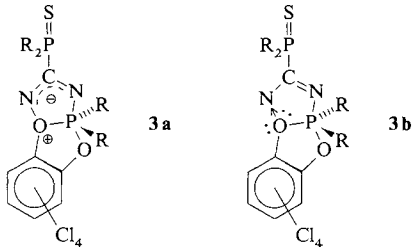

3a **3b**

When the reaction of nitrile imine **1a** with TCBQ was monitored by NMR spectroscopy at − 50 °C, an intermediate could be detected which rearranged to **3** at − 45 °C. The ^{31}P NMR spectrum ($\delta = 58.5$ and 2.6, $J_{PP} = 13.0$ Hz) was in agreement with a $\sigma^4\lambda^5$ and a $\sigma^5\lambda^5$ phosphorus, and the presence of a signal at $\delta = 151.1$ (dd, $J_{PC} = 191.6$, 24.4 Hz) in the ^{13}C NMR spectrum[10] could be in agreement with the isodiazirine structure **6**.[14] Attempts to confirm this structure are under investigation.

In summary, the reaction of nitrile imine **1a** with TCBQ probably affords a transient new nitrile imine **4**, which rearranges into imidoylnitrene **3**, possibly via a spectroscopically observable isodiazirine **6**.

Experimental Procedure

All operations were performed under dried atmosphere. A chloroform solution (1.5 mL) of tetrachloro-*o*-benzoquinone (0.15 g, 0.61 mmol) was added at − 78 °C to a chloroform solution (1.5 mL) of nitrile imine **1a** (0.30 g, 0.56 mmol). The reaction mixture was then allowed to warm to room temperature and **3** (0.37 g, 84% yield) crystallized slowly from the solution.

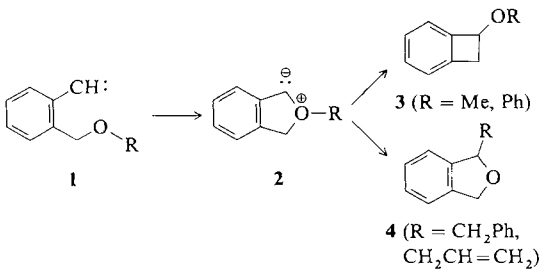
Intramolecular Insertion of Arylcarbenes into C–Si Bonds

By *Wolfgang Kirmse** and *Wolfgang Konrad*

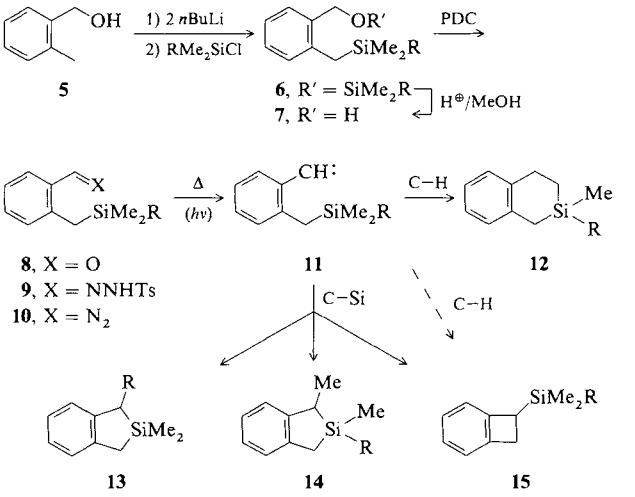
Dedicated to Professor Wolfgang R. Roth on the occasion of his 60th birthday

Recently, we reported on arylcarbenes that contain an ether function in an *ortho* side chain.[1] *Electrophilic* attack of the carbenes **1** at the oxygen produces oxonium ylides **2**, which are trapped by protic solvents or rearranged to **3** and **4**. The observed migration tendencies (allyl,benzyl > alkyl > methyl, phenyl) are consistent with the radical-pair mechanism of the Stevens rearrangement.[2]



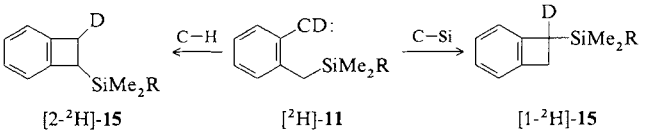
1 2

With the intention of reversing the polarities, we have now examined the analogous silicon compounds. We obtained the necessary starting compounds by double metalation and silylation[3] of 2-methylbenzyl alcohol **5** (Scheme 1), followed by hydrolysis of the silyl ethers **6** to **7** and oxidation to the aldehydes **8**. On treatment with 50% NaOH/dioxane, at 80–90 °C,[4] the tosylhydrazones **9** furnish the diazo compounds **10**; with D_2O/DONa, H/D exchange leads to formation of the deuteriated diazo compounds ArylCDN_2. We generated the carbenes **11** by thermolysis of the tosylhydrazone sodium salts **9**-Na or the diazo compounds **10** at 280–300 °C.



Scheme 1. **a**, R = CH_3; **b**, R = Ph; **c**, R = CH_2Ph. PDC = pyridinium dichromate.

Insertion of the carbenes **11** into the C–H bonds of the methyl groups leads to the silacyclohexanes **12**, insertion into Si–R and Si–Me bonds to the silacyclopentanes **13** and **14**, respectively. The benzocyclobutenes **15** can be formed by insertion into the benzyl–Si bond and by insertion into the benzylic C–H bonds. These two reaction routes can be differentiated with the help of the deuteriated carbenes [^{2}H]-**11**.



[2-^{2}H]-**15** [^{2}H]-**11** [1-^{2}H]-**15**

As revealed by the NMR data of [^{2}H]-**15**, C–Si insertion is the preferred, but not exclusive bonding mode of **15** (see Table 1).

Table 1. Reaction products of the carbenes **11** (amounts in mol-% from thermolyses of **10** at 280–300 °C).

	C-H			C-Si			Addition	
R	**12**	**15**	**19**	**13**	**14**	**15**	**17**	**18**
CH_3	55	5		7		33		
Ph	21	4		22	5	16	32	
$PhCH_2$	25	7	32	1	2	29		4

Aside from the previously discussed reactions, intramolecular addition is observed with **11b** and **11c**. In **11b** the C-1′–C-2′ bond of the Si-phenyl moiety is reactive; the cycloheptatriene **17** and its double bond isomers are formed via **16** (by 1,5 H-shift). In contrast, **11c** adds to the C-2′–C-3′ bond of the Si-benzyl residue to give the stable norcaradiene **18** (opening of the three-membered ring would yield a bridgehead alkene). We attribute the regioselectivity to substituent effects of Me_3Si and Me_3SiCH_2 respectively: electrophiles preferentially attack the *ipso*-position of Me_3SiPh, but the

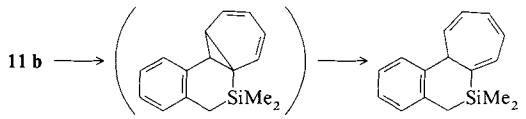
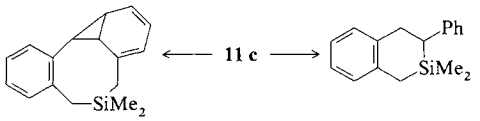
o,p-position of Me_3SiCH_2Ph.[5] Apart from **12c–14c** and **18**, **11c** affords still another C–H insertion product, namely **19**.

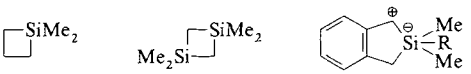


16 **17** (+ isomers)



18 **19**

In the arylcarbenes **11**, the intramolecular insertion into C–Si bonds (30–40%, Table 1) may effectively compete with the insertion into C–H bonds and the addition to arenes. In contrast, intermolecular C–Si insertions have previously only been detected in reactions of the strained siletanes **20** and **21** with dichlorocarbene[6] and methylene.[7] We likewise found no insertion into Si–phenyl and Si–benzyl bonds, respectively, during thermolyses or photolyses of phenyldiazomethane in trimethylphenylsilane and benzyltrimethylsilane. Further experiments will have to show what causes the high intermolecular reactivity of these bonds and



20 **21** **22**

whether "inverse ylides" **22** are involved with pentacoordinated silicon.[8] The "migration tendency" in C–Si insertions (Ph > alkyl, benzyl) is reminiscent of cationic rearrangements[9] and differs strongly from the behavior of the oxonium ylides **2**. Intermediates of type **22** would be compatible with these observations.

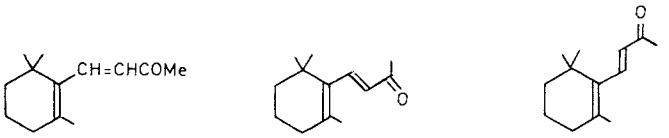
Isolation of Conformational Isomers of α- and β-Ionones by Inclusion Complex Formation

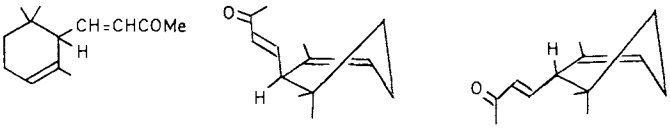
By *Fumio Toda*,* *Koichi Tanaka*, and *Takaji Fujiwara*

Conformational study of β-ionone (**1**) has long been interesting because **1** is closely related to the retinal chromophore, whose binding within rhodopsin is known to be conformationally dependent.[1] However, no conformational isomer of **1** has yet been isolated in pure state. NMR studies of the solution conformation of β-ionone[2] have shown it to exist mainly in the s-*cis* form (**1a**).

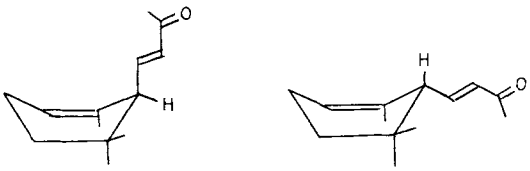
We now report the isolation of the s-*trans* conformer **1a** and the s-*cis* conformer **1b** of β-ionone (**1**) as inclusion complexes with the host compounds **3**[3] and **4**,[4] respectively. We also report the isolation of the axial quasi-chair form **2a** of α-ionone (**2**) as an inclusion compound with 9,9′-bianthryl (**5**).[5]



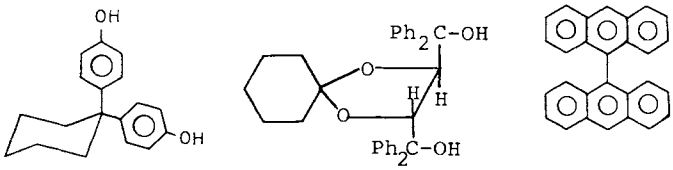
1 **1b** **1a**



2 **2a** **2b**



2c **2d**



3 **4** **5**

β-Ionone (**1**) and **3** form a 2:1 inclusion compound, **6**, in which, according to X-ray crystal structure analysis, **1** is accommodated in an almost planar s-*trans* form (**1a**) be-

tween two molecules of the host **3** (Fig. 1).[6] It is energetically easier for **3** to form a cavity which accommodates **1a** through van der Waals and hydrogen-bonding interactions.

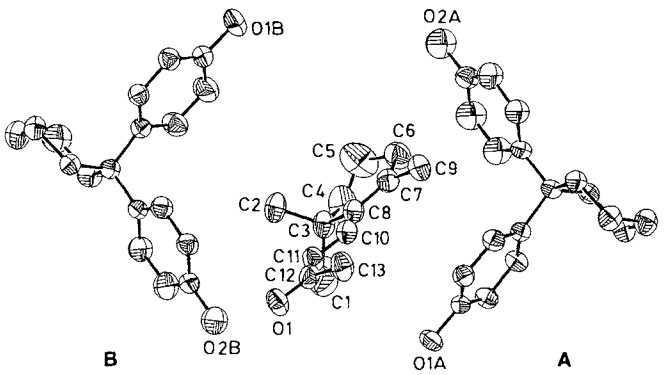

Fig. 1. Molecular structure of **6**. $M_r = 729.01$, triclinic, space group $P\bar{1}$, $Z = 2$, $a = 17.598(6)$, $b = 12.484(3)$, $c = 10.955(4)$ Å, $\alpha = 113.59(2)$, $\beta = 110.90(3)$, $\gamma = 76.70(3)°$, $V = 2050(1)$ Å^3, $\varrho_{exp} = 1.188(2)$, $\varrho_{calcd} = 1.181$ Mg m^{-3}, $\mu = 5.92$ cm^{-1}, $R = 0.056$ for 5360 reflections with $F_0 > 3\sigma(F_0)$. The C4, C5, and C10 atoms are displaced by 0.300(8), − 0.370(8), and − 0.049(7) Å, respectively, out of the best plane through the C3, C6, C7, and C8 atoms (maximum deviation = 0.014 Å). The C10 atom deviates slightly from the plane. The hosts **A** are connected by the hydrogen bond of O2A-H···O1A [$(x, y, 1+z) = 2.778(3)$ Å], and the hosts **B** by the O1B-H···O2B [$(x, y, 1+z) = 2.731(3)$ Å] hydrogen bond. The host and guest are linked by the hydrogen bonds O2B-H···O1 [2.686(3) Å] and O1···H-O1A [$(1-x, -y, -z) = 2.682(3)$ Å], where O1 connects both chains of hosts **A** and **B**. The structural unit of the zigzag chain formed by hosts **A**, the guest molecules, and the zigzag chain formed by hosts **B** repeats along the c axis [6].

On the other hand, **1** and **4** form a 1:1 inclusion compound, **7**, in which **1** exhibits the s-*cis* form (**1b**). Although an X-ray crystal structure analysis of **7** could not be carried out because of difficulty in obtaining a good crystal, the s-*cis* conformation of **1** in **7** was determined by spectroscopic methods. In the IR spectrum, the C=O band ($\tilde{\nu} = 1675$ cm^{-1}) of **1b** in **7** was at higher frequencies than the C=O band ($\tilde{\nu} = 1590$ cm^{-1}) of **1a** in **6**. It has been well established that s-*cis* enones show the C=O absorption at higher frequencies than do the s-*trans* isomers.[7] In the UV spectrum in the solid state, **1b** in **7** showed λ_{max} at shorter wavelengths than did **1a** in **6** (Fig. 2). It has also been established that s-*cis* enones absorb in the UV at shorter wavelengths than do s-*trans* enones.[8]

In the relatively small cavity of the 1:1 complex **7**, the less bulky s-*cis* isomer **1b** should be accommodated favorably. By contrast, the more bulky s-*trans* isomer **1a** should be accommodated favorably in the relatively large cavity of the 2:1 complex **6**. α-Ionone **2** also forms inclusion compounds, but not with **3**. Thus, by exploiting this selective inclusion, **1** and **2** can be separated efficiently.

Interestingly, α-ionone (**2**) and **5** form a 1:1 inclusion compound, **8**, in which the quasi-chair form with an axial enone group, **2a**, is present. X-ray crystal structure analysis of **8** shows that the molecules of **5** are arranged so as to form a channel-type complex with **2a**. In a channel, two molecules of **2a** of the same chirality face each other and display contacts through their acyl groups (Fig. 2). The structure of the axial quasi-chair form **2a** is shown in Figure 3. The cavity formed by **5** is fitted to accommodate **2a** but not the equatorial quasi-chair form **2b**, the axial quasi-boat form **2c**, or the equatorial quasi-boat form **2d**. Hydrocarbon hosts such as **5**,[5] 1,1,2,2-tetraphenylethane,[9] and 1,2,4,5-hexatetraene derivatives[10] are known to form inclusion compounds with a wide variety of guests including hydrocarbons.

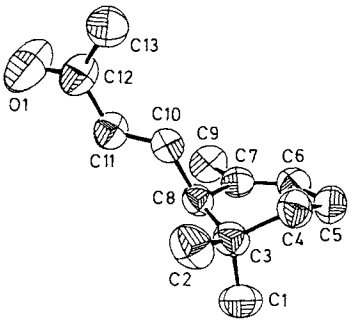

Fig. 3. Conformation of **2a** in the inclusion compound **8**.

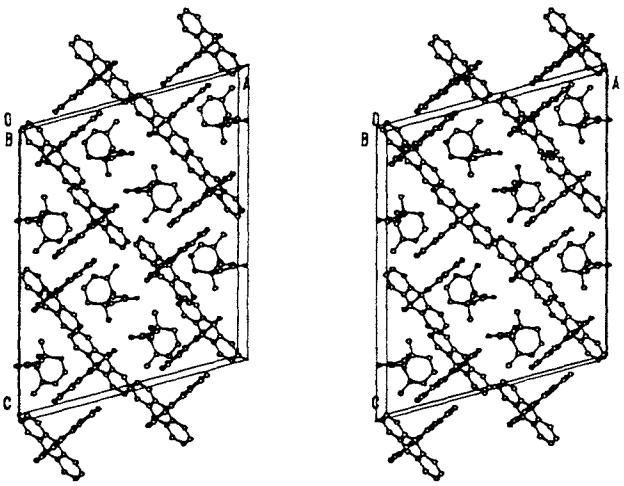

Fig. 2. Packing diagram of **8**. $M_r = 546.8$, monoclinic, space group $C2/c$, $Z = 8$, $a = 21.293(2)$, $b = 11.244(1)$, $c = 27.199(1)$ Å, $\beta = 105.98(1)°$, $V = 6260(1)$ Å^3, $\varrho_{exp} = 1.160$ Mg m^{-3}, $\mu = 6.23$ cm^{-3}, $R/wR = 0.045/0.056$ for reflections with $F_0 > 3\sigma(F_0)$ [6].

The above results suggest that the inclusion complexation method is applicable to the isolation of unstable conformers of various organic compounds.

Experimental Procedure

6: When a solution of **3** (1 g) in **1** (5 g) was kept at room temperature for 12 h, the 2:1 inclusion complex **6** was obtained as pale yellow prisms (1.2 g); m.p. 132–134 °C, $\tilde{\nu}$(C=O) (Nujol mull) = 1590 cm^{-1}.

7: When a solution of **4** (1 g) in **1** (5 g) was treated as above, the 1:1 inclusion complex **7** was obtained as colorless plates (0.9 g); m.p. 68–70 °C, $\tilde{\nu}$(C=O) (Nujol mull) = 1675 cm^{-1}.

8: When a solution of **5** (0.5 g) in *rac*-**2** (5 g) was treated as above, the 1:1 inclusion complex **8** was obtained as colorless prisms (0.35 g); m.p. not clear, $\tilde{\nu}$(C=O) (Nujol mull) = 1675 cm^{-1}. Separation of **1** and **2** by complexation with **3**: When a solution of **3** (1 g) and a 1:1 mixture of **1** and **2** (1.43 g) in EtOAc (2 mL) was kept at room temperature for 2 h, **6** was formed (0.85 g). Upon distillation in vacuo, **6** gave **1** of 95.3% purity (by gas chromatography) (0.35 g, 46% yield).

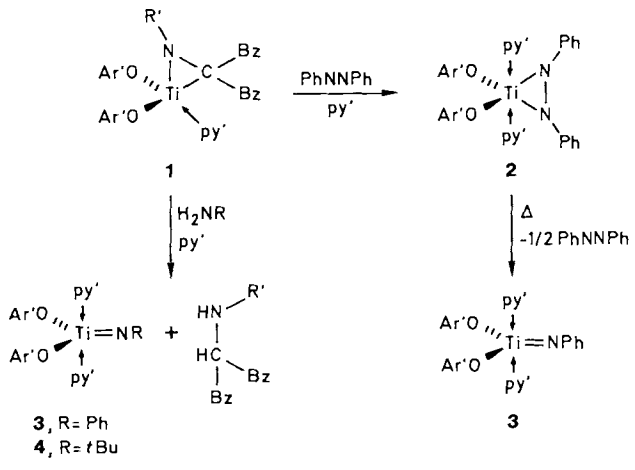
Synthesis, Structure, and Reactivity of Aryloxo(imido)titanium Complexes**

By *John E. Hill, Robert D. Profilet, Phillip E. Fanwick*, and *Ian P. Rothwell**

The chemistry of transition-metal terminal oxo (M=O)[1-3] and related alkylimido (M=NR)[1,4-7] functional groups has received considerable research attention over the past few years. In particular, the work of *Bergman* et al.[6] and *Wolczanski* et al.[7] has shown that terminal alkylimido compounds of zirconium can exhibit interesting reactivity including the activation of hydrocarbon C–H bonds. During our study of the chemistry of titanium supported by ancillary, aryloxide ligation we have isolated various terminal alkylimido derivatives of this metal. Here we report on the various synthetic strategies possible for the isolation of these compounds as well as on their structure and reactivity.[8]

Previous work by our group has shown that the η^2-imine complex **1** (py′ = pyridine or 4-substituted pyridine) is a very useful intermediate for the formation of both high- and low-valent compounds of titanium.[9,10] Reaction of this η^2-imine complex with azobenzene in the presence of 4-pyrrolidinopyridine (py′) leads to the formation of the highly colored η^2-azobenzene complex **2** in high yield (Scheme 1).[11] The pyridine analogue of **2** has been structurally characterized previously.[9b] In hydrocarbon solvents, compound **2** is thermally unstable. At 100 °C over days the formation of a new titanium complex **3**[12] along with free azobenzene is observed. The identity of **3** as a terminal phenylimido complex was confirmed by a single-crystal X-ray diffraction analysis (Fig. 1).[13]



Scheme 1. Synthesis of **3** and **4**. Bz = CH_2Ph; py′ = 4-pyrrolidinopyridine; Ar′O = 2,6-$iPr_2C_6H_3O$; R′ = *t*Bu.

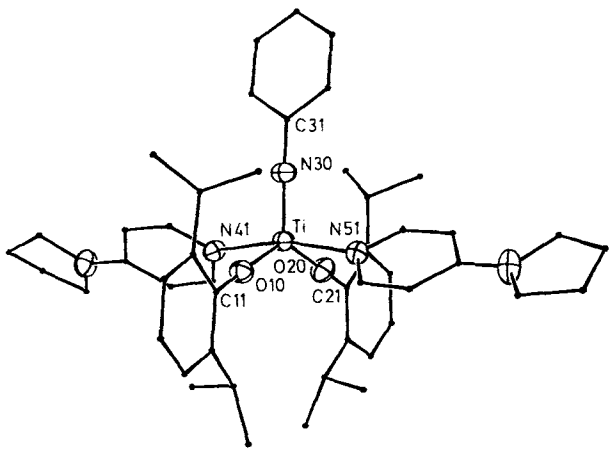


Fig. 1. ORTEP view of the phenylimido compound **3**. Selected distances [pm] and angles [°]: Ti-N30 171.9(3), Ti-N41 220.6(3), Ti-N51 222.3(3), Ti-O10 188.0(3), Ti-O20 186.7(3); Ti-N30-O31 173.1(3), N41-Ti-N51 165.8(1), O10-Ti-O20 133.2(1), Ti-O10-O11 172.0(2), Ti-O20-O23 173.8(3).

The coordination environment about the metal center in **3** is best described as distorted trigonal-bipyramidal with *trans*, axial pyridine ligands [py′-Ti-py′ = 165.8(1)°]. The remaining two aryloxide ligands and terminal phenylimido group occupy the three equatorial sites. Compound **3** represents the first structurally characterized terminal alkylimido derivative of titanium.[1,8,13] The Ti–N distance of 171.9(3) pm is considerably shorter than the distances found to terminal amido ligands (compare the Ti–NHPh distances of 188.1(3) and 189.(3) pm in **5**).[14] An interesting structural comparison can also be made between **3** and the related terminal oxo compound $[(2,6\text{-}iPr_2C_6H_3O)_2Ti(=O)(py')_2]$,[10] where an essentially identical coordination environment is present with a Ti–O distance of 165.7(6) pm.

Besides the cleavage of azobenzene, an alternative method for the formation of **3** involves direct reaction of the η^2-imine complex **1** with aniline in the presence of pyrrolidinopyridine (Scheme 1). This latter reaction also allows the formation of the *tert*-butylimido complex **4**.[15]

In a directly related study, the reactivity of the dialkyl compounds $[(2,6\text{-}Ph_2C_6H_3O)_2TiR_2]$ ($R = CH_2SiMe_3$, C_6H_5)[16] with aniline has also been investigated. Although reaction of the trimethylsilylmethyl derivative is slow, treatment of the diphenyl compound with two equivalents of $PhNH_2$ in benzene solution at room temperature was found to lead to the deep-red bis(phenylamido) complex **5** in high yield (Scheme 2).[17] A single-crystal X-ray diffraction analysis of **5** was carried out and confirmed the stoichiometry.[18] Treatment of **5** with 4-pyrrolidinopyridine (py′) rapidly leads to the elimination of one equivalent of aniline and formation of the phenylimido complex **6**.

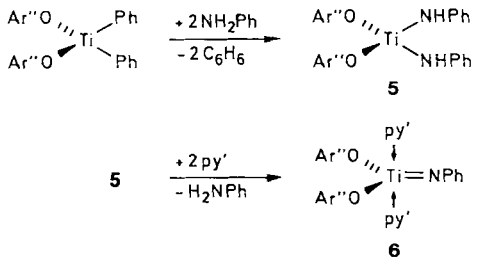
Department of Chemistry, Purdue University
West Lafayette, IN 47907 (USA)

[**] This work was supported by the National Science Foundation.



Scheme 2. Synthesis of **5** and **6**. Ar″O = 2,6-$Ph_2C_6H_3O$.

The new terminal aryl- and alkylimido compounds **3**, **4**, and **6** are surprisingly unreactive. Neither significant decomposition nor evidence for reaction with 3-hexyne is observed upon thermolysis at 110 °C for days in [D_6]benzene. Furthermore, given the fact that the previously reported zirconium imido compounds undergo reaction with a range of carbon–hydrogen bonds,[6b, 7] it is of note that compound **6** does not undergo cyclometalation of the 2,6-diphenylphenoxide ligands.[19] Moreover, although the phenylimido complex **6** does not react with 3-hexyne, the bis(phenylamido) complex **5** will catalyze the reaction of aniline with 3-hexyne to produce the *N*-phenylimine of 3-hexanone.[6b] Whether this reaction proceeds via an unsolvated, and hence more reactive, phenylimido intermediate is presently being investigated.

Intramolecular Hetero-Diels–Alder Reactions of Oxadienes: Influence of Substituents of the Tether on the Diastereoselectivity**

By *Lutz F. Tietze,* Siegbert Brand, Thomas Brumby*, and *Jens Fennen*

Intramolecular cyclization reactions such as the intramolecular Diels–Alder and ene reactions are widely used for synthesizing carbo- and heterocycles.[1] There is considerable interest in the extent to which substituents on the tether influence such reactions in the formation of new stereogenic centers. The stereoselectivity of reactions of this type depends crucially on the energy differences between the conformational transition states which lead to the diastereomeric products. Whereas the influence of substituents on the conformations of molecules in the ground state has been very thoroughly studied, especially for cyclohexane,[2] there have so far been scarcely any similar energetic studies on transition states, despite the fact that many examples of intramolecular cyclizations of substrates having substituents on the tether are already known.[3] The aim of our study is to use accurate analyses of the product mixtures from intramolecular pericyclic, free radical, and ionic cyclizations to deduce the geometry of the transition states, and hence to determine quantitatively, as accurately as possible, the effects of tether substituents.

In this communication we investigate how the stereochemistry of the intramolecular Diels–Alder reaction of oxadienes[4] is influenced by a methyl group at different positions on a C_4 tether. We chose as a model the alkylidene-α,α′-

[**] Inter- and Intramolecular Hetero-Diels–Alder Reactions, Part 30. This research was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 29: L. F. Tietze, U. Beifuss, M. Lökös, M. Rischer, A. Göhrt, G. M. Sheldrick, *Angew. Chem. 102* (1990) 545; *Angew. Chem. Int. Ed. Engl. 29* (1990) 527.

dioxo compound **3**, which can be prepared by condensation of 7-methyl-6-octenal (**1**) with *N*,*N*-dimethylbarbituric acid (**2**) in the presence of catalytic amounts of ethylenediammonium diacetate. The intramolecular cycloaddition of **3**, formed in situ, gives, within 2 h at 20 °C, a 98.8:1.20 mixture of the diastereomeric cycloadducts *rac*-**5a** and *rac*-**5c**.[5] This is assumed to be a concerted reaction,[6] in which the *trans*-annelated product is formed via an *exo-E-anti* transition state and the *cis*-annelated product via an *endo-E-syn* and/or an *exo-Z-syn* transition state.[7] In addition, 17% of the ene reaction product *rac*-**4** is obtained; this can be cyclized to give *rac*-**5a** by reaction with $BF_3 \cdot OEt_2$.

a	α	β (*trans*)
b	β	α (*trans*)
c	α	α (*cis*)
d	β	β (*cis*)

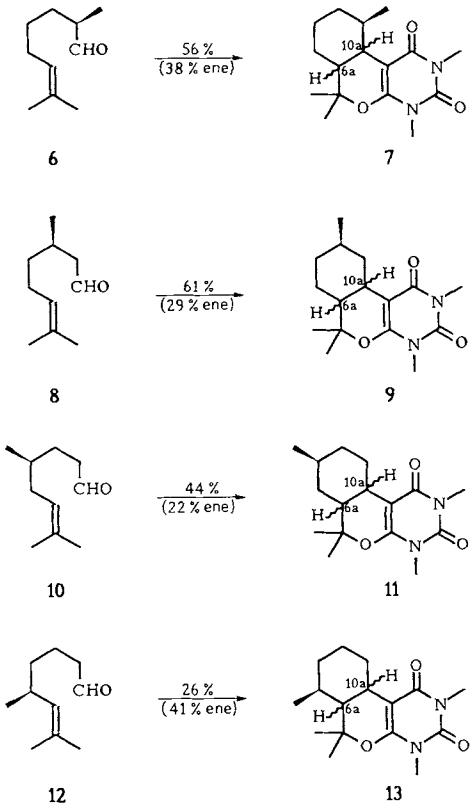
The tandem Knoevenagel–hetero-Diels–Alder reaction of the aldehyde **6**[8] with **2** affords, in addition to ene products, only one *trans* and one *cis* cycloadduct, **7a** and **7d**, respectively, which have been isolated and identified by NMR spectroscopy.[5] The induced diastereoselectivity[9] for the formation of **7a** is found to be greater than 99.5:0.5, whereas the noninduced diastereoselectivity,[9] with a value of 97.9:2.10, is slightly lower than that for the synthesis of the unsubstituted system **5**.[10] In the transition state leading to **7a** the methyl group on the tether adopts an equatorial position; here, it should be noted that force-field calculations[11] indicate that **7a** is about 12.5 kJ mol^{-1} less stable than **7b** with the methyl group in the axial position; **7b** is not found in this reaction. The lower thermodynamic stability of **7a** is probably caused by a strong interaction between the methyl group and one of the C=O groups.

The reaction of the aldehyde **8** with **2** yields all four possible diastereomers **9a–d**, with **9b** as the main product (Table 1). In this case, too, all the diastereomers were isolated by preparative HPLC and identified by NMR spectroscopy.[5] Surprisingly, it was found that there is a high induced diastereoselectivity for the formation of the *trans* cycloadducts **9a** and **9b** and almost no selectivity for that of the *cis* compounds **9c** and **9d**. The noninduced diastereoselectivity is the same as for the cycloaddition of **3**. A similar result is also found for the reaction of the aldehyde **10** with **2**. In this case, however, only the *trans* products **11a** and **11b** could be identified by NMR spectroscopy.[5] An additional HPLC peak with a retention time similar to that of **9c** was observed and assigned to the *cis* products **11c** and/or **11d** (Table 1).

Table 1. Selectivities [%]/$\Delta\Delta G^{\neq}$ values [kJ mol^{-1}] in the intramolecular hetero-Diels–Alder reaction of alkylidenebarbiturates.

Product	a	b	c	d
7	97.9/0.0	<0.5/–	<0.5/–	2.10/9.12
9	3.60/8.12	95.2/0.0	0.5/13.0	0.7/12.1
11	94.1/0.0	4.7/7.37	1.2/10.8	
13	<0.5/–	98.3/0.0	0.9/11.7 ⟷	0.8/12.1

The aldehyde **12** yields, with high induced diastereoselectivity (>99.5:0.5), the *trans* cycloadduct **13b** as the main product.[5] Two additional peaks were observed in the HPLC chromatogram and assigned to the *cis* products **13c** and **13d** (Table 1).



6 **7** **8** **9** **10** **11** **12** **13**

The high noninduced diastereoselectivity of the hetero-Diels–Alder reactions of **3** and its methyl-substituted analogues is surprising, since the intramolecular Diels–Alder reaction of the related hydrocarbon 1,3,9-decatriene yields an approximately 1:1 mixture of the two cycloadducts. *Houk* et al. assumed that this reaction occurs via a nearly symmetrical transition state, and their experimental results were in good agreement with calculations on that basis.[12] Thus, we explain the observed high *trans* selectivity of the reactions of **3**, **6**, **8**, **10**, and **12** by the existence of nonsymmetric transition states.[13]

The observed diastereofacial differentiation in the cycloaddition is basically due to two contributions, which can either act in the same sense or oppose each other: (1) steric

interactions of the substituents with the diene or dienophile moiety ("steric effect") and (2) 1,3-diaxial interactions between the substituents on the tether ("conformational effect"). Thus, the high induced diastereoselectivity in the reactions of the aldehydes **6** and **12** (with a methyl group at the α position relative to the diene or dienophile moiety) can be attributed to steric interactions between the methyl group and the diene or dieneophile moiety of the molecule, whereas in the aldehydes **8** and **10** (methyl group at the β position relative to the diene or dienophile moiety) conformational effects are dominant. The geminal substitution of the acceptor alkene unit confers high conformational rigidity on the transition states due to the "partial" 1,3-allyl strain (sp^2 geminal effect[15]).[14] It can be assumed that the formation of the *trans* products **9b**, **9a**, **11a**, and **11b** occurs via a chairlike transition state, with the methyl group in either the equatorial (**9b**, **11a**) or axial (**9a**, **11b**) position. The calculated ΔG value for the transition states leading to **9b** and **9a** is 8.12 kJ mol^{-1} and for the transition states leading to **11a** and **11b**, 7.37 kJ mol^{-1}. These values are greater than the experimentally measured energy difference between the methylcyclohexane conformers with the methyl group in the equatorial and axial positions.[2] It must be assumed, therefore, that in the transition states leading to **9a** and **11b** there is a stronger 1,3-diaxial interaction due to close approach of the axial methyl group to the "inwardly" directed hydrogen atom on C-1′ and C-6′, respectively (with the carbon atoms numbered as in **3**).

[7] The conventions used in describing the structures of the transition states are as follows: (1) *Endo/exo* refer to the position of the tether relative to the diene moiety of the molecule. If the chain is below the diene moiety, the transition state has an *endo* structure. (2) *E/Z* refer to the configuration of the C–C double bond of the oxadiene, with the higher priority given to the reacting C=O group. (3) *Syn/anti* refer to the relative positions of the hydrogens which appear at the linking positions of the newly formed ring in the product. In *ortho* additions, *syn* and *anti* transition states give, respectively, *cis*- and *trans*-annelated products.

[8] The aldehydes **6**, **8**, **10**, and **12** were used as racemic mixtures, and consequently the corresponding products **7**, **9**, **11**, and **13** were also obtained as racemic mixtures. The syntheses of the aldehydes **6**, **10**, and **12** will be described elsewhere.

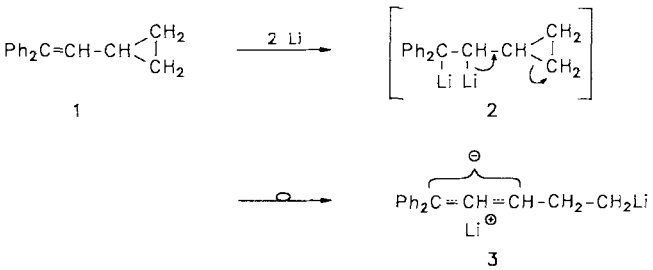
Reductive Scission of a Cyclopropane σ-Bond During the Action of Elemental Lithium on Cyclopropylacetylenes – A *cis*-1,2-Dilithioalkene as Intermediate**

By *Adalbert Maercker** and *Ulrich Girreser*

Dedicated to Professor Paul von Ragué Schleyer on the occasion of his 60th birthday

The first observation of the scission of a cyclopropane σ-bond was in the reaction of 2-cyclopropyl-1,1-diphenylethylene **1** with lithium metal (giving **3**),[1] but the existence of the postulated primary adduct **2** could not be proven experimentally.



1 2 3

However, such proof has now been obtained for the analogous reaction of cyclopropylphenylacetylene **4** with

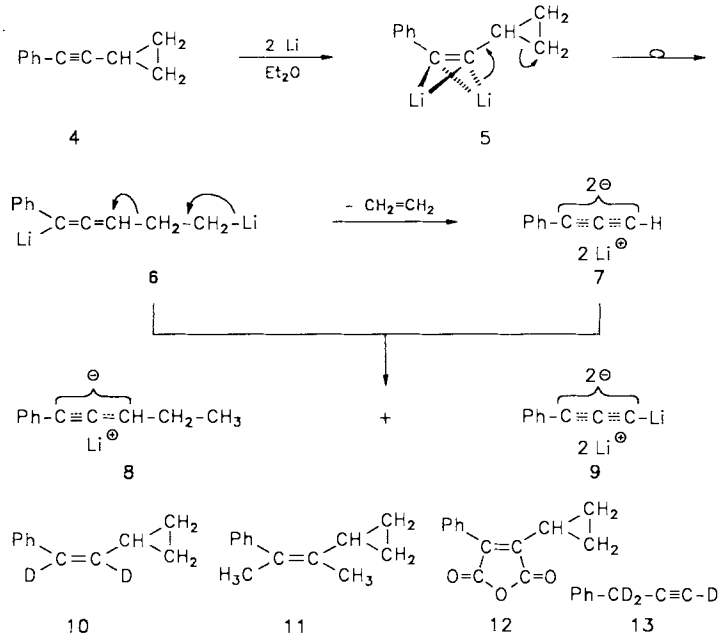
[**] Polylithiumorganic Compounds, Part 12. This research was supported by the Ministerium für Wissenschaft und Forschung, Nordrhein-Westfalen, and by the Fonds der Chemischen Industrie.—Part 11: A. Maercker, F. Brauers, W. Brieden, B. Engelen, *J. Organomet. Chem. 377* (1989) C45.

elemental lithium at $-30\,^{\circ}C$ in diethylether, by the observation of the vicinal dilithioalkene **5**, in which the lithium atoms, which are thought to be in a bridging configuration,[2] are in any case exclusively in the *cis* configuration. This was shown by derivatization with CH_3OD, dimethyl sulfate and CO_2 in turn, which gave the products **10** (77%),[3] **11** (83%)[4] and **12** (22%) respectively, not even trace amounts of the corresponding *trans* derivatives being detected in each case (Table 1).



Previously the *cis* addition of lithium has only been observed for cyclooctyne[5] and, under certain conditions, for diphenylacetylene;[6] aliphatic alkynes react much more slowly and undergo exclusively *trans* addition.

Above $-30\,^{\circ}C$ the cyclopropylmethyl part of **5** undergoes a ring–chain rearrangement, but the open-chain dilithium compound **6**, like **3**, is unstable. In contrast to **3** in diethyl ether,[1] **6** converts to a more stable form, not by loss of lithium hydride, but by loss of ethylene to give **7**, a "sesquiacetylene",[7] which then undergoes deprotonation to give the already known trilithium compound **9**.[8] Following deuterolysis (1 h at room temperature) the compound **13**[8] was finally isolated with a yield of 18%. Also formed in this reaction were the isomeric hydrocarbons phenylallene (4%) and 1-phenyl-1-propyne (2%), both of which were also triply deuterated to a level of more than 80%. The fragmentation of **6** is reminiscent of the loss of ethylene from 3,3-diphenylpropyllithium forming diphenylmethyllithium.[9]

If the phenyl group in **4** is replaced by a second cyclopropyl group (**14**), it is found that the compound no longer undergoes reaction with lithium metal. Even several hours' heating in diethyl ether or THF under reflux and with ultrasonic activation produced no result. In contrast, **14** reacts readily with lithium-4,4'-di-*tert*-butylbiphenyl[10] in THF even at $-30\,^{\circ}C$, requiring only catalytic amounts of 4,4'-di-*tert*-butylbiphenyl. However, the expected primary product, the 1,2-dilithioethylene derivative, is not observed. The first

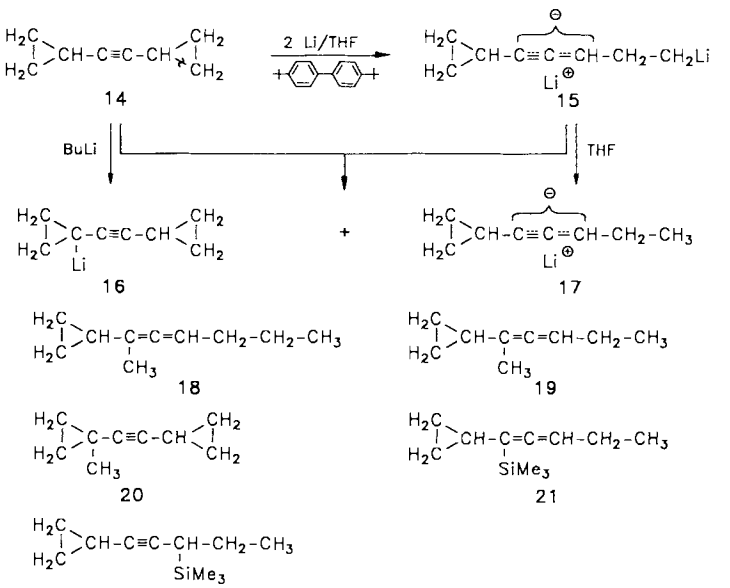


Table 1. Relevant physical data for the compounds **10**–**13** and **18**–**22**[a].

10: ^1H NMR: $\delta = 7.55-7.10$ (m; C_6H_5), 2.20–1.60 (m; cyclopropyl-CH), 1.00–0.35 (m; 2 cyclopropyl-CH_2). – ^{13}C NMR: $\delta = 137.9, 128.6, 128.1, 126.3$ (C_6H_5), 136.2, 126.9 (= CD), 10.9, 8.0 (cyclopropyl). – IR (CCl_4): $\tilde{\nu} = 3045$ (m), 2250 (m) cm^{-1}. – MS: *m/z* 146 ($M^{\oplus}$, 59%), 145(31), 131(100), 130(77), 129(45), 117(22), 116(17). – B.p. 40–45 °C/0.3 torr. – cf. [a] 80 MHz ^1H- and 100.6 MHz ^{13}C-NMR spectra in $CDCl_3$ unless stated otherwise; mass spectra at 70 eV.

detectable dilithium compound is **15**; derivatizing this with dimethyl sulfate gave the allene **18** in 40% yield, together with 1% of the isomeric 1-substituted 1-hexyne derivative. Unlike **6**, **15** does not undergo fragmentation with loss of ethylene, but instead, like **3** in THF,[1] it gradually becomes protonated, forming **17**. In this reaction the educt **14** also serves to some extent as a source of protons, as is shown by the formation of a small amount of **20** (6%) in addition to the main product **19** (65%) in the derivatization with dimethyl sulfate (12 h, 0 °C, Table 1). The lithium compound **16** could also be obtained in a yield of 80% by deprotonation of **14** with *n*-butyllithium.[11] In this case too, the main product of methylation is the allene **19**; the isomeric 1-cyclopropyl-3-methyl-1-pentyne is formed in only trace amounts (3%). A different situation is found when **17** is derivatized using chlorotrimethylsilane, which in addition to the allene **21** (30%) gives the alkyne **22** (15%) (Table 1). It is interesting that the second cyclopropane ring is not opened under the conditions used.

Experimental

5: A suspension of 0.7 g (100 mmol) of lithium powder (2% sodium)[12] in 130 mL of dry diethyl ether was prepared, and into this at 0 °C under argon was first dropped about 5% of a solution of 2.0 g (14 mmol) of **4**[13] in 20 mL of diethyl ether. When the reaction had got under way (as shown by a yellow coloration of the reaction mixture), the rest of the solution was added at − 30 °C. To obtain a good yield it was extremely important to carry this out very slowly over a period of 6 h, preferably using a syringe metering system (such as that made by INFORS AG, Bottmingen, Switzerland). The mixture was then stirred for a further 1 h at − 30 °C and the deep-red solution was then filtered under inert gas to remove excess lithium. The derivatization was carried out at − 70 °C. Yield: 77–83%.

15: 0.5 g (2 mmol) of 4,4'-di-*tert*-butylbiphenyl and 0.5 g (70 mmol) of lithium powder (2% sodium)[12] were mixed together in 80 mL of dry THF and stirred for 2 h at 0 °C. To the resulting deep-green solution at − 30 °C under argon was slowly added over a period of 6 h, using a syringe metering system, a solution of 1.05 g (10 mmol) of **14**[11] in 20 mL of THF, and the mixture was then stirred for a further 1 h at − 30 °C. After filtering to remove excess lithium, the derivatization was carried out at − 80 °C under inert gas. Yield: 41% of **15**, together with 16% of the educt **14**, 15% of **17** and 7% of **16**. If instead the reaction is carried out at − 45 °C, one obtains only 7% of **17** and 2% of **16** together with 31% of **15**, but in this case 41% of the educt **14** is left behind (the rest presumably consists of polymers).

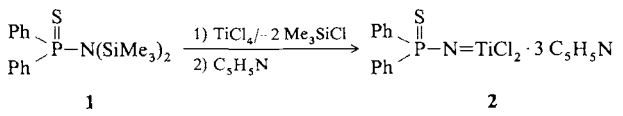
Synthesis and Structure of $Ph_2P(S)N=TiCl_2 \cdot 3C_5H_5N$, the First Imidotitanium Complex**

By *Herbert W. Roesky,** *Heike Voelker, Michael Witt,* and *Mathias Noltemeyer*

Compounds containing M=N bonds are well known for the elements of subgroups 5 to 8.[1] In contrast, for titanium and its homologues up to now only imidozirconocenes have been isolated and characterized.[2] *Wolczanski* et al. have also reported the occurrence of $(t\mathrm{Bu_3SiNH})_2\mathrm{Zr}=\mathrm{NSi}t\mathrm{Bu_3}$ as a reactive intermediate.[3] No corresponding titanium compounds have yet been reported, despite the fact that they would be of great interest as catalysts for the activation of C–H bonds or for polymerizations.[4]

In the course of our studies on metal-nitrogen bonds,[5, 6] *N*,*N*-bis(trimethylsilyl)diphenylthiophosphinamide **1**, prepared from *N*,*N*-bis(trimethylsilyl)aminodiphenylphosphane[7] and elemental sulfur, was allowed to react with titanium tetrachloride. In this reaction chlorotrimethylsilane is eliminated with the formation of a yellow amorphous solid whose ^{31}P-NMR spectrum consists of three singlets (δ = 47.3, 49.0, 51.5). This intermediate is then treated with pyridine to form the title compound **2**. In contrast, reaction of the oxygen analogue of **1** with $TiCl_4$ leads to an eight-membered ring compound.[8] Similar cyclic structures can be assumed for the intermediate involved in the formation of **2**.



1 **2**

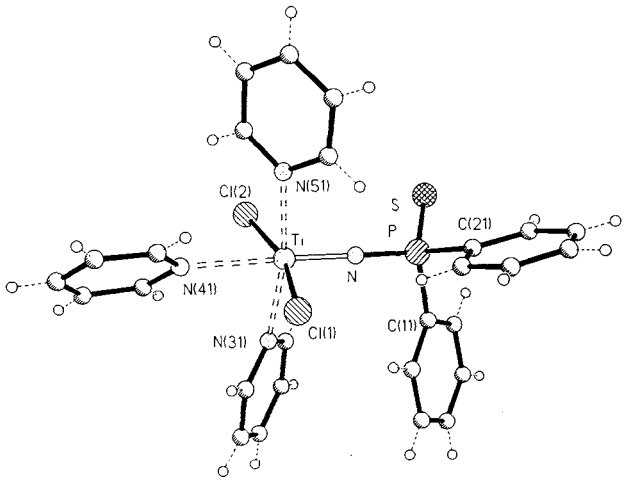


Fig. 1. Crystal structure of **2**. Selected bond lengths [pm] and angles [°]: Ti-Cl1 238.4(1), Ti-Cl2 234.9(1), Ti-N 172.0(2), Ti-N31 222.9(2), Ti-N41 243.9(2), Ti-N51 222.4(3), N-P 164.7(2), P-S 195.4(1); Cl1-Ti-Cl2 163.5(1), Cl1-Ti-N 97.4(1), Cl2-Ti-N 99.1(1), Cl1-Ti-N31 90.8(1), Cl2-Ti-N31 87.8(1), N-Ti-N31 94.0(1), Cl1-Ti-N41 81.1(1), Cl2-Ti-N41 82.4(1), N-Ti-N41 177.9(1), N31-Ti-N41 84.4(1), Cl1-Ti-N51 89.7(1), Cl2-Ti-N51 88.9(1), N-Ti-N51 95.9(1), N31-Ti-N51 169.9(1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen Foundation and the Fonds der Chemischen Industrie.

2 is an orange-red crystalline solid whose ^{31}P-NMR spectrum exhibits a singlet ($\delta = 42.0$). Crystallization of **2** from pyridine/*n*-hexane (2/1) yields single crystals suitable for determining the structure by X-ray diffraction[9] (Fig. 1). The titanium atom has a distorted octahedral coordination, the corners of the octahedron being formed by three pyridine molecules (N31, N41, N51), two chlorine atoms (Cl1, Cl2) and the nitrogen atoms of the imido ligand. The Ti–N bond length (172.0(2) pm) is similar to that in the Ti–N unit of the eight-membered P-O-N-Ti heterocycle $[Ph_2PONTiCl_2 \cdot 2MeCN]_2$ (173.9 pm).[8] The coordination of the imido ligand to the titanium atom is almost linear (Ti–N–P 172.5(2)°), showing that the ligand acts as a four-electron donor. The pyridine molecule *trans* to the imido ligand is much more loosely bound (Ti–N41 243.9(2) pm) than the other two pyridine molecules (average Ti–N 222.7 pm).

Evidently, therefore, the imidotitanium compounds that have so long been sought can be stabilized by coordination with electron pair donors on the titanium atom. The first results on the chemistry of these compounds are reported by *Rothwell* et al. in another communication.[4]

Experimental

1: 10 g (29.0 mmol) of *N*,*N*-bis(trimethylsilyl)aminodiphenylphosphane was dissolved in 150 mL of benzene, mixed with 0.93 g of sulfur (3.625 mmol, referred to S_8), and heated for 3 h at 50–60 °C. After evaporating off the solvent under vacuum the colorless residue was recrystallized from MeCN. Yield 9.7 g (89%); m.p. 116 °C. ^{31}P NMR (101.26 MHz, 85% H_3PO_4, C_6H_6, $CDCl_3$): $\delta = 61.0$ (s); ^{29}Si NMR (49.69 MHz, TMS, C_6H_6, $CDCl_3$): $\delta = 10.7$ (d, $^2J(^{29}Si,^{31}P) = 1.2$ Hz); MS (EI): *m/z* 377 ($M^{\oplus}$, 16%), 362 ($M^{\oplus}$ – Me, 100%).

2: Into a solution of 1.5 g (4.0 mmol) of **1** in 50 mL CH_2Cl_2 at –15 °C was slowly added a solution of 0.76 g (4.0 mmol) of $TiCl_4$ in 25 mL of CH_2Cl_2. The mixture was then allowed to slowly warm up to room temperature and was stirred for a further 20 h. After evaporating off the solvent under vacuum the yellow residue was recrystallized from pyridine/*n*-hexane (2/1). This yielded a mixture of a yellow powdery solid and orange-red crystals of **2**. The solvent and the powdery solid were decanted off from the crystals, which were then sorted to find a crystal suitable for the X-ray structure determination. Yield of **2** 0.63 g (27%). M.p. 125 °C (decomp.). IR (Nujol/KBr): $\nu = 1605$(st), 1377(st), 1110(st), 1070(st), 1012(st), 698(st), 520(st) cm^{-1}.

Electron Transfer between Covalently Linked Porphyrin and Quinone Units: Synthesis, Magnetic Resonance and Picosecond Fluorescence Spectroscopy**

By *Jörg von Gersdorff, Martina Huber, Heike Schubert, Dominique Niethammer, Burkhard Kirste, Martin Plato, Klaus Möbius,* Harry Kurreck,* Rainer Eichberger, Reinhard Kietzmann*, and *Frank Willig**

Quinones covalently linked with porphyrin are suitable as biomimetic models for the study of light-induced charge separations in the primary process of photosynthesis with the help of spectroscopic methods and electron transfer (ET) theories.[1]

We have synthesized the porphyrin-quinones **1a** and **2a**, linked via flexible bridges, as well as the essentially rigid porphyrin derivative **3** and its fragments **5** and **6**.

The functionalized porphyrins **1c** and **2d** were obtained by condensation of pyrrole, benzaldehyde, and *p*-nitrobenzaldehyde or 4(e)-(hydroxymethyl)cyclohexane-(e)-aldehyde in boiling propionic acid and subsequent chromatographic work-up (**6** was synthesized analogously with cyclohexanealdehyde). The 4-(hydroxymethyl)cyclohexanealdehyde was accessible by single tosylation[2] of 1(e),4(e)-bis(hydroxymethyl)cyclohexane and subsequent oxidation of the tosylate with DMSO.[3] For the synthesis of **1b**, the compound **1c**, after reduction of the nitro group with $SnCl_2$/HCl, was allowed to react with acetylated gentisic acid in the presence of ethyl 2-ethoxy-1,2-dihydroquinoline-1-carboxylate (EEDQ).[4] **1b** is formed after removal of the protecting groups with methanolic HCl. Compound **2b** was obtained by esterification of **2d** with acetylated gentisic chloride and subsequent removal of the protecting groups (see above). Oxidation to the porphyrin-quinones **1a** and **2a** was achieved with activated PbO_2 immediately before the measurement.[5]

For the synthesis of **5**, methyl 1,4-cyclohexanedicarboxylate was linked with *p*-benzoquinone in an oxidative-decarboxylating reaction using $(NH_4)_2S_2O_8/AgNO_3$.[6] After conversion of **5** into the corresponding hydroquinone with sodium dithionite, the aldehyde **4** was accessible by reduction of the ester group with diisobutylaluminum hydride (DIBAH).[7] Condensation of **4** with pyrrole and benzaldehyde in boiling propionic acid in the presence of atmospheric oxygen yielded directly, after chromatographic work-up, the porphyrin-quinone **3**. The porphyrin derivatives (final yields 2–4%) were metalated with zinc acetate in methanol/chloroform.

Since the ET rates are essentially determined by the geometric arrangement of donor, bridge and quinone, we have ascertained the preferred conformations by NMR measure-

ments (NOE) on the fragments Zn-**6** and cyclohexylbenzoquinone and by electron nuclear double resonance (ENDOR) measurements[8] on the corresponding radical ions. In the case of Zn-**6**, strong nuclear Overhauser effects (9–16%) between the cyclohexyl proton in position 1 and the axial protons in positions 2 and 6 and the neighboring pyrrole protons (at $\delta = 9.83$) were observed. From this a perpendicular arrangement of the two ring planes is deduced, which also follows from the hyperfine coupling constants (HFC; all < 2 MHz) of the radical cation of Zn-**6** ($AgClO_4$/iodine oxidation, CH_2Cl_2[9]) on applying the Heller-McConnell relationship.[10] In the case of 2-cyclohexyl-1,4-benzoquinone a considerable NOE (10%) between the axial protons in positions 2 and 6 and the neighboring quinone proton was observed, thus indicating a preferred conformation with the proton in position 1 in the neighborhood of the oxygen atom. From the HFC (3.2 MHz) of the corresponding proton of the cyclohexyl substituent in the radical anion of **5** (benzoin reduction, trimethylbenzylammonium hydroxide, isopropanol) there follows, by comparison with the methyl HFC of the corresponding methylsemiquinone radical anion (5.6 MHz), a (mean) dihedral angle of ca. 60°.[10] RHF-INDO/SP calculations[11] gave an energy minimum for the radical cation of Mg-**6**[12] with approximately perpendicular arrangement of porphyrin and cyclohexane planes. In contrast, several flat local energy minima of comparable depth were obtained for the radical ion of the cyclohexylquinone; the best agreement with the measured HFC was found for a dihedral angle of ca. 70°.

The electron transfer rates k_{ET} were estimated for the compound **3**, which is characterized by a relatively rigid conformation.[13] The quotient of the k_{ET} values for the charge separation (CS) and charge recombination (CR) is a measure of the efficiency of the separation process and thus also a measure of the suitability of donor (D)–acceptor(A) complexes as model systems for the primary processes of photosynthesis. For non-adiabatic electron transfer, Equation (1) applies,[14]

$$k_{ET} = \frac{2\pi}{\hbar} |V_{DA}|^2 \cdot F \qquad (1)$$

where $\hbar = h/2\pi$ is Planck's constant, V_{DA} the electronic interaction matrix element between D and A and F the thermally averaged Franck-Condon factor. The explicit calculation of V_{DA}[15] enables the influence of the distance and orientation of D and A as well as the influence of the MO coefficients in the frontier orbitals of D and A on k_{ET} to be investigated.[16] V_{DA} was calculated for a perpendicular arrangement of the mean cyclohexane plane and porphyrin plane for several orientations of the quinone.[13]

The ratios $V_{DA}(CS)/V_{DA}(CR)$ for the two arrangements of the quinone perpendicular to the mean cyclohexane plane are 0.82 and 1.06, respectively (dihedral angle $\pm 90°$); for non-orthogonal orientations the quotient is $\ll 1$. This unfavorable ratio for a biomimetic model compound [in analogy to the photosynthetic primary processes, $k_{ET}(CS) \gg k_{ET}(CR)$ would be desired, which, e.g., would be realizable by $V_{DA}(CS) \gg V_{DA}(CR)$] is mainly attributed to the large MO coefficients of the HOMOs at the site of linkage of the porphyrin with the cyclohexane, whereby $k_{ET}(CR)$ is increased.[13]

The efficiency of the charge separation is determined by the product of $V_{DA}(CS)/V_{DA}(CR)$ and the ratio of the Franck-Condon factors, $F(CS)/F(CR)$. An estimation according to the classical method of *Marcus* et al.[17] shows that $F(CS)/F(CR)$ can compensate an unfavorable ratio $V_{DA}(CS)/V_{DA}(CR)$ for biomimetic models. The experimental checking of this prediction will only be possible by measurement of $k_{ET}(CR)$ in combination with the measurements of $k_{ET}(CS)$ described below.

The rate constants for the charge separation were determined by picosecond fluorescence spectroscopy. Fluorescence decay curves were recorded[20] by time-resolved single-photon counting[18] or with a Streak synchroscan camera.[19] In the case of Zn-**1b**, **2b**, Zn-**2b**, Zn-**2c**, and Zn-**6** the fluorescence intensity decreases monoexponentially over more than five lifetimes. Variation of the substituents in the *meso* position has no measurable influence on the decay curve. The incorporation of zinc into the metal-free compounds, on the other hand, effects a drastic shortening of the lifetime, since the intersystem crossing then becomes the dominating decay channel.[21] Both results agree with stationary measurements of the fluorescence yield.[22]

For the excited singlet state of the porphyrin-quinones, $^1P^*$, a further decay channel is opened up if an electron (with k_{ET}) can be transferred to the quinone fragment. The rate constant for the decay of $^1P^*$ is then $k = \tau^{-1} + k_{ET}$, where τ is the lifetime of the analogous compound with hydroquinone instead of quinone residue. The decay curve of Zn-**2a** differs from those of the compounds with hydroquinone moiety (Zn-**2b**) and without quinone moiety (Zn-**2c**, Zn-**6**), respectively.

As expected, the k_{ET} values (Table 1) become smaller with increasing length of the bridge between porphyrin and quinone. They are also in good agreement with the data quoted in the literature for other similar porphyrin-quinone complexes.[23] A comparison of measured ET rate constants and calculated $k_{ET}(CS)$ values with structural information obtained from the ENDOR data is possible in the case of the relatively rigid Zn-**3**. The values of $V_{DA}(CS)$ calculated for

Table 1. Measured fluorescence lifetimes k^{-1} and electron transfer rates k_{ET} (room temperature).

Cpd.	k^{-1}	k_{ET} [s^{-1}]
Zn-**1a**	253 ps	3.4×10^9

Zn-**6**	1.8 ns	–

different conformations (dihedral angle) of comparable energy vary between 0.2×10^{-3} and 3.9×10^{-3} eV. A value of $V_{DA}(CS) = 2.4 \times 10^{-3}$ eV is obtained for the conformation with a dihedral angle of 70° (see above). With this value and the parameters ΔG° and λ[17] one obtains for $T = 293$ K according to Equations (1) and (2)[17] $k_{ET}(CS) = 5.7 \times 10^{10}$ and 9.9×10^{10} s^{-1} for $\lambda = 0.62$ and 0.9 eV, respectively, in satisfactory agreement with the experimentally determined ET rate constant of 4×10^{10} s^{-1} (Table 1).

Summary: For an efficient charge separation in quinones coupled covalently with porphyrin, the MO coefficient in the HOMO of the porphyrin at the site of coupling should be as small as possible and the orientation of the quinone to the cyclohexane bridge as orthogonal as possible.

[16] In the case of **3**, V_{DA} was calculated by the MO method RHF-INDO [11] in analogy to a concept with which V_{DA} was recently determined for the primary ET step in bacterial photosynthesis from the atomic coordinates of the participating pigments [cf. H. Michel, O. Epp, J. Deisenhofer, *EMBO J. 5* (1986) 2445]: M. Plato, K. Möbius, M. E. Michel-Beyerle, M. Bixon, J. Jortner, *J. Am. Chem. Soc. 110* (1988) 7279. Unlike the pigments of the photosynthesis, D and A in Zn-**3** are linked covalently via the cyclohexanediyl bridge. The influence of the bridge on the electronic structure of D and A was taken into account in the MO calculations.
[17] According to *Marcus* et al. [14] Equation (2) holds true,

$$F = (4\pi\lambda k_B T)^{-1/2} \exp\left[-(\lambda + \Delta G^0)^2/(4\lambda k_B T)\right] \quad (2)$$

where λ is the total reorganization energy, ΔG^0 the free standard reaction enthalpy, k_B the Boltzmann constant, and T the absolute temperature. ΔG^0 values for the charge separation and charge recombination were estimated from the cyclovoltammetrically determined redox potentials of Zn-**6** and **5** and the energy of the first singlet excitation state E_{00} of zinc tetraphenylporphyrin [$E_{00} = 2.1$ eV, cf. M. R. Wasielewski, M. P. Niemczyk, *J. Am. Chem. Soc. 106* (1984) 5043] to be $\Delta G^0(CS) = -0.84$, $\Delta G^0(CR) = -1.26$ eV. In the estimation of $\lambda = \lambda_i + \lambda_0$ [λ_i is the internal reorganization energy arising from changes in geometry of the reacting porphyrins (P) and quinones (Q) and λ_0 is the external reorganization energy by changes in the surrounding medium], λ_i was neglected, since the changes in geometry between the $^1P^*Q$ and $P^{\oplus}Q^{\ominus}$ states caused by photoinduced charge separation can be regarded as small [13, 23]; cf. also M. R. Wasielewski, M. P. Niemczyk, W. A. Svec, E. B. Pewitt, *J. Am. Chem. Soc. 107*, (1985) 1080. λ_0 was estimated according to the method of *Marcus* [R. A. Marcus, *J. Chem. Phys. 24* (1956) 966] using geometric data ($r_P = 6$, $r_Q = 4$, $r_{P,Q} = 10.6$ Å) and dielectric data of the solvent CH_2Cl_2 ($n_D = 1.42$, $\varepsilon = 9.08$) to be $\lambda_0 = 0.62$ eV [13]. With these ΔG^0 and λ values, Equation (2) gives $F(CS)/F(CR) = 320$. This value is regarded as the upper limit, since the decrease in F in the inverted region ($-\Delta G^0 > \lambda$) is, according to investigations on comparable systems [cf. J. Ulstrup, J. Jortner, *J. Chem. Phys. 63* (1975) 4358] significantly smaller than is predicted according to Equation (2). For comparison with the value of λ calculated here, an experimentally determined value of $\lambda = 0.9$ eV can be resorted to which was obtained by M. R. Wasielewski et al. (see above) from measurements of the transient absorption for porphyrin-quinones with comparably large center-to-center separation $r_{P,Q}$ as in the case of Zn-**3**. With this value of λ, $F(CS)/F(CR) = 4$.

[20] Excitation was repetitive with laser pulses (6 ps halfwidth, $< 10^{10}$ photons per pulse) at 590 nm and a repetition frequency of 800 kHz upon time-resolved photon counting and 4 MHz upon measurement with the synchroscan camera. The first method of measurement with 40 ps apparent laser pulse width was used if the time constants of the decay curves were greater than 150 ps. If the smallest time constant of the decay curves was less than 150 ps then the second method of measurement was used with 15–25 ps apparent laser pulse width, depending on the integration time.

Concanavalin A Binds Pyranosides and Their Tetraacetates Stereoselectively**

By *Jürgen-Hinrich Fuhrhop** and *Michael Arlt*

The protein concanavalin A (= Con A) stereoselectively binds carbohydrate head groups that appear as neighboring hexose units on the surfaces of glycoproteins[1] or vesicles.[2]

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 312 "Vectorial Membrane Processes"), the Förderungskommission für Forschung und wissenschaftlichen Nachwuchs der Freien Universität, and the Fonds der chemischen Industrie.

D-Glucopyranose and D-mannopyranose units are agglutinated, whereas D-galactopyranose units are not. Clefts,[3] shallow pockets,[4] as well as nonspecific[5] or substrate-dependent[6] binding sites have been characterized by X-ray crystal structure analyses of monosaccharide complexes. None of the resulting binding models agree with the experimental results described in this paper.

Agglutination experiments with 10^{-4} M aqueous suspensions of the glycolipids **1a–1d**[7] and 1 mg of Con A per mL[8] yielded expected results: D-glucose and D-mannose
